This puts a barrier on gate elimination proofs that do not use specific properties of the functions while analyzing how their circuits degrade after substitutions. Indeed, in most proofs it is usually the case (properties of the function are used for estimating *how many substitutions* can the function withstand).

However, there is one exception: in order to estimate the number of “bad” local situations on the top of a circuit computing the function, [11] uses the fact that the function is an affine disperser. While we believe that in this particular case it can be overcome, there may be new techniques exploiting the function properties. Thus the first open question is:

- *Show that interesting classes of functions contain functions resistant to gate elimination. For example, it would be interesting to show that the class of affine dispersers, or more generally every large enough class of functions, contains a series of functions resistant to gate elimination.*

Another possible direction is to extend the result to other possible complexity measures, because some syntactic measures can lack subadditivity (for example, composition can in principle introduce more “bad” local situations). One can imagine, for example, “local” measures that count specific small patterns in a circuit.

- *Extend the result to local complexity measures or another wide class.*

While the results of this paper capture all types of substitutions, another possible directions is:

- *Allow induction to descend to arbitrary varieties instead of the varieties described by substitutions (for example, allow restrictions of the form $xy = zt$).*

The situation might become much easier if we switch from arbitrary Boolean functions to n-bit linear maps $\{0,1\}^n \to \{0,1\}^n$. They have non-linear complexity in principle but, again, we do not have non-linear lower bounds for explicit functions. Can gate elimination prove non-linear bounds here? What if we restrict ourselves to linear operations in the circuit and linear substitutions? The gadgets used in this paper are non-linear and thus cannot help.

- *Extend the result to linear maps.*

We show that there exist functions such that after a constant number of substitutions the complexity of these functions decreases only by a constant. How far can it be strengthened w.r.t. the number of substitutions?

- *Does there exist a function f of nonlinear complexity such that after $m = \Omega(n)$ substitutions its circuit complexity drops by $O(m)$ gates only?*

Abstract

The fastest known algorithm for factoring univariate polynomials over finite fields is the Kedlaya-Umans [13] (fast modular composition) implementation of the Kaltofen-Shoup algorithm [12, § 2]. It is randomized and takes $\widetilde{O}(n^{3/2}\log q + n\log^2 q)$ time to factor polynomials of degree n over the finite field $\mathbb{F}_q$ with q elements. A significant open problem is if the 3/2 exponent can be improved. We study a collection of algebraic problems and establish a web of reductions between them. A consequence is that an algorithm for any one of these problems with exponent better than 3/2 would yield an algorithm for polynomial factorization with exponent better than 3/2.

1 Introduction

A recent trend in discrete algorithms has been to establish very efficient reductions between problems with polynomial time algorithms, with the intention of identifying barriers (conceptual or concrete) to improving the polynomial running time of the best known algorithms. A standard example is the problem 3-SUM, which seems to require essentially quadratic time, and which has been reduced to many other problems. More recently, the study of "fine-grained" complexity has broadened, with several connections established between central problems in discrete algorithms, and new conjectures beyond the 3-SUM conjecture entering the picture (see, e.g. [1, 2, 3, 17, 18, 22, 23, 24]).

In this paper we focus on a "barrier" in *algebraic* algorithms, that of improving the exponent 3/2 for univariate polynomial factorization and several other problems. Generally, algebraic problems have two relevant "size" parameters – n, and the field size q. It is typical for the dependence on q to be polylogarithmic (it is for all of the problems we consider), and so we focus on the exponent on n in this work. We find that exponent 3/2 seems to be a barrier for a number of problems. This points to a need to move beyond the so-called "baby steps giant steps" methodology which tends to give rise to the exponent 3/2 behavior.

* The authors were supported by NSF grant CCF 1423544 and a Simons Foundation Investigator grant.

The reductions in this paper can be seen as giving evidence that improving the 3/2 exponent may not be possible for these problems, but we believe that it "merely" gives evidence that this improvement requires a conceptual breakthrough (along the lines of going beyond the baby-steps giant-steps approach). Using the connections established in this paper, such a breakthrough for any one of the problems considered here would improve the exponent for all of them. In the discussion below, we use $\widetilde{O}$ to suppress $n^{o(1)}$ terms and $\log^{o(1)} q$ terms, in order to highlight the exponent on n that is our main object of study. We also use the phrase "nearly linear time reduction" to mean a reduction that runs in time $\widetilde{O}(n \log q)$, and the phrase "3/2 exponent reducible" to mean the weaker connection that shows that beating exponent 3/2 for one problem implies beating exponent 3/2 for the other.

1.1 Algebraic problems with 3/2 exponent algorithms

We investigate the complexity of factoring a univariate polynomial over a finite field into its irreducible factors. The problem formally stated is,

- FACTOR: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$ of degree n, write $f(x)$ as a product of its monic irreducible factors.*

The square free assumption is without loss of generality [14, 25]. FACTOR can be solved in randomized polynomial time [4] and there is an extensive line of research [5, 12, 21] leading to a randomized algorithm [13] with exponent 3/2. Surprisingly, even determining the *degree* of a single irreducible factor rapidly would be sufficient to improve the exponent of this algorithm. We formulate this problem as

- FACTOR DEGREE: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$, find the degree of an irreducible factor of $f(x)$.*

and prove in § 2 that FACTOR is 3/2-exponent reducible to FACTOR DEGREE. That is, an algorithm for FACTOR DEGREE with exponent less than 3/2 yields one for FACTOR. Observe that FACTOR DEGREE merely seeks one, not necessarily all, irreducible factor degrees. We next investigate two linear algebraic problems, both we will demonstrate to be nearly linear time reducible to FACTOR.

- FROBENIUS MIN-POLY: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$, compute the minimal polynomial of the Frobenius endomorphism on $\mathbb{F}_q[x]/(f(x))$ which takes $a(x) \mod f(x)$ to $a(x)^q \mod f(x)$.*
- CARLITZ CHAR-POLY: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$, compute the characteristic polynomial of the Carlitz endomorphism on $\mathbb{F}_q[x]/(f(x))$ which takes $a(x) \mod f(x)$ to $xa(x) + a(x)^q \mod f(x)$.*

In § 4, we prove that FACTOR DEGREE is nearly linear time reducible to CARLITZ CHAR-POLY, under certain restrictions on the characteristic of $\mathbb{F}_q$. These restrictions were removed in [15] by passing from Carlitz to Drinfeld modules. In § 3, through a novel recursive argument, we prove that FACTOR is 3/2-exponent reducible to FROBENIUS MIN-POLY.

FROBENIUS MIN-POLY was known [12, 11] to be nearly linear time reducible to

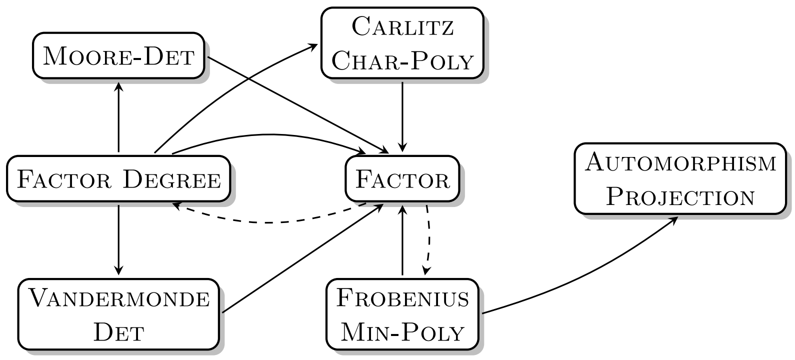
- AUTOMORPHISM PROJECTION: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$, $\alpha \in \mathbb{F}_q[x]/(f(x))$ and an $\mathbb{F}_q$-linear map $u : \mathbb{F}_q[x]/(f(x)) \longrightarrow \mathbb{F}_q$, compute $u(\alpha^{q^i}), \forall i \in \{1, 2, \dots, \deg(f)\}$.*

Thus, as a consequence of the reduction in § 3, we conclude that FACTOR is 3/2-exponent reducible to AUTOMORPHISM PROJECTION. This should be contrasted with the connection established in [12, 11]. They show that FACTOR is nearly linear time reducible to AUTOMORPHISM PROJECTION *assuming an $\mathbb{F}_q$-linear straight line program algorithm* for AUTOMORPHISM PROJECTION. This assumption allows them to use the "transpose" problem AUTOMORPHISM EVALUATION. Our reduction to AUTOMORPHISM PROJECTION is novel, direct, and holds without any assumptions.

The final two problems pertain to zero testing Moore and Vandermonde determinants.

- MOORE-DET: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$ and a positive integer m, decide if the determinant of the m by m square matrix with entries $m_{ij} := x^{jq^i} \mod f(x)$ is zero.*
- VANDERMONDE-DET: *Given a monic square free $f(x) \in \mathbb{F}_q[x]$ and a positive integer $b \leq \sqrt{\deg(f)}$, decide if the determinant of the Vandermonde matrix with first row $(x^{q^i} \mod f(x), i = 0, 1, 2, \ldots, b-1, b, 2b, 3b, \ldots, (b-1)b, b^2)$ is zero.*

In § 5, we prove that FACTOR DEGREE is nearly linear time reducible to each of these problems and that each of these problems is nearly linear time reducible to FACTOR. In summary, we have the following diagram where solid lines denote nearly linear time reductions and dotted lines denote 3/2-exponent reductions.



An interesting open question is if the dotted lines can be made solid. Except for AUTOMORPHISM PROJECTION, every listed problem has a known randomized algorithm with exponent 3/2. If the matrix multiplication exponent is 2, then a randomized algorithm for AUTOMORPHISM PROJECTION with exponent 3/2 is known. Another open problem is if this dependence on the matrix multiplication exponent can be removed – perhaps by reducing AUTOMORPHISM PROJECTION to one of the other problems in the figure. Regardless, an algorithm for any of the problems in the figure with exponent less that 3/2 would yield an algorithm with exponent 3/2 for FACTOR, and this is one of the main points of this paper.

2 Factorization and Finding a Factor Degree

Clearly, if one can solve the problem FACTOR in time $T(n, q)$ then one can solve the problem FACTOR DEGREE in time $T(n, q)$. In this section we show a reduction in the reverse direction, which leads to the surprising conclusion that one *only* needs to compute the *degree* of a single irreducible factor of the polynomial $f(x)$ with exponent better than 3/2 to be able to factor $f(x)$ completely with exponent better than 3/2.

▶ **Theorem 1.** *If there is an algorithm that solves* FACTOR DEGREE *in the time $T(n, q)$ where $T(n, q) = \Omega(n \log^2 q)$* [1]*, then there is an algorithm that solves* FACTOR *in time $\widetilde{O}(n \cdot T(n, q)^{1/3} \log^{4/3} q)$.*

Observe that when FACTOR DEGREE has an exponent 3/2 algorithm (as it does), this reduction recovers a 3/2 exponent algorithm for FACTOR. A sub-3/2 exponent algorithm for FACTOR DEGREE implies a sub-3/2 exponent algorithm for FACTOR, with a nearly-linear time algorithm yielding exponent 4/3 for FACTOR.

[1] The assumption $T(n, q) = \Omega(n \log^2 q)$ is without loss of generality. For otherwise we slow down an algorithm with runtime $T(n, q)$ until it is $\Omega(n \log^2 q)$.

Proof. We are given a monic, square-free polynomial $f(x) \in \mathbb{F}_q[x]$ of degree n. Let $g(x)$ be the product of irreducible factors of $f(x)$ with degrees at most t (for a parameter t to be chosen later). If $s(x)$ is defined as $s(x) = \prod_{i=1}^{t}(x^{q^i} - x)^{a_i}$, for some positive integers $a_1, a_2, \ldots, a_t$, then we have that $g(x) = \gcd(s(x), f(x))$. Using fast modular composition [13] and the method of Kaltofen-Shoup [12], we can compute $s(x) \bmod f(x)$ in time $\widetilde{O}(n\sqrt{t}\log^2 q)$ time. We then proceed to factor $g(x)$ completely, using the Kedlaya-Umans implementation of the Kaltofen-Shoup algorithm. The bottleneck in this algorithm is computing the splitting polynomials, which are all polynomials of the form of $s(x)$, with i ranging from 1 up to $t' \le t$. This portion of the algorithm runs in time $\widetilde{O}(n\sqrt{t}\log^2 q)$ and factors $g(x)$ completely.

Now we invoke the algorithm to solve FACTOR DEGREE, on input $f(x)/g(x)$. Upon finding the degree d of an irreducible factor, we compute $\gcd(x^{q^d} - x \bmod f(x), f(x))$ to split off the factors with that degree. We then repeat. The number of repetitions is bounded by n/t, since each irreducible factor of $f(x)/g(x)$ has degree at least t. Each repetition takes time $T(n,q) + \widetilde{O}(n\log^2 q)$. Thus this portion of the algorithm runs in time $\widetilde{O}(n/t\cdot(T(n,q)+n\log^2 q)) = \widetilde{O}(n/t\cdot T(n,q))$. Finally we factor completely using equal-degree factorization which takes $\widetilde{O}(n\log^2 q)$ time. Optimizing, we set $t = (T(n,q)/\log^2 q)^{2/3}$, and the overall running time becomes $\widetilde{O}(n \cdot T(n,q)^{1/3}\log^{4/3} q)$ for each of the two stages, and hence in total as well. ◀

3 Factoring and Minimal Polynomial of Frobenius

For a monic square free $f(x)$, let $g(\lambda) \in \mathbb{F}_q[\lambda]$ denote the minimal polynomial of the q^{th} power Frobenius endomorphism $\sigma : \mathbb{F}_q[x]/(f(x)) \to \mathbb{F}_q[x]/(f(x))$. That is, $g(\lambda)$ is the unique nonzero monic polynomial of least degree such that the endomorphism $g(\sigma)$ on $\mathbb{F}_q[x]/(f(x))$ is zero. The problem FROBENIUS MIN-POLY is to determine $g(\lambda)$ given $f(x)$. Since $g(\lambda)$ is the least common multiple of $\lambda^d - 1$ as d runs through the degrees of the irreducible factors of $f(x)$, FROBENIUS MIN-POLY is nearly linear time reducible to FACTOR. In this section, we conversely prove that FACTOR is 3/2-exponent reducible to FROBENIUS MIN-POLY.

Let `FrobMinPoly` be an oracle that solves FROBENIUS MIN-POLY. We present an algorithm `Factor` that invokes `FrobMinPoly` and solves FACTOR. For $k \in \mathbb{N}^+$, denote by Φ_k the kth cyclotomic polynomial over $\mathbb{F}_q$. Write $\phi(\cdot)$ for the Euler totient function.

Algorithm 1 `Factor`$(f(x))$

```
Input: Monic square free polynomial $f(x) \in \mathbb{F}_q[x]$ of degree $n$.
Output: Monic irreducible factors of $f(x)$.
Oracle: FrobMinPoly
1: Using [13], output and remove all monic irreducible factors of $f(x)$ of degree at most
   $n^{2/3}$. If at most one irreducible factor of degree greater than $n^{2/3}$ remains, output and
   exit.
2: $g(\lambda) \leftarrow$ FrobMinPoly$(f(x))$.
3: Perform square free factorization on $g(\lambda)$, and then run Factor recursively on the outputs
   to obtain the list of monic irreducible factors $g_1(\lambda), \ldots, g_m(\lambda)$ of $g(\lambda)$.
4: Run FindT$(g_1(\lambda), \ldots, g_m(\lambda))$ computing the set $T := \{k : p \nmid k \text{ and } \Phi_k(\lambda) | g(\lambda)\}$ as well
   as $m_k$, the multiplicity of $\Phi_k(\lambda)$ in $g(\lambda)$, for each $k \in T$.
5: Compute $S := \{kp^e : k \in T, 0 \le e \le \log_p m_k\}$.
6: for each $s \in S$ greater than $n^{2/3}$, set $f_s(x) \leftarrow \gcd(f(x), x^{q^s} - x \bmod f(x))$, $f(x) \leftarrow$
   $f(x)/f_s(x)$ and perform equal-degree factorization on $f_s(x)$.
```

The algorithm begins by extracting all monic irreducible factors of degree at most $n^{2/3}$. After Line 1, $f(x)$ only has large (at least $n^{2/3}$) degree factors. Suppose $d_1, d_2, \ldots, d_m$ are the degrees of the (remaining) monic irreducible factors of $f(x)$. Then the minimal polynomial $g(\lambda) \in \mathbb{F}_q[\lambda]$ of the Frobenius acting on $\mathbb{F}_q[x]/(f(x))$ is

$$g(\lambda) = \operatorname{lcm}\left(\lambda^{d_1} - 1, \ldots, \lambda^{d_m} - 1\right).$$

In particular, the cyclotomic polynomials $\Phi_{d_1}(\lambda), \ldots, \Phi_{d_m}(\lambda)$ divide $g(\lambda)$ and the factorization of $g(\lambda)$ contains information about $d_1, d_2, \ldots, d_m$. We devise a novel procedure to infer $d_1, d_2, \ldots, d_m$ efficiently.

On Line 2, $g(\lambda)$ is computed by invoking `FrobMinPoly`. To infer $d_1, d_2, \ldots, d_m$, we seek the factorization of $g(\lambda)$. To this end, a key idea is to factor $g(\lambda)$ recursively on Line 3 and obtain a list $g_1(\lambda), g_2(\lambda), \ldots, g_m(\lambda)$ of its monic irreducible factors. Since $f(x)$ is not irreducible at this point, $g(\lambda)$ has degree strictly less than $f(x)$ and the algorithm runs to completion.

Then we use a procedure `FindT`$(g_1(\lambda), \ldots, g_m(\lambda))$ to compute the set T and integers m_k as defined on Line 4. This step is the most technical part of the algorithm, and we defer its description and analysis to the next subsection, where we prove the following theorem:

▶ **Theorem 2.** `FindT`$(g_1(\lambda), \ldots, g_m(\lambda))$ *can be implemented to run in* $\widetilde{O}(n \log q)$ *time.*

Once T is known, to compute S on Line 5 is straightforward. The following lemma shows that S indeed contains $d_1, d_2, \ldots, d_m$.

▶ **Lemma 3.** $d_1, d_2, \ldots, d_m \in S$.

Proof. Consider an arbitrary $d \in \{d_1, d_2, \ldots, d_m\}$ and write it as $d = kp^e$ with $p \nmid k$. By definition $(\lambda^d - 1) | g(\lambda)$. Since $\lambda^d - 1 = (\lambda^k - 1)^{p^e}$ and $\lambda^k - 1 = \prod_{k_0 | k} \Phi_{k_0}(\lambda)$, $\Phi_k(\lambda)$ is a factor of $g(\lambda)$ with multiplicity at least p^e. So $k \in T$ and $m_k \geq p^e$, implying $d = kp^e \in S$. ◀

To conclude, by Line 6, all the irreducible factors of $f(x)$ are indeed output.

▶ **Theorem 4.** *Suppose the oracle* `FrobMinPoly` *runs in time* $T(n, q)$ *which is monotone in* n *and* q*. Then* `Factor` *factors a degree-*n *polynomial in* $\widetilde{O}(T(n, q) + n^{4/3} \log^2 q)$ *time.*

Proof. We first analyze the running time of each step except the recursive call. Line 1 can be implemented in $\widetilde{O}(n^{4/3} \log^2 q)$ time using the baby-step-giant-step strategy [12, 13]. The oracle `FrobMinPoly` on Line 2 runs in time $T(n, q)$. The set T on Line 4 could be found in time $\widetilde{O}(n \log q)$ by Theorem 2. Since $\prod_{k \in T} \Phi_k(\lambda)^{m_k}$ divides $g(\lambda)$, we have $\sum_{k \in T} m_k \phi(k) \leq \deg(g(\lambda)) \leq n$. Hence $|T| \leq n$ and $m_k \leq n$ for all $k \in T$, implying S on Line 5 could be computed in time $\widetilde{O}(n)$. Further,

$$\sum_{s \in S} s \leq \sum_{k \in T, 0 \leq e \leq \log_p m_k} kp^e \leq \log n \sum_{k \in T} k m_k \leq O(\log \log n) \cdot \log n \sum_{k \in T} m_k \phi(k) = \widetilde{O}(n)$$

where we use $k/\phi(k) = O(\log \log k)$ [19] and $\sum_{k \in T} m_k \phi(k) \leq n$. Hence the number of $s \in S$ greater than $n^{2/3}$ is at most $(\sum_{s \in S} s)/n^{2/3} = \widetilde{O}(n^{1/3})$. For each $s \in S$, Computing $f_s(x)$ takes $\widetilde{O}(n \log^2 q)$ time for each $s \in S$ [13] and hence $\widetilde{O}(n^{4/3} \log^2 q)$ time in total. Equal degree factorization on Line 6 takes $\widetilde{O}(n \log^2 q)$ time in total.

Let $d_{\max}(f(x))$ denote the maximal degree of the irreducible factors of $f(x)$. We claim that $d_{\max}(f(x))$ shrinks by at least a factor of two every two recursive calls. It implies that the recursive tree has depth no more than $O(\log n)$, so the total running time is bounded by $O(\log n) \cdot (T(n, q) + \widetilde{O}(n^{4/3} \log^2 q)) = \widetilde{O}(T(n, q) + n^{4/3} \log^2 q)$, as desired.

Consider an irreducible factor $g_0(\lambda)$ of $g(\lambda)$. We know $g_0(\lambda)$ divides $\lambda^k - 1 = \prod_{k_0|k} \Phi_{k_0}(\lambda)$ for a positive integer k corresponding to some degree k irreducible factor $f_0(x)$ of $f(x)$. If $g_0(\lambda)$ divides $\Phi_{k_0}(\lambda)$ for some proper divisor k_0 of k, we have $\deg(g_0(\lambda)) \le \phi(k_0) \le k_0 \le k/2$. Likewise, if $g_0(\lambda)$ is a proper irreducible factor of $\Phi_k(\lambda)$, we have $\deg(g_0(\lambda)) \le \phi(k)/2 \le k/2$ as well. So assume $g_0(\lambda) = \Phi_k(\lambda)$. Suppose $k = \prod_\ell \ell^{e_\ell}$, ℓ running over prime divisors of k. Then $\phi(k) = \prod_\ell (\ell - 1)\ell^{e_\ell - 1}$. If k is even, we have $e_2 \ge 1$ implying $\deg(g_0(\lambda)) = \phi(k) \le k/2$ (since for $\ell = 2$, $(\ell - 1)\ell^{e_\ell - 1} = \ell^{e_\ell}/2$). If k is odd, $\deg(g_0(\lambda)) = \phi(k) = \prod_\ell (\ell - 1)\ell^{e_\ell - 1}$ is even. The argument above applied to $g_0(\lambda)$ and $g(\lambda)$ in place of $f_0(x)$ and $f(x)$ shows that the degree shrinks by at least a factor of two in the next recursive call. The claim follows. ◀

▶ Remark. One may easily check that the same algorithm and analysis also work if the polynomial $g(\lambda)$ computed by the oracle is the *characteristic polynomial* of the Frobenius endomorphism instead of the minimal polynomial. The only difference is that $g(\lambda)$ is the product of $\lambda^{d_1} - 1, \ldots, \lambda^{d_m} - 1$ rather than their lcm.

3.1 Computing the Set T

We next devise a nearly linear time procedure to implement `FindT`. It relies on solutions to the following two problems: (1) finding all irreducible factors of $\Phi_k(\lambda)$ over $\mathbb{F}_q$ from a single irreducible factor $g_0(\lambda)$ and (2) finding the corresponding integer k. We deal with these two problems individually before describing `FindT`.

3.1.1 Finding the irreducible factors of $\Phi_k(\lambda)$

Let $k \in [1, n]$ be an integer coprime to p. Our goal is to find all the irreducible factors of $\Phi_k(\lambda)$ over $\mathbb{F}_q$ from a single irreducible factor $g_0(\lambda)|\Phi_k(\lambda)$. To achieve it, we need to know how $\Phi_k(\lambda)$ factorizes over $\mathbb{F}_q$.

3.1.1.1 Factorization of $\Phi_k(\lambda)$ over $\mathbb{F}_q$.

As k is coprime to p, there are $\phi(k)$ distinct primitive kth roots of unity in $\overline{\mathbb{F}}_q$ which are exactly the roots of $\Phi_k(\lambda)$. Denote this set of roots by μ_k. Let G be the abelian group $(\mathbb{Z}/k\mathbb{Z})^\times$ of order $\phi(k)$. For $d \in \mathbb{Z}$, we write $\bar{d}$ for the image of d in $\mathbb{Z}/k\mathbb{Z}$. The group G acts on μ_k such that $\bar{d} \in G$ sends any $\theta \in \mu_k$ to θ^d. This is a regular action, meaning that for fixed $\theta \in \mu_k$, the map $\bar{d} \mapsto \theta^d$ is a bijection between G and μ_k. As p is coprime to k, we have $\bar{q} \in G$. Let $G_0 = \langle \bar{q} \rangle \subseteq G$ and $s = [G : G_0]$. Restrict the G-action on μ_k to a G_0-action. Then μ_k is partitioned into s distinct G_0-orbits represented by $\theta_1, \ldots, \theta_s \in \mu_k$. It is well-known that the factorization of $\Phi_k(\lambda)$ over $\mathbb{F}_q$ is then determined in the following way:

▶ **Lemma 5.** *Under the notations above, $\Phi_k(\lambda)$ has s irreducible factors $g_1(\lambda), \ldots, g_s(\lambda)$ over $\mathbb{F}_q$ corresponding to the G_0-orbits $G_0\theta_1, \ldots, G_0\theta_s$ of μ_k in the sense that the set of roots of $g_i(\lambda)$ is exactly $G_0\theta_i$.*

Proof. Let $g(\lambda)$ be an irreducible factor of $\Phi_k(\lambda)$ over $\mathbb{F}_q$ and $\theta \in \mu_k$ be a root of $g(\lambda)$. Then $\mathbb{F}_q[\theta]$ is Galois over $\mathbb{F}_q$ with the Galois group generated by the Frobenius map $a \mapsto a^q$. So $a \in \mathbb{F}_q[\theta]$ is a root of $g(\lambda)$ if and only if a^q is a root of $g(\lambda)$. Therefore $G_0\theta$ is the set of roots of $g(\lambda)$ and the lemma follows. ◀

From now on we fix a root $\theta \in \mu_k$ of the given irreducible factor g_0 of Φ_k. For any subgroup $H \subseteq G$ containing G_0, the G-action on μ_k restricts to an H-action. The H-orbit $H\theta$ is partitioned into a disjoint union of G_0-orbits and hence corresponds to a subset L of irreducible factors of $\Phi_k(\lambda)$ by Lemma 5. Note that L also determines H: $h \in G$ lies in H if and only if the minimal polynomial of $h\theta$ over $\mathbb{F}_q$ is in L. We say L is *associated with* the subgroup H.

We need an auxiliary procedure `FindOrder`(ℓ, L) to find the order of $H\bar{\ell}$ in G/H.

▶ **Lemma 6.** *There exists a procedure* `FindOrder`(ℓ, L) *that takes an integer ℓ and the set L associated with H, and returns the following result: if $\bar{\ell} \in G = (\mathbb{Z}/k\mathbb{Z})^\times$, it returns the order of $H\bar{\ell}$ in G/H, i.e. the smallest $e > 1$ for which $\bar{\ell}^e \in H$. Otherwise it returns zero. Moreover* `FindOrder`(ℓ, L) *could be implemented in time $\widetilde{O}(\phi(k)\log q)$.*

See the full version of this paper [10] for the proof of Lemma 6 and the description of `FindOrder`(ℓ, L).

We use a randomized procedure `FindCyclotomic`$(g_0(\lambda), n)$ to find all irreducible factors of $\Phi_k(\lambda)$ over $\mathbb{F}_q$. Here $g_0(\lambda)$ is one irreducible factor of $\Phi_k(\lambda)$ and n is the degree of the polynomial $f(x)$.[2]

Algorithm 2 `FindCyclotomic`$(g_0(\lambda), n)$

Input: Irreducible factor $g_0(\lambda)$ of $\Phi_k(\lambda)$ over $\mathbb{F}_q$ and degree n of $f(x)$
Output: The list of irreducible factors of $\Phi_k(\lambda)$ over $\mathbb{F}_q$

```
1: $L \leftarrow \{g_0(\lambda)\}$
2: for $t$ from 1 to $N = \lfloor c \log n \log\log n \rfloor$ do        ▷ $c > 0$ is a large enough constant
3:     Pick an integer $\ell \in [1, n]$ at random
4:     $e \leftarrow$ FindOrder$(\ell, L)$
5:     for each $h(\lambda) \in L$ do
6:         $r_0 \leftarrow \lambda \bmod h(\lambda) \in \mathbb{F}_q[\lambda]/(h(\lambda))$, $r_i \leftarrow r_{i-1}^{\ell}$ for $i = 1, \ldots, e-1$
7:         Let $f_i(\lambda)$ be the minimal polynomial of $r_i$ over $\mathbb{F}_q$ for $i = 1, \ldots, e-1$
8:         Add $f_1(\lambda), \ldots, f_{e-1}(\lambda)$ to $L$
9:     end for
10: end for
11: return $L$
```

The procedure `FindCyclotomic`$(g_0(\lambda), n)$ maintains a subset L of irreducible factors of $\Phi_k(\lambda)$ associated with some subgroup of G containing G_0. Initially $L = \{g_0(\lambda)\}$, associated with $H_0 := G_0$. We claim:

▶ **Lemma 7.** *Suppose L is associated with H_{i-1} at the beginning ith execution of the outer loop of* `FindCyclotomic`$(g_0(\lambda), n)$*. Then at the end of the ith execution, the set L is associated with a subgroup $H_i \supseteq H_{i-1}$. Moreover, $H_i = H_{i-1}$ if $\bar{\ell} \notin G$ in the ith execution of the outer loop. Otherwise $H_i = H_{i-1}\langle\bar{\ell}\rangle$.*

Proof. If $\ell \notin G$ in the ith execution of the outer loop, then e is set to zero by Lemma 6 and the claim is trivial. So assume $\ell \in G$ and let $H = H_{i-1}\langle\bar{\ell}\rangle$. Then e is the order of $H_{i-1}\bar{\ell}$ in H/H_{i-1} by Lemma 6, or $[H : H_{i-1}]$. Suppose the irreducible factors in L at the beginning of the ith execution correspond to distinct G_0-orbits $G_0\theta_1, \ldots, G_0\theta_m$ whose union is the H_{i-1}-orbit $H_{i-1}\theta$, $m = [H_{i-1} : G_0]$. The inner loop enumerates $G_0\theta_j$, and for each of them, adds the irreducible factor corresponding to $G_0\theta_j^{\ell^s}$ to L, $s = 1, \ldots, e-1$. Note that the union of these G_0-orbits $G_0\theta_j^{\ell^s} = G_0\bar{\ell}^s\theta_j = \bar{\ell}^s G_0\theta_j$ where $1 \le j \le m$, $0 \le s \le e-1$ equals

[2] The argument n is only used on Line 2 and 3 to control the number of repetitions and the range of ℓ, which is related to the error probability.

the union of H_{i-1}-orbits $\bar{\ell}^s H_{i-1}\theta_j$, which equals the H-orbit $H\theta$. And these G_0-orbits are all distinct since the number of them is $me = [H : G_0]$. So L is associated with H at the end of the ith execution of the outer loop. ◀

▶ **Lemma 8.** *The procedure* `FindCyclotomic`$(g_0(\lambda), n)$ *returns a set* L *associated with* $H_N \subseteq G$*. And* $H_N = G$ *with probability* $1 - \mathrm{poly}(n)$ *in which case* L *contains all irreducible factors of* $\Phi_k(\lambda)$ *over* $\mathbb{F}_q$*. Moreover* `FindCyclotomic`$(g_0(\lambda), n)$ *could be implemented in time* $\widetilde{O}(\phi(k) \log q)$*.*

Proof. We want to show $H_N = G$ with probability $1 - \mathrm{poly}(n)$. By Lemma 6 and Lemma 7, it is equivalent to showing the set of $\bar{\ell} \in G$ generates G. Identify G with a product of at most $\log |G| \leq \log n$ primary cyclic groups C_i whose orders are coprime to each other. We only need to show the the set of holomorphic images of $\bar{\ell} \in G$ generates C_i for each i with probability $1 - \mathrm{poly}(n)$ and then apply the union bound.

So fix one such C_i and let $m = |C_i|$. Then $\phi(m)$ out of the m elements in C_i are generators of C_i. Let α be the probability that the holomorphic image of $\bar{\ell}$ is among these $\phi(m)$ elements, where ℓ is randomly sampled from $[1, n]$ as on Line 3. As m is a prime power, we have $\phi(m) \geq m/2$. Therefore

$$\alpha \geq \frac{\lfloor n/k \rfloor}{n} \cdot \frac{\phi(m)}{m} \cdot |G| = \Omega(\phi(k)/k) = \Omega(1/\log\log k)$$

where we use $k/\phi(k) = O(\log\log k)$ [19]. So for sufficiently large $N = \lfloor c \log n \log\log n \rfloor$, the claim holds with probability $1 - \mathrm{poly}(n)$.

Then we analyze the running time: Line 4 runs in time $\widetilde{O}(\phi(k) \log q)$ by Lemma 6. Line 7 could be implemented in time $\widetilde{O}(|G_0| \log q)$ [13, 20]. And Line 3–9 runs in time $|L| \cdot \max\{e, 1\} \cdot \widetilde{O}(|G_0| \log q)$. This is bounded by $\widetilde{O}(\phi(k) \log q)$ since $|L| = [H_{i-1} : G_0]$, $\max\{e, 1\} = [H_i : H_{i-1}]$, and $|G| = \phi(k)$. As $N = \Theta(\log n \log\log n)$, the total running time is bounded by $\widetilde{O}(\phi(k) \log q)$. ◀

3.1.2 Finding the integer k

Another problem we need to solve is finding the integer k given an irreducible factor $g_0(\lambda)$ of $\Phi_k(\lambda)$ over $\mathbb{F}_q$. Using the procedure `FindCyclotomic`$(g_0(\lambda))$, we could find all the irreducible factors of $\Phi_k(\lambda)$ and hence $\Phi_k(\lambda)$ itself. The degree $d := \deg(\Phi_k(\lambda)) = \phi(k)$ is hence also known. If $|\phi^{-1}(d)|$ is small, we could find k by enumerating $k_0 \in \phi^{-1}(d)$ and checking if $\Phi_{k_0}(\lambda) = \Phi_k(\lambda)$. However, Erdős [9] showed that for some constant $c > 0$, there are infinitely many integers d for which $|\phi^{-1}(d)| \geq d^c$. So this approach is not affordable in general. Based on more sophisticated ideas, we show that it is possible to find k efficiently:

▶ **Lemma 9.** *There exists a procedure* `Findk`$(d, g_0(\lambda))$ *that takes an integer* $d > 0$ *dividing* $\phi(k)$ *and an irreducible factor* $g_0(\lambda)$ *of* $\Phi_k(\lambda)$*, and returns a positive integer* $k_0 | k$ *in time* $\widetilde{O}(\phi(k) \log q)$*. Moreover* $k_0 = k$ *if* $d = \phi(k)$*.*

See the full version of this paper [10] for the proof of Lemma 9 and the description of `Findk`$(d, g_0(\lambda))$.

3.1.3 Finding the set T

Now we are ready to describe the procedure `FindT`$(g_1(\lambda), \ldots, g_m(\lambda))$:

Algorithm 3 `FindT`$(g_1(\lambda), \ldots, g_m(\lambda))$

Input: The irreducible factors $g_1(\lambda), \ldots, g_m(\lambda)$ of $g(\lambda)$ over $\mathbb{F}_q$
Output: The set T and multiplicities m_k for each $k \in T$

```
1:  $L_0 \leftarrow \{g_1(\lambda), \ldots, g_m(\lambda)\}$ as a multi-set and $T \leftarrow \emptyset$
2:  repeat
3:      Pick an arbitrary element $g_0(\lambda) \in L_0$
4:      $L \leftarrow$ FindCyclotomic$(g_0(\lambda))$
5:      $h(\lambda) \leftarrow \prod_{f_i(\lambda) \in L} f_i(\lambda)$, $d \leftarrow \deg(h(\lambda))$
6:      $k_0 \leftarrow$ Findk$(d, g_0)$
7:      if $h(\lambda) | \lambda^{k_0} - 1$ then
8:          if $k_0 \notin T$ then $m_{k_0} \leftarrow 0$
9:          $T \leftarrow T \cup \{k_0\}$, $m_{k_0} \leftarrow m_{k_0} + 1$
10:         $L_0 \leftarrow L_0 - L$
11:     end if
12: until $L_0 = \emptyset$
13: return $T$
```

▶ **Theorem 10** (Theorem 2 restated). `FindT`$(g_1(\lambda), \ldots, g_m(\lambda))$ *computes the set* T *and multiplicities* m_k *as defined in Algorithm 1, Line* 4*. Moreover it halts in time* $\widetilde{O}(n \log q)$ *with probability* $1 - 1/\mathrm{poly}(n)$.

Proof. The algorithm picks $g_0(\lambda)$ from L_0, calls `FindCyclotomic` to find a list $L \subseteq L_0$ that almost surely contains all the irreducible factors of $\Phi_k(\lambda)$, and remove these factors from L_0. It repeats these steps until L_0 is empty. Each time it also determines the integer k using `Findk`, adds it to T and updates m_k.

Note that with small probability, the list L returned by `FindCyclotomic` may not contain all the irreducible factors, in which case it is associated with a proper subgroup $H_N \subseteq G$ (c.f. Lemma 8). In any case we have $\deg(h(\lambda))|\phi(k)$ and therefore by Lemma 9, the integer k_0 returned by `Findk` divides k. We verify that $k = k_0$ on Line 7: $h(\lambda)|(\lambda^{k_0} - 1)$ if and only if $k|k_0$ if and only if $k = k_0$ since we know $k_0|k$. And if we find $k \neq k_0$ we do nothing in that round. The correctness of the algorithm is then straightforward.

For the running time, note that each round runs in time $\widetilde{O}(\phi(k) \log q)$ by Lemma 8 and Lemma 9, and then factors of total degree $\phi(k)$ are removed from L_0 with probability $1 - 1/\mathrm{poly}(n)$. So with probability $1 - 1/\mathrm{poly}(n)$, the total running time is bounded by $\sum_{i=1}^{m} \widetilde{O}(\deg(g_i(\lambda)) \log q) = \widetilde{O}(n \log q)$. ◀

4 Polynomial Factorization Using Carlitz Modules

We next establish connections between polynomial factorization and the Carlitz action. We prove two nearly linear reductions, namely Factor Degree to Carlitz Char-Poly and Carlitz Char-Poly to Factor. The former reduction requires that the characteristic p of $\mathbb{F}_q$ is larger than the number of irreducible factors.

4.1 Carlitz Modules

Let A be an $\mathbb{F}_q[x]$-algebra. For $f(x) \in \mathbb{F}_q[x]$ and $\alpha \in A$, $f(x)\alpha$ is understood to be the result of the $\mathbb{F}_q[x]$ action of $f(x)$ on α in A. Let $\sigma : A \longrightarrow A$ and $\tau : A \longrightarrow A$ denote the q^{th} power Frobenius endomorphism and the multiplication by x endomorphism respectively. That is,

$\forall \alpha \in A$, $\sigma(\alpha) = \alpha^q$ and $\tau(\alpha) = x\alpha$. In [6, 7], Carlitz endowed a new $\mathbb{F}_q[x]$-module structure on A by defining $m(x) = \sum_i m_i x^i \in \mathbb{F}_q[x]$ to act on $\alpha \in A$ as

$$\rho_m(\alpha) := (m(\sigma+\tau))(\alpha) = \left(\sum_i m_i(\sigma+\tau)^i\right)(\alpha).$$

In particular, $\forall \alpha \in A$, $\rho_x(\alpha) = \alpha^q + x\alpha$ and $\forall u \in \mathbb{F}_q$, $\rho_u(\alpha) = u\alpha$. Let $\rho(A)$ denote the $\mathbb{F}_q[x]$-module structure thus endowed to A by the Carlitz action. To factor a monic square free polynomial $f(x)$, we will concern ourselves with $\rho(\mathbb{F}_q[x]/(f(x)))$. Let $\chi_f(x) \in \mathbb{F}_q[x]$ denote the characteristic polynomial of the $\mathbb{F}_q$ linear transformation on $\mathbb{F}_q[x]/(f(x))$ that takes $\alpha \in \mathbb{F}_q[x]/(f(x))$ to $\rho_x(\alpha)$. Hence Carlitz Char-Poly may be restated as

▶ **Problem 11.** Given a monic square free $f(x) \in \mathbb{F}_q[x]$, compute $\chi_f(x)$.

By Lemma 12, knowledge of factorization of $f(x)$ immediately yields $\chi_f(x)$ in $\widetilde{O}(n \log q)$ time. Thus Problem Carlitz Char-Poly is linear time reducible to Factor. We next reduce Factor Degree to Carlitz Char-Poly.

4.2 Factor Degree Estimation using Carlitz Modules

▶ **Lemma 12.** *Let $f(x) = \prod_i f_i(x)$ be a factorization of a monic square free $f(x) \in \mathbb{F}_q[x]$ into monic irreducible polynomials . Then $\rho(\mathbb{F}_q[x]/(f(x))) \cong \bigoplus_i \mathbb{F}_q[x]/(f_i(x) - 1)$. In particular, $\chi_f(x) = \prod_i (f_i(x) - 1)$.*

Proof. By the Chinese remainder theorem, $\mathbb{F}_q[x]/(f(x)) \cong \prod_i \mathbb{F}_q[x]/(f_i(x))$

$$\Rightarrow \rho(\mathbb{F}_q[x]/(f(x))) \cong \rho\left(\prod_i \mathbb{F}_q[x]/(f_i(x))\right) \cong \bigoplus_i \rho\left(\mathbb{F}_q[x]/(f_i(x))\right). \tag{4.1}$$

The final congruence holds since for every direct product $C \cong A \times B$ of $\mathbb{F}_q[x]$-algebras, we have the corresponding direct sum $\rho(C) \cong \rho(A) \oplus \rho(B)$ of $\mathbb{F}_q[x]$-modules [8]. For a monic irreducible $g(x)$ ([8]),

$$\rho(\mathbb{F}_q[x]/(g(x))) \cong \mathbb{F}_q[x]/(g(x) - 1). \tag{4.2}$$

Equation 4.1 and 4.2 together prove the lemma. ◀

▶ **Lemma 13.** *If p does not divide the number of smallest degree factors of a monic square free $f(x) \in \mathbb{F}_q[x]$, then the smallest irreducible factor degree of $f(x)$ is* $\deg(f(x)) - \deg(f(x) - \chi_f(x))$.

Proof. Let $f(x) = \prod_i f_i(x)$ be a factorization of a monic square free $f(x) \in \mathbb{F}_q[x]$ into monic irreducible polynomials. Let d be the smallest degree of factors of $f(x)$. Then

$$f(x) - \chi_f(x) = f(x) - \prod_i (f_i(x) - 1) = \sum_i \frac{f(x)}{f_i(x)} + (\text{terms of degree less than } \deg(f(x)) - d).$$

The first equality is from Lemma 12. Since $f(x)$ and $f_i(x)$ are all monic and p does not divide the number of $f_i(x)$ of degree d, the leading term of $\sum_i (f(x)/f_i(x))$ is of degree $\deg(f(x)) - d$. Therefore $\deg(f(x) - \chi_f(x)) = \deg(f(x)) - d$ and the lemma follows. ◀

Lemma 13 reduces in nearly linear time Factor Degree (when restricted to p greater than the number of factors of $f(x)$) to Carlitz Char-Poly. To see this, given $f(x)$, we may call an algorithm that solves Problem 11 to obtain $\chi_f(x)$ and output $\deg(f(x)) - \deg(f(x) - \chi_f(x))$.

5 Moore and Vandermonde Determinants

5.1 Moore Determinants and Carlitz Factorials

Let A be a finitely generated $\mathbb{F}_q$ algebra and n a positive integer. The Moore matrix M_w with first row $w = (w_1, w_2, \dots, w_n) \in A^n$ is defined as

$$M_w := \begin{bmatrix} w_1 & w_2 & w_3 & \dots & w_n \\ w_1^q & w_2^q & w_3^q & \dots & w_n^q \\ w_1^{q^2} & w_2^{q^2} & w_3^{q^2} & \dots & w_n^{q^2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ w_1^{q^{n-1}} & w_2^{q^{n-1}} & w_3^{q^{n-1}} & \dots & w_n^{q^{n-1}} \end{bmatrix}$$

and its determinant $det(M_w)$ is denoted by $\Delta(w_1, w_2, \dots, w_n)$. For a positive integer m, the m^{th} Carlitz factorial

$$\prod_{0 \le i < j \le m} \left(x^{q^{j-i}} - x\right)^{q^i},$$

is the product of all polynomials over $\mathbb{F}_q$ of degree at most m [6]. We next recall Carlitz's identity and from it reduce FACTOR DEGREE to computing certain Moore determinants.

▶ **Lemma 14.** *(Carlitz [6]) For every positive integer m,*

$$\Delta(1, x, x^2, \dots, x^m) = \prod_{0 \le i < j \le m} \left(x^{q^{j-i}} - x\right)^{q^i},$$

Proof. The Moore matrix with first row $(1, x, x^2, \dots, x^m)$, when viewed column-wise is Vandermonde. By the Vandermonde determinant formula,

$$det\left(\begin{bmatrix} 1 & x & x^2 & \dots & x^m \\ 1 & x^q & x^{2q} & \dots & x^{mq} \\ 1 & x^{q^2} & x^{2q^2} & \dots & x^{mq^2} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & x^{q^{n-1}} & x^{2q^{n-1}} & \dots & x^{mq^{n-1}} \end{bmatrix}\right) = \prod_{0 \le i < j \le m} (x^{q^j} - x^{q^i}) = \prod_{0 \le i < j \le m} \left(x^{q^{j-i}} - x\right)^{q^i}$$

◀

MOORE-DET may be restated as

▶ **Problem 15.** Given a square free monic polynomial $f(x) \in \mathbb{F}_q[x]$ of degree n and a positive integer $m \le n$, decide if $\Delta(1, x, \dots, x^m) \mod f(x)$ is 0.

Problem 15 can be solved in $\widetilde{O}(n^{3/2} \log q + n \log^2 q)$ time [13, Lemma 8.4].

▶ **Theorem 16.** *If there is a $T(n, m, \log q)$ time algorithm for Problem 15, then* FACTOR DEGREE *can be solved in $O(T(n, \lceil n/2 \rceil, \log q) \log n)$ time. That is,* FACTOR DEGREE *is nearly linear time reducible to* MOORE-DET.

Proof. By Lemma 14, for a monic square free $f(x) \in \mathbb{F}_q[x]$ and $m \le \deg(f(x))$, we have $\Delta(1, x, \dots, x^m) \mod f(x) = 0$ if and only if

$$\prod_{0 \le i < j \le m} \left(x^{q^{j-i}} - x\right)^{q^i} = 0 \mod f(x). \tag{5.1}$$

Since $f(x)$ is square free, Equation 5.1 holds if and only if every irreducible factor of $f(x)$ has degree at most m. Given oracle access to an algorithm for Problem 15, a binary search leads to the determination of the largest irreducible factor degree of $f(x)$. ◀

5.2 Vandermonde Determinants

The determinants involved in the previous subsection were both Moore and Vandermonde. Here we study determinants that are Vandermonde but not Moore. Further, the matrices involved are of dimension significantly smaller than the degree of the polynomial factored.

For a positive integer m, let

$$S_m := \{0, 1, 2, \dots, \lfloor\sqrt{m}\rfloor - 1, \lfloor\sqrt{m}\rfloor, 2\lfloor\sqrt{m}\rfloor, 3\lfloor\sqrt{m}\rfloor, \dots, (\lfloor\sqrt{m}\rfloor - 1)\lfloor\sqrt{m}\rfloor, \lfloor\sqrt{m}\rfloor^2, m\}.$$

This ensures that $|S_m| \leq 2\lfloor\sqrt{m}\rfloor + 1$ and $\{j - i | i, j \in S_m, i < j\} = \{1, 2, \dots, m-1, m\}$.

For a positive integer m, let $V_m(x) \in \mathbb{F}_q[x]$ denote the determinant of the Vandermonde matrix with first row $\{x^{q^i}, i \in S_m\}$.

▶ **Lemma 17.** *For every monic square free $f(x) \in \mathbb{F}_q[x]$ and every positive integer m,*

$$\gcd(V_m(x), f(x)) = \gcd\left(\prod_{0\leq i\leq m}\left(x^{q^i} - x\right), f(x)\right).$$

Proof. By the Vandermonde determinant formula,

$$V_m(x) = \prod_{i,j\in S_m|i<j}\left(x^{q^j} - x^{q^i}\right) = \prod_{i,j\in S_m|i<j}\left(x^{q^{j-i}} - x\right)^{q^i}. \tag{5.2}$$

Since $f(x)$ is square free and $\{j - i | i, j \in S_m, i < j\} = \{1, 2, \dots, m-1, m\}$,

$$\gcd\left(\prod_{i,j\in S_m|i<j}\left(x^{q^{j-i}} - x\right)^{q^i}, f(x)\right) = \gcd\left(\prod_{0\leq i\leq m}\left(x^{q^i} - x\right), f(x)\right). \tag{5.3}$$

By Equations 5.2 and 5.3, the lemma follows. ◀

Vandermonde Det may be restated as

▶ **Problem 18.** Given a square free monic polynomial $f(x) \in \mathbb{F}_q[x]$ of degree n and a positive integer $m \leq n$, decide if $V_m(x) \mod f(x)$ is 0.

We next sketch a fast algorithm for Problem 18. Since $|S_m| \leq \sqrt{n}$, the first row $\{x^{q^i} \mod f(x), i \in S_m\}$ can be computed in $\widetilde{O}(n^{3/2}\log q + n\log^2 q)$ time using iterated Frobenius algorithm [21] implemented using fast modular composition [13]. Given the first row of a Vandermonde matrix over a commutative ring, the square of its determinant can be computed with nearly linearly many operations over the ring [16]. Hence, $V_m(x) \mod f(x)$ can be zero tested in $\widetilde{O}(n^{3/2}\log q + n\log^2 q)$ time.

▶ **Theorem 19.** *If there is a $T(n, m, \log q)$ time algorithm for Problem 18, then* Factor Degree *can be solved in $O(T(n, \lceil\sqrt{n}\rceil, \log q)\log n)$ time. That is,* Factor Degree *is nearly linear time reducible to* Vandermonde Det.

Proof. By Lemma 14 and Lemma 17, for every monic square free $f(x) \in \mathbb{F}_q[x]$ and positive integer $m \leq \deg(f(x))$,

$$\gcd(V_m(x), f(x)) = \gcd(\Delta(1, x, \dots, x^m), f(x)).$$

Hence Problems 15 and 18 are identical and our theorem follows from Theorem 16. ◀

Abstract

An automaton is synchronizing if there exists a word that sends all states of the automaton to a single state. A coloring of a digraph with a fixed out-degree k is a distribution of k labels over the edges resulting in a deterministic finite automaton. The famous road coloring theorem states that every primitive digraph has a synchronizing coloring. We study recent conjectures claiming that the number of synchronizing colorings is large in the worst and average cases.

Our approach is based on the spectral properties of the adjacency matrix $\mathcal{A}(G)$ of a digraph G. Namely, we study the relation between the number of synchronizing colorings of G and the structure of the dominant eigenvector $\vec{v}$ of $\mathcal{A}(G)$. We show that a vector $\vec{v}$ has no partition of coordinates into blocks of equal sum if and only if all colorings of the digraphs associated with $\vec{v}$ are synchronizing. Furthermore, if for each b there exists at most one partition of the coordinates of $\vec{v}$ into blocks summing up to b, and the total number of partitions is equal to s, then the fraction of synchronizing colorings among all colorings of G is at least $\frac{k-s}{k}$. We also give a combinatorial interpretation of some known results concerning an upper bound on the minimal length of synchronizing words in terms of $\vec{v}$.

1 Introduction

Let $\mathscr{A} = (Q, \Sigma, \delta)$ be a finite deterministic complete automaton with an alphabet Σ, a set of states Q and a transition function δ. The automaton $\mathscr{A}$ is *synchronizing* if there exist a word u and a state p such that for every state $q \in Q$ we have $q \cdot u = p$, where $q \cdot u$ denotes the image of q under the action of u. Any such word u is called *synchronizing* (or *reset*) word for $\mathscr{A}$. The length of the shortest synchronizing word $\mathrm{rt}(\mathscr{A})$ is called *the reset threshold* of $\mathscr{A}$. Synchronizing automata naturally appear in algebra, coding theory, industrial automation,

discrete dynamical systems, etc. A brief survey of the theory of synchronizing automata may be found in [19].

Two fundamental problems about synchronizing automata that were intensively investigated in the last decades are the Černý conjecture and the road coloring problem. The former states that the reset threshold of an n-state automaton is at most $(n-1)^2$ [9]. Despite intensive research efforts it remains open for already half a century. The latter problem states a certain connection between primitive digraphs and synchronizing automata, which we will explain shortly, and was recently resolved by Trakhtman [18] after crucial insight by Culik, Karhumäki, and Kari [10]. Our paper is devoted to the generalizations of the road coloring theorem.

1.1 The road coloring theorem

The underlying digraph $\mathcal{G}(\mathscr{A})$ of an automaton $\mathscr{A}$ is a digraph with Q as a set of vertices, and for each $u \in Q, x \in \Sigma$ there is an edge $(u, u \cdot x)$. We allow loops and multiple edges, thus $\mathcal{G}(\mathscr{A})$ has a fixed out-degree equal to the cardinality of the alphabet Σ, i.e., $\mathcal{G}(\mathscr{A})$ is a $|\Sigma|$-out-regular digraph.

Vice versa, given a digraph G with a fixed out-degree k and a finite alphabet Σ with k letters, we can obtain a deterministic finite automaton by distributing the letters of Σ over the edges of G. Any automaton obtained in this way is called a *coloring* of G. A digraph is *primitive* if there exists a number t such that for any two vertices u and v there exists a path from u to v of length exactly t. An automaton is *strongly connected* if its underlying digraph is strongly connected.

▶ **Theorem 1** (Road coloring theorem). *A strongly connected digraph G with a fixed out-degree k has a synchronizing coloring if and only if it is primitive.*

This theorem was stated as a conjecture in 1977 [1]. The authors' original motivation comes from symbolic dynamics. Namely, synchronizing coloring defines a morphism from a shift of finite type given by G to a full shift over Σ with special properties, see [3].

The origin of the terminology is as follows. A digraph G represents a network of one-way roads. A coloring of G defines labels of the roads that can be perceived by drivers. If the coloring is synchronizing then the drivers who are unaware of their current location have the following strategy to relocate themselves: they can simply follow roads labelled by a synchronizing word and their final position will be well defined.

Although the road coloring theorem gives an answer for a principal connection between digraphs and synchronizing automata, there are still basic quantitative questions that remain unanswered. Namely, how many synchronizing colorings a primitive digraph G can have and what is the number of synchronizing colorings of an average (or random) digraph? These questions were addressed in [13] and two conjectures were formulated as a result of extensive computational experiments. In order to state them, we will need some definitions.

The *synchronizing ratio* of a digraph G is the number of synchronizing colorings divided by the total number of colorings. Note, that a coloring is a mapping from the set of edges to Σ with parallel edges being distinguished. Thus, the total number of colorings of a k-out-regular digraph with n states is always k^n.

▶ **Conjecture 2.** *The minimum value of the synchronizing ratio among all k-out-regular primitive digraphs with n vertices is equal to $\frac{k-1}{k}$, except for the case $k = 2$ and $n = 6$ when it is equal to $\frac{30}{64}$.*

We say that the digraph is *totally synchronizing* if its synchronizing ratio is equal to 1, i.e., every coloroing is synchronizing.

▶ **Conjecture 3.** *For every $k \geq 2$, the fraction of totally synchronizing digraphs among all k-out-regular primitive digraphs with n vertices tends to 1 as n goes to infinity.*

If both conjectures are true, then the road coloring theorem is a relatively weak statement that gives us just the first step towards satisfactory understanding of the synchronizing properties of automata and digraphs.

We want to mention another direction to strengthen the road coloring theorem.

▶ **Conjecture 4** (Hybrid Černý–Road Coloring Problem)**.** *Every primitive k-out-regular digraph with n vertices has a synchronizing coloring with the reset threshold at most $n^2 - 3n + 3$.*

This conjecture was made by M. V. Volkov and partial results were obtained in [17, 8].

1.2 Our contributions

One of the major obstacles in approaching conjectures 2 and 3 comes from the difficulty of proving that a coloring under consideration is synchronizing. A simple and straightforward proof of this fact tends to be tedious and technical even for relatively simple automata, see for example [12]. In order to overcome this difficulty we rely on spectral properties of the adjacency matrix $\mathcal{A}(G)$ of a primitive k-out-regular digraph G.

More precisely, Perron-Frobenius theorem [15, Chapter 8] implies existence of entrywise positive eigenvector $\vec{v}$ of $\mathcal{A}(G)$ associated with the unique largest eigenvalue, which we will simply call *the eigenvector* of G. The vector $\vec{v}$ can also be seen as the unique stationary distribution of the Markov chain associated with G by assigning the probability $\frac{1}{k}$ for each of the outgoing edges.

The importance of the eigenvector of G in the context of synchronizing automata was demonstrated by Friedman [11]. We will require a few definitions to state his result. Let $Q = \{1, \ldots, n\}$, and $\vec{v}[i]$ be the ith entry of $\vec{v}$. The *weight* of a subset $S \subseteq Q$ is given by $\mathrm{wg}(S) = \sum_{i \in S} \vec{v}[i]$. The subset $S \subseteq Q$ is *synchronizing* if there exists a word u and a state p such that for every $q \in S$ we have $q \cdot u = p$.

▶ **Theorem 5.** *Every coloring $\mathscr{A}$ of G has a partition of vertices into synchronizing subsets $Q_1, \ldots, Q_\ell$ such that $\mathrm{wg}(Q_1) = \ldots = \mathrm{wg}(Q_\ell)$ and for any other synchronizing subset S we have $\mathrm{wg}(S) \leq \mathrm{wg}(Q_1)$.*

A simple corollary of this statement allows us to easily identify a relatively large class of totally synchronizing digraphs. We will say that a vector $\vec{v}$ is *partitionable* if there exists a partition of $\vec{v}$ into blocks of equal weight b, i.e., a partition $Q_1, \ldots, Q_\ell$ of Q with $\ell > 1$ such that $\sum_{i \in Q_1} \vec{v}[i] = \ldots = \sum_{i \in Q_\ell} \vec{v}[i] = b$. Clearly, a digraph with non-partitionable eigenvector is totally synchronizing, otherwise maximal synchronizing subsets, i.e. synchronizing subsets with the largest weight, give rise to a partition by theorem 5. Our first contribution is the converse (in some sense) of this statement. Namely, let $\mathcal{G}(\vec{v})$ be the class of primitive digraphs of fixed out-degree with the eigenvector $\vec{v}$. We show that all digraphs in $\mathcal{G}(\vec{v})$ are totally synchronizing if and only if $\vec{v}$ is non-partitionable. We also formulate an algebraic conjecture that implies conjecture 3. These results are given in section 3.

Our second contribution is a lower bound on the synchronizing ratio of G depending on the structure of $\vec{v}$. We say that the partition $Q_1, \ldots, Q_\ell$ of $\vec{v}$ into blocks of weight b is *unique* if for every partition $Q'_1, \ldots, Q'_\ell$ of weight b there exists a permutation of $1, \ldots, \ell$ such that $Q_i = Q'_{\sigma(i)}$ for all i. In section 4 we show that if all partitions of $\vec{v}$ into blocks of equal weight are unique and their number is bounded by s, then the synchronizing ratio of G is at least $\frac{k-s}{k}$. Note, that for $s = 1$ we obtain the bound of conjecture 2. To the best of our knowledge it is the first result that shows validity of the conjecture on a relatively large class of digraphs, e.g., this class contains all primitive Eulerian[1] digraphs with a prime number of states.

Let $\mathscr{A}$ be a coloring of G. We can consider an arbitrary probability distribution on the letters of $\mathscr{A}$ turning it into a Markov chain. Similarly to the previous uniform case we obtain an eigenvector $\vec{v'}$ corresponding to the unique stationary distribution. The vector $\vec{v'}$ played an important role in various proofs of the Černý conjecture in the special classes of automata, see e.g. [16, 5, 6]. Our third contribution is related to such approaches. First, in section 2 we generalize theorem 5 to the case of arbitrary probability distributions on the alphabet. Secondly, in section 5 we present a combinatorial reduction from an arbitrary synchronizing automaton $\mathscr{A}$ to an Eulerian automaton with possibly larger number of states, which has the same reset threshold as $\mathscr{A}$. This reduction gives a combinatorial view of results by Berlinkov [4] and Steinberg [16].

2 Partitions into synchronizing subsets

In the present section we will prove a generalization of Theorem 5. Let $\mathscr{A}$ be a strongly connected automaton with the set of states $\{1, 2, \ldots, n\}$. Let $A_1, A_2, \ldots, A_k$ be the adjacency matrices of the letters of $\mathscr{A}$, i.e., $A_\ell[i, j] = 1$ if i is mapped to j under the action of the ℓth letter, and $A_\ell[i, j] = 0$ otherwise.

Consider the matrix $A = \sum_{i=0}^{k} p_i A_i$, where $p_i > 0$ are rational for all i and $\sum_{i=0}^{k} p_i = 1$. Since the matrix A is row-stochastic the largest eigenvalue of A is equal to 1. By the Perron-Frobenius theorem [15, Chapter 8] there exists a positive left eigenvector $\vec{u}$ such that $\vec{u}A = \vec{u}$. Since the entries of A are rational, so are the entries of $\vec{u}$. Let $\vec{w} = \ell\vec{u}$, where ℓ is the least common multiple of the denominators of entries of $\vec{u}$. We will call the vector $\vec{w}$ *the eigenvector* of $\mathscr{A}$ in accordance with the distribution $p_1, \ldots, p_k$. If the distribution is uniform, i.e., $p_1 = p_2 = \ldots = p_k = \frac{1}{k}$, then we will usually omit its description. Since all colorings of a digraph G have the same eigenvector $\vec{w}$ in accordance with the uniform distribution we will call $\vec{w}$ obtained in this way *the eigenvector* of G.

The *kernel* of a word x with respect to an automaton $\mathscr{A}$ is an equivalence relation ρ on the set of states Q such that $i\rho j$ if and only if $i \cdot x = j \cdot x$. A subset S is *synchronizing* if there exists a word x such that the cardinality of $S \cdot x = \{q \cdot x \mid q \in S\}$ is equal to 1. By $S \cdot x^{-1}$ we denote the full preimage of the set S under the action of a word x, i.e., $S \cdot x^{-1} = \{q \in Q \mid q \cdot x \in S\}$. Let $\vec{w}$ be the eigenvector of the automaton $\mathscr{A}$. We define *the weight* $\mathrm{wg}(i)$ of a state i as $\vec{w}[i]$. The weight of a set S is defined as $\mathrm{wg}(S) = \sum_{i \in S} \mathrm{wg}(i)$.

▶ **Theorem 6.** *Let $\vec{w}$ be the eigenvector of a strongly connected automaton $\mathscr{A}$ in accordance with a distribution $p_1, p_2, \ldots, p_k$. There exists a partition of the states of $\mathscr{A}$ into synchronizing subsets of maximal weight. Furthermore, this partition is equal to the kernel of some word x.*

[1] A digraph is *Eulerian* if the outdegree and indegree of each vertex is equal to k for some constant k. The eigenvector of such digraph is equal to $(1, 1, \ldots, 1)$.

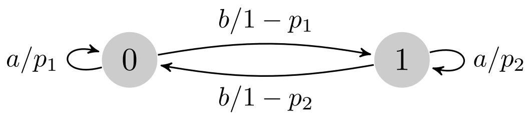

Figure 1 Automaton $\mathscr{F}$.

Proof. Let $\Sigma = \{a_1, a_2, \dots, a_k\}$, and let S be an arbitrary subset of Q. Note the following equality:

$$\sum_{i=1}^{k} p_i \operatorname{wg}(S \cdot a_i^{-1}) = \operatorname{wg}(S)$$

(the incoming edges to S in total bring the weight equal to $\operatorname{wg}(S)$, and each preimage brings $p_i \operatorname{wg}(Sa_i^{-1})$; the weights are equal, since $\vec{w}$ is the eigenvector of $\mathscr{A}$). If S is a synchronizing subset of maximal weight, then the weights of preimages are bounded by $\operatorname{wg}(S)$, since every preimage is also a synchronizing subset. Moreover, every preimage has the weight equal to $\operatorname{wg}(S)$, otherwise the left-hand side would be strictly less than the right-hand side. Therefore, if S is a synchronizing subset of maximal weight, then every preimage of S is a synchronizing subset of maximal weight.

We will iteratively construct a partition of the set of states of $\mathscr{A}$ into synchronizing subsets of maximal weight. Let S_0 be a synchronizing subset of maximal weight. Let u be a word synchronizing S_0 to some state q: $S_0 \cdot u = q$. If $S_0 = Q$, then the automaton is synchronizing, and the proof is complete. Otherwise, let p be a state that doesn't belong to S_0. Since the automaton $\mathscr{A}$ is strongly connected, there exists a word v such that $q \cdot v = p$. Consider now the sets $S_1 = S_0 \cdot (uv)^{-1}$ and S_0. Note, that S_1 is also a maximal synchronizing subset by the preceding paragraph. Furthermore, both sets are synchronized by uvu. But their images are different, since q is not equal to $p \cdot u$ due to maximality of S_0. Continuing in the same manner we will eventually construct the desired partition of Q. ◀

From the matrix theory point of view, independent assignment of probabilities to the edges of the underlying digraph of $\mathscr{A}$ is more natural than the assignment of probabilities to the letters. Unfortunately, Theorem 6 does not hold in this case. Let $\mathscr{F}$ be the automaton depicted in Fig. 1. The notation ℓ/p means that the edge is labelled by ℓ and has the probability p. Note, that the eigenvector of $\mathscr{F}$ is equal to $(1-p_2, 1-p_1)$. Since every letter acts as a permutation, the automaton $\mathscr{F}$ is not synchronizing. Therefore, the partition of the states into synchronizing subsets should be of the form $\{\{0\},\{1\}\}$, but for $p_2 = \frac{1}{3}$ and $p_1 = \frac{1}{2}$ these subsets have different weight.

▶ **Corollary 7.** *Let $\vec{w}$ be the eigenvector of an automaton $\mathscr{A}$ in accordance with a distribution $p_1, p_2, \dots, p_k$, and the weight of a subset of states S is given by $\sum_{i \in S} \vec{w}[i]$. If there is no partition of the states into subsets of equal weight, then the automaton $\mathscr{A}$ is synchronizing.*

Unfortunately, the converse of this corollary does not hold. Let $\mathscr{B}$ be an automaton depicted in Fig. 2. It is synchronized by the word *bbaab* to the state 1. If p and $1-p$ are the probabilities of the letters a and b respectively, then the eigenvector of $\mathscr{B}$ is equal to $(1, 1, p, p)$. Thus, the subsets $\{0, 2\}$ and $\{1, 3\}$ form a partition of the states of $\mathscr{B}$ for any p, in other words, there is no witness of the fact that $\mathscr{B}$ is synchronizing.

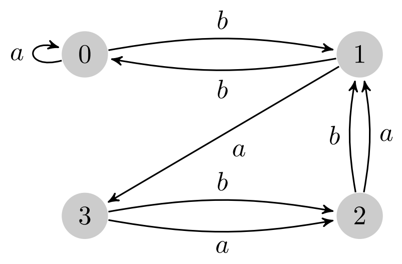

Figure 2 Automaton $\mathscr{B}$.

3 The eigenvectors of totally synchronizing digraphs

Let $\vec{w}$ be an entrywise positive integer vector. We denote by $\mathcal{G}(\vec{w})$ the class of primitive digraphs with the eigenvector $\vec{w}$ such that every digraph in this class has a fixed out-degree (which can be different for two different digraphs from the class). In this section we will characterize in terms of $\vec{w}$ the classes $\mathcal{G}(\vec{w})$ consisting of only totally synchronizing digraphs.

Let $\mathscr{A}$ be an automaton with the set of states Q and an alphabet Σ. Recall that an equivalence relation $\sim$ on Q is a *congruence* if $i \sim j$ implies $i \cdot x \sim j \cdot x$ for all $i, j \in Q$ and $x \in \Sigma$. The *factor automaton* $\mathscr{A}/\sim$ of $\mathscr{A}$ with respect to $\sim$ is defined as follows. The set of states of $\mathscr{A}/\sim$ is equal to the equivalence classes of $\sim$, and its alphabet is equal to Σ. The action of a letter x on an equivalence class C defined in accordance with the representative $c \in C$, i.e., $C \cdot x$ is equal to the class of $c \cdot x$ in $\mathscr{A}$. Since $\sim$ is a congruence, this definition is correct and does not depend on the representative c.

We will call an equivalence relation β on the coordinates of $\vec{w}$ a *partition* if it has at least two classes and satisfies the following property: there exists a constant b such that for every class B of β we have $\sum_{i \in B} \vec{w}[i] = b$. We will refer to the classes of partition β as *blocks*. If $\vec{w}$ is the eigenvector of an automaton $\mathscr{A}$, then every coordinate corresponds to a state of $\mathscr{A}$. Thus, we can naturally obtain an equivalence relation β' on the states of $\mathscr{A}$ from the partition β. Abusing notation, we will refer to β' as β. A vector $\vec{w}$ is called *partitionable* if it possesses a partition.

▶ **Theorem 8.** *An entrywise positive integer vector $\vec{w}$ is not partitionable if and only if all digraphs from $\mathcal{G}(\vec{w})$ are totally synchronizing.*

Proof. Let G be a digraph from $\mathcal{G}(\vec{w})$. If G has a non-synchronizing coloring, then by Theorem 6 it admits a partition of the states into synchronizing subsets of equal weight. Since the coloring is not synchronizing such partition has at least two blocks. Thus, the vector $\vec{w}$ is also partitionable.

Assume now that $\vec{w}$ is partitionable, i.e., there are sets $B_1, B_2, \ldots, B_\ell$ such that for every i we have $\sum_{j \in B_i} \vec{w}[j] = b$. Let n be the number of entries of $\vec{w}$. We will construct a digraph G belonging to $\mathcal{G}(\vec{w})$ on the set of vertices $V = \{0, 1, \ldots, n-1\}$ that is not totally synchronizing as follows: for every pair of vertices i and j there is an edge (i, j) of multiplicity $\vec{w}[j]$.

First, let us show that $G \in \mathcal{G}(\vec{w})$. Note, that the out-degree of every vertex is equal to the sum of entries of $\vec{w}$, i.e., $b\ell$. Furthermore, the digraph G is primitive since there is a path of length 1 between every two vertices. It remains to show that $\vec{w}$ is the eigenvector of G corresponding to the eigenvalue 1. Let $c_{ij} = \vec{w}[j]$ be the multiplicity of the edge from i to j, and $c = b\ell$ be the out-degree of G. We have

$$\sum_{i\in V} \frac{c_{ij}}{c}\vec{w}[i] = \sum_{i\in V} \frac{\vec{w}[j]}{c}\vec{w}[i] = \vec{w}[j]\sum_{i\in V} \frac{\vec{w}[i]}{c} = \vec{w}[j]$$

(the incoming and the outgoing weights are equal). Therefore, $\vec{w}$ is the eigenvector of G.

Now we are going to construct a non-synchronizing coloring of G. We will write $i\,\beta\,j$ for $i, j \in V$ if both i and j belong to B_s for some s. Let $\mathcal{A}$ be the set of colorings of G that have β as a congruence, i.e., for every letter x and for every pair of states i, j such that $i\,\beta\,j$ we necessarily have that $(i \cdot x)\,\beta\,(j \cdot x)$. The set $\mathcal{A}$ is not empty, since it contains the following coloring: the action of the first $\vec{w}[1]$ letters brings all states to the state 1, the action of the next $\vec{w}[2]$ letters brings all states to the state 2, and so on.

Let us fix some automaton $\mathscr{A} \in \mathcal{A}$. Recall that an automaton over k-letter alphabet is Eulerian if the indegree (and the out-degree) of every state is equal to k. Clearly, an automaton is Eulearian if and only if its eigenvector is equal to $(1, 1, \ldots, 1)$. We will show now that the factor automaton $\mathscr{A}'$ of $\mathscr{A}$ with respect to β is Eulerian. Let Σ be the alphabet of $\mathscr{A}$ and $\mathscr{A}'$. Relying on the fact that $\vec{w}$ is the eigenvector of $\mathscr{A}$ we have the following equalities for every block B_t:

$$\sum_{\substack{i\in Q, x\in\Sigma\\ i\cdot x = j}} \frac{1}{c}\vec{w}[i] = \vec{w}[j] \quad\Rightarrow \sum_{\substack{i\in Q, x\in\Sigma\\ i\cdot x \in B_t}} \frac{1}{c}\vec{w}[i] = b \quad\Rightarrow \sum_{\substack{B_s, x\in\Sigma\\ B_s\cdot x = B_t}} \frac{1}{c} b = b$$

The last equality ensures that $(b, b, \ldots, b)$ is the eigenvector of $\mathscr{A}'$, thus, it is Eulerian.

Lemma 1 from [14] states that every Eulerian automaton has a non-synchronizing coloring[2]. Thus, we can recolor an automaton $\mathscr{A}'$ into a non-synchronizing automaton $\mathscr{B}'$. Such recoloring procedure can be seen as a sequence of basic flips, i.e., for a fixed B_t, $x_1, x_2 \in \Sigma$ we change the label from x_1 to x_2 and vice versa on the outgoing edges of B_t. Therefore, this recoloring can be applied to $\mathscr{A}$ leading to an automaton $\mathscr{B}$ in the following manner: a basic flip is applied simultaneously to all states of B_t. The latter ensures that β is a congruence of $\mathscr{B}$ and $\mathscr{B}'$ is the factor automaton of $\mathscr{B}$ with respect to β. Note that the automaton $\mathscr{B}$ is not synchronizing, since any synchronizing word of the automaton $\mathscr{B}$ will synchronize the automaton $\mathscr{B}'$ leading to a contradiction. ◀

Theorem 8 allows us to obtain very simple proofs for otherwise non-obvious statements. Recall that the Černý automaton $\mathscr{C}_n$ [9] can be defined as $\langle\{0, \ldots, n-1\}, \{a, b\}, \delta\rangle$, where $\delta(i, a) = i + 1$ for $i < n - 1$, $\delta(n - 1, a) = 0$, $\delta(n - 1, b) = 0$, and $\delta(i, b) = i$ for $i < n - 1$.

▶ **Proposition 9.** *[13, Proposition 2] The underlying digraph of the Černý automaton $\mathscr{C}_n$ is totally synchronizing.*

Proof. It is easy to verify that the eigenvector $\vec{w}$ of the underlying digraph of the n-state Černý automaton is equal to $(2, 2, \ldots, 2, 1)$. Since in every partition exactly one block will have an odd sum, we conclude that $\vec{w}$ is not partitionable. Thus, the digraph is totally synchronizing. ◀

A similar proof can be presented for many other examples in [2].

Another application of theorem 8 is related to conjecture 3. We believe that significant progress on this conjecture can be made through the study of the eigenvectors of digraphs.

[2] It is also a relatively simple corollary of the Birkhoff-von Neumann theorem

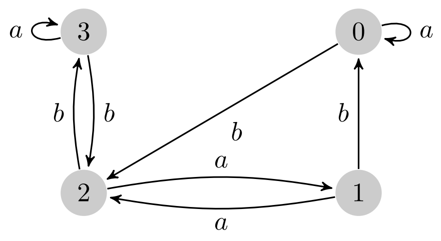

Figure 3 Automaton $\mathscr{D}$.

Despite the fact that the statement of Theorem 8 gives only a necessary condition for a digraph to be totally synchronizing we expect it to hold in most cases. More formally, we state the following conjecture:

▶ **Conjecture 10.** *The eigenvector of a random primitive k-out-regular digraph with n vertices has no partition into blocks of equal sum with probability 1 as n goes to infinity.*

This conjecture has the following interpretation in terms of Markov chains theory. A primitive k-out-regular digraph G correspond to Markov chain via the distribution of the probability $\frac{1}{k}$ for each edge. Furthermore, this chain is mixing, i.e., irreducible and aperiodic, and its stationary distribution is equal to the eigenvector of the the digraph. Informally speaking, a partition of the eigenvector corresponds to a partition of states of the Markov chain into classes such that an infinitely long random walk will spend equal amount of time in each of the classes. Conjecture 10 states that the fraction of Markov chains with this property goes to 0 as the number of states grows.

▶ **Corollary 11.** *If the eigenvector of G is not partitionable, then G is totally synchronizing.*

There are classes of digraphs $\mathcal{G}(\vec{w})$ that contain both totally synchronizing and not totally synchronizing digraphs. Let $\vec{w}$ be $(1, 1, 2, 2)$. The underlying digraph of the automaton $\mathscr{D}$, see fig. 3, belongs to $\mathcal{G}(\vec{w})$. It is not totally synchronizing, since the pair $\{2, 3\}$ is not synchronizable in the coloring $\mathscr{D}$. At the same time, it is easy to see that the underlying digraph of the automaton $\mathscr{B}$, see fig. 2, belongs to $\mathcal{G}(\vec{w})$ and it is totally synchronizing.

There are also classes of digraphs $\mathcal{G}(\vec{w})$ which do not contain totally synchronizing digraphs at all. Namely, if $\vec{w} = (1, 1, \ldots, 1)$ then every digraph in $\mathcal{G}(\vec{w})$ is Eulerian, thus it possesses a non-synchronizing coloring [14, Lemma 1].

4 Partitions of the eigenvectors and the synchronizing ratios

In this section we will present a bound on the synchronizing ratio of a digraph G depending on the structure of its eigenvector. It can be seen as the the first theoretical statement supporting conjecture 2. In order to obtain our result we will rely on the following key lemma:

▶ **Lemma 12.** *Let $\mathscr{A}$ be a non-synchronizing automaton with the eigenvector $\vec{w}$. A partition into maximal synchronizing subsets is unique if and only if it is a congruence.*

Proof. Assume first that the partition into maximal synchronizing subsets is unique. We will denote the block containing a state p by $[p]$. If the partition is not a congruence, then there exists a letter ℓ such that $[p] = [q]$ and $[p\ell] \neq [q\ell]$ for some states p and q. Note, that the preimage of a maximal synchronizing subset by any letter is also a maximal synchronizing subset (see the proof of Theorem 6). Hence, the preimage of a partition into maximal synchronizing subsets is also a partition into maximal synchronizing subsets. Thus, $[p\ell]\ell^{-1}$ is a maximal synchronizing subset and $[p\ell]\ell^{-1} \cap [p] \neq \varnothing$. We also have $[p\ell]\ell^{-1} \neq [p]$, otherwise we get $[p\ell] = [p]\ell$ which implies $[p\ell] = [q\ell]$. Therefore, the preimage of the partition by the letter ℓ is a different partition into maximal synchronizing subsets. A contradiction.

Let τ be a partition into maximal synchronizing subsets. Let us assume that the partition τ is a congruence. Assume to the contrary that there is another partition σ into synchronizing subsets of maximal weight. Note, that there are states p and q such that $p \sim_\sigma q$ and $p \nsim_\tau q$, otherwise σ is a refinement of τ, and σ is not a partition into synchronizing subsets of maximal weight. Since $p \sim_\sigma q$ there exists a word u such that $pu = qu$. Let $[p]$ and $[q]$ be the blocks of the partition τ of p and q respectively. Since τ is a congruence both $[p]u$ and $[q]u$ are subsets of the same block $[r]$ for some state r. The subset $[r]$ is synchronizing. Therefore, the subset $[p] \cup [q]$ is also synchronizing, which contradicts maximality of $[p]$ and $[q]$. ◀

▶ **Corollary 13.** *A digraph G with the eigenvector $\vec{w}$ is totally synchronizing if the following conditions hold:*
1. *if there exists a partition of $\vec{w}$ into blocks of weight b, then it is unique;*
2. *every partition of $\vec{w}$ is not a congruence for every coloring.*

Let Q be a set of states of an automaton $\mathscr{A}$ with the eigenvector $\vec{w}$. A partition of $\vec{w}$ into blocks of weight b is a partition $Q_1, \ldots, Q_\ell$ of Q with $\ell > 1$ such that $\sum_{i \in Q_1} \vec{w}[i] = \ldots = \sum_{i \in Q_\ell} \vec{w}[i] = b$. For simplicity in this section we will sometimes say "a partition" meaning a partition into blocks of equal weight. A partition $Q_1, \ldots, Q_\ell$ of $\vec{w}$ into blocks of weight b is unique if for every partition $Q'_1, \ldots, Q'_\ell$ of weight b there exists a permutation of $1, \ldots, \ell$ such that $Q_i = Q'_{\sigma(i)}$ for all i.

▶ **Theorem 14.** *If all partitions of the eigenvector $\vec{w}$ are unique and their number is equal to s, then the synchronizing ratio of every k-out-regular digraph in $\mathcal{G}(\vec{w})$ is at least $\frac{k-s}{k}$.*

Proof. Every non-synchronizing coloring is associated with a partition of $\vec{w}$ according to theorem 6. We will show that with every partition at most $\frac{1}{k} \cdot k^n$ such colorings can be associated. Thus, the total number of non-synchronizing colorings will be bounded by $\frac{s}{k} \cdot k^n$, and the theorem will follow.

Let G be a digraph in $\mathcal{G}(\vec{w})$, and let β be one of the partitions of $\vec{w}$. In order to show that the fraction of non-synchronizing colorings associated with β is at most $\frac{1}{k}$ we will consider two cases depending on the structure of G and β.

Case I: there are two distinct vetrices q, p belonging to the same block B of β with the following property: there are edges (q, q') and (p, p') such that q' and p' belong to different blocks of β. Let $\mathscr{A}$ be a non-synchronizing coloring associated with β (if there is no such coloring, then the proof is complete). By lemma 12 the partition β is a congruence for $\mathscr{A}$. Thus, for every block B' there is the same number of letters (and edges) going from q to B' and from p to B'. Let k_1 be the number of edges going from q to B_1, k_2 be the number of edges going from q to B_2, …, k_ℓ be the number of edges going from q to B_ℓ, where $B_1, \ldots, B_\ell$ are blocks of β and $k_1, \ldots, k_\ell$ are positive integers such that $\sum_{i=1}^{\ell} k_i = k$.

Now we will divide all colorings of G into classes and show that the fraction of non-synchronizing colorings in each class is at most $\frac{1}{k}$. Let us fix a coloring C of all edges, except for the outgoing edges of q and p. Let $\mathcal{A}(C)$ be the set of automata obtainable from C by all possible colorings of the remaining edges. We will show that the fraction of non-synchronizing automata in $\mathcal{A}(C)$ is at most $\frac{1}{k}$. By lemma 12 every non-synchronizing coloring of G associated with β must be a congruence. Note, that there are at most

$\binom{k}{k_1}(k_1!)^2\binom{k-k_1}{k_2}(k_2!)^2\dots\binom{k_\ell}{k_\ell}(k_\ell!)^2$ automata in $\mathcal{A}(C)$ that have β as a congruence. Whereas the total number of automata in $\mathcal{A}(C)$ is $(k!)^2$. Thus, the fraction of non-synchronizing automata is at most $\frac{k_1!k_2!\dots k_\ell!}{k!}$. It is not hard to see, that this value is bounded by $\frac{1}{k}$. Since every coloring of G belongs to $\mathcal{A}(C)$ for some C, the result will follow.

