Preface

This volume contains the extended abstracts selected for presentation at ESA 2016, the 24th European Symposium on Algorithms, held in Aarhus, Denmark, on 22–24 August 2016, as part of ALGO 2016. The ESA symposia are devoted to fostering and disseminating the results of high-quality research on algorithms and data structures. ESA seeks original algorithmic contributions for problems with relevant theoretical and/or practical applications and aims at bringing together researchers in the computer science and operations research communities. Ever since 2002, it has had two tracks, the Design and Analysis Track (Track A), intended for papers on the design and mathematical analysis of algorithms, and the Engineering and Applications Track (Track B), for submissions dealing with real-world applications, engineering, and experimental analysis of algorithms. Information on past symposia, including locations and proceedings, is maintained at http://esa-symposium.org.

In response to the call for papers, ESA 2016 attracted a rather high number of 282 submissions, 230 for Track A and 52 for Track B. Paper selection was based on originality, technical quality, and relevance. Considerable effort was devoted to the evaluation of the submissions, with at least three reviews per paper. With the help of more than 1040 expert reviews and more than 470 external reviewers, the two committees selected 76 papers for inclusion in the scientific program of ESA 2016, 63 in Track A and 13 in Track B, yielding an acceptance rate of about 27%. In addition to the accepted contributions, the symposium featured two invited lectures by Guiseppe Italiano (University of Roma "Tor Vergata", Italy) and Ola Svensson (EPFL, Switzerland). Contributions of the invited lectures are also included in this volume.

The European Association for Theoretical Computer Science (EATCS) sponsored a best paper award and a best student paper award. A submission was eligible for the best student paper award if all authors were doctoral, master, or bachelor students at the time of submission.

The best student paper award was shared by two papers: one by Michele Borassi and Emanuele Natale for their contribution "KADABRA is an ADaptive Algorithm for Betweenness via Random Approximation", and the other by Adam Kunysz "The Strongly Stable Roommates Problem".

The best paper award went to two papers: one by Stefan Kratsch for his contribution "A randomized polynomial kernelization for Vertex Cover with a smaller parameter" and the other one by Thomas Bläsius, Tobias Friedrich, Anton Krohmer and Sören Laue for their contribution "Efficient Embedding of Scale-Free Graphs in the Hyperbolic Plane". Our warmest congratulations to all of them for these achievements!

We wish to thank all the authors who submitted papers for consideration, the invited speakers, the members of the Program Committees for their hard work, and all the external reviewers who assisted the Program Committees in the evaluation process. Special thanks go to the Local Organizing Committee, who helped us with the organization of the conference.

Abstract

We survey some recent results on 2-edge and 2-vertex connectivity problems in directed graphs. Despite being complete analogs of the corresponding notions on undirected graphs, in digraphs 2-vertex and 2-edge connectivity have a much richer and more complicated structure. It is thus not surprising that 2-connectivity problems on directed graphs appear to be more difficult than on undirected graphs. For undirected graphs it has been known for over 40 years how to compute all bridges, articulation points, 2-edge- and 2-vertex-connected components in linear time, by simply using depth-first search. In the case of digraphs, however, the very same problems have been much more challenging and required the development of new tools and techniques.

Category Invited Talk

1 Preliminaries

Let $G = (V, E)$ be an *undirected* (resp., *directed*) graph, with m edges and n vertices. Throughout the paper, we use interchangeably the term directed graph and digraph. Edge and vertex connectivity are fundamental concepts in graph theory with numerous practical applications [2, 32]. As an example, we mention the computation of disjoint paths in routing and reliable communication, both in undirected and directed graphs [21, 24].

We assume that the reader is familiar with the standard graph terminology, as contained for instance in [7]. An *undirected path* (resp., *directed path*) in G is a sequence of vertices v_1, v_2, …, v_k, such that edge $(v_i, v_{i+1}) \in E$ for $i = 1, 2, \ldots, k-1$. An undirected graph G is *connected* if there is an undirected path from each vertex to every other vertex. The *connected components* of an undirected graph are its maximal connected subgraphs. A directed graph G is *strongly connected* if there is a directed path from each vertex to every other vertex. The *strongly connected components* of a directed graph are its maximal connected subgraphs.

* Partially supported by MIUR, the Italian Ministry of Education, University and Research, under Project AMANDA (Algorithmics for MAssive and Networked DAta).

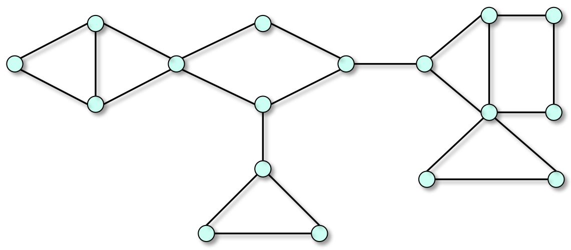

Figure 1 An undirected graph G.

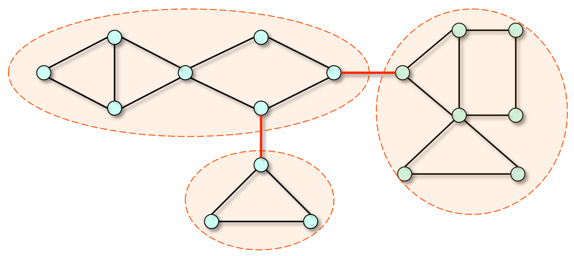

Figure 2 The bridges and 2-edge-connected components of the graph G in Figure 1. (Better viewed in color).

1.1 2-Connectivity in Undirected Graphs

Given an undirected graph $G = (V, E)$, an edge is a *bridge* if its removal increases the number of connected components of G. A graph G is 2-edge-connected if it has no bridges. The *2-edge-connected components* of G are its maximal 2-edge-connected subgraphs. Figure 1 shows an undirected graph, and Figure 2 highlights its bridges and 2-edge-connected components.

Two vertices v and w are 2-edge-connected if there are two edge-disjoint paths between v and w: we denote this relation by $v \leftrightarrow_{2\mathrm{e}} w$. Equivalently, by Menger's Theorem [31], v and w are 2-edge-connected if the removal of any edge leaves them in the same connected component.

Analogous definitions can be given for 2-vertex connectivity. In particular, a vertex is an *articulation point* if its removal increases the number of connected components of G. Figure 3 shows the articulation points of the graph in Figure 1. A graph G is 2-vertex-connected if it has at least three vertices and no articulation points. The 2-*vertex-connected components* of G are its maximal 2-vertex-connected subgraphs. Note that the condition on the minimum number of vertices in a 2-vertex-connected graph disallows degenerate 2-vertex-connected components consisting of one single edge. Figure 4 shows the 2-vertex-connected components of the graph in Figure 1.

Two vertices v and w are 2-vertex-connected if there are two internally vertex-disjoint paths between v and w: we denote this relation by $v \leftrightarrow_{2\mathrm{v}} w$. If v and w are 2-vertex-connected then Menger's Theorem implies that the removal of any vertex different from v and w leaves them in the same connected component. The converse does not necessarily hold, since v and w may be adjacent but not 2-vertex-connected. It is easy to show that $v \leftrightarrow_{2\mathrm{e}} w$ (resp., $v \leftrightarrow_{2\mathrm{v}} w$) if and only if v and w are in a same 2-edge-connected (resp., 2-vertex-connected) component.

All bridges, articulation points, 2-edge- and 2-vertex-connected components of undirected graphs can be computed in linear time essentially by the same algorithm, which is simply based on depth-first search [34].

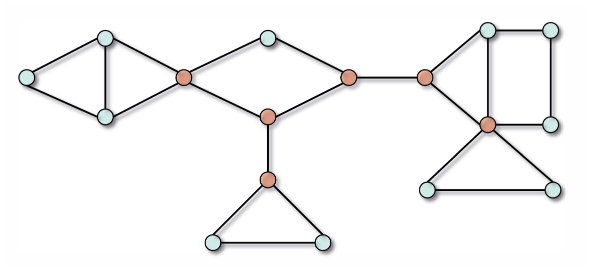

Figure 3 The articulation points of the graph G in Figure 1. (Better viewed in color).

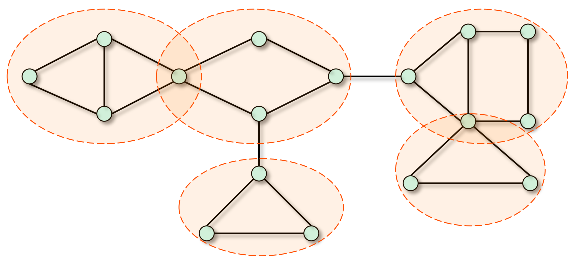

Figure 4 The 2-vertex-connected components of the graph G in Figure 1. (Better viewed in color).

1.2 2-Connectivity in Directed Graphs

The notions of 2-edge and 2-vertex connectivity can be naturally extended to directed graphs. The main idea is that now the role of connected components is played by strongly connected components. Given a digraph G, an edge (resp., a vertex) is a *strong bridge* (resp., a *strong articulation point*) if its removal increases the number of strongly connected components of G. A digraph G is 2-edge-connected if it has no strong bridges; G is 2-vertex-connected if it has at least three vertices and no strong articulation points. The 2-edge-connected (resp., 2-vertex-connected) components of G are its maximal 2-edge-connected (resp., 2-vertex-connected) subgraphs. Again, the condition on the minimum number of verti ces disallows for degenerate 2-vertex-connected components consisting of two mutually adjacent vertices (i.e., two vertices v and w and the two edges (v, w) and (w, v)).

Similarly to the undirected case, we say that two vertices v and w are 2-edge-connected (resp., 2-vertex-connected), and we denote again this relation by $v \leftrightarrow_{2\mathrm{e}} w$ (resp., $v \leftrightarrow_{2\mathrm{v}} w$), if there are two edge-disjoint (resp., internally vertex-disjoint) directed paths from v to w and two edge-disjoint (resp., internally vertex-disjoint) directed paths from w to v. (Note that a path from v to w and a path from w to v need not be edge-disjoint or vertex-disjoint). It is easy to see that $v \leftrightarrow_{2\mathrm{e}} w$ if and only if the removal of any edge leaves v and w in the same strongly connected component. Similarly, $v \leftrightarrow_{2\mathrm{v}} w$ implies that the removal of any vertex different from v and w leaves v and w in the same strongly connected component. We define a 2-*edge-connected block* (resp., 2-*vertex-connected block*) of a digraph $G = (V, E)$ as a maximal subset $B \subseteq V$ such that $u \leftrightarrow_{2\mathrm{e}} v$ (resp., $u \leftrightarrow_{2\mathrm{v}} v$) for all $u, v \in B$. Figure 5 illustrates (a) a strongly connected digraph G together with its strong articulation points and strong bridges, (b) the 2-vertex-connected components of G, (c) the 2-vertex-connected blocks of G, (d) the 2-edge-connected components of G, and (e) the 2-edge-connected blocks of G.

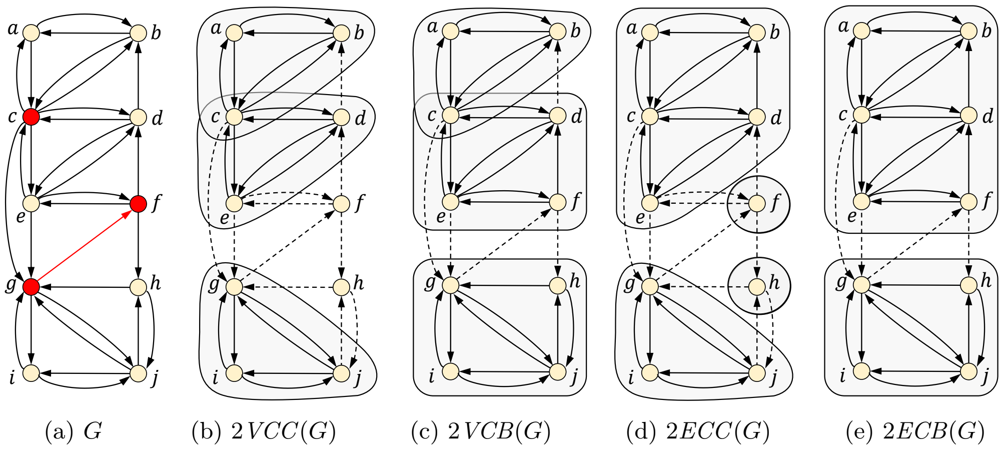

Figure 5 (a) A strongly connected digraph G, with strong articulation points and strong bridges shown in red (better viewed in color). (b) The 2-vertex-connected components of G. (c) The 2-vertex-connected blocks of G. (d) The 2-edge-connected components of G. (e) The 2-edge-connected blocks of G. Note that vertices e and f are in the same 2-vertex- (resp., 2-edge-) connected block of G since there are two internally vertex-disjoint (resp., edge-disjoint) paths from e to f and from f to e. However, e and f are not in the same 2-vertex (resp., 2-edge-) connected component of G. (Better viewed in color).

1.3 Differences between 2-Connectivity in Undirected and Directed Graphs

Connectivity-related problems for digraphs are notoriously harder than for undirected graphs, and indeed many notions for undirected connectivity do not translate to the directed case. Differently from undirected graphs, in digraphs 2-edge- and 2-vertex-connected blocks do not correspond to 2-edge- and 2-vertex-connected components, as it is clearly illustrated in Figure 5. Namely, two vertices may be 2-edge-connected (resp., 2-vertex-connected) but lie in different 2-edge-connected (resp., 2-vertex-connected) components. Furthermore, these notions seem to have a much richer and more complicated structure in digraphs, as depicted in Figure 6. Just to give an example, we observe that while in the case of undirected connected graphs the 2-edge-connected components (which correspond to the 2-edge-connected blocks) are exactly the connected components left after the removal of all bridges, for directed strongly connected graphs the 2-edge-connected components, the 2-edge-connected blocks, and the strongly connected components left after the removal of all strong bridges are not necessarily the same (see Figure 7).

Finally, we observe that an undirected graph is naturally decomposed by bridges (resp., articulation points) into a tree of 2-edge- (resp., 2-vertex-) connected components, known as the bridge-block (resp., block) tree (see, e.g., [36]). In digraphs, the decomposition induced by strong bridges and strong articulation points becomes much more complicated (see Figure 8): in general, it was shown by Benczúr that in digraphs there can be no “cut” tree for various connectivity concepts [3].

It is thus not surprising that, despite being complete analogs of the corresponding notions on undirected graphs, 2-edge and 2-vertex connectivity problems appear to be much more difficult on digraphs.

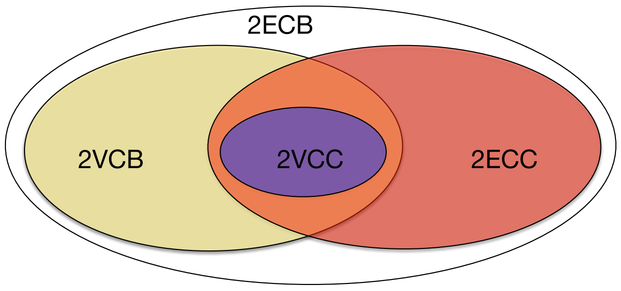

Figure 6 The relation among various notions of 2-connectivity in directed graphs. Two vertices that are 2-edge-connected (resp., 2-vertex-connected) are in the same 2-edge-connected (resp., 2-vertex-connected) block but not necessarily in the same 2-edge-connected (resp., 2-vertex-connected) component. Also, a 2-vertex-connected component is included in a 2-edge-connected component. (Better viewed in color).

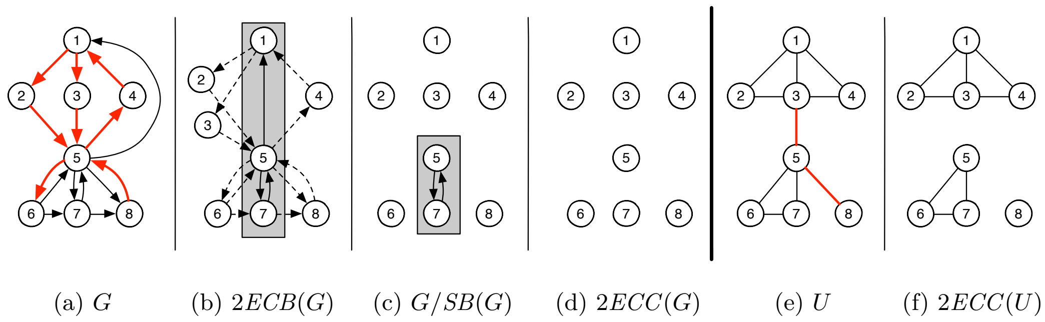

Figure 7 (a) A digraph G with strong bridges shown in red; (b) The 2-edge-connected blocks of G; (c) The strongly connected components left after removing all the strong bridges from G; (d) The 2-edge-connected components of G. (e) An undirected graph U with bridges shown in red; (f) The 2-edge-connected components of U, corresponding to the 2-edge-connected blocks and to the connected components left after the removal of all bridges of U. (Better viewed in color).

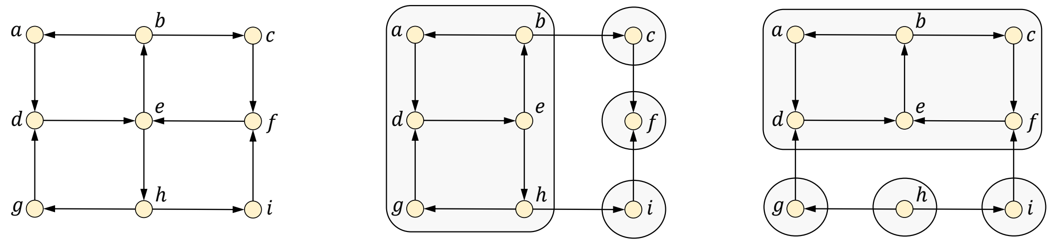
2 Simple-minded Algorithms for 2-edge and 2-vertex Connectivity in Directed Graphs

A simple algorithm for computing the 2-edge-connected components can be obtained by repeatedly removing all the strong bridges in the graph (and repeating this process until no strong bridges are left). At each round all the strong bridges can be computed in $O(m+n)$ time [26] and since there can be at most $O(n)$ rounds, the total time taken by this algorithm is $O(mn)$. The same bound was previously achieved by Nagamochi and Watanabe [33]. As for 2-vertex connectivity, Erusalimskii and Svetlov [9] proposed an algorithm that reduces the problem of computing the 2-vertex-connected components of a digraph to the computation of the 2-vertex-connected components in an undirected graph, but did not analyze the running time of their algorithm. Jaberi [28] showed that the algorithm of Erusalimskii and Svetlov has $O(nm^2)$ running time, and proposed two different algorithms with running time $O(mn)$. Both algorithms follow substantially the same high-level approach as the simple algorithm for computing the 2-edge-connected components of a digraph sketched before.

A simple algorithm for computing the 2-edge- or 2-vertex-connected blocks of a digraph G takes $O(mn)$ time: given a vertex v, one can find in linear time all the vertices that are



(a) G (b) $G \setminus (f, e)$ (c) $G \setminus (e, h)$

Figure 8 An example illustrating the complicated structure of 1-edge cuts in digraphs. (a) A strongly connected digraph G. (b) The strongly connected components in $G \setminus (f, e)$. (c) The strongly connected components in $G \setminus (e, h)$. Note that a strongly connected component in $G \setminus (f, e)$ and a strongly connected component in $G \setminus (e, h)$ are neither disjoint nor nested. In fact, all edges are strong bridges, and the deletion of each edge creates many non-disjoint and non-nested sets in the resulting partitions.

2-edge- or 2-vertex-connected with v with the help of dominator trees [11]. Since in the worst case this step must be repeated for all vertices v in G, the total time required by this simple algorithm is $O(mn)$. Very recently, Jaberi [27] presented algorithms for computing the 2-vertex-connected and 2-edge-connected blocks. His algorithms require $O(n \cdot \min\{m, b^*n\})$ time for computing the 2-edge-connected blocks and $O(n \cdot \min\{m, (a^* + b^*)n\})$ time for computing the 2-vertex-connected blocks, where a^* and b^* are respectively the number of strong articulation points and strong bridges in the digraph G. Since both a^* and b^* can be as large as $O(n)$, both bounds are $O(mn)$ in the worst case.

3 Flow Graphs and Dominators

In this section, we introduce some of the main tools that provided to be useful for solving 2-connectivity problems. Let $G = (V, E)$ be a strongly connected graph. Throughout, we denote by $G^R = (V, E^R)$ the *reverse digraph* of G, i.e., the digraph obtained by reversing the direction of all edges.

A *flow graph* is a digraph with a distinguished *start vertex* s such that every vertex is reachable from s. Let s be a fixed but arbitrary start vertex of a strongly connected digraph G. Since G is strongly connected, all vertices are reachable from s and reach s, so we can view both G and G^R as flow graphs with start vertex s. To avoid ambiguities, throughout the paper we will denote those flow graphs respectively by G_s and G_s^R. Vertex u is a *dominator* of vertex v (u *dominates* v) in G_s if every path from s to v in G_s contains u. Vertex u is a *proper dominator* of v if u dominates v and $u \neq v$. Let $dom(v)$ be the set of dominators of v. Clearly, $dom(s) = \{s\}$ and for any $v \neq s$ we have that $\{s, v\} \subseteq dom(v)$: we say that s and v are the *trivial dominators* of v in the flow graph G_s. The dominator relation is reflexive and transitive. Its transitive reduction is a rooted tree, the *dominator tree* D: u dominates v if and only if u is an ancestor of v in D. For any $v \neq s$, we denote by $d(v)$ the parent of v in D. Similarly, we can define the dominator relation in the flow graph G_s^R, and let D^R denote the dominator tree of G_s^R, and $d^R(v)$ the parent of v in D^R. Throughout the paper, we let N (resp., N^R) denote the set of nontrivial dominators of G_s (resp., G_s^R). Lengauer and Tarjan [30] presented an algorithm for computing dominators in $O(m\alpha(m, n))$ time for a flow graph with n vertices and m edges, where α is a functional inverse of Ackermann's function [35]. Subsequently, several linear-time algorithms were discovered [1, 4, 11, 12].

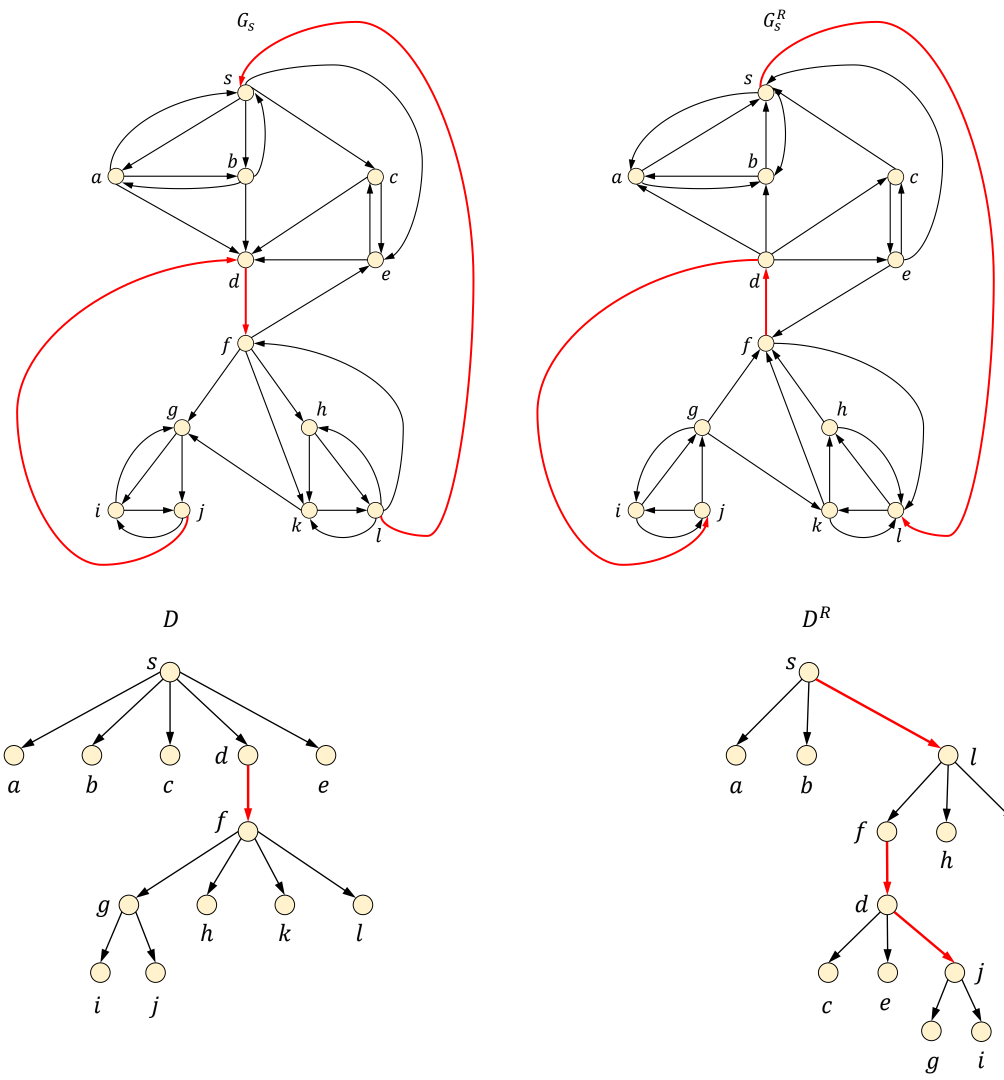


Figure 9 A flow graph G_s and its reverse G_s^R, and their dominator trees D and D^R. The corresponding digraph G is strongly connected. Strong bridges of G and G^R and bridges of G_s and G_s^R in D and D^R are shown red. (Better viewed in color.)

Figure 9 shows a flow graph G_s, its reverse G_s^R, and their dominator trees D and D^R.

An edge (u, v) is a *bridge* of a flow graph G_s if all paths from s to v include (u, v).[1] Let s be an arbitrary start vertex of G. As shown in [26], an edge $e = (u, v)$ is strong bridge of G if and only if it is either a bridge of G_s or a bridge of G_s^R. As a consequence, all the strong bridges of G can be obtained from the bridges of the flow graphs G_s and G_s^R, and thus there can be at most $2(n-1)$ strong bridges overall.

[1] Throughout the paper, to avoid confusion we use consistently the term *bridge* to refer to a bridge of a flow graph and the term *strong bridge* to refer to a strong bridge in the original graph.

4 Efficient Algorithms for 2-Connectivity in Directed Graphs

In this section, we show how to exploit the basic tools described in Section 3 to obtain fast algorithms for 2-connectivity in digraphs. We start by showing a connection between strong articulation points and dominators in flowgraphs. Consider the problem of finding all strong articulation points of a strongly connected digraph $G = (V, E)$. Let s be any vertex in G. Since G is strongly connected, every vertex in G is reachable from s: thus for every vertex $s \in V$, G_s is a flowgraph. Note that there can be n flowgraphs for each strongly connected graph. The following lemmas show a close relationship between strong articulation points in strongly connected graphs and non-trivial dominators in flow graphs.

▶ **Lemma 1** ([26]). *Let $G = (V, E)$ be a strongly connected graph, and let s be any vertex in G. Let G_s be the flowgraph with start vertex s. If a vertex u is a non-trivial dominator of a vertex v in G_s, then u is a strong articulation point in G.*

Proof. If u is a non-trivial dominator of v in the flowgraph G_s, then $u \neq s$, $u \neq v$ and all the paths in G from s to v must include u. Consequently, $G \setminus \{u\}$ is not strongly connected and thus u must be a strong articulation point in G. ◀

▶ **Lemma 2** ([26]). *Let $G = (V, E)$ be a strongly connected graph. If u is a strong articulation point in G, then there must be a vertex $s \in V$ such that u is a non-trivial dominator of a vertex v in the flowgraph G_s.*

Proof. If u is a strong articulation point of G, then there must exist two vertices s and v in G, $s \neq u$, $v \neq u$, such that every path from s to v contains vertex u. This implies that u must be a non-trivial dominator of vertex v in the flowgraph G_s. ◀

We note that Lemmas 1 and 2 are still not sufficient to achieve a linear-time algorithm for our problem: indeed, to compute all the strong articulation points of a strongly connected graph G, we need to compute all the non-trivial dominators in the flowgraphs $G(s)$, for each vertex s in V. Since the dominators of a flowgraph can be computed in $O(m + n)$ time [1, 4, 11, 12] and there are exactly n flowgraphs to be considered, the running time of this algorithm is $O(n(m + n))$. We show next how a more careful exploitation of the relationship between strong articulation points and dominators yields a linear-time algorithm for computing the strong articulation points of a directed graph.

▶ **Theorem 3** ([26]). *Let $G = (V, E)$ be a strongly connected graph, and let $s \in V$ be any vertex in G. Let G_s and G_s^R be respectively the flowgraphs with start vertex s, D and D^R their dominator trees, and N and N^R the non-trivial dominators in D and D^R. Then vertex $v \neq s$ is a strong articulation point in G if and only if $v \in N \cup N^R$.*

Proof. We first prove that if v is a strong articulation point in G, $v \neq s$, then v must be a non-trivial dominator either in D or in D^R. Assume not: namely, assume that v is a strong articulation point in G, $v \neq s$, but $v \notin N \cup N^R$. Since v is a strong articulation point in G, then $G \setminus \{v\}$ is not strongly connected. As a consequence, there must be a vertex w in G, $w \neq s$, $w \neq v$, such that the following is true: w is in the same strongly connected component as s in G, but w is not in the same strongly connected component as s in $G \setminus \{v\}$. Namely, $v \neq s$, $v \neq w$, and either (a) there is a path from s to w in G, but there is no path from s to w in $G \setminus \{v\}$, or (b) there is a path from w to s in G, but there is no path from w to s in $G \setminus \{v\}$. If we are in case (a), then all the paths from s to w in G must contain vertex v. This is equivalent to saying that v is a non-trivial dominator of w in the flowgraph G_s, which clearly contradicts our assumption that $v \notin N$. If we are in case (b), then all the paths from w to s in G must contain vertex v. This is equivalent to saying that v is a non-trivial dominator of w in the flowgraph G_s^R, which contradicts our assumption that $v \notin N^R$. This shows that if v is a strong articulation point in G, then v must be in N or in N^R.

To prove the converse, let v be any vertex such that $v \in N$ or $v \in N^R$. If $v \in N$, v is a non-trivial dominator in G_s, and thus v must be a strong articulation point in G by Lemma 1. Analogously, if $v \in N^R$, again by Lemma 1 v must be a strong articulation point in G^R, and thus in G. This completes the proof of the theorem. ◀

Note that Theorem 3 provides no information on whether vertex s is a strong articulation point. However, this can be easily checked in linear time, yielding the following theorem.

▶ **Theorem 4** ([26]). *All the strong articulation points of a directed graph G can be computed in $O(m+n)$ time in the worst case.*

The strong bridges of a directed graph can be found in an analogous fashion, giving rise to the following theorem:

▶ **Theorem 5** ([26]). *All the strong bridges of a directed graph G can be computed in $O(m+n)$ time in the worst case.*

A more sophisticated usage of dominator trees, combined with other properties, gives rise to efficient algorithms for computing the 2-edge-connected and 2-vertex-connected blocks and components of a directed graph, as stated in the remainder of this section.

In particular, Georgiadis et al. [16] gave a linear-time algorithms for computing the 2-edge-connected blocks of a digraph. Their approach hinges on two different algorithms. The first is a simple iterative algorithm that builds the 2-edge-connected blocks by removing one strong bridge at a time. The second algorithm is more involved and recursive: the main idea is to consider simultaneously how different strong bridges partition vertices with the help of dominator trees. Although both algorithms run in $O(mn)$ time in the worst case, Georgiadis et al. [16] showed that a sophisticated combination of the iterative and the recursive method is able to achieve a linear-time bound, as shown in the following theorem.

▶ **Theorem 6** ([16]). *The 2-edge-connected blocks of a directed graph G can be computed in $O(m+n)$ time in the worst case.*

Using the linear-time algorithm for computing the 2-edge-connected blocks, one can preprocess a digraph in linear time, and then can answer in constant time queries on whether any two vertices are 2-edge-connected. Additionally, when two query vertices v and w are not 2-edge-connected, one can produce in constant time a "witness" of this property, by exhibiting an edge that is contained in all paths from v to w or in all paths from w to v. As a consequence of the linear-time algorithm of Theorem 6, one can also compute in linear time a sparse certificate for 2-edge-connected blocks, i.e., a subgraph of the input graph that has $O(n)$ edges and maintains the same 2-edge-connected blocks as the input graph. The interested reader is referred to [16] for all the details.

Following the high-level approach of [16] for finding the 2-edge-connected blocks, Georgiadis et al. [17] were able to prove that also the 2-vertex-connected blocks of a digraph can be computed in linear time. The algorithm for computing the 2-vertex-connected blocks is much more involved than the 2-edge connectivity algorithm required several novel ideas and more sophisticated techniques to achieve the claimed bounds. Moreover, differently from 2-edge connectivity, 2-vertex connectivity in digraphs is plagued with several degenerate special cases, which are not only more tedious but also more cumbersome to deal with. For instance, the algorithm in [16] exploits implicitly the property that two vertices v and w are 2-edge-connected if and only if the removal of any edge leaves v and w in the same strongly connected component. Unfortunately, this property no longer holds for 2-vertex connectivity, as for instance two mutually adjacent vertices are always left in the same strongly connected component by the removal of any other vertex, but they are not necessarily 2-vertex-connected. This is summarized in the following theorem.

▶ **Theorem 7** ([17]). *The 2-vertex-connected blocks of a directed graph G can be computed in $O(m+n)$ time in the worst case.*

Similary to the case of 2-edge connectivity, other side results can be obtained as an application of this algorithm. In particular, one can construct an $O(n)$-space data structure that reports in constant time if two vertices are 2-vertex-connected. by exhibiting a vertex (i.e., a strong articulation point) or an edge (i.e., a strong bridge) that separates them. Once again, one can also compute in linear time a sparse certificate for 2-vertex connectivity, i.e., a subgraph of the input graph that has $O(n)$ edges and maintains the same 2-vertex connectivity properties.

We now turn to the problem of computing the 2-edge- and 2-vertex-connected components of a digraph. In this case, Henzinger et al. [23], presented fast algorithms for computing the 2-edge- and 2-vertex-connected components of a directed graph. The main idea behind their algorithm is a hierarchical graph sparsification that was introduced by Henzinger et al. [22] for undirected graphs and extended to directed graphs in [5]. Roughly speaking, this sparsification technique allows one to replace the m in the $O(mn)$ running times by an n, yielding $O(n^2)$ running times in place of $O(mn)$. Henzinger et al. [23] were able to find structural properties of 2-edge and 2-vertex connectivity in directed graphs that allow one to apply this technique starting from the simple-minded $O(mn)$ algorithms and a clever use of dominators. Those bounds are summarized in the following theorem.

▶ **Theorem 8** ([23]). *The 2-edge- and 2-vertex-connected components of a directed graph G can be computed in $O(n^2)$ time in the worst case.*

Additionally, Henzinger et al. [23] presented an $O(m^2/\log n)$ time algorithm for computing the 2-edge-connected components, which provides a small improvement for sparse graphs, i.e., $m = O(n)$. The same approach can be extended to k-edge- and k-vertex-connected components, for any constant k, with a running time of $O(n^2 \log n)$ for k-edge connectivity and $O(n^3)$ for k-vertex connectivity.

Finally, we mention that Georgiadis et al. [19] initiated the study of the dynamic maintenance of 2-edge-connectivity relationships in directed graphs. In particular, they presented an algorithm that can update the 2-edge-connected blocks of a digraph G with n vertices through a sequence of m edge insertions in a total of $O(mn)$ time. After each insertion, one can answer the following queries in asymptotically optimal time:

- Test in constant time if two query vertices v and w are 2-edge-connected. Moreover, if v and w are not 2-edge-connected, one can produce in constant time a “witness” of this property, by exhibiting an edge that is contained in all paths from v to w or in all paths from w to v.
- Report in $O(n)$ time all the 2-edge-connected blocks of G.

▶ **Theorem 9** ([19]). *The 2-edge-connected blocks of a digraph with n vertices can be maintained through a sequence of edge insertions in $O(mn)$ time, where m is the total number of edges in G after all insertions.*

We remark that this is the first known dynamic algorithm for 2-connectivity problems on digraphs, and it matches the best known bounds for simpler problems, such as incremental transitive closure [25].

5 Sparse Subgraphs Preserving 2-Connectivity in Directed Graphs

Other problems that were considered in the area of 2-connectivity for directed graphs are related to the computation of a minimum spanning subgraph (i.e., a subgraph with minimum number of edges) that maintains certain 2-connectivity requirements in addition to strong connectivity. More specifically, one problem that has been investigated is finding a smallest strongly connected spanning subgraph of a digraph G that has the same 2-edge- (respectively, 2-vertex-) connectivity properties as G. Both for 2-edge- and for 2-vertex connectivity, this problem is known to be NP-hard [13, 18]. We next review some of the algorithms proposed in the literature respectively for edge and for vertex connectivity.

Laekhanukit et al. [29] gave a randomized $(1+1/k)$-approximation algorithm for computing the smallest k-edge-connected spanning subgraph of a k-edge-connected graph. Georgiadis et al. [18] used the algorithm in [29] to compute a 3/2-approximate minimum spanning subgraph that has the same 2-edge-connected components and additionally presented a faster 2-approximation algorithm that runs in linear time. Let G be a strongly connected graph. Jaberi [27] considered the problem of computing a smallest subgraph that has the same 2-edge-connected blocks (or the same 2-vertex-connected blocks) as G. Unfortunately, the approximation ratio in Jaberi's algorithms is $O(n)$ in the worst case. Georgiadis et al. [18] improved this result by presenting a linear-time 4-approximation algorithm for computing the smallest strongly connected spanning subgraph that has the same 2-edge-connected blocks as G. Additionally, they presented a linear-time algorithm for the problem of computing the smallest subgraph that has both the same 2-edge-connected components and the same 2-edge-connected blocks as G. The algorithms in [18] that compute spanning subgraphs with the same 2-edge-connected components as G run in linear time once the 2-edge-connected components of G are available (we remark that the currently best known bound for computing the 2-edge-connected components is $O(n^2)$ [23]).

For the smallest k-vertex-connected spanning subgraph, Cheriyan and Thurimella [6], gave a $(1+1/k)$-approximation algorithm that runs in $O(km^2)$ time. For $k=2$, Georgiadis [14] presented a linear time algorithm with approximation ratio 3. Based on the algorithm from [14], the running time of Cheriyan and Thurimella's algorithm was improved to $O(m\sqrt{n}+n^2)$ for $k=2$. Let G be a strongly connected graph. Georgiadis et al. [15] presented a constant-factor approximation algorithm for the problem of computing the smallest subgraph that preserves the 2-vertex-connected blocks of G. More specifically, they gave a linear-time 6-approximation algorithm for this problems, and further extended this algorithm to compute a sparse subgraph with the same approximation gurantee that has both the same 2-vertex-connected components and the same 2-vertex-connected blocks as G. The algorithm that computes a sparse subgraph that preserves both the 2-vertex-connected blocks and the 2-vertex-connected components of the input graph G runs in linear time, once the 2-vertex-connected components of G are available (we remark that the currently best known bound for computing the 2-vertex-connected components is $O(n^2)$ [23]). Finally, in [15] Georgiadis et al. presented a 6-approximation algorithm for computing a strongly connected spanning subgraph of G that preserves all the 2-connectivity relations, i.e., both the 2-edge- and the 2-vertex-connected components and the 2-edge- and the 2-vertex-connected blocks. Once again, this algorithm runs in linear time, provided that the 2-edge- and the 2-vertex-connected components of G are available.

We remark that references [15, 18] provide efficient implementations of all those approximation algorithms that run very fast in practice. Additionally, they also present several heuristics that improve the quality (i.e., the number of edges) of the computed spanning subgraphs, and assess how all these algorithms perform in practical scenarios by conducting a thorough experimental study.

6 Conclusions and Open Problems

We have surveyed some very recent results on 2-edge and 2-vertex connectivity problems in directed graphs, which revealed to be harder than their counterparts on undirected graphs. Experimental studies for algorithms that compute dominators, strong bridges, strong articulation points, 2-edge- and 2-vertex-connected blocks are presented in [8, 10, 20]. Those experimental results are very promising, as they show that the corresponding fast algorithms given in [11, 16, 17, 26] perform very well in practice even on very large graphs.

This recent bulk of work has raised some interesting and perhaps intriguing questions. In particular, the main open problem is whether the 2-edge-connected or the 2-vertex-connected components of a digraph can be computed in linear time. Moreover, the dynamic maintenance of 2-edge and 2-vertex connectivity in directed graphs deserves further investigation. Finally, we have described in Section 5 linear-time constant-factor approximation algorithms for computing minimum spanning subgraphs that preserve the 2-edge- and 2-vertex-connected blocks of a graph [15, 18]. The trade-offs between running times and approximation guarantees need further study. In particular, can the approximation guarantees in [15, 18] be improved while still maintaining linear running times? Can they match the corresponding approximation ratios for computing the 2-edge- and 2-vertex-connected spanning subgraphs of 2-edge- and 2-vertex-connected graphs [6, 29], respectively?

Abstract

In this talk, we give an overview of the current best approximation algorithms for fundamental clustering problems, such as k-center, k-median, k-means, and facility location. We focus on recent progress and point out several important open problems.

For the uncapacitated versions, a variety of algorithmic methodologies, such as LP-rounding and primal-dual method, have been applied to a standard linear programming relaxation. This has given a uniform way of addressing these problems resulting in small constant approximation guarantees.

In spite of this impressive progress, it remains a challenging open problem to give tight guarantees. Moreover, this collection of powerful algorithmic techniques is not easily applicable to the capacitated setting. In fact, there is no simple strong convex relaxation known for the capacitated versions. As a result, our understanding of these problems is significantly weaker and several fundamental questions remain open.

Abstract

We prove the first non-trivial performance ratios strictly above 0.5 for weighted versions of the oblivious matching problem. Even for the unweighted version, since Aronson, Dyer, Frieze, and Suen first proved a non-trivial ratio above 0.5 in the mid-1990s, during the next twenty years several attempts have been made to improve this ratio, until Chan, Chen, Wu and Zhao successfully achieved a significant ratio of 0.523 very recently (SODA 2014). To the best of our knowledge, our work is the first in the literature that considers the node-weighted and edge-weighted versions of the problem in arbitrary graphs (as opposed to bipartite graphs).

(1) For arbitrary node weights, we prove that a weighted version of the Ranking algorithm has ratio strictly above 0.5. We have discovered a new structural property of the ranking algorithm: if a node has two unmatched neighbors at the end of algorithm, then it will still be matched even when its rank is demoted to the bottom. This property allows us to form LP constraints for both the node-weighted and the unweighted oblivious matching problems. As a result, we prove that the ratio for the node-weighted case is at least 0.501512. Interestingly via the structural

1 Introduction

While the classical maximum matching problem [14] is well understood, the oblivious version is motivated by exchange settings [15] and online advertising [9, 1], in which information about the underlying graphs might be unknown. For instance, in the kidney exchange problem [15], donor-recipient pairs are probed and greedily matched when two pairs are compatible. Another example is pay-per-click online advertising, in which the revenue for a click on a particular ad showing on a particular page is known, but it is unknown whether the user will actually click on that ad. In this paper, we analyze two weighted versions of the oblivious matching problem (ObMP). To be more specific, we first state the edge-weighted (Ew) ObMP (and the node-weighted (Nw) version as a special case) formally as follows.

EwObMP. An *adversary* commits to a simple undirected graph $G = (V, E)$, where **every** unordered pair of nodes $e = \{u, v\}$ (even if $e \notin E$) has non-negative weight w_e. The *unweighted* case is the special case in which all pairs have the same weight. The nodes V (where $n = |V|$) and the weights of all pairs are revealed to the (randomized) *algorithm*, while the edges E are kept secret. The algorithm returns a list L that gives a permutation of the set $\binom{V}{2}$ of unordered pairs of nodes. Each pair of nodes in G is probed according to the order specified by L to form a matching greedily. In the round when a pair $e = \{u, v\}$ is probed, if both nodes are currently *unmatched* and the edge e is in E, then the two nodes will be *matched* to each other; otherwise, we skip to the next pair in L until all pairs in L are probed. The goal is to maximize the ***performance ratio*** of the (expected) sum of weights of edges in the matching produced by the algorithm to that of a maximum weight matching in G. The node-weighted version is related to the edge-weighted version as follows.

NwObMP. The node-weighted version is a special case of EwObMP in which each node $u \in V$ has a non-negative weight w_u and the weight of each pair $e = \{u, v\}$ is $w_e = w_u + w_v$.

Greedy Algorithms. Greedy algorithms can achieve ratio 0.5 for both the edge-weighted and node-weighted versions. For the edge-weighted version, the probing order is given by sorting pairs in non-increasing order of weight. For the node-weighted version, the nodes are sorted in non-increasing order of weight to induce a lexicographical order on the pairs. As far as we know, this work is the first in the literature to achieve algorithms for both weighted versions with ratios strictly greater than 0.5.

To achieve non-trivial ratios, different variants of the Ranking algorithm have been investigated for various matching problems [12, 1, 6, 5]. We analyze the following variant that is relevant to NwObMP on arbitrary graphs.

Weighted Ranking Algorithm for NwObMP. Given the node weights w, the algorithm determines a distribution $\mathcal{D}_w$ on permutations of V. It samples a permutation π from $\mathcal{D}_w$, and returns a list L of unordered pairs according to the lexicographical order induced by π, where nodes appearing earlier in the permutation have higher priority. Specifically, for a permutation $\pi : V \to [n]$, given two pairs e_1 and e_2 (where for each j, $e_j = \{u_j, v_j\}$ and $\pi(u_j) < \pi(v_j)$), the pair e_1 has higher priority than e_2 if (i) $\pi(u_1) < \pi(u_2)$, or (ii) $u_1 = u_2$ and $\pi(v_1) < \pi(v_2)$.

Sampling a permutation. Previous works [1, 6] have considered the following way to sample a permutation of nodes. The algorithm uses an *adjustment function* $\varphi(t) := 1 - e^{t-1}$ for $t \in [0,1]$, and samples a *configuration* $\sigma \in \Omega_\infty := [0,1]^V$ uniformly at random, i.e., each node u receives independently a random number $\sigma(u)$ in $[0,1]$ uniformly at random. A permutation is given by sorting the nodes in non-increasing order of the *adjusted weight* $w(\sigma, u) := \varphi(\sigma(u)) \cdot w_u$. Observe that for the unweighted case (i.e., all nodes have the same weight), this is equivalent to sampling a permutation uniformly at random. We consider different adjustment functions φ in this paper.

1.1 Summary of Our Results

Extending previous linear programming (LP) approaches [1, 13, 11, 5], we prove that a weighted Ranking algorithm has ratio greater than 0.5 for NwObMP with arbitrary node weights in general graphs.

▶ **Theorem 1** (Weighted Ranking for NwObMP). *For $m = 10000$, weighted* Ranking *using the discrete sample space $[0,1]_m^V$ (where $[0,1]_m := \{\frac{i}{m} : i \in [m]\}$ is a discretization of $[0,1]$) and adjustment function $\varphi(t) := 1 - \frac{e^{17t}-1}{e^{17}-1}$ has performance ratio at least 0.501505.*

In the analysis, we have discovered new structural properties of the Ranking algorithm. For instance, if a node has two unmatched neighbors, then it will still be matched even when its rank is demoted to the bottom. These properties enable us to form better LP constraints. We use continuous LP techniques to prove that the above ratio can be improved to 0.501512 if continuous random sample space $[0,1]^V$ is used (due to space constraints, the complete proof is deferred to the full version). Interestingly via these structural properties, we also improve the analysis of (unweighted) Ranking for the unweighted ObMP over the previous best ratio of 0.523166 in the SODA 2014 paper [5].

▶ **Theorem 2** (Ranking for Unweighted ObMP). *The* Ranking *algorithm for unweighted* ObMP *has performance ratio at least* 0.526823.

For EwObMP with a bounded number of distinct edge weights, we show that ratio strictly above 0.5 can be achieved by partitioning edges carefully according to the weights, and running the (unweighted) Ranking algorithm on each part.

▶ **Theorem 3** (EwObMP with Bounded Number of Distinct Weights). *Suppose there is an algorithm on unweighted* ObMP *with performance ratio $\frac{1}{2} + \xi_1$. Then, for each positive integer*

$k > 1$, there exists $\xi_k = \Omega(\xi_1)^{O(k^2)}$ such that the following holds. There exists an algorithm for EwObMP *such that on instances with k distinct edge weights, the performance ratio is at least $\frac{1}{2} + \xi_k$.*

Our analysis is based on a new primal-dual framework of the standard matching LP known as *matching coverage*, in which dual feasibility is bypassed. Instead, only dual constraints corresponding to edges in an optimal matching are satisfied. Indeed the framework of matching coverage introduced for weighted oblivious matching has applications for other well-known problems. In particular using this framework we also design and analyze an algorithm for the *edge-weighted online bipartite matching problem with free disposal.* We prove that for the case of bounded online degrees, the ratio is strictly above 0.5.

EwOnBiMP with free disposal. An adversary fixes an edge-weighted bipartite graph $G(U \cup V, E)$ between a set U of *online* nodes and a set V of *offline* nodes, and determines the arrival order of the online nodes. When an online node u arrives, all the weights w_{uv}'s of edges between u and the offline nodes v in V are revealed to the (randomized) algorithm. The algorithm matches u to one of the offline nodes v. Even if an offline node v is already matched to a previous online node u', the algorithm is allowed to dispose of the edge $\{u', v\}$ and include the edge $\{u, v\}$ in the matching. The goal is to maximize the performance ratio, which is the (expected) sum of weights of edges in the final matching to that of a maximum weight matching in hindsight.

Feldman et al. [8] proved that a greedy algorithm can achieve ratio 0.5. We proposed a randomized algorithm that achieves ratio strictly greater than 0.5 for the case in which each online node has bounded degree.

▶ **Theorem 4** (EwOnBiMP with Bounded Online Degree)**.** *There exists an algorithm for edge-weighted online bipartite matching with free disposal such that on instances in which every online node has degree at most Δ, the performance ratio is $\frac{1}{2} + \Omega(\frac{1}{\Delta^2})$.*

1.2 Related Work

Unweighted ObMP. For the unweighted version, Dyer and Frieze [7] showed that the performance ratio is $0.5 + o(1)$ when the permutation of unordered pairs is chosen uniformly at random. In the mid-1990s, Aronson et al. [2] showed that the Modified Randomized Greedy (MRG) algorithm has ratio $0.5 + \epsilon$ (where $\epsilon = \frac{1}{400000}$). Goel and Tripathi [10] showed a hardness result of 0.7916 for any algorithm and 0.75 for adaptive vertex-iterative algorithms. In a recent SODA 2014 paper, Chan et al. [5] proved that Ranking algorithm has performance ratio at least 0.523166. We improve their analysis and performance ratio in this paper.

A version of the ranking algorithm was first proposed by Karp et al. [12] to solve the online bipartite matching problem (OnBiMP) with ratio $1 - \frac{1}{e}$. Subsequent works by Goel and Mehta [9], and Birnbaum and Mathieu [3] simplified the proof. Since the arrival order of online nodes is arbitrary, the same analysis carries over to obtain the same ratio for ObMP on bipartite graphs.

Since running Ranking on bipartite graphs for ObMP is equivalent to running the ranking algorithm for OnBiMP with *random arrival order*, the result of Karande et al. [11] implies that the ranking algorithm has a ratio at least 0.653 for the ObMP on bipartite graphs. Mahdian and Yan [13] improved the ratio to 0.696 using the technique of strongly factor-revealing LP. Karande et al. [11] also constructed a hard instance in which Ranking performs no better than 0.727.

Weighted Ranking. Aggarwal et al. [1] showed that the ranking algorithm can be applied to OnBiMP when the offline nodes have general weights. They proved that the performance ratio is $1 - \frac{1}{e}$. Devanur et al. [6] gave an alternative proof using randomized primal-dual analysis. We observe that their analysis can be applied to the NwObMP on bipartite graphs. Since their analysis assumes that the online nodes arrive in arbitrary order, by exchanging the roles of online and offline nodes for both partition of nodes, it can be shown that weighted Ranking achieves the same ratio of $1 - \frac{1}{e}$ on bipartite graphs.

EwOnBiMP with Free Disposal. Feldman et al. [8] proposed the free disposal feature for EwOnBiMP. They considered the setting in which each offline node v has capacity $n(v)$, and an online algorithm benefits from the $n(v)$ highest-weighted edges matched to v. They proposed an online algorithm with ratio $1 - \frac{1}{e_k}$, where $e_k = (1 + \frac{1}{k})^k$, and k is a lower bound on capacities. Thus, the proposed algorithm has performance ratio $\frac{1}{2}$ for the classic weighted version, when all capacities are 1.

1.3 Analyzing NwObMP via Linear Programming

A common technique [1, 11, 13, 10, 5] for analyzing Ranking algorithms is to define variables capturing the behavior of the algorithm in question, and derive structural properties that translate into constraints on the variables. A minimization LP with the performance ratio as the objective expressed in terms of the variables gives a lower bound on the ratio of the algorithm.

Let Ω be the sample space of configurations from which the algorithm derives its randomness. An *instance* $(\sigma, u) \in \Omega \times V$ is *good* if node u is matched when the algorithm is run with σ, and *bad* otherwise. We first describe the challenges encountered when previous techniques are applied to the node-weighted version of the problem on general graphs.

- *Why is the problem difficult on general graphs (as opposed to bipartite graphs)?* Bipartite graphs have the following nice property. Suppose in configuration σ, node u is unmatched, while its partner u^* in the optimal matching is matched to some node v. If the rank of u is promoted to form configuration σ', then u^* will be matched to some node v' such that the adjusted weight $w(\sigma', v') \geq w(\sigma, v)$ does not decrease. This naturally gives a way to relate the bad instance (σ, u) to the good instance (σ', v') [12, 11, 13, 1, 6], but unfortunately this property does not hold in general graphs. In fact, u^* might be unmatched in σ' as a result of u's promotion.
- *Why is the problem difficult when nodes have arbitrary weights (as opposed to uniform weight)?* In previous work [5] on the unweighted case, when u^* is matched in σ' in the above scenario, it is argued that the bad instance (σ, u) can be related to the good instance (σ', v), where v is matched in σ' to u^*. However, there is no guarantee that the adjusted weight $w(\sigma', v)$ of the good instance is at least $w(\sigma, u)$, which is needed as in [1, 6] to analyze the ratio for the weighted version.

To overcome the difficulties mentioned above, we have exploited the following structural properties of the Ranking algorithm. We analyze how the resulting matching would change if the rank of one node is changed (in Lemma 14), and give finer classification of good instances. In particular, the following notions are useful for relating bad instances to good instances in order to form LP constraints.

- **Graceful Instance.** A good instance (σ, u) is *graceful* if u is currently matched to a node v such that its optimal partner v^* does not exist or is also matched in σ.

- **Perpetual Instance.** If in a good instance (σ, u), node u has two unmatched neighbors, then (σ, u) is *perpetually good* in the sense that u will still be matched even when its rank is demoted to the bottom.

Breaking 0.5 Ratio for NwObMP. As in [1], we analyze the discrete sample space $\Omega_m := [m]^V$ (with the adjustment function $\varphi(t) := 1 - \frac{e^{17t}-1}{e^{17}-1}$, $\psi(i) := \varphi(\frac{i}{m})$ and adjusted weight $w(\sigma, u) := \psi(\sigma(u)) \cdot w_u$), and show that the performance ratio of weighted Ranking is at least the optimal value of some finite LP_m^ψ with m variables. Since LP_m^ψ does not depend on the size of G, computing the optimal value of LP_m^ψ for some large enough m is sufficient to prove a lower bound on the ratio of weighted Ranking. We show in our full version that a slightly better ratio can be analyzed using continuous LP for the limiting case as m tends to infinity.

We are aware of other adjustment functions that can achieve even slightly better ratios for the weighted Ranking, but we just present here a simple form that crosses the 0.5 barrier. Our result for the node-weighted case achieves the first non-trivial performance ratio that is strictly larger than 0.5.

Improved Ratio for Unweighted ObMP. We also apply our new combinatorial analysis to derive a new finite LP_n^U, that gives a lower bound on the performance ratio of unweighted Ranking running on graphs of size n. For the unweighted version of the problem, the limiting behavior of LP_n^U is analyzed when n tends to infinity and an improved lower bound on the performance ratio of unweighted Ranking is proved using a new class of continuous LP with jump discontinuity. The ideas for formulating the constraints are similar to the node-weighted case and we defer the proof to the full version.

1.4 Analyzing EwObMP and EwOnBiMP via Matching Coverage

Researchers have successfully applied the primal-dual LP framework to design approximation algorithms for matching problems [4, 6]. Consider the following standard maximum weight matching LP relaxation for an undirected graph $G = (V, E)$ with non-negative edge weights. Its dual is known as *vertex cover.*

$$\begin{aligned} \max \quad & w(x) := \sum_{\{u,v\}\in E} w_{uv} x_{uv} && (1) \\ \text{s.t} \quad & \sum_{u:\{u,v\}\in E} x_{uv} \le 1, && \forall v \in V \\ & x_{uv} \ge 0, && \forall \{u,v\} \in E \end{aligned} \qquad \begin{aligned} \min \quad & C(\alpha) := \sum_{u\in V} \alpha_u && (2) \\ \text{s.t} \quad & \alpha_v + \alpha_u \ge w_{uv}, && \forall \{u,v\} \in E \\ & \alpha_v \ge 0, && \forall v \in V \end{aligned}$$

An integral feasible primal solution x indicates whether an edge is selected and corresponds to some matching M, whose weight is denoted by $w(M) := w(x)$. When G is a bipartite graph between U and V, we use α_u for the variables for nodes in U and β_v for those corresponding to V.

Standard Primal-Dual Analysis. Typically, during the execution of an algorithm, both a primal and a dual solution are constructed. To analyze the approximation ratio, the value of the primal solution returned by the algorithm is compared with that of the dual solution. Since the primal is a maximization problem, any feasible dual provides an upper bound on the optimal primal value and can guarantee some approximation ratio. Hence, it is crucial in such a framework to establish the feasibility of the dual solution, for instance by either ensuring feasibility during construction, or scale the dual solution at the end by some appropriate factor. Dual feasibility requires that, for every edge in the graph, the sum of the dual values of its incident nodes is large enough.

New Framework. We observe that this strict requirement of dual feasibility is an artifact of the approximation analysis, and instead explore a new analysis method in which dual feasibility can be bypassed. Specifically, we use this new approach for different variations of edge-weighted maximum matching, and call it *matching coverage*. To emphasize that we do not achieve dual feasibility of any kind, we use a *vector* to mean an assignment of a non-negative value to each node.

▶ **Definition 5** (Matching Coverage)**.** Let M be a matching in graph G. A vector $\alpha \in \mathbb{R}^V$ is a *matching coverage* for matching M if α is non-negative, and the dual constraints of LP (2) corresponding to the edges of M are satisfied. In other words, for each $\{u, v\} \in M$, $\alpha_u + \alpha_v \geq w_{uv}$.

▶ Remark. Since any two distinct edges in a matching do not share any node, it follows that if a vector α is a matching coverage for a matching M, then $C(\alpha) \geq w(M)$.

General Framework of Matching Coverage. In our new analysis framework, the algorithm does not construct any dual solution (not even an infeasible one). This is a major departure from the conventional primal-dual framework in which some dual solution is usually constructed by an algorithm, whereas in our approach, the vector is used only for analysis. In the analysis, we imagine that as an algorithm ALG is executed, a vector α is constructed alongside with the knowledge of an optimal matching M^*. The idea is that the values in α are increased just enough to make sure that α is a matching coverage for M^*.

Why does this help the analysis? Since the vector α is a matching coverage for M^*, by Remark 1.4, we have $w(M^*) \leq C(\alpha)$. As α does not have to be feasible for all edge constraints, it is possible that the resulting value $C(\alpha)$ could be smaller than that of a feasible dual. Therefore, we can hope to get a smaller value of F when we compare $C(\alpha) \leq F \cdot w(M_{\mathsf{ALG}})$ with the weight of the matching M_{ALG} returned by ALG, thereby getting a larger performance ratio $w(M_{\mathsf{ALG}}) \geq \frac{1}{F} \cdot C(\alpha) \geq \frac{1}{F} \cdot w(M^*)$.

We use the framework of matching coverage to design and analyze algorithms for the following problems.

- EwObMP. In Section 4, we present an algorithm that achieves ratio strictly greater than 0.5 when the number of distinct edge weights is bounded. The full analysis is included in our full version.
- EwOnBiMP with Free Disposal. We present and analyze (in our full version) an algorithm that achieves ratio strictly greater than 0.5 when the online nodes have bounded degree. We show that without the free disposal assumption, no randomized algorithm can achieve any non-trivial constant guarantee on the ratio.

2 Defining Variables for Weighted Ranking on NwObMP

An adversary commits to a graph $G = (V, E)$ with $n = |V|$ nodes, where each node u has a non-negative weight w_u. We fix some maximum weight matching OPT in G. When the context is clear, we also use OPT to denote the set of nodes covered by the matching. Observe that in general OPT might be a proper subset of V. Let $w(\mathsf{OPT}) = \sum_{u \in \mathsf{OPT}} w_u$ be the total weight of OPT. For any $u \in V$, if u is matched in OPT, then we denote by u^* the partner of u in OPT, and we call u^* the *optimal partner* of u. If $u \notin \mathsf{OPT}$, then we say that u^* does not exist.

Weighted Ranking. As described in the introduction, the algorithm derives its randomness by sampling from $\Omega_m := [m]^V$ uniformly at random, where m is a sufficiently large integer and $[m] = \{1, 2, \ldots, m\}$. (We omit the subscript for Ω when the context is clear.) This is equivalent to picking $\sigma(u) \in [m]$ uniformly at random and independently for each $u \in V$. As in [1, 6], the algorithm fixes an *adjustment function* $\varphi : [0,1] \to [0,1]$ that is non-increasing. The function $\varphi(t) := 1 - e^{t-1}$ is used in [1, 6]. We shall consider other adjustment functions such that $\varphi(1) = 0$ also holds.

We denote $\psi(i) := \varphi(\frac{i}{m})$. Then, a permutation on V is induced by σ by sorting the nodes in non-increasing order of *adjusted weight* $w(\sigma, u) := \psi(\sigma(u)) \cdot w_u$, where ties are resolved deterministically (for instance by the identities of the nodes). This permutation on V induces a lexicographical order on the node pairs that is used for probing. We denote $(\sigma, u) > (\sigma, v)$ when node u comes before v in the permutation induced by σ, in which case u has higher priority than v.

We denote $\mathcal{U} := \Omega \times V$ as the set of *instances*. Let $M(\sigma)$ be the matching obtained when Ranking is run with configuration σ. If u is matched to some v after running Ranking with configuration σ, then we say that u is matched in σ and v is the (current) partner of u in σ. An instance (σ, u) is *good* if u is matched in σ, and otherwise *bad*. An event is a subset of instances.

Given $\sigma \in \Omega_m$, let σ_u^j be obtained by setting $\sigma_u^j(u) = j$ and $\sigma_u^j(v) = \sigma(v)$ for all $v \neq u$.

▶ **Definition 6** (Events)**.** For each $i \in [m]$, define the following:
- Rank-i good event: $Q_i := \{(\sigma, u) | \sigma(u) = i \textit{ and } u \textit{ is matched in } \sigma\}$
- Rank-i bad event: $R_i := \{(\sigma, u) | \sigma(u) = i, u \textit{ is not matched in } \sigma \text{ and } u \in \mathsf{OPT}\}$

Let $Q := \cup_{i \in [m]} Q_i$ and $R := \cup_{i \in [m]} R_i$.

Notice that Q_i and R_i are disjoint. While Q_i could involve nodes that are not in OPT, R_i only involves nodes in OPT; this idea also appears in [1] for dealing with the case when OPT is a proper subset of V. Define $x_i := \frac{\sum_{(\sigma,u) \in Q_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}}$, which can be interpreted as the conditional expected contribution of the nodes given that they are at rank i. We next derive some properties of the x_i's.

- **Monotonicity.** For $i \geq 2$, we have $x_{i-1} \geq x_i \geq 0$, since if $(\sigma, u) \in Q_i$, then $(\sigma_u^{i-1}, u) \in Q_{i-1}$. However, $1 \geq x_1$ does not necessarily hold since there may exist $u \notin \mathsf{OPT}$ and $(\sigma, u) \in Q_1$.
- **Loss due to unmatched nodes.** Similar to x_i associated with Q_i, we consider an analogous quantity associated with R_i:

$$\begin{aligned} \overline{x}_i := & \frac{\sum_{(\sigma,u) \in R_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} = \frac{\sum_{(\sigma,u) \in Q_i \cup R_i} w_u - \sum_{(\sigma,u) \in Q_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} \\ \geq & \frac{w(\mathsf{OPT}) \cdot m^{n-1} - \sum_{(\sigma,u) \in Q_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} = 1 - x_i, \end{aligned} \tag{3}$$

where the inequality $\sum_{(\sigma,u) \in Q_i \cup R_i} w_u \geq w(\mathsf{OPT}) \cdot m^{n-1}$ could be strict because Q_i might involve nodes not in OPT.

- **Performance Ratio.** The performance ratio is the expected sum of weights of matched nodes divided by $w(\mathsf{OPT})$, which is given by $\frac{\sum_{(\sigma,u)\in Q} w_u}{w(\mathsf{OPT})\cdot m^n} = \frac{1}{m}\sum_{i=1}^m x_i$.

▶ **Definition 7** (Marginally Bad Event). For $i \in [m]$, we define rank-i marginally bad event as follows. Let $S_1 := R_1$; for $i \geq 2$, let $S_i := \{(\sigma, u) \in R_i | (\sigma_u^{i-1}, u) \in Q_{i-1}\}$.

Let $S := \cup_{i\in[m]} S_i$ and $\alpha_i := \frac{\sum_{(\sigma,u)\in S_i} w_u}{w(\mathsf{OPT})\cdot m^{n-1}}$ for all $i \in [m]$.

Observe that for an instance (σ, u) such that (σ_u^m, u) is bad, there exists a unique $j \in [m]$ such that $(\sigma_u^j, u) \in S_j$, and we say that j is the *marginal position* of (σ, u).

Relating x_i's and α_i's. From a marginally bad instance $(\sigma, u) \in S_i$, node u will be matched when its rank is promoted to $i - 1$. Hence, for $i \geq 2$, we immediately have

$$\alpha_i \leq \frac{\sum_{(\sigma,u)\in Q_{i-1}} w_u - \sum_{(\sigma,u)\in Q_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} = x_{i-1} - x_i. \tag{4}$$

Moreover, for $i \in [m]$, any bad instance $(\sigma, u) \in R_i$ has a unique marginal position $j \in [i]$ such that $(\sigma_u^j, u) \in S_j$; for each $(\sigma, u) \in S_j$ such that $j \leq i$, we also have $(\sigma_u^i, u) \in R_i$. Hence, there is a one-one correspondence between R_i and $\cup_{j=1}^i S_j$, and so we have:

$$\sum_{j=1}^{i} \alpha_j = \frac{\sum_{j=1}^i \sum_{(\sigma,u)\in S_j} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} = \frac{\sum_{(\sigma,u)\in R_i} w_u}{w(\mathsf{OPT}) \cdot m^{n-1}} = \overline{x}_i \geq 1 - x_i. \tag{5}$$

▶ Remark. Observe that when all nodes in V are covered by OPT, equality holds for both (4) and (5). In fact, Lemma 9 allow us to remove the α_i's from the LP constraints.

▶ **Fact 8** (Ranking is Greedy). *Suppose* Ranking *is run with configuration σ. If (σ, u) is bad, then each neighbor of u (in G) is matched in σ to some node v such that $(\sigma, v) > (\sigma, u)$.*

3 Analyzing NwObMP Using Graceful and Perpetual Instances

In this section we define some relations from (marginally) bad events to good events to formulate our LP constraints. We describe a general principle which is a weighted version of the argument used in [5].

As mentioned above, the following lemma is used to remove the α_i's from the LP constraints.

▶ **Lemma 9.** *Suppose that $\{b_i\}_{i=1}^{m+1}$ is non-negative and non-increasing such that $b_{m+1} = 0$, and $\{c_i\}_{i=1}^{m+1}$ is non-decreasing such that $c_1 = 0$. Then, we have*
(a) $\sum_{i=1}^m b_i\alpha_i \geq b_1 - \sum_{i=1}^m (b_i - b_{i+1})x_i$.
(b) $\sum_{i=1}^m b_i c_i \alpha_i \geq -\sum_{i=1}^m (b_i c_i - b_{i+1}c_{i+1})x_i$.

Proof. Statement (a) follows because

$$\sum_{i=1}^m b_i\alpha_i = \sum_{i=1}^m (b_i - b_{i+1}) \sum_{j=1}^i \alpha_j \geq \sum_{i=1}^m (b_i - b_{i+1})(1 - x_i) = b_1 - \sum_{i=1}^m (b_i - b_{i+1})x_i\,,$$

where the inequality comes from (5).

For statement (b), observing that $c_1 = 0$, we can assume that $\alpha_1 = x_0 - x_1$, where $x_0 = 1$. Let $C = \max_i c_i$, and define $d_i := C - c_i \geq 0$. Then, we have

$$\sum_{i=1}^{m} b_i c_i \alpha_i = \sum_{i=1}^{m} C b_i \alpha_i - \sum_{i=1}^{m} b_i d_i \alpha_i \geq C b_1 - C \sum_{i=1}^{m} (b_i - b_{i+1}) x_i - \sum_{i=1}^{m} b_i d_i (x_{i-1} - x_i)$$
$$= - \sum_{i=1}^{m} (b_i c_i - b_{i+1} c_{i+1}) x_i \,,$$

where in the inequality we apply statement (a) to the first term (which is still valid because $\alpha_1 \geq 1 - x_1$ holds), and apply $\alpha_1 = x_0 - x_1$ and (4) to the second term. ◀

Weighting Principle. Suppose f is a relation from subset A to subset B of instances, where $f(a)$ is the set of elements in B that are related to $a \in A$, and $f^{-1}(b)$ is the set of elements in A that are related to $b \in B$. Recall that each instance $a = (\sigma, u)$ has adjusted weight $w(a) = w(\sigma, u)$. Suppose further that for all $a \in A$, for all $b \in f(a)$, $w(a) \leq w(b)$. Then, by considering the bipartite graph H induced by f on $A \cup B$, and comparing the weights of end-points for each edge in H, it follows that $\sum_{a \in A} |f(a)| \cdot w(a) \leq \sum_{b \in B} |f^{-1}(b)| \cdot w(b)$.

We shall formulate constraints by considering relations between subsets of instances. The injectivity of a relation f is the minimum integer q such that for all $b \in B$, $|f^{-1}(b)| \leq q$. In this case, we have

$$\textstyle\sum_{a \in A} |f(a)| \cdot w(a) \leq q \sum_{b \in B} w(b). \tag{6}$$

3.1 Demoting Marginally Bad Instances

▶ **Lemma 10.** *We have:* $\frac{1}{m} \sum_{i=1}^{m} [2\psi(i) + (m-i)(\psi(i) - \psi(i+1))] x_i \geq \psi(1)$.

Proof. We define a relation f from the set S of marginally bad instances to the set Q of good instances. Observe that for a (marginally) bad instance (σ, u), u is unmatched in σ and its optimal partner u^* exists. If we further demote u by setting its rank to $j \geq \sigma(u)$, the resulting matching is unchanged. Therefore, by Fact 8, for each $j \geq \sigma(u)$, u^* is matched to the same v such that $w(\sigma, u) \leq w(\sigma, v) = w(\sigma_u^j, v)$. Hence, we can define $f(\sigma, u) := \{(\sigma_u^j, v) | u^* \textit{ is matched to } v \textit{ in } \sigma_u^j, j \geq \sigma(u)\} \subseteq Q$, where $|f(\sigma, u)| = m - \sigma(u) + 1$, and $w(\sigma, u) \leq w(\sigma', v)$ for all $(\sigma', v) \in f(\sigma, u)$.

We next check the injectivity of f. Suppose $(\rho, v) \in f(\sigma, u)$. Then, u^* is the current partner of v in ρ, and this uniquely determines u, which is unmatched in ρ. Hence, $\sigma = \rho_u^j$, where j is uniquely determined as the marginal position of (ρ, u). Therefore, the injectivity is 1.

Hence, our weighting principle (6) gives the following:

$$\sum_{i=1}^{m} \sum_{(\sigma,u) \in S_i} (m - i + 1)\psi(i) w_u = \sum_{a \in S} |f(a)| \cdot w(a) \leq \sum_{b \in Q} w(b) = \sum_{i=1}^{m} \sum_{(\rho,v) \in Q_i} \psi(i) w_v.$$

Dividing both sides by $w(\mathsf{OPT}) \cdot m^n$ gives $\frac{1}{m} \sum_{i=1}^{m} (m - i + 1)\psi(i)\alpha_i \leq \frac{1}{m} \sum_{i=1}^{m} \psi(i) x_i$.

Since we do not wish α_i's to appear in our constraints, we derive a lower bound for the LHS in terms of x_i's by applying Lemma 9 with $b_i := (m - i + 1)\psi(i)$, where $\psi(m+1)$ can be chosen to be any value. Rearranging gives the required inequality. ◀

3.2 Promoting Marginally Bad Instances

▶ **Lemma 11.** *We have:* $\frac{2}{m}\sum_{i=1}^{m}\psi(i)\cdot x_m + \frac{1}{m}\sum_{i=1}^{m}[5\psi(i) - i(\psi(i+1) - \psi(i))]\cdot x_i \geq \frac{3}{m}\sum_{i=1}^{m}\psi(i)$.

To use the weighting principle, we shall define relations from marginally bad instances S to the following subsets of special good instances.

▶ **Definition 12** (*If v is matched, would v^* still be matched?*)**.** For $i \in [m]$, let the graceful instances be $Y_i := \{(\sigma, u) \in Q_i | u$ is matched in σ to some v s.t. v^* does not exist or is also matched in $\sigma\}$. Let $y_i := \frac{\sum_{(\sigma,u)\in Y_i} w_u}{w(\mathsf{OPT})\cdot m^{n-1}}$ and $Y := \cup_{i\in[m]} Y_i$.

▶ **Definition 13** (*You will be matched even at the bottom*)**.** For $i \in [m]$, let the perpetual instances be $Z_i = \{(\sigma, u) \in Q_i | (\sigma_u^m, u) \in Q_m\}$. Let $z_i = \frac{\sum_{(\sigma,u)\in Z_i} w_u}{w(OPT)\cdot m^{n-1}}$ and $Z := \cup_{i\in[m]} Z_i$.

By definition, we know that $Y_i \subseteq Q_i$ and hence $x_i \geq y_i \geq 0$. Moreover, observing that there exists a bijection between Z_i and Q_m that maps each $(\sigma, u) \in Z_i$ to $(\sigma_u^m, u) \in Q_m$, we have $z_i = x_m$.

Suppose (σ, u) is a good instance that has marginal position j. We wish to compare the matchings produced by σ and σ_u^j. Sometimes it is more convenient to consider an unmatched node as being ignored. Specifically, given a configuration σ and a node u, running Ranking with σ_u means that we still use σ to generate the probing order, but any edge involving u is ignored. Observe that if (σ, u) has a marginal position j, then σ_u and σ_u^j will produce the same matching.

▶ **Lemma 14** (Ignoring One Node)**.** *Suppose u is covered by the matching $M(\sigma)$ produced by σ, and $M(\sigma_u)$ is the matching produced by using the same probing list, but any edge involving u is ignored. The symmetric difference $M(\sigma) \oplus M(\sigma_u)$ is an alternating path $P = (u = u_1, u_2, \ldots, u_p)$ such that for all $i \in [p-2]$, $(\sigma, u_i) > (\sigma, u_{i+2})$.*

Proof. We can view probing G with σ_u as using the same list L of unordered node pairs to probe another graph G_u, which is the same as G except that the node u is labelled *unavailable* and will not be matched in any case. After each round of probing, we compare what happens to the partially constructed matchings $M(\sigma)$ in G and $M(\sigma_u)$ in G_u. For the sake of this proof, "unavailable" and "matched" are the same *availability status*, while "unmatched" is a different availability status.

We apply induction on the number of rounds of probing. Observe that the following invariants hold initially. (i) There is exactly one node known as the *crucial* node (which is initially u) that has different availability in G and G_u. (ii) The symmetric difference $M(\sigma) \oplus M(\sigma_u)$ is an alternating path P connecting u to the current crucial node; initially, both $M(\sigma)$ and $M(\sigma_u)$ are empty, and path P is degenerate and contains only u. (iii) If the path $P = (u = u_1, u_2, \ldots, u_l)$ contains $l \geq 3$ nodes, then for all $i \in [l-2]$, then $(\sigma, u_i) > (\sigma, u_{i+2})$.

Consider the inductive step. Suppose currently the alternating path $M(\sigma) \oplus M(\sigma_u)$ contains l nodes, where u_l is crucial. Observe that the crucial node and $M(\sigma) \oplus M(\sigma_u)$ do not change in a round except for the case when the pair being probed is an edge in G (and G_u), involving the crucial node u_l with another currently unmatched node u_{l+1} in G, which is also unmatched in G_u (because the induction hypothesis states that all nodes but u_l have the same availability status in G and G_u).

Since u_l has different availability in G and G_u, but u_{l+1} is unmatched in both G and G_u, it follows that the edge $e := \{u_l, u_{l+1}\}$ is added to exactly one of $M(\sigma)$ and $M(\sigma_u)$.

Hence, the edge e is added to extend the alternating path $M(\sigma) \oplus M(\sigma_u)$, and the node u_{l+1} becomes crucial.

Next, it remains to show that if $l \geq 2$, then $(\sigma, u_{l-1}) > (\sigma, u_{l+1})$. Suppose we go back in time, and consider at the beginning of the round when the edge $\{u_{l-1}, u_l\}$ is about to be probed, and u_{l-1} is crucial. By the induction hypothesis, both u_l and u_{l+1} are unmatched in both G and G_u. It follows that $(\sigma, u_{l-1}) > (\sigma, u_{l+1})$, because otherwise the edge $\{u_{l-1}, u_l\}$ would have lower probing priority than $\{u_{l+1}, u_l\}$. This completes the inductive step. ◀

▶ **Lemma 15** (Two Unmatched Neighbors Implies Perpetual). *Suppose in configuration σ, node u is matched and has two unmatched neighbors in G. Then, $(\sigma, u) \in Z$ is perpetual.*

Proof. If we assume the opposite, then u will be unmatched in σ_u^m. Suppose x and y are two neighbors of u that are unmatched in σ. Then, by Lemma 14, the symmetric difference $M(\sigma) \oplus M(\sigma_u^m)$ is an alternating path starting from u, and hence at most one of x and y will remain unmatched in σ_u^m.

This implies that in σ_u^m, the unmatched node u will have at least one unmatched neighbor; this contradicts the fact that that Ranking will always produce a maximal matching. ◀

Next we derive inequalities involving the graceful instances. Combining the inequalities, we can obtain the crucial constraint involving only x_i's for achieving a ratio that is strictly larger than 0.5.

▶ **Lemma 16** (*You are unmatched because someone is not graceful.*). *We have the following inequality: $\frac{1}{m}\sum_{i=1}^{m} \psi(i) y_i \leq \frac{1}{m}\sum_{i=1}^{m} \psi(i)(2x_i - 1)$.*

Proof. We define a relation from the set R of bad instances to the set $Q \setminus Y$ of good instances that are not graceful.

Given any bad instance $(\sigma, u) \in R$, we know that u^* exists and is matched to some node v such that $w(\sigma, v) \geq w(\sigma, u)$, by Fact 8. Moreover, since v is matched to u^* such that u is unmatched, we know that $(\sigma, v) \in Q \setminus Y$ is good but not graceful. Hence, we define $f(\sigma, u) := \{(\sigma, v)\}$, where v is the current partner of u^*. Observe that each $(\sigma, v) \in Q \setminus Y$ can be related to a unique $(\sigma, u) \in R$, where u is the optimal partner of v's current partner in σ. Hence, the injectivity of f is 1.

Hence, the weighting principle (6) gives: $\sum_{(\sigma,u)\in R} w(\sigma, u) \leq \sum_{(\sigma,v)\in Q\setminus Y} w(\sigma, v)$. Dividing both sides by $w(\mathsf{OPT}) \cdot m^n$ gives: $\frac{1}{m}\sum_{i=1}^{m} \psi(i)\overline{x}_i \leq \frac{1}{m}\sum_{i=1}^{m} \psi(i)(x_i - y_i)$.

Finally, using $\overline{x}_i \geq 1 - x_i$ from (3) and rearranging gives the required inequality. ◀

▶ **Lemma 17** (*If you are marginal, someone else is either graceful or perpetual*). *We have the inequality: $\frac{1}{m}\sum_{i=1}^{m}(i-1)\psi(i)\alpha_i \leq \frac{1}{m}\sum_{i=1}^{m} \psi(i)(3y_i + 2z_i)$.*

Proof. As mentioned earlier, we shall define two relations f and g from marginally bad S to graceful Y and perpetual Z, respectively, such that the following properties hold.

1. For each $a \in S$, for each $b \in f(a) \cup g(a)$, $w(a) \leq w(b)$.
2. For each $a \in S$, $|f(a)| + |g(a)| = \sigma(u) - 1$.
3. The injectivity of f is at most 3 and the injectivity of g is at most 2.

Suppose we have f and g with these properties. Then, our weighting principle (6) gives:

$$\sum_{(\sigma,u)\in S} (\sigma(u) - 1) w(\sigma, u) \leq \sum_{(\rho,v)\in Y} 3w(\rho, v) + \sum_{(\rho,v)\in Z} 2w(\rho, v),$$

which by definition is equivalent to

$$\sum_{i=1}^{m}(i-1)\psi(i)\sum_{(\sigma,u)\in S_i} w_u \le \sum_{i=1}^{m}\psi(i)(3\sum_{(\rho,v)\in Y_i} w_u + 2\sum_{(\rho,v)\in Z_i} w_u).$$

Dividing both sides by $w(\mathsf{OPT})\cdot m^n$ gives the required inequality.

Next we show how f and g are constructed such that all required properties hold.

Given marginally bad $(\sigma,u)\in S$, we consider good instance $(\sigma',u)\in Q$, where $\sigma' = \sigma_u^j, j<\sigma(u)$ is obtained by "promoting" u's rank in σ. Note that by Fact 8, u^* must be matched in σ to some node v_0 such that $(\sigma,v_0) > (\sigma,u)$. Let the partner of u in σ' be p. The next claim is crucial for the construction of f and g.

▶ **Claim 18.** *If $w(\sigma',p) < w(\sigma,u)$, then u^* is matched in σ' to some node v such that $w(\sigma',v)\ge w(\sigma,v_0)\ge w(\sigma,u)$.*

Proof. By Lemma 14, we know that the symmetric difference $M(\sigma')\oplus M(\sigma)$ is an alternating path $(u=u_1, p=u_2, u_3, u_4\ldots)$ that starts with u. Moreover, we have $w(\sigma',u)\ge w(\sigma',u_3)\ge w(\sigma',u_5)\ge\ldots$ and $w(\sigma',p)\ge w(\sigma',u_4)\ge w(\sigma',u_6)\ge\ldots$. If u^* is not contained in the alternating path, then directly we have $v=v_0$ and hence the claim holds.

Assume that u^* is contained in the alternating path. Then, v_0 must also appear in the alternating path. Let $v_0=u_i$. Since $w(\sigma',v_0)=w(\sigma,v_0)\ge w(\sigma,u) > w(\sigma',p)$, we conclude that i must be odd. By Lemma 14, we know that u^* must be u_{i-1} since u_i is matched to u_{i-1} in σ. Moreover, we know that $u^*=u_{i-1}$ is matched to u_{i-2} in σ' such that $w(\sigma',u_{i-2})\ge w(\sigma',u_i)=w(\sigma,v_0)$. ◀

Next we include instances in Y into $f(\sigma,u)$ and instances in Z into $g(\sigma,u)$ on a case by case basis. Recall that for each $1\le j<\sigma(u)$, we consider $\sigma'=\sigma_u^j$; moreover, after promoting u to rank j, u is matched in σ' to p.

Case-1(a). u^* is matched in σ' and $w(\sigma',p)=w(\sigma,p)\ge w(\sigma,u)$. In this case, (σ',p) is graceful, because p is matched in σ' to u, whose optimal partner u^* is also matched. Hence, we include $(\sigma',p)\in Y$ in $f(\sigma,u)$.

Case-1(b). u^* is matched in σ' and $w(\sigma',p)=w(\sigma,p)<w(\sigma,u)$. By Claim 18, u^* is matched in σ' to some node v such that $w(\sigma',v)\ge w(\sigma,u)$. Observe that (σ',v) is graceful, and we include $(\sigma',v)\in Y$ in $f(\sigma,u)$.

Case-2(a). u^* is unmatched in σ', and p^* (if it exists) is also matched in σ'. Note that after promoting u, we have $w(\sigma',u)\ge w(\sigma,u)$. Moreover, (σ',u) is graceful, because the optimal partner p^* either does not exist or is matched in σ'. We include $(\sigma',u)\in Y$ in $f(\sigma,u)$.

Case-2(b). u^* is unmatched in σ', p^* exists and is the only unmatched neighbor of p in σ'. By Claim 18, since u^* is unmatched in σ', we have $w(\sigma,p)=w(\sigma',p)\ge w(\sigma,u)$; also, since p is matched in σ', $p\ne u^*$. Moreover, by Lemma 14, the symmetric difference $M(\sigma)\oplus M(\sigma')$ is an alternating path, and only two nodes (u and u^*) can have different matching status in σ and σ'.

Hence, in σ, p must remain matched and p^* must remain unmatched; this means that p has exactly two unmatched neighbors, namely u and p^*, in σ. By Lemma 15, we conclude that (σ,p) is perpetual, and include $(\sigma,p)\in Z$ in $g(\sigma,u)$.

Case-2(c). u^* is unmatched in σ', p^* exists and is not the only unmatched neighbor of p in σ'. Similar to Case-2(b), in this case, $w(\sigma', p) = w(\sigma, p) \geq w(\sigma, u)$ and p has two different unmatched neighbors in σ', so (σ', p) is perpetual by Lemma 15. We include $(\sigma', p) \in Z$ in $g(\sigma, u)$.

By construction, property 1 holds. Moreover, for each $1 \leq j < \sigma(u)$ and $\sigma' = \sigma_u^j$, exactly one of the above 5 cases happens. Hence, we also have property 2: $|f(\sigma, u)| + |g(\sigma, u)| = \sigma(u) - 1$. Next, we prove the injectivity.

Injectivity Analysis. Observe that in our construction, if $(\rho, v) \in f(\sigma, u) \cup g(\sigma, u)$, then $\sigma = \rho_u^t$, where t is the marginal position of (ρ, u). Hence, in the injectivity analysis, once (ρ, v) and u are identified, σ can be uniquely determined.

For relation f, suppose $(\rho, v) \in Y$ is included in some $f(\sigma, u)$ in the following cases.

- **Case-1(a).** Node u is uniquely identified as the current partner of v in ρ.
- **Case-1(b).** Node u is uniquely identified as the optimal partner of v's current partner.
- **Case-2(a).** Node u is the same as v.

Hence, each $(\rho, v) \in Y$ is related to at most 3 instances in S, which means that f has injectivity at most 3.

For relation g, suppose $(\rho, v) \in Z$ is included in some $g(\sigma, u)$ in the following cases.

- **Case-2(b).** By construction $\rho = \sigma$, and v has exactly two neighbors that are unmatched in ρ, one of which is v^*. Node u is uniquely identified as the other unmatched neighbor.
- **Case-2(c).** Node u is uniquely identified as the current partner of v in ρ.

Hence, each $(\rho, v) \in Z$ is related to at most 2 instances in S, which means that g has injectivity at most 2. This completes the proof of Lemma 17. ◀

We can now derive the main constraint of this subsection.

Proof of Lemma 11. We start from the inequality in Lemma 16. Observing that $z_i = x_m$, and using the upper bound for $\frac{1}{m}\sum_{i=1}^m \psi(i) y_i$ in Lemma 17, we have $\frac{1}{m}\sum_{i=1}^m (i-1)\psi(i)\alpha_i \leq \frac{1}{m}\sum_{i=1}^m \psi(i)(6x_i + 2x_m - 3)$.

We next use Lemma 9 by setting $b_i := \psi(i)$ and $c_i := i - 1$; observe that $c_1 = 0$, and we set $\psi(m+1) := 0$, which is consistent with $\psi(m) \geq 0 = \psi(m+1)$. Hence, we have the following lower bound for the LHS: $\frac{1}{m}\sum_{i=1}^m (i-1)\psi(i)\alpha_i \geq \frac{1}{m}\sum_{i=1}^m (\psi(i) + i(\psi(i+1) - \psi(i))) \cdot x_i$.

Rearranging gives the required inequality. ◀

3.3 Using LP to Bound Performance Ratio

Putting all achieved constraints on x_i's together, we obtain the following linear program LP_m^ψ, which is a lower bound on the performance ratio when weighted Ranking is run with weight adjustment function ψ and sample space $\Omega_m = [m]^V$.

$$
\begin{array}{llll}
\mathsf{LP}_m^\psi & \min & \frac{1}{m}\sum_{i=1}^m x_i & \\
& \text{s.t.} & x_i - x_{i+1} \geq 0, & i \in [m-1] \\
\multicolumn{3}{r}{\frac{2}{m}\sum_{i=1}^m \psi(i) \cdot x_m + \frac{1}{m}\sum_{i=1}^m [5\psi(i) - i(\psi(i+1) - \psi(i))] \cdot x_i \geq \frac{3}{m}\sum_{i=1}^m \psi(i)} & (7) \\
\multicolumn{3}{r}{\frac{1}{m}\sum_{i=1}^m [2\psi(i) + (m-i)(\psi(i) - \psi(i+1))] x_i \geq \psi(1)} & (8) \\
& & x_i \geq 0, & i \in [m].
\end{array}
$$

Achieving ratio strictly larger than 0.5. Observe that LP_m^ψ is independent of the size of G. Hence, to obtain a lower bound on the ratio, we can use an LP solver to solve LP_m^ψ for some large enough m and some appropriate non-negative non-increasing sequence $\{\psi(i)\}_{i=1}^m$. In particular, there exists a weighted Ranking algorithm with ratio strictly above 0.5.

▶ **Theorem 19.** *Using $m = 10000$ and $\psi(i) := 1 - \frac{e^{\frac{17i}{m}}-1}{e^{17}-1}$, the weighted* Ranking *algorithm has performance ratio at least the value given by LP_m^ψ: 0.501505.*

Although the function $\varphi(t) := 1 - e^{t-1}$ (that is used in [1, 6]) cannot give a ratio better 0.5 from our LP, it is still possible that the function could have good performance ratio. More experimental results and our source code can be downloaded at:
`http://i.cs.hku.hk/~algth/project/online_matching/weighted.html`.

Limiting case when m tends to infinity. Experiments show that LP_m^ψ is increasing in m. This suggests that a (slightly) better analysis may be achieved if Ranking samples σ from the continuous space $\Omega_\infty = [0,1]^V$, and uses adjusted weight $w(\sigma, u) := \varphi(\sigma(u)) \cdot w_u$ for each node u.

The variables x_i's are replaced by the function $z(t) := \frac{\sum_{u \in V} \Pr_\sigma[(\sigma,u) \text{ is good} | \sigma(u)=t] \cdot w_u}{w(\mathsf{OPT})}$. Our combinatorial counting argument can be replaced by measure analysis. For instance, $\Omega_\infty = [0,1]^V$ is equipped with the uniform n-dimensional measure, while $z(t)$ has measure of dimension $n-1$. Since we assume that $\psi(m+1) = 0$ in the finite analysis, this corresponds to $\varphi(1) = 0$ in continuous case.

Observe that it is possible to describe a continuous version of the weighting principle using measure theory to derive all the corresponding constraints involving z. However, the formal rigorous proof is out of the scope of this paper, and one can intuitively see that each constraint involving the x_i's translates naturally to a constraint involving z in the limiting case. Hence, the following continuous $\mathsf{LP}_\infty^\varphi$ gives a lower bound on the ratio when Ranking samples continuously, and we analyze it in our full version as a case study.

$$\begin{array}{lll}
\mathsf{LP}_\infty^\varphi & \min & \int_0^1 z(t)dt \\
& \text{s.t.} & z'(t) \le 0 \qquad \forall t \in [0,1] \\

▶ **Theorem 20** (Weighted Ranking with Continuous Sampling)**.** *Using continuous sample space Ω_∞ (with adjustment function $\varphi(t) := 1 - \frac{e^{17t}-1}{e^{17}-1}$), weighted* Ranking *has performance ratio at least* 0.501512.

4 Beating Ratio 0.5 for EwObMP

We consider EwObMP where the number of distinct weights is k. We give an algorithm whose performance ratio is $\frac{1}{2} + \xi_k$, where ξ_k only depends on k. As a subroutine, we use an algorithm $\mathcal{A}^{un}$ for the unweighted version of the problem with performance ratio $\frac{1}{2} + \xi_1$, where $\xi_1 > 0$. For instance, Theorem 2 implies that $\xi_1 \ge 0.0268$. When we run $\mathcal{A}^{un}$ on a subset $H \subseteq \binom{V}{2}$, $\mathcal{A}^{un}$ is first run to produce a random order L of node pairs. Only pairs in H are kept in L, while pairs not in H are removed. Then, the list L is used for probing as before. We partition the pairs in $\binom{V}{2}$ into batches $\{H_i\}_{i\geq 1}$, where the weights of pairs in each batch are similar. Then, starting from the batch with largest weights, we run $\mathcal{A}^{un}$ on each batch H_i to produce a list L_i, and return the concatenated list used for probing.

The following lemma, whose proof can be found in the full version, describes the properties of the intervals picked by the algorithm. Recall that $\mathcal{A}^{un}$ has performance ratio $\frac{1}{2}+\xi_1$ on unweighted ObMP. Given two real numbers $a \leq b$, we denote $\mathsf{dist}(a,b) := 1-\frac{a}{b}$.

▶ **Lemma 21** (Partitioning Weights into Batches). *Given a set W of k distinct weights, there exists an integer $r = O(k^2)$ and $\epsilon = \frac{\xi_1}{2}$ such that the algorithm can return disjoint intervals $\{I_i := [a_i,b_i]\}_{i\geq 1}$, whose union contains W, and for each $i \geq 1$, $b_{i+1} < a_i$, $\mathsf{dist}(a_i,b_i) \leq \epsilon^r$ and $\mathsf{dist}(b_{i+1},b_i) \geq \epsilon^{r-1}$.*

Algorithm 1 Algorithm for Edge-Weighted ObMP

```
1: $W \leftarrow \{w_e : e \in \binom{V}{2}\}$                    ▷ Set of weights of pairs in $\binom{V}{2}$.
2: $\{I_i := [a_i,b_i]\}_{i=1}^K \leftarrow$ Disjoint intervals as given in Lemma 21 to partition $W$, where $I_1$ is
   the interval with the largest weights.
3: for $i$ from 1 to $K$ do
4:     $H_i \leftarrow$ Pairs in $\binom{V}{2}$ with weights in $I_i$
5:     $L_i \leftarrow$ List produced by running unweighted $\mathcal{A}^{un}$ on $H_i$ using independent randomness
6: return concatenated list $L := L_1 \oplus L_2 \oplus \cdots \oplus L_K$
```

Assuming the knowledge of an optimal matching OPT, we construct a matching coverage $\alpha \in \mathbb{R}^V$ for OPT during an execution of the algorithm. For a matching M, we use $|M|$ to denote its cardinality and $w(M)$ to denote the sum of weights of its edges. We say an edge e in OPT is *destroyed* by a matching M if edge e is not in M but at least one end-point of e is matched in M. Moreover, two edges *intersect* if they share at least one end-point. We define the following edge sets for $i \geq 1$.

- ALG_i is the set of edges the algorithm includes in the matching when list L_i is probed.
- OPT_i is the set of edges in OPT that intersect with edges in ALG_i, but do not intersect with edges in ALG_j, for all $j < i$.
- $\mathsf{OPT}_i^H := \mathsf{OPT}_i \cap H_i$, each of which has weight in $[a_i,b_i]$.

The matching resulting from the probing list L returned by the algorithm is $\mathsf{ALG} := \cup_i \mathsf{ALG}_i$. Since ALG is a maximal matching in G, it follows that every edge in OPT appears in exactly one OPT_i.

Suppose V_i is the set of nodes matched in ALG_i. Let $C(\alpha_{V_i}) := \sum_{v\in V_i} \alpha_v$, where α_{V_i} is the vector α restricted to coordinates corresponding to V_i.

We defer the proof of the following lemma to our full version.

▶ **Lemma 22** (Local Performance Ratio). *Suppose the weights of H_i are in $[a_i,b_i]$, where $\eta := \mathsf{dist}(a_i,b_i)$; moreover, let $\lambda := \mathsf{dist}(b_{i+1},b_i)$. Then, $\mathbf{E}[w(\mathsf{ALG}_i)] \geq (1-\eta)\cdot(\frac{1}{2}+\frac{\xi_1\lambda}{1+2\xi_1})\cdot \mathbf{E}[C(\alpha_{V_i})]$.*

Finally, we are ready to prove the performance ratio of the algorithm.

Proof of Theorem 3. From Lemma 21, it follows that the parameters in Lemma 22 satisfy $\lambda \geq \epsilon^{r-1}$ and $\eta \leq \epsilon^r$, where $r = O(k^2)$. Observing that $\epsilon = \frac{\xi_1}{2} \leq \frac{1}{4}$, it follows that the local performance ratio is

$$\begin{aligned}\frac{\mathbf{E}[w(\mathsf{ALG}_i)]}{\mathbf{E}[C(\alpha_{V_i})]} &\geq (1-\eta)\left(\frac{1}{2}+\frac{\xi_1\lambda}{1+2\xi_1}\right) \geq (1-\epsilon^r)\left(\frac{1}{2}+\frac{\xi_1\epsilon^{r-1}}{1+2\xi_1}\right)\\ &=(1-\epsilon^r)\left(\frac{1}{2}+\frac{2\epsilon^r}{1+2\xi_1}\right)\\ &=\frac{1}{2}+\frac{\epsilon^r}{2+4\xi_1}\cdot(3-4(\epsilon+\epsilon^r)) \geq \frac{1}{2}+\frac{1}{2+4\xi_1}(\frac{\xi_1}{2})^r,\end{aligned}$$

where the last inequality follows because $r \geq 1$ and $\epsilon \leq \frac{1}{4}$.

Hence, we have $\mathbf{E}[\mathsf{ALG}] = \sum_i \mathbf{E}[\mathsf{ALG}_i] \geq (\frac{1}{2}+\frac{1}{2+4\xi_1}(\frac{\xi_1}{2})^r)\sum_i \mathbf{E}[C(\alpha_{V_i})]$. Finally, observe that $\sum_i \mathbf{E}[C(\alpha_{V_i})] = E[C(\alpha)] \geq w(\mathsf{OPT})$, as α is a matching coverage for OPT. Therefore, we conclude that the performance ratio for the whole algorithm is at least $\frac{1}{2}+\xi_k$, where $\xi_k = \frac{1}{2+4\xi_1}(\frac{\xi_1}{2})^r = \Omega(\xi_1)^{O(k^2)}$, as required. ◀

Abstract

We describe the first algorithm to compute the outer common tangents of two disjoint simple polygons using linear time and only constant workspace. A tangent of a polygon is a line touching the polygon such that all of the polygon lies on the same side of the line. An outer common tangent of two polygons is a tangent of both polygons such that the polygons lie on the same side of the tangent. Each polygon is given as a read-only array of its corners in cyclic order. The algorithm detects if an outer common tangent does not exist, which is the case if and only if the convex hull of one of the polygons is contained in the convex hull of the other. Otherwise, two corners defining an outer common tangent are returned.

1 Introduction

A tangent of a polygon is a line touching the polygon such that all of the polygon lies on the same side of the line. An outer common tangent of two polygons is a tangent of both polygons such that the polygons lie on the same side of the tangent. Two disjoint polygons have exactly two outer common tangents unless their convex hulls are nested. If they are properly nested, there is no outer common tangent. In this paper, we study the problem of computing the outer common tangents of two disjoint simple polygons, each given as a read-only array of its corners in cyclic order. We give an algorithm computing the outer common tangents in linear time using only a constant number of variables each storing a boolean value or an index of a corner in the array. We are therefore working in the *constant workspace model* of computation.

The constant workspace model is a restricted version of the RAM model in which the input is read-only, the output is write-only, and only $O(\log n)$ additional bits of *workspace* (with both read and write access) are available, where n is the size of the input. Clearly, $\Omega(\log n)$ bits in the workspace are necessary to solve any interesting computational problem, because that many bits are required to store an index of or a pointer to an entry in the input. Since blocks of $\Theta(\log n)$ bits are considered to form *words* in the memory, algorithms in the constant workspace model use $O(1)$ words of memory, which explains the name of the model.

* Research partially supported by Mikkel Thorup's Advanced Grant from the Danish Council for Independent Research under the Sapere Aude research career programme.

The practical relevance of studying problems in the constant workspace model is increasing, as there are many current and emerging memory technologies where writing can be much more expensive than reading in terms of time and energy [8].

The constant workspace model was first studied explicitly for geometric problems by Asano et al. [4]. Recently, there has been growing interest in algorithms for geometric problems using constant or restricted workspace, see for instance [1, 3, 5, 6, 9, 11, 14].

The problem of computing common tangents of two polygons has received most attention in the case that the polygons are convex. For instance, computing the outer common tangents of disjoint convex polygons is used as a subroutine in the classical divide-and-conquer algorithm for the convex hull of a set of n points in the plane due to Preparata and Hong [17]. They give a naive linear-time algorithm for outer common tangents, as it suffices for an $O(n \log n)$-time convex hull algorithm. The problem is also considered in various dynamic convex hull algorithms [7, 12, 16]. Overmars and van Leeuwen [16] give an $O(\log n)$-time algorithm for computing an outer common tangent of two disjoint convex polygons when a separating line is known, where each polygon has at most n corners. Kirkpatrick and Snoeyink [13] give an $O(\log n)$-time algorithm for the same problem but without using a separating line. Guibas et al. [10] give a lower bound of $\Omega(\log^2 n)$ on the time required to compute an outer common tangent of two intersecting convex polygons, even if they are known to intersect in at most two points. They also describe an algorithm achieving that bound. Toussaint [18] considers the problem of computing separating common tangents of convex polygons and notes that the problem occurs in problems related to visibility, collision avoidance, range fitting, etc. He gives a linear-time algorithm. Guibas et al. [10] give an $O(\log n)$-time algorithm for the same problem. All the above-mentioned algorithms with sublinear running times make essential use of the convexity of the polygons. If the polygons are not convex, a linear-time algorithm can be used to compute the convex hulls before computing the tangents [15]. However, if the polygons are given in read-only memory, $\Omega(n)$ extra bits are required to store the convex hulls, so this approach does not work in the constant workspace model.

Abrahamsen [2] gives a linear-time constant-workspace algorithm to compute the outer common tangents of two simple polygons the convex hulls of which are disjoint. In this paper, we show that the same is possible as long as the polygons (but not necessarily their convex hulls) are disjoint. The algorithm is only slightly different from the one in [2], but its proof of correctness requires much more effort. In particular, the proof relies on an intricate continuous analysis of the algorithm. Before, it was not even clear whether to expect existence of a linear-time constant-workspace algorithm that does not require the convex hulls to be disjoint, because it happens quite often that a computational problem exhibits different behavior for disjoint polygons and for polygons that are not disjoint. For instance, as it has been mentioned above, the outer common tangents of two disjoint convex polygons can be computed in time $O(\log n)$, while doing the same for two convex polygons that intersect in two points requires time $\Omega(\log^2 n)$.

A separating common tangent of two polygons is a tangent of both polygons such that the polygons lie on the opposite sides of the tangent. Two disjoint polygons have exactly two separating common tangents provided that their convex hulls are disjoint. If they intersect properly, there is no separating common tangent. Abrahamsen [2] describes a linear-time constant-workspace algorithm that computes the separating common tangents of two simple polygons. In particular, it detects whether the convex hulls of two simple polygons are disjoint. Our current algorithm can decide whether the convex hulls two simple polygons are nested, which happens when it is unable to find an outer common tangent. To the best of our knowledge, this was not known to be possible in linear time and constant workspace prior to this work. Our algorithm and the algorithm from [2] together enable us to determine, for two disjoint simple polygons in general position, the full relation between their convex hulls (whether they are nested, overlapping, or disjoint) in linear time and constant workspace.

It remains open whether an outer common tangent of two polygons that are not disjoint can be found in linear time using constant workspace.

2 Terminology and Notation

For any two points a and b in the plane, the closed line segment with endpoints a and b is denoted by ab. When $a \neq b$, the straight line containing a and b that is infinite in both directions is denoted by $\mathcal{L}(a, b)$, and the ray starting at a and going through b is denoted by $\mathcal{R}(a, b)$. For three points a, b, and c, consider the line $\mathcal{L}(a, b)$ as oriented from a towards b, and define $\mathcal{T}(a, b, c)$ to be 1 if c lies to the left of $\mathcal{L}(a, b)$, 0 if a, b, c are collinear, and -1 if c lies to the right of $\mathcal{L}(a, b)$. Let $\mathrm{LHP}(a, b)$ denote the closed half-plane lying to the left of $\mathcal{L}(a, b)$ and $\mathrm{RHP}(a, b)$ denote the closed half-plane lying to the right of $\mathcal{L}(a, b)$.

A *simple polygon*, or just a *polygon*, with *corners* $x_0, \dots, x_{n-1}$ is a closed polygonal curve in the plane composed of n *edges* $x_0x_1, \dots, x_{n-2}x_{n-1}, x_{n-1}x_0$ such that the segments have no common points other than the common endpoints of pairs of consecutive edges. The region of the plane bounded by a polygon P (including P itself) is a *polygonal region*.

Assume for the rest of this paper that P_0 and P_1 are two disjoint simple polygons with n_0 and n_1 corners, respectively. (We allow one of P_0 and P_1 to be contained in the "interior region" of the other – in that case our algorithm will report that the convex hulls are nested and no outer common tangent exists.) Assume that P_k is defined by a read-only array of its corners $p_k[0], p_k[1], \dots, p_k[n_k - 1]$ for $k \in \{0, 1\}$. Assume further, without loss of generality, that the corners of P_0 are given in counterclockwise order and the corners of P_1 are given in clockwise order. (The orientation of a polygon can be easily tested in linear time using constant workspace, and the algorithm can choose to traverse the polygon forwards or backwards, accordingly.) Finally, assume that the corners are in general position in the sense that P_0 and P_1 have no corners in common and the combined set of corners $\{p_0[0], \dots, p_0[n_0 - 1], p_1[0], \dots, p_1[n_1 - 1]\}$ contains no triple of collinear points.

Indices of the corners of P_k are considered modulo n_k, so that $p_k[i]$ and $p_k[j]$ denote the same corner when $i \equiv j \pmod{n_k}$. For $a, b \in P_k$, the *chain* $P_k[a, b]$ is the portion of P_k from a to b in the order assigned to P_k (counterclockwise for P_0, clockwise for P_1). If i and j are indices of corners on P_k, we write $P_k[i, j]$ to denote $P_k[p_k[i], p_k[j]]$.

A *tangent* of P_k is a line ℓ such that ℓ and P_k are not disjoint and P_k is contained in one of the closed half-planes determined by ℓ. The line ℓ is a *common tangent* of P_0 and P_1 if it is a tangent of both P_0 and P_1. A common tangent is an *outer common tangent* if P_0 and P_1 are on the same side of the tangent, otherwise the common tangent is *separating*.

For a simple polygon P, let $\mathcal{H}(P)$ denote the convex hull of P. The following lemma asserts well-known properties of common tangents of polygons. See Figures 1–3.

▶ **Lemma 1.** *A line is a tangent of a polygon P if and only if it is a tangent of $\mathcal{H}(P)$. Under our general position assumptions, the following holds. If one of $\mathcal{H}(P_0)$ and $\mathcal{H}(P_1)$ is completely contained in the other, there are no outer common tangents of P_0 and P_1. Otherwise, there are two or more, and there are exactly two if P_0 and P_1 are disjoint. If $\mathcal{H}(P_0)$ and $\mathcal{H}(P_1)$ are not disjoint, there are no separating common tangents of P_0 and P_1. Otherwise, there are exactly two.*

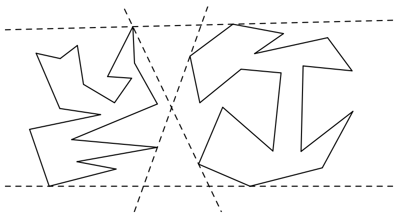

Figure 1 The convex hulls are disjoint – separating and outer common tangents exist.

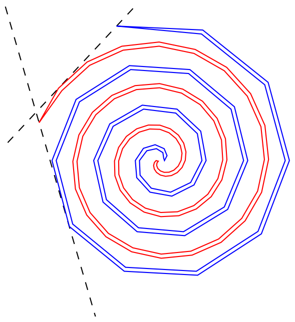

Figure 2 The convex hulls overlap – only outer common tangents exist.

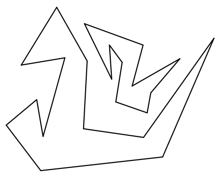

Figure 3 The convex hulls are nested – no common tangents exist.

Algorithm 1: `OuterCommonTangent`(P_0, P_1)

```
1  $s_0 \leftarrow 0$;  $v_0 \leftarrow 0$;  $b_0 \leftarrow$ false;  $s_1 \leftarrow 0$;  $v_1 \leftarrow 0$;  $b_1 \leftarrow$ false;  $u \leftarrow 0$
2  while $s_0 < 2n_0$ and $s_1 < 2n_1$ and $(v_0 < s_0 + n_0$ or $v_1 < s_1 + n_1)$
3      $v_u \leftarrow v_u + 1$
4      if $\mathcal{T}(p_0[s_0], p_1[s_1], p_u[v_u]) = 1$
5          if $p_{1-u}[s_{1-u}] \in \Delta(p_u[s_u], p_u[v_u - 1], p_u[v_u])$
6              $b_u \leftarrow$ true
7          if not $b_u$
8              $s_u \leftarrow v_u$;  $v_{1-u} \leftarrow s_{1-u}$;  $b_{1-u} \leftarrow$ false
9      $u \leftarrow 1 - u$
10 if $s_0 \geq 2n_0$ or $s_1 \geq 2n_1$ or $b_0$ or $b_1$
11     return nested
12 return $(s_0, s_1)$
```

3 Algorithm

Let the outer common tangents of P_0 and P_1 be defined by pairs of corners (ℓ_0, ℓ_1) and (r_0, r_1) so that $\ell_0, r_0 \in P_0$, $\ell_1, r_1 \in P_1$, and $P_0, P_1 \subset \mathrm{LHP}(\ell_0, \ell_1) \cap \mathrm{RHP}(r_0, r_1)$. Algorithm 1 returns a pair of indices (s_0, s_1) such that $(r_0, r_1) = (p_0[s_0], p_1[s_1])$ or, if the convex hulls of P_0 and P_1 are nested so that the tangents do not exist, the algorithm reports that by returning `nested`. Finding (ℓ_0, ℓ_1) requires running Algorithm 1 with the roles of P_0 and P_1 interchanged and with the orders of the corners of P_0 and P_1 reversed – each array reference $p_k[i]$ is translated to $p_{1-k}[-i]$ for $k \in \{0, 1\}$, and the returned result is (s_1, s_0) such that $(\ell_0, \ell_1) = (p_0[s_0], p_1[s_1])$.

The algorithm maintains a pair of indices (s_0, s_1) which determines the *tangent candidate* $\mathcal{L}(p_0[s_0], p_1[s_1])$. Starting from $(s_0, s_1) = (0, 0)$ and advancing the indices s_0, s_1 appropriately, the algorithm attempts to reach a situation that $(p_0[s_0], p_1[s_1]) = (r_0, r_1)$, that is, $P_0, P_1 \subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$. At the start and after each update to (s_0, s_1), the algorithm traverses P_0 and P_1 in parallel with indices (v_0, v_1), starting from $(v_0, v_1) = (s_0, s_1)$ and advancing v_0 and v_1 alternately. The variable $u \in \{0, 1\}$ determines the polygon P_u in which we advance the traversal in a given iteration. If the test in line 4 happens to be positive, then the corner $p_u[v_u]$ lies on the "wrong side" of the tangent candidate, witnessing $P_u \not\subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$.

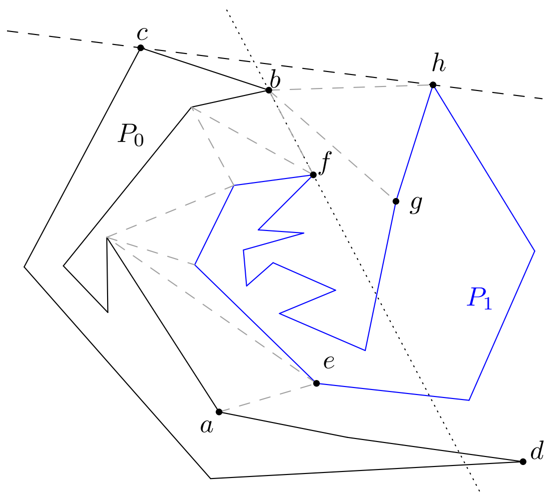

Figure 4 An example of how Algorithm 1 finds the outer common tangent $\mathcal{L}(c, h)$ of P_0 and P_1. The start points are $(p_0[0], p_1[0]) = (a, e)$. The gray dashed line segments are the segments $p_0[s_0]p_1[s_1]$ on the various tangent candidates. In the 11th iteration, an update makes $(p_0[s_0], p_1[s_1]) = (b, f)$, so the tangent candidate becomes the dotted line $\mathcal{L}(b, f)$. In the 19th iteration, $u = 0$ and $p_0[v_0] = d$, so b_0 is set to `true`. In the 28th iteration, $u = 1$ and $p_1[v_1] = g$, and therefore b_0 is cleared. In the 31st iteration, an update makes $(p_0[s_0], p_1[s_1]) = (c, h)$ and the outer common tangent has been found.

In that case, the algorithm updates the tangent candidate by setting $s_u \leftarrow v_u$ and reverts v_{1-u} back to s_{1-u} in line 8, unless a special boolean variable b_u is set, which we will comment on shortly. The reason for reverting v_{1-u} back to s_{1-u} in line 8 is that a corner of P_{1-u} which was on the correct side of the tangent candidate before the update to s_u can be on the wrong side of the tangent candidate after the update to s_u, and then it needs to be traversed again in order to be detected. The algorithm returns (s_0, s_1) in line 12 when it has traversed both polygons entirely with indices v_0 and v_1 after last updates to s_0 and s_1 without detecting any corner on the wrong side of the tangent candidate. That can happen only when $P_0, P_1 \subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$. See Figure 4 for an example of how the algorithm proceeds.

In the test in line 5, $\Delta(a, b, c)$ denotes the filled triangle with corners a, b, c. If that test is positive, then $p_{1-u}[s_{1-u}]$ belongs to the convex hull of P_u, so $p_{1-u}[s_{1-u}] \neq r_{1-u}$. In that case, the boolean variable b_u is set, and then it prevents any updates to s_u in line 8 until it is cleared after a later update to s_{1-u} in line 8. It will be shown in the proof of Lemma 3 that such an update to s_{1-u} must occur if the convex hulls of P_0 and P_1 are not nested.

The main effort in proving correctness of Algorithm 1 lies in the following lemma, which is proved in Section 4.

▶ **Lemma 2.** *If the outer common tangents of P_0 and P_1 exist, then the loop in line 2 of Algorithm 1 ends with $s_0 < 2n_0$ and $s_1 < 2n_1$.*

The above implies that the algorithm ends up returning (s_0, s_1) in line 12 provided that $b_0 = b_1 =$ `false` when the loop in line 2 ends (this will be proved in Lemma 3).

To explain the role of the special variables b_0 and b_1, suppose temporarily that the conditions $s_0 < 2n_0$ and $s_1 < 2n_1$ are omitted from the test in line 2. If we were making the updates in line 8 regardless of the current values of b_0 and b_1, the algorithm could never end making updates to s_0 and s_1 even if the outer common tangents exist (see [2] for an example of such a behavior). In particular, Lemma 2 would no longer be true. On the other hand, if the convex hulls of P_0 and P_1 are nested, then one of the following happens:

- the algorithm never ends making updates to s_0 and s_1,
- one of b_0, b_1, say b_k, is `true` and the algorithm has traversed P_{1-k} entirely with the index v_{1-k} after last update to s_{1-k} without detecting any corner on the wrong side of the tangent candidate.

In both cases, taking the conditions $s_0 < 2n_0$ and $s_1 < 2n_1$ in line 2 back into account, the algorithm reports that the convex hulls of P_0 and P_1 are nested in line 11.

▶ **Lemma 3.** *If the outer common tangents of P_0 and P_1 exist, then the loop in line 2 of Algorithm 1 ends with $b_0 = b_1 =$ `false`.*

Proof. We prove a slightly stronger statement, namely, that at most one of b_0 and b_1 can be `true` at a time, and if one of b_0 and b_1 is `true`, then it will be cleared subsequently. Hence, the algorithm cannot terminate with $b_0 =$ `true` or $b_1 =$ `true`.

Consider an iteration i of the loop in line 2 which leads to changing the value of b_0 from `false` to `true` in line 6. By induction, we can assume that $b_1 =$ `false`. Since the test in line 5 is positive, the edge $P_0[v_0 - 1, v_0]$ intersects $\mathcal{L}(p_0[s_0], p_1[s_1])$ at a point x such that $p_1[s_1]$ lies on the segment $p_0[s_0]x$. Moreover, $P_0[p_0[s_0], x] \subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$, otherwise b_0 would be set before. Let y be the first corner of P_1 after $p_1[s_1]$ such that $y \notin \mathrm{RHP}(p_0[s_0], p_1[s_1])$. Such a corner exists, otherwise P_1 would be contained in the convex hull of P_0. It follows that the test in line 4 will be positive in the first iteration j after i in which $u = 1$ and $p_1[v_1] = y$. The edge $P_1[v_1 - 1, v_1]$ intersects $\mathcal{L}(p_0[s_0], p_1[s_1])$ at a point on the segment $p_0[s_0]x$, and hence the test in line 5 is negative in iteration j. Therefore, b_0 is cleared and we again have $b_0 = b_1 =$ `false`. The same argument shows that b_1 will be cleared after being set. ◀

▶ **Theorem 4.** *Algorithm 1 is correct, runs in linear time, and uses constant workspace. Specifically, if the outer common tangents exist, then Algorithm 1 returns a pair of indices (s_0, s_1) such that $(r_0, r_1) = (p_0[s_0], p_1[s_1])$, that is, $P_0, P_1 \subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$. Otherwise, the algorithm returns* `nested`.

Proof. First, suppose the algorithm returns (s_0, s_1) in line 12. Consider the final values of s_0, s_1, b_0 and b_1. Due to the test in line 10, we have $s_0 < 2n_0$, $s_1 < 2n_1$, and $b_0 = b_1 =$ `false`, so the loop in line 2 has ended because $v_0 \geq s_0 + n_0$ and $v_1 \geq s_1 + n_1$. After the last update to (s_0, s_1), the test in line 4 has been performed for every $v_0 \in \{s_0 + 1, \ldots, s_0 + n_0\}$ and every $v_1 \in \{s_1 + 1, \ldots, s_1 + n_1\}$ and was negative – otherwise a further update would have been performed in line 8, as $b_0 = b_1 =$ `false`. This shows that $P_0, P_1 \subset \mathrm{RHP}(p_0[s_0], p_1[s_1])$.

Now, suppose that the outer common tangents exist. By Lemma 2 and Lemma 3, the loop in line 2 ends with $s_0 < 2n_0$, $s_1 < 2n_1$, and $b_0 = b_1 =$ `false`. Hence (s_0, s_1) is returned in line 12. In view of the discussion above, this proves correctness of the algorithm.

It is clear that Algorithm 1 uses constant workspace. For the running time, note that if an update to (s_0, s_1) happens in iteration i, the sum $s_0 + s_1$ is increased by at least $\frac{i-j}{2}$, where j is the number of the previous iteration in which an update to (s_0, s_1) happened or $j = 0$ if there has been no update before. By induction, we see that there have been at most $2(s_0 + s_1)$ iterations until an update to (s_0, s_1). Suppose first that $s_0 < 2n_0$ and $s_1 < 2n_1$ when the loop in line 2 terminates. There have been at most $4(n_0 + n_1)$ iterations until the final update to (s_0, s_1). Thereafter, at most $2\max\{n_0, n_1\} \leq 2(n_0 + n_1)$ iterations follow until $v_0 \geq s_0 + n_0$ and $v_1 \geq s_1 + n_1$, when the loop in line 2 terminates. Hence, there are at most $6(n_0 + n_1)$ iterations in total. Now, suppose that $s_0 \geq 2n_0$ or $s_1 \geq 2n_1$ when the loop terminates. By the same argument, the second to last update to (s_0, s_1) happens after at most $4(n_0 + n_1)$ iterations, after which at most $2(n_0 + n_1)$ iterations follow until the last update to (s_0, s_1). The loop is terminated immediately after the last update. Hence, we get the same bound of $6(n_0+n_1)$ iterations. Clearly, each iteration takes constant time, so the total running time of the algorithm is linear. ◀

4 Proof of Lemma 2

For our analysis, it will be convenient to imagine the execution of Algorithm 1 in continuous time. By considering various discrete events happening during the continuous execution of the algorithm, we are able to prove the invariant stated in Lemma 2.

4.1 Additional Terminology and Notation

For $U \subseteq \mathbb{R}^2$, let $\mathcal{F}(U)$ denote the set of compact subsets of U. By an *interval*, we mean a bounded interval of real numbers. We allow an interval to be closed or open at each endpoint independently. We shall consider functions defined on an interval I with the following sets (or their subsets) as codomains: $\mathbb{R}$ with the standard metric, $\mathbb{R}^2$ with the Euclidean metric, and $\mathcal{F}(\mathbb{R}^2)$ with the Hausdorff metric, a set $\mathcal{S}$ of functions with the discrete metric, and the power set $2^{\mathcal{S}}$ of a set $\mathcal{S}$ of functions, again with the discrete metric. The only purpose of these metrics is to have a suitable notion of convergence. We think of the domain I as *time*. If f is a function with domain I and I' is a subinterval of I, then $f \restriction I'$ denotes the restriction of f to I'. For a function $f\colon I \to X$, where X is (a subset of) one of the codomains above, a point in time $t \in I$ is a *discontinuity* of f if f is not continuous at t. We write

- $f(\nearrow t^\star)$ to denote the limit of $f(t)$ as $t \to t^\star$ from below, where $t^\star \in I \setminus \{\inf I\}$,
- $f(\searrow t^\star)$ to denote the limit of $f(t)$ as $t \to t^\star$ from above, where $t^\star \in I \setminus \{\sup I\}$.

If the limits $f(\nearrow t^\star)$ exist for all $t^\star \in I \setminus \{\inf I\}$ and the limits $f(\searrow t^\star)$ exist for all $t^\star \in I \setminus \{\sup I\}$, then we say that f has *one-sided limits*. Each of the functions f that we consider has one-sided limits and finitely many discontinuities. Note that f has a discontinuity at a point in time $t \in I$ if and only if $f(\nearrow t) \neq f(t)$ or $f(\searrow t) \neq f(t)$. A function $f\colon I \to \mathcal{F}(U)$, where $U \subseteq \mathbb{R}^2$, is *monotonically decreasing* if $f(t) \supseteq f(t')$ for any $t, t' \in I$ such that $t < t'$.

▶ **Lemma 5.** *Let I be an interval and $f\colon I \to \mathcal{F}(U)$ be a function with one-sided limits and finitely many discontinuities, where $U \subseteq \mathbb{R}^2$. Suppose $f \restriction I'$ is monotonically decreasing for every subinterval $I' \subseteq I$ such that $f \restriction I'$ is continuous on I'. Furthermore, suppose that*

- *$f(\nearrow t) \supseteq f(t)$ for any $t \in I \setminus \{\inf I\}$ such that $f(\nearrow t) \neq f(t)$,*
- *$f(t) \supseteq f(\searrow t)$ for any $t \in I \setminus \{\sup I\}$ such that $f(t) \neq f(\searrow t)$.*

Then f is monotonically decreasing in the entire domain I.

Proof. Let $t_1 < \cdots < t_n$ be the discontinuities of f. Let $t, t' \in I$ and $t < t'$. If there is no i with $t \le t_i \le t'$, then $f \restriction [t, t']$ is continuous, so it follows from the assumption that $f(t) \supseteq f(t')$. Otherwise, let i be minimum and j be maximum such that $t \le t_i \le t_j \le t'$. If $t < t_i$, then the assumptions yield $f(t) \supseteq f(\nearrow t_i) \supseteq f(t_i)$, Similarly, the assumptions yield $f(t_k) \supseteq f(\searrow t_k) \supseteq f(\nearrow t_{k+1}) \supseteq f(t_{k+1})$ for $k \in \{i, \ldots, j-1\}$, and $f(t_j) \supseteq f(\searrow t_j) \supseteq f(t')$ if $t_j < t'$. Thus $f(t) \supseteq f(t')$. ◀

4.2 Continuous Interpretation of the Algorithm

Let m denote the number of iterations of the loop in line 2 performed by Algorithm 1. For $i \in \{0, \ldots, m\}$ and $k \in \{0, 1\}$, let $v_k(i)$ and $s_k(i)$ denote the values of v_k and s_k, respectively, after i iterations of the loop. In particular, $v_k(0) = s_k(0) = 0$. For $x \in \mathbb{R} \setminus \mathbb{Z}$, let $p_k[x]$ denote the interpolated point $(\lceil x \rceil - x)p_k[\lfloor x \rfloor] + (x - \lfloor x \rfloor)p_k[\lceil x \rceil]$ on the edge $P_k[\lfloor x \rfloor, \lceil x \rceil]$.

We extend the functions s_0 and s_1 to the real interval $[0, m]$ as follows. We imagine that the ith iteration of the loop in line 2 starts at time $i-1$ and ends at time i, and during that iteration v_u grows continuously from $v_u(i-1) = v_u(i) - 1$ to $v_u(i)$. Thus we define $v_u(t) = v_u(i) - i + t$ for $t \in (i-1, i)$. Suppose that the update in line 8 is to be performed in the ith iteration. If $s_u(i-1) = v_u(i-1)$, then all of the edge $P_u[v_u(i-1), v_u(i)]$ is in $\mathrm{LHP}(p_0[s_0(i-1)], p_1[s_1(i-1)])$. We therefore imagine that the update happens at time $i-1$ and then s_u grows continuously together with v_u up to $v_u(i)$; thus we define $s_u(t) = v_u(t)$ and $v_{1-u}(t) = s_{1-u}(i-1)$ for $t \in (i-1, i)$. If $s_u(i-1) < v_u(i-1)$, then the edge $P_u[v_u(i-1), v_u(i)]$ intersects the tangent candidate at a point $p_u[v_u(t^\star)]$, where $t^\star \in (i-1, i)$. We therefore imagine that the update in line 8 happens at time $t^\star$ and then s_u grows continuously together with v_u up to $v_u(i)$; thus we define

- $s_u(t) = s_u(i-1)$ and $v_{1-u}(t) = v_{1-u}(i-1)$ for $t \in (i-1, t^\star]$,
- $s_u(t) = v_u(t)$ and $v_{1-u}(t) = s_{1-u}(i-1)$ for $t \in (t^\star, i)$,

and we say that s_u *jumps* from $s_u(t^\star)$ to $v_u(t^\star) = s_u(\searrow t^\star)$ at time $t^\star$. Finally, in either case, we define $s_{1-u}(t) = s_{1-u}(i-1)$ for $t \in (i-1, i)$. The functions $s_0, s_1 \colon [0, m] \to \mathbb{R}$ thus defined are nondecreasing, have one-sided limits and finitely many discontinuities, and are left-continuous, that is, $s_0(\nearrow t) = s_0(t)$ and $s_1(\nearrow t) = s_1(t)$ for every $t \in (0, m]$. We have also defined functions $v_0, v_1 \colon [0, m] \to \mathbb{R}$, but we are not going to use them any more.

▶ **Observation 6.** *At any point in time during the execution of the continuous version of Algorithm 1, at most one of s_0, s_1 is changing. The tangent candidate $\mathcal{L}(p_0[s_0], p_1[s_1])$ either is not moving, or is turning continuously counterclockwise around $p_0[s_0]$ (when s_1 is changing), or is turning continuously clockwise around $p_1[s_1]$ (when s_0 is changing).*

The following is trivial if $s_k(t) = s_k(\searrow t)$ and otherwise is a direct consequence of the test in line 5 and of the fact that the update in line 8 is only performed when $b_u = \texttt{false}$.

▶ **Observation 7.** *If $t \in [0, m)$ and $k \in \{0, 1\}$, then $p_k[s_k(\searrow t)] \in \mathcal{R}(p_{1-k}[s_{1-k}(t)], p_k[s_k(t)])$ and $P_k[s_k(t), s_k(\searrow t)] \subset \mathrm{RHP}(p_0[s_0(t)], p_1[s_1(t)])$.*

4.3 Auxiliary Structure on the Polygons

In this subsection, we introduce some auxiliary concepts used in the proof of Lemma 2. They are defined in terms of the polygons P_0, P_1 only and are independent of the algorithm.

Assume for this entire subsection that the convex hulls of P_0 and P_1 are not nested. Thus there are two outer common tangents – let them be given by points $\ell_0, r_0 \in P_0$ and $\ell_1, r_1 \in P_1$ such that $P_0, P_1 \subset \mathrm{LHP}(\ell_0, \ell_1) \cap \mathrm{RHP}(r_0, r_1)$. Let $L = \ell_0\ell_1$ and $R = r_0r_1$. Let E be the polygonal region bounded by the chains $P_0[\ell_0, r_0]$, $P_1[\ell_1, r_1]$ and by the segments L, R. Since P_0 is oriented counterclockwise and P_1 clockwise, the interiors of P_0 and P_1 lie outside E.

▶ **Lemma 8.** *Every segment xy such that $xy \cap P_0 = \{x\}$ and $xy \cap P_1 = \{y\}$ is contained in E.*

Proof. The set $E \smallsetminus (P_0[\ell_0, r_0] \cup P_1[\ell_1, r_1])$ separates P_0 and P_1 in $\mathrm{LHP}(\ell_0, \ell_1) \cap \mathrm{RHP}(r_0, r_1)$, so it contains a point z in common with the segment xy. If $z \in L$ or $z \in R$, then $xy = \ell_0\ell_1$ or $xy = r_0r_1$, respectively, so xy lies in E. So suppose z is in the interior of E. The segment zx cannot cross the boundary of E at any point other than x, and zy at any point other than y. This shows that xy lies in E. ◀

See Figure 5. Let $q_0 \in P_0$ and $q_1 \in P_1$ be fixed points such that at least one of q_0, q_1 is a corner of the respective polygon P_0 or P_1. Let $S = q_0q_1$. We consider the segment S as oriented from q_0 to q_1, so that we can speak of the *left side* of S, $\mathrm{LHP}(q_0, q_1)$, and the

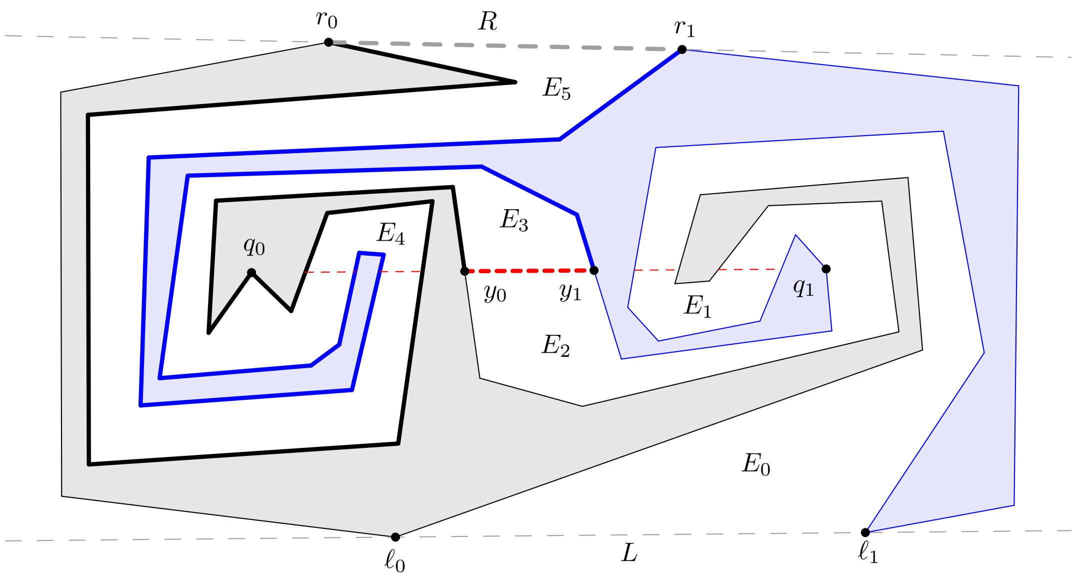

Figure 5 The doors are the five dashed segments on $S = q_0q_1$: D_4, D_5, D_3, D_1, D_2 in the order from q_0 to q_1. The weights of the doors are 2, 1, 1, -1, 0, respectively. $D_3 = y_0y_1$ is the primary door. The boundary of the primary region $E' = E_3 \cup E_4 \cup E_5$ is drawn with thick lines.

right side of S, $\mathrm{RHP}(q_0, q_1)$. A *door* is a subsegment xy of S such that $xy \cap P_k = \{x\}$ and $xy \cap P_{1-k} = \{y\}$ for some $k \in \{0, 1\}$. By Lemma 8, every door is contained in E. A *fence* is a subsegment xy of S such that $xy \subset E$, $xy \cap P_k = \{x, y\}$, and $xy \cap P_{1-k} = \emptyset$ for some $k \in \{0, 1\}$. Exceptionally, when S contains an edge xy of P_k, we call the whole edge xy a fence. Since at least one of q_0, q_1 is a corner, the latter is possible only when $x = q_k$ or $y = q_k$. Let $\mathcal{D}$ be the set of all doors defined by the fixed points q_0 and q_1. Figure 5 also illustrates the following lemma.

▶ **Lemma 9.** *The doors in $\mathcal{D}$ can be ordered as $D_1, \ldots, D_d$ so that if $D_i \cap P_0 = \{x_i\}$ and $D_i \cap P_1 = \{y_i\}$ for $i \in \{1, \ldots, d\}$, then*

- *the order of points along $P_0[\ell_0, r_0]$ is $\ell_0, x_1, \ldots, x_d, r_0$ (with possible coincidences),*
- *the order of points along $P_1[\ell_1, r_1]$ is $\ell_1, y_1, \ldots, y_d, r_1$ (with possible coincidences).*

The doors partition E into polygonal regions $E_0, \ldots, E_d$ such that

- *E_0 is bounded by L, $P_0[\ell_0, x_1]$, D_1 and $P_1[\ell_1, y_1]$ (it is degenerate when $D_1 = L$),*
- *E_i is bounded by D_i, $P_0[x_i, x_{i+1}]$, D_{i+1} and $P_1[y_i, y_{i+1}]$, for $i \in \{1, \ldots, d-1\}$,*
- *E_d is bounded by D_d, $P_0[x_d, r_0]$, R and $P_1[y_d, r_1]$ (it is degenerate when $D_d = R$).*

Proof. Suppose there are doors $xy, x'y' \in \mathcal{D}$ such that x is strictly before x' on $P_0[\ell_0, r_0]$ while y' is strictly before y on $P_1[\ell_1, r_1]$. It follows that the clockwise order of the four points along the boundary of E is x, x', y, y' and no two of these points coincide. By Lemma 8, both xy and $x'y'$ lie in E, so they must cross at a point different from their endpoints, which is a contradiction. This shows that the order of endpoints of the doors along $P_0[\ell_0, r_0]$ agrees with that along $P_1[\ell_1, r_1]$, which proves the first statement. The second statement is a straightforward corollary to the first. ◀

From now on, we use $D_1, \ldots, D_d$ to denote the doors in their order according to Lemma 9, and we use $E_0, \ldots, E_d$ to denote the regions defined in Lemma 9.

Recall that we consider S as a segment oriented from q_0 to q_1. Every door inherits that orientation, so that we can speak of the left side and the right side of the door. Taking into account that the regions E_{i-1} and E_i lie on opposite sides of D_i, we classify each door D_i as

- a *right-door* if E_{i-1} lies to the right and E_i lies to the left of D_i (in particular, if $D_i = L$),
- a *left-door* if E_{i-1} lies to the left and E_i lies to the right of D_i (in particular, if $D_i = R$).

▶ **Lemma 10.** *Consider a chain $P_k[a,b]$, where $k \in \{0,1\}$. If $P_k[a,b] \cap S = \{a,b\}$ and $P_k[a,b] \subset \mathrm{RHP}(q_0,q_1)$, then all doors contained in the segment ab occur in pairs of a left-door followed by a right-door, consecutive in the order on $\mathcal{D}$.*

Proof. Consider the polygonal region F bounded by the chain $P_k[a,b]$ and by the segment ab. It follows that $F \subset \mathrm{RHP}(q_0,q_1)$. Each of the regions $E_0,\dots,E_d$ lies either inside or outside F, where E_0 and E_d lie outside F. Each region E_i lying inside F connects the door D_i, which is therefore a left-door, and the door D_{i+1}, which is therefore a right-door. ◀

So far we were considering q_0 and q_1 as fixed points. Now, we allow them to change in time. Specifically, let I be a real interval that can be open or closed at each endpoint independently, and consider q_0 and q_1 as continuous functions $q_0\colon I \to P_0$ and $q_1\colon I \to P_1$. This way S becomes a continuous function $S\colon I \to \mathcal{F}(\mathbb{R}^2)$. Furthermore, suppose at least one of $q_0(t)$, $q_1(t)$ is a corner of the respective polygon for every $t \in I$, so that $S(t)$ can contain at most one other corner (by the general position assumption). Let $X(t)$ denote the set of intersection points of $S(t)$ with $P_0 \cup P_1$. In the exceptional case that $S(t)$ contains an edge of P_0 or P_1, we only include the endpoints of the edge in $X(t)$. The points in $X(t)$ are changing continuously except that an intersection point appears or disappears at a point in time $t \in I$ when $S(t)$ sweeps over a corner whose both incident edges lie on the same side of $S(t)$. Note that since the corners of P_0 and P_1 are assumed to be in general position and one of q_0 and q_1 is a corner, at most one point can appear in or disappear from $X(t)$ at any point in time. The doors are changing continuously except when one of the following *door events* happens as a point appears in or disappears from $X(t)$:

1. a fence splits into two doors,
2. two doors merge into a fence,
3. a door splits into a smaller door and a fence,
4. a door and a fence merge into a larger door.

Specifically, every door D can be represented as a continuous function $D\colon I_D \to \mathcal{F}(\mathbb{R}^2)$, where I_D is a subinterval of I (open or closed at each endpoint independently) such that

1. if $t = \inf I_D \in I_D$, then an endpoint of $D(t)$ is in $X(t)$ but not in $X(\nearrow t)$,
2. if $t = \sup I_D \in I_D$, then an endpoint of $D(t)$ is in $X(t)$ but not in $X(\searrow t)$,
3. if $t = \sup I_D \notin I_D$, then an interior point of $D(\nearrow t)$ is in $X(t)$ but not in $X(\nearrow t)$,
4. if $t = \inf I_D \notin I_D$, then an interior point of $D(\searrow t)$ is in $X(t)$ but not in $X(\searrow t)$.

At any point in time $t \in I$, the set of doors $\mathcal{D}(t)$ consists of the doors D such that $t \in I_D$ ordered according to Lemma 9. The following observation, a straightforward consequence of Lemma 9, summarizes how $\mathcal{D}(t)$ and the order on $\mathcal{D}(t)$ are changing in time.

▶ **Observation 11.** *The set $\mathcal{D}(t)$ and the order on $\mathcal{D}(t)$ are constant in time intervals where no door event happens. A door event at time t makes the following change to $\mathcal{D}(t)$:*

1. *if a fence splits into two doors D and D', then D and D' are added to $\mathcal{D}(\nearrow t)$ as consecutive doors to form $\mathcal{D}(t)$,*
2. *if two doors D and D' merge into a fence, then D and D' are consecutive in $\mathcal{D}(t)$ and they are removed from $\mathcal{D}(t)$ to form $\mathcal{D}(\searrow t)$,*

3. *if a door D splits into a smaller door D' and a fence, then D is replaced by D' in $\mathcal{D}(\nearrow t)$ to form $\mathcal{D}(t)$,*
4. *if a door D and a fence merge into a larger door D', then D is replaced by D' in $\mathcal{D}(t)$ to form $\mathcal{D}(\searrow t)$.*

In case of door events 1 and 2, the two doors D and D' are, in their order in $\mathcal{D}(t)$,

- *a right-door followed by a left-door if the edges incident to w lie to the right of $S(t)$,*
- *a left-door followed by a right-door if the edges incident to w lie to the left of $S(t)$,*

where w denotes the corner that triggers the event (i.e., the corner that appears in or disappears from $X(t)$ at time t). In case of door events 3 and 4, the door D' keeps the left/right-door status of D. The left/right-door status of every door D remains constant over the entire time interval I_D.

Now, consider q_0 and q_1 again as fixed points. Recall that $D_1, \ldots, D_d$ denote the doors in their order according to Lemma 9. We define the *weight* $W(D_i)$ of every door D_i by induction, as follows:

$$W(D_1) = \begin{cases} 1 & \text{if } D_1 \text{ is a right-door,} \\ -1 & \text{if } D_1 \text{ is a left-door,} \end{cases} \qquad W(D_i) = \begin{cases} W(D_{i-1}) + 1 & \text{if } D_i \text{ is a right-door,} \\ W(D_{i-1}) - 1 & \text{if } D_i \text{ is a left-door,} \end{cases}$$

for $i \in \{2, \ldots, d\}$. See Figure 5. The following is a direct consequence of Observation 11.

▶ **Observation 12.** *When $q_0 \colon I \to P_0$, $q_1 \colon I \to P_1$ are continuous functions, every door $D \colon I_D \to \mathcal{F}(\mathbb{R}^2)$ maintains constant weight over the entire time interval I_D. Furthermore, the function $W^\star \colon I \to \mathbb{Z}$ defined so that $W^\star(t)$ is the weight of the last door in the order on $\mathcal{D}(t)$ is constant over the entire time interval I.*

▶ **Lemma 13.** *For any fixed points q_0, q_1, there is at least one door with weight 1.*

Proof. The statement is obvious if $q_0 = \ell_0$ and $q_1 = \ell_1$, because in that case there is just one door L, which is a right-door by definition, so it has weight 1. To prove the lemma in general, let $I = [0, 1]$ and (abusing notation) consider arbitrary continuous functions $q_0 \colon I \to P_0$ and $q_1 \colon I \to P_1$ such that $q_0(0) = \ell_0$, $q_1(0) = \ell_1$, and $q_0(1)$, $q_1(1)$ are the points q_0, q_1 fixed in the statement of the lemma. By Observation 12, the function $W^\star \colon I \to \mathbb{Z}$ is constant over I, so $W^\star(1) = W^\star(0) = 1$ as observed above. This shows that the last door in the order on $\mathcal{D}(1)$ has weight 1. ◀

For any fixed points q_0, q_1, let the *primary door* D' be the first door with weight 1 in the order on $\mathcal{D}$. Such a door always exists due to Lemma 13.

▶ **Observation 14.** *The primary door D' is a right-door and is not preceded by a left-door in the order on $\mathcal{D}$.*

Let y_0 and y_1 denote the endpoints of D' so that $y_0 \in P_0$ and $y_1 \in P_1$. Let $Y_0 = P_0[y_0, r_0]$ and $Y_1 = P_1[y_1, r_1]$. Finally, let the *primary region* E' be defined as the polygonal region determined by D', Y_0, R and Y_1. See Figure 5.

▶ **Observation 15.** *If $D' = D_i$, then E' is the union of $E_i, \ldots, E_d$. In particular, E' contains the doors $D_{i+1}, \ldots, D_d$. By Observation 14, the region E' meets D' from the left.*

4.4 Back to the Algorithm

We recall the functions $s_0, s_1\colon [0,m] \to \mathbb{R}$ describing the execution of Algorithm 1 as explained in Section 4.2, and we define functions $q_0\colon [0,m] \to P_0$ and $q_1\colon [0,m] \to P_1$ as follows:

$$q_0(t) = p_0[s_0(t)], \quad q_1(t) = p_1[s_1(t)] \quad \text{for } t \in [0,m].$$

They have the property that at least one of $q_0(t)$, $q_1(t)$ is a corner at any point in time $t \in [0,m]$. Some other objects that have been defined in Section 4.3 based on fixed points q_0, q_1 now become functions of time $t \in [0,m]$: the segment S, the primary door D', the points y_0, y_1, the chains Y_0, Y_1, and the primary region E'.

The functions q_0 and q_1 have finitely many discontinuities – the points of time $t \in [0,m)$ when the respective s_k jumps from $s_k(t)$ to $s_k(\searrow t)$. It is also clear that they have one-sided limits, since the functions s_0 and s_1 are bounded and piecewise monotone. It follows that the functions $D'\colon [0,m] \to \mathcal{F}(\mathbb{R}^2)$, $y_0\colon [0,m] \to P_0$, $y_1\colon [0,m] \to P_1$, $Y_0\colon [0,m] \to \mathcal{F}(P_0)$, $Y_1\colon [0,m] \to \mathcal{F}(P_1)$, and $E'\colon [0,m] \to \mathcal{F}(\mathbb{R}^2)$ also have one-sided limits and finitely many discontinuities, which arise from discontinuities of q_0, q_1 and from door events in between.

The following lemma is the heart of the proof of correctness of the algorithm. Informally speaking, it asserts that the primary region E' can only shrink in time, since the primary door D' always sweeps continuously into or jumps into E'.

▶ **Lemma 16.** *The functions Y_0 and Y_1 are monotonically decreasing.*

Proof. First, we let I be an arbitrary subinterval of $[0,m]$ in which q_0 and q_1 are continuous, and we prove the lemma for functions restricted to I: $y_0 \upharpoonright I$, $y_1 \upharpoonright I$, $Y_0 \upharpoonright I$ and $Y_1 \upharpoonright I$. Following the convention from Section 4.3, we consider doors as continuous functions $D\colon I_D \to \mathcal{F}(\mathbb{R}^2)$ with $I_D \subseteq I$ and, for $t \in I$, we let $\mathcal{D}(t)$ denote the set of doors D such that $t \in I_D$. Accordingly, we redefine $D'(t)$ to denote the function $D\colon I_D \to \mathcal{F}(\mathbb{R}^2)$ that is chosen as the primary door at time $t \in I$.

By Observation 12, every door $D\colon I_D \to \mathcal{F}(\mathbb{R}^2)$ maintains constant weight over the entire time interval I_D. By Observation 11, the only possible changes to $\mathcal{D}$ and to the order on $\mathcal{D}$ over time interval I are that doors are being added to or removed from $\mathcal{D}$. Therefore, any change to the choice of the primary door can only occur at a point in time $t \in I$ when a door event happens; moreover, the primary door $D'(t)$ must participate in that event, that is, if $D'(t) = D$, then $t = \inf I_D$ or $t = \sup I_D$.

Consider an interval $I' \subseteq I$ over which the choice of the primary door remains constant, that is, there is a door $D\colon I_D \to \mathcal{F}(\mathbb{R}^2)$ such that $I' \subseteq I_D$ and $D'(t) = D$ for every $t \in I'$. Since D is a continuous function, so are the functions $y_0 \upharpoonright I'$, $y_1 \upharpoonright I'$, $Y_0 \upharpoonright I'$ and $Y_1 \upharpoonright I'$. Furthermore, it follows from Observation 6 that the segment S is constant or is sweeping continuously to the left at any point in time $t \in I$. By Observation 15, D can only be moving towards the interior of E' in time interval I'. This shows that $E' \upharpoonright I'$ and hence $Y_0 \upharpoonright I'$ and $Y_1 \upharpoonright I'$ are monotonically decreasing functions.

In view of Lemma 5, to complete the proof that $Y_0 \upharpoonright I$ and $Y_1 \upharpoonright I$ are monotonically decreasing, it remains to prove that

- $Y_0(\nearrow t) \supseteq Y_0(t)$ and $Y_1(\nearrow t) \supseteq Y_1(t)$ whenever $D'(\nearrow t) \neq D'(t)$, for $t \in I \setminus \{\inf I\}$,
- $Y_0(\searrow t) \subseteq Y_0(t)$ and $Y_1(\searrow t) \subseteq Y_1(t)$ whenever $D'(\searrow t) \neq D'(t)$, for $t \in I \setminus \{\sup I\}$.

We consider the kinds of door events as identified in Section 4.3, looking for events happening at time $t \in I$ that result in a primary door being added to or removed from $\mathcal{D}$.

1. A fence splits into two doors. Since $S(t)$ can only be sweeping to the left, both polygon edges incident to the corner triggering that event lie to the left of $S(t)$. Therefore, by

Observation 11, the two doors are a left-door followed by a right-door in the order on $\mathcal{D}(t)$. Consequently, by Observation 14, neither of the two doors can be primary.

2. Two doors merge into a fence. If $D'(t)$ is one of the two doors, then the choice of the primary door changes to some door $D \in \mathcal{D}(\searrow t) \subset \mathcal{D}(t)$ that is after $D'(t)$ in the order on $\mathcal{D}(t)$. By Lemma 9, the endpoints $y_0(\searrow t)$ and $y_1(\searrow t)$ of $D(t)$ lie on $Y_0(t)$ and $Y_1(t)$, respectively, so $Y_0(\searrow t) \subseteq Y_0(t)$ and $Y_1(\searrow t) \subseteq Y_1(t)$ as required.
3. A door splits into a smaller door and a fence. It follows from Observation 11 that the door added to $\mathcal{D}(t)$ maintains the weight of the door removed from $\mathcal{D}(\nearrow t)$. Therefore, assuming $D'(t) \neq D'(\nearrow t)$, $D'(t)$ is the door added to $\mathcal{D}(t)$ and $D'(\nearrow t)$ is the one removed from $\mathcal{D}(\nearrow t)$. Let $w \in P_k$ denote the corner that triggers the event, where $k \in \{0,1\}$. It follows that $y_{1-k}(t) = y_{1-k}(\nearrow t)$, so $Y_{1-k}(t) = Y_{1-k}(\nearrow t)$. Since $w = y_k(t)$, we need to prove that $w \in Y_k(\nearrow t)$. Let $D = D'(\nearrow t)$ and let t_0 be a value in $I_D \cap I$ such that $t_0 < t$ and no door event happens in time interval $[t_0, t)$. For every $t' \in [t_0, t)$, let $\varphi(t')$ be the point on $D(t')$ closest to w. Since D moves continuously, φ is a continuous curve. Since $\varphi(t') \in E'(t')$ and $E'(t') \subset E'(t_0)$ as shown before for every $t' \in [t_0, t)$, φ must be contained in $E'(t_0)$. Since $w \in D(\nearrow t)$, we have $\varphi(\nearrow t) = w$. Furthermore, $E'(t_0)$ is a closed set, and hence $w \in E'(t_0)$. The interior of $E'(t_0)$ is disjoint from P_0 and P_1, so w must be a corner on the chain $Y_k(t_0) = P_k[y_k(t_0), r_k]$. Since $w = y_k(t)$, it follows that $Y_k(t) \subseteq Y_k(t_0)$. By letting t_0 approach t from below, we get $Y_k(t) \subseteq Y_k(\nearrow t)$.
4. A door and a fence merge into a larger door. Again, it follows from Observation 11 that the door added to $\mathcal{D}(\searrow t)$ maintains the weight of the door removed from $\mathcal{D}(t)$. Therefore, assuming $D'(t) \neq D'(\searrow t)$, $D'(t)$ is the door removed from $\mathcal{D}(t)$ and $D'(\searrow t)$ is the one added to $\mathcal{D}(\searrow t)$. Let $w \in P_k$ denote the corner that triggers the event, where $k \in \{0,1\}$. It follows that $y_{1-k}(t) = y_{1-k}(\searrow t)$, so $Y_{1-k}(t) = Y_{1-k}(\searrow t)$. We make an argument similar to the one in the above case to show that $Y_k(\searrow t) \subseteq Y_k(t)$, but using reversed time. Let $D = D'(\searrow t)$ and let t_0 be a value in $I_D \cap I$ such that $t_0 > t$ and no door event happens in time interval $(t, t_0]$. For every $t' \in (t, t_0]$, let $\varphi(t')$ be the point on $D(t')$ closest to w. Since D moves continuously, φ is a continuous curve. For every $t' \in [0, m]$, let $F(t')$ be the polygonal region bounded by $P_0[\ell_0, y_0(t')]$, the primary door at time t', $P_1[\ell_1, y_1(t')]$, and the segment $L = \ell_0\ell_1$. Thus $F(t')$ is a sort of complementary region to $E'(t')$ in the region E. Since E' is monotonically decreasing on $(t, t_0]$ as shown before, F' is monotonically increasing on $(t, t_0]$. Therefore, since $\varphi(t') \in F(t')$, φ must be contained in $F(t_0)$. Since $w \in D(\searrow t)$, we have $\varphi(\searrow t) = w$. Furthermore, $F(t_0)$ is a closed set, and hence $w \in F(t_0)$. The interior of $F(t_0)$ is disjoint from P_0 and P_1, so w must be a corner on the chain $P_k[\ell_k, y_k(t_0)]$. Since $w = y_k(t)$, it follows that $P_k[\ell_k, y_k(t)] \subseteq P_k[\ell_k, y_k(t_0)]$. By letting t_0 approach t from above, we get $P_k[\ell_k, y_k(t)] \subseteq P_k[\ell_k, y_k(\searrow t)]$. Hence, $y_k(\searrow t)$ is on the chain $Y_k(t) = P_k[y_k(t), r_k]$ and therefore $Y_k(\searrow t) \subseteq Y_k(t)$.

Now, we return to the general case of functions y_0, y_1, Y_0 and Y_1 defined on the entire interval $[0, m]$. Consider a point in time $t \in [0, m)$ that is a discontinuity of q_k, where $k \in \{0,1\}$. That is, s_k jumps from $s_k(t)$ to $s_k(\searrow t)$ at time t. We shall see that the jump of s_k has no effect on the choice of the primary door. By Observation 7, the point $p_k[s_k(\searrow t)] = q_k(\searrow t)$ lies on the ray $\mathcal{R}(q_{1-k}(t), q_k(t))$ and the chain $P_k[q_k(t), q_k(\searrow t)]$ belongs to $\mathrm{RHP}(q_0(t), q_1(t))$. Let $\mathcal{D}(t)$ and $\mathcal{D}(\searrow t)$ denote the sets of doors as defined for the segments $S(t)$ and $S(\searrow t)$, respectively. We shall prove that the primary door with respect to $\mathcal{D}(t)$ (i.e., defined for $S(t)$) is the same as with respect to $\mathcal{D}(\searrow t)$ (i.e., defined for $S(\searrow t)$).

Suppose $q_k(\searrow t)$ is on the segment $S(t)$. It follows that $S(\searrow t) \subset S(t)$, $\mathcal{D}(\searrow t) \subseteq \mathcal{D}(t)$, and $\mathcal{D}(t) \setminus \mathcal{D}(\searrow t)$ is the set of doors on $S(t) \setminus S(\searrow t)$. Since $P_k[q_k(t), q_k(\searrow t)] \subset \mathrm{RHP}(q_0(t), q_1(t))$, it follows from Lemma 10 that the doors in $\mathcal{D}(t) \setminus \mathcal{D}(\searrow t)$ occur in pairs of a left-door followed by a right-door, consecutive in the order on $\mathcal{D}(t)$. Therefore, the weights of every door $D \in \mathcal{D}(\searrow t)$ with respect to the sets of doors $\mathcal{D}(\searrow t)$ and $\mathcal{D}(t)$ are equal. By Observation 14, none of the doors in $\mathcal{D}(t) \setminus \mathcal{D}(\searrow t)$ can be primary with respect to $\mathcal{D}(t)$, so the primary door is the same with respect to $\mathcal{D}(t)$ as with respect to $\mathcal{D}(\searrow t)$.

Now, suppose $q_k(\searrow t)$ is not on the segment $S(t)$. It follows that $S(t) \subset S(\searrow t)$, $\mathcal{D}(t) \subseteq \mathcal{D}(\searrow t)$, and $\mathcal{D}(\searrow t) \setminus \mathcal{D}(t)$ is the set of doors on $S(\searrow t) \setminus S(t)$. An argument analogous to that for $q_k(\searrow t) \in S(t)$ above shows that the primary door is the same with respect to $\mathcal{D}(\searrow t)$ as with respect to $\mathcal{D}(t)$.

To conclude, let $t_0 = 0$, $t_1, \dots, t_{n-1}$ be the discontinuities of q_0 or q_1 ordered so that $t_1 < \dots < t_{n-1}$, and $t_n = m$, and consider the closed intervals $I_i = [t_{i-1}, t_i]$ for $i \in \{1, \dots, n\}$. Fix an index i and consider the restrictions $q_0 \restriction I_i$ and $q_1 \restriction I_i$. Only one of them, say $q_k \restriction I_i$, is not continuous, and the only discontinuity of $q_k \restriction I_i$ is t_{i-1}. As we have proved above, if we redefine $q_k(t_{i-1})$ by letting $q_k(t_{i-1}) = q_k(\searrow t_{i-1})$, the primary door $D'(t_{i-1})$ does not change, but then $q_k \restriction I_i$ becomes continuous. Therefore, what we have proved for restrictions of Y_0 and Y_1 to subintervals $I \subseteq [0, m]$ such that $q_0 \restriction I$ and $q_1 \restriction I$ are continuous implies that $Y_0 \restriction I_i$ and $Y_1 \restriction I_i$ are monotonically decreasing, for every $i \in \{1, \dots, n\}$. The assumptions of Lemma 5 are satisfied for Y_0 and Y_1, so Y_0 and Y_1 are monotonically decreasing in the entire domain $[0, m]$. ◀

We are now ready to prove Lemma 2. Using the continuous interpretation of the algorithm, it can be rephrased as follows.

▶ **Lemma 17.** *For any $t \in [0, m]$, we have $0 \le s_0(t) < 2n_0$ and $0 \le s_1(t) < 2n_1$.*

Proof. We only present the proof of the bound on $s_0(t)$. That for $s_1(t)$ is analogous. Let $c_0(0)$ be the unique real in the interval $[0, n_0)$ such that $y_0(0) = p_0[c_0(0)]$. Let $\hat{c}_0$ be the unique real in the interval $[c_0(0), c_0(0) + n_0)$ such that $r_0 = p_0[\hat{c}_0]$. By Lemma 16, for $t \in (0, m]$, there is a unique real $c_0(t) \in [c_0(0), \hat{c}_0]$ such that $y_0(t) = p_0[c_0(t)]$, and this defines a nondecreasing function $c_0 \colon [0, m] \to \mathbb{R}$ with one-sided limits and finitely many discontinuities. Obviously, $0 \le s_0(t)$ and $c_0(t) \le \hat{c}_0 < c_0(0) + n_0 < 2n_0$. It remains to prove $s_0(t) \le c_0(t)$ for $t \in [0, m]$.

We first prove that for every $t \in [0, m)$ with $s_0(t) \le c_0(t)$, there is $\varepsilon > 0$ such that $s_0(t') \le c_0(t')$ for all $t' \in [t, t + \varepsilon)$. Let $t \in [0, m)$ be such that $s_0(t) \le c_0(t)$. First, suppose s_0 is continuous and either constant or strictly increasing on some interval $[t, t + \varepsilon)$ with $\varepsilon > 0$. If $s_0(t) < c_0(t)$, then the statement is clear, so suppose $s_0(t) = c_0(t)$. If s_0 is constant on $[t, t + \varepsilon)$, then the statement is clear, as c_0 is nondecreasing. If s_0 is strictly increasing on $[t, t + \varepsilon)$, we either have $c_0(t') = s_0(t')$ for $t' \in [t, t + \varepsilon')$, for some $\varepsilon' \in (0, \varepsilon]$, or c_0 jumps at time t to a higher value, that is, $c_0(t) < c_0(\searrow t)$. In both cases, the statement holds.

Now, suppose s_0 jumps at time t, that is, $s_0(t) < s_0(\searrow t)$. By choosing $\varepsilon > 0$ small enough, we can assume that s_0 is continuous on the interval $(t, t + \varepsilon)$ and that the points $\{p_0[s_0(t')] \colon t' \in (t, t + \varepsilon)\}$ are a part of one edge e of P_0, which also contains the point $p_0[s_0(\searrow t)]$. By Observation 7, we have $P_0[s_0(t), s_0(\searrow t)] \subset \mathrm{RHP}(p_0[s_0(t)], p_1[s_1])$. This and the facts that $p_0[c_0(t')] \in S(t')$ and $S(t') \cap \mathrm{RHP}(p_0[s_0(t)], p_1[s_1]) = \{p_1[s_1]\}$ imply $c_0(t') > s_0(\searrow t)$, for every $t' \in (t, t + \varepsilon)$. We conclude that for every $t' \in (t, t + \varepsilon)$, either $c_0(t') = s_0(t')$ or $p_0[c_0(t')]$ is on an edge of P_0 other than e, in which case $c_0(t') > s_0(t')$.

We now return to proving that $s_0(t) \le c_0(t)$ for every $t \in [0, m]$. Suppose the contrary, and let $t^\star = \inf\{t \in [0, m] \colon s_0(t) > c_0(t)\}$. In view of the discussion above, we must have $s_0(t^\star) > c_0(t^\star)$. Then $t^\star > 0$, because $c_0(0) \ge 0 = s_0(0)$. By the definition of s_0, we have $s_0(\nearrow t^\star) = s_0(t^\star) > c_0(t^\star) \ge c_0(\nearrow t^\star)$. This contradicts the definition of $t^\star$. ◀

Abstract

A distance labeling scheme labels the n nodes of a graph with binary strings such that, given the labels of any two nodes, one can determine the distance in the graph between the two nodes by looking only at the labels. A D-preserving distance labeling scheme only returns precise distances between pairs of nodes that are at distance at least D from each other. In this paper we consider distance labeling schemes for the classical case of unweighted and undirected graphs.

We present a $O(\frac{n}{D}\log^2 D)$ bit D-preserving distance labeling scheme, improving the previous bound by Bollobás et al. [SIAM J. Discrete Math. 2005]. We also give an almost matching lower bound of $\Omega(\frac{n}{D})$. With our D-preserving distance labeling scheme as a building block, we additionally achieve the following results:

1. We present the first distance labeling scheme of size $o(n)$ for sparse graphs (and hence bounded degree graphs). This addresses an open problem by Gavoille et al. [J. Algo. 2004], hereby separating the complexity from distance labeling in general graphs which require $\Omega(n)$ bits, Moon [Proc. of Glasgow Math. Association 1965].[1]
2. For approximate r-additive labeling schemes, that return distances within an additive error of r we show a scheme of size $O\left(\frac{n}{r}\cdot\frac{\operatorname{polylog}(r\log n)}{\log n}\right)$ for $r \geq 2$. This improves on the current best bound of $O\left(\frac{n}{r}\right)$ by Alstrup et. al. [SODA 2016] for sub-polynomial r, and is a generalization of a result by Gawrychowski et al. [arXiv preprint 2015] who showed this for $r = 2$.

[1] This result for sparse graphs was made available online in a preliminary version of this paper [6]. The label size was subsequently slightly improved by an $O(\log\log n)$ factor by Gawrychowski et al. [25].

1 Introduction

The concept of *informative labeling schemes* dates back to Breuer and Folkman [12, 13] and was formally introduced by Kannan et al. [30, 34]. A labeling scheme is a way to represent a graph in a distributed setting by assigning bit strings (called *labels*) to each node of the graph. In a distance labeling scheme we assign labels to a graph G from a family $\mathcal{G}$ such that, given *only* the labels of a pair of nodes, we can compute the distance between them without the need for a centralized data structure. When designing a labeling scheme the main goal is to minimize the *maximum label size* over all nodes of all graphs G in the family $\mathcal{G}$. We call this the size of the labeling scheme. As a secondary goal some papers consider the *ecoding* and *decoding* time of the labeling scheme in various computational models. In this paper we study the classical case of *undirected* and *unweighted* graphs.

Exact distances. The problem of exact distance labeling in general graphs is a classic problem that was studied thoroughly in the 1970/80's. Graham and Pollak [26] and Winkler [39] showed that labels of size $\lceil (n-1) \cdot \log_2 3 \rceil$ suffice in this case. Combining [30] and [33] gives a lower bound of $\lceil n/2 \rceil$ bits (see also [24]). Recently, Alstrup et al. [7] improved the label size to $\frac{\log_2 3}{2} n + O\left(\log^2 n\right)$ bits.

Distance labeling schemes have also been investigated for various families of graphs, providing both upper and lower bounds. For trees, Peleg [35] showed that labels of size $O(\log^2 n)$ suffice with a matching lower bound by Gavoille et. al [24]. Gavoille et. al [24] also showed a $\Omega(n^{1/3})$ lower bound for planar graphs and $\Omega(\sqrt{n})$ bound for bounded degree (and thus sparse) graphs. They also provided an $O(\sqrt{n}\log n)$ labeling scheme for planar graphs, however nothing better than the $O(n)$ scheme for general graphs is known for bounded-degree graphs. It remains a major open problem in the field of labeling schemes whether a scheme of size $O(\sqrt{n})$ or even $o(n)$ exists for bounded-degree graphs as stated in e.g. [24].

Other families of graphs studied include distance-hereditary [22], bounded clique-width [16], some non-positively curved plane [15], as well as interval [23] and permutation graphs [10].

Approximate distances. For some applications, the $\Omega(poly(n))$ requirement on the label size for several graph classes is prohibitive. Therefore a large body of work is dedicated to labeling schemes for approximating distances in various families of graphs [2, 14, 19, 24, 27, 28, 32, 35, 36, 37, 38]. Such labeling schemes often provide efficient implementations of other data structures like distance oracles [37] and dynamic graph algorithms [2].

In [35] a labeling scheme of size $O(\log^2 n \cdot \kappa \cdot n^{1/\kappa})$ was presented for approximating distances up to a factor[2] of $\sqrt{8\kappa}$. In [37] a scheme of poly-logarithmic size was given for planar graphs when distances need only be reported within a factor of $(1+\varepsilon)$. Labeling schemes of additive error have also been investigated. For general graphs Alstrup et. al [7] gave a scheme of size $O(n/r)$ for r-additive distance labeling with $r \geq 2$ and a lower bound of $\Omega(\sqrt{n/r})$ was given by Gavoille et al. [21]. For $r = 1$ a lower bound of $\Omega(n)$ can be established by observing that such a scheme can answer adjacency queries in bipartite graphs.

Distance preserving. An alternative to approximating all distances is to only report exact distances above some certain threshold D. A labeling scheme, which reports exact distances

[2] This does not break the Girth Conjecture, as the labeling scheme may under-estimate the distance as well.

for nodes u, v where $dist(u,v) \geq D$ is called a *D-preserving distance labeling scheme*[3]. Bollobás et al. [11] introduced this notion and gave a labeling scheme of size $O(\frac{n}{D}\log^2 n)$ for both directed and undirected graphs. They also provided an $\Omega(\frac{n}{D}\log D)$ lower bound for directed graphs.

1.1 Related work

A problem closely related to distance labeling is adjacency labeling. For some classes such as general graphs the best-known lower bounds for distance is actually that of adjacency. Adjacency labeling has been studied for various classes of graphs. In [8] the label size for adjacency in general undirected graphs was improved from $n/2 + O(\log n)$ [30, 33] to optimal size $n/2+O(1)$, and in [5] adjacency labeling for trees was improved from $\log_2 n+O(\log^* n)$ [9] to optimal size $\log_2 n + O(1)$.

Distance labeling schemes and related 2-hop labeling are used in SIGMOD and is central for some real-world applications [4, 17, 29]. Approximate distance labeling schemes have found applications in several fields such as reachability and distance oracles [37] and communication networks [35]. An overview of distance labeling schemes can be found in [7].

1.2 Our results

We address open problems of [7, 11, 24] improving the label sizes for *exact distances in sparse graphs*, *r-additive distance in general graphs*, and *D-preserving distance labeling.* We do this by showing a strong relationship between D-preserving distance labeling and several other labeling problems using D-preserving distance labels as a black box. Thus, by improving the result of [11] we are able to obtain the first sublinear labeling schemes for several problems studied at SODA over the past decades. Our results are summarized below.

Sparse graphs. We present the first sublinear distance labeling scheme for sparse graphs giving the following theorem:

▶ **Theorem 1.** *Let $\mathcal{S}_n$ denote the family of undirected and unweighted graphs on n nodes with at most $n^{1+o(1)}$ edges. Then there exists a distance labeling scheme for $\mathcal{S}_n$ with maximum label size $o(n)$.*

As noted, prior to this work the best-known bound for this family was the $O(n)$ scheme of [7] for general graphs. Thus, Theorem 1 separates the family of sparse graphs from the family of general graphs requiring $\Omega(n)$ label size. Our result uses a black-box reduction from sparse graphs to the D-preserving distance scheme of Theorem 3 below. The result of Theorem 1 was made available online in a preliminary version of this paper [6] and was subsequently slightly improved by Gawrychowski et al. [25] by noting, that one of the steps in the construction of our D-preserving distance scheme can be skipped when only considering sparse graphs[4].

Approximate labeling schemes. For r-additive distance labeling Gawrychowski et al. [25] showed that a sublinear labeling scheme for sparse graphs implies a sublinear labeling scheme

[3] In this paper we adopt the convention that the labeling scheme returns an upper-bound if $dist(u,v) < D$.

[4] The scheme presented in this paper has labels of length $O\left(\frac{n \operatorname{polylog} \Delta}{\Delta}\right)$, where $\Delta = \frac{\log n}{1+\log\frac{m+n}{n}}$. In [25] they improve the exponent of the polylog Δ term from 2 to 1.

for $r = 2$ in general graphs. We generalise this result to $r \geq 2$ by a reduction to the D-preserving scheme. We note that a reduction to sparse graphs does not suffice in this case, and the scheme of [25] thus only works for $r = 2$. More precisely, we show the following:

▶ **Theorem 2.** *For any $r \geq 2$, there exists an approximate r-additive labeling schemes for the family $\mathcal{G}_n$ of undirected and unweighted graphs on n nodes with maximum label size*

$$O\left(\frac{n}{r} \cdot \frac{\operatorname{polylog}(r \log n)}{\log n}\right) .$$

Theorem 2 improves on the previous best bound of $O\left(\frac{n}{r}\right)$ by [7] whenever $r = 2^{o\left(\sqrt{\log n}\right)}$, e.g. when $r = \operatorname{polylog} n$.

D-preserving labeling schemes. For D-preserving labeling schemes we show that:

▶ **Theorem 3.** *For any integer $D \in [1, n]$, there exists a D-preserving distance labeling scheme for the family $\mathcal{G}_n$ of undirected and unweighted graphs on n nodes with maximum label size*

$$O\left(\frac{n}{D} \max\left\{\log^2 D, 1\right\}\right) .$$

Theorem 3 improves the result of [11] by a factor of $O(\log^2 n / \log^2 D)$ giving the first sublinear size labels for this problem for any $D = \omega(1)$. This sublinearity is the main ingredient in showing the results of Theorems 1 and 2. Our scheme uses sampling similar to that of [11]. By sampling fewer nodes we show that not “too many” nodes end up being problematic and handle these separately by using a tree structure similar to [7][5].

Finally, we give an almost matching lower bound showing:

▶ **Theorem 4.** *A D-preserving distance labeling scheme for the family $\mathcal{G}_n$ of undirected and unweighted graphs on n nodes require label size $\Omega(\frac{n}{D})$, when D is an integer in $[1, n-1]$.*

This bound is a slight modification of the $\Omega(\frac{n}{D} \log D)$ lower bound for directed graphs given in [11].

2 Preliminaries

Throughout the paper we adopt the convention that $\lg x = \max(\log_2 x, 1)$ and $\log x = \ln x$. When $x \leq 0$ we define $\lg x = 1$. In this paper we assume the word-RAM model, with word size $w = \Theta(\log n)$. If s is a bitstring we denote its length by $|s|$ and will also use s to denote the integer value of s when this is clear from context. We use $s \circ s'$ to denote concatenation of bit strings. Finally, we use the Elias γ code [18] to encode a bitstring s of unknown length using $2|s|$ bits such that we may concatenate several such bitstrings and decode them again.

Labeling schemes. A *distance labeling scheme* for a family of graphs $\mathcal{G}$ consists of an encoder e and a decoder d. Given a graph $G \in \mathcal{G}$ the encoder computes a *label assignment* $e_G : V(G) \to \{0,1\}^*$, which assigns a *label* to each node of G. The decoder is a function such that given any graph $G \in \mathcal{G}$ and any pair of nodes $u, v \in V(G)$ we have $d(e_G(u), e_G(v)) =$

[5] We note that after making this result available online in a preliminary version [6], the bound of Theorem 3 was slightly improved by Gawrychowski et al. [25] to $O(\frac{n}{D} \log D)$.

$dist_G(u, v)$. Note that the decoder is oblivious to the actual graph G and is only given the two labels $e_G(u)$ and $e_G(v)$.

The *size* of a labeling scheme is defined as the maximum label size $|e_G(u)|$ over all graphs $G \in \mathcal{G}$ and all nodes $u \in V(G)$. If for all graphs $G \in \mathcal{G}$ the mapping e_G is injective we say that the labeling scheme assigns *unique labels* (note that two different graphs $G, G' \in \mathcal{G}$ may share a label).

If the encoder and graph is clear from the context, we will sometimes denote the label of a node u by $\ell(u) = e_G(u)$.

Various computability requirements are sometimes imposed on labeling schemes [1, 30, 31].

3 D-preserving distance labeling schemes

In this section we will prove Theorem 3. Observe first that for $D = 1$ Theorem 3 is exactly the classic problem of distance labeling and we may use the result of [7]. We will therefore assume that $D \geq 2$ for the remainder of this paper. Let us first formalize the definition of a D-preserving distance labeling scheme.

▶ **Definition 5.** Let D be a positive integer let $\mathcal{G}$ be a family of graphs. For each graph $G \in \mathcal{G}$ let $e_G : V(G) \to \{0, 1\}^*$ be a mapping of nodes to labels. Let $d : \{0, 1\}^* \times \{0, 1\}^* \to \mathbb{Z}$ be a decoder. If e and d satisfy the following two properties, we say that the pair (e, d) is a *D-distance preserving labeling scheme* for the graph family $\mathcal{G}$.

1. $d(e_G(u), e_G(v)) \geq dist_G(u, v)$ for all $u, v \in G$ for any $G \in \mathcal{G}$.
2. $d(e_G(u), e_G(v)) = dist_G(u, v)$ for all $u, v \in G$ with $dist_G(u, v) \geq D$ for any $G \in \mathcal{G}$.

The idea of the labeling scheme presented in this section is to first make a labeling scheme for distances in the range $[D, 2D]$ and use this scheme for increasingly bigger distances until all distances of at least D are covered. Loosely speaking, the scheme is obtained by sampling a set of nodes R, such that *most* shortest paths of length at least D contain a node from R. Then all nodes are partitioned into *sick* and *healthy* nodes adding the sick nodes to the set R. All nodes then store their distance to each node of R and healthy nodes will store the distance to all nodes, for which the shortest path is not *covered* by some node in R.

3.1 A sample-based approach

As a warm-up, we first present the $O\left(\frac{n}{D} \log^2 n\right)$ scheme of Bollobás et al. in [11] with a slight modification.

Given a graph $G = (V, E) \in \mathcal{G}$ we pick a random multiset $R \subseteq V$ consisting of $\left\lceil c \cdot \frac{n}{D} \log n \right\rceil$ nodes for a constant c to be decided. Each element of R is picked uniformly and independently at random from V (i.e. the same node might be picked several times)[6]. We order R arbitrarily as $(w_1, \ldots, w_{|R|})$ and assign the label of a node $u \in V$ as

$$\ell(u) = dist_G(u, w_1) \circ dist_G(u, w_2) \circ \ldots \circ dist_G(u, w_{|R|})$$

▶ **Lemma 6.** *Let u and v be two nodes of some graph $G \in \mathcal{G}$. Set*

$$d = \min_{w \in R} dist_G(u, w) + dist_G(v, w) \ . \tag{1}$$

Then $d \geq dist_G(u, v)$ and $d = dist_G(u, v)$ if R contains a node from a shortest path between u and v.

[6] In [11] they instead picked R by including each node of G with probability $\frac{c \log n}{D}$.

Proof. Let $z \in R$ be the node corresponding to the minimum value of (1). We then have $d = dist_G(u,z) + dist_G(z,v)$. By the triangle inequality this implies $d \geq dist(u,v)$.

Now let p be some shortest path between u and v in G and assume that $z \in p$. Then $dist_G(u,v) = dist_G(u,z) + dist_G(z,v)$, implying that $d \leq dist_G(u,v)$, and thus $d = dist(u,v)$. ◀

By Lemma 6 it only remains to show that the set R is likely to contain a node on a shortest path between any pair of nodes $u, v \in V$ with $dist_G(u,v) \geq D$.

▶ **Lemma 7.** *Let R be defined as above. Then the probability that there exists a pair of nodes $u, v \in V$ such that $dist_G(u,v) \geq D$ and no node on the shortest path between u and v is sampled is at most n^{2-c}.*

Proof. Consider a pair of nodes $u, v \in V$ with $dist_G(u,v) \geq D$. Let p be a shortest path between u and v, then $|p| \geq D$. Each element of R has probability at least D/n of belonging to p (independently), so the probability that no element of R belonging to p is at most

$$\left(1 - \frac{D}{n}\right)^{|R|} \leq \exp\left(-\frac{D}{n} \cdot |R|\right) \leq \exp(-c \log n) = n^{-c} \ . \tag{2}$$

Since there are at most n^2 such pairs, by a union bound the probability that there exists a pair u, v with $dist_G(u,v) \geq D$, such that no element on a shortest path between u and v is sampled in R is thus at most $n^2 \cdot n^{-c} = n^{2-c}$ ◀

By setting $c > 2$ we can ensure that the expected number of times we have to re-sample the set R until the condition of Lemma 7 is satisfied is $O(1)$. The labels can be assigned using $O(|R| \log n) = O(\frac{n}{D} \log^2 n)$ bits as each distance can be stored using $O(\log n)$ bits.

3.2 A scheme for medium distances

We now present a scheme, which preserves distances in the range $[D, 2D]$ using $O\big(\frac{n}{D} \log^2 D\big)$ bits. More formally, we present a labeling scheme such that given a family of unweighted undirected graphs $\mathcal{G}$ the encoder and the decoder satisfies the following constraints for any $G \in \mathcal{G}$:

1. $d(e_G(u), e_G(v)) \geq dist_G(u,v)$ for any $u, v \in G$.
2. $d(e_G(u), e_G(v)) = dist_G(u,v)$ for any $u, v \in G$ with $dist_G(u,v) \in [D, 2D]$.

Let such a labeling scheme be called a *$[D, 2D]$-preserving distance labeling scheme.*

The labeling scheme is based on a sampling procedure similar to that presented in Section 3.1, but improves the label size by introducing the notion of *sick* and *healthy* nodes.

Let $G = (V, E) \in \mathcal{G}$. We sample a multiset R of size $2 \cdot \frac{n}{D} \log D$. Similar to Section 3.1, each element of R is picked uniformly at random from V.

▶ **Definition 8.** Let R be as defined above and fix some node u. We say that a node v is *uncovered* for u if $dist_G(u,v) \geq D$ and no node in R is contained in a shortest path between u and v. A node u with more than $\frac{n}{D}$ uncovered nodes is called *sick* and all other nodes are called *healthy.*

Let S denote the set of sick nodes and let $\mathrm{uc}(u)$ denote the set of uncovered nodes for u. The main outline of the scheme is as follows:

1. Each node u stores the distance from itself to each node of $R \cup S$ using a tree structure to be described.

2. If u is healthy, u stores the distance from itself to every $v \in \mathrm{uc}(u)$ for which $dist_G(u, v) \in [D, 2D]$.

We start by showing that the set of sick nodes has size $O(n/D)$ with probability at least $1/2$. This is captured by the following lemma.

▶ **Lemma 9.** *Let R be defined as above and let S be the set of sick nodes. Then*

$$\Pr\left[|S| \geq 2\frac{n}{D}\right] \leq 1/2 \ .$$

Proof. Fix some node $u \in V$ and let $v \in V$ be a node such that $dist_G(u, v) \geq D$. Using the same argument as in (2) of Lemma 7 we see that the probability that v is uncovered for u is at most D^{-2}. Therefore $\mathbf{E}[|\mathrm{uc}(u)|] \leq \frac{n}{D^2}$. By Markov's inequality we have

$$\Pr[u \text{ is sick}] = \Pr\left[|\mathrm{uc}(u)| \geq D \cdot \frac{n}{D^2}\right] \leq \frac{1}{D} \ ,$$

and thus $\mathbf{E}[|S|] \leq n/D$. We again use Markov's inequality to conclude that

$$\Pr\left[|S| \geq 2\frac{n}{D}\right] \leq 1/2 \, .$$ ◀

The goal is now to store the distances to the nodes of $R \cup S$ as well as $\mathrm{uc}(u)$ using few bits. First consider the distances to $R \cup S$. We will store these distances using a tree structure similar to that of [7]. To do this we will use the following algorithm:

1. Let $r \in V$ be an arbitrary node.
2. Let T' be the BFS-tree of r in G rooted in r.
3. For $i \in \{0, \dots, D-1\}$, let $A_i = \{u \in V \mid dist_G(r, u) \equiv i \mod D\}$.
4. Let $j = \arg\min_{i \in \{0,\dots,D-1\}} |A_i|$.
5. Let T be a graph with $V(T) = A_j \cup \{r\} \cup R \cup S$ and $E(T) = \emptyset$.
6. For each $u \in V(T) \setminus \{r\}$ let v be the nearest ancestor of u in $T' \setminus \{u\}$ such that $v \in V(T)$. Add the edge (v, u) to T with weight $dist_G(v, u) = dist_{T'}(v, u)$.

This process is illustrated in Figure 1.

▶ **Lemma 10.** *Let T be the tree created by the algorithm above. Then T contains $O(\frac{n}{D} \log D)$ nodes with probability at least $1/2$ and each edge of T has weight at most D.*

Proof. Let T', r and A_j be as defined in the algorithm above.

The size of T is at most $|S| + |R| + |A_j| + 1$. By our choice of A_j and R this is bounded by

$$|S| + 2 \cdot \frac{n}{D} \log D + \left\lfloor \frac{n}{D} \right\rfloor + 1 \ .$$

Using Lemma 9 we see that this is $O\big(\frac{n}{D} \log D\big)$ with probability at least $1/2$.

Consider now any edge $(u, p(u)) \in E(T)$ and let $d = dist_G(u, r)$. If $d \leq D$ it follows from the definition of T that $dist_G(u, p(u)) \leq D$, as r is an ancestor of all nodes, and thus also u, in T'. If $d > D$ consider the unique path from u to r in T' and denote the nodes on this path as $(u, v_1, v_2, \dots, v_k, r)$. It follows that $dist_G(v_1, r) = d - 1$, $dist_G(v_2, r) = d - 2$, etc. Since $d > D$ we have $k \geq D$ and thus one of $v_1, \dots, v_D$ is contained in the set A_j and has distance at most D to u. It now follows that $dist_G(u, p(u)) \leq D$ and thus $dist_T(u, p(u)) \leq D$. ◀

Using Lemma 10 we are able to store the distance from any node u to all nodes of T by storing the differences between the distance from u to adjacent nodes in T. This is captured in the following lemma:

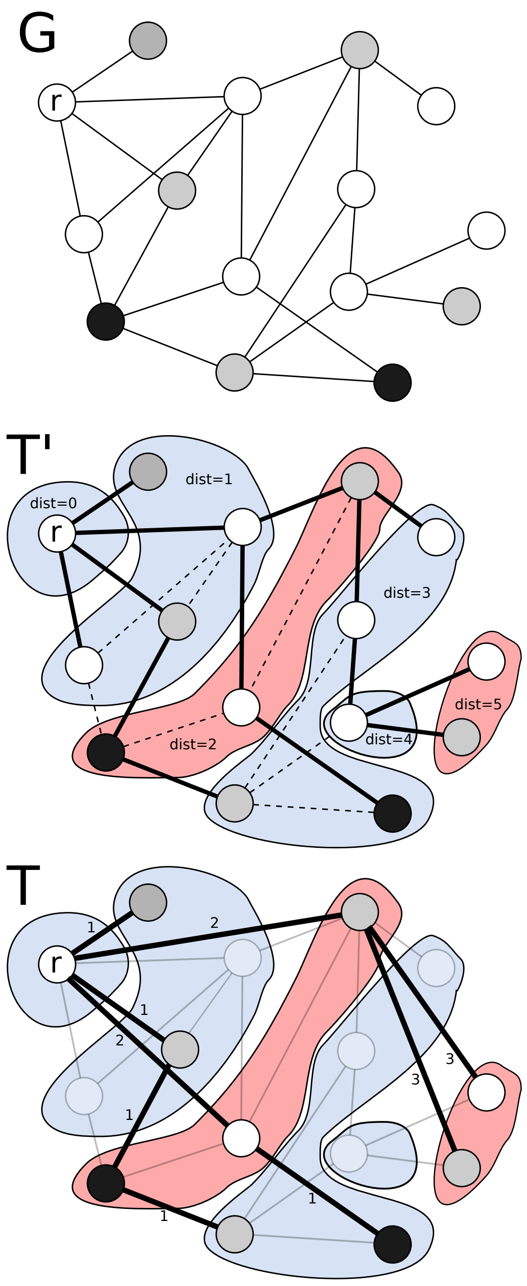

Figure 1 The process of creating T as described above. Gray nodes are the sampled nodes, R, and black nodes are the sick nodes, S. We assume $D = 3$ and pick A_2 as the smallest set (marked in red). *Note that the black nodes are only for illustration and might not actually be sick by our definition.*

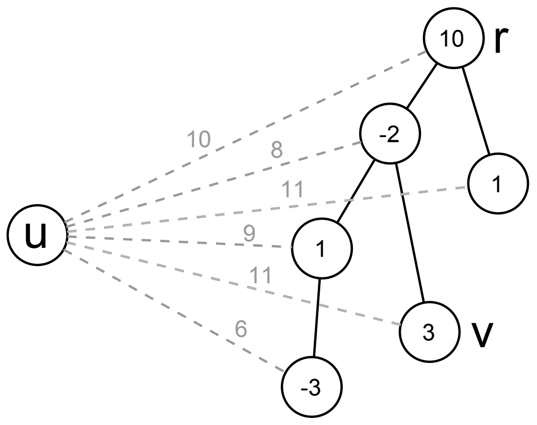

Figure 2 Storing the tree $T = (V', E')$ using few bits. For each node $u \in V'$, we store $dist(u, v) - dist(u, p(v))$. Shortest path distances from u in G are denoted in gray. The distance from u to v is calculated as $10 + (-2) + 1 + (-3) - (-3) - 1 + 3 = 11$.

▶ **Lemma 11.** *Let u be some node in $G = (V, E)$ and let $T = (V', E')$ be the tree resulting from the algorithm above rooted in r. Then we can store the distance from u to every node in T using $O\left(\frac{n}{D}\log^2 D\right)$ bits.*

Proof. Consider the following encoding: We fix some canonical DFS ordering of T and describe it using $2|T|$ bits. This will be the same for all nodes $u \in V$. Next, we store $dist_G(u, r)$ using $\lceil \lg n \rceil$ bits. For each node $v \in V' \setminus \{r\}$ taken in the DFS ordering of T we store $dist_G(u, v) - dist_G(u, p(v))$. Using this description, we can calculate $dist_G(u, v)$ for any $v \in V'$ by summing up the differences on the path from v to r and adding the distance from u to r.

We now argue that $dist_G(u, v) - dist_G(u, p(v))$ can be stored using $\lceil \lg(2D + 1) \rceil$ bits for any node $v \in V' \setminus \{r\}$. Set $t = dist_G(u, p(v))$. By Lemma 10 and the triangle inequality it holds that

$$dist_G(u, v) \le dist_G(u, p(v)) + dist_G(p(v), v) \le t + D\ .$$

Similarly,

$$dist_G(u, v) \ge dist_G(u, p(v)) - dist_G(v, p(v)) \ge t - D\ .$$

Thus, it follows that

$$dist_G(u, v) - dist_G(u, p(v)) \in \{-D, \dots, 0, \dots, D\}\ ,$$

which can be stored using $\lceil \lg(2D + 1) \rceil$ bits. We can thus store all the information using

$$O(2|T| + \log n + |T| \log D) = O\left(\frac{n}{D}\log^2 D\right)$$

bits. ◀

The values $dist_G(u, v) - dist_G(u, p(v))$ are illustrated in Figure 2.

We may now assign the label $\ell(u)$ of a node u to be $id(u)$ concatenated with the bitstring resulting for Lemma 11 and if u is healthy this is concatenated with the id of the nodes in $uc(u)$ whose distance from u is in the interval $[D, 2D]$ along with these distances. The decoder works by simply checking if one nodes stores the others distance or by taking the minimum of going via any node in T.

Label size. In order to bound the size of the label we only need to bound the size of storing id's and distances to the nodes of $uc(u)$ whose distance is in $[D, 2D]$. Since we only store this for healthy nodes this set has size at most n/D and can be described using at most $O(\frac{n}{D}\log D)$ bits. Since each distance can be stored using $O(\log D)$ bits we conclude that the total label size is bounded by $O\big(\frac{n}{D}\log^2 D\big)$.

▶ **Theorem 12.** *There exists a $[D, 2D]$-preserving distance labeling scheme for the family $\mathcal{G}_n$ of undirected and unweighted graphs on n nodes with maximum label size*

$$O\Big(\frac{n}{D}\log^2 D\Big) .$$

Proof. This is a direct corollary of the discussion above. ◀

3.3 Bootstrapping the scheme

In order to show Theorem 3 we will concatenate several instances of the label from Theorem 12. First define $\ell_D(u)$ to be the $[D, 2D]$-preserving distance label for the node u assigned by the scheme of Theorem 12. Now assign the following label to each node u:

$$\ell(u) = \ell_D(u) \circ \ell_{2D}(u) \circ \ell_{4D}(u) \circ \ldots \circ \ell_{2^k D}(u) , \tag{3}$$

where $k = \lfloor \lg(n/D) \rfloor$. Let d_D be the distance returned by running the decoder of Theorem 12 on the corresponding component of the label $\ell(u)$. Then we let the decoder of the full labeling scheme return

$$\hat{d} = \min(d_D, d_{2D}, \ldots, d_{2^k D}) , \tag{4}$$

with k defined as above. We are now ready to prove Theorem 3.

Proof of Theorem 3. Consider any pair of nodes u, v in some graph $G \in \mathcal{G}_n$ and let $d = dist_G(u, v)$. Also, let $\hat{d}$ be the value returned by the decoder for $\ell(u)$ and $\ell(v)$. If $d \le D$ we have $\hat{d} \ge d$. Now assume that $d \in [2^i \cdot D, 2^{i+1} \cdot D]$ for some non-negative integer i. Then, by Theorem 12 and (4) we have $\hat{d} = d$.

The size of the label assigned by (3) is bounded by

$$\begin{aligned}\sum_{i=0}^{\lfloor \lg_2(n/D) \rfloor} O\Big(\frac{n}{2^i \cdot D}\log^2(2^i \cdot D)\Big) &\le \sum_{i=0}^{\infty} O\Big(\frac{n}{2^i \cdot D}\log^2(2^i \cdot D)\Big) \\ &\le O\left(\frac{n}{D}\log^2(D)\sum_{i=1}^{\infty}\frac{i^2+1}{2^i}\right) \\ &= O\Big(\frac{n}{D}\log^2(D)\Big) .\end{aligned}$$

◀

3.4 Lower bound

Proof of Theorem 4. Let $k = \left\lfloor \frac{n}{D+1} \right\rfloor$ and let L and R be sets of k nodes which make up the left and right side of a bipartite graph respectively. Furthermore, let each node of R be the first node on a path of D nodes.

Consider now the family of all such bipartite graphs (L, R) with the attached paths. There are exactly 2^{k^2} such graphs.

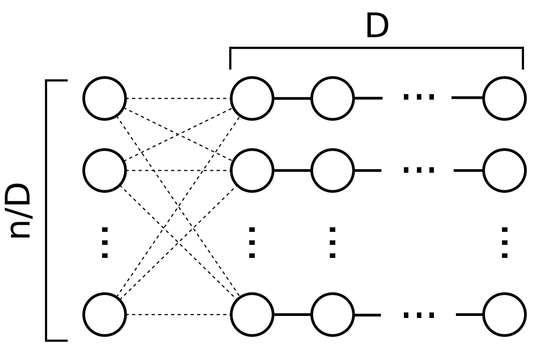

Figure 3 Illustration of the graph family used in the proof of Section 3.4.

Now observe, that a node $u \in L$ is adjacent to a node $v \in R$ if and only if $dist(u, w) = D$, where w is the last node on the path starting in v. By querying all such pairs (u, w) we obtain k^2 bits of information using only $2k$ labels, thus at least one label of size

$$\frac{k^2}{2k} = \frac{\left\lfloor \frac{n}{D+1} \right\rfloor}{2} \geq \frac{n}{8D}$$

is needed. Since the graph has $\leq n$ nodes this implies the result. ◀

This is illustrated in Figure 3.

4 Sparse and bounded degree graphs

We are now ready to prove Theorem 1. In fact we will show the following more general lemma:

▶ **Lemma 13.** *Let $\mathcal{H}_{n,m}$ denote the family of undirected and unweighted graphs on n nodes with at most m edges. Then there exists a distance labeling scheme for $\mathcal{H}_{n,m}$ with maximum label size*

$$O\left(\frac{n}{D} \cdot \log^2 D\right), \text{ where } D = \frac{\log n}{1 + \log \frac{m+n}{n}}$$

Since $\frac{\log n}{1+\log \frac{m+n}{n}} = \omega(1)$ when $m = n^{1+o(1)}$ it will suffice to prove Lemma 13. In order to do so we first show the following lemma for bounded-degree graphs:

▶ **Lemma 14.** *Let $\mathcal{B}_n(\Delta)$ be the family of graphs on n nodes with maximum degree Δ. There exists a distance labeling scheme for $\mathcal{B}_n(\Delta)$ with maximum label size*

$$O\left(\frac{n}{D} \log^2 D\right), \text{ where } D = \frac{\log n}{1 + \log \Delta}$$

Proof. Suppose we are labeling some graph $G \in \mathcal{B}_n(\Delta)$ and let $u \in G$. Let $D = \left\lceil \frac{\log n}{1+2\log \Delta} \right\rceil$ and let $\ell_D(u)$ be the D-distance preserving label assigned by using Theorem 3 with parameter D. Using this label we can deduce the distance to all nodes of distance at least D to u.

Since $G \in \mathcal{B}_n(\Delta)$ there are at most $\Delta^D = O(\sqrt{n})$ nodes closer than distance D to u. Thus, we may describe the IDs and distances of these nodes using at most $O(\sqrt{n} \log n)$ bits. This gives the desired total label size of

$$|\ell(u)| = O\left(\sqrt{n} \log n + \frac{n}{D} \log^2 D\right) = O\left(\frac{n}{D} \log^2 D\right) .$$ ◀

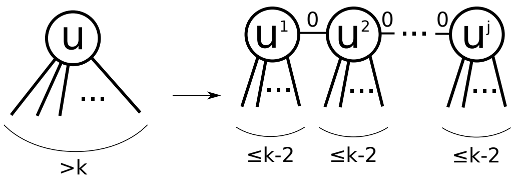

Figure 4 Illustration of the transformation from sparse graph to bounded degree graph.

Using this result we may now prove Lemma 13 by reducing to the bounded degree case in Lemma 14. This has been done before e.g. in distance oracles [20, 3].

Proof of Lemma 13. Let $G \in \mathcal{H}_{n,m}$ be some graph and let $k = \max\left\{\left\lceil \frac{m}{n} \right\rceil, 3\right\}$. Let $u \in G$ be some node with more than k incident edges. If no such node exists, we may apply Lemma 14 directly and we are done. Otherwise we split u into $\lceil \deg(u)/(k-2) \rceil$ nodes and connect these nodes with a path of 0-weight edges. Denote these nodes $u^1, \ldots, u^{\lceil \deg(u)/(k-2) \rceil}$. For each edge (u, v) in G we assign the end-point at u to a node u^i with $\deg(u^i) < k$. This process is illustrated in Figure 4.

Let the graph resulting from performing this process for every node $u \in G$ be denoted by G'. We then have $\Delta(G') \leq k$. Furthermore it holds that for every pair of nodes $u, v \in G$ we have $dist_G(u, v) = dist_{G'}(u^1, v^1)$. Consider now using the labeling scheme of Lemma 14 on G' and setting $\ell(u) = \ell(u^1)$ for each node $u \in G$. By observing that the labeling scheme of Theorem 3 preserves distances for nodes who have at least D *edges* on the shortest path we see that this is actually a distance labeling scheme for G. The number of nodes in G' is bounded by

$$\sum_{u \in G} \left\lceil \frac{\deg(u)}{k-2} \right\rceil \leq \sum_{u \in G} \left(\frac{\deg(u)}{k-2} + 1 \right) = \frac{2m}{k-2} + n = O(n) ,$$

which means that Lemma 14 gives the desired label size. ◀

5 Additive error

We will now show how we can use our D-preserving labeling scheme of Theorem 3 to generalize the 2-additive distance labeling scheme of Gawrychowski et al. [25]. We will assume that $r \leq n^{1/10}$ for simplicity.

Let $t = r \log^{10} n$ and let $D = \frac{r \log n}{4 \log t}$. We describe the scheme in three parts:

1. Let G^r be a copy of G, where an edge is added between any pair of nodes whose distance is at most $r/2$ in G. Let $V^r_{\geq t}$ be the set of nodes in G^r with degree at least t and let S be a minimum dominating set of $V^r_{\geq t}$ in G_r. Then $|S| = O(\frac{n \log t}{t})$.

   For all nodes $u \in G$ we store $dist(u, v)$ and $id(v)$ for all $v \in S$.
2. Consider now the subgraph of G induced by $V \setminus V^r_{\geq t}$. For a node $u \notin V^r_{\geq t}$, let $B_u(D)$ be the ball of radius D around u in this induced subgraph Then $|B_u(D)| \leq t^{2D/r} = O(\sqrt{n})$. This follows from the definition of $V^r_{\geq t}$: There are at most t nodes within distance $r/2$ from u and thus at most t^2 nodes within distance r from u, etc.

   For all $u \notin V^r_{\geq t}$ we store $dist(u, v)$ and $id(v)$ for all $v \in B_u(D)$.
3. Finally we store a D-preserving distance label for all $u \in G$.

The total label size is then

$$O\left(n \cdot \frac{\log n \log t}{t} + \sqrt{n}\log n + \frac{n \log t}{r \log n} \cdot (\log(r \log n))^2\right) = O\left(\frac{n}{r \log n} \cdot \text{polylog}(\log n \cdot r)\right) ,$$

as stated in Theorem 2.

Decoding. To see that the distance between two nodes u and v can be calculated within an additive error r we split into several cases:

- If $dist(u,v) \geq D$ we can report the exact distance between u and v using the D-preserving distance scheme.
- If $dist(u,v) \leq D$ and $deg_{G_r}(v) \geq t$ we can find a node $z \in S$ such that $dist(z,v) \leq r/2$ and thus

  $$dist(u,z) + dist(z,v) \leq dist(u,v) + dist(v,z) + dist(z,v) \leq dist(u,v) + r ,$$

  and symmetrically if $deg_{G_r}(u) \geq t$.
- Finally, if $dist(u,v) \leq D$ and $deg_{G_r}(u) < t$ and $deg_{G_r}(v) < t$, then we $v \in B_u(D)$ and we can thus report the exact distance between u and v.

Abstract

An estimated 30 % of urban traffic is caused by search for parking spots [8]. Suggesting routes along highly probable parking spots could reduce traffic. In this paper, we formalize parking search as a probabilistic problem on a road graph and show that it is NP-complete. We explore heuristics that optimize for the driving duration and the walking distance to the destination. Routes are constrained to reach a certain probability threshold of finding a spot. Empirically estimated probabilities of successful parking attempts are provided by TomTom on a per-street basis. We release these probabilities as a dataset of about 80,000 roads covering the Berlin area. This allows to evaluate parking search algorithms on a real road network with realistic probabilities for the first time. However, for many other areas, parking probabilities are not openly available. Because they are effortful to collect, we propose an algorithm that relies on conventional road attributes only. Our experiments show that this algorithm comes close to the baseline by a factor of 1.3 in our cost measure. This leads to the conclusion that conventional road attributes may be sufficient to compute reasonably good parking search routes.

1 Introduction

Searching for a parking spot is expensive, time-consuming, and causes a significant amount of urban traffic: An estimated 30 % of traffic is due to people searching for parking spots [8]. Drivers could be assisted in their search by suggesting a route along streets with a high probability of yielding a vacant on-street parking spot. In this paper, we investigate the problem of generating these routes. While off-street parking options, such as car parks, are valid alternatives and have been explored, e.g., by Cassady and Kobza [2], we focus on *free of charge on-street parking*, which makes up a majority of the parking capacity in most cities [3].

Parking search is probabilistic by nature. Modeling the road network as a graph, each edge has a probability of having a vacant parking spot. Several works on probabilistic graph routing have been conducted as outlaid in section 2. Most relevant, Jossé, Schmid and Schubert [5] recently proposed a probabilistic model for parking search that we build on.

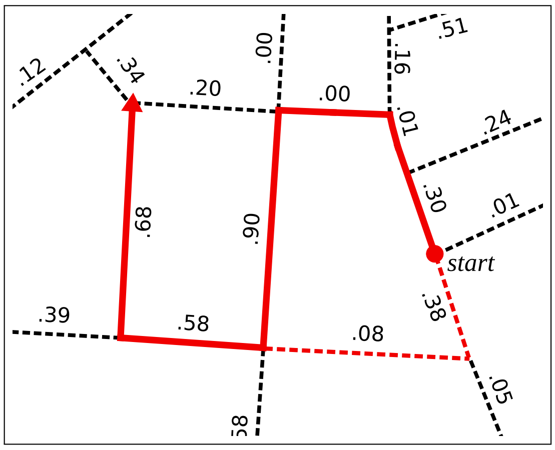

Figure 1 A simple route computed by our **Branch and Bound** algorithm (red line). While a greedy route (dashed red line) would collect more probability mass with the first two segments by leading South and West, the shown route reaches the 90 % edge slightly earlier and can collect the 58 % edge right afterward.

In theory, parking routes can have an infinite length, since a parking spot can never be guaranteed. To evaluate our algorithms, however, we have to restrict routes to a finite length. In our formalization in section 3, we thus introduce a bound on the converse probability mass of routes, similar to previous work [5, 6]. Traversing the graph, at each edge the algorithm collects the probability of having found a parking spot. A route is considered successful if its collected probability mass reaches a certain threshold. See figure 1 for an example of a successful route. We evaluate routes based on the two criteria *driving duration* and *walking distance* to the desired destination.

For generating good parking search routes, we propose two algorithms in Section 4. The first one, **Branch and Bound**, is our baseline. Since it considers routes that reach a probability mass threshold constraint, it requires know ledge of per-street probabilities. For the case where those probabilities are not available, we propose a **Heuristic Search** algorithm that iteratively explores sub-routes scored by a heuristic. This approach comes close to the baseline by a factor of 1.3 in our cost.

Along with our work, we release a *dataset of empirically estimated probabilities* of parking successes collected by TomTom. Those probabilities are given per-street and for each hour of day and day of week. The data was obtained from several million anonymously collected user records. In Section 5, we describe the collection and preprocessing processes. We then explore characteristics of the dataset such as the difference of the probability distributions at day- and nighttime.

Based on the dataset, we evaluate our algorithms in Section 6. First, we compare our **Branch and Bound** and **Heuristic Search** algorithms and a greedy algorithm proposed by Jossé et al. [5] at different *times of day.* Second, we compare different choices for *weighting the cost.* Since our cost is composed of two objectives, we can simulate different preferences. We show that finding a parking spot quickly tends to be easier than finding one that is close to the desired destination. Third, we assess the *impact of inaccurate probabilities* by considering our dataset as ground-truth and showing a disturbed version of it to the algorithms. We show that **Branch and Bound** still works well under a high level of noise but is outperformed by **Heuristic Search** later.

2 Related Work

Routing on conventional road networks has been subject to extensive research. Especially the approach of route queries on probabilistic graphs has recently gained increasing attention. More specifically, the problem of finding a parking spot in urban areas, which can be distinguished into on-street and off-street parking, has been examined.

Kanza et al. [6] calculate routes to a given destination on a probabilistic graph, maximizing the certainty of visiting relevant points of interest. Hua and Pei [4] study routing under uncertain travel time. They either bound probability or duration and optimize for the other. In our scenario, after bounding the probability, we still have to optimize a multi-objective problem with *driving duration* and *walking distance*. Moreover, their algorithms assume a specified destination which does not exist in parking search, thus we can not apply their algorithms to our problem.

Probabilistic routing is usually modeled as a graph of resources that each can either be available or not [7, 6, 5]. Kanza et al. [6] and Jossé et al. [5] both abstract from the road network and span their graphs over resources only. Since we have a probability of parking success for each road, we must span our graph over the complete road network. While this is conceptually the same, it results in large graphs where back-tracking, as used by Jossé et al. [5], is not suitable anymore.

Kanza et al. [6] refer to uncertainty as the probability of a particular resource being relevant and available, comparable to our per-street probabilities. As an answer to a *route-search query*, they suggest two complementary length-bounded and probability-bounded scenarios. We use the latter approach with our probability mass threshold. For on-street parking search, a bounded-probability scenario makes sense since a parking spot can never be guaranteed completely and routes can potentially be infinite.

As mentioned, Jossé et al. [5] propose a resource graph model that they use to answer parking search queries. Their main focus lies on resource reappearance. In their model, the observed state of a resource decays over time, allowing consumed resources to reappear with a certain probability. They differentiate between long-term and short-term observations. Long-term observations correspond to our static probability model, while we do not model short-term observations because real reappearance data is not available.

3 Problem

3.1 Formalization

We now give a formal definition of our parking search scenario and prove that it is NP-complete. We model the road network as a directed graph whose edges are augmented with information about the distance of an edge to the destination, the time to traverse the edge, and the probability of finding a parking spot.

The search process starts at a crossing in the network, given by a specified node v_0. For simplicity, this node is also the desired destination, since we assume that the driver has already reached the destination and now starts looking for a parking spot from there. Our proposed algorithms can work with other destinations without any modifications. The parking route is represented as a path P on the graph and is considered successful if the probability of not finding a parking spot is at most ε.

The overall cost of a successful path is a convex combination with parameter λ of, on the one hand, the time spent not finding a parking place and, on the other hand, the distance to the destination v_0. Note that probabilities do not reappear, that is, an edge can contribute a positive probability of finding a parking spot at most once.

Since a driver usually scans opposing lanes of a single street at once, we further introduce a function D that maps edges of the graph to sets of edges that share a single probability. If we traverse an edge (u, v), the probabilities of all edges in $D\big((u, v)\big)$ disappear as well. Normally, for an edge (u, v), $D\big((u, v)\big)$ would consist of at most (u, v) and (v, u). If, however, opposing lanes were separated, only choosing $D\big((u, v)\big) = \{(u, v)\}$ would make sense.

▶ **Definition 1** (Minimal Parking Spot Search (MPSS)).

Instance: Directed graph $G = (V, E)$, time function $t\colon E \to \mathbb{R}_{\geq 0}$, distance function $d\colon E \to \mathbb{R}_{\geq 0}$, probability function $p\colon E \to [0, 1]$, specified vertex $v_0 \in V$, threshold $\varepsilon \in [0, 1]$, and value $\lambda \in [0, 1]$. Let $D\colon E \to \mathcal{P}(E)$ such that, for all $e \in E$, $e \in D(e)$.

Solution: Edge sequence $P = (e_1, e_2, \dots, e_l) \in E^l$ with $l \leq |E|^2$ such that $e_1 = (v_0, v)$ for some $v \in V$ and $\forall\ i \in \{1, 2, \dots, l-1\}\ \exists\ u, v, w \in V\colon e_i = (u, v) \wedge e_{i+1} = (v, w)$ and $\prod_{\substack{i=1:\\ \forall j<i\colon e_i \notin D(e_j)}}^{l} \big(1 - p(e_i)\big) \leq \varepsilon$.

Measure: Minimize the cost c(P) defined as

$$c(P) = \lambda \sum_{i=1}^{l} t(e_i) \cdot \left(\prod_{\substack{j=1:\\ \forall k<j\colon e_j \notin D(e_k)}}^{i-1} \big(1 - p(e_j)\big) \right) + (1-\lambda) \sum_{\substack{i=1:\\ \forall k<i\colon e_i \notin D(e_k)}}^{l} p(e_i) \cdot d(e_i) \cdot \left(\prod_{\substack{j=1:\\ \forall k<j\colon e_j \notin D(e_k)}}^{i-1} \big(1 - p(e_j)\big) \right) .$$

Note that our measure is equivalent to

$$\sum_{\substack{i=1:\\ \forall k<i\colon e_i \notin D(e_k)}}^{l} p(e_i) \left(\prod_{\substack{j=1:\\ \forall k<j\colon e_j \notin D(e_k)}}^{i-1} \big(1 - p(e_j)\big) \right) \cdot \left(\lambda \sum_{j=1}^{i} t(e_j) + (1-\lambda) \cdot d(e_i) \right) +$$
$$\lambda \sum_{i=1}^{l} t(e_i) \cdot \prod_{\substack{j=1:\\ \forall k<j\colon e_j \notin D(e_k)}}^{l} \big(1 - p(e_j)\big) .$$

The last term models an optimistic extension of the route by a road which contributes zero time, zero distance and a probability of one.

3.2 NP-Completeness

Let k-Minimal Parking Spot Search (k-MPSS) be the decision version of MPSS, i.e., the problem to decide if there is a feasible solution of cost at most k. We prove the NP-completeness of k-MPSS by a polynomial time reduction from Hamiltonian Path, i.e., the problem of finding a simple path in G which visits each node exactly once.

▶ **Theorem 2.** *k-MPSS is NP-complete.*

Proof. First of all, k-MPSS is in NP, since we can guess an edge sequence of size at most $|E|^2$ at random and it can be tested in polynomial time if the edge sequence is a feasible solution and if its cost is at most k.

Now we sketch how to reduce an instance of Hamiltonian Path to an instance of k-MPSS in polynomial time. Suppose we are given a directed graph $G = (V, E)$ as an input for Hamiltonian Path. We construct a new graph $G' = (V', E')$ with $V' = \{v_0\} \cup \big\{v^{\text{in}}, v^{\text{out}} \mid v \in V\big\}$ and $E' = \big\{(v_0, v^{\text{in}}) \mid v \in V\big\} \cup \big\{(v^{\text{in}}, v^{\text{out}}) \mid v \in V\big\} \cup \big\{(u^{\text{out}}, v^{\text{in}}) \mid (u, v) \in E\big\}$. We define

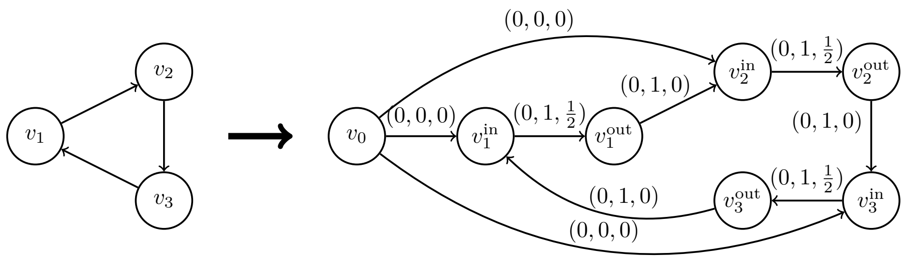

Figure 2 An exemplary reduction from Hamiltonian Path to k-MPSS. The graph on the left is transformed into the one on the right. The triple of an edge e in the right graph has the form $\big(d(e), t(e), p(e)\big)$.

$d(e) = 0$ for all $e \in E'$, $t(e) = 1$ for all $e \in E' \setminus \{(v_0, v^{\text{in}}) \mid v \in V\}$ and $t(e) = 0$ for all $e \in \{(v_0, v^{\text{in}}) \mid v \in V\}$. For all $e \in E'$, we choose $p(e) = \frac{1}{2}$ if $e = (v^{\text{in}}, v^{\text{out}})$ for some $v \in V$ and $p(e) = 0$ otherwise. Further, we define, for all $e \in E'$, $D(e) = \{e\}$, i.e., for two edges e_i and e_j, our proposition of $e_i \notin D(e_j)$ in the problem formalization simplifies to $e_i \neq e_j$. Finally, we choose $\lambda = 1$, $\varepsilon = 2^{-|V|}$ and $k = \sum_{i=1}^{2|V|-1} \left(\frac{1}{2}\right)^{\lfloor i/2 \rfloor}$. An example of such a reduction can be seen in Figure 2.

Suppose the graph G has a Hamiltonian path $(v_{i_1}, v_{i_2}, \dots, v_{i_{|V|}})$. Then the edge sequence

$$\big((v_0, v_{i_1}^{\text{in}}), (v_{i_1}^{\text{in}}, v_{i_1}^{\text{out}}), (v_{i_1}^{\text{out}}, v_{i_2}^{\text{in}}), \dots, (v_{i_{|V|}}^{\text{in}}, v_{i_{|V|}}^{\text{out}})\big)$$

is a feasible solution for k-MPSS. Since $(v_{i_1}, v_{i_2}, \dots, v_{i_{|V|}})$ is a Hamiltonian path, each $(v^{\text{in}}, v^{\text{out}})$-edge is traversed exactly once with exactly one other edge in-between. Also, each edge is traversed at most once. The sequence consists of $2|V| \le |E'|$ edges and amounts to

$$\prod_{\substack{i=0:\\ \forall j<i:\ e_i \neq e_j}}^{l} \big(1 - p(e_i)\big) = 2^{-|V|} = \varepsilon\,.$$

The cost of the sequence is

$$\sum_{i=1}^{2|V|} t(e_i) \cdot \left(\prod_{\substack{j=1:\\ \forall k<j:\ e_j \neq e_k}}^{i-1} \big(1 - p(e_j)\big) \right) = \sum_{i=2}^{2|V|} \left(\prod_{j=1}^{i-1} \big(1 - p(e_j)\big) \right)$$
$$= \sum_{i=2}^{2|V|} \left(\frac{1}{2}\right)^{\lfloor (i-1)/2 \rfloor} = \sum_{i=1}^{2|V|-1} \left(\frac{1}{2}\right)^{\lfloor i/2 \rfloor} = k\ ,$$

since $t(e_1) = 0$, $t(e_i) = 1$ for all $i \ge 2$, $1 - p(e_i) = \frac{1}{2}$ if i even and $1 - p(e_i) = 1$ if i odd.

To transform a solution $(e_1, e_2, \dots, e_l)$ of k-MPSS into a solution of Hamiltonian Path, we simply take the nodes $(v_{i_1}, v_{i_2}, \dots, v_{i_{|V|}})$ according to the order in which their corresponding $(v^{\text{in}}, v^{\text{out}})$-edges are traversed.

Now suppose we have a solution $(e_1, e_2, \dots, e_l)$ of k-MPSS. To achieve

$$\prod_{\substack{i=0:\\ \forall j<i:\ e_i \neq e_j}}^{l} \big(1 - p(e_i)\big) \le 2^{-|V|}\,,$$

all $(v^{\text{in}}, v^{\text{out}})$-edges have to be visited at least once. Due to the construction of G', every edge sequence has to alternate between $(v^{\text{in}}, v^{\text{out}})$-edges and $(u^{\text{out}}, v^{\text{in}})$-edges. The factor in the cost term only changes if we visit a new $(v^{\text{in}}, v^{\text{out}})$-edge. If we visit any other edge or an edge we already visited, the same factor as before is added to the cost. That means, visiting e_i with $i > 1$ adds $(1/2)^{|\{(v^{\text{in}},v^{\text{out}})|v \in V\} \cap \{e_1,e_2,\ldots,e_{i-1}\}|}$ to the cost. Since each $(v^{\text{in}}, v^{\text{out}})$-edge has to be visited at least once and the edge sequence has to be alternating, starting at some edge (v_0, u^{in}) with cost 0, the cost of every feasible edge sequence is at least k. Furthermore, to reach a cost of at most k, each $(v^{\text{in}}, v^{\text{out}})$-edge can be visited at most once, i.e., after transforming the solution, we get a path in G which visits each node exactly once. ◀

4 Algorithms

We now introduce two algorithms for optimizing the problem defined in Section 3. The space of potential solutions for this problem forms a tree where each node holds a route. Each route begins with an outgoing road of the start node, and children in the tree extend their parent route by one possible edge each. Because of the number of outgoing edges at each node, the time of brute-force search in this tree grows exponentially in depth. As we already showed, the problem is NP-complete, so our algorithms only explore this *solution tree* partially, in order to make computations viable on large road networks.

Our **Branch and Bound** algorithm serves as *baseline* for a given probability mass threshold ε. For the case of not having probability data available, we propose a **Heuristic Search** algorithm that explores the solution tree shallowly to compute sub-routes. We iterate this routine to obtain routes of theoretically infinite length. Since we cannot compute the cost of a route without probabilities, we have to make estimations. For this, we mention heuristics varying in their required knowledge of road attributes.

4.1 Branch and Bound

Branch and Bound, as shown in Algorithm 1, has knowledge of per-street probabilities and the evaluation threshold ε. As an outline, we follow the branch and bound paradigm and obtain an initial upper bound B on the cost of a best route from v_0. We then explore the solution tree by pruning intermediate routes that exceed this bound. If a considered route reaches ε before getting pruned, it must be better than the previous bound. Thus, we update B with the cost of this route and proceed exploring the remaining solutions.[1]

For the initial upper bound, we greedily expand a single route from v_0. At each node, we choose an outgoing edge e with the largest term $\frac{p(e)}{c(P+e)-c(P)}$ as the next segment. Eventually, this route reaches ε. The cost of this serves as an initial upper bound $B := c(P)$ on the cost of the best route from v_0 that satisfies the threshold constraint.

We then explore the whole solution tree discarding any intermediate route P' if $c(P') \geq B$. We restrict the number of explored routes with an *expands* parameter. In comparison to restricting the depth of the search, this allows for consistent computation times, as it is independent of the local branching factors of the road network. We traverse the restricted solution tree in a *breadth-first search* manner to look at shorter routes first, with random ordering within each level. We use this algorithm as baseline in the experiments in Section 6.

[1] Jossé et al. [5] also proposed an algorithm based on the branch and bound paradigm. They suggest an expensive forward estimation of the remaining cost of intermediate routes. We found this to be ineffective compared to the increased amount of routes that can be considered otherwise.

Algorithm 1: Branch and Bound($expands$)

```
1  $queue \leftarrow$ queue with empty route;
2  $best \leftarrow$ empty route;
3  while probability mass of $best < 1 - \varepsilon$ do
4      $best \leftarrow best$ concatenated with outgoing edge $e$ where $\frac{p(e)}{c(best+e)-c(best)}$ is largest;
5      if $best.length > 50$ then
6          $c(best) \leftarrow \infty$;
7          break;
8  for $n = 1$ to $expands$ do
9      $route \leftarrow queue.pop()$;
10     foreach outgoing $edge$ from $route$ do
11         if $c(route$ concatenated with $edge) > c(best)$ then
12             continue;
13         if $probability\ mass\ of\ route < 1 - \varepsilon$ then
14             $best \leftarrow route$;
15             continue;
16         $queue.push(route$ concatenated with $edge)$;
17 return $best$;
```

Note that in reality a parking spot can never be guaranteed and routes found by **Branch and Bound** may not lead along a vacant parking spot. The algorithm can be modified to handle this scenario: If the returned route ends before we found a vacant parking spot, we restart the algorithm with the last visited node as new start node. Since it knows per-street probabilities, visited routes stay at zero probability. We use this approach for the experiment on inaccurate probabilities in Section 6.3, where the algorithm sees disturbed probabilities and the returned route might not reach the probability mass threshold.

4.2 Heuristic Search

For some cities, the data used for generating probabilities may not be available and only map data can be used. Therefore, we introduce **Heuristic Search** (Algorithm 2) which computes sub-routes using *breadth-first search*, also limited by the number of *expands*. Since the algorithm does not access probabilities, it cannot evaluate the real cost for a route. In order to choose a good route from the explored solution tree, it uses a heuristic $h(P)$. Whenever the current route is exhausted, the algorithm restarts to compute the next sub-route. However, it memorizes all visited edges.

We design $h(P)$ mainly based on the distances of the edges in P to the desired destination. This makes the heuristic widely applicable. In our formalization, later edges tend to contribute less to the cost since a parking spot likely is already found. Without the correct probabilities, we have to estimate this discount function $s(i)$. Our heuristic is given by

$$h(P) = \sum_{\substack{i=0: \\ \forall j<i:\ e_i \notin D(e_j)}}^{|P|} \frac{s(i)}{d(e_i)} \ .$$

We tried to improve the heuristic using commonly available road attributes, such as

Algorithm 2: Heuristic Search(*expands*)

```
1 $queue \leftarrow$ queue with empty route;
2 for $n = 1$ to $expands$ do
3     $route \leftarrow queue.pop()$;
4     foreach outgoing $edge$ from $route$ do
5         $queue.push(route$ concatenated with $edge)$;
6 return $P \in queue$ where $h(P)$ is largest;
```

information about nearby points of interest and the importance of a road, but none of them yielded significant performance improvements. Although there was some correlation to the probability, nearly all of it could be explained by a shared correlation to the road length. Correcting this by using the probability density as defined in section 5 yielded no significant correlations. Incorporating more information, such as demographic data, could potentially yield better heuristics, but this data may not be as widely available.

5 Dataset

Complementary to the specification of a theoretical model, we evaluate realistic scenarios on the central area of Berlin, Germany. In the following section, we describe this dataset and its collection process conducted by TomTom[2]. While some of the provided information could be extracted from public sources, we did not identify any party that made a comparable amount of on-street parking measures available or used such data for research on simulated parking scenarios. Our dataset will be made available at `https://hpi.de/friedrich/research/parking/`.

The dataset contains a road network reflecting the graph described in Section 3. Each edge contains data about the *nodes it leads from and to*, its *opposite edge*, the *parking probability*, and various other properties like the *length*, *functional road class*, and *average speed*. Unlike the other properties, the probabilities are broken up by hour of day and day of week. Since we determined the probability data empirically, they include a human factor. For example, drivers might have rejected a vacant parking spot because of small space or expensive parking fees. We interpret our experiments in Section 6 accordingly.

The raw data was collected by TomTom as floating-car data: Anonymized GPS positioning-information was analyzed and filtered to detect on-street parking events based on navigational destinations, driving speed, and behavior. The results were aggregated over a multitude of traces to find the number of parking searches and successes for each road segment. We further adjust the probabilities for each road, using the lower bound of the Agresti-Coull confidence interval [1] with a confidence level of 95 %. This results in pessimistic estimates of parking probabilities, based on the number of observations for each edge. Thus, we avoid unrealistic probabilities of 1.0 that might be observed in streets with too few detected parking searches for a meaningful result.

From the probability $p(e)$ and length $l(e)$ of a road e, we compute a *probability density* $1 - \big(1 - p(e)\big)^{\frac{1}{l(e)}}$ that resembles the probability of a unit-length part of the road. The collected probability mass stays the same, no matter whether we observe the whole road at

[2] TomTom Development Germany GmbH, An den Treptowers 1, 12435 Berlin, Germany.

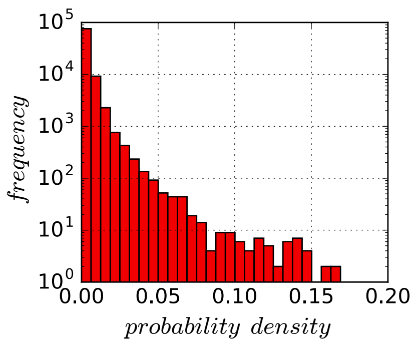

Figure 3 The *probability density* is a measure for the parking probability per meter. For our dataset, we assume an underlying Pareto II distribution. (Mon–Sun, 9 a.m.–4 p.m.)

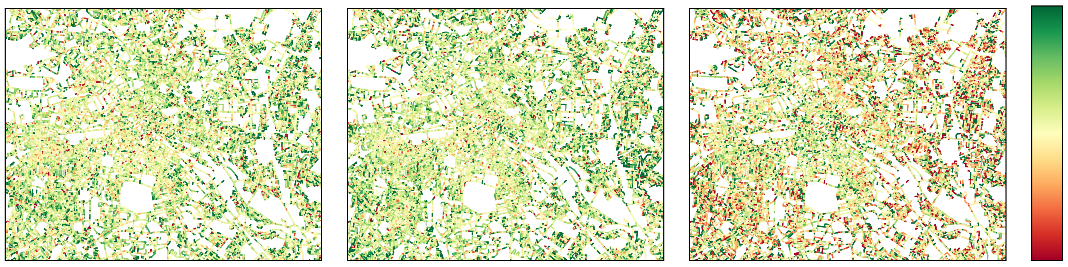


(a) Morning, 6 a.m. to 2 p.m. **(b)** Evening, 2 p.m. to 9 p.m. **(c)** Night, 9 p.m. to 6 a.m.

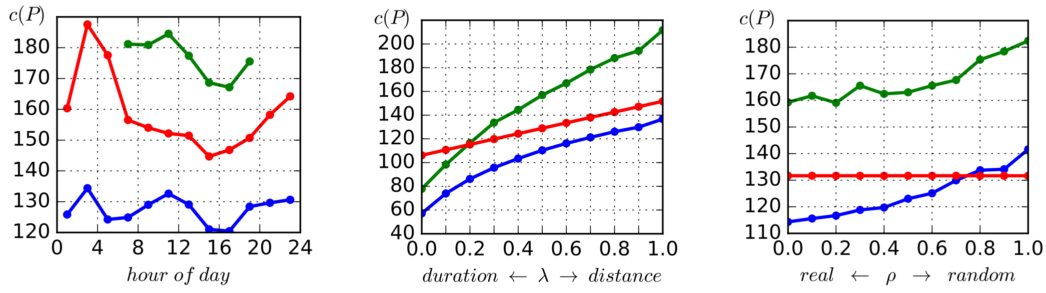
Figure 4 We compute the probability densities of all roads at different times of day. The three heat maps show differences to the per-street averages over the whole day. Containing 90 % of values, we map the interval $(-0.003, +0.003)$ from red (worse than average) to green (better than average). One can see that parking becomes harder at night, especially in residential areas, which can also be observed in our experiments in Section 6. (All data for Mon–Sun; best viewed in color.)

once or each unit length separately. This is necessary, because the probability correlates strongly with the length of the road, because long roads can simply fit more parking spots. Therefore, we can counteract arbitrary splitting of roads into segments in the map by using densities.

We found the probability mass to be Pareto-distributed as shown in Figure 3. The fitted distribution with parameters $\sigma = 1.3445$, $\mu = 0.0000$, and $\xi = 0.0022$ is the basis for our experiments on inaccurate probabilities in Section 6. We further compare the probability density at different time spans with the density averaged across the whole day in Figure 4. Between weekdays and weekends, we did not find a prominent difference. We also tried to reconstruct the probabilities from other attributes of that road, using a statistical model, which did not yield meaningful results. This, however, emphasizes the uniqueness of the released dataset.

6 Experiments

We conduct three experiments that we will describe and interpret in this section. In all of them, we compare our **Branch and Bound**, our **Heuristic Search**, and the **G2** algorithm proposed by Jossé et al. [5], which greedily chooses the next edge that maximizes the probability per cost. We do not consider computation time in our evaluation because all three



(a) Average algorithm costs throughout the day. We only show data points where the algorithm finds a successful route in at least 95 % of all v_0.

(b) Average algorithm costs at different weightings of driving duration and walking distance. Cost is doubled to match the other experiments at $\lambda = 0.5$.

(c) Average algorithm costs when operating on probability data that is disturbed to varying levels. Our heuristic search algorithm is unaffected.

Figure 5 Algorithm performance in the three experiments we conducted. Averaged over 1000 sampled start nodes v_0. From bottom to top: **Branch and Bound**, **Heuristic Search**, and **G2** by Jossé et al. [5].

algorithms take less than one second to compute. A query time in this order of magnitude does not affect applicability in practice.

In contrast to the problem formalization in Section 3, we weight the two cost terms slightly differently to make interpretation easier. While in the formalization, *driving duration* and *walking distance* are weighted with factors λ and $1 - \lambda$, we first divide the walking distance by a typical walking speed of $1.4\,\frac{\text{m}}{\text{s}}$ and then add up both measures. Therefore, $c(P)$ refers to the total duration for finding a parking spot in this section.