Case II: for all **distinct** vetrices q, p belonging to the same block B of β and for all edges (q, q') and (p, p') we have that q' and p' belong to the same block of β. Thus, there is at least one singleton, i.e. a block of β consisting of a single vertex. Indeed, if it is not the case, then each of the blocks has a unique successor. It implies that there are no paths of the same length leading from vertices belonging to different blocks to some fixed vertex, so G is not primitive. Note, that β is a congruence for every coloring of G.

First, we will show that a coloring $\mathscr{A}$ of G is synchronizing if and only if the factor automaton $\mathscr{A}/\beta$ is synchronizing. Clearly, if $\mathscr{A}$ is synchronizing, then $\mathscr{A}/\beta$ is synchronizing too. Assume now that $\mathscr{A}/\beta$ has a synchronizing word u that brings it to a state i. Let j be the state belonging to a singleton block of β. Since G is primitive, there is a word v that brings i to j. It is not hard to see that the word uv is synchronizing for the automaton $\mathscr{A}$.

Secondly, we note that the factor automaton $\mathscr{A}/\beta$ is Eulerian with a prime number of states. Indeed, since β is a partition into blocks of equal weight, we conclude that $\mathscr{A}/\beta$ is Eulerian (see the proof of Theorem 8). If the number of states of $\mathscr{A}/\beta$ is not prime, then the partition β will not be unique. Now it remains to show that the synchronizing ratio of G/β is at least $\frac{k-1}{k}$. The proof of this fact is reminiscent of case I.

Note, that there exist a vertex q and edges $(q, r), (q, s)$ for $r \neq s$, otherwise G is not primitive. Let all the k outgoing edges of q be (q, p_1) of multiplicity k_1, (q, p_2) of multiplicity k_2, …, (q, p_ℓ) of multiplicity k_ℓ. Let us fix a coloring C of all edges, except for the outgoing edges of q. Let $\mathcal{A}(C)$ be the set of automata obtainable from C by all possible colorings of the remaining edges. In order to show that the synchronizing ratio of G is at least $\frac{k-1}{k}$ we will demonstrate that the fraction of non-synchronizing automata in $\mathcal{A}(C)$ is at most $\frac{1}{k}$.

If all automata in $\mathcal{A}(C)$ are synchronizing, then the statement holds true. Otherwise, let $\mathscr{A} \in \mathcal{A}(C)$ be a non-synchronizing automaton. Since the number of states is prime and the eigenvector of $\mathscr{A}$ is equal to $(1, 1, \dots, 1)$, by Theorem 6 we conclude that every letter of $\mathscr{A}$ acts as a permutation on the set of states. Note, that if edges (q, p_1) and (q, p_2) are labelled by x and y respectively, then the automaton $\mathscr{A}' \in \mathcal{A}(C)$ obtained by flipping the labels on these edges, i.e., assigning letter y to (q, p_1) and letter x to (q, p_2), is synchronizing. Indeed, either p_1 or p_2 is not equal to q. Without loss of generality we will assume that $p_1 \neq q$. Since every letter in $\mathscr{A}$ acts as a permutation, there exists a state r such that $r \cdot y = p_1$. Thus, $r \cdot y = q \cdot y$ for the automaton $\mathscr{A}'$ and it is synchronizing by Theorem 6. More generally, there are at most $k_1!k_2!\dots k_\ell!$ permutations of labels on the outgoing edges of q that keep the resulting automaton non-synchronizing. Since the value of the fraction $\frac{k_1!k_2!\dots k_\ell!}{k!}$ is bounded by $\frac{1}{k}$ we obtain the desired statement. ◀

5 The eigenvectors and the reset thresholds

The structure of the eigenvector an automaton $\mathscr{A}$ in accordance with some distribution can be utilized to bound the reset threshold of $\mathscr{A}$. To the best of our knowledge, the first such result was obtained by Kari [14]. He bounded the reset threshold of automata with the eigenvector $(1, 1, \dots, 1)$ in accordance with the uniform distribution, i.e., Eulerian automata.

▶ **Theorem 15.** *The reset threshold of an Eulerian automaton with n states is at most $n^2 - 3n + 3$.*

Afterwards, Steinberg noticed that the same bound holds true for automata with the eigenvector $(1, 1, \dots, 1)$ in accordance with *some* distribution [16]. Both of these results were later subsumed by the following theorem[3] of Berlinkov [4, Corollary 1].

▶ **Theorem 16.** *Let* $\mathbf{w}$ *be the sum of the coordinates of the integer eigenvector* $\vec{w}$ *of a strongly connected automaton* $\mathscr{A}$ *in accordance with some distribution. If* $\mathscr{A}$ *is synchronizing, then the reset threshold of* $\mathscr{A}$ *is at most* $1 + (n-1)(\mathbf{w} - 2)$.

Note, that the eigenvector of $\mathscr{A}$ in accordance with the uniform distribution depends only on $\mathcal{G}(\mathscr{A})$. Therefore, the bound given in this theorem will be valid for every recoloring of $\mathscr{A}$.

In this section we will present a simple reduction from an automaton $\mathscr{A}$ with the eigenvector $\vec{w}$ to an Eulerian automaton $\mathscr{B}$ with $\mathbf{w} = \sum_i \vec{w}[i]$ states such that $\mathrm{rt}(\mathscr{A}) \le \mathrm{rt}(\mathscr{B}) \le \mathrm{rt}(\mathscr{A}) + 1$. Thus, we will be able to utilize results of Kari about Eulerian automata to analyze $\mathscr{A}$. This reduction also gives a combinatorial interpretation of the aforementioned results by Steinberg and, to some extent, of Berlinkov.

▶ **Theorem 17.** *Let* $\mathbf{w}$ *be the sum of the coordinates of the integer eigenvector* $\vec{w}$ *of a strongly connected automaton* $\mathscr{A}$ *in accordance with a distribution* $p_1, p_2, \dots, p_k$*. If* $\mathscr{A}$ *is synchronizing, then there exists a synchronizing Eulerian automaton* $\mathscr{B}$ *with* $\mathbf{w}$ *states such that* $\mathscr{A}$ *is the factor automaton of* $\mathscr{B}$ *and* $\mathrm{rt}(\mathscr{A}) \le \mathrm{rt}(\mathscr{B}) \le \mathrm{rt}(\mathscr{A}) + 1$.

Proof. Let $\Sigma = \{a_1, a_2, \dots, a_k\}$ and $p_i = \frac{m_i}{\ell}$ for $1 \le i \le k$, where m_i, ℓ are positive integers. If there exists p_i such that $p_i \ne \frac{1}{k}$, then we will perform the next step, otherwise we proceed to step II.

Step I. We are going to duplicate certain letters of $\mathscr{A}$ in order to obtain an automaton $\mathscr{A}'$ such that its eigenvector in accordance with the uniform distribution is equal to $\vec{w}$. The alphabet of $\mathscr{A}'$ is equal to $\Sigma' = \{a_1^1, a_1^2, \dots, a_1^{m_1}, a_2^1, a_2^2, \dots, a_2^{m_2}, \dots, a_k^1, a_k^2, \dots, a_k^{m_k}\}$. The actions of these letters are as follows: for every i and j the action of the letter a_i^j in $\mathscr{A}'$ coincides with the action of the letter a_i in $\mathscr{A}$. It is easy to see that $\mathscr{A}'$ is synchronizing and $\mathrm{rt}(\mathscr{A}') = \mathrm{rt}(\mathscr{A})$. Furthermore, the eigenvector of $\mathscr{A}'$ in accordance with the uniform distribution coincides with $\vec{w}$. Thus, if $\vec{w} = (1, 1, \dots, 1)$, then $\mathrm{rt}(\mathscr{A}) = \mathrm{rt}(\mathscr{A}') \le n^2 - 3n + 3$ by Theorem 15. Therefore, this simple reduction gives an alternative way to obtain the result of Steinberg.

Step II. Now we are going to construct an Eulerian automaton $\mathscr{B}$ on a larger set of states and on a larger alphabet such that $\mathrm{rt}(\mathscr{A}) \le \mathrm{rt}(\mathscr{B}) \le \mathrm{rt}(\mathscr{A}) + 1$. Let $Q = \{1, \dots, n\}$ be the set of states of $\mathscr{A}'$ and Σ' be the alphabet of $\mathscr{A}'$. The set of states of $\mathscr{B}$ is equal to $\{(i, j) \mid i \in Q, 1 \le j \le \vec{w}[i]\}$. The alphabet of $\mathscr{B}$ is equal to $\Sigma' \cup \Lambda$, where Λ is a set of letters that we will define shortly. We will denote the set $\{(i, j) \mid 1 \le j \le \vec{w}[i]\}$ by S_i. Note that the number of states in $\mathscr{B}$ is equal to $\mathbf{w}$. Our construction of $\mathscr{B}$ will ensure the following properties:

1. $\mathscr{B}$ is Eulerian, and for every $i \in Q, x \in \Lambda$ we have $S_i \cdot x \subseteq S_i$;
2. for every i and $x \in \Sigma'$ we have $S_i \cdot x \subseteq S_{i \cdot x}$, where $i \cdot x$ is an image of i under the action of x in $\mathscr{A}'$.

Note, that these conditions imply that the partition $S_1, \dots, S_n$ is a congruence for the automaton $\mathscr{B}$, and the factor automaton with respect to this congruence is equal to the automaton $\mathscr{A}'$.

[3] In the original formulation of the theorem the bound is given in terms of the least common multiple L of the coordinates' denominators of the eigenvector $\vec{v}$ associated with the eigenvalue 1 such that $\sum_i \vec{v}[i] = 1$. Clearly, $\mathbf{w} = L$.

Let $k' = |\Sigma'|$ be the cardinality of Σ' and c_{ij} be the number of letters in Σ' that bring i to j in the automaton $\mathscr{A}'$. By the definition of $\vec{w}$ we have $\sum_{i \in Q} c_{ij}\vec{w}[i] = k'\vec{w}[j]$ for every j. Since $\vec{w}[i] = |S_i|$ we derive the equality $\sum_{i \in Q} c_{ij}|S_i| = k'|S_j|$ for every j. Due to the second property, $c_{ij}|S_i|$ is the total number of edges labelled by Σ' going from S_i to S_j in $\mathscr{B}$. Since the total number of incoming edges to S_j labelled by Σ' is equal to $k'|S_j|$, we can arrange them in such a way that every state of S_j has exactly k' incoming edges labelled by Σ'. We fix any such arrangement to define the action of Σ' on $\mathscr{B}$. Note, that the automaton $\mathscr{B}$ restricted to the alphabet Σ' is Eulerian.

The additional set of letters Λ is defined as follows. For every $i \in Q$ and every $j \in S_i$ we add a letter u_i^j. The action of u_i^j brings all states from S_i to j, and all the remaining states are fixed. Note, that the automaton $\mathscr{B}$ restricted to the alphabet Λ is Eulerian. Therefore, the first property is satisfied.

Step III. We will show now that the automaton $\mathscr{B}$ is synchronizing and $\mathrm{rt}(\mathscr{A}) \leq \mathrm{rt}(\mathscr{B}) \leq \mathrm{rt}(\mathscr{A}) + 1$. Let u be the shortest synchronizing word of $\mathscr{A}'$, and the action of u brings it to a state i. Since $\mathscr{A}'$ is the factor automaton of $\mathscr{B}$, we conclude that the automaton $\mathscr{B}$ is brought to S_i under the action of u. Thus, uu_i^i is a synchronizing word of $\mathscr{B}$ and $\mathrm{rt}(\mathscr{B}) \leq \mathrm{rt}(\mathscr{A}) + 1$.

Let u be a synchronizing word of $\mathscr{B}$, and the action of u brings it to a state in S_i for some i. Let v be a word over the alphabet Σ' obtained from u by removing all the letters from Λ. Since the action of every letter x from Λ of the automaton $\mathscr{B}$ satisfies $S_i \cdot x \subseteq S_i$ and $\mathscr{A}'$ is the factor automaton of $\mathscr{B}$, we conclude that u is a synchronizing word for the automaton $\mathscr{A}'$ and $\mathrm{rt}(\mathscr{A}) \leq \mathrm{rt}(\mathscr{B})$. ◀

▶ **Corollary 18.** *Let* $\mathbf{w}$ *be the sum of the coordinates of the integer eigenvector* $\vec{w}$ *of a strongly connected automaton* $\mathscr{A}$ *in accordance with a distribution* $p_1, p_2, \ldots, p_k$*. If* $\mathscr{A}$ *is synchronizing, then* $\mathrm{rt}(\mathscr{A}) \leq \mathbf{w}^2 - 3\mathbf{w} + 3$.

Clearly, this corollary is much weaker than Theorem 16. Nevertheless, both of these statements give $O(n^2)$ bound when $\mathbf{w} = O(n)$. This case is the most typical application of Theorem 16. At the same time, we believe that such simple reduction to an Eulerian automaton is of interest by itself.

To conclude this section we will estimate entries of the eigenvector of an arbitrary digraph. In general, they can be exponential in terms of the number of vertices. Consider the following k-out-regular digraph $U_{n,k}$. The set of vertices is equal to $\{0, 1, 2, \ldots, n-1\}$. For each $0 \leq i \leq n-1$ there is an edge $(i, 0)$ of multiplicity $k-1$ and an edge $(i, i+1 \mod n)$. It is easy to verify that the integer eigenvector of $U_{n,k}$ is $(k^{n-1}, k^{n-2}, \ldots, k, 1)$. Thus, the upper bound given by Theorem 16 can be exponential in n.

▶ **Proposition 19.** *Let* G *be a primitive* k*-out-regular digraph with* n *vertices. The entries of the eigenvector* $\vec{w}$ *are at most* $(2k^2)^{\frac{n-1}{2}}$.

Proof. Let A be the adjacency matrix of G, i.e., $A[i,j] = 1$ if there exists an edge going from i to j and $A[i,j] = 0$ otherwise. According to the definition of the eigenvector $\vec{w}$ in Section 2 we have the equality $\vec{w}(\frac{1}{k}A) = \vec{w}$. After rearrangement we get $\vec{w}(A - kI) = 0$, where I is the identity matrix. By Perron-Frobenius theorem we conclude that the rank of $A - kI$ is equal to $n-1$, since the eigenspace associated with $\vec{w}$ is one-dimensional. The main result of [7] states that for every integer matrix M of rank r if a system of linear equations $Mx = 0$ admits a nontrivial non-negative integer solution, then there exists such solution with entries bounded by the maximum of the absolute values of the $r \times r$ minors of M.

Thus, we conclude that there exists a non-negative integer vector $\vec{w'}$ such that $\vec{w'}(A - kI) = 0$ and entries of $\vec{w'}$ are bounded by the maximum of the absolute values of the $(n-1) \times (n-1)$

minors of $A - kI$. Note, that the Eucledean norm of each row of every minor is at most $\sqrt{2k^2}$, since the absolute of the entries is at most k and their sum is at most $2k$. Thus, by the Hadamard's inequality for the determinant we obtain an upper bound $(2k^2)^{\frac{n-1}{2}}$ on the minors. Since the non-negative vector $\vec{w'}$ is an eigenvector of A associated with the largest eigenvalue, we immediately conclude that $\vec{w'}$ is positive by the Perron-Frobenius theorem. ◀

Abstract

In competitive packet routing games, packets are routed selfishly through a network and scheduling policies at edges determine which packages are forwarded first if there is not enough capacity on an edge to forward all packages at once. We analyze the impact of *priority lists* on the worst-case quality of pure Nash equilibria. A priority list is an ordered list of players that may or may not depend on the edge. Whenever the number of packets entering an edge exceeds the inflow capacity, packets are processed in list order. We derive several new bounds on the price of anarchy and stability for global and local priority policies. We also consider the question of the complexity of computing an optimal priority list. It turns out that even for very restricted cases, i.e., for routing on a tree, the computation of an optimal priority list is APX-hard.

1 Introduction

A fundamental combinatorial optimization problem that has received considerable attention in the past (cf. [4, 14, 17, 18, 21, 24]) is *packet routing* in graphs. We are given a set of packets, which may, for example, correspond to unit-sized messages/bits in a communication network. Originated at possibly different start vertices, the goal is to transfer all packets as fast as possible to their respective destination vertices. It is assumed that each edge is equipped with a capacity (or bandwidth) and a travel time. A prominent variant is *discrete store-and-forward packet routing*, where every vertex can store arbitrarily many packets, but only a limited number can enter an edge simultaneously at each discrete time step, see [17]. Applications can be found in routing models used in synchronized systems with a given clock-rate. Imagine, for example, a chip with components and wires corresponding to the nodes and edges, respectively, of the associated graph, and with a centralized clock rate for the chip given by a crystal oscillator.

In this work, we focus on *selfish* or *competitive* packet routing using the discrete store-and-forward packet routing model. We are given a multi- or single-commodity network, where the commodities are specified by a source and a sink vertex and represent the players that route rational and selfishly one packet from their source to their sink through the network. Each edge of the network is endowed with an integral travel time and an integral capacity. The capacity of the edge defines the number of players that may enter the edge simultaneously. For each edge, we are given a priority list (i.e., an ordered list of the players) to resolve conflicts whenever more than capacity many players seek to enter that edge at the same point in time. All players are ready to start right from the beginning (i.e., there are no release dates) and aim to minimize their respective arrival time at the sink. Since the outcome of this competitive situation intrinsically depends on the priority lists employed on the edges, the problem of finding *good* priority lists renders into a coordination mechanism design problem. See [6] for the first landmark paper and several follow ups [1, 5, 7, 12].

1.1 Our Contribution

In this paper, we further explore properties of selfish discrete store-and-forward packet routing with *priority based* scheduling policies. We consider local priority lists and global priority lists (that may or may not depend on the edge). We obtain the following results.

Price of Anarchy/Stability

For global priority lists and multiple source-sink instances we show that the price of stability (PoS for short) behaves as $PoS \in \Omega(\sqrt{n})$ and the price of anarchy (PoA) is $PoA \in \mathcal{O}(n^3)$, where n denotes the number of players. For global priority lists and symmetric games (that is, all packets travel from a common source to a common sink) the PoS is one, while the PoA for these games is exactly $^{(n+1)}/_2$ and this bound holds even for multiple sources and a single sink.

For general local priority lists (that is, the predefined order may be different among edges) and asymmetric multi-commodity games we derive that the PoA is in between $^T/_4$ and $4T^2$, where T is a kind of *dilation* of the graph, i.e., the maximal length of a path, where edges with travel time 0 contribute 1 to the path. This result is obtained via adapting the primal-dual technique introduced by Kulkarni and Mirrokni [16]. Note that the network model in [16] is different to ours in the sense that it allows for different weights and sizes of the packets. See Section 1.2 for comparison. While the result in [16] holds for a very specific local scheduling policy only, namely, *Highest Density First*, our result even applies to *arbitrary* local priority lists, due to the special network structure in our model. As a byproduct of applying the primal-dual technique, we obtain the same bounds even for correlated equilibria which are guaranteed to exist.

Computational Complexity

We turn to the question of computing *optimal* priority lists, that is, priority lists that induce best possible social optima or Nash equilibria. We show that even for the special case of tree graphs, the resulting problem is APX-hard. Note that this is the first hardness result for the underlying coordination mechanism design problem and complements several approximability results for the tree case recently derived by Bhattacharya et al. [2]. Technically, we adapt a construction of Peis et al. [21], where it is shown that the problem to compute a schedule minimizing the makespan (the latest arrival of any packet) is APX-hard. Our result implies that the problem of defining global as well as local priority lists for minimizing the cost of any Nash equilibrium or of any social optimum is APX-hard.

We finally derive several further hardness results for our model: In multi-commodity games with local priority lists it is NP-hard to compute a pure Nash equilibrium. Moreover, it is NP-hard to compute a best response in symmetric games with local priority lists. These results are obtained by adapting the reduction described in Hoefer et al. [11] used to prove hardness in a more general setting. For global priority lists, we get an efficient Dijkstra-type algorithm for computing a best response and thus a pure Nash equilibrium.

1.2 Related work

Competitive Routing over Time

Hoefer et al. [11] considered weighted network congestion games in the continuous-time setting. In their model, the edges represent machines with predefined speed. Each job has a weight and the time needed to traverse an edge is given by the product of speed and weight. In contrast to our model, traversal times in [11] might be rational, but zero travel times are not allowed. Furthermore, the type of capacity constraints is different: While [11] capacitates the total weight of players using an edge at the same point in time, our model capacitates the number of players that may enter an edge simultaneously. Hoefer et al. analyzed four different scheduling policies: *FIFO*, *non-preemptive global ranking*, *preemptive global ranking* and *fair Time-Sharing*. They showed that in the case of a global priority list at least one equilibrium exists and it can be computed efficiently by iteratively and greedily routing the players with respect to the global order. Further results include the non-existence of equilibria for the FIFO scheduling policy and the complexity of computing equilibria and best responses.

The model of Kulkarni and Mirrokni [16] is a generalization of the model of Hoefer et al. [11] with two main differences. First, each packet has a size as well as a weight. The size determines how long it takes to traverse an edge and the weight denotes the contribution of this packet to the social cost. Observe that the authors also exclude edges with traversal time zero for a packet by their definition of the processing time as size divided by speed of an edge. The second difference to our model is that Kulkarni and Mirrokni assume that the strategy space of a packet is a subset of the simple paths from its source to its sink, whereas it is the set of all simple source-sink paths in [11] and in our model. Kulkarni and Mirrokni consider a variant of the robust price of anarchy, which is the worst-case ratio of the social cost of a coarse-correlated equilibrium and that of a social optimum [16]. A general framework to bound the robust price of anarchy via LP-Duality or Fenchel Duality was introduced by [16]. For the *Highest Density First* scheduling policy, they derive an upper bound of $4D^2$ for the robust price of anarchy, where D is the dilation of the graph. They also show a lower bound of $D/16$.

Flows over Time

Non-competitive packet routing can be interpreted as a special variant of *flows over time* (also known under the name *dynamic flows*) as introduced by Ford and Fulkerson in their seminal paper [10]. In fact, (non-competitive) packet routing is exactly the problem to find an integral multi-commodity flow satisfying unit demands of minimum time horizon. For an introduction to flows over time we refer to Skutella [23].

Koch and Skutella introduced in [15] a game-theoretic variant of flows over time. In their model, a continuum of players routes selfishly from a source to a sink through a network and flow enters an edge in a continuous fashion. They showed the existence of equilibria and analyzed the price of anarchy for their model, see also Cominetti et al. for a constructive proof for the existence and uniqueness of equilibria in [8]. Koch et al. [13] introduced discrete time steps for a single-commodity model. One could see our work as an extension to unsplittable flow particles and multi-commodity networks.

2 Preliminaries

An instance of a competitive packet routing game is a tuple (N, G, u, τ, π) consisting of a directed graph $G = (V, E)$ with integral travel times $\tau_e \in \mathbb{Z}_0^+$ denoting the time needed to traverse an edge $e \in E$. Additionally, each edge $e \in E$ is endowed with a capacity $u_e \in \mathbb{Z}^+$ denoting the number of players that can enter an edge e simultaneously at *each* integral time step. Note that this is independent of the travel times, even for $\tau_e = 0$. The set of players is denoted by $N = \{1, \ldots n\}$. Each player $i \in N$ is associated with a source s_i and sink t_i, inducing a strategy space $\mathcal{P}_i \subseteq 2^E$ consisting of all possible simple paths in G linking the respective source and sink. We call an instance *symmetric* if all players start at the same node and have the same sink, i.e. $s_i = s_j$ and $t_i = t_j$ for all players $i, j \in N$.

Depending on the chosen strategies there might be more than u_e-many players seeking to enter an edge at the same integral time step $\theta \in \mathbb{Z}_0^+$. In our model, we are given priority lists $\pi_e : N \to \{1, \ldots, n\}$ on each $e \in E$ to resolve such conflicts: among those players seeking to traverse edge e at time $\theta \in \mathbb{Z}_0^+$, the u_e players of highest priority according to list π_e may enter and travel along edge e, while the remaining players need to wait (at least) one time step. A priority list $\pi = (\pi_e)_{e \in E}$ is called *global* if $\pi_e = \pi_{e'}$ for all edges e and e', otherwise it is called local.

Given an instance (N, G, u, τ, π), each player $i \in N$ selects one path P_i from $\mathcal{P}_i$ with the goal to minimize the time when its packet entirely reaches its sink t_i. This time not only depends on the length $\tau(P_i) = \sum_{e \in P_i} \tau_e$ of path P_i, but also on the time the packet needs to wait at intermediate nodes due to interferences with players of higher priority. Given a strategy profile or state $P = (P_1, \ldots, P_n)$, we denote by $C_i(P)$ [or C_i if the context is clear] the time needed for player i's packet to entirely reach sink t_i. We define

$$C_i(P) = \left(\sum_{e \in P_i} \tau_e + w_{i,e}(P) \right), \tag{1}$$

where $w_{i,e}(P)$ is the waiting time for player i on the entry of edge e under profile P. The *social cost* of state $P = (P_1, \ldots, P_n)$ is the sum of all players' costs, i.e., $C(P) = \sum_{i \in N} C_i(P)$. We call a profile P *(socially) optimal* if it minimizes the social cost $C(P)$ over the set of all possible profiles. State P is a *pure Nash equilibrium (PNE)* if $C_i(P) \leq C_i(P_{-i}, P_i')$ holds for each player $i \in N$ and each alternative strategy $P_i' \in \mathcal{P}_i$. Here, as usual, state (P_{-i}, P_i') is obtained from P by replacing strategy P_i with P_i'.

In the definition of the arrival time of player i (cf. (1)), we implicitly assumed that the values $C_i(P), i \in N$ for a given state $P = (P_1, \ldots, P_n)$ are actually well-defined. We show in the following example that directed cycles of length 0 might be harmful:

▶ **Example 2.1.** Consider the graph depicted in Figure 1. We are given 3 players and player i travels from s_i to t_i for $i \in \{1, 2, 3\}$. In this example, each player has exactly one strategy and the priority lists on the edges e_1, e_2 and e_3 are given as $\pi_{e_1} = \{2, 3\}$, $\pi_{e_2} = \{3, 1\}$, $\pi_{e_3} = \{1, 2\}$. The travel times on the edges e_1, e_2, e_3 are equal to zero, where all other edges have travel time 1. The capacities of all edges are equal to 1. Now, there is no feasible integral flow over time respecting both the capacity constraints as well as the priority lists. Therefore, it is not possible to map each player $i \in N$ to a real-valued arrival time $C_i(P)$.

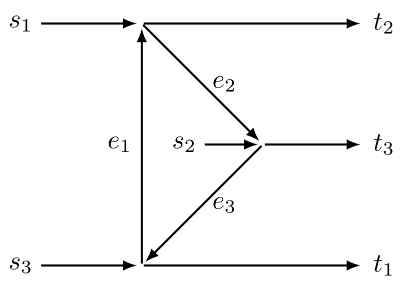

Figure 1 A graph showing that the mapping of paths to arrival times is not necessarily well-defined.

This observation motivates the exclusion of directed 0-cycles, that is, cycles C of length $\tau(C) = \sum_{e \in C} \tau_e = 0$. We assume in the following that there are no paths $P \in \mathcal{P}_i$ with total travel time equal to 0. Under this assumption, the following proposition shows that, given any strategy profile P, the embedding of players to arrival times $C_i(P), i \in N$, is well-defined, as long as directed 0-cycles are excluded.

▶ **Proposition 2.2.** *Given an instance without directed 0-cycles, we can use a Dijkstra-like algorithm to map given paths $P = (P_1, \dots, P_n)$ to a flow over time, thus to arrival times $C_i(P)$ in polynomial time.*

Proof. The idea is to adapt Dijkstra's algorithm [9] as follows. For each vertex v, we additionally define a list containing the arrival times of the players at v by the following procedure: initialize all source nodes s_i with arrival time 0 for every player starting at s_i. Use a priority queue of vertices sorted by the earliest arrival time of any player at that vertex. In each step, extract all vertices of minimal arrival time from the queue. Consider the graph H induced by these vertices and the corresponding edges of length $\tau_e = 0$. Repeatedly choose a vertex without incoming edges. Note that such a vertex needs to exist, since graph G is assumed to be free of 0-cycles . For each chosen vertex, route all players being able to depart according to the priority lists of the outgoing edges and delete the arrival time of the routed players. Add the arrival time of the routed players to the next vertex on their paths and reintroduce the vertex into the priority queue, if necessary. If the vertex is already in the priority queue, we possibly change its order in the queue. Now, delete the current vertex from H and go on with the next vertex without incoming edge. If H is empty continue with the next vertices from the queue. For a formal description of the algorithm, we refer to the full version. ◀

Using the relationship between packet routing and integral flows over time [23], we show that at least in the symmetric setting, a social optimum can be computed via Earliest Arrival Flows.

▶ **Definition 2.3.** Let $s, t \in V$. An *integral s-t-flow over time* is a set of functions $f_e : \mathbb{N} \to \mathbb{N}$ for all $e \in E$ satisfying the following two constraints:

$$f_e(\theta) \leq u_e \qquad \forall e \in E, \theta \in \mathbb{N} \tag{2}$$

$$\sum_{e \in \delta^-(v)} \sum_{\theta=0}^{\xi - \tau_e} f_e(\theta) \geq \sum_{e \in \delta^+(v)} \sum_{\theta=0}^{\xi} f_e(\theta) \qquad \forall \xi \in \mathbb{N}, v \in V \setminus \{s, t\} \tag{3}$$

The first inequality constrains the capacity and the second one represents weak flow conservation. If (3) is fulfilled with equality, the flow is said to satisfy strong flow conservation. An

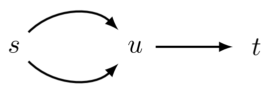

Figure 2 A network without pure Nash equilibrium.

integral s-t-flow over time fulfills the *earliest arrival property* if it maximizes the amount of flow arriving at the sink t for every integral time step. An integral s-t-flow over time that fulfills the earliest arrival property is called an *integral earliest arrival s-t-flow.*

▶ **Lemma 2.4** (Wilkinson [25]). *An integral earliest arrival s-t-flow with strong flow conservation can be computed in pseudo-polynomial time by an adapted successive shortest path algorithm.*

Wilkinson's algorithm combines the ideas of the push-and-relabel algorithm and the successive shortest path algorithm. During the execution of the algorithm one can easily transfer an integral earliest arrival s-t flow x into a strategy profile P with the following properties. The paths P_i are cycle-free, there are no waiting times at intermediate nodes and the demands are fulfilled. We call such a path profile an *earliest arrival state.*

▶ **Lemma 2.5.** *An earliest arrival state in a symmetric network corresponds to a social optimum, and vice versa.*

Proof. Let P be a social optimum and P' be an earliest arrival state. Let $N_\theta^P = |\{i : C_i(P) \leq \theta\}|$ denote the number of players with arrival time less than or equal to θ. Note that inequality $\sum_{i\in N} C_i(P) \leq \sum_{i\in N} C_i(P')$ can be equivalently written as $\sum_{\theta\in\mathbb{Z}_+}\left(N_\theta^P - N_{\theta-1}^P\right)\theta \leq \sum_{\theta\in\mathbb{Z}_+}\left(N_\theta^{P'} - N_{\theta-1}^{P'}\right)\theta$. Adding $(N_{\theta-1}^P - N_\theta^{P'})\theta$ on both sides of the inequality yields

$$\sum_{\theta\in\mathbb{Z}_+}\left(N_\theta^P - N_\theta^{P'}\right)\theta \leq \sum_{\theta\in\mathbb{Z}_+}\left(N_{\theta-1}^P - N_{\theta-1}^{P'}\right)\theta = \sum_{\theta\in\mathbb{Z}_+}\left(N_\theta^P - N_\theta^{P'}\right)\theta + \sum_{\theta\in\mathbb{Z}_+}\left(N_{\theta-1}^P - N_{\theta-1}^{P'}\right).$$

It follows that $\sum_{\theta\in\mathbb{Z}_+}\left(N_{\theta-1}^P - N_{\theta-1}^{P'}\right) \geq 0$. On the other hand, $N_{\theta-1}^P - N_{\theta-1}^{P'} \leq 0$ for all θ due to the earliest arrival property of P'. As a consequence, $N_\theta^P = N_\theta^{P'}$ for all θ. This completes the proof. ◀

We conclude that we can compute a social optimum via an adapted successive shortest path algorithm.

▶ **Proposition 2.6.** *A social optimum of a symmetric competitive packet routing instance is computable via an adapted version of the successive shortest path algorithm even for local priority lists.*

While this proposition shows that a socially optimal profile can be computed via a successive shortest path algorithm in symmetric games, we prove in Section 4 that the computational complexity of computing the social optimum or the socially optimal Nash equilibrium becomes APX-hard in non-symmetric games, even when restricted to global priority lists.

The following example shows that PNE do not necessarily exist even in very simple two-player games:

Table 1 The inefficiency of packet routing games with a global scheduling policy.

	Price of stability		Price of anarchy	
symmetric	1	Thm. 3.1	$\frac{n+1}{2}$	Thm. 3.2
multi-commodity	$\Omega(\sqrt{n})$	Prop. 3.3	$O(n^3)$	Prop. 3.4

▶ **Example 2.7.** Consider the network shown in Figure 2 with three vertices $V = \{s, u, t\}$, two parallel edges e_1, e_2 linking s and u, and one edge e_3 linking u and t, all edges of unit capacity and unit travel time. Suppose we are given two players, both with source s and sink t. Now, if the priorities are chosen such that player 1 has priority on the two s-leaving edges, i.e., $\pi_{e_1} = \pi_{e_2} = (1, 2)$, and player 2 has priority on the t-entering edge, i.e., $\pi_{e_3} = (2, 1)$, then the resulting packet routing game does not admit an equilibrium. In this game player 1 tries to choose the same path as player 2 and player 2 always chooses the free path. It follows that already this very simple two-player symmetric (i.e., single-source-single-sink) game does not admit an equilibrium.

We have seen that not all priority lists guarantee pure Nash equilibria in competitive packet routing games. However, for games with global priority lists a pure Nash equilibrium can be guaranteed to exist by adding players one by one according to the priority list, see Hoefer et al. [11].

Certainly, the social cost of a profile highly depends on the chosen priority lists $\pi_e, e \in E$. In the full version we show that the restriction to global priority lists might in fact lead to higher social cost and that this gap might be arbitrarily large.

3 Inefficiency of Nash equilibria

In this section, we examine the inefficiency of Nash equilibria. For the case of global priority lists, we find tight bounds for the PoS and PoA for symmetric games, a multi-commodity game with PoS in the order of $\sqrt{n}$ and an upper bound for the PoA in the multi-commodity case. An overview of the results for global priority lists is depicted in Table 1.

For local priority lists it turns out that it is much harder to find bounds on the price of anarchy and price of stability. We use a technique introduced in [3] and [16] to prove that the PoA is between $T/4$ and $4T^2$, where T is some kind of dilation of the graph.

3.1 Global Priority Lists

▶ **Theorem 3.1.** *In symmetric competitive packet routing games with global priorities, the price of stability is equal to 1.*

Proof. Consider a symmetric instance with global priority list π. Note that the choice of the priority list does not matter since all players have the same start and target node. Up to renaming, suppose $\pi = \{1, ..., n\}$. Observe that a social optimum P fulfills the earliest arrival property due to Lemma 2.5. Note that $C_i(P) \leq C_j(P)$ whenever $i \leq j$. For the sake of contradiction, suppose there exists at least one player with an improving move. Among all players with an improving move, we choose one of smallest index, say k. If k improves her strategy by switching from path P_k to P'_k, the arrival time of player k decreases, while the arrival time of players $\{1, ..., k-1\}$ stays the same. However, this is a contradiction to the fact that a socially optimal profile admits the earliest arrival property. ◀

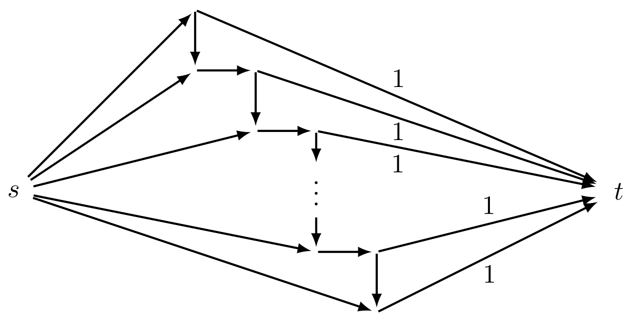

Figure 3 A game with price of anarchy equal to $(n+1)/2$.

Theorem 3.1 shows that there always exists a socially optimal Nash equilibrium, as long as we restrict to global priority lists and symmetric games. In the following, we show that the price of anarchy for this case is exactly $(n+1)/2$.

▶ **Theorem 3.2.** *For all symmetric competitive packet routing games with global priority lists and n players, the price of anarchy is upper bounded by $1 + (n-1)/2k$, this bound is tight for $k = 1$.*

Proof. We first prove the upper bound. Let $S = (S_1, \dots, S_n)$ be any Nash equilibrium. We start by showing that the cost of the Nash equilibrium S is at most

$$C(S) \le n \cdot k + \frac{n^2}{2} - \frac{n}{2},$$

for k being the length of a shortest $s-t$-path with respect to the travel times τ_e. Since $\sum_{i=1}^{n} (k + i - 1) = n \cdot k + n^2/2 - n/2$, it suffices to show that the arrival time of the i-th player in the priority list does not exceed $k + i - 1$ time units. Suppose this is not the case, i.e. there are players arriving later. Clearly, the first player in the priority list needs k time units. Now, let j be the player who is the first one arriving late in the order of the priority list. It follows that player j has the following improvement move: she can start at source s and follow player 1. If she has to wait at the entry of any edge, she follows the player entering the edge directly ahead of her. Player j can only be delayed by players arriving on time. By using this strategy she arrives at sink t at the latest one time unit after the last player being able to delay her. Hence, she can guarantee to reach sink t by time $k + i - 1$.

Observe that no player can arrive before time unit k. So, the cost of the optimal solution can be lower bounded by nk. This yields the following bound.

$$\text{PoA} \le \frac{C(S)}{C(\text{OPT})} \le \frac{n \cdot k + \frac{n^2}{2} - \frac{n}{2}}{nk} = \frac{k - \frac{1}{2} + \frac{n}{2}}{k} = 1 + \frac{(n-1)}{2k},$$

This completes the proof for the upper bound on the PoA and is well defined since $k \ge 1$.

For showing the tightness of the result, note that $1 + (n-1)/2k = (n+1)/2$ for $k = 1$. Now, consider the example depicted by the graph of Figure 3. This Braess-like graph topology has been used before to show lower bounds on the PoA in other settings, e.g. see [16]. The travel times τ_e are depicted next to the edges, where edges without label have $\tau_e = 0$. We define $u_e = 1$ for all edges $e \in E$. Note that there are n direct paths (i.e., those without vertical edges), each with travel time 1. Thus, in an optimal solution, all players pick a direct path, resulting in an arrival time of 1 for each player, and an optimal social cost of n. However, the profile in which all players use the path containing all vertical edges is a Nash equilibrium as

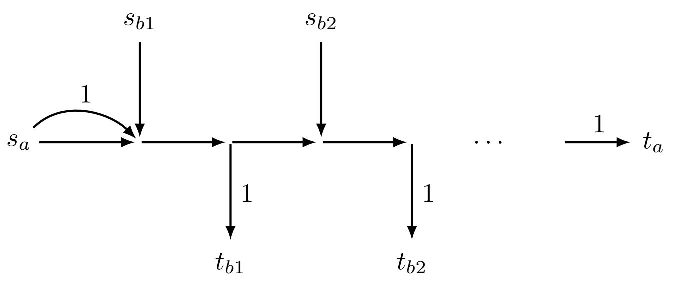

Figure 4 A game with price of stability in $\theta(\sqrt{n})$.

well. The i-th player in the order of the priority list arrives at time i and has no incentive to deviate, since there is no possible path she can use without waiting for all players of higher priority. Thus, there is a Nash equilibrium of social cost equal to $1 + 2 + \cdots + n = {n(n+1)}/{2}$. As a consequence, we obtain PoA $= \frac{n(n+1)}{2}/n = {(n+1)}/{2}$, which completes the proof. ◀

▶ Remark. Theorem 3.2 can be extended to networks with multiple sources and one sink.

For multi-commodity competitive packet routing games, earliest arrival flows do not necessarily exist [23]. It turns out that the price of stability might not even be constant in this more general setting. We provide an example where the price of stability is in $\theta(\sqrt{n})$.

▶ **Proposition 3.3.** *There is a multi-commodity competitive packet routing game with a global priority list and price of stability in $\theta(\sqrt{n})$.*

Proof. Consider the game illustrated by the graph in Figure 4. There are a players with source s_a and sink t_a, and b players each with individual source s_{bi} and sink t_{bi}, $i \in \{1, \dots, b\}$. All edges have unit capacity. The travel time is 0 if not depicted otherwise in Figure 4. We consider a global priority list in which all horizontal players have priority over the vertical players.

In the only Nash equilibrium, all horizontal players choose the direct path. Thus, their arrival times sum up to $\sum_{i=1}^{a} i$. The vertical players need to wait until all horizontal players have passed. Thus, their arrival times sum up to $b \cdot (a + 1)$. In an optimal solution, all horizontal players choose the longer path with the first edge of travel time 1. Therefore, their cost is $\sum_{i=1}^{a} i + 1$, while the cost of the vertical players decreases to b. Due to these considerations, the price of stability of this game can be expressed by

$$\text{PoS} = \frac{\frac{a^2}{2} + ba + b + \frac{a}{2}}{b + \frac{a^2}{2} + \frac{3a}{2}}.$$

If we replace b by $n - a$, we can differentiate the expression with respect to a. Taking the root we get $-2 + \sqrt{2n - 3}$. By substitution we get a price of stability which is in $\theta(\sqrt{n})$. ◀

In the following proposition, we give a bound on the price of anarchy by estimating the waiting times of the players. The proof can be found in the full version.

▶ **Proposition 3.4.** *The price of anarchy in a multi-commodity competitive packet routing game with a global priority list is upper bounded by $1 + {n^3}/{2} \in O(n^3)$.*

3.2 Local Priority Lists

All results presented so far deal with global priority lists. For local priority lists, we derive the following upper bound on the price of anarchy.

▶ **Theorem 3.5.** *In instances in which Nash equilibria exist, the price of anarchy is upper bounded by $4T^2$ for all priority lists, where $T = \max_{i\in N} \max_{P_j \in \mathcal{P}_i} \sum_{e\in P_j} \max\{\tau_e, 1\}$.*

In a related model of competitive routing games, Kulkarni and Mirrokni [16] prove a bound on the robust price of anarchy of $4D^2$, where D denotes the number of edges of the longest feasible path of any player. For the differences in the two models, see Section 1.2. Note that an instance of a competitive packet routing game, in the special case where no 0-travel times exist, can be fit into the model defined by Kulkarni and Mirrokni by replacing any edge of length τ_e by τ_e edges of length 1. After this procedure, the values T and D coincide.

In contrast to [16], our result holds for *arbitrary* local priority lists, whereas the result of [16] applies only to the *Highest-Density-First*-rule. Besides, our analysis turns out to be much simpler.

Proof. We start with the following preprocessing in order to ensure binary travel times and unit-capacities. For a given instance, we substitute each edge $e \in E$ of travel time $\tau_e > 1$ by τ_e-many edges of length one, each with the same priority lists $\pi(e)$. This results in an instance with travel times $\tau_e \in \{0,1\}$. Similar, we replace each edge of capacity $u_e > 1$ by u_e-many parallel edges of unit capacity. Now, consider the following linear program.

$$\begin{array}{lrcll}
\min & \sum_{i\in N}\sum_{P_j\in\mathcal{P}_i}\sum_{e\in P_j}\sum_{\theta\in\mathbb{Z}_+} x_{eij\theta}\cdot(\theta+\tau_e) & & & \\
\text{s.t.} & \sum_{P_j\in\mathcal{P}_i} x_{ij} & \geq & 1 & \forall i \in N\\
 & \sum_{\theta\in\mathbb{Z}_+} x_{eij\theta} & \geq & x_{ij} & \forall e\in E, i\in N, j: P_j\in\mathcal{P}_i\\
 & \sum_{i\in N}\sum_{P_j\in\mathcal{P}_i} x_{eij\theta} & \leq & 1 & \forall e\in E, \theta\in\mathbb{Z}_+\\
 & x_{ij}, x_{eij\theta} & \geq & 0 & \forall e\in E, \theta\in\mathbb{Z}_+, i\in N, j: P_j\in\mathcal{P}_i
\end{array}$$

We claim that the optimal LP-solution value is a T-approximation on the cost of a social optimum for the following reason. Given a socially optimal profile $P = (P_1, \dots, P_n)$ with completion times $C_i(P), i \in N$, assign $x_{ij} = 1$ if player i chooses path $P_j \in \mathcal{P}_i$, and $x_{ij} = 0$ otherwise. Furthermore, assign $x_{eij\theta} = 1$ if player i enters edge e on her selected path P_j at time step θ, and $x_{eij\theta} = 0$ otherwise. It is easy to check that this is a feasible solution for the LP. For bounding the objective function we consider $x_{eij\theta}\cdot\tau_e$ and $x_{eij\theta}\cdot\theta$ separately. Clearly, $x_{eij\theta}\cdot\theta \leq C_i(P)$ since a player has not yet arrived at her sink if she uses edge e. By definition of T, there are at most T edges on every path P_j. Additionally we consider $\min_{e,j,\theta}\{\theta | x_{eij\theta} = 1\}$ as the starting time of player i and get

$$\sum_{P_j\in\mathcal{P}_i}\sum_{e\in P_j}\sum_{\theta\in\mathbb{Z}_+} x_{eij\theta}\cdot\tau_e + \min_{e,j,\theta}\{\theta | x_{eij\theta}=1\} \leq C_i(P) \quad \text{and}$$

$$\sum_{P_j\in\mathcal{P}_i}\sum_{e\in P_j}\sum_{\theta\in\mathbb{Z}_+} x_{eij\theta}\cdot\theta - \min_{e,j,\theta}\{\theta | x_{eij\theta}=1\} \leq (T-1)C_i(P).$$

Thus, the optimal solution value of the LP is upper bounded by $\sum_{i\in N}(T-1)C_i(P)+C_i(P) = T\cdot\text{OPT}$, where $\text{OPT} = \sum_{i\in N} C_i(P)$ denotes the optimal social value of the competitive routing game.

Let us now modify the LP by dividing the right-hand side of the third constraint by $2T$. That is, we replace constraint $\sum_{i\in N}\sum_{P_j\in\mathcal{P}_i} x_{eij\theta} \leq 1$ by $\sum_{i\in N}\sum_{P_j\in\mathcal{P}_i} x_{eij\theta} \leq 1/2T$ for all $e \in E, \theta \in \mathbb{Z}_+$. Let LP^* denote the optimal objective value of the modified LP. By scaling the $x_{eij\theta}$ variables of the LP-solution as described above by $1/2T$ and repeating the original solution $2T$ times, we achieve a feasible solution for the modified LP which loses a factor of at most $2T$ in the objective compared to the prior solution. Hence, the modified LP is a $2T^2$-approximation on the cost of a socially optimal profile. That is, $LP^* \leq 2T^2 \cdot \mathrm{OPT}$.

In the remainder of the proof, we show that even the worst PNE has a social cost of at most $2 \cdot LP^*$ yielding the desired bound of $4T^2$ on the price of anarchy. Consider the dual of the modified LP:

$$\begin{array}{rrcll}
\max & \displaystyle\sum_{i\in N} \alpha_i - \frac{1}{2T}\sum_{e\in E}\sum_{\theta\in\mathbb{Z}_+}\beta_{e\theta} & & & \\
\text{s.t.} & \displaystyle\alpha_i - \sum_{e\in P_j}\nu_{eij} & \leq & 0 & \forall i \in N, j : P_j \in \mathcal{P}_i \\
& \nu_{eij} - \beta_{e\theta} & \leq & \theta + \tau_e & \forall e \in E, i \in N, j : P_j \in \mathcal{P}_i, \theta \in \mathbb{Z}_+ \\
& \alpha_i, \beta_{e\theta}, \nu_{eij} & \geq & 0 & \forall e \in E, i \in N, j : P_j \in \mathcal{P}_i, \theta \in \mathbb{Z}_+
\end{array}$$

By weak linear programming duality, we know that any feasible dual solution has objective value at most LP^*. It suffices to show that any pure Nash equilibrium $\bar{P}$ induces a feasible dual solution of objective value $1/2 \sum_{i\in N} C_i(\bar{P})$.

Let $\bar{P} = (\bar{P}_1, \dots, \bar{P}_n)$ be any PNE. Define a dual solution $\bar{\alpha}, \bar{\beta}, \bar{\nu}$ as follows. For each $i \in N$ let $\bar{\alpha}_i = C_i(\bar{P})$. Furthermore, for each $\theta \in \mathbb{Z}_+$ and $e \in E$, let $\bar{\beta}_{e\theta} = |\{i \in N \mid e \in \bar{P}_i,\ \theta \leq C_i(\bar{P})\}|$ denote the number of players who have not yet arrived at their sink at time θ under profile $\bar{P}$. Finally, let $\bar{\nu}_{eij} = \tau_e + w_{ie}(P_j, \bar{P}_{-i})$ denote the waiting time at the entry of e plus the traversing time τ_e in case player i switches from strategy $\bar{P}_i$ to P_j. Note that the first dual constraint is easily seen to be satisfied by this definition of the dual variables, since $\bar{\alpha}_i - \sum_{e\in P_j}\bar{\nu}_{eij} \leq 0$ is equivalent to $C_i(\bar{P}) \leq \sum_{e\in P_j}(\tau_e + w_{ie}(P_j, \bar{P}_{-i})) = C_i(P_j, \bar{P}_{-i})$, which follows by the definition of PNE. The second constraint $\bar{\nu}_{eij} - \bar{\beta}_{e\theta} \leq \theta + \tau_e$ can equivalently be written as $w_{ie}(P_j, \bar{P}_{-i}) \leq \theta + \bar{\beta}_{e\theta}$ which is certainly satisfied, since at each time step θ, any player i, after switching from $\bar{P}_i$ to path P_j, will never wait at the entry of any edge e longer than θ plus the total number of players which have not yet arrived at their sink at time θ. This concludes the proof. ◀

▶ Remark. We get an example with price of anarchy $T/4$ from the proof of Theorem 3.2.

▶ Remark. Since our proof goes along the same lines as the primal-dual proof technique of Kulkarni and Mirrokni [16], it is not hard to verify that our results also hold for coarse-correlated equilibria, which are guaranteed to exist. This includes the case of correlated equilibria and mixed Nash equilibria, see [22].

4 Computational Complexity

The problem to design either local or global priority lists to minimize the cost of a social optimum, or the cost of any Nash equilibrium, turns out to be APX-hard.

▶ **Theorem 4.1.** *Even in graphs that form a tree, i.e. every player has a pre-defined strategy, designing priority lists that minimize the social cost or the cost of a Nash equilibrium is APX-hard both in the case of global or local priority lists.*

Proof (Sketch). We describe the main ideas of the proof. More details can be found in the full version. Assume we are given an instance of 3-OCCURRENCE-MAX-3-SAT, i.e. a maximum satisfiability problem with n variables, each of which occuring at most 3 times, together with m clauses where each clause contains exactly 3 variables. Inspired by [21], we define an instance of a competitive packet routing game as follows. We design a tree graph with 8 players per variable and 3 players per clause such that the sum of the arrival times is equal to $34n + 6m + \#(\text{unsatisfied clauses})$. For each variable we introduce 4 variable-players and 4 dummy-players. The variable-players correspond to either the first or second occurrence of this variable, as a positive or negative literal, respectively. These players share an edge with one of the corresponding clause-players if the variable is the first or second occurrence of this variable as a positive or negative literal in the clause. The scheduling policies of the (fixed) starting edges of these players decode the variable assignment of the satisfiability problem. The 4 dummy-players per variable guarantee that the two players corresponding to the positive or negative occurrences leave at the same time, respectively. With this idea, we can decode the variable assignment in the satisfiability problem. We design the network and the travel times in such a way, that exactly one clause player and variable player meet, i.e. impose a waiting time of 1, if and only if the clause is not fulfilled by any variable. Thus maximizing the number of satisfied clauses in the satisfiability problem is equivalent to minimizing the social cost in the competitive routing instance. Since 3-OCCURRENCE-MAX-3-SAT is APX-hard (see [19, 20]), we derive APX-hardness for our problem. The variable-players and the topology of the graph are the same as in [21]. Due to the different objective function, we need to introduce the dummy players with their paths and conduct a different analysis. ◀

For computing best responses and Nash equilibria, the complexity status highly depends on the chosen priority list.

▶ **Proposition 4.2.** *In competitive packet routing games with local priority lists it is NP-hard to compute a best response for a player, even in the symmetric setting. Moreover, given a game with local priority lists, it is NP-hard to compute a Nash equilibrium if one exists.*

The proof of this proposition is based on a proof of [11]. The difference is that Hoefer et al. use the FIFO policy with a global tie breaking rule, where we use local priority policies. Their model allows to schedule a player with lower priority before another player by slight perturbation of the travel times. This does not work in our model due to the integral time steps and integral travel times, so we use local priority policies. In order to show the hardness for computing Nash equilibria we had to modify the graph and introduce an exclusive start-node for every player.

The following observation shows that we can compute best-responses and a Nash equilibrium in games with global priority policies. The main idea is to use a Dijkstra-like algorithm and the fact, that a player is never influenced by players with a lower priority. This idea has also been used in [11]. The proofs are obtained by extending the proofs of [11] step-by-step to edges with 0-travel times. We refer to the full version for further details.

▶ **Observation 4.3.** *For games with global priority policies there is a polynomial time algorithm to compute a Nash equilibrium and a best response of any given player.*

Abstract

We study the following natural variant of the budgeted maximum coverage problem: We are given a budget B and a hypergraph $G = (V, E)$, where each vertex has a non-negative cost and a non-negative profit. The goal is to select a set of hyperedges $T \subseteq E$ such that the total cost of the vertices covered by T is at most B and the total profit of all covered vertices is maximized. Besides being a natural generalization of the well-studied maximum coverage problem, our motivation for investigating this problem originates from its application in the context of bid optimization in sponsored search auctions, such as Google AdWords.

It is easily seen that this problem is strictly harder than budgeted max coverage, which means that the problem is $(1 - 1/e)$-inapproximable. The difference of our problem to the budgeted maximum coverage problem is that the costs are associated with the covered vertices instead of the selected hyperedges. As it turns out, this difference refutes the applicability of standard greedy approaches which are used to obtain constant factor approximation algorithms for several other variants of the maximum coverage problem. Our main results are as follows:

- We obtain a $(1 - 1/\sqrt{e})/2$-approximation algorithm for graphs.
- We derive a fully polynomial-time approximation scheme (FPTAS) if the incidence graph of the hypergraph is a forest (i.e., the hypergraph is *Berge-acyclic*). We also extend this result to incidence graphs with a fixed-size feedback hyperedge node set.
- We give a $(1 - \varepsilon)/(2d^2)$-approximation algorithm for every $\varepsilon > 0$, where d is the maximum degree of a vertex in the hypergraph.

1 Introduction

In the *budgeted maximum coverage problem* we are given a hypergraph $G = (V, E)$ with a non-negative cost $c(e) \in \mathbb{R}_{\geq 0}$ for every hyperedge $e \in E$ and a non-negative profit $p(i) \in \mathbb{R}_{\geq 0}$

for every vertex $i \in V$, and a non-negative budget $B \in \mathbb{R}_{\geq 0}$. The goal is to select a set of hyperedges $T \subseteq E$ whose total cost is at most B such that the total profit of all vertices covered by the hyperedges in T is maximized.

This is a fundamental combinatorial optimization problem with many applications in resource allocation, job scheduling and facility location (see, e.g., [6] for examples). Feige [4] showed that this problem is not polynomial-time approximable within a factor of $(1 - 1/e)$ unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log \log n)})$, even if all hyperedges have unit cost. Khuller, Moss and Naor [9] derived a $(1 - 1/e)$-approximation algorithm for the budgeted maximum coverage problem (which is the best possible). Their algorithms are based on a natural greedy approach in combination with a standard enumeration technique. Similar approaches were used to derive constant factor approximation algorithms for several other variants and generalizations of the maximum coverage problem.

In this paper, we study the following natural variant of the budgeted maximum coverage problem, which we call the *ground-set-cost budgeted maximum coverage problem (GBMC)*: We are given a hypergraph $G = (V, E)$ with a non-negative cost $c(i) \in \mathbb{R}_{\geq 0}$ and a non-negative profit $p(i) \in \mathbb{R}_{\geq 0}$ for every vertex $i \in V$, and a non-negative budget $B \in \mathbb{R}_{\geq 0}$. For a subset $T \subseteq E$, define $c(T) = \sum_{i \in \cup T} c(i)$ and $p(T) = \sum_{i \in \cup T} p(i)$ as the total cost and profit, respectively, of all vertices covered by the hyperedges in T.[1] Our goal is to select a set of hyperedges $T \subseteq E$ such that the total cost $c(T)$ of all covered vertices is at most B and the total profit $p(T)$ of all covered vertices is maximized. To the best of our knowledge, this problem has not been studied before.

Note that a crucial difference here is that in our problem costs are incurred per covered vertex, while in the budgeted maximum coverage problem costs are incurred per selected hyperedge. Albeit seemingly minor, this change makes the problem much harder to tackle algorithmically. More specifically, most greedy approaches (which give rise to constant factor approximation guarantees for several variants of the maximum coverage problem) turn out to be inapplicable in our setting because of the following reason: The basic idea underlying these greedy approaches is to select in each iteration a hyperedge that is most *cost-efficient*, i.e., maximizes the ratio of the profit of newly covered vertices over the cost of selecting the hyperedge. A property that is crucially exploited in the analysis of these algorithms is that the cost for selecting a hyperedge is constant, i.e., its cost-efficiency can only decrease throughout the course of the algorithm (as more of its vertices get covered). However, this monotonicity property is no longer guaranteed in our setting because the cost for picking a hyperedge depends on the set of already covered vertices. In fact, it is not hard to see that the cost-efficiency of a hyperedge can change arbitrarily from one iteration to the next.

Our motivation for investigating the vertex-cost budgeted maximum coverage problem is two-fold: (i) It is a generalization of the well-studied maximum coverage problem and a natural variant of the budgeted maximum coverage problem. (ii) It is a fundamental combinatorial optimization problem having several applications in practice. Of particular importance is its relation to the problem of computing optimal bids in sponsored search auctions such as Google AdWords (details will be given in the full version of the paper).

Our contributions

The contributions presented in this paper are as follows:

1. We obtain a $(1 - 1/\sqrt{e})/2$-approximation algorithm for graphs (Sections 2 and 3).

[1] Throughout this paper, for a collection of sets F we write $\cup F$ to refer to the set $\cup_{S \in F} S$.

The main idea here is to reduce this problem to the budgeted maximum coverage problem with an exponential number of hyperedges. However, we do not need to generate the exponentially large instance explicitly; but instead we make use of a concise representation of the instance and show that such instances can be approximated in polynomial time, given that we have access to an oracle that can select in polynomial time a hyperedge with approximately highest profit per unit of cost. As a last step in our reduction, we prove that such an oracle exists.

2. We derive in Section 5 a pseudo-polynomial time algorithm for the case when the incidence graph of the hypergraph is a forest (i.e., the hypergraph is *Berge-acyclic*). Further, we adapt this algorithm into a fully polynomial-time approximation scheme (FPTAS).
   At the core of this algorithm lies a bi-level dynamic program. The case of forests is important in its own right and, additionally, this algorithm constitutes an important building block of our $O(1/d^2)$-approximation algorithm (see Contribution 4).
3. In Section 6, we extend the above algorithm to a pseudo-polynomial time algorithm for incidence graphs with a bounded set of nodes that covers all cycles (i.e., the general case, but parametrized).
   More specifically, we show that for any incidence graph with a fixed-size *feedback hyperedge node set*, i.e., a hyperedge node set such that removing it from the incidence graph leaves no cycles, there exists a pseudo-polynomial time algorithm for the GBMC problem.
4. We give a $(1-\varepsilon)/(2d^2)$-approximation algorithm for every $\varepsilon > 0$ for the general case, where d is the maximum degree of a vertex in the hypergraph (Section 4).
   In this algorithm, we first decompose the incidence graph of the hypergraph into a collection of at most d trees for which we compute an approximate solution by using our FPTAS for forests above. From this we then extract a solution that is feasible for the original instance and guarantees an approximation ratio of at least $(1-\varepsilon)/(2d^2)$.

Related work

Much literature is available on the maximum coverage problem and its variants (see, e.g., [1, 3, 9] and the references therein). Most related to our problem is the budgeted maximum coverage problem [9]. As outlined above, the greedy approach of [9] cannot take into account that the costs are incurred per vertex instead of per set. Moreover, in [3], a generalized version of the budgeted maximum coverage problem is studied, but this generalization does not include GBMC as a special case.

Note that our GBMC problem on graphs reduces to the knapsack problem if the incidence graph is a matching. This problem is known to be weakly NP-hard and admits an FPTAS (see, e.g., [8]).

Our GBMC problem is related to the *budgeted bid optimization problem*. This problem was first proposed in the paper by Feldman et al. [5]. The authors derive a $(1-1/e)$-approximation algorithm if the budget constraint is *soft*, i.e., has to be met in expectation only. In contrast, in the budgeted bid optimization problem considered here, this budget constraint is hard.

The GBMC problem can be seen as a special case of a more general set of problems where we have to maximize a submodular profit function subject to the constraint that a submodular cost function does not exceed a given budget. This can be seen by considering the set of hyperedges to be the ground set of the submodular functions. However, when we have oracle access to both submodular functions, it has been shown that this more general problem is not approximable within a factor of $\log(m)/\sqrt{m}$, where m is the number of elements in the ground set. This holds even for the special case that the objective function is the modular function that returns the cardinality of the set. This follows from Theorem 4.2 in [10]; see also [7].

Preliminaries

For an integer $a \in \mathbb{N}$, we write $[a]$ and $[a]_0$ to denote the sets $\{1, \dots, a\}$ and $\{0, 1, \dots, a\}$ respectively. When F is a family of sets, we write $\bigcup F$ to denote the set $\bigcup_{S \in F} S$.

Let $G = (V, E)$ be a hypergraph. The *incidence graph* $I(G)$ of G is defined as the bipartite graph $I(G) = (E \cup V, H)$ with $H = \{\{e, v\} \mid v \in e\}$. We say that G is *acyclic* if its incidence graph $I(G)$ does not contain a cycle. Given a subset $E' \subseteq E$, we use $G[E']$ to refer to the *subgraph* of G induced by the hyperedges in E', i.e., $G[E'] = (V', E')$ with $V' = \cup E'$. A hypergraph T is called a *subtree* of G if T is a subgraph of G that is acyclic.

Throughout this paper we will use the convention that when discussing a hypergraph, n denotes the number of vertices of the hypergraph and m denotes the number of hyperedges of the hypergraph. Moreover, in the remainder of this paper, we assume without loss of generality that all costs (on the nodes or edges) are strictly positive.

It is not hard to prove that GBMC cannot be approximated to within a factor of $(1-1/e)$ in polynomial time, unless $\mathsf{NP} \subseteq \mathsf{DTIME}(n^{O(\log\log n)})$ (details will be provided in the full version of the paper).

Due to space limitations, some figures and technical content is omitted from this paper and will be provided in the full version.

2 Budgeted Maximum Coverage with Oracles

In this section we first consider the classical budgeted maximum coverage problem. The result presented in this section will serve as a building block in the approximation algorithm presented in the next section, for solving GBMC on graphs.

A polynomial-time $(1-1/e)$-approximation algorithm for the budgeted maximum coverage problem was previously given in [9]. In the same paper, various simpler algorithms with worse approximation factors are presented. In this section, we present a variation of one of these algorithms that achieves a $(1 - 1/e)/2$-approximation guarantee, which can run even if the algorithm is not granted direct access to the input instance. We make this precise in the following definition.

▶ **Definition 1** (cost-efficiency oracle)**.** Let $I = (G = (V, E), c, p, B)$ be an instance of the budgeted maximum coverage problem, i.e., $G = (V, E)$ is a hypergraph, $c : E \to \mathbb{Q}_{\geq 0}$ is a function that specifies a cost $c(e)$ for each hyperedge $e \in E$, $p : V \to \mathbb{Q}$ is a function that specifies a profit $p(i)$ for each vertex $i \in V$, with $B \in \mathbb{Q}$ the budget. For $\alpha \in [0, 1]$, an *α-approximate cost-efficiency oracle* for I is a function $f_I : 2^V \to E$ that maps a set of vertices $S \subseteq V$ to a hyperedge $e \in E$ such that $c(e) \leq B$ and

$$\sum_{i \in e \setminus S} \frac{p(i)}{c(e)} \geq \alpha \cdot \sum_{i \in e' \setminus S} \frac{p(i)}{c(e')}.$$

for all $e' \in E$ with $c(e') \leq B$. Thus, a cost-efficiency oracle takes as input vertex set S and selects the hyperedge with the approximately highest cost-efficiency (up to a factor α), excluding the profit that would be contributed by vertices in S. Only hyperedges of which the cost does not exceed the budget are considered.

Let $I = (G = (V, E), c, p, B)$ be an instance of the budgeted maximum coverage problem, and let f_I be an α-approximate cost-efficiency oracle for this instance for some $\alpha \in (0, 1]$.

Consider now the following greedy algorithm $\mathcal{A}$ that takes as input only the cost-efficiency oracle f_I.

1. Set $S := \varnothing$ and $X := \varnothing$. Throughout the execution of the algorithm, X represents a feasible solution and S represents the set of vertices covered by X.
2. Let $e := f_I(S)$. If $S = V$ (i.e., there is no profitable hyperedge left) or if $c(e) + \sum_{e' \in X} c(e') > B$ (i.e., adding the hyperedge to X would exceed the budget), go to Step 3. Otherwise, set $X := X \cup \{e\}$, set $S = \bigcup X$, and repeat this step.
3. Output the solution with the highest total profit among the two solutions X and $\{e\}$.

▶ **Theorem 2.** *Algorithm $\mathcal{A}$ outputs an $(1 - 1/e^{\alpha})/2$-approximate solution to I in time $O(n \cdot t)$, where t is the amount of time it takes to evaluate f_I.*

The approximation factor is obtained by following rather closely the analysis given in [9] for a similar algorithm (that works without oracle access).

3 GBMC on Graphs

In this section, we present a $(1 - 1/\sqrt{e})/2$-approximation algorithm for the GBMC problem when the hypergraph is a graph. We do this by reducing the problem to the budgeted maximum coverage problem. An instance I of GBMC is reduced to an instance $r(I)$ of budgeted maximum coverage on the same set of vertices, such that the optimal solution of $r(I)$ has the same profit as the optimal solution of I. The instance $r(I)$ may have a superpolynomial number of hyperedges. However, instead of generating the budgeted maximum coverage instance explicitly, we construct only a 1/2-approximate cost-efficiency oracle $f_{r(I)}$ for $r(I)$. We then use Algorithm $\mathcal{A}$ on $f_{r(I)}$ in order to obtain a $(1 - 1/\sqrt{e})/2$-approximately optimal solution to $r(I)$ in polynomial time. Last, we show how to transform in polynomial time a feasible solution for $r(I)$ into a feasible solution for I with equal profit.

We begin by defining our reduction r.

▶ **Definition 3.** Let $I = (G = (V, E), c, p, B)$ be an instance of GBMC where G is a graph. Define the budgeted maximum coverage instance $r(I)$ as $r(I) = (G' = (V, E'), c', p, B)$, where

$$E' = \bigcup_{i \in V} E'_i \qquad \text{and} \qquad E'_i = \{S \cup \{i\} \mid \forall i' \in S : \{i', i\} \in E\},$$

that is, E'_i consists of the hyperedges X such that i is in X and all other vertices in X are connected to i by an edge. In other words, E' are all hyperedges corresponding to the stars of G. The cost function c' assigns a cost to each *hyperedge*: for a hyperedge $e \in E'$ we set $c'(e) = \sum_{i \in e} c(i)$. Note that c is a function that assigns a cost to each *vertex*, while c' is a function that assigns a cost to each *hyperedge in E'*. Note that the vertex sets, profit functions, and budgets of I and $r(I)$ are equal.

We first show that every feasible solution X' for $r(I)$ can be transformed into a feasible solution X for I in polynomial time such that the profit is preserved. Consider the following function g_I that maps solutions of $r(I)$ to I:

▶ **Definition 4.** Let $I = (G = (V, E), c, p, B)$ be an instance of GBMC and let X' be a feasible solution for $r(I) = (G' = (V, E'), c', p, B)$. The function g_I maps X' to the following solution for I.

$$g_I(X') = \left\{ \{i', i\} \in E \middle| \{i', i\} \in \bigcup X \right\}.$$

In words, $g_I(X')$ is the set of edges of G that are contained in a hyperedge of X'.

▶ **Lemma 5.** *Let X' be a feasible solution for $r(I)$. The edge set $g_I(X')$ is computable in time $O(mn|X'|)$. Moreover, the solution $g_I(X')$ is feasible (i.e., the total cost of all vertices covered by $g_I(X')$ does not exceed B). Also, $p(X') = p(g_I(X'))$.*

Proof. For the first claim, observe that for each hyperedge in X' and edge in E we need to check if that edge is contained in the hyperedge. This can be done in $O(n)$ time.

The second claim follows from the fact that the edge set $g_I(X')$ covers the same vertex set as X', and by definition

$$B \geq \sum_{e \in X'} c'(e) = \sum_{i \in \bigcup X'} c(i) \cdot |\{e \in X' : i \in e\}| \geq \sum_{i \in \bigcup X'} c(i) = \sum_{i \in \bigcup X'} c(i).$$

The third claim follows from the fact that the edge set $g_I(X')$ covers the same vertex set as X'. ◀

Next we show that the optimal solution for I is at most the profit of the optimal solution for $r(I)$. (Combined with the previous lemma, this entails that the optimal profits of I and $r(I)$ are equal.)

▶ **Lemma 6.** *Let p_{opt} be the maximum profit achievable in instance I. There exists a solution for $r(I)$ with profit p_{opt}.*

Proof. Let X be a profit-maximizing feasible solution for I. Assume without loss of generality that all paths in X are of size at most 2. In other words: no edge in X covers two vertices that are both covered by another edge (such an edge can be removed from X without decreasing the profit). Under this assumption, X is a set of stars. We construct from X a feasible solution X' for $r(I)$ that has the same profit, as follows. We define X' to be the collection of hyperedges that correspond to the maximal stars of X, i.e., for each maximal star of X, we add to X' the hyperedge consisting of the vertices covered by the star.

Since no pair of hyperedges in X' intersects, by definition of c' the total cost $\sum_{e \in X'} c'(e)$ equals $\sum_{i \in \bigcup X} c(i) < B$, and therefore X' is a feasible solution for $r(I)$. Moreover, X' and X cover the same set of vertices, and therefore profits of X in I equals the profit of X' in $r(I)$. ◀

A final ingredient that we need is a 1/2-approximate cost-efficiency oracle f for $r(I)$.

▶ **Definition 7.** We define the function f algorithmically as follows. Let S be the input argument to f. (As a reminder, S represents the set of vertices already covered during the execution of algorithm $\mathcal{A}$.) The high level idea is that we compute for each vertex i a set of vertices e_i in the star centered at i. Our goal for each of these stars is to select for each such i the substar with the (approximately) highest possible cost-efficiency, such that the cost of the vertices in the substar does not exceed the budget. We output the set in $\{e_i : i \in V\}$ that has the highest cost-efficiency.

1. Let V' be subset of vertices of V that have at least one neighbor not in S. For each $i \in V'$ (note that i itself may be in S):
   - **a.** Initialize $e_i := \{i\}$, and $d_i = c(i)$. If $i \in S$, set $n_i := 0$, and otherwise set $n_i := p(i)$.
   - **b.** Order non-increasingly the vertices i' that are not in S and are attached to i in graph G, according to ratio $p(i')/c(i')$. Denote this ordering by σ_i.
   - **c.** Let i' be the next vertex of σ_i (starting with the first vertex). If $(n_i+p(i'))/(d_i+c(i')) \geq n_i/d_i$, then add i' to e_i, set $n_i := n_i+p(i')$, and set $d_i := d_i+c(i')$, and repeat this step in case the total cost of e_i does not exceed B. Otherwise, if $(n_i+p(i'))/(d_i+c(i')) < n_i/d_i$ or if e_i exceeds the budget, stop iterating this step.

d. If the total cost of e_i lies within the budget, skip this step. Otherwise, let i' be the vertex last added in the previous step (i.e., the vertex in e_i with the least $p(i')/c(i')$). We consider two substars of e_i that are within the budget: The one consisting only of vertices i and i', and the one consisting of vertices $e_i \setminus \{i'\}$. We set e_i to be the substar with the highest cost-efficiency. Formally:

i. If $i \notin S$: if $(p(i)+p(i'))/(c(i)+c(i')) \geq (n_i - p(i'))/(d_i - p(i'))$ then set $e_i = \{i, i'\}$, $n_i := p(i)+p(i')$, and $d_i := c(i)+c(i')$. Otherwise set $e_i := e_i \setminus \{i'\}$, $n_i := n_i - p(i')$, and $d_i := d_i - c(i')$.

ii. If $i \in S$: if $p(i')/(c(i)+c(i')) \geq (n_i - p(i'))/(d_i - p(i'))$ then set $e_i := \{i, i'\}$, $n_i := p(i')$, and $d_i := c(i)+c(i')$ otherwise set $e_i := e_i \setminus \{i'\}$, $n_i := n_i - p(i')$, and $d_i := d_i - c(i')$.

2. Output the set in $\{e_i : |e_i| \geq 2 \wedge i \in V'\}$ with the highest cost-efficiency (i.e., the ratio n_i/d_i).

▶ **Lemma 8.** *The function f is a $1/2$-approximate cost-efficiency oracle for $r(I)$ and can be computed in time $O(n^2)$.*

Proof. It is easy to see that the set output by f is always a hyperedge in E', as it only outputs sets of hyperedges that correspond to stars of G. Moreover, in the last step, it is easy to verify that the set $\{e_i : |e_i| \geq 2 \wedge i \in V'\}$ is never empty when $S \neq V$. This implies that f is a valid cost-efficiency oracle. From the description of the algorithm above, it is also straightforward to see that f runs in time n^2: For each vertex, all neighbors are considered, where processing each neighbor takes a constant amount of time. (Not taking into account the bit-complexity of the arithmetic operations in this analysis, although the runtime would remain polynomial if we would take this aspect into account.)

What still needs to be proved is the approximation factor. Let $e_1, e_2, \ldots$ be the sets used in Step 2 of the algorithm. It suffices to show that for each $i \in V'$ for which it holds that $|e_i| \geq 2$, the ratio n_i/d_i is at least $(1/2) \cdot \sum_{i \in e' \setminus S} p(i)/c(e')$ for all $e' \in E'_i$. In words, the cost-efficiency n_i/d_i of the set e_i is at least half the maximum cost-efficiency among all hyperedges in E'_i (with respect to the input set S). (Note that we need not consider those $i \in V'$ for which $|e_i| = 1$: It can be easily verified that in this case, the optimal star centered at i is a single edge $\{i, i'\}$. This edge is also in $E'_{i'}$, and it is necessarily true that $|e'_i| \geq 2$.)

Let $i \in V'$ such that $|e_i| \geq 2$. Denote by $\Gamma(i)$ the vertices attached to i that are not in S. We will compare $|e_i|$ to an optimal *fractional* solution x: In this fractional solution each of the vertices i' attached to i (and not in S) is picked with a certain fraction $x_{i'} \in [0, 1]$, and vertex i is selected with fraction $x_i = 1$. The cost-efficiency is defined as $\frac{p(i)+\sum_{i' \in \Gamma(S)} x_{i'} p(i')}{\sum_{i' \in \Gamma(S)} x'_i c(i')}$ if $i \notin S$, and otherwise as $\frac{\sum_{i' \in \Gamma(S)} x_{i'} p(i')}{\sum_{i' \in \Gamma(S)} x'_i c(i')}$. Then it holds that the cost-efficiency of e_i^{frac} exceeds the cost-efficiency of the hyperedge $e_i^* \in E'_i$ that maximizes $\sum_{i \in e^* \setminus S} p(i)/c(e^*)$, which would be the optimal integral solution.

We claim that x is obtained by greedily selecting vertices in $\Gamma(i)$ according to non-increasing cost-efficiency (i.e., according to the order σ_i as given in Definition 7). A considered vertex is selected with the highest possible fraction as long as the budget is not exceeded, and as long as adding the vertex increases the cost-efficiency of the solution. Hence, in x all vertices of $\Gamma(i)$ are selected with either fraction 0 or 1, except at most one vertex, which is selected with a fraction in $(0, 1)$.

To see why this is true, suppose for contradiction that x has a different structure. In that case, if there is a vertex $i' \in \Gamma(i)$ with $x_{i'} > 0$ such that the cost-efficiency of i' is less than the cost-efficiency of x, then setting $x_{i'}$ to 0 will increase the cost-efficiency of the solution. Therefore, we may assume that the only vertices that are selected with a positive fraction, are vertices that have a cost-efficiency of at least the cost-efficiency of x. We can then consider the following operation: There must be two vertices $i', i'' \in \Gamma(i)$ for which it holds that $x_i' < 1$, $x_i'' > 0$, and the cost-efficiency of i' exceeds that of i''. In that case, decreasing $x_{i''}$ by an amount ϵ and increasing $x_{i'}$ by a maximal amount would increase the cost-efficiency (for a suitably small choice of ϵ), which is a contradiction to x being optimal. This shows that x is obtained by the aforementioned greedy procedure.

Next, we observe that if x happens to be integral, then the set of integrally selected vertices is precisely e_i, which means that e_i is the vertex set that maximizes the cost-efficiency. In this case the claim is proved. We now consider the case that x is not integral. From now on, let i' be the vertex that is fractionally selected in x and let S' be the integral vertices of x excluding i, i.e., $S' = \{i'' : i'' \neq i \wedge x_{i''} = 1\}$. It follows from Definition 7 that e_i is either the set $\{i\} \cup S$ or the set $\{i, i'\}$.

We distinguish four (very similar) subcases.

- We first consider the case that $i \notin S$ and $p(i') \geq \sum_{i'' \in S'} p(i'')$. Because x is the optimal fractional solution, the cost-efficiency of $S' \cup i, i'$ exceeds the optimal fractional solution and thus also the cost-efficiency of the optimal hyperedge e_i^*. Therefore, we conclude that the cost-efficiency of e_i is at least

$$\frac{p(i) + p(i')}{c(i) + c(i')} \geq \frac{p(i) + p(i')}{c(i) + c(i') + \sum_{i'' \in S'} c(i'')} \geq \frac{1}{2} \cdot \frac{p(i) + p(i') + \sum_{i'' \in S'} c(i'')}{c(i) + c(i') + \sum_{i'' \in S'} c(i'')}$$
$$\geq \frac{1}{2} \cdot \frac{\sum_{i'' \in e_i^*} p(i)}{\sum_{i'' \in e_i^*} c(i)},$$

as needed.

- In case $i \notin S$ and $p(i') < \sum_{i'' \in S'} p(i'')$ we similarly obtain that the cost-efficiency of e_i is at least

$$\frac{p(i) + \sum_{i' \in S'} p(i'')}{c(i) + \sum_{i'' \in S'} c(i'')} \geq \frac{p(i) + \sum_{i'' \in S'} p(i'')}{c(i) + c(i') + \sum_{i'' \in S'} c(i'')} \geq \frac{1}{2} \cdot \frac{p(i) + p(i') + \sum_{i'' \in S'} c(i'')}{c(i) + c(i') + \sum_{i'' \in S'} c(i'')}$$
$$\geq \frac{1}{2} \cdot \frac{\sum_{i'' \in e_i^*} p(i)}{\sum_{i'' \in e_i^*} c(i)}.$$

- The remaining two cases are analogous to the above two, where we replace $p(i)$ with 0.

◀

We are now ready to present the algorithm for GBMC on graphs, which we refer to as Algorithm $\mathcal{B}$. The algorithm is defined as follows. Let $I = (G = (V, E), c, p, B)$ be an input instance of GBMC where G is a graph.

- Run algorithm $\mathcal{A}$ on the 1/2-approximate cost-efficiency oracle f of Definition 7. This results in a solution X' for instance $r(I)$ (where $r(I)$ is given in Definition 3).
- Compute and output $g_I(X')$ (see Definition 4).

The correctness, polynomial runtime, and approximation factor of $(1 - 1/\sqrt{e})/2$ of algorithm $\mathcal{B}$ follow directly from the lemmas and definitions above. Note that the bound on the runtime can most likely be improved by a more careful analysis, but that is beyond the scope and goal of this work.

4 GBMC with bounded degree vertices

In this section we derive an approximation algorithm for GBMC for arbitrary hypergraphs $G = (V, E)$ with approximation ratio of $\mathcal{O}(1/d^2)$, where d refers to the maximum *frequency* of a node in a decomposition of G into trees. We first define formally the notions of *trees of hypergraphs*, and *frequency*.

A *tree of a hypergraph* G is defined as a partial hypergraph (i.e., a hypergraph that can be obtained by removing from each hyperedge a set of vertices) of which the incidence graph is a tree (i.e., a partial hypergraph that is *Berge-acyclic*). A *decomposition of a hypergraph* G *into trees* is a collection of trees of G such that (i) the incidence graphs of any two trees in the collection have disjoint edge sets, and (ii) the union of the incidence graphs of these trees equals the incidence graph of G. For a node $i \in V$, define the *frequency* d_i of i with respect to the tree collection $\mathcal{T}$ as the number of times i occurs in a tree of the collection, i.e., $d_i = |\{T_t \in \mathcal{T} \mid i \in V_t\}|$. Let the *maximum frequency* of a tree collection $\mathcal{T}$ be defined as $d = \max_{i \in V} d_i$. Therefore, in the worst case, d is the maximum degree of a node, as we can always decompose a hypergraph into subtrees that each consist of a single hyperedge of G. Our algorithm, which we name Algorithm $\mathcal{C}$, proceeds in three steps:

Step 1: Decomposition into trees. Let $I = (G = (V, E), p, c, B)$ be an instance of GBMC. We first decompose G into a collection of subtrees of G as follows: Initialize $t = 0$ and let $G_0 = G$ be the initial hypergraph. For $t \geq 0$ extract a subtree $T_{t+1} = (V_{t+1}, E_{t+1})$ from G_t and let $G_{t+1} = G_t \setminus T_{t+1}$ be the hypergraph that remains if we remove all hyperedges in E_{t+1} (but not the nodes) from G_t. Repeat the above procedure until eventually we obtain a graph G_z whose set of hyperedges is empty. Let $\mathcal{T} = \{T_1, \dots, T_z\}$ be the collection of subtrees extracted throughout this procedure. Note that by construction, for every two distinct trees $T_t, T_{t'} \in \mathcal{T}$ the set of hyperedges E_t and $E_{t'}$ are disjoint.

Using the above decomposition, we now define a new instance $I' = (G', p', c', B')$ of GBMC. The hypergraph G' consists of all trees $T_1, \dots, T_z$, where each tree $T_t = (V_t, E_t)$, $t \in [z]$, has its own "representative" for each node in V_t (with costs and profits being identical to the original ones). Thus, each node $i \in V$ has at most d_i representatives in G' and all trees in G' are node-disjoint. Finally, the budget B' of I' is set to $B' = dB$.

Step 2: Bin-packing the optimal solution of the decomposed instance. We compute a $(1 - \varepsilon)$-approximate solution X' for I' which respects the overall budget $B' = dB$ and also ensures that the total cost of every $T_t \in \mathcal{T}$ is at most B. The latter condition can easily be incorporated in our dynamic program for forests (thus also in our FPTAS) in Section 5.

The next step is to partition the trees in $\mathcal{T} = \{T_1, \dots, T_z\}$ into at most $2d$ sets $\mathcal{T}_1, \dots, \mathcal{T}_{2d}$ such that the total cost (according to X') in each set does not exceed B. This is in essence a bin-packing problem (i.e., packing a set of items of varying weights in a set of bins of limited capacity). Because every tree induces cost at most B and the total cost is at most dB, standard bin-packing arguments show that such a partition exists and can be computed in polynomial time [11].[2]

Step 3: Obtaining a solution for the original instance. Let $\mathcal{T}$ be a set of maximum profit (according to X') among the sets $\mathcal{T}_1, \dots, \mathcal{T}_{2d}$. We obtain the solution X from X' by picking

[2] To clarify: We can view each tree as an item of weight equal to the cost induced by X'. The goal then is to pack these items into bins of capacity B.

all hyperedges chosen in $\mathcal{T}$. Note that X is a feasible solution for I' but also for I as argued in Step 2. The algorithm outputs X.

▶ **Theorem 9.** *Algorithm $\mathcal{C}$ is a $(1-\varepsilon)/(2d^2)$-approximation algorithm for GBMC that runs in polynomial time, where d is the maximum frequency of a node.*

Proof. It is clear that the algorithm runs in polynomial time. Moreover, the algorithm outputs a feasible solution because the total cost induced by the nodes covered by X' in $\mathcal{T}$ is at most B (by construction). Therefore, the total cost of X in I is at most B.

It remains to analyze the approximation ratio. Let OPT_I be the optimal profit of the original instance I and let $OPT_{I'}$ be the optimal profit of the decomposed instance. Note that any feasible solution for I is also feasible for I'. This follows because the total cost of a solution for I is at most d times larger in I' and $B' = dB$. Therefore, the total profit $p_{I'}(X')$ of X' in I' is at least $(1-\varepsilon)OPT_{I'} \geq (1-\varepsilon)OPT_I$.

Because we choose the maximum set $\mathcal{T}$ among the $2d$ many sets, the total profit of X in I' is at least $(1-\varepsilon)OPT_I/(2d)$. Also, the total profit of X in I is at most a factor d less than the total profit it induces in I'. Therefore, the total profit $p_I(X)$ of X in I satisfies $p_I(X) \geq (1-\varepsilon)OPT_I/(2d^2)$, which completes the proof. ◀

5 GBMC when the incidence graph is a forest

In this section, we derive a bi-level dynamic program for the case when the incidence graph is a forest. We refer to this special case as GBMC-Forest. We also show that our dynamic program can be turned into an FPTAS, for which we introduce P as the maximum profit of a vertex, i.e., $P = \max_{v \in V} p(v)$.

▶ **Theorem 10.** GBMC-Forest *can be solved optimally in time $\mathcal{O}(mn^3P^2)$.*

Suppose the given incidence graph is a forest and consists of z trees $T_1, \dots, T_z$. In order to facilitate the exposition of our dynamic program we combine these trees simply into a single tree T as follows. Introduce an artificial hyperedge e_0, representing the root of the tree. Furthermore, we introduce for each tree T_t with $t \in [z]$ a dummy vertex node d_t with zero profit and cost, i.e., $p(d_t) = c(d_t) = 0$, and connect it to e_0. Finally, we connect d_t to its respective tree T_t by adding an edge in the incidence graph from d_t to an arbitrary hyperedge from T_t.

This yields a bipartite graph that is a single tree. Note that the nodes along a path from the root to any other node are alternately hyperedge/vertex nodes. Assume we “unfold” this tree in order to draw the bipartite graph in a layered manner, as illustrated in Figure 1.

Our dynamic program processes the unfolded tree T in a bottom-up manner. It consists of two separate dynamic programs, one for the hyperedges, and one for the vertices. We describe these programs informally in this section (technical details of the dynamic program will be given in the full version).

Consider an arbitrary subtree in T rooted at either a node represented by a hyperedge or vertex. Both dynamic programs rely on the fact that a subset of this subtree can be solved to optimality, which immediately can be used to solve a greater subset to optimality. In case the subtree is rooted at a node represented by a hyperedge, we consider the subtree up until the first s children in the subtree of the hyperedge. Once the optimal solutions (minimum required cost to obtain a specific profit, if possible) are known for every possible profit (upper bounded by nP), it is possible to find optimal solutions for the subtree until the first $s+1$ children by linear enumeration. A similar, but slightly adapted method works in case the subtree is rooted by a vertex rather than a hyperedge.

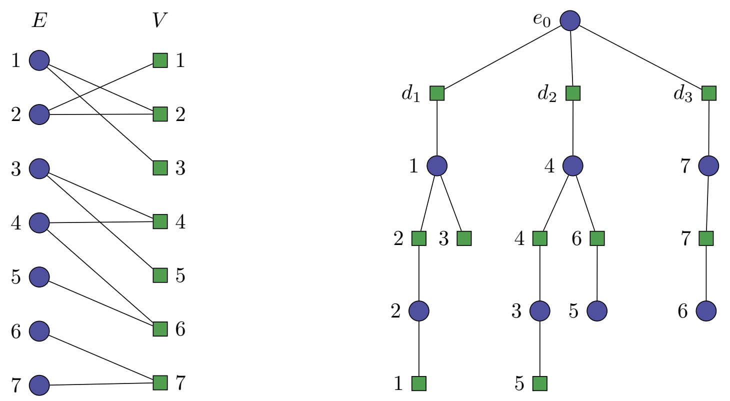

Figure 1 Example of a incidence graph (left) and its "unfolded' tree (right).

Furthermore, we can employ standard techniques (profit truncation) to turn the above pseudo-polynomial time algorithm into an FPTAS, i.e., an algorithm that takes an error parameter $\varepsilon > 0$ and computes in time polynomial in the input size and $1/\varepsilon$ a $(1 - \varepsilon)$-approximation to the optimal solution.

▶ **Theorem 11.** *There exists an FPTAS for* GBMC-FOREST *that runs in time* $\mathcal{O}(mn^5/\epsilon^2)$.

6 GBMC with a bounded size feedback vertex set

We have shown in the previous section that GBMC-FOREST can be solved in pseudo-polynomial time and that there is an FPTAS. This implies that the inapproximability of the general problem is caused by the cycles in the incidence graph. In this section, we provide a fixed parameter tractability result that allows us to handle incidence graphs with cycles. The fixed parameter is the minimum number α of hyperedge nodes that we need to remove in order to make the incidence graph acyclic.

To provide an initial intuition, construct a graph $G' = (E, E')$ where every hyperedge $e \in E$ is represented by a node, and two nodes are connected if and only if the corresponding hyperedges share at least one element. This defines the edge set E' in the new graph. Consider the case in which G contains solely one cycle. Select a hyperedge node of the cycle and fix whether this hyperedge is chosen or not in a solution (i.e., set $x = 0$ or 1). We then consider the reduced problem in which hyperedge e is removed. The incidence graph of the reduced problem is a forest and can thus be solved optimally by using the pseudo-polynomial time algorithm (or approximately by using the FPTAS) of the previous section. Solving this GBMC-FOREST problem for every possible choice of hyperedge to remove, and taking the best solution, yields a solution to the general GBMC problem for the instance with one cycle. Thus, if the graph contains one cycle, the running time is multiplied by 2. We can extend this idea to more general graphs.

Define α as the minimum number of hyperedges whose removal turn the graph into a forest, i.e., α is the cardinality of the *minimum feedback vertex subset* of the hyperedge nodes of the incidence graph. We refer to the latter as the *minimum feedback hyperedge node set*. Then the running time of the algorithms mentioned in the previous sections is multiplied by a factor of 2^α, because it is necessary to solve the problem on a forest for every combination on those α hyperedges.

The problem of finding a minimum feedback vertex set is NP-hard in general, but it is fixed parameter tractable. Cao et al. [2] give an $\mathcal{O}(3.83^\alpha \alpha n^2)$ time algorithm to solve the

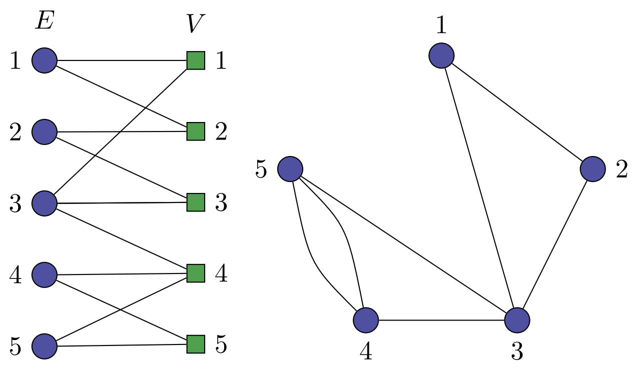

Figure 2 Example of a transformation to the feedback vertex set problem.

problem, where n here refers to the number of nodes in the graph. We use this to prove the following theorem.

▶ **Theorem 12.** *GBMC is solvable in $\mathcal{O}(mn^3P^22^\alpha + 3.83^\alpha \alpha m^2)$ time, where α is the size of the minimum feedback hyperedge node set.*

All that needs to be shown is how to use the $\mathcal{O}(3.83^\alpha \alpha n^2)$ algorithm of [2] in order to find a minimum feedback vertex set restricted to only the hyperedge nodes of the incidence graph. This is straightforward: We reduce the incidence graph of G to the aforementioned multigraph $G' = (E, E')$ with only E as its vertex set. The edge set E' is constructed as follows: there exists an edge between two hyperedges if they share at least one vertex in the original graph. It is now easy to see that there is a one-to-one correspondence between the cycles in the incidence graph of G and the cycles in G', and each cycle in the incidence graph of G corresponds to a cycle in G' on the same set of vertices. Therefore, a minimum feedback vertex set of G' corresponds to a minimum feedback hyperedge node set of G, and the algorithm of Cao et al. will find such a set in $\mathcal{O}(3.83^\alpha \alpha n^2)$ time.

The transformation is illustrated in Figure 2. There, hyperedge 3 and 5 are connected by vertex 4 in (the incidence graph representation of) G, thus an edge $\{3, 5\}$ is added in G'. The edge labels are omitted. Note that hyperedge 4 and 5 are connected by two edges, because they are both connected to vertex 4 and vertex 5.

7 Conclusions

In this paper we have presented various approximation algorithms for important special cases of the GBMC problem. Clearly, the most interesting open problem that remains to be solved is whether there exists a constant factor approximation algorithm for the general GBMC problem that runs in polynomial-time. Such a result would form a very interesting contrast with the inapproximability result for the problem of submodular function maximization with a submodular budget constraint under the oracle access model, which we mentioned in the introduction.

An interesting and challenging intermediate goal would be to find a constant factor approximation algorithm for the case that the hyperedges have a fixed size k. Algorithm $\mathcal{A}$ and Theorem 2 might serve as a useful tool for achieving this goal.

Abstract

The partial string avoidability problem, also known as partial word avoidability, is stated as follows: given a finite set of strings with possible "holes" (undefined symbols), determine whether there exists any two-sided infinite string containing no substrings from this set, assuming that a hole matches every symbol. The problem is known to be NP-hard and in PSPACE, and this paper establishes its PSPACE-completeness. Next, string avoidability over the binary alphabet is interpreted as a version of conjunctive normal form (CNF) satisfiability problem (SAT), with each clause having infinitely many shifted variants. Non-satisfiability of these formulas can be proved using variants of classical propositional proof systems, augmented with derivation rules for shifting constraints (such as clauses, inequalities, polynomials, etc). Two results on their proof complexity are established. First, there is a particular formula that has a short refutation in Resolution with shift, but requires classical proofs of exponential size (Resolution, Cutting Plane, Polynomial Calculus, etc.). At the same time, exponential lower bounds for shifted versions of classical proof systems are established.

1 Introduction

The field of proof complexity is concerned with the size of proofs for different kinds of logical formulas, under various measures of size. The most common subject, motivated by SAT-solvers, are Boolean formulas in conjunctive normal form (CNF), and there is a substantial body of literature on lower bounds on the size of a proof that a given CNF formula is unsatisfiable. For instance, there are exponential lower bounds on the size of Resolution [9, 16], Cutting Plane [14] and Polynomial Calculus proofs [15, 10], whereas for Frege and Lovász–Schrijver proof systems, no superlinear lower bounds are known [7]. This line of research is aimed, in particular, at separating the NP and co-NP complexity classes [8].

This paper investigates the complexity issues for a variant of CNF formulae, in which every clause exists in countably many variants, with variable numbers shifted by any constant.

For example, if a formula contains a clause $x_1 \vee \neg x_4$, then it contains all clauses of the form $x_{1+i} \vee \neg x_{4+i}$, where i is any integer. The resulting *Shift-CNF* depends on countably many variables, and represents uniformly defined constraints applied to all blocks of variables. It can be alternatively written as a finite formula, with each clause using a universal quantifier on position numbers, such as in $(\forall i \in \mathbb{Z})(x_{i+1} \vee \neg x_{i+4})$. These formulas have a compactness property (that is, their satisfiability can be tested on a sufficiently large finite block of variables), and several proof systems, such as Resolution, can be applied to clauses of this form. Those systems are a natural subject for proof complexity studies.

Another motivation to study the satisfiability problem for Shift-CNF is that it is equivalent to the *partial substring avoidability problem*, which received some attention in formal language theory [6, 5]. To see this relationship, first consider the following (fairly obvious) representation of the satisfiability problem for standard CNF formulae (SAT) in terms of strings. Let $x_1, \ldots, x_n$ be the set of variables of a CNF formula. Then, each clause in the formula may be written down as a string of length n over the 3-symbol alphabet $\Sigma = \{0, 1, \Box\}$, which lists the values of variables that make this clause false: to be precise, each i-th position in the string contains 0 if the clause contains a literal x_i, or 1 if there is a literal $\neg x_i$, or a "hole" ($\Box$) if this variable does not occur in the clause. Thus, a CNF formula is presented as a set of *forbidden strings*, and its satisfying assignments are exactly all binary strings of length n that *do not match* the string representation of each clause.

In this setting, all strings are of the same length n, and cannot be moved in relation to each other, because that would mean shifting variable numbers. If this restriction is lifted, then each forbidden partial string represents a pattern that may not occur in a desired binary string *beginning from any position.* This is the partial substring avoidability problem, which precisely corresponds to the Shift-CNF satisfiability problem (Shift-SAT).

In the special case when forbidden strings are complete strings (without holes), their avoidability can be decided in linear time using the algorithm by Aho and Corasick [1]. Another solution to this problem, given in Lothaire [13], uses a special case of Resolution proofs, applied to strings instead of clauses: two strings $xy0$ and $y1$ can be resolved to xy. Lothaire [13] proves that a set of (complete) strings is unavoidable if and only if the empty string can be derived; furthermore, the length of this derivation is linear.

The computational complexity of the full case of the partial string avoidability problem was studied by Blanchet-Sadri et al. [6], who proved that it is NP-hard. Soon thereafter, Blakeley et al. [5] showed that the problem is in PSPACE. Its exact complexity remained open. The first result of this paper is that partial string avoidability is actually PSPACE-complete: this is established in Section 3 by a direct reduction from the polynomial-space Turing machine membership problem.

This result puts the Shift-SAT problem in the context of proof systems for PSPACE-complete languages. The proof complexity of such systems is important, in particular, as an approach to separating NP from PSPACE. A generalized Resolution proof system for the Quantified Boolean Formula (QBF) problems—the *Q-Resolution*—was introduced by Kleine Büning et al. [12], and other Resolution-based proof systems for QBF and their proof complexity have recently been studied by Beyersdorff et al. [3, 4], by Balabanov et al. [2] and by Janota and Marques-Silva [11].

The Shift-SAT problem is attractive for being similar to the classical SAT problem, to the point that all proof systems for UNSAT, such as Resolution, Cutting Plane, Polynomial Calculus, etc., can be directly applied to Shift-SAT formulas. For every such proof system Π, there is its shifted version, Shift-Π, with an additional derivation rule for adding an arbitrary integer to the numbers of all variables in a constraint.

Two results on the proof complexity of shifted systems are presented in this paper. Lower bounds on the size of shifted proofs, given in Section 5, are obtained by encoding any of the known superpolynomial lower bounds on classical proofs. Efficient proofs using shifts are presented in Section 6, as an example of an unsatisfiable shifted CNF formula which has a polynomial-sized Shift-Resolution proof, whereas its proofs in every classical proof system are of at least exponential size.

The proof system for complete strings defined by Lothaire [13], is a special case of Shift-Resolution. Lothaire's [13] clauses contain *contiguous blocks* of variables $x_i, x_{i+1}, \dots, x_j$, whereas general CNF and Shift-CNF clauses may have gaps between variable numbers. The results on the proof complexity of Shift-Resolution obtained in this paper, in particular, imply an *unconditional separation* between these two problems, in terms of the length of resolution derivations—as compared to the separation in terms of computational complexity, which is conditional to P $\neq$ PSPACE.

2 The partial string avoidability problem

Any finite set of symbols Σ is called an *alphabet.* A *(two-sided) infinite string* over Σ is a mapping $\alpha\colon \mathbb{Z} \to \Sigma$. If two infinite strings, α and β, are the same up to shifting them by a constant number of positions, that is, if for some offset $d \in \mathbb{Z}$, $\alpha(n) = \beta(n+d)$ for all $n \in \mathbb{Z}$, then α and β are said to be *equal*, and are considered to be the same infinite string.

The set of all infinite strings over an alphabet Σ is denoted by Σ^∞, whereas Σ^* is the set of all finite strings $a_1 \dots a_n$, with $n \geqslant 0$ and $a_1, \dots, a_n \in \Sigma$. Each i-th symbol of a finite string $w = a_1 \dots a_n$ shall be denoted by $w[i] = a_i$, and a *substring* $a_i \dots a_j$ is denoted by $w[i..j]$. The same notation is used to extract a finite substring $\alpha[i..j]$ from an infinite string α.

For a set of finite strings $L \subseteq \Sigma^*$, the set of infinite strings formed by concatenating any elements of L is denoted by $L^\infty = \{\, \dots w_{-1} w_0 w_1 w_2 \dots \mid w_i \in L \text{ for all } i \in \mathbb{Z} \,\}$. In particular, the infinite string formed by repeating a finite string $w \in \Sigma^*$ is $w^\infty = \dots www \dots$

A *partial string* over an alphabet Σ is a finite string over the alphabet $\Sigma \cup \{\square\}$, where a square ($\square$) denotes an unknown symbol (a hole). For the purposes of string matching, a hole may stand for any symbol from Σ: to be precise, two partial strings of the same length, u and v, are said to be *compatible*, if, whenever they differ in some j-th position ($u[j] \neq v[j]$), either $u[j] = \square$ or $v[j] = \square$.

An infinite string α over an alphabet Σ is said to *avoid a partial string* w, if every substring of α of the same length as w is incompatible with w: that is, $\alpha[i+1..i+|w|]$ is incompatible with w for every $i \in \mathbb{Z}$. A finite string avoiding w is defined similarly. A finite or infinite string is said to *avoid a set of partial strings* L, if it avoids every element of L.

The *partial string avoidability problem* is then stated as follows: given an alphabet Σ and a finite set of partial strings S over Σ, determine whether there exists an infinite string that avoids this set.

The first thing to observe is that if a finite set of partial strings is avoided by a sufficiently long finite string then it is avoided by an infinite string. Therefore, the avoidability problem may be regarded as a problem on finite strings, and is guaranteed to have an effective solution.

▶ **Lemma 1.** *Let Σ be an alphabet containing m symbols, let $L \subset (\Sigma \cup \{\square\})^*$ be a finite set of partial strings, and let ℓ be the length of the longest string in L. Then, L is avoided by an infinite string if and only if L is avoided by a finite string of length $m^\ell + \ell$.*

Lemma 1 provides an obvious NEXPTIME algorithm for testing partial string avoidability. However, the problem is known to be easier.

▶ **Lemma 2** (Blakeley et al. [5, Cor. 2]). *The partial string avoidability problem is in* PSPACE.

Sketch of a proof. Let $k = \max_{w \in S} |w|$, and consider the graph with the set of vertices $\{0,1\}^k$, which contains an arc from $u \in \{0,1\}^k$ to $v \in \{0,1\}^k$, if the string uv contains no forbidden substrings from S. An infinite string avoiding all substrings from S exists if and only if there is a cycle in the graph. A polynomial-space nondeterministic Turing machine can guess this cycle by walking over the graph. ◀

In addition, Blakeley et al. [6] proved that the partial string avoidability problem is NP-hard, but its exact complexity remained open. The first contribution of this paper, presented in Section 3, is that this problem is actually PSPACE-complete.

Another crucial property of the partial string avoidability problem is that it can be reduced to the same problem over the binary alphabet.

▶ **Lemma 3** (Blakeley et al. [5, Thm. 7]). *The partial string avoidability problem is reducible in polynomial time to the partial string avoidability problem over the alphabet* $\Sigma = \{0,1\}$.

This allows an interpretation of this problem as a logical formula. An investigation of the proof complexity aspects of testing avoidability is carried out later in Sections 4–6.

3 The PSPACE-hardness proof

The first contribution of this paper is the exact computational complexity of the partial substring avoidability problem (Avoidability).

▶ **Theorem 4.** Avoidability *is* PSPACE-*complete.*

The problem is in PSPACE by Lemma 2, and it remains to prove that it is PSPACE-hard. Let L be any language in PSPACE, that is, there exists a one-tape Turing machine M and a polynomial $s(\ell)$, such that on any input string of length ℓ, the machine M uses $s(\ell)$ space and eventually halts in an accepting state, if the input is in L, or in a rejecting state otherwise. Assume that M is modified, so that, instead of halting in a rejecting state, it loops without using any additional space.

Theorem 4 follows from Lemma 5 applied to M.

▶ **Lemma 5.** *For every Turing machine that uses at most $s(\ell)$ space on inputs of length ℓ and for every input string $w \in \Sigma^\ell$, there exists an alphabet Ω and a finite set of partial strings $P \subset (\Omega \cup \{\Box\})^*$, such that the Turing machine loops on w if and only if there exists a two-sided infinite string $\alpha \in \Omega^\infty$ that avoids all partial strings in P. Given the machine, P can be constructed in time polynomial in $s(\ell)$.*

Consider computation histories of a Turing machine, where its configurations are written one after another. The general plan is to use forbidden strings to ensure that each listed configuration is the successor of the previous one. If the Turing machine loops, then there is an infinite string containing its infinite computation. A final configuration has no successor, so if it is ever reached, then the list of configurations cannot be continued to an infinite string.

However, there is a problem with this idea. If a Turing machine loops on the input, this means that it loops *starting from its initial configuration.* But there could also exist some looping computations beginning from unreachable configurations. These computations give rise to undesired infinite strings.

This problem can be circumvented in the following way. Let the Turing machine be augmented with an *alarm clock* containing a counter that is incremented at every step. The time until the alarm is triggered must be long enough for any accepting computation to terminate. Then, once the counter overflows, this means that the machine has looped, and the alarm clock resets the machine to its initial configuration. This shall ensure that if the machine does not loop starting from the initial configuration, then there is no infinite string.

Denote the Turing machine by $T = (\Sigma, \Gamma, Q, q_0, \delta, q_{acc})$, where Σ is the input alphabet; Γ is the tape alphabet, with $\Sigma \subseteq \Gamma$; Q is a finite set of states, $q_0 \in Q$ is the initial state, $\delta \colon (\Gamma \cup \{\vdash, \dashv\}) \times Q \to (\Gamma \cup \{\vdash, \dashv\}) \times Q \times \{-1, +1\}$ is the transition function, and $q_{acc} \in Q$ is the accepting state.

The machine operates on a tape containing $n = s(\ell)$ symbols from Γ enclosed between left and right end-markers ($\vdash$, $\dashv$). It has $(n+2) \cdot |Q| \cdot |\Gamma|^n$ possible configurations. Attached to the tape, there is a separate k-bit counter, with $k = \lceil \log_2(n+2) + \log_2 |Q| + n \log_2 |\Gamma| + 1 \rceil$, that is, with 2^k greater than the number of possible configurations. This information is encoded in a $(n+k+2)$-symbol *block* that consists of a Turing machine configuration ($n+2$ symbols) and of the alarm clock's counter (k digits).

Each symbol in the block is of the form (X, i), where $i \in \{0, \ldots, n+k+1\}$ is a number of the position in the block, and X is a payload, to be defined later. The Turing machine tape is encoded in positions $0, \ldots, n+1$, and the counter is in positions $n+2, \ldots, n+k+1$.

For each symbol used for encoding the tape, the payload is a triple (a, q, f), where $a \in \Gamma \cup \{\vdash, \dashv\}$ is a tape symbol, $q \in Q \cup \{-\}$ is either a state of the Turing machine (if the head is in this square) or a minus sign (if the head is elsewhere), while the third component $f \in \{\text{N}, \text{R}\}$ is a flag used for restarting the machine.

In each cell of the counter, the payload is any of the two digits: *zero* (0) and *one* (1).

Altogether, the following alphabet is used.

$$\Omega = \big((\Gamma \cup \{\vdash, \dashv\}) \times (Q \cup \{-\}) \times \{\text{N}, \text{R}\} \times \{0, \ldots, n+1\}\big) \cup \\ \cup \big(\{0, 1\} \times \{n+2, \ldots, n+k+1\}\big)$$

Some symbols of this alphabet are actually unnecessary. These symbols shall be identified in the proof, and then they can either be removed from the alphabet, or, equivalently, they can be listed as 1-symbol forbidden strings.

In this proof, the set of forbidden substrings P is constructed gradually, with each instalment of substrings ensuring further properties of any infinite string avoiding those substrings.

The first step of the construction is to ensure that the infinite string consists of blocks of length $n+k+2$, each correctly split into tape symbols and counter digits, and with all positions in the block correctly numbered. The payload is not checked yet, with the exception for the correct position of end-markers, namely, that they occur in the beginning and in the end of the tape, and nowhere else.

▶ **Claim 6.** *If a two-sided infinite string contains no forbidden substrings from P, then it is of the form $\ldots \alpha_{-1} \alpha_0 \alpha_1 \alpha_2 \ldots \alpha_\ell \ldots$, where each α_i is a string of the following form, for some tape symbols $a_1, \ldots, a_n \in \Gamma$, states $p_0, \ldots, p_{n+1} \in Q \cup \{-\}$, flags $f_0, \ldots, f_{n+1} \in \{\text{N}, \text{R}\}$ and counter digits $d_0, \ldots, d_{k-1} \in \{0, 1\}$.*

$$\alpha_i = (\vdash, p_0, f_0, 0)(a_1, p_1, f_1, 1) \ldots (a_n, p_n, f_n, n)(\dashv, p_{n+1}, f_{n+1}, n+1) \\ (d_{k-1}, n+2) \ldots (d_1, n+k)(d_0, n+k+1)$$

This is achieved by using two-symbol forbidden strings of the form $(X, i)(Y, j)$, where $i + 1 \neq j \pmod{n+2+k}$, while X and Y represent any payload. The correct use of end-markers on the tape is enforced by removing a few invalid symbols, such as $(\dashv, 0)$, from the alphabet (alternatively, they can be listed as one-symbol forbidden strings).

With the enumeration of positions in place, consider the implementation of the alarm clock. The alarm clock uses a k-bit binary counter, with the least significant digit in position $n + k + 1$ and with the most significant digit in position $n + 2$. The counter is incremented at every step. Upon overflow, it is reset to zero, and at the same time a restart signal is sent to the left into the Turing machine tape.

▶ **Claim 7.** *In every block, the payload in the counter digits forms a binary string, $d_{k-1} \dots d_1 d_0$. The number represented by this string is greater by* 1 *(modulo 2^k) than the number represented in the previous block.*

Then, in particular, the enumeration of the blocks $(\dots, \alpha_{-1}, \alpha_0, \alpha_1, \alpha_2, \dots)$ assumed in the proof can be shifted so that the value of the counter in each α_i is exactly i modulo 2^k.

The forbidden strings implementing Claim 7 ensure that the corresponding digits of two subsequent counters, which are $n + 2 + k$ positions apart, correctly implement addition of 1. For example, two forbidden partial strings, $(0, n + k + 1)\square^{n+k+1}(0, n + k + 1)$ and $(1, n + k + 1)\square^{n+k+1}(1, n + k + 1)$, set the least significant digit to alternate between 0 and 1. Incrementation in further digits is controlled by similarly defined partial strings.

If the most significant digit of the counter changes from 1 to 0, this indicates counter overflow, and therefore the alarm clock sends the restart signal (R) to the left of the current symbol, from where it propagates to all tape squares in this block. The restart flag is handled in the next group of forbidden strings.

▶ **Claim 8.** *In every block α_i, if $i \not\equiv 0 \pmod{2^k}$, then each tape square is marked as normal* (N)*. If $i \equiv 0 \pmod{2^k}$, then each tape square has a restart flag* (R)*.*

The next group of restrictions ensures that if the restart signal sweeps over the tape in some block, then at the same time the Turing machine configuration to overwritten with its initial configuration.

▶ **Claim 9.** *If a restart occurs in a block, then this block contains the initial configuration of the Turing machine on the input string w.*

The last group of forbidden strings ensures the simulation of the Turing machine's transitions in normal situations, when no reset takes place. Every tape square in a configuration depends on three squares in the previous configuration: namely, on the same square, its left neighbour and its right neighbour. This dependence is checked by prohibiting all mismatches.

▶ **Claim 10.** *If a block contains a syntactically correct Turing machine configuration, and no reset occurs at the subsequent block, then the subsequent block contains a syntactically correct configuration at the next step.*

Once a set of forbidden partial strings satisfying Claims 6–10 is constructed, the proof of Lemma 5 follows from these Claims.

4 Proof systems

As outlined in the introduction, the avoidability problem over a binary alphabet $\Sigma = \{0, 1\}$ can be treated as a logical question. Let $\Gamma = \{x_i\}_{i \in \mathbb{Z}}$ be the set of numbered Boolean variables. Any variable x_i or its negation $\neg x_i$ is called a *literal*; a literal of an unknown sign can be denoted by x_i^σ, with $\sigma \in \{0, 1\}$, so that $x_i^0 = x_i$ and $x_i^1 = \neg x_i$. A *clause* is a disjunction of finitely many literals, such as $x_1 \vee \neg x_4$. A clause is *shifted* by adding the same integer to all variable numbers. The conjunction of all shifts of a clause C is denoted by $\mathrm{Shifts}(C)$ and called a *moveable clause.* For instance, in the above example, $\mathrm{Shifts}(x_1 \vee \neg x_4) = \bigwedge_{i \in \mathbb{Z}} (x_{i+1} \vee \neg x_{i+4})$.

A conjunctive normal form (CNF) formula φ is a conjunction of finitely many clauses, and it accordingly depends on finitely many variables. From the perspective of proof systems, it may be regarded as a finite *set of clauses.* If these clauses are replaced with the corresponding moveable clauses, the resulting formula, denoted by $\mathrm{Shifts}(\varphi)$, is called a *Shift-CNF.* A CNF, or a Shift-CNF, it is said to be *satisfiable*, if, for some assignment of Boolean values to variables, all its clauses hold true.

In terms of strings, a clause is a partial string that lists all values that make its literals false, with holes instead of the unused variables. A clause is matched at a specific position in the strings, whereas a moveable clause means that a string is matched at all positions. For example, the above moveable clause $\mathrm{Shifts}(x_1 \vee \neg x_4)$ may be regarded as a forbidden partial string $0\square\square1$. If all the listed values hold at once, then the clause is false. Accordingly, avoidance of all partial strings representing the moveable clauses in a Shift-CNF is equivalent to its satisfiability.

In view of this equivalence, Lemma 1 states that satisfiability of a Shift-CNF can be tested by considering finitely many shifts of each moveable clause—namely, those involving the variables $x_1, x_2, \ldots, x_{2^\ell+\ell}$.

Unsatisfiability of sets of clauses can be proved using *proof systems.* A refutation of a set of clauses in the Resolution proof system is a sequence of clauses $C_1, C_2, \ldots, C_s$, where C_s is the *empty clause* (false), and each clause C_i, with $i \in \{0, \ldots, s-1\}$, is either a clause from the given set, or is derived from some earlier clauses using the weakening rule or the resolution rule. By the *weakening rule*, a clause $C \vee D$ is derived from a clause C by adding any extra literals D. The *resolution rule* is applied to a pair of clauses $x \vee C$ and $\neg x \vee D$, where x is a variable, deriving the clause $C \vee D$. The *length* of a Resolution proof is the number of clauses therein. For an unsatisfiable formula φ, the length of its shortest Resolution refutation is denoted by $S_{Res}(\varphi)$.

The following estimation of the length of Resolution proofs is well-known.

▶ **Lemma 11.** *Let F be an unsatisfiable CNF formula, and let x be one of its variables. Then, $S_{Res}(F) \leqslant S_{Res}(F[x := 0]) + S_{Res}(F[x := 1]) + 1$.*

The definition of Resolution proofs equally applies to infinite sets of clauses. It is known that a set of clauses, finite or infinite, has a Resolution refutation if and only if that set is unsatisfiable. For infinite sets of clauses, this result generally holds by the compactness theorem, although it gives no estimations of the size of a refutation. For infinite formulas of the form $\mathrm{Shifts}(\varphi)$ studied in this paper, there is the following upper bound on the length of their Resolution refutations.

▶ **Lemma 12.** *Assume that an unsatisfiable CNF formula φ depends on variables $x_1, x_2, \ldots, x_n$, and assume that in each clause, the least and the greatest variable numbers differ by at most $k \geqslant 2$. Then φ has a Resolution refutation of size at most $2n^k$.*

Sketch of a proof. Using Lemma 11, a Resolution proof for φ can be constructed by selecting a few (t) variables and substituting all possible values into them. Each substituted formula has a derivation; let T be the length of the longest of them. Then, φ has a derivation of length $2^t T + 2^t - 1$.

Let the middle block of k variables be selected: that is, all variables with numbers between $\frac{n-k}{2}$ and $\frac{n+k}{2}$. Substituting all their values splits the formula into two independent subformulas, and it is sufficient to refute only one of them. Thus, the problem has been reduced to the same problem for $\frac{n-k}{2}$ variables, and the result follows by an inductive argument. ◀

Returning to the avoidability problem for partial strings $w_1, w_2, \ldots, w_m$, Lemma 1 implies that the avoidability test is given by a CNF with $2^k + k$ consecutive variables, where $k = \max_i |w_i|$. Then, by Lemma 12, this formula has a Resolution refutation of size $2^{O(k^2)}$.

For the Resolution method for Shift-CNF formulas, there is a natural derivation rule to be added: the *shifting rule*, by which, from any clause $x_{i_1}^{\sigma_1} \vee x_{i_2}^{\sigma_2} \vee \cdots \vee x_{i_k}^{\sigma_k}$, one can derive any clause $x_{i_1+n}^{\sigma_1} \vee x_{i_2+n}^{\sigma_2} \vee \cdots \vee x_{i_k+n}^{\sigma_k}$, for any $n \in \mathbb{Z}$. In the resulting system, called Shift-Resolution, one can prove only the statements provable in the classical Resolution. Indeed, every application of the shifting rule can be eliminated by deriving each shifted clause from scratch: this is possible, because the formula contains all shifts of the original clauses. However, as will be shown in Section 6, there is a formula, for which a Shift-Resolution proof is exponentially shorter than any classical proofs.

The shifting rule can be similarly added to other proof systems, such as Cutting Plane, Polynomial Calculus, etc. For a proof system Π, its extension with the shifting rule is denoted by Shift-Π.

5 Lower bounds on the size of shifted proofs

Lower bounds on the size of proofs with shifting can be inferred from the known lower bounds on classical proofs, as follows. Let φ_n be an unsatisfiable CNF formula in variables $x_1, \ldots, x_n$. This formula shall be encoded in a Shift-CNF formula Φ_n, in a way that for every proof system Π, from any Shift-Π proof of Φ_n, one could extract a (typically, smaller) classical Π-proof of φ_n. Then, every known lower bound on the size a Π-proof of φ_n translates to a lower bound on the size of Shift-Π proof of Φ_n.

The general idea of encoding a CNF formula φ in a Shift-CNF Φ is that every satisfying assignment $x_1, \ldots, x_n$ to φ should be repeated as something like an infinite binary string $(x_1 \ldots x_n)^\infty$ representing a satisfying assignment to Φ. The main challenge is that φ is not designed to be shifted, and therefore Φ should somehow apply φ only *to every n-th substring* of length n, that is, $x_1 \ldots x_n$, and not to any improperly shifted substrings $x_i \ldots x_n x_1 \ldots x_{i-1}$, with $i \in \{2, \ldots, n\}$. Since, by definition, shifted formulas apply to all shifts, this selective evaluation is not possible, and it is necessary to use some kind of encoding that would disable all unintended shifts.

The proposed encoding of φ represents each of its variables x_i as four consecutive Boolean variables: y_{4i+1}, y_{4i+2}, y_{4i+3} and y_{4i+4}. The first three of them shall always have values 011, whereas the last variable, y_{4i+4}, holds the actual value of x_i. In order to distinguish the encoded variable x_1, a special separator code 0100 is inserted between every two complete blocks of n encoded variables.

The formula Φ_n is a conjunction of two parts: the first part W_n ensures that the infinite string representing the variable values is a valid encoding of the form described above, while H_n simulates φ over that encoding.

The formula W_n has to make sure that the infinite string is of the form $(\$\{\widetilde{0}, \widetilde{1}\}^n)^\infty$, where $\$ = 0100$, $\widetilde{0} = 0110$ and $\widetilde{1} = 0111$. The first task towards this goal is to define all sequences of the form $\{\$, \widetilde{0}, \widetilde{1}\}^\infty$. This is done by nine constraints (Shift-CNF clauses). First, all substrings of length 5 that do not contain the control pair 01 are forbidden: namely, 11111, 11110, 11100, 11000, 10000 and 00000. Two more forbidden partial substrings 01□□1 and 01□□00 ensure that for each control pair 01, after two symbols, there cannot be anything except another control pair 01. The last forbidden substring 0101 makes sure that the data digits between two control pairs cannot be 01.

It remains to ensure that separators ($) never occur close to each other, and that there is a separator after every n encoded digits. The former is done by adding n forbidden partial strings $0100\square^{4k}0100$, for all $k \in \{0, ..., n-1\}$, and the existence of separators is asserted by prohibiting $n+1$ subsequent encoded digits using a partial string $(011\square)^{n+1}$. This completes the formula W_n.

The second part of the formula, denoted by H_n, contains as many clauses as φ_n. Whenever φ_n contains a clause $x_{i_1}^{\sigma_1} \vee \ldots \vee x_{i_k}^{\sigma_k}$, it is represented in H_n by the following corresponding clause.

$$\underbrace{y_1 \vee \neg y_2 \vee y_3 \vee y_4}_{D_\$\text{: false only on 0100 (\$)}} \quad \vee \quad \underbrace{y_{4i_1+4}^{\sigma_1} \vee \ldots \vee y_{4i_k+4}^{\sigma_k}}_{p(x_{i_1}^{\sigma_1} \vee \ldots \vee x_{i_k}^{\sigma_k})}$$

The disjunction of the first four literals is true, unless there is a substring 0100 there, that is, the separator ($). For that reason, any unintended shifts of this clause hold true, and are therefore irrelevant. On a correct shift, the first four literals are false, and the rest, denoted by $p(C)$, correctly apply the original clause C to the encoded variables of φ_n.

Each satisfying assignment to the Shift-CNF formula $\text{Shifts}(W_n \wedge H_n)$ encodes at least one satisfying assignment to the original CNF formula φ, and since the latter is unsatisfiable by assumption, so is $\text{Shifts}(W_n \wedge H_n)$.

The proposed lower bound method applies to a class of proof systems, so that a lower bound on the size of a Π-proof of φ_n, where Π is a proof system, implies a fairly close lower bound on the size of Shift-Π proofs for $\text{Shifts}(W_n \wedge H_n)$. To keep things simple, in this extended abstract, the theorem is formulated for three well-known proof methods, and actually established only for the case of Resolution (other cases are similar).

▶ **Theorem 13.** *Let Π be one of the three proof systems: Resolution, Cutting Plane or Polynomial Calculus. Then the length of any Shift-Π refutation of $\text{Shifts}(W_n \wedge H_n)$ is at least $\Omega\left(\frac{S_\Pi(\varphi_n)}{n}\right)$, where $S_\Pi(\varphi_n)$ is the length of the shortest Π-refutation of φ_n. The same holds true for the total size of refutations.*

The proof consists of two parts. First, a Shift-Π refutation of $\text{Shifts}(W_n \wedge H_n)$ is transformed to a Π-refutation of the same formula, by mapping each variable y_i, with $i \in \mathbb{Z}$, to $y_{(i \bmod 4n+4)}$ and then eliminating the shift rules. Then the latter Π-refutation of $\text{Shifts}(W_n \wedge H_n)$ is transformed by substituting the sequence $\$(011\square)^n$ into all auxiliary variables, resulting in a Π-refutation of φ_n of the stated size.

Proof for the case of Resolution. Consider any refutation π of $\text{Shifts}(W_n \wedge H_n)$ in the Shift-Resolution proof system, and let λ_n be its length. Let σ be a substitution that maps each variable y_i, with $i \in \mathbb{Z}$, to the variable $y_{(i \bmod m)}$, where $m = 4(n+1)$. Then, $\pi[\sigma]$ denotes the sequence of clauses in π under the substitution σ.

As stated in the following lemma, this substituted refutation remains a valid resolution refutation.

▶ **Lemma 14.** *Let $C_1, C_2, \ldots, C_s$ be a Resolution refutation of a set of clauses F, and let τ be a substitution of a variable with another variable ($x := y$) or with a constant ($x := 0$ or $x := 1$). Then, the list of substituted clauses $C_1[\tau], C_2[\tau], \ldots, C_s[\tau]$, with all constant true clauses omitted, is a valid Resolution refutation of $F[\tau]$.*

For every clause C with variables from $\Gamma = \{y_i\}_{i \in \mathbb{Z}}$, under the substitution σ, there are at most m distinct shifts of C. Hence, the size of the formula $\text{Shifts}(W_n \wedge H_n)[\sigma]$ is at most m times the size of $W_n \wedge H_n$. In order to transform the proof $\pi[\sigma]$ to a Resolution refutation of the formula $\text{Shifts}(W_n \wedge H_n)[\sigma]$, one should eliminate the shift rules. For that purpose, along with every clause, all its shifts need to be deduced as well. Let π' be the resulting refutation, which is of size at most $m\lambda_n$.

Consider a substitution into π', defined by $y_0 \dots y_{m-1} := \$(011\Box)^n$, where each square ($\Box$) indicates a variable unaffected by the substitution. Under such a substitution, all clauses of $\text{Shifts}(W_n)[\sigma]$ are satisfied. The clauses of $\text{Shifts}(H_n)[\sigma]$ are either satisfied or are reduced to clauses of the form $p(C)$, where C is a clause from φ_n. In the end, all such clauses are obtained. Let $p(\varphi_n)$ denote their conjunction. By Lemma 14, there is a derivation that contains no true clauses, that is, a refutation of the formula $p(\varphi_n)$. Also, the lemma asserts that the length of the proof is not increased.

Thus, a Resolution refutation of φ_n of size at most $m\lambda_n$ has been obtained. Therefore, $\lambda_n \geqslant \Omega\left(\frac{S_\Pi(\varphi_n)}{n}\right)$. ◀

▶ **Corollary 15.** *For each number $n \geqslant 1$, there exists a 3-CNF formula φ_n of n variables and with $O(n)$ clauses, such that every Shift-Resolution proof of the corresponding Shift-CNF Φ_n is of size at least $2^{\Omega(n)}$.*

Proof. It is sufficient to take any family of formulas with Resolution proof complexity $2^{\Omega(n)}$. Such a family is constructed, for instance, by Urquhart [16]. ◀

▶ **Corollary 16.** *There exists such a CNF formula φ_n of size n, that every Shift-Cutting Plane proof of the corresponding Shift-CNF Φ_n is of size at least $2^{n^{\Omega(1)}}$.*

Proof. The proof uses a family of formulas with the Cutting Plane proof complexity $2^{n^{\Omega(1)}}$. Such formulas were constructed by Pudlák [14]. ◀

▶ **Corollary 17.** *For some CNF formula φ_n of size $O(n^2)$, the size of every Shift-Polynomial Calculus proof of the corresponding Shift-CNF Φ_n is at least $2^{n^{\Omega(1)}}$.*

Proof. The proof uses the formulas that encode the pigeonhole principle $\mathrm{PHP}_\mathrm{n}^{\mathrm{n}+1}$. By the results of Razborov [15] and of Impagliazzo et al. [10], every Polynomial Calculus derivation of $\mathrm{PHP}_\mathrm{n}^{\mathrm{n}+1}$ is of size at least $2^{n^{\Omega(1)}}$. ◀

6 Separation of Resolution with and without shift

In this section, it is shown that, in some cases, Shift-Resolution can be exponentially more succinct than classical proof systems without shifts. This is proved by presenting a certain false formula, which has a small refutation in Shift-Resolution, whereas in classical proof systems, it requires exponential-size refutations.

For a constant $n \geqslant 1$, the formula Ψ_n asserts the existence of an infinite string of the form $\dots\$w_{-1}\$w_0\$w_1\dots$, where each w_i is an n-digit binary notation of a certain natural number, and every subsequent number in the list is greater by 1 than the previous number. For every number $i \in \{0, \dots, 2^n - 1\}$, let $\text{bin}(i) \in \{0,1\}^n$ be its n-bit binary representation. The longest finite string, on which this formula is true, is $\$\text{bin}(0)\$\text{bin}(1)\$\dots\$\text{bin}(2^n-1)\$$, but for any longer string, in particular for any infinite string, the counter eventually overflows and the formula becomes false. In view of Lemma 1, this formula contains a finite set of contradictory clauses, and hence is subject to classical proof methods.

The construction of the formula is based on the encoding of digits and separators given in Section 5. In particular, the formula $\text{Shifts}(W_n)$ ensuring that the infinite string is of the form $(\$\{\widetilde{0},\widetilde{1}\}^n)^\infty$, where $\$ = 0100$, $\widetilde{0} = 0110$ and $\widetilde{1} = 0111$, is used again, and so is the clause $D_\$ = y_1 \vee \neg y_2 \vee y_3 \vee y_4$ that identifies a separator (\$) beginning at y_1.

With the syntactic structure defined by the formula W_n, the desired counter is implemented by a CNF formula $Step^n_k(x_1, x_2, \dots, x_n; y_1, y_2, \dots, y_n)$, with $n \geqslant 1$ and $k \in \{0, 1, 2, \dots, n-1\}$, which is true if and only if the binary number $(x_1x_2 \dots x_n)_2$ is greater than $(y_1y_2 \dots y_n)_2$ exactly by 2^k. There is a formula with this property that contains $\Theta(n)$ clauses of constant size.

Given two propositions $Step^n_k$ about adding 2^k, one asserting that $x + 2^k = y$ and the other that $y + 2^k = z$, one can infer from them that $x + 2^{k+1} = z$, that is, a proposition using the formula $Step^n_{k+1}$. The next lemma formalizes this intuition, and shows that this inference can be carried out using resolutions.

▶ **Lemma 18.** *For any $n \geqslant 1$ and $k \in \{0, 1, 2, \dots, n-2\}$, given all clauses of the CNF formula $Step^n_k(x_1, x_2, \dots, x_n; y_1, y_2, \dots, y_n) \wedge Step^n_k(y_1, y_2, \dots, y_n; z_1, z_2, \dots, z_n)$, all clauses of $Step^n_{k+1}(x_1, x_2, \dots, x_n; z_1, z_2, \dots, z_n)$ can be derived using $O(n)$ resolutions.*

For every CNF formula $\varphi = C_1 \wedge \dots \wedge C_k$ and for every clause D, the CNF formula obtained from φ by adding all literals from D into every clause is denoted by $D \vee \varphi = (D \vee C_1) \wedge \dots \wedge (D \vee C_k)$.

Furthermore, denote by V_n a CNF formula containing the following clauses which assert that after the current separator (\$), there is another one $4n$ symbols later: $D_\$ \vee \neg x_{4n+5}$, $D_\$ \vee x_{4n+6}$, $D_\$ \vee \neg x_{4n+7}$ and $D_\$ \vee \neg x_{4n+8}$. These conditions actually follow from W_n, but it is more convenient to add them than to derive them using Resolution.

In this notation, the formula separating classical proof systems from Shift-Resolution is constructed as follows.

▶ **Theorem 19.** *For every classical proof system Π, every Π-refutation of the following formula is of size $\Omega(2^n)$.*

$$\Psi_n = \text{Shifts}\big(W_n \wedge \big(D_\$ \vee Step^n_0(x_8, x_{12}, \dots, x_{4n+4}; x_{4n+12}, x_{4n+16}, \dots, x_{8n+8})\big) \wedge V_n \wedge (D_\$ \vee \neg x_8)\big)$$

At the same time, there exists a Shift-Resolution refutation of Ψ_n of size $\text{poly}(n)$.

The first part of Ψ_n is W_n, which enforces the syntactic structure of the string. The second part $(D_\$ \vee Step^n_0(x_8, x_{12}, \dots, x_{4n+4}; x_{4n+12}, x_{4n+16}, \dots, x_{8n+8})$ states that any two subsequent values of the counter differ by 1. The last part $(D_\$ \vee \neg x_8)$, requires the highest digit of the counter to be 0. The formula Ψ_n is unsatisfiable, because, after a series of incrementations, the highest digit shall eventually become 1.

Sketch of a proof. The lower bound on the size of Π-refutations of Ψ_n is based on the fact that every such refutation must use more than $\frac{1}{3}2^{n-2}$ clauses of this formula. This is proved by showing that the conjunction of any $\frac{1}{3}2^{n-2}$ clauses of Ψ_n is satisfiable.

The key element of a small Shift-Resolution refutation of Ψ_n is the use of Lemma 18. The formula contains a clause about incrementing the counter by 1; by Lemma 18, it can be shifted, and two such clauses resolved, to obtain a clause about incrementing by 2. The latter clause can be again shifted and resolved, resulting in a clause about adding 4, and so on. This gives a proof of an appropriate $Step^n_{n-1}$ formula, in $\Theta(n)$ steps. A contradiction is obtained by resolving that formula with other clauses of Ψ_n. ◀

7 Conclusion

An interesting direction for further research would be to prove a lower bound for any proof system with shift, for which no non-trivial lower bounds are known in the classical case, such as for the Lovász–Schrijver proof system. This task may potentially be easier than proving a lower bound in the classical case, because some instances of shift-CNF encode harder problems, such as PSPACE-complete problems, and therefore proving lower bounds on their proof complexity could actually be less difficult.

Deciding Semantic Finiteness of Pushdown Processes and First-Order Grammars w.r.t. Bisimulation Equivalence

Petr Jančar

Dept. of Computer Science, FEI, Technical University Ostrava, Czech Republic
petr.jancar@vsb.cz

Abstract

The problem if a given configuration of a pushdown automaton (PDA) is bisimilar with some (unspecified) finite-state process is shown to be decidable. The decidability is proven in the framework of first-order grammars, which are given by finite sets of labelled rules that rewrite roots of first-order terms. The framework is equivalent to PDA where also deterministic popping epsilon-steps are allowed, i.e. to the model for which Sénizergues showed an involved procedure deciding bisimilarity (FOCS 1998). Such a procedure is here used as a black-box part of the algorithm. For deterministic PDA the regularity problem was shown decidable by Valiant (JACM 1975) but the decidability question for nondeterministic PDA, answered positively here, had been open (as indicated, e.g., by Broadbent and Goeller, FSTTCS 2012).

1 Introduction

The question of deciding semantic equivalences of systems, like language equivalence, has been a frequent topic in computer science. A closely related question asks if a given system in a class $\mathcal{C}_1$ has an equivalent in a simpler class $\mathcal{C}_2$. Pushdown automata (PDA) constitute a well-known example. Language equivalence and regularity are undecidable for PDA. In the case of deterministic PDA (DPDA), the decidability and complexity results for regularity (see [13] and the references therein) preceded the famous decidability result for equivalence by Sénizergues [9].

In concurrency theory, logic, verification, and other areas, a finer equivalence, called *bisimulation equivalence* or *bisimilarity*, has emerged as another fundamental behavioural equivalence; on deterministic systems it essentially coincides with language equivalence. An on-line survey of the results which study this equivalence in a specific area of process rewrite systems is maintained by Srba [11].

Among the most involved results in this area is the decidability of bisimilarity for pushdown processes, generated by (nondeterministic) PDA with only deterministic and popping ε-steps; this was shown by Sénizergues [10] who thus generalized his above mentioned result for DPDA. There is no known upper bound on the complexity of this decidable problem. The nonelementary lower bound established in [1] is, in fact, TOWER-hardness in the terminology of [8], and it holds even for real-time PDA, i.e. PDA with no ε-steps. For the above mentioned PDA with deterministic and popping ε-steps the bisimilarity problem is even not primitive recursive, its Ackermann-hardness is shown in [5]. In the deterministic case, the equivalence problem is known to be PTIME-hard, and has a primitive recursive upper bound shown by Stirling [12] (where a finer analysis places the problem in TOWER [5]).

Extrapolating the deterministic case, we might expect that for PDA the "regularity" problem w.r.t. bisimilarity (asking if a given PDA-configuration is bisimilar with a state in a finite-state system) is decidable as well, and that this problem might be easier than the equivalence problem solved in [10]; "only" EXPTIME-hardness is known here (see [7], and [11] for detailed references). Nevertheless, this decidability question has been open so far, as also indicated in [2] (besides [11]).

Contribution of this paper. We show that semantic finiteness of pushdown configurations w.r.t. bisimilarity is decidable. The decidability is proven in the framework of *first-order grammars*, i.e. of finite sets of labelled rules that rewrite roots of first-order terms. The framework is equivalent to PDA where also deterministic and popping ε-steps are allowed, i.e. to the model to which Sénizergues's general decidability proof [10] applies. (A simplified proof directly in the first-order grammar framework is given in [4].) The presented algorithm, answering if a given configuration, i.e. a first-order term in the labelled transition system generated by a first-order grammar, has a bisimilar finite-state system, uses the result of [10] (or of [4]) as a black-box procedure. By [5] we cannot get a primitive recursive upper bound via a black-box use of the decision procedure for bisimilarity.

Semidecidability of the semantic finiteness problem has been long clear, hence it is the existence of finite effectively verifiable witnesses of the negative case that is the crucial point here. Such witnesses are shown by considering "limits" of repeated substitutions, resulting in regular terms (i.e.infinite terms with only finitely many subterms). Some finite paths with "pumpable" segments are shown to be increasing the "equivalence-level" with the respective limit above any bound while never reaching the equivalence class of the limit. The (black-box) procedure deciding equivalence is used to show a verifiable bound on the number of segment-pumpings that allows to confirm the witness property of a path.

A full version of this paper is planned to appear as the second version of the paper at `http://arxiv.org/abs/1305.0516`; it will contain detailed proofs.

2 Basic Notions and Result

In this section we define the basic notions and state the result in the form of a theorem. Some standard definitions are restricted when we do not need the full generality. We finish the section by a note about a transformation of pushdown automata to first-order grammars.

By $\mathbb{N}$ and $\mathbb{N}_+$ we denote the sets of nonnegative integers and of positive integers, respectively. By $[i,j]$ we denote the set $\{i, i{+}1, \dots, j\}$. For a set $\mathcal{A}$, by $\mathcal{A}^*$ we denote the set of finite sequences of elements of $\mathcal{A}$, which are also called *words* (over $\mathcal{A}$). By $|w|$ we denote the *length* of $w \in \mathcal{A}^*$, and by ε the *empty sequence* (hence $|\varepsilon| = 0$). We put $\mathcal{A}^+ = \mathcal{A}^* \smallsetminus \{\varepsilon\}$.

Labelled transition systems. A *labelled transition system*, an *LTS* for short, is a tuple $\mathcal{L} = (\mathcal{S}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$ where $\mathcal{S}$ is a finite or countable set of *states*, Σ is a finite set of *actions* (or *letters*), and $\xrightarrow{a} \subseteq \mathcal{S} \times \mathcal{S}$ is a set of *a-transitions* (for each $a \in \Sigma$). We say that $\mathcal{L}$ is a *deterministic LTS* if for each pair $s \in \mathcal{S}$, $a \in \Sigma$ there is at most one s' such that $s \xrightarrow{a} s'$ (which stands for $(s, s') \in \xrightarrow{a}$). By $s \xrightarrow{w} s'$, where $w = a_1 a_2 \dots a_n \in \Sigma^*$, we denote that there is a *path* $s = s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} s_2 \cdots \xrightarrow{a_n} s_n = s'$; if $s \xrightarrow{w} s'$, then s' is *reachable from* s. By $s \xrightarrow{w}$ we denote that w is *enabled in* s, i.e., $s \xrightarrow{w} s'$ for some s'. If $\mathcal{L}$ is deterministic, then $s \xrightarrow{w} s'$ or $s \xrightarrow{w}$ denotes a unique path.

Bisimilarity. Given $\mathcal{L} = (\mathcal{S}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$, we say that a *set* $\mathcal{B} \subseteq \mathcal{S} \times \mathcal{S}$ *covers* $(s,t) \in \mathcal{S} \times \mathcal{S}$ if for any $s \xrightarrow{a} s'$ there is $t \xrightarrow{a} t'$ such that $(s',t') \in \mathcal{B}$, and for any $t \xrightarrow{a} t'$ there is $s \xrightarrow{a} s'$ such that $(s',t') \in \mathcal{B}$. For $\mathcal{B}, \mathcal{B}' \subseteq \mathcal{S} \times \mathcal{S}$ we say that $\mathcal{B}'$ *covers* $\mathcal{B}$ if $\mathcal{B}'$ covers each $(s,t) \in \mathcal{B}$. A set $\mathcal{B} \subseteq \mathcal{S} \times \mathcal{S}$ is a *bisimulation* if $\mathcal{B}$ covers $\mathcal{B}$. States $s,t \in \mathcal{S}$ are *bisimilar*, written $s \sim t$, if there is a bisimulation $\mathcal{B}$ containing (s,t). A standard fact is that $\sim \subseteq \mathcal{S} \times \mathcal{S}$ is an equivalence relation, and it is the largest bisimulation, the union of all bisimulations.

Semantic finiteness. Given $\mathcal{L} = (\mathcal{S}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$, we say that $s_0 \in \mathcal{S}$ is *finite up to bisimilarity*, or *bisim-finite* for short, if there is some state f in some finite LTS such that $s_0 \sim f$; otherwise s_0 is *infinite up to bisimilarity*, or *bisim-infinite*. (When comparing states from different LTSs, we implicitly refer to the disjoint union of these LTSs.)

First-order terms, regular terms, finite graph presentations. We will consider LTSs in which states are first-order regular terms. They are built from *variables* from a fixed countable set $\textsc{Var} = \{x_1, x_2, x_3, \dots\}$ and from *function symbols*, also called *(ranked) nonterminals*, from some specified finite set $\mathcal{N}$; each $A \in \mathcal{N}$ has $arity(A) \in \mathbb{N}$. (An example of a finite term is $C(D(x_3, B), x_2)$, where the arities of B, C, D are $0, 2, 2$, respectively.)

Transitions will be determined by a finite set of (schematic) *root-rewriting* rules (that can be exemplified by $A(x_1, x_2, x_3) \xrightarrow{b} C(D(x_3, B), x_2)$, where x_1, x_2, x_3 serve as the "place-holders" for the depth-1 subterms of a term with the root A that might be rewritten by performing action b). We will now formalize this, making also some conventions on the use of (finite and infinite) terms and substitutions.

We identify terms with their syntactic trees. Thus a *term over* $\mathcal{N}$ is (viewed as) a rooted, ordered, finite or infinite tree where each node has a label from $\mathcal{N} \cup \textsc{Var}$; if the label of a node is $x_i \in \textsc{Var}$, then the node has no successors, and if the label is $A \in \mathcal{N}$, then it has m (immediate) successor-nodes where $m = arity(A)$. A subtree of a term E is also called a *subterm* of E. We make no difference between isomorphic (sub)trees, and thus a subterm can have more (maybe infinitely many) *occurrences* in E. Each *subterm-occurrence* has its (nesting) *depth in* E, which is its (naturally defined) distance from the root of E. We also use the standard notation for terms: we write $E = x_i$ or $E = A(G_1, \dots, G_m)$ with the obvious meaning; in the latter case we have $\textsc{root}(E) = A \in \mathcal{N}$, $m = arity(A)$, and $G_1, \dots, G_m$ are the ordered occurrences of depth-1 subterms of E.

A *term* is *finite* if the respective tree is finite. A (possibly infinite) *term* is *regular* if it has only finitely many subterms (though the subterms may be infinite and can have infinitely many occurrences). We note that any regular term has at least one *finite-graph presentation*, i.e. a finite directed graph, with a designated root, where each node has a label from $\mathcal{N} \cup \textsc{Var}$; if the label of a node is $x_i \in \textsc{Var}$, then the node has no outgoing arcs, if the label is $A \in \mathcal{N}$, then it has m ordered outgoing arcs where $m = arity(A)$. The standard tree-unfolding of the graph is the respective term, which is infinite if there are cycles in the graph. The nodes in the least presentation of E are bijectively mapped onto (the roots of) the subterms of E.

In what follows, by a "term" we mean a "regular term" unless the context makes clear that the term is finite. (We do not consider non-regular terms.) We reserve symbols A, B, C, D to range over nonterminals, and E, F, G, H to range over (regular) terms.

Substitutions, associative composition, limits of infinite compositions. By $\textsc{Terms}_{\mathcal{N}}$ we denote the set of all (regular) terms over a set $\mathcal{N}$ of (ranked) nonterminals (and over the set $\textsc{Var}$ of variables). A *substitution* σ is a mapping $\sigma : \textsc{Var} \to \textsc{Terms}_{\mathcal{N}}$ whose *support* $\textsc{supp}(\sigma) = \{x_i \mid \sigma(x_i) \neq x_i\}$ is *finite*; we reserve the symbol σ for substitutions. By *applying* *a substitution* σ to a term E we get the term $E\sigma$ that arises from E by replacing each occurrence of x_i with $\sigma(x_i)$; given graph presentations, in the graph of E we just redirect each arc leading to x_i towards the root of $\sigma(x_i)$ (which includes the special "root-designating arc" when $E = x_i$). Hence $E = x_i$ implies $E\sigma = x_i\,\sigma = \sigma(x_i)$.

The natural *composition of substitutions*, where $\sigma = \sigma_1\sigma_2$ is defined by $x_i\sigma = (x_i\sigma_1)\sigma_2$, can be easily verified to be associative. We thus write simply $E\sigma_1\sigma_2$ when meaning $(E\sigma_1)\sigma_2$ or $E(\sigma_1\sigma_2)$. We let σ^0 be the empty-support substitution, and we put $\sigma^{i+1} = \sigma\sigma^i$. If σ is *guarded*, which means that $x_i\sigma = x_j$ implies $i = j$ (in other words, for each $x_i \in \textsc{supp}(\sigma)$ the root of $E_i = x_i\sigma$ is a nonterminal "guarding" the occurrences of variables in E_i), then even the limit σ^ω is well-defined: "operationally", to get graph presentations of terms $x_i\sigma^\omega$ from graph presentations of $x_i\sigma$, for all $x_i \in \textsc{supp}(\sigma)$, we redirect any arc leading to x_j, where $x_j \in \textsc{supp}(\sigma)$, towards the root of (the presentation of) $x_j\sigma$. We note that no variable $x_i \in \textsc{supp}(\sigma)$ occurs in any term $E\sigma^\omega$, for any guarded substitution σ; such variables "disappear" by applying σ^ω. (Hence $E\sigma^\omega$ can only contain variables x_i for which $x_i\sigma = x_i$.)

First-order grammars. A *first-order grammar*, or just a *grammar* for short, is a tuple $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$ where $\mathcal{N} = \{A_1, A_2, \dots\}$ is a finite set of ranked *nonterminals*, viewed as function symbols with arities, $\Sigma = \{a_1, a_2, \dots\}$ is a finite set of *actions* (or letters), and $\mathcal{R} = \{r_1, r_2, \dots\}$ is a finite set of *rules* of the form

$$A(x_1, x_2, \dots, x_m) \xrightarrow{a} E \tag{1}$$

where $A \in \mathcal{N}$, $arity(A) = m$, $a \in \Sigma$, and E is a *finite* term over $\mathcal{N}$ in which each occurring variable is from the set $\{x_1, x_2, \dots, x_m\}$. We can exemplify the rules by $A(x_1, x_2, x_3) \xrightarrow{b} C(D(x_3, B), x_2)$, $A(x_1, x_2, x_3) \xrightarrow{b} x_2$, $D(x_1, x_2) \xrightarrow{a} A(D(x_2, x_2), x_1, B)$; here the arities of A, B, C, D are $3, 0, 2, 2$, respectively.

A rule $A(x_1, x_2, \dots, x_m) \xrightarrow{a} E$ will generate a-transitions $A(x_1, x_2, \dots, x_m)\sigma \xrightarrow{a} E\sigma$ for all substitutions σ. The concrete rule $A(x_1, x_2, x_3) \xrightarrow{b} C(D(x_3, B), x_2)$ generates the transitions like $A(x_1, x_2, x_3) \xrightarrow{b} C(D(x_3, B), x_2)$ and $A(x_5, x_5, x_2) \xrightarrow{b} C(D(x_2, B), x_5)$, and more generally $A(G_1, G_2, G_3) \xrightarrow{b} C(D(G_3, B), G_2)$ for any (regular) terms G_1, G_2, G_3. The rule $A(x_1, x_2, x_3) \xrightarrow{b} x_2$ generates $A(G_1, G_2, G_3) \xrightarrow{b} G_2$. We now give a more formal definition.

LTSs generated by grammars. Given $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$, by $\mathcal{L}^{\text{R}}_{\mathcal{G}}$ we denote the (*rule-based*) LTS $\mathcal{L}^{\text{R}}_{\mathcal{G}} = (\textsc{Terms}_{\mathcal{N}}, \mathcal{R}, (\xrightarrow{r})_{r\in\mathcal{R}})$ where each rule r of the form $A(x_1, x_2, \dots, x_m) \xrightarrow{a} E$ induces transitions $A(x_1, \dots, x_m)\sigma \xrightarrow{r} E\sigma$ for any substitution σ (also unguarded; we can have $x_i\sigma = x_j$ for $i \neq j$). Thus the rule $A(x_1, \dots, x_m) \xrightarrow{r} E$ is itself a transition, using σ with $\textsc{supp}(\sigma) = \emptyset$.
The LTS $\mathcal{L}^{\text{R}}_{\mathcal{G}}$ is deterministic, since for each F and r there is at most one H such that $F \xrightarrow{r} H$. We note that *variables* are *dead* (have no outgoing transitions), and *transitions cannot add variables*, i.e., $F \xrightarrow{w} H$ implies that each variable occurring in H also occurs in F (but not necessarily vice versa).

Since the rhs (right-hand sides) E in the rules (1) are finite, all terms reachable from a finite term are finite. (It is convenient to have the rhs finite while including regular terms into our LTSs; the other options are in principle equivalent.)

The deterministic rule-based LTS $\mathcal{L}^{\text{R}}_{\mathcal{G}}$ is helpful technically, but we are primarily interested in the (generally nondeterministic) *action-based* LTS $\mathcal{L}^{\text{A}}_{\mathcal{G}} = (\textsc{Terms}_{\mathcal{N}}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$ where each rule $A(x_1,\ldots,x_m) \xrightarrow{a} E$ induces the transitions $A(x_1,\ldots,x_m)\sigma \xrightarrow{a} E\sigma$ for all substitutions σ.

Given a grammar $\mathcal{G} = (\mathcal{N},\Sigma,\mathcal{R})$, two *terms* from $\textsc{Terms}_{\mathcal{N}}$ are *bisimilar* if they are bisimilar as states in the action-based LTS $\mathcal{L}^{\mathrm{A}}_{\mathcal{G}}$. By our definitions all variables are bisimilar, since they are dead terms. The variables serve us primarily as "place-holders for subterm-occurrences" in terms (that might themselves be variable-free); such a use of variables has been already exemplified in the rules (1).

Main result, and its relation to pushdown automata. We now state the theorem, to be proven in the next section, and we mention why the result also applies to pushdown automata (PDA) with deterministic popping ε-steps.

▶ **Theorem 1.** *There is an algorithm that, given a grammar $\mathcal{G} = (\mathcal{N},\Sigma,\mathcal{R})$ and (a finite presentation of) $E_0 \in \textsc{Terms}(\mathcal{N})$, decides if E_0 is bisim-finite (i.e., if $E_0 \sim f$ for a state f in some finite LTS).*

A transformation of (nondeterministic) PDA in which deterministic popping ε-steps are allowed to first-order grammars (with no ε-steps) is recalled in the full arxiv-version. This makes clear that the semantic finiteness of PDA with deterministic popping ε-steps (w.r.t. bisimilarity) is also decidable. In fact, the problems are interreducible; the close relationship between (D)PDA and first-order schemes has been long known (see, e.g., [3]). The proof of Theorem 1 presented here uses the fact that bisimilarity of first-order grammars is decidable; this was shown for the above mentioned PDA model by Sénizergues [10], and a direct proof in the first-order-term framework was presented in [4]. We note that for PDA where popping ε-steps can be in conflict with "visible" steps bisimilarity is already undecidable [6]; hence the proof presented here does not yield the decidability of semantic finiteness in this more general model.

3 Proof of Theorem 1

3.1 Computability of eq-levels, and semidecidability of bisim-finiteness

We will note that the semidecidability of bisim-finiteness is clear, but we first recall the computability of eq-levels, which is one crucial ingredient in our proof of semidecidability of bisim-infiniteness.

Stratified equivalence, and eq-levels. Assuming an LTS $\mathcal{L} = (\mathcal{S},\Sigma,(\xrightarrow{a})_{a\in\Sigma})$, we put $\sim_0 = \mathcal{S}\times\mathcal{S}$, and define $\sim_{k+1} \subseteq \mathcal{S}\times\mathcal{S}$ (for $k \in \mathbb{N}$) as the set of pairs covered by $\sim_k$. (Hence $s \sim_{k+1} t$ iff for any $s \xrightarrow{a} s'$ there is $t \xrightarrow{a} t'$ such that $s' \sim_k t'$ and for any $t \xrightarrow{a} t'$ there is $s \xrightarrow{a} s'$ such that $s' \sim_k t'$.)

We easily verify that $\sim_k$ are equivalence relations, and that $\sim_0 \supseteq \sim_1 \supseteq \sim_2 \supseteq \cdots\cdots \supseteq \sim$. For the (first infinite) ordinal ω we put $s \sim_\omega t$ if $s \sim_k t$ for all $k \in \mathbb{N}$; hence $\sim_\omega = \bigcap_{k\in\mathbb{N}} \sim_k$. It is standard (and can be easily checked) that $\bigcap_{k\in\mathbb{N}} \sim_k$ is a bisimulation in image-finite LTSs, and thus $\sim = \bigcap_{k\in\mathbb{N}} \sim_k = \sim_\omega$. We recall that $\mathcal{L}$ is *image-finite* if the set $\{s' \mid s \xrightarrow{a} s'\}$ is finite for each pair $s \in \mathcal{S}$, $a \in \Sigma$. Our grammar-generated LTSs $\mathcal{L}^{\mathrm{A}}_{\mathcal{G}}$ are obviously image-finite (while $\mathcal{L}^{\mathrm{R}}_{\mathcal{G}}$ are even deterministic); we thus further assume image-finiteness.

We attach the *equivalence level* (eq-level) $\textsc{EqLv}(s,t) = \max\{k \in \mathbb{N}\cup\{\omega\} \mid s \sim_k t\}$ to each pair of states.

Eq-levels are computable for first-order grammars. We now state an important lemma that follows easily from the involved decidability proof in [10] (and a transformation to first-order grammars); as already mentioned, a proof given directly for the first-order grammars was presented in [4]. (This is surely a *fundamental theorem* in general, the name *lemma* has been chosen here to reflect that it is a prerequisite for the only theorem proven in this paper.)

▶ **Lemma 2.** *There is an algorithm that, given $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$ and $E_0, F_0 \in \textsc{Terms}(\mathcal{N})$, computes $\textsc{EqLv}(E_0, F_0)$ in $\mathcal{L}^{\mathsf{A}}_{\mathcal{G}}$ (and thus also decides if $E_0 \sim F_0$).*

Proof. For each fixed $k \in \mathbb{N}$ it is decidable if $E_0 \sim_k F_0$, as can be shown by a straightforward induction on k. The question $E_0 \overset{?}{\sim} F_0$, i.e. $E_0 \overset{?}{\sim}_\omega F_0$, can be decided by [10] (and [4]). ◀

Semidecidability of bisim-finiteness. Given $\mathcal{G}$ and E_0, we can systematically generate all finite LTSs, presenting them by first-order grammars with nullary nonterminals (which then coincide with states); for each state f of each generated system we can check if $E_0 \sim f$ by Lemma 2. In fact, Lemma 2 is not crucial here, since decidability of $E_0 \sim f$ can be shown in a much simpler way (see, e.g., [7]).

3.2 Semidecidability of bisim-infiniteness.

In Section 3.2.1 we note a few simple general facts on bisim-infiniteness, and also note the obvious compositionality (congruence properties) of bisimulation equivalence in our framework of first-order terms. In Section 3.2.2 we describe some finite structures that are candidates for witnessing bisim-infiniteness of a given term, and show an algorithm checking if a candidate is indeed a witness. In Section 3.2.3 we then show that each bisim-infinite term has a witness. Together this yields a proof of Theorem 1.

3.2.1 Some facts on bisim-infiniteness, and compositionality

Bisimilarity quotient. Given an LTS $\mathcal{L} = (\mathcal{S}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$, the *quotient-LTS* $\mathcal{L}_\sim$ is the tuple $(\{\,[s]; s \in \mathcal{S}\,\}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$ where $[s] = \{s' \mid s' \sim s\}$, and $[s] \xrightarrow{a} [t]$ if $s' \xrightarrow{a} t'$ for some $s' \in [s]$ and $t' \in [t]$; in fact, $[s] \xrightarrow{a} [t]$ implies that for each $s' \in [s]$ there is $t' \in [t]$ such that $s' \xrightarrow{a} t'$. We have $s \sim [s]$, since $\{(s, [s]) \mid s \in \mathcal{S}\}$ is a bisimulation (in the union of $\mathcal{L}$ and $\mathcal{L}_\sim$). We refer to the states of $\mathcal{L}_\sim$ as to the *bisim-classes* (of $\mathcal{L}$).

A sufficient condition for bisim-infiniteness. We recall that $s_0 \in \mathcal{S}$ is *bisim-finite* if there is some state f in a finite LTS such that $s_0 \sim f$; otherwise s_0 is *bisim-infinite*. We observe that s_0 is bisim-infinite in $\mathcal{L}$ iff the reachability set of $[s_0]$ in $\mathcal{L}_\sim$, i.e. the set of states reachable from $[s_0]$ in $\mathcal{L}_\sim$, is infinite. The LTSs generated by first-order grammars are *finitely branching* (i.e., the set $\{s' \mid s \xrightarrow{a} s'$ for some $a\}$ is finite for each $s \in \mathcal{S}$), and we also use (one implication in) the following simple fact:

▶ **Proposition 3.** *A state s_0 of a finitely branching LTS is bisim-infinite iff there is an infinite path $s_0 \xrightarrow{a_1} s_1 \xrightarrow{a_2} s_2 \xrightarrow{a_3} \cdots$ where $s_i \not\sim s_j$ for all $i \neq j$.*

To demonstrate that s_0 is bisim-infinite, it suffices to show that its reachability set contains states with arbitrarily large *finite* eq-levels w.r.t. a "test state" t. The sufficiency of this condition is based on the simple fact that $s \sim s'$ implies $\textsc{EqLv}(s, t) = \textsc{EqLv}(s', t)$. More formally:

▶ **Proposition 4.** *Given $\mathcal{L} = (\mathcal{S}, \Sigma, (\xrightarrow{a})_{a\in\Sigma})$ and states s_0, t, if for every $e \in \mathbb{N}$ there is s' that is reachable from s_0 and satisfies $e < \textsc{EqLv}(s', t) < \omega$, then s_0 is bisim-infinite.*

Eq-levels w.r.t. a test set in a bounded region. Our final general observation (tailored to a later use) is also straightforward: if two states are bisimilar, then the states in their equally bounded reachability regions must yield the same eq-levels when compared with states from a fixed (test) set. We formalize this observation as follows.

For any $s \in \mathcal{S}$ and $d \in \mathbb{N}$ (a distance, or a "radius") we put

$$\textsc{Region}(s,d) = \{s' \mid s \xrightarrow{w} s' \text{ for some } w \in \Sigma^* \text{ where } |w| \leq d\}.$$

For any $s \in \mathcal{S}$, $d \in \mathbb{N}$, and $\mathcal{T} \subseteq \mathcal{S}$ (a test set), we define the following subset of $\mathbb{N}$ (*finite* TestEqLevels):

$$\mathrm{TEL}(s,d,\mathcal{T}) = \{e \in \mathbb{N} \mid e = \textsc{EqLv}(s',t) \text{ for some } s' \in \textsc{Region}(s,d) \text{ and some } t \in \mathcal{T}\}.$$

▶ **Proposition 5.** *If* $\mathrm{TEL}(s,d,\mathcal{T}) \neq \mathrm{TEL}(s',d,\mathcal{T})$ *then* $s \not\sim s'$.

Compositionality of the states of the grammar-generated LTSs. Regarding the congruence properties, in principle it suffices for us to observe that if in a term E we replace a subterm F with F' such that $F' \sim F$ then the resulting term E' satisfies $E' \sim E$ (replacing a subterm with an equivalent one does not change the bisim-class). Hence $A(G_1,\dots,G_m) \not\sim A(G'_1,\dots,G'_m)$ implies that $G_i \not\sim G'_i$ for some $i \in [1,m]$. (This is surely not specific to bisimilarity.) Formally, we put $\sigma \sim \sigma'$ if $x_i\sigma \sim x_i\sigma'$ for each x_i, and we note:

▶ **Proposition 6.** *If* $\sigma \sim \sigma'$*, then* $E\sigma \sim E\sigma'$*.*
(Hence $E\sigma \not\sim E\sigma'$ *implies that* $x_i\sigma \not\sim x_i\sigma'$ *for some* x_i *occurring in* E*.)*

Conventions. We further consider only the *normalized* grammars $\mathcal{G} = (\mathcal{N},\Sigma,\mathcal{R})$, i.e. those satisfying the following condition: for any $A(x_1,\dots,x_m)$ and any $i \in [1,m]$ there is a word w such that $A(x_1,\dots,x_m) \xrightarrow{w} x_i$; hence for any E it is possible to "sink" to any of its subterm-occurrences by applying the grammar-rules. Such a normalization can be efficiently achieved by harmless modifications of the nonterminal arities and of the rules in $\mathcal{R}$, while the LTS $\mathcal{L}^{\mathrm{A}}_{\mathcal{G}}$ remains the same up to isomorphism.

For convenience, in our notation we use m as the arity of all nonterminals in the considered grammar, though formally the *maximum* arity is meant. We will thus harmlessly write $A(G_1,\dots,G_m)$ instead of $A(G_1,\dots,G_{m_A})$ where $m_A = arity(A)$. (In fact, such uniformity can be achieved while keeping the above normalization condition, when a slight problem with arity 0 is handled; but this is not necessary for us to discuss.)

From now on, we view the expressions like $G \xrightarrow{w} H$ as referring to the deterministic LTS $\mathcal{L}^{\mathrm{R}}_{\mathcal{G}}$ (hence $w \in \mathcal{R}^*$), though $\sim_k$, $\sim$, and the eq-levels refer solely to (the action-based LTS) $\mathcal{L}^{\mathrm{A}}_{\mathcal{G}}$.

3.2.2 Simple witnesses of bisim-infiniteness

We fix a grammar $\mathcal{G} = (\mathcal{N},\Sigma,\mathcal{R})$. Before defining the candidates for witnesses of bisim-infiniteness, we discuss some building segments of ("non-sinking") paths in the LTS $\mathcal{L}^{\mathrm{R}}_{\mathcal{G}}$.

Stairs, direct stairs, simple stairs, stairs eligible for "pumping". A nonempty sequence of rules $w = r_1r_2\dots r_\ell \in \mathcal{R}^+$ is a *stair* if we have $A(x_1,\dots,x_m) \xrightarrow{w} F$ where the rule r_1 is of the form $A(x_1,\dots,x_m) \xrightarrow{a} E$, and F has a nonterminal-root (hence F is not a variable x_i, i.e., the path $A(x_1,\dots,x_m) \xrightarrow{w} F$ does not "sink"); such w is a *direct stair* if there is no v such that $|v| < |w|$ and $A(x_1,\dots,x_m) \xrightarrow{v} F$. If (the above) w is a direct stair and F is a subterm of E (the right-hand side of r_1), then w is a *simple stair.* A *stair* w has the *type* (A, B) ("from A to B") if $A(x_1, \dots, x_m) \xrightarrow{w} F$ where $\textsc{root}(F) = B$.

(E.g., the sequence r_1r_2 of rules used in the path $A(G_1, G_2, G_3) \xrightarrow{r_1} C(D(G_3, B), G_2) \xrightarrow{r_2} D(G_3, B)$ is a stair, of type (A, D), that might be a simple stair; on the other hand r_2 is no stair. Some simple stairs can be of the form $A(x_1, \dots, x_m) \xrightarrow{w} A'(x_{i_1}, \dots, x_{i_m})$, where $\{i_1, \dots, i_m\} \subseteq \{1, \dots, m\}$; we might even have $A = A'$ but in this case $(x_1, \dots, x_m) \neq (x_{i_1}, \dots, x_{i_m})$ since $A(x_1, \dots, x_m) \xrightarrow{w} A(x_1, \dots, x_m)$ is no direct stair.)

It is easy to observe that any direct stair w is a sequence of compatible simple stairs, i.e., $w = w_1w_2 \dots w_n$ where w_i is a simple stair of type (A_{i-1}, A_i), for each $i \in [1, n]$; we thus have $A_0(x_1, \dots, x_m) \xrightarrow{w_1} A_1(x_1, \dots, x_m)\sigma_1 \xrightarrow{w_2} A_2(x_1, \dots, x_m)\sigma_2\sigma_1 \xrightarrow{w_3} \cdots$ for the respective (not necessarily guarded) substitutions σ_i.