In all the following experiments, we choose probability mass threshold $\varepsilon = 0.05$. Thus a route is considered successful if it leads along a vacant parking spot with a probability of at least 95 %. We sample 1000 start nodes v_0, proportional to the amount of parking searches in the time bin as of our dataset. If not stated otherwise the time bin we use for the simulation is Monday to Friday from 9 a.m. to 5 p.m.

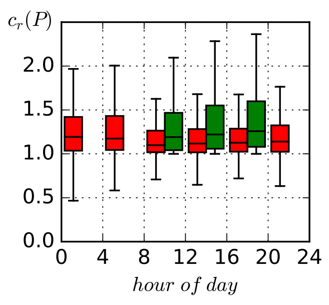
For **Branch and Bound**, the *expands* parameter is 10000 while for **Heuristic Search** it is 1000. For both algorithms, we did not find a significant improvement in cost above those values. In other applications, we suggest to experimentally determine the number of expands as they may vary based on the road network. Further, we use a fall off function of $s(i) = 1 - \frac{i}{20}$ for **Heuristic Search** that we determined through parameter search. **G2** does not have any free parameters.

To prevent infinite loops when algorithms drive through cycles of streets with no probabilities, we limited the route length to 100 edges. We do not include routes that exceed this length. If an algorithm does not reach the probability mass threshold ε in at least 95 % of all sampled starting positions v_0 we declare it as failing in a certain scenario.

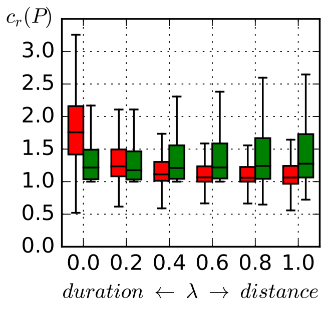
The box plots in Figure 6 provide statistical information for the costs of the algorithms used in the line diagrams in Figure 5. The whiskers limit 95 % of all values while the box represents the first and the third quartiles with the central black line showing the median.

6.1 Time of Day

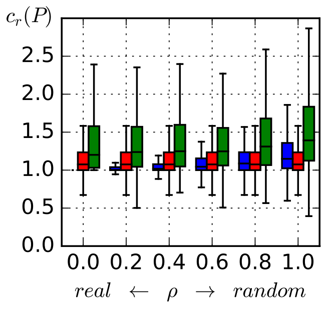
In 5a we compare the three algorithms against each other in cost throughout the day. To avoid the aforementioned infinite loops, we merged the data into two-hour blocks. Nevertheless,



(a) Algorithm costs throughout the day, relative to the baseline. We only show boxes where the algorithm finds a successful route in at least 95 % of all v_0.



(b) Algorithm cost at different weightings of driving duration and walking distance, relative to the baseline.



(c) Algorithm cost using probabilities with different levels of accuracy, relative to the baseline at $\rho = 0.0$.

Figure 6 Relative algorithm performance $c_r(P)$ divided by the **Branch and Bound** baseline. The respective baseline is represented by just a line. Boxes from left to right: **Branch and Bound**, **Heuristic Search**, and **G2** by Jossé et al. [5].

G2 achieved ε only during rush hours in more than 95 % of the runs. **Heuristic Search** and **Branch and Bound** both do experience decreasing costs in the early morning and the afternoon. Besides that, **Branch and Bound** is relatively consistent while **Heuristic Search** has a significant peak between 2 and 4 a.m., being 30 % more expensive than at its optimal time. Over the whole day, the baseline stays ahead of our heuristic approach by a factor of 1.3 on average.

6.2 Cost Weighting

Until now, we weighted all our cost measures equally. Because walking speeds and user preferences may differ, our cost weighting is not universal. To investigate the influence of the weighting parameters on the algorithms, we ran our experiments with a range of different weightings. For each cost weighting $\lambda \in [0, 1]$, we simulated the algorithms with the same starting points. The new weighted cost is defined as $c(P) = 2\big(\lambda \cdot \mathit{distance} + (1 - \lambda)\mathit{duration}\big)$. It is important to note that the algorithms *did* have access to this cost function.

We see that **Heuristic Search** performs well compared to the other algorithms when distance has a larger weight, because its heuristic relies heavily on the distance. All algorithms perform better when duration is weighted high, since it is faster to drive to segments with high probabilities than walking back from them.

6.3 Impact of Inaccurate Probabilities

We can assume that, despite a high number of parking observations, computed success probabilities do not fully correspond to real-life circumstances. Hence, we need to assess the impact of inaccurate probability values. We do this by applying an interpolated noise model. When simulating noise, all algorithms work with gradually mutated probabilities while their results continue to be evaluated on the original setting with ground-truth data provided by TomTom. This means, that an algorithm requesting the costs of its next step would obtain a noisy response and act potentially less accurate. A probability-agnostic algorithm, however, would always perform the same, no matter which noise setting. A noise parameter ρ from the interval $[0, 1]$ determines the level of accuracy, with 0 implying unaltered probabilities and 1 fully applied noise. We conducted simulations on various noise distributions, but here we focus on an interpolated Pareto II distribution. For this model, we take random samples from a Pareto distribution, fitted on the probability densities of all roads on the map.

Figure 5c compares the costs of our algorithms on noise levels within the interval of $[0, 1]$. As expected, the performance of all algorithms decreases with a rising noise level. Notably, Branch and Bound turns out to be particularly stable against noise and outperforms the other algorithms on all levels. A higher accuracy of the collected probabilities results in a lower cost. Furthermore, we see that until an assumed noise of 0.7, knowledge of the probabilities means an advantage over the heuristic approaches.

7 Conclusion

We proposed two algorithmic approaches for solving the NP-complete problem of parking search. Our **Branch and Bound** algorithm finds the best route within all routes up to a certain length as measured by the cost. For the scenario where no probability data is available, we proposed our **Heuristic Search** algorithm that on average comes close to the baseline by a factor of 1.3 in cost. This leads to the conclusion that per-street probabilities of parking successes are beneficial but not strictly necessary to compute good parking routes. Also, it might be possible to reduce the effort of collecting probability data, since less accurate values still yield attractive results.

We evaluated our algorithms on real per-street probability data for the Berlin area. We released this dataset along with the paper to allow the community to evaluate further parking search algorithms on real data. However, it is unclear how our heuristics would perform in *other cities*. Building on the presented work, two directions of further research sound promising to us. First, we assumed that the probability of a parking spot stays 0 after visiting it once. It is natural to assume that the observed information decays over time. However, including recovery adds extra assumptions to the model. A *dataset of per-street recovery functions*, e.g., as modeled in [5], would be very interesting in order to explore the impact of recovery in a realistic model. Second, a limitation of our model is to assume independence between the probabilities of nearby roads. Again, real data on this is not available. We conclude that collecting and releasing additional metrics would open the doors to additional research in the field of parking search.

Acknowledgments. We thank TomTom Development Germany GmbH, An den Treptowers 1, 12435 Berlin and its engineering team including our contact persons Steffen Wiesner and Peter Mieth. During our work, we received valuable feedback and support from them. They provided us with the collected probability data and additional road attributes. We are grateful for the permission to release the dataset used in this paper to the public.

Abstract

Isocontours in road networks represent the area that is reachable from a source within a given resource limit. We study the problem of computing accurate isocontours in realistic, large-scale networks. We propose isocontours represented by polygons with minimum number of segments that separate reachable and unreachable components of the network. Since the resulting problem is not known to be solvable in polynomial time, we introduce several heuristics that run in (almost) linear time and are simple enough to be implemented in practice. A key ingredient is a new practical linear-time algorithm for minimum-link paths in simple polygons. Experiments in a challenging realistic setting show excellent performance of our algorithms in practice, computing near-optimal solutions in a few milliseconds on average, even for long ranges.

1 Introduction

How far can I drive my battery electric vehicle (EV), given my position and the current state of charge? – This question can be answered by a map visualizing the reachable region. This region is bounded by *isocontours* representing points that require the same amount of energy to be reached. Isocontours are typically considered in the context of functions $f\colon \mathbb{R}^2 \to \mathbb{R}$, in our case describing the energy necessary to reach a point in the plane. However, f is defined only at certain points, namely vertices of the graph representing the road network. We have to fill the gaps by deciding how an isocontour should pass through regions between roads. The fact that the quality of the resulting visualization heavily depends on these decisions makes

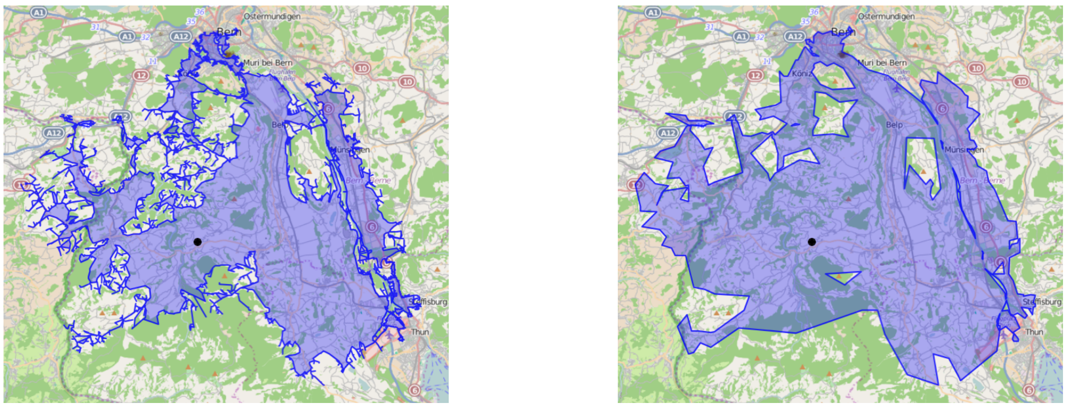

Figure 1 Isocontours in a mountainous area (near Bern, Switzerland), showing the range of an EV positioned at the black disk with a state of charge of 2 kWh. Note that the polygons contain holes, due to unreachable high-ground areas. Left: state-of-the-art approach (over 10 000 segments, computed by `RP-RC` from Section 4); right: our approach (416 segments, computed by `RP-CU`).

computing isocontours in road networks an interesting algorithmic problem. Besides range visualization for EVs, isocontour visualization is relevant in a wide range of applications, including reachability analyses in urban planning [2, 20, 22, 25], geomarketing [10], and environmental and social sciences [20].

Several techniques consider the problem of computing the subnetwork that is reachable within a given timespan (but not the actual isocontour), enabling query times in the order of milliseconds [4, 11, 12]. O'Sullivan et al. [25] introduce basic approaches for isocontour visualization based on merging shapes covering the reachable area. Marciuska and Gamper [22] propose isocontours induced by reachable points in the network, but their approaches are too slow for interactive applications (several seconds for small and medium ranges). In contrast, our work is motivated by more challenging scenarios, e. g., visualizing the range of high-end Tesla models or the area reachable by a truck driver within a day of work. Our algorithms are guided by three major objectives: Isocontours must be *exact*, i. e., correctly separate the reachable subgraph from the remaining unreachable part; they should be polygons of low *complexity*, i. e., consist of few segments (enabling fast rendering and a clear, uncluttered visualization); algorithms should be fast enough for interactive applications, even on large inputs. Figure 1 compares an example resembling state-of-the-art techniques [9, 10, 12, 22] to one of our approaches. The original works also consider inexact variants of the approach we refer to as state-of-the-art (e. g., by omitting holes or degeneracies from the polygon). We resort to an exact variant, in accordance with our objectives.

Contribution and Outline. We propose several new algorithms for computing polygons that represent isocontours in road networks. All approaches compute exact isocontours, while having low complexity. Their efficient performance is both proven in theory and demonstrated in practice on large, realistic instances. Section 2 states the precise problem and outlines our algorithmic approach. Section 3 attacks the important subproblem of separating the boundaries of a hole-free region by a polygon with minimum number of segments. While it can be solved in $O(n \log n)$ time [28], we propose a simpler algorithm that uses at most two additional segments, runs in linear time, and requires computation of only a single minimum-link path. We also propose a minimum-link path algorithm that is simpler than previous approaches [26]. Section 4 extends these results to the general case, where unreachable parts of the network can induce holes between the boundaries to be separated. As the complexity of this problem is unknown, we focus on efficient heuristic approaches that work well in practice, but do not give (nontrivial) guarantees on the complexity of the resulting range polygons. Section 5 contains our extensive experimental evaluation. It demonstrates that all approaches are fast enough even for use in interactive applications. Section 6 concludes with final remarks. See the full version for omitted details and proofs [3].

2 Problem Statement and General Approach

Let $G = (V, E)$ be a road network, which we consider as a geometric graph where vertices have a fixed position in the plane and edges are straight-line segments between their endpoints. The function $\mathrm{cons}\colon E \to \mathbb{R}$ assigns resource consumption to all edges. A source $s \in V$ and range $r \in \mathbb{R}_{\geq 0}$ partition the graph into two parts, one that is within range r from s, and the part that is not. A vertex v is *reachable* if the resource consumption $\mathrm{cons}(\pi_v)$ on the shortest (wrt. a nonnegative length function on the edges) s–v-path π_v is at most r. An edge (u, v) is *passable* if it can be traversed in at least one direction, i. e., $\mathrm{cons}(\pi_u) + \mathrm{cons}((u, v)) \leq r$ or $\mathrm{cons}(\pi_v) + \mathrm{cons}((v, u)) \leq r$. Let V_r be the set of reachable vertices and E_r the set of passable edges. The *reachable subgraph* is $G_r = (V_r, E_r)$. Let $V_u = V \setminus V_r$ be the set of *unreachable vertices* and E_u the set of *unreachable edges* for which both endpoints are unreachable. The *unreachable subgraph* is $G_u = (V_u, E_u)$. Edges in $E \setminus (E_r \cup E_u)$ are called *boundary edges*. A *range polygon* is a plane (not necessarily simple) polygon P separating G_r and G_u, such that its interior contains G_r and has empty intersection with G_u. Note that if G is not planar, a range polygon may not even exist: If a passable edge intersects an unreachable edge, the requirements of including the passable and excluding the unreachable edge obviously contradict. To resolve this issue, we consider the planarization G_p of G, which is obtained from G by considering each intersection point p as a *dummy vertex* that subdivides all edges of G that contain p. A dummy vertex is reachable if and only if it subdivides a passable edge of the original graph. An edge in G_p is passable if and only if the edge in G containing it is passable. As before, an edge of G_p is unreachable if both endpoints are unreachable. Finally, let the graph G' consist of the union of the reachable and unreachable subgraph of G_p. A face of G' incident to both the reachable and unreachable subgraph is a *border region*.

Given a source $s \in V$ and a range $r \in \mathbb{R}_{\geq 0}$, we seek to compute a range polygon wrt. G_p that has the minimum number of holes, and among these we seek to minimize the complexity of the range polygon. This can be achieved as follows.

1. Compute the reachable and unreachable subgraph of G.
2. Planarize G, compute the reachable and unreachable subgraph of its planarization G_p.
3. Compute the border regions.
4. For each border region B, compute a simple polygon of minimum complexity contained in B that separates the unreachable components incident to B from the reachable component.

Step 1 is solved by a variant of Dijkstra's algorithm [8]. Tailored preprocessing-based algorithms for road networks exist [4, 11]. For Step 2, we planarize G during preprocessing in a single run of the well-known sweep line algorithm [6] to obtain G_p. In a query (i. e., for given $s \in V$ and $r \in \mathbb{R}_{\geq 0}$), reachability of dummy vertices is then determined in a linear scan of all original edges containing a dummy vertex. This produces limited overhead in practice, since the number of dummy vertices in graphs representing road networks is typically small (as large parts of the input are already planar). Border regions are extracted in Step 3 by traversing faces of G_p that contain at least one boundary edge. In the remainder of this work, we focus on Step 4. Each connected component of the boundary of a border region

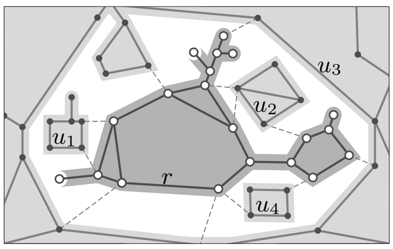

Figure 2 Border region (white), with the reachable boundary $R = \{r\}$ and the unreachable boundary with components $U = \{u_1, u_2, u_3, u_4\}$. Reachable and unreachable parts are shaded.

is a hole-free non-crossing polygon. Note that these polygons are not necessarily simple in the sense that they may contain the same segment twice in different directions; see Figure 2. Each border region is defined by two sets R and U of such polygons, where R contains the reachable components and U contains the unreachable components. We seek a simple polygon with minimum number of segments that separates U from R. Guibas et al. [17] showed that this problem is NP-complete in general. In our case, however, it is $|R| = 1$ since the reachable subgraph is, by definition, connected. Guibas et al. left this case as an open problem and, to the best of our knowledge, it has not been resolved.

3 Range Polygons in Border Regions Without Holes

In this section, we consider the special case of a border region B with $|R| = |U| = 1$. A polygon of minimum complexity that separates the two polygons can be found in $O(n \log n)$ time [28]. However, the algorithm is rather involved and requires computation of several minimum-link paths. We propose a simpler algorithm that uses at most two additional segments, runs in linear time, and computes a single minimum-link path. It adds an edge e to B that connects both boundaries. In the resulting polygon B', it computes a minimum-link path π that connects the two sides of e. The algorithm of Suri [26] finds such a path π in linear time. We obtain a separating polygon by connecting the endpoints of π along e.

We address the subproblem of computing a *minimum-link path* between two edges a and b of a simple polygon P, i. e., a polygonal path with minimum number of segments that connects a and b and lies in the interior of P. The algorithm of Suri [26] starts by triangulating the input polygon. We preprocess this step by triangulating all faces of the planarized input graph only once. Afterwards, in each step of Suri's algorithm a *window* (which we define in a moment) is computed. To this end, several visibilty polygons are constructed. This suffices to prove linear running time, but seems wasteful from a practical point of view. Below, we present a simpler linear-time algorithm for computing the windows, called FMLP (*fast minimum-link path*). It can be seen as a generalization of an algorithm for approximating piecewise linear functions [19].

Windows and Visibility. Let T be the graph obtained by arbitrarily triangulating P. Let t_a and t_b be the triangles incident to a and b, respectively. As T is an outerplanar graph, its (weak) dual graph has a unique path $t_a = t_1, t_2, \dots, t_{k-1}, t_k = t_b$ from t_a to t_b; see Figure 3a. We call the triangles on this path *important* and their position in the path their *index*. The *visibility polygon* $V(a)$ of the edge a in P is the polygon that contains a point p in its interior if and only if there is a point q on a such that the line segment pq lies inside P. Let i be the highest index such that the intersection of the triangle t_i with the visibility polygon $V(a)$ is

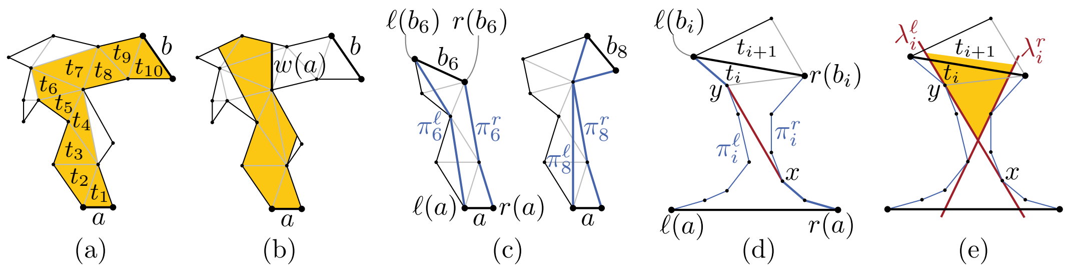

Figure 3 (a) Important triangles wrt. a and b. (b) The window $w(a)$ is an edge of the (shaded) visibility polygon. (c) The left and right shortest paths (blue) intersect for $i = 8$ but not for $i = 6$. (d) The shortest path from $r(a)$ to $\ell(b_i)$ contains the bold prefix of π_i^r, the red segment, and the bold suffix of π_i^ℓ. (e) Visibility lines spanning the (shaded) visibility cone.

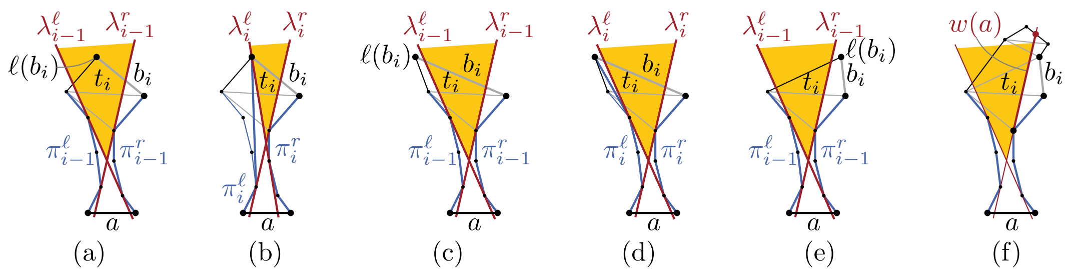
not empty. The *window* $w(a)$ is the edge of $V(a)$ that intersects t_i closest (wrt. minimum Euclidean distance) to the edge between t_i and t_{i+1}; see Figure 3b. Note that $w(a)$ separates the polygon P into two parts. Let P' be the part containing the edge b that we want to reach. A minimum-link path from a to b in P can then be obtained by adding an edge from a to $w(a)$ to a minimum-link path from $w(a)$ to b in P'. Thus, the next window is computed in P' starting with the previous window $w(a)$. Below, we first describe how to compute the first window and then discuss what has to be changed to compute the subsequent windows.

Let T_i be the subgraph of T induced by the triangles $t_1, \dots, t_i$ and let P_i be the polygon bounding the outer face of T_i. The polygon P_i has two special edges, namely a and the edge shared by t_i and t_{i+1}, which we call b_i. Let $\ell(a)$ and $r(a)$, and $\ell(b_i)$ and $r(b_i)$ be the endpoints of a and b_i, respectively, such that their clockwise order is $r(a)$, $\ell(a)$, $\ell(b_i)$, $r(b_i)$ (think of $\ell(\cdot)$ and $r(\cdot)$ being the left and right endpoints, respectively); see Figure 3c. We define the *left shortest path* π_i^ℓ to be the shortest polygonal path (shortest in terms of Euclidean length) that connects $\ell(a)$ with $\ell(b_i)$ and lies inside or on the boundary of P_i. The *right shortest path* π_i^r is defined analogously for $r(a)$ and $r(b_i)$; see Figure 3c.

Assume that the edge b_i is visible from a, i.e., there exists a line segment in the interior of P_i that starts at a and ends at b_i. Such a visibility line separates the polygon into a left and a right part. Observe that it follows from the triangle inequality that the left shortest path π_i^ℓ and the right shortest path π_i^r lie inside the left and right part, respectively. Thus, these two paths do not intersect. Moreover, the two shortest paths are *outward convex* in the sense that the left shortest path π_i^ℓ has only left bends when traversing it from $\ell(a)$ to $\ell(b_i)$ (the symmetric property holds for π_i^r); see the case $i = 6$ in Figure 3c. We note that the outward convex paths are sometimes also called “inward convex” and the polygon consisting of the two outward convex paths together with the edges a and b_i is also called *hourglass* [15]. The following lemma, which is similar to a statement shown by Guibas et al. [16, Lemma 3.1], summarizes the above observation.

▶ **Lemma 1.** *If the triangle t_i is visible from a, then the left and right shortest path in P_{i-1} have empty intersection. Moreover, if these paths do not intersect, they are outward convex.*

Guibas et al. [16] argue that the converse of the first statement is also true, i.e., if the two paths have empty intersection, then the triangle t_{i+1} is visible from a. Their main arguments go as follows. The shortest path (wrt. Euclidean length) in the hourglass that connects $r(a)$ with $\ell(b_i)$ is the concatenation of a prefix of π_i^r, a line segment from a vertex x of π_i^r to a vertex y of π_i^ℓ, and a suffix of π_i^ℓ; see Figure 3d. We call the straight line through x and y the *left visibility line* and denote it by λ_i^ℓ. We assume λ_i^ℓ to be oriented from x to y and call



λ_{i-1}^{ℓ} λ_{i-1}^{r} $\ell(b_i)$ t_i b_i π_{i-1}^{ℓ} π_{i-1}^{r} a (a)
λ_i^{ℓ} λ_i^{r} t_i b_i π_i^{r} π_i^{ℓ} a (b)
λ_{i-1}^{ℓ} λ_{i-1}^{r} $\ell(b_i)$ b_i t_i π_{i-1}^{ℓ} π_{i-1}^{r} a (c)
λ_i^{ℓ} λ_i^{r} b_i t_i π_i^{ℓ} π_i^{r} a (d)
λ_{i-1}^{ℓ} λ_{i-1}^{r} $\ell(b_i)$ b_i t_i π_{i-1}^{ℓ} π_{i-1}^{r} a (e)
$w(a)$ b_i t_i a (f)

Figure 4 (a) The new vertex $\ell(b_i)$ lies in the visibility cone. (b) The updated left shortest path π_i^{ℓ} and left visibility line λ_i^{ℓ}. (c) The vertex $\ell(b_i)$ lies to the left of λ_{i-1}^{ℓ}. (d) The left shortest path has to be updated, the left visibility line remains unchanged. (e) The vertex $\ell(b_i)$ lies to the right of λ_{i-1}^{r}, i.e., t_{i+1} is not visible from a. (f) The window $w(a)$ is a segment of λ_{i-1}^{r}.

x and y the *source* and *target* of λ_i^{ℓ}. Analogously, one can define the *right visibility line* λ_i^{r}; see Figure 3e. We call the intersection of the half-plane to the right of λ_i^{ℓ} with the half-plane to the left of λ_i^{r} the *visibility cone*. It follows that the intersection of the visibility cone with the edge b_i is not empty and a point on the edge b_i is visible from a if and only if it lies in this intersection [16]. This directly extends to the following lemma.

▶ **Lemma 2.** *If the left and right shortest path in P_{i-1} have empty intersection, t_i is visible from a. Moreover, a point in t_i is visible from a if and only if it lies in the visibility cone.*

The above observations then justify the following approach for computing the window. We iteratively increase i until the left and the right shortest path of the polygon P_i intersect. We then know that the triangle t_{i+1} is no longer visible; see Lemma 1. Moreover, as the left and the right shortest path did not intersect in P_{i-1}, the triangle t_i is visible from a; see Lemma 2. To find the window, it remains to find the edge of the visibility polygon $V(a)$ that intersects t_i closest to the edge between t_i and t_{i+1}. Thus, by the second statement of Lemma 2, the window must be a segment of one of the two visibility lines. It remains to fill out the details of this algorithm, argue that it runs in overall linear time, and describe what has to be done in later steps, when we start at a window instead of an edge.

Computing the First Window. We start with the details of the algorithm starting from an edge. Assume the triangle t_i is still visible from a, i.e., π_{i-1}^{ℓ} and π_{i-1}^{r} do not intersect. Assume further that we have computed the left and right shortest path π_{i-1}^{ℓ} and π_{i-1}^{r} as well as the corresponding visibility lines λ_{i-1}^{ℓ} and λ_{i-1}^{r} in a previous step. Assume without loss of generality that the three corners of the triangle t_i are $\ell(b_{i-1})$, $\ell(b_i)$, and $r(b_i) = r(b_{i-1})$. There are three possibilities shown in Figure 4, i.e., the new vertex $\ell(b_i)$ lies either in the visibility cone spanned by λ_{i-1}^{ℓ} and λ_{i-1}^{r} (Figure 4a), to the left of the left visibility line λ_{i-1}^{ℓ} (Figure 4c), or to the right of the right visibility line λ_{i-1}^{r} (Figure 4e).

By Lemma 2, a point in t_i is visible from a if and only if it lies inside the visibility cone. Thus, the edge b_i between t_i and t_{i+1} is no longer visible if and only if the new vertex $\ell(b_i)$ lies to the right of λ_{i-1}^{r}; see Figure 4e. In this case, we can stop and the desired window $w(a)$ is the segment of λ_{i-1}^{r} starting at its touching point with π_{i-1}^{r} and ending at its first intersection with an edge of P; see Figure 4f.

In the other two cases (Figure 4a and Figure 4c), we have to compute the new left and right shortest path π_i^{ℓ} and π_i^{r} and the new visibility lines λ_i^{ℓ} and λ_i^{r} (Figure 4b and Figure 4d). Note that the old and new right shortest path π_{i-1}^{r} and π_i^{r} connect the same endpoints $r(a)$ and $r(b_{i-1}) = r(b_i)$. As the path cannot become shorter by going through the new triangle t_i,

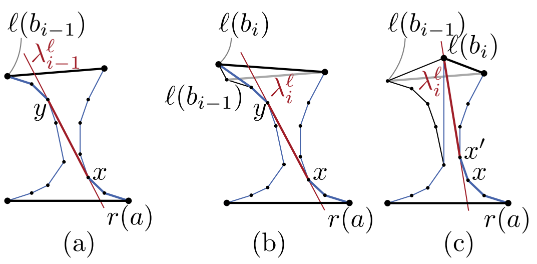


Figure 5 (a) The shortest path from $r(a)$ to $\ell(b_{i-1})$ (bold) defining the left visibility line λ^ℓ_{i-1}. (b) The visibility line does not change if $\ell(b_i)$ lies to the left of λ^ℓ_{i-1}. (c) Illustration how the visibility line changes when $\ell(b_i)$ lies to the right of λ^ℓ_{i-1}.

we have $\pi^r_i = \pi^r_{i-1}$. The same argument shows that $\lambda^r_i = \lambda^r_{i-1}$ (recall that the visibility lines were defined using a shortest path from $\ell(a)$ to $r(b_{i-1}) = r(b_i)$).

We compute the new left shortest path π^ℓ_i as follows. Let x be the latest vertex on π^ℓ_{i-1} such that the prefix of π^ℓ_{i-1} ending at x concatenated with the segment from x to $\ell(b_i)$ is outward convex. We claim that π^ℓ_i is the path obtained by this concatenation, i.e., this path lies inside P_i and there is no shorter path lying inside P_i. It follows by the outward convexity, that there cannot be a shorter path inside P_i from $\ell(a)$ to $\ell(b_i)$. Moreover, by the assumption that π^ℓ_{i-1} was the correct left shortest path in P_{i-1}, the subpath from $\ell(a)$ to x lies inside P_i. Assume for contradiction that the new segment from x to $\ell(b_i)$ does not lie entirely inside P_i. Then it has to intersect the right shortest path and it follows that the right shortest path and the correct left shortest path have non-empty intersection, which is not true by Lemma 1.

To get the new left visibility line λ^ℓ_i, we have to consider the shortest path in P_i that connects $r(a)$ with $\ell(b_i)$. Let x and y be the source and target of λ^ℓ_{i-1}, respectively, i.e., the shortest path from $r(a)$ to $\ell(b_{i-1})$ is as shown in Figure 5a. If the new vertex $\ell(b_i)$ lies to the left of λ^ℓ_{i-1} (Figure 5b), then the shortest path from $r(a)$ to $\ell(b_i)$ also includes the segment from x to y. Thus, $\lambda^\ell_i = \lambda^\ell_{i-1}$ holds in this case. Assume the new vertex $\ell(b_i)$ lies to the right of λ^ℓ_{i-1} (Figure 5c). Let x' be the latest vertex on the path π^r_i such that the concatenation of the subpath from $r(a)$ to x' with the segment from x' to the new vertex $\ell(b_i)$ is outward convex in the sense that it has only right bends; see Figure 5c. We claim that this path lies inside P_i and that there is no shorter path inside P_i. Moreover, we claim that x' is either a successor of x in π^r_{i-1} or $x' = x$. Clearly, the concatenation of the path from $r(a)$ to x with the segment from x to $\ell(b_i)$ is outward convex, thus the latter claim follows. It follows that the segment from x' to $\ell(b_i)$ lies to the right of the old visibility line λ^ℓ_{i-1}. Thus, it cannot intersect the path π^ℓ_i (except in its endpoint $\ell(b_i)$), as π^ℓ_{i-1} lies to the left of λ^ℓ_{i-1}. Moreover, as we chose x' to be the last vertex on π^r_{i-1} with the above property, this new segment does not intersect π^r_i (except in x'). Hence, the segment from x' to $\ell(b_i)$ lies inside P_i. As before, it follows from the convexity that there is no shorter path inside P_i. Thus, λ^ℓ_i is the line through x' and $\ell(b_i)$ (x' is the new source and $\ell(b_i)$ is the new target).

▶ **Lemma 3.** *Let t_h be the triangle with the highest index that is visible from a. Then, the algorithm FMLP computes the first window $w(a)$ in $O(h)$ time.*

Computation of Subsequent Windows. As mentioned before, the first window $w(a)$ we compute separates P into two smaller polygons. Let P' be the part including the edge b (and not a). In the following, we denote $w(a)$ by a'. To get the next window $w(a')$, we have to apply the above procedure to P' starting with a'. However, this would require to partially

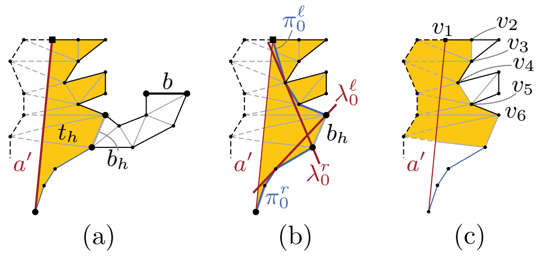

Figure 6 (a) Polygon P' after computing the window a'; P'_0 is shaded. (b) Shortest paths π_0^ℓ and π_0^r (blue) and visibility lines (red). (c) Sequence $v_1, \dots, v_6$, triangles intersected by a' are shaded.

retriangulate the polygon P'. More precisely, let t_h be the triangle with the highest index that is visible from a and let b_h be the edge between t_h and t_{h+1}; see Figure 6a. Then b_h separates P' into an initial part P'_0 (the shaded part in Figure 6a) and the rest (having b on its boundary). The latter part is properly triangulated, however, the initial part P'_0 is not. The conceptually simplest solution is to retriangulate P'_0. However, this would require an efficient subroutine for triangulation (and dynamic data structures that allow us to update P and T, which produces overhead in practice). Instead, we propose a much simpler method for computing the next window. The general idea is to compute the shortest paths in P'_0 from $\ell(a')$ to $\ell(b_h)$ and from $r(a')$ to $r(b_h)$; see Figure 6b. We denote these paths by π_0^ℓ and π_0^r, respectively. Moreover, we want to compute the corresponding visibility lines λ_0^ℓ and λ_0^r. Afterwards, we can continue with the correctly triangulated part as before.

Concerning the shortest paths, note that the right shortest path π_0^r is a suffix of the previous right shortest path, which we already know. For the left shortest path π_0^ℓ, first consider the polygon induced by the triangles intersected by a'; see Figure 6c. Let $v_1, \dots, v_g$ be the path on the outer face of this polygon (in clockwise direction) from $\ell(a') = v_1$ to $\ell(b_h) = v_g$. We obtain π_0^ℓ using *Graham's scan* [14] on the sequence $v_1, \dots, v_g$, i. e., starting with an empty path, we iteratively append the next vertex of the sequence $v_1, \dots, v_g$ while maintaining the path's outward convexity by successively removing the second to last vertex, if necessary. It remains to compute the visibility lines λ_0^ℓ and λ_0^r in the hourglass consisting of a', b_h, and the paths π_0^ℓ and π_0^r. Note that the whole edge b_h is visible from a', since a' intersects the triangle t_h. Thus, the visibility lines go through the endpoints of b_h. It follows that λ_0^ℓ is the line that goes through $\ell(b_h)$ and the unique vertex on π_0^r such that it is tangent to π_0^r; see Figure 6b. This can clearly be found in linear time in the length of π_0^r. The same holds for the right visibility line.

▶ **Lemma 4.** *The algorithm FMLP computes the initial left and right shortest paths π_0^ℓ and π_0^r as well as the corresponding visibility lines in $O(|P'_0|)$ time.*

We compute subsequent windows until we find the last edge b. A minimum-link path π is obtained by connecting each window $w(a)$ to its corresponding first edge a with a straight line [26]. In our implementation, we do not construct P and its triangulation T explicitly, but work directly on the triangulated input graph. The next important triangle is then computed on-the-fly as follows. Consider an important triangle $t_i = uvw$, and let uv be the edge shared by the current and the previous important triangle. Clearly, exactly one endpoint of uv is part of the reachable boundary, so without loss of generality let u be this endpoint. Then the next important triangle is the triangle sharing vw with t_i if w is reachable, and the triangle sharing uw with t_i otherwise. In other words, the next triangle is determined by the unique edge that has exactly one reachable endpoint. Linear running time of the algorithm follows immediately from Lemma 3 and Lemma 4. Theorem 5 summarizes our findings.

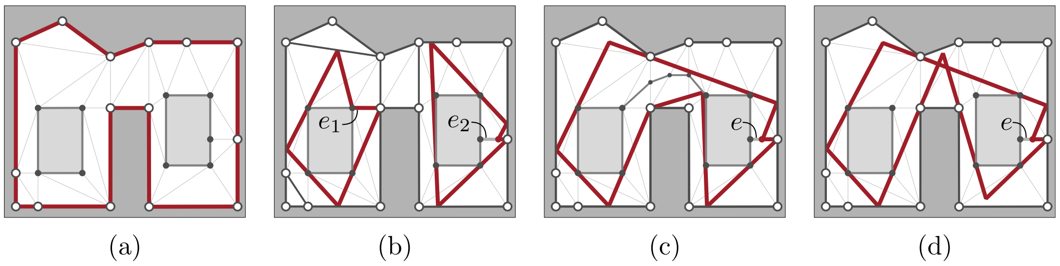

Figure 7 Results of `RP-RC` (a), `RP-TS` (b), `RP-CU` (c), and `RP-SI` (d), starting at indicated edges.

▶ **Theorem 5.** *Given two edges a and b of a simple polygon P, the algorithm FMLP computes a minimum-link path from a to b contained in P in linear time.*

4 Heuristic Approaches for General Border Regions

A border region B may consist of several unreachable components, i.e., $|U| > 1$. In this general case, it is not clear whether one can compute a (non-intersecting) range polygon of minimum complexity in polynomial time [17]. Even for the simpler subproblem of computing a minimum-link path in a polygon with holes (without assigning the holes to the reachable or unreachable part), the fastest known algorithm has quadratic running time [21, 24]. This is impractical for large instances. We propose heuristics with (almost) linear running time (in the size of B) that are simple and fast in practice. Figure 7 shows examples.

The first approach, `RP-RC` (*range polygon*, extracted *reachable components*), simply extracts and returns the reachable boundary R; see Figure 7a. The result resembles previous approaches [12, 22], so it can be seen as an efficient implementation of the state-of-the-art.

Separating Border Regions Along the Triangulation. The second approach, denoted `RP-TS` (*triangular separators*), works as follows. For each border region B, we consider its triangulation. We add all edges of the triangulation that either connect two reachable vertices or two unreachable vertices of G_p to the boundary of B, possibly splitting B into several regions $B' = R' \cup U'$ (see bold edges separating the border region in Figure 7b). For each region B', we obtain $|U'| \leq 1$, since two components of U must be connected by an edge of the triangulation or separated by an edge with two endpoints in R. Then, we run the algorithm presented in Section 3 on each instance B' with $|U'| = 1$ to get the range polygon. Linear running time follows, as FMLP is run on disjoint subregions of B.

Clearly, the set of edges added to B is not minimal (we could possibly omit some and still obtain $|U'| \leq 1$). However, it allows us to implement `RP-TS` without explicitly constructing B': Starting from an arbitrary (unvisited) boundary edge in B with one endpoint in each R and U, we run FMLP and determine the important triangles on-the-fly (as described in Section 3). We mark encountered boundary edges and repeat this procedure until all boundary edges in B (with endpoints in both R and U) were visited. Note that FMLP becomes even simpler in this variant, because regions B' contain only important triangles. However, the number of modified regions B' can become quite large. Below, we propose a more sophisticated approach to obtain regions with a single unreachable component.

Connecting Unreachable Components. Third, `RP-CU` (*connecting unreachable* components) adds new edges to border regions B with $|U| > 1$ to connect all components in U without intersecting the reachable boundary; see Figure 7c.

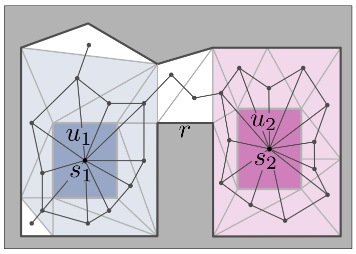

Figure 8 Dual graph with super sources s_1 and s_2. Shaded triangles are assigned to u_1 and u_2, respectively.

Given a border region B with $|U| > 1$, the heuristic starts by checking for each pair of components in U whether it can be connected directly by an edge of the triangulation. This requires traversal of the vertices in unreachable components, scanning for each vertex its incident edges in the triangulation. Edges that connect two unreachable components are added to the boundary of B and the adjacent components are merged (i. e., considered equal in the further course of the algorithm). To connect all remaining unreachable components after this first step, we consider the (weak) dual graph of the triangulation of B; see Figure 8. Since no pair of remaining unreachable components can be connected by a single edge in the primal graph, each triangle intersects at most one unreachable component. We assign a component to each dual vertex, namely, the reachable component if the corresponding triangle contains only reachable vertices, and the unique unreachable component it intersects, otherwise. For each unreachable component, we add a *super source* to the dual graph that is connected to all vertices assigned to this component. Since we want to add as few edges to the primal graph as possible, our goal is to find a tree of minimum total length in the modified dual graph that connects all super sources. Finding such a minimum Steiner tree is NP-hard [13], so we run a heuristic search. It iteratively adds shortest paths between two sources that are not yet connected in a greedy fashion. This is achieved by a multi-source variant of a breadth-first search (BFS) starting from all super sources. Whenever a path connecting two super sources is found, the corresponding components are merged. The algorithm stops when all super sources are connected. Finally, we add new vertices and edges to B along the obtained paths to connect all components in U, as illustrated in Figure 7c. We add further edges to maintain the triangulation, if necessary. The resulting border region B' is solved by the algorithm presented in Section 3. Making use of a union-find data structure, the BFS runs in $O(n\alpha(n))$ time [27], where n is the size of B and α the inverse Ackermann function. All remaining steps run in linear time, so the overall running time is almost linear.

A crucial observation is that realistic instances of border regions often consist of one major unreachable component and many tiny components, as illustrated in Figure 2. To significantly reduce the (empirical) running time, we start the BFS from all but the largest component. This requires little overhead (traversing unreachable components to identify the largest one), but searches from small components are likely to quickly converge to the large component. Moreover, after extracting the next vertex from the queue, we first check whether its source was connected to the largest component in the meantime. If this is the case, we prune the search at this vertex, because it now represents the search from the largest component. Similarly, before running the BFS we also omit traversal of the vertices of the largest component when checking for edges in the triangulation that connect two components. For further (practical) speedup, we modify the BFS to always expand the search from the component that is currently the smallest. This can be done by using a priority queue whose

(b)

Figure 9 Edge indices starting at e for each direction of traversal (∞ if not specified). Separator edge indices are given in the list (the next index is shaded). (a) The second triangle (shaded yellow) has two possible next triangles t_{uw} and t_{vw} (shaded blue). The next one is t_{uw}, since the index of the edge vw with higher index (12) is greater than the next separator edge index (4). Observe that the yellow triangle is visited a second time during the course of the algorithm. (b) The next triangle is t_{uw}. The index of the next separator edge is updated from 15 to 16.

elements are components. Additionally, we maintain a queue for each component that stores the vertices visited by the BFS (extracting them in first-in-first-out order). In each step of the BFS, we check for the smallest component in the priority queue, and extract the next vertex from the queue of this component. Note that the use of a priority queue actually increases the asymptotic running time of the BFS, however, we observe a significant speedup in practice.

Self-Intersecting Minimum-Link Paths. Our last approach is denoted `RP-SI` (*self intersecting* polygons). It computes a minimum-link path that separates reachable and unreachable boundaries of B. This path has at most $\mathrm{OPT}+1$ segments (inducing a lower bound for B), but may intersect itself; see Figure 7d. To obtain a range polygon, we add more segments to resolve intersections. Below, we generalize FMLP to border regions with several unreachable components. Note that the (weak) dual graph of the triangulation of B is not outerplanar if $|U| > 1$. Thus, paths between dual vertices are no longer unique and we have to compute a *shortest* path in the dual graph that separates the boundaries. Vertices may even occur multiple times in such a path; see the triangles crossed by the polygon in Figure 7d.

Given a boundary edge e with endpoints in R and U, we compute a sequence $t_1, \dots, t_k$ of important triangles that must be passed in this order by a minimum-link path (between the two sides of e) that separates R and U. Our approach runs in two phases. Exploiting that the reachable boundary is connected, the first phase traverses it starting from e. It assigns *indices* to all edges in the triangulation incident to the reachable boundary, according to the order in which they are traversed. In doing so, we distinguish both sides of edges; see Figure 9. For consistency, sides of edges that are not traversed get the index ∞. During this traversal, we also collect an ordered list of indices corresponding to *separator edges* in the triangulation, i. e., edges with one endpoint in each R and U. Every separator edge in B is traversed exactly once. Moreover, the minimum-link path must intersect these edges in the same order (lest having unreachable components on both sides of the path).

The second phase uses this information to compute the actual sequence of important triangles. This sequence must pass all separator edges exactly once and in increasing order of their indices. Therefore, we obtain the sequence of important triangles by computing shortest paths in the dual graph between pairs of consecutive separator edges. We maintain the index of the next separator edge that was not traversed yet, initialized to the first element of the list. Starting at the triangle t_1 containing the first edge e, we add triangles to the sequence

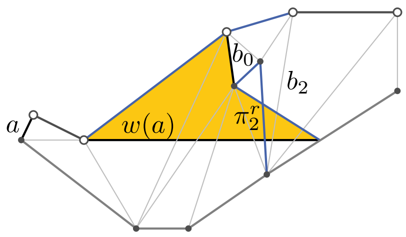

Figure 10 The path π_2^r (blue) between the right endpoints of $w(a)$ and b_2 intersects itself; P_0' is shaded. Note that two unreachable vertices (black) are not connected to the remaining unreachable boundary.

of important triangles until e is reached again. Let $t_i = uvw$ denote the previous triangle appended to this sequence, and uv the edge shared by t_i and t_{i-1} (if $i = 1$, let $uv = e$). We determine the next important triangle t_{i+1}; see Figure 9. We consider the possible next triangles t_{uw} containing the edge uw and t_{vw} containing vw. Without loss of generality, let the index of uw be lower than the index of vw (and thus, finite). This implies that uw is not contained in the boundary of B. If both u and w are part of the reachable boundary, uw separates B into two subregions; see Figure 9a. Thus, t_{uw} is the next triangle if and only if the subregion containing t_{uw} contains a separator edge that was not passed yet. Therefore, we continue with t_{uw} if and only if the index of the other edge vw is higher than the index of the next separator edge. If either u or w is part of the unreachable boundary, uw is the next separator edge; see Figure 9b. We update the index of the next separator edge to the next element in the according list. We continue until the first edge e is reached again. Note that this second phase can be performed on-the-fly within FMLP.

To preserve correctness of FMLP, further modifications are necessary, as a path in the hourglass may intersect itself. Figure 10 shows an example where the subpath of the right shortest path π_2^r starting at edge b_0 intersects the segment from the right endpoint of $w(a)$ to the right endpoint of b_0. The last segment of the right shortest path π_2^r from $w(a)$ to b_2 is called *visibility-intersecting*, as it reaches into the area P_0' visible from $w(a)$. Visibility-intersecting segments may lead to wrong results in certain cases [3]. However, one can show that a segment is visibility-intersecting if and only if it intersects the previous window. Moreover, it can safely be omitted from the shortest path computed by the algorithm without affecting correctness. Thus, FMLP is restored with a simple additional intersection test. In summary, our algorithm consists of two steps (traversing the reachable boundary, running a modified version of FMLP), which clearly run in linear time. The resulting polygon has at most OPT + 2 segments. We rearrange it at intersections to obtain the range polygon [3].

5 Experiments

We implemented all approaches in C++, using g++ 4.8.3 (-O3) as compiler. Experiments were conducted on a single core of a 4-core Intel Xeon E5-1630v3 clocked at 3.7 GHz, with 128 GiB of DDR4-2133 RAM, 10 MiB of L3, and 256 KiB of L2 cache.

Our graph is based on the road network of Western Europe, kindly provided by PTV AG (`ptvgroup.com`). Edge lengths are set to given travel times. For EV range visualization, we also consider energy consumption derived from a detailed micro-scale emission model [18]. Removing edges without reasonable energy consumption (e. g., due to missing elevation data), we obtain a graph with 22 198 628 vertices and 51 088 095 edges. To improve spatial locality, we reorder these vertices according to a vertex partition [5]. During preprocessing, the graph is planarized (654 765 split edges, 293 741 dummy vertices) and triangulated.

Table 1 Computing isochrones and EV range for medium and long ranges. We report average figures for the number of components of the range polygon (Cp.), complexity of the range polygon (Seg.), number of self-intersections (Int.), and running time of the algorithm in ms (Time).

		Med. (16 kWh / 60 min)				Long (85 kWh / 500 min)			
	Algorithm	Cp.	Seg.	Int.	Time	Cp.	Seg.	Int.	Time
EV Range	`RP-RC`	41	19 396	—	4.50	131	92 554	—	9.46
	`RP-TS`	69	610	—	4.30	219	1 973	—	7.78
	`RP-CU`	41	561	—	10.15	131	1 820	—	25.11
	`RP-SI`	41	549	4.79	7.52	131	1 781	15.06	22.25
Isochrones	`RP-RC`	53	22 458	—	4.75	231	238 123	—	20.25
	`RP-TS`	151	1 076	—	4.65	694	4 981	—	14.96
	`RP-CU`	53	913	—	12.11	231	4 208	—	65.09
	`RP-SI`	53	881	9.95	8.70	231	4 055	45.80	51.94

We consider two scenarios, namely isochrones (i. e., travel time is the consumed resource) and range visualization of an EV. For both, we evaluate queries of medium (60 min and 16 kWh, respectively) and long ranges (500 min and 85 kWh). We focus on Steps 2 to 4 outlined in Section 2, since implementation of the first step was examined in previous work [4].

Evaluating Queries. Table 1 shows results for the different scenarios. Each figure is the average of 1 000 queries, with source vertices picked uniformly at random. For `RP-SI`, figures are reported as-is after running FMLP (i. e., for polygons with self-intersections). Thus, figures slightly change after resolving the intersections (both the number of components and the complexity may increase). All approaches perform excellently in practice, with timings of at most 65 ms even for long ranges. The simpler algorithms, `RP-RC` and `RP-TS` are faster by a factor of 2 to 5. On the other hand, range polygons generated by `RP-RC` have a much higher complexity, exceeding the optimum by more than an order of magnitude. For long ranges, polygons consist of more than 200 000 segments. This clearly justifies the use of our novel algorithms. Besides a more appealing visualization, a significant decrease in complexity enables fast rendering and more efficient transmission over mobile networks. The heuristic `RP-TS` provides much better results in terms of complexity, but is still outperformed by the other two approaches. Moreover, the triangular separation increases the number of components (i. e., the number of holes) in the result by up to a factor of 3, while all other approaches are optimal in this criterion. The two more involved approaches, `RP-CU` and `RP-SI`, keep the complexity close to the optimum, so the additional effort clearly pays off. Deriving lower bounds from the results of `RP-SI`, the average relative error of both `RP-CU` (at most 7 %) and `RP-SI` (4 %) is negligible in practice. The number of intersections produced by `RP-SI` is also rather low, but the majority of computed range polygons contains at least one intersection. Isochrones are slightly harder to solve in all cases. For long-range queries, this is due to larger border regions. Setting the resource limit to 500 minutes for isochrones yields one of the hardest scenarios in our instance. For medium ranges, border region sizes are similar in both scenarios. Here, differences in performance can be explained by different shapes of the border regions: Isocontours representing the range of an EV typically have a more circular shape (highways allow to move faster, but also consume more energy). On the contrary, isochrones require more segments and yield more challenging scenarios.

Table 2 Different phases (isochrones, 500 min), showing average time (in ms) for border region extraction (BE), connecting components (CC), range polygon computation with FMLP (RP), testing for self-intersections (SI), and total time (Total).

Algo.	BE	CC	RP	SI	Total
`RP-RC`	12.01	—	—	—	20.25
`RP-TS`	—	—	6.45	—	14.96
`RP-CU`	26.66	22.99	7.81	—	65.09
`RP-SI`	31.79	—	9.53	2.34	51.94

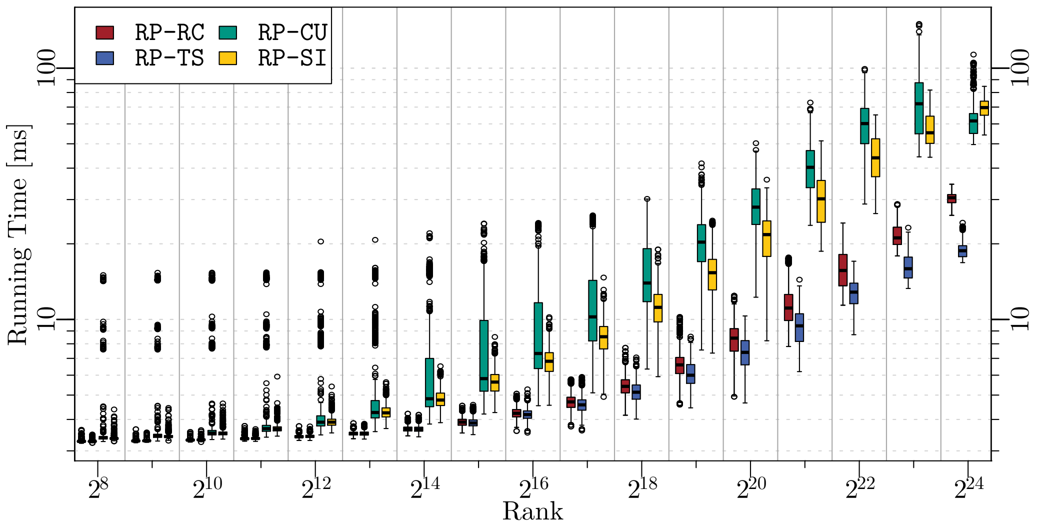

Figure 11 Running times of all approaches subject to Dijkstra rank. Smaller ranks indicate queries of shorter range. For each rank, we report results of 1 000 random queries.

Table 2 shows details on different phases of the algorithms for the hardest scenario (isochrones, 500 min). Step 2 (transferring input to the planar graph) is identical for all approaches, taking 8.2 ms on average (not reported in the table). Border region extraction does not apply to `RP-TS`, where this is done implicitly. Since `RP-RC` extracts only the reachable boundary, this takes less than half the time compared to `RP-CU` (the reachable boundary is typically smaller). On the other hand, `RP-SI` spends most time in this step, since it runs on the triangulated graph.

Despite its simplicity, extraction takes a major fraction of the total effort. This is due to the size of the border regions (500 000 segments per query), while only parts of them are visited in later phases. Consequently, connecting unreachable components takes less time for `RP-CU`. Running FMLP is fastest for `RP-TS`, since it visits only important triangles. The slowest approach in this phase is `RP-SI`, mostly because no artificial edges are added to border regions (windows become longer on average, increasing the number of visited triangles).

Evaluating Scalability. Figure 11 analyzes scalability of our algorithms. We follow the methodology of Dijkstra ranks [1], defined as the number of queue extractions performed by Dijkstra's algorithm in a shortest-path query. Higher ranks reflect harder queries. To generate queries, we ran Dijkstra's algorithm 1 000 times from sources chosen uniformly at random. For a source s, consider the resource consumption c at the vertex extracted from the queue in step 2^i of the algorithm. We consider a query from s with range c as a query of rank 2^i. For each rank in $\{2^1, \dots, 2^{\log |V|}\}$, we obtain 1 000 queries this way.

Query times of all approaches increase with the Dijkstra rank, which correlates well with the complexity of the border region. Scaling behavior is similar for all approaches: In accordance with our theoretical findings, it increases linearly in the size of the border region for queries beyond a rank of 2^{12}. For queries of lower rank, transferring the input to the planar graph dominates running time (which is linear in the graph size). The approach RP-TS is consistently the fastest on average for ranks beyond 2^{16}. Except for very few outliers, query times are well below 100 ms. For more local queries (i. e., smaller ranges), query times are much faster (20 ms and below if the rank is at most 2^{20}, corresponding to about a million vertices visited by Dijkstra's algorithm). Interestingly, the more expensive approaches have a higher variance and produce more outliers, which is explained by their more complex phases. For example, the performance of the BFS used in RP-CU heavily depends on how close unreachable components of the border region are in the dual graph.

Minimum-Link Path Computation. In Table 3, we evaluate FMLP in the four main scenarios (ranges for 16 kWh and 85 kWh batteries and isochrones for 60 min and 500 min). For each of the 1 000 queries per scenario, we modified the largest border region such that $|U| = 1$ (using RP-CU). Then, we added an edge connecting the two remaining components and computed a minimum-link path between its two sides. We also report figures for Suri's algorithm [26], which finds the next window starting from a window a by computing multiple visibility polygons in the following way. Starting with the polygon bounding all important triangles intersected by a, it doubles the number of important triangles until a triangle is (partially) invisible from a. To obtain the window, a final visibility polygon is computed in a polygon bounding the same set of important triangles together with all non-important triangles whose closest important triangle (wrt. distance in the dual graph) belongs to this set. The next window is an edge of this visibility polygon. While a fair comparison with running times of Suri's algorithm is beyond the scope of this work (as it requires an equally tuned implementation), we provide implementation-independent measures. In particular, we report the total number of visible triangles per query, in all polygons that require visibility computation. A recent experimental study on visibility polygon computation [7] presents a practical algorithm based on triangulations that processes only visible triangles, making this figure a good indicator for running time of an efficient implementation of Suri's algorithm.

Different scenarios in Table 3 represent certain levels of difficulty. As expected, the number of segments of the resulting path and the running time of FMLP increase with the complexity of the input. In all scenarios, Suri's algorithm requires several thousand calls to its subroutine for computing visibility polygons. The total number of segments in the input of this subroutine is beyond 1.5 million for long-range isochrones, which even rules out their explicit construction in practice. Additionally, the total number of triangles visited by Suri's algorithm (using the proposed subroutine [7]) is larger by a factor of 5 to 6. Moreover, we argue that this factor is a rather conservative estimate on the resulting speedup: While the workload per triangle is very low for FMLP, the proposed subroutine of Suri's algorithm is recursive and therefore possibly less cache efficient. Suri's algorithm also requires additional

Table 3 Average performance of minimum-link path algorithms. For each scenario, we report complexity of the input polygon ($|P|$) and minimum number of links in resulting paths (Seg.). For Suri's algorithm [26], we show the number of computed visibility polygons (V. Pol.), the total number of segments in the input for these computations (Pol. Seg.), and the total number of visible triangles (Trng.). For FMLP, we provide the number of visited triangles (Trng.) and running time in ms.

			Suri [26]			FMLP	
Scenario	$\|P\|$	Seg.	V. Pol.	Pol. Seg.	Trng.	Trng.	Time
EV, 16 kWh	134 049	415	2 010	307 583	48 762	8 901	0.74
Iso, 60 min	135 112	700	3 413	320 244	57 549	11 250	1.05
EV, 85 kWh	357 335	1 328	6 442	850 293	178 574	31 657	3.17
Iso, 500 min	637 224	3 203	15 655	1 547 962	359 969	66 163	6.67

overhead for generating input polygons and determining the actual windows. Given its simplicity, we conclude that FMLP is much more suitable for practical use. Even for input consisting of more than half a million segments, it takes less than 7 ms.

6 Conclusion

This work introduced algorithms for computing isocontours in large-scale road networks. Following the objectives of exact results, low result complexity, and practical performance, we presented three novel algorithms to compute near-optimal solutions in (almost) linear time. Their key ingredient is a new linear-time algorithm for minimum-link paths in simple polygons, making it the first practical approach to a problem well-studied in theory [21, 23, 24, 26]. Our experimental evaluation reveals that all approaches are fast enough for interactive applications on inputs of continental scale.

There are multiple lines of future work. Extending our algorithms to the case $|R| > 1$ is an open problem relevant for multi-source isocontours and multimodal networks [12]. For aesthetic reasons, one could aim at avoiding long straight segments in the range polygon (which are likely to occur in faces encompassing large areas corresponding to, e. g., big lakes or mountains). Such constraints could be integrated by adding (during preprocessing) artificial boundaries to faces whose area exceeds a certain threshold. Alternatively, one could further reduce result complexity at the cost of inexact results. However, such methods should avoid intersections between different components of the range polygon (i. e., maintain its topology), and error measures should consider the graph-based distance from the source to parts of the network that are classified incorrectly (since vertices close to each other wrt. Euclidean distance may in fact be far apart in the graph).

Abstract

We present the first analysis of Fisher markets with buyers that have budget-additive utility functions. Budget-additive utilities are elementary concave functions with numerous applications in online adword markets and revenue optimization problems. They extend the standard case of linear utilities and have been studied in a variety of other market models. In contrast to the frequently studied CES utilities, they have a global satiation point which can imply multiple market equilibria with quite different characteristics. Our main result is an efficient combinatorial algorithm to compute a market equilibrium with a Pareto-optimal allocation of goods. It relies on a new descending-price approach and, as a special case, also implies a novel combinatorial algorithm for computing a market equilibrium in linear Fisher markets. We complement this positive result with a number of hardness results for related computational questions. We prove that it is NP-hard to compute a market equilibrium that maximizes social welfare, and it is PPAD-hard to find any market equilibrium with utility functions with separate satiation points for each buyer and each good.

1 Introduction

The concept of market equilibrium is a fundamental and well-established notion in economics to analyze and predict the outcomes of strategic interaction in large markets. Initiated by Walras in 1874, the study of market equilibrium has become a cornerstone of microeconomic analysis, mostly due to general results that established existence under very mild conditions [2]. Since efficient computation is a fundamental criterion to evaluate the plausibility of equilibrium concepts, the algorithmic aspects of market equilibrium are one of the central domains in algorithmic game theory. Over the last decade, several new algorithmic approaches to compute market equilibria were discovered. Efficient algorithms based on convex programming techniques can compute equilibria in a large variety of domains [12, 22, 25]. More importantly, several approaches were proposed that avoid the use of heavy algorithmic machinery and follow combinatorial strategies [17, 26, 29, 32, 20, 19], or even work as a tâtonnement process in unknown market environments [13, 10, 4]. Designing such combinatorial algorithms is useful also beyond the study of markets, since the underlying ideas can be applied in other areas. Variants of these algorithms were shown to solve scheduling [23, 24] and cloud computing problems [15], or can be used for fair allocation of indivisible items [14].

In this paper, we design a new combinatorial polynomial time algorithm for computing equilibria in Fisher markets with budget-additive utilities. In a Fisher market, there is a single seller with a set $G = \{1, \ldots, m\}$ of goods. W.l.o.g. we assume that the total quantity of each good is 1. There is a set $B = \{1, \ldots, n\}$ of buyers. Each buyer i has a budget $M_i > 0$ of money and a utility function u_i. For budget-additive utilities, $u_{ij} \geq 0$ is the utility of buyer i if one unit of good j is allocated to her. There is a *happiness cap* $c_i > 0$, and the utility function is

$$u_i(\mathbf{x}_i) = \min\left\{ c_i, \sum_{j \in G} u_{ij} x_{ij} \right\} \quad ,$$

where $\mathbf{x}_i = (x_{ij})_{j \in G}$ is any bundle of goods assigned to buyer i. If $u_i(\mathbf{x}_i) = c_i$, then buyer i is called *capped buyer* for allocation $\mathbf{x}$. We assume all u_{ij}, c_i, M_i are rational numbers.

Our goal is to compute an *allocation* $\mathbf{x} = (\mathbf{x}_i)_{i \in B}$ of goods and *prices* $\mathbf{p} = (p_j)_{j \in G}$ such that the pair $(\mathbf{x}, \mathbf{p})$ is a market equilibrium. Given prices $\mathbf{p}$, a *demand bundle* $\mathbf{x}_i^*$ of buyer i is a bundle of goods that maximizes the utility of buyer i for its budget, i.e., $\mathbf{x}_i^* \in \arg\max \left\{ u_i(\mathbf{x}_i) \mid \sum_j p_j x_{ij} \leq M_i \right\}$. Note that $\sum_j u_{ij} x_{ij}^* > c_i$ is allowed. A *market equilibrium* $(\mathbf{x}, \mathbf{p})$ is a pair such that

- $\mathbf{p} \geq 0$ (prices are nonnegative),
- $\sum_i x_{ij} \leq 1$ for every $j \in G$ (no overallocation),
- $\mathbf{x}_i$ is a demand bundle for every $i \in B$, and
- Walras' law holds: $p_j(1 - \sum_i x_{ij}) = 0$ for every $j \in G$.

Note that if $\sum_i x_{ij} < 1$, then $p_j = 0$. An equilibrium $(\mathbf{x}, \mathbf{p})$ is *Pareto-optimal* if there is no equilibrium $(\mathbf{x}', \mathbf{p}')$ such that $u_i(\mathbf{x}) \leq u_i(\mathbf{x}')$ for all i and $u_i(\mathbf{x}) < u_i(\mathbf{x}')$ for at least one i.

Budget-additive utility functions are a simple class of submodular and concave functions and a natural generalization of the standard and well-understood case of linear utilities. These utility functions arise naturally in cases where agents have an intrinsic upper bound on their utility. For example, if the goods are food and the utility of a food item for a particular buyer is its calorie content, calories above a certain threshold do not increase the utility of the buyer. In addition, there are a variety of further applications in adword auctions and revenue maximization problems [1, 3, 8, 6]. Recently, market models where agents have budget-additive utilities attracted a significant amount of research interest, e.g., for the allocation of indivisible goods in offline [1, 3, 8] and online [6, 27] scenarios, for truthful mechanism design [7], and for the study of Walrasian equilibrium with quasi-linear utilities [21, 18, 30]. As simple variants of submodular functions, they capture many of the inherent difficulties of more general domains. Given this amount of interest, it is perhaps surprising that they are not well-understood within the classic Fisher and exchange markets.

Results and Contribution. We study Fisher markets with budget-additive utilities. Our initial observations about these markets reveal that they have different properties than the ones with CES utilities usually studied in the literature. Due to the satiated nature of the utilities, capped buyers might not spend all their money or spend money on goods that do not give them maximum utility per unit of money, so prices and utilities in market equilibrium are not unique and can be quite different. It is possible to simply ignore the satiation and assume linear utilities. Then a variety of existing algorithms [17, 29, 20, 19, 4] can be used to compute a market equilibrium. It continues to be a market equilibrium for the market with budget-additive utilities. However, this equilibrium may be undesirable, as in many cases it does not even satisfy Pareto-optimality of the allocation.

▶ **Example 1.** Consider a *linear* market with two buyers and two goods, $u_{11} = 5$, $u_{21} = 2$, and $u_{12} = u_{22} = 1$. The budgets are $M_1 = 3$ and $M_2 = 1$. For the unique equilibrium we allocate good 1 completely to buyer 1 and good 2 completely to buyer 2, i.e., $x_{11} = x_{22} = 1$. The buyers' utilities amount to 5 and 1, resp., and the prices are $p_1 = 3$ and $p_2 = 1$.

Now suppose buyer 1 has a budget-additive utility function with cap $c_1 = 1$. Then $(\mathbf{x}, \mathbf{p})$ described above remains an equilibrium, since both buyers obtain a demand bundle (buyer 1 now has utility 1 instead of 5). Alternatively, suppose we allocate good 1 completely to buyer 2 and good 2 completely to buyer 1, i.e., $x_{12} = x_{21} = 1$. The utilities amount to 1 and 2, resp., and the prices can be chosen as $p_1 = 1$ and $p_2 \in [0.5, 3]$. Here buyer 1 buys a bundle of goods with optimal utility of 1. Buyer 2 buys a demand bundle since he spends all its budget on a good that gives him the maximum *bang-per-buck ratio*. All goods are exactly allocated, and Walras' law holds. Thus, it represents another market equilibrium. Note if $p_2 < 3$, buyer 1 does not spend all of its money, but it is still a demand bundle for because he achieves the maximum utility. Furthermore, such an equilibrium Pareto-dominates the one derived from the linear case in terms of utilities. ◀

We strive to compute a market equilibrium with a Pareto-optimal allocation and focus on a subset of market equilibria, in which we restrict the allocation to demand bundles which we call thrifty and modest – buyers spend the least amount of money that can achieve their optimal utilities and receive a bundle of goods that has a minimality property. In Section 2, we show that such *modest MBB equilibria* can be captured by a generalization of the classic Eisenberg-Gale convex program, their utilities are unique, and their allocation is always Pareto-optimal (w.r.t. all possible allocations, attainable in market equilibrium or not). We highlight that the set of modest MBB equilibria can be partially ordered with respect to their price vectors and forms a lattice. As such, there are modest MBB equilibria with pointwise largest and smallest prices, resp. Among all modest MBB equilibria they yield maximum and minimum revenue for the seller, resp.

Section 3 contains our main contribution – a combinatorial algorithm that computes price and allocation vectors of a modest MBB equilibrium in time $O(mn^6(\log(m + n) + (m + n)\log U))$, where n is the number of agents, m the number of goods, and U the largest integer in the market parameters. The computed equilibrium has a Pareto-optimal allocation, as well as pointwise largest prices and maximum revenue among all modest MBB equilibria.

Our algorithm represents a novel approach to compute market equilibria based on the idea of descending prices. While some parts of our algorithm are in spirit of combinatorial algorithms for linear markets [17, 20, 19, 4], all these approaches are ascending-price algorithms. This technique and its usual analysis based on the 1-norm of excess money does not apply in our case, since the norm is non-monotonic and cannot be used to measure progress towards equilibrium. Surprisingly, our novel descending-price approach overcomes the 1-norm issue, but we need to address additional challenges in establishing polynomial running time due to varying and non-increasing active budgets, and in showing that intermediate prices remain polynomially bounded. Note that, as a special case, this also yields a new combinatorial descending-price algorithm for linear Fisher markets.

In Section 4 we exploit the lattice structure of modest MBB equilibria and design a procedure, using which we can turn any modest MBB equilibrium into one with smallest prices and minimum revenue. In combination with the descending-price algorithm, it computes a modest MBB equilibrium with minimum revenue within the same asymptotic time bound.

Finally, we study two extensions in Section 5. Facing multiple equilibria, a natural goal is to compute an allocation that maximizes utilitarian social welfare. We prove that this problem is NP-hard, even when social welfare is measured by a k-norm of the vector of buyer utilities, for any constant $k > 0$. Moreover, we consider a variant of budget-additive utilities with a satiation point for *each buyer and each good.* They constitute a special class of separable piecewise-linear concave (SPLC) utilities, where each piecewise-linear component consists of two segments with the second one being constant. We show that even in this very special case computing any market equilibrium becomes PPAD-hard.

Related Work. The computation of market equilibria is a central area in algorithmic game theory. There are a variety of polynomial-time algorithms to compute approximate market equilibria based on solving different convex programming formulations [12, 22, 25]. Our paper is closer to work on markets with linear utilities and combinatorial algorithms that compute an exact equilibrium in polynomial time [17, 29, 20, 19]. Directly related to our approach is the classic combinatorial algorithm for linear Fisher markets [17]. In contrast, our algorithm is based on a new descending price approach where buyers are always saturated and goods have non-negative surplus. Further, the *active* budgets of buyers vary with the price change, which creates new challenges in establishing a polynomial bound on the number of iterations and the representation size of intermediate prices.

Independently of our work, Devanur et al [16] very recently presented the same convex program for Fisher markets with satiated buyers. They propose a polynomial-time algorithm for finding an arbitrary modest MBB equilibrium, but it is based on the ellipsoid method without any explicit running time bound.

Recently, algorithmic work has also started to address unknown markets, where utilities and budgets of buyers are unknown. Instead, algorithms iteratively set prices and query a demand oracle. In this domain, tâtonnement dynamics have been studied for Fisher markets and extensions with concave utilities. For many classes of these markets, a notion of $(1+\epsilon)$-approximate market equilibrium can be reached after a convergence time polynomial in $1/\epsilon$ and other market parameters [13, 10, 11, 5]. In some cases, the convergence time can even be reduced to $\log(1/\epsilon)$ [10]. A similar convergence rate is obtained by a more general algorithm even for general unknown exchange markets with weak gross-substitutes property, and even for linear markets with non-continuous demands and oracles using suitable tie-breaking [4].

Allocation of indivisible items to agents with budget-additive utilities is an active area of research interest. There are constant-factor approximation algorithms for optimizing the allocation in offline [1, 3, 8] and online [6, 27] scenarios. Closer to our work is the study of markets with money. The existence of Walrasian equilibrium with quasi-linear utilities and algorithmic issues of bundling items were studied in [21, 18, 30]. Strategic agents and truthful mechanisms for budget-additive markets have been analyzed in [7]. There are strong lower bounds for the approximation ratio of certain classes of truthful mechanisms, and a truthful mechanism with constant-factor approximation for budget-additive utilities is one of the most interesting open problems in combinatorial auctions.

2 Preliminaries

For a given price vector $\mathbf{p}$ and buyer i, we denote the *maximum bang-per-buck (MBB)* ratio by $\alpha_i = \max_j u_{ij}/p_j$, where we make the assumption that $0/0 = 0$. Budget-additive utilities strictly generalize linear utilities: when all c_i's are large enough, they are equivalent to linear utilities. If buyer i is uncapped in a market equilibrium $(\mathbf{x}, \mathbf{p})$, it behaves as in the linear case, spends all its budget, and buys only MBB goods ($x_{ij} > 0$ only if $u_{ij}/p_j = \alpha_i$). Otherwise, if buyer i is capped in $(\mathbf{x}, \mathbf{p})$, it might buy non-MBB goods and not spend all of its budget. This implies that unlike the case of linear utilities, market equilibrium prices and utilities are not unique with budget-additive utilities.

It is easy to see that we can obtain one market equilibrium by simply ignoring the happiness caps and treating the market as a linear one. However, this equilibrium is often undesirable since it is not always Pareto-optimal.

Our main goal in this paper is to find a market equilibrium that is Pareto-optimal. More generally, we will also be concerned with finding a (Pareto-optimal) market equilibrium that can maximize social welfare $\sum_{i\in B} u_i(\mathbf{x}_i)$. For the former we provide a polynomial-time algorithm, the latter we prove it to be NP-hard.

Modest MBB Equilibria, Pareto-Optimality, and Uniqueness. The main challenges in budget-additive markets arise from capped buyers, who may possibly have multiple choices for the demand bundle. Let us introduce two convenient restrictions on the allocation to capped buyers.

- An allocation $\mathbf{x}_i$ for buyer i is called *modest* if $\sum_j u_{ij}x_{ij} \le c_i$. By definition, for uncapped buyers every demand bundle is modest. For capped buyers, a modest bundle of goods $\mathbf{x}_i$ is such that utility breaks even between the linear part and c_i, i.e., $c_i = \sum_j u_{ij}x_{ij}$.
- A demand bundle $\mathbf{x}_i$ is called *thrifty* or *MBB* if it consists of only MBB goods: $x_{ij} > 0$ only if $u_{ij}/p_j = \alpha_i$. As noted above, for uncapped buyers every demand bundle is MBB.

We call a market equilibrium $(\mathbf{x}, \mathbf{p})$ a *modest MBB equilibrium* if $\mathbf{x}_i$ is modest and MBB for every buyer $i \in B$. We show an algorithm to compute in polynomial time such an equilibrium where $\mathbf{x}$ is also Pareto-optimal. Such an equilibrium is also desirable because it captures the behavioral assumption that each buyer is thrifty and spends the least amount of money in order to obtain a utility maximizing bundle of goods.

Consider the following Eisenberg-Gale program (1), which allows us to find a modest and Pareto-optimal allocation.

$$\begin{array}{lrcll}
\text{Max.} & \displaystyle\sum_{i\in B} M_i \log \sum_{j\in G} u_{ij}x_{ij} & & & \\
\text{s.t.} & \displaystyle\sum_{j\in G} u_{ij}x_{ij} & \le & c_i & i \in B \\
 & \displaystyle\sum_{i\in B} x_{ij} & \le & 1 & j \in G \\
 & x_{ij} & \ge & 0 & i \in B,\ j \in G
\end{array} \tag{1}$$

By standard arguments, we consider the dual for (1) using dual variables γ_i and p_j for the first two constraints, resp., and the KKT conditions read:

1. $p_j/u_{ij} \ge M_i/u_i - \gamma_i$
2. $x_{ij} > 0 \Rightarrow p_j/u_{ij} = M_i/u_i - \gamma_i$
3. $p_j \ge 0$ and $p_j > 0 \Rightarrow \sum_{i\in B} x_{ij} = 1$
4. $\gamma_i \ge 0$ and $\gamma_i > 0 \Rightarrow u_i = c_i$

Observe that the Lagrange multiplier γ_i indicates if the cap c_i represents a tight constraint in the optimum solution. The dual variables p_j can be interpreted as prices. Note that conditions 1 and 2 imply that $x_{ij} > 0$ if and only if $j \in \arg\min_{j'} p_{j'}/u_{ij'} = \arg\max_{j'} u_{ij'}/p_{j'}$, i.e., all agents purchase goods with maximum bang-per-buck. Hence, similarly as for linear markets [31], the KKT conditions imply that an optimal solution to the EG program (1) and corresponding dual prices constitute a market equilibrium, in which every agent buys goods that have maximum bang-per-buck. The KKT conditions postulate this also for agents whose utility reaches the cap. Thus, the optimal solution to this program is a modest MBB equilibrium. Furthermore, we obtain the following favorable analytical properties.

▶ **Proposition 2.** *The optimal solutions to* (1) *are exactly the modest MBB equilibria. The utility vector is unique across all such equilibria and each such equilibrium is Pareto-optimal. In particular, there is a unique set of capped buyers. Non-capped buyers spend all their money. Capped buyers do not overspend.*

While utilities are unique, allocation and prices of modest MBB equilibria might not be unique. Consider a market with two identical buyers and two goods, where $u_{11} = u_{12} = u_{21} = u_{22} = 1$, $c_1 = c_2 = 1$, and $M_1 = M_2 = 5$. The unique equilibrium utility of both buyers is $u_1 = u_2 = 1$, which can be obtained for any $p_1 = p_2 = p$, where $p \in [0, 5]$ and allocation $\mathbf{x}$ satisfying $x_{11} + x_{12} = 1$; $x_{21} + x_{22} = 1$; $x_{11} + x_{21} = 1$; $x_{12} + x_{22} = 1$.

▶ **Example 1** (continued)**.** For our example above, the modest MBB equilibrium obtained from solving the convex program is $x_{11} = 1/5$, $x_{12} = 0$, $x_{21} = 4/5$ and $x_{22} = 1$ with prices $p_1 = 10/13$ and $p_2 = 5/13$. Buyer 1 spends 2/13, buyer 2 spends the entire budget. The utilities are 1 and 13/5. It is easy to see that the KKT conditions hold. This equilibrium is Pareto-optimal and also the best equilibrium in terms of social welfare. ◀

Structure of Modest MBB Equilibria. Let us characterize the set of price vectors of modest MBB equilibria, which we denote by $\mathcal{P} = \{\mathbf{p} \mid (\mathbf{x}, \mathbf{p}) \text{ is modest MBB equilibrium }\}$. We consider the coordinate-wise comparison, i.e., $\mathbf{p} \geq \mathbf{p}'$ iff $p_j \geq p'_j$ for all $j \in G$.

▶ **Theorem 3.** *The pair* $(\mathcal{P}, \geq)$ *is a lattice.*

Given $\mathbf{p}$ and $\mathbf{p}'$, we partition the set of goods into three sets: $S_0 = \{j \mid p_j = p'_j\}$, $S_1 = \{j \mid p_j < p'_j\}$ and $S_2 = \{j \mid p_j > p'_j\}$. Let $\Gamma(T, \mathbf{p}) = \{i \mid x_{ij} > 0 \text{ for some } j \in T\}$ denote the set of buyers who are allocated a nonzero amount of any good in set T in the equilibrium $(\mathbf{x}, \mathbf{p})$. The proof of Theorem 3 exploits the following properties about the sets S_0, S_1 and S_2.

▶ **Lemma 4.** *Given any two modest MBB equilibria* $(\mathbf{x}, \mathbf{p})$ *and* $(\mathbf{x}', \mathbf{p}')$*, we have*
- **(i)** $\Gamma(S_i, \mathbf{p}) = \Gamma(S_i, \mathbf{p}')$ *for* $i = 0, 1, 2$*, i.e., the set of buyers who buy the goods of* S_i *with respect to prices* $\mathbf{p}$ *and* $\mathbf{p}'$ *are same.*
- **(ii)** $\Gamma(S_0, \mathbf{p}), \Gamma(S_1, \mathbf{p})$ *and* $\Gamma(S_2, \mathbf{p})$ *are mutually disjoint.*
- **(iii)** *All buyers in* $\Gamma(S_1, \mathbf{p})$ *and* $\Gamma(S_2, \mathbf{p})$ *are capped buyers in both* $(\mathbf{x}, \mathbf{p})$ *and* $(\mathbf{x}', \mathbf{p}')$.

Thus, there exists a modest MBB equilibrium with coordinate-wise highest (resp. lowest) prices. It yields the maximum (resp. minimum) revenue for the seller among all modest MBB equilibria.

▶ **Example 5.** Consider the following market with two buyers and two goods. Let $u_{11} = u_{12} = u_{22} = 1$ and $u_{21} = 0$. Let $M_1 = M_2 = 1$ and $c_1 = 1$. Then $x_{11} = x_{22} = 1$, $x_{12} = 0$, $p_1 = p_2 = 1$ is a modest MBB equilibrium with maximum revenue. A modest MBB equilibrium with minimum revenue has the same allocation and $p_1 = 0$ and $p_2 = 1$.

3 Computing a Modest MBB Equilibrium with Maximum Revenue

In this section, we describe an efficient algorithm to compute a modest MBB equilibrium. In fact, we compute the one with coordinate-wise highest prices and maximum revenue among all modest MBB equilibria. We define the *active budget* of buyer i at prices $\mathbf{p}$ as $M_i^a = \min\{M_i, c_i/\alpha_i\}$, where $\alpha_i = \max_{j\in G} u_{ij}/p_j$ is the MBB ratio. The active budget of buyer i is the minimum of M_i and the minimum amount of money needed to buy a bundle of goods with utility c_i. If $M_i^a = c_i/\alpha_i$, then buyer i is capped, otherwise uncapped.

3.1 Flow Network and Initialization

Given prices $\mathbf{p}$, let $A = \{(i,j) \subseteq B \times G \mid u_{ij}/p_j = \alpha_i\}$ be the set of equality edges, and the bipartite graph $(B \cup G, A)$ be the *equality graph*. We set up the following flow network N_p using the equality graph by adding a source s and sink t. It has nodes $\{s,t\} \cup B \cup G$ and edges (s,i) for $i \in B$, (j,t) for $j \in G$ and the equality edges. The edge (s,i) has capacity M_i^a, and the edge (j,t) has capacity p_j. The equality edges have infinite capacity. The flow in the network corresponds to money. We will maintain the following invariants throughout the algorithm.

Invariants:

- The edges out of s are saturated.
- Prices and active budgets never increase.
- Total utility of a buyer never decreases. Once a buyer is capped, it stays capped.

We initialize the prices to large values, namely $p_j = \sum_i M_i$. W.l.o.g. we will assume that all budgets, caps, and utilities are integers.

The surplus (residual capacity) of good j is $r_j = p_j - f_{jt}$, where f_{jt} is the flow from good j to t. Then $1 - f_{jt}/p_j$ is the fraction of good j that is not sold. We also keep track of the allocations x_{ij}. There might be prices equal to zero, and then the allocation cannot be computed from the money flow. Goods that have price zero have no surplus. There is no money flowing through them, although they may be (partially) allocated.

A subset T of buyers is called *tight* with respect to prices $\mathbf{p}$ if $\sum_{i\in T} M_i^a = \sum_{j\in\Gamma(T)} p_j$, where $\Gamma(T) \subseteq S$ is the set of goods connected to T in the equality graph.

A *balanced flow* is a maximum flow in N_p which minimizes the 2-norm of surplus vector r. Let $|r| = |r_1| + \ldots + |r_n|$ and $\|r\| = (r_1^2 + \ldots + r_n^2)^{1/2}$ be the ℓ_1 and ℓ_2 norm of r, resp.

3.2 The Algorithm

The complete algorithm is shown in Figure 1. We initialize price p_j of each good j to $\sum_i M_i$. This ensures that the invariants are satisfied, namely a maximum flow in network N_p saturates all edges out of s. We initialize every active budget $M_i^a = \min\{M_i, \min_j c_i p_j/u_{ij}\}$, and flow f and allocation x equal to zero.

The algorithm is divided into a set of phases, and each phase is further divided into a set of iterations. A phase starts with the computation of a balanced flow in N_p. Let the surplus of good j be $p_j - f_{jt}$. We pick a good j with maximum surplus, and we compute a set of goods S containing j and the goods which can reach j in the residual network corresponding to N_p without using nodes s and t. The surplus of each good in S is the same, and maximum among all goods. We denote by B' the set of buyers who have equality edges to goods in S, and by B'_c and B'_u the sets of capped and uncapped buyers in B', resp. Note that $x_{ij} = 0$ for all $i \in B'$ and $j \notin S$, since $x_{ij} > 0$ would imply $j \in S$.

We begin with an iteration, where we use a factor x to set the price of each good $j \in S$ to xp_j and the active budget of each buyer $i \in B'_c$ to xM_i^a. The prices and active budgets of the remaining goods and buyers remain unchanged. We decrease $x \leq 1$ continuously until

```
Input: A market with a set of buyers $B$ and a set of goods $G$;
       Budget $M_i$, happiness cap $c_i$, and utility parameters $u_{ij}$, $\forall i \in B, j \in G$;
Output: Equilibrium prices $\mathbf{p}$, allocation $x$;
$n \leftarrow |B|$; $m \leftarrow |G|$; $U \leftarrow \max_{i\in B, j\in G}\{M_i, c_i, u_{ij}\}$; $\epsilon \leftarrow 1/((m+n)U^{4(m+n)})$;
Initialize price $p_j \leftarrow \sum_i M_i$ for each good $j$;
Initialize active budget $M_i^a \leftarrow \min\{M_i, \min_j c_i p_j/u_{ij}\}$ for each buyer $i$;
$f_{ij} \leftarrow 0$, $x_{ij} \leftarrow 0$, $\forall i \in B, j \in G$;
Repeat // phase
    $f \leftarrow$ balanced flow in $N_p$; $x_{ij} \leftarrow f_{ij}/p_j$ if $p_j \neq 0$; $r_j \leftarrow p_j - f_{jt}$;
    $\delta \leftarrow \max_j r_j$; Pick a good $j$ with surplus $\delta$;
    $S \leftarrow \{j\} \cup \{k \in G \mid k$ can reach $j$ in the residual network w.r.t. $f$ in $N_p \setminus \{s,t\}\}$;
    Repeat // iteration
        $B' \leftarrow$ Set of buyers who have incident equality edges to $S$;
        $B'_c \leftarrow$ Set of capped buyers in $B'$ (a buyer $i$ is capped if $M_i^a = \min_j {}^{c_i p_j}/_{u_{ij}}$);
        $B'_u \leftarrow B' \setminus B'_c$ (set of uncapped buyers);
        $x \leftarrow 1$; Set prices and active budgets as follows:
            $p_j \leftarrow x p_j$, $\forall j \in S$; $M_i^a \leftarrow x M_i^a$, $\forall i \in B'_c$;
        Decrease $x$ continuously down from 1 until one of the following events occurs
        Event 1: An uncapped buyer becomes capped
        Event 2: A new equality edge appears
            Recompute $N_p$;
            $f \leftarrow$ balanced flow in $N_p$; $x_{ij} \leftarrow f_{ij}/p_j$ if $p_j \neq 0$;
            $S \leftarrow S \cup \{j \in G \mid j$ can reach $S$ in the residual network w.r.t. $f$ in $N_p \setminus \{s,t\}\}$;
        Event 3: A subset of $B'$ becomes tight // phase ends
    Until Event 3 occurs;
Until $|r| \leq \epsilon$;
Recompute $N_p$;
$f \leftarrow$ balanced flow in $N_p$; $x_{ij} \leftarrow f_{ij}/p_j$ if $p_j \neq 0$;
```

Figure 1 The complete algorithm.

some structural change happens. Our goal here is to decrease prices as much as possible. By changing prices in this manner, all the equality edges between B' and S stay intact and the equality edges between B' and $G \setminus S$ become non-equality.

A possible structural change is that an uncapped buyer becomes capped. When a buyer $i \in B'$ is uncapped, $M_i < \min_j c_i p_j/u_{ij}$. Prices are decreasing, so this may become an equality. We term the first such change Event 1. Then we move buyer i from B'_u to B'_c.

Another possible change is that a new equality edge appears from a buyer in $B \setminus B'$ to a good in S. Prices of goods in S are decreasing, so goods in S are becoming attractive to buyers outside B'. Note that there cannot be a new equality edge from a buyer in B' to a good outside S. We term the first such change Event 2. Then we recompute the flow network N_p and a balanced flow in N_p. Next, we compute the set S' of goods $j \in G \setminus S$ that can reach a good in S in the residual graph corresponding to N_p without using the nodes s and t. Due to the property of balanced flows, the surplus of each good in S' is at least the surplus of some good in S. Finally, we add goods in S' to S.

Apart from the structural changes, we also maintain the invariants. The only invariant that can become violated with these changes is that the edges out of s are saturated. Hence, we need to stop when a subset T of B' becomes tight. Clearly, if prices are decreased further, then buyers in T will not be saturated, so we stop decreasing prices at this stage. We term this Event 3, and then the phase ends. We show in Lemma 10 below that during a phase, the 2-norm of the surplus vector decreases geometrically. The last phase ends when the total surplus becomes tiny. In fact, we will show that the surplus is actually zero at this point. We recompute a balanced flow and terminate.

When the prices of a set of goods hit zero in an iteration of the algorithm, then we do not change the allocation of these goods, and all the buyers interested in these goods must be capped. Since each buyer gets a modest allocation before the prices hit zero, the same allocation remains modest. None of the goods in the set is completely allocated. We delete these goods and the buyers to which they are allocated from consideration.

▶ **Example 1** (continued). Consider our algorithm applied to the example market above. We initialize p_1 and p_2 to $M_1 + M_2 = 4$. The active budgets become $M_1^a = \min_j c_1 p_j / u_{ij} = 4/5$ and $M_2^a = 1$. The edges $(1,1)$ and $(2,1)$ are equality edges and the balanced flow is $f_{11} = 4/5$, $f_{21} = 1$, and $f_{12} = f_{22} = 0$. The surpluses are $r_1 = 4 - 9/5 = 11/5$ and $r_2 = 4 - 0 = 4$. Thus $S = \{2\}$. We decrease p_2 to xp_2. At $x = 1/2$, the edge $(2,2)$ becomes an equality edge. Now $p_2 = 2$. The balanced flow does not change and hence $r_1 = 11/5$ and $r_2 = 2$. Thus $S = \{1\}$. We decrease M_1^a to $4x/5$ and p_1 to $4x$. At $x = 5/16$, B' becomes tight. We now have $M_1^a = 1/4$ and $p_1 = 5/4$. The balanced flow is $f_{11} = 1/4$ and $f_{21} = 1$. Thus $r_1 = 0$ and $r_2 = 2$. So $S = \{2\}$. We change p_2 to $p_2 x$. At $x = 5/16$, the edge $(2,2)$ becomes an equality edge. Now $p_2 = 5/8$. The balanced flow is $f_{11} = 1/4$, $f_{21} = 11/16$, and $f_{22} = 5/16$. Then $r_1 = r_2 = 5/16$. Thus $S = \{1,2\}$. We now decrease M_1^a to $x \cdot 1/4$, p_1 to $5x/4$ and p_2 to $5x/8$. At $x = 8/13$, B' becomes tight and we have $p_1 = 10/13$, $p_2 = 5/13$, $M_1^a = 2/13$, $x_{11} = 1/5$, $x_{21} = 4/5$, $x_{22} = 1$, $f_{11} = 2/13$, $f_{21} = 8/13$, and $f_{22} = 5/13$. ◀

3.3 Analysis

▶ **Lemma 6.** *The invariants hold during the run of the algorithm.*

Phases consist of iterations, which end with Event 1, 2, or 3. A phase ends with Event 3.

▶ **Lemma 7.** *Each phase has at most $2n$ iterations.*

Our next goal is to show that the 2-norm of the surplus vector decreases substantially during a phase. Let r and r' be the surplus vectors at the beginning and at the end of a phase, resp. For the purpose of our analysis we also maintain an intermediate flow f continuously as we change prices in each iteration; this flow is *not* maintained by the algorithm. When we recompute a balanced flow during Event 2, then f will be reset to the balanced flow. It is defined as $\forall i \in B'_c : f_{ij} \leftarrow x f_{ij}$ and $\forall i \in B'_u : f_{ij} \leftarrow f_{ij}$. f ensures that all buyers are saturated. If the surplus of a good j becomes zero corresponding to f, then we keep its surplus equal to zero and reroute extra flow from j to some other good with positive surplus, using a path in the residual network corresponding to f. If there is no such path, then this implies Event 3 has occurred, in which case the current phase is done. Consider an intermediate iteration t. With respect to f, let $r^t = (r_1^t, \ldots, r_m^t)$ be the surplus vector at the beginning of iteration t, and let $\tilde{r}^t = (\tilde{r}_1^t, \ldots, \tilde{r}_m^t)$ be the surplus vector before we recompute a balanced flow in iteration t if Event 2 occurs.

▶ **Lemma 8.** *$\tilde{r}_j^t \le r_j^t$, $\forall j \in G$, and $\|r^{t+1}\| \le \|\tilde{r}^t\| \le \|r^t\|$.*

▶ **Lemma 9.** *[17] Suppose f and f^* are a feasible and a balanced flow in N_p, resp., and r and r^* are the surplus vectors w.r.t. f and f^*, resp. If $r_j^* = r_j - \delta$ for some good j and $\delta > 0$, then $\|r^*\|^2 \le \|r\|^2 - \delta^2$.*

▶ **Lemma 10.** $\|r'\|^2 \leq (1 - 1/4mn)\|r\|^2$.

Proof. Consider the value of $\gamma = \min\{r_j \mid j \in S\}$ during a phase. When the phase begins, $\gamma = \delta$, and when it ends $\gamma = 0$. Recall that S only grows, and when we add a new good k to S, then the surplus of k is at least the surplus of some good already in S. This implies that γ does not change when we add new goods to S.

Let $t_1, \ldots, t_l$ be the iterations where γ decreases, and let $\delta_i > 0$ be the amount of decrease in iteration t_i. Further we break each δ_i into two parts δ_{i1} and δ_{i2} such that $\delta_i = \delta_{i1} + \delta_{i2}$. Here δ_{i1} is the amount of decrease due to the flow change before we recompute balanced flow, and δ_{i2} is the amount of decrease due to recomputation of balanced flow. Next consider only positive δ_{i1}'s and δ_{i2}'s. Clearly, $l \leq 2n$ and $\sum_{i:\delta_{i1}>0,\delta_{i2}>0}(\delta_{i1} + \delta_{i2}) \geq \delta$. Using Lemmas 8 and 9, we have $\|r'\|^2 \leq \|r\|^2 - (\delta_{11}^2 + \delta_{12}^2 + \cdots + \delta_{l1}^2 + \delta_{l2}^2) \leq \|r\|^2 - \delta^2/4n$. Since $\|r\|^2 \leq m\delta^2$, we have $\|r'\|^2 \leq (1 - 1/4mn)\|r\|^2$. ◀

Polynomial Running Time. In each iteration, the prices of goods in S are multiplied by a value that itself depends on the prices. It is not obvious why the size of the numbers in the computation is polynomially bounded. Here we show that, indeed, the sizes of all intermediate prices and flows in our algorithm remain polynomially bounded.

▶ **Lemma 11.** *All goods in S are connected by equality edges at all times. There is no flow from buyers in B' to goods outside S.*

Cap-events occur only at a cap-event prices. A cap-event price is any price p with $M_i = c_i p/u_{ij}$ for some i and j. Let $P_c = \{M_i u_{ij}/c_i \mid 1 \leq i \leq n, 1 \leq j \leq m\}$.

Let A' be any subset of the edge set with positive utility such that the graph formed by it is connected. Let B' and G' be the buyers and goods in this connected graph. The prices in the component have only one degree of freedom, i.e., we can select one of the prices, say p, as a base price and express any other price in the component as αp, where α is a rational whose numerator and denominator are products of at most m utilities. Consider an arbitrary partition of B' into capped buyers B'_c and uncapped buyers B'_u; B'_u must be nonempty. The budget of a capped buyer is of the form $c\alpha p$, where c is a cap and α is as above. If there are no surpluses, p must satisfy that (budget of capped buyers + budget of uncapped buyers) equals sum of the prices (in the component). We call a price that can be obtained in this way a submarket price; note that not all submarket prices can actually occur. Let P_m be the set of *submarket prices.*

Let P_i be the set consisting of the initial price and zero. A price is *1-linked* if it is of the form $(U_1/U_2)p$ where $p \in P_c \cup P_m \cup P_i$ and U_1 and U_2 are products of at most n utilities each. A price is *2-linked* if it of the form $(U_1/U_2)p$, where p is 1-linked and U_1 and U_2 are products of at most n utilities each.

▶ **Lemma 12.** *Assuming that all budgets, happiness caps and utilities are integers bounded by U, 1-linked and 2-linked prices are rational numbers whose bit-length is at most* $\log(m+n) + 3(m+n)\log U$.

▶ **Lemma 13.** *At the beginning of a phase, all prices are 1-linked. During a phase, prices outside S are 1-linked. At the end of each iteration, prices in S are 2-linked.*

▶ **Theorem 14.** *The algorithm in Figure 1 computes a modest MBB equilibrium.*

Proof. When the algorithm terminates, we claim that at this stage total surplus $\sum_j r_j = 0$. This will imply that the algorithm in Figure 1 computes a market equilibrium. Consider any good j and the component C of the equality graph containing good j. The total surplus

$\sum_{j\in C} r_j$ in the component is $\sum_{j\in C} p_j - \sum_{i\in C} M_i^a$. This is non-negative and less than ϵ. All prices and active budgets of capped buyers can be expressed in terms of one price variable p using equality relations. By Lemma 12, p is a rational number with bounded denominator, and the above inequalities imply $\sum_{j\in C} r_j = 0$. Thus $r_j = 0$ for all j. ◀

Let x_{ts} denote the value of x when Event 3 occurs in the algorithm. Next we show that x_{ts} can be computed using at most n max-flow computations. This is a generalization of a procedure in [17] for computing tight set in case of *linear* Fisher markets.

▶ **Lemma 15.** *x_{ts} can be computed using at most n max-flow computation.*

Maximum Revenue. Finally, we show that our algorithm gives a modest MBB equilibrium with maximum revenue among all modest MBB equilibria.

▶ **Lemma 16.** *Consider the price vector $\mathbf{p}$ at the end of any phase of the algorithm. We have $\mathbf{p} \geq \mathbf{p}'$ for any price vector $\mathbf{p}' \in \mathcal{P}$ of a modest MBB equilibrium.*

For the main result in this section, assume that all budgets, happiness caps and utilities are integers bounded by U.

▶ **Theorem 17.** *The algorithm in Figure 1 computes a modest MBB equilibrium with maximum revenue in $O(mn^6(\log(m+n) + (m+n)\log U))$ time.*

Proof. In the beginning, the 2-norm of surplus vector r satisfies $\|r\|^2 \leq mn^2U^2$. By Theorem 14, the algorithm will terminate before the norm becomes $\|r'\|^2 = 1/m(m+n)^2U^{8(m+n)}$. Let k denote the number of phases when the surplus becomes r'. From Lemma 10, we have $\|r\|^2(1-1/4mn)^k = \|r'\|^2$, which implies that the total number of phases in the algorithm is $O(mn(\log(m+n) + (m+n)\log U))$.

In each phase, we have at most $2n$ iterations, and in each iteration we need to compute the maximum $0 \leq x \leq 1$ when one of the three events occurs. Let x_c, x_{eq} and x_{ts} respectively denote the maximum value of x where Event 1, 2 and 3 occurs. Clearly, x_c can be obtained in $O(n)$ time, x_{eq} can be obtained in $O(mn)$ time, and x_{ts} can be obtained using at most n max-flow computations due to Lemma 15. Further, we recompute a balanced flow in case of Event 2 which further requires at most n max-flow computations [17]. Since a max-flow can be obtained in $O(n^3)$ time, each iteration can be implemented in $O(n^4)$ time. Hence, the total running time of the algorithm is $O(mn^6(\log(m+n) + (m+n)\log U))$. ◀

We conjecture that the running time in Theorem 17 can be reduced by a factor of $\tilde{O}(n^2)$ using the perturbation technique from [19] which requires a max-flow to be computed only in a network with forest structure. We have not worked out the details.

4 Computing a Modest MBB Equilibrium with Minimum Revenue

In this section, we show how to transform in polynomial time any modest MBB equilibrium into one with minimum revenue using the postprocessing procedure in Fig. 2.

▶ **Theorem 18.** *The algorithm in Figure 2 computes a modest MBB equilibrium with minimum revenue.*

Proof. It is easy to check that throughout the algorithm, $(\mathbf{x}, \mathbf{p})$ always remains a modest MBB equilibrium. Assume by contradiction that at the end of the algorithm, $(\mathbf{x}, \mathbf{p})$ is not an equilibrium with smallest prices. Let $(\mathbf{x}', \mathbf{p}')$ be an equilibrium with smallest prices, and

```
Input: A market with a set of buyers $B$ and a set of goods $G$;
        Budget $M_i$, happiness cap $c_i$, and utility parameters $u_{ij}$, $\forall i \in B, j \in G$;
        Any modest MBB equilibrium $(\mathbf{x}, \mathbf{p})$;
Output: A modest MBB equilibrium $(\mathbf{x}, \mathbf{p})$ with minimum revenue;
Initialize active budget $M_i' \leftarrow \min\{M_i, \min_j c_i p_j / u_{ij}\}$ for each buyer $i$;
$S \leftarrow \{j | p_j > 0$ and $j$ does not have incident equality edges to any uncapped buyer$\}$;
While $S \neq \emptyset$
    $B' \leftarrow$ Set of buyers who have incident equality edges to $S$;
    $x \leftarrow 1$; Define prices and active budgets as follows:
        $p_j \leftarrow x p_j$, $\forall j \in S$; $M_i^a \leftarrow x M_i^a$, $\forall i \in B_c'$;
    Decrease $x$ continuously down from 1 until one of the following events occurs
    Event 1: $x$ becomes zero;
    Event 2: A new equality edge appears
    Recompute $N_p$ and $S$;
EndWhile
```

Figure 2 The postprocessing algorithm for an equilibrium with minimum revenue.

define $S_1 = \{j \mid p_j > p_j'\}$. By Lemma 4 property (3), all buyers in $\Gamma(S_1, \mathbf{p})$ are capped buyers. Because prices of goods in set S_1 decrease from $\mathbf{p}$ to $\mathbf{p}'$, every buyer i incident to S_1 in the equality graph with prices $\mathbf{p}$ will only have equality edges to S_1 with prices $\mathbf{p}'$. Therefore we have $i \in \Gamma(S_1, \mathbf{p}') = \Gamma(S_1, \mathbf{p})$ (the equality is again by Lemma 4). This implies $\Gamma(S_1, \mathbf{p})$ is also the set of buyers who have incident equality edges to S_1 with prices $\mathbf{p}$. Hence, set S is nonempty for the While loop, and the algorithm should not terminate. ◀

5 Extensions

In the previous section, we proposed an algorithm for computing a modest MBB equilibrium, which has a Pareto-optimal allocation. When we depart from the set of such equilibria, then utilities in market equilibrium are not uniquely determined. In fact, we show that market equilibria with maximum social welfare might not be modest MBB equilibria, and computing such optimal equilibria becomes NP-hard. As a corollary, we note that the proof can also be used to show NP-hardness for optimizing any constant norm of utility values.

▶ **Theorem 19.** *It is* NP*-hard to compute a market equilibrium that maximizes social welfare.*

▶ **Corollary 20.** *It is* NP*-hard to compute a market equilibrium* $(\mathbf{x}, \mathbf{p})$ *that maximizes* $\sum_i (u_i(\mathbf{x}))^\rho$*, for every constant* $\rho > 0$.

There are several ways of introducing satiation points into the utility function. Instead of a global cap, let us assume there is a cap c_{ij} for the utility buyer i can obtain from good j. A good-based budget-additive utility of buyer i is then $u_i(\mathbf{x}_i) = \sum_j \min(c_{ij}, u_{ij} x_{ij})$. This variant turns out to be an elementary special case of separable piecewise-linear concave (SPLC) utilities, in which every piece consists of a linear segment followed by a constant segment. We show that even finding a single market equilibrium here becomes PPAD-hard. The proof adjusts a construction put forward in [9].

▶ **Theorem 21.** *It is* PPAD*-hard to compute a market equilibrium in Fisher markets with good-based budget-additive utilities.*

Abstract

We introduce and study the *Lattice Distortion Problem* (LDP). LDP asks how "similar" two lattices are. I.e., what is the minimal distortion of a linear bijection between the two lattices? LDP generalizes the Lattice Isomorphism Problem (the lattice analogue of Graph Isomorphism), which simply asks whether the minimal distortion is one.

As our first contribution, we show that the distortion between any two lattices is approximated up to a $n^{O(\log n)}$ factor by a simple function of their successive minima. Our methods are constructive, allowing us to compute low-distortion mappings that are within a $2^{O(n \log \log n / \log n)}$ factor of optimal in polynomial time and within a $n^{O(\log n)}$ factor of optimal in singly exponential time. Our algorithms rely on a notion of basis reduction introduced by Seysen (Combinatorica 1993), which we show is intimately related to lattice distortion. Lastly, we show that LDP is NP-hard to approximate to within any constant factor (under randomized reductions), by a reduction from the Shortest Vector Problem.

1 Introduction

An n-dimensional *lattice* $\mathcal{L} \subset \mathbb{R}^n$ is the set of all integer linear combinations of linearly independent vectors $B = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ with $\mathbf{b}_i \in \mathbb{R}^n$. We write the lattice generated by basis B as $\mathcal{L}(B) = \{\sum_{i=1}^n a_i \mathbf{b}_i : a_i \in \mathbb{Z}\}$.

Lattices are very well-studied classical mathematical objects (e.g., [25, 9]), and over the past few decades, computational problems on lattices have found a remarkably large number of applications in computer science. Algorithms for lattice problems have proven to be quite useful, and they have therefore been studied extensively (e.g., [20, 16, 3, 24]). And, over the past twenty years, many strong cryptographic primitives have been constructed with

* The full version of this paper is available at `http://arxiv.org/abs/1605.03613`.

their security based on the (worst-case) hardness of various computational lattice problems (e.g., [1, 23, 12, 11, 28, 8]).

In this paper, we address a natural question: how "similar" are two lattices? I.e., given lattices $\mathcal{L}_1, \mathcal{L}_2$, does there exist a linear bijective mapping $T : \mathcal{L}_1 \to \mathcal{L}_2$ that does not change the distances between points by much? If we insist that T exactly preserves distances, then this is the *Lattice Isomorphism Problem* (LIP), which was studied in [26, 32, 15, 21]. We extend this to the *Lattice Distortion Problem* (LDP), which asks how well such a mapping T can *approximately* preserve distances between points.

Given two lattices $\mathcal{L}_1, \mathcal{L}_2$, we define the *distortion* between them as

$$\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) = \min\{\|T\|\|T^{-1}\| \,:\, T(\mathcal{L}_1) = \mathcal{L}_2\} \ ,$$

where $\|T\| = \sup_{\|\mathbf{x}\|=1} \|T\mathbf{x}\|$ is the *operator norm.* The quantity $\kappa(T) = \|T\| \cdot \|T^{-1}\|$ is the *condition number* of T, which measures how much T "distorts distances" (up to a fixed scaling). It is easy to check that $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$ bounds the ratio between most natural geometric parameters of $\mathcal{L}_1$ and $\mathcal{L}_2$ (up to scaling), and hence $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$ is a strong measure of "similarity" between lattices. In particular, $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) = 1$ if and only if $\mathcal{L}_1, \mathcal{L}_2$ are isomorphic (i.e., if and only if they are related by a scaled orthogonal transformation).

The *Lattice Distortion Problem* (LDP) is then defined in the natural way as follows. The input is two n-dimensional lattices $\mathcal{L}_1, \mathcal{L}_2$ (each represented by a basis), and the goal is to compute a bijective linear transformation T mapping $\mathcal{L}_1$ to $\mathcal{L}_2$ such that $\kappa(T) = \mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$. In this work, we study the approximate search and decisional versions of this problem, defined in the usual way. We refer to them as γ-LDP and γ-GapLDP respectively, where $\gamma = \gamma(n) \geq 1$ is the approximation factor. (See Section 2.4 for precise definitions.)

1.1 Our Contribution

As our first main contribution, we show that the distortion between any two lattices can be approximated by a natural function of geometric lattice parameters. Indeed, our proof techniques are constructive, leading to our second main contribution: an algorithm that computes low-distortion mappings, with a trade-off between the running time and the approximation factor. Finally, we show hardness of approximating lattice distortion.

To derive useful bounds on the distortion between two lattices, it is intuitively clear that one should study the "different scales over which the two lattices live." A natural notion of this is given by the successive minima, which are defined as follows. The i^{th} successive minimum, $\lambda_i(\mathcal{L})$, of $\mathcal{L}$ is the minimum radius $r > 0$ such that $\mathcal{L}$ contains i linearly independent vectors of norm at most r. For example, a lattice generated by a basis of orthogonal vectors of lengths $0 < a_1 \leq \cdots \leq a_n$ has successive minima $\lambda_i(\mathcal{L}) = a_i$. Since low-distortion mappings approximately preserve distances, it is intuitively clear that two lattices can only be related by a low-distortion mapping if their successive minima are close to each other (up to a fixed scaling).

Concretely, for two n-dimensional lattices $\mathcal{L}_1, \mathcal{L}_2$, we define

$$M(\mathcal{L}_1, \mathcal{L}_2) = \max_{i \in [n]} \frac{\lambda_i(\mathcal{L}_2)}{\lambda_i(\mathcal{L}_1)} \ , \tag{1}$$

which measures how much we need to scale up $\mathcal{L}_1$ so that its successive minima are at least as large as those of $\mathcal{L}_2$. For any linear map T from $\mathcal{L}_1$ to $\mathcal{L}_2$, it is easy to see that $\lambda_i(\mathcal{L}_2) \leq \|T\|\lambda_i(\mathcal{L}_1)$. Thus, by definition $M(\mathcal{L}_1, \mathcal{L}_2) \leq \|T\|$. Applying the same reasoning for T^{-1}, we derive the following simple lower bound on distortion.

$$\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) \geq M(\mathcal{L}_1, \mathcal{L}_2) \cdot M(\mathcal{L}_2, \mathcal{L}_1) \ . \tag{2}$$

We note that this lower bound is tight when $\mathcal{L}_1, \mathcal{L}_2$ are each generated by bases of orthogonal vectors. But, it is a priori unclear if any comparable upper bound should hold for general lattices, since the successive minima are a very "coarse" characterization of the geometry of the lattice. Nevertheless, we show a corresponding upper bound.

▶ **Theorem 1.** *Let $\mathcal{L}_1, \mathcal{L}_2$ be n-dimensional lattices. Then,*

$$M(\mathcal{L}_1, \mathcal{L}_2) \cdot M(\mathcal{L}_2, \mathcal{L}_1) \le \mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) \le n^{O(\log n)} \cdot M(\mathcal{L}_1, \mathcal{L}_2) \cdot M(\mathcal{L}_2, \mathcal{L}_1) \ .$$

In particular, Theorem 1, together with standard transference theorems (e.g., [7]), implies that $n^{O(\log n)}$-GapLDP is in $\mathsf{NP} \cap \mathsf{coNP}$. While the factor on the right-hand side of the theorem might be far from optimal, we show in Section 5.1 that it cannot be improved below $\Omega(\sqrt{n})$. Intuitively, this is because there exist lattices that are much more dense than $\mathbb{Z}^n$ over large scales but still have $\lambda_i(\mathcal{L}) = \Theta(1)$ for all i. I.e., there exist very dense lattice sphere packings (see, e.g., [31]).

To prove the above theorem, we make use of the intuition that a low-distortion mapping T from $\mathcal{L}_1$ to $\mathcal{L}_2$ should map a "short" basis B_1 of $\mathcal{L}_1$ to a "short" basis B_2 of $\mathcal{L}_2$. (Note that the condition $TB_1 = B_2$ completely determines $T = B_2 B_1^{-1}$.) The difficulty here is that standard notions of "short" fail for the purpose of capturing low-distortion mappings. In particular, in Section 5.2, we show that Hermite-Korkine-Zolotarev (HKZ) reduced bases, one of the strongest notions of "shortest possible" lattice bases, do not suffice by themselves for building low-distortion mappings. (See Section 2.6 for the definition of HKZ-reduced bases.) In particular, we give a simple example of a lattice $\mathcal{L}$ where an HKZ-reduced basis of $\mathcal{L}$ misses the optimal distortion $\mathcal{D}(\mathbb{Z}^n, \mathcal{L})$ by an exponential factor.

Fortunately, we show that a suitable notion of shortness does exist for building low-distortion mappings by making a novel connection between low-distortion mappings and a notion of basis reduction introduced by Seysen [30]. In particular, for a basis $B = [\mathbf{b}_1, \dots, \mathbf{b}_n]$ and dual basis $B^* = B^{-T} = [\mathbf{b}_1^*, \dots, \mathbf{b}_n^*]$, Seysen's condition number is defined as

$$S(B) = \max_{i \in [n]} \|\mathbf{b}_i\| \|\mathbf{b}_i^*\| \ .$$

Note that we always have $\langle \mathbf{b}_i, \mathbf{b}_i^* \rangle = 1$, so this parameter measures how tight the Cauchy-Schwarz inequality is over all primal-dual basis-vector pairs. We extend this notion and define $S(\mathcal{L})$ as the minimum of $S(B)$ over all bases B of $\mathcal{L}$. Using this notion, we give an effective version of Theorem 1 as follows.

▶ **Theorem 2.** *Let $\mathcal{L}_1, \mathcal{L}_2$ be n-dimensional lattices. Let $B_1, B_2 \in \mathbb{R}^{n \times n}$ be bases of $\mathcal{L}_1, \mathcal{L}_2$ whose columns are sorted in non-decreasing order of length. Then, we have that*

$$M(\mathcal{L}_1, \mathcal{L}_2) M(\mathcal{L}_2, \mathcal{L}_1) \le \kappa(B_2 B_1^{-1}) \le n^4 S(B_1)^2 S(B_2)^2 \cdot M(\mathcal{L}_1, \mathcal{L}_2) M(\mathcal{L}_2, \mathcal{L}_1) \ .$$

In particular, we have that

$$M(\mathcal{L}_1, \mathcal{L}_2) M(\mathcal{L}_2, \mathcal{L}_1) \le \mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) \le n^4 S(\mathcal{L}_1)^2 S(\mathcal{L}_2)^2 \cdot M(\mathcal{L}_1, \mathcal{L}_2) M(\mathcal{L}_2, \mathcal{L}_1) \ .$$

From here, the bound in Theorem 1 follows directly from the following (surprising) theorem of Seysen.

▶ **Theorem 3** (Seysen [30]). *For any $\mathcal{L} \subset \mathbb{R}^n$, $S(\mathcal{L}) \le n^{O(\log n)}$.*

This immediately yields an algorithm for approximating the distortion between two lattices, by using standard lattice algorithms to approximate $M(\mathcal{L}_1, \mathcal{L}_2)$ and $M(\mathcal{L}_2, \mathcal{L}_1)$. But, Seysen's proof of the above theorem is actually constructive! In particular, he shows how to efficiently convert any suitably reduced lattice basis into a basis with a low Seysen condition number. (See Section 2.6.2 for details.) Using this methodology, combined with standard basis reduction techniques, we derive the following time-approximation trade-off for γ-LDP.

▶ **Theorem 4** (Algorithm for LDP). *For any $\log n \leq k \leq n$, there is an algorithm solving $k^{O(n/k+\log n)}$-LDP in time $2^{O(k)}$.*

In other words, using the bounds in Theorem 1 together with known algorithms, we are able to approximate the distortion between two lattices. But, with a bit more work, we are able to solve *search* LDP by explicitly computing a low-distortion mapping between the input lattices.

We also prove the following lower bound for LDP.

▶ **Theorem 5** (Hardness of LDP). *γ-GapLDP is NP-hard under randomized polynomial-time reductions for any constant $\gamma \geq 1$.*

In particular, we show a reduction from approximating the (decisional) Shortest Vector Problem (GapSVP) over lattices to γ-GapLDP, where the approximation factor that we obtain for GapSVP is $O(\gamma)$. Since hardness of GapSVP is quite well-studied [2, 22, 17, 14], we are immediately able to import many hardness results to GapLDP. (See Corollary 30 and Theorem 31 for the precise statements.)

1.2 Comparison to related work

The main related work of which we are aware is that of Haviv and Regev [15] on the Lattice Isomorphism Problem (LIP). In their paper, they give an $n^{O(n)}$-time algorithm for solving LIP exactly, which proceeds by cleverly identifying a small candidate set of bases of $\mathcal{L}_1$ and $\mathcal{L}_2$ that must be mapped to each other by any isomorphism. One might expect that such an approach should also work for the purpose of solving LDP either exactly or for approximation factors below $n^{O(\log n)}$. However, the crucial assumption in LIP, that vectors in one lattice must be mapped to vectors of the same length in the other, completely breaks down in the current context. We thus do not know how to extend their techniques to LDP.

Much more generally, we note that LIP is closely related to the Graph Isomorphism Problem (GI). For example, both problems are in SZK but not known to be in P (although recent work on algorithms for GI has been quite exciting [6]!), and GI reduces to LIP [32]. Therefore, LDP is qualitatively similar to the Approximate Graph Isomorphism Problem, which was studied by Arora, Frieze, and Kaplan [4], who showed an upper bound, and Arvind, Köbler, Kuhnert, and Vasudev [5], who proved both upper and lower bounds. In particular, [5] showed that various versions of this problem are NP-hard to approximate to within a constant factor. Qualitatively, these hardness results are similar to our Theorem 5.

1.3 Conclusions and Open Problems

In conclusion, we introduce the Lattice Distortion Problem and show a connection between LDP and the notion of Seysen-reduced bases. We use this connection to derive time-approximation trade-offs for LDP. We also prove approximation hardness for GapLDP, showing a qualitative difference with LIP (which is unlikely to be NP-hard under reasonable complexity theoretic assumptions).

One major open question is what the correct bound in Theorem 3 is. In particular, there are no known families of lattices for which the Seysen condition number is provably superpolynomial, and hence it is possible that $S(\mathcal{L}) = \mathrm{poly}(n)$ for any n-dimensional lattice $\mathcal{L}$. A better bound would immediately improve our Theorem 2 and give a better approximation factor for GapLDP.

We also note that all of our algorithms solve LDP for arguably very large approximation factors $n^{\Omega(\log n)}$. We currently do not even know whether there exists a fixed-dimension polynomial-time algorithm for γ-LDP for any $\gamma = n^{o(\log n)}$. The main problem here is that we do not have any good characterization of nearly optimal distortion mappings between lattices.

Organization. In Section 2, we present necessary background material. In Section 3, we give our approximations for lattice distortion, proving Theorems 2 and 4. In Section 4, we give the hardness for lattice distortion, proving Theorem 5. In Section 5, we give some illustrative example instances of lattice distortion.

2 Preliminaries

For $\mathbf{x} \in \mathbb{R}^n$, we write $\|\mathbf{x}\|$ for the Euclidean norm of $\mathbf{x}$. We omit any mention of the bit length in the running time of our algorithms. In particular, all of our algorithms take as input vectors in $\mathbb{Q}^n$ and run in time $f(n) \cdot \mathrm{poly}(m)$ for some f, where m is the maximal bit length of an input vector. We therefore suppress the factor of $\mathrm{poly}(m)$.

2.1 Lattices

The i^{th} *successive minimum* of a lattice $\mathcal{L}$ is defined as $\lambda_i(\mathcal{L}) = \inf \{r > 0 : \dim(\mathrm{span}(rB_2^n \cap \mathcal{L})) \geq i\}$. That is, the first successive minimum is the length of the shortest non-zero lattice vector, the second successive minimum is the length of the shortest lattice vector which is linearly independent of a vector achieving the first, and so on. When $\mathcal{L}$ is clear from context, we simply write λ_i.

The *dual lattice* of $\mathcal{L}$ is defined as $\mathcal{L}^* = \{\mathbf{x} \in \mathbb{R}^n : \forall \mathbf{y} \in \mathcal{L}\ \langle \mathbf{x}, \mathbf{y} \rangle \in \mathbb{Z}\}$. If $\mathcal{L} = \mathcal{L}(B)$ then $\mathcal{L}^* = \mathcal{L}(B^*)$ where $B^* = B^{-T}$, the inverse transpose of B. We call $B^* = [\mathbf{b}_1^*, \ldots, \mathbf{b}_n^*]$ the *dual basis* of B, and write $\lambda_i^* = \lambda_i(\mathcal{L}^*)$. We will repeatedly use Banaszczyk's Transference Theorem, which relates the successive minima of a lattice to those of its dual.

▶ **Theorem 6** (Banaszczyk's Transference Theorem [7]). *For every rank n lattice $\mathcal{L}$ and every $i \in [n]$, $1 \leq \lambda_i(\mathcal{L})\lambda_{n-i+1}(\mathcal{L}^*) \leq n$.*

Given a lattice $\mathcal{L}$, we define the *determinant* of $\mathcal{L}$ as $\det(\mathcal{L}) := |\det(B)|$, where B is a basis with $\mathcal{L}(B) = \mathcal{L}$. Since two bases B, B' of $\mathcal{L}$ differ by a unimodular transformation, we have that $|\det(B)| = |\det(B')|$ so that $\det(\mathcal{L})$ is well-defined.

We sometimes work with lattices that do not have full rank—i.e., lattices generated by d linearly independent vectors $\mathcal{L} = \mathcal{L}(\mathbf{b}_1, \ldots, \mathbf{b}_d)$ with $d < n$. In this case, we simply identify $\mathrm{span}(\mathbf{b}_1, \ldots, \mathbf{b}_d)$ with $\mathbb{R}^d$ and consider the lattice to be embedded in this space.

2.2 Linear mappings between lattices

We next characterize linear mappings between lattices in terms of bases.

▶ **Lemma 7.** *Let $\mathcal{L}_1, \mathcal{L}_2$ be full-rank lattices. Then a mapping $T : \mathcal{L}_1 \to \mathcal{L}_2$ is bijective and linear if and only if $T = BA^{-1}$ for some bases A, B of $\mathcal{L}_1, \mathcal{L}_2$ respectively. In particular, for any basis A of $\mathcal{L}_1$, $T(A)$ is a basis of $\mathcal{L}_2$.*

Proof. We first show that such a mapping is a bijection from $\mathcal{L}_1$ to $\mathcal{L}_2$. Let $T = BA^{-1}$ where $A = [\mathbf{a}_1, \dots, \mathbf{a}_n]$ and $B = [\mathbf{b}_1, \dots, \mathbf{b}_n]$ are bases of $\mathcal{L}_1, \mathcal{L}_2$ respectively. Because T has full rank, it is injective as a mapping from $\mathbb{R}^n$ to $\mathbb{R}^n$, and it is therefore injective as a mapping from $\mathcal{L}_1$ to $\mathcal{L}_2$. We have that for every $\mathbf{w} \in \mathcal{L}_2$, $\mathbf{w} = \sum_{i=1}^n c_i \mathbf{b}_i$ with $c_i \in \mathbb{Z}$. Let $\mathbf{v} = \sum_{i=1}^n c_i \mathbf{a}_i \in \mathcal{L}_1$. Then, $T(\mathbf{v}) = T(\sum_{i=1}^n c_i \mathbf{a}_i) = \sum_{i=1}^n c_i \mathbf{b}_i = \mathbf{w}$. Therefore, T is a bijection from $\mathcal{L}_1$ to $\mathcal{L}_2$.

We next show that any linear map T with $T(\mathcal{L}_1) = \mathcal{L}_2$ must have this form. Let $A = [\mathbf{a}_1, \dots, \mathbf{a}_n]$ be a basis of $\mathcal{L}_1$, and let $B = T(A)$. We claim that $B = [\mathbf{b}_1, \dots, \mathbf{b}_n]$ is a basis of $\mathcal{L}_2$.

Let $\mathbf{w} \in \mathcal{L}_2$. Because T is a bijection between $\mathcal{L}_1$ and $\mathcal{L}_2$, there exists $\mathbf{v} \in \mathcal{L}_1$ such that $T\mathbf{v} = w$. Using the definition of a basis and the linearity of T,

$$\mathbf{w} = T\mathbf{v} = T\big(\sum_{i=1}^n c_i \mathbf{a}_i\big) = \sum_{i=1}^n c_i \mathbf{b}_i,$$

for some $c_1, \dots, c_n \in \mathbb{Z}$. Because $\mathbf{w}$ was picked arbitrarily, it follows that B is a basis of $\mathcal{L}_2$. ◀

2.3 Seysen's condition number $S(B)$

Seysen shows how to take any basis with relatively low multiplicative drop in its Gram-Schmidt vectors and convert it into a basis with relatively low $S(B) = \max_i \|\mathbf{b}_i\| \|\mathbf{b}_i^*\|$ [30]. By combining this with Gama and Nguyen's slide reduction technique [10], we obtain the following result.

▶ **Theorem 8.** *For every* $\log n \leq k \leq n$ *there exists an algorithm that takes a lattice* $\mathcal{L}$ *as input and computes a basis* B *of* $\mathcal{L}$ *with* $S(B) \leq k^{O(n/k + \log k)}$ *in time* $2^{O(k)}$.

In particular, applying Seysen's procedure to slide-reduced bases suffices. We include a proof of Theorem 8 and a high-level description of Seysen's procedure in Section 2.6.

2.4 The Lattice Distortion Problem

▶ **Definition 9.** For any $\gamma = \gamma(n) \geq 1$, the γ-Lattice Distortion Problem (γ-LDP) is the search problem defined as follows. The input consists of two lattices $\mathcal{L}_1, \mathcal{L}_2$ (represented by bases $B_1, B_2 \in \mathbb{Q}^{n \times n}$). The goal is to output a matrix $T \in \mathbb{R}^{n \times n}$ such that $T(\mathcal{L}_1) = \mathcal{L}_2$ and $\kappa(T) \leq \gamma \cdot \mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$.

▶ **Definition 10.** For any $\gamma = \gamma(n) \geq 1$, the γ-GapLDP is the promise problem defined as follows. The input consists of two lattices $\mathcal{L}_1, \mathcal{L}_2$ (represented by bases $B_1, B_2 \in \mathbb{Q}^{n \times n}$) and a number $c \geq 1$. The goal is to decide between a 'YES' instance where $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) \leq c$ and a 'NO' instance where $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2) > \gamma \cdot c$.

2.5 Complexity of LDP

We show some basic facts about the complexity of GapLDP. First, we show that the Lattice Isomorphism Problem (LIP) corresponds to the special case of GapLDP where $c = 1$. LIP takes bases of $\mathcal{L}_1, \mathcal{L}_2$ as input and asks if there exists an orthogonal linear transformation O such that $O(\mathcal{L}_1) = \mathcal{L}_2$. Haviv and Regev [15] show that there exists an $n^{O(n)}$-time algorithm for LIP, and that LIP is in the complexity class SZK.

▶ **Lemma 11.** *There is a polynomial-time reduction from LIP to* 1*-GapLDP.*

Proof. Let $\mathcal{L}_1, \mathcal{L}_2$ be an LIP instance. First check that $\det(\mathcal{L}_1) = \det(\mathcal{L}_2)$. If not, then output a trivial 'NO' instance of 1-GapLDP. Otherwise, map the LIP instance to the 1-GapLDP instance with the same input bases and $c = 1$. For any $T : \mathcal{L}_1 \to \mathcal{L}_2$, we must have $\det(T) = 1$, and therefore $\kappa(T) = 1$ if and only if $\|T\| = \|T^{-1}\| = 1$. So, this is a 'YES' instance of GapLDP if and only if $\mathcal{L}_1, \mathcal{L}_2$ are isomorphic. ◀

▶ **Lemma 12.** 1-*GapLDP is in* NP.

Proof. Let $I = (\mathcal{L}_1, \mathcal{L}_2, c)$ be an instance of GapLDP, and let s be the length of I. We will show that for a 'YES' instance, there are bases A, B of $\mathcal{L}_1, \mathcal{L}_2$ respectively such that $T = BA^{-1}$ requires at most poly(s) bits to specify and $\kappa(T) \le c$. Assume without loss of generality that $\mathcal{L}_1, \mathcal{L}_2 \subseteq \mathbb{Z}^n$. Otherwise, scale the input lattices to achieve this at the expense of a factor s blow-up in input size.

To satisfy $\|T\| \|T^{-1}\| \le c$, we must have that $|t_{ij}| \le \|T\| \le c \cdot \det(\mathcal{L}_2)/\det(\mathcal{L}_1) \le c \cdot \det(\mathcal{L}_2)$ for each entry t_{ij} of T. By Cramer's rule, each entry of A^{-1} and hence T will be an integer multiple of $\frac{1}{\det \mathcal{L}_1}$, so we can assume without loss of generality that the denominator of each entry of T is $\det \mathcal{L}_1$.

Combining these bounds and applying Hadamard's inequality, we get that $|t_{ij}|$ takes at most

$$\log(c \cdot \det(\mathcal{L}_1)\det(\mathcal{L}_2)) \le \log\Big(c \cdot \prod_{i=1}^{n} \|\mathbf{a}_i\| \prod_{i=1}^{n} \|\mathbf{b}_i\|\Big)$$

bits to specify. Accounting for the sign of each t_{ij}, it follows that T takes at most $n^2 \cdot \log(2c \cdot \prod_{i=1}^{n} \|\mathbf{a}_i\| \|\mathbf{b}_i\|) \le n^2 \cdot (s+1)$ bits to specify. ◀

We remark that we can replace c with the quantity $n^{O(\log n)} M(\mathcal{L}_1, \mathcal{L}_2) M(\mathcal{L}_2, \mathcal{L}_1)$ (as given by the upper bound in Theorem 1) in the preceding argument to obtain an upper bound on the distortion of an *optimal* mapping T that does not depend on c.

2.6 Basis reduction

In this section, we define various notions of basis reductions and show how to use them to prove Theorem 8.

For a basis $B = [\mathbf{b}_1, \dots, \mathbf{b}_n]$, we write $\pi_i^{(B)} := \pi_{\{\mathbf{b}_1, \dots, \mathbf{b}_{i-1}\}^\perp}$ to represent projection onto the subspace $\{\mathbf{b}_1, \dots, \mathbf{b}_{i-1}\}^\perp$. We then define the *Gram-Schmidt* orthogonalization of B, $(\tilde{b}_1, \dots, \tilde{b}_n)$ as $\tilde{b}_i = \pi_i^{(B)}(\mathbf{b}_i)$. By construction the vectors $\tilde{b}_1, \dots, \tilde{b}_n$ are orthogonal, and each $\mathbf{b}_i$ is a linear combination of $\tilde{b}_1, \dots, \tilde{b}_i$. We define $\mu_{ij} = \frac{\langle \mathbf{b}_i, \tilde{b}_j \rangle}{\langle \tilde{b}_j, \tilde{b}_j \rangle}$.

We define the QR-decomposition of a full-rank matrix B as $B = QR$ where Q has orthonormal columns, and R is upper triangular. The QR-decomposition of a matrix is unique, and can be computed efficiently by applying Gram-Schmidt orthogonalization to the columns of B.

Unimodular matrices, denoted $GL(n, \mathbb{Z})$, form the multiplicative group of $n \times n$ matrices with integer entries and determinant ± 1.

▶ **Fact 13.** $\mathcal{L}(B) = \mathcal{L}(B')$ *if and only if there exists* $U \in GL(n, \mathbb{Z})$ *such that* $B' = B \cdot U$.

Based on this, a useful way to view basis reduction is as right-multiplication by unimodular matrices.

2.6.1 Slide-reduced bases

A very strong notion of basis reduction introduced by Korkine and Zolotareff [18] gives one way of formalizing what it means to be a "shortest-possible" lattice basis.

▶ **Definition 14** ([18], Definition 1 in [30]). Let B be a basis of $\mathcal{L}$. $B = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ is HKZ (Hermite-Korkine-Zolotareff) reduced if

1. $\forall j < i$, $|\mu_{ij}| \leq \frac{1}{2}$;
2. $\|b_1\| = \lambda_1(\mathcal{L}(B))$; and
3. if $n > 1$, then $[\pi_2^{(B)}(\mathbf{b}_2), \ldots, \pi_2^{(B)}(\mathbf{b}_n)]$ is an HKZ basis of $\pi_2^{(B)}(\mathcal{L})$.

By definition, the first vector $\mathbf{b}_1$ in an HKZ basis is a shortest vector in the lattice. Furthermore, computing an HKZ basis can be achieved by making n calls to an SVP oracle. So, the two problems have the same time complexity up to a factor of n. In particular, computing HKZ bases is NP-hard.

Gama and Nguyen (building on the work of Schnorr [29]) introduced the notion of slide-reduced bases [10], which can be thought of as a relaxed notion of HKZ bases that can be computed more efficiently.

▶ **Definition 15** ([10, Definition 1]). Let B be a basis of $\mathcal{L} \subset \mathbb{Q}^n$ and $\varepsilon > 0$. We say that B is ε-DSVP (dual SVP) reduced if its corresponding dual basis $[\mathbf{b}_1^*, \ldots, \mathbf{b}_n^*]$ satisfies $\|\mathbf{b}_n^*\| \leq (1+\varepsilon) \cdot \lambda_1(\mathcal{L}^*)$.

Then, for $k \geq 2$ an integer dividing n, we say that $B = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ is (ε, k)-slide reduced if

1. $\forall j < i$, $|\mu_{ij}| \leq \frac{1}{2}$;
2. $\forall 0 \leq i \leq n/k - 1$, the "projected truncated basis" $[\pi_{ik+1}^{(B)}(\mathbf{b}_{ik+1}), \ldots, \pi_{ik+1}^{(B)}(\mathbf{b}_{ik+k})]$ is HKZ reduced; and
3. $\forall 0 \leq i \leq n/k-2$, the "shifted projected truncated basis" $[\pi_{ik+2}^{(B)}(\mathbf{b}_{ik+2}), \ldots, \pi_{ik+2}^{(B)}(\mathbf{b}_{ik+k+1})]$ is ε-DSVP reduced.

▶ **Theorem 16** ([10]). *There is an algorithm that takes as input a lattice $\mathcal{L} \subset \mathbb{Q}^n$, $\varepsilon > 0$, and integer $k \geq \log n$ dividing n and outputs a (k, ε)-slide-reduced basis of $\mathcal{L}$ in time* $\mathrm{poly}(1/\varepsilon) \cdot 2^{O(k)}$.

We will be particularly concerned with the ratios between the length of the Gram-Schmidt vectors of a given basis. We prefer bases whose Gram-Schmidt vectors do not "decay too quickly," and we measure this decay by

$$\eta(B) = \max_{i \leq j} \frac{\|\tilde{b}_i\|}{\|\tilde{b}_j\|} \ .$$

Previous work bounded $\eta(B)$ for HKZ-reduced bases as follows.

▶ **Theorem 17** ([19, Proposition 4.2]). *For any HKZ-reduced basis B over $\mathbb{Q}^n$, $\eta(B) \leq n^{O(\log n)}$.*

Using Theorem 17 and some of the results in [10] we get a bound on $\eta(B)$ for slide-reduced bases.

▶ Proposition 18. For any $\log n \leq k \leq n$, there is an algorithm that takes as input a lattice $\mathcal{L} \subset \mathbb{Q}^n$ and outputs a basis B of $\mathcal{L}$ such that $\eta(B) \leq k^{O(n/k + \log k)}$. Furthermore, the algorithm runs in time $2^{O(k)}$.

See the full version of this paper for a proof of Proposition 18.

2.6.2 Seysen bases

Although slide-reduced bases B consist of short vectors and have bounded $\eta(B)$, they make only weak guarantees about the length of vectors in the dual basis B^*. Of course, one way to compute a basis whose dual will contain short dual basis is short is to simply compute B such that B^* is a suitably reduced basis of $\mathcal{L}^*$. Such a basis B is called a dual-reduced basis, and sees use in applications such as [15].

However, we would like to compute a basis such that the vectors in B and B^* are both short, which Seysen addressed in his work [30]. Seysen's main result finds a basis B such that both B and B^* are short by dividing this problem into two subproblems. The first involves finding a basis with small $\eta(B)$, as in Section 2.6.1. The second subproblem, discussed in [30, Section 3], involves conditioning unipotent matrices. Let $N(n, \mathbb{R})$ be the multiplicative group of unipotent $n \times n$-matrices. That is, a matrix $A \in N(n, \mathbb{R})$ if $a_{ii} = 1$ and $a_{ij} = 0$ for $i > j$ (i.e., A is upper triangular and has ones on the main diagonal). Let $N(n, \mathbb{Z})$ be the subgroup of $N(n, \mathbb{R})$ with integer entries. Because $N(n, \mathbb{Z})$ is a subset of $GL(n, \mathbb{Z})$, we trivially have that $\mathcal{L}(B) = \mathcal{L}(B \cdot U)$ for every $U \in N(n, \mathbb{Z})$.

Let $\|B\|_\infty := \max_{i,j \in [n]} |b_{ij}|$ denote the largest magnitude of an entry in B. We follow Seysen [30] and define $S'(B) = \max\{\|B\|_\infty, \|B^{-1}\|_\infty\}$. We also let

$$\zeta(n) = \sup_{A \in N(n,\mathbb{R})} \Big\{ \inf_{U \in N(n,\mathbb{Z})} \{S'(A \cdot U)\} \Big\}.$$

▶ **Theorem 19** ([30, Prop. 5 and Thm. 6]). *There exists an algorithm* Seysen *that takes as input $A \in N(n, \mathbb{R})$ and outputs $A \cdot U$ where $U \in N(n, \mathbb{Z})$ and $S'(A \cdot U) \le n^{O(\log n)}$ in time $O(n^3)$. In particular, $\zeta(n) \le n^{O(\log n)}$.*

Let $B = QR$ be a QR-decomposition of B. We may further decompose R as $R = DR'$, where $d_{ii} = \|\tilde{b}_i\|$ and

$$r'_{ij} = \begin{cases} 0 & \text{if } j < i, \\ 1 & \text{if } j = i, \\ \mu_{ji} & \text{if } j > i. \end{cases}$$

In particular, note that $R' \in N(n, \mathbb{R})$. It is easy to see that $\eta(B)$ controls $\|D\|\|D^{-1}\|$. On the other hand, using the bound on $\zeta(n)$, we can always multiply B on the right by $U \in N(n, \mathbb{Z})$ to control the size of $\|R'\|\|R'^{-1}\|$. Roughly speaking, these two facts imply Theorem 20.

▶ **Theorem 20** ([30, Theorem 7]). *Let B =* Seysen*(B') where B' is a matrix. Then $S(B) \le n \cdot \eta(B') \cdot \zeta(n)^2$.*

Proof of Theorem 8. Let $B =$ Seysen(B'), where B' is a basis as computed in Proposition 18. We then have that

$$\begin{aligned} S(B) &\le n \cdot \eta(B') \cdot \zeta(n)^2 && \text{(by Theorem 20)} \\ &\le n \cdot k^{O(n/k + \log k)} \cdot \zeta(n)^2 && \text{(by Proposition 18)} \\ &\le n \cdot k^{O(n/k + \log k)} \cdot (n^{O(\log n)})^2 && \text{(by Theorem 19)} \\ &\le k^{O(n/k + \log k)}. \end{aligned}$$

We can compute B' in $2^{O(k)}$ time using Proposition 18. Moreover, by Theorem 19, Seysen runs in $O(n^3)$ time. Therefore the algorithm runs in $2^{O(k)}$ time. ◀

3 Approximating lattice distortion

In this section, we show how to compute low-distortion mappings between lattices by using bases with low $S(B)$.

3.1 Basis length bounds in terms of $S(B)$

Call a basis $B = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ *sorted* if $\|\mathbf{b}_1\| \le \cdots \le \|\mathbf{b}_n\|$. Clearly, $\|\mathbf{b}_i\| / \lambda_i \ge 1$ for a sorted basis B. Note that sorting B does not change $S(B)$, since $S(\cdot)$ is invariant under permutations of the basis vectors.

A natural way to quantify the "shortness" of a lattice basis is to upper bound $\|\mathbf{b}_k\| / \lambda_k$ for all $k \in [n]$. For example, [19] shows that $\|\mathbf{b}_k\| / \lambda_k \le \sqrt{n}$ when B is an HKZ basis. We prove a characterization of Seysen-reduced bases, showing that *both* the primal basis vectors and the dual basis vectors are not much longer than the successive minima. Namely, we show that $S(B)$ is an upper bound on both $\|\mathbf{b}_k\| / \lambda_k$ and $\|\mathbf{b}_k^*\| / \lambda_{n-k+1}^*$ for sorted bases B. This characterization is key to bounding the distortion between two lattices, and it might be of independent interest.

▶ **Lemma 21.** *Let B be a sorted basis of $\mathcal{L}$. Then $\max_{k \in [n]} \|\mathbf{b}_k\| / \lambda_k \le S(B)$.*

Proof. For every $k \in [n]$, we have

$$\begin{aligned}
\|\mathbf{b}_k\| / \lambda_k &\le \|\mathbf{b}_k\| \lambda_{n-k+1}^* && \text{(by the lower bound in Theorem 6)} \\
&\le \|\mathbf{b}_k\| \max_{i \in \{k,\ldots,n\}} \|\mathbf{b}_i^*\| && \text{(the } \mathbf{b}_i^* \text{ are linearly independent)} \\
&\le \max_{i \in \{k,\ldots,n\}} \|\mathbf{b}_i\| \|\mathbf{b}_i^*\| && (B \text{ is sorted}) \\
&\le S(B).
\end{aligned}$$

◀

▶ **Lemma 22.** *Let B be a sorted basis of $\mathcal{L}$. Then $\max_{k \in [n]} \|\mathbf{b}_k^*\| / \lambda_{n-k+1}^* \le S(B)$.*

Proof. For every $k \in [n]$, we have

$$\frac{\|\mathbf{b}_k^*\|}{\lambda_{n-k+1}^*} \le \frac{\|\mathbf{b}_k\| \|\mathbf{b}_k^*\|}{\lambda_k \lambda_{n-k+1}^*} \le \max_{i \in [n]} \|\mathbf{b}_i\| \|\mathbf{b}_i^*\| = S(B).$$

The first inequality follows from the assumption that B is sorted, and the second follows from the lower bound in Theorem 6. ◀

3.2 Approximating LDP using Seysen bases

In this section, we bound the distortion $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$ between lattices $\mathcal{L}_1, \mathcal{L}_2$. The upper bound is constructive and depends on $S(B_1), S(B_2)$, which naturally leads to Theorem 4.

▶ **Lemma 23.** *Let $A = [\mathbf{a}_1, \ldots, \mathbf{a}_n]$ and $B = [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ be sorted bases of $\mathcal{L}_1, \mathcal{L}_2$ respectively. Then,*

$$\|BA^{-1}\| \le n^2 S(A) S(B) M(\mathcal{L}_1, \mathcal{L}_2).$$

Proof.

$$\begin{aligned}
\|BA^{-1}\| &= \Big\| \sum_{i=1}^{n} \mathbf{b}_i (\mathbf{a}_i^*)^T \Big\| \\
&\le \sum_{i=1}^{n} \|\mathbf{b}_i (\mathbf{a}_i^*)^T\| && \text{(by triangle inequality)} \\
&= \sum_{i=1}^{n} \|\mathbf{b}_i\| \, \|\mathbf{a}_i^*\| \\
&\le n \max_{i \in [n]} \|\mathbf{b}_i\| \, \|\mathbf{a}_i^*\| \\
&\le nS(B) \max_{i \in [n]} \lambda_i(\mathcal{L}_2) \, \|\mathbf{a}_i^*\| && \text{(by Lemma 21)} \\
&\le nS(A)S(B) \max_{i \in [n]} \lambda_i(\mathcal{L}_2) \lambda_{n-i+1}^*(\mathcal{L}_1) && \text{(by Lemma 22)} \\
&\le n^2 S(A)S(B)M(\mathcal{L}_1, \mathcal{L}_2). && \text{(by Theorem 6)}
\end{aligned}$$

◀

Proof of Theorem 2. Note that by definition there always exist bases B_1, B_2 of $\mathcal{L}_1, \mathcal{L}_2$ respectively achieving $S(B_i) = S(\mathcal{L}_i)$. Therefore, applying Lemma 23 twice to bound both $\|B_2 B_1^{-1}\|$ and $\|B_1 B_2^{-1}\|$, we get the upper bound.

For the lower bound, let $\mathbf{v}_1, \ldots, \mathbf{v}_n \in \mathcal{L}_1$ be linearly independent vectors such that $\|\mathbf{v}_i\| = \lambda_i(\mathcal{L}_1)$ for every i. Then, for every i,

$$\lambda_i(\mathcal{L}_2) \le \max_{j \in [i]} \|T\mathbf{v}_j\| \le \|T\| \max_{j \in [i]} \|\mathbf{v}_j\| = \|T\| \, \lambda_i(\mathcal{L}_1).$$

Rearranging, we get that $\lambda_i(\mathcal{L}_2)/\lambda_i(\mathcal{L}_1) \le \|T\|$. This holds for arbitrary i, so in particular $\max_{i \in [n]} \lambda_i(\mathcal{L}_2)/\lambda_i(\mathcal{L}_1) = M(\mathcal{L}_1, \mathcal{L}_2) \le \|T\|$. The same computation with $\mathcal{L}_1, \mathcal{L}_2$ reversed shows that $M(\mathcal{L}_2, \mathcal{L}_1) \le \|T^{-1}\|$. Multiplying these bounds together implies the lower bound in the theorem statement. ◀

We can now prove Theorem 4.

Proof of Theorem 4. Let $(\mathcal{L}_1, \mathcal{L}_2)$ be an instance of LDP. For $i = 1, 2$, compute a basis B_i of $\mathcal{L}_i$ using the algorithm described in Theorem 8 with parameter k. We have that $S(B_i) \le k^{O(n/k + \log k)}$. This computation takes $2^{O(k)}$ time. The algorithm then simply outputs $T = B_2 B_1^{-1}$.

By Lemma 23 and the upper bounds on $S(B_i)$, we get that $\kappa(T) \le k^{O(n/k + \log k)} \cdot M(\mathcal{L}_1, \mathcal{L}_2) \cdot M(\mathcal{L}_2, \mathcal{L}_1)$. This is within a factor of $k^{O(n/k + \log k)} \cdot n^{O(\log n)} = k^{O(n/k + \log k)}$ of $\mathcal{D}(\mathcal{L}_1, \mathcal{L}_2)$ by Theorem 1. So, the algorithm is correct. ◀

4 Hardness of LDP

In this section, we prove the hardness of γ-GapLDP. (See Theorem 31.) Our reduction works in two steps. First, we show how to use an oracle for GapLDP to solve a variant of GapCVP that we call γ-GapCVP$^\alpha$. (See Definition 24 and Theorem 26.) Given a CVP instance consisting of a lattice $\mathcal{L}$ and a target vector $\mathbf{t}$, our idea is to compare "$\mathcal{L}$ with $\mathbf{t}$ appended to it" to "$\mathcal{L}$ with an extra orthogonal vector appended to it." (See Eq. (3).) We show that, if $\operatorname{dist}(\mathbf{t}, \mathcal{L})$ is small, then these lattices will be similar. On the other hand, if (1) $\operatorname{dist}(k\mathbf{t}, \mathcal{L})$ is large for all non-zero integers k, and (2) $\lambda_1(\mathcal{L})$ is not too small; then the two lattices must be quite dissimilar.

We next show that γ-GapCVP$^\alpha$ is as hard as GapSVP. (See Theorem 29.) This reduction is a variant of the celebrated reduction of [13]. It differs from the original in that it "works in base p" instead of in base two, and it "adds an extra coordinate to $\mathbf{t}$." We show that this is sufficient to satisfy the promises required by γ-GapCVP$^\alpha$.

Both reductions are relatively straightforward.

4.1 Reduction from a variant of CVP

▶ **Definition 24.** For any $\gamma = \gamma(n) \geq 1$ and $\alpha = \alpha(n) > 0$, γ-GapCVP$^\alpha$ is the promise problem defined as follows. The input is a lattice $\mathcal{L} \subset \mathbb{Q}^n$, a target $\mathbf{t} \in \mathbb{Q}^n$, and a distance $d > 0$. It is a 'YES' instance if $\mathrm{dist}(\mathbf{t}, \mathcal{L}) \leq d$ and a 'NO' instance if $\mathrm{dist}(k\mathbf{t}, \mathcal{L}) > \gamma d$ for all non-zero integers k *and* $d < \alpha \cdot \lambda_1(\mathcal{L})$.

We will need the following characterization of the operator norm of a matrix in terms of its behavior over a lattice. Intuitively, this says that "a lattice has a point in every direction."

▶ **Fact 25.** *For any matrix $A \in \mathbb{R}^{n\times n}$ and (full-rank) lattice $\mathcal{L} \subset \mathbb{R}^n$,*

$$\|A\| = \sup_{\mathbf{y}\in\mathcal{L}\setminus\{0\}} \frac{\|A\mathbf{y}\|}{\|\mathbf{y}\|} \ .$$

Proof. It suffices to note that, for any $\mathbf{x} \in \mathbb{R}^n$ with $\|\mathbf{x}\| = 1$ and any full-rank lattice $\mathcal{L} \subset \mathbb{R}^n$, there is a sequence $\mathbf{y}_1, \mathbf{y}_2, \ldots$ of vectors $\mathbf{y}_i \in \mathcal{L}$ such that

$$\lim_{m\to\infty} \frac{\mathbf{y}_m}{\|\mathbf{y}_m\|} = \mathbf{x} \ .$$

Indeed, this follows immediately from the fact that the rationals are dense in the reals. ◀

▶ **Theorem 26.** *For any $\gamma = \gamma(n) \geq 1$, there is an efficient reduction from γ'-*GapCVP$^{1/\gamma'}$ *to γ-GapLDP, where $\gamma' = O(\gamma)$.*

Proof. On input $\mathcal{L} \subset \mathbb{Q}^n$ with basis $(\mathbf{b}_1, \ldots, \mathbf{b}_n)$, $\mathbf{t} \in \mathbb{Q}^n$, and $d > 0$, the reduction behaves as follows. Let $\mathcal{L}_1 := \mathcal{L}(\mathbf{b}_1, \ldots, \mathbf{b}_n, r \cdot \mathbf{e}_{n+1})$ with $r > 0$ to be set in the analysis. Let $\mathcal{L}_2 := \mathcal{L}(\mathbf{b}_1, \ldots, \mathbf{b}_n, \mathbf{t} + r \cdot \mathbf{e}_{n+1})$. I.e.,

$$\mathcal{L}_1 = \mathcal{L}\begin{pmatrix} B & \mathbf{0} \\ 0 & r \end{pmatrix} \qquad\qquad \mathcal{L}_2 = \mathcal{L}\begin{pmatrix} B & \mathbf{t} \\ 0 & r \end{pmatrix} . \tag{3}$$

(Formally, we must embed the $\mathbf{b}_i$ and $\mathbf{t}$ in $\mathbb{Q}^{n+1}$ under the natural embedding, but we ignore this for simplicity.) The reduction then calls its γ-GapLDP oracle with input $\mathcal{L}_1$, $\mathcal{L}_2$, and $c > 0$ to be set in the analysis and outputs its response.

It is clear that the reduction runs in polynomial time. Suppose that $\mathrm{dist}(\mathbf{t}, \mathcal{L}) \leq d$. We note that $\mathcal{L}_2$ does not change if we shift $\mathbf{t}$ by a lattice vector. So, we may assume without loss of generality that $\mathbf{0}$ is a closest lattice vector to $\mathbf{t}$ and therefore $\|\mathbf{t}\| \leq d$.

Let $B_1 := [\mathbf{b}_1, \ldots, \mathbf{b}_n, r \cdot \mathbf{e}_{n+1}]$ and $B_2 := [\mathbf{b}_1, \ldots, \mathbf{b}_n, \mathbf{t} + r \cdot \mathbf{e}_{n+1}]$ be the bases from the reduction. It suffices to show that $\kappa(B_2 B_1^{-1})$ is small. Indeed, for any $\mathbf{y} \in \mathcal{L}_1$, we can write $\mathbf{y} = (\mathbf{y}', kr)$ for some $k \in \mathbb{Z}$ and $\mathbf{y}' \in \mathcal{L}$. Then, we have

$$\|B_2 B_1^{-1}\mathbf{y}\| = \|(\mathbf{y}' + k\mathbf{t}, kr)\| \leq \|(\mathbf{y}', kr)\| + |k|\|\mathbf{t}\| \leq (1 + d/r)\|\mathbf{y}\| \ .$$

Similarly, $\|B_2B_1^{-1}\mathbf{y}\| \geq \|\mathbf{y}\| - |k|\|\mathbf{t}\| \geq (1-d/r)\|\mathbf{y}\|$. Therefore, by Fact 25, $\kappa(B_2B_1^{-1}) \leq (1+d/r)/(1-d/r)$. So, we take $c := (1+d/r)/(1-d/r)$, and the oracle will therefore output 'YES'.

Now, suppose $\operatorname{dist}(z\mathbf{t}, \mathcal{L}) > 10\gamma d$ for all non-zero integers z, and $\lambda_1(\mathcal{L}) > 10\gamma d$. (I.e., we take $\gamma' = 10\gamma = O(\gamma)$.) Let A be a linear map with $A\mathcal{L}_1 = \mathcal{L}_2$. Note that A has determinant one, so that $\kappa(A) \geq \frac{\|A\mathbf{x}\|}{\|\mathbf{x}\|}$ for any $\mathbf{x} \in \mathbb{Q}^{n+1} \setminus \{\mathbf{0}\}$. We have that $A(\mathbf{0}, r) = (\mathbf{y}', kr)$ for some $\mathbf{y}' \in \mathcal{L} + k\mathbf{t}$ and $k \in \mathbb{Z}$. If $k \neq 0$, then $\|A(\mathbf{0}, r)\| \geq \operatorname{dist}(k\mathbf{t}, \mathcal{L}) > 10\gamma d$. So, $\kappa(A) \geq \|A(\mathbf{0}, r)\|/r > 10\gamma d/r$.

If, on the other hand, $k = 0$, then $\mathbf{y}' \in \mathcal{L} \setminus \{\mathbf{0}\}$ and $\|A(\mathbf{0}, r)\| = \|(\mathbf{y}', 0)\| \geq \lambda_1(\mathcal{L}) > 10\gamma d$, so that we again have $\kappa(A) \geq \|A(\mathbf{0}, r)\|/r > 10\gamma d/r$. Taking $r = 2\gamma d$ gives $\kappa(A) > \gamma \cdot c$, so that the oracle will output 'NO', as needed. ◀

4.2 Hardness of This Variant of GapCVP

We recall the definition of (the decision version of) γ-GapSVP.

▶ **Definition 27.** For any $\gamma = \gamma(n) \geq 1$, γ-GapSVP is the promise problem defined as follows: The input is a lattice $\mathcal{L} \subset \mathbb{Q}^n$, and a distance $d > 0$. It is a 'YES' instance if $\lambda_1(\mathcal{L}) \leq d$ and a 'NO' instance if $\lambda_1(\mathcal{L}) > \gamma d$.

Haviv and Regev (building on work of Ajtai, Micciancio, and Khot [2, 22, 17]) proved the following strong hardness result for γ-GapSVP [14].

▶ **Theorem 28** ([14, Theorem 1.1]).
1. *γ-GapSVP is* NP*-hard under randomized polynomial-time reductions for any constant $\gamma \geq 1$. I.e., there is no randomized polynomial-time algorithm for γ-GapSVP unless* NP $\subseteq$ RP.
2. *$2^{\log^{1-\varepsilon} n}$-GapSVP is* NP*-hard under randomized quasipolynomial-time reductions for any constant $\varepsilon > 0$. I.e., there is no randomized polynomial-time algorithm for $2^{\log^{1-\varepsilon} n}$-GapSVP unless* NP $\subseteq$ RTIME$(2^{\mathrm{polylog}(n)})$.
3. *$n^{c/\log\log n}$-GapSVP is* NP*-hard under randomized subexponential-time reductions for some universal constant $c > 0$. I.e., there is no randomized polynomial-time algorithm for $n^{c/\log\log n}$-GapSVP unless* NP $\subseteq$ RSUBEXP $:= \bigcap_{\delta>0}$ RTIME(2^{n^δ}).

In particular, to prove Theorem 5, it suffices to reduce γ'-GapSVP to γ-CVP$^{1/\gamma}$ for $\gamma' = O(\gamma)$.

▶ **Theorem 29.** *For any $1 \leq \gamma = \gamma(n) \leq \mathrm{poly}(n)$, there is an efficient reduction from γ'-GapSVP to γ-*GapCVP$^{1/\gamma}$*, where $\gamma' = \gamma \cdot (1 + o(1))$.*

Proof. Let p be a prime with $10\gamma n \leq p \leq 20\gamma n \leq \mathrm{poly}(n)$. We take $\gamma' = \gamma \cdot (1 + o(1))$ so that

$$\gamma = \frac{\gamma'}{\sqrt{1 - \gamma'^2/(p-1)^2}}.$$

On input a basis $B := [\mathbf{b}_1, \ldots, \mathbf{b}_n]$ for a lattice $\mathcal{L} \subset \mathbb{Q}^n$, and $d > 0$, the reduction behaves as follows. For $i = 1, \ldots, n$, let $\mathcal{L}_i := \mathcal{L}(\mathbf{b}_1, \ldots, p\mathbf{b}_i, \ldots, \mathbf{b}_n)$ be "$\mathcal{L}$ with its ith basis vector multiplied by p." And, for all i and $1 \leq j < p$, let $\mathbf{t}_{i,j} := j\mathbf{b}_i + r\mathbf{e}_{n+1}$, with $r > 0$ to be set in the analysis. For each i, j, the reduction calls its γ-GapCVP$^{1/\gamma}$ oracle on input $\mathcal{L}_i$, $\mathbf{t}_{i,j}$, and $d' := \sqrt{d^2 + r^2}$. Finally, it outputs 'YES' if the oracle answered 'YES' for any query. Otherwise, it outputs 'NO'.

It is clear that the algorithm is efficient. Note that

$$\operatorname{dist}(j\mathbf{b}_i, \mathcal{L}_i) = \min\left\{ \Big\| \sum_{\ell=1}^{n} a_\ell \mathbf{b}_\ell \Big\| \ : \ a_\ell \in \mathbb{Z},\ a_i \equiv j \bmod p \right\} .$$

In particular, $\lambda_1(\mathcal{L}) = \min_{i,j} \operatorname{dist}(j\mathbf{b}_i, \mathcal{L}_i)$.

So, suppose $\lambda_1(\mathcal{L}) \le d$. Then, there must be some i, j such that $\operatorname{dist}(\mathbf{t}_{i,j}, \mathcal{L}_i)^2 \le r^2 + \lambda_1(\mathcal{L})^2 \le r^2 + d^2 = d'^2$. So, the oracle answers 'YES' at least once.

Now, suppose $\lambda_1(\mathcal{L}) > \gamma' d$. Since $\mathcal{L}_i \subset \mathcal{L}$, we have $\lambda_1(\mathcal{L}_i) \ge \lambda_1(\mathcal{L}) > \gamma' d$, and therefore $d < \lambda_1(\mathcal{L}_i)/\gamma' < \lambda_1(\mathcal{L}_i)/\gamma$, as needed. And, by the above observation, we have $\operatorname{dist}(j\mathbf{b}_i, \mathcal{L}_i) \ge \lambda_1(\mathcal{L}) > \gamma' d$ for all $1 \le i \le n$ and $1 \le j < p$. Furthermore, for any integer $1 \le z < p$, we have $\operatorname{dist}(zj\mathbf{b}_i, \mathcal{L}_i) = \operatorname{dist}((zj \bmod p) \cdot \mathbf{b}_i, \mathcal{L}_i) > \gamma' d$, where we have used the fact that p is prime so that $zj \not\equiv 0 \bmod p$. It follows that $\operatorname{dist}(z\mathbf{t}_{i,j}, \mathcal{L}_i) > \operatorname{dist}(zj\mathbf{b}_i, \mathcal{L}_i) > \gamma' d$. And, for $z \ge p$, it is trivially the case that $\operatorname{dist}(z\mathbf{t}_{i,j}, \mathcal{L}_i) \ge zr \ge pr$. Taking $r := \gamma' d/(p-1)$, we have that in both cases

$$\operatorname{dist}(z\mathbf{t}_{i,j}, \mathcal{L}_i) > \gamma' d = \frac{\gamma' d'}{\sqrt{1 - r^2}} = \frac{\gamma' d'}{\sqrt{1 - \gamma'^2/(p-1)^2}} = \gamma d .$$

So, the oracle will always answer 'NO'. ◀

▶ **Corollary 30.** *For any $1 \le \gamma = \gamma(n) \le \operatorname{poly}(n)$, there is an efficient reduction from γ'-GapSVP to γ-GapLDP, where $\gamma' = O(\gamma)$.*

Proof. Combine Theorems 26 and 29. ◀

With this, the proof of our main hardness result is immediate.

▶ **Theorem 31.** *The three hardness results in Theorem 28 hold with GapLDP in place of GapSVP.*

Proof. Combine Theorem 28 with Corollary 30. ◀

5 Some illustrative examples

5.1 Separating distortion from the successive minima

We now show that, for every n, there exists a $\mathcal{L}$ such that $\mathcal{D}(\mathcal{L}, \mathbb{Z}^n) \ge \Omega(\sqrt{n}) \cdot M(\mathcal{L}, \mathbb{Z}^n) \cdot M(\mathbb{Z}^n, \mathcal{L})$. Indeed, it suffices to take any lattice with $\det(\mathcal{L})^{1/n} \le O(n^{-1/2})$ but $\lambda_i(\mathcal{L}) = \Theta(1)$. (This is true for almost all lattices in a certain precise sense. See, e.g., [31].)

▶ **Lemma 32.** *For any $n \ge 1$, there is a lattice $\mathcal{L} \subset \mathbb{Q}^n$ such that $\det(\mathcal{L})^{1/n} \le O(n^{-1/2})$ and $\lambda_i(\mathcal{L}) = \Theta(1)$ for all i.*

▶ Proposition 33. For any $n \ge 1$, there exists a lattice $\mathcal{L} \subset \mathbb{Q}^n$ such that

$$\mathcal{D}(\mathcal{L}, \mathbb{Z}^n) \ge \Omega(\sqrt{n}) \cdot M(\mathcal{L}, \mathbb{Z}^n) \cdot M(\mathbb{Z}^n, \mathcal{L}) .$$

Proof. Let $\mathcal{L} \subset \mathbb{Q}^n$ be any lattice as in Lemma 32. In particular, $M(\mathcal{L}, \mathbb{Z}^n) \cdot M(\mathbb{Z}^n, \mathcal{L}) = O(1)$. However, for any linear map T with $T(\mathcal{L}) = \mathbb{Z}^n$, we of course have

$$\|T\| \ge |\det(T)|^{1/n} = \det(\mathbb{Z}^n)^{1/n} / \det(\mathcal{L})^{1/n} \ge \Omega(\sqrt{n}) .$$

(To see the first inequality, it suffices to recall that $|\det(T)| = \prod \sigma_i$ and $\|T\| = \max \sigma_i$, where the σ_i are the singular values of T.) And, $T^{-1}\mathbf{e}_1$ must be a non-zero lattice vector, so $\|T^{-1}\| \ge \|T^{-1}\mathbf{e}_1\| \ge \lambda_1(\mathcal{L}) \ge \Omega(1)$. Therefore, $\kappa(T) = \|T\|\|T^{-1}\| \ge \Omega(\sqrt{n})$, as needed. ◀

5.2 Non-optimality of HKZ bases for distortion

We show an example demonstrating that mappings between lattices built using HKZ bases are non-optimal in terms of their distortion. Namely, we give a family of $n \times n$ HKZ bases $\{B_n\}$ such that $\mathcal{D}(\mathbb{Z}^n, \mathcal{L}(B_n)) \leq n^{O(\log n)}$, but where the mapping $T = B_n$ from $\mathbb{Z}^n$ to $\mathcal{L}(B_n)$ has exponential distortion. This shows the necessity of using Seysen reduction in addition to HKZ reduction.

▶ **Theorem 34.** *For every $n \geq 1$, there exists an $n \times n$ HKZ basis B such that $\mathcal{D}(\mathbb{Z}^n, \mathcal{L}(B)) \leq n^{O(\log n)}$, but $\kappa(B) \geq \Omega(1.5^n)$.*

Recall that $\|B\|_\infty$ denotes the largest magnitude of an entry in B. It holds that $\|B\|_\infty \leq \|B\| \leq n\,\|B\|_\infty$.

▶ **Lemma 35.** *Let $B = B_n$ denote the $n \times n$ basis defined as*

$$b_{ij} = \begin{cases} 0 & \text{if } j < i, \\ 1 & \text{if } j = i, \\ -\frac{1}{2} & \text{if } j > i. \end{cases}$$

Then B is an HKZ basis and $\kappa(B) = \Omega(1.5^n)$.

Proof. For every basis A, it holds that $\min_{i\in[n]} \|\tilde{\mathbf{a}}_i\| \leq \lambda_1(\mathcal{L}(A))$ (see, e.g., [27]). Note that for $i \geq 0$ the i^{th} Gram-Schmidt vector of $(\pi_k^{(B)}(\mathbf{b}_k), \dots, \pi_k^{(B)}(\mathbf{b}_n))$ is simply $\tilde{b}_{i+k}$. Let $k \in [n]$. We then have that $1 = \min_{i\in[n]} \|\tilde{b}_i\| \leq \lambda_1(\pi_k(\mathcal{L}))$. On the other hand, $\lambda_1(\pi_k(\mathcal{L})) \leq \|\tilde{b}_k\| = \left\|\pi_k^{(B)}(\mathbf{b}_k)\right\| = 1$, implying that $\lambda_1(\pi_k(\mathcal{L}(B))) = 1$. It follows that B is an HKZ basis.

Because $\|B\|_\infty = 1$, it suffices to show that $\|B^{-1}\|_\infty \geq \Omega(1.5^n)$. Let $\mathbf{x}$ denote the nth column of B^{-1}. We must then have that $B\mathbf{x} = e_n$. Because B is upper triangular, we get the following formula by back substitution (see, e.g., [33]):

$$x_j = \begin{cases} 1 & \text{if } j = n, \\ \frac{1}{2}\sum_{k=j+1}^{n} x_k & \text{otherwise.} \end{cases} \tag{4}$$

We therefore have that $x_n = 1, x_{n-1} = \frac{1}{2}$. Using Eq. (4), we get that for $1 \leq m \leq n-2$,

$$x_m = \frac{1}{2}\sum_{k=m+1}^{n} x_k = \frac{1}{2}\cdot x_{m+1} + \frac{1}{2}\cdot\sum_{k=m+2}^{n} x_k = 1.5 \cdot x_{m+1} \; .$$

Applying this formula recursively, we get that $x_m = \frac{1}{2}\cdot 1.5^{n-m-1}$ for $1 \leq m \leq n-1$. ◀

The proof of Theorem 34 follows.

Proof of Theorem 34. Let $B' = B_n$ be an HKZ basis as specified in Lemma 35, and take I_n as the basis of $\mathbb{Z}_n$. Then $\kappa(B' \cdot I_n) = \Omega(1.5^n)$.

On the other hand, let $B = \text{SEYSEN}(B')$. Then, because $\eta(B') = 1$, $S(B) = n^{O(\log n)}$ by Theorem 20. Clearly, $\lambda_i(\mathbb{Z}_n) = 1$ for all $i \in [n]$. On the other hand, $1 \leq \lambda_i(\mathcal{L}(B)) \leq \sqrt{n}$ for all $i \in [n]$. The lower bound holds because $\min \|\tilde{b}_i\| = 1$, and the upper bound comes from the fact that $\|\mathbf{b}_i'\| \leq \sqrt{n}$ for all $i \in [n]$ and the linear independence of the $\mathbf{b}_i'$.[1] It follows that $M(\mathbb{Z}^n, \mathcal{L}(B)) \leq \sqrt{n}$ and $M(\mathcal{L}(B), \mathbb{Z}^n) \leq 1$. Applying Lemma 23 to B and B^{-1}, we then get that $\kappa(B \cdot I_n) \leq n^{O(\log n)}$. ◀

[1] In fact, $\lambda_n(\mathcal{L}(B)) = O(1)$.

Abstract

We consider *plurality consensus* in networks of n nodes. Initially, each node has one of k opinions. The nodes execute a (randomized) distributed protocol to agree on the *plurality opinion* (the opinion initially supported by the most nodes). In certain types of networks the nodes can be quite cheap and simple, and hence one seeks protocols that are not only time efficient but also simple and space efficient. Typically, protocols depend heavily on the employed communication mechanism, which ranges from sequential (only one pair of nodes communicates at any time) to fully parallel (all nodes communicate with all their neighbors at once) and everything in-between.

We propose a framework to design protocols for a multitude of communication mechanisms. We introduce protocols that solve the plurality consensus problem and are, with probability $1 - o(1)$, both time and space efficient. Our protocols are based on an interesting relationship between plurality consensus and distributed load balancing. This relationship allows us to design protocols that generalize the state of the art for a large range of problem parameters.

1 Introduction

The objective in the *plurality consensus* problem is to find the so-called *plurality opinion* (i.e., the opinion that is initially supported by the largest subset of nodes) in a network G where, initially, each of the n nodes has one of k opinions. Applications of this problem include distributed computing [20, 30, 31], social networks [29, 17, 28], as well as modeling of biological interactions [16, 15]. All these areas typically demand both very simple and space-efficient protocols. Communication models, however, can vary from anything between simple sequential communication with a single neighbor (often used in biological settings as a simple variant of asynchronous communication [5]) to fully parallel communication where all nodes communicate with all their neighbors simultaneously (like broadcasting models in distributed computing). This diversity turns out to be a major obstacle in algorithm

design, since protocols (and their analyses) to a large degree depend upon the employed communication mechanism.

In this paper we present two simple plurality consensus protocols called Shuffle and Balance. Both protocols work in a very general discrete-time communication model. The communication partners are determined by a (possibly randomized) sequence $(\boldsymbol{M}_t)_{t \leq N}$ of *communication matrices*, where we assume[1] N to be some suitably large polynomial in n. That is, nodes u and v can communicate in round t if and only if $\boldsymbol{M}_t[u, v] = 1$. In that case, we call the edge $\{ u, v \}$ *active*; see [6, 32] for related graph models. Our results allow for a wide class of communication patterns (which can even vary over time) as long as the communication matrices have certain "smoothing" properties (cf. Section 2). These smoothing properties are inspired by similar smoothing properties used by Thomas Sauerwald and He Sun [32] for load balancing in the dimension exchange model. In fact, load balancing is the source of inspiration for our protocols. Initially, each node creates a suitably chosen number of tokens labeled with its own opinion. Our Balance protocol then performs discrete load balancing on these tokens, allowing each node to get an estimate on the total number of tokens for each opinion. The Shuffle protocol keeps the number of tokens on every node fixed, but shuffles tokens between communication partners. By keeping track of how many tokens of their own opinion (label) were exchanged in total, nodes gain an estimate on the total (global) number of such tokens. Together with a simple broadcast routine, all nodes can determine the plurality opinion.

The running time of our protocols is the smallest time t for which all nodes have stabilized on the plurality opinion. That is, all nodes have determined the plurality opinion and will not change. This time depends on the network G, the communication pattern $(\boldsymbol{M}_t)_{t \leq N}$, and the initial bias towards the plurality opinion (cf. Section 2). For both protocols we show a strong correlation between their running time, the mixing time of certain random walks and the (related) *smoothing time*, both of which are used in the analysis of recent load balancing results [32]. To give some more concrete examples of our results, let $T \coloneqq \mathrm{O}\left(\log n/(1 - \lambda_2)\right)$, where $1 - \lambda_2$ is the spectral gap of G. If the bias is sufficiently high, then both our protocols Shuffle and Balance determine the plurality opinion in time

- $n \cdot T$ in the *sequential model* (only one pair of nodes communicates per time step);
- $d \cdot T$ in the *balancing circuit model* (communication partners are chosen according to d (deterministic) perfect matchings in a round-robin fashion); and
- T in the *diffusion model* (all nodes communicate with all their neighbors at once).

To the best of our knowledge, these match the best known bounds in the corresponding models. For an arbitrary bias (in particular, *arbitrarily small* bias), the protocols differ in their time and space requirements. More details of our results can be found in Section 1.2.

1.1 Related Work

There is a diverse body of literature that analyzes consensus problems under various models and assumptions. Results differ in the considered topology (e.g., arbitrary or complete), the restrictions on model parameters (e.g., the number of opinions or the *initial bias*[2]), the time model (synchronous or asynchronous), or the required knowledge (e.g., n, maximal degree,

[1] For simplicity and without loss of generality; our protocols run in polynomial time in all considered models.

[2] The bias is $\alpha \coloneqq (n_1 - n_2)/n$, n_1 and n_2 being the support of the most and second most common opinions.

Table 1 Summary of plurality consensus results.

	Arbitrary Graph	Number of Opinions	Required Bias α O-notation	Time O-notation	Model	Space O-notation
Shuffle	✓	arbitrary	arbitrary	$T \cdot t_{\text{mix}}$ $T \cdot \log(n)/(1-\lambda_2)$ (d-reg graph)	sync & async	see Theorem 2
Balance	✓	arbitrary	arbitrary	τ $\log(n)/(1-\lambda_2)$ (d-reg graph)	sync & async	$k \cdot \log(n)$
[26]	✓	arbitrary	arbitrary	$D + \frac{F_2}{n_1^2} \cdot \log(k)$	broadcast	–
[27]	✓	2	arbitrary	n^5	async	1
[21]	✓	2	arbitrary	$\log n/\delta(G, n_1/n)$	async	1
[19]	expander	2	$vol(1) - vol(2) \geq 4\lambda_2^2 \cdot \lvert E \rvert$	$\log(n)$	sync	1
[18]	random d-reg	2	$\sqrt{1/d + d/n}$	$\log(n)$	sync	1
[9]	✗	$\leq n$	$\sqrt{\min\left\{k, \sqrt[3]{\frac{n}{\log(n)}}\right\} \cdot \frac{\log(n)}{n}}$	$\min\left\{k, \sqrt[3]{\frac{n}{\log(n)}}\right\} \cdot \log n$	sync	$\log(k)$
[8]	✗	$O((\frac{n}{\log(n)})^{1/3})$	$\epsilon \cdot n_2/n$	$md(c) \cdot \log(n)$	sync	$\log(k)$
[23]	✗	$O(n^\epsilon)$	$\sqrt{\log n/n}$	$k + \log(n)$	sync	$\log(k)$
[13]	✗	$o(\sqrt{n/\log(n)})$	$\gg \sqrt{\log n/n}$	$\log(n) \cdot \log\log(n)$	sync	$\log(k)$
[2]	✗	2	arbitrary	$\frac{\log^2(n)}{s\alpha} + \log^2(n)$	async	$s = O(n)$ states
[3]	✗	2	$\gg \log(n)/\sqrt{n}$	$\log(n)$	async	1

Shuffle assumes rough bounds on t_{mix} and n. Bounds on α can reduce the space requirements of our protocols. [26] requires a spanning tree and a common set of quasi-random hash functions. Time in the async model use parallel time. All results, except for [21], hold w.p. $1 - o(1)$. [2] also gives an expected time of $o(\log(n)/(s\alpha) + \log(n) \cdot \log(s))$.

or spanning tree). To capture this diverse spectrum, we classify[3] results into *population protocols*, *sensor networks*, and *pull voting*. A condensed form of this discussion is given in Table 1. We will not discuss work whose focus is too far away from this paper's, e.g., consensus on some arbitrary opinion, leader election, robustness concerns, or Byzantine models.

Population Protocols. The first line of work considers *population protocols* for consensus and models interactions between large populations of very simple entities (like molecules). Entities are modeled as finite state machines with a small state space and communicate asynchronously. In each step, an edge is chosen uniformly at random and only the two connected nodes communicate. We refer to this communication model as the *sequential model*. See [5, 4] for detailed introductions. Dana Angluin, James Aspnes, and David Eisenstat [3] propose a 3-state population protocol for majority voting (i.e., $k = 2$) on the clique. If the initial bias α is $\omega(\log n/\sqrt{n})$, their protocol agrees (w.h.p.) on the majority opinion in $O(n \cdot \log n)$ steps. George B. Mertzios, Sotiris E. Nikoletseas, Christoforos Raptopoulos, and Paul G. Spirakis [27] suggest a 4-state protocol for *exact* majority voting, which always returns the majority opinion (independent of α) in time $O(n^6)$ in arbitrary graphs and in time $O(n^2 \cdot \log(n)/\alpha)$ in the clique. This is optimal in that no population protocol for exact majority can have fewer than four states [27]. Dan Alistarh, Rati Gelashvili, and Milan Vojnovic [2] gives a protocol for $k = 2$ in the clique that allows for a speed-memory trade-off. It solves exact majority and has expected *parallel running time*[4] $O\left(\frac{\log n}{s \cdot \alpha} + \log n \cdot \log s\right)$ and (w.h.p.) $O\left(\frac{\log^2 n}{s \cdot \alpha} + \log^2 n\right)$.

Here, s is the number of states and must be in the range $s = O(n)$ and $s = \Omega(\log n \cdot \log\log n)$.

[3] This classification is neither unique nor injective but merely an attempt to make the overview more accessible.

[4] The number of steps divided by n. A typical measure for population protocols, based on the intuition that each node communicates roughly once in n steps.

In contrast to these population results, our protocols consider the case of arbitrary $k \geq 2$. Also, with the notable exception of [27], the above results are restricted to the complete graph. These restrictions are not surprising, given that these protocols operate on a very constrained state space. Our protocols work in arbitrary, even dynamic graphs. Balance can be seen as a slightly simplified and generalized version of [2], and Shuffle uses a similar idea for a speed-memory trade-off.

Sensor Networks. Another line of work has a background in sensor networks. *Quantized interval consensus* draws its motivation from signal processing. Initially, nodes measure quantized values (signals) and then communicate through a network to agree on the quantized values that enclose the average. This can be used to solve majority consensus ($k = 2$). The communication model is typically sequential. Florence Bénézit, Patrick Thiran, and Martin Vetterli [10] propose a protocol that is equivalent to the 4-state population protocol of [27] and prove that with probability 1 it converges in finite time, but without bounds on that convergence time. A more recent result by Moez Draief and Milan Vojnovic [21] shows that this protocol (and thus [27]) needs $\mathrm{O}\big(\frac{\log n}{\delta(Q_S,\alpha)}\big)$ steps in expectation. Here, $\delta(Q_S, \alpha)$ depends on the bias α and on the spectrum of a set of matrixes Q_S related to the underlying graph. The authors give concrete bounds for several specific graphs (e.g., in the complete graph the consensus time is of order[5] $\mathrm{O}(\log n/\alpha)$). The only related result for $k > 2$ we are aware of is [11] which again proves only convergence in finite time.

Another consensus variant is *mode computation*. For example, Fabian Kuhn, Thomas Locher, and Stefan Schmid [26] consider a graph of diameter D where each node has one or several of k distinct elements. The authors use a protocol based on a complex hashing scheme to compute the *mode* (the most frequent element) w.h.p. in time $\mathrm{O}\big(D + F_2/n_1^2 \cdot \log k\big)$. Here, $F_2 = \sum_i n_i^2$ is the second frequency moment and n_i the frequency of the i-th most common element. $F_2/n_1^2 \in [1, k]$ can be seen as an alternative bias measure. Nodes communicate via synchronous broadcasts and need a precomputed spanning tree and hash functions. [26] can also be used for aggregate computation as done by David Kempe, Alin Dobra, and Johannes Gehrke [25] (where the authors provide an elegant protocol to compute sums or averages in complete graphs).

Overall, [21] and [26] are probably most closely related to our work, as they consider arbitrary graphs. However, we cover more general communication models, including dynamic graphs. Similar to [21], our results for $k = 2$ rely on spectral properties of the underlying graph (and are asymptotically the same for their concrete examples). However, our bounds are related to well-studied load balancing bounds and mixing times of random walks (which we believe are easier to get a handle on than their $\delta(Q_S, \alpha)$).

Gossip Protocols. The third major research line on plurality consensus has its roots in gossiping and rumor spreading. Here, communication is typically restricted to synchronous pull requests (nodes query other nodes' opinions and use simple rules to update their own). See [30] for a slightly dated but thorough survey. Colin Cooper, Robert Elsässer, and Tomasz Radzik [18] consider a voting process for $k = 2$ opinions on d-regular graphs. They pull two random neighbors and, if they have the same opinion, adopt it. For random d-regular graphs and $\alpha = \Omega\big(\sqrt{1/d + d/n}\big)$, all nodes agree (w.h.p.) in $\mathrm{O}(\log n)$ rounds on the plurality opinion. For an arbitrary d-regular graph G, they need $\alpha = \Omega(\lambda_2)$ (where $1 - \lambda_2$ is the spectral gap of G). In the follow up paper Colin Cooper, Robert Elsässer, Tomasz Radzik,

[5] We state their bound in terms of our $\alpha = (n_1 - n_2)/n$; their definition of α differs slightly.

Nicolas Rivera, and Takeharu Shiraga [19] extend these results to expanders: The run time is $\mathrm{O}(\log n)$ for a bias of $\mathrm{vol}(1) - \mathrm{vol}(2) \geq 4\lambda_2^2 \cdot |E|$, where vol(1) and vol(2) denote the sum of degrees over nodes having Opinion 1 and 2, respectively. Luca Becchetti, Andrea E. F. Clementi, Emanuele Natale, Francesco Pasquale, Riccardo Silvestri, and Luca Trevisan [9] consider a similar update rule on the clique for k opinions. Here, each node pulls the opinion of three random neighbors and adopts the majority among those. They need $\mathrm{O}(\log k)$ memory bits and prove (w.h.p.) a tight running time of $\Theta(k \cdot \log n)$ (given a sufficiently high bias α). Luca Becchetti, Andrea Clementi, Emanuele Natale, Francesco Pasquale, and Riccardo Silvestri [8] build upon the idea of the 3-state population protocol from [3] (but in the gossip model) and generalize it to k opinions. Nodes pull the opinion of a random neighbor in each round. If $n_1 \geq (1+\varepsilon) \cdot n_2$ for a constant $\varepsilon > 0$ and if $k = \mathrm{O}\left((n/\log n)^{1/3}\right)$, they agree (w.h.p.) on the plurality opinion in time $\mathrm{O}(\mathrm{md} \cdot \log n)$ on the clique and need $\log k + 1$ bits. The *monochromatic distance* $\mathrm{md} \in [1, k]$ is an alternative bias measure (based on an idea similar to the frequency moment in [26]). Petra Berenbrink, Tom Friedetzky, George Giakkoupis, and Peter Kling [13] build upon [3] and design a protocol that reaches plurality consensus (w.h.p.) in time $\mathrm{O}(\log n \cdot \log\log n)$ and uses $\log k + 4$ bits.

The running times of gossip protocols are relatively good when compared to other protocols, like population protocols or those introduced here (cf. Table 1). In particular, these results do typically not show a linear dependency on the bias, as our Shuffle protocol or [2, 21, 27] do. This efficiency however comes at the expense of parameter constraints. In particular, results like [8, 13] do not seem to easily extend to arbitrary graphs and have inherent constraints on both k and α. Comparing these results seems to indicate that, at least for arbitrary graphs, there is a jump in complexity depending on whether or not one allows the protocol to fail for small absolute bias values.

1.2 Our Contribution

We introduce two protocols for plurality consensus, called Shuffle and Balance. Both solve plurality consensus under a diverse set of (randomized or adversarial) communication patterns in arbitrary graphs for any positive bias. We continue with a detailed description of our results.

Shuffle. Our main result is the Shuffle protocol. In the first time step each node generates γ tokens labeled with its initial opinion. During round t, any pair of nodes connected by an active edge (as specified by the communication pattern $(\boldsymbol{M}_t)_{t \leq N}$) exchanges tokens. We show that Shuffle solves plurality consensus and allows for a trade-off between running time and memory. More exactly, let the number of tokens be $\gamma = \mathrm{O}\left(\log n/(\alpha^2 \cdot T)\right)$, where T is a parameter to control the trade-off between memory and running time[6]. Moreover, let t_{mix} be such that any time interval $[t, t + t_{\mathrm{mix}}]$ is *ε-smoothing*[7] (cf. Section 2). Given knowledge of the *maximum number of communication partners* Δ and the *mixing time* t_{mix} of the underlying communication pattern[8], Shuffle lets all nodes agree on the plurality opinion in $\mathrm{O}(T \cdot t_{\mathrm{mix}})$ rounds (w.h.p.), using $\mathrm{O}\left(\log n/(\alpha^2 T) \cdot \log k + \log(T \cdot t_{\mathrm{mix}})\right)$ memory bits per

[6] The protocol works for any integral choice of γ (this fixes the trade-off parameter T).

[7] Intuitively, this means that the communication pattern has good load balancing properties during any time window of length t_{mix}. This coincides with the worst-case mixing time of a lazy random walk on active edges.

[8] For static graphs, Δ is the maximal degree which can be easily computed in a distributed way, see for example [14]. For t_{mix}, good bounds are known for many static graphs [1, Chapter 5].

node. This implies, for example, that plurality consensus on expanders in the sequential model is achieved in $\mathrm{O}\left(T \cdot n \log n\right)$ time steps and with $\mathrm{O}\left(\log n \cdot \log k/T + \log(Tn)\right)$ memory bits (assuming a constant initial bias). For arbitrary graphs, arbitrary bias, and many natural communication patterns (e.g., communicating with all neighbors in every round or communicating via random matchings), the time for plurality consensus is closely related to the spectral gap of the underlying communication network (cf. Corollary 3).

While our protocol is relatively simple, the analysis is quite involved. The idea is to observe that after t_{mix} time steps, each single token is on any node with (roughly) the same probability; the difficulty is that token movements are not independent. The main ingredients for our analysis are Lemmas 6 and 7, which generalize a result by Thomas Sauerwald and He Sun [32] (we believe that this generalization is interesting in its own right). These lemmas show that the joint distribution of token locations is negatively correlated, allowing us to derive a suitable Chernoff bound. Once this is proven, nodes can "count" tokens every t_{mix} time steps, building up over time an estimate of the total number of tokens labeled with their own opinion. By broadcasting these estimates, all nodes determine the plurality opinion.

Balance. The previous protocol, Shuffle, allows for a nice trade-off between running time and memory. If the number of opinions is relartively small, our much simpler Balance protocol gives better results. In Balance, each node u maintains a k-dimensional load vector. If j denotes u's initial opinion, the j-th dimension of this load vector is initialized with $\gamma \in \mathbb{N}$ (a sufficiently large value) and any other dimension is initialized with zero. In each time step, all nodes perform a simple, discrete load balancing on each dimension of these load vectors. Our results imply, for example, that plurality consensus on expanders in the sequential model is achieved in only $\mathrm{O}\left(n \cdot \log n\right)$ time steps with $\mathrm{O}\left(k\right)$ memory bits per node (assuming a constant initial bias).

Balance can be thought of as a (slightly simplified) version of [2] or [25] that generalizes naturally to $k \geq 2$ and arbitrary (even dynamic) graphs. In the setting of [2] (but as opposed to [2] for arbitrary k), it achieves plurality consensus with probability $1 - \mathrm{o}\left(1\right)$ in parallel time $\mathrm{O}\left(\log n\right)$ and uses $\mathrm{O}\left(k \cdot \log(1/\alpha)\right) = \mathrm{O}\left(k \cdot \log n\right)$ bits per node (Corollary 13), an improvement by a $\log(n)$ factor.

2 Model & General Definitions

We consider an undirected graph $G = (V, E)$ of $n \in \mathbb{N}$ nodes and let $1 - \lambda_2$ denote the eigenvalue (or spectral) gap of G. Each node u is assigned an *opinion* $o_u \in \{1, 2, \dots, k\}$. For $i \in \{1, 2, \dots, k\}$, we use $n_i \in \mathbb{N}$ to denote the number of nodes which have initially opinion i. Without loss of generality (w.l.o.g), we assume $n_1 > n_2 \geq \dots \geq n_k$, such that 1 is the opinion that is initially supported by the largest subset of nodes. We also say that 1 is the *plurality opinion*. The value $\alpha := \frac{n_1 - n_2}{n} \in [1/n, 1]$ denotes the *initial bias* towards the plurality opinion. In the *plurality consensus problem*, the goal is to design simple, distributed protocols that let all nodes agree on the plurality opinion. Time is measured in discrete rounds, such that the (randomized) running time of our protocols is the number of rounds it takes until all nodes are aware of the plurality opinion. As a second quality measure, we consider the total number of memory bits per node that are required by our protocols. All our statements and proofs assume n to be sufficiently large.

Communication Model. In any given round, two nodes u and v can communicate if and only if the edge between u and v is *active*. We use $\boldsymbol{M}_t$ to denote the symmetric *communication matrix* at time t, where $\boldsymbol{M}_t[u,v] = \boldsymbol{M}_t[v,u] = 1$ if $\{u,v\}$ is active and $\boldsymbol{M}_t[u,v] = \boldsymbol{M}_t[v,u] = 0$ otherwise. We assume (w.l.o.g) $\boldsymbol{M}_t[u,u] = 1$ (allowing nodes to "communicate" with themselves). Typically, the sequence $\boldsymbol{M} = (\boldsymbol{M}_t)_{t\in\mathbb{N}}$ of communication matrices (the *communication pattern*) is either randomized or adversarial, and our statements merely require that $\boldsymbol{M}$ satisfies certain smoothing properties (see below). For the ease of presentation, we restrict ourselves to polynomial number of time steps and consider only communication patterns $\boldsymbol{M} = (\boldsymbol{M}_t)_{t\leq N}$ where $N = N(n)$ is an arbitrarily large polynomial. Let us briefly mention some natural and common communication models covered by such patterns:

- *Diffusion Model:* All edges of the graph are permanently activated.
- *Random matching model:* In every round t, the active edges are given by a random matching. We require that random matchings from different rounds are mutually independent[9]. Results for the random matching model dependent on $p_{\min} := \min_{t\in\mathbb{N},\{u,v\}\in E} \Pr(\boldsymbol{M}_t[u,v] = 1)$.
- *Balancing Circuit Model:* There are d perfect matchings $\boldsymbol{M}_0, \boldsymbol{M}_1, \ldots, \boldsymbol{M}_{d-1}$ given. They are used in a round-robin fashion, such that for $t \geq d$ we have $\boldsymbol{M}_t = \boldsymbol{M}_{t \bmod d}$.
- *Sequential Model:* In each round t an uniformly random edge $\{u,v\} \in E$ is activated.

Notation. We use $\|\boldsymbol{x}\|_\ell$ to denote the ℓ-norm of vector $\boldsymbol{x}$, where the ∞-norm is the vector's maximum absolute entry. In general, bold font indicates vectors and matrices, and $x(i)$ refers to the i-th component of $\boldsymbol{x}$. The *discrepancy* of $\boldsymbol{x}$ is defined as $\operatorname{disc}(\boldsymbol{x}) := \max_i x(i) - \min_i x(i)$. For $i \in \mathbb{N}$ we define $[i] := \{1, 2, \ldots, i\}$ as the set of the first i integers. We use $\log x$ to denote the binary logarithm of $x \in \mathbb{R}_{>0}$. We write $a \mid b$ if a divides b. For any node $u \in V$, we use $d(u)$ to denote u's degree in G and $d_t(u) := \sum_v \boldsymbol{M}_t[u,v]$ to denote its *active degree* at time t (i.e., its degree when restricted to active edges). Similarly, $N(u)$ and $N_t(u)$ refer to u's (active) neighborhood. Moreover, $\Delta := \max_{t,u} d_t(u)$ is the maximum active degree of any node. We assume knowledge of Δ. On static graphs it can be computed efficiently in a distributed manner [14] and it is given by many dynamic graph models (e.g., 1 for the sequential model, d for balancing circuits). We say an event happens with high probability (w.h.p.) if its probability is at least $1 - 1/n^c$ for $c \in \mathbb{N}$.

Smoothing Property. The running time of our protocols is closely related to the runnig time ("smoothing time") of diffusion load balancing algorithms, which in turn is a function of the mixing time of a random walk on G (see also [6, 32]). More exactly, we consider a random walk on G that is restricted to the active edges in each time step. As indicated in Section 1.2, this random walk should converge towards the uniform distribution over the nodes of G. This leads to the following definition of the random walk's transition matrices $\boldsymbol{P}_t$ based on the communication matrices $\boldsymbol{M}_t$:

$$\boldsymbol{P}_t[u,v] := \begin{cases} \frac{1}{2\Delta} & \text{if } \boldsymbol{M}_t[u,v] = 1 \text{ and } u \neq v, \\ 1 - \frac{d_t(u)}{2\Delta} & \text{if } \boldsymbol{M}_t[u,v] = 1 \text{ and } u = v, \\ 0 & \text{if } \boldsymbol{M}_t[u,v] = 0. \end{cases} \tag{1}$$

Obviously, $\boldsymbol{P}_t$ is doubly stochastic for all $t \in \mathbb{N}$. Moreover, note that the random walk is trivial in any matching-based model, while we get $\boldsymbol{P}_t[u,v] = \frac{1}{2d}$ for every edge $\{u,v\} \in E$ in

[9] Note that there are several simple, distributed protocols to obtain such matchings [24, 14].

the diffusion model on a d-regular graph. We are now ready to define the required smoothing property.

▶ **Definition 1** (ε-smoothing)**.** Consider a fixed sequence $(\boldsymbol{M}_t)_{t\leq N}$ of communication matrices and a time interval $[t_1, t_2]$. We say $[t_1, t_2]$ is *ε-smoothing* (under $(\boldsymbol{M}_t)_{t\leq N}$) if for any non-negative vector $\boldsymbol{x}$ with $\|\boldsymbol{x}\|_\infty = 1$ it holds that $\operatorname{disc}(\boldsymbol{x} \cdot \prod_{t=t_1}^{t_2} \boldsymbol{P}_t) \leq \varepsilon$. Moreover, we define the *mixing time* $t_{\text{mix}}(\varepsilon)$ as the smallest number of steps such that any time window of length $t_{\text{mix}}(\varepsilon)$ is ε-smoothing. That is, $t_{\text{mix}}(\varepsilon) \coloneqq \min \{ t' \mid \forall t \in \mathbb{N}\colon [t, t+t'] \text{ is } \varepsilon\text{-smoothing} \}$.

The mixing time can be seen as the worst-case time required by a random walk to get "close" to the uniform distribution. If the parameter ε is not explicitly stated, we consider $t_{\text{mix}} \coloneqq t_{\text{mix}}(n^{-5})$. Note that Shuffle assumes knowledge of a bound on t_{mix} (cf. Section 1.2).

3 Protocol Shuffle

Our main result is the following theorem, stating the correctness as well as the time-/space-efficiency of Shuffle. The protocol is described in Section 3.1, followed by its analysis in Section 3.2.

▶ **Theorem 2.** *Let $\alpha = \frac{n_1 - n_2}{n} \in [1/n, 1]$ denotes the initial bias. Consider a fixed communication pattern $(\boldsymbol{M}_t)_{t\leq N}$ and an arbitrary parameter $T \in \mathbb{N}$. Protocol* Shuffle *ensures that all nodes know the plurality opinion after $\mathrm{O}(T \cdot t_{mix})$ rounds (w.h.p.) and requires $\left(12 \cdot \frac{\log(n)}{\alpha^2 \cdot T} + 4\right) \cdot \log(k) + 4\log\left(\frac{12 \cdot \log(n)}{\alpha^2}\right) + \log(T \cdot t_{mix})$ memory bits per node.*

The parameter T in the statement serves as a lever to trade running time for memory. Since t_{mix} depends on the graph and communication pattern, Theorem 2 might look a bit unwieldy. The following corollary gives a few concrete examples for common communication patterns on general graphs.

▶ **Corollary 3.** *Let G be an arbitrary d-regular graph.* Shuffle *ensures that all nodes agree on the plurality opinion (w.h.p.) using $\left(12 \cdot \frac{\log(n)}{\alpha^2 \cdot T} + 4\right) \cdot \log(k) + 4\log\left(\frac{12 \cdot \log(n)}{\alpha^2}\right) + \log(T \cdot t_{mix})$ bits of memory in time*

- $\mathrm{O}\left(T \cdot \frac{\log(n)}{1-\lambda_2}\right)$ *in the diffusion model,*
- $\mathrm{O}\left(\frac{T}{d \cdot p_{min}} \cdot \frac{\log(n)}{1-\lambda_2}\right)$ *in the random matching model,*
- $\mathrm{O}\left(T \cdot d \cdot \frac{\log(n)}{1-\lambda_2}\right)$ *in the balancing circuit model, and*
- $\mathrm{O}\left(T \cdot n \cdot \frac{\log(n)}{1-\lambda_2}\right)$ *in the sequential model.*

3.1 Protocol Description

We continue to explain the Shuffle protocol given in Listing 1. Our protocol consists of three parts that are executed in each time step: the *shuffle* part, the *broadcast* part, and the *update* part.

Every node u is initialized with $\gamma \in \mathbb{N}$ tokens labeled with u's opinion o_u. Our protocol sends 2Δ tokens chosen uniformly at random (without replacement) over each edge $\{ u, v \} \in E$. Here, $\gamma \geq 2\Delta^2$ is a parameter depending on T and α to be fixed during the analysis[10]. Shuffle maintains the invariant that, at any time, all nodes have exactly γ tokens. In addition to storing the tokens, each node maintains a set of auxiliary variables. The variable

[10] Shuffle needs not to know α, it works for any choice of γ; such a choice merely fixes the trade-off parameter T.

```
for $\{u, v\} \in E$ with $M_t[u, v] = 1$:                              {shuffle part}
  send $2\Delta$ tokens chosen u.a.r. (without replacement) to $v$

for $\{u, v\} \in E$ with $M_t[u, v] = 1$:                              {broadcast part}
  send    $(dom_u, e_u)$
  receive $(dom_v, e_v)$
$v := w$ with $e_w \geq e_{w'}$  $\forall w, w' \in N_t(u) \cup \{u\}$
$(dom_u, e_u) := (dom_v, e_v)$

if $t \equiv 0 \pmod{t_{\text{mix}}}$:                                  {update part}
  increase $c_u$ by the number of tokens labeled $o_u$ held by $u$
  $plu_u := dom_u$            {plurality guess: last broadcast's dom. op.}
  $(dom_u, e_u) := (o_u, c_u)$   {reset broadcast}
```

Listing 1 Protocol SHUFFLE as executed by node u at time t. At time zero, each node u creates γ tokens labeled o_u and sets $c_u := 0$ and $(dom_u, e_u) := (o_u, c_u)$.

c_u is increased during the update part and counts tokens labeled o_u. The variable pair (dom_u, e_u) is a temporary guess of the plurality opinion and its frequency. During the broadcast part, nodes broadcast these pairs, replacing their own pair whenever they observe a pair with higher frequency. Finally, the variable plu_u represents the opinion currently believed to be the plurality opinion. The shuffle and broadcast parts are executed in each time step, while the update part is executed only every t_{mix} time steps

Waiting t_{mix} time steps for each update gives the broadcast enough time to inform all nodes and ensures that the tokens of each opinion are well distributed. The latter implies that, if we consider a node u with opinion $o_u = i$ at time $T \cdot t_{\text{mix}}$, the value c_u is a good estimate of $T \cdot \gamma n_i / n$ (which is maximized for the plurality opinion). When we reset the broadcast (Line 13), the subsequent t_{mix} broadcast steps ensure that all nodes get to know the pair (o_u, c_u) for which c_u is maximal. Thus, if we can ensure that c_u is a good enough approximation of $T \cdot \gamma n_i / n$, all nodes get to know the plurality.

3.2 Analysis of Shuffle

Fix a communication pattern $(M_t)_{t \leq N}$ and an arbitrary parameter $T \in \mathbb{N}$. Remember that $t_{\text{mix}} = t_{\text{mix}}(n^{-5})$ denotes the smallest number such that any time window of length t_{mix} is n^{-5}-smoothing under $(M_t)_{t \leq N}$. We set the number of tokens stored in each node to $\gamma := \lceil c \cdot \frac{\log n}{\alpha^2 T} \rceil$, where c is a suitable constant. The analysis of SHUFFLE is largely based on Lemma 11, which states that, after $O(T \cdot t_{\text{mix}})$ time steps, the counter values c_u can be used to reliably separate the plurality opinion from any other opinion. The main technical difficulty is the huge dependency between the tokens' movements, rendering standard Chernoff-bounds inapplicable. Instead, we show that certain random variables satisfy the negative regression condition (Lemma 6), which allows us to majorize the token distribution by a random walk (Lemma 7) and to derive the Chernoff type bound in Lemma 10. This Chernoff type bound can be used to show that all counter values are concentrated which is the main pillar of the proof of Theorem 2.

Majorizing Shuffle by Random Walks

While our SHUFFLE protocol assumes that 2Δ divides γ, here we assume the slightly weaker requirement that $P_t[u, v] \cdot \gamma \in \mathbb{N}$ for any $u, v \in V$ and $t \in \mathbb{N}$. Let us first introduce some notation for the shuffle part at time t of our protocol. To ease the discussion, we consider u as a neighbor of itself and speak of $d_t(u)+1$ neighbors. For $i \in [d_t(u)+1]$, let $N_t(u,i) \in V$ denote the i-th neighbor of u (in an arbitrary order). Fix a node u and let u's tokens be numbered from 1 to γ. Our assumption on γ allows us to partition the tokens into $d_t(u)+1$ disjoint subsets (*slots*) $S_i \subseteq [\gamma]$ of size $\boldsymbol{P}_t[u,v] \cdot \gamma$ each, where $v = N_t(u,i)$. Let $\pi_{t,u} \colon [\gamma] \to [\gamma]$ be a random permutation. Token j with $\pi_{t,u}(j) \in S_i$ is sent to u's i-th neighbor. To ease notation, we drop the time index t and write π_u instead of $\pi_{t,u}$ (and, similarly for $d(u)$ and $N(u,i)$).

A *configuration* c describes the location of *all* γn tokens at a given point in time. For a token $j \in [\gamma n]$ we use $u_j \in V$ to denote its location in configuration c (which will always be clear from the context). For each such token j we define a random variable $X_j \in [d(u_j)+1]$ with $X_j = i$ if and only if $\pi_{u_j}(j) \in S_i$. In other words, X_j indicates to which of u_j's neighbors token j is sent. Our key technical lemma (Lemma 6) establishes the *negative regression condition* for these $(X_j)_{j\in[\gamma n]}$ variables. Negative regression is defined as follows:

▶ **Definition 4** (Neg. Regression [22, Def. 21]). A vector $(X_1, X_2, \ldots, X_n)$ of random variables is said to satisfy the *negative regression* condition if $\mathbb{E}\left[f(X_l, l \in \mathcal{L}) \mid X_r = x_r, r \in \mathcal{R}\right]$ is non-increasing in each x_r for any disjoint $\mathcal{L}, \mathcal{R} \subseteq [n]$ and for any non-decreasing function f.

▶ **Lemma 5** ([22, Lemma 26]). *Let $(X_1, X_2, \ldots, X_n)$ satisfy the negative regression condition and consider an arbitrary index set $I \subseteq [n]$ as well as any family of non-decreasing functions f_i $(i \in \{ I \})$. Then, we have*

$$\mathbb{E}\left[\prod_{i\in I} f_i(X_i)\right] \le \prod_{i\in I} \mathbb{E}\left[f_i(X_i)\right] \tag{2}$$

▶ **Lemma 6** (NRC). *Fix a configuration c and consider the random variables $(X_j)_{j\in[\gamma n]}$. Then $(X_j)_{j\in[\gamma n]}$ satisfies the negative regression condition (*NRC*).*

Proof. Remember that u_j is the location of token j in configuration c and that $X_j \in [d(u_j)+1]$ indicates where token j is sent in the next step. We show for any $u \in V$ that $(X_j)_{j\colon u_j=u}$ satisfies the NRC. The lemma's statement follows since the π_u are chosen independently (if two independent vectors (X_j) and (Y_j) satisfy the NRC, then so do both together).

Fix a node u and disjoint subsets $\mathcal{L}, \mathcal{R} \subseteq \{ j \in [\gamma n] \mid u_j = u \}$ of tokens on u. Define $d \coloneqq d(u)$ and let $f \colon [d+1]^{|\mathcal{L}|} \to \mathbb{R}$ be an arbitrary non-decreasing function. We have to show that $\mathbb{E}\left[f(X_l, l \in \mathcal{L}) \mid X_r = x_r, r \in \mathcal{R}\right]$ is non-increasing in each x_r (cf. Definition 4). That is, we need

$$\mathbb{E}\left[f(X_l, l \in \mathcal{L}) \mid X_r = x_r, r \in \mathcal{R}\right] \le \mathbb{E}\left[f(X_l, l \in \mathcal{L}) \mid X_r = \tilde{x}_r, r \in \mathcal{R}\right], \tag{3}$$

where $x_r = \tilde{x}_r$ holds for all $r \in \mathcal{R} \setminus \{ \hat{r} \}$ and $x_{\hat{r}} > \tilde{x}_{\hat{r}}$ for a fixed index $\hat{r} \in \mathcal{R}$. We prove Inequality (3) via a coupling of the processes on the left-hand side (LHS process) and right-hand side (RHS process) of that inequality. Since $x_{\hat{r}} \neq \tilde{x}_{\hat{r}}$, these processes involve two slightly different probability spaces Ω and $\tilde{\Omega}$, respectively. To couple these, we employ a common uniform random variable $U_i \in [0,1)$. By partitioning $[0,1)$ into $d+1$ suitable slots for each process (corresponding to the slots S_i mentioned above), we can use the outcome of U_i to set the X_j in both Ω and $\tilde{\Omega}$. We first explain how to handle the case $x_{\hat{r}} - \tilde{x}_{\hat{r}} = 1$. The case $x_{\hat{r}} - \tilde{x}_{\hat{r}} > 1$ follows from this by a simple reordering argument.

So assume $x_{\hat{r}} - \tilde{x}_{\hat{r}} = 1$. We reveal the yet unset random variables X_j (i.e., $j \in [\gamma n] \setminus \mathcal{R}$) one by one in order of increasing indices. To ease the description assume (w.l.o.g.) that the tokens from $\mathcal{R}$ are numbered from 1 to $|\mathcal{R}|$. When we reveal the j-th variable (which indicates

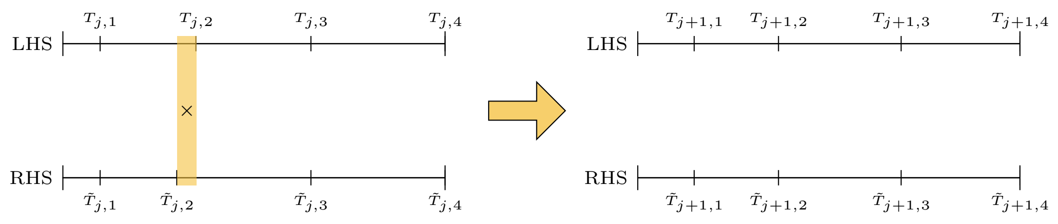

Figure 1 Illustration showing the $d+1=4$ different slots for the LHS and RHS process and how they change. In this example, $x_{\hat{r}}=3$ and $\tilde{x}_{\hat{r}}=2$. On the left, the uniform random variable U_j falls into slot $[T_1,T_2)$ for the LHS process (causing j to be sent to node $N(u,2)$) and into slot $[\tilde{T}_2,\tilde{T}_3)$ for the RHS process (causing j to be sent to node $N(u,3)$).

the new location of the j-th token), note that the probability $p_{j,i}$ that token j is assigned to $N(u,i)$ depends solely on the *number* of previous tokens $j'<j$ that were assigned to $N(u,i)$. Thus, we can consider $p_{j,i}\colon \mathbb{N}\to[0,1]$ as a function mapping $x\in\mathbb{N}$ to the probability that j is assigned to $N(u,i)$ conditioned on the event that exactly x previous tokens were assigned to $N(u,i)$. Note that $p_{j,i}$ is non-increasing. For a vector $\boldsymbol{x}\in\mathbb{N}^{d+1}$, we define a threshold function $T_{j,i}\colon\mathbb{N}^{d+1}\to[0,1]$ by $T_{j,i}(\boldsymbol{x}) \coloneqq \sum_{i'\leq i} p_{j,i'}(x_{i'})$ for each $i\in[d+1]$. To define our coupling, let $\beta_{j,i}\coloneqq |\{\, j'<j \mid X_{j'}=i\,\}|$ denote the number of already revealed variables with value i in the LHS process and define, similarly, $\tilde{\beta}_{j,i}\coloneqq|\{\, j'<j \mid \tilde{X}_{j'}=i\,\}|$ for the RHS process. We use $\boldsymbol{\beta_j},\boldsymbol{\tilde{\beta}_j}\in\mathbb{N}^{d+1}$ to denote the corresponding vectors. Now, to assign token j we consider a uniform random variable $U_j\in[0,1)$ and assign j in both processes using customized partitions of the unit interval. To this end, let $T_{j,i}\coloneqq T_{j,i}(\boldsymbol{\beta_j})$ and $\tilde{T}_{j,i}\coloneqq T_{j,i}(\boldsymbol{\tilde{\beta}_j})$ for each $i\in[d+1]$. We assign X_j in the LHS and RHS process as follows:

- **LHS Process:** $X_j=x_j=i$ if and only if $U_j\in[T_{j,i-1},T_{j,i})$,
- **RHS Process:** $X_j=\tilde{x}_j=i$ if and only if $U_j\in[\tilde{T}_{j,i-1},\tilde{T}_{j,i})$.

See Figure 1 for an illustration. Our construction guarantees that, considered in isolation, both the LHS and RHS process behave correctly.

At the beginning of this coupling, only the variables X_r corresponding to tokens $r\in\mathcal{R}$ are set, and these differ in the LHS and RHS process only for the index $\hat{r}\in\mathcal{R}$, for which we have $X_{\hat{r}}=x_{\hat{r}}$ (LHS) and $X_{\hat{r}}=\tilde{x}_{\hat{r}}=x_{\hat{r}}-1$ (RHS). Let $\iota\coloneqq x_{\hat{r}}$. For the first revealed token $j=\hat{r}+1$, this implies $\beta_{j,\iota}=\tilde{\beta}_{j,\iota}+1$, $\beta_{j,\iota-1}=\tilde{\beta}_{j,\iota-1}-1$, and $\beta_{j,i}=\tilde{\beta}_{j,i}$ for all $i\not\in\{\,\iota,\iota-1\,\}$. By the definitions of the slots for both processes, we get $T_{j,i}=\tilde{T}_{j,i}$ for all $i\neq\iota-1$ and $T_{j,\iota-1}>\tilde{T}_{j,\iota-1}$ (cf. Figure 1). Thus, the LHS and RHS process behave different if and only if $U_i\in[\tilde{T}_{j,\iota-1},T_{j,\iota-1})$. If this happens, we get $x_j<\tilde{x}_j$ (i.e., token j is assigned to a smaller neighbor in the LHS process). This implies $\boldsymbol{\beta_{j+1}}=\boldsymbol{\tilde{\beta}_{j+1}}$ and both processes behave identical from now on. Otherwise, if $U_i\not\in[\tilde{T}_{j,\iota-1},T_{j,\iota-1})$, we have $\boldsymbol{\beta_{j+1}}-\boldsymbol{\beta_{j+1}}=\boldsymbol{\beta_j}-\boldsymbol{\beta_j}$ and we can repeat the above argument. Thus, after all X_j are revealed, there is at most one $j\in\mathcal{L}$ for which $x_j\neq\tilde{x}_j$, and for this we have $x_j<\tilde{x}_j$. Since f is non-decreasing, this guarantees Inequality (3). To handle the case $x_{\hat{r}}-\tilde{x}_{\hat{r}}>1$, note that we can reorder the slots $[T_{j,i-1},T_{j,i})$ used for the assignment of the variables such that the slots for $x_{\hat{r}}$ and $\tilde{x}_{\hat{r}}$ are neighboring. Formally, this merely changes in which order we consider the neighbors in the definition of the functions $T_{j,i}$. With this change, the same arguments as above apply. ◀

Before proving the majorization of tokens with random walks (Lemma 7) we require further notation. Let $\mathcal{S}$ denote our random Shuffle process, and $\mathcal{W}$ the random walk process in which each of the γn tokens performs an independent random walk according to the sequence of random walk matrices $(\boldsymbol{P}_t)_{t\in\mathbb{N}}$ (i.e., a token on u uses $P_t(u,\cdot)$ for the transition probabilities). We use $w_j^{\mathcal{P}}(t)$ to denote the position of token j after t steps of a process $\mathcal{P}$. We assume (w.l.o.g.) $w_j^{\mathcal{S}}(0) = w_j^{\mathcal{W}}(0)$ for all j. While there are strong correlations between the tokens' movements in $\mathcal{S}$ (e.g., not all tokens can move to the same neighbor), Lemma 7 shows that these correlations are negative.

▶ **Lemma 7** (Majorizing RWs). *Consider a time $t \geq 0$, a token j, and node v. Let $B \subseteq [\gamma n]$ and $D \subseteq V$ be arbitrary subsets of tokens and nodes, respectively. The following holds:*

1. $\Pr\left(w_j^{\mathcal{S}}(t) = v\right) = \Pr\left(w_j^{\mathcal{W}}(t) = v\right)$ *and*

2. $\Pr\left(\bigcap_{j \in B}\left(w_j^{\mathcal{S}}(t) \in D\right)\right) \leq \Pr\left(\bigcap_{j \in B}\left(w_j^{\mathcal{W}}(t) \in D\right)\right) = \prod_{j \in B} \Pr\left(w_j^{\mathcal{W}}(t) \in D\right)$.

Proof. The first statement follows immediately from the definition of our process. For the second statement, note that the equality on the right-hand side holds trivially, since the tokens perform independent random walks in $\mathcal{W}$. To show the inequality, we define the intermediate process $\mathcal{SW}(t')$ ($t' \leq t$) that performs t' steps of $\mathcal{S}$ followed by $t - t'$ steps of $\mathcal{W}$. By this definition, $\mathcal{SW}(0)$ is identical to $\mathcal{W}$ restricted to t steps and, similar, $\mathcal{SW}(t)$ is identical to $\mathcal{S}$ restricted to t steps. Define

$$\mathcal{E}_{t'} \coloneqq \bigcap_{j \in B} \left(w_j^{\mathcal{SW}(t')}(t) \in D\right) \tag{4}$$

(the event that all tokens from B end up at nodes from D under process $\mathcal{SW}(t')$). The lemma's statement is equivalent to $\Pr(\mathcal{E}_t) \leq \Pr(\mathcal{E}_0)$. To prove this, we show $\Pr(\mathcal{E}_{t'+1}) \leq \Pr(\mathcal{E}_{t'})$ for all $t' \in \{0, 1, \ldots, t-1\}$. Combining these inequalities yields the desired result.

Fix an arbitrary $t' \in \{0, 1, \ldots, t-1\}$ and note that $\mathcal{SW}(t')$ and $\mathcal{SW}(t'+1)$ behave identical up to and including step t'. Hence, we can fix an arbitrary configuration (i.e., the location of each token) $c(t') = c$ immediately before time step $t'+1$. Remember that $u_j \in V$ denotes the location of j in configuration c. The auxiliary functions $h_j \colon [d(u_j)+1] \to [0,1]$ describe the probability that a random walk starting at time $t'+1$ from u_j's i-th neighbor ends up in a node from D. Formally,

$$h_j(i) \coloneqq \Pr\left(w_j^{\mathcal{W}}(t) \in D \;\middle|\; w_j^{\mathcal{W}}(t'+1) = N(u_j, i)\right). \tag{5}$$

We can assume (w.l.o.g.) that all h_j are non-decreasing (by reordering the neighborhood of u_j).

Now, by Lemma 6 the variables $(X_j)_{j \in B}$ satisfy the negative regression condition. Thus, we can apply Lemma 5 (a well-known characterization of negative regression) to the functions h_j. Using another simple auxiliary result (Claim 8) we can relate the (conditioned) probabilities of the events $\mathcal{E}_{t'}$ and $\mathcal{E}_{t'+1}$ to the expectations over the different $h_j(X_j)$. That is, for $p \coloneqq \Pr(\mathcal{E}_{t'+1} \mid c(t') = c)$ we compute

$$p \overset{Clm.\ 8(a)}{=} \mathbb{E}\left[\prod_{j \in B} h_j(X_j) \;\middle|\; c(t') = c\right] \overset{Lem.\ 5}{\leq} \prod_{j \in B} \mathbb{E}\left[h_j(X_j) \mid c(t') = c\right]$$
$$\overset{Clm.\ 8(b)}{=} \Pr(\mathcal{E}_{t'} \mid c(t') = c).$$

Using the law of total probability, we conclude $\Pr(\mathcal{E}_{t'+1}) \leq \Pr(\mathcal{E}_{t'})$, as required. ◀

▶ **Claim 8.** *Fix a time $t' \in \{0, 1, \ldots, t-1\}$ and consider an arbitrary configuration c. Then the following identities hold:*

(a) $\Pr(\mathcal{E}_{t'+1} \mid c(t') = c) = \mathbb{E}\left[\prod_{j \in B} h_j(X_j) \;\middle|\; c(t') = c\right]$, *and*

(b) $\Pr(\mathcal{E}_{t'} \mid c(t') = c) = \prod_{j \in B} \mathbb{E}\left[h_j(X_j) \mid c(t') = c\right]$.

Proof. Remember the definitions from Lemma 7 and its proof. We use the shorthand $d(u_j) = d_{t'+1}(u_j)$. Remember that each X_j indicates to which of the $d(u_j)+1$ neighbors of u_j (where u_j is considered a neighbor of itself) a token j moves during time step $t'+1$. Thus, given the configuration $c(t') = c$ immediately before time step $t'+1$, there is a bijection between any possible configuration $c(t'+1)$ and outcomes of the random variable vector $\boldsymbol{X} = (X_j)_{j\in[\gamma n]}$. Let $c_{\boldsymbol{x}}$ denote the configuration corresponding to a concrete outcome $\boldsymbol{X} = \boldsymbol{x} \in [d(u_j)+1]^{\gamma n}$. Thus, we have $\Pr(c(t'+1) = c_{\boldsymbol{x}} \mid c(t') = c) = \Pr(\boldsymbol{X} = \boldsymbol{x} \mid c(t') = c)$, and conditioning on $c(t'+1)$ is equivalent to conditioning on $\boldsymbol{X}$ and $c(t')$. For the claim's first statement, we calculate

$$\begin{aligned}\Pr\left(\mathcal{E}_{t'+1} \;\middle|\; c(t') = c\right) &= \sum_{c_{\boldsymbol{x}}} \Pr\left(\mathcal{E}_{t'+1} \;\middle|\; c(t'+1) = c_{\boldsymbol{x}}\right) \cdot \Pr\left(c(t'+1) = c_{\boldsymbol{x}} \;\middle|\; c(t') = c\right)\\ &= \sum_{c_{\boldsymbol{x}}} \prod_{j\in B} \Pr\left(w_j^{\mathcal{SW}(t'+1)}(t) \in D \;\middle|\; \boldsymbol{X} = \boldsymbol{x}, c(t') = c\right) \cdot \Pr\left(\boldsymbol{X} = \boldsymbol{x} \;\middle|\; c(t') = c\right)\\ &= \sum_{c_{\boldsymbol{x}}} \prod_{j\in B} h_j(x_j) \cdot \Pr\left(\boldsymbol{X} = \boldsymbol{x} \;\middle|\; c(t') = c\right)\\ &= \sum_{\boldsymbol{x}} \prod_{j\in B} h_j(x_j) \cdot \Pr\left(\boldsymbol{X} = \boldsymbol{x} \;\middle|\; c(t') = c\right) = \mathbb{E}\left[\prod_{j\in B} h_j(X_j) \;\middle|\; c(t') = c\right].\end{aligned}$$

Here, we first apply the law of total probability. Then, we use the bijection between $c(t'+1)$ and $\boldsymbol{X}$ (if $c(t')$ is given) and that the process $\mathcal{SW}(t'+1)$ consists of independent random walks if $c(t'+1)$ is fixed. Finally, we use the definition of the auxiliary functions $h_j(i)$, which equal the probability that a random walk starting at time $t'+1$ from u_j's i-th neighbor reaches a node from D.

For the claim's second statement, we do a similar calculation for the process $\mathcal{SW}(t')$. By definition, this process consists already from time t' onward of a collection of independent random walks. Thus, we can swap the expectation and the product in the last term of the above calculation, yielding the desired result. ◀

Separating the Plurality via Chernoff

▶ **Lemma 9** ([7, Lemma 3.1]). *Let $X_1, X_2, \ldots, X_n$ be a sequence of random variables with values in an arbitrary domain and let $Y_1, Y_2, \ldots, Y_n$ be a sequence of binary random variables with the property that $Y_i = Y_i(X_1, \ldots, X_i)$. If $\Pr(Y_i = 1 \mid X_1, \ldots, X_{i-1}) \leq p$, then*

$$\Pr\left(\sum Y_i \geq \ell\right) \leq \Pr(\mathrm{Bin}(n,p) \geq \ell) \tag{6}$$

and, similarly, if $\Pr(Y_i = 1 \mid X_1, \ldots, X_{i-1}) \geq p$, then

$$\Pr\left(\sum Y_i \leq \ell\right) \leq \Pr(\mathrm{Bin}(n,p) \leq \ell). \tag{7}$$

Here, $\mathrm{Bin}(n,p)$ denotes the binomial distribution with parameters n and p.

We are finally able to prove the following Chernoff-like bound.

▶ **Lemma 10** (Token Concentration). *Consider any subset B of tokens, a node $u \in V$, and an integer T. Let $X := \sum_{t\leq T} \sum_{j\in B} X_{j,t}$, where $X_{j,t}$ is 1 if token j is on node u at time $t \cdot t_{mix}$. With $\mu := (1/n + 1/n^5) \cdot |B| \cdot T$, we have $\Pr(X \geq (1+\delta)\cdot\mu) \leq e^{\delta^2\mu/3}$.*

Proof. Let $v_{j,t}$ denote the location of token j at time $(t-1)\cdot t_{\mathrm{mix}}$. For all $t \leq T$ and $\ell \in \mathbb{N}$ define the random indicator variable $Y_{j,t}$ to be 1 if and only if the random walk starting at

$v_{j,t}$ is at node u after t_{mix} time steps. By Lemma 7 we have for each $B' \subseteq B$ and $t \le T$ that

$$\Pr\left(\bigcap_{i\in B'} X_{j,t}=1\right) \le \prod_{j\in B'} \Pr\left(Y_{j,t}=1\right). \tag{8}$$

Hence for all $t \le T$ and $\ell \in \mathbb{N}$ we have $\Pr\left(\sum_{j\in B} X_{j,t} \ge \ell\right) \le \Pr\left(\sum_{j\in B} Y_{j,t} \ge \ell\right)$ and

$$\Pr\left(X \ge \ell\right) = \Pr\left(\sum_{t\le T}\sum_{j\in B} X_{j,t} \ge \ell\right) \le \Pr\left(\sum_{t\le T}\sum_{j\in B} Y_{j,t} \ge \ell\right). \tag{9}$$

Let us define $p := 1/n + 1/n^5$. By the definition of t_{mix}, we have for all $j \in B$ and $t \le T$ that

$$\Pr\left(Y_{j,t}=1 \mid Y_{1,1}, Y_{2,1}, \ldots, Y_{|B|,1}, Y_{1,2}, \ldots, Y_{j-1,t}\right) \le p. \tag{10}$$

Combining our observations with Lemma 9 (see above), we get $\Pr\left(X \ge \ell\right) \le \mathrm{Bin}(T \cdot |B|, p)$. Recall that $\mu = T \cdot |B| \cdot p$. Thus, by applying standard Chernoff bounds we get

$$\Pr\left(X \ge (1+\delta)\mu\right) \le \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\mu} \le e^{\delta^2\mu/3}, \tag{11}$$

which yields the desired statement. ◀

Together, these lemmas generalize a result given in [32] to a setting with considerably more dependencies. Equipped with this Chernoff bound, we prove concentration of the counter values.

▶ **Lemma 11** (Counter Seperation). *Let $c \ge 12$. For every time $t \ge c \cdot T \cdot t_{mix}$ there exist values $\ell_\top > \ell_\perp$ such that*
(a) *For all nodes w with $o_w \ge 2$ we have (w.h.p.) $c_w \le \ell_\perp$.*
(b) *For all nodes v with $o_v = 1$ we have (w.h.p.) $c_v \ge \ell_\top$.*

Proof. For two nodes v and w with $o_v = 1$ and $o_w \ge 2$, $\mu_i := (1/n + 1/n^5)c \cdot T \cdot \gamma \cdot n_k$ for all $i \in [k]$, and $\mu' := (1/n + 1/n^5)c \cdot T \cdot \gamma \cdot (n - n_1)$. For $i \in [k]$ define

$$\ell_\perp(i) := \mu_i + \sqrt{c^2 \cdot \log n \cdot T \cdot \gamma \frac{n_i}{n}} \qquad \text{and} \qquad \ell_\top := T\gamma - \mu' - \sqrt{c^2 \cdot \log n \cdot T \cdot \gamma \frac{n-n_1}{n}}.$$

We set $\ell_\perp := \ell_\perp(2)$. It is easy to show that $\ell_\perp < \ell_\top$. Now, let all γn tokens be labeled from 1 to γn. It remains to prove the lemma's statements:

- For the first statement, consider a node w with $o_w \ge 2$ and set $\lambda(o_w) := \ell_\perp(o_w) - \mu_{o_w} = \sqrt{c^2 \cdot \log n \cdot T \cdot \gamma \cdot n_{o_w}/n}$. Set the random indicator variable $X_{i,t}$ to be 1 if and only if i is on node w at time t and if i's label is o_w. Let $c_w = \sum_{i\in[\gamma n]}\sum_{j\le T} X_{i,j\cdot t_{\mathrm{mix}}}$. We compute

$$\begin{aligned}\Pr\left(c_w \ge \ell_\perp\right) \le \Pr\left(c_w \ge \mu_{o_w} + \lambda(o_w)\right) &= \Pr\left(c_w \ge \left(1 + \frac{\lambda(o_w)}{\mu_{o_w}}\right) \cdot \mu_{o_w}\right) \\ &\le \exp\left(-\frac{\lambda^2(o_w)}{3\mu_{o_w}}\right) \le \exp\left(-\frac{c}{6}\log n\right),\end{aligned} \tag{12}$$

  where the last line follows by Lemma 10 applied to $c_w = \sum_{i\in[\gamma n]}\sum_{j\le T} X_{i,j\cdot t_{\mathrm{mix}}}$ and setting B to the set of all tokens with label o_w. Hence, the claim follows for c large enough after taking the union bound over all $n - n_1 \le n$ nodes w with $o_w \ge 2$.

- For the lemma's second statement, consider a node v with $o_v = 1$ and set $\lambda' := \mu' - \ell_\top$. Define the random indicator variable $Y_{i,t}$ to be 1 if and only if token i is on node v at time t and if i's label is not 1. Set $Y = \sum_{j \le T} \sum_{i \in [\gamma n]} Y_{i,j \cdot t_{\text{mix}}}$ and note that $c_v = T\gamma - Y$. We compute

$$\Pr(c_v \le \ell_\top) = \Pr(T\gamma - Y \le \ell_\top) = \Pr(T\gamma - Y \le T\gamma - \mu' - \lambda') = \Pr(Y \ge \mu' + \lambda')$$
$$= \Pr\left(Y \ge \left(1 + \frac{\lambda'}{\mu'}\right) \cdot \mu'\right) \le \exp\left(-\frac{\lambda'^2}{3\mu'}\right) \le \exp\left(\frac{c}{6}\log n\right),$$

where the first inequality follows by Lemma 10 applied to Y and using B to denote the set of all tokens with a label other than 1. Hence, the claim follows for c large enough after taking the union bound over all $n_1 \le n$ nodes v with $o_u \ge 2$. ◀

We now give the proof of our main theorem.