A *stair* w where $A(x_1, \dots, x_m) \xrightarrow{w} A(E_1, \dots, E_m)$ is *eligible* (for "pumping") if the set of "root-sticks" $R = \{x_i \mid E_j = x_i \text{ for some } j \in [1, m]\}$ is equal to $\{x_i \mid i \in [1, m], E_i = x_i\}$.

(E.g., the stair $A(x_1, x_2, x_3, x_4) \xrightarrow{w} A(x_1, B(x_2, x_2, x_4, x_1), x_3, x_3)$ is eligible, with $R = \{x_1, x_3\}$. The stair $A(x_1, x_2, x_3, x_4) \xrightarrow{v} A(x_2, B(x_2, x_2, x_4, x_1), x_3, x_3)$ is not eligible but the respective "double" stair $A(x_1, x_2, x_3, x_4) \xrightarrow{vv} A(B(x_2, x_2, x_4, x_1), B(\dots), x_3, x_3)$ is eligible. In particular, if in $A(x_1, \dots, x_m) \xrightarrow{w} A(E_1, \dots, E_m)$ all E_j have nonterminal-roots, then w is eligible, with $R = \emptyset$.)

An important fact is that for any eligible stair w, where $A(x_1, \dots, x_m) \xrightarrow{w} A(x_1, \dots, x_m)\sigma$, we can define the terms $G_{(w,z)}$ for all $z \in \mathbb{N} \cup \{\omega\}$ by putting

$$A(x_1, \dots, x_m) \xrightarrow{w^z} A(x_1, \dots, x_m)\sigma^z = G_{(w,z)}$$

which is well defined also for $z = \omega$. (Though σ might be not guarded, we have that $x_j\sigma = x_i$ for $i \neq j$ implies $x_i\sigma = x_i$ due to the eligibility and thus $x_j\sigma^\omega = x_i$.)

Candidates for simple witnesses of bisim-infiniteness. Given a grammar $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$ and a term E_0, by a *candidate for a simple witness* (of bisim-infiniteness of E_0), or by a *candidate* for short, we mean a pair (u, w) where $u \in \mathcal{R}^*$, $w \in \mathcal{R}^+$, $E_0 \xrightarrow{uw}$, and w is an eligible stair, of the form $A(x_1, \dots, x_m) \xrightarrow{w} A(x_1, \dots, x_m)\sigma$; we thus have

$$E_0 \xrightarrow{u} A(x_1, \dots, x_m)\sigma_0 \xrightarrow{w} G_{(w,1)}\sigma_0 \xrightarrow{w} G_{(w,2)}\sigma_0 \xrightarrow{w} G_{(w,3)}\sigma_0 \xrightarrow{w} \cdots$$

for the respective substitution σ_0. We have $G_{(w,j)} = A(x_1, \dots, x_m)\sigma^j$, and we denote the term $G_{(w,\omega)} = A(x_1, \dots, x_m)\sigma^\omega$ also by $\textsc{Lim}$.

We now formalize the simple observation that the terms $G_{(w,k)}\sigma_0$ with increasing $k \in \mathbb{N}$ "approach" the term $\textsc{Lim}\,\sigma_0$ syntactically, and thus also semantically.

Top-tails presentations. Given a term G and (depth) $d \in \mathbb{N}$, let $\textsc{nod}_1, \textsc{nod}_2, \dots, \textsc{nod}_n$ ($n \geq 0$) be the ordered nodes of (the syntactic tree of) G in depth d (if there are some); let $F_1, F_2, \dots, F_n$ be the (occurrences of) subterms of G rooted in $\textsc{nod}_1, \textsc{nod}_2, \dots, \textsc{nod}_n$.

- By $\textsc{Top}_d(G)$ we denote the term that coincides with G up to depth $d-1$ while its ordered nodes in depth d are (leaves) labelled with $x_1, x_2, \dots, x_n$, respectively; here we assume that no x_i, $i \in [1, n]$, occurs in G in the depths less than d.
- By $\textsc{tails}_d(G)$ we mean the substitution defined by $x_i\, \textsc{tails}_d(G) = F_i$ for $i \in [1, n]$.

We have $G = (\textsc{Top}_d(G))\sigma$ where $\sigma = \textsc{tails}_d(G)$. In particular, if $G = A(F_1, \dots, F_m)$, then $G = (\textsc{Top}_1(G))\textsc{tails}_1(G) = A(x_1, \dots, x_m)\sigma$ where $x_i\sigma = F_i$.

If some x_i occur in G in the depths less than d, then we define $\textsc{Top}_d(G)$, $\textsc{tails}_d(G)$ by introducing the variables (in the role of place-holders) other than such x_i. In the following example we highlight this by using "another set of variables" y_i.

For $G = A(B(x_3,x_2,x_2),x_2,C(x_1,B(x_2,x_3,x_1),x_1))$ we have

- $\textsc{Top}_2(G) = A(B(y_1,y_2,y_3),x_2,C(y_4,y_5,y_6))$, and
- $\textsc{tails}_2(G) = \{(y_1,x_3),(y_2,x_2),(y_3,x_2),(y_4,x_1),(y_5,B(x_2,x_3,x_1)),(y_6,x_1)\}$.

The next proposition refers to a candidate $E_0 \xrightarrow{u} A(x_1,\dots,x_m)\sigma_0 \xrightarrow{w} A(x_1,\dots,x_m)\sigma\sigma_0$ where we denote $x_i\sigma$ by E_i for $i \in [1,m]$.

▶ **Proposition 7.** *The following conditions hold for all $k \in \mathbb{N}$ and $i \in [1,m]$.*

1. $\textsc{Top}_k(E_i\sigma^k\sigma_0) = \textsc{Top}_k(E_i\sigma^\omega\sigma_0)$, *hence* $\textsc{Top}_k(G_{(w,k)}\sigma_0) = \textsc{Top}_k(\textsc{Lim}\,\sigma_0)$.
2. $E_i\sigma^k\sigma_0 \sim_k E_i\sigma^\omega\sigma_0$ *and thus* $\textsc{EqLv}(G_{(w,k)}\sigma_0, \textsc{Lim}\,\sigma_0) \geq k$.

Checking if a candidate is a simple witness. A candidate $E_0 \xrightarrow{u} A(x_1,\dots,x_m)\sigma_0 \xrightarrow{w}$ is a *simple witness* (of bisim-infiniteness of E_0) if $G_{(w,k)}\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$ for infinitely many $k \in \mathbb{N}$. Since $\textsc{EqLv}(G_{(w,k)}\sigma_0, \textsc{Lim}\,\sigma_0) \geq k$ (Prop. 7(2)), we then have

$$e < \textsc{EqLv}(G_{(w,e+1)}\,\sigma_0, \textsc{Lim}\,\sigma_0) < \omega \text{ for infinitely many } e \in \mathbb{N},$$

and by Prop. 4 we derive that E_0 is bisim-infinite if it has a simple witness.

The existence of an algorithm checking if a candidate is a simple witness follows from the next lemma, if we recall the fundamental fact captured by Lemma 2.

▶ **Lemma 8.** *Given a candidate $E_0 \xrightarrow{u} A(x_1,\dots,x_m)\sigma_0 \xrightarrow{w} A(E_1,\dots,E_m)\sigma_0$, there is a computable number e such that one of the following conditions holds:*

1. $G_{(w,e)}\sigma_0 \sim \textsc{Lim}\,\sigma_0$, *in which case* $G_{(w,k)}\sigma_0 \sim \textsc{Lim}\,\sigma_0$ *for all* $k \geq e$, *or*
2. $G_{(w,e)}\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$, *in which case* $G_{(w,k)}\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$ *for all* $k \geq e$.

(The candidate is a simple witness of bisim-infiniteness of E_0 in the case 2.)

Proof. We restrict our attention to those E_i that "almost always matter" when we apply σ, where $x_i\sigma = E_i$, to the term $A(E_1,\dots,E_m)\sigma^\ell$, for growing $\ell \in \mathbb{N}$. The sets

$$\mathcal{V}_\ell = \{x_i \mid x_i \text{ occurs in } A(E_1,\dots,E_m)\sigma^\ell\}$$

satisfy $\mathcal{V}_{\ell+1} = \{x_j \mid x_j \text{ occurs in } E_i \text{ for some } i \text{ such that } x_i \in \mathcal{V}_\ell\}$, and thus $\{x_1,\dots,x_m\} \supseteq \mathcal{V}_0 \supseteq \mathcal{V}_1 \supseteq \mathcal{V}_2 \supseteq \cdots$. Let ℓ_0 be the smallest such that $\mathcal{V}_{\ell_0} = \mathcal{V}_{\ell_0+1}$ $(= \mathcal{V}_{\ell_0+2} = \cdots)$; hence $\ell_0 \leq m$.

We can compute a number d (the "radius" for the below defined region that will be used in the application of Prop. 5) so that within d transition-steps we can reach any variable $x_i \in \mathcal{V}_{\ell_0}$ from both $A(E_1,\dots,E_m)\sigma^{\ell_0}$ and $A(E_1,\dots,E_m)\sigma^{\ell_0+1}$.

Suppose now that $A(E_1,\dots,E_m)\sigma^k\sigma_0 \not\sim A(E_1,\dots,E_m)\sigma^\omega\sigma_0$ (i.e., $G_{(w,k+1)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$) and $k > \ell_0$; then by compositionality (Prop. 6) we deduce that $x_i\sigma^{k-\ell_0}\sigma_0 \not\sim x_i\sigma^\omega\sigma_0$ for some $x_i \in \mathcal{V}_{\ell_0}$, and also $x_{i'}\sigma^{k-\ell_0-1}\sigma_0 \not\sim x_{i'}\sigma^\omega\sigma_0$ for some $x_{i'} \in \mathcal{V}_{\ell_0}$. In other words,

$$E_i\sigma^{k-\ell_0-1}\sigma_0 \not\sim E_i\sigma^\omega\sigma_0, \text{ and } E_{i'}\sigma^{k-\ell_0-2}\sigma_0 \not\sim E_{i'}\sigma^\omega\sigma_0 \text{ for some } i,i' \text{ such that } x_i, x_{i'} \in \mathcal{V}_{\ell_0}.$$

Since x_i occurs in $A(E_1,\dots,E_m)\sigma^{\ell_0}$ and $x_{i'}$ occurs in $A(E_1,\dots,E_m)\sigma^{\ell_0+1}$, we have that both $E_i\sigma^{k-\ell_0-1}\sigma_0$ and $E_{i'}\sigma^{k-\ell_0-2}\sigma_0$ are in $\textsc{Region}(G_{(w,k+1)}\,\sigma_0, d)$, for the above defined "radius" d.

We would like to deduce that also $G_{(w,k+2)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$, using the fact that $E_i\sigma^{k-\ell_0-1}\sigma_0$ is in $\textsc{Region}(G_{(w,k+2)}\sigma_0, d)$ (though maybe farther than previously but still within the bound d). But this deduction is unsubstantiated in general.

Hence we recall Prop. 5, and compute the maximum $\textsc{Max}_{\text{TEL}}$ in the set $\text{TEL}(\textsc{Lim}\,\sigma_0, d, \mathcal{T})$ where the test set is $\mathcal{T} = \{E_i\sigma^\omega\sigma_0 \mid x_i \in \mathcal{V}_{\ell_0}\}$. (We can compute this set by Lemma 2.) Let

$$e = \textsc{Max}_{\text{TEL}} + m + 3. \text{ Hence } e \geq \textsc{Max}_{\text{TEL}} + \ell_0 + 3.$$

If we return to the above analysis of the case $A(E_1,\dots,E_m)\sigma^k\sigma_0 \not\sim A(E_1,\dots,E_m)\sigma^\omega\sigma_0$, now assuming $k \geq e$, then the fact that $E_i\sigma^{k-\ell_0-1}\sigma_0$ (for which $E_i\sigma^{k-\ell_0-1}\sigma_0 \not\sim E_i\sigma^\omega\sigma_0$) is also present in $\textsc{Region}(G_{(w,k+2)}\,\sigma_0, d)$ indeed testifies that $G_{(w,k+2)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$.

(Since $E_i\sigma^{k-\ell_0-1}\sigma_0 \sim_{k-\ell_0-1} E_i\sigma^\omega\sigma_0$, and $k-\ell_0-1 \geq e-\ell_0-1 > \textsc{Max}_{\mathrm{TEL}}$, the value $\textsc{EqLv}(E_i\sigma^{k-\ell_0-1}\sigma_0, E_i\sigma^\omega\sigma_0)$ is finite but bigger than $\textsc{Max}_{\mathrm{TEL}}$; we thus must have $G_{(w,k+2)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$ by Prop. 5.)

Then $G_{(w,k+2)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$ similarly entails that $G_{(w,k+3)}\,\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$, etc.

To finish a demonstration that the above e proves the claim, we note that $G_{(w,e)}\,\sigma_0 \sim \textsc{Lim}\,\sigma_0$ entails that we have $E_i\sigma^{e-\ell_0-1}\sigma_0 \sim E_i\sigma^\omega\sigma_0$ for all i (where $x_i \in \mathcal{V}_{\ell_0}$), since otherwise the sets $\mathrm{TEL}(G_{(w,e)}\sigma_0, d, \mathcal{T})$ and $\mathrm{TEL}(\textsc{Lim}\,\sigma_0, d, \mathcal{T})$ would differ. Then $G_{(w,k)}\sigma_0 \sim \textsc{Lim}\,\sigma_0$ for all $k \geq e$ by compositionality. ◀

3.2.3 Each bisim-infinite term has a simple witness

Once we show the next lemma, the proof of Theorem 1 will be finished.

▶ **Lemma 9.** *For any grammar $\mathcal{G}$ and any bisim-infinite E_0 there is a simple witness satisfying the condition 2 in Lemma 8 ($G_{(w,e)}\sigma_0 \not\sim \textsc{Lim}\,\sigma_0$ for the respective computable e).*

We prove the lemma in the rest of this section. We assume a given grammar $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$ and a term E_0 that is bisim-infinite.

An infinite simple-stair sequence witnessing bisim-infiniteness. Let us fix an infinite path $E_0 \xrightarrow{r_1} E_1 \xrightarrow{r_2} E_2 \xrightarrow{r_3} \cdots$ in $\mathcal{L}^{\mathrm{R}}_{\mathcal{G}}$ such that $E_i \not\sim E_j$ (in $\mathcal{L}^{\mathrm{A}}_{\mathcal{G}}$) for all $i \neq j$ (recall Prop. 3); this entails that there is *no repeat*, i.e., we have $E_i \neq E_j$ for all $i \neq j$. Hence there must be the least $i_0 \in \mathbb{N}$ such that $r_{i_0+1}r_{i_0+2}\dots r_{i_0+\ell}$ is a stair for each $\ell \in \mathbb{N}$. (This obviously holds even if E_0 is an infinite term, since it has only finitely many subterms due to its regularity.) Moreover, given i_j, there must be the least i_{j+1} such that $i_j < i_{j+1}$ and $r_{i_{j+1}+1}r_{i_{j+1}+2}\dots r_{i_{j+1}+\ell}$ is a stair for each $\ell \in \mathbb{N}$.

For each $j \in \mathbb{N}$ we put $H_j = E_{i_j}$, and we present the suffix of the above path starting with E_{i_0} as

$$H_0 \xrightarrow{w_1} H_1 \xrightarrow{w_2} H_2 \xrightarrow{w_3} \cdots, \text{ denoting } H_j = A_j(x_1,\dots,x_m)\sigma_j\sigma_{j-1}\cdots\sigma_0 \tag{2}$$

where $A_j(x_1,\dots,x_m) \xrightarrow{w_{j+1}} A_{j+1}(x_1,\dots,x_m)\sigma_{j+1}$. We also write $H_j = A_j(x_1,\dots,x_m)\sigma'_j$.

The words w_i are stairs; we can even assume that w_i are direct stairs (i.e., we replace them with the respective direct stairs if they are not direct stairs) while keeping the property that $H_i \not\sim H_j$ for all $i \neq j$. We thus assume that w_i are *direct stairs*, which in our case obviously implies that they are *simple stairs*.

A specific "keep-and-drown task" extracted from the bisim-infinite stair path. Prop. 10 captures a first step in demonstrating the existence of a simple witness induced by the path $H_0 \xrightarrow{w_1} H_1 \xrightarrow{w_2} H_2 \xrightarrow{w_3} \cdots$ (2), related to a fixed grammar $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{R})$.

A *task* T is a tuple $(A, \textsc{Drown}, \textsc{keep})$ where $A \in \mathcal{N}$, $\textsc{Drown} \subseteq \{x_1,\dots,x_m\}$, and $\textsc{keep} \in [1,m]$, $x_{\textsc{keep}} \in \textsc{Drown}$. We put $\textsc{NotCare} = \{x_1,\dots,x_m\} \smallsetminus \textsc{Drown}$.

For a term G, by $G \models (\textsc{Drown}, z)$, for $z \in \mathbb{N} \cup \{\omega\}$, we denote that the depth of each occurrence of $x_i \in \textsc{Drown}$ in G (if there is any) is at least z, which means that x_i does not occur in G when $z = \omega$. By $G \models \textsc{keep}$ we denote that $x_{\textsc{keep}}$ occurs in G, and $G \models (\textsc{Drown}, z) \wedge \textsc{keep}$ denotes that we have $G \models (\textsc{Drown}, z)$ and $G \models \textsc{keep}$.

A *task* $\mathrm{T} = (A, \textsc{Drown}, \textsc{keep})$ is *satisfied for* $k \in \mathbb{N}$, which is denoted by $\models (\mathrm{T}, k)$, if there is $w \in \mathcal{R}^*$ and G such that $A(x_1, \dots, x_m) \xrightarrow{w} G$ and $G \models (\textsc{Drown}, k) \wedge \textsc{keep}$. By $\models (\mathrm{T}, \omega)$ we denote that we have $\models (\mathrm{T}, k)$ for all $k \in \mathbb{N}$.

A technical proof of the next proposition is given in the full arxiv-version.

▶ **Proposition 10.** *There is a task* $\mathrm{T} = (A, \textsc{Drown}, \textsc{keep})$ *and an infinite subsequence* $\textsc{Seq}$ *of the sequence* $0, 1, 2, \dots$ *such that* $\models (\mathrm{T}, \omega)$ *and the following conditions hold in the path (2), where we use the notation* $H_j = A_j(x_1, \dots, x_m)\sigma'_j$*:*
1. $A_j = A$ *for all* $j \in \textsc{Seq}$*;*
2. *for each* $x_i \in \textsc{NotCare}$ *we have* $x_i\sigma'_{j_1} \sim x_i\sigma'_{j_2}$ *for all* $j_1, j_2 \in \textsc{Seq}$*;*
3. *for each* $x_i \in \textsc{Drown}$ *we have* $x_i\sigma'_{j_1} \not\sim x_i\sigma'_{j_2}$ *for any* $j_1 \neq j_2$ *where* $j_1, j_2 \in \textsc{Seq}$.

Witness schemes. For our fixed path $H_0 \xrightarrow{w_1} H_1 \xrightarrow{w_2} H_2 \xrightarrow{w_3} \cdots$ (2) we aim to show that there are a stair u and an eligible stair w such that $H_0 \xrightarrow{u}\xrightarrow{w}$ is a simple witness (of bisim-infiniteness of H_0 and thus also of E_0). We will also have that both u and w are sequences of simple stairs, hence $uw = w_1 w_2 \cdots w_\ell$ where $A_0(x_1, \dots, x_m) \xrightarrow{w_1}\xrightarrow{w_2} \cdots \xrightarrow{w_\ell}$, each w_i is a simple stair, and the sequence $w = w_j w_{j+1} \dots w_\ell$ is *marked as a pumping stair*. It is useful to make the following generalization (of simple witnesses).

A *stair-scheme*, or just a *scheme* for short, is a sequence $W = w_1, w_2, \dots, w_\ell$ of (compatible) simple stairs, where $A(x_1, \dots, x_m) \xrightarrow{w_1}\xrightarrow{w_2} \cdots \xrightarrow{w_\ell}$ for A determined by the first grammar-rule r_1 in w_1, and where any segment $w_i w_{i+1} \dots w_j$ that is an eligible stair might be marked as a *pumping stair*; the pumping stairs can be "nested", one can be contained in another, but no pumping stair can start or end inside another pumping stair.

We use the notation of regular expressions with concatenation and iteration (star) to denote such schemes; an example is $u_1((v_1)^* u_2 (v_2)^*)^* u_3 (v_3)^* u_4 u_5 ((v_5)^* u_6)^*$ (where we have six pumping stairs, namely v_1, v_2, $v_1 u_2 v_2$, v_3, v_5, and $v_5 u_6$).

For a scheme W (like above), by $\textsc{Pump}(W, z)$, where $z \in \mathbb{N} \cup \{\omega\}$, we denote the sequence arising from $w_1 w_2 \dots w_\ell$ by repeating each pumping stair z times. (In our example, $\textsc{Pump}(W, z)$ is $u_1((v_1)^z u_2 (v_2)^z)^z u_3 (v_3)^z u_4 u_5 ((v_5)^z u_6)^z$.) In the case $z = \omega$ we get infinite "words" whose ordinal lengths can be bigger than ω, but since all pumping stairs are eligible, we can soundly define the terms $G_{(W,z)}$ by

$$A(x_1, \dots, x_m) \xrightarrow{\textsc{Pump}(W,z)} G_{(W,z)}; \text{ we also put } \textsc{Lim}_W = G_{(W,\omega)}.$$

We say that a scheme W, where A is the left-hand side nonterminal of the first rule in W, is a ("non-simple") *witness* (of bisim-infiniteness) *for* $A(x_1, \dots, x_m)\sigma$ if $G_{(W,k)}\sigma \not\sim \textsc{Lim}_W\sigma$ for infinitely many $k \in \mathbb{N}$.

It is not difficult to generalize Lemma 8 for schemes (viewed as candidates for witnesses), and to derive the next proposition (as is shown in the full version).

▶ **Proposition 11.** *A term* E_0 *has a simple witness (of bisim-infiniteness) iff there is a term* $H = A(x_1, \dots, x_m)\sigma$ *reachable from* E_0 *for which there is (a scheme* W *that is) a witness.*

It suffices that $\models (\mathrm{T}, \omega)$ can be demonstrated by a scheme. We first show that Lemma 12 suffices for finishing the proof of Theorem 1, and then we sketch a proof idea for the lemma.

▶ **Lemma 12.** *For any task* $\mathrm{T} = (A, \textsc{Drown}, \textsc{keep})$ *where* $\models (\mathrm{T}, \omega)$ *there is a scheme* W*, starting from* $A(x_1, \dots, x_m)$*, such that* $G_{(W,k)} \models \textsc{keep}$ *for all* $k \in \mathbb{N}$ *and* $G_{(W,\omega)} \models (\textsc{Drown}, \omega)$*; for such* W *we have* $G_{(W,k)} \models (\textsc{Drown}, k) \wedge \textsc{keep}$ *for all* $k \in \mathbb{N}$.

We consider a task $\mathrm{T} = (A, \textsc{Drown}, \textsc{keep})$, where $\models (\mathrm{T}, \omega)$, that can be extracted from the path $H_0 \xrightarrow{w_1} H_1 \xrightarrow{w_2} H_2 \xrightarrow{w_3} \cdots$ (2) by Prop. 10; we also recall the respective sequence $\textsc{Seq}$ and the notation $H_j = A(x_1, \dots, x_m)\sigma'_j$. Let W be a scheme guaranteed by Lemma 12 for T; we recall the notation $\textsc{Lim}_W = G_{(W,\omega)}$. For all $j \in \textsc{Seq}$ the terms $\textsc{Lim}_W\, \sigma'_j$ are from the same bisim-class (by 2 in Prop. 10); let $\textsc{Lim}$ be a term representing this class.

For the sake of contradiction we now suppose that W is not a witness for any $H_j = A(x_1, \dots, x_m)\sigma'_j$. Then there is some $e \in \mathbb{N}$ (determined by $\textsc{Lim}$) such that $G_{(W,e)}\sigma'_j \sim \textsc{Lim}$ for all $j \in \textsc{Seq}$ (due to the mentioned generalization of Lemma 8). Since there is $d \in \mathbb{N}$ such that $x_{\textsc{keep}}\sigma'_j \in \textsc{Region}(G_{(W,e)}\sigma'_j, d)$ for all $j \in \textsc{Seq}$, all bisim-classes $[x_{\textsc{keep}}\sigma'_j]_\sim$ for $j \in \textsc{Seq}$ must be in $\textsc{Region}([\textsc{Lim}]_\sim, d)$ in the quotient-LTS $(\mathcal{L}^{\mathsf{A}}_{\mathcal{G}})_\sim$ (which follows from the fact $G_{(W,e)}\sigma'_j \sim \textsc{Lim}$). There are thus only finitely many bisim-classes $[x_{\textsc{keep}}\sigma'_j]_\sim$ where $j \in \textsc{Seq}$, which contradicts with the condition 3 of Prop. 10 that $x_{\textsc{keep}}\sigma'_{j_1} \not\sim x_{\textsc{keep}}\sigma'_{j_2}$ for any $j_1 \neq j_2$ in $\textsc{Seq}$ (recall that $x_{\textsc{keep}} \in \textsc{Drown}$).

Hence W is a witness for some $H_j = A(x_1, \dots, x_m)\sigma'_j$; by Prop. 11 this proves Lemma 9 (and thus Theorem 1).

The fact $\models (\mathrm{T}, \omega)$ can be demonstrated by a scheme. We now sketch a proof idea for Lemma 12. If $\models (\mathrm{T}, \omega)$, where $\mathrm{T} = (A, \textsc{Drown}, \textsc{keep})$, then there is a collection of paths $A(x_1, \dots, x_m) \xrightarrow{w_k} G_k$ where $G_k \models (\textsc{Drown}, k) \wedge \textsc{keep}$, for all $k \in \mathbb{N}$. We can choose shortest possible words w_k; in fact, they are sequences of simple stairs.

Each path $A(x_1, \dots, x_m) \xrightarrow{w_k} G_k$ must be progressing to its goal, stepwise "drowning" the (occurrences of) variables $x_i \in \textsc{Drown}$, while keeping at least one occurrence of $x_{\textsc{keep}}$. For a term F we can define its *drown-quality* as the function $\mathrm{DQ}(F) : \textsc{Drown} \to \mathbb{N} \cup \{\omega\}$ where $\mathrm{DQ}(F)(x_i)$ is the smallest (shallowest) depth of an occurrence of x_i in F (where $\mathrm{DQ}(F)(x_i) = \omega$ means that x_i does not occur in F). The *keep-quality* $\mathrm{KQ}(F)$ is one bit (1 ir 0) that captures the fact if $x_{\textsc{keep}}$ occurs in F. For each term $H = B(F_1, \dots, F_m)$ on a path $A(x_1, \dots, x_m) \xrightarrow{w_k} G_k$ we define its *level-quality* as $\mathrm{LQ}(H) = (B, \mathrm{DQ}(F_1), \dots, \mathrm{DQ}(F_m), \mathrm{KQ}(F_1), \dots, \mathrm{KQ}(F_m))$.

By standard facts, in particular Dickson's Lemma and König's Lemma, in any sufficiently long w_k there is an eligible stair that keeps or increases the level-quality in each component (where we put $B \leq B'$ if $B = B$). This does not solve the problem completely, due to the possible long segments with root-sticking depth-1 subterms. This subtle point is handled in the full arxiv-version.

4 Additional Remarks

The mentioned deterministic case studied by Valiant [13] could be roughly explained as follows: for a deterministic grammar, if an eligible stair is reachable from E_0 where the start and the end of the stair are non-equivalent, then E_0 is bisim-infinite. Hence by compositionality a bound on the size of the potential equivalent finite system can be derived, and thus decidability of the full equivalence is not needed here.

In the case equivalent to *normed* pushdown processes, the regularity problem essentially coincides with the boundedness problem, and is thus much simpler. (See, e.g., [11] for a further discussion.)

Acknowledgements. This work has been supported by the Grant Agency of the Czech Rep., project GAČR:15-13784S. I also thank Stefan Göller for drawing my attention to the decidability question for regularity of pushdown processes, and for discussions about some related works (like [13]).

Abstract

The problem of constructing a *minimally resolved phylogenetic supertree* (i.e., having the smallest possible number of internal nodes) that contains all of the rooted triplets from a consistent set $\mathcal{R}$ is known to be NP-hard. In this paper, we prove that constructing a phylogenetic tree consistent with $\mathcal{R}$ that contains the minimum number of additional rooted triplets is also NP-hard, and develop exact, exponential-time algorithms for both problems. The new algorithms are applied to construct two variants of the *local consensus tree*; for any set $\mathcal{S}$ of phylogenetic trees over some leaf label set L, this gives a minimal phylogenetic tree over L that contains every rooted triplet present in all trees in $\mathcal{S}$, where "minimal" means either having the smallest possible number of internal nodes or the smallest possible number of rooted triplets. The second variant generalizes the *RV-II tree*, introduced by Kannan, Warnow, and Yooseph in 1998.

1 Introduction

Phylogenetic trees are used to describe evolutionary relationships between species [11]. The *supertree approach* is a relatively new divide-and-conquer-based technique for reconstructing phylogenetic trees that may be useful when dealing with very big datasets [4]. The general idea behind it is to first infer a set of highly accurate trees for overlapping subsets of the species (e.g., using a computationally expensive method such as maximum likelihood [9, 11]) and then combine all the trees into one tree according to some well-defined rule. An example of a famous phylogenetic supertree for more than 4500 species can be found in [5]; see also [4, 15] for references to many other supertrees in the biological literature. One class of supertree methods consists of the BUILD algorithm [2] and its various extensions [10, 13, 14, 18, 19, 20, 21, 24] for combining a set of *rooted triplets* (binary phylogenetic trees with three leaves each), e.g., inferred by the method in [9].

A *consensus tree* [1, 7, 17] can be regarded as the special case of a phylogenetic supertree where all the trees that are to be combined have the same leaf label set. Such inputs

* Funded by The Hakubi Project and KAKENHI grant number 26330014.

arise when a collection of alternative datasets, each covering all the species, is available, or when applying bootstrapping or different tree reconstruction algorithms to the same basic dataset [11]. A consensus tree can also measure the similarity between two identically leaf-labeled trees or identify parts of trees that are similar. Many different types of consensus trees, whose formal definitions of how to handle conflicts differ, have been proposed in the last 45 years. See the surveys in [7], Chapter 30 in [11], and Chapter 8.4 in [23] for more details about different consensus trees and their advantages and disadvantages.

In situations where more than one phylogenetic tree can explain some given experimental data equally well, it is natural to select a "minimal" tree that supports the data while making as few extra statements about the evolutionary history as possible. A *minimally resolved phylogenetic supertree* [16] is a supertree that is consistent with all of the input and that has the minimum number of internal nodes. By minimizing the number of internal nodes, the risk of creating false groupings called "spurious novel clades" [4] is reduced. Furthermore, such a tree gives a simpler overview of the data than a tree with many internal nodes and can in general be stored in less memory. Another way to define "minimal" above, giving what we call a *minimally rooted-triplet-inducing phylogenetic supertree*, instead requires that the supertree contains the minimum number of rooted triplets. This interpretation of minimal was previously considered in the definition of the *RV-II local consensus tree* in [17].

The goal of this paper is further develop the mathematical framework of minimal phylogenetic supertrees and to design new supertree algorithms that can also be applied to the construction of consensus trees.

1.1 Problem Definitions

A *rooted phylogenetic tree* is a rooted, unordered, leaf-labeled tree in which all leaf labels are different and every internal node has at least two children. For example, T_1 and T_2 in Figure 1 are two rooted phylogenetic trees. In this paper, rooted phylogenetic trees are referred to as "trees" and every leaf in a tree is identified with its unique label.

Let T be a tree. The set of all nodes in T, the set of internal nodes in T, and the set of leaves in T are denoted by $V(T)$, $I(T)$, and $\Lambda(T)$, respectively. For any $u, v \in V(T)$, if u is a descendant of v and $u \neq v$ then we write $u \prec v$. $lca(u, v)$ means the lowest common ancestor of u and v.

A *rooted triplet* is a binary tree with exactly three leaves. We use the notation $xy|z$ to refer to the rooted triplet with leaf label set $\{x, y, z\}$ such that $lca(x, y) \prec lca(x, z) = lca(y, z)$. Let T be a tree. For any $x, y, z \in \Lambda(T)$, if $lca(x, y) \prec lca(x, z) = lca(y, z)$ holds in T then the rooted triplet $xy|z$ and T are said to be *consistent* with each other. For example, $ab|c$ is consistent with T_1 but not with T_2 in Figure 1. Observe that for any $\{x, y, z\} \subseteq \Lambda(T)$, exactly zero or one of the three rooted triplets $xy|z$, $xz|y$, and $yz|x$ is consistent with T. The set of all rooted triplets that are consistent with T is denoted by $r(T)$. For any set $\mathcal{R}$ of rooted triplets, if $\mathcal{R} \subseteq r(T)$ then $\mathcal{R}$ and T are *consistent* with each other. Finally, a set $\mathcal{R}$ of rooted triplets is *consistent* if there exists a tree that is consistent with $\mathcal{R}$.

Next, we give the definitions of the *minimally resolved phylogenetic supertree consistent with rooted triplets problem* (MinRS) (studied in [16]) and the *minimally rooted-triplet-inducing phylogenetic supertree consistent with rooted triplets problem* (MinIS). In both problems, the input is a consistent set $\mathcal{R}$ of rooted triplets[1], and the output is a tree T

[1] This paper assumes without loss of generality that the input $\mathcal{R}$ to MinRS/MinIS is consistent. The reason is that given an arbitrary $\mathcal{R}$, one can check whether $\mathcal{R}$ is consistent or not in polynomial time using the BUILD algorithm [2] described below.

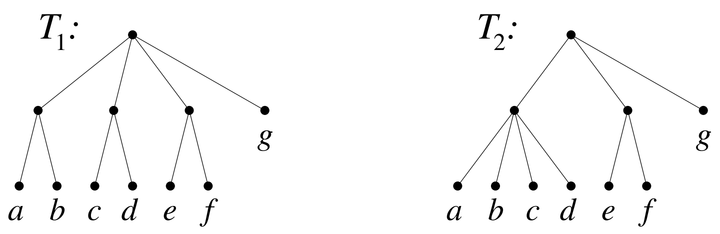

Figure 1 An example. Let $\mathcal{S} = \{T_1, T_2\}$ as above with $\Lambda(T_1) = \Lambda(T_2) = \{a, b, c, d, e, f, g\}$. Then $r(T_1) \cap r(T_2) = \{ab|e,\ ab|f,\ ab|g,\ cd|e,\ cd|f,\ cd|g,\ ef|a,\ ef|b,\ ef|c,\ ef|d,\ ef|g\}$ and T_2 is an optimal solution to MinRLC. On the other hand, $|r(T_1)| = 15$ while $|r(T_2)| = 23$, so T_2 cannot be an optimal solution to MinILC.

satisfying $\Lambda(T) = \bigcup_{t\in\mathcal{R}} \Lambda(t)$ and $\mathcal{R} \subseteq r(T)$. The objectives are to minimize the value of $|I(T)|$ (for MinRS) and to minimize the value of $|r(T)|$ (for MinIS), respectively.

In the *minimally resolved local consensus tree problem* (MinRLC) and the *minimally rooted-triplet-inducing local consensus tree problem* (MinILC) (introduced in [17] for the special case $k = 2$), the input is a set $\mathcal{S} = \{T_1, T_2, \ldots, T_k\}$ of trees with $\Lambda(T_1) = \Lambda(T_2) = \ldots = \Lambda(T_k) = L$ for some leaf label set L, and the output is a tree T satisfying $\Lambda(T) = L$ and $\bigcap_{i=1}^{k} r(T_i) \subseteq r(T)$. The objectives in MinRLC and MinILC are, respectively, to minimize the value of $|I(T)|$ and to minimize the value of $|r(T)|$.

Note that MinRLC and MinILC admit trivial polynomial-time reductions to MinRS and MinIS, respectively, by letting $\mathcal{R} = \bigcap_{i=1}^{k} r(T_i)$.

See Figure 1 for a simple example showing that MinRLC and MinILC are indeed different problems, and consequently, that MinRS is different from MinIS. From here on, we will use *Newick notation*[2] to describe trees compactly. E.g., in Figure 1, we have $T_1 = ((a, b),\ (c, d),\ (e, f),\ g)$; and $T_2 = ((a, b, c, d),\ (e, f),\ g)$;.

Throughout the paper, the size of the input to MinRS/MinIS is expressed in terms of $k = |\mathcal{R}|$ and $n = |L|$, where $L = \bigcup_{t\in\mathcal{R}} \Lambda(t)$. For MinRLC/MinILC, $k = |\mathcal{S}|$ and $n = |L|$, where $L = \Lambda(T_1) = \Lambda(T_2) = \ldots = \Lambda(T_k)$.

1.2 Previous Work

Here, we give an overview of some relevant results from the literature.

BUILD: Aho *et al.* [2] presented a polynomial-time algorithm called BUILD for determining if an input set $\mathcal{R}$ of rooted triplets is consistent, and if so, constructing a tree T with $\Lambda(T) = \bigcup_{t\in\mathcal{R}} \Lambda(t)$ and $\mathcal{R} \subseteq r(T)$. (When the input $\mathcal{R}$ is *not* consistent, one can for example look for a tree T that maximizes $|r(T) \cap \mathcal{R}|$; cf. Section 2 in [8] for a survey on this problem variant.) BUILD is summarized in Section 2.1 below. Henzinger *et al.* [15] gave a faster implementation of BUILD, and we note that substituting the data structure for dynamic graph connectivity used in the proof of Theorem 1 in [15] by the one in [25] yields a time complexity of $\min\{O(n + k\frac{\log^2 n}{\log\log n}),\ O(k + n^2 \log n)\}$, where $k = |\mathcal{R}|$ and $n = |\bigcup_{t\in\mathcal{R}} \Lambda(t)|$.

Importantly, BUILD does not solve MinRS and MinIS. This was first observed by Bryant [6, Section 2.5.2], who gave the following counterexample: $\mathcal{R} = \{bc|a,\ bd|a,\ ef|a,\ eg|a\}$. Given $\mathcal{R}$ as input, BUILD constructs the tree $T_B = (a,\ (b, c, d),\ (e, f, g))$;, which has three

[2] See, e.g., `http://evolution.genetics.washington.edu/phylip/newicktree.html`.

internal nodes and 24 rooted triplets. In contrast, the optimal solution to both MinRS and MinIS is the tree $T_O = (a,\ (b, c, d, e, f, g));$, which has two internal nodes and 15 rooted triplets. As pointed out in [16], the claim by Henzinger *et al.* in [15] that their Algorithm A' always constructs a minimal tree is therefore false. In another highly cited paper, Ng and Wormald [18] presented an extension of BUILD named OneTree to so-called *fans*. However, Note 2 in Section 4 of [18] incorrectly states that OneTree outputs a tree with the minimum number of nodes.

MinRS: For MinRS, the following strong negative result is known: MinRS cannot be approximated within $n^{1-\epsilon}$ for any constant $\epsilon > 0$ in polynomial time, unless P = NP [16]. An algorithm named AllMinTrees in [19] outputs all minor-minimal trees consistent with $\mathcal{R}$, where a tree T is *minor-minimal* if it is consistent with $\mathcal{R}$ and it is not possible to obtain a tree consistent with $\mathcal{R}$ by contracting any edges of T, and this algorithm can be used to solve MinRS. However, it runs in $\Omega((\frac{n}{2})^{n/2})$ time [16], which is self-exponential in $n/2$. Some special cases of MinRS can be solved in polynomial time; e.g., if the output tree has at most three internal nodes or if it is a caterpillar (a tree in which every node has at most one child that is an internal node) [16]. Also, for any positive integer p, if every node in the output tree has at most p children which are internal nodes then MinRS can be solved in $p^{O(n)}$ time [16].

MinIS: To determine the computational complexity of MinIS was listed as an open problem in Section 6 in [16]. As far as we know, it has not been studied previously.

MinRLC, MinILC, and local consensus trees: The MinILC problem originates from Kannan *et al.* [17], who gave several alternative definitions of a "local consensus tree". They called a tree T an *RV-II* ("relaxed version II") tree of two trees T_1 and T_2 with identical leaf label sets if $r(T_1) \cap r(T_2) \subseteq r(T)$ and $|r(T)|$ is minimized. (Thus, an RV-II tree is a solution to MinILC when $k = 2$.) In Section 5.4 of [17], the authors suggested that applying BUILD to the set $r(T_1) \cap r(T_2)$ always produces an RV-II tree, but this is not correct. A counterexample, analogous to the one for MinRS and MinIS above, is obtained by letting T_1 and T_2 be the two trees T_B and T_O, which gives $r(T_1) \cap r(T_2) = \{bc|a,\ bd|a,\ cd|a,\ ef|a,\ eg|a,\ fg|a\}$, so that the solution to both MinRLC and MinILC is T_O while BUILD's output is T_B. This shows that one cannot solve MinRLC and MinILC by taking $\mathcal{R} = \bigcap_{i=1}^{k} r(T_i)$ and applying BUILD directly.

Bryant [7] later defined the "local consensus tree" as the output of BUILD when given $\bigcap_{i=1}^{k} r(T_i)$ as input. The algorithm in Section 5.4.1 of [17] constructs such a tree in $O(n^2)$ time for the case $k = 2$, while the $O(kn^3)$-time algorithm in Theorem 7 in [15] by Henzinger *et al.* can be used for unbounded k. Note that finding a tree T satisfying only $\bigcap_{i=1}^{k} r(T_i) \subseteq r(T)$ is trivial since one can just select $T = T_1$, so some additional conditions are needed to make the tree informative. The advantages of Bryant's local consensus tree are that it is unique and can be computed efficiently; the disadvantages are that it does not minimize the number of nodes or induced rooted triplets and that it is defined in terms of the output of an algorithm and not axiomatically.

1.3 Our New Results and Organization of the Paper

Section 2 reviews the BUILD algorithm from [2] and a useful result by Semple in [19] that characterizes all trees consistent with the input $\mathcal{R}$. Based on Semple's characterization, Section 3 presents an $O^*((1+\sqrt{3})^n) = O(2.733^n)$-time algorithm[3] for MinRS and an $O(kn^3 + 2.733^n)$-time algorithm for MinRLC, and Section 4 presents an $O^*(4^n)$-time algorithm for MinIS and an $O(kn^3 + 4^n \cdot poly(n))$-time algorithm for MinILC.

All four problems are NP-hard; MinRS was shown to be NP-hard in [16], and we complement this result by establishing the NP-hardness of MinRLC in Section 5 and the NP-hardness of MinIS and MinILC in Section 6.

2 Preliminaries

2.1 Aho et al.'s BUILD Algorithm [2]

The BUILD algorithm [2] is a recursive, top-down algorithm that takes as input a set $\mathcal{R}$ of rooted triplets and a leaf label set L such that $\bigcup_{t \in \mathcal{R}} \Lambda(t) \subseteq L$ and outputs a tree T with $\Lambda(T) = L$ that is consistent with all of the rooted triplets in $\mathcal{R}$, if such a tree exists; otherwise, it outputs *fail*. The time complexity of BUILD is polynomial (q.v., Section 1.2).

A summary of how BUILD works is given here. It first partitions the leaf label set L into *blocks* based on the information contained in $\mathcal{R}$. More precisely, BUILD constructs an *auxiliary graph*, defined as the undirected graph $\mathcal{G}(L) = (L, E)$ where for any $x, y \in L$, the edge $\{x, y\}$ belongs to E if and only if $\mathcal{R}$ contains at least one rooted triplet of the form $xy|z$ with $z \in L$. It then computes the connected components in $\mathcal{G}(L)$ and assigns the leaf labels in each connected component to one block. (Henceforth, the set of leaf labels belonging to any connected component C in $\mathcal{G}(L)$ is denoted by $\Lambda(C)$, and for every $L' \subseteq L$, we define $\mathcal{R}|L' = \{t \in \mathcal{R} : \Lambda(t) \subseteq L'\}$.) Next, for each block $\Lambda(C)$, BUILD builds a tree T_C by calling itself recursively using $\mathcal{R}|\Lambda(C)$ together with $\Lambda(C)$ as input. Finally, BUILD returns a tree consisting of a newly created root node whose children are the roots of all the recursively constructed T_C-trees. The recursion's base case is when the leaf label set consists of one element x, in which case the algorithm just returns a tree with a single leaf labeled by x. If any auxiliary graph $\mathcal{G}(L')$ constructed during BUILD's execution has only one connected component and $|L'| > 1$ holds then the algorithm terminates and outputs *fail*. See, e.g., [2] for the correctness proof and further details.

Returning to the example in Section 1.2 where $\mathcal{R} = \{bc|a,\ bd|a,\ ef|a,\ eg|a\}$ and $L = \{a, b, c, d, e, f, g\}$, the blocks in the auxiliary graph $\mathcal{G}(L)$ are $\{a\}$, $\{b, c, d\}$, and $\{e, f, g\}$. The auxiliary graphs on the successive recursive levels contain no edges, so BUILD outputs the tree $(a,\ (b, c, d),\ (e, f, g));$.

2.2 Semple's Characterization

In [19], Semple clarified the relationship between the auxiliary graph $\mathcal{G}(L)$ used in the BUILD algorithm and the trees consistent with $\mathcal{R}$. For any tree T, define $\pi(T)$ as the partition of $\Lambda(T)$ whose parts are the leaves in the different subtrees attached to the root of T; as an example, $\pi(T_1) = \{\{a, b\}, \{c, d\}, \{e, f\}, \{g\}\}$ in Figure 1. With this notation, Semple's characterization can be expressed as:

▶ **Lemma 1.** *(Corollary 3.3 in [19]) Let T be any tree that is consistent with $\mathcal{R}$. For each connected component C in $\mathcal{G}(L)$, $\Lambda(C) \subseteq B$ for some $B \in \pi(T)$.*

Lemma 1 implies that if T is any tree consistent with $\mathcal{R}$ then the partition $\pi(T)$ can be obtained by performing zero or more mergings of $\mathcal{G}(L)$'s connected components. Thus, every

[3] The notation $O^*(f(n))$ means $O(f(n) \cdot poly(n))$.

tree consistent with $\mathcal{R}$ can be recovered by trying all possible mergings of the connected components in $\mathcal{G}(L)$ at each recursion level.[4]

We remark that Lemma 1 is very useful. For example, it can be employed to prove the non-uniqueness of solutions to MinRLC and MinILC (and hence, MinRS and MinIS) by considering the instance $\mathcal{S} = \{T_1, T_2, T_3\}$ with $T_1 = ((1,2,3,4,5,6),\ (7,8),\ (9,10),\ 11);$, $T_2 = ((1,2,3,4,5,6,7,8),\ (9,10),\ 11);$, and $T_3 = ((1,2,3,4,5,6,9,10),\ (7,8),\ 11);$. The connected components in $\mathcal{G}(L)$, where $\mathcal{R} = \bigcap_{i=1}^{3} r(T_i)$, consist of $\{1,2,3,4,5,6\}$, $\{7,8\}$, $\{9,10\}$, and $\{11\}$. By Lemma 1, we only need to check a few possible candidate trees (corresponding to the different ways of merging these connected components), and we find that each of T_1, T_2, and T_3 is an optimal solution to MinILC since $|r(T_1)| = |r(T_2)| = |r(T_3)| = 93$. Furthermore, each of T_2 and T_3 is an optimal solution to MinRLC.

3 Exponential-Time Algorithms for MinRS and MinRLC

This section presents an exact $O(2.733^n)$-time algorithm for MinRS. As a consequence, MinRLC can be solved in $O(kn^3 + 2.733^n)$ time.

The main idea is to use Lemma 1 together with dynamic programming. For every $L' \subseteq L$, let $opt(L')$ be the number of internal nodes in an optimal solution to MinRS for $\mathcal{R}|L'$. Clearly, if $|L'| = 1$ then $opt(L') = 0$. To compute $opt(L')$ when $|L'| \geq 2$, observe that if T' is any optimal solution for $\mathcal{R}|L'$ then T' consists of a root node whose children are the roots of the optimal solutions for $\mathcal{R}|P_1$, $\mathcal{R}|P_2$, …, $\mathcal{R}|P_t$, where $\{P_1, P_2, \ldots, P_t\}$ is equal to $\pi(T')$. The partition $\pi(T')$ can be found by enumerating partitions of L' and using dynamic programming to identify the best one; according to Lemma 1, only partitions corresponding to the different ways of merging connected components in the auxiliary graph $\mathcal{G}(L')$ need to be considered.

The details are explained next. Let $\mathcal{C}_{L'}$ be the set of connected components in $\mathcal{G}(L')$. For every subset $\mathcal{D} \subseteq \mathcal{C}_{L'}$, define $Merge(\mathcal{D})$ as the set of all leaf labels belonging to components in $\mathcal{D}$, i.e., $Merge(\mathcal{D}) = \bigcup_{Q \in \mathcal{D}} \Lambda(Q)$. Also define $DP(\mathcal{D})$ for every $\mathcal{D} \subseteq \mathcal{C}_{L'}$ to be the minimum value of $\sum_{\mathcal{X} \in \mathcal{Q}} opt(Merge(\mathcal{X}))$ taken over all possible true partitions $\mathcal{Q}$ of $\mathcal{D}$, where we say that a partition $\mathcal{Q}$ of a set X is a *true partition of* X if $|X| \geq 2$ and $\mathcal{Q} \neq \{X\}$ (i.e., if $|\mathcal{Q}| > 1$), or if $|X| = |\mathcal{Q}| = 1$. Then:

▶ **Lemma 2.** *For every $L' \subseteq L$ with $|L'| \geq 2$, it holds that $opt(L') = DP(\mathcal{C}_{L'}) + 1$.*

Proof. Let T' be any optimal tree for $\mathcal{R}|L'$. The children of the root of T' are the roots of the optimal solutions for $\mathcal{R}|P_1$, $\mathcal{R}|P_2$, …, $\mathcal{R}|P_t$, where each P_i equals $Merge(\mathcal{D})$ for some $\mathcal{D} \subseteq \mathcal{C}_{L'}$ because of Lemma 1. By definition, $DP(\mathcal{C}_{L'})$ is the minimum value of $\sum_{\mathcal{X} \in \mathcal{P}} opt(\mathcal{X})$ over all true partitions $\mathcal{P}$ of L' such that each $\mathcal{X} \in \mathcal{P}$ equals $Merge(\mathcal{D})$ for some $\mathcal{D} \subseteq \mathcal{C}_{L'}$. Together with the common root node, this gives $opt(L') = DP(\mathcal{C}_{L'}) + 1$. ◀

▶ **Lemma 3.** *For every $\mathcal{D} \subseteq \mathcal{C}_{L'}$ with $|\mathcal{D}| \geq 2$, $DP(\mathcal{D}) = \min_{\emptyset \neq \mathcal{X} \subsetneq \mathcal{D}} \big\{ opt(Merge(\mathcal{X})) + \min\{DP(\mathcal{D} \setminus \mathcal{X}),\ opt(Merge(\mathcal{D} \setminus \mathcal{X}))\} \big\}$.*

Proof. $DP(\mathcal{D}) = \min\big\{\sum_{\mathcal{X} \in \mathcal{Q}} opt(Merge(\mathcal{X})) : \mathcal{Q}$ is a true partition of $\mathcal{D}\big\} = \min\big\{opt(Merge(\mathcal{X})) + \min\{DP(\mathcal{D} \setminus \mathcal{X}),\ opt(Merge(\mathcal{D} \setminus \mathcal{X}))\} : \mathcal{X} \in \mathcal{Q},\ \mathcal{Q}$ is a true partition of $\mathcal{D}\big\} = \min\big\{opt(Merge(\mathcal{X})) + \min\{DP(\mathcal{D} \setminus \mathcal{X}),\ opt(Merge(\mathcal{D} \setminus \mathcal{X}))\} : \emptyset \neq \mathcal{X} \subsetneq \mathcal{D}\big\}$. ◀

[4] This technique was actually used even earlier than [19]; the SUPERB algorithm in [10] outputs all binary trees consistent with $\mathcal{R}$ by considering all ways of merging the connected components of $\mathcal{G}(L)$ into exactly two connected components at each recursion level.

```
Algorithm MinRS_exact
Input: Set $\mathcal{R}$ of rooted triplets over a leaf label set $L$.
Output: The number of internal nodes in a minimally resolved tree consistent with $\mathcal{R}$
and leaf-labeled by $L$.
1:  For every $x \in L$, initialize $opt(\{x\}) := 0$;
2:  for $i := 2$ to $n$ do
3:    for every cardinality-$i$ subset $L'$ of $L$ do
4:      Construct $\mathcal{G}(L')$. Let $\mathcal{C}$ and $\mathcal{U}$ be the set of connected components and the set
        of singleton components, respectively, in $\mathcal{G}(L')$;
5:      Let $DP(\emptyset) := 0$. For every $X \in \mathcal{C} \setminus \mathcal{U}$, let $DP(\{X\}) := opt(\Lambda(X))$;
6:      for $j := 2$ to $|\mathcal{C}| - |\mathcal{U}|$ do
7:        for every cardinality-$j$ subset $\mathcal{D}$ of $\mathcal{C} \setminus \mathcal{U}$ do
8:          $DP(\mathcal{D}) :=$
              $\min_{\emptyset \neq \mathcal{X} \subsetneq \mathcal{D}} \{opt(\bigcup_{Q \in \mathcal{X}} \Lambda(Q)) + \min\{DP(\mathcal{D} \setminus \mathcal{X}), opt(\bigcup_{Q \in \mathcal{D} \setminus \mathcal{X}} \Lambda(Q))\}\}$;
9:        end for
10:     end for
11:     $opt(L') := DP(\mathcal{C} \setminus \mathcal{U}) + 1$;
12:   end for
13: end for
14: return $opt(L)$;
```

Figure 2 Algorithm `MinRS_exact`.

Lemmas 2 and 3 suggest the following strategy: Compute $opt(L')$ for all subsets L' of L in order of increasing cardinality by evaluating the formula in Lemma 2, while using dynamic programming to compute and store the relevant DP-values. To do this, for each L', we first construct $\mathcal{G}(L')$ in polynomial time. We then enumerate all subsets $\mathcal{D}$ of $\mathcal{C}_{L'}$ in a loop having $|\mathcal{C}_{L'}|$ iterations in which iteration j uses Lemma 3 to compute all $DP(\mathcal{D})$-values where $|\mathcal{D}| = j$. Each application of Lemma 3 takes $O^*(2^{|\mathcal{D}|})$ time, so this takes a total of $O^*(\sum_{j=1}^{|\mathcal{C}_{L'}|} \binom{|\mathcal{C}_{L'}|}{j} 2^j) = O^*((2+1)^{|\mathcal{C}_{L'}|}) = O^*(3^{|\mathcal{C}_{L'}|})$ time for each L'. To obtain $opt(L)$, we iterate over all subsets L' of L of cardinality $i = 1, 2, \ldots, n$; iteration i computes $opt(L')$ for each L' with $|L'| = i$ in $O^*(3^{|\mathcal{C}_{L'}|})$ time as just described. The total running time becomes $O^*(\sum_{i=1}^{n} \binom{n}{i} 3^i) = O^*((3+1)^n) = O^*(4^n)$.

To reduce the time complexity, we will reduce the number of applications of Lemma 3 in the main loop that computes $opt(L')$ for any $L' \subseteq L$. We rely on the following simple observation, which essentially tells us that the singleton components of $\mathcal{G}(L')$ can be ignored.

▶ **Lemma 4.** *Let $\mathcal{U}$ be the set of singleton components in $\mathcal{G}(L')$. $DP(\mathcal{C}_{L'}) = DP(\mathcal{C}_{L'} \setminus \mathcal{U})$.*

Proof. Consider any $x \in \mathcal{U}$. By the construction of $\mathcal{G}(L')$ and $\mathcal{U}$, there are no rooted triplets of the form $xy|z$ for any $y, z \in L'$ in the set $\mathcal{R}|L'$. Hence, there exists a minimally resolved tree consistent with $\mathcal{R}|L'$ in which x is attached directly to the root. The lemma follows. ◀

The resulting algorithm, called `MinRS_exact`, is summarized in Figure 2.

▶ **Theorem 5.** *Algorithm `MinRS_exact` solves* MinRS *in $O^*((1+\sqrt{3})^n)$ time.*

Proof. First note that $\mathcal{C}_{L'} \setminus \mathcal{U}$ contains no singleton components. Therefore, the number of connected components in $\mathcal{C}_{L'} \setminus \mathcal{U}$ is at most $\frac{|L'|}{2}$, i.e., $|\mathcal{C}_{L'}| - |\mathcal{U}| \leq \frac{|L'|}{2}$. Now, when computing

$opt(L')$ for any subset L' of L, the number of applications of the formula in Lemma 3 is reduced since there no are subsets $\mathcal{D}$ of cardinality larger than $|\mathcal{C}_{L'}| - |\mathcal{U}|$. More precisely, the time for each L' is reduced to $O^*(\sum_{j=1}^{|\mathcal{C}_{L'}|-|\mathcal{U}|} \binom{|\mathcal{C}_{L'}|-|\mathcal{U}|}{j} 2^j) = O^*((2+1)^{|\mathcal{C}_{L'}|-|\mathcal{U}|}) = O^*(3^{|\mathcal{C}_{L'}|-|\mathcal{U}|}) = O^*(\sqrt{3}^{|L'|})$. Finally, replacing $O^*(3^{|\mathcal{C}_{L'}|})$ by $O^*(\sqrt{3}^{|L'|})$ in the analysis of computing $opt(L)$ above gives a total time complexity of $O^*(\sum_{i=1}^{n} \binom{n}{i} \sqrt{3}^i) = O^*((\sqrt{3}+1)^n)$. ◀

▶ Remark. The algorithm as presented here returns $opt(L)$. An optimal tree with this number of internal nodes can be obtained by standard traceback techniques.

▶ **Corollary 6.** MinRLC *can be solved in* $O(kn^3 + (1+\sqrt{3})^n \cdot poly(n))$ *time.*

Proof. First construct $\mathcal{R} = \bigcap_{i=1}^{k} r(T_i)$ in $O(kn^3)$ time, e.g., by preprocessing each T_i in $O(n)$ time so that any query of the form $lca(x, y)$ in T_i with $x, y \in L$ can be answered in $O(1)$ time [3] and then, for every $L' \subseteq L$ with $|L'| = 3$, doing $3k$ *lca*-queries to see if L' induces the same rooted triplet in all of the k trees. Next, run `MinRS_exact` on $\mathcal{R}$. ◀

4 Exponential-Time Algorithms for MinIS and MinILC

We now describe an $O^*(4^n)$-time algorithm for MinIS based on the technique from Section 3. Applying it to MinILC yields an $O(kn^3 + 4^n \cdot poly(n))$-time algorithm for the latter.

Lemma 1 guarantees that every valid solution to MinIS can be discovered by trying all ways of merging connected components in the auxiliary graphs $\mathcal{G}(L')$. As in Section 3, we use dynamic programming to compute and store optimal values to subproblems but make the following modifications. First of all, redefine opt so that $opt(L')$ for every $L' \subseteq L$ means the value of $|r(T')|$ for an optimal solution T' to MinIS for $\mathcal{R}|L'$. Secondly, redefine $DP(\mathcal{D})$ for every $\mathcal{D} \subseteq \mathcal{C}_{L'}$ to mean the minimum value of $\sum_{\mathcal{X} \in \mathcal{Q}}(opt(Merge(\mathcal{X})) + \binom{|Merge(\mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{X})|)$, taken over all possible true partitions $\mathcal{Q}$ of $\mathcal{D}$. With the new definitions of opt and DP, the analogues of Lemmas 2 and 3 become:

▶ **Lemma 7.** *For every* $L' \subseteq L$ *with* $|L'| \geq 2$*, it holds that* $opt(L') = DP(\mathcal{C}_{L'})$*.*

Proof. $DP(\mathcal{C}_{L'})$ counts the minimum number of rooted triplets in a tree consistent with $\mathcal{R}|L'$ among all partitions $\mathcal{Q}$ of $\mathcal{C}_{L'}$. Hence, $opt(L') = DP(\mathcal{C}_{L'})$. ◀

▶ **Lemma 8.** *For every* $\mathcal{D} \subseteq \mathcal{C}_{L'}$ *with* $|\mathcal{D}| \geq 2$, $DP(\mathcal{D}) = \min_{\emptyset \neq \mathcal{X} \subsetneq \mathcal{D}} \{opt(Merge(\mathcal{X})) + \binom{|Merge(\mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{X})| + \min\{DP(\mathcal{D} \setminus \mathcal{X}),\ opt(Merge(\mathcal{D} \setminus \mathcal{X})) + \binom{|Merge(\mathcal{D} \setminus \mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{D} \setminus \mathcal{X})|\}\}$.

Proof. $DP(\mathcal{D}) = \min\{\sum_{\mathcal{X} \in \mathcal{Q}}(opt(Merge(\mathcal{X})) + \binom{|Merge(\mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{X})|) : \mathcal{Q}$ is a true partition of $\mathcal{D}\} = \min\{opt(Merge(\mathcal{X})) + \binom{|Merge(\mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{X})| + \min\{DP(\mathcal{D} \setminus X),\ opt(Merge(\mathcal{D} \setminus \mathcal{X})) + \binom{|Merge(\mathcal{D} \setminus \mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{D} \setminus \mathcal{X})|\} : \mathcal{X} \in \mathcal{Q},\ \mathcal{Q}$ is a true partition of $\mathcal{D}\}$ $= \min\{opt(Merge(\mathcal{X})) + \binom{|Merge(\mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{X})| + \min\{DP(\mathcal{D} \setminus X),\ opt(Merge(\mathcal{D} \setminus \mathcal{X})) + \binom{|Merge(\mathcal{D} \setminus \mathcal{X})|}{2} \cdot |L' \setminus Merge(\mathcal{D} \setminus \mathcal{X})|\} : \emptyset \neq \mathcal{X} \subsetneq \mathcal{D}\}$. ◀

The new algorithm, called `MinIS_exact`, is obtained by modifying Algorithm `MinRS_exact` as follows:

- Change Step 8 so that it computes $DP(\mathcal{D})$ using Lemma 8 instead Lemma 3.
- Change Step 11 so that it assigns $opt(L') := DP(\mathcal{C}_{L'})$, in accordance with Lemma 7.
- Change Step 4 so that it always sets $\mathcal{U}$ to $\emptyset$.

The reason why we force $\mathcal{U} = \emptyset$ is that we do not have an analogue of Lemma 4 for MinIS that would allow us to ignore the singleton components. The algorithm therefore spends $O^*(\sum_{j=1}^{|\mathcal{C}_{L'}|} \binom{|\mathcal{C}_{L'}|}{j} 2^j) = O^*((2+1)^{|\mathcal{C}_{L'}|}) = O^*(3^{|\mathcal{C}_{L'}|})$ time for each L', just like the slower version of Algorithm `MinRS_exact` in Section 3, and the total running time is $O^*(\sum_{i=1}^{n} \binom{n}{i} 3^i)$ $= O^*((3+1)^n) = O^*(4^n)$.

▶ **Theorem 9.** *Algorithm* `MinIS_exact` *solves* MinIS *in $O^*(4^n)$ time.*

▶ **Corollary 10.** MinILC *can be solved in $O(kn^3 + 4^n \cdot poly(n))$ time.*

5 NP-Hardness of MinRLC

Section 3 in [16] proved that MinRS is NP-hard. It follows from the proof in [16] that MinRS remains NP-hard even if restricted to a particular special case which we now describe.

Suppose that $L_0 = \{v_1, v_2, \ldots, v_q\}$ is a set of elements. Define $L_0' = \{v_{1'}, v_{1''}, v_{2'}, v_{2''}, \ldots,$ $v_{q'}, v_{q''}\}$, and for any integers i, j with $1 \leq i < j \leq q$, define $\mathcal{R}(v_i, v_j)$ as the set of four rooted triplets $\{v_{i'}v_{i''}|v_{j'},\ v_{i'}v_{i''}|v_{j''},\ v_{j'}v_{j''}|v_{i'},\ v_{j'}v_{j''}|v_{i''}\}$ over L_0'. For any set S, let $\binom{S}{2}$ denote the set of all subsets of S of cardinality 2. According to Section 3 in [16], MinRS is NP-hard even if restricted to instances where $\mathcal{R}$ has the form $\mathcal{R} = \bigcup_{\{v_i, v_j\} \in Z} \mathcal{R}(v_i, v_j)$ for some set L_0 and some $Z \subseteq \binom{L_0}{2}$.

▶ **Theorem 11.** MinRLC *is NP-hard.*

Proof. We reduce from the above variant of MinRS. Let $\mathcal{R}$ be any given instance of the problem. Let P be the set of pairs of indices that form rooted triplets in $\mathcal{R}$, i.e., $P = \bigl\{\{i, j\} : v_{i'}v_{i''}|v_{j'},\ v_{i'}v_{i''}|v_{j''},\ v_{j'}v_{j''}|v_{i'},\ v_{j'}v_{j''}|v_{i''} \in \mathcal{R}\bigr\}$, and let $Q = \binom{\{1,2,\ldots,q\}}{2} \setminus P$.

Define a tree $T_0 = ((v_{1'}, v_{1''}), (v_{2'}, v_{2''}), \ldots, (v_{q'}, v_{q''}))$; and for every $f = \{x, y\} \in Q$, define a tree T_f by taking a copy of T_0 and merging the two subtrees $(v_{x'}, v_{x''})$ and $(v_{y'}, v_{y''})$ so that $T_f = ((v_{x'}, v_{x''}, v_{y'}, v_{y''}), (v_{1'}, v_{1''}), (v_{2'}, v_{2''}), \ldots, (v_{n'}, v_{n''}))$;. Let $\mathcal{S} = \{T_0\} \cup \{T_f :$ $f \in Q\}$. Note that $\mathcal{R} = \bigcap_{T_i \in \mathcal{S}} r(T_i)$. This is because for any $\{x, y\} \in P$, the four rooted triplets $v_{x'}v_{x''}|v_{y'},\ v_{x'}v_{x''}|v_{y''},\ v_{y'}v_{y''}|v_{x'},\ v_{y'}v_{y''}|v_{x''}$ appear in $\mathcal{R}$ as well as in $r(T_i)$ for every $T_i \in \mathcal{S}$. On the other hand, for any $\{x, y\} \in Q$, $v_{x'}v_{x''}|v_{y'},\ v_{x'}v_{x''}|v_{y''},\ v_{y'}v_{y''}|v_{x'},\ v_{y'}v_{y''}|v_{x''}$ do not appear in $\mathcal{R}$ or in $r(T_{\{x,y\}})$. Thus, there exists a tree T with $\bigcap_{T_i \in \mathcal{S}} r(T_i) \subseteq r(T)$ having x internal nodes if and only if there exists a tree T' with $\mathcal{R} \subseteq r(T')$ having x internal nodes. ◀

6 NP-Hardness of MinILC and MinIS

To prove the NP-hardness of MinILC, we give a polynomial-time reduction from the Maximum Clique problem, which is NP-hard [12]. Maximum Clique takes as input an undirected graph $G = (V, E)$ and asks for a largest clique in G, where $X \subseteq V$ is a *clique in G* if every two vertices belonging to X are adjacent in G.

The reduction is as follows. Let $n = |V|$ and write $V = \{1, 2, \ldots, n\}$. Create a set L of leaf labels such that $L = \{v_i, v_i' : i \in V\} \cup \{z, w_1, w_2, \ldots, w_{n^2}\}$. Define a tree $T_\emptyset =$ $(z, (w_1, w_2, \ldots, w_{n^2}), (v_1, v_1'), (v_2, v_2'), \ldots, (v_n, v_n'))$; with $\Lambda(T_\emptyset) = L$. For any nonempty subset $X = \{i_1, i_2, \ldots, i_p\} \subseteq V$, let T_X be the tree with $\Lambda(T_X) = L$ obtained by taking a copy of $T_\emptyset$, deleting the subtrees (v_i, v_i') for all $i \in X$, and replacing the subtree $(w_1, w_2, \ldots, w_{n^2})$ by $((w_1, w_2, \ldots, w_{n^2}, v_{i_1}, v_{i_2}, \ldots, v_{i_p}),\ v_{i_1}', v_{i_2}', \ldots, v_{i_p}')$. Finally, let $\mathcal{S} = \{T_\emptyset\} \cup \{T_{\{i\}} : i \in$ $V\} \cup \{T_{\{i,j\}} : \{i, j\} \in E\}$.

Section 6.1 first states some general properties satisfied by the trees defined above. Then, Section 6.2 establishes some specific properties satisfied by any local consensus tree of $\mathcal{S}$. After that, we will prove that for any $X \subseteq V$, X is a maximum clique in G if and only if T_X is a local consensus tree of $\mathcal{S}$ with the smallest possible number of rooted triplets, giving the main result of this section.

6.1 General Properties

The following additional notation is used. For any tree H, *Child*(H) is the set of children of the root of H. For any $u \in V(H)$, the subtree of H induced by u and all proper descendants of u is called *the subtree of H rooted at u* and is denoted by H^u. For any $L' \subseteq \Lambda(H)$, $H|L'$ is the tree obtained from H by deleting all nodes with no descendants in L' and their incident edges, and then contracting every edge between a node having one child and its child. Finally, for every positive integer n, define a function $f_n(k) = n^5 - \frac{k-1}{2}n^4 + 4kn^3 - \frac{6k^2-3k-3}{2}n^2 + (4k^2-4k-1)n - \frac{7k^3-7k^2}{2}$. We immediately have:

▶ **Lemma 12.** *For any tree H, $|r(H)| = \sum_{u \in Child(H)} \Big(|r(H^u)| + \binom{|\Lambda(H^u)|}{2} \cdot (|\Lambda(H)| - |\Lambda(H^u)|)\Big)$.*

▶ **Lemma 13.** *Let X be any subset of the given V. Write $k = |X|$. Then $|r(T_X)| = f_n(k)$.*

Proof. By Lemma 12, the number of rooted triplets consistent with T_X is $\binom{n^2+k}{2} \cdot k + \binom{n^2+2k}{2} \cdot (2n - 2k + 1) + (n-k) \cdot (n^2 + 2n - 1)$. Expanding this expression yields the formula. ◀

▶ **Corollary 14.** *For any fixed $n \geq 8$, $f_n(k)$ is strictly decreasing as k increases.*

Proof. By Lemma 13, $f_n(k+1) - f_n(k) = -\frac{1}{2}n^4 + 4n^3 - \frac{12k+3}{2}n^2 + 8kn - \frac{7}{2}(3k^2 + k)$. Since $n \geq 8$, $-\frac{1}{2}n^4 + 4n^3 \leq 0$ holds. Also, $\frac{12k+3}{2}n > 8k$ for $n \geq 8$ and $-\frac{7}{2}(3k^2+k) \leq 0$. The corollary follows. ◀

▶ **Lemma 15.** *Consider any $u \in Child(H)$ in a tree H. Suppose that $\Lambda(H^u) = \alpha \cup \beta$ for some $\alpha, \beta \neq \emptyset$ with $\alpha \cap \beta = \emptyset$. Let H' be the tree obtained from H by deleting H^u and its parent edge and attaching the roots of $H|\alpha$ and $H|\beta$ as children of the root of H. If $|\alpha| + |\beta| \leq \frac{2|\Lambda(H)|}{3}$ then $|r(H')| < |r(H)|$.*

Proof. Define $m = |\Lambda(H)|$. Lemma 12 gives $|r(H)| - |r(H')| = |r(H^u)| + \binom{|\alpha|+|\beta|}{2} \cdot (m - |\alpha| - |\beta|) - |r(H|\alpha)| - \binom{|\alpha|}{2} \cdot (m - |\alpha|) - |r(H|\beta)| - \binom{|\beta|}{2} \cdot (m - |\beta|)$. Noting that $|r(H^u)| \geq |r(H|\alpha)| + |r(H|\beta)|$, we have $|r(H)| - |r(H')| \geq \binom{|\alpha|+|\beta|}{2} \cdot (m - |\alpha| - |\beta|) - \binom{|\alpha|}{2} \cdot (m - |\alpha|) - \binom{|\beta|}{2} \cdot (m - |\beta|) = |\alpha| \cdot |\beta| \cdot (m + 1 - \frac{3}{2} \cdot (|\alpha| + |\beta|)) \geq |\alpha| \cdot |\beta| \cdot (m + 1 - m) = |\alpha| \cdot |\beta| > 0$. ◀

6.2 Properties of a Local Consensus Tree of $\mathcal{S}$

By the definition of $\mathcal{S}$, we have the next lemma.

▶ **Lemma 16.** *The set $\bigcap_{T_i \in \mathcal{S}} r(T_i)$ consists of the following rooted triplets:*

- *$w_i w_j | z$ for all $1 \leq i < j \leq n^2$ and $v_i v'_i | z$ for all $1 \leq i \leq n$;*
- *$w_i w_j | v'_k$ for all $1 \leq i < j \leq n^2$ and $1 \leq k \leq n$;*
- *$v_i v'_i | v_j$, $v_i v'_i | v'_j$, $v_j v'_j | v_i$, and $v_j v'_j | v'_i$ for all $1 \leq i < j \leq n$ with $\{i, j\} \notin E$.*

Let T be any local consensus tree of $\mathcal{S}$, i.e., any tree T such that $\Lambda(T) = L$ and $\bigcap_{T_i \in \mathcal{S}} r(T_i) \subseteq r(T)$. According to Lemma 16, $r(T)$ contains $v_i v'_i | z$ for all $1 \leq i \leq n$, so the two leaves v_i and v'_i must belong to the same subtree attached to the root of T for all $1 \leq i \leq n$. Similarly, all leaves in $\{w_1, w_2, \ldots, w_{n^2}\}$ must belong to one subtree attached to the root of T. The *core of* T, denoted by γ_T, is the subtree of T rooted at the node $lca(w_1, w_2, \ldots, w_{n^2})$. The path from the root of T to the parent of γ_T is called the *core path of* T. For any node $u \in V(T)$, if u is a child of the core path of T that does not belong to the core path itself and $u \neq lca(w_1, w_2, \ldots, w_{n^2})$, the subtree of T rooted at u is called a *secondary subtree of* T. Note that the secondary subtrees of T are disjoint. Define $C_T = \{i : v_i \in \Lambda(\gamma_T)\}$.

▶ **Lemma 17.** *Let T be a local consensus tree of $\mathcal{S}$. T has the following properties:*

1. *The core γ_T does not contain the leaf v'_i for any $1 \leq i \leq n$.*
2. *C_T forms a clique in G.*
3. *For any $i \in \{1, 2, \ldots n\}$, if $C_T \cup \{i\}$ is not a clique in G then v_i and v'_i belong to the same secondary subtree of T.*

Proof.

1. Suppose $v'_i \in \Lambda(\gamma_T)$. Let w_a, w_b be any two leaves such that $lca(\{w_a, w_b\}) = lca(\{w_1, w_2, \ldots, w_{n^2}\})$. Then, $w_a w_b | v'_i \notin r(T)$, contradicting Lemma 16.
2. Consider any $i, j \in C_T$ with $i \neq j$. By point 1., $v_i v_j | v'_i \in r(T)$, so $v_i v'_i | v_j \notin r(T)$. According to Lemma 16, $\{i, j\} \notin E$ does not hold, which means that $\{i, j\} \in E$.
3. Since $C_T \cup \{i\}$ is not a clique, there exists some $j \in C_T$ where $\{i, j\} \notin E$. By Lemma 16, $v_i v'_i | v_j \in r(T)$. Thus, v_i and v'_i are in the same subtree attached to the core path.

◀

Observe that Lemma 17.1 implies $\Lambda(\gamma_T) = \{w_1, w_2, \ldots, w_{n^2}\} \cup \{v_p \mid p \in C_T\}$. Moreover, by Lemma 17.3, for any $i \in \{1, 2, \ldots n\}$, if v_i and v'_i belong to subtrees attached to different nodes on the core path then $C_T \cup \{i\}$ is a clique in G.

▶ **Lemma 18.** *Let $n \geq 10$ and let T be a local consensus tree of $\mathcal{S}$. T can be transformed into a local consensus tree of $\mathcal{S}$ of the form T_X for some $X \subseteq V$ where X is a clique in G and $|r(T_X)| \leq |r(T)|$.*

Proof. We describe a sequence of transformations that can be applied to T without increasing the number of rooted triplets consistent with it. After each transformation, the resulting tree still contains all of the rooted triplets listed in Lemma 16, so it is still a local consensus tree of $\mathcal{S}$.

First, consider the leaf z in T. Let P be the path from the root of T to z, and let $\rho_1, \rho_2, \ldots, \rho_e$ be the disjoint subtrees of T attached to P whose roots do not belong to P themselves. Let T^1 be the tree formed by removing P and attaching z and the roots of $\rho_1, \rho_2, \ldots, \rho_e$ as children of the root. Then $|r(T^1)| \leq |r(T)|$, and T^1 has the property that z is a child of the root of T^1.

Secondly, transform T^1 to T^2 by contracting the core γ_{T^1}, i.e., by replacing γ_{T^1} by a single node to which all leaves in $\Lambda(\gamma_{T^1})$ are directly attached. Clearly, $|r(T^2)| \leq |r(T^1)|$.

Thirdly, suppose that for some $q \in \{1, 2, \ldots, n\}$, it holds that $q \notin C_{T^2}$ while $C_{T^2} \cup \{q\}$ is a clique in G. Let T^3 be the tree formed by removing the leaf v_q from its location in T^2 and attaching it to the root of γ_{T^2}, and attaching the leaf v'_q as a child of the root of γ_{T^2}. There are two types of rooted triplets involving v_q: (i) $x v_q | y$ and (ii) $xy | v_q$. For (i), there are at most $n^2 + n - 1$ choices of x by Lemma 17.1 and at most $2n$ choices of y, so T^3 has at most $(n^2 + n - 1) \cdot 2n$ more rooted triplets than T^2 of this form. For (ii), there are at least

$\binom{n^2}{2}$ such rooted triplets in T^2 but not in T^3, corresponding to pairs of the form (w_i, w_j), and at most $\binom{2n}{2}$ such rooted triplets in T^3 that are not present in T^2. Similarly, there are two types of rooted triplets involving v'_q: (iii) $xv'_q|y$ and (iv) $xy|v'_q$. As above, T^3 has at most $(n^2+n-1)\cdot 2n$ more rooted triplets than T^2 of the form (iii) and at most $\binom{2n}{2}$ rooted triplets of the form (iv). Hence, by transforming T^2 to T^3, the number of rooted triplets is reduced by at least $\binom{n^2}{2} - 2\cdot\binom{2n}{2} - 2\cdot(n^2+2-1)\cdot(2n)$, which is larger than 0 when $n \geq 10$. We repeat this step until T^3 has no leaf v_q such that $q \notin C_{T^3}$ and $C_{T^3} \cup \{q\}$ is a clique. This gives $|r(T^3)| \leq |r(T^2)|$.

Next, transform T^3 to a tree T^4 in which every secondary subtree contains at most two leaves and, furthermore, the leaves in any secondary subtree with precisely two leaves are of the form $\{v_q, v'_q\}$ where $C_{T^4} \cup \{q\}$ is not a clique in G. To do this, consider each secondary subtree s of T^3. By the definition of T^3 in the previous paragraph, $C_{T^3} \cup \{q\}$ is not a clique in G for any $v_q \in \Lambda(s)$. While $|\Lambda(s)| > 2$, extract any pair of leaves $\{v_q, v'_q\}$ from s (recall from Lemma 17.3 that any two leaves of the form v_i and v'_i must belong to the same secondary subtree), and create a new secondary subtree with the leaves $\{v_q, v'_q\}$ attached to the core path as a sibling of s. Every secondary subtree s satisfies $|\Lambda(s)| \leq 2n \leq \frac{2n^2}{3} \leq \frac{2|\Lambda(H)|}{3}$, where H is the subtree rooted at the parent of the root of s, so we get $|r(T^4)| \leq |r(T^3)|$ by Lemma 15.

Lastly, transform T^4 to a tree T^5 whose core path consists of a single edge (u_0, u_1), where u_0 is the root of T^5, as follows. Attach each secondary subtree of T^4 having two leaves as a child of u_0, and attach each secondary subtree of T^4 having one leaf as a child of u_1. Attach z as a child of u_0 and the core γ_{T^4} as a child of u_1. Note that this will not destroy any of the rooted triplets in Lemma 16, and that $|r(T^5)| \leq |r(T^4)|$.

By the definition of T_X, T^5 is equal to T_X if we select $X = C_{T^5}$. Finally, C_{T^5} is a clique in G by Lemma 17.2. ◀

▶ **Lemma 19.** *Let $n \geq 10$. $X \subseteq V$ is a maximum clique in G if and only if T_X is a local consensus tree of $\mathcal{S}$ that minimizes the number of rooted triplets.*

Proof. ($\rightarrow$) For the purpose of obtaining a contradiction, suppose there exists a local consensus tree T' of $\mathcal{S}$ with $|r(T')| < |r(T_X)|$. Apply Lemma 18 to T' to get a tree T_Q that is also a local consensus tree of $\mathcal{S}$ with $|r(T_Q)| \leq |r(T')|$ and where Q is a clique in G. Then $|Q| > |X|$ by Lemma 13 and Corollary 14, which is impossible.

($\leftarrow$) Suppose X' is a larger clique in G than X. Lemma 13 and Corollary 14 imply $|r(T_{X'})| < |r(T_X)|$, contradicting that T_X is a local consensus tree of $\mathcal{S}$ minimizing the number of rooted triplets. ◀

Now, assuming without loss of generality that $n \geq 10$ in the reduction from Maximum Clique above, Lemma 19 gives:

▶ **Theorem 20.** MinILC *is NP-hard.*

Finally, by the reduction from MinILC to MinIS mentioned in Section 1.1:

▶ **Corollary 21.** MinIS *is NP-hard.*

7 Concluding Remarks

The main open problem is to obtain faster exponential-time algorithms than the ones presented here. In particular, can MinRS be solved in $O^*(2^n)$ time?

Another open problem is to extend the algorithms in this paper to unrooted phylogenetic trees. This would be interesting because many existing methods for inferring phylogenetic trees produce unrooted trees [11]. The unrooted case appears to be much harder than the rooted case, as the basic problem of determining the consistency of an input set of rooted triplets is solvable in polynomial time (see Section 1.2), while the corresponding problem for *unrooted quartets* (unrooted, distinctly leaf-labeled trees with exactly four leaves each and in which every internal node has at least three neighbors) is already NP-hard [22].

Abstract

Computing set joins of two inputs is a common task in database theory. Recently, Van Gucht, Williams, Woodruff and Zhang [PODS 2015] considered the complexity of such problems in the natural model of (classical) two-party communication complexity and obtained tight bounds for the complexity of several important distributed set joins.

In this paper we initiate the study of the *quantum* communication complexity of distributed set joins. We design a quantum protocol for distributed Boolean matrix multiplication, which corresponds to computing the *composition join* of two databases, showing that the product of two $n \times n$ Boolean matrices, each owned by one of two respective parties, can be computed with $\widetilde{O}(\sqrt{n}\ell^{3/4})$ qubits of communication, where ℓ denotes the number of non-zero entries of the product. Since Van Gucht et al. showed that the classical communication complexity of this problem is $\widetilde{\Theta}(n\sqrt{\ell})$, our quantum algorithm outperforms classical protocols whenever the output matrix is sparse. We also show a quantum lower bound and a matching classical upper bound on the communication complexity of distributed matrix multiplication over $\mathbb{F}_2$.