Proof of Theorem 2. Fix an arbitrary time $t \in [c \cdot T \cdot t_{\text{mix}}, N]$ with $t_{\text{mix}} \mid t$, where c is the constant from the statement of Lemma 11. From Lemma 11 we have that (w.h.p.) the node u with the highest counter c_u has $o_u = 1$ (ties are broken arbitrarily). In the following we condition on $o_u = 1$. We claim that at time $t' = t + t_{\text{mix}}$ all nodes $v \in V$ have $plu_v = 1$. This is because the counters during the "broadcast part" (Lines 4 to 8) propagate the highest counter received after time t. The time τ until all nodes $v \in V$ have $plu_v = 1$ is bounded by the mixing by definition: In order for $[t, t']$ to be $1/n^5$-smoothing, the random walk starting at u at time t is with probability at least $1/n - 1/n^5$ on node v and, thus, there exists a path from u to v (with respect to the communication matrices). If there is such a path for every node v, the counter of u was also propagated to that v and we have $\tau \le t_{\text{mix}}$. Consequently, at time t' all nodes have the correct majority opinion. This implies the desired time bound. For the memory requirements, note that each node u stores γ tokens with a label from the set $[k]$ ($\gamma \cdot \mathrm{O}(\log k)$ bits), three opinions (its own, its plurality guess, and the dominating opinion; $\mathrm{O}(\log k)$ bits), the two counters c_u and e_u and the time step counter. The memory to store the counter c_u and e_u is $\mathrm{O}(\gamma T)$. Finally, the time step counter is bounded by $\mathrm{O}(\log(T \cdot t_{\text{mix}}))$ bits. This yields the claimed space bound. ◀

4 Protocol Balance

Protocol Description. The idea of our Balance protocol is quite simple: Every node u stores a k-dimensional vector $\boldsymbol{\ell_t(u)}$ with k integer entries, one for each opinion. Balance performs an entry-wise load balancing on $\boldsymbol{\ell_t(u)}$ according to the communication pattern $\boldsymbol{M} = (\boldsymbol{M}_t)_{t \le N}$ and the corresponding transition matrices $\boldsymbol{P}_t$ (cf. Section 2). Once the load is properly balanced, the nodes look at their largest entry and assume that this is the plurality opinion (stored in the variable plu_u).

In order to ensure a low memory footprint, we must not send fractional loads over active edges. To this end, we use a rounding scheme from [12, 32], which works as follows: Consider a dimension $i \in [k]$ and let $\ell_{i,t}(u) \in \mathbb{N}$ denote the current (integral) load at u in dimension i. Then u sends $\lfloor \ell_{i,t}(u) \cdot \boldsymbol{P}_t[u,v] \rfloor$ tokens to all neighbors v with $\boldsymbol{M}_t[u,v] = 1$. This results in at most $d_t(u)$ remaining *excess tokens* ($\ell_{i,t}(u)$ minus the total number of tokens sent out). These are then randomly distributed (without replacement), where neighbor v receives a token with probability $\boldsymbol{P}_t[u,v]$. In the following we call the resulting balancing algorithm *vertex-based balancing* algorithm. The formal description of protocol Balance is given in Listing 2.

```
for $i \in [k]$:
  for $\{u, v\} \in E$ with $\boldsymbol{M}_t[u,v] = 1$:
    send $\lfloor \ell_{i,t}(u) \cdot \boldsymbol{P}_t[u,v] \rfloor$ tokens from dimension $i$ to $v$
  $x := \ell_{i,t}(u) - \sum_{v:\, \boldsymbol{M}_t[u,v]=1} \lfloor \ell_{i,t}(u) \cdot \boldsymbol{P}_t[u,v] \rfloor$        {excess tokens}
  randomly distribute $x$ tokens such that:
    every $v \neq v$ with $\boldsymbol{M}_t[u,v] = 1$ receives 1 token w.p. $\boldsymbol{P}_t[u,v]$
    (and zero otherwise)
$plu_u := i$ with $\ell_{i,t}(u) \geq \ell_{j,t}(u) \quad \forall 1 \leq i,j \leq k$        {plurality guess}
```

Listing 2 Protocol Balance as executed by node u at time t. At time zero, each node initializes $\ell_{o_u,0}(u) := \gamma$ and $\ell_{j,0}(u) := 0$ for all $j \neq o_u$.

Analysis of Balance. Consider initial load vectors $\boldsymbol{\ell_0}$ with $\|\boldsymbol{\ell_0}\|_\infty \leq n^5$. Let $\tau := \tau(g, \boldsymbol{M})$ be the first time step when Vertex-Based Balancer under the (fixed) communication pattern $\boldsymbol{M} = (\boldsymbol{M}_t)_{t \leq N}$ is able to balance any such vector $\boldsymbol{\ell_0}$ up to a g-discrepancy. With this, we show:

▶ **Theorem 12.** *Let $\alpha = \frac{n_1 - n_2}{n} \in [1/n, 1]$ denote the initial bias. Consider a fixed communication pattern $\boldsymbol{M} = (\boldsymbol{M}_t)_{t \leq N}$ and an integer $\gamma \in [3 \cdot \frac{g}{\alpha}, n^5]$. Protocol* Balance *ensures that all nodes know the plurality opinion after $\tau(g, \boldsymbol{M})$ rounds and requires $k \cdot \log(\gamma)$ memory bits per node.*

Proof. Recall that $\gamma \geq 3\frac{g}{\alpha} = 3g \cdot \frac{n}{n_1 - n_2}$. For $i \in [k]$ let $\bar{\ell}_i := n_i \cdot \gamma / n$. The definition of $\tau(g, \boldsymbol{M})$ implies $\ell_{1,t}(u) \geq \bar{\ell}_1 - g$ and $\ell_{i,t}(u) \leq \bar{\ell}_i + g$ for all nodes u and $i \geq 2$. Consequently, we get

$$\ell_{1,t}(u) - \ell_{i,t}(u) \geq \bar{\ell}_1 - \bar{\ell}_i - 2g = 3g \cdot \frac{n_1 - n_i}{n_1 - n_2} - 2g > 0\,. \tag{13}$$

Thus, every node u has the correct plurality guess at time t. ◀

The memory usage of Balance depends on the number of opinions (k) and on the number of tokens generated on every node (γ). The algorithm is very efficient for small values of k but it becomes rather impractical if k is large. Note that if one chooses γ sufficiently large, it is easy to adjust the algorithm such that every node knows the frequency of *all* opinions in the network. The next corollary gives a few concrete examples for common communication patterns on general graphs.

▶ **Corollary 13.** *Let G be an arbitrary d-regular graph.* Balance *ensures that all nodes agree on the plurality opinion with probability $1 - e^{-(\log(n))^c}$ for some constant c*

(a) *using $\mathrm{O}(k \cdot \log n)$ bits of memory in time $\mathrm{O}\big(\frac{\log n}{1-\lambda_2}\big)$ in the diffusion model,*

(b) *using $\mathrm{O}(k \cdot \log n)$ bits of memory in time $\mathrm{O}\big(\frac{1}{d \cdot p_{min}} \cdot \frac{\log n}{1-\lambda_2}\big)$ in the random matching model,*

(c) *using $\mathrm{O}\left(k \cdot \log(\alpha^{-1})\right)$ bits of memory in time $\mathrm{O}\big(d \cdot \frac{\log n}{1-\lambda_2}\big)$ in the balancing circuit model, and*

(d) *using $\mathrm{O}\left(k \cdot \log(\alpha^{-1})\right)$ bits of memory in time $\mathrm{O}\big(n \cdot \frac{\log n}{1-\lambda_2}\big)$ in the sequential model.*

Proof. Part (a) follows directly from [33, Theorem 6.6] and Part (c) follows directly from [33, Theorem 1.1]. To show Part (b) and (d) we choose τ such that $\boldsymbol{M}_1, \boldsymbol{M}_2, \ldots, \boldsymbol{M}_\tau$ enable Vertex-Based Balancer to balance any vector $\boldsymbol{\ell_0}$ (with initial discrepancy of at most n^5) up to a *g-discrepancy*. The bound on τ then follows from [33, Theorem 1.1]. ◀

Abstract

This work investigates the hardness of computing sparse solutions to systems of linear equations over $\mathbb{F}_2$. Consider the k-EvenSet problem: given a homogeneous system of linear equations over $\mathbb{F}_2$ on n variables, decide if there exists a nonzero solution of Hamming weight at most k (i.e. a k-sparse solution). While there is a simple $O(n^{k/2})$-time algorithm for it, establishing fixed parameter intractability for k-EvenSet has been a notorious open problem. Towards this goal, we show that unless k-Clique can be solved in $n^{o(k)}$ time, k-EvenSet has no polynomial time algorithm when $k = \omega(\log^2 n)$.

Our work also shows that the non-homogeneous generalization of the problem – which we call k-VectorSum – is W[1]-hard on instances where the number of equations is $O(k \log n)$, improving on previous reductions which produced $\Omega(n)$ equations. We use the hardness of k-VectorSum as a starting point to prove the result for k-EvenSet, and additionally strengthen the former to show the hardness of *approximately learning k-juntas*. In particular, we prove that given a system of $O(\exp(O(k)) \cdot \log n)$ linear equations, it is W[1]-hard to decide if there is a k-sparse linear form satisfying all the equations or any function on at most k-variables (a k-junta) satisfies at most $(1/2 + \varepsilon)$-fraction of the equations, for any constant $\varepsilon > 0$. In the setting of computational learning, this shows hardness of approximate *non-proper* learning of k-parities. In a similar vein, we use the hardness of k-EvenSet to show that that for any constant d, unless k-Clique can be solved in $n^{o(k)}$ time, there is no $\mathrm{poly}(m, n) \cdot 2^{o(\sqrt{k})}$ time algorithm to decide whether a given set of m points in $\mathbb{F}_2^n$ satisfies: (i) there exists a non-trivial k-sparse homogeneous linear form evaluating to 0 on all the points, or (ii) any non-trivial degree d polynomial P supported on at most k variables evaluates to zero on $\approx \mathbf{Pr}_{\mathbb{F}_2^n}[P(\mathbf{z}) = 0]$ fraction of the points i.e., P is *fooled* by the set of points.

Lastly, we study the approximation in the sparsity of the solution. Let the Gap-k-VectorSum problem be: given an instance of k-VectorSum of size n, decide if there exist a k-sparse solution, or every solution is of sparsity at least $k' = (1 + \delta_0)k$. Assuming the Exponential Time Hypothesis, we show that for some constants c_0, $\delta_0 > 0$ there is no $\mathrm{poly}(n)$ time algorithm for Gap-k-VectorSum when $k = \omega((\log \log n)^{c_0})$.

1 Introduction

Given a system of linear equations over $\mathbb{F}_2$, does there exist a sparse non-trivial solution? This question is studied in different guises in several areas of mathematics and computer science. For instance, in coding theory, if the system of linear equations is $\mathbf{Mx} = \mathbf{0}$ where $\mathbf{M}$ is the parity check matrix of a binary code, then the minimum (Hamming) weight of a nonzero solution is the distance of the code. This also captures the problem of determining whether a binary matroid has a short cycle, as the latter reduces to deciding whether there is a sparse nonzero $\mathbf{x}$ such that $\mathbf{Mx} = \mathbf{0}$. In learning theory, the well known sparse parity problem is: given a binary matrix $\mathbf{M}$ and a vector $\mathbf{b}$ decide whether there is a small weight nonzero vector $\mathbf{x}$ satisfying $\mathbf{Mx} = \mathbf{b}$. The version where $\mathbf{Mx}$ is required to equal $\mathbf{b}$ in most coordinates, but not necessarily all, is also well studied as the problem of learning noisy parities.

Let a vector $\mathbf{x} \in \mathbb{F}_2^n$ be called *k-sparse* if it is nonzero in at most k positions, i.e. it has Hamming weight at most k. In this work, we show that learning a k-sparse solution to a system of linear equations is fixed parameter intractable, even when (i) the number of equations is only *logarithmic* in the number of variables, (ii) the learning is allowed to be *approximate*, i.e. satisfy only 51% of the equations and, (iii) is allowed to output as hypothesis any function (junta) supported on at most k variables. We also prove variants of these results for the case when the system of equations is homogeneous, which correspond to hardness of the well known k-EvenSet problem. Note that it is always possible to recover a k-sparse solution in $O(n^k)$ time simply by enumerating over all k-sparse vectors. Our results show that for many settings of k, no substantially faster algorithm is possible for k-EvenSet unless widely believed conjectures are false. Assuming similar conjectures, we also rule out fast algorithms for learning γk-sparse solutions to a linear system promising the existence of a k sparse solutions, for some $\gamma > 1$.

In the next few paragraphs we recall previous related work and place our results in their context. Let us first formally define the basic objects of our study:

▶ **Definition 1.** k-VectorSum: Given a matrix $\mathbf{M} \in \mathbb{F}_2^{m\times n}$ and a vector $\mathbf{b} \in \mathbb{F}_2^m$, and a positive integer k as parameter, decide if there exists a k-sparse vector $\mathbf{x}$ such that $\mathbf{Mx} = \mathbf{b}$.

▶ **Definition 2.** k-EvenSet: Given a matrix $\mathbf{M} \in \mathbb{F}_2^{m\times n}$, and a positive integer k as parameter, decide if there exists a nonzero k-sparse vector $\mathbf{x}$ such that $\mathbf{Mx} = \mathbf{0}$.

▶ Remark. In the language of coding theory, k-VectorSum is also known as the Maximum-LikelihoodDecoding problem and k-EvenSet as the MinimumDistance problem.

Clearly, k-VectorSum is as hard as k-EvenSet[1]. The k-VectorSum problem was shown to be W[1]-hard[2] by Downey, Fellows, Vardy and Whittle [15], even in the special

[1] The name k-EvenSet is from the following interpretation of the problem: given a set system $\mathcal{F}$ over a universe U and a parameter k, find a nonempty subset $S \subseteq U$ of size at most k such that the intersection of S with every set in $\mathcal{F}$ has even size.

[2] Standard definitions in parameterized complexity appear in Section 2.

case of the vector $\mathbf{b}$ consisting of all 1's. More recently, Bhattacharyya, Indyk, Woodruff, and Xie [6] showed that the time complexity of k-VectorSum is at least $\min(2^{\Theta(m)}, n^{\Theta(k)})$, assuming the Exponential Time Hypothesis (i.e., 3-SAT has no $2^{o(n)}$ time algorithm) [24].

In contrast, the complexity of k-EvenSet remains unresolved, other than its containment in W[2] shown in [15]. Proving W[1]-hardness for k-EvenSet was listed as an open problem in Downey and Fellows' 1999 monograph [17] and has been reiterated more recently in lists of open problems [21, 19]. Note that if we ask for a vector $\mathbf{x}$ whose weight is *exactly* k instead of at most k, the problem is known to be W[1]-hard [15]. Our work gives evidence ruling out efficient algorithms for k-EvenSet for a wide range of settings of k.

In the non-parameterized setting, where k is part of the input, these problems are very well-studied. Vardy showed that EvenSet (or MinimumDistance) is NP-hard [33]. The question of approximating k, the minimum distance of the associated code, has also received attention. Dumer, Micciancio, and Sudan [18] showed that if $\mathsf{RP} \neq \mathsf{NP}$, then k is hard to approximate within some constant factor $\gamma > 1$. Cheng and Wan [11, 12] proved the same assuming $\mathsf{P} \neq \mathsf{NP}$, and subsequently Austrin and Khot [4] gave a simpler deterministic reduction for this problem. The results of [11, 12] and [4] were further strengthened by Micciancio [30].

From a computational learning perspective, the k-VectorSum problem can be restated as: given an m-sized set of n-dimensional point and value pairs (i.e. elements of $\mathbb{F}_2^n \times \mathbb{F}_2$), decide if there exists a parity (i.e. a homogeneous linear form) supported on at most k variables (i.e. a k-parity) that is consistent with all the pairs. This has been extensively studied as a promise problem when the points are generated uniformly at random. Note that in this case, if $m = \Omega(n)$, there is a unique solution w.h.p and can be found efficiently by Gaussian elimination. On the other hand, for $m = O(k \log n)$, the best known running time of $O(n^{k/2})$ is given in [28] (credited to Dan Spielman). Obtaining a polynomial time algorithm for $m = \text{poly}(k \log n)$ would imply *attribute-efficient learning* of k-parities and is a long-standing open problem in the area [7].

A natural question studied in this work is whether one can do better if the learning algorithm is allowed to be *non-proper* (i.e., output a hypothesis that is not a k-parity) and is allowed to not satisfy all the point-value pairs. To further motivate this problem, let us look at the case when k is not fixed along with a promise that there exists a parity consistent with $1 - \delta$ (for some constant $\delta > 0$) fraction of the point-value pairs, i.e., the agnostic setting. When the points are adversarially drawn, there is no non-trivial proper algorithm known but there is a non-proper algorithm due to Kalai, Mansour, and Verbin [25] that runs in time $2^{O(n/\log n)}$ and outputs a circuit C consistent with at least $\left(1 - \delta - 2^{-n^{0.99}}\right)$ of the point-value pairs. On the hardness side, Håstad's inapproximability for Max-3LIN [23] implies that properly learning a noisy parity in the agnostic setting is NP-hard, even for $1/2+\varepsilon$ accuracy, for any constant $\varepsilon > 0$. Nearly a decade later, Gopalan, Khot, and Saket [22] showed that achieving an accuracy of $1-1/2^d+\varepsilon$ using degree-d polynomials as hypotheses is NP-hard and subsequently, Khot [26] proved NP-hardness for learning with accuracy $1/2+\varepsilon$ using constant degree polynomials[3]. Our work studies the intractability of approximate non-proper learning of k-parity and extends the hardness result for k-VectorSum to learning by juntas of k variables and for k-EvenSet to learning using constant degree polynomials on k variables.

[3] As far as we know, this result is unpublished although it was communicated to the fourth author of this paper. The full version of this paper [5] includes a proof of Khot's result with his permission to illustrate some of the techniques which inspire part of this work.

Another interesting question in the parameterized setting is related to a gap in the sparsity parameter k, i.e. how tractable it is to learn a γk-sparse solution when the existence of a k-sparse solution is guaranteed, for some constant $\gamma > 1$. Previously, Bonnet et al. [8] and Khot and Shinkar [27] studied the approximation problem corresponding to k-Clique, and both these works show conditional hardness results. More generally, there have been several previous works studying approximation algorithms with the optimum value being a parameter; see references in Marx's survey [29]. In our work, we prove a "gap in k" hardness result for k-VectorSum similar to that obtained in [8] for k-Clique.

In the rest of this section we formally describe our results for k-VectorSum and k-EvenSet, and give a brief description of the techniques used to obtain them.

1.1 Our Results

All the reductions given in this section run in time polynomial in the size of the output instances. We do not make this explicit for ease of notation.

Hardness of exact problems

The main result of this paper is the following hardness reduction from k-VectorSum to the k-EvenSet problem.

▶ **Theorem 3** (Hardness of k-EvenSet). *There is an* FPT *reduction from an instance* $(\mathbf{M}, \mathbf{t})$ *of* k-VectorSum, *where* $\mathbf{M} \in \mathbb{F}_2^{m \times n}$ *and* $\mathbf{t} \in \mathbb{F}_2^m$, *to an instance* $\mathbf{M}'$ *of* $O((k \log n)^2)$-EvenSet, *where* $\mathbf{M}' \in \mathbb{F}_2^{m' \times n'}$ *such that both* m' *and* n' *are bounded by fixed polynomials in* m *and* n.

Combined with the W[1]-hardness of k-VectorSum ([15, 13] or Theorem 5 below), the above yields the following corollary.

▶ **Corollary 4.** *There does not exist a* $\text{poly}(n)$ *time algorithm for* k-EvenSet *when* $k = \omega(\log^2 n)$, *assuming that* k-Clique *does not have a polynomial time algorithm for any* $k = \omega_n(1)$. *More generally, under the same assumption,* k-EvenSet *does not admit a* $\text{poly}(n) \cdot 2^{o(\sqrt{k})}$ *time algorithm for unrestricted* k.

Proof. Suppose there is a $T(n, k)$ algorithm for k-EvenSet. Chaining the W[1]-hardness of k-VectorSum from Theorem 5 with the reduction in Theorem 3, we obtain a $T\left(\text{poly}(n), O\left((k^2 \log n)^2\right)\right)$ algorithm for k-Clique. Choosing $k = \omega_n(1)$ implies the first part of the corollary. For the second part, observe that if $f(x) = 2^{o(\sqrt{x})}$, then we have $f\left((k^2 \log n)^2\right) = n^{o(1)}$ for some $k = \omega_n(1)$. ◀

To the best of our knowledge, Corollary 4 gives the first nontrivial hardness results for parameterized k-EvenSet. Theorem 3 is obtained by adapting the hardness reduction for the inapproximability of MinimumDistance by Austrin and Khot [4] to the parameterized setting.

We also give a reduction from k-Clique showing the W[1]-hardness of k-VectorSum on instances which have a small number of rows.

▶ **Theorem 5** (W[1]-hardness of k-VectorSum). *The* k-VectorSum *problem is* W[1]*-hard on instances* $(\mathbf{M}, \mathbf{b})$ *where* $\mathbf{M} \in \mathbb{F}_2^{m \times n}$ *and* $\mathbf{b} \in \mathbb{F}_2^m$ *such that* $m = O(k \log n)$. *This is obtained by an* FPT *reduction from an* r*-vertex instance of* ℓ-Clique *to* $(\mathbf{M}, \mathbf{b})$ *such that* $m = O(\ell^2 \log r)$, $n = O((\ell r)^2)$ *and* $k = \Theta(\ell^2)$. *Our reduction implies, in particular, that* k-VectorSum *does not admit an* $n^{o(\sqrt{k})}$ *time algorithm on such instances, unless* k-Clique *on* r*-vertex graphs has an* $r^{o(k)}$ *time algorithm.*

As far as we know, in previous proofs of the W[1]-hardness of k-VectorSum [15, 13], the number of rows in the matrix output by the reduction was linear in n. Our proof is inspired by a recent proof of the W[1]-hardness of k-Sum [1]. Additionally, in Section 7 , we give a simple $O(n \cdot 2^m)$ time algorithm for k-VectorSum, which suggests that m cannot be made sublogarithmic in n for hard instances. The logarithmic upper bound on the number of equations in our hardness reduction to k-VectorSum also leads to a similarly efficient W[1]-hardness of approximate non-proper learning of k-parities (Theorem 7 below) which uses Theorem 5 as the starting point.

Hardness of non-proper and approximately learning sparse parities

Theorem 5 can be restated in terms of W[1]-hardness of learning a k-parity[4].

▶ **Theorem 6** (Theorem 5 restated). *The following is* W[1]*-hard: given $m = O(k \log n)$ point-value pairs $\{(\mathbf{y}_i, a_i)\}_{i=1}^m \subseteq \mathbb{F}_2^n \times \mathbb{F}_2$, decide whether there exists a k-parity L which satisfies all the point-value pairs, i.e., $L(\mathbf{y}_i) = a_i$ for all $i = 1, \ldots, m$.*

Next, we strengthen the above theorem in two ways. We show that the W[1]-hardness holds for learning a k-parity using a k-junta, and additionally for any desired accuracy exceeding 50 Here, a k-junta is any function depending on at most k variables.

▶ **Theorem 7.** *The following is W[1]-hard: for any constant $\delta > 0$, given $m = O(k \cdot 2^{3k} \cdot (\log n)/\delta^3)$ point-value pairs $\{(\mathbf{z}_i, b_i)\}_{i=1}^m \subseteq \mathbb{F}_2^n \times \mathbb{F}_2$, decide whether:*

YES Case. *There exists a k-parity which satisfies all the point-value pairs.*

NO Case. *Any function $f : \mathbb{F}_2^n \mapsto \mathbb{F}_2$ depending on at most k variables satisfies at most $1/2 + \delta$ fraction of the point-value pairs.*

Theorem 7 also implies hardness for *approximately* learning k-juntas as stated in the following corollary:

▶ **Corollary 8.** *There exists no $n^{o(k)}$ time algorithm which given $m = O(k \cdot 2^{3k} \cdot (\log n)/\delta^3)$ point-value pairs $\{(\mathbf{z}_i, b_i)\}_{i=1}^m$, computes a k-junta $f : \mathbb{F}_2^n \mapsto \mathbb{F}_2$ which satisfies at least $1/2 + \delta$ fraction of the point-value pairs, unless k-Clique on n vertices can be solved in $n^{o(k)}$ time.*

In comparison, the problem of *exactly* learning k-juntas previously shown to be W[2]-hard by Arvind, Köbler, and Lindner [3]. Note that the current best algorithm for learning k-juntas, even over the uniform distribution, takes $n^{\Omega(k)}$ time [32, 31].

We similarly strengthen Theorem 3 to rule out efficient algorithms for approximately learning a k-sparse solution to a homogeneous linear system using constant degree polynomials supported on at most k variables.

▶ **Theorem 9.** *For any constants $\delta > 0$ and positive integer d, given an instance $(\mathbf{A}, \mathbf{b})$ of k'-VectorSum, where $\mathbf{A} \in \mathbb{F}_2^{m' \times n'}$ and $\mathbf{b} \in \mathbb{F}_2^{m'}$, there is an* FPT *reduction to a set of m points $\{\mathbf{z}_i\}_{i=1}^m \subseteq \mathbb{F}_2^n$ such that for some $k = O((k' \log n')^2)$,*

YES Case. *There exists a non-trivial k-parity L such that $L(\mathbf{z}_i) = 0$ for all $i = 1, \ldots, m$.*

[4] Note that Theorem 5 as stated shows hardness of learning homogeneous k-sparse linear forms (without the constant term). The result can easily be made to hold for learning by general k-sparse linear forms by adding a point-value pair which is $(\mathbf{0}, 0)$.

NO Case. *Any degree d polynomial $P : \mathbb{F}_2^n \mapsto \mathbb{F}_2$ depending on at most k variables satisfies $P(\mathbf{z}_i) = 0$ for at most $\left(\mathbf{Pr}_{\mathbf{z}\in_U \mathbb{F}_2^n}[P(\mathbf{z}) = 0] + \delta\right)$ fraction of the points*[5]*, where $\mathbf{z} \in_U \mathbb{F}_2^n$ is sampled u.a.r.*

In the above m and n are bounded by polynomials in m' and n'.

In particular, if we assume that k-Clique does not have a poly(n) time algorithm for any $k = \omega(1)$, then for any constant $\delta > 0$ and positive integer d there is no poly$(m, n) \cdot 2^{o(\sqrt{k})}$ time algorithm to decide whether a given set of points $\{\mathbf{z}_i\}_{i=1}^m \subseteq \mathbb{F}_2^n$ satisfies the YES or the NO case. The proof of Theorem 9 relies on an application of Viola's [34] pseudorandom generator for constant degree polynomials, and is inspired by Khot's [26] NP-hardness of learning linear forms using constant degree polynomials.

Gap in sparsity parameter

Using techniques similar to those employed in [8], we prove the following *gap in k* hardness for k-VectorSum, i.e., hardness of Gap-k-VectorSum.

▶ **Theorem 10.** *Assuming the Exponential Time Hypothesis, there are universal constants $\delta_0 > 0$ and c_0 such that there is no* poly(N) *time algorithm to determine whether an instance of* Gap-k-VectorSum *of size N admits a solution of sparsity k or all solutions are of sparsity at least $(1 + \delta_0)k$, for any $k = \omega((\log\log N)^{c_0})$. More generally, under the same assumption, this problem does not admit an $N^{O(k/\omega((\log\log N)^{c_0}))}$ time algorithm for unrestricted k.*

1.2 Our Techniques

Our reduction for proving Theorem 3 proceeds by homogenizing a W[1]-hard instance of k-VectorSum by including $\mathbf{b}$ as a column of $\mathbf{M}$. To force the solution to always choose $\mathbf{b}$, we use the approach of Austrin and Khot [4] who face the same issue when reducing to the MinimumDistance problem. But since we need to retain the bound on the sparsity of the solution, we cannot use their techniques directly. Instead, for a purported sparse solution $\mathbf{x}$, we construct a small length sketch $\mathbf{y}$ that also belongs to an ε-balanced code $\mathcal{C}$. Now, consider $\mathbf{Y}$ that supposedly equals $\mathbf{y}\mathbf{y}^{\mathbf{T}}$. Note that we can check through a system of linear constraints that $\mathbf{Y}$ belongs to the tensor product code $\mathcal{C} \otimes \mathcal{C}$. We then proceed as in [4] to ensure that in the soundness analysis, $\mathbf{Y}$ has non-trivially large weight whenever $\mathbf{x}$ is set to $\mathbf{0}$, implying that the derived k-EvenSet instance is unsatisfiable. Our construction inflates the parameter k to $O((k \log n)^2)$.

The proof of Theorem 5 is based on a gadget reduction from an n-vertex instance of k-Clique creating columns of $\mathbf{M}$ corresponding to the vertices and edges of the graph along with a target vector $\mathbf{b}$. Unlike previous reductions in which the number of coordinates (rows of $\mathbf{M}$) are linear in the number of vertices, we reuse the same set of coordinates for the vertices and edges by assigning unique logarithmic length patterns to each vertex. In total we create k columns for each vertex and $\binom{k}{2}$ columns for each edge, using $O(k^2 \log n)$ coordinates. The target vector $\mathbf{b}$ ensures that a solution always has at least $k + \binom{k}{2}$ columns, which suffices in the YES case while the NO case requires strictly more columns to sum to $\mathbf{b}$.

The hardness of approximately learning k-parities with k-juntas given in Theorem 7 is obtained by transforming the instance of Theorem 5 using an ε-balanced code, along with an analysis of the Fourier spectrum of any k-junta on the resulting distribution. In contrast,

[5] Note that $\mathbf{Pr}_{\mathbf{z}\in_U \mathbb{F}_2^n}[P(\mathbf{z}) = 0] \leqslant 1 - 2^{-d}$, for any non-trivial degree d polynomial P.

Theorem 9 is obtained by taking the uniform distribution over the equations in the hard instance of Theorem 3 (appropriately transformed using an ε-balanced code) as an input to Viola's construction [34] of pseudorandom generators for degree d polynomials. Note that the $\exp(k)$ blowup in the reduction for Theorem 7 rules out its use for proving Theorem 9 due to the presence of a $(\log^2 n)$ factor in the sparsity parameter of the instance obtained in Theorem 3. On the other hand, the non-homogeneity of the k-VectorSum problem hinders the use of Viola's pseudorandom generator for proving a version (for degree d polynomials on k variables instead of k-juntas) of Theorem 7 which avoids the $\exp(k)$ blowup.

For Theorem 10, we use the improved *sparsification lemma* of Calabro, Impagliazzo, and Paturi [10] followed by Dinur's almost linear PCP construction [14] to reduce an n-variable 3-SAT instance to $2^{\varepsilon n}$ Gap-3-SAT instances with almost linear in n clauses and variables. For each instance, a corresponding k-VectorSum instance is created by partitioning the clauses into k blocks and adding $\mathbb{F}_2$-valued variables for partial assignments to each block along with non-triviality and consistency equations. In the YES case setting one variable from each block to 1 (i.e. a k-sparse solution) suffices, whereas in the NO case at least γk variables need to be set to 1, for some constant $\gamma > 1$. The parameters are such that an efficient algorithm to decide the YES and NO cases would violate the Exponential Time Hypothesis for 3-SAT.

Organization of the paper. Reducing from a W[1]-hard instance of k-VectorSum, Theorem 3 is proved in Section 3. This is extended in Section 4 to prove Theorem 9. The reduction proving Theorem 7 is given in Section 5, and starts with a hard instance from Theorem 6 (restatement of Theorem 5). Lastly, we given an efficient reduction from k-Clique to k-VectorSum in in Section 6. Due to lack of space, we do not include the proof of Theorem 10, which can be found in the full version [5] of the paper instead.

In the next section we give some definitions and results which shall prove useful for the subsequent proofs.

2 Preliminaries

2.1 Parameterized Complexity

A *parameterization* of a problem is a poly(n)-time computable function that assigns an integer $k \geqslant 0$ to each problem instance x of length n (bits). The pair (x, k) is an instance of the corresponding parameterized problem. The parameterized problem is said to be *fixed parameter tractable (FPT)* if it admits an algorithm that runs in time $f(k) \cdot \text{poly}(n)$ where k is the parameter of the input, n is the size of the input, and f is an arbitrary computable function. The W-*hierarchy*, introduced by Downey and Fellows [16, 17], is a sequence of parameterized complexity classes with $\text{FPT} = \text{W}[0] \subseteq \text{W}[1] \subseteq \text{W}[2] \subseteq \cdots$. It is widely believed that $\text{FPT} \neq \text{W}[1]$.

These hierarchical classes admit notions of completeness and hardness under FPT reductions i.e., $f(k) \cdot \text{poly}(n)$-time transformations from a problem A instance (x, k) where $|x| = n$, to an instance (x', k') of problem B where $|x'| \leqslant f(k) \cdot \text{poly}(n)$ and k' is bounded by $f(k)$. For example, consider the k-Clique problem: given a graph G on n vertices and an integer parameter k, decide if G has a clique of size k. The k-Clique problem is W[1]-complete, and serves as a canonical hard problem for many W[1]-hardness reductions including those in this work.

For a precise definition of the W-hierarchy, and a general background on parameterized algorithms and complexity, see [17, 20, 13].

2.2 Coding Theoretic Tools

Our hardness reductions use some basic results from coding theory. For our purposes, we shall be restricting our attention to *linear* codes over $\mathbb{F}_2$ i.e., those which form linear subspaces. A code $\mathcal{C} \subseteq \mathbb{F}_2^n$ is said to be a $[n, k, d]$-binary linear code if $\mathcal{C}$ forms a k-dimensional subspace of $\mathbb{F}_2^n$ such that all nonzero elements (codewords) in $\mathcal{C}$ are of Hamming weight at least d. We use weight $\mathrm{wt}(\mathbf{x})$ of a codeword $\mathbf{x}$ to denote its Hamming weight, *distance* of a code to denote the minimum weight of any nonzero codeword, and *rate* to denote the fraction k/n. A *generator* matrix $\mathbf{G} \in \mathbb{F}_2^{n\times k}$ for $\mathcal{C}$ is such that $\mathcal{C} = \{\mathbf{Gx} \mid \mathbf{x} \in \mathbb{F}_2^k\}$. Also associated with $\mathcal{C}$ is a *parity check matrix* $\mathbf{G}^\perp \in \mathbb{F}_2^{(n-k)\times n}$ satisfying: $\mathbf{G}^\perp\mathbf{y} = \mathbf{0}$ *iff* $\mathbf{y} \in \mathcal{C}$. We shall use the generator and parity check matrices of well studied code constructions whose properties we state below.

▶ **Theorem 11** (BCH Codes, Theorem 3 [9])**.** *The dimension of the BCH code of block length $n = (2^m - 1)$ and distance d, is at least $\left(n - \lceil \frac{d-1}{2} \rceil m\right)$. Further, the corresponding parity check matrix is constructible in time* $\mathrm{poly}(n)$*.*

While the above theorem restricts the block length to be of the form $(2^m - 1)$, for general n we can use as the parity check matrix any n columns of the parity check matrix of a BCH code of the minimum length $(2^m - 1)$ greater than or equal to n. In particular, we have the following corollary tailored for our purpose.

▶ **Corollary 12.** *For all lengths n and positive integers $k < n$, there exists a parity check matrix $\mathbf{R} \in \mathbb{F}_2^{20k\log n \times n}$ such that $\mathbf{Rx} \neq 0$ whenever $0 < \mathrm{wt}(\mathbf{x}) < 18k$. Moreover, this matrix can be computed in time* $\mathrm{poly}(n)$*.*

The following explicit family of ε-balanced binary linear codes of constant rate was given by Alon et al. [2].

▶ **Theorem 13** (ε-balanced codes [2])**.** *There exists an explicit family of codes $\mathcal{C} \subseteq \mathbb{F}_2^n$ such that every codeword in $\mathcal{C}$ has normalized weight in the range $[1/2 - \varepsilon, 1/2 + \varepsilon]$, and rate $\Omega(\varepsilon^3)$, which can be constructed in time $\mathrm{poly}(n, \frac{1}{\varepsilon})$, where $\varepsilon > 0$ is any arbitrarily small constant.*

Given a linear code $\mathcal{C} \subseteq \mathbb{F}_2^n$, the product code $\mathcal{C}^{\otimes 2}$ consists of $n \times n$ matrices where each row and each column belongs to $\mathcal{C}$; equivalently, $\mathcal{C}^{\otimes 2} = \{\mathbf{GXG}^{\mathrm{T}} : \mathbf{X} \in \mathbb{F}_2^{k\times k}\}$ where $\mathbf{G} \in \mathbb{F}_2^{n\times k}$ is the generator matrix for the code $\mathcal{C}$. If the distance $d(\mathcal{C}) = d$, then it is easy to verify that $d(\mathcal{C}^{\otimes 2}) \geqslant d^2$. However, we shall use the following lemma from [4] for a tighter lower bound on the Hamming weight when the code word satisfies certain properties.

▶ **Lemma 14** (Density of Product Codes [4])**.** *Let $\mathcal{C} \subseteq \mathbb{F}_2^n$ be a binary linear code of distance $d = d(\mathcal{C})$, and let $\mathbf{Y} \in \mathcal{C}^{\otimes 2}$ be a nonzero codeword with the additional properties that $\mathrm{diag}(\mathbf{Y}) = \mathbf{0}$, and $\mathbf{Y} = \mathbf{Y}^{\mathsf{T}}$. Then, the Hamming weight of $\mathbf{Y}$ is at least $\frac{3}{2}d^2$.*

2.3 Viola's Pseudorandom Generator

The proof of Theorem 9 in Section 4 uses Viola's [34] construction of pseudorandom generators which we describe below.

▶ **Definition 15.** A distribution $\mathcal{D}$ over $\mathbb{F}_2^n$ is said to *ε-fool* degree d polynomials in n-variables over $\mathbb{F}_2$ if for any degree d polynomial P:

$$\left| \mathop{\mathbf{E}}_{\mathbf{z}\leftarrow\mathcal{D}} [e(P(\mathbf{z}))] - \mathop{\mathbf{E}}_{\mathbf{z}\leftarrow\mathcal{U}} [e(P(\mathbf{z}))] \right| \leqslant \varepsilon,$$

where $\mathcal{U}$ is the uniform distribution over $\mathbb{F}_2^n$ and $e(x) := (-1)^x$ for $x \in \{0, 1\}$.

▶ **Theorem 16.** *Let $\mathcal{Y}_1, \ldots, \mathcal{Y}_d$ be d independent distributions on $\mathbb{F}_2^n$ that each ε-fool linear polynomials. Then the distribution $\mathcal{W} = \mathcal{Y}_1 + \cdots + \mathcal{Y}_d$ ε_d-fools degree-d polynomials where $\varepsilon_d := 16 \cdot \varepsilon^{1/2^{d-1}}$.*

3 Parameterized Reduction for the k-EvenSet problem

This section is devoted to proving the Theorem 3. The next few paragraphs give an informal description of the reduction. We then define the variables and equations of the k-EvenSet instance, and analyze the completeness and soundness of the reduction.

3.1 Reduction Overview

Let $\mathbf{Mx} = \mathbf{t}$ be a hard instance of k-VectorSum i.e., in the YES case there exists a k-sparse solution, whereas in the NO case all solutions have Hamming weight at least $(k+1)$. We homogenize this affine system by replacing the target vector $\mathbf{t}$ by $a_0\mathbf{t}$ for some $\mathbb{F}_2$-variable a_0, where $a_0\mathbf{t}$ is a coordinate-wise multiplication of $\mathbf{t}$ with the scalar a_0. Clearly, if all $(k+1)$-sparse (including a_0 as a variable) solutions to $\mathbf{Mx} = a_0\mathbf{t}$ have $a_0 = 1$ then the hardness of k-VectorSum implies the desired hardness result for k-EvenSet. However, this may not be true in general: there could exist a k-sparse $\mathbf{x}$ such that $\mathbf{Mx} = \mathbf{0}$. The objective of our reduction therefore, is to ensure that any solution to $\mathbf{Mx} = a_0\mathbf{t}$ that has $a_0 = 0$ with a k-sparse $\mathbf{x}$, must have significantly large weight in other auxiliary variables which we shall add in the construction.

Towards this end, we borrow some techniques from the proof of the inapproximability of MinimumDistance by Austrin and Khot [4]. Using transformations by suitable codes we first obtain a $K = O(k \log n)$-length *sketch* $\mathbf{y} = (y_1, \ldots, y_K)$ of $\mathbf{x}$, such that $\mathbf{y}$ is of normalized weight nearly $1/2$ when $\mathbf{x}$ is k-sparse but nonzero. We then construct a codeword $\mathbf{Y} \in \mathbb{F}_2^{K \times K}$, which is intended to be the product codeword $\mathbf{yy}^T$. However, this relationship cannot be expressed explicitly in terms of linear equations. Instead, for each pair of coordinates $(i,j) \in [K] \times [K]$, we introduce functions $Z_{ij} : \mathbb{F}_2 \times \mathbb{F}_2 \mapsto \mathbb{F}_2$ indicating the value taken by the pair (y_i, y_j) along with constraints that relate the Z_{ij} variables to codewords $\mathbf{y}$ and $\mathbf{Y}$. In fact, the explicit variables $\{Z_{ij}\}$ determine both $\mathbf{y}$ and $\mathbf{Y}$ which are implicit. The constraints also satisfy the key property: if $\mathbf{x}$ is k-sparse, then the number of nonzero Z_{ij} variables is significantly larger when $a_0 = 0$ than when $a_0 = 1$. This forces all sparse solutions to set $a_0 = 1$, which gives us the desired separation in sparsities between the YES and NO cases.

3.2 Constraints

Let $\mathbf{Mx} = \mathbf{t}$ be the instance of k-VectorSum over $\mathbb{F}_2$, in n variables and m equations. We homogenize this system by introducing a new $\mathbb{F}_2$-variable a_0 so that the new system of equations is then given by

$$\mathbf{Mx} = a_0\mathbf{t}, \tag{1}$$

where the $a_0\mathbf{t}$ is the coordinate wise product of $\mathbf{t}$ with the scalar a_0. We also add the following additional constraints and variables.

Linear Sketch Constraints: Let $\mathbf{R} \in \mathbb{F}^{k' \times n}$ be the parity check matrix of a $[n, n-k', 18k]$ linear code, where $k' = 20k \log n$, as defined in Corollary 12. Define $\boldsymbol{\eta}$ to be a k'-length sketch of $\mathbf{x}$ using $\mathbf{R}$ as,

$$\boldsymbol{\eta} = \mathbf{Rx}. \tag{2}$$

Mixing Constraints: Let $\mathbf{C} \in \mathbb{F}_2^{K \times k'}$ be the generator matrix of a linear code $\mathcal{C} \subseteq \mathbb{F}_2^K$ as defined in Theorem 13 where $\mathcal{C}$ has relative distance $\frac{1}{2} - \varepsilon$ and rate $\Omega(\varepsilon^3)$ for some small $\varepsilon > 0$ and $K = \frac{k'}{\Omega(\varepsilon^3)} \leqslant \frac{20k \log n}{c\varepsilon^3}$, for some constant $c > 0$. We add the constraint

$$\mathbf{y} = \mathbf{C}\boldsymbol{\eta} = \mathbf{C}\mathbf{R}\mathbf{x}. \tag{3}$$

Product Code Constraints: Let $\mathcal{C}^{\otimes 2} := \mathcal{C} \bigotimes \mathcal{C}$ be the product code with relative distance $\left(\frac{1}{2} - \varepsilon\right)^2$, constructed from $\mathcal{C}$. Let $\mathbf{Y} = \{Y_{ij}\}_{1 \leqslant i,j \leqslant K} \in \mathbb{F}_2^{K \times K}$ be such that $\mathbf{Y} = \mathbf{y}\mathbf{y}^\mathsf{T}$. To represent this relation linearly, we introduce variables $\{Z_{ij}(a,b)\}_{a,b \in \mathbb{F}_2}$ for each $1 \leqslant i,j \leqslant K$, which are intended to indicate the value assigned to the pair (y_i, y_j) i.e., $Z_{ij}(a,b) = \mathbb{1}\{y_i = a, y_j = b\}$. For each $(i,j) \in [K] \times [K]$ we add the following equations,

$$\begin{aligned} Z_{ij}(0,0) + Z_{ij}(0,1) + Z_{ij}(1,0) + Z_{ij}(1,1) &= a_0 & (4)\\ Z_{ij}(1,0) + Z_{ij}(1,1) &= y_i & (5)\\ Z_{ij}(0,1) + Z_{ij}(1,1) &= y_j & (6)\\ Z_{ij}(1,1) &= Y_{ij}. & (7) \end{aligned}$$

Furthermore, we add the constraints

$$\mathbf{Q}\mathbf{Y} = \mathbf{0}, \tag{8}$$

where $\mathbf{Q}$ is the parity check matrix for the product code $\mathcal{C}^{\otimes 2}$, and

$$\begin{aligned} Y_{ij} &= Y_{ji} \qquad \forall i \neq j, & (9)\\ Y_{ii} &= y_i \qquad \forall i \in [K], & (10) \end{aligned}$$

so that $\mathbf{Y}$ preserves the diagonal entries and symmetry of $\mathbf{y}\mathbf{y}^T$. Finally, we introduce $\mathbf{x}^1, \mathbf{x}^2, \ldots, \mathbf{x}^{r-1}$ and constraints

$$\mathbf{x}^i = \mathbf{x} \qquad \forall i \in [r-1], \tag{11}$$

where $r = \frac{K^2}{16k} \leqslant \frac{25k(\log n)^2}{c^2\varepsilon^6}$. These $r-1$ explicit copies of the vector $\mathbf{x}$ are used to balance the Hamming weight of the final solution. Observe that all the variables described above are linear combinations of $a_0, \{Z_{ij}(\cdot,\cdot)\}_{i,j \in [k]}$ and the coordinates of the vectors $\mathbf{x}$ and $\{\mathbf{x}^i\}_{i \in [r-1]}$. Hence, we analyze the sparsity of the solution restricted to these explicit variables. The total number of variables considered is $4K^2 + r \cdot n + 1$.

▶ Remark. The key difference between [4] and our reduction is in Equation (2) which constructs a small $(O(k \log n))$-length sketch of the n-length vector $\mathbf{x}$. This helps us contain the blowup in the sparsity of the solution to $O(k^2 \log^2 n)$ instead of $O(n)$.

3.3 Completeness

In the YES case, setting $a_0 = 1$ we obtain a k-sparse $\mathbf{x}$ such that $\mathbf{M}\mathbf{x} = a_0\mathbf{t} = \mathbf{t}$. Furthermore, for each $i,j \in [K]$, exactly one of the Z_{ij} variables would be nonzero. Hence, we have a solution of weight $K^2 + rk + 1$.

3.4 Soundness

Since the solution has to be non-trivial, at least one of $a_0, \mathbf{x}, \mathbf{y}, \mathbf{Y}$ must be nonzero. Note that when $\mathbf{x} = \mathbf{0}$, $\mathbf{y} = \mathbf{0}$ since $\mathbf{y}$ is a homogeneous linear transformation of $\mathbf{x}$. Moreover, we may assume that the weight of $\mathbf{x}$ is at most $\frac{K^2+1}{r} + k + 1 < 18k$ by our setting of r, otherwise the total weight of the solution would be at least $r \cdot \left(\frac{K^2+1}{r} + k + 1\right) \geqslant K^2 + r(k+1) + 1$ due to the copies of $\mathbf{x}$ and we would be done. The construction of $\mathbf{y}$ along with the upper bound of $18k$ on the weight of $\mathbf{x}$ constrains $\mathbf{y}$ to be nonzero when $\mathbf{x}$ is nonzero. Thus, the only three cases we need to consider are:

Case (i): $a_0 = 1$. In this case, any solution $\mathbf{x}$ to $\mathbf{Mx} = a_0\mathbf{t} = \mathbf{t}$ has weight at least $k+1$. Furthermore, for each $i, j \in [K]$, at least one of the four Z_{ij} variables must be nonzero since $a_0 = 1$. Hence, the total Hamming weight of the solution is at least $K^2 + r(k+1) + 1$.

Case (ii): $a_0 = 0, \mathbf{x} \neq \mathbf{0}, \mathbf{y} \neq \mathbf{0}$. By construction, since $\mathbf{y}$ is nonzero it has weight $\geqslant \left(\frac{1}{2} - \varepsilon\right) K$. Therefore, for at least $1 - \left(\frac{1}{2} + \varepsilon\right)^2 \geqslant \frac{3}{4} - 2\varepsilon$ fraction of the pairs $(i,j) \in [K] \times [K]$, either $y_i = 1$ or $y_j = 1$. Observe that for each such pair, at least two Z_{ij} variables are set to 1. Thus, the weight of any solution in this case is at least $2\left(\frac{3}{4} - 2\varepsilon\right)K^2 = \left(\frac{3}{2} - 4\varepsilon\right)K^2$.

Case (iii): $a_0 = 0, \mathbf{x} = \mathbf{0}, \mathbf{y} = \mathbf{0}, \mathbf{Y} \neq \mathbf{0}$. We have that $\text{diag}(\mathbf{Y}) = \mathbf{y} = \mathbf{0}$, $\mathbf{Y}$ is symmetric and it belongs to the product code $\mathcal{C}^{\otimes 2}$ (as enforced by Equations (8) and (9)). Then by Lemma 14, the weight of $\mathbf{Y}$ is at least $\left(\frac{3}{8} - 3\varepsilon\right) K^2$. Observe that for each $i, j \in [K]$ such that $Y_{ij} = 1$, Equations (4)-(7) force all four Z_{ij} variables to be set to 1. Hence, the number of nonzero Z_{ij}'s are at least $\left(\frac{3}{2} - 12\varepsilon\right) K^2$.

The above analysis yields that in contrast to the YES case which admits a $(K^2 + rk + 1)$-sparse solution, in the NO case all solutions are of weight at least

$$\min\left\{\left(K^2 + r(k+1) + 1\right), \left(\left(\frac{3}{2} - 12\varepsilon\right) K^2\right)\right\} \geqslant K^2 + r(k+1) + 1$$

by choice of the parameter r. Thus, solving the d-EvenSet problem with $d = K^2 + rk + 1 = O(k^2(\log n)^2)$ solves the k-VectorSum instance $\mathbf{Mx} = \mathbf{t}$.

4 Proof of Theorem 9

We first prove the following strengthening of Theorem 3.

▶ **Theorem 17** (Hardness of approximate k-EvenSet). *For any constant $\varepsilon > 0$, given an instance $(\mathbf{A}, \mathbf{b})$ of k'-VectorSum, where $\mathbf{A} \in \mathbb{F}_2^{m' \times n'}$ and $\mathbf{b} \in \mathbb{F}_2^{m'}$, there is an* FPT *reduction to an instance $\mathbf{B} \in \mathbb{F}_2^{m \times n}$ of k-EvenSet for some $k = O((k' \log n')^2)$, such that*

YES Case. *There is a nonzero k-sparse vector $\mathbf{x}$ which satisfies $\mathbf{Bx} = 0$.*

NO Case. *For any nonzero k-sparse vector $\mathbf{x}$ the weight of $\mathbf{Bx}$ is in the range $[1/2 - \varepsilon, 1/2 + \varepsilon]$.*

Here both m and n are bounded by fixed polynomials in m' and n'.

Proof. Let $\mathbf{M} \in \mathbb{F}_2^{r \times n}$ be the instance of k-EvenSet obtained by applying Theorem 3 to the instance $(\mathbf{A}, \mathbf{b})$ of k'-VectorSum we start with. Let $\mathbf{W} \in \mathbb{F}_2^{m \times r}$ be the generator matrix of an ε-balanced linear code given by Theorem 13, where $m = O(r/\varepsilon^3)$. Taking $\mathbf{B} := \mathbf{WM}$ completes the proof. ◀

It is easy to see that in the NO case the uniform distribution on the rows of the matrix $\mathbf{B}$ fools all linear forms (with error ε) over k variables.

Viola's result [34] (Theorem 16) implies that for any constant d, taking d-wise sums of the rows of $\mathbf{B}$ yields a distribution on which the YES case solution evaluates to 0, while in the NO case it fools all degree d polynomials supported on at most k variables with error $16 \cdot \varepsilon^{1/2^{d-1}}$. Taking ε to be a small enough constant completes the proof of Theorem 9.

5 Hardness of Learning k-Parities using k-Juntas

This section gives the proof of Theorem 7. Combining Theorem 6 with a small bias linear code we first induce an approximation gap for learning k-parities along with extending the result to non-homogeneous linear forms. In particular, let $\mathbf{W} = \{W_{ij}\} \in \mathbb{F}_2^{t\times m}$ be the generator matrix of an ε-balanced linear code given by Theorem 13, where $t = O(m/\varepsilon^3)$. Here, we choose $\varepsilon := \delta \cdot 2^{-k}$, where δ is as given in Theorem 7. Given an instance $\{(\mathbf{y}_j, a_j)\}_{j=1}^m$ from Theorem 6, let $\mathbf{z}_i = \sum_{j=1}^m W_{ij}\mathbf{y}_j$, and $b_i = \sum_{j=1}^m W_{ij}a_j$, for $i = 1,\ldots,t$. In the YES case, there is a homogeneous linear form L^* supported on at most k variables that satisfies all $\{(\mathbf{y}_j, a_j)\}_{j=1}^m$ and thus satisfies linear combinations of these point-value pairs, in particular $\{(\mathbf{z}_i, b_i)\}_{i=1}^t$.

For the NO case, we begin with the following lemma.

▶ **Lemma 18.** *If $\{(\mathbf{y}_j, a_j)\}_{j=1}^m$ is a* NO *instance, then any linear form $L(\mathbf{x}) + c$ supported on at most k variables satisfies a fraction in the range $[1/2 - \varepsilon, 1/2 + \varepsilon]$ of the point-value pairs $\{(\mathbf{z}_i, b_i)\}_{i=1}^t$.*

Proof. Since the homogeneous part L does not satisfy all pairs $\{(\mathbf{y}_j, a_j)\}_{j=1}^m$, it will satisfy a fraction in the range $[1/2 - \varepsilon, 1/2 + \varepsilon]$ of the pairs $\{(\mathbf{z}_i, b_i)\}_{i=1}^t$, due the lower and upper bounds bound on the weight of the nonzero codewords in the column space of $\mathbf{W}$. This also holds for $L + c$ for any constant c. ◀

We now extend the NO case to k-juntas. Let $f : \mathbb{F}_2^n \mapsto \mathbb{F}_2$ be a function depending only a subset $S \subseteq [n]$ of coordinates where $|S| \leqslant k$. Define an extension $g : \mathbb{F}_2^{n+1} \mapsto \mathbb{F}_2$ as $g(x_1,\ldots,x_n,x_{n+1}) := f(x_1,\ldots,x_n) + x_{n+1}$. For convenience we shall abuse notation to denote $(\mathbf{z}, b) = (z_1,\ldots,z_n,b)$ where $\mathbf{z} = (z_1,\ldots,z_n) \in \mathbb{F}_2^n$ and $b \in \mathbb{F}_2$. To complete the proof we need to show that,

$$\left| \underset{(\mathbf{z},b)\in\mathcal{Z}}{\mathbf{E}} [e(g(\mathbf{z},b))] \right| \leqslant 2\delta, \tag{12}$$

where $e(x) := (-1)^x$. For some real values C_α ($\alpha \subseteq [n+1]$), the Fourier expansion of $e(g)$ is given by,

$$e(g) = \sum_{\alpha\subseteq[n+1]} C_\alpha \chi_\alpha.$$

Since $e(g(x_1,\ldots,x_{n+1})) = e(f(x_1,\ldots,x_n) + x_{n+1})$ and f depends only on coordinates in S, it is easy to see that the Fourier spectrum of $e(g)$ is supported only on characters χ_α such that $\alpha \subseteq S \cup \{n+1\}$. Further, since $e(g(x_1,\ldots,x_{n+1}))$ changes sign on flipping x_{n+1}, $C_\alpha \neq 0 \Rightarrow (n+1) \in \alpha$. Thus,

$$e(g) = \sum_{\substack{\alpha\subseteq S\cup\{n+1\}\\ (n+1)\in\alpha}} C_\alpha \chi_\alpha. \tag{13}$$

Observe that for any α in the sum above, $\chi_\alpha(x_1,\ldots,x_n,b) = e(L(x_1,\ldots,x_n) + b)$ where L is a homogeneous linear form supported on at most k variables. For any such α, Lemma 18 implies

$$\left| \underset{(\mathbf{z},b)\in\mathcal{Z}}{\mathbf{E}} [\chi_\alpha(\mathbf{z},b)] \right| \leqslant 2\varepsilon. \tag{14}$$

Using the above along with Equation (13) yields,

$$\left|\underset{(\mathbf{z},b)\in\mathcal{Z}}{\mathbf{E}}[e(g(\mathbf{z},b))]\right| \leqslant (2\varepsilon)\cdot\sum_{\substack{\alpha\subseteq S\cup\{n+1\}\\(n+1)\in\alpha}}|C_\alpha| \leqslant (2\varepsilon)\cdot 2^k = 2\delta,$$

where the last inequality is because there are at most 2^k subsets α in the sum on the RHS of Equation (13) and each $|C_\alpha|\leqslant 1$ since $e(g)$ is a $\{-1,1\}$-valued function.

6 W[1]-hardness of k-VectorSum on $O(k\log n)$ Equations

The following theorem implies Theorem 5.

▶ **Theorem 19.** *There is an* FPT *reduction from an instance $G(V,E)$ of k-*Clique*, over n vertices and m edges, to an instance $(\mathbf{M},\mathbf{b})$ of k'-*VectorSum*, where $\mathbf{M}\in\mathbb{F}_2^{d\times n'}$ such that $k'=\Theta(k^2)$, $d=O(k^2\log n)$ and $n'=O(nk+mk^2)$.*

The rest of this section is devoted to proving the above theorem. We start by observing that a k-clique in a graph $G(V,E)$ can be certified by the pair of mappings $f:[k]\mapsto V$ and $g:\binom{[k]}{2}\mapsto E$, such that $g(i,j)=(f(i),f(j))\in E \quad \forall i,j\in[k], i<j$. Here, we use $\binom{[k]}{2}$ to represent $\{(i,j)\mid 1\leqslant i<j\leqslant k\}$. The underlying idea behind the reduction is to construct $\mathbf{M}$ and $\mathbf{b}$ such that f and g exist *iff* there is a sparse set of columns of $\mathbf{M}$ that sums up to $\mathbf{b}$.

Construction of M and b. Let $G(V,E)$ be a k-Clique instance on $n=|V|$ vertices and $m=|E|$ edges, where $V=\{v_1,v_2,\ldots,v_n\}$. For each vertex $v_i\in V$, assign a distinct $N=\lceil\log(n+1)\rceil$ bit nonzero binary pattern denoted by $\mathbf{q}_i\in\mathbb{F}_2^N$. We first construct a set of vectors – which shall be the columns of $\mathbf{M}$ – corresponding to the vertices and edges. The dimension over which the vectors are defined is partitioned into three sets of coordinates:

Edge-Vertex Incidence Coordinates: These consist of k slots, where each slot consists of $(k-1)$ subslots, and each subslot in turn consists of N coordinates. In any column of $\mathbf{M}$, a subslot may either contain the N-length pattern of a vertex, or it might be all zeros.

Edge Indicator Coordinates: These are a set of $\binom{k}{2}$ coordinates corresponding to $\{(i,j)\mid 1\leqslant i<j\leqslant k\}$, indicating whether the vector represents an edge mapped from (i,j). Any column of $\mathbf{M}$ may have at most one of these coordinates set to 1.

Vertex Indicator Coordinates: These are a set of k coordinates corresponding to indices $i\in\{1,\ldots,k\}$, which indicate whether the vector represents a vertex mapped from i. Any column of $\mathbf{M}$ may have at most one of these coordinates set to 1.

Thus, each vector is a concatenation of $k(k-1)N$ edge-vertex incidence bits, followed by $\binom{k}{2}$ edge indicator bits and k vertex indicator bits, so that $d=k(k-1)N+\binom{k}{2}+k=O(k^2\log n)$. For ease of notation, let S_l^j represent the N-sized subset of coordinates belonging to the subslot l of slot j where $j\in[k]$ and $l\in[k-1]$. We define $\mathbf{q}_i(S_l^j)\in\mathbb{F}_2^d$ to be the vector which contains the pattern of vertex v_i in S_l^j, and is zero everywhere else. For $1\leqslant i<j\leqslant k$, let $\boldsymbol{\delta}_{i,j}\in\mathbb{F}_2^d$ be the vector which has a 1 at the edge indicator coordinate corresponding to (i,j), and is 0 everywhere else. Similarly, $\boldsymbol{\delta}_i\in\mathbb{F}_2^d$ is the indicator vector which has its ith vertex indicator coordinate set to 1, everything else being 0. Using these components we construct the vertex and edge vectors as follows.

Vertex Vectors: For each vertex $v_i \in V$ and $j \in [k]$, we introduce a vector $\boldsymbol{\eta}(v_i, j) \in \mathbb{F}_2^d$ which indicates that vertex v_i is mapped from index (slot) j i.e., $f(j) = v_i$. The vector is constructed as follows: populate each of the $(k-1)$ subslots of the jth slot with the pattern $\mathbf{q}_i$ of vertex v_i, and set its jth vertex indicator coordinate to 1. Formally, $\boldsymbol{\eta}(v_i, j) := \sum_{l=1}^{k-1} \mathbf{q}_i(S_l^j) + \boldsymbol{\delta}_j$. For each vertex there are k vertex vectors resulting in a total of nk vertex vectors.

Edge Vectors: For each edge $e = (v_{i_1}, v_{i_2}) \in E$ where $i_1 < i_2$, and $1 \leqslant j_1 < j_2 \leqslant k$, we introduce a vector that indicates that the pair of indices (slots) (j_1, j_2) is mapped to (v_{i_1}, v_{i_2}) i.e., $g(j_1, j_2) = (v_{i_1}, v_{i_2})$. We construct the vector $\boldsymbol{\eta}(e, j_1, j_2) \in \mathbb{F}_2^d$ as follows: populate $S_{j_2-1}^{j_1}$ with the pattern of vertex v_{i_1}, and $S_{j_1}^{j_2}$ with the pattern of vertex v_{i_2}. Additionally, we set the edge indicator coordinate corresponding to (j_1, j_2) to 1. The vector is formally expressed as, $\boldsymbol{\eta}(e, j_1, j_2) := \mathbf{q}_{i_1}(S_{j_2-1}^{j_1}) + \mathbf{q}_{i_2}(S_{j_1}^{j_2}) + \boldsymbol{\delta}_{j_1,j_2}$. Intuitively, for the lower ordered vertex v_{i_1}, $\boldsymbol{\eta}(e, j_1, j_2)$ cancels out the (j_2-1)th subslot of slot j_1, and for the higher ordered vertex v_{i_2}, it cancels out the j_1th subslot of its j_2th slot. Note that we are treating (v_{i_1}, v_{i_2}) as an *unordered* pair since $i_1 < i_2$. Therefore, for each edge $e \in E$, and for each choice of $1 \leqslant j_1 < j_2 \leqslant k$, we introduce one edge vector. Hence, there are a total of $m \cdot \binom{k}{2}$ edge vectors in the set.

The vertex and edge vectors constructed above constitute the columns of $\mathbf{M}$. The target vector $\mathbf{b}$ ensures that (i) every solution must have at least k vertex vectors, and $\binom{k}{2}$ edge vectors and (ii) the vectors must cancel each other out in the Edge-Vertex Incidence coordinates. Formally, $\mathbf{b} = \sum_{i \in [k]} \boldsymbol{\delta}_i + \sum_{1 \leqslant i < j < k} \boldsymbol{\delta}_{i,j}$. In other words, all the edge and vertex indicator coordinates of $\mathbf{b}$ are set to 1, and everything else to 0.

6.1 YES case

We show that if $G(V, E)$ has a k-Clique, then there exists a set of $k + \binom{k}{2}$ columns of $\mathbf{M}$ that sum to $\mathbf{b}$. Assume that $v_{i_1}, v_{i_2}, \ldots, v_{i_k}$ form a k-clique where $i_1 < i_2 < \cdots < i_k$. We select k vertex vectors $\{\boldsymbol{\eta}(v_{i_j}, j)\}_{j \in [k]}$, and $\binom{k}{2}$ edge vectors $\{\boldsymbol{\eta}(e, j_1, j_2) \mid e = (v_{i_{j_1}}, v_{i_{j_2}}), 1 \leqslant j_1 < j_2 \leqslant k\}$. Since the k vertices form a clique, these vectors always exists. Observe that for any fixed $j \in [k]$, (i) for $\ell = 1, \ldots, j-1$, $\boldsymbol{\eta}(v_{i_j}, j)$ and $\boldsymbol{\eta}(e, \ell, j)$ have the same pattern $\mathbf{q}_{i_j}$ in subslot ℓ of slot j, where $e = (v_{i_\ell}, v_{i_j})$, and (ii) for $\ell = j+1, \ldots, k$, $\boldsymbol{\eta}(v_{i_j}, j)$ and $\boldsymbol{\eta}(e, j, \ell)$ have the same pattern $\mathbf{q}_{i_j}$ in subslot $(\ell - 1)$ of slot j, where $e = (v_{i_j}, v_{i_\ell})$. Thus, the $k + \binom{k}{2}$ selected vectors sum to zero on all but the vertex and edge indicator coordinates and thus sum up to $\mathbf{b}$.

6.2 NO Case

Suppose for a contradiction that $\mathcal{S}$ is a subset of columns of $\mathbf{M}$ that sum to $\mathbf{b}$ and that $|\mathcal{S}| \leqslant k + \binom{k}{2}$.

► **Proposition 20.** *There are exactly k vertex vectors corresponding to indices (slots) $i \in [k]$ in $\mathcal{S}$. Also, there are exactly $\binom{k}{2}$ edge vectors, one for each pair (i, j) $(1 \leqslant i < j \leqslant k)$ of slots, in $\mathcal{S}$.*

Proof. This follows from the observation that there are $k + \binom{k}{2}$ nonzero indicator coordinates in the target $\mathbf{b}$, and each (edge or vertex) vector contributes exactly one nonzero (edge or vertex) indicator coordinate. Therefore, by a counting argument, k vertex vectors, one each for the indices (slots) $i \in [k]$, must contribute to the k vertex indicator bits. Similarly, $\binom{k}{2}$

edge vectors, one for each pair of slots (i, j) $(1 \leqslant i < j \leqslant k)$, must contribute to the $\binom{k}{2}$ edge indicator bits. ◀

The above proposition implies that for each pair of vertex vectors there is exactly one edge vector which has a common populated subslot with each of them. So there are exactly $(k-1)$ edge vectors which share a populated subslot with any given vertex vector in $\mathcal{S}$.

Since the k vertex vectors in $\mathcal{S}$ populate distinct slots, in total $k(k-1)$ subslots are populated by the sum of the k vertex vectors. Note that any edge vector populates exactly 2 subslots. Thus, for the $\binom{k}{2} = k(k-1)/2$ edge vectors in $\mathcal{S}$ to sum up to the values in $k(k-1)$ subslots, it must be that the edge vectors populate distinct subslots. In other words, no two edge vectors are both nonzero in the same slot-subslot combination.

Thus, for each vertex vector there are exactly $(k-1)$ edge vectors which share distinct populated subslots with it, and these edge vectors must cancel out the corresponding subslots i.e., have the same pattern in the shared subslot as that of the vertex vector. In other words, for any two vertex vectors corresponding to slots i and j respectively $(i < j)$, the edge vector corresponding to the pair (i, j) must cancel one subslot from each one of the two vertex vectors. This is possible only if (i) the k vertex vectors correspond to distinct vertices in G, and (ii) each pair of these vertices have an edge between them for the corresponding edge vector to exist. This implies that G has a k-clique which is a contradiction.

7 A simple $O(n \cdot 2^m)$ -time algorithm for k-VectorSum

Let $(\mathbf{M}, \mathbf{b})$ be an instance of k-VectorSum where $\mathbf{M} \in \mathbb{F}_2^{m \times n}$ and $\mathbf{b} \in \mathbb{F}_2^m$. Construct a graph G on vertex set $V = \mathbb{F}_2^m$ and edge set given by,

$$E = \left\{ \{\mathbf{u}, \mathbf{v}\} \in \binom{V}{2} \mid \mathbf{u} + \mathbf{v} \text{ is a column of } \mathbf{M} \right\}.$$

We say that an edge $\{\mathbf{u}, \mathbf{v}\} \in E$ is labeled by the column $\mathbf{u} + \mathbf{v}$ of $\mathbf{M}$. Clearly, if there is a vector $\mathbf{x}$ of Hamming weight at most k such that $\mathbf{M}\mathbf{x} = \mathbf{b}$ then there is a path of length at most k in G from $\mathbf{0}$ to $\mathbf{b}$ given by choosing the edges labeled by the columns corresponding to the non-zero entries of $\mathbf{x}$ in any sequence. On the other hand, if there is a path in G from $\mathbf{0}$ to $\mathbf{b}$ of length at most k, then there is a sequence of at most k columns (with possible repetitions) of $\mathbf{M}$ which sum up to $\mathbf{b}$. Cancelling out even number of repetitions of any column yields a subset of at most k distinct columns of $\mathbf{M}$ that sum up to $\mathbf{b}$. Thus, deciding k-VectorSum reduces to determining whether there is a path of length at most k from $\mathbf{0}$ to $\mathbf{b}$.

The size of V is 2^r and of E is at most $n \cdot 2^m$, and the graph can be constructed in time $O(n \cdot 2^m)$. Doing a Breadth First Search yields a running time of $O(n \cdot 2^m)$.

Abstract

In the *Multi-Level Aggregation Problem* (MLAP), requests arrive at the nodes of an edge-weighted tree $\mathcal{T}$, and have to be served eventually. A *service* is defined as a subtree X of $\mathcal{T}$ that contains its root. This subtree X serves all requests that are pending in the nodes of X, and the cost of this service is equal to the total weight of X. Each request also incurs waiting cost between its arrival and service times. The objective is to minimize the total waiting cost of all requests plus the total cost of all service subtrees. MLAP is a generalization of some well-studied optimization problems; for example, for trees of depth 1, MLAP is equivalent to the TCP Acknowledgment Problem, while for trees of depth 2, it is equivalent to the Joint Replenishment Problem. Aggregation problem for trees of arbitrary depth arise in multicasting, sensor networks, communication in organization hierarchies, and in supply-chain management. The instances of MLAP associated with these applications are naturally online, in the sense that aggregation decisions need to be made without information about future requests.

Constant-competitive online algorithms are known for MLAP with one or two levels. However, it has been open whether there exist constant competitive online algorithms for trees of depth more than 2. Addressing this open problem, we give the first constant competitive online algorithm for networks of arbitrary (fixed) number of levels. The competitive ratio is $O(D^4 2^D)$, where D is the depth of $\mathcal{T}$. The algorithm works for arbitrary waiting cost functions, including the variant with deadlines. We include several additional results in the paper. We show that a standard lower-bound technique for MLAP, based on so-called *Single-Phase* instances, cannot give super-constant lower bounds (as a function of the tree depth). This result is established by giving an online algorithm with optimal competitive ratio 4 for such instances on arbitrary trees. We also study the MLAP variant when the tree is a path, for which we give a lower bound of 4 on the competitive ratio, improving the lower bound known for general MLAP. We complement this with a matching upper bound for the deadline setting.

1 Introduction

Certain optimization problems can be formulated as aggregation problems. They typically arise when expensive resources can be shared by multiple agents, who incur additional expenses for accessing a resource. For example, costs may be associated with waiting until the resource is accessible, or, if the resource is not in the desired state, a costly setup or retooling may be required.

1-level aggregation

A simple example of an aggregation problem is the *TCP Acknowledgment Problem (*TCP-AP*)*, where control messages ("agents") waiting for transmission across a network link can be aggregated and transmitted in a single packet ("resource"). Such aggregation can reduce network traffic, but it also results in undesirable delays. A reasonable compromise is to balance the two costs, namely the number of transmitted packets and the total delay, by minimizing their weighted sum [15]. Interestingly, TCP-AP is equivalent to the classical Lot Sizing Problem studied in the operations research literature since the 1950s. (See, for example, [30].) In the offline variant of TCP-AP, that is when all arrival times of control messages are known beforehand, an optimal schedule for aggregated packets can be computed with dynamic programming in time $O(n \log n)$ [1]. In practice, however, packet aggregation decisions must be done on the fly, without any information about future message releases. This scenario is captured by the online variant of TCP-AP that has also been well studied; it is known that the optimal competitive ratio is 2 in the deterministic case [15] and $\mathrm{e}/(\mathrm{e}-1) \approx 1.582$ in the randomized case [17, 11, 28].

2-level aggregation

Another optimization problem involving aggregation is the *Joint Replenishment Problem (JRP)*, well-studied in operations research. JRP models tradeoffs that arise in supply-chain management. One such scenario involves optimizing shipments of goods from a supplier to retailers, through a shared warehouse, in response to their demands. In JRP, aggregation takes place at two levels: items addressed to different retailers can be shipped together to the warehouse, at a fixed cost, and then multiple items destined to the same retailer can be shipped from the warehouse to this retailer together, also at a fixed cost, which can be different for different retailers. Pending demands accrue waiting cost until they are satisfied by a shipment. The objective is to minimize the sum of all shipment costs and all waiting costs.

JRP is known to be $\mathbb{NP}$-hard [2], and even $\mathbb{APX}$-hard [25, 5]. The currently best approximation, due to Bienkowski et al. [6], achieves a factor of 1.791, improving on earlier work by Levi et al. [21, 23, 24]. In the deadline variant of JRP, denoted JRP-D, there is no cost for waiting, but each demand needs to be satisfied before its deadline. As shown in [5], JRP-D can be approximated with ratio 1.574.

For the online variant of JRP, Buchbinder et al. [10] gave a 3-competitive algorithm using a primal-dual scheme (improving an earlier bound of 5 in [9]) and proved a lower bound of

2.64, that was subsequently improved to 2.754 [6]. The optimal competitive ratio for JRP-D is 2 [6].

Multiple-level aggregation

TCP-AP and JRP can be thought of as aggregation problems on edge-weighted trees of depth 1 and 2, respectively. In TCP-AP, this tree is just a single edge between the sender and the recipient. In JRP, this tree consists of the root (supplier), with one child (warehouse), and any number of grandchildren (retailers). A shipment can be represented by a subtree of this tree and edge weights represent shipping costs. These trees capture the general problem on trees of depth 1 and 2, as the children of the root can be considered separately (see Section 2).

This naturally extends to trees of any depth D, where aggregation is allowed at each level. Multi-level message aggregation has been, in fact, studied in communication networks in several contexts. In multicasting, protocols for aggregating control messages (see [8, 3], for example) can be used to reduce the so-called *ack-implosion*, the proliferation of control messages routed to the source. A similar problem arises in energy-efficient data aggregation and fusion in sensor networks [16, 31]. Outside of networking, tradeoffs between the cost of communication and delay arise in message aggregation in organizational hierarchies [26]. In supply-chain management, multi-level variants of lot sizing have been studied [14, 19]. The need to consider more tree-like (in a broad sense) supply hierarchies has also been advocated in [20].

These applications have inspired research on offline and online approximation algorithms for multi-level aggregation problems. Becchetti et al. [4] gave a 2-approximation algorithm for the deadline case. (See also [9].) Pedrosa [27] showed, adapting an algorithm of Levi et al. [22] for the multi-stage assembly problem, that there is a $(2 + \varepsilon)$-approximation algorithm for general waiting cost functions, where ε can be made arbitrarily small.

In the online case, Khanna et al. [18] gave a rent-or-buy solution (that serves a group of requests once their waiting cost reaches the cost of their service) and showed that their algorithm is $O(\log \alpha)$-competitive, where α is defined as the sum of all edge weights. However, they assumed that each request has to wait at least one time unit. This assumption is crucial for their proof, as demonstrated by Brito et al. [9], who showed that the competitive ratio of a rent-or-buy strategy is $\Omega(D)$, even for paths with D edges. The same assumption of a minimal cost for a request and a ratio dependent on the edge-weights is also essential for Vaya [29], who studies a variant of the problem with bounded bandwidth (the number of packets that can be served by a single edge in a single service).

The existence of a primal-dual $(2 + \varepsilon)$-approximation algorithm [27, 22] for the offline problem suggests the possibility of constructing an online algorithm along the lines of [11]. Nevertheless, despite substantial effort of many researchers, the online multi-level setting remains wide open. This is perhaps partly due to impossibility of direct emulation of the cleanup phase in the primal-dual offline algorithms in the online setting, as this cleanup is performed in the "reverse time" order.

The case when the tree is just a path has also been studied. An offline polynomial-time algorithm that computes an optimal schedule was given in [7]. For the online variant, Brito et al. [9] gave an 8-competitive algorithm. This result was improved by Bienkowski et al. [7] who showed that the competitive ratio of this problem is between $2 + \phi \approx 3.618$ and 5.

Table 1 Previous and current bounds on the competitive ratios for MLAP for trees of various depths. Ratios written in bold are shown in this paper. Unreferenced results are either immediate consequences of other entries in the table or trivial observations. Asterisked ratios represent results for MLAP with arbitrary waiting cost functions, which, though not explicitly stated in the respective papers, are straightforward extensions of the corresponding results for MLAP-L.

	MLAP and MLAP-L		MLAP-D	
	upper	lower	upper	lower
depth 1	2^* [15]	2 [15]	1	1
rand. alg. for depth 1	1.582^* [17]	1.582 [28]	1	1
depth 2	3 [10]	2.754 [6]	2 [6]	2 [6]
fixed depth $D \geq 2$	$\mathbf{O(D^4 2^D)}$	2.754	$\mathbf{D^2 2^D}$	2
paths of arbitrary depth	5^* [7]	3.618 [7], **4**	**4**	**4**

1.1 Our Contributions

We study online competitive algorithms for multi-level aggregation. Minor technical differences notwithstanding, our model is equivalent to those studied in [9, 18], also extending the deadline variant in [4] and the assembly problem in [22]. We have decided to choose a more generic terminology to emphasize general applicability of our model and techniques.

Formally, our model consists of a tree $\mathcal{T}$ with positive weights assigned to edges, and a set of requests $\mathcal{R}$ that arrive in the nodes of $\mathcal{T}$ over time. These requests are served by subtrees rooted at the root of $\mathcal{T}$. Such a subtree X serves all requests pending at the nodes of X at cost equal to the total weight of X. Each request incurs a waiting cost, defined by a non-negative and non-decreasing function of time, which may be different for each request. The objective is to minimize the sum of the total service and waiting costs. We call this the *Multi-Level Aggregation Problem* (MLAP).

In most earlier papers on aggregation problems, the waiting cost function is linear, that is, it is assumed to be simply the delay between the times when a request arrives and when it is served. We denote this version by MLAP-L. However, most of the algorithms for this model extend naturally to arbitrary cost functions. Another variant is MLAP-D, where each request is given a certain deadline, has to be served before or at its deadline, and there is no penalty associated with waiting. This can be modeled by the waiting cost function that is 0 up to the deadline and $+\infty$ afterwards.

In this paper, we mostly focus on the online version of MLAP, where an algorithm needs to produce a schedule in response to requests that arrive over time. When a request appears, its waiting cost function is also revealed. At each time t, the online algorithm needs to decide whether to generate a service tree at this time, and if so, which nodes should be included in this tree.

The main result of our paper is an $O(D^4 2^D)$-competitive algorithm for MLAP for trees of depth D, presented in Section 4. A simpler $D^2 2^D$-competitive algorithm for MLAP-D is presented in Section 3. No competitive algorithms have been known so far for online MLAP for arbitrary depth trees, even for the special case of MLAP-D on trees of depth 3.

For both results we use a reduction of the general problem to the special case of trees with fast decreasing weights. For such trees we then provide an explicit competitive algorithm. While our algorithm is compact and elegant, it is not a straightforward extension of the 2-level algorithm. (In fact, we have been able to show that naïve extensions of the latter algorithm are not competitive.) It is based on carefully constructing a sufficiently large service tree whenever it appears that an urgent request must be served. The specific structure of the service tree is then heavily exploited in an amortization argument that constructs a mapping from the algorithm's cost to the cost of the optimal schedule. We believe that these three new techniques: the reduction to trees with fast decreasing weights, the construction of the service trees, and our charging scheme, will be useful in further studies of online aggregation problems.

In Section 5 we study a version of MLAP, that we refer to as *Single-Phase* MLAP (or 1P-MLAP), in which all requests arrive at the beginning, but they also have a common *expiration time* that we denote by θ. Any request not served by time θ pays waiting cost at time θ and does not need to be served anymore. In spite of the expiration-date feature, it can be shown that 1P-MLAP can be represented as a special case of MLAP. 1P-MLAP is a crucial tool in all the lower bound proofs in the literature for competitive ratios of MLAP, including those in [10, 7], as well as in our lower bounds in Section 6. It also has a natural interpretation in the context of JRP (2-level MLAP), if we allow all orders to be canceled, say, due to changed market circumstances. In the online variant of 1P-MLAP all requests are known at the beginning, but the expiration time θ is unknown. For this version we give an online algorithm with competitive ratio 4, matching the lower bound. Since 1P-MLAP can be expressed as a special case of MLAP, our result implies that the techniques from [10, 7] cannot be used to prove a lower bound on the competitive ratio for MLAP larger than 4, and any study of the dependence of the competitive ratio on the depth D will require new insights and techniques.

In Section 6 we consider MLAP on paths. For this case, we give a 4-competitive algorithm for MLAP-D and we provide a matching lower bound. We show that the same lower bound of 4 applies to MLAP-L as well, improving the previous lower bound of 3.618 from [7].

Due to the page limit, most of the proofs will be given in the full version of the paper.

2 Preliminaries

Let $\mathcal{T}$ be a tree with root r. For any set of nodes $Z \subseteq \mathcal{T}$ and a node x, Z_x denotes the set of all descendants of x in Z; in particular, $\mathcal{T}_x$ is the subtree of $\mathcal{T}$ rooted at x. The parent of a node x is denoted $\mathit{parent}(x)$. The *depth of* x, denoted $\mathit{depth}(x)$, is the number of edges on the simple path from r to x. In particular, r is at depth 0. The depth D of $\mathcal{T}$ is the maximum depth of a node of $\mathcal{T}$.

We will deal with weighted trees in this paper. For $x \neq r$, by ℓ_x or $\ell(x)$ we denote the weight of the edge connecting node x to its parent. We assume that all these weights are positive. We extend this notation to r by setting $\ell_r = 0$. If Z is any set of nodes of $\mathcal{T}$, then the weight of Z is $\ell(Z) = \sum_{x \in Z} \ell_x$.

Definition of MLAP

A *request* ρ is specified by a triple $\rho = (\sigma_\rho, a_\rho, \omega_\rho)$, where σ_ρ is the node of $\mathcal{T}$ in which ρ is issued, a_ρ is the *arrival time* of ρ, and ω_ρ is the waiting cost function of ρ. We assume that $\omega_\rho(t) = 0$ for $t \leq a_\rho$ and $\omega_\rho(t)$ is non-decreasing for $t \geq a_\rho$. MLAP-L is the variant of MLAP with linear waiting costs; that is, for each request ρ we have $\omega_\rho(t) = t - a_\rho$, for $t \geq a_\rho$. In MLAP-D, the variant with deadlines, we have $\omega_\rho(t) = 0$ for $t \leq d_\rho$ and $\omega_\rho(t) = \infty$ for $t > d_\rho$, where d_ρ is called the *deadline* of request ρ.

In our algorithms for MLAP with general costs we will be assuming that all waiting cost functions are continuous. This is only for technical convenience and we discuss more general waiting cost functions in the full version of the paper; we also show there that MLAP-D can be considered a special case of MLAP, and that our algorithms can be extended to the discrete-time model.

A *service* is a pair (X, t), where X is a subtree of $\mathcal{T}$ rooted at r and t is the time of this service. We will occasionally refer to X as the service tree (or just service) at time t, or even omit t altogether if it is understood from context.

An instance $\mathcal{J} = \langle \mathcal{T}, \mathcal{R} \rangle$ of the *Multi-Level Aggregation Problem* (MLAP) consists of a weighted tree $\mathcal{T}$ with root r and a set $\mathcal{R}$ of requests arriving at the nodes of $\mathcal{T}$. A *schedule* is a set S of services. For a request ρ, let (X, t) be the service in S with minimal t such that $\sigma_\rho \in X$ and $t \geq a_\rho$. We then say that (X, t) *serves* ρ and the *waiting cost* of ρ in S is defined as $\mathsf{wcost}(\rho, \mathsf{S}) = \omega_\rho(t)$. Furthermore, the request ρ is called *pending* at all times in the interval $[a_\rho, t]$. Schedule S is called *feasible* if all requests in $\mathcal{R}$ are served by S.

The cost of a feasible schedule S, denoted $\mathsf{cost}(\mathsf{S})$, is defined by

$$\mathsf{cost}(\mathsf{S}) = \mathsf{scost}(\mathsf{S}) + \mathsf{wcost}(\mathsf{S}),$$

where $\mathsf{scost}(\mathsf{S})$ is the total service cost and $\mathsf{wcost}(\mathsf{S})$ is the total waiting cost, that is

$$\mathsf{scost}(\mathsf{S}) = \sum_{(X,t) \in \mathsf{S}} \ell(X) \quad \text{and} \quad \mathsf{wcost}(\mathsf{S}) = \sum_{\rho \in \mathcal{R}} \mathsf{wcost}(\rho, \mathsf{S}).$$

The objective of MLAP is to compute a feasible schedule S for $\mathcal{J}$ with minimum $\mathsf{cost}(\mathsf{S})$.

Online algorithms

We use the standard and natural definition of online algorithms and the competitive ratio. We assume the continuous time model. The computation starts at time 0 and from then on the time gradually progresses. At any time t new requests can arrive. If the current time is t, the algorithm has complete information about the requests that arrived up until time t, but has no information about any requests whose arrival times are after time t. The instance includes a time horizon H that is not known to the online algorithm, which is revealed only at time $t = H$. At time H, all requests that are still pending must be served. (In the offline case, H can be assumed to be equal to the maximum request arrival time.)

If $\mathcal{A}$ is an online algorithm and $R \geq 1$, we say that $\mathcal{A}$ is *R-competitive* if $\mathsf{cost}(\mathsf{S}) \leq R \cdot \mathsf{opt}(\mathcal{J})$ for any instance $\mathcal{J}$ of MLAP, where S is the schedule computed by $\mathcal{A}$ on $\mathcal{J}$ and $\mathsf{opt}(\mathcal{J})$ is the optimum cost for $\mathcal{J}$.

Quasi-root assumption

Throughout the paper we will assume that r, the root of $\mathcal{T}$, has only one child. This is without loss of generality, because if we have an algorithm (online or offline) for MLAP on such trees, we can apply it independently to each child of r and its subtree. This will give us an algorithm for MLAP on arbitrary trees with the same performance. From now on, let us call the single child the *quasi-root* of $\mathcal{T}$ and denote it by q. Note that q is included in every (non-trivial) service.

Reduction to L-Decreasing Trees

One basic intuition that emerges from earlier works on trees of depth 2 (see [10, 9, 6]) is that the hardest case of the problem is when ℓ_q, the weight of the quasi-root, is much larger than the weights of leaves. For arbitrary depth trees, the hard case is when the weights of nodes quickly decrease with their depth. We show that this is indeed the case, by defining the notion of L-decreasing trees that captures this intuition and showing that MLAP reduces to the special case of MLAP for such L-decreasing trees, increasing the competitive ratio by a factor of at most DL. This is a general result, not limited only to algorithms in our paper.

Formally, for $L \geq 1$, we say that $\mathcal{T}$ is *L-decreasing* if for each node $u \neq r$ and each child v of u we have $\ell_u \geq L \cdot \ell_v$. (The value of L used in our algorithms will be fixed later.)

▶ **Theorem 2.1.** *Assume that there exists an R-competitive algorithm $\mathcal{A}$ for MLAP (resp. MLAP-D) on L-decreasing trees (where R can be a function of D, the tree depth). Then there exists a (DLR)-competitive algorithm $\mathcal{B}$ for MLAP (resp. MLAP-D) on arbitrary trees.*

Proof. Fix the underlying instance $\mathcal{J} = (\mathcal{T}, \mathcal{R})$, where $\mathcal{T}$ is a tree and $\mathcal{R}$ is a sequence of requests in $\mathcal{T}$.

We start by constructing an L-decreasing tree $\mathcal{T}'$ on the same set of nodes. For any node $u \in \mathcal{T} - \{r\}$, the parent of u in $\mathcal{T}'$ will be the lowest (closest to u) ancestor w of u in $\mathcal{T}$ such that $\ell_w \geq L \cdot \ell_u$; if no such w exists, we take $w = r$. Note that $\mathcal{T}'$ may violate the quasi-root assumption, which does not change the validity of the reduction, as we may use independent instances of the algorithm for each child of r in $\mathcal{T}'$. Since in $\mathcal{T}'$ each node u is connected to one of its ancestors from $\mathcal{T}$, it follows that $\mathcal{T}'$ is a tree rooted at r with depth at most D. Obviously, $\mathcal{T}'$ is L-decreasing.

It follows that if a set of vertices X is a service subtree of $\mathcal{T}$, then it is also a service subtree for $\mathcal{T}'$. (Note that the actual topology of the trees induced by X in $\mathcal{T}$ and $\mathcal{T}'$ may be very different.) Thus, also any schedule for $\mathcal{J}$ is also a schedule for $\mathcal{J}' = (\mathcal{T}', \mathcal{R})$, which gives us that $\mathsf{opt}(\mathcal{J}') \leq \mathsf{opt}(\mathcal{J})$.

The algorithm $\mathcal{B}$ for $\mathcal{T}$ is defined as follows: On a request sequence $\mathcal{R}$, we simulate $\mathcal{A}$ for $\mathcal{R}$ in $\mathcal{T}'$, and whenever $\mathcal{A}$ contains a service X, $\mathcal{B}$ issues the service $X' \supseteq X$, created from X as follows: Start with $X' = X$. Then, for each $u \in X - \{r\}$, if w is the parent of u in $\mathcal{T}'$, then add to X' all inner nodes on the path from u to w in $\mathcal{T}$. By the construction of $\mathcal{T}'$, for each u we add at most $D - 1$ nodes, each of cost less than $L \cdot \ell_u$. It follows that $\ell(X') \leq ((D-1)L + 1)\ell(X) \leq DL \cdot \ell(X)$.

In total, the service cost of $\mathcal{B}$ is at most DL times the service cost of $\mathcal{A}$. Any request served by $\mathcal{A}$ is served by $\mathcal{B}$ at the same time or earlier, thus the waiting cost of $\mathcal{B}$ is at most the waiting cost of $\mathcal{A}$ (resp. for MLAP-D, $\mathcal{B}$ produces a valid schedule for $\mathcal{J}$). Since $\mathcal{A}$ is R-competitive, we obtain

$$\mathsf{cost}(\mathcal{B}, \mathcal{J}) \leq DL \cdot \mathsf{cost}(\mathcal{A}, \mathcal{J}') \leq DLR \cdot \mathsf{opt}(\mathcal{J}') \leq DLR \cdot \mathsf{opt}(\mathcal{J}),$$

and thus $\mathcal{B}$ is DLR-competitive. ◀

3 A Competitive Algorithm for MLAP-D

In this section we present our online algorithm for MLAP-D with competitive ratio at most $D^2 2^D$. To this end, we will give an online algorithm that achieves competitive ratio $R_L = (2 + 1/L)^{D-1}$ for L-decreasing trees. Taking $L = D/2$ and using the reduction to L-decreasing trees from Theorem 2.1 then leads to a $D^2 2^D$-competitive algorithm for arbitrary trees.

3.1 Intuitions

Consider the optimal 2-competitive algorithm for MLAP-D for trees of depth 2 [6]. Assume that the tree is L-decreasing, for some large L. (Thus $\ell_q \gg \ell_v$, for each leaf v.) Whenever a pending request reaches its deadline, this algorithm serves a subtree X consisting of r, q and the set of leaves with the earliest deadlines and total weight of about ℓ_q. This is a natural strategy: We have to pay at least ℓ_q to serve the expiring request, so including an additional set of leaves of total weight ℓ_q can at most double our overall cost. But, assuming that no new requests arrive, serving this X can significantly reduce the cost in the future, since servicing these leaves individually is expensive: it would cost $\ell_v + \ell_q$ per each leaf v, compared to the incremental cost of ℓ_v to include v in X.

For L-decreasing trees with three levels (that is, for $D = 3$), we may try to iterate this idea. When constructing a service tree X, we start by adding to X the set of most urgent children of q whose total weight is roughly ℓ_q. Now, when choosing nodes of depth 3, we have two possibilities: (1) for each $v \in X - \{r, q\}$ we can add to X its most urgent children of combined weight ℓ_v (note that their total weight will add up to roughly ℓ_q, because of the L-decreasing property), or (2) from the set of *all* children of the nodes in $X - \{r, q\}$, add to X the set of total weight roughly ℓ_q consisting of (globally) most urgent children.

It is not hard to show that the option (1) does not lead to a constant-competitive algorithm: The counter-example involves an instance with one node w of depth 2 having many children with requests with early deadlines and all other leaves having requests with very distant deadlines. Assume that $\ell_q = L^2$, $\ell_w = L$, and that each leaf has weight 1. The example forces the algorithm to serve the children of w in small batches of size L with cost more than L^2 per batch or L per each child of w, while the optimum can serve all the requests in the children of w at once with cost $O(1)$ per request, giving a lower bound $\Omega(L)$ on the competitive ratio. (The requests at other vertices can be ignored in the optimal solution, as we can keep repeating the above strategy, similar to the lower-bound technique for 1P-MLAP that will be described in the full version of the paper. Reissuing requests at the vertices other than w will not increase the cost of the optimum.) A more intricate example shows that option (2) by itself is not sufficient to guarantee constant competitiveness either.

The idea behind our algorithm, for trees of depth $D = 3$, is to do *both* (1) and (2) to obtain X. This increases the cost of each service by a constant factor, but it protects the algorithm against both bad instances. The extension of our algorithm to depths $D > 3$ carefully iterates the process of constructing the service tree X, to ensure that for each node $v \in X$ and for each level i below v we add to X sufficiently many urgent descendants of v at that level.

3.2 Notations

To give a formal description, we need some more notations. For any set of nodes $Z \subseteq \mathcal{T}$, let Z^i denote the set of nodes in Z of depth i in tree $\mathcal{T}$ (recall that r has depth 0, q has depth 1, and leaves have depth at most D). Let also $Z^{<i} = \bigcup_{j=0}^{i-1} Z^j$ and $Z^{\leq i} = Z^{<i} \cup Z^i$. These notations can be combined with the notation Z_x, so, e.g., $Z_x^{<i}$ is the set of all descendants of x in Z whose depth in $\mathcal{T}$ is smaller than i.

Let $f : \mathcal{T} \to \mathbb{R} \cup \{+\infty\}$ be some function that measures urgency of nodes, so that the nodes with smaller values of f are more urgent. (For MLAP-D, urgency is measured by the deadlines, in which case the function f is set to d^t, while for MLAP we need to use a different measure.) For any set A of nodes in $\mathcal{T}$ and a real number β, let $\mathsf{Urgent}(A, \beta, f)$ be a set of nodes obtained by choosing the nodes from A in order of urgency, until either their total weight exceeds β or we run out of nodes. More precisely, we define $\mathsf{Urgent}(A, \beta, f)$ as a smallest set of nodes in A such that (i) for all $u \in \mathsf{Urgent}(A, \beta, f)$, and $v \in A - \mathsf{Urgent}(A, \beta, f)$ we have $f(u) \leq f(v)$, and (ii) either $\ell(\mathsf{Urgent}(A, \beta, f)) \geq \beta$ or $\mathsf{Urgent}(A, \beta, f) = A$.

We assume that all the deadlines in the given instance are distinct. This may be done without loss of generality, as in case of ties we can modify the deadlines by infinitesimally small perturbations and obtain an algorithm for the general case.

At any given time t during the computation of the algorithm, for each node v, let $d^t(v)$ denote the earliest deadline among all requests in $\mathcal{T}_v$ (i.e., among all descendants of v) that are pending for the algorithm; if there is no pending request in $\mathcal{T}_v$, we set $d^t(v) = +\infty$. We will use the function d^t as the urgency of vertices at time t, i.e., a node u will be considered more urgent than a node v if $d^t(u) < d^t(v)$.

3.3 Algorithm OnlTreeD

At any time t when some request expires, that is when $t = d^t(r)$, the algorithm serves a subtree X constructed by first initializing $X = \{r, q\}$, and then incrementally augmenting X according to the following pseudo-code:

```
for each depth $i = 2, \dots, D$
    $Z^i \leftarrow$ set of all children of nodes in $X^{i-1}$
    for each $v \in X^{<i}$
        $U(v, i, t) \leftarrow \mathsf{Urgent}(Z^i_v, \ell_v, d^t)$
        $X \leftarrow X \cup U(v, i, t)$
```

In other words, at depth i, we restrict our attention to Z^i, the children of all the nodes in X^{i-1}, i.e., of the nodes that we have previously selected to X at level $i-1$. (We start with $i = 2$ and $X^1 = \{q\}$.) Then we iterate over all $v \in X^{<i}$ and we add to X the set $U(v, i, t)$ of vertices from $\mathcal{T}^i_v$ (descendants of v at depth i) whose parents are in X, one by one, in the order of increasing deadlines, stopping when either their total weight exceeds ℓ_v or when we run out of such vertices. Note that these sets do not need to be disjoint.

The constructed set X is a service tree, as we are adding to it only nodes that are children of the nodes already in X.

Let ρ be the request triggering the service at time t, i.e., satisfying $d_\rho = t$. (By the assumption about different deadlines, ρ is unique.) Naturally, all the nodes u on the path from r to σ_ρ have $d^t(u) = t$ and qualify as the most urgent, thus the node σ_ρ is included in X. Therefore every request is served before its deadline.

Intuitively, it should be clear that the described algorithm cannot have a better competitive ratio than $\ell(X)/\ell_q$: If all requests are in q, the optimum will serve only q, while our algorithm uses a set X with many nodes that turn out to be useless. As we will show, via an iterative charging argument, the ratio $\ell(X)/\ell_q$ is actually achieved by the algorithm.

Recall that $R_L = (2 + 1/L)^{D-1}$. We now prove a bound on the cost of the service tree.

▶ **Lemma 3.1.** *Let X be the service tree produced by Algorithm* OnlTreeD *at time t. Then $\ell(X) \le R_L \cdot \ell_q$.*

Proof. We prove by induction that $\ell(X^{\le i}) \le (2 + 1/L)^{i-1}\ell_q$ for all $i \le D$.

The base case of $i = 1$ is trivial, as $X^{\le 1} = \{r, q\}$ and $\ell_r = 0$. For $i \ge 2$, X^i is a union of the sets $U(v, i, t)$ over all nodes $v \in X^{<i}$. Since $\mathcal{T}$ is L-decreasing, each node in the set $U(v, i, t)$ has weight at most ℓ_v/L. Thus the total weight of $U(v, i, t)$ is at most $\ell(U(v, i, t)) \le \ell_v + \ell_v/L = (1 + 1/L)\ell_v$. Therefore, by the inductive assumption, we get that

$$\begin{aligned}\ell(X^{\le i}) &\le (1 + (1 + 1/L)) \cdot \ell(X^{<i}) \\ &\le (2 + 1/L) \cdot (2 + 1/L)^{i-2}\ell_q = (2 + 1/L)^{i-1}\ell_q\,,\end{aligned}$$

proving the induction step and completing the proof that $\ell(X) \le R_L \cdot \ell_q$. ◀

3.4 Analysis

The competitive analysis uses a charging scheme. Fix some optimal schedule S^*. Consider a service (X, t) of Algorithm OnlTreeD. We will identify in X a subset of "critically overdue" nodes (to be defined shortly) of total weight at least $\ell_q \geq \ell(X)/R_L$, and we will show that for each such critically overdue node v we can charge the portion ℓ_v of the service cost of X to an earlier service in S^* that contains v. Further, any node in service of S^* will be charged at most once. This implies that the total cost of our algorithm is at most R_L times the optimal cost, giving us an upper bound of R_L on the competitive ratio for L-decreasing trees.

In the proof, by opt_v^t we denote the time of the first service in S^* that includes v and is strictly after time t; we also let $\mathsf{opt}_v^t = +\infty$ if no such service exists. For a service (X, t) of the algorithm, we say that a node $v \in X$ is *overdue* at time t if $d^t(v) < \mathsf{opt}_v^t$. Servicing of such v is delayed in comparison to S^*, because S^* must have served v before (or at) time t. Note also that r and q are overdue at time t, as $d^t(r) = d^t(q) = t$ by the choice of the service time. We define $v \in X$ to be *critically overdue* at time t if (i) v is overdue at t, and (ii) there is no other service of the algorithm in the time interval (t, opt_v^t) in which v is overdue.

We are now ready to define the charging for a service (X, t). For each $v \in X$ that is critically overdue, we charge its weight ℓ_v to the last service of v in S^* before or at time t. This charging is well-defined as, for each overdue v, there must exist a previous service of v in S^*. The charging is obviously one-to-one because between any two services in S^* that involve v there may be at most one service of the algorithm in which v is critically overdue. The following lemma shows that the total charge from X is large enough.

► **Lemma 3.2.** *Let (X, t) be a service of Algorithm* OnlTreeD *and suppose that $v \in X$ is overdue at time t. Then the total weight of critically overdue nodes in X_v at time t is at least ℓ_v.*

Proof. The proof is by induction on the depth of $\mathcal{T}_v$, the subtree rooted at v.

The base case is when $\mathcal{T}_v$ has depth 0, that is when v is a leaf. We show that in this case v must be critically overdue, which implies the conclusion of the lemma. Towards contradiction, suppose that there is some other service at time $t' \in (t, \mathsf{opt}_v^t)$ in which v is overdue. Since v is a leaf, after the service at time t there are no pending requests in $\mathcal{T}_v = \{v\}$. This would imply that there is a request ρ with $\sigma_\rho = v$ such that $t < a_\rho \leq d_\rho < \mathsf{opt}_v^t$. But this is not possible, because S^* does not serve v in the time interval (t, opt_v^t). Thus v is critically overdue and the base case holds.

Assume now that v is not a leaf, and that the lemma holds for all descendants of v. If v is critically overdue, the conclusion of the lemma holds.

Thus we can now assume that v is not critically overdue. This means that there is a service (Y, t') of Algorithm OnlTreeD with $t < t' < \mathsf{opt}_v^t$ which contains v and such that v is overdue at t'. Thus $\mathsf{opt}_v^t = \mathsf{opt}_v^{t'}$.

Let ρ be the request with $d_\rho = d^{t'}(v)$, i.e., the most urgent request in $\mathcal{T}_v$ at time t'.

We claim that $a_\rho \leq t$, i.e., ρ arrived no later than at time t. Indeed, since v is overdue at time t', it follows that $d_\rho < \mathsf{opt}_v^{t'} = \mathsf{opt}_v^t$. The optimal schedule S^* cannot serve ρ after time t, as S^* has no service from v in the interval $(t, d_\rho]$. Thus S^* must have served ρ before or at t, and hence $a_\rho \leq t$, as claimed.

Now consider the path from σ_ρ to v in Y. (See Figure 1.) As ρ is pending for the algorithm at time t and ρ is not served by (X, t), it follows that $\sigma_\rho \notin X$. Let w be the last node on this path in $Y - X$. Then w is well-defined and $w \neq v$, as $v \in X$. Let i be the depth of w. Note that the parent of w is in $X_v^{<i}$, so $w \in Z^i$ in the algorithm when X is constructed.

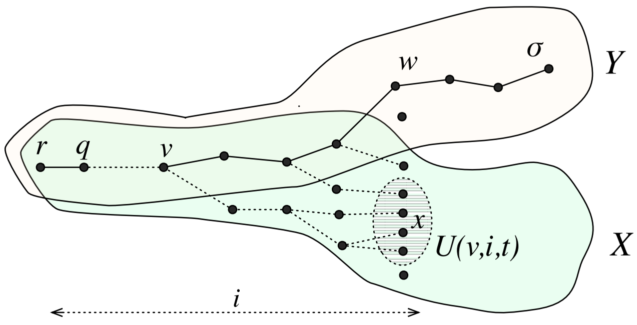

Figure 1 Illustration of the proof of Lemma 3.2.

The node σ_ρ is in $\mathcal{T}_w$ and ρ is pending at t, thus we have $d^t(w) \leq d_\rho$. Since $w \in Z^i$ but w was not added to X at time t, we have that $\ell(U(v,i,t)) \geq \ell_v$ and each $x \in U(v,i,t)$ is at least as urgent as w. This implies that such x satisfies

$$d^t(x) \leq d^t(w) \leq d_\rho < \mathsf{opt}_v^{t'} = \mathsf{opt}_v^t \leq \mathsf{opt}_x^t,$$

thus x is overdue at time t. By the inductive assumption, the total weight of critically overdue nodes in each subtree X_x is at least ℓ_x. Adding these weights over all $x \in U(v,i,t)$, we obtain that the total weight of critically overdue nodes in X_v is least $\ell(U(v,i,t)) \geq \ell_v$, completing the proof. ◀

Now consider a service (X,t) of the algorithm. The quasi-root q is overdue at time t, so Lemmas 3.2 and 3.1 imply that the charge from (X,t) is at least $\ell_q \geq \ell(X)/R_L$. Since each node in any service in S^* is charged at most once, we conclude that Algorithm OnlTreeD is R_L-competitive for any L-decreasing $\mathcal{T}$.

From the previous paragraph, using Theorem 2.1, we now obtain that there exists a $DLR_L = DL(2+1/L)^{D-1}$-competitive algorithm for general trees. For $D \geq 2$, choosing $L = D/2$ yields a competitive ratio bounded by $\frac{1}{2}D^2 2^{D-1} \cdot (1+1/D)^D \leq \frac{1}{4}D^2 2^D \cdot \mathrm{e} \leq D^2 2^D$. (For $D = 1$ there is a trivial 1-competitive algorithm for MLAP-D.) Summarizing, we obtain the following result.

▶ **Theorem 3.3.** *There exists a $D^2 2^D$-competitive online algorithm for MLAP-D.*

4 A Competitive Algorithm for MLAP

In this section we give an online algorithm for MLAP that achieves a constant competitive ratio for trees of bounded depth. Specifically, for trees of depth D the competitive ratio of this algorithm is at most $O(D^4 2^D)$. As before, Theorem 2.1 allows us to assume that the tree in the instance is L-decreasing.

4.1 Preliminaries and notations

We use some of the notation introduced in Section 3 and introduce some more.

Recall that $\omega_\rho(t)$ is the waiting cost function of a request ρ which is assumed to be continuous. We will overload this notation, so that we can talk about the waiting cost function for a set of requests or a set of vertices. Specifically, for a set P of requests and a set Z of nodes, let

$$\omega_P(Z,t) = \sum_{\rho \in P : \sigma_\rho \in Z} \omega_\rho(t).$$

Thus $\omega_P(Z,t)$ is the total waiting cost of the requests from P that are issued in Z.

Maturity time

In the algorithm for MLAP-D, the times of services and the urgency of nodes are both naturally determined by the deadlines. For MLAP with continuous waiting costs there are no hard deadlines; however, we can still introduce a useful notion of *maturity time* of a node, which is, roughly speaking, the time when some subtree rooted at this node has its waiting cost equal to its service cost; this subtree is then called *mature*. This turns out to be natural both for the quasi-root as the time to service it and for the other vertices as a measure of their urgency in the algorithm. We proceed to define these notions.

Consider some time t and any set $P \subseteq \mathcal{R}$ of requests. A subtree Z of $\mathcal{T}$ (not necessarily rooted at r) is called *P-mature* at time t if $\omega_P(Z,t) \geq \ell(Z)$. Also, let $\mu_P(Z)$ denote the minimal time τ such that $\omega_P(Z,\tau) = \ell(Z)$; we let $\mu_P(Z) = \infty$ if such τ does not exist. In other words, $\mu_P(Z)$ is the earliest τ at which Z is P-mature. Since $\omega_P(Z,0) = 0$ and $\omega_P(Z,t)$ is non-decreasing and continuous function of t, $\mu_P(Z)$ is well-defined.

For a node v, let the *P-maturity time of v*, denoted $M_P(v)$, be the minimum of values $\mu_P(Z)$ over all subtrees Z of $\mathcal{T}$ rooted at v. The tree Z that achieves this minimum will be denoted $C_P(v)$ and called the *P-critical tree rooted at v*; if there are more such trees, choose one arbitrarily.

The following simple lemma guarantees that the maturity time of any node in the P-critical tree $C_P(v)$ is at most the maturity time of v.

▶ **Lemma 4.1.** *Let $u \in C_P(v)$ and let $Y = (C_P(v))_u$ be the subtree of the $C_P(v)$ rooted at u. Then $M_P(u) \leq \mu_P(Y) \leq M_P(v)$.*

Proof. The first inequality is trivial. To show the second inequality, we proceed by contradiction. If the second inequality does not hold, then $u \neq v$ and $\omega_P(Y, M_P(v)) < \ell(Y)$. Take $Y' = C_P(v) \setminus Y$, which is a tree rooted at v. Since $\omega_P(C_P(v), M_P(v)) = \ell(C_P(v))$, we have that $\omega_P(Y', M_P(v)) = \omega_P(C_P(v), M_P(v)) - \omega_P(Y, M_P(v)) > \ell(C_P(v)) - \ell(Y) = \ell(Y')$. This in turn implies that $\mu_P(Y') < M_P(v)$, which is a contradiction with the definition of $M_P(v)$. ◀

Most of the references to maturity of a node or to its critical set will be made with respect to the set of requests pending for our algorithm at a given time. (In particular, if the algorithm schedules a service at some time t, the maturity times are computed with respect to the requests that are pending at time t *before* the service is executed.) Thus, for any time t, we will use notation $M^t(v)$ and $C^t(v)$ to denote the time $M_P(v)$ and the P-critical tree $C_P(v)$, where P is the set of requests pending for the algorithm at time t. Note that in general it is possible that $M^t(v) < t$. However, our algorithm will maintain the invariant that for the quasi-root q we will have $M^t(q) \geq t$ at each time t.

4.2 Algorithm

We now describe our algorithm. A service will occur at any maturity time of the quasi-root q, that is at a time t for which $t = M^t(q)$. At such a time, the algorithm chooses a service that contains the critical tree C of q and an extra set E, whose service cost is not much more expensive than that of C. The extra set is constructed similarly as in OnlTreeD, where the urgency of nodes is now measured by their maturity time. As before, this extra set will be a union of a system of sets $U(v,i,t)$ for $i = 2,\ldots,D$, and $v \in C^{<i} \cup E^{<i}$, except that now the sets $U(v,i,t)$ will be mutually disjoint and also disjoint from C.

Algorithm OnlTree

At any time t such that $t = M^t(q)$, serve the set $X = C \cup E$ constructed according to the following pseudo-code:

```
$C \leftarrow C^t(q) \cup \{r\}$
$E \leftarrow \emptyset$
for each depth $i = 2,\ldots,D$
    $Z^i \leftarrow$ set of all nodes in $\mathcal{T}^i \setminus C$ whose parent is in $C \cup E$
    for each $v \in (C \cup E)^{<i}$
        $U(v,i,t) \leftarrow \mathsf{Urgent}(Z^i_v, \ell_v, M^t)$
        $E \leftarrow E \cup U(v,i,t)$
        $Z^i \leftarrow Z^i \setminus U(v,i,t)$
```

At the end of the instance (when $t = H$, the time horizon) issue the last service that contains all vertices v with a pending request in $\mathcal{T}_v$.

The analysis of the algorithm will be given in the full version of the paper. We obtain:

▶ **Theorem 4.2.** *There exists an $O(D^4 2^D)$-competitive algorithm for MLAP on trees of depth D.*

5 Single-Phase MLAP

We now consider a restricted variant of MLAP that we refer to as *Single-Phase* MLAP, or 1P-MLAP. In 1P-MLAP all requests arrive at the beginning, at time 0. The instance also includes a parameter θ representing the common *expiration time* for all requests. We do not require that all requests are served. Any unserved request pays only the cost of waiting until the expiration time θ.

In the online variant of 1P-MLAP, all requests, including their waiting cost functions, are known to the online algorithm at time 0. The only unknown is the expiration time θ.

Although not explicitly named, variants of 1P-MLAP have been considered in [10, 7], where they were used to show lower bounds on competitive ratios for MLAP. These proofs consist of two steps, first showing a lower bound for online 1P-MLAP and then arguing that, in the online scenario, 1P-MLAP can be expressed as a special case of MLAP. (A corresponding property holds in the offline case as well, but is quite trivial.)

Since most lower bounds on competitive ratio of online algorithms for variants of MLAP use Single-Phase instances, a natural approach is to try such a construction in an attempt to construct super-constant lower bounds for MLAP. We show that this approach cannot be successful in the context of MLAP.

▶ **Theorem 5.1.** *There exists a 4-competitive algorithm for the Single-Phase MLAP.*

A detailed description of the algorithm will be given in the full version of the paper.

6 MLAP on Paths

We now consider the case when the tree is just a path. For simplicity we will assume a generalization to the continuous case, that we refer to as *the MLAP problem on the line*, when the path is represented by the half-line $[0, \infty)$; that is the requests can occur at any point $x \in [0, \infty)$. Then the point 0 corresponds to the root, each vertex is a point $x \in [0, \infty)$, and each service is an interval of the form $[0, x]$. We say that an algorithm *delivers from* x if it serves the interval $[0, x]$.

We provide several results for the MLAP problem on the line. We first prove that the competitive ratio of MLAP-D (the variant with deadlines) on the line is exactly 4, by providing matching upper and lower bounds. Then later we will show that the lower bound of 4 can be modified to work for MLAP-L (that is, for linear waiting costs).

Algorithm OnlLine

The algorithm creates a service only when a deadline of a pending request is reached. If a deadline of a request at x is reached, then OnlLine delivers from $2x$.

▶ **Theorem 6.1.** *Algorithm* OnlLine *is* 4*-competitive for MLAP-D on the line.*

Proof. The proof uses a charging strategy. We represent each adversary service, say when the adversary delivers from a point y, by an interval $[0, y]$. The cost of each service of OnlLine is then charged to a segment of one of those adversary service intervals.

Consider a service triggered by a deadline t of a request ρ at some point x; that is, OnlLine delivered from $2x$. The adversary must have served ρ between its arrival time and its deadline t. Fix the last such service of the adversary, where at a time $t' \leq t$ the adversary delivered from a point $x' \geq x$. We charge the cost $2x$ of the algorithm's service to the segment $[x/2, x]$ of the adversary's service interval $[0, x']$ at time t'.

We now claim that no part of the adversary's service is charged twice. To justify this claim, suppose that there are two services of OnlLine, at times $t_1 < t_2$, triggered by requests from points x_1 and x_2, respectively, that both charge to an adversary's service from x' at time $t' \leq t_1$. By the definition of charging, the request at x_2 was already present at time t'. As x_2 was not served by OnlLine's service at t_1, it means that $x_2 > 2x_1$, and thus the charged segments $[x_1/2, x_1]$ and $[x_2/2, x_2]$ of the adversary service interval at time t' are disjoint.

Summarizing, for any adversary service interval $[0, y]$, its charged segments are disjoint. Any charged segment receives the charge equal to 4 times its length. Thus this interval receives the total charge at most $4y$. This implies that the competitive ratio is at most 4. ◀

Lower bounds

We now show lower bounds of 4 for MLAP-D and MLAP-L on the line. In both proofs we show the bound for the corresponding variant of 1P-MLAP, using a reduction from the online bidding problem [13, 12]. Roughly speaking, in online bidding, for a given universe $\mathcal{U}$ of real numbers, the adversary chooses a secret value $u \in \mathcal{U}$ and the goal of the algorithm is to find an upper-bound on u. To this end, the algorithm outputs an increasing sequence of numbers $x_1, x_2, x_3, \ldots$. The game is stopped after the first x_k that is at least u and the bidding ratio is then defined as $\sum_{i=1}^{k} x_i/u$.

Chrobak et al. [12] proved that the optimal bidding ratio is exactly 4, even if it is restricted to sets $\mathcal{U}$ of the form $\{1, 2, \ldots, B\}$, for some integer B. More precisely, they proved the following result.

▶ **Lemma 6.2.** *For any $R < 4$, there exists B, such that any sequence of integers $0 = x_0 < x_1 < x_2 < \ldots < x_{m-1} < x_m = B$ has an index $k \geq 1$ with $\sum_{i=0}^{k} x_i > R \cdot (x_{k-1} + 1)$.*

▶ **Theorem 6.3.** *There is no online algorithm for MLAP-D on the line with competitive ratio smaller than 4.*

Proof. We show that no online algorithm for 1P-MLAP-D (the deadline variant of 1P-MLAP) on the line can attain competitive ratio smaller than 4. Assume the contrary, i.e., that there exists a deterministic algorithm ALG that is R-competitive, where $R < 4$. Let B be the integer whose existence is guaranteed by Lemma 6.2. We create an instance of 1P-MLAP-D, where for every $x \in \{1, \ldots, B\}$ there is a request at x with deadline x.

Without loss of generality, ALG issues services only at integer times $1, 2, ..., B$. The strategy of ALG can be now defined as a sequence of services at times $t_1 < t_2 < \ldots < t_m$, where at time t_i it delivers from $x_i \in \{t_i, t_i + 1, ..., B\}$. Without loss of generality, $x_1 < x_2 < \ldots < x_m$. We may assume that $x_m = B$ (otherwise the algorithm is not competitive at all); we also add a dummy service from $x_0 = 0$ at time $t_0 = 0$.

The adversary now chooses $k \geq 1$ and stops the game at the expiration time that is right after the algorithm's kth service, say $\theta = t_k + \frac{1}{2}$. ALG's cost is then $\sum_{i=0}^{k} x_i$. The request at $x_{k-1} + 1$ is not served at time t_{k-1}, so, to meet the deadline of this request, the schedule of ALG must satisfy $t_k \leq x_{k-1} + 1$. This implies that $\theta < x_{k-1} + 2$, that is, all requests at points $x_{k-1} + 2, x_{k-1} + 3, ..., B$ expire before their deadlines and do not need to be served. Therefore, to serve this instance, the optimal solution may simply deliver from $x_{k-1} + 1$ at time 0. Hence, the competitive ratio of ALG is at least $\sum_{i=0}^{k} x_i/(x_{k-1} + 1)$. By Lemma 6.2, it is possible to choose k such that this ratio is strictly greater than R, a contradiction with R-competitiveness of ALG. ◀

Next, we show that the same lower bound applies to MLAP-L, the version of MLAP where the waiting cost function is linear. This improves the lower bound of 3.618 from [7].

▶ **Theorem 6.4.** *There is no online algorithm for MLAP-L on the line with competitive ratio smaller than 4.*

Proof. Similarly to the proof of Theorem 6.3, we create an instance of 1P-MLAP-L (the variant of 1P-MLAP with linear waiting cost functions) that does not allow a better than 4-competitive online algorithm. Fix any online algorithm ALG for 1P-MLAP-L and, towards a contradiction, suppose that it is R-competitive, for some $R < 4$. Again, let B be the integer whose existence is guaranteed by Lemma 6.2. In our instance of 1P-MLAP-L, there are 6^{B-x} requests at x for any $x \in \{1, 2, \ldots, B\}$.

Without loss of generality, we make the same assumptions as in the proof of Theorem 6.3: algorithm ALG is defined by a sequence of services at times $0 = t_0 < t_1 < t_2 < \ldots < t_m$, where at each time t_i it delivers from some point x_i. Without loss of generality, we can assume that $0 = x_0 < x_1 < \ldots < x_m = B$.

Again, the strategy of the adversary is to stop the game at some expiration time θ that is right after some time t_k, say $\theta = t_k + \epsilon$, for some small $\epsilon > 0$. The algorithm pays $\sum_{i=0}^{k} x_i$ for serving the requests. The requests at $x_{k-1} + 1$ waited for time t_k in ALG's schedule and hence ALG's waiting cost is at least $6^{B-x_{k-1}-1} \cdot t_k$.

The adversary delivers from point $x_{k-1} + 1$ at time 0. The remaining, unserved requests at points $x_{k-1}+2, x_{k-1}+3, \ldots, B$ pay time θ each for waiting. There are $\sum_{j=x_{k-1}+2}^{B} 6^{B-j} \leq \frac{1}{5} \cdot 6^{B-x_{k-1}-1}$ such requests and hence the adversary's waiting cost is at most $\frac{1}{5} \cdot 6^{B-x_{k-1}-1} \cdot (t_k + \epsilon)$.

Therefore, the algorithm-to-adversary ratio on the waiting costs is at least $5t_k/(t_k+\epsilon)$. For any k we can choose a sufficiently small ϵ so that this ratio is larger than 4. By Lemma 6.2, it is possible to choose k for which the ratio on servicing cost is strictly greater than R. This yields a contradiction to the R-competitiveness of ALG. ◀

We point out that the analysis in the proof above gives some insight into the behavior of any 4-competitive algorithm for 1P-MLAP-L (we know such an algorithm exists, by the results in Section 5), namely that, for the type of instances used in the above proof, its waiting cost must be negligible compared to the service cost.

Abstract

Let s denote a distinguished source vertex of a non-negatively real weighted and undirected graph G with n vertices and m edges. In this paper we present two efficient *single-source approximate-distance sensitivity oracles*, namely *compact* data structures which are able to *quickly* report an approximate (by a multiplicative stretch factor) distance from s to any node of G following the failure of any edge in G. More precisely, we first present a sensitivity oracle of size $O(n)$ which is able to report 2-approximate distances from the source in $O(1)$ time. Then, we further develop our construction by building, for any $0 < \varepsilon < 1$, another sensitivity oracle having size $O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$, and is able to report a $(1+\varepsilon)$-approximate distance from s to any vertex of G in $O\left(\log n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ time. Thus, this latter oracle is essentially optimal as far as size and stretch are concerned, and it only asks for a logarithmic query time. Finally, our results are complemented with a space lower bound for the related class of single-source *additively-stretched* sensitivity oracles, which is helpful to realize the hardness of designing compact oracles of this type.

1 Introduction

The term *distance oracle* was coined by Thorup and Zwick [19], to emphasize the quality of a data structure that, despite its sparseness, is able to report very quickly provably good approximate distances between any pair of nodes in a graph. Indeed, it is well-known that in huge graphs the trade-off between time and space for *exact* distance queries is a very critical issue: at its extremes, either we use a quadratic (unfeasible) space to reply in constant time, or we use a linear space to reply at an unsustainable large time. Thus, a wide body of literature focused on the problem of developing intermediate solutions in between these two opposite approaches, with the goal of designing more and more compact and fast oracles. This already complex task is further complicated as soon as edge or vertex failures enter

* A full version of the paper is available at `http://arxiv.org/abs/1608.04769`.

into play: here, the oracle should be able to return (approximate) distances following the failure of some component(s) in the underlying graph, or in other words to be *fault-tolerant*, thus introducing an additional overload to the problem complexity. This kind of oracle is also known as *distance sensitivity oracle*. In this paper we focus our attention on a such challenging scenario, but we restrict our attention to the prominent case in which concerned distances are from a fixed source only, which is of special interest in several network-based applications.

1.1 Related work

Let s denote a distinguished source vertex of a non-negatively real weighted and undirected n-vertex and m-edge graph $G = (V(G), E(G), w)$. For the sake of avoiding technicalities, we assume that G is 2-edge-connected, although this assumption can be easily relaxed without affecting our results. A *single-edge-fault-tolerant α-single-source distance oracle* (EFT α-SSDO in the following), with $\alpha \geq 1$, is a data structure that for any $v \in V(G)$ and any $e \in E(G)$ is able to return an estimate of the distance in $G - e$ (i.e., the graph G deprived by e) between s and v, say $d_{G-e}(s, v)$, within the range $[d_{G-e}(s, v), \alpha \cdot d_{G-e}(s, v)]$. The term α is a.k.a. the *stretch factor* of the oracle.

A natural counterpart of such an oracle is an EFT *α-approximate shortest-path tree* (α-ASPT), i.e., a subgraph of G which, besides a SPT of G rooted at s, contains α-stretched shortest paths from s after the failure of any edge e in G. Such a structure is also known as a *single-source EFT α-spanner*. In some sense, a SSDO aims to convert in an explicit form the distance information that a corresponding ASPT may retain just in an implicit form, similarly to the process of maintaining in an n-size array all the distances from the source induced by the paths of a corresponding SPT. However, such a conversion process is far to be trivial in general and should be accomplished carefully, since the exploitation of the implicit information may introduce a dilatation in the final size of the oracle.

While the study of sensitivity oracles for all-pairs distances started right after the first appearance of [19], the single-source case was faced only later. More precisely, in [10] it was first proven that if we aim at *exact* distances, then $\Theta(n^2)$ space may be needed, already for undirected graphs and single edge failures, and independently of the query time. Then, in [1] the authors build in $O(m \log n + n \log^2 n)$ time a *single-vertex-fault-tolerant* (VFT) 3-SSDO of size $O(n \log n)$ and with constant query time. In the same paper, for *unweighted* graphs and for any $\varepsilon > 0$, the authors build in $O(m\sqrt{n/\varepsilon})$ time a VFT $(1 + \varepsilon)$-SSDO of size $O(\frac{n}{\varepsilon^3} + n \log n)$ and with constant query time. Both oracles are *path reporting*, i.e., they are able to report the corresponding approximate shortest path from the source in time proportional to the path size. Moreover, as discussed in [5], in both oracles/spanners the log-term in the size can be removed if *edge* failures are considered, instead of vertex failures. Finally, they can easily be transformed into corresponding E/VFT ASPTs having a same size and stretch. As far as this latter result is concerned, this was improved in [5], where it was given, for any (even non-constant) $\varepsilon > 0$, an E/VFT $(1 + \varepsilon)$-ASPT of size $O(\frac{n \log n}{\varepsilon^2})$, without providing a corresponding oracle, though.

Summarizing, we therefore have the following state-of-the-art for EFT SSDOs: if we insist on having linear-size and constant query time, then a $(1 + \varepsilon)$-stretch can be obtained only for unweighted graphs, while for weighted graphs the best current stretch is 3. Actually, this latter value can be reduced only by either paying a quadratic size (by storing for every $e \in E(G)$, the explicit distances from s in $G - e$), or an almost linear size but a super-linear query time (by storing and then inspecting the structure provided in [5]). So, the main open question is the following: can we develop a good space-time trade-off (ideally, linear space and constant query time) by guaranteeing a stretch less than 3 (ideally, arbitrarily close to 1)? In this paper, we make significant progresses in this direction.

1.2 Our results

Our main result is, for any arbitrary small $\varepsilon > 0$, the construction in $O(mn + n^2 \log n)$ time and $O\left(m + n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ space of an EFT $(1+\varepsilon)$-SSDO having size $O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ and query time $O\left(\log n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$. Thus, when ε is constant w.r.t. n, we get close to the ideal situation we were depicting above: our oracle has linear space, stretch arbitrarily close to 1, and a logarithmic query time. Moreover, it is interesting to notice that size and query time have an almost linear dependency on $1/\varepsilon$.

To the best of our knowledge, this is the first EFT SSDO guaranteeing a $(1+\varepsilon)$-stretch factor on weighted graphs. Interestingly, our construction is not obtained by the EFT $(1+\varepsilon)$-ASPT of size $O(\frac{n \log n}{\varepsilon^2})$ given in [5], whose conversion to a same size-stretch trade-off oracle sounds very hard, and is instead based on a quite different approach. More precisely, to get our size and query time bounds, we select a subset of *landmark* nodes of G, and for each one of them we store $O\left(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ *exact* post-failure (for an appropriate set of failing edges) distances from s. Then, when an edge e fails and we want to retrieve an approximate distance from s towards a fixed destination node t, we efficiently select with the promised query time a pivotal landmark node that actually sits on a path in $G - e$ from s to t whose length is within the bound. Notice that such a path is not *explicitly* stored in our oracle, so unfortunately we cannot return it in a time proportional to its size (besides the query time). In other words, our oracle is not inherently path-reporting, an we leave this point as a challenging open problem.

To get the reader acquainted with our technique, we first develop in $O(mn + n^2 \log n)$ time and $O(m)$ space an EFT 2-SSDO of size $O(n)$ and constant query time. This result is of independent interest, since it is the first EFT SSDO with both optimal size and query time having a stretch better than the long-standing barrier of 3. In this other oracle, once again we select a subset of landmark nodes of G, but in this case, to get the promised stretch, we do not need to maintain explicitly any exact distances towards them. Rather, for the failure of an edge e of G and for a fixed destination node t, a structural property of 2-stretched post-failure paths will allow us to return the 2-approximate distance from s by simply understanding whether there exists a pivotal landmark node associated with t. Actually, we show that such an association can be established by formulating a corresponding *bottleneck vertex query* problem on a rooted tree, that can be answered in $O(1)$ time by using a linear-size efficient data structure developed in [9].

Finally, in order to better appreciate the quality of our former oracle, we provide a lower bound on the bit size of any EFT *β-additive* SSDO, i.e., an oracle which is able to report a distance from s following an edge failure which is exact unless an additive term β. Notice that for weighted graphs, as in our setting, it only makes sense that such a β is depending on the actual queried distance d. Notice also that our linear-size EFT $(1+\varepsilon)$-SSDO can be revised as an EFT $(\varepsilon \cdot d)$-additive SSDO. So, a naturally arising question is: for a given $0 < \delta \leq 1$, can we devise a compact EFT $(\varepsilon \cdot d^{1-\delta})$-additive SSDO? We provide an answer in the negative, by showing a class of graphs for which a corresponding set of oracles of this sort would contain at least an element of $\Omega(n^2)$ bit size, regardless of its query time. Due to space limitations, the proof of this latter result will be given in the full version of the paper.

1.3 Other related results

Besides the aforementioned related work on single-source distance sensitivity oracles, we mention some further papers on the topic. For directed graphs with integer positive edge weights bounded by M, in [12] the authors show how to build efficiently in $\widetilde{O}(Mn^{\omega})$ time a *randomized* EFT SSDO of size $\Theta(n^2)$ and with $O(1)$ query time, where returned distances are exact w.h.p., and $\omega < 2.373$ denotes the matrix multiplication exponent. As far as *multiple* edge failures are concerned, in [6], for the failure of any set $F \subseteq E(G)$ of at most f edges of G, the authors build in $O(fm\,\alpha(m,n) + fn\log^3 n)$ time an f-EFT $(2|F|+1)$-SSDO of size $O(\min\{m, fn\}\log^2 n)$, with a query time of $O(|F|^2 \log^2 n)$, and that is also able to report the corresponding path in the same time plus the path size. Notice that this oracle is obtained by converting a corresponding single-source f-EFT spanner having size $O(fn)$ and a same stretch. Notice also that if one is willing to use $O(m\log^2 n)$ space, such oracle will be able to handle any number of edge failures (i.e., up to m). Recently in [8], the authors faced the special case of *shortest-path failures*, in which the failure of a set F of at most f adjacent edges along any source-leaf path has to be tolerated. For this problem, they build in $O(n(m+f^2))$ time, a $(2k-1)(2|F|+1)$-SSDO of size $O(kn\,f^{1+1/k})$ and constant query time, where $|F|$ denotes the size of the actual failing path, and $k \geq 1$ is a parameter of choice. Moreover, for the special case of $f = 2$, they give an ad-hoc solution, i.e., a 3-SSDO that can be built in $O(nm + n^2\log n)$ time, has size $O(n\log n)$ and constant query time.

In the past, several other research efforts have been devoted to *all-pairs distance oracles* (APDO) tolerating single/multiple edge/vertex failures. Quite interestingly, here $\widetilde{O}(n^2)$-size exact-distance sensitivity oracles are instead known, as opposed to the $\Omega(n^2)$ lower bound for the single-source case. More precisely, in [4] the authors built (on directed graphs) in $\widetilde{O}(mn)$ time a 1-E/VFT 1-APDO of size $\widetilde{O}(n^2)$ and with query time $O(1)$. For two failures, in [11] the authors built, still on directed graphs, a 2-E/VFT 1-APDO of size $\widetilde{O}(n^2)$ and with query time $O(\log n)$. Concerning multiple-edge failures, in [7] the authors built, for any integer $k \geq 1$, an f-EFT $(8k-2)(f+1)$-APDO of size $O(fk\,n^{1+1/k}\log(nW))$, where W is the ratio of the maximum to the minimum edge weight in G, and with a query time of $\widetilde{O}(|F|\,\log\log d)$, where F is the actual set of failing edges, and d is the distance between the queried pair of nodes in $G - F$.

As we said before, the natural counterpart of distance sensitivity oracles are the fault-tolerant spanners. Due to space limitations, for this related topic we refer the reader to the discussion and the references provided in [6]. However, it is worth mentioning that there is a line of papers on EFT ASPTs [14, 15, 16, 17], that as we said are very close in spirit to EFT SSDOs.

Finally, we mention that there is a large body of literature concerned with the design of ordinary (i.e., fault-free) distance oracles, and an extensive recent survey on the topic is given in [18].

1.4 Notation

For two given vertices x and y of an edge weighted graph H, we denote by $\pi_H(x,y)$ a shortest path between x and y in H and we denote by $d_H(x,y)$ the total length of $\pi_H(x,y)$. For two given paths P and P' such that P is a path between x and y and P' is a path between y and z, we denote by $P \circ P'$ the path from x to z obtained by concatening P and P'.

Let T be an SPT of G rooted at s, and let $e = (u,v)$ be an edge of T. In the rest of the paper, we always assume that u is closer to s than v w.r.t. the number of hops in T. Furthermore, we denote by T_v the subtree of T rooted at v. Finally, for a vertex $t \in T_v$, we denote by $A(t,e) = V(\pi_T(v,t))$ the set of *living ancestors* of T, t included, contained in T_v.

2 The EFT 2-SSDO

In this section we describe our EFT 2-SSDO with linear size and constant query time. Some of the ideas we develop here will be used in the next section, where we provide our main result.

For the rest of the paper, let T be a fixed SPT of G rooted at s that is stored in our distance oracle. First of all, observe that if there is no edge failure or the edge that has failed is not contained in T, then, for any vertex t, our distance oracle can return the (exact) distance value $d_T(s,t)$ in constant time. This is the case also when the edge $e=(u,v)$ that has failed is contained in T, but t is not a vertex of T_v. Therefore, in the rest of this section, we describe only how our distance oracle computes an approximate distance from s to t in $G-e$ when the edge $e=(u,v)$ that has failed is contained in T and the vertex t is contained in the subtree T_v.

The following lemma describes a simple but still interesting property that we exploit as key ingredient in our oracle. Let $e=(u,v)$ be a failing edge, we define a special replacement path from s to t as follows: $P_e(t)=\pi_{G-e}(s,v)\circ\pi_G(v,t)$.

▶ **Lemma 1.** *Let $e=(u,v)$ be a failing edge and $t\in V(T_v)$. At least one of the following conditions holds: (i) $d_{G-e}(s,t)\le w(P_e(t))\le 2d_{G-e}(s,t)$, (ii) $d_{G-e}(s,t)<2d_G(s,t)$.*

Proof. We assume that (ii) is false (i.e., $d_{G-e}(s,t)\ge 2d_G(s,t)$) and we prove that (i) must hold. Indeed:

$$\begin{aligned}d_{G-e}(s,t)\le w(P_e(t)) &= d_{G-e}(s,v)+d_G(v,t)\le d_{G-e}(s,t)+d_{G-e}(v,t)+d_G(v,t)\\ &= d_{G-e}(s,t)+2d_G(v,t)\le d_{G-e}(s,t)+2d_G(s,t)\le 2d_{G-e}(s,t).\end{aligned}$$ ◀

Notice that the length of $P_e(t)$ is available in constant time once we store $O(n)$ distance values, namely $d_{G-e}(s,v)$ for each $e=(u,v)\in E(T)$. Hence, the challenge here is to understand when $w(P_e(t))$ provides a 2-approximation of the distance $d_{G-e}(s,t)$ and when we can instead return the value $2d_G(s,t)\le 2d_{G-e}(s,t)$ (observe that $2d_G(s,t)$ could be in general smaller than $d_{G-e}(s,t)$). The idea of our oracle is that of selecting a subset of *marked* vertices for which this information can be stored and retrieved efficiently and from which we can derive the same information for the other nodes.

To this aim, we now describe an algorithm that preprocesses the graph and collects compact information that we will use later to efficiently answer distance queries. Consider the edges of T as traversed by a preorder visit from s. We define a total order relation $\prec$ on $E(T)$ as follows: we say that $e'\prec e''$ iff e' is traversed before e''. We also use $e'\preceq e''$ to denote that either $e'\prec e''$ or $e'=e''$.

Algorithm 1 considers the failing edges $e\in E(T)$ in preorder and computes a label $\ell(v)$ for each vertex $v\in V(G)$. This value will be either ∞ or a suitable edge $e\in E(T)$. Here we treat ∞ as a special label that satisfies $e'\prec\infty$ for every edge $e'\in E(T)$. We say that v is *marked* if $\ell(v)\ne\infty$, and we say that v is *marked at time* e if $\ell(v)\preceq e$. Intuitively, $\ell(v)$ is the time at which v first becomes marked.

More precisely, for each failing edge e, Algorithm 1, marks a vertex $t\in V(T_v)$ (at time e) iff vertex t fails two tests: the *distance test* and the *ancestor test*. In the distance test we check whether the path $P_e(t)$ suffices to provide a 2-stretched distance to t, while in the ancestor test we check whether a living ancestor of t has already been marked. Notice that the ancestor test guarantees that each vertex t is marked at most once during the whole execution of the algorithm (since $t\in A(t,e)$ by definition).

As a simple consequence of the above algorithm, we have:

Algorithm 1: Mark-up algorithm

```
1  for $v \in V$ do
2      $\ell(v) \leftarrow \infty$
3  for $e = (u, v) \in E(T)$ in preorder w.r.t. $T$ do
4      for $t \in V(T_v)$ in preorder w.r.t. $T$ do
5          if $w(P_e(t)) \leq 2d_{G-e}(s, t)$ then                // Distance test
6              do nothing
7          else if $\exists z \in A(t, e) : \ell(z) \neq \infty$ then      // Ancestor test
8              do nothing
9          else                                            // Both tests failed
10             $\ell(t) \leftarrow e$                                 // Mark $t$ at time $e$
```

▶ **Lemma 2.** *Let $e \in E(T)$ be a failing edge and let t be a vertex such that $\ell(t) = e$, we have $d_{G-e}(s, t) < 2d_G(s, t)$.*

Proof. Since t is first marked at time e, it must have failed the distance test, i.e., $w(P_e(t)) > 2d_{G-e}(s, t)$. This means that condition (i) of Lemma 1 is false and hence condition (ii) must hold. ◀

Another useful property of the marked vertices is the following:

▶ **Lemma 3.** *Let $e \in E(T)$ be a failing edge and let t be a vertex such that $\ell(t) = e$, then $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$ are edge disjoint.*

Proof. Let $e = (u, v)$ and assume by contradiction that $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$ are not edge disjoint. Let (z, z') be an edge belonging to both paths, with z closer to v than z'. Notice that both z and z' are living ancestors of t, and that $z \neq t$.

Since t is first marked at time e, it must have failed the ancestor test. This implies that no other living ancestor of t is marked at time e. Moreover, as z is visited by the algorithm before t, it must have failed the ancestor test as well. Since z it is not marked at time e, it follows that it must have passed the distance test, i.e., $w(P_e(z)) \leq 2d_{G-e}(s, z)$. We have $P_e(t) = P_e(z) \circ \pi_G(z, t)$ and hence:

$$\begin{aligned} w(P_e(t)) = w(P_e(z)) + d_G(z, t) &\leq 2d_{G-e}(s, z) + d_G(z, t) \\ &\leq 2d_{G-e}(s, z) + 2d_{G-e}(z, t) = 2d_{G-e}(s, t) \end{aligned}$$

which implies that t has passed the distance test and contradicts the hypothesis $\ell(t) = e$. ◀

The next lemma is the last ingredient of our oracle, and allows to distinguish the two cases of Lemma 1.

▶ **Lemma 4.** *Let $e = (u, v) \in E(T)$ be a failing edge and let $t \in V(T_v)$. If there exists $z \in A(t, e)$ such that $\ell(z) \preceq e$, then $d_{G-e}(s, t) \leq 2d_G(s, t)$. If no such vertex z exists, then $d_{G-e}(s, t) \leq w(P_e(t)) \leq 2d_{G-e}(s, t)$.*

Proof. Let z be any vertex in $A(t, e)$ such that $\ell(z) \preceq e$, and let $e' = \ell(z)$. By the definition of living ancestor and by Lemma 3 we have that $\pi_{G-e'}(s, z)$ does not use the edge e (see

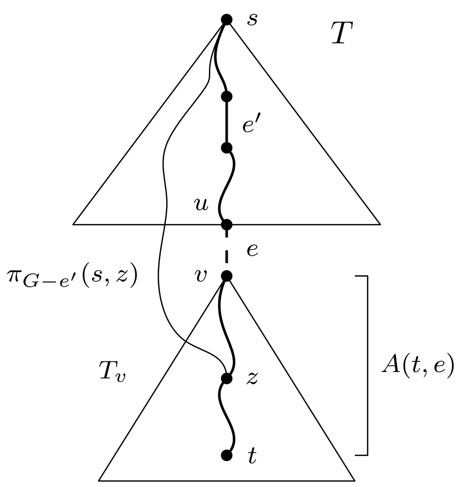

Figure 1 Representation of the proof of Lemma 4. The shortest path between s and t in T is shown in bold while the failing edge e is dashed. Notice that the path $\pi_{G-e'}(s,z)$ is edge disjoint from the path $\pi_T(v,z)$.

Figure 1). Since z is marked at time e' we have $d_{G-e'}(s,z) < 2d_G(s,z)$ (see Lemma 2). Thus, we have that $d_{G-e}(s,z) \le w(\pi_{G-e'}(s,z)) = d_{G-e'}(s,z) < 2d_G(s,z)$. Therefore:

$$d_{G-e}(s,t) \le d_{G-e}(s,z) + d_G(z,t) \le 2d_G(s,z) + d_G(z,t) \le 2d_G(s,z) + 2d_G(z,t) = 2d_G(s,t).$$

If no such vertex z exists, then when Algorithm 1 considered edge e, the vertex z failed the ancestor test. Since t is not marked at time e (as otherwise we could choose $z = t$) it must have passed the distance test, i.e., $w(P_e(t)) \le 2d_{G-e}(s,t)$. ◀

This latter lemma is exactly what we need in order to implement the query operation of our oracle. When edge $e = (u,v)$ is failing and we are queried for the distance of a vertex t, we first test whether $e \in E(T)$ and $t \in V(T_v)$: if the test fails we return the original distance $d_G(s,t)$.[1] If the test succeeds, we look for a vertex $z \in A(t,e)$ such that $\ell(z) \preceq e$. If such a vertex exists we return $2d_G(s,t)$, otherwise we return $w(P_e(t))$. Observe that in both cases we return a feasible 2-approximation of the distance $d_{G-e}(s,t)$.

In the following we will show how it is possible to determine in constant time whether such a vertex z exists. More precisely we only need to look for a vertex $x \in A(t,e)$ minimizing $\ell(x)$. If such a vertex satisfies $\ell(x) \preceq e$ then $z = x$ and we are done. On the converse, if $e \prec \ell(x)$, then we know that no vertex $z \in A(t,e)$ with $\ell(z) \preceq e$ can exist.

To this aim, we use a data structure for the *bottleneck vertex query* problem on trees (`BVQ` for short). In the `BVQ` problem we want to preprocess a vertex-weighted tree $\mathcal{T}$ in order to answer queries of this form: given two vertices $x, y \in V(\mathcal{T})$ report the lightest vertex on the (unique) path between x and y in $\mathcal{T}$. In [9], the authors show how to build, in $O(|V(\mathcal{T})| \log |V(\mathcal{T})|)$ time, a data structure having linear size and constant query time.[2]

[1] To see whether t is contained in $V(T_v)$ or not, it suffices to check whether the least common ancestor of t and v in T corresponds to v or not. The least common ancestor between any pair of vertices of a tree can be computed in constant time after a linear time preprocessing [13].

[2] Actually, in [9] the *bottleneck edge query* (`BEQ`) problem is considered instead. However it is easy to see that the `BEQ` and the problems `BVQ` are essentially equivalent.

In our preprocessing, we build such a structure on the tree T where each vertex $x \in T$ weighs $\ell(x)$, and then we use it to locate x in the path between v and t whenever we need to report an approximate distance for $d_{G-(u,v)}(s,t)$.

We are now ready to state the main result of this section.

▶ **Theorem 5.** *Let G be a non-negatively real weighted and undirected n-vertex and m-edge graph, and let s be a source node. There exists an EFT 2-SSDO that has size $O(n)$ and constant query time, and that can be constructed using $O(mn + n^2 \log n)$ time and $O(m)$ space.*

Proof. As we already discussed it is easy to answer a query in constant time once we store: (i) the SPT T of G w.r.t. s, (ii) the label $\ell(v)$ for each v, (iii) the value $w(\pi_{G-e}(s,v))$ for each $(u,v) \in E(T)$, and (iv) a data structure for the `BVQ` problem. The total space used is hence $O(n)$.

Concerning the time and the space used by Algorithm 1, observe that for each edge $e = (u,v)$, we can compute an SPT of $G - e$ with source s in $O(m + n \log n)$ time and $O(m)$ space. Therefore, for each t the distance test can be accomplished in $O(1)$ time. It remains to show that also the ancestor test can be done in constant time. To this aim, it is sufficient to maintain for each vertex x the (current) number ν_x of marked ancestors of x in T, and check whether $\nu_t - \nu_u > 0$. The maintenance of these values can be clearly done with constant time and space overhead, from which the claim follows. ◀

3 The EFT $(1+\varepsilon)$-SSDO

In this section we describe our main result, namely how to build, given any $0 < \varepsilon < 1$, an EFT $(1+\varepsilon)$-SSDO having $O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ size and $O\left(\log n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ query time.

Our distance oracle stores a set of $O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ (exact) distance values that are computed by a preprocessing algorithm that we describe below. From a high-level point of view, we follow the same approach used in the previous section, but here a vertex t can be marked several times, each corresponding to a specific failing edge $e = (u,v) \in E(T)$ for which the algorithm computes the shortest path $\pi_{G-e}(s,t)$ that is edge disjoint from $\pi_T(v,t)$. We will show that such paths have strictly decreasing lengths and that they are $O\left(\frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ in number. We will store all these distance values and we will show that they can be used to efficiently answer any distance query by suitably combining them with distances in T.

More precisely, for every $e = (u,v) \in E(T)$ and every $t \in V(T_v)$, the preprocessing algorithm computes a value $\texttt{dist}(t,e)$ that satisfies $d_{G-e}(s,t) \le \texttt{dist}(t,e) \le \sqrt{1+\varepsilon} \cdot d_{G-e}(s,t)$. Furthermore, each value $\texttt{dist}(t,e)$ represents the total length of a path P from s to t in $G - e$, whose structure can be either of the following two types:

type 1: $P = \pi_{G-e}(s,t)$;

type 2: P can be decomposed into $\pi_{G-e'}(s,z)$, for some e' and z such that $\texttt{dist}(z,e') = d_{G-e'}(s,z)$, and $\pi_T(z,t)$ (possibly, either $e = e'$ or $z = t$).

Since each path of type 2 can be easily derived by combining a path of type 1 with a path in T, our oracle stores only all the values $\texttt{dist}(t,e) = d_{G-e}(s,t)$ that represent paths of type 1. In the next two subsections, we will show that, for every $e \in E(T)$ and every t, our distance oracle can compute a $(\sqrt{1+\varepsilon})$-approximation of $\texttt{dist}(t,e)$ in $O\left(\log n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ time.

3.1 The preprocessing algorithm

The preprocessing algorithm (see the pseudocode of Algorithm 2) visits all the edges of T in preorder and, for each $e = (u, v) \in E(T)$, it visits all the vertices of T_v in preorder. For the rest of this section, unless stated otherwise, let $e = (u, v)$ be a fixed edge of T that is visited by the algorithm. The algorithm sets $\texttt{dist}(v, e) = d_{G-e}(s, v)$, i.e., $\texttt{dist}(v, e)$ always represents a path of type 1. When the algorithm visits t, with $t \neq v$, it first checks whether the shortest, among several paths from s to t in $G - e$ of type 2, has a total length of at most $\sqrt{1+\varepsilon} \cdot d_{G-e}(s, t)$. If this is the case, then the algorithm sets $\texttt{dist}(t, e)$ equal to the total length of such a path, otherwise it sets $\texttt{dist}(t, e) = d_{G-e}(s, t)$, i.e., $\texttt{dist}(t, e)$ represents a path of type 1. The preprocessing algorithm returns the set of all distance values that represent the paths of type 1.

For each vertex t, the algorithm stores the total length of the last path from s to t of type 1 that has computed in the variable $\texttt{last}(t)$.

Algorithm 2: Selects paths of type 1 whose lengths are stored in the oracle.

```
  // Initialization of variables
1 $S, S' = \emptyset$ for every $t \in V(G)$ do
2     $\texttt{last}(t) = \infty$

  // All the values $\texttt{dist}(t, e)$ are computed
3 for every $e = (u, v) \in E(T)$ in preorder w.r.t. $T$ do
4     $\texttt{last}(v), \texttt{dist}(v, e) = d_{G-e}(s, v)$; add $d_{G-e}(s, v)$ to $S'$        // path of type 1
5     for every $t \in V(T_v) \setminus \{v\}$ in preorder w.r.t. $T$ do
          // The length of a path from $s$ to $t$ in $G - e$ of type 2 is computed
6         $\texttt{dist}(t, e) = \min\{\texttt{last}(z) + d_T(z, t) \mid z \in A(t, e)\}$
7         if $\texttt{dist}(t, e) > \sqrt{1+\varepsilon} \cdot d_{G-e}(s, t)$ then
8             $\texttt{last}(t), \texttt{dist}(t, e) = d_{G-e}(s, t)$; add $d_{G-e}(s, t)$ to $S$   // path of type 1

9 return $S$ and $S'$.
```

For the rest of this section, unless stated otherwise, let t be a fixed vertex of T_v that is visited by the algorithm. The proof of the following proposition is trivial.

▶ **Proposition 6.** *At the end of the visit of t, $\texttt{dist}(t, e) \leq \sqrt{1+\varepsilon} \cdot d_{G-e}(s, t)$.*

The following lemma is similar to Lemma 3 and it is useful to prove that $\texttt{dist}(t, e) \geq d_{G-e}(s, t)$.

▶ **Lemma 7.** *If $d_{G-e}(s, t)$ is added to $S \cup S'$, then $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$ are edge disjoint.*

Proof. The claim trivially holds when $t = v$ since $\pi_T(v, v)$ contains no edge. Therefore, we assume that $t \neq v$. We prove the claim by contradiction by showing that if $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$ were not edge disjoint, then the algorithm would not add $d_{G-e}(s, t)$ to $S \cup S'$. So, we assume that $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$ are not edge disjoint. Let t' be, among the vertices that are contained in both $\pi_{G-e}(s, t)$ and $\pi_T(v, t)$, the one that is closest to v w.r.t. the number of hops in $\pi_T(v, t)$. Clearly, $t' \neq t$ and $\pi_T(t', t)$ is a shortest path from t' to t in G as well as in $G - e$. Thus, by the suboptimality property of shortest paths, $d_{G-e}(s, t) = d_{G-e}(s, t') + d_{G-e}(t', t) = d_{G-e}(s, t') + d_T(t', t)$. Let $z \in A(t', e)$ be the vertex such that $\texttt{dist}(t', e) = \texttt{last}(z) + d_T(z, t')$ (possibly $z = t'$). As the algorithm visits t' before visiting t, by Proposition 6, $\texttt{dist}(t',e) \le \sqrt{1+\varepsilon} \cdot d_{G-e}(s,t')$ at the beginning of the visit of t. Therefore

$$\begin{aligned}\texttt{last}(z) + d_T(z,t) &= \texttt{last}(z) + d_T(z,t') + d_T(t',t)\\ &= \texttt{dist}(t',e) + d_T(t',t)\\ &\le \sqrt{1+\varepsilon} \cdot d_{G-e}(s,t') + d_T(t',t)\\ &\le \sqrt{1+\varepsilon} \cdot d_{G-e}(s,t).\end{aligned}$$

As $\texttt{dist}(t,e) \le \texttt{last}(z) + d_T(z,t)$ already before the execution of the if statement during the visit of t, the algorithm never adds $d_{G-e}(s,t)$ to $S \cup S'$. The claim follows. ◀

We now prove that $\texttt{dist}(t,e) \ge d_{G-e}(s,t)$.

▶ **Lemma 8.** *At the end of the visit of t, $\texttt{dist}(t,e) \ge d_{G-e}(s,t)$.*

Proof. The claim trivially holds if the algorithm sets $\texttt{dist}(t,e) = d_{G-e}(s,t)$. Therefore, we need to prove the claim when the condition of the if statement during the visit of t is not satisfied, i.e., $\texttt{dist}(t,e) = \texttt{last}(z) + d_T(z,t)$, for some vertex $z \in A(t,e)$ (possibly, $z = t$). Let $\texttt{last}(z) = d_{G-e'}(s,z)$, for some $e' = (u',v')$ such that z is a vertex of $T_{v'}$ (possibly $e' = e$). We divide the proof into the following two cases according to whether $e' = e$ or not.

Consider the case in which $e' = e$ and observe that e is not contained in $\pi_T(z,t)$. Therefore $\texttt{dist}(t,e) = d_{G-e'}(s,z) + d_T(z,t) = d_{G-e}(s,z) + d_{G-e}(z,t) \ge d_{G-e}(s,t)$.

Consider the case in which $e' \ne e$ and observe that e is an edge of the path $\pi_T(v',z)$. Furthermore, $\texttt{last}(z) = d_{G-e'}(s,z)$ implies that the algorithm has added $d_{G-e'}(s,z)$ to $S \cup S'$. Therefore, by Lemma 7, $\pi_{G-e'}(s,z)$ and $\pi_T(v',z)$ are edge disjoint. This implies that e is contained neither in $\pi_{G-e'}(s,z)$ nor in $\pi_T(z,t)$. Therefore, $d_{G-e}(s,t) \le d_{G-e'}(s,z) + d_T(z,t) = \texttt{last}(z) + d_T(z,t) = \texttt{dist}(t,e)$, and the claim follows. ◀

The following proposition allows us to prove that the number of paths of type 1 computed by the algorithm is almost linear in n.

▶ **Proposition 9.** *Let $e_0, e_1, \dots, e_k$ be all the pairwise distinct edges of T, in the order in which they are visited by the algorithm, such that $d_{G-e_i}(s,t) \in S$. Then, for every $i = 0,1,\dots,k$, $d_{G-e_i}(s,t) < 2/\big((\sqrt{1+\varepsilon}-1)(1+\varepsilon)^{i/2}\big) d_G(s,t)$. Furthermore, $k < 2 \cdot \frac{\log\left(2/(\sqrt{1+\varepsilon}-1)\right)}{\log(1+\varepsilon)}$.*

Proof. Let $e_0 = (u_0,v_0)$ and observe that at the end of the visit of e_0 and v_0

$$\begin{aligned}\texttt{last}(v_0) + d_T(v_0,t) &= d_{G-e_0}(s,v_0) + d_T(v_0,t)\\ &\le d_{G-e_0}(s,t) + d_T(t,v_0) + d_T(v_0,t)\\ &\le d_{G-e_0}(s,t) + 2d_T(s,t)\\ &= d_{G-e_0}(s,t) + 2d_G(s,t).\end{aligned}$$

Since $d_{G-e_0}(s,t) \in S$, $\sqrt{1+\varepsilon} \cdot d_{G-e_0}(s,t) < \texttt{last}(v_0) + d_T(v_0,t)$, and therefore

$$d_{G-e_0}(s,t) < \frac{2}{\sqrt{1+\varepsilon}-1} d_G(s,t). \qquad (1)$$

Next, observe that the value $\texttt{last}(t)$ at the beginning of the visit of edge e_i, with $1 \le i \le k$, is equal to $d_{G-e_{i-1}}(s,t)$. Since $d_{G-e_i}(s,t) \in S$, we have that

$$\sqrt{1+\varepsilon} \cdot d_{G-e_i}(s,t) < d_{G-e_{i-1}}(s,t) \qquad \text{for every } i = 1,\dots,k. \qquad (2)$$

Thus, if, for any $i > 0$, we combine inequality (1) and all the inequalities (2) with $j \le i$, we obtain $(1+\varepsilon)^{i/2} d_{G-e_i}(s,t) < 2/(\sqrt{1+\varepsilon}-1) d_G(s,t)$, i.e.,

$$d_{G-e_i}(s,t) < \frac{2}{(\sqrt{1+\varepsilon}-1)(1+\varepsilon)^{i/2}} d_G(s,t).$$

Moreover, using $d_G(s,t) \le d_{G-e_k}(s,t)$ in $d_{G-e_k}(s,t) < 2/\big((\sqrt{1+\varepsilon}-1)(1+\varepsilon)^{k/2}\big) d_G(s,t)$ we obtain $(1+\varepsilon)^{k/2} < 2/(\sqrt{1+\varepsilon}-1)$, i.e.,

$$k < 2 \cdot \frac{\log\big(2/(\sqrt{1+\varepsilon}-1)\big)}{\log(1+\varepsilon)}.$$

The claim follows. ◀

Observe that $\log\big(2/(\sqrt{1+\varepsilon}-1)\big) = O(\log(1/\varepsilon))$, and that $\log(1+\varepsilon) = \Theta(\varepsilon)$. Therefore, using Proposition 9 and the fact that $|S'| = n-1$, we obtain

▶ **Corollary 10.** $|S \cup S'| = O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$.

▶ **Lemma 11.** *Algorithm 2 can be implemented to run in $O(mn + n^2 \log n)$ time and $O\left(m + n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ space.*

Proof. First we prove the time bound. Clearly, the inizialization of variables takes $O(n)$ time. Let $e = (u,v)$ be an edge that is visited by the algorithm. The algorithm computes an SPT of $G - e$ rooted at s in $O(m + n\log n)$ time. Let $t \ne v$ be the vertex that is going to be visited by the algorithm and let t' be the parent of t in T. Observe that

$$\begin{aligned}\min_{z\in A(t,e)}\{\texttt{last}(z) + d_T(z,t)\} &= \min\left\{\texttt{last}(t), \min_{z\in A(t',e)}\{\texttt{last}(z) + d_T(z,t)\}\right\}\\ &= \min\left\{\texttt{last}(t), \min_{z\in A(t',e)}\{\texttt{last}(z) + d_T(z,t')\} + w(t',t)\right\} \qquad (3)\\ &= \min\{\texttt{last}(t), \texttt{dist}(t',e) + w(t',t)\},\end{aligned}$$

Therefore, each value $\texttt{dist}(t,e)$ can be computed in constant time rather than in $O(n)$ time. Hence, the overall running time is $O(mn + n^2 \log n)$.

Concerning the space complexity, observe that, from Equation (3), the algorithm does not need to store all the values $\texttt{dist}(t,e)$ but, for each t, it is enough to remember the last computed value $\texttt{dist}(t,e)$. This can be clearly done with an array of n elements. Next, observe that, during the visit of e, the algorithm only needs the one-to-all distances in $G - e$. This implies that there is no need to keep all the $n-1$ SPT's of $G - e$, for every $e \in E(T)$, at the same time and therefore, all these SPT's can share the same $O(n)$ space. Finally, $|S \cup S'| = O\left(n \cdot \frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ by Corollary 10. The claim follows. ◀

3.2 The data structure

We now describe how the values in S and S' can be organized in a data structure of size $O\left(n \cdot \frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ so that our distance oracle can compute a $(\sqrt{1+\varepsilon})$-approximation of $\texttt{dist}(t,e)$ in $O\left(\log n \cdot \frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ time.

Remind that we say that $e' \prec e''$ if the preprocessing algorithm has visited e' before visiting e'', and that we also use $e' \preceq e''$ to denote that either $e' \prec e''$ or $e' = e''$. Let $k = \left\lfloor 2 \cdot \frac{\log\left(2/(\sqrt{1+\varepsilon}-1)\right)}{\log(1+\varepsilon)} \right\rfloor$ and let $a_i = \frac{2}{(\sqrt{1+\varepsilon}-1)(1+\varepsilon)^{i/2}}$. Finally, for every $i = 0, 1, \ldots, k$, let

$$S_i = \Big\{d_{G-e'}(s,z) \in S \mid a_{i+1} \cdot d_G(s,z) \le d_{G-e'}(s,z) < a_i \cdot d_G(s,z)\Big\}.$$

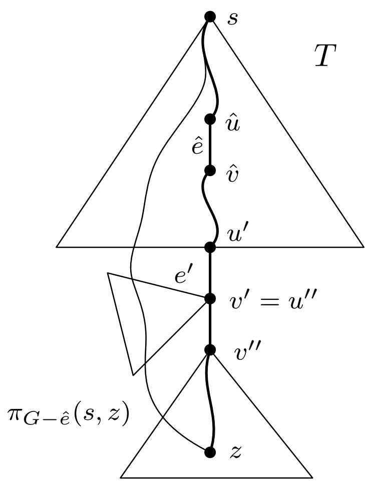

Figure 2 Representation of the proof of Proposition 12. The shortest path between s and t in T is shown. Notice that the path $\pi_{G-\hat{e}}(s,z)$ is edge disjoint from the path $\pi_T(\hat{v},z)$.

By Proposition 9, we have that $\{S_i \mid i = 0,1,\ldots,k\}$ is a partition of S.

We maintain a set of $k+1$ trees $\mathcal{T}_0, \mathcal{T}_1, \ldots, \mathcal{T}_k$, one for each S_i. Each tree $\mathcal{T}_i$ is a copy of T, where each vertex z, such that $d_{G-e'}(s,z) \in S_i$, has a label $\ell_i(z) = e'$. Every other vertex $z \in V(G) \setminus S_i$ has a label $\ell_i(z) = \infty$ such that $e' \prec \infty$, for every edge $e' \in E(T)$.

In the following, we denote the value of $\texttt{last}(z)$ at the end of the visit of edge e' by $\texttt{last}(z,e')$. First of all, we prove the following proposition.

▶ **Proposition 12.** *If* $e' \preceq e''$*, then* $\texttt{last}(z,e'') \leq \texttt{last}(z,e')$.

Proof. Let $e' = (u',v')$ and $e'' = (u'',v'')$. Notice that the claim can be proved by showing that it holds under the assumption that $v' = u''$. Furthermore, we can also assume that $\texttt{last}(z,e') \neq \infty$ as well as $\texttt{last}(z,e'') \neq \texttt{last}(z,e')$, otherwise the claim would be trivially true. This last assumption together with $v' = u''$ imply that $\texttt{last}(z,e'') = d_{G-e''}(s,z)$. Let $\texttt{last}(z,e') = d_{G-\hat{e}}(s,z)$, for some $\hat{e} \preceq e'$, with $\hat{e} = (\hat{u},\hat{v})$. Clearly, $d_{G-\hat{e}}(s,z) \in S \cup S'$. Therefore, by Lemma 7, $\pi_{G-\hat{e}}(s,z)$ and $\pi_T(\hat{v},z)$ are edge disjoint (see Figure 2). Since e'' is an edge of $\pi_T(\hat{v},z)$, $\pi_{G-\hat{e}}(s,z)$ is also a path from s to t in $G-e''$ and therefore $\texttt{last}(z,e'') = d_{G-e''}(s,z) \leq d_{G-\hat{e}}(s,z) = \texttt{last}(z,e')$. ◀

Let $e = (u,v) \in E(T)$ and let t be a vertex of T_v. Using Proposition 12, we have that either $\texttt{dist}(t,e) = \texttt{last}(v,e) + d_T(v,t) = d_{G-e}(s,v) + d_T(v,t)$, or

$$\begin{aligned}
&\texttt{dist}(t,e) = \min\left\{\texttt{last}(z,e) + d_T(z,t) \mid z \in A(t,e) \setminus \{v\}\right\}\\
&= \min\left\{\texttt{last}(z,e) + d_T(z,t) \mid z \in A(t,e)\right\}\\
&= \min_{i=0,1,\ldots,k}\left\{\min\left\{\texttt{last}(z,\ell_i(z)) + d_T(z,t) \mid z \in A(t,e) \wedge \ell_i(z) \preceq e\right\}\right\}\\
&= \min_{i=0,1,\ldots,k}\left\{\delta_i := \min\left\{d_{G-e'}(s,z) + d_T(z,t) \mid z \in A(t,e) \wedge d_{G-e'}(s,z) \in S_i \wedge e' \preceq e\right\}\right\}.
\end{aligned}$$

In the former case, $\texttt{dist}(t,e)$ is available in $O(1)$ time, since $d_{G-e}(s,v)$ is stored in S'. In the latter case, we now show how to compute, for any fixed $i = 0,1,\ldots,k$, a $(\sqrt{1+\varepsilon})$-approximate upper bound to δ_i in $O(\log n)$ time. Using Proposition 9, this will imply that our oracle is able to answer a query in $O\left(\log n \cdot \frac{1}{\varepsilon}\log\frac{1}{\varepsilon}\right)$ time.

First of all, we prove that the labels of each $\mathcal{T}_i$ satisfy a nice property.

▶ **Lemma 13.** *Let z' and z'' be two distinct vertices of $A(t,e)$ such that z'' is a proper ancestor of z' and $\ell_i(z') = e'$ and $\ell_i(z'') = e''$, for some edges $e', e'' \in E(T)$, with $e', e'' \preceq e$ (possibly, $e' = e''$). We have that $d_{G-e''}(s,z'') + d_T(z'',t) \leq \sqrt{1+\varepsilon} \cdot \big(d_{G-e'}(s,z') + d_T(z',t)\big)$.*

Proof. Since $d_{G-e''}(s,z'') \in S_i$, we have that $d_{G-e''}(s,z'') < a_i \cdot d_G(s,z'')$. Furthermore, $d_{G-e'}(s,z') \in S_i$ implies that $d_{G-e'}(s,z') \geq a_{i+1} \cdot d_G(s,z') = a_i/\sqrt{1+\varepsilon} \cdot d_G(s,z')$. As a consequence, $d_{G-e''}(s,z'') + d_T(z'',t) < a_i \cdot d_G(s,z'') + d_T(z'',z') + d_T(z',t) \leq a_i \cdot d_G(s,z') + d_T(z',t) \leq \sqrt{1+\varepsilon} \cdot d_{G-e'}(s,z') + d_T(z',t) \leq \sqrt{1+\varepsilon} \cdot \big(d_{G-e'}(s,z') + d_T(z',t)\big)$. ◀

Let $z'' \in A(t,e)$ be the vertex closest to v w.r.t. T such that $\ell_i(z) = e'' \preceq e$, if such a vertex exist. Let $\delta_i = d_{G-e'}(s,z') + d_T(z',t)$, for some e' and z' such that $z' \in A(t,e)$, $d_{G-e'}(s,z') \in S_i$, and $e' \preceq e$. Observe that $d_{G-e''}(s,z'') + d_T(z'',t) \geq \delta_i$. Moreover, since z' and z'' satisfy all the hyphotesis of Lemma 13, we have that

$$\delta_i \leq d_{G-e''}(s,z'') + d_T(z'',t) \leq \sqrt{1+\varepsilon} \cdot \delta_i.$$

Therefore, the value $d_{G-e''}(s,z'') + d_T(z'',t)$ is a $(\sqrt{1+\varepsilon})$-approximate upper bound to the value δ_i. Now we show how the vertex z'' can be computed in $O(\log n)$ time.

To this aim, we preprocess each tree $\mathcal{T}_i$ in order to build a linear-size data structure that answers `BVQ` queries in constant time. This can be done in $O(n \log n)$ time per tree. We also preprocess T so we are able to perform *level-ancestor* queries in constant time. The size needed by this latter data structure is $O(n)$ and it can be built in linear-time [3, 2]. In a level ancestor query, we are given a vertex $x \in V(T)$ and a positive integer h, and we ask for the ancestor y of x such that $\pi_T(x,y)$ contains exactly h edges. We can then find z'' by performing a binary search over the vertices of $A(t,e)$, as follows.

Let $e = (u,v)$, we perform a level ancestor query on T to find the vertex x of $\pi_T(v,t)$ that divides the path into roughly two halves. Let x' be the parent of x, and let y and y' be the vertices of $\pi_T(x,t)$ and $\pi_T(v,x')$ of minimum labels, respectively. Notice that y and y' can be found in constant time by performing two `BVQ` queries on $\mathcal{T}_i$. If $\ell_i(y') \preceq e$, then we remember y' as the best vertex found so far and we iterate the binary search in $\pi_T(v,x')$. Otherwise, if $e \prec \ell_i(y')$, then we compare $\ell_i(y)$ and e. If $\ell_i(y) \preceq e$, then we remember y as the best vertex found so far and we iterate the binary search in $\pi_T(x,t)$. If $e \prec \ell_i(y)$, then we can complete our binary search and return the best vertex found, if any.

We have then proven the following:

▶ **Theorem 14.** *Let G be a non-negatively real weighted and undirected n-vertex and m-edge graph, and let s be a source node. For any arbitrarily small $0 < \varepsilon < 1$, there exists an EFT $(1+\varepsilon)$-SSDO that has size $O\left(n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ and $O\left(\log n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ query time, and that can be constructed using $O(mn + n^2 \log n)$ time and $O\left(m + n \cdot \frac{1}{\varepsilon} \log \frac{1}{\varepsilon}\right)$ space.*

4 Lower bounds on the size of additive EFT ASPT and SSDO

In this section, we give a lower bound on the bit size of an EFT $\beta(d)$-additive SSDO. Recall that after the failure of any edge, such an oracle must return an estimation d' of the actual distance d between s and any node such that $d \leq d' \leq d + \beta(d)$, where β is any positive real function. Due to space limitations, the proof of next theorem is omitted and will be given in the full version of the paper.

▶ **Theorem 15.** *Let $\beta(d) = kd^{1-\delta}$, for arbitrary $k \geq 1$ and $0 < \delta \leq 1$. Then, there exist classes of polynomially weighted graphs with n nodes such that:*

1. *any* EFT *$\beta(d)$-additive ASPT has $\Omega(n^2)$ edges;*
2. *any* EFT *$\beta(d)$-additive SSDO has $\Omega(n^2)$ bit size for at least an input graph, regardless of its query time.*

Abstract

In several emerging technologies for computer memory (main memory), the cost of reading is significantly cheaper than the cost of writing. Such asymmetry in memory costs poses a fundamentally different model from the RAM for algorithm design. In this paper we study lower and upper bounds for various problems under such asymmetric read and write costs. We consider both the case in which all but $O(1)$ memory has asymmetric cost, and the case of a small cache of symmetric memory. We model both cases using the (M, ω)-ARAM, in which there is a small (symmetric) memory of size M and a large unbounded (asymmetric) memory, both random access, and where reading from the large memory has unit cost, but writing has cost $\omega \gg 1$.

For FFT and sorting networks we show a lower bound cost of $\Omega(\omega n \log_{\omega M} n)$, which indicates that it is not possible to achieve asymptotic improvements with cheaper reads when ω is bounded by a polynomial in M. Moreover, there is an asymptotic gap (of $\min(\omega, \log n)/\log(\omega M)$) between the cost of sorting networks and comparison sorting in the model. This contrasts with the RAM, and most other models, in which the asymptotic costs are the same. We also show a lower bound for computations on an $n \times n$ diamond DAG of $\Omega(\omega n^2/M)$ cost, which indicates no asymptotic improvement is achievable with fast reads. However, we show that for the minimum edit distance problem (and related problems), which would seem to be a diamond DAG, we can beat this lower bound with an algorithm with only $O(\omega n^2/(M \min(\omega^{1/3}, M^{1/2})))$ cost. To achieve this we make use of a "path sketch" technique that is forbidden in a strict DAG computation. Finally, we show several interesting upper bounds for shortest path problems, minimum spanning trees, and other problems. A common theme in many of the upper bounds is that they require redundant computation and a tradeoff between reads and writes.

1 Introduction

Fifty years of algorithms research has focused on settings in which reads and writes (to memory) have similar cost. But what if reads and writes to memory have significantly *different* costs? How would that impact algorithm design? What new techniques are useful for trading-off doing more cheaper operations (say more reads) in order to do fewer expensive operations (say fewer writes)? What are the fundamental limitations on such trade-offs (lower bounds)? What well-known equivalences for traditional memory fail to hold for asymmetric memories?

Such questions are coming to the fore with the arrival of new **main-memory** technologies [29, 32] that offer key potential benefits over existing technologies such as DRAM, including nonvolatility, signicantly lower energy consumption, and higher density (more bits stored per unit area). These emerging memories will sit on the processor's memory bus and be accessed at byte granularity via loads and stores (like DRAM), and are projected to become the dominant main memory within the decade [36, 49].[1] Because these emerging technologies store data as "states" of a given material, the cost of reading (checking the current state) is significantly cheaper than the cost of writing (modifying the physical state of the material): Reads are up to an order of magnitude or more lower energy, lower latency, and higher (per-module) bandwidth than writes [5, 6, 10, 11, 20, 21, 30, 31, 33, 41, 47].

This paper provides a first step towards answering these fundamental questions about asymmetric memories. We introduce a simple model for studying such memories, and a number of new results. In the simplest model we consider, there is an asymmetric random-access memory such that reads cost 1 and writes cost $\omega \gg 1$, as well as a constant number of symmetric "registers" that can be read or written at unit cost. More generally, we consider settings in which the amount of symmetric memory is $M \ll n$, where n is the input size: We define the (M, ω)-*Asymmetric RAM (ARAM)*, comprised of a symmetric small-memory of size M and an asymmetric large-memory of unbounded size with write cost ω. The *ARAM cost* Q is the number of reads from large-memory plus ω times the number of writes to large-memory. The *time* T is Q plus the number of reads and writes to small-memory.

We present a number of lower and upper bounds for the (M, ω)-ARAM, as summarized in Table 1. These results consider a number of fundamental problems and demonstrate how the asymptotic algorithm costs decrease as a function of M, e.g., polynomially, logarithmically, or not at all.

For FFT we show an $\Omega(\omega n \log_{\omega M} n)$ lower bound on the ARAM cost, and a matching upper bound. Thus, even allowing for redundant (re)computation of nodes (to save writes), it is not possible to achieve asymptotic improvements with cheaper reads when $\omega \in O(M^c)$ for a constant c. Prior lower bound approaches for FFTs for symmetric memory fail to carry over to asymmetric memory, so a new lower bound technique is required. We use an interesting new accounting argument for fractionally assigning a unit weight for each node of the network to subcomputations that each have cost ωM. The assignment shows that each subcomputation has on average at most $M \log(\omega M)$ weight assigned to it, and hence the total cost across all $\Theta(n \log n)$ nodes yields the lower bound.

For sorting, we show the surprising result that on asymmetric memories, comparison sorting is asymptotically faster than sorting networks. This contrasts with the RAM model (and I/O models, parallel models such as the PRAM, etc.), in which the asymptotic costs are the same! The lower bound leverages the same key partitioning lemma as in the FFT proof.

[1] While the exact technology is continually evolving, candidate technologies include phase-change memory, spin-torque transfer magnetic RAM, and memristor-based resistive RAM.

Table 1 Summary of Our Results for the (M, ω)-ARAM (†indicates main results).

problem	**ARAM cost** $Q(n)$ **or** $Q(n,m)$	**time** $T(n)$ **or** $T(n,m)$	**section**

minimum spanning tree	$O(m \min(\log n, n/M) + \omega n)^\dagger$	$O(Q(n,m) + n \log n)$	6

We present a tight lower bound for DAG computation on diamond DAGs that shows there is no asymptotic advantage of cheaper reads. On the other hand, we also show that allowing a vertex to be "partially" computed before all its immediate predecessors have been computed (thereby violating a DAG computation rule), we can beat the lower bound and show asymptotic advantage. Specifically, for both the longest common subsequence and edit distance problems (normally thought of as diamond DAG computations), we devise a new "path sketch" technique that leverages partial aggregation on the DAG vertices. Again we know of no other models in which such techniques are needed.

Finally, we show how to adapt Dijkstra's single-source shortest-paths algorithm using phases so that the priority queue is kept in small-memory, and briefly sketch how to adapt Borůvka's minimum spanning tree algorithm to reduce the number of shortcuts and hence writes that are needed. A common theme in many of our algorithms is that they use redundant computations and require a tradeoff between reads and writes.

Related Work. Prior work [7, 22, 25, 37, 38, 46] has studied read-write asymmetries in NAND flash memory, but this work has focused on (i) the asymmetric *granularity* of reads and writes in NAND flash chips: bits can only be cleared by incurring the overhead of erasing a large block of memory, and/or (ii) the asymmetric *endurance* of reads and writes: individual cells wear out after tens of thousands of writes to the cell. Emerging memories, in contrast, can read and write arbitrary bytes in-place and have many orders of magnitude higher write endurance, enabling system software to readily balance application writes across individual physical cells by adjusting its virtual-to-physical mapping. Other prior work has studied database query processing under asymmetric read-write costs [12, 13, 45, 46] or looked at other systems considerations [14, 30, 35, 48, 50, 51]. Our recent paper [10] introduced the general study of parallel (and external memory) models and algorithms with asymmetric read and write costs, focusing on sorting. Our follow-on paper [8] defined an abstract nested-parallel model of computation with asymmetric read-write costs that maps efficiently onto more concrete parallel machine models using a work-stealing scheduler, and presented reduced-write, work-efficient, highly-parallel algorithms for a number of fundamental problems such as tree contraction and convex hull. In contrast, this paper considers a much simpler model (the sequential (M, ω)-ARAM) and presents not just algorithms but also lower bounds—plus, the techniques are new. Finally, concurrent with this paper, Carson et al. [11] developed interesting upper and lower bounds for various linear algebra problems and direct N-body methods under asymmetric read and write costs. For sequential algorithms, they define a model similar to the (M, ω)-ARAM (as well as a cache-oblivious variant), and show that for "bounded data reuse" algorithms, i.e., algorithms in which each input or computed value is used only a constant number of times, the number of writes to asymmetric memory is asymptotically the same as the sum of the reads and writes to asymmetric memory. This implies, for example, a tight $\Omega(n \log n / \log M)$ lower bound on the number of writes for FFT under the bounded data reuse restriction; in contrast, our tight bounds for FFT do not have this restriction and use fewer writes. They also presented algorithms without this restriction for matrix multiplication, triangular solve, and Cholesky factorization that reduce the number of writes to Θ(output size), without increasing the number of reads, as well as various distributed-memory parallel algorithms.

2 Model and Preliminaries

We analyze algorithms in an *(M, ω)-ARAM*. In the model we assume a symmetric *small-memory* of size $M \geq 1$, an asymmetric *large-memory* of unbounded size, and a *write cost* $\omega \geq 1$, which we assume without loss of generality is an integer. (Typically, we are interested in the setting where $n \gg M$, where n is the input size, and $\omega \gg 1$.) We assume standard random access machine (RAM) instructions. We consider two cost measures for computations in the model. We define the (asymmetric) *ARAM cost Q* as the total number of reads from large-memory plus ω times the number of writes to large-memory. We define the (asymmetric) *time T* as the ARAM cost plus the number of reads from and writes to small-memory.[2] Because all instructions are from memory, this includes any cost of computation. In the paper we present results for both cost measures.

The model contrasts with the widely-studied external-memory model [1] in the asymmetry of the read and write costs. Also for simplicity in this paper we do not partition the memory into blocks of size B. Another difference is that the asymmetry implies that even the case of $M = O(1)$ (studied in [10] for sorting) is interesting. We note that our ARAM cost is a special case of the general flash model cost proposed in [4]; however that paper presents algorithms only for another special case of the model with symmetric read-write costs.

We use the term *value* to refer to an object that fits in one word (location) of the memory. We assume words are of size $\Theta(\log n)$ for input size n. The size M is the number of words in small-memory. All logarithms are base 2 unless otherwise noted. The DAG computation problem is given a DAG and a value for each of its input vertices (in-degree = 0), compute the value for each of its output vertices (out-degree = 0). The value of any non-input vertex can be computed in unit time given the value of all its immediate predecessors. As in standard I/O models [1] we assume values are atomic and cannot be split when mapped into the memory. The DAG computation problem can be modeled as a pebbling game

[2] The time metric models the fact that reads to certain emerging asymmetric memories are projected to be roughly as fast as reads to symmetric memory (DRAM). The ARAM cost metric Q does not make this assumption and hence is more generally applicable.

on the DAG [28]. Note that we allow (unbounded) recomputation of a DAG vertex, and indeed recomputation is a useful technique for reducing the number of writes (at the cost of additional reads).

3 Lower Bounds

We start by showing lower bounds for FFT DAGs, sorting networks and diamond DAGs. The idea in showing the lower bounds is to partition a computation into subcomputations that each have a lower bound on cost, but an upper bound on the number of inputs and outputs they can use. Our lower bound for FFT DAGs then uses an interesting accounting technique that gives every node in the DAG a unit weight, and fractionally assigns this weight across the subcomputations. In the special case $\omega = 1$, this leads to a simpler proof for the lower bound on the I/O complexity of FFT DAGs than the well-known bound by Hong and Kung [27].

We refer to a *subcomputation* as any contiguous sequence of instructions. The *outputs* of a subcomputation are the values written by the subcomputation that are either an output of the full computation or read by a later subcomputation. Symmetrically, the *inputs* of a subcomputation are the values read by the subcomputation that are either an input of the full computation or written by a previous subcomputation. An (l, m)-*partitioning* of a computation is a partitioning of instructions into subcomputations such that each has at most l inputs and at most m outputs. We allow for recomputation—instructions in different subcomputations might compute the same value.

▶ **Lemma 1.** *Any computation in the (M, ω)-ARAM has an $((\omega + 1)M, 2M)$-partitioning such that at most one of the subcomputations has ARAM cost $Q < \omega M$.*

Proof. We generate the partitioning constructively. Starting at the beginning, partition the instructions into contiguous blocks such that all but possibly the last block has cost $Q \geq \omega M$, but removing the last instruction from the block would have cost $Q < \omega M$. To remain within the cost bound each such subcomputation can read at most ωM values from large-memory. It can also read the at most M values that are in the small-memory when the subcomputation starts. Therefore it can read at most $(\omega + 1)M$ distinct values from the input or from previous subcomputations. Similarly, each subcomputation can write at most M values to large-memory, and an additional M values that remain in small-memory when the subcomputation ends. Therefore it can write at most $2M$ distinct values that are available to later subcomputations or the output. ◀

FFT. We now consider lower bounds for the DAG computation problem for the family of FFT DAGs (also called FFT networks, or butterfly networks). The FFT DAG of input size $n = 2^k$ consists of $k + 1$ levels each with n vertices (for a total of $n \log 2n$ vertices). Each vertex (i, j) at level $i \in 0, \ldots, k - 1$ and row j has two out-edges, which go to vertices $(i + 1, j)$ and $(i + 1, j \oplus 2^i)$ ($\oplus$ is the exclusive-or of the bit representation). This is the DAG used by the standard FFT (Fast Fourier Transform) computation. We note that in the FFT DAG there is at most a single path from any vertex to another.

▶ **Lemma 2.** *Any (l, m)-partitioning of a computation for simulating an n input FFT DAG has at least $n \log n/(m \log l)$ subcomputations.*

Proof. We refer to all vertices whose values are outputs of any subcomputation, as *partition output vertices*. We assign each such vertex arbitrarily to one of the subcomputations for which it is an output.

Consider the following accounting scheme for fractionally assigning a unit weight for each non-input vertex to some set of partition output vertices. If a vertex is a partition output vertex, then assign the weight to itself. Otherwise take the weight, divide it evenly between its two immediate descendants (out-edges) in the FFT DAG, and recursively assign that weight to each. For example, for a vertex x that is not a partition output vertex, if an immediate descendant y is a partition output vertex, then y gets a weight of $1/2$ from x, but if not and one of y's immediate descendants z is, then z gets a weight of $1/4$ from x. Since each non-input vertex is fully assigned across some partition output vertices, the sum of the weights assigned across the partition output vertices exactly equals $|V| - n = n \log n$. We now argue that every partition output vertex can have at most $\log l$ weight assigned to it. Looking back from an output vertex we see a binary tree rooted at the output. If we follow each branch of the tree until we reach an input for the subcomputation, we get a tree with at most l leaves, since there are at most l inputs and at most a single path from every vertex to the output. The contribution of each vertex in the tree to the output is $1/2^i$, where i is its depth (the root is depth 0). The leaves (subcomputation inputs) are not included since they are partition output vertices themselves, or inputs to the whole computation, which we have excluded. By induction on the tree structure, the weight of that tree is maximized when it is perfectly balanced, which gives a total weight of $\log l$.

Because every subcomputation can have at most m outputs, the total weight assigned to each subcomputation is at most $m \log l$. Since the total weight across all subcomputations is $n \log n$, the total number of subcomputations is at least $n \log n/(m \log l)$. ◀

▶ **Theorem 3** (FFT Lower Bound). *Any solution to the DAG computation problem on the family of FFT DAGs parametrized by input size n has costs $Q(n) = \Omega(\omega n \log n/ \log(\omega M))$ and $T(n) = \Omega(Q(n) + n \log n)$ on the (M, ω)-ARAM.*

Proof. By Lemma 1 every computation must have an $((\omega + 1)M, 2M)$-partitioning with subcomputation cost $Q \geq \omega M$ (except perhaps one). Plugging in Lemma 2 we have $Q(n) \geq \omega M n \log n/(2M \log((\omega + 1)M))$, which gives our bound on $Q(n)$. For $T(n)$ we just add in the cost of the computation of each vertex. ◀

Note that when $\omega \in O(M^c)$ for a constant c, these lower bounds match those for the standard external memory model [1, 27] assuming both reads and writes have cost ω. This implies that cheaper reads do not help asymptotically in this case. However, when this is not the case, cheaper reads do provide an asymptotic advantage, as will be seen by our matching upper bound given in Section 6.

Sorting Networks. A sorting network is a acyclic network of comparators, each of which takes two input keys and returns the minimum of the keys on one output, and the maximum on the other. For a family of sorting networks parametrized by n, each network takes n inputs, has n ordered outputs, and when propagating the inputs to the outputs must place the keys in sorted order on the outputs. A sorting network can be modeled as a DAG in the obvious way. Ajtai, Komlós and Szemerédi [3] described a family of sorting networks that have $O(n \log n)$ comparators and $O(\log n)$ depth. Follow-on work has provided many simplifications and constant factor improvements, including the well-known Patterson variant [40] and a simplification by Seiferas [43]. Recently Goodrich [26] gave a much simpler construction of an $O(n \log n)$ comparator network, but it requires polynomial depth. Here we show lower bounds for simulating any sorting network on the (M, ω)-ARAM.

▶ **Theorem 4** (Sorting Lower Bound). *Simulating any family of sorting networks parametrized on input size n has $Q(n) = \Omega(\omega n \log n / \log(\omega M))$ and $T(n) = \Omega(Q(n) + n \log n)$ on the (M, ω)-ARAM.*

Proof. Consider an (l, m)-partitioning of the computation. Each subcomputation has at most l inputs from the network, and m outputs for the network. The computation is oblivious to the values in the network (it can only place the minimum and maximum on the outputs of each comparator). Therefore locations of the inputs and outputs are independent of the input values. The total number of choices the subcomputation has is therefore $\binom{l}{m} m! = l!/(l-m)! < l^m$. Since there are $n!$ possible permutations, we have that the number of subcomputations k must satisfy $(l^m)^k \geq n!$. Taking the logarithm of both sides, rearranging, and using Stirling's formula we have $k > \log(n!)/(m \log l) > \frac{1}{2} n \log n/(m \log l)$ (for $n > e^2$). By Lemma 1 we have $Q(n) > \omega M \cdot \frac{1}{2} n \log n/(2M \log((1+\omega)M)) = \frac{1}{4} \omega n \log n / \log((1+\omega)M)$ (for $n > e^2$). ◀

These bounds are the same as for simulating an FFT DAG, and, as with FFTs, they indicate that faster reads do not asymptotically affect the lower bound unless ω is larger than any polynomial in M. These lower bounds rely on the sort being done on a network, and in particular that the location of all read and writes are oblivious to the data itself. As discussed in Section 6, for *general* comparison sorting algorithms, we can get better upper bounds than indicated by these lower bounds.

Diamond DAG. We consider the family of *diamond DAGs* parametrized by size $n \times m$. Each DAG has nm vertices arranged in a $n \times m$ grid such that every vertex $(i, j), 0 \leq i < (n-1), 0 \leq j < (m-1)$ has two out-edges to $(i+1, j)$ and $(i, j+1)$. The DAG has one input at $(0, 0)$ and one output at $(n-1, m-1)$. Diamond DAGs have many applications in dynamic programs, such as for the edit distance (ED), longest common subsequence (LCS), and optimal sequence alignment problems.

▶ **Lemma 5** (Cook and Sethi, 1976). *Solving the DAG computation problem on the family of diamond DAGs of size $n \times n$ requires n memory locations to store vertex values from the DAG.*

Proof. Cook and Sethi [16] showed that evaluating the top half of an $n \times n$ diamond DAG $(i + j \geq n - 1)$, which they call a pyramid DAG, requires n memory locations to store partial results. Because all paths of the diamond DAG must go through the top half, it follows for the diamond DAG. ◀

▶ **Theorem 6** (Diamond DAG Lower Bound). *The family of diamond DAGs parametrized by size $n \times m$ has $Q(n, m) = \Omega(\omega nm/M)$ and $T(n, m) = \Omega(Q(n, m) + nm)$ on the (M, ω)-ARAM.*

Proof. Consider the sub-DAG induced by a $2M \times 2M$ diamond $(a \leq i < a + 2M, b \leq j < b + 2M)$ of vertices. By Lemma 5 any subcomputation that computes the last output vertex of the sub-DAG requires $2M$ memory locations to store values from the diamond. The extra in-edges along two sides and out-edges along the other two can only make the problem harder. Half of the $2M$ required memory can be from small-memory, and so the remaining M must require writing those values to large-memory. Therefore every $2M \times 2M$ diamond requires M writes of values within the diamond. Partitioning the full diamond DAG into $2M \times 2M$ sub-diamonds, gives us $nm/(2M)^2$ partitions. Therefore the total number of writes is at least $M \times nm/(2M)^2 = nm/(4M)$, each with cost ω. For the time bound we need to add the nm calculations for all vertex values. ◀

This lower bound is asymptotically tight since a diamond DAG can be evaluated with matching upper bounds by evaluating each $M/2 \times M/2$ diamond sub-DAG as a subcomputation with M inputs, outputs and memory.

These bounds show that for the DAG computation problem on the family of diamond DAGs there is no asymptotic advantage of having cheaper reads. In Section 4 we show that for the ED and LCS problems (normally thought of as a diamond DAG computation), it is possible to do better than the lower bounds. This requires breaking the DAG computation rule by partially computing the values of each vertex before all inputs are ready. The lower bounds are interesting since they show that improving asymptotic performance with cheaper reads requires breaking the DAG computation rule.

4 Longest Common Subsequence and Edit Distance

This section describes a more efficient dynamic-programming algorithm for longest common subsequence (LCS) and edit distance (ED). The standard approach for these problems (an $M \times M$ tiling) results in an ARAM cost of $O(mn\omega/M)$ and time of $O(mn+mn\omega/M)$, where m and n are the length of the two input strings. Lemma 6 states that the standard bound is optimal under the standard DAG computation rule that all inputs must be available before evaluating a node. Perhaps surprisingly, we are able to beat these bounds by leveraging the fact that dynamic programs do not perform arbitrary functions at each node, and hence we do not necessarily need all inputs to begin evaluating a node.

Our main result is captured by the following theorem for large input strings. For smaller strings, we can do even better (see the full version of the paper [9]).

▶ **Theorem 7.** *Let $k_T = \min((\omega/M)^{1/3}, \sqrt{M})$ and suppose $m, n = \Omega(k_T M)$. Then it is possible to compute the ED or length of the LCS with time $T(m,n) = O(mn + mn\omega/(k_T M))$.*

Let $k_Q = \min(\omega^{1/3}, \sqrt{M})$ and suppose $m, n = \Omega(k_Q M)$. Then it is possible to compute the ED or length of the LCS with an ARAM cost of $Q(m,n) = O(mn\omega/(k_Q M))$.

To understand these bounds, our algorithm beats the ARAM cost of the standard tiling algorithm by a k_Q factor. And if $\omega \geq M$, our algorithm (using different tuning parameters) beats the time of the standard tiling algorithm by a k_T factor.

Overview. The dynamic programs for LCS and ED correspond to computing the shortest path through an $m \times n$ grid with diagonal edges, where m and n are the string lengths. We focus here on computing the length of the shortest path, but it is possible to output the path as well with the same asymptotic complexity (see [9]). Without loss of generality, we assume that $m \leq n$, so the grid is at least as wide as it is tall. For LCS, all horizontal and vertical edges have weight 0; the diagonal edges have weight -1 if the corresponding characters in the strings match, and weight ∞ otherwise. For ED, horizontal and vertical edges have weight 1, and diagonal edges have weights either 0 or 1 depending on whether the characters match. Our algorithm is not sensitive to the particular weights of the edges, and thus it applies to both problems and their generalizations.

Note that the $m \times n$ grid is not built explicitly since building and storing the graph would take $\Theta(mn)$ writes if $mn \gg M$. To get any improvement, it is important that subgrids reuse the same space. The weights of each edge can be inferred by reading the appropriate characters in each input string.

Our algorithm partitions the implicit grid into size-$(hM' \times kM')$, where h and k are parameters of the algorithm to be set later, and $M' = M/c$ for large enough constant $c > 1$

to give sufficient working space in small-memory. When string lengths m and $n \geq m$ are both "large", we use $h = k$ and thus usually work with $kM' \times kM'$ square subgrids. If the smaller string length m is small enough, we instead use parameters $h < k$. To simplify the description of the algorithm, we assume without loss of generality that m and n are divisible by hM' and kM', respectively, and that M is divisible by c.

Our algorithm operates on one $hM' \times kM'$ rectangle at a time, where the edges are directed right and down. The shortest-path distances to all nodes along the bottom and right boundary of each rectangle are explicitly written out, but all other intermediate computations are discarded. We label the vertices $u_{i,j}$ for $1 \leq i \leq hM'$ and $1 \leq j \leq kM'$ according to their row and column in the square, respectively, starting from the top-left corner. We call the vertices immediately above or to the left of the square the *input nodes*. The input nodes are all outputs for some previously computed rectangle. We call the vertices $u_{hM',j}$ along the bottom boundary and $u_{i,kM'}$ along the right boundary the *output nodes*.

The goal is to reduce the number of writes, thereby decreasing the overall cost of computing the output nodes, which we do by sacrificing reads and time. It is not hard to see that recomputing internal nodes enables us to reduce the number of writes. Consider, for example, the following simple approach assuming $M = \Theta(1)$: For each output node of a $k \times k$ square, try all possible paths through the square, keeping track of the best distance seen so far; perform a write at the end to output the best value.[3] Each output node tries $2^{\Theta(k)}$ paths, but only a $\Theta(1/k)$-fraction of nodes are output nodes. Setting $k = \Theta(\lg \omega)$ reduces the number of writes by a $\Theta(\lg \omega)$-factor at the cost of $\omega^{O(1)}$ reads. This same approach can be extended to larger M, giving the same $\lg \omega$ improvement, by computing "bands" of nearby paths simultaneously. But our main algorithm, which we discuss next, is much better as M gets larger (see Theorem 7).

Path sketch. The key feature of the grid leveraged by our algorithm is that shortest paths do not cross, which enables us to avoid the exponential recomputation of the simple approach. The noncrossing property has been exploited previously for building shortest-path data structures on the grid (e.g., [42]) and more generally planar graphs (e.g., [23, 34]). These previous approaches do not consider the cost of writing to large-memory, and they build data structures that would be too large for our use. Our algorithm leverages the available small-memory to compute bands of nearby paths simultaneously. We capture both the noncrossing and band ideas through what we call a path sketch, which we define as follows. The path sketch enables us to cheaply recompute the shortest paths to nodes.

We call every M'-th row in the square a *superrow*, meaning there are h superrows in the square. The algorithm partitions the i-th superrow into *segments* $\langle i, \ell, r\rangle$ of consecutive elements $u_{iM',\ell}, u_{iM',\ell+1}, \ldots, u_{iM',r}$. The main restriction on segments is that $r < \ell + M'$, i.e., each segment consists of at most M' consecutive elements in the superrow. Note that the segment boundaries are determined by the algorithm and are input dependent.

A *path sketch* is a sequence of segments $\langle s, \ell_s, r_s\rangle$, $\langle s+1, \ell_{s+1}, r_{s+1}\rangle$, $\langle s+2, \ell_{s+2}, r_{s+2}\rangle, \ldots,$ $\langle i, \ell_i, r_i\rangle$, summarizing the shortest paths to the segment. Specifically, this sketch means that for each vertex in the last segment, there is a shortest path to that vertex that goes through a vertex in each of the segments in the sketch. If the sketch starts at superrow 1, then the path originates from a node above the first superrow (i.e., the top boundary or the topmost

[3] This approach requires constant small-memory to keep the best distance, the current distance, and working space for computing the current distance. We also need bits proportional to the path length to enumerate paths.

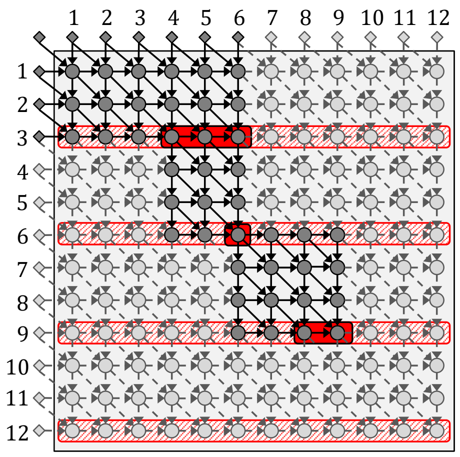

Figure 1 Example square grid and path sketch for $M' = 3$ and $h = k = 4$. The circles are nodes in the square. The diamonds are input nodes (outputs of adjacent squares), omitting irrelevant edges. The red slashes are the 4 superrows, and the solid red are the sketch segments.

M' nodes of the left boundary). If the sketch starts with superrow $s > 1$, then the path originates at one of the M' nodes on the left boundary between superrows $s-1$ and s. Since paths cannot go left, the path sketch also satisfies $\ell_s \leq \ell_{s+1} \leq \cdots \leq \ell_i$.

Evaluating a path sketch. Given a path sketch, we refer to the process of determining the shortest-path distances to all nodes in the final segment $\langle i, \ell_i, r_i \rangle$ as *evaluating the path sketch* or *evaluating the segment*, with the distances in small-memory when the process completes. Note that we have not yet described how to build the path sketch, as the building process uses evaluation as a subroutine.

The main idea of evaluating the sketch is captured by Figure 1 for the example sketch $\langle 1, 4, 6 \rangle, \langle 2, 6, 6 \rangle, \langle 3, 8, 9 \rangle$. The sketch tells us that shortest paths to $u_{9,8}$ and $u_{9,9}$ pass through one of $u_{3,4}, u_{3,5}, u_{3,6}$ and the node $u_{6,6}$. Thus, to compute the distances to $u_{9,8}$ and $u_{9,9}$, we need only consider paths through the darker nodes and solid edges—the lighter nodes and dashed edges are not recomputed during evaluation.

The algorithm works as follows. First compute the shortest-path distances to the first segment in the sketch. To do so, horizontally sweep a height-$(M'+1)$ column across the $(M'+1) \times kM'$ slab raising above the s-th superrow, keeping two columns in small-memory at a time. Also keep the newly computed distances to the first segment in small-memory, and stop the sweep at the right edge of the segment. More generally, given the distances to a segment in small-memory, we can compute the values for the next segment in the same manner by sweeping a column through the slab. This algorithm yields the following performance.

▶ **Lemma 8.** *Given a path sketch $\langle s, \ell_s, r_s \rangle, \ldots, \langle i, \ell_i, r_i \rangle$ in an $hM' \times kM'$ grid with distances to all input nodes computed, our algorithm correctly computes the shortest-path distances to all nodes in the segment $\langle i, \ell_i, r_i \rangle$. Assuming $k \geq h$ and small-memory size $M \geq 5M' + \Theta(1)$, the algorithm requires $O(kM^2)$ operations in small-memory, $O(kM)$ reads, and 0 writes.*

Proof. Correctness follows from the definition of the path sketch: the sweep performed by the algorithm considers all possible paths that pass through these segments.

The algorithm requires space in small-memory to store two columns in the current slab, the previous segment in the sketch, and the next segment in the sketch, and the two segment boundaries themselves, totaling $4M' + \Theta(1)$ small-memory. Due to the monotonically increasing left endpoints of each segment, the horizontal sweep repeats at most M' columns per supperrow, so the total number of column iterations is $O(kM' + hM') = O(kM')$. Multiplying by M' gives the number of nodes computed.

The main contributor to reads is the input strings themselves to infer the structure/weights of the grid. With M' additional small-memory, we can store the "vertical" portion of the input string used while computing each slab, and thus the vertical string is read only once with $O(hM') = O(kM')$ reads. The "horizontal" input characters can be read with each of the $O(kM')$ column-sweep iterations. An additional k reads suffice to read the sketch itself, which is a lower-order term. ◀

Building the path sketch. The main algorithm on each rectangle involves building the set of sketches to segments in the bottom superrow. At some point during the sketch-building process, the distances to each output node is computed, at which point it can be written out. The main idea of the algorithm is a sketch-extension subroutine: given segments in the i-th superrow and their sketches, extend the sketches to produce segments in the $(i+1)$-th superrow along with their sketches.

Our algorithm builds up an ordered list of consecutive path sketches, one superrow at a time. The first superrow is partitioned into k segments, each containing exactly M' consecutive nodes. The list of sketches is initialized to these segments.

Given a list of sketches to the i-th superrow, our algorithm extends the list of sketches to the $(i+1)$-th superrow as follows. The algorithm sweeps a height-$(M'+1)$ column across the $(M'+1) \times kM'$ slab between these superrows (inclusive). The sweep begins at the left end of the slab, reading the input values from the left boundary, and continuing across the entire width of the slab. In small-memory, we evaluate the first segment of the i-th superrow (using the algorithm from Lemma 8). Whenever the sweep crosses a segment boundary in the i-th superrow, again evaluate the next segment in the i-th superrow. For each node in the slab, the sweep calculates both the shortest-path distance and a pointer to the segment in the previous superrow from whence the shortest path originates (or a null pointer if it originates from the left boundary). When the originating segment of the bottom node (the node in the $(i+1)$-th superrow) changes, the algorithm creates a new segment for the $(i+1)$-th superrow and appends it to the sketch of the originating segment. If the segment in the current segment in the $(i+1)$-th superrow grows past M' elements, a new segment is created instead and the current path sketch is copied and spliced into the list of sketches. Any sketch that is not extended through this process is no longer relevant and may be spliced out of the list of sketches. When the sweep reaches a node on the output boundary (right edge or bottom edge of the square), the distance to that node is written out.

▶ **Lemma 9.** *The sketching algorithm partitions the i-th superrow into at most ik segments.*

Proof. The proof is by induction over superrows. As a base case, the first superrow consists of exactly k segments. For the inductive step, there are two cases in which a new segment is started in the $(i+1)$-th superrow. The first case is that the originating segment changes, which can occur at most ik times by inductive assumption. The second case is that the current segment grows too large, which can occur at most k times. We thus have at most $(i+1)k$ segments in the $(i+1)$-th superrow. ◀

▶ **Lemma 10.** *Suppose $h \le k$ and small-memory $M \ge 11M' + \Theta(1)$, and consider an $hM' \times kM'$ grid with distances to input nodes already computed. Then the sketch building algorithm correctly computes the distances to all output boundary nodes using $O((hk)^2 M^2)$*

operations in small-memory, $O((hk)^2M)$ reads from large-memory, and $O(h^2k + X)$ writes to large-memory, where $X = O(kM)$ is the number of boundary nodes written out.

Proof. Consider the cost of computing each slab, ignoring the writes to the output nodes. We reserve $5M' + \Theta(1)$ small-memory for the process of evaluating segments in the previous superrow. To perform the sweep in the current slab, we reserve M' small-memory to store one segment in the previous row, M' small-memory to store characters in the “vertical” input string, $4(M' + 1)$ small-memory to store two columns (each with distances and pointers) for the sweep, and an additional $\Theta(1)$ small-memory to keep, e.g., the current segment boundaries. Since there are at most hk segments in the previous superrow (Lemma 9), the algorithm evaluates at most hk segments; applying Lemma 8, the cost is $O(hk^2M^2)$ operations, $O(hk^2M)$ reads, and 0 writes. There are an additional $O(kM^2)$ operations to sweep through the kM^2 nodes in the slab, plus $O(kM)$ reads to scan the “horizontal” input string. Finally, there are $O(hk)$ writes to extend existing sketches and $O(hk)$ writes to copy at most k sketches.

Summing across all h slabs and accounting for the output nodes, we get $O((hk)^2M^2 + hkM^2)$ operations, $O((hk)^2M + hkM)$ reads, and $O(h^2k + X)$ writes. Removing the lower-order terms gives the lemma. ◀

Combining across all rectangles in the grid, we get the following corollary.

▶ **Corollary 11.** *Let $m \leq n$ be the length of the two input strings, with $m \geq M$. Suppose $h = O(m/M)$ and $k = O(n/M)$ with $h \leq k$. Then it is possible to compute the LCS or edit distance of the strings with $O(mnhk)$ operations in small-memory, $O(mnhk/M)$ reads to large-memory, and $O(mnh/M^2 + mn/(hM))$ writes to large-memory.*

Proof. There are $\Theta(mn/(hkM^2))$ size-$(hM/11) \times (kM/11)$ subgrids. Multiplying by the cost of each grid (Lemma 10) gives the bound. ◀

Setting $h = k = 1$ gives the standard $M \times M$ tiling with $O(nm)$ time and $O(mn\omega/M)$ ARAM cost. As the size of squares increase, the fraction of output nodes and hence writes decreases, at the cost of more overhead for operations in small-memory and reads from large-memory. Assuming both n and m are large enough to do so, plugging in $h = k = \max\{1, k_T\}$ or $h = k = k_Q$ with a few steps of algebra to eliminate terms yields Theorem 7.

5 Single-Source Shortest Paths

The single-source shortest-paths (SSSP) problem takes a directed weighted graph $G = (V, E)$ and a source vertex $s \in V$, and outputs the shortest distances $d(s, v)$ from s to every other vertex in $v \in V$. For graphs with non-negative edge weights, the most efficient algorithm is Dijkstra’s algorithm [19].

In this section we will study (variants of) Dijkstra’s algorithm in the asymmetric setting. We describe and analyze three versions (two classical and one new variant) of Dijkstra’s algorithm, and the best version can be chosen based on the values of M, ω, the number of vertices $n = |V|$, and the number of edges $m = |E|$.

▶ **Theorem 12.** *The SSSP problem on a graph $G = (V, E)$ with non-negative edge weights can be solved with $Q(n, m) = O(\min(n(\omega + m/M), (m + n \log n)\omega, m(\omega + \log n)))$ and $T(n, m) = O(Q(n, m) + n \log n)$, both in expectation, on the (M, ω)-ARAM.*

We start with the classical Dijkstra's algorithm [19], which maintains for each vertex v, $\delta(v)$, a tentative upper bound on the distance, initialized to $+\infty$ (except for $\delta(s)$, which is initialized to 0). The algorithm consists of $n-1$ iterations, and the final distances from s are stored in $\delta(\cdot)$. In each iteration, the algorithm selects the unvisited vertex u with smallest finite $\delta(u)$, marks it as *visited*, and uses its outgoing edges to relax (update) all of its neighbors' distances. A priority queue is required to efficiently select the unvisited vertex with minimum distance. Using a Fibonacci heap [24], the time of the algorithm is $O(m+n\log n)$ in the standard (symmetric) RAM model. In the (M,ω)-ARAM, the costs are $Q = T = O((m+n\log n)\omega)$ since the Fibonacci heap requires asymptotically as many writes as reads. Alternatively, using a binary search tree for the priority queue reduces the number of writes (see Section 6) at the cost of increasing the number of reads, giving $Q = T = O(m\log n + \omega m)$. These bounds are better when $m = o(\omega n)$. Both of these variants store the priority queue in large-memory, requiring at least one write to large-memory per edge.

We now describe an algorithm, which we refer to as *phased Dijkstra*, that fully maintains the priority queue in small-memory and only requires $O(n)$ writes to large-memory. The idea is to partition the computation into phases such that for a parameter M' each phase needs a priority queue of size at most $2M'$ and visits at least M' vertices. By selecting $M' = M/c$ for an appropriate constant c, the priority queue fits in small-memory, and the only writes to large-memory are the final distances.

Each phase starts and ends with an empty priority queue P and consists of two parts. A Fibonacci heap is used for P, but is kept small by discarding the M' largest elements (vertex distances) whenever $|P| = 2M'$. To do this P is flattened into an array, the M'-th smallest element d_{max} is found by selection, and the Fibonacci heap is reconstructed from the elements no greater than d_{max}, all taking linear time. All further insertions in a given phase are not added to P if they have a value greater than d_{max}. The first part of each phase loops over all edges in the graph and relaxes any that go from a visited to an unvisited vertex (possibly inserting or decreasing a key in P). The second part then runs the standard Dijkstra's algorithm, repeatedly visiting the vertex with minimum distance and relaxing its neighbors until P is empty. To implement relax, the algorithm needs to know whether a vertex is already in P, and if so its location in P so that it can do a decrease-key on it. It is too costly to store this information with the vertex in large-memory, but it can be stored in small-memory using a hash table.

The correctness of this phased Dijkstra's algorithm follows from the fact that it only ever visits the closest unvisited vertex, as with the standard Dijkstra's algorithm.

▶ **Lemma 13.** *Phased Dijkstra's has $Q(n,m) = O(n(\omega + m/M))$ and $T(n,m) = O(Q(n,m) + n\log n)$ both in expectation (for $M \le n$).*

Proof. During a phase either the size of P will grow to $2M'$ (and hence delete some entries) or it will finish the algorithm. If P grows to $2M'$ then at least M' vertices are visited during the phase since that many need to be deleted with delete-min to empty P. Therefore the number of phases is at most $\lceil n/M' \rceil$. Visiting all edges in the first part of each phase involves at most m insertions and decrease-keys into P, each taking $O(1)$ amortized time in small-memory, and $O(1)$ time to read the edge from large-memory. Since compacting Q when it overflows takes linear time, its cost can be amortized against the insertions that caused the overflow. The cost across all phases for the first part is therefore $Q = W = O(m\lceil n/M' \rceil)$. For the second part, every vertex is visited once and every edge relaxed at most once across all phases. Visiting a vertex requires a delete-min in small-memory and a write to large-memory, while relaxing an edge requires an insert or decrease-key in small-memory, and $O(1)$ reads from large-memory. We therefore have for this second part (across all phases) that $Q = O(\omega n + m)$

and $W = O(n(\omega + \log n) + m)$. The operations on P each include an expected $O(1)$ cost for the hash table operations. Together this gives our bounds. ◀

Compared to the first two versions of Dijkstra's algorithm with $Q = T = O(\omega m + \min(\omega n \log n, m \log n))$, the new algorithm is strictly better when $\omega M > n$. More specifically, the new algorithm performs better when $nm/M < \max\{\omega m, \min(\omega n \log n, m \log n)\}$. Combining these three algorithms proves Theorem 12, when the best one is chosen based on the parameters M, ω, n, and m.

6 Further Results and Open Problems

In this section we outline results for a variety of other problems. The bounds are summarized as part of Table 1.

FFT. For the FFT we can match the lower bound using the algorithm described elsewhere [10], although in that case the computation cost was not considered. The idea is to first split the DAG into layers of $\log(\omega M)$ levels. Then divide each layer so that the last $\log M$ levels are partitioned into FFT networks of output size M. Attach to each partition all needed inputs from the layer and the vertices needed to reach them (note that these vertices will overlap among partitions). Each extended partition will have ωM inputs and M outputs, and can be computed in M small-memory with $Q = O(\omega M)$, and $T = O((\omega + \log M)M)$. This gives a total upper bound of $Q = O(\omega M \times n \log n/(M \log(\omega M))) = O(\omega n \log n/\log(\omega M))$, and $T = O(Q(n) + n \log n)$, which matches the lower bound (asymptotically). All computations are done within the DAG model.

Search Trees and Priority Queues. We now consider algorithms for some problems that can be implemented efficiently using balanced binary search trees. In the following discussion we assume $M = O(1)$. Red-black trees with appropriate rebalancing rules require only $O(1)$ amortized time per update (insertion or deletion) once the location for the key is found [44]. For a tree of size n finding a key's location uses $O(\log n)$ reads but no writes, so the total amortized cost $Q = T = O(\omega + \log n)$ per update in the (M, ω)-ARAM. For arbitrary sequences of searches and updates, $\Omega(\omega + \log n)$ is a matching lower bound on the amortized cost per operation when $M = O(1)$. Because priority queues can be implemented with a binary search tree, insertion and delete-min have the same bounds. It seems more difficult, however, to reduce the number of writes for priority queues that support efficient melding or decrease-key.

Sorting. Sorting can be implemented with $Q = T = O(n(\log n + \omega))$ by inserting all keys into a red-black tree and then reading them off in priority order [10]. We note that this bound on time is better than the sorting network lower bound (Theorem 4). For example, when $\omega = M = \log n$ it gives a factor of $\log n/\log\log n$ improvement. The additional power is a consequence of being able to randomly write to one of n locations at the leaves of the tree for each insertion. The bound is optimal for T because n writes are required for the output and comparison-based sorting requires $O(n \log n)$ operations.

Convex Hull and Triangulation. A variety of problems in computational geometry can be solved optimally using balanced trees and sorting. The planar convex-hull problem can be solved by first sorting the points by x coordinates and then either using Overmars' technique or Graham's scan [18]. In both cases, the second part takes linear time so the overall cost is

$O(\mathit{Sort}(n))$. The planar Delaunay triangulation problem can be solved efficiently with the plane sweep method [18]. This involves maintaining a priority queue on x coordinate, and maintaining a balanced binary search tree on the y coordinate. A total of $O(n)$ operations are required on each, again giving bounds $O(\mathit{Sort}(n))$.

BFS and DFS. Breadth-first and depth-first search can be performed with $Q = T = O(\omega n + m)$. In particular each vertex only requires a constant number of writes when it is first added to the frontier (the stack or queue) and a constant number of writes when it is finished (removed from the stack or queue). Searches along an edge to an already visited vertex require no writes. This implies that several problems based on BFS and DFS also only require $Q = T = O(\mathit{DFS}(n))$. Such problems include topological sort, biconnected components, and strongly connected components. The analysis is based on the fact that there are only $O(n)$ forward edges in the DFS. However when using priority-first search on a weighted graph (e.g., Dijkstra's or Prim's algorithm) then the problem is more difficult to perform optimally as the priority queue might need to be updated for every visited edge.

Dynamic Programming. With regards to dynamic programming, some problems are reasonably easy and some harder. We covered LCS and ED in Section 4. The standard Floyd-Warshall algorithm for the all-pairs shortest-path (APSP) problem uses $O(n^3)$ writes. However, by rearranging the loops and carefully scheduling the writes it is possible to implement the algorithm using only $O(n^2)$ writes and $O(n^3)$ reads, giving $T = O(\omega n^2 + n^3)$ [9]. This version, however, is not efficient in terms of Q. Kleene's divide-and-conquer algorithm [2] can be used to reduce the ARAM cost [39]. Each recursive call makes two calls to itself on problems of half the size, and six calls to matrix multiply over the semiring $(\min, +)$. Here we analyze the algorithm in the (M, ω)-ARAM. The matrix multiplies on two matrices of size $n \times n$ can be done in the model in $Q_M(n) = O(n^2(\omega + n/\sqrt{M}))$ [10]. This leads to the recurrence $Q_{\mathit{Kleene}}(n) = 2Q_{\mathit{Kleene}}(n/2) + O(Q_M(n)) + O(\omega n^2)$, which solves to $Q_{\mathit{Kleene}}(n) = O(Q_M(n))$ because the cost is dominated at the root of the recurrence. It is not known whether this is optimal. A similar approach can be used for several other problems, including sequence alignment with gaps, optimal binary search trees, and matrix chain multiplication [15].

Minimum Spanning Tree. The standard algorithms for the minimum spanning tree (MST) problem are not write efficient. However using a variant of Borůvka's algorithm, and careful management of a union-find data structure, MST can be made write-efficient. In particular, for an input graph in adjacency-list format with n vertices and m edges, MST has cost $Q(n, m) = T(n, m) = O(m \log n + \omega n)$ on the (M, ω)-ARAM, with $M = O(1)$. We outline the idea here—a more detailed description is given in the full paper [9].

The algorithm proceeds in two phases. For the first phase, consisting of the first $\log\log n$ rounds of Borůvka steps, the algorithm performs no shortcuts on a union-find tree. Thus it will leave chains of length up to $\log\log n$ that need to be followed for each root lookup. Also all vertices of each component are maintained in a linked list so that a component (root) can be searched with just reads. Because there are at most $O(m \log\log n)$ queries during the first $\log\log n$ rounds, the total number of reads for identifying the minimum edges between components in the first phase is $O(m(\log\log n)^2)$. There are $O(n)$ writes for creating links in the tree, linking components in the lists, and outputting selected edges.

After this first phase, the algorithm shortcuts all vertices to point directly to their root ($O(n)$ reads and writes). We refer to the roots as the phase-one components. In the second phase, after each of the remaining rounds the algorithm shortcuts the phase-one components to point directly to their new root. Because there can only be at most $n/\log n$ phase-one components, and at most $\log n - \log\log n$ rounds in the second phase, the total number of reads and writes for these updates is $O(n)$. Looking up a vertex takes two steps: one to find its phase-one component and another to get to the current component (root), both taking constant time. Therefore the total number of reads for identifying the minimum edges between components in the second phase is $O(m) \times (\log n - \log\log n) = O(m\log n)$. Summing the reads and writes gives the above bounds. Observing that the SSSP algorithm in Section 5 can be adapted to implement Prim's MST algorithm [17] yields the bounds in Table 1 (the n/M term is in expectation).

Abstract

Hyperbolic random graphs share many common properties with complex real-world networks; e.g., small diameter and average distance, large clustering coefficient, and a power-law degree sequence with adjustable exponent β. Thus, when analyzing algorithms for large networks, potentially more realistic results can be achieved by assuming the input to be a hyperbolic random graph of size n. The worst-case run-time is then replaced by the expected run-time or by bounds that hold *with high probability (whp)*, i.e., with probability $1 - O(1/n)$. Though many structural properties of hyperbolic random graphs have been studied, almost no algorithmic results are known.

Divide-and-conquer is an important algorithmic design principle that works particularly well if the instance admits small separators. We show that hyperbolic random graphs in fact have comparatively small separators. More precisely, we show that they can be expected to have balanced separator hierarchies with separators of size $O(\sqrt{n^{3-\beta}})$, $O(\log n)$, and $O(1)$ if $2 < \beta < 3$, $\beta = 3$, and $3 < \beta$, respectively. We infer that these graphs have whp a treewidth of $O(\sqrt{n^{3-\beta}})$, $O(\log^2 n)$, and $O(\log n)$, respectively. For $2 < \beta < 3$, this matches a known lower bound.

To demonstrate the usefulness of our results, we give several algorithmic applications.

1 Introduction

A geometric random graph is obtained by randomly placing vertices into the plane and connecting two vertices if and only if they are close. When using the hyperbolic plane, one obtains a (threshold) hyperbolic random graph, as introduced by Krioukov et al. [21]. More precisely, vertices are placed in a disk D_R of radius R (which depends on n) and two vertices are connected if their distance is at most R. An important property of the hyperbolic plane is that the perimeter of a circle grows exponentially with the radius. Thus, when sampling uniformly, we obtain many vertices close to the boundary and few close to the center of D_R. As distances close to the boundary are larger (due to the exponentially growing perimeter), this leads to many vertices of low degree and few vertices of high degree. The resulting degree distribution actually follows a power law with exponent $\beta = 3$ [18, 28]. One can tweak this exponent using a parameter α. Choosing $1/2 \leq \alpha < 1$ increases the probability of vertices with small radius (and thus of higher degree), while for $\alpha > 1$, the vertices are shifted towards the boundary of D_R. The resulting power-law exponent is $\beta = 2\alpha + 1$.

Besides a power-law degree-distribution, hyperbolic random graphs exhibit other properties of large real-world graphs. Due to the geometric notion of closeness, vertices with a common neighbor are likely also connected, leading to a constant clustering coefficient [18]. We note that this property distinguishes hyperbolic random graphs from other models that also generate scale-free graphs (i.e., graphs with a power-law degree-distribution) such as the Chung-Lu model [7] and the Barabási-Albert model [2]. These models produce graphs that have clustering coefficient $o(1)$ [5, 29]. Beyond a non-vanishing clustering coefficient, hyperbolic random graphs have polylogarithmic diameter [15, 20] and average distance $O(\log \log n)$ between vertex pairs [1, 6], i.e., they are ultra-small-world networks. Thus, hyperbolic random graphs seem to be well suited for representing large real-world networks. This is further supported by the work of Boguñá, Papadopoulos and Krioukov [4] who embedded the internet into the hyperbolic plane and demonstrated that the resulting coordinates lead to an almost optimal greedy routing.

Despite these promising properties, we note that hyperbolic random graphs are clearly not a perfect and domain-independent representation of the real world. The degree distribution of real-world data does for example not always follow a power-law [8]. Moreover, very large cliques [14] seem unrealistic as one would expect at least a few edges to be missing. Such missing edges can be achieved by considering the so-called binomial model, in which vertices are connected with a certain probability depending on their hyperbolic distance (see Section 6). Recently, hyperbolic random graphs have been generalized to geometric inhomogeneous random graphs (GIRGs) [6]. In a GIRG, the degree distribution depends on chosen weights and is thus not necessarily fixed to a power law. Moreover, GIRGs allow for more flexibility in the choice of the underlying (potentially higher dimensional) geometry.

Divide-and-conquer algorithms separate the given instance into smaller subinstances, solve these subinstances recursively, and then combine the results to a solution of the original instance. Such an approach works well if (i) both subinstances have roughly the same size (leading to a logarithmic recursion depth); and (ii) a small interface between the subinstances allows a combination of partial solutions with only few tweaks. For graphs, one is thus interested in finding small *balanced separators*, i.e., sets of vertices whose removal separates the graph into disconnected subgraphs of roughly the same size. A famous example is the planar separator theorem by Lipton and Tarjan [24] stating that every planar graph with n vertices has a separator of size $O(\sqrt{n})$ such that both resulting subgraphs have at least $1/3n$ vertices. This for example leads to a PTAS for Independent Set on planar graphs [25].

Closely related to separators is the concept of treewidth, which is a key concept in the field of parameterized complexity as many NP-hard graph problems are actually FPT with respect to the treewidth [9, 10]. The treewidth has been intensively studied on different random graph models (all results we mention in the following hold with probability tending to 1 for $n \to \infty$). Erdős-Rényi graphs [12] have linear treewidth if the edge-vertex ratio is above $1/2$ [16, 17, 22]. This bound is sharp as the treewidth is 2 if the edge-vertex ratio is below $1/2$ [22]. For random intersection graphs [19] and for the Barabási-Albert model (which produces scale-free graphs) [2], Gao [17] gave linear lower bounds for the treewidth.

Besides these negative results, there are positive results for geometric random graphs (in the euclidean geometry). Depending on the maximum distance for which two vertices are connected, the treewidth can be shown to be $\Theta(\log n / \log \log n)$ [27] or $\Theta(r\sqrt{n})$ [23, 27]. Recently, Bringmann et al. [6] showed that a GIRG has a balanced cut of sub-linear size, which implies the same for hyperbolic random graphs.

Contribution & Outline. We present a hierarchical decomposition (the *hyperdisk decomposition*) of a disk in the hyperbolic plane into equally sized regions that have large distance from each other while the separators have small area; see Section 3. This decomposition carries over to hyperbolic random graphs leading to a hierarchy of balanced separators, each of expected size $O(n^{1-\alpha})$, $O(\log n)$, and $O(1)$ if $\alpha < 1$, $\alpha = 1$, and $\alpha > 1$, respectively.

In Section 4, we infer that hyperbolic random graphs have whp treewidth $O(n^{1-\alpha})$, $O(\log^2 n)$, and $O(\log n)$ if $\alpha < 1$, $\alpha = 1$, and $\alpha > 1$, respectively. For $\alpha < 1$, this matches the lower bound implied by the clique number of hyperbolic random graphs [14]. For $\alpha = 1$ and $\alpha > 1$, this is above the lower bounds by factors of $\log n \log\log n$ and $\log\log n$, respectively.

We demonstrate algorithmic applications in Section 5. For Independent Set, we give an approximation scheme whose algorithms have expected approximation ratio $1-\varepsilon$ ($\varepsilon > 0$) and expected polynomial run-time (in n). Choosing ε suitably, the polynomial run-time and the approximation ratio $1-O(1)/\log^{\alpha} n$ hold whp. Moreover, we show that maximum matchings in hyperbolic random graphs can whp be computed in time $O(n^{2-\alpha})$ ($O(n^{2-\alpha}\log n)$ with edge weights). As $\alpha \geq 1/2$, this improves upon the worst-case complexity of the fastest known algorithm for general graphs with run-time $O(\sqrt{n}m)$ [26]. For both results, we assume that the geometry of the graph is known, which lets us compute the hyperdisk decomposition. Otherwise, one can still apply the results by Fomin et al. [13] to obtain fast algorithms for various problems; see Section 5.3.

In Section 6, we consider the binomial model, where two vertices are connected with a certain probability depending on their distance. For $\alpha < 1$ we obtain the treewidth $O(n^{2-(\alpha+1)/(\alpha t+1)})$ (t is a constant and $t \to 0$ leads to the threshold model).

2 Preliminaries

Hyperbolic Random Graphs. We consider three parameters, the number of vertices n, the parameter $\alpha \geq 1/2$ controlling the power-law exponent, and C controlling the average degree. We obtain a hyperbolic random graph by sampling n points in the disk D_R with radius $R = 2\log n + C$. A point is described using radial coordinates (r, θ) with the center of D_R as origin. The angle θ is drawn uniformly from $[0, 2\pi]$ and the radius r is chosen according to the density $d(r) = \alpha \sinh(\alpha r)/(\cosh(\alpha R) - 1)$. Thus, the points are distributed according to the following density function (which depends on the radius r but not on the angle θ).

$$f(r,\theta) = f(r) = \frac{\alpha}{2\pi} \cdot \frac{\sinh(\alpha r)}{\cosh(\alpha R) - 1} \tag{1}$$

For $S \subseteq D_R$, the probability measure $\mu(S) = \int_S f(r)\,\mathrm{d}r$ gives the probability that a specific vertex lies in S. Note that $\mu(D_R) = 1$ and for $\alpha = 1$, $\mu(S)$ is the area of S divided by the area of D. Two vertices are connected if and only if their (hyperbolic) distance is at most R.

We are often interested in the number of vertices lying in a certain region S. To this end, let $X_i \in \{0, 1\}$ be the random variable with the interpretation that $X_i = 1$ if and only if the vertex i lies in S. Note that $\mathbb{E}[X_i] = \mu(S)$. Moreover, the random variable $X = \sum_{i=1}^{n} X_i$ describes the number of vertices in S. The following theorem directly follows from Chernoff bounds [11] and helps to give bounds that hold whp (i.e., with probability $1 - O(1/n)$).

▶ **Theorem 1.** *Let $X_1, \dots, X_n$ be independent random variables with $X_i \in \{0, 1\}$ and let X be their sum. Let $f(n) = \Omega(\log n)$. If $f(n)$ is an upper (resp. lower) bound for $\mathbb{E}[X]$, then for each constant c there is a constant c' such that $X \leq c' f(n)$ (resp. $X \geq c' f(n)$) holds with probability $1 - O(n^{-c})$.*

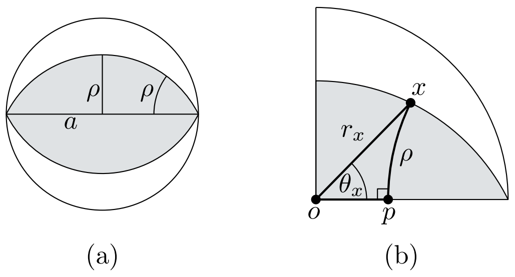

Figure 1 (a) The hyperdisk (gray) with radius ρ and horizontal axis a going through the origin. (b) A right triangle in the hyperbolic plane.

Separator Hierarchy. Let D be a metric space (e.g., a disk in hyperbolic space or a graph). A *separator hierarchy* of D is a rooted tree T with t nodes where each node i is associated with a subset $S_i \in D$ such that $\mathcal{S} = \{S_1, \dots, S_t\}$ partitions D, i.e., $D = \bigcup_{S_i \in \mathcal{S}} S_i$ and $S_i \cap S_j = \emptyset$ for $i \neq j$. For every node i, let $U_i = S_i \cup \bigcup_{j \in \mathrm{desc}(i)} S_j$, where $\mathrm{desc}(i)$ are the descendants of i in T. For $(T, \mathcal{S})$ to be a separator hierarchy, we require that for every pair of sibling nodes i and j (i.e., nodes with the same parent) the set U_i is disconnected from U_j. For the parent k of i and j, we also say that S_k is the *separator* that separates U_i from U_j.

The *diameter* of the separator S_k (separating U_i and U_j) is the largest value d such that every element in U_i has distance at least d form every element in U_j. The diameter of the separator hierarchy $(T, \mathcal{S})$ is the minimum diameter of all its separators. For a given measure μ on D, the separator S_k is *balanced* if $\mu(U_i) \leq 1/2\mu(U_k)$ and $\mu(U_j) \leq 1/2\mu(U_k)$. If these inequalities hold in expectation, we say that S_k is *expected to be balanced.* The separator hierarchy is balanced (in expectation) if each separator is balanced (in expectation).