Besides their applications to database theory, the communication complexity of set joins is interesting due to its connections to direct product theorems in communication complexity. In this work we also introduce a notion of *all-pairs* product theorem, and relate this notion to standard direct product theorems in communication complexity.

1 Introduction

Background

Set joins are basic operations in relational database theory. The notion of set join was introduced to the database community more than forty years ago by Codd [6] to express operations combining two tables in relational databases. This seminal paper considered, in particular, the *composition join*: given two (relational) databases A and B, A represented as a subset of $\{1,\ldots,m\}\times\{1,\ldots,n\}$ and B as a subset of $\{1,\ldots,n\}\times\{1,\ldots,m\}$, the composition join of A and B is the set $\{(i,j) \mid \exists k : (i,k) \in A \text{ and } (k,j) \in B\} \subseteq \{1,\ldots,m\} \times \{1,\ldots,m\}$. Many other join operations have been defined so far and have found many applications (see, e.g., [3, 6, 9, 15, 17, 18, 19, 23]).

The computational complexity of join operations is naturally an important issue. Very recently Van Gucht, Williams, Woodruff and Zhang [23] have investigated this question in the two-party communication complexity model where one party owns the first database, the second party owns the second database, and both parties collaborate to compute the join of these two databases using as little communication as possible. This model is interesting for two main reasons. First, it models the natural and practical task of distributed computation of join operations. Second, in the communication complexity setting it is possible to show strong lower bounds on the complexity of problems. Indeed, one of the main contributions of [23] was to show quantitative differences between the (communication) complexities of various join operations.

Many join operations studied in database theory actually correspond to fundamental and well-studied computational tasks in other areas of computer science. The composition join mentioned above, in particular, corresponds to Boolean matrix multiplication, one central problems in theoretical computer science: if we represent the database A by an $m \times n$ matrix M_A and B by an $n \times m$ matrix M_B (such that $M_A[i,j] = 1$ if and only if $(i,j) \in A$, and similarly for M_B), the matrix representation of the composition join of A and B is precisely the output of the Boolean matrix multiplication of M_A and M_B (i.e., the $m \times m$ matrix C such that $C[i,j] = \bigvee_{k=1}^{n} M_A[i,k] \wedge M_B[k,j]$). The result by Van Gucht et al. on the communication complexity of the composition join [23] shows that the communication complexity of Boolean matrix multiplication is $\widetilde{\Theta}(n\sqrt{\ell})$ for the square case $m = n$ (a more complicated formula is also given for the rectangular case), where ℓ denotes the number of non-zero entries in the product C. Since the parameter ℓ represents the sparsity of the output matrix, algorithms and communication protocols with complexity depending explicitly on ℓ are sometimes called output-sensitive and have been studied in several settings other than communication complexity as well [2, 5, 11, 16].

Our Results

In this paper we initiate the study of the *quantum* communication complexity of distributed set joins. Our main result is about the set joins related to matrix multiplication. We first show that the quantum communication complexity of the composition join (i.e., Boolean matrix multiplication) is $O(\sqrt{n}\ell^{3/4}\log m)$ (Theorem 7). This is better than the best possible classical protocol, which costs $\Omega(n\sqrt{\ell})$ as mentioned above. We also consider matrix multiplication over the binary field and show that its quantum communication complexity (and actually even its classical communication complexity) is $\widetilde{O}(n\sqrt{\ell})$ (Theorem 8). We give a matching lower bound as well (Theorem 11).

These bounds are also interesting since they confirm and substantiate our current understanding of the power of quantum algorithms for problems related to matrix multiplication. Indeed, while matrix multiplication over a field seems harder than Boolean matrix multiplication for quantum computers, we currently do not have any technique to prove such a statement in the time complexity setting. Our results prove this statement in the communication complexity setting, for instances with sparse output matrices.

In addition to these concrete results, this work presents several interesting new open problems. An *OR lemma* is a composition lemma that says that the quantum communication complexity of the function $f^{\vee m}(a_1, \ldots, a_m, b_1, \ldots, b_m) = \bigvee_{i=1}^{m} f(a_i, b_i)$ is at least $\Omega(\sqrt{m}Q(f))$, where $Q(f)$ is the quantum query complexity of f. We show that our upper bound for composition join is tight up to logarithmic factors assuming the problem of Boolean matrix multiplication satisfies an OR lemma (Proposition 14). We give further evidence that our upper bound is indeed tight by showing that it is tight at extreme values of ℓ, when $\ell = O(1)$ (Proposition 12) and when $\ell = \Omega(n^2)$ (Proposition 13).

We believe that proving lower bounds on set joins is a very interesting area of future research, as doing so may give insight into direct product theorems in communication complexity, as well as lower bounds in quantum query complexity for problems that involve *read-many formulas*, in which different parts of the input are used multiple times, which makes it difficult to prove lower bounds using standard composition theorems.

Organization

The remainder of this paper is organized as follows. In Section 2, we give the necessary preliminaries, including quantum communication complexity, and the groundwork for studying the quantum communication complexity of set joins. In Section 3, we present our communication protocol for composition join. In Section 4, we present our classical communication protocol and matching quantum lower bound for matrix multiplication over $\mathbb{F}_2$. Finally, in Section 5, we give some evidence that our upper bound for composition join is tight, by reducing a matching lower bound to a plausible OR lemma.

2 Preliminaries

2.1 Notation

Let $2^{[n]}$ denote the set of subsets of $[n]$. A subset S of $[n] := \{1, \dots, n\}$ can be represented by an n-bit string, and we will sometimes conflate these two notions. Let $S[i]$ denote the i-th bit of the string corresponding to S, so $S[i] = 1$ if and only if $i \in S$. For any $x \in \{0,1\}^n$, we let $|x|$ denote the Hamming weight, which is the size of the corresponding subset of $[n]$. Similarly, for a Boolean matrix A (i.e., a matrix with entries in $\{0,1\}$), let $|A|$ denote the number of 1s in A. Given an $m \times n$ Boolean matrix A and an $n \times m$ Boolean matrix B, we write the Boolean product $A * B$ and let AB denote their product over the finite field $\mathbb{F}_2 = \{0,1\}$. Morever, for any integer $k \in [n]$ we let $A[\cdot, k]$ denote the k-th column of A and $B[k, \cdot]$ the k-th row of B.

2.2 Quantum Communication Complexity

A communication problem is a function $f : A \times B \to Y$ whose input has two parts, $a \in A$, which we call Alice's input, and $b \in B$, which we call Bob's input. In the model of communication complexity, first defined by Yao [25], Alice and Bob want to run a protocol such that, at the end of the protocol, Alice and Bob both output $f(a, b)$ with high probability, and they want to minimize the number of bits they need to communicate in order to achieve this.

In the model of quantum communication, also introduced by Yao [26], Alice and Bob are allowed a quantum communication channel (for a detailed introduction to the theory of quantum information, see [24]) and they want to minimize the number of quantum bits (qubits) they need to communicate in order to compute the function. More precisely, a quantum communication protocol consists of finite inner product spaces $\mathcal{X}$ and $\mathcal{Y}$, a measurement $\{\Pi, I - \Pi\}$ on $\mathcal{Y}$, and unitary operators $\{U_i\}_{i=1}^T$, such that for odd i, U_i acts on $\mathcal{X} \otimes \mathcal{C}$, where $\mathcal{C} = \mathbb{C}^2$ is a single-qubit system, and for even i, U_i acts on $\mathcal{C} \otimes \mathcal{Y}$. The protocol is said to have quantum communication complexity T. The protocol is said to compute f with bounded error $1/3$ if for all $(a, b) \in A \times B$, there exist states ρ_a and ρ_b on $\mathcal{X}$ and $\mathcal{Y}$ respectively, such that

$$|\operatorname{Tr}\left((I_{\mathcal{X}} \otimes I_{\mathcal{C}} \otimes \Pi) U_T \dots U_1 (\rho_a \otimes |0\rangle\langle 0| \otimes \rho_b)\right) - f(a, b)| \leq 1/3.$$

That is, Alice begins the protocol in some state ρ_a depending on her input, and Bob begins the protocol in some state ρ_b depending on his input, and Alice also has an additional system, $\mathcal{C}$, initialized to $|0\rangle$,which will be used for communication with Bob. Alice applies U_1 to $\mathcal{X}\otimes\mathcal{C}$, and then sends $\mathcal{C}$ to Bob, who applies U_2 to $\mathcal{C}\otimes\mathcal{Y}$, before sending $\mathcal{C}$ back to Alice. They continue until they have applied all T unitaries, at which point, Bob measures $\mathcal{Y}$, and the outcome determines $f(a,b)$ with error at most $1/3$.

The *bounded error quantum communication complexity* of f, denoted $Q(f)$, is the minimum T such that there exists a quantum communication protocol computing f with bounded error $1/3$ with quantum communication complexity T. We will also consider the bounded error quantum communication complexity of partial functions $f : D \to \{0,1\}$ for $D \subseteq A \times B$.

There are many variants of this model, including the setting of *one-way* communication complexity, in which Alice can send messages to Bob, but Bob cannot send messages to Alice, and only Bob is required to output the correct answer. We let $Q^1(f)$ denote the one-way communication complexity of f.

An important problem in the study of quantum communication complexity is the problem of set disjointness, which is defined as follows.

Set Disjointness, DISJ_n
Alice's input: $a \in \{0,1\}^n$
Bob's input: $b \in \{0,1\}^n$
Output: $\mathsf{DISJ}_n(a,b) = \bigvee_{i=1}^n a_i b_i$

It is well known that $Q(\mathsf{DISJ}_n) = \Theta(\sqrt{n})$ [4, 10, 1, 21], beating the classical communication complexity of $\Theta(n)$ [12, 20]. When one of the two input sets is small, we can do even better as shown in the following elementary lemma.

▶ **Lemma 1** (Set disjointness for small sets). *The bounded error quantum communication complexity of* $\mathsf{DISJ}_n(a,b)$ *is* $O\left(\sqrt{\frac{\min\{|a|,|b|\}}{|a\cap b|+1}}\log n\right)$. *Furthermore, if* $\mathsf{DISJ}_n(a,b)=1$*, then the protocol also returns a uniform random* $i \in a\cap b$.

Proof. To begin the protocol, Alice sends Bob $|a|$ using $\lceil \log_2 n\rceil$ bits of communication, and Bob sends Alice $|b|$ using $\lceil \log_2 n\rceil$ bits of communication. If $|a|<|b|$, Alice and Bob perform Grover search on the set $S_A = \{i \in [n] : a_i = 1\}$ for an index $i \in S_A$ such that $f_B(i)=1$, where $f_B(i) = b_i$. They do this as follows. Alice computes $|\pi(S_A)\rangle = \sum_{i\in S_A}\frac{1}{\sqrt{|a|}}|i\rangle$. In order to perform the search, Alice and Bob must alternate $R_A = 2|\pi(S_A)\rangle\langle\pi(S_A)| - I$ and $R_B = \sum_{i\in[n]}(-1)^{b_i}|i\rangle\langle i|$, $O\left(\sqrt{\frac{|a|}{|a\cap b|+1}}\right)$ times. Clearly Alice can implement R_A, and Bob can implement R_B, so they can implement this algorithm using $O\left(\sqrt{\frac{|a|}{|a\cap b|+1}}\right)$ rounds of communication, each time communicating a $\lceil \log_2 n\rceil$-qubit state. Bob measures some $i\in[n]$, and sends $i, f_B(i)$ to Alice. Both Alice and Bob output $f_B(i)$. If $|a| \geq |b|$, they do the protocol obtained by reversing Alice and Bob's roles. ◀

The algorithm in Lemma 1 actually finds a witness $i \in a\cap b$, which is slightly stronger than what is required to solve DISJ. We will also consider the problem of finding the entire intersection:

Find-all Set Intersection, $\mathsf{DISJall}_n$
Alice's input: $a \in \{0,1\}^n$
Bob's input: $b \in \{0,1\}^n$
Output: $\mathsf{DISJall}_n(a,b) = \{i\in[n] : a_i = b_i = 1\}$

In this case, we also have an advantage when a or b is small, as shown in the following lemma.

▶ **Lemma 2** (Find-all set intersection for small sets). *The bounded error quantum communication complexity of* $\mathsf{DISJall}_n(a,b)$ *is* $O(\sqrt{|a\cap b|\min\{|a|,|b|\}}\log n)$.

Proof. Alice and Bob run the following protocol.

1. $S \leftarrow \emptyset$, $\tilde{a} \leftarrow a$, $\tilde{b} \leftarrow b$.
2. Repeat:
   - **a.** Use the protocol for $\mathsf{DISJ}_n(\tilde{a},\tilde{b})$ to obtain $i \in \tilde{a}\cap\tilde{b}$. If $\mathsf{DISJ}_n(\tilde{a},\tilde{b}) = 0$, output S.
   - **b.** $S \leftarrow S\cup\{i\}$, $\tilde{a}_i \leftarrow 0$, $\tilde{b}_i \leftarrow 0$.

This protocol has communication complexity

$$\sum_{i=1}^{|a\cap b|}\sqrt{\frac{\min\{|a|,|b|\}}{|a\cap b|-i+1}}\log n = \Theta\left(\sqrt{|a\cap b|\min\{|a|,|b|\}}\log n\right)$$

qubits. ◀

2.3 Set Joins and Direct Product Theorems

In this paper, we consider various *set join* problems. For any predicate $\mathcal{P}_n : 2^{[n]}\times 2^{[n]} \to \{0,1\}$, we can define a set join, as follows.

$\mathcal{P}$-Set Join, $\mathcal{P}_n^{\otimes m}$

Alice's input: $\mathcal{A} = (A_1,\dots,A_m)$, $A_i \subseteq [n]$

Bob's input: $\mathcal{B} = (B_1,\dots,B_m)$, $B_i \subseteq [n]$

Output: $\{(i,j)\in[m]\times[m] : \mathcal{P}_n(A_i,B_j) = 1\}$

When $\mathcal{P}_n$ is the predicate such that $\mathcal{P}_n(A,B) = 1$ if and only if $A\cap B \neq \emptyset$, the resulting join is called the *composition join* or sometimes *set-intersection-non-empty join*. As mentioned in the introduction, this join is equivalent to Boolean matrix multiplication, where we consider $A_1,\dots,A_m$ to be the rows of a matrix $A\in\{0,1\}^{m\times n}$, and $B_1,\dots,B_m$ to be the columns of a matrix $B\in\{0,1\}^{n\times m}$.

Consider a related construction: the direct product.

Direct product, $\mathcal{P}_n^{(m)}$

Alice's input: $\mathcal{A} = (A_1,\dots,A_m)$, $A_i \subseteq [n]$

Bob's input: $\mathcal{B} = (B_1,\dots,B_m)$, $B_i \subseteq [n]$

Output: $\{i\in[m] : \mathcal{P}_n(A_i,B_i)\}$

Unlike set joins, such problems are well-studied, and much is known. Clearly, we have $Q(\mathcal{P}_n^{(m)}) = O(m\mathcal{P}_n\log m)$ for any predicate $\mathcal{P}_n$. Intuitively, one can usually expect that the resources needed to solve m instances of $\mathcal{P}_n$ scale as at least m times the resources needed to solve one instance, that is: $Q(\mathcal{P}_n^{(m)}) = \Omega(mQ(\mathcal{P}_n))$. This is called a *(weak) direct product theorem* for $\mathcal{P}_n$. In fact, we can sometimes prove a stronger statement: that even solving $\mathcal{P}_n^{(m)}$ with success probability 2^{-m} requires $\Omega(mQ(\mathcal{P}_n))$ quantum communication. Such a statement is called a *strong direct product theorem*. Although such a statement likely holds for many problems in quantum communication complexity, it can be very difficult to prove (see, e.g., [22] and the references therein).

In the case of set joins, it is also easy to see that $Q(\mathcal{P}_n^{\otimes m}) = O(m^2Q(\mathcal{P}_n)\log m)$, however, unlike the case of direct products, this naive upper bound is often not tight. For example, let $Q^1(\mathcal{P}_n)$ denote the *one-way communication complexity* of $\mathcal{P}_n$. Then we have the following:

▶ **Theorem 3.** *For any predicate $\mathcal{P}_n$, $Q(\mathcal{P}_n^{\otimes m}) \leq O(mQ^1(\mathcal{P}_n)\log m)$.*

Proof. Consider an optimal one-way quantum communication protocol for $\mathcal{P}_n$. Let $\rho(A)$ be the mixed state on at most $Q^1(\mathcal{P}_n)$ qubits that Alice sends Bob and let $U(B)$ be the unitary that Bob applies to $\rho(A) \otimes |0\rangle\langle 0|_{\mathcal{W}} \otimes |0\rangle\langle 0|_{\mathcal{A}}$, for some workspace $\mathcal{W}$ and single-qubit answer register $\mathcal{A}$, so that he measures $\mathcal{P}_n(A, B)$ in the answer register with probability at least $2/3$.

We construct a (one-way) protocol for $\mathcal{P}_n^{\otimes m}$ as follows. Let Alice have input $A_1, \dots, A_m$, and Bob $B_1, \dots, B_m$. For every $i \in [m]$, Alice sends Bob $(\rho(A_i))^{\otimes c \log m}$, where c is a large enough constant. For each $i, j \in [m]$, Bob applies $U(B_j)^{\otimes c \log m}$ to $(\rho(A_i) \otimes |0\rangle\langle 0|_{\mathcal{W}} \otimes |0\rangle\langle 0|_{\mathcal{A}})^{\otimes c \log m}$. He then computes the majority of the answer registers in a new single-qubit register, which he measures. Let $\rho(A_i, B_j) := U(B_j)(\rho(A_i) \otimes |0\rangle\langle 0|_{\mathcal{W}} \otimes |0\rangle\langle 0|_{\mathcal{A}})U(B_j)^\dagger = \sum_{b,b' \in \{0,1\}} \rho_{b,b'} \otimes |b\rangle\langle b'|$, so the state Bob measures is (up to permuting registers):

$$\sum_{x,x' \in \{0,1\}^\ell} \bigotimes_{i=1}^{\ell} \rho_{x_i, x_i'} \otimes |x\rangle\langle x'| \otimes |\mathrm{maj}(x)\rangle\langle \mathrm{maj}(x')|,$$

where $\mathrm{maj}(x) = 1$ if $|x| \geq \ell/2$ and 0 otherwise. Assume that $\mathcal{P}_n(A_i, B_j) = 1$, as the 0 case is nearly identical. Then the probability of success in a single round is $\mathrm{Tr}(\rho_{1,1}) \geq 2/3$, so the probability of success upon measuring the majority register is:

$$\sum_{\substack{x \in \{0,1\}^\ell: \\ |x| \geq \ell/2}} \Pi_{i=1}^{\ell} \mathrm{Tr}(\rho_{x_i,x_i}) = \sum_{k=0}^{\lfloor \ell/2 \rfloor} \binom{\ell}{k} \mathrm{Tr}(\rho_{1,1})^k (1 - \mathrm{Tr}(\rho_{1,1}))^{\ell-k} \geq 1 - e^{-\Omega(\ell)} = 1 - m^{-\Omega(1)},$$

where the inequality follows from Hoeffding's inequality, and the constant in $\Omega(1)$ depends on c. Thus, Bob gets the correct answer with high probability, but furthermore, this measurement causes negligible damage to the state $\rho(A_i, B_j)^{\otimes \ell}$, so Bob can apply $(U(B_j)^\dagger)^{\otimes \ell}$ to recover $\rho(A_i)^{\otimes \ell}$, to be used again. The error in the state remains negligible as long as Bob does this no more than $m^{O(1)}$ times. ◀

Call a theorem of the form $Q(\mathcal{P}_n^{\otimes m}) = \Omega(\min\{mn, m^2 Q(\mathcal{P}_n)\})$ a *(weak) all-pairs product theorem*. The $\min\{mn, \cdot\}$ is to account for the fact that we always have a trivial upper bound of mn, and so if we did not include this, the statement would always be false for some values of m and n. In this work, we give an example of a set-join for which an all-pairs direct product theorem does not hold — in particular, in Section 3 we will give an upper bound of $O(m^{3/2}\sqrt{n})$ for the composition join, showing that this problem does not satisfy an all-pairs product theorem. Although we show that such a statement holds for matrix multiplication over $\mathbb{F}_2$, in that case, we have $\min\{mn, m^2 Q(\mathcal{P}_n)\} = mn$ for all m and n, so the best strategy is always for Alice to send her whole input to Bob, rather than for Alice and Bob to compute m^2 instances of $\mathcal{P}_n$. It is an open question whether or not there exists a predicate for which an all-pairs product theorem holds in a non-trivial sense — that is, the best strategy is to compute m^2 instances of $\mathcal{P}_n$.

3 Composition Join (Boolean Matrix Multiplication)

In this section, we give an upper bound on the communication complexity of Boolean matrix multiplication (equivalent to computing the composition join), proving our main theorem. As in [23], we consider the following promise version of the problem, in which the output has at most ℓ ones.

Boolean Matrix Multiplication, $\mathsf{BMM}_{m,n,\ell}$

Alice's input: $A \in \{0,1\}^{m\times n}$
Bob's input: $B \in \{0,1\}^{n\times m}$
Promise: $|A * B| \leq \ell$
Output: $\mathsf{BMM}_{m,n,\ell}(A,B) = A*B = \{(i,j)\in[m]\times[m] : \exists k\in[n], A[i,k]=B[k,j]=1\}$

The communication protocol we give is inspired by the query-optimal quantum algorithm for Boolean matrix multiplication given in [11]. The algorithm of [11] is based on a subroutine for a problem called *graph collision*. For any family of bipartite graphs G on n vertices, the communication version of graph collision on G is as follows.

Graph Collision, GC_G

Alice's input: $f_A \in \{0,1\}^n$
Bob's input: $f_B \in \{0,1\}^n$
Output: $\mathsf{GC}_G(f_A,f_B) = \bigvee_{(i,j)\in G} f_A(i)f_B(j)$

An efficient protocol for this problem can easily be constructed in the communication complexity setting:

▶ **Lemma 4** (Graph collision). *$Q(\mathsf{GC}_G(f_A,f_B)) = O(\sqrt{\min\{|f_A|,|f_B|\}})$ for any family of bipartite graphs G.*

Proof. Alice sends Bob $|f_A|$, and Bob sends Alice $|f_B|$ using $2\log n$ bits of communication. If $|f_A|\leq|f_B|$, Alice sets $a=f_A$ and Bob sets $b=\{i\in[n] : \exists j\in[n],(i,j)\in G, f_B(j)=1\}$. Otherwise, Alice sets $a=\{j\in[n] : \exists i\in[n],(i,j)\in G, f_A(i)=1\}$ and Bob sets $b=f_B$. They finally compute $\mathsf{DISJ}(a,b)$. ◀

When we solve graph collision as a subroutine, we will actually want to additionally find *all* graph collisions in a particular instance. That is, we will want to solve the following problem.

Find All Graph Collisions, GCall_G

Alice's input: $f_A \in \{0,1\}^n$
Bob's input: $f_B \in \{0,1\}^n$
Output: $\mathsf{GCall}_G(f_A,f_B) = \{(i,j)\in G : f_A(i)=f_B(j)=1\}$

The following upper bound for GCall_G is a corollary of the previous lemma (its proof is similar to the proof of Lemma 2).

▶ **Corollary 5** (Find all graph collisions). *$Q(\mathsf{GCall}_G(f_A,f_B)) = O(\sqrt{\lambda\min\{|f_A|,|f_B|\}})$, where $\lambda = |\{(i,j)\in G : f_A(i)=f_B(j)=1\}|$.*

The final ingredient we need before presenting our quantum communication protocol for Boolean matrix multiplication is a quantum communication protocol that searches for a 1-instance among n independent instances of a communication problem. Its proof is fairly straightforward and simply combines quantum search with the original communication protocol.

▶ **Lemma 6** (Search over communication instances). *Let $f : X\times Y\to\{0,1\}$ be a communication problem with bounded error quantum communication complexity $Q(f)$. Let $F : X^n\times Y^n\to\{0,1\}$ be the problem of finding some $i\in[n]$ such that $f(x_i,y_i)=1$. Then $Q(F)=O(\sqrt{\frac{n}{t}}Q(f)\log n)$, where $t=|\{i\in[n] : f(x_i,y_i)=1\}|$.*

Proof. Alice creates $|\pi\rangle = \sum_{i\in[n]} \frac{1}{\sqrt{n}}|i\rangle$. Alice and Bob implement quantum search by repeating the reflections

$$R_1 = 2|\pi\rangle\langle\pi| - I \quad \text{and} \quad R_2 = \sum_{i\in[n]} (-1)^{f(x_i,y_i)}|i\rangle\langle i|$$

$O(\sqrt{n/t})$ times. Each implementation of R_2 is accomplished as follows. Let Alice's state be $\sum_{i\in[n]} \alpha_i|i\rangle$. Alice performs the mapping $|i\rangle \mapsto |i,i\rangle$, to get $\sum_{i\in[n]} \alpha_i|i,i\rangle$ and sends half of the state to Bob. Conditioned on their quantum state, Alice and Bob perform the protocol for f using input (x_i, y_i), that is, they perform the protocol on a superposition of inputs. This leaves the state $\sum_{i\in[n]} \alpha_i|i, f(x_i, y_i)\rangle_A|i, f(x_i, y_i)\rangle_B$ (here we assume, without loss of generality, that the final state in the protocol for f does not contain any garbage). Alice then maps this state to $\sum_i(-1)^{f(x_i,y_i)}|i, f(x_i, y_i)\rangle_A|i, f(x_i, y_i)\rangle_B$. They run the protocol in reverse to uncompute $f(x_i, y_i)$, leaving $\sum_i \alpha_i(-1)^{f(x_i,y_i)}|i\rangle_A|i\rangle_B$. Bob sends his half to Alice, so she can uncompute it, leaving the state $\sum_i \alpha_i(-1)^{f(x_i,y_i)}|i\rangle$, and thus implementing R_2. ◀

We are now ready to state and prove our main theorem.

▶ **Theorem 7** (Upper bound for Boolean matrix multiplication). *For all $\ell \in \{1, \ldots, m^2\}$,*

$$Q(\mathsf{BMM}_{m,n,\ell}) = O(\sqrt{n}\ell^{3/4} \log m).$$

Proof. Alice and Bob run the following communication protocol.

1. Alice and Bob individually store the all-zero matrix C of size $m \times m$.
2. Repeat:
   a. Alice and Bob jointly find $k \in [n]$ such that $\mathsf{GC}_{\overline{C}}(A[\cdot, k], B[k, \cdot]) = 1$. If none exists, Alice and Bob output C.
   b. Alice and Bob jointly compute $S \leftarrow \mathsf{GCall}_{\overline{C}}(A[\cdot, k], B[k, \cdot])$.
   c. Alice and Bob individually compute $C \leftarrow C + S$.

In this protocol Alice and Bob each maintain a matrix C containing the 1s of the product $A * B$ found by the protocol so far. They repeatedly search for a new $k \in [n]$ such that $f^k_A = A[\cdot, k]$ and $f^k_B = B[k, \cdot]$ have graph collisions with respect to the graph given by the complement of C. When they find such a k, they compute all graph collisions. Suppose they find $\{k_1, \ldots, k_t\}$ before there are no more k to be found, and let λ_i be the number of ones found at round i. By Lemma 4 and Lemma 6, in round i step 2a costs $O\left(\sqrt{\frac{n}{t-i+1}\min\{|f^{k_i}_A|, f^{k_i}_B|\}\log m}\right)$. By Corollary 5, in round i step 2b costs $O\left(\sqrt{\lambda_i \min\{|f^{k_i}_A|, |f^{k_i}_B|\}\log m}\right)$. Thus, the total cost is at most:

$$\sum_{i=1}^{t}\left(\sqrt{\frac{n}{t-i+1}}\sqrt{\min\{|f^{k_i}_A|, |f^{k_i}_B|\}} + \sqrt{\lambda_i \min\{|f^{k_i}_A|, f^{k_i}_B|\}}\right)\log m.$$

Note that for any k, every (i, j) such that $f^k_A(i) = f^k_B(j) = 1$ implies that $(A * B)[i, j] = 1$, so we necessarily have $\ell \geq |f^k_A| \cdot |f^k_B|$. We therefore have $\min\{|f^k_A|, |f^k_B|\} \leq \sqrt{\ell}$ for all $k \in [n]$, and thus, the total cost is at most (up to constants):

$$\begin{aligned}\ell^{1/4}\sum_{i=1}^{t}\left(\sqrt{\frac{n}{t-i+1}} + \sqrt{\lambda_i}\right)\log m \quad &\leq \quad \ell^{1/4}\left(\sqrt{nt} + \sqrt{t\sum_{i=1}^{t}\lambda_i}\right)\log m \\ &\leq \quad \ell^{1/4}(\sqrt{nt} + \sqrt{t\ell})\log m,\end{aligned}$$

where in the first line we use the fact that $\sum_{i=1}^{t} i^{-1/2} = \Theta(\sqrt{t})$ and Cauchy-Schwartz inequality, and in the second line we use the fact that $\sum_{i=1}^{t} \lambda_i = \ell$, since ℓ is the total number of ones we find over all rounds. Finally, observe that since t is the number of distinct witnesses $k \in [n]$ found, $t \leq n$, and since we find at least one new 1 in every round except the last, we also have $t \leq \ell + 1$. Thus, the total communication is at most

$$(\ell^{1/4}\sqrt{n} + \ell^{3/4})\sqrt{\min\{n,\ell\}}\log m = O\left(\ell^{3/4}\sqrt{n}\log m\right),$$

as claimed. ◀

4 Matrix Multiplication over Finite Fields

In this section we consider matrix multiplication over finite fields and give tight bounds (up to possible polylogarithmic factors) on its communication complexity. We work out here only the case of square matrices over the binary field. Formally, the problem we consider is the following.

Square matrix multiplication over $\mathbb{F}_2$, $\mathsf{MM}_{n,\ell}$
Alice's input: $A \in \mathbb{F}_2^{n\times n}$
Bob's input: $B \in \mathbb{F}_2^{n\times n}$
Promise: $|AB| \leq \ell$
Output: the matrix $AB \in \mathbb{F}_2^{n\times n}$

The main result of this section is the following upper bound on the classical (and thus quantum) communication complexity of this problem.

▶ **Theorem 8** (Upper bound for matrix multiplication over $\mathbb{F}_2$). *The classical communication complexity of $\mathsf{MM}_{n,\ell}$ is $\widetilde{O}(n\sqrt{\ell})$.*

We will need two lemmas to prove Theorem 8. The first lemma is a finite-field version of a result related to compressed sensing used in [23]. The proof of this finite-field version can be found in [7].

▶ **Lemma 9.** *For any positive integer n and any integer $\kappa \in \{1,\dots,n\}$, there are a distribution on random matrices $M \in \mathbb{F}_2^{O(\kappa)\times n}$ and a reconstruction function $\mathsf{Rec}(\cdot)$ such that for any vector $x \in \mathbb{F}_2^n$ with at most κ non-zero entries the inequality*

$$\Pr_M\left[\mathsf{Rec}(Mx) = x\right] > 0.99.$$

holds (i.e., $\mathsf{Rec}(\cdot)$ applied on Mx returns x with high probability).

The second lemma shows how to use Freivalds' technique to detect non-zero columns of a matrix product. Similar ideas were used in [8].

▶ **Lemma 10.** *Let m and n be two positive integers. Consider the setting where Alice has for input a matrix $A \in \mathbb{F}_2^{m\times n}$ and Bob has for input a matrix $B \in \mathbb{F}_2^{n\times n}$. Alice and Bob can detect, with high probability, which columns of AB contain at least one non-zero entry with $\widetilde{O}(n)$ communication.*

Proof. Consider the following procedure: Alice takes a vector v uniformly at random in $\mathbb{F}_2^m$; Alice sends the row-vector $v^T A \in \mathbb{F}_2^n$ to Bob; Bob sends the row-vector $v^T AB \in \mathbb{F}_2^n$ to Alice. This procedure has communication complexity $2n$ and, for each column of AB, enables Alice and Bob to decide with probability at least 1/2 whether this column contains at least one non-zero entry. By repeating this procedure a logarithmic number of times, Alice and Bob are able to find, with high probability, which columns of AB contain at least one non-zero entry. ◀

We are now ready to prove Theorem 8.

Proof of Theorem 8. We assume for convenience that both $\sqrt{\ell}$ and $n/\sqrt{\ell}$ are integers (the general case is handled similarly). We will say that a column of AB is dense if it contains at least $0.9\sqrt{\ell}$ non-zero entries, and say that a column of AB is sparse if it contains at most $1.1\sqrt{\ell}$ non-zero entries (note that a column can be both sparse and dense). The protocol is as follows.

1. Alice and Bob partition the columns of AB into dense columns and sparse columns: they compute a set of indexes $S \subseteq \{1, \dots, n\}$ such that, for any $j \in \{1, \dots, n\}$, the j-th column of AB is dense if $j \in S$ and sparse if $j \notin S$.
2. Alice and Bob compute all entries of all columns of AB with index in S.
3. Alice and Bob compute all entries of all the columns of AB with index in $[n] \setminus S$.

Step 1 can be done probabilistically with $\widetilde{O}(n)$ bits of communication by repeating the following procedure: Alice constructs a $(n/\sqrt{\ell}) \times n$ matrix A' by selecting $n/\sqrt{\ell}$ rows of A uniformly at random; Alice and Bob then use the protocol of Lemma 10 (with A' as Alice's input and B as Bob's input) to decide which columns of $A'B$ have more than one non-zero entry. Repeating this procedure a logarithmic number of times enables Alice and Bob to decide, with high probability, which columns of AB are not dense: for a non-dense column of AB (i.e., a column with less than $0.9\sqrt{\ell}$ non-zero entries) the corresponding column of $A'B$ will not contain any non-zero entry with high probability (on the choice of A'). The indices of the other columns are collected in S. The indices in S thus correspond only to dense columns of AB. While the set S may not contain the indices of all the dense columns of AB, it can be seen from a similar argument that all non-sparse columns of AB (i.e., the columns with at least $1.1\sqrt{\ell}$ non-zero entries) will be put in S, which means that all indices in $[n] \setminus S$ correspond to columns of AB that are sparse.

Step 2 can be done with $O(|S|n) = O(\sqrt{\ell}n)$ bits of communication (note that $|S| \leq \frac{1}{0.9}\sqrt{\ell}$ since AB has only at most ℓ non-zero entries): Bob simply sends the entries $B[i,j]$ for all $(i,j) \in \{1, \dots, n\} \times S$, and then Alice computes $AB[i,j]$ for all $(i,j) \in \{1, \dots, n\} \times S$.

Step 3 can be done with $\widetilde{O}(n\sqrt{\ell})$ bits of communication using Lemma 9 with $\kappa = \lceil 1.1\sqrt{\ell} \rceil$, by repeating the following procedure a logarithmic number of times: Alice chooses a random matrix M as in Lemma 9 and sends MA to Bob; for each $j \in \{1, \dots, n\} \setminus S$, Bob computes $\mathsf{Rec}(MAz)$ where z denotes the j-th column of B. ◀

We now show a lower bound on the quantum (and thus also classical) communication complexity of matrix multiplication over $\mathbb{F}_2$, which matches the upper bound of Theorem 8 up to polylogarithmic factors.

▶ **Theorem 11.** *The quantum communication complexity of* $\mathsf{MM}_{n,\ell}$ *is* $\Omega(n\sqrt{\ell})$.

Proof. Assume for convenience that $\sqrt{\ell}$ is an integer (the general case is handled similarly). Let $x^1, \dots, x^{\sqrt{\ell}}, y^1, \dots, y^{\sqrt{\ell}}$ be $2\sqrt{\ell}$ vectors in $\mathbb{F}_2^n$. Let $x \in \mathbb{F}_2^{n\sqrt{\ell}}$ be the vector obtained by concatenating $x^1, \dots, x^{\sqrt{\ell}}$, and $y \in \mathbb{F}_2^{n\sqrt{\ell}}$ be the vector obtained by concatenating $y^1, \dots, y^{\sqrt{\ell}}$.

Construct the $n \times n$ matrix A by putting the vector x^i as its i-th row, for each $i \in \{1, \dots, \sqrt{\ell}\}$, and setting the next $n - \sqrt{\ell}$ rows to zero (observe that $\sqrt{\ell} \leq n$ since $\ell \leq n^2$). Construct the $n \times n$ matrix B by putting the vector y^j as its j-th column, for each $j \in$

$\{1, \dots, \sqrt{\ell}\}$, and setting the next $n - \sqrt{\ell}$ columns to zero. Observe that $|AB| \leq \ell$ and the parity of the diagonal entries of the matrix product AB is equal to

$$\bigoplus_{i=1}^{\sqrt{\ell}} x^i \cdot y^i = x \cdot y.$$

We thus obtain a reduction from computing the inner product of two vectors in $\mathbb{F}_2^{n\sqrt{\ell}}$ to solving $\mathsf{MM}_{n,\ell}$. Since the quantum communication complexity of the former problem is $\Omega(n\sqrt{\ell})$, as shown in [14], we obtain the same lower bound for $\mathsf{MM}_{n,\ell}$. ◀

5 Lower Bounds for Boolean Matrix Multiplication

An important open problem of this work is to prove a tight lower bound on the bounded error quantum communication complexity of Boolean matrix multiplication, i.e., to show that the upper bound of Theorem 7 is tight. Let us focus on the square case (i.e., $m = n$). We are able to prove two lower bounds, each of which is tight for one extreme value of ℓ: $\ell = O(1)$ or $\ell = \Omega(n^2)$, but neither is tight for the range $\ell \in (\omega(1), o(n^2))$. We further show that assuming a plausible OR-lemma, our upper bound is indeed tight, up to logarithmic factors.

▶ **Proposition 12.** *For all $\ell \in \{1, \dots, n^2\}$, $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\sqrt{n\ell})$. In particular, when $\ell = O(1)$, then $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\sqrt{n}\ell^{3/4})$.*

Proof. We can embed $\sqrt{\ell} \leq n$ instances $\{(a^{(i)}, b^{(i)})\}_{i=1}^{\sqrt{\ell}}$ of DISJ_n in an instance of $\mathsf{BMM}_{n,n,\ell}$ as follows. Let A have $a^{(i)}$ in the i-th row for $i = 1, \dots, \sqrt{\ell}$, and all zeros elsewhere, and let B have $b^{(i)}$ in the i-th column for $i = 1, \dots, \sqrt{\ell}$, and zeros elsewhere. Then AB is 0 except in the upper left $\sqrt{\ell} \times \sqrt{\ell}$ submatrix, so $|AB| \leq \ell$, and $(AB)[i,i] = \mathsf{DISJ}_n(a^{(i)}, b^{(i)})$, so AB encodes $\mathsf{DISJ}_n^{(\sqrt{\ell})}(a^{(1)}, \dots, a^{(\sqrt{\ell})}, b^{(1)}, \dots, b^{(\sqrt{\ell})})$. The result follows from the $\Omega(\sqrt{\ell}\sqrt{n})$ lower bound on $Q(\mathsf{DISJ}_n^{(\sqrt{\ell})})$ shown in [13]. ◀

▶ **Proposition 13.** *For all $\ell \in \{1, \dots, n^2\}$, $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\ell)$. In particular, when $\ell = \Omega(n^2)$, then $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\ell^{3/4}\sqrt{n})$.*

Proof. We can embed an instance (a, b) of the inner product function IP_ℓ in an instance of $\mathsf{BMM}_{n,n,\ell}$ as follows. Let $B = I$ be the identity matrix, and let A contain the ℓ-bit string a in the first ℓ positions. Then Alice and Bob jointly compute $AB = A$, and Bob can compute $\mathsf{IP}(a, b)$ and send the resulting bit to Alice. Since $Q(\mathsf{IP}_\ell) = \Omega(\ell)$, we have $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\ell)$. ◀

▶ **Proposition 14.** *Suppose computing the entrywise-OR of k independent instances of BMM_{n,n,n^2} has bounded error quantum communication complexity $\Omega(\sqrt{k}Q(\mathsf{BMM}_{n,n,n^2}))$. Then for any $\ell \in [n^2]$, $Q(\mathsf{BMM}_{n,n,\ell}) = \Omega(\ell^{3/4}\sqrt{n})$.*

Proof. Let $(A_1, B_1), \dots, (A_k, B_k)$ be independent instances of $\mathsf{BMM}_{\sqrt{\ell},\sqrt{\ell},\ell}$, for $k = \frac{n}{\sqrt{\ell}}$. Define A and B as follows:

$$A = \begin{bmatrix} A_1 & \dots & A_k \\ 0 & \dots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \dots & 0 \end{bmatrix}, \qquad B = \begin{bmatrix} B_1 & 0 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ B_k & 0 & \dots & 0 \end{bmatrix}.$$

Then $A * B$ has $\bigvee_{i=1}^{k} A_i * B_i$ in the top left corner, and zeros elsewhere. So $|A * B| \leq \ell$, and computing $A * B$ costs at least $\sqrt{k}Q(\mathsf{BMM}_{\sqrt{\ell},\sqrt{\ell},\ell}) \geq \sqrt{\frac{n}{\sqrt{\ell}}}\ell = \ell^{3/4}\sqrt{n}$. ◀

The above proposition actually holds equally true for $\mathsf{BMM}_{m,n} = \mathsf{BMM}_{m,n,m^2}$, the non-promise problem, and would imply $Q(\mathsf{BMM}_{m,n}) = \Omega(m^{3/2}\sqrt{n})$.

Abstract

In the deterministic binary majority process we are given a simple graph where each node has one out of two initial opinions. In every round, each node adopts the majority opinion among its neighbors. It is known that this process always converges in $\mathrm{O}(|E|)$ rounds to a two-periodic state in which every node either keeps its opinion or changes it in every round.

It has been shown by Frischknecht, Keller, and Wattenhofer (2013) that the $\mathrm{O}(|E|)$ bound on the convergence time of the deterministic binary majority process is even for dense graphs tight. However, in many graphs such as the complete graph the process converges in just a constant number of rounds from any initial opinion assignment.

We show that it is NP-hard to decide whether there exists an initial opinion assignment for which it takes more than k rounds to converge to the two-periodic state, for a given integer k. We then give a new upper bound on the voting time of the deterministic binary majority process. Our bound can be computed in linear time by carefully exploiting the structure of the potential function by Goles and Olivos. We identify certain modules of a graph G to obtain a new graph G^{Δ}. This new graph G^{Δ} has the property that the worst-case convergence time of G^{Δ} is an upper bound on that of G. Our new bounds asymptotically improve the best known bounds for various graph classes.

1 Introduction

Distributed voting is a fundamental problem in distributed computing. We are given a network of players modeled as a graph. Each player in the network starts with one initial opinion out of a set of possible opinions. Then the voting process runs either synchronously in discrete rounds or asynchronously according to some activation mechanism. During these rounds in the synchronous case, or upon activation in the asynchronous case, the players are allowed to communicate with their direct neighbors in the network with the main goal to eventually agree on one of the initial opinions. If all nodes agree on one opinion, we say this

[*] Research was supported by Austrian Science Fund (FWF): P 27613

opinion *wins* and the process *converges*. Usually, voting algorithms are required to be simple, fault-tolerant, and easy to implement [22, 24].

In this paper, we study the *deterministic binary majority process* which is defined as follows. We are given a graph $G = (V, E)$ where each node has one out of two opinions. The process runs synchronously in discrete rounds where each node in every round computes and adopts the majority opinion among all of its neighbors. It is known that this process always converges to a two-periodic state. The *convergence time* of a given graph for a given initial opinion assignment is the time required until this two-periodic state is reached. In this work we improve the bounds on the convergence time for given initial opinions and then we analyze the *voting time* of the process, which is the maximum convergence time over all possible initial opinion assignments.

In distributed computing, various variants of the majority process are used in fault-tolerant distributed consensus algorithms. In the analysis of structures of large networks, the deterministic binary majority process has widespread applications in the study of so-called *influence networks* [15]. Early applications can be found in distributed databases [16]. Further fields include sensor networks [6], the analysis of opinions in social networks [32], social behavior in game theory [12], chemical reaction networks [14], neural and automata networks [18], and cells' behavior in biology [7]. Variants of the deterministic binary majority process have been used in the area of distributed community detection [38, 28, 10]. In this context, the proposed community detection protocols exhibit a convergence time which can be bounded by the voting time of the deterministic binary majority process.

Among its many probabilistic variants that have been previously considered, plenty of work concerns *randomized voting* where in each step every node is allowed to contact a random sample of its neighbors and updates its current opinion according to the majority opinion in that sample [1, 5, 9, 13, 22, 23, 29, 30, 31, 33].

In an algorithmic game theoretic setting, the deterministic binary majority process can be seen as the simplest *discrete preference games* [8]. In this game theoretic perspective, the existence of *monopolies* has been investigated [2]. A monopoly in a graph is a set of nodes which start with the same opinion and cause all other nodes to eventually adopt this opinion. In the distributed computing area, a lot of research has been done to find small monopolies, see for example [34]. It has also been shown that there exist families of graphs with constant-size monopolies [4]. More recently, classes of graphs which do not have small monopolies have been investigated [35].

Many of these results relate to the voting time of the deterministic binary majority process. It was proven independently by Goles and Olivos [20], and Poljak and Sůra [36] with the same potential function argument that the deterministic binary majority process always converges to a two-periodic state. They later (independently) refined and generalized the potential function argument in several directions [17, 19, 21, 37]. Their proof was popularized in the *Puzzled* columns of Communications of the ACM [41, 42]. Recently, the same problem has been studied on infinite graphs w.r.t. a given probability distribution on the initial opinion assignments [3]. In [40], the authors provide a bound on the number of times a node in a given bounded-degree graph changes its opinion. Both [3] and [40] also investigate the probability that in the two-periodic state all nodes hold the same opinion.

As for the maximum time it takes for the process to converge over all initial opinion assignments, Frischknecht et al. [15] note that the potential argument by Goles et al. [20, 36, 42] can be used to prove an $\mathrm{O}(|E|)$ upper bound. They furthermore show that this upper bound is tight in general, by designing a class of graphs in which the deterministic binary majority process takes at least $\Omega\left(|V|^2\right)$ rounds to converge from a given initial opinion assignment. This construction has later been extended to prove lower bounds for weighted and multi-edges graphs by Keller et al. [27].

Once the process converges to the two-periodic state, each node stays either with its own opinion or changes its opinion in every round. A lot of attention has been given to the opinions to which the deterministic binary majority process converges. However, regarding the voting time, besides the $\mathrm{O}(|E|)$ upper bound that follows from the result by Goles et al. [20, 36, 42], no further upper bound on the voting time that holds for any initial opinion assignment has been proved. Still, one can observe that in many graphs the voting time is much smaller than $\mathrm{O}(|E|)$. For example, the voting time of the complete graph is one.

We show that for the deterministic binary majority process the question whether the voting time is greater than a given number is NP-hard. While for many generalizations of the deterministic binary majority process many decision problems are known to be NP-hard, at the best of our knowledge this is the first NP-hardness proof that does not require any additional mechanisms besides the bare majority rule of the deterministic binary majority process. However, as we show in the rest of the paper, it is possible to obtain upper bounds on the voting time which can be computed in linear time. A module of a graph is a subset of vertices S such that for each pair of nodes $u, v \in S$ it holds that $N(u) \setminus S = N(v) \setminus S$, where $N(u)$ denotes the set of neighbors of a node u. By carefully exploiting the structure of the potential function by Goles et al. we leverage the particular behavior that certain modules, which we call *families*, exhibit and prove that the voting time of a graph can be bounded by the voting time of a smaller graph that can be constructed in linear time by contracting suitable vertices.

We obtain a new upper bound that asymptotically improves the previous $\mathrm{O}(|E|)$ bound on graph classes which are characterized by a high number of modules that are either cliques or independent sets. An example for such graphs is the Turán graph $T(n, r)$, formed by partitioning a set of n vertices into r subsets of (almost) equal sizes and connecting two vertices by an edge whenever they belong to different subsets. For the convergence time of the Turán graph $T(n, r)$ we obtain an $\mathrm{O}\left(r^2\right)$ bound, compared to the previously best known bound of $\mathrm{O}\left(n^2\right)$. Also, for the convergence time of full d-ary trees we get an $\mathrm{O}(|V|/d)$ bound, compared to $\mathrm{O}(|V|)$ originating from the $\mathrm{O}(|E|)$ bounds. Further examples include the clique and the star graph, for which our bound gives a constant $\mathrm{O}(1)$ convergence time. Our bound relies on a well-known graph contraction technique based on identifying *equivalent nodes*. This technique is used in other related disciplines as well, including parallel and distributed computing. See, for example, the notion of *identical nodes* in the work by Sarıyüce et al. [39].

1.1 Preliminaries

We are given a graph $G = (V, E)$ and an initial opinion assignment defined as follows.

▶ **Definition 1.** An opinion assignment f_t in round $t \geq 0$ is a function $f_t : V \to \{0, 1\}$ which assigns for each $v \in V$ one out of two possible opinions. We will also denote opinion 1 as *white* and opinion 0 as *black*. The opinion assignment at time $t = 0$ is called *initial opinion assignment*.

The deterministic binary majority process can be defined as follows. Let v be an arbitrary but fixed vertex and $N(v)$ the set of neighbors of v. To compute $f_{t+1}(v)$ the node v computes the majority opinion of all of its neighbors in $N(v)$. In the case of a tie the node behaves *lazily*, that is, v stays with its own opinion. Otherwise, there is a *clear majority* and the node adopts the majority opinion. This leads to the following definition.

▶ **Definition 2.** Let $G = (V, E)$ be a graph and let f_0 be an initial opinion assignment such that $f_0 : V \to \{0, 1\}$. The deterministic binary majority process is the series of opinion assignments that satisfy the rule

$$f_{t+1}(v) = \begin{cases} 0 & \text{if } |\{u \in N(v) : f_t(u) = 0\}| > |\{u \in N(v) : f_t(u) = 1\}| \\ 1 & \text{if } |\{u \in N(v) : f_t(u) = 0\}| < |\{u \in N(v) : f_t(u) = 1\}| \\ f_t(v) & \text{otherwise.} \end{cases}$$

Note that the pair (G, f_0) completely determines the behavior of the system according to the majority process. We now define the main object of this work, the voting time.

▶ **Definition 3.** Given a graph $G = (V, E)$ and any initial opinion assignment f_0 on V, the *convergence time* $\mathfrak{T}$ of the majority process on G w.r.t. f_0 is $\mathfrak{T} = \mathfrak{T}(G, f_0) = \min \{t : \forall v \; f_{t+2}(v) = f_t(v)\}$. The *voting time* of G is defined as $\max_{f_0 \in \{0,1\}^V} \mathfrak{T}(G, f_0)$.

Observe that $\mathfrak{T}$ is indeed the number of steps until the process converges to a two-periodic state. This holds since the process is completely determined by the current opinion assignment. Thus $f_{t+2}(v) = f_t(v)$ also implies that $f_{t+3}(v) = f_{t+1}(v)$ for all nodes v.

In the following we assume without loss of generality that G is connected. For disconnected graphs the deterministic binary majority process runs independently in each connected component. Therefore, the resulting upper bounds on the voting time can be replaced by the maximum over the corresponding bounds in the individual connected components of G.

1.2 Our Contribution

First we define the *voting time decision problem* VTDP and show that it is NP-complete.

▶ **Definition 4** (voting time decision problem VTDP)**.** For a given graph G and an integer k, is there an assignment of initial opinions such that the voting time of G is at least k?

▶ **Theorem 5.** *Given a general simple graph G,* VTDP *is NP-complete.*

In Section 3 we extend known approaches to derive upper bounds on the voting time, which are tight for general graphs. In Section 3.2, we identify the following subsets of nodes that play a crucial role in determining the voting time of the deterministic binary majority process.

▶ **Definition 6.** A set of nodes S is called a *family* if and only if for all pairs of nodes $u, v \in S$ we have $N(u) \setminus \{v\} = N(v) \setminus \{u\}$. We say that a family S is *proper* if $|S| > 1$.

The set of families of a graph forms a partition of the nodes into equivalence classes. Our main contribution is a proof that the voting time of the deterministic binary majority process is bounded by that of a new graph obtained by contracting its families into one or two nodes, as stated in the following theorem.

▶ **Definition 7.** Given a graph $G = (V, E)$, its *asymmetric graph* $G^{\Delta} = (V^{\Delta}, E^{\Delta})$ is the subgraph of G induced by the subset $V^{\Delta} \subseteq V$ constructed by contracting every family of odd-degree non-adjacent nodes to one node, and any other proper family to two nodes.

Let in the following V_{even} be the set of even-degree vertices in V and, analogously, let V_{odd} be the set of odd-degree vertices. Based on above definition of G^{Δ}, we give the following bound on the voting time.

▶ **Theorem 8.** *Given any initial opinion assignment on a graph $G = (V, E)$, the voting time of the deterministic binary majority process is at most*

$$1 + \min\left\{|E^\Delta| - \frac{|V^\Delta_{odd}|}{2}, \frac{|E^\Delta|}{2} + \frac{|V^\Delta_{even}|}{4} + \frac{7}{4} \cdot |V^\Delta|\right\} .$$

Furthermore, this bound can be computed in $\mathrm{O}(|E|)$ *time.*

As mentioned before, this bound becomes $\mathrm{O}\left(r^2\right)$ for the Turán graph $T(n, r)$ and $\mathrm{O}(|V|/d)$ for d-ary trees. Finally, in Section 3 we also give some insight into further interesting computational properties of the deterministic binary majority process. For example, we disprove a monotonicity of the convergence time w.r.t. the potential function and argue that the voting time is not, at least straightforwardly, bounded by the diameter of the graph.

2 NP-Completeness

If it was possible to efficiently compute the worst-case voting time, there would have been not much interest in investigating good upper bounds for it. In this section, we show that this is unlikely to be the case. We prove Theorem 5 by reducing 3SAT to the voting time decision problem. Given $\Phi \in$ 3SAT, we construct a graph $G = G(\Phi)$ such that the deterministic binary majority process on G simulates the evaluation of Φ. The graph G consists of h layers where $h = 3 + 4 \cdot n$. The first layer represents an assignment of the variables in Φ, the remaining layers represent Φ and ensure that the assignment of variables in Φ is valid. We will show that if Φ is satisfiable, then there exists an initial assignment of opinions for which the convergence time is exactly $h + 1$. If, however, Φ is not satisfiable, then any assignment of opinions will result in a convergence time strictly less than $h + 1$. We now give the formal proof.

Let $\Phi \in$ 3SAT be a Boolean formula in 3-conjunctive normal form. Let n be the number of variables of Φ. Let m be the number of clauses of Φ. The Boolean formula is of the form $\Phi = (l_{1,1} \vee l_{1,2} \vee l_{1,3}) \wedge \cdots \wedge (l_{m,1} \vee l_{m,2} \vee l_{m,3})$, where $l_{i,j} \in \{x_1, \overline{x}_1, x_2, \overline{x}_2, \cdots, x_n, \overline{x}_n\}$ is a literal for $1 \leq i \leq m$ and $1 \leq j \leq 3$.

We construct a graph G to simulate the evaluation of Φ as follows. Let $\ell = 10 \cdot (m+n)+1$. The graph consists of several layers. On the first layer, we place so-called literal cliques of size ℓ, and on the layers above we place the gates. In our reduction, we use OR-gates, an AND-gate, and 2/3-gates. Each gate consists of one or several nodes. Additionally, we have two so-called *mega-cliques* K_{white} and K_{black} of size ℓ.

Let g be an arbitrary but fixed gate. We denote a node on a layer below g which does not belong to g but is connected to g as *input node* to g. Additionally, we will denote a node that belongs to g and is connected to another gate on a layer above g as *output node* of g.

In the following, we assume that opinion 1, white, corresponds to Boolean TRUE and 0, black, corresponds to FALSE. The main idea of the construction is to show that an *activation signal* is transmitted from the bottom up through all layers. If the current assignment of opinions on the literal cliques corresponds to a satisfying assignment of Boolean values to Φ, then the process requires $h + 1$ steps. The main purpose of the OR-gates and the AND-gate is to evaluate Φ. The 2/3-gates check whether the opinion assignment to literal nodes is valid. That is, we need to enforce that the corresponding literal nodes for x_i and $\overline{x}_i$ are of opposite colors for every variable x_i of Φ. If either this condition is violated and variables x_i exist for which $x_i = \overline{x}_i$ or the current assignment of opinions on the literal cliques does not corresponds to a satisfying assignment of Boolean values to Φ, the construction enforces that the process stops prematurely after strictly fewer than $h + 1$ steps.

Figure 1 Literal nodes and OR-gate.

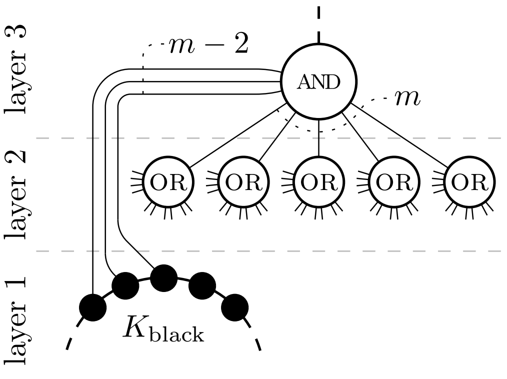

Figure 2 AND-gate.

Layer 1: Literal Cliques. We represent each variable x_i with two cliques, one for x_i and one for $\overline{x}_i$. Each clique has a size of ℓ which is defined above. Note that ℓ is odd. Additionally, we distinguish three so-called *representative nodes* in each of these cliques. Furthermore, we add two cliques of size ℓ to the graph which we call mega-cliques. Intuitively, these mega-cliques represent the Boolean values TRUE and FALSE. We will show that they cannot have the same color in order to achieve a long convergence time. The mega-cliques are used in all other gates.

Layer 2: Parallel OR-Gates. The OR-gates are placed on layer 2 and consist of one node v which is also the output node. There is one OR-gate for every clause. Fix a clause $(l_{j,1} \vee l_{j,2} \vee l_{j,3})$. Input nodes are three pairs of nodes (v_1, v_1'), (v_2, v_2'), and (v_3, v_3'), where (v_1, v_1') are two representative nodes of the literal clique for $l_{j,1}$, (v_2, v_2') are representatives of $l_{j,2}$, and (v_3, v_3') are representatives of $l_{j,3}$. That is, for each literal in the clause we connect the OR-gate on layer 2 to two of the three representative nodes of the corresponding literal clique on layer 1. The output node v is additionally connected to 4 nodes of the K_{white} mega-clique. Intuitively, we use the OR-gates to verify that for each clause at least one literal is TRUE. All clauses are evaluated simultaneously using an OR-gate for each clause. The OR-gate is shown in Figure 1.

Layer 3: AND-Gate. There is exactly one AND-gate on layer 3. This AND-gate consists of one output node denoted u_0, which has the following input nodes. It is connected to every output node of the OR-gates on layer 2 and to $m-2$ distinct nodes of the K_{black} mega-clique. Intuitively, the AND-gate is used toverify that every clause is satisfied. It is shown in Figure 2.

Layers 4 to 3 + 4n: 2/3-Gates. The 2/3-gates consist of a path v_1, v_2, v_3, and v_4. Each node of this path is connected to two distinct nodes of the K_{white}. The output node of the gate is v_4. The node v_1 of the first 2/3-gate on layer 4 is connected to the AND-gate on layer 3. The node v_1 of each of the following 2/3-gates is connected to the node v_4 of the previous 2/3-gate. Additionally, the input node of the i-th 2/3-gate is connected to three distinct nodes of the literal clique representing x_i and to three distinct nodes of the literal clique representing $\overline{x}_i$ on layer 1. The output node of the final 2/3-gate is connected to K_{black}. An example is shown in Figure 3. The 2/3-gates are used to verify that we do not have variables x_i in Φ for which the literal cliques of x_i and $\overline{x}_i$ have the same color. Observe that 2/3-gates span over 4 layers, and we have n such 2/3-gates.

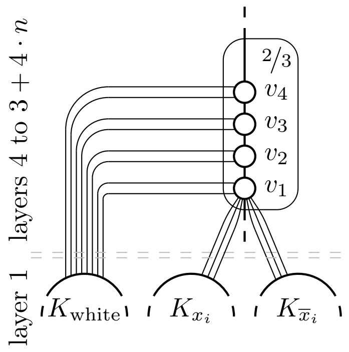

Figure 3 The 2/3-gate.

Literal cliques, OR-gates, and the AND-gate use only one layer, and 2/3-gates span over 4 layers. Therefore, the total number of layers is $h = 3 + 4 \cdot n$, which results from one layer for the literal cliques, one layer for the OR-gates, one layer for the AND-gate, and $4 \cdot n$ layers containing n concatenated 2/3-gates. A detailed example for such a graph G is given in [26]. Based on above description of G we prove the following lemmas, which are then used to show Theorem 5.

▶ **Lemma 9.** *If Φ is satisfiable, then there exists an assignment of opinions such that the convergence time in G is at least $h + 1$.*

To show Theorem 9, we construct an initial opinion assignment for which the gates change from black to white one layer after the other, assuming Φ is satisfiable. The full proof can be found in [26].

It remains to show that if Φ is not satisfiable, then the voting time in G is strictly less than $h + 1$. Recall that the voting time is the maximum of the convergence time over all possible initial opinion assignments.

▶ **Lemma 10.** *If Φ is not satisfiable, then there is no assignment of opinions such that the convergence time in G is at least $h + 1$.*

Before we prove this lemma, we establish several auxiliary lemmas which require the following definitions. Let u_0 denote the output node of the AND-gate. Consider the graph G' induced by the nodes of the AND-gate and the nodes of the 2/3-gates. Let u_i be the node at distance i to u_0 in G'. We observe that G' is a path $u_0, \ldots, u_\kappa$ consisting of the $4 \cdot n + 1$ top layers of the graph G. Consequently, $\kappa = 4 \cdot n$ and u_i is the i-th node on this path.

▶ **Definition 11** (Stable Time). We define the *stable time* $s(v)$ for any node $v \in V$ to be the first time step such that v does not change its opinion in any subsequent time step $t' > s(v)$ over all possible initial configurations. That is,

$$s(v) = \min \left\{ t : \forall f_0 \in \{0,1\}^V \ \ \forall t' \geq t \quad f_{t'}(v) = f_t(v) \right\} .$$

Accordingly, let for any subset $V' \subseteq V$ be $s(V')$ defined as $s(V') = \max \{s(v) : v \in V'\}$.

In the following, let V_K be the set of nodes of all cliques in $G(\Phi)$, that is, the nodes contained in the literal cliques and in the mega-cliques on layer 1. Furthermore, let $V_{K^{\text{R}}}$ be the set of representatives of the cliques and $V_{K^-} = V_K \setminus V_{K^{\text{R}}}$. That is, every clique K on layer 1 consists of $K^- \cup K^{\text{R}}$. Finally, let V_{OR} be the set of all output nodes of OR-gates. The following lemma shows that the layers become stable one after the other.

▶ **Lemma 12.** *It takes at most* 3 *time steps for the layers* 1 *and* 2 *consisting of literal cliques and* OR*-gates to become stable. Precisely, we have* (i) $s\left(V_{K^-}\right) = 1$*,* (ii) $s\left(V_{K^{\mathrm{R}}}\right) = 2$*, and* (iii) $s\left(V_{\mathrm{OR}}\right) = 3$*.*

The above lemma gives bounds on the stable time of layers 1 and 2. In the following, we argue that whenever a node changes its opinion in any step t after time step 3, it will not change its color in any subsequent time step $t' \geq t$ any more. We therefore define the so-called *activation time* of a node $v \in G'$ as follows.

▶ **Definition 13** (Activation Time)**.** Let c be the color of the K_{black} mega-clique at time 2 and let f_0 be an arbitrary but fixed initial opinion assignment. We define the *activation time* of a node $v \in G'$ to be the first time step after time step 3 in which the node v adopts opinion c. That is, $a(v) = \min\{t \geq 3 : f_t(v) = c\}$. If v does not change its color after time step 3 we write $a(v) = 3$.

We now use the above definition to state the following lemma, which describes that every node $u_i \in G'$ with $i \geq 1$ changes its color at most once after time step 3. Note that this covers the nodes of the 2/3-gates.

▶ **Lemma 14.** *Let f_0 be an arbitrary but fixed initial opinion assignment. Let t be the activation time w.r.t. f_0 of the node $u_i \in G'$ with $i \geq 1$ such that $t = a(u_i)$. Then for all $t' \geq t$ we have $f_{t'}(u_i) = f_t(u_i)$.*

Proof. By Theorem 12, all nodes $u \in V_{K^{\mathrm{R}}}$ are stable at $t' \geq 2$. We now distinguish two cases.

Case 1: $i \mod 4 \neq 1$. Observe that u_i can only change its color at time $t = a(u_i)$, if it had a different color than K_{white} in the previous round. This holds, since every node u_i with $i \mod 4 \neq 1$ has the same number of connections to K_{white} than to nodes in $V \setminus K_{\text{white}}$. Since furthermore the process behaves lazy, any node u_i which has the same color as K_{white} cannot change its opinion back to the opposite color any more.
Case 2: $i \mod 4 = 1$. The node u_i is a v_1 node of the j-th 2/3-gate with $j = \lceil i/4 \rceil$. Therefore it is connected to three representatives of each literal clique for x_j and $\overline{x}_j$. The literal representatives of x_j and $\overline{x}_j$ are stable at time $t' \geq 2$. Now if x_j and $\overline{x}_j$ have the same color c, then u_i has $6 > |N(u_i)|/2$ edges to nodes of color c. Therefore, the node does not change its color any more after time step 3. That is, we have $a(u_i) = 3$ and also $f_{t'}(u_i) = c$ for any consecutive time step $t' \geq 3$. If, however, x_j and $\overline{x}_j$ do not have the same color, these edge *cancel* each other out and the color of node u_i is determined by u_{i-1}, u_{i+1}, and K_{white}. Therefore, the same argument as in the first case holds. ◀

In the following we examine the behavior of layer 3 which contains only the AND-gate. Recall that u_0 is the output node of the AND-gate. The next lemma describes the following fact. The AND-gate u_0 can only change its color in a time step $t \geq 4$ if u_1 changed its color in time step $t - 1$. After this change at time t, the node u_0 cannot change its color again.

▶ **Lemma 15.** *Let f_0 be an arbitrary but fixed initial opinion assignment and let furthermore t be the round after node u_1 has been activated such that $t = a(u_1) + 1$. For all consecutive rounds $t' \geq t$ we have $f_{t'}(u_0) = f_t(u_0)$. That is, the* AND*-gate does not change its opinion any more once the node u_1 has become stable.*

The following lemma implies that in order to reach a convergence time of $h + 1$ the gates on the path $u_0, \ldots, u_\kappa$ in G' have to activate one after the other starting with u_0 at time 4. Recall that $\kappa = 4 \cdot n$.

▶ **Lemma 16.** *Let f_0 be an arbitrary but fixed initial opinion assignment and let $u_i \in G'$ be a node with $0 \le i \le \kappa$. If $a(u_i) < i + 4$ w.r.t. f_0, then $\mathfrak{T}(G(\Phi), f_0) < h + 1$.*

In the following two lemmas, we enforce that initial opinion assignments which do not represent valid assignments of Boolean values to literal cliques result in premature termination of the deterministic binary majority process in $G(\Phi)$. An assignment is called *illegal* if there exist literal cliques such that the majority of x_i and the majority of $\overline{x}_i$ have the same initial color.

▶ **Lemma 17.** *For any illegal initial opinion assignment f_I to $G(\Phi)$, the convergence time $\mathfrak{T}(G(\Phi), f_I)$ is strictly less than $h + 1$.*

▶ **Lemma 18.** *If after two time steps K_{white} and K_{black} have the same color, the process stops after strictly fewer steps than $h + 1$.*

From above lemmas we conclude that Theorem 10 holds, and together with Theorem 9, Theorem 10 yields Theorem 5. The full proofs can be found in [26].

Proof of Theorem 5. It is easy to see that VTDP is in NP. Furthermore, we can polynomially reduce 3SAT to VTDP. The correctness proof of the reduction follows from Theorem 9 and Theorem 10. Therefore we conclude that VTDP is NP-complete. ◀

3 Bounds on the Voting Time

Since the problem is NP hard, we cannot hope to calculate the voting time of a graph efficiently. Nevertheless, in this section we show, that it is possible to obtain non-trivial upper bounds on the voting time that are easy to compute. This section is dedicated to proving our upper bound on the voting time, Theorem 8. The main contribution of this theorem is the influence of symmetry which is studied in Section 3.2.

We start by giving a formal version of the potential function argument [20, 36] as conceived in [42]. In the following we assume that each edge in $\{x, y\} \in E$ can be replaced by two directed edges (x, y) and (y, x). The main idea is based on so-called *bad arrows* defined as follows.

▶ **Definition 19.** Let $G = (V, E)$ be a graph with initial opinion assignment f_0. Let v denote an arbitrary but fixed node and $u \in N(v)$ a neighbor of v. Let t denote an arbitrary but fixed round. The directed edge (v, u) is called *bad arrow* if and only if the opinion of u in round $t + 1$ differs from the opinion of v in round t. We will also denote the bad arrows which have their tail at round $t = 0$ as *initial bad arrows.*

Intuitively, each of these directed edges (v, u) can be seen as *advice* given from v to u in the voting process. In the case of a bad arrow the advice was not followed by u since it has a different opinion in the following round than v. Observe that each bad arrow is incident at exactly two nodes and thus we say it is *outgoing* in the node at its tail and incoming in the node at its head. An example of such a bad arrow can be seen in Figure 4.

▶ **Theorem 20.** *Let $G = (V, E)$ be a graph which contains only vertices of odd degree. The voting time of the deterministic binary majority process on G is at most $1 + W_{bad}$ where W_{bad} is an upper bound on the number of initial bad arrows for any initial opinion assignment on G. In particular, the voting time of G is at most $2 \cdot |E| + 1$.*

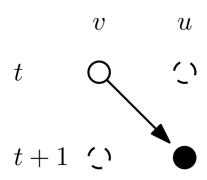

Figure 4 A *bad arrow* from node v to node u in round t.

The idea of the proof is to define a potential function ϕ_t that is strictly monotonically decreasing over the time. Let f_0 be any initial opinion assignment. The potential function ϕ_t is simply the number of bad arrows defined in Theorem 19, that is

$$\phi_t = \phi_t(G, f_t) = |\{(v, u) \in E : f_{t+1}(u) \neq f_t(v)\}| \quad .$$

For the full proof, see [26]. Note that in Theorem 20 it is assumed that all nodes of the graph have odd-degree. In the following we show how to remove this assumption.

▶ **Definition 21.** Let $G = (V, E)$ be a graph. The graph $G^* = (V, E^*)$ is the graph obtained by adding a self loop to every node of even degree in G. More formally,

$$E^* = E \ \cup \bigcup_{v \in V_{\text{even}}} (v, v) \quad .$$

From the definition it follows that $|E^*| = |E| + |V_{\text{even}}|$.

▶ **Theorem 22.** *The voting time of the deterministic binary majority process on any graph $G = (V, E)$ is at most $1 + W_{bad}$, where W_{bad} is an upper bound on the number of initial bad arrows in G^*.*

The proof is based on the fact that for every node $v \in V$ the sequence of opinions, $(f_t(v))$, is exactly the same for the deterministic binary majority process in G as for the deterministic binary majority process in G^*. For the full proof, see [26].

Observe, that while the number of bad arrows is used in the potential function, the convergence time is, however, not monotone w.r.t. the number of initial bad arrows.

▶ **Lemma 23.** *The convergence time is not monotone w.r.t. the number of initial bad arrows.*

The upper bound on the voting time considered in [27] follows from the $2 \cdot |E|$ upper bound on the number of bad arrows of Theorem 20. Clearly, this result can be improved by a factor of 2 by simply applying the observation that the number of initial bad arrows in G^* is at most $|E| - |V_{odd}|/2$. Therefore, from Theorem 22 we obtain the following corollary.

▶ **Corollary 24.** *The voting time of the deterministic binary majority process on any graph $G = (V, E)$ is at most $1 + |E| - |V_{odd}|/2$.*

▶ Remark. Theorem 24 is tight for general graphs up to an additive constant of 1. Indeed, consider a path with an initial opinion assignment on which the opinions alternate except for the last two nodes, which share the same opinion.

Suppose that, instead of specifying the initial opinion assignment, we decide in advance what bad arrows are there. We can do that by deciding for each ordered pair (u, v) for which $\{u, v\} \in E$ whether we want to have a bad arrow going from u to v. We formalize this notion by means of the following definitions.

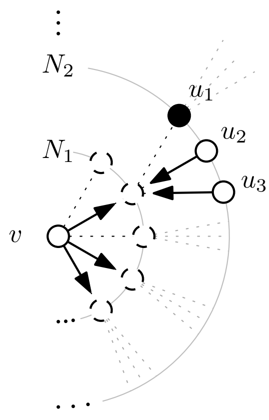

Figure 5 The opinions of each second neighborhood are uniquely determined.

▶ **Definition 25.** Let $G = (V, E)$ be a graph and $\beta : V \times V \to \{0, 1\}$ denote a characteristic function on $V \times V$. Then β is a bad arrows assignment on G if there exists an opinion assignment f on G that determines β such that β is the indicator function of the bad arrows we have on G w.r.t. the opinion assignment f.

In proving upper bounds on the voting time we consider the bad arrows assignment determined by the initial opinion assignment. One may wonder whether in doing so we are *losing information*. In the following lemma we show that, given a valid bad arrows assignment, we can reconstruct the initial opinion assignment up to exchanging black and white (and up to two more possibilities in bipartite graphs).

▶ **Lemma 26.** *Let G be a connected graph and let β be a valid bad arrows assignment on G. If the graph is not bipartite, there are exactly two opinion assignments, otherwise there are exactly four opinion assignments that determine β.*

Proof. Let $v \in V$ denote an arbitrary but fixed vertex. We now denote the set $\{v\}$ as N_0 and the set of direct neighbors of v as N_1 to define the i-th neighborhood N_i for $i \geq 2$ as

$$N_i = \left(\bigcup_{u \in N_{i-1}} N(u) \right) \setminus \left(\bigcup_{j=1}^{i-1} N_j \right) .$$

We now show by an induction on $k = 0, 1, 2, \ldots$ that the colors of all nodes in $N_{2 \cdot k}$ are determined by the color of v. The base-case is trivial since for $k = 0$ we have $N_0 = \{v\}$. For the induction step we observe that according to the induction hypothesis the color of each node in $N_{2 \cdot k}$ is determined. We now observe that the color at time 1 of each node in $N_{2 \cdot k+1}$ is determined by β and the colors at time 0 of the nodes in $N_{2 \cdot k}$. Vice versa, also the colors at time 0 of nodes in $N_{2 \cdot (k+1)}$ are determined by β and the colors at time 1 of each node in $N_{2 \cdot k+1}$. This concludes the induction.

An example is shown in Figure 5. In this figure it is clear that v and, e.g., u_1 must have a different color, for the following reason. Since u_1 does not have a bad arrow to its neighbor in N_1, it has the same color in the next round as this neighbor. But this neighbor's color in the next round is different to the current color of v because of the bad arrow assignment.

Observe that from above induction the lemma follows immediately for bipartite graphs. We can fix the colors for two arbitrary nodes, one from each of the two sets of non-adjacent nodes, to determine all other nodes' colors. This gives us four possible opinion assignments for a given bad arrow assignment β. If the graph is not bipartite there must exist a cycle of odd length. The opinion assignments for all nodes of this cycle are determined by β with the same argument as in above induction. Therefore, not only the colors of even neighborhoods N_{2k} are determined, but also of odd neighborhoods N_{2k+1}. This leaves us with exactly two possible initial opinion assignments, which concludes the proof. ◀

3.1 Improved Bounds for Dense Graphs

We observe that Theorem 24 is (almost) tight, and it gives us a voting time linear in the number of vertices for sparse graphs where $|E| = \mathrm{O}(|V|)$. However, for dense graphs with, e.g., $|E| = \Omega\left(|V|^2\right)$ there is room for improvement. Now the main goal in this following subsection is to reduce the dominant term of the voting time even further, which leads us to the following theorem which is formally shown in [26].

▶ **Theorem 27.** *Let $G = (V, E)$ be a graph. For any initial opinion assignment f_0 on G, the convergence time of the deterministic binary majority process is at most $1 + \frac{|E|}{2} + \frac{|V_{\text{even}}|}{4} + \frac{7}{4} \cdot |V|$.*

▶ Remark. One might intuitively assume that the voting time is bounded by the diameter of the network. However, this is not true, at least straightforwardly, as there exist graphs G where the convergence time w.r.t. a given initial opinion assignments f_0 is asymptotically larger than the diameter of the network, that is, $\mathfrak{T}(G, f_0) \gg \operatorname{diam}(G)$.

3.2 The Influence of Symmetry

We observe that the majority process is much faster on graphs that exhibit certain types of symmetry, such as the star graph, the complete graph and many other graphs in which several nodes share a common neighborhood. We investigate this feature of the process to further improve the bounds obtained so far. We recall that a set of nodes S is called a *family* if and only if for all nodes $u, v \in S$ we have $N(u) \setminus \{v\} = N(v) \setminus \{u\}$. The key fact is that these nodes of any family will behave in a similar way after the first step.

▶ **Definition 28.** Let $\operatorname{fam}(u)$ denote the family of u. We write $u \sim v$ if $\operatorname{fam}(u) = \operatorname{fam}(v)$.

▶ **Lemma 29.** *The relation $\sim$ defines an equivalence class. In particular, all nodes in the same family either form a clique or a stable set, and they all have the same degree in G.*

▶ **Corollary 30.** *For any graph G, its asymmetric graph G^{Δ} is well-defined.*

Proof. According to Theorem 29, the set of families is a partition of the nodes of G. By construction of G^{Δ}, every family S in G is replaced by one or two nodes in G^{Δ}. Therefore, there is a bijection between the families in G and the corresponding node or pair of nodes in G^{Δ}. Hence G^{Δ} is well-defined. ◀

We are now ready to prove Theorem 8.

▶ Remark. While we show that for the voting time we have $\max_f \mathfrak{T}(G^{\Delta}, f) \geq \max_f \mathfrak{T}(G, f)$, in general it is not the case that $\mathfrak{T}(G^{\Delta}, f) \geq \mathfrak{T}(G, f)$ for every opinion assignment f. A formal statement along with a counterexample is given in [26].

Proof of Theorem 8. Let v and v' be two nodes of the same family $\operatorname{fam}(v) = \operatorname{fam}(v')$, having the same color at time t. Since v and v' observe the same opinions in their respective neighborhood, v and v' will also have the same color anytime after t. It follows that if at some time t there is a bad arrow going from v to some neighbor u (or from u to v), then there will also be a bad arrow from v' to u (or from u to v'). In particular, this implies that whenever the number of bad arrows adjacent to v is decreased by some amount c, also the identical number of bad arrows adjacent to v' will be decrease by the same amount c.

Recall the proofs of Theorem 24 and Theorem 27. An estimate of the voting time is obtained by upper bounding the number of bad arrows that can possibly disappear during the process. The main argument is the following. It suffices to only consider the bad-arrows adjacent to v in $G^{\triangle}$, since the corresponding bad arrows adjacent to v' will disappear whenever those adjacent to v do.

Let v and v' be two nodes with $\text{fam}(v) = \text{fam}(v')$ having a different color at time t. We can divide every such family that contains nodes of different opinions into two sets S_0 and S_1 according to their initial opinion in the first round. Note that all nodes in either set behave identically. In particular, an adjacent bad arrow from a node u to all nodes of either set disappears at the same time. Since there is bijection between the families of G and the pairs of nodes and singletons of $G^{\triangle}$, and by applying Theorem 24 and Theorem 27 we can bound the voting time by bounding the bad arrows in $G^{\triangle}$. This yields the first part of the claim. Using [11], one can obtain the modular decomposition of G in $\mathrm{O}(|E|)$ time steps. In another $\mathrm{O}(|E|)$ time steps one can select from the modular decomposition those modules that form a family, using that all nodes of a family have the same degree. Hence, $G^{\triangle}$ can be constructed in linear time. ◀

Abstract

We present space-efficient algorithms for computing cut vertices in a given graph with n vertices and m edges in linear time using $O(n + \min\{m, n \log\log n\})$ bits. With the same time and using $O(n + m)$ bits, we can compute the biconnected components of a graph. We use this result to show an algorithm for the recognition of (maximal) outerplanar graphs in $O(n \log\log n)$ time using $O(n)$ bits.

1 Introduction

Nowadays the use of small mobile devices like tablets and smartphones is ubiquitous. Typically they will not be equipped with large memory and common actions like storing (many) pictures may even decrease the available memory significantly. This triggers the interest in data structures and algorithms being space-efficient. (Time) Efficient algorithms are a classical subject in computer science. The corresponding algorithms course is often based on the textbook of Cormen et al. [8]. There is also a long tradition in the development of algorithms that use as few bits as possible; famous results are the two results of Savitch [19] and Reingold [18] on reachability in directed and undirected graphs, respectively. However, the running times of their algorithms are far away from the fastest algorithms for that problem and are therefore of small practical interest. Moreover, Edmonds et al. [10] have shown in the so-called NNJAG model that only a slightly sublinear working-space bound is possible for an algorithm that solves the reachability problem when required to run in polynomial time. This motivates the recent interest in *space-efficient algorithms*, i.e., algorithms that use as few working space as possible under the condition that their running time (almost) matches the running time of the best algorithm(s) without any space restrictions.

A useful model of computation for the development of algorithms in that context is the word RAM with a read-only input, a read-write working memory, and a write-only output. As usual, we assume that for a given instances of size n, the word size is $\Omega(\log n)$. One of the first problems considered for space-efficient algorithms is sorting [16], which was finally solved to optimality [5, 17]. Other researchers considered problems in geometry [1, 3, 4].

Recent research started to focus on space-efficient graph algorithms [2, 11]. However, there is still only a very short list of problems with space-efficient graph algorithms: depth-first search, breadth-first search, (strongly) connected components, topological sorting, shortest path.

We continue this work on space-efficient graph algorithms and consider the basic problems to compute the cut vertices and to decompose a given undirected graph into its biconnected components. Tarjan's linear time algorithm [20] solving this problem has been implemented in almost any usual programming language. However the algorithm requires $\Omega(n \log n)$ bits on n-vertex graphs. The idea of our algorithm is to classify the edges via a DFS as tree and back edges and to mark those tree edges that build a cycle with a back edge. The marking allows us subsequently to determine the cut vertices and the biconnected components. Given a graph with n vertices and m edges, the whole algorithm runs in $O(n+m)$ time using $O(n + \min\{m, n \log\log n\})$ bits, which is $O(n)$ in sparse graphs. Due to the lower bound of Edmonds et al. [10], there is not much hope for an algorithm that uses $o(n)$ bits.

Finally we study the recognition of outerplanar graphs, i.e., those graphs having a planar embedding with all vertices on the outer face. The problem has been studied in various settings and linear time algorithms have been given, e.g., by Mitchell [15] and Wiegers [21]. However, both algorithms modify the given graph by removing vertices of degree 2, which is not possible in our model. An easy solution would be to copy the given graph in the working memory, but this requires $\Omega(n \log n)$ bits for a graph with n vertices. Another problem is that if the neighbors of a removed vertex are not adjacent, then both algorithms above want to add a new edge connecting the neighbors. Storing all these new edges also can require $\Omega(n \log n)$ bits. Our algorithm runs in time $O(n \log\log n)$ and uses $O(n)$ bits, and determines if the input graph is outerplanar, as well as if it is maximal outerplanar. To obtain our algorithm, we can not simply remove vertices of degree 2. With each removed vertex v we have to remove the so-called chain of vertices of degree 2 that contains v and we have to choose the chains carefully such that we have only very few new edges at a time in our graph.

2 Preliminary

For graph-theoretic notions not defined in the paper we refer to the monograph of Diestel [9]. For basic notions in construction and analysis of algorithms and a large collection of fundamental algorithms like, e.g., depth-first search (DFS) we refer to the textbook of Cormen et al. [8]. To develop space-efficient algorithms, the details of the representation of an input graph are more important than in the classic setting because it is rarely possible to modify and store a given representation. We use the terminology of [11]. In particular, if we say that a graph is represented via *adjacency arrays*, then we assume that, given a vertex u and an index i, we can determine the ith edge $\{u, v\}$ of u in constant time. Moreover, *cross pointers* allow us to determine the index of $\{u, v\}$ in the adjacency array of v in constant time. As usual, we always assume that an n-vertex graph has vertices $V = \{1, \ldots, n\}$.

Our algorithms make use of *rank-select data structures*. A rank-select data structure is initialized on a bit sequence $B = (b_1, \ldots, b_n)$ and then supports the following two queries.
$\boldsymbol{rank_B(j)}$ $(j \in \{0, \ldots, n\})$: Return $\sum_{i=1}^{j} b_i$
$\boldsymbol{select_B(k)}$ $(k \in \{1, \ldots, \sum_{i=1}^{n} b_i\})$: Return the smallest $j \in \{1, \ldots, n\}$ with $rank_B(j) = k$.
Rank-select data structures for bit sequences of length n that support rank and select queries in constant time and occupy $O(n)$ bits can be constructed in $O(n)$ time [7].

Assume that $d_1, \ldots, d_n \in \mathbb{N}_0$ and that it is desired to allocate n bit strings $A_1, \ldots, A_n$ such that, for $k = 1, \ldots, n$, A_k consists of d_k bits and (the beginning of) A_k can be located in constant time. Take $N = \sum_{j=1}^{n} d_j$. We say that $A_1, \ldots, A_n$ are stored with *static space allocation* if we allocate $A_1, \ldots, A_n$ within an array of size N. In $O(n+N)$ time, we can compute the sums $s_k = k + \sum_{j=1}^{k-1} d_j$ for $k = 1, \ldots, n$ and a rank-select data structure for the bit vector B of size $n+N$ whose ith bit, for $i = 1, \ldots, n+N$, is 1 exactly if $i = s_k$ for some $k \in \{1, \ldots, n\}$. This allows us, given a $k \in \{1, \ldots, n\}$ to compute the number of bits used by the arrays $A_1, \ldots, A_{k-1}$ and thus the location of A_k in constant time by evaluating $select_B(k) - k$. One application of static space allocation—as already shown by [13]—is to store data for each vertex v consisting of $O(\deg(v))$ bits where $\deg(v)$ is the degree of v. Given a vertex, we then can locate its data in constant time and the whole data can be stored with $O(n+m)$ bits.

To maintain subsets of vertices or of edge indices we use a data structure by Hagerup and Kammer [12, Lemma 4.4] that is called a choice dictionary.

▶ **Theorem 1.** *Let $n \in I\!N$. A choice dictionary is a data structure that maintains an initially empty subset S of $\{1, \ldots, n\}$ under insertion, deletion, membership queries, and an operation called choice that returns an arbitrary element of S. The data structure can be initialized in $O(1)$ time using $O(n)$ bits of working space and supports each of its operations in constant time. The choice dictionary can also be extended by an operation called iteration that returns all elements in S in a time linear in $|S|$.*

We also use a simplified version of the ragged dictionary that was introduced by of Elmasry et al. [11, Lemma 2.1] and named in [12]. Missing proofs can be found in [14].

▶ **Theorem 2.** *For every fixed $n \in I\!N = \{1, 2, \ldots\}$ as well as integers $b = O(\log n)$ and $\kappa = O(n/\log n)$, there is a dictionary that can store a subset A of $\{1, \ldots, n\}$ with $|A| \leq \kappa$, each $a \in A$ with a string h_a of satellite data of b bits, in $O(n)$ bits such that the following operations all run in $O(\log \log n)$ time: h_a can be inspected for each $a \in A$ and elements with their satellite data can be inserted in and deleted from A.*

3 Cut Vertices

A *cut vertex* of a connected undirected graph G is a vertex v such that $G - v$ is disconnected. Furthermore a graph is *biconnected* if it is connected and does not have a cut vertex. We first show how to compute cut vertices in $O(n+m)$ time using $O(n+m)$ bits on an undirected graph $G = (V, E)$ with $n = |V|$ and $m = |E|$. Afterwards, we present a second algorithm that has the same running time and uses $O(n \log \log n)$ bits.

We start with the description of an algorithm, but for the time being, do not care on the running time and the amount of working space. Using a single DFS we are able to classify all edges as either tree edges or back edges. During the execution of a DFS we call a vertex white if it has not been reached by the DFS, gray if the DFS has reached the vertex, but has not yet retracted from it and black if the DFS has retracted from the vertex. W.l.o.g., we assume that all our DFS runs are deterministic such that every DFS run explores the edges of G in the same order. Let T denote the *DFS tree* of G, i.e., the subgraph of G consisting only of tree edges, which we always assume to be rooted at the start vertex of the DFS. We call a tree edge $\{u, v\}$ of T with u being the parent of v *full marked* if there is a back edge from a descendant of v to a strict ancestor of u, *half marked* if it is not full marked and there exists a back edge from a descendant of v to u, and *unmarked*, otherwise. Then one can easily prove the next lemma.

▶ **Lemma 3.** *Let T denote a DFS tree of a graph G with root r, then the following holds:*
1. *Every vertex $u \neq r$ is a cut vertex of G exactly if at least one of the edges from u to one of its children is either an unmarked edge or a half marked edge.*
2. *The vertex r is a cut vertex of G exactly if it has at least two children in T.*

Since we want to use the lemma above, we have to mark the tree edges as full marked, half marked or unmarked. Therefore, we run two DFS. In the first run, we classify all tree edges, which we initially unmark. During the second, whenever we discover a back edge $\{w, u\}$ with w being a descendant of u, it becomes evident that both u and w belong to the same biconnected component as do all vertices that are both, descendants of u and ancestors of w, since they induce a cycle C. Let v be the ancestor of w that is child of u. We mark the edge from u to v as half marked and all the other tree edges on C as full marked. If the edge $\{u, v\}$ has already been full marked in a previous step, this will not be overwritten. Note that if $\{u, v\}$ is half marked and u has a back edge to one of its ancestors such that the edge connecting u to its parent p becomes full marked, v and p do not belong to the same biconnected component, but u belongs to both, the biconnected component containing v and the biconnected component containing p. The notion to distinguish between half marked and full marked is to indicate this gap between biconnected components.

After the second DFS each cut vertex can be determined by the edge markings of the tree edges connecting it to its children. For a space-efficient implementation, the first DFS can be taken from [11]. The second one with making the markings is described in the next sections and depends on the used working space.

3.1 Cut Vertices with $O(n + m)$ bits

We use static space allocation to address $O(\deg(v))$ bits for each vertex v of degree $\deg(v)$. Within these bits, we store for every edge $\{u, v\}$ adjacent to v if (1) it is a tree or back edge, (2) u or v is closer to the root of the DFS tree, and (3) its markings in case it is a tree edge. Additionally, using $O(\log deg(v))$ bits, when a vertex v is encountered by the DFS for the first time, we store the position of the tree edge $\{u, v\}$ in the adjacency array of v, where u denotes the parent of v in the DFS tree. This information can later be used, when the DFS retreats from v, such that we can perform the DFS without explicitly having to store the DFS stack. (This idea to obtain a DFS in $O(n + m)$ time using $O(n + m)$ bits was already described by Hagerup et al. [13].) To bound the time of marking the tree edges during the second DFS by $O(n+m)$, we perform the following steps. Whenever we encounter a vertex u for the first time during the second DFS via a tree edge, we scan its entire adjacency array for back edges that lead to descendants w of u. For each such back edge $\{u, w\}$, we perform the following substep. As long as there is a tree edge from w to its parent $v \neq u$ that is not full marked, we mark $\{v, w\}$ as full marked and continue with v becoming the new w. If we encounter an edge $\{v, w\}$ that is already marked as full marked, we terminate the substep without marking any more edges. If at some point the parent v of w becomes u, we mark $\{v, w\}$ as half marked if it has not been full marked, yet, and terminate the substep thereafter.

It is easy to see that this procedure results in the correct markings for every edge. The order in which back edges are worked on assures whenever a tree edge $\{v, w\}$ is already full marked so are all tree edges between v and the child of u. Because we store, for each vertex, the position of the edge that connects it with its parent in T, the time of each substep is at most the number of tree edges that are marked plus additional constant time. Since each tree edge is marked at most twice, once as half marked and once as full marked, and the number of back edges is at most m, altogether we use $O(m)$ time.

3.2 Cut Vertices with $O(n \log \log n)$ bits

The key ideas to make the algorithm more space-efficient are to perform the classification of edges as tree edges or back edges on the fly whenever an edge is explored by the DFS, to use a second stack $\mathcal{U}$, and to apply the stack restoration technique by Elmasry et al. [11] to both stacks. We thus reconsider that paper. To obtain a DFS with a linear running time using $O(n \log \log n)$ bits, the stack is partitioned into $O(\log n)$ segments of $\Theta(n/\log n)$ entries, each consisting basically of a vertex. During the DFS, only the $O(1)$ latest segments are kept in the working memory; the remaining are thrown away. Whenever a segment that was thrown away is needed, a restoration recovers it in a time linear in the number of vertices of the segment. To restore a segment in a time linear to its size, the vertices of the ith segment have a *hue* (value) i. For a slight modification of that algorithm, one can easily see that it is not important that the segments consist of $\Omega(n/\log n)$ vertices stored in the stack, as long as their number is bounded by $O(\log n)$ and the vertices with the same hue form a connected subsequence of the sequence of elements in the stack. Therefore, we build segments not based on the entries of the stack; instead, we define the first $\Theta(n/\log n)$ vertices that are visited by the DFS as the first segment, the next $\Theta(n/\log n)$ vertices as the next segment, etc. The hue values are determined via an extra DFS at the beginning. They are stored in addition to the colors white, gray and black that are used during a "standard" DFS. The space consumption of the algorithm sums up to $O(n)$ for the segments plus $O(n \log \log n)$ bits for the hue.

A normal DFS stack $\mathcal{S}$ contains at any moment during the execution of a DFS the vertices on the path within T from its root to the vertex that is currently explored, which are all the vertices that are currently gray. The depth dp_w of a vertex w is the number of edges connecting the vertices on the path from w to the root r of T that consists solely of tree edges. The second stack $\mathcal{U}$ contains those gray vertices u that have a gray child v such that $e_u = \{u, v\}$ is not full marked. Hence, the vertices in $\mathcal{U}$ denote a subset of the vertices in $\mathcal{S}$. More exactly, each entry of $\mathcal{U}$ is a tuple of a vertex u and its depth within T. When v is explored, v is pushed onto $\mathcal{S}$ and its parent u (together with its depth) is pushed onto $\mathcal{U}$. When the DFS retreats from v, it is popped from $\mathcal{S}$ and u is popped from $\mathcal{U}$ if it is still present in $\mathcal{U}$. A second way for u to be removed from $\mathcal{U}$ is when the edge e_u becomes full marked.

Let w denote the vertex at the top of $\mathcal{S}$. Whenever the DFS tries to explore a vertex u that is gray, then $\{w, u\}$ is a back edge. Under the assumption that we know the depth of every vertex, we can mark edges as follows: While there is a vertex u' on the top of $\mathcal{U}$ whose depth is higher than dp_u, we full mark the edge $e_{u'} = \{u', v'\}$ that connects u' with its gray child v' and pop u' from $\mathcal{U}$. This loop stops if either u becomes the vertex at the top of $\mathcal{U}$ or a vertex with a lower depth than u becomes the top vertex of $\mathcal{U}$. In the first case, we half mark e_u. In the second case, we do not mark the edge $\{u, v\}$ that connects u with its gray child v since u is not on $\mathcal{U}$ because the edge $\{u, v\}$ must have been full marked during the processing of a previous back edge.

We now discuss the computation of cut vertices. When retreating from a vertex v to its parent u that is not the root of T, we check if $\{u, v\}$ is half marked or unmarked. If that is the case, we output u as a cut vertex. For the root vertex r, we maintain a counter that indicates if at least two children of r have been explored during the DFS. If so, r is outputted. Using a bit vector over the vertices, we can avoid outputting a cut vertex more than once.

For the implementation of the algorithm, the remaining problems are maintaining both stacks $\mathcal{S}$ and $\mathcal{U}$ as well as determining the depth of u, whenever processing a back edge $\{w, u\}$ with u being the ancestor of w in the DFS tree T. For the first problem, we store for every vertex its hue and use the stack restoration techniques introduced by Elmasry et al. [11], but use it with the modified size as described above. Restorations of segments in $\mathcal{S}$ and $\mathcal{U}$ are performed independently of each other.

The second problem is more complicated and considered now. Let k be the hue of vertices that we currently process, and let Z be the set consisting of every hue $i \neq k$ that is present in $\mathcal{U}$. Our goal is to store the depth of all vertices in $\mathcal{U}$ with a hue in $\max(Z) \cup \{k\}$ such that it can be addressed by the vertex. The idea is to use one array A addressed with static space allocation to store the depth for all vertices in $\mathcal{U}$ of one segment, i.e., one hue. This allows us to build and destroy the arrays for each hue independently. However, the rank-select structure used by the static space allocation is to slow in its construction since we want a running time of $O(n/\log n)$. Therefore, we define *blocks* where block $i \in \{0, \ldots, \lceil n/\lceil(\log n)/2\rceil\rceil - 1\}$ consist of the vertices $1 + i\lceil(\log n)/2\rceil, \ldots, (i+1)\lceil(\log n)/2\rceil$—the last block may be smaller. In an auxiliary array B addressed with static space allocation, for each non-empty block b, we store a pointer to the first entry in A for a vertex in b. Within each block we use table lookup to find the exact position in A where the depth of a vertex is stored. This allows us to store the depth of the vertices in the upcoming segment in an array with static space allocation. We also restore the depth of the vertices of a segment in $\mathcal{U}$ whenever we restore it.

When processing a back edge $\{u, w\}$ (w having a hue k) with u being the ancestor of w and having a hue i there are two possibilities: If $i \in \max(Z) \cup \{k\}$, then the depth of $\mathcal{U}$ can be determined in constant time. Otherwise, $i < j = \max(Z)$ and, we iteratively restore those segments in $\{j-1, j-2, \ldots, i\}$ that have a vertex in $\mathcal{U}$ and process the vertices within these segments that are present in $\mathcal{U}$ as described above until we finally restore the segment of vertices with hue i together with their depth.

We summarize the space bound as follows. For every vertex we store in $O(n)$ bits its current color (white, gray, black), and if it yet has been outputted as a cut vertex. The set Z can be easily maintained with $O((\log n)^2)$ bits. Using $O(n \log\log n)$ bits we can store for every vertex its hue. We use additional $O(n)$ bits to store a constant number of stack segments of $O(n/\log n)$ vertices each. Since the depths of those vertices are stored compactly in arrays, each such array A together with its auxiliary array B can be implemented with $O(n)$ bits. Moreover, we use two bits for each vertex u on the stack to store if the edge connecting u and its child on the stack, if any, has been half or fully marked. Thus, the overall space bound is $O(n \log\log n)$ bits.

We finally determine the time bounds. As analyzed in [11], the DFS including the stack restorations of $\mathcal{S}$, but without the extra computations for the back edges runs in $O(n+m)$ time as do the intermediate computations in total. Assume for the moment, that we do not throw away and restore segments of $\mathcal{U}$. Then, the total time to mark the tree edges due to the back edges is $O(n+m')$ where m' is the number of back edges since each tree edge is marked at most twice using the stack $\mathcal{U}$. The tests if a vertex is a cut vertex can be performed in total time $O(m)$. It remains to bound the time for the restorations of $\mathcal{U}$. Whenever we restore a segment of $\mathcal{U}$, a hue value is removed from the set Z and never returns. This means that we have only $O(\log n)$ restorations of a segment of $\mathcal{U}$, which can be done in total time $O(n)$.

Combining the algorithms of Section 3.1 and this section, we obtain our first theorem.

▶ **Theorem 4.** *There is an algorithm that, given an n-vertex m-edge graph G in an adjacency array representation with cross pointers, runs in time $O(n+m)$ and uses $O(n + \min\{m, n\log\log n\})$ bits of working space, and determines the cut vertices of G.*

3.3 Biconnected Components

We next show that we can compute the biconnected components of an undirected graph. Recall that a graph is biconnected if it is connected and has no cut vertices. A biconnected component of a graph G is a maximal biconnected induced subgraph of G. Whenever we say in the following theorem and proof that we output an edge $\{x, y\}$, then we mean that we output the index of the edge in the adjacency array of both x and y.

▶ **Theorem 5.** *There is a data structure that, given an n-vertex m-edge graph G in an adjacency array representation with cross pointers, runs $O(n + m)$ initialization time and uses $O(n + m)$ bits of working space and that afterwards, given an edge e, computes the vertices and/or the edges of the biconnected component B of G with B containing e in a time that is linear in the number of vertices and edges that are output.*

Proof. To initialize the data structure, first run our algorithm from Section 3.1 to compute a DFS tree T with a root r, for each edge $\{u, v\}$ the ancestor-descendant relationship in T between u and v as well as the markings of the tree edges. Also store for each vertex $v \neq r$ the index of its edge connecting v to its parent. Then build a rank-select data structure for each vertex v that allows us to iterate over the fully marked tree edges and the back edges to ancestors of v in $O(1)$ time per edge. It is easy to see that the initialization runs in $O(n+m)$ time and all information can be stored with $O(n + m)$ bits using static-space allocation.

Afterwards, given an edge $e = \{u, v\}$ with u being an ancestor of v, we can output the biconnected component B containing e by running a DFS from v and traversing only tree edges (to both directions, parent and children) such that we never explore new vertices from a vertex that was reached by a half marked or unmarked edge and such that we never use a half marked or unmarked edge moving from a parent to its child via such an edge. During the DFS, we output all visited vertices as well as all traversed tree edges. Since a back edge $\{x, y\}$ with x ancestor of y always belongs to the same biconnected component as y, we output $\{x, y\}$ only if we visit y. In this case, we output the edge as an edge of y and, using cross pointers, also of x. The algorithm can easily be modified such that it only outputs the vertices/edges of the biconnected component. Using the rank-select data structures, this can be done in the time stated in the lemma.

To see that each outputted B is indeed a biconnected component observe that B is connected. Assume that B has a cut vertex v with a child u that cuts off the subtree T_u with root u, and we want to output the component containing the edge connecting v and its parent. In that case the edge $\{v, u\}$ is half marked or not marked. Hence, such an edge is not used to go from a parent to a child. On the other hand, if we want to output a component B for which a vertex v is a cut vertex disconnecting B and r, then the edge connecting v with the rest of B is half marked. Hence, we output v, but we do not visit other vertices. Finally, B is maximal by construction since all tree edges that are in B are fully marked except for the "highest" edge in T that is half marked; thus all vertices of B are found by the DFS. ◀

4 Outerplanar Graphs

Outerplanar graphs and maximal outerplanar graphs are well-studied subclasses of planar graphs. For their structural properties we refer to the monograph of Brandstädt et al. [6].

Given a biconnected outerplanar graph $G = (V, E)$, we call an edge that is incident to the outer face an *outer edge* and an edge that is incident to two inner faces an *inner edge*. We now describe a set of well-known properties for outerplanar graphs that help us to describe and prove our algorithm of Section 4.1. Every maximal outerplanar graph with at least three vertices is biconnected and, for every biconnected outerplanar graph G, the set of outer edges induce a unique Hamiltonian cycle that contains all vertices of G. Every biconnected outerplanar graph $G = (V, E)$ with $V = \{1, \dots, n\}$ and $|E| > n$ contains at least one inner edge. Let the vertices of G be labeled according to their position on the Hamiltonian cycle of G, by $1, \dots, n$, and let $\{u, v\}$ denote an inner edge that connects the vertices u and v. W.l.o.g., let $u < v$. Then the graph $G' = G[\{u, \dots, v\}]$ is biconnected and outerplanar. Since $\{u, v\}$ is an inner edge, $1 < v - u < n - 1$ holds and there are exactly $v - u - 1 > 0$ vertices between u and v on the path part of the Hamiltonian cycle that belongs to G'. This path together with the edge $\{v, u\}$ forms the Hamiltonian cycle of G'.

Usually, one decomposes an outerplanar graph by repeatedly removing a vertex v of degree 2. However, this needs to test if the neighbors of v are connected by an edge and, if not, to add such an edge. Because the test is too time consuming and storing all such edges needs too much space, we search instead for a closed or good chain defined next.

We define a *chain* in an outerplanar graph G as either a cycle that consists solely of vertices of degree 2 or a path that contains at least three pairwise distinct vertices with the property that its first and its last vertex have a degree larger than 2 while the rest must have degree 2. We denote the first and the last vertex of a chain as its *endpoints* unless the chain C is a cycle, in which case the endpoints can be chosen arbitrarily as long as they are adjacent to each other. Furthermore, we call a cycle a *loop* if it contains one vertex of degree larger than 2 and all other vertices have a degree 2. A chain is called a *good chain* if one of its endpoints has a degree of at most 4. Let us call a face F *induced* by a chain C if the endpoints u and v of C are adjacent to each other and C together with the edge $\{u, v\}$ is the boundary of F. We denote a chain C that induces a face F as a *closed chain*. For simplicity, we sometimes consider a chain also as a set of edges.

▶ **Lemma 6.** *Let $G = (\{1, \dots, n\}, E)$ denote a biconnected outerplanar graph with $n \geq 4$ vertices. Then G contains a good closed chain C.*

The next two lemmas are used to show the correctness of our algorithm.

▶ **Lemma 7.** *Let $G = (V, E)$ be a biconnected outerplanar graph, then the following properties hold:*

(i) *For every chain C in G with endpoints v_1 and v_2, the graph $G' := G[(E \setminus C) \cup \{\{v_1, v_2\}\}]$ induced by the edge set $(E \setminus C) \cup \{\{v_1, v_2\}\}$ is biconnected and outerplanar.*

(ii) *For all $v_1, v_2 \in V$, there are at most two internal vertex-disjoint paths with at least two edges each.*

Proof. To prove the first part note that G' is a minor of G. Thus, G' is outerplanar. For all vertices u_1, u_2 of G', there are two internal vertex-disjoint paths in G. Since C is a chain, it can only be a complete part of such a path and therefore replaced by the edge $\{v_1, v_2\}$. It follows there are two internal vertex-disjoint paths between u_1 and u_2 in G' and G' is biconnected. We prove the second part by contradiction. Assume that Prop. ii does not hold. Then $K_{2,3}$ is a minor of G. This is a contradiction to G being outerplanar. ◀

▶ **Lemma 8.** *Let $G = (V, E)$ be a graph for which the following properties hold.*

(1) *There is a chain C in G with endpoints v_1 and v_2 such that the graph $G' := G[(E \setminus C) \cup \{\{v_1, v_2\}\}]$ is biconnected and outerplanar.*

(2) *There are at most two internal vertex-disjoint paths with at least 2 edges each in G that connect v_1 and v_2.*

Then G is biconnected and outerplanar.

Proof. The existence of a chain follows from Lemma 6. G' is biconnected outerplanar because of Prop. 1. Because of Prop. 2 there is at most one internal vertex-disjoint path connecting v_1 and v_2 in $G[E \setminus C]$. Hence, the edge $\{v_1, v_2\}$ is part of the outer face of G'. It follows that we can embed C in the outer face of an embedding of G' to yield an outerplanar embedding of G. Because $\{v_1, v_2\}$ is part of the outer face of G', it is part of the Hamiltonian cycle of G'. We can extend the Hamiltonian cycle of G' by replacing $\{v_1, v_2\}$ with C to get a Hamiltonian cycle of G. Thus G is biconnected. ◀

4.1 Our Algorithm on Biconnected Outerplanar Graphs

For the time being, we assume that the given graph is biconnected. Our algorithm works in two phases and can be sketched as follows. Before our actual algorithm starts we test whether $m \leq 2n - 3$. If not, the graph is not outerplanar and we terminate immediately. Otherwise we start our algorithm that modifies the input graph into a smaller outerplanar graph as described in Lemma 8 Prop. 1 while checking Prop. 2 of Lemma 8. Lemma 7 guarantees that it does not matter which chain we take, the modification is always possible and that the check never fails unless G is not biconnected outerplanar. A main obstacle is to handle the edges replacing the chains that we call subsequently *artificial edges*.

To check Prop. 2 of Lemma 8, we keep in both phases counters P_e for every (original or artificial) edge e to count the number of internal vertex-disjoint paths with at least 2 edges that connect the endpoints of e. Whenever we remove a chain with both endpoints in e, we increment P_e. If P_e at any time exceeds 2, the graph can not be outerplanar by Lemma 7 (ii). We check this after every incrementation of an counter P_e and terminate eventually.

We start to sketch the two phases of our algorithm. The details of the phases are given subsequently. Let $G = (V, E)$ denote the input graph, which is located in read-only input space, and G' denote the subgraph of G that we are currently considering in our algorithm. Initially, $G' := G$. Thereafter, within our algorithm the edges of chains are either removed from G' if they induce a face or replaced by artificial edges that connect the endpoints of the chain directly. Consequently, G' is always a minor of G.

The purpose of the first phase is to limit the number of artificial edges that are required for the second phase to $O(n/\log n)$. The first phase consists of $\Theta(\log\log n)$ *rounds*, in each of which we iterate over all chains, but only remove the closed ones.

In the second phase, we repeatedly take a vertex of degree 2 and determine its chain. Depending on the kind of the chain, we proceed: Good closed chains are removed from G'. The edges of chains that turn out to be good, but not closed are replaced by an artificial edge connecting its endpoints. The counter of vertex-disjoint paths with the same endpoints $\{u, v\}$ for a newly created artificial edge $\{u, v\}$ is initialized with 1 to account for the chain that has been replaced by $\{u, v\}$. When processing a chain C that turns out to be not good, we implement a *shortcut* that is a pair of pointers, each one addressed by the vertex of degree 2 in C that is next to a endpoint of C and pointing to the vertex of degree 2 in C that is adjacent to the other endpoint. This way, when the degree of either one of the endpoints is lowered to 2 by the removal of adjacent chains and thus C becomes connected with an other chain, C does not have to be traversed again to check if the new chain is good.

If the input graph is outerplanar, the algorithm terminates either in Phase 1 or in Phase 2 as soon as the last good chain, which is a cycle, is processed and a single edge that is the edge between its endpoints remains. Otherwise, if the input graph is not outerplanar, at some moment one of the checks fails and the algorithm stops and answers that the input is not biconnected outerplanar. Possible conditions for a failed check are if no good chain remains and the graph has at least vertices, if the counter that counts the internal vertex-disjoint paths with at least 2 edges between the endpoints of an edge exceeds 2 for some edge, if some loop is detected, or if a vertex turns out to be incident to at least three vertices of degree 2.

To lower the time that is required to iterate through the adjacency array of a vertex v, we initialize, for each vertex $v \in V$ with degree $deg_G(v)$ in G, a choice dictionary with universe $\{1, \ldots, deg_G(v)\}$ that represents the edges that are adjacent to v and still present within the current subgraph. The choice dictionary contains i with $i \in \{1, \ldots, deg_G(v)\}$ exactly if the ith entry of the adjacency array of v represents an edge of the input graph G that is still present in the current graph G'. Thus, future iterations through the adjacency array of v can be performed within a time that is linear in the number of edges that are incident on v in G'. Hence, the time to determine the adjacency of two endpoints v and w of a chain is bound by $O(\min\{deg_{G'}(v), deg_{G'}(w)\})$.

Phase 1: At the beginning of each round we unmark all vertices and insert all vertices of degree 2 of the current graph G' into a choice dictionary D.

For a more detailed description we subdivide the $\Theta(\log \log n)$ rounds into stages. As long as there is a vertex u in D, we extract it from D and start a new stage. Let C denote the chain that u belongs to. A stage works as follows. If C contains a vertex that is marked as *tried* or C is not closed, the stage stops. Otherwise, we increment the counter P_e for every edge e on C as well as for the edge connecting its endpoints and remove the vertices and edges of C from the graph. If the current chain C is not the first chain processed in the current stage so far, we mark every vertex of degree 2 that has been processed within the current stage and still remains in the graph as *tried*. If one or both of the endpoints of C thereby become a vertex of degree 2, the procedure is repeated immediately for the new chain C' that incorporates both endpoints of C. The stage ends if no new chain is found. At the end of the stage we remove the vertices of degree 2 that have been processed within the current stage from D. A round ends if D is empty.

Phase 2: We start to initialize a choice dictionary D consisting of one vertex of degree 2 for each good closed chain. (During Phase 2, vertices of other chains may be added into D.) Take q as the initial number of vertices in D. As we prove in Corollary 11, the number of chains that induce a face is at most $O(n/\log n)$ after Phase 1 unless G is not outerplanar. If G' contains more such chains, we can terminate immediately. Otherwise, we can store a constant number of artificial edges and shortcuts for each such chain. Whenever we process a vertex u from D, we determine the chain C that u is part of, the endpoints v and w of C, and then distinguish three cases.

- If C is good and closed, we increment the counter P_e for every edge e that is part of C and for the edge that connects its endpoints. Finally, we remove the edges of C from G'.
- If C is good and not closed, we insert an artificial edge e_a that connects the endpoints of C, increment the counter P_e for every edge e in C by 1 and remove all the edges and inner vertices of C from G'. Finally, the counter P_{e_a} of e_a is initialized with 1.
- Otherwise, C is not good. We remove all vertices of C from D and insert a shortcut between the vertices of degree 2 in C that are adjacent to the endpoints of C. If there are old shortcuts connecting other inner vertices of C, they become obsolete and are removed.

Whenever the degree of v or w decreases, we perform the following subroutine. If $deg_{G'}(v) \in \{3, 4\}$, we insert all vertices u of degree 2 that are adjacent to v into D. Note that u and w are neighbors of v on the unique Hamiltonian Cycle of G'. Thus, if G is biconnected outerplanar, there is at most one such vertex u. If $deg_{G'}(v) = 2$, we insert v into D. We proceed with w analogously. We so guarantee that each good closed chain of G' has a vertex in D. As shown by Lemma 12, if the number of artificial edges and shortcuts that are simultaneously in use exceeds $2q$, G is not outerplanar and we stop.

Since the removal of chains is performed in accordance with Lemma 7 and Lemma 8, to show the correctness of the algorithm, it remains to verify that the checks on the counters P_e are correct and sufficient.

▶ **Lemma 9.** *The counter P_e counts for any edge $e = \{v_1, v_2\}$ that belongs at some moment during our algorithm to the current graph G' the number of internal vertex-disjoint paths with at least 2 edges between v_1 and v_2 that have been removed from G so far.*

By our counters P_e for all original and artificial edges, we count the number of internal vertex-disjoint paths between vertices that have been endpoints of a removed chain. Thus, our tests are sufficient by Lemma 8. By Lemma 7 (ii) the counting of the internal vertex-disjoint paths between the endpoints of other edges and terminating if one of these counters exceeds 2 is correct.

4.2 Space-Efficient Implementation and Space Bounds

Before any allocation of space is performed the first check of the algorithm is to verify that the number m of edges within the input graph G is at most $2n - 3$, where n denotes the number of vertices in G. From now on, we assume that $m = O(n)$. During Phase 1 we use a bit vector of n bits that allows us to mark vertices as *tried*.

The current graph G' is represented as follows. We use a choice dictionary of O(n) bits, where i is in the set represented by the choice dictionary exactly if the vertex i is still part of G'. In addition, for each vertex v of initial degree $deg_G(v)$, we store $\Theta(deg_G(v))$ bits. Within this space we use a choice dictionary C_v with universe $\{1, \ldots, deg_G(v)\}$ as already described above and a counter that maintains the current degree of v in G'. It follows that, ignoring artificial edges and shortcuts, a representation of the current graph G' with one choice dictionary for each vertex fits in $O(n)$ bits of working space.

We next want to bound the number of artificial edges and shortcuts. We start to bound the number of chains that induce a face after Phase 1. For this purpose, let us define the *dual tree* T_G of a biconnected and outerplanar graph G as the dual graph of G minus the vertex that represents the outer face of G. Since G is biconnected and outerplanar, T_G is a tree. The leaves of T_G correspond to those faces of G that are induced by chains. Thus, the removal of a closed chain C that induces a face F in G', which results in the merging of F with the outer face, corresponds to the removal of the leaf F in $T_{G'}$.

▶ **Lemma 10.** *If the input graph G with n vertices is biconnected outerplanar, then the number of chains that induce a face in the current graph G' after the tth round of Phase 1 is at most $n/2^t$.*

Proof. It is easy to see that the initial number of chains that induce a face before the first round is at most n. Recall that, in each stage of Phase 1, we consider a vertex u of degree 2 and test whether it is part of a closed chain C within our current graph G'. If so, we remove the chain C from G' and thereafter continue recursively on one endpoint v of C if the removal of C results in v becoming a vertex of degree 2. Let us analyze the modifications of the algorithm in the dual tree. Whenever we remove a chain, this means that we remove a leaf and then recursively try if its parent thereby has become a leaf and can be removed as well until a node of degree at least 2 is encountered.

Vertices of a chain C that is incident to a face F are marked as *tried* if F could not be merged with the outer face after a face that was incident to F has been successfully merged with the outer face by the removal of the chain that induced it. The removal of F fails only if F is not induced by C and there remain at least two faces in $T_{G'}$ that are incident on F. We conclude that F had degree at least 3 at the beginning of the current round. Since in every round leaves are removed until a node is encountered that had at the beginning of the round a degree of at least 3, the number of leaves is at least halved in every round. ◀

▶ **Corollary 11.** *If the input graph G with n vertices is biconnected outerplanar, the number of closed chains after Phase 1 in the current graph G' is $O(n/\log n)$.*

We next bound the number of artificial edges and shortcuts.

▶ **Lemma 12.** *The initial number q of chains at the beginning of Round 2 that have vertices in D only doubles during Phase 2, and the number of artificial edges and shortcuts that are simultaneously in use by the algorithm is $2q = O(n/\log n)$.*

Proof. By the corollary above, $q = O(n/\log n)$ at the beginning of Phase 2. One may consider these chains cutting the Hamilton cycle of G' into q parts. Since we add new vertices into D at the end of Phase 2 only if we were in Case 1 before, a new chain C' is always neighbored to an old chain C, which is then deleted from G' before a vertex of C' is added into D. Roughly speaking, the chains at the beginning of Phase 2 are fires that can spread to new chains on the left and on the right along the Hamilton cycle, but the fire can never return and ends immediately at the moment when a new chain starts to burn. It is easy to see that at most $2q$ chains are on fire. If we define that a chain that is processed with Case 2 or 3 is still on fire, then we have to store artificial edges or shortcuts only for chains that are on fire, and thus, their number is bounded by $2q = O(n/\log n)$. ◀

We can use a bit vector of $O(n)$ bits to store for every vertex v the information whether an artificial edge or shortcut exists at v or not. As a consequence of the last lemma, we can store all artificial edges as well as all shortcuts in a ragged dictionary and the total space bound of the algorithm is $O(n)$ bits.

▶ **Lemma 13.** *There is an algorithm that, given an n-vertex biconnected graph G in an adjacency array representation with cross pointers, runs in $O(n \log\log n)$ time and uses $O(n)$ bits of working space, and determines whether G is biconnected outerplanar.*

4.3 Algorithm for General Outerplanar Graphs

We next sketch the generalization of our recognition algorithm of biconnected outerplanar graphs to general outerplanar graphs. Since a graph is outerplanar exactly if all of its biconnected components are outerplanar, we can iterate over the biconnected components of a given graph G using our framework of Section 3.3—to avoid using $\Omega(m)$ time or bits if a non-outerplanar, dense graph is given, one should initially check that $m \leq 2n - 3$. For each biconnected component, we first stream all its vertices and build an initially empty choice dictionary C_v with $\deg_G(v)$ keys for each such vertex v, then stream the edges of the biconnected component and fill in the indices of each edge in the choice dictionaries of its endpoints. In addition, we compute and store for each vertex of the biconnected component its degree.

Recall that our subgraph G' is represented by a choice dictionary that contains those vertices of G that are still part of G' and a choice dictionary C_v for every vertex v such that $i \in \{1, \ldots, deg_G(v)\}$ is present in C_v exactly if the ith entry of the adjacency array of v contains an edge that is still present G'. We initialize these choice dictionaries with the values that are streamed from the algorithm that determines biconnected components to initialize a representation of a biconnected subgraph. The time to test if the subgraph is biconnected outerplanar is bound by the number of vertices and edges of the subgraph alone.

Finally note that a check if a outerplanar graph $G = (V, E)$ is maximal outerplanar can be easily performed by checking if $2|V| - 3 = |E|$.

▶ **Theorem 14.** *There is an algorithm that, given an n-vertex graph G in an adjacency array representation with cross pointers, runs in time $O(n \log\log n)$ and uses $O(n)$ bits of working space, and determines if G is (maximal) outerplanar.*

Abstract

We introduce the new measure of *Public Information Complexity* (PIC), as a tool for the study of multi-party computation protocols, and of quantities such as their communication complexity, or the amount of randomness they require in the context of information-theoretic private computations. We are able to use this measure directly in the natural asynchronous message-passing *peer-to-peer* model and show a number of interesting properties and applications of our new notion: the Public Information Complexity is a lower bound on the Communication Complexity and an upper bound on the Information Complexity; the difference between the Public Information Complexity and the Information Complexity provides a lower bound on the amount of randomness used in a protocol; any communication protocol can be compressed to its Public Information Cost; an explicit calculation of the zero-error Public Information Complexity of the k-party, n-bit Parity function, where a player outputs the bit-wise parity of the inputs. The latter result establishes that the amount of randomness needed for a private protocol that computes this function is $\Omega(n)$.

1 Introduction

Communication complexity, originally introduced by Yao [44], is a prolific field of research in theoretical computer science that yielded many important results in various fields. Informally, it answers the question "How many bits must the players transmit to solve a distributed problem ?" The study of the two-party case has produced a large number of interesting and important results, upper and lower bounds, with many applications in other areas in theoretical computer science such as circuit complexity, data structures, streaming algorithms and distributed computation (see, e.g., [35, 36, 24, 40, 23]).

‡ Research supported in part by ERC grant QCC and ANR grant RDAM.

A powerful tool recently introduced for the study of two-party communication protocols is the measure of *Information Complexity* (or *cost*). This measure, originally defined in [1] and [14], extends the notions of information theory, originally introduced by Shannon [42], to interactive settings. It quantifies, roughly speaking, the amount of information about their respective inputs that Alice and Bob must leak to each other in order to compute a given function f of their inputs. Information complexity (IC) has been used in a long series of papers to prove lower bounds on communication complexity and other properties of (two-party) communication protocols (e.g., [2, 3, 11, 6]). An interesting property of information complexity is that it satisfies a direct sum. The *direct sum* question, one of the most interesting questions in complexity theory, asks whether solving n independent copies of the same problem must cost (in a given measure) n times the cost of solving a single instance. In the case of communication complexity, this question has been studied in, e.g., [20, 14, 41, 31, 29, 3, 33, 30] and in many cases it remains open whether a direct sum property holds.

Another important question in communication complexity is the relation between the information complexity of a function and its communication complexity. We would like to know if is it possible to compute a function by sending a number of bits which is not (too much) more than the information the protocol actually has to reveal. Put differently, is it always possible to *compress* the communication cost of a protocol to its information cost? For the two-party case it is known that perfect compression is not possible [26, 27]. Still, several interesting compression results are known. The equality between information cost and amortized communication cost is shown in [11, 6], and other compression techniques are given in [3, 4, 12, 37]. It remains open if one can compress interactive communication up to some small loss (for example logarithmic in the size of the input).

When trying to study the *multi-party* (i.e., where at least 3 players are involved) communication setting using similar information-theoretic methods, such as IC, one encounters a serious problem. The celebrated results on information-theoretic private computation [5, 18] state that if the number of players is at least 3, then *any function* can be computed by a randomized protocol such that *no information* about the inputs is revealed to the other players (other than what is implied by the value of the function and their own input). Thus, in the multi-party case, the IC of any function f is 0 (or only the entropy of f, depending on the definition of IC), and cannot serve to study multi-party protocols.

For this reason, information complexity has rarely been used in the multi-party setting, where most results have been obtained via combinatorial techniques. Among the interesting works on multi-party setting are [38, 43] which introduce the techniques of *symmetrization* and *composition*, and [16, 17] which study the influence of the topology of the network. One notable exception is the work of Braverman et al. [7] which studies the *set-disjointness* problem using information theoretic tools. Braverman et al. provide almost tight bounds in the so-called coordinator model (that differs from the more natural peer-to-peer model) by analyzing the information leaked between the players but also the information obtained by the coordinator itself. The set disjointness problem is maybe one of the most extensively studied problem in communication complexity (cf. [6, 2, 13, 28, 32, 9]). This line of research was followed by [15] which also uses information complexity to obtain tight bounds on the communication complexity of the function *Tribes* in the coordinator model. Information complexity is also used in [10] to study set-disjointness in the broadcast model.

A number of sub-models have been considered in the literature for the multi-party computation protocols setting: the *number in hand model* (NIH), where each player has a private input, is maybe the most natural one, while in the *number on the forehead* model

(NOF), each player i knows all inputs x_j, $j \neq i$, i.e., the "inputs" of all players except its own. As to the communication pattern, a number of variants exist as well: in the *blackboard* model, the players communicate by broadcasting messages (or writing them on a "blackboard"); in the *message passing* model, each pair of players is given a private channel to mutually communicate (for more details on different variants see [35]). Most of the results obtained in multi-party communication complexity were obtained for the NOF model and/or the blackboard model. The present paper studies, however, the NIH, message passing (peer to peer) model, which is also the most closely related to the work done on message passing protocols in the distributed computing and networking communities.

1.1 Our contributions

Our main goal is to introduce novel information-theoretical measures for the study of number in hand, message-passing multi-party protocols, coupled with a natural model that, among other things, allows private protocols (which is not the case for, e.g., the coordinator model)

We define the new measure of *Public Information Complexity* (PIC), as a tool for the study of multi-party computation protocols, and of quantities such as their communication complexity, or the amount of randomness they require in the context of information-theoretic private computations. Intuitively, our new measure captures a combination of the amount of information about the inputs that the players leak to other players, and the amount of randomness that the protocol uses. By proving lower bounds on PIC for a given multi-party function f, we are able to give lower bounds on the communication complexity of f and on the amount of randomness needed to privately compute f. The crucial point is that the PIC of functions, in our multi-party model, is not always 0, unlike their IC.

Our new measure works in a model which is a slight restriction of the most general asynchronous model, where, for a given player at a given time, the set of players from which that player waits for a message can be determined by that player's own local view. This allows us to have the property that for any protocol, the information which is leaked during the execution of the protocol is at most the communication cost of the protocol. Note that in the multi-party case, the information cost of a protocol may be higher than its communication cost, because the identity of the player from which one receives a message might carry some information. This is another issue when trying to use IC in the peer-to-peer multi-party setting. We are able to define our measure and use it directly in a natural asynchronous *peer-to-peer* model (and not, e.g., in the coordinator model used in most works studying the multi-party case, c.f. [19]). The latter point is particularly important when one is interested in privacy, since our model allows for private protocols, while this is not necessarily the case for other models, including the coordinator model. Furthermore, if one seeks to accurately understand the natural peer-to-peer model, suppressing polylog-factor inaccuracies, one has to study directly the peer-to-peer model (see the comparison of models in subsection 2.1).

We go on to show a number of interesting properties and applications of our new notion:

- The Public Information Complexity is a lower bound on the Communication Complexity and an upper bound on the Information Complexity. In fact, it can be strictly larger than the Information Complexity.
- The difference between the Public Information Complexity and the Information Complexity provides a lower bound on the amount of randomness used in a protocol.
- We compress any communication protocol to their PIC (up to logarithmic factors), by extending to the multi-party setting the work of Brody et al. [12] and Pankratov [37].
- We show that one can approach the central question of direct sum in communication complexity by trying to prove a direct sum result for PIC. Indeed, we show that a direct sum property for PIC implies a certain direct sum property for communication complexity.

- We explicitly calculate the zero-error *Public Information Complexity* of the k-party, n-bit Parity function (Par), where a player outputs the bit-wise parity of the inputs. We show that the PIC of this function is $n(k-1)$. This result is tight and it also establishes that the amount of randomness needed for a private protocol that computes this function is $\Omega(n)$. While this sounds a reasonable assertion no previous proof for such claim existed.

The paper is organized as follows. In Section 2 we define the communication model and a number of traditional complexity measures. In Section 3 we define the new measure PIC that we introduce in the present paper, and in Section 4 we discuss its relation to randomness and multi-party private computation. In section 5 we discuss the existence of a direct sum property for PIC, and in Section 6 we give tight bounds for Par using PIC. We conclude the paper in Section 7. All proofs are deferred to the full version of the paper.

2 The model

We start by defining a number of notations. We denote by k the number of players. We often use n to denote the size (in bits) of the input to each player. Calligraphic letters will be used to denote sets. Upper case letters will be used to denote random variables, and given two random variables A and B, we will denote by AB the joint random variable (A, B). Given a string (of bits) s, $|s|$ denotes the length of s. Using parentheses we denote an ordered set (family) of items, e.g., (Y_i). Given a family (Y_i), Y_{-i} denotes the sub-family which is the family (Y_i) *without* the element Y_i. The letter X will usually denote the input to the players, and we thus use the shortened notation X for (X_i), *i.e.* the input to all players. π will be used to denote a protocol. We use the term *entropy* to talk about binary entropy.

We now define a natural communication model which is a slight restriction of the most general asynchronous peer-to-peer model. Its restriction is that for a given player at a given time, the set of players from which that player waits for a message can be determined by that player's own local view. This allows us to define information theoretical tools that pertain to the transcripts of the protocols, and at the same time to use these tools as lower bounds for communication complexity. This restriction however does not exclude the existence of private protocols, as other special cases of the general asynchronous model do. We observe that without such restriction the information revealed by the execution of a protocol might be higher than the number of bits transmitted and that, on the other hand, practically all multi-party protocols in the literature are implicitly defined in our model. We also compare our model to the general one and to other restricted ones and explain the usefulness and logic of our specific model.

2.1 Definition of the model

We work in the *multi-party number in hand peer-to-peer* model. Each player has unbounded local computation power and, in addition to its input X_i, has access to a source of private randomness R_i. We will use the notation R for (R_i), *i.e.*, the private randomness of all players. A source of public randomness R^p is also available to all players. The system consists of k players and a family of k functions $f = (f_i)_{i \in [\![1,k]\!]}$, with $\forall\ i \in [\![1,k]\!], f_i : \prod_{l=1}^{k} \mathcal{X}_l \to \mathcal{Y}_i$, where $\mathcal{X}_l$ denotes the set of possible inputs of player l, and $\mathcal{Y}_i$ denotes the set of possible outputs of player i. The players are given some input $x = (x_i) \in \prod_{i=1}^{k} \mathcal{X}_i$, and for every i, player i has to compute $f_i(x)$. Each player has a special write-only output tape.

We define the communication model as follows, which is the asynchronous setting, with some restrictions. To make the discussion simpler we assume a global time which is *unknown* to the players. Every pair of players is connected by a bidirectional communication link that allows them to send messages in both directions. There is no bound on the delivery time of a message, but every message is delivered in finite time, and the communication link maintains FIFO order in each of the two directions. Given a specific time we define the *view* of player i, denoted D_i, as the input of that player, X_i, its private randomness, R_i, and the messages received so far by player i. The protocol of each player i runs in *local* rounds. In each round, player i sends messages to some subset of the other players. The identity of these players, as well as the content of these messages, depend on the current view of player i. The player also decides whether to write a (nonempty) string on its output tape. Then, the player waits for messages from a certain subset of the other players, where this subset is also determined by the current view of the player. Then the (local) round of player i terminates[1]. To make it possible for the player to identify the arrival of the *complete* message that it waits for, we require that each message sent by a player in the protocol is self-delimiting.

Denote by D_i^j the view of player i at the end of local round j, $j \geq 0$, where the beginning of the protocol is considered round 0. Formally, a protocol π is defined by a sequence of functions for each player i, parametrized by the *local* round j, $j \geq 1$:

- $\overline{S_i^j} : D_i^{j-1} \to 2^{\{1,\ldots,k\}\setminus\{i\}}$, defining the set of players to which player i sends the messages.
- $m_{i,q}^j : D_i^{j-1} \to \{0,1\}^*$, for all $q \in \overline{S_i^j}(D_i^{j-1})$, defining the content of the messages player i sends. Each such message has to be self-delimiting.
- $O_i^j : D_i^{j-1} \to \{0,1\}^*$, defining what the player writes on the output tape. Each player can write on its output tape a non-empty string only once.[2]
- $S_i^j : D_i^{j-1} \to 2^{\{1,\ldots,k\}\setminus\{i\}}$, defining the set of players from which player i waits for a message.

We note that the model does not impose "coherence" between the players. That is, the model does not preclude the possibility that a certain player waits indefinitely for a message that is never sent to it.

We define the transcript of the protocol of player i, denoted Π_i, as the concatenation of the messages read by player i from the links of the sets $S_i^1, S_i^2, \ldots$, ordered by local round number, and within each round by, say, the index of the player. We denote by $\overleftrightarrow{\Pi}_i$ the concatenation of Π_i together with a similar concatenation of the messages sent by player i to the sets $\overline{S}_i^0, \overline{S}_i^1, \ldots$. We denote by $\Pi_{i \to j}$ the concatenation of the messages sent by player i to player j during the course of the protocol. The transcript of the (whole) protocol, denoted Π, is obtained by concatenating all the Π_i ordered by, say, player index.

We will give most of the definitions for the case where all functions f_i are the same function, that we denote by f. The definitions in the case of family of functions are similar.

▶ **Definition 1.** For $\epsilon \geq 0$, a protocol π *ϵ-computes* a function f if for all $x \in \prod_{i=1}^{k} \mathcal{X}_i$:

1. For all possible assignments for the random sources R_i, $1 \leq i \leq k$, and R^p, every player eventually (i.e., in finite time) writes on its output tape (a non-empty string).

[1] The fact that the receiving of the incoming messages comes as the last step of the (local) round comes only to emphasize that the sending of the messages and the writing on the output tape are a function of only the messages received in previous (local) rounds.

[2] We require that each player writes only once on its output tape so that the local view of the player determines the local output of the protocol (i.e., so that players itself "knows" the output). This requirement is needed since a player may not know locally that the protocol ended.

2. With probability at least $1 - \epsilon$ (over all random sources) the following event occurs: each player i writes on its output tape the value $f(x)$, i.e., the correct value of the function.

For simplicity we also assume that a protocol must eventually stop. That is, for all possible inputs and all possible assignments for the random sources, eventually (i.e., in finite time) there is no message in transit.

2.2 Comparison to other models

The somewhat restricted model (compared to the general asynchronous model) that we work with allows us to define a measure similar to information cost that we will later show to have desirable properties and to be of use. Notice that the general asynchronous model is problematic in this respect since one bit of communication can bring $\log(k)$ bits of information, as not only the content of the message but also the identity of the sender may reveal information. Thus, information cannot be used as a lower bound on communication. In our case, the sets S_i^l and $\overline{S_i^l}$ are determined by the current view of the player, (Π_i) contains only the content of the messages, and thus the desirable relation between the communication and the information is maintained. On the other hand, our restriction is natural, does not seem to be very restrictive (practically all protocols in the literature adhere to our model), and does not exclude the existence of private protocols.

To exemplify the above mentioned issue in the general asynchronous model consider the following simple example of a deterministic protocol, for 4 players A, B and C, D, which allows A to transmit to B its input bit x, but where all messages sent in the protocol are the bit 0, and the protocol generates only a single transcript over all possible inputs.

A: If $x = 0$ send 0 to C; after receiving 0 from C, send 0 to D.
If $x = 1$ send 0 to D; after receiving 0 from D, send 0 to C

B: After receiving 0 from a player, send 0 back to that player.

C,D: After receiving 0 from A send 0 to B. After receiving 0 from B send 0 to A.

It is easy to see that B learns the value of x from the order of the messages it gets.

There has been a long series of works about multi-party communication protocols in different variants of models, for example [13, 28, 32, 38, 16, 17]. In [7], Braverman et al. consider a restricted class of protocols working in the *coordinator model*: an additional player with no input can communicate privately with each player, and the players can only communicate with the coordinator.

We first note that the coordinator model does not yield exact bounds for the multi-party communication complexity in the peer-to-peer model (neither in our model nor in the most general one). Namely, a protocol in the peer-to-peer model can be transformed into a protocol in the coordinator model with an $O(\log k)$ multiplicative factor in the communication complexity, by sending any message to the coordinator with a $O(\log k)$-bit label indicating its destination. This factor is sometimes necessary, e.g., for the q`-index` function, where players P_i, $0 \leq i \leq k-1$, each holds an input bit x_i, player P_k holds q indices $0 \leq j_\ell \leq k-1$, $1 \leq \ell \leq q$, and P_k should learn the vector $(x_{j_1}, x_{j_1}, \ldots, x_{j_q})$: in the coordinator model the communication complexity of this function is $\Theta(\min\{k, q \log k\})$, while in both peer-to-peer models there is a protocol for this function that sends only (at most) $\min\{k, 2q\}$ bits, where P_k just queries the appropriate other players. But this multiplicative factor between the complexities in the two models is not always necessary: the communication complexity of the parity function Par is $\Theta(k)$ both in the peer-to-peer models and in the coordinator model.

Moreover, when studying private protocols in the peer-to-peer model, the coordinator model does not offer any insight. In the (asynchronous) coordinator model, described in [19] and used for instance in [7], if there is no privacy requirement with respect to the coordinator, it is trivial to have a private protocol by all players sending their input to the coordinator, and the coordinator returning the results to the players. If there is a privacy requirement with respect to the coordinator, then if there is a random source shared by all the players (but not the coordinator), privacy is always possible using the protocol of [21]. If no such source exists, privacy is impossible in general. This follows from the results of Braverman et al. [7] who show a non-zero lower bound on the total internal information complexity of all parties (including the coordinator) for the function *Disjointness* in that model.

Note also that the private protocols described in [5, 18] (and further work) are defined in the synchronous setting, and thus can be adapted to our communication model (the sets $\overline{S_i^j}$ and S_i^j are always all the players and hence even independent of the current views).

In the sequel we also use a special case of our model, where the sets $\overline{S_i^j}$ and S_i^j are a function only of i and j, and not of the entire current view of the player. This is a natural special case for protocols which we call *oblivious protocols*, where the communication pattern is fixed and is not a function of the input or randomness. Clearly, the messages themselves remain a function of the view of the players. This model also allows for private protocols.

2.3 Communication complexity and information complexity

Communication complexity, introduced in [44], measures how many bits of communication are needed in order for a set of players to compute with error ϵ a given function of their inputs. The allowed error ϵ, implicit in many of the contexts, will be written explicitly as a superscript when necessary.

▶ **Definition 2.** The *communication cost* of a protocol π, $\mathsf{CC}(\pi)$, is the maximal length of the transcript of π over all possible inputs, private randomness and public randomness.

▶ **Definition 3.** $\mathsf{CC}(f)$ denotes the communication cost of the best protocol computing f.

Information complexity measures the amount of information that must be transmitted so that the players can compute a given function of their joint inputs. One of its main uses is to provide a lower bound on the communication complexity of the function. In the two-party setting, this measure led to interesting results on the communication complexity of various functions, such as *AND* and *Disjointness*. We now focus on designing an analogue to the information cost, for the multi-party setting. The notion of internal information cost for two-party protocols (c.f. [14, 2, 6]) can be easily generalized to any number of players:

▶ **Definition 4.** The *internal information cost* of a protocol π for k players, with respect to input distribution μ, is the sum of the information revealed to each player about the inputs of the other players: $\mathsf{IC}_\mu(\pi) = \sum_{i=1}^{k} I(X_{-i}; \Pi_i \mid X_i R_i R^p)$.

Intuitively, the information cost of a protocol is the amount of information each player learns about the inputs of the other players during the protocol. The definition we give above, when restricted to two players is the same as in [6], even though they look slightly different. This is because we explicit the role of the randomness, which will allow us to later bound the amount of randomness needed for private protocols in the multi-party setting.

The *internal information complexity* of a function f with respect to input distribution μ, as well as the *internal information complexity* of a function f, can be defined for the multi-party case based on the information cost of a protocol, just as in the 2-party case.

▶ **Definition 5.** The *internal information complexity* of a function f, with respect to input distribution μ, is the infimum of the internal information cost over all protocols computing f on input distribution μ: $\mathsf{IC}_\mu(f) = \inf_{\pi \text{ computing } f} \mathsf{IC}_\mu(\pi)$.

▶ **Definition 6.** The *internal information complexity* of a function f is the infimum, over all protocols π computing f, of the information cost of π when run on the worst input distribution for that protocol: $\mathsf{IC}(f) = \inf_{\pi \text{ computing } f} \sup_{\mu} \mathsf{IC}_\mu(\pi)$.

▶ **Proposition 7** ([11])**.** For any protocol π and input distribution μ, $\mathsf{CC}(\pi) \geq \mathsf{IC}_\mu(\pi)$. Thus, for any function f, $\mathsf{CC}(f) \geq \mathsf{IC}(f)$.

The information revealed to a given player by a protocol can be written in several ways:

▶ **Proposition 8.** For any protocol π, for any player i:

$$I(X_{-i}; \overleftrightarrow{\Pi_i} \mid X_i R^p) = I(X_{-i}; \overleftrightarrow{\Pi_i} \mid X_i R_i R^p) = I(X_{-i}; \Pi_i \mid X_i R_i R^p) \quad \text{and}$$

$$I(X_{-i}; \overleftrightarrow{\Pi_i} \mid X_i R^p f(X)) = I(X_{-i}; \overleftrightarrow{\Pi_i} \mid X_i R_i R^p f(X)) = I(X_{-i}; \Pi_i \mid X_i R_i R^p f(X)).$$

2.4 Information complexity and privacy

The definition of a *private protocol* as defined in [5, 18] is the following.

▶ **Definition 9.** A k-player protocol π for computing a family of functions (f_i) is *private*[3] if for every player $i \in [\![1, k]\!]$, for all pair of inputs $x = (x_1, \ldots, x_k)$ and $x' = (x'_1, \ldots, x'_k)$, such that $f_i(x) = f_i(x')$ and $x_i = x'_i$, for all possible private random tapes r_i of player i, and all possible public random tapes r^p, it holds that for any transcript T
$\Pr[\Pi_i = T \mid R_i = r_i \ ; \ X = x \ ; \ R^p = r^p] = Pr[\Pi_i = T \mid R_i = r_i \ ; \ X = x' \ ; \ R^p = r^p]$,
where the probability is over the randomness R_{-i}.

The notion of privacy has an equivalent formulation in terms of information.

▶ **Proposition 10.** A protocol π is private iff for all μ, $\sum_{i=1}^{k} I(X_{-i}; \Pi_i \mid X_i R_i R^p f_i(X)) = 0$.

It is well known that in the multi-party number-in-the-hand peer-to-peer setting (for $k \geq 3$), unlike in the two-party case, any function can be privately computed.

▶ **Theorem 11** ([5],[18])**.** *Any function of more than two variables can be privately computed.*

Using the above theorem, we can give the following lemma.

▶ **Lemma 12.** *For any family of functions (f_i) of more than two variables and any μ, $\mathsf{IC}_\mu(f) \leq \sum_{i=1}^{k} H(f_i(X))$, where X is distributed according to μ.*

This lemma shows that IC cannot be used in the multi-party setting for any meaningful lower bounds on the communication complexity, since its value is always upper bounded by the entropies of the functions. Our goal is to get lower bounds tight in both k and n. For this reason, we introduce a new information theoretic quantity for the multi-party setting.

[3] In this paper we consider only the setting of 1-privacy, which we call here for simplicity, privacy.

3 The new measure: Public Information Cost

We now introduce a new information theoretic quantity which can be used instead of IC in the multi-party setting. The notion we define will be suitable for studying multi-party communication in a model which is only a slight restriction on the general asynchronous model, and which allows for private protocols. This means that while IC will be at most the entropies of the functions, our new notion remains a strong lower bound for communication.

▶ **Definition 13.** For any protocol π and any μ, the *public information cost* of π is:

$$\mathsf{PIC}_\mu(\pi) = \sum_{i=1}^{k} I(X_{-i}; \Pi_i R_{-i} \mid X_i R_i R^p).$$

The difference between PIC and IC is the presence of the other parties private coins, R_{-i}, in the formula. If π is a protocol using only public randomness, then for any input distribution μ, $\mathsf{PIC}_\mu(\pi) = \mathsf{IC}_\mu(\pi)$, and hence the name public information cost.

The public information cost measures both the information about the inputs learned by the players and the information that is hidden by the use of private coins. It can be decomposed, using the chain rule, into two terms, making explicit the contribution of the internal information cost and of the private randomness of the players.

▶ **Proposition 14.** For any π and any μ, $\mathsf{PIC}_\mu(\pi) = \mathsf{IC}_\mu(\pi) + \sum_{i=1}^{k} I(R_{-i}; X_{-i} | X_i \Pi_i R_i R^p)$.

The meaning of the second term is the following. At the end of the protocol, player i knows its input X_i, its private coins R_i, the public coins R^p and its transcript Π_i. Suppose that the private randomness R_{-i} of the other players is now revealed to player i. This brings to it some new information $I(R_{-i}; X_{-i} | X_i \Pi_i R_i R^p)$ about the inputs X_{-i} of the other players.

We also define the public information complexity of a function.

▶ **Definition 15.** For any f and any μ, $\mathsf{PIC}_\mu(f) = \inf_{\pi \text{ computing } f} \mathsf{PIC}_\mu(\pi)$.

▶ **Definition 16.** For any f, we define the quantity $\mathsf{PIC}(f) = \inf_{\pi \text{ computing } f} \sup_{\mu} \mathsf{PIC}_\mu(\pi)$.

The public information cost is a lower bound for the communication complexity.

▶ **Proposition 17.** For any π and μ, $\mathsf{CC}(\pi) \geq \mathsf{PIC}_\mu(\pi)$. Thus, for any f, $\mathsf{CC}(f) \geq \mathsf{PIC}(f)$.

In fact, as we show below, the public information cost of a function is equal to its internal information cost in a setting where only public randomness is allowed. The role of private coins in communication protocol has been studied for example in [8, 12, 34]. In the next section we will see that the difference between the public information cost and the information cost is related to the private coins used during the protocol.

▶ **Theorem 18.** *For any function f and input distribution μ,*

$$\mathsf{PIC}_\mu(f) = \inf_{\pi \textit{ computing } f,\textit{ using only public coins}} \mathsf{IC}_\mu(\pi)\ ,\ \textit{and}$$

$$\mathsf{PIC}(f) = \inf_{\pi \textit{ computing } f,\textit{ using only public coins}} \sup_{\mu} \mathsf{IC}_\mu(\pi).$$

The following property of the public information cost will be useful for zero-error protocols.

▶ **Proposition 19.** For any function f, for any input distribution μ, $\mathsf{PIC}^0_\mu(f) = \mathsf{IC}^{\det}_\mu(f)$ where $\mathsf{IC}^{\det}_\mu(f) = \inf_{\pi \text{ deterministic protocol computing } f} \mathsf{IC}_\mu(\pi)$.

PIC and IC are strictly different even in the two party case. We prove below that for the AND function, the public information cost is $\log 3 \simeq 1.58$, while, as shown in [9], $\mathsf{IC}^0(\mathsf{AND}) \simeq 1.49$. This implies that the protocol that achieves the optimal information cost for AND must use private coins. We remark also that in [9] it is shown that the external information cost of AND, that we do not consider here, is $\log(3)$.

▶ **Proposition 20.** For two players, $\mathsf{PIC}^0(\mathsf{AND}) = \log(3) \simeq 1.58$.

4 Private computation, randomness, and PIC

We have seen that the public information cost of a function is equal to the information cost of the function when we only consider public coin protocols, and that in order to decrease the information cost even further, the players must use private randomness. We will see now that the difference between the public information cost of a protocol and its information cost can provide a lower bound on the amount of private randomness the players use during the protocol. The entropy of the transcript of the protocol, conditioned on the inputs and the public coins, is defined as $H(\Pi \mid XR^p)$. Once the input and the public coins are fixed, the entropy of the transcript of the protocol comes solely from the private randomness. Thus it provides a lower bound on the entropy of the private randomness used by the players.

▶ **Theorem 21.** *Let $f = (f_i)$ be a family of functions of k variables. Let π be a protocol for f. For any input distribution μ, it holds: $H_\mu(\Pi \mid XR^p) \geq \dfrac{\mathsf{PIC}_\mu(\pi) - \mathsf{IC}_\mu(\pi)}{k-1}$. Thus running a protocol for f with information cost I_μ requires entropy $H_\mu(\Pi \mid XR^p) \geq \dfrac{\mathsf{PIC}_\mu(f) - I_\mu}{k-1}$.*

5 A direct sum for PIC ?

The *direct sum* property is a fundamental question in complexity theory, and has been studied for many computation models. A direct sum theorem affirms that the amount of resources needed to perform t independent tasks is at least the sum of the resources needed to perform each of the t tasks. In this section we show that a direct sum property for PIC implies a direct sum property for CC. For this, we prove a compression result by extending [12, 37] to the multi-party case. Note that information complexity has a direct sum property in the multi-party case. For PIC, it is easy to prove the following inequality.

▶ **Theorem 22.** *For any k-variable functions f and g, for any μ on inputs of f, for any η on inputs of g, $\mathsf{PIC}_{\mu\times\eta}(f \times g) \leq \mathsf{PIC}_\mu(f) + \mathsf{PIC}_\eta(g)$.*

In order to understand whether the opposite inequality holds, i.e., whether a direct sum property holds for PIC, we first need to study the problem of compressing communication.

5.1 Relation between PIC and CC: A compression result

An important open question is how well we can compress the communication cost of an interactive protocol. Compression results have appeared in [3, 11, 12, 37, 4], while, on the other hand, [25, 27, 39, 22, 26] focus on the hardness of compressing communication protocols. Here, we present a compression result with regards to the average-case communication complexity and the public information cost.

▶ **Definition 23.** The *average-case communication complexity* of a protocol π with respect to the input distribution μ, denoted $\mathsf{ACC}_\mu(\pi)$, is the expected number of bits that are transmitted in an execution of π for inputs distributed according to μ and uniform randomness.

▶ **Theorem 24.** *Suppose there exists a protocol π to compute a k-variable function f over the distribution μ with error probability ϵ. Then there exists a public-coin protocol ρ that computes f over μ with error $\epsilon + \delta$, and with average communication complexity*

$$\mathsf{ACC}_\mu(\rho) = \mathcal{O}\left(k^2\mathsf{PIC}_\mu(\pi)\log(\mathsf{CC}(\pi))\left(\log(k\mathsf{CC}(\pi)) + \log\frac{k^2\mathsf{PIC}_\mu(\pi)\log(\mathsf{CC}(\pi))}{\delta}\right)\right).$$

The proof of the above theorem will follow from extending the compression result presented in [12, 37] to the case of $k > 2$ players.

▶ **Theorem 25.** *Suppose there exists a public coin protocol π to compute a k-variable function f over the distribution μ with error probability ϵ. Then there exists a public-coin protocol ρ that computes f over μ with error $\epsilon + \delta$, and with average communication complexity*

$$\mathsf{ACC}_\mu(\rho) = \mathcal{O}\left(k^2\mathsf{IC}_\mu(\pi)\log(\mathsf{CC}(\pi))\left(\log(k\mathsf{CC}(\pi)) + \log\frac{k^2\mathsf{IC}_\mu(\pi)\log(\mathsf{CC}(\pi))}{\delta}\right)\right).$$

Theorems 25 and 18, which make the link between the public information cost of general protocols and the information cost of public coins protocol, imply theorem 24.

In the two-party compression scheme of [12, 37], the two players, given their own input, try to guess the transcript $\pi(x_1, x_2)$ of the protocol π. For this, player 1 picks a candidate t_1 from the set $\mathrm{Im}(\pi(x_1, \cdot))$ of possible transcripts knowing that it has input x_1, while player 2 picks a candidate t_2 from the set $\mathrm{Im}(\pi(\cdot, x_2))$. The two players then communicate in order to find the first bit on which t_1 and t_2 disagree. The general structure of protocols ensures that the common prefix of t_1 and t_2 (until the first bit of disagreement) is identical to the beginning of the correct transcript on inputs x_1 and x_2, i.e., identical to $\pi(x_1, x_2)$. Starting from this correct prefix, the players then pick new candidates for the transcript of the protocol $\pi(x_1, x_2)$, and so on, until they agree on the full transcript $\pi(x_1, x_2)$. Clever choices of the candidates, along with an efficient technique to find the first bit which differs between the candidates, lead to a protocol with little communication.

In extending the proof in [12, 37] to the multi-party case, new difficulties occur. The players can no longer try to guess the full transcript, as they have little information about the conversation between the other players, but can only try to guess their partial transcripts, according to their own input. Then, in order to find the first disagreement in the global transcript, every pair of players needs to find and communicate the place of the first disagreement in their partial transcripts. This induces the k^2 factor in our compression scheme. It is unclear if this is necessary. Moreover, the players lack a common reference time. To solve this, we will introduce, as a technical tool in the proof, a *coordinator*, whose role is to introduce a round structure in the protocol π. Note that this is only in the proof, and that the stated results hold in the model we define in Section 2.

5.2 A direct sum for PIC implies a direct sum for CC

▶ **Theorem 26.** *Given a k-variable function f and a distribution μ on inputs of f, if the existence of a protocol π computing $f^{\otimes t}$ with error $\epsilon \geq 0$ implies that there exists a protocol π' computing f with error ϵ and verifying $\mathsf{PIC}_\mu(\pi') \leq \frac{1}{t}\mathsf{PIC}_{\mu^{\otimes t}}(\pi)$, $\mathsf{CC}(\pi') \leq \mathsf{CC}(\pi)$, then*

$$\mathsf{CC}^{2(\epsilon+\delta)}(f) = \mathcal{O}\left(\frac{k^2}{t(\epsilon+\delta)}\mathsf{CC}^\epsilon(f^{\otimes t})\log(\mathsf{CC}^\epsilon(f^{\otimes t}))\log(k)\log\frac{k^2\mathsf{CC}^\epsilon(f^{\otimes t})\log(\mathsf{CC}^\epsilon(f^{\otimes t}))}{\delta}\right).$$

Note that the result of this theorem is meaningful when t is large with respect to k.

6 Tight lower bounds for the parity function Par

We now show how one can indeed use PIC to study multi-party communication protocols and to prove tight bounds. We study one of the canonical problems for zero-error multi-party computation, the parity function. The k-party parity problem with n-bit inputs Par_k^n is defined as follows. Each player i receives n bits $(x_i^p)_{p\in[\![1,n]\!]}$ and Player 1 has to output the bitwise XOR of the inputs $\left(\bigoplus_{i=1}^{k} x_i^1, \bigoplus_{i=1}^{k} x_i^2, \ldots, \bigoplus_{i=1}^{k} x_i^n\right)$.

There is a simple private protocol for Par_k^n that uses n bits of private randomness. Player 1 uses a private random n-bit string r and sends to Player 2 the string $x_1 \oplus r$. Then, Player 2 computes the bit-wise parity of its input with the message and sends $x_2 \oplus x_1 \oplus r$ to Player 3. The players continue until Player 1 receives back the message $x_k \oplus \ldots \oplus x_1 \oplus r$. Player 1 then takes the bit-wise parity of this message with the private string r to compute the value of the parity function. It is easy to see that this protocol has information cost equal to n, since Player 1 just learns the value of the function and all other players learn nothing. We thus see that information cost cannot provide here lower bounds that scale with k.

We now prove tight lower bounds for this problem using the measure of PIC. For this, we study a restricted class of protocols: we only consider protocols such that for any player i, the sets $(S_i^l)_l$ and $(\overline{S}_i^l)_l$ do not depend on the input x or on the randomness. In other words, the structure of the protocol is fixed and independent of the input and randomness. Note that the private protocol we described above fits in this model.

Our bound for Par_k^n is in fact proved for a wider class of protocols, where we allow the player outputting $\oplus_{i=1}^k x_i^p$ to be different for each coordinate p and to depend on the input.

▶ **Theorem 27.** $\mathsf{PIC}_\mu^0(\mathsf{Par}_k^n) \geq n(k-1)$ *where μ is the uniform input distribution.*

▶ **Theorem 28.** *The entropy in the private randomness of a private protocol for Par_k^n is at least $\dfrac{k-2}{k-1}n$.*

Where the last theorem follows from Theorems 27 and 21. Using Theorem 21 we can also give a lower bound on the randomness one needs for protocols that are allowed to leak some limited amount of information about the inputs of the players.

7 Conclusions

In this paper we introduce a new information-theoretic measure, that we call PIC, for the study of multi-party computation protocols in the number-in-hand, peer-to-peer model. This is probably the most natural (distributed) computation model, and also closely related to the models used in the distributed algorithms community. Previous information-theoretic measures that were used successfully for the study of two-party computation protocols do not extend immediately to the multi-party case due to the fact that private protocols exist for any function in the multi-party setting [5, 18]. Our notion of PIC provides an alternative way of studying multi-party protocols, especially when one is interested in notions of privacy. Furthermore, PIC may yield tight results for certain functions, for which using other models, such as the coordinator model, would imply a loss of a logarithmic factor.

We define this measure in a slightly restricted computation model which however still allows private protocols, and applies to almost any protocol in the literature. We prove a number of properties of our new measure, PIC, and a number of connections to other complexity notions, e.g., the amount of randomness needed for private computation or the central question of direct sum (in communication complexity).

Our work opens the way to interesting directions for further work. A challenging direction would be to prove a tight lower bound for Disjointness in the message passing peer-to-peer model (without the loss of a logarithmic factor). An even more ambitious goal would be to use our result from Section 5 to try and prove the direct sum property for communication complexity, in either the two-party or multi-party setting, via our measure of PIC.

Dividing by Zero – How Bad Is It, Really?*

Abstract

In computable analysis testing a real number for being zero is a fundamental example of a non-computable task. This causes problems for division: We cannot ensure that the number we want to divide by is not zero. In many cases, any real number would be an acceptable outcome if the divisor is zero - but even this cannot be done in a computable way.

In this note we investigate the strength of the computational problem *Robust division*: Given a pair of real numbers, the first not greater than the other, output their quotient if well-defined and any real number else. The formal framework is provided by Weihrauch reducibility. One particular result is that having later calls to the problem depending on the outcomes of earlier ones is strictly more powerful than performing all calls concurrently. However, having a nesting depths of two already provides the full power. This solves an open problem raised at a recent Dagstuhl meeting on Weihrauch reducibility.

As application for *Robust division*, we show that it suffices to execute Gaussian elimination.

1 Introduction

We cannot divide by zero! is probably the first mathematical impossibility statement everyone encounters. In the setting we see it first, arithmetic of concrete integers, this does not cause any problems: Since it is obvious whether some number is zero or not, we simply refrain from attempting it – and the multiplicative absorption of 0 ensures that we have no reason for an attempt anyway. As our mathematical world expands to include more kinds of numbers and variables, we may have to introduce case distinctions at times in order to avoid this problem[1].

In most practical situations, this may seem unproblematic. However, a fundamental observation by Brouwer in the early development of constructive mathematics was that *we cannot in general decide whether a real number is zero or not.* Thus, a case distinction based on whether our intended denominator is zero or not is not constructive. In a constructive setting, we can only divide by a number we know to be different from zero.

* The first author was partially supported by a Grant-in-Aid for JSPS fellows. The second author was partially supported by the ERC inVEST (279499) project.

[1] Forgetting about these cases has probably caused a lot of anguish to pupils learning the outcome of their exams.

To consider a concrete example where we might want to divide by a number that could be zero, consider $a, b \in \mathbb{R}$ with $0 \leq a \leq b$, and the linear equation $a = bx$. We know that there is a solution $x_0 \in [0,1]$: If $b \neq 0$, then $x_0 := \frac{a}{b}$, otherwise $b = a = 0$, and any x works. We see that we do not actually care about whether $b = 0$ or not, and we do not even need any particular outcome of a misguided attempt to calculate $\frac{0}{0}$ – any number would do.

Unfortunately, the algorithm to divide a real number a by a real number b starts with searching for a rational number bounding b away from 0. If no such number exists, there will be no output at all, rather than some arbitrary number. The *robust division* we would like to employ to solve linear equations as above is not actually computable.

In this note, we study the extent of non-computability of robust division in the formal setting of Weihrauch reducibility. Some results had already been obtained in [17]. We will recall that robust division lies strictly in between the traditional non-constructive principles LLPO and LPO and some other basic properties. Our concern then is with the question how multiple uses of robust division interact. We show that sequential uses of robust division cannot be reduced to parallel uses – however, it suffices to have a nesting depths of 2.

In [17], finding the solution to systems of linear inequalities via a modified Fourier-Motzkin elimination, and finding Nash equilibria in bimatrix games were explored as applications of robust division. Here, we shall consider Gaussian elimination as additional example.

An extended version of this article is available as [15].

2 Background

Computability on the reals and other represented spaces

The long history of studying computability on the real numbers presumably goes back to Borel [2] (see [1] for a detailed historical picture). Here, we follow the school of Weihrauch [28]. Computability is initially introduced over $\{0,1\}^{\mathbb{N}}$ by means of Type-2 machines. These are obtained from the usual Turing machine model via a simple modification: The head on output tape can move to the right only (and in particular does so whenever a symbol is written), and the machines never halt. The restriction on the output tape ensures that as the computation proceeds, longer and longer finite prefixes of the ultimate infinite output are available.

The transfer of computability from $\{0,1\}^{\mathbb{N}}$ to the spaces of actual interest is achieved via the notion of a represented space. For a more detailed introduction to the theory of represented spaces, we refer to [21]. A represented space is a pair $\mathbf{X} = (X, \delta_X)$ of a set X and a partial surjection $\delta_X :\subseteq \{0,1\}^{\mathbb{N}} \to X$ (the representation).

A multi-valued function[2] between represented spaces is a multi-valued function between the underlying sets. For $f :\subseteq \mathbf{X} \rightrightarrows \mathbf{Y}$ and $F :\subseteq \{0,1\}^{\mathbb{N}} \to \{0,1\}^{\mathbb{N}}$, we call F a realizer of f (notation $F \vdash f$), iff $\delta_Y(F(p)) \in f(\delta_X(p))$ for all $p \in \operatorname{dom}(f\delta_X)$.

$$\begin{tikzcd}
\{0,1\}^{\mathbb{N}} \arrow[r, "F"] \arrow[d, "\delta_{\mathbf{X}}"] & \{0,1\}^{\mathbb{N}} \arrow[d, "\delta_{\mathbf{Y}}"] \\
\mathbf{X} \arrow[r, "f"] & \mathbf{Y}
\end{tikzcd}$$

A map between represented spaces is called computable (continuous), iff it has a computable (continuous) realizer. Note that a priori, the notion of continuity for maps between represented

[2] For a discussion of the notion of a multi-valued function, and in particular the difference to the notion of a relation, we refer to [23], [20].

spaces differs from topological continuity. For the admissible represented spaces (in the sense of [24]), the two notions do coincide, if a represented space is equipped with the final topology inherited from Cantor space along the representation. All representations we are concerned with in this note are admissible.

Before we introduce the standard representation of the real numbers, we fix some standard enumeration $\nu_\mathbb{Q} : \mathbb{N} \to \mathbb{Q}$ of the rationals. Now we define $\rho :\subseteq \{0,1\}^\mathbb{N} \to \mathbb{R}$ via $\rho(0^{n_0}10^{n_1}1\ldots) = x$ iff $\forall i \in \mathbb{N}\ |\nu_\mathbb{Q}(n_i) - x| < 2^{-n}$. Note that using e.g. the binary or decimal expansion would not have worked satisfactorily[3]. The choice of ρ ensures that, informally spoken, every naturally encountered continuous function on the reals will be computable.

The naturals are represented in the obvious way by $\delta_\mathbb{N}(0^n1^\mathbb{N}) = n$. The finite spaces $\{0,\ldots,n\}$ are just the corresponding subspaces of $\mathbb{N}$. Likewise, we introduce the represented space $[0,1]$ as a subspace of $\mathbb{R}$. The space $\mathbb{S}$ has the elements $\{\bot,\top\}$ represented via $\delta_\mathbb{S}(0^\mathbb{N}) = \bot$ and $\delta_\mathbb{S}(p) = \top$ for $p \neq 0^\mathbb{N}$.

For any represented space $\mathbf{X}$, there is a canonical definition of the represented space $\mathcal{A}(\mathbf{X})$ of closed subsets of $\mathbf{X}$. We only require this for the specific choices of $\mathbf{X} = [0,1], \{0,\ldots,n\}$: In the former case, a closed subset is a closed subset in the usual sense, and it is represented by a list of rational open balls exhausting its complement in $[0,1]$. In the latter, any subset of $\{0,\ldots,n\}$ is an element of $\mathcal{A}(\{0,\ldots,n\})$, and a set A is represented by $p \in \{0,1\}^\mathbb{N}$ iff 01^k0 occurs somewhere in p iff $k \notin A$ for any $k \in \{0,\ldots,n\}$.

As there are canonical tupling functions $\langle\ldots\rangle : (\{0,1\}^\mathbb{N})^n \to \{0,1\}^\mathbb{N}$ available, we can define products of represented spaces in a straight-forward way. We obtain binary and countable disjoint unions by $(\delta_0 + \delta_1)(0p) = \delta_0(p)$ and $(\delta_0 + \delta_1)(1p) = \delta_1(p)$, and $(\coprod_{i\in\mathbb{N}} \delta_i)(0^n1p) = \delta_n(p)$. We will iterate the binary product, starting with the convention $\mathbf{X}^0 = \{0\}$ and setting $\mathbf{X}^{n+1} = \mathbf{X}^n \times \mathbf{X}$. Finally, $\mathbf{X}^*$ is shorthand for $\coprod_{i\in\mathbb{N}} \mathbf{X}^i$.

Weihrauch reducibility

Weihrauch reducibility is a computable many-one reduction comparing multi-valued functions between represented spaces. So $f \leq_\mathrm{W} g$ informally means that f could be computed with the help of a single oracle-call to g.