Treewidth. Let T be a tree with t nodes and let $\mathcal{X} = \{X_1, \dots, X_t\}$ be a family of sets. For each node i of T, the set X_i is called the *bag* of i. The pair $(T, \mathcal{X})$ is a *tree decomposition* of a graph $G = (V, E)$ if the bags are subsets of V satisfying the following two properties.

(i) For each vertex $v \in V$, the nodes of T whose bags contain v induce a subtree of T.
(ii) For each edge $uv \in E$, there exist a bag $X \in \mathcal{X}$ with $u \in X$ and $v \in X$.

The *width* of a tree decomposition is the size of the largest bag minus 1. The *treewidth* $\mathrm{tw}(G)$ of a graph G is the smallest k for which G has a tree decomposition of width k.

3 Hyperdisk Decomposition

In this section, we define a separator hierarchy for a disk D in the hyperbolic plane. We assume that D is centered at the origin. The separators are (parts of) hyperdisks, which are defined as follows. Let a be a line in the hyperbolic plane. The set of points with distance ρ from a form the *hypercircle* with *radius* ρ and *axis* a. The set of points with distance at most ρ from a is the corresponding *hyperdisk*; see[1] Fig. 1a. We usually consider lines through the origin as axes. By a_γ, we denote such a line whose points have angle γ or $\gamma + \pi$.

Let $x = (r_x, \theta_x)$ be a point on the hypercircle with axis a_0 and radius ρ. Moreover, let o be the origin and let p be the point on a_γ such that the line through x and p is perpendicular to a_γ. Then o, p, and x form a triangle with right angle at p; see Fig. 1b. The angle at o

[1] We use the Poincaré disk model in illustrations. Thus, the disk shown in Fig. 1 (as well as the outer-most disk in every later illustration) is not D but the Poincaré disk representing the whole hyperbolic plane.

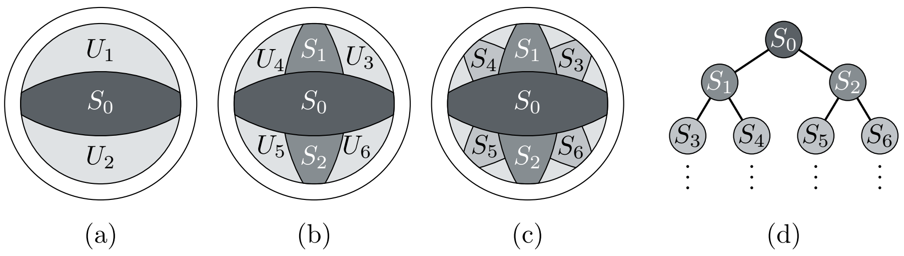

Figure 2 (a) The disk D (gray area) is separated by S_0 (dark gray) into the two regions U_1 and U_2 (light gray). (b, c) The separators on levels 1 and 2. (d) The corresponding separator hierarchy represented as tree in which each node corresponds to a separator.

is θ_x, the length of the opposite side xp is ρ, and the length of the hypotenuse is r_x. The trigonometry of hyperbolic right triangles yields the following equation, which we need later.

$$\sin(\theta_x) = \frac{\sinh(\rho)}{\sinh(r_x)} \tag{2}$$

The *hyperdisk decomposition* of D is the following separator hierarchy. The top-level separator (level 0) S_0 is the intersection of D with the hyperdisk with axis a_0 (all hyperdisks we consider have arbitrary but fixed radius ρ). This symmetrically separates D into regions U_1 and U_2 above and below S_0; see Fig. 2a. The region U_1 (and analogously U_2) is again symmetrically separated into two parts by its intersection with the hyperdisk with axis $a_{\pi/2}$. Denote the resulting separator by S_1 and the two separated regions by U_3 and U_4; see Fig. 2b. On the next level, U_3 (and analogously $U_4, \dots, U_6$) is separated by its intersection with the hyperdisk with axis $a_{\pi/4}$; see Fig. 2c. We continue this decomposition until $S_i = U_i$. Clearly, this leads to a separator hierarchy $(T, \mathcal{S})$ and T is a complete binary tree; see Fig. 2d.

3.1 Properties of the Hyperdisk Decomposition

In the following, we investigate different properties of the hyperdisk decomposition, depending on the radius R of the disk D, on the radius ρ of the hyperdisks, and on a measure μ on D. We start with two simple observations. The first observation follows from the fact that two points on different sides of a hyperdisk with radius ρ have distance at least 2ρ (they have distance ρ from the hyperdisk's axis and the line segment connecting them crosses the axis).

▶ **Observation 2.** *The hyperdisk decomposition has diameter at least* 2ρ.

We will later set $\rho = R/2$ (Section 3.2) or to something even larger (Section 6). However, the bounds we prove in this section hold for more general choices of ρ.

The next observation follows from the fact that for two nodes i and j on the same level, the regions U_i and U_j are symmetric with respect to rotation around the origin.

▶ **Observation 3.** *The hyperdisk decomposition is balanced for every measure that is invariant under rotation around the origin.*

The measure we are particularly interested in is μ given by $\mu(S) = \int_S f(r)\, \mathrm{d}r$ with the density function $f(r)$ as defined in Equation (1). Note that μ is clearly invariant under rotation around the origin as f does not depend on the angle of a given point. In the remainder of this section, we always assume μ to be this measure.

Our main goal in the following is to bound the measure of the separators in the hyperdisk decomposition. Clearly, the measure of the separators decreases for increasing level. To quantify this, we first show the following lemma.

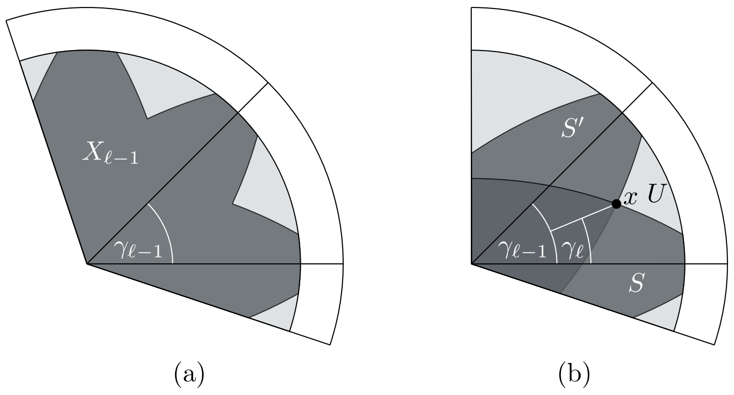

Figure 3 (a) The region $X_{\ell-1}$. (b) Two consecutive hyperdisks enclosing the region U.

▶ **Lemma 4.** *Let S be a separator on level $\ell \geq 1$ of the hyperdisk decomposition and let $x \in S$ be a point with radius r_x. Then the following holds:*

$$r_x \geq r_{\min} = \max\{\rho, \rho + \log(1 - e^{-2\rho}) - \log(2^{2-\ell} - 2^{2-2\ell})\}\,.$$

Proof. We show that the inequality holds for every point x that is not contained in a separator of level less than ℓ. Clearly, $r_x \geq \rho$ holds as every point with smaller radius is contained in the top-level separator. It remains to show $r_x \geq \rho + \log(1 - e^{-2\rho}) - \log(2^{2-\ell} - 2^{2-2\ell})$.

First assume $\ell = 1$. In this case $\log(2^{2-\ell} - 2^{2-2\ell}) = 0$. Moreover, $\log(1 - e^{-2\rho}) < 0$. Thus the claim is weaker than $r_x \geq \rho$, which we already proved above. We assume in the following that $\ell \geq 2$, which implies that there are at least two separators with level less than ℓ.

Let $\gamma_\ell = \pi/2^\ell$ and consider all hyperdisks that have an axis whose angle is a multiple of $\gamma_{\ell-1}$. Let $X_{\ell-1}$ be the union of these hyperdisks; see Fig. 3a. By the definition of the hyperdisk decomposition, the union of all separators of level less than ℓ equals $X_{\ell-1}$. We show that all points not in $X_{\ell-1}$ (and thus all points in a separator of level ℓ) satisfy the claimed inequality. To this end, first note that rotating the disc D by a multiple of $\gamma_{\ell-1}$ around the origin maps $X_{\ell-1}$ to itself. Thus, it suffices to prove the claim for points with angles between 0 and $\gamma_{\ell-1}$.

Let S and S' be the hyperdisks whose axes have angles 0 and $\gamma_{\ell-1}$, respectively, let U be the region between them, and let x be the point where S, S', and U touch; see Fig. 3b. In the following we first show that actually no point in U has radius smaller than x (which is intuitively true when looking at Fig. 3a). Afterwards it remains to show the claimed lower bound for the point x.

Let $y \in U$ be a point with coordinates (r_y, θ_y) and let ρ_y be the distance of y from the horizontal axis a_0. By Equation (2), we have $\sinh(\rho_y) = \sinh(r_y)\sin(\theta_y)$. Thus, for all relevant angles θ_y, the distance ρ_y is increasing with increasing radius and with increasing angle. Hence, in case $\theta_y \leq \theta_x$, the assumption $r_y < r_x$ implies that $\rho_y < \rho$ (recall that ρ is the distance of x from the horizontal axis). Thus, y is contained in the hyperdisk S and cannot be contained in U. Symmetrically, if $\theta_y \geq \theta_x$ and $r_y < r_x$, then y is contained in S'. Hence, no point in U has smaller radius than x.

It thus remains to show the claimed inequality for the point x. Note that x has the angle $\theta_x = \gamma_\ell$. Thus, by Equation (2), we have the following.

$$\sin(\gamma_\ell) = \frac{\sinh(\rho)}{\sinh(r_x)}$$

$$\begin{aligned}
\Leftrightarrow\qquad && \sinh(r_x) &= \frac{\sinh(\rho)}{\sin(\gamma_\ell)} \\
\Leftrightarrow\qquad && e^{r_x} - e^{-r_x} &= \frac{e^{\rho} - e^{-\rho}}{\sin(\gamma_\ell)} \\
\Rightarrow\qquad && e^{r_x} &\geq \frac{e^{\rho} - e^{-\rho}}{\sin(\gamma_\ell)} \\
\Leftrightarrow\qquad && r_x &\geq \log(e^{\rho} - e^{-\rho}) - \log(\sin(\gamma_\ell)) \\
&& &= \rho + \log(1 - e^{-2\rho}) - \log(\sin(\gamma_\ell))
\end{aligned}$$

We use that $\sin(\gamma) \leq 1 - (1 - 2/\pi \cdot \gamma)^2$ for $\gamma \in [0, \pi/2]$ to obtain the following.

$$\sin(\gamma_\ell) \leq 1 - \left(1 - \frac{2}{\pi}\gamma_\ell\right)^2 = 1 - \left(1 - 2^{1-\ell}\right)^2 = 2^{2-\ell} - 2^{2-2\ell}$$

Together with the previous inequality, this yields the claimed bound. ◀

The above lemma together with a simple calculation shows the following. With the height of the hyperdisk decomposition (which is a separator hierarchy), we refer to the height of the corresponding tree, i.e., to the maximum distance from a node to the root.

▶ **Lemma 5.** *The hyperdisk decomposition has height $O(R)$ if $\rho \geq \varepsilon$ for a constant ε.*

Proof. We show that setting $\ell = \log_2(c \cdot e^R) + 2 = O(R)$ (for a suitable constant c) results in $r_{\min} \geq R$. Thus, the separators with smaller levels already cover the whole disk of radius R. The last part of the formula given for $r_{\min}$ in Lemma 4 can be rewritten as follows.

$$-\log\left(2^{2-\ell} - 2^{2-2\ell}\right) \geq -\log\left(2^{2-\ell}\right) = \log\left(2^{\ell-2}\right) = \log(c) + R$$

When choosing $c = (1 - e^{-2\varepsilon})^{-1}$, Lemma 4 yields $r_{\min} \geq R$. ◀

In the following, we upper bound the measure of a separator S on level ℓ of the hyperdisk decomposition. Let H be the hyperdisk corresponding to S. To simplify the calculations, we rotate the disk such that a_0 (i.e., the horizontal line through the origin) is the axis of H. First assume that $\ell \geq 1$ and let $r_{\min}$ be the lower bound for the radius shown in Lemma 4. Consider the set S' of all points in H with radius at least $r_{\min}$ that lie to the right of the origin (angle between $-\pi/2$ and $\pi/2$). Clearly $S \subseteq S'$ and thus $\mu(S) \leq \mu(S')$.

To compute $\mu(S')$, let $\theta_\rho(r)$ be the angle between 0 and $\pi/2$ such that the point $(r, \theta_\rho(r))$ lies on the hypercircle bounding H. By Equation (2), we have $\theta_\rho(r) = \arcsin(\sinh(\rho)/\sinh(r))$. We obtain the following (recall that $f(r)$ is the density function).

$$\mu(S') = \int_{S'} f(r)\,\mathrm{d}r = \int_{r_{\min}}^{R} \int_{-\theta_\rho(r)}^{\theta_\rho(r)} f(r)\,\mathrm{d}\theta\,\mathrm{d}r = \int_{r_{\min}}^{R} 2\theta_\rho(r) f(r)\,\mathrm{d}r \tag{3}$$

Note that $\theta_\rho(r)$ is only well-defined if $r \geq \rho$. For $\ell \geq 1$, this is not an issue as $r_{\min} \geq \rho$ by Lemma 4. However, the case that $S = H$ is the top-level separator needs special treatment. In this case, we partition S into the disk D_ρ of radius ρ and the subsets S' and S'' of H whose points have radius at least ρ and lie to the right and left of the origin, respectively. Due to symmetry, $\mu(S') = \mu(S'')$. Thus, $\mu(S) = \mu(D_\rho) + 2\mu(S')$. Gugelmann et al. [18] showed that $\mu(D_\rho) = e^{-\alpha(R-\rho)}(1 + o(1))$. Moreover, for $\mu(S')$ we again obtain Equation (3) with $r_{\min} = \rho$. We thus obtain the following lemma by bounding $\mu(S')$ from above. Note that we require ρ to be linear in R here.

▶ **Lemma 6.** *Let S be a separator on level ℓ of the hyperdisk decomposition of D_R with hyperdisks of radius $\rho \in \Omega(R)$. Then the following holds.*

$$\mu(S) = \begin{cases} O\left(e^{\alpha\rho-\alpha R}\right) \cdot \left(2^{1-\alpha}\right)^{-\ell} & \textit{for } \alpha < 1 \\ O\left(e^{\rho-R} \cdot R\right) & \textit{for } \alpha = 1 \\ O\left(e^{\rho-R}\right) & \textit{for } \alpha > 1 \end{cases}$$

Proof. For the special case $\ell = 0$, $\mu(D_\rho) = O(e^{\alpha\rho-\alpha R})$ is dominated by the claimed bounds for all α. Thus, for all cases, it remains to prove the bounds for $\mu(S')$. Starting with Equation (3) and using that $\arcsin(x) \le x \cdot \pi/2$ (for $x \ge 0$), we get the following.

$$\begin{aligned}
\int_{r_{\min}}^{R} 2\theta_\rho(r) f(r)\,\mathrm{d}r &\le \int_{r_{\min}}^{R} 2 \cdot \frac{\pi}{2} \cdot \frac{\sinh(\rho)}{\sinh(r)} \cdot \frac{\alpha}{2\pi} \cdot \frac{\sinh(\alpha r)}{\cosh(\alpha R) - 1}\,\mathrm{d}r \\
&= \frac{\alpha}{2} \cdot \frac{\sinh(\rho)}{\cosh(\alpha R) - 1} \cdot \int_{r_{\min}}^{R} \frac{\sinh(\alpha r)}{\sinh(r)}\,\mathrm{d}r \\
&= \frac{\alpha}{2} \cdot \frac{\sinh(\rho)}{\cosh(\alpha R) - 1} \cdot \int_{r_{\min}}^{R} \frac{e^{\alpha r} - e^{-\alpha r}}{e^{r} - e^{-r}}\,\mathrm{d}r \\
&= \frac{\alpha}{2} \cdot \frac{\sinh(\rho)}{\cosh(\alpha R) - 1} \cdot \int_{r_{\min}}^{R} \frac{e^{r}}{e^{r} - e^{-r}} \cdot \frac{e^{\alpha r} - e^{-\alpha r}}{e^{r}}\,\mathrm{d}r \\
&\le \frac{\alpha}{2} \cdot \frac{\sinh(\rho)}{\cosh(\alpha R) - 1} \cdot \frac{e^{\rho}}{e^{\rho} - e^{-\rho}} \cdot \int_{r_{\min}}^{R} \frac{e^{\alpha r}}{e^{r}}\,\mathrm{d}r \\
&= O\left(e^{\rho-\alpha R}\right) \cdot \int_{r_{\min}}^{R} e^{(\alpha-1)r}\,\mathrm{d}r
\end{aligned}$$

The last inequality follows from the facts that $\frac{e^r}{e^r - e^{-r}}$ is monotonically decreasing (and thus maximal for $r = r_{\min} \ge \rho$) and that $e^{-\alpha r}$ is positive. In case $\alpha = 1$, the integral equals to $R - r_{\min} \le R$, yielding $\mu(S') = O(e^{\rho-R} \cdot R)$. Otherwise, we have the following.

$$\int_{r_{\min}}^{R} \frac{e^{\alpha r}}{e^{r}}\,\mathrm{d}r = \left[\frac{e^{(\alpha-1)r}}{\alpha - 1}\right]_{r_{\min}}^{R} = \frac{e^{(\alpha-1)R} - e^{(\alpha-1)r_{\min}}}{\alpha - 1}$$

If $\alpha > 1$, the integral is dominated by $e^{(\alpha-1)R}$, yielding $\mu(S') = O(e^{\rho-\alpha R} \cdot e^{\alpha R - R}) = O(e^{\rho-R})$. If $\alpha < 1$, the integral is dominated by $e^{(\alpha-1)r_{\min}}$. Using the bound for $r_{\min}$ given by Lemma 4, we obtain the following.

$$\begin{aligned}
\mu(S') &= O\left(e^{\rho-\alpha R}\right) \cdot e^{(\alpha-1)r_{\min}} \\
&= O\left(e^{\rho-\alpha R}\right) \cdot e^{(\alpha-1)\rho} \cdot \left(1 - e^{-2\rho}\right)^{\alpha-1} \cdot \left(2^{2-\ell} - 2^{2-2\ell}\right)^{1-\alpha}
\end{aligned}$$

In this product, the first two factors simplify to $O(e^{\alpha\rho-\alpha R})$. The third factor tends to 1 for increasing ρ (and $\rho \in \Omega(R)$). The fourth factor can be written as $2^{-\ell(1-\alpha)}(2^2 - 2^{2-\ell})^{1-\alpha}$. As $(2^2 - 2^{2-\ell})^{1-\alpha}$ is bounded by the constant $4^{1-\alpha}$, we obtain the claimed bound. ◀

3.2 Decomposing Hyperbolic Random Graphs

Recall that one obtains a hyperbolic random graph G by randomly placing n vertices in the disk D of radius $R = 2\log n + C$ according to the probability measure μ and connecting two vertices if and only if their distance is less than R. For a subset $S \subseteq D$, let $G[S]$ be the subgraph of G induced by vertices in S.

Let $(T, \mathcal{S})$ be the hyperdisk decomposition of D with hyperdisks of radius $\rho = R/2$. Let further k be a node of T with children i and j. By Observation 2, the diameter of the separator S_k (separating U_i from U_j) is at least $2\rho = R$. This implies that no vertex in U_i is connected to a vertex in U_j. Thus, the graph $G[U_k]$ is separated by the vertices in S_k into the subgraphs $G[U_i]$ and $G[U_j]$. Hence, the hyperdisk decomposition of D translates into a separator hierarchy of the graph G. We also call this separator hierarchy the *hyperdisk decomposition* of G. The properties of the separators in D directly translate to the separators in G, i.e., we can expect the separators to be balanced (Observation 3) and small (Lemma 6).

▶ **Theorem 7.** *The hyperdisk decomposition of a hyperbolic random graph is expected to be balanced and for a separator S on level ℓ, the following holds.*

$$\mathbb{E}\left[|S|\right] = \begin{cases} O\left(n^{1-\alpha}\right) \cdot \left(2^{1-\alpha}\right)^{-\ell} & \text{for } \alpha < 1 \\ O\left(\log n\right) & \text{for } \alpha = 1 \\ O\left(1\right) & \text{for } \alpha > 1 \end{cases}$$

4 The Treewidth of Hyperbolic Random Graphs

The treewidth of a graph G is closely related to the size of separators in G. If G has treewidth k, it is known to have a balanced separator of size $k+1$. This follows from the fact that a tree (e.g., the decomposition tree of width k) has a (weighted) balanced separator of size 1. Conversely, if G can be recursively decomposed by small balanced separators, i.e., if it has a balanced separator hierarchy with small separators, its treewidth is also small.

The following statement is easy to prove and for example used to show that planar graphs have treewidth $\sqrt{n}$ based on the planar separator theorem.

▶ **Lemma 8.** *Let $(T, \mathcal{S})$ be a separator hierarchy of G. For each node i of T, let X_i be the union of S_i and all separators S_j for which j is an ancestor of i in T. Then $(T, \mathcal{X} = \{X_1, \dots, X_t\})$ is a tree decomposition of G.*

Proof. We have to show that for each vertex $v \in V$ the bags containing v form a subtree of T and that for each edge $uv \in E$, there exists a bag containing u and v. For the former, let v be a vertex and let i be the unique node of T such that $v \in S_i$. Then $v \in X_j$ if and only if $j = i$ or j is an descendant of i. The node i together with its descendants clearly is a subtree of T. For the second condition, let $uv \in E$, let $u \in S_i$ and $v \in S_j$. Due to their edge, u and v cannot be separated, which implies that i is an ancestor of j or vice versa. Without loss of generality, we assume i is an ancestor of j. Then X_j includes S_j and S_i, which proves the claim. ◀

Using the properties of the hyperdisk decomposition as stated in Lemma 5 and Theorem 7 together with Lemma 8, we obtain a tree decomposition with upper bounds on the expected size of each bag. Applying a Chernoff bound (Theorem 1) leads to the following theorem.

▶ **Theorem 9.** *For the treewidth* $\operatorname{tw}(G)$ *of a hyperbolic random graph* G*, the following holds with high probability.*

$$\operatorname{tw}(G) = \begin{cases} \Theta\left(n^{1-\alpha}\right) & \text{for } \alpha < 1 \\ O\left(\log^2 n\right) & \text{for } \alpha = 1 \\ O\left(\log n\right) & \text{for } \alpha > 1 \end{cases}$$

Note that the theorem states a matching lower bound if $\alpha < 1$. It follows from the fact that hyperbolic random graphs have clique number $\Theta(n^{1-\alpha})$ if $\alpha < 1$ [14]. For $\alpha \geq 1$, the clique number is $\Theta(\log n / \log\log n)$ [14]. Thus, our upper bounds for $\alpha = 1$ and $\alpha > 1$ differ from this lower bound by factors $\log n \log\log n$ and $\log\log n$, respectively.

5 Applications

Our results from the previous sections have several algorithmic implications. In particular, the logarithmic treewidth for $\alpha > 1$ leads to efficient algorithms for numerous NP-hard problems, e.g., Vertex Cover, Independent Set, Dominating Set, Odd Cycle Traversal, and Max Cut [9]. We note that the size of the largest connected component in a hyperbolic random graph is whp polynomial even for $\alpha > 1$ as the maximum degree [18] is a lower bound for the size of the largest component. Thus, for $\alpha > 1$, the treewidth is not only logarithmic in the size of the whole (potentially disconnected) hyperbolic random graph but also in the size of the largest component.

For $\alpha < 1$, the separators are larger and thus algorithmic applications are less obvious. Moreover, there exists a *giant component* [3], i.e., a connected component of linear size. In the following sections, we present several algorithmic applications for the case that G is the giant component of a hyperbolic random graph with $\alpha < 1$. We note that all results still hold when considering the whole hyperbolic random graph instead of only the giant component (in fact, some arguments actually get simpler).

We give an approximation scheme for Independent Set (Section 5.1) and a fast algorithm for computing maximum matchings (Section 5.2). Both results assume that the geometry of the hyperbolic random graph is known (which is a strong but not completely unreasonable assumption [4]). In Section 5.3 we give applications that do not rely on knowing the geometry.

5.1 An Approximation Scheme for Independent Set

As an independent set forms a clique in the complement graph and vice versa, it is NP-hard to approximate Independent Set with approximation ratio better than $O(n^{1-\varepsilon})$ for any $\varepsilon > 0$ [30]. However, based on the planar separator theorem (stating that planar graphs have balanced separators of size $O(\sqrt{n})$), Lipton and Tarjan [25] showed that Independent Set on planar graphs has a *PTAS (polynomial-time approximation scheme)*, i.e., for every constant $\varepsilon > 0$, it admits an efficient approximation algorithm with approximation ratio $1 - \varepsilon$. We adapt their approach to show that there is an approximation scheme for Independent Set if the input is a hyperbolic random graph given in its geometric representation.

The PTAS for planar graphs is based on two facts. First, planar graphs have a balanced separator hierarchy with separators of size $O(\sqrt{n})$. Second, planar graphs have independent sets of linear size. The latter follows directly from the fact that planar graphs have bounded chromatic number. For hyperbolic random graphs, this is not true, as they include comparatively large cliques [14]. However, as the degree sequence follows a power law, we find a subgraph of linear size whose vertices have bounded degree. This subgraph can then be colored with a constant number of colors which implies a large independent set. To obtain the following lemma, we have to apply this argument to the giant component of a hyperbolic random graph.

▶ **Lemma 10.** *The giant component of a hyperbolic random graph has whp independent sets of linear size.*

Following the approach of Lipton and Tarjan [25], we prove the following lemma. The rough idea is to choose V' to be the union of all separators of the hyperdisk decomposition with level at most $\lfloor \log_2(n/k) \rfloor$.

▶ **Lemma 11.** *Let $G = (V, E)$ be a hyperbolic random graph with $\alpha < 1$ and let $k \in \mathbb{N}$. Then there is a vertex set $V' \subseteq V$ of expected size $O(n)/k^\alpha$ such that the connected components of $G - V'$ have expected size at most k.*

Proof. Consider the hyperdisk decomposition $(T, \mathcal{S})$ of G and let i be a node on level ℓ. Recall that U_i denotes the set of vertices such that $G[U_i]$ is the subgraph whose separators are represented by the descendants of i in T. Due to the fact that the hyperdisk decomposition is balanced (Theorem 7), the expected size of U_i is at most $n2^{-\ell}$. We choose V' to be the union of all separators with level at most $\ell_{\max} = \lfloor \log_2(n/k) \rfloor$. Each connected component of $G - V'$ is then a subgraph of $G[U_i]$ for a vertex i with level $\ell_{\max} + 1$. Thus, the expected size of these components is at most k.

It remains to bound $\mathbb{E}[|V'|]$. Recall from Theorem 7 that a separator on level ℓ has expected size $O(n^{1-\alpha}) \cdot 2^{-\ell(1-\alpha)}$. Moreover, as T is a complete binary tree, there are 2^ℓ separators on level ℓ. Thus, the total size of separators on level ℓ is $O(n^{1-\alpha}) \cdot 2^{-\ell(1-\alpha)} 2^\ell = O(n^{1-\alpha}) \cdot 2^{\alpha\ell}$. We thus obtain the following for the expected size of V'.

$$\begin{aligned}\mathbb{E}\left[|V'|\right] &= \sum_{\ell=0}^{\ell_{\max}} O\left(n^{1-\alpha}\right) \cdot 2^{\alpha\ell} \\ &= O\left(n^{1-\alpha}\right) \cdot \sum_{\ell=0}^{\ell_{\max}} 2^{\alpha\ell}\end{aligned}$$

To conclude the proof, it remains to proof that the sum equals $(n/k)^\alpha \cdot O(1)$, which follows from the following calculation and from the fact that the geometric series converges.

$$\begin{aligned}\sum_{\ell=0}^{\ell_{\max}} 2^{\alpha\ell} &= \sum_{i=0}^{\ell_{\max}} 2^{\alpha(\ell_{\max}-i)} \\ &= 2^{\alpha\ell_{\max}} \sum_{i=0}^{\ell_{\max}} 2^{-\alpha i} \\ &= \left(n/k\right)^{\alpha} \cdot O(1)\end{aligned}$$ ◀

To approximate Independent Set, one can apply Lemma 11 to the given hyperbolic random graph G and then compute for each of the resulting connected components an optimal independent set in expected time $O(k2^k)$. For all $O(n/k)$ connected components, this takes expected $O(n2^k)$ time. The union of these independent sets is an independent set of G. Let I be this independent set, restricted to the giant component H of G. Comparing this to the size of an optimal independent set $I^\star$ of H, we miss at most the vertices in the separator V', thus $\mathbb{E}[|I^\star| - |I|] = O(n)/k^\alpha$. As $|I^\star|$ is linear with high probability (Lemma 10), dividing by $|I^\star|$ yields $\mathbb{E}[1 - |I|/|I^\star|] = k^{-\alpha} \cdot O(1)$ and thus $\mathbb{E}[|I|/|I^\star|] = 1 - k^{-\alpha} \cdot O(1)$.

This directly implies the claimed approximation scheme: for every given $\varepsilon > 0$, one can choose the k such that the expected approximation ratio is $1 - \varepsilon$. As the k we have to chose does not depend on n, the resulting running time is polynomial in n (but exponential in $1/\varepsilon$). Additionally applying concentration bounds if $k = \log n$ yields the following theorem.

▶ **Theorem 12.** *For the giant components of hyperbolic random graphs given in their geometric representation,* Independent Set *can be approximated in expected $O(n2^k)$ time with expected approximation ratio $1 - k^{-\alpha} \cdot O(1)$. If $k = \log n$, the algorithm runs whp in polynomial time and the bound on the approximation ratio holds whp.*

Proof. It remains to consider the case $k = \log n$. We apply Lemma 11 with $k = \log n$ leading to connected components of expected size $\log n$. Using a Chernoff bound (Theorem 1) shows that the size of the connected components is whp at most $c \log n$ for a constant c. Thus, the algorithm described above has whp polynomial run-time.

Concerning the approximation ratio, note that the separator V' has expected size $O(n)/\log^\alpha n$. Thus, there are constants c_1 and $n_{\min}$ such that the $\mathbb{E}[|V'|] \leq c_1 n/\log^\alpha n$ if $n > n_{\min}$. As we can brute-force smaller instances, we can assume the latter assumption to be true. Applying a Chernoff bound (Theorem 1) we get that V' includes whp at most $c_2 n/\log^\alpha n$ vertices for another constant c_2. As before let I be the independent set we computed and let $I^\star$ be an optimal independent set of the giant component. Then, $|I^\star| - |I| \leq c_2 n/\log^\alpha n$ holds whp. As whp $|I^\star| \geq c_3 n$ (at least for sufficiently large instances; see Lemma 10), the calculations from above show that $|I|/|I^\star| \geq 1 - c/\log^\alpha n$ holds whp for $c = c_2/c_3$. ◀

5.2 Computing Matchings in $O(n^{2-\alpha})$ Time

Lipton and Tarjan [25] also gave $O(n^{3/2})$ and $O(n^{3/2} \log n)$ algorithms that compute matchings of maximum cardinality and matchings of maximum weight, respectively, in a planar graph. Their algorithm uses the following divide-and-conquer strategy. Find a separator, recursively compute maximum matchings for both subgraphs, and finally combine these solutions by iteratively adding the vertices of the separator while maintaining a maximum matching. The latter can be done by finding a single augmenting path, which can be done in $O(m)$ and $O(m \log n)$ time for unweighted and weighted graphs, respectively (m is the number of edges).

To obtain the following theorem, we apply this divide-and-conquer strategy to hyperbolic random graphs, show that m is actually linear in n (even for the subgraphs for which we compute the augmenting paths), and apply concentration bounds.

▶ **Theorem 13.** *Let G be the giant component of a hyperbolic random graph given in its geometric representation. Whp, a maximum matching in G can be computed in $O(n^{2-\alpha})$ and $O(n^{2-\alpha} \log n)$ time if G is unweighted and weighted, respectively.*

5.3 In Case the Geometry is Unknown

The two previous applications relied on the fact that we know the geometric representation of the given hyperbolic random graph. However, even if the geometry is unknown, we can still benefit from the knowledge that hyperbolic random graphs have low treewidth by using an algorithm of Fomin et al. [13]. It takes a graph G and an integer k as input and either decides that $\operatorname{tw}(G) > k$ or returns a tree decomposition of width k^2. It runs in $O(k^7 n \log n)$

time. By spending an additional factor of $\log(\mathrm{tw}(G))$ we can actually compute the smallest k for which the algorithm succeeds to compute a tree decomposition.

Given a tree decomposition of width k, Fomin et al. [13] show (among other algorithms) how to compute a matching with maximum weight and a maximum vertex flow in a directed graph in $O(k^4 n \log^2 n)$ and $O(k^2 n \log n)$ time, respectively. For sufficiently large α, this leads to algorithms solving these problems faster than the best known algorithms for general graphs. E.g., for $\alpha = 31/32$, the treewidth of G is $O(n^{1/32})$ with high probability (Theorem 9). Thus, we get a tree decomposition of width $O(n^{1/16})$ in $O(n^{7/32} \cdot n \log^2 n)$ time. Computing a matching of maximum weight then takes $O(n^{1/4} \cdot n \log^2 n)$. Thus, the overall running time is $O(n^{5/4} \log^2 n)$. Also note that this approach leads to almost linear (i.e., linear up to a polylogarithmic factor) run-times if $\alpha \geq 1$.

6 Binomial Hyperbolic Random Graphs

So far, we considered the so-called *threshold* model of hyperbolic random graphs where vertices are connected if and only if they have distance at most R. A more realistic (but technically more difficult) model is the *binomial* model, in which longer edges and shorter non-edges are allowed with a certain probability. More precisely, two vertices with distance d are connected with the following probability $p(d)$ depending on the constant t (usually $0 < t < 1$). Note that we obtain the threshold model for $t \to 0$.

$$p(d) = \left(1 + e^{\frac{1}{2t}(d-R)}\right)^{-1}$$

As before, we start with a hyperdisk decomposition $(T, \mathcal{S})$ of the disk D and then transfer it to a separator hierarchy of a hyperbolic random graph. In the threshold model, separators in $(T, \mathcal{S})$ translated to separators in the graph if $\rho \geq R/2$. This is not true in the binomial model as vertices with distance greater than R are still connected with a certain probability.

However, we obtain separators as follows. Let k be a node of T with children i and j, i.e., S_k separates U_k into U_i and U_j. An edge of the graph G is *critical* with respect to S_k if it connects a vertex located in U_i with a vertex in U_j. As before, let $G[U_k]$ be the graph induced by vertices in U_k. Then the vertices located in S_k together with the endvertices of critical edges separate $G[U_k]$ into (subgraphs of) $G[U_i]$ and $G[U_j]$. In this way, we again obtain a separator hierarchy for G, which we call the *extended hyperdisk decomposition.*

To bound the size of the resulting separators, we have to bound the number of vertices in S_k and the number of critical edges. For the former, we can use the previous results (in particular Lemma 6). For the latter, note that the expected number of vertices in U_i is at most $n2^{-\ell}$ if i has level ℓ (as the hyperdisk decomposition is balanced). As the same holds for U_j, there are only $(n2^{-\ell})^2$ vertex pairs that potentially form critical edges, each with a probability of at most $p(2\rho)$ (as their distance is at least 2ρ). Thus, the expected number of critical edges is at most $n^2 p(2\rho) 2^{-2\ell}$. Plugging a carefully chosen value for ρ into this formula as well as into the formula given by Lemma 6 leads to the following theorem.

▶ **Theorem 14.** *Let G be a binomial hyperbolic random graph with $\alpha < 1$ and consider its extended hyperdisk decomposition with hyperdisks of radius $\rho = \frac{2\alpha t + t + 1}{2\alpha t + 2} R$. For a separator S on level ℓ, the following holds.*

$$\mathbb{E}(|S|) = O\left(n^{2 - \frac{\alpha+1}{\alpha t + 1}}\right) \cdot \left(2^{1-\alpha}\right)^{-\ell}$$

Proof. As mentioned above, the number of critical edges is bounded by the following term.

$$n^2 p(2\rho) 2^{-2\ell} = n^2 p\left(\frac{2\alpha t + t + 1}{\alpha t + 1} R\right) 2^{-2\ell}$$

$$
\begin{aligned}
&= n^2 \left(1 + e^{\frac{1}{2t}\left(\frac{2\alpha t+t+1}{\alpha t+1}R - R\right)}\right)^{-1} 2^{-2\ell} \\
&= n^2 \left(1 + e^{\frac{1}{2}\frac{\alpha+1}{\alpha t+1}R}\right)^{-1} 2^{-2\ell} \\
&= n^2 \left(1 + e^{\frac{1}{2}\frac{\alpha+1}{\alpha t+1}(2\log n + C)}\right)^{-1} 2^{-2\ell} \\
&\le n^2 \left(1 + e^{\frac{\alpha+1}{\alpha t+1}(\log n + C/2)}\right)^{-1} 2^{-(1-\alpha)\ell} \\
&= O\left(n^{2-\frac{\alpha+1}{\alpha t+1}}\right) \cdot \left(2^{1-\alpha}\right)^{-\ell}
\end{aligned}
$$

For the second part, we go one step back and assume that S is a separator in the hyperdisk decomposition of the disk D_R in the hyperbolic plane (instead of a separator in graph). By Lemma 6, we get the following bound on the measure of S.

$$
\begin{aligned}
\mu(S) &= O\left(e^{\alpha\rho - \alpha R}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(e^{\alpha\frac{2\alpha t+t+1}{2\alpha t+2}R - \alpha R}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(e^{\alpha\frac{t-1}{2\alpha t+2}R}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(e^{\alpha\frac{t-1}{2\alpha t+2}(2\log n + C)}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(n^{\frac{\alpha t-\alpha}{\alpha t+1}}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(n^{\frac{\alpha t+1-\alpha-1}{\alpha t+1}}\right)\left(2^{1-\alpha}\right)^{-\ell} \\
&= O\left(n^{1-\frac{\alpha+1}{\alpha t+1}}\right)\left(2^{1-\alpha}\right)^{-\ell}
\end{aligned}
$$

Multiplying with n (as we have n vertices) leads to the claimed bound. ◀

Note that this bound coincides with our result for the threshold model when $t \to 0$. Moreover, for $t \in (0, 1)$, we obtain separators of sublinear size. As for the threshold model, we can use Lemma 8 to obtain bounds for the treewidth (compare Section 4).

7 Conclusion

We have shown that hyperbolic random graphs have small separators, as well as a small treewidth (with a phase transition from polynomial to logarithmic at $\beta = 3$). This stands in stark contrast to other popular random graph models like Erdős-Rényi [12] or Barabási-Albert [2] that have linear separators [17]. Beyond providing new insights on the structural properties of hyperbolic random graphs, our results give rise to several algorithmic applications.

To judge the practical merit of these algorithms, an interesting next step is therefore to compare separators on real graphs with predictions made by the various models. It is, however, a challenge to compute small separators in a given massive graph. Depending on the precise problem formulation, this is likely to be an NP-complete problem.

A more theoretical open question is whether our results are tight or can be improved to achieve even smaller separators. Of interest is especially the binomial model, since it allows for long range edges in the graph; and there exists no lower bound on the treewidth in the current literature.

Abstract

Hyperbolic geo metry appears to be intrinsic in many large real networks. We construct and implement a new maximum likelihood estimation algorithm that embeds scale-free graphs in the hyperbolic space. All previous approaches of similar embedding algorithms require a runtime of $\Omega(n^2)$. Our algorithm achieves quasilinear runtime, which makes it the first algorithm that can embed networks with hundreds of thousands of nodes in less than one hour. We demonstrate the performance of our algorithm on artificial and real networks. In all typical metrics like Log-likelihood and greedy routing our algorithm discovers embeddings that are very close to the ground truth.

1 Introduction

The study and analysis of complex real-world networks is a rapidly growing field. There are a number of commonly observed properties of complex networks like power-law degree distribution, small clustering coefficient, and small average distances. During the last decade, dozens of models for such *scale-free networks* have been proposed. The most popular model is the preferential attachment model by Barabási and Albert [5]. Most accessible for mathematical analysis is the inhomogeneous random graph model by van der Hofstad [33], which generalizes the models of Chung and Lu [10, 1, 2] and Norros and Reittu [26].

All aforementioned network models observe a power-law degree distribution, small diameter and average distances. However, all of them naturally also have a *small clustering coefficient*, that is, the number of triangles and small cliques in such artificial networks is magnitudes lower than observed in real-world networks. The reason is that in the standard definitions of these network models, the edges are (merely) independent, which is not true

* Sören Laue acknowledges the support of Deutsche Forschungsgemeinschaft (DFG) under grant GI-711/5-1 within the priority program "Algorithms for Big Data".

for real-world networks. For social networks the reason is easy to see: If someone is friends with two people, it is likelier that they know each other as well than it would be for two random strangers to forge a connection. There are a number of modifications of above models that incorporate this intuition [34, 25, 23], however, all these fixes introduce other artificial artifacts and can not explain *why* the clustering occurs in the first place.

Hyperbolic Random Graphs. A natural definition of a scale-free network model with all aforementioned properties emerges when adding an appropriate geometry. It is well studied that geometric random graphs with an Euclidean space result in a Poisson degree distribution [30]. Krioukov et al. [20] took a different approach by assuming an underlying *hyperbolic geometry* to the network. The most prominent feature of a hyperbolic space is its exponential expansion around a given point, in contrast to Euclidean space, which expands only polynomially. *Hyperbolic random graphs* are obtained by placing all nodes in the hyperbolic plane, and connecting two nodes whenever they are a small (hyperbolic) distance apart. The desired clustering then naturally emerges as a reflection of the geometric proximity. This model has been analyzed to have a power-law degree distribution and high clustering [16, 20], to have a polylogarithmic diameter and ultra-short average distances of order $\mathcal{O}(\log\log n)$ [15, 9], and allows fast bootstrap percolation [19].

Generating Hyperbolic Random Graphs. With most fundamental structural properties of hyperbolic random graphs settled, the next step is studying algorithms on the network model. The first addressed algorithmic problem is efficiently *generating* such a graph or, equivalently, *sampling* a graph from the probability distribution defined by hyperbolic random graphs. The naive generation of a hyperbolic random graph takes $\Theta(n^2)$ time [3]. Using a polar quadtree adapted to hyperbolic space, von Looz et al. [36] achieved a time complexity of $\mathcal{O}((n^{3/2} + m) \log n)$; and by a more sophisticated partitioning of the space, Bringmann et al. [9] obtained an optimal expected linear runtime for generation, which is crucial for large-scale experiments.

Visualizing Data in Hyperbolic Geometry. It is well known in the visualization community that hierarchical or tree-like structures can be well represented in a hyperbolic space [32]. There are three approaches to embed a network in the hyperbolic space:

- A popular way to obtain hyperbolic coordinates for the nodes of a network is embedding a spanning tree of the network in hyperbolic space [38, 37, 24]. As trees can be embedded perfectly, this is a very efficient way to map a network and has been used for interactive network browsers, which allow assigning more display space to the interesting portions of a network [21, 22]. The result might reduce visual clutter and help focus, but it ignores most structural details of the network. Nodes which are close in graph distance are not necessarily close in hyperbolic space. In fact, clusters and most local structures are not preserved.
- Another approach is determining shortest path distances and finding an embedding where metric distances match the graph distances. Computing the all-pair-shortest-path matrix can be done with the well established Euclidean data analysis method Multidimensional Scaling (MDS) [13], which has been translated to hyperbolic geometry [12]. Due to the quadratic size of the distance matrix, this approach only works for graphs with a few hundred nodes [4]. To reduce the runtime, it is possible to (randomly) select a small subset of the pairwise distances [31, 35, 42].

- Our objective is slightly different. Instead of preserving distances between nodes, we aim at inferring the *popularity* (reflected by radial coordinates) and *similarity* (reflected by angular coordinates) of all nodes [28]. The reason why a connection between vertices exist can be twofold: Either, the two vertices are similar, which holds e. g. for close friends in social networks; or for geographically close ASs in the Internet graph. On the other hand, a connection may be present due to the popularity of one end vertex: For instance, many people follow Lady Gaga on Twitter; but most are arguably not very similar to her. Embedded shortest path distances lose this information. Our goal is to recover this information using the most likely embedding assuming a hyperbolic nature of the graph in the first place. For this, we use the random network model of Krioukov et al. [20].

Maximum Likelihood Estimation Embedding of Graphs in Hyperbolic Space. We focus on the last-mentioned approach of maximum likelihood estimation (MLE) algorithms, i.e., we want to find the node coordinates in the network by maximizing the probability that the network is produced by some underlying hyperbolic model. Boguñá et al. [8] were the first to find such an embedding for the Internet graph ($m = 58\,416$ connections between $n = 23\,752$ autonomous systems) in the hyperbolic space. It is impressive that greedy navigation along these hyperbolic coordinates is almost maximally efficient, i.e., it almost always finds the shortest paths between almost any two pairs of vertices in the same component. However, the described method to discover the hyperbolic coordinates "require[s] substantial manual intervention and do[es] not scale to large networks" [20]. A general algorithm for embedding a network in a hyperbolic space was later presented by Papadopoulos et al. [29]. Their HyperMap algorithm is an approximate maximum likelihood estimation (MLE) algorithm. They demonstrate their algorithm on synthetic networks with $n = 5\,000$ nodes and $m = 20\,000$ edges and a subset of the aforementioned Internet graph with $n = 8\,220$ nodes. The asymptotic runtime was improved in a subsequent paper from $\mathcal{O}(n^3)$ to $\mathcal{O}(n^2)$ [27]. The authors present no runtime measurements [29, 27], but their HyperMap code on our machine requires more than 1.5 hours for a graph of size 2 000 (cf. Section 6.2). The algorithm was further refined in [39], who use a community detection algorithm for the coarse layout of the nodes; and an MLE to find precise positions. While their runtime is still $\Omega(n^2)$, our techniques extend to their case.

Our New Hyperbolic Embedder. We design and implement a new algorithm for computing hyperbolic MLE embeddings of massive networks (Section 5).[1] Compared to previous approaches that need $\Omega(n^2)$ runtime, our algorithm runs in quasilinear runtime. To this end, we developed several new techniques. First, we use an analytical approach to compute the expected angles between pairs of high-degree nodes based on their number of common neighbors. In contrast to [27], this approach does not rely on expensive numerical computations, making it fast in practice. The resulting angle distance matrix is then fed to a spring embedder that finds good positions for high-degree nodes in linear time. For small degree nodes, we substantially improve runtime by using the geometric data structure of Bringmann et al. [9] that allows traversing nodes of close proximity in expected amortized constant time.

This enables us to embed significantly larger graphs than before. For instance, we computed in under one hour a hyperbolic embedding of the Amazon product recommendation network which has over 300 000 nodes. To evaluate the quality of our embedding, we conduct large-scale experiments on 6 250 generated graphs and compare our embedding with the

[1] Our code will be made available at `https://hpi.de/friedrich/research/hyperbolic`.

ground truth data (Section 6). We observe that in typical metrics like Log-likelihood and greedy routing, our algorithm achieves embeddings that are competitive with the original.

Furthermore, we investigate the performance of two classical methods of embedding graphs in the Euclidean space, namely spring embedders and maximum variance unfolding, when applied to the hyperbolic space (Sections 3 and 4). We find that both of them can work under some strong assumptions, but generally fail to translate to large real-world graphs.

2 Preliminaries

In this section, we briefly introduce the hyperbolic random graph model. Due to space constraints, we keep the definitions concise and refer the reader to previous work for a more intuitive introduction, see e.g. [20, 16]. We use the native representation of the hyperbolic space [20] of curvature -1, where points are identified by radial coordinates (r, φ). The first coordinate describes the hyperbolic distance from the origin, and two points x, y have hyperbolic distance

$$\operatorname{dist}(x,y) := \cosh^{-1}(\cosh(r_x)\cosh(r_y) - \sinh(r_x)\sinh(r_y)\cos(\varphi_x - \varphi_y)).$$

The hyperbolic random graph model formally defines a probability distribution over the set of all graphs of size n. A graph G on n vertices is sampled from this distribution as follows. Consider a disc D_n of radius $R = 2\log n + C$ in the hyperbolic space, where C is a parameter adjusting the average degree of the resulting graph. Each vertex v is randomly equipped with hyperbolic coordinates (r_v, φ_v) sampled from the probability density function $f(r,\varphi) = \frac{\alpha \sinh(\alpha r)}{2\pi(\cosh(\alpha R)-1)}$, for a parameter α adjusting the power-law exponent $\beta = 2\alpha + 1$ of the resulting network. Then, every two vertices u, v are connected with probability

$$p(\operatorname{dist}(u,v)) := \left(1 + \exp(\tfrac{1}{2T} \cdot (\operatorname{dist}(u,v) - R))\right)^{-1}, \tag{2.1}$$

where T is a parameter regulating the importance of the underlying geometry: When $T \to 0$, we obtain the so-called *step model*, where an edge $\{u, v\}$ is present if and only if $\operatorname{dist}(u, v) \leqslant R$. For $T > 0$, we obtain the *binomial model*, where long-range edges are possible (but unlikely). Typically, one assumes $0 \leqslant T < 1$. This yields a random graph depending on 4 parameters: n, R (or C), α, and T. Following standard graph notation, we write $\Gamma(v)$ for the set of neighbors of v, and we use δ to refer to the average degree of G.

Further, given a graph $G = (V, E)$ and any mapping from nodes to hyperbolic coordinates $\{r_i, \varphi_i\}_{i=1}^n$, we define the *Log-likelihood* as

$$\mathcal{L}(\{r_i,\varphi_i\}_{i=1}^n \mid G) := \sum_{\{u,v\}\in E} \log(p(\operatorname{dist}(u,v))) + \sum_{\{u,v\}\notin E} \log(1 - p(\operatorname{dist}(u,v))),$$

where the hyperbolic distances dist are taken with respect to the coordinates $\{r_i, \varphi_i\}_{i=1}^n$. To simplify presentation, we write

$$\mathcal{L}(v) := \sum_{u\in\Gamma(v)} \log(p(\operatorname{dist}(u,v))) + \sum_{u\notin\Gamma(v)} \log(1 - p(\operatorname{dist}(u,v))), \tag{2.2}$$

so that we have $\mathcal{L}(\{r_i,\varphi_i\}_{i=1}^n \mid G) = \frac{1}{2}\sum_{v\in V} \mathcal{L}(v)$.

Our goal is to devise an algorithm which, given only the network structure (i.e. a list of edges) of a generated hyperbolic random graph, can re-infer the hyperbolic coordinates of the original embedding. As additional requirements, we would like that the algorithm is robust to noise (i.e. works reasonably well even if the supplied graph was not hyperbolic).

Before presenting our algorithm, we revisit two popular embedding techniques in the Euclidean plane and investigate their performance when applied to the hyperbolic setting.

3 Spring Embedder

A heavily used technique to embed graphs in the Euclidean plane is the force-directed method (also called spring embedder) [17], which works roughly as follows. For every edge one assumes an attractive force pulling its end vertices toward each other, and for every pair of vertices one assumes a repulsive force pushing them away. The algorithm starts with some initial drawing (e.g., by choosing random positions) and computes for each vertex the total force acting on it. Then, all vertices are moved by a small step according to these forces. This is iterated until a stable configuration is reached.

In a drawing generated by a spring embedder, edges are usually short and non-adjacent vertices are usually far away from each other. Moreover, the repulsive forces lead to a somewhat uniform distribution of the vertices in the available space. Note that these are exactly the properties we wish to obtain for our embeddings in the hyperbolic plane. It thus seems natural to adapt spring embedders to the hyperbolic geometry, which actually has been done before by Kobourov and Wampler [18]. In the following we discuss why the straight-forward way of implementing a spring embedder in the hyperbolic plane does not work in our setting. For several adaptations that lead to good results at least for smaller graphs, see the online version.

3.1 Difficulties in the Hyperbolic Plane

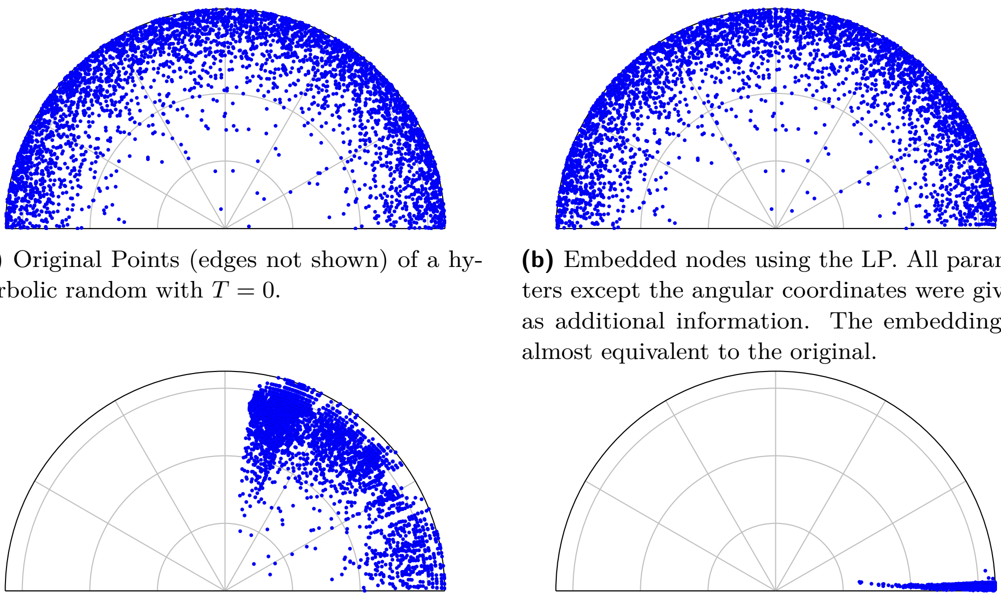
To understand the difficulties in the hyperbolic plane, first consider the following artificial situation in the Euclidean plane. Assume v is a vertex only connected to u; and assume the current drawing is already stable except that v is far away from u. Now when v moves towards u, it also gets closer to other vertices it is not connected to, which then push v back towards the direction where it came from. This is not a problem, however, as there are usually only few vertices close enough to v such that their force is noticeable. Moreover, vertices on the opposite side of v support the movement towards u.

In the hyperbolic plane, an analogous situation works out differently. The geodesic line between v and u contains points with smaller radius, such that v first moves almost directly towards the origin. In turn, the distance to *all* other nodes decreases, which immediately pushes v back to a position with larger radius. Thus, even bad embeddings are stable.

Judging from the pictures presented by Kobourov and Wampler [18], it seems that they did not encounter these issues in their spring embedder. This can be explained by the fact that the radii they use are all rather small, which can be deduced from the presented drawings by observing that the vertices are very well separated from the boundary of the Poincaré disk (which is only true for very small radii). However, for such small radii the hyperbolic plane behaves very similar to the Euclidean plane. We note that using small radii is reasonable for visualizing small graphs using a fish-eye view. However, as the radii in a hyperbolic random graph grow logarithmically with an increasing number of vertices, this is not suitable for our purpose.

4 Maximum Variance Unfolding

Another popular method for embedding graphs into the Euclidean plane is maximum variance unfolding (MVU) [40]. This is essentially a semidefinite program whose objective function spreads out nodes while using constraints to keep neighbors close together. In the one-dimensional case it is equivalent to an LP.



(a) Original Points (edges not shown) of a hyperbolic random with $T = 0$.

(b) Embedded nodes using the LP. All parameters except the angular coordinates were given as additional information. The embedding is almost equivalent to the original.

(c) Embedded nodes using the LP with estimated radial coordinates (See Section 5.1). The quality of the LP solution quickly degrades.

(d) Embedded nodes using the LP with all other parameters given. The graph was generated using $T = 0.5$. The embedding is essentially unusable.

Figure 1 First phase of the LP. Since nodes are placed in $[0, \pi]$, half of D_n is hidden.

The use-case in the hyperbolic geometry is similar: Nodes shall have distance $< R$ if they have an edge, and distance $\geqslant R$ otherwise. It is possible to encode this into the following LP:

$$\begin{array}{lll} \text{maximize} & \sum_{j=1}^{n} \varphi_j & \\ \text{subject to} & \varphi_i - \varphi_j \leqslant \theta(r_i, r_j), & i,j = 1,\dots,n, \quad i \neq j \\ & \varphi_j - \varphi_i \leqslant \theta(r_i, r_j), & i,j = 1,\dots,n, \quad i \neq j \\ & 0 \leqslant \varphi_i \leqslant \pi & i = 1,\dots,n \\ & \varphi_v = 0, & \text{for some starting node } v \end{array}$$

where $\theta(r_i, r_j)$ is the maximal angular distance such that nodes $\operatorname{dist}(i,j) \leqslant R$, i. e.

$$\theta(r_i, r_j) = \arccos\left(\frac{\cosh(r_i)\cosh(r_j) - \cosh(R)}{\sinh(r_i)\sinh(r_j)}\right). \tag{4.1}$$

The LP has a caveat: It is only able to spread nodes on the half circle $[0, \pi]$; since for larger angular coordinates the hyperbolic distances start decreasing again, which is not encodable in the LP. This can be fixed, however, using a small trick: First, embed all nodes on a half-circle with an arbitrary starting node v. Then, pick the node u in the embedding with angular coordinate closest to $\frac{\pi}{2}$; and embed the graph again using u as the starting node.

This yields all nodes that belong in the lower half of D_n: If w has angular distance at least $\frac{\pi}{2}$ from u in the second embedding, we set $\varphi_w = \varphi_w + \pi$ in the first embedding.

This simple method works surprisingly well on generated hyperbolic random graphs that are drawn from the step model, when given all global parameters and radial coordinates, see Figure 1a–b. It is, however, extremely volatile to the quality of the estimated parameters; and it fails completely when used on a real graph or even a graph generated by the binomial

Algorithm 1 Fast Embedding Algorithm

```

6:         for all $v \in \bigcup_{j \geqslant i} L_j$ do
7:             Embed $v$ by optimizing its Log-likelihood    ▷ See Sections 5.3 and 5.4
```

model, see Figure 1c–d. The reason is that the LP has a constraint for each edge in the graph: If there is just one long-range edge, the MVU can no longer unfold the graph and all nodes are mapped to an extremely small range of angular coordinates. This behavior persists even after adding different error terms for edges; and we were not able to make this approach work on noisy data.

5 The Embedder

Our embedding algorithm is inspired by the Metropolis-Hastings Algorithm from [8]. Algorithm 1 contains a bird's eye view over the whole algorithm. Detailed description of individual steps follow in the next sections.

The algorithm proceeds in three phases: First, it estimates all parameters that are computationally easy to guess. This includes the radial coordinates of all nodes, see Section 5.1.

In the second phase, high-degree nodes are embedded by considering their common neighbors. Producing a good initial ordering of nodes in inner layers is crucial for the success of the algorithm since nodes in all subsequent layers are typically placed close to their neighbors in higher layers. This step is described in Section 5.2.

In the third phase, the algorithm embeds the rest of the graph layer-wise. To embed a layer L_i, we iterate over all nodes $v \in L_i$. In each iteration, $\mathcal{O}(\log n)$ angular coordinates for v are sampled; and v is moved to the position with the best Log-likelihood, see Sections 5.3 and 5.4. This is repeated $\log n$ times per layer. While this step is similar to HyperMap [8, 27, 29], we improve upon their algorithm by achieving an amortized polylogarithmic runtime per node as compared to their linear runtime. Our overall algorithm thus runs in $\mathcal{O}(n \cdot \mathrm{polylog}(n))$.

5.1 Parameter Estimation

To bootstrap the embedding algorithm, the global graph parameters have to be known: The original number of nodes n, the radius R of the disc D_n, the parameter α adjusting the power-law exponent; and the parameter T adjusting the clustering. These values are required for instance for evaluating the probability that two nodes are connected, see equation (2.1) which in turn is needed to produce the Log-likelihood. In the following, we give some brief explanations on how each parameter is guessed.

Estimating n. Algorithm 1 expects a connected graph as input, since disconnected components can be placed anywhere in the graph as there is no adjacency information.

The hyperbolic random graph, however, does typically not produce a connected graph. For power-law exponents $2 < \beta < 3$, its giant component is of size $\Theta(n)$ [6, 7]; and for $\beta \geqslant 3$ the graph breaks up into components of order $o(n)$. Unfortunately, the leading constant of the size of the giant component is yet unknown; and a numerical estimation is hard since it is governed by a non-linear system of equations together with other parameters [8].

We have found experimentally that the majority of nodes missing from the giant component are of degree 0. Surprisingly, the most effective and robust method for estimating the number of these nodes was by simply extrapolating from the number of 1- and 2-degree nodes. Let $\hat{n} \cdot F(k)$ be the number of nodes of degree k, where $\hat{n}$ is the total number of nodes in the input graph. Then, we estimate n simply by setting $n := \hat{n}(1 + \max\{0, 2F(1) - F(2)\})$.

Estimating α. The parameter α adjusts the power-law exponent β of the hyperbolic random graph via the functional behavior $\beta = 2\alpha + 1$ [16]. We estimate β from the cumulative degree distribution using the classical algorithm by Clauset et al. [11].

Estimating T. Recall that this parameter adjusts the importance of the underlying geometric structure. It has recently been observed, however, that T does not have a big influence on the quality of the embedding [27]. We found that setting T to a small fixed value like 0.1 produces good results. We investigate the role of T closer in the online version.

Estimating R and r_i. We estimate these values using the above determined parameters. Good analytical estimates have been derived in previous work [8]:

$$R = 2\log\left(\frac{4n^2\alpha^2 T}{|E| \cdot \sin(\pi T)(2\alpha - 1)^2}\right), \quad r_i = \min\left\{R,\ \ 2\log\left(\frac{2n\alpha T}{\deg(i) \cdot \sin(\pi T)(\alpha - \frac{1}{2})}\right)\right\}$$

5.2 Embedding the Core

Laying out the large-degree nodes (also called the *core* of the graph) has a huge impact on the overall performance of the embedding. We consider all nodes v with radial coordinates $r_v < R/2$ to be in the core, of which there are $\Theta(n^{1-\alpha})$ in expectation [14]. If the node ordering of the core is roughly correct, the algorithm will usually yield excellent embeddings. One the other hand, if the core was embedded poorly, the remaining steps can not salvage the poor initialization. Thus, we put considerable care into embedding the core correctly.

HyperMap [29] uses the number of common neighbors of large degree nodes to lay out the core: For two nodes u, v they compute the number $c_{uv} = |\Gamma(u) \cap \Gamma(v)|$, and numerically determined the angle $\varphi(c_{uv}, r_u, r_v)$ that maximizes the likelihood that the nodes u, v have c_{uv} common neighbors. This is a promising approach, as the common neighborhood of large nodes is tightly concentrated around its expected value. Determining the likelihood numerically, however, is a computationally expensive operation.

To overcome this, we analytically derive in Section 5.2.1 an approximate expression for the relative angle of two nodes up to constant factors. Using this, we present a spring embedder in Section 5.2.2 that embeds the core based on the estimated pair-wise angle differences.

5.2.1 Estimating the Angle-Differences

To estimate the relative angle between two nodes, we use their inferred radial coordinates and the number of their common neighbors. We perform this computation in the step model; however, we have experimentally found that our results hold up well in the binomial model.

Let u, v be the two nodes whose (expected number of) common neighbors we wish to compute. They have radii r_u and r_v, respectively, and a relative angle of $\Delta\theta(u, v)$. W. l. o. g., we assume that $r_u \leqslant r_v$. Consider now a third node w. We compute the probability that w

is connected to both u and v. Under the assumption that $r_u + r_w \geqslant R$ and $r_v + r_w \geqslant R$, we know from [16] that this only holds if

$$\begin{aligned}&\Delta\theta(u,w) \leqslant 2e^{\frac{1}{2}(R-r_u-r_w)}(1+\Theta(e^{R-r_u-r_w})), \quad \text{and}\\ &\Delta\theta(v,w) \leqslant 2e^{\frac{1}{2}(R-r_v-r_w)}(1+\Theta(e^{R-r_v-r_w})). \end{aligned} \tag{5.1}$$

Assume $r_v + r_w \geqslant R$ does not hold. In this case, the distance between v and w is obviously at most R and thus they are connected. Moreover, note that in this case the right hand side of the above formula increases with increasing R and thus the inequality is satisfied for any angle $\Delta\theta(v,w)$ if R is sufficiently large. Thus, under the assumption that R is sufficiently large, we may use equation (5.1).

Observe now that for large enough radii r_w, the node w is not connected to either u or v (unless $\Delta\theta(u,v) \leqslant \mathcal{O}(\frac{1}{n})$). On the other hand, when $R - r_v - r_w = \Omega(1)$, w is connected with constant probability to both u and v. Thus, depending on the radius r_w, there is a "good" fraction of the angular coordinates $[0,2\pi)$ where w will be connected to both nodes, and a "bad" fraction where it will be connected to only one or neither of u, v. We call the probability to be connected to both nodes $p_g(r_w)$.

We already know that $p_g(r_w) = 1 \Leftrightarrow r_w = R - r_v \pm \Theta(1)$. We label this critical value of r_w with r_1. On the other hand, $p_g(r_w) = 0$ holds when $\theta(r_u, r_w) + \theta(r_v, r_w) \leqslant \Delta\theta(u,v)$, since then there is no possible angle for φ_w where it is connected to both nodes u, v, see equation (4.1). The critical value r_0 for which this number becomes positive is when $\theta(r_u, r_w) + \theta(r_v, r_w) = \Delta\theta(u,v)$ and thereby

$$\begin{aligned}\Delta\theta(u,v) &= 2e^{\frac{1}{2}(R-r_u-r_0)}(1 \pm \Theta(e^{R-r_u-r_0})) + 2e^{\frac{1}{2}(R-r_v-r_0)}(1 \pm \Theta(e^{R-r_v-r_0}))\\ &= \Theta(1) \cdot e^{\frac{1}{2}(R-r_u-r_0)}.\end{aligned}$$

Solving for r_0, this holds whenever $r_0 = \min\{R, R - r_u - 2\log(\Delta\theta(u,v)) \pm \Theta(1)\}$.

For values $r_1 \leqslant r_w \leqslant r_0$, the regions in which w connects to u, v both increase as in equation (5.1). Thus, the intersection of these regions increases as $p_g(r_w) \sim e^{-r_w/2}$. To determine the function up to constants, we set

$$1 = p_g(r_1) = A \cdot e^{-r_1/2} + B, \quad \text{and} \quad 0 = p_g(r_0) = A \cdot e^{-r_0/2} + B.$$

Solving this system of equations, we obtain that $p_g(r_w) = \Theta(1) \cdot (e^{\frac{1}{2}(r_1-r_w)} - e^{\frac{1}{2}(r_1-r_0)})$. Thus, we may compute the probability that an arbitrary node is connected to both u and v using the cumulative distribution function and p_g. We thereby have

$$\begin{aligned}\Pr[w \sim u,v] &= \int_0^R \rho(r) \cdot p_g(r)\,\mathrm{d}r\\ &= \Pr[r_w \leqslant r_1] + \Theta(1) \cdot \int_{r_1}^{r_0} e^{\alpha r - \alpha R} \cdot (e^{\frac{1}{2}(r_1-r)} - e^{\frac{1}{2}(r_1-r_0)})\,\mathrm{d}r\\ &= e^{\alpha r_1 - \alpha R} + \Theta(1) \cdot \left[e^{\alpha r - \alpha R} \cdot (\tfrac{1}{\alpha - \frac{1}{2}} e^{\frac{1}{2}(r_1-r)} - \tfrac{1}{\alpha} e^{\frac{1}{2}(r_1-r_0)})\right]_{r_1}^{r_0}\\ &= \Theta(1) \cdot e^{\alpha r_0 - \alpha R + \frac{1}{2}(r_1-r_0)}.\end{aligned}$$

Hence, the expected number of common neighbors of u and v is

$$c_{uv} = \Theta(1) \cdot \exp(\tfrac{R}{2} + (\tfrac{1}{2} - \alpha)r_u - \tfrac{1}{2}r_v) \cdot \Delta\theta(u,v)^{1-2\alpha}.$$

To find the angle $\varphi(c_{uv}, r_u, r_v)$ maximizing the Log-likelihood in the step model, we observe that the number of common neighbors of u, v is a binomial random variable: There exists a set $S \subseteq D_n$ in which each node is connected to both u, v and each node in $D_n \setminus S$ connected to at most one of u, v. Since the maximum likelihood estimator for binomial random variables is the number of successes divided by the number of trials, we obtain the maximum likelihood for $\Delta\theta(u, v)$ by rearranging above equation.

$$\varphi(c_{uv}, r_u, r_v) = \Theta(1) \cdot c_{uv}^{\frac{1}{1-2\alpha}} \cdot \exp(-\tfrac{1}{2}r_u + (\tfrac{1}{2-4\alpha})(r_v - R)).$$

To obtain actual values for $\Delta\theta(u, v)$ we first simply omit the constant factor hidden by $\Theta(1)$ in the above expression. To obtain reasonable angles, observe that the largest angle should likely be π. To obtain this, one can simply rescale all values of $\varphi(c_{uv}, r_u, r_v)$ with the same constant factor such that the maximum is π. As this is prone to errors if outliers exist, we instead scale all angles by the same constant such that their median is $\pi/2$. Angles that are larger than π after this scaling are then set to π. Preliminary experiments showed that using the logarithm of the above expression for initially computing $\Delta\theta(u, v)$ (before the scaling) improved the robustness of our algorithm.

5.2.2 Embedding According to the Estimated Angles

In this section, we assume that we know the desired angle $\Delta\theta(u, v)$ between any pair of vertices u and v in the core. Our goal is to assign an angle to each vertex that realizes these differences as good as possible. To this end, we use a 1-dimensional spring embedder (see Section 3 for a short introduction to spring embedders) that basically works as follows. We start with random initial angles. Then in each iteration, we consider every pair u, v of vertices. If the the current angle between u and v is larger than $\Delta\theta(u, v)$ we get an attractive force, otherwise we get a repulsive force. W. l. o. g., we assume $0 \leqslant \varphi_u < \varphi_v \leqslant \pi$ (the other cases work symmetrically). Moreover, let $\mathrm{err}(u, v) = \varphi_v - \varphi_u - \varphi(c_{uv}, r_u, r_v)$. The force $F_u(v)$ acting on u due to v is then given by

$$F_u(v) = \begin{cases} -\operatorname{err}(u,v)^2 & \text{if } \operatorname{err}(u,v) \leqslant 0, \\ \operatorname{err}(u,v)^2 & \text{if } 0 < \operatorname{err}(u,v) \leqslant \frac{\pi}{2}, and \\ (\pi - \operatorname{err}(u,v))^2 & \text{if } \frac{\pi}{2} < \operatorname{err}(u,v) \leqslant \pi. \end{cases}$$

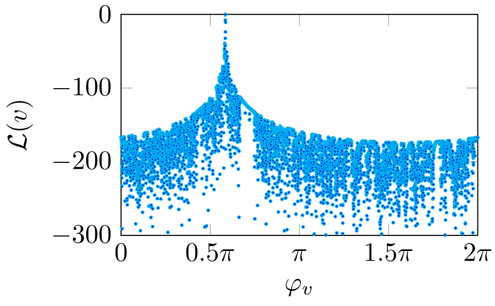
To interpret this formula, first note that $\mathrm{err}(u, v) < 0$ holds if the current angle is too small. Thus, $F_u(v)$ is negative (pushing u away from v) and the strength of the force increases quadratically in the distance to the desired angle. Conversely, if the current angle is too large, we get a repulsive force increasing quadratically in the distance to the desired angle as long as this distance is at most $\pi/2$. For larger distances, the strength of the force actually decreases again. This has the following reason. Imagine the extreme case that u and v have angle π between them but actually want to have a very small angle. Then it does not really matter whether the angle of u increases or decreases as it comes closer to v not matter what. Thus, we do not really want a very strong force in one of the two directions, which is the reason why we decrease the strength of attractive forces when $\mathrm{err}(u, v)$ becomes very large.

Similar to Section 3, the total force acting on u is defined as

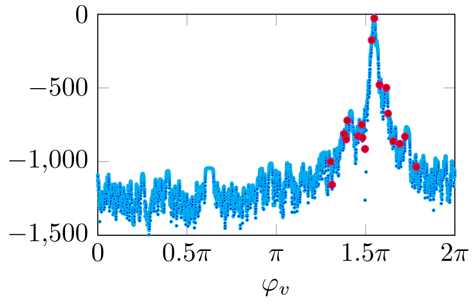
$$F_u = \sum_{v \in V \setminus u} F_u(v)$$

and the new angle of u is obtained by setting $\varphi_u = \varphi_u + cF_u$. The value for c is again chosen such that the maximum step size does not exceed a parameter $\theta_{\max} := \max_{u \in V}\{cF_u\}$.

Due to the 1-dimensionality of this spring embedder, we encounter a similar problem as for the hyperbolic spring embedder in Section 3: to move a vertex u to a specific position,



(a) Exemplary fitness landscape for a node v with 3 neighbors. Both methods for computing the fitness landscape exhibit no visible difference in the plot.



(b) Fitness landscape of a node v and the coordinates at which the efficient algorithm samples the fitness. Red points indicate the sampled angles.

Figure 2 Fitness landscape of a node v computed with the efficient algorithm.

it necessarily has to pass through all vertices in between and there is no second dimension that could be used to get around them. This leads to strong repulsive forces hindering u in getting to the desired position and we observed in our experiments that the algorithm often gets stuck in a local minimum. As before, we use velocity and a rather large step size $\theta_{\max}$ to circumvent this issue. Preliminary experiments showed that we obtain good results using the following parameters. We set $\theta_{\max} = 0.55\pi$ in the first iteration, decreasing it linearly down to 0 in the final iteration. For the velocity assume F_u is the force from iteration i. Then we add cF_u to the force in iteration $i+1$ where c is 1 in the first iteration and linearly decreases down to 0.5 in the last iteration. Since there are $\Theta(n^{1-\alpha})$ nodes in the core [14], the total runtime of the spring embedder is $\mathcal{O}(k \cdot n^{2-2\alpha})$, where k is the number of iterations. Choosing $k = \mathcal{O}(n^{2\alpha-1})$, we achieve a runtime of $\mathcal{O}(n)$.

The performance of this algorithm depends on the randomly chosen initial angles. To be able to compare core embeddings, we define a score S as

$$S = \sum_{u \in V} \sum_{v \in V \setminus u} |F_u(v)| \, .$$

A smaller score then indicates a better embedding. We define s_{opt} as the score that is obtained when the spring embedder is initialized with the original coordinates. We then say that a core embedding is *good*, if it has a score $s \leqslant 1.2 \cdot s_{\text{opt}}$. Each graph thus has a certain probability that the core embedding is good, depending on the randomly chosen initial positions. To further increase the probability of getting a good embedding for the core, we run the spring embedder 5 times with different initial angles and use the best result, which boosts the probability of getting a good embedding to 95% for the *worst* of over 3 000 randomly generated hyperbolic random graphs (see Section 6 for the experimental setup). This suggests that the spring embedder is rather robust, i.e. we rarely encounter initial drawings that lead to bad results.

5.3 Computing the Log-likelihood efficiently

A key ingredient to achieve a quasilinear runtime is to improve the runtime of the Log-likelihood computation $\mathcal{L}(v)$. By a naive implementation of the Log-likelihood $\mathcal{L}(v)$ (see equation (2.2)), one needs $\Omega(n)$ time to compute the Log-likelihood of a single node. A more careful inspection, however, allows for a significant speedup.

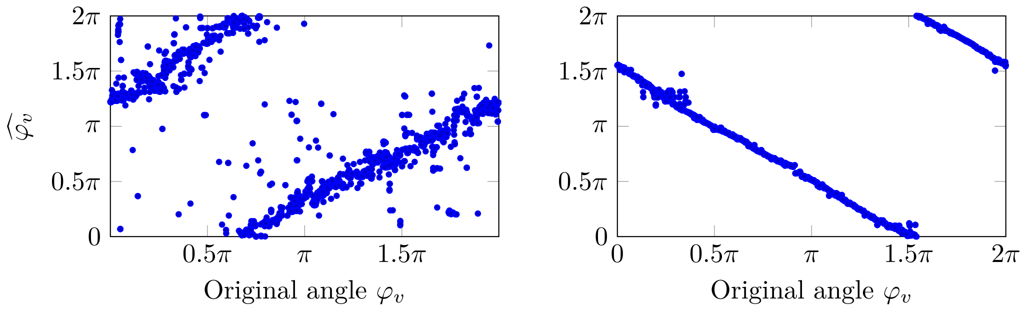


Figure 3 The plots correspond to embeddings with average squared deviation $\Delta\varphi_G = 0.44$ (left) and $\Delta\varphi_G = 0.01$ (right). For each vertex v the plot contains one point with x-coordinate φ_v (angle of v in the original embedding) and y-coordinate $\widehat{\varphi_v}$ (angle in the computed embedding).

First, observe that the total number of edges in a hyperbolic random graph is of order $\mathcal{O}(n)$; so the term $\sum_{u\in\Gamma(v)} \log(p_{uv})$ can be computed in amortized constant time. To speed up the computation of the second summand, we observe that the term $\log(1-p_{uv})$ is very close to 0 whenever $\mathrm{dist}(u,v) \gg R$, since

$$p_{uv} := (1+\exp(\tfrac{1}{2T}(\mathrm{dist}(u,v)-R)))^{-1} \approx \exp(-\tfrac{1}{2T}(\mathrm{dist}(u,v)-R)),$$

and by a Taylor series for $p_{uv} \to 0$ we get

$$\log(1-p_{uv}) = -p_{uv} - \mathcal{O}(p_{uv}^2) \approx -\exp(-\tfrac{1}{2T}(\mathrm{dist}(u,v)-R)).$$

This implies that non-neighbors that are far away from v barely contribute to its Log-likelihood. If, on the other hand, $\mathrm{dist}(u,v) \ll R$, we have $p_{uv} \to 1$, and thus

$$\log(1-p_{uv}) \approx \log(1-(1-\exp(\tfrac{1}{2T}(\mathrm{dist}(u,v)-R)))) = \tfrac{1}{2T}(\mathrm{dist}(u,v)-R).$$

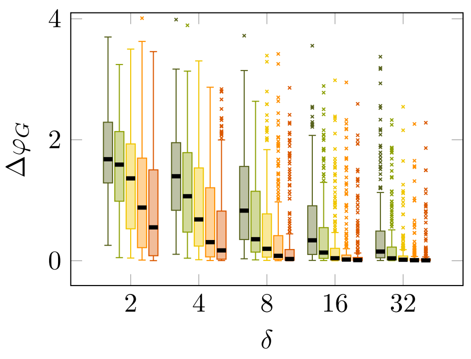
Thus, it suffices to take into account non-neighbors with low distance from u while either ignoring or coarsely approximating the influence of far away non-neighbors on the Log-likelihood. To this end, we implemented the geometric data structures introduced by Bringmann et al. [9]. These were originally used to generate hyperbolic random graphs in linear time by partitioning the disc D_n into suitably sized cells. To compute the Log-likelihood of a node, one can then compare it directly with nodes in neighboring cells (that have a big influence on the Log-likelihood); while averaging over all nodes in far away cells. As shown in [9], this runs in amortized time $\mathcal{O}(1)$. We need an extra $\mathcal{O}(\log n)$ factor to update the cells whenever a node is moved during the embedding algorithm.

Figure 2a shows the fitness landscapes of a node v; computed once via the classical exact $\Omega(n)$ method, and once using our amortized $\mathcal{O}(1)$ method. Both methods exhibit no visible differences in the plot; and we found that the relative error made by the fast Log-likelihood computation is $\leqslant 1.0025$ at all coordinates except one, where it was $\leqslant 1.02$.

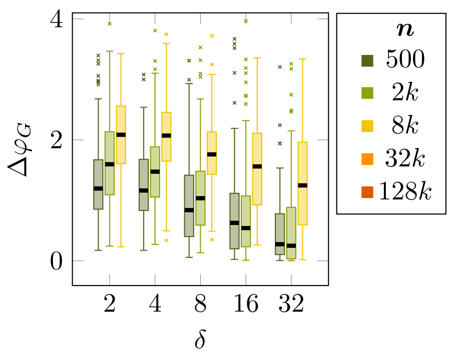
5.4 Finding the Optimal Angle

To find a good angular coordinate for a node v, previous algorithms typically scan the whole range $[0, 2\pi)$ at resolution $\frac{2\pi}{n}$; and evaluate at each angle the Log-likelihood $\mathcal{L}(v)$. This incurs another factor $\Omega(n)$ on the overall runtime.

To save on this, we sample only few points around a region where a node has their maximum likelihood. To this end, we observe that the coarse likelihood landscape for a node



(a) Our main algorithm.



(b) Our hyperbolic spring embedder.

Figure 4 Each data point in the box plot represents the value of $\Delta\varphi_G$ for a single graph G (y-axis) depending on the average degree a (x-axis). The graphs are grouped into small, medium, and large graphs.

v (for small T) is governed by the position of v's neighbors. Furthermore, neighbors with large radii have a larger influence on the fitness landscape, as the hyperbolic distance to these nodes increases more quickly than to neighbors with small radial coordinates. Hence, v needs to be placed close to its embedded low-degree neighbors.

Ignoring non-neighbors for now, we achieve this by computing a weighted average over the angles of all neighbors of v. Let $u_1, \dots, u_k$ be the embedded neighbors of v. Then, v's angle is computed as follows.

$$\varphi_v = \arctan\left(\frac{\sum_{i=1}^{k} \exp(r_{u_i}) \cdot \sin(\varphi_{u_i})}{\sum_{i=1}^{k} \exp(r_{u_i}) \cdot \cos(\varphi_{u_i})}\right)$$

To take non-neighbors into consideration, we then randomly sample $\mathcal{O}(\log(n))$ points around this angle and use the one with the smallest Log-likelihood. Figure 2b shows the fitness landscape of an exemplary node u, as well as the randomly sampled angles. As can be seen, the heuristic typically finds good candidates whose angles are close to the optimal angle.

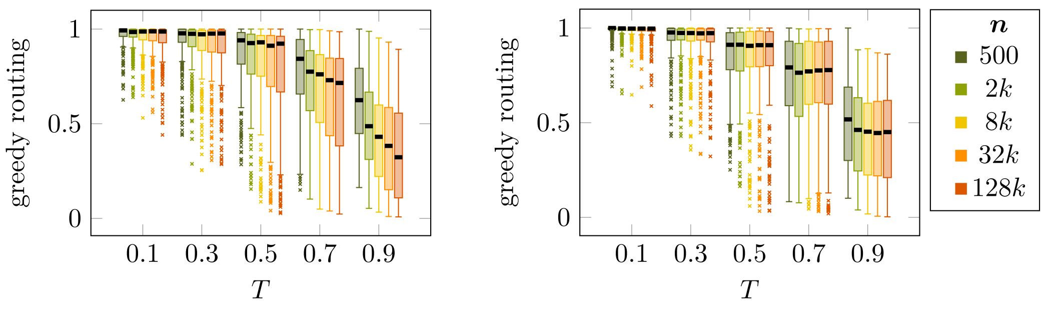
6 Experiments

To evaluate the quality of our algorithm, we sampled 10 different graphs for every combination of the following parameters: $\alpha \in \{0.55, 0.65, 0.75, 0.85, 0.95\}$, $T \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$, $\delta \in \{2, 4, 8, 16, 32\}$, $n \in \{500, 2\,000, 8\,000, 32\,000, 128\,000\}$. This results in a total of 6 250 graphs. For each of these graphs, we computed the following statistics: Log-likelihood, success ratio of greedy routing and the average squared deviation in the original angle vs. estimated angle plot. We present the most insightful statistics in standard box plot form.[2]

6.1 Quality

A popular way to judge whether an embedding makes sense is to plot the embedded angular coordinates against the original generated coordinates. If the result resembles a straight line

[2] A box contains 50% of all data points; the median is marked black. Points are considered outliers if they have distance more than 1.5× IQR to the box. The whiskers depict the closest data point to the box that is not an outlier.



(a) Our main algorithm. **(b)** Originally generated embeddings.

Figure 5 The success ratio of greedy routing (x-axis) depending on the value of T (y-axis) grouped with respect to the number of vertices (colors).

(that might have a cyclic shift), then the relative ordering of nodes has been reconstructed well in the embedding. Two examples for such plots are shown in Figure 3. To allow for comparisons that scale to a large amount of graphs, we derive the following quality measure. For a vertex v let $\Delta\varphi_v$ be the quadratic difference between φ_v in the original embedding and φ_v in the computed embedding. For a graph $G = (V, E)$, the value $\Delta\varphi_G = \sum_{v \in V} \Delta\varphi_v / n$ then describes the average squared deviation in G.

The box plot in Figure 4a plots $\Delta\varphi_G$ against the average degree δ; grouped by the size of the graph. In this and all other plots, we average over all parameters that are not explicitly grouped by. Observe that $\Delta\varphi_G$ is high if the average degree is small, as the few existing edges are not sufficient to uniquely determine the single best embedding. Thus, several embeddings may be equally good. In fact, for small δ, our algorithm finds an embedding with a Log-likelihood very close to the Log-likelihood of the original embedding (the mean values for large graphs with $\delta = 2$ are $-2.39 \cdot 10^5$ for the embedding and $-2.19 \cdot 10^5$ for the original, respectively, while the corresponding values for $\delta = 16$ are $-1.78 \cdot 10^6$ and $-1.16 \cdot 10^6$). For an average degree of 8, the mean value for $\Delta\varphi_G$ of all medium sized and large graphs is 0.2 and 0.04, respectively. For comparison, note that the plots in Figure 3 correspond to graphs with values 0.01 and 0.44. Also note that our algorithm performs particularly well on large graphs, which was the goal we aimed for.

For comparison with the spring embedder described in the online version, see Figure 4b. As the spring embedder is too slow on large graphs, we only ran the experiments on medium and small graphs. Note that the quality of the spring embedder decreases for increasing graph size. In contrast, it performs comparatively well on small graphs (and in some cases actually better than our main algorithm) while it is heavily outperformed on the medium sized graphs. Hence, the spring embedder is a reasonable option for graphs with up to 1 000 vertices, while our main algorithm is the better option for larger graphs.

A quality measure previously used for hyperbolic embeddings is the success ratio of greedy routing. Figure 5a shows this ratio for the embeddings generated by our algorithm depending on the parameter T, grouped by the size of the graph. Observe that the ratio is close to 100% for small values of T but drops significantly for larger values. This is unfortunate as real world graphs are considered to have fairly large values of T, e.g., $T = 0.7$ was used for the embedding of the Internet graph [8]. Though this particular embedding allows greedy routing with success ratio 97%, the ratios of around 80% we obtain for $T = 0.7$ seem to reflect the typical behavior of random hyperbolic graphs much better; see Figure 5b.

Note that these observations imply that maximizing the Log-likelihood will not necessarily lead to the desired result in terms of greedy routing. Conversely, optimizing the embedding

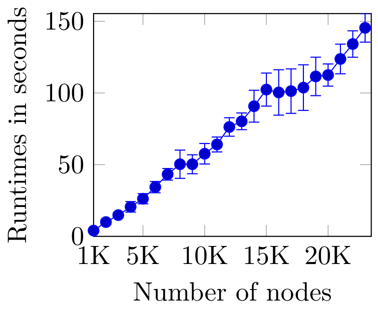


Figure 6 Runtimes for the embedding algorithm. Error bars show the standard deviation.

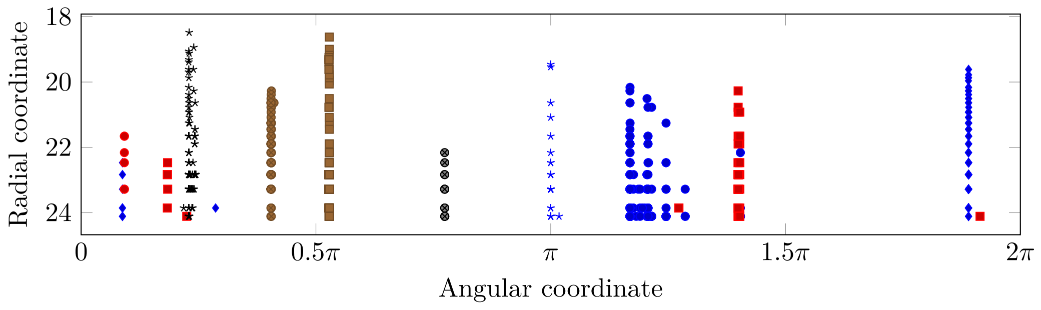

Figure 7 The nine largest communities in the amazon product recommendation network. For clarity, only nodes that belong to a single community are shown. Nodes belonging to the same community are typically placed nearby, even though the embedding algorithm had no knowledge of the ground truth communities.

for greedy routing will probably not lead to an embedding that is close to the original embedding of a hyperbolic random graph. Hence, we do not see the low success ratios our embeddings achieve for large T as a weakness but rather as a strength as it matches the behavior of the original embedding.

6.2 Runtime

A key contribution of our algorithm is its significant improvement on the runtimes compared to previous approaches. The runtime experiments were performed on commodity hardware, i.e. a 2.7 GHz Core i7 with 8 GB of RAM. Figure 6 shows the runtimes depending on n. Note that compared to available algorithms these are fairly quick: Graphs of size 20 000 can be embedded in under two minutes. We even embedded graphs of size 330 000 in under one hour, see Section 6.3. For comparison, the reference algorithm HyperMap [27, 29] needs over 1.5 hours for a graph of size 2 000.

6.3 Embedding a Real-World Graph

As a proof of concept, we embed the Amazon product recommendation network [41]. It has $n = 334\,863$ nodes with an average degree of 5.53, the degree distribution follows a power-law with exponent $\beta = 3.6$ and the average clustering coefficient is 0.4. The nodes represent products available on Amazon, and an edge $\{u, v\}$ is present if product u is recommended together with product v. Product categories define ground truth communities in this graph.

The embedding took 50 minutes on a single 2.7 GHz Core i7. While the number of nodes is too large to visually inspect the whole graph, we have plotted the nine largest communities in Figure 7. Most nodes belonging to a single community are mapped close together; which suggests that the hyperbolic embedding might be a useful tool in discovering hidden communities in a large network.

Abstract

An *α-spanner* of a graph G is a subgraph H such that H preserves all distances of G within a factor of α. In this paper, we give fully dynamic algorithms for maintaining a spanner H of a graph G undergoing edge insertions and deletions with worst-case guarantees on the running time after each update. In particular, our algorithms maintain:

- a 3-spanner with $\tilde{O}(n^{1+1/2})$ edges with worst-case update time $\tilde{O}(n^{3/4})$, or
- a 5-spanner with $\tilde{O}(n^{1+1/3})$ edges with worst-case update time $\tilde{O}(n^{5/9})$.

These size/stretch tradeoffs are best possible (up to logarithmic factors). They can be extended to the weighted setting at very minor cost. Our algorithms are randomized and correct with high probability against an oblivious adversary. We also further extend our techniques to construct a 5-spanner with suboptimal size/stretch tradeoff, but improved worst-case update time.

To the best of our knowledge, these are the *first* dynamic spanner algorithms with sublinear worst-case update time guarantees. Since it is known how to maintain a spanner using small *amortized* but large *worst-case* update time [Baswana et al. SODA'08], obtaining algorithms with strong worst-case bounds, as presented in this paper, seems to be the next natural step for this problem.

1 Introduction

An *α-spanner* of a graph G is a sparse subgraph that preserves all original distances within a multiplicative factor of α. Spanners are an extremely important and well-studied primitive in graph algorithms. They were formally introduced by Peleg and Schäfer [34] in the late eighties after appearing naturally in several network problems [36]. Today, they have been successfully applied in diverse fields such as routing schemes [16, 17, 36, 39, 43], approximate shortest paths algorithms [19, 20, 9], distance oracles [9, 14, 15, 37, 44], broadcasting [25], etc. A landmark upper bound result due to Awerbuch [6] states that for any integer k, every graph has a $(2k-1)$-spanner on $O(n^{1+1/k})$ edges. Moreover, the extremely popular *girth conjecture* of Erdős [24] implies the existence of graphs for which $\Omega(n^{1+1/k})$ edges are

* This work was partially done while the authors were visiting the Simons Institute for the Theory of Computing.

necessary in any $(2k-1)$-spanner. Thus, the primary question of the optimal sparsity of a graph spanner is essentially resolved.

The next natural question in the field of spanners is to obtain efficient algorithms for computing a sparse spanner of an input graph G. This problem is well understood in the static setting; notable results include [6, 11, 38, 43]. However, in many of the above applications of spanners, the underlying graph can experience minor changes and the application requires the algorithm designer to have a spanner available at all times. Here, it is very wasteful to recompute a spanner from scratch after every modification. The challenge is instead to *dynamically maintain* a spanner under edge insertions and deletions with only a small amount of time required per update. This is precisely the problem we address in this paper.

The pioneering work on dynamic spanners was by Ausiello et al. [5], who showed how to maintain a 3- or 5-spanner with amortized update time proportional to the maximum degree Δ of the graph, i.e. for any sequence of u updates the algorithm takes time $O(u \cdot \Delta)$ in total. In sufficiently dense graphs, Δ might be $\Omega(n)$. Elkin [22] showed how to maintain a $(2k-1)$ spanner of optimal size using $\tilde{O}(mn^{-1/k})$ expected update time; i.e. *super-linear* time for dense enough graphs. Finally, Baswana et al. [10] gave fully dynamic algorithms that maintain $(2k-1)$-spanners with essentially optimal size/stretch tradeoff using *amortized* $O(k^2 \log^2 n)$ or $O(1)^k$ time per update. Their *worst-case* guarantees are much weaker: any individual update in their algorithm can require $\Omega(n)$ time. It is very notable that *every* previously known fully dynamic spanner algorithm carries the drawback of $\Omega(n)$ worst-case update time. It is thus an important open question whether this update time is an intrinsic part of the dynamic spanner problem, or whether this linear time threshold can be broken with new algorithmic ideas.

There are concrete reasons to prefer worst-case update time bounds to their amortized counterparts. In real-time systems, hard guarantees on update times are often needed to serve each request before the next one arrives. Amortized guarantees, meanwhile, can cause undesirable behavior in which the system periodically stalls on certain inputs. Despite this motivation, good worst-case update times often pose a veritable challenge to dynamic algorithm designers, and are thus significantly rarer in the literature. Historically, the fastest dynamic algorithms usually first come with amortized time bounds, and comparable worst-case bounds are achieved only after considerable research effort. For example, this was the case for the dynamic connectivity problem on undirected graphs [31] and the dynamic transitive closure problem on directed graphs [41]. In other problems, a substantial gap between amortized and worst-case algorithms remains, despite decades of research. This holds in the cases of fully dynamically maintaining minimum spanning trees [30, 27, 23], all-pairs shortest paths [18, 42], and more. Thus, strong amortized update time bounds for a problem do not at all imply the existence of strong worst-case update time bounds, and once strong amortized algorithms are found it becomes an important open problem to discover whether or not there are interesting worst-case bounds to follow.

The main result of this paper is that highly nontrivial worst-case time bounds are indeed available for fully dynamic spanners. We present the first ever algorithms that maintain spanners with essentially optimal size/stretch tradeoff and *polynomially sublinear* (in the number of nodes in the graph) worst-case update time. Our main technique is a very general new framework for boosting the performance of an orientation-based algorithm, which we hope can have applications in related dynamic problems.

1.1 Our results

We obtain fully dynamic algorithms for maintaining spanners of graphs undergoing edge insertions and deletions. In particular, in the unweighted setting we can maintain:

- a 3-spanner of size $O(n^{1+1/2}\log^{1/2} n \log\log n)$ with worst-case update time $O(n^{3/4}\log^4 n)$, or
- a 5-spanner of size $O(n^{1+1/3}\log^{2/3} n \log\log n)$ with worst-case update time $O(n^{5/9}\log^4 n)$, or
- a 5-spanner of size $O(n^{1+1/2}\log^{1/2} n \log\log n)$ with worst-case update time $O(n^{1/2}\log^4 n)$.

Naturally, these results assume that the initial graph is empty; otherwise, a lengthy initialization step is unavoidable.

Using standard techniques, these results can be extended into the setting of arbitrary positive edge weights, at the cost of an increase in the stretch by a factor of $1+\epsilon$ and an increase in the size by a factor of $\log_{1+\epsilon} W$ (for any $\epsilon > 0$, where W is the ratio between the largest and smallest edge weights).

Our algorithms are randomized and correct with high probability against an *oblivious adversary* [12] who chooses its sequence of updates independently from the random choices made by the algorithm.[1] This adversarial model is the same one used in the previous randomized algorithms with amortized update time [10]. Since the girth conjecture has been proven unconditionally for $k = 2$ and $k = 3$ [46], the first two spanners have optimal size/stretch tradeoff (up to the log factor). The third result sacrifices a non-optimal size/stretch tradeoff in exchange for improved update time.

1.2 Technical Contributions

Our main new idea is a general technique for boosting the performance of orientation-based algorithms.

Our algorithm contains three new high-level ideas. First, let $\vec{G}$ be an arbitrary orientation of the input graph G; i.e. replace every undirected edge $\{u, v\}$ by a directed edge, either (u, v) or (v, u). We give an algorithm ALG for maintaining either a 3-spanner or a 5-spanner of G with update time proportional to the maximum *out-degree* of the oriented graph $\vec{G}$. This algorithm is based on the clustering approach used in [11]. For maintaining 3- and 5-spanners we only need to consider clusters of diameter at most 2 consisting of the set of neighbors of certain cluster centers.

This alone is of course not enough, as generally the maximum out-degree of $\vec{G}$ can be as large as $n - 1$. To solve this problem, we combine ALG with the following simple out-degree reduction technique. Partition outgoing edges of every node into at most $t \leq \lceil n/s \rceil$ groups of size at most s each. For any $1 \leq i \leq t$, we combine the edges of the i-th groups and on the corresponding subgraph G_i we run an instance of ALG to maintain a 3-spanner with update time $O(s)$, the maximum out-degree in $\vec{G}_i$. By the decomposability of spanners, the union of all these sub-spanners $H_1 \cup \ldots H_t$ is a 3-spanner of G. In this way we can obtain an algorithm for maintaining a 3-spanner of size $|H_1| + \ldots |H_t| = O(n^{5/2}/s)$ with worst-case update time $O(s)$ for any $1 \leq s \leq n$. We remark that the general technique of partitioning a graph into subgraphs of low out-degree has been used before, e.g. [7]; however, our recursive conversion of these subgraphs into spanners is original and an important technical contribution of this paper.

[1] In particular, this means that the adversary is *not* allowed to see the current edges of the spanner.

The partitioning is still not enough, as the optimal size of a 3-spanner is $O(n^{3/2})$, which would then require $s = \Omega(n)$ worst-case update time. However, we can improve upon this tradeoff once more with a more fine-grained application of ALG. In particular, on each subgraph $\vec{G}_i$, ALG maintains two subgraphs A_i^1 and $\vec{B}_i^1$, such that:

- A_i^1 is a 'partial' 3-spanner of G_i of size $\tilde{O}(n^{1+1/2} \cdot s/n)$, and
- The maximum out-degree in $\vec{B}_i^1$ is considerably smaller than the maximum out-degree in $\vec{G}_i$.

We then recursively apply ALG on $\vec{B}_1^1 \cup \cdots \cup \vec{B}_t^1$ to some depth ℓ at which the out-degree can no longer be reduced by a meaningful amount. Our final spanner is then the union of all the sets A_i^j, for $1 \leq i \leq t$ and $1 \leq j \leq \ell$, as well as the "remainder" graphs $\vec{B}_1^\ell \cup \cdots \cup \vec{B}_t^\ell$, which have low out-degree and are thus sparse.

In principle, the recursive application of ALG could be problematic, as one update in G could lead to several changes to the edges in the B_i^1 subgraphs, which then propagate as an increasing number of updates in the recursive calls of the algorithm. This places another constraint on ALG. We carefully design ALG in such a way that it performs only a constant number of changes to each B_i^1 with any update in G, and we only recurse to depth $\ell = o(\log n)$ so that the total number of changes at each level is subpolynomial.

Overall, we remark that our framework for performing out-degree reduction is fairly generic, and seems likely applicable to other algorithms that admit the design of an ALG with suitable properties. The main technical challenges are designing ALG with these properties, and performing some fairly involved parameter balancing to optimize the running time used by the recursive calls. However, we do not know how to extend our approach to sparser spanners with larger stretches since corresponding constructions usually need clusters of larger diameter and maintaining such clusters with update time proportional to the maximum (out)-degree of the graph seems challenging.

1.3 Other Related Work

There has been some related work attacking the spanner problem in other models of computation. Some of the work on streaming spanner algorithms, in particular [8, 26], was converted into purely *incremental* dynamic algorithms, which maintain spanners under edge insertions but cannot handle deletions. This line of research culminated in an incremental algorithm with worst-case update time $O(1)$ per edge insertion [22]. Elkin [21] also gave a near-optimal algorithm for maintaining spanners in the distributed setting.

A concept closely related to spanners are *emulators* [19], in which the graph H for approximately preserving the distances may contain arbitrary weighted edges and is not necessarily a subgraph of G. Dynamic algorithms for maintaining emulators have been commonly used as subroutines to obtain faster dynamic algorithms for maintaining (approximate) shortest paths or distances. Some of the work on this problem includes [40, 13, 28, 29, 2, 1].

As outlined above, one of the main technical contributions of this paper is a framework for exploiting orientations of undirected graphs. The idea of orienting undirected graphs has been key to many recent advances in dynamic graph algorithms. Examples include [33, 32, 35, 4, 3].

2 Preliminaries

We consider unweighted, undirected graphs $G = (V, E)$ undergoing edge insertions and edge deletions. For all pairs of nodes u and v we denote by $d_G(u, v)$ the distance between u and v in G. An *α-spanner* of a graph $G = (V, E)$ is a subgraph $H = (V, E') \subseteq G$ such that

$d_H(u,v) \leq \alpha \cdot d_G(u,v)$ for all $u, v \in V$.[2] The parameter α is called the *stretch* of the spanner. We will use the well-known fact that it suffices to only span distances over the edges of G.

▶ **Lemma 1** (Spanner Adjacency Lemma (Folklore)). *If $H = (V, E')$ is a subgraph of $G = (V, E)$ that satisfies $d_H(u,v) \leq \alpha \cdot d_G(u,v)$ for all $(u,v) \in E$, then H is an α-spanner of G.*

We will work with *orientations* of undirected graphs. We denote an undirected edge with endpoints u and v by $\{u,v\}$ and a directed edge from u to v by (u,v). An *orientation* $\vec{G} = (V, \vec{E})$ of an undirected graph $G = (V, E)$ is a directed graph on the same set of nodes such that for every edge $\{u,v\}$ of G, $\vec{G}$ either contains the edge (u,v) or the edge (v,u). Conversely, G is the *undirected projection* of $\vec{G}$. In an undirected graph G, we denote by $N(v) := \{w \mid \{v,w\} \in G\}$ the set of neighbors of v. In an oriented graph $\vec{G}$, we denote by $\mathit{Out}(v) := \{w \mid (v,w) \in \vec{G}\}$ the set of outgoing neighbors of v. Similarly, by $\mathit{In}(v) := \{u \mid (u,v) \in \vec{G}\}$ we denote the set of incoming neighbors of v. We denote by $\Delta^+(\vec{G})$ the maximum out-degree of $\vec{G}$.

Our algorithms can easily be extended to graphs with edge weights, via the standard technique of weight binning:

▶ **Lemma 2** (Weight Binning, e.g. [10]). *Suppose there is an algorithm that dynamically maintains a spanner of an arbitrary unweighted graph with some particular size, stretch, and update time. Then for any $\epsilon > 0$, there is an algorithm that dynamically maintains a spanner of an arbitrary graph with positive edge weights, at the cost of an increase in the stretch by a factor of $1 + \epsilon$ and an increase in the update time by a factor of $O(\log_{1+\epsilon} W)$ (and no change in update time). Here, W is the ratio between the largest and smallest edge weight in the graph.*

Since this extension is already well known, we will not discuss it further. Instead, we will simplify the rest of the paper by focusing only on the unweighted setting; that is, all further graphs in this paper are unweighted and undirected.

In our algorithms, we will use the well-known fact that good hitting sets can be obtained by random sampling. This technique was first used in the context of shortest paths by Ullman and Yannakakis [45]. A general lemma on the size of the hitting set can be formulated as follows.

▶ **Lemma 3** (Hitting Sets). *Let $a \geq 1$, let V be a set of size n and let $U_1, U_2, \ldots, U_r$, be subsets of V of size at least q. Let S be a subset of V obtained by choosing each element of V independently at random with probability $p = \min(x/q, 1)$ where $x = a \ln(rn) + 1$. Then, with high probability (whp), i.e. probability at least $1 - 1/n^a$, both the following two properties hold:*

1. *For every $1 \leq i \leq r$, the set S contains a node in U_i, i.e. $U_i \cap S \neq \emptyset$.*
2. *$|S| \leq 3xn/q = O(an \ln(rn)/q)$.*

A well-known property of spanners is *decomposability.* We will exploit this property to run our dynamic algorithm on carefully chosen subgraphs.

▶ **Lemma 4** (Spanner Decomposability, [10]). *Let $G = (V, E)$ be an undirected (possibly weighted) graph, let $E_1, \ldots, E_t$ be a partition of the set of edges E, and let, for every $1 \leq i \leq t$, H_i be an α-spanner of $G_i = (V, E_i)$ for some $\alpha \geq 1$. Then $H = \bigcup_{i=1}^{t} H_i$ is an α-spanner of G.*

[2] If u and v are disconnected in G, then $d_G(u,v) = \infty$ and so they may be disconnected in the spanner as well.

In our algorithms we use a reduction for getting a fully dynamic spanner algorithm for an arbitrarily long sequence of updates from a fully dynamic spanner algorithm that only works for a polynomially bounded number of updates. This is particularly useful for randomized algorithms whose high-probability guarantees are obtained by taking a union bound over a polynomially bounded number of events.

▶ **Lemma 5** (Update Extension, Implicit in [3]). *Assume there is a fully dynamic algorithm for maintaining an α-spanner (for some $\alpha \geq 1$) of size at most $S(m, n, W)$ with worst-case update time $T(m, n, W)$ for up to $4n^2$ updates in G. Then there also is a fully dynamic algorithm for maintaining an α-spanner of size at most $O(S(m, n, W))$ with worst-case update time $O(T(m, n, W))$ for an arbitrary number of updates.*

For completeness, we give the proof of this lemma in an appendix. We remark that is is entirely identical to the one given in [3].

3 Algorithms for Partial Spanner Computation

Our goal in this section is to describe fully dynamic algorithm for *partial* spanner computation. We prove lemmas that can informally be summarized as follows: given a graph G with an orientation $\vec{G}$, one can build a very sparse spanner that only covers the edges leaving nodes with large out-degree in $\vec{G}$. There is a smooth tradeoff between the sparsity of the spanner and the out-degree threshold beyond which edges are spanned.

As a crucial subroutine, our algorithms employ a fully dynamic algorithm for maintaining certain structural information related to a *clustering* of G. We will describe this subroutine first.

3.1 Maintaining a clustering structure

In the spanner literature, a *clustering* of a graph $G = (V, E)$ is a partition of the nodes V into *clusters* $C_1, \dots, C_k$, as well as a “leftover” set of *free* nodes F, with the following properties:

- For each cluster C_i, there exists a “center” node $x_i \in V$ such that all nodes in C_i are adjacent to x_i.
- The free nodes F are precisely the nodes that are not adjacent to any cluster center.

In this paper, we will represent clusterings with a vector c indexed by V, such that for any clustered $v \in V$ we have $c[v]$ equal to its cluster center, and for any free $v \in V$ we use the convention $c[v] = \infty$.

We will use the following subroutine in our main algorithms:

▶ **Lemma 6.** *Given an oriented graph $\vec{G} = (V, \vec{E})$ and a set of cluster centers $S = \{s_1, \dots, s_k\}$, there is a fully dynamic algorithm that simultaneously maintains:*

1. *A clustering c of $G = (V, E)$ with centers S*
2. *For each node v and each cluster index $i \in \{1, \dots, k\}$, the set*

$$In(v, i) := \{u \in In(v) \mid c[u] = i\}$$

(i.e. the incoming neighbors to v from cluster i)

3. *For every pair of cluster indices $i, j \in \{1, \dots, k\}$, the set*

$$In(i, j) := \{(u, v) \in \vec{E} \mid c[u] = j, c[v] = i\}$$

(i.e. the incoming neighbors to cluster i from cluster j).

This algorithm has worst-case update time $O(\Delta^+(\vec{G})\log n)$, where $\Delta^+(\vec{G})$ is the maximum out-degree of $\vec{G}$.

The second $In(v, i)$ sets will be useful for the 3-spanner, while the third $In(i, j)$ sets will be useful for the 5-spanner.

The implementation of this lemma is extremely straightforward; it is not hard to show that the necessary data structures can be maintained in the naive way by simply passing a message along the outgoing edges from u and v whenever an edge (u, v) is inserted or deleted. Due to space constraints, we defer full implementation details and pseudocode to Appendix A.

3.2 Maintaining a partial 3-spanner

We next show how to convert Lemma 6 into a fully dynamic algorithm for maintaining a partial 3-spanner of a graph, as described in the introduction. Specifically:

▶ **Lemma 7.** *For every integer $1 \leq d \leq n$, there is a fully dynamic algorithm that takes an oriented graph $\vec{G} = (V, \vec{E})$ on input and maintains subgraphs $A = (V, E_A), \vec{B} = (V, \vec{E}_B)$ (i.e. $\vec{B}$ is oriented but A is not) over a sequence of $4n^2$ updates with the following properties:*
- *$d_A(u, v) \leq 3$ for every edge $\{u, v\}$ in $E \setminus E_B$*
- *A has size $|A| = O(n^2(\log n)/d + n)$*
- *The maximum out-degree of $\vec{B}$ is $\Delta^+(\vec{B}) \leq d$.*
- *With every update in G, at most 4 edges are changed in $\vec{B}$.*

Further, this algorithm has worst-case update time $O(\Delta^+(\vec{G})\log n)$. The algorithm is randomized, and all of the above properties hold with high probability against an oblivious adversary.

Informally, this lemma states the following. Edges leaving nodes with high out-degree are easy for us to span; we maintain A as a sparse spanner of these edges. Edges leaving nodes with low out-degree are harder for us to span, and we maintain $\vec{B}$ as a collection of these edges.

Note that this lemma is considerably *stronger* than the existence of a 3-spanner. In particular, by setting $d = \sqrt{n \log n}$ and then using $A \cup \vec{B}$ as a spanner of G, we obtain a fully dynamic algorithm for maintaining a 3-spanner:

▶ **Corollary 8.** *There is a fully dynamic algorithm for maintaining a 3-spanner of size $O(n^{1+1/2}\sqrt{\log n})$ for an oriented graph $\vec{G}$ with worst-case update time $O(\Delta^+(\vec{G})\log n)$. The stretch and the size guarantee both hold with high probability against an oblivious adversary.*

The proof is essentially immediate from Lemma 7; we omit it because it is non-essential. The detail of handling only $4n^2$ updates is not necessary in this corollary, due to Lemma 5.

Looking forward, we will wait until Lemma 4 to show precisely how the extra generality in Lemma 7 is useful towards strong worst-case update time. The rest of this subsection is devoted to the proof of Lemma 7.

3.2.1 Algorithm

It will be useful in this algorithm to fix an arbitrary ordering of the nodes in the graph. This allows us to discuss the "smallest" or "largest" node in a list, etc.

We initialize the algorithm by determining a set of cluster centers S via random sampling. Specifically, every node of G is added to S independently with probability $p = \min(x/d, 1)$

where $x = a \ln(4n^5) + 1$ for some error parameter $a \geq 1$. We then use the algorithm of Lemma 6 above to maintain a clustering with $S = \{s_1, \dots, s_k\}$ as the set of cluster centers. The subgraphs A and $\vec{B}$ are defined according to the following three rules:

1. For every clustered node v (i.e. $c[v] \neq \infty$), A contains the edge $\{v, c[v]\}$ from v to its cluster center in S.
2. For every clustered node v (i.e. $c[v] \neq \infty$) and every cluster index $1 \leq i \leq k$, A contains the edge $\{u, v\}$ to the first node $u \in \mathit{In}(v, i)$ (unless $\mathit{In}(v, i) = \emptyset$).
3. For every node u and every node v among the *first* d neighbors of u in $N(u)$ (with respect to an arbitrary fixed ordering of the nodes), $\vec{B}$ contains the edge (u, v). Alternately, if $|N(u)| \leq d$, then $\vec{B}$ contains all such edges (u, v).

We maintain the subgraph $\vec{B}$ in the following straightforward way. For every node u we store $N(u)$, the set of neighbors of u, in two self-balancing binary search trees: $N_{\leq d}(u)$ for the first d neighbors and $N_{>d}(u)$ for the remaining neighbors. Every time an edge (u, v) or an edge (v, u) is inserted into $\vec{G}$, we add v to $N_{\leq d}(u)$ and we add (u, v) to $\vec{B}$. If $N_{\leq d}(u)$ now contains more than d nodes, we remove the largest element v', add it to $N_{>d}(u)$, and remove (u, v') from $\vec{B}$.[3] Similarly, every time an edge (u, v) or an edge (v, u) is deleted from $\vec{G}$, we first check if v is contained in $N_{>d}(u)$ and if so remove it from $N_{>d}(u)$. Otherwise, we first remove v from $N_{\leq d}(u)$ and (u, v) from $\vec{B}$. Then we find the smallest node v' in $N_{>d}(u)$, remove v' from $N_{>d}(u)$, add v' to $N_{\leq d}(u)$, and add (u, v) to $\vec{B}$.

We now explain how to maintain the subgraph A. As an underlying subroutine, we use the algorithm of Lemma 6 to maintain a clustering w.r.t. centers S. On each edge insertion/deletion, we first update the clustering, and then perform the following steps:

1. For every node v for which $c[v]$ has just changed from some center s_i to some other center s_j, we remove the edge $\{v, s_i\}$ from A (if $i \neq \infty$) and add the edge $\{v, s_j\}$ to A (if $j \neq \infty$).
2. For every node u that has been added to $\mathit{In}(v, i)$ for some node v and some $1 \leq i \leq k$, we check if u is now the first node in $\mathit{In}(v, i)$. If so, we add the edge $\{u, v\}$ to A and remove the edge $\{u', v\}$ for the previous first node u' of $\mathit{In}(v, i)$ (if $\mathit{In}(v, i)$ was previously non-empty).
3. For every node u that is removed from $\mathit{In}(v, i)$ for some node v and some $1 \leq i \leq k$, we check if u was the first node in $\mathit{In}(v, i)$ and if so remove the edge $\{u, v\}$ from A and add the edge $\{u', v\}$ for the new first node u' of $\mathit{In}(v, i)$ (if $\mathit{In}(v, i)$ is still non-empty).

3.2.2 Analysis

To bound the update time required by this algorithm, we will argue that we spend $O(\Delta^+(\vec{G}) \log n)$ time per update maintaining A, and $O(\log n)$ time per update maintaining $\vec{B}$ (which, in our applications, is always dominated by $O(\Delta^+(\vec{G}) \log n)$). By Lemma 6, the clustering structure can be updated in time $O(\Delta^+(\vec{G}) \log n)$. Each operation in steps 1, 2, and 3 above can be charged to the corresponding changes in s_i and $\mathit{In}(v, i)$ and thus can also be carried out within the same $O(\Delta^+(\vec{G}) \log n)$ time bound. Updating the subgraph $\vec{B}$ takes time $O(\log n)$, since we must perform a constant number of queries and updates in the corresponding self-balancing binary search trees.

We now show that the subgraphs A and $\vec{B}$ have all of the properties claimed in Lemma 7. First, we will discuss the sparsity bounds on A and $\vec{B}$. Observe that rule 1 contributes at

[3] Note that the node v' that is removed from $N_{\leq d}(u)$ might be the node v we have added in the first place.

most n edges to A, since every node is contained in at most one cluster. Next, recall that the number of cluster centers S is $|S| = k = O(n(\log n)/d)$ (by Lemma 3, with high probability). Thus, A contains only $O(nk) = O(n^2(\log n)/d)$ edges due to rule 2. As the only edges of $\vec{B}$ come from rule 3, the maximum out-degree in $\vec{B}$ is d. The claimed sparsity bounds therefore hold. Furthermore, with every insertion or deletion of an edge $\{u, v\}$ in G, at most one edge is added to or removed from the first d neighbors of u and v, respectively. This implies that there are at most 4 changes to $\vec{B}$ with every update in G. It now only remains to show that A is a 3-spanner of $G \setminus B$.

▶ **Lemma 9.** *For up to $4n^3$ updates, $d_A(u, v) \leq 3$ for every edge $\{u, v\}$ in $E \setminus E_B$ with high probability.*

Proof. Let $\{u, v\}$ be an edge of $E \setminus E_B$. Assume without loss of generality that the edge is oriented from u to v in $\vec{G}$. As $\{u, v\}$ is not contained in B, by rule 3 above we have $|N(u)| > d$. Thus, by Lemma 3, since the cluster centers S were chosen by random sampling, with high probability there exists a cluster center in the first d outgoing neighbors of each node in all of up to $4n^3$ different versions of G (i.e. one version for each of the $4n^3$ updates considered). Therefore $c[u] = i$ for some $1 \leq i \leq k$ and, by rule 1, A contains the edge $\{u, s_i\}$. Since $c[u] = i$, and u is an incoming neighbor of v in $\vec{G}$, we have $In(v, i) \neq \emptyset$, and thus, for the first element u' of $In(v, i)$, A contains the edge $\{u', v\}$ (by rule 2). As $c[u'] = i$, A contains the edge $\{s_i, u'\}$ by rule 1. This means that A contains the edges $\{u, s_i\}$, $\{s_i, u'\}$, and $\{u', v\}$, and thus there is a path from u to v of length 3 in A as desired. ◀

This now also completes the proof of Lemma 7.

3.3 5-spanner

The 5-spanner algorithm is very similar to the 3-spanner algorithm above, but we define the edges of the spanner in a slightly different way. Instead of including an edge from each node to each cluster, we have an edge between each *pair* of clusters. Thus, the subgraphs A and $\vec{B}$ are defined according to the following three rules:

1. For every clustered node v (i.e. $c[v] \neq \infty$), A contains the edge $\{v, c[v]\}$ from v to its cluster center in S.
2. For every pair of distinct cluster indices $1 \leq i, j \leq k$, A contains the edge $\{u, v\}$, where $\{u, v\}$ is the first element in $In(i, j)$ (unless $In(i, j) = \emptyset$).
3. For every node u and every node v among the *first* d neighbors of u in $N(u)$ (with respect to an arbitrary fixed ordering of the nodes), $\vec{B}$ contains the edge (u, v). Alternately, if $|N(u)| \leq d$, then $\vec{B}$ contains all such edges (u, v)..

Beyond this slightly altered definition, we use the same approach for maintaining A and $\vec{B}$ as in the 3-spanner. The guarantee on the stretch can be proved as follows.

▶ **Lemma 10.** *For up to $4n^3$ updates, $d_A(u, v) \leq 5$ for every edge $\{u, v\}$ in $E \setminus E_B$ with high probability.*

Proof. Let $\{u, v\}$ be an edge of $E \setminus E_B$. Assume without loss of generality that the edge is oriented from u to v in $\vec{G}$. As $\{u, v\}$ is not contained in B, by rule 3 above we have $|N(v)| > d$. We now apply Lemma 3 to argue that there is a cluster center in the first d outgoing neighbors of each node in up to $4n^3$ versions of the graph (one version for each update to be considered). Thus, $N(v)$ contains a cluster center from S with high probability. Therefore $c[v] = i$ for some $1 \leq i \leq k$ and, by rule 1, A contains the edge $\{v, s_i\}$. By the same argument, $N(u)$ contains a cluster center from S with high probability and thus A contains an edge $\{u, s_j\}$ where $c[u] = j$ for some $1 \leq j \leq k$. Since $c[v] = i$, $c[u] = j$, and u is an incoming neighbor of v in $\vec{G}$, we have $In(i, j) \neq \emptyset$, and thus, for the first element (u', v') of $In(i, j)$, A contains the edge $\{u', v'\}$ (by rule 2). As $c[v'] = i$, $c[u'] = j$, A contains the edges $\{v', s_i\}$ and $\{u', s_j\}$ by rule 1. This means that A contains the edges $\{u, s_i\}$, $\{s_i, u'\}$, $\{u', v'\}$, $\{v', s_i\}$ and $\{s_i, v\}$, and thus there is a path from u to v of length 5 in A as desired. ◀

Note that in this proof we exploit the fact that we have cluster centers for both u and v whenever the edge $\{u, v\}$ is missing. This motivates our design choice for considering the whole neighborhood of a node to determine its cluster. If we only considered cluster centers in the outgoing neighbors of a node, the resulting clustering would still be good enough for the 3-spanner, but the argument above for the 5-spanner would break down.

All other properties of the 5-spanner can be proved in an essentially identical manner to the 3-spanner. We can summarize the obtained guarantees as follows.

▶ **Lemma 11.** *For every integer $1 \leq d \leq n$, there is a fully dynamic algorithm that takes an oriented graph $\vec{G} = (V, \vec{E})$ on input and maintains subgraphs $A = (V, E_A), \vec{B} = (V, \vec{E}_B)$ (i.e. $\vec{B}$ is oriented but A is not) over a sequence of $4n^2$ updates with the following properties:*

- *$d_A(u, v) \leq 5$ for every edge $\{u, v\}$ in $E \setminus E_B$*
- *A has size $|A| = O((n^2 \log^2 n)/d^2 + n)$*
- *The maximum out-degree of $\vec{B}$ is $\Delta^+(\vec{B}) \leq d$.*
- *With every update in G, at most 4 edges are changed in $\vec{B}$.*

Further, this algorithm has worst-case update time $O(\Delta^+(\vec{G}) \log n)$. The algorithm is randomized, and all of the above properties hold with high probability against an oblivious adversary.

Once again, this lemma generalizes the construction of a sparse 5-spanner. By setting $d = (n \log n)^{2/3}$ we can obtain:

▶ **Corollary 12.** *There is a fully dynamic algorithm for maintaining a 5-spanner of size $O(n^{1+1/3} \log^{2/3} n)$ for an oriented graph $\vec{G}$ with worst-case update time $O(\Delta^+(\vec{G}) \log n)$. The stretch and the size guarantee both hold with high probability against an oblivious adversary.*

4 Out-degree Reduction for Improved Update Time

Our goal is now to use Lemmas 7 and 11 to obtain spanner algorithms with sublinear update time. Since we obtain our 3-spanner and 5-spanner in an essentially identical manner, we will explain only the 3-spanner in full detail, and then sketch the 5-spanner construction.

We next establish the following simple generalization of Lemma 7:

▶ **Lemma 13.** *For every integer $1 \leq s \leq n$ and $1 \leq d \leq n$, there is a fully dynamic algorithm that takes an oriented graph $\vec{G} = (V, \vec{E})$ on input and maintains subgraphs $A = (V, E_A), \vec{B} = (V, \vec{E}_B)$ (i.e. $\vec{B}$ is oriented but A is not) over a sequence of $4n^2$ updates with the following properties:*

- *$d_A(u, v) \leq 3$ for every edge $\{u, v\}$ in $E \setminus E_B$*
- *A has size $|A| = O(\Delta^+(\vec{G}) n^2 (\log n)/(sd))$*
- *The maximum out-degree of $\vec{B}$ is $\Delta^+(\vec{B}) \leq \Delta^+(\vec{G}) \cdot d/s$.*
- *With every update in G, at most 4 edges are changed in $\vec{B}$.*

Further, this algorithm has worst-case update time $O(s \log n)$. The algorithm is randomized, and all of the above properties hold with high probability against an oblivious adversary.

In particular, Lemma 7 is the special case of this lemma in which $s = \Delta^+(\vec{G})$.

Proof. We orient each incoming edge of G in an arbitrary way. We then maintain a partitioning of the (oriented) edges of G into $t := \lceil \Delta^+(\vec{G})/s \rceil$ groups, such that in each group each node has at most s outgoing edges. Specifically, we perform this partitioning by maintaining the current out-degree of each node u in $\vec{G}$, and we assign a new edge (u, v) which is the x^{th} edge leaving u in $\vec{G}$ to the subgraph $\vec{G}_{\lceil x/s \rceil}$. In this way, we form t subgraphs $\vec{G}_1, \dots \vec{G}_t$ of $\vec{G}$, each of which has $\Delta^+(\vec{G}_i) \leq s$.

We now run the algorithm of Lemma 7 on each $\vec{G}_i$ to maintain, for each $1 \leq i \leq t$, two subgraphs A_i and $\vec{B}_i$ as specified in the lemma. Let $A = \bigcup A_i$ and $\vec{B} = \bigcup \vec{B}_i$ denote the unions of these subgraphs.

Observe that every update in G only changes exactly one of the subgraphs $\vec{G}_i$ and thus only must be executed in one corresponding instance of the algorithm of Lemma 7. As we have "artificially" bounded the maximum out-degree of every subgraph $\vec{G}_i$ by s, the claimed bounds on the update time and the properties of A and $\vec{B}$ now follow simply from Lemma 7. ◀

We now recursively apply the "out-degree reduction" of the previous lemma to obtain subgraphs $\vec{B}$ of smaller and smaller out-degree. Finally, at bottom level, the maximum out-degree is small enough that we can apply a "regular" spanner algorithm to it.

▶ **Theorem 14.** *There is a fully dynamic algorithm for maintaining a 3-spanner of size $O(n^{1+1/2} \log^{1/2} n \log \log n)$ with worst-case update time $O(n^{3/4} \log^4 n)$.*

Proof. Our spanner construction is as follows (we temporarily omit details related to parameter choices, which influence the resulting update time). Apply Lemma 13 to obtain subgraphs $A_1, \vec{B}_1$. Include all edges in A in the spanner, and then recursively apply Lemma 13 to $\vec{B}$ to obtain $A_2, \vec{B}_2$. Repeat to depth ℓ (for some parameter ℓ that will be chosen later). At bottom level, instead of recursing, we apply the algorithm from Corollary 8 to obtain a 3-spanner of $\vec{B}$.

More formally, we set $\vec{B}_0 = \vec{G}_0$, and for every $1 \leq j \leq \ell$ we let A_j and $\vec{B}_j$ be the graphs maintained by the algorithm of Lemma 13 on input $\vec{B}_{j-1}$ using parameters s and d_j to be chosen later.[4] Further, we let H' be the spanner maintained by the algorithm of Corollary 8 on input $\vec{B}_\ell$. The resulting graph maintained by our algorithm is $H = \bigcup_{1 \leq j \leq \ell} A_j \cup H'$. Then, by Lemma 13, we have the following properties for every $1 \leq j \leq \ell$:

- $d_{A_j}(u, v) \leq 3$ for every edge $\{u, v\}$ in $B_{j-1} \setminus B_j$
- A_j has size $|A_j| = O(\Delta^+(\vec{B}_{j-1}) n^2 (\log n)/(s d_j))$
- The maximum out-degree of $\vec{B}_j$ is $\Delta^+(\vec{B}_j) \leq \Delta^+(\vec{B}_{j-1}) \cdot d_j/s$.
- With every update in $\vec{B}_{j-1}$, at most 4 edges are changed in $\vec{B}_j$.

It is straightforward to see that the resulting graph H is a 3-spanner of G: At each level j of the recursion, A_j spans all edges of B_{j-1} *except* those that appear in the current subgraph $\vec{B}_j$. Thus, at bottom level, the only non-spanned edges of G are those in the final subgraph $\vec{B}_\ell$. For these edges we explicitly add a 3-spanner H' of $\vec{B}_\ell$ to H. By Lemma 1, this suffices to produce a 3-spanner of all of G.

Now that we have correctness of the construction, it remains to bound the number of edges in the output spanner. First, observe that, by induction,

$$\Delta^+(\vec{B}_j) \leq n \cdot \prod_{1 \leq j' \leq j} d_{j'}/s^j$$

[4] Note that the parameter s is the same for all levels of the recursion, whereas the parameter d_j is not.

for all $1 \leq j \leq \ell$. Since additionally H' has size $O(n^{1+1/2}\log^{1/2} n)$ by Corollary 8, the total number of edges in H is

$$|H| = \sum_{1\leq j\leq \ell} |A_j| + |H'| \leq \sum_{1\leq j\leq \ell} O\left(\frac{\Delta^+(B_{j-1})n^2\log n}{sd_j}\right) + O(n^{1+1/2}\log^{1/2} n)$$
$$\leq \sum_{1\leq j\leq \ell} O\left(\frac{\left(\prod_{1\leq j'\leq j-1} d_{j'}\right) n^3 \log n}{s^j d_j}\right) + O(n^{1+1/2}\log^{1/2} n)\,.$$

Thus, our spanner satisfies the claimed sparsity bound so long as the union of all ℓ of the A_j subgraphs fit within the claimed sparsity bound; this will be the case if we balance all summands.

We next bound the update time of our algorithm. Each change to some $\vec{B}_j$ causes at most 4 changes in the next level $\vec{B}_{j+1}$, and thus the number of changes to $\vec{B}_j$ can propagate exponentially. Thus, for every $0 \leq j \leq \ell - 1$, a single update in $\vec{G}$ could cause at most 4^j changes to $\vec{B}_j$. Each of the ℓ instances of the algorithm of Lemma 13 has a worst-case update time of $O(s\log n)$ and the algorithm of Corollary 8 has a worst-case update time of $\Delta^+(\vec{B}_\ell \log n)$. Since

$$\Delta^+(\vec{B}_\ell) \leq n \cdot \prod_{1\leq j\leq \ell} d_j/s^\ell$$

the worst-case update time of our overall algorithm is

$$O\left(\left(\sum_{j=0}^{\ell-1} 4^j s + 4^\ell \Delta^+(\vec{B}_\ell)\right)\cdot \log n\right) \leq O\left(\left(s + \frac{n\cdot \prod_{1\leq j\leq \ell} d_j}{s^\ell}\right)\cdot 4^\ell \log n\right)\,.$$

Our goal is now to choose parameters s_j, d, ℓ to minimize this expression subject to the constraint on spanner size given above. To achieve this, we set parameters as follows:

$$\begin{aligned} \ell &= \log\log n\,, \\ s &= n^{(3\cdot 2^\ell - 1)/(2^{\ell+2}-2)}\log n\,,\ \text{and} \\ d_j &= n^{(3\cdot 2^\ell - 2^{j-1} - 1)/(2^{\ell+2}-2)}\log n\,. \end{aligned}$$

These values were obtained with the help of a computer algebra solver, so we do not have explicit computations to show for them. ◀

We now turn our attention to the 5-spanner. Similar to Lemma 13 above, we can use Lemma 11 to perform a similar out-degree reduction step for our dynamic 5-spanner algorithm.

▶ **Lemma 15.** *For every integer $1 \leq s \leq n$ and $1 \leq d \leq n$, there is a fully dynamic algorithm that takes an oriented graph $\vec{G} = (V, \vec{E})$ on input and maintains subgraphs $A = (V, E_A), \vec{B} = (V, \vec{E}_B)$ (i.e. $\vec{B}$ is oriented but A is not) over a sequence of $4n^2$ updates with the following properties:*

- *$d_A(u, v) \leq 5$ for every edge $\{u, v\}$ in $E \setminus E_B$*
- *A has size $|A| = O(\Delta^+(\vec{G})n^2(\log^2 n)/(sd^2))$*
- *The maximum out-degree of $\vec{B}$ is $\Delta^+(\vec{B}) \leq \Delta^+(\vec{G})\cdot d/s$.*
- *With every update in G, at most 4 edges are changed in $\vec{B}$.*

Further, this algorithm has worst-case update time $O(s \log n)$. The algorithm is randomized, and all of the above properties hold with high probability against an oblivious adversary.

The proof of this lemma is essentially identical to the proof of Lemma 13 and has thus been omitted.

Just as in the case of the 3-spanner, we use this lemma to show:

▶ **Theorem 16.** *There is a fully dynamic algorithm for maintaining a 5-spanner of size $O(n^{1+1/3} \log^{2/3} n \log\log n)$ with worst-case update time $O(n^{5/9} \log^4 n)$.*

Proof. The proof is identical to the proof of Theorem 14, except that the proper parameter balance is now:

$$\begin{aligned} \ell &= \log\log n\,, \\ s &= n^{(5\cdot 3^{\ell} - 2^{\ell+1})/(3^{\ell+2} - 3\cdot 2^{\ell+1})} \log n\,, \text{ and} \\ d_j &= n^{(5\cdot 3^{\ell} - 3^{j-1} 2^{\ell-j+2} - 2^{\ell+1})/(3^{\ell+2} - 3\cdot 2^{\ell+1})} \log n\,. \end{aligned}$$

◀

Finally, we can also show:

▶ **Theorem 17.** *There is a fully dynamic algorithm for maintaining a 5-spanner of size $O(n^{1+1/2} \log^{1/2} n \log\log n)$ with worst-case update time $O(n^{1/2} \log^4 n)$.*

Proof. The proof is identical to the proof of Theorems 14 and 16, except that we now use the parameter balance

$$\begin{aligned} \ell &= \log\log n\,, \\ s &= n^{(3^{\ell+1} - 2^{\ell})/(2\cdot 3^{\ell+1} - 2^{\ell+2})} \log n\,, \text{ and} \\ d_j &= n^{(3^{\ell+1} - 3^{j}\cdot 2^{\ell-j} - 2^{\ell})/(2\cdot 3^{\ell+1} - 2^{\ell+2})} \log n\,. \end{aligned}$$

and we maintain the dynamic 3-spanner H' of size $O(n^{1+1/2} \log^{1/2} n)$ from Corollary 12 at bottom level. ◀

This spanner has non-optimal size/stretch tradeoff, but enjoys the best worst-case update time that we are currently able to construct.

Acknowledgements. We want to thank Seeun William Umboh for many fruitful discussions at Simons.

A Updating the Clustering

In the following we give the straightforward algorithm for maintaining the clustering with worst-case update time proportional to the maximum out-degree of the original graph mentioned in Section 3.1. To make the presentation of this algorithm more succinct we assume that there is some (arbitrary, but fixed) ordering on the nodes. Furthermore, we assume that the nodes of S are given according to this order, i.e. $s_1 \leq s_2 \leq \cdots \leq s_k$. For every node v, we maintain $c[v]$ as the smallest i such that s_i is a neighbor of v (or ∞ if no such neighbor exists). Additionally, we naturally extend the sets $In(v, i)$ and $In(i, j)$ to the case $i, j \in \{1, \ldots, k, \infty\}$.

We begin with an empty graph $G = (V, \emptyset)$, a cluster vector c with $c[v] = \infty$ for all $v \in V$, and empty sets $In(i, j)$ and $In(i, v)$ for all cluster indices $1 \leq i, j \leq k$ and $v \in V$. We then modify these data structures under edge insertions and deletions as follows.

Correctness of the algorithms that follow is immediate, and is not shown formally.

A.1 Insertion of an edge (u, v)

- Add u to $In(v, i)$ for $i = c[u]$.
- Add (u, v) to $In(j, i)$ for $i = c[u]$ and $j = c[v]$
- If $u = s_i$ for some $1 \leq i \leq k$:
  - Set $j = c[v]$ (might be ∞)
  - Add u to $C[v]$.
  - If $i < j$:
    * Set $c[v] = i$
    * For every outgoing neighbor v' of v:
      Remove v from $In(v', j)$ and add v to $In(v', i)$.
      Remove (v, v') from $In(i', j)$ and add (v, v') to $In(i', i)$ where $i' = c[v']$.
- If $v = s_i$ for some $1 \leq i \leq k$:
  - Set $j = c[u]$ (might be ∞)
  - Add v to $C[u]$.

  - If $i < j$:
    * Set $c[u] = i$
    * For every outgoing neighbor v' of u:
      Remove u from $In(v', j)$ and add u to $In(v', i)$.
      Remove (u, v') from $In(i', j)$ and add (u, v') to $In(i', i)$ where $i' = c[v']$.

A.2 Deletion of an edge (u, v):

- Remove u from $In(v, i)$ for $i = c[u]$.
- Remove (u, v) from $In(j, i)$ for $i = c[u]$ and $j = c[v]$
- If $u = s_i$ for some $1 \leq i \leq k$:
  - Remove u from $C[v]$.
  - If $c[v] = s_i$:
    * Let j be minimal such that s_j is in $C[v]$ (might be ∞)
    * Set $c[v] = j$
    * For every outgoing neighbor v' of v:
      Remove v from $In(v', i)$ and add v to $In(v', j)$.
      Remove (v, v') from $In(i', j)$ and add (v, v') to $In(i', i)$ where $i' = c[v']$
- If $v = s_i$ for some $1 \leq i \leq k$:
  - Remove v from $C[u]$.
  - If $c[u] = s_i$:
    * Let j be minimal such that s_j is in $C[u]$ (might be ∞)
    * Set $c[u] = j$
    * For every outgoing neighbor v' of u:
      Remove u from $In(v', i)$ and add u to $In(v', j)$.
      Remove (u, v') from $In(i', j)$ and add (u, v') to $In(i', i)$ where $i' = c[v']$

B Proof of Lemma 5

We exploit the decomposability of spanners. We maintain a partition of G into two disjoint subgraphs G_1 and G_2 and run two instances A_1 and A_2 of the dynamic algorithm on G_1 and G_2, respectively. These two algorithms maintain a t-spanner of H_1 of G_1 and a t-spanner H_2 of G_2. By Lemma 4, the union $H = H_1 \cup H_2$ is a t-spanner of $G = G_1 \cup G_2$.

We divide the sequence of updates into phases of length n^2 each. In each phase of updates one of the two instances A_1, A_2 is in the state *growing* and the other one is in the state *shrinking*. A_1 and A_2 switch their states at the end of each phase. In the following we describe the algorithm's actions during one phase. Assume without loss of generality that, in the phase we are fixing, A_1 is growing and A_2 is shrinking.

At the beginning of the phase we restart the growing instance A_1. We will orchestrate the algorithm in such a way that at the beginning of the phase G_1 is the empty graph and $G_2 = G$. After every update in G we execute the following steps:

1. If the update was the insertion of some edge e, then e is added to the graph G_1 and this insertion is propagated to the *growing* instance A_1.
2. If the update was the deletion of some edge e, then e is removed from the graph G_i it is contained in and this deletion is propagated to the corresponding instance A_i.
3. In addition to processing the update in G, if G_2 is non-empty, then one arbitrary edge e is first removed from G_2 and deleted from instance A_2 and then added to G_1 and inserted into instance A_1.

Observe that these rules indeed guarantee that G_1 and G_2 are disjoint and together contain all edges of G. Furthermore, since the graph G_2 of the shrinking instance has at most n^2 edges at the beginning of the phase, the length of n^2 updates per phase guarantees that G_2 is empty at the end of the phase. Thus, the growing instance always starts with an empty graph G_1.

As both H_1 and H_2 have size at most $S(n, m, W)$, the size of $H = H_1 \cup H_2$ is $O(S(n, m, W))$. With every update in G we perform at most 2 updates in each of A_1 and A_2. It follows that the worst-case update time of our overall algorithm is $O(T(m, n, W))$. Furthermore since each of the instances A_1 and A_2 is restarted every other phase, each instance of the dynamic algorithm sees at most $4n^2$ updates before it is restarted.

Fixed-Parameter Approximability of Boolean MinCSPs[*]

Abstract

The minimum unsatisfiability version of a constraint satisfaction problem (MinCSP) asks for an assignment where the number of unsatisfied constraints is minimum possible, or equivalently, asks for a minimum-size set of constraints whose deletion makes the instance satisfiable. For a finite set Γ of constraints, we denote by MinCSP(Γ) the restriction of the problem where each constraint is from Γ. The polynomial-time solvability and the polynomial-time approximability of MinCSP(Γ) were fully characterized by Khanna et al. [33]. Here we study the fixed-parameter (FP-) approximability of the problem: given an instance and an integer k, one has to find a solution of size at most $g(k)$ in time $f(k) \cdot n^{O(1)}$ if a solution of size at most k exists. We especially focus on the case of constant-factor FP-approximability. Our main result classifies each finite constraint language Γ into one of three classes: (1) MinCSP(Γ) has a constant-factor FP-approximation; (2) MinCSP(Γ) has a (constant-factor) FP-approximation if and only if Nearest Codeword has a (constant-factor) FP-approximation; (3) MinCSP(Γ) has no FP-approximation, unless FPT = W[P]. We show that problems in the second class do not have constant-factor FP-approximations if both the Exponential-Time Hypothesis (ETH) and the Linear PCP Conjecture (LPC) hold. We also show that such an approximation would imply the existence of an FP-approximation for the k-Densest Subgraph problem with ratio $1 - \epsilon$ for any $\epsilon > 0$.

1 Introduction

Satisfiability problems and, more generally, Boolean constraint satisfaction problems (CSPs) are basic algorithmic problems arising in various theoretical and applied contexts. An instance of a Boolean CSP consists of a set of Boolean variables and a set of constraints; each

[†] The second author was supported by NSERC.

constraint restricts the allowed combination of values that can appear on a certain subset of variables. In the decision version of the problem, the goal is to find an assignment that simultaneously satisfies every constraint. One can also define optimization versions of CSPs: the goal can be to find an assignment that maximizes the number of satisfied constraints, minimizes the number of unsatisfied constraints, maximizes/minimizes the weight (number of 1s) of the assignment, etc. [19].

Since these problems are usually NP-hard in their full generality, a well-established line of research is to investigate how the complexity of the problem changes for restricted versions of the problem. A large body of research deals with language-based restrictions: given any finite set Γ of Boolean constraints, one can consider the special case where each constraint is restricted to be a member of Γ. The ultimate research goal of this approach is to prove a *dichotomy theorem*: a complete classification result that specifies for each finite constraint set Γ whether the restriction to Γ yields and easy or hard problem. Numerous classification theorems of this form have been proved for various decision and optimization versions for Boolean and non-Boolean CSPs [46, 13, 10, 11, 9, 12, 8, 26, 32, 34, 47, 38]. In particular, for MinCSP(Γ), which is the optimization problem asking for an assignment minimizing the number of unsatisfied constraints, Creignou et al. [19] obtained a classification of the approximability for every finite Boolean constraint language Γ. The goal of this paper is to characterize the approximability of Boolean MinCSP(Γ) with respect to the more relaxed notion of fixed-parameter approximability.

Parameterized complexity [27, 29, 23] analyzes the running time of a computational problem not as a univariate function of the input size n, but as a function of both the input size n and a relevant parameter k of the input. For example, given a MinCSP instance of size n where we are looking for a solution satisfying all but k of the constraints, it is natural to analyze the running time of the problem as a function of both n and k. We say that a problem with parameter k is *fixed-parameter tractable (FPT)* if it can be solved in time $f(k) \cdot n^{O(1)}$ for some computable function f depending only on k. Intuitively, even if f is, say, an exponential function, this means that problem instances with “small” k can be solved efficiently, as the combinatorial explosion can be confined to the parameter k. This can be contrasted with algorithms with running time of the form $n^{O(k)}$ that are highly inefficient even for small values of k. There are hundreds of parameterized problems where brute force gives trivial $n^{O(k)}$ algorithms, but the problem can be shown to be FPT using nontrivial techniques; see the recent textbooks by Downey and Fellows [27] and by Cygan et al. [23]. In particular, there are fixed-parameter tractability results and characterization theorems for various CSPs [38, 13, 35, 36].

The notion of fixed-parameter tractability has been combined with the notion of approximability [16, 17, 28, 14, 18]. Following [16, 39], we say that a minimization problem is *fixed-parameter approximable (FPA)* if there is an algorithm that, given an instance and an integer k, in time $f_1(k) \cdot n^{O(1)}$ either returns a solution of cost at most $f_2(k) \cdot k$, or correctly states that there is no solution of cost at most k. The two crucial differences compared to the usual setup of polynomial-time approximation is that (1) the running time is not polynomial, but can have an arbitrary factor $f(k)$ depending only on k and (2) the approximation ratio is defined not as a function of the input size n but as a function of k. In this paper, we mostly focus on the case of constant-factor FPA, that is, when $f_2(k) = c$ for some constant c.

Schaefer’s Dichotomy Theorem [46] identified six classes of finite Boolean constraint languages (0-valid, 1-valid, Horn, dual-Horn, bijunctive, affine) for which the decision CSP is polynomial-time solvable, and shows that every language Γ outside these classes yields NP-hard problems. Therefore, one has to study MinCSP only within these six classes, as it is otherwise already NP-hard to decide if the optimum is 0 or not, making approximation or fixed-parameter tractability irrelevant. Within these classes, polynomial-time approximability and fixed-parameter tractability seem to appear in orthogonal ways: the classes where we have positive results for one approach is very different from the classes where the other approach helps. For example, 2CNF Deletion (also called Almost 2SAT) is fixed-parameter tractable [45, 37], but has no polynomial-time approximation algorithm with constant approximation ratio, assuming the Unique Games Conjecture [15]. On the other hand, if Γ consists of the three constraints (x), $(\bar{x})$, and $(a \to b) \wedge (c \to d)$, then the problem is W[1]-hard [41], but belongs to the class IHS-B[1] and hence admits a constant-factor approximation in polynomial time [33].

By investigating constant-factor FP-approximation, we are identifying a class of tractable constraints that unifies and generalizes the polynomial-time constant-factor approximable and fixed-parameter tractable cases. We observe that if each constraint in Γ can be expressed by a 2SAT formula (i.e., Γ is bijunctive), then we can treat the MinCSP instance as an instance of 2SAT Deletion, at the cost of a constant-factor loss in the approximation ratio. Thus the fixed-parameter tractability of 2SAT Deletion implies MinCSP has a constant-factor FP-approximation if the finite set Γ is bijunctive. If Γ is in IHS-B, then MinCSP is known to have a constant-factor approximation in polynomial time, which clearly gives another class of constant-factor FP-approximable constraints. Our main results show that probably these two classes cover all the easy cases with respect to FP-approximation (see Section 2 for the definitions involving properties of constraints).

▶ **Theorem 1.** *Let Γ be a finite Boolean constraint language.*
1. *If Γ is bijunctive or IHS-B, then* MinCSP(Γ) *has a constant-factor FP-approximation.*
2. *Otherwise, if Γ is affine, then* MinCSP(Γ) *has an FP-approximation (resp., constant-factor FP-approximation) if and only if* Nearest Codeword *has an FP-approximation (resp., constant-factor FP-approximation).*
3. *Otherwise,* MinCSP(Γ) *has no fixed-parameter approximation, unless* FPT = W[P].

Given a linear code over $GF[2]$ and a vector, the Nearest Codeword (NC) problem asks for a codeword in the code that has minimum Hamming distance to the given vector. There are various equivalent formulations of this problem: Odd Set is a variant of Hitting Set where one has to select at most k elements to hit each set exactly an odd number of times, and it is also possible to express the problem as finding a solution to a system of linear equations over $GF[2]$ that minimizes the number of unsatisfied equations. Arora et al. [2] showed that, assuming NP $\not\subseteq$ DTIME($n^{\text{polylog}\, n}$), it is not possible to approximate NC within ratio $2^{\log^{1-\epsilon} n}$ for any $\epsilon > 0$. In particular, this implies that a constant-factor polynomial-time approximation is unlikely. We give some evidence that even constant-factor FP-approximation is unlikely. First, we rule out this possibility under the assumption that the Linear PCP Conjecture (LPC) and the Exponential-Time Hypothesis (ETH) both hold.

▶ **Theorem 2.** *Assuming LPC and ETH, for any constant r,* NC *has no factor-r FP-approximation.*

Second, we connect the FP-approximability of NC with the k-Densest Subgraph problem, where the task is to find k vertices that induce the maximum number of edges.

▶ **Theorem 3.** *If* NC *has a factor-r FP-approximation for some constant r, then for every $\epsilon > 0$, there is a factor-$(1-\epsilon)$ FP-approximation for k-*Densest Subgraph.

[1] IHS-B stands for Implicative Hitting Set-Bounded, see definition in Section 2.

Thus a constant-factor FP-approximation for NC implies that k-DENSEST SUBGRAPH can be approximated arbitrarily well, which seems unlikely. Note that Theorems 2 and 3 remain valid for the other equivalent versions of NC, such as ODD SET. These theorems form the technically more involved parts of the paper.

Post's lattice is a very useful tool for classifying the complexity of Boolean CSPs (see e.g., [1, 20, 3]). A (possibly infinite) set Γ of constraints is a co-clone if it is closed under pp-definitions, that is, whenever a relation R can be expressed by relations in Γ using only equality, conjunctions, and projections, then relation R is already in Γ. Post's co-clone lattice characterizes every possible co-clone of Boolean constraints. From the complexity-theoretic point of view, Post's lattice becomes very relevant if the complexity of the CSP problem under study does not change by adding new pp-definable relations to the set Γ of allowed relations. For example, this is true for the decision version of Boolean CSP. In this case, it is sufficient to determine the complexity for each co-clone in the lattice, and a complete classification for every finite set Γ of constraints follows. For MINCSP, neither the polynomial-time solvability nor the fixed-parameter tractability of the problem is closed under pp-definitions, hence Post's lattice cannot be used directly to obtain a complexity classification. However, as observed by Khanna et al. [33] and subsequently exploited by Dalmau et al. [24, 25], the constant-factor approximability of MINCSP is closed under pp-definitions (modulo a small technicality related to equality constraints). We observe that the same holds for constant-factor FP-approximability and hence Post's lattice can be used for our purposes. Thus, the classification result amounts to identifying the maximal easy and the minimal hard co-clones.

The paper is organized as follows. Sections 2 and 3 contain preliminaries on CSPs, approximability, Post's lattice, and reductions. A more technical restatement of Theorem 1 in terms of co-clones is stated at the end of Section 3. Section 4 gives FPA algorithms, Section 5 establishes the equivalence of some CSPs with ODD SET, and Section 6 proves inapproximability results for CSPs. Section 7 proves Theorems 2 and 3, the conditional hardness results for ODD SET. Due to space restrictions, less difficult proofs appear only in the arxiv version [6].

2 Preliminaries

A subset R of $\{0,1\}^n$ is called an n-ary *Boolean relation.* If $n = 2$, relation R is *binary.* In this paper, a *constraint language* Γ is a finite collection of finitary Boolean relations. When a constraint language Γ contains only a single relation R, i.e., $\Gamma = \{R\}$, we write R instead of $\{R\}$. The decision version of CSP, restricted to finite constraint language Γ is defined as:

CSP(Γ)
Input: A pair $\langle V, \mathcal{C}\rangle$, where
- V is a set of variables,
- $\mathcal{C}$ is a multiset of constraints $\{C_1, \dots, C_q\}$, i.e., $C_i = \langle s_i, R_i\rangle$, where s_i is a tuple of variables of length n_i, and $R_i \in \Gamma$ is an n_i-ary relation.

Question: Does there exist a solution, that is, a function $\varphi : V \to \{0,1\}$ such that for each constraint $\langle s, R\rangle \in \mathcal{C}$, with $s = \langle v_1, \dots, v_n\rangle$, the tuple $\varphi(v_1), \dots, \varphi(v_n)$ belongs to R?

Note that we can alternatively look at a constraint as a Boolean function $f : \{0,1\}^n \to \{0,1\}$, where n is a non-negative integer called the arity of f. We say that f is satisfied by an assignment $s \in \{0,1\}^n$ if $f(s) = 1$. For example, if $f(x, y) = x + y \mod 2$, then the corresponding relation is $\{(0,1), (1,0)\}$; we also denote addition modulo 2 with $x \oplus y$.

We recall the definition of a few well-known classes of constraint languages. A Boolean constraint language Γ is:

- *0-valid* (*1-valid*), if each $R \in \Gamma$ contains a tuple in which all entries are 0 (1);
- *k-IHS-B+* (*k-IHS-B–*), where $k \in \mathbb{Z}^+$, if each $R \in \Gamma$ can be expressed by a conjunction of clauses of the form $\neg x$, $\neg x \vee y$, or $x_1 \vee \cdots \vee x_k$ (x, $\neg x \vee y$, $\neg x_1 \vee \cdots \vee \neg x_k$); *IHS-B+* (*IHS-B–*) stands for k-IHS-B+ (k-IHS-B–) for some k; *IHS-B* stands for IHS-B+ or IHS-B–;
- *bijunctive*, if each $R \in \Gamma$ can be expressed by a conjunction of binary clauses;
- *Horn* (*dual-Horn*), if each $R \in \Gamma$ can be expressed by a conjunction of Horn (dual-Horn) clauses, i.e., clauses that have at most one positive (negative) literal;
- *affine*, if each relation $R \in \Gamma$ can be expressed by a conjunction of relations defined by equations of the form $x_1 \oplus \cdots \oplus x_n = c$, where $c \in \{0, 1\}$;
- *self-dual* if for each relation $R \in \Gamma$, $(a_1, \ldots, a_n) \in R \Rightarrow (\neg a_1, \ldots, \neg a_n) \in R$.

MinCSP(Γ)
Input: An instance $\langle V, \mathcal{C} \rangle$ of CSP(Γ), and an integer k.
Question: Is there a deletion set $W \subseteq \mathcal{C}$ such that $|W| \leq k$, and the CSP(Γ)-instance $\langle V, \mathcal{C} \setminus W \rangle$ has a solution?

MinCSP*(Γ)
Input: An instance $\langle V, \mathcal{C} \rangle$ of CSP(Γ), a subset $\mathcal{C}^* \subseteq \mathcal{C}$ of undeletable constraints, and an integer k.
Question: Is there a deletion set $W \subseteq \mathcal{C} \setminus \mathcal{C}^*$ such that $|W| \leq k$ and the CSP(Γ)-instance $\langle V, \mathcal{C} \setminus W \rangle$ has a solution?

For every finite constraint language Γ, we consider the problem MinCSP above. For technical reasons, it will be convenient to work with a slight generalization of the problem, MinCSP*(defined above), where we can specify that certain constraints are "undeletable." For these two problems, a set of potentially more than k constraints whose removal yields a satisfiable instance is called a *feasible solution*. Note that, contrary to MinCSP for which removing all the constraints constitute a trivially feasible solution, it is possible that an instance of MinCSP* has no feasible solution. A *feasible instance* is an instance that admits at least one feasible solution. We will use two types of reductions to connect the approximability of optimization problems. The first type perfectly preserves the optimum value (or cost) of instances.

▶ **Definition 4.** An optimization problem A has a *cost-preserving reduction* to problem B if there are two polynomial-time computable functions F and G such that

1. For any feasible instance I of A, $F(I)$ is a feasible instance of B having the same optimum cost as I.
2. For any feasible instance I of A, if S' is a feasible solution for $F(I)$, then $G(I, S')$ is a feasible solution of I having cost at most the cost of $F(I)$.

The following easy lemma shows that the existence of undeletable constraints does not make the problem significantly more general. Note that, in the previous definition, if instance I has no feasible solution, then the behavior of F on I is not defined.

▶ **Lemma 5.** *There is a cost-preserving reduction from* MinCSP* *to* MinCSP.

The second type of reduction that we use is the standard notion of A-reductions [21], which preserve approximation ratios up to constant factors. We slightly deviate from the standard definition by not requiring any specific behavior of F when I has no feasible solution.

▶ **Definition 6.** A minimization problem A is *A-reducible* to problem B if there are two polynomial-time computable functions F and G and a constant α such that

1. For any feasible instance I of A, $F(I)$ is a feasible instance of B.
2. For any feasible instance I of A, and any feasible solution S' of $F(I)$, $G(I, S')$ is a feasible solution for I.
3. For any feasible instance I of A, and any $r \geq 1$, if S' is an r-approximate feasible solution for $F(I)$, then $G(I, S')$ is an (αr)-approximate feasible solution for I.

▶ **Proposition 7.** *If optimization problem A is A-reducible to optimization problem B and B admits a constant-factor FPA algorithm, then A also has a constant-factor FPA algorithm.*

3 Post's lattice, co-clone lattice, and a simple reduction

A *clone* is a set of Boolean functions that contains all projections (that is, the functions $f(a_1, \ldots, a_n) = a_k$ for $1 \leq k \leq n$) and is closed under arbitrary composition. *All* clones of Boolean functions were identified by Post [44], and he also described their inclusion structure, hence the name Post's lattice. To make use of this lattice for CSPs, Post's lattice can be transformed to another lattice whose elements are not sets of functions closed under composition, but sets of relations closed under the following notion of definability.

▶ **Definition 8.** Let Γ be a constraint language over some domain A. We say that a relation R is *pp-definable* from Γ if there exists a (primitive positive) formula $\varphi(x_1, \ldots, x_k) \equiv \exists y_1, \ldots, y_l \psi(x_1, \ldots, x_k, y_1, \ldots, y_l)$, where ψ is a conjunction of atomic formulas with relations in Γ and EQ_A (the binary relation $\{(a, a) : a \in A\}$) such that for every $(a_1, \ldots, a_k) \in A^k$ $(a_1, \ldots, a_k) \in R$ if and only if $\varphi(a_1, \ldots, a_k)$ holds. If ψ does not contain EQ_A, then we say that R is *pp-definable* from Γ *without equality*. For brevity, we often write "$\exists\wedge$-definable" instead of "pp-definable without equality". If S is a set of relations, S is *pp-definable* ($\exists\wedge$-definable) from Γ if every relation in S is *pp*-definable ($\exists\wedge$-definable) from Γ.

For a set of relations Γ, we denote by $\langle\Gamma\rangle$ the set of all relations that can be pp-defined over Γ. We refer to $\langle\Gamma\rangle$ as the *co-clone* generated by Γ. The set of all co-clones forms a lattice. To give an idea about the connection between Post's lattice and the co-clone lattice, we briefly mention the following theorem, and refer the reader to, for example, [5] for more information. Roughly speaking, the following theorem says that the co-clone lattice is essentially Post's lattice turned upside down, i.e., the inclusion between neighboring nodes are inverted.

▶ **Theorem 9** ([43], Theorem 3.1.3). *The lattices of Boolean clones and Boolean co-clones are anti-isomorphic.*

Using the above comments, it can be seen (and it is well known) that the lattice of Boolean co-clones has the structure shown in Figure 1. In the figure, if co-clone C_2 is above co-clone C_1, then $C_2 \supset C_1$. The names of the co-clones are indicated in the nodes[2], where we follow the notation of Böhler et al [5].

[2] If the name of a clone is L_3, for example, then the corresponding co-clone is $\mathrm{Inv}(\mathrm{L}_3)$ (Inv is defined, for example, in [5]), which is denoted by IL_3.

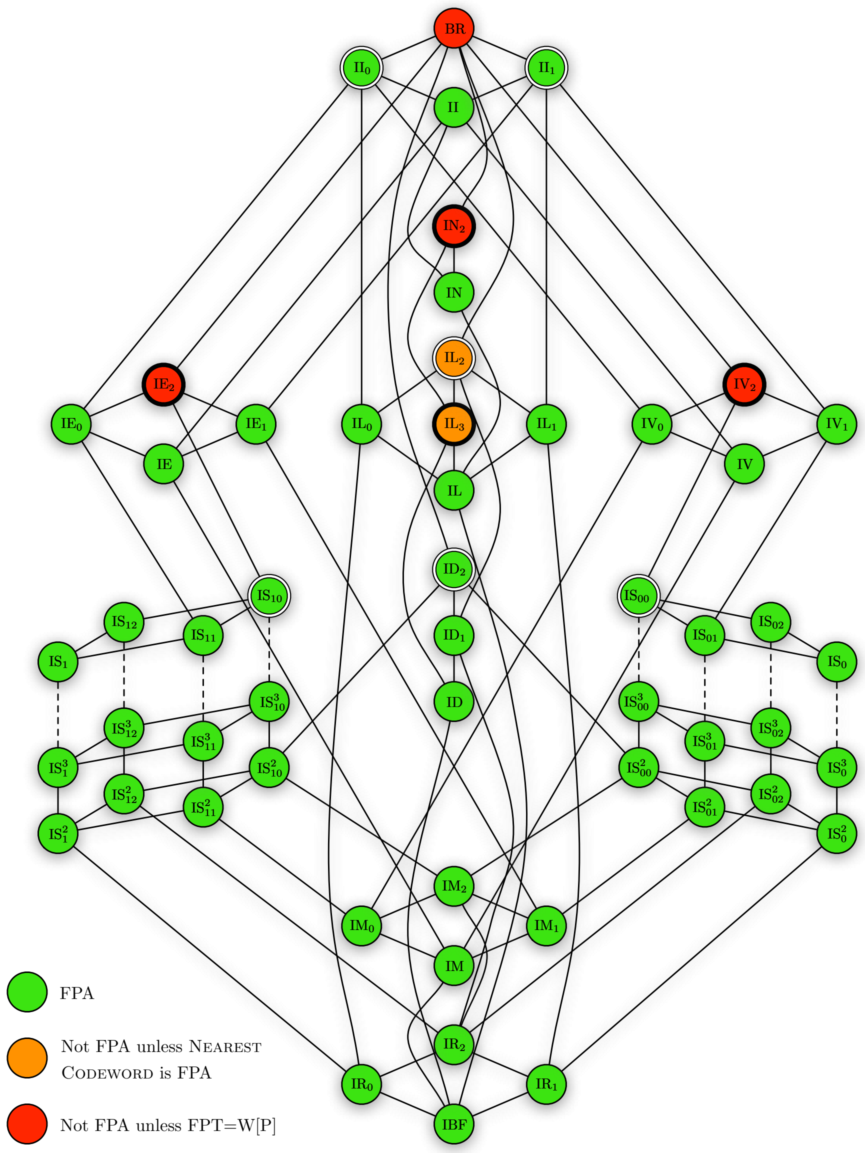

Figure 1 Classification of Boolean CSPs according to constant ratio fixed-parameter approximability. (*We thank Heribert Vollmer and Yuichi Yoshida for giving us access to their Post's lattice diagrams.*)

For a co-clone C we say that a set of relations Γ is a *base* for C if $C = \langle \Gamma \rangle$, that is, any relation in C can be pp-defined using relations in Γ. Böhler et al. give bases for all co-clones in [5], and the reader can consult this paper for details. We reproduce this list in Table 1.[3]

It is well-known that pp-definitions preserve the complexity of the decision version of CSP: if $\Gamma_2 \subseteq \langle \Gamma_1 \rangle$ for two finite languages Γ_1 and Γ_2, then there is a natural polynomial-time

[3] We note that EVEN^4 can be pp-defined using DUP^3. Therefore the base $\{\mathrm{DUP}^3, \mathrm{EVEN}^4, x \oplus y\}$ given by Böhler et al. [5] for IN_2 can be actually simplified to $\{\mathrm{DUP}^3, x \oplus y\}$.

Table 1 Bases for all Boolean co-clones. (See [5] for a complete definition of relations that appear.) The order of a co-clone is the minimum over all bases of the maximum arity of a relation in the base. The order is defined to be infinite if there is no finite base for that co-clone.

Co-clone	Order	Base	Co-clone	Order	Base
IBF	0	$\{=\}$, $\{\emptyset\}$	IS_{10}	∞	$\{\mathrm{NAND}^m \mid m \geq 2\} \cup \{x, \bar{x}, x \to y\}$
IR_0	1	$\{\bar{x}\}$	ID	2	$\{x \oplus y\}$
IR_1	1	$\{x\}$	ID_1	2	$\{x \oplus y, x\}$, every $R \in \{\{(a_1, a_2, a_3), (b_1, b_2, b_3)\} \mid \exists c \in \{1, 2\}$ such that $\sum_{i=1}^{3} a_i = \sum_{i=i}^{3} b_i = c\}$

reduction from $\mathrm{CSP}(\Gamma_2)$ to $\mathrm{CSP}(\Gamma_1)$. The same is not true for MinCSP: the approximation ratio can change in the reduction. However, it has been observed that this change of the approximation ratio is at most a constant (depending on Γ_1 and Γ_2) [33, 24, 25]; we show the same here in the context of parameterized reductions.

▶ **Lemma 10.** *Let Γ be a constraint language, and R be a relation that is pp-definable over Γ without equality. Then there is an A-reduction from* MinCSP$(\Gamma \cup \{R\})$ *to* MinCSP(Γ).

By repeated applications of Lemma 10, the following corollary establishes that we need to provide approximation algorithms only for a few MinCSPs, and these algorithms can be used for other MinCSPs associated with the same co-clone.

▶ **Corollary 11.** *Let C be a co-clone and B be a base for C. If the equality relation can be $\exists\wedge$-defined from B, then for any finite $\Gamma \subseteq C$, there is an A-reduction from* MinCSP(Γ) *to* MinCSP(B).

For hardness results, we wish to argue that if a co-clone C is hard, then any constraint language Γ generating the co-clone is hard. However, there are two technical issues. First, co-clones are infinite and our constraint languages are finite. Therefore, we formulate this requirement instead by saying that a finite base B of the co-clone C is hard. Second, pp-definitions require equality relations, which may not be expressible by Γ. However, as the following theorem shows, this is an issue only if B contains relations where the coordinates are always equal (which will not be the case in our proofs). A k-ary relation R is *irredundant* if for every two different coordinates $1 \leq i < j \leq k$, R contains a tuple $(a_1, \dots, a_k)$ with $a_i \neq a_j$. A set of relations S is *irredundant* if any relation in S is irredundant.

▶ **Theorem 12** ([30, 4]). *If $S \subseteq \langle \Gamma \rangle$ and S is irredundant, then S is $\exists\wedge$-definable from Γ.*

Thus, considering an irredundant base B of co-clone C, we can formulate the following result.

▶ **Corollary 13.** *Let B be an irredundant base for some co-clone C. If Γ is a finite constraint language with $C \subseteq \langle \Gamma \rangle$, then there is an A-reduction from* MinCSP(B) *to* MinCSP(Γ).

By the following lemma, if the constraint language is self-dual, then we can assume that it also contains the constant relations.

▶ **Lemma 14.** *Let Γ be a self-dual constraint language. Assume that $x \oplus y \in \Gamma$. Then there is a cost-preserving reduction from* MinCSP($\Gamma \cup \{x, \bar{x}\}$) *to* MinCSP($\Gamma$).

The following theorem states our trichotomy classification in terms of co-clones.

▶ **Theorem 15.** *Let Γ be a finite set of Boolean relations.*

1. *If $\langle \Gamma \rangle \subseteq C$ (equivalently, if $\Gamma \subseteq C$), with $C \in \{\mathrm{II}_0, \mathrm{II}_1, \mathrm{IS}_{00}, \mathrm{IS}_{10}, \mathrm{ID}_2\}$, then* MinCSP($\Gamma$) *has a constant-factor* FPA *algorithm. (Note in these cases Γ is 0-valid, 1-valid, IHS-B+, IHS-B−, or bijunctive, respectively.)*
2. *If $\langle \Gamma \rangle \in \{\mathrm{IL}_2, \mathrm{IL}_3\}$, then* MinCSP($\Gamma$) *is equivalent to* Nearest Codeword *and to* Odd Set *under A-reductions (Note that these constraint languages are affine.)*
3. *If $C \subseteq \langle \Gamma \rangle$, where $C \in \{\mathrm{IE}_2, \mathrm{IV}_2, \mathrm{IN}_2\}$, then* MinCSP($\Gamma$) *does not have a constant-factor* FPA *algorithm unless* FPT = W[P]. *(Note that in these cases Γ can $\exists\wedge$-define either arbitrary Horn relations, or arbitrary dual Horn relations, or the relation $\mathrm{NAE}^3 = \{0,1\}^3 \setminus \{(0,0,0),(1,1,1)\}$.)*

Looking at the co-clone lattice, it is easy to see that Theorem 15 covers all cases. It is also easy to check that Theorem 1 formulated in the introduction follows from Theorem 15. Theorem 15 is proved the following way. Statement 1 is proved in Section 4 (Lemma 16, and Corollaries 18 and 21). Statement 2 is proved in Section 5 (Theorem 23). Statement 3 is proved in Sections 6 (Corollary 27 and Lemma 28).

4 CSPs with FPA algorithms

We prove the first statement of Theorem 15 by going through co-clones one by one. As every relation of a 0-valid MinCSP is always satisfied by the all 0 assignment, and every relation of a 1-valid MinCSP is always satisfied by the all 1 assignment, we have a trivial algorithm for these problems.

▶ **Lemma 16.** *If $\langle \Gamma \rangle \subseteq \mathrm{II}_0$ or $\langle \Gamma \rangle \subseteq \mathrm{II}_1$, then* MinCSP($\Gamma$) *is polynomial-time solvable.*

Consider now the co-clone ID_2. Almost 2-SAT is defined as MinCSP(Γ(2-SAT)), where $\Gamma(\text{2-SAT}) = \{x \vee y, x \vee \neg y, \neg x \vee \neg y\}$.

▶ **Theorem 17** ([45]). Almost 2-SAT *is fixed-parameter tractable.*

Since every bijunctive relation can be pp-defined by 2-SAT, the constant-factor FP-approximability of bijunctive languages easily follows from the FPT algorithm for Almost 2-SAT and from Corollary 11.

▶ **Corollary 18.** *If* $\langle\Gamma\rangle \subseteq \mathrm{ID}_2$*, then* MinCSP($\Gamma$) *has a constant-factor* FPA *algorithm.*

Proof. We check in Table 1 that $B = \{x \oplus y, x \to y\}$ is a base for the co-clone ID_2. Relations in B (and equality) can be $\exists\wedge$-defined over Γ(2-SAT), so the result follows from Corollary 11. ◀

We consider now IS_{00} and IS_{10}. We first note that if $\langle\Gamma\rangle$ is in IS_{00} or IS_{10}, then the language is k-IHS-B+ or k-IHS– for some $k \geq 2$.

▶ **Lemma 19.** *If* $\langle\Gamma\rangle \subseteq \mathrm{IS}_{00}$*, then there is an integer* $k \geq 2$ *such that* Γ *is k-IHS-B+. If* $\langle\Gamma\rangle \subseteq \mathrm{IS}_{10}$*, then there is an integer* $k \geq 2$ *such that* Γ *is k-IHS-B–.*

By Lemma 19, if $\langle\Gamma\rangle \subseteq \mathrm{IS}_{00}$, then Γ is generated by the relations $\neg x, x \to y, x_1 \vee \cdots \vee x_k$ for some $k \geq 2$. The MinCSP problem for this set of relations is known to admit a constant-factor approximation.

▶ **Theorem 20** ([19], Lemma 7.29)**.** MinCSP($\neg x, x \to y, x_1 \vee \cdots \vee x_k$) *has a* $(k+1)$*-factor approximation algorithm (and hence has a constant-factor FPA algorithm).*

Now Theorem 20 and Corollary 11 imply that there is a constant-factor FPA algorithm for MinCSP(Γ) whenever $\langle\Gamma\rangle$ is in the co-clone IS_{00} or IS_{10} (note that equality can be $\exists\wedge$-defined using $x \to y$). In fact, the resulting algorithm is a polynomial-time approximation algorithm: Theorem 20 gives a polynomial-time algorithm and this is preserved by Corollary 11.

▶ **Corollary 21.** *If* $\langle\Gamma\rangle \subseteq \mathrm{IS}_{00}$ *or* $\langle\Gamma\rangle \subseteq \mathrm{IS}_{10}$*, then* MinCSP($\Gamma$) *has a constant-factor* FPA *algorithm.*

Note that Theorem 7.25 in [19] gives a complete classification of Boolean MinCSPs with respect to constant-factor approximability. As mentioned, these MinCSPs also admit a constant-factor approximation algorithm. The reason we need Corollary 21 is to have the characterization in terms of the co-clone lattice.

5 CSPs equivalent to Odd Set

In this section we show the equivalence of several problems under A-reductions. We identify CSPs that are equivalent to the following well-known combinatorial problems. In the Nearest Codeword (NC) problem, the input is an $m \times n$ matrix A, and an m-dimensional vector b. The output is an n dimensional vector x that minimizes the Hamming distance between Ax and b. In the Odd Set problem, the input is a set-system $\mathcal{S} = \{S_1, S_2, \ldots, S_m\}$ over universe U. The output is a subset $T \subseteq U$ of minimum size such that every set of $\mathcal{S}$ is hit an odd number of times by T, that is, $\forall i \in [m]$, $|S_i \cap T|$ is odd.

Even/Odd Set is the same problem as Odd Set, except that we can specify whether a set should be hit an even or odd number of times (the objective is the same as in Odd Set: find a subset of minimum size satisfying the requirements). We show that there is a parameter preserving reduction from Even/Odd Set to Odd Set.

▶ **Lemma 22.** *There is a cost-preserving reduction from* Even/Odd Set *to* Odd Set*.*

We define the relations $\mathrm{EVEN}^m = \{(a_1, \ldots, a_m) \in \{0,1\}^m : \sum_{i=1}^m a_i \text{ is even}\}$, $\mathrm{ODD}^m = \{(a_1, \ldots, a_m) \in \{0,1\}^m : \sum_{i=1}^m a_i \text{ is odd}\}$, and the languages $B_2 = \{\mathrm{EVEN}^4, x, \bar{x}\}$, $B_3 = \{\mathrm{EVEN}^4, x \oplus y\}$. Note that B_2 and B_3 are bases for the co-clones IL_2 and IL_3, respectively.

▶ **Theorem 23.** [4] *The following problems are equivalent under cost-preserving reductions:* (1) Nearest Codeword, (2) Odd Set, (3) MinCSP(B_2), *and* (4) MinCSP(B_3).

6 Hard CSPs: Horn (IV_2), dual-Horn (IE_2) and IN_2

In this section, we establish statement 3 of Theorem 15 by proving the inapproximability of MinCSP(Γ) if Γ generates one of the co-clones IE_2, IV_2, or IN_2. The inapproximability proof uses previous results on the inapproximability of circuit satisfiability problems.

A *Boolean circuit* is a directed acyclic graph, where each node with in-degree at least 2 is labeled as either an AND node or as an OR node, each node of in-degree 1 is labeled as a negation node, and each node of in-degree 0 is an input node. Furthermore, there is a node with out-degree 0 that is the output node. Given an assignment φ from the input nodes of circuit C to $\{0, 1\}$, we say that assignment φ satisfies C if the value of the output node (computed in the obvious way) is 1. The *weight* of an assignment is the number of input nodes with value 1. Circuit C is k-satisfiable if there is a weight-k assignment satisfying C. A circuit is *monotone* if it contains no negation gates. The problem Monotone Circuit Satisfiability (MCS) takes as input a monotone circuit C and an integer k, and the task is to decide if there is a satisfying assignment of weight at most k. The following theorem is a restatement of a result of Marx [40]. We use this to show that Horn-CSPs are hard.

▶ **Theorem 24** ([40]). Monotone Circuit Satisfiability *does not have an* FPA *algorithm, unless* FPT $=$ W[P].

▶ **Corollary 25.** Monotone Circuit Satisfiability, *where circuits are restricted to have gates of in-degree at most* 2, *does not have an FPA algorithm, unless* FPT $=$ W[P].

We use Corollary 25 to establish the inapproximability of Horn-SAT and dual-Horn-SAT, assuming that FPT $\neq$ W[P]. Using the co-clone lattice, this will show hardness of approximability of MinCSP(Γ) if $\langle\Gamma\rangle \in \{IV_2, IE_2\}$.

▶ **Lemma 26.** *If there is an* FPA *algorithm for* MinCSP($\{x \vee y \vee \bar{z}, x, \bar{x}\}$) *or* MinCSP($\{\bar{x} \vee \bar{y} \vee z, x, \bar{x}\}$) *with constant approximation ratio, then* FPT $=$ W[P].

Proof. We prove that there is a parameter preserving polynomial-time reduction from Monotone Circuit Satisfiability to MinCSP*($\{x \vee y \vee \bar{z}, x, \bar{x}\}$). This is sufficient by Corollary 25. Let C be the MCS instance. We produce an instance I of MinCSP* as follows. We think of inputs of C as gates, and we refer to these as "input gates". This will simplify the discussion. For each gate of C, we introduce a new variable into I, and we let f denote the natural bijection from the gates and inputs of C to the variables of the instance I.

We add constraints to simulate each AND gate of C as follows. Observe first that the implication relation $x \to y$ can be expressed as $y \vee y \vee \bar{x}$. For each AND gate $G_\wedge$ such that G_1 and G_2 are the gates feeding into $G_\wedge$ (note that G_1 and G_2 are allowed to be input gates), we add two constraints to I as follows. Let $y = f(G_\wedge)$, $x_1 = f(G_1)$, and $x_2 = f(G_2)$. We place the constraints $y \to x_1, y \to x_2$ into I. We observe that the only way variable y could take on value 1 is if both x_1 and x_2 are assigned 1. (In this case, note that y could also be assigned 0 but that will be easy to fix.)

Similarly, we add constraints to simulate each OR gate of C as follows. For each OR gate $G_\vee$ such that G_1 and G_2 are the gates feeding into $G_\vee$, we add a constraint to I, we add

[4] Note that Lemma 1 in [22] can be adapted to obtain the reduction from Odd Set to MinCSP(B_2).

the constraint $x_1 \vee x_2 \vee \bar{y}$ to I, where $y = f(G_\vee)$, $x_1 = f(G_1)$, and $x_2 = f(G_2)$. Note that if both x_1 and x_2 are 0, than y is forced to have value 0. (Otherwise y can take on either value 0 or 1, but again, this difference between an OR gate and our gadget will be easy to handle.)

In addition, we add a constraint $x_o = 1$, where x_o is the variable such that $x_o = f(G)$, where G is the output gate. We define all constraints that appeared until now to be undeletable, so that they cannot be removed in solution of the MinCSP* instance. To finish the construction, for each variable x such that $x = f(G)$ where G is an input gate, we add a constraint $x = 0$ to I. We call these constraints *input constraints*. Note that only input constraints can be removed.

If there is a satisfying assignment φ_C of C (from gates of C to $\{0, 1\}$) of weight k, then we remove the input constraints $x = 0$ of I such that $\varphi_C(G) = 1$, where $f(G) = x$. Clearly, the map $\varphi_C \circ f^{-1}$ is a satisfying assignment for I, where we needed k deletions.

For the other direction, assume that we have a satisfying assignment φ_I for I after removing some k input constraints (note that if any other constraints are removed, we can simply ignore those deletions). We repeatedly change φ_I as long as either of the following conditions apply. If x_1, x_2 and y are such that $f^{-1}(x_1)$ and $f^{-1}(x_2)$ are gates feeding into gate $f^{-1}(y)$ where $f^{-1}(y)$ is an AND gate, and $\varphi_I(x_1) = 1, \varphi_I(x_2) = 1, \varphi_I(y) = 0$, then we change $\varphi_I(y)$ to 1. Similarly, if $f^{-1}(y)$ is an OR gate, $1 \in \{\varphi_I(x_1), \varphi_I(x_2)\}, \varphi_I(y) = 0$, then we change $\varphi_I(y)$ to 1. It follows form the definition of the constraints we introduced for AND and OR gates that once we finished modifying φ_I, the resulting assignment φ'_I is still a satisfying assignment. Now it follows that $\varphi'_I \circ f$ is a weight k satisfying assignment for C.

To show the inapproximability of MinCSP$(\{\bar{x} \vee \bar{y} \vee z, x, \bar{x}\})$, we note that there is a parameter preserving bijection between instances of MinCSP$(\{\bar{x} \vee \bar{y} \vee z, x, \bar{x}\})$ and MinCSP$(\{x \vee y \vee \bar{z}, x, \bar{x}\})$: given an instance I of either problem, we obtain an equivalent instance of the other problem by replacing every literal ℓ with $\neg\ell$. Satisfying assignments are converted by replacing 0-s with 1-s and vice versa. ◀

As $\{x \vee y \vee \bar{z}, x, \bar{x}\}$ (resp., $\{\bar{x} \vee \bar{y} \vee z, x, \bar{x}\}$) is an irredundant base of IV_2 (resp., IE_2), Corollary 13 implies hardness if $\langle\Gamma\rangle$ contains IV_2 or IE_2.

▶ **Corollary 27.** *If Γ is a (finite) constraint language with $\mathrm{IV}_2 \subseteq \langle\Gamma\rangle$ or $\mathrm{IE}_2 \subseteq \langle\Gamma\rangle$, then* MinCSP$(\Gamma)$ *is not FP-approximable, unless* FPT = W[P].

▶ **Lemma 28.** *If Γ is a (finite) constraint language with $\mathrm{IN}_2 \subseteq \langle\Gamma\rangle$ then* MinCSP(Γ) *is not FP-approximable, unless* P = NP.

7 Odd Set is probably hard

We provide evidence that problems equivalent to NC and Odd Set (in particular, problems in Theorem 15(2)) are hard, i.e., they are unlikely to have a constant-factor FPA algorithm.

In the k-Densest Subgraph problem, we are given a graph $G = (V, E)$ and an integer k; the task is to find a set S of k vertices that maximizes the number of edges in the induced subgraph $G[S]$. Note that an exact algorithm for k-Densest Subgraph would imply an exact algorithm for Clique. Due to its similarity to Clique, it is reasonable to assume that k-Densest Subgraph is even hard to approximate. We formulate the following specific hardness assumption.

▶ **Assumption 29.** *There is an $\varepsilon > 0$ such that for any function f, one cannot approximate k-*Densest Subgraph *within ratio $1 - \varepsilon$ in time $f(k) \cdot n^{O(1)}$.*

It will be more convenient to work with a slightly different version of k-Densest Subgraph. In the Multicolored k-Densest Subgraph problem, we are given a graph $G = (V, E)$ whose vertex-set V is partitioned into k classes $C_1, \ldots, C_k$, and the goal is to find a set $S = \{v_1, \ldots, v_k\}$ of k vertices satisfying $v_i \in C_i$ for each $i \in [k]$, and maximizing the number of edges in the induced subgraph $G[S]$. We argue in the arxiv version that Assumption 29 implies Assumption 30 [6].

▶ **Assumption 30.** *There is an $\varepsilon > 0$ such that for any function f, one cannot approximate* Multicolored k-Densest Subgraph *within ratio $1 - \varepsilon$ in time $f(k) \cdot n^{O(1)}$.*

Odd Set has the so-called *self-improvement* property. Informally, a polynomial time (resp. fixed-parameter time) approximation within some ratio r can be turned into a polynomial time (resp. fixed-parameter time) approximation within some ratio close to $\sqrt{r}$.

▶ **Lemma 31.** *If there is an r-approximation for* Odd Set *running in time $f(n, m, k)$ where n is the size of the universe, m the number of sets, and k the size of an optimal solution, then for any $\varepsilon > 0$, there is a $(1+\varepsilon)\sqrt{r}$-approximation running in time* $\max(f(1+n+n^2, 1+m+nm, 1+k+k^2), O(n^{1+\frac{1}{\varepsilon}}m))$.

Proof. The following reduction is inspired by the one showing the self-improvement property of NC [2]. Let $\mathcal{S} = \{S_1, \ldots, S_m\}$ be any instance over universe $U = \{x_1, \ldots, x_n\}$. Let $\varepsilon > 0$ be any real positive value and k be the size of an optimal solution. We can assume that $k \geqslant \frac{1}{\varepsilon}$ since one can find an optimal solution by exhaustive search in time $O(n^{1+\frac{1}{\varepsilon}}m)$. We build the set-system $\mathcal{S}' = \mathcal{S} \cup \bigcup_{i \in [n], j \in [m]} S^i_j \cup \{\{e\}\}$ over universe $U' = U \cup \bigcup_{i,h \in [n]} \{x^i_h\} \cup \{e\}$ such that $S^i_j = \{e, x_i\} \cup \{x^i_h \mid x_h \in S_j\}$. Note that the size of the new instance is squared. We show that there is a solution of size at most k to instance $\mathcal{S}$ if and only if there is a solution of size at most $1 + k + k^2$ to instance $\mathcal{S}'$.

If T is a solution to $\mathcal{S}$, then $T' = \{e\} \cup T \cup \{x^i_h \mid x_i, x_h \in T\}$ is a solution to $\mathcal{S}'$. Indeed, sets in $\mathcal{S} \cup \{\{e\}\}$ are obviously hit an odd number of times. And, for any $i \in [n]$ and $j \in [m]$, set S^i_j is hit exactly once (by e) if $x_i \notin T$, and is hit by e, x_i, plus as many elements as S_j is hit by T; so again an odd number of times. Finally, $|T'| = 1 + |T| + |T|^2$.

Conversely, any solution to $\mathcal{S}'$ should contain element e (to hit $\{e\}$), and should intersect U in a subset T hitting an odd number of times each set S_i ($\forall i \in [m]$). Then, for each $x_i \in T$, each set S^i_j with $j \in [m]$ is hit exactly twice by e and x_i. Thus, one has to select a subset of $\{x^i_1, \ldots, x^i_n\}$ to hit each set of the family $\{S^i_1, \ldots, S^i_m\}$ an odd number of times. Again, this needs as many elements as a solution to $\mathcal{S}$ needs. So, if there is a solution to $\mathcal{S}'$ of size at most $1 + k + k^2$, then there is a solution to $\mathcal{S}$ of size at most k. In fact, we will only use the weaker property that if there is a solution to $\mathcal{S}'$ of size at most k, then there is a solution to $\mathcal{S}$ of size at most $\sqrt{k}$.

Now, assuming there is an r-approximation for Odd Set running in time $f(n, m, k)$, we run that algorithm on the instance $\mathcal{S}'$ produced from $\mathcal{S}$. This takes time $f(1+n+n^2, 1+m+nm, 1+k+k^2)$ and produces a solution of size $r(1+k+k^2)$. From that solution, we can extract a solution T to $\mathcal{S}$ by taking its intersection with U. And T has size smaller than $\sqrt{r(1+k+k^2)} \leqslant \sqrt{r}(k+1) = (1+\frac{1}{k})\sqrt{r}k \leqslant (1+\varepsilon)\sqrt{r}k$. ◀

Repeated application of the self-improvement in Lemma 31 shows that any constant-ratio approximation implies the existence of $(1+\varepsilon)$-approximation for arbitrary small $\varepsilon > 0$.

▶ **Corollary 32.** *If* Odd Set *admits an FPA algorithm with some ratio r, then, for any $\varepsilon > 0$, it also admits an FPA algorithm with ratio $1 + \varepsilon$.*

Now we show that an approximation for Odd Set with ratio $1 + \frac{\varepsilon}{3}$ implies the existence of a $(1 - \epsilon)$-approximation for k-Densest Subgraph. In light of Corollary 32, this means that any constant-factor approximation for Odd Set would violate Assumption 29.

▶ **Theorem 33.** *For any ratio r,* Odd Set *does not have an FPA algorithm with ratio r, unless Assumption 29 fails.*

Proof. Let $\varepsilon > 0$ be such that k-Densest Subgraph and therefore Multicolored k-Densest Subgraph do not admit a fixed-parameter $(1 - \varepsilon)$-approximation. We show that an FPA algorithm with ratio $1 + \frac{\varepsilon}{3}$ for Odd Set would contradict Assumption 29, and we conclude with Corollary 32. Let $G = (V = C_1 \uplus \ldots \uplus C_k, E)$ be an instance of Multicolored k-Densest Subgraph, and let X be an optimal solution inducing m edges. For any $\{i, j\} \in \binom{[k]}{2}$, we let $E_{\{i,j\}}$ be the set of edges between C_i and C_j.

We build $2^{\binom{k}{2}}$ instances of Odd Set: one for each subset of $\binom{[k]}{2}$. One such subset is $\mathcal{P} := \{\{i, j\} \mid E_{\{i,j\}} \cap E(X) \neq \emptyset\}$. In words, $\mathcal{P}$ is a correct guess of which $E_{\{i,j\}}$ are inhabited by the edges induced by the optimal solution X. Let $\mathcal{V}$ be the subset of indices $i \in [k]$ such that i appears in at least one pair of $\mathcal{P}$, and let $k' = |\mathcal{V}|$. Informally, $\mathcal{V}$ corresponds to the color classes of the vertices which are not isolated in the subgraph induced by X.

The universe U consists of an element x_v per vertex v of C_i such that $i \in \mathcal{V}$ and an element x_e per edge e in $E_{\{i,j\}}$ such that $\{i, j\} \in \mathcal{P}$. For any vertex $u \in C_i$ and any $j \in [k]$ such that $\{i, j\} \in \mathcal{P}$, we set $S_{u,j} = \{x_v \mid v \in C_i \text{ and } v \neq u\} \cup \{x_{vw} \mid vw \in E_{\{i,j\}} \text{ and } u \in \{v, w\}\}$, and for each $i \in \mathcal{V}$, $S_i = \{x_v \mid v \in C_i\}$. The set-system is $\mathcal{I} = (U, \mathcal{S} = \bigcup_{u \in C_i, \{i,j\} \in \mathcal{P}} S_{u,j} \uplus \bigcup_{i \in \mathcal{V}} S_i)$.

First, we show that the instance of Odd Set built for subset $\mathcal{P}$ admits a solution of size $k' + m$. Let $X' = \{a_1, \ldots, a_{k'}\} \subseteq X$ be the k' vertices which are not isolated in $G[X]$. We claim that $Z = \{x_{a_i}\}_{i=1}^{k'} \cup \{x_e\}_{e \in E(X')}$ is an odd set of $\mathcal{I}$. Each S_i with $i \in \mathcal{V}$ is hit by exactly one element of Z since no two a_p's can come from the same color class. Each $S_{u,j}$ with $u \in C_i$, $\{i, j\} \in \mathcal{P}$, and $u \notin X'$ is hit exactly once by x_{a_p} where the color class of a_p is C_i. Each $S_{u,j}$ with $u = a_p \in C_i \cap X'$, $\{i, j\} \in \mathcal{P}$ is hit exactly once by $x_{a_p a_q}$ where the color class of a_q is C_j. Finally, Z has the desired size $|X'| + |E(X')| = k' + |E(X)| = k' + m$.

Since we have established that $\mathcal{I}$ has an odd set of size $k' + m$, our supposed $1 + \frac{\varepsilon}{3}$-approximation would return a solution Z of at most $(1 + \frac{\varepsilon}{3})(k' + m)$ elements. We now show how to obtain a good approximation for Multicolored k-Densest Subgraph from such a solution to Odd Set. By construction, for each $i \in \mathcal{V}$, the set S_i should be hit an odd number of times, that is $|Z \cup S_i|$ is odd. In particular, $Z \cup S_i$ is non-empty. So, we can build a set $\{x_{u_i} | i \in \mathcal{V}\}$ where x_{u_i} is an arbitrary element of $Z \cup S_i$.

Let $\mathcal{E} = \{S_{u_i,j} \mid \{i, j\} \in \mathcal{P}\}$. Each of the $2|\mathcal{P}|$ sets of $\mathcal{E}$ (note that if, say, $\{1, 2\} \in \mathcal{P}$, then both $S_{u_1,2}$ and $S_{u_2,1}$ become a member of $\mathcal{E}$) are hit an even number of times by $Z \cap \bigcup_{i \in \mathcal{V}} S_i$. Indeed, $|(Z \cap \bigcup_{i \in \mathcal{V}} S_i) \cap S_{u_i,j}| = |Z \cap S_i \setminus \{x_{u_i}\}| = |Z \cap S_i| - 1$ which is even. We observe that each $S_{u_i,j} \in \mathcal{E}$ intersects with only one other set of $\mathcal{E}$, namely, $S_{u_j,i}$. So, we need at least $|\mathcal{P}|$ elements to hit the sets in $\mathcal{E}$. If there is an edge between u_i and u_j, both $S_{u_i,j}$ and $S_{u_j,i}$ can be hit at the same time by including element $x_{u_i u_j}$ into the solution. Otherwise $S_{u_i,j}$ and $S_{u_j,i}$ are disjoint and at least two elements are necessary to hit them. As there are at least $\frac{k'}{2}$ edges on k' non isolated vertices, we have $y \geq \frac{k'}{2}$. The set $Z \setminus (S_1 \cup \cdots \cup S_k)$ contains at most $|Z| - k \leq (1 + \frac{\varepsilon}{3})m + \frac{\varepsilon}{3}k' \leq (1 + \frac{\varepsilon}{3})m + \frac{2\varepsilon}{3}m = (1 + \varepsilon)m$ elements and these elements hit every set in $\mathcal{E}$. Thus, it can be true only for at most εm of the m pairs in $\mathcal{P}$ that the two sets $S_{u_i,j}, S_{u_j,i} \in \mathcal{E}$ cannot be hit by a single element of Z. Equivalently, it is true for at least $(1 - \varepsilon)m$ of the m pairs in $\mathcal{P}$ that the two sets $S_{u_i,j}, S_{u_j,i} \in \mathcal{E}$ are hit by a single element of Z. As mentioned previously, that element can only be $x_{u_i u_j}$. The fact that such an element actually exists means that there is an edge between u_i and u_j. Therefore, $\{u_i\}_{i \in \mathcal{V}}$

induces at least $(1-\varepsilon)m$ edges. It follows that Z is an $(1-\varepsilon)$-approximate solution for the instance of MULTICOLORED k-DENSEST SUBGRAPH; a contradiction to Assumption 29. ◀

▶ **Assumption 34** (Linear PCP Conjecture). *There exist constants $0 < \alpha < 1$, $A, B > 0$, such that* MAX 3-SAT *on n variables can be decided with completeness 1 and error α by a verifier using $\log n + A$ random bits and reading B bits of the proof.*

LPC is probably better thought of as an open problem rather than a conjecture. In previous work, LPC has almost always proved to be a necessary hypothesis in showing that a specific problem cannot admit an FPA algorithm [7]. If LPC turns out to be true, the consequence for approximation is that there is a linear reduction introducing a constant gap from 3-SAT to MAX 3-SAT. Thus, if we combine this fact with the sparsification lemma of Impagliazzo et al. [31], we may observe the following result:

▶ **Lemma 35** (Lemma 2, [7]). *Under LPC and ETH, there are two constants $r < 1$ and $\delta > 0$ such that one cannot distinguish satisfiable instances of* MAX 3-SAT *with m clauses from instances where at most rm clauses are satisfied in time $2^{\delta m}$.*

The previous result was in fact stated slightly more generally allowing a weaker form of LPC where the completeness is not 1 but $1-\varepsilon$. We re-stated the lemma this way since we will need perfect completeness. The state-of-the-art PCP concerning the inapproximability of MAX 3-SAT only implies the following:

▶ **Theorem 36** ([42]). *Under ETH, one cannot distinguish satisfiable instances of* MAX 3-SAT *from instances where at most $(\frac{7}{8}+o(1))m$ clauses are satisfied in time $2^{m^{1-o(1)}}$.*

Now, we are set for the following result:

▶ **Theorem 37.** *Under LPC and ETH, for any ratio r,* ODD SET *does not have an FPA algorithm with ratio r.*

Proof. Again, the idea is to assume an FPA algorithm with ratio $1+\varepsilon$ for ODD SET (with parameter k), and show that it would imply a too good approximation for MAX 3-SAT in subexponential time, therefore contradicting Lemma 35, and then conclude with Lemma 31.

Let $\phi = \bigwedge_{1 \leqslant i \leqslant m} C_i$ be any instance of MAX 3-SAT, where the C_is are 3-clauses over the set of n variables V. We partition the clauses arbitrarily into k sets $A_1, A_2, \dots, A_k$ of size roughly $\frac{m}{k}$. We denote by V_i the set of all the variables appearing in at least one clause of A_i; each V_i has size at most $\frac{3m}{k}$. Of course, while the A_i's are a partition of the clauses, the V_i's can intersect with each other. We build an instance $\mathcal{I} = (U, \mathcal{S})$ of ODD SET the following way. For each $i \in [k]$, set U_i contains one element $x(\mathcal{A}, i)$ per assignment $\mathcal{A}$ of V_i that satisfies all the clauses inside A_i. The universe U is $\bigcup_i U_i$. For each $i \neq j \in [k]$, for each variable $y \in V_i \cap V_j$, we set $S_{y,i,j} = \{x(\mathcal{A}, i) \mid y \text{ is set to true by } \mathcal{A}\} \cup \{x(\mathcal{A}, j) \mid y \text{ is set to false by } \mathcal{A}\}$. Observe that $S_{y,i,j}$ and $S_{y,j,i}$ are two different sets. Finally, $\mathcal{S} = \bigcup_{i \in [k]} \{U_i\} \cup \bigcup_{i \neq j \in [k], y \in V_i \cap V_j} S_{y,i,j}$.

If ϕ is satisfiable, we fix a (global) satisfying assignment $\mathcal{A}_g$. We claim that $S = \{x(\mathcal{A}, i) \mid \mathcal{A} \text{ agrees with } \mathcal{A}_g \text{ in the entire } V_i\}$ is a solution of size k to the ODD SET instance. Set S is of size k since for each $i \in [k]$ exactly one element $x(\mathcal{A}, i)$ can be such $\mathcal{A}$ agrees with $\mathcal{A}_g$. This also shows that each set U_i is hit exactly once by S. Finally, for each $i \neq j \in [k]$ and for each variable $y \in V_i \cap V_j$, sets $\{x(\mathcal{A}, i) \mid y \text{ is set to true by } \mathcal{A}\}$ and $\{x(\mathcal{A}, j) \mid y \text{ is set to false by } \mathcal{A}\}$ can be hit at most once. Besides, $\{x(\mathcal{A}, i) \mid y \text{ is set to true by } \mathcal{A}\}$ is hit exactly once by S if and only if $\{x(\mathcal{A}, j) \mid y \text{ is set to false by } \mathcal{A}\}$ is not hit by S, since the partial assignments mapped to the elements in S necessarily agree. Therefore, $S_{y,i,j}$ is hit exactly once by S, and S is a solution.

Now, we assume that Odd Set admits an FPA algorithm with ratio $1+\varepsilon$ for a small ε that we will fix later. If the solution S returned by this algorithm on instance $\mathcal{I}$ is of size greater than $(1+\varepsilon)k$, then we know that an optimal odd set has more than k elements, so we know that ϕ is not satisfiable. So, we can assume that $|S| \leqslant (1+\varepsilon)k$. Each U_i has to be hit at least once and U_is are pairwise disjoint, so we can arbitrarily decompose S into $P \uplus R$, where P is of size k and hits each U_i exactly once, and therefore $|R| \leqslant \varepsilon k$. Thus, at least $(1-\varepsilon)k$ sets U_is are hit exactly once by S. We denote by $\mathcal{U}$ the set of such sets U_i. Let $\mathcal{A}_g$ be the assignment of V agreeing on each assignment $\mathcal{A}$ of V_i such that $x(\mathcal{A}, i)$ is the only element hitting $U_i \in \mathcal{U}$ (and setting the potential remaining variable arbitrarily). Assignment $\mathcal{A}_g$ is well defined since if $x(\mathcal{A}, i)$ is the only element hitting $U_i \in \mathcal{U}$ and $x(\mathcal{A}', j)$ is the only element hitting $U_j \in \mathcal{U}$, and assignments $\mathcal{A}$ and $\mathcal{A}'$ disagree on a variable y, then $S_{y,i,j}$ would be hit an even number of times (0 or 2). By construction, $\mathcal{A}_g$ satisfies all the clauses in the A_is such that $U_i \in \mathcal{U}$, that is at least $(1-\varepsilon)k \times \frac{m}{k} = (1-\varepsilon)m$ clauses. Let r and δ be two constants satisfying Lemma 35. If we choose $\varepsilon = \frac{1-r}{2}$, this number of clauses exceed rm, so we would know that the instance is satisfiable.

Say, the running time of the FPA algorithm is $f(k)(|U| + |\mathcal{S}|)^c$ for some constant c. We may observe that $|U| \leqslant k2^{\frac{3m}{k}}$ and $|\mathcal{S}| \leqslant k + 2\binom{k}{2}n$. Thus, the running time is $g(k)n^c 2^{\frac{3mc}{k}}$. Setting $k = \frac{6c}{\delta}$, this running time would be better than $2^{\delta m}$, contradicting LPC or ETH. ◀

Abstract

Given a simple polygon $\mathcal{P}$ on n vertices, two points x, y in $\mathcal{P}$ are said to be visible to each other if the line segment between x and y is contained in $\mathcal{P}$. The Point Guard Art Gallery problem asks for a minimum set S such that every point in $\mathcal{P}$ is visible from a point in S. The Vertex Guard Art Gallery problem asks for such a set S subset of the vertices of $\mathcal{P}$. A point in the set S is referred to as a guard. For both variants, we rule out a $f(k)n^{o(k/\log k)}$ algorithm, for any computable function f, where $k := |S|$ is the number of guards, unless the Exponential Time Hypothesis fails. These lower bounds almost match the $n^{O(k)}$ algorithms that exist for both problems.

1 Introduction

Given a simple polygon $\mathcal{P}$ on n vertices, two points x, y in $\mathcal{P}$ are said to be visible to each other if the line segment between x and y is contained in $\mathcal{P}$. The Point Guard Art Gallery problem asks for a minimum set S such that every point in $\mathcal{P}$ is visible from a point in S. The Vertex Guard Art Gallery problem asks for such a set S subset of the vertices of $\mathcal{P}$. The set S is referred to as guards. In what follows, n refers to the number of vertices of $\mathcal{P}$ and k to the size of an optimal set of guards.

The art gallery problem is arguably one of the most well-known problems in discrete and computational geometry. Since its introduction by Viktor Klee in 1976, three books [32, 34, 14] and two extensive surveys appeared [33, 8]. O'Rourke's book from 1987 has over a thousand citations, and each year, top conferences publish new results on the topic. Many variants of the art gallery problem, based on different definitions of visibility, restricted classes of polygons, different shapes of guards, have been defined and analyzed. One of the first results is the elegant proof of Fisk that $\lfloor n/3 \rfloor$ guards are always sufficient and sometimes necessary for a polygon with n vertices [12].

NP-hardness and APX-hardness have been shown for many variants of the art gallery problem and other related problems [11, 23, 4, 26]. Due to those negative results, most

papers concentrate on finding approximation algorithms and restrictions that are polynomially tractable [15, 25, 24, 30, 26]. However, considering the recent lack of progress in this direction, the study of other approaches becomes interesting. One such approach is finding heuristics to solve large instances of the art gallery problem [8]. The fundamental drawback of this approach is the lack of performance guarantee.

In the last twenty-five years, a fruitful paradigm, parameterized complexity, has been gaining some popularity. The underlying idea is to study algorithmic problems with dependence on a natural parameter. If the dependence on the parameter is practical and the parameter is small for real-life instances, one gets algorithms that give optimal solutions with reasonable running times. For a gentle introduction to parameterized complexity, we recommend Niedermeier's book [31]. For a thorough reading highlighting complexity classes, we suggest the book by Downey and Fellows [9]. For a recent book on the topic with an emphasize on algorithms, we advise to read the book by Cygan et al. [6]. An approach based on logic is given by Flum and Grohe [13]. Despite the recent successes of parameterized complexity, only very few results on the art gallery problem are known.

The first such result is the trivial algorithm for the vertex guard variant to check if a solution of size k exists in a polygon with n vertices. The algorithm runs in $O(n^{k+2})$ time, by checking all possible subsets of size k of the vertices. The second *not so well-known* result is the fact that one can find in time $n^{O(k)}$ a set of k guards for the point guard variant, if it exists [10], using tools from real algebraic geometry [2]. This was first observed by Sharir [10, Acknowledgment]. Despite the fact that the first algorithm is extremely basic and the second algorithm, even with remarkably sophisticated tools, uses almost no problem-specific insights, no better exact parameterized algorithms are known.

The Exponential Time Hypothesis (ETH) asserts that there is no $2^{o(N)}$ time algorithm for Sat on N variables. The ETH is used to attain more precise conditional lower bounds than the mere NP-hardness. A simple reduction from Set Cover by Eidenbenz et al. shows that there is no $n^{o(k)}$ algorithm for these problems, when we consider polygons with holes [11, Sec.4], unless the ETH fails. However, polygons with holes are very different from simple polygons. For instance, they have unbounded VC-dimension while simple polygons have bounded VC-dimension [35, 20, 22, 19]. Our contribution is to show that, even on simple polygons, one cannot expect a large improvement over the $n^{O(k)}$ algorithms. More precisely, we prove:

▶ **Theorem 1** (Parameterized hardness point guard). *Assuming the ETH,* Point Guard Art Gallery *is not solvable in time $f(k)\, n^{o(k/\log k)}$, for any computable function f, even on simple polygons, where n is the number of vertices of the polygon and k is the number of guards allowed.*

▶ **Theorem 2** (Parameterized hardness vertex guard). *Assuming the ETH,* Vertex Guard Art Gallery *is not solvable in time $f(k)\, n^{o(k/\log k)}$, for any computable function f, even on simple polygons, where n is the number of vertices of the polygon and k is the number of guards allowed.*

Our reductions are from Subgraph Isomorphism. Therefore an algorithm solving the art gallery problem in time $f(k)\, n^{o(k/\log k)}$ would also improve current running times for Subgraph Isomorphism and for solving CSPs parameterized by treewidth, which are major open questions [28]. Our results imply, in particular, that both variants are $W[1]$-hard parameterized by the number of guards.

Finally, let us mention a sample of works on the parameterized complexity (with an emphasis on hardness) of other geometric problems. The complexity of some fundamental

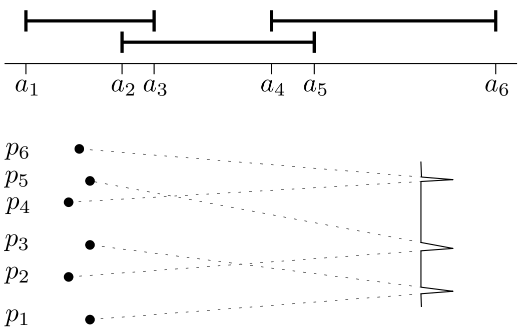

Figure 1 Reduction from Hitting Set on interval graphs to a restricted version of the art gallery problem.

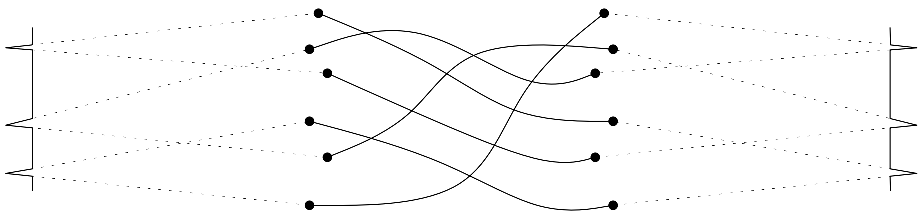

Figure 2 Two instances of Hitting Set "magically" linked.

problems parameterized by the dimension d has been addressed [17]; it was shown that, assuming the ETH, algorithms running in time $n^{O(d)}$ are essentially optimal (with n being the size of the instance). Extracting from a finite set of points of $\mathbb{R}^3$ the largest subset in convex position and whose convex-hull interior is empty is W[1]-hard [16]. More results on geometric covering or packing problems include the following papers [5, 27, 1, 29, 7]. We refer the interested reader to the extensive survey of Giannopoulos et al. [18].

Proof ideas. In order to achieve these results, we slightly extend some known hardness results of geometric set cover/hitting set problems and combine them with problem-specific insights of the art gallery problem. One of the first problem-specific insights is the ability to encode Hitting Set on interval graphs. The reader can refer to Figure 1 for the following description. Assume that we have some fixed points $p_1, \ldots, p_n$ with increasing y-coordinates in the plane. We can build a pocket "far enough to the right" that can be seen only from $\{p_i, \ldots, p_j\}$ for any $1 \leq i < j \leq n$.

Let $I_1, \ldots, I_n$ be n intervals with endpoints $a_1, \ldots, a_{2n}$. Then, we construct $2n$ points $p_1, \ldots, p_{2n}$ representing $a_1, \ldots, a_{2n}$. Further, we construct one pocket "far enough to the right" for each interval as described above. This way, we reduce Hitting Set on interval graphs to a restricted version of the art gallery problem. This observation is *not* so useful in itself since hitting set on interval graphs can be solved in polynomial time.

The situation changes rapidly if we consider Hitting Set on 2-track interval graphs, as described in Section 2. Unfortunately, we are not able to just "magically" link some specific pairs of points in the polygon of the art gallery instance. Therefore, we construct linker gadgets, which basically work as follows. We are given two set of points P and Q and a bijection σ between P and Q. The linker gadget is built in a way that it can be covered by two points (p, q) of $P \times Q$, if and only if $q = \sigma(p)$. The Structured 2-Track Hitting Set problem will be specifically designed so that the linker gadget is the main remaining ingredient to show hardness.

Organization of the paper. In Section 2, we introduce some notations, discuss the encoding of the polygon, and give some useful ETH-based lower bounds. We show a lower bound for Structured 2-Track Hitting Set based on the lower bound known for Multicolored Subgraph Isomorphism. Due to space limitation, this proof is only included in the arxiv version of the paper [3]. Then, we reduce from the particularly convenient Structured 2-Track Hitting Set. In Section 3, we show the lower bound for the Point Guard Art Gallery problem (Theorem 1). We design a linker gadget, show its correctness, and show how several linker gadgets can be combined consistently. In Section 4, we tackle the Vertex Guard Art Gallery problem (Theorem 2). We have to design a very different linker gadget, that has to be combined with other gadgets and ideas.

2 Preliminaries

For any two integers $x \leqslant y$, we set $[x, y] := \{x, x+1, \dots, y-1, y\}$, and for any positive integer x, $[x] := [1, x]$. Given two points a, b in the plane, we define $\mathrm{seg}(a, b)$ as the line segment with endpoints a, b. Given n points $v_1, \dots, v_n \in \mathbb{R}^2$, we define a polygonal closed curve c by $\mathrm{seg}(v_1, v_2)$, …, $\mathrm{seg}(v_{n-1}, v_n)$, $\mathrm{seg}(v_n, v_1)$. If c is not self intersecting, it partitions the plane into a closed bounded area and an unbounded area. The closed bounded area is a *simple polygon* on the vertices $v_1, \dots, v_n$. Note that we do not consider the boundary as the polygon but rather all the points bounded by the curve c as described above. Given two points a, b in a simple polygon $\mathcal{P}$, we say that *a sees b* or a is *visible* from b if $\mathrm{seg}(a, b)$ is contained in $\mathcal{P}$. By this definition, it is possible to "see through" vertices of the polygon. We say that S is a set of *point guards* of $\mathcal{P}$, if every point $p \in \mathcal{P}$ is visible from a point of S. We say that S is a set of *vertex guards* of $\mathcal{P}$, if additionally S is a subset of the vertices of $\mathcal{P}$. The Point Guard Art Gallery problem and the Vertex Guard Art Gallery problem are formally defined as follows.

Point Guard Art Gallery
Input: The vertices of a simple polygon $\mathcal{P}$ in the plane and a natural number k.
Question: Does there exist a set of k point guards for $\mathcal{P}$?

Vertex Guard Art Gallery
Input: A simple polygon $\mathcal{P}$ on n vertices in the plane and a natural number k.
Question: Does there exist a set of k vertex guards for $\mathcal{P}$?

For any two distinct points v and w in the plane we denote by $\mathrm{ray}(v, w)$ the ray starting at v and passing through w, and by $\ell(v, w)$ the supporting line passing through v and w. For any point x in a polygon $\mathcal{P}$, $V_{\mathcal{P}}(x)$, or simply $V(x)$, denotes the *visibility region* of x within $\mathcal{P}$, that is the set of all the points $y \in \mathcal{P}$ seen by x. We say that two vertices v and w of a polygon $\mathcal{P}$ are *neighbors* or *consecutive* if vw is an edge of $\mathcal{P}$. A *sub-polygon* $\mathcal{P}'$ of a simple polygon $\mathcal{P}$ is defined by any l distinct consecutive vertices $v_1, v_2, \dots, v_l$ of $\mathcal{P}$ (that is, for every $i \in [l-1]$, v_i and v_{i+1} are neighbors in $\mathcal{P}$) such that $v_1 v_l$ does not cross any edge of $\mathcal{P}$. In particular, $\mathcal{P}'$ is a simple polygon.

We assume that the vertices of the polygon are either given by integers or by rational numbers. We also assume that the output is given either by integers or by rational numbers. The instances we generate as a result of Theorem 1 and Theorem 2 have rational coordinates. We can represent them by specifying the nominator and denominator. The number of bits is bounded by $O(\log n)$ in both cases. We can transform the coordinates to integers by multiplying every coordinate with the least common multiple of all denominators. However, this leads to integers using $O(n \log n)$ bits.

ETH-based lower bounds. The *Exponential Time Hypothesis* (ETH) is a conjecture by Impagliazzo et al. [21] asserting that there is no $2^{o(n)}$-time algorithm for 3-SAT on instances with n variables.

The MULTICOLORED SUBGRAPH ISOMORPHISM problem can be defined in the following equivalent way. One is given a graph with n vertices partitioned into l color classes $V_1, \dots, V_l$ such that only k of the $\binom{l}{2}$ sets $E_{ij} = E(V_i, V_j)$ are non empty. The goal is to pick one vertex in each color class so that the selected vertices induce k edges. Observe that l corresponds to the number of vertices of the pattern graph. The technique of color coding and a result of Marx imply that:

▶ **Theorem 3** ([28]). *Unless the ETH fails,* MULTICOLORED SUBGRAPH ISOMORPHISM *cannot be solved in time $f(k)\, n^{o(k/\log k)}$ where k is the number of edges of the solution and f any computable function.*

Naturally, this result still holds when restricted to connected input graphs. In that case, $k \geqslant l - 1$.

In the 2-TRACK HITTING SET problem, the input consists of an integer k, two totally ordered ground sets A and B of the same cardinality, and two sets $\mathcal{S}_A$ of A-intervals, and $\mathcal{S}_B$ of B-intervals. In addition, the elements of A and B are in one-to-one correspondence $\phi : A \to B$ and each pair $(a, \phi(a))$ is called a 2-*element*. The goal is to find, if possible, a set S of k 2-elements such that the first projection of S is a hitting set of $\mathcal{S}_A$, and the second projection of S is a hitting set of $\mathcal{S}_B$.

STRUCTURED 2-TRACK HITTING SET is the same problem with color classes over the 2-elements, and a restriction on the one-to-one mapping ϕ. Given two integers k and t, A is partitioned into $(C_1, C_2, \dots, C_k)$ where $C_j = \{a^j_1, a^j_2, \dots, a^j_t\}$ for each $j \in [k]$. A is ordered: $a^1_1, a^1_2, \dots, a^1_t, a^2_1, a^2_2, \dots, a^2_t, \dots, a^k_1, a^k_2, \dots, a^k_t$. We define $C'_j := \phi(C_j)$ and $b^j_i := \phi(a^j_i)$ for all $i \in [t]$ and $j \in [k]$. We now impose that ϕ is such that, for each $j \in [k]$, the set C'_j is a B-interval. That is, B is ordered: $C'_{\sigma(1)}, C'_{\sigma(2)}, \dots, C'_{\sigma(k)}$ for some permutation on $[k]$, $\sigma \in \mathfrak{S}_k$. For each $j \in [k]$, the order of the elements within C'_j can be described by a permutation $\sigma_j \in \mathfrak{S}_t$ such that the ordering of C'_j is: $b^j_{\sigma_j(1)}, b^j_{\sigma_j(2)}, \dots, b^j_{\sigma_j(t)}$. In what follows, it will be convenient to see an instance of STRUCTURED 2-TRACK HITTING SET as a tuple $\mathcal{I} = (k \in \mathbb{N}, t \in \mathbb{N}, \sigma \in \mathfrak{S}_k, \sigma_1 \in \mathfrak{S}_t, \dots, \sigma_k \in \mathfrak{S}_t, \mathcal{S}_A, \mathcal{S}_B)$, where we recall that $\mathcal{S}_A$ is a set of A-intervals and $\mathcal{S}_B$ is a set of B-intervals. We denote by $[a^j_i, a^{j'}_{i'}]$ (resp. $[b^j_i, b^{j'}_{i'}]$) all the elements $a \in A$ (resp. $b \in B$) such that $a^j_i \leq_A a \leq_A a^{j'}_{i'}$ (resp. $b^j_i \leq_B b \leq_B b^{j'}_{i'}$).

Taking inspiration from previous results, we show hardness of STRUCTURED 2-TRACK HITTING SET by a reduction from MULTICOLORED SUBGRAPH ISOMORPHISM. Due to lack of space, we do no include the proof of the following theorem. The interested reader can find this proof in the arxiv version of the paper [3].

▶ **Theorem 4.** STRUCTURED 2-TRACK HITTING SET *is $W[1]$-hard, and not solvable in time $f(k)\, |\mathcal{I}|^{o(k/\log k)}$ for any computable function f, unless the ETH fails.*

3 Parameterized hardness of the point guard variant

As exposed in the introduction, we give a reduction from the STRUCTURED 2-TRACK HITTING SET problem. The main challenge is to design a *linker* gadget that groups together specific pairs of points in the polygon. The following introductory lemma inspires the *linker* gadgets for both POINT GUARD ART GALLERY and VERTEX GUARD ART GALLERY.

Figure 3 An illustration of the $k+1$ permutations $\sigma \in \mathfrak{S}_k$, $\sigma_1 \in \mathfrak{S}_t$, ..., $\sigma_k \in \mathfrak{S}_t$ of an instance of Structured 2-Track Hitting Set, with $k = 4$ and $t = 6$.

▶ **Lemma 5.** *The only minimum hitting sets of the set-system* $\mathcal{S} = \{S_i = \{1, 2, \dots, i, \overline{i+1}, \overline{i+2}, \dots, \overline{n}\} \mid i \in [n]\} \cup \{\overline{S}_i = \{\overline{1}, \overline{2}, \dots, \overline{i}, i+1, i+2, \dots, n\} \mid i \in [n]\}$ *are* $\{i, \overline{i}\}$*, for each* $i \in [n]$.

Proof. First, for each $i \in [n]$, one may easily observe that $\{i, \overline{i}\}$ is a hitting set of $\mathcal{S}$. Now, because of the sets S_n and $\overline{S}_n$ one should pick one element i and one element $\overline{j}$ for some $i, j \in [n]$. If $i < j$, then set $\overline{S}_i$ is not hit, and if $i > j$, then S_j is not hit. Therefore, i should be equal to j. ◀

▶ **Theorem 1** (Parameterized hardness point guard). *Assuming the ETH,* Point Guard Art Gallery *is not solvable in time* $f(k)\, n^{o(k/\log k)}$*, for any computable function* f*, even on simple polygons, where* n *is the number of vertices of the polygon and* k *is the number of guards allowed.*

Proof. Given an instance $\mathcal{I} = (k \in \mathbb{N}, t \in \mathbb{N}, \sigma \in \mathfrak{S}_k, \sigma_1 \in \mathfrak{S}_t, \dots, \sigma_k \in \mathfrak{S}_t, \mathcal{S}_A, \mathcal{S}_B)$ of Structured 2-Track Hitting Set, we build a simple polygon $\mathcal{P}$ with $O(kt + |\mathcal{S}_A| + |\mathcal{S}_B|)$ vertices, such that $\mathcal{I}$ is a YES-instance iff $\mathcal{P}$ can be guarded by $3k$ points.

Outline. We recall that A's order is: $a^1_1, \dots, a^1_t, \dots, a^k_1, \dots, a^k_t$ and B's order is determined by σ and the σ_j's (see Figure 3). Let us focus on one color class $j \in [k]$ together with a permutation $\sigma_j : A \to B$. The global strategy of the reduction is to *allocate*, $2t$ special points for this polygon. The points $a^j_1, \dots, a^j_t$ on track A are represented by $\alpha^j_1, \dots, \alpha^j_t$ points in $\mathcal{P}$. and the points $\sigma_j(a^j_1), \dots, \sigma_j(a^j_t)$ on track B are represented by $\beta^j_1, \dots, \beta^j_t$ in the polygon. Placing a guard in α^j_i and β^j_i shall correspond to picking the 2-element $(a^j_i, \sigma_j(b^j_i))$. The points α^j_i's and β^j_i's ordered by increasing y-coordinates will match the order of the a^j_i's along the order $\leq_A$ and then of the b^j_i's along $\leq_B$. Then, far in the horizontal direction, we will place pockets to encode each A-interval of $\mathcal{S}_A$, and each B-interval of $\mathcal{S}_B$.

The first critical issue will be to *link* point α^j_i to point β^j_i. Indeed, in the Structured 2-Track Hitting Set problem, one selects 2-elements (one per color class), so we should prevent one from placing two guards in α^j_i and $\beta^j_{i'}$ with $i \neq i'$. The so-called *point linker* gadget will realize the intervals as described in Lemma 5.

The second critical issue is to enforce these positions. For this purpose, we will need to introduce a *copy* $\overline{\alpha}^j_i$ of each α^j_i. In each part of the gallery encoding a color class $j \in [k]$, the only way of guarding all the pockets with only three guards will be to place them in α^j_i, $\overline{\alpha}^j_i$, and β^j_i for some $i \in [t]$ (see Figure 5). Hence, $3k$ guards will be necessary and sufficient to guard the whole $\mathcal{P}$ iff there is a solution to the instance of Structured 2-Track Hitting Set.

We now get into the details of the reduction. We will introduce several characteristic lengths and compare them; when $l_1 \ll l_2$ means that l_1 should be thought as really small compared to l_2, and $l_1 \approx l_2$ means that l_1 and l_2 are roughly of the same order. The motivation is to guide the intuition of the reader without bothering her/him too much about the details. At the end of the construction, we will specify more concretely how those lengths are chosen.

Construction. We start with an explicit specification of the coordinates. The description will be dependent on some parameters x, y, L, D, F that we will specify later. The value x represents the offset between elements with respect to the x-coordinate and likewise the value y represents the offset between elements with respect to the y-coordinate. D represents the vertical distance between different color classes and L represents the horizontal distance between all the $\alpha's$ and the $\beta's$, see also Figure 6. The value F will become relevant later and describes the distance of the points to the pockets to the far right. The crucial point of the construction is that the order of the α's corresponds exactly to the order of the a's along track A and the same relation holds between the β's and b's.

We recall that we want the points α_i^j's and β_i^j's ordered by increasing y-coordinates, to match the order of the a_i^j's and b_i^j's along $\leq_A$ and $\leq_B$, with first all the elements of A and then all the elements of B. Starting from some y-coordinate y_1 (which is the one given to point α_1^1), the y-coordinates of the α_i^j's are regularly spaced out by an offset y; that is, the y-coordinate of α_i^j is $y_1 + (i + (j-1)t)y$. Between the y-coordinate of the last element in A (i.e., a_t^k whose y-coordinate is $y_1 + (kt-1)y$) and the first element in B, there is a large offset L, such that the y-coordinate of β_i^j is $y_1 + (kt-1)y + L + (\text{ord}(b_i^j) - 1)y$ (for any $j \in [k]$ and $i \in [t]$) where $\text{ord}(b_i^j)$ is the rank of b_i^j along the order $\leq_B$.

For each color class $j \in [k]$, let $x_j := x_1 + (j-1)D$ for some x-coordinate x_1 and value D, and $y_j := y_1 + (j-1)ty$. The allocated points $\alpha_1^j, \alpha_2^j, \alpha_3^j, \ldots, \alpha_t^j$ are on a line at coordinates: $(x_j, y_j), (x_j + x, y_j + y), (x_j + 2x, y_j + 2y), \ldots, (x_j + (t-1)x, y_j + (t-1)y)$, for some value x. We place, to the left of those points, a rectangular pocket $\mathcal{P}_{j,r}$ of width, say, y and length, say[1], tx such that the uppermost longer side of the rectangular pocket lies on the line $\ell(\alpha_1^j, \alpha_t^j)$ (see Figure 4). The y-coordinates of $\beta_1^j, \beta_2^j, \beta_3^j, \ldots, \beta_t^j$ have already been defined. We set, for each $i \in [t]$, the x-coordinate of β_i^j to $x_j + (i-1)x$, so that β_i^j and α_i^j share the same x-coordinate. One can check that it is consistent with the previous paragraph. We also observe that, by the choice of the y-coordinate for the β_i^j's, we have both encoded the permutations σ_j's and permutation σ (see Figure 6 or Figure 4). This finishes the description of the coordinates.

Now, we will give a description how, we can encode intervals by on track A and B by small pockets and, we describe, where to place them. From hereon, for a vertex v and two points p and p', we informally call *triangular pocket rooted at vertex v and supported by ray(v,p) and ray(v,p')* a sub-polygon w, v, w' (a triangle) such that $\text{ray}(v,w)$ passes through p, $\text{ray}(v,w')$ passes through p', while w and w' are close to v (sufficiently close not to interfere with the rest of the construction). We say that v is the *root* of the triangular pocket, that we often denote by $\mathcal{P}(v)$. We also say that the pocket $\mathcal{P}(v)$ *points* towards p and p'. It is easy to see that each point that sees v also sees the entire triangular pocket $P(v)$.

[1] The exact width and length of this pocket are not relevant; the reader may just think of $\mathcal{P}_{j,r}$ as a thin pocket which forces to place a guard on a thin strip whose uppermost boundary is $\ell(\alpha_1^j, \alpha_t^j)$

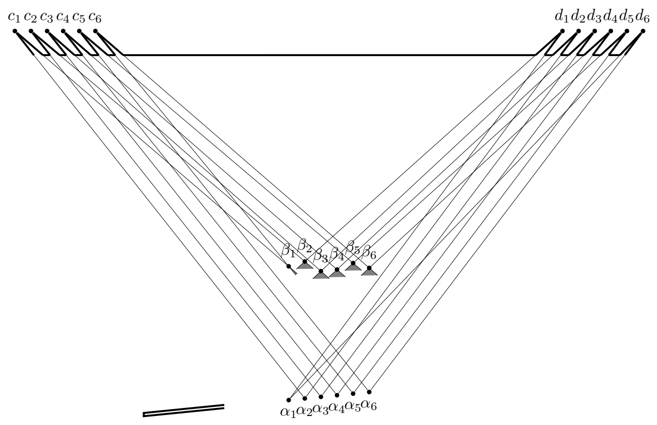
For each A-interval $I_q = [a_i^j, a_{i'}^{j'}] \in \mathcal{S}_A$ we construct one triangular pocket $\mathcal{P}(z_{A,q})$ rooted at vertex $z_{A,q}$ and supported by $\text{ray}(z_{A,q}, \alpha_i^j)$ and $\text{ray}(z_{A,q}, \alpha_{i'}^{j'})$. The placement of this triangular pocket is very far to the right. The x-coordinate of $z_{A,q}$ equals $x_k + (t-1)x + F$, for some large value F to be specified later. The y-coordinate shall be between y_1 and $y_k + (kt-1)y$. We place those $|\mathcal{S}_A|$ pockets along the y-axis, and space them out by some small distance s. To guarantee that we have enough room to place all those pockets, s will be chosen sufficiently small ($s \ll y$).

We will show later, for appropriate values $y \ll x \ll D \ll F$, the only $\alpha_{i''}^{j''}$ seeing vertex $z_{A,q}$ should be the points such that $a_i^j \leq_A a_{i''}^{j''} \leq_A a_{i'}^{j'}$ (see Figure 6).

Similarly, we represent each interval $I_q \in \mathcal{S}_B$ by a triangular pocket rooted at $z_{B,q}$. These pockets are placed at the x-coordinate $x_k + (t-1)x + F$ and spaced out by distance s along the y-axis between y-coordinates $y_1 + (kt-1)y + L$ and $y_1 + 2(kt-1)y + L$. The B-interval $I_q = [b_i^j, b_{i'}^{j'}]$ is represented by the triangular pocket $\mathcal{P}(z_{B,q})$ rooted at vertex $z_{B,q}$ supported by $\text{ray}(z_{B,q}, \sigma_j(a_i^j))$ and $\text{ray}(z_{B,q}, \sigma_j(a_{i'}^{j'}))$. Note that $\sigma_j(a_i^j)$ is the point on track B that corresponds to β_i^j. The different values (s, x, y, D, L, and F) introduced so far compare in the following way: $s \ll y \ll x \ll D \ll F$, and $x \ll L \ll F$, see Figure 6.

Now, we describe how we *link* each point α_i^j to its associate β_i^j. For each $j \in [k]$, let us mentally draw $\text{ray}(\alpha_t^j, \beta_1^j)$ and consider points slightly to the left of this ray at a distance, say, L' from point α_t^j. Let us call $\mathcal{R}_{\text{left}}^j$ that informal region of points. Any point in $\mathcal{R}_{\text{left}}^j$ sees, from right to left, in the order α_1^j, α_2^j up to α_t^j, and then, β_1^j, β_2^j up to β_t^j. This observation relies on the fact that $y \ll x \ll L$. So, from the distance, the points $\beta_1^j, \dots, \beta_t^j$ look almost *flat*. It makes the following construction possible. In $\mathcal{R}_{\text{left}}^j$, for each $i \in [t-1]$, we place a triangular pocket $\mathcal{P}(c_i^j)$ rooted at vertex c_i^j and supported by $\text{ray}(c_i^j, \alpha_{i+1}^j)$ and $\text{ray}(c_i^j, \beta_i^j)$. We place also a triangular pocket $\mathcal{P}(c_t^j)$ rooted at c_t^j supported by $\text{ray}(c_i^j, \beta_1^j)$ and $\text{ray}(c_i^j, \beta_t^j)$. We place vertices c_i^j and c_{i+1}^j at the same y-coordinate and spaced out by distance x along the x-axis (see Figure 4). Similarly, let us informally refer to the region slightly to the right of $\text{ray}(\alpha_1^j, \beta_t^j)$ at a distance L' from point α_1^j, as $\mathcal{R}_{\text{right}}^j$. Any point $\mathcal{R}_{\text{right}}^j$ sees, from right to left, in this order β_1^j, β_2^j up to β_t^j, and then, α_1^j, α_2^j up to α_t^j. Therefore, one can place in $\mathcal{R}_{\text{left}}^j$, for each $i \in [t-1]$, a triangular pocket $\mathcal{P}(d_i^j)$ rooted at d_i^j supported by $\text{ray}(d_i^j, \beta_{i+1}^j)$ and $\text{ray}(c_i^j, \alpha_i^j)$. We place also a triangular pocket $\mathcal{P}(d_t^j)$ rooted at d_t^j supported by $\text{ray}(d_i^j, \alpha_1^j)$ and $\text{ray}(c_i^j, \alpha_t^j)$. Again, those t pockets are placed at the same y-coordinate and spaced out horizontally by x (see Figure 4). We denote by $\mathcal{P}_{j,\alpha,\beta}$ the set of pockets $\{\mathcal{P}(c_1^j), \dots, \mathcal{P}(c_t^j), \mathcal{P}(d_1^j), \dots, \mathcal{P}(d_t^j)\}$ and informally call it the *weak point linker* (or simply, *weak linker*) of $\alpha_1^j, \dots, \alpha_t^j$ and $\beta_1^j, \dots, \beta_t^j$. We may call the pockets of $\mathcal{R}_{\text{left}}^j$ (resp. $\mathcal{R}_{\text{right}}^j$) *left* pockets (resp. *right* pockets).

As we will show later, if one wants to guard with only two points all the pockets of $\mathcal{P}_{j,\alpha,\beta} = \{\mathcal{P}(c_1^j), \dots, \mathcal{P}(c_t^j), \mathcal{P}(d_1^j), \dots, \mathcal{P}(d_t^j)\}$ and one first decides to put a guard on point α_i^j (for some $i \in [t]$), then one is not forced to put the other guard on point β_i^j but only on an area whose uppermost point is β_i^j (see the shaded areas below the b_i^j's in Figure 4). Now, if the points $\beta_1^j, \dots, \beta_t^j$ would all lie on a common line ℓ, we could shrink the shaded area of each β_i^j (Figure 4) down to the single point β_i^j by adding a thin rectangular pocket on ℓ (similarly to what we have for $\alpha_1^j, \dots, \alpha_t^j$). Naturally, we need that $\beta_1^j, \dots, \beta_t^j$ are *not* on a common line to be able to encode the permutation σ_j. The remedy we pursue is the following. For each $j \in [k]$, we allocate t points $\overline{\alpha}_1^j, \overline{\alpha}_2^j, \dots, \overline{\alpha}_t^j$ on a horizontal line, spaced out by distance x, say, $\approx \frac{D}{2}$ to the right and $\approx L$ above of β_t^j. We place a thin horizontal rectangular pocket $\mathcal{P}_{j,\overline{r}}$ of the same dimension as $\mathcal{P}_{j,r}$ such that the lowermost longer side of $\mathcal{P}_{j,\overline{r}}$ is on the line $\ell(\overline{\alpha}_1^j, \overline{\alpha}_t^j)$. We add the $2t$ pockets corresponding to a weak



$c_1\,c_2\,c_3\,c_4\,c_5\,c_6$
$d_1d_2d_3d_4d_5d_6$
$\beta_1\beta_2\beta_3\beta_4\beta_5\beta_6$
$\alpha_1\alpha_2\alpha_3\alpha_4\alpha_5\alpha_6$

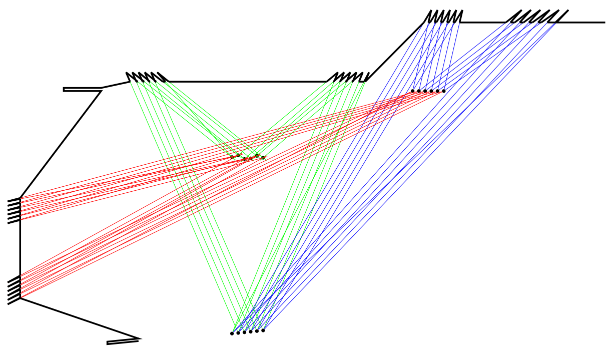

Figure 5 Point linker gadget: a triangle of (three) weak point linkers.

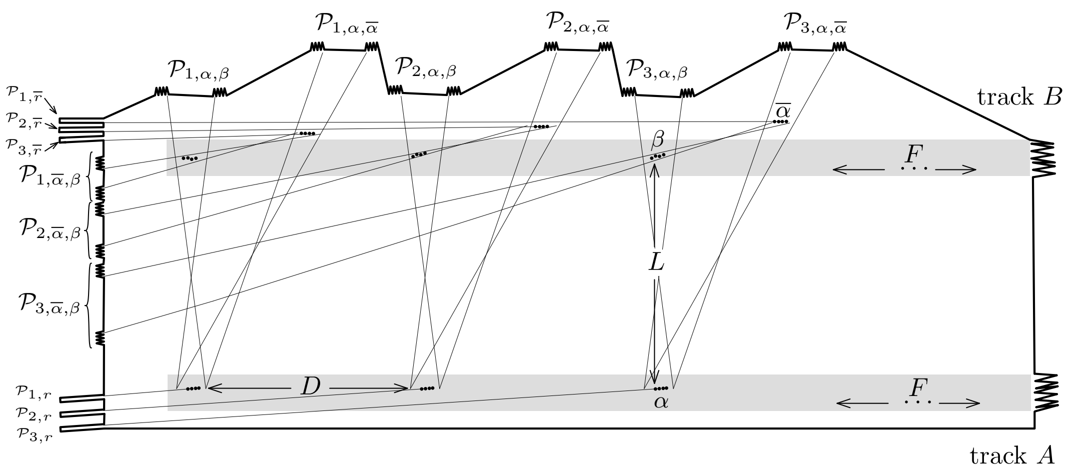
linker $\mathcal{P}_{j,\alpha,\overline{\alpha}}$ between $\alpha^j_1, \ldots, \alpha^j_t$ and $\overline{\alpha}^j_1, \ldots, \overline{\alpha}^j_t$ as well as the $2t$ pockets of a weak linker $\mathcal{P}_{j,\overline{\alpha},\beta}$ between $\overline{\alpha}^j_1, \ldots, \overline{\alpha}^j_t$ and $\beta^j_1, \ldots, \beta^j_t$ as pictured in Figure 5. We denote by $\mathcal{P}_j$ the union $\mathcal{P}_{j,r} \cup \mathcal{P}_{j,\overline{r}} \cup \mathcal{P}_{j,\alpha,\beta} \cup \mathcal{P}_{j,\alpha,\overline{\alpha}} \cup \mathcal{P}_{j,\overline{\alpha},\beta}$ of all the pockets involved in the encoding of color class j. Now, say, one wants to guard all the pockets of $\mathcal{P}_j$ with only three points, and chooses to put a guard on α^j_i (for some $i \in [t]$). Because of the pockets of $\mathcal{P}_{j,\alpha,\overline{\alpha}} \cup P_{j,\overline{r}}$, one is forced to place a second guard precisely on $\overline{\alpha}^j_i$. Now, because of the weak linker $\mathcal{P}_{j,\alpha,\beta}$ the third guard should be on a region whose uppermost point is β^j_i, while, because of $\mathcal{P}_{j,\overline{\alpha},\beta}$ the third guard should be on a region whose lowermost point is β^j_i. The conclusion is that the third guard should be put precisely on β^j_i. This *triangle* of weak linkers is called the *linker* of color class j. The k linkers are placed accordingly to Figure 6. This ends the construction.

Specification of the distances. We can specify the coordinates of positions of all the vertices by fractions of integers. These integers are polynomially bounded in n. If we want to get integer coordinates, we can transform the rational coordinates to integer coordinates by multiplying all of them with the least common multiple of all the denominators, which is not polynomially bounded anymore. The length of the integers in binary is still polynomially bounded.

We can safely set s to one, as it is the smallest length, we specified. We will put $|\mathcal{S}_a|$ pockets on track A and $|\mathcal{S}_b|$ pockets on track B. It is sufficient to have an opening space of one between them. Thus, the space on the right side of $\mathcal{P}$, for all pockets of track A is bounded by $2|\mathcal{S}_a|$. Thus setting y to $|\mathcal{S}_a| + |\mathcal{S}_b|$ secures us that we have plenty of space to



$\mathcal{P}_{1,\alpha,\overline{\alpha}}$

Figure 6 The overall picture of the reduction with $k = 3$.

place all the pockets. We specify $F = (|\mathcal{S}_a| + |\mathcal{S}_b|)Dk = yDk$. We have to show that this is large enough to guarantee that the pockets on track A distinguish the picked points only by the y-coordinate. Let p and q be two points among the α_i^j. Their vertical distance is upper bounded by Dk and their horizontal distance is lower bounded by y. Thus the slope of $\ell = \ell(p, q)$ is at least $\frac{y}{Dk}$. At the right side of $\mathcal{P}$ the line ℓ will be at least $F\frac{y}{Dk}$ above the pockets of track A. Note $F\frac{y}{Dk} = yDk\frac{y}{Dk} > y^2 > |\mathcal{S}_a|^2 > 2|\mathcal{S}_a|$. The same argument shows that F is sufficiently large for track B.

The remaining lengths x, L, L', and D can be specified in a similar fashion. For the construction of the pockets, let $s \in \mathcal{S}_a$ be an A-interval with endpoints a and b, represented by some points p and q and assume the opening vertices v and w of the triangular pocket are already specified. Then the two lines $\ell(p, v)$ and $\ell(q, w)$ will meet at some point x to the right of v and w. It is easy to see that x has rational coordinates and the integers to represent them can be expressed by the coordinates of p, q, v, and w. This way, all the pockets can be explicitly constructed using rational coordinates as claimed above.

Soundness. We now show that the reduction is correct. The following lemma is the main argument for the easier implication: *if $\mathcal{I}$ is a YES-instance, then the gallery that we build can be guarded with $3k$ points.*

▶ **Lemma 6.** *$\forall j \in [k]$, $\forall i \in [t]$, the three associate points α_i^j, $\overline{\alpha}_i^j$, β_i^j guard entirely $\mathcal{P}_j$.*

Proof. The rectangular pockets $\mathcal{P}_{j,r}$ and $\mathcal{P}_{j,\overline{r}}$ are entirely seen by respectively α_i^j and $\overline{\alpha}_i^j$. The pockets $\mathcal{P}(c_1^j), \mathcal{P}(c_2^j), \dots \mathcal{P}(c_{i-1}^j)$ and $\mathcal{P}(d_i^j), \mathcal{P}(d_{i+1}^j), \dots \mathcal{P}(d_t^j)$ are all entirely seen by α_i^j, while the pockets $\mathcal{P}(c_i^j), \mathcal{P}(c_{i+1}^j), \dots \mathcal{P}(c_t^j)$ and $\mathcal{P}(d_1^j), \mathcal{P}(d_2^j), \dots \mathcal{P}(d_{i-1}^j)$ are all entirely seen by β_i^j. This means that α_i^j and β_i^j jointly see all the pockets of $\mathcal{P}_{j,\alpha,\beta}$. Similarly, α_i^j and $\overline{\alpha}_i^j$ jointly see all the pockets of $\mathcal{P}_{j,\alpha,\overline{\alpha}}$, and $\overline{\alpha}_i^j$ and β_i^j jointly see all the pockets of $\mathcal{P}_{j,\overline{\alpha},\beta}$. Therefore, α_i^j, $\overline{\alpha}_i^j$, β_i^j jointly see all the pockets of $\mathcal{P}_j$. ◀

Assume that $\mathcal{I}$ is a YES-instance and let $\{(a_{s_1}^1, b_{s_1}^1), \dots, (a_{s_k}^k, b_{s_k}^k)\}$ be a solution. We claim that $G = \{\alpha_{s_1}^1, \overline{\alpha}_{s_1}^1, \beta_{s_1}^1, \dots, \alpha_{s_k}^k, \overline{\alpha}_{s_k}^k, \beta_{s_k}^k\}$ guard the whole polygon $\mathcal{P}$. By Lemma 6, $\forall j \in [k]$, $\mathcal{P}_j$ is guarded. For each A-interval (resp. B-interval) in $\mathcal{S}_A$ (resp. $\mathcal{S}_B$) there is at least one 2-element $(a_{s_j}^j, b_{s_j}^j)$ such that $a_{s_j}^j \in \mathcal{S}_A$ (resp. $b_{s_j}^j \in \mathcal{S}_B$). Thus, the corresponding pocket is guarded by $\alpha_{s_j}^j$ (resp. $\beta_{s_j}^j$). The rest of the polygon $\mathcal{P}$ (which is not part of pockets) is guarded by, for instance, $\{\overline{\alpha}^1_{s_1}, \ldots, \overline{\alpha}^k_{s_k}\}$. So, G is indeed a solution and it contains $3k$ points.

Assume now that there is no solution to the instance $\mathcal{I}$ of Structured 2-Track Hitting Set. We show that there is no set of $3k$ points guarding $\mathcal{P}$. We observe that no point of $\mathcal{P}$ sees inside two triangular pockets one being in $\mathcal{P}_{j,\alpha,\gamma}$ and the other in $\mathcal{P}_{j',\alpha,\gamma'}$ with $j \neq j'$ and $\gamma, \gamma' \in \{\beta, \overline{\alpha}\}$. Further, $V(r(\mathcal{P}_{j,\alpha,\beta} \cup \mathcal{P}_{j,\alpha,\overline{\alpha}})) \cap V(r(\mathcal{P}_{j',\alpha,\beta} \cup \mathcal{P}_{j',\alpha,\overline{\alpha}})) = \emptyset$ when $j \neq j'$, where r maps a set of triangular pockets to the set of their root. Also, for each $j \in [k]$, seeing entirely $\mathcal{P}_{j,\alpha,\beta}$ and $\mathcal{P}_{j,\alpha,\overline{\alpha}}$ requires at least 3 points. This means that for each $j \in [k]$, one should place three guards in $V(r(\mathcal{P}_{j,\alpha,\beta} \cup \mathcal{P}_{j,\alpha,\overline{\alpha}}))$. Furthermore, one can observe among those three points one should guard a triangular pocket $\mathcal{P}_{j',r}$ and another should guard $\mathcal{P}_{j'',\overline{r}}$. Let us try to guard entirely $\mathcal{P}_1$ and two rectangular pockets $\mathcal{P}_{j',r}$ and $\mathcal{P}_{j'',\overline{r}}$, with only three guards. Let call ℓ_1 (resp. ℓ'_1) the line corresponding to the extension of the uppermost (resp. lowermost) longer side of $\mathcal{P}_{1,r}$ (resp. $\mathcal{P}_{1,\overline{r}}$). The only points of $\mathcal{P}$ that can see a rectangular pocket $\mathcal{P}_{j',r}$ and at least t pockets of $\mathcal{P}_{1,\alpha,\overline{\alpha}}$ are on ℓ_1: more specifically, they are the points $\alpha^1_1, \ldots, \alpha^1_t$. The only points that can see a rectangular pocket $\mathcal{P}_{j'',\overline{r}}$ and at least t pockets of $\mathcal{P}_{1,\alpha,\overline{\alpha}}$ are on ℓ'_1: they are the points $\overline{\alpha}^1_1, \ldots, \overline{\alpha}^1_t$. As $\mathcal{P}_{1,\alpha,\overline{\alpha}}$ has $2t$ pockets, one has to take a point α^1_i and $\overline{\alpha}^1_{i'}$. By the same argument argument as in Lemma 5, i should be equal to i' (otherwise, $i < i'$ and the left pocket pointing towards $\overline{\alpha}^1_{i'-1}$ and $\alpha^1_{i'}$ is not seen, or $i > i'$ and the right pocket pointing towards α^1_{i+1} and $\overline{\alpha}^1_i$ is not seen). We now denote by s_1 this shared value. Now, to see the left pocket $\mathcal{P}(c^1_{s_1})$ and the right pocket $\mathcal{P}(d^1_{s_1-1})$ (that should still be seen), the third guard should be to the left of $\ell(c^1_{s_1}, \beta^1_{s_1})$ and to the right of $\ell(d^1_{s_1-1}, \beta^1_{s_1})$ (see shaded area of Figure 4). That is, the third guard should be on a region in which $\beta^1_{s_1}$ is the uppermost point. The same argument with the pockets of $\mathcal{P}_{1,\overline{\alpha},\beta}$ implies that the third guard should also be on a region in which $\beta^1_{s_1}$ is the lowermost point. Thus, the position of the third guard has to be point $\beta^1_{s_1}$. Therefore, one should put guards on points $\alpha^1_{s_1}$, $\overline{\alpha}^1_{s_1}$, and $\beta^1_{s_1}$, for some $\alpha_1 \in [t]$.

As none of those three points see any pocket $\mathcal{P}_{j,\overline{\alpha},\beta}$ with $j > 1$ (we already mentioned that no pocket of $\mathcal{P}_{j,\alpha,\beta}$ and $\mathcal{P}_{j,\alpha,\overline{\alpha}}$ with $j > 1$ can be seen by those points), we can repeat the argument for the second color class; and so forth up to color class k. Thus, a potential solution with $3k$ guards should be of the form $\{\alpha^1_{s_1}, \overline{\alpha}^1_{s_1}, \beta^1_{s_1}, \ldots, \alpha^k_{s_k}, \overline{\alpha}^k_{s_k}, \beta^k_{s_k}\}$. As there is no solution to $\mathcal{I}$, there should be a set in $\mathcal{S}_A \cup \mathcal{S}_B$ that is not hit by $\{(a^1_{s_1}, b^1_{s_1}), \ldots, (a^k_{s_k}, b^k_{s_k})\}$. By construction, the pocket associated to this set is not entirely seen. ◀

4 Parameterized hardness of the vertex guard variant

We now turn to the vertex guard variant and show the same hardness result. Again, we reduce from Structured 2-Track Hitting Set and our main task is to design a *linker gadget*. Though, *linking* pairs of vertices turns out to be very different from *linking* pairs of points. Therefore, we have to come up with fresh ideas to carry out the reduction. In a nutshell, the principal ingredient is to *link* pairs of convex vertices by introducing reflex vertices at strategic places. As placing guards on those reflex vertices is not supposed to happen in the Structured 2-Track Hitting Set instance, we design a so-called *filter gadget* to prevent any solution from doing so.

▶ **Theorem 2** (Parameterized hardness vertex guard). *Assuming the ETH,* Vertex Guard Art Gallery *is not solvable in time $f(k)\, n^{o(k/\log k)}$, for any computable function f, even on simple polygons, where n is the number of vertices of the polygon and k is the number of guards allowed.*

Proof. From an instance $\mathcal{I} = (k \in \mathbb{N}, t \in \mathbb{N}, \sigma \in \mathfrak{S}_k, \sigma_1 \in \mathfrak{S}_t, \ldots, \sigma_k \in \mathfrak{S}_t, \mathcal{S}_A, \mathcal{S}_B)$, we build

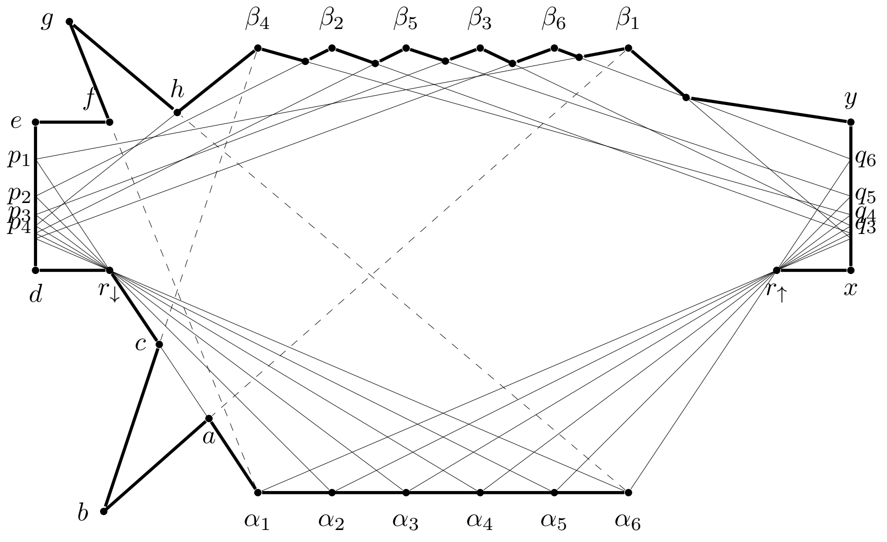

Figure 7 Vertex linker gadget. We omitted the superscript j in all the labels. Here, $\sigma_j(1) = 4,\ \sigma_j(2) = 2,\ \sigma_j(3) = 5,\ \sigma_j(4) = 3,\ \sigma_j(5) = 6,\ \sigma_j(6) = 1$.

a simple polygon $\mathcal{P}$ with $O(kt + |\mathcal{S}_A| + |\mathcal{S}_B|)$ vertices, such that $\mathcal{I}$ is a YES-instance iff $\mathcal{P}$ can be guarded by $3k$ vertices.

Linker gadget. For each $j \in [k]$, permutation σ_j will be encoded by a sub-polygon $\mathcal{P}_j$ that we call *vertex linker*, or simply *linker* (see Figure 7). We regularly set t consecutive vertices $\alpha_1^j, \alpha_2^j, \ldots, \alpha_t^j$ in this order, along the x-axis. Opposite to this *segment*, we place t vertices $\beta^j_{\sigma_j(1)}, \beta^j_{\sigma_j(2)}, \ldots, \beta^j_{\sigma_j(t)}$ in this order, along the x-axis, too. The $\beta^j_{\sigma_j(1)}, \ldots, \beta^j_{\sigma_j(t)}$, contrary to $\alpha_1^j, \ldots, \alpha_t^j$, are *not* consecutive; we will later add some reflex vertices between them. At mid-distance between α_1^j and $\beta^j_{\sigma_j(1)}$, to the left, we put a reflex vertex $r^j_\downarrow$. *Behind* this reflex vertex, we place a vertical *wall* d^je^j ($r^j_\downarrow$, d^j, and e^j are three consecutive vertices of $\mathcal{P}$), so that ray$(\alpha_1^j, r^j_\downarrow)$ and ray$(\alpha_t^j, r^j_\downarrow)$ both intersect seg(d^j, e^j). That implies that for each $i \in [t]$, ray$(\alpha_i^j, r^j_\downarrow)$ intersects seg(d^j, e^j). We denote by p_i^j this intersection. The greater i, the closer p_i^j is to d^j. Similarly, at mid-distance between α_t^j and $\beta^j_{\sigma_j(t)}$, to the right, we put a reflex vertex $r^j_\uparrow$ and place a vertical wall x^jy^j ($r^j_\uparrow$, x^j, and y^j are consecutive), so that ray$(\alpha_1^j, r^j_\uparrow)$ and ray$(\alpha_t^j, r^j_\uparrow)$ both intersect seg(x^j, y^j). For each $i \in [t]$, we denote by q_i^j the intersection between ray$(\alpha_i^j, r^j_\uparrow)$ and seg(x^j, y^j). The smaller i, the closer q_i^j is to x^j.

For each $i \in [t]$, we put around β_i^j two reflex vertices, one in ray(β_i^j, p_i^j) and one in ray(β_i^j, q_i^j). In Figure 7, we merged some reflex vertices but the essential part is that $V(\beta_i^j) \cap \text{seg}(d^j, e^j) = \text{seg}(d^j, p_i^j)$ and $V(\beta_i^j) \cap \text{seg}(x^j, y^j) = \text{seg}(x^j, q_i^j)$. Finally, we add a triangular pocket rooted at g^j and supported by ray(g^j, α_1^j) and ray(g^j, α_t^j), as well as a triangular pocket rooted at b^j and supported by ray$(g^j, \beta^j_{\sigma_j(1)})$ and ray$(g^j, \beta^j_{\sigma_j(t)})$. This ends the description of the vertex linker (see Figure 7).

The following lemma formalizes how exactly the vertices α_i^j and β_i^j are linked: say, one chooses to put a guard on a vertex α_i^j, then the only way to see entirely $\mathcal{P}_j$ by putting a second guard on a vertex of $\{\beta_1^j, \ldots, \beta_t^j\}$ is to place it on the vertex β_i^j.

▶ **Lemma 7.** *For any $j \in [k]$, the sub-polygon $\mathcal{P}_j$ is seen entirely by $\{\alpha_v^j, \beta_w^j\}$ iff $v = w$.*

Proof. The regions of $\mathcal{P}_j$ not seen by α^j_v (i.e., $\mathcal{P}_j \setminus V(\alpha^j_v)$) consist of the triangles $d^j r^j_{\downarrow} p^j_v$, $x^j r^j_{\uparrow} q^j_v$ and partially the triangle $a^j b^j c^j$. The triangle $a^j b^j c^j$ is anyway entirely seen by the vertex β^j_i, for any $i \in [t]$. It remains to prove that $d^j r^j_{\downarrow} p^j_v \cup x^j r^j_{\uparrow} q^j_v \subseteq V(\beta^j_w)$ iff $v = w$.

It holds that $d^j r^j_{\downarrow} p^j_v \cup x^j r^j_{\uparrow} q^j_v \subseteq V(\beta^j_v)$ since, by construction, the two reflex vertices neighboring β^j_v are such that β^j_v sees $\text{seg}(d^j, p^j_\alpha)$ (hence, the whole triangle $d^j r^j_{\downarrow} p^j_v$) and $\text{seg}(x^j, q^j_\alpha)$ (hence, the whole triangle $x^j r^j_{\uparrow} q^j_v$). Now, let us assume that $v \neq w$. If $v < w$, the interior of the segment $\text{seg}(p_v, p_w)$ is not seen by $\{\alpha^j_v, \beta^j_w\}$, and if $v > w$, the interior of the segment $\text{seg}(q_v, q_w)$ is not seen by $\{\alpha^j_v, \beta^j_w\}$. ◀

The issue we now have is that one could decide to place a guard on a vertex α^j_i and a second guard on a reflex vertex between $\beta^j_{\sigma_j(w)}$ and $\beta^j_{\sigma_j(w+1)}$ (for some $w \in [t-1]$). This is indeed another way to guard the whole $\mathcal{P}_j$. We will now describe a sub-polygon $\mathcal{F}_j$ (for each $j \in [k]$) called *filter gadget* (see Figure 8) satisfying the property that all its (triangular) pockets can be guarded by adding only one guard on a vertex of $\mathcal{F}_j$ iff there is already a guard on a vertex β^j_i of $\mathcal{P}_j$. Therefore, the filter gadget will prevent one from placing a guard on a reflex vertex of $\mathcal{P}_j$. The functioning of the gadget is again based on Lemma 5.

Filter gadget. Let $d^j_1, \ldots, d^j_t$ be t consecutive vertices of a regular, say, $20t$-gon, so that the angle made by $\text{ray}(d^j_1, d^j_2)$ and the x-axis is a bit below 45°, while the angle made by $\text{ray}(d^j_{t-1}, d^j_t)$ and the x-axis is a bit above 45°. The vertices $d^j_1, \ldots, d^j_t$ can therefore be seen as the discretization of an arc $\mathcal{C}$. We now mentally draw two lines ℓ_h and ℓ_v; ℓ_h is a horizontal line a bit below d^j_1, while ℓ_v is a vertical line a bit to the right of d^j_t. We put, for each $i \in [t]$, a vertex x^j_i at the intersection of ℓ_h and the tangent to $\mathcal{C}$ passing through d^j_i. Then, for each $i \in [t-1]$, we set a triangular pocket $\mathcal{P}(x^j_i)$ rooted at x^j_i and supported by $\text{ray}(x^j_i, d^j_1)$ and $\text{ray}(x^j_i, \beta^j_{\sigma_j(i+1)})$. For convenience, each point $\beta^j_{\sigma_j(i)}$ is denoted by c^j_i on Figure 8. We also set a triangular pocket $\mathcal{P}(x^j_t)$ rooted at x^j_t and supported by $\text{ray}(x^j_t, d^j_1)$ and $\text{ray}(x^j_t, d^j_t)$. Similarly, we place, for each $i \in [t-1]$, a vertex y^j_i at the intersection of ℓ_v and the tangent to $\mathcal{C}$ passing through d^j_{i+1}. Finally, we set a triangular pocket $\mathcal{P}(y^j_i)$ rooted at y^j_i and supported by $\text{ray}(y^j_i, \beta^j_{\sigma_j(i)})$ and $\text{ray}(y^j_i, d^j_t)$, for each $i \in [t-1]$ (see Figure 8). We denote by $\mathcal{P}(\mathcal{F}_j)$ the $2t-1$ triangular pockets of $\mathcal{F}_j$.

▶ **Lemma 8.** *For each $j \in [k]$, the only ways to see entirely $\mathcal{P}(\mathcal{F}_j)$ and the triangle $a^j b^j c^j$ with only two guards on vertices of $\mathcal{P}_j \cup \mathcal{F}_j$ is to place them on vertices c^j_i and d^j_i (for any $i \in [t]$).*

Proof. Proving this lemma will, in particular, entail that it is not possible to see entirely $\mathcal{P}(\mathcal{F}_j)$ with only two vertices if one of them is a reflex vertex between c^j_i and c^j_{i+1}. Let us call such a vertex an intermediate reflex vertex (in color class j). Because of the pocket $a^j b^j c^j$, one should put a guard on a c^j_i (for some $i \in [t]$) or on an intermediate reflex vertex in class j. As vertices a^j, b^j, and c^j do not see anything of $\mathcal{P}(\mathcal{F}_j)$, placing the first guard at one of those three vertices cannot work as a consequence of what follows.

Say, the first guard is placed at c^j_i $(= \beta^j_{\sigma(i)})$. The pockets $\mathcal{P}(x^j_1), \mathcal{P}(x^j_2), \ldots, \mathcal{P}(x^j_{i-1})$ and $\mathcal{P}(y^j_i), \mathcal{P}(y^j_{i+1}), \ldots, \mathcal{P}(x^j_{t-1})$ are entirely seen, while the vertices $x^j_i, x^j_{i+1}, \ldots, x^j_t$ and $y^j_1, y^j_2, \ldots, y^j_{i-1}$ are not. The only vertex that sees simultaneously all those vertices is d^j_i. The vertex d^j_i even sees the *whole* pockets $\mathcal{P}(x^j_i), \mathcal{P}(x^j_{i+1}), \ldots, \mathcal{P}(x^j_t)$ and $\mathcal{P}(y^j_1), \mathcal{P}(y^j_2), \ldots,$ $\mathcal{P}(y^j_{i-1})$. Therefore, all the pockets $\mathcal{P}(\mathcal{F}_j)$ are fully seen.

Now, say, the first guard is put on an intermediate reflex vertex r between c^j_i and c^j_{i+1} (for some $i \in [t-1]$). Both vertices x^j_i and y^j_i, as well as x^j_t, are not seen by r and should

Figure 8 The filter gadget $\mathcal{F}_j$. Again, we omit the superscript j on the labels. Vertices $c_1, c_2, \dots, c_t$ are not part of $\mathcal{F}_j$ and are in fact the vertices $\beta^j_{\sigma_j(1)}, \beta^j_{\sigma_j(2)}, \dots, \beta^j_{\sigma_j(t)}$ and the vertices in between the c_i's are the reflex vertices that we have to *filter out*.

therefore be seen by the second guard. However, no vertex simultaneously sees those three vertices. ◀

Putting the pieces together. The permutation σ is encoded the following way. We position the vertex linkers $\mathcal{P}_1, \mathcal{P}_2, \dots, \mathcal{P}_k$ such that $\mathcal{P}_{i+1}$ is below and slightly to the left of $\mathcal{P}_i$. Far below and to the right of the $\mathcal{P}_i$'s, we place the $\mathcal{F}_i$'s such that the uppermost vertex of $\mathcal{F}_{\sigma(i)}$ is close and connected to the leftmost vertex of $\mathcal{F}_{\sigma(i+1)}$, for all $i \in [t-1]$. We add a constant number of vertices in the vicinity of each $\mathcal{P}_j$, so that the only filter gadget that vertices $\beta^j_1, \dots, \beta^j_t$ can see is $\mathcal{F}_{\sigma(j)}$ (see Figure 9). Similarly to the point guard version, we place vertically and far from the α^j_i's, one triangular pocket $\mathcal{P}(z_{A,q})$ rooted at vertex $z_{A,q}$ and supported by ray$(z_{A,q}, \alpha^j_i)$ and ray$(z_{A,q}, \alpha^{j'}_{i'})$, for each A-interval $I_q = [a^j_i, a^{j'}_{i'}] \in \mathcal{S}_A$ (Track A). Finally, we place vertically and far from the d^j_i's, one triangular pocket $\mathcal{P}(z_{B,q})$ rooted at vertex $z_{B,q}$ and supported by ray$(z_{B,q}, d^j_i)$ and ray$(z_{B,q}, d^{j'}_{i'})$, for each B-interval $I_q = [b^j_{\sigma_j(i)}, b^{j'}_{\sigma_{j'}(i')}] \in \mathcal{S}_B$ (Track B). This ends the construction (see Figure 9).

Soundness. We now prove the correctness of the reduction. Assume that $\mathcal{I}$ is a YES-instance and let $\{(a^1_{s_1}, b^1_{s_1}), \dots, (a^k_{s_k}, b^k_{s_k})\}$ be a solution. We claim that the set of vertices $G = \{\alpha^1_{s_1}, \beta^1_{s_1}, d^1_{\sigma_1^{-1}(s_1)}, \dots, \alpha^k_{s_k}, \beta^k_{s_k}, d^k_{\sigma_k^{-1}(s_k)}\}$ guards the whole polygon $\mathcal{P}$. Let $z^j := d^j_{\sigma_j^{-1}(s_j)}$ for notational convenience. By Lemma 7, for each $j \in [k]$, the sub-polygon $\mathcal{P}_j$ is entirely seen, since there are guards on $\alpha^j_{s_j}$ and $\beta^j_{s_j}$. By Lemma 8, for each $j \in [k]$, all the pockets of $\mathcal{F}_j$ are entirely seen, since there are guards on $\beta^j_{s_j} = c^j_{\sigma_j^{-1}(s_j)}$ and $d^j_{\sigma_j^{-1}(s_j)} = z^j$. For each A-interval (resp. B-interval) in $\mathcal{S}_A$ (resp. $\mathcal{S}_B$) there is at least one 2-element $(a^j_{s_j}, b^j_{s_j})$ such that $a^j_{s_j} \in \mathcal{S}_A$ (resp. $b^j_{s_j} \in \mathcal{S}_B$). Thus, the corresponding pocket is guarded by $\alpha^j_{s_j}$ (resp. $\beta^j_{s_j}$). The rest of the polygon is seen by, for instance, $z^{\sigma(1)}$ and $z^{\sigma(k)}$.

Assume now that there is no solution to the instance $\mathcal{I}$ of Structured 2-Track Hitting Set, and, for the sake of contradiction, that there is a set G of $3k$ vertices guarding $\mathcal{P}$. For each $j \in [k]$, vertices b^j, g^j, and x^j_t are seen by three disjoint set of vertices. The first

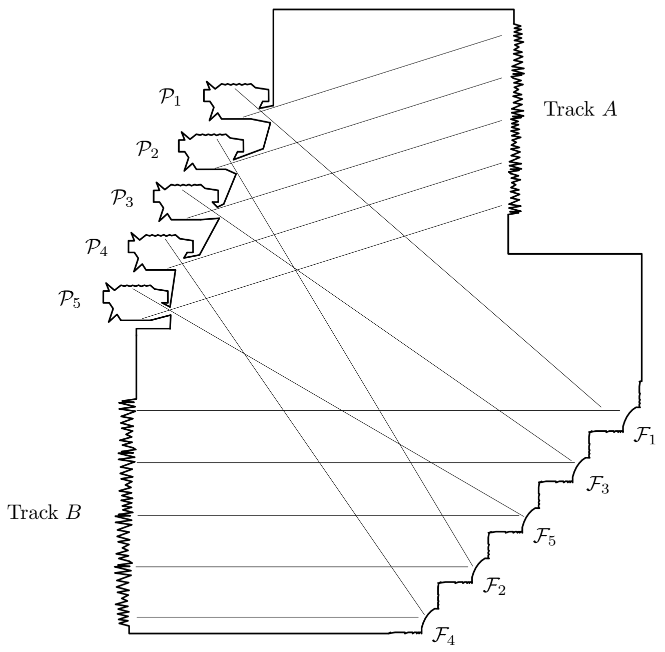

Figure 9 Overall picture of the reduction with $k = 5$.

two sets are contained in the vertices of sub-polygon $\mathcal{P}_j$ and the third one is contained in the vertices of $\mathcal{F}_j$. Therefore, to see entirely $\mathcal{P}_j \cup \mathcal{P}(\mathcal{F}_j)$, three vertices are necessary. Summing that over the k color classes, this corresponds already to $3k$ vertices which is the size of the supposed set G. Thus, there should *exactly* 3 guards placed among the vertices of $\mathcal{P}_j \cup \mathcal{F}_j$. Therefore, by Lemma 8, there should be an $s_j \in [t]$ such that both $d^j_{s_j}$ and $c^j_{s_j} = \beta^j_{\sigma_j(s_j)}$ are in G. Then, by Lemma 7, a guard should be placed at vertex $\alpha^j_{\sigma_j(s_j)}$. Indeed, the only vertices seeing g^j are f^j, g^j, h^j and $a^j_1, \dots, a^j_t$; but, if the third guard is placed at vertex f^j, g^j, or h^j, then vertices β^j_w (with $w \neq \sigma_j(i)$) are not seen. So far, we showed that G should be of the form $\{\alpha^1_{\sigma_1(s_1)}, \beta^1_{\sigma_1(s_1)}, d^1_{s_1}, \dots, \alpha^j_{\sigma_j(s_j)}, \beta^j_{\sigma_j(s_j)}, d^j_{s_j}, \dots, \alpha^k_{\sigma_k(s_k)}, \beta^k_{\sigma_k(s_k)}, d^k_{s_k}, \}$. Though, as there is no solution to $\mathcal{I}$, there should be a set in $\mathcal{S}_A \cup \mathcal{S}_B$ that is not hit by $\{(a^1_{\sigma_1(s_1)}, b^1_{\sigma_1(s_1)}), \dots, (a^k_{\sigma_k(s_k)}, b^k_{\sigma_k(s_k)})\}$. By construction, the pocket associated to this set is not entirely seen; a contradiction.

Let us bound the number of vertices of $\mathcal{P}$. Each sub-polygon $\mathcal{P}_j$ or $\mathcal{F}_j$ contains $O(t)$ vertices. *Track A* contains $3|\mathcal{S}_A|$ vertices and *Track B* contains $3|\mathcal{S}_B|$ vertices. Linking everything together requires $O(k)$ additional vertices. So, in total, there are $O(kt+|\mathcal{S}_A|+|\mathcal{S}_B|)$ vertices. Thus, this reduction together with Theorem 4 implies that Vertex Guard Art Gallery is W[1]-hard and cannot be solved in time $f(k)\, n^{o(k/\log k)}$ for any computable function f, where n is the number of vertices of the polygon and k the number of guards, unless the ETH fails. ◀

Acknowledgment. We thank Saeed Mehrabi and Meirav Zehavi for fruitful discussions.

Abstract

We present KADABRA, a new algorithm to approximate betweenness centrality in directed and undirected graphs, which significantly outperforms all previous approaches on real-world complex networks. The efficiency of the new algorithm relies on two new theoretical contributions, of independent interest.

The first contribution focuses on sampling shortest paths, a subroutine used by most algorithms that approximate betweenness centrality. We show that, on realistic random graph models, we can perform this task in time $|E|^{\frac{1}{2}+o(1)}$ with high probability, obtaining a significant speedup with respect to the $\Theta(|E|)$ worst-case performance. We experimentally show that this new technique achieves similar speedups on real-world complex networks, as well.

The second contribution is a new rigorous application of the adaptive sampling technique. This approach decreases the total number of shortest paths that need to be sampled to compute all betweenness centralities with a given absolute error, and it also handles more general problems, such as computing the k most central nodes. Furthermore, our analysis is general, and it might be extended to other settings, as well.

1 Introduction

In this work we focus on estimating the *betweenness centrality*, which is one of the most famous measures of *centrality* for nodes and edges of real-world complex networks [19, 30]. The rigorous definition of betweenness centrality has its roots in sociology, dating back to the Seventies, when Freeman formalized the informal concept discussed in the previous decades in different scientific communities [6, 40, 39, 17, 13], although the definition already appeared in [4]. Since then, this notion has been very successful in network science [44, 31, 22, 30].

A probabilistic way to define the betweenness centrality[1] $\mathrm{bc}(v)$ of a node v in a graph $G = (V, E)$ is the following. We choose two nodes s and t, and we go from s to t through a shortest path π; if the choices of s, t and π are made uniformly at random, the betweenness centrality of a node v is the probability that we pass through v.

* This work was done while the authors were visiting the Simons Institute for the Theory of Computing.
[1] As explained in Section 2, to simplify notation we consider the *normalized* betweenness centrality.

In a seminal paper [14], Brandes showed that it is possible to exactly compute the betweenness centrality of all the nodes in a graph in time $\mathcal{O}(mn)$, where n is the number of nodes and m is the number of edges. A corresponding lower bound was proved in [10]: if we are able to compute the betweenness centrality of a single node in time $\mathcal{O}(mn^{1-\epsilon})$ for some $\epsilon > 0$, then the Strong Exponential Time Hypothesis [23] is false.

This result further motivates the rich line of research on computing approximations of betweenness centrality, with the goal of trading precision with efficiency. The main idea is to define a probability distribution over the set of all paths, by choosing two uniformly random nodes s, t, and then a uniformly distributed st-path $\boldsymbol{\pi}$, so that $\Pr(v \in \boldsymbol{\pi}) = \mathrm{bc}(v)$. As a consequence, we can approximate $\mathrm{bc}(v)$ by sampling paths $\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_\tau$ according to this distribution, and estimating $\tilde{\boldsymbol{b}}(v) := \frac{1}{\tau}\sum_{i=1}^{\tau} \boldsymbol{X}_i(v)$, where $\boldsymbol{X}_i(v) = 1$ if $v \in \boldsymbol{\pi}_i$ (and $v \neq s, t$), 0 otherwise.

The tricky part of this approach is to provide probabilistic guarantees on the quality of this approximation: the goal is to obtain a $1 - \delta$ confidence interval $\boldsymbol{I}(v) = [\tilde{\boldsymbol{b}}(v) - \lambda_L, \tilde{\boldsymbol{b}}(v) + \lambda_U]$ for $\mathrm{bc}(v)$, which means that $\Pr(\forall v \in V, \mathrm{bc}(v) \in \boldsymbol{I}(v)) \geq 1 - \delta$. Thus, the research for approximating betweenness centrality has been focusing on obtaining, as fast as possible, the smallest possible $\boldsymbol{I}$.

Our Contribution

In this work, we propose a new and faster algorithm to approximate betweenness centrality in directed and undirected graphs, named KADABRA. In the standard task of approximating betweenness centralities with absolute error at most λ, we show that, on average, the new algorithm is more than 100 times faster than the previous ones, on graphs with approximately 10 000 nodes. Moreover, differently from previous approaches, our algorithm can perform more general tasks, since it does not need all confidence intervals to be equal. As an example, we consider the computation of the k most central nodes: all previous approaches compute all centralities with an error λ, and use this approximation to obtain the ranking. Conversely, our approach allows us to use small confidence interval only when they are needed, and allows bigger confidence intervals for nodes whose centrality values are "well separated". This way, we can compute for the first time an approximation of the k most central nodes in networks with millions of nodes and hundreds of millions of edges, like the Wikipedia citation network and the IMDB actor collaboration network.

Our results rely on two main theoretical contributions, which are interesting in their own right, since their generality naturally extends to other applications.

Balanced bidirectional breadth-first search. By leveraging on recent advanced results, we prove that, on many realistic random models of real-world complex networks, it is possible to sample a random path between two nodes s and t in time $m^{\frac{1}{2}+o(1)}$ if the degree distribution has finite second moment, or $m^{\frac{4-\beta}{2}+o(1)}$ if the degree distribution is power law with exponent $2 < \beta < 3$. The models considered are the Configuration Model [9], and all Rank-1 Inhomogeneous Random Graph models [42, Chapter 3], such as the Chung-Lu model [29], the Norros-Reittu model [32], and the Generalized Random Graph [42, Chapter 3]. Our proof techniques have the merit of adopting a unified approach that simultaneously works in all models considered. These models well represent metric properties of real-world networks [11]: indeed, our results are confirmed by practical experiments.

The algorithm used is simply a balanced bidirectional BFS (bb-BFS): we perform a BFS from each of the two endpoints s and t, in such a way that the two BFSs are likely to explore about the same number of edges, and we stop as soon as the two BFSs "touch each other". Rather surprisingly, this technique was never implemented to approximate betweenness centrality, and it is rarely used in the experimental algorithm community. Our theoretical analysis provides a clear explanation of the reason why this technique improves over the standard BFS: this means that many state-of-the-art algorithm for real-world complex networks can be improved by the bb-BFS.

Adaptive sampling made rigorous. To speed up the estimation of the betweenness centrality, previous work make use of the technique of adaptive sampling, which consists in testing during the execution of the algorithm whether some condition on the sample obtained so far has been met, and terminating the execution of the algorithm as soon as this happens. However, this technique introduces a subtle stochastic dependence between the time in which the algorithm terminates and the correctness of the given output, which previous papers claiming a formal analysis of the technique did not realize (see Section 3 for details). With an argument based on martingale theory, we provide a general analysis of such useful technique. Through this result, we do not only improve previous estimators, but we also make it possible to define more general stopping conditions, that can be decided "on the fly": this way, with little modifications, we can adapt our algorithm to perform more general tasks than previous ones.

To better illustrate the power of our techniques, we focus on the unweighted, static graphs, and to the centrality of nodes. However, our algorithm can be easily adapted to compute the centrality of edges, to handle weighted graphs and, since its core part consists merely in sampling paths, we conjecture that it may be coupled with the existing techniques in [8] to handle dynamic graphs.

Related Work

Computing Betweenness Centrality. With the recent event of big data, the major shortcoming of betweenness centrality has been the lack of efficient methods to compute it [14]. In the worst case, the best exact algorithm to compute the centrality of all the nodes is due to Brandes [14], and its time complexity is $\mathcal{O}(mn)$: the basic idea of the algorithm is to define the dependency $\delta_s(v) = \sum_{t \in V} \frac{\sigma_{st}(v)}{\sigma_{st}}$, which can be computed in time $\mathcal{O}(m)$, for each $v \in V$ (we denote by $\sigma_{st}(v)$ the number of shortest paths from s to t passing through v, and by σ_{st} the number of st-shortest paths). In [10], it is also shown that Brandes algorithm is almost optimal on sparse graphs: an algorithm that computes the betweenness centrality of a single vertex in time $\mathcal{O}(mn^{1-\epsilon})$ falsifies widely believed complexity assumptions, such as the Strong Exponential Time Hypothesis [23], the Orthogonal Vector conjecture [2], or the Hitting Set conjecture [45]. Corresponding results in the dense, weighted case are available in [1]: computing the betweenness centrality exactly is as hard as computing the All Pairs Shortest Path, and computing an approximation with a given relative error is as hard as computing the diameter. For both these problems, there is no algorithm with running-time $\mathcal{O}(n^{3-\epsilon})$, for any $\epsilon > 0$. This shows that, for dense graphs, having an additive approximation rather than a multiplicative one is essential for a provably fast algorithm to exist. These negative results further motivates the already rich line of research on approaches that overcome this barrier. A first possibility is to use heuristics, that do not provide analytical guarantees on their performance [38, 21, 43]. Another line of research has defined variants of betweenness centrality, that might be easier to compute [15, 33, 18]. Finally, a third line of research has investigated approximation algorithms, which trade accuracy for speed [24, 16, 22, 26]. Our work follows the latter approach. The first approximation algorithm proposed in the literature [24] adapts Eppstein and Wang's approach for computing closeness centrality [20], using Hoeffding's inequality and the union bound technique. This way, it is possible to obtain an estimate of the betweenness centrality of every node that is correct up to an additive error λ with probability δ, by sampling $\mathcal{O}(\frac{D^2}{\lambda^2}\log\frac{n}{\delta})$ nodes, where D is the diameter of the graph. In [22], it is shown that this can lead to an overestimation. Riondato and Kornaropoulos improve this sampling-based approach by sampling single shortest paths instead of the whole dependency of a node [36], introducing the use of the VC-dimension. As a result, the number of samples is decreased to $\frac{c}{\lambda^2}(\lfloor\log_2(\mathrm{VD}-2)\rfloor+1+\log(\frac{1}{\delta}))$, where VD is the vertex diameter, that is, the minimum number of nodes in a shortest path in G (it can be different from $D+1$ if the graph is weighted). This use of the VC-dimension is further developed and generalized in [37]. Finally, many of these results were adapted to handle dynamic networks [8, 37].

Approximating the top-k betweenness centrality set. Let us order the nodes $v_1,...,v_n$ such that $\mathrm{bc}(v_1) \geq ... \geq \mathrm{bc}(v_n)$ and define $TOP(k) = \{(v_i, \mathrm{bc}(v_i)) : i \leq k\}$. In [36] and [37], the authors provide an algorithm that, for any given δ, ϵ, with probability $1-\delta$ outputs a set $\widetilde{TOP}(k) = \{(v_i, \tilde{\boldsymbol{b}}(v_i))\}$ such that: i) If $v \in TOP(k)$ then $v \in \widetilde{TOP}(k)$ and $|\mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v)| \leq \epsilon\,\mathrm{bc}(v)$; ii) If $v \in \widetilde{TOP}(k)$ but $v \notin TOP(k)$ then $\tilde{\boldsymbol{b}}(v) \leq (\mathbf{b}_k - \epsilon)(1+\epsilon)$ where $\mathbf{b}_k$ is the k-th largest betweenness given by a preliminary phase of the algorithm.

Adaptive sampling. In [5, 37], the number of samples required is substantially reduced using the adaptive sampling technique introduced by Lipton and Naughton in [28, 27]. Let us clarify that, by adaptive sampling, we mean that the termination of the sampling process depends on the sample observed so far (in other cases, the same expression refers to the fact that the distribution of the new samples is a function of the previous ones [3], while the sample size is fixed in advance). Except for [34], previous approaches tacitly assume that there is little dependency between the stopping time and the correctness of the output: indeed, they prove that, for each *fixed* τ, the probability that the estimate is wrong at time τ is below δ. However, the stopping time $\boldsymbol{\tau}$ is a random variable, and in principle there might be dependency between the event $\boldsymbol{\tau} = \tau$ and the event that the estimate is correct at time τ. As for [34], they consider a specific stopping condition and their proof technique does not seem to extend to other settings. For a more thorough discussion of this issue, we defer the reader to Section 3.

Bidirectional BFS. The possibility of speeding up a breadth-first search for the shortest-path problem by performing, at the same time, a BFS from the final end-point, has been considered since the Seventies [35]. Unfortunately, because of the lack of theoretical results dealing with its efficiency, the bidirectional BFS has apparently not been considered a fundamental heuristic improvement [25]. However, in [36] (and in some public talks by M. Riondato), the bidirectional BFS was proposed as a possible way to improve the performance of betweenness centrality approximation algorithms.

Structure of the Paper

In Section 2, we describe our algorithm, and in Section 3 we discuss the main difficulty of the adaptive sampling, and the reasons why our techniques are not affected. In Section 4, we define the balanced bidirectional BFS, and we sketch the proof of its efficiency on random graphs. In Section 5, we show that our algorithm can be adapted to compute the k most central nodes. In Section 6 we experimentally show the effectiveness of our new algorithm. Finally, all our proofs are in the appendix.

2 Algorithm Overview

To simplify notation, we always consider the *normalized* betweenness centrality of a node v, which is defined by:

$$\mathrm{bc}(v) = \frac{1}{n(n-1)} \sum_{s \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}}$$

where σ_{st} is the number of shortest paths between s and t, and $\sigma_{st}(v)$ is the number of shortest paths between s and t that pass through v. Furthermore, to simplify the exposition, we use bold symbols to denote random variables, and light symbols to denote deterministic quantities. On the same line of previous works, our algorithm samples random paths $\boldsymbol{\pi}_1, \ldots, \boldsymbol{\pi}_\tau$, where $\boldsymbol{\pi}_i$ is chosen by selecting uniformly at random two nodes s, t, and then selecting uniformly at random one of the shortest paths from s to t. Then, it estimates $\mathrm{bc}(v)$ with $\tilde{\boldsymbol{b}}(v) := \frac{1}{\tau}\sum_{i=1}^{\tau} \boldsymbol{X}_i(v)$, where $\boldsymbol{X}_i(v) = 1$ if $v \in \boldsymbol{\pi}_i$, 0 otherwise. By definition of $\boldsymbol{\pi}_i$, $\mathbb{E}\left[\tilde{\boldsymbol{b}}(v)\right] = \mathrm{bc}(v)$.

The tricky part is to bound the distance between $\tilde{\boldsymbol{b}}(v)$ and its expected value. With a straightforward application of Hoeffding's inequality (see Appendix B of the full version [12]), it is possible to prove that $\Pr\left(\left|\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)\right| \geq \lambda\right) \leq 2e^{-2\tau\lambda^2}$. A direct application of this inequality considers a union bound on all possible nodes v, obtaining $\Pr(\exists v \in V, |\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)| \geq \lambda) \leq 2ne^{-2\tau\lambda^2}$. This means that the algorithm can safely stop as soon as $2ne^{-2\tau\lambda^2} \leq \delta$, that is, after $\tau = \frac{1}{2\lambda^2}\log(\frac{2n}{\delta})$ steps.

In order to improve this idea, we can start from the Chernoff bound (see Appendix B of the full version [12]), instead of Hoeffding inequality, obtaining that $\Pr\left(\left|\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)\right| \geq \lambda\right) \leq 2\exp(-\frac{\tau\lambda^2}{2(\mathrm{bc}(v)+\lambda/3)})$.

If we assume the error λ to be small, this inequality is stronger than the previous one for all values of $\mathrm{bc}(v) < \frac{1}{4}$ (a condition which holds for almost all nodes, in almost all graphs considered). However, in order to apply this inequality, we have to deal with the fact that we do not know $\mathrm{bc}(v)$ in advance, and hence we do not know when to stop. Intuitively, to solve this problem, we make a "change of variable", and we rewrite the previous inequality as

$$\Pr\left(\mathrm{bc}(v) \leq \tilde{\boldsymbol{b}}(v) - f\right) \leq \delta_L^{(v)} \quad \text{and} \quad \Pr\left(\mathrm{bc}(v) \geq \tilde{\boldsymbol{b}}(v) + g\right) \leq \delta_U^{(v)}, \tag{1}$$

for some functions $f = f(\tilde{\boldsymbol{b}}(v), \delta_L^{(v)}, \tau), g = g(\tilde{\boldsymbol{b}}(v), \delta_U^{(v)}, \tau)$. Our algorithm fixes at the beginning the values $\delta_L^{(v)}, \delta_U^{(v)}$ for each node v, and, at each step, it tests if $f(\tilde{\boldsymbol{b}}(v), \delta_L^{(v)}, \tau)$ and $g(\tilde{\boldsymbol{b}}(v), \delta_U^{(v)}, \tau)$ are small enough. If this condition is satisfied, the algorithm stops. Note that this approach lets us define very general stopping conditions, that might depend on the centralities computed until now, on the single nodes, and so on.

▶ Remark. Instead of fixing the values $\delta_L^{(v)}, \delta_U^{(v)}$ at the beginning, one might want to decide them during the algorithm, depending on the outcome. However, this is not formally correct, because of dependency issues (for example, (1) does not even make sense, if $\delta_L^{(v)}, \delta_U^{(v)}$ are random). Finding a way to overcome this issue is left as a challenging open problem (more details are provided in Section 3).

In order to implement this idea, we still need to solve an issue: (1) holds for each *fixed* time τ, but the stopping time of our algorithm is a random variable $\boldsymbol{\tau}$, and there might be dependency between the value of $\boldsymbol{\tau}$ and the probability in (1). To this purpose, we use Mcdiarmid's inequality (see Appendix B of the full version [12]), that holds even if $\boldsymbol{\tau}$ is a random variable. However, to use this inequality, we need to assume that $\boldsymbol{\tau} < \omega$ for some deterministic ω: in our algorithm, we choose $\omega = \frac{c}{\lambda^2}\left(\lfloor \log_2(\mathrm{VD}-2) \rfloor + 1 + \log\left(\frac{2}{\delta}\right)\right)$, because, by the results in [36], after ω samples, the maximum error is at most λ, with probability $1-\frac{\delta}{2}$. Furthermore, also f and g should be modified, since they now depend on the value of ω. The pseudocode of the algorithm obtained is available in Algorithm 1 (as was done in previous approaches, we can easily parallelize the while loop in Line 5).

Algorithm 1: our algorithm for approximating betweenness centrality.

```
Input  : a graph $G=(V,E)$
Output : for each $v \in V$, an approximation $\tilde{\boldsymbol{b}}(v)$ of $\mathrm{bc}(v)$ such that
         $\Pr\left(\forall v, |\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)| \leq \lambda\right) \geq 1-\delta$
1  $\omega \leftarrow \frac{c}{\lambda^2}\left(\lfloor \log_2(\mathrm{VD}-2)\rfloor + 1 + \log\left(\frac{2}{\delta}\right)\right)$;
2  $(\delta_L^{(v)}, \delta_U^{(v)}) \leftarrow$ computeDelta();
3  $\tau \leftarrow 0$;
4  foreach $v \in V$ do $\tilde{\boldsymbol{b}}(v) \leftarrow 0$;
5  while $\tau < \omega$ and not haveToStop ($\tilde{\boldsymbol{b}}, \delta_L, \delta_U, \omega, \tau$) do
6      $\boldsymbol{\pi}$ = samplePath();
7      foreach $v \in \boldsymbol{\pi}$ do $\tilde{\boldsymbol{b}}(v) \leftarrow \tilde{\boldsymbol{b}}(v) + 1$;
8      $\tau \leftarrow \tau + 1$;
9  end
10 foreach $v \in V$ do $\tilde{\boldsymbol{b}}(v) \leftarrow \tilde{\boldsymbol{b}}(v)/\tau$;
11 return $\tilde{\boldsymbol{b}}$
```

Algorithm 2: the function `computeDelta`.

```
Input  : a graph $G=(V,E)$, and two values $\lambda_L^{(v)}, \lambda_U^{(v)}$ for each $v \in V$
Output : for each $v \in V$, two values $\delta_L^{(v)}, \delta_U^{(v)}$
1  $\alpha \leftarrow \frac{\omega}{100}$;
2  $\epsilon \leftarrow 0.0001$;
3  foreach $i \in [1, \alpha]$ do
4      $\boldsymbol{\pi}$ = samplePath();
5      foreach $v \in \boldsymbol{\pi}$ do $\tilde{\boldsymbol{b}}(v) \leftarrow \tilde{\boldsymbol{b}}(v) + 1$;
6  end
7  foreach $v \in V$ do
8      $\tilde{\boldsymbol{b}}(v) \leftarrow \tilde{\boldsymbol{b}}(v)/\alpha$;
9      $c_L(v) \leftarrow \frac{2\tilde{b}(v)\omega}{(\lambda_L^{(v)})^2}$;
10     $c_U(v) \leftarrow \frac{2\tilde{b}(v)\omega}{(\lambda_U^{(v)})^2}$;
11 end
12 Binary search to find $C$ such that $\sum_{v \in V} \exp\left(-\frac{C}{c_L(v)}\right) + \exp\left(-\frac{C}{c_U(v)}\right) = \frac{\delta}{2} - \epsilon\delta$;
13 foreach $v \in V$ do
14     $\delta_L^{(v)} \leftarrow \exp\left(-\frac{C}{c_L(v)}\right) + \frac{\epsilon\delta}{2n}$;
15     $\delta_U^{(v)} \leftarrow \exp\left(-\frac{C}{c_U(v)}\right) + \frac{\epsilon\delta}{2n}$;
16 end
17 return $\boldsymbol{b}$;
```

The correctness of the algorithm follows from the following theorem, which is the base of our adaptive sampling, and which we prove in Section 2.1 (where we also define the functions f and g).

▶ **Theorem 1.** *Let $\tilde{\boldsymbol{b}}(v)$ be the output of Algorithm 1, and let $\boldsymbol{\tau}$ be the number of samples at the end of the algorithm. Then, with probability $1-\delta$, the following conditions hold:*

- *if $\boldsymbol{\tau} = \omega$, $|\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)| < \lambda$ for all v;*
- *if $\boldsymbol{\tau} < \omega$, $-f(\boldsymbol{\tau}, \tilde{\boldsymbol{b}}(v), \delta_L^{(v)}, \omega) \leq \mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v) \leq g(\boldsymbol{\tau}, \tilde{\boldsymbol{b}}(v), \delta_U^{(v)}, \omega)$ for all v.*

Algorithm 3: The function `haveToStop` to compute the top-k nodes.

```
Input   : for each node $v$, the values of $\tilde{\boldsymbol{b}}(v), \delta_L^{(v)}, \delta_U^{(v)}$, and the values of $\omega$ and $\tau$
Output : True if the algorithm should stop, False otherwise
Sort nodes in decreasing order of $\tilde{\boldsymbol{b}}(v)$, obtaining $v_1, \dots, v_n$;
for $i \in [1, \dots, k]$ do
    if $f(\tilde{\boldsymbol{b}}(v_i), \delta_L^{(v_i)}, \omega, \tau) > \lambda$ or $g(\tilde{\boldsymbol{b}}(v_i), \delta_U^{(v_i)}, \omega, \tau) > \lambda$ then
        if $\tilde{\boldsymbol{b}}(v_{i-1}) - f(\tilde{\boldsymbol{b}}(v_{i-1}), \delta_L^{(v_{i-1})}, \omega, \tau) < \tilde{\boldsymbol{b}}(v_i) + g(\tilde{\boldsymbol{b}}(v_i), \delta_U^{(v_i)}, \omega, \tau)$ or
          $\tilde{\boldsymbol{b}}(v_i) - f(\tilde{\boldsymbol{b}}(v_i), \delta_L^{(v_i)}, \omega, \tau) < \tilde{\boldsymbol{b}}(v_{i+1}) + g(\tilde{\boldsymbol{b}}(v_{i+1}), \delta_U^{(v_{i+1})}, \omega, \tau)$ then
            return False;
        end
    end
end
for $i \in [k+1, \dots, n]$ do
    if $f(\tilde{\boldsymbol{b}}(v_i), \delta_L^{(v_i)}, \omega, \tau) > \lambda$ or $g(\tilde{\boldsymbol{b}}(v_i), \delta_U^{(v_i)}, \omega, \tau) > \lambda$ then
        if $\tilde{\boldsymbol{b}}(v_k) - f(\tilde{\boldsymbol{b}}(v_k), \delta_L^{(v_k)}, \omega, \tau) < \tilde{\boldsymbol{b}}(v_i) + g(\tilde{\boldsymbol{b}}(v_i), \delta_U^{(v_i)}, \omega, \tau)$ then
            return False;
        end
    end
end
return True;
```

▶ Remark. This theorem says that, at the beginning of the algorithm, we know that, with probability $1-\delta$, one of the two conditions will hold when the algorithm stops, independently of the final value of $\boldsymbol{\tau}$. This is essential to avoid the stochastic dependence that we discuss in Section 3.

In order to apply this theorem, we choose λ such that our goal is reached if all centralities are known with error at most λ. Then, we choose the function `haveToStop` in a way that our goal is reached if the stopping condition is satisfied. This way, our algorithm is correct, both if $\boldsymbol{\tau} = \omega$ and if $\boldsymbol{\tau} < \omega$. For example, if we want to compute all centralities with bounded absolute error, we simply choose λ as the bound we want to achieve, and we plug the stopping condition $f, g \leq \lambda$ in the function `haveToStop`. Instead, if we want to compute an approximation of the k most central nodes, we need a different definition of f and g, which is provided in Section 5.

To complete the description of this algorithm, we need to specify the following functions.

`computeDelta`: The algorithm works for any choice of the $\delta_L^{(v)}, \delta_U^{(v)}$s, but a good choice yields better running times. We adopt the heuristic given in Algorithm 2, which we discuss in Appendix D of the full version.

`samplePath`: In order to sample a path between two random nodes s and t, we use a balanced bidirectional BFS (see Appendix E of the full version [12] for a detailed description).

2.1 Proof of Theorem 1

In our algorithm, we sample $\boldsymbol{\tau}$ shortest paths $\boldsymbol{\pi}_i$, where $\boldsymbol{\tau}$ is a random variable such that $\boldsymbol{\tau} = \tau$ can be decided by looking at the first τ paths sampled (see Algorithm 1). Furthermore, thanks to Eq. (3) in [36], we assume that $\boldsymbol{\tau} \leq \omega$ for some fixed $\omega \in \mathbb{R}^+$ such that, after ω steps, $\Pr(\forall v, |\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)| \leq \lambda) \geq 1 - \frac{\delta}{2}$. When the algorithm stops, our estimate of the betweenness is $\tilde{\boldsymbol{b}}(v) := \frac{1}{\boldsymbol{\tau}} \sum_{i=1}^{\boldsymbol{\tau}} \boldsymbol{X}_i(v)$, where $\boldsymbol{X}_i(v)$ is 1 if v belongs to $\boldsymbol{\pi}_i$, 0 otherwise.

To estimate the error, we use the following theorem.

▶ **Theorem 2.** *For each node v and for every fixed real numbers δ_L, δ_U, it holds*

$$\Pr\left(\mathrm{bc}(v) \leq \tilde{\boldsymbol{b}}(v) - f\left(\tilde{\boldsymbol{b}}(v), \delta_L, \omega, \boldsymbol{\tau}\right)\right) \leq \delta_L \quad \textit{and}$$
$$\Pr\left(\mathrm{bc}(v) \geq \tilde{\boldsymbol{b}}(v) + g\left(\tilde{\boldsymbol{b}}(v), \delta_U, \omega, \boldsymbol{\tau}\right)\right) \leq \delta_U,$$

where

$$f\left(\tilde{\boldsymbol{b}}(v), \delta_L, \omega, \boldsymbol{\tau}\right) = \frac{1}{\boldsymbol{\tau}} \log \frac{1}{\delta_L} \left(\frac{1}{3} - \frac{\omega}{\boldsymbol{\tau}} + \sqrt{\left(\frac{1}{3} - \frac{\omega}{\boldsymbol{\tau}}\right)^2 + \frac{2\tilde{\boldsymbol{b}}(v)\omega}{\log \frac{1}{\delta_L}}}\right) \quad \textit{and} \tag{2}$$

$$g\left(\tilde{\boldsymbol{b}}(v), \delta_U, \omega, \boldsymbol{\tau}\right) = \frac{1}{\boldsymbol{\tau}} \log \frac{1}{\delta_U} \left(\frac{1}{3} + \frac{\omega}{\boldsymbol{\tau}} + \sqrt{\left(\frac{1}{3} + \frac{\omega}{\boldsymbol{\tau}}\right)^2 + \frac{2\tilde{\boldsymbol{b}}(v)\omega}{\log \frac{1}{\delta_U}}}\right). \tag{3}$$

Before proving Theorem 2, let us see how this theorem implies Theorem 1. To simplify notation, we often omit the arguments of the function f and g.

Proof of Theorem 1. Let $\boldsymbol{E}_1$ be the event $(\boldsymbol{\tau} = \omega \wedge \exists v \in V, |\tilde{\boldsymbol{b}}(v) - \mathrm{bc}(v)| > \lambda)$, and let $\boldsymbol{E}_2$ be the event $(\boldsymbol{\tau} < \omega \wedge (\exists v \in V, -f \geq \mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v) \vee \mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v) \geq g))$. Let us also denote $\tilde{\boldsymbol{b}}_\tau(v) = \frac{1}{\tau}\sum_{i=1}^{\tau} \boldsymbol{X}_i(v)$ (note that $\tilde{\boldsymbol{b}}_{\boldsymbol{\tau}}(v) = \tilde{\boldsymbol{b}}(v)$).

By our choice of ω and Eq. (3) in [36],

$$\Pr(\boldsymbol{E}_1) \leq \Pr(\exists v \in V, |\tilde{\boldsymbol{b}}_\omega(v) - \mathrm{bc}(v)| > \lambda) \leq \frac{\delta}{2}$$

where $\tilde{\boldsymbol{b}}_\omega(v)$ is the approximate betweenness of v after ω samples. Furthermore, by Theorem 2,

$$\begin{aligned}\Pr(\boldsymbol{E}_2) &\leq \sum_{v \in V} \Pr(\boldsymbol{\tau} < \omega \wedge -f \geq \mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v)) + \Pr(\boldsymbol{\tau} < \omega \wedge \mathrm{bc}(v) - \tilde{\boldsymbol{b}}(v) \leq g) \\ &\leq \sum_{v \in V} \delta_L^{(v)} + \delta_U^{(v)} \leq \frac{\delta}{2}.\end{aligned}$$

By a union bound, $\Pr(\boldsymbol{E}_1 \vee \boldsymbol{E}_2) \leq \Pr(\boldsymbol{E}_1) + \Pr(\boldsymbol{E}_1) \leq \delta$, concluding the proof of Theorem 1. ◀

Thus, it remains to prove Theorem 2.

Proof of Theorem 2. Since this theorem deals with a single node v, let us simply write $\mathrm{bc} = \mathrm{bc}(v), \tilde{\boldsymbol{b}} = \tilde{\boldsymbol{b}}(v), \boldsymbol{X}_i = \boldsymbol{X}_i(v)$. Let us consider $\boldsymbol{Y}^\tau = \sum_{i=1}^{\tau}(\boldsymbol{X}_i - \mathrm{bc})$ (we recall that $\boldsymbol{X}_i = 1$ if v is in the i-th path sampled, $\boldsymbol{X}_i = 0$ otherwise). Clearly, $\boldsymbol{Y}^\tau$ is a martingale, and $\boldsymbol{\tau}$ is a stopping time for $\boldsymbol{Y}^\tau$: this means that also $\boldsymbol{Z}^\tau = \boldsymbol{Y}^{\min(\boldsymbol{\tau}, \tau)}$ is a martingale.

Let us apply Mcdiarmid's inequality (see e.g. Theorem 8 in Appendix B of the full version [12]) to the martingales $\boldsymbol{Z}$ and $-\boldsymbol{Z}$: for each fixed $\lambda_L, \lambda_U > 0$ we have

$$\Pr\left(\boldsymbol{Z}^\omega \geq \lambda_L\right) = \Pr\left(\boldsymbol{\tau}\tilde{\boldsymbol{b}} - \boldsymbol{\tau}\,\mathrm{bc} \geq \lambda_L\right) \leq \exp\left(-\frac{\lambda_L^2}{2\left(\omega\,\mathrm{bc} + \lambda_L/3\right)}\right) = \delta_L \quad \text{and} \tag{4}$$

$$\Pr\left(-\boldsymbol{Z}^\omega \geq \lambda_U\right) = \Pr\left(\boldsymbol{\tau}\tilde{\boldsymbol{b}} - \boldsymbol{\tau}\,\mathrm{bc} \leq -\lambda_U\right) \leq \exp\left(-\frac{\lambda_U^2}{2\left(\omega\,\mathrm{bc} + \lambda_U/3\right)}\right) = \delta_U. \tag{5}$$

We now show how to prove (2) from (4). The way to derive (3) from (5) is analogous.

If we express λ_L as a function of δ_L we get

$$\lambda_L^2 = 2\log\frac{1}{\delta_L}\left(\omega\,\mathrm{bc} + \frac{\lambda_L}{3}\right) \iff \lambda_L^2 - \frac{2}{3}\lambda_L \log\frac{1}{\delta_L} - 2\omega\,\mathrm{bc}\log\frac{1}{\delta_L} = 0,$$

which implies that

$$\lambda_L = \frac{1}{3}\log\frac{1}{\delta_L} \pm \sqrt{\frac{1}{9}\left(\log\frac{1}{\delta_L}\right)^2 + 2\omega\,\mathrm{bc}\log\frac{1}{\delta_L}}.$$

Since (4) holds for any positive value λ_L, it also holds for the value corresponding to the positive solution of this equation, that is,

$$\lambda_L = \frac{1}{3}\log\frac{1}{\delta_L} + \sqrt{\frac{1}{9}\left(\log\frac{1}{\delta_L}\right)^2 + 2\omega\,\mathrm{bc}\log\frac{1}{\delta_L}}.$$

Plugging this value into (4), we obtain

$$\Pr\left(\boldsymbol{\tau}\tilde{\boldsymbol{b}} - \boldsymbol{\tau}\,\mathrm{bc} \geq \frac{1}{3}\log\frac{1}{\delta_L} + \sqrt{\frac{1}{9}\left(\log\frac{1}{\delta_L}\right)^2 + 2\omega\,\mathrm{bc}\log\frac{1}{\delta_L}}\right) \leq \delta_L. \tag{6}$$

By assuming $\tilde{\boldsymbol{b}} - \mathrm{bc} \geq \frac{1}{3\boldsymbol{\tau}}\log(\frac{1}{\delta_L})$, the event in (6) can be rewritten as

$$(\boldsymbol{\tau}\,\mathrm{bc})^2 - 2\,\mathrm{bc}\left(\boldsymbol{\tau}^2\tilde{\boldsymbol{b}} + \omega\log\frac{1}{\delta_L} - \frac{1}{3}\boldsymbol{\tau}\log\frac{1}{\delta_L}\right) - \frac{2}{3}\log\frac{1}{\delta_L}\boldsymbol{\tau}\tilde{\boldsymbol{b}} + \left(\boldsymbol{\tau}\tilde{\boldsymbol{b}}\right)^2 \geq 0.$$

By solving the previous quadratic equation w.r.t. bc we get

$$\mathrm{bc} \leq \tilde{\boldsymbol{b}} + \log\frac{1}{\delta_L}\left(\frac{\omega}{\boldsymbol{\tau}^2} - \frac{1}{3\boldsymbol{\tau}} - \sqrt{\left(\frac{\tilde{\boldsymbol{b}}}{\log\frac{1}{\delta_L}} + \frac{\omega}{\boldsymbol{\tau}^2} - \frac{1}{3\boldsymbol{\tau}}\right)^2 - \left(\frac{\tilde{\boldsymbol{b}}}{\log\frac{1}{\delta_L}}\right)^2 + \frac{2}{3\boldsymbol{\tau}}\frac{\tilde{\boldsymbol{b}}}{\log\frac{1}{\delta_L}}}\right),$$

where we only considered the solution which upper bounds bc, since we assumed $\tilde{\boldsymbol{b}} - \mathrm{bc} \geq \frac{1}{3\tau}\log(\frac{1}{\delta_L})$. After simplifying the terms under the square root in the previous expression, we get

$$\mathrm{bc} \leq \tilde{\boldsymbol{b}} + \log\frac{1}{\delta_L}\left(\frac{\omega}{\boldsymbol{\tau}^2} - \frac{1}{3\boldsymbol{\tau}} - \sqrt{\left(\frac{\omega}{\boldsymbol{\tau}^2} - \frac{1}{3\boldsymbol{\tau}}\right)^2 + \frac{2\tilde{\boldsymbol{b}}\omega}{\boldsymbol{\tau}^2\log\frac{1}{\delta_L}}}\right),$$

which means that

$$\Pr\left(\mathrm{bc} \leq \tilde{\boldsymbol{b}} - f\left(\tilde{\boldsymbol{b}}, \delta_L, \omega, \boldsymbol{\tau}\right)\right) \leq \delta_L,$$

concluding the proof. ◀

3 Adaptive Sampling

In this section, we highlight the main technical difficulty in the formalization of adaptive sampling, which previous works claiming analogous results did not address. Furthermore, we sketch the way we overcome this difficulty: our argument is quite general, and it could be easily adapted to formalize these claims.

As already said, the problem is the stochastic dependence between the time $\boldsymbol{\tau}$ in which the algorithm terminates and the event $\boldsymbol{A}_\tau$ = "at time τ, the estimate is within the required distance from the true value", since both $\boldsymbol{\tau}$ and $\boldsymbol{A}_\tau$ are functions of the same random sample. Since it is typically possible to prove that $\Pr(\neg\boldsymbol{A}_\tau) \leq \delta$ for every fixed τ, one may be tempted to argue that also $\Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}}) \leq \delta$, by applying these inequalities at time $\boldsymbol{\tau}$. However, this is not correct: indeed, if we have no assumptions on $\boldsymbol{\tau}$, $\boldsymbol{\tau}$ could even be defined as the smallest τ such that $\boldsymbol{A}_{\tau}$ does not hold!

More formally, if we want to link $\Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}})$ to $\Pr(\neg \boldsymbol{A}_{\tau})$, we have to use the law of total probability, that says that:

$$\Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}}) = \sum_{\tau=1}^{\infty} \Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}} \,|\, \boldsymbol{\tau} = \tau) \Pr(\boldsymbol{\tau} = \tau) \tag{7}$$

$$= \Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}} \,|\, \boldsymbol{\tau} < \tau) \Pr(\boldsymbol{\tau} < \tau) + \Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}} \,|\, \boldsymbol{\tau} \geq \tau) \Pr(\boldsymbol{\tau} \geq \tau). \tag{8}$$

Then, if we want to bound $\Pr(\neg \boldsymbol{A}_{\boldsymbol{\tau}})$, we need to assume that

$$\Pr(\neg A_{\boldsymbol{\tau}} \,|\, \boldsymbol{\tau} = \tau) \leq \Pr(\neg A_{\tau}) \quad \text{or that} \quad \Pr(\neg A_{\tau} \,|\, \boldsymbol{\tau} \geq \tau) \leq \Pr(\neg A_{\tau}), \tag{9}$$

which would allow to bound (7) or (8) from above. The equations in (9) are implicitly assumed to be true in previous works adopting adaptive sampling techniques. Unfortunately, because of the stochastic dependence, it is quite difficult to prove such inequalities, even if some approaches managed to overcome these difficulties [34].

For this reason, our proofs avoid dealing with such relations: in the proof of Theorem 1, we fix a deterministic time ω, we impose that $\boldsymbol{\tau} \leq \omega$, and we apply the inequalities with $\tau = \omega$. Then, using martingale theory, we convert results that hold at time ω to results that hold at the stopping time $\boldsymbol{\tau}$ (see Section 2.1).

4 Balanced Bidirectional BFS

A major improvement of our algorithm, with respect to previous counterparts, is that we sample shortest paths through a balanced bidirectional BFS, instead of a standard BFS. In this section, we describe this technique, and we bound its running time on realistic models of random graphs, with high probability. The idea behind this technique is very simple: if we need to sample a uniformly random shortest path from s to t, instead of performing a full BFS from s until we reach t, we perform at the same time a BFS from s and a BFS from t, until the two BFSs touch each other (if the graph is directed, we perform a “forward” BFS from s and a “backward” BFS from t).

More formally, assume that we have visited up to level l_s from s and to level l_t from t, let $\Gamma^{l_s}(s)$ be the set of nodes at distance l_s from s, and similarly let $\Gamma^{l_t}(t)$ be the set of nodes at distance l_t from t. If $\sum_{v \in \Gamma^{l_s}(s)} \deg(v) \leq \sum_{v \in \Gamma^{l_t}(t)} \deg(v)$, we process all nodes in $\Gamma^{l_s}(s)$, otherwise we process all nodes in $\Gamma^{l_t}(t)$ (since the time needed to process level l_s is proportional to $\sum_{v \in \Gamma^{l_s}(s)} \deg(v)$, this choice minimizes the time needed to visit the next level). Assume that we are processing the node $v \in \Gamma^{l_s}(s)$ (the other case is analogous). For each neighbor w of v we do the following:

- if w was never visited, we add w to $\Gamma^{l_s+1}(s)$;
- if w was already visited in the BFS from s, we do not do anything;
- if w was visited in the BFS from t, we add the edge (v, w) to the set Π of candidate edges in the shortest path.

After we have processed a level, we stop if $\Gamma^{l_s}(s)$ or $\Gamma^{l_t}(t)$ is empty (in this case, s and t are not connected), or if Π is not empty. In the latter case, we select an edge from Π, so that the probability of choosing the edge (v, w) is proportional to $\sigma_{sv}\sigma_{wt}$ (we recall that σ_{xy} is the number of shortest paths from x to y, and it can be computed during the BFS as in [16]).

Then, the path is selected by considering the concatenation of a random path from s to v, the edge (v, w), and a random path from w to t. These random paths can be easily chosen by backtracking, as shown in [36] (since the number of paths might be exponential in the input size, in order to avoid pathological cases, we assume that we can perform arithmetic operations in $\mathcal{O}(1)$ time).

4.1 Analysis on Random Graph

In order to show the effectiveness of the balanced bidirectional BFS, we bound its running time in several models of random graphs: the Configuration Model (CM, [9]), and Rank-1 Inhomogeneous Random Graph models (IRG, [42, Chapter 3]), such as the Chung-Lu model [29], the Norros-Reittu model [32], and the Generalized Random Graph [42, Chapter 3]. In these models, we fix the number n of nodes, and we give a weight ρ_u to each node. In the CM, we create edges by giving ρ_u half-edges to each node u, and pairing these half-edges uniformly at random; in IRG we connect each pair of nodes (u, v) independently with probability close to $\rho_u\rho_v/\sum_{w\in V}\rho_w$. With some technical assumptions discussed in Appendix E of the full version [12], we prove the following theorem.

▶ **Theorem 3.** *Let G be a graph generated through the aforementioned models. Then, for each fixed $\epsilon > 0$, and for each pair of nodes s, t, w.h.p., the time needed to compute an st-shortest path through a bidirectional BFS is $\mathcal{O}(n^{\frac{1}{2}+\epsilon})$ if the degree distribution λ has finite second moment, $\mathcal{O}(n^{\frac{4-\beta}{2}} + \epsilon)$ if λ is a power law distribution with $2 < \beta < 3$.*

Sketch of proof. The idea of the proof is that the time needed by a bidirectional BFS is proportional to the number of visited edges, which is close to the sum of the degrees of the visited nodes, which are very close to their weights. Hence, we have to analyze the weights of the visited edges: for this reason, if V' is a subset of V, we define the volume of V' as $\rho_{V'} = \sum_{v\in V'}\rho_v$.

Our visit proceeds by "levels" in the BFS trees from s and t: if we never process a level with total weight at least $n^{\frac{1}{2}+\epsilon}$, since the diameter is $\mathcal{O}(\log n)$, the volume of the set of processed vertices is $\mathcal{O}(n^{\frac{1}{2}+\epsilon}\log n)$, and the number of visited edges cannot be much bigger (for example, this happens if s and t are not connected). Otherwise, assume that, at some point, we process a level l_s in the BFS from s with total weight $n^{\frac{1}{2}+\epsilon}$: then, the corresponding level l_t in the BFS from t has also weight $n^{\frac{1}{2}+\epsilon}$ (otherwise, we would have expanded from t, because weights and degrees are strongly correlated). We use the "birthday paradox": levels $l_s + 1$ in the BFS from s, and level $l_t + 1$ in the BFS from t are random sets of nodes with size close to $n^{\frac{1}{2}+\epsilon}$, and hence there is a node that is common to both, w.h.p.. This means that the time needed by the bidirectional BFS is proportional to the volume of all levels in the BFS tree from s, until l_s, plus the volume of all levels in the BFS tree from t, until l_t (note that we do not expand levels $l_s + 1$ and $l_t + 1$). All levels except the last have volume at most $n^{\frac{1}{2}+\epsilon}$, and there are $\mathcal{O}(\log n)$ such levels because the diameter is $\mathcal{O}(\log n)$: it only remains to estimate the volume of the last level.

By definition of the models, the probability that a node v with weight ρ_v belongs to the last level is about $\frac{\rho_v\rho_{\mathbf{\Gamma}^{l_s-1}(s)}}{M} \leq \rho_v n^{-\frac{1}{2}+\epsilon}$: hence, the expected volume of $\mathbf{\Gamma}^{l_s}(s)$ is at most $\sum_{v\in V}\rho_v \Pr(v \in \mathbf{\Gamma}^{l_s-1}(s)) \leq \sum_{v\in V}\rho_v^2 n^{-\frac{1}{2}+\epsilon}$. Through standard concentration inequalities, we prove that this random variable is concentrated: hence, we only need to compute this expected value. If the degree distribution has finite second moment, then $\sum_{v\in V}\rho_v^2 = \mathcal{O}(n)$, concluding the proof. If the degree distribution is power law with $2 < \beta < 3$, then we have to consider separately nodes v such that $\rho_v < n^{\frac{1}{2}}$ and such that $\rho_v > n^{\frac{1}{2}}$. In the first case, $\sum_{\rho_v<n^{\frac{1}{2}}}\rho_v^2 \approx \sum_{d=0}^{n^{\frac{1}{2}}} nd^2\lambda(d) \approx \sum_{d=0}^{n^{\frac{1}{2}}} nd^{2-\beta} \approx n^{1+\frac{3-\beta}{2}}$. In the second case, we prove that

the volume of the set of nodes with weight bigger than $n^{\frac{1}{2}}$ is at most $n^{\frac{4-\beta}{2}}$. Hence, the total volume of $\mathbf{\Gamma}^{l_s}(s)$ is at most $n^{-\frac{1}{2}+\epsilon}n^{1+\frac{3-\beta}{2}}+n^{\frac{4-\beta}{2}} \approx n^{\frac{4-\beta}{2}}$. ◀

5 Computing the k Most Central Nodes

Differently from previous works, our algorithm is more flexible, making it possible to compute the betweenness centrality of different nodes with different precision. This feature can be exploited if we only want to rank the nodes: for instance, if v is much more central than all the other nodes, we do not need a very precise estimation on the centrality of v to say that it is the top node. Following this idea, in this section we adapt our approach to the approximation of the ranking of the k most central nodes: as far as we know, this is the first approach which computes the ranking without computing a λ-approximation of all betweenness centralities, allowing significant speedups. Clearly, we cannot expect our ranking to be always correct, otherwise the algorithm does not terminate if two of the k most central nodes have the same centrality. For this reason, the user fixes a parameter λ, and, for each node v, the algorithm does one of the following:

- it provides the exact position of v in the ranking;
- it guarantees that v is not in the top-k;
- it provides a value $\tilde{\boldsymbol{b}}(v)$ such that $|\operatorname{bc}(v)-\tilde{\boldsymbol{b}}(v)| \leq \lambda$.

In other words, similarly to what is done in [36], the algorithm provides a set of $k' \geq k$ nodes containing the top-k nodes, and for each pair of nodes v, w in this subset, either we can rank correctly v and w, or v and w are almost even, that is, $|\operatorname{bc}(v)-\operatorname{bc}(w)| \leq 2\lambda$. In order to obtain this result, we plug into Algorithm 1 the aforementioned conditions in the function `haveToStop` (see Algorithm 3 in the appendix).

Then, we have to adapt the function `computeDelta` to optimize the $\delta_L^{(v)}$s and the $\delta_U^{(v)}$s to the new stopping condition: in other words, we have to choose the values of $\lambda_L^{(v)}$ and $\lambda_U^{(v)}$ that should be plugged into the function `computeDelta` (we recall that the heuristic `computeDelta` chooses the $\delta_L^{(v)}$s so that we can guarantee as fast as possible that $\tilde{\boldsymbol{b}}(v)-\lambda_L^{(v)} \leq \operatorname{bc}(v) \leq \tilde{\boldsymbol{b}}(v)+\lambda_U^{(v)}$). To this purpose, we estimate the betweenness of all nodes with few samples and we sort all nodes according to these approximate values $\tilde{b}(v)$, obtaining $v_1, \ldots, v_n$. The basic idea is that, for the first k nodes, we set $\lambda_U^{(v_i)} = \frac{\tilde{b}(v_{i-1})-\tilde{b}(v_i)}{2}$, and $\lambda_L^{(v_i)} = \frac{\tilde{b}(v_i)-\tilde{b}(v_{i+1})}{2}$ (the goal is to find confidence intervals that separate the betweenness of v_i from the betweenness of v_{i+1} and v_{i-1}). For nodes that are not in the top-k, we choose $\lambda_L^{(v)} = 1$ and $\lambda_U^{(v)} = \tilde{b}(v_k)-\lambda_L^{(v_k)}-\tilde{b}(v_i)$ (the goal is to prove that v_i is not in the top-k). Finally, if $\tilde{b}(v_i)-\tilde{b}(v_{i+1})$ is small, we simply set $\lambda_L^{(v_i)} = \lambda_U^{(v_i)} = \lambda_L^{(v_{i+1})} = \lambda_U^{(v_{i+1})} = \lambda$, because we do not know if $\operatorname{bc}(v_{i+1}) > \operatorname{bc}(v_i)$, or viceversa.

6 Experimental Results

In this section, we test the four variations of our algorithm on several real-world networks, in order to evaluate their performances. The platform for our tests is a server with 1515 GB RAM and 48 Intel(R) Xeon(R) CPU E7-8857 v2 cores at 3.00GHz, running Debian GNU Linux 8. The algorithms are implemented in C++, and they are compiled using gcc 5.3.1. The source code of our algorithm is available at `https://sites.google.com/a/imtlucca.it/borassi/publications`.

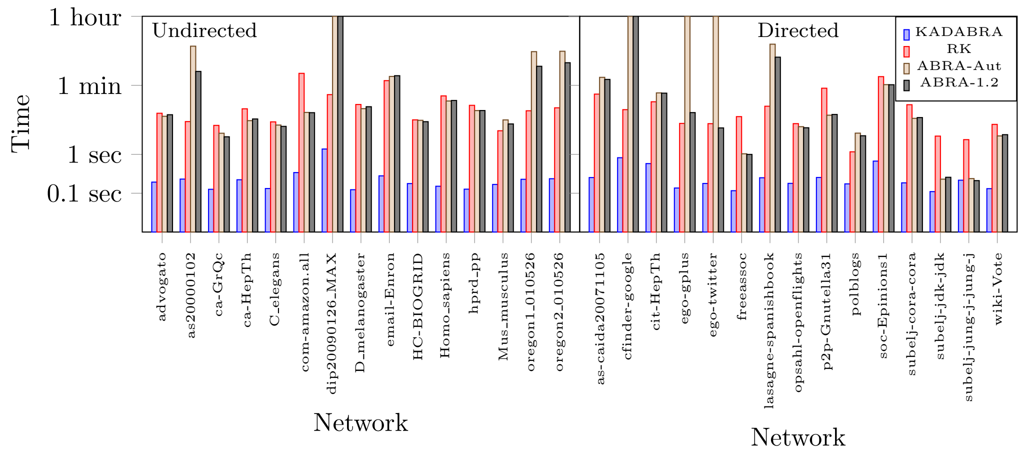

Figure 1 The time needed by the different algorithms, on all the graphs of our dataset.

Comparison with the State of the Art

The first experiment compares the performances of our algorithm KADABRA with the state of the art. The first competitor is the RK algorithm [36], available in the open-source *NetworKit* framework [41]. This algorithm uses the same estimator as our algorithm, but the stopping condition is different: it simply stops after sampling $k = \frac{c}{\epsilon^2}\left(\lfloor \log_2(\text{VD}-2)\rfloor + 1 + \log\left(\frac{1}{\delta}\right)\right)$, and it uses a heuristic to upper bound the vertex diameter. Following suggestions by the author of the *NetworKit* implementation, we set to 20 the number of samples used in the latter heuristic [7].

The second competitor is the ABRA algorithm [37], available at `http://matteo.rionda.to/software/ABRA-radebetw.tbz2`. This algorithm samples pairs of nodes (s,t), and it adds the fraction of st-paths passing from v to the approximation of the betweenness of v, for each node v. The stopping condition is based on a key result in statistical learning theory, and there is a scheduler that decides when it should be tested. Following the suggestions by the authors, we use both the automatic scheduler ABRA-Aut, which uses a heuristic approach to decide when the stopping condition should be tested, and the geometric scheduler ABRA-1.2, which tests the stopping condition after $(1.2)^i k$ iterations, for each integer i.

The test is performed on a dataset made by 15 undirected and 15 directed real-world networks, taken from the datasets SNAP (`snap.stanford.edu/`), LASAGNE (`piluc.dsi.unifi.it/lasagne`), and KONECT (`http://konect.uni-koblenz.de/networks/`). As in [37], we have considered all values of $\lambda \in \{0.03, 0.025, 0.02, 0.015, 0.01, 0.005\}$, and $\delta = 0.1$. All the algorithms have to provide an approximation $\tilde{\boldsymbol{b}}(v)$ of $\text{bc}(v)$ for each v such that $\Pr\left(\forall v, \left|\tilde{\boldsymbol{b}}(v) - \text{bc}(v)\right| \le \lambda\right) \ge 1-\delta$. In Figure 1, we report the time needed by the different algorithms on every graph for $\lambda = 0.005$ (the behavior with different values of λ is very similar). More detailed results are reported in Appendix F of the full version [12].

From the figure, we see that KADABRA is much faster than all the other algorithms, on all graphs: on average, our algorithm is about 100 times faster than RK in undirected graphs, and about 70 times faster in directed graphs; it is also more than 1 000 times faster than ABRA. The latter value is due to the fact that the ABRA algorithm has large running times on few networks: in some cases, it did not even conclude its computation within one hour. The authors confirmed that this behavior might be due to some bugs in the code, which seems to affect it only on specific graphs: indeed, in most networks, the performances

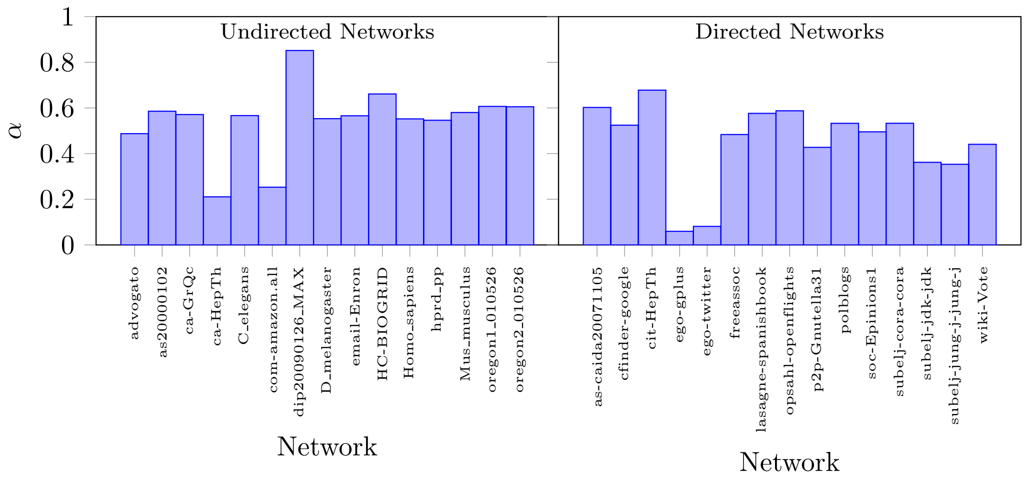

Figure 2 The exponent α such that the average number of edges visited during a bidirectional BFS is n^{α}.

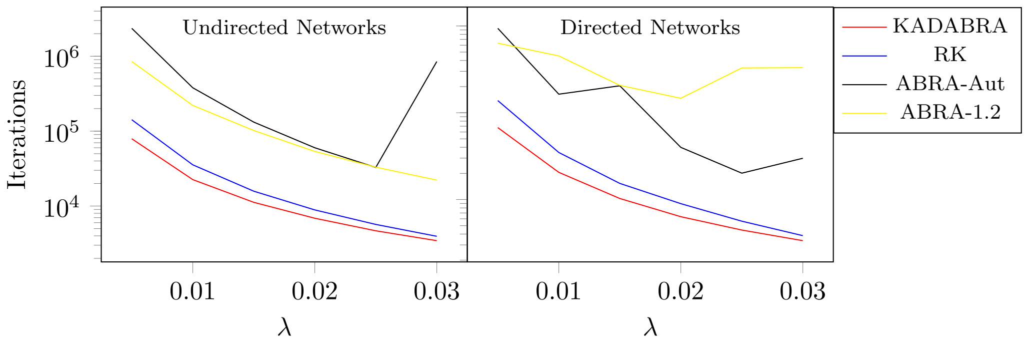

Figure 3 The average number of samples needed by the different algorithms.

of ABRA are better than those of the RK algorithm (but, still, not better than KADABRA).

In order to explain these data, we take a closer look at the improvements obtained through the bidirectional BFS, by considering the average number of edges m_{avg} that the algorithm visits in order to sample a shortest path (for all our competitors, $m_{\text{avg}} = m$, since they perform a full BFS). In Figure 2, for each graph in our dataset, we plot $\alpha = \frac{\log(m_{\text{avg}})}{\log(m)}$ (intuitively, this means that the average number of edges visited is m^{α}).

The figure shows that, apart from few cases, the number of edges visited is close to $n^{\frac{1}{2}}$, confirming the results in Section 4. This means that, since many of our networks have approximately 10 000 edges, the bidirectional BFS is about 100 times faster than the standard BFS. Finally, for each value of λ, we report in Figure 3 the number of samples needed by all the algorithms, averaged over all the graphs in the dataset.

From the figure, KADABRA needs to sample the smallest amount of shortest paths, and the average improvement over RK grows when λ tends to 0, from a factor 1.14 (resp., 1.14) if $\lambda = 0.03$, to a factor 1.79 (resp., 2.05) if $\lambda = 0.005$ in the case of undirected (resp., directed) networks. Again, the behavior of ABRA is highly influenced by the behavior on few networks, and as a consequence the average number of samples is higher. In any case, also in the graphs where ABRA has good performances, KADABRA still needs a smaller number of samples.

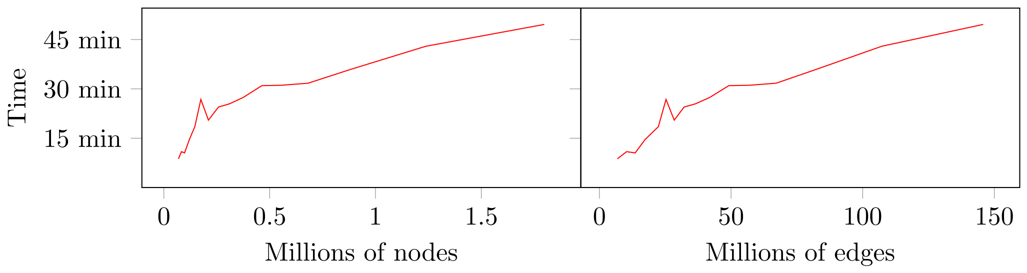

Figure 4 The total time of computation of KADABRA on increasing snapshots of the IMDB graph.

Computing Top-k Centralities

In the second experiment, we let KADABRA compute the top-k betweenness centralities of large graphs, which were unfeasible to handle with the previous algorithms.

The first set of graph is a series of temporal snapshots of the IMDB actor collaboration network, in which two actors are connected if they played together in a movie. The snapshots are taken every 5 years from 1940 to 2010, including a last snapshot in 2014, with 1 797 446 nodes and 145 760 312 edges. The graphs are extracted from the IMDB website (`http://www.imdb.com`), and they do not consider TV-series, awards-shows, documentaries, game-shows, news, realities and talk-shows, in accordance to what was done in `http://oracleofbacon.org`.

The other graph considered is the Wikipedia citation network, whose nodes are Wikipedia pages, and which contains an edge from page p_1 to page p_2 if the text of page p_1 contains a link to page p_2. The graph is extracted from DBPedia 3.7 (`http://wiki.dbpedia.org/`), and it consists of 4 229 697 nodes and 102 165 832 edges.

We have run our algorithm with $\lambda = 0.0002$ and $\delta = 0.1$: as discussed in Section 5, this means that either two nodes are ranked correctly, or their centrality is known with precision at most λ. As a consequence, if two nodes are not ranked correctly, the difference between their real betweenness is at most 2λ. The full results are available in Appendix G of the full version [12].

All the graphs were processed in less than one hour, apart from the Wikipedia graph, which was processed in approximately 1 hour and 38 minutes. In Figure 4, we plot the running times for the actor graphs: from the figure, it seems that the time needed by our algorithm scales slightly sublinearly with respect to the size of the graph. This result respects the results in Section 4, because the degrees in the actor collaboration network are power law distributed with exponent $\beta \approx 2.13$ (`http://konect.uni-koblenz.de/networks/actor-collaboration`). Finally, we observe that the ranking is quite precise: indeed, most of the times, there are very few nodes in the top-5 with the same ranking, and the ranking rarely contains significantly more than 10 nodes.

Acknowledgements. The authors would like to thank Matteo Riondato for several constructive comments on an earlier version of this work. We also thank Elisabetta Bergamini, Richard Lipton, and Sebastiano Vigna for helpful discussions and Holger Dell for his help with the experiments.

Abstract

Cycle inequalities play an important role in the polyhedral study of the periodic timetabling problem. We give the first pseudo-polynomial time separation algorithm for cycle inequalities, and we give a rigorous proof for the pseudo-polynomial time separability of the change-cycle inequalities. The efficiency of these cutting planes is demonstrated on real-world instances of the periodic timetabling problem.

1 Introduction

Periodic timetable construction is a fascinating problem because it is intuitively understood and mathematically formulated, but very hard to solve. In fact, even though real world instances give rise to relatively small optimization models, branch-and-bound based methods can easily stall with large duality gaps. The likely reasons for this resistivity are the occurrence of genuine integer variables, symmetries, and modulo constraints.

The classical approach to periodic timetabling is to use a formulation in terms of the periodic event scheduling problem (PESP) by Serafini and Ukovich [14]. This model has been the basis for the development of a variety of exact and heuristic solution methods for the optimization and the feasibility version. Integer programming approaches were proposed, e.g., by Nachtigall [9], Lindner [7], and Liebchen [3]. A topological search method based on cohomology feasibility was used by Schrijver [12] to optimize a Dutch railway timetable. A modulo network simplex heuristic was invented by Nachtigall and Opitz [8]. Liebchen and Peeters [5] studied the relation to integral cycle bases to find tighter lower bounds. A SAT approach for the feasibility problem was developed by Kümmling et al. [2]. A comprehensive and up-to-date survey of the literature on mathematical timetable optimization and its applications is summarized in Sels et al. [13].

The best method to compute lower bounds for the optimization problem is to study the polyhedral structure of the periodic timetabling problem (PTP) associated with the PESP.

* This research was carried out in the framework of MATHEON supported by Einstein Foundation Berlin.

Several classes of valid inequalities have been identified, namely, chain, cycle, change-cycle, flow, and multi-circuit inequalities, see [3, 7, 9, 10, 11]. Some of them are known to be facet defining or in some Chvátal closure for the PESP polytope or relaxations of it under certain conditions [6]. It is also known that the change-cycle inequalities can be separated in pseudo-polynomial time [9]. The cycle inequalities have been used computationally by means of heuristic separation. They improve the lower bound significantly and are considered to be "the computationally most interesting cuts" [3, p. 210].

We study in this paper the separation problem for the cycle and the change-cycle inequalities for the periodic timetabling problem. We give the first pseudo-polynomial time separation algorithm for cycle inequalities. Its complexity is $\mathcal{O}(Tn^2m)$, where T is the period time, n the number of nodes, and m the number of arcs. The change-cycle inequalities have been studied by Nachtigall [9], who gave a rough sketch of a pseudo-polynomial algorithm and claimed a complexity of $\mathcal{O}(T(mn+n^2))$. We cannot follow this argument, but give a precise description of the algorithm and prove a complexity of $\mathcal{O}(T^2n^2m)$. Computational results on real world instances from a Dutch railway system and two German cities corroborate the efficiency of these cuts.

The paper is structured as follows. Section 2 gives a mathematical statement of the problem. Section 3 introduces the periodic slack polyhedron and states the cycle and the change-cycle inequalities. Sections 4 and 5 contain the separation algorithms for the change-cycle inequalities and the cycle inequalities. They are based on similar ideas, but cycle separation requires the setup of an additional auxiliary graph. Section 6 concludes with computational results.

2 Periodic Timetabling Problem and PESP

Most models in the literature about periodic timetabling are based on the *periodic event scheduling problem* (PESP) developed by [14]. In this problem, we are given a directed graph $\mathcal{N} = (V, A)$, the *event-activity network*. The nodes V are called *events* and represent arrivals and departures of lines at their stations. The arcs $A \subseteq V \times V$ are called *activities* and model lines driving between stations, waiting at stations, and possible transfers for passengers between lines at stations. Further, each activity $a \in A$ is associated with a lower and an upper time bound $\ell_a, u_a \in \mathbb{Q}_{\geq 0}$, respectively, on its duration. Let $n = |V|$ be the number of events and $m = |A|$ be the number of activities.

A *periodic timetable* $\pi : V \to [0, T)$ determines the timings of all events, which are assumed to repeat periodically w.r.t. a *period time* $T \in \mathbb{N}$. Given $x \in \mathbb{Q}$, we define the modulo operator by $[x]_T := \min\{x + zT : x + zT \geq 0, z \in \mathbb{Z}\}$. We call a timetable *feasible* if the *periodic interval constraints*

$$[\pi_w - \pi_v - \ell_a]_T \in [0, u_a - \ell_a] \quad \forall\, a = (v, w) \in A \tag{1}$$

are satisfied. We assume w.l.o.g. that $\ell_a < T$ and $u_a - \ell_a < T$ for all $a \in A$. Many operational requirements can be modeled with the constraints (1), see [4]. For a feasible timetable π, the *periodic tension* of activity $a \in A$ is defined by $x_a := \ell_a + [\pi_w - \pi_v - \ell_a]_T$ and corresponds to its duration. The *periodic slack* of activity $a \in A$ is defined by $y_a := [\pi_w - \pi_v - \ell_a]_T$. Given activity weights $w \in \mathbb{Q}^A$, the goal of the periodic timetabling problem is to find a feasible timetable that minimizes the weighted sum of the periodic slacks, i.e., $\min \sum_{a \in A} w_a\, y_a$.

An *oriented cycle* C in $\mathcal{N}$ is a sequence $C = (v_0, a_1, v_1, \ldots, a_k, v_k)$, where $k \geq 1$, $v_1, \ldots, v_k \in V$, $a_1, \ldots, a_k \in A$, $v_0 = v_k$, and $a_i \in \{(v_{i-1}, v_i), (v_i, v_{i-1})\}$. Activities with $a_i = (v_{i-1}, v_i) \in C$ are called *forward directed* and activities with $a_i = (v_i, v_{i-1}) \in C$

backward directed. An oriented cycle containing only forward directed activities is called a *circuit*. An oriented cycle is *elementary* if no event appears more than once in the sequence. For an oriented cycle C in $\mathcal{N}$, we define its incident vector $\gamma_C \in \{-1, 0, 1\}^A$ as

$$\gamma_{C_a} = \begin{cases} 1 & \text{if } a \in C \text{ and } a \text{ is forward directed,} \\ -1 & \text{if } a \in C \text{ and } a \text{ is backward directed,} \\ 0 & \text{if } a \notin C. \end{cases}$$

For convenience, we will refer interchangeably to C and γ_C. Let $\mathcal{B} = \{C_1, \dots, C_\nu\}$, $\nu = m - n + 1$, be a cycle basis of $\mathcal{N}$ and denote by $\Gamma \in \mathbb{Z}^{\mathcal{B} \times A}$ the corresponding cycle matrix, i.e., the rows of Γ correspond to the characteristic vectors $\gamma_{C_i} \in \{-1, 0, 1\}^A$, $i \in \{1, \dots, \nu\}$. Introducing periodic slack variables $y \in \mathbb{R}^A$ and *periodic offset* variables $z \in \mathbb{Z}^A$, we can state the periodic timetabling problem as the following mixed-integer program [9, 3]:

$$\begin{aligned} \text{(PTP)} \quad \min \quad & \sum_{a \in A} w_a y_a \\ \text{s.t.} \quad & \Gamma\, y - T\, \Gamma\, z = -\Gamma \ell && (2) \\ & 0 \leq y \leq u - \ell && (3) \\ & z \in \mathbb{Z}^A && (4) \end{aligned}$$

3 Periodic Slack Polyhedron

The literature considers different versions of the PTP polyhedron, e.g., the projection on the space of the periodic slack variables or the periodic offset variables, see [9, 3, 6]. Nachtigall [9] also considers the polyhedron that is obtained when the upper bounds in constraints (3) are omitted. In the following, we study the polyhedron $P_{IP}(\text{PTP})$ associated with the feasible solutions of (PTP), i.e., a polyhedron defined in the slack and offset space. We recall the cycle and change-cycle inequalities in a unified notation.

▶ **Definition 1.** The *periodic slack and offset space* is defined by

$$\mathcal{S} = \left\{ (y, z) \in \mathbb{R}^A \times \mathbb{Z}^A | \Gamma\, y - T\, \Gamma\, z = -\Gamma \ell, 0 \leq y \leq u - \ell \right\}.$$

The *periodic slack polyhedron* is defined by

$$P_{IP}(\text{PTP}) = \text{conv}(\mathcal{S})$$

and the corresponding LP relaxation by

$$P_{LP}(\text{PTP}) = \left\{ (y, z) \in \mathbb{R}^A \times \mathbb{R}^A | \Gamma\, y - T\, \Gamma\, z = -\Gamma \ell, 0 \leq y \leq u - \ell \right\}.$$

The following lemma shows that the cycle equations (2) do not only hold for integer periodic offset variables and the cycles of the cycle basis but for any feasible solution of the LP relaxation of (PTP) and any cycle in the event-activity network.

▶ **Lemma 2.** *Let $(y, z) \in P_{LP}(\text{PTP})$ and let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$. Then we have*

$$\gamma^t y = -\gamma^t \ell + T\, \gamma^t z.$$

Proof. Since $\mathcal{B}$ is a cycle basis, there exists a vector $\lambda \in \mathbb{R}^\nu$ such that $\gamma = \Gamma^t\, \lambda$. Hence, we get

$$\gamma^t y = \lambda^t\, \Gamma\, y = \lambda^t\, (-\Gamma\, \ell + T\, \Gamma\, z) = -(\Gamma^t\, \lambda)^t \ell + T\, (\Gamma^t\, \lambda)^t\, z = -\gamma^t \ell + T\, \gamma^t\, z. \qquad ◀$$

Lemma 2 implies that for any feasible solution of (PTP) the following modulo cycle equations hold.

▶ **Corollary 3.** *Let $(y, z) \in \mathcal{S}$ and let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$. Then we have*

$$\gamma^t y \equiv_T -\gamma^t \ell.$$

Proof. The corollary follows directly from $\gamma^t z \in \mathbb{Z}$ and Lemma 2. ◀

For convenience, we introduce further notation. For an oriented cycle $\gamma \in \mathbb{Z}^m$ in $\mathcal{N}$ we define the positive part $\gamma_+ \in \mathbb{Z}^m$ and the negative part $\gamma_- \in \mathbb{Z}^m$, respectively, by

$$\gamma_{+,a} = \begin{cases} 1 & \text{if } \gamma_a = 1 \\ 0 & \text{else} \end{cases} \quad \text{and} \quad \gamma_{-,a} = \begin{cases} 1 & \text{if } \gamma_a = -1 \\ 0 & \text{else} \end{cases}$$

for all $a \in A$ i.e., $\gamma = \gamma_+ - \gamma_-$.

The following class of valid inequalities was introduced by Nachtigall [9] and are defined for every oriented cycle in the event-activity network.

▶ **Theorem 4.** *Let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$ and define $\alpha = [-\gamma^t \ell]_T$. Then the* change-cycle inequality

$$(T - \alpha)\, \gamma_+^t y + \alpha\, \gamma_-^t y \geq \alpha\, (T - \alpha) \tag{5}$$

is valid for P_{IP}(PTP)*.*

A second class of inequalities are also induced by the oriented cycles in the event-activity network and were first described by Odijk [10]. These inequalities are denoted as *cycle inequalities*. They are usually defined in terms of the periodic offset variables. We will show next that they can also be defined in terms of the slack variables.

▶ **Theorem 5.** *Let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$. Then the z*-cycle inequality

$$\gamma^t\, z \geq \left\lceil \frac{1}{T} \left(\gamma_+^t \ell - \gamma_-^t u \right) \right\rceil \tag{6}$$

is valid for P_{IP}(PTP)*.*

Proof. Let $(y, z) \in \mathcal{S}$. We have with Lemma 2

$$T\, \gamma^t\, z = \gamma^t y + \gamma^t \ell = \gamma_+^t y - \gamma_-^t y + \gamma^t \ell \geq -\gamma_-^t\, (u - \ell) + \gamma^t \ell = \gamma_+^t \ell - \gamma_-^t u.$$

Since $\gamma^t\, z \in \mathbb{Z}$, the inequality (6) follows. ◀

▶ **Lemma 6.** *Let $\alpha \in \mathbb{R}$, then*

$$[-\alpha]_T + \alpha = T \left\lceil \frac{1}{T} \alpha \right\rceil. \tag{7}$$

Proof. Let $z \in \mathbb{Z}$ and $\alpha \in \mathbb{R}$ then $-\alpha - T\, z = [-\alpha]_T$ and $-1 < -\frac{1}{T}\, [-\alpha]_T \leq 0$. We get

$$\begin{aligned} [-\alpha]_T + \alpha = -T\, z &= T\Big(-z + \underbrace{\left\lceil -\frac{1}{T}\, [-\alpha]_T \right\rceil}_{=0} \Big) \\ &= T \left\lceil -z - \frac{1}{T}\, [-\alpha]_T \right\rceil = T \left\lceil \frac{1}{T}(-T\, z - [-\alpha]_T) \right\rceil = T \left\lceil \frac{1}{T} \alpha \right\rceil. \end{aligned}$$ ◀

With Lemma 6 we can show that the z-cycle inequalities can be expressed equivalently in terms of the slack variables.

▶ **Theorem 7.** *Let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$. Let $(y, z) \in P_{LP}(\text{PTP})$, then the* z-cycle inequality (6) *holds if and only if the the* y-cycle inequality

$$\gamma^t y \geq \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_-^t (\ell - u) \tag{8}$$

holds.

Proof. Let $(y, z) \in P_{LP}(\text{PTP})$ and assume that z satisfies the *z-cycle inequality* (6) for γ. Using first Lemma 6 and then Lemma 2 we have

$$\begin{aligned}
& & \gamma^t z &\geq \left\lceil \frac{1}{T}\left(\gamma_+^t \ell - \gamma_-^t u\right) \right\rceil \\
& & &= \frac{1}{T}\left(\left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_+^t \ell - \gamma_-^t u\right) \\
\Leftrightarrow & & \gamma^t y + \gamma^t \ell &\geq \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_+^t \ell - \gamma_-^t u \\
\Leftrightarrow & & \gamma^t y &\geq \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_+^t \ell - \gamma_-^t u - \gamma^t \ell \\
& & &= \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_+^t \ell - \gamma_-^t u - \gamma_+^t \ell + \gamma_-^t \ell \\
& & &= \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T - \gamma_-^t u + \gamma_-^t \ell \\
& & &= \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_-^t (\ell - u).
\end{aligned}$$ ◀

▶ **Corollary 8.** *Let $\gamma \in \mathbb{Z}^A$ be an oriented cycle in $\mathcal{N}$. Then the* y-cycle inequality

$$\gamma^t y \geq \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_-^t (\ell - u)$$

is valid for $P_{IP}(\text{PTP})$.

4 Separation of Change-Cycle Inequalities

In this section we describe a pseudo-polynomial dynamic programming procedure to separate violated change-cycle inequalities (5). The idea of this algorithm was originally proposed by Nachtigall [9]. He claimed a running time of $\mathcal{O}(T(mn + n^2)$, but did not give a proof. We prove a complexity of $\mathcal{O}(T^2 n^2 m)$.

Given a point $(y^*, z^*) \in P_{LP}(\text{PTP})$, the separation problem is to find an oriented cycle γ in $\mathcal{N}$ such that the change-cycle inequality (5) induced by γ is violated, i.e., for $\alpha_0 = [-\gamma^t \ell]_T$ it holds

$$(T - \alpha_0)\gamma_+^t y^* + \alpha_0\, \gamma_-^t y^* < \alpha_0\, (T - \alpha_0),$$

or to conclude that no such cycle exists. The idea is to solve for each fixed $\alpha_0 \in \{0, \ldots, T-1\}$ the problem

$$f^*(\alpha_0) = \min\{(T - \alpha_0)\gamma_+^t y^* + \alpha_0\, \gamma_-^t y^* | \gamma \text{ oriented cycle in } \mathcal{N}, \left[-\gamma^t \ell\right]_T = \alpha_0\}, \tag{9}$$

which is to find the minimum cost cycle w.r.t.

$$c_a = \begin{cases} (T - \alpha_0) y_a^* & \text{if } \gamma_a = 1 \\ \alpha_0 y_a^* & \text{if } \gamma_a = -1 \\ 0 & \text{else} \end{cases}$$

of all oriented cycles with $[-\gamma^t \ell]_T = \alpha_0$. Note that a violated change-cycle inequality exists if and only if for some $\alpha_0 \in \{0, \dots, T-1\}$ it holds $f^*(\alpha_0) < \alpha_0 \, (T - \alpha_0)$.

The minimization problem (9), again, can be solved with a dynamic program that iterates over the cycle lengths w.r.t. the number of activities. We denote by a *chain* a path that can contain forward directed activities as well as backward directed activities. Let $\mathcal{C}_{ij}^k$ be the set of all chains in $\mathcal{N}$ from event $i \in V$ to event $j \in V$ that contain exactly k activities, given by their characteristic vectors. For $\alpha \in \{0, \dots, T-1\}$, let

$$f_{ij}^k(\alpha_0, \alpha) := \min \left\{ (T - \alpha_0) \sum_{\substack{a \in A: \\ p_a > 0}} y_a^* + \alpha_0 \sum_{\substack{a \in A: \\ p_a < 0}} y_a^* \middle| p \in \mathcal{C}_{ij}^k, \alpha = \left[-p^t \ell\right]_T \right\}$$

be the minimum length w.r.t. c_a of all chains in $\mathcal{C}_{ij}^k$ with $\alpha = [-p^t \ell]_T$. Since a chain of length $k \geq 2$ consists of a chain of length $k-1$ and an additional activity, the following recursive equation holds

$$f_{ij}^{k+1}(\alpha_0, \alpha) := \min \left\{ \min_{\substack{a=(u,j) \\ \left[\alpha' - \ell_a\right]_T = \alpha}} f_{iu}^k(\alpha_0, \alpha') + (T - \alpha_0) y_a^*, \min_{\substack{a=(j,u) \\ \left[\alpha' + \ell_a\right]_T = \alpha}} f_{iu}^k(\alpha_0, \alpha') + \alpha_0 y_a^* \right\}, \tag{10}$$

for all $k \geq 0$ with

$$f_{ij}^0(\alpha_0, \alpha) = \begin{cases} 0 & \text{if } i = j, \alpha = 0 \\ \infty & \text{else.} \end{cases}$$

Since every elementary cycle has at most n activities and $c_a \geq 0$ for all $a \in A$, the minimum length w.r.t. c of all oriented cycles γ with $\alpha_0 = [-\gamma^t \ell]_T$ is given by

$$f^*(\alpha_0) = \min_{i \in V} \min_{k=1}^{n} f_{ii}^k(\alpha_0, \alpha_0).$$

For fixed $k \in \{0, \dots, n-1\}$, the recursive equation (10) can be solved with Algorithm 1.

▶ **Theorem 9.** *For given $\alpha_0 \in \{0, \dots, T-1\}$, $k \in \{0, \dots, n-1\}$, and f_{ij}^k for all $i, j \in V$, Algorithm 1 computes $f_{ij}^{k+1}(\alpha_0, \alpha)$ for all $i, j \in V$ and $\alpha \in \{0, \dots, T-1\}$ in $\mathcal{O}(Tmn)$.*

Proof. For a given $k \in \{0, \dots, n-1\}$ and $\alpha_0 \in \{0, \dots, T-1\}$, Algorithm 1 obviously solves equation (10) for all $i, j \in V$ and for all $\alpha \in \{0, \dots, T-1\}$. The computation involves $\mathcal{O}(Tmn)$ elementary operations. ◀

The described separation algorithm is given in pseudocode in Algorithm 2.

▶ **Theorem 10.** *Algorithm 2 solves the separation problem for the change-cycle inequalities* (5) *in $\mathcal{O}(T^2 n^2 m)$.*

Proof. The Algorithm 2 solves for each $\alpha_0 \in \{0, \dots, T-1\}$ the minimization problem (9) and correctly reports if there exists an $\alpha_0 \in \{0, \dots, T-1\}$ such that $f^*(\alpha_0) < \alpha_0 \, (T - \alpha_0)$. Hence, with the previous argumentation, the correctness of the algorithm follows. The algorithm needs to call Algorithm 1, see line 6 of Algorithm 2, in total kT-times. By Theorem 9, this results in a running time in $\mathcal{O}(T^2 n^2 m)$. ◀

Algorithm 1: Computing $f_{ij}^{k+1}(\alpha_0, \alpha)$ for all $\alpha \in \{0, \ldots, T-1\}$

```
Input  : $(y^*, z^*) \in P_{LP}(\text{PTP})$, $\alpha_0 \in \{0, \ldots, T-1\}$, $k \in \{0, \ldots, n-1\}$,
         $f_{ij}^k, \forall i, j \in V$
Output : $f_{ij}^{k+1}, \forall i, j \in V$
1  for $a = (u, v) \in A$ do
2      for $\alpha' := 0, \ldots, T-1$ do
3          for $i \in V$ do
4              $\alpha := [\alpha' - \ell_a]_T$

16 else
17     return $NULL$
18 end
```

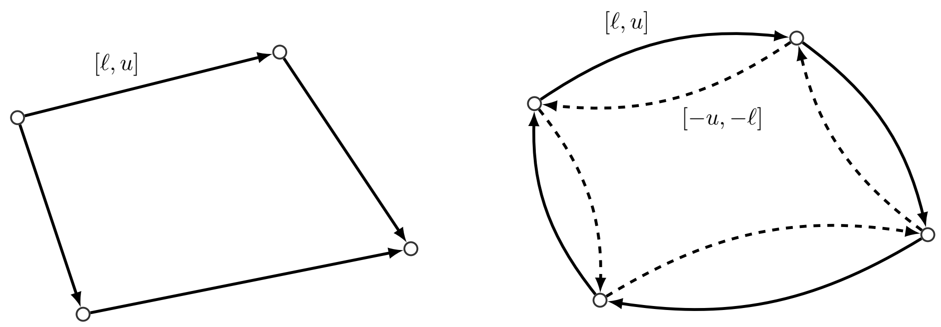

Figure 1 *Left*: the network $\mathcal{N}$, *Right*: the auxiliary network $\tilde{\mathcal{N}}$. The solid arcs correspond to the cycle γ and the circuit $\tilde{\gamma}$ from Theorem 11, respectively.

5 Separation of Cycle Inequalities

In this section we describe a pseudo-polynomial dynamic programming procedure to separate violated cycle inequalities (8) using an auxiliary network that was proposed by Nachtigall [9]. The auxiliary network allows to reduce cycle separation to finding certain modulo constrained circuits. Such a circuit can be found by a modification of the change-cycle separation Algorithm 2.

We obtain $\tilde{\mathcal{N}}$ by copying $\mathcal{N}$ and additionally introducing for each activity $a = (i, j)$ the back activity $\bar{a} = (j, i)$. The copies of the original activities keep their bounds, the bounds of the back activities are set to $\tilde{\ell}_{\bar{a}} = -u_a$ and $\tilde{u}_{\bar{a}} = -\ell_a$, see Figure 1. For a point $(y, z) \in P_{LP}(\text{PTP})$ we define $\tilde{y}$ on the activities of $\tilde{\mathcal{N}}$ by $\tilde{y}_a = y_a$ and $\tilde{y}_{\bar{a}} = u_a - \ell_a - y_a$.

▶ **Theorem 11.** *Let be $(y^*, z^*) \in P_{LP}(\text{PTP})$. Then, $\mathcal{N}$ contains a cycle γ that violates the y-cycle inequality (8), i.e.,*

$$\gamma^t y^* < \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_-^t (\ell - u),$$

if and only if $\tilde{\mathcal{N}}$ contains a circuit $\tilde{\gamma}$ (cycle containing only forward directed activities) with

$$\tilde{\gamma}^t \tilde{y}^* < \left[-\tilde{\gamma}^t \tilde{\ell}\right]_T.$$

Proof. Let γ be a cycle in $\mathcal{N}$ and $\tilde{\gamma}$ be the circuit in $\tilde{\mathcal{N}}$ obtained by replacing all backward directed activities in γ with their auxiliary back activities, see Figure 1. Then we get

$$\begin{aligned}
& & \gamma^t y^* &< \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T + \gamma_-^t (\ell - u) \\
&\Leftrightarrow & \gamma_+^t y^* + \gamma_-^t (u - \ell - y^*) &< \left[-\gamma_+^t \ell + \gamma_-^t u\right]_T \\
&\Leftrightarrow & \gamma_+^t \tilde{y}^* + \gamma_-^t \tilde{y}^* &< \left[-\gamma_+^t \ell - \gamma_-^t (-u)\right]_T \\
&\Leftrightarrow & \tilde{\gamma}^t \tilde{y}^* &< \left[-\tilde{\gamma}^t \tilde{\ell}\right]_T
\end{aligned}$$ ◀

By Theorem 11, there exists a violated cycle inequality (8) if and only if

$$\delta^* := \min\{\tilde{\gamma}^t \tilde{y}^* - \left[-\tilde{\gamma}^t \tilde{\ell}\right]_T | \tilde{\gamma} \text{ directed circuit in } \tilde{\mathcal{N}}\} < 0.$$

Hence, we can solve the separation problem by minimizing $\delta(\tilde{\gamma}) := \tilde{\gamma}^t \tilde{y}^* - \left[-\tilde{\gamma}^t \tilde{\ell}\right]_T$ over all directed circuits in the auxiliary network $\tilde{\mathcal{N}}$. We describe in the following the idea of the algorithm, which is given in pseudocode in Algorithm 3.

Let $\mathcal{P}_{ij}^k$ be the set of all (i,j)-paths in $\tilde{\mathcal{N}}$ that contain exactly k activities, given by their characteristic vectors. For $\alpha \in \{0,\dots,T-1\}$, let

$$d_{ij}^k(\alpha) := \min \left\{ \sum_{a \in A: p_a > 0} \tilde{y}_a^* \middle| p \in \mathcal{P}_{ij}^k, \alpha = \left[-p^t \tilde{\ell}\right]_T \right\} \tag{11}$$

be the minimum length with respect to $\tilde{y}^*$ of all paths in $\mathcal{P}_{ij}^k$ with $\alpha = \left[-p^t \tilde{\ell}\right]_T$. We can use the following recursive equation to compute (11)

$$d_{ij}^{k+1}(\alpha) := \min_{\substack{a=(u,j) \\ \left[\alpha' - \ell_a\right]_T = \alpha}} d_{iu}^k(\alpha') + \tilde{y}_a^*, \quad \forall\, k \geq 0$$

with

$$d_{ij}^0(\alpha) = \begin{cases} 0 & \text{if } i = j, \alpha = 0 \\ \infty & \text{else.} \end{cases}$$

Since every elementary circuit has at most n activities and $\tilde{y}_a^* \geq 0$ for all $a \in A$, the minimum length w.r.t. $\tilde{y}^*$ of all directed circuits $\tilde{\gamma}$ with $\alpha = \left[-\tilde{\gamma}^t \tilde{\ell}\right]_T$ is given by

$$d^*(\alpha) = \min_{i \in V} \min_{k=1}^{n} d_{ii}^k(\alpha)$$

and we have

$$\delta^* = \min\{d^*(\alpha) - \alpha | \alpha \in \{0,\dots,T-1\}\}.$$

▶ **Theorem 12.** *Algorithm 3 detects a violated cycle inequality in $\mathcal{O}(Tn^2m)$.*

Proof. The argumentation in this section proves that the algorithm computes δ^* and, thus, correctly detects violated cycle inequalities. The algorithm involves in total $\mathcal{O}(Tn^2m)$ elementary operations. ◀

6 Computational Results

This section gives some indication of the computational usefulness of cycle-separation compared to a heuristic separation.

As far as we know, the cycle inequalities (6) are added in cutting-plane algorithms only with heuristic separation algorithms, see [9, 3, 6]. In the so-called spanning tree heuristic, a minimum spanning tree of the event-activity network weighted with the slack values of the LP-solution is computed and the fundamental cycles of this tree are checked for violated inequalities.

We have implemented a full separation algorithm according to Algorithm 3 to separate all violated cycle inequalities (8) with a given maximum length. Such a length restriction is necessary to handle the memory consumption and the computation time of the separation algorithm. We tested a length restriction of 10, 15, and 20.

Our test set consists of seven instances, which are given in Table 1. The instance Wuppertal is based on the real multi-modal public transportation network of the city of Wuppertal for 2013. The remaining Wuppertal-instances are obtained by selecting a subset of lines of this instance. The Dutch instance is based on a network that was introduced

Algorithm 3: Separation of Cycle Inequalities

```
Input  : LP-point $(y^*, z^*) \in P_{LP}(\text{PTP})$
Output : Cycle $\gamma \in \mathcal{N}$ such that the cycle inequality (8) is violated, or $NULL$ if
         no such cycle exists.
1  $d^* := \infty$
2  $\delta^* = 0$
3  $d_{ij}^k(\alpha) := \begin{cases} 0 & \text{if } k = 0, i = j, \alpha = 0 \\ \infty & \text{else} \end{cases}$
4  for $k := 1, \dots, n$ do
5      for $a = (u, v) \in \tilde{A}$ do
6          for $\alpha' \in \{0, \dots, T-1\}$, $i \in V$ with $d_{iu}^k(\alpha') < \infty$ do
7              $\alpha := [\alpha' - \tilde{\ell}_a]_T$
8              if $d_{iv}^k(\alpha) > d_{iu}^{k-1}(\alpha') + \tilde{y}_a^*$ then
9                  $d_{iv}^k(\alpha) := d_{iu}^{k-1}(\alpha') + \tilde{y}_a^*$
10                 if $i = v$ and $d_{ii}^k(\alpha) - \alpha < \delta^*$ then
11                     $d^* := d_{ii}^k(\alpha)$
12                     $\delta^* := d_{ii}^k(\alpha) - \alpha$
13                 end
14             end
15         end
16     end
17 end
18 if $\delta^* < 0$ then
19     return $\gamma(d^*)$
20 else
21     return $NULL$
22 end
```

Table 1 Statistics on the test instances. The columns list the instance name, the number of stations and lines of the transportation network, the number of events and activities of the event-activity network, the number of slack variables, periodic offset variables, and constraints in the original problem, and the number of variables and constraints after preprocessing.

by Bussieck in the context of line planning [1]. The Potsdam instance is based on the real multi-modal public transportation network for 1998. We consider a period time of 20 for all instances. The activity weights are obtained by computing an uncapacitated multi-commodity flow in the event-activity network for a given passenger demand.

Our code is based on the constraint integer programming framework SCIP version 3.2.0 using Cplex 12.6.3 as an LP-solver. All computations were done on an Intel(R) Xeon(R) CPU E3-1245, 3.4 GHz computer (in 64 bit mode) with 8 MB cache, running Linux and 32 GB of memory. We set the time limit to one hour.

We compare the performance of the general MIP separators implemented in SCIP (*no add. cuts*), adding either the spanning-tree heuristic (*heuristic*) or our separation algorithm with a given length restriction (*length* ≤ 10, *length* ≤ 15, and *length* ≤ 20). The additional separators are only called at the root node. The results are listed in Table 2.

Looking at the root dual bound, one can see significant improvements, e.g., of up to 90% for Wuppertal 98, in comparison to the strategy without cycle cuts, and almost 75% over heuristic cycle cut separation. Hence, the separation algorithm has a greater effect on the dual bound than the heuristic, even though the separator only considers cycles of a restricted length. Only Wuppertal 14 has a smaller root dual bound if all cycles of maximum length 20 are separated compared to a cycle length of 10 or 15. This is not caused by the cycle inequalities, but by the additional “flow cover” and “strong cg” inequalities (heuristically) found by the default separator of SCIP. The given length restriction influences the performance of the separation algorithm: Separating cycle inequalities with higher length increases the computation time, but also, in general, the dual bound, especially for larger instances. In particular, the root dual bound for Potsdam can be further improved by 30% by using a length restriction of 20 compared to a length restriction of 10. Potsdam features the largest number of events, see Table 1, and benefits from a consideration of longer cycles.

Abstract

We show how to represent a simple polygon P by a (pixel-based) grid polygon Q that is simple and whose Hausdorff or Fréchet distance to P is small. For any simple polygon P, a grid polygon exists with constant Hausdorff distance between their boundaries and their interiors. Moreover, we show that with a realistic input assumption we can also realize constant Fréchet distance between the boundaries. We present algorithms accompanying these constructions, heuristics to improve their output while keeping the distance bounds, and experiments to assess the output.

1 Introduction

Transforming the representation of objects from the real plane onto a grid has been studied for decades due to its applications in computer graphics, computer vision, and finite-precision computational geometry [14]. Two interpretations of the grid are possible: (i) the grid graph, consisting of vertices at all points with integer coordinates, and horizontal and vertical edges

between vertices at unit distance; (ii) the pixel grid, where the only elements are pixels (unit squares). In the latter, one can choose between 4-neighbor or 8-neighbor grid topology. In this paper we adopt the pixel grid view with 4-neighbor topology.

The issues involved when moving from the real plane to a grid begin with the definition of a line segment on a grid, known as a *digital straight segment* [18]. For example, it is already difficult to represent line segments such that the intersection between any pair is a connected set (or empty). In general, the challenge is to represent objects on a grid in such a way that certain properties of those objects in the real plane transfer to related properties on the grid; connectedness of the intersection of two line segments is an example of this.

While most of the research related to *digital geometry* has the graphics or vision perspective [17, 18], computational geometry has made a number of contributions as well. Besides finite-precision computational geometry [12, 14] these include snap rounding [11, 13, 16], the integer hull [4, 15], and consistent digital rays with small Hausdorff distance [10].

Mapping polygons. We consider the problem of representing a simple polygon P as a similar polygon in the grid (see Fig. 1). A *grid cycle* is a simple cycle of edges and vertices of the grid graph. A *grid polygon* is a set of pixels whose boundary is a grid cycle. This problem is motivated by schematization of country or building outlines and by nonograms.

The most well-known form of schematization in cartography is called a metro map, in which metro lines are shown in an abstract manner by polygonal lines whose edges typically have only four orientations. It is common to also depict region outlines with these orientations on such maps. It is possible to go one step further in schematization by using only integer coordinates for the vertices, which often aligns vertices vertically or horizontally, and leads to a more abstracted view. Certain types of cartograms like mosaic maps [8] are examples of maps following this visualization style. The version based on a square grid is often used to show electoral votes after elections. Another cartographic application of grid polygons lies in the schematization of building outlines [20].

Nonograms – also known as Japanese or picture logic puzzles – are popular in puzzle books, newspapers, and in digital form. The objective is to reconstruct a pixel drawing from a code that is associated with every row and column. The algorithmic problem of solving these puzzles is well-studied and known to be NP-complete [6]. To generate a nonogram from a vector drawing, a grid polygon needs to be made on a coarse grid. We are interested in the generation of grid polygons from shapes like animal outlines, which could be used to construct nonograms. To our knowledge, two papers address this problem. Ortíz-García et al. [22] study the problem of generating a nonogram from an image; both the black-and-white and color versions are studied. Their approach uses image processing techniques and heuristics. Batenburg et al. [5] also start with an image, but concentrate on generating nonograms from an image with varying difficulty levels, according to some definition of difficulty.

Considering the above, our work also relates to image downscaling (e.g. [19]), though this usually starts from a raster image instead of continuous geometric objects. Kopf et al. [19]

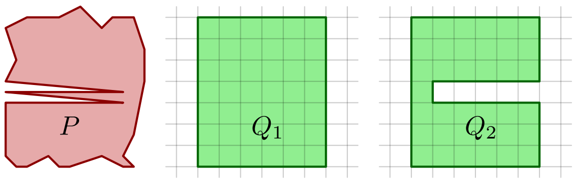

Figure 2 $d_H(P, Q_1)$ is small but $d_H(\partial P, \partial Q_1)$ is not. $d_H(P, Q_2)$ and $d_H(\partial P, \partial Q_2)$ are both small but the Fréchet distance $d_F(\partial P, \partial Q_2)$ is not.

apply their technique to vector images, stating that the outline remains connected where possible. In contrast to our work, the quality is not measured as the geometric similarity and the conditions necessary to guarantee a connected outline remain unexplored.

Similarity. There are at least three common ways of defining the similarity of two simple polygons: the symmetric difference[1], the Hausdorff distance [1], and the Fréchet distance [2]. The first does not consider similarity of the polygon boundaries, whereas the third usually applies to boundaries only. The Hausdorff distance between polygon interiors and between polygon boundaries both exist and are different measures; this distance can be directed or undirected. Let X and Y be two closed subsets of a metric space. The (directed) *Hausdorff distance* $d_H(X, Y)$ from X to Y is defined as the maximum distance from any point in X to its closest point in Y. The undirected version is the maximum of the two directed versions. To define the *Fréchet distance*, let X and Y be two curves in the plane. The Fréchet distance $d_F(X, Y)$ is the minimum leash length needed to let a man walk over X and a dog over Y, where neither may walk backwards (a formal definition can be found in [2]).

Contributions. In Section 2 we show that any simple polygon P admits a grid polygon Q with $d_H(P, Q) \leq \frac{1}{2}\sqrt{2}$ and $d_H(Q, P) \leq \frac{3}{2}\sqrt{2}$ on the unit grid. Furthermore, the constructed polygon satisfies the same bounds between the boundaries ∂P and ∂Q. This is not equivalent, since the point that realizes the maximum smallest distance to the other polygon may lie in the interior (Fig. 2). Our proof is constructive, but the construction often does not give intuitive results (Fig. 2, P and Q_2). Therefore, we extend our construction with heuristics that reduce the symmetric difference whilst keeping the Hausdorff distance within $\frac{3}{2}\sqrt{2}$. The Fréchet distance d_F [2] between two polygon boundaries is often considered to be a better measure for similarity. Unlike the Hausdorff distance, however, not every polygon boundary ∂P can be represented by a grid cycle with constant Fréchet distance. In Section 3 we present a condition on the input polygon boundary related to fatness (in fact, to κ-straightness [3]) and show that it allows a grid cycle representation with constant Fréchet distance. Finally, in Section 4 we evaluate how our algorithms perform on realistic input polygons.

2 Hausdorff distance

We consider the problem of constructing a grid polygon Q with small Hausdorff distance to P. Though minimizing the Hausdorff distance is NP-hard (Theorem 1, see [7]), we present an algorithm that achieves low, constant Hausdorff distance between both the boundaries and the interiors of the input polygon P and the resulting grid polygon Q. We first show

[1] The symmetric difference between two sets A and B is defined as the set $(A \setminus B) \cup (B \setminus A)$. When using symmetric difference as a quality measure, we actually mean the area of the symmetric difference.

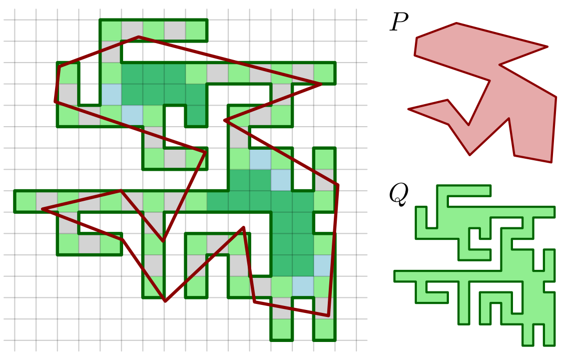

Figure 4 Example of the Hausdorff algorithm; the input and output are shown on the right. Colors: 🟩 Q_1, 🟩 Q_2, 🟦 Q_3, ⬜ Q_4.

how to construct such a grid polygon. Then, we provide an efficient algorithm to compute Q. Finally, we describe heuristics that can be used to improve the results in practice.

▶ **Theorem 1.** *Given a polygon P, it is NP-hard to decide whether there exists a grid polygon Q such that both $d_H(\partial P, \partial Q) \leq \frac{1}{2}$ and $d_H(\partial Q, \partial P) \leq \frac{1}{2}$.*

2.1 Construction

We represent the grid polygon Q as a set of cells (or pixels). We say that two cells are *adjacent* if they share a segment. If two cells share only a point, then they are *point-adjacent*. If two cells $c_1 \in Q$ and $c_2 \in Q$ are point-adjacent, and there is no cell $c \in Q$ that is adjacent to both c_1 and c_2, then c_1 and c_2 share a *point-contact*. We construct Q as the union of four sets Q_1, Q_2, Q_3, Q_4 (not necessarily disjoint). To define these sets, we define the *module* $\mathcal{M}(c)$ of a cell c as the 2×2-region centered at the center of c (see Fig. 3). Furthermore, we assume the rows and columns are numbered, so we can speak of even-even cells, odd-odd cells, odd-even cells, and even-odd cells. The four sets are defined as follows; see also Fig. 4.

Q_1: All cells c for which $\mathcal{M}(c) \subseteq P$.
Q_2: All even-even cells c for which $\mathcal{M}(c) \cap P \neq \emptyset$.
Q_3: For all cells $c_1, c_2 \in Q_1 \cup Q_2$ that share a point-contact, the two cells that are adjacent to both c_1 and c_2 are in Q_3.
Q_4: A minimal set of cells that makes Q connected, and where each cell $c \in Q_4$ is adjacent to two cells in Q_2 and $\mathcal{M}(c) \cap P \neq \emptyset$.

Set $Q_1 \cup Q_2$ is sufficient to achieve the desired Hausdorff distance. We add Q_3 to resolve point-contacts, and Q_4 to make the set Q simply connected (a polygon without holes). The lemmas below show that Q is indeed a grid polygon.

▶ **Lemma 2.** *The set $Q_1 \cup Q_2$ is hole-free, even when including point-adjacencies.*

Proof. For the sake of contradiction, let H be a maximal set of cells comprising a hole. Let set B contain all cells in $Q_1 \cup Q_2$ that surround H and are adjacent to a cell in H. Since Q_2 contains only even-even cells, every cell in $Q_2 \cap B$ is (point-)adjacent to two cells in $Q_1 \cap B$ (see Fig. 5). Hence, the outer boundary of the union of all modules of cells in $Q_1 \cap B$ is a single closed curve C. Since $C \subset P$ by the definition of Q_1, the interior of C must also be in P. Since all modules of cells in H lie completely inside C, they are also in P, so the cells in H must all be in Q_1. This contradicts that H is a hole. ◀

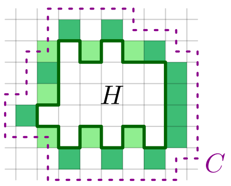

Figure 5 A hole in Q. Colors: 🟩 $Q_1 \cap B$; 🟩 $Q_2 \cap B$.

▶ **Lemma 3.** *The set Q is simply connected and does not contain point-contacts.*

Proof. Consider a point-contact between two cells $c_1, c_2 \in Q_1 \cup Q_2$ and a cell $c \notin Q_1 \cup Q_2$ that is adjacent to both c_1 and c_2 (so $c \in Q_3$). Since Q_2 contains only even-even cells, we may assume that $c_1 \in Q_1$. Recall that $\mathcal{M}(c_1) \subseteq P$ by definition. We may further assume that c_1 is an odd-odd cell, for otherwise a cell in Q_2 would eliminate the point-contact. Hence, all cells point-adjacent to c_1 are in $Q_1 \cup Q_2$, and thus c has three adjacent cells in $Q_1 \cup Q_2$. This implies that adding $c \in Q_3$ to $Q_1 \cup Q_2$ cannot introduce point-contacts or holes. Similarly, cells in Q_4 connect two oppositely adjacent cells in Q_2, and thus cannot introduce point-contacts (or holes, by definition). Combining this with Lemma 2 implies that Q is hole-free and does not contain point-contacts.

It remains to show that Q is connected, that is, the set Q_4 exists. Consider two cells $c_1, c_2 \in Q$. We show that c_1 and c_2 are connected in Q. We may further assume that $c_1, c_2 \in Q_2$, as cells in $Q_1 \cup Q_3 \cup Q_4$ must be adjacent or point-adjacent to a cell in Q_2. Let $p \in \mathcal{M}(c_1) \cap P$, $q \in \mathcal{M}(c_2) \cap P$ and consider a path π between p and q inside P. Every even-even cell c with $\mathcal{M}(c) \cap \pi \neq \emptyset$ must be in Q_2. Furthermore, the modules of even-even cells cover the plane. Every cell connecting a consecutive pair of even-even cells intersecting π satisfies the conditions of Q_4, and thus can be added to make c_1 and c_2 connected in Q. ◀

Upper bounds. To prove our bounds, note that $\mathcal{M}(c) \cap P \neq \emptyset$ for every cell $c \in Q$. This is explicit for cells in Q_1, Q_2, and Q_4. For cells in Q_3, note that these cells must be adjacent to a cell in Q_1, and thus contain a point in P.

▶ **Lemma 4.** $d_H(P, Q)$, $d_H(\partial P, \partial Q) \leq \frac{1}{2}\sqrt{2}$.

Proof. Let $p \in P$ and consider the even-even cell c such that $p \in \mathcal{M}(c)$. Since $c \in Q_2$, the distance $d_H(p, Q) \leq d_H(p, c) \leq \frac{1}{2}\sqrt{2}$. Now consider a point $p \in \partial P$. There is a 2×2-set of cells whose modules contain p. This set contains an even-even cell $c \in Q$ and an odd-odd cell $c' \notin Q$. The latter is true, because odd-odd cells in Q must be in Q_1. Therefore, the point q shared by c and c' must be in ∂Q. Thus, $d_H(p, \partial Q) \leq d_H(p, q) \leq \frac{1}{2}\sqrt{2}$. ◀

▶ **Lemma 5.** $d_H(Q, P)$, $d_H(\partial Q, \partial P) \leq \frac{3}{2}\sqrt{2}$.

Proof. Let q be a point in Q and let $c \in Q$ be the cell that contains q. Since $\mathcal{M}(c) \cap P \neq \emptyset$, we can choose a point $p \in \mathcal{M}(c) \cap P$. It directly follows that $d_H(q, P) \leq d_H(q, p) \leq \frac{3}{2}\sqrt{2}$. Now consider a point $q \in \partial Q$, and let $c \in Q$ and $c' \notin Q$ be two adjacent cells such that $q \in \partial c \cap \partial c'$. We claim that $(\mathcal{M}(c) \cup \mathcal{M}(c')) \cap \partial P \neq \emptyset$. If $c \notin Q_1$, then $\mathcal{M}(c) \not\subseteq P$. As furthermore $\mathcal{M}(c) \cap P \neq \emptyset$, we have that $\mathcal{M}(c) \cap \partial P \neq \emptyset$. On the other hand, if $c \in Q_1$, then $\mathcal{M}(c) \subseteq P$, so $\mathcal{M}(c') \cap P \neq \emptyset$. As furthermore $\mathcal{M}(c') \not\subseteq P$ (otherwise $c' \in Q_1$), we have that $\mathcal{M}(c') \cap \partial P \neq \emptyset$. Let $p \in (\mathcal{M}(c) \cup \mathcal{M}(c')) \cap \partial P$. Then $d_H(q, \partial P) \leq d_H(q, p) \leq \frac{3}{2}\sqrt{2}$. ◀

▶ **Theorem 6.** *For every simple polygon P a simply connected grid polygon Q without point-contacts exists such that $d_H(P, Q)$, $d_H(\partial P, \partial Q) \leq \frac{1}{2}\sqrt{2}$ and $d_H(Q, P)$, $d_H(\partial Q, \partial P) \leq \frac{3}{2}\sqrt{2}$.*

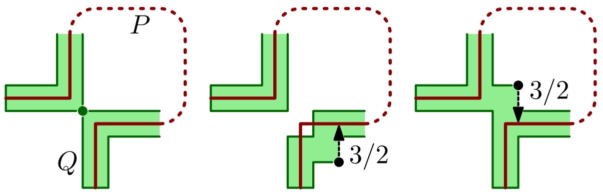

Figure 6 A polygon that does not admit a grid polygon with Hausdorff distance smaller than 3/2. The brown line signifies an infinitesimally thin polygon.

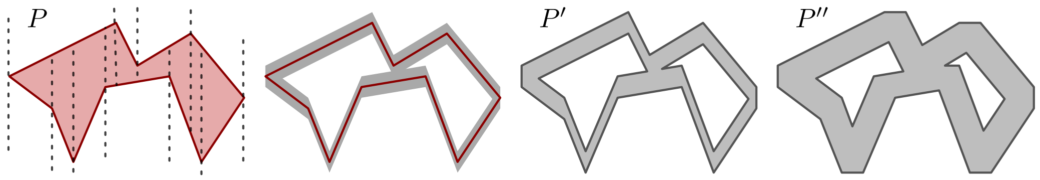

Figure 7 A simple polygon P with its vertical decomposition, and the construction of P' and P''.

Lower bound. Fig. 6 illustrates a polygon P for which no grid polygon Q exists with low $d(Q, P)$. A naive construction results in a nonsimple polygon (left). To make it simple, we can either remove a cell (center) or add a cell (right). Both methods result in $d_H(Q, P) \geq 3/2 - \epsilon$. Alternatively, we can fill the entire upper-right part of the grid polygon (not shown), resulting in a high $d_H(Q, P)$. This leads to the following theorem.

▶ **Theorem 7.** *For any $\epsilon > 0$, there exists a polygon P for which no grid polygon Q exists with $d(Q, P) < 3/2 - \epsilon$.*

In the L_∞ metric, the lower bound of $3/2 - \epsilon$ given in Fig. 6 also holds. A straightforward modification of the upper-bound proofs can be used to show that the Hausdorff distance is at most 3/2 in the L_∞ metric. In other words, our bounds are tight under the L_∞ metric.

2.2 Algorithm

To compute a grid polygon for a given polygon P with n edges, we need to determine the cells in the sets Q_1–Q_4. This is easy once we know which cells intersect ∂P. One way to do this is to trace the edges of P in the grid. The time this takes is proportional to the number of crossings between cells and ∂P. Let us denote the number of grid cells that intersect ∂P by b. Clearly, there are simple polygons with $\Theta(nb)$ polygon boundary-to-cell crossings. We show how to achieve a time bound of $O(n + B)$, where B is the number of cells in the output. The key idea is to first compute the Minkowski sum of ∂P with a square of side length 2 and use that to quickly find the cells intersecting ∂P.

To compute this Minkowski sum we first compute the vertical decomposition of ∂P, see Fig. 7. For every of the $O(n)$ quadrilaterals, determine the parts that are within vertical distance 1 from the bounding edges. The result P' is a simple polygon with holes with a total of $O(n)$ edges, and $\partial P \subset P'$. We compute the horizontal decomposition of every hole and the exterior of P' and determine all parts that are within horizontal distance 1 from the bounding edges. We add this to P', giving P''. These steps take $O(n)$ time if we use Chazelle's triangulation algorithm [9]. Essentially, the above steps constitute computing the Minkowski sum of ∂P with a square of side length 2, centered at the origin and axis-parallel.

▶ **Lemma 8.** *For any cell c, at most four edges of P'' intersect its boundary twice.*

Proof. For any edge of P'', by construction, the whole part vertically above or below it over distance at least 2 is inside P'', and the same is true for left or right. For any edge e that intersects the boundary of c twice, one side of that edge is fully in the interior of P'', and hence, cannot contain other edges of P''. Hence, e can be charged uniquely to a corner of c. ◀

▶ **Corollary 9.** *The number of polygon boundary-to-cell crossings of P'' is $O(n+b)$, where b is the number of grid cells intersecting ∂P.*

By tracing the boundary of P'', we can identify all cells that intersect it. Then we can determine all cells that intersect the boundary of P, because these are the cells that lie fully inside P''. The modifications needed to find all cells whose module lies inside P are straightforward. In particular, we can find all cells whose module lies inside P, but have a neighbor for which this is not the case in $O(n+b)$ time. This allows us to find the $O(B)$ cells selected in step Q_1 in $O(n+B)$ time. Steps Q_2 and Q_3 are now straightforward as well.

We now have a number of connected components of chosen grid cells. No component has holes, and if there are k components, we can connect them into one with only $k-1$ extra grid cells. We walk around the perimeter of some component and mark all non-chosen cells adjacent to it. If a cell is marked twice, it is immediately removed from consideration. Cells that are marked once but are adjacent to two chosen cells will merge two different components. We choose one of them, then walk around the perimeter of the new part and mark the adjacent cells. Again, cells that are marked twice (possibly, both times from the new part, or once from the old and once from the new part) are removed from consideration. Continuing this process unites all components without creating holes.

▶ **Theorem 10.** *For any simple polygon P with n edges, we can determine a set of B cells that together form a grid polygon Q in $O(n+B)$ time, such that $d_H(P,Q)$, $d_H(\partial P, \partial Q) \le \frac{1}{2}\sqrt{2}$ and $d_H(Q,P)$, $d_H(\partial Q, \partial P) \le \frac{3}{2}\sqrt{2}$.*

2.3 Heuristic improvements

The grid polygon Q constructed in Section 2.1 does not follow the shape of P closely (see Fig. 4). Although the boundary of Q remains close to the boundary of P, it tends to zigzag around it due to the way it is constructed. As a result, the symmetric difference between P and Q is relatively high. We consider two modifications of our algorithm to reduce the symmetric difference between P and Q while maintaining a small Hausdorff distance:

1. We construct Q_4 with symmetric difference in mind.
2. We post-process the resulting polygon Q by adding, removing, or shifting cells.

Construction of Q_4. Instead of picking cells arbitrarily when constructing Q_4 we improve the construction with two goals in mind: (1) to directly reduce the symmetric difference between P and Q, and (2) to enable the post-processing to be more effective. To that end, we construct Q_4 by repeatedly adding the cell c (not introducing holes) that has the largest overlap with P. These cells are the ones that reduce the symmetric difference between P and Q the most.

Post-processing. After computing the grid polygon Q, we allow three operations to reduce the symmetric difference: (1) adding a cell, (2) removing a cell, and (3) shifting a cell to a neighboring position. These operations are applied iteratively until there is no operation that can reduce the symmetric difference. Every operation must maintain the following conditions:

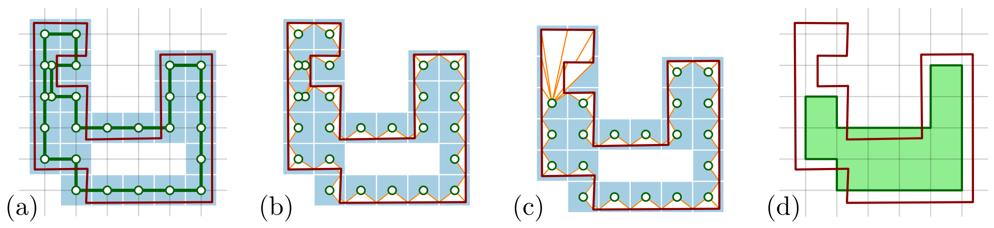

Figure 8 Constructing Q for the upper bound on the Fréchet distance. (a) Input polygon on the grid and the squares it visits (shaded); initial state of C with revisited vertices slightly offset for legibility. (b) Initial mapping μ (white triangles) between the vertices of C and ∂P. (c) Removal of duplicate vertices in C, and its effect on μ. (d) Resulting cycle represents a grid polygon.

(1) Q is simply connected, and (2) the Hausdorff distance between P (∂P) and Q (∂Q) is small. For the second condition we allow a slight relaxation with regard to the bounds of Lemma 4: $d_H(P, Q)$ and $d_H(\partial P, \partial Q)$ can be at most $\frac{3}{2}\sqrt{2}$ (like $d_H(Q, P)$ and $d_H(\partial Q, \partial P)$). This relaxation gives the post-processing more room to reduce the symmetric difference.

3 Fréchet distance

The Fréchet distance d_F between two curves is generally considered a better measure for similarity than the Hausdorff distance. For an input polygon P, we consider computing a grid polygon Q such that $d_F(\partial P, \partial Q)$ is bounded by a small constant. We study under what conditions on ∂P this is possible and prove an upper and lower bound. However, if ∂P zigzags back and forth within a single row of grid cells, any grid polygon must have a large Fréchet distance: the grid is too coarse to follow ∂P closely. To account for this in our analysis, we introduce a realistic input model, as explained below.

Narrow polygons. For $a, b \in \partial P$, we use $|ab|_{\partial P}$ to denote the perimeter distance, i.e., the shortest distance from a to b along ∂P. We define *narrowness* as follows.

▶ **Definition 11.** A polygon P is (α, β)*-narrow*, if for any two points $a, b \in \partial P$ with $|ab| \leq \alpha$, $|ab|_{\partial P} \leq \beta$.

Given a value for α, we refer to the minimal β as the α-narrowness of a polygon. We assume $\alpha < \beta$, to avoid degenerately small polygons. We note that narrowness is a more forgiving model than straightness [3]. A polygon P is κ*-straight* if for any two points $a, b \in \partial P$, $|ab|_{\partial P} \leq \kappa \cdot \|a - b\|$. A κ-straight polygon is $(\alpha, \kappa\alpha)$-narrow for any α, but not the other way around. In particular, a finite polygon that intersects itself (or comes infinitesimally close to doing so) has a bounded narrowness, whereas its straightness becomes unbounded.

Upper bound. With our realistic input model in place, we can bound the Fréchet distance needed for a grid polygon from above. In particular, we prove the following theorem.

▶ **Theorem 12.** *Given a* $(\sqrt{2}, \beta)$*-narrow polygon* P *with* $\beta \geq \sqrt{2}$*, there exists a grid polygon* Q *such that* $d_F(\partial P, \partial Q) \leq (\beta + \sqrt{2})/2$.

Proof. To prove the claimed upper bound, we construct Q via a grid cycle C that defines ∂Q. The construction is illustrated in Fig. 8. We define the *square* of a grid-graph vertex v to be the 1×1-square centered on v. Let C be the cyclic chain of vertices whose square is intersected by ∂P, in the order in which ∂P visits them. We define a mapping μ between the

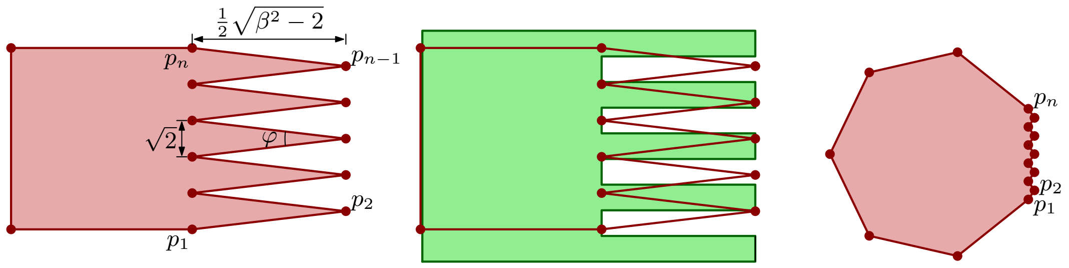

Figure 9 Polygon P (left) for which any grid polygon will have high Fréchet distance (center); polygon P for $\beta < 2$ (right).

vertices of C and ∂P. In particular, for each $c \in C$, let $\mu(c)$ be the "visit" of ∂P that led to c's existence in C, that is, the part of ∂P within the square of c. By construction, we have that $\|c - p_c\| \leq \sqrt{2}/2$ for all $c \in C$ and $p_c \in \mu(c)$. The visits $\mu(c)$ and $\mu(c')$ for two consecutive vertices, c and c', in C intersect in a point (or, in degenerate cases, in a line segment) that lies on the common boundary of the squares of c and c'; let p denote such a point. For any point σ on the line segment between c and c', we have that $\|\sigma - p\| \leq \max\{\|c-p\|, \|c'-p\|\} \leq \sqrt{2}/2$, as the Euclidean distance is convex (i.e., its unit disk is a convex set). Hence, μ describes a continuous mapping on ∂P and acts as a witness for $d_F(\partial P, C) \leq \sqrt{2}/2$.

However, C may contain duplicates and thus not describe a grid polygon Q. We argue here that we can remove the duplicates and maintain μ in such a way that it remains a witness to prove that $d_F(\partial P, C) \leq (\beta + \sqrt{2})/2$. Let c and c' be two occurrences in C of the same vertex v. Let $p \in \mu(c)$ and $p' \in \mu(c')$, both in the square of v. As they lie within the same square, $\|p - p'\| \leq \sqrt{2}$ and hence we know that $|pp'|_{\partial P} \leq \beta$. Hence, at least one of the two subsequences of C strictly in between c and c' maps via μ to a part of ∂P that has length at most β. We pick one such subsequence and remove it as well as c' from C. We concatenate to $\mu(c)$ the mapped parts of ∂P from the removed vertices. As the length of the mapped parts is bounded by β, the maximal distance between any point on these mapped parts is $\beta/2 + \sqrt{2}/2$. Hence, after removing all duplicates, we are left with a cycle C, with μ as a witness to testify that $d_F(\partial P, C) \leq (\beta + \sqrt{2})/2$.

If C contains at least three vertices, it describes a grid polygon and we are done. However, if C consists of at most two vertices, then it does not describe a grid polygon. We can extend C easily into a 4-cycle for which the bound still holds (see [7] for details). ◀

The proof of the theorem readily leads to a straightforward algorithm to compute such a grid polygon. The construction poses no restrictions on the order in which to remove duplicates and the decisions are based solely on the lengths of $\mu(v)$. Hence, the algorithm runs in linear time by walking over P to find C and handling duplicates as they arise.

Lower bound. To show a lower bound, we construct a $(\sqrt{2}, \beta)$-narrow polygon P for which there is no grid polygon with Fréchet distance smaller than $\frac{1}{4}\sqrt{\beta^2-2}$ to P, for any $\beta > \sqrt{2}$. First, construct a polygonal line $L = (p_1, \ldots, p_n)$, where $n = 2\left\lceil \frac{1}{4}\sqrt{\beta^2-2} \right\rceil + 1$. Vertex p_i is $(0, i/2)$ if i is odd and $(\frac{1}{2}\sqrt{\beta^2-2},\ i/\sqrt{2})$ otherwise. Now, consider a regular k-gon with side length $(n-1)/\sqrt{2}$ and $k \geq 4$ such that its interior angles are at least $\varphi = \arccos(1 - 4/\beta^2)$. Assume the k-gon has a vertical edge on the right-hand side. We replace this edge by L to construct our polygon P. Fig. 9 shows a polygon for $k = 4$ ($\beta \geq 2$) and for $k = 7$ ($\beta < 2$).

The two lemmas below readily imply our lower bound on the Fréchet distance. We omit proof of the first, but details can be found in [7].

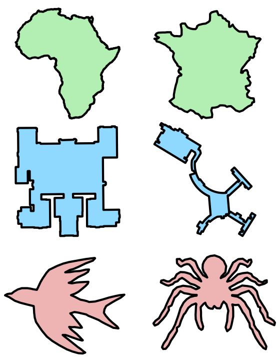

Figure 10 The input categories.

▶ **Lemma 13.** *The constructed polygon P described above is $(\sqrt{2}, \beta)$-narrow.*

▶ **Lemma 14.** *For constructed polygon P and any grid polygon Q, $d_F(\partial P, \partial Q) \geq \frac{1}{4}\sqrt{\beta^2 - 2}$.*

Proof. We show this by contradiction: assume that a grid polygon Q exists with $d_F(\partial P, \partial Q) = \varepsilon < \frac{1}{4}\sqrt{\beta^2 - 2}$. For any vertex p_i of P, there must be a point $q_i \in \partial Q$ (not necessarily a vertex) such that $\|p_i - q_i\| < \varepsilon$. Moreover, these points $q_1, \ldots, q_n$ need to appear on ∂Q in order. Equivalently, if we draw disks with radius ε centered at $p_1, \ldots, p_n$, curve ∂Q needs to visit these disks in order.

The disks centered at $p_1, p_3, \ldots, p_n$ never intersect the disks centered at $p_2, p_4, \ldots, p_{n-1}$. In particular, the disks centered at $p_1, p_3, \ldots, p_n$ are all to the left of the vertical line $v \colon x = \frac{1}{4}\sqrt{\beta^2 - 2}$, and all disks centered at $p_2, p_4, \ldots, p_{n-1}$ are all to the right of this line. Hence, between q_1 and q_2, ∂Q must contain at least one horizontal line segment crossing line v to the right, and between q_2 and q_3 there must be at least one horizontal segment crossing v to the left, and so on until we reach q_n. Since Q is simple, this requires that the difference between the maximum and the minimum y-coordinate of the these horizontal segments on ∂Q is at least $n - 1$. The y-difference between p_1 and p_n is only $(n-1)/\sqrt{2}$. This implies $d_F(\partial P, \partial Q) \geq n - 1 - (n-1)/\sqrt{2} > \frac{1}{4}\sqrt{\beta^2 - 2}$ and thus contradicts our assumption. ◀

▶ **Theorem 15.** *For any $\beta > \sqrt{2}$, there exists a $(\sqrt{2}, \beta)$-narrow polygon P such that $d_F(\partial P, \partial Q) \geq \frac{1}{4}\sqrt{\beta^2 - 2}$ holds for any grid polygon Q.*

4 Experiments

Here, we apply our algorithms to a set of polygons that can be encountered in practice. We investigate the performance of the Hausdorff algorithm and its heuristics as well as the Fréchet algorithm. Moreover, we consider the effects of grid resolution and the placement of the input. Full details on the experiments can be found in [7].

Data set. We use a set of 34 polygons: 14 territorial outlines (countries, provinces, islands), 11 building footprints and 9 animal silhouettes (see Fig. 10 for six examples). We scale all input polygons such that their bounding box has area r; we call r the resolution. Unless stated otherwise, we use $r = 100$. This scaling is used to eliminate any bias introduced from comparing different resolutions.

Table 1 Normalized symmetric difference, as an increase percentage w.r.t. optimal, of the algorithms. Note that "optimal" here means optimal for the symmetric difference when not insisting on a connected set of cells. For the Hausdorff algorithm, results for the various heuristic improvements are shown. In the second row, *None* means that no postprocessing heuristic was used; A, R and S mean additions, removals and shifts, respectively. In the third row, ✓ and ✗ indicate whether Q_4 was chosen arbitrarily (✗) or using the symmetric difference heuristic (✓).

	Optimal	**Hausdorff**						**Fréchet**
postproc.		*None*		A/R		$A/R/S$		
Q_4 *heur.*		✗	✓	✗	✓	✗	✓	
Maps	0.223	+316 %	+238 %	+39 %	+3 %	+11 %	+3 %	+23 %
Buildings	0.257	+270 %	+197 %	+47 %	+9 %	+21 %	+8 %	+17 %
Animals	0.333	+246 %	+188 %	+60 %	+12 %	+29 %	+11 %	+8 %

4.1 Symmetric difference

We start our investigation by measuring the symmetric difference between the input and output polygon. If the symmetric difference is small, this indicates that the output is similar to the input. We normalize the symmetric difference by dividing it by the area of the input polygon. The results of our algorithms depend on the position of the input polygon relative to the grid. Hence, for every input polygon we computed the average normalized symmetric difference over 20 random placements.

Computing a (simply connected) grid polygon that minimizes symmetric difference is NP-hard [21]. Hence, as a baseline for our comparison, we compute the set of cells with the best possible symmetric difference by simply taking all cells that are covered by the input polygon for at least 50 %. This set of cells is optimal with respect to symmetric difference but may not be simply connected. It can hence be thought of as a lower bound.

Overview. In Table 1, we compare the Fréchet algorithm and the various instantiations of the Hausdorff algorithm in terms of the (normalized) symmetric difference. The second column lists the average symmetric difference of the symmetric-difference optimal solution, calculated as described above. The other columns are hence given as a percentage representing the increase with respect to the optimal value. We aggregated the results per input type.

The table tells us that, with the use of heuristics, the Hausdorff algorithm gets quite close to the optimal symmetric difference, while still bounding the Hausdorff distance and guaranteeing a grid polygon. The Fréchet algorithm is performing more poorly in comparison, though interestingly performs *better* on the animal contours.

Fig. 11 shows three solutions for one of the input polygons: symmetric-difference optimal, Fréchet algorithm and Hausdorff algorithm with heuristics. The symmetric-difference optimal solution looks like the input, but consists of multiple disconnected polygons. The result of the Fréchet algorithm is a single grid polygon, but the algorithm cuts off narrow parts. The result of the Hausdorff algorithm is also a single grid polygon, but does not have to cut off parts when input is narrow.

Below, we examine the effect of the different heuristics for the Hausdorff algorithm to explain their success. Moreover, we show that the performance of the Fréchet algorithm is highly dependent on the grid resolution.

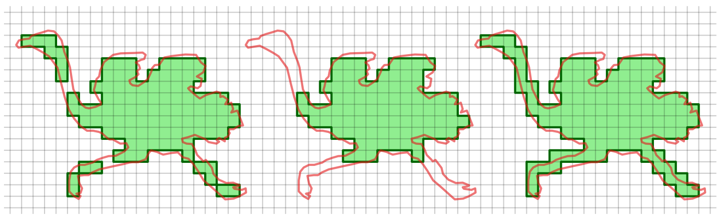

Figure 11 Example outputs for the symmetric-difference optimal algorithm (left), the Fréchet algorithm (center) and the Hausdorff algorithm (right). Note that the first does not yield a grid polygon.

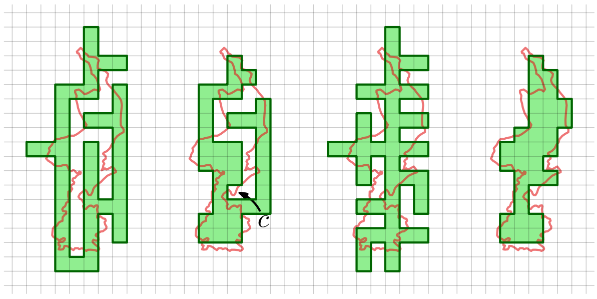

Figure 12 Without the heuristic for the Q_4 construction (a), the algorithm gets stuck in the post processing phase (b). The smart Q_4 construction gives a better starting point (c) resulting in the desired shape (d).

Hausdorff heuristics. Table 1 shows that using the heuristic for Q_4 makes a tremendous difference, especially if a postprocessing heuristic is used as well. Fig. 12 illustrates this finding with four results on the same input. In (a–b) Q_4 is chosen arbitrarily and the resulting shape does not look like the input – even after postprocessing. In particular, the postprocessing heuristic cannot progress further: the cell marked c cannot be added to Q since that would increase the symmetric difference. In (c–d) Q_4 is chosen using the heuristic; it provides a better initial solution which allows the postprocessing to create a nice result.

In the postprocessing heuristic, allowing or disallowing shifts can influence the result. See for example Fig. 13. Without shifts, the heuristic cannot move the connection between the two ends of the input polygon to the correct location as it would first need to increase the symmetric difference. With a series of diagonal shifts this can be achieved. Our experiments show that in practice allowing shifts indeed decreases the symmetric difference. However, the effect is only marginal if we use the heuristic for the Q_4 construction. Hence, we conclude that shifts only significantly improve the result if Q_4 is chosen badly.

Resolution and placement. While developing our algorithm we noticed that not just the grid resolution but also the placement of the input polygon effected the symmetric difference. Hence we set up experiments to investigate these factors. First we tested how much the resolution influences the symmetric differences. In Table 2, the results are shown, averaged over all 34 inputs. As expected, for all algorithms, the normalized symmetric difference decreases when the resolution increases.

To investigate how much the results of our algorithms depend on the input placement, we compared the minimal, maximal and average symmetric difference over 20 runs of the algorithms. The polygons were placed randomly for each run, but per polygon the same 20 positions were used for all three algorithms. We found that the difference between the

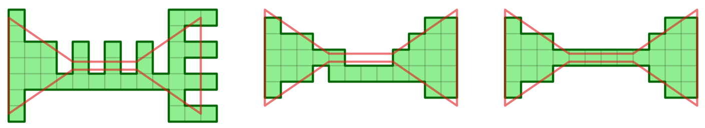

Figure 13 Without allowing shifts, the post-processing phase cannot move the cells in the middle to coincide with the input polygon. With shifts, this is possible.

Table 2 Normalized symmetric difference for the various algorithms on five resolutions.

	$r = 100$	$r = 225$	$r = 400$	$r = 625$	$r = 900$
Optimal	0.263	0.188	0.147	0.119	0.101
Hausdorff	0.282	0.201	0.155	0.123	0.103
Fréchet	0.306	0.227	0.184	0.148	0.122

minimum and the maximum symmetric difference for each algorithm / polygon combination is rather large. We hence concluded that placement can have a significant effect on the achieved symmetric difference. Hence, if the application permits us to choose the placement, it is advisable to do so to obtain the best possible result. This leads to an interesting open question of whether we can algorithmically optimize the placement, to avoid the need to find a good placement with trial and error. In the upcoming analysis, we also consider the effect of resolution and placement, with respect to the Fréchet distance.

4.2 Fréchet analysis

Theorem 12 predicts an upper bound on the Fréchet distance based on $\sqrt{2}$-narrowness. However, if the points defining the narrowness lie within different squares of grid vertices, this bound may be naive. Moreover, it assumes a worst-case detour, going away in a thin triangle to maximize the distance between the detour and a doubly-visited cell. Hence, the algorithm has the potential to perform better, depending on the actual geometry and its placement with respect to the grid. Here, we discuss our investigation of these effects.

Procedure. We use all 34 polygons for our experiments. As we may expect the grid resolution to significantly affect results, we used 20 different resolutions. In particular, we use resolutions varying from 10 000 to 25, using $(100/s)^2$ with scale $s \in \{1, \ldots, 20\}$.

For each resolution-polygon combination (case), we measure its $\sqrt{2}$-narrowness (see [7] for details on how to compute narrowness) and derive the predicted upper bound. Then, we run the Fréchet algorithm, using the 25 possible offsets in $\{0, 0.2, 0.4, 0.6, 0.8\}^2$, and measure the precise Fréchet distance between input and output. We keep track of three summary statistics for each case: the minimum (best), average ("expected") and maximum (worst) measured Fréchet distance.

Effect of placement. We consider placement with respect to the grid (offset) to have a significant effect on the result computed for a polygon, if the difference between the maximal and minimal Fréchet distance over the 25 offsets is at least 2. Almost 30 % of cases exhibit such a significant effect, with the animal contours being particularly affected (35 % significant). Again, this raises the question of whether we can algorithmically determine a good placement.

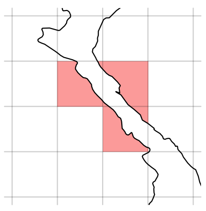

Figure 14 Red cells cause a cut-off and have high symmetric difference.

Upper bound quality. We define the performance as the measured Fréchet distance as a percentage of the upper bound. We consider a performance of 40 % significantly better than the upper bound. Using the best placement, over 95 % of cases perform significantly better. Averaging performance over placement, we still find such a majority (over 81 %). Interestingly, this drop is mostly due to the animal contours, of which only 63 % now perform significantly better. Thus, although we have a provable upper bound, we may typically expect our simple algorithm to perform significantly better than the upper bound. This holds even without any postprocessing to further optimize the result and when taking a random offset.

Effect of resolution. The influence of the resolution on the above results does not seem to exhibit a clear pattern. Nonetheless, resolution likely plays an important role in these results, but not as straightforward as either low or high resolution being more problematic. Instead, it is likely the most problematic resolutions are those at which the $\sqrt{2}$-narrowness of the polygon jumps as a new pair of edges comes within distance $\sqrt{2}$ of each other. However, an in-depth investigation of this is beyond the scope of this paper.

Heuristic improvement. In contrast to the Hausdorff algorithm, the Fréchet algorithm needs no heuristic improvement on inputs that are not too narrow. However, badly placed narrow polygons can be problematic: large parts of the polygon may be cut, greatly diminishing similarity. A solution may be to select an appropriate resolution (if our application permits us to). In our experiments the algorithm tends to perform well at resolutions where the symmetric-difference optimal solution is a single grid polygon. The advantage of our Fréchet algorithm is that it guarantees a grid polygon on all outputs and bounds the Fréchet distance.

Nonetheless, we may want to consider heuristic postprocessing to obtain a locally-optimal result. If we want to do this in terms of the symmetric difference, we may use similar techniques as for the Hausdorff algorithm. However, this does not perform well: the narrow strip that causes the Fréchet algorithm to perform badly tends to effect a high symmetric difference for the nearby grid cells (Fig. 14). As such, the result is already (close to) a local optimum in terms of the symmetric difference.

5 Conclusion

We presented two algorithms to map simple polygons to grid polygons that capture the shape of the polygon well. For measuring the distance between the input and the output, we considered the Hausdorff and the Fréchet distance. We achieved a constant bound on the Hausdorff distance; for the Fréchet distance we require a realistic input assumption to achieve a constant bound. We also evaluated our algorithms in practice. Although the Hausdorff algorithm does not produce great results directly, the algorithm achieves good results when combined with heuristic improvements. The Fréchet algorithm, on the other hand, struggles with narrow polygons, and it is not clear how to improve the results using heuristics. Designing an algorithm for the Fréchet distance that also works well in practice remains an interesting open problem. Another interesting open problem is to algorithmically optimize the placement of the input polygon, for the best results of both the Hausdorff and the Fréchet algorithm.

Abstract

We study the complexity of the Hitting Set problem in set systems (hypergraphs) that avoid certain sub-structures. In particular, we characterize the classical and parameterized complexity of the problem when the Vapnik-Chervonenkis dimension (VC-dimension) of the input is small.

VC-dimension is a natural measure of complexity of set systems. Several tractable instances of Hitting Set with a geometric or graph-theoretical flavor are known to have low VC-dimension. In set systems of bounded VC-dimension, Hitting Set is known to admit efficient and almost optimal approximation algorithms (Brönnimann and Goodrich, 1995; Even, Rawitz, and Shahar, 2005; Agarwal and Pan, 2014).

In contrast to these approximation-results, a low VC-dimension does not necessarily imply tractability in the parameterized sense. In fact, we show that Hitting Set is $W[1]$-hard already on inputs with VC-dimension 2, even if the VC-dimension of the dual set system is also 2. Thus, Hitting Set is very unlikely to be fixed-parameter tractable even in this arguably simple case. This answers an open question raised by King in 2010. For set systems whose (primal or dual) VC-dimension is 1, we show that Hitting Set is solvable in polynomial time.

To bridge the gap in complexity between the classes of inputs with VC-dimension 1 and 2, we use a measure that is more fine-grained than VC-dimension. In terms of this measure, we identify a sharp threshold where the complexity of Hitting Set transitions from polynomial-time-solvable to NP-hard. The tractable class that lies just under the threshold is a generalization of Edge Cover, and thus extends the domain of polynomial-time tractability of Hitting Set.

1 Introduction

Let $\mathcal{C}$ be a collection of subsets of a finite set X. We call the pair $(X, \mathcal{C})$ a *set system*.[1] A *hitting set* of $(X, \mathcal{C})$ is a subset of X that has non-empty intersection with all members of $\mathcal{C}$.

[1] Alternative names in the literature are *hypergraph* and *range space*.

The decision version of the Hitting Set problem asks, given a positive integer k, whether a set system has a hitting set of size at most k.

Hitting Set and its dual, Set Cover, are both ubiquitous and notoriously difficult problems. For an arbitrary set system $(X, \mathcal{C})$, Hitting Set is NP-hard to approximate [28, 3] with a multiplicative factor better than $c \cdot \log(|\mathcal{C}| \cdot |X|)$, for some constant $c > 0$.

Given a set system $\mathcal{F} = (X, \mathcal{C})$, and a set $A \subseteq X$, we define the *projection*[2] *of $\mathcal{F}$ on A* as $PR_{\mathcal{F}}(A) = \{R \cap A \mid R \in \mathcal{C}\}$. A set A is said to be *shattered* by $\mathcal{F}$ if $PR_{\mathcal{F}}(A) = 2^A$, i.e. the set of all subsets of A. The *Vapnik-Chervonenkis dimension* (or *VC-dimension*) of a set system $\mathcal{F}$, denoted $VC(\mathcal{F})$, is the cardinality of the largest set shattered by $\mathcal{F}$. VC-dimension was originally introduced in learning theory [39, 4], where it captures the sample complexity in the PAC model. Since its introduction, VC-dimension has seen many further applications both inside and outside learning theory (see e.g. [8, 31]) and it has become a standard measure of complexity of set systems.

Allowing a set system to have large VC-dimension means that less restrictions are placed on its structure, making it more difficult as a Hitting Set instance. In this paper we study both the classical and parameterized complexity of Hitting Set when the VC-dimension of the input set system is bounded.

Hitting Set and parameterized complexity. In parameterized complexity, a problem is called *fixed-parameter tractable* (FPT) with respect to a parameter[3] k, if there exists an algorithm that solves it in time $O(f(k) \cdot n^{O(1)})$ for an arbitrary function f (where n is the input size). Fixed-parameter tractability has emerged as a powerful tool to deal with hard combinatorial problems. We refer the reader to [12, 34, 15] for more details. Unfortunately, Hitting Set is $W[2]$-hard [15], and thus unlikely to be FPT, meaning that it is hopelessly difficult even from a parameterized perspective.

However, instances arising in various applications (e.g. in graph-theoretical or in geometric settings) often have special structure that can be algorithmically exploited. Indeed, the literature abounds with studies of problems - many of them FPT - that can be seen as special cases of Hitting Set.

Graph-theoretical examples of Hitting Set problems include Vertex Cover, Edge Cover, Feedback Vertex Set, and Dominating Set. In each of these problems the input set system is implicitly defined by an underlying graph G, with sets corresponding to the edges, vertices, cycles, and neighborhoods of G, respectively. The first three of these problems are well-known to be FPT (Edge Cover is even in P). Dominating Set remains $W[2]$-hard, but is FPT in certain families of graphs (see Table 1). Intuitively, Dominating Set is hard because it places very few restrictions on the input: Every set system whose incidence matrix is symmetric can be a Dominating Set instance. Special cases where Dominating Set is FPT include *biclique-free* graphs [35, 38] (a family that contains *bounded genus*, *planar*, *bounded treewidth*, and many other natural classes), *claw-free* graphs [25], and graphs *with girth at least five* [36]. The structure that makes these special cases of Dominating Set tractable can be described in terms of *forbidden patterns* in the adjacency matrix of G. For instance, biclique-freeness simply translates to the avoidance of an all-1s submatrix of a certain size. Our work continues this line of investigation: A VC-dimension smaller than d can be interpreted as the avoidance of every matrix with d columns that contain all 2^d different boolean vectors in its rows.

[2] Also known in the literature as the *trace* of a set system.
[3] In this paper we always use the standard parameter, i.e. the solution size k.

In geometric examples of Hitting Set, the input set system is defined by the incidences between (typically) low complexity geometric shapes, such as points, intervals, lines, disks, rectangles, hyperplanes, etc. VC-dimension is a natural and useful complexity measure for geometrically defined set systems [39, 4, 6, 23]. In Table 1 we list some representative examples of Hitting Set problems from the literature.

Hitting Set and VC-dimension. Given the difficulty of Hitting Set and the wealth of special cases that are FPT or polynomial-time solvable, it is natural to ask for a general structural property of set systems that guarantees tractability. Such a question has been successfully answered in the field of approximation algorithms: After a series of approximation-results for concrete geometric problems, the landmark result of Brönnimann and Goodrich [7] gave an almost optimal[4] approximation algorithm for Hitting Set on set systems with bounded VC-dimension. The algorithm has been further improved by Even at al. [14] and recently by Agarwal and Pan [1]. In this paper we consider this question from a parameterized viewpoint.

In general, the relevance of VC-dimension to Hitting Set has long been known: Low VC-dimension implies the existence of an ϵ-net of small size [23]. An ϵ-net can be seen as a relaxed form of hitting set in which we are only interested in hitting all sets whose size is at least an ϵ-fraction of the universe size. For set systems with low VC-dimension the size of the fractional hitting set is close to the size of the integral hitting set - this observation is the basis of the approximation-result of Brönnimann and Goodrich [7].

Dual VC-dimension. The *incidence matrix* of a set system $\mathcal{F} = (X, \mathcal{C})$ is a 0/1 matrix with columns indexed by elements of X, and rows indexed by members of $\mathcal{C}$. An entry (A, x) of the incidence matrix (where $A \in \mathcal{C}$ and $x \in X$) is 1 if $x \in A$, and 0 otherwise.

Given a set system $\mathcal{F}$, it is natural to consider its *dual* set system denoted $\mathcal{F}^T$, obtained by interchanging the roles of elements and sets (i.e. transposing the incidence matrix of the set system[5]). The Hitting Set problem on the dual set system is known as *Set Cover*. The VC-dimension of the dual set system, denoted $VC(\mathcal{F}^T)$ is a further natural parameter of set systems. It is well-known that if $VC(\mathcal{F}) = d$, then the inequality $VC(\mathcal{F}^T) < 2^{d+1}$ holds.

Our results. We study the classical and parameterized complexity of Hitting Set restricted to set systems with small VC-dimension. In light of Table 1, there is no clear separation at any value of the VC-dimension: Some FPT classes have unbounded VC dimension, while $W[1]$-hard classes with VC-dimension 3 are known[6]. However, an FPT result for Hitting Set restricted to VC-dimension 2 would generalize many known FPT results for special cases of Hitting Set. Hence, we study the existence of a small threshold value of VC-dimension, below which Hitting Set is tractable and at which it becomes intractable (both in the parameterized and in the classical sense). The program of finding such a dichotomy for the FPT complexity of Hitting Set in terms of the VC-dimension has also been proposed by King [26].

[4] As a further witness to the difficulty of Hitting Set, *almost optimal* here means a *logarithmic factor of the optimum*, i.e. $O(\log k)$. For more restricted geometric problems better approximation ratios are known, see e.g. [9, 33].

[5] The transposed incidence matrix may contain duplicate rows, contradicting the definition of a set system. It is safe to discard such duplicates, as this does not affect the VC-dimension or the Hitting Set solution.

[6] To the best of our knowledge, prior to our paper there were no $W[1]$-hard examples known with VC-dimension *or* dual VC-dimension lower than 3. In fact, we are not aware of $W[1]$-hard examples with *explicitly stated* VC-dimension lower than 4, see § B.

Table 1 Special cases of Hitting Set in the FPT literature, and their VC-dimension. For hardness results, the values for VC-dimension should be prefixed with "at least", for algorithmic results (P and FPT) with "at most". The results in the table are discussed in the Appendix § A and § B.

Graph problem	FPT status	VC-dimension
Edge Cover	P	2

Rectangle Stabbing [11]	$W[1]$-hard	3

In this paper, we show the threshold of tractability to be at the (surprisingly low) value of 2, i.e., we prove $W[1]$-hardness of Hitting Set restricted to VC-dimension 2 (even if also the dual VC-dimension is 2). The phenomenon of a large gap between the complexity of set systems of VC-dimension 1 and set systems of VC-dimension 2 also occurs in other areas such as communication complexity, machine learning, and geometry [2, 32]. Moreover, assuming the Exponential Time Hypothesis (ETH) we obtain an almost matching lower bound for the trivial $n^{O(k)}$ algorithm. We prove this result in § 2.

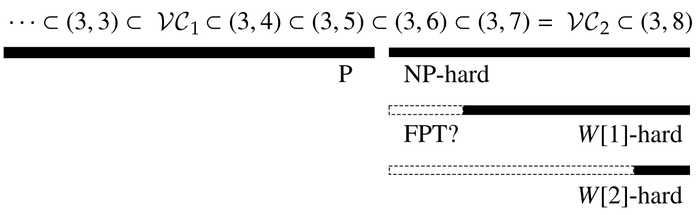
▶ **Theorem 1.** *Hitting Set and Set Cover restricted to set systems $\mathcal{F} = (X, \mathcal{C})$ with $VC(\mathcal{F}) = VC(\mathcal{F}^T) = 2$ are $W[1]$-hard. Moreover, if any of these problems can be solved in time $f(k) \cdot |X|^{o(k/\log k)}$, where f is an arbitrary function and k is the solution size, then ETH fails.*

Note. Theorem 1 could be stated with $|X|$ replaced by $|\mathcal{C}|$ or $|\mathcal{C}| \cdot |X|$, which are perhaps more natural as a measure of input length. However, the Sauer-Perles-Shelah lemma (see e.g. [37]) states that if $VC(\mathcal{F}) = d$, then $|\mathcal{C}| \leq \sum_{j=0}^{d} \binom{|X|}{j}$. Therefore, $|X|$ and $|\mathcal{C}|$ are within a polynomial factor of each other, which allows us to use $|X|$.

The hardness result of Theorem 1 can be strengthened to set systems with symmetric incidence matrices, i.e. the result also holds for Dominating Set. The construction is more involved in that case, and we omit it in this version of the paper.

On the positive side, given a set system $\mathcal{F}$, if $VC(\mathcal{F}) = 1$ *or* $VC(\mathcal{F}^T) = 1$, we show that Hitting Set is in P. The proof is simple and self-contained (see § 3). The $VC(\mathcal{F}) = 1$ case was known prior to this work [26], but we are not aware of a published proof.

To bridge the rather large gap in complexity between set systems of VC-dimension 1 and 2, we use a finer parameterization which was also used in [2, 32]. For a pair of integers $\alpha, \beta \geq 1$, a set system $\mathcal{F} = (X, \mathcal{C})$ is an (α, β)-system if for any set $A \subseteq X$ with $|A| \leq \alpha$ the projection



$\cdots \subset (3,3) \subset \mathcal{VC}_1 \subset (3,4) \subset (3,5) \subset (3,6) \subset (3,7) = \mathcal{VC}_2 \subset (3,8)$
P
NP-hard
FPT?
$W[1]$-hard
$W[2]$-hard

Figure 1 The complexity of Hitting Set when the VC-dimension is low.

$PR_{\mathcal{F}}(A)$ has cardinality at most β. In other words, a set system is an (α, β)-system, if every submatrix of its incidence matrix with α columns has at most β different vectors in its rows. Let $\mathcal{VC}_d$ denote the class of set systems with VC-dimension at most d. Observe that $\mathcal{VC}_{d-1}$ is equal to the class of $(d, 2^d - 1)$-systems. Moreover, every set system is a $(d, 2^d)$-system, for arbitrary $d \geq 1$. Hence, Hitting Set on $(3, 8)$-systems is the standard Hitting Set problem (without restrictions) and thus $W[2]$-hard.

The Sauer-Perles-Shelah Lemma can also be stated using this notation: Every $(d, 2^d - 1)$-system is a $(m, \sum_{j=0}^{d-1} \binom{m}{j})$-system for every $m \geq d$. In particular, every set system in $\mathcal{VC}_1$ is a $(3, 4)$-system. Further, we prove that every Edge Cover instance is a $(3, 5)$-system, but the reverse does not hold. Edge Cover is well-known to be solvable in polynomial time using matching techniques [17]. The next result (see § 3) extends the domain of polynomial-time solvability from Edge Cover to the larger class of $(3, 5)$-systems.

▶ **Theorem 2.** *Hitting Set on $(3, 5)$-systems is in P.*

The algorithm we present for proving Theorem 2 is fairly simple. However, its analysis is quite involved – revealing some of the combinatorial structure underlying $(3, 5)$-systems.

In contrast to $(3, 5)$-systems, it is not hard to see that there are $(3, 6)$-systems for which the Hitting Set problem is NP-hard.

▶ **Theorem 3.** *Hitting Set on $(3, 6)$-systems is NP-hard.*

This discussion yields a complete characterization of the complexity of Hitting Set on $(3, \beta)$-systems with a transition from polynomially-solvable to NP-hard between the β values of 5 and 6. Regarding the FPT status of the problem, the picture is almost complete, with the question of $(3, 6)$-systems remaining open. The results are illustrated in Figure 1.

Open questions. An immediate open question raised by our work is whether Hitting Set is FPT on $(3, 6)$-systems. The (α, β)-parameterization provides an ever finer hierarchy of set systems, as α increases. A more ambitious goal would be a full characterization of the complexity of Hitting Set in (α, β)-systems for $\alpha \geq 3$. We only have preliminary results in this direction. Finally, we leave open the question whether Hitting Set is even $W[2]$-hard on set systems of bounded VC-dimension.

Related work. Langerman and Morin [27] study the parameterized complexity of an abstract covering problem with a dimension parameter that has some connections to the VC-dimension. However, the results are not directly comparable with ours: The instances studied by Langerman and Morin can have arbitrarily large VC-dimension and are restricted by other conditions, whereas the instances we study have very low VC-dimension, but have no further constraints.

Notation. Consider a set system $\mathcal{F} = (X, \mathcal{C})$. Let $b_1, \dots, b_t \in X$ be distinct elements and $(p_1, \dots, p_t) \in \{0,1\}^t$. We say that $(b_1, \dots, b_t)$ *realizes the pattern* $p_1 \dots p_t$ if the set $\{b_i \mid p_i = 1\}$ is contained in $PR_{\mathcal{F}}(\{b_1, \dots, b_t\})$.

2 Hitting Set with VC-dimension 2 is W[1]-hard

In this section we prove the $W[1]$-hardness of Hitting Set and Set Cover on set systems of VC-dimension 2 and dual VC-dimension 2. The NP-hardness of this class was known, implied for example, by the NP-hardness of Vertex Cover.

▶ **Theorem 1** (restated). *Hitting Set and Set Cover restricted to set systems $\mathcal{F} = (X, \mathcal{C})$ with $VC(\mathcal{F}) = VC(\mathcal{F}^T) = 2$ are $W[1]$-hard. Moreover, if any of these problems can be solved in time $f(k) \cdot |X|^{o(k/\log k)}$, where f is an arbitrary function and k is the solution size, then ETH fails.*

In the remainder of this section we prove Theorem 1. Since Hitting Set on a set system $\mathcal{F}$ is equivalent to Set Cover on set system $\mathcal{F}^T$, it suffices to prove hardness of Hitting Set.

We reduce to Hitting Set from the Partitioned Subgraph Isomorphism problem: Given a host graph $G = (V, E)$ with a partitioning of the vertices $V = V_1 \cup \ldots \cup V_t$ and a pattern graph $H = ([t], F)$ with $|F| = k$, decide whether there are vertices $u_1 \in V_1, \dots, u_t \in V_t$ such that $u_i u_j \in E$ for every $ij \in F$. It is known that Partitioned Subgraph Isomorphism is W[1]-hard and cannot be solved in time $f(k) \cdot n^{o(k/\log k)}$, where $n = |V|$, and f is an arbitrary function, unless ETH fails [30].

We first show that we may assume the hard instance to have $t = k$, i.e. that the number of vertices and the number of edges in H are equal. Consider an arbitrary instance of Partitioned Subgraph Isomorphism. Since Partitioned Subgraph Isomorphism splits naturally over connected components of H, we may assume that H is connected. If $k > t$, add $k - t$ isolated vertices to H, and add the corresponding partitions containing isolated vertices $V_{t+1} = \{v_{t+1}\}, \dots, V_k = \{v_k\}$ to G, without changing the existence of a solution. Observe that the parameter k is unchanged. In the case when $k < t$, since H is connected, it follows that $k = t - 1$. We add two components to H: a clique on 4 vertices and an isolated vertex. To G we add the partitions $V_{t+1} = \{v_{t+1}\}, \dots, V_{t+5} = \{v_{t+5}\}$ such that $v_{t+1}, \dots, v_{t+4}$ form a clique, and v_{t+5} is an isolated vertex. After the transformation, H contains $k + 6 = t + 5$ edges and vertices. Furthermore, the equivalence of the solutions is preserved, and the parameter k (the number of edges in H), increases by a constant only.

For ease of notation we let $E \subseteq [n] \times [n]$ and write uv for an edge in E. Since G is undirected, the set E contains uv if and only if it contains vu. Similarly, $F \subseteq [k] \times [k]$ and $ij \in F$ if and only if $ji \in F$. We fix any ordering $<$ on V and the lexicographic[7] ordering $<$ on $V \times V$ and thus on E. We write $E_{ij} := E \cap (V_i \times V_j)$.

We construct an equivalent Hitting Set instance $\mathcal{F}$. We start by defining $\mathcal{F}$ and proving correctness, and later prove $VC(\mathcal{F}) = 2$ and $VC(\mathcal{F}^T) = 2$.

2.1 Construction of $\mathcal{F}$

We construct a set system $\mathcal{F} = (X, \mathcal{C})$ as follows. The elements of X are

$x^{\ell}_{i,u}$	for $i \in [k]$, $u \in V_i$, $\ell \in [2\deg_H(i)]$,
$y^{\ell}_{ij,uv}$	for $ij \in F$, $uv \in E_{ij}$, $\ell \in [5]$.

[7] $uv < wz \iff (u < w \lor (u = w \land v < z))$.

It will be convenient to structure these elements into disjoint *ground sets* $X_i^\ell = \{x_{i,u}^\ell \mid u \in V_i\}$ and $Y_{ij}^\ell = \{y_{ij,uv}^\ell \mid uv \in E_{ij}\}$. We will force each hitting set to pick exactly one element from every ground set; these elements will encode the desired copy of H (should it exist).

In the remainder we define the sets in $\mathcal{C}$. First we introduce the following sets of $\mathcal{C}$.

$$A_{i,u}^\ell = \{x_{i,v}^\ell \mid v < u\} \cup \{x_{i,v}^{\ell+1} \mid v \ge u\}, \qquad \text{for } i \in [k], u \in V_i,\ \ell \in [2\deg_H(i)],$$
$$B_{ij,uv}^\ell = \{y_{ij,wz}^\ell \mid wz < uv\} \cup \{y_{ij,wz}^{\ell+1} \mid wz \ge uv\}, \qquad \text{for } ij \in F,\ uv \in E_{ij},\ \ell \in [5].$$

Here, $x_{i,v}^{\ell+1}$ is to be interpreted as $x_{i,v}^1$ for $\ell = 2\deg_H(i)$, and $y_{ij,wz}^{\ell+1}$ as $y_{ij,wz}^1$ for $\ell = 5$, i.e. there is a wrap-around of the index ℓ. Note that the disjoint ground sets appear as sets $A_{i,u}^\ell$ (where u is the smallest vertex in V_i) and $B_{ij,uv}^\ell$ (where uv is the lexicographic smallest edge in E_{ij}). Hence, any hitting set of $\mathcal{F}$ contains at least one element of every ground set.

Note that the total number of ground sets is

$$k' = 5\,|F| + \sum_{i\in[k]} 2\deg_H(i) = 9k.$$

We set the number of vertices to be chosen in the hitting set to k', i.e. from now on we only consider hitting sets of size k' of $\mathcal{F}$. Since there are exactly k' ground sets, and they are mutually disjoint, it follows that any hitting set of $\mathcal{F}$ of size k' contains exactly one element $x_{i,u(i,\ell)}^\ell$ of any ground set X_i^ℓ, and exactly one element $y_{ij,e(ij,\ell)}^\ell$ of any ground set Y_{ij}^ℓ. Moreover, observe that hitting the set $A_{i,u}^\ell$ implies $u(i,\ell) < u \vee u(i,\ell+1) \ge u$.

This holds for all $u \in V$, and so $u(i,\ell) \le u(i,\ell+1)$ for all ℓ. Since there is a cyclic wrap-around of ℓ it follows that $u(i,\ell) = u(i,\ell+1)$ for all ℓ, and so let $u_i \in V_i$ such that $u(i,\ell) = u_i$ for all ℓ. Similarly, the sets $B_{ij,uv}^\ell$ ensure that $e(ij,\ell) = e_{ij}$ for all ℓ and some $e_{ij} = v_{ij}w_{ij} \in E_{ij}$.

Observe that the picked edges $e_{ij} = v_{ij}w_{ij}$ form a subgraph of G. This subgraph is isomorphic to H if we additionally ensure $u_i = v_{ij}$ and $u_j = w_{ij}$ for all $ij \in F$. To this end, we introduce the sets $C_{ij,u}$ and $C'_{ij,u}$ for $ij \in F$, $u \in V_i$. If ij is the d-th edge incident to vertex i in H, then we set

$$C_{ij,u} = \{x_{i,v}^{2d-1} \mid v < u\} \cup \{y_{ij,wz}^1 \mid w \ge u,\ z \in V_j\},$$
$$C'_{ij,u} = \{x_{i,v}^{2d} \mid v > u\} \cup \{y_{ij,wz}^2 \mid w \le u,\ z \in V_j\}.$$

Observe that this ensures $u_i = v_{ij}$ for all $ij \in F$. Indeed, fixing u_i the sets C_{ij,u_i} and C'_{ij,u_i} are only hit if we choose $y_{ij,v_{ij}w_{ij}}^1$ with $v_{ij} \ge u_i$ and $y_{ij,v_{ij}w_{ij}}^2$ with $v_{ij} \le u_i$.

We implement the remaining condition $u_j = w_{ij}$ indirectly by introducing the sets

$$D_{ij,uv} = \{y_{ij,wz}^3 \mid wz < uv\} \cup \{y_{ij,wz}^5 \mid wz > uv\} \cup \{y_{ji,vu}^4\}, \quad \text{for } ij \in F,\ i<j,\ uv \in E_{ij}.$$

This encodes the formula $e_{ij} \ne uv \vee e_{ji} = vu$ for all $uv \in E_{ij}$, and thus ensures that $v_{ij} = w_{ji}$ and $w_{ij} = v_{ji}$ for all $ij \in F$ with $i < j$ (and thus also for all $ij \in F$ without the condition $i < j$). This indirectly encodes the restriction $u_j = w_{ij}$, since $u_j = v_{ji}$ (by the sets of type $C_{ji,*}$ and $C'_{ji,*}$) and $v_{ji} = w_{ij}$ (by the sets of type $D_{ji,*}$).

In total, any hitting set of $\mathcal{F}$ of size k' yields a subgraph of G that is equal to H. It is easy to show that the inverse holds as well: If $u_1 \in V_1, \dots, u_k \in V_k$ induce a copy of H in G, then picking the elements x_{i,u_i}^ℓ and $y_{ij,u_iu_j}^\ell$ for all ij, ℓ yields a hitting set of $\mathcal{F}$ of size k'. This shows the correctness of our construction.

We show that $VC(\mathcal{F}) = VC(\mathcal{F}^T) = 2$ in the next two sections. Since $k' = O(k)$, $|\mathcal{F}| = n^{O(1)}$, and the construction of $\mathcal{F}$ can be done in polynomial time, W[1]-hardness of Hitting Set restricted to $VC(\mathcal{F}) = VC(\mathcal{F}^T) = 2$ follows, and any $f(k')|\mathcal{F}|^{o(k'/\log k')}$ algorithm for this problem would yield an $f(k)n^{o(k/\log k)}$ algorithm for Partitioned Subgraph Isomorphism, contradicting ETH.

2.2 VC-dimension 2

It is easy to see that in general $VC(\mathcal{F})$ can be at least 2, e.g., the elements $x_{i,1}^2, x_{i,2}^2$ are shattered by the sets $A_{i,1}^1$ (pattern 11), $A_{i,2}^1$ (pattern 01), $A_{i,2}^2$ (pattern 10), and any set of type B (pattern 00).

To prove that $\mathcal{F}$ has VC-dimension at most 2, we first argue that we can remove the single element $y_{ji,vu}^4$ from $D_{ij,uv}$, i.e. we replace any set $D_{ij,uv}$ by

$$D_{ij,uv}^* := D_{ij,uv} \setminus \{y_{ji,vu}^4\} = \{y_{ij,wz}^3 \mid wz < uv\} \cup \{y_{ij,wz}^5 \mid wz > uv\},$$

to obtain a set system $\mathcal{F}^*$. We claim that if there are elements a, b, c realizing the patterns $110, 101, 011, 111$ in F then these elements also realize these patterns in $\mathcal{F}^*$. Indeed, assume for the sake of contradiction that there are elements a, b, c realizing all of the patterns 110, 101, 011, and 111 in $\mathcal{F}$ but not in $\mathcal{F}^*$. Then without loss of generality, for some $ij \in F, uv \in E_{ij}$, $a = y_{ji,vu}^4$ and $b \in D_{ij,uv} \setminus \{a\} = D_{ij,uv}^*$. Now, there is only one set in $\mathcal{F}$ containing both a and b, namely $D_{ij,uv}$ (since $D_{ij,uv}$ is the only set which intersects both Y_{ji}^4 and $Y_{ij}^3 \cup Y_{ij}^5$). Thus, one of the patterns 110 and 111 is missing, contradicting the assumption that a, b, c realize all patterns 110, 101, 011, and 111. Hence, if we show that $\mathcal{F}^*$ contains no three elements realizing all patterns 110, 101, 011, and 111, then no three elements of $\mathcal{F}$ are shattered.

To this end, we first lift the ordering of V and the lexicographic ordering of E to orderings on the ground sets, i.e. for $u < v$ we set $x_{i,u}^\ell < x_{i,v}^\ell$ and for $uv < wz$ we set $y_{ij,uv}^\ell < y_{ij,wz}^\ell$. We use the following crucial observation about this ordering and $\mathcal{F}^*$.

▶ **Observation 4.** *Any set system in $\mathcal{F}^*$ intersects at most two ground sets. Any set system in $\mathcal{F}^*$ restricted to any ground set S forms an* interval *(with respect to the ordering on S). Moreover, for any pair of ground sets $S_1 \neq S_2$, the sets of $\mathcal{F}^*$ intersecting both S_1 and S_2 either all intersect in the smallest element of S_1 or all intersect in the largest element of S_1.*

With this observation at hand, consider any elements $a, b, c \in X$. We do a case distinction over the number of different ground sets that a, b, c are contained in.

(1) If a, b, c come from the same ground set S, then they are ordered in S, say $a < b < c$. Since each set of $\mathcal{F}^*$ forms an interval in S, there is no set of $\mathcal{F}^*$ containing a and c but not b.

(2) If a and b come from the same ground set S_1, say with $a < b$, and c comes from a different ground set S_2, then we consider the last part of Observation 4. If all sets of $\mathcal{F}^*$ containing elements of S_1 and S_2 contain the smallest element of S_1, then since these sets form an interval restricted to S_1, there is no set of $\mathcal{F}^*$ containing b and c but not a. We argue similarly if all sets of $\mathcal{F}^*$ containing elements of S_1 and S_2 contain the largest element of S_1.

(3) If a, b, c all come from different ground sets, then no set in $\mathcal{F}^*$ contains all three elements, since any set of $\mathcal{F}^*$ intersects at most two ground sets.

In all cases we showed that one of the patterns 110, 101, 011, and 111 is missing for any elements $a, b, c \in X$. This finishes the proof of $VC(\mathcal{F}) \leq 2$.

2.3 Dual VC-dimension 2

It is easy to see that in general the dual VC-dimension of $\mathcal{F}$ is at least 2, e.g., the sets $A_{i,1}^1, A_{i,2}^1$ are shattered by the elements $x_{i,2}^2$ (pattern 11), $x_{i,1}^2$ (pattern 10), $x_{i,1}^1$ (pattern 01), and any element of the form $y_{ij,uv}^\ell$ (pattern 00).

To show that the dual VC-dimension of $\mathcal{F}$ is at most 2, we first reduce to the set system $\mathcal{F}^*$ like in the previous section. Consider any sets $M_1, M_2, M_3 \in \mathcal{C}$ and assume for the sake of contradiction that they realize all of the patterns 110, 101, 011, and 111 in $\mathcal{F}$ but the corresponding sets M_1^*, M_2^*, M_3^* do not realize all patterns 110, 101, 011, 111 in $\mathcal{F}^*$. Without loss of generality, assume that M_1 is of the form $D_{ij,uv}$ and its element $y^4_{ji,vu}$ is also contained in M_2, so that $y^4_{ji,vu}$ induces one of the patterns 110 or 111. This yields that M_2 is of the form $B^\ell_{ji,wz}$ for appropriate $\ell \in [5], wz \in E_{ji}$. However, any such set has only one element in common with $D_{ij,uv}$, namely $y^4_{ji,vu}$. Thus, one of the patterns 110, 111 is missing, which is a contradiction. Hence, if we show that $\mathcal{F}^*$ contains no three sets realizing all patterns 110, 101, 011, and 111, then no three sets of $\mathcal{F}$ are shattered.

Consider any sets M_1^*, M_2^*, M_3^* of $\mathcal{F}^*$ and assume for the sake of contradiction that they realize all of the patterns 110, 101, 011, and 111. Restricted to any ground set S the sets M_1^*, M_2^*, M_3^* form intervals, and thus S cannot induce all four patterns 110, 101, 011, and 111 on M_1^*, M_2^*, M_3^* (as can be checked easily and follows from the proof of the well-known fact that intervals have dual VC-dimension 2).

Hence, without loss of generality there is a ground set S_1 with an element inducing the pattern 111 and another ground set S_2 with an element inducing the pattern 110 on M_1^*, M_2^*, M_3^*. Note that M_1^* and M_2^* are contained in $S_1 \cup S_2$, since every set of $\mathcal{F}^*$ intersects at most two ground sets. By Observation 4, since M_1^* and M_2^* intersect both S_1 and S_2, they both contain the smallest or largest element e_1 of S_1 and the smallest or largest element e_2 of S_2. In particular, restricted to S_1 we have without loss of generality $M_1^* \subseteq M_2^*$. Now, if M_3^* does not intersect S_2, then the pattern 101 is missing, since only elements of S_1 can be contained in both M_1^* and M_3^*, but any such element is also contained in M_2^*. Otherwise, M_3^* also contains e_1 and e_2, so that restricted to S_1 we have a linear ordering $M^*_{\pi(1)} \subseteq M^*_{\pi(2)} \subseteq M^*_{\pi(3)}$ and restricted to S_2 we have a linear ordering $M^*_{\sigma(1)} \subseteq M^*_{\sigma(2)} \subseteq M^*_{\sigma(3)}$ (for permutations π, σ). However, two linear orderings can only induce two of the patterns 110, 101, and 011. This contradicts M_1^*, M_2^*, M_3^* realizing all patterns 110, 101, 011, and 111, and finishes the proof of $VC(\mathcal{F}^T) \leq 2$.

3 Efficiently solvable classes of Hitting Set

In this section, we consider efficiently solvable special cases of Hitting Set. The following result can be seen a warmup for a similar but more involved argument in § 3.1.

▶ **Theorem 5.** *Hitting Set is polynomial-time solvable on set systems of VC-dimension* 1 *and on set systems of dual VC-dimension* 1.

Proof. Let $\mathcal{F} = (X, \mathcal{C})$ be a set system of VC-dimension 1. If every set in $\mathcal{C}$ has non-empty intersection with some $\{x, y\} \subseteq X$ then $\{x, y\}$ is a hitting set of size 2, and the minimal hitting set can be found by a brute-force search over all subsets of X of size 1 or 2.

Assume therefore that there is no pair $\{x, y\} \subseteq X$ which hits every set in $\mathcal{C}$. Let $x, y \in X$. We say that x *dominates* y if every set in $\mathcal{C}$ which contains y also contains x. Note that if x dominates y, then removing y from all sets in $\mathcal{C}$ does not affect the size of the minimum hitting set. Let $\{x, y\}$ be a two-element set which is contained in some set $A \in \mathcal{C}$. We claim that x dominates y or y dominates x. Indeed, (x, y) realizes the patterns 00 (by the first observation that no pair $\{x, y\}$ hits every set in $\mathcal{C}$) and 11 (since $\{x, y\} \subset A$). Since $\{x, y\}$ is not shattered, one of 01 and 10 must be missing – implying that one of x or y dominates the other. We proceed by repeatedly removing dominated elements, until we are left with singleton sets which immediately yields the minimum hitting set.

Now consider the case of dual VC-dimension 1. This condition implies that for every pair of sets $A, B \in \mathcal{C}$, at least one of the following holds: $A \subseteq B$, $B \subseteq A$, $A \cap B = \emptyset$, or $A \cup B = X$.

If there exist $A, B \in \mathcal{C}$ such that $A \subseteq B$, then we can consider the modified set system in which B is removed, without affecting the size of a minimal hitting set. Thus, we may assume that no set in $\mathcal{C}$ contains another set of $\mathcal{C}$. If the sets in $\mathcal{C}$ are all pairwise disjoint, then the minimum hitting set contains an arbitrary element from each set, and can easily be found. Thus, we can assume that there exist two sets $A, B \in \mathcal{C}$ such that $A \cup B = X$. Any other set $C \in \mathcal{C}$ intersects both A and B (otherwise it would be contained in one of them). From this we conclude that every $C \in \mathcal{C} \setminus \{A, B\}$ satisfies $C \cup A = X$, and $C \cup B = X$, or equivalently C must contain $B \setminus A$ and $A \setminus B$. It follows that the size of the minimum hitting set is at most 2, and thus can be computed in polynomial time. ◀

The Sauer-Perles-Shelah Lemma implies that set systems of VC-dimension 1 are $(k, k+1)$-systems for every k, and in particular they are $(3, 4)$-systems. Thus, a natural question is whether Hitting Set is polynomial-time solvable for every $(3, 4)$-system. We next show that the answer is yes, even for the more general case of $(3, 5)$-systems, thus extending Theorem 5.

3.1 (3,5)-systems

In this subsection we prove that Hitting Set on $(3, 5)$-systems is solvable in polynomial time. Before presenting the algorithm, we briefly observe that the class of $(3, 5)$-systems is a proper generalization of Edge Cover instances (i.e. where every element occurs in exactly two sets). More generally, an Edge Cover instance is a $(k, k + \lfloor k/2 \rfloor + 1)$-system for any $k \geq 1$. This is because the incidence matrix of an Edge Cover instance can have at most $2k$ one-entries in any k columns, and every collection of $k + \lfloor k/2 \rfloor + 2$ distinct k-vectors has at least $2k + 1$ one-entries. To see that Edge Cover instances are a proper subset of $(3, 5)$-systems, observe that in a $(k, k + \lfloor k/2 \rfloor + 1)$-system, an element can occur in an arbitrary number of sets.

▶ **Theorem 2** (restated). *Hitting set on $(3, 5)$-systems is in P.*

Let $\mathcal{F} = (X, \mathcal{C})$ be a $(3, 5)$-system. We present a polynomial-time algorithm which outputs a minimum hitting set for $\mathcal{F}$. First check whether $\emptyset \in \mathcal{C}$; if this is the case, then report "no solution". Otherwise perform the following preprocessing steps repeatedly, until none of the steps can be performed.

0. If $\mathcal{F}$ is not connected, i.e. there are set systems $(X_1, \mathcal{C}_1)$, $(X_2, \mathcal{C}_2)$ with disjoint X_1, X_2 and $\mathcal{F} = (X_1 \cup X_2, \mathcal{C}_1 \cup \mathcal{C}_2)$, then recursively solve $(X_1, \mathcal{C}_1)$ and $(X_2, \mathcal{C}_2)$ and return the union of the solutions.

1. If $\{x, y, z\} \subseteq X$, and the pattern 000 is not realized on (x, y, z), then a minimum hitting set is of size at most 3, and we find it by exhaustive search over all subsets of size at most 3.

2. If $\{x, y\} \subseteq X$, and the pattern 01 is not realized on (x, y), then remove y from X, as x dominates y (whenever y occurs, x also occurs).

3. If $A, B \in \mathcal{C}$ such that $A \subseteq B$, then remove B from $\mathcal{C}$, as whenever we hit A, we also hit B.

4. If there is a singleton set $\{x\} \in \mathcal{C}$, then add x to the solution, remove x from X and remove every set containing x from $\mathcal{C}$.

5. (only if steps $0, \ldots, 4$ cannot be applied) If $A, B, C \in \mathcal{C}$, and there is an element $x \in (A \cap B \cap C)$, then add x to the solution, remove x from X and remove every set containing x from $\mathcal{C}$.

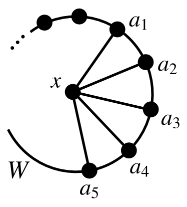


Figure 2 Illustration of the proof of Lemma 6.

Observe that after every preprocessing step the resulting set system is still a $(3,5)$-system. Moreover, after the preprocessing, every element of X is contained in exactly two sets of $\mathcal{C}$ (otherwise rule 2,4, or 5 is applicable). In other words, after preprocessing, $(X,\mathcal{C})$ is an instance of Edge Cover - such an instance can be solved in polynomial time by computing a maximum matching, and then augmenting with additional edges to cover the unmatched vertices [17]. The total asymptotic running time (including the time of the preprocessing) is dominated by the time needed to find a maximum matching in a graph with $|\mathcal{C}|$ vertices and $|X|$ edges.

The correctness of the algorithm hinges on the validity of the preprocessing steps. Note that only step 5 is not trivially valid. Theorem 2 thus follows from the following claim.

▶ **Lemma 6.** *If preprocessing steps $0,\ldots,4$ cannot be applied, and if there exists an element x contained in at least three sets of $\mathcal{C}$, then x is part of any minimum hitting set.*

Proof. We make use of the following claim that we prove later.

▶ **Lemma 7.** *If preprocessing steps $0,\ldots,4$ cannot be applied, then for any two sets $A,B\in\mathcal{C}$, we have $|A\cap B|\le 1$.*

Suppose that there is an element $x\in X$ contained in t sets of $\mathcal{C}$, where $t\ge 3$, and let $A_1,\ldots,A_t$ denote the sets containing x. Each of these sets must also contain some element other than x (by preprocessing step 4), so let $a_1\in A_1\setminus\{x\},\ldots,a_t\in A_t\setminus\{x\}$. Observe that since $t\ge 3$, Lemma 7 implies that for all $i\ne j$: $A_i\cap A_j=\{x\}$ and therefore, $a_1,\ldots,a_t$ are distinct.

The proof proceeds by showing that every hitting set that does not contain x must contain $a_1,\ldots,a_t$, and that replacing $a_2,\ldots,a_t$ by x preserves the property of being a hitting set.

For every a_i there exists a set $A_i'\in\mathcal{C}$ such that $a_i\in A_i'$ and $x\notin A_i'$, as otherwise a_i would have been deleted in step 2 of the preprocessing, as it is dominated by x.

We show that $A_i'=A_j'$ for all $i,j\le t$. Suppose first, towards contradiction, that there exist two indices i and j, such that $a_i\notin A_j'$. Let k be an index $(1\le k\le t)$ different from i and j. In this case, the triple (x,a_i,a_j) realizes the patterns 000 (by preprocessing step 1), 100 (from A_k), 110 (from A_i), 101 (from A_j), 001 (from A_j'), and either 011 or 010 (from A_i'), in both cases contradicting the hypothesis that $\mathcal{F}$ is a $(3,5)$-system. We conclude that for all indices i and j, $a_i\in A_j'$. Thus, we have $\{a_i,a_j\}\subseteq A_i'\cap A_j'$ for all i,j. From Lemma 7 we conclude that $A_i'=A_j'$. Let us denote $W=A_1'=\cdots=A_t'$.

Since the above reasoning holds for any element in $A_i\setminus\{x\}$, we even have $W\supset A_i\setminus\{x\}$ for all $i\le t$. Observe that $|A_i|=2$, for all $i\le t$, as otherwise W would intersect A_i in more than one element, contradicting Lemma 7. See Figure 2 for an illustration.

Suppose that there exists a set $Q\in\mathcal{C}$, such that $a_i\in Q$, and $Q\ne A_i$, and $Q\ne W$, and let j, k be two indices different from i. Note that since $|Q\cap W|,|Q\cap A_i|\le 1$, and $a_i\in Q\cap A_i$, and $a_i\in Q\cap W$, it follows that $a_j\notin Q$ and $x\notin Q$. Thus the triple (x,a_i,a_j) realizes the patterns 000 (by preprocessing step 1), 100 (from A_k), 110 (from A_i), 101 (from

A_j), 010 (from Q), and 011 (from W), contradicting the hypothesis that $\mathcal{F}$ is a $(3,5)$-system. Therefore, A_i and W are the only sets in $\mathcal{C}$ containing a_i.

Let H be a hitting set that does not contain x. Since each of the sets $A_1,\dots,A_t$ is of size 2, in order to hit them we must have $a_1,\dots,a_t \in H$. However, as a_i (for all i) is contained only in A_i and W, we can improve the solution by removing $a_2,\dots,a_t$ and adding x. In this way, all the sets containing the removed elements are still hit. This means that H is not a minimum hitting set, and thus preprocessing step 5 is justified. ◀

It remains to prove Lemma 7. We proceed via two intermediate claims.

▶ **Lemma 8.** *Let $\mathcal{F} = (X,\mathcal{C})$ be a $(3,5)$-system such that preprocessing steps $0,\dots,4$ cannot be applied. Let $Y \subseteq X$ with $|Y| = k \geq 4$. Then the following properties are equivalent. If they are satisfied, we say that $\mathcal{F}$ contains a B_k-system (induced by Y).*

- *$PR_{\mathcal{F}}(Y)$ contains all subsets of Y of size $k-1$,*
- *$PR_{\mathcal{F}}(Y)$ contains no set S with $0 < |S| \leq k-2$.*

Proof. To see that the second property implies the first, observe that all 01-patterns must be present (by preprocessing step 2), and these patterns can only be realized by having all sets of the form $Y \setminus \{y\}$ for $y \in Y$. To see that the first property implies the second, assume for contradiction that there is a set $S \in PR_{\mathcal{F}}(Y)$ with $0 < |S| \leq k-2$. Then S realizes pattern 100 on some y_1, y_2, y_3. Since patterns 110, 101, 011, 111 are realized (by the first property and $k \geq 4$) and 000 is realized (by preprocessing step 1), we obtain a contradiction. ◀

▶ **Lemma 9.** *Let $\mathcal{F} = (X,\mathcal{C})$ be a $(3,5)$-system such that preprocessing steps $0,\dots,4$ cannot be applied. If there are two sets $A, B \in \mathcal{C}$ with $|A \cap B| \geq 2$, then there exists a set $Q = \{x,y,z,t\} \subseteq X$ with the following properties:*

(i) *Q induces a B_4-system on $\mathcal{F}$, and*
(ii) *Q is a hitting set of $\mathcal{F}$.*

Proof.

(i) Consider two elements $x, y \in A \cap B$. By preprocessing step 3 there exist $z \in A \setminus B$ and $t \in B \setminus A$. On the triple (z,x,y) we realize 000 (by preprocessing step 1), 111 (by A), 011 (by B). The missing 01 patterns on (x,z), (y,z), (x,y), (y,x) can be realized with the assumption that $\mathcal{F}$ is a $(3,5)$-system, only if the remaining two patterns on (z,x,y) are 101 and 110. A similar argument shows that on the triple (t,x,y) the following five patterns are realized: 000 (by preprocessing step 1), 111 (by B), 011 (by A), and to obtain 01 on each pair: 101 and 110. Observe that if (x,y) realizes 00, 01, or 10, then the pattern on z and t is uniquely determined. This yields on the tuple (z,t,x,y) the following patterns: 0000, 1110, 1101 (by joining uniquely the patterns that realize 00, 01, and 10 on (x,y)). We need to realize 01 on both (z,t) and (t,z). The only way to achieve this is with the patterns 0111 and 1011 on (z,x,y,t). With this we conclude that $PR_{\mathcal{F}}(\{x,y,z,t\})$ contains all possible sets of size 3, satisfying the first condition of Lemma 8 and hence $\mathcal{F}$ contains a B_4 system induced by $\{x,y,z,t\}$.

(ii) Suppose for contradiction that $\{x,y,z,t\}$ is not a hitting set of $\mathcal{F}$. Pick $D, D' \in \mathcal{C}$ such that $D \cap \{x,y,z,t\} = \emptyset$, $D' \cap D \neq \emptyset$, and $D' \cap \{x,y,z,t\} \neq \emptyset$ (such D, D' exist since $\mathcal{F}$ is connected and $\{x,y,z,t\}$ is not a hitting set of $\mathcal{F}$). Let $s \in D \cap D'$. Observe that $|D' \cap \{x,y,z,t\}| \geq 3$ (by Lemma 8). Let x_1, x_2, x_3 be distinct elements from $\{x,y,z,t\}$ that belong to D'. Let $E \in \mathcal{C}$ such that E induces the pattern 110 on (x_1,x_2,x_3). Such an E exists since $\{x,y,z,t\}$ induce a B_4-system on $\mathcal{F}$. We consider two cases: (1) when

$s \in E$, and (2) when $s \notin E$. (1) On the triple (s, x_2, x_3), we have the patterns 000 (from the preprocessing), 111 (by D'), 100 (by D), 110 (by E), and to get 01 on (x_2, x_3) and 01 (s, x_2), we need at least two more patterns on (s, x_2, x_3), contradicting that $\mathcal{F}$ is a $(3, 5)$-system. (2) On the triple (s, x_1, x_2) we have the patterns 000 (from the preprocessing), 111 (by D'), 100 (by D), and 011 (from E). To realize 01 and 10 on (x_1, x_2), we need two more patterns on (s, x_1, x_2), contradicting that $\mathcal{F}$ is a $(3, 5)$-system. We reached a contradiction, proving that such a D cannot exist, and hence $\{x, y, z, t\}$ is a hitting set of $\mathcal{F}$. ◀

Suppose that preprocessing steps $0, \ldots, 4$ cannot be applied to $\mathcal{F}$, and there exist sets $A, B \in \mathcal{C}$ with $|A \cap B| \geq 2$. Then, from Lemma 9 it follows that there exists a hitting set $\{x, y, z, t\}$ of $\mathcal{F}$, such that $\{x, y, z, t\}$ induces a B_4-system in $\mathcal{F}$. From the definition of hitting set it follows that $PR_{\mathcal{F}}(\{x, y, z, t\})$ does not contain the empty set. From Lemma 8 it follows that $PR_{\mathcal{F}}(\{x, y, z, t\})$ does not contain a set of size 1. Hence, on the triple (x, y, z) the pattern 000 cannot be realized, contradicting the assumption that preprocessing step 1 cannot be applied.

This concludes the proof of Lemma 7 and the proof of correctness for the algorithm.

The following theorem gives a sharp threshold on the complexity of Hitting Set by showing the NP-hardness of Hitting Set on $(3, 6)$-set systems.

▶ **Theorem 3** (restated). *Hitting set on* $(3, 6)$*-systems is in NP-hard.*

The proof follows by considering the Hitting Set instance that corresponds to Vertex Cover in a triangle-free graph. Indeed, the following two observations establish NP-hardness and the $(3, 6)$-property: (i) Vertex Cover in triangle-free graphs is NP-hard. This can be seen by taking an arbitrary Vertex Cover instance and splitting every edge by adding two internal vertices. The resulting graph is triangle-free. Also, the size of its optimum vertex cover is the original plus the number of edges in the original graph, and (ii) in a triangle-free Vertex Cover instance, on any three elements (vertices) the pattern 111 and one of the patterns in $\{011, 110, 101\}$ are not realized.

A Complexity claims in Table 1

The exact definitions and the complexity results for the various Hitting Set instances can be found by following the respective references. Edge Cover and Vertex Cover are standard problems, described e.g. in [17]. The study of Hitting Set (a.k.a. *transversal* problem) on line intervals goes back to early work of Gallai [13]. The folklore polynomial-time algorithm follows directly from his combinatorial observations.

The fact that Hitting Set is FPT in set systems defined by pseudolines is folklore, and can easily be explained by the property that any two points are contained in at most one set (i.e. line). A generalization of this property holds for arrangements of hyperplanes in $\mathbb{R}^d$: Here any d points are contained in at most one hyperplane. Both properties are subsumed by the biclique-free property, or equivalently the avoidance of a submatrix consisting of all 1s[8]. The definition of the halfspace arrangement problem and a simple proof of hardness in three dimensions is included in § C.

B VC-dimension claims in Table 1

The computation of the VC-dimension is an easy exercise for most of the examples in Table 1. We mention that for some of the problems (especially those related to graphs), the value of the VC-dimension seems not to have been explicitly computed in the literature. In some cases this computation leads to approximation-results (via Brönnimann and Goodrich [7]) that match the best known approximation ratio obtained via other means. We give a brief overview of the examples listed in Table 1.

The set systems of Vertex Cover and Edge Cover instances are simple: Each set is of size 2, respectively, each element appears in 2 sets. In both cases it is easy to see that both the VC-dimension and the dual VC-dimension is at most 2.

In Tree-Like Hitting Set, the sets are restricted to be subtrees of a tree. Here we can shatter an arbitrary number of elements: Consider the set of all leaves of a tree, and pick any subset of the leaves. Observe that there is a subtree that contains exactly the picked set of leaves and no other leaves. A similar argument holds for the Feedback Vertex Set problem. In a complete graph, color half of the vertices blue, and observe that if we pick any set of blue vertices (possibly the empty set), there can be a cycle containing all the blue vertices of the chosen set and no other blue vertices.

The set system associated with the *Dominating Set* problem is the set of all closed vertex neighborhoods of a graph. Since the incidence matrix of this set system is a symmetric square matrix, the dual VC-dimension is the same as the VC-dimension.

Triangle-free graphs: The VC-dimension can be arbitrarily large. To see this, consider an independent set X of size n, and add 2^n further vertices, each connected to a different subset of X. Observe that X is shattered, while the graph is triangle-free.

A similar argument holds for *graphs free of induced* $K_{t,1}$, for $t \geq 3$. Consider a k-clique X and a 2^k-clique Y, and for each subset $X' \subseteq X$ (including the empty set), connect one vertex of Y to X', and to none of the vertices in $X \setminus X'$. Clearly X is shattered, and thus the VC-dimension is at least k. If the constructed graph contains an induced $K_{t,1}$ for $t \geq 3$, then at least two non-connected vertices of the induced subgraph must be both in X or both in Y. This is a contradiction, since X and Y are cliques.