▶ **Definition 1.** Let $f :\subseteq \mathbf{X} \rightrightarrows \mathbf{Y}$ and $g :\subseteq \mathbf{U} \rightrightarrows \mathbf{V}$ be partial multivalued functions between represented spaces. Say that f is Weihrauch reducible to g, in symbols $f \leq_\mathrm{W} g$, if there are computable functions $K :\subseteq \{0,1\}^\mathbb{N} \times \{0,1\}^\mathbb{N} \to \{0,1\}^\mathbb{N}$ and $H :\subseteq \{0,1\}^\mathbb{N} \to \{0,1\}^\mathbb{N}$ such that whenever G is a realizer of g, the function $F := (p \mapsto K(p, G(H(p))))$ is a realizer for f.

Based on earlier work by Weihrauch [26, 27], Weihrauch reducibility was suggested as a framework for computable metamathematics in [5, 4] (see also [12, 17]). We point to the introduction of [6] for a recent overview on the development of the field so far.

We shall denote the set of Weihrauch degrees by $\mathfrak{W}$, and point out some operations on them. As shown in [18], the binary product $\times$, the binary disjoint union $\sqcup$, the countable disjoint union $\coprod$ and the operation * all can be lifted from represented spaces via multivalued functions between represented spaces to Weihrauch degrees. $\mathfrak{W}$ is a distributive lattice, and $\sqcup$ is the join. However, no non-trivial countable suprema exist in $\mathfrak{W}$ as shown in [13]. In particular, $\coprod$ is not the countable join.

Informally, $f \sqcup g$ means that both f and g are available for use, but the user has to decide for each instance on one of the two to call. A call to $f \times g$ means making two independent

[3] As already noted by Turing [25].

Figure 1 Illustrating Definition 1.[4]

calls, one to f and one to g. Using f^* means that we first decide on some number $n \in \mathbb{N}$, and then make n independent calls to f.

We want to use a further operation; corresponding to first making a call to some g and then a call to f depending on the outcome of the call to g. In [9, 7] the operation $\star$ was defined as $f \star g := \max_{\leq_W}\{f' \circ g' \mid f' \leq_W f \wedge g' \leq_W g\}$. Here the maximum is understood to range over all f', g' with types such that $f' \circ g'$ is well-defined. While it is not obvious that this maximum exists, an explicit construction is provided in [11]. Informally, an input to $f \star g$ consists of an input to g together with a multivalued function computing some input to f from an output to g. The output is the output of g together with the output of f.

We iterate both $\times$ and $\star$: $f^0 = f^{(0)} = \text{id}_{\{0,1\}^\mathbb{N}}$, and $f^{n+1} = f^n \times f$ and $f^{(n+1)} = f^{(n)} \star f$.

Special Weihrauch degrees

We will refer to a number of well-studied specific Weihrauch degrees in this paper. We shall first recall the degrees LPO and LLPO from [27], the Weihrauch degree counterparts to the Brouwerian counterexamples in intuitionistic mathematics. $\text{LPO} : \{0,1\}^\mathbb{N} \to \{0,1\}$ maps $0^\mathbb{N}$ to 1 and each $p \neq 0^\mathbb{N}$ to 0. This map is equivalent to the characteristic function of 0 in $\mathbb{R}$ or $[0,1]$, and we will not distinguish these maps. The map $\text{LLPO} : \{0,1\}^\mathbb{N} \rightrightarrows \{0,1\}$ outputs 0 if the first 1 in the input occurs at an even position, and 1 if it occurs at an odd position. If the input was $0^\mathbb{N}$, both 0 and 1 are valid outputs. An alternative characterization would be $\text{LLPO} : \mathbb{R} \times \mathbb{R} \to \{0,1\}$ with $0 \in \text{LLPO}(0,y)$, $1 \in \text{LLPO}(x,0)$ and $0,1 \in \text{LLPO}(x,y)$ if $x \neq 0 \neq y$. It holds that $\text{LLPO} <_W \text{LPO}$.

A bountiful source of calibrating principles is found in the closed choice principles and their restrictions:

▶ **Definition 2.** $\text{C}_\mathbf{X} :\subseteq \mathcal{A}(\mathbf{X}) \rightrightarrows \mathbf{X}$, $\text{dom}(\text{C}_\mathbf{X}) = \{A \in \mathcal{A}(\mathbf{X}) \mid A \neq \emptyset\}$, $x \in \text{C}_\mathbf{X}(A) \Leftrightarrow x \in A$.

Thus, closed choice is the task to find a point in a given non-empty closed set. As being non-empty is merely promised rather than constructively witnessed, this task is generally not computable: As long as there is more than one remaining choice, whenever we start

[4] This figure was taken from [22].

outputting some point we might learn next that this point is not in the closed set after all (e.g. by reading some rational ball containing it in the name of the closed set).

These principles have been extensively studied [4, 3, 10, 9, 16, 6]. Depending on the topological properties of the space $\mathbf{X}$ and potentially restrictions to certain subsets, these principles have been revealed to be useful in characterizing many other principles.

Most relevant for us are the principles $\mathrm{C}_{\{0,\ldots,n\}}$. It was shown in [17] that $\mathrm{C}_{\{0,\ldots,n\}} \leq_{\mathrm{W}} \mathrm{C}_{\{0,1\}}^n$, and it follows from the independent choice theorem in [3] that $\mathrm{C}_{\{0,1\}}^n \leq_{\mathrm{W}} \mathrm{C}_{\{0,1\}}^{(n)} \leq_{\mathrm{W}} \mathrm{C}_{\{0,\ldots,2^n-1\}}$. It is quite easy to see that $\mathrm{C}_{\{0,1\}} \equiv_{\mathrm{W}} \mathrm{LLPO}$.

We make passing references to $\mathrm{C}_{\mathbb{N}}$ (and use that $\mathrm{C}_{\mathbb{N}} \equiv_{\mathrm{W}} \mathrm{C}_{\mathbb{N}} \star \mathrm{C}_{\mathbb{N}}$ by the independent choice theorem from [3]), to $\mathrm{CC}_{[0,1]}$, the restriction of $\mathrm{C}_{[0,1]}$ to connected subsets and to $\mathrm{PCC}_{[0,1]}$, the restriction of $\mathrm{C}_{[0,1]}$ to connected sets with positive Lebesgue measure. We also mention $\star$-WWKL from [6], which is $\coprod_{n\in\mathbb{N}}(2^{-n})$-WWKL, where ε-WWKL is the restriction of $\mathrm{C}_{\{0,1\}^{\mathbb{N}}}$ to sets with measure at least ε. By $\mathrm{UC}_{\mathbf{X}}$ we denote the restriction of $\mathrm{C}_{\mathbf{X}}$ to singletons [3]. Finally, $\mathrm{C}_{\sharp=2}$ and $\mathrm{C}_{\sharp\leq 2}$ from [16] are the restrictions of $\mathrm{C}_{\{0,1\}^{\mathbb{N}}}$ to sets with cardinality 2 and at most 2 respectively.

3 Robust division

We consider two variants of robust division: In one case, we know an upper bound on the result, in the second, we do not. Modulo the rescaling, the first case corresponds to knowing that the denominator is at least as big as the numerator.

▶ **Definition 3** ([17]). Define $\mathrm{rDiv} : \mathbb{R} \times \mathbb{R} \rightrightarrows [0,1]$ via $\frac{\min\{|x|,|y|\}}{|y|} \in \mathrm{rDiv}(x,y)$ iff $y \neq 0$ and $z \in \mathrm{rDiv}(x,0)$ for all $x \in \mathbb{R}, z \in [0,1]$.

To simplify notation, we will usually assume that inputs (x,y) for rDiv already satisfy $0 \leq x \leq y$, so that $\frac{\min\{|x|,|y|\}}{|y|} = \frac{x}{y}$ holds.

▶ **Definition 4.** Define $\mathrm{ubrDiv} : \mathbb{R}\times\mathbb{R} \rightrightarrows \mathbb{R}$ by $\frac{x}{y} \in \mathrm{ubrDiv}(x,y)$ iff $y \neq 0$ and $z \in \mathrm{ubrDiv}(x,0)$ for all $x, z \in \mathbb{R}$.

It turns out that the case distinction on $y \neq 0$ or $y = 0$ is equivalent to the unbounded case ubrDiv. Thus, we do not need to investigate ubrDiv as an independent basic operation. Note that the following proof also establishes that it makes no difference for the degree of ubrDiv if the result is presumed to be non-negative.

▶ **Proposition 5.** $\mathrm{ubrDiv} \equiv_W$ *LPO.*

Proof. The direction $\mathrm{ubrDiv} \leq_{\mathrm{W}} \mathrm{LPO}$ follows from computability of division where well-defined and the definition.

For the other direction, note that given some $p \in \{0,1\}^{\mathbb{N}}$ we can compute $x, y \in \mathbb{R}$ such that if $p \neq 0^{\mathbb{N}}$, then $\frac{x}{y} = \min\{n \in \mathbb{N} \mid p(n) = 1\}$ and $x = y = 0$ if $p = 0^{\mathbb{N}}$. Furthermore, there is a computable multivalued retract $\tau : \mathbb{R} \rightrightarrows \mathbb{N}$, so we may pretend that the output of $\mathrm{ubrDiv}(x,y)$ is a natural number n indicating the position of the first 1 in p, if it exists. Given this number, we can then check whether $p(n)$ is 1 or not, which in turn determines the answer to $\mathrm{LPO}(p)$. ◀

The bounded variant of robust division was already established as a *new* degree in [17]. We recall some results on this degree from the literature before continuing its investigation.

▶ **Proposition 6** ([17]).

1. $C_{\{0,1\}} <_W \mathrm{rDiv} <_W LPO$.
2. $\mathrm{rDiv} <_W CC_{[0,1]}$.
3. $\mathrm{rDiv} \not\leq_W C^*_{\{0,1\}}$.

▶ **Proposition 7** ([6, Theorem 16.3, Corollary 16.5 & Theorem 16.6]).

1. $\mathrm{rDiv} <_W PCC_{[0,1]}$.
2. rDiv *is join-irreducible.*
3. $\mathrm{rDiv} \not\leq_W *\text{-}WWKL$.

The preceding results from [6] intuitively state that there is a mechanism to solve rDiv in a probabilistic way with positive probability and error detection. However, there is no way to obtain a positive lower bound on the probability of solving a given instance correctly.

It is a well-known phenomenon in the study of Weihrauch reducibility that closed choice principles make very convenient representatives of Weihrauch degrees (cf. [4, 3, 10, 9, 16]). The case of robust division is no different: For a represented space $\mathbf{X}$ we denote by $\mathrm{AoUC}_\mathbf{X}$ the restriction of $\mathrm{C}_\mathbf{X}$ to $\{A \in \mathcal{A}(\mathbf{X}) \mid |A| = 1\} \cup \{X\}$ following an idea of Brattka. Just by its definition, it is clear that $\mathrm{UC}_\mathbf{X} \leq_W \mathrm{AoUC}_\mathbf{X} \leq_W \mathrm{C}_\mathbf{X}$ holds for any space $\mathbf{X}$. In the following we shall focus on $\mathrm{AoUC}_{[0,1]}$.

▶ **Proposition 8.** [5] $\mathrm{rDiv} \equiv_W AoUC_{[0,1]}$.

Proof. The reduction $\mathrm{rDiv} \leq_\mathrm{W} \mathrm{AoUC}_{[0,1]}$ is straight-forward: On input $(x, y) \in \mathbb{R}^2$ for rDiv, while the search for a $k \in \mathbb{N}$ with $y > 2^{-k}$ continues, the input to $\mathrm{AoUC}_{[0,1]}$ is kept at $[0, 1]$. If such a k is ever found, one can compute $\frac{x}{y}$, and hence also $\{\frac{x}{y}\}$ as $[0, 1]$ is computably Hausdorff and collapse the unit interval to it.

For the other direction, as long as the input to $\mathrm{AoUC}_{[0,1]}$ has not collapsed, one starts to input $(0, 0)$ to rDiv. If the input of $\mathrm{AoUC}_{[0,1]}$ ever collapsed to $\{z\}$, one can compute z. The input to rDiv can still be chosen from some interval $[0, 2^{-k}] \times [0, 2^{-k}]$. In particular, $x = 2^{-k}z$ and $y = 2^{-k}$ works and forces the correct output. ◀

4 Sequential versus concurrent uses of rDiv

If multiple uses of some noncomputable principle are needed to solve a particular task, an important distinction is whether these have to be sequential, or can be applied in a concurrent fashion. In the former case, some instances to the principle may depend on outputs obtained from prior invocations. In the latter, each instantiation is independent of the others. For various principles, however, we find that sequential uses can be reduced to concurrent uses.

▶ **Definition 9.** We call f *finitely concurrent*, iff $f^* \equiv_\mathrm{W} \coprod_{n\in\mathbb{N}} f^{(n)}$.

▶ **Proposition 10** ([16]). *The following are finitely concurrent:*

1. LPO
2. $LLPO \equiv_W C_{\{0,1\}}$
3. $C_{\sharp=2}$
4. $C_{\sharp\leq 2}$

[5] This result was suggested to the author by Brattka, and has been shown in [19].

Whether rDiv is finitely concurrent in this sense was posed as an open question during the Dagstuhl workshop *Measuring the Complexity of Computational Content* in September 2015 [8]. We can now provide a negative answer[6]:

▶ **Theorem 11.** *LLPO* $\star$ *AoUC*$_{[0,1]} \not\leq_W$ *AoUC*$^k_{[0,1]}$ *for all* $k \in \mathbb{N}$.

Proof. We say that a binary tree $T \subseteq \{0,1\}^*$ is an *a.o.u. tree* if for any height $n \in \mathbb{N}$ either $|T \cap \{0,1\}^n| = 2^n$ or $|T \cap \{0,1\}^n| = 1$. Clearly, one can identify $\mathrm{AoUC}_{[0,1]}$ with the partial multi-valued function sending an a.o.u. tree T to all infinite paths through T. We often identify a set $S \subseteq \{0,1\}^*$ with its characteristic function $\chi_S : \{0,1\}^* \to \{0,1\}$. Under this identification, a partial function $t :\subseteq \{0,1\}^* \to \{0,1\}$ is called a *partial tree* if $\mathrm{Tr}(t) := \{\sigma \in \mathrm{dom}(t) : t(\sigma) = 1\}$ forms a subtree of $\{0,1\}^*$. If such t is computable, we call t a *partial computable tree*. Note that a tree is computable if and only if it is of the form $\mathrm{Tr}(t)$ for a partial computable tree t which is *total*, that is, $\mathrm{dom}(t) = \{0,1\}^*$. We say that a partial computable tree t *looks like an a.o.u. tree at* (l,s) if

1. $t(\sigma)[s]$ converges for any binary string σ of length l,
2. for any $n < l$, the cardinality of $\mathrm{Tr}(t) \cap \{0,1\}^n$ is either 2^n or 1,

where $t(\sigma)[s]$ is the result of the computation of $t(\sigma)$ by stage s. Note that given $(l,s) \in \mathbb{N}^2$, we can effectively decide whether t looks like an a.o.u. tree at (l,s) or not. By $\mathrm{aou}(t,s)$ we denote the greatest $l \leq s$ such that t looks like an a.o.u. tree at (l,s).

Consider two partial multi-valued functions $Z_0 = \mathrm{AoUC}_{[0,1]} \times \mathrm{id}_{\mathbf{X}}$ and $Z_1 = (\mathrm{id}_{\{0,1\}^{\mathbb{N}}} \circ \pi_0, \mathrm{C}_{\{0,1\}} \circ \mathrm{eval})$, where $\mathbf{X}$ is the represented space $C(\{0,1\}^{\mathbb{N}}, \mathrm{dom}(\mathrm{C}_{\{0,1\}}))$ of continuous functions from Cantor space $\{0,1\}^{\mathbb{N}}$ into the hyperspace $\mathrm{dom}(\mathrm{C}_{\{0,1\}}) = \mathcal{A}(\{0,1\}) \setminus \{\emptyset\}$ of nonempty closed subsets of $\{0,1\}$. More explicitly, we consider the following two partial multi-valued functions:

$$Z_0 : \mathrm{dom}(\mathrm{AoUC}_{[0,1]}) \times \mathbf{X} \rightrightarrows \{0,1\}^{\mathbb{N}} \times \mathbf{X},$$
$$Z_0(T,S) = \mathrm{AoUC}_{[0,1]}(T) \times \{S\},$$
$$Z_1 : \{0,1\}^{\mathbb{N}} \times \mathbf{X} \rightrightarrows \{0,1\}^{\mathbb{N}} \times 2,$$
$$Z_1(x,S) = \{x\} \times \mathrm{C}_{\{0,1\}}(S(x)).$$

Clearly, $Z_0 \leq_W \mathrm{AoUC}_{[0,1]}$ and $Z_1 \leq_W \mathrm{C}_{\{0,1\}}$. We will show that $Z_1 \circ Z_0 \not\leq_W \mathrm{AoUC}^k_{[0,1]}$. Let $\{(\mathbf{t}^e, \varphi_e, \psi_e)\}_{e \in \mathbb{N}}$ be an effective enumeration of all triples of k-tuples $\mathbf{t}^e = (t^e_i)_{i<k}$ of partial computable trees, partial computable functions $\varphi_e :\subseteq (\{0,1\}^{\mathbb{N}})^k \to \{0,1\}^{\mathbb{N}}$ and $\psi_e :\subseteq (\{0,1\}^{\mathbb{N}})^k \to \{0,1\}$. Intuitively, $(\mathbf{t}^e, \varphi_e, \psi_e)$ is a triple constructed by the opponent Opp, who tries to show $Z_1 \circ Z_0 \leq_W \mathrm{AoUC}^k_{[0,1]}$ for some k. The game proceeds as follows: The proponent Pro of our claim gives an instance (T_r, S_r) of $Z_1 \circ Z_0$, so that $(T_r, S_r) \in \mathrm{dom}(\mathrm{AoUC}_{[0,1]}) \times \mathbf{X}$. In particular, T_r is an a.o.u. tree, and S_r is a continuous function from $[T_r]$ into $\mathcal{A}(\{0,1\})$. Then, Opp reacts with an instance $\mathbf{t}^r$ of $\mathrm{AoUC}^k_{[0,1]}$, that is, a k-tuple $\mathbf{t}^r = (t^r_i)_{i<k}$ of *total* a.o.u. trees. If Opp wins, Opp has to ensure that if $(p_i)_{i<k}$ is a k-tuple of infinite paths through Opp's a.o.u. trees, that is, $p_i \in [\mathrm{Tr}(t^r_i)]$, then $\varphi_r((p_i)_{i<k}) = x$ is a path through Pro's a.o.u. tree T_r and $\psi_r((p_i)_{i<k})$ chooses an element of Pro's set $S_r(x)$, where Opp can use information on (names of) T_r and S_r to construct φ_r and ψ_r. Our purpose is to prevent Opp's strategy.

Given e, we will introduce the e-th strategy, which works as a proponent Pro of our claim. The e-th strategy Pro will construct a computable a.o.u. tree $T_e \subseteq \{0,1\}^*$ and a computable

[6] Which also disproves a claim made in the PhD thesis of the second author [19, Theorem 5.2.1.6].

function $S_e : \{0,1\}^{\mathbb{N}} \to \mathcal{A}(\{0,1\})$ in a computable way uniformly in e. These will prevent Opp's strategy, that is, there is a k-tuple $(p_i)_{i<k}$ of infinite paths through Opp's a.o.u. trees such that if $\varphi_e((p_i)_{i<k}) = x$ chooses a path through Pro's a.o.u. tree T_e then $\psi_e((p_i)_{i<k})$ cannot be an element of Pro's set $S_e(x)$.

We will also define $\mathtt{state}(e,s) \in \{0,\dots,k\} \cup \{\mathtt{end}\}$. The value $\mathtt{state}(e,s) = q$ for $q \neq \mathtt{end}$ indicates that the e-th strategy Pro believes that by stage s, *at least q many trees $(t^e_{u(j)})_{j<q}$ in Opp's k-tuple $(t^e_i)_{i<k}$ have been forced not to have more than one infinite path*, that is, $\mathrm{Tr}(t^e_{u(j)})$ for each $j < q$ has a unique infinite path whenever the opponent Opp has a chance of winning this game with the triple $(\mathbf{t}^e, \varphi_e, \psi_e)$. Under this assumption, if $\mathtt{state}(e,s) = q$, the fact that these q many trees has no more than one infinite path will be witnessed at some stage. The value $\mathtt{state}(e,s) = \mathtt{end}$ indicates that the winning of Pro is already witnessed by Pro's action of shrinking Pro's a.o.u. tree T_e to a tree having a unique path which avoids all φ_e-values made by Opp.

By induction on s, we determine the set $T_e \cap \{0,1\}^s$ of strings in T_e of length s and $\mathtt{state}(e,s)$. In the beginning of our construction, we define $\mathtt{state}(e,0) = 0$. At stage s, we inductively assume that $T_e \cap \{0,1\}^{s-1}$ and $\mathtt{state}(e,s-1)$ have already been defined, say $\mathtt{state}(e,s-1) = q$, and that if $\mathtt{state}(e,s-1) \neq \mathtt{end}$ then $T_e \cap \{0,1\}^{s-1} = \{0,1\}^{s-1}$.

At stage s, the e-th strategy Pro acts as follows:

1. Ask whether there exists $l \leq s$ such that t^e_i for each $i < k$ looks like an a.o.u. tree at (l,s), and at least q-many trees among Opp's k-tuple $(t^e_i)_{i<k}$ have no more than one node above height l. In other words, for $\mathrm{aou}(e,s) := \min_{i<k} \mathrm{aou}(t^e_i, s)$, ask whether there are at least q many $i < k$ such that $|\mathrm{Tr}(t^e_i) \cap \{0,1\}^{\mathrm{aou}(e,s)}| = 1$.
   - **a.** If no, we go to the next stage $s+1$ after setting $\mathtt{state}(e,s) = \mathtt{state}(e,s-1)$ and $T_e \cap \{0,1\}^s = \{0,1\}^s$.
   - **b.** If yes, go to item (2).
2. Ask whether $\varphi_e((p_i)_{i<k})$ already computes a node (of Pro's a.o.u. tree T_e) of length at least $q+1$ for any k-tuple of paths p_i through Opp's a.o.u. trees t^e_i, that is,

$$(\forall i < k)(\forall (\sigma_i)_{i<k})\ [((\forall i < k)\ \sigma_i \in \mathrm{Tr}(t^e_i) \cap \{0,1\}^{\mathrm{aou}(e,s)}) \\ \to\ (\forall m \leq q)\ \varphi_e((\sigma_i)_{i<k})(m)[s] \downarrow].$$

   Here, by effective continuity, the Type-2 computation $\varphi_e : (\{0,1\}^{\mathbb{N}})^k \to \{0,1\}^{\mathbb{N}}$ is approximated by a Type-1 computation $\tilde{\varphi}_e : (\{0,1\}^*)^k \to \{0,1\}^*$ (e.g., consider the Type-2 Turing machine model). We always identify φ_e with $\tilde{\varphi}_e$, and therefore, the notation $\varphi_e((\sigma_i)_{i<k})(m)$ makes sense, that is, by $\varphi_e((\sigma_i)_{i<k})(m)[s] \downarrow$, we mean that the computation of $\tilde{\varphi}_e((\sigma_i)_{i<k})(m)$ halts by stage s.
   - **a.** If no, we go to the next stage $s+1$ after setting $\mathtt{state}(e,s) = \mathtt{state}(e,s-1)$ and $T_e \cap \{0,1\}^s = \{0,1\}^s$.
   - **b.** If yes, go to item (3).
3. Ask whether the image of the product of k many closed sets generated by Opp's k-tuple $\mathbf{t}^e$ under the map φ_e covers the whole space $\{0,1\}^{\mathbb{N}}$. Formally speaking, let us consider the following set:

$$\varphi_e[\mathrm{Tr}(\mathbf{t}^e) \cap \{0,1\}^l] \upharpoonright p := \{\varphi_e((\sigma_i)_{i<k}) \upharpoonright p : (\forall i < k)\ \sigma_i \in \mathrm{Tr}(t^e_i) \cap \{0,1\}^l\},$$

   and then ask whether $\tau \in \varphi_e[\mathrm{Tr}(\mathbf{t}^e) \cap \{0,1\}^{\mathrm{aou}(e,s)}] \upharpoonright q+1$ for all $\tau \in \{0,1\}^{q+1}$.
   - **a.** If no, choose a witness τ, and we finish the construction by setting $\mathtt{state}(e,s) = \mathtt{end}$ after defining T_e as a tree having a unique infinite path $\tau^\frown 0^\infty := \tau^\frown 000\dots$.
   - **b.** If yes, go to item (4).

4. Ask whether $\psi_e((p_i)_{i<k})$ already computes some value $j \in \{0,1\}$ for any k-tuple of paths p_i through Opp's a.o.u. trees t_i^e, that is,

$$(\forall i<k)(\forall(\sigma_i)_{i<k})\ [((\forall i<k)\ \sigma_i \in \mathrm{Tr}(t_i^e)\cap\{0,1\}^{\mathrm{aou}(e,s)}) \ \rightarrow\ \psi_e(\sigma)[s]\downarrow].$$

   a. If no, go to the next stage $s+1$ after setting $\mathtt{state}(e,s) = \mathtt{state}(e,s-1)$ and $T_e \cap \{0,1\}^s = \{0,1\}^s$.
   b. If yes, let $D_{e,s} = \{\sigma \in \mathrm{Tr}(\mathbf{t}^e)\cap\{0,1\}^{\mathrm{aou}(e,s)} : \varphi_e(\sigma) \succeq 0^q1\}$. Note that $D_{e,s} \neq \emptyset$ since we answered yes in item (3); therefore $\varphi_e[\mathrm{Tr}(\mathbf{t}^e)\cap\{0,1\}^{\mathrm{aou}(e,s)}] \upharpoonright q+1 = \{0,1\}^{q+1}$. If $i \notin \psi_e[D_{e,s}]$ for some $i \in \{0,1\}$, then remove $1-i$ from $S_e(0^q1)$ (hence, we have $S_e(0^q1) = \{i\}$). If $\psi_e[D_{e,s}] = \{0,1\}$ then remove 0 from $S_e(0^q1)$. In these cases, set $\mathtt{state}(e,s) = q+1$ and $T_e \cap \{0,1\}^s = \{0,1\}^s$.

Eventually, T_e is constructed as an a.o.u. tree, and $S_e(x) \in \mathrm{dom}(\mathsf{C}_2)$.

▶ **Claim.** *Assume that $(t_i^e)_{i<k}$ determines a k-tuple of a.o.u. trees. Then, there is a realizer G of $\mathrm{AoUC}_{[0,1]}^k$ such that $(\varphi_e \circ G((t_i^e)_{i<k}), \psi_e \circ G((t_i^e)_{i<k}))$ is not a solution to $Z_1 \circ Z_0(T_e, S_e)$, that is, $\varphi_e \circ G((t_i^e)_{i<k}) \notin [T_e]$ or otherwise $\psi_e \circ G((t_i^e)_{i<k}) \notin S_e \circ \varphi_e \circ G((t_i^e)_{i<k})$, where $[T_e]$ denotes the set of all infinite paths through T_e.*

Proof. Assume that $\mathbf{t}^e = (t_i^e)_{i<k}$ determines a k-tuple of a.o.u. trees. In this case, t_i^e is a total tree for each $i<k$. Suppose for the sake of contradiction that the conclusion fails (that is, Opp wins). Then φ_e and ψ_e are defined on all tuples of infinite paths through $\mathrm{Tr}(t_i^e)$, $i<k$. Since $q=0$ at first, the condition in item (1) is automatically fulfilled. Note that since t_i^e is a total a.o.u. tree, the value $\mathrm{aou}(e,s)$ tends to infinity as $s\to\infty$. Therefore, since φ_e is defined on all paths of Opp's trees, by compactness, the condition in item (2) is also satisfied at some stage s. If $\tau \notin \varphi_e[\mathrm{Tr}(\mathbf{t}^e)\cap\{0,1\}^{\mathrm{aou}(e,s)}] \upharpoonright q+1$, then T_e has a unique infinite path $\tau^\frown 0^\infty$; therefore $\varphi_e \circ G(\mathbf{t}^e) \notin [T_e]$ for any realizer G, which contradicts our assumption. Therefore, $\varphi_e[\mathrm{Tr}(\mathbf{t}^e)\cap\{0,1\}^{\mathrm{aou}(e,s)}] \upharpoonright q+1 = \{0,1\}^{q+1}$. By compactness, the condition in item (4) is eventually satisfied. In any cases, for some $\sigma = (\sigma_i)_{i<k} \in D_{e,s}$, $\psi_e(\sigma) \notin S_e(\varphi_e(\sigma))$ by our construction. In order for Opp to win this game, Opp has to declare that σ_i for some $i<k$ is not extendible to an infinite path through t_i^e. Consequently, under our assumption that Opp wins, Pro's strategy forces such t_i^e not to be the full binary tree; therefore t_i^e has only one path since t_i^e is an a.o.u. tree. Then we continue the same argument with $q=1$. We can still satisfy the condition in item (1) at some stage since we know at most one tree t_i^e has only one path. Eventually, this construction forces that any of t_i^e has only one path. Then, however, it is impossible to satisfy $\varphi_e[\mathrm{Tr}(\mathbf{t}^e)\cap\{0,1\}^{\mathrm{aou}(e,s)}] \upharpoonright q+1 = \{0,1\}^{q+1}$. ◀

Suppose for the sake of contradiction that $Z_1 \circ Z_0 \leq_{\mathrm{W}} \mathrm{AoUC}_{[0,1]}^k$ holds via computable H and $K = \langle K_0, K_1\rangle$, i.e., given (T,S), for any k-tuple $\mathbf{p}$ of infinite paths through trees $H(T,S) = \{H_i(T,S)\}_{i<k}$, $(K_0(\mathbf{p},T,S), K_1(\mathbf{p},T,S)) \in Z_1 \circ Z_0(T,S)$, that is, $K_0(\mathbf{p},T,S) \in [T]$ and $K_1(\mathbf{p},T,S) \in S(K_0(\mathbf{p},T,S))$. Choose a computable function f such that $\mathbf{t}^{f(e)} = H(T_e,S_e)$, $\varphi_{f(e)} = \lambda\mathbf{p}.K_0(\mathbf{p},T_e,S_e)$, and $\psi_{f(e)} = \lambda\mathbf{p}.K_1(\mathbf{p},T_e,S_e)$. By Kleene's recursion theorem, there is r such that $(\mathbf{t}^{f(r)}, \varphi_{f(r)}, \psi_{f(r)}) = (\mathbf{t}^r, \varphi_r, \psi_r)$. This triple clearly satisfies the premise of the above claim. The realizer G in the claim witnesses the failure of $Z_1 \circ Z_0 \leq_{\mathrm{W}} \mathrm{AoUC}_{[0,1]}^k$ via H and K. Consequently, $\mathsf{LLPO} \star \mathrm{AoUC}_{[0,1]} \not\leq_{\mathrm{W}} \mathrm{AoUC}_{[0,1]}^k$ for all $k \in \mathbb{N}$. ◀

We point out that the preceding theorem relativizes, i.e. even provides a separation w.r.t. continuous Weihrauch reductions. The same holds for all other separation results in this article.

▶ **Corollary 12.** *$LLPO \star AoUC_{[0,1]} \not\leq_W AoUC_{[0,1]}^*$.*

Proof. Assume to the contrary that $\mathrm{C}_{\{0,1\}} \star \mathrm{AoUC}_{[0,1]} \leq_{\mathrm{W}} \mathrm{AoUC}^*_{[0,1]}$. Consider as input to $\mathrm{LLPO} \star \mathrm{AoUC}_{[0,1]}$ the set $[0,1]$ together with the constant function $h : [0,1] \to \mathcal{A}(\{0,1\})$, $x \mapsto \{0,1\}$. The latter can be represented in such a way that it shares arbitrarily long prefixes with names for any other continuous function of that type. The reduction has to chose some $k \in \mathbb{N}$ eventually that serves as the first component of the derived input to $\mathrm{AoUC}^*_{[0,1]}$. But since the original input can still be altered to any other suitable input, this would imply $\mathrm{LLPO} \star \mathrm{AoUC}_{[0,1]} \leq_{\mathrm{W}} \mathrm{AoUC}^k_{[0,1]}$, thus contradicting Theorem 11. ◀

▶ **Corollary 13.** rDiv *is not finitely concurrent.*

Proof. By Proposition 8, $\mathrm{rDiv} \equiv_{\mathrm{W}} \mathrm{AoUC}_{[0,1]}$ and by Proposition 6 $\mathrm{LLPO} \equiv_{\mathrm{W}} C_{\{0,1\}} \leq_{\mathrm{W}} \mathrm{rDiv}$. Thus, Corollary 12 implies $\mathrm{rDiv} \star \mathrm{rDiv} \nleq_{\mathrm{W}} \mathrm{rDiv}^*$. ◀

We will find next that rDiv only barely fails being finitely concurrent: While some amount of nesting is required to obtain the full power of finitely many uses of rDiv, nesting depths 2 already suffices. This result will be proven via a number of individual technical contributions.

Let $\mathcal{O}(\mathbb{N})$ denote subsets of $\mathbb{N}$ represented via an enumeration of their elements. Call a set $A \subseteq \mathcal{O}(\mathbb{N})$ *nice*, if $\emptyset \in A$ and A contains a computable dense sequence $(a_n)_{n\in\mathbb{N}}$.

▶ **Proposition 14.** *Let $f :\subseteq \mathcal{O}(\mathbb{N}) \rightrightarrows \mathbf{X}$ have a nice domain and a computable closed graph. Then $f \star AoUC^k_{[0,1]} \leq_W C_{\{1,\ldots,2^k\}} \star \left(f^{2^k} \times AoUC^k_{[0,1]}\right)$.*

Proof. For any subset $I \subseteq \{1,\ldots,k\}$ we compute an input to f under the assumption that the components $i \in I$ for $\mathrm{AoUC}^k_{[0,1]}$ are singletons, and the components $i \notin I$ are the whole interval. We start with providing a name for $\emptyset \in \mathrm{dom}(f)$ and wait until all components $i \in I$ have started to collapse. Then we can compute the actual values in those singletons, and can attempt to compute the input to f associated with those values, together with $0 \in [0,1]$ for those components $i \notin I$. Before actually fixing any values, we make sure that there is some element a_n of the dense sequence extending the current finite prefix. If we ever find that some component $i \notin I$ is starting to collapse, we abandon the attempt to find the correct input to f, and just extend the current prefix to some suitable a_n. By the assumption that $\mathrm{dom}(f)$ is nice, this is guaranteed to produce a valid input to f, and if I was indeed the correct choice, will be the correct input.

Now we consider the output of f on each of these values, together with the output$(x_1,\ldots,x_k)$ of $\mathrm{AoUC}^k_{[0,1]}$ on the original input. We replace those x_i with $i \notin I$ with 0, and ask whether this is still a correct output. As the graph of f is a computable closed set, we can ask whether this output matches the input to f obtained from the so modified output of $\mathrm{AoUC}^k_{[0,1]}$. We can compute a truth value $t_I \in \mathbb{S}$ which is false iff both questions answer to true. If I was indeed correct, the corresponding t_I will be false. If t_I is false, then the combined outputs of f and $\mathrm{AoUC}^k_{[0,1]}$ allow us to solve the original question to $f \star \mathrm{AoUC}^k_{[0,1]}$. We can use $\mathrm{C}_{\{1,\ldots,2^k\}}$ to pick some false t_I. ◀

▶ **Corollary 15.** $AoUC^l_{[0,1]} \star AoUC^m_{[0,1]} \leq_W C_{\{1,\ldots,2^m\}} \star AoUC^{l2^m+m}_{[0,1]}$.

Proof. We just need to argue that $\mathrm{AoUC}_{[0,1]}$ is equivalent to some $f :\subseteq \mathcal{O}(\mathbb{N}) \rightrightarrows \mathbf{X}$ satisfying the criteria of Proposition 14. Recall that $A \in \mathcal{A}([0,1]) \supseteq \mathrm{dom}(\mathrm{AoUC}_{[0,1]})$ is represented by enumerating rational open balls exhausting the complement of A. By letting f be equal to $\mathrm{AoUC}_{[0,1]}$, but acting on the enumerations rather than the sets themselves, we have found the required candidate. ◀

▶ **Proposition 16.** *Let $f :\subseteq \mathcal{O}(\mathbb{N}) \rightrightarrows \mathbf{X}$ have a nice domain. Then $f \star C_{\{1,\ldots,n\}} \leq_W f^n \times C_{\{1,\ldots,n\}}$.*

Proof. For each $i \in \{1, \dots, n\}$ we attempt to compute the suitable input to f if i were the output provided by $\mathrm{C}_{\{1,\dots,n\}}$. We only actually write a finite prefix of the output once we have found an element a_n extending it. If we ever learn that i is not a correct output of $\mathrm{C}_{\{1,\dots,n\}}$, we abandon the attempt and simply extend the current input to f to some a_n. The nice domain of f ensures that this procedure results in a valid input for f. If we do this for all choices of i in parallel, and also compute a suitable i, we can then read of a correct output to $f \star \mathrm{C}_{\{1,\dots,n\}}$. ◀

▶ **Corollary 17.** $AoUC^l_{[0,1]} \star C_{\{1,\dots,m\}} \leq_W AoUC^{lm+m-1}_{[0,1]}$.

Proof. To argue that we may use $\mathrm{AoUC}_{[0,1]}$ in place of f in Proposition 16, we argue as we did to obtain Corollary 15 from Proposition 14. Now $\mathrm{C}_{\{1,\dots,m\}} \leq_{\mathrm{W}} C^{m-1}_{\{0,1\}}$ and $C_{\{0,1\}} \leq_{\mathrm{W}} \mathrm{AoUC}_{[0,1]}$ from [17] complete the argument. ◀

So we do find that 3 (or more) consecutive applications of powers of $\mathrm{AoUC}_{[0,1]}$ do reduce to 2:

▶ **Corollary 18.** $AoUC^l_{[0,1]} \star AoUC^m_{[0,1]} \star AoUC^k_{[0,1]} \leq_W AoUC^{(l+1)2^k-1}_{[0,1]} \star AoUC^{m2^k+k}_{[0,1]}$

▶ **Proposition 19.** *Let $f : \mathbf{X} \rightrightarrows \mathbb{N}$ be such that $n \in f(x) \wedge m > n \Rightarrow m \in f(x)$. Then if $f \leq_W C_{\{0,1\}^\mathbb{N}}$, f is already computable.*

▶ **Corollary 20.**

$$\begin{aligned} AoUC^*_{[0,1]} \star AoUC^*_{[0,1]} \quad & \equiv_W \coprod_{n\in\mathbb{N}} (AoUC^n_{[0,1]} \star AoUC^n_{[0,1]}) \\ \equiv_W \coprod_{n\in\mathbb{N}} AoUC^{(n)}_{[0,1]} \equiv_W C^*_{\{0,1\}} \star AoUC^*_{[0,1]} \quad & \equiv_W \left(AoUC^*_{[0,1]}\right)^{(n+1)} \end{aligned}$$

Proof. By Proposition 19 it follows that in e.g. $\mathrm{AoUC}^*_{[0,1]} \star \mathrm{AoUC}^*_{[0,1]}$ the number of oracle calls made in the second round can be bounded in advance. The equivalences now follow from the uniform versions of Corollaries 15, 18. ◀

5 Gaussian Elimination

Most work on algorithms in linear algebra assumes equality to be decidable, and is thus applicable to computability over the rational or algebraic numbers, but not to computability over the real numbers. In the latter setting, computability of some basic questions (rank, eigenvectors,...) was studied in [30], with some additional results in [29, 10]. Here, we shall consider LU-decomposition and Gaussian elimination.

Gaussian elimination is one of the basic algorithms in linear algebra, used in particular to compute the LU-decomposition of matrices. The goal is to transform a given matrix into row echelon form by means of swapping rows (and maybe columns) and adding multiples of one row to another. Sometimes the leading non-zero coefficients in each row are required to be 1, however, as this is easily seen to require equality testing, we shall not include this requirement.

▶ **Definition 21.** $\text{LU-Decomp}_{P,Q}$ takes as input a matrix A, and outputs permutation matrices P, Q, a matrix U in upper echelon form and a matrix L in lower echelon form with all diagonal elements being 1 such that $PAQ = LU$. By LU-Decomp_Q we denote the extension where P is required to be the identity matrix.

▶ **Theorem 22.** *LU-Decomp*$_{P,Q} \equiv_W \mathrm{rDiv}^*$ *and* $\mathrm{rDiv}^* \leq_W$ *LU-Decomp*$_Q \leq_W \mathrm{rDiv}^* \star \mathrm{rDiv}^*$.

The proof of the preceding theorem follows in form of some lemmata. We point out that the upper bounds are proven via variants of Gaussian elimination. In the case of LU-Decomp$_{P,Q}$ and its matching lower bound, this shows that Gaussian elimination exhibits no more incomputability than inherent in the problem it solves. It is consistent with the classifications that the extra freedom in choosing the pivot elements in solving LU-Decomp$_{P,Q}$ compared to solving LU-Decomp$_Q$ makes the problem less incomputable. Resolving the precise degree of LU-Decomp$_Q$ seems to be beyond the reach of our current methods though.

▶ **Lemma 23.** *LU-Decomp*$_{P,Q} \equiv_W$ *LU-Decomp*$^*_{P,Q}$ *and LU-Decomp*$_Q \equiv_W$ *LU-Decomp*$^*_Q$.

Proof. An LU-decomposition of $\left(\begin{array}{cc} A & 0 \\ 0 & B \end{array}\right)$ gives rise to LU-decompositions of both A and B. ◀

▶ **Lemma 24.** *LU-Decomp*$_{P,Q} \leq_W \mathrm{rDiv}^*$.

Proof. Initially, we rearrange all the matrix elements such that at each step the pivot element chosen has the largest absolute value amongst the remaining elements, and obtain their signs. This can be achieved by $\mathrm{C}_{\{0,\ldots,k\}}$ for suitable k. Then we can compute all the relevant divisions simultaneously, using some rDiv^l. Corollary 17 then shows that this reduces to rDiv^*. ◀

▶ **Lemma 25.** *LU-Decomp*$_Q \leq_W \mathrm{rDiv}^* \star \mathrm{rDiv}^*$.

Proof. Given some real matrix $(a_{ij})_{i\leq n, j\leq m}$ we can use $\mathrm{C}_{\{0,\ldots,n-1\}}$ to pick some i_0 such that $|a_{i_0,1}| = \max_{i\leq n} |a_{i,1}|$, and permute the rows to move the i_0-th row to the top. We can use $C^n_{\{0,1\}}$ to figure out for each i whether $|a_{i,1}|$ is non-negative or non-positive. For each $i \neq i_0$ we compute $\mathrm{rDiv}(|a_{i,1}|, |a_{i_0,1}|)$, pick the sign depending on the putative signs on $a_{i,1}$ and $a_{i_0,1}$ and then subtract the corresponding multiple of the i_0-th row from the i-th row. By choice of i_0, either all $a_{i,1}$ are 0 anyway, or $a_{i_0,1} \neq 0$ – in both cases, this ensures that in all rows but the i_0-th the first entry is zero after the operation.

The procedure so far made use of $\mathrm{rDiv}^{n-1} \star \left(\mathrm{C}_{\{0,\ldots,n-1\}} \times C^n_{\{0,1\}}\right)$.

After the first round, the now first row is fixed. Amongst the remaining ones, we pick one with the largest absolute value in the second column (using $\mathrm{C}_{\{0,\ldots,n-2\}}$), determine the signs of entries in the second column (using $C^{n-2}_{\{0,1\}}$) and again use rDiv to compute the coefficients for subtracting the second row from the lower ones.

This is repeated until each row has been dealt with. Overall, we use $n-1$ rounds, so the procedure is reducible to $\left[\mathrm{rDiv}^{n-1} \star \left(\mathrm{C}_{\{0,\ldots,n-1\}} \times C^n_{\{0,1\}}\right)\right]^{(n)}$. By repeated application of Corollaries 17,18 this reduces to $\mathrm{AoUC}^k_{[0,1]} \star \mathrm{AoUC}^k_{[0,1]}$ for sufficiently big k (depending effectively on n). ◀

▶ **Lemma 26.** $\mathrm{rDiv} \leq_W$ *LU-Decomp*$_{P,Q}$.

Proof. We consider the computable function $B : [0,1] \to \mathbb{R}^{2\times 2}$ of matrices defined via:

$$B(\varepsilon) = \exp(-\varepsilon^{-2}) \left(\begin{array}{cc} \cos(\varepsilon^{-1}) & \sin(\varepsilon^{-1}) \\ -\sin(\varepsilon^{-1}) & \cos(\varepsilon^{-1}) \end{array}\right) \text{ for } \varepsilon > 0 \quad B(0) = \left(\begin{array}{cc} 0 & 0 \\ 0 & 0 \end{array}\right)$$

This is based on a counterexample due to Rellich (cmp. [14, II.5.3], [30, Example 18]). If $\varepsilon \neq 0$, then the lower-left corner of L in an LU-decomposition of $B(\varepsilon)$ will be one of $\tan \varepsilon^{-1}$,

$\cot \varepsilon^{-1}$ or $-\cot \varepsilon^{-1}$. The relevant case can be obtained from P and Q. As arctan and arccot are total, we can apply the relevant inverse even if $\varepsilon = 0$, and thus the lower-left corner of L is an arbitrary real number. Let x'_ε be the result, and $x_\varepsilon = \max\{0, \min\{1, x'_\varepsilon\}\}$.

We want to show that $\mathrm{AoUC}_{[0,1]} \leq_{\mathrm{W}} \text{LU-Decomp}_{P,Q}$ (which is equivalent to the claim by Proposition 8). Given $A \in \mathrm{dom}(\mathrm{AoUC}_{[0,1]})$, we show how to compute some $\varepsilon \in [0,1]$ such that $x_\varepsilon \in A$. As long as $A = [0,1]$ is consistent with our knowledge of the input, we specify that $\varepsilon \in [0, 2^{-t}]$ for smaller and smaller $t \in \mathbb{N}$. If we learn at time t that $A \neq [0,1]$, we compute y such that $A = \{y\}$ and choose $k \in \mathbb{N}$ such that $(2k\pi)^{-k} \leq 2^{-t}$. We can then specify $\varepsilon = (2k\pi + y)^{-1}$. But now $x_\varepsilon = y$. If $A = [0,1]$, then $x_\varepsilon \in A$ anyway by definition. ◀

Based on the preceding lemma and [30, Example 18], we can also see that rDiv is reducible to finding eigenvectors of a matrix.

Abstract

Several well-studied graph problems aim to select a largest (or smallest) induced subgraph with a given property of the input graph. Examples include maximum independent set, maximum planar graph, maximum clique, minimum feedback vertex set, and many others. In online versions of these problems, the vertices of the graph are presented in an adversarial order, and with each vertex, the online algorithm must irreversibly decide whether to include it into the constructed subgraph, based only on the subgraph induced by the vertices presented so far. We study the properties that are common to all these problems by investigating a generalized problem: for an arbitrary but fixed hereditary property π, find some maximal induced subgraph having π. We investigate this problem from the point of view of advice complexity, i. e., we ask how some additional information about the yet unrevealed parts of the input can influence the solution quality. We evaluate the information in a quantitative way by considering the best possible advice of given size that describes the unknown input. Using a result from Boyar et al. [STACS 2015, LIPIcs 30], we give a tight trade-off relationship stating that, for inputs of length n, roughly n/c bits of advice are both needed and sufficient to obtain a solution with competitive ratio c, regardless of the choice of π, for any c (possibly a function of n). This complements the results from Bartal et al. [SIAM Journal on Computing 36(2), 2006] stating that, without any advice, even a randomized algorithm cannot achieve a competitive ratio better than $\Omega(n^{1-\log_4 3-o(1)})$. Surprisingly, for a given cohereditary property π and the objective to find a minimum subgraph having π, the advice complexity varies significantly with the choice of π. We also consider a preemptive online model, inspired by some applications mainly in networking and scheduling, where the decision of the algorithm is not completely irreversible. In particular, the algorithm may discard some vertices previously assigned to the constructed set, but discarded vertices cannot be reinserted into the set. We show that, for the maximum induced subgraph problem, preemption does not significantly help by giving a lower bound of $\Omega(n/(c^2 \log c))$ on the bits of advice that are needed to obtain competitive ratio c, where c is any increasing function bounded from above by $\sqrt{n/\log n}$. We also give a linear lower bound for c close to 1.

1 Introduction

Online algorithms get their input gradually, and this way have to produce parts of the output without full knowledge of the instance at hand, which is a large disadvantage compared to classical *offline computation*, yet a realistic model of many real-world scenarios [5]. Most of the offline problems have their online counterpart. Instead of asking about the time and space complexity of algorithms to solve a computational problem, *competitive analysis* is commonly used as a tool to study how well online algorithms perform [5, 18] without any time or space restrictions; the analogous offline measurement is the analysis of the *approximation ratio.* A large class of computational problems for both online and offline computation are formulated on graphs; we call such problems (online) *graph problems.*

In this paper, we deal with problems on unweighted undirected graphs that are given to an online algorithm vertex by vertex in consecutive discrete time steps. Formally, we are given a graph $G = (V, E)$, where $|V| = n$, with an ordering $\prec$ on V. Without loss of generality, assume $V = \{v_1, \ldots, v_n\}$, and $v_1 \prec \ldots \prec v_n$ specifies the order in which the vertices of G are presented to an online algorithm; this way, the vertex v_i is given in the ith time step. Together with v_i, all edges $\{v_j, v_i\} \in E$ are revealed for all $v_j \prec v_i$. If v_i is revealed, an online algorithm must decide whether to accept v_i or discard it. Neither G nor n are known to the online algorithm. We study two versions of online problems; with and without preemption. In the former case, the decision whether v_i is accepted or not is definite. In the latter case, in every time step, the online algorithm may preempt (discard) some of the vertices it previously accepted; however, a vertex that was once discarded cannot be part of the solution anymore.

For an instance $I = (v_1, \ldots, v_n)$ of some graph problem, we denote by $\textsc{Alg}(I)$ the solution computed by some online algorithm $\textsc{Alg}$; $\textsc{Opt}(I)$ denotes an optimal solution for I, which can generally only be computed with the full knowledge of I. We assume that I is constructed in an *adversarial manner* to give worst-case bounds on the solution quality of any online algorithm. This means that we explicitly think of I as being given by an adversary that knows $\textsc{Alg}$ and wants to make it perform as poorly as possible; for more details, we refer to the standard literature [5].

For maximization problems with an associated *profit function* called profit, an online algorithm $\textsc{Alg}$ is called *c-competitive* if, for every instance I of the given problem, it holds that

$$\text{profit}(\textsc{Alg}(I)) \geq 1/c \cdot \text{profit}(\textsc{Opt}(I)) \; ; \tag{1}$$

likewise, for minimization problems with a *cost function* called cost, we require

$$\text{cost}(\textsc{Alg}(I)) \leq c \cdot \text{cost}(\textsc{Opt}(I)) \tag{2}$$

for every instance I. In this context, $c > 1$ may be a constant or a function that increases with the input length n. We will use c and $c(n)$ interchangeably to refer to the competitive ratio; the latter is simply used to emphasize that c may depend on n.

Throughout this paper, log denotes the binary logarithm $\log_2$.

Instead of studying specific graph problems, in this paper, we investigate a large class of such problems, which are defined by *hereditary properties.* This class includes many well-known problems such as *maximum independent set*, *maximum planar graph*, *maximum induced clique*, and *maximum acyclic subgraph.* The *cohereditary problems* we consider are online versions of the offline problem of searching for a specific structure within a graph. An example is to find the shortest cycle; this defines the girth of the graph. *Online cycle finding* was considered by Boyar et al. [7].

We call any collection of graphs a *graph property* π. A graph has (or *satisfies*) property π if it is in the collection. Examples include the property of being planar (the collection contains all planar graphs), or being an independent set (the collection contains all graphs with no edges). We only consider properties that are *non-trivial*, i. e., they are both true for infinitely many graphs and false for infinitely many graphs. A property is called *hereditary* if it holds that, if a graph G satisfies π, then also any induced subgraph G' of G satisfies π; conversely, it is called *cohereditary* if it holds that, if a graph G satisfies π, and G is an induced subgraph of G', then also G' satisfies π. For a graph $G = (V, E)$ and a subset of vertices $S = \{v_1, \ldots, v_i\} \subseteq V$, let $G[S]$ (or $G[v_1, \ldots, v_i]$) denote the subgraph of G induced by the vertices from S. For a graph $G = (V, E)$, let $\overline{G} = (V, \overline{E})$ be the complement of G, i. e., $\{u, v\} \in \overline{E}$ if and only if $\{u, v\} \notin E$. Let K_n denote the complete graph on n vertices, and let $\overline{K}_n$ denote the independent set on n vertices. We consider the online version of the problem of finding maximal (minimal, respectively) induced subgraphs satisfying a hereditary (cohereditary, respectively) property π, denoted by $\textsc{Max}$-π ($\textsc{Min}$-π, respectively). For the ease of presentation, we will call such problems *hereditary (cohereditary, respectively) problems*. Let $S_{\textsc{Alg}} := \textsc{Alg}(I)$ denote the set of vertices accepted by some online algorithm $\textsc{Alg}$ for some instance I of a hereditary problem. Then, for $\textsc{Max}$-π, the profit of $\textsc{Alg}$ is $|S_{\textsc{Alg}}| := \text{profit}(\textsc{Alg}(I))$ if $G[S_{\textsc{Alg}}]$ has the property π and $-\infty$ otherwise; the goal is to maximize the profit. Conversely, for $\textsc{Min}$-π, the cost of $\textsc{Alg}$ is $|S_{\textsc{Alg}}| := \text{cost}(\textsc{Alg}(I))$ if $G[S_{\textsc{Alg}}]$ has the property π and ∞ otherwise; the goal is to minimize the cost. As an example, consider the *online maximum independent set* problem; the set of all independent sets is clearly a hereditary property (every independent set is a feasible solution, and every induced subset of an independent set is again an independent set). When a vertex is revealed, an online algorithm needs to decide whether it becomes part of the solution or not. The goal is to compute an independent set that is as large as possible; the profit of the solution is thus equal to $|S_{\textsc{Alg}}|$. It is straightforward to define the problem without or with preemption.

In this paper, we study *online algorithms with advice* for hereditary and cohereditary problems. In this setup, an online algorithm is equipped with an additional resource that contains information about the instance it is dealing with. A related model was originally introduced by Dobrev et al. [9]. Revised versions were defined by Emek et al. [11], Böckenhauer et al. [4], and Hromkovič et al. [12]. Here, we use the model of the latter two papers. Consider an input $I = (v_1, \ldots, v_n)$ of a hereditary problem. An *online algorithm* $\textsc{Alg}$ *with advice* computes the output sequence $\textsc{Alg}^{\phi}(I) = (y_1, \ldots, y_n)$ such that y_i is computed from $\phi, v_1, \ldots, v_i$, where ϕ is the content of the advice tape, i. e., an infinite binary sequence. We denote the cost (profit, respectively) of the computed output by $\text{cost}(\textsc{Alg}^{\phi}(I))$ ($\text{profit}(\textsc{Alg}^{\phi}(I))$, respectively). The algorithm $\textsc{Alg}$ is *c-competitive with advice complexity* $b(n)$ if, for every n and for each I of length at most n, there exists some ϕ such that $\text{cost}(\textsc{Alg}^{\phi}(I)) \leq c \cdot \text{cost}(\textsc{Opt}(I))$ ($\text{profit}(\textsc{Alg}^{\phi}(I)) \geq 1/c \cdot \text{profit}(\textsc{Opt}(I))$, respectively) and at most the first $b(n)$ bits of ϕ have been accessed by $\textsc{Alg}$.[1] We sometimes simply write b instead of $b(n)$ to increase readability.

The motivation for online algorithms with advice is mostly of a theoretical nature, as we may think of the information necessary and sufficient to compute an optimal solution as the *information content* of the given problem [12]. Moreover, there is a non-trivial connection to randomized online algorithms [3, 13]. Lower bounds on the advice complexity often translate

[1] Note that usually an additive constant is included in the definition of c-competitiveness, i. e., in (1) and (2). However, for the problems we consider, this changes the advice complexity by at most $O(\log n)$; see Remark 9 in Boyar et al. [7].

to lower bounds for semi-online algorithms. Essentially, here one studies whether knowing some small parameter of an online problem (such as the length of the input or the number of requests of a certain type) results in a much better competitive ratio. Lower bound results using advice can often help to answer this question. Similarly, lookahead can be seen as a special kind of advice that is supplied to an algorithm. This way, online algorithms with advice generalize a number of concepts introduced to give online algorithms more power. However, the main question posed is how much any kind of (computable) information could help; and maybe even more importantly, which amount of information will never help to overcome some certain threshold, no matter what this information actually is.

Organization, Related Work, and Results

We are mainly concerned with proving lower bounds of the form that a particular number of advice bits is necessary in order to obtain some certain output quality for a given hereditary property. We make heavy use of online reductions between generic problems and the studied ones that allow us to bound the number of advice bits necessary from below. Emek et al. [11] used this technique in order to prove lower bounds for metrical task systems. The foundations of the reductions as we perform them here are due to Böckenhauer et al. [2], who introduced the *string guessing problem*, and Boyar et al. [7], who studied a problem called *asymmetric string guessing*. Mikkelsen [20] introduced a problem, which we call the *anti-string guessing problem*, and which is a variant of string guessing with a more "friendly" cost function. Our reductions rely on some results from Bartal et al. [1] that characterize hereditary properties by forbidden subgraphs together with some insights from Ramsey theory (see, e. g., Diestel [8]).

In Section 2, we recall some basic results from Ramsey theory and define the generic online problems that we use as a basis of our reductions. In Section 3, we study both Max-π and Min-π in the case that no preemption is allowed; using a reduction from the asymmetric string guessing problem, we show that any c-competitive online algorithm for Max-π needs roughly n/c advice bits, and this is essentially tight. This complements results from Bartal et al. [1], which state that, without any advice, even a randomized algorithm cannot achieve a competitive ratio better than $\Omega(n^{1-\log_4 3-o(1)})$. The advice complexity of the maximum independent set problem on bipartite and sparse graphs was studied by Dobrev et al. [10]. In the subsequent sections, we allow the online algorithm to use preemption. In Section 4, we use a reduction from the string guessing problem to show a lower bound of $\Omega(n/(c^2 \log c))$ on the number of advice bits that are needed to obtain competitive ratio c, where c is any increasing function bounded from above by $\sqrt{n/\log n}$. In Section 5, using a reduction from the anti-string guessing problem, we also give a linear lower bound for c being close to 1.

Due to space constraints, some of the proofs are omitted.

2 Preliminaries

Hereditary properties can be characterized by forbidden induced subgraphs as follows: if a graph G does not satisfy a hereditary property π, then any graph H such that G is an induced subgraph of H does not satisfy π neither. Hence, there is a (potentially infinite) set of minimal forbidden graphs (w.r.t. being induced subgraph) S_π such that G satisfies π if and only if no graphs from S_π are induced subgraphs of G. Conversely, any set of graphs S defines a hereditary property π_S of not having a graph from S as induced subgraph.

Furthermore, there is the following bijection between hereditary and cohereditary properties: for a hereditary property π we can define a property $\overline{\pi}$ such that a graph G satisfies $\overline{\pi}$

if and only if it does not satisfy π (it is easy to see that $\overline{\pi}$ is cohereditary), and vice versa. Hence, a cohereditary property $\overline{\pi}$ can be characterized by a set of minimal (w.r.t. being induced subgraph) *obligatory* subgraphs $S_{\overline{\pi}}$ such that a graph G has the property $\overline{\pi}$ if and only if at least one graph from $S_{\overline{\pi}}$ is an induced subgraph of G.

To each property π we can define the complementary property π^c such that a graph G satisfies π^c if and only if the complement of G satisfies π. Clearly, if π is (co)hereditary, so is π^c. Moreover, if H is forbidden (obligatory, respectively) for π, $\overline{H}$ is forbidden (obligatory, respectively) for π^c. The following statement is due to Lewis and Yannakakis.

▶ **Lemma 1** (Lewis and Yannakakis [15], proof of Theorem 4)**.** *Every non-trivial hereditary property π is satisfied either by all cliques or by all independent sets.*

Proof. Assume, for the sake of contradiction, that there is a hereditary property π, and two numbers m, n, such that K_m and $\overline{K}_n$ do not satisfy π. Let $r(m,n)$ be the Ramsey number[17], such that every graph with at least $r(m,n)$ vertices contains K_m or $\overline{K}_n$ as induced subgraph. Since π is non-trivial, there is a graph G with more than $r(m,n)$ vertices that satisfies π. G contains either K_m or $\overline{K}_n$ as induced subgraph, and since π is hereditary, either K_m or $\overline{K}_n$ satisfies π. ◀

Bartal et al. proved the following theorem. It is formulated in the known supergraph model, where a graph $G=(V,E)$ with n vertices is a-priori known to the algorithm, and the input is a sequence of vertices $v_1,\ldots,v_k$. The task is to select in an online manner the subgraph of the induced graph $G[v_1,\ldots,v_k]$ having property π.

▶ **Theorem 2** (Bartal et al. [1] and references therein)**.** *In the known supergraph model, any randomized algorithm for the* Max-π *problem has competitive ratio*

$$\Omega\left(n^{1-\log_4 3-o(1)}\right),$$

even if preemption is allowed.

Note that n in the previous theorem thus refers to the size of the known supergraph, and not to the length of the input sequence. However, in the proof a graph with $n=4^i$ vertices is considered, from which subgraphs of size 3^i are presented. Each of these instances has an optimal solution of size at least 2^i, and it is shown that any deterministic algorithm can have a profit of at most $\alpha(3/2)^i\log n$ on average, for some constant α. From that, using Yao's principle [19] as stated in [6], the result follows. The same set of instances thus yields the following result.

▶ **Theorem 3** (Bartal et al. [1])**.** *Any randomized algorithm for the* Max-π *problem has competitive ratio*

$$\Omega\left(n^{2/\log 3-1-o(1)}\right),$$

even if preemption is allowed.

Next, we describe some specific online problems that allow us to give lower bounds on the advice complexity using a special kind of reduction. Böckenhauer et al. [2] introduced a very generic online problem called *string guessing with known history over alphabets of size σ* (σ-SGKH). The input is a sequence of requests $(x_0,\ldots,x_n)$ where $x_0=n$ and for $i\geq 1$, $x_i\in\{1,\ldots,\sigma\}$. The algorithm has to produce a sequence of answers $(y_1,\ldots,y_n,y_{n+1})$, where $y_i\in\{1,\ldots,\sigma\}$ and $y_{n+1}=\perp$ and where y_i is allowed to depend on $x_0,\ldots,x_{i-1}$ (and of course any advice bits the algorithm reads). The cost is the number of positions i for which $y_i\neq x_i$.

▶ **Theorem 4** (Böckenhauer et al. [2]). *Let $\sigma \geq 2$. Any online algorithm with advice for σ-SGKH that guesses γn bits of the input correctly must read at least*

$$\left(1 + (1-\gamma)\log_\sigma\left(\frac{1-\gamma}{\sigma-1}\right) + \gamma \log_\sigma \gamma\right) n \log \sigma$$

bits of advice.

Mikkelsen [20] introduced the problem *anti-string guessing with known history over alphabets of size σ* (Anti-σ-SGKH). It is defined exactly as σ-SGKH except that the cost is the number of positions i for which $y_i = x_i$.

▶ **Theorem 5** (Mikkelsen [20, Theorem 11]). *Let $\sigma \geq 2$ and let $1 \leq c < \sigma/(\sigma-1)$. Any c-competitive Anti-σ-SGKH algorithm must read at least*

$$\left(1 - h_\sigma\left(\frac{1}{c}\right)\right) n \log \sigma$$

bits of advice, where n is the input length. This holds even if n is known in advance. Here, h_σ is the σ-ary entropy function given by $h_\sigma(x) = x\log_\sigma(\sigma-1) - x\log_\sigma x - (1-x)\log_\sigma(1-x)$.

Boyar et al. [7] investigated a problem called *maximum asymmetric string guessing* (maxASGk). The input is a sequence of requests $(x_0, \ldots, x_n)$ where $x_0 = \perp$ and for $i \geq 1$, $x_i \in \{0,1\}$. The algorithm has to produce a sequence of answers $(y_1, \ldots, y_n, y_{n+1})$. The output is feasible if $x_i \leq y_i$ for all $1 \leq i \leq n$. The profit of the algorithm is the number of zeros in $y_1, \ldots, y_n$ for feasible outputs, and $-\infty$ otherwise. The "blind" version of the problem, where the algorithm has to produce the output without actually seeing the requests (i. e., in each step, the algorithm receives some dummy request $\perp$), is denoted maxASGu. In what follows, let

$$B_c := \log\left(1 + \frac{(c-1)^{c-1}}{c^c}\right) \approx \frac{1}{c} \cdot \frac{1}{\mathrm{e}\ln 2}\ .$$

▶ **Theorem 6** (Boyar et al. [7]). *For any function $c(n)$ such that $1 \leq c(n) \leq n$, there is a c-competitive algorithm for maxASGk (maxASGu, respectively) with advice of size $B_c \cdot n + O(\log n)$. Moreover, any c-competitive algorithm for maxASGk (maxASGu, respectively) must read at least*

$$B_c \cdot n - O(\log n)$$

bits of advice.

Note that, in general, it does not make much difference if the length of the input is initially known to the algorithm or not. More specifically, it changes the advice complexity by at most $O(\log n)$.

3 Max-π and Min-π without Preemption

First, we show that for any non-trivial hereditary property π, the Max-π problem is equivalent to asymmetric string guessing in the following sense.

▶ **Theorem 7.** *If there is a c-competitive algorithm for maxASGu, then there is a c-competitive algorithm for Max-π using the same advice.*

▶ **Theorem 8.** *If there is a c-competitive algorithm for* Max-Π *that reads $b(n)$ bits of advice, then there is a c-competitive algorithm for* maxASGk *using*

$$b(n) + O(\log^2 n)$$

bits of advice.

The proof of Theorem 7 is omitted due to space constraints. Before proving Theorem 8, let us recall Lemma 3 from Bartal et al. [1].

▶ **Lemma 9** (Bartal et al. [1]). *Given any graph H, there exist constants n_0 and α such that for all $n > n_0$ there exists a graph G on n vertices such that any induced subgraph of G on at least $\alpha \log n$ vertices contains H as an induced subgraph.*

This is a variant of Lemma 9 from Lund and Yannakakis[2] [16].

▶ **Lemma 10** (Lund and Yannakakis [16]). *Let H be a graph on k vertices. For sufficiently large N, for any graph G on N vertices and for all $\ell = \Omega(\log N)$, a random subgraph G' of G does not, with probability $1/2$, contain a subset S of ℓ vertices that is a clique in G but H is not an induced subgraph of $G'[S]$.*

Proof of Theorem 8. According to Lemma 1, π is satisfied either by all cliques or by all independent sets. Without loss of generality, suppose the latter (otherwise, swap the edges and non-edges in the following arguments).

Consider a binary string $\nu = x_1, \ldots, x_n$ (for large enough n). Let us consider the graph $G_\nu = (V, E)$ defined as follows. Let H be an arbitrary but fixed forbidden subgraph of π. Let G' be the n-vertex graph from Lemma 9 with vertices $V = \{v_1, \ldots, v_n\}$. If $x_i = 0$ for some i, delete from G' all edges $\{v_i, v_j\}$ for $j > i$. In the graph G_ν defined this way, the vertices v_i for which the corresponding x_i satisfies $x_i = 0$ (denoted by $I_\nu \subseteq V$ in the sequel) form an independent set, and hence $G_\nu[I_\nu]$ has property π. On the other hand, any induced subgraph $G_\nu[S]$ with property π can contain at most $\alpha \log n$ vertices from $V \setminus I_\nu$ (otherwise it would contain the forbidden graph H as induced subgraph). Note that, with $O(\log n)$ bits of advice to encode n, the graph G_ν can be constructed from the string ν in an online manner: the base graph G' is fixed for a fixed n, and the subgraph $G_\nu[v_1, \ldots, v_i]$ depends only on the values of $x_1, \ldots, x_{i-1}$.

Now consider a c-competitive algorithm Alg$_\pi$ for Max-Π that uses b bits of advice. Let us describe how to derive an algorithm Alg for maxASGk from Alg$_\pi$. For a given string $\nu = x_1, \ldots, x_n$, where $\perp, x_1, \ldots, x_n$ is the input for maxASGk, the advice for Alg consists of three parts: first, there is a self-delimiting encoding of n using $O(\log n)$ bits, followed by a (self-delimiting) correction string e_ν of length $O(\log^2 n)$ bits described later, and the rest is the advice for Alg$_\pi$ on the input G_ν. Let S be the solution (set of vertices) returned by Alg$_\pi$ on G_ν (with the proper advice). As argued before, S can contain at most $\alpha \log n$ vertices from $V \setminus I_\nu$. The indices of these vertices from $S_{\text{out}} := S \cap (V \setminus I_\nu)$ are part of the string e_ν. Apart from that, e_ν contains the indices of at most $\alpha \log n$ vertices $S_{\text{in}} \subseteq I_\nu$ such that $|(S \setminus S_{\text{out}}) \cup S_{\text{in}}| = \min\{|S|, |I_\nu|\}$.

The algorithm Alg works as follows: at the beginning, it constructs the graph G'. When a request x_i arrives, Alg sends the new vertex v_i of G_ν to Alg$_\pi$, and finds out whether

[2] Note that the original lemma speaks about pseudo-random subgraphs, which is a stronger assumption that we do not need here.

$v_i \in S$. If $v_i \in S_{\text{in}}$, ALG answers 0 regardless of the answer of ALG_π. Similarly, if $v_i \in S_{\text{out}}$, ALG answers 1. Otherwise, ALG answers 0 if and only if $v_i \in S$.

First, note that ALG always produces a feasible solution: if the input $x_i = 1$, then either $v_i \notin S$ and ALG returns $y_i = 1$, or else v_i is included in S_{out}. Moreover, the number of zeros (the profit) in the output of ALG is $\min\{|S|, |I_\nu|\}$, where $|I_\nu|$ is the profit of the optimal solution. Since ALG_π is c-competitive, $|S| \geq 1/c \cdot \text{profit}(\text{OPT}(G_\nu)) \geq 1/c \cdot |I_\nu|$. ◀

▶ **Corollary 11.** *Let π be any non-trivial hereditary property. Let $A_{c,n}$ be the minimum advice needed for a c-competitive* MAX-Π *algorithm. Then*

$$B_c \cdot n - O(\log^2 n) \leq A_{c,n} \leq B_c \cdot n + O(\log n) \ .$$

We have shown that the advice complexity of MAX-Π essentially does not depend on the choice of the property π. Interestingly, this is not the case for cohereditary properties and MIN-Π. On the one hand, there are cohereditary properties where little advice is sufficient for optimality as the following theorem shows.

▶ **Theorem 12.** *If a cohereditary property π can be characterized by finitely many obligatory subgraphs, there is an optimal algorithm for* MIN-Π *with advice $O(\log n)$.*

Proof. Since each obligatory subgraph has constant size, $O(\log n)$ bits can be used to encode the indices of the vertices (forming the smallest obligatory subgraph) that are included in an optimal solution. ◀

On the other hand, there are properties for which MIN-Π requires large advice as stated by the following theorem, which was proven by Boyar et al. [7]. The problem *minimum cycle finding* requires to identify a smallest possible set of vertices S such that $G[S]$ contains a cycle. Hence, it is the MIN-Π problem for the non-trivial cohereditary property "contains cycle."

▶ **Theorem 13** (Boyar et al. [7]). *Any c-competitive algorithm for the* minimum cycle finding problem *must read at least*

$$B_c \cdot n - O(\log n)$$

bits of advice.

An upper bound analogous to Theorem 7 also follows from the results of Boyar et al. [7]. Note that, for the minimum cycle finding problem, this bound is tight up to an additive constant of $O(\log n)$.

▶ **Theorem 14.** *Let π be any non-trivial cohereditary property. There is a c-competitive algorithm for* MIN-Π *which reads*

$$B_c \cdot n + O(\log n)$$

bits of advice.

4 Max-Π with Preemption – Large Competitive Ratios

In this and the subsequent section, we consider the problem MAX-Π with preemption where π is a non-trivial hereditary property. In every time step, an online algorithm can either accept or reject the currently given vertex and preempt any number of vertices that it accepted in previous time steps. However, vertices that were once rejected or preempted cannot be accepted in later time steps. The goal is to accept as many vertices as possible. After each request, the current solution is required to have the property π.[3] Using a string guessing reduction, we can prove the following theorem; due to space constraints, we only give the idea.

▶ **Theorem 15.** *Consider the* Max-Π *problem with preemption for a hereditary property π with a forbidden subgraph H, such that π holds for all independent sets. Let $c(n)$ be an increasing function such that $c(n)\log c(n) = o(\sqrt{n/\log n})$. Any $c(n)$-competitive* Max-Π *algorithm must read at least*

$$\Omega\left(\frac{n}{c(n)^2 \log c(n)}\right)$$

bits of advice.

Proof Sketch. First, for some given n and σ, let us define the graph $G_{n,\sigma}$ that will be used in the reduction. To ease the presentation, assume that $n' = n/\sigma$ is integer. Let G_1 be a graph with σ vertices, the existence of which is asserted by Lemma 9, such that any subgraph of G_1 with at least $\kappa_1 \log \sigma$ vertices contains H as induced subgraph. Let G_B be the complement of a union of n' cliques of size σ each (i. e., G_B consists of n' independent sets $V_1, \ldots, V_{n'}$ of size σ each, and all remaining pairs of vertices are connected by edges). Applying Lemma 10 to G_B proves the existence of a graph $G_2 \subseteq G_B$ such that any subset of G_2 with at least $\kappa_2 \log n$ vertices contains H as an induced subgraph. The graph $G_{n,\sigma}$ is obtained from G_2 by replacing each independent set V_i with a copy of G_1 (each such copy is called a "layer" in what follows).

Let us suppose that a $c(n)$-competitive Max-Π algorithm Alg is given that uses $b(n)$ advice bits on instances of size n. Now fix an arbitrary n, and choose $\sigma := 4c\kappa_1 \log(4c\kappa_1)$. We show how to solve instances of σ-SGKH of length $n'-1$ using Alg. Let $q_1, \ldots, q_{n'-1}$ be the instance of σ-SGKH, where $q_i \in \{1, \ldots, \sigma\}$. The corresponding instance G for the Max-Π problem is as follows: take the graph $G_{n,\sigma}$, and denote by $v_{i,1}, \ldots, v_{i,\sigma}$ the vertices of the set V_i. Let v_{i,q_i} be the *distinguished* vertex in set V_i. Delete from $G_{n,\sigma}$ all edges of the form $\{v_{i,q_i}, v_{i',q_{i'}}\}$ where $i' > i$. The resulting graph G is presented to Alg in the order $v_{1,1}, \ldots, v_{1,\sigma}, v_{2,1}, \ldots, v_{2,\sigma}, \ldots$.

Note that G can be constructed online based on the instance $q_1, \ldots, q_{n'-1}$. The distinguished vertices form an independent set of size n', and thus a feasible solution. On the other hand, apart from the distinguished vertices, any solution can have at most $\kappa_1 \log \sigma$ vertices in one layer (otherwise, there would be a forbidden subgraph in that layer), and at most $\kappa_2 \log n$ layers with vertices other than the distinguished ones (if there are more than $\kappa_2 \log n$ nonempty layers, choose one vertex from each nonempty layer; these form a clique in G_B, and due to Lemma 10 induce H in G_2, and thus also in G). Hence, $n' \le \text{profit}(\text{Opt}(G)) \le n' + K$, where $K := \kappa_1\kappa_2 \log \sigma \log n$.

Since Alg is c-competitive, it produces a solution of size at least $\text{profit}(\text{Opt}(G))/c$. Since any solution can have at most K non-distinguished vertices, the solution of Alg contains at least $g := \text{profit}(\text{Opt}(G))/c - K$ distinguished vertices.

[3] Note that without preemption, the condition to maintain π in every time step is implicit. Indeed, if π is violated in some step, the algorithm has accepted a forbidden subgraph, which means that no matter how the sequence continues, the solution will ultimately be invalid. Let us emphasize that any algorithm that works for the case without preemption also works with preemption.

Consider an algorithm ALG$'$ for σ-SGKH on an instance of length $n'-1$, which simulates ALG. For the ith request, it presents ALG the layer of vertices V_i. Let $\mathrm{Cand}(i) \subseteq V_i$ (the *candidate* set) be the set of vertices selected by ALG from V_i. As stated before, $|\mathrm{Cand}(i)| \leq \kappa_1 \log \sigma$. A set $\mathrm{Cand}(i)$ is *good* if it contains the distinguished vertex v_{i,q_i}. It follows from the definition of the problem that there are at least g good candidate sets.

ALG$'$ uses an additional $O(\log\log\sigma)$ bits of advice to describe a number j with $1 \leq j \leq \kappa_1 \log \sigma$, and selects the jth vertex from any set $\mathrm{Cand}(i)$ as an answer (if $|\mathrm{Cand}(i)|$ is smaller than j, it is extended in an arbitrary fixed way). The number j is selected in such a way that ALG$'$ gives the correct answer for a fraction of $1/(\kappa_1 \log \sigma)$ of the good sets. As a result, the fraction of correctly guessed numbers by ALG$'$ is at least

$$\alpha := \frac{n' - cK}{c\kappa_1 \log \sigma (n'-1)} \ .$$

Note that $1/(c\kappa_1 \log\sigma) \geq \alpha \geq 1/(2c\kappa_1 \log \sigma)$ holds for large enough n, provided that $n' \geq 2cK - 1$. To see that this inequality holds, note that

$$n' \geq 2cK - 1 \iff \frac{n}{4c\kappa_1 \log(4c\kappa_1)} \geq 2cK - 1 \iff (2cK-1)4c\kappa_1 \log(4c\kappa_1) \leq n \ .$$

The last inequality holds for large enough n by the choice of $c(\cdot)$ due to the fact that

$$(2cK-1)4c\kappa_1 \log(4c\kappa_1) \in O(c(n)^2 K \log c(n)) = O((c(n)\log c(n))^2 \log n) = o(n) \ .$$

Due to Theorem 4, any algorithm for σ-SGKH that correctly guesses a fraction of α numbers (for $1/\sigma \leq \alpha \leq 1$) on an input of length $n'-1$ requires at least $b := F(\sigma,\alpha)\cdot(n'-1)\cdot\log\sigma$ bits of advice where

$$F(\sigma,\alpha) := 1 + (1-\alpha)\log_\sigma\left(\frac{1-\alpha}{\sigma-1}\right) + \alpha \log_\sigma \alpha \ .$$

It can be shown that $F(\sigma,\alpha)\log\sigma \in \Omega(1/c)$. Finally, the theorem follows by noting that $n'-1 \in \Omega(n/(c\log c))$. ◀

Using a similar approach, we can get a stronger bound for the independent set problem; the proof is omitted due to space constraints.

▶ **Theorem 16.** *Let $c(n)$ be any function such that*

$$8 \leq c(n) \leq \frac{1+\sqrt{1+4n}}{4} \ .$$

Any $c(n)$-competitive independent set algorithm that can use preemption must read at least

$$\frac{0.01 \cdot \log(2c)}{2c^2}(n-2c)$$

bits of advice.

5 Max-π with Preemption – Small Competitive Ratios

In this section, we use Theorem 5 to give bounds for small constant values of the competitive ratio for algorithms for MAX-π complementing the bounds from Theorem 15. In what follows, π is a non-trivial hereditary property and k is the size of a smallest forbidden subgraph with respect to π.

▶ **Theorem 17.** *If there is a c-competitive algorithm for* Max-Π *with preemption that reads $b(kn)$ bits of advice for inputs of length kn, then there exists a c-competitive algorithm for Anti-k-SGKH, which, for inputs of length n, reads*

$$b(kn) + O(\log^2 n)$$

bits of advice.

Proof. According to Lemma 1, π is satisfied either by all cliques or by all independent sets. As in the proof of Theorem 8, we assume in the following that π is satisfied by all independent sets (if it is not, we can use the same argument by swapping edges and non-edges between layers). We describe how to transform an instance of Anti-k-SGKH into an instance of Max-Π with preemption. The length of the instance for Max-Π with preemption will be k times as long as the length n of the Anti-k-SGKH instance. We proceed to show that a c-competitive algorithm for the latter implies a c-competitive algorithm for the former which reads at most $O((\log n)^2)$ additional advice bits.

Let $\nu = x_1, \ldots, x_n$ with $x_i \in \{1, \ldots, k\}$ be an instance of Anti-k-SGKH. Consider the n-vertex graph $\tilde{G} = (V(\tilde{G}), E(\tilde{G}))$ given by Lemma 9 for a size-k smallest minimal forbidden subgraph $H = (V(H), E(H))$ for π. Recall that any induced subgraph of $\tilde{G}$ with at least $\alpha \log n$ vertices contains H as an induced subgraph. Let us denote $V(\tilde{G}) = \{\tilde{v}_1, \ldots, \tilde{v}_n\}$ and $V(H) = \{h_1, \ldots, h_k\}$. We now describe the construction of a graph $G_\nu = (V(G_\nu), E(G_\nu))$, which will be the input for the given algorithm for Max-Π. To this end, let

$$V(G_\nu) := \bigcup_{i=1}^{n} \bigcup_{j=1}^{k} v_j^i,$$

$$E(G_\nu) := \{\{v_j^i, v_{j'}^i\} \mid \{h_j, h_{j'}\} \in E(H)\} \cup \{\{v_j^i, v_{j'}^{i'}\} \mid i < i', \{\tilde{v_j}, \tilde{v_{j'}}\} \in E(\tilde{G}), j \neq x_i\},$$

where we assume an ordering $v_1^1, \ldots, v_k^1, v_1^2, \ldots, v_k^2, \ldots, v_1^n, \ldots, v_k^n$ on the vertices. Moreover, we denote the requests $v_1^i, \ldots, v_k^i$ as layer i. Let X denote the set of vertices $v_{x_i}^i$ for $i \in \{1, \ldots, n\}$.

We start with a few observations about G_ν that are straightforward.

▶ **Observation 18.** *$G_\nu[X]$ is an independent set of size n. In particular, it has property π.*

▶ **Observation 19.** *$G_\nu[v_1^i, \ldots, v_k^i] = H$ for an arbitrary but fixed i. Thus, any induced subgraph of G_ν that contains $G_\nu[v_1^i, \ldots, v_k^i]$ does not have property π.*

▶ **Observation 20.** *Consider a set of vertices, V, in G_ν which is disjoint from X. If $|V| \geq k\alpha \log n$, then $G_\nu[V]$ does not have property π. Note that V must in this case contain vertices from at least $\alpha \log n$ different layers. These have H as an induced subgraph since none of them are in X.*

Now consider a c-competitive algorithm Alg$_\pi$ for Max-Π with preemption reading $b(kn)$ bits of advice (recall that kn is the length of its input G_ν). We start by describing an algorithm Alg$'$ for Anti-k-SGKH, which uses $b(kn)$ bits of advice (n is the length of its input). Afterwards, we use Alg$'$ to define another algorithm Alg for Anti-k-SGKH, which uses $O(\log^2 n)$ additional advice bits and is c-competitive.