Planar graphs: A simple case-analysis shows that if a set of five vertices is shattered by the closed vertex neighborhood of a graph, then the graph must contain $K_{3,3}$ or K_5 as a

[8] In the literature, the fixed-parameter tractability on biclique-free instances is shown for *Dominating Set*, but the result easily transfers to *Hitting Set*.

subgraph, and thus it cannot be planar. On the other hand, it is easy to construct a planar graph instance where a set of four vertices is shattered.

Graphs of girth at least 5: A simple case analysis shows that if 3 vertices are shattered, then the graph has a triangle or a cycle of length 4. On the other hand, 2 vertices can be shattered in this graph class. Therefore, the VC-dimension is 2 (see e.g. [5]). An immediate consequence of the boundedness of the VC-dimension is an $O(\log k)$-factor approximation algorithm for Dominating Set on this class of graphs, as a corollary of the result of Brönnimann and Goodrich [7]. A matching result was obtained by Raman and Saurabh [36] using sophisticated techniques.

The claim for *unit disk graphs* follows from simple geometric arguments (see e.g. [5]). For *graphs avoiding* $K_{t,t}$, the incidence matrix can not contain a t-by-t all-1s submatrix. It is easy to check that a matrix with $t + \lceil \log_2 t \rceil$ columns that contains all possible 0/1 vectors on its rows contains such a submatrix, whereas a similar matrix with one fewer columns does not. The claim on the VC-dimension follows.

For most geometric set systems in Table 1, the VC-dimension is well known from the computational geometry and learning theory literature.

Line intervals: Given three points on a line, no interval can contain the two outer points without containing the one in the middle. Thus the VC-dimension is at most 2. If 3 intervals share a common point, then one interval is in the union of the other two. This ensures that no three intervals can be shattered, thus the dual VC-dimension is at most 2 as well. Both values are tight.

Pseudolines: Since any two sets intersect at most once, a 2-by-2 submatrix of 1s can not exist in the incidence matrix. This implies that no 3 points can be shattered by the set system or by its dual. On the other hand, 2 points can be shattered by both set systems. The claim follows. The boundedness of the VC-dimension yields an $O(\log k)$-factor approximation algorithm for this problem. A similar result for a special case of the problem was obtained by Grantson and Levcopoulos [19] using different techniques.

Halfplanes: It is easy to show that not every subset of size 2 of a set of 4 points in the plane can be realized by halfplanes. On the other hand, for 3 points in general position every subset can be realized. Thus the VC-dimension is 3. Observe that the dual VC-dimension is 2, since three lines create at most 7 cells in the plane, therefore not all patterns on 3 sets can be realized. On the other hand, the 4 patterns on 2 sets can be realized.

The claims for *hyperplanes in* $\mathbb{R}^d$, *unit disks* and *unit squares* follow from similar geometric arguments and we omit them.

Rectangle Stabbing: In this problem the set system is defined by the incidences between a set of axis parallel rectangles (playing the role of sets), and a set of horizontal and vertical lines (playing the role of elements). Note that at most 4 lines can be shattered, as three lines with the same orientation can not be shattered (by the same argument as for intervals), thus the VC-dimension is at most 4 (this can be reached). However, the families of instances constructed in the hardness proof of Dom et al. [11] have VC-dimension 3. The same value is obtained for the dual VC-dimension. We omit the details. For *Disjoint Rectangle Stabbing* the VC-dimension is 2, by an argument similar to the one used for line intervals.

C Hardness of Hitting Set for halfspaces in $d \geq 3$

We prove now that the halfspace arrangement problem in R^d is $W[1]$-hard for $d \geq 3$. The halfspace arrangement problem is a special case of Hitting Set, defined as follows: The input has n points and n halfspaces in R^d, and a number k. The goal is to select k halfspaces such that each of the given points is contained in at least one of the k halfspaces. The special case for $d = 2$ appears in Table 1 as *halfplane arrangement*, and is known to be in P.

▶ **Theorem 10.** *In $R^d, d \geq 3$, the halfspace arrangement problem is NP-hard and even $W[1]$-hard.*

Proof. We reduce from Dominating Set on the intersection graphs of unit disks, which is known to be $W[1]$-hard [29]. First, observe that the problem stays $W[1]$-hard if we consider disks with unit radius r on the two-dimensional sphere $S^2 = \{(x_1, x_2, x_3) \in R^3 : x_1^2+x_2^2+x_3^2 = 1\}$. This is because we can embed any unit disk graph on a tiny part of the sphere S^2 that approximates the plane sufficiently well. Given the embedding with disk midpoints $p_1, ..., p_n$ on S^2 and the radius r, we want to find a dominating set of the intersection graph of these disks. This is equivalent to finding k indices $i_1, \ldots, i_k$ such that the disks of radius $2r$ around $p_{i_1}, .., p_{i_k}$ cover all points $p_1, \ldots, p_n$. We construct an equivalent instance of the halfspace arrangement problem as follows: The n points are $p_1, \ldots, p_n$. Let $0 < s < 1$. For $1 \leq i \leq n$ we add a halfspace $H_i = \{x \in R^3 : p_i.x \geq s\}$ with normal vector p_i. Crucially, observe that by setting s appropriately, $H_i \cap S^2$ is equal to the disk of radius $2r$ around p_i. Since all points p_i lie on S^2, it is equivalent whether we consider H_i or $H_i \cap S^2$ as sets (of the arrangement problem). ◀

New Algorithms, Better Bounds, and a Novel Model for Online Stochastic Matching[*][†]

Abstract

Online matching has received significant attention over the last 15 years due to its close connection to Internet advertising. As the seminal work of Karp, Vazirani, and Vazirani has an optimal $(1 - 1/e)$ competitive ratio in the standard adversarial online model, much effort has gone into developing useful online models that incorporate some stochasticity in the arrival process. One such popular model is the "known I.I.D. model" where different customer-types arrive online from a known distribution. We develop algorithms with improved competitive ratios for some basic variants of this model with integral arrival rates, including: (a) the case of general weighted edges, where we improve the best-known ratio of 0.667 due to Haeupler, Mirrokni and Zadimoghaddam [11] to 0.705; and (b) the vertex-weighted case, where we improve the 0.7250 ratio of Jaillet and Lu [12] to 0.7299. We also consider two extensions, one is "known I.I.D." with non-integral arrival rate and stochastic rewards; the other is "known I.I.D." b-matching with non-integral arrival rate and stochastic rewards. We present a simple non-adaptive algorithm which works well simultaneously on the two extensions.

One of the key ingredients of our improvement is the following (offline) approach to bipartite-matching polytopes with additional constraints. We first add several valid constraints in order to get a good fractional solution $\mathbf{f}$; however, these give us less control over the structure of $\mathbf{f}$. We next *remove* all these additional constraints and randomly move from $\mathbf{f}$ to a feasible point on the matching polytope with all coordinates being from the set $\{0, 1/k, 2/k, \ldots, 1\}$ for a chosen integer k. The structure of this solution is inspired by Jaillet and Lu (*Mathematics of Operations Research*, 2013) and is a tractable structure for algorithm design and analysis. The appropriate random move preserves many of the removed constraints (approximately [exactly] with high probability [in expectation]). This underlies some of our improvements, and, we hope, could be of independent interest.

1 Introduction

Applications to Internet advertising have driven the study of online matching problems in recent years [19]. In these problems, we consider a bipartite graph $G = (U, V, E)$ in which the set U is available offline while the vertices in V arrive online. Whenever some vertex v arrives, it must be matched immediately to at most one vertex in U. Each offline vertex u can be matched to at most one v or in the b-matching generalization, at most b vertices in V. In the context of Internet advertising, U is the set of advertisers, V is a set of impressions, and the edges E define the impressions that interest a particular advertiser. When v arrives, we must choose an available advertiser (if any) to match with it. Initially, we consider the case where $v \in V$ can be matched at most once. We later relax this condition to it being matched up to b times. Since advertising forms the key source of revenue for many large Internet companies, finding good matching algorithms and obtaining even small performance gains can have high impact. Additionally, bipartite matching is a fundamental combinatorial optimization problem. Hence, any improvements is interesting from a theoretical standpoint.

In the *stochastic known I.I.D.* model of arrival, we are given the bipartite graph in advance and each arriving vertex v is drawn with replacement from a known distribution on the vertices in V. This captures the fact that we often have background data about the impressions and can predict the frequency with which each type of impression will arrive. Edge-weighted matching [8] is a general model in the context of advertising: every advertiser gains a given revenue for being matched to a particular type of impression. Here, a *type* of impression refers to a class of users (e.g., a demographic group) who are interested in the same subset of advertisements. A special case of this model is vertex-weighted matching [1], where weights are associated only with the advertisers. In other words, a given advertiser has the same revenue generated for matching any of the user types interested in it.

In some modern business models, revenue is not generated upon matching advertisements, but only when a user *clicks* on the advertisement: this is the *pay-per-click* model. From background data, one can assign the probability of a particular advertisement being clicked by a type of user. Works including [20],[21] capture this notion by assigning a probability to each edge.

One unifying theme in most of our approaches is to use an LP benchmark with additional valid constraints that hold for the respective stochastic-arrival models, combined with some form of dependent rounding.

1.1 Related work

For readers not familiar with these problems, they are encouraged to first read parts of section 2 for formal definitions before getting into the related work. The study of online matching began with the seminal work of Karp, Vazirani, Vazirani [14], where they gave an optimal online algorithm for a version of the unweighted bipartite matching problem in which vertices arrive in adversarial order. Following that, a series of works have studied various related models. The book by Mehta [19] gives a detailed overview. The vertex-weighted version of this problem was introduced by Aggarwal, Goel and Karande [1], where they give an optimal $\left(1 - \frac{1}{e}\right)$ ratio for the adversarial arrival model. The edge-weighted setting has been studied in the adversarial model by Feldman, Korula, Mirrokni and Muthukrishnan [8], where they consider an additional relaxation of “free-disposal".

Beyond the adversarial model, these problems are studied under the name *stochastic matching*, where the online vertices either arrive in random order or are drawn I.I.D. from a known distribution. The works [5, 15, 16, 17] among others, study the random arrival order model; papers including [4, 9, 11, 12, 18, 6] study the I.I.D. arrival order model. Another variant of this problem is when the edges have stochastic rewards. Models with stochastic rewards have been previously studied by [20], [21] among others, but not in the known I.I.D. model.

Related Work in the Vertex-Weighted and Unweighted Settings: The vertex-weighted and unweighted settings have many results starting with Feldman, Mehta, Mirrokni and Muthukrishnan [9] who were the first to beat $1 - 1/e$ with a competitive ratio of 0.67 for the unweighted problem. This was improved by Manshadi, Gharan, and Saberi [18] to 0.705 with an adaptive algorithm. In addition, they showed that even in the unweighted variant with integral arrival rates, no algorithm can achieve a ratio better than $1 - e^{-2} \approx 0.86$. Finally, Jaillet and Lu [12] presented an adaptive algorithm which used a clever LP to achieve 0.725 and $1 - 2e^{-2} \approx 0.729$ for the vertex-weighted and unweighted problems, respectively.

Related Work in the Edge-Weighted Setting: For this model, Haeupler, Mirrokni, Zadimoghaddam [11] were the first to beat $1 - 1/e$ by achieving a competitive ratio of 0.667. They use a *discounted LP* with tighter constraints than the basic matching LP (a similar LP can be seen in 2.1) and they employ the *power of two choices* by constructing two matchings offline to guide their online algorithm.

Related Work in Online *b*-matching: In the model of b-matching, we assume each vertex u has a uniform capacity of b, where b is a parameter which is generally a large integral value. The model of unweighted b-matching can be viewed as a special case of Adwords or Display Ads. There is extensive literature for Adwords or Display Ads under various settings (see the book by Mehta [19]). In particular, [13] shows that their algorithm BALANCE is optimal for online b-matching under the adversarial model, which achieves a ratio of $1 - \frac{1}{(1+1/b)^b}$.

In this paper, we consider edge-weighted b-matching with stochastic rewards under the known I.I.D. model with arbitrary arrival rates. To the best of our knowledge, we are the first to consider this very general model. Devanur *et al* [7] gave an algorithm which achieves a ratio of $1 - 1/\sqrt{2\pi k}$ for the Adwords problem in the Unknown I.I.D. arrival model with knowledge of the optimal budget utilization and when the bid to budget ratios are at most $1/k$. Notice that even the problem of general edge-weighted b-matching with deterministic rewards cannot be captured in the Adwords model. Alaei *et al* [2] consider the Prophet-Inequality Matching problem, in which v arrives from a distinct (known) distribution $\mathcal{D}_t$, in each round t. They gave a $1 - 1/\sqrt{k+3}$ competitive algorithm, where k is the minimum capacity of u. They assume deterministic rewards however, and it is non-trivial to extend their result to the stochastic reward setting. In this paper, we present a very simple algorithm which achieves a ratio of $1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$ for any given $\epsilon > 0$. It is worthwhile to see that our algorithm (5) can be trivially extended to the case where each vertex u has a distinct capacity b_u. The value of b in the final ratio would be replaced by $\min_{u \in U} b_u$.

2 Preliminaries

In the *Unweighted Online Known I.I.D. Stochastic Bipartite Matching* problem, we are given a bipartite graph $G = (U, V, E)$. The set U is available offline while the vertices v arrive online and are drawn with replacement from an I.I.D. distribution on V. For each $v \in V$, we are given an *arrival rate* r_v, which is the expected number of times v will arrive. With the exception of Sections 5 and 6, this paper will focus on the integral-arrival-rates setting where all $r_v \in \mathbb{Z}^+$. As described in [11], WLOG we can assume in this setting that $\forall v \in V, r_v = 1$. Let $n = \sum_{v \in V} r_v$ be the expected number of vertices arriving during the online phase.

In the **vertex-weighted** variant, every vertex $u \in U$ has a weight w_u and we seek a maximum weight matching. In the **edge-weighted** variant, every edge $e \in E$ has a weight w_e and we seek a maximum weight matching. In the **stochastic rewards** variant [1], additionally, each edge has a probability p_e and we seek to maximize the expected weight of the matching. In the **b-matching** model, every vertex in U can be matched upto b times. Throughout, we will use "WS" to refer to the worst case for various algorithms. Asymptotic assumption and notation: We will always assume n is large and analyze algorithms as n goes to infinity: e.g., if $x \leq 1-(1-2/n)^n$, we will just write this as "$x \leq 1-1/e^2$" instead of the more-accurate "$x \leq 1-1/e^2+o(1)$". These suppressed $o(1)$ terms will subtract at most $o(1)$ from our competitive ratios. Another fact to note is that the **competitive ratio** is defined slightly different than usual, for this set of problems (Similar to notation used in [19]). In particular, it is defined as $\frac{\mathbb{E}[ALG]}{\mathbb{E}[OPT]}$. Algorithms can be **adaptive** or **non-adaptive**. When v arrives, an adaptive algorithm can check which neighbors are still available to be matched, but a non-adaptive algorithm cannot.

2.1 LP Benchmark

We will use the following LP to upper bound the optimal offline solution and guide our algorithm. We will first show an LP for the unweighted variant, then describe changes for the vertex-weighted and edge-weighted settings. As usual, we have a variable f_e for each edge. Let $\partial(w)$ be the set of edges adjacent to a vertex $w \in U \cup V$ and let $f_w = \sum_{e \in \partial(w)} f_e$.

$$\begin{aligned}
\text{maximize} \quad & \sum_{e \in E} f_e && && (2.1)\\
\text{subject to} \quad & \sum_{e \in \partial(u)} f_e \leq 1 && \forall u \in U && (2.2)\\
& \sum_{e \in \partial(v)} f_e \leq 1 && \forall v \in V && (2.3)\\
& 0 \leq f_e \leq 1-1/e && \forall e \in E && (2.4)\\
& f_e + f_{e'} \leq 1-1/e^2 && \forall e, e' \in \partial(u), \forall u \in U && (2.5)
\end{aligned}$$

Variants: The objective function is: maximize $\sum_{u \in U} \sum_{e \in \partial(u)} f_e w_u$ in the vertex-weighted variant and maximize $\sum_{e \in E} f_e w_e$ in the edge-weighted variant.

Constraint 2.2 is the matching constraint for vertices in U. Constraint 2.3 is valid because each vertex in V has an arrival rate of 1. Constraint 2.4 is used in [18] and [11]. It captures the fact that the expected number of matches for any edge is at most $1-1/e$. This is valid for large n because the probability that a given vertex doesn't arrive after n rounds is $1/e$. Constraint 2.5 is similar to the previous one, but for pairs of edges. For any two neighbors of a given $u \in U$, the probability that neither of them arrive is $1/e^2$. Therefore, the sum of variables for any two distinct edges in $\partial(u)$ cannot exceed $1-1/e^2$. Notice that constraints 2.4 and 2.5 reduces the gap between the optimal LP solution and the performance

[1] The edge realization process is independent from one another. At each step, the algorithm "probes" the edge. With probability p_e the edge exists and with remaining probability it doesn't. Once realization of an edge is determined, it doesn't change for the rest of the algorithm

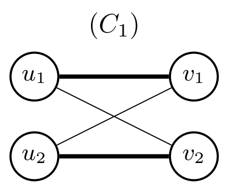

Figure 1 This cycle is the source of the negative result described by Jaillet and Lu [12]. Thick edges have $f_e = 2/3$ while thin edges have $f_e = 1/3$.

of the optimal online algorithm. In fact, without constraint 2.4, we cannot in general achieve a competitive ratio better than $1 - 1/e$.

2.2 Overview of vertex-weighted algorithm and contributions

A key challenge encountered by [12] was that their special LP could lead to length four cycles of type C_1 shown in Figure 1. In fact, they used this cycle to show that no algorithm could perform better than $1 - 2/e^2 \approx 0.7293$ using their LP. They mentioned that tighter LP constraints such as 2.4 and 2.5 in the LP from Section 2 could avoid this bottleneck, but they did not propose a technique to use them. Note that the $\{0, 1/3, 2/3\}$ solution produced by their LP was an essential component of their Random List algorithm.

We show a randomized rounding algorithm to construct a similar, simplified $\{0, 1/3, 2/3\}$ vector from the solution of a stricter benchmark LP. This allows for the inclusion of additional constraints, most importantly constraint 2.5. Using this rounding algorithm combined with tighter constraints, we will upper bound the probability of a vertex appearing in the cycle C_1 from Figure 1 at $2-3/e \approx 0.89$. (See Lemma 6) Additionally, we show how to deterministically break all other length four cycles which are not of type C_1 without creating any new cycles of type C_1. Finally, we describe an algorithm which utilizes these techniques to improve previous results in both the vertex-weighted and unweighted settings.

For this algorithm, we first solve the LP in Section 2 on the input graph. In Section 4, we show how to use the technique in sub-section 2.6 to obtain a sparse fractional vector. We then present a randomized online algorithm (similar to the one in [12]) which uses the sparse fractional vector as a guide to achieve a competitive ratio of 0.7299. Previously, there was gap between the best unweighted algorithm with a ratio of $1 - 2e^{-2}$ due to [12] and the negative result of $1 - e^{-2}$ due to [18]. We take a step towards closing that gap by showing that an algorithm can achieve $0.7299 > 1 - 2e^{-2}$ for both the unweighted and vertex-weighted variants with integral arrival rates.

2.3 Overview of edge-weighted algorithm and contributions

A challenge that arises in applying the *power of two choices* to this setting is when the same edge (u, v) is included in both matchings M_1 and M_2. In this case, the copy of (u, v) in M_2 can offer no benefit and a second arrival of v is wasted. To use an example from related work, Haeupler *et al.* [11] choose two matchings in the following way. M_1 is attained by solving an LP with constraints 2.2, 2.3 and 2.4 and rounding to an integral solution. M_2 is constructed by finding a maximum weight matching and removing any edges which have already been included in M_1. A key element of their proof is showing that the probability of an edge being removed from M_2 is at most $1 - 1/e \approx 0.63$.

The approach in this paper is to construct two or three matchings together in a correlated manner to reduce the probability that some edge is included in all matchings. We will show a general technique to construct an ordered set of k matchings where k is an easily adjustable parameter. For $k = 2$, we show that the probability of an edge appearing in both M_1 and M_2 is at most $1 - 2/e \approx 0.26$.

For the algorithms presented, we first solve an LP on the input graph. We then round the LP solution vector to a sparse integral vector and use this vector to construct a randomly ordered set of matchings which will guide our algorithm during the online phase. We begin Section 3 with a simple warm-up algorithm which uses a set of two matchings as a guide to achieve a 0.688 competitive ratio, improving the best known result for this problem. We follow it up with a slight variation that improves the ratio to 0.7 and a more complex 0.705-competitive algorithm which relies on a convex combination of a 3-matching algorithm and a separate *pseudo-matching* algorithm.

2.4 Overview of non-integral arrival rates with stochastic rewards contributions

This algorithm is presented in Section 5. We believe the known I.I.D. model with stochastic rewards is an interesting new direction motivated by the work of [20] and [21] in the adversarial model. We introduce a new, more general LP specifically for this setting and show that a simple algorithm using the LP solution directly can achieve a competitive ratio of $1 - 1/e$. In [21], it is shown that no randomized algorithm can achieve a ratio better than 0.62 $< 1 - 1/e$ in the adversarial model. Hence, achieving a $1 - 1/e$ for the i.i.d. model shows that this lower bound does not extend to this model.

In Section 6, we extend this simple algorithm[2] to the b-matching generalization of this problem where each offline vertex u can match with up to b arriving vertices. We show that our algorithm achieves a competitive ratio of at least $1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$ for any given $\epsilon > 0$. Note that this result makes progress on Open Question 14 in the online matching and ad allocation survey [19] which asks about stochastic rewards in non-adversarial models.

2.5 Summary of our contributions

▶ **Theorem 1.** *For vertex-weighted online stochastic matching with integral arrival rates, online algorithm* VW *achieves a competitive ratio of at least* 0.7299.

▶ **Theorem 2.** *For edge-weighted online stochastic matching with integral arrival rates, there exists an algorithm which achieves a competitive ratio of at least* 0.7 *and algorithm* EW$[q]$ *with* $q = 0.149251$ *achieves a competitive ratio of at least* 0.70546.

▶ **Theorem 3.** *For edge-weighted online stochastic matching with arbitrary arrival rates and stochastic rewards, online algorithm* SM (4) *achieves a competitive ratio of* $1 - 1/e$.

▶ **Theorem 4.** *For edge-weighted online stochastic b-matching with arbitrary arrival rates and stochastic rewards, online algorithm* SM$_\mathsf{b}$ (5) *achieves a competitive ratio of at least* $1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$ *for any given* $\epsilon > 0$.

[2] Recently, we have come to know that the result in Section 6 can be obtained as a special case of [3]. Our approach gives an alternative, and a simpler algorithm for this special case.

b-matching, Stochastic Rewards (Section 6)	N/A	$1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$

2.6 LP rounding technique

For the algorithms presented, we will first solve the benchmark LP in sub-section 2.1 for the input instance to get a fractional solution vector $\mathbf{f}$. We then round $\mathbf{f}$ to an integral solution $\mathbf{F}$ using a two step process we call $\mathsf{DR}[\mathbf{f}, k]$. The first step is to multiply $\mathbf{f}$ by k. The second step is to apply the dependent rounding techniques of Gandhi, Khuller, Parthasarathy and Srinivasan [10] to this new vector. In this paper, we will always choose k to be 2 or 3. This will help us handle the fact that a vertex in V may appear more than once, but probably not more than two or three times.

While dependent rounding is typically applied to values between 0 and 1, the useful properties extend naturally to our case in which kf_e may be greater than 1 for some edge e. To understand this process, it is easiest to imagine splitting each kf_e into two edges with the integer value $f'_e = \lfloor kf_e \rfloor$ and fractional value $f''_e = kf_e - \lfloor kf_e \rfloor$. The former will remain unchanged by the dependent rounding since it is already an integer while the latter will be rounded to 1 with probability f''_e and 0 otherwise. Our final value F_e would be the sum of those two rounded values. The two properties of dependent rounding we will use are:

1. **Marginal distribution:** For every edge e, let $p_e = kf_e - \lfloor kf_e \rfloor$. Then, $\Pr[F_e = \lceil kf_e \rceil] = p_e$ and $\Pr[F_e = \lfloor kf_e \rfloor] = 1 - p_e$.
2. **Degree-preservation:** For any vertex $w \in U \cup V$, let its fractional degree kf_w be $\sum_{e \in \partial(w)} kf_e$ and integral degree be the random variable $F_w = \sum_{e \in \partial(w)} F_e$. Then $F_w \in \{\lfloor kf_w \rfloor, \lceil kf_w \rceil\}$.

3 Edge-weighted matching with integral arrival rates

3.1 A simple 0.688-competitive algorithm

As a warm-up, we will describe a simple algorithm which achieves a competitive ratio of 0.688 and introduces key ideas in our approach. We begin by solving the LP in sub-section 2.1 to get a fractional solution vector $\mathbf{f}$ and applying $\mathsf{DR}[\mathbf{f}, 2]$ as described in Subsection 2.6 to get an integral vector $\mathbf{F}$. We construct a bipartite graph $G_{\mathbf{F}}$ with F_e copies of each edge e. Note that $G_{\mathbf{F}}$ will have max degree 2 since for all $w \in U \cup V$, $F_w \leq \lceil 2f_w \rceil \leq 2$ and therefore we can decompose it into two matchings using *Hall's Theorem*. Finally, we randomly permute the two matchings into an ordered pair of matchings, $[M_1, M_2]$. These matchings serve as a guide for the online phase of the algorithm, similar to [11].

The entire warm-up algorithm for the edge-weighted model, denoted by EW_0, is summarized in Algorithm 1.

```
Algorithm 1: [EW_0]
1 Construct and solve the benchmark LP in sub-section 2.1 for the input instance.
2 Let $\mathbf{f}$ be an optimal fraction solution vector. Call $\mathsf{DR}[\mathbf{f}, 2]$ to get an integral vector $\mathbf{F}$.
3 Create the graph $G_{\mathbf{F}}$ with $F_e$ copies of each edge $e \in E$ and decompose it into two
    matchings.
4 Randomly permute the matchings to get a random ordered pair of matchings, say
    $[M_1, M_2]$.
5 When a vertex $v$ arrives for the first time, try to assign $v$ to some $u_1$ if $(u_1, v) \in M_1$;
    when $v$ arrives for the second time, try to assign $v$ to some $u_2$ if $(u_2, v) \in M_2$.
6 When a vertex $v$ arrives for the third time or more, do nothing in that step.
```

3.1.1 Analysis of algorithm EW_0

We will show that EW_0 (Algorithm 1) achieves a competitive ratio of 0.688. Let $[M_1, M_2]$ be our randomly ordered pair of matchings. Note that there might exist some edge e which appears in both matchings if $f_e > 1/2$. Therefore, we consider three types of edges. We say an edge e is of type ψ_1, denoted by $e \in \psi_1$, iff e appears *only* in M_1. Similarly $e \in \psi_2$, iff e appears *only* in M_2 and $e \in \psi_b$, iff e appears in *both* M_1 and M_2.

Let P_1, P_2, P_b be the probabilities of getting matched for $e \in \psi_1$, $e \in \psi_2$, and $e \in \psi_b$ respectively. According to the result in Haeupler *et al.* [11], the respective values are shown as follows.

► **Lemma 5.** *(Proof details in Section 3 of [11]) Given M_1 and M_2, in the worst case* (1) $P_1 = 0.5808$*;* (2) $P_2 = 0.14849$ *and* (3) $P_b = 0.632$.

Proof. (Analysis for EW_0) Consider following two cases.

Case 1: $0 \leq f_e \leq 1/2$: By the marginal distribution property of dependent rounding, there can be at most one copy of e in $G_{\mathbf{F}}$ and the probability of including e in $G_{\mathbf{F}}$ is $2f_e$. Since an edge in $G_{\mathbf{F}}$ can appear in either M_1 or M_2 with equal probability 1/2, we have $\Pr[e \in \psi_1] = \Pr[e \in \psi_2] = f_e$. Thus, the ratio is $(f_e P_1 + f_e P_2)/f_e = P_1 + P_2 = 0.729$.

Case 2: $1/2 \leq f_e \leq 1 - 1/e$: Similarly, by marginal distribution, $\Pr[e \in \psi_b] = \Pr[F_e = \lceil 2f_e \rceil] = 2f_e - \lfloor 2f_e \rfloor = 2f_e - 1$. It follows that $\Pr[e \in \psi_1] = \Pr[e \in \psi_2] = (1/2)(1 - (2f_e - 1)) = 1 - f_e$. Thus, the ratio is $((1 - f_e)(P_1 + P_2) + (2f_e - 1)P_b)/f_e \geq 0.688$, where the WS is for an edge e with $f_e = 1 - 1/e$. ◄

3.2 A 0.7-competitive algorithm

In this section, we describe an improvement upon the previous warm-up algorithm to get a competitive ratio of 0.7. We start by making an observation about the performance of the warm-up algorithm. After solving the LP, let edges with $f_e > 1/2$ be called *large* and edges with $f_e \leq 1/2$ be called *small*. Let L and S, be the sets of large and small edges, respectively. Notice that in the previous analysis, small edges achieved a much higher competitive ratio of 0.729 versus 0.688 for large edges. This is primarily due to the fact that we may get two copies of a large edge in $G_{\mathbf{F}}$. In this case, the copy in M_1 has a better chance of being matched, since there is no edge which can block it, but the copy that is in M_2 has no chance of being matched.

To correct this imbalance, we make an additional modification to the f_e values *before* applying $\mathsf{DR}[\mathbf{f}, k]$. The rest of the algorithm is exactly the same. Let η be a parameter to be optimized later. For all large edges $\ell \in L$ such that $f_\ell > 1/2$, we set $f_\ell = f_\ell + \eta$. For all small edges $s \in S$ which are adjacent to some large edge, let $\ell \in L$ be the largest edge adjacent to s such that $f_\ell > 1/2$. Note that it is possible for e to have two large neighbors, but we only care about the largest one. We set $f_s = f_s\left(\frac{1-(f_\ell+\eta)}{1-f_\ell}\right)$.

In other words, we increase the values of large edges while ensuring that for all $w \in U \cup V$, $f_w \leq 1$ by reducing the values of neighboring small edges proportional to their original values. Note that it is not possible for two large edges to be adjacent since they must both have $f_e > 1/2$. For all other small edges which are not adjacent to any large edges, we leave their values unchanged. We then apply $\mathsf{DR}[\mathbf{f}, 2]$ to this new vector, multiplying by 2 and applying dependent rounding as before.

3.2.1 Analysis

We can now prove Theorem 2.

Proof. As in the warm-up analysis, we'll consider large and small edges separately

- $0 \leq f_s \leq \frac{1}{2}$: Here we have two cases
  - Case 1: s is not adjacent to any large edges. In this case, the analysis is the same as the warm-up algorithm and we still get a 0.729 competitive ratio for these edges.
  - Case 2: s is adjacent to some large edge ℓ. For this case, let f_ℓ be the value of the largest neighboring edge in the original LP solution. Then s achieves a ratio of

$$f_s\left(\frac{1-(f_\ell+\eta)}{1-f_\ell}\right)(0.1484+0.5803)/f_s = \left(\frac{1-(f_\ell+\eta)}{1-f_\ell}\right)(0.1484+0.5803)$$

  Note that for $f_\ell \in [0,1)$ this is a decreasing function with respect to f_ℓ. So the worst case is $f_\ell = 1-1/e$ and we have a ratio of

$$\left(\frac{1-(1-1/e+\eta)}{1-(1-1/e)}\right)(0.1484+0.5803) = \left(\frac{1/e-\eta}{1/e}\right)(0.1484+0.5803)$$

- $\frac{1}{2} < f_\ell \leq 1-\frac{1}{e}$: Here, the ratio is $((1-(f_\ell+\eta))(P_1+P_2)+(2(f_\ell+\eta)-1)P_b)/f_\ell$, where the WS is for an edge e with $f_\ell = 1-1/e$ since this is a decreasing function with respect to f_ℓ.

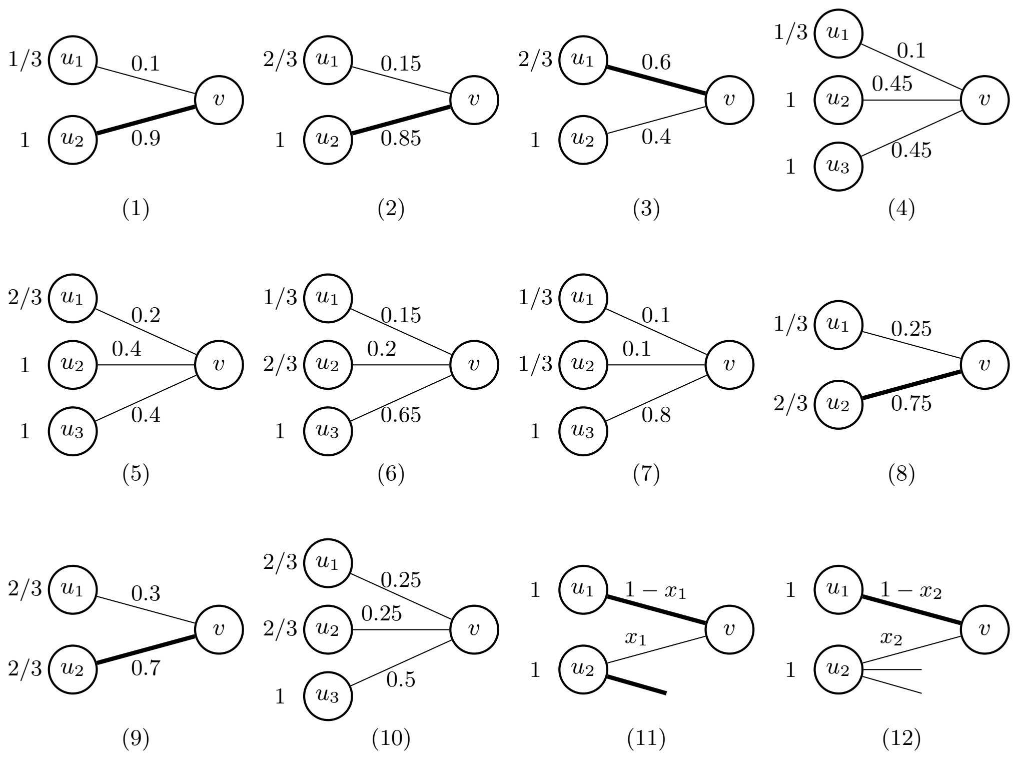
Choosing the optimal value of $\eta = 0.0142$, yields an overall competitive ratio of 0.7 for this new algorithm. ◀

3.3 A 0.705-competitive algorithm

The details of algorithm and the proof of Theorem 2 can be found in the full version of this paper.

4 Vertex-weighted stochastic I.I.D. matching with integral arrival rates

In this section, we will consider vertex-weighted online stochastic matching on a bipartite graph G under known $I.I.D.$ model with integral arrival rates. We will present an algorithm in which each u has a competitive ratio of at least 0.72998. Recall that after invoking $\mathsf{DR}[\mathbf{f}, 3]$,



1/3 u1 0.1 v 1 u2 0.9 (1)
2/3 u1 0.15 v 1 u2 0.85 (2)
2/3 u1 0.6 v 1 u2 0.4 (3)
1/3 u1 0.1 1 u2 0.45 v 1 u3 0.45 (4)
2/3 u1 0.2 1 u2 0.4 v 1 u3 0.4 (5)
1/3 u1 0.15 2/3 u2 0.2 v 1 u3 0.65 (6)
1/3 u1 0.1 1/3 u2 0.1 v 1 u3 0.8 (7)
1/3 u1 0.25 v 2/3 u2 0.75 (8)
2/3 u1 0.3 v 2/3 u2 0.7 (9)
2/3 u1 0.25 2/3 u2 0.25 v 1 u3 0.5 (10)
1 u1 1 − x1 x1 v 1 u2 (11)
1 u1 1 − x2 x2 v 1 u2 (12)

Figure 2 Illustration for second modification to $\mathbf{H}$. The value assigned to each edge represents the value after the second modification. Here, $x_1 = 0.2744$ and $x_2 = 0.15877$.

we can obtain a (*random*) integral vector $\mathbf{F}$ with $F_e \in \{0, 1, 2\}$. Define $\mathbf{H} = \mathbf{F}/3$ and let $G_{\mathbf{H}}$ be the graph induced by $\mathbf{H}$ and each edge takes the value $H_e \in \{0, 1/3, 2/3\}$.

In this section, we focus on the sparse graph $G_{\mathbf{H}}$. The main steps of the algorithm are:

1. Solve the vertex-weighted benchmark LP in sub-section 2.1. Let $\mathbf{f}$ be an optimal solution vector.
2. Invoke DR[$\mathbf{f}$, 3] to obtain an integral vector $\mathbf{F}$ and a fractional vector $\mathbf{H}$ with $\mathbf{H} = \mathbf{F}/3$.
3. Apply a series of modifications to $\mathbf{H}$ and transform it to another solution $\mathbf{H}'$. See sub-section 4.1.
4. Run the randomized list algorithm (RLA) [12] induced by $\mathbf{H}'$ on the graph $G_{\mathbf{H}}$. See the details in full version of this paper.

The WS for vertex-weighted case in [12] is shown in Figure 3, which arrives at node u with a competitive ratio of 0.725. From their analysis, we find node u_1 has a competitive ratio of at least 0.736. Hence, we *boost* the performance of u at the cost of u_1. In other words, we increase the value of $H_{(u,v1)}$ and decrease the value $H_{(u_1,v_1)}$. Case (10) and (11) in Figure 2 illustrates this. After this modification, the new WS for vertex-weighted is now the C_1 cycle shown in Figure 1. In fact, this is the WS for the unweighted case in [12]. However, Lemma 6 and the cycle breaking algorithm, implies that C_1 cycle can be avoided with probability at least $3/e - 1$. This helps us improve the ratio even for the unweighted case in [12].

▶ **Lemma 6.** *For any given $u \in U$, u appears in a C_1 cycle after* DR[$\boldsymbol{f}$, 3] *with probability at most $2 - 3/e$.*

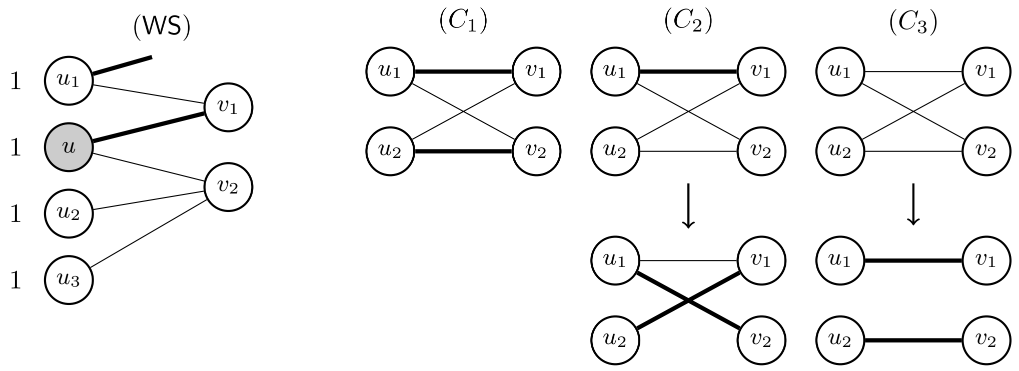


Figure 3 Left: The WS for Jaillet and Lu [12] for their vertex-weighted case. Right: The three possible types of cycles of length 4 after applying DR$[\mathbf{f}, 3]$. Thin edges have $H_e = 1/3$ and thick edges have $H_e = 2/3$.

Proof. Consider the graph $G_{\mathbf{H}}$ obtained after DR$[\mathbf{f}, 3]$. Notice that for some vertex u to appear in a C_1 cycle, it must have a neighboring edge with $H_e = 2/3$. Now we try to bound the probability of this event. It is easy to see that for some $e \in \partial(u)$ with $f_e \leq 1/3$, $F_e \leq 1$ after DR$[\mathbf{f}, 3]$, and hence $H_e = F_e/3 \leq 1/3$. Thus only those edges $e \in \partial(u)$ with $f_e > 1/3$ will possibly be rounded to $H_e = 2/3$. Note that, there can be at most two such edges in $\partial(u)$, since $\sum_{e \in \partial(u)} f_e \leq 1$. Hence, we have the following two cases.

Case 1: $\partial(u)$ contains only one edge e with $f_e > 1/3$. Let $q_1 = \Pr[H_e = 1/3]$ and $q_2 = \Pr[H_e = 2/3]$ after DR$[\mathbf{f}, 3]$. By DR$[\mathbf{f}, 3]$, we know that $\mathbb{E}[H_e] = \mathbb{E}[F_e]/3 = q_2(2/3) + q_1(1/3) = f_e$.
Notice that $q_1 + q_2 = 1$ and hence $q_2 = 3f_e - 1$. Since this is an increasing function of f_e and $f_e \leq 1 - 1/e$ from LP constraint 2.4, we have $q_2 \leq 3(1 - 1/e) - 1 = 2 - 3/e$.

Case 2: $\partial(u)$ contains two edges e_1 and e_2 with $f_{e_1} > 1/3$ and $f_{e_2} > 1/3$. Let q_2 be the probability that after DR$[\mathbf{f}, 3]$, either $H_{e_1} = 2/3$ or $H_{e_2} = 2/3$. Note that, these two events are mutually exclusive since $H_u \leq 1$. Using the analysis from case 1, it follows that $q_2 = (3f_{e_1} - 1) + (3f_{e_2} - 1) = 3(f_{e_1} + f_{e_2}) - 2$.
From LP constraint 2.5, we know that $f_{e_1} + f_{e_2} \leq 1 - 1/e^2$, and hence $q_2 \leq 3(1 - 1/e^2) - 2 < 2 - 3/e$. ◀

4.1 Two kinds of Modifications to H

The first modification is to break the cycles deterministically.

There are three possible cycles of length 4 in the graph $G_{\mathbf{H}}$, denoted C_1, C_2, and C_3. In [12], they give an efficient way to break C_2 and C_3, as shown in Figure 3. Cycle C_1 cannot be modified further and hence, is the bottleneck for their unweighted case. Notice that, while breaking the cycles of C_2 and C_3, new cycles of C_1 can be created in the graph. Since our randomized construction of solution $\mathbf{H}$ gives us control on the probability of cycles C_1 occurring, we would like to break C_2 and C_3 in a controlled way, so as to not create any new C_1 cycles. This procedure is summarized in Algorithm 2. The proof of Lemma 7 can be found in the full version of this paper.

▶ **Lemma 7.** *After applying Algorithm 2 to $G_{\mathbf{H}}$, we have (1) the value H_w is preserved for each $w \in U \cup V$; (2) no cycle of type C_2 or C_3 exists; (3) no new cycle of type C_1 is added.*

Algorithm 2: [Cycle breaking algorithm] Offline Phase

```
1 While there is some cycle of type $C_2$ or $C_3$, Do:
2 Break all cycles of type $C_2$.
3 Break one cycle of type $C_3$ and return to the first step.
```

The second modification is to decrease the rates of lists associated with those nodes u with $H_u = 1/3$ or $H_u = 2/3$ and increase the rates of lists associated with nodes u with $H_u = 1$. All details can be found in the full version. Let $\mathbf{H}'$ be the solution vector obtained by applying two kinds of modifications to $\mathbf{H}$. The algorithm for the vertex-weighted case, denoted by VW, is summarized below. The detailed analysis can be found in the full version of this paper.

Algorithm 3: VW [Vertex Weighted]

```
1 Construct and solve the LP in sub-section 2.1 for the input instance.
2 Invoke DR[$\mathbf{f}$, 3] to output $\mathbf{F}$ and $\mathbf{H}$. Apply the two kinds of modifications to morph $\mathbf{H}$
   to $\mathbf{H}'$.
3 Run RLA[$\mathbf{H}'$] on the graph $G_{\mathbf{H}}$.
```

5 Non-integral arrival rates with stochastic rewards

The setting here is strictly generalized over the previous sections in the following ways. Firstly, it allows an arbitrary arrival rate (say r_v) which can be fractional for each stochastic vertex v. Notice that, $\sum_v r_v = n$ where n is the total number of rounds.

Secondly, each $e = (v, u) \in E$ is associated with a value p_e, which indicates the probability that edge $e = (u, v)$ is present when we assign v to u. We assume this process is independent of the stochastic arrival of each v. We will show that the simple non-adaptive algorithm introduced in [11] can be extended to this general case. This achieves a competitive ratio of $(1 - \frac{1}{e})$. Note that Manshadi *et al.* [18] show that no non-adaptive algorithm can possibly achieve a ratio better than $(1 - 1/e)$ for the non-integral arrival rates, even for the case of all $p_e = 1$. Thus, our algorithm is an optimal non-adaptive algorithm for this model.

$$\max \quad \sum_{e \in E} w_e f_e p_e : \tag{5.1}$$

$$\text{s.t.} \quad \sum_{e \in \partial(u)} f_e p_e \le 1, \forall u \in U \tag{5.2}$$

$$\sum_{e \in \partial(v)} f_e \le r_v, \forall v \in V \tag{5.3}$$

We use a similar LP as [12] for the case of non-integral arrival rates. For each $e \in E$, let f_e be the probability that e gets matched in the offline optimal algorithm.

Our algorithm is summarized in Algorithm 4. Notice that the last constraint ensures that step 2 in the algorithm is valid. Let us now prove theorem 3.

Proof. Let $B(u, t)$ be the event that u is safe at beginning of round t and $A(u, t)$ to be the event that vertex u is matched during the round t conditioned on $B(u, t)$. From

```
Algorithm 4: SM
1 Construct and solve LP (5.1). WLOG assume $\{f_e | e \in E\}$ is an optimal solution.
2 When a vertex $v$ arrives, assign $v$ to each of its neighbor $u$ with a probability $\frac{f_{(u,v)}}{r_v}$.
```

the algorithm, we know $\Pr[A(u,t)] \le \sum_{v \sim u} \frac{r_v}{n} \frac{f_{u,v}}{r_v} p_e \le \frac{1}{n}$, which follows by $Pr[B(u,t)] = \Pr\left[\bigwedge_{i=1}^{t-1}(\neg A(u,i))\right] \ge \left(1-\frac{1}{n}\right)^{t-1}$.

Consider an edge $e = (u,v)$ in the graph. Notice that the probability that e gets matched in SM should be

$$\begin{aligned}\Pr[e \text{ is matched}] &= \sum_{t=1}^{n} \Pr[\text{v arrives at } t \text{ and } B(u,t)\ ] \cdot \frac{f_e p_e}{r_v} \\ &\ge \sum_{t=1}^{n} \left(1-\frac{1}{n}\right)^{t-1} \frac{r_v}{n} \frac{f_e p_e}{r_v} \ge \left(1-\frac{1}{e}\right) f_e p_e\,.\end{aligned}$$ ◀

6 Extension to b-matching with stochastic rewards

In this section, we further generalize the model in Section 5 to the case where each u in the offline set U has a uniform integral capacity b (i.e., each vertex u can be matched at most b times). Otherwise, we retain the same setting as Section 5; we allow non-integral arrival rates and stochastic rewards. We will generalize the simple algorithm used in the previous setting (i.e., Section 5) to this new setting. Consider the following updated LP:

$$\max \quad \sum_{e \in E} w_e f_e p_e : \tag{6.1}$$

$$\text{s.t.} \quad \sum_{e \in \partial(u)} f_e p_e \le b, \forall u \in U \tag{6.2}$$

$$\sum_{e \in \partial(v)} f_e \le r_v, \forall v \in V \tag{6.3}$$

We modify Algorithm 4 for the b-matching problem as shown in Algorithm 5. Let us now prove Theorem 4.

```
Algorithm 5: SM_b
1 Construct and solve LP (6.1). WLOG assume $\{f_e | e \in E\}$ is an optimal solution.
2 When a vertex $v$ arrives, assign $v$ to each of its neighbor $u$ with a probability $\frac{f_{(u,v)}}{r_v}$.
```

Proof. The proof is similar to that of Theorem 3. Let A_t be the number of times u has been matched at the beginning of round t.

Let $B(u,t)$ be the event that u is safe at the beginning of round t, which is defined as $A_t \le b-1$. For any given edge e, let X_e be the number of times that e gets matched over the n rounds. Thus we have

$$\mathbb{E}[X_e] = \sum_{t=1}^{n} \Pr[B(u,t)] \frac{r_v}{n} \frac{f_e}{r_v} p_e = \frac{f_e p_e}{n} \sum_{t=1}^{n} \Pr[A_t \le b-1]\,.$$

Now we upper bound the value of $\Pr[A_t \geq b]$. For each $1 \leq i \leq t$, let Z_i be the indicator random variable for u to be matched during round i. Thus $A_{t+1} = \sum_{i=1}^{t} Z_i$. Notice that for each i, we have

$$\mathbb{E}[Z_i] \leq \sum_{v \sim u} \frac{r_v}{n} \frac{f_{(u,v)}}{r_v} p_{(u,v)} \leq \frac{b}{n}.$$

It follows that for any $t \leq n(1-\tau)$ with $0 < \tau < 1$, we have $\mathbb{E}[A_{t+1}] \leq (1-\tau)b$. By applying Chernoff-Hoeffding bounds, we get $\Pr[A_{t+1} \geq b] \leq e^{-b\tau^2/3}$. Therefore

$$\begin{aligned}\mathbb{E}[X_e] &= \frac{f_e p_e}{n} \sum_{t=1}^{n} \Pr[A_t \leq b-1] \\ &\geq \frac{f_e p_e}{n} \sum_{t=1}^{n(1-\tau)} (1 - e^{-b\tau^2/3}) = f_e p_e (1-\tau)(1 - e^{-b\tau^2/3})\end{aligned}$$

For any given $\epsilon > 0$, choose $\tau = b^{-1/2+\epsilon}$ to get a competitive ratio of $1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$. ◀

7 Conclusion and Future Directions

In this paper, we gave improved algorithms for the Edge-Weighted and Vertex-Weighted models. Previously, there was a gap between the best unweighted algorithm with a ratio of $1 - 2e^{-2}$ due to [12] and the negative result of $1 - e^{-2}$ due to [18]. We took a step towards closing that gap by showing that an algorithm can achieve $0.7299 > 1 - 2e^{-2}$ for both the unweighted and vertex-weighted variants with integral arrival rates. In doing so, we made progess on Open Questions 3 and 4 in the online matching and ad allocation survey [19]. This was possible because our approach of rounding to a simpler fractional solution allowed us to employ a stricter LP. For the edge-weighted variant, we showed that one can significantly improve the power of two choices approach by generating two matchings from the same LP solution. For the variant with edge weights, non-integral arrival rates, and stochastic rewards, we presented a $(1-1/e)$-competitive algorithm. This showed that the $0.62 < 1 - 1/e$ bound given in [21] for the adversarial model with stochastic rewards does not extend to the known I.I.D. model. Furthermore, we considered the online edge-weighted b-matching problem with stochastic rewards under the known IID setting. We gave a very simple non-adaptive algorithm which achieves a ratio of $1 - b^{-1/2+\epsilon} - O(e^{-b^{2\epsilon}/3})$ for any given $\epsilon > 0$.

A natural next step in the edge-weighted setting is to use an *adaptive* strategy. For the vertex-weighted problem, one can easily see that the stricter LP we use still has a gap. In addition, we only utilize fractional solutions $\{0, 1/3, 2/3\}$. However, dependent rounding gives solutions in $\{0, 1/k, 2/k, \ldots, \lceil k(1-1/e) \rceil / k\}$; allowing for random lists of length greater than three. Stricter LPs and longer lists could both yield improved results. In the stochastic rewards model with non-integral arrival rates, an open question is to either improve upon the $\left(1 - \frac{1}{e}\right)$ ratio or consider a simpler model with integral arrival rates and improve the ratio for this restricted model. Lastly, there is a gap between our result for b-matching with stochastic rewards and the results of [7] and [2] for similar problems with deterministic rewards. It would be nice to see a result for this problem that is $1 - O(k^{-1/2})$.

Abstract

The k-SUM problem is given n input real numbers to determine whether any k of them sum to zero. The problem is of tremendous importance in the emerging field of complexity theory within P, and it is in particular open whether it admits an algorithm of complexity $O(n^c)$ with $c < \lceil \frac{k}{2} \rceil$. Inspired by an algorithm due to Meiser (1993), we show that there exist linear decision trees and algebraic computation trees of depth $O(n^3 \log^2 n)$ solving k-SUM. Furthermore, we show that there exists a randomized algorithm that runs in $\tilde{O}(n^{\lceil \frac{k}{2} \rceil + 8})$ time, and performs $O(n^3 \log^2 n)$ linear queries on the input. Thus, we show that it is possible to have an algorithm with a runtime almost identical (up to the +8) to the best known algorithm but for the first time also with the number of queries on the input a polynomial that is independent of k. The $O(n^3 \log^2 n)$ bound on the number of linear queries is also a tighter bound than any known algorithm solving k-SUM, even allowing unlimited total time outside of the queries. By simultaneously achieving few queries to the input without significantly sacrificing runtime vis-à-vis known algorithms, we deepen the understanding of this canonical problem which is a cornerstone of complexity-within-P.

We also consider a range of tradeoffs between the number of terms involved in the queries and the depth of the decision tree. In particular, we prove that there exist $o(n)$-linear decision trees of depth $\tilde{O}(n^3)$ for the k-SUM problem.

1 Introduction

The k-SUM problem is defined as follows: given a collection of n real numbers decide whether any k of them sum to zero, where k is a constant. It is a fixed-parameter version of the subset-sum problem, a standard NP-complete problem. The k-SUM problem, and in particular the special case of 3SUM, has proved to be a cornerstone of the fine-grained complexity program aiming at the construction of a complexity theory for problems in P. In particular, there are deep connections between the complexity of k-SUM, the Strong

Exponential Time Hypothesis [30, 12], and the complexity of many other major problems in P [20, 7, 28, 29, 5, 2, 23, 25, 1, 3, 13].

It has been long known that the k-SUM problem can be solved in time $O(n^{\frac{k}{2}} \log n)$ for even k, and $O(n^{\frac{k+1}{2}})$ for odd k. Erickson [17] proved a near-matching lower bound in the k-linear decision tree model. In this model, the complexity is measured by the depth of a decision tree, every node of which corresponds to a query of the form $q_{i_1} + q_{i_2} + \cdots + q_{i_k} \leq^? 0$, where $q_1, q_2, \ldots, q_n$ are the input numbers. In a recent breakthrough paper, Grønlund and Pettie [23] showed that in the $(2k-2)$-linear decision tree model, where queries test the sign of weighted sums of up to $2k-2$ input numbers, only $O(n^{\frac{k}{2}}\sqrt{\log n})$ queries are required for odd values of k. In particular, there exists a 4-linear decision tree for 3SUM of depth $\tilde{O}(n^{\frac{3}{2}})$ (here the notation $\tilde{O}$ ignores polylogarithmic factors), while every 3-linear decision tree has depth $\Omega(n^2)$ [17]. This indicates that increasing the size of the queries, defined as the maximum number of input numbers involved in a query, can yield significant improvements on the depth of the minimal-height decision tree. Ailon and Chazelle [4] slightly extended the range of query sizes for which a nontrivial lower bound could be established, elaborating on Erickson's technique.

It has been well established that there exist nonuniform polynomial-time algorithms for the subset-sum problem. One of them was described by Meiser [26], and is derived from a data structure for point location in arrangements of hyperplanes using the bottom vertex decomposition. This algorithm can be cast as the construction of a linear decision tree in which the queries have non-constant size.

1.1 Our results

In Section 3, we show the existence of an n-linear decision tree of depth $\tilde{O}(n^3)$ for k-SUM using a careful implementation of Meiser's algorithm [26]. Although the high-level algorithm itself is not new, we refine the implementation and analysis for the k-SUM problem.[1] Meiser presented his algorithm as a general method of point location in m given n-dimensional hyperplanes that yielded a $\tilde{O}(n^4 \log m)$-depth algebraic computation tree; when viewing the k-SUM problem as a point location problem, m is $O(n^k)$ and thus Meiser's algorithm can be viewed as giving a $\tilde{O}(n^4)$-depth algebraic computation tree. We show that while the original algorithm was cast as a nonuniform polynomial-time algorithm, it can be implemented in the linear decision tree model with an $\tilde{O}(n^3)$ upper bound. Moreover, this result implies the same improved upper bound on the depth of algebraic computation trees for the k-SUM problem, as shown in Appendix B.

There are two subtleties to this result. The first is inherent to the chosen complexity model: even if the number of queries to the input is small (in particular, the degree of the polynomial complexity is invariant on k), the time required to *determine which queries should be performed* may be arbitrary. In a naïve analysis, we show it can be trivially bounded by $\tilde{O}(n^{k+2})$. In Section 4 we present an algorithm to choose which decisions to perform whereby the running time can be reduced to $\tilde{O}(n^{\frac{k}{2}+8})$. Hence, we obtain an $\tilde{O}(n^{\frac{k}{2}+8})$ time randomized algorithm in the RAM model expected to perform $\tilde{O}(n^3)$ linear queries on the input[2].

[1] After submitting this manuscript, we learned from a personal communication with Hervé Fournier that a similar analysis appears in his PhD thesis [18] (in French).

[2] Grønlund and Pettie [23] mention the algorithms of Meyer auf der Heyde [27] and Meiser [26], and state "(...) it was known that all k-LDT problems can be solved by n-linear decision trees with depth $O(n^5 \log n)$ [26], or with depth $O(n^4 \log(nK))$ if the coefficients of the linear function are integers with

Table 1 Complexities of our new algorithms for the k-SUM problem. The query size is the maximum number of elements of the input that can be involved in a single linear query. The number of blocks is a parameter that allows us to change the query size (see Section 5). The origin of the constant in the exponent of the time complexity is due to Lemma 9. We conjecture it can be reduced, though substantial changes in the analysis will likely be needed to do so.

	# blocks	query size	# queries	time
Theorem 3	1	n	$\tilde{O}(n^3)$	$\tilde{O}(n^{\lceil \frac{k}{2} \rceil + 8})$
Theorem 11	b	$k\lceil \frac{n}{b} \rceil$	$\tilde{O}(b^{k-4}n^3)$	$\tilde{O}(b^{\lfloor \frac{k}{2} \rfloor - 9}n^{\lceil \frac{k}{2} \rceil + 8})$
Corollary 12	$b = \Theta(\text{polylog}(n))$	$o(n)$	$\tilde{O}(n^3)$	$\tilde{O}(n^{\lceil \frac{k}{2} \rceil + 8})$
Corollary 13	$b = \Theta(n^{\alpha})$	$O(n^{1-\alpha})$	$\tilde{O}(n^{3+(k-4)\alpha})$	$\tilde{O}(n^{(1+\alpha)\frac{k}{2} + 8.5})$

The second issue we address is that the linear queries in the above algorithm may have size n, that is, they may use all the components of the input. The lower bound of Erickson shows that if the queries are of minimal size, the number of queries cannot be a polynomial independent of k such as what we obtain, so non-minimal query size is clearly essential to a drastic reduction in the number of queries needed. This gives rise to the natural question as to what is the relation between query size and number of queries. In particular, one natural question is whether queries of size less than n would still allow the problem to be solved using a number of queries that is a polynomial independent of k. We show that this is possible; in Section 5, we introduce a range of algorithms exhibiting an explicit tradeoff between the number of queries and their size. Using a blocking scheme, we show that we can restrict to $o(n)$-linear decision trees. We also give a range of tradeoffs for $O(n^{1-\alpha})$-linear decision trees. Although the proposed algorithms still involve nonconstant-size queries, this is the first time such tradeoffs are explicitly tackled. Table 1 summarizes our results.

2 Definitions and previous work

2.1 Definitions

We consider the k-SUM problem for $k = O(1)$. In what follows, we use the notation $[n] = \{ 1, 2, \dots, n \}$.

▶ **Problem** (k-SUM). *Given an input vector $q \in \mathbb{R}^n$, decide whether there exists a k-tuple $(i_1, i_2, \dots, i_k) \in [n]^k$ such that $\sum_{j=1}^{k} q_{i_j} = 0$.*

The problem amounts to deciding in n-dimensional space, for each hyperplane H of equation $x_{i_1} + x_{i_2} + \cdots + x_{i_k} = 0$, whether q lies on, above, or below H. Hence this indeed amounts to locating the point q in the arrangement formed by those hyperplanes. We emphasize that the set of hyperplanes depends only on k and n and not on the actual input vector q.

Linear degeneracy testing (k-LDT) is a generalization of k-SUM where we have arbitrary rational coefficients[3] and an independent term in the equations of the hyperplanes.

▶ **Problem** (k-LDT). *Given an input vectors $q \in \mathbb{R}^n$ and $\alpha \in \mathbb{Q}^n$ and constant $c \in \mathbb{Q}$ decide whether there exists a k-tuple $(i_1, i_2, \dots, i_k) \in [n]^k$ such that $c + \sum_{j=1}^{k} \alpha_j q_{i_j} = 0$.*

absolute value at most K [27]. Unfortunately these decision trees are not efficiently constructible. The time required to determine *which* comparisons to make is exponential." We prove that the trees can have depth $\tilde{O}(n^3)$ and that the whole algorithm can run in randomized polynomial-time.

[3] The usual definition of k-LDT allows arbitrary *real* coefficients. However, the algorithm we provide for Lemma 8 needs the vertices of the arrangement of hyperplanes to have rational coordinates.

Our algorithms apply to this more general problem with only minor changes.

The *s-linear decision tree model* is a standard model of computation in which several lower bounds for k-SUM have been proven. In the decision tree model, one may ask well-defined questions to an oracle that are answered “yes” or “no.” For s-linear decision trees, a well-defined question consists of testing the sign of a linear function on at most s numbers $q_{i_1}, \dots, q_{i_s}$ of the input $q_1, \dots, q_n$ and can be written as

$$c + \alpha_1 q_{i_1} + \cdots + \alpha_s q_{i_s} \overset{?}{\leq} 0\,.$$

Each question is defined to cost a single unit. All other operations can be carried out for free but may not examine the input vector q. We refer to n-linear decision trees simply as linear decision trees.

In this paper, we consider algorithms in the standard integer RAM model with $\Theta(\log n)$-size words, but in which the input $q \in \mathbb{R}^n$ is accessible *only* via a linear query oracle. Hence we are not allowed to manipulate the input numbers directly. The complexity is measured in two ways: by counting the total number of queries, just as in the linear decision tree model, and by measuring the overall running time, taking into account the time required to determine the sequence of linear queries. This two-track computation model, in which the running time is distinguished from the query complexity, is commonly used in results on comparison-based sorting problems where analyses of both runtime and comparisons are of interest (see for instance [31, 10, 11]).

2.2 Previous Results

The seminal paper by Gajentaan and Overmars [20] showed the crucial role of 3SUM in understanding the complexity of several problems in computational geometry. Since then, there has been an enormous amount of work focusing on the complexity of 3SUM and this problem is now considered a key tool of complexity-within-P [20, 7, 28, 6, 29, 5, 2, 23, 25, 1, 3, 13]. The current conjecture is that no $O(n^{2-\delta})$-time algorithm exists for 3SUM. It has been known for long that k-SUM is $W[1]$-hard. Recently, it was shown to be $W[1]$-complete by Abboud et al. [1].

In Erickson [17], it is shown that we cannot solve 3SUM in subquadratic time in the 3-linear decision tree model:

▶ **Theorem 1** (Erickson [17]). *The optimal depth of a k-linear decision tree that solves the k-LDT problem is $\Theta(n^{\lceil \frac{k}{2} \rceil})$.*

The proof uses an adversary argument which can be explained geometrically. As we already observed, we can solve k-LDT problems by modeling them as point location problems in an arrangement of hyperplanes. Solving one such problem amounts to determining which cell of the arrangement contains the input point. The adversary argument of Erickson [17] is that there exists a cell having $\Omega(n^{\lceil \frac{k}{2} \rceil})$ boundary facets and in this model point location in such a cell requires testing each facet.

Ailon and Chazelle [4] study s-linear decision trees to solve the k-SUM problem when $s > k$. In particular, they give an additional proof for the $\Omega(n^{\lceil \frac{k}{2} \rceil})$ lower bound of Erickson [17] and generalize the lower bound for the s-linear decision tree model when $s > k$. Note that the exact lower bound given by Erickson [17] for $s = k$ is $\Omega((nk^{-k})^{\lceil \frac{k}{2} \rceil})$ while the one given by Ailon and Chazelle [4] is $\Omega((nk^{-3})^{\lceil \frac{k}{2} \rceil})$. Their result improves therefore the lower bound for $s = k$ when k is large. The lower bound they prove for $s > k$ is the following:

▶ **Theorem 2** (Ailon and Chazelle [4]). *The depth of an s-linear decision tree solving the k-LDT problem is*

$$\Omega\left(\left(nk^{-3}\right)^{\frac{2k-s}{2\lceil\frac{s-k+1}{2}\rceil}(1-\epsilon_k)}\right),$$

where $\epsilon_k > 0$ tends to 0 as $k \to \infty$.

This lower bound breaks down when $k = \Omega(n^{1/3})$ or $s \geq 2k$ and the cases where $k < 6$ give trivial lower bounds. For example, in the case of 3SUM with $s = 4$ we only get an $\Omega(n)$ lower bound.

As for upper bounds, Baran et al. [6] gave subquadratic Las Vegas algorithms for 3SUM on integer and rational numbers in the circuit RAM, word RAM, external memory, and cache-oblivious models of computation. The idea of their approach is to exploit the parallelism of the models, using linear and universal hashing.

More recently, Grønlund and Pettie [23] proved the existence of a linear decision tree solving the 3SUM problem using a strongly subquadratic number of linear queries. The classical quadratic algorithm for 3SUM uses 3-linear queries while the decision tree of Grønlund and Pettie uses 4-linear queries and requires $O(n^{3/2}\sqrt{\log n})$ of them. Moreover, they show that their decision tree can be used to get better upper bounds for k-SUM when k is odd.

They also provide two subquadratic 3SUM algorithms. A deterministic one running in $O(n^2/(\log n/\log\log n)^{2/3})$ time and a randomized one running in $O(n^2(\log\log n)^2/\log n)$ time with high probability. These results refuted the long-lived conjecture that 3SUM cannot be solved in subquadratic time in the RAM model.

Freund [19] and Gold and Sharir [21] later gave improvements on the results of Grønlund and Pettie [23]. Freund [19] gave a deterministic algorithm for 3SUM running in $O(n^2 \log\log n/\log n)$ time. Gold and Sharir [21] gave another deterministic algorithm for 3SUM with the same running time and shaved off the $\sqrt{\log n}$ factor in the decision tree complexities of 3SUM and k-SUM given by Grønlund and Pettie.

Meyer auf der Heide [27] gave the first point location algorithm to solve the knapsack problem in the linear decision tree model in polynomial time. He thereby answers a question raised by Dobkin and Lipton [15, 16], Yao [32] and others. However, if one uses this algorithm to locate a point in an arbitrary arrangement of hyperplanes the running time is increased by a factor linear in the greatest coefficient in the equations of all hyperplanes. On the other hand, the complexity of Meiser's point location algorithm is polynomial in the dimension, logarithmic in the number of hyperplanes and does not depend on the value of the coefficients in the equations of the hyperplanes. A useful complete description of the latter is also given by Bürgisser et al. [9] (Section 3.4).

3 Query complexity

In this section and the next, we prove the following first result.

▶ **Theorem 3.** *There exist linear decision trees of depth at most $O(n^3 \log^2 n)$ solving the k-SUM and the k-LDT problems. Furthermore, for the two problems there exists an $\tilde{O}(n^{\lceil\frac{k}{2}\rceil+8})$ Las Vegas algorithm in the RAM model expected to perform $O(n^3 \log^2 n)$ linear queries on the input.*

3.1 Algorithm outline

For a fixed set of hyperplanes $\mathcal{H}$ and given input vertex q in $\mathbb{R}^n$, Meiser's algorithm allows us to determine the cell of the arrangement $\mathcal{A}(\mathcal{H})$ that contains q in its interior (or that *is* q if q is a 0-cell of $\mathcal{A}(\mathcal{H})$), that is, the positions $\sigma(H,q) \in \{-,0,+\}$ of q with respect to all hyperplanes $H \in \mathcal{H}$. In the k-SUM problem, the set $\mathcal{H}$ is the set of $\Theta(n^k)$ hyperplanes with equations of the form $x_{i_1} + x_{i_2} + \cdots + x_{i_k} = 0$. These equations can be modified accordingly for k-LDT.

We use standard results on ε-nets. By combining a theorem due to Blumer et al. [8] with the results of Meiser [26][4], it is possible to construct an ε-net $\mathcal{N}$ for the range space defined by hyperplanes and simplices using a random uniform sampling on $\mathcal{H}$.

▶ **Theorem 4.** *For all real numbers $\varepsilon > 0, c \geq 1$, if we choose at least $cn^2 \log n\varepsilon^{-1} \log \varepsilon^{-1}$ hyperplanes of $\mathcal{H}$ uniformly at random and denote this selection $\mathcal{N}$ then for any simplex intersected by more than $\varepsilon|\mathcal{H}|$ hyperplanes of $\mathcal{H}$, with probability $1 - 2^{-\Omega(c)}$, at least one of the intersecting hyperplanes is contained in $\mathcal{N}$.*

The contrapositive states that if no hyperplane in $\mathcal{N}$ intersects a given simplex, then with high probability the number of hyperplanes of $\mathcal{H}$ intersecting the simplex is at most $\varepsilon|\mathcal{H}|$.

We can use this to design a prune and search algorithm as follows:

(A) construct an ε-net $\mathcal{N}$,
(B) compute the cell C of $\mathcal{A}(\mathcal{N})$ containing the input point q in its interior,
(C) construct a simplex S inscribed in C and containing q in its interior,
(D) recurse on the hyperplanes of $\mathcal{H}$ intersecting the interior of S.

Proceeding this way with a constant ε guarantees that at most a constant fraction ε of the hyperplanes remains after the pruning step, and thus the cumulative number of queries made to determine the enclosing cell at each step is $O(n^2 \log n \log |\mathcal{H}|)$ when done in a brute-force way. However, we still need to explain how to find a simplex S inscribed in C and containing q in its interior. This procedure corresponds to the well-known *bottom vertex decomposition* (or *triangulation*) of a hyperplane arrangement [22, 14].

3.2 Finding a simplex

In order to simplify the exposition of the algorithm, we assume, without loss of generality, that the input numbers q_i all lie in the interval $[-1, 1]$. This assumption is justified by observing that we can normalize all the input numbers by the largest absolute value of a component of q. One can then see that every linear query on the normalized input can be implemented as a linear query on the original input. A similar transformation can be carried out for the k-LDT problem. This allows us to use bounding hyperplanes of equations $x_i = \pm 1, i \in [n]$. We denote by $\mathcal{B}$ this set of hyperplanes. Hence, if we choose a subset $\mathcal{N}$ of the hyperplanes, the input point is located in a bounded cell of the arrangement $\mathcal{A}(\mathcal{N} \cup \mathcal{B})$. Note that $|\mathcal{N} \cup \mathcal{B}| = O(|\mathcal{N}|)$ for all interesting values of ε.

We now explain how to construct S under this assumption. The algorithm can be sketched as follows. (Recall that $\sigma(H,p)$ denotes the relative position of p with respect to the hyperplane H.)

[4] Note that Meiser used an older result due to Haussler and Welzl [24] and got an extra $\log n$ factor in the size of the ε-net.

Algorithm 1 (Constructing S)**.**

```
Input: A point $q$ in $[-1,1]^n$, a set $\mathcal{I}$ of hyperplanes not containing $q$, and a set $\mathcal{E}$ of
    hyperplanes in general position containing $q$, such that the cell
        $C = \{\, p\colon\ \sigma(H,p) = \sigma(H,q) \text{ or } \sigma(H,p) = 0 \text{ for all } H \in (\mathcal{I} \cup \mathcal{E})\,\}$
    is a bounded polytope. The value $\sigma(H,q)$ is known for all $H \in (\mathcal{I} \cup \mathcal{E})$.
Output: A simplex $S \in C$ that contains $q$ in its interior (if it is not a point), and all
    vertices of which are vertices of $C$.
0. If $|\mathcal{E}| = n$, return $q$.
1. Determine a vertex $\nu$ of $C$.
2. Let $q'$ be the projection of $q$ along $\vec{\nu q}$ on the boundary of $C$. Compute $\mathcal{I}_\theta \subseteq \mathcal{I}$, the
    subset of hyperplanes in $\mathcal{I}$ containing $q'$. Compute $\mathcal{I}_\tau \subseteq \mathcal{I}_\theta$, a maximal subset of those
    hyperplanes such that $\mathcal{E}' = \mathcal{E} \cup \mathcal{I}_\tau$ is a set of hyperplanes in general position.
3. Recurse on $q'$, $\mathcal{I}' = \mathcal{I} \setminus \mathcal{I}_\theta$, and $\mathcal{E}'$, and store the result in $S'$.
4. Return $S$, the convex hull of $S' \cup \{\, \nu \,\}$.
```

Step **0** is the base case of the recursion: when there is only one point left, just return that point. This step uses no query.

We can solve step **1** by using linear programming with the known values of $\sigma(H,q)$ as linear constraints. We arbitrarily choose an objective function with a gradient non-orthogonal to all hyperplanes in $\mathcal{I}$ and look for the optimal solution. The optimal solution being a vertex of the arrangement, its coordinates are independent of q, and thus this step involves no query at all.

Step **2** prepares the recursive step by finding the hyperplanes containing q'. This can be implemented as a ray-shooting algorithm that performs a number of comparisons between projections of q on different hyperplanes of $\mathcal{I}$ without explicitly computing them. In Appendix A, we prove that all such comparisons can be implemented using $O(|\mathcal{I}|)$ linear queries. Constructing $\mathcal{E}'$ can be done by solving systems of linear equations that do not involve q.

In step **3**, the input conditions are satisfied, that is, $q' \in [-1,1]^n$, $\mathcal{I}'$ is a set of hyperplanes not containing q', $\mathcal{E}'$ is a set of hyperplanes in general position containing q', C' is a d-cell of C and is thus a bounded polytope. The value $\sigma(H,q')$ differs from $\sigma(H,q)$ only for hyperplanes that have been removed from $\mathcal{I}$, and for those $\sigma(H,q') = 0$, hence we know all necessary values $\sigma(H,q')$ in advance.

Since $|\mathcal{I}'| < |\mathcal{I}|$, $|\mathcal{E}'| > |\mathcal{E}|$, and $|\mathcal{I} \setminus \mathcal{I}'| - |\mathcal{E}' \setminus \mathcal{E}| \geq 0$, the complexity of the recursive call is no more than that of the parent call, and the maximal depth of the recursion is n. Thus, the total number of linear queries made to compute S is $O(n|\mathcal{I}|)$.

Hence given an input point $q \in [-1,1]$, an arrangement of hyperplanes $\mathcal{A}(\mathcal{N})$, and the value of $\sigma(H,q)$ for all $H \in (\mathcal{N} \cup \mathcal{B})$, we can compute the desired simplex S by running Algorithm 1 on q, $\mathcal{I} = \{\, H \in (\mathcal{N} \cup \mathcal{B})\colon\ \sigma(H,q) \neq 0\,\}$, and $\mathcal{E} \subseteq (\mathcal{N} \cup \mathcal{B}) \setminus \mathcal{I}$. This uses $O(n^3 \log n)$ linear queries. Figure 1 illustrates a step of the algorithm.

3.3 Assembling the pieces

Let us summarize the algorithm
Algorithm 2.

```
Input: $q \in [-1,1]^n$
```

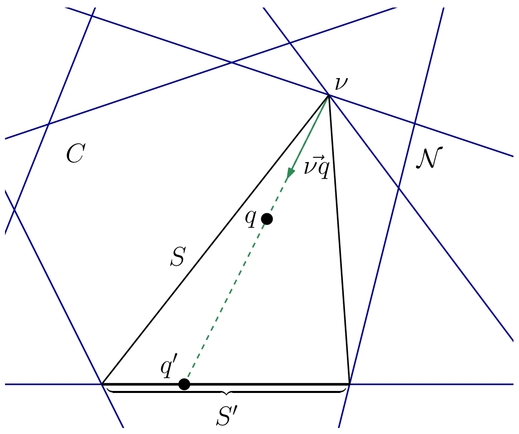

Figure 1 Illustration of a step of Algorithm 1.

1. Pick $O(n^2 \log n)$ hyperplanes of $\mathcal{H}$ at random and locate q in this arrangement. Call C the cell containing q.
2. Construct the simplex S containing q and inscribed in C, using Algorithm 1.
3. For every hyperplane of $\mathcal{H}$ containing S, output a solution.
4. Recurse on hyperplanes of $\mathcal{H}$ intersecting the interior of S.

The query complexity of step **1** is $O(n^2 \log n)$, and that of step **2** is $O(n^3 \log n)$. Steps **3** and **4** do not involve any query at all. The recursion depth is $O(\log |\mathcal{H}|)$, with $|\mathcal{H}| = O(n^k)$, hence the total query complexity of this algorithm is $O(n^3 \log^2 n)$. This proves the first part of Theorem 3.

We can also consider the overall complexity of the algorithm in the RAM model, that is, taking into account the steps that do not require any query, but for which we still have to process the set $\mathcal{H}$. Note that the complexity bottleneck of the algorithm are steps **3-4**, where we need to prune the list of hyperplanes according to their relative positions with respect to S. For this purpose, we simply maintain explicitly the list of all hyperplanes, starting with the initial set corresponding to all k-tuples. Then the pruning step can be performed by looking at the position of each vertex of S relative to each hyperplane of $\mathcal{H}$. Because in our case hyperplanes have only k nonzero coefficients, this uses a number of integer arithmetic operations on $\tilde{O}(n)$ bits integers that is proportional to the number of vertices times the number of hyperplanes. (For the justification of the bound on the number of bits needed to represent vertices of the arrangement see Appendix D.) Since we recurse on a fraction of the set, the overall complexity is $\tilde{O}(n^2|\mathcal{H}|) = \tilde{O}(n^{k+2})$. The next section is devoted to improving this running time.

4 Time complexity

Proving the second part of Theorem 3 involves efficient implementations of the two most time-consuming steps of Algorithm 2. In order to efficiently implement the pruning step, we define an intermediate problem, that we call the *double k-SUM* problem.

▶ **Problem** (double k-SUM). *Given two vectors $\nu_1, \nu_2 \in [-1,1]^n$, where the coordinates of ν_i can be written down as fractions whose numerator and denominator lie in the interval*

$[-M, M]$, enumerate all $i \in [n]^k$ such that

$$\left(\sum_{j=1}^{k} \nu_{1,i_j}\right)\left(\sum_{j=1}^{k} \nu_{2,i_j}\right) < 0.$$

In other words, we wish to list all hyperplanes of $\mathcal{H}$ intersecting the open line segment $\nu_1\nu_2$. We give an efficient output-sensitive algorithm for this problem.

▶ **Lemma 5.** *The double k-SUM problem can be solved in time $O(n^{\lceil \frac{k}{2} \rceil} \log n \log M + Z)$, where Z is the size of the solution.*

Proof. If k is even, we consider all possible $\frac{k}{2}$-tuples of numbers in ν_1 and ν_2 and sort their sums in increasing order. This takes time $O(n^{\frac{k}{2}} \log n)$ and yields two permutations π_1 and π_2 of $[n^{\frac{k}{2}}]$. If k is odd, then we sort both the $\lceil \frac{k}{2} \rceil$-tuples and the $\lfloor \frac{k}{2} \rfloor$-tuples. For simplicity, we will only consider the even case in what follows. The odd case carries through.

We let $N = n^{\frac{k}{2}}$. For $i \in [N]$ and $m \in \{1, 2\}$, let $\Sigma_{m,i}$ be the sum of the $\frac{k}{2}$ components of the ith $\frac{k}{2}$-tuple in ν_m, in the order prescribed by π_m.

We now consider the two $N \times N$ matrices M_1 and M_2 giving all possible sums of two $\frac{k}{2}$-tuples, for both ν_1 with the ordering π_1 and ν_2 with the ordering π_2.

We first solve the k-SUM problem on ν_1, by finding the sign of all pairs $\Sigma_{1,i} + \Sigma_{1,j}$, $i, j \in [N]$. This can be done in time $O(N)$ by parsing the matrix M_1, just as in the standard k-SUM algorithm. We do the same with M_2.

The set of all indices $i, j \in [N]$ such that $\Sigma_{1,i} + \Sigma_{1,j}$ is positive forms a staircase in M_1. We sweep M_1 column by column in order of increasing $j \in [N]$, in such a way that the number of indices i such that $\Sigma_{1,i} + \Sigma_{1,j} > 0$ is growing. For each new such value i that is encountered during the sweep, we insert the corresponding $i' = \pi_2(\pi_1^{-1}(i))$ in a balanced binary search tree.

After each sweep step in M_1 — that is, after incrementing j and adding the set of new indices i' in the tree — we search the tree to identify all the indices i' such that $\Sigma_{2,i'} + \Sigma_{2,j'} < 0$, where $j' = \pi_2(\pi_1^{-1}(j))$. Since those indices form an interval in the ordering π_2 when restricted to the indices in the tree, we can search for the largest i'_0 such that $\Sigma_{2,i'_0} < -\Sigma_{2,j'}$ and retain all indices $i' \le i'_0$ that are in the tree. If we denote by z the number of such indices, this can be done in $O(\log N + z) = O(\log n + z)$ time. Now all the pairs i', j' found in this way are such that $\Sigma_{1,i} + \Sigma_{1,j}$ is positive and $\Sigma_{2,i'} + \Sigma_{2,j'}$ is negative, hence we can output the corresponding k-tuples. To get all the pairs i', j' such that $\Sigma_{1,i} + \Sigma_{1,j}$ is negative and $\Sigma_{2,i'} + \Sigma_{2,j'}$ positive, we repeat the sweeping algorithm after swapping the roles of ν_1 and ν_2.

Every matching k-tuple is output exactly once, and every $\frac{k}{2}$-tuple is inserted at most once in the binary search tree. Hence the algorithm runs in the claimed time.

Note that we only manipulate rational numbers that are the sum of at most k rational numbers of size $O(\log M)$. ◀

Now observe that a hyperplane intersects the interior of a simplex if and only if it intersects the interior of one of its edges. Hence given a simplex S we can find all hyperplanes of $\mathcal{H}$ intersecting its interior by running the above algorithm $\binom{n}{2}$ times, once for each pair of vertices (ν_1, ν_2) of S, and take the union of the solutions. The overall running time for this implementation will therefore be $\tilde{O}(n^2(n^{\lceil \frac{k}{2} \rceil} \log M + Z))$, where Z is at most the number of intersecting hyperplanes and M is to be determined later. This provides an implementation of the pruning step in Meiser's algorithm, that is, step **4** of Algorithm 2.

▶ **Corollary 6.** *Given a simplex S, we can compute all k-SUM hyperplanes intersecting its interior in $\tilde{O}(n^2(n^{\lceil \frac{k}{2} \rceil} \log M + Z))$ time, where $\log M$ is proportional to the number of bits necessary to represent S.*

In order to detect solutions in step **3** of Algorithm 2, we also need to be able to quickly solve the following problem.

▶ **Problem** (multiple k-SUM). *Given d points $\nu_1, \nu_2, \ldots, \nu_d \in \mathbb{R}^n$, where the coordinates of ν_i can be written down as fractions whose numerator and denominator lie in the interval $[-M, M]$, decide whether there exists a hyperplane with equation of the form $x_{i_1} + x_{i_2} + \cdots + x_{i_k} = 0$ containing all of them.*

Here the standard k-SUM algorithm can be applied, taking advantage of the fact that the coordinates lie in a small discrete set.

▶ **Lemma 7.** *k-SUM on n integers $\in [-V, V]$ can be solved in time $\tilde{O}(n^{\lceil \frac{k}{2} \rceil} \log V)$.*

▶ **Lemma 8.** *Multiple k-SUM can be solved in time $\tilde{O}(dn^{\lceil \frac{k}{2} \rceil + 2} \log M)$.*

Proof. Let $\mu_{i,j}$ and $\delta_{i,j}$ be the numerator and denominator of $\nu_{i,j}$ when written as an irreducible fraction. We define

$$\zeta_{i,j} = \nu_{i,j} \prod_{(i,j) \in [d] \times [n]} \delta_{i,j} = \frac{\mu_{i,j} \prod_{(i',j') \in [d] \times [n]} \delta_{i',j'}}{\delta_{i,j}}.$$

By definition $\zeta_{i,j}$ is an integer and its absolute value is bounded by $U = M^{n^2}$, that is, it can be represented using $O(n^2 \log M)$ bits. Moreover, if one of the hyperplanes contains the point $(\zeta_{i,1}, \zeta_{i,2}, \ldots, \zeta_{i,n})$, then it contains ν_i. Construct n integers of $O(dn^2 \log M)$ bits that can be written $\zeta_{1,j} + U, \zeta_{2,j} + U, \ldots, \zeta_{d,j} + U$ in base $2Uk + 1$. The answer to our decision problem is "yes" if and only if there exists k of those numbers whose sum is $kU, kU, \ldots, kU$. We simply subtract the number $U, U, \ldots, U$ to all n input numbers to obtain a standard k-SUM instance on n integers of $O(dn^2 \log M)$ bits. ◀

We now have efficient implementations of steps **3** and **4** of Algorithm 2 and can proceed to the proof of the second part of Theorem 3.

Proof. The main idea consists of modifying the first iteration of Algorithm 2, by letting $\varepsilon = \Theta(n^{-\frac{k}{2}})$. Hence we pick a random subset $\mathcal{N}$ of $O(n^{k/2+2} \log n)$ hyperplanes in $\mathcal{H}$ and use this as an ε-net. This can be done efficiently, as shown in Appendix C.

Next, we need to locate the input q in the arrangement induced by $\mathcal{N}$. This can be done by running Algorithm 2 on the set $\mathcal{N}$. From the previous considerations on Algorithm 2, the running time of this step is

$$O(n|\mathcal{N}|) = \tilde{O}(n^{k/2+4}),$$

and the number of queries is $O(n^3 \log^2 n)$.

Then, in order to prune the hyperplanes in $\mathcal{H}$, we have to compute a simplex S that does not intersect any hyperplane of $\mathcal{N}$. For this, we observe that the above call to Algorithm 2 involves computing a sequence of simplices for the successive pruning steps. We save the description of those simplices. Recall that there are $O(\log n)$ of them, all of them contain the input q and have vertices coinciding with vertices of the original arrangement $\mathcal{A}(\mathcal{H})$. In order to compute a simplex S avoiding all hyperplanes of $\mathcal{N}$, we can simply apply Algorithm 1 on the set of hyperplanes bounding the intersection of these simplices. The running time and number of queries for this step are bounded respectively by $n^{O(1)}$ and $O(n^2 \log n)$.

Note that the vertices of S are not vertices of $\mathcal{A}(\mathcal{H})$ anymore. However, their coordinates lie in a finite set (see Appendix D)

▶ **Lemma 9.** *Vertices of S have rational coordinates whose fraction representations have their numerators and denominators absolute values bounded above by $C^{4n^5} n^{2n^5+n^3+\frac{n}{2}}$, where C is a constant.*

We now are in position to perform the pruning of the hyperplanes in $\mathcal{H}$ with respect to S. The number of remaining hyperplanes after the pruning is at most $\varepsilon n^k = O(n^{k/2})$. Hence from Corollary 6, the pruning can be performed in time proportional $\tilde{O}(n^{\lceil k/2 \rceil + 7})$.

Similarly, we can detect any hyperplane of $\mathcal{H}$ containing S using the result of Lemma 8 in time $\tilde{O}(n^{\lceil k/2 \rceil + 8})$. Note that those last two steps do not require any query.

Finally, it remains to detect any solution that may lie in the remaining set of hyperplanes of size $O(n^{k/2})$. We can again fall back on Algorithm 2, restricted to those hyperplanes. The running time is $\tilde{O}(n^{k/2+2})$, and the number of queries is still $O(n^3 \log^2 n)$.

Overall, the maximum running time of a step is $\tilde{O}(n^{\lceil \frac{k}{2} \rceil + 8})$, while the number of queries is always bounded by $O(n^3 \log^2 n)$. ◀

5 Query size

In this section, we consider a simple blocking scheme that allows us to explore a tradeoff between the number of queries and the size of the queries.

▶ **Lemma 10.** *For any integer $b > 0$, an instance of the k-SUM problem on $n > b$ numbers can be split into $O(b^{k-1})$ instances on at most $k\lceil \frac{n}{b} \rceil$ numbers, so that every k-tuple forming a solution is found in exactly one of the subproblems. The transformation can be carried out in time $O(n \log n + b^{k-1})$.*

Proof. Given an instance on n numbers, we can sort them in time $O(n \log n)$, then partition the sorted sequence into b consecutive blocks $B_1, B_2, \ldots, B_b$ of equal size. This partition can be associated with a partition of the real line into b intervals, say $I_1, I_2, \ldots, I_b$. Now consider the partition of $\mathbb{R}^k$ into grid cells defined by the kth power of the partition $I_1, I_2, \ldots, I_b$. The hyperplane of equation $x_1 + x_2 + \cdots + x_k = 0$ hits $O(b^{k-1})$ such grid cells. Each grid cell $I_{i_1} \times I_{i_2} \times \cdots \times I_{i_k}$ corresponds to a k-SUM problem on the numbers in the set $B_{i_1} \cup B_{i_2} \cup \ldots \cup B_{i_k}$ (note that the indices i_j need not be distinct). Hence each such instance has size at most $k\lceil \frac{n}{b} \rceil$. ◀

Combining Lemma 10 and Theorem 3 directly yields the following.

▶ **Theorem 11.** *For any integer $b > 0$, there exists a $k\lceil \frac{n}{b} \rceil$-linear decision tree of depth $\tilde{O}(b^{k-4} n^3)$ solving the k-SUM problem. Moreover, this decision tree can be implemented as an $\tilde{O}(b^{\lfloor \frac{k}{2} \rfloor - 9} n^{\lceil \frac{k}{2} \rceil + 8})$ Las Vegas algorithm.*

The following two corollaries are obtained by taking $b = \Theta(\text{polylog}(n))$, and $b = \Theta(n^\alpha)$, respectively

▶ **Corollary 12.** *There exists an $o(n)$-linear decision tree of depth $\tilde{O}(n^3)$ solving the k-SUM problem. Moreover, this decision tree can be implemented as an $\tilde{O}(n^{\lceil \frac{k}{2} \rceil + 8})$ Las Vegas algorithm.*

▶ **Corollary 13.** *For any α such that $0 < \alpha < 1$, there exists an $O(n^{1-\alpha})$-linear decision tree of depth $\tilde{O}(n^{3+(k-4)\alpha})$ solving the k-SUM problem. Moreover, this decision tree can be implemented as an $\tilde{O}(n^{(1+\alpha)\frac{k}{2}+8.5})$ Las Vegas algorithm.*

Note that the latter query complexity improves on $\tilde{O}(n^{\frac{k}{2}})$ whenever $\alpha < \frac{k-6}{2k-8}$ and $k \geq 7$. By choosing $\alpha = \frac{k-6}{2k-8} - \frac{\beta}{k-4}$ we obtain $O(n^{1-\frac{k-6}{2k-8}+\frac{\beta}{k-4}})$-linear decision trees of depth $\tilde{O}(n^{\frac{k}{2}-\beta})$ for any $k \geq 7$. Hence for instance, we obtain $O(n^{\frac{3}{4}+\frac{\beta}{4}})$-linear decision trees of depth $\tilde{O}(n^{4-\beta})$ for the 8SUM problem.

A Keeping queries linear in Algorithm 1

In Algorithm 1, we want to ensure that the queries we make in step **2** are linear and that the queries we will make in the recursion step remain linear too.

▶ **Lemma 14.** *Algorithm 1 can be implemented so that it uses $O(n|I|)$ linear queries.*

Proof. Let us first analyze what the queries of step **2** look like. In addition to the input point q we are given a vertex ν and we want to find the projection q' of q in direction $\vec{\nu q}$ on the hyperplanes of $\mathcal{I}_\theta$. Let the equation of H_i be $\Pi_i(x) = c_i + d_i \cdot x = 0$ where c_i is a scalar and d_i is a vector. The projection of q along $\vec{\nu q}$ on a hyperplane H_i can thus be written[5]

[5] Note that we project from ν instead of q. We are allowed to do this since $\nu + \lambda_i \vec{\nu q} = q + (\lambda_i - 1)\vec{\nu q}$ and there is no hyperplane separating q from ν.

$\rho(q,\nu,H_i) = \nu + \lambda_i \vec{\nu q}$ such that $\Pi_i(\nu + \lambda_i \vec{\nu q}) = c_i + d_i \cdot \nu + \lambda_i d_i \cdot \vec{\nu q} = 0$. Computing the closest hyperplane amounts to finding $\lambda_\theta = \min_{\lambda_i > 0} \lambda_i$. Since $\lambda_i = -\frac{c_i + d_i \cdot \nu}{d_i \cdot \vec{\nu q}}$ we can test whether $\lambda_i > 0$ using the linear query[6] $-\frac{d_i \cdot \vec{\nu q}}{c_i + d_i \cdot \nu} >^? 0$. Moreover, if $\lambda_i > 0$ and $\lambda_j > 0$ we can test whether $\lambda_i < \lambda_j$ using the linear query $\frac{d_i \cdot \vec{\nu q}}{c_i + d_i \cdot \nu} <^? \frac{d_j \cdot \vec{\nu q}}{c_j + d_j \cdot \nu}$. Step **2** can thus be achieved using $O(1)$ $(2k)$-linear queries per hyperplane of $\mathcal{N}$.

In step **4**, the recursive step is carried out on $q' = \nu + \lambda_\theta \vec{\nu q} = \nu - \frac{c_\theta + d_\theta \cdot \nu}{d_\theta \cdot \vec{\nu q}} \vec{\nu q}$ hence comparing λ'_i to 0 amounts to performing the query $-\frac{d_i \cdot \vec{\nu q}'}{c_i + d_i \cdot \nu'} >^? 0$, which is not linear in q. The same goes for comparing λ'_i to λ'_j with the query $\frac{d_i \cdot \vec{\nu q}'}{c_i + d_i \cdot \nu'} <^? \frac{d_j \cdot \vec{\nu q}'}{c_j + d_j \cdot \nu'}$.

However, we can multiply both sides of the inequality test by $d_\theta \vec{\nu q}$ to keep the queries linear as shown below. We must be careful to take into account the sign of the expression $d_\theta \vec{\nu q}$, this costs us one additional linear query.

This trick can be used at each step of the recursion. Let $q^{(0)} = q$, then we have

$$q^{(s+1)} = \nu^{(s)} - \frac{c_{\theta_s} + d_{\theta_s} \cdot \nu^{(s)}}{d_{\theta_s} \cdot \vec{\nu q}^{(s)}} \vec{\nu q}^{(s)}$$

and $(d_{\theta_s} \cdot \vec{\nu q}^{(s)}) q^{(s+1)}$ yields a vector whose components are linear in $q^{(s)}$. Hence, $(\prod_{k=0}^{s} d_{\theta_k} \cdot \vec{\nu q}^{(k)}) q^{(s+1)}$ yields a vector whose components are linear in q, and for all pairs of vectors d_i and $\nu^{(s+1)}$ we have that $(\prod_{k=0}^{s} d_{\theta_k} \cdot \vec{\nu q}^{(k)})(d_i \cdot \vec{\nu q}^{(s+1)})$ is linear in q.

Hence at the sth recursive step of the algorithm, we will perform at most $|\mathcal{N}|$ linear queries of the type

$$-\left(\prod_{k=0}^{s-1} d_{\theta_k} \cdot \vec{\nu q}^{(k)}\right) \frac{d_i \cdot \vec{\nu q}^{(s)}}{c_i + d_i \cdot \nu^{(s)}} \overset{?}{>} 0$$

$|\mathcal{N}| - 1$ linear queries of the type

$$\left(\prod_{k=0}^{s-1} d_{\theta_k} \cdot \vec{\nu q}^{(k)}\right) \frac{d_i \cdot \vec{\nu q}^{(s)}}{c_i + d_i \cdot \nu^{(s)}} \overset{?}{<} \left(\prod_{k=0}^{s-1} d_{\theta_k} \cdot \vec{\nu q}^{(k)}\right) \frac{d_j \cdot \vec{\nu q}^{(s)}}{c_j + d_j \cdot \nu^{(s)}}$$

and a single linear query of the type

$$d_{\theta_{s-1}} \cdot \vec{\nu q}^{(s-1)} \overset{?}{<} 0.$$

In order to detect all hyperplanes H_i such that $\lambda_i = \lambda_\theta$ we can afford to compute the query $f(q) > g(q)$ for all query $f(q) < g(q)$ that we issue, and vice versa.

Note that, without further analysis, the queries can become n-linear as soon as we enter the $\frac{n}{k}$th recursive step. ◀

B Algebraic computation trees

We consider *algebraic computation trees*, whose internal nodes are labeled with arithmetic $(r \leftarrow o_1 \operatorname{op} o_2, \operatorname{op} \in \{+,-,\times,\div\})$ and branching $(z : 0)$ operations. We say that an algebraic computation tree T *realizes* an algorithm A if the paths from the root to the leaves of T correspond to the execution paths of A on all possible inputs $q \in \mathbb{R}^n$, where n is fixed. A leaf is labeled with the output of the corresponding execution path of A. Such a tree is

[6] Note that if $c_i + d_i \cdot \nu = 0$ then $\lambda_i = 0$, we can check this beforehand for free.

well-defined if any internal node labeled $r \leftarrow o_1 \,\mathrm{op}\, o_2$ has outdegree 1 and is such that either $o_k = q_i$ for some i or there exists an ancestor $o_k \leftarrow x \,\mathrm{op}\, y$ of this node, and any internal node labeled $z : 0$ has outdegree 3 and is such that either $z = q_i$ for some i or there exists an ancestor $z \leftarrow x \,\mathrm{op}\, y$ of this node. In the algebraic computation tree model, we define the complexity $f(n)$ of an algorithm A to be the minimum depth of a well-defined computation tree that realizes A for inputs of size n.

In the algebraic computation tree model, we only count the operations that involve the input, that is, members of the input or results of previous operations involving the input. The following theorem follows immediately from the analysis of the linearity of queries

▶ **Theorem 15.** *The algebraic computation tree complexity of k-LDT is $\tilde{O}(n^3)$.*

Proof. We go through each step of Algorithm 2. Indeed, each k-linear query of step **1** can be implemented as $O(k)$ arithmetic operations, so step **1** has complexity $O(|\mathcal{N}|)$. The construction of the simplex in step **2** must be handled carefully. What we need to show is that each n-linear query we use can be implemented using $O(k)$ arithmetic operations. It is not difficult to see from the expressions given in Appendix A that a constant number of arithmetic operations and dot products suffice to compute the queries. A dot product in this case involves a constant number of arithmetic operations because the d_i are such that they each have exactly k non-zero components. The only expression that involves a non-constant number of operations is the product $\prod_{k=0}^{s} d_{\theta_k} \cdot \vec{\nu q}^{(k)}$, but this is equivalent to $(\prod_{k=0}^{s-1} d_{\theta_k} \cdot \vec{\nu q}^{(k)})(d_{\theta_s} \cdot \vec{\nu q}^{(s)})$ where the first factor has already been computed during a previous step and the second factor is of constant complexity. Since each query costs a constant number of arithmetic operations and branching operations, step **2** has complexity $O(n|\mathcal{N}|)$. Finally, steps **3** and **4** are free since they do not involve the input. The complexity of Algorithm 2 in this model is thus also $O(n^3 \log n \log |\mathcal{H}|)$. ◀

C Uniform random sampling

Theorem 4 requires us to pick a sample of the hyperplanes uniformly at random. Actually the theorem is a little stronger; we can draw each element of $\mathcal{N}$ uniformly at random, only keeping distinct elements. This is not too difficult to achieve for k-LDT when the $\alpha_i, i \in [k]$ are all distinct: to pick a hyperplane of the form $\alpha_0 + \alpha_1 x_{i_1} + \alpha_2 x_{i_2} + \cdots + \alpha_k x_{i_k} = 0$ uniformly at random, we can draw each $i_j \in [n]$ independently and there are n^k possible outcomes. However, in the case of k-SUM, we only have $\binom{n}{k}$ distinct hyperplanes. A simple dynamic programming approach solves the problem for k-SUM. For k-LDT we can use the same approach, once for each class of equal α_i.

▶ **Lemma 16.** *Given $n \in \mathbb{N}$ and $(\alpha_0, \alpha_1, \ldots, \alpha_k) \in \mathbb{R}^{k+1}$, m independent uniform random draws of hyperplanes in $\mathbb{R}^n$ with equations of the form $\alpha_0 + \alpha_1 x_{i_1} + \alpha_2 x_{i_2} + \cdots + \alpha_k x_{i_k} = 0$ can be computed in time $O(mk^2 \log n)$ and preprocessing time $O(k^2 n)$.*

Proof. We want to pick an assignment $a = \{ (\alpha_1, x_{i_1}), (\alpha_2, x_{i_2}), \ldots, (\alpha_k, x_{i_k}) \}$ uniformly at random. Note that all x_i are distinct while the α_j can be equal.

Without loss of generality, suppose $\alpha_1 \leq \alpha_2 \leq \cdots \leq \alpha_k$. There is a bijection between assignments and lexicographically sorted k-tuples $((\alpha_1, x_{i_1}), (\alpha_2, x_{i_2}), \ldots, (\alpha_k, x_{i_k}))$.

Observe that x_{i_j} can be drawn independently of $x_{i_{j'}}$ whenever $\alpha_j \neq \alpha_{j'}$. Hence, it suffices to generate a lexicographically sorted $|\chi|$-tuple of x_i for each class χ of equal α_i.

Let $\omega(m, l)$ denote the number of lexicographically sorted l-tuples, where each element comes from a set of m distinct x_i. We have

$$\omega(m,l) = \begin{cases} 1 & \text{if } l = 0 \\ \sum_{i=1}^{m} \omega(i, l-1) & \text{otherwise.} \end{cases}$$

To pick such a tuple $(x_{i_1}, x_{i_2}, \dots, x_{i_l})$ uniformly at random we choose $x_{i_l} = x_o$ with probability

$$P(x_{i_l} = x_o) = \begin{cases} 0 & \text{if } o > m \\ \frac{\omega(o,l-1)}{\omega(m,l)} & \text{otherwise} \end{cases}$$

that we append to a prefix $(l-1)$-tuple (apply the procedure recursively), whose elements come from a set of o symbols. If $l = 0$ we just return the empty tuple.

Obviously, the probability for a given l-tuple to be picked is equal to $\frac{1}{\omega(m,l)}$.

Let X denote the partiton of the α_i into equivalence classes, then the number of assignments is equal to $\prod_{\chi \in X} \omega(n, |\chi|)$. (Note that for k-SUM this is simply $\omega(n,k)$ since there is only a single class of equivalence.) For each equivalence class χ we draw independently a lexicographically sorted $|\chi|$-tuple on n symbols using the procedure above. This yields a given assignment with probability $\frac{1}{\prod_{\chi \in X} \omega(n,|\chi|)}$. Hence, this corresponds to a uniform random draw over the assignments.

It is a well known fact that $\omega(n,k) = \binom{n+k-1}{k-1}$, hence each number we manipulate fits in $O(k \log n)$ bits, that is, $O(k)$ words. Moreover $\omega(n,k) = \omega(n-1,k) + \omega(n-1,k-1)$ so each $\omega(m,l)$ can be computed using a single addition on numbers of $O(k)$ words.

For given n and k, there are at most nk values $\omega(m,l)$ to compute, and for a given k-LDT instance, it must be computed only once. One way to perform the random draws is to compute the cumulative distribution functions of the discrete distributions defined above, then to draw x_{i_l}, we use binary search to find a generated random integer of $O(k)$ words in the cumulative distribution function. Computing the values $\omega(m,l)$ and all cumulative distributions functions can be done as a preprocessing step in $O(k^2 n)$ time. Assuming the generation of a random sequence of words takes linear time, performing a random draw takes time $O(k^2 \log n)$. ◀

D Proof of Lemma 9

▶ **Theorem 17** (Cramer's rule). *If a system of n linear equations for n unknowns, represented in matrix multiplication form $Ax = b$, has a unique solution $x = (x_1, x_2, \dots, x_n)^T$ then, for all $i \in [n]$,*

$$x_i = \frac{\det(A_i)}{\det(A)}$$

where A_i is A with the ith column replaced by the column vector b.

▶ **Lemma 18** (Meyer auf der Heide[27]). *The absolute value of the determinant of an $n \times n$ matrix $M = M_{i=1\dots n, j=1\dots n}$ with integer entries is an integer that is at most $C^n n^{\frac{n}{2}}$, where C is the maximum absolute value in M.*

Proof. The determinant of M must be an integer and is the volume of the hyperparalleliped spanned by the row vectors of M, hence

$$|\det(M)| \leq \prod_{i=1}^{n} \sqrt{\sum_{j=1}^{n} M_{i,j}^2} \leq \left(\sqrt{nC^2}\right)^n \leq C^n n^{\frac{n}{2}}.$$

◀

▶ **Lemma 19.** *The determinant of an $n \times n$ matrix $M = M_{i=1\dots n, j=1\dots n}$ with rational entries can be represented as a fraction whose numerators and denominators absolute values are bounded above by $(ND^{n-1})^n n^{\frac{n}{2}}$ and D^{n^2} respectively, where N and D are respectively the maximum absolute value of a numerator and a denominator in M.*

Proof. Le $\delta_{i,j}$ denote the denominator of $M_{i,j}$. Multiply each row M_i of M by $\prod_j \delta_{i,j}$. Apply Lemma 18. ◀

We can now proceed to the proof of Lemma 9.

Proof. Coefficients of the hyperplanes of the arrangement are constant rational numbers, those can be changed to constant integers (because each hyperplane has at most k nonzero coefficients). Let C denote the maximum absolute value of those coefficients.

Because of Theorem 17 and Lemma 18, vertices of the arrangement have rational coordinates whose numerators and denominators absolute values are bounded above by $C^n n^{\frac{n}{2}}$.

Given simplices whose vertices are vertices of the arrangement, hyperplanes that define the faces of those simplices have rational coefficients whose numerators and denominators absolute values are bounded above by $C^{2n^3} n^{n^3+\frac{n}{2}}$ by Theorem 17 and Lemma 19. (Note that some simplices might be not fully dimensional, but we can handle those by adding vertices with coordinates that are not much larger than that of already existing vertices).

By applying Theorem 17 and Lemma 19 again, we obtain that vertices of the arrangement of those new hyperplanes (and thus vertices of S) have rational coefficients whose numerators and denominators absolute values are bounded above by $C^{4n^5} n^{2n^5+n^3+\frac{n}{2}}$. ◀

Optimal Staged Self-Assembly of General Shapes*

Abstract

We analyze the number of stages, tiles, and bins needed to construct $n \times n$ squares and scaled shapes in the staged tile assembly model. In particular, we prove that there exists a staged system with b bins and t tile types assembling an $n \times n$ square using $\mathcal{O}(\frac{\log n - tb - t\log t}{b^2} + \frac{\log\log b}{\log t})$ stages and $\Omega(\frac{\log n - tb - t\log t}{b^2})$ are necessary for almost all n. For a shape S, we prove $\mathcal{O}(\frac{K(S) - tb - t\log t}{b^2} + \frac{\log\log b}{\log t})$ stages suffice and $\Omega(\frac{K(S) - tb - t\log t}{b^2})$ are necessary for the assembly of a scaled version of S, where $K(S)$ denotes the Kolmogorov complexity of S. Similarly tight bounds are also obtained when more powerful *flexible* glue functions are permitted. These are the first staged results that hold for all choices of b and t and generalize prior results. The upper bound constructions use a new technique for efficiently converting each both sources of system complexity, namely the tile types and mixing graph, into a "bit string" assembly.

1 Introduction

The *staged* self-assembly model is a generalization of the *two-handed* [1, 4, 7, 8] or *hierarchical* [5, 12] tile self-assembly models. In tile self-assembly, system monomers are unit squares with edge labels that collide randomly and attach permanently if abutting edge labels match sufficiently. This simple model is an abstraction of a DNA-based molecular implementation at

the nanoscale [13, 21] and is computationally universal [21]. The staged variant is motivated by experimental settings, where parallelism and mixing can be achieved (e.g. test tubes). Liquid-handling robots have been used to perform complex mixing instructions in the lab [15], similar to the mixing algorithms of staged self-assembly systems.

The staged model [8] extends the two-handed model by carrying out separate assembly processes in multiple *bins*. Assembly in each bin begins with *input assemblies* previously assembled in other bins. These bins are stratified into stages, and a *mix graph* specifies which bins in the previous stage supply each bin with input assemblies. The *output* of a staged self-assembly system is the set of assemblies produced in the bins of the final stage.

A common goal in the design of self-assembling systems is the construction of a desired shape. Here we consider the design of *efficient* systems with minimal complexity for a given shape. Three metrics exist for staged systems: the number of distinct tile types used in the system (*tile complexity*), the maximum number of bins used in any stage (*bin complexity*), and the number of stages (*stage complexity*). Efficient construction for various classes of shapes [8, 10] and patterns [9, 22] have been considered, and further extensions and variants of the staged self-assembly model have also been studied [1, 3, 11, 16, 17, 18].

Our results. Here we study the two classic benchmarks for the efficiency a tile self-assembly model: the assembly of $n \times n$ squares and arbitrary shapes (with scaling permitted). Previous works [19, 20, 2] achieved matching upper and lower (univariate) bounds on the minimum complexity of systems that assemble these shape classes in the very first tile assembly model [21]. Here we give nearly matching upper and lower (trivariate) bounds for assembling these shapes in the staged model; our results are summarized in Table 1.

For a given number of tile types t and bins b, we prove that any $n \times n$ square is constructed by a system with $\mathcal{O}(\frac{\log n - t\log t - tb}{b^2} + \frac{\log\log b}{\log t})$ stages and a scaled version[1] of any shape S is assembled by a system with $\mathcal{O}(\frac{K(S) - t\log t - tb}{b^2} + \frac{\log\log b}{\log t})$ stages, where $K(S)$ denotes the Kolmogorov complexity of S with respect to some fixed universal Turing machine. We pair these results with nearly matching lower bounds, proving that for almost all natural numbers n^2, $\Omega(\frac{\log n - t\log t - tb}{b^2})$ stages are needed to assemble an $n \times n$ square, and for all shapes S, $\Omega(\frac{K(S) - t\log t - tb}{b^2})$ stages are needed to assemble a scaled version of a given shape S.

We further explore the stage complexity of these shapes within the *flexible glue* model of tile attachment [6] (where non-matching glue labels can have strength), and prove that $n \times n$ squares and scaled shapes can be assembled using $\mathcal{O}(\frac{\log n - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$ and $\mathcal{O}(\frac{K(S) - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$ stages, respectively. We pair this with nearly matching lower bound stage complexities of $\Omega(\frac{\log n - t^2 - tb}{b^2})$ and $\Omega(\frac{K(S) - t^2 - tb}{b^2})$.

Our upper bounds both use a new technique to efficiently assemble *bit string pads*: constant-width assemblies with an exposed sequence of glues encoding a given bit string. This technique converts all three forms of system complexity (tile, bin, and stage) into bits of the string with only a constant-factor loss of information. In other words, the number of bits in the bit string pad rises linearly with the number of bits needed to specify the tile types and mix graph of the construction.

[1] The scale factor is proportional to the product of the time and space used by the fixed universal Turing machine to encode S using $K(S)$ bits.

[2] The fraction of values for which the statement holds reaches 1 in the limit as $n \to \infty$.

Table 1 The main results obtained in this work: upper and lower bounds on the number of stages of a staged self-assembly system with b bins and t tile types uniquely assembling $n \times n$ squares and scaled shapes. $K(S)$ denotes the Kolmogorov complexity of a shape.

Standard Glue Stage Complexity Results

Shape	Upper Bound	Theorem	Lower Bound	Theorem
$n \times n$	$\mathcal{O}(\frac{\log n - t\log t - tb}{b^2} + \frac{\log\log b}{\log t})$	11	$\Omega(\frac{\log n - t\log t - tb}{b^2})$	12
Scaled shapes	$\mathcal{O}(\frac{K(S) - t\log t - tb}{b^2} + \frac{\log\log b}{\log t})$	13	$\Omega(\frac{K(S) - t\log t - tb}{b^2})$	14

Flexible Glue Stage Complexity Results

Shape	Upper Bound	Theorem	Lower Bound	Theorem
$n \times n$	$\mathcal{O}(\frac{\log n - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$	20	$\Omega(\frac{\log n - t^2 - tb}{b^2})$	21
Scaled shapes	$\mathcal{O}(\frac{K(S) - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$	22	$\Omega(\frac{K(S) - t^2 - tb}{b^2})$	23

Comparison with prior work. In providing a class of nearly optimal staged systems for any choice of bin and tile count, our results also generalize and improve on prior results. For instance, Theorem 11 implies construction of $n \times n$ squares using $\mathcal{O}(1)$ bins, $\mathcal{O}(\frac{\log n}{\log\log n})$ tile types, and $\mathcal{O}(1)$ stages, matching a result of [2] (up to constant factors). For flexible glues, this is improved to $\mathcal{O}(\sqrt{\log n})$ tile types, a result of [6]. The same theorem also yields constructions using $\mathcal{O}(1)$ bins, $\mathcal{O}(1)$ tile types, and $\mathcal{O}(\log n)$ stages (matching a result of [8]) or $\mathcal{O}(\sqrt{\log n})$ bins, $\mathcal{O}(1)$ tile types, and $\mathcal{O}(\log\log\log n)$ stages, substantially improving over the $\mathcal{O}(\log\log n)$ stages used in [8]. For constructing scaled shapes, Theorem 13 implies systems using $\mathcal{O}(1)$ bins, $\mathcal{O}(\frac{K(S)}{\log K(S)})$ tile types, and $\mathcal{O}(1)$ stages, a result of [20].

2 The Staged Assembly Model

Tiles. A *tile* is a non-rotatable unit square with each edge labeled with a *glue* from a set Σ. Each pair of glues $g_1, g_2 \in \Sigma$ has a non-negative integer *strength*, denoted $\text{str}(g_1, g_2)$. Every set Σ contains a special *null glue* whose strength with every other glue is 0. If the glue strengths do not obey $\text{str}(g_1, g_2) = 0$ for all $g_1 \neq g_2$, then the glues are *flexible*. Unless otherwise stated, we assume that glues are not flexible.

Configurations, assemblies, and shapes. A *configuration* is a partial function $A : \mathbb{Z}^2 \to T$ for some set of tiles T, i.e., an arrangement of tiles on a square grid. For a configuration A and vector $\vec{u} = \langle u_x, u_y \rangle \in \mathbb{Z}^2$, $A + \vec{u}$ denotes the configuration $f \circ A$, where $f(x, y) = (x + u_x, y + u_y)$. For two configurations A and B, B is a *translation* of A, written $B \simeq A$, provided that $B = A + \vec{u}$ for some vector $\vec{u}$. For a configuration A, the *assembly* of A is the set $\tilde{A} = \{B : B \simeq A\}$. The *shape* of an assembly $\tilde{A}$ is $\{\text{dom}(A) : A \in \tilde{A}\}$ where dom() is the domain of a configuration. A shape S' is a *scaled* version of shape S provided that for some $k \in \mathbb{N}$ and $D \in S$, $\bigcup_{(x,y) \in D} \bigcup_{(i,j) \in \{0,1,\ldots,k-1\}^2} (kx + i, ky + j) \in S'$.

Bond graphs and stability. For a configuration A, define the *bond graph* G_A to be the weighted grid graph in which each element of dom(A) is a vertex, and the weight of the edge between a pair of tiles is equal to the strength of the coincident glue pair. A configuration is *τ-stable* for $\tau \in \mathbb{N}$ if every edge cut of G_A has strength at least τ, and is *τ-unstable* otherwise. Similarly, an assembly is *τ-stable* provided the configurations it contains are τ-stable. Assemblies $\tilde{A}$ and $\tilde{B}$ are *τ-combinable* into an assembly $\tilde{C}$ provided there exist $A \in \tilde{A}$, $B \in \tilde{B}$, and $C \in \tilde{C}$ such that $A \cup B = C$ and $\tilde{C}$ is τ-stable.

Two-handed assembly and bins. We define the assembly process via bins. A bin is an ordered tuple (S, τ) where S is a set of *initial* assemblies and $\tau \in \mathbb{N}$ is the *temperature*. In this work, τ is always equal to 2. For a bin (S, τ), the set of *produced* assemblies $P'_{(S,\tau)}$ is defined recursively as follows:

1. $S \subseteq P'_{(S,\tau)}$.
2. If $A, B \in P'_{(S,\tau)}$ are τ-combinable into C, then $C \subseteq P'_{(S,\tau)}$.

A produced assembly is *terminal* provided it is not τ-combinable with any other producible assembly, and the set of all terminal assemblies of a bin (S, τ) is denoted $P_{(S,\tau)}$. That is, $P'_{(S,\tau)}$ represents the set of all possible supertiles that can assemble from the initial set S, whereas $P_{(S,\tau)}$ represents only the set of supertiles that cannot grow any further.

If all assemblies in $P'_{(S,\tau)}$ have finite size, then the assemblies in $P_{(S,\tau)}$ are *uniquely* produced by bin (S, τ). Unique production implies that every producible assembly can be repeatedly combined with others to form an assembly in $P_{(S,\tau)}$.

Staged assembly systems. An *r-stage b-bin mix graph M* is an acyclic r-partite digraph consisting of rb vertices $m_{i,j}$ for $1 \le i \le r$ and $1 \le j \le b$, and edges of the form $(m_{i,j}, m_{i+1,j'})$ for some i, j, j'. A *staged assembly system* is a 3-tuple $\langle M_{r,b}, \{T_1, T_2, \dots, T_b\}, \tau\rangle$ where $M_{r,b}$ is an r-stage b-bin mix graph, T_i is a set of tile types, and $\tau \in \mathbb{N}$ is the temperature. Given a staged assembly system, for each $1 \le i \le r$, $1 \le j \le b$, a corresponding bin $(R_{i,j}, \tau)$ is defined as follows:

1. $R_{1,j} = T_j$ (this is a bin in the first stage);
2. For $i \ge 2$, $R_{i,j} = \Big(\bigcup\limits_{k:\ (m_{i-1,k}, m_{i,j}) \in M_{r,b}} P_{(R_{(i-1,k)}, \tau_{i-1,k})} \Big)$.

Thus, bins in stage 1 are tile sets T_j, and each bin in any subsequent stage receives an initial set of assemblies consisting of the terminally produced assemblies from a subset of the bins in the previous stage as dictated by the edges of the mix graph.[3] The *output* of a staged system is the union of the set of terminal assemblies of the bins in the final stage.[4] The output of a staged system is *uniquely produced* provided each bin in the staged system uniquely produces its terminal assemblies.

3 Key Lemmas

Our results rely on two key lemmas. The first is an upper bound on the information content of a staged system that implies the lower bounds on system complexity. The second is a formal statement of the previously mentioned bit string pad construction.

▶ **Lemma 1.** *A staged system of fixed temperature τ with b bins, s stages, and t tile types can be specified using $\mathcal{O}(t \log t + sb^2 + tb)$ bits. Such a system with flexible glues can be specified using $\mathcal{O}(t^2 + sb^2 + tb)$ bits.*

[3] The original staged model [8] only considered $\mathcal{O}(1)$ distinct tile types, and thus for simplicity allowed tiles to be added at any stage (since $\mathcal{O}(1)$ extra bins could hold the individual tile types to mix at any stage). Because systems here may have super-constant tile complexity, we restrict tiles to only be added at the initial stage.

[4] This is a slight modification of the original staged model [8] in that there is no requirement of a final stage with a single output bin. It may be easier in general to solve problems in this variant of the model, so we consider it for lower bound purposes. However, all of our results apply to both variants of the model.

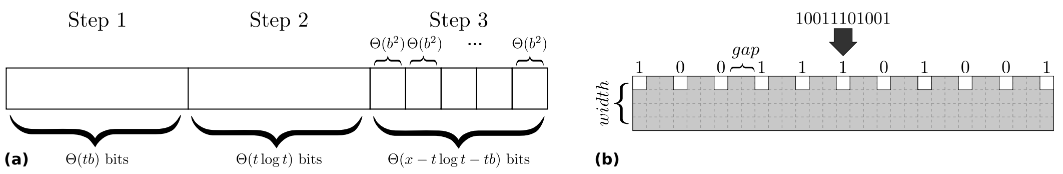

Figure 1 (a) The decomposition of a bit string pad's bits into those encoded by the three steps of a staged system with t tile types and b bins. (b) An example bit string $r = 10011101001$ encoded as a *width*-4 *gap*-2 11-*bit string pad* where the top glues correspond to the bits in r.

Proof. A staged system can be specified in four parts: the tile types, the glue function, the mix graph, and the assignment of tile types to stage-1 bins. We separately bound the number of bits required to specify each.

A set of t tile types has up to $4t$ glue types, so specifying each tile requires $\mathcal{O}(\log t)$ bits, and the entire tile set takes $\mathcal{O}(t \log t)$ bits. If the system does not have flexible glues, then the glue function can be specified in $\mathcal{O}(4t) = \mathcal{O}(t)$ bits, using $\mathcal{O}(\log \tau) = \mathcal{O}(1)$ bits per glue type to specify the glue's strength. If the system has flexible glues, then the glue function can be specified using $\mathcal{O}(1)$ bits per pairwise glue interaction and $\mathcal{O}((4t)^2) = \mathcal{O}(t^2)$ bits total.

The mix graph consists of bs nodes. Each pair of nodes in adjacent stages optionally share a directed edge pointing upwards. Thus specifying these edges takes $\mathcal{O}(b^2(s-1)) = \mathcal{O}(b^2 s)$ bits. The assignment of tile types to stage-1 bins requires one bit per each choice of tile type and bin, or $\mathcal{O}(tb)$ bits total.

Thus a staged system without flexible glues can be specified in $\mathcal{O}(t \log t + t + b^2 s + tb)$ bits, and otherwise in $\mathcal{O}(t \log t + t^2 + b^2 s + tb)$ bits. ◀

It immediately follows from Lemma 1 that for most bit strings of length x, any staged system with b bins and t tiles that encodes the bit string must have $\Omega(\frac{x-tb-t\log t}{b^2})$ stages with standard glues and $\Omega(\frac{x-tb-t^2}{b^2})$ stages with flexible glues.

The two main positive results of this work, efficient assembly of squares and general scaled shapes, both rely mainly on efficient assembly of *bit string pads*: assemblies that expose a sequence of north glues that encode a bit string. An example is shown in Figure 1(b). Squares and general scaled shapes are assembled by combining a universal set of "computation" tiles with efficiently assembled "input" bit string pads.

▶ **Definition 2** (bit string pad). A *width-k gap-f r-bit string pad* is a $k \times (f(r-1)+1)$ rectangular assembly with r glues from a set of two glue types $\{0,1\}$ exposed on the north face of the rectangle at intervals of length f, starting from the leftmost north edge. Unless otherwise specified, a bit string pad is gap-0. All remaining exposed glues on the north tile edges have some common label f. The remaining exposed south, east, and west tile edges have glues g_S, g_E, and g_W. A bit string pad *represents* a given string of r bits if the exposed "0" and "1" glues from left to right are equal to the given bit string.

Bit string pads are constructed by decomposing the pad into three subpads and constructing each in a separate step using a different source of system complexity (see Figure 1(a)):

- Step 1: $\Theta(tb)$ bits from assigning tile types to stage-1 bins (Section 4.2).
- Step 2: $\Theta(t \log t)$ bits from the tile types themselves as in [2, 6, 14, 20] (Section 4.3).
- Step 3: $\Theta(x - t\log t - tb)$ bits from the mix graph using a variant of "crazy mixing" [8] (Section 4.4).

These subpads are then combined into the complete pad. If flexible glues are permitted, Step 2 is modified as in [6] to achieve $\mathcal{O}(\frac{x-tb-t\log t}{b^2} + \frac{\log\log b}{\log t})$ stages.

▶ **Lemma 3.** *There exist constants $c, d \in \mathbb{N}$ such that, for any $t, b \in \mathbb{N}$ with $t > c$, $b > d$ and bit string S of length x, there exists a staged system with b bins, t tiles, and $\mathcal{O}(\frac{x-tb-t\log t}{b^2} + \frac{\log\log b}{\log t})$ stages that assembles a width-9 gap-$\Theta(\log b)$ l-bit string pad representing S.*

Proof. Let $t' = \frac{t-10}{4}$ and $b' = \frac{b-10}{4}$. Using an approach similar to that in Section 4.1, construct a length $1 \times 2\log\frac{b'-15}{9} + 2$ *filler assembly* using t' tile types and b' bins in $\mathcal{O}(\frac{\log\log b'}{\log t'})$ stages such that the assembly has glue e on its west edge (matching that of the east side of the bit string pads) and glue w on its east edge. Next, use Lemma 5 with t' tile types, b' bins, and $\mathcal{O}(\frac{\log\log b'}{\log t'})$ stages to construct a width-9 gap-$2\log\frac{b'-15}{9} + 2$ $\Theta(tb)$-bit string pad. Then use Lemma 9 with t' tile types, b' bins, and $\mathcal{O}(1)$ stages to construct a width-3, gap-$2\log\frac{b'-15}{9} + 2$, $\Theta(t\log t)$-bit string pad.

So far, $\Theta(tb) + \Theta(t\log t)$ bits have been encoded and so $\Theta(x - tb - t\log t)$ bits remain. Invoke Lemma 10 with t' tile types, b' bins, and $\mathcal{O}(\frac{x-tb-t\log t}{b^2} + \frac{\log\log b'}{\log t'})$ stages to construct a width-9 gap-$2\log\frac{b'-15}{9} + 2$ $\Theta(x - tb - t\log t)$-bit string pad. In one final stage, concatenate two bit string pads using the filler assembly and in one more stage concatenate the third.

By concatenating the length $\Theta(tb)$-bit string pad, the length $\Theta(t\log t)$-bit string pad, and the $\Theta(x - tb - t\log t)$-bit string pad, each separated by the $2\log\frac{b'-15}{9} + 2$ filler assembly, an x-bit string pad with $\mathcal{O}(\log b)$ spacing is constructed; use 10 additional tile types (in 10 bins) to "fill in" the portions of the assembly with width less than 9.

The total number of tile types and bins used are $4t' + 10 = t$ and $4b' + 10 = b$, respectively, with $4t'$ and $4b'$ used for the three bit string pads and one connector assembly and the remainder for filling in the pad to width 9. The total number of stages used is $\mathcal{O}(\frac{\log\log b'}{\log t'}) + \mathcal{O}(1) + \mathcal{O}(\frac{x-tb-t\log t}{b^2} + \frac{\log\log b'}{\log t'}) = \mathcal{O}(\frac{\log b}{t} + \frac{x-tb-t\log t}{b^2})$. ◀

The additive gap between the upper and lower bounds implied by these lemmas comes from the $\mathcal{O}(\frac{\log\log b}{\log t})$ additional stages used to construct some of the machinery needed to carry out the three steps of Lemma 3.

4 Bit String Pad Construction

As mentioned, bit string pads are assembled by combining three subpads constructed via separate and independent methods that utilize distinct sources of information complexity in a staged self-assembly system. Each subpad encodes a number of bits roughly proportional to the number needed to describe the corresponding portion of the staged system, i.e., an asympotitically optimal number of bits are encoded.

4.1 Wings

The additive gap in our upper and lower bounds come from a helpful subconstruction used in Steps 1 and 3 described here. This subconstruction assembles all 1-gapped width-2 bit string pads of a given length in separate bins:

▶ **Lemma 4.** *There exist constants $c, d \in \mathbb{N}$ such that, for any $t, b \in \mathbb{N}$ with $t > c$ and $b > d$, there is a staged self-assembly system with b bins, t tile types, and $\mathcal{O}(\frac{\log\log b}{\log t})$ stages that assembles all gap-1, width-2, $\log(b)$-bit string pads, each placed in a distinct bin.*

Due to space constraints, the proof of this and some later results are omitted. We give proof sketches instead. Let $\gamma = \lfloor\frac{t-6}{2}\rfloor$ and $\eta = \gamma + 1$. If $\gamma \geq 2\log(b)$, directly build all the bit string pads in $\mathcal{O}(1)$ stages. Otherwise, repeatedly apply a constant-stage "round" that

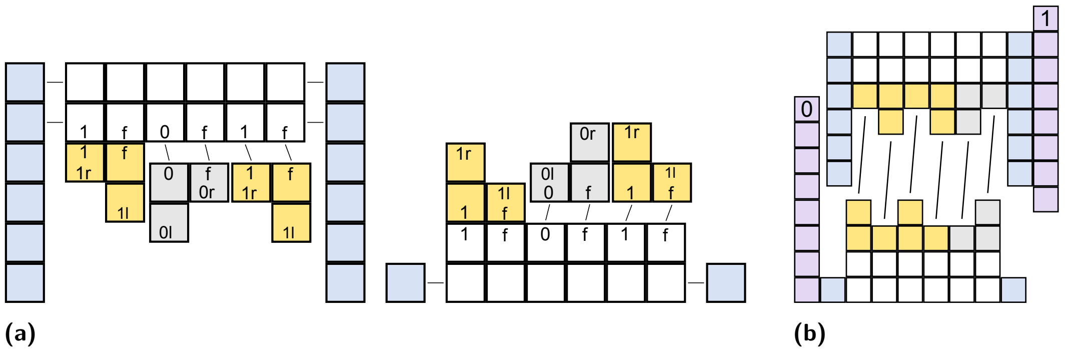

Figure 2 (a) The attachment of extra subassemblies onto bit string pads to create left and right wings. Each of the two size 3 subassemblies use 3 tiles to deterministically assemble the respective L shape in their own bins. **(b)** The attachment of two bit strips using matching wings. Note that the geometry attached to the sides of each wing prevent misaligned, non-matching wings to attach.

starts with all binary gadgets of a given length and yields all binary gadgets of a factor of η longer, starting with just two bit string pads encoding the two bit strings of length 1.

Use $\mathcal{O}(1)$ additional tile types, bins, and stages to augment the the bit string pads assembled by Lemma 4 into left and right *wings* (seen in the left and right portions of Figure 2(a)) that attach when the underlying bit strings are identical. These wings are used in Steps 1 and 3 to achieve ordered assembly of bit string subpads into larger bit string pads.

4.2 Step 1: encoding via initial tile-to-bin assignment

Recall that in a staged system, each of the system's b stage-1 bins is assigned a subset of t total tile types. Here we design an assignment that assembles a $\Theta(tb)$-bit string subpad of the final bit string pad using $\mathcal{O}(\log\log b/\log t)$ stages - enough to utilize the wings of Section 4.1. The assignment yields b bins that contain assemblies encoding distinct equal-length substrings of the $\Theta(tb)$ bits. These assemblies are then combined using wings.

▶ **Lemma 5.** *There exist $c, d \in \mathbb{N}$ such that, for all $t, b \in \mathbb{N}$ with $t > c$ and $b > d$ and bit string S of length $\Theta(tb)$, there is a staged self-assembly system with b bins, t tiles, and $\mathcal{O}(\frac{\log\log b}{\log t})$ stages that assembles a gap-$(2\log\lfloor\frac{b-15}{9}\rfloor + 2)$ $\Theta(tb)$-bit string pad representing S.*

See Figure 3 for a sketch of the idea. Let γ and β be constant fractions of t and b, respectively. Use γ tiles and β bins to construct all left and right $\log(\beta)$-bit wings according to Section 4.1. Also construct $\frac{\gamma}{2}$ constant-sized *bit strip* subassemblies that expose a 0 or 1 north glue and have wings attached to their right and left sides such that any $\frac{\gamma}{2}$-bit string pad can be assembled from $\frac{\gamma}{2}$ bit strips attached sequentially.

In each of β bins, assemble $\frac{\gamma}{2}$ bit strips into a distinct $\frac{\gamma}{2}$-bit string subpad of the desired pad. Combine these β subpads with wings that encode their locations in the pad, and then combine these "wing-labeled" subpads to assemble the complete $\Theta(tb)$-bit string pad. The number of stages used is $\mathcal{O}(\frac{\log\log b}{\log t})$ (for the wings, see Lemma 4) plus $\mathcal{O}(1)$ (the subpads of the desired pad).

4.3 Step 2: encoding via tile types

Here the goal is to design a collection of t tile types that encodes $\Theta(t\log t)$ bits. The solution is to utilize the base conversion approach of [2, 6, 14, 20]. In this approach, tile

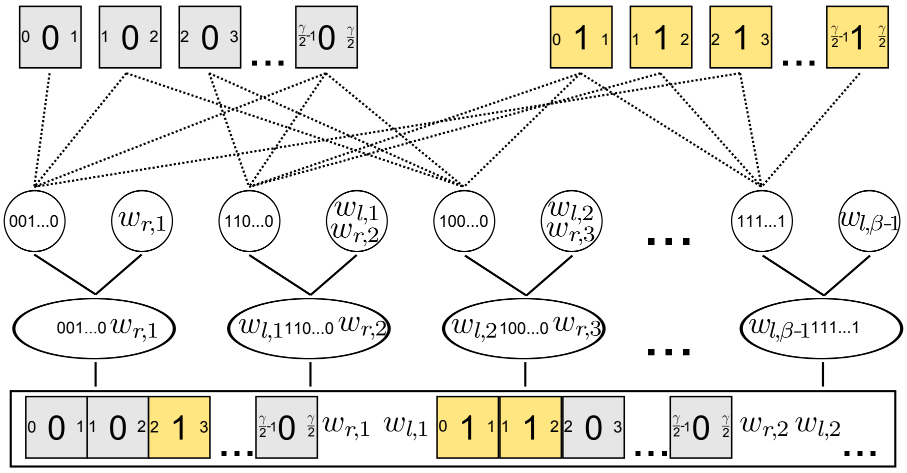

Figure 3 The creation of $\gamma\beta$-bit string pads. The squares labeled 0 and 1 represent bit strips. The dotted lines indicate tile to bin assignments before the first stage of the system; $w_{r,i}$ and $w_{l,i}$ represent the i^{th} right and left wings respectively.

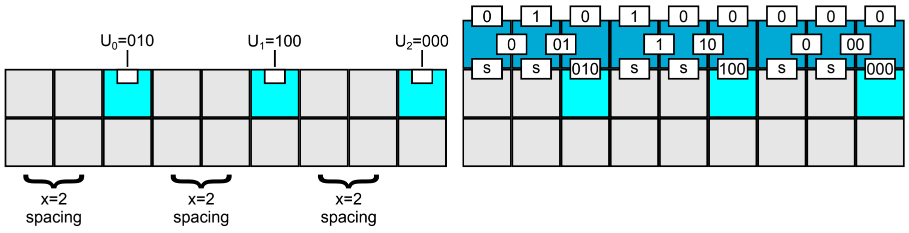

Figure 4 Left: a width-2 gap-log $z-1$ decompression pad representing a bit string $S = 010100000$ in base $z = 8$. Right: $\mathcal{O}(z)$ decompression tiles interact with the north glues of the decompression pad to combine into a width-3 bit string pad representing S in base 2.

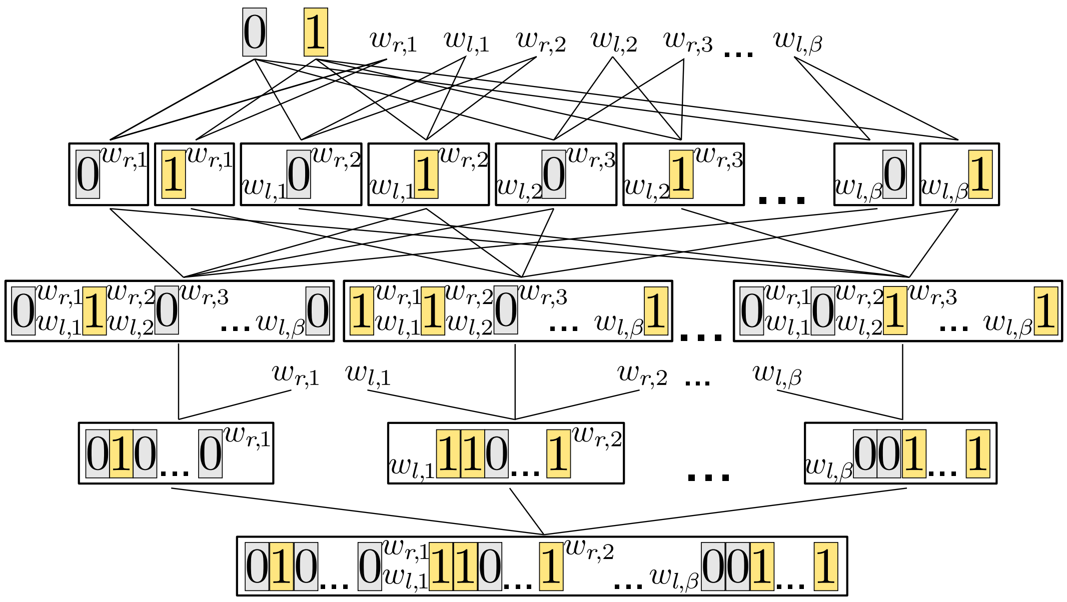
types optimally encode integer values in a high base and then "decompressed" into a binary representation. In total, t tile types are used to encode (in a high base) and decompress (into a binary) $\Theta(t \log t)$ bits.

▶ **Definition 6** (decompression pad). For $k, r, x \in \mathbb{N}$ and $u = 2^x$, a width-k, r-digit, base-u decompression pad is a $k \times rx$ rectangular assembly with r glues from a set of $u-1$ glue types $\{0, 1, ..., u-1\}$ exposed on the north face of the rectangle at intervals of length $x-1$ and starting from the leftmost northern edge. All remaining glues on the north surface have a common type n. The remaining exposed south, east, and west tile edges have glues g_S, g_E, and g_W. A decompression pad *represents* a given string of digits in base u if the exposed glues from left to right, disregarding glues of type n, are equal to the given digit string in base u.

Consider the following example, also seen in Figure 4). Let $S = 010100000$ ($S = 240$ in base 8) be a bit string, with the goal of constructing a width-3 9-bit string pad representing S. First, build a decompression pad representing S in base 8 by combining 3 different $3 \times \log_2(8)$ blocks. Then convert the decompression pad into a bit string pad representing S using $\mathcal{O}(z)$ tile types.

▶ **Lemma 7.** *Given integers $x \geq 3$, $d \geq 1$ and $z = 2^x$, there exists a 1-stage, 1-bin staged self-assembly system that assembles a d-digit decompression pad of width-2 and base-z, using at most $5d + \log z - 2$ tile types.*



0

$w_{r,1}$ $w_{l,1}$ $w_{r,2}$ $w_{l,2}$ $w_{r,3}$ ... $w_{l,\beta}$

Figure 5 The creation of β^2-bit string pads using β wings and $\mathcal{O}(1)$ stages. The rectangles 0 and 1 represent bit strips that may attach wings on either side; $w_{r,i}$ and $w_{l,i}$ represent the i^{th} right and left wings respectively.

▶ **Lemma 8.** *Given integers $d \geq 3$, $x \geq 3$, $z = 2^x$, and bit string S of length $d\log(z)$, there exists a staged self-assembly system with 1 bin, $5d + 2z + \log z - 4$ tile types, and 1 stage that assembles a width-3 $d\log(z)$-bit string pad representing S.*

▶ **Lemma 9.** *There exists some constant $c \in \mathbb{N}$ such that, for any $t \geq c$ and bit string S of length $\Theta(t\log t)$, there exists a staged self-assembly system with 1 bin, t tile types, and 1 stage assembling a width-3 $\Theta(t\log t)$-bit string pad representing S.*

Omitted additional details are needed to convert these gap-0 pads to higher-gap pads consistent with those assembled in Section 4.4.

4.4 Step 3: encoding via mix graph

This step uses a mix graph to encode encodes a achieves the following efficient assembly:

▶ **Lemma 10.** *There exist $c, d \in \mathbb{N}$ such that, for any $t > c$ and $b > d$ and bit string S of length x, there is a staged self-assembly system with t bins, b tile types, and $\mathcal{O}(\frac{x}{b^2} + \frac{\log\log b}{\log t})$ stages that assembles a width-9 gap-$(2\log\frac{b-15}{9} + 2)$ x-bit string pad representing S.*

An overview of the construction is shown in Figure 5. Let γ and β represent some constant fractions of t and b respectively. Utilize γ tiles and β bins to construct all length-$\log_2(\beta)$ left and right wings according to Section 4.1 and denote the i^{th} left and wings by $w_{l,i}$ and $w_{r,i}$, respectively. Also construct two constant-sized *bit strip* subassemblies that expose a 0 or 1 north glue and allow wings to be attached to their right and left sides.

In the first stage and for all $1 \leq i \leq \beta$, mix $w_{r,i}$ and $w_{l,i-1}$ with bit strip 0 into a bin denoted b_i^0. Similarly, mix $w_{r,i}$ and $w_{l,i-1}$ with bit strip 1 into a bin denoted b_i^1 for a total of 2β bins.

In the second stage, selectively mix specific 0 or 1 winged bit strips to assemble specific β-bit string pads across β bins. Specifically, mix either b_i^0 or b_i^1 for each i across β bins for a total of β different β-bit string pads.

In the third stage, attach wings to each of the β-bit string pads. For each of the β bins, mix $w_{r,i}$ and $w_{l,i-1}$ into the bins such that $w_{r,1}$ is mixed with the first β bits of the desired β^2-bit string pad, $w_{r,2}$ and $w_{l,1}$ are mixed with the second β bits of the desired β^2-bit string pad, etc.

In the final stage, mix all β bins, each containing a β-bit string pads, into a common bin to create β^2-bit string pads. The wings ensure that the bit string pads attach in the desired order. Repeat this process $\frac{x}{\beta^2}$ times, each time concatenating the β^2-bit string pad onto each preceding bit string pad. In the end, a single x-bit string pad results. In total, $\mathcal{O}(\frac{\log\log b}{\log t})$ stages are used to construct the wings and $\mathcal{O}(\frac{x}{b^2})$ stages are used to assemble $\frac{x}{\beta^2}$ unique β^2-bit string pads. Thus this step has total stage complexity of $\mathcal{O}(\frac{x}{\beta^2} + \frac{\log\log\beta}{\log t}) = \mathcal{O}(\frac{x}{b^2} + \frac{\log\log b}{\log t})$.

5 Assembly of $n \times n$ Squares

Efficient assembly of $n \times n$ squares is obtained by combining bit string pads with a technique of Rothemund and Winfree [19]. Their technique utilizes a binary counting mechanism which constructs a length $\Theta(n)$ rectangle with $\Theta(\log n)$ width. The mechanism uses $\mathcal{O}(\log n)$ tile types to seed the counter at a certain value, and then $\mathcal{O}(1)$ tile types attach in a "zig-zag" pattern, where "zigs" copy the value from the row below and "zags" increment the the value by 1. Once the binary counter increments to its maximum value (a string of 1), the assembly stops growing. Two rectangles assembled this way can be combined to form a bounding box that is then filled to form a square. We utilize the bit string pad construction of Section 4 to efficiently assemble the seed for the binary counting mechanism, requiring only an additional $\mathcal{O}(1)$ tile types and 1 stage to perform the binary counting and square filling.

▶ **Theorem 11.** *There exist constants $b_0, t_0 \in \mathbb{N}$ such that for any $b, t, n \in \mathbb{N}$ with $b \geq b_0$, $t \geq t_0$, there exists a staged self-assembly system with b bins, t tile types, and $\mathcal{O}(\frac{\log n - t\log t - tb}{b^2} + \frac{\log\log b}{\log t})$ stages that uniquely produces an $n \times n$ square.*

Proof. Let c be the (constant) number of tile types used to implement the fixed-width "zig-zag" binary counting mechanism shown in [19]. Let $t' = t - c$, $b' = b - 2$, and $n' = \lceil \log n \rceil$. Let $m = 2^{n'-1} - (n-22)/2 - n'(2\log b' + 2)$. Using Lemma 3, construct two $\Theta(\log b)$-gap $\lceil \log m \rceil$-bit string pads encoding m, where each construction each uses b' bins, t' tile types and $\mathcal{O}(\frac{\lceil \log m \rceil - tb - t\log t}{b^2} + \frac{\log\log b}{\log t})$ stages. Figure 6 shows the construction, including modifications to the technique shown in [19].

On both pads, a small modification is made: the glues of the first and last bits are made unique and the first bit's glue strength is set to 2. This modification is necessary to implement a fixed-width binary counting mechanism as in [19] and uses $\mathcal{O}(1)$ additional tile types. Also, on the north-facing (east-facing) bit string pad, a unique strength-2 glue C2 is placed on the south (west) face of the pad's bottommost rightmost (topmost leftmost) tile. This special glue is used to combine the two pads with a unique tile type.

Note that the bit string pads assembled in Section 4 have substantial spacing between the exposed binary glues, but the counter of [19] has spacing 0. This is resolved by adding generic tiles which transfer information horizontally. These generic tiles use cooperative binding between a south-facing f glue (which matches the glue that spaces the bits on the bit string pad) and west/east glues representing the information to be passed horizontally across spacing of f glues. The tiles also expose a north-facing f glue to be used when the

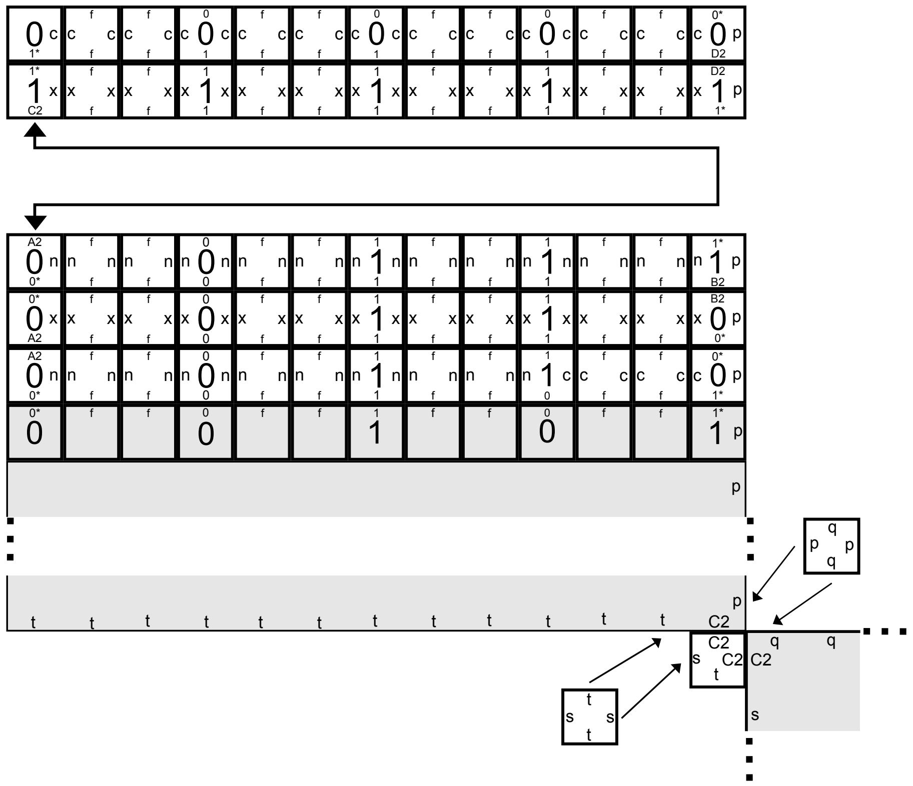

Figure 6 Constructing a counter seed. The bit string pads are shown in gray. Glues with a "2" in the string have strength-2, all other glues have strength 1.

information needs to be transferred across the spacing in the row above. Without loss of generality, rotated versions of these tiles are used in the east-growing counter.

The stage complexity of the system is $\mathcal{O}(\frac{\lceil \log n \rceil - tb - t \log t}{b^2} + \frac{\log \log b}{\log t})$. Note that the length of the bit string pads assembled according to Lemma 3 is dependent on b, the number of bins used to construct the bit string pad. If b is so large that the spacing between bits causes the width of the bit string pad to exceed n (roughly $\log b > n$), we instead directly construct the appropriate bit string pad with spacing 0 using $\mathcal{O}(\frac{\log \log b}{\log t})$ stages. ◀

The following lower bound is derived from Lemma 1 by observing that for almost all $n \in \mathbb{N}$, $\lfloor \log n \rfloor$ bits are needed to represent n.

▶ **Theorem 12.** *For any $b, t \in \mathbb{N}$ and almost all $n \in \mathbb{N}$, any staged self-assembly system which uses at most b bins and t tile types that uniquely assembles an $n \times n$ square must use $\Omega(\frac{\log n - t \log t - tb}{b^2})$ stages.*

6 Assembly of Scaled Shapes

Efficient assembly of arbitrary shapes (up to scaling) is achieved by combining bit string pads with the shape-building scheme of Soloveichik and Winfree [20]. Their construction uses two subsets of tile types: a varying set to encode the binary description of the target shape and a fixed set to decode the binary description and build the shape. We replace the first set with a bit string pad encoding the same information.

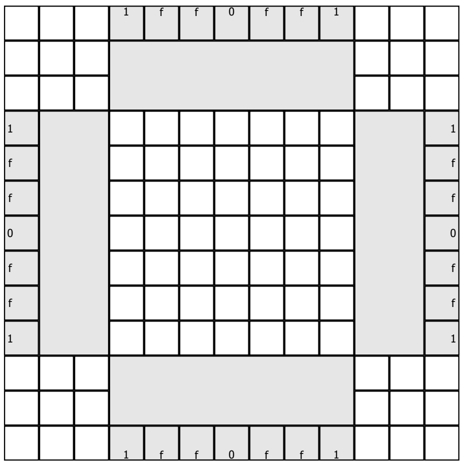

Figure 7 Construction of the modified seed block. Bit string pads are colored in gray. We concatenate four $K(S)$-bit string pads representing S.

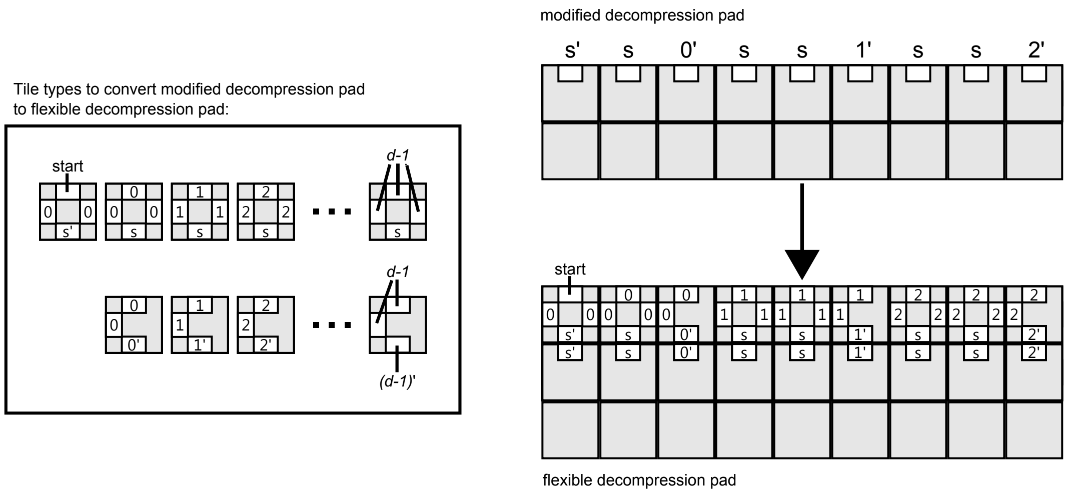
▶ **Theorem 13.** *There exist constants $b_0, t_0 \in \mathbb{N}$ such that for any shape S of Kolmogorov complexity $K(S)$ and $b, t \in \mathbb{N}$ such that $b \geq b_0$ and $t \geq t_0$, there exists a staged self-assembly system with b bins, t tile types, and $\mathcal{O}(\frac{K(S)-t\log t-tb}{b^2} + \frac{\log\log b}{\log t})$ stages that uniquely produces S at some scale factor.*

Proof. Observe that the tile set described in [20] uniquely constructs the same terminal assembly, namely a *scaled* version of S where each cell is replaced by a square block of cells, when run at temperature 2 in the two-handed mixing model. It does so via a Kolmogorov-complexity-optimal Turing machine simulation of a machine that computes a spanning tree of the shape given a seed assembly or *seed block* encoding the shape. The simulation is then run as it "fills in" the shape, beginning with the seed block. Here a similar seed block is constructed and consists of four bit string pads, a square "core" and additional filler tiles.

Let $t' = \frac{t-c}{5}$ where c is the (constant) number of tile types required by [20] to carry out the simulation of a (fixed) universal Turing machine. Let $b' = \frac{b-1}{5}$.

Use the method of Lemma 3 to construct the modified seed block by assembling four different $K(S)$-bit string pads representing a program that outputs S, each using b' bins, t' tile types and $\mathcal{O}(\frac{K(S)-t'\log t'-t'b'}{b'^2} + \frac{\log\log b'}{\log t'})$ stages. These four pads (each with dimensions $(2K(S)\log K(S)+2) \times \mathcal{O}(1)$) are attached to the four sides of a $(2K(S)\log K(S)+2) \times (2K(S)\log K(S)+2)$ square constructed as in Theorem 11 using t' tile and b' bins in $\mathcal{O}(\frac{\log(2K(S)\log K(S)+2)-t'\log t'-t'b'}{b'^2} + \frac{\log\log b'}{\log t'})$ stages. An abstract figure of the completed seed block can be seen in Figure 7. The Turing simulation occurs in one stage by mixing the four concatenated bit string pads into one bin which contains the fixed set of Turing-machine-simulation tiles of [20]. The bit string pads contain spacing between the exposed binary glues, while the simulation tile types of [20] expect adjacent glues. This is resolved by modifying the Turing-machine-simulation tile set to include generic tiles for transferring information across spacing, similar to the tiles of the same purpose discussed in the proof of Theorem 11. We need at most 1 such tile for each tile in the (constant-sized) Turing-machine-simulation tile set, for a constant increase in tile complexity. The stage complexity is $4 \times \mathcal{O}(\frac{K(S)-t'\log t'-t'b'}{b'^2} + \frac{\log\log b'}{\log t'}) + \mathcal{O}(\frac{\log(2K(S)\log K(S)+2)-t'\log t'-t'b'}{b'^2} + \frac{\log\log b'}{\log t'}) = \mathcal{O}(\frac{K(S)-t\log t-tb}{b^2} + \frac{\log\log b}{\log t})$. ◀

The following theorem follows from the information-theoretic bound of Lemma 1.



Tile types to convert modified decompression pad

start
flexible decompression pad

Figure 8 The templates to convert a modified decompression pad to a flexible decompression pad using $2d + 1$ tile types, where integer $d \geq 3$, on the left. Using these additional tile types, a modified decompression pad is converted into a flexible decompression pad. A *modified decompression pad* has a westmost northmost glue of s' and every non-s glue on the north surface is a special *prime* version distinct from other similar glue types. On the left, a width-2 modified decompression pad representing the string 012 in base-8 is converted to a width-3 length-9 flexible decompression pad.

▶ **Theorem 14.** *For any $b, t \in \mathbb{N}$ and shape S with Kolmogorov complexity $K(S)$, any staged self-assembly system which uses at most b bins and t tile types that uniquely assembles S must use $\Omega(\frac{K(S)-t\log t-tb}{b^2})$ stages.*

7 Flexible Glues

Here, an alternate model permitting non-diagonal glue functions, also called *flexible glues* is considered. By modifying Step 2 of the bit string pad construction of Section 4 to encode $\Theta(t^2)$ bits rather than $\Theta(t\log(t))$ bits in t tile types, similarly tight results are obtained for the same problems in this more powerful model. The technique uses a modified decompression bad, similar to the technique introduced in [6].

▶ **Definition 15** (flexible decompression pad)**.** A width-k length-r^2 flexible decompression pad is a $k \times r^2$ rectangular assembly with r^2 north glue types from the set $\{\text{start}, 0, 1, \ldots, r\}$ exposed on the north face of the rectangle. The westmost glue is “start”, the following $r - 1$ glues have type “0”, followed by r glues of type “1”, r glues of type “2”, and so on. The exposed south, east, and west tile edges have glues g_S, g_E, and g_W, respectively.

In order to build the flexible decompression pad, a modified decompression pad representing a number $C = c_0c_1 \ldots c_{d-1}$ in base 2^d is needed.

▶ **Lemma 16.** *Given an integer $d \geq 3$, there exists a staged assembly system with 1 bin, $8d - 1$ tile types, and 1 stage that assembles a width-3 length-d^2 flexible decompression pad.*

Proof. Start with the construction of Lemma 7 that yields a a width-2 length-d^2 decompression pad encoding C. Modify the tile types of this construction such that the leftmost northmost glue is s' and every non-s glue on the north surface is a special *prime* version, to differentiate between other similar glue types. Then add $2d + 1$ tiles that modify the north surface decompression pad to yield width-3 flexible decompression pad, as seen in Figure 8.

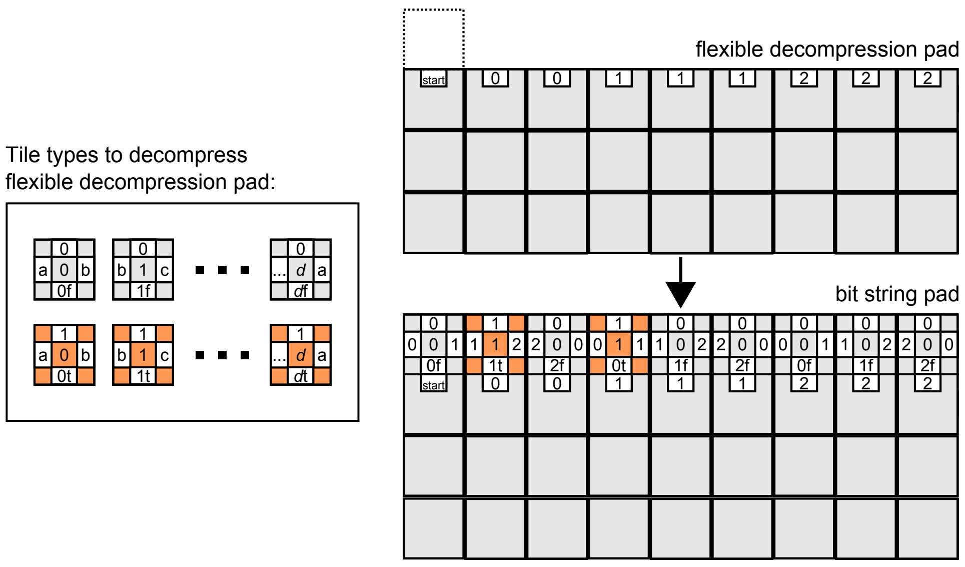

Figure 9 On the left, the templates for the decompression tiles needed to decompress a flexible decompression pad for any given $d \geq 3$. In the top right, an example of a length-9 flexible decompression pad. In the bottom right, the decompression tiles interact with the flexible decompression pad and glue function to assemble a bit string pad from a flexible decompression pad, representing the bit string “010100000”. The flexible glues form a bond of strength 2 between the glue pair (‘start’, ‘0f’), strength 1 between glues pairs (‘0’, ‘0’), (‘1’, ‘1’), (‘2’, ‘2’), (‘0’, ‘1t’), (‘0’, ‘2f’), (‘1’, ‘0t’), (‘1’, ‘1f’), (‘1’, ‘2f’), (‘2’, ‘0f’), (‘2’, ‘1f’), and (‘2’, ‘2f’), and strength 0 between all other glue pairs.

This step requires $5d + \log 2^d - 2$ tile types to build a modified decompression pad and $2d+1$ tiles to convert this modified decompression pad that into a flexible decompression pad. Thus $2d + 1 + 5d + \log 2^d - 2 \leq 8d - 1$ tile types are used in total. ◀

▶ **Lemma 17.** *Given integers $d \geq 3$ and any length d^2 bit string R, there exists a 1 stage, 1 bin, staged assembly system with flexible glues that assembles a width-4 gap-0 d^2-bit string pad representing R, using at most $10d - 1$ tile types.*

Proof. Consider a width-3, length d^2 flexible decompression pad. The idea is to use $2d$ tile types and flexible glues to build a width-4 gap-0 d^2-bit string pad from the flexible decompression pad (see Figure 9). Consider a sequence of d bitstrings $D = D_0, D_1, \ldots, D_{d-1}$ with each $D_i = s_0 s_1 s_2 \ldots s_{d-1}$ such that the in-order concatenation of all bitstrings in D equals R. Let $D_{i,j}$ denote the j^{th} bit of the i^{th} bit string of D.

The goal is to construct a glue function such that it specifies the tiles that can attached to the top of the flexible decompression pad to be the concatenation of the bitstrings in D. Note that the tiles that have a “0” or “1” glue as those with labels that end in “f” or “t”, respectively. Let $str(g_1, g_2)$ denote the strength between glues g_1 and g_2. Set the tile that attaches to the “start” glue to be one that exposes “0” or a “1” by setting $str(start, 0f) = 2$ or $str(start, 0t) = 2$, respectively. For all $D_{i,j}$, we set $str(i, jf) = 0$ if and only if $D_{i,j} = 0$ and $str(i, jt) = 1$, otherwise. In addition, we set $str(a, a) = 1$, $str(b, b) = 1$, and so on.

With this, we build a width-4 gap-0 d^2-bit string pad from the flexible decompression pad. An example of this can be seen in Figure 9. Also, $8d - 1$ tile types are used to build a width-3, length d^2 flexible decompression pad. An additional $2d$ tile types are needed to decompress, using flexible glues, into a width-4 d^2-bit string pad. So the total number of tile types used is $10d - 1$. ◀

▶ **Lemma 18.** *Given $t \in \mathbb{N}$, there exists some constant $c \in \mathbb{N}$, such that for all cases where $t \geq c$, there exists a staged self-assembly system with t tiles which assembles any width-4 $\Theta(t^2)$-bit string pad using 1 stage, 1 bin, and flexible glues.*

Proof. Given t tile types, consider how many bits can be produced using Lemma 17. Let $d = \lfloor \frac{t+1}{10} \rfloor$. Invoke Lemma 17 to build a width-4 d^2-bit string pad with flexible glues using $10d - 1$ tiles. The number of bits produced is $y = d^2 = (\lfloor \frac{t+1}{10} \rfloor)^2 = \Theta(t^2)$. Then by Lemma 17, any width-4 $(\lfloor \frac{t+1}{10} \rfloor)^2$-bit string pad can be build in the flexible glue model using at most t tiles, 1 stage, and 1 bin. The smallest choice of d requires $d = \lfloor \frac{t+1}{10} \rfloor \geq 3$, implying $t \geq 29$. For all cases where $t \geq c$ we have a constant, $c = 29$, where this lemma holds true. ◀

The improvements to Lemmas 17 and 18 allow for a larger bit string pad to be built in Step 2 when compared to standard glues, reducing stage complexity to $\mathcal{O}(\frac{\log\log b}{\log t} + \frac{x-tb-t^2}{b^2})$:

▶ **Lemma 19.** *Given $t, b \in \mathbb{N}$ and a bit string r where $x = |r|$. Then, there exist some constants $c, d \in \mathbb{N}$, such that for all cases where $t > c$ and $b > d$, there is a staged self-assembly system using flexible glues with b bins and t tiles which assembles an x-bit string pad representing r with width 9 and gap $\Theta(\log b)$ using $\mathcal{O}(\frac{x-tb-t^2}{b^2} + \frac{\log\log b}{\log t})$ stages.*

Nearly tight upper and lower bounds for square and general shape construction in the flexible glue model are obtained by replacing the bit string construction of Lemma 3 with Lemma 19, and applying the flexible glue lower bound of Lemma 1:

▶ **Theorem 20.** *For any $b, t, n \in \mathbb{N}$ and constants c_b, c_t such that $b \geq c_b$ and $t \geq c_t$, there exists a staged self-assembly system using flexible glues with b bins and t tile types that uniquely produces an $n \times n$ square using $\mathcal{O}(\frac{\log n - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$ stages.*

▶ **Theorem 21.** *For any $b, t \in \mathbb{N}$ and almost all $n \in \mathbb{N}$, any staged self-assembly system with flexible glues which uses at most b bins and t tile types that uniquely assembles an $n \times n$ square must use $\Omega(\frac{\log n - t^2 - tb}{b^2})$ stages.*

▶ **Theorem 22.** *For any shape S and $b, t \in \mathbb{N}$ and constants c_b, c_t such that $b \geq c_b$ and $t \geq c_t$, there exists a staged self-assembly system using flexible glues with b bins and t tile types which uniquely produces S at some scale factor using $\mathcal{O}(\frac{K(S) - t^2 - tb}{b^2} + \frac{\log\log b}{\log t})$ stages.*

▶ **Theorem 23.** *For any $b, t \in \mathbb{N}$ and shape S with Kolmogorov complexity $K(S)$, any staged self-assembly system with flexible glues which uses at most b bins and t tile types that uniquely assembles S must use $\Omega(\frac{K(S) - t^2 - tb}{b^2})$ stages.*

8 Conclusion

In this work, we achieved nearly optimal staged assembly of two classic benchmark shape classes. These constructions generalize the known upper bounds of [2, 6, 8, 20] to arbitrary choices of tile type and bin counts, as well as to the flexible glue model. The natural problem left open is the elimination of the additive $\mathcal{O}(\frac{\log\log b}{\log t})$ gap between the upper and lower bounds induced by the wings subconstruction of Section 4.1. Although this subconstruction is the cause of an additive gap in an otherwise optimal result, it is a useful approach for general assembly labeling and coordinated attachment and is likely useful in other staged constructions. The constant width of our bit string pads can also potentially be exploited for efficient construction of shapes with geometric bottlenecks, e.g., thin rectangles.

Abstract

An important task in trajectory analysis is defining a meaningful representative for a cluster of similar trajectories. Formally defining and computing such a representative r is a challenging problem. We propose and discuss two new definitions, both of which use only the geometry of the input trajectories. The definitions are based on the homotopy area as a measure of similarity between two curves, which is a minimum area swept by all possible deformations of one curve into the other. In the first definition we wish to minimize the maximum homotopy area between r and any input trajectory, whereas in the second definition we wish to minimize the sum of the homotopy areas between r and the input trajectories. For both definitions computing an optimal representative is NP-hard. However, for the case of minimizing the sum of the homotopy areas, an optimal representative can be found efficiently in a natural class of restricted inputs, namely, when the arrangement of trajectories forms a directed acyclic graph.

1 Introduction

Motivated by GIS applications, the question of extracting a meaningful representative trajectory from a collection of similar trajectories has recently received considerable attention in the computational geometry community [3, 11, 12, 16, 19, 1, 10, 2]. In many trajectory analysis applications, only the locations (and not the corresponding time stamps) in the

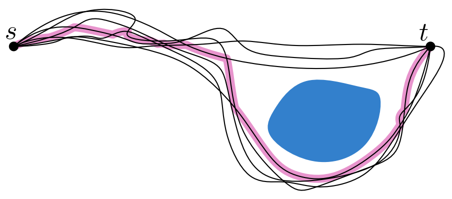

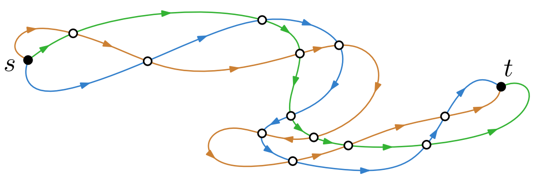

Figure 1 Left: Curves representing hiking trajectories between two points, and a possible representative. A pointwise average trajectory would go through the lake. Right: The trajectory graph G. In this example, G is acyclic.

trajectories are relevant. Consider, for example, the case in the input trajectories originate from hikers that walked a similar trail, but possibly on different days. In such a setting the trajectories are just curves in the plane, and hence we wish to find a representative curve that captures important features shared by most of the input curves. It has been argued before that it is desirable that the representative uses only pieces of the input trajectories, so that it avoids obstacles in the underlying space [4]. See for example Fig. 1 (left). Hence, we will restrict our attention to representatives that consist of pieces of the input trajectories, and that ignore any temporal information available.

Buchin et al. investigate whether a reasonable notion of a median exists in such a setting that depends only on the intersections in a set of trajectories [4]. Their *simple median* is essentially not using the geometry. They also present a second definition, that incorporates a notion of the topology of the underlying space, by placing obstacles in large open regions and restricting the class of trajectories to the same *homotopy type*, that is, they require the representative trajectory to "wind around" the obstacles in the same way as the majority of the input trajectories. For example, in Fig. 1 (left), a user could for example mark the lake as an obstacle. Buchin et al. conclude that while computation of the median is possible to some extent, some notion of geometry and topology seems necessary to handle practical situations.

In this paper, we include some geometric and topological information in the selection of a representative trajectory (curve), namely, the area of the faces in the arrangement of trajectories. As a measure of similarity between two curves, we use the *homotopy area* from Chambers and Wang [7], which is the minimum area swept by a deformation of one non-self-intersecting curve into the other. More formally, if $H : [0,1] \times [0,1] \to \mathbb{R}^2$ is a continuous deformation of curve μ into τ, the homotopy area of H is

$$A(H) = \int_{s\in[0,1]} \int_{t\in[0,1]} \left| \frac{\mathrm{d}H}{\mathrm{d}s} \times \frac{\mathrm{d}H}{\mathrm{d}t} \right| \mathrm{d}s\, \mathrm{d}t.$$

The infimum $\mathrm{HA}(\mu, \tau)$ of A over all continuous deformations between μ and τ is the homotopy area. The notion of homotopy area seems particularly attractive in our setting as it implicitly penalizes a representative trajectory for deviating from the bulk of the trajectories without making it necessary to artificially place obstacles in the ambient space, which was the solution used in prior work [4]. Homotopy area is defined only on curves which are non-self-intersecting, so we must also place this constraint on each of our input trajectories.

Problem Statement. We are given a set of *trajectories* $\mathcal{T} = \{\tau_1, .., \tau_n\}$, which are piecewise curves, each piece of low algebraic degree, in the plane. We wish to compute a single trajectory μ^* that best represents all trajectories in $\mathcal{T}$. As we will use homotopy area to measure the quality of μ^* we require that each individual trajectory τ_i is *simple*, that is, it has no self-intersections (otherwise homotopy area is not well defined). Consider the arrangement of the trajectories $\mathcal{T}$ in $\mathbb{R}^2$, and orient each edge so that its direction corresponds to that of the trajectory defining it. We refer to this arrangement as the *trajectory graph* G. See Fig. 1.

Initially, we will assume that all trajectories start and end at the same points, say s and t respectively, and that s and t lie in the outer face of the arrangement of the trajectories. We will (partially) lift these restrictions in Sections 4.2 and 4.3.

For the output trajectory μ^* we require that it is a simple path in the trajectory graph; this means that it can consist only of segments of the input trajectories, that it is simple, and that it uses each segment in the same direction as used in the input trajectory.

Among all possible output trajectories (simple paths in G), we wish to construct one that represents $\mathcal{T}$ best. We measure this by the distance between the (candidate) median μ and the trajectories in $\mathcal{T}$. Let $\text{HA}(\mu, \tau_i)$ be the minimum homotopy area between μ and a trajectory $\tau_i \in \mathcal{T}$. We consider two variants: minimizing the maximum distance $\text{HA}_{\text{max}}(\mu, \mathcal{T}) = \max_{\tau_i \in \mathcal{T}} \text{HA}(\mu, \tau_i)$ between μ and the trajectories in $\mathcal{T}$, and the sum of the distances $\text{HA}_{\text{sum}}(\mu, \mathcal{T}) = \sum_{\tau_i \in \mathcal{T}} \text{HA}(\mu, \tau_i)$ between μ and the trajectories in $\mathcal{T}$. If $\mathcal{T}$ is clear from the context we will write $\text{HA}_{\text{max}}(\mu) = \text{HA}_{\text{max}}(\mu, \mathcal{T})$ and $\text{HA}_{\text{sum}}(\mu) = \text{HA}_{\text{sum}}(\mu, \mathcal{T})$.

Results. We show that the first variant considered, minimizing the maximum distance, is NP-hard, even if we have only two trajectories, both of which are x-monotone (Section 2). In general, minimizing the sum of the distances, HA_{sum}, is also NP-hard, as we show in Section 3. However, the second hardness reduction is more involved and critically relies on cycles in the trajectory graph. If the trajectory graph is a directed acyclic graph (DAG), then we can compute a representative minimizing HA_{sum} efficiently, as we show in Section 4. Quite surprisingly, our results show that when the graph is a DAG and all trajectories share a start and end point on the outer face, the simple median from Buchin et al. [4] that does not incorporate areas in any way, remains the optimal choice for minimizing HA_{sum}. Hence, even though the best running time to compute homotopy area between two curves is $O(n + I^2 \log n)$ time, where n is the complexity of the input curves and I is the number of intersections between the two curves [7], we are able to calculate a median trajectory under homotopy area much more quickly using the simple median algorithm [4]. We also show that our approach generalizes to the case when the start and end points of the trajectories are in different, arbitrary faces of the DAG, although the simple median is no longer the curve minimizing HA_{sum}. Instead, a simple median must be computed between lifts of the trajectories in a particular covering space of the plane. Omitted proofs are in the full version.

2 Minimizing the Maximum Distance HA_{max} is NP-hard

In this section we consider computing a representative that minimizes the maximum distance to all other trajectories. Unfortunately, this problem is NP-hard, even for the case of a constant number of x-monotone input curves.

▶ **Theorem 1.** *Given a set of trajectories $\mathcal{T}$, computing a median μ that minimizes HA_{max} is NP-hard, even if $\mathcal{T}$ contains only two trajectories, both of which are x-monotone.*

Proof. We reduce from the Partition problem, which, given a set $A = \{a_1, .., a_n\}$ of positive integers, asks for a partition of A into sets A_1 and A_2 such that $\sum_{a_i \in A_1} a_i = \sum_{a_i \in A_2} a_i = \sum_{a_i \in A} a_i/2$. Given the set A, we construct two x-monotone trajectories τ_1 and τ_2 such that the faces between successive intersections have area equal to some $a_i \in A$. See Fig. 2.

Any candidate trajectory μ corresponds to a partition of A into A_1 and A_2: $a_i \in A_1$ if and only if μ uses the piece of τ_1 that bounds the face corresponding to a_i. It

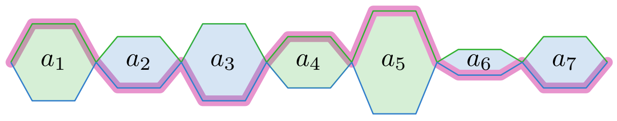

Figure 2 An illustration of the NP-hardness reduction from Partition. The purple curve represents the partition $B = \{a_2, a_3, a_6, a_7\}$ and $G = \{a_1, a_4, a_5\}$.

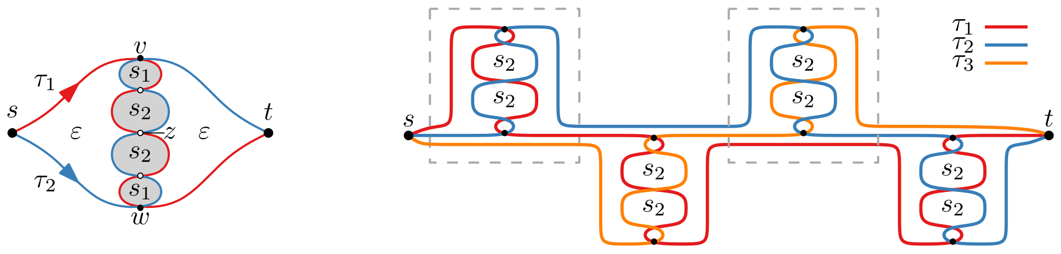

Figure 3 Left: The *braid* construction—a basic building block for hardness proof gadgets. Optimal representative trajectory does not switch at intersections. $\mathrm{HA}_{\mathrm{sum}} = 4s_1 + 2\varepsilon$. Right: Four building blocks joint together. Optimal representative trajectory follows the red or the blue trajectory all the way from s to t and does not switch at intersections. $\mathrm{HA}_{\mathrm{sum}} = 5s_2 + O(s_1)$.

follows that the homotopy area between μ and τ_j is exactly $\sum_{a_i \in A_j} a_i$. Thus $\mathrm{HA}_{\max}(\mu) = \max\left\{\sum_{a_i \in A_1} a_i, \sum_{a_i \in A_2} a_i\right\}$. Let μ^* be a trajectory minimizing $\mathrm{HA}_{\max}$. We have that $\mathrm{HA}_{\max}(\mu^*) = \sum_{a_i \in A} a_i/2$ if and only if A can be partitioned such that $\sum_{a_i \in A_1} a_i = \sum_{a_i \in A_2} a_i$. Therefore minimizing $\mathrm{HA}_{\max}$ is (weakly) NP-hard. ◀

3 Minimizing the Sum of Distances $\mathrm{HA}_{\mathrm{sum}}$ is NP-hard

In this section we show that minimizing the total sum of the distances from the representative trajectory to all the trajectories in $\mathcal{T}$ is NP-hard in general.

Before we describe the gadgets for variables and clauses, consider the two trajectories τ_1 and τ_2 in Fig. 3 (left). Let $\varepsilon \ll s_1 \ll s_2$ be the areas swept by the deformation of τ_1 into τ_2 between the intersection points, and let μ^* be a representative trajectory that minimizes $\mathrm{HA}_{\mathrm{sum}}$. We will call this construction a *braid* of τ_1 and τ_2. We will show that in a braid $\mu^* = \tau_1$ or $\mu^* = \tau_2$, i.e., μ^* does not switch to another trajectory at any intersection point.

▶ **Lemma 2.** *If the areas of the faces of the arrangement of $\mathcal{T} = \{\tau_1, \tau_2\}$, for a braid construction of two trajectories τ_1 and τ_2 (depicted in Fig. 3 (left)), satisfy $\varepsilon \ll s_1 \ll s_2$, then the optimal representative trajectory $\mu^* = \tau_1$ or $\mu^* = \tau_2$.*

The braid construction is a crossing gadget, it allows two trajectories to cross while enforcing that μ^* does not switch to another trajectory at intersections. We will use it as a basic building element in the hardness proof gadgets.

Now consider an arrangement of three trajectories in Fig. 3 (right). There are four braids of pairs of trajectories used in this arrangement. The red trajectory, τ_1, and the blue trajectory, τ_2, are rotationally symmetrical. Let μ^* be a representative trajectory that minimizes $\mathrm{HA}_{\mathrm{sum}}$.

▶ **Lemma 3.** *For the arrangement of three trajectories $\mathcal{T} = \{\tau_1, \tau_2, \tau_3\}$ depicted in Fig. 3 (right) the optimal representative trajectory $\mu^* = \tau_1$ or $\mu^* = \tau_2$.*

▶ **Theorem 4.** *Minimizing HA_{sum} is NP-hard.*

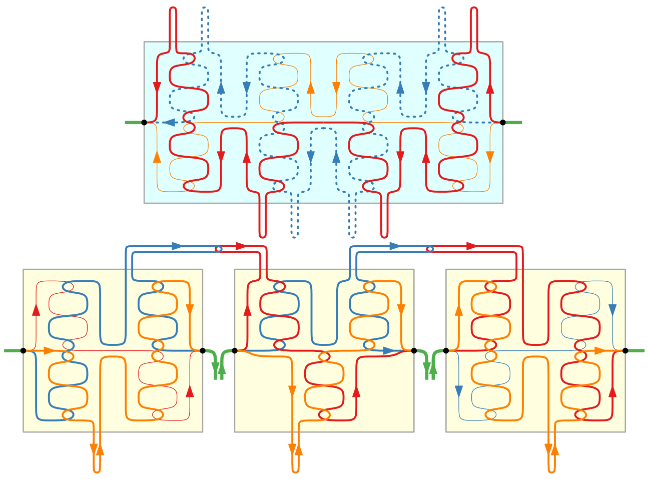

Figure 4 Left: An example of a variable gadget consisting of two building blocks. Variable gadgets are traversed by trajectories from right to left. Right: The clause gadget is traversed from left to right.

Proof. We prove that it is NP-hard to minimize HA_{sum} by a reduction from planar 3-SAT [17]: given an instance of a planar 3-SAT formula Φ with n variables and m clauses, and a rectilinear embedding[1] of its graph [15], we construct a set of three trajectories $\mathcal{T}$ such that minimizing HA_{sum} for $\mathcal{T}$ is equivalent to answering the question if Φ is satisfiable.

Variable gadget. The variable gadget (refer to Fig. 4 (left)) consists of a series of building blocks from Fig. 3 (right) with red and blue trajectories having two thin extensions (such that the area covered by them is $O(\varepsilon)$) that will serve as connectors to clauses. Up until entering the variable gadget all three trajectories follow the same path (shown in green in the figure), and they diverge after entering into the gadget. Selecting the red or the blue trajectory for the optimal representative trajectory μ^* to follow at this moment corresponds to setting the variable to true or false. As the variable gadget consists of building blocks that prevent μ^* from switching the color, the next color change can only occur once μ^* exits the variable gadget. One block of the variable gadget contributes $5s_2 + O(s_1)$ area to the total homotopy area between μ^* and the three trajectories.

Clause gadget. The clause gadget (shown in Fig. 4 (right)) consists of three blocks that will be connected to the corresponding variable gadgets: the leftmost and the rightmost blocks are the same as in Fig. 3 (right) (up to change of colors), and the middle block is a similar construction but consists of only three braids from Fig. 3 (left). The green trajectories in-between the blocks represent all three trajectories (red, blue, and yellow) following the same path that connect the current clause to the other clauses in hierarchical order (for more details refer to the next paragraph). The first block allows μ^* to follow the blue or the orange trajectory. In the second block all three trajectories will contribute the same amount to the area measure, thus any of the three trajectories can be chosen by μ^*. The third block allows μ^* to follow the red or the orange trajectory. Moreover, μ^* cannot choose

[1] Recall that in a rectilinear embedding of a graph of a 3-SAT formula, the variable-vertices are placed on a horizontal line, and the clause-vertices are placed above and below the horizontal line and connected to the corresponding variable-vertices with axis-aligned L-shape connectors.

the blue trajectory in the first block and the red trajectory in the second block at the same time, as this would cause a self-intersection. Similarly, μ^* cannot choose the blue trajectory in the second block and the red trajectory in the third block at the same time. Thus, μ^* has to choose the orange trajectory in at least one of the three blocks. Choosing the orange trajectory corresponds to satisfying the clause with the value of the corresponding variable. A clause gadget contributes $5s_2 + O(s_1) + 4s_2 + O(s_1) + 5s_2 + O(s_1) = 14s_2 + O(s_1)$ area to the total homotopy area between μ^* and the three trajectories.

Fig. 5 (left) shows an example of a clause $(\neg x \vee y \vee z)$ connected to the three corresponding variables. It is depicting the case when the clause is satisfied by setting the value of y to true.

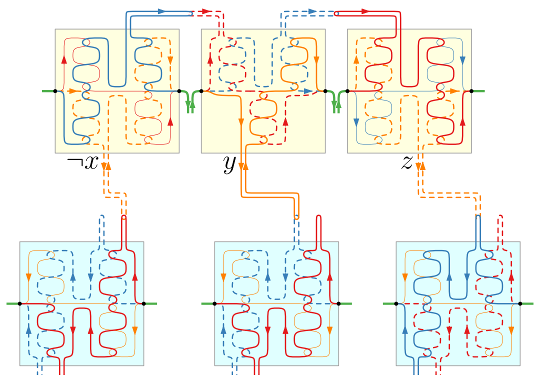
Putting all the building blocks together. Given the rectilinear embedding of the graph of the planar 3-SAT formula, we construct the gadgets for the variables and the clauses. The embedding provides a hierarchy of the clauses that leads to a natural order in which the clauses can be traversed (refer to Fig. 5 (right)). The outermost clause gets traversed the first; the clauses that lie between the first two legs of the outermost clause get traversed after the first block and before the second block of that clause; analogously, the clauses that lie between the second and the third legs of the outermost clause get traversed after the second block and before the third block of that clause; sibling clauses that lie in the same level get traversed one after another. Thus, the three trajectories will start at the top left of the embedding, traversing all the clauses that lie above the horizontal line containing the variables, then they traverse all the variables in order of appearance on the horizontal line, and then they traverse the clauses that lie below the variable line. If formula Φ is satisfiable, the total homotopy area of μ^* is

$$\mathrm{HA}_{\mathrm{sum}}(\mu^*, \mathcal{T}) = (\sum_{1}^{n} 5k_i + 14m)s_2 + (\sum_{1}^{n} 5k_i + 14m)O(s_1) \leq 29ms_2 + 29mO(s_1)\,,$$

where k_i is the number of blocks in the variable x_i's gadget, and since some of the blocks can be connected to multiple clauses, $\sum_1^n k_i \leq 3m$. Let $s_2 = 1$, and $s_1 = o(\frac{1}{m})$. If μ^* switches a trajectory at any intersection point inside of any gadget, the total area added as a penalty to $\mathrm{HA}_{\mathrm{sum}}$ shall be $\gg 29m$. This can be easily achieved by increasing the space between the gadgets. Therefore, deciding if there exists a μ^* such that the total homotopy area $\mathrm{HA}_{\mathrm{sum}}(\mu^*, \mathcal{T})$ is not greater than $29m + o(1)$, is equivalent to deciding if Φ is satisfiable. The size of the construction is polynomial in size of the 3-SAT instance, therefore, it is NP-hard to find a representative trajectory that minimizes $\mathrm{HA}_{\mathrm{sum}}$. ◀

4 Minimizing the Sum of Distances $\mathrm{HA}_{\mathrm{sum}}$ when G is a DAG

We now describe how to compute a representative trajectory that minimizes $\mathrm{HA}_{\mathrm{sum}}$ for a set of trajectories $\mathcal{T}$ whose trajectory graph is acyclic. For simplicity of presentation, we assume that n is odd. All our proofs can be extended to the case when n is even. As a warmup, we consider the case in which the trajectories in $\mathcal{T}$ are x-monotone. Next, we expand to the case when s and t lie on the boundary of the outer face of G but the trajectories are no longer required to be x-monotone. Finally, we consider the most general case, when s and t lie in the interior faces of G.



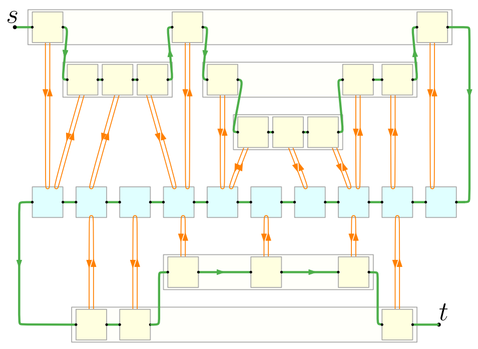


Figure 5 Left: An example of clause $(\neg x \vee y \vee z)$ connected to the three corresponding variables. Here, $x =$ true, $y =$ true and $z =$ false. Right: An order of traversal of the clause and variable gadgets is induced by the embedding of the planar graph of Φ.

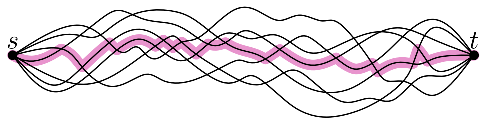

Figure 6 The simple median for a set of x-monotone trajectories.

4.1 Minimizing $\mathsf{HA}_{\mathsf{sum}}$ for x-Monotone Trajectories

In this section we will show that for x-monotone trajectories, the *simple median*, as defined by Buchin et al. [4], minimizes the sum of the homotopy areas $\mathrm{HA}_{\mathrm{sum}}$. At the starting point s, the simple median starts at the $\lceil n/2 \rceil^{\text{th}}$ curve (ranking the trajectories by their y-coordinate just after s). It switches to the other trajectory at every intersection point it encounters, thus staying on the $\lceil n/2 \rceil^{\text{th}}$ trajectory. So, for x-monotone trajectories the simple median corresponds to the $\lceil n/2 \rceil$-level in G. See Fig. 6.

To show that the simple median μ^* minimizes $\mathrm{HA}_{\mathrm{sum}}$ we now write $\mathrm{HA}_{\mathrm{sum}}(\mu)$ as an integral $\int f(x)\,\mathrm{d}x$. The value $f(x)$ represents the sum of the lengths of a set of intervals along a vertical line with abscissa x. All intervals share a common endpoint $\mu(x)$. The total length of these intervals is minimal when μ has the same number of trajectories above and below it, that is, when it coincides with the simple median.

▶ **Lemma 5.** *The simple median μ^* minimizes* $F(\mu) = \displaystyle\int_x \sum_{\tau_i \in \mathcal{T}} |\mu(x) - \tau_i(x)|\,\mathrm{d}x$.

Proof. Let $y_1,..,y_n$ denote the (y-coordinates of the) intersection points of the trajectories with a vertical line ℓ with abscissa x. Any valid representative trajectory uses one of the points y_i, i.e., $\mu(x) \in \{y_1,..,y_n\}$. Note, that the median point $y_{\lceil n/2 \rceil}$ minimizes $f(y) = \sum_{i=1}^n |y - y_i|$. The simple median μ^* is on the $\lceil n/2 \rceil^{\text{th}}$ trajectory at any coordinate x. Therefore, μ^* minimizes $\int_x f(y)\,\mathrm{d}x = \int_x \sum_{i=1}^n |\mu(x) - \tau_i(x)|$. ◀

▶ Remark. When n is even, there are two points $y_{\frac{n}{2}}$ and $y_{\frac{n}{2}+1}$ that minimize $f(y) = \sum_{i=1}^n |y - y_i|$. Therefore, any trajectory switching between the levels $\frac{n}{2}$ and $(\frac{n}{2}+1)$ will minimize $F(\mu) = \int_x \sum_{\tau_i \in \mathcal{T}} |\mu(x) - \tau_i(x)|\,\mathrm{d}x$.

Given a point p let $\omega(p, \delta)$ denote the winding number of p with respect to an oriented closed curve δ. We say that δ is *atomic* if $\omega(p, \delta)$ is either all non-negative, or all non-positive,

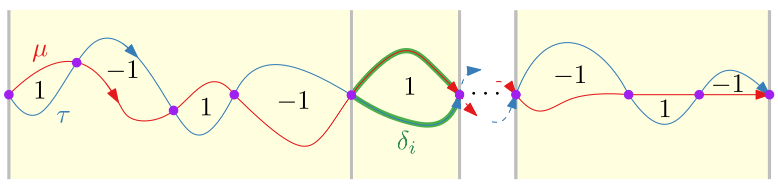

Figure 7 There is a subsequence $p_1,..,p_\ell$ of intersection vertices (purple) that partition μ and τ (in red and blue, respectively) into subcurves $\delta_1,..,\delta_k$, such that all faces in $\delta_i = \mathit{loop}(\mu_i, \tau_i)$ (green) have either winding number one or minus one.

for all points $p \in \mathbb{R}^2$. Furthermore, let $W(\delta) = \int_{p\in\mathbb{R}^2} \omega(p,\delta)\,\mathrm{d}p$ denote the *total winding number* of curve δ.

Let μ and τ be two curves from s to t, let $\delta = \mathit{loop}(\mu,\tau)$ denote the closed curve obtained by concatenating μ and the reverse of τ, and let $s = p_1,..,p_\ell = t$ denote the intersection points between μ and τ, ordered along μ. Chambers and Wang [7] show that there is a (not necessarily contiguous) subsequence of the intersection points $\{p_i\}$ that decompose δ into a set of atomic closed curves $\Delta(\mu,\tau) = \delta_1,..,\delta_k$, such that the minimum homotopy area $\mathrm{HA}(\mu,\tau) = \sum_{i=1}^{k} |W(\delta_i)|$. See Fig. 7 for an illustration.

▶ **Observation 6.** *If μ and τ are x-monotone curves, the atomic curves in $\Delta(\mu,\tau)$ are pairwise disjoint (except for the subsequence of the intersection points $\{p_i\}$).*

▶ **Theorem 7.** *Let $\mathcal{T}$ be a set of x-monotone trajectories. The simple median μ^* minimizes HA_{sum}.*

Proof. We will show that $\mathrm{HA}_{\mathrm{sum}}(\mu) = F(\mu)$. The theorem then follows from Lemma 5. Using the result of Chambers and Wang [7] we can then rewrite $\mathrm{HA}_{\mathrm{sum}}(\mu)$ as

$$\begin{aligned}
\mathrm{HA}_{\mathrm{sum}}(\mu) &= \sum_{\tau_i\in\mathcal{T}} \mathrm{HA}(\mu,\tau_i) = \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} |W(\delta)| = \\
&= \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} \left| \int_{p\in\mathbb{R}^2} \omega(p,\delta)\,\mathrm{d}p \right| = \\
&= \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} \int_{x\in\mathbb{R}} \int_{y\in\mathbb{R}} |\omega((x,y),\delta)|\,\mathrm{d}y\,\mathrm{d}x = \\
&= \int_{x\in\mathbb{R}} \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} \int_{y\in\mathbb{R}} |\omega((x,y),\delta)|\,\mathrm{d}y\,\mathrm{d}x\,.
\end{aligned}$$

A vertical line ℓ_x with x-coordinate x intersects (the faces of) G in a set of intervals $\mathcal{I}(x) = I_1,..,I_n$. So, for any curve δ that uses only edges of G, all points (values) in an interval I_i have the same winding number $\omega(I_i,\delta)$. So,

$$\begin{aligned}
\mathrm{HA}_{\mathrm{sum}}(\mu) &= \int_{x\in\mathbb{R}} \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} \sum_{I\in\mathcal{I}(x)} \int_{y\in I} |\omega((x,y),\delta)|\,\mathrm{d}y\,\mathrm{d}x = \\
&= \int_{x\in\mathbb{R}} \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} \sum_{I\in\mathcal{I}(x)} |\omega(I,\delta)| \cdot |I|\,\mathrm{d}x\,.
\end{aligned}$$

Since the trajectories are x-monotone, so is μ. The curves $\delta \in \Delta(\mu,\tau_i)$ are built by concatenating a piece of μ and a reversed piece of τ_i. Hence, any vertical line ℓ_x intersects δ in exactly two points: $\mu(x)$ and $\tau_i(x)$. Therefore, any point p on ℓ_x that lies in between these points has winding number one or minus one with respect to δ. Any point outside the interval defined by $\mu(x)$ and $\tau_i(x)$ has winding number zero. Thus, we get

$$\mathrm{HA}_{\mathrm{sum}}(\mu) = \int_{x\in\mathbb{R}} \sum_{\tau_i\in\mathcal{T}} \sum_{\delta\in\Delta(\mu,\tau_i)} |\mu(x) - \tau_i(x)|\,\mathrm{d}x\,.$$

Since μ and all τ_i are x-monotone, Observation 6 gives us that all curves in $\Delta(\mu,\tau_i)$ are pairwise disjoint. This gives us

$$\mathrm{HA}_{\mathrm{sum}}(\mu) = \int_{x\in\mathbb{R}} \sum_{\tau_i\in\mathcal{T}} |\mu(x) - \tau_i(x)|\,\mathrm{d}x = F(\mu)\,. \qquad \blacktriangleleft$$

4.2 Extending to Acyclic G with s and t on the Outer Face

The proof from the previous section consists of two steps: (i) show that the simple median minimizes the function F, which represents the sum of interval lengths along a sweep-line; and (ii) show that minimizing the sum of interval lengths along this sweep-line is equivalent to minimizing $\mathrm{HA}_{\mathrm{sum}}$. The two key ideas to extend the algorithm to the case in which the trajectory graph is a DAG that has s and t on the outer face (but is otherwise unconstrained), are that (a) we can generalize (i) to minimizing curve-intervals lengths along a sweep-curve, and, (b) a suitable sweep-curve exists for which minimizing the sum of curve-intervals lengths is again the same as minimizing $\mathrm{HA}_{\mathrm{sum}}$.

We say that a curve is *conforming* to trajectories $\mathcal{T}$ if and only if it is simple and intersects all trajectories of $\mathcal{T}$ exactly once. Let $\gamma : \mathbb{R}\times\mathbb{R} \to \mathbb{R}^2$ be a continuous map such that for any $u \in [0,1]$, $\gamma(u) = \bigcup_{z\in\mathbb{R}} \gamma(u,z)$ is an (open) conforming curve that separates s and t, such that for any u, $\gamma(u,-\infty)_y = -\infty$ and $\gamma(u,+\infty)_y = +\infty$, and for any $u \notin [0,1]$, $\gamma(u) = \bigcup_{z\in\mathbb{R}} \gamma(u,z)$ is an open curve that does not intersect $\mathcal{T}$. We say that γ is a (conforming) sweep-curve. Assume, without loss of generality, that s lies to the left of $\gamma(u)$ and t to the right of $\gamma(u)$ for all $u \in (0,1)$.

Let $c(\gamma,u,i)$ denote the i^{th} intersection point of $\gamma(u)$ with a trajectory in $\mathcal{T}$, and let μ_γ be the curve that for any value u corresponds to the $\lceil n/2\rceil^{\mathrm{th}}$ intersection point on $\gamma(u)$, i.e. $\mu_\gamma(u) = c(\gamma,u,\lceil n/2\rceil)$. Note that μ_γ is simply connected.

▶ **Lemma 8.** *Let φ_0 and φ_1 be conforming curves. Furthermore, assume that the only point from $\bigcup\mathcal{T}$ to the left of φ_1 is s. There is a conforming sweep-curve γ that deforms $\gamma(0) = \varphi_0$ into $\gamma(1) = \varphi_1$.*

Proof. Let $k(\varphi)$ denote the number of vertices of the trajectory graph G that lie to the left the conforming curve φ. We have $k(\varphi_1) = 1$, and $k(\varphi_0) = m+1$, for some $m \in \mathbb{N}$. We now prove by induction on m that we can continuously deform φ_0 into φ_1 while remaining conforming. The lemma then follows.

The base case $m = 0$ is trivial, because two conforming curves without vertices of G between them must intersect exactly the same edges in exactly the same order. Hence, such curves are actually combinatorially equivalent.

For the induction step, let $V = v_0, v_1, .., v_z$ denote the vertices of G in topological order, let L be the set of vertices left of φ_0, and let v_ℓ be the last vertex (with respect to order V) in L. Since φ_0 is conforming, it separates s from t. It follows that $v_\ell \neq t = v_z$, and thus $\ell < z$. Since $v = v_\ell$ is the last vertex in V that lies left of φ_0, and $\ell < z$, both its outgoing edges cross φ_0. Furthermore, the area enclosed by these edges and φ_0 is empty of other vertices: the trajectories that visit such a vertex would have to cross φ_0 twice, or they would have to intersect the outgoing edges of v (see Fig. 8). Since such an intersection point would

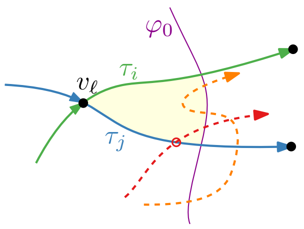

Figure 8 The region enclosed by the outgoing edges of $v_\ell = v$ and φ_0 (yellow) must be empty.

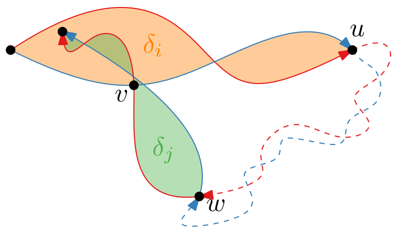

Figure 9 If δ_i and δ_j intersect in v then u, w, and v form a cycle.

have been a vertex in G both these cases cannot occur. Let τ_i and τ_j be the trajectories on the outgoing edges of v. Since φ_0 is conforming, it intersects τ_i and τ_j at most once, namely on the outgoing edges of v. Therefore, φ_0 does not intersect the incoming edges of v. It follows that we can continuously deform φ_0 into a conforming curve φ'_0 that (a) intersects the trajectories in the same order as φ_0, with the exception of τ_i and τ_j; they are swapped, and (b) has the set of vertices $L \setminus \{v\}$ to its left, by sweeping over vertex v, and while remaining conforming at any time. Since the number of vertices to the left of φ'_0 is only $m-1$, the induction hypothesis gives us that there is a continuous deformation from φ'_0 into φ_1. This completes the proof. ◀

▶ **Lemma 9.** *Let φ_0 and φ_1 be conforming curves. There is a conforming sweep-curve γ that deforms $\gamma(0) = \varphi_0$ into $\gamma(1) = \varphi_1$.*

▶ **Lemma 10.** *Let γ_1 and γ_2 be two conforming sweep-curves, with $\gamma_1(0) = \gamma_2(0)$ and $\gamma_1(1) = \gamma_2(1)$, and let $\mu_1 = \mu_{\gamma_1}(u)$ and $\mu_2 = \mu_{\gamma_2}(u)$ be their corresponding median curves for $u \in [0,1]$. We have that $\mu_1 = \mu_2$.*

Proof. Let $u_1,..,u_k$ and $v_1,..,v_\ell$ be the vertices of μ_1 and μ_2, respectively. Since, $\gamma_1(0) = \gamma_2(0)$, the order in which $\gamma_1(0)$ and $\gamma_2(0)$ intersect the trajectories is the same. It follows that $\mu_1(0) = c(\gamma_0, 0, \lceil n/2 \rceil) = c(\gamma_1, 0, \lceil n/2 \rceil) = \mu_2(0)$, and thus $u_1 = v_1$.

Assume by contradiction that i is the index at which μ_1 and μ_2 diverge for the first time. So, μ_1 and μ_2 both arrive at $v = u_i = v_i$ on the same incoming edge, and leave on different outgoing edges of v. Clearly, μ_j, $j \in [1,2]$, changes only if γ_j sweeps over a vertex of G. However, since γ_j is conforming, the number of curves intersected by γ_j before v does not change when it sweeps over a vertex $w \neq v$. This means that μ_1 and μ_2 also use the same outgoing edge of $v = v_i = u_i$. This contradicts the fact that i is the first index on which μ_1 and μ_2 diverge. ◀

Recall that μ_γ is the curve that for any value u corresponds to the $\lceil n/2 \rceil^{\text{th}}$ intersection point on $\gamma(u)$. Lemma 10 then implies:

▶ **Corollary 11.** *There is a unique curve μ^* connecting s to t, such that for any conforming sweep-curve γ, we have that $\mu_\gamma \subseteq \mu^*$.*

A conforming sweep-curve γ is *complete* if and only if the only point from $\bigcup \mathcal{T}$ left of $\gamma(0)$ is s, and the only point from $\bigcup \mathcal{T}$ right of $\gamma(1)$ is t. We then have:

▶ **Lemma 12.** *Let γ be a conforming sweep-curve that is complete, as defined above. The simple median μ^* minimizes* $F_\gamma(\mu) = \displaystyle\int_{u\in[0,1]} \sum_{\tau_i \in \mathcal{T}} \int_{z \in [z_{\mu(u)}, z_{\tau_i}(u)]} |J(u,z)| \,\mathrm{d}z\,\mathrm{d}u,$

where $J(u,z)$ is the Jacobian determinant of γ, and $z_{\mu(u)}$ and $z_{\tau_i}(u)$ are the z-coordinates of points $\mu(u)$ and $\tau_i(u)$ respectively.

Proof. The inner integral $\int_{z\in[z_{\mu(u)},z_{\tau_i}(u)]}|J(u,z)|\,\mathrm{d}z$ represents the length of the curve $\gamma(u)$ between the two intersection points with curves μ and τ_i. Analogous to Lemma 5 we note that $\mu_\gamma(u)$ minimizes $f(\mu)=\sum_{i=1}^{n} len_\gamma(\mu(u)-\tau_i(u))$, and therefore μ_γ minimizes $F_\gamma(\mu)$. The lemma follows from the fact that $\mu^*=\mu_\gamma$. ◀

As in Theorem 7 we now rewrite $\mathrm{HA}_{\mathrm{sum}}(\mu)$ as an integral over u. However, instead of directly mapping u to a vertical line we map it to a conforming curve. The resulting mapping is a conforming sweep-curve. Thus, we prove:

▶ **Lemma 13.** *For any pair of simple paths A and B in G from s to t, the atomic curves in $\Delta(A,B)$ are disjoint.*

Proof. Assume, by contradiction, that $\delta_i\in\Delta(A,B)$ and $\delta_j\in\Delta(A,B)$, with $i<j$, are not disjoint. Then there is an intersection vertex v between δ_i and δ_j. Let $\prec$ denote the topological order of the vertices in G, let u be the ending vertex of δ_i and let w be the starting vertex of δ_j (see Fig. 9). Since $i<j$ we have that $u\prec w$, and since v lies on δ_i we have that $v\prec u$. However, v lies also on δ_j, so we have $w\prec v$, and thus $v\prec u\prec w\prec v$. Contradiction. ◀

▶ **Theorem 14.** *Let $\mathcal{T}$ be a set of trajectories for which G is acyclic, and s and t are on the outer face of G. The simple median μ^* minimizes HA_{sum}.*

Proof. It is easy to see that there is a conforming curve φ_0 which, from the points in $\bigcup\mathcal{T}$, has just s to its left. Similarly, there exists a conforming curve φ_1 that has only t to its right. Therefore, by Lemma 9 there is a complete conforming sweep-curve γ. Lemma 12 then gives us that the simple median μ^* minimizes $F_\gamma(m)$. We now show that $\mathrm{HA}_{\mathrm{sum}}(\mu)=F_\gamma(m)$. Using the result of Chambers and Wang [7] we again rewrite $\mathrm{HA}_{\mathrm{sum}}(\mu)$ as

$$\begin{aligned}\mathrm{HA}_{\mathrm{sum}}(\mu)&=\sum_{\tau_i\in\mathcal{T}}\mathrm{HA}(\mu,\tau_i)=\sum_{\tau_i\in\mathcal{T}}\sum_{\delta\in\Delta(\mu,\tau_i)}|W(\delta)|=\\&=\sum_{\tau_i\in\mathcal{T}}\sum_{\delta\in\Delta(\mu,\tau_i)}\iint_{(x,y)\in\mathbb{R}^2}|\omega(p(x,y),\delta)|\,\mathrm{d}x\,\mathrm{d}y=\\&=\sum_{\tau_i\in\mathcal{T}}\sum_{\delta\in\Delta(\mu,\tau_i)}\int_{u\in\mathbb{R}}\int_{z\in\mathbb{R}}|\omega(\gamma(u,z),\delta)|\,|J(u,z)|\,\mathrm{d}z\,\mathrm{d}u\,.\end{aligned}$$

Since for all $u\in[0,1]$, $\gamma(u)$ intersects every atomic closed curve $\delta\in\Delta(\mu,\tau_i)$ in exactly two points, and due to Lemma 13 the curves in $\Delta(\mu,\tau_i)$ are pairwise disjoint, we get that

$$\sum_{\delta\in\Delta(\mu,\tau_i)}\int_{z\in\mathbb{R}}|\omega(\gamma(u,z),\delta)|\,|J(u,z)|\,\mathrm{d}z=\int_{z\in[z_{\mu(u)},z_{\tau_i}(u)]}|J(u,z)|\,\mathrm{d}z\,,$$

where $z_{\mu(u)}$ and $z_{\tau_i}(u)$ are z-coordinates of the intersection points of $\gamma(u)$ with μ and τ_i respectively. And since $\gamma(u)$ does not intersect any trajectory in $\mathcal{T}$ for $u\notin[0,1]$,

$$\begin{aligned}\mathrm{HA}_{\mathrm{sum}}(\mu)&=\sum_{\tau_i\in\mathcal{T}}\int_{u\in\mathbb{R}}\int_{z\in[z_{\mu(u)},z_{\tau_i}(u)]}|J(u,z)|\,\mathrm{d}z\,\mathrm{d}u=\\&=\int_{u\in[0,1]}\mathrm{d}u\cdot\sum_{\tau_i\in\mathcal{T}}\int_{z\in[z_{\mu(u)},z_{\tau_i}(u)]}|J(u,z)|\,\mathrm{d}z=F_\gamma(\mu)\,.\end{aligned}$$ ◀

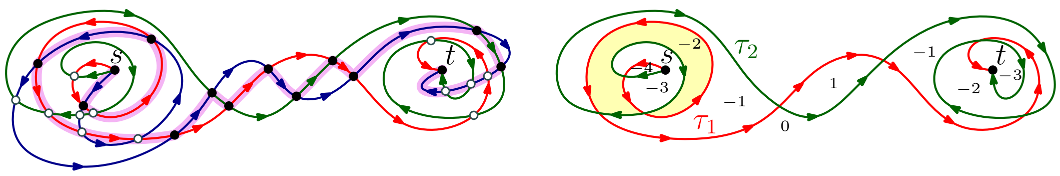

Figure 10 Left: A set of three trajectories with s and t lying on the boundary of an interior face. The optimal representative (light-purple) does not switch at every intersection. Right: The winding numbers for $loop(\tau_1, \tau_2)$. The highlighted face is swept twice by a minimal homotopy.

▶ **Observation 15.** *Note that the simple median μ^* minimizes F_γ, and thus HA_{sum}, among all curves from s to t, even ones that are not necessarily restricted to consist of pieces of the input trajectories.*

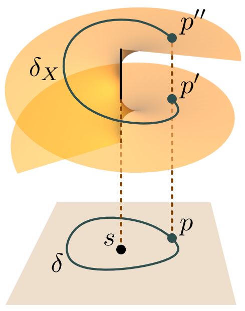
▶ Remark. When n is odd there is a unique curve that minimizes F_γ, and it is simple median μ^*. When n is even there can be multiple curves, not necessarily restricted to consist of pieces of the input trajectories, that all minimize F_γ. These curves are all bounded by the $\frac{n}{2}$- and $(\frac{n}{2}+1)$-levels of the trajectories.

4.3 Extending to Acyclic G with Unrestricted s and t

In this section we extend our approach to compute an optimal representative trajectory when s and t can be anywhere in the DAG. However, unlike in the previous two sections, we can no longer start at the median trajectory from s and switch at every intersection point we encounter. Fig. 10 (left) shows an example of a set of trajectories in which any curve that always switches is not optimal, no matter where we start. The main reason why our argument breaks here is that the winding numbers between the individual pairs of curves are no longer just in the range $[-1, 1]$. Hence, an optimal homotopy may have to sweep over a face more than once.

Instead, we will lift the trajectories into a space X that we will construct from the covering spaces of $\mathbb{R}^2 \setminus s$ and $\mathbb{R}^2 \setminus t$; we refer the reader to a standard topology text for detailed definitions of covering spaces [14, 18]. The key in this setting is that we will be able to lift the trajectories into X in such a way that the trajectory graph will form a DAG with s and t on the outer face and the pairwise homotopy areas between lifted trajectories will be the same as the homotopy area in the plane. We then compute an optimal representative for the lifted trajectories, using our simple median algorithm, and show that its corresponding projection is an optimal representative for the original trajectories.

The space X. Intuitively, we start with a covering space of the space formed from the plane by cutting out small disks around s and t, where each of the boundaries is collapsed to a single point, and then obtain space X by adding the points s and t back. This means that X will cover $\mathbb{R}^2 \setminus \{s, t\}$ with infinitely many "layers" forming Riemann-like spirals around points s and t. Consider a simple cycle δ in $\mathbb{R}^2$ that goes through some point p and that encloses s or t. A walk along δ starting at p and ending at p in $\mathbb{R}^2$ corresponds to a curve in X that starts at the copy of p in some layer i and ends at the copy of p in layer $i+1$ or $i-1$. See Fig. 11 for an illustration. We formalize this more carefully (including the metric on the space X, which will be necessary in order to argue about the homotopy area) using a particular conforming curve, as follows:



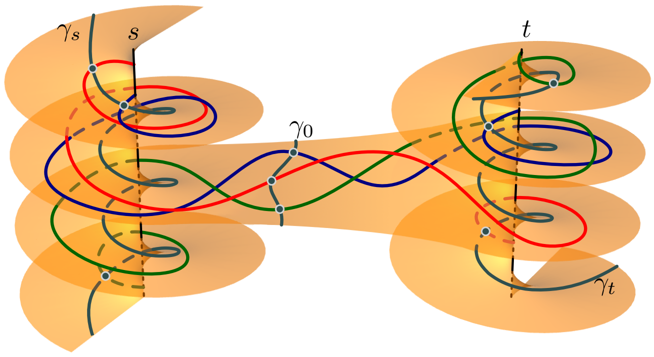


Figure 11 Lifting cycle δ from $\mathbb{R}^2$ into X.

Figure 12 Input trajectories lifted into the space X.

▶ **Lemma 16.** *Given a set of simple trajectories $\mathcal{T}$ that start at s and end in t, whose arrangement forms a directed acyclic graph G, there exists a conforming curve γ with endpoints at infinity that separates s and t.*

Proof. The graph G defines a partial order on the intersection points of the trajectories in $\mathcal{T}$. Consider a conforming 0-length cycle δ enclosing s. Let δ grow by sweeping over the vertices of G according to their partial order. As in Lemma 8 we can do this while maintaining conformity with respect to $\mathcal{T}$. Once γ crosses some intersection point that lies on the outer face of G, we can cut it at any point in the outer face and pull the endpoints toward infinity. The resulting open curve γ is conforming and separates s from t. ◀

Let $\gamma \subset \mathbb{R}^2$ be a conforming curve that separates s from t and has its end-points at infinity, and let p_0 be an arbitrary point on γ. Note that by Lemma 16 such a curve exists. Define space X_s corresponding to $\mathbb{R}^2\backslash\{s\}$ in terms of polar coordinates, taking s to be the origin: Let r be the "radius" parameter, and let θ be the angular parameter, such that point $(0, \|sp_0\|) \in X_s$ corresponds to point $p_0 \in \mathbb{R}^2\backslash\{s\}$, and a positive θ corresponds to a clockwise turn. We then have $X_s = \{(\theta, r) \mid (\theta, r \in \mathbb{R}\backslash\{s\}) \wedge r > 0\}$. Note that in the definition of X_s we explicitly do *not* limit the range of θ to $[0, 2\pi)$ (which would give us exactly $\mathbb{R}^2$, parameterized around s). Instead, our space X_s allows us to "wind around" s an arbitrary number of times. Analogously, define X_t. Note, that X_s and X_t are the universal covers of $\mathbb{R}^2\backslash\{s\}$ and $\mathbb{R}^2\backslash\{t\}$, respectively.

We partition X_s into *layers* L_i, with $i \in \mathbb{Z}$. A point $(\theta, r) \in X_s$ lies in layer L_i, if and only if $\lfloor \theta/2\pi \rfloor = i$. We define layers analogously for X_t.

Recall that γ separates s and t in $\mathbb{R}^2$, and hence we can consider a copy of γ in each of X_s and X_t. We cut each space along the copy of γ, and glue the part of X_s containing s and the part of X_t containing t together along each's copy of γ. Furthermore, we again add the points s and t, and connect them to all the layers of X_s and X_t. Note, that we add the points s and t only so that all trajectories again start at s and end at t rather than arbitrarily close to s and t. Let X to be the resulting space.

Lifting trajectories. Next, we describe the image of trajectories $\mathcal{T}$ in X. (See Fig. 12.) For each trajectory $\tau_i \in \mathcal{T}$, we construct its corresponding trajectory τ_i' in X by starting at the image of the intersection point of τ_i with γ, and moving along τ_i while continuously mapping the points to τ_i'. We call this process *lifting* trajectory τ_i to space X. Let $\mathcal{T}' = \{\tau_i' \mid \tau_i \in \mathcal{T}\}$ denote the set of resulting trajectories, and let G' be the corresponding trajectory graph.

We note that all trajectories cross the conforming curve γ and hence are fixed on a common reference, although not at a common lift of a base point as is more commonly seen in topology. However, we obtain that each trajectory lifts to a unique curve in X. In addition, since we have local homeomorphisms which lift everywhere (except right at s and t), we can also lift the definition of a winding number for any point p inside $loop(\tau_i', \tau_j')$ for any pair of lifted trajectories τ_i' and τ_j'. This leads to the following observation:

▶ **Observation 17.** *The points s and t lie on the outer face of G'. Thus, for any simple paths A and B in G' from s to t, and for any point $p \in X$, we have that $|\omega(p, loop(A, B))| \leq 1$.*

▶ **Lemma 18.** *For any two curves ϕ_1 and ϕ_2 in $\mathbb{R}^2$ that connect s to t. We have $HA(\phi_1, \phi_2) = HA(\phi_1', \phi_2')$, where ϕ_1' and ϕ_2' are the corresponding curves lifted into space X.*

Proof. It is easy to see that $\mathrm{HA}(\phi_1, \phi_2) \leq \mathrm{HA}(\phi_1', \phi_2')$: the covering map f_X is continuous, so a minimum homotopy between ϕ_1' and ϕ_2' defines a homotopy between ϕ_1 and ϕ_2 of cost $\mathrm{HA}(\phi_1', \phi_2')$. Since $\mathrm{HA}(\phi_1, \phi_2)$ is a minimum homotopy we have that $\mathrm{HA}(\phi_1, \phi_2) \leq \mathrm{HA}(\phi_1', \phi_2')$.

Next, we show that $\mathrm{HA}(\phi_1, \phi_2) \geq \mathrm{HA}(\phi_1', \phi_2')$. The lemma then follows. Let $\delta = loop(\phi_1, \phi_2)$ and $\delta' = loop(\phi_1', \phi_2')$. Now assume, by contradiction, that $\mathrm{HA}(\phi_1, \phi_2) > \mathrm{HA}(\phi_1', \phi_2')$. It follows that there is a point $p \in \mathbb{R}^2$, with $\omega(p, \delta) = k$ that is swept by a minimum homotopy H between ϕ_1' and ϕ_2' more than k times. Furthermore, assume without loss of generality that p lies left of γ, and thus the copies of p lie in X_s. Since all winding numbers in X are in the range $[-1, 1]$ (Observation 17) that means there must be more than k copies of point p swept by H. It follows that there is a point q' in layer L_ℓ or layer $L_{-\ell}$, with $\ell > k$, that lies on δ', and has a larger r-coordinate than p' (otherwise we would not sweep over p'). Furthermore, note that δ' intersects γ (as the curves ϕ_1' and ϕ_2' connect s to t), and thus contains a point on in layer L_0. Now consider traversing δ', starting from point q'. It follows that the total turning angle is at least $2\ell\pi$ (since we must visit layer L_0). This means that the total turning angle of curve δ with respect to $f_X(p)$ is also at least $\ell 2\pi$. Therefore $\omega(p, \delta) \geq \ell > k$. Contradiction. ◀

▶ **Corollary 19.** *Let μ be a representative for the set of trajectories $\mathcal{T}$, and let μ' be its corresponding representative for $\mathcal{T}'$. We have that $HA_{sum}(\mu, \mathcal{T}) = HA_{sum}(\mu', \mathcal{T}')$.*

Any representative trajectory μ in X corresponds to some representative trajectory μ' in $\mathbb{R}^2$. However, not every representative trajectory in $\mathbb{R}^2$ has a corresponding representative trajectory in X. The difference between the two cases comes from the fact, that some of the intersection points between trajectories $\mathcal{T}$ that existed in $\mathbb{R}^2$ no longer exist once the trajectories are lifted to X. We call the intersection points of $\mathcal{T}$ that remain in X *legal*, and the ones that disappear *illegal*. Following the projection to $\mathbb{R}^2$ of the median trajectory μ_*' corresponds to switching the trajectory at every legal intersection point. Next we will prove, that this projection of μ_*' to $\mathbb{R}^2$ gives an optimal representative trajectory for trajectories $\mathcal{T}$.

▶ **Theorem 20.** *Let $\mathcal{T}$ be a set of trajectories for which G is acyclic, let μ_*' be the simple median on the lifted trajectories in X. The representative curve $\mu^* = f_X(\mu_*')$ corresponding to μ_*' minimizes HA_{sum} with respect to $\mathcal{T}$.*

Proof. Suppose there exists some representative trajectory μ with the total homotopy area $\mathrm{HA}_{\mathrm{sum}}(\mu, \mathcal{T}) < \mathrm{HA}_{\mathrm{sum}}(\mu^*, \mathcal{T})$. Let curve μ' be μ lifted to X. If μ uses only legal intersections in G, then μ' is a candidate representative for the set of trajectories $\mathcal{T}'$. By Corollary 19 we then have that $\mathrm{HA}_{\mathrm{sum}}(\mu, \mathcal{T}) = \mathrm{HA}_{\mathrm{sum}}(\mu', \mathcal{T}') < \mathrm{HA}_{\mathrm{sum}}(\mu_*', \mathcal{T}') = \mathrm{HA}_{\mathrm{sum}}(\mu^*, \mathcal{T})$. Contradiction. If μ uses also illegal intersections, then μ' does not consist of pieces of the trajectories $\mathcal{T}'$.

Theorem 14 and Observation 15 then implies that $\mathrm{HA}_{\mathrm{sum}}(\mu', \mathcal{T}') \geq \mathrm{HA}_{\mathrm{sum}}(\mu'_*, \mathcal{T}')$. Applying Corollary 19 on both sides then gives us $\mathrm{HA}_{\mathrm{sum}}(\mu, \mathcal{T}) \geq \mathrm{HA}_{\mathrm{sum}}(\mu^*, \mathcal{T})$. Contradiction. ◀

5 Computing a Representative Trajectory

From Theorem 14 it immediately follows that if s and t lie on the outer face of G, we can compute a representative μ^* trajectory that minimizes $\mathrm{HA}_{\mathrm{sum}}$ using the algorithm of Buchin et al. [4]. Thus, we can compute μ^* in $O((N+k)\alpha(N)\log(N))$ time, where N is the total complexity of the input trajectories, and k is the output complexity. For an arbitrary DAG G, we have $k = O(N^2)$. If the trajectories are x-monotone, the simple median corresponds to the $\lceil n/2 \rceil$-level in an arrangement of n curves, and thus bounds on the complexity of the $\lceil n/2 \rceil$-level also bound the complexity of μ^*. In case our trajectories (curves) are all polylines with at most m vertices each, we have $k = O(mn^{4/3} \log^{1/3-\varepsilon} n)$, for some arbitrarily small constant $\varepsilon > 0$ [9]. Similarly, we can derive the results for more general types of curves.

Unrestricted s and t. When s and t are not restricted to lie on the outer face we first construct a conforming curve γ that separates s from t and intersects the outer face. This allows us to find the $\lceil n/2 \rceil^{\mathrm{th}}$ intersection p of γ with the trajectories $\mathcal{T}$, which is guaranteed to lie on the representative μ'_* that minimizes the homotopy area of the lifted trajectories $\mathcal{T}'$. We can now construct G' from G by walking along the trajectories, starting from their intersection points with γ. Similarly, we can trace μ'_* trough G', starting from p. The representative μ'_* then also gives us an optimal representative μ^* (Theorem 20). All that remains is to describe how to construct γ. We do this using the same procedure as used in the proof of Lemma 16: we explicitly construct G, sort the vertices in topological order, and add the vertices in this order to some set L. Once L contains a vertex v on the outer face of G, we can construct γ, starting on the outgoing edge of v incident to the outer face, and walking through G, while keeping exactly the set of vertices L to our left. It is easy to see that computing μ^* using this algorithm takes $O(|G|) = O(N^2)$ time. We summarize our results in the following theorem.

▶ **Theorem 21.** *Let $\mathcal{T}$ be a set of trajectories that all start in s and end in t, and whose trajectory graph G is acyclic. If s and t lie on the outer face, a representative trajectory μ^* that minimizes HA_{sum} can be computed in $O((N+k)\alpha(N)\log(N))$ time, where N is the total complexity of the trajectories in $\mathcal{T}$, and k is the complexity of the resulting trajectory. If s and t can be anywhere in G, μ^* can be computed in $O(|G|) = O(N^2)$ time.*

6 Future Work

We have shown that computing a representative that minimizes $\mathrm{HA}_{\mathrm{sum}}$ is NP-hard when the trajectory graph G may be an arbitrary graph, and we have presented an efficient algorithm for when G is a DAG. Hence, our results cover all cases. However, clearly there are situations in which the trajectories are similar, but for which the trajectory graph is not a DAG. Hence, we would like a more fine grained classification which kind of graphs allow us to find a representative efficiently.

We expect that we can extend our approach from Section 4.3 to cases in which the trajectories are have a similar "shape" but their trajectory graph contains cycles. In particular, we again lift the trajectories into a space, or *corridor*, that captures the global shape of the trajectories, and in which the trajectory graph forms a DAG. We then compute a concrete curve representing the trajectories in this space. The conceptual existence of a

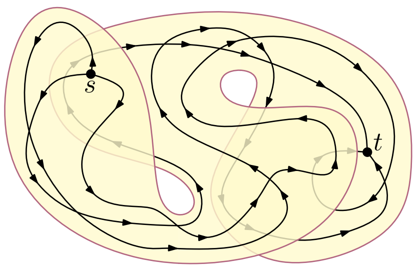

Figure 13 Even when trajectories do not form a DAG, the trajectories may lie in a "corridor".

corridor is justified by the assumption that the input trajectories are similar. See Fig. 13 for an illustration.

While we focused on using the homotopy area to measure distance between the trajectories, there are other alternative measures that balance topology and geometry. Homotopy width (or homotopic Fréchet distance) [8] and homotopy height [5, 13] are obvious options, as is homology area [6], although it is unclear if any of these are tractable or useful in practice.

Abstract

We consider data-structures for answering reachability and distance queries on constant-treewidth graphs with n nodes, on the standard RAM computational model with wordsize $W = \Theta(\log n)$. Our first contribution is a data-structure that after $O(n)$ preprocessing time, allows (1) pair reachability queries in $O(1)$ time; and (2) single-source reachability queries in $O(\frac{n}{\log n})$ time. This is (asymptotically) *optimal* and is *faster than DFS/BFS* when answering more than a constant number of single-source queries. The data-structure uses at all times $O(n)$ space. Our second contribution is a space-time tradeoff data-structure for distance queries. For any $\epsilon \in [\frac{1}{2}, 1]$, we provide a data-structure with polynomial preprocessing time that allows pair queries in $O(n^{1-\epsilon} \cdot \alpha(n))$ time, where α is the inverse of the Ackermann function, and at all times uses $O(n^{\epsilon})$ space. The input graph G is not considered in the space complexity.

1 Introduction

In this work we consider two of the most classic graph algorithmic problems, namely the reachability and distance problems, on low-treewidth graphs. We consider the case where the input is a graph G with n nodes and a tree-decomposition Tree(G) of G with $b = O(n)$ bags and width t. The computational model is the standard RAM with wordsize $W = \Theta(\log n)$.

Low-treewidth graphs. A very well-known concept in graph theory is the notion of *treewidth* of a graph, which is a measure of how similar a graph is to a tree (a graph has treewidth 1 precisely if it is a tree) [30]. The treewidth of a graph is defined based on a *tree decomposition* of the graph [24], see Section 2 for a formal definition. Beyond the mathematical elegance of the treewidth property for graphs, there are many classes of graphs

* The research was partly supported by Austrian Science Fund (FWF) Grant No P23499-N23, FWF NFN Grant No S11407-N23 (RiSE/SHiNE) and ERC Start grant (279307: Graph Games).

which arise in practice and have low (even constant) treewidth. An important example is that the control flow graph for goto-free programs for many programming languages are of constant treewidth [32]. Also many chemical compounds have treewidth 3 [34]. For many other applications see the surveys [11, 10]. Given a tree decomposition of a graph with low treewidth t, many problems on the graph become complexity-wise easier (i.e., many NP-complete problems for arbitrary graphs can be solved in time polynomial in the size of the graph, but exponential in t, given a tree decomposition [3, 7, 8]). Even for problems that can be solved in polynomial time, faster algorithms can be obtained for low-treewidth graphs, for example, for the distance (or the shortest path) problem [16]. The constant treewidth of control flow graphs has also been shown to lead to faster algorithms for interprocedural analysis [14], quantitative verification [15], and analysis of concurrent programs [13].

Reachability/distance problems. The *pair* reachability (resp., distance) problem is one of the most classic graph algorithmic problems that, given a pair of nodes u, v, asks to compute if there is a path from u to v (resp., the weight of the shortest path from u to v). The *single-source* variant problem given a node u asks to solve the pair problem u, v for every node v. Finally, the *all pairs* variant asks to solve the pair problem for each pair u, v. While there exist many classic algorithms for the distance problem, such as A^*-algorithm (pair) [26], Dijkstra's algorithm (single-source) [19], Bellman-Ford algorithm (single-source) [5, 23, 28], Floyd-Warshall algorithm (all pairs) [22, 33, 31], and Johnson's algorithm (all pairs) [27] and others for various special cases, there exist in essence only two different algorithmic ideas for reachability: Fast matrix multiplication (all pairs) [21] and DFS/BFS (single-source) [18].

Previous results. The algorithmic question of the distance (pair, single-source, all pairs) problem for low-treewidth graphs has been considered extensively in the literature, and many data-structures have been presented [2, 16, 29, 1, 4, 17]. The previous results are incomparable, in the sense that the best data-structure depends on the treewidth and the number of queries. The pair query reachability for low-treewidth graphs has been considered in [35]. Despite many results for constant (or low) treewidth graphs, none of them improves the complexity for the basic single-source reachability problem, i.e., the bound for DFS/BFS has not been improved in any of the previous works.

Our results. Our algorithms take as input a graph G with n nodes. Our main contributions are as follows (summarized in Table 1 and Table 2):

1. Our first contribution is a data-structure that supports reachability queries in G. The computational complexity we achieve is as follows: (i) $O(n \cdot t^2)$ preprocessing (construction) time; (ii) $O(n \cdot t)$ space; (iii) $O(\lceil t/\log n \rceil)$ pair-query time; and (iv) $O(n \cdot t/\log n)$ time for single-source queries. Note that for constant-treewidth graphs, the data-structure is *optimal* in the sense that it only uses linear preprocessing time, and supports answering queries in the size of the output (the output for single-source queries requires one bit per node, and thus has size $\Theta(n/W) = \Theta(n/\log n)$). Moreover, also for constant-treewidth graphs, the data-structure answers single-source queries faster than DFS/BFS, after linear preprocessing time (which is asymptotically the same as for DFS/BFS). Thus there exists a constant c_0 such that the total of the preprocessing and querying time of the data-structure is smaller than that of DFS/BFS for answering at least c_0 single-source queries.
2. Second, we present a space-time tradeoff data-structure that supports distance pair queries in G and given a number $\epsilon \in [\frac{1}{2}, 1]$. The weights of G come from the set of

Table 1 Data-structures for pair and single-source reachability queries, on a directed graph G with n nodes, m edges, and a treewidth t. The model of computation is the standard RAM model with wordsize $W = \Theta(\log n)$. Space usage refers to the total space used during the preprocessing and query phase. Rows 1 and 2 are previous results, and row i is the result of this paper.

Row	Preprocessing time	Space usage	Pair query time	Single-source query time	From
1	$O(n \cdot \log n)$	$O(n \cdot \log n)$	$O(\log n)$	$O(n \cdot \log n)$ a)	[35] b)
2	–	$O(\lceil n/\log n \rceil)$	$O(m)$	$O(m)$	DFS/BFS [18]
i	$O(n \cdot t^2)$	$O(n \cdot t)$	$O(\lceil \frac{t}{\log n} \rceil)$	$O(\frac{n \cdot t}{\log n})$	Theorem 6

a) Obtained by multiplying the time for a pair query by n.
b) The result is only stated for constant treewidth.

Table 2 Data-structures for pair and single-source distance queries, on a weighted directed graph G with n nodes, m edges, and a tree decomposition of width $O(1)$ and height h. The number ϵ can be any fixed number in $[\frac{1}{2}, 1]$ and $\alpha(n)$ is the inverse Ackermann function. Space usage refers to the total space used during the preprocessing and query phase. When measuring space complexity, we do not count the input size. Rows 1-6 are previous results, and row i is the result of this paper.

Row	Preprocessing time	Space usage	Pair query time	Single-source query time	From
1	$O(n^2)$	$O(n^2)$	$O(1)$	$O(n)$	[29] a)
2	$O(n)$	$O(n)$	$O(\alpha(n))$	$O(n)$	[16]
3	$O(n \cdot \log h)$	$O(n)$	$O(\log \log n)$	$O(n \cdot \log \log n)$ b)	[2]
4	$O(n \cdot \log^2 n)$	$O(n \cdot \log n)$	$O(\log n)$	$O(n \cdot \log n)$ b)	[1]
5	$O(n \cdot \log n)$	$O(n \cdot \log n)$	$O(\log^2 n)$	$O(n \cdot \log^2 n)$ b)	[4, 17]
6	Not given	$O(n^\epsilon \cdot \log^2 n)$ c)	$O(n^{1-\epsilon} \cdot \log n)$	– d)	[2] e)
i	polynomial	$O(n^\epsilon)$	$O(n^{1-\epsilon} \cdot \alpha(n))$	– d)	Theorem 13

a) This data-structure solves the all pairs problem in the given time and space bounds.
b) Obtained by multiplying the time for a pair query by n.
c) This is the space usage after preprocessing.
d) Not given/supported since the size of the output is larger than the data-structure.
e) Note that [2] does not explicitly state the tradeoff given (they only state linear space), but it follows from their technique by picking other values for their variable k. Also, note that [2] requires a tree-decomposition to be part of the input, whereas our data-structure only requires that the graph G is part of the input.

integers $\mathbb{Z}$, but we do not allow negative cycles. For constant-treewidth graphs, our data-structure requires (i) polynomial preprocessing time; (ii) $O(n^\epsilon)$ working space; and (iii) $O(n^{1-\epsilon} \cdot \alpha(n))$ time for pair queries.

The graph G is considered part of the input, and is not counted towards the space complexity.

Technical contributions. Our results rely on three key technical contributions:

1. For pair reachability queries, the key idea is to store reachability information from each node to $O(\log n)$ other nodes. For single-source queries, for some nodes this reachability information might be of size $\Theta(n)$, but on average remains $O(\log n)$. Our data-structure computes reachability information in such a way that allows for compact representation and fast retrieval using word tricks, which for constant-treewidth graphs leads to asymptotically optimal preprocessing and query (both pair and single-source) bounds. The idea of storing $O(\log n)$ information per node has appeared before ([35, 16]) however those algorithms follow different approaches, where word tricks do not seem to be applicable (at least not without significantly modifying the algorithms).
2. For distance queries, we devise a procedure for shrinking a tree-decomposition of size $O(n)$ to one of size $O(n^{1-\epsilon})$, by partitioning the tree-decomposition to components of

sufficient size. A key property of this partitioning is that each component has only a constant number of neighbor components. We show how this shrank tree-decomposition can be preprocessed for answering pair distance queries in the stated bounds.

2 Preliminaries

Graphs. We consider weighted directed graphs $G = (V, E, \mathsf{wt})$ where V is a set of n nodes, $E \subseteq V \times V$ is an edge relation of m edges, and $\mathsf{wt} : E \to \mathbb{Z}$ is a weight function where $\mathbb{Z}$ is the set of integers. In the sequel we write graphs for directed graphs, and explicitly mention if the graph is undirected. Given a set $X \subseteq V$, we denote by $G[X]$ the subgraph $(X, E \cap (X \times X))$ of G induced by the set of nodes X. A path $P : u \rightsquigarrow v$ is a sequence of nodes $(x_1, \dots, x_k)$ such that $u = x_1$, $v = x_k$, and for all $1 \leq i \leq k-1$ we have $(x_i, x_{i+1}) \in E$. The path P is *simple* if every node appears at most once in P. The length of P is $k-1$, and a single node is by itself a 0-length path. We denote by $E^* \subseteq V \times V$ the transitive closure of E, i.e., $(u, v) \in E^*$ iff there exists a path $P : u \rightsquigarrow v$. Given a path P, a node u, and a set of nodes A, we use the set notation $u \in P$ to denote that u appears in P, and $A \cap P$ to refer to the set of nodes that appear in both P and A. The weight function is extended to paths, and the weight of a path $P = (x_1, \dots, x_k)$ is $\mathsf{wt}(P) = \sum_{i=1}^{k-1} \mathsf{wt}(x_i, x_{i+1})$ if $k > 1$, else $\mathsf{wt}(P) = 0$. For $u, v \in V$, the distance from u to v is defined as $d(u, v) = \min_{P : u \rightsquigarrow v} \mathsf{wt}(P)$, where P ranges over simple paths in G (and $d(u, v) = \infty$ if no such path exists). We consider that G does not have negative cycles.

Trees. A (rooted) tree $T = (V_T, E_T)$ is an undirected graph with a distinguished node r which is the root such that there is a unique simple path $P_u^v : u \rightsquigarrow v$ for each pair of nodes u, v. The *size* of T is $|V_T|$. Given a tree T with root r, the *level* $\mathsf{Lv}(u)$ of a node u is the length of the simple path P_u^r from u to the root r, and every node in P_u^r is an *ancestor* of u. If v is an ancestor of u, then u is a *descendant* of v. Note that a node u is both an ancestor and descendant of itself. For a pair of nodes $u, v \in V_T$, the *lowest common ancestor (LCA)* of u and v is the common ancestor of u and v with the largest level. The *parent* u of v is the unique ancestor of v in level $\mathsf{Lv}(v) - 1$, and v is a *child* of u. A *leaf* of T is a node with no children. For a node $u \in V_T$, we denote by $T(u)$ the subtree of T rooted in u (i.e., the tree consisting of all descendants of u). The tree T is *binary* if every node has at most two children. The *height* of T is $\max_u \mathsf{Lv}(u)$ (i.e., it is the length of the longest path P_u^r), and T is *balanced* if its height is $O(\log |V_T|)$. Given a tree T, a *connected component* $C \subseteq V_T$ of T is a set of nodes of T such that for every pair of nodes $u, v \in C$, the unique simple path P_u^v in T visits only nodes in C.

Tree decompositions. Given a graph G, a tree-decomposition $\mathrm{Tree}(G) = (V_T, E_T)$ is a tree with the following properties.

T1: $V_T = \{B_1, \dots, B_b :$ for all $1 \leq i \leq b.\ B_i \subseteq V\}$ and $\bigcup_{B_i \in V_T} B_i = V$.

T2: For all $(u, v) \in E$ there exists $B_i \in V_T$ such that $u, v \in B_i$.

T3: For all B_i, B_j and any bag B_k that appears in the simple path $B_i \rightsquigarrow B_j$ in $\mathrm{Tree}(G)$, we have $B_i \cap B_j \subseteq B_k$.

The sets B_i which are nodes in V_T are called *bags*. The *width* of a tree-decomposition $\mathrm{Tree}(G)$ is the size of the largest bag minus 1, and the *treewidth* of G is the width of a minimum-width tree decomposition of G. Let G be a graph, $T = \mathrm{Tree}(G)$, and B_0 be the root of T. For $u \in V$, we say that a bag B is the *root bag* of u if B is the bag with the smallest level among all bags that contain u. By definition, for every node u there exists a unique bag which is the root of u. We often write B_u for the root bag of u, i.e., $B_u = \arg\min_{B_i \in V_T\colon u \in B_i} \mathsf{Lv}(B_i)$, and denote by $\mathsf{Lv}(u) = \mathsf{Lv}(B_u)$. A bag B is said to *introduce* a node $u \in B$ if either B is a leaf, or u does not appear in any child of B. In this work we consider only *binary* tree decompositions (if not, a tree decomposition can be made binary by a standard process that increases its size by a constant factor while keeping the width the same). The following lemma states a well-known "separator property" of tree decompositions.

▶ **Lemma 1.** *Consider a graph $G = (V, E)$, a binary tree-decomposition $T = \mathrm{Tree}(G)$, and a bag B of T. Let $(C_i)_{1\le i\le 3}$ be the components of T created by removing B from T, and let V_i be the set of nodes that appear in bags of component C_i. For every $i \neq j$, nodes $u \in V_i$, $v \in V_j$ and path $P : u \rightsquigarrow v$, we have that $P \cap B \neq \emptyset$ (i.e., all paths between u and v go through some node in B).*

Using Lemma 1, we prove the following stronger version of the separator property, which will be useful throughout the paper.

▶ **Lemma 2.** *Consider a graph $G = (V, E)$ and a tree-decomposition $\mathrm{Tree}(G)$. Let $u, v \in V$, and consider two distinct bags B_1 and B_j such that $u \in B_1$ and $v \in B_j$. Let $P' : B_1, B_2, \dots, B_j$ be the unique simple path in T from B_1 to B_j. For each $i \in \{2, \dots, j\}$ and for each path $P : u \rightsquigarrow v$, there exists a node $x_i \in (B_{i-1} \cap B_i \cap P)$.*

Proof. Let $T = \mathrm{Tree}(G)$. Fix a number $i \in \{2, \dots, j\}$. We argue that for each path $P : u \rightsquigarrow v$, there exists a node $x_i \in (B_{i-1} \cap B_i \cap P)$. We construct a tree T', which is similar to T except that instead of having an edge between bag B_{i-1} and bag B_i, there is a new bag B, that contains the nodes in $B_{i-1} \cap B_i$, and there is an edge between B_{i-1} and B and one between B and B_i. It is easy to see that T' satisfies the properties T1-T3 of a tree-decomposition of G. By Lemma 1, each bag B' in the unique path $P'' : B_1, \dots, B_{i-1}, B, B_i, \dots, B_j$ in T' separates u from v in G. Hence, each path $u \rightsquigarrow v$ must go through some node in B, and the result follows. ◀

The following lemma states that for nodes that appear in bags B, B' of the tree-decomposition $T = \mathrm{Tree}(G)$, their distance can be written as a sum of distances $d(x_i, x_{i+1})$ between pairs of nodes (x_i, x_{i+1}) that appear in bags B_i that constitute the unique $B \rightsquigarrow B'$ path in T.

▶ **Lemma 3.** *Consider a weighted graph $G = (V, E, \mathsf{wt})$ and a tree-decomposition $\mathrm{Tree}(G)$. Let $u, v \in V$, and $P' : B_1, B_2, \dots, B_j$ be a simple path in T such that $u \in B_1$ and $v \in B_j$. Let $A = \{u\} \times \left(\prod_{1<i\le j} (B_{i-1} \cap B_i)\right) \times \{v\}$. Then $d(u, v) = \min_{(x_1,\dots,x_{j+1})\in A} \sum_{i=1}^{j} d(x_i, x_{i+1})$.*

Proof. Consider a witness path $P : u \rightsquigarrow v$ such that $\mathsf{wt}(P) = d(u, v)$. By Lemma 2, there exists some node $x_i \in (B_{i-1} \cap B_i \cap P)$, for each $i \in \{1, \dots, j\}$. It easily follows that $d(u, v) = \sum_{i=1}^{j} d(x_i, x_{i+1})$ with $x_1, \dots x_{j+1} \in A$. ◀

Small tree decompositions. A tree-decomposition $T = \mathrm{Tree}(G) = (V_T, E_T)$ is called *small* if $|V_T| = O(\frac{n}{t})$.

▶ **Lemma 4.** *Given a tree decomposition $\mathrm{Tree}(G)$ of G of width $O(t)$ and $O(n)$ bags, a small, binary tree decomposition $\mathrm{Tree}'(G)$ of width $O(t)$ can be constructed in $O(n \cdot t)$ time. Moreover, if $\mathrm{Tree}(G)$ is balanced, then so is $\mathrm{Tree}'(G)$.*

Proof. Let $k = O(t)$ be the width of $\mathrm{Tree}(G)$. The construction is achieved using the following steps.

1. Following the steps of [9, Lemma 2.4], we turn $\mathrm{Tree}(G)$ to a *smooth* tree-decomposition $T_1 = (V_1, E_1)$, which has the properties that (i) for every bag $B \in V_1$ we have $|B| = k+1$, and (ii) for every pair of bags $(B_1, B_2) \in E_1$ we have $|B_1 \cap B_2| = k$. The process of [9, Lemma 2.4] can be performed $O(n \cdot t)$ time and increases the height by at most a factor 2, hence if $\mathrm{Tree}(G)$ is balanced, T_1 is also balanced, and by [9, Lemma 2.5], we have $|V_1| = O(n)$.
2. We turn T_1 to a binary tree-decomposition $T_2 = (V_2, E_2)$, by a standard tree-binarization process [16, Fact 3], which increases the size and the height of T_2 by at most a factor 2.
3. We construct a tree-decomposition $T_3 = (V_3, E_3)$ by partitioning T_2 to disjoint connected components of size between $\frac{k}{2}$ and k each (the last component might have size less than $\frac{k}{2}$) and contracting each such component to a single bag in T_3. Since T_2 is smooth, the number of nodes in the union of the bags of each component is at most $2 \cdot k$. Hence the width of T_3 is $O(k)$. The partitioning is done as follows. We traverse T_2 bottom-up and group bags into components in a greedy way. In particular, given that the traversal is on a current bag B, we keep track of the number of bags i_B below B (not including B) that have not been grouped to a component yet. The first time we find $i_B \geq t$, let B' be the child of B with the largest number $i_{B'}$ among the children of B. We group B' and its ungrouped descendants into a new component C, and continue with the traversal. Observe that the size of C is $\frac{k}{2} \leq |C| < k$.
4. Finally, we construct $\mathrm{Tree}'(G)$ by turning T_3 to a binary tree-decomposition as in Step 2.

Note that all steps above require $O(n \cdot t)$ time. The desired result follows. ◀

▶ **Lemma 5** ([16]). *Given a weighted graph $G = (V, E, \mathsf{wt})$ of treewidth t and a tree-decomposition $T = (V_T, E_T)$ of G of width $O(t)$, we can compute for all bags $B \in V_T$ a* local distance map $\mathsf{LD}_B : B \times B \to \mathbb{Z}$ *with $\mathsf{LD}_B(u, v) = d(u, v)$ in total time $O(|V_T| \cdot t^3)$ and space $O(|V_T| \cdot t^2)$.*

Model and word tricks. We consider the standard RAM model with word size $W = \Theta(\log n)$, where $\mathsf{poly}(n)$ is the size of the input. Our reachability algorithm (in Section 3) uses so called "word tricks" heavily. We use constant-time LCA queries which also use word tricks [25, 6].

3 Optimal Reachability for Low-Treewidth Graphs

In this section we present algorithms for building and querying a data-structure $\mathsf{Reachability}$, which handles single-source and pair reachability queries over an input a graph G of n nodes and treewidth t. In particular, we establish the following.

▶ **Theorem 6.** *Given a graph G of n nodes and treewidth t, let $\mathcal{T}(G)$ be the time and $\mathcal{S}(G)$ be the space required for constructing a balanced tree-decomposition $\mathrm{Tree}(G)$ of $O(n)$ bags and width $O(t)$ on the standard RAM with wordsize $W = \Theta(\log n)$. The data-structure* $\mathsf{Reachability}$ *correctly answers reachability queries and requires*
1. *$O(\mathcal{T}(G) + n \cdot t^2)$ preprocessing time;*
2. *$O(\mathcal{S}(G) + n \cdot t)$ preprocessing space;*
3. *$O\left(\left\lceil \frac{t}{\log n} \right\rceil\right)$ pair query time; and*
4. *$O\left(\frac{n \cdot t}{\log n}\right)$ single-source query time.*

For constant-treewidth graphs we have that $\mathcal{T}(G) = O(n)$ and $\mathcal{S}(G) = O(n)$ ([12, Lemma 2]), and thus along with Theorem 6 we obtain the following corollary.

▶ **Corollary 7.** *Given a graph G of n nodes and constant treewidth, the data-structure* Reachability *requires $O(n)$ preprocessing time and space, and correctly answers (i) pair reachability queries in $O(1)$ time, and (ii) single-source reachability queries in $O\left(\frac{n}{\log n}\right)$ time.*

Intuition. Informally, the preprocessing consists of first obtaining a small, balanced and binary tree-decomposition T of G, and computing the local reachability information in each bag B (i.e., the pairs $(u, v) \in E^*$ with $u, v \in B$) using Lemma 5. Then, the whole of preprocessing is done on T, by constructing two types of sets, which are represented as bit sequences and packed into words of length $W = \Theta(\log n)$. Initially, every node u receives an *index* i_u, such that for every bag B, the indices of nodes whose root bag is in $T(B)$ form a contiguous interval. Additionally, for every appearance of node u in a bag B, the node u receives a *local index* l_u^B in B. For brevity, a sequence $(A^0, A^1, \dots A^k)$ will be denoted by $(A^i)_{0 \leq i \leq k}$. When k is implied, we simply write $(A^i)_i$. The following two types of sets are constructed.

1. Sets that store information about subtrees. Specifically, for every node u, the set F_u stores the relative indices of nodes v that can be reached from u, and whose root bag is in $T(B_u)$. These sets are used to answer single-source queries.
2. Sets that store information about ancestors. Specifically, for every node u, two sequences of sets are stored $(\mathsf{F}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$, $(\mathsf{T}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$, such that F_u^i (resp., T_u^i) contains the local indices of nodes v in the ancestor bag B_u^i of B_u at level i, such that $(u, v) \in E^*$ (resp., $(v, u) \in E^*$). These sets are used to answer pair queries.

The sets of the first type are constructed by a bottom-up pass, whereas the sets of the second type are constructed by a top-down pass. Both passes are based on the separator property of tree decompositions (recall Lemma1 and Lemma 2), which informally states that reachability properties between nodes in distant bags will be captured transitively, through nodes in intermediate bags.

Reachability Preprocessing. We now give a formal description of the preprocessing of Reachability that takes as input a graph G of n nodes and treewidth t, and a balanced tree-decomposition $T = \text{Tree}(G)$ of width $O(t)$. After the preprocessing, Reachability supports single-source and pair reachability queries. We say that we "insert" set A to set A' meaning that we replace A' with $A \cup A'$. Sets are represented as bit sequences where 1 denotes membership in the set, and the operation of inserting a set A "at the i-th position" of a set A' is performed by taking the bit-wise logical OR between A and the segment $[i, i + |A|]$ of A'. The preprocessing consists of the following steps.

1. Turn T to a small, balanced binary tree-decomposition of G of width $O(t)$, using Lemma 4.
2. Preprocess T to answer LCA queries in $O(1)$ time [25].
3. Compute the local distance map $\mathsf{LD}_B : B \times B \to \mathbb{Z}$ for every bag B w.r.t reachability, i.e., for any bag B and nodes $u, v \in B$, we have $\mathsf{LD}_B(u, v) = 1$ iff $(u, v) \in E^*$.
4. Apply a pre-order traversal on T, and assign an incremental index i_u to each node u at the time the root bag B of u is visited. If there are multiple nodes u for which B is the root bag, assign the indices to those nodes in some arbitrary order. Additionally, store the number s_u of nodes whose root bag is in $T(B)$ and have index at least i_u. Finally, for each bag B and $u \in B$, assign a unique local index l_u^B to u, and store in B the number of nodes (with multiplicities) a_B contained in all ancestors of B, and the number b_B of nodes in B.
5. For every node u, initialize a bit set F_u of length s_u, pack it into words, and set the first bit to 1.

6. Traverse T bottom-up, and for every bag B execute the following step. For every pair of nodes $u, v \in B$ such that B is the root bag of v and $i_u < i_v$ and $\mathsf{LD}_B(u,v) = 1$, insert F_v to the segment $[i_v - i_u, i_v - i_u + s_v]$ of F_u (the nodes reachable from v now become reachable from u, through v).
7. For every node u initialize two sequences of bit sets $(\mathsf{T}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$, $(\mathsf{F}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$, and pack them into consecutive words. Each set T_u^i and F_u^i has size $b_{B_u^i}$, where B_u^i is the ancestor of B_u at level i.
8. Traverse T top-down, and for B the bag currently visited, for every node $x \in B$, maintain two sequences of bit sets $(\overline{\mathsf{T}}_x^i)_{0 \leq i \leq \mathsf{Lv}(B)}$ and $(\overline{\mathsf{F}}_x^i)_{0 \leq i \leq \mathsf{Lv}(B)}$. Each set $\overline{\mathsf{T}}_x^i$ and $\overline{\mathsf{F}}_x^i$ has size b_{B^i}, where B^i is the ancestor of B at level i. Initially, B is the root of T (hence $\mathsf{Lv}(B) = 0$), and set the position l_w^B of $\overline{\mathsf{F}}_x^0$ (resp., $\overline{\mathsf{T}}_x^0$) to 1 for every node w such that $\mathsf{LD}_B(x,w) = 1$ (resp., $\mathsf{LD}_B(w,x) = 1$). For each other bag B encountered in the traversal, do as follows. Let $S = B \cap B'$, where B' is the parent of B in T, and let x range over S.
   a. For each node x, create a set $\overline{\mathsf{T}}_x$ (resp., $\overline{\mathsf{F}}_x$) of 0s of length b_B, and for every $w \in B$ such that $\mathsf{LD}_B(x,w) = 1$ (resp., $\mathsf{LD}_B(w,x) = 1$), set the l_w^B-th bit of $\overline{\mathsf{F}}_x$ (resp., $\overline{\mathsf{T}}_x$) to 1. Append the set $\overline{\mathsf{T}}_x$ (resp., $\overline{\mathsf{F}}_x$) to $(\overline{\mathsf{T}}_x^i)_i$ (resp., $(\overline{\mathsf{F}}_x^i)_i$). Now each set sequence $(\overline{\mathsf{T}}_x^i)_i$ and $(\overline{\mathsf{F}}_x^i)_i$ has size $a_B + b_B$.
   b. For each $u \in B$ whose root bag is B, initialize set sequences $(\overline{\mathsf{F}}_u^i)_i$ and $(\overline{\mathsf{T}}_u^i)_i$ with 0s of length $a_B + b_B$ each, and set the bit at position l_u^B of $\overline{\mathsf{F}}_u^{\mathsf{Lv}(B)}$ and $\overline{\mathsf{T}}_u^{\mathsf{Lv}(B)}$ to 1. For every $w \in B$ with $\mathsf{LD}_B(u,w) = 1$ (resp., $\mathsf{LD}_B(w,u) = 1$), insert $(\overline{\mathsf{F}}_w^i)_i$ to $(\overline{\mathsf{F}}_u^i)_i$ (resp., $(\overline{\mathsf{T}}_w^i)_i$ to $(\overline{\mathsf{T}}_u^i)_i$). Finally, set $(\mathsf{F}_u^i)_i$ equal to $(\overline{\mathsf{F}}_u^i)_i$ (resp., $(\mathsf{T}_u^i)_i$ equal to $(\overline{\mathsf{T}}_u^i)_i$).

Figure 1 illustrates the constructed sets on a small example.

It is fairly straightforward that at the end of the preprocessing, the i-th position of each set F_u is 1 only if $(u,v) \in E^*$, where v is such that $i_v - i_u = i$. The following lemma states the opposite direction, namely that each such i-th position will be 1, as long as the path $P : u \rightsquigarrow v$ only visits nodes with certain indices.

▶ **Lemma 8.** *At the end of preprocessing, for every pair of nodes u and v with $i_u \leq i_v \leq i_u + s_u$, if there exists a path $P : u \rightsquigarrow v$ such that for every $w \in P$, we have $i_u \leq i_w \leq i_u + s_u$, then the $(i_v - i_u)$-th bit of F_u is 1.*

Proof. We prove inductively the following claim. For every ancestor B of B_v, if there exists $w \in B$ and a path $P_1 : w \rightsquigarrow v$, then exists $x \in B \cap P_1$ such that $i_x \leq i_v \leq i_x + s_x$ and the $i_v - i_x$-th bit of F_x is 1. The proof is by induction on the length of the simple path $P_2 : B \rightsquigarrow B_v$.

1. If $|P_2| = 0$, the statement is true by taking $x = v$, since the 0-th bit of F_v is 1.
2. If $|P_2| > 0$, examine the child B' of B in P_2. By Lemma 2, there exists $x \in B \cap B' \cap P$, and let $P_3 : x \rightsquigarrow v$. By the induction hypothesis there exists some $y \in B' \cap P_3$ with $i_y \leq i_v \leq i_y + s_y$ and the $i_v - i_y$-th bit of F_y is 1. If $y \in B$, we take $x = y$. Otherwise, B' is the root bag of y, and by the local distance computation of Lemma 5, it is $\mathsf{LD}_{B'}(x,y) = 1$. By the choice of x, y we have that B_x is an ancestor of B_y. Thus, by construction we have $i_x < i_y$ and $s_x \geq s_y + i_y - i_x$, and hence $i_x \leq i_v \leq i_x + s_x$. Then in step 5, F_y is inserted in position $i_y - i_x$ of F_x, thus the bit at position $i_y - i_x + i_v - i_y = i_v - i_x$ of F_x will be 1, and we are done.

When B_u is examined, by the above claim there exists $x \in P$ such that $i_x \leq i_v$ and the $i_v - i_x$-th bit of F_x is 1. If $x = u$ we are done. Otherwise, by the choice of P, we have $i_u < i_x$, which can only happen if B_u is also the root bag of x. Then in step 5, F_x is inserted

(c) **(d)**

Figure 1 a, c: A graph G and a tree-decomposition Tree(G). b: The sets F_u constructed from step 5 to answer single-source queries. The j-th bit of a set F_u is 1 iff $(u, v) \in E^*$, where v is such that $i_v - i_u = j$. d: The set sequences $(\mathsf{F}_u^i)_i$ and $(\mathsf{T}_u^i)_i$ constructed from step 6 to answer pair queries, for $u = 6$. For every $i \in \{0, 1, 2, 3\}$ and ancestor B_6^i of B_6 at level i, every node $v \in B_u^i$ is assigned a local index $l_v^{B_6^i}$. The j-th bit of set F_6^i (resp. T_6^i) is 1 iff $(6, v) \in E^*$ (resp. $(v, 6) \in E^*$), where v is such that $l_v^{B_6^i} = j$.

in position $i_x - i_u$ of F_u, and hence the bit at position $i_x - i_u + i_v - i_x = i_v - i_u$ of F_x will be 1, as desired. ◀

Similarly, given a node u and an ancestor bag B_u^i of B_u at level i, the j-th position of the set F_u^i (resp., T_u^i) is 1 only if $(u, v) \in E^*$ (resp., $(v, u) \in E^*$), where $v \in B_u^i$ is such that $l_v^{B_u^i} = j$. The following lemma states that the inverse is also true.

▶ **Lemma 9.** *At the end of preprocessing, for every node u, for every $v \in B_u^i$ where B_u^i is the ancestor of B_u at level i, we have that if $(u, v) \in E^*$ (resp., $(v, u) \in E^*$), then the $l_v^{B_u^i}$-th bit of F_u^i (resp., T_u^i) is 1 .*

▶ **Lemma 10.** *Given a graph G with n nodes and treewidth t, let $\mathcal{T}(G)$ be the time and $\mathcal{S}(G)$ be the space required for constructing a balanced tree-decomposition of G with $O(n)$ bags and width $O(t)$. The preprocessing phase of* Reachability *on G requires $O(\mathcal{T}(G) + n \cdot t^2)$ time and $O(\mathcal{S}(G) + n \cdot t)$ space.*

Proof. First, we construct a balanced tree-decomposition $T = \text{Tree}(G)$ of G in $\mathcal{T}(G)$ time and $\mathcal{S}(G)$ space. We establish the complexity of each preprocessing step separately.

1. Using Lemma 4, this step requires $O(n \cdot t)$ time. From this point on, T consists of $b = O(\frac{n}{t})$ bags, has height $h = O(\log n)$, and width $t' = O(t)$.

2. By a standard construction for balanced trees, preprocessing T to answer LCA queries in $O(1)$ time requires $O(b) = O(\frac{n}{t})$ time.

3. By Lemma 5, this step requires $O(b \cdot t'^3) = O(\frac{n}{t} \cdot t^3) = O(n \cdot t^2)$ time and $O(b \cdot t'^2) = O(\frac{n}{t} \cdot t^2) = O(n \cdot t)$ space.

4. Every bag B is visited once, and each operation on B takes constant time. We make $O(t')$ such operations in B, hence this step requires $O(b \cdot t') = O(n)$ time in total.

5–6. The space required in this step is the space for storing all the sets F_u of size s_u each, packed into words of length W:

$$\sum_{u \in V} \left\lceil \frac{s_u}{W} \right\rceil = \sum_{i=0}^{h} \sum_{u:\mathsf{Lv}(u)=i} \left\lceil \frac{s_u}{W} \right\rceil \leq \sum_{i=0}^{h} \sum_{u:\mathsf{Lv}(u)=i} \left(\frac{s_u}{W} + 1 \right)$$
$$= \frac{1}{W} \cdot \sum_{i=0}^{h} \sum_{u:\mathsf{Lv}(u)=i} s_u + \sum_{i=0}^{h} \sum_{u:\mathsf{Lv}(u)=i} 1 \leq \frac{1}{W} \cdot \sum_{i=0}^{h} n \cdot (t'+1) + n = O(n \cdot t)$$

since $h = O(\log n)$, $t' = O(t)$ and $W = \Theta(\log n)$. Note that we have $\sum_{u:\mathsf{Lv}(u)=i} s_u \leq n \cdot (t'+1)$ because $|\bigcup_u \mathsf{F}_u| \leq n$ (as there are n nodes) and every element of $\bigcup_u \mathsf{F}_u$ belongs to at most $t'+1$ such sets F_u (i.e., for those u that share the same root bag at level i). The time required in this step is $O(n \cdot t)$ in total for iterating over all pairs of nodes (u, v) in each bag B such that B is the root bag of either u or v, and $O(n \cdot t^2)$ for the set operations, by amortizing $O(t)$ operations per word used.

7. The time and space required for storing each sequence of the sets $(\mathsf{F}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$ and $(\mathsf{T}_u^i)_{0 \leq i \leq \mathsf{Lv}(u)}$ is:

$$\sum_{u \in V} 2 \cdot \left\lceil \frac{a_{B_u} + b_{B_u}}{W} \right\rceil \leq 2 \cdot n \cdot \left\lceil \frac{(t'+1) \cdot h}{W} \right\rceil = O(n \cdot t)$$

since $a_{B_u} + b_{B_u} \leq (t'+1) \cdot h$, $h = O(\log n)$ and $W = \Theta(\log n)$.

8. The space required is the space for storing the set sequences $(\overline{\mathsf{T}}_v^i)_i$ and $(\overline{\mathsf{F}}_v^i)_i$, which is $O(t^2)$ by a similar argument as in the previous item. The time required is $O(t)$ for initializing every new set sequence $(\overline{\mathsf{T}}_u^i)_i$ and $(\overline{\mathsf{F}}_u^i)_i$ and this will happen once for each node u at its root bag B_u, hence the total time is $O(n \cdot t)$. ◀

Reachability Querying. We now turn our attention to the querying phase.

Pair query. Given a pair query (u, v), find the LCA B of bags B_u and B_v. Obtain the sets $\mathsf{F}_u^{\mathsf{Lv}(B)}$ and $\mathsf{T}_v^{\mathsf{Lv}(B)}$ of size b_B. Each set starts in bit position a_B of the corresponding sequence $(\mathsf{F}_u^i)_i$ and $(\mathsf{T}_v^i)_i$. Return True iff the logical-AND of $\mathsf{F}_u^{\mathsf{Lv}(B)}$ and $\mathsf{T}_v^{\mathsf{Lv}(B)}$ contains an entry which is 1.

Single-source query. Given a single-source query u, create a bit set A of size n, initially all 0s. For every node $x \in B_u$ with $i_x \leq i_u$, if the $l_x^{B_u}$-th bit of $\mathsf{F}_u^{\mathsf{Lv}(u)}$ is 1, insert F_x to the segment $[i_x, i_x + s_x]$ of A. Then traverse the path from B_u to the root of T, and let B_u^i be the ancestor of B_u at level $i < \mathsf{Lv}(B_u)$. For every node $x \in B_u^i$, if the $l_x^{B_u^i}$-th bit of F_u^i is 1, set the i_x-th bit of A to 1. Additionally, if B_u^i has two children, let B be the child of B_u^i that is not ancestor of B_u, and $j_{\min}$ and $j_{\max}$ the smallest and largest indices, respectively, of nodes whose root bag is in $T(B)$. Insert the segment $[j_{\min} - i_x, j_{\max} - i_x]$ of F_x to the segment $[j_{\min}, j_{\max}]$ of A. Report that the nodes v reached from u are those v for which the i_v-th bit of A is 1.

The following lemma establishes the correctness and complexity of the query phase.

▶ **Lemma 11.** *After the preprocessing phase of* Reachability*, pair and single-source reachability queries are answered correctly in* $O\left(\left\lceil\frac{t}{\log n}\right\rceil\right)$ *and* $O\left(\frac{n\cdot t}{\log n}\right)$ *time respectively.*

Proof. Let $t' = O(t)$ be the width of the small tree-decomposition constructed in Step 1. The correctness of the pair query comes immediately from Lemma 9 and Lemma 1, which implies that every path $u \rightsquigarrow v$ must go through the LCA of B_u and B_v. The time complexity follows from the $O\left(\left\lceil\frac{t}{W}\right\rceil\right)$ word operations on the sets $\mathsf{F}_u^{\mathsf{Lv}(B)}$ and $\mathsf{T}_v^{\mathsf{Lv}(B)}$ of size $O(t)$ each.

Now consider the single-source query from a node u and let v be any node such that there is a path $P : u \rightsquigarrow v$. Let B be the LCA of B_u, B_v, and by Lemma 1, there is a node $y \in B \cap P$. Let x be the last such node in P, and let $P' : x \rightsquigarrow v$ be the suffix of P from x. It follows that P' is a path such that for every $w \in P'$ we have $i_x \leq i_w \leq i_x + s_x$.

1. If B_v is an ancestor of B_u, then necessarily $x = v$, and by Lemma 9, the l_v^B-th bit of $\mathsf{F}_u^{\mathsf{Lv}(B)}$ is 1. Then the algorithm sets the i_v-th bit of A to 1.
2. Else, B_x is an ancestor of B_v (recall that a bag is an ancestor of itself), and by Lemma 8, the $(i_v - i_x)$-th bit of F_x is 1.
   a. If B is B_u, the algorithm will insert F_x to the segment $[i_x, i_x + s_x]$ of A, thus the $i_x + i_v - i_x = i_v$-th bit of A is set to 1.
   b. If B is not B_u, it can be seen that $j_{\min} \leq i_v \leq j_{\max}$, where $j_{\min}$ and $j_{\max}$ are the smallest and largest indices of nodes whose root bag is in $T(B')$, with B' the child of B that is not ancestor of B_u. Since the $(i_v - i_x)$-th bit of F_x is 1, the $(i_v - j_{\min})$-th bit of the $[j_{\min}, j_{\max}]$ segment of F_x is 1, thus the $j_{\min} + i_v - j_{\min} = i_v$-th bit of A is set to 1.

Regarding the time complexity, the algorithm performs $O(h \cdot t') = O(h \cdot t)$ set insertions to A. For every position j of A, the number of such set insertions that overlap on j is at most $t' + 1$ (once for every node in the LCA of B_u and B_v, where v is such that $i_v = j$). Hence if H_i is the size of the i-th insertion in A, we have $\sum_i H_i \leq n \cdot (t' + 1)$. Since the insertions are word operations, the total time spent for the single source query is

$$\sum_{i=0}^{h} \left\lceil \frac{H_i}{W} \right\rceil \leq h + \sum_{i=0}^{h} \frac{H_i}{W} \leq h + \frac{n \cdot (t'+1)}{W} = O\left(\frac{n \cdot t}{\log n}\right)$$

since $h = O(\log n)$, $t' = O(t)$ and $W = \Theta(\log n)$. ◀

4 Space vs Query Time Tradeoff for Sub-linear Space

In this section we present the data-structure LowSpDis, for low-space distance queries. Our results make use of the following lemma.

▶ **Lemma 12** ([16]). *Consider a weighted graph* $G = (V, E, \mathsf{wt})$ *of* n *nodes and constant-treewidth, and a tree-decomposition* T *of* G *of* $O(n)$ *nodes and constant width be given. There exists a data-structure* DistanceLP *that answers distance queries on* G *and requires*
1. $O(n)$ *preprocessing time and space; and*
2. $O(\alpha(n))$ *pair query time.*

Throughout this section we fix a constant $\epsilon \in [\frac{1}{2}, 1]$. The main idea is to partition the initial tree-decomposition T to sufficiently large components, and discard all bags that don't appear in the boundary of their component. We use Lemma 12 to preprocess $\overline{T}$ and the induced graph. Answering a pair query (u, v) is performed similarly as in Lemma 12, but requires additional time for processing the components in which u and v appear (since they have not been preprocessed). The challenge comes in performing these computations within the targeted space and time bounds. We establish the following theorem.

▶ **Theorem 13.** *Let (1) a constant $\epsilon \in [\frac{1}{2}, 1]$; and (2) a weighted graph $G = (V, E, \mathsf{wt})$ with n nodes and of constant treewidth, be given. The data structure* LowSpDis *correctly answers pair distance queries on G and requires*
1. *Polynomial in n preprocessing time;*
2. *$O(n^{\epsilon})$ working space; and*
3. *$O(n^{1-\epsilon} \cdot \alpha(n))$ pair query time.*

▶ Remark. The data-structure LowSpDis accesses the graph in the input space, i.e., the graph and is not counted for the working space bound of LowSpDis.

Informal description. Here we outline the key steps required for LowSpDis to achieve the bounds stated in Theorem 13. The preprocessing consists of the following conceptual steps.
1. A binary tree-decomposition $T = \text{Tree}(G)$ of $O(n)$ bags is constructed in polynomial time and logarithmic space, using [20]. Hence, LowSpDis does not store T explicitly, but uses the logspace construction of [20] to traverse T and access its bags.
2. A tree-partitioning algorithm LowSpTreePart is used to partition T into $O(n^{1-\epsilon})$ components C of size $O(n^{\epsilon})$ each. A key point in this construction is that every such component C contains a constant number of bags on its boundary.
3. Given a list of components $\mathcal{C} = (C_1, \dots, C_\ell)$ constructed in the previous step, a tree of bags called *summary tree* $\overline{T}$ is constructed. The summary tree occurs by contracting every component C_i of T to a single bag $\mathcal{B}_i$. Moreover, $\mathcal{B}_i$ contains precisely the nodes that appear in the bags of the boundary of C_i. Since there are $O(1)$ such bags for every component, each $\mathcal{B}_i$ has constant size. The key point in this step is that $\overline{T}$ is a tree-decomposition of G restricted on the nodes that appear in bags of $\overline{T}$. Moreover, $\overline{T}$ has size $O(n^{1-\epsilon})$ instead of $O(n)$, which is the size of the initial tree-decomposition T.
4. Since $\overline{T}$ is a tree-decomposition, Lemma 12 applies to preprocess $\overline{T}$ in the stated bounds.
5. An algorithm LowSpLD is used to compute the distance $d(u, v)$ between any pair of nodes u, v that appear together in some boundary bag of a component C_i. This is achieved by traversing T in a particular way, and applying a standard, linear-space computation on each component C_i separately. Since $|C_i| = O(n^{\epsilon})$, this requires $O(n^{\epsilon})$ space. Since the boundary bags of C_i are constantly many, the algorithm only needs to store constant-size information per component, and thus $O(n^{1-\epsilon}) = O(n^{\epsilon})$ information in total.
6. Finally, given a node u, it is crucial to obtain the set V_u of nodes that u can reach going through nodes v that appear in bags of $\overline{T}$. Moreover, this set needs to be obtained in linear time in the size of the component, i.e., $O(n^{1-\epsilon})$. This is achieved by a graph traversal on G starting from u, in combination with perfect hashing for testing in $O(1)$ time whether a node v appears in bags of $\overline{T}$.

A query u, v is answered by LowSpDis using the following conceptual steps.
1. First, the algorithm retrieves the sets V_u and V_v. If $v \in V_u$, then the distance $d(u, v)$ is retrieved by constructing a tree-decomposition T_u of $G[V_u]$, and using standard methods for solving the problem in T_u, in $O(n^{\epsilon})$ time. Similarly if $u \in V_v$.
2. If $v \notin V_u$ and $u \notin V_v$, then the algorithm again constructs the tree-decompositions T_u and T_v of $G[V_u]$ and $G[V_v]$ respectively. The algorithm retrieves two bags $\mathcal{B}_u$ and $\mathcal{B}_v$ of $\overline{T}$ with $\mathcal{B}_u \subseteq V_u$ and $\mathcal{B}_v \subseteq V_v$, and uses the standard methods of the previous item to obtain the distances $d(u, x)$ and $d(y, v)$, for every node $x \in \mathcal{B}_u$ and $\mathcal{B}_v$. Additionally, the

algorithm uses Lemma 12 to obtain the distance $d(x, y)$ between every such pair x, y. Finally, the algorithm returns the value $\min_{x\in\mathcal{B}_u, y\in\mathcal{B}_v}(d(u, x) + d(x, y) + d(y, v))$.

In the remaining of this section we describe in detail the above phases of LowSpDis.

Tree partitioning: The algorithm LowSpTreePart. We first describe algorithm LowSpTreePart, which operates on a binary tree-decomposition $T = (V_T, E_T)$ of $O(n)$ bags. Given a constant ϵ, LowSpTreePart splits T to $O(n^{1-\epsilon})$ connected components $C \subseteq V_T$ of size $|C| = O(n^\epsilon)$. Each component C is implicitly represented as a list of bags $C(B_1, \dots, B_k)$, which mark the boundaries of C in T. The *root* of $C(B_1, \dots, B_k)$ is $B = \arg\min_{B_i} \mathsf{Lv}(B_i)$, i.e., the smallest-level bag among all B_i. We will consider w.l.o.g. that B_1 is always the root bag of component $C(B_1, \dots, B_k)$. A bag B' belongs to C iff the $\mathsf{Lv}(B') \geq \mathsf{Lv}(B_1)$ and the unique simple path $B \rightsquigarrow B_1$ in T does not contain any of the B_i as intermediate bags.

The algorithm traverses T in post-order, and maintains a two variables $x, y \in \mathbb{N}$, that represent the size of the current component C and the number of components that appear directly below C. As the algorithm backtracks to a bag B, it updates $x = x_1 + x_2 + 1$ and $y = y_1 + y_2$, where x_i, y_i is the pair corresponding to the child B'_i of B (recall that T is binary), or sets $x = x_1 + 1$ and $y = y_1$ if B has only one child B'_1. If $x \geq n^\epsilon$ or $y \geq 3$, the algorithm creates a new component $C(B_1, \dots, B_k)$, where B_1 is the current bag B, and $B_2, \dots, B_k$ are parents of roots of components that have been constructed already (or leaves of T). Finally, the algorithm sets $x = 0$ and $y = 1$, and proceeds to the parent of B.

▶ **Lemma 14.** LowSpTreePart *constructs* $O(n^{1-\epsilon})$ *components. For every constructed component* $C(B_1, \dots, B_k)$ *we have* $|C| \leq 2 \cdot n^\epsilon - 1$ *and* $k \leq 5$.

Proof. If $|C| > 2 \cdot n^\epsilon - 1$, then, before backtracking to B_1, the algorithm examined a child B of B_1 with value $x \geq j$, and thus would have grouped B and B_1 in different components. It is easy to see that every root of a component appears in the same component with its children, a contradiction. A similar argument holds for showing that $k \leq 5$. We now argue that LowSpTreePart constructs $O(n^{1-\epsilon})$ components. We say that the algorithm "performs a type A cut" and "performs a type B cut" when it constructs a component based on the criterion $x \geq j$ and $y \geq 3$ respectively. Let X and Y be the number of type A and type B cuts. Every type A cut constructs a component of size at least j, hence $X = O(n^{1-\epsilon})$. Additionally, we have $Y \leq X$, hence $X + Y = O(n^{1-\epsilon})$, as desired. To see that $Y \leq X$, let Z be a counter that counts the sum of the y values that LowSpTreePart maintains at any point in the traversal. Observe that a type A cut increases Z by at most one, and a type B cut decreases Z by at least one. Since Z is always non-negative, we have that there is at least one type A cut for each type B cut, thus $Y \leq X$. The desired result follows. ◀

We denote by $\mathsf{Root}(C)$ the root bag of a component C. Given two components C_1, C_2 constructed by LowSpTreePart, we say that C_1 is the *parent* of C_2 if $\mathsf{Root}(C_1)$ is the lowest ancestor of $\mathsf{Root}(C_2)$ among all bags that appear as roots in some component. In such case, C_2 is a *child* of C_1. Given a component C that is the parent of components $C_1, \dots, C_i$, we let $\mathsf{Merge}(C) = C \cup \bigcup_j C_j$.

The summary tree construction SummaryTree. Let $\mathcal{C} = (C_1, \dots, C_\ell) = \mathsf{LowSpTreePart}(T)$ be the list of components that LowSpTreePart returns, where each component is implicitly represented by the bags of its boundary, i.e., $C_i = C_i(B_1^i, \dots, B_{k_i}^i)$. We construct a *summary tree* of bags $\overline{T} = \mathsf{SummaryTree}(\mathcal{C}) = (\overline{V}, \overline{E})$ as follows.

1. $\overline{V}$ consists of bags $\mathcal{B}_i$ for $1 \leq i \leq \ell$, where $\mathcal{B}_i = B_1^i \cup \cdots \cup B_{k_i}^i$, i.e., $\mathcal{B}_i$ is the union of all bags in the boundary of C_i.
2. We have $(\mathcal{B}_i, \mathcal{B}_j) \in \overline{E}$ if C_i is a parent of C_j.

The following lemma follows easily from Lemma 14 and the above construction.

▶ **Lemma 15.** *Let $V_S = \bigcup_{\mathcal{B}_i \in \overline{V}} \mathcal{B}_i$ be the set of nodes of G that appear in bags of the summary tree $\overline{T}$. Then $\overline{T}$ is a tree-decomposition of the graph $G[V_S]$ induced by V_S. $\overline{T}$ has $O(n^{1-\epsilon})$ bags and constant width.*

Local distance computation in low space LowSpLD. Let $\mathcal{C} = (C_1, \dots, C_\ell) = \mathsf{LowSpTreePart}(T)$ be the list of components constructed by LowSpTreePart. We describe algorithm LowSpLD, which computes the distance $d(u, v)$ between any pair of nodes u, v that appear in the root bag $\mathsf{Root}(C_i)$ of some component C_i. Let $T_i = \mathrm{Tree}(G)[\mathsf{Merge}(C_i)]$ be the subtree of $\mathrm{Tree}(G)$ restricted in the bags of component C_i and its children components, and $V_i = \bigcup_{B \in \mathsf{Merge}(C_i)} B$ the set of nodes that appear in bags of $\mathsf{Merge}(C_i)$. It is easy to verify that T_i is a subtree of T, and thus a tree decomposition of the graph $G[V_i] = (V_i, E_i)$ induced by V_i. The algorithm LowSpLD operates as follows. For every component C, it maintains a local distance map $\mathsf{LD}_{\mathsf{Root}(C)} : \mathsf{Root}(C) \times \mathsf{Root}(C) \to \mathbb{Z}$. Initially, $\mathsf{LD}_{\mathsf{Root}(C)}(u, v) = \mathsf{wt}(u, v)$ for every component C and pair of nodes $u, v \in \mathsf{Root}(C)$. Then, LowSpLD performs the following two passes.

1. Traverse $\overline{T}$ bottom-up, and for every encountered bag $\mathcal{B}$ that corresponds to component C, let $C_1, \dots, C_k$ be the children components of C. Obtain the tree-decomposition T_i, and construct a weight function $\mathsf{wt}_i : E_i \to \mathbb{Z}$ defined as follows:

$$\mathsf{wt}_i(u, v) = \begin{cases} \mathsf{LD}_{\mathsf{Root}(C)}(u, v) & \text{if } u, v \in \mathsf{Root}(C) \\ \mathsf{LD}_{\mathsf{Root}(C_i)}(u, v) & \text{if } u, v \in \mathsf{Root}(C_i) \text{ for some } 1 \leq i \leq k \\ \mathsf{wt}(u, v) & \text{otherwise} \end{cases}$$

   and execute the local distance computation of Lemma 5 Afterwards, update $\mathsf{LD}_{\mathsf{Root}(C)}$ and $\mathsf{LD}_{\mathsf{Root}(C_i)}$ for all $1 \leq i \leq k$ with the newly discovered distances.
2. Traverse $\overline{T}$ top-down, and for every encountered bag $\mathcal{B}$ execute the steps of Step 1.

▶ **Lemma 16.** *At the end of* LowSpLD*, for every component C and nodes $u, v \in \mathsf{Root}(C)$ we have $\mathsf{LD}_{\mathsf{Root}(C)}(u, v) = d(u, v)$. Moreover,* LowSpLD *operates in $O(n^\epsilon)$ space and polynomial time.*

Proof. The correctness of LowSpLD follows straightforwardly from Lemma 5 and Lemma 3. Since T has constant width, the size of each local distance map $\mathsf{LD}_{\mathsf{Root}(C)}$ has constant size. Hence the space used by the algorithm is asymptotically the space required for storing $\overline{T}$, plus the space for constructing each tree-decomposition T_i. By Lemma 15 the former requires $O(n^{1-\epsilon})$ space, while by Lemma 14 the latter $O(n^\epsilon)$ space. Since $\epsilon \geq \frac{1}{2}$, we conclude that the space usage is $O(n^\epsilon)$. The polynomial time bound follows from the space bound. ◀

Fast component retrieval GetCompNodes. Given a node u of G, we are interested in retrieving the set V_u of nodes that u can reach in G without going through nodes v that appear in bags of $\overline{T}$. The desired set V_u can be obtained in $O(n^\epsilon)$ time by a performing any standard graph traversal on G starting from u, and making sure that the traversal never expands a node v that appears in the bags of $\overline{T}$. This can be done if testing whether v appears in any of the bags of $\overline{T}$ can be performed in constant time. Let $V_S = \bigcup_{\mathcal{B}_i \in \overline{V}} \mathcal{B}_i$ be the set of all such nodes, and $k = |V_S| = O(n^{1-\epsilon})$. We cannot store V_S as a standard bit-set which allows $O(1)$ membership testing, as this would require linear space (i.e., beyond our space bound $O(n^\epsilon)$). The problem can be solved using standard techniques from perfect hashing to store the set V_S. In the query phase, given a node u, GetCompNodes detects that $u \in V_S$ by testing whether u equals its entry in the hash table.

LowSpDis Preprocessing. We now describe the preprocessing phase of LowSpDis. The input is a weighted graph $G = (V, E, \mathsf{wt})$ of constant treewidth, and a constant $\epsilon \in [\frac{1}{2}, 1]$.

1. Construct a binary tree-decomposition $T = \text{Tree}(G)$ in logspace [20].
2. Use LowSpTreePart to construct a list of components $\mathcal{C} = (C_1, \dots, C_\ell) = \mathsf{LowSpTreePart}(T)$, with $\ell = n^{1-\epsilon}$ (i.e., LowSpTreePart is executed with $j = n^\epsilon$).
3. Construct the local distance maps $\mathsf{LD}_{\mathsf{Root}(C)}$ using LowSpLD.
4. Construct the summary tree $\overline{T} = \mathsf{SummaryTree}(\mathcal{C}) = (\overline{V}, \overline{E})$. For every component C_i that corresponds to $\mathcal{B}_i$ in $\overline{T}$, find a node $z \not\in \mathcal{B}_i$ that appears in bags of C_i, and associate z with $\mathcal{B}_i$.
5. Use Lemma 12 to build a data-structure DistanceLP on $G[V_S]$ and $\overline{T}$.
6. Let $V_S = \bigcup_{\mathcal{B}_i \in \overline{V}} \mathcal{B}_i$ be the set of nodes of G that appear in bags of the summary tree $\overline{T}$. Construct the data-structure GetCompNodes on V_S.

LowSpDis Querying. We now turn our attention to the query phase of LowSpDis.

1. Use the data-structure GetCompNodes to construct the sets V_u and V_v.
2. Construct the tree-decompositions T_u and T_v of the graphs $G[V_u]$ and $G[V_v]$ induced by V_u and V_v. This is done using some standard linear-time algorithm, e.g. [12, Lemma 2]. If $u \in V_v$, insert u to every bag of T_v, and use Lemma 5 to obtain the distance $d(u, v)$. Similarly if $v \in V_u$.
3. If $u \not\in V_v$ and $v \not\in V_u$ let $\mathcal{B}_u$ be the unique bag of $\overline{T}$ with that is associated with a node $z_u \in V_u$, and $\mathcal{B}_v$ the unique bag of $\overline{T}$ that is associated with a node $z_v \in V_v$. Insert every node of $\mathcal{B}_u$ in every bag of T_u, and every node of $\mathcal{B}_v$ in every bag of T_u, and use Lemma 5 to obtain the distances $d(u, x)$ and $d(y, v)$ for every node $x \in \mathcal{B}_u$ and $y \in \mathcal{B}_v$. Return the value $\min_{x \in \mathcal{B}_u, y \in \mathcal{B}_v}(d(u, x) + d(x, y) + d(y, v))$ where for every pair x, y the distance $d(x, y)$ is obtained by querying DistanceLP.

Proof of Theorem 13. It is clear from Lemma 12, Lemma 14, Lemma 15 and Lemma 16 that the preprocessing of LowSpDis requires polynomial time and $O(n^\epsilon)$ space, where $\epsilon \geq \frac{1}{2}$. In the query phase, LowSpDis uses $O(n^\epsilon)$ time and space for extracting the sets V_u and V_v, since each has size $O(n^\epsilon)$. Using a linear time and space algorithm for constructing the tree-decompositions T_u and T_v, this step also requires $O(n^{1-\epsilon})$ time and space. If $u \in V_v$ or $v \in V_u$, applying Lemma 5 on T_u and T_v is also done in $O(n^{1-\epsilon})$ time and space.

If $u \not\in V_v$ and $v \not\in V_u$, note that by Lemma 15 $\mathcal{B}_u$ and $\mathcal{B}_v$ have constant size, hence after inserting every node of $\mathcal{B}_u$ to every bag of T_u and every node of $\mathcal{B}_v$ to every bag of T_v, T_u and T_v still have constant width. Hence all distances $d(u, x)$ and $d(v, y)$ can be obtained using Lemma 5 in $O(n^{1-\epsilon})$ time and space. Finally, DistanceLP will be queried for the distances $d(x, y)$ of a constant number of pairs x, y, and by Lemma 12, all such queries can be served in $O(n^{1-\epsilon} \cdot \alpha(n))$ time. ◀

Abstract

Formally, approaches based on mathematical programming are able to find provably optimal solutions. However, the demands on a verifiable formal proof are typically much higher than the guarantees we can sensibly attribute to implementations of mathematical programs. We consider this in the context of the *crossing number problem*, one of the most prominent problems in topological graph theory. The problem asks for the minimum number of edge crossings in any drawing of a given graph. Graph-theoretic proofs for this problem are known to be notoriously hard to obtain. At the same time, proofs even for very specific graphs are often of interest in crossing number research, as they can, e.g., form the basis for inductive proofs.

We propose a system to automatically generate a formal proof based on an ILP computation. Such a proof is (relatively) easily verifiable, and does not require the understanding of any complex ILP codes. As such, we hope our proof system may serve as a showcase for the necessary steps and central design goals of how to establish formal proof systems based on mathematical programming formulations.

1 Introduction

A typical corner stone of (integral) mathematical programming formulations for combinatorial optimization problems is that solving the formulation constitutes a *proof* that the obtained solution is in fact optimal. While this is true in theory, it is not clear, per se, that this actually transfers into practice, as many factors may influence or invalidate the program's outcome: the probably most prominent ones are hidden bugs in the software or numerical instabilities. E.g. [1] discusses the problems and challenges of proving the correct computation of an optimal TSP tour for *one* specific instance; we are interested in a system to deduce proofs automatically, without any human interaction.

Hence, while there exist many successful formulations, e.g. as ILPs, to many important graph-theoretic (optimization) problems, successful computations are generally not considered to be proofs accepted by the graph theory community.

We aim at bridging this gap for the well-known *crossing number problem*, to be defined below, which is arguably one of the most prominent and notorious problems in topological

* This research has been supported by the German Research Foundation (DFG) project CH 897/2-1.

graph theory. We propose a system to extract a *simply verifiable* proof from a successful ILP computation, which can be accepted by graph theorists: it is shielded against ill-effects based on the software realization of the mathematical model. To understand the proof, the graph theorist does *not* have to have a deeper understanding of mathematical programming nor the required implementations; she only has to understand the mathematical model (and possibly a simple proof verification program, designed to be readable and checkable by non-experts).

When describing the proof system, we will also pinpoint the generally necessary differences in the formulation-, algorithm-, and software-design between the typical goal of obtaining a strong and fast solver and the goal of obtaining a system for easily understandable proofs. Crossing number formulations are in particular interesting in that respect, as their implementations need to combine a diverse set of different tools (branch-and-cut-and-prize with exact and heuristic constraint separation, column generation with non-standard bounding schemes, intricate heuristics for primal bounds, etc.) to obtain a system that can solve realistically-sized instances. This inevitably leads to a software too complex to directly check against all possible bugs. As such, even though we focus on the crossing number problem, our system may serve as a showcase of how to obtain trustworthy mathematical programming based proof systems for graph-theoretic problems whose formulations do not allow easily checkable implementations.

We will start with describing the crossing number problem, the reason why we are interested in formal proofs for the crossing number of specific graphs, and the currently available methods to obtain solutions. In Section 3 we will discuss the central design goals of our proof system, as well as their realization. This includes a new column generation scheme, balancing simplicity and effectiveness. A brief experimental study in Section 4 shows the applicability of our approach.

2 Crossing Number Problem

The crossing number $cr(G)$ of a graph G is the minimum number of pairwise edge crossings in any drawing of G in the plane. The problem garnered a lot of contributions since its first mention over 70 years ago; see [30, 29] for an extensive bibliography and survey. Beside its own inherent appeal, crossing numbers also occur, e.g., in conjectures relating $cr(G)$ to graph colorings and knot theory.

Nonetheless, some of the most natural questions are still open, most importantly the crossing number of nearly all classical graph classes like complete graphs (known only for K_n with $n \leq 12$ [28]), complete bipartite graphs, etc. The quest for crossing number proofs of particular families is a lively research field in graph theory, see, e.g., [3, 16, 21, 22, 26], and even partial results (like proving that K_{13} cannot have crossing number 217 [25]) are publishable in renowned journals. Several such proofs start out with a set of base cases for which the crossing number has to be proven in excruciating detail by hand, before employing an inductive proof to consider a full graph class. Obtaining sound, automatic, and standardized proofs for such base cases is one of the goals of our proof system.

Deciding the crossing number of an arbitrary graph G is known to be NP-complete [17]; this holds even for restricted graph classes like cubic graphs [18] or graphs that become planar when removing a single edge [6]. While there are several known practically strong heuristics and (partial) approximation results, we do, e.g., not even know if the problem allows a constant approximation ratio; we only know that the problem does not allow a PTAS [5]. The problem is known to be fixed-parameter tractable with parameter $cr(G)$ [20]. However, the algorithm's runtime is doubly-exponentially dependent on the parameter and it is, as already mentioned in [20], not feasible in practice.

The only known practical method to obtain the crossing number of a given graph is based in integer linear programs [4, 11, 12], based on two different modeling ideas to be described below. However, the models contain both too many variables and too many constraints to be solved directly via off-the-shelf techniques, and require a lot of (bug-prone) implementation effort. Even if implemented correctly, solving such ILPs can be error-prone due to numerical instabilities. This constitutes a problem for graph theorists, interested in utilizing the computed crossing number in a proof.

Basics

Kuratowski's famous theorem [24] states that a graph G is planar if and only if it does not contain a subdivision of a complete graph on five vertices (K_5) or a complete bipartite graph on three vertices per partition set ($K_{3,3}$) as a subgraph. We will call these subgraphs *Kuratowski subdivisions* of G. The paths in the subdivision that resemble a single edge of the K_5 or $K_{3,3}$ are referred to as *Kuratowski paths* in the following. We use this theorem to argue that every such subdivision in given G is required to be drawn with at least one crossing.

When considering the crossing number of a graph, it is well-known that it suffices to consider *good* drawings: no edge crosses itself; adjacent edges do not cross; each pair of edges crosses at most once; and no three edges cross in a common point. Considering such an optimal drawing of G, we can obtain a *planarization* of G, which is the graph arising from G when replacing each crossing with a new *dummy* vertex of degree 4. We may speak of a *partial planarization* if we substitute only certain crossings via new vertices such that the obtained graph possibly remains non-planar.

2.1 Known ILP Models

All known ILP models have a common core idea; they differ in how to handle the arising *realizability problem*, described below. We will only describe the formulation on a level necessary to comprehend the proof system (and the design decisions that lead to it). For a more detailed and formal description see the individual publications [4, 11, 12] or the full compilation in [7].

Let $G = (V, E)$ be the given simple and undirected graph for which to compute $cr(G)$, and let $\mathcal{CP} := \big\{\{e, f\} \subseteq E : e \cap f = \varnothing\big\}$ be the set of edge pairs that potentially cross in a good drawing of G. Consider a binary variable x_c for each $c \in \mathcal{CP}$ that is 1 if and only if the edge pair crosses. This gives the objective function

$$\min \sum_{\{e,f\} \in \mathcal{CP}} w(e) \cdot w(f) \cdot x_{\{e,f\}} \tag{1}$$

where $w(e)$ denotes the (integral) weight of edge e. For usual (i.e., unweighted) graphs we have $w(e) = 1$ for all $e \in E$. In our implementation we first preprocess G to obtain a smaller but integrally-weighted graph with the same crossing number [9].

To guarantee feasible solutions we may be tempted to introduce the following *Kuratowski constraints*. Let $K \subseteq E$ be an edge subset forming a Kuratowski subdivision; we want to ensure that each such K gives rise to at least one crossing. We say that a crossing $c \in \binom{K}{2} \cap \mathcal{CP}$ is *planarizing* if the graph obtained from K by realizing c via a dummy vertex is planar. Clearly, a crossing is planarizing if and only if the crossing edges do *not* belong to adjacent (or identical) Kuratowski paths. Let $\mathcal{CP}(K)$ be the set of planarizing crossings for

$K \subseteq E$.

$$\sum_{c \in \mathcal{CP}(K)} x_c \geq 1 \quad \forall \text{ Kuratowski subdivisions } K \text{ in } G.$$

While these constraints form facets of the crossing number polytope [8], they do not suffice to guarantee feasibility: On the one hand, we also have to consider Kuratowski subdivisions that only appear in partial planarizations due to dummy vertices. On the other hand, even those do not suffice: Let $R \subseteq \mathcal{CP}$ be edge pairs that are supposed to cross. The *realizability problem* is to decide whether there exists a drawing of G such that only the edge pairs R cross. Interestingly, even this seemingly simpler problem is still NP-hard for general graphs [23]. Hence, our simple set of x-variables cannot suffice to describe the crossing number polytope. The key problem is that when two edges f, g both cross an edge e, the *order* of these two crossings along e is of central importance and cannot be deduced in polynomial time (unless $\mathrm{P} = \mathrm{NP}$).

There are two approaches to tackle this problem. Both lead to a variable increase that, although polynomial, makes the models intractable in practice unless a dynamic column generation scheme is used. Assume in the following that we assign an arbitrary but fixed direction to each edge.

Subdivision-based exact crossing minimization (SECM)

Let $G^{[\ell]}$ be the graph obtained from G by splitting each edge into a chain of $\ell \in \mathbb{N}^+$ edges (henceforth called segments). Instead of directly using the above model on G, we consider $G^{[\ell]}$ instead. We observe that the corresponding set $\mathcal{CP}^{[\ell]}$ will not need to contain edge pairs (segment pairs, in fact) where both segments belong to the same original edge in G (the underlying G does not require self-crossings).

On $G^{[\ell]}$, we search for the smallest number of crossings under the restriction that each segment is involved in at most one crossing. This restriction is trivial to ensure via linear constraints (see later for details). The so-restricted crossing number is often called the *simple* crossing number, even though it is still NP-complete to decide. There can be at most $\chi := \min\{cr(G), |E| - 1\}$ crossings on an edge in the optimal drawing of G. Hence, we may use any upper bound on χ as ℓ to ensure that the optimal solution to the restricted crossing number problem on $G^{[\ell]}$ induces an optimal solution for the usual crossing number on G. Since there are instances where an edge e needs to be crossed by $\Omega(|E|)$ many other edges in the optimal solution, our transformation may increase the number of variables $\Theta(|E|^2)$-fold.

The benefit of considering the simple crossing number is that the realizability problem becomes linear time solvable. We say a subset $R \subset \mathcal{CP}^{[\ell]}$ is *simple* if each segment occurs at most once over all segment pairs in R (i.e., it is a potential solution to the simple crossing number). For such an R, its corresponding (partial) planarization $P(R)$ – obtained by substituting the crossings R in G with dummy vertices – is hence unique. We have R realizable iff $P(R)$ is planar.

Finally, we can ensure feasible solutions using more general Kuratowski-constraints. Let $\mathcal{K}(R)$ be the set of all Kuratowski subdivisions in $P(R)$. Each subdivision is specified by its edge set. Clearly, if the crossings R are part of the solution, each Kuratowski subdivision in $\mathcal{K}(R)$ will require at least one crossing. We have:

$$\sum_{c \in \mathcal{CP}(K)} x_c \geq 1 - \sum_{c \in R}(1 - x_c) \quad \forall \text{ simple } R \subseteq \mathcal{CP}, K \in \mathcal{K}(R) \tag{2}$$

In order to prove a lower bound of the crossing number, it suffices to understand that the constraints in the above model need to hold for any feasible solution. We do not need to argue about sufficiency (see also property ⟨2⟩ below).

Ordering-based exact crossing minimization (OECM)

The alternative formulation [12] introduces *linear ordering variables* to resolve the order of crossings along each edge without subdividing the input graph. This has some advantages regarding performance, e.g., since every Kuratowski constraint in this model can cover more than just one specific partial planarization. Technically, these linear orderings are modeled using $\Theta(|E|^3)$ additional variables that are linked to the crossing variables using several constraint classes. Overall, it has to be observed that the OECM model, while offering superior performance, is much harder to understand and requires even more technically intricate column generation schemes, book-keeping, and subalgorithms, compared to SECM.

3 Proof System

Without a proof system, one would need to check the ILP algorithms for correctness. All SECM and OECM implementations known to the authors are intertwined with the Open Graph Drawing Framework (OGDF, `www.ogdf.net`, [10]) and heavily utilize the ABACUS framework (`http://www.informatik.uni-koeln.de/abacus`, [19]); they are all written in C++. The core of both algorithms roughly spans across 8,000 Lines of Code (LOC) while the OGDF amounts to a total of about 170,000 LOC. Already the main code paths of the research code are hard to comprehend without intricate knowledge of the algorithms. Furthermore, the programs use sophisticated column generation routines, requiring complex book-keeping and special constraint liftings to prevent a decrease of the lower bound when adding variables. Tracking variables and constraints over an entire algorithm is disproportionately harder than simply verifying each branch-and-bound (B&B) leaf. Furthermore, there are several possibilities for hidden bugs due to numerical instabilities that may arise without any means of detection, or hidden buffer overruns when generating atypically many variables or constraints in one pass.

All these facts make a formal verification of the main algorithms intractable in practice. For comparison, our proof system proposes a verification procedure (written in Java) of less than 1,000 LOC (including rich documentation and comments), with a virtually complete test coverage.

In our context, a *proof* consists of three parts:

- a mathematical model (in our case the ILP formulation),
- a *witness* of the dual bound, and
- a primal *solution*, matching the above dual bound.

The first is independent of the specific instance but needs to be understood only once for a specific problem domain (crossing number, in our case). The latter two are instance-dependent. We want to make the proof as easily digestible by pure graph theorists as possible. To understand the proof it must be sufficient to understand the following:

⟨1⟩ *Solution.* One needs to be able to check the feasibility of a primal solution and evaluate its objective value. In our case, one needs to be able to recognize a feasible planarization of G, and to count the number of dummy vertices.

⟨2⟩ *Feasibility of the mathematical model.* It is only necessary to understand that all described constraints of the formulation are feasible; one need not concern oneself with understanding why the model is sufficient. Generally, it should be understood that any optimal fractional solution w.r.t. a subset of the constraints gives a feasible dual (in our case, lower) bound.

⟨3⟩ *Witness format.* The information contained in the witness that is required to verify the dual bound.

⟨4⟩ *Verification procedure.* The steps required to verify the dual bound claimed by the witness.

An ILP-based *proof system* should consist of two major components: the proof generation and the verification procedure. The arbitrarily complex proof generation produces a witness for the optimality of the primal solution. This witness contains all information required to create relaxed linear programs for several *subcases* (the leaves in the B&B tree), all of which yield the dual bound. B&B leaves naturally resemble an easily verifiable case distinction, as used ubiquitously in graph-theoretic proofs.

The verification of the witness could *theoretically* be done by hand. It follows from the nature of NP-complete problems that (unless $\mathrm{P} = \mathrm{NP}$) there *cannot* be a really "simple" proof for the dual bound in general. If we want a simple-to-check witness for the dual bound (which is, most importantly, checkable in polynomial time w.r.t. to its size), we *have* to live with the fact that the witness' size can grow exponentially with the size of G. In most cases, this sheer size will require us to introduce an – algorithmically very simple – computer-based verification procedure. Most importantly, the verification procedure only needs to check that the subcases described in the witness form linear programs that are subsets of the underlying mathematical model. It requires no knowledge about the generation of constraints, variables, or branches.

We can summarize the general design goals for an ILP-based proof system:

G1. *Simplicity of model.* There should be few classes of constraints and variables. Comprehensibility outweighs performance as long as the proof procedure is still "fast enough".

G2. *Column generation.* Column generation should only be used if ultimately required. The variable subsets need to be as simple as possible.

G3. *LP-solver flexibility/provability.* The LP-solver used during verification should be easily interchangeable or self-proving.

G4. *Few Branches.* Superfluous branching decisions should be eliminated from the witness to keep it small. This can, e.g., be achieved by starting the extraction with a supposedly optimal primal bound, see below.

G5. *Human-readability.* One should be able to investigate certain aspects of the proof by hand. To achieve this, we may allow redundancy as long as conflicts are detected easily by the verifier.

G6. *Standalone verification.* The verifier must *not* share any resources (most importantly code fragments) with the extraction procedure. The witness and the primal solution constitute the sole interchange of information between generation and verification.

G7. *Coding standards.* Adhering to well-established coding standards when implementing the verifier increases readability. Likewise, an established programming language should be used. The verification procedure should be described in detail such that one might re-implement it easily.

Although the OECM formulation offers better performance than SECM in practice, goal G1 lets us favor the comparably much easier to understand SECM formulation. It also allows us to sacrifice more constraints classes to adhere to G1. Concerning G2, both formulations require complex column generation schemes to be feasible in practice. However, as we will describe below, SECM allows us to propose a new column generation scheme

Algorithm 1: Proof generation

```
Require: graph $G$                        // we are interested in $cr(G)$
1: $P$, $UB \leftarrow$ OECM($G$)            // find presumably optimal planarization $P$
                                          //          (with objective value $UB$)
2: $W \leftarrow$ Modified-SECM($G$, $UB$)   // generate a witness $W$ for the lower bound,
                                          //          i.e., $UB - 1$ is infeasible to achieve
3: print $P$ and $W$                        // output the proof
```

that is considerably simpler than any of the previously published ones for either of the two formulations, while increasing the runtime and number of variables only mildly.

Alg. 1 gives an outline of the proof generation. In order to obtain a small proof (G4), we solve the crossing number problem *twice*: First, we use the fastest OECM variant together with strong upper bound heuristics to obtain the presumably optimal solution. This procedure can be seen as a black box, as we are only interested in the fact that the solution gives an upper bound – we can check the feasibility of the primal solution straight-forwardly. If our proof generation succeeds, this is the solution used as part of the overall proof. Now having this primal bound, we can start our modified SECM formulation (see below for details) without any primal heuristics and ask for a solution strictly better (at least one crossing less) than the obtained upper bound. From this second ILP run, we can extract all required information for each B&B leaf, to reconstruct each linear program that yields a lower bound on the number of crossings restricted to the solution space spanned by the branch. In general, the set of variables and constraints differ for any two leaves.

We observe that if OECM did *not* find an optimum solution (e.g., due to a hidden bug), we may already detect this now as SECM's dual bound does not match our upper bound.

3.1 Modified-SECM

There are two known column generation schemes for SECM [11]. The *algebraic pricing*, based on the standard Dantzig-Wolfe decomposition theory, performs relatively weak and uses a quite unstructured variable subset. The more efficient *combinatorial* column generation scheme (denoted as *sparse* column generation in the following) can decide upon the addition of variables in a purely combinatorial fashion, and requires the fewest active variables in general. However, the required variable subset structure (and hence the reasoning for its sufficiency) is too complicated to easily describe and comprehend for the purpose of a graph-theoretic proof. We hence propose a new column generation scheme – called *homogeneous* in the following – by means of describing an SECM variant that is slightly modified compared to the model described above.

Instead of a simple number, let $\ell\colon E \to \mathbb{N}$ be a mapping describing the *expansion status* of G, i.e., we consider each edge $e \in E$ of G to be subdivided into $\ell(e)$ segments. We define our ILP using the resulting graph G^ℓ. For notational simplicity, let $e_1, e_2, \dots, e_{\ell(e)}$ denote the segments of an original edge $e \in E$. As before, the new graph induces a set of segment pairs $\mathcal{CP}^\ell$ that may cross in an optimal solution. We explicitly allow (and expect) values $\ell(e)$ to be smaller than the upper bound of crossings over e. To this end, we allow at most one crossing over each segment *except for the first segment of each edge*: it may be crossed an arbitrary number of times. In general, this could lead to problems with testing realizability. However, this is of no concern to us, as we only require that our model is *feasible*, i.e., it allows to describe an optimal solution (see ⟨2⟩). This is trivially the case in this setting (already when $\ell(e) = 1$ for all $e \in E$).

Algorithm 2: Proof verification

```
Require: graph $G$, subcases $\mathcal{L}$ (=B&B leaves), claimed lower bound $b \in \mathbb{N}^+$
1: assert branchCoverage($\mathcal{L}$)
2: for all $\nu \in \mathcal{L}$ do
3:     $\ell \leftarrow$ expansion status at $\nu$
4:     $\mathcal{K} \leftarrow$ set of Kuratowski subdivisions observed at $\nu$
5:     for all $C \in \mathcal{K}$ do
6:         assert isKuratowski($G^\ell, C$)
7:     $P \leftarrow$ generateLinearProgram($G, \mathcal{K}$)
8:     assert lpsolve($P$) $> b - 1$
```

Symmetric solutions increase our set of subcases in the proof, often drastically. We can require w.l.o.g. that the crossings over an original edge may be *aligned* in such a way that there is only a crossing on segment $i > 2$ if there also is a crossing on segment $i - 1$. Segment 1 is typically not part of this alignment scheme, as it allows multiple crossings. However, observe that any edge $e = \{u, v\} \in E$ may be crossed at most $u_e := \min\{UB, |E|+1-\deg(u)-\deg(v)\}$ times in the optimum solution, where UB is an upper bound on $cr(G)$. If an edge is fully expanded, i.e., $\ell(e) = u_e$, we do allow at most one crossing over segment 1; to avoid symmetries we can assume to have less crossings on segment 1 than on segment $\ell(e)$. The following constraints establish these segment properties. They, together with the objective function (1) and the Kuratowski constraints (2) (both applied to the set $\mathcal{CP}^\ell$), form our full mathematical model.

$$\sum_{\{e_i,f\}\in\mathcal{CP}^\ell} x_{\{e_i,f\}} \le \begin{cases} 1 & \text{if } i = 2 \\ \sum_{\{e_{i-1},f\}\in\mathcal{CP}^\ell} x_{\{e_{i-1},f\}} & \text{else} \end{cases} \qquad \forall e \in E, 2 \le i \le \ell(e) \tag{3}$$

$$\sum_{\{e_1,f\}\in\mathcal{CP}^\ell} x_{\{e_1,f\}} \le \sum_{\{e_{\ell(e)},f\}\in\mathcal{CP}^\ell} x_{\{e_{\ell(e)},f\}} \qquad \forall e \in E : \ell(e) = u_e \tag{4}$$

Remark (Irrelevant to understanding the proof)

As in SECM, Kuratowski constraints are separated via a planarity-test based procedure on a rounded solution S. An effective column generation similar to [4] is achieved by starting with a unit vector ℓ and incrementing $\ell(e)$ whenever there are at least 2 crossings on e_1 in S (i.e., the realization problem cannot be solved uniquely).

3.2 Verification Procedure

Finally, we can focus on the actual verification steps necessary to prove the lower bound obtained by the above Modified-SECM model. Alg. 2 gives an overview.

Branch Coverage

We need to make sure that the entire solution space is covered. Therefore, we consider the variable fixings in all subcases. Since we only branch on single variables, we iteratively merge two subcases that differ by the assignment of a single variable, giving a more general subcase without this variable being fixed at all. In a valid proof, this procedure must end with a single subcase, which does not have any variable fixings at all.

Algorithm 3: Coverage verification

```
Require: subcases $\mathcal{L}$ (see text)
1: while $\exists \mu, \nu \in \mathcal{L}$ with $\exists c \in \mathcal{CP}^\ell : \mu \triangle \nu = \{(c,0),(c,1)\}$ do
2:     $L \leftarrow \{\mu \cap \nu\} \cup L \setminus \{\mu, \nu\}$
3: assert $\mathcal{L} = \{\varnothing\}$
```

The following pseudo-code shows how to algorithmically verify that the subcases span the whole solution space. Here, we consider each subcase ν to be a set of tuples from $\mathcal{CP}^\ell \times \{0,1\}$, i.e., a set of segment pairs that are specified to either cross (1) or not (0). Segment pairs not listed in ν are free to do either. Let $\triangle$ denote the symmetric difference.

Kuratowski Constraints

For each subcase, we need to check that only feasible constraints are considered. A Kuratowski constraint for a subgraph K that is not a Kuratowski subdivision would be an error. It would enforce a crossing that may not be necessary in the optimal solution. For each subcase, our witness explicitly stores each used Kuratowski subgraph K, together with the required crossings (R) that need to exist for K to arise[1]. More specifically, K is stored by means of Kuratowski paths $p_1^K, \dots, p_k^K$. This storage pattern allows for a simpler verification (see below) than a general Kuratowski verification routine as described in [27].

To verify that K is really a Kuratowski subdivision, we first check whether each p_i^K is in fact a valid path (only exploiting crossings of R, if any). Then we check that all paths are pairwise internally-disjoint (i.e., they are disjoint except for possibly common start/end vertices). Finally, the set of nodes that constitute the start or end of all Kuratowski paths is collected. The size of this set (5, 6) and the number of Kuratowski paths (10, 9) is verified according to the type of the subdivision (K_5, $K_{3,3}$, respectively). The structural verification of a K_5 subdivision simply checks whether all 5 nodes are directly connected to one another via Kuratowski paths. For a $K_{3,3}$, we perform a two-coloring (interpreting the paths as edges); each of the 6 nodes must be connected to exactly 3 distinct nodes of the opposite color.

Lower Bound

Finally, we need to verify the lower bound for each subcase. We can trivially generate a linear program (no integrality constraints) according to our model. From the expansion status ℓ we can construct $\mathcal{CP}^\ell$, the objective function (1) and the segment-oriented constraints (3) and (4). For each (already verified) Kuratowski subdivision considered in the subcase, we generate the corresponding constraint (2).

By writing this LP in a standard file, we can use *any* LP-solver (or multiple, to gain confidence) to verify that the LP's solution value is strictly larger than $UB - 1$. For a more formal proof, we may check the basis of the final tableau/the dual solution to verify the lower bound and/or use self-proving LP solvers [2, 13].

[1] While constraints *could* be stored without explicitly stating R, this would decrease the readability of the proof and the verification procedure, cf. G5.

4 Practice and Experiments

4.1 Web-Service

Already prior to our proof system, we offered a (free) web-service to compute the crossing number of an uploaded graph (see `http://crossings.uos.de`). Over the last years it has been used as a tool by several research groups worldwide, to help validate or falsify crossing number conjectures and ideas. We collected the thereby uploaded instances. However, the web-service would (formally) only give a primal solution, together with the assertion that this *should* be the optimum. Now, we relaunched the web-service to also hand out the formal proof. The user can download the stand-alone Java verification program, check it, and use it to verify her proof independently.

4.2 Experimental Evaluation

To determine the applicability of the proof system, we tested the algorithms on three benchmark sets: the 3110 non-trivial Rome graphs [14], the 1277 North graphs [15], and the 145 non-planar graphs (`http://crossings.uos.de/instances`) collected by our crossing number web-service.

All experiments were conducted using an Intel Xeon E5-2430 v2, 2.50 GHz with 192 GB RAM running on Debian 8. We compiled with g++ 4.9.0 (64bit, -O3), used CPLEX 12.6.0 as the backend LP-solver, and applied a time-limit of 60 minutes for each computation. All algorithms except the verifier are implemented as part of the OGDF (using ABACUS as the ILP-framework). We compare the *sparse* to the newly introduced *homogeneous* column generation scheme, to understand the runtime costs of the simpler but supposedly weaker column generation scheme. For both schemes we consider the cases whether we start with a *tight* upper bound (the optimum) or not; the former is the setting we typically use within our proof system. Fig. 1 summarizes the results. While *tight homogeneous* requires more time than *tight sparse* on larger instances, it is still faster than *sparse* without a tight upper bound. On all instances with crossing number at most 22, *homogeneous* is at most 5 times slower than *sparse* (for both upper bound modes, considering only those instances solved by both schemes). Using the tight upper bound reduces the runtime to about 30% on average for *homogeneous*. Out of all 3393 instances solved by *tight sparse*, only 11 could not also be solved by *tight homogeneous* in time. Thus, we conclude that the increase in running time due to the simpler column generation is reasonable in practice. The runtime of the verification procedure is negligibly small.

5 Conclusion

We considered the problem of bridging the gap between "provably optimal" solutions obtained via mathematical programming and the demands on a verifiable formal proof. To this end, we laid out the general central design goals and steps to turn a mathematical program into a proof system.

We combined this with a showcase of how to automatically obtain a verifiable proof for the graph-theoretic crossing number problem, whose known ILP implementations are far from being formally checkable. To this end, we also introduced a novel column generation scheme for the problem's model, which, while much simpler, is still very effective in practice. The final proof system is available online for free academic use.

Figure 1 Running time of different SECM variants (see text). The tight variants finished in roughly 10^{-5} seconds for instances with crossing number 1.

Abstract

In this paper, we study contention resolution protocols from a game-theoretic perspective. We focus on *acknowledgment-based* protocols, where a user gets feedback from the channel only when she attempts transmission. In this case she will learn whether her transmission was successful or not. Users that do not transmit will not receive any feedback. We are interested in equilibrium protocols, where no player has an incentive to deviate.

The limited feedback makes the design of equilibrium protocols a hard task as best response policies usually have to be modeled as Partially Observable Markov Decision Processes, which are hard to analyze. Nevertheless, we show how to circumvent this for the case of two players and present an equilibrium protocol. For many players, we give impossibility results for a large class of acknowledgment-based protocols, namely *age-based* and *backoff* protocols with finite expected finishing time. Finally, we provide an age-based equilibrium protocol, which has infinite expected finishing time, but every player finishes in linear time with high probability.

1 Introduction

Contention resolution in multiple access channels is one of the most fundamental problems in networking. In a multiple access channel (or broadcast channel) multiple users want to communicate with each other by sending messages into the channel. The channel is not centrally controlled, so two or more users can transmit their messages at the same time. If this happens then the messages collide and the transmission is unsuccessful. Contention resolution protocols specify how to resolve such conflicts, while simultaneously optimizing some performance measure, like channel utilization or average throughput.

In this paper we follow the standard assumption that time is divided into discrete time slots, messages are broken up into fixed sized packets, and one packet fits exactly into one time slot. Moreover, we consider one of the simplest possible scenarios where there are n users, each of them having a single packet that needs to be transmitted through the channel. When exactly one user attempts transmission in a given slot, the transmission is successful. However, if more than one users attempt transmission in the same slot, a collision occurs, their transmission fails and they need to retransmit their packages in later time slots.

Under centralized control of the users, avoiding collisions would be simple: exactly one user would transmit at each time step, alternating in a round-robin fashion. The complexity of the problem stems from the fact that there is no centralized control and therefore channel access has to be managed by a distributed protocol. There is a large body of literature that studies efficient distributed contention resolution protocols (see Section 1.2). However, these protocols work under the assumption that users will obediently follow the algorithm. In this paper we follow [9] by dropping this assumption. We model the situation as a non-cooperative stochastic game, where each user acts as a selfish *player* and tries to minimize the expected time before she transmits successfully. Therefore a player will only obey a protocol if it is in her best interest, given the other players stick to the protocol.

Fiat, Mansour, and Nadav [9] designed an incentive-compatible transmission protocol which guarantees that (with high probability) all players will transmit successfully in time linear in n. Their protocol works for a very simple channel feedback structure, where each player receives feedback of the form $0/1/2^+$ after each time step (*ternary* feedback), indicating whether zero, one, or more than one transmission was attempted. Christodoulou, Ligett and Pyrga [8] designed equilibrium protocols for *multiplicity* feedback, where each player receives as feedback the number of players that attempted transmission[1].

The above protocols fall in the class of *full-sensing* protocols [13] where the channel feedback is broadcasted to all sources. However, in wireless channels, there are situations where full-sensing is not possible because of the *hidden-terminal problem* [27]. In this paper, we focus on *acknowledgment-based* protocols, which use a more limited feedback model – the only feedback that a user gets is whether her transmission was successful or not. A user that does not transmit cannot "listen" to channel and therefore does not get any feedback. In other words, the only information that a user has is the history of her own transmission attempts. Acknowledgment-based protocols have been extensively studied in the literature (see e.g. [13] and references therein). *Age-based* and *backoff* protocols both belong to the class of acknowledgment-based protocols.

Age-based protocols can be described by a sequence of probabilities (one for each time-step) of transmitting in each time step. Those probabilities are given beforehand and do not change based on the transmission history. The well known ALOHA protocol [1] is a special

[1] They also assume non-zero transmission costs, as opposed to [9] and to this work.

age-based protocol, where – except for the first round – users always transmit with the same probability. In contrast, in *backoff* protocols, the probability of transmitting in the next time step only depends on the number of unsuccessful transmissions for the user. Here, a popular representative is the *binary exponential backoff* mechanism, which is also used by the Ethernet protocol [20].

The design and the limitations of acknowledgment-based protocols is well-understood [10, 18] if the users are not strategic. In this paper, we focus on the game-theoretic aspect of those protocols.

1.1 Our Results

We study the design of acknowledgment-based *equilibrium protocols*. A user gets feedback only when she attempts transmission, in which case she either receives an acknowledgment, in case of success, or she realizes that a collision occurred (by the lack of an acknowledgment). This model allows for very limited feedback, as opposed to *full-sensing* protocols studied in [9, 8] where all players, even those who did not attempt transmission receive channel feedback.

The feedback models used in [9, 8] allow players, at each given time, to know exactly the number of pending players. This information is very useful for the design of equilibrium protocols. In our case, we assume that the number of pending players is common knowledge only at the beginning. If a player chooses not to transmit during a time-slot, then she is not sure how many players are still in the game. From this time on, she can only sense the existence of other pending players when she participates in a collision.

The analysis of acknowledgment-based equilibrium protocols requires different techniques. In full-sensing protocols, a best response for a source can be modeled as an optimal policy of a Markov Decision Process (MDP) [9]. For an acknowledgment-based protocol, this is in general no longer possible, due to the uncertainty imposed by a non-transmission. However, the best response policy in this case can be modeled as a *Partially Observable Markov Decision Processes* (POMDP), which are more complicated to analyze.

Lack of information makes the design of equilibrium protocols a hard task. In particular, we show in Section 4 that it is impossible to design an age-based or backoff protocol that is in equilibrium and has finite expected finishing time [2]. These impossibility results contribute to a partial characterisation of such protocols and even hold for the case of two players. This stands in contrast to the full-sensing case for which the authors in [9] give an equilibrium protocol, where the k remaining players transmit with probability $\Theta\left(\frac{1}{\sqrt{k}}\right)$. This protocol finishes in finite but exponential time.

In Section 3, we introduce and analyze an equilibrium protocol for two players. An interesting feature of our protocol is that each player is using only limited information of her own history. More precisely, the probability of transmission in a time-slot, depends only on whether a player attempted transmission in the previous slot. Our proof reduces the POMDP for the best response policy to a *finite* MDP, which we then analyze. This reduction crucially relies on the nature of our protocol. We further show that our equilibrium protocol is the unique stationary equilibrium protocol.

For more than two players, we present an age-based equilibrium protocol. Although it has infinite expected finishing time, every player finishes in linear time with high probability. Our

[2] Note, that for more than two players, always transmitting is an equilibrium protocol with *infinite* expected finishing time [9].

protocol circumvents the lack of information by maintaining an estimation on the number of pending players, which with high probability is an upper bound on the actual number. The protocol uses a deadline mechanism similar to [9]. Their protocol exploits the existence of their finite time equilibrium protocol mentioned above. For our more restricted model it is not known if such a finite time protocol exists for more than two players. This is the main open question left from our work. We stress that our negative results exclude the possibility that such a protocol can be age-based or backoff.

1.2 Related Work

The ALOHA protocol, introduced by Abramson [1] (and modified by Roberts [25] to its slotted version), is a multiple-access communication protocol, which has been around since the 70's. Many subsequent papers study the efficiency of multiple-access protocols when packets are generated by some stochastic process (see for example [12, 11, 24]), while worst-case scenarios of bursty inputs, were studied in [5]. To model such a worst-case scenario, one needs n nodes, each of which must simultaneously transmit a packet; this is also the model we use in this work.

A large class of contention resolution protocols explicitly deals with *conflict resolution*; where if $k \geq 2$ users collide (out of a total of n users), then a resolution algorithm is called on to resolve this conflict (by ensuring that all the colliding packets are successfully transmitted), before any other source is allowed to use the channel [7, 6, 15, 28]. There have been many positive and negative results on the efficiency of protocols under various information models (see [13] for an overview of results). When k is known, [10] provides an $O(k + \log k \log n)$ *acknowledgment-based* algorithm, while [18] provides a matching lower bound. For the ternary model, [14] provides a bound of $\Omega(k(\log n / \log k))$ for all deterministic algorithms.

A variety of game theoretic models of slotted ALOHA have also been proposed and studied; see for example [2, 17, 3]. However, much of this work only considers transmission protocols that always transmit with the same fixed probability (perhaps as a function of the number of players in the game). Other game theoretic approaches have considered pricing schemes [29] and cases in which the channel quality changes with time and players must choose their transmission levels accordingly [19, 30, 4]. [16] studied a game-thoretic model that lies between the contention and congestion model, where the decision of *when* to submit is part of the action space of the players. As discussed in the previous section, the most relevant game-theoretic model to our work, is the one studied by Fiat, Mansour, and Nadav [9] and by Christodoulou, Ligett, and Pyrga [8]. In [8], efficient ϵ-equilibrium protocols are designed, but the authors assume non-zero transmission costs, in which case the efficient protocol of [9] does not apply. Their protocols use *multiplicity* feedback (the number of attempted transmissions) which again falls in the class of full-sensing protocols.

2 Model

Game Structure. Let $N = \{1, 2, \ldots, n\}$ be the set of agents, each one of which has a single packet that he wants to send through a common channel. All players know n. We assume time is discretized into slots $t = 1, 2, \ldots$. The players that have not yet successfully transmitted their packet are called *pending* and initially all n players are pending. At any given time slot t, a pending player i has two available actions, either to *transmit* his packet or to *remain quiet*. In a *(mixed) strategy*, a player i transmits his packet at time t with some probability that potentially depends on information that i has gained from the channel based on previous transmission attempts. If exactly one player transmits in a given slot t, then his transmission is *successful*, the successful player exits the game (i.e. he is no longer pending), and the game continues with the rest of the players. On the other hand, whenever two or more agents try to access the channel (i.e. transmit) at the same slot, a *collision* occurs and their transmissions fail, in which case the agents remain in the game. Therefore, in case of collision or if the channel is idle (i.e. no player attempts to transmit) the set of pending agents remains unchanged. The game continues until all players have successfully transmitted their packets.

Transmission protocols. Let $X_{i,t}$ be the indicator variable that indicates whether player i attempted transmission at time t. For any $t \geq 1$, we denote by $\vec{X}_t$ the transmission vector at time t, i.e. $\vec{X}_t = (X_{1,t}, X_{2,t}, \dots, X_{n,t})$. An *acknowlegment-based* protocol, uses very limited channel feedback. After each time step t, only players that attempted a transmission receive feedback, and the rest get no information. In fact, the information received by a player i who transmitted during t is whether his transmission was successful (in which case he gets an acknowledgement and exits the game) or whether there was a collision.

Let $\vec{h}_{i,t}$ be the vector of the *personal transmission history* of player i up to time t, i.e. $\vec{h}_{i,t} = (X_{i,1}, X_{i,2}, \dots, X_{i,t})$. We also denote by $\vec{h}_t$ the transmission history of all players up to time t, i.e. $\vec{h}_t = (\vec{h}_{1,t}, \vec{h}_{2,t}, \dots, \vec{h}_{n,t})$. In an acknowledgement-based protocol, the actions of player i at time t depend only (a) on his personal history $\vec{h}_{i,t-1}$ and (b) on whether he is pending or not at t. A *decision rule* $f_{i,t}$ for a pending player i at time t, is a function that maps $\vec{h}_{i,t-1}$ to a probability $\Pr(X_{i,t} = 1|\vec{h}_{i,t-1})$. For a player $i \in N$, a *(transmission) protocol* f_i is a sequence of decision rules $f_i = \{f_{i,t}\}_{t\geq 1} = f_{i,1}, f_{i,2}, \cdots$.

A transmission protocol is *anonymous* if and only if the decision rule assigns the same transmission probability to all players with the same personal history. In particular, for any two players $i \neq j$ and any $t \geq 0$, if $\vec{h}_{i,t-1} = \vec{h}_{j,t-1}$, it holds that $f_{i,t}(\vec{h}_{i,t-1}) = f_{j,t}(\vec{h}_{j,t-1})$. In this case, we drop the subscript i in the notation, i.e. we write $f = f_1 = \cdots = f_n$.

We call a protocol f_i for player i *age-based* if and only if, for any $t \geq 1$, the transmission probability $\Pr(X_{i,t} = 1|\vec{h}_{i,t-1})$ depends only (a) on time t and (b) on whether player i is pending or not at t. In this case, we will denote the transmission probability by $p_{i,t} \overset{def}{=} \Pr(X_{i,t} = 1|\vec{h}_{i,t-1}) = f_{i,t}(\vec{h}_{i,t-1})$.

A protocol is called *backoff* if the decision rule at time t is a function of the number of *unsuccessful* transmissions. We call a transmission protocol f_i *non-blocking* if and only if, for any $t \geq 1$ and any transition history $\vec{h}_{i,t-1}$, the transmission probability $\Pr(X_{i,t} = 1|\vec{h}_{i,t-1})$ is always smaller than 1. A protocol f_i for player i is a *deadline protocol with deadline* $t_0 \in \{1, 2, \dots\}$ if and only if $f_{i,t}(\vec{h}_{i,t-1}) = 1$, for any player i, any time slot $t \geq t_0$ and any transmission history $\vec{h}_{i,t-1}$. A *persistent player* is one that uses the deadline protocol with deadline 1.

Efficiency. Assume that all n players in the game employ an anonymous protocol f. We will say that f is *efficient* if and only if all players will have successfully transmitted by time $\Theta(n)$ with high probability (i.e. with probability tending to 1, as n goes to infinity).

Individual utility. Let $\vec{f} = (f_1, f_2, \dots, f_n)$ be such that player i uses protocol $f_i, i \in N$. For a given transmission sequence $\vec{X}_1, \vec{X}_2, \dots$, which is consistent with $\vec{f}$, define the *latency* or *success time* of agent i as $T_i \overset{def}{=} \inf\{t : X_{i,t} = 1, X_{j,t} = 0,\ \forall j \neq i\}$. That is, T_i is the time at which i successfully transmits. Given a transmission history $\vec{h}_t$, the n-tuple of protocols $\vec{f}$ induces a probability distribution over sequences of further transmissions. In that case, we write $C_i^{\vec{f}}(\vec{h}_t) \overset{def}{=} \mathbb{E}[T_i|\vec{h}_t, \vec{f}] = \mathbb{E}[T_i|\vec{h}_{i,t}, \vec{f}]$ for the expected latency of agent i incurred by a sequence of transmissions that starts with $\vec{h}_t$ and then continues based on $\vec{f}$. For anonymous protocols, i.e. when $f_1 = f_2 = \cdots = f_n = f$, we will simply write $C_i^f(\vec{h}_t)$ instead[3].

Equilibria. The objective of every agent is to minimize her expected latency. We say that $\vec{f} = \{f_1, f_2, \ldots, f_n\}$ is in *equilibrium* if for any transmission history $\vec{h}_t$ the agents cannot decrease their expected latency by unilaterally deviating after t; that is, for all agents i, for all time slots t, and for all decision rules f'_i for agent i, we have

$$C_i^{\vec{f}}(\vec{h}_t) \leq C_i^{(\vec{f}_{-i}, f'_i)}(\vec{h}_t),$$

where $(\vec{f}_{-i}, f'_i)$ denotes the protocol profile[4] where every agent $j \neq i$ uses protocol f_j and agent i uses protocol f'_i.

3 An equilibrium protocol for two players

In this section we show that there is an anonymous acknowledgment-based protocol in equilibrium, when $n = 2$.

We define the protocol f as follows: for any $t \geq 1$, player i and transmission history $\vec{h}_{i,t-1}$,

$$f_{i,t}(\vec{h}_{i,t-1}) = \begin{cases} \frac{2}{3}, & \text{if } X_{i,t-1} = 1 \text{ or } t = 1 \\ 1, & \text{if } X_{i,t-1} = 0. \end{cases} \tag{1}$$

▶ **Theorem 1.** *There is an anonymous acknowledgment-based equilibrium protocol for two players.*

Proof. We will show that protocol f is in equilibrium. Let Alice and Bob be the two players in the system. We will show that when Bob sticks with playing f, any deviation for Alice, at any possible slot, will be less profitable for her.

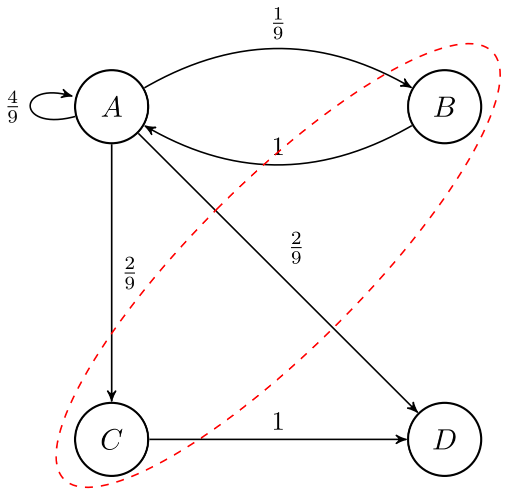
Let's denote by $C_i^{f,j}$, for $j \in \{0,1\}$, the expected success time for a pending player i given that in the last round he attempted transmission ($j = 1$) or not ($j = 0$) i.e., $C_i^{f,j} = \mathbb{E}[T_i | \vec{h}_t, f, X_{i,t} = j]$. The following claim asserts that the expected success time for Alice depends only on whether she attempted a transmission or not in the previous slot. For the proof, we compute the expected time to absorption for the Markov chain $\mathcal{M}$ shown in Figure 1a, starting from states A and B.

▶ **Claim 2.** $C_{Alice}^{f,j} = 2 + j$*, for* $j \in \{0,1\}$.

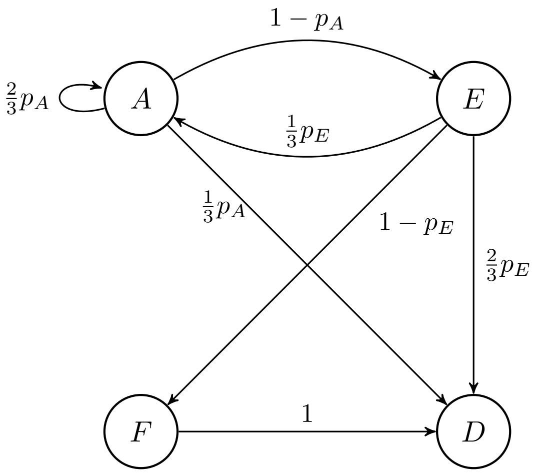
Proof. The situation from Alice's perspective can be modeled as a Markov chain $\mathcal{M}$ with state space $\{A, B, C, D\}$. A is the initial state where both players are pending (and they both know this). A is reached either in $t = 1$, or when Alice transmitted in the previous time step and there was a collision. State B models the case when both players are pending, but Alice does not know this, because she did not transmit in the previous time step. State C is reached when only Alice is pending; notice that, by definition of the protocol, there is no way for Alice to distinguish with certainty between states B and C if both herself and Bob

[3] Abusing notation slightly, we will also write $C_i^{\vec{f}}(\vec{h}_0)$ for the *unconditional* expected latency of player i induced by $\vec{f}$.

[4] For an anonymous protocol f, we denote by (f_{-i}, f'_i) the profile where agent $j \neq i$ uses protocol f and agent i uses protocol f'_i.



(a) Markov chain $\mathcal{M}$.



(b) Markov chain $\mathcal{M}'$.

Figure 1 Markov chains used in the analysis.

use f. Finally, D is the state in which Alice has successfully transmitted. The transition graph of $\mathcal{M}$ is shown in Figure 1a.

For example, we can see from the transition graph that the probability that we visit state A at time $t+1$, given that we are in B at t is given by $\Pr(\mathcal{M}_{t+1} = A|\mathcal{M}_t = B) = 1$. Indeed, if $\mathcal{M}_t = B$, neither player transmitted at t, so both will transmit with probability 1 at $t+1$, causing a collision, after which Alice (and also Bob) can deduce that all players are still pending. Similarly, $\Pr(\mathcal{M}_{t+1} = D|\mathcal{M}_t = C) = 1$, because, being at C means that only Bob transmitted (successfully) at t and so Alice will transmit (also successfully, being the only pending player) at $t+1$ with probability 1.

Clearly, $C^{f,1}_{Alice}$ is equal to the expected hitting time k^D_A that $\mathcal{M}$ needs to reach state D, given that we start from A. By definition, we have $k^D_C = 1$, $k^D_D = 0$, and by the Markov property, we get $k^D_B = k^D_A + 1$ and $k^D_A = 1 + \frac{4}{9}k^D_A + \frac{1}{9}k^D_B + \frac{2}{9}k^D_C + \frac{2}{9}k^D_D$. By rearranging terms and making the substitutions, we conclude that $C^{f,1}_{Alice} = 3$.

Calculating $C^{f,0}_{Alice}$ is a bit more tricky, because since Alice did not attempt transmission at the previous slot, she cannot be certain in which state she is, but she knows that is at state B with probability $1/3$ and in C with $2/3$. Therefore $C^{f,0}_{Alice} = \frac{1}{3}k^D_B + \frac{2}{3}k^D_C = 2$. ◀

It remains to be shown that for any transmission history up to any time t, the optimal (best-response) strategy for Alice is to follow f. Notice that this situation from Alice's point of view can be described by an infinite-horizon, undiscounted *Partially observable Markov Decision Process (POMDP)*, by the direct modification of the Markov chain $\mathcal{M}$ that is described in the proof of Claim 2. This process is partially observable due to the uncertainty created whenever Alice does not attempt transmission. This creates complications in the analysis, as general results about the existence of optimal stationary policies in MDPs [23], do not carry over immediately and also optimal policies are not always well-defined for undiscounted POMDPs with infinite horizon [22]. Fortunately, by exploiting the nature of our specific protocol f, and in particular the fact that a player using f never misses two transmissions in a row, we are able to circumvent this difficulty and model the situation as an MDP.

Following the notation in [21], the *state space* of the MDP is $\mathcal{I} = \{A, E, F, D\}$. The states are interpreted as follows: As in the Markov chain $\mathcal{M}$, state A describes the situation in which both players are pending and they both know it (this is reached just after a collision, or at time $t = 1$) and state D corresponds to the state in which Alice successfully transmitted. F is the state in which Alice did not transmit for two consecutive rounds. Since Bob follows f, he will have transmitted in one of these two rounds. Thus, in F Alice is the only pending player and she knows it. Note that in F the unique optimal strategy for Alice is to transmit in the next round. Finally, E is the state in which Alice is uncertain whether she is the only pending player in the system; this happens at t if she did not transmit at $t-1$, but transmitted at $t-2$ and there was a collision. State E essentially corresponds to a combination of states B and C in Figure 1a.

Since Alice clearly starts at state A, the *initial distribution* of the MDP is λ, where $\lambda_A = 1$ and $\lambda_E = \lambda_F = \lambda_D = 0$. The set of *actions* for Alice is $\mathcal{A} = [0, 1]$. In particular, if Alice decides to take action $a \in \mathcal{A}$ at time t, then she will transmit with probability a at t. Furthermore, the *cost function* of the MDP is $c(a) = (c_s(a) : s \in \mathcal{I})$ and we have $c_A(a) = c_E(a) = c_F(a) = 1$ and $c_D(a) = 0$ for all $a \in \mathcal{A}$. Finally, for the *transition matrix* of our MDP, notice that, since the MDP describes the situation from Alice's perspective, we calculate transition probabilities by "deferring" the relevant decisions taken by Bob until the time that Alice gets feedback . The transition matrix of our MDP is shown in equation (2) and it is explained in more detailed below.

$$P(a) = \begin{bmatrix} \frac{2a}{3} & 1-a & 0 & \frac{a}{3} \\ \frac{a}{3} & 0 & 1-a & \frac{2a}{3} \\ 0 & 0 & 1-a & a \\ 0 & 0 & 0 & 1 \end{bmatrix}. \tag{2}$$

In particular, we can see from (2) that the probability to visit state A in one step, given that we are at state E and the action taken is $a \in [0, 1]$, is $P_{E,A}(a) = \frac{a}{3}$. Indeed, this happens at some time t if at time $t-1$ Alice did not transmit but Bob did not transmit either; therefore, by definition of f, given that we are at E (i.e. Alice did not transmit at time $t-1$), the probability that we reach A is equal to the probability that Alice transmits at t (which happens with probability a) multiplied by the probability that Bob did not transmit at $t-1$ (which happens with probability $\frac{1}{3}$). Similarly, the probability that we visit D in one step, given that we are at state E and the action taken is $a \in [0, 1]$, is $P_{E,D}(a) = \frac{2a}{3}$, which is the probability that Alice transmits in the current step and Bob transmitted in the previous one (in which Alice did not transmit, thus Bob was successful).

By Lemma 5.4.2 and Theorem 5.4.3 from [21], there is a stationary policy (i.e. protocol) u^* that is optimal in the sense that it achieves the minimum expected total cost, given that we start at state A. The fact that u^* is stationary significantly reduces the search space of optimal strategies. In particular, this allows us to only consider strategies for which the actions taken by Alice (in the above MDP) depend only on the current state. In fact, we can further reduce the family of optimal strategies considered by noting that in any optimal strategy Alice will transmit with probability 1 when in state F; indeed, when Alice knows that she is the only pending player, she will decide to transmit with probability 1 in the next time step. Therefore, it only remains to determine the probability of transmission when we are at either state A of E; denote those by p_A and p_E respectively. Therefore, this leads to a Markov chain $\mathcal{M}'$ with state space $\mathcal{I}' = \mathcal{I}$ and transition probabilities that correspond to actions from the above MDP. The transition graph of $\mathcal{M}'$ is shown in Figure 1b.

Clearly, the expected latency of Alice when she uses protocol u^* and Bob uses protocol f is equal to the expected hitting time $k_A'^D$ that $\mathcal{M}'$ needs to reach state D, given that we start from A. By definition, we have $k_F'^D = 1, k_D'^D = 0$, and by the Markov property, we get

$k_A^{'D} = 1 + \frac{2}{3}p_A k_A^{'D} + (1-p_A)k_E^{'D}$ and $k_E^{'D} = 1 + \frac{1}{3}p_E k_A^{'D} + (1-p_E)k_F^{'D}$. Rearranging and after substitutions we get $k_A^{'D} = 3$ and $k_E^{'D} = 2$, for any $p_A, p_E \in [0,1]$. Comparing this to Claim 2, we conclude that if Bob uses f, a best response for Alice is to also follow f. This completes the proof of the Theorem. ◀

3.1 Uniqueness

We will say that a protocol is *stationary* if the decision rule for each player at some time t depends on the information state of the player at t. In particular, the protocol defined in equation (1) is stationary. In this section we show that there are no other stationary equilibria.

▶ **Theorem 3.** *For two players, the unique stationary anonymous protocol that is in equilibrium is the one defined in equation (1).*

Proof. For the sake of contradiction, assume that there is another stationary protocol that is in equilibrium. As in the analysis of protocol (1) in Section 3, we denote by A the state where both players know they are both pending. Let Alice be one of the two players. Notice that, every time Alice transmits, either there is a collision (in which case Alice returns to state A) or the transmission is successful (so Alice is no longer pending).

For $k = 1, 2, \dots$, let p_k denote the probability that Alice transmits in step k, given that she starts from A at $t = 0$ and she does not transmit in time steps 1 to $k-1$. Therefore, given that we start from A at time 0, the probability that Alice attempts to transmit for the first time after k steps is $p_k \prod_{k'=1}^{k-1}(1-p_{k'})$. In particular, in the equilibrium described in the previous section, we had $p_1 = \frac{2}{3}$ and $p_2 = 1$.

First, assume there is another stationary protocol g that is in equilibrium, for which $p_2 = 1$ and $p_1 = p \neq \frac{2}{3}$. Adjusting the transition probabilities in the Markov chain in Figure 1a accordingly, and doing the same analysis we can derive that the expected latency of Alice when both players use protocol g is $k_A^D = \frac{2-p}{2p(1-p)}$. We will show that for all $p \neq \frac{2}{3}$ a player has a profitable deviation. Indeed, first observe that $p > \frac{2}{3}$ implies $k_A^D > 3$. In this case Alice can improve her expected latency by not transmitting for two consecutive time steps and then (successfully) transmitting in the third time step. Second, for the case that $p < \frac{2}{3}$, persistently transmitting in each time step is a deviation which gives the deviator an expected latency of $\frac{1}{1-p}$. For $p < \frac{2}{3}$ this is strictly less than the expected latency $k_A^D = \frac{2-p}{2p(1-p)}$ that Alice has when both players use protocol g. From both cases, we conclude that there is no stationary protocol in equilibrium for which $p_2 = 1$ and $p_1 \neq \frac{2}{3}$.

Now assume that there is another stationary protocol z in equilibrium, for which $p_2 < 1$. Denote α_z the expected latency of Alice when both players use protocol z. Similarly denote $\alpha_{(z')}$ the expected latency of Alice when she unilaterally deviates from z to some other protocol z'. We will consider the following three protocols that Alice can use instead of z: (i) Using protocol $(1z)$, Alice will transmit in the first time step and then continue by following protocol z. (ii) Using protocol $(01z)$, Alice will not transmit in the first time step, but will transmit in the second time step and then follow the protocol z. (iii) Finally, using protocol $(001z)$, Alice will not transmit for the first two time steps, but will transmit in the third time step and then follow the protocol z. The expected latency of Alice when she uses each of those protocols while the other player uses z is given by:

$$\begin{aligned} \alpha_{(1z)} &= 1 + p_1\alpha_z \\ \alpha_{(01z)} &= 2 + (1-p_1)p_2\alpha_z \\ \alpha_{(001z)} &= 3 + (1-p_1)(1-p_2)p_3\alpha_z. \end{aligned}$$

Notice now that all three transmission sequences $(1), (0,1)$ and $(0,0,1)$ are consistent with z. Furthermore, z is acknowledgment-based, so Lemma 4 applies here. Therefore, the above expected latencies must all be equal to α_z. Using the identities $\alpha_z = \alpha_{(1z)} = \alpha_{(01z)}$ we get that $\alpha_z = 2 + p_2 < 3$. But clearly $3 \leq \alpha_{(001z)}$, which is a contradiction to the fact that $\alpha_z = \alpha_{(001z)}$. Thus, there is no equilibrium protocol with $p_2 < 1$. This completes the proof of the theorem. ◀

4 Age-based and backoff protocols

In this section, we focus on two special prominent classes of acknowledgment-based protocols, namely *age-based* and *backoff*, and we show that these cannot be implemented in equilibrium if we insist on finite expected latency.

In what follows, for any protocol f, any player i that uses f and any time t, we will say that $\vec{h}_{i,t}$ is *consistent with* f if and only if there is a non-zero probability that $\vec{h}_{i,t}$ will occur for player i.

Now we are ready to show in the next Lemma a useful property of all *acknowledgment-based* equilibrium protocols that is essentially an analogue of the property of Nash equilibria for finite games that all pure strategies in the support of a Nash equilibrium are best responses.

▶ **Lemma 4.** *Let $f \overset{def}{=} \{f_t\}_{t\geq 1}$ be an anonymous acknowledgment-based protocol and let $\pi \overset{def}{=} \pi_1, \pi_2, \ldots$ be any 0-1 sequence which is consistent with f. For any (finite) positive integer τ^*, define the protocol*

$$g = g(\tau^*) \overset{def}{=} \begin{cases} \pi_t, & \text{for } 1 \leq t \leq \tau^* \\ f_t, & \text{for } t > \tau^*. \end{cases} \tag{3}$$

We then have that, for any fixed player i, if f is in equilibrium, then

$$C_i^f(\vec{h}_0) = C_i^{(f_{-i},g)}(\vec{h}_0).$$

Proof. Since we consider acknowledgment-based protocols, for the sake of the analysis, we will assume that players continue to flip coins even after successfully transmitting, so that they eventually find out what their decisions would have been at any time t.[5]

For a fixed player i, we obtain

$$C_i^f(\vec{h}_0) = \mathbb{E}[T_i|\vec{h}_{i,0}, f] = \sum_{\vec{h}_{i,\tau^*}} \mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] \Pr\left\{\vec{h}_{i,\tau^*} \text{ happens for } i\right\}. \tag{4}$$

Notice now that, since f is acknowledgment-based, the event $\left\{\vec{h}_{i,\tau^*} \text{ happens for } i\right\}$ is independent of the transmission sequences of other players. Therefore, $\mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f]$ is equal to the unconditional (i.e. conditioned on $\vec{h}_{i,0}$) expected latency of player i when she uses the protocol defined in equation (3), where the first τ^* terms of π are replaced by $(\pi_1, \ldots, \pi_{\tau^*}) = (\vec{X}_{i,1}, \ldots, \vec{X}_{i,\tau^*}) = \vec{h}_{i,\tau^*}$.[6] In particular, we have that $\mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, g)] = C_i^{(f_{-i},g)}(\vec{h}_0)$.

[5] In fact, we only need this assumption to hold for any t which is at most some predefined fixed upper bound τ^*.

[6] Note that this observation is not true for general protocols and different kinds of feedback, which is why the present analysis cannot be used to prove an impossibility result in the case of protocols like those in [9].

Assume now for the sake of contradiction that there is a transmission history $\vec{h}_{i,\tau^*}$ for player i such that $\mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] \neq \mathbb{E}[T_i|\vec{h}_{i,0}, f]$. Clearly, if $\mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] < \mathbb{E}[T_i|\vec{h}_{i,0}, f]$, then the protocol g is a better protocol for player i, which contradicts the fact that f is in equilibrium. On the other hand, if $\mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] > \mathbb{E}[T_i|\vec{h}_{i,0}, f]$, then equation (4) implies that there must be another transmission history $\vec{h}'_{i,\tau^*}$ for which $\mathbb{E}[T_i|\vec{h}'_{i,\tau^*}, f] < \mathbb{E}[T_i|\vec{h}_{i,0}, f]$.

Therefore, we have that $C_i^{(f_{-i},g)}(\vec{h}_0) = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, g)] = \mathbb{E}[T_i|\vec{h}_{i,\tau^*}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, f] = C_i^f(\vec{h}_0)$, for any transmission history $\vec{h}_{i,\tau^*}$, and for any finite $\tau^* \geq 1$, thus also for any 0-1 sequence π that is consistent with f. ◀

The next corollary is an interesting consequence of Lemma 4 regarding *non-blocking* anonymous age-based protocols.

▶ **Corollary 5.** *Let $f \overset{def}{=} \{f_t\}_{t\geq 1}$ be a non-blocking anonymous age-based protocol. If the expected latency of a player using protocol f is finite, i.e. $\mathbb{E}[T_i|\vec{h}_{i,0}, f] < \infty$, then f is not in equilibrium.*

Proof. Assume for the sake of contradiction that f is in equilibrium and let $\tau^* \overset{def}{=} \left\lfloor \mathbb{E}[T_i|\vec{h}_{i,0}, f] \right\rfloor$ be finite, where i is a fixed player using f. Consider the protocol $g = g(\tau^*)$ as defined in (3), where the first τ^* terms of π are set equal to 0. Clearly, any player using g has expected latency at least $\tau^* + 1$, irrespectively of the transmissions of the other players. Notice also that π is consistent with f up to τ^*, since $\Pr\{\vec{h}_{i,\tau^*} = (0, \dots, 0)|f\} = \prod_{t=1}^{\tau^*}(1 - p_{i,t}) > 0$. Therefore, by Lemma 4 we have that $\tau^* + 1 > \mathbb{E}[T_i|\vec{h}_{i,0}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, g)] \geq \tau^* + 1$, which is a contradiction. We conclude that either f is not in equilibrium, or τ^* is ∞. ◀

We are now ready to show the main result of this section.

▶ **Theorem 6.** *There is no anonymous age-based protocol f for $n \geq 2$ players that is in equilibrium and has $\mathbb{E}[T_i|\vec{h}_{i,0}, f] < \infty$, for any player i.*

Proof. For the sake of contradiction, let's assume that $f = \{f_t\}_{t\geq 1}$ is an age-based protocol in equilibrium with finite expected latency, i.e. $\mathbb{E}[T_i|\vec{h}_0, f] < \infty$. The next claim asserts the existence of a finite positive integer τ^* where the protocol dictates transmission, with certain properties, which will be a useful ingredient for the rest of the proof.

▶ **Claim 7.** *Let f be an anonymous age-based protocol for n players that is in equilibrium and has $\mathbb{E}[T_i|\vec{h}_{i,0}, f] < \infty$, then there is a finite positive integer τ^* such that*
(a) $f_{\tau^*} = 1$,
(b) $f_{\tau^*-1} < 1$ *and*
(c) *there exist $\tau_1 < \cdots < \tau_{n-1} < \tau^*$, such that $f_{\tau_j} < 1$, for all $j = 1, \dots, n-1$.*

Proof. For any time t, define Z_t^f to be the number of non-blocking probabilities of the protocol f up to t, i.e. $Z_t^f \overset{def}{=} \sum_{t'\leq t}(1 - \lfloor f_{t'} \rfloor)$. Set $\tau' \overset{def}{=} \inf\{t : f_t = 1, Z_t^f \geq n-1\}$. Assume for the sake of contradiction that there does not exist a τ^* with the properties described in the claim. In particular, this means that $\tau' = \infty$. However, the latter can happen if one of the following cases is true:
(i) There is no finite τ such that $f_\tau = 1$.
(ii) There exists finite τ such that $f_\tau = 1$, $Z_t^f \leq n-2$ and $f_t = 1$, for all $t \geq \tau$.
(iii) There exists finite τ such that $f_\tau = 1$, $Z_t^f \leq n-2$ and $f_t < 1$, for all $t \geq \tau$.

We now prove that in all those cases we get a contradiction. Case (i) comes in contradiction with Corollary 5.

If case (ii) holds, then clearly, if all players use f, at most $n-2$ players can successfully transmit before τ and the rest will remain pending for ever. But this means that the expected latency of a player i using f is at least

$$\Pr\{i \text{ does not successfully transmit before } \tau | \vec{h}_{i,0}, f\} \cdot \infty = \infty,$$

which leads to a contradiction, since we assumed $\mathbb{E}[T_i|\vec{h}_{i,0}, f] < \infty$.

Suppose now that case (iii) holds. Consider the protocol g defined as follows:

$$g \overset{def}{=} \begin{cases} 0, & \text{if } f_t < 1, \text{ for } 1 \leq t \leq \mathbb{E}[T_i|\vec{h}_{i,0}, f] \\ 1, & \text{if } f_t = 1, \text{ for } 1 \leq t \leq \mathbb{E}[T_i|\vec{h}_{i,0}, f] \\ f_t, & \text{for } t > \mathbb{E}[T_i|\vec{h}_{i,0}, f]. \end{cases} \tag{5}$$

Let i be a fixed player (say Alice). Notice that, if all other players use f and Alice uses g, then Alice has expected latency strictly larger than $\mathbb{E}[T_i|\vec{h}_{i,0}, f]$; indeed, for any $t \leq \mathbb{E}[T_i|\vec{h}_{i,0}, f]$, Alice only attempts a transmission when $f_t = 1$ and there is at least one more other pending player using f, and so there is a collision. However, since the initial (deterministic) sequence of $\left\lfloor \mathbb{E}[T_i|\vec{h}_{i,0}, f] \right\rfloor$ transmissions of g is consistent with f, by Lemma 4 we have that $\mathbb{E}[T_i|\vec{h}_{i,0}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, g)] > \mathbb{E}[T_i|\vec{h}_{i,0}, f]$, which is a contradiction. This completes the proof of the claim. ◀

Take a τ^* as described in the above claim and consider the protocol Q defined as follows

$$Q \overset{def}{=} \begin{cases} 0, & \text{if } f_t < 1, \text{ for } 1 \leq t \leq \tau^* - 2 \\ 1, & \text{if } f_t = 1, \text{ for } 1 \leq t \leq \tau^* - 2 \\ 1, & \text{for } t = \tau^* - 1 \text{ and } t = \tau^* \\ f_t, & \text{for } t > \tau^*. \end{cases} \tag{6}$$

Notice that, since the initial (deterministic) sequence of transmissions of Q is consistent with f, by Lemma 4 we have that $\mathbb{E}[T_i|\vec{h}_{i,0}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, Q)]$.

Now consider the protocol Q', which is the same as Q, with the only difference[7] that $Q'_{\tau^*} = 0$. In fact, we show that, $\mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, Q')] < \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, Q)]$ which implies $\mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, Q')] < \mathbb{E}[T_i|\vec{h}_{i,0}, f]$, which contradicts the assumption that f is in equilibrium.

Notice now that protocols Q and Q' are identical for any $t \neq \tau^*$, and if there are at least 3 pending players at τ^* (i.e. Alice and at least two others), then there would be a collision at τ^* no matter which of the two protocols Alice uses (i.e. the same players that were pending at τ^* would be pending at the start of time slot $\tau^* + 1$ as well). Therefore, the two protocols behave the same in this case. However, if there are exactly 2 pending players at τ^* (i.e. Alice and exactly one more, say Bob) the two protocols behave differently. Indeed, if Alice uses protocol Q, then there will be a collision at τ^*, leaving exactly 2 pending players at $\tau^* + 1$. However, if Alice uses protocol Q', then Bob will be able to successfully transmit at τ^*, leaving Alice the only pending player at time $\tau^* + 1$, which implies a strictly smaller expected latency. The proof is completed by noting that, by definition of τ^*, the probability that there will be exactly 2 players pending at τ^* is strictly positive (since there are at least $n-2$ steps before $\tau^* - 1$ with transmission probability strictly less than 1). ◀

[7] Note that Q' does not agree with f whenever $f_t = 1$, so Lemma 4 does not apply to Q'.

Now we conclude with the impossibility result for backoff protocols, the proof of which shares similarities to the proof of Corollary 5.

▶ **Theorem 8.** *There is no anonymous backoff protocol f in equilibrium for $n \geq 2$ players with $\mathbb{E}[T_i|\vec{h}_{i,0}, f] < \infty$, for any player i.*

Proof. Assume for the sake of contradiction that f is in equilibrium and let $\tau^* \overset{def}{=} \left\lfloor \mathbb{E}[T_i|\vec{h}_{i,0}, f] \right\rfloor$ be finite, where i is a fixed player using f. By definition, we have that $f_i = \{p_{i,k}\}_{k\geq 0}$, where $p_{i,k}$ denotes the transmission probability of player i after k unsuccessful transmissions. Notice also that we may assume without loss of generality that $p_{i,0} \neq 1$. Indeed, suppose there is finite integer $s > 0$, such that $p_{i,k'} = 1$, for all $k' < s$ and $p_{i,s} \neq 1$ (if s is not finite, then clearly f does not have finite expected latency). Then the protocol $f' = \{p'_{i,k}\}_{k\geq 0}$, with $p'_{i,k} = p_{i,k+s}$, for all $k \geq 0$ is also an equilibrium.

Consider now the protocol $g = g(\tau^*)$ defined in equation (3), where the first τ^* terms of π are set to 0. Clearly, any player using g has expected latency at least $\tau^* + 1$. Notice also that π is consistent with f up to τ^*, since $\Pr\{\vec{h}_{i,\tau^*} = (0, \dots, 0)|f\} = (1 - p_{i,0})^{\tau^*} > 0$. Therefore, by Lemma 4 we have that $\tau^* + 1 > \mathbb{E}[T_i|\vec{h}_{i,0}, f] = \mathbb{E}[T_i|\vec{h}_{i,0}, (f_{-i}, g)] \geq \tau^* + 1$, which is a contradiction. But this implies that, either f is not in equilibrium, or τ^* is ∞. ◀

5 An efficient protocol in equilibrium

In this section we present a deadline protocol for n players that is efficient, i.e. with high probability the latency of any player is $\Theta(n)$. Let $t_0 = t_0(n)$ be an integer, to be determined later and let $\beta \in (0, 1)$ be a fixed constant. We consider the following deadline protocol $\mathcal{Q}$ with deadline t_0, which is defined as follows: The $t_0 - 1$ time steps before the deadline are partitioned into $k + 1$ consecutive intervals $I_1, I_2, \dots, I_{k+1}$, where $k = k(n)$ is the unique integer satisfying $\beta^{k+1}n \leq \sqrt{n} < \beta^k n$. For any $j \in \{1, \dots, k+1\}$, define $n_j = \beta^j n$. For $j \in \{1, \dots, k\}$ the length of interval I_j is $\ell_j = \left\lfloor \frac{e}{\beta} n_j \right\rfloor$. Interval I_{k+1} is special and has length $\ell_{k+1} = n$. In particular, this gives

$$t_0 \overset{def}{=} 1 + \sum_{j=1}^{k+1} \ell_j \leq 1 + n + en \sum_{j=1}^{k} \beta^{j-1} = 1 + n + en \frac{1 - \beta^{k-1}}{1 - \beta} \leq n \left(1 + \frac{e}{1 - \beta}\right),$$

where the last inequality holds for any constant $\beta \in (0, 1)$ and $n \to \infty$. For any $t \geq 1$, the decision rule at time t for protocol $\mathcal{Q}$ is given by

$$\mathcal{Q}_t = \begin{cases} \frac{1}{n_j}, & \text{if } t \in I_j, j = 1, 2, \dots, k+1 \\ 1, & \text{if } t \geq t_0. \end{cases} \tag{7}$$

Notice that, by definition, $\mathcal{Q}$ is an age-based protocol. Furthermore, if at least two out of n players use protocol $\mathcal{Q}$, then, no matter what protocol the rest of the players use, there is a non-zero probability that there will be no successful transmission until the deadline t_0, and thus all players will remain pending for ever. In particular, this is at least the probability that the two players using $\mathcal{Q}$ attempt a transmission in every step until t_0, which happens with probability $\prod_{t=1}^{t_0-1} (\mathcal{Q}_t)^2 \geq \frac{1}{n^{t_0}} > 0$. Therefore, if there are at least two players using $\mathcal{Q}$, the expected latency of any player is ∞, hence $\mathcal{Q}$ is in equilibrium, for any $n \geq 3$ and deadline t_0.

In Theorem 11 we prove that $\mathcal{Q}$ is also efficient; when all players in the system use protocol $\mathcal{Q}$, then with high probability all players will successfully transmit before the deadline t_0.

For the proof, we use two elementary Lemmas that formalize the fact that, in each interval, a significant number of players successfully transmit with high probability. For the proofs, we employ standard concentration results from probability theory.

▶ **Lemma 9.** *Assume that all players in the system use protocol $\mathcal{Q}$. For any $j \in \{1, \ldots, k\}$, if the number of pending players before interval I_j is at most n_j, then after I_j, with probability at least $1 - \exp(-\frac{1}{3}\beta^{j+2}n)$ there will be at most n_{j+1} pending players.*

Proof. Fix $j \in \{1, \ldots, k\}$ and assume that the precondition of the lemma is fulfilled, i.e., before interval I_j there are at most n_j pending players. Let r_t denote the number of pending players at time t. In particular, for any $t \in I_j$, if the preconditions of the lemma is fulfilled, we have $r_t \leq n_j$. Therefore the probability of a successful transmission in round $t \in I_j$ is given by

$$r_t\mathcal{Q}_t(1-\mathcal{Q}_t)^{r_t-1} \geq r_t\mathcal{Q}_t(1-\mathcal{Q}_t)^{n_j-1} = r_t\frac{1}{n_j}\left(1-\frac{1}{n_j}\right)^{n_j-1} \geq \frac{1}{e}\frac{r_t}{n_j},$$

where in the last inequality we used the fact that $\left(1-\frac{1}{x}\right)^{x-1} \geq \frac{1}{e}$, for any $x > 1$. Therefore, for any round $t \in I_j$, either we already have $r_t \leq n_{j+1} = \beta n_j$ pending players, or the probability of a successful transmission in round t is at least $a \overset{def}{=} \frac{1}{e}\frac{n_{j+1}}{n_j} = \frac{\beta}{e}$.

Let now X_j be the random variable counting the number of successful transmissions in interval I_j. Notice that, by the above discussion, given that at the start of interval I_j there are at least n_{j+1} pending players, X_j stochastically dominates a Binomial random variable $Y_j \sim Bin(\ell_j, a)$, with mean value $\ell_j \cdot a$. Therefore, by a Chernoff bound (see [26]), we get

$$\Pr(X_j < (1-\beta)\ell_j \cdot a) \leq \Pr(Y_j < (1-\beta)\ell_j \cdot a) \leq \exp\left(-\frac{1}{2}\beta^2\ell_j \cdot a\right) \leq \exp\left(-\frac{1}{3}\beta^2 n_j\right),$$

where in the last inequality we used the fact that, by definition, $n_j \geq \sqrt{n}$, for all $j \leq k$, thus $\ell_j \cdot \frac{\beta}{e} \geq \frac{2}{3}n_j$. This directly implies the lemma. ◀

▶ **Lemma 10.** *If the number of pending players at the start of interval I_{k+1} is at most n_{k+1}, then after interval I_{k+1}, with probability at least $1 - \exp\left(-\frac{1}{3}n_{k+1}\right)$ all players will have successfully transmitted.*

Proof. Consider a fixed player (say Alice) that is pending at the start of interval I_{k+1}. Given that there are at most $n_{k+1} = \beta^{k+1}n$ pending players at any time step $t \in I_{k+1}$, the probability that Alice successfully transmits during t is at least

$$\mathcal{Q}_t(1-\mathcal{Q}_t)^{n_{k+1}-1} = \frac{1}{n_{k+1}}\left(1-\frac{1}{n_{k+1}}\right)^{n_{k+1}-1}.$$

Therefore, since $|I_{k+1}| = \ell_{k+1} = n$, the probability that Alice is still pending after interval I_{k+1} is at most

$$\left(1-\frac{1}{n_{k+1}}\left(1-\frac{1}{n_{k+1}}\right)^{n_{k+1}-1}\right)^n \leq \exp\left(-\frac{n}{n_{k+1}}\left(1-\frac{1}{n_{k+1}}\right)^{n_{k+1}-1}\right). \quad (8)$$

Recall that, by definition, k is the (unique) smallest integer satisfying $n_{k+1} \leq \sqrt{n} < n_k$. In particular, this implies that $n_{k+1} > \beta\sqrt{n}$, therefore n_{k+1} goes to ∞ as $n \to \infty$. Additionally, we have that $\frac{n}{n_{k+1}} \geq n_{k+1}$. Therefore, using the fact that $\left(1-\frac{1}{x}\right)^{x-1} \geq \frac{1}{e}$, for any $x > 1$, the right hand side of (8) is at most $\exp\left(-\frac{1}{e}n_{k+1}\right)$.

By the union bound, given that there are at most n_{k+1} pending players at the start of interval I_{k+1}, the probability that there is at least one pending player after I_{k+1} is at most $n_{k+1} \exp\left(-\frac{1}{e}n_{k+1}\right) \leq \exp\left(-\frac{1}{3}n_{k+1}\right)$, as stated in the Lemma. ◀

We are now ready to prove our main Theorem.

▶ **Theorem 11.** *Protocol $\mathcal{Q}$ is efficient. In particular, for any constant $\beta \in (0,1)$, when all players use $\mathcal{Q}$, the probability that there is a pending player after time $t_0 \leq n\left(1+\frac{e}{1-\beta}\right)$ is at most $\exp(-\Theta(\sqrt{n}))$.*

Proof. It suffices to show that with high probability every player will have successfully transmitted before t_0. Note that, the probability that there are still pending players at $t_0 = \Theta(n)$ is upper bounded by the probability that (a) there exists $j \in \{1, 2, \ldots, k\}$ such that, at the end of interval I_j there are more than n_{j+1} pending players, or (b) there are still pending players after interval I_{k+1}.

Therefore, by Lemma 9 and Lemma 10 and the union bound, the probability that not all players successfully transmit before t_0 is at most

$$\exp\left(-\frac{1}{3}n_{k+1}\right) + \sum_{j=1}^{k} \exp\left(-\frac{1}{3}\beta^2 n_j\right). \tag{9}$$

Since $n_j \geq n_{k+1} \geq \beta\sqrt{n}$, for any $j \in \{1, 2, \ldots, k\}$, the above upper bound becomes $(k+1)\exp\left(-\Theta(\sqrt{n})\right)$. The proof is concluded by noting that, by definition of k, we have $k = \Theta(\log n)$. ◀

We note that, in our analysis, $\beta \in (0,1)$ can be any constant arbitrarily close to 0, therefore, by Theorem 11, the upper bound on the latency of protocol $\mathcal{Q}$ can be as small as $(1+e)n + o(n)$ with high probability.

Abstract

We revisit the complexity of online computation in the cell probe model. We consider a class of problems where we are first given a fixed pattern F of n symbols and then one symbol arrives at a time in a stream. After each symbol has arrived we must output some function of F and the n-length suffix of the arriving stream. Cell probe bounds of $\Omega(\delta \lg n/w)$ have previously been shown for both convolution and Hamming distance in this setting, where δ is the size of a symbol in bits and $w \in \Omega(\lg n)$ is the cell size in bits. However, when δ is a constant, as it is in many natural situations, the existing approaches no longer give us non-trivial bounds.

We introduce a *lop-sided information transfer* proof technique which enables us to prove meaningful lower bounds even for constant size input alphabets. Our new framework is capable of proving amortised cell probe lower bounds of $\Omega(\lg^2 n/(w \cdot \lg\lg n))$ time per arriving *bit*. We demonstrate this technique by showing a new lower bound for a problem known as pattern matching with address errors or the L_2-rearrangement distance problem. This gives the first non-trivial cell probe lower bound for any online problem on bit streams that still holds when the cell size is large.

1 Introduction

We revisit the complexity of online computation in the cell probe model. In recent years there has been considerable progress towards the challenging goal of establishing lower bounds for both static and dynamic data structure problems. A third class of data structure problems which fall somewhere between these two classic settings, is online computation in a streaming setting. Here one symbol arrives at a time and a new output must be given after each symbol arrives and before the next symbol is processed. The key conceptual difference to a standard dynamic data structure problem is that although each arriving symbol can be regarded as a new update operation at a prespecified index, there is only one type of query which is to output the latest value of some function of the stream.

Online pattern matching is particularly suited to study in this setting and cell probe lower bounds have previously been shown for different measures of distance including Hamming distance, inner product/convolution and edit distance [3, 4, 5]. All these previous cell probe lower bounds have relied on only one proof technique, the so-called *information transfer technique* of Pătraşcu and Demaine [14]. In loose terms the basic idea is as follows. First one defines a random input distribution over updates. Here we regard an arriving symbol as an update and after each update we perform one query which simply returns the latest distance between a predefined pattern and the updated suffix of the stream. One then has to argue that knowledge of the answers to ℓ consecutive queries is sufficient to infer at least a constant fraction of the information encoded by ℓ consecutive updates that occurred in the past. If one can show this is true for all power of two lengths ℓ then a logarithmic lower bound per update/query operation follows.

In recent years a consensus has been arrived at that the most natural cell size is $w \in \Omega(\lg n)$. This is for two main reasons. The first is simply that a cell should be large enough to be able to address all of memory. The second, more practical reason is that lower bounds that we derive directly give time lower bounds for problems analysed in the popular word-RAM model. When cells are of this size a cell probe lower bound of $\Omega(\delta \lg n/w)$ for both online Hamming distance and convolution using the information transfer technique has been shown, where δ is the number of bits in an input symbol, w is the cell size in bits and n is the length of the fixed pattern [3, 4]. When $\delta \geq w \geq \lg n$, there is also a matching upper bound in the cell probe model and so no further progress is possible. However, when the symbol size δ does not grow with the input size as is often the case in applied settings, the best lower bound that is derivable reduces trivially to be constant. This is an unfortunate situation as a particularly natural setting of parameters is when the input alphabet is of constant size but the cell size is not.

This small input alphabet, large cell size setting has received some study in the past. Using a sophisticated variant of the information transfer technique, Pătraşcu and Demaine [14] proved an $\Omega(\lg n/ \lg\lg n)$ cell probe lower bound for the classic prefix sum problem when the random update *values* contain $\delta = O(1)$ bits and the cell size is $\Theta(\lg n)$. However, as they themselves highlight in their paper, their proof technique relies on the fact that the update *indices* contain $\Omega(\lg n)$ random bits and it is this information which is then used to provide the lower bound. This is in contrast to our streaming setting where both the update and query indices are fixed and the update values contain only a constant number of bits each.

In this paper we introduce a new variant of the information transfer technique which we call the *lop-sided information transfer technique.* This will enable us to give meaningful lower bounds for precisely this setting, that is when $\delta \in O(1)$, $w \in \Omega(\lg n)$ and both the query and update indices are fixed. Our proof technique will rely on being able to show for specific problems that we need only ℓ query answers to infer at least a constant fraction of the information encoded in the previous $\ell \lg \ell$ updates.

We demonstrate our new framework by applying it to a pattern matching problem with address errors known as L_2-rearrangement distance. This measure of distance, which was first studied in SODA 2006 [1, 2], arises in pattern matching problems where errors occur not in the content of the data but in the addresses where the data is stored. Our proof technique is fundamentally combinatorial in nature. We demonstrate an input distribution which has the property that individual bits of the $\Theta(\lg n)$ sized outputs encode individual bits of the stream. In this way we can infer $\Omega(\ell \lg \ell)$ updates from only $O(\ell)$ outputs as we require. We believe our proof technique is also directly applicable to other simpler distance measures such as the Hamming distance. However establishing the key technical lemma (Lemma 5) appears to be out of reach at present.

The cell probe model and previous lower bounds

Our bounds hold in a particularly strong computational model, the *cell-probe model*, introduced originally by Minsky and Papert [11] in a different context and then subsequently by Fredman [7] and Yao [17]. In this model, there is a separation between the computing unit and the memory, which is external and consists of a set of cells of w bits each. The computing unit cannot remember any information between operations. Computation is free and the cost is measured only in the number of cell reads or writes (cell-probes). This general view makes the model very strong, subsuming for instance the popular word-RAM model.

The first techniques known for establishing dynamic data structure lower bounds had historically been based on the chronogram technique of Fredman and Saks [8] which can at best give bounds of $\Omega(\lg n/\lg\lg n)$. In 2004, Pǎtraşcu and Demaine gave us the first $\Omega(\lg n)$ lower bounds for dynamic data structure problems [14]. Their technique is based on information theoretic arguments which also form the basis for the work we present in this paper. Pǎtraşcu and Demaine also presented ideas which allowed them to express more refined lower bounds such as trade-offs between updates and queries of dynamic data structures. For a list of data structure problems and their lower bounds using these and related techniques, see for example [12]. More recently, a further breakthrough was made by Larsen who showed lower bounds of roughly $\Omega((\lg n/\lg\lg n)^2)$ time per operation for dynamic weighted range counting problem and polynomial evaluation [9, 10]. Subsequent application of this new proof technique has also provided the same lower bound for dynamic matrix-vector multiplication [15]. These lower bounds remain the state of the art for any dynamic structure problem to this day. It is particularly relevant that Larsen's lower bound for dynamic weighted range counting problem cannot yet be applied to the unweighted range counting problem due to a very similar limitation in proof technique to the one we address in this paper.

1.1 Our Results

The lop-sided information transfer technique

In the standard formulation of Demaine and Pǎtraşcu's information transfer technique [13], two adjacent time intervals $[t_0, t_1]$ and $[t_1+1, t_2]$ are considered, with equal, power of two length ℓ. To apply this technique in a streaming setting, the core argument one has to make is that for the given problem, knowledge of the outputs during $[t_1+1, t_2]$ is sufficient to infer a constant fraction of the information encoded by updates during $[t_0, t_1]$. As this information about the updates can be inferred *from* the outputs, the algorithm must know this information *to compute* the outputs. In particular this implies that while computing the outputs during $[t_1+1, t_2]$, the algorithm must probe sufficiently many cells written during $[t_0, t_1]$ to uniquely recover this information. We can think of these cell probes as being associated with interval length ℓ and offset t_0 which uniquely defines the two intervals. The final lower bound is obtained by summing the cell probe lower bounds associated with every power-of-two length ℓ and $t_0 = \ell, 2\ell, 3\ell \ldots$. This final step relies crucially on the fundamental property of the information transfer technique that this summation step does not double count cell probes. In particular that a cell probe associated with some t_0, ℓ is not also associated with some other t_0', ℓ'.

As the argument is information theoretic, to obtain a *logarithmic* lower bound via this approach, both the ℓ updates during $[t_0, t_1]$ and the ℓ outputs during $[t_1+1, t_2]$ must contain $\Omega(\ell\lg\ell)$ bits. However in the bit streaming setting, each update contains $O(1)$ bits so the updates in $[t_0, t_1]$ contain only $O(\ell)$ bits in total.

To overcome this we increase the size of the interval $[t_0, t_1]$ to have length $\ell\lg\ell$ so that both intervals contain $\Omega(\ell\lg\ell)$ bits as required. Unfortunately this modification breaks the fundamental property of the information transfer technique that there is no double counting of cell probes. In fact, direct application of our approach causes each cell probe to be counted $\Theta(\lg n)$ times, negating the possibility of a non-trivial lower bound.

To overcome this we place gaps in time between the end of one interval and the start of another and argue carefully both that not too much of the information can be lost in these gaps and that we can still sum the cell probes over a sufficient number of distinct interval lengths without too much double counting. Our hope is that this new technique will lead to a new class of cell probe lower bounds which could not be proved with existing methods.

Online pattern matching with address errors (L_2-rearrangement distance)

We give an explicit distance function for which we can now obtain the first unconditional online cell probe lower bound for symbol size $\delta = 1$. Consider two strings S_1 and S_2 both of length n where S_2 is a permutation of S_1. Now consider the set of permutations Π so that for all $\pi \in \Pi$, $S_1[\pi(0), \ldots, \pi(n-1)] = S_2$. The L_2-rearrangement distance is defined to be $\min_{\pi\in\Pi} \sum_{j=0}^{n-1}(j - \pi(j))^2$ [2]. In other words, the cost of a permutation is the sum of the square of the number of positions each character is moved. The distance is the minimum cost of any permutation. If Π is empty, that is S_2 is in fact not a permutation of S_1, then the L_2-rearrangement distance is defined to be ∞. As an example, the L_2-rearrangement distance between strings 11100 and 10110 is $0+1+1+2^2+0=6$. In the online L_2-rearrangement problem we are given a fixed pattern $F \in \{0,1\}^n$ and the stream arrives one symbol at a time. After each symbol arrives we must output the L_2-rearrangement distance between F and the most recent n-length suffix of the stream. This online version can be solved in $O(\lg^2 n)$ time per arriving symbol in the word-RAM model [6].

Our technique allows us to recover $\Omega(\lg n)$ distinct bits of the stream from each output. This is achieved by constructing F and carefully choosing a highly structured random input distribution for the incoming stream in such a way that the contributions to the output from different regions of the stream have different magnitudes. We can then use the result to extract distinct information about the stream from different parts of each output.

Using this approach we get the following cell probe lower bound:

▶ **Theorem 1** (Online L_2-rearrangement). *In the cell-probe model with $w \in \Omega(\lg n)$ bits per cell, for any randomised algorithm solving the online L_2-rearrangement distance problem on binary inputs there exist instances such that the expected amortised number of probes per arriving value is*

$$\Omega\left(\frac{\lg^2 n}{w \cdot \lg\lg n}\right).$$

2 Lop-sided information transfer

In this section we will formally define our variant of information transfer, which is a particular set of cells probed by the algorithm, and explain how a bound on the size of the information transfer can be used when proving the overall lower bound of Theorems 1. Our lower bound holds for any randomised algorithm on its worst case input. This will be achieved by applying *Yao's minimax principle* [16]. As a result, from this point onwards we consider an arbitrary deterministic algorithm running with some fixed array F on a random input of n stream values over the binary alphabet $\Sigma = \{0,1\}$. The algorithm may depend on F. As is common in the literature we will refer to the choice of F and the distribution of stream values as the *hard distribution.*

We will let $U \in \{0,1\}^n$ denote the *update array* which describes a sequence of n update operations corresponding to values that arrive in the stream. We will usually refer to the t-th update as the *arrival* of the value $U[t]$. Observe that just after arrival t, the values

$U[t+1, n-1]$ are still not known to the algorithm. We will proceed under the assumption that before the 0-th update, $U[0]$ arrives, the stream contains at least n symbols chosen arbitrarily from the support of the stream distribution. All logarithms are in base two.

2.1 Notation – Two intervals and a gap

In order to define the concept of information transfer from one interval of arriving values in the stream to another interval of arriving values, we first define the set L which contains the interval lengths that we will consider,

$$L = \left\{ n^{1/4} \cdot (\lg n)^{2i} \;\middle|\; i \in \left\{0, 1, 2, \ldots, \frac{\lg n}{4 \lg\lg n}\right\} \right\}.$$

To avoid cluttering the presentation with floors and ceilings, we assume throughout that the value of n is such that any division or power nicely yields an integer. Whenever it is impossible to obtain an integer we assume that suitable floors or ceilings are used. In particular, L contains only integers.

In contrast to the original information transfer method, we define *three* intervals $[t_0, t_1]$, $[t_1+1, t_2-1]$ and $[t_2, t_3]$, referred to as the *left interval*, the *gap* and the *right interval*, respectively. These intervals are functions of a length $\ell \in L$ and an offset $t \in [n/2]$. The left interval has length $\ell \lg \ell$, the gap has length $4\ell/\lg n$ and the right interval has length ℓ. Precisely we define the following four values:

$$t_0 = t, \qquad t_1 = t_0 + \ell \lg \ell - 1, \qquad t_2 = t_1 + \frac{4\ell}{\lg n} + 1, \qquad t_3 = t_2 + \ell - 1.$$

Formally the values t_0, t_1, t_2 and t_3 are functions of ℓ and t but for brevity we will often write just t_0 instead of $t_0(\ell, t)$, and so on, whenever the parameters ℓ and t are obvious from context.

We now highlight some useful properties of these intervals which are easily verified. First observe that the intervals are disjoint and that all intervals are contained in $[0, n-1]$ for sufficiently large n. Second, suppose that $\ell' \in L$ is one size larger than $\ell \in L$, that is $\ell' = \ell \cdot (\lg n)^2$. For ℓ' the length of the gap is $4\ell'/\lg n$, which is sufficiently large that it spans the length of the left interval, the right interval and the gap associated with ℓ. This second property will be particularly important in proving that we do not over-count cell probes.

2.2 Information transfer over gaps

Towards the definition of information transfer, we define, for $\ell \in L$ and $t \in [n/2]$, the subarray $U_{\ell,t} = U[t_0, \ldots, t_1]$ to represent the $\ell \lg \ell$ values arriving in the stream during the left interval. We define the subarray $A_{\ell,t}$ to represent the ℓ outputs during the right interval $[t_2, \ldots, t_3]$. Lastly we define $\widetilde{U}_{\ell,t}$ to be the concatenation of $U[0, (t_0 - 1)]$ and $U[(t_1+1), (n-1)]$. That is, $\widetilde{U}_{\ell,t}$ contains all values of U except for those in $U_{\ell,t}$.

For $\ell \in L$ and $t \in [n/2]$ we first define the *information transfer to the gap*, denoted $\mathcal{G}_{\ell,t}$, to be the set of memory cells c such that c is probed during the left interval $[t_0, t_1]$ of arriving values and also probed during the arrivals of the values $U[t_1+1, t_2-1]$ in the gap. Similarly we define the information transfer to the right interval, or simply *the information transfer*, denoted $\mathcal{I}_{\ell,t}$, to be the set of memory cells c such that c is probed during the left interval $[t_0, t_1]$ of arriving symbols and also probed during the arrivals of symbols in the right interval $[t_2, t_3]$ but *not* in the gap. That is, any cell $c \in \mathcal{G}_{\ell,t}$ cannot also be contained in the information transfer $\mathcal{I}_{\ell,t}$.

The cells in the information transfer $\mathcal{I}_{\ell,t}$ may contain information about the values in $U_{\ell,t}$ that the algorithm uses in order to correctly produce the outputs $A_{\ell,t}$. However, since cells that are probed in the gap are not included in the information transfer, the information transfer might not contain all the information about the values in $U_{\ell,t}$ that the algorithm uses while outputting $A_{\ell,t}$. We will see that the gap is small enough that a large fraction of the information about $U_{\ell,t}$ has to be fetched from cells in the information transfer $\mathcal{I}_{\ell,t}$.

Since cells in the information transfer are by definition probed at some point by the algorithm, we can use $\mathcal{I}_{\ell,t}$ to measure, or at least give a lower bound for, the number of cell probes. As a shorthand we let $I_{\ell,t} = |\mathcal{I}_{\ell,t}|$ denote the size of the information transfer $\mathcal{I}_{\ell,t}$. Similarly we let $G_{\ell,t} = |\mathcal{G}_{\ell,t}|$ denote the size of the information transfer to the gap. By adding up the sizes $I_{\ell,t}$ of the information transfers over all $\ell \in L$ and certain values of $t \in [n/2]$, we get a lower bound on the total number of cells probed by the algorithm during the n arriving values in U. The choice of the values t is crucial as we do not want to over-count the number of cell probes. In the next two lemmas we will deal with the potential danger of over-counting.

For a cell $c \in \mathcal{I}_{\ell,t}$, we write *the probe of c with respect to $\mathcal{I}_{\ell,t}$* to refer to the first probe of c during the arrivals in the right interval. These are the probes of the cells in the information transfer that we count.

▶ **Lemma 2.** *For any $\ell \in L$ and $t, t' \in [n/2]$ such that $|t - t'| \geq \ell$, if a cell c is in both $\mathcal{I}_{\ell,t}$ and $\mathcal{I}_{\ell,t'}$ then the probe of c with respect to $\mathcal{I}_{\ell,t}$ and the probe of c with respect to $\mathcal{I}_{\ell',t'}$ are distinct.*

Proof. Since t and t' are at least ℓ apart, the right intervals associated with t and t', respectively, must be disjoint. Hence the probe of c with respect to $\mathcal{I}_{\ell,t}$ and the probe of c with respect $\mathcal{I}_{\ell,t'}$ must be distinct. ◀

From the previous lemma we know that there is no risk of over-counting cell probes of a cell over information transfers $\mathcal{I}_{\ell,t}$ under a fixed value of $\ell \in L$, as long as no two values of t are closer than ℓ. The proof follows directly from the fact that as $|t - t'| \geq \ell$, the corresponding right intervals for t and t' do not overlap. Distinctness then follows directly from the definition of information transfer. In the next lemma we consider information transfers under different values of $\ell \in L$. The proof follows from the property introduced in Section 2.1 that if (wlog.) $\ell' > \ell$, the gap associated with ℓ' is spans all three intervals associated with ℓ. This implies that either the right intervals for t and t' do not overlap or the left intervals do not overlap. In either case, once again, distinctness follows directly from the definition of information transfer.

▶ **Lemma 3.** *For any $\ell, \ell' \in L$ such that $\ell \neq \ell'$, and any $t, t' \in [n/2]$, if a cell c is in both $\mathcal{I}_{\ell,t}$ and $\mathcal{I}_{\ell',t'}$ then the probe of c with respect to $\mathcal{I}_{\ell,t}$ and the probe of c with respect to $\mathcal{I}_{\ell',t'}$ must be distinct.*

Proof. Let p be the probe of c with respect to $\mathcal{I}_{\ell,t}$, and let p' be the probe of c with respect $\mathcal{I}_{\ell',t'}$. We will show that $p \neq p'$. Suppose without loss of generality that $\ell < \ell'$. From the properties of the intervals that were given in the previous section we know that the length of the gap associated with ℓ' is larger than the sum of lengths of the left interval, the gap and the right interval associated with ℓ.

Suppose for contradiction that $p = p'$. By definition of $\mathcal{I}_{\ell,t}$, the cell c is probed also in the left interval associated with ℓ. Let p_{first} denote any such cell probe. Because the gap associated with ℓ' is so large, p_{first} must take place either in the right interval or the gap associated with ℓ'. If p_{first} is in the gap, then c cannot be in $\mathcal{I}_{\ell',t'}$. If p_{first} is in the right interval then p' cannot equal p. ◀

In order to give a lower bound for the total number of cell probes performed by the algorithm over the n arrivals in U we will define, for each $\ell \in L$, a set $T_\ell \subseteq [n/2]$ of arrivals, such that for any distinct $t, t' \in T_\ell$, $|t - t'| \geq \ell$. It then follows from Lemmas 2 and 3 that

$$\sum_{\ell \in L} \sum_{t \in T_\ell} I_{\ell,t}$$

is a lower bound on the number of cell probes. Our goal is to give a lower bound for the expected value of this double-sum. The exact definition of T_ℓ will be given in Section 3.3 once we have introduced relevant notation.

3 Proving the lower bound

In this section we give the overall proof for the lower bound of Theorem 1. Let $\ell \in L$ and let $t \in [n/2]$. Suppose that $\widetilde{U}_{\ell,t}$ is fixed but the values in $U_{\ell,t}$ are drawn at random in accordance with the distribution for U, conditioned on the fixed value of $\widetilde{U}_{\ell,t}$. This induces a distribution for the outputs $A_{\ell,t}$. We want to show that if the entropy of $A_{\ell,t}$ is large, conditioned on the fixed $\widetilde{U}_{\ell,t}$, then the information transfer $\mathcal{I}_{\ell,t}$ is large, since only the variation in the inputs $U_{\ell,t}$ can alter the outputs $A_{\ell,t}$. We will soon make this claim more precise.

3.1 Upper bound on entropy

We write $H(A_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t})$ to denote the entropy of $A_{\ell,t}$ conditioned on fixed $\widetilde{U}_{\ell,t}$. Towards showing that high conditional entropy $H(A_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t})$ implies large information transfer we use the information transfer $\mathcal{I}_{\ell,t}$ and the information transfer to the gap, $\mathcal{G}_{\ell,t}$, to describe an encoding of the outputs $A_{\ell,t}$. The following lemma gives a direct relationship between $I_{\ell,t} + G_{\ell,t}$ and the entropy which is applicable to both of our online problems. A marginally simpler version of the lemma, stated with different notation, was first given in [14] under the absence of gaps.

▶ **Lemma 4.** *Under the assumption that the address of any cell can be specified in w bits, for any $\ell \in L$ and $t \in [n/2]$, the entropy $H(A_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t}) \leq 2w + 2w \cdot \mathbb{E}[I_{\ell,t} + G_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t}]$.*

Proof. The expected length of any encoding of $A_{\ell,t}$ under fixed $\widetilde{U}_{\ell,t}$ is an upper bound on the conditional entropy of $A_{\ell,t}$. We use the information transfer $\mathcal{I}_{\ell,t}$ and the information transfer to the gap, $\mathcal{G}_{\ell,t}$, to define an encoding of $A_{\ell,t}$ in the following way. For every cell $c \in \mathcal{I}_{\ell,t} \cup \mathcal{G}_{\ell,t}$ we store the address of c, which takes at most w bits under the assumption that a cell can hold the address of any cell in memory. We also store the contents of c that it holds at the very end of the left interval, just before the beginning of the gap. The contents of c is specified with w bits. In total this requires $2w \cdot (I_{\ell,t} + G_{\ell,t})$ bits.

We will use the algorithm, which is fixed, and the fixed values $\widetilde{u}_{\ell,t}$ of $\widetilde{U}_{\ell,t}$ as part of the decoder to obtain $A_{\ell,t}$ from the encoding. Since the encoding is of variable length we also store the size $I_{\ell,t}$ of the information transfer and the size $G_{\ell,t}$ of the information transfer to the gap. This requires at most $2w$ additional bits.

In order to prove that the described encoding of $A_{\ell,t}$ is valid we now describe how to decode it. First we simulate the algorithm on the fixed input $\widetilde{U}_{\ell,t}$ from the first arrival $U[0]$ until just before the left interval when the first value in $U_{\ell,t}$ arrives. We then skip over all inputs in $U_{\ell,t}$ and resume simulating the algorithm from the beginning of the gap, that is when the value $U[t_1+1]$ arrives. We simulate the algorithm over the arrivals in the gap and the right interval until all values in $A_{\ell,t}$ have been outputted. For every cell being read, we check if it is contained in either the information transfer $\mathcal{I}_{\ell,t}$ or the information transfer to the gap $\mathcal{G}_{\ell,t}$ by looking up its address in the encoding. If the address is found then the contents of the cell is fetched from the encoding. If not, its contents is available from simulating the algorithm on the fixed inputs $\widetilde{U}_{\ell,t}$. ◀

3.2 Lower bound on entropy

Lemma 4 above provides a direct way to obtain a lower bound on the expected value of $I_{\ell,t}+G_{\ell,t}$ if given a lower bound on the conditional entropy $H(A_{\ell,t} \mid \widetilde{U}_{\ell,t}=\widetilde{u}_{\ell,t})$. In Lemma 5 we provide such an entropy lower bound for L_2-rearrangement distance. The proof is deferred to Section 4.

▶ **Lemma 5.** *For the L_2-rearrangement distance problem there exists a real constant $\kappa>0$ and, for any n, a fixed array $F\in\{0,1\}^n$ such that for all $\ell\in L$ and all $t\in[n/2]$ such that $t \bmod 4 = 0$, when U is chosen uniformly at random from $\{0101,1010\}^{\frac{n}{4}}$ then,*

$$H(A_{\ell,t} \mid \widetilde{U}_{\ell,t}=\widetilde{u}_{\ell,t}) \geq \kappa\cdot\ell\cdot\lg n, \text{ for any fixed } \widetilde{u}_{\ell,t}.$$

Before we proceed with the lower bound on the information transfer we make a short remark on the bounds that this lemmas gives. Observe that the maximum conditional entropy of $A_{\ell,t}$ is bounded by the entropy of $U_{\ell,t}$, which is $O(\ell\lg\ell)$ since the length of the left interval is $\ell\lg\ell$. Recall also that the values in L range from $n^{1/4}$ to $n^{3/4}$. Thus, for a constant κ, the entropy lower bound is tight up to a multiplicative constant factor.

3.3 A lower bound on the information transfer and quick gaps

In this section we prove our main lower bound results. We assume that κ is the constant and F is the fixed array of Lemma 5, and that U is chosen uniformly at random from $\{0101,1010\}^{\frac{n}{4}}$.

By combining the upper and lower bounds on the conditional entropy from Lemmas 4 and 5 we have that there is a hard distribution and a real constant $\kappa>0$ such that,

$$\mathbb{E}[I_{\ell,t}+G_{\ell,t} \mid \widetilde{U}_{\ell,t}=\widetilde{u}_{\ell,t}] \geq \frac{\kappa\cdot\ell\cdot\lg n}{2w}-1 \text{ for any } \widetilde{u}_{\ell,t}.$$

We may remove the conditioning by taking expectation over $\widetilde{U}_{\ell,t}$ under random U. Thus,

$$\mathbb{E}[I_{\ell,t}+G_{\ell,t}] \geq \frac{\kappa\cdot\ell\cdot\lg n}{2w}-1, \text{ or equivalently,}$$

$$\mathbb{E}[I_{\ell,t}] \geq \frac{\kappa\cdot\ell\cdot\lg n}{2w}-1-\mathbb{E}[G_{\ell,t}]. \tag{1}$$

Recall that our goal is to give a lower bound for

$$\mathbb{E}\left[\sum_{\ell\in L}\sum_{t\in T_\ell} I_{\ell,t}\right]=\sum_{\ell\in L}\sum_{t\in T_\ell}\mathbb{E}\left[I_{\ell,t}\right], \text{ where } T_\ell \text{ contains suitable values of } t.$$

Using inequality (1) would immediately provide such a lower bound, however, there is an imminent risk that the $\mathbb{E}[G_{\ell,t}]$ terms could devalue such a bound into something trivially small. Now, for this to happen, the algorithm must perform sufficiently many cell probes in the gap. Since the length of the gap is considerably shorter than the right interval, a cap on the worst-case number of cell probes per arriving value would certainly ensure that $\mathbb{E}[G_{\ell,t}]$ stays small, but as we want a stronger amortised lower bound we need something more refined. The answer lies in how we define T_ℓ. We discuss this next.

For $\ell \in L$ and $f \in [\ell]$ we first define $T_{\ell,f} = \left\{ f + i\ell \;\middle|\; i \in \{0,1,2,\dots\} \text{ and } f + i\ell \leq \frac{n}{2} \right\}$ to be the set of arrivals. The values in $T_{\ell,f}$ are evenly spread out, distance ℓ apart, starting at f. We may think of f as the offset of the sequence of values in $T_{\ell,f}$. The largest value in the set is no more than $n/2$. We will define the set T_ℓ to equal a subset of one of the sets $T_{\ell,f}$ for some f. More precisely, we will show that there must exist an offset f such that at least half of the values $t \in T_{\ell,f}$ have the property that the time spent in the gap associated with ℓ and t is small enough to ensure that the information transfer to the gap is small. We begin with some definitions.

▶ **Definition 6** (Quick gaps and sets). For any $\ell \in L$ and $t \in [n/2]$ we say that the gap associated with ℓ and t is *quick* if the expected number of cell probes during the arrivals in the gap is no more than $\kappa\ell \lg n/(4w)$, where κ is the constant from Lemma 5. Further, for any $f \in [\ell]$ we say that the set $T_{\ell,f}$ is *quick* if, for at least half of all $t \in T_{\ell,f}$, the gap associated with ℓ and t is quick.

The next lemma says that for sufficiently fast algorithms there is always an offset f such that $T_{\ell,f}$ is quick. The proof intuition is that if $T_{\ell,f}$ is not quick for any offset f then the whole algorithm must be slow which gives a contradiction.

▶ **Lemma 7.** *Suppose that the expected total number of cell probes over the n arrivals in U is less than $\kappa n(\lg^2 n)/(32w)$. Then, for any $\ell \in L$, there is an $f \in [\ell]$ such that $T_{\ell,f}$ is quick.*

Proof. In accordance with the lemma, suppose that the expected total number of cell probes over the n arrivals in U is less than $\kappa n(\lg^2 n)/(32w)$. For contradiction, suppose that there is no $f \in [\ell]$ such that $T_{\ell,f}$ is quick. We will show that the expected number of cell probes over the n arrivals must then be at least $\kappa n(\lg^2 n)/(32w)$.

For any $f \in [\ell]$, let $R_f \subseteq [n]$ be the union of all arrivals that belong to a gap associated with ℓ and any $t \in T_{\ell,f}$. Let P_f be the number of cell probes performed by the algorithm over the arrivals in R_f. Thus, for any set $T_{\ell,f}$ that is *not quick* we have by linearity of expectation $\mathbb{E}[P_f] \geq \frac{|T_{\ell,f}|}{2} \cdot \frac{\kappa \cdot \ell \cdot \lg n}{4w} = \frac{n/2}{2\ell} \cdot \frac{\kappa \cdot \ell \cdot \lg n}{4w} = \frac{\kappa \cdot n \cdot \lg n}{8w}$.

Let the set of offsets $\mathcal{F} = \left\{ i \cdot \frac{4\ell}{\lg n} \;\middle|\; i \in \left[\frac{\lg n}{4}\right] \right\} \subseteq [\ell]$. The values in $\mathcal{F}$ are spread out with distance $4\ell/\lg n$, which equals the gap length. Thus, for any two distinct $f, f' \in \mathcal{F}$, the sets R_f and $R_{f'}$ are disjoint. We therefore have that the total running time over all n arrivals in U must be bounded below by $\sum_{f\in\mathcal{F}} P_f$. Under the assumption that no $T_{\ell,f}$ is quick, we have that the expected total running time is at least $\mathbb{E}\left[\sum_{f\in\mathcal{F}} P_f\right] = \sum_{f\in\mathcal{F}} \mathbb{E}[P_f] \geq |\mathcal{F}| \cdot \frac{\kappa \cdot n \cdot \lg n}{8w} = \frac{\lg n}{4} \cdot \frac{\kappa \cdot n \cdot \lg n}{8w} = \frac{\kappa \cdot n \cdot \lg^2 n}{32w}$, which is the contradiction we wanted. Thus, under the assumption that the running time over the n arrivals in U is less than $\kappa n(\lg^2 n)/(32w)$ there must be an $f \in [\ell]$ such that $T_{\ell,f}$ is quick. ◀

We now proceed under the assumption that the expected running time over the n arrivals in U is less than $\kappa n(\lg^2 n)/(32w)$. If this is not the case then we have already established the lower bound of Theorem 1.

Let f be a value in $[\ell]$ such that $T_{\ell,f}$ is a quick set. Such an f exists due to Lemma 7. We now let $T_\ell \subseteq T_{\ell,f}$ be the set of all $t \in T_{\ell,f}$ for which the gap associated with ℓ and t is quick. Hence $|T_\ell| \geq |T_{\ell,f}|/2 = n/(4\ell)$. Since $G_{\ell,t}$ cannot be larger than the number of cell probes in the gap, we have by the definition of a quick gap that for any $t \in T_\ell$,

$$\mathbb{E}\left[G_{\ell,t}\right] \leq \frac{\kappa \cdot \ell \cdot \lg n}{4w}.$$

By combining the inequalities we can finally provide a non-trivial lower bound on the sum of the information transfers:

$$\begin{aligned}
\sum_{\ell \in L, t \in T_\ell} \mathbb{E}\left[I_{\ell,t}\right] &\geq \sum_{\ell \in L, t \in T_\ell} \left(\frac{\kappa \cdot \ell \cdot \lg n}{2w} - 1 - \mathbb{E}[G_{\ell,t}]\right) \\
&\geq \sum_{\ell \in L, t \in T_\ell} \left(\frac{\kappa \cdot \ell \cdot \lg n}{2w} - 1 - \frac{\kappa \cdot \ell \cdot \lg n}{4w}\right) \geq \frac{\kappa \cdot \lg n}{5w} \sum_{\ell \in L, t \in T_\ell} \ell \\
&\geq \frac{\kappa \cdot \lg n}{5w} \sum_{\ell \in L} (|T_\ell| \cdot \ell) \geq \frac{\kappa \cdot \lg n}{5w} \sum_{\ell \in L} \left(\frac{n}{4\ell} \cdot \ell\right) = \frac{\kappa \cdot n \cdot \lg n}{20w} \cdot |L| \\
&\geq \frac{\kappa \cdot n \cdot \lg n}{20w} \cdot \frac{\lg n}{4 \lg \lg n} \in \Theta\left(\frac{n \cdot \lg^2 n}{w \cdot \lg \lg n}\right).
\end{aligned}$$

By Lemmas 2 and 3 this lower bound is also a bound on the expected total number of cell probes performed by the algorithm over the n arrivals in U. The amortised time per arriving value is obtained by dividing the running time by n, concluding the proof of Theorem 1.

4 The hard distribution for L_2-rearrangement

In this section we prove Lemma 5. Recall that U is chosen uniformly at random from $\{0101, 1010\}^{\frac{n}{4}}$. For each $\ell \in L$ there is a subarray of F of length $\ell \lg \ell + \ell$. Each such subarray, which we denote F_ℓ, is at distance $4\ell/\lg n + 1$ from the right-hand end of F, which is one more than the length of the gap associated with ℓ. By the properties discussed in Section 2.1 we know that the length of the gap associated with ℓ' is larger than the length of F_ℓ plus the length of the gap associated with ℓ. Hence there is no overlap between the subarrays F_ℓ and $F_{\ell'}$.

Given any of the subarrays F_ℓ and an array U_ℓ of length $(\ell \lg \ell)$, we write $F_\ell \odot U_\ell$ to denote the $(\ell/4)$-length array that consists of the L_2-rearrangement distances between U_ℓ and every *fourth* $(\ell \lg \ell)$-length substring of F_ℓ. More precisely, for $4i \in [\ell]$, the value of $F_\ell \odot U_\ell[i]$ is the L_2-rearrangement distance between $F_\ell[4i, 4i + \ell \lg \ell - 1]$ and U_ℓ.

The main focus of this section is proving Lemma 8 which can be seen as an analogue of Lemma 5 for a fixed length of ℓ:

▶ **Lemma 8.** *There exists a real constant $\epsilon > 0$ such that for all n and $\ell \in L$ there is a subarray F_ℓ for which the entropy of $F_\ell \odot U_\ell$ is at least $\epsilon \cdot \ell \lg \ell$ when U_ℓ is drawn uniformly at random from $\{0101, 1010\}^{\frac{\ell}{4} \lg \ell}$. F_ℓ contains an equal number of 0s and 1s.*

In order to finish the description of the array F we choose each subarray F_ℓ in accordance with Lemma 8. Any region of F that is not part of any of the subarrays F_ℓ is filled with repeats of '01'. This ensures that these regions contain an equal number of zeros and ones. This concludes the description of the array F.

The proof of Lemma 5 then follows from Lemma 8 by arguing that the outputs in $F_\ell \odot U_\ell$ can be calculated from the outputs in $A_{\ell,t}$ by subtracting the contributions from $F_{\ell'} \odot U_{\ell'}$ for all $\ell' \neq \ell$. As each required value from $U_{\ell'}$ is contained in $\widetilde{U}_{\ell,t}$ which is fixed to equal $\widetilde{u}_{\ell,t}$, we have that $H(A_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t}) \geq H(F_\ell \odot U_\ell)$ as required. This argument requires that for each output, the globally optimal (lowest cost) permutation is always compatible with the locally optimal permutation of each U_ℓ. In particular we need to rule out the possibility of characters from some U_ℓ being moved to positions in $F_{\ell'}$ for $\ell \neq \ell'$. The proof (and the lower bound in general) relies on a key property of L_2-arrangement (proven in Lemma 3.1 from [1]) which states that under the optimal permutation, the i-th one (resp. zero) in one string is moved to the i-th one (resp. zero) in the other. By controlling how the zeros and ones are distributed in U and F, we can limit how far any character is moved. For brevity the details are left for the full version.

We are now ready to prove Lemma 5, the lower bound on the conditional entropy of $A_{\ell,t}$.

Proof of Lemma 5. Let F be the array described above and let U be drawn uniformly at random from $\{0101, 1010\}^{\frac{n}{4}}$. Let $\ell \in L$ and $t \in [n/2]$. Thus, conditioned on any fixed $\widetilde{U}_{\ell,t}$, the distribution of $U_{\ell,t}$ is uniform on $\{0101, 1010\}^{\frac{\ell}{4}\lg \ell}$.

Recall that $U_{\ell,t}$ arrives in the stream between arrival t_0 and t_1, after which $4\ell/\lg n$ values arrive in the gap. Thus, at the beginning of the right interval, at arrival t_2, $U_{\ell,t}$ is aligned with the $(\ell \lg \ell)$-length suffix of the subarray F_ℓ of F. Over the ℓ arrivals in the right interval, $U_{\ell,t}$ slides along F_ℓ. We now prove that since all values in $\widetilde{U}_{\ell,t}$ are fixed, the outputs $A_{\ell,t}$ uniquely specify $F_\ell \odot U_{\ell,t}$. The analogous property for convolution was immediate. First observe that by construction the prefix of F up to the start of F_ℓ contains an equal number of 0s and 1s. Similarly for F_ℓ itself and the suffix from F_ℓ to the end of F. Once in every four arrivals, the substring of U aligned with F is guaranteed (by construction) to also have an equal number of 0s and 1s. Therefore the L_2-rearrangement distance is finite. It was proven in Lemma 3.1 from [1] that (rephrased in our notation) under the optimal rearrangement permutation, the k-th one (resp. zero) in F is moved to the k-th one (resp. zero) in U. Therefore, every element of U_ℓ is moved to an element in F_ℓ. We can therefore recover any output in $F_\ell \odot U_{\ell,t}$ by taking the corresponding output in $A_{\ell,t}$ and subtracting, the costs of moving the elements that are in U but not in U_ℓ. It is easily verified that as t is divisible by four, the corresponding output in $A_{\ell,t}$ is one of those guaranteed to have an equal number of 0s and 1s. Thus, by Lemma 8, the conditional entropy

$$H(A_{\ell,t} \mid \widetilde{U}_{\ell,t} = \widetilde{u}_{\ell,t}) \geq \epsilon \cdot \ell \cdot \lg \ell, \geq \frac{\epsilon}{4} \cdot \ell \cdot \lg n,$$

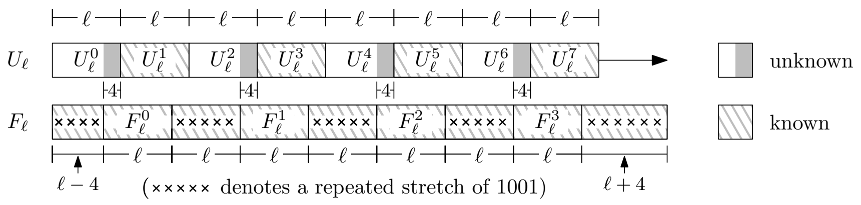
since $\ell \geq n^{1/4}$. By setting the constant κ to $\epsilon/4$ we have proved Lemma 5. ◀

4.1 High entropy for fixed ℓ – the proof of Lemma 8

In this section we prove Lemma 8. We begin by explaining the high-level approach which will make one final composition of both F_ℓ and U_ℓ into subarrays. For any $j \geq 0$, let $U_\ell^j = U_\ell[\ell \cdot j, \ell \cdot (j+1) - 1]$ i.e. U_ℓ^j is the j-th consecutive ℓ-length subarray of U_ℓ. The key property that we will need is given in Lemma 9 which intuitively states that given half of the bits in U_ℓ, we can compute the other half with certainty.

▶ **Lemma 9.** *Let U_ℓ be chosen arbitrarily from $\{0101, 1010\}^{\frac{\ell}{4}}$. Given F_ℓ, $F_\ell \odot U_\ell$ and U_ℓ^{2j+1} for all $j \geq 0$, it is possible to uniquely determine U_ℓ^{2j} for all $j \geq 0$.*

We briefly justify why Lemma 8 is in-fact a straight-forward corollary of Lemma 9. If we pick U_ℓ uniformly at random from $\{0101, 1010\}^{\frac{\ell}{4}}$ then by Lemma 9, the conditional entropy, $H(F_\ell \odot U_\ell \mid U_\ell^{2j+1}$ for all $j)$ is $\Omega(\ell \lg \ell)$. This is because we always recover $\Theta(\lg \ell)$ distinct U_ℓ^{2j}, each of which is independent and has entropy $\Omega(\ell)$ bits. It then immediately follows that $H(F_\ell \odot U_\ell) \geq H(F_\ell \odot U_\ell \mid U_\ell^{2j+1}$ for all $j)$ as required. We also require for Lemma 8 that F_ℓ



U_ℓ
U_ℓ^0 U_ℓ^1 U_ℓ^2 U_ℓ^3 U_ℓ^4 U_ℓ^5 U_ℓ^6 U_ℓ^7
ℓ
4
F_ℓ
F_ℓ^0 F_ℓ^1 F_ℓ^2 F_ℓ^3
$\ell - 4$
(××××× denotes a repeated stretch of 1001)
$\ell + 4$
unknown
known

Figure 1 We can determine $U_\ell^{2j}[\ell-4,\ell-1]$ if we know F_ℓ, every U_ℓ^{2j+1} and $F_\ell \odot U_\ell$.

contains an equal number ones and zeros. This follows immediately from the description of F_ℓ below.

4.2 The subarray F_ℓ

We now give the description of F_ℓ which requires one final decomposition into subarrays which is also shown in Figure 1 below. For each $j \in [\lfloor(\lg \ell)/2\rfloor]$, F_ℓ contains a subarray F_ℓ^j of length ℓ. Intuitively, each subarray F_ℓ^j will be responsible for recovering U_ℓ^{2j}. These subarrays occur in order in F_ℓ. Before and after each F_ℓ^j there are stretches of repeats of the string 1001. Specifically, before F_ℓ^1 there are $\ell/4-1$ repeats the string 1001. Between each F_ℓ^j and F_ℓ^{j+1} there are $\ell/4$ repeats of the string 1001 and after $F_\ell^{\lfloor(\lg \ell)/2\rfloor-1}$ there are $\ell/4+1$ repeats. These repeats of 1001 are simply for structural padding and as we will see the contribution of these repeated 1001 strings to the L_2-rearrangement distance is independent of U_ℓ. This follows because the cost of permuting 1001 into 1010 or 0101 is always 2.

Finally, the structure of F_ℓ^j is as follows $F_\ell^j = 10^{(2^j+3)}1^{(\ell/4-1)}0^{(\ell/4-(2^j+3))}$. Here 0^z (resp. 1^z) is a string of z zeros (resp. ones). Intuitively, the reason that the stretch of 0s at the start of F_ℓ^j is the exponentially increasing with j is so that the number of positions the second one in F_ℓ^j (immediately after the stretch of 0s) is forced to move is also exponentially increasing with j as demonstrated in Figure 2 below. This is will allow us to recover each U_ℓ^{2j} from a different bit in the outputs. This will claim will be made precise in the proof below.

4.3 Recovering half of the updates – the proof of Lemma 9

We are now in a position to prove Lemma 9. Our main focus will be on first proving that given F_ℓ, U_ℓ^{2j+1} for all j and $F_\ell \odot U_\ell$, we can uniquely determine $U_\ell^{2j}[\ell-4,\ell-1]$ for each $j \geq 0$. That is, for each j whether the last four symbols of U_ℓ^{2j} are 0101 or 1010. This is shown diagrammatically in Figure 1. We will then argue that by a straight-forward repeated application of this argument we can in-fact recover the whole of U_ℓ^{2j} for all $j \geq 0$.

We will begin by making some simplifying observations about $(F_\ell \odot U_\ell)[0]$. Recall that $(F_\ell \odot U_\ell)[0]$ was defined to be the L_2-rearrangement distance between $F_\ell[0,|U_\ell|-1]$ and U_ℓ. The first observation is that the distance is finite because both strings contain an equal number of zeros and ones.

The L_2-rearrangement distance $(F_\ell \odot U_\ell)[0]$ can be expressed as the sum of the *contributions* from moving each $U_\ell[i]$, over all $i \in [m]$. Let the contribution of $U_\ell[i]$, denoted, $\mathrm{CT}(i)$ be the square of the number of positions that $U_\ell[i]$ is moved by under the optimal permutation. We then have that $(F_\ell \odot U_\ell)[0] = \sum_i \mathrm{CT}(j)$. Finally, we let $D^\star$ be the sum of the contributions of the locations in every $U_\ell^{2j}[\ell-4,\ell-1]$, i.e. $D^\star = \sum_j \sum_{k=0}^{3} (\mathrm{CT}(2j\cdot\ell+(\ell-4)+k)$. We will also refer to the contribution of a substring which is defined naturally to be the sum of the contributions of its constituent characters. For example the contribution of the substring U_ℓ^j is equal to $\sum\{\mathrm{CT}(r) \,|\, r \in [\ell\cdot j, \ell\cdot(j+1)-1]\}$.

Our proof will be in two stages. First we will prove in Lemma 10 that we can compute $D^\star$ from F_ℓ, $F_\ell \odot U_\ell$ and U_ℓ^{2j+1} for all $j \geq 0$. Second we will prove that for any $j > 0$, we can determine $U_\ell^{2j}[\ell-4, \ell-1]$ from $D^\star$.

In the proof of Lemma 10 we argue that $D^\star$ can be calculated directly from $(F_\ell \odot U_\ell)[0]$ by subtracting the contributions of U_ℓ^{2j+1} and $U_\ell^{2j}[0, \ell-5]$ for all $j \geq 0$. More specifically, we will prove that the contribution of any U_ℓ^{2j+1} can calculated from U_ℓ^{2j+1} and F_ℓ, which are both known. In particular, the contribution of any U_ℓ^{2j+1} is independent of every unknown U_ℓ^{2j}. Further, we will prove that although U_ℓ^{2j} is unknown, the contribution of $U_\ell^{2j}[0, \ell-5]$, always equals $\ell/2 - 2$, regardless of the choice of U_ℓ.

▶ **Lemma 10.** *$D^\star$ can be computed from F_ℓ, $F_\ell \odot U_\ell$ and U_ℓ^{2j+1} for all $j \geq 0$.*

Proof. In this proof we rely heavily on Lemma 3.1 from [1] which states that under the optimal permutation, the i-th one (resp. zero) in U_ℓ is moved to the i-th one (resp. zero) in $F_\ell[0, |U_\ell|-1]$. For any j, consider, U_ℓ^{2j} and U_ℓ^{2j+1}. The number of ones in U_ℓ^{2j} (resp. U_ℓ^{2j+1}) is fixed, independent of the choice of U_ℓ. In particular there are exactly $\ell/2$ zeros and $\ell/2$ ones. It is easily verified that, by construction, $F_\ell[2j \cdot \ell, (2j+2)\cdot\ell - 1]$ also contains exactly ℓ zeros and ℓ ones. Therefore, the i-th one (resp. zero) in U_ℓ^{2j} is moved to the i-th one (resp. zero) in $F_\ell[2j \cdot \ell, (2j+2)\cdot\ell - 1]$. Similarly, the i-th one (resp. zero) in U_ℓ^{2j} is moved to the $(i+\ell/2)$-th one (resp. zero) in $F_\ell[2j \cdot \ell, (2j+2)\cdot\ell - 1]$

Consider any U_ℓ^{2j+1} which is known. By the above observation, we can therefore determine which position in $F_\ell[2j \cdot \ell, (2j+2)\cdot\ell - 1]$, each character in U_ℓ^{2j+1} is moved to under the optimal permutation. From this we can then directly compute the contribution of each U_ℓ^{2j+1} to $(F_\ell \odot U_\ell)[0]$.

Consider any U_ℓ^{2j} which is unknown. As observed above, the i-th one (resp. zero) in U_ℓ^{2j} is moved to the i-th one (resp. zero) in $F_\ell[2j \cdot \ell, (2j+2)\cdot\ell - 1]$. By construction, we have that $F_\ell[2j \cdot \ell, (2j+1)\cdot\ell - 5]$ consists entirely of repeats of 1001. Further for any i, we have that $U_\ell^{2j}[4i, 4i+3]$ is either 1010 or 0101. Therefore for all $i < \ell/4$ we have that the two ones (resp. zeros) in $U_\ell^{2j}[4i, 4i+3]$ are moved to the two ones (resp. zeros) in $F_\ell[2j \cdot \ell + 4i, 2j \cdot \ell + 4i + 3] = 1001$. The key observation is that regardless of whether $U_\ell^{2j}[4i, 4i+3] = 1010$ or 0101, the contribution of $U_\ell^{2j}[4i, 4i+3]$ is 2. Therefore for any U_ℓ, the contribution of $U_\ell^{2j}[0, \ell-5]$ is always $\ell/2 - 2$.

Finally, the value of $D^\star$ is can be calculated directly from $(F_\ell \odot U_\ell)[0]$ as claimed by subtracting the calculated contributions of U_ℓ^{2j+1} and $U_\ell^{2j}[0, \ell-5]$ for all $j \geq 0$. ◀

In Lemma 12 we will prove that we can compute $U_\ell^{2j}[\ell-4, \ell-1]$ from $D^\star$ (for any sufficiently large j). The intuition behind this is given by Lemma 11 which gives an explicit formula for the contribution of $U_\ell^{2j}[\ell-4, \ell-1]$. Observe that the contribution depends only on whether $U_\ell^{2j}[\ell-4, \ell-1]$ equals 1010 ($v_j = 1$) or 0101 ($v_j = 0$). In the proof we begin by arguing that under the optimal permutation, the two ones (resp. zeros) in $U_\ell^{2j}[\ell-4, \ell-1]$ are moved to the leftmost two ones (resp. zeros) in F_ℓ^j as illustrated in Figure 2. The key observation is that regardless of whether v_j equals 0 or 1, by construction the right one in $U_\ell^{2j}[\ell-4, \ell-1]$ is moved exponentially far (as a function of j). Furthermore, in the $v_j = 1$ case the right one moves one position further than in the $v_j = 0$ case. As the contribution is the square of the number of positions a character moves, this creates a exponentially large change in the contribution. The exact contribution given in the Lemma can be calculated straightforwardly by considering each of the four symbols in $U_\ell^{2j}[\ell-4, \ell-1]$ individually.

▶ **Lemma 11.** *For any j, let $v_j = 1$ if $U_\ell^{2j}[\ell-4, \ell-1] = 1010$ and $v_j = 0$ otherwise. The contribution of $U_\ell^{2j}[\ell-4, \ell-1]$ is exactly $v_j \cdot 2^{j+1} + 2^{2j} + 2$.*

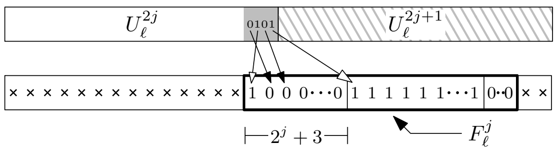


Figure 2 The permutation of the symbols in $U_\ell^{2j}[\ell-4,\ell-1]$ under the optimal permutation. The highlighted region is F_ℓ^j.

We can now prove Lemma 12 which follows almost immediately from Lemma 11.

▶ **Lemma 12.** *For any $j \geq 0$, it is possible to compute $U_\ell^{2j}[\ell-4,\ell-1]$ from $D^\star$.*

Proof. Let $D_2^\star$ equal $D^\star - \sum_j(2^{2j}+2)$ which can be calculated directly from $D^\star$. An alternative and equivalent definition of $D_2^\star$ follows from Lemma 11 and is given by $D_2^\star = \sum_j v_j \cdot 2^{j+1}$. We can therefore compute v_j and hence $U_\ell^{2j}[\ell-4,\ell-1]$ by inspecting the $(j+1)$-th bit in the binary representation of $D_2^\star$. ◀

Recall from Lemma 10 that $D^\star$ can in turn be computed from F_ℓ, $F_\ell \odot U_\ell$ and U_ℓ^{2j+1} for all $j \geq 0$. Therefore as claimed, given F_ℓ, $F_\ell \odot U_\ell$ and U_ℓ^{2j+1} for all $j \geq 0$, we can uniquely determine $U_\ell^{2j}[\ell-4,\ell-1]$ for each $j \geq 0$. Lemma 9 now follows almost immediately by repeat application of this argument as we now set out.

Recovering the rest of $U_{\ell,(2j)}$

So far we have only proven that we can recover $U_\ell^{2j}[\ell-4,\ell-1]$ for all j. The claim that we can in-fact recover the whole of U_ℓ^{2j} follows by repeatedly application of the argument above. Specifically, once we have recovered $U_\ell^{2j}[\ell-4,\ell-1]$ for all j, we can use this additional information (and $(F_\ell \odot U_\ell)[1]$ instead of $(F_\ell \odot U_\ell)[0]$) to recover $U_\ell^{2j}[\ell-8,\ell-5]$ for all j and so on. More formally we proceed by induction on increasing k by observing that using the above argument given F_ℓ, $(F_\ell \odot U_\ell)[k]$, U_ℓ^{2j+1} for all $j \geq 0$ and $U_\ell^{2j+1}[\ell-4k,\ell-1]$ for all $j \geq 0$ we can recover $U_\ell^{2j+1}[\ell-4k-4,\ell-4k-1]$ for all j.

Stochastic Streams: Sample Complexity vs. Space Complexity

Abstract

We address the trade-off between the computational resources needed to process a large data set and the number of samples available from the data set. Specifically, we consider the following abstraction: we receive a potentially infinite stream of IID samples from some unknown distribution D, and are tasked with computing some function $f(D)$. If the stream is observed for time t, how much memory, s, is required to estimate $f(D)$? We refer to t as the sample complexity and s as the space complexity. The main focus of this paper is investigating the trade-offs between the space and sample complexity. We study these trade-offs for several canonical problems studied in the data stream model: estimating the collision probability, i.e., the second moment of a distribution, deciding if a graph is connected, and approximating the dimension of an unknown subspace. Our results are based on techniques for simulating different classical sampling procedures in this model, emulating random walks given a sequence of IID samples, as well as leveraging a characterization between communication bounded protocols and statistical query algorithms.

1 Introduction

Big data systems must process data at multiple levels of a hierarchy, starting at local per-process or per-container monitoring and extending up to aggregate statistics for entire databases or data centers. When designing monitoring or analytics for these systems, some of the first decisions which must be made are which levels of the hierarchy should hold the analytics, and consequently what computational resources are available for processing data without introducing significant overhead. In this paper, we initiate the theoretical investigation of one of the fundamental trade-offs involved in architecting these systems: the amount of memory needed to process incoming data and the total amount of data the system must collect.

In algorithmic terms, we consider the following abstraction: we receive a stream of IID samples from some unknown distribution D, and are tasked with estimating some function $f(D)$ of the distribution. Two natural questions about this task have been studied extensively:

* This work was partially supported by NSF Awards CCF-0953754, CCF-1320719, and a Google Research Award.

1. The statistics question is how to bound the *sample complexity*: how many samples are required to estimate $f(D)$ to some prescribed accuracy with high probability?
2. The data stream question is how to bound the *space complexity*: how much memory is required to compute or approximate the estimator for $f(D)$?

In real systems, of course, both questions are important. Requiring more samples adds processing overhead to the system, and increases the time necessary for the system to detect and react to changes in the underlying distribution. Requiring additional memory increases the overhead on the system, and may make some analytics impractical, or require them to be relocated to separate machines or systems.

Despite the clear importance of this trade-off, our work is the first to our knowledge which explicitly examines the trade-off between the number of samples which must be taken from a stream and the amount of memory necessary to process these samples. We begin this investigation with a study of three canonical problems from the data streaming literature: estimating the collision probability, also known as the second frequency moment [2], undirected connectivity [13, 14, 35], and rank estimation [10, 25, 6]. For all three problems, we find trade-offs between the sample and space requirements.

Sufficient Statistics and Data Streams. The goal of space-efficiency in statistical estimation is not new. In the study of *sufficient statistics* [15] the goal is to prove that it suffices to maintain a small number of statistics about the input when estimating certain parameters of the source distribution D. For example, to estimate μ if $D \sim N(\mu, 1)$, it is sufficient to maintain the sum and count of the samples; other information can be discarded. However, for non-parametric problems sufficient statistics typically do not exist. Our work could be seen as “approximate sufficient statistics” – statistics about the stream of samples that can be computed online that will suffice to estimate the relevant properties of the input with high probability.

In contrast to the majority of data stream research, in our setting we do not need to consider adversarially-ordered streams since the assumption is that the input stream is generated by a stochastic process. There is a growing body of work on randomly-ordered streams [20, 33, 29, 8, 27, 17, 7]. Some work has also explicitly considered streams of IID samples [9, 41, 19, 30]. There has also been work on hypothesis testing given limited space [23, 21].

Subsampling vs. Supersampling. Other related work includes a paper by an overlapping set of authors [26] (see also [37]) that considered the problem of processing data streams whose arrival rate was so high that it was not possible to observe every element of the stream. Consequently, it was presumed that the stream was first *subsampled* and then properties of the original stream had to be deduced from the samples. In contrast, in this work we essentially consider oversampling, or *supersampling* the data set. The motivation is two-fold. First, in many applications there is an abundance of redundant data, e.g., from sensors that continually monitor a static environment, and it makes sense to find a way to capitalize on this data. Second, it may be preferable from a computational point of view, to run a fast light-weight algorithm on a lot of data rather than a computationally expensive algorithm on a small amount of data.

A number of early works consider learning in online settings, and we only mention a few here. There is a line of work on hypothesis testing and statistical estimation with finite memory, see, e.g., [11, 24], but the lower bounds in such models come from finite precision constraints, and do not seem directly related to the model or problems that we study. Other work [31] considers lower bounds for algorithms given data in a specific form, i.e., in so-called oracle models, and the limitations of such assumptions on the model have been exploited to design faster algorithms in some cases [32].

More recently, [38, 39] consider the question of learning with memory or communication constraints in the setting in which the algorithm has access to a stream of randomly drawn labeled examples. Their algorithmic "memory bounded" model corresponds to our model. We note that these works study a different set of problems than the ones from the data stream literature that we focus on, reinforcing the naturalness of the model. The lower bounds in these works use a more general communication model than our streaming machines: given a communication bound of b bits per example, an algorithm must compress the ith example according to an arbitrary function that may depend on the compressed versions of the first $i-1$ examples; the algorithm may then compute an arbitrary function of the compressed examples. The authors show tight connections between communication bounded protocols, and statistical query algorithms, and we leverage their characterization to show a communication lower bound, and ultimately space lower bound in Section 4.

Our Results. We study the trade-off between sample and space complexity for canonical problems in the data stream literature such as estimating the collision probability or second frequency moment [2], undirected connectivity [13, 14, 35], and rank estimation [10, 25, 6]; see also the references therein. We obtain the following tradeoffs:

1. *Collision Probability.* Suppose $D = D_p$ is a distribution $(p_1, \ldots, p_n)$ over $[n]$. Then, to estimate $F_2(D) = \sum_i p_i^2$ up to a factor $(1+\epsilon)$ with probability $1-\delta$, for any[1] $t \geq t^* = \tilde{\Omega}_{\epsilon,\delta}(n^{1/2})$ it is sufficient for

   $$s \cdot t = \tilde{O}_{\epsilon,\delta}(n)\,.$$

   Moreover, we show a lower bound that $s \cdot t^{1.5} = \tilde{\Omega}(n^{5/4})$ space is necessary to return a constant factor approximation with constant probability, which is tight when s and t are $\tilde{\Theta}_{\epsilon,\delta}(\sqrt{n})$. We also point out an error in existing work, which if fixable, would result in the tight $s \cdot t = \tilde{\Omega}(n)$ tradeoff. We present these results in Section 2.
2. *Graph Connectivity.* Suppose $D = D_G$ is the uniform distribution of the set of edges of an undirected, unweighted graph G. We show in Section 3 that for $t \geq t^* = \Omega(|E| \log |E|)$, it suffices for

   $$s^2 \cdot t = \tilde{O}(|E| \cdot |V|^2)\,.$$

3. *Subspace Approximation.* In Section 4 we consider the problem of determining whether a set of samples from $\{0,1\}^n$ is being drawn from the entire space or from some rank $n/2$ subspace. We first note an $s = O(\log n)$-bit space streaming algorithm which achieves sample complexity $t = O(2^n)$. More interestingly, we then show that this is near-optimal by showing that any streaming algorithm using $s \leq n/8$ space requires

   $$2^s \cdot t = \Omega(2^{n/8})\ .$$

   So even if one allows say, $s = n/16$ bits of space, one still needs $2^{\Omega(n)}$ examples.

We believe one of the main contributions of our work is the new framework for analyzing tradeoffs between the sample and space complexity of streaming algorithms. We have chosen

[1] $\tilde{O}_{\epsilon,\delta}(f(n))$ and $\tilde{\Omega}_{\epsilon,\delta}$ omit $\text{poly}(\log(n/\delta), 1/\epsilon)$ terms.

this set of problems because it is representative of well-studied sub-areas in the data stream literature such as estimating statistical quantities such as frequency moments, graph problems in the semi-streaming model, and numerical linear algebra problems.

2 Collision Probability

The collision probability is a fundamental quantity quantifying how far a distribution is from the uniform distribution, the latter having the smallest possible collision probability. Estimating the empirical collision probability is well-studied for worst case data streams of a given length, dating back to the seminal work of Alon, Matias, and Szegedy [2]. It has applications to estimating self-join sizes in databases, and is also known as the *repeat rate* or *Gini's Index of homogeneity*, which is used to compute the *surprise index* [16].

Here we consider a stream of independent samples $\langle a_1, a_2, a_3, \ldots \rangle$ from an unknown discrete distribution p over $[n]$. Let $p_j = \mathbb{P}[a_i = j]$ and let $F_2 = \sum_j p_j^2$.

2.1 The Upper Bound

▶ **Theorem 1.** *For $t = \tilde{\Omega}_{\epsilon,\delta}(n^{1/2})$, estimating F_2 up to a factor $(1 \pm \epsilon)$ given t samples with probability at least $1-\delta$ is possible in $\tilde{O}_{\epsilon,\delta}(1 + n/t)$ bits of space.*

Proof. We can assume δ is a constant, since the algorithm generalizes to smaller δ simply by increasing the sample complexity by a factor of $\log(1/\delta)$, running our algorithm $\log(1/\delta)$ times in sequence on each of $\log(1/\delta)$ independent groups of samples, and taking the median. Note $t = \Omega(n^{1/2})$ was shown necessary by Bar-Yossef [4]; with fewer samples estimating F_2 is information-theoretically impossible.

Our algorithm partitions the input stream into t/w groups of w consecutive samples. We now analyze one specific group of w samples. Suppose the samples are $a_1, \ldots, a_w$. For each pair $i \neq j \in \{1, 2, \ldots, w\}$, let $X_{i,j}$ be an indicator random variable which is 1 iff $a_i = a_j$. Let $X = \frac{1}{\binom{w}{2}} \sum_{i \neq j} X_{i,j}$. Then $\mathbf{E}[X]$ is equal to $\mathbf{E}[X_{i,j}]$ for an arbitrary $i \neq j$, and the latter is precisely $F_2 = \sum_i p_i^2$. We also have, assuming $i \neq j$ and $i' \neq j'$ in the following:

$$\begin{aligned}
\binom{w}{2}^2 \mathbf{Var}[X] &= \sum_{(i,j)=(i',j')} \mathbf{E}[X_{i,j}X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] \\
&\quad + \sum_{|\{i,j,i',j'\}|=3} \mathbf{E}[X_{i,j}X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] \\
&\quad + \sum_{|\{i,j,i',j'\}|=4} \mathbf{E}[X_{i,j}X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] \\
&= \sum_{(i,j)} \mathbf{E}[X_{i,j}^2] - \mathbf{E}^2[X_{i,j}] + \sum_{|\{i,j,i',j'\}|=3} \mathbf{E}[X_{i,j}X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] \\
&\quad + \sum_{|\{i,j,i',j'\}|=4} \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}] \\
&\leq \sum_{(i,j)} \mathbf{E}[X_{i,j}^2] + \sum_{|\{i,j,i',j'\}|=3} \mathbf{E}[X_{i,j}X_{i',j'}] - \mathbf{E}[X_{i,j}]\mathbf{E}[X_{i',j'}],
\end{aligned}$$

where the first equality follows by expanding the variance into covariances, the second equality uses independence of disjoint indices, and the inequality cancels the terms for which

$|\{i,j,i',j'\}| = 4$ and drops non-positive terms. Therefore,

$$\begin{aligned}
\mathbf{Var}[X] &\le \frac{1}{\binom{w}{2}^2}\left(\sum_{(i,j)} \mathbf{E}[X_{i,j}^2] + \sum_{|\{i,j,i',j'\}|=3} \mathbf{E}[X_{i,j}X_{i',j'}]\right)\\
&= \frac{\mathbf{E}[X]}{\binom{w}{2}} + \Theta\left(\frac{1}{w^4}\right) \sum_{\text{distinct } i,j,k} \mathbf{E}[X_{i,j}X_{j,k}]\\
&= \frac{F_2}{\binom{w}{2}} + \Theta\left(\frac{1}{w^4}\right) \sum_{\text{distinct } i,j,k} \Pr[X_{i,j}=1 \mid X_{j,k}=1]\cdot \Pr[X_{j,k}=1]\\
&= \frac{F_2}{\binom{w}{2}} + \Theta\left(\frac{1}{w^4}\right) \sum_{\text{distinct } i,j,k} \sum_{\ell} \Pr[X_{i,j}=1 \mid a_j=\ell]\cdot \Pr[a_j=\ell \mid X_{j,k}=1]\cdot F_2\\
&= \frac{F_2}{\binom{w}{2}} + \Theta\left(\frac{1}{w^4}\right) \sum_{\text{distinct } i,j,k} \sum_{\ell} p_\ell \cdot \frac{p_\ell^2}{F_2}\cdot F_2\\
&= \frac{F_2}{\binom{w}{2}} + \Theta\left(\frac{F_3}{w}\right),
\end{aligned}$$

where we have used the law of total probability and the definitions, and here $F_3 = \sum_j p_j^3$.

In the stream, we will use $O(w \log n)$ bits of space to compute X as above. Then, since we have partitioned the samples into $q = t/w$ groups (which we can assume is an integer w.l.o.g.), we will compute an independent estimate X for each group, and take their average, obtaining a random variable Y. Thus Y can be computed in $O(w \log n)$ bits of space. Then $\mathbf{E}[Y] = \mathbf{E}[X] = F_2$ and $\mathbf{Var}[Y] = \mathbf{Var}[X]/q$. By Chebyshev's inequality,

$$\begin{aligned}
\Pr[|Y - F_2| \ge \epsilon F_2] &\le \frac{\mathbf{Var}[X]}{q\epsilon^2 F_2^2} \le \frac{1}{\binom{w}{2}F_2 q\epsilon^2} + O\left(\frac{F_3}{wq\epsilon^2 F_2}\right)\\
&= O\left(\frac{n}{w^2 q\epsilon^2}\right) + O\left(\frac{\sqrt{n}}{wq\epsilon^2}\right),
\end{aligned}$$

where the final inequality uses that $F_2 \ge 1/n$ in the first expression, while the second expression uses Hölder's inequality to show that $F_3 \le \sqrt{n}F_2$.

Plugging in $q = t/w$, this probability is $O(n/(tw\epsilon^2) + \sqrt{n}/(t\epsilon^2))$. Thus, for $t = \Omega(n^{1/2}\epsilon^{-2})$ samples, we can set $w = O(n/t)$ and have this probability be smaller than an arbirarily small constant. Note that as a sanity check, we need $t = \Omega(n^{1/2})$ to ensure $w \le t$, as required by the definition of these variables. This completes the proof. ◀

2.2 The Lower Bound

Our lower bound relies on a result by Andoni et al. [3] for the random order data stream model, which is different than the model we consider in this paper. We note that an improvement to the work of Andoni et al. [3] was claimed in [18]; however, after communication with the authors, the proof given in [18] seems to have a bug and is currently not known to be fixable. If the result in [18] is fixable, then we obtain an optimal tradeoff of $s \cdot t = \tilde{\Omega}(n)$; otherwise we obtain the slightly weaker tradeoff presented here.

The work of [3] concerns distinguishing between the following two cases with constant probability, and shows that $\Omega(t/r^{2.5})$ space is required:

1. (Case 1) A sequence of t samples from a distribution p^{no} that is uniform on some subset $S \subseteq [t]$ of size $\Theta(t)$.
2. (Case 2) A sequence of t samples from a distribution p^{yes} such that $p_i^{\text{yes}} = r/t$ for some $i \in [t]$ and uniform on some subset $T \subseteq [t] \setminus \{i\}$.

By combining this result with a hashing technique we establish the following result.

▶ **Theorem 2.** *Any constant factor approximation of $F_2(D)$ with constant probability given a sequence of t IID samples on $[n]$ requires $\Omega(n^{5/4}/((\log^{2.5} n) \cdot t^{1.5}))$ bits of space.*

Proof. Let $h : [t] \to [n]$ be a fully-random hash function and consider the problem of distinguishing p^{no} and p^{yes} where we set $r = c \log n \cdot t \cdot n^{-1/2}$ for some constant $c > 0$. By applying h on each distribution (i.e., applying h to each observed sample) we generate two new distributions q^{no} and q^{yes} over $[n]$ where:

$$q_i^{\text{no}} = \sum_{j:h(j)=i} p_j^{\text{no}} \quad \text{and} \quad q_i^{\text{yes}} = \sum_{j:h(j)=i} p_j^{\text{yes}} .$$

Note that with high probability $\max_i q_i^{\text{no}} = O(\log n \cdot 1/n)$ and hence $F_2(q^{\text{no}}) \leq n \cdot O((\log n \cdot 1/n)^2) = O(\log^2 n \cdot n^{-1/2})$. However, $\max_i q_i^{\text{yes}} \geq r/t$ and so $F_2(q^{\text{yes}}) \geq r^2/t^2 = c^2 \cdot \log^2 n \cdot n^{1/2}$. Hence, for a sufficiently large value of the constant $c > 0$ we can ensure that any constant approximation of F_2 distinguishes between q^{yes} and q^{no} and hence, also distinguishes between p^{yes} and p^{no}. However, by the result of Andoni et al. [3] we know that this requires $\Omega(t/r^{2.5}) = \Omega(n^{2.5(1/2)}/((\log^{2.5} n) \cdot t^{1.5}))$ bits of space. ◀

3 Connectivity

In this section, we consider a graph model where our input stream is a sequence of t random samples drawn (with replacement) from the graph's entire edge set E. This model is appropriate for random processes where the "graph" involved is defined only implicitly, and is not available for querying. For example, on a large social network, we can imagine a graph where nodes represent users and weighted edges represent user frequencies of interaction. We may not have enough space or processing power to analyze the history of interactions between users directly, or to provide random access to this history; according to [40] an estimated 50 billion text messages per day were sent in 2014. However, the stream of ongoing interactions approximates random samples from the weighted edge distribution.

We begin the study of this model by first examining unweighted graphs, and by examining the canonical problem of determining connectivity for such graphs. Our algorithm uses the sampled edges to simulate classical random walks on the graph. In Section 3.1, we discuss how to simulate and tightly analyze random walks in our model. The main technical difficulty is ensuring independence when simulating multiple random walks in parallel. Then, in Section 3.2, we adapt a connectivity algorithm of Feige [14] to achieve the required space/sample trade-off. Since our algorithm provides a general technique for space/sample trade-offs in simulating random walks, we believe it will be a useful starting point for examining additional problems in this model.

For notational convenience, denote the graph by $G = (V, E)$, the number of nodes by $n = |V|$, and the number of edges by $m = |E|$.

3.1 Technique: Emulating Classical Random Walks

Consider the following basic algorithm: given a node v, we sample edges until we receive an edge $\{v, u\}$ for some u. At this point, we move to node u, and repeat. We refer to this method as a *sampling walk*. Note that the expected time to leave v is $m/d(v)$ samples[2] where

[2] This is because the number of samples is geometrically distributed with parameter $d(v)/m$.

$d(v)$ is the degree of a node v, and so a single step of a classical random walk may require $\Omega(m)$ samples if v has low degree.

An Inefficient Connectivity Algorithm. This basic algorithm already leads to a $O(\log n)$ space algorithm which uses $O(m^2n^2)$ samples in expectation. This follows by starting a sampling walk at node 1 and emulating a classical walk until it traverses nodes $2, 3, \ldots, n$ in order. The expected length of this walk is $O(mn^2)$ because the cover time of G, i.e., the expected length of walk until it visits all nodes (see e.g., [28]), is $O(mn)$ and there are $n-1$ segments in the traversal. Hence, emulating the random walk takes $O(m^2n^2)$ samples in expectation. The space use is $O(\log n)$ bits because the algorithm just needs to remember the current node and the furthest node that has been reached in the sequence. In what follows, we will improve upon the number of samples required and generalize to algorithms that use more space.

The Loopy Graph and an Improved Analysis. The first improvement comes via a better analysis. At a node v with $d(v)$ neighbors, there are $d(v)$ possible samples which would result in a move, and $m - d(v)$ samples which would not. We can thus view our sampling-based walk on G as a classical random walk on a new graph H formed by adding $m - d(v)$ self-loops to each vertex v in G. We call H the "loopy graph".

This view of the sampling walk illuminates its properties. Specifically, H's cover time is $O(mn^2)$ since there are mn edges and n nodes. Hence, the above "inefficient" algorithm actually only requires $(n-1) \times \text{cover-time}(H) = O(mn^3)$ samples. We will also subsequently use the fact that since H is m-regular, its stable distribution is uniform across all nodes.

3.1.1 Multiple Independent Random Walks

Random walks experience dramatic speedups in cover time, hitting time, etc., when they are split into multiple shorter walks; [12] provides a recent survey and results. These speedups naturally require the walks to be independent. In this section, we consider performing $p \leq n$ random walks in parallel, with the starting point of each walk chosen independently and uniformly from the nodes (and thus according to the stationary distribution on H). Running these p walks will require $O(p \log n)$ space. The main theorem of this section establishes that it is possible to efficiently perform p independent, parallel walks in H.

▶ **Theorem 3.** *Given $p \leq n$ parallel random walks in H, each starting at an independently-chosen uniformly random node, we can simulate one independent step of each walk using $O(\log n/\log\log n)$ total samples.*

Issue 1: Multiple Walks can use a Sampled Edge. The first issue we encounter is that a single sample may be a valid move for multiple walks. If we allow multiple walks to use the same sample, we introduce obvious dependence; if we only allow one of our walks to use the sample, we are "slowing down" walks that have collisions, and again introducing dependence.

When multiple walks are at the same node, we will handle them independently in the following way. We partition the p walks into $B_1 \cup B_2 \cup \ldots \cup B_r$ where each B_i contains at most one walk at each node. We process each batch in turn and hence the total number of samples required equals the number of samples required for a batch multiplied by the number of batches. The next lemma establishes that it suffices to consider $r = O(\log n/\log\log n)$ batches.

▶ **Lemma 4.** *With high probability, no node ever contains more than $O(\log n/\log\log n)$ walks.*

Proof. Consider a fixed node at a fixed time. Let Z be the number of walks in this node. Note that $Z \sim Bin(p, 1/n)$ since each walk is independent and is equally likely to be at any node. Hence $\mathbb{E}[Z] = p/n \leq 1$. By an application of the Chernoff bound, for some large constant c we have $\mathbb{P}[Z \geq c\log n/\log\log n] \leq n^{-10}$. The lemma follows by taking the union bound over the n nodes and poly n time-steps. ◀

Henceforth, we assume that at most one walk is at each node, i.e., we analyze how many samples are required to process a single batch. The remaining case where a sampled edge may be valid for multiple walks is if there are walks at both endpoints. To solve this problem, we randomly orient each sampled edge so that it is valid for only one walk. This increases the expected number of samples required by a factor of 2.

Issue 2: Negative Correlation. We have reduced the problem to the following situation: we have p distinct nodes $u_1, \ldots, u_p$ and can sample arcs uv uniformly from the set $E^+ = \{uv : \{u, v\} \in E_G\}$, i.e., the set of arcs formed by bidirecting each edge in E_G. Note that $|E^+| = 2|E_G|$. The goal is to generate a set of arcs $\{u_1v_1, \ldots, u_pv_p\}$ such that each arc is chosen independently and for each i,

$$v_i = \begin{cases} v \in_R \Gamma(u_i) & \text{with probability } d_G(v_i)/|E^+| \\ u_i & \text{with probability } 1 - d_G(v_i)/|E^+| \end{cases} \tag{1}$$

where $\Gamma(u_i) = \{v : \{u, v\} \in E\}$ is the neighborhood of u_i in G, and where $v \in_R \Gamma(u_i)$ denotes an edge drawn randomly from the uniform distribution over the set $\Gamma(u_i)$.

Consider the following procedure: draw a single sample $uv \in_R E^+$ and, for each i, set $v_i = v$ if $u = u_i$, or $v_i = u_i$ otherwise. This procedure picks each v_i according to the desired distribution:

$$\mathbb{P}[v_i = u_i] = 1 - d_G(v_i)/|E^+|$$

and conditioned on $\{v_i \neq u_i\}$, v_i is uniformly chosen from $\Gamma(u_i)$. Unfortunately, the procedure obviously does not satisfy the independence requirement because the events $\{u_i = v_i\}$ and $\{u_j = v_j\}$ are negatively correlated. However, the following theorem establishes that, with only $O(1)$ samples from E^+ in expectation, it is possible to sample independently according to the desired distribution.

▶ **Theorem 5** (Efficient Parallel Sampling). *There exists an algorithm that returns samples $(v_1, \ldots, v_p)$ drawn from the desired distribution (1) while using at most $2e - 1$ samples from E^+ in expectation.*

Proof. Our algorithm operates in rounds; each round uses at most 2 samples from E^+. At the beginning of a round, suppose we have already assigned values to $v_1, \ldots, v_i$ for $i \geq 0$. Then the round proceeds as follows:

1. Sample $uv \in E^+$:
   - **a.** If $u \notin \{u_{i+1}, \ldots, u_p\}$ then set $v_{i+1} = u_{i+1}, \ldots, v_p = u_p$
   - **b.** If $u = u_j$ for some $j \in \{i+1, \ldots, p\}$ then sample an additional arc $wx \in E^+$
     - **i.** If $w \in \{u_{i+1}, \ldots, u_{j-1}\}$ then set $v_{i+1} = u_{i+1}, \ldots, v_{j-1} = u_{j-1}, v_j = u_j$
     - **ii.** If $w \notin \{u_{i+1}, \ldots, u_{j-1}\}$ then set $v_{i+1} = u_{i+1}, \ldots, v_{j-1} = u_{j-1}, v_j = v$

and we repeat the process until all $v_1, \ldots, v_p$ have been assigned.

To analyze the algorithm we define $T_j = \{u_j v : \{u_j, v\} \in E_G\}$ to be the set of $d_G(u_j)$ arcs leaving u_j and note that because $u_1, \ldots, u_p$ are distinct, $T_1, \ldots, T_p$ are disjoint. Also define A_j to be the event that $\{v_j \neq u_j\}$. Then, in any round in which v_j hasn't yet been assigned:

$$\begin{aligned}\mathbb{P}\left[v_j \text{ is assigned and } A_j | v_j \text{ is assigned}\right] &= \frac{|T_j|}{|E^+| - \sum_{k=i+1}^{j-1} |T_k|} \cdot \frac{|E^+| - \sum_{k=i+1}^{j-1} |T_k|}{|E^+|} \\ &= \frac{|T_j|}{|E^+|} \qquad (2)\end{aligned}$$

and hence v_j is chosen according the desired distribution.

We next show that each v_j is chosen independently. First observe that, conditioned on A_j, v_j is independent of $(v_1, \ldots, v_{j-1}, v_{j+1}, \ldots, v_p)$. Hence, it suffices to show that all A_j are independent. Note that the RHS of (2) does not depend on decisions made in previous rounds. Hence, we may deduce that A_j is independent of the outcome of rounds before v_j is assigned. Hence, for any $1 \leq i_1 < i_2 < \ldots < i_r \leq p$,

$$\begin{aligned}\mathbb{P}\left[A_{i_1} \cap \ldots \cap A_{i_r}\right] &= \mathbb{P}\left[A_{i_1}\right] \mathbb{P}\left[A_{i_2} | A_{i_1}\right] \ldots \mathbb{P}\left[A_{i_r} | A_{i_1} \cap \ldots \cap A_{i_{r-1}}\right] \\ &= \mathbb{P}\left[A_{i_1}\right] \mathbb{P}\left[A_{i_2}\right] \ldots \mathbb{P}\left[A_{i_r}\right] .\end{aligned}$$

The worst case for the expected number of samples is achieved when $p = |E^+|$ and each set is of size 1. For the algorithm not to terminate in a given round, we need $u \in \{u_{i+1}, \ldots, u_p\}$ and hence the index of the sampled u needs to strictly increase over previous rounds. The probability of this happening for r rounds is $\binom{m}{r}/m^r$ and the expected number of rounds which do not terminate is $\sum_{r=1}^{m} \binom{m}{r}/m^r \leq e - 1$. Because each non-terminating round involves two samples, the expected total number of samples is thus at most $2e - 1$. ◀

3.2 Connectivity Algorithm and Analysis

Our algorithm adapts a technique of Feige [13] for determining graph connectivity via a two step process. We first test whether G contains any connected components containing k or fewer nodes (for some $k < n$ to be chosen). If all of the connected components of G contain at least k nodes, we choose $O((n \log n)/k)$ nodes at random, and verify that they are all connected to each other. Note that we can expect to have chosen a vertex from each connected component. If we find that all of our chosen vertices are connected, we conclude that G is connected; otherwise, we conclude that G is disconnected.

Our connectivity algorithm thus relies on algorithms for two problems: 1) determining whether the graph has any connected components below a certain size, and 2) determining whether a set of nodes is mutually connected in the graph. In the next two sections, we develop algorithms with sample/space tradeoffs for each of these two problems. We then use them in an algorithm for determining whether the graph G is connected.

3.2.1 Finding Small Components

Our first subproblem is to determine whether the graph has any connected components below a certain size. Given a node v, let the set of nodes in the connected component containing v be denoted $\mathrm{cc}(v)$.

▶ **Lemma 6.** *Given a node v of G and a parameter r, we can distinguish between the case where $|\mathrm{cc}(v)| < r$ and the case where $|\mathrm{cc}(v)| > 2r$ with constant probability using $O(mr^2)$ samples and $\tilde{O}(1)$ space.*

Proof. We perform a sampling walk of length $O(mr^2)$ samples. During this walk, we maintain a 1.1-approximation of the number of distinct vertices visited using an F_0 estimator [22]. If the estimated number of vertices visited is at least $3r/2$, we conclude that $|\mathrm{cc}(v)| \geq r$; otherwise, we conclude that $|\mathrm{cc}(v)| \leq 2r$.

If $|\mathrm{cc}(v)| \leq r$, we will clearly visit at most r nodes. Our algorithm correctly concludes this so long as the F_0 estimator returns the promised approximation. If $|\mathrm{cc}(v)| \geq 2r$, we need to argue that in $O(mr^2)$ samples we will hit at least $2r$ distinct nodes (except with constant probability). This follows from a result by Barnes [5, Thm 1.3] that states that for any connected (multi-)graph, it takes $O(\mathcal{M}\mathcal{N})$ time in expectation to hit either $\mathcal{N}$ distinct nodes or $\mathcal{M}$ distinct edges. Using $\mathcal{M} = 2mr$ and $\mathcal{N} = 2r$ establishes the result. ◀

▶ **Theorem 7.** *We can determine whether G has a connected component of size less than 2^k using $O(p)$ space and $\tilde{O}(2^k \cdot mn/p)$ samples for any $p \leq n$.*

Proof. Our algorithm has k rounds, each corresponding to a value $r = 1, 2, 4, \ldots, 2^{k-1}$. In each round we reach one of two conclusions: 1) G has no connected components with size in the range $[r, 2r]$ or 2) there exists a connected component of G of size $< 3r$. All graphs satisfy at least one of these conclusions. We then determine G has no connected component of size less than 2^k if we never reach the first conclusion.

At a given value of r, we choose $O(n \log n/r)$ nodes, so that we hit any connected component of at least r nodes with high probability. From each node, we perform $\tilde{O}(1)$ random walks of length $\tilde{O}(mr^2)$ samples; from Lemma 6 this will suffice to determine with high probability whether any of these nodes is in a connected component of size $\leq 2r$.

We choose p nodes at a time, and perform p walks in parallel. From Theorem 3 we can perform each set of p walks using $\tilde{O}(mr^2)$ samples. The number of samples required for each r value is then $O(\frac{n}{rp} mr^2) = O(mnr/p)$, and we thus require a total number of samples $O(mn2^k/p)$. ◀

3.2.2 Checking Mutual Connectivity

The remaining subproblem is to determine whether a set of randomly-chosen nodes is mutually connected.

▶ **Lemma 8.** *We can determine whether a set of $O(p)$ randomly-chosen nodes is mutually connected in G using $\tilde{O}(p)$ space and $\tilde{O}(mn^2/p^2)$ samples for any $p \leq n$.*

Proof. In the context of traditional random walks, Feige [14] provides a method for testing whether two nodes s and t are connected using space $\tilde{O}(p)$ and a total of $\tilde{O}(mn/p)$ random-walk steps. They proceed by choosing p "landmark" nodes; we then run $O(\log n)$ random walks from each landmark and from s and t. Each walk is of length $\tilde{O}(mn/p^2)$. During these walks we build a union-find data structure indicating which sets of landmark nodes are connected. At the end of the algorithm, we conclude that s and t are connected if they are in the same union-find component.

Since H is regular, the landmark selection process chooses each node with equal probability. Using Feige's algorithm on the p randomly-chosen landmarks determines whether this set of p nodes is mutually connected. The graph H has n nodes and mn edges, so from [14] each walk should be of length $\tilde{O}(mn^2/p^2)$. Using Theorem 3 we can simulate the p walks with a total of $\tilde{O}(mn^2/p^2)$ samples. ◀

We are now ready to prove our main connectivity result.

▶ **Theorem 9.** *Given sampling access to a graph G, we can determine with high probability whether G is connected using $O(p \log n)$ space and $\tilde{O}(mn^2/p^2)$ samples, for any $p \leq n$.*

Proof. We use Theorem 7 with $2^k = n/p$ to verify that G has no connected components of size less than n/p. If it has such a component, then G is disconnected. If not, we choose $O(p \log n)$ random vertices, hitting each remaining component with high probability. Using Lemma 8, we test that these vertices are mutually connected. Since we have chosen enough vertices to hit every connected component, this suffices to show that the graph is connected. Each of the two subproblems requires $O(mn^2/p^2)$ samples and $\tilde{O}(p)$ space, so these are the sample and space requirements of our algorithm. ◀

4 Rank Estimation

In this section we study the rank estimation problem, namely, that of distinguishing if a stream of vectors is coming from a full dimensional subspace or a subspace of low rank. This is quite useful in data streams and machine learning tasks, for which the vectors correspond to examples. If the subspace is rank-deficient, then one might be interested in a low rank approximation to it. This problem is also relevant in testing codewords, which has been studied in the streaming model in [36].

We will start with a lower bound and then mention a simple matching upper bound for a natural setting of parameters. The lower bound is described in terms of communication complexity, though it yields a lower bound on the memory for data stream algorithms via a standard simulation whereby the state of the streaming algorithm is the message between players in a communication protocol. We mention this after presenting the lower bound for the communication game.

The authors of [39] show a tight connection between learning tasks that can be accomplished via bounded communication algorithms and learning tasks that can be accomplished via "statistical query" algorithms. They operate in the following quite general communication model, and we leverage their result to show a space-sample lower bound trade-off for a streaming version of the rank estimation problem: the task is to distinguish

1. (Case 1) A sequence of t samples chosen uniformly from some rank $n/2$ subspace $S \subseteq \{0,1\}^n$.
2. (Case 2) A sequence of t samples chosen uniformly from $\{0,1\}^n$.

A "statistical query" algorithm for this task, in the language of [39], is an algorithm that adaptively proposes a sequence of functions $f_1, f_2, \ldots$ with $f_i : \{0,1\}^n \to [-1,1]$, and receives estimates of $E_x[f_i(x)]$ that have been corrupted via some adversarial noise. We say that there exists an n-query statistical query algorithm with tolerance τ for this testing task if, for every rank $n/2$ subspace S, after asking n statistical queries $f_1, \ldots, f_n$, with responses $r_1, \ldots, r_n$ that satisfy $|r_i - \mathrm{E}_{x \leftarrow unif[S]}[f_i(x)]| \leq \tau$, the algorithm will output *rank n/2* with probability at least 3/4, and if the responses satisfy $|r_i - \mathrm{E}_{x \leftarrow unif[\{0,1\}^n]}[f_i(x)]| \leq \tau$, then the algorithm will output *full rank* with probability at least 3/4, where the probability is over the randomness of the algorithm that decides on the next query f_i given $f_1, \ldots, f_{i-1}$ and $r_1, \ldots, r_{i-1}$.

▶ **Proposition 10.** *Any statistical query algorithm for distinguishing the uniform distribution over rank $n/2$ subspaces of $\{0,1\}^n$ from a uniform distribution over $\{0,1\}^n$ using statistical queries of tolerance $\tau > \frac{1}{2^{n/8}}$ requires at least $\Theta(2^{n/4})$ statistical queries.*

The following lemma is the core to the proof.

▶ **Lemma 11.** *Let $f : \{0,1\}^n \to [-1,1]$ be a function with $\sum_{x\in\{0,1\}^n} \frac{f(x)}{2^n} = \mu$, and let S be a rank $n/2$ subspace of $\{0,1\}^n$. Define the random variable X_f by choosing S uniformly at random from the set of all rank $n/2$ subspaces of $\{0,1\}^n$, and then set $X_f = E_{x\leftarrow S}[f(x)]$.*

$$\Pr[|X_f - \mu| > \frac{1}{2^{n/8}}] = O(1/2^{n/4}).$$

Proof. First note that $\mathrm{E}[X_f] \in [\mu - 1/2^{n/2}, \mu + 1/2^{n/2}]$, as the distribution obtained by selecting a random rank $n/2$ subspace S, then choosing a random $x \in S$ places probability $1/2^{n/2}$ on the zero vector $\vec{0}$, and the remaining $2^n - 1$ vectors have equal weight. We will now upper bound $\mathrm{Var}[X_f]$, and then apply Chebyshev's inequality. In the following calculations, $\#S$ denotes the number of rank $n/2$ subspaces of $\{0,1\}^n$.

$$\begin{aligned}\mathrm{E}[X_f^2] &= \mathrm{E}_S\left[\left(\frac{1}{2^{n/2}}\sum_{x\in S} f(x)\right)^2\right] = \mathrm{E}_S\left[\frac{1}{2^n}\sum_{x\in S} f(x)^2 + \frac{1}{2^n}\sum_{x,x'\in S, x\neq x'} f(x)f(x')\right] \\ &\le 1/2^{n/2} + \frac{1}{2^n}\frac{1}{\#S}\sum_S \sum_{x,x'\in S,x\neq x'} f(x)f(x'),\end{aligned}$$

which is equal to

$$2^{-n/2} + \frac{2^{-n}}{\#S}\left(2f(\vec{0})\frac{\#S}{2^{n/2}-1}\sum_{x'\neq 0} f(x') + \sum_{x\neq\vec{0}} f(x)\frac{\#S}{(2^{n/2}-1)(2^{n/2}-2)}\sum_{x'\notin\{\vec{0},x\}} f(x')\right).$$

Noting that $|f(x)| \le 1$, and $\sum_{x\neq\vec{0}} f(x) \in [2^n\mu - 1, 2^n\mu + 1]$, and $\sum_{x'\notin\{\vec{0},x\}} f(x') \in [2^n\mu - 2, 2^n\mu + 2]$, the above expression lies in the range $\mu \pm O(1/2^{n/2})$. Hence $\mathrm{Var}[X_f] = O(1/2^{n/2})$, and $\Pr[|X_f - \mu| \ge 1/2^{n/8}] \le O(1/2^{n/4})$, as desired. ◀

Proof of Proposition 10. Let distribution D be defined to be the uniform distribution over $\{0,1\}^n$, and let S be a rank $n/2$ subspace that has been chosen uniformly at random from the set of rank $n/2$ subspaces of $\{0,1\}^n$, and define D_S to be the uniform distribution over S. Let $f_1, \ldots, f_n$ be a sequence of $n = \Theta(2^{n/4})$ statistical queries, corresponding to the responses $r_1, \ldots, r_n$ with $r_i = \mathrm{E}_{x\leftarrow D}[f(x)]$. We will now show that, with probability greater than $1/2$ over the randomness of the choice of subspace S, it will hold that $|r_i - \mathrm{E}_{x\leftarrow D_S}[f_i(x)]| \le 1/2^{n/8}$. Indeed, this follows immediately from Lemma 11 via a union bound over the n events. To conclude, this shows that after n queries of tolerance at most $1/2^{n/8}$, with probability at least $1/2$, no information is given regarding whether the responses correspond to D versus D_S for some S, hence the probability of correctly guessing "D" versus "D_S" can be at most $3/4$ in one of the two cases. ◀

For the purposes of our lower bound, Lemma 3.3 from [39] (restated below) immediately translates the statistical query lower bound of Proposition 10 into a lower bound on the number of samples required by any algorithm in the following bounded communication model: there is one player per example, and the t players each speak once, one after the other. The i-th player sees the message sent of each of the first $i-1$ players, and then sends its message.

▶ **Lemma 12** (Lemma 3.3 from [39] (restated))**.** *If a given testing (or learning) task can be solved with probability $> 1-\delta$ using t examples via a communication bounded protocol that employs s bits of communication per example then it can be solved with probability $> 1-2\delta$ via a statistical query algorithm that asks $2st$ statistical queries of tolerance $\tau = \delta/(t2^s)$.*

Proposition 10 and Lemma 12 yield the following:

▶ **Theorem 13.** *Any bounded-communication protocol that distinguishes samples from a rank $n/2$ subspace of $\{0,1\}^n$ with constant probability of success above $1/2$ that uses $s \leq n/8$ bits of communication per example requires at least $\Theta(2^{n/8-s})$ samples.*

Streaming Lower Bound: This communication bound implies an equivalent bound on the bits of memory required by any streaming algorithm, via the standard technique of noting that the memory contents of the streaming algorithm after seeing each example "communicates" information between examples of the input stream. Note that this lower bound holds even if the lower bound of Theorem 13 were instead only to hold in the communication model in which the i-th player only sees the message sent of the $(i-1)$-st player.

Nearly Matching Upper Bound: Our lower bound is tight to within constant factors for the natural case of $s = O(\log n)$ and $t = O(2^n)$, where a naïve algorithm suffices: choose a random coordinate unit vector $x = e_i$. Note that for any rank $n/2$ space, at most $n/2$ of these can lie in it. Take $O(2^n)$ samples, looking to see if any of them equal x. If we are sampling from a rank-n space, then we will find x with high constant probability; if we are sampling from a rank $n/2$ space, we will find it with probability at most $1/2$.

We note that very recently the work of Raz [34] improves upon the framework of [39]. It may be possible to apply it to strengthen the above theorem to require $b = \Omega(n^2)$ bits of space with fewer than $2^{\Omega(n)}$ samples, though it is not immediate. In either case, our result shows an exponential number of samples is needed to achieve polylogarithmic memory by a data stream algorithm, and we do not know how to prove this in a different way, e.g., by using more standard reductions from communication complexity.

5 Conclusions

We have introduced a new model for analyzing tradeoffs between sample and space complexity of streaming algorithms.

There are a number of open questions, a few of which we list here:

1. (Collision Probability) For the collision probability question, what is the optimal space complexity? We conjecture that $s \cdot t = \tilde{\Omega}(n)$ should hold. After resolving the dependence on n, a next natural question would be to understand the dependence on ϵ and δ. Recent work [1] may be helpful in this regard.
2. (Frequeny Moments) Can one obtain optimal tradeoffs for other frequency moments $F_k = \sum_j p_j^k$? In this work we focused solely on F_2. Perhaps more generally one could provide a general set of techniques for analyzing various distribution learning problems in this framework.
3. (Connectivity) What lower bounds can one show for testing connectivity? It seems we can show some preliminary lower bounds via a reduction from the set disjointness problem, though currently they are far from the upper bounds.
4. (General) The techniques used for the different problems studied here are not directly related to each other. Is it possible to develop a more general framework which unifies the results for these problems?

Acknowledgments. We thank the anonymous referees for their helpful comments.

Counting Matchings with k Unmatched Vertices in Planar Graphs

Radu Curticapean[*][†]

Abstract

We consider the problem of counting matchings in planar graphs. While *perfect* matchings in planar graphs can be counted by a classical polynomial-time algorithm [26, 33, 27], the problem of counting all matchings (possibly containing unmatched vertices, also known as *defects*) is known to be #P-complete on planar graphs [23].

To interpolate between matchings and perfect matchings, we study the parameterized problem of counting matchings with k unmatched vertices in a planar graph G, on input G and k. This setting has a natural interpretation in statistical physics, and it is a special case of counting perfect matchings in k-apex graphs (graphs that become planar after removing k vertices). Starting from a recent #W[1]-hardness proof for counting perfect matchings on k-apex graphs [12], we obtain:

- Counting matchings with k unmatched vertices in planar graphs is #W[1]-hard.
- In contrast, given a plane graph G with s distinguished faces, there is an $\mathcal{O}(2^s \cdot n^3)$ time algorithm for counting those matchings with k unmatched vertices such that all unmatched vertices lie on the distinguished faces. This implies an $f(k,s) \cdot n^{O(1)}$ time algorithm for counting perfect matchings in k-apex graphs whose apex neighborhood is covered by s faces.

1 Introduction

The study of the computational complexity of counting problems was introduced in a seminal paper by Valiant [34] that established the class #P and proved that counting perfect matchings in an unweighted bipartite graph is #P-complete. In a companion paper [35], Valiant proved that counting all (not necessarily perfect) matchings in a graph is #P-complete as well. Even prior to these initial complexity-theoretic results, problems related to matchings and perfect matchings have played an important role in various scientific disciplines.

For instance, the number of perfect matchings in a bipartite graph G arises in enumerative combinatorics and algebraic complexity as the *permanent* of the bi-adjacency matrix associated with G [3, 1]. In statistical physics, counting perfect matchings amounts to evaluating the *partition function* of the *dimer model* [27, 26, 33]: The physical interpretation here is that vertices are discrete points that are occupied by atoms, while edges are interpreted as bonds

[*] Part of this work was carried out while the author was a PhD student at Saarland University in Saarbrücken, Germany, and while he was visiting the Simons Institute for the Theory of Computing in Berkeley, USA. The material also appears in his PhD thesis [10].
[†] The author is supported by the ERC grant PARAMTIGHT, no. 280152.

between the corresponding atoms. The partition function of G is then essentially defined as the number of perfect matchings in G, and it encodes thermodynamic properties of the associated system. Likewise, the problem of counting all matchings is known to statistical physicists as the *monomer-dimer model* [23]; in this setting, some points may be unoccupied by atoms. In the intersection of chemistry and computer science, the number of matchings of a graph (representing a molecule) is known as its *Hosoya index* [20].

In view of these applications and the #P-hardness of counting matchings and perfect matchings, several relaxations were considered to cope with these problems. Among these, *approximate* counting and the restriction to *planar* graphs proved most successful. However, once we start incorporating these relaxations, the seemingly very similar problems of counting matchings and counting perfect matchings exhibit stark differences:

- On planar graphs, perfect matchings can be counted in polynomial time by the classical and somewhat marvelous FKT method [27, 26, 33], which reduces this problem to the determinant. The problem of counting all matchings is however #P-complete on planar graphs [23]. In particular, the algebraic machinery in the FKT method breaks down for non-perfect matchings.
- It was shown that the number of matchings in a graph admits a polynomial-time randomized approximation scheme (FPRAS) on general graphs [24]. By a substantial extension of this approach, an FPRAS for counting perfect matchings in bipartite graphs was obtained [25] – but despite great efforts, no FPRAS is known for general graphs.

In the present paper, we focus on the differing behavior of matchings and perfect matchings on planar graphs. To this end, we study the problem #PlanarDefectMatch of counting matchings with k unmatched vertices (which we call k-defect matchings) in a planar graph G, on input G and k. This problem is clearly #P-hard under Turing reductions, as the #P-hard number of matchings in G can be obtained as the sum of numbers of k-defect matchings in G for $k = 0, \dots, |V(G)|$. On the other hand, #PlanarDefectMatch can easily be solved in time $|V(G)|^{\mathcal{O}(k)}$, as we can simply enumerate all k-subsets $X \subseteq V(G)$ that represent potential defects, count perfect matchings in the planar graph $G - X$ by the FKT method, and sum up these numbers.

1.1 Parameterized counting problems

The fact that #PlanarDefectMatch is #P-hard and polynomial-time solvable for constant k suggests that this problem benefits from the framework of *parameterized counting complexity* [15]. This area is concerned with *parameterized* counting problems, whose instances x come with *parameters* k, such as #PlanarDefectMatch or the problem #Clique of counting k-cliques in an n-vertex graph. Intuitively, the parameterized problem #PlanarDefectMatch considers k-defect matchings in planar graphs with $k \ll n$, and the physical interpretation in terms of the monomer-dimer model is that each configuration of the system admits only a small number of "vacant" points that are not occupied by atoms.

Note that both #PlanarDefectMatch and #Clique can be solved in time $n^{\mathcal{O}(k)}$ and are hence in the so-called class XP. One important goal for such problems lies in finding algorithms with running times $f(k) \cdot |x|^{\mathcal{O}(1)}$ for computable functions f, which renders the problems *fixed-parameter tractable* (FPT) [15, 16]. If no FPT-algorithms can be found for a given problem, one can try to show its #W[1]-hardness. This essentially boils down to finding a parameterized reduction from #Clique, and it shows that FPT-algorithms for the problem would imply FPT-algorithms for #Clique, which is considered unlikely.

For instance, to prove #W[1]-hardness of #PlanarDefectMatch by reduction from #Clique, we would need to find an algorithm that counts k-cliques of an n-vertex graph in time

$f(k) \cdot n^{\mathcal{O}(1)}$ with an oracle for #PlanarDefectMatch. Additionally, the algorithm should only invoke the oracle for counting k'-defect matchings with $k' \leq g(k)$. Here, both the function f appearing in the running time and the blow-up function g are arbitrary computable functions.

Furthermore, parameterized reductions can also be used to obtain lower bounds under the exponential-time hypothesis #ETH, which postulates that the satisfying assignments to formulas φ in 3-CNF cannot be counted in time $2^{o(n)}$ [13, 21, 22]. For instance, it is known that #Clique cannot be solved in time $n^{o(k)}$ unless #ETH fails [5]. If we reduce from #Clique to a target problem by means of a reduction that invokes only blow-up $\mathcal{O}(k)$, then #ETH also rules out $n^{o(k)}$ time algorithms for the target problem [29].

1.2 Perfect matchings with planar-like parameters

To put #PlanarDefectMatch into context, let us survey some parameterizations for the problem #PerfMatch of counting perfect matchings and see how these connect to #PlanarDefectMatch.

- The FKT method for planar graphs was extended [18, 30, 12] from planar graphs to graphs of fixed genus g, resulting in $\mathcal{O}(4^g \cdot n^3)$ time algorithms for #PerfMatch.
- Polynomial-time algorithms for #PerfMatch were obtained for $K_{3,3}$-free graphs [28, 38] and K_5-free graphs [32]. More generally, for every class of graphs excluding a fixed single-crossing minor H (that is, H can be drawn in the plane with at most one crossing), an $f(H) \cdot n^4$ time algorithm is known [7].
- A simple dynamic programming algorithm yields a running time of $3^t \cdot n^{\mathcal{O}(1)}$ for #PerfMatch on graphs of treewidth t. By using fast subset convolution [37], the running time can be improved to $2^t \cdot n^{\mathcal{O}(1)}$.

Since all of the tractable classes above exclude fixed minors for fixed parameter values, one is tempted to believe that #PerfMatch could be polynomial-time solvable on *each* class of graphs excluding a fixed minor H, and possibly even admit an FPT-algorithm when parameterized by the minimum size of an excluded minor. This last possibility was however ruled out by the following result:[1]

- #PerfMatch is #W[1]-hard on k-apex graphs [12]. For $k \in \mathbb{N}$, a graph G is k-apex if there is a set $A \subseteq V(G)$ of size k such that $G - A$ is planar. The vertices in A are called *apices*. Since k-apex graphs exclude minors on $\mathcal{O}(k)$ vertices, the #W[1]-hardness result for #PerfMatch on k-apex graphs implies #W[1]-hardness of #PerfMatch on graphs excluding fixed minors H (when parameterized by the minimum size of such an H).

Note that #PerfMatch can be solved in time $n^{\mathcal{O}(k)}$ on k-apex graphs by brute-force in a similar way as #PlanarDefectMatch. To cope with the #W[1]-hardness of #PerfMatch in k-apex graphs and potentially obtain faster algorithms, we study two special cases:

1. We consider #PlanarDefectMatch, which is indeed a special case, as discussed below.
2. We consider #PerfMatch in k-apex graphs whose apices are adjacent with only a bounded number of faces in the underlying planar graph. More in Section 1.4 of the introduction.

1.3 From k apices to k defects

To count the k-defect matchings in a planar graph G, we can equivalently count perfect matchings in the k-apex graph G' obtained from G by adding k independent apex vertices adjacent to all vertices of G: Every perfect matching of G' then corresponds to a k-defect matching of G, and likewise, every k-defect matching of G corresponds to precisely $k!$ perfect

[1] In fact, recent unpublished work suggests the existence of constant-sized minors H such that #PerfMatch is #P-hard on H-minor free graphs.

Table 1 Counting matchings under different parameterizations and input restrictions

counting matchings	on planar inputs	on general inputs
with k edges	FPT by [17]	#W[1]-complete by [6, 11]
with k defects	#W[1]-hard by Thm. 1	#P-complete for $k = 0$ by [34]

matchings of G'. This shows that #PlanarDefectMatch reduces to #PerfMatch on k-apex graphs, even when the apices in these latter graphs form an independent set and each apex is adjacent with all non-apex vertices. Note that the #W[1]-hardness for the general problem of #PerfMatch on k-apex graphs does a priori not carry over to the special case #PlanarDefectMatch, as the edges between apices and the planar graph cannot be assumed to be complete bipartite graphs in the general problem.

Nevertheless, we show in Section 3 that #PlanarDefectMatch is #W[1]-hard. To this end, we reduce from #PerfMatch on k-apex graphs by means of a "truncated" polynomial interpolation where we wish to recover only the first k coefficients from a polynomial of degree n. The technique is comparable to that used in the first #W[1]-hardness proofs for counting matchings with k edges [2, 6]. Interestingly enough, our reduction maps k-apex graphs to instances of counting k-defect matchings without incurring any parameter blowup at all. In particular, we obtain the same almost-tight lower bound under #ETH that was known for #PerfMatch on k-apex graphs [12].

▶ **Theorem 1.** #PlanarDefectMatch *is* #W[1]*-hard and admits no* $n^{o(k/\log k)}$ *time algorithm unless* #ETH *fails.*

It should be noted that the "primal" problem of counting matchings with k edges is #W[1]-hard on general graphs [6, 11], but becomes FPT on planar graphs [17]. Furthermore, recall that counting matchings with 0 defects (that is, perfect matchings) in general graphs is #P-hard. See also Table 1 for the complexity of counting matchings in various settings.

1.4 Few apices that also see few faces

In Section 4, we show that #PerfMatch becomes easier in k-apex graphs G when the apex neighborhoods can all be covered by s faces of the underlying planar graph. This setting is motivated by a structural decomposition theorem for graphs G excluding a fixed 1-apex minor H: As shown in [14], based on [31], if G excludes a fixed 1-apex minor H, then there is a constant $c_H \in \mathbb{N}$ such that G can be obtained by gluing together (in a formalized way) graphs that have genus $\leq c_H$ after removing "vortices" from $\leq c_H$ faces and a set A of $\leq c_H$ apex vertices, whose neighborhood in $G - A$ is however covered by $\leq c_H$ faces. Our setting is a simplification of this general situation as we forbid vortices, gluing, and restrict the genus to 0. We obtain an FPT-algorithm for this restricted case:

▶ **Theorem 2.** *Given as input a graph G, a set $A \subseteq V(G)$ of size k and a drawing of $G - A$ in the plane with s distinguished faces $F_1, \ldots, F_s$ such that the neighborhood of A is contained in the union of $F_1, \ldots, F_s$, we can count the perfect matchings of G in time* $2^{\mathcal{O}(2^k \cdot \log(k)+s)} \cdot n^4$.

Note that even with $k = 3$ and $s = 1$, such graphs can have unbounded genus, as witnessed by the graphs $K_{3,n}$ for $n \in \mathbb{N}$: Each graph $K_{3,n}$ is a 3-apex graph whose underlying planar graph (which is an independent set) can be drawn on one single face. However, the genus of $K_{3,n}$ is known to be $\Omega(n)$ [19].

To prove Theorem 2, we first consider a variant of #PlanarDefectMatch where the input graph G is given as a planar drawing with s distinguished faces. The task in this variant is to count k-defect matchings such that all defects are contained in the distinguished faces. This problem is FPT, even when k is not part of the parameter.

▶ **Theorem 3.** *Given as input a planar drawing of a graph G with s distinguished faces $F_1, \ldots, F_s$, the following problem can be solved in time $\mathcal{O}(2^s \cdot n^3)$: Count the matchings in G for which every defect is contained in $V(F_1) \cup \ldots \cup V(F_s)$.*

To prove Theorem 3, we implicitly use the technique of combined signatures [12]: Using a linear combination of two planar gadgets from [36], we show that counting the particular matchings needed in Theorem 3 can be reduced to 2^s instances of #PerfMatch in planar graphs. We can phrase this result in a self-contained way that does not require the general machinery of combined signatures. It should be noted that the case $s = 1$ was already solved by Valiant [36] and that our proof of Theorem 3 is a rather simple generalization of his construction. In a different context, this idea is also used in [9].

More effort is then required to prove Theorem 2, and we do so by reduction to Theorem 3. To this end, we label each vertex in the planar graph $G - A$ with its neighborhood in the apex set A. Each k-defect matching in $G - A$ then has a *type*, which is the k-element multiset of A-neighborhoods of its k defects.[2] We will be able to count k-defect matchings M of any specified type among the $(2^k)^k$ possible types, and we observe that the number of extensions from M to a perfect matching in G depends only on its type. This will allow us to recover the number of perfect matchings in G.

2 Preliminaries

For $n \in \mathbb{N}$, write $[n] = \{1, \ldots, n\}$. Graphs G are undirected and simple. They are unweighted unless specified otherwise. We write $N_G(v)$ for the neighborhood of $v \in V(G)$ in G.

2.1 Polynomials

We denote the degree of a polynomial $p \in \mathbb{Q}[x]$ by $\deg(p)$. If $\mathbf{x} = (x_1, \ldots, x_t)$ is a list of indeterminates, then we write $\mathbb{N}^{\mathbf{x}}$ for the set of all monomials over $\mathbf{x}$. A *multivariate polynomial* $p \in \mathbb{Q}[\mathbf{x}]$ is a polynomial $p = \sum_{\theta \in \mathbb{N}^{\mathbf{x}}} a(\theta) \cdot \theta$ with $a(\theta) \in \mathbb{Q}$ for all $\theta \in \mathbb{N}^{\mathbf{x}}$, where a has finite support. The polynomial p *contains* a given monomial $\theta \in \mathbb{N}^{\mathbf{x}}$ if $a(\theta) \neq 0$ holds. If x is an indeterminate from $\mathbf{x}$, then we write $\deg_x(p)$ for the *degree of* x in p. This is the maximum number $k \in \mathbb{N}$ such that p contains a monomial θ with factor x^k. If $\mathbf{y}$ is a list of indeterminates, then we denote the *total degree of* $\mathbf{y}$ in p as the maximum degree of any monomial $\mathbb{N}^{\mathbf{y}}$ that is contained as a factor of a monomial in p.

Furthermore, if $p \in \mathbb{Q}[x, y]$ is a bivariate polynomial and $\xi \in \mathbb{Q}$ is some arbitrary fixed value, we write $p(\cdot, \xi)$ for the result of the substitution $y \leftarrow \xi$ in p, and we observe that $p(\cdot, \xi) \in \mathbb{Q}[x]$. Likewise, we write $p(\xi, \cdot)$ for the result of substituting $x \leftarrow \xi$.

2.2 (Perfect) matching polynomials

If G is a graph, then a set $M \subseteq E(G)$ of vertex-disjoint edges is called a matching. We write $\mathcal{M}[G]$ for the set of all matchings of G. For $M \in \mathcal{M}[G]$, we write $\mathrm{usat}(M)$ for the set of unmatched vertices in M. If $|\mathrm{usat}(M)| = k$ for $k \in \mathbb{N}$, we say that M is a k-defect matching, and we write $\mathcal{DM}_k[G]$ for the set of k-defect matchings of G. We also write $\mathcal{PM}[G] = \mathcal{DM}_0[G]$ for the set of perfect matchings of G.

[2] This resembles an idea from an algorithm for counting subgraphs of bounded vertex-cover number [11].

If G is an edge-weighted graph with edge-weights $w : E(G) \to \mathbb{Q}$, then we define

$$\#\mathsf{PerfMatch}(G) = \sum_{M \in \mathcal{PM}[G]} \prod_{e \in M} w(e). \tag{1}$$

On planar graphs G, we can efficiently compute $\#\mathsf{PerfMatch}(G)$.

▶ **Theorem 4** ([26, 33, 27])**.** *For planar edge-weighted graphs G, the value $\#\mathsf{PerfMatch}(G)$ can be computed in time $\mathcal{O}(n^3)$.*

If G is a vertex-weighted graph with vertex-weights $w : V(G) \to \mathbb{Q}$, we define

$$\#\mathsf{MatchSum}(G) = \sum_{M \in \mathcal{M}[G]} \prod_{v \in \mathrm{usat}(M)} w(v). \tag{2}$$

Both $\#\mathsf{PerfMatch}$ and $\#\mathsf{MatchSum}$ are also used in [36]. Note that zero-weights have different semantics in the two expressions: A vertex $v \in V(G)$ with $w(v) = 0$ is required to be matched in all matchings $M \in \mathcal{M}[G]$ that contribute a non-zero term to $\#\mathsf{MatchSum}$. An edge $e \in E(G)$ with $w(e) = 0$ can simply be deleted from G without affecting $\#\mathsf{PerfMatch}(G)$.

Finally, if X is a formal indeterminate, we define the defect-generating matching polynomial of unweighted graphs G as

$$\mu(G) := \sum_{M \in \mathcal{M}[G]} X^{|\mathrm{usat}(M)|} = \sum_{k=0}^{n} \#\mathcal{DM}_k[G] \cdot X^k. \tag{3}$$

Note that $\mu(G) = \#\mathsf{MatchSum}(G')$ when G' is obtained from G by assigning weight X to every vertex of G. In this paper, we will be interested in the first k coefficients of $\mu(G)$.

▶ Remark. It is known [4] that for every fixed $\xi \in \mathbb{Q} \setminus \{0\}$, the problem of evaluating $\mu(G; \xi)$ on input G is #P-complete, even on planar bipartite graphs G of maximum degree 3. Note that the evaluation $\mu(G; 0)$ counts the perfect matchings of G.

2.3 Techniques from parameterized counting

Please consider Section 1.1 for an introduction to parameterized counting complexity, and [15] for a more formal treatment. We write $\leq^T_{fpt}$ for parameterized (Turing) reductions between problems (as introduced in Section 1.1). Furthermore, we write $\leq^{lin}_{fpt}$ for such parameterized reductions that incur only linear parameter blowup, i.e., on instances x with parameter k, they only issue queries with parameter $\mathcal{O}(k)$.

Given a universe Ω and several "bad" subsets of Ω, the inclusion-exclusion principle allows us to count those elements of Ω that avoid all bad subsets, provided that we know the sizes of intersections of bad subsets.

▶ **Lemma 5.** *Let Ω be a set and let $A_1, \ldots, A_t \subseteq \Omega$. For $\emptyset \subset S \subseteq [t]$, let $A_S := \bigcap_{i \in S} A_i$ and define $A_\emptyset := \Omega$. Then we have $\left|\Omega \setminus \bigcup_{i \in [t]} A_i\right| = \sum_{S \subseteq [t]} (-1)^{|S|} |A_S|$.*

In applications of Lemma 5, the left-hand side of the equation corresponds to a quantity we wish to determine, while the numbers $|A_S|$ for $S \subseteq [t]$ are computed by oracle calls.

We will also generously use the technique of polynomial interpolation: if a univariate polynomial p has degree n and we can evaluate $p(\xi)$ at $n + 1$ distinct values ξ, then we can recover the coefficients of p. This can be generalized to multivariate polynomials: If p has n variables, all of maximum degree d, and we are given sets $\Xi_1, \ldots, \Xi_n$, all of size $d + 1$, along with evaluations of $p(\xi)$ on all grid points $\xi \in \Xi_1 \times \ldots \times \Xi_n$, then we can determine the coefficients of p in time $\mathcal{O}((d + 1)^{3n})$.

▶ **Lemma 6** ([8]). *Let $p \in \mathbb{Z}[x_1, \ldots, x_n]$ be a multivariate polynomial, and for $i \in [n]$, let the degree of x_i in p be bounded by $d_i \in \mathbb{N}$. Let $\Xi = \Xi_1 \times \ldots \times \Xi_n \subseteq \mathbb{Q}^n$ with $|\Xi_i| = d_i + 1$* for all *$i \in [n]$. Then we can compute the coefficients of p with $\mathcal{O}(|\Xi|^3)$ arithmetic operations when given as input the set $\{(\xi, p(\xi)) \mid \xi \in \Xi\}$.*

3 Hardness of #PlanarDefectMatch

We now prove Theorem 1: Given a *planar* graph G and $k \in \mathbb{N}$, it is #W[1]-hard to count the k-defect matchings of G. This amounts to computing the coefficient of X^k in the matching-defect polynomial $\mu(G)$. We start from the #W[1]-hardness for the following problem #ApexPerfMatch, which follows from Theorem 1.2 and Remark 5.6 in [12]:

▶ **Theorem 7** ([12]). *The following problem #ApexPerfMatch is #W[1]-hard: Compute the value of #PerfMatch(G), when given as input an unweighted graph G and an independent set $A \subseteq V(G)$ of size k such that $G - A$ is planar and each vertex $v \in V(G) \setminus A$ satisfies $|N_G(v) \cap A| \leq 1$. The parameter in this problem is k. Furthermore, assuming #ETH, the problem cannot be solved in time $n^{o(k/\log k)}$.*

In the proof of Theorem 1, we introduce an intermediate problem #RestrDefectMatch:

▶ **Problem 8.** The problem #RestrDefectMatch is defined as follows: Given as input a triple (G, S, k) where G is a planar graph, $S \subseteq V(G)$ is a set of vertices, and $k \in \mathbb{N}$ is an integer, count those k-defect matchings of G whose defects all avoid S, i.e., those k-defect matchings M with $S \cap \mathrm{usat}(M) = \emptyset$. The parameter is k.

The problem #RestrDefectMatch is equivalent (up to multiplication by a simple factor) to the problem #ApexPerfMatch on graphs G whose apices A are all adjacent to a common subset S of the planar graph $G - A$, and to no other vertices. Our overall reduction then proceeds along the chain

$$\#\mathsf{ApexPerfMatch} \leq_{fpt}^{lin} \#\mathsf{RestrDefectMatch} \leq_{fpt}^{lin} \#\mathsf{PlanarDefectMatch}. \tag{4}$$

3.1 From #ApexPerfMatch to #RestrDefectMatch

The first reduction in (4) follows from an application of the inclusion-exclusion principle.

▶ **Lemma 9.** *We have #ApexPerfMatch $\leq_{fpt}^{lin}$ #RestrDefectMatch.*

Proof of Lemma 9. We reduce from #ApexPerfMatch and wish to count perfect matchings in an unweighted graph G with apex set $A = \{a_1, \ldots, a_k\}$ and planar base graph $H = G - A$. Note that A is given as part of the input, and it is an independent set. Furthermore, by definition of #ApexPerfMatch, the set $V(H)$ admits a partition into $V_1 \cup \ldots \cup V_k \cup W$ such that all vertices $v \in V_i$ for $i \in [k]$ are adjacent to the apex a_i and to no other apices, while no vertex $v \in W$ is adjacent to any apex. In other words, each vertex $v \in V(H)$ can be colored by its unique adjacent apex, or by a neutral color if $v \in W$.

Recall that $\mathcal{DM}_k[H]$ denotes the set of k-defect matchings in H. We call a k-defect matching $M \in \mathcal{DM}_k[H]$ *colorful* if $|\mathrm{usat}(M) \cap V_i| = 1$ holds for all $i \in [k]$, and we write $\mathcal{C}$ for the set of all such M. Note that $\mathrm{usat}(M) \cap W = \emptyset$ for $M \in \mathcal{C}$, since none of its k defects are left over for W.

We claim that $\mathcal{PM}[G] \simeq \mathcal{C}$: If $M \in \mathcal{PM}[G]$, then $N = M - A$ satisfies $N \in \mathcal{C}$. Conversely, every $N \in \mathcal{C}$ can be extended to a unique $M \in \mathcal{PM}[G]$ by matching the unique i-colored defect to its unique adjacent apex a_i.

Given oracle access to #RestrDefectMatch, we can determine $\#\mathcal{C}$ by the inclusion-exclusion principle from Lemma 5: For $i \in [k]$, let $\mathcal{A}_i$ denote the set of those $M \in \mathcal{DM}_k[H]$ whose defects avoid color i, i.e., they satisfy $\mathrm{usat}(H, M) \cap V_i = \emptyset$. Then $\mathcal{C} = \mathcal{DM}_k[H] \setminus \bigcup_{i \in [k]} \mathcal{A}_i$.

For $S \subseteq [k]$, write $\mathcal{A}_S = \bigcap_{i \in S} \mathcal{A}_i$ and note that we can compute $\#\mathcal{A}_S$ by an oracle call to #RestrDefectMatch on the instance $(H, \bigcup_{i \in S} V_i, k)$. We can hence compute $\#\mathcal{C} = \#\mathcal{PM}[G]$ via inclusion-exclusion (Lemma 5) and 2^k oracle calls to #RestrDefectMatch. ◀

3.2 From #RestrDefectMatch to #PlanarDefectMatch

For the second reduction in (4), we wish to solve instances (G, S, k) to #RestrDefectMatch when given only an oracle for counting k-defect matchings in planar graphs, *without* the ability of specifying the set S. Let G, S and k be fixed in the following. Our reduction involves manipulations on polynomials, such as a truncated version of polynomial division:

▶ **Lemma 10.** *Let X be an indeterminate, and let $p, q \in \mathbb{Z}[X]$ be polynomials $p = \sum_{i=0}^{m} b_i X^i$ and $q = \sum_{i=0}^{n} a_i X^i$ with $a_0 \neq 0$. For all $t \in \mathbb{N}$, we can compute $b_0, \dots, b_t$ with $\mathcal{O}(t^2)$ arithmetic operations from $a_0, \dots, a_t$ and the first $t+1$ coefficients of the product pq.*

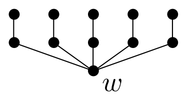
Proof. Let $c_0, \dots, c_{n+m}$ enumerate the coefficients of the product pq. By elementary algebra, we have $c_i = \sum_{\kappa=0}^{i} a_\kappa b_{i-\kappa}$, which implies the linear system

$$\begin{pmatrix} a_0 & & \\ \vdots & \ddots & \\ a_t & \dots & a_0 \end{pmatrix} \begin{pmatrix} b_0 \\ \vdots \\ b_t \end{pmatrix} = \begin{pmatrix} c_0 \\ \vdots \\ c_t \end{pmatrix}. \tag{5}$$

As this system is triangular with $a_0 \neq 0$ on its main diagonal, it has full rank and can be solved uniquely for $b_0, \dots, b_t$ with $\mathcal{O}(t^2)$ arithmetic operations. ◀

Our proof also relies upon a gadget which will allow to distinguish S from $V(G) \setminus S$.

▶ **Definition 11.** For $\ell \in \mathbb{N}$, an ℓ-rake R_ℓ is a matching M of size ℓ, together with an additional vertex w adjacent to one vertex of each edge in M:



Let $G_{S,\ell}$ be the graph obtained from attaching R_ℓ to each $v \in S$. This means adding a local copy of R_ℓ to v and identifying the copy of w with v. Please note that vertices $v \in V(G) \setminus S$ receive no attachments in $G_{S,\ell}$.

It is obvious that $G_{S,\ell}$ is planar if G is. Recall the defect-generating matching polynomial μ from (3). We first show that, for fixed $\ell \in \mathbb{N}$, the polynomial $\mu(G_{S,\ell})$ can be written as a weighted sum over matchings $M \in \mathcal{M}[G]$, where each M is weighted by an expression that depends on the number $|\mathrm{usat}(M) \cap S|$. Ultimately, we want to tweak these weights in such a way that only matchings with $|\mathrm{usat}(M) \cap S| = 0$ are counted.

▶ **Lemma 12.** *Define polynomials $r, f_\ell \in \mathbb{Z}[X]$ and $s \in \mathbb{Z}[X, \ell]$ by*

$$r(X) = 1 + X^2, \qquad s(X, \ell) = \ell + 1 + X^2, \qquad f_\ell(X) = (1 + X^2)^{|S|(\ell-1)}.$$

Then it holds that

$$\mu(G_{S,\ell}, X) = f_\ell \cdot \sum_{M \in \mathcal{M}[G]} X^{|\mathrm{usat}(M)|} \cdot r^{|S \setminus \mathrm{usat}(M)|} \cdot s^{|S \cap \mathrm{usat}(M)|}. \tag{6}$$

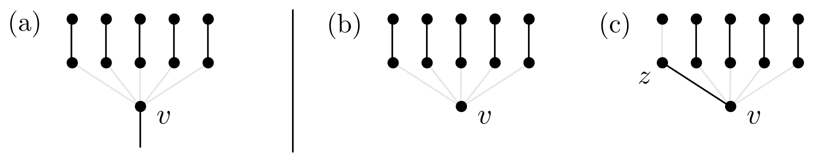


Figure 1 Possible types of extensions of the rake at v. The left case corresponds to $v \notin \mathrm{usat}(M)$, and the two right cases correspond to $v \in \mathrm{usat}(M)$.

Proof. Every matching $M \in \mathcal{M}[G]$ induces a certain set $\mathcal{C}_M \subseteq \mathcal{M}[G_{S,\ell}]$ of matchings in $G_{S,\ell}$, where each matching $N \in \mathcal{C}_M$ consists of M together with an extension by rake edges. The family $\{\mathcal{C}_M\}_{M\in\mathcal{M}[G]}$ is easily seen to partition $\mathcal{M}[G_{S,\ell}]$, and we obtain

$$\mu(G_{S,\ell}, X) = \sum_{M\in\mathcal{M}[G]} \underbrace{\sum_{N\in\mathcal{C}_M} X^{|\mathrm{usat}(N)|}}_{=:e(M)}. \tag{7}$$

Every matching $N \in \mathcal{C}_M$ consists of M and rake edges, which are added independently at each vertex $v \in S$. Hence, the expression $e(M)$ in (6) can be computed from the product of the individual extensions at each $v \in S$. To calculate the factor obtained by such an extension, we have to distinguish whether v is unmatched in M or not. The possible extensions at v are also shown in Figure 1.

$v \notin \mathrm{usat}(M)$: We can extend M at v by any subset of the ℓ rake edges not adjacent to v, as shown in Figure 1.a. In total, these 2^ℓ extensions contribute the factor $(1 + X^2)^\ell = (1 + X^2)^{\ell-1}r$.

$v \in \mathrm{usat}(M)$: We have two choices for extending, shown in the right part of Figure 1: Firstly, we can extend as in the case $v \notin \mathrm{usat}(M)$, and then we obtain the factor $X(1 + X^2)^\ell$. Here, the additional factor X corresponds to the unmatched vertex v. This situation is shown in Figure 1.b. Secondly, we can match v to one of its ℓ incident rake edges, say to $e = vz$ for a rake vertex z, as in Figure 1.c. Then we can choose a matching among the $\ell - 1$ rake edges not incident with z. This gives a factor of $\ell X(1 + X^2)^{\ell-1}$. Note that v is matched, but the vertex adjacent to z is not, yielding a factor of X.
In total, if $v \in \mathrm{usat}(M)$, we obtain the factor $X(1+X^2)^\ell+\ell X(1+X^2)^{\ell-1} = X(1+X^2)^{\ell-1}s$.

In each matching $N \in \mathcal{C}_M$, every unmatched vertex in $\bar{S} = V(G) \setminus S$ contributes a factor X. By multiplying the contributions of all $v \in V(G)$, we have thus shown that

$$\begin{aligned} e(M) &= f_\ell(X) \cdot X^{|\bar{S}\cap\mathrm{usat}(M)|} \cdot r^{|S\setminus\mathrm{usat}(M)|} \cdot (Xs)^{|S\cap\mathrm{usat}(M)|} \\ &= f_\ell(X) \cdot X^{|\mathrm{usat}(M)|} \cdot r^{|S\setminus\mathrm{usat}(M)|} \cdot s^{|S\cap\mathrm{usat}(M)|} \end{aligned}$$

and together with (7), this proves the claim. ◀

Due to the factor f_ℓ, the expression $\mu(G_{S,\ell})$ is not a polynomial in the indeterminates X and ℓ. We define a polynomial $p \in \mathbb{Z}[X, \ell]$ by removing this factor.

$$p(X, \ell) := \sum_{M\in\mathcal{M}[G]} X^{|\mathrm{usat}(M)|} \cdot r^{|S\setminus\mathrm{usat}(M)|} \cdot s^{|S\cap\mathrm{usat}(M)|}. \tag{8}$$

Depending upon the concrete application, we will consider $p \in \mathbb{Z}[X, \ell]$ as a polynomial in the indeterminates ℓ and X, or as a polynomial $p \in (\mathbb{Z}[\ell])[X]$ in the indeterminate X with coefficients from $\mathbb{Z}[\ell]$. In this last case, we write $p = \sum_{i=0}^{n} a_i X^i$ with coefficients $a_i \in \mathbb{Z}[\ell]$ for $i \in \mathbb{N}$ that are in turn polynomials. Then we define

$$[p]_k := \sum_{i=0}^{k} a_i X^i \tag{9}$$

as the restriction of p to its first $k+1$ coefficients. For later use, let us observe the following simple fact about $[p]_k$, considered as a polynomial $[p]_k \in \mathbb{Z}[X, \ell]$.

▶ **Fact 13.** *For $i, j \in \mathbb{N}$, every monomial $\ell^i X^j$ appearing in $[p]_k$ satisfies $i \le j \le k$.*

Proof. Recall r and s from Lemma 12. The indeterminate ℓ appears in s with degree 1, but it does not appear in r. In the right-hand side of (8), every term containing a factor s^t, for $t \in \mathbb{N}$, also contains the factor X^t, because $|S \cap \mathrm{usat}(M)| \le |\mathrm{usat}(M)|$ trivially holds. Hence, whenever $\ell^i X^j$ is a monomial in p, then $i \le j$. Since the maximum degree of X in $[p]_k$ is k by definition, the claim follows. ◀

In the next lemma, we show that knowing the coefficients of $[p]_k$ allows to solve the instance (G, S, k) to #RestrDefectMatch from the beginning of this subsection. After that, we will show how to compute $[p]_k$ with an oracle for #PlanarDefectMatch.

▶ **Lemma 14.** *Let $\mathcal{N}$ denote the set of (not necessarily k-defect) matchings in G with $\mathrm{usat}(M) \cap S = \emptyset$. For all $k \in \mathbb{N}$, we can compute the number of k-defect matchings in $\mathcal{N}$ in polynomial time when given the coefficients of $[p]_k$.*

Proof. For ease of presentation, assume first we knew *all* coefficients of p rather than only those of $[p]_k$. We will later show how to solve the problem when given only $[p]_k$.

Starting from p, we perform the substitution

$$\ell \leftarrow -(1 + X^2) \tag{10}$$

to obtain a new polynomial $q \in \mathbb{Z}[X]$ from p. By definition of s (see Lemma 12), we have

$$s(X, -(1 + X^2)) = 0, \tag{11}$$

so every matching $M \notin \mathcal{N}$ has zero weight in q. To see this, note that by (8), the weight of each matching $M \in \mathcal{M}[G]$ in p contains a factor $s^{|S \cap \mathrm{usat}(M)|}$. But due to (11), the corresponding term in q is non-zero only if $|S \cap \mathrm{usat}(M)| = 0$. We obtain

$$q = \sum_{M \in \mathcal{N}} X^{|\mathrm{usat}(M)|} \cdot (1 + X^2)^{|S \setminus \mathrm{usat}(M)|}.$$

Since every $M \in \mathcal{N}$ satisfies $|S \setminus \mathrm{usat}(M)| = |S|$, this simplifies to

$$q = (1 + X^2)^{|S|} \cdot \underbrace{\sum_{M \in \mathcal{N}} X^{|\mathrm{usat}(M)|}}_{=:q'} \tag{12}$$

and we can use standard polynomial division by $(1 + X^2)^{|S|}$ to obtain

$$q' = q/(1 + X^2)^{|S|}. \tag{13}$$

By (12), for all $k \in \mathbb{N}$, the coefficient of X^k in q' counts precisely the k-defect matchings in $\mathcal{N}$. This finishes the discussion of the idealized setting when all coefficients of p are known.

Recall the three steps involved: The substitution in (10), the polynomial division in (13), and the extraction of the coefficient X^k from q'.

The full claim, when only $[p]_k$ rather than p is given, can be shown similarly, but some additional care has to be taken. First, we perform the substitution (10) on $[p]_k$ rather than p. This results in a polynomial $b \in \mathbb{Z}[X]$, for which we claim the following:

▶ **Claim 15.** *We have* $[b]_k = [q]_k$.

Proof. Let $\Theta_{\leq i}$ for $i \in \mathbb{N}$ denote the set of monomials in p with degree $\leq i$ in X. The substitution (10) maps every monomial θ in the indeterminates X and ℓ to some polynomial $g_\theta \in \mathbb{Z}[X]$. Writing $a(\theta) \in \mathbb{Z}$ for the coefficient of θ in p, we obtain $q, b \in \mathbb{Z}[X]$ with

$$q = \sum_{\theta \in \Theta_{\leq n}} a(\theta) \cdot g_\theta, \tag{14}$$

$$b = \sum_{\theta \in \Theta_{\leq k}} a(\theta) \cdot g_\theta. \tag{15}$$

We can conclude that

$$[q]_k \underset{(14)}{=} \left[\sum_{\theta \in \Theta_{\leq n}} a(\theta) \cdot g_\theta \right]_k = \left[\sum_{\theta \in \Theta_{\leq k}} a(\theta) \cdot g_\theta \right]_k \underset{(15)}{=} [b]_k \,, \tag{16}$$

where the second identity holds since, whenever θ has degree i in X, for $i \in \mathbb{N}$, then g_θ contains a factor X^i. Hence, for $\theta \in \Theta_{\leq n} \setminus \Theta_{\leq k}$, no terms of the polynomial g_θ appear in $\left[\sum_{\theta \in \Theta_{\leq n}} a(\theta) \cdot g_\theta\right]_k$. This proves the claim. ◀

Recall the polynomial q' from (13); it remains to apply polynomial division as in (13) to recover $[q']_k$ from $[b]_k$. To this end, we observe that the constant coefficient in $(1+X^2)^{|S|}$ is 1, and that all coefficients of $(1+X^2)^{|S|}$ can be computed by a closed formula. We can thus divide $[b]_k = [q]_k$ by $[(1+X^2)^{|S|}]_k$ via truncated polynomial division (Lemma 10) to obtain $[q']_k$, whose k-th coefficient counts the k-defect matchings in $\mathcal{N}$, as in the idealized setting discussed before. ◀

Using a combination of truncated polynomial division (Lemma 10) and interpolation, we compute the coefficients of $[p]_k$ with oracle access for #PlanarDefectMatch. This completes the reduction from #RestrDefectMatch to #PlanarDefectMatch.

▶ **Lemma 16.** *We can compute* $[p]_k$ *by a Turing fpt-reduction to* #PlanarDefectMatch *such that all queries have maximum parameter* k.

Proof. For ξ with $0 \leq \xi \leq k$, let $f_\xi \in \mathbb{Z}[X]$ be the evaluation of the expression f_ℓ defined in Lemma 12 at $\ell = \xi$. Define $p_\xi^{(k)} \in \mathbb{Z}[X]$ by

$$p_\xi^{(k)} := [\mu(G_{S,\xi})/f_\xi]_k \,. \tag{17}$$

▶ **Claim 17.** *We have* $p_\xi^{(k)} = [p(\cdot,\xi)]_k = [p]_k(\cdot,\xi)$.

Proof. The first identity holds by the definition of p in (8), and by the definition of $p_\xi^{(k)}$. The second identity holds because, for all $t \in \mathbb{N}$, the coefficient of X^t in p is a polynomial in ℓ and does not depend on X. Hence we may arbitrarily interchange (i) the operation of substituting ℓ by expressions not depending on X (and by numbers $\xi \in \mathbb{N}$ in particular), and (ii) the operation of truncating to the first k coefficients. ◀

Recall that $a_t \in \mathbb{Z}[\ell]$ for $t \in \mathbb{N}$ denotes the coefficient of X^t in p, which has degree at most k (in the indeterminate ℓ) by Fact 13. Hence, for fixed $t \in \mathbb{N}$, if we knew the values $a_t(0), \ldots, a_t(k)$, we could recover the coefficients of $a_t \in \mathbb{Z}[\ell]$ via univariate polynomial interpolation. But for $0 \leq \xi, t \leq k$, we can obtain the value $a_t(\xi)$ as the coefficient of X^t in $p_\xi^{(k)}$. This follows from Claim 17. It remains to compute the polynomials $p_0^{(k)}, \ldots, p_k^{(k)}$ with an oracle for #PlanarDefectMatch: First, we observe that the constant coefficient in f_ξ is 1 for all $0 \leq \xi \leq k$, so we can apply the definition of $p_\xi^{(k)}$ from (17) and truncated polynomial division (Lemma 10) to compute $p_\xi^{(k)}$ from $[\mu(G_{S,\xi})]_k$ and f_ξ.

It remains only to compute $[\mu(G_{S,\xi})]_k$ and f_ξ. Note that the coefficients of f_ξ admit a closed expression by definition, and that $[\mu(G_{S,\xi})]_k$ can be computed by querying the oracle for #PlanarDefectMatch to obtain the number of matchings in $G_{S,\xi}$ with $0, \ldots, k$ defects. ◀

We recapitulate the proof of Theorem 1 in the following.

Proof of Theorem 1. By Theorem 7, the problem #ApexPerfMatch is #W[1]-hard, and we have reduced it to #RestrDefectMatch in Lemma 9. By Lemma 16, we can use oracle calls to #PlanarDefectMatch with maximum parameter k to compute the polynomial $[p]_k$, and by Lemma 14, the coefficients of $[p]_k$ allow to recover the solution to #RestrDefectMatch in polynomial time. These two steps establish the second reduction in (4).

Note that both reductions incur only linear blowup on the parameter. Hence, the lower bound of $n^{\Omega(k/\log k)}$ for #ApexPerfMatch under #ETH from Theorem 7 carries over to #PlanarDefectMatch. ◀

4 Apices with few adjacent faces

We prove Theorem 2: We present an FPT-algorithm for a restricted version of the problem #PerfMatch on graphs G with an apex set A of size k such that every apex can see only a bounded number of faces. To this end, we first prove a stronger version of Theorem 3 that allows us to compute #MatchSum(G) rather than just count matchings in G.

▶ **Theorem 18.** *Assume we are given a drawing of a planar graph G with vertex-weights $w : V(G) \to \mathbb{Q}$ and faces $F_1, \ldots, F_s$ for $s \in \mathbb{N}$ such that all vertices $v \in V(G)$ with $w(v) \neq 0$ satisfy $v \in V(F_1) \cup \ldots \cup V(F_s)$. Then we can compute #MatchSum(G) in time $\mathcal{O}(2^s \cdot n^3)$.*

Proof. We first create a partition $B_1, \ldots, B_s$ of $\bigcup_{i \in [s]} V(F_i)$ such that $B_i \subseteq F_i$ for $i \in [s]$ and $B_i \cap B_j = \emptyset$ for $i \neq j$. This can be achieved trivially by assigning each vertex that occurs in several faces F_i to some arbitrarily chosen set B_i.

Now we define a type $\theta_M \in \{0,1\}^s$ for each $M \in \mathcal{M}[G]$. For $i \in [s]$, we define

$$\theta_M(i) := \begin{cases} 1 & |\mathrm{usat}(M) \cap B_i| \text{ odd}, \\ 0 & |\mathrm{usat}(M) \cap B_i| \text{ even}. \end{cases}$$

For $\theta \in \{0,1\}^s$, let $\mathcal{M}_\theta[G]$ denote the set of matchings $M \in \mathcal{M}[G]$ with $\theta_M = \theta$, and define

$$S_\theta = \sum_{M \in \mathcal{M}_\theta[G]} \prod_{v \in \mathrm{usat}(M)} w(v).$$

It is clear that #MatchSum$(G) = \sum_{\theta \in \{0,1\}^s} S_\theta$. We show how to compute S_θ for fixed θ in time $\mathcal{O}(n^3)$ by reduction to #PerfMatch in planar graphs. For this argument, we momentarily define $\#\mathsf{MatchSum}(G)$ on graphs that have vertex- and edge-weights $w : V(G) \cup E(G) \to \mathbb{Q}$:

$$\#\mathsf{MatchSum}(G) = \sum_{M \in \mathcal{M}[G]} \left(\prod_{v \in \mathrm{usat}(M)} w(v) \right) \left(\prod_{e \in M} w(e) \right).$$

As shown in the proof of Theorem 3.3 in [36], and in Example 15 in [9], for every $t \in \mathbb{N}$, there exist explicit planar graphs D_t^0 and D_t^1 with $\mathcal{O}(t)$ vertices, which contain special vertices $u_1, \dots, u_t$ such that all of the following holds:

1. The graphs D_t^0 and D_t^1 can be drawn in the plane with $u_1, \dots, u_t$ on their outer faces.
2. Let H be a vertex- and edge-weighted graph with distinct vertices $X = \{v_1, \dots, v_t\} \subseteq V(H)$ and let H' be obtained from H by placing a disjoint copy of D_t^0 into H and connecting v_i to u_i with an edge of weight $w(v_i)$ for all $i \in [t]$. Assign weight 0 to the vertices v_i and to all vertices of D_t^0. Then
$$\#\mathsf{MatchSum}(H') = \sum_{\substack{M \in \mathcal{M}[H] \\ |\mathrm{usat}(M) \cap X| \text{ even}}} \left(\prod_{v \in \mathrm{usat}(M)} w(v) \right) \left(\prod_{e \in M} w(e) \right) \tag{18}$$
3. The above statement also applies for D_t^1, but the corresponding sum in (18) ranges over those $M \in \mathcal{M}[H]$ where $|\mathrm{usat}(M) \cap X|$ is odd rather than even.

We observe that inserting D_t^0 or D_t^1 into the face of a planar graph preserves planarity. Hence, we can insert $D_{|B_i|}^{\theta(i)}$ at the vertices B_i along face F_i in G, for each $i \in [s]$, and obtain a planar graph G_θ. By construction, we have $\#\mathsf{MatchSum}(G_\theta) = S_\theta$. Furthermore, all vertex-weights in G_θ are 0 by construction, so we actually have $\#\mathsf{MatchSum}(G_\theta) = \#\mathsf{PerfMatch}(G_\theta)$. Since G_θ is planar, we can evaluate $\#\mathsf{PerfMatch}(G_\theta)$ in time $\mathcal{O}(n^3)$, thus concluding the proof. ◀

Note that the above theorem allows us to recover the number of k-defect matchings in G that have all defects on fixed distinguished faces, for any $k \in \mathbb{N}$: Let G_X be obtained from G by assigning weight X to each vertex. Then $p := \#\mathsf{MatchSum}(G_X)$ is a polynomial of degree at most n and can be interpolated from evaluations $p(0), \dots p(n)$, but each of these evaluations can be computed in time $\mathcal{O}(2^s \cdot n^3)$ by Theorem 18. As we know, the k-th coefficient of $p(X)$ is equal to the number of k-defect matchings in G.

In the following, we extend this argument by using a variant of multivariate polynomial interpolation (Lemma 6) that applies when we do not require the values of *all* coefficients, but rather only those in a "slice" of total degree k, for fixed $k \in \mathbb{N}$. Here, the polynomial p to be interpolated features a distinguished indeterminate X, and we wish to extract the coefficient a_k of X^k, which is in turn a polynomial. Under certain restrictions, this can be achieved with $f(k) \cdot n$ evaluations, where n denotes the degree of X in p.

▶ **Lemma 19.** *Let $p \in \mathbb{Z}[X, \lambda]$ be a multivariate polynomial in the indeterminates X and $\lambda = (\lambda_1, \dots, \lambda_t)$. Consider $p \in (\mathbb{Z}[\lambda])[X]$ and assume that p has degree n in X, and that for all $s \in \mathbb{N}$, the coefficient $a_s \in \mathbb{Z}[\lambda]$ of X^s in p has total degree at most s. Let $k \in \mathbb{N}$ be a given parameter, and let $\Xi = \Xi_0 \times \ldots \times \Xi_t \subseteq \mathbb{Q}^{t+1}$ with $|\Xi_0| = n + 1$ and $|\Xi_i| = k + 1$ for all $i > 0$. Then we can compute the coefficients of the polynomial $a_k \in \mathbb{Z}[\lambda]$ with $\mathcal{O}(|\Xi|^3)$ arithmetic operations when given as input the set $\{(\xi, p(\xi)) \mid \xi \in \Xi\}$.*

Proof. We consider the grid Ξ' defined by removing the first component from Ξ, that is, $\Xi' = \Xi_1 \times \ldots \times \Xi_t$. Observe that $p(\cdot, \xi') \in \mathbb{Z}[X]$ holds for $\xi' \in \Xi'$. Write $\Xi_0 = \{c_0, \dots, c_n\}$ and note that, for fixed $\xi' \in \Xi'$, our input contains all evaluations

$$p(c_0, \xi'), \dots, p(c_n, \xi'),$$

so we can use univariate interpolation to determine the coefficient of X^k in $p(\cdot, \xi')$. This coefficient is equal to $a_k(\xi')$ by definition. By performing this process for all $\xi' \in \Xi'$, we can evaluate $a_k(\xi')$ on all $\xi' \in \Xi'$, and hence interpolate the polynomial $a_k \in \mathbb{Z}[\lambda]$ via grid interpolation (Lemma 6). ◀

This brings us closer to the proof of Theorem 2. To proceed, we first consider the case that A is an independent set; the full algorithm is obtained by reduction to this case.

▶ **Lemma 20.** *Let G be an edge-weighted graph, given as input together with an independent set $A \subseteq V(G)$ of size k, a planar drawing of $H = G - A$, and faces $F_1, \dots, F_s$ that contain all neighbors of A. Then we can compute $\#\mathsf{PerfMatch}(G)$ in time $k^{\mathcal{O}(2^k)} \cdot 2^{\mathcal{O}(s)} \cdot n^4$.*

▶ Remark. We may assume that every edge $av \in E(G)$ with $a \in A$ and $v \in V(G) \setminus A$ has weight 1: Otherwise, replace av by a path ar_1r_2v with fresh vertices r_1, r_2, together with edges ar_1 and r_1r_2 of unit weight, and an edge r_2v of weight $w(e)$. This clearly preserves the apex number, the value of $\#\mathsf{PerfMatch}$, and ensures that every apex is only incident with unweighted edges.

Proof. Recall that $\mathcal{DM}_k[H]$ denotes the set of k-defect matchings in H. By Remark 4, we can assume that all edges incident with A have unit weight. Let

$$\mathcal{C} = \{M \in \mathcal{DM}_k[H] \mid \mathrm{usat}(M) \subseteq N_G(A)\}.$$

Given any matching $M \in \mathcal{C}$, let $t(M)$ denote its *type*[3], which is defined as the following *multiset* with precisely k elements from 2^A:

$$t(M) = \{N_G(v) \cap A \mid v \in \mathrm{usat}(M)\}.$$

For the set of all such types, we write $\mathcal{T} = \{t(M) \mid M \in \mathcal{C}\}$ and observe that $|\mathcal{T}| \leq (2^k)^k = 2^{k^2}$. For $t \in \mathcal{T}$, define a graph S_t as follows: Create an independent set $[k]$, corresponding to A. Then, for each $N \in t$, create a vertex v_N that is adjacent to all of $N \subseteq [k]$. We note that every *perfect* matching $M \in \mathcal{PM}[G]$ can be decomposed uniquely as $M = B(M) \dot\cup I(M)$ with a k-defect matching $B(M) \in \mathcal{C}$ and a perfect matching $I(M) \in \mathcal{PM}[S_{t(B(M))}]$. That is, $B(M) = M - A$ and $I(M) = M[A \cup \mathrm{usat}(B(M))]$. For $t \in \mathcal{T}$, let

$$\begin{aligned} \mathcal{C}_t &= \{M \in \mathcal{C} \mid t(M) = t\}, \\ P_t &:= \sum_{N \in \mathcal{C}_t} \prod_{e \in N} w(e). \end{aligned}$$

It is clear that $\{\mathcal{C}_t\}_{t \in \mathcal{T}}$ partitions $\mathcal{C}$, and this implies

$$\#\mathsf{PerfMatch}(G) = \sum_{t \in \mathcal{T}} P_t \cdot \#\mathsf{PerfMatch}(S_t). \tag{19}$$

To see this, note that each perfect matching of type t can be obtained by extending some matching $M \in \mathcal{C}_t$ (all of which have k defects) by a perfect matching from $\mathrm{usat}(M)$ to A, which is precisely a perfect matching of S_t. Note that we require here that edges between $\mathrm{usat}(M)$ and A have unit weight, otherwise the graphs S_t would have to be edge-weighted as well and might no longer depend on t only, but would also have to incorporate the edge-weights of G.

[3] Please note that these types have no connection to those used in the proof of Theorem 18.

Since $|E(S_t)| \leq k^2$, we can compute $\#\mathsf{PerfMatch}(S_t)$ in time $2^{\mathcal{O}(k^2)}$ by brute force for each $t \in \mathcal{T}$. Hence, we can use (19) to determine $\#\mathsf{PerfMatch}(G)$ in time $|\mathcal{T}| \cdot 2^{\mathcal{O}(k^2)}$ if we know P_t for all $t \in \mathcal{T}$. In the remainder of this proof, we show how to compute P_t by using multivariate polynomial interpolation and the algorithm for $\#\mathsf{MatchSum}$ presented in Theorem 18. To this end, define indeterminates $\lambda = \{\lambda_R \mid R \subseteq A\}$ corresponding to subsets of the apices. Let X denote an additional distinguished indeterminate, and define the following polynomial $p \in \mathbb{Z}[X, \lambda]$. In this definition, we abbreviate $w(M) := \prod_{e \in M} w(e)$.

$$p(X, \lambda) := \sum_{M \in \mathcal{C}} w(M) \cdot X^{|\mathrm{usat}(M)|} \cdot \prod_{v \in \mathrm{usat}(M)} \lambda_{N_G(v) \cap A}. \tag{20}$$

For each type $t \in \mathcal{T}$, say $t = \{N_1, \ldots, N_k\}$, the coefficient of $X^k \cdot \lambda_{N_1} \cdot \ldots \cdot \lambda_{N_k}$ in p is equal to P_t. Hence, we can extract P_t for all $t \in \mathcal{T}$ from the coefficients of the monomials in p that have degree exactly k in X. Let us denote these monomials by $\mathfrak{N}$, and observe that each monomial $\nu \in \mathfrak{N}$ has total degree k in λ by the definition of p in (20).

If we can evaluate p on the elements (r, ξ) from the grid $\Xi = [n+1] \times [k+1]^{2^{|A|}}$, then we can compute the coefficients of all $\nu \in \mathfrak{N}$ in p, and thus P_t for all $t \in \mathcal{T}$, by sliced grid interpolation (Lemma 19). Note that $|\Xi| \leq \mathcal{O}(n \cdot k^{2^k})$. We compute these evaluations $p(r, \xi)$ as $p(r, \xi) = \#\mathsf{MatchSum}(H')$, where the vertex-weighted graph $H' = H'(r, \xi)$ is obtained from H via the weight function

$$w(v) := \begin{cases} 0 & \text{if } v \notin N_G(A), \\ r \cdot \xi_{N_G(v) \cap A} & \text{otherwise.} \end{cases}$$

Since all vertices with non-zero weight in H' are contained in the faces $F_1, \ldots, F_s$, we can compute $\#\mathsf{MatchSum}(H')$ in time $\mathcal{O}(2^s \cdot n^3)$ with Theorem 18. We obtain the values P_t for all $t \in \mathcal{T}$, so we obtain $\#\mathsf{PerfMatch}(G)$ via (19) in the required time. ◀

It remains to lift Lemma 20 to the case that A is not an independent set. This follows easily from the fact that, whenever $E(G) = E \dot\cup E'$, then every perfect matching $M \in \mathcal{PM}[G]$ must match every vertex $v \in V(G)$ into exactly one of the sets E or E'.

Proof of Theorem 2. Let $\mathcal{A} = \mathcal{M}[G[A]]$ denote the set of (not necessarily perfect) matchings of the induced subgraph $G[A]$, and note that $|\mathcal{A}| \leq 2^{k^2}$. For $M \in \mathcal{A}$, let $a_M = \#\mathsf{PerfMatch}(G_M)$, where G_M is defined by keeping from A only $\mathrm{usat}(M)$, and then deleting all edges between the remaining vertices of A. We can compute a_M by Lemma 20, since the remaining part of A in G_M is an independent set. It is also easily verified that $\#\mathsf{PerfMatch}(G) = \sum_{M \in \mathcal{A}} a_M \cdot \prod_{e \in M} w(e)$, so we can compute $\#\mathsf{PerfMatch}$ as a linear combination of 2^{k^2} values, each of which can be computed by Lemma 20. ◀

Acknowledgments. The author wishes to thank Dániel Marx and Holger Dell for pointing out the connection between perfect matchings in k-apex graphs and $\#\mathsf{PlanarDefectMatch}$ during the Dagstuhl Seminar 10481 on Computational Counting in 2010. Furthermore, thanks to Mingji Xia for interesting discussions about this topic. In particular, Theorem 3 was found in joint work on combined signatures back in 2013. Thanks also to Markus Bläser for reading earlier drafts of this material as it appeared in my PhD thesis, and thanks to the reviewers of this version for providing helpful comments.

Abstract

We show that for any set of n moving points in $\mathbb{R}^d$ and any parameter $2 \leq k \leq n$, one can select a fixed non-empty subset of the points of size $O(k \log k)$, such that the Voronoi diagram of this subset is "balanced" at any given time (i.e., it contains $O(n/k)$ points per cell). We also show that the bound $O(k \log k)$ is near optimal even for the one dimensional case in which points move linearly in time. As an application, we show that one can assign communication radii to the sensors of a network of n moving sensors so that at any given time, their interference is $O(\sqrt{n \log n})$. This is optimal up to an $O(\sqrt{\log n})$ factor.

1 Introduction

We consider the following kinetic facility location problem: given n clients (i.e., points) that are moving in $\mathbb{R}^d$ along simple trajectories and a parameter $k \leq n$, we wish to select few of them to become facilities to serve the remaining clients. We follow the usual assumption

[*] M. K. was supported in part by the ELC project (MEXT KAKENHI Nos. 12H00855 and 15H02665).
[†] S. S. was partially supported by Grant 1136/12 from the Israel Science Foundation and by the Swiss National Science Foundation Grants 200020144531 and 200021-137574.

that at any instant of time a client is served by its nearest facility. Our aim is to select the facilities so that none serves too many customers. Specifically, we wish to maintain the invariant that at any given time the number of clients served by each of the chosen facilities is bounded by n/k.

The pigeon-hole principle directly implies that we cannot select fewer than k facilities. Our main result is that a subset of size $O(k \log k)$ will suffice. We also show that one cannot improve this bound to $O(k)$, even for $d = 1$. As an application, we show how to construct a communication graph among a set of n moving sensors such that at any given time, the interference of the communication graph is bounded by $O(\sqrt{n \log n})$ (and its hop-diameter is three). Intuitively speaking, the interference of a sensor is the in-degree (i.e., the number of sensors that can communicate to him directly, see more details in Section 5). This bound is near optimal as already, in the static case, there are examples where the interference is at least $\Omega(\sqrt{n})$ [6].

In order to obtain our results we use the machinery of geometric hypergraphs and the theory of VC-dimension and ε-nets. By a geometric hypergraph (also called a range-space) we mean the following: suppose we are given a finite set P of points in $\mathbb{R}^d$ and a family of simple geometric regions, such as the family of all halfspaces in $\mathbb{R}^d$. Then we consider the combinatorial structure of the set system $(P, \{h \cap P\})$ where h is any halfspace. A key property of such hypergraphs is bounded VC-dimension (see Section 2 for exact definitions). In this paper we study a more general structure by allowing the underlying set of points to move along some "reasonable" trajectories (i.e., the coordinates of each point can be described with a polynomial function of bounded degree). Even though the static case is well-known, little research has been done for the case in which the points move. We show that those more complex hypergraphs, defined as the union of all hypergraphs obtained at all possible times, still have a bounded VC-dimension.

In addition to the above mentioned applications, we believe that the bounded VC-dimension of such hypergraphs is of independent interest and to the best of our knowledge has not been observed before. We hope that this paper will have many follow-up applications, since bounded VC-dimension has applications in many other areas of mathematics and computer science.

The paper is organized as follows: in Section 2 we introduce several key concepts as well as review known results that hold for static range spaces. In Section 3 we extend these results to the kinetic case. In Sections 4 and 5 we prove our main results concerning Voronoi diagrams for moving points and the interference problem mentioned above.

2 Preliminaries and Previous Work

A hypergraph $H = (V, \mathcal{E})$ is a pair of sets such that $\mathcal{E} \subseteq 2^V$. A geometric hypergraph is one that can be realized in a geometric way. For example, consider the hypergraph $H = (V, \mathcal{E})$, where V is a finite subset of $\mathbb{R}^d$ and $\mathcal{E}$ consists of all subsets of V that can be cut-off from V by intersecting it with a shape belonging to some family of "nice" geometric shapes, such as the family of all halfspaces. The elements of V are called *vertices*, and the elements of $\mathcal{E}$ are called *hyperedges*. For a subset $V' \subseteq V$, the hypergraph $H[V'] = (V', \{V' \cap S \colon S \in \mathcal{E}\})$ is the *sub-hypergraph* induced by V'.

We consider the following families of geometric hypergraphs: Let P be a set of points in $\mathbb{R}^2$ (or, in general, in $\mathbb{R}^d$) and let $\mathcal{R}$ be a family of regions in the same space. We refer to the hypergraph $H = (P, \{P \cap r \colon r \in \mathcal{R}\})$ as the hypergraph induced by P with respect to $\mathcal{R}$. When $\mathcal{R}$ is clear from the context, we sometimes refer to it as the hypergraph induced by P. In the literature, hypergraphs that are induced by points with respect to geometric regions of some specific kind are also referred to as *range spaces*. We sometimes abuse the notation and write $(P, \mathcal{R})$, instead of $H = (P, E)$, where $E = \{P \cap r : r \in \mathcal{R}\}$.

ε-nets and VC-dimension

A subset $T \subset V$ is called a *transversal* (or a *hitting set*) of a hypergraph $H = (V, \mathcal{E})$, if it intersects all sets of $\mathcal{E}$. The *transversal number* of H, denoted by $\tau(H)$, is the smallest possible cardinality of a transversal of H. The fundamental notion of a transversal of a hypergraph is central in many areas of combinatorics and its relatives. In computational geometry, there is a particular interest in transversals, since many geometric problems can be rephrased as questions on the transversal number of certain hypergraphs. An important special case arises when we are interested in finding a small size set $N \subset V$ that intersects all "relatively large" sets of $\mathcal{E}$. This is captured in the notion of an ε-net for a hypergraph:

▶ **Definition 1** (ε-net)**.** Let $H = (V, \mathcal{E})$ be a hypergraph with V finite. Let $\varepsilon \in [0, 1]$ be a real number. A set $N \subseteq V$ (not necessarily in $\mathcal{E}$) is called an *ε-net* for H if for every hyperedge $S \in \mathcal{E}$ with $|S| \geq \varepsilon|V|$ we have $S \cap N \neq \emptyset$.[1]

In other words, a set N is an ε-net for a hypergraph $H = (V, \mathcal{E})$ if it stabs all "large" hyperedges (i.e., those of cardinality at least $\varepsilon|V|$). The well-known result of Haussler and Welzl [7] provides a combinatorial condition on hypergraphs that guarantees the existence of small ε-nets (see below). This requires the following well-studied notion of the Vapnik-Chervonenkis dimension [16]:

▶ **Definition 2** (VC-dimension)**.** Let $H = (V, \mathcal{E})$ be a hypergraph. A subset $X \subset V$ (not necessarily in $\mathcal{E}$) is said to be *shattered* by H if $\{X \cap S : S \in \mathcal{E}\} = 2^X$. The *Vapnik-Chervonenkis dimension*, also denoted the VC-*dimension* of H, is the maximum size of a subset of V shattered by H.

Relation between ε-nets and the VC-dimension

Haussler and Welzl [7] proved the following fundamental theorem regarding the existence of small ε-nets for hypergraphs with small VC-dimension.

▶ **Theorem 3** (ε-net theorem)**.** *Let $H = (V, \mathcal{E})$ be a hypergraph with* VC*-dimension d. For every $\varepsilon \in (0, 1)$, there exists an ε-net $N \subset V$ with cardinality at most* $O\left(\frac{d}{\varepsilon} \log \frac{1}{\varepsilon}\right)$.

In fact, it can be shown that a random sample of vertices of size $O(\frac{d}{\varepsilon} \log \frac{1}{\varepsilon})$ is an ε-net for H with a positive constant probability (see [10] for details on how to compute such nets).

Many hypergraphs studied in computational geometry and learning theory have a "small" VC-dimension, where by "small" we mean a constant independent of the number of vertices of the underlying hypergraph. It is known that whenever range spaces are defined through semi-algebraic sets of constant description complexity (i.e., sets defined as a Boolean combination of a constant number of polynomial equations and inequalities of constant maximum degree), the resulting hypergraph has finite VC-dimension. Halfspaces, balls, boxes, etc. are examples of such sets; see, e.g., [11, 13] for more details.

[1] An analogous definition applies when V is not necessarily finite and H is endowed with a probability measure.

Thus, by Theorem 3, these hypergraphs admit "small" size ε-nets. Kómlos *et al.* [8] proved that the bound $O(\frac{d}{\varepsilon}\log\frac{1}{\varepsilon})$ on the size of an ε-net for hypergraphs with VC-dimension d is best possible. Namely, for a constant d, they construct a hypergraph H with VC-dimension d such that any ε-net for H must have size of at least $\Omega(\frac{1}{\varepsilon}\log\frac{1}{\varepsilon})$. Recently, several breakthrough results provided better lower and upper bounds on the size of ε-nets in several special cases [1, 2, 14].

3 Kinetic hypergraphs

We start by extending the concept of geometric hypergraphs to the kinetic model. Let $P = \{p_1, \ldots, p_n\}$ denote a set of n moving points in $\mathbb{R}^d$, where each point is moving along some "simple" trajectory. That is, each p_i is a function $p_i : [0, \infty) \to \mathbb{R}^d$ of the form $p_i(t) = (x_1^i(t), \ldots, x_d^i(t))$, where $x_j^i(t)$ is a univariate polynomial $(1 \leq j \leq d)$. For a given real number $t \geq 0$ and a subset $P' \subset P$, we denote by $P'(t)$ the fixed set of points $\{p(t) \colon p \in P'\}$.

Let $\mathcal{R}$ be a (not necessarily finite) family of ranges; for example, the family of all half-spaces in $\mathbb{R}^d$. We define the *kinetic hypergraph* induced by $\mathcal{R}$:

▶ **Definition 4** (kinetic hypergraph). Let P be a set of moving points in $\mathbb{R}^d$ and let $\mathcal{R}$ be a family of ranges. Let $(P, \mathcal{E})$ denote the hypergraph where $\mathcal{E}$ consists of all subsets $P' \subseteq P$ for which there exists a time t and a range $r \in \mathcal{R}$ such that $P'(t) = P(t) \cap r$. We call $(P, \mathcal{E})$ the *kinetic hypergraph* induced by $\mathcal{R}$.

As in the static case we abuse the notation and denote the kinetic hypergraph by $(P, \mathcal{R})$. In order to apply our techniques, we need the following "bounded description complexity" assumption concerning the movement of the points of P. We say that a point $p_i = p_i(t) = (x_1^i(t), \ldots, x_d^i(t)) \in P$ moves with *description complexity* $s > 0$ if for each $1 \leq j \leq d$, the univariate polynomial $x_j^i(t)$ has degree at most s. In the remainder of this paper, we assume that $P(0)$ is in "general position". That is, at time $t = 0$ no $d+1$ points of $P(0)$ are on a common hyperplane. This assumption can be removed through usual symbolic perturbation techniques.

3.1 VC-Dimension of kinetic hypergraphs

In this section we prove that for many of the static range spaces that have small VC-dimension, their kinetic counterparts also have small VC-dimension. We start with the family $\mathcal{H}_d$ of all halfspaces in $\mathbb{R}^d$.

▶ **Theorem 5.** *Let $P \subset \mathbb{R}^d$ be a set of moving points with bounded description complexity s. Then, the kinetic-range space $(P, \mathcal{H}_d)$ has VC-dimension bounded by $O(d \log d)$.*

To prove Theorem 5, we need the following known definition and lemma (see, e.g., [11]). The *primal shatter function* of a hypergraph $H = (V, \mathcal{E})$ denoted by π_H is a function:

$$\pi_H : \{1, \ldots, |V|\} \to \mathbb{N}$$

defined by $\pi_H(i) = max_{V' \subseteq V, |V'|=i} |H[V']|$, where $|H[V']|$ denotes the number of hyperedges in the sub-hypergraph $H[V']$.

▶ **Lemma 6.** *Let $H = (V, \mathcal{E})$ be a hypergraph whose primal shatter function π_H satisfies $\pi_H(m) = O(m^c)$ for some constant $c \geq 2$. Then the VC-dimension of H is $O(c \log c)$.*

We provide a sketch of the proof of Lemma 6 for the sake of completeness.

Proof. Let d denote the VC-dimension of H, and let $V' \subseteq V$ be a shattered subset of cardinality d. On one hand it means that the number of possible subsets of V' that can be realized as the intersection of V' and a hyperedge in $\mathcal{E}$ is 2^d. On the other hand, by our assumption on π_H, for a subset of size d, there can be at most Ad^c hyperedges in the sub-hypergraph induced by it, for some appropriate constant A. In other words we have $2^d \leq \pi_H(d) \leq Ad^c$. This is easily seen to imply that $d = O(c \log c)$. Indeed, by choosing, say, $d = 10Ac \log c$, the above inequality does not hold, a contradiction. This completes the proof of the lemma. ◀

Proof of Theorem 5. By Lemma 6 it suffices to bound the primal shatter function $\pi_{\mathcal{H}_d}(m)$ by a polynomial of constant degree. It is a well known fact that the number of combinatorially distinct half-spaces determined by n (static) points in $\mathbb{R}^d$ is $O(n^d)$. This can be easily seen by charging hyperplanes to d-tuples of points (using rotations and translations) and observing that each tuple can be charged at most a constant (depending on the dimension d) number of times. Thus, at any given time, the number of hyperedges is bounded by $O(n^d)$. Next, note that as t varies, a combinatorial change in the hypergraph $(P(t), \mathcal{R})$ can occur only when $d+1$ points $p_1(t), \ldots, p_{d+1}(t)$ become affinely dependent. Indeed, a hyperedge is defined by a hyperplane that contains d points of $P(t)$, and that hyperedge changes when an additional point of $P(t)$ crosses the hyperplane (and thus $d+1$ points become affinely dependent). This happens if and only if the following determinant condition holds:

$$\begin{vmatrix} x_1^1(t) & x_2^1(t) & \cdots & x_d^1(t) & 1 \\ x_1^2(t) & x_2^2(t) & \cdots & x_d^2(t) & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ x_1^{d+1}(t) & x_2^{d+1}(t) & \cdots & x_d^{d+1}(t) & 1 \end{vmatrix} = 0 \tag{1}$$

where $x_i^j(t)$ denotes the i'th coordinate of $p_j(t)$. The left side of the equation is a univariate polynomial of degree at most ds. By our general position assumption this polynomial is not identically zero and thus can have at most ds solutions.

That is, a tuple of $d+1$ points of $P(t)$ generates at most ds events. Hence, the total number of such events is bounded by $O(\binom{n}{d+1}) = O(n^{d+1})$. Between any two events we have a fixed set of at most $O(n^d)$ distinct hyperedges, thus we can have $O(n^{2d+1})$ distinct hyperedges along all instants of time.

Since each hyperedge is defined by the points on its boundary, this property is hereditary. That is, for any subset $P' \subseteq P$ the hypergraph $H[P']$ has at most $O(|P'|^{2d+1})$ hyperedges. Thus, the shatter function satisfies $\pi_H(m) = O(m^{2d+1})$. Then by Lemma 6, $(P, \mathcal{H}_d)$ has bounded constant VC-dimension, where the constant depends only on d and s. ◀

Theorem 5 can be further generalized to arbitrary ranges with so-called bounded description complexity as defined below:

▶ **Theorem 7.** *Let $\mathcal{R}$ be a collection of semi-algebraic subsets of $\mathbb{R}^d$, each of which can be expressed as a Boolean combination of a constant number of polynomial equations and inequalities of maximum degree c (for some constant c). Let P be a set of moving points in $\mathbb{R}^d$ with bounded description complexity. Then the kinetic range-space $(P, \mathcal{R})$ has bounded* VC*-dimension.*

Proof. The proof combines Lemma 6 with Theorem 5 and the so-called Veronese lifting map from Algebraic Geometry. We omit the details as it is very similar to the proof for the static case. See, e.g., [11]. ◀

4 Balanced Voronoi cells for moving points

In this section we tackle the facility location problem for a set of moving clients, where the goal is to ensure a balanced division of the load among the facilities at any instance of time. Given a set P of moving points or *clients* in $\mathbb{R}^d$, locate a small number of the points to serve as *facilities* so that at every instance of time no facility is serving more than n/k clients. We make the usual assumption that each client goes to its nearest facility. In the following we show how to obtain an almost optimal balancing (up to a $\log k$ factor), even under the restriction that facilities may be located only at points of P.

▶ **Theorem 8.** *Let $P = \{p_1, \dots, p_n\}$ be any set of n moving points in $\mathbb{R}^d$ with bounded description complexity. For any integer $2 \le k \le n$, there exists a subset $N \subset P$ of cardinality $O(k \log k)$, such that for any time $t \ge 0$, each cell of the Voronoi diagram Vor$(N(t))$ contains at most $O(n/k)$ points of $P(t)$.*

Before proceeding with the proof of Theorem 8 we need the following result. An *infinite cone* with apex $a \in \mathbb{R}^d$ and angle $\theta \in \mathbb{R}$ is defined as the union of all halflines emanating from a whose orientations belong to some fixed cap of the sphere $\mathcal{S}^{d-1}$. Equivalently, it can be defined as the set:

$$\{x \in \mathbb{R}^d \colon (x-a) \cdot (b-a) \ge \|x-a\| \cos\theta\} \ ,$$

where "$\|\|$" denotes the Euclidean norm, " $\cdot$ " denotes the scalar product and b is a vector such that $\|b-a\| = 1$. A *bounded cone* is the intersection of an infinite cone with a ball centered at its apex.

▶ **Lemma 9.** *Let P be a set of moving points in $\mathbb{R}^d$ with bounded description complexity s, and let $\mathcal{R}$ be the family of all bounded cones. The kinetic hypergraph $(P, \mathcal{R})$ has bounded* VC*-dimension.*

Proof. As shown above, the boundary surface of an infinite cone is a quadric (i.e., a polynomial of degree 2). In particular, the ranges of $\mathcal{R}$ can be expressed as semi-algebraic sets of constant description complexity. Thus, by Theorem 7 the hypergraph $(P, \mathcal{R})$ has constant VC-dimension as claimed. ◀

Proof of Theorem 8. Let $\mathcal{W}$ be the family of all bounded cones in $\mathbb{R}^d$. Let $H = (P, \mathcal{W})$ be the corresponding kinetic hypergraph. By Lemma 9, H has constant VC-dimension.

We fix $\varepsilon = \frac{1}{k}$ and let $N \subset P$ be an ε-net for H of size $O(k \log k)$ (refer to Theorem 3). We show that N satisfies the desired property. That is, for any time $t \ge 0$ and point $q \in N$, the Voronoi cell of $q(t)$ in the Voronoi diagram Vor$(N(t))$ contains at most $O(n/k)$ points of $P(t)$. Let C_d be the minimum number of sixty-degree caps that are needed to cover the unit sphere $\mathcal{S}^{d-1}$. Using packing arguments it is easily seen that C_d is a constant that depends only on d; see, e.g., [3].

Assume to the contrary that the Voronoi cell of $q(t)$ contains a subset $P'(t) \subset P(t)$ of more than $C_d n/k$ points. By definition, each of the points in $P'(t)$ is closer to $q(t)$ than to any other point in $N(t)$. By the pigeonhole principle, there is an infinite sixty-degree cone W which has $q(t)$ as its apex and that contains at least $n/k + 1$ of the points of $P'(t)$. Sort the points of $P'(t) \cap W$ in increasing distance from $q(t)$; let $p_1(t), \dots, p_j(t)$ be the obtained order (note that by assumption, we have $j \ge n/k + 1$). Slightly perturb the cone W and bound it to obtain a bounded cone W' that contains the points $p_1(t), \dots, p_j(t)$ but does not contain $q(t)$ (or any other point of $P(t)$). This can always be done by choosing a sufficiently large radius, doing an infinitesimally small translation of the apex and (if necessary) changing the angle of the cone. Since N is an ε-net with respect to bounded cones, W' must contain a point $q'(t) \in N(t)$ (other than $q(t)$).

Since any point in $P(t) \cap W'$ also belongs to W, which is a cone of sixty degrees, any point $p(t) \in P(t) \cap W'$ for which $d(p(t), q(t)) \geq d(q'(t), q(t))$ must be closer to $q'(t)$ than to $q(t)$. In particular, $p_j(t)$ satisfies this inequality and thus belongs to the Voronoi cell of $q'(t)$ (and not of $q(t)$), which is a contradiction. ◀

In fact, a careful look at the proof above shows that the following stronger result holds:

▶ **Corollary 10.** *Let $N \subset P$, $|N| = O(k \log k)$, as in Theorem 8. Then, for any finite point set $S \subset \mathbb{R}^d$, and for any $t \geq 0$, the cell of any $q \in S$ in the Voronoi diagram $Vor(N(t) \cup S)$ contains at most $O(n/k)$ points of $P(t)$.*

Remark

We note that the bound of $O(k \log k)$ in Theorem 8 is near optimal. Clearly, if there are only $o(k)$ points in N then by the pigeonhole principle one of the Voronoi cells must contain $\omega(n/k)$ points of P. We also note that reducing the size of the set N seems to be out of reach and maybe impossible, even for the one dimensional case where the points move with constant speed. This follows from a recent lower-bound construction of Alon [1] for ε-nets for static hypergraphs consisting of points with respect to strips in the plane.

Indeed, assume that $d = 1$ and each point $p \in P$ is described with a linear equation of the form $p(t) = at + b$ (i.e., a line). Assume that there exists a subset $N \subset P$ such that for any $t > 0$ and $q \in N$, the Voronoi cell of $q(t)$ contains at most n/k points of $P(t)$. In particular, this implies that there are at most $2n/k$ points of $P(t)$ between any pair of consecutive points of $N(t)$. If we view the moving points in $\mathbb{R}$ as lines in $\mathbb{R}^2$, this is equivalent to choosing a subset of the lines with the property that any vertical segment (i.e., a range of the form $t_0 \times [c, d]$ for constants $t_0 > 0$, $c, d \in \mathbb{R}$) that intersects more than $2n/k$ of the above lines will also intersect one of the chosen lines. By standard point-line duality in two dimensions, this is equivalent to the problem of finding an $\varepsilon = \frac{2}{k}$-net for points with respect to strips in the plane, which still remains an open problem. Recently, Alon [1] gave a construction showing that such hypergraphs cannot have linear (in $\frac{1}{\varepsilon}$) size ε-nets. Since their problem can be reduced to ours, the same lower bound holds for our problem.

5 Low interference for moving transmitters

Here we show how to tackle the problem of minimizing interference among a set of wireless moving transmitters while keeping the number of topological changes of the underlying network subquadratic. In the following we define the concept of (receiver-based) *interference* of a set of ad-hoc sensors [17] (see Figure 1).

▶ **Definition 11.** Let $P = \{p_1, \ldots, p_n\}$ be a set of n points in $\mathbb{R}^d$ and let $r_1, \ldots, r_n$ be n non-negative reals representing power levels (or transmission radii) assigned to the points $p_1, \ldots, p_n$, respectively. Let $G = (P, E)$ be the graph associated with this power assignment, where $E = \{\{p, q\} \colon d(p, q) \leq min\{r_p, r_q\}\}$. That is, points p, q are neighbors in G if and only if p is contained in the ball centered at q with radius r_q and *vice versa*. Let $D = \{d_1, \ldots, d_n\}$ denote the set of balls where d_i is the ball centered at p_i and having radius r_i.

Let $I(D)$ denote the maximum depth of the arrangement of the balls in D. That is $I(D) = \max_{q \in \mathbb{R}^d} \{|\{d \in D \colon q \in d\}|\}$. We call $I(D)$ the *interference* of D, which is also the

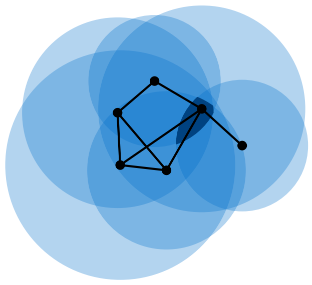

Figure 1 Given a set of fixed points in $\mathbb{R}^2$ and their power assignments represented by disks, the interference is the deepest point in the arrangement of the disks (the highlighted region in the figure). The underlying communication graph is shown with solid edges.

interference of the network. Note that both G and $I(D)$ are determined by P and $r_1, \ldots, r_n$. Given a set P of points in $\mathbb{R}^d$, the *interference* of P (denoted $I(P)$) is the smallest possible interference $I(D)$, where D corresponds to a power assignment whose associated graph is connected. The *interference minimization problem* asks for the power assignment for which $I(P) = I(D)$.

Empirically, (in dimension two) it has been observed that networks with high interference have high rates of message collision. This requires messages to be repeated often, which slows down the network and reduces battery life of the sensors [17]. Thus, a significant amount of research has focused in the creation of connected networks with low interference (see, e.g., [6, 9]). It is known that computing $I(P)$ (or even approximating it by a constant factor) is an NP-complete problem [4], but some worst-case bounds are known.

▶ **Theorem 12** ([6]). *Let P be a set of n points in the plane. Then $I(P) = O(\sqrt{n})$. Furthermore, this bound is asymptotically tight, in the sense that for any n there exists a set P of n points such that $I(P) = \Omega(\sqrt{n})$.*

Here, we turn our attention to the kinetic version of the interference problem in arbitrary but fixed dimension. We wish to maintain a connected graph of a set of moving points (representing moving sensors) that always has low interference. Unless the distances between sensors remain constant, no static radii assignment can work for a long period of time (since points will eventually be far from each other). Instead, we describe the network in a combinatorial way. That is, we look for a function $f : P \times [0, \infty) \to P$ that determines, for each sensor of P and instance of time, its furthest away sensor that must be reached. Then, at time t the communication radius of a sensor $p \in P$ is simply set equal to the distance between p and $f(p, t)$. Ideally, we would like to construct a network that not only has small interference at any instance of time, but also the underlying graph has a small amount of combinatorial changes along time.

Our algorithm to maintain a connected graph is based on the ideas used in [6] for the static case. We first pick a subset $N \subset P$ of "hubs". Those hubs will never change along time and will always have transmission radius big enough to cover all other points. Each other point in $P \setminus N$ will be assigned at every instance of time to its nearest hub. In the following we show that a careful choice of hubs will ensure a small interference, and overall small number of combinatorial changes in the radii assignment protocol. To bound the number of combinatorial changes, we need to use the machinery of Davenport-Schinzel sequences: A finite sequence $\sigma = (e_1, \ldots, e_m)$ over an alphabet of n symbols is called a *Davenport-Schinzel sequence* of order t when no two consecutive elements of σ are equal, and for any two distinct symbols x, y, there does not exist a subsequence where x and y alternate $t + 2$

times. Several bounds are known on the maximum length of Davenport-Schinzel sequences of a given order. In particular, we are interested in upper bounds. See [15] for more details on Davenport-Schinzel sequences.

▶ **Theorem 13** (Upper bound on Davenport-Schinzel sequences [12])**.** *A Davenport-Schinzel sequence of order t on n symbols has length at most $O(n2^{O(\alpha(n)^{\lfloor(t-2)/2\rfloor})})$, where $\alpha(n)$ is the inverse of the Ackermann function.*

The Ackermann function is a function that grows very rapidly, hence its inverse is usually regarded as a small constant (indeed, it is known that $\alpha(n) \leq 5$ for any input that can be stored explicitly in current computers). Davenport-Schinzel sequences are often used to bound the complexity of upper (or lower) envelopes of polynomial functions. Whenever we have a family of n functions such that no two graphs of those functions cross more than t times (for some bounded constant t), we can use Theorem 13 to bound the complexity of their upper and lower envelope.

▶ **Theorem 14.** *Let P be a set of n moving points in $\mathbb{R}^d$ with bounded description complexity s. Then, there is a power assignment with updates, such that at any given time t the interference of the network is at most $O(\sqrt{n \log n})$. Moreover, the total number of combinatorial changes in the network is at most $O^*(n^{1.5}\sqrt{\log n})$, where the O^* notation hides a term involving the inverse Ackermann function that depends on d and s.*

Proof. We use Theorem 8 for some value of k that will be determined later. We obtain a set N of size $O(k \log k)$ with the properties guaranteed by Theorem 8. The elements of N are called *hubs*, and we assign to each of them the largest possible radius. That is, at any instance of time $t \geq 0$, a point $p \in N$ is assigned the distance to its furthest point in P. In other words, $f(p,t)$ is equal to the point $q \in P$ that maximizes the distance $d(p(t), q(t))$. Other points of P are assigned the distance to their nearest hub. More formally, $f(p,t)$, for a point $p \in P \setminus N$, is equal to the point $q \in N$ that minimizes the distance $d(p(t), q(t))$. Equivalently, if we consider the Voronoi diagram with sites $N(t)$, the function $f(p,t)$ will match $p(t)$ with the site associated to the Voronoi cell that contains $p(t)$ at time t.

First observe that the network is connected: indeed, all hubs are connected to each other forming a clique. Moreover, each point of $P \setminus N$ has radius large enough to reach one point of N. In particular, any two points of P can reach each other after hopping through at most two intermediate sensors of N (thus, the constructed network has diameter 3).

We now pick the correct value of k so that the interference of this protocol is minimized. Since N has $O(k \log k)$ points, the overall interference contribution by hubs is bounded by the same amount. By Corollary 10, we also know that no point $q \in \mathbb{R}^d$ can be reached by more than $O(n/k)$ points of $P \setminus N$ at any instance of time. That is, the total interference of any point $q \in \mathbb{R}^d$ is at most $O(k \log k)$ from hubs, and at most $O(n/k)$ from non-hubs. Thus, by setting $k = \sqrt{n/\log n}$ we obtain the claimed bound.

We now bound the total number of combinatorial changes that will happen to the network along time. Let $p \in P$, we will show that the number of combinatorial changes of p is bounded. Recall that, if p is a hub it will connect to its furthest away point of P. Otherwise, p will connect to its nearest hub. In either case, it suffices to bound the number of combinatorial changes of the nearest/furthest point within a group of moving points with respect to the moving point p. Equivalently, we are looking at the number of combinatorial changes of the upper envelope of the family of functions $\mathcal{F}_1 = \{d(p(t), p'(t)) \colon p' \in P\}$ for points $p \in N$, or the lower envelope of the family of functions $\mathcal{F}_2 = \{d(p(t), p'(t)) \colon p' \in N\}$ for points $p \notin N$. By the bounded description complexity assumption, functions of $\mathcal{F}_1$ and

$\mathcal{F}_2$ are such that the graphs of any pair of them cross $O(s)$ times. Thus, by the Davenport-Schinzel Theorem we can bound the number of combinatorial changes of the upper envelope of $\mathcal{F}_1$ by $O(\lambda_{O(s)}(n))$, where $\lambda_t(m)$ denotes the maximum length of a Davenport-Schinzel sequence of order t on m symbols. Similarly, the number of changes of the lower envelope of $\mathcal{F}_2$ is bounded by $O(\lambda_{O(s)}(\sqrt{n \log n}))$.

Ignoring the terms that depend on the inverse of the Ackermann function, we have that for any fixed constant s, $\lambda_t(m) = O^*(m)$. Combining this with the fact that we have $O(\sqrt{n \log n})$ hubs and at most n non-hub points, the overall number of combinatorial changes is bounded by $O^*(n \times \sqrt{n \log n} + \sqrt{n \log n} \times n) = O^*(n^{1.5}\sqrt{\log n})$ as claimed. ◀

6 Conclusion

Using the the machinery of VC-dimension we have shown that the difference between static and kinetic environments for our facility location problem is small. We believe that a similar approach can be used for other problems. Some directly follow from Theorem 7 (such as kinetic range counting or discrepancy, see details in the extended version of this paper [5]). We hope that future research will show other interesting applications.

In Section 4 we argued that it is unlikely that the "balanced" property can be significantly improved. Similarly, it seems unlikely that the "reasonable" constraint can be removed, even in one dimension. Indeed, if points are allowed to move arbitrarily, they can create all $n!$ orderings along time. In particular, for any set $N \subset P$ we can always find a time and range that contains all points of $P \setminus N$. Thus, no subset $N \subset P$ can act as an ε-net for all instances of time. Further note that, since the alternation in orderings can be repeated arbitrarily many times, the number of times that we need to change the set N can also be unbounded. This behaviour can be created with trigonometric functions of low description complexity.

Abstract

In topological data analysis, a point cloud data P extracted from a metric space is often analyzed by computing the persistence diagram or barcodes of a sequence of Rips complexes built on P indexed by a scale parameter. Unfortunately, even for input of moderate size, the size of the Rips complex may become prohibitively large as the scale parameter increases. Starting with the *Sparse Rips filtration* introduced by Sheehy, some existing methods aim to reduce the size of the complex so as to improve the time efficiency as well. However, as we demonstrate, existing approaches still fall short of scaling well, especially for high dimensional data. In this paper, we investigate the advantages and limitations of existing approaches. Based on insights gained from the experiments, we propose an efficient new algorithm, called *SimBa*, for approximating the persistent homology of Rips filtrations with quality guarantees. Our new algorithm leverages a batch collapse strategy as well as a new sparse Rips-like filtration. We experiment on a variety of low and high dimensional data sets. We show that our strategy presents a significant size reduction, and our algorithm for approximating Rips filtration persistence is order of magnitude faster than existing methods in practice.

1 Introduction

In recent years, topological ideas and methods have emerged as a new paradigm for analyzing complex data [8, 24]. An important line of work in this direction is the theory and applications of persistent homology. It provides a powerful and flexible framework to inspect data for characterizing and summarizing important features that persist across different scales. Since its introduction [25, 26, 34], there have been many fundamental developments [7, 9, 10, 12, 14, 17, 18, 19, 39] both to generalize the framework and to provide theoretical understanding

[*] This work has been supported by NSF grants CCF-1318595 and CCF-1526513.

for various aspects of it (such as its stability). These developments help to provide foundation and justification of the practical usage of persistent homology; see e.g, [13, 15, 22, 37, 33].

A determining factor in applying persistent homology to a broad range of data analysis problems is the availability of efficient and scalable software. Given the rapidly increasing size of modern data, the "efficiency" necessarily concerns both time and space complexities. The original algorithm to compute persistent homology takes $O(n^3)$ time and $O(n^2)$ space for a filtration involving n number of total simplices [25]. Various practical improvements have been suggested [16, 20]. An early software widely used for computing persistence is Morozov's Dionysus [23]. Later, Bauer et al. developed the PHAT toolbox [3], based on several efficient matrix reduction strategies (mostly focusing on time efficiency) as described in [2]. A more recently developed library called GUDHI [38] considers the improvement both in time and space efficiencies. In particular, it uses an efficient data structure, called the simplex tree [5], to encode input simplicial complexes, and uses the *compressed annotation matrix* [4] to implement the persistent cohomology algorithm. Dionysus, PHAT, and GUDHI offer efficient software for computing persistence induced by inclusions. For our algorithm, we need persistence induced by more general simplicial maps for which we use Simpers [36] developed on the basis of the algorithm in [21].

The above results and software cater to general persistence computations. In practice, often the persistence needs to be computed for a particular filtration called the *Vietoris-Rips* or *Rips filtration* in short. Given a set of points P embedded in $\mathbb{R}^d$ (or in more general metric spaces), the Rips complex $\mathcal{R}^\alpha(P)$ with radius or scale α is the clique complex induced by the set of edges $\{(p,p') \mid d(p,p') \le \alpha, p, p' \in P\}$. One is interested in the persistent homology induced by the sequence of Rips complexes $\mathcal{R}^{\alpha_1} \subseteq \mathcal{R}^{\alpha_2} \subseteq \cdots \subseteq \mathcal{R}^{\alpha_m}$ for a growing sequence of radii $\alpha_1 \le \alpha_2 \le \ldots \le \alpha_m$. Intuitively, the Rips complex at a specific scale α approximates the union of radius-α balls around sample points in P. Thus, it captures the structure formed by input points P at different scales.

Unfortunately, even for a modest size of n (in the range of thousands), the size of Rips complex (as well as the slightly more economical Čech complex) becomes prohibitively large as the radius α increases. In [35], Sheehy proposed an elegant solution for this problem by introducing a *sparse Rips filtration* to approximate the persistent homology of the Rips filtration for a set of points P. An alternative approach of collapsing input points in batches with increasing radius α was proposed in [21], which leveraged the persistence algorithm proposed in the same paper for filtrations arising out of simplicial maps.

New work

Given the importance of the Rips filtration in practice, our goal is to investigate the practical performance of the existing proposed methods, understand their advantages and limitations, and develop an efficient implementation for approximating the persistent homology of Rips filtrations. To this end, we make the following contributions.

1. We investigate the advantages and limitations of three existing methods, two based on Sparse Rips [35, 11], and another on Batch-collapse [21]. Specifically, experiments show that while the sparse Rips algorithm by Sheehy [35] has a theoretical guarantee on the size of the filtration and gives good approximation of the persistence diagrams for the Rips filtration in practice, it generates simplicial complexes of large size even for input of moderate size. This problem becomes more severe as the dimension of the input data increases. The algorithm fails to finish for several high dimensional data sets of rather moderate size. See Table 1 for some examples. The batch-collapse approach is much more space efficient (which leads to time efficiency as well). Nevertheless, we find that its size still becomes prohibitive for high dimensional data.

2. Based on the insights gained from experimenting with the existing approaches, we propose a new algorithm called *SimBa* that approximates a Rips filtration persistence via simplicial batch-collapses. Our algorithm is a modification of the previous batch-collapse of Rips filtration proposed in [21]. While theoretically, the modification may not seem major, empirically, it reduces the size of the filtration significantly and thus leads to a much more efficient approximation of the Rips filtration persistence. Furthermore, we show that this modification maintains a similar approximation guarantee as the batch-collapse of Rips filtration proposed in [21]. We describe the details of an efficient and practical implementation of SimBa, the software for which has been made publicly available from [36].

Two concepts, homology groups of a simplicial complex, and simplicial maps between two complexes are used throughout this paper. We refer the reader to any standard text such as [32] for details. We denote the p-dimensional homology group of a simplicial complex $\mathcal{K}$ under $\mathbb{Z}_2$ coefficients by $H_p(\mathcal{K})$.

2 Rips filtration and its approximation

Given a set of points $P \subset \mathbb{R}^d$, let $\langle p_0, \ldots, p_s \rangle$ denote the s-dimensional simplex spanned by vertices $p_0, \ldots, p_s \in P$. The Rips complex at scalar α is defined as $\mathcal{R}^\alpha(P) = \{\langle p_0, \ldots, p_s \rangle \mid \|p_i - p_j\| \leq \alpha, \text{ for any } i, j \in [0, s]\}$. Now consider the following *Rips filtration*:

$$\{\mathcal{R}^\alpha(P)\}_{\alpha>0} \;:=\; \mathcal{R}^{\alpha_1}(P) \hookrightarrow \mathcal{R}^{\alpha_2}(P) \cdots \hookrightarrow \mathcal{R}^{\alpha_n}(P) \cdots \tag{1}$$

The inclusion maps between consecutive complexes above induce homomorphisms between respective homology groups, giving rise to a so called *persistence module* for dimension p:

$$H_p(\mathcal{R}^{\alpha_1}(P)) \to H_p(\mathcal{R}^{\alpha_2}(P)) \to \ldots \to H_p(\mathcal{R}^{\alpha_n}(P)) \cdots \tag{2}$$

If a homology class is created at $\mathcal{R}^{\alpha_i}(P)$ (i.e, does not have pre-image under homomorphism $H_p(\mathcal{R}^{\alpha_{i-1}}) \to H_p(\mathcal{R}^{\alpha_i})$) and dies entering $\mathcal{R}^{\alpha_j}(P)$ (i.e, its image vanishes under homomorphism $H_p(\mathcal{R}^{\alpha_{j-1}}(P)) \to H_p(\mathcal{R}^{\alpha_j}(P))$, then α_i is its *birth time*, α_j is its *death time*, and the difference $\alpha_j - \alpha_i$ is called the *persistence* of the class. In each dimension, the persistence barcodes capture the persistence of such homology classes by using a horizontal bar with left and right end points at α_i and α_j respectively. These *persistence barcodes* of the above Rips filtration are often the target summary of P and/or of the space P samples, which one wishes to compute in topological data analysis.

The main bottleneck for computing the barcodes of a Rips filtration stems from its size blowup. As the parameter α grows, the Rips complex $\mathcal{R}^\alpha(P)$ can become huge very quickly. To address this blowup in size, Sheehy [35] suggested a novel approach of sparsifying the point set P as one proceeds with increasing α in a way that does not alter the barcodes too much. The idea is to replace the original Rips filtration $\{\mathcal{R}^\alpha(P)\}_{\alpha>0}$ on P with a sequence of smaller complexes $\{\mathcal{S}^\alpha\}_{\alpha>0}$ and show that the two sequences *interleave* at the homology level. Then, appealing to the results of interleaving persistence modules [12], one can show that the barcodes of $\{\mathcal{S}^\alpha\}_{\alpha>0}$ approximate those of $\{\mathcal{R}^\alpha(P)\}_{\alpha>0}$ reasonably. The complexes $\mathcal{S}^\alpha$ are constructed as the *union* of Rips-like complexes built on a sequence of subsets of P rather than the entire set P.

The union allows the complexes in $\{\mathcal{S}^\alpha\}_{\alpha>0}$ to be connected with inclusions and hence permits using efficient algorithms and software designed for inclusion induced persistence. However, the size of $\mathcal{S}^\alpha$ may still be large due to the union operation. An alternative is to avoid the union operation but allow deletion or collapse of vertices (and simplices) at larger scale α [11, 35] resulting into a sequence of Rips-like complexes connected with simplicial maps instead of inclusions. This approach, which we refer to as *Sparse Rips with collapse*, however achieves only moderate improvements in size reduction. We find that much more aggressive size reduction can be achieved by considering the collapse in a batched fashion that gives rise to the approach of *Batch-collapsed Rips* [21].

Finally, building on the batch-collapse idea, we propose a new approach, called *SimBa* that significantly reduces the size of Rips-like complexes and their computations. This is achieved primarily by replacing inter-point distances with *set distances* while computing the complexes. We prove that this approach still provably approximates the barcodes of the original Rips filtration in sequence (1).

In what follows, we provide more details about each existing method along with its performance in practice, which explains the motivation behind the new tool SimBa.

2.1 Sparse Rips filtration (inclusions)

Let P be a set of points in a metric space $(\mathcal{M}, d)$. A *greedy permutation* $\{p_1, .., p_n\}$ of P is defined recursively as follows: Let $p_1 \in P$ be any point and define p_i recursively as $p_i = \text{argmax}_{p \in P \setminus P_{i-1}} d(p, P_{i-1})$, where $P_{i-1} = \{p_1, ..., p_{i-1}\}$. This gives rise to a nested sequence of subsets $P_1 \subset P_2 \subset \cdots P_n = P$. Furthermore, each subset P_i is locally dense and uniform (net) in the following sense. Define the insertion radius λ_{p_i} of a point p_i as $\lambda_{p_i} = d(p_i, P_{i-1})$. Each P_i is a λ_{p_i}-net of P, meaning that $d(p, P_i) \leq \lambda_{p_i}$ for every $p \in P$ and $d(p, q) \geq \lambda_{p_i}$ for every distinct pairs $p, q \in P_i$. These nets can be extended to a single-parameter family of nets as $\{N_\gamma\}$ where $N_\gamma = \{p \in P | \lambda_p > \gamma\}$ is a γ-net of P.

Using the idea of Sheehy [35], Buchet et al. [6] define a Rips-like filtration using the above specific nets and assigning weights to points whose geometric interpretation is explained in [11]. Each point $p \in P$ is associated with a weight $w_p(\alpha)$ at scale α as

$$w_p(\alpha) = \begin{cases} 0 & \text{if } \alpha \leq \frac{\lambda_p}{\varepsilon} \\ \alpha - \frac{\lambda_p}{\varepsilon} & \text{if } \frac{\lambda_p}{\varepsilon} < \alpha \leq \frac{\lambda_p}{\varepsilon(1-\varepsilon)} \\ \varepsilon\alpha & \text{if } \frac{\lambda_p}{\varepsilon(1-\varepsilon)} \leq \alpha \end{cases}$$

where $0 < \varepsilon < 1$ is an input constant that controls the sparsity of the filtration. Then, the perturbed distance between pairs of points is defined as

$$\hat{d}_\alpha(p, q) = d(p, q) + w_p(\alpha) + w_q(\alpha).$$

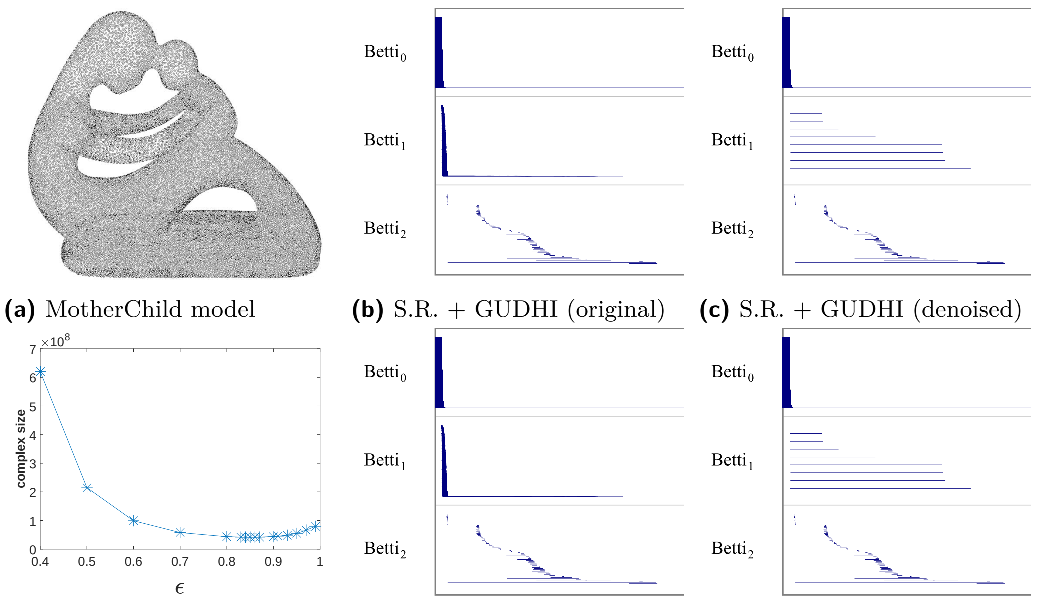
Using the perturbed distance $\hat{d}_\alpha$, the Sparse Rips complex at scale α is defined as

$$\mathcal{Q}^\alpha = \{\sigma \subset N_{\varepsilon(1-\varepsilon)\alpha} \mid \forall p, q \in \sigma,\ \hat{d}_\alpha(p, q) \leq 2\alpha\}.$$

The sequence of $\{\mathcal{Q}^\alpha\}_{\alpha>0}$ does not form a nested sequence of spaces because the vertex set of each $\mathcal{Q}^\alpha$ comes from the net $N_{\varepsilon(1-\varepsilon)\alpha}$ and may decrease as α increases. However, one can take $\mathcal{S}^\alpha = \bigcup_{\alpha' \leq \alpha} \mathcal{Q}^{\alpha'}$ and build a natural filtration $\{\mathcal{S}^\alpha \hookrightarrow \mathcal{S}^{\alpha'}\}_{\alpha < \alpha'}$ connected by inclusions. It is shown that the persistence barcodes of the filtration $\{\mathcal{S}^\alpha\}_{\alpha>0}$ approximate those of the Rips filtration $\{\mathcal{R}^\alpha\}_{\alpha>0}$ [35].

We use the code from [6] to compute this sparse Rips filtration $\{\mathcal{S}^\alpha\}_{\alpha>0}$. We then use GUDHI [38] to compute its persistent barcodes as GUDHI has the state-of-the-art performance for handling large complexes due to a compression technique [4] for inclusion-based filtrations.

As a common test case to illustrate the performance of various existing methods, we use a 3-dimensional point set sampled from a surface model called MotherChild; see Figure



(a) MotherChild model **(b)** S.R. + GUDHI (original) **(c)** S.R. + GUDHI (denoised)

(d) cumulative size **(e)** S.R. + Simpers (original) **(f)** S.R. + Simpers (denoised)

Figure 1 MotherChild surface model and its persistence barcodes computed by Sparse Rips (S.R.) based approaches. Since the surface has genus 4, its barcodes contain long bars: 1 for H_0, 8 for H_1, and 1 for H_2. The minimum cumulative size for complexes, which is about 43 million, is achieved around $\varepsilon = 0.8$.

1a. We choose this model because the ground truth is available and also because existing methods have trouble (to different degrees) handling high-dimensional data. The size of the point set is 23075. For indicating memory consumption, we refer to *cumulative size* which is the total number of simplices arising in the filtration, and also to *maximum size* which is the maximum over all complexes arising in the filtration. For Sparse Rips filtrations two sizes coincide at the last complex due to inclusions. Figure 1d shows the cumulative size with different Sparse Rips parameter ε. It is minimum when ε is between 0.8 and 0.9. So, we choose $\varepsilon = 0.8$ to achieve the best performance while observing that the approximation quality does not suffer much as predicted by the theory.

The original persistence barcodes are shown in Figure 1b. Since it becomes hard to see the main (long) bars in presence of all spurious ones creating excessive overlaps, we remove all short bars whose ratio between death and birth time is smaller than a threshold for 1-dimensional homology group H_1. The bars for H_0 and H_2 are not denoised. Unless specified otherwise, all barcodes are denoised in the same way. The denoised barcodes are shown in Figure 1c, one for H_0, four short and four long for H_1 (MotherChild has genus 4), and one for H_2. The cumulative size of the Sparse Rips complexes in the filtration is 43.5 million and the total time cost is about 350 seconds.

2.2 Sparse Rips with collapse

The persistence barcodes for the inclusion-based filtration $\{\mathcal{S}^\alpha\}_{\alpha>0}$ are the same as the barcodes of the filtration $\{\mathcal{Q}^\alpha\}_{\alpha>0}$ connected by simplicial maps $\mathcal{Q}^\alpha \to \mathcal{Q}^{\alpha'}$ for $\alpha < \alpha'$. Specifically, these simplicial maps originate from vertex collapses defined by the following projection map:

$$\mu_\alpha(p) = \begin{cases} p & \text{if } p \in N_{\varepsilon(1-\varepsilon)\alpha} \\ \operatorname*{argmin}_{q \in N_{\varepsilon\alpha}} d(p,q) & \text{otherwise} \end{cases}$$

For any scale α, the projection μ_α maps the points of P to the net $N_{\varepsilon(1-\varepsilon)\alpha} \supseteq N_{\varepsilon\alpha}$. One can view it as p being deleted at time (scale) $\alpha_p = \frac{\lambda_p}{\varepsilon(1-\varepsilon)}$. We can construct the sequence of Sparse Rips complexes $\{\mathcal{Q}^\alpha\}_{\alpha>0}$ connected with simplicial maps induced by insertions and vertex collapses as α increases: Specifically, we delete the vertex p and all its incident simplices by collapsing it to its projection $\mu_{\alpha_p}(p)$ where $\alpha_p = \frac{\lambda_p}{\varepsilon(1-\varepsilon)}$, when entering complex $\mathcal{Q}^{\alpha_p}$. See [11] for more details.

In this approach we need to compute the persistence induced with simplicial maps. For this, we use the only available software Simpers [36] based on the algorithm presented in [21]. Our experimental results on the MotherChild model of Figure 1a with $\varepsilon = 0.8$ are given in Figure 1e and 1f. The barcodes are exactly the same as those in Figure 1b and 1c. The cumulative size of the entire sequence is the same, 43.5 million, because the final complex in $\mathcal{S}^\alpha$ is the union of all complexes in $\{\mathcal{Q}^\alpha\}_{\alpha>0}$. However, the maximum size in the sequence is 24.9 million due to vertex collapses in contrast to the maximum size for $\{\mathcal{S}^\alpha\}_{\alpha>0}$ which equals the cumulative size. The time cost for this approach is 463.7 seconds which is larger than that for Sparse Rips with GUDHI. So compared to Sparse Rips with GUDHI, this approach has smaller maximum size due to collapse but costs more time for computing persistence since Simpers computes persistence over collapses which are slower operations than inclusions.

While the size of these Sparse Rips complexes is linear in the number of input points, the hidden constant factor depends exponentially on the doubling dimension of the metric space where points are sampled from. Empirically, we note that the size is still large, and becomes much worse as the dimension of data increases. For example, for the Gesture Phase data in Table 1 which has only 1747 points in $\mathbb{R}^{18}$, the cumulative size of the Sparse Rips filtration is 45.6 million, which approaches the limit GUDHI or Simpers can handle. For other larger data sets such as Primary Circle or Survivin, the complex reaches a size beyond this limit. Moreover, one has to pre-compute a greedy permutation of the input point set before constructing the Sparse Rips filtration. This computation is usually costly requiring furthest point computations for which software as efficient as ANN (for nearest neighbors) is not available. This motivates us to consider the batched approach considered next.

2.3 Batch-collapsed Rips

For handling large and high dimensional data, we need a more aggressive sparsification than the Sparse Rips filtration. We consider the Batch-collapsed Rips filtration, which has been proposed previously in [21] (section 6.1).

Given a set of points P, first set $V_0 := P$ and compute the shortest pairwise distance α. We next construct a sequence of vertex sets $V_k, k \in [0, m]$ such that V_{k+1} is an αc^{k+1}-net of V_k where $c > 1$ is a parameter that controls the rate of the scale increase. Consider the vertex map $\pi_k : V_k \to V_{k+1}$, for $k \in [0, m-1]$, such that for any $v \in V_k$, $\pi_k(v)$ is v's nearest neighbor in V_{k+1}. It can be shown that each vertex map π_k induces a well-defined simplicial map $s_k : \mathcal{R}^{\alpha c^k \frac{3c-1}{c-1}}(V_k) \to \mathcal{R}^{\alpha c^{k+1} \frac{3c-1}{c-1}}(V_{k+1})$. The *Batch-collapsed Rips filtration* is:

$$\mathcal{R}^0(V_0) \xrightarrow{s_0} \mathcal{R}^{\alpha c \frac{3c-1}{c-1}}(V_1) \cdots \xrightarrow{s_{m-1}} \mathcal{R}^{\alpha c^m \frac{3c-1}{c-1}}(V_m). \tag{3}$$

Using the line of proof in [21], one can show that the persistence of this sequence is a $3\log(\frac{2}{c-1}+3)$-approximation of the persistence diagram of Rips filtration given below.

$$\mathcal{R}^0(V_0) \hookrightarrow \mathcal{R}^{\alpha c}(V_0) \cdots \hookrightarrow \mathcal{R}^{\alpha c^m}(V_0). \tag{4}$$

The blowup in scale by the factor of $\frac{3c-1}{c-1}$ results from the proof, which in practice causes some problems. We elaborate this further. To satisfy the approximation guarantee, one has to show that the persistence modules arising from Batch-collapsed Rips in sequence (3) and the standard Rips in sequence (4) interleave. In particular, this requires that we have well-defined simplicial maps from complexes in sequence (3) to those in sequence (4) and vice versa. The multiplicative factor $\frac{3c-1}{c-1}$ is needed to ensure that there is a well-defined simplicial map $\mathcal{R}^{\alpha c^k}(V_0) \to \mathcal{R}^{\alpha c^k \frac{3c-1}{c-1}}(V_k)$, as $\mathcal{R}^{\alpha c^k \frac{3c-1}{c-1}}(V_k)$ has to be sufficiently connected to include all the images of the simplices in the domain Rips complex $\mathcal{R}^{\alpha c^k}(V_0)$. The side effect of this is that the Batch-collapsed Rips complex has to be built at a much larger scale than the Rips complex, and it ends up with many unnecessary connections and thus more simplices in practice. This also causes a trade-off: Larger c reduces the over-connection but results in a worse approximation factor leading to a worse approximation quality. It is not clear how to set an increase rate that achieves both good approximation quality and efficiency for a specific data set.

We experimented Batch-collapsed Rips with Simpers on the same MotherChild model. Figure 2a, 2b and 2c show the persistence barcodes for different values of c. Observe that smaller values of c give better approximation. The barcode for $c = 1.3$ is the most similar among the three to that of Sparse Rips filtration in Figure 1b which is supposed to be more accurate theoretically. On the other hand, when c grows more than 1.8, it starts to lose some main bars in H_1 and noisy bars get longer in H_2. On the other hand, Figure 3 shows that, as c increases, both complex size and time cost decrease drastically. When $c = 2.0$, it only involves less than $216K$ simplices and takes time 9.4 seconds while, although $c = 1.3$ gives more accurate barcode, its size (22.5 million) and time (325s) approach those of the Sparse Rips. This demonstrates the dilemma that Batch-collapsed Rips faces in practice. We address this issue in our new approach SimBa. In particular, when $c \le 2$, SimBa performs better than Batch-collapsed Rips for both size and time as shown in Figure 3 while capturing all main bars correctly as shown in Figure 2.

3 SimBa

To tame the over-connection in Batch-collapsed Rips, we replace the sequence in (3) with the sequence below where the parameter does not incur the extra factor $\frac{3c-1}{c-1}$:

$$\mathcal{B}^0(V_0) \to \mathcal{B}^{\alpha c}(V_1) \to \cdots \mathcal{B}^{\alpha c^m}(V_m) \tag{5}$$

The complexes $\mathcal{B}^{\alpha c^k}(V_k)$ are built on the same vertex sequence $\{V_k\}$ as in Batch-collapsed Rips, but the distances among the vertices of V_k are replaced with a *set distance* which allows us to avoid the over-connection. For two sets of points (clusters) $A, B \subset P$, we define their set distance as $d(A,B) = \min_{a\in A, b\in B} d(a,b)$. The sets that we consider are the pre-images of the vertices in V_k under the composition of projections π_i's, namely, for a vertex $v \in V_k$, we consider the set

$$B_v^k = \{p \in V_0 \mid \hat{\pi}_k(p) = v\} \text{ where } \hat{\pi}_k : V_0 \to V_k \text{ is defined as } \hat{\pi}_k = \pi_{k-1} \circ \cdots \circ \pi_0.$$

The complex $\mathcal{B}^{\alpha c^k}(V_k)$ is simply the clique complex induced by edges $\{(u,v) \in V_k \mid d(B_u^k, B_v^k) \le \alpha c^k\}$. Observe that $d(u,v) \ge d(B_u^k, B_v^k)$ which ensures that the normal connection between u and v for a Rips filtration at the respective scale is not missed by considering the set distance while still avoiding the over-connection.

It turns out that each vertex map (nearest neighbor projection) $\pi_k : V_k \to V_{k+1}$ induces a simplicial map $h_k : \mathcal{B}^{\alpha c^k}(V_k) \to \mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$. Instead of recomputing the simplicial complex each time, we generate elementary insertion and collapse operations incrementally for each h_k in three steps: (i) collapse each $v \in V_k \setminus V_{k+1}$ to its image $\pi_k(v)$ in V_{k+1} along with all incident simplices, (ii) insert new edges between two vertices in V_{k+1} if the distance between the two sets they represent are smaller than or equal to the current scale, and (iii) insert all new clique simplices containing new edges generated by (i) and (ii). Each h_k is processed in one batch, starting from a simplicial complex on vertices in V_k and resulting in a simplicial complex on vertices in V_{k+1}. The collapse and insertions of new simplices are exactly what Simpers need for computing the persistence.

3.1 Implementation Details

The advantage of SimBa (and Batch-collapsed Rips) over Sparse Rips filtrations is mainly due to the batched approach, which requires us to compute δ-nets of a point set for some δ repeatedly. Its advantage over the Batch-collapsed Rips is credited to the use of set distances. These computations require k-nearest neighbor search and fixed radius search for which efficient library like ANN [31] exists. We take advantage of this available software.

To compute a δ-net of a given point set (to obtain V_{k+1} from V_k), we randomly pick an untouched point, say p, use fixed-radius search to find all points in the ball of radius δ around p, map them to it, and mark them processed. We do this repeatedly until there is no untouched point left. We observe that this sub-sampling procedure can be carried out faster at early stage when δ is small because those points whose nearest neighbor distances are larger than the current δ can be taken directly into the net–they are all mapped to themselves and no other points are mapped to them. So, we maintain a list L of the points ordered by their nearest neighbor distances in increasing order and process them sequentially for δ-net computations. To compute the net points V_{k+1} from V_k, we carry out the full sub-sampling process only on the points in V_k that are already known to have nearest neighbor distances below δ and the new ones that qualify from L for increased δ. After δ becomes more than the largest nearest neighbor distance, we convert to the usual net computation.

Next, we describe an efficient implementation of the set distance computation, which being a basic operation in SimBa, speeds it up significantly. A straightforward implementation requires quadratic time, but we can make it more efficient in practice with the help of the ANN library. We use a hybrid strategy as follows. The sets B_u^k for vertices $u \in V_k$ are maintained by a union-find data structure. As vertices are collapsed while going from V_k to V_{k+1}, the sets of the collapsed vertices are merged to that of the target vertex. At early stages, when the number of sets (i.e, the size of V_k) is large and the diameter of each set is potentially small, we avoid computing set distances for all pairs. For each processing set B_u^k, we only need to find all the sets B_v^k whose distances to B_u^k are smaller than the current scale $\alpha' = \alpha c^k$. If so, we add an edge between u and v. To find all these nearby sets, we can do a fixed-radius search in $V_0 = P$ around each point in B_u^k within α' distance. For each point v returned by the search, we find v in the union-find data structure to identify its image $\hat{\pi}_k(v) \in V_k$. If the representing set of v is different from that of u, we add the edge $\hat{\pi}_k(u)\hat{\pi}_k(v)$.

Later when α' becomes large, it may not be efficient to continue this fixed-radius search, as the number of candidate points from P may be too large (can be n in the worst case). So we fall back on pairwise set distance computation. In particular, when the cardinality of V_k becomes lower than a threshold, say 1/10 of the number of input points, we compute a pairwise set distance matrix (of size $|V_k| \times |V_k|$) among the surviving sets once and then keep updating the matrix with batch collapse thereafter. In particular, note that given sets A, B, and C, the set distance $d(A \cup B, C) = \min\{d(A, C), d(B, C)\}$.

3.2 SimBa on MotherChild model

We compare SimBa with other approaches on the same MotherChild model. Figure 2d, 2e and 2f show the persistence barcodes computed by SimBa with different values of c. We see that SimBa captures all the main 0, 1, 2-dimensional bars for all values of c in the range from 1.3 to 2.0 as opposed to Batch-collapsed Rips which fails to capture the main H_1 bars for $c > 1.8$. It tolerates larger range of c and thus is more robust than Batch-collapsed Rips. As expected, larger values of c produce less bars since there are less batches. So, in practice, we should choose smaller c, say less than 1.5. More importantly, as Figure 3 shows, the size and time for SimBa are also stable against different values of c, all less than $100K$ simplices and 10 seconds respectively for $c \leq 2$. These are less than those for Batch-collapsed Rips and significantly less than those for Sparse Rips: In particular, when $c = 1.3$, the maximum size for SimBa is $100K$, similar to when $c = 2$. However, for Batch-collapsed Rips, the maximum size is closer to that of SimBa when $c = 2$, and is 22.5 and 1.4 million when $c = 1.3$ and $c = 1.5$ respectively. This size difference becomes even more prominent for high dimensional data, as Table 1 shows. Although the approximation quality of SimBa is slightly worse than that of Sparse Rips based approaches, it does capture all the main bars, and more importantly, costs significantly less time. This advantage allows SimBa to process much larger high dimensional data sets which no previous approaches can handle, as we illustrate in section 5.

4 Approximation guarantee of SimBa

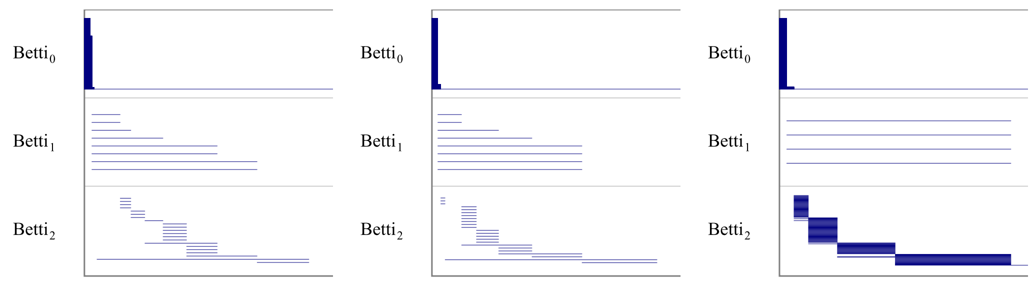
Recall that the simplicial complex $\mathcal{B}^\alpha(V_k)$ appearing in SimBa's filtration is defined as:

$$\mathcal{B}^\alpha(V_k) = \{\sigma \subset V_k \mid \forall u, v \in \sigma, d(B_u^k, B_v^k) \leq \alpha\}.$$

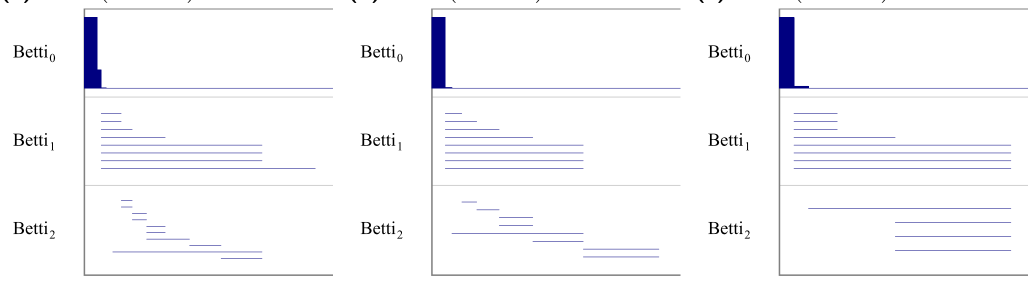
We prove that the persistence barcodes of SimBa's filtration in sequence (5) approximates those of the Rips filtration in (4) by showing that the persistence modules induced by these two sequences interleave.

First, observe that each vertex map π_k induces a well-defined simplicial map $h_k : \mathcal{B}^{\alpha c^k}(V_k) \to \mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$. Indeed, for any edge $\{u, v\}$ in $\mathcal{B}^{\alpha c^k}(V_k)$, suppose $u' = \pi_k(u), v' = \pi_k(v)$, then $B_u^k \subset B_{u'}^{k+1}$ and $B_v^k \subset B_{v'}^{k+1}$. So we have $d(B_{u'}^{k+1}, B_{v'}^{k+1}) \leq d(B_u^k, B_v^k) \leq \alpha c^k < \alpha c^{k+1}$. Therefore $\{u', v'\}$ must be an edge in $\mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$ as well. Since each complex in SimBa's filtration is a clique complex determined by edges, every simplex in $\mathcal{B}^{\alpha c^k}(V_k)$ has a well-defined image in $\mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$. Thus, each h_k is well-defined.

Recall that the map $\hat{\pi}_k : V_0 \to V_{k+1}$ is defined as $\hat{\pi}_k(v) = \pi_k \circ \cdots \circ \pi_0(v)$, which tracks the image of any point in $V_0 = P$ during the batch collapse process. Observe that the vertex map $\hat{\pi}_k$ also induces a simplicial map $\hat{h}_k : \mathcal{R}^{\alpha c^k}(V_0) \to \mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$: specifically, for any edge $(u, v) \in \mathcal{R}^{\alpha c^k}(V_0)$ with $d(u, v) \leq \alpha c^k$, it is easy to see that $d(B_{\hat{\pi}_k(u)}^k, B_{\hat{\pi}_k(v)}^k) \leq d(u, v) \leq \alpha c^k < \alpha c^{k+1}$, implying that $(\hat{\pi}_k(u), \hat{\pi}_k(v))$ is an edge in $\mathcal{B}^{\alpha c^{k+1}}(V_{k+1})$. The key observation is the following lemma.



(a) B.R. (c = 1.3) **(b)** B.R. (c = 1.5) **(c)** B.R. (c = 2.0)



(d) SimBa (c = 1.3) **(e)** SimBa (c = 1.5) **(f)** SimBa (c = 2.0)

Figure 2 Persistence barcodes computed by Batch-collapsed Rips plus Simpes (B.R.) and SimBa on the same MotherChild model. B.R. captures main bars for H_1 correctly for smaller values of c as shown in Figure (a) and (b) and loses some for $c = 2.0$ as shown in Figure (c), while SimBa works for $c = 2.0$.

▶ **Lemma 1.** *Each triangle in the diagram below commutes at homology level, where i_k and j_k are induced by inclusions, $h_{k,t} := h_{k+t-1} \circ \cdots \circ h_k$, $c > 1$, $t \geq \log_c(\frac{2}{c-1} + 3)$ and $t \in Z$.*

$$\begin{tikzcd}
\mathcal{R}^{\alpha c^k}(V_0) \arrow[r, hook, "i_k"] \arrow[d, "\hat{h}_k"] & \mathcal{R}^{\alpha c^{k+t}}(V_0) \arrow[d, "\hat{h}_{k+t}"] \\
\mathcal{B}^{\alpha c^k}(V_k) \arrow[ur, hook, "j_k"] \arrow[r, "h_{k,t}"] & \mathcal{B}^{\alpha c^{k+t}}(V_{k+t})
\end{tikzcd}$$

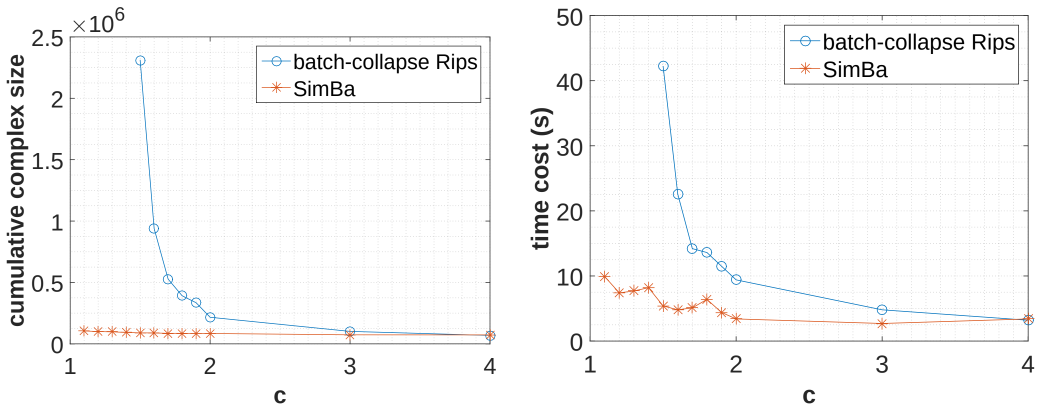
Proof. First, we prove that there is indeed an inclusion map $j_k : \mathcal{B}^{\alpha c^k}(V_k) \hookrightarrow \mathcal{R}^{\alpha c^{k+t}}(V_0)$. In particular, we show for each edge (u, v) in $\mathcal{B}^{\alpha c^k}(V_k)$, it's also an edge in $\mathcal{R}^{\alpha c^{k+t}}(V_0)$. Suppose the set distance $d(B_u^k, B_v^k)$ is achieved by the closest pair (u_0, v_0) between the two sets where $u_0 \in B_u^k, v_0 \in B_v^k$. Then $d(B_u^k, B_v^k) = d(u_0, v_0) \leq \alpha c^k$. Since V_{i+1} is an αc^{i+1}-net of V_i for each $i \in [0, k-1]$, it follows that $d(u, u_0) \leq \alpha c^k \sum_{i=0}^{k-1} \frac{1}{c^i} < \alpha c^k \frac{c}{c-1}$. Similar bound holds for $d(v, v_0)$. Thus:

$$d(u, v) \leq d(u, u_0) + d(v, v_0) + d(u_0, v_0) \leq \alpha c^k (\frac{2c}{c-1} + 1) = \alpha c^k (\frac{2}{c-1} + 3) \leq \alpha c^{k+t}.$$

Hence u, v is an edge in $\mathcal{R}^{\alpha c^{k+t}}(V_0)$.

Next, observe that the vertex map $\hat{\pi}_{k+t}$ restricted on the set of vertices V_k is exactly the same as the vertex map $\pi_{k,t} := \pi_{k+t-1} \circ \cdots \circ \pi_k$ (this vertex map induces the simplicial map $h_{k,t}$ in the diagram). Namely, for a vertex $u \in V_k \subseteq V_0$, $h_{k,t}(u) = \hat{h}_{k+t}(u)$. Thus $h_{k,t} = \hat{h}_{k+t} \circ j_k$. Hence the bottom triangle commutes both at the complex and the homology level.

We now consider the top triangle. Specifically, we prove that the map $j_k \circ \hat{h}_k$ is contiguous to the inclusion map i_k. Since two contiguous maps induce the same homomorphisms at the homology level, the top triangle commutes at the homology level.



(a) cumulative size **(b)** time cost

Figure 3 Complex size and time cost comparison between Batch-collapsed Rips and SimBa. SimBa beats Batch-collapsed Rips for both size and time when $c \leq 2$. For $c > 2$, the barcodes of both batch-based approaches become too coarse to be useful in practice.

Indeed, given a simplex $\sigma \in \mathcal{R}^{\alpha c^k}(V_0)$, we need to show that vertices from $i_k(\sigma) \cup j_k \circ \hat{h}_k(\sigma)$ span a simplex in $\mathcal{R}^{\alpha c^{k+t}}(V_0)$. Since both are Rips complexes and i_k and j_k are inclusion maps, we only need to prove that for any two vertices u and v from $\sigma \cup \hat{h}_k(\sigma)$, $d(u,v) \leq \alpha c^{k+t}$ (namely, (u,v) is an edge in $\mathcal{R}^{\alpha c^{k+t}}(V_0)$). If u and v are both from σ or both from $\hat{h}_k(\sigma)$, then $d(u,v) \leq \alpha c^{k+t}$ trivially. Otherwise, assume without loss of generality that $v \in \sigma$ and $u \in \hat{h}_k(\sigma)$, where $u = \hat{\pi}_k(u')$ for some $u' \in \sigma$. Since V_{i+1} is an is an αc^{i+1}-net of V_i for each $i \in [0, k-1]$, it follows that $d(u,u') \leq \alpha c^k \sum_{i=0}^{k-1} \frac{1}{c^i} < \alpha c^k \frac{c}{c-1}$. One then has

$$d(u,v) \quad \leq \quad d(u,u') + d(u',v) \leq \alpha c^k \frac{c}{c-1} + \alpha c^k = \alpha c^k \frac{2c-1}{c-1} < \alpha c^k (\frac{2}{c-1} + 3) \leq \alpha c^{k+t}.$$

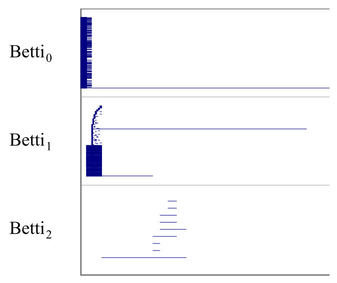
Thus i_k is contiguous to $j_k \circ \hat{h}_k$ and the lemma follows. ◀

The above result implies that the persistence modules induced by sequences (5) and (4) are weakly $\log c^t$-interleaved at the log-scale. Since $t \geq \log_c(\frac{2}{c-1} + 3)$, we have $c^t \geq \frac{2}{c-1} + 3$. By Theorem 4.3 of [12], we conclude with the following:

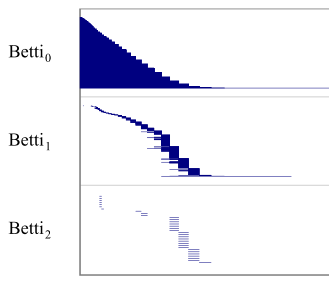
▶ **Theorem 2.** *The persistence diagram of the sequence (5) provides a $3\log(\frac{2}{c-1} + 3)$-approximation of the persistence diagram of the sequence (4) at the log-scale for $c > 1$.*

5 Experiments

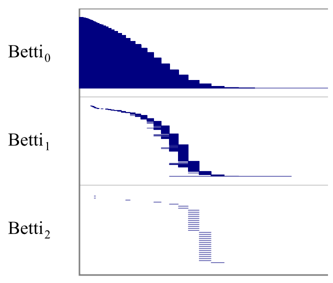
In this section, we report some experimental results of SimBa on large high dimensional data sets from other fields such as image processing, machine learning, and computational biology. For most of the data sets, previous approaches are not efficient enough to finish processing. They either ran out of memory ('∞' in size) or ran more than one day ('∞' in time). Table 1 at the end of this section provides the cumulative size and time cost for all four approaches mentioned in this paper. All approaches are implemented in C++. Note that we only compute persistences up to dimension 2 (which means we build simplicial complexes up to dimension 3). For Sparse Rips with GUDHI and Sparse Rips with Simpers, we choose parameter $\varepsilon = 0.8$ which gives the best performance while not sacrificing much of the approximation quality. For Batch-collapsed Rips with Simpers, we choose $c = 1.5$



(a) Klein Bottle in $\mathbb{R}^4$



(b) Primary Circle in $\mathbb{R}^{25}$



(c) Primary Circle in $\mathbb{R}^{49}$

Figure 4 Original persistence barcodes computed by SimBa on data sets with ground truth.

which appears to reach a good trade-off between efficiency and quality. For SimBa, we choose $c = 1.1$ which in practice appears to have best quality – note that the choice of c does not seem to change the empirical efficiency much as Figure 3 illustrates. All experiments were run on a 64-bit Windows machine with a 3.50GHz Intel processor and 16GB RAM.

Data with ground truth

We first test with two data sets whose ground truth persistences are known. They help demonstrate that SimBa works properly and efficiently in practice. All persistence barcodes shown in Figure 4 are original and not cleaned up.

We first consider a uniform sample of 22500 points from a Klein bottle in $\mathbb{R}^4$, and use SimBa to compute its barcode which is shown in Figure 4a. There are two main bars for H_1 and one for H_2 as expected.

Next, we consider the primary circle of natural image data in [1], which has 15000 points. Each point is a 5×5 or 7×7 image patch, thus considered as a point in $\mathbb{R}^{25}$ or $\mathbb{R}^{49}$. From Figures 4b and 4c, we can see the primary circle bar for H_1 for data both in $\mathbb{R}^{25}$ and $\mathbb{R}^{49}$. All short bars for H_2 persist for only one batch step and thus can be regarded as noise.

Data without ground truth

Next, we provide some experiments on the data sets whose ground truth persistences are not known. We used SimBa to compute their persistences and found some relatively long bars which are likely to be features and may worth further investigation by domain experts. The persistence barcodes shown in Figure 5 and 6d are denoised for H_1. The rest of Figure 6 are original.

We first take the Gesture Phase Segmentation data set [30] from UCI machine learning repository [28]. This data set was used in [29]. It comprises of features extracted from 7 videos with people gesticulating. Each video is represented by a raw file that contains the positions of hands, wrists, head, and spine of the user in each frame. We took the raw file from video A1 of 1747 frames. Since there are six sensors each with x, y, z coordinates, we have in total 1747 points in $\mathbb{R}^{18}$. There are five gesture phases in the videos: rest, preparation, stroke, hold, and retraction. Indeed, there are five long bars for H_0 in 5a (although they overlap and do not stand out in the picture), which seems to match the five clusters of different phases. We see some long bars for H_1, which could be created due to periodic patterns in these gesture movements.

Another data set is the Survivin protein data from [27]. There are totally 252996 protein conformations and each conformation is considered as a point in $\mathbb{R}^{150}$. We used PCA to

Sur150	252996	150	?	∞	–	∞	–	–	∞	$3.1 \cdot 10^6$	5089.7

reduce the data dimension to 3. We ran SimBa on both data sets and show the barcodes in Figure 5c and 5b. We can see that there are some long bars for H_1.

Performance results

We provide the performance results for all data sets mentioned in Table 1, which includes cumulative size and time cost of each approach. The time is obtained by adding the time to construct the complexes and the time to compute persistence. **S.R.+GUDHI**, **S.R.+Simpers**, **B.R.+Simpers** and **SimBa** stand for Sparse Rips plus GUDHI, Sparse Rips plus Simpers, Batch-collapsed Rips plus Simpers, and SimBa respectively. **Mother**, **KlBt**, **PrCi25**, **PrCi49**, **GePh**, **Sur3** and **Sur150** stand for MotherChild model, Klein Bottle, Primary Circle in $\mathbb{R}^{25}$, Primary Circle in $\mathbb{R}^{25}$, Gesture Phase Segmentation data, Survivin protein data in $\mathbb{R}^3$ and in $\mathbb{R}^{150}$ respectively. Each data set has size n, ambient dimension D, and intrinsic dimension d. The symbol ∞ means that the program either ran out of memory or did not finish after a day. From the table, we can see that SimBa out-performed the other three approaches significantly. Notice that for those larger cases of SimBa, the nearest neighbor search operations (ANN) usually take most of time and become the bottleneck. This is why **Sur150** costs much more time than **PrCi49** while its cumulative size is smaller. It would be an interesting future work to make nearest neighbor search more efficient so that SimBa performs better even for such cases.

Abstract

We propose a general approach to modelling algorithmic paradigms for the exact solution of NP-hard problems. Our approach is based on polynomial time reductions to succinct versions of problems solvable in polynomial time. We use this viewpoint to explore and compare the power of paradigms such as branching and dynamic programming, and to shed light on the true complexity of various problems.

As one instantiation, we model branching using the notion of witness compression, i.e., reducibility to the circuit satisfiability problem parameterized by the number of variables of the circuit. We show this is equivalent to the previously studied notion of 'OPP-algorithms', and provide a technique for proving conditional lower bounds for witness compressions via a constructive variant of AND-composition, which is a notion previously studied in theory of preprocessing. In the context of parameterized complexity we use this to show that problems such as Pathwidth and Treewidth and Independent Set parameterized by pathwidth do not have witness compression, assuming $NP \not\subseteq coNP/poly$. Since these problems admit fast fixed parameter tractable algorithms via dynamic programming, this shows that dynamic programming can be stronger than branching, under a standard complexity hypothesis. Our approach has applications outside parameterized complexity as well: for example, we show if a polynomial time algorithm outputs a maximum independent set of a given planar graph on n vertices with probability $\exp(-n^{1-\epsilon})$ for some $\epsilon > 0$, then $NP \subseteq coNP/poly$. This negative result dims the prospects for one very natural approach to sub-exponential time algorithms for problems on planar graphs.

As two other illustrations (more exploratory) of our approach, we model algorithms based on inclusion-exclusion or group algebras via the notion of "parity compression", and we model a subclass of dynamic programming algorithms with the notion of "disjunctive dynamic programming". These models give us a way to naturally classify various parameterized problems with FPT algorithms. In the case of the dynamic programming model, we show that Independent Set parameterized by pathwidth is complete for this model.

1 Introduction

The successes of theoretical computer science have often been driven by simple but general algorithmic approaches, or *paradigms*, leading to efficient algorithms in many different application domains. Indeed, paradigms such as divide-and-conquer, branching, dynamic programming and linear programming have been applied over and over to design algorithms.

A natural question that arises is to *quantify* the power and limitations of a given algorithmic paradigm. Doing so may have several benefits. It can help us understand what makes the paradigm effective. It can make algorithm design and analysis less ad hoc, with greater clarity about when and for which problems the paradigm is relevant. It can also enable us to compare various algorithmic paradigms with each other in terms of their power and usefulness. A crucial challenge in studying the power of algorithmic paradigms is the *modelling* question. We need a modelling framework which is rich enough to capture existing, successful algorithms within the paradigm. On the other hand, we need the modelling framework to be meaningfully restricted, so that we can prove interesting things about these models and the limits of their power. These goals are often in tension.

We aim to model exponential time algorithms. Understanding what can be computed in exponential time seems to be harder than understanding what can be computed in polynomial time, and less is known. In particular, showing general exponential-time lower bounds based on standard hypotheses about *polynomial-time* computation (for example, the hypotheses that $P \neq NP$ or that the Polynomial Hierarchy is infinite) seems out of reach. We propose to bypass this issue by arguing that several specific, established algorithmic paradigms can be modelled as polynomial-time reductions to (succinct) problems, so that limitations to their power may follow from these kinds of traditional hypotheses.

Approaches to algorithmic modelling can be broadly classified into syntactic and semantic approaches. Syntactic approaches attempt to faithfully represent the step-by-step operation of algorithms conforming to the method. Examples include the modelling of 1. DPLL algorithms by proof systems such as Resolution, 2. backtracking and dynamic programming by certain kinds of branching programs [1], 3. dynamic programming by feasible dominance relations [16], 4. linear programming by extended formulations [5]. These approaches, though natural, suffer from some drawbacks. The first is their lack of flexibility—they can fail to capture simple-looking variants of the method, e.g., the failure of proof systems to capture randomization. Second, in the search for accuracy, the models produced by such approaches can get quite complicated, which makes them hard to analyze.

Our models, in contrast, are semantic—we try to capture broad features of the algorithmic method rather than trying to model it in a step-by-step fashion. In particular, we allow arbitrary polynomial-time computations as constituent subroutines. This allows the model to flexibly accommodate preprocessing and natural variants of the method, and makes sense for the intended applications to exponential time algorithms. Our use of parameterization enables us to distinguish between algorithmic methods in a way that a traditional complexity-theoretic approach cannot. Although our approach is coarser than most syntactic approaches, it is more uniform, applying to a variety of algorithmic methods at once, and enables us to get useful information about the relative power of these methods.

Related Previous Work

A large number of problems have been shown to be *Fixed Parameter Tractable (FPT)*, i.e., solvable in time $O^*(f(k))$, where k is a parameter provided with each input, $O^*(\cdot)$ suppresses factors polynomial in the input size, and $f(\cdot)$ is some computable function. For many problems we now know essentially the optimal running time: there is an $O^*(f(k))$ time algorithm and an $O^*(g(k))$ time algorithm for any $g(k) < f(o(k))$ contradicts the Exponential Time Hypothesis (ETH). For a few problems we even know that $O^*(f(k))$ time algorithms cannot be improved to $O^*(f(k)^{1-\Omega(1)})$ time algorithm under stronger hypotheses as the Strong ETH. In this work we are mostly interested in problems for which $f(k) = 2^{\mathrm{poly}(k)}$ - this is the case for most natural FPT parameterizations of NP-complete problems.

Kernelization. A natural paradigm to prove a problem is solvable in $O^*(2^{\mathrm{poly}(k)})$ time is preprocessing plus brute force: given an instance (x, k) of a parameterized problem, transform it in polynomial time to an instance (x', k') of the same problem where $|x'|, k'$ are polynomial in k (this part is called the *polynomial kernel*), and then solve the smaller instance using brute-force search.[1] The power of polynomial kernelization has been extensively investigated, and is by now fairly well understood. For many parameterized problems, we have either found a polynomial kernel, or showed they do not exist unless $NP \subseteq coNP/poly$; the latter is proved by providing an *(OR* or *AND)-composition*, and appealing to results in [3, 13, 11] and related works. This fits as an excellent starting point for our study since it gives a lower bound for a class of exponential-time algorithms modelled via polynomial-time reductions, and is conditional on an hypothesis concerning polynomial-time computation.

Branching. Another heavily used paradigm to solve a problem in $O^*(2^{\mathrm{poly}(k)})$ time is that of *branching*, or *bounded search trees*. A natural model for this paradigm is the model of *One-sided Probabilistic Polynomial (OPP) algorithms* proposed by Paturi and Pudlak [24] in their study of algorithms for satisfiability. OPP algorithms are polynomial-time algorithms with one-sided error which never accept no-instances but only detect yes-instances with small but non-trivial probability (called the *success probability*). An OPP algorithm with success probability $f(n)$ can be converted to a bounded-error randomized algorithm running in time $\mathrm{poly}(n)/f(n)$ just by taking the OR of $f(n)$ independent trials. On the other hand if an exponential-time algorithm can be thought of as traversing an exponential-size recursion tree which performs polynomial-time checks at leaves and returns true if at some leaf true is returned, then we can cast this as an OPP algorithm provided we are able to sample leaves of the branching tree in an efficient, nearly uniform way (in [24], this observation was attributed to Eppstein [12]). We would like to remark that OPP is more powerful than one might think at first sight as it also directly captures, for example, Schöning's algorithm [27].

Concerning lower bounds, Paturi and Pudlak [24] showed that OPP algorithms with success probability significantly better than 2^{-n} for circuit satisfiability on n variables would have unlikely consequences. Particularly relevant for our work is work by Drucker [10] showing a $2^{-n^{1-\epsilon}}$ upper bound of OPP algorithms' success probability for 3-CNF-SAT (for any $\epsilon > 0$), assuming $NP \nsubseteq coNP/poly$.

Several closely-related formalisms of branching algorithms have been proposed in the literature [4, 26, 31]. In the context of parameterized complexity, Marx proposed a study of branching [20, 21] using a model 'BFPT' of branching FPT algorithms.[2] Also relevant is work of Dantsin and Hirsch [8], which discusses a notion closely related to our notion of witness compression in the context of exact algorithms for Satisfiability, and provides lower bounds conditioned on ETH.

[1] That is, try all bit-strings and see if a certificate arises.
[2] That turns out to be equivalent to OPP algorithms with success probability $2^{-O(k)}$.

Our Contribution

In this work, we argue that many contemporary exponential-time algorithms can be rewritten as polynomial-time reductions to succinct version of problems in P, and we also give several concrete results on the applicability of specific algorithmic paradigms to different problems. We outline these results next.

Branching. Our main technical contributions address branching algorithms as modelled by OPP algorithms or equivalently witness compressions (defined below). Building on machinery developed by Drucker [10] we give lower bounds for constructive OPP algorithms. For instance:

▶ **Theorem 1.1.** *If there is a polynomial time algorithm that given a planar graph outputs a maximum independent set of n vertices with probability* $\exp(-O(n^{1-\epsilon}))$ *for some* $\epsilon > 0$*, then* $NP \subseteq coNP/poly$.

Note that $\exp(O(\sqrt{n}))$ time algorithms are known (e.g. [18]), so this indicates that a rich class of branching algorithms is incapable of exploiting planarity for solving independent set. We also give a simple OPP algorithm that actually establishes success probability $\exp(-O(n/\sqrt{\log(n)}))$.

Following a hashing lemma from [24], we observe that having an OPP algorithm with success probability $f(k)$ is equivalent to having a polynomial-time Monte Carlo reduction from the problem at hand to CKT-SAT[3] with $1/\log(f(k))$ input gates. Thus in the generic context sketched in this paper, the succinct problem corresponding to our model of branching is CKT-SAT. If $f(k) = 2^{-\text{poly}(k)}$, there are witnesses for the problem of size poly(k) and we will refer to the polynomial time Monte Carlo reduction as a *polynomial witness compression* since a satisfying solution of the circuit that the reduction outputs can be seen as a witness for the original instance to be a yes-instance. We call a witness compression *Levin* or *constructive* if we can determine a solution of the original problem given a satisfying assignment of the circuit.

We define a type of reduction we call 'constructive AND-composition' that is closely related to AND-compositions from kernelization theory, and show that assuming $NP \not\subseteq coNP/poly$ no parameterized problem can both have a constructive AND-composition and a Levin polynomial witness compression. As one particular application, we use this to *separate* dynamic programming from branching (as modelled via OPP algorithms). Specifically, we show that Independent Set parameterized by pathwidth,[4] which is known to be FPT via a dynamic programming algorithm, does not have Levin polynomial witness compressions unless $NP \not\subseteq coNP/poly$. An important question[5] is how fast this problem can be solved using only polynomial space. In [19], the authors provide an $O^*(2^{O(\mathtt{pw}^2)})$-time and polynomial-space algorithm based on a tradeoff between dynamic programming and Savitch's theorem, but the folklore dynamic programming algorithm uses $O^*(2^{\mathtt{pw}})$ time and space. Our results thus indicate that branching algorithms of the OPP type, a very natural class of polynomial space algorithms, will not be useful here.

We emphasize that the model of OPP algorithms and witness compressions are powerful by observing that problems such as Steiner Tree, Long Path and Directed Feedback

[3] Refer to Section 2 for a definition.
[4] That is, we assume a path decomposition of width `pw` is given as input.
[5] This question first appeared in print in [19], but was explicitly asked before at least in [22].

Vertex Set (DFVS) do have polynomial witness compressions as a consequence of methods from previous works.

Kernelization. The above results on branching have a number of consequences for kernelization theory. To explain these, let us first stress that it seems that if a problem has an AND-composition it seems very likely it also has an constructive AND-composition since all known AND-compositions are known to be constructive.

There has been interest recently in relaxed versions of kernelization, such as OR-kernels, where rather than computing one small instance from the initial instance, we compute a list of instances, at least one of which is in the language if and only if the original instance was. It is easy to see that a polynomial witness compression is a far reaching generalization of OR-kernelization: if a problem has a OR-kernel the witness would indicate which output of the OR-kernel is a yes-instance along with a certificate of this instance being a YES. On the other hand, a problem as CKT-SAT with k input variables is known to not have polynomial kernelization assuming $NP \not\subseteq coNP/poly$ (see e.g., [9]) but trivially has a polynomial witness compression. Our observation thus implies that problems cannot have both constructive AND-compositions and OR-kernelizations simultaneously unless $NP \subseteq coNP/poly$.

Our connection between constructive AND-composition and witness compressions combined with the polynomial witness compressions for Steiner Tree, Long Path and DFVS implies that these problems do not have constructive AND-compositions, which is a clear indication that they do not admit AND-compositions as studied in kernelization theory. We feel this is a useful insight especially for DFVS because the existence of a polynomial compression for this is a major open problem [6], and since we currently only know how to exclude polynomial compressions via AND- and OR-compressions our connection indicates we probably should not look for AND-compressions.

Parity Compression. There are several other important paradigms that in many cases seem essential to known algorithms for various problems, especially to obtain the best known bounds on the function $f(k)$. In [24], the authors mention as examples the paradigms of exponential-time divide-and-conquer; inclusion-exclusion; dynamic programming; group algebra; and Voronoi cell decomposition; and they argue that 'OPP and its generalizations could serve as an excellent starting point for the study of exponential-time algorithms for NP-complete problems in general', although they leave such generalizations unspecified.

We further explore this direction, using our unifying perspective via succinct parameterized problems. Similar to witness compression, we define a notion of "parity compression" corresponding to reducibility to the problem $\oplus$CKT-SAT parameterized by the number of variables. The idea here is that algebraic and inclusion-exclusion based approaches to FPT algorithms often implicitly reduce the problem to a succinctly represented parity of exponentially many input bits, i.e, an instance of $\oplus$CKT-SAT. We illustrate this phenomenon by capturing the Long Path and K-Cycle problems in our model.

Disjunctive Dynamic Programming. We model a subclass of dynamic programming algorithms which we refer to as "disjunctive dynamic programming". Intuitively, this corresponds to dynamic programming tables whose entries are Boolean ORs of lexicographically-prior entries. We model this class via reducibility to the problem CNF-Reach, an instance of which is a directed graph succinctly encoded by a CNF, with the question being whether there is a source-sink path of a prescribed length in the graph. The parameter is the number of variables of the CNF. Essentially, the existence of a path corresponds to a "trace" of a disjunctive dynamic programming algorithm with a YES answer.

More generally, one could study succinctness implemented by circuits rather than CNFs; however, the choice of CNFs has a nice benefit: it allows us to find natural complete problems for our model. Specifically, we show that Independent Set parameterized by pathwidth is complete for this model, thus in some sense dynamic programming is the "right" algorithmic technique for this problem. The completeness of Independent Set parameterized by pathwidth may also be interpreted as another signal that polynomial space algorithms for problems parameterized by pathwidth might be hard to find as they need to exploit the succinctness given by the CNF representation or otherwise need to improve over Savitch's theorem for short reachability. Let us remark that related research has been proposed earlier: the reduction as outlined here has been conjectured in the second author's PhD-thesis [23], and the aforementioned signal was remarked in [23, 2, 25]

Organization. This work is organized as follows: in Section 2 we provide a few preliminaries. Note that due to space constraints we do not cover basic definitions from parameterized complexity such as definitions of fixed-parameter tractability that provide context for our work; we refer the reader to a recent textbook [7]. Section 3 presents our main technical results, which are on branching algorithms. Section 4 introduces the model of parity compression, Section 5 introduces the model of disjunctive dynamic programming and in Section 6 we list a number of interesting directions for further research.

2 Preliminaries and Notation

For an integer p, $[p] := \{1, \dots, p\}$, and $\binom{X}{p}$ denotes the family of size-p subsets of a set X.

Probabilistic Circuits. A *probabilistic circuit* is a (De Morgan) Boolean circuit $C(x, r)$ which, in addition to its input gates $x \in \{0,1\}^n$, has a designated set of "randomness gates" $r \in \{0,1\}^{\mathrm{poly}(n)}$. We say such a circuit computes a function $f(x)$ with success probability $p(n)$ if, for all $x \in \{0,1\}^n$, $\Pr_r[C(x,r) = f(x)] \geq p(n)$. Here the probability is taken over a uniform random setting to r. By Cook's transformation, any polynomial time randomized algorithm can be expressed as a (logspace-uniform) family of polynomial-size probabilistic circuits.

Problem Definitions. *PC* denotes the set of search problems whose solutions can be verified in polynomial time (following [14]). For $L \subseteq \{0,1\}^*$, χ_L denotes the characteristic vector of L. A *parameterized problem* is a set $Q \subseteq \{0,1\}^* \times \mathbb{N}$.

We use the following notation to define (parameterized) (search) problems in NP or PC: if k is some parameter of an unparameterized problem R, R$/k$ denotes the associated problem parameterized by k. When a problem has a natural search version, we will use this to define it, as the decision version follows from the search version. We use L_Q to denote the decision version of a search problem Q. The following parameterized search problems will be important for this paper:

CKT-Sat **Parameter:** n
Instance: A Boolean circuit C on n variables.
Witness: An assignment $x \in \{0,1\}^n$ such that $C(x) = 1$.

(d)-CNF-Sat **Parameter:** n
Instance: A Boolean (d)-CNF-formula C on n variables.
Witness: An assignment $x \in \{0,1\}^n$ such that $C(x) = 1$.

For any search problem $R \in PC$, we define a search problem $AND(R)$ as follows:

$AND(R)$ **Parameter:** n
Instance: Instances $x_1, \dots, x_t \in \{0,1\}^n$
Witness: $y_1, \dots, y_t$ such that $(x_i, y_i) \in R$ for every i.

Reductions. For search problems[6] $Q, R \in PC$, a *Levin reduction* from Q to R consists of two polynomial time algorithms, A_1 and A_2, such that (i) $\exists y : (x, y) \in Q$ if and only if $\exists y' : (A_1(x), y') \in R$, (ii) if $(A_1(x), y') \in R$, then $(x, A_2(x, y')) \in Q$. A *Monte Carlo reduction* from language L to language L' is a randomized polynomial time algorithm that takes $x \in \{0,1\}^*$ as input and outputs $y \in \{0,1\}^*$ such that (i) if $x \notin L$ then $y \notin L'$, (ii) if $x \in L$ then $\Pr[y \in L'] \geq 1/4$. A *Levin Monte Carlo reduction* from search problem Q to search problem R is a pair of two randomized polynomial time algorithms A and B with the following properties: (i) A is a Monte Carlo reduction from L_Q to L_R mapping x to x', (ii) B takes as input x, x' and y', and if $(x', y') \in R$, then with probability $1/4$, B outputs y such that $(x, y) \in Q$.

Success Probability of Polynomial Time Algorithms. Let $f : \mathbb{N} \times \mathbb{N} \to \mathbb{R}$. We say that an algorithm *solves a parameterized problem Q with success probability f*, if given (x, k) it returns NO if $(x, k) \notin L_Q$ and YES with probability at least $f(|x|, k)$ if $(x, k) \in L_Q$. Moreover, if $Q \in PC$, *it finds solutions for* Q with probability at least f if given (x, k) it returns NO if $(x, k) \notin L_Q$ and it returns a certificate for $(x, k) \in L_Q$ with probability at least $f(|x|, k)$, otherwise. Note that an algorithm finding solutions for Q also solves Q.

By standard boosting arguments we see that if there is a polynomial time algorithm solving Q or finding solutions for Q with probability at least f, then for any polynomial p there is also a polynomial time algorithm solving Q or finding solutions for Q with probability at least $\min\{\frac{1}{2}, p(|x|) f(|x|, k)\}$. Therefore, if $f(|x|, k)$ is $1/(\mathrm{poly}(|x|) f(k))$, we say it solves or finds solutions for Q with probability at least $f'(k)$ where $f'(k) = f(1, k)$.

Non-deterministic Direct Product Reductions. For a function $f : A \to B$ and integer t, we denote $f^{\otimes t} : A^t \to B^t$ to be the t-fold direct product of f, e.g., for $x_1, \dots, x_t \in A$ we let $f^{\otimes t}(x_1, \dots, x_t) = (f(x_1), \dots, f(x_t))$. The following result will be crucial for this work:

▶ **Theorem 2.1** (Theorem 1.2 of [10]). *Let $f = \{f_N\}$ be a family of Boolean functions on N input bits, and suppose that $f \notin NP/poly \cap coNP/poly$. Let $100 \leq t(N) \leq \mathrm{poly}(N)$ be a parameter and let $\{C_N\}_{N>0}$ be any family of polynomial-size probabilistic circuits outputting $t(N)$ bits. Then for infinitely many choices of N and $x \in \{0,1\}^{N \times t(N)}$,*

$$\Pr[C_N = f_N^{\otimes t(N)}(x)] < \exp(-\Omega(t(N)). \tag{2.1}$$

[6] In this work, we implicitly cast a parameterized (search) problem as a normal (search) problem by omitting the parameter where convenient.

3 Branching via OPP Algorithms and Witness Compressions

In this section we present our results on branching algorithms. We first formally define the notion of constructive AND-compositions and state how they exclude OPP algorithms. Then we formally introduce witness compressions and show their close relation with OPP algorithms. Subsequently, we point out implications to parameterized complexity.

Constructive AND-Compositions and Their Consequences.

▶ **Definition 3.1** (Constructive AND-composition). Let L be a search problem, Q be a parameterized search problem and d be a constant. We say that a pair of algorithms (A,B) is a *constructive AND-composition of degree d from L into Q* if the following conditions hold:

1. A is given $x_1, x_2, \dots, x_t$ and outputs an instance $(x, k) \in \Sigma^* \times \mathbb{N}$ in time polynomial in $\sum_{i=1}^{t} |x_i|$ such that $k \leq \mathrm{poly}(\max_i |x_i| \log(t))$ and $|x| \leq \mathrm{poly}(\max_i |x_i| \log(t))t^d$,
2. if for every i there exist y_i such that $(x_i, y_i) \in L$, then B does the following: B takes as input $x_1, x_2, \dots, x_t$, the instance (x, k), and a certificate y such that $(x, k, y) \in Q$, and outputs y_i for every i such that

$$\Pr[\forall i : (x_i, y_i) \in L] \geq \exp\left(-\mathrm{poly}\left(\max_i |x_i|\right) \log(t)\right).$$

This is closely related to AND-compositions as studied in kernelization complexity (see e.g. [7, Section 15.1.3]): it is more strict in the sense that the reduction needs to be Levin, but more general in the sense that we only need a weak probabilistic guarantee on the output. We will see that even constructive AND-compositions of degree 1 with trivial parameterizations have interesting consequences.

▶ **Theorem 3.2.** *If there is a constructive AND-composition of degree d from a PC-hard search problem L into a parameterized search problem Q, then no polynomial time algorithm finds solutions for every instance (x, k) of Q with probability* $\exp(-\mathrm{poly}(k)|x|^{1/d-\Omega(1)})$*, unless $NP \subseteq coNP/poly$.*

As one concrete application we obtain the Theorem as mentioned in the introduction:

▶ **Theorem 1.1** (restated). *If there is a polynomial time algorithm that, given a planar graph, outputs a maximum independent set of n vertices with probability* $\exp(-n^{1-\epsilon})$ *for some* $\epsilon > 0$*, then $NP \subseteq coNP/poly$.*

Proof. Let L be the following search problem: given the adjacency list of a planar graph G and integer θ, find an independent set of G of size at least θ. The decision variant of this problem NP-complete and by inspecting the known reductions, the problem is also seen to be PC-complete. Let Q be L with a trivial parameterization (e.g., the parameter equals 1). We now give a constructive AND-composition of degree 1 from L to Q. Given instances $(G_1 = (V_1, E_1), \theta_1), \dots, (G_t = (V_t, E_t), \theta_t)$, create an instance (G, θ^*) of Q where G is the disjoint union of $G_1, \dots, G_t$ (i.e. it has each graph G_i as a connected component in it), and θ^* is picked uniformly at random from $\{1, \dots, \sum_{i=1}^{t} |V_i|\}$. We see that with probability $1/\sum_{i=1}^{t} |V_i| \geq \exp\left(-\mathrm{poly}\left(\max_i |x_i|\right) \log(t)\right)$, we have that θ^* equals the size of the maximum independent set. Moreover, if we are given a maximum independent set of G, its intersection with every component must be a maximum independent set in that component so if all instances are YES instances we find maximum independent sets of size at least θ_i in G_i for every i. Since (G, θ) is represented with $\mathrm{poly}(\max_i |V_i|)t \log(t)$ bits, we therefore found a constructive AND-composition of degree 1, and no polynomial time algorithm finds solutions for Q with probability $\exp(-|x|^{1-\Omega(1)})$ by Theorem 3.2. This implies the statement since $|x|$ is $n \log n$ for n-vertex graphs. ◀

We remark the naïve guessing procedure here is not optimal (the proof is postponed to the full version):

▶ **Theorem 3.3.** *There exists a polynomial time algorithm that outputs a maximum independent set of a planar graph on n vertices with probability* $\exp(-n/\sqrt{\log n})$.

Witness Compressions. We will now give an equivalent interpretation of OPP algorithms that paves the way for defining models of other paradigms in the next sections.

▶ **Definition 3.4** ((Levin) Witness Compression)**.** A *(Levin) $h(k,N)$-witness compression* for a parameterized (search) problem Q is a (Levin) Monte-Carlo reduction from Q to CKT-SAT that maps (x,k) with $|x| = N$ to (y,n) with $n \le h(k,N)$.

Note that having a $h(k,N)$-witness compression is equivalent to having a $h(k, N+\lg(N))$-witness compression since we can brute-force over all assignments of $\lg(N)$ input bits in polynomial time. We say a (Levin) $h(k,N)$-witness compression is *polynomial* if $h(k,N) \le \text{poly}(k)$ (or equivalently $\text{poly}(k) + \log(N)$). The following lemma shows the equivalence of witness compression and OPP algorithms.

▶ **Lemma 3.5.** *A parameterized (search) problem has a* (Levin) $h(k,N)$-witness compression *if and only if there is a polynomial time algorithm solving it (respectively, finding solutions) with success probability at least* $2^{-h(k,N)}$.

The proof is postponed to the full version. The forward direction in both variants is immediate. For the backward direction, we use the 'Hash-Down lemma' from [24] to prove both variants. Our proof of the equivalence takes advantage of the fact that we allow randomized reductions in the definition of witness compression. If we were to only allow deterministic reductions in the definition, the equivalence would still hold under a sufficiently strong derandomization hypothesis - we omit the details.

We emphasize the power of polynomial witness compression by revisiting a few FPT-algorithms and observing that they give rise to efficient witness compressions. Marx [21] observes that VERTEX COVER and FEEDBACK VERTEX SET have a witness compression with $h(k)$ linear. Here, we add a few non-trivial witness compressions to this list with $h(k)$ quasi-linear. The relevant problem statements and proof of the following theorem can be found in the full version. All these results go via the connection from Theorem 3.5.

▶ **Theorem 3.6.** STEINER TREE *and* LONG PATH *have Levin $O(k \log k)$-witness compressions, and* DFVS *has a Levin $O(k \log^3(k))$-witness compression.*

Implications to Parameterized Complexity. As mentioned in the introduction, polynomial witness compression appears significantly more powerful than polynomial kernelization. Indeed if a problem has an OR-kernelization,[7] it is easily seen we have a polynomial witness compression:

[7] Where rather than computing one small instance from the initial instance as in kernelization, we compute a list of instances at least one of which is in the language if and only if the original instance was, see e.g.[17] where the name 'disjunctive kernelization' was used.

▶ **Observation 3.7.** If Q admits a polynomial (Levin) OR-kernelization to a problem in NP, it admits a polynomial (Levin) witness compression.

On the other hand, let us remark here that there may be problems in NP that admit polynomial compressions[8] but no polynomial witness compression: Wahlström [30] gives an interesting polynomial compression of the K-cycle problem (see the full version for the problem definition) to a language that is not in NP, and remarks that this seems to separate polynomial kernelization from polynomial compression since it is not clear whether K-cycle has polynomial witness compressions.

The above connection is relevant for kernelization complexity because Theorem 3.8 suggests that parameterized problems with AND-compositions have no OR-kernelizations. Another interesting consequence obtained by combining Theorem 3.2 and Theorem 3.6 is (since the problems at hand are easily seen to be PC-complete):

▶ **Theorem 3.8.** Steiner Tree*,* Long Path*, and* DFVS *do not admit constructive AND-compositions unless $NP \subseteq coNP/poly$.*

As mentioned before, this is a useful fact especially for DFVS because the existence of a polynomial compressions for this is a big open problem [6], and we currently only know how to exclude polynomial compressions via AND- and OR-compressions Theorem 3.8. So this indicates researchers attacking this open problem probably should not look for AND-compressions.

Another useful implication concerns the following parameterized problem:

Independent Set (IS/pw) **Parameter:** `pw`
Instance: A graph G, path decomposition of G of width `pw`, integer θ.
Witness: An independent set of G of size at least θ.

As mentioned in the introduction, it is an important open question how fast this problem can be solved using only polynomial space. We show that branching algorithms (which is a subset of all polynomial space algorithms) are not useful here:

▶ **Theorem 3.9.** *Suppose a polynomial time algorithm takes as input a path decomposition of width* `pw` *of a graph G on n vertices, and outputs with probability* $\exp(-\text{poly}(\texttt{pw})n^{1-\Omega(1)})$ *a maximum independent set of G, then $NP \subseteq coNP/poly$.*

Since the proof is very similar to the proof of Theorem 1.1, it is postponed to the full version. Let us remark that several other interesting graph problems admit constructive AND-compositions. For example, following Lemma 7 from [3] we have that

▶ **Observation 3.10.** Let L be a parameterized graph search problem such that for any pair of graphs G_1 and G_2, and integer $k \in \mathbb{N}$, $(G_1, k) \in L \wedge (G_2, k) \in L \leftrightarrow (G_1 \cup G_2, k)$ where $G_1 \cup G_2$ is the disjoint union of G_1 and G_2. Then L admits a constructive AND-composition of degree 1.

Similar as in [3], this implies hardness for several problems. We refer to [3] for the definitions of these problems since our only goal is to point out the applicability of our framework.

[8] A compression is a kernelization where the target problem might be different (and crucially here, not even in NP).

▶ **Theorem 3.11.** *No polynomial time algorithm finds solutions for any instance* (x, k) *of* Cutwidth, Modified Cutwidth, Pathwidth, Branchwidth, Search Number, Gate Matrix Layout, *and* Front Size *with probability* $\exp(-\mathrm{poly}(k)|x|^{1-\Omega(1)})$ *unless* $NP \not\subseteq coNP/poly$.

Proof. Following [3], we have by Observation 3.10 that all the above problems admit constructive AND-compositions. By inspection it can be seen that the reductions from these problems to CKT-Sat (which exist since all the above problems are NP-complete) are all Levin reductions, thus all problems are PC-complete. The claim follows from Theorem 3.2. ◀

4 Parity Compression

As mentioned before, witness compression tightly captures a large part of contemporary FPT-algorithms, but still far from all of them. Motivated by this, we propose the following natural generalization of witness compression, based on the definition of witness compression as a reduction to CKT-Sat. A *parity compression* is a polynomial time Monte Carlo reduction from the problem at hand to the $\oplus$CKT-Sat problem, defined as follows:

$\oplus$CKT-Sat **Parameter:** n
Instance: A Boolean circuit C on n variables
Asked: Whether the parity of the size of the set $\{x \in \{0,1\}^n : C(x) = 1\}$ is odd.

Analogous to witness compressions, we can interpret parity compressions as exponential time algorithms by solving the resulting $\oplus$CKT-Sat instance in time $2^n|x|^{O(1)}$ (the analogue of witness compressions was to solve the CKT-Sat instance by simple brute-force enumeration). By an easy application of the Isolation Lemma of [29], there is a polynomial time Monte Carlo reduction from CKT-Sat to $\oplus$CKT-Sat that increases the number of input variables by $O(\mathrm{polylog}(|C|))$. Thus parity compression is a generalization of witness compression. No polynomial-time reduction in the reverse direction is known, and such a reduction (even randomized) would imply a collapse of PH in light of Toda's theorem [28].

While we are not yet able to show lower bounds for parity compressions since its study is still in its infancy, we do argue in the full version that several interesting contemporary algorithms (mainly, ones using inclusion/exclusion or group algebra) are exponential parities. This motivates a very interesting future research direction:

▶ **Open Problem 1.** Find non-trivial evidence against a polynomial time Monte Carlo reduction from CKT-Sat on n-variable circuits to $\oplus$CKT-Sat on n' circuits where $n' << n$.

Another goal would be to further exclude more polynomial space paradigms that are able to solve Independent Set parameterized by the pathwidth:

▶ **Open Problem 2.** Find evidence against a polynomial time Monte Carlo reduction from IS/pw to $\oplus$CKT-Sat where $n = o(\mathtt{pw}^2)$.

5 Disjunctive Dynamic Programming

One natural other algorithmic paradigm unaddressed so far (as highlighted in Theorem 3.9 and Open Problem 2) is dynamic programming. We focus in this work on a subclass of dynamic programming algorithms which we call 'disjunctive dynamic programming' - this corresponds to dynamic programming tables where the entries are Boolean ORs of previous entries. Specifically, we say a disjunctive dynamic programming algorithm is a polynomial time parameter reduction to the following problem:

CNF-Reach **Parameter:** n
Instance: A CNF-formula $\varphi : \{0,1\}^n \to \{0,1\}$ with m clauses and n even, integer $\ell = \text{poly}(n)$.
Witness: $x^1, \dots, x^\ell \in \{0,1\}^{n/2}$ with $x^1 = 0 \cdots 0, x^\ell = 1 \cdots 1$ and $\varphi(x^i x^{i+1}) = 1$ for every $0 \leq i \leq \ell - 1$.

In the full version we show that IS/PW is almost equivalent to CNF-Reach[9] by giving almost tight reductions between the two problems. Thus IS/PW can be seen as complete for the class of problems efficiently solvable with disjunctive dynamic programming. We feel such a reduction expresses the hardness of a problem typically solved with dynamic programming better than e.g., a reduction to CNF-Sat or even CKT-Sat since these problem do have small witnesses and polynomial-space algorithms. Next to Theorem 3.9, this may be seen as additional evidence that finding fast space-efficient algorithms for IS/PW might be very hard (e.g., we either need to exploit the succinct representation via CNF-formula's or find new algorithms for the directed reachability problem).

We also show that an algorithm for Set Cover is a disjunctive dynamic programming algorithm: we reduce Set Cover to CNF-Reach in the full version.

6 Directions for Further Research

We conclude this paper with a few open questions. First, for several problems, the existence of polynomial witness compression is open (see the full version for missing problem definitions):

▶ **Open Problem 3.** Do Subset Sum, Knapsack, Knapsack/Weight-Value, K-Cycle or Disjoint Paths have polynomial witness compressions?

Note that currently, it is not clear whether there exists a parameterized problem that has a polynomial compression but no polynomial witness compression, although as suggested in [30] the K-Cycle would be a good candidate for such a problem.

One algorithmic paradigm not addressed is exponential time divide and conquer [15], which is also closely related to applications of Savitch's Theorem as used by [19]:

▶ **Open Problem 4.** Is there a good model of exponential time divide and conquer based on reductions to a succinct version of a natural problem? Can it solve IS/PW in $O^*(2^{o(\texttt{pw}^2)})$ time?

Ambitiously, having finer-grained lower bounds would be very insightful:

▶ **Open Problem 5.** Can we rule out linear witness compressions for some problems with quasilinear witness compressions under standard assumptions?

Abstract

While randomized online algorithms have access to a sequence of uniform random bits, deterministic online algorithms with advice have access to a sequence of *advice bits*, i.e., bits that are set by an all-powerful oracle prior to the processing of the request sequence. Advice bits are at least as helpful as random bits, but how helpful are they? In this work, we investigate the power of advice bits and random bits for online maximum bipartite matching (MBM).

The well-known Karp-Vazirani-Vazirani algorithm [24] is an optimal randomized $(1-\frac{1}{e})$-competitive algorithm for MBM that requires access to $\Theta(n \log n)$ uniform random bits. We show that $\Omega(\log(\frac{1}{\epsilon})n)$ advice bits are necessary and $O(\frac{1}{\epsilon^5}n)$ sufficient in order to obtain a $(1-\epsilon)$-competitive deterministic advice algorithm. Furthermore, for a large natural class of deterministic advice algorithms, we prove that $\Omega(\log \log \log n)$ advice bits are required in order to improve on the $\frac{1}{2}$-competitiveness of the best deterministic online algorithm, while it is known that $O(\log n)$ bits are sufficient [9].

Last, we give a randomized online algorithm that uses cn random bits, for integers $c \geq 1$, and a competitive ratio that approaches $1-\frac{1}{e}$ very quickly as c is increasing. For example if $c = 10$, then the difference between $1-\frac{1}{e}$ and the achieved competitive ratio is less than 0.0002.

1 Introduction

Online Bipartite Matching. The maximum bipartite matching problem (MBM) is a well-studied problem in the area of online algorithms [24, 5, 12]. Let $G = (A, B, E)$ be a bipartite graph with $A = [n] := \{1, \dots, n\}$ and $B = [m]$, for some integers n, m. We assume $m = \Theta(n)$ allowing bounds to be stated as simple functions of n rather than of n and m. The A-vertices together with their incident edges arrive online, one at a time, in some adversarial chosen order $\pi : [n] \to [n]$. Upon arrival of a vertex $a \in A$, the online algorithm has to irrevocably decide to which of its incident (and yet unmatched) B-vertices it should be matched. The considered quality measure is the well-established *competitive ratio* [32], where the performance of an

online algorithm is compared to the performance of the best offline algorithm: A randomized online algorithm $\mathbf{A}$ for MBM is c-competitive if the matching M output by $\mathbf{A}$ is such that $\mathbb{E}|M| \geq c \cdot |M^*|$, where the expectation is taken over the random coin flips, and M^* is a maximum matching.

In 1990, Karp, Vazirani and Vazirani [24] initiated research on online MBM and presented a $(1 - \frac{1}{e})$-competitive randomized algorithm denoted KVV. It chooses a permutation $\sigma : [m] \rightarrow [m]$ of the B-vertices uniformly at random and then runs the algorithm Ranking(σ), which matches each incoming A-vertex a to the free incident B-vertex b of minimum rank (i.e., $\sigma(b) < \sigma(c)$ for all free incident vertices $c \neq b$). If there is no free B-vertex, then a remains unmatched. They showed that no online algorithm has a better competitive ratio than $1 - \frac{1}{e}$, implying that KVV is optimal. For deterministic online algorithms, it is well-known that the Greedy matching algorithm, which can be seen as running Ranking(σ) using a fixed arbitrary σ, is $\frac{1}{2}$-competitive, and is optimal for the class of deterministic online algorithms.

Improving on $1 - \frac{1}{e}$. Additional assumptions are needed in order to improve on the competitive ratio $1 - \frac{1}{e}$. For example, Feldman et al. [17] introduced the online stochastic matching problem, where a bipartite graph $G' = (A', B', E')$ and a probability distribution $\mathcal{D}$ is given to the algorithm. The request sequence then consists of vertices of A' that are drawn according to $\mathcal{D}$. Feldman et al. showed that the additional knowledge can be used to improve the competitive ratio to 0.67, which has subsequently been further improved [3, 27]. Another example is a work by Mahdian and Yan [26], who considered the classical online bipartite matching problem with a random arrival order of vertices. They analysed the KVV algorithm for this situation and proved that it is 0.696-competitive.

Online Algorithms with Advice. It is a common theme in online algorithms to equip an algorithm with additional knowledge that allows it to narrow down the set of potential future requests and, thus, design algorithms that have better competitive ratios as compared to algorithms that have no knowledge about the future. Additional knowledge can be provided in many different ways, e.g. access to lookahead [22, 19], probability distributions about future requests [17, 26], or even by giving an isomorphic copy of the input graph to the algorithm beforehand [21]. Dobrev et al. [13] and later Emek et al. [15] first quantified the amount of additional knowledge (advice) given to an online algorithm in an information theoretic sense. They showed that a specific problem requires at least $b(n)$ bits of advice, for some function b, in order to achieve optimality [13] or in order to achieve a particular competitive ratio [15]. Advice lower bounds are meaningful in practice as they apply to any potential type of additional information that could be given to an algorithm.

In the advice model, a computationally all-powerful oracle is given the entire request sequence and computes an advice string that is provided to the algorithm. Algorithms with advice are not usually designed with practical considerations in mind but to show a theoretical limit on what can be done. As such, the algorithms are often impractical due to the nature of the advice or the complexity in calculating the advice. However, from a theoretical perspective, advice algorithms are necessary to determine the exact advice complexity of online problems (how many advice bits are necessary and sufficient) and thus provide limits on the achievable and more practically relevant lower bounds.

Our Objective and Previous Results. Our objectives are to determine the advice complexity of MBM and to investigate the power of random and advice bits for this problem.

A starting point is a result of Böckenhauer et al. [9], who gave a method that allows the transformation of a randomized online algorithm into a deterministic one with advice with a similar approximation ratio. More precisely, given a randomized online algorithm $\mathbf{A}$ for a minimization problem $\mathcal{P}$ with approximation factor c and possible inputs $\mathcal{I}(n)$ of length n, Böckenhauer et al. showed that a $(1+\epsilon)c$-competitive deterministic online algorithm $\mathbf{B}$ with $\log n + 2\log\log n + \log \frac{\log|\mathcal{I}(n)|}{\log(1+\epsilon)}$ bits[1] of advice can be deduced from $\mathbf{A}$, for any $\epsilon > 0$, where log is the binary logarithm in this paper. The calculation of the advice and the computations executed by $\mathbf{B}$ require exponential time, since $\mathbf{A}$ has to be simulated on all potential inputs $\mathcal{I}(n)$ on all potential random coin flips.

The technique of Böckenhauer et al. [9] can also be applied to maximization problems such as MBM[2]. Applied to the KVV algorithm, we obtain:

▶ **Theorem 1.** *There is a deterministic online algorithm with* $\mathrm{O}(\log n)$ *bits of advice for* MBM *with competitive ratio* $(1-\epsilon)(1-1/e)$, *for any* $\epsilon > 0$.

This result is complemented by a recent result of Mikkelsen [28], who showed that for *repeatable problems* (see [28] for details) such as MBM, no deterministic online algorithm with advice sub-linear in n has a substantially better competitive ratio than any randomized algorithm without advice. Thus, using $\mathrm{O}(\log n)$ advice bits, a $(1-\epsilon)(1-\frac{1}{e})$-competitive deterministic algorithm can be obtained, and no algorithm using $o(n)$ advice bits can substantially improve on this result. Furthermore, Miyazaki [29] showed that $\Theta(\log(n!)) = \Theta(n\log n)$ advice bits are necessary and sufficient in order to compute a maximum matching.

Our Results on Online Algorithms with Advice. Consider a deterministic online algorithm with $f(n)$ bits of advice for MBM. Our previous exposition of related works shows that the ranges $f(n) \in \Omega(\log n) \cap o(n)$ and $f(n) \in \Theta(n\log n)$ are well understood. In this work, we thus focus on the ranges $f(n) \in o(\log n)$ and $f(n) \in \Omega(n) \cap o(n\log n)$. Our first set of results concerns $(1-\epsilon)$-competitive deterministic advice algorithms. We show:

1. There is a deterministic $(1-\epsilon)$-competitive online algorithm, using $\mathrm{O}(\frac{1}{\epsilon^5}n)$ advice bits for MBM.
2. Every deterministic $(1-\epsilon)$-competitive online algorithm for MBM uses $\Omega(\log(\frac{1}{\epsilon})n)$ bits of advice.

Our lower bound result is obtained by a reduction from the *string guessing game* of Böckenhauer et al. [6], a problem that is difficult even in the presence of a large number of advice bits. This technique has repeatedly been applied for obtaining advice lower bounds, e.g. [1, 20, 10, 2, 11, 4]. Our algorithm simulates an augmenting-paths-based algorithm by Eggert et al. [14], that has originally been designed for the data streaming model, with the help of advice bits. It is fundamentally different to the KVV algorithm, however, inspired by the simplicity of KVV, we are particularly interested in the following class of algorithms:

▶ **Definition 2** (Ranking-algorithm). An online algorithm $\mathbf{A}$ for MBM is called Ranking-algorithm if it follows the steps: (1) Determine a ranking σ; (2) Return Ranking(σ).

The KVV algorithm is a Ranking-algorithm, where in step (1), the permutation σ is chosen uniformly at random. The algorithm described in Theorem 1 is a deterministic Ranking-algorithm with $\mathrm{O}(\log n)$ bits of advice that computes the permutation σ from the

[1] Throughout the paper, logarithms, where the base is omitted, are implicitly binary logarithms.
[2] It is straightforward to adapt the proof of Theorem 5 of [9] accordingly. For completeness, a proof is given in the full version of this paper.

available advice bits. While we cannot answer the question how many advice bits are needed for deterministic online algorithms in order to obtain a competitive ratio strictly larger than $\frac{1}{2}$ (and thus to improve on Greedy), we make progress concerning Ranking algorithms:

3. Every Ranking-algorithm that chooses σ from a set of at most $C \log \log n$ permutations, for a small constant C, has approximation factor at most $(\frac{1}{2} + \delta)$, for any $\delta > 0$.

The previous result implies that every $(\frac{1}{2} + \delta)$-competitive deterministic online Ranking-algorithm requires $\Omega(\log \log \log n)$ advice bits.

Next, since the computation of the advice and the algorithm of Theorem 1 are not efficient, we are interested in fast and simple Ranking algorithms. We identify a subclass of Ranking algorithms, denoted Category algorithms, that leads to interesting results, both as deterministic algorithms with advice and randomized algorithms without advice.

▶ **Definition 3** (Category-algorithm). A Ranking-algorithm **A** is called a Category-algorithm if it follows the steps:

- Determine a category function $c : B \to \{1, 2, 3, \dots, 2^k\}$ for some integer $k \geq 1$ with $2^k < m$;
- Let $\sigma_c : [m] \to [m]$ be the unique permutation of the B-vertices such that for two vertices $b_1, b_2 \in B : \sigma_c(b_1) < \sigma_c(b_2)$ if and only if $c(b_1) < c(b_2)$ or $(c(b_1) = c(b_2)$ and $b_1 < b_2)$.
- Return Ranking(σ_c).

Categories can be seen as coarsened versions of rankings, where multiple items with adjacent ranks are grouped into the same category and within a category, the natural ordering by vertex identifier is used. We prove the following:

4. There is a deterministic $\frac{3}{5}$-competitive online Category-algorithm, using m bits of advice (and thus two categories).

The oracle determines the categories depending on whether a B-vertex would be matched by a run of Greedy. We believe that this type of advice is particularly interesting since it does not require the oracle to compute an optimal solution.

Our Results on Randomized Algorithms. Last, we consider randomized algorithms with limited access to random bits. The KVV-algorithm selects a permutation σ uniformly at random, and, since there are $m!$ potential permutations, $\log(m!) = \Theta(m \log m)$ random bits are required in order to obtain a uniform choice. We are interested in randomized algorithms that employ fewer random bits. We consider the class of randomized Category-algorithms, where the categories of the B-vertices are chosen uniformly at random. We show:

5. There is a randomized Category-algorithm using km random bits with approximation factor $1 - \left(\frac{2^k}{2^k+1}\right)^{2k}$, for any integer $k \geq 1$.

For $k = 1$, the competitive ratio evaluates to $5/9$. It approaches $1 - 1/e$ very quickly, for example, for $k = 10$ the absolute difference between the competitive ratio and $1 - 1/e$ is less than 0.0002. Our analysis is based on the analysis of the KVV algorithm by Birnbaum and Mathieu [5] and uses a result by Konrad et al. [25] concerning the performance of the Greedy algorithm on a randomly sampled subgraph which was originally developed in the context of streaming algorithms.

The results as described above are summarized in Table 1.

Models for Online Algorithms with Advice. The two main models for online computation with advice are the per-request model of Emek et at. [15] and the tape model of Böckenhauer et al. [7]. Both models were inspired by the original model proposed by Dobrev et al. [13]. In the model of Emek et at. [15], a bit string of a fixed length is received by the algorithm with

Table 1 Overview of our results, sorted with decreasing competitiveness.

Deterministic ratio	# of advice bits	Description and Authors
1	$\Theta(n \log n)$	(Miyazaki [29])
$1-\epsilon$	$\mathrm{O}(\frac{1}{\epsilon^5}n)$	Application of Eggert et al. [14] (here)

$1-\frac{1}{e}$	$\mathrm{O}(\log n)$	Exp. time Ranking-alg. (Böckenhauer et al. [9])
$\frac{3}{5}$	m	Category-algorithm using two categories (here)
$\frac{1}{2}+\epsilon$	$\Omega(\log\log\log n)$	LB holds for Ranking-algorithms (here)
Randomized ratio	**# of random bits**	**Description and Authors**
$1-\frac{1}{e}$	$m \log m$	KVV algorithm (Karp, Vazirani, Vazirani [24])
$1-\left(\frac{2^k}{2^k+1}\right)^{2k}$	km	Category-algorithm using 2^k categories (here)

each request for a total amount of advice that is at least linear in the size of the input. For this work, we use the tape model of Böckenhauer et al. [7], where the algorithm has access to an infinite advice string that it can access at any time (see Section 2 for a formal definition), allowing for advice that is sub-linear in the size of the input. Many online problems have been studied in the setting of online algorithms with advice (e.g. metrical task system [15], k-server problem [15, 9, 30, 20], paging [13, 7], bin packing problem [31, 11, 2], knapsack problem [8], reordering buffer management problem [1], list update problem [10], minimum spanning tree problem [4] and others). Interestingly, a variant of the algorithm with advice for list update problem of [10] was used to gain significant improvements in the compression rates for Burrows-Wheeler transform compression schemes [23]. The information-theoretic lower bound techniques for online algorithms with advice proposed by Emek et al. [15] applies to randomized algorithms and uses a reduction to a matching pennies game (essentially equivalent to the string guessing game). The reduction technique using the string guessing game of Böckenhauer et al. [6] is a refinement specifically for deterministic algorithms of the techniques of Emek et al.

Outline. Preliminaries are discussed in Section 2. Our $(1-\epsilon)$-competitive algorithm and a related advice lower bound are presented in Section 3. Then, in Section 4, we give the advice lower bound for $(\frac{1}{2}+\epsilon)$-competitive Ranking-algorithms. Last, in Section 5, we consider our randomized Category algorithm and our $\frac{3}{5}$-competitive advice Category algorithm.

2 Preliminaries

Unless stated otherwise, we consider a bipartite input graph $G=(A,B,E)$ with $A=[n]$ and $B=[m]$, for integers m,n such that $m=\Theta(n)$. The neighbourhood of a vertex v in graph G is denoted by $\Gamma_G(v)$. Let M be a matching in G. We denote the set of vertices matched in M by $V(M)$. For a vertex $v \in V(M)$, $M(v)$ denotes the vertex that is matched to v in M. Generally, we write M^* to denote a maximum matching, i.e., a matching of largest cardinality. For $A' \subseteq A, B' \subseteq B$, $opt(A',B')$ denotes the size of a maximum matching in $G[A' \cup B']$, the subgraph induced by $A' \cup B'$.

The Ranking Algorithm. Given permutations $\pi : [n] \to [n]$ and $\sigma : [m] \to [m]$, we write Ranking(G,π,σ) to denote the output matching of the Ranking algorithm when the A-vertices arrive in the order given by π, and the B-vertices are ranked according to σ. We may write Ranking(σ) to denote Ranking(G,π,σ) if π and G are clear from the context.

The Greedy Matching Algorithm. Greedy processes the edges of a graph in arbitrary order and inserts the current edge e into an initially empty matching M if $M \cup \{e\}$ is a matching. It computes a maximal matching which is of size at least $\frac{1}{2}|M^*|$.

Category Algorithms. For an integer k, let $c : [m] \to \{1, \dots, 2^k\}$ be an assignment of categories to the B-vertices. Then let $\sigma_c : [m] \to [m]$ be the unique permutation of the B-vertices such that for two vertices $b_1, b_2 \in B : \sigma_c(b_1) < \sigma_c(b_2)$ if and only if $c(b_1) < c(b_2)$ or $(c(b_1) = c(b_2)$ and $b_1 < b_2)$. The previous definition of σ_c is based on the natural ordering of the B-vertices. This gives a certain stability to the resulting permutation, since changing the category of a single vertex b does not affect the relative order of the vertices $B \setminus \{b\}$.

The Tape Advice Model. For a given request sequence I of length n for a maximization problem, an *online algorithm with advice* in the *tape advice model* computes the output sequence $\text{ALG}(I, \Phi) = \langle y_1, y_2, \dots, y_n \rangle$, where y_i is a function of the requests from 1 to i of I and the infinite binary advice string Φ. Algorithm ALG has an advice complexity of $b(n)$ if, for all n and any input sequence of length n, ALG reads no more than $b(n)$ bits from Φ.

3 Deterministic $(1 - \epsilon)$-competitive Advice Algorithms

3.1 Algorithm With $O(\frac{1}{\epsilon^5}n)$ Bits of Advice

The main idea of our online algorithm is the simulation of an augmenting-paths-based algorithm with the help of advice bits. We employ the deterministic algorithm of Eggert et al. [14] that has been designed for the data streaming model. It computes a $(1 - \epsilon)$-approximate matching, using $O(\frac{1}{\epsilon^5})$ passes over the edges of the input graph, where each pass i is used to compute a matching M_i in a subgraph $G_i = G[A_i \cup B_i]$, for some subsets $A_i \subseteq A$ and $B_i \subseteq B$, using the Greedy matching algorithm. In the first pass, M_1 is computed in G and thus constitutes a $\frac{1}{2}$-approximation. Let $M = M_1$. Then, $O(\frac{1}{\epsilon^2})$ phases follow, where in each phase, a set of disjoint augmenting paths is computed using $O(\frac{1}{\epsilon^3})$ applications of the Greedy matching algorithm (and thus $O(\frac{1}{\epsilon^3})$ passes per phase). At the end of a phase, M is augmented using the augmenting-paths found in this phase. Upon termination of the algorithm, M constitutes a $(1 - \epsilon)$-approximation (see [14] for the analysis).

The important property that allows us to translate this algorithm into an online algorithm with advice is the simple observation that the computed matching M is a subset of $\bigcup_i M_i$. For every i, we encode the vertices $A_i \subseteq A$ and $B_i \subseteq B$ that constitute the vertices of G_i using $n+m$ advice bits. Furthermore, for every vertex $a \in A$, we also encode the index $j(a)$ of the matching $M_{j(a)}$ that contains the edge that is incident to a in the final matching M (if a is not matched in M, then we set $j(a) = 0$). Last, using $O(\log n)$ bits, we encode the integers n and m, using a self-delimited encoding. Parameters n, m are required in order to determine the word size that allows the storage of the indices $j(a)$, and to determine the subgraphs G_i. The total number of advice bits is hence $O(\frac{1}{\epsilon^5}(n + m) + \log(\frac{1}{\epsilon^5})(m) + \log(n)) = O(\frac{1}{\epsilon^5}n)$.

After having read the advice bits, our online algorithm computes the $O(\frac{1}{\epsilon^5})$ Greedy matchings M_i simultaneously in the background while receiving the requests. Upon arrival of an $a \in A$, we match it to the $b \in B$ such that $ab \in M_{j(a)}$ incident to a if $j(a) \geq 1$, and we leave it unmatched if $j(a) = 0$. We thus obtain the following theorem:

▶ **Theorem 4.** *For every $\epsilon > 0$, there is a $(1 - \epsilon)$-competitive deterministic online algorithm for* MBM *that uses $O(\frac{1}{\epsilon^5}n)$ bits of advice.*

3.2 $\Omega(\log(\frac{1}{\epsilon})n)$ Advice Lower Bound

We complement the advice algorithm of the previous section with an $\Omega(\log(\frac{1}{\epsilon})n)$ advice lower bound for $(1-\epsilon)$-competitive deterministic advice algorithms. To show this, we make use of the lower bound techniques of [6] using the *string guessing game*, which is defined as follows.

▶ **Definition 5** (q-SGKH [6]). The *string guessing problem with known history* over an alphabet Σ of size $q \geq 2$ (q-SGKH) is an online minimization problem. The input consists of n and a request sequence $\sigma = r_1, \ldots, r_n$ of the characters, in order, of an n length string. An online algorithm A outputs a sequence $a_1, \ldots, a_n$ such that $a_i = f_i(n, r_1, \ldots, r_{i-1}) \in \Sigma$ for some computable function f_i. An important aspect of this problem is that the algorithm needs to produce its output character *before* the corresponding request: request r_i is revealed immediately after the algorithm outputs a_i. The cost of A is the Hamming distance between $a_1, \ldots, a_n$ and $r_1, \ldots, r_n$.

In [6], the following lower bound on the number of advice bits is shown for q-SGKH.

▶ **Theorem 6** ([6]). *Consider an input string of length n for q-SGKH. The minimum number of advice bits for any deterministic online algorithm that is correct for more than αn characters, for $\frac{1}{q} \leq \alpha < 1$, is $((1 - H_q(1-\alpha)) \log_2 q)n$, where $H_q(p) = p \log_q(q-1) - p \log_q p - (1-p) \log_q(1-p)$ is the q-ary entropy function.*

First, we define a sub-graph that is used in the construction of the lower bound sequence.

▶ **Definition 7.** A bipartite graph is *c-semi complete*, if it is isomorphic to $G = (A, B, E)$ with $A = \{a_1, \ldots, a_c\}, B = \{b_1, \ldots, b_c\}$, and $E = \{a_i, b_j : j \geq i\}$.

The following lemma presents the reduction from q-SGKH to MBM.

▶ **Lemma 8.** *For an integer $c \geq 3$, suppose that there is a deterministic ρ-competitive online algorithm for* MBM, *using bn bits of advice, where $1 - \frac{1}{c} + \frac{1}{c!} \leq \rho < 1$. Then, there exists a deterministic algorithm for $c!$-SGKH, using cbn bits of advice, that is correct for at least $(1-(1-\rho)c)n$ characters of the n-length string.*

Proof. Let ALG_{MAT} be a deterministic ρ-competitive online algorithm for MBM, using bn bits of advice, with $1 - \frac{1}{c} + \frac{1}{c!} \leq \rho$, for an integer $c \geq 3$. We will present an algorithm $\text{ALG}_{c!\text{-SGKH}}$ that, in an online manner, will generate a request sequence I_{MAT} based on its input, I (of length n), that can be processed by ALG_{MAT}. Further, the advice received by $\text{ALG}_{c!\text{-SGKH}}$ will be the advice that ALG_{MAT} requires for I_{MAT}. As shown below, the length of I_{MAT} is cn, hence $\text{ALG}_{c!\text{-SGKH}}$ requires cbn bits of advice. The solution produced by ALG_{MAT} on I_{MAT} will define the output produced by $\text{ALG}_{c!\text{-SGKH}}$.

Suppose first that the entire input sequence I is known in advance (we will argue later how to get around this assumption). Let Π be an enumeration of all the permutations of length c, and let $g : \Sigma \to \{1, \ldots, c!\}$ be a bijection between Σ, the alphabet of the $c!$-SGKH problem, and an index of a permutation in Π. The request sequence I_{MAT} has a length of cn, consisting of n distinct c-semi-complete graphs, where each graph is based on a request of I. That is, for each request r_i in I, we append c requests to I_{MAT} that correspond to the A-vertices of a c-semi-complete graph, where the indices of the B-vertices are permuted according to the permutation $\Pi[g(r_i)]$.

Since I is not known in advance, we must construct I_{MAT} in an online manner while predicting the requests r_j. For each request r_j, the procedure is as follows:

Let I_{MAT}^{j-1} be the $c(j-1)$-length prefix of I_{MAT}. Note that when predicting request r_j, requests $r_1, \ldots, r_{j-1}$ have already been revealed, and I_{MAT}^{j-1} can thus be constructed. The algorithm $\textsc{alg}_{c!\text{-}\textsc{sgkh}}$ simulates $\textsc{alg}_{\textsc{mat}}$ on $I^{j-1}_{\textsc{mat}}$ followed by another c-semi-complete graph $G_j = (A_j, B_j, E_j)$ such that, for $1 \le k \le c$, when vertex $a_k \in A_j$ is revealed, the B-vertices incident to a_k correspond exactly to the unmatched B-vertices of B_j in the current matching of $\textsc{alg}_{\textsc{mat}}$. By construction, $\textsc{alg}_{\textsc{mat}}$ computes a perfect matching in G_j. The computed perfect matching corresponds to a permutation π at some index z of Π, and algorithm $\textsc{alg}_{c!\text{-}\textsc{sgkh}}$ outputs $g^{-1}(z)$ as a prediction for r_j.

Consider a run of $\textsc{alg}_{\textsc{mat}}$ on $I_{\textsc{mat}}$. If $\textsc{alg}_{\textsc{mat}}$ computes a perfect matching on the jth semi-complete graph, then our algorithm predicted r_j correctly. Similarly, if this matching is not perfect, then our algorithm failed to predict r_j. Let ν be the total number of imperfect matchings, let $\textsc{alg}_{\textsc{mat}}(I_{\textsc{mat}})$ denote the matching computed by $\textsc{alg}_{\textsc{mat}}$ on $I_{\textsc{mat}}$, and let $\textsc{opt}(I_{\textsc{mat}})$ denote a perfect matching in the graph given by $I_{\textsc{mat}}$. Then:

$$|\textsc{alg}_{\textsc{mat}}(I_{\textsc{mat}})| \le |\textsc{opt}(I_{\textsc{mat}})| - \nu \iff \nu \le |\textsc{opt}(I_{\textsc{mat}})| - \rho \cdot |\textsc{opt}(I_{\textsc{mat}})| = (1-\rho)cn\,. \blacktriangleleft$$

We prove now the main lower bound result of this section.

▶ **Theorem 9.** *For an integer $c \ge 3$, any deterministic online algorithm with advice for* MBM *requires at least $\left(\frac{(1-H_q(1-\alpha))}{2}\log c\right) n$ bits of advice to be ρ-competitive for $1 - \frac{1}{c} + \frac{1}{c!} \le \rho < 1$, where H_q is the q-ary entropy function and $\alpha = 1-(1-\rho)c$.*

Proof. For $1 - \frac{1}{c} + \frac{1}{c!} \le \rho < 1$, let $\textsc{alg}_{\textsc{mat}}$ be a deterministic ρ-competitive online algorithm for MBM, using bn bits of advice. By Lemma 8, there exists an algorithm for $c!$-$\textsc{sgkh}$ that uses cbn bits of advice and is correct for at least αn characters of the n-length input string. The bounds on ρ and c imply $1/(c!) \le \alpha \le 1$. Thus, Theorem 6 implies $cbn \ge ((1-H_q(1-\alpha))\log(c!))n$ and, hence,

$$b \ge \frac{(1-H_q(1-\alpha))}{c}\log(c!) \ge \frac{(1-H_q(1-\alpha))}{2}\log c, \text{ as } c! \ge c^{c/2}. \qquad \blacktriangleleft$$

Setting $\varepsilon = 1/(2c) < 1/c - 1/(c!)$ for all $c \ge 3$, we get the following corollary. Note that, as ρ approaches 1 from below, α also approaches 1 from below and $H_q(1-\alpha)$ approaches 0.

▶ **Corollary 10.** *For any $0 < \varepsilon \le 1/6$, any $(1-\varepsilon)$-competitive deterministic online algorithm with advice for* MBM *requires $O(\log(\frac{1}{\epsilon})n)$ bits of advice.*

4 Advice Lower Bound for Ranking Algorithms

Let $\sigma_1, \ldots, \sigma_k : [n] \to [n]$ be rankings. We will show that there is a $2n$-vertex graph $G = (A, B, E)$ and an arrival order π such that $|\textsc{Ranking}(G, \pi, \sigma_i)| \le n(\frac{1}{2} + \epsilon) + o(n)$, for every σ_i and every constant $\epsilon > 0$, while G contains a perfect matching. Furthermore, the construction is such that $k \in \Omega(\log \log n)$.

The key property required for our lower bound is the fact that we can partition the set of B-vertices into disjoint subsets $B_1, \ldots, B_q$, each of large enough size, such that for every B_i with $B_i = \{b_1, \ldots, b_p\}$ and $b_1 < b_2 < \cdots < b_p$, the sequence $(\sigma_j(b_i))_i$ is monotonic, for every $1 \le j \le k$. In other words, the ranks of the nodes $b_1, \ldots, b_p$ appear in the rankings σ_i in either increasing or decreasing order. For each set B_i, we will construct a vertex-disjoint subgraph G_i on which $\textsc{Ranking}$ computes a matching that is close to a $\frac{1}{2}$-approximation. The subgraphs G_i are based on graph H_z that we define next.

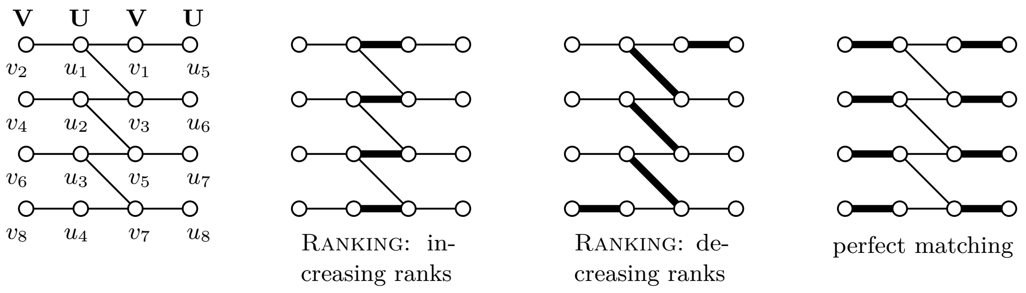

Figure 1 Left: U-vertices arrive in order $u_1, u_2, \ldots, u_8$. 'RANKING: increasing ranks' shows the resulting matching when $\sigma(v_1) < \sigma(v_2) < \cdots < \sigma(v_8)$. 'RANKING: decreasing ranks' shows the resulting matching when $\sigma(v_1) > \sigma(v_2) > \cdots > \sigma(v_8)$. Right: Perfect matching.

Construction of H_z. We construct now graph $H_z = (U, V, F)$ with $U = V = [z]$, for some even integer z, on which RANKING computes a matching that is close to a $\frac{1}{2}$-approximation, provided that the V vertices are ranked in either increasing or decreasing order.

Let $U = \{u_1, \ldots u_z\}$ be so that u_i arrives before u_{i+1} in π. Let $V = \{v_1, \ldots v_z\}$ be so that $v_i < v_{i+1}$ (which implies $v_i = i$). Then, for $1 \leq i \leq z/2$ we define $\Gamma_{H_z}(u_i) = \{v_{2i-1}, v_{2i}, v_{2i+1}\}$, and for $z/2 < i \leq z$ we define $\Gamma_{H_z}(u_i) = \{v_{2i-z-1}\}$. The graph H_8 is illustrated in Figure 1. It has the following properties:

1. If the sequence $(\sigma_i(b_j))_j$ is increasing, then $|\text{RANKING}(H_z, \pi, \sigma_i)| = z/2$.
2. If the sequence $(\sigma_i(b_j))_j$ is decreasing, then $|\text{RANKING}(H_z, \pi, \sigma_i)| = z/2 + 1$.
3. H_z has a perfect matching (of size z).

Lower Bound Proof. We prove first that we can appropriately partition the B-vertices that allow us to define the graphs G_i. Our prove relies on the well-known Erdős-Szekeres theorem [16] that we state in the form we need first.

▶ **Theorem 11** (Erdős-Szekeres [16]). *Every sequence of distinct integers of length n contains a monotonic (either increasing or decreasing) subsequence of length $\lceil \sqrt{n} \rceil$.*

▶ **Lemma 12.** *Let $\epsilon > 0$ be an arbitrary small constant. Then for any k permutations $\sigma_1, \ldots, \sigma_k : [n] \to [n]$ with $k \leq \log\log n - \log\log \frac{1}{\epsilon} - 2$, there is a partition of $B = [n]$ into subsets $C, B_1, B_2, \ldots$ such that:*

1. *$|B_i| \geq 1/\epsilon$ for every i,*
2. *$|C| \leq \sqrt{n}$,*
3. *For every $B_i = \{b_1, \ldots, b_p\}$ with $b_1 < b_2 < \cdots < b_p$, and every σ_j, the sequence $(\sigma_j(b_l))_l$ is monotonic.*

Proof. Let $S = B$. We iteratively remove subsets B_i from S until $|S| \leq \sqrt{n}$. The remaining elements then define set C. Thus, by construction, Item 2 is fulfilled.

Suppose that we have already defined sets $B_1, \ldots, B_i$. We show how to obtain set B_{i+1}. Let $S = B \setminus \bigcup_{j=1}^{i} B_j$ ($S = B$ if $i = 0$). Note that $|S| \geq \sqrt{n}$. By Theorem 11, there is a subset $B'_1 = \{b^1_1, \ldots, b^1_{\lceil n^{1/4} \rceil}\} \subseteq S$ with $b^1_1 < b^1_2 < \cdots < b^1_{\lceil n^{1/4} \rceil}$ such that the sequence $(\sigma_1(b_i))_{b_i \in B'_1}$ is monotonic. Then, again by Theorem 11, there is a subset $B'_2 = \{b^2_1, \ldots, b^2_{\lceil n^{1/8} \rceil}\} \subseteq B'_1$ with $b^2_1 < b^2_2 < \cdots < b^2_{\lceil n^{1/8} \rceil}$ such that the sequences $(\sigma_j(b_i))_{b_i \in B'_2}$ are monotonic, for every $j \in \{1, 2\}$. Similarly, we obtain that there is a subset $B'_w = \{b^w_1, \ldots, b^w_{\lceil n^{(1/2)^{w+1}} \rceil}\} \subseteq B'_{w-1}$ with $b^w_1 < b^w_2 < \cdots < b_{\lceil n^{(1/2)^{w+1}} \rceil}$ such that the sequences $(\sigma_j(b_i))_{b_i \in B'_w}$ are monotonic, for every $j \in \{1, \ldots, w\}$.

In order to guarantee Item 1, we solve the inequality $n^{(\frac{1}{2})^{w+1}} \geq \frac{1}{\epsilon}$ for w, and we obtain $w \leq \log\log n - \log\log\frac{1}{\epsilon} - 2$. This completes the proof. ◀

Equipped with the previous lemma, we are ready to prove our lower bound result.

▶ **Theorem 13.** *Let $\epsilon > 0$ be an arbitrary constant. For any k permutations $\sigma_1, \dots, \sigma_k : [n] \to [n]$ with $k \leq \log\log n - \log\log\frac{2}{\epsilon} - 2$ and arrival order $\pi : [n] \to [n]$, there is a graph $G = (A, B, E)$ such that for every σ_i:*

$$|\textsc{Ranking}(G, \pi, \sigma_i)| \leq (\frac{1}{2} + \epsilon)n + o(n),$$

while G contains a perfect matching.

Proof. Let $\epsilon' = \epsilon/2$. Let $G = (A, B, E)$ denote the hard instance graph. Let $C, B_1, B_2, \dots$ denote the partition of B according to Lemma 12 with respect to value ϵ'. Then, partition A into sets $A_0, A_1, \dots$ such that $|A_0| = |C|$ and for $i \geq 1$, $|A_i| = |B_i|$. Graph G is the disjoint union of subgraphs $G_0 = (A_0, C, E_0)$ and $G_i = (A_i, B_i, E_i)$, for $i \geq 1$. Subgraph G_0 is an arbitrary graph that contains a perfect matching. If $|B_i|$ is even, then G_i is an isomorphic copy of H_i. If $|B_i|$ is odd, then G_i is the disjoint union of an isomorphic copy of H_{i-1} and one edge. Then,

$$|\textsc{Ranking}(G, \pi, \sigma_i)| \leq \sum_{B_i}(|B_i|/2 + 2) + |C| \leq n/2 + 2\epsilon' n + \sqrt{n}.$$ ◀

5 Category Algorithms

5.1 Randomized Category Algorithm

In this section, we analyse the following randomized Ranking-algorithm:

Algorithm 1 Randomized Category Algorithm

```
Require: $G = (A, B, E)$, integer parameter $k \geq 1$
  For every $b \in B : c(b) \leftarrow$ random number in $\{1, 2, 3, \dots, 2^k\}$
  $\sigma_c \leftarrow$ permutation on $[m]$ such that $\sigma_c(b_1) < \sigma_c(b_2)$ iff $(c(b_1) < c(b_2))$ or $(c(b_1) = c(b_2)$
  and $b_1 < b_2)$, for every $b_1, b_2 \in B$
  return Ranking($\sigma_c$)
```

Considering Graphs with Perfect Matchings. First, similar to [5], we argue that the worst-case performance ratio of Algorithm 1 is obtained if the input graph contains a perfect matching. It requires the following observation:

▶ **Theorem 14** (Monotonicity [18, 24]). *Consider a fixed arrival order π and ranking σ for an input graph $G = (A, B, E)$. Let $H = G \setminus \{v\}$ for some vertex $v \in A \cup B$. Let π', σ' be the arrival order/ranking when restricted to vertices $A \cup B \setminus \{v\}$. Then,* Ranking(G, π, σ) *and* Ranking(H, π', σ') *are either identical or differ by a single alternating path starting at v.*

The previous theorem shows that the size of the matching produced by Algorithm 1 is monotonic with respect to vertex removals. Hence, if H is the graph obtained from G by removing all vertices that are not matched by a maximum matching in G, then the performance ratio of Ranking on H cannot be better than on G. We can thus assume that the input graph G has a perfect matching and $|A| = |B| = n$.

Analysis: General Idea. Let $B_i = \{b \in B : c(b) = i\}$, and denote the matching computed by the algorithm by M. The important quantities to consider for the analysis of Algorithm 1 are the probabilities:

$$x_i = \Pr_{b \in B} [b \in V(M) \mid b \in B_i],$$

i.e., the probability that a randomly chosen B-vertex of category i is matched by the algorithm. Determining lower bounds for the quantities x_i is enough in order to bound the expected matching size, since

$$\begin{aligned} \mathbb{E}|M| &= \sum_{b \in B} \Pr[b \in V(M)] = \sum_{b \in B} \sum_{i=1}^{2^k} \Pr[b \in B_i] \cdot \Pr[b \in V(M) \mid b \in B_i] \\ &= \frac{1}{2^k} \sum_{b \in B} \sum_{i=1}^{2^k} \Pr[b \in V(M) \mid b \in B_i] = \frac{n}{2^k} \sum_{i=1}^{2^k} x_i. \end{aligned} \tag{1}$$

We will first prove a bound on x_1 using a previous result of Konrad et al. [25]. Then, using similar ideas as Birnbaum and Mathieu [5], we will prove inequalities of the form $x_{i+1} \geq f(x_i, \ldots, x_1)$, for some function f which allow us to bound the probabilities $(x_i)_{i \geq 2}$.

Bounding x_1. Let $H = (U, V, F)$ be an arbitrary bipartite graph and let $U' \subseteq U$ be a uniform and random sample of U such that a node $u \in U$ is in U' with probability p. Konrad et al. showed in [25] that when running Greedy on the subgraph induced by vertices $U' \cup \Gamma_G(U')$, a relatively large fraction of the U'-vertices will be matched, for any order in which the edges of the input graph are processed that is independent of the choice of U'. More precisely, they prove the following theorem (Greedy(H', ω) denotes the output of Greedy on subgraph H' if edges of H' are considered in the order given by ω):

▶ **Theorem 15** ([25]). *Let $H = (U, V, F)$ be a bipartite graph, M^* a maximum matching, and let $U' \subseteq U$ be a uniform and independent random sample of U such that every vertex belongs to U' with probability p, $0 < p \leq 1$. Then for any edge arrival order ω,*

$$\mathbb{E}|\textsc{Greedy}(H[U' \cup \Gamma_H(U')], \omega)| \geq \frac{p}{1+p} |M^*|.$$

In Ranking, the vertices B_1 are always preferred over vertices $B \setminus B_1$. Thus, the matching $M_1 = \{ab \in M \mid b \in B_1\}$ is identical to the matching obtained when running Ranking on the subgraph induced by $A \cup B_1$. Since the previous theorem holds for any edge arrival order (that is independent from the choice of B'), we can apply the theorem (setting $B' = B_1, p = \frac{1}{2^k}$) and we obtain:

$$\mathbb{E}|B_1 \cap V(M)| \geq \frac{\frac{1}{2^k}}{1 + \frac{1}{2^k}} n = \frac{1}{2^k + 1} n.$$

Since $\mathbb{E}|B_1 \cap V(M)| = \sum_{b \in B} \Pr[b \in B_1] \cdot \Pr[b \in V(M) \mid b \in B_1] = \frac{n}{2^k} x_1$, we obtain $x_1 \geq 1 - \frac{1}{2^k+1}$.

Bounding $(x_i)_{i \geq 2}$. The key idea of the analysis of Birnbaum and Mathieu for the KVV-algorithm is the observation that, if a B-vertex of rank i is not matched by the algorithm, then its partner in an optimal matching is matched to a vertex of rank smaller than i.

Applied to our algorithm, if a B-vertex of category i is not matched, then its optimal partner $M^*(b)$ is matched to a B-vertex that belongs to a category $j \leq i$. Thus:

$$1 - x_i = \Pr_{b \in B}[b \notin V(M) \,|\, b \in B_i] = \\ \Pr_{b \in B}[b \notin V(M) \text{ and } M^*(b) \text{ matched in } M \text{ to a } b' \text{ with } c(b') \leq i \,|\, b \in B_i]\,. \quad (2)$$

The following lemma is similar to a clever argument by Birnbaum and Mathieu [5].

▶ **Lemma 16.**

$$\Pr_{b \in B}[b \notin V(M) \textit{ and } M^*(b) \textit{ matched in } M \textit{ to a } b' \textit{ with } c(b') \leq i \,|\, b \in B_i] \\ \leq \Pr_{b \in B}[M^*(b) \textit{ matched in } M \textit{ to a } b' \textit{ with } c(b') \leq i]\,. \quad (3)$$

Proof. Let c be uniformly distributed and let σ_c be the respective ranking. Pick now a random $\tilde{b} \in B$ and create new categories c' such that $c'(\tilde{b}) = i$ and for all $b \neq \tilde{b} : c'(b) = c(b)$. Let $\sigma_{c'}$ be the ranking given by c'.

Let $\tilde{a} = M^*(\tilde{b})$. Suppose that in a run of Ranking($\sigma_{c'}$), $\tilde{a}$ is matched to a vertex d' with $c'(d') \leq i$ and $\tilde{b}$ remains unmatched. Then, we will show that in the run of Ranking(σ_c), $\tilde{a}$ is matched to a vertex d with $c(d) \leq i$. This implies our result.

First, suppose that $\tilde{b}$ remains unmatched in Ranking(σ_c). Then, Ranking(σ_c) = Ranking($\sigma_{c'}$) and the claim is trivially true. Suppose now that $\tilde{b}$ is matched in Ranking(σ_c). Then, similar to the argument of [5], it can be seen that Ranking(σ_c) and Ranking($\sigma_{c'}$) differ only by one alternating path $b_0, a_1, b_1, a_2, b_2, \ldots$ starting at $b_0 = \tilde{b}$ such that for all i, (1) $a_{i+1}b_i \in$ Ranking(σ_c), (2) $a_i b_i \in$ Ranking($\sigma_{c'}$), and (3) $\sigma_c(b_i) > \sigma_c(b_{i+1})$. Property (3) implies $c(b_i) \leq c(b_{i+1})$. Thus if the category $\sigma_{c'}$ of the node that a_i is matched to in Ranking($\sigma_{c'}$) is k, then the category c of the node that a_i is matched to in Ranking(σ_c) is also at most k. ◀

The right side of Inequality 3 can be computed explicitly as follows:

$$\begin{aligned}\Pr_{b \in B}[M^*(b) \text{ matched in } M \text{ to a } b' \text{ with } c(b') \leq i] &= \Pr_{b \in B}[c(b) \leq i \text{ and } b \in V(M)] \\ &= \frac{1}{2^k} \sum_{j=1}^{i} x_j\,.\end{aligned}$$

This, together with Inequalities 2 and 3, yields $1 - x_i \leq \frac{1}{2^k} \sum_{j=1}^{i} x_j$. We obtain:

▶ **Theorem 17.** *Let $k \geq 1$ be an integer. Then Algorithm 1 is a randomized online algorithm for* MBM *with competitive ratio $1 - \left(\frac{2^k}{2^k+1}\right)^{2k}$ that uses $k \cdot m$ random bits.*

Proof. Following [5], the inequality $1 - x_i \leq \frac{1}{2^k} \sum_{j=1}^{i} x_j$ yields $S_i(1 + \frac{1}{2^k}) \geq 1 + S_{i-1}$, where $S_i = \sum_{j=1}^{i} x_i$ and $S_1 = x_1 \geq 1 - \frac{1}{2^k+1}$. According to Equality 1, we need to bound S_{2^k} from below. Quantity S_{2^k} is minimized if $S_i(1 + \frac{1}{2^k}) = 1 + S_{i-1}$, for all $i \geq 2$, which yields

$$S_i = \sum_{j=1}^{i} (1 - \frac{1}{2^k + 1})^j = 2^k \cdot \left(1 - \left(\frac{2^k}{2^k + 1}\right)^i\right)\,.$$

The result follows by plugging S_{2^k} into Equality 1. ◀

5.2 Advice Category Algorithm

Let $\sigma : [m] \to [m]$ be the identity function, and let $M = \text{Ranking}(\sigma)$. It is well-known that M might be as poor as a $\frac{1}{2}$-approximation. Intuitively, B-vertices that are not matched in M are ranked too high in σ and have therefore no chance of being matched. We therefore assign category 1 to B-vertices that are not matched in M, and category 2 to all other nodes, see Algorithm 2. We will prove that this strategy gives a $\frac{3}{5}$-approximation algorithm.

Algorithm 2 Category-Advice Algorithm

```
**Computation of advice bits**
$\sigma \leftarrow$ permutation such that $\sigma(b) = b$, $M_G \leftarrow \text{Ranking}(\sigma)$, $M^* \leftarrow$ maximum matching
$\forall b \in B : c(b) \leftarrow \begin{cases} 1, & \text{if } b \notin V(M), \\ 2, & \text{otherwise.} \end{cases}$
**Online Algorithm with Advice** {Function $c$ is provided using $m$ advice bits}
$\sigma_c \leftarrow$ permutation on $[m]$ such that $\sigma_c(b_1) < \sigma_c(b_2)$ iff $(c(b_1) < c(b_2))$ or $(c(b_1) = c(b_2)$ and $b_1 < b_2)$, for every $b_1, b_2 \in B$
**return** $\text{Ranking}(\sigma_c)$
```

Our analysis requires a property of Ranking that has been previously used, e.g., in [5].

▶ **Lemma 18** (Upgrading unmatched vertices, Lemma 4 of [5]). *Let σ be a ranking and let $M = \text{Ranking}(\sigma)$. Let $b \in B$ be a vertex that is not matched in M. Let σ' be the ranking obtained from σ by changing the rank of b to any rank that is smaller than $\sigma(b)$ (and shifting the ranks of other vertices accordingly), and let $M' = \text{Ranking}(\sigma')$. Then, every vertex $a \in A$ matched in M to a vertex $b \in B$ is matched in M' to a vertex $b' \in B$ with $\sigma(b') \leq \sigma(b)$.*

▶ **Theorem 19.** *Alg. 2 is a $\frac{3}{5}$-competitive online algorithm for* MBM *using m advice bits.*

Proof. Let M denote the matching computed by the algorithm. Let $A_2 \subseteq A$, $B_2 \subseteq B$ be the subsets of vertices that are matched in M_G. Further, let $A_1 = A \setminus A_2$ and $B_1 = B \setminus B_2$ (the vertices not matched in M_G). See Figure 2 for an illustration of these quantities.

Then, for $i \in \{1, 2\}$, let $B_i^* = B_i \cap V(M^*)$. Let $M_{ij} = \{ab \in M \mid a \in A_i \text{ and } b \in B_j\}$. Then, $M = M_{21} \cup M_{12} \cup M_{22}$ since $M_{11} = \varnothing$ (the input graph does not contain any edges between A_1 and B_1 since otherwise some of them would also be contained in M_G). This setting is illustrated in Figure 2 in the appendix. We will bound now the sizes of M_{21}, M_{12} and M_{22} separately:

- *Bounding* $|M_{21}|$. Since B_1-vertices are preferred over B_2-vertices in $\text{Ranking}(\sigma_c)$ and since there are no edges between A_1 and B_1, M_{21} is a maximal matching between A_2 and B_1. Since $opt(A_2, B_1) = |B_1^*|$, we have $|M_{21}| \geq \frac{1}{2}|B_1^*|$.
- *Bounding* $|M_{22}|$. By Lemma 18, all A_2-vertices are matched in M. Thus, $|M_{22}| = |A_2| - |M_{21}|$.

- *Bounding* $|M_{12}|$. The algorithm finds a maximal matching between A_1 and $B_2 \setminus B(M_{22})$. Since $opt(A_1, B_2) \geq |A_1^*|$, we have $opt(A_1, B_2 \setminus B(M_{22})) \geq |A_1^*| - |M_{22}|$, and thus $|M_{12}| \geq \frac{1}{2}(|A_1^*| - |M_{22}|)$.

We combine the previous bounds and we obtain:

$$|M| = |M_{21}| + |M_{22}| + |M_{12}| \geq |A_2| + \frac{1}{2}(|A_1^*| - |A_2| + |M_{21}|) \geq \frac{1}{2}(|A_1^*| + |A_2| + \frac{1}{2}|B_1^*|).$$

Next, note that $|A_2| \geq |B_1^*|$ and $|A_1^*| + |B_1^*| = |M^*|$. We thus obtain $|M| \geq \frac{1}{2}|M^*| + \frac{1}{4}|B_1^*|$. Since $|B_1^*| \geq |M^*| - |M_G|$, we obtain $|M| \geq \frac{3}{4}|M^*| - \frac{1}{4}|M_G|$. Furthermore, Lemma 18 implies $|M| \geq |M_G|$, and hence $|M| \geq \max\{|M_G|, \frac{3}{4}|M^*| - \frac{1}{4}|M_G|\}$ which is at least $\frac{3}{5}|M^*|$. ◀