For a given string $\nu = x_1, \ldots, x_n$, let $\perp, x_1, \ldots, x_n$ be the input for Anti-k-SGKH. Let S be the solution (set of vertices) returned by Alg$_\pi$ on G_ν (with the proper advice). Note that this is the resulting set of vertices after the unwanted vertices have been preempted. Alg$'$ works as follows: It constructs the graph G_ν online and simulates Alg$_\pi$ on it. When a request i arrives, the goal of Alg$'$ is to guess a number in $\{1, \ldots, k\}$ different from x_i.

It does this by presenting all vertices in layer i to $\textsc{Alg}_\pi$. It is important to note that the vertices in layer i can be presented without knowledge of $x_i, \ldots, x_n$. Let S_i denote the set of these vertices, which are accepted by $\textsc{Alg}_\pi$ and have not been preempted after request v_k^i. In layer i, $\textsc{Alg}'$ outputs $y_i = w$ where w is the smallest number in $\{1, \ldots, k\}$ such that $v_w^i \notin S_i$. Note that such a number always exists due to Observation 19.

We now describe $\textsc{Alg}$, which uses $O(\log^2 n)$ additional advice bits. The advice for $\textsc{Alg}$ consists of three parts (similar to the proof of Theorem 8). First, it contains a self-delimiting encoding of n (this requires $O(\log n)$ bits). This is followed by a list of up to $k\alpha \log n$ indices i, where $\textsc{Alg}'$ outputs $y_i = x_i$. Let S_{error} denote the set of these indices. A self-delimiting encoding of this requires $O(\log^2 n)$ bits (recall that α and k are constant). Finally, the advice which $\textsc{Alg}'$ received is included. This is $b(kn)$ bits.

$\textsc{Alg}$ works as follows for each request. If the request is not in S_{error}, it outputs the same as $\textsc{Alg}'$. Conversely, if the request is in S_{error}, it outputs another number in $\{1, \ldots, k\}$.

We now argue that $\textsc{Alg}$ is c-competitive. Note that the optimal offline solution for G_ν contains at most $k\alpha \log n$ vertices not in X. The same of course holds for the solution produced by $\textsc{Alg}_\pi$. Moreover, it holds that if in layer i the algorithm $\textsc{Alg}_\pi$ accepts a vertex in X, then $\textsc{Alg}'$ outputs $y_i \neq x_i$. This means that the score of $\textsc{Alg}_\pi$ is at most $k\alpha \log n$ more than the score of $\textsc{Alg}'$. Since the score of $\textsc{Alg}$ is $k\alpha \log n$ more than the score of $\textsc{Alg}'$, we have that $\textsc{Alg}$ is c-competitive. ◀

Combining Theorems 5 and 17, we get the following corollary.

▶ **Corollary 21.** *Let $1 < c < k/(k-1)$. Let π be any non-trivial hereditary property with a minimal forbidden subgraph of size k. Any c-competitive algorithm for* $\textsc{Max}$-Π *with preemption must read at least*

$$\left(1 - h_k\left(\frac{1}{c}\right)\right) n \frac{\log k}{k} - O(\log^2 n)$$

bits of advice, where n is the input length. Here, h_k is the k-ary entropy function given by $h_k(x) = x \log_k(k-1) - x \log_k x - (1-x)\log_k(1-x)$.

6 Closing Remarks

In Corollary 11, we describe lower and upper bounds for the advice complexity of all online hereditary graph problems, which are essentially tight (there is just a gap of $O(\log^2 n)$). It turns out that, for all of them, roughly the same amount of information about the future is required to achieve a certain competitive ratio.

Intriguingly, we see quite a different picture for cohereditary properties. Theorem 14 gives the same upper bound as we had for hereditary properties, and Theorem 13 shows that this upper bound is essentially tight. However, Theorem 12 shows that there exist cohereditary problems that have an advice complexity as low as $O(\log n)$ bits to be optimal. It remains open if it is only those problems with a finite set of obligatory graphs that have this very low advice complexity, or if this can also happen for cohereditary problems with an infinite set of obligatory graphs.

For hereditary problems with preemption, we show that to achieve a competitive ratio strictly smaller than $k/(k-1)$, a linear number of advice bits is needed. This is asymptotically tight, since optimality (even without preemption) can be achieved with n bits. Furthermore, we show a lower bound for non-constant competitive ratios (that are roughly smaller than $\sqrt{n}$). It remains open if there is an algorithm for the preemptive case which uses fewer advice bits than the algorithms solving the same problem in the non-preemptive case.

Abstract

We study the complexity of predicate logics based on team semantics. We show that the satisfiability problems of two-variable independence logic and inclusion logic are both *NEXPTIME*-complete. Furthermore, we show that the validity problem of two-variable dependence logic is undecidable, thereby solving an open problem from the team semantics literature. We also briefly analyse the complexity of the Bernays-Schönfinkel-Ramsey prefix classes of dependence logic.

1 Introduction

The satisfiability problem of *two-variable logic* FO^2 was shown to be *NEXPTIME*-complete in [9]. The extension of two-variable logic with counting quantifiers, FOC^2, was proved decidable in [10, 22], and it was subsequently shown to be *NEXPTIME*-complete in [23]. Research on extensions and variants of two-variable logic is currently very active. Recent research efforts have mainly concerned decidability and complexity issues in restriction to particular classes of structures and also questions related to different built-in features and operators that increase the expressivity of the base language. Recent articles in the field include for example [1], [4], [13], [16], [24], and several others.

In this article we study two-variable fragments of logics based on *team semantics*. Team semantics was originally conceived in [15] in the context of *independence friendly* (IF) *logic* [14]. In [25], Väänänen introduced *dependence logic*, which is a novel approach to IF logic based on new atomic formulas $=(x_1, ...x_k, y)$ stating that the interpretation of the variable y is functionally determined by the interpretations of the variables $x_1, ..., x_k$.

After the introduction of dependence logic, research on logics based on team semantics has been active. Several different logics with different applications have been suggested. In particular, team semantics has proved to be a powerful framework for studying different kinds of *dependency notions*. *Independence logic* [11] is a variant of dependence logic that extends first-order logic by new atomic formulas $x_1, ..., x_k \perp y_1, ..., y_l$ with the intuitive meaning that the interpretations of the variables $x_1, ..., x_k$ are informationally independent of the interpretations of the variables $y_1, ..., y_l$. *Inclusion logic* [6] extends first-order logic by atomic formulas $x_1, ..., x_k \subseteq y_1, ..., y_k$, whose intuitive meaning is that tuples interpreting the variables $x_1, ..., x_k$ are also tuples interpreting $y_1, ..., y_k$. Currently dependence, independence and inclusion logics are the three most important and most widely studied systems based on team semantics.

Both dependence logic and independence logic are equiexpressive with existential second-order logic (see [25], [11]), and thereby capture NP. Curiously, inclusion logic is equiexpressive with *greatest fixed point logic* (see [7]), and thereby characterizes P on finite ordered models. While the descriptive complexity of most known logics based on team semantics is understood reasonably well, the complexity of related satisfiability problems has received somewhat less attention. The satisfiability problem of the two-variable fragment of dependence logic and IF-logic have been studied in [18]. It is shown that while the two-variable IF-logic is undecidable, the corresponding fragment of dependence logic is *NEXPTIME*-complete.

In this article we establish that the satisfiablity problems of the two-variable fragments of independence and inclusion logics are likewise *NEXPTIME*-complete. This result is established via proving a more general theorem that implies also a range of other decidability results for a variety of team-semantics-based logics with generalized dependency notions. Furthermore, we prove that the *validity* problem of two-variable dependence logic is undecidable; this result is the main result of the paper. The problem has been open for some time in the team semantics literature and has been explicitly posed in, e.g., [5], [18], [26], and elsewhere.

In addition to studying two-variable logics, we study the Bernays-Schönfinkel-Ramsey prefix class, i.e., sentences with the quantifier prefix $\exists^*\forall^*$. We show that—as in the case of ordinary first-order logic—the prefix class $\exists^*\forall^*$ of $\mathsf{FO}(\mathcal{A})$ is decidable for any uniformly polynomial time computable class $\mathcal{A}$ of generalized dependencies closed under substructures. We prove inclusion in 2*NEXPTIME*, and furthermore, for vocabularies of fixed arity, we show *NEXPTIME*-completeness. We also prove a partial converse of the result concerning logics $\mathsf{FO}(\mathcal{A})$ with a decidable prefix class $\exists^*\forall^*$, see Theorem 22.

2 Preliminaries

The domain of a structure $\mathfrak{A}$ is denoted by A. We assume that the reader is familiar with first-order logic FO. The extension of FO with counting quantifiers $\exists^{\geq i}$ is denoted by FOC. The two-variable fragments FO^2 and FOC^2 are the fragments of FO and FOC with formulas in which only the variables x and y appear. We let Σ_1^1 denote the fragment of formulas of second-order logic of the form $\exists X_1 ... \exists X_k\, \varphi$, where $X_1, ..., X_k$ are relation symbols and φ a first-order formula. $\Sigma_1^1(\mathsf{FOC}^2)$ is the extension of FOC^2 consisting of formulas of the form $\exists X_1 ... \exists X_k\, \chi$, where $X_1, ..., X_k$ are relation symbols and χ a formula of FOC^2.

2.1 Logics based on team semantics

Let $\mathbb{Z}_+$ denote the set of positive integers, and let $\mathrm{VAR} = \{ v_i \mid i \in \mathbb{Z}_+ \}$ be the set of exactly all first-order *variable symbols*. We mainly use metavariables x, y, z, x_1, x_2, etc., in order to refer to variable symbols in VAR. We let $\overline{x}, \overline{y}, \overline{z}, \overline{x}_1, \overline{x}_2$, etc., denote finite nonempty tuples of variable symbols, i.e., tuples in VAR^n for some $n \in \mathbb{Z}_+$. When we study two-variable logics, we use the metavariables x and y, and assume they denote distinct variables in VAR.

Let $D \subseteq \mathrm{VAR}$ be a *finite*, possibly empty set. Let $\mathfrak{A}$ be a model. We do not allow for models to have an empty domain, so $A \neq \emptyset$. A function $s : D \to A$ is called an *assignment* with codomain A. If $\overline{x} = (x_1, \ldots, x_n)$, we denote $(s(x_1), \ldots, s(x_n))$ by $s(\overline{x})$. We let $s[a/x]$ denote the variable assignment with the domain $D \cup \{ x \}$ and codomain A defined such that $s[a/x](y) = a$ if $y = x$, and $s[a/x](y) = s(y)$ if $y \neq x$. Let $T \in \mathcal{P}(A)$, where $\mathcal{P}$ denotes the power set operator. We define $s[\,T/x\,] \;=\; \{\; s[a/x] \mid a \in T \;\}$.

Let $D \subseteq \mathrm{VAR}$ be a finite, possibly empty set of first-order variable symbols. Let X be a set of assignments $s : D \to A$. Such a set X is a *team* with the *domain* D and *codomain* A. Note that the empty set is a team, as is the set $\{\emptyset\}$ containing only the empty assignment. The team $\emptyset$ does not have a unique domain; any finite subset of VAR is a domain of $\emptyset$. The domain of the team $\{\emptyset\}$ is $\emptyset$.

Let X be a team with the domain D and codomain A. Let $T \subseteq A$. We define $X[T/x] = \{\; s[a/x] \mid a \in T,\;\; s \in X \;\}$. Let $F : X \to \mathcal{P}(A)$ be a function. We define $X[\,F/x\,] = \bigcup_{s\in X} s[\,F(s)/x\,]$. Let $C \subseteq A$. We define $X \upharpoonright C = \{\, s \in X \mid s(x) \in C$ for all $x \in D \,\}$.

Let X be a team with domain D. Let $k \in \mathbb{Z}_+$, and let $y_1, ..., y_k$ be variable symbols. Assume that $\{y_1, ..., y_k\} \subseteq D$. We define $\mathrm{rel}\big(X, (y_1, ..., y_k)\big) \;=\; \{\; \big(s(y_1), ..., s(y_k)\big) \mid s \in X \;\}$.

Let τ be a relational vocabulary, i.e., a vocabulary containing relation symbols only. (In this article we consider only relational vocabularies.) The syntax of a logic based on team semantics is usually given in negation normal form. We shall also follow this convention in the current article. For this reason, we define the syntax of first-order logic as follows.

$$\varphi \quad ::= \quad R(\overline{x}) \mid \neg R(\overline{x}) \mid x_1 = x_2 \mid \neg x_1 = x_2 \mid (\varphi_1 \vee \varphi_2) \mid (\varphi_1 \wedge \varphi_2) \mid \;\exists x\varphi \mid \forall x\varphi \;,$$

where $R \in \tau$. The first four formula formation rules above introduce *first-order literals* to the language. Below we shall consider logics $\mathsf{FO}(\mathcal{A})$, where the above syntax is extended by clauses of the type $A_Q\,(\overline{y}_1, ..., \overline{y}_k)$. Here A_Q is (a symbol corresponding to) a *generalized atom* in $\mathcal{A}$ and each $\overline{y}_i$ is a tuple of variables. Before considering such novel atoms, let us define *lax team semantics* for first-order logic.

▶ **Definition 1** ([15, 25])**.** Let $\mathfrak{A}$ be a model and X a team with codomain A. The satisfaction relation $\mathfrak{A} \models_X \varphi$ is defined as follows.

1. If φ is a first-order literal, then $\mathfrak{A} \models_X \varphi$ iff for all $s \in X$: $\mathfrak{A}, s \models_{\mathsf{FO}} \varphi$. Here $\models_{\mathsf{FO}}$ refers to the ordinary Tarskian satisfaction relation of first-order logic.
2. $\mathfrak{A} \models_X \psi \wedge \varphi$ iff $\mathfrak{A} \models_X \psi$ and $\mathfrak{A} \models_X \varphi$.
3. $\mathfrak{A} \models_X \psi \vee \varphi$ iff there exist teams Y and Z such that $X = Y \cup Z$, $\mathfrak{A} \models_Y \psi$, and $\mathfrak{A} \models_Z \varphi$.
4. $\mathfrak{A} \models_X \exists x\, \psi$ iff $\mathfrak{A} \models_{X[F/x]} \psi$ for some $F\colon X \to (\mathcal{P}(A) \setminus \{\emptyset\})$.
5. $\mathfrak{A} \models_X \forall x\, \psi$ iff $\mathfrak{A} \models_{X[A/x]} \psi$.

Finally, a sentence φ is true in a model $\mathfrak{A}$ ($\mathfrak{A} \models \varphi$) if $\mathfrak{A} \models_{\{\emptyset\}} \varphi$.

▶ **Proposition 2** ([15, 25])**.** *Let ψ be a formula of first-order logic. We have $\mathfrak{A} \models_X \psi$ iff $\mathfrak{A}, s \models_{\mathsf{FO}} \psi$ for all $s \in X$.*

In this paper we consider first-order logic extended with generalized dependency atoms. Before formally introducing the notion of a generalized dependency atom, we recall some particular atoms familiar from the literature related to team semantics.

Dependence atoms $=\!(\overline{x}, y)$, inspired by the slashed quantifiers of Hintikka and Sandu [14], were introduced by Väänänen [25]. The intuitive meaning of the atom $=\!(\overline{x}, y)$ is that the value of the variable y depends solely on the values of the variables in $\overline{x}$. The semantics for dependence atoms is defined as follows: $\mathfrak{A} \models_X =\!(\overline{x}, y)$ iff $\forall s, s' \in X :$ if $s(\overline{x}) = s'(\overline{x})$ then $s(y) = s'(y)$. *Dependence logic* (D) is the extension of first-order logic with dependence atoms.

While dependence atoms of dependence logic declare dependences between variables, *independence atoms*, introduced by Grädel and Väänänen [11], do just the opposite; independence atoms are used to declare independencies between variables. Independence atom is an atomic formula of the form $(x_1, ..., x_k) \perp_{(z_1,...,z_t)} (y_1, ..., y_l)$ with the intuitive meaning that for any fixed interpretation of the variables $z_1, \ldots, z_t$, the interpretations of the variables $x_1, ..., x_k$ are independent of the interpretations of the variables $y_1, ..., y_l$. The semantics for independence atoms is defined as follows:

$$\mathfrak{A} \models_X (x_1, ..., x_k) \perp_{(z_1,...,z_t)} (y_1, ..., y_l) \text{ iff } \forall s, s' \in X\, \exists s'' \in X : \bigwedge_{i \le t} s(z_i) = s'(z_i)$$

$$\text{implies that } \bigwedge_{i \le k} s''(x_i) = s(x_i) \wedge \bigwedge_{i \le t} s''(z_i) = s(z_i) \wedge \bigwedge_{i \le l} s''(y_i) = s'(y_i).$$

Independence logic (Ind) is the extension of first-order logic with independence atoms.

Galliani [6] introduced *inclusion* and *exclusion atoms*. The intuitive meaning of the inclusion atom $(x_1, \ldots, x_n) \subseteq (y_1, \ldots, y_n)$ is that tuples interpreting the variables $x_1 \ldots, x_n$ are also tuples interpreting $y_1, \ldots, y_n$. The intuitive meaning of the exclusion atom $(x_1, \ldots, x_n) \mid (y_1, \ldots, y_n)$ on the other hand is that tuples interpreting the variables $x_1 \ldots, x_n$ and the tuples interpreting $y_1, \ldots, y_n$ are distinct. The semantics for inclusion atoms and exclusion atoms is defined as follows:

$$\mathfrak{A} \models_X \overline{x} \subseteq \overline{y} \text{ iff } \forall s \in X\, \exists s' \in X : s(\overline{x}) = s'(\overline{y}), \quad \mathfrak{A} \models_X \overline{x} \mid \overline{y} \text{ iff } \forall s, s' \in X : s(\overline{x}) \neq s'(\overline{y}).$$

The extension of first-order logic with inclusion atoms (exclusion atoms) is called *inclusion logic* (*exclusion logic*) and denoted by Inc (Exc). The extension of first-order logic with both inclusion atoms and exclusion atoms is called *inclusion/exclusion logic* and denoted by Inc/Exc.

2.2 Generalized atoms

In this section we first give the well known definition of generalized quantifiers (Lindström quantifiers [21]). We then show how each generalized quantifier naturally gives rise to a generalized atom. Finally, we discuss on some fundamental properties of first-order logic extended with generalized atoms. Generalized atoms were first defined in [20].

Let $(i_1, ..., i_n)$ be a nonempty sequence of positive integers. A generalized quantifier of the type $(i_1, ..., i_n)$ is a class $\mathcal{C}$ of structures $(A, B_1, ..., B_n)$ such that the following conditions hold.

1. $A \neq \emptyset$, and for each $j \in \{1, ..., n\}$, we have $B_j \subseteq A^{i_j}$.
2. If $(A', B'_1, ..., B'_n) \in \mathcal{C}$ and if there is an isomorphism $f : A' \to A''$ from $(A', B'_1, ..., B'_n)$ to another structure $(A'', B''_1, ..., B''_n)$, then $(A'', B''_1, ..., B''_n) \in \mathcal{C}$.

Let Q be a generalized quantifier of the type $(i_1, ..., i_n)$. Let $\mathfrak{A}$ be a model with the domain A. We define $Q^{\mathfrak{A}}$ to be the set $\{\ (B_1, ..., B_n) \mid (A, B_1, ..., B_n) \in Q\ \}$.

Let n be a positive integer. Let Q be a generalized quantifier of the type $(i_1, ..., i_n)$. Extend the syntax of first-order logic with atomic expressions of the type $A_Q(\overline{y}_1, ..., \overline{y}_n)$, where each $\overline{y}_j$ is a tuple of variables of length i_j. Let X be a team whose domain contains all variables occurring in the tuples $\overline{y}_1, ..., \overline{y}_n$. Extend team semantics such that $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_n)$ if and only if $\big(\mathrm{rel}(X, \overline{y}_1), ..., \mathrm{rel}(X, \overline{y}_n)\big) \in Q^{\mathfrak{A}}$. The generalized quantifier Q defines a *generalized atom* A_Q of the type $(i_1, ..., i_n)$.

A generalized atom A_Q is *downwards closed* if for all $\mathfrak{A}$, X and $\overline{y}_1, ..., \overline{y}_k$, it holds that if $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_k)$ and $Y \subseteq X$, then $\mathfrak{A} \models_Y A_Q(\overline{y}_1, ..., \overline{y}_k)$. Similarly, a generalized atom A_Q is *closed under substructures* if for all $\mathfrak{A}$, X and $\overline{y}_1, ..., \overline{y}_k$, it holds that if $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_k)$, $\mathfrak{A}' := \mathfrak{A} \upharpoonright B$ and $X' := X \upharpoonright B$ for some $B \subseteq A$, then we have $\mathfrak{A}' \models_{X'} A_Q(\overline{y}_1, ..., \overline{y}_k)$. Finally, a generalized atom A_Q is *universe independent* if for all $\mathfrak{A}$, $\mathfrak{B}$, X and $\overline{y}_1, ..., \overline{y}_k$, where both A and B are codomains for X, it holds that $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_k)$ if and only if $\mathfrak{B} \models_X A_Q(\overline{y}_1, ..., \overline{y}_k)$.

Let φ be a formula of first-order logic, possibly extended with generalized atoms. The set $\mathrm{Fr}(\varphi)$ of *free variables* of φ is defined in the same way as in first-order logic. The set $\mathrm{Fr}(A_Q(\overline{y}_1, ..., \overline{y}_k))$ of course contains exactly all variable that occur in the tuples $\overline{y}_i$. The satisfiability problem of a (possibly team-semantics-based) logic L takes as an input a sentence of L and asks whether $\mathfrak{A} \models \varphi$ for some model $\mathfrak{A}$. The validity problem asks, given a sentence φ, whether $\mathfrak{A} \models \varphi$ for all models $\mathfrak{A}$.

Let $k \in \mathbb{Z}_+$ and let A_Q be a generalized atom of the type $(i_1, ..., i_n)$, where $i_j \leq k$ for each j. Let $\varphi(R_1, ..., R_n)$ be a sentence of $\Sigma_1^1(\mathsf{FOC}^k)$ with unquantified relation symbols $R_1, ..., R_n$ of arities $i_1, ..., i_n$, respectively. Assume that for all models $\mathfrak{A}$ and teams X with codomain A and domain containing the variables in $A_Q(\overline{x}_1, ..., \overline{x}_n)$, we have $\mathfrak{A} \models_X A_Q(\overline{x}_1, ..., \overline{x}_n)$ iff

$$\big(\mathfrak{A}, R_1 := \mathrm{rel}(X, \overline{x}_1), ..., R_n := \mathrm{rel}(X, \overline{x}_n)\big) \models_{\mathsf{FO}} \varphi(R_1, ..., R_n).$$

Then we say that the atom A_Q is definable in $\Sigma_1^1(\mathsf{FOC}^k)$.

We now show that, *for any generalized atom* A_Q, the logic $\mathsf{FO}(A_Q)$ has the so-called locality property. We also show that, for a downwards closed atom A_Q, all formulas of $\mathsf{FO}(A_Q)$ satisfy the downwards closure property. These two properties have previously turned out to be very useful in the study of dependence logic.

Let X be a team with domain $\{x_1, \ldots, x_k\}$, and let $V \subseteq \{x_1, \ldots, x_k\}$. We denote by $X(V)$ the team $\{s \upharpoonright V \mid s \in X\}$ with the domain V. The following proposition shows that the truth of an $\mathsf{FO}(A_Q)$-formula depends only on the interpretations of the variables occurring free in the formula. The proof uses the fact that generalized atoms satisfy the claim by definition. Otherwise the proof is identical to the corresponding proof given in [6].

▶ **Proposition 3** (Locality). *Let A_Q be a generalized atom and $\varphi \in \mathsf{FO}(A_Q)$ a formula. If $V \supseteq \mathrm{Fr}(\varphi)$, then $\mathfrak{A} \models_X \varphi$ if and only if $\mathfrak{A} \models_{X(V)} \varphi$.*

The next proposition is also very useful. The proof is almost identical to the corresponding proof for dependence logic, see [25]. The additional case for generalized atoms follows by the assumption of downwards closure.

▶ **Proposition 4** (Downward closure). *Let A_Q be a downwards closed generalized atom. Suppose φ is an $\mathsf{FO}(A_Q)$-formula, $\mathfrak{A}$ a model, and $Y \subseteq X$ teams. Then $\mathfrak{A} \models_X \varphi$ implies $\mathfrak{A} \models_Y \varphi$.*

3 Satisfiability problems of logics $\mathsf{FO}^2(\mathcal{A})$

In this section we show that for any finite collection $\mathcal{A}$ of $\Sigma_1^1(\mathsf{FOC}^2)$-definable atoms A_Q, both $\textsc{Sat}(\mathsf{FO}^2(\mathcal{A}))$ and $\textsc{FinSat}(\mathsf{FO}^2(\mathcal{A}))$ are *NEXPTIME*-complete. Our proof relies on a translation from $\mathsf{FO}^2(\mathcal{A})$ into $\Sigma_1^1(\mathsf{FOC}^2)$ and the fact that $\textsc{Sat}(\mathsf{FOC}^2)$ and $\textsc{FinSat}(\mathsf{FOC}^2)$ are *NEXPTIME*-complete [23].

We start by establishing a more general translation. We show that for every $k \geq 1$ and every $\Sigma_1^1(\mathsf{FOC}^k)$ definable atom A_Q, we have $\mathsf{FO}^k(A_Q) \leq \Sigma_1^1(\mathsf{FOC}^k)$. Note that strictly speaking $\mathsf{FO}^k(A_Q)$ uses only one atom A_Q instead of a finite collection $\mathcal{A}$ of atoms, but our proof below generalizes *directly* to the case with a finite collection of atoms. The reason for considering a single atom is simply to keep the notation light.

When considering k-variable logic, we let $\{x_1, ..., x_k\}$ denote the k distinct variables used in the syntax of the logic, and we let $\mathit{rel}(X)$ denote $\mathit{rel}\big(X, (x_1, ..., x_k)\big)$. The proof of the following lemma (see the full version in arXiv [19]) significantly modifies and extends the argument establishing Lemma 3.3.14 of [26]. See also [18] and Theorem 6.2 in [25].

▶ **Lemma 5.** *Assume that $k, t \geq 1$. Let τ be a relational vocabulary, let $R \notin \tau$ be a k-ary relation symbol and let A_Q be a $\Sigma^1_1(\mathsf{FOC}^k)$-definable atom of type $(i_1, \ldots, i_t)$, where $i_j \leq k$ for each j. For every formula $\varphi \in \mathsf{FO}^k(A_Q)$ there exists a sentence $\varphi^* \in \Sigma^1_1(\mathsf{FOC}^k)(\tau \cup \{R\})$ such that for every model $\mathfrak{A}$ and team X with codomain A and $\mathrm{dom}(X) = \{x_1, \ldots, x_k\}$, we have*

$$\mathfrak{A} \models_X \varphi \quad \textit{iff} \quad \big(\mathfrak{A}, \mathrm{rel}(X)\big) \models \varphi^*, \tag{1}$$

where $(\mathfrak{A}, \mathrm{rel}(X))$ is the expansion $\mathfrak{A}'$ of $\mathfrak{A}$ into the vocabulary $\tau \cup \{R\}$ such that $R^{\mathfrak{A}'} := \mathrm{rel}(X)$. Moreover φ^* is computable from φ in polynomial time.

▶ **Theorem 6.** *For every $k \geq 1$ and for every $\Sigma^1_1(\mathsf{FOC}^k)$-definable atom A_Q it holds that $\mathsf{FO}^k(A_Q) \leq \Sigma^1_1(\mathsf{FOC}^k)$, i.e., for every sentence of $\mathsf{FO}^k(A_Q)$, there exists an equivalent sentence of $\Sigma^1_1(\mathsf{FOC}^k)$.*

Proof. Let τ be a relational vocabulary, $k \geq 1$, and A_Q a $\Sigma^1_1(\mathsf{FOC}^k)$-definable atom. Let φ be an $\mathsf{FO}^k(A_Q)(\tau)$-sentence and $\varphi^* = \exists R_1 \ldots \exists R_n \psi$ the related $\Sigma^1_1(\mathsf{FOC}^k)(\tau \cup \{R\})$-sentence given by Lemma 5. The following conditions are equivalent.

1. $\mathfrak{A} \models \varphi$.
2. $\mathfrak{A} \models_X \varphi$ for some nonempty team X such that $\mathrm{dom}(X) = \{x_1, \ldots, x_k\}$.
3. $\big(\mathfrak{A}, \mathrm{rel}(X)\big) \models \varphi^*$ for some nonempty team X such that $\mathrm{dom}(X) = \{x_1, \ldots, x_k\}$.
4. $(\mathfrak{A}, R) \models \exists R_1 \ldots \exists R_n \big(\exists x_1 \ldots \exists x_k R(x_1, \ldots, x_k) \wedge \psi\big)$ for some $R \subseteq A^k$.
5. $\mathfrak{A} \models \exists R \exists R_1 \ldots \exists R_n \big(\exists x_1 \ldots \exists x_k R(x_1, \ldots, x_k) \wedge \psi\big)$.

The equivalence of 1 and 2 follows from Proposition 3 and the fact that $\mathrm{Fr}(\varphi) = \emptyset$. By Lemma 5, conditions 2 and 3 are equivalent. The equivalence of 3 and 4 follows from the fact that $\varphi^* = \exists R_1 \ldots \exists R_n \psi$. The conditions 4 are 5 clearly equivalent. ◀

▶ **Theorem 7.** *Let A_Q be a $\Sigma^1_1(\mathsf{FOC}^2)$-definable generalized atom. Then* $\textsc{Sat}(\mathsf{FO}^2(A_Q))$ *and* $\textsc{FinSat}(\mathsf{FO}^2(A_Q))$ *are NEXPTIME-complete.*

Proof. Since the translation $\varphi \mapsto \varphi^*$ is computable in polynomial time and (finite) satisfiability of $\Sigma^1_1(\mathsf{FOC}^2)$ can be checked in *NEXPTIME* [23], we conclude that both $\textsc{Sat}(\mathsf{FO}^2(A_Q))$ and $\textsc{FinSat}(\mathsf{FO}^2(A_Q))$ are in *NEXPTIME*. On the other hand, since $\mathsf{FO}^2 \leq \mathsf{FO}^2(A_Q)$ by Proposition 2, and since both $\textsc{Sat}(\mathsf{FO}^2)$ and $\textsc{FinSat}(\mathsf{FO}^2)$ are *NEXPTIME*-hard [9], it follows that both $\textsc{Sat}(\mathsf{FO}^2(A_Q))$ and also $\textsc{FinSat}(\mathsf{FO}^2(A_Q))$ are as well. ◀

The result of Theorem 7 can be directly generalized to concern finite collections $\mathcal{A}$ of generalized atoms. The proof of the following theorem is practically the same as that of Theorem 7.

▶ **Theorem 8.** *Let $\mathcal{A}$ be a finite collection of $\Sigma^1_1(\mathsf{FOC}^2)$-definable generalized atoms. The satisfiability and the finite satisfiability problems of $\mathsf{FO}^2(\mathcal{A})$ are NEXPTIME-complete.*

We shall next make use of Theorem 8 in order to show that the satisfiability and the finite satisfiability problems of two-variable fragments of dependence logic, inclusion logic, exclusion logic and independence logic are *NEXPTIME*-complete. The result for two-variable dependence logic was already established in [18]. Note that when regarded as generalized atoms, each of the dependency notions above correspond to a collection of generalized atoms; for example the atomic formulas $=(x, y)$ and $=(x, y, z)$ refer to two different atoms, one of type (2) and the other of type (3). However, in order to capture the two-variable fragments of of these logics, we only need a finite number of generalized atoms for each logic, as we shall see. We define $\varphi_{const} := \exists^{\leq 1} x R(x)$, $\varphi_{dep} := \forall x \exists^{\leq 1} y R(x, y)$, $\varphi_{inc} := \forall x \forall y \big(R(x, y) \rightarrow$

$S(x,y)\big)$, $\varphi_{exc} := \forall x \forall y \big(R(x,y) \to \neg S(x,y)\big), \varphi_{ind} := \forall x \forall y \big((\exists y R(x,y) \wedge \exists x R(x,y)) \to R(x,y)\big)$.

The formulas φ_{const}, φ_{dep}, φ_{inc}, φ_{exc} and φ_{ind} define the generalized atoms A_{const} of type (1), A_{dep} of type (2), A_{inc} of type $(2,2)$, A_{exc} of type $(2,2)$, and A_{ind} of type (2), respectively.

▶ **Theorem 9.** *The satisfiability and finite satisfiability problems of the two-variable fragments of dependence logic, inclusion logic, exclusion logic, inclusion/exclusion logic, and independence logic are all NEXPTIME-complete.*

Proof. The proof proceeds via polynomial time translations $\mathsf{D}^2 \to \mathsf{FO}^2(\{A_{const}, A_{dep}\})$, $\mathsf{Inc}^2 \to \mathsf{FO}^2(A_{inc})$, $\mathsf{Exc}^2 \to \mathsf{FO}^2(A_{exc})$, $\mathsf{Inc/Exc}^2 \to \mathsf{FO}^2(A_{inc}, A_{exc})$, $\mathsf{Ind}^2 \to \mathsf{FO}^2(\{A_{const}, A_{dep}, A_{ind}\})$ that preserve equivalence. The result then follows from Lemma 8 and the fact that the generalised atoms A_{const}, A_{dep}, A_{exc}, A_{inc}, A_{ind} are all $\Sigma^1_1(\mathsf{FOC}^2)$-definable. For the full proof, see [19]. ◀

4 Undecidability via non-tiling

In this section we introduce structures and methods that we will later employ to prove undecidability of the validity problem of two-variable dependence logic. Curiously, all attempts (by us or known to us) to use the standard (Π^0_1-complete) tiling problem for the undecidability proof have failed; we will instead use the (Σ^0_1-complete) non-tiling problem in our arguments below.

The grid is the structure $\mathfrak{G} = (\mathbb{N}^2, V, H)$, where $V = \{\big((i,j),(i,j{+}1)\big) \in \mathbb{N}^2 \times \mathbb{N}^2 \mid i,j \in \mathbb{N}\}$ and $H = \{\big((i,j),(i+1,j)\big) \in \mathbb{N}^2 \times \mathbb{N}^2 \mid i,j \in \mathbb{N}\}$. A function $t : 4 \longrightarrow \mathbb{N}$ is called a *tile type*. Define the set TILES $:= \{P_t \mid t$ is a tile type$\}$ of unary relation symbols. The unary relation symbols in the set TILES are called *tiles*. The number $t(0)$ is the *top colour*, $t(1)$ the *right colour*, $t(2)$ the *bottom colour*, and $t(3)$ the *left colour* of P_t.

Let T be a finite nonempty set of tiles and V and H binary relation symbols. We say that a structure $\mathfrak{A} = (A, V, H)$ is T-*tilable*, if there exists an expansion of $\mathfrak{A}$ to the vocabulary $\{H, V\} \cup \{ P_t \mid P_t \in T \}$ such that the following conditions hold for all $u, v \in A$.

1. The point u belongs to the extension of exactly one symbol P_t in T.
2. If uHv, $P_t(u)$ and $P_s(v)$, then the right colour of P_t is the same as the left colour of P_s.
3. If uVv, $P_t(u)$ and $P_s(v)$, then the top colour of P_t is the same as the bottom colour of P_s.

We will next define the *tiling problem* and the *non-tiling problem*. Let $\mathcal{F}$ denote the set of finite, nonempty subsets of TILES. We define $\mathcal{T} := \{T \in \mathcal{F} \mid \mathfrak{G}$ is T-tilable$\}$ and $\bar{\mathcal{T}}' := \{T \in \mathcal{F} \mid \mathfrak{G}$ is not T-tilable$\}$. The *tiling problem (non-tiling problem,* resp.) is the membership problem of the set $\mathcal{T}$ ($\bar{\mathcal{T}}'$, resp.) with the input set $\mathcal{F}$.

▶ **Theorem 10** ([2]). *The tiling problem is Π^0_1-complete.*

The *non-tiling problem* is the complement of the tiling problem. Thus the following corollary follows.

▶ **Corollary 11.** *The non-tiling problem is Σ^0_1-complete.*

The proof of the following lemma is straightforward.

▶ **Lemma 12.** *There is a computable function associating each input T to the non-tiling problem with an FO^2-sentence φ_T of the vocabulary $\tau := \{H, V\} \cup T$ such that for every structure $\mathfrak{A}$ of the vocabulary $\{H, V\}$, the structure $\mathfrak{A}$ is not T-tilable iff for every expansion $\mathfrak{A}^*$ of $\mathfrak{A}$ to the vocabulary τ, it holds that $\mathfrak{A}^* \models \varphi_T$.*

▶ **Definition 13.** Let $\tau = \{V, H\}$ be a vocabulary where V and H are binary relation symbols. Let $\mathfrak{A} = (A, V, H)$ be a τ-structure. We say that $\mathfrak{A}$ is *gridlike* if the below conditions hold.

1. The extension of V in $\mathfrak{A}$ is serial (i.e., $\forall x \in A\ \exists y \in A$ s.t. $V(x, y)$).
2. The extension of H in $\mathfrak{A}$ is serial (i.e., $\forall x \in A\ \exists y \in A$ s.t. $H(x, y)$).
3. If $a, b, c, b', c' \in A$ are such that $V(a, b)$, $H(b, c)$, $H(a, b')$, and $V(b', c')$, then $c = c'$.

Note that it follows from the above definition that in gridlike structures, for every point a, there exist points b, c and d such that $H(a, b)$, $V(a, c)$, $V(b, d)$, and $H(c, d)$.

Let τ be the vocabulary of gridlike structures and U, P, Q, C unary relation symbols. We say that a $\tau \cup \{U, P, Q, C\}$-structure $\mathfrak{A}$ is *striped and gridlike* if the τ-reduct of $\mathfrak{A}$ is gridlike, the extensions of P and Q in $\mathfrak{A}$ are *distinct* singleton sets, the extension of U in $\mathfrak{A}$ is the union of the extensions of P and Q, and $\mathfrak{A}$ has the following property (intuitively C creates stripes in $\mathfrak{A}$):

$$\big(H(a, b) \Rightarrow (C(a) \Leftrightarrow C(b))\big) \text{ and } \big(V(a, b) \Rightarrow (C(a) \Leftrightarrow \neg C(b))\big). \tag{2}$$

The following lemma can be now proven by a simple inductive argument.

▶ **Lemma 14.** *If $\mathfrak{A}$ is striped and gridlike, then there exists a homomorphism from the grid into $\mathfrak{A}$.*

▶ **Lemma 15.** *Let T be an input to the non-tiling problem. The grid is non-T-tilable iff (the $\{H, V\}$-reduct of) every striped gridlike structure is non-T-tilable.*

Proof. The direction from left to right follows from Lemma 14 in a straightforward way. The converse holds since the grid is an {H,V}-reduct of a striped gridlike structure. ◀

5 The validity problem of D^2 is undecidable

In this section we give a reduction from the non-tiling problem to the validity problem of D^2.

Let $\tau = \{V, H, C, U, P, Q\}$ be the vocabulary of striped gridlike structures. We will first define a formula $\varphi_{non-grid}$ of D^2 such that $\mathfrak{A}$ is not striped and gridlike iff $\mathfrak{A} \models \varphi_{non-grid}$. We first notice that the first two conditions of Definition 13 are easy to deal with. Define $\varphi_{non-serial} := \exists x \forall y \neg V(x, y) \vee \exists x \forall y \neg H(x, y)$. The third condition of Definition 13 is nontrivial. In the below construction, we will use the predicates P, Q, U for counting (only). We will first show how to force the extensions of P and Q to be distinct singletons and the extension of U to be the union of P and Q. The next formulae will be used for dealing with the cases where this *does not* hold.

$$\begin{aligned}
\varphi_{non-singleton}(X) &:= \forall x \neg X(x) \vee \exists x \exists y \big(X(x) \wedge X(y) \wedge \neg x = y\big)\\
\varphi_{non-distinct}(X, Y) &:= \exists x \big(X(x) \wedge Y(x)\big)\\
\varphi_{non-union}(X, Y, Z) &:= \exists x \Big(X(x) \wedge \big(\neg Y(x) \vee \neg Z(x)\big)\Big) \vee \exists x \Big(\neg X(x) \wedge \big(Y(x) \vee Z(x)\big)\Big)\\
\varphi_{|U| \neq 2} &:= \varphi_{non-singleton}(P) \vee \varphi_{non-singleton}(Q) \vee \varphi_{non-distinct}(P, Q)\\
&\quad\ \vee \varphi_{non-union}(U, P, Q).
\end{aligned}$$

It is easy to check that the τ-models $\mathfrak{A}$ such that $\mathfrak{A} \not\models \varphi_{|U| \neq 2}$ are exactly those models where the extensions of P and Q are distinct singletons and the extension of U is the union of the extensions of P and Q (and thus the cardinality of the extension of U is 2).

We will now show how to enforce Equation (2). The formula $\varphi_{non-stripes}$ below takes care of the cases where (2) does *not* hold. Define

$$\varphi_{non-stripes} := \exists x \exists y \Big(\big(H(x,y) \wedge (C(x) \leftrightarrow \neg C(y)) \big) \vee \big(V(x,y) \wedge (C(x) \leftrightarrow C(y)) \big) \Big).$$

We are now ready to show how to deal with models that violate the last condition of Definition 13. To understand the intended meaning of the following formula, assume that the extension of U is of size two and that the condition given by Equation (2) holds. Note also that from (2) it follows that if such points c and c' exist that violate the last condition of Definition 13, then c and c' agree about C, i.e., we have $C(c)$ iff $C(c')$. We first deal with the case where $C(c)$ and $C(c')$ both hold. We denote by $\varphi_{non-C^{+}-join}$ the following formula (whose meaning is fully explained in the proof of Lemma 16):

$$\forall x \Big(\neg U(x) \vee \exists y \Big(C(y) \wedge {=}(y,x) \wedge \exists x \Big({=}(x,y) \wedge \big(({=}(x) \wedge H(x,y)) \vee ({=}(x) \wedge V(x,y)) \big) \wedge \exists y \big({=}(y) \wedge \big(V(y,x) \vee H(y,x) \big) \wedge \neg C(y) \big) \Big) \Big) \Big).$$

To deal with the case where $\neg C(c)$ and $\neg C(c')$, we define the formula $\varphi_{non-C^{-}-join}$ which is obtained from $\varphi_{non-C^{+}-join}$ by simultaneously replacing each $C(x)$ and $C(y)$ by $\neg C(x)$ and $\neg C(y)$, respectively. Finally, we define that $\varphi_{non-join} := \varphi_{non-C^{+}-join} \vee \varphi_{non-C^{-}-join}$ and $\varphi_{non-grid} := \varphi_{non-serial} \vee \varphi_{|U| \neq 2} \vee \varphi_{non-stripes} \vee \varphi_{non-join}$.

▶ **Lemma 16.** *Let $\tau = \{V, H, C, U, P, Q\}$ be the vocabulary of striped gridlike structures. Let $\mathfrak{A}$ be a τ-structure such that the extension of U is of cardinality 2. Assume the condition (2) holds. Then $\mathfrak{A} \models \varphi_{non-join}$ iff the last condition of Definition 13 fails in $\mathfrak{A}$.*

Proof. From (2) it follows that if such c and c' exist in $\mathfrak{A}$ that violate the last condition of Definition 13, then c and c' agree on C. We will show that

$$\mathfrak{A} \models \varphi_{non-C^{+}-join} \text{ iff the last condition of Definition 13 fails in } \mathfrak{A} \text{ for some } c, c' \text{ s.t. } C(c) \,\&\, C(c'). \quad (3)$$

The analogous argument for $\varphi_{non-C^{-}-join}$ and the case where $\neg C(c)$ and $\neg C(c')$ hold is similar.

Below we denote by $\{(x_1, v_1), ..., (x_k, v_k)\}$ the variable assignment that maps x_i to v_i for each i. Let u, u' be the elements that are in the extension of U in $\mathfrak{A}$. We thus have $\mathfrak{A} \models \varphi_{non-C^{+}-join}$ iff

$$\mathfrak{A} \models_{X_1} \exists y \Big(C(y) \wedge {=}(y,x) \wedge \exists x \Big({=}(x,y) \wedge \big(({=}(x) \wedge H(x,y)) \vee ({=}(x) \wedge V(x,y)) \big) \wedge \exists y \big({=}(y) \wedge \big(V(y,x) \vee H(y,x) \big) \wedge \neg C(y) \big) \Big) \Big),$$

where $X_1 = \{\{(x,u)\}, \{(x,u')\}\}$. Now, recalling that dependence logic has the downwards closure property (cf. proposition 4), we observe that the above holds if and only if there exist *distinct* (distinctness being due to the atom ${=}(y,x)$) points c, c' in the extension of C such that

$$\mathfrak{A} \models_{X_2} \exists x \Big({=}(x,y) \wedge \big(({=}(x) \wedge H(x,y)) \vee ({=}(x) \wedge V(x,y)) \big) \wedge \exists y \big({=}(y) \wedge \big(V(y,x) \vee H(y,x) \big) \wedge \neg C(y) \big) \Big),$$

where $X_2 = \{\{(x,u), (y,c)\}, \{(x,u'), (y,c')\}\}$. The above holds if and only if there exist distinct points b, b' of $\mathfrak{A}$ such that $H(b,c)$ and $V(b',c')$ (or $V(b,c)$ and $H(b',c')$ in which case the argument is analogous) and

$$\mathfrak{A} \models_{X_3} \exists y \big({=}(y) \wedge \big(V(y,x) \vee H(y,x) \big) \wedge \neg C(y) \big),$$

where $X_3 = \{\{(x,b),(y,c)\},\{(x,b'),(y,c')\}\}$. The above holds if and only if there exists a point a in $\mathfrak{A}$ such that $\neg C(a)$, ($V(a,b)$ or $H(a,b)$) and ($V(a,b')$ or $H(a,b')$). Since $C(c)$ and $C(c')$ hold, it follows from the assumption that (2) holds that $C(b)$ and $\neg C(b')$. Now since also $\neg C(a)$ holds, it follows again from (2) that $V(a,b)$ and $H(a,b')$. When all of the above is combined, we obtain (3). The analogous condition where $\neg C(c)$ and $\neg C(c')$ is proved similarly. Since (2) holds for $\mathfrak{A}$, any points c and c' of $\mathfrak{A}$ that violate the last condition of Definition 13, must agree on C. Thus the lemma holds. ◀

The next lemma follows from Lemma 16 together with the observations made above.

▶ **Lemma 17.** *Let $\tau = \{V,H,C,U,P,Q\}$ be the vocabulary of striped gridlike structures and let $\mathfrak{A}$ be a τ-model. Then $\mathfrak{A}$ is striped and gridlike iff $\mathfrak{A} \not\models \varphi_{non-grid}$.*

▶ **Theorem 18.** *The validity problem for D^2 is undecidable (more precisely, Σ^0_1-hard).*

Proof. We give a computable reduction from the non-tiling problem to the validity problem of D^2. Since the former is Σ^0_1-complete (Corollary 11), we obtain Σ^0_1-hardness for the latter.

If T is an input to the non-tiling problem, then φ_T denotes the FO^2-sentence given by Lemma 12 and $\varphi_{non-T-tiling} := (\varphi_{non-grid} \vee \varphi_T)$. Let τ be as defined in Lemma 17. Let $C_{\tau,T}$ denote the class of all $\tau \cup T$-structures and let $\mathcal{C}^{\tau,T}_{s-gridlike}$ be the class of exactly all expansions of striped gridlike structures to the vocabulary $\tau \cup T$.

Let T be an input to the non-tiling problem. We will show that the grid is non-T-tilable iff the D^2-sentence $\varphi_{non-T-tiling}$ is valid. By definition, $\varphi_{non-T-tiling}$ is valid iff $\mathfrak{A} \models \varphi_{non-grid} \vee \varphi_T$ holds for every $\mathfrak{A} \in \mathcal{C}_{\tau,T}$. Since $\varphi_{non-grid}$ and φ_T are sentences, the right-hand side of this equivalence is equivalent to the claim that

$$\forall \mathfrak{A} \in \mathcal{C}_{\tau,T} : \mathfrak{A} \models \varphi_{non-grid} \text{ or } \mathfrak{A} \models \varphi_T. \tag{4}$$

By Lemma 17, $\mathfrak{B}^* \models \varphi_{non-grid}$ holds for every τ-reduct $\mathfrak{B}^*$ of $\mathfrak{B} \in \mathcal{C}_{\tau,T}$ that is not striped and gridlike. Hence for every $\mathfrak{B} \in \mathcal{C}_{\tau,T}$ such that the τ-reduct $\mathfrak{B}^*$ of $\mathfrak{B}$ is not striped and gridlike, it holds that $\mathfrak{B} \models \varphi_{non-grid}$. Thus (4) is equivalent to the claim that

$$\forall \mathfrak{A} \in \mathcal{C}^{\tau,T}_{s-gridlike} : \mathfrak{A} \models \varphi_{non-grid} \text{ or } \mathfrak{A} \models \varphi_T. \tag{5}$$

Now let $\mathfrak{B}$ be an arbitrary striped and gridlike τ-structure. By Lemma 17, $\mathfrak{B} \not\models \varphi_{non-grid}$. Thus $\mathfrak{B}^* \not\models \varphi_{non-grid}$ for every expansion $\mathfrak{B}^*$ of $\mathfrak{B}$ to the vocabulary $\tau \cup T$. From this it follows that (5) is equivalent to the claim that

$$\forall \mathfrak{A} \in \mathcal{C}^{\tau,T}_{s-gridlike} : \mathfrak{A} \models \varphi_T. \tag{6}$$

Thus, by Lemma 12, (6) holds if and only if every striped gridlike structure is non-T-tilable. Finally, from Lemma 15 it follows that this is equivalent to the claim that the grid is non-T-tilable. ◀

6 Satisfiability of $\exists^*\forall^*$-formulas

In this section we consider the complexity of satisfiability for sentences of dependence logic and its variants in the prefix class $\exists^*\forall^*$. For first-order logic, the satisfiability and finite satisfiability problems of the prefix class $\exists^*\forall^*$ are known to be *NEXPTIME*-complete. The results hold for both the case with equality and the case without equality, see [3].

Let $\mathcal{A}$ be a collection of generalized atoms. We denote by $\exists^*\forall^*[\mathcal{A}]$ the class of sentences of $\mathsf{FO}(\mathcal{A})$ of the form $\exists x_0 \cdots \exists x_n \forall y_0 \cdots \forall y_m \theta$, where θ is a quantifier-free formula whose generalized atoms are in $\mathcal{A}$. It is worth noting that, depending on the set $\mathcal{A}$, the expressive power and complexity of sentences in $\exists^*\forall^*[\mathcal{A}]$ can vary considerably even when $\mathcal{A}$ is finite and contains only computationally non-complex atoms. For example, there are universal sentences of dependence logic that define NP-complete problems [17]. Furthermore, every sentence of inclusion logic is equivalent to a sentence with a prefix of the form $\exists^*\forall^1$ [12] implying that the satisfiability problem of the $\exists^*\forall^*$-fragment of inclusion logic is undecidable.

Recall that we say that a formula φ is *closed under substructures* if for all $\mathfrak{A}$ and X it holds that if $\mathfrak{A} \models_X \varphi$, $\mathfrak{A}' := \mathfrak{A} \upharpoonright B$ and $X' := X \upharpoonright B$ for some $B \subseteq A$, then we have $\mathfrak{A}' \models_{X'} \varphi$.

▶ **Lemma 19.** *Let $\mathcal{A}$ be a collection of generalized atoms that are closed under substructures. Then the following conditions hold.*

1. *Suppose $\varphi \in \mathsf{FO}[\mathcal{A}]$ is of the form $\forall y_0 \cdots \forall y_m \theta$, where θ is quantifier-free. Then φ is closed under substructures.*
2. *Let $\varphi \in \exists^*\forall^*[\mathcal{A}]$ be a sentence. Then, if φ is satisfiable, φ has a model with at most $max\{1, k\}$ elements, where k refers to the number of existentially quantified variables in φ.*

Proof. We will first prove claim (1). Suppose that $\varphi := \forall y_0 \cdots \forall y_m \theta$. We will first show the claim for quantifier-free formulas θ, i.e., we will show that for all $\mathfrak{A}$, X, $\mathfrak{A}'$, and X' such that $\mathfrak{A}' := \mathfrak{A} \upharpoonright B$ and $X' := X \upharpoonright B$ for some $B \subseteq A$, the following implication holds.

$$\mathfrak{A} \models_X \theta \Rightarrow \mathfrak{A}' \models_{X'} \theta. \tag{7}$$

The claim obviously holds if θ is a first-order literal. If θ is a generalized atom from $\mathcal{A}$, then the claim holds by assumption. The case $\theta := \psi_1 \wedge \psi_2$ follows immediately from the induction hypothesis. Let us then assume that $\theta := \psi_1 \vee \psi_2$. Since $\mathfrak{A} \models_X \theta$, there are sets Y and Z such that $Y \cup Z = X$, $\mathfrak{A} \models_Y \psi_1$ and $\mathfrak{A} \models_Z \psi_2$. By the induction hypothesis, we have $\mathfrak{A}' \models_{Y'} \psi_1$ and $\mathfrak{A}' \models_{Z'} \psi_2$, where $Y' := Y \upharpoonright B$ and $Z' := Z \upharpoonright B$. Since $Y' \cup Z' = X'$, it follows that $\mathfrak{A}' \models_{X'} \theta$.

We will now show that the claim also holds for φ. Suppose that $\mathfrak{A} \models_X \varphi$. Then, by the truth definition, $\mathfrak{A} \models_{X[A/y_0]\cdots[A/y_m]} \theta$. Using (7), we have $\mathfrak{A}' \models_{(X[A/y_0]\cdots[A/y_m])\upharpoonright B} \theta$. It is easy to check that $(X[A/y_0]\cdots[A/y_m]) \upharpoonright B = (X \upharpoonright B)[B/y_0]\cdots[B/y_m]$. Hence we have $\mathfrak{A}' \models_{X'} \varphi$.

Let us then prove 2. Assume φ is a sentence of the form $\exists x_0 \cdots \exists x_n \forall y_0 \cdots \forall y_m \theta$, where θ is quantifier-free, and that there is a structure $\mathfrak{A}$ such that $\mathfrak{A} \models \varphi$. Hence there exists functions F_i such that $\mathfrak{A} \models_X \forall y_0 \cdots \forall y_m \theta$, where $X = \{\emptyset\}[F_0/x_0]\cdots[F_n/x_n]$. Let s be some assignment in X. Let range(s) denote the set of elements b such that $s(x) = b$ for some variable x in the domain of s. If range$(s) \neq \emptyset$ define $B :=$ range(s), and if range$(s) = \emptyset$ (i.e., $s = \emptyset$), define $B = \{b\}$, where b is an arbitrary element in A. By claim (1), the formula $\forall y_0 \cdots \forall y_m \theta$ is closed under substructures. Thus $\mathfrak{A} \upharpoonright B \models_{X \upharpoonright B} \forall y_0 \cdots \forall y_m \theta$. Thus it follows that $\mathfrak{A} \upharpoonright B \models \varphi$. ◀

A generalized atom A_Q is said to be *polynomial time computable* if the question whether $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_n)$ holds can be decided in time polynomial in the size of $\mathfrak{A}$ and X. A class of atoms $\mathcal{A}$ is said to be *uniformly polynomial time computable* if there exists a polynomial function $f : \mathbb{N} \to \mathbb{N}$ such that for every atom $A_Q \in \mathcal{A}$ it holds that the question whether $\mathfrak{A} \models_X A_Q(\overline{y}_1, ..., \overline{y}_n)$ holds can be decided in time $f\big(|\mathfrak{A}| + |X| + |A_Q(\overline{y}_1, ..., \overline{y}_n)|\big)$. Note that every finite class of polynomial time computable atoms is also uniformly polynomial time computable.

The following theorem now follows from Lemma 19. We will make use of the recent result of Grädel showing that for a uniformly polynomial time computable collection $\mathcal{A}$ of atoms, the model checking problem for $\mathsf{FO}(\mathcal{A})$-formulas is in *NEXPTIME* [8].

▶ **Theorem 20.** *Let A_Q be a generalized atom that is closed under substructures and polynomial time computable. Then* $\textsc{Sat}(\exists^*\forall^*[A_Q])$ *and* $\textsc{FinSat}(\exists^*\forall^*[A_Q])$ *are in* 2*NEXPTIME. If τ is a vocabulary consisting of relation symbols of arity at most k, $k \in \mathbb{Z}_+$, then* $\textsc{Sat}(\exists^*\forall^*[A_Q](\tau))$ *and* $\textsc{FinSat}(\exists^*\forall^*[A_Q](\tau))$ *are NEXPTIME-complete.*

Proof. Note first that the lower bounds follow from the fact that both $\textsc{Sat}(\exists^*\forall^*)$ and $\textsc{FinSat}(\exists^*\forall^*)$ are already *NEXPTIME*-complete. It hence suffices to show containments in 2*NEXPTIME* and *NEXPTIME*, respectively.

Let $\varphi \in \exists^*\forall^*[A_Q]$. By Lemma 19, φ is satisfiable if and only if it has a model of cardinality at most $|\varphi|$. We can decide satisfiability of φ as follows: non-deterministically guess a structure $\mathfrak{A}$ of cardinality at most $|\varphi|$ and accept iff $\mathfrak{A} \models \varphi$. By the result of Grädel in [8], the question whether $\mathfrak{A} \models \varphi$ can be checked non-deterministically in exponential time with input $\mathfrak{A}$ and φ. Assume first that the maximum arity of relation symbols that may occur in φ is not a fixed constant. Relation symbols of arity at most $|\varphi|$ may occur in φ. Thus the size of the *binary encoding of a model* $\mathfrak{A}$ of φ such that $A \leq |\varphi|$ is worst case exponential with respect to $|\varphi|$. If, on the other hand, the maximum arity of relation symbols that can occur in φ is a fixed constant, then the size of the encoding of $\mathfrak{A}$ is just worst case polynomial with respect to $|\varphi|$. Therefore it follows that our algorithm for checking satisfiability of φ is in *NEXPTIME* in the case of fixed arity vocabularies and in 2*NEXPTIME* in the general case. The corresponding results for the finite satisfiability problem follow by the observation that $\exists^*\forall^*[A_Q]$ has the finite model property, Lemma 19. ◀

▶ **Corollary 21.** *Let $\mathcal{A}$ be a uniformly polynomial time computable class of generalized atoms that are closed under substructures. Then* $\textsc{Sat}(\exists^*\forall^*[\mathcal{A}])$ *and* $\textsc{FinSat}(\exists^*\forall^*[\mathcal{A}])$ *are in* 2*NEXPTIME. If τ is a vocabulary consisting of relation symbols of arity at most k, $k \in \mathbb{Z}_+$, then* $\textsc{Sat}(\exists^*\forall^*[\mathcal{A}](\tau))$ *and* $\textsc{FinSat}(\exists^*\forall^*[\mathcal{A}](\tau))$ *are NEXPTIME-complete.*

In the following sense Theorem 20 is optimal: there exists a polynomial time computable generalized atom A_Q such that $\textsc{Sat}(\exists^3\forall[A_Q])$ and $\textsc{FinSat}(\exists^3\forall[A_Q])$ are undecidable. This already holds for vocabularies with at least one binary relation symbol and a countably infinite set of unary relation symbols. Let $\varphi_{5-inc} := \forall x_1 \ldots \forall x_5 \big(R(x_1, \ldots, x_5) \rightarrow S(x_1, \ldots x_5)\big)$, and let A_{5-inc} be the related generalized atom of the type $(5, 5)$, i.e., A_{5-inc} is the 5-ary inclusion atom interpreted as a generalized atom. Clearly A_{5-inc} is computable in polynomial time.

▶ **Theorem 22.** *Let τ be a vocabulary consisting of one binary relation symbol and a countably infinite set of unary relation symbols. Then both* $\textsc{Sat}(\exists^3\forall[A_{5-inc}](\tau))$ *and* $\textsc{FinSat}(\exists^3\forall[A_{5-inc}](\tau))$ *are undecidable.*

Proof. It well known that for the Kahr class (i.e., the prefix class $\forall\exists\forall$ of FO with vocabulary τ) the satisfiability and the finite satisfiability problems are undecidable (see, e.g., [3]). From the proof of [12, Theorem 5] it follows that there exists a polynomial time translation $\varphi \mapsto \varphi^*$ from the Kahr class into $\exists^3\forall[A_{5-inc}](\tau)$ such that $\mathfrak{A} \models_X \varphi \Leftrightarrow \mathfrak{A} \models_X \varphi^*$ holds for every model $\mathfrak{A}$ and team X with codomain A. Thus $\textsc{Sat}(\exists^3\forall[A_{5-inc}](\tau))$ and $\textsc{FinSat}(\exists^3\forall[A_{5-inc}](\tau))$ are undecidable. ◀

It is easy to see that dependence atoms viewed as generalized atoms are closed under substructures since they are downwards closed and universe independent. Likewise, it is straightforward to check that the class of dependence atoms is uniformly polynomial time computable. Hence we obtain:

▶ **Corollary 23.** *Both the satisfiability and the finite satisfiability problems for the* $\exists^*\forall^*$*-sentences of dependence logic are in* 2*NEXPTIME. If* τ *is a vocabulary consisting of relation symbols of arity at most* k*, then the satisfiability and the finite satisfiability problems for the* $\exists^*\forall^*$*-sentences of dependence logic over the vocabulary* τ *are NEXPTIME-complete.*

7 Conclusion

We have tied some loose ends concerning the complexity of predicate logics based on team semantics. Using a general approach, we have shown that the satisfiability and the finite satisfiability problems of the two-variable fragments of inclusion logic, exclusion logic, inclusion/exclusion logic, and independence logic are all *NEXPTIME*-complete. Additionally, we have shown that the satisfiability and the finite satisfiability problems of the prefix class $\exists^*\forall^*$ of dependence logic are *NEXPTIME*-complete for any vocabulary of bounded arity, and in 2*NEXPTIME* in the general case. The general approach we have employed of course also implies a range of other results on team-semantics-based logics. Finally, we have proved that the validity problem of two-variable dependence logic is undecidable, thereby answering an open problem from the literature on team semantics.

This article clears path to a more comprehensive classification of the decidability and complexity of different fragments of logics with generalized atoms and team semantics. In the future, we aim to identify further interesting related systems with a decidable satisfiability problem.

Abstract

Partially ordered nondeterminsitic finite automata (poNFAs) are NFAs whose transition relation induces a partial order on states, i.e., for which cycles occur only in the form of self-loops on a single state. A poNFA is universal if it accepts all words over its input alphabet. Deciding universality is PSpace-complete for poNFAs, and we show that this remains true even when restricting to a fixed alphabet. This is nontrivial since standard encodings of alphabet symbols in, e.g., binary can turn self-loops into longer cycles. A lower coNP-complete complexity bound can be obtained if we require that all self-loops in the poNFA are deterministic, in the sense that the symbol read in the loop cannot occur in any other transition from that state. We find that such restricted poNFAs (rpoNFAs) characterise the class of $\mathcal{R}$-trivial languages, and we establish the complexity of deciding if the language of an NFA is $\mathcal{R}$-trivial. Nevertheless, the limitation to fixed alphabets turns out to be essential even in the restricted case: deciding universality of rpoNFAs with unbounded alphabets is PSpace-complete. Our results also prove the complexity of the inclusion and equivalence problems, since universality provides the lower bound, while the upper bound is mostly known or proved in the paper.

1 Introduction

The universality problem asks if a given automaton (or grammar) accepts (or generates) all possible words over its alphabet. In typical cases, deciding universality is more difficult than deciding the word problem. For example, universality is undecidable for context-free grammars [3] and PSpace-complete for nondeterministic finite automata (NFAs) [25]. The study of universality (and its complement, emptiness) has a long tradition in formal languages, with many applications across computer science, e.g., in the context of formal knowledge representation and database theory [10, 33, 4]. Recent studies investigate the problem for specific types of automata or grammars, e.g., for prefixes or factors of regular languages [28].

Table 1 Complexity of deciding universality.

	Unary alphabet		Fixed alphabet		Arbitrary alphabet	
DFA	in P		in P		in P	
rpoNFA	in P	(Thm. 4)	coNP-comp.	(Cor. 16)	PSpace-comp.	(Thm. 19)
poNFA	in P	(Thm. 4)	PSpace-comp.	(Thm. 3)	PSpace-comp.	[1]
NFA	coNP-comp.	[34]	PSpace-comp.	[1]	PSpace-comp.	[1]

In this paper, we are interested in the universality problem for *partially ordered NFAs* (poNFAs) and special cases thereof. An NFA is partially ordered if its transition relation induces a partial order on states: the only cycles that are allowed are self-loops on a single state. Partially ordered NFAs define a natural class of languages that has been shown to coincide with level $\frac{3}{2}$ of the Straubing-Thérien hierarchy [31] and with Alphabetical Pattern Constraint (APC) languages, a subclass of regular languages effectively closed under permutation rewriting [6]. Deciding if an automaton recognises an APC language (and hence whether it can be recognised by a poNFA) is PSpace-complete for NFAs and NL-complete for DFAs [6].

Restricting to partially ordered deterministic finite automata (poDFAs), we can capture further classes of interest: two-way poDFAs characterise languages whose syntactic monoid belongs to the variety **DA** [31], introduced by Schützenberger [30]; poDFAs characterise $\mathcal{R}$-trivial languages [9]; and confluent poDFAs characterise level 1 of the Straubing-Thérien hierarchy, also known as $\mathcal{J}$-trivial languages or piecewise testable languages [32]. Other relevant classes of partially ordered automata include partially ordered Büchi automata [20] and two-way poDFAs with look-around [21].

A first result on the complexity of universality for poNFAs is readily obtained. It is well known that universality of regular expressions is PSpace-complete [1, Lemma 10.2], and it is easy to verify that the regular expressions used in the proof can be expressed in poNFAs:

▶ **Corollary 1** (Lemma 10.2 [1]). *The universality problem for poNFAs is* PSpace*-complete.*

A closer look at the proof reveals that the underlying encoding requires an alphabet of size linear in the input: PSpace-hardness is not established for alphabets of bounded size. Usually, one could simply encode alphabet symbols σ by sequences $\sigma_1 \cdots \sigma_n$ of symbols from a smaller alphabet, say $\{0,1\}$. However, doing this requires self-loops $q \xrightarrow{\sigma} q$ to be replaced by nontrivial cycles $q \xrightarrow{\sigma_1} \dots \xrightarrow{\sigma_n} q$, which are not permitted in poNFAs.

We settle this open problem by showing that PSpace-hardness is retained even for binary alphabets.

This negative result leads us to ask if there is a natural subclass of poNFAs for which universality does become simpler. We consider *restricted* poNFAs (rpoNFAs), which require self-loops to be deterministic in the sense that the automaton contains no transition as in Figure 1. Large parts of the former hardness proof hinge on transitions of this form, which, speaking intuitively, allow the automaton to navigate to an arbitrary position in the input (using the loop) and, thereafter, continue checking an arbitrary pattern. Indeed, we find that the universality becomes coNP-complete for rpoNFAs with a fixed alphabet.

However, this reduction of complexity is not preserved for unrestricted alphabets. We use a novel construction of rpoNFAs that characterise certain exponentially long words to show that universality is PSpace-complete even for rpoNFAs if the alphabet may grow polynomially. Our complexity results are summarised in Table 1.

As a by-product, we show that rpoNFAs provide another characterisation of $\mathcal{R}$-trivial languages introduced and studied by Brzozowski and Fich [9], and we establish the complexity of detecting $\mathcal{R}$-triviality and k-$\mathcal{R}$-triviality for rpoNFAs.

The complexity of the inclusion and equivalence problems of regular expressions of several special forms has been investigated by Martens et al. [22]. Some of them are expressible by poNFAs. The results have been established for alphabets of unbounded size. We point out here that our results also apply to the inclusion and equivalence problems. The complexity of universality provides the lower bound. The upper bound for the case of PSpace-complete problems then follows from the complexity for general NFAs, whereas for the coNP-complete problems it is shown in Theorem 15. Hence the results of Table 1 also hold for inclusion and equivalence.

Finally, we mention the relationship to deterministic regular expressions (DRE) [7], which are of interest in schema languages for XML data – Document Type Definition (DTD) and XML Schema Definition (XSD) – since the World Wide Web Consortium standards require that the regular expressions in their specification are deterministic. The important question is then whether a regular expression or an NFA is expressible as a DRE. This problem has been shown to be PSpace-complete [12]. Since the non-DRE-definable language $(a+b)^*b(a+b)$ [7] can be expressed by a poNFA, the problem is nontrivial for poNFAs. Its complexity (PSpace-complete), however, follows from the existing results, namely from the proof given in [5] showing PSpace-hardness of DRE-definability for regular expressions, since the regular expression constructed there can be expressed as a poNFA. On the other hand, all rpoNFA languages are DRE-definable by the automata characterization presented in [7].

Proofs omitted in the text can be found in the corresponding technical report [19].

2 Preliminaries and Definitions

We assume that the reader is familiar with automata theory [1]. The cardinality of a set A is denoted by $|A|$ and the power set of A by 2^A. An *alphabet* Σ is a finite nonempty set. A *word* over Σ is any element of the free monoid Σ^*, the *empty word* is denoted by ε. A *language* over Σ is a subset of Σ^*. For a language L over Σ, let $\overline{L} = \Sigma^* \setminus L$ denote its complement.

A *subword* of w is a word u such that $w = w_1uw_2$, for some words w_1, w_2; u is a *prefix* of w if $w_1 = \varepsilon$ and it is a *suffix* of w if $w_2 = \varepsilon$.

A *nondeterministic finite automaton* (NFA) is a quintuple $\mathcal{A} = (Q, \Sigma, \cdot, I, F)$, where Q is a finite nonempty set of states, Σ is an input alphabet, $I \subseteq Q$ is a set of initial states, $F \subseteq Q$ is a set of accepting states, and $\cdot : Q \times \Sigma \to 2^Q$ is the transition function that can be extended to the domain $2^Q \times \Sigma^*$ by induction. The language *accepted* by $\mathcal{A}$ is the set $L(\mathcal{A}) = \{w \in \Sigma^* \mid I \cdot w \cap F \neq \emptyset\}$. We often omit $\cdot$ and write simply Iw instead. The NFA $\mathcal{A}$ is *complete* if for every state q and every letter a in Σ, the set $q \cdot a$ is nonempty. It is *deterministic* (DFA) if $|I| = 1$ and $|q \cdot a| = 1$ for every state q in Q and every letter a in Σ.

A *path* π from a state q_0 to a state q_n under a word $a_1a_2\cdots a_n$, for some $n \geq 0$, is a sequence of states and input symbols $q_0a_1q_1a_2\ldots q_{n-1}a_nq_n$ such that $q_{i+1} \in q_i \cdot a_{i+1}$, for $i = 0, 1, \ldots, n-1$. Path π is *accepting* if $q_0 \in I$ and $q_n \in F$. A path is *simple* if all the states are pairwise distinct.

A *deterministic Turing machine* (DTM) is a tuple $M = (Q, T, I, \delta, \sqcup, q_o, q_f)$, where Q is the finite state set, T is the tape alphabet, $I \subseteq T$ is the input alphabet, $\sqcup \in T \setminus I$ is the blank symbol, q_o is the initial state, q_f is the accepting state, and δ is the transition function mapping $Q \times T$ to $Q \times T \times \{L, R, S\}$, see the details in [1].

The *universality problem* asks, given an automaton $\mathcal{A}$ over Σ, whether $L(\mathcal{A}) = \Sigma^*$.

3 Partially Ordered NFAs

In this section, we introduce poNFAs, recall their characterisation in terms of the Straubing-Thérien hierarchy, and show that universality remains PSPACE-complete even when restricting to binary alphabets. Merely the case of unary alphabets turns out to be simpler.

▶ **Definition 2.** Let $\mathcal{A}$ be an NFA. A state q is *reachable* from a state p, written $p \leq q$, if there is a word $w \in \Sigma^*$ such that $q \in p \cdot w$. We write $p < q$ if $p \leq q$ and $p \neq q$. $\mathcal{A}$ is a *partially ordered NFA* (*poNFA*) if $\leq$ is a partial order.

The expressive power of poNFAs can be characterised by the *Straubing-Thérien (ST) hierarchy* [35, 37]. For an alphabet Σ, level 0 of this hierarchy is defined as $\mathcal{L}(0) = \{\emptyset, \Sigma^*\}$. For integers $n \geq 0$, the levels $\mathcal{L}(n)$ and $\mathcal{L}(n + \frac{1}{2})$ are as follows:

- $\mathcal{L}(n + \frac{1}{2})$ consists of all finite unions of languages $L_0 a_1 L_1 a_2 \dots a_k L_k$, with $k \geq 0$, $L_0, \dots, L_k \in \mathcal{L}(n)$, and $a_1, \dots, a_k \in \Sigma$;
- $\mathcal{L}(n + 1)$ consists of all finite Boolean combinations of languages from level $\mathcal{L}(n + \frac{1}{2})$.

Note that the levels of the hierarchy contain only *star-free* languages by definition. It is known that the hierarchy does not collapse on any level [8], but the problem of deciding if a language belongs to some level k is largely open for $k > \frac{5}{2}$ [2, 27]. The ST hierarchy further has close relations to the *dot-depth hierarchy* [11, 8, 36] and to complexity theory [38].

Interestingly, the languages recognised by poNFAs are exactly the languages on level $\frac{3}{2}$ of the Straubing-Thérien hierarchy [31]. Since the hierarchy is proper, this means that poNFAs can only recognise a strict subset of star-free regular languages. In spite of this rather low expressive power, the universality problem of poNFAs has the same worst-case complexity as for general NFAs, even when restricting to a fixed alphabet with only a few letters.

▶ **Theorem 3.** *For every alphabet Σ with $|\Sigma| \geq 2$, the universality problem for poNFAs over Σ is* PSPACE*-complete.*

Proof. Membership follows from the fact that universality is in PSPACE for NFAs [14].

To show hardness, we modify the construction of Aho et al. [1] to work on a two-letter alphabet. Consider a polynomial p and a p-space-bounded DTM $M = \langle Q, T, I, \delta, \sqcup, q_o, q_f \rangle$. Without loss of generality, we assume $q_0 \neq q_f$. We define an encoding of runs of M as a word over a given alphabet. For any input $x \in I^*$, we construct, in polynomial time, a regular expression R_x that represents all words that do *not* encode an accepting run of M on x. Therefore, R_x matches all words iff M does not accept x. The claim then follows by showing that R_x can be encoded by a poNFA.

A configuration of M on an input x consists of a current state $q \in Q$, the position $0 \leq \ell \leq p(|x|)$ of the read/write head, and the current tape contents $\theta_0, \dots, \theta_{p(|x|)}$ with $\theta_i \in T$. We represent it by a sequence $\langle \theta_0, \varepsilon \rangle \cdots \langle \theta_{\ell-1}, \varepsilon \rangle \langle \theta_\ell, q \rangle \langle \theta_{\ell+1}, \varepsilon \rangle \cdots \langle \theta_{p(|x|)}, \varepsilon \rangle$ of symbols from $T \times (Q \cup \{\varepsilon\})$. We denote $T \times (Q \cup \{\varepsilon\})$ by Δ. A potential run of M on x is represented by word $\# w_1 \# w_2 \# \cdots \# w_m \#$, where $w_i \in \Delta^{p(|x|)}$ and $\# \notin \Delta$ is a fresh separator symbol. One can construct a regular expression recognising all words over $\Delta \cup \{\#\}$ that do not correctly encode a run of M at all, or that encode a run that is not accepting [1].

We encode symbols of $\Delta \cup \{\#\}$ using a fixed alphabet $\Sigma = \{0, 1\}$. For each $\delta \in \Delta \cup \{\#\}$, let $\hat{\delta}_1 \cdots \hat{\delta}_K \in \{0, 1\}^K$ be a unique binary encoding of length $K = \lceil \log(|\Delta \cup \{\#\}|) \rceil$. We define $\mathit{enc}(\delta)$ to be the binary sequence $001\hat{\delta}_1 1\hat{\delta}_2 1 \cdots \hat{\delta}_K 1$ of length $L = 2K + 3$. We extend enc to words and sets of symbols as usual: $\mathit{enc}(\delta_1 \cdots \delta_m) = \mathit{enc}(\delta_1) \cdots \mathit{enc}(\delta_m)$ and $\mathit{enc}(\Delta') = \{\mathit{enc}(\delta) \mid \delta \in \Delta'\}$. Importantly, any word of the form $\mathit{enc}(\delta_1 \cdots \delta_m)$ contains 00 only at positions that are multiples of L, marking the start of one encoded symbol.

We now construct the regular expression R_x that matches all words of Σ^* that do not represent an accepting computation of M on x. We proceed in four steps: (A) we detect all words that contain words from Σ^* that are not of the form $\mathit{enc}(\delta)$; (B) we detect all words that do not start with the initial configuration; (C) we detect all words that do not encode a valid run since they violate a transition rule; and (D) we detect all words that encode non-accepting runs, or runs that end prematurely.

For (A), note that a word $w \in \Sigma^*$ that is not of the form $\mathit{enc}(v)$ for any word $v \in (\Delta \cup \{\#\})^*$ must either (A.1) start with 1 or 01; (A.2) end with 0; (A.3) contain a word $00\Sigma^{L-2}$ that is not in $\mathit{enc}(\Delta \cup \{\#\})$; (A.4) contain a word from $\mathit{enc}(\Delta \cup \{\#\})\{1, 01\}$; or (A.5) end in a word $00\Sigma^M$ with $M < L - 2$. Using E to abbreviate $\mathit{enc}(\Delta \cup \{\#\})$ and $\bar{E}$ to abbreviate $00\Sigma^{L-2} \setminus E$ (both sets of polynomially many binary sequences), we can express (A.1)–(A.5) in the regular expression

$$(1\Sigma^* + 01\Sigma^*) + (\Sigma^* 0) + \left(\Sigma^* \bar{E} \Sigma^*\right) + (\Sigma^* E (1 + 01) \Sigma^*) + \left(\Sigma^* 00 (\Sigma + \Sigma^2 + \ldots + \Sigma^{L-3})\right) \quad (1)$$

where we use finite sets $\{e_1, \ldots, e_m\}$ to denote regular expressions $(e_1 + \ldots + e_m)$, as usual. All sets in (1) are polynomial in size, so that the overall expression is polynomial. The expression (1) can be captured by a poNFA since the only cycles required arise when translating Σ^*; they can be expressed as self-loops. All other repetitions of the form Σ^i in (1) can be expanded to polynomial-length sequences without cycles.

For (B), we want to detect all words that do not start with the word $w = \mathit{enc}(\#\langle x_1, q_0\rangle \langle x_2, \varepsilon\rangle \cdots \langle x_{|x|}, \varepsilon\rangle \langle \sqcup, \varepsilon\rangle \cdots \langle \sqcup, \varepsilon\rangle \#)$ of length $(p(|x|) + 2)L$. This happens if (B.1) the word is shorter than $(p(|x|) + 2)L$, or (B.2), starting at position jL for $0 \leq j \leq p(|x|) + 1$, there is a word from the polynomial set $\Sigma^L \setminus \{\mathit{enc}(w_j)\}$, which we abbreviate by $\bar{E}_j$. We can capture (B.1) and (B.2) in the regular expression

$$\left(\varepsilon + \Sigma + \Sigma^2 + \ldots + \Sigma^{L(p(|x|)+2)-1}\right) + \sum_{0 \leq j \leq p(|x|)+1} (\Sigma^{jL} \cdot \bar{E}_j \cdot \Sigma^*) \quad (2)$$

The empty expression ε is used for readability; it can easily be expressed in the NFA encoding. As before, it is easy to see that this expression is polynomial and does not require any nontrivial cycles when encoded in an NFA. Note that we ensure that the surrounding # in the initial configuration are present.

For (C), we need to check for incorrect transitions. Consider again the encoding $\# w_1 \# \ldots \# w_m \#$ of a sequence of configurations with a word over $\Delta \cup \{\#\}$, where we can assume that w_1 encodes the initial configuration according to (A) and (B). In an encoding of a valid run, the symbol at any position $j \geq p(|x|) + 2$ is uniquely determined by the symbols at positions $j - p(|x|) - 2$, $j - p(|x|) - 1$, and $j - p(|x|)$, corresponding to the cell and its left and right neighbour in the previous configuration. Given symbols $\delta_\ell, \delta, \delta_r \in \Delta \cup \{\#\}$, we can therefore define $f(\delta_\ell, \delta, \delta_r) \in \Delta \cup \{\#\}$ to be the symbol required in the next configuration. The case where $\delta_\ell = \#$ or $\delta_r = \#$ corresponds to transitions applied at the left and right edge of the tape, respectively; for the case that $\delta = \#$, we define $f(\delta_\ell, \delta, \delta_r) = \#$, ensuring that the separator # is always present in successor configurations as well. We can then check for invalid transitions using the regular expression

$$\sum_{\delta_\ell, \delta, \delta_r \in \Delta \cup \{\#\}} \Sigma^* \cdot \mathit{enc}(\delta_\ell \delta \delta_r) \cdot \Sigma^{L(p(|x|)-1)} \cdot \mathit{enc}(\overline{f}(\delta_\ell, \delta, \delta_r)) \cdot \Sigma^* \quad (3)$$

where $\overline{f}(\delta_\ell, \delta, \delta_r) = \Delta \cup \{\#\} \setminus \{f(\delta_\ell, \delta, \delta_r)\}$. Polynomiality and poNFA-expressibility are again immediate. Note that expression (3) only detects wrong transitions if a (long enough) next configuration exists. The case that the run stops prematurely is covered next.

Finally, for (D) we detect all words that either (D.1) end in a configuration that is incomplete (too short) or (D.2) end in a configuration that is not in the final state q_f. Abbreviating $T \times (Q \setminus \{q_f\})$ as $\bar{E}_f$, and using similar ideas as above, we obtain

$$\Big(\Sigma^* enc(\#)(\Sigma^L + \ldots + \Sigma^{p(|x|)L})\Big) + \Big(\Sigma^* \bar{E}_f(\varepsilon + \Sigma^L + \ldots + \Sigma^{(p(|x|)-1)L})enc(\#)\Big) \qquad (4)$$

and this can again be expressed as a polynomial poNFA.

The expressions (1)–(4) together then detect all non-accepting or wrongly encoded runs of M. In particular, if we start from the correct initial configuration ((2) does not match), then for (3) not to match, all complete future configurations must have exactly one state and be delimited by encodings of $\#$. Expressing the regular expressions as a single poNFA of polynomial size, we have thus reduced the word problem of polynomially space-bounded Turing machines to the universality problem of poNFAs. ◀

Ellul et al. give an example of a regular expression over a 5-letter alphabet such that the shortest non-accepted word is of exponential length, and which can also be encoded as a poNFA [13, Section 5]. Our previous proof shows such an example for an alphabet of two letters, if we use a Turing machine that runs for exponentially many steps before accepting. Note, however, that this property alone would not imply Theorem 3.

Unary Alphabet. Reducing the size of the alphabet to one leads to a reduction in complexity. This is expected, since the universality problem for NFAs over a unary alphabet is merely coNP-complete [34]. For poNFAs, however, the situation is even simpler:

▶ **Theorem 4.** *The universality problem for poNFAs over a unary alphabet is in* P.

Proof. If the language is infinite, then there must be a simple path from an initial state to an accepting state via a state with a self-loop. Let k denote the length of this path, which is bounded by the number of states. Then this path accepts all words of length at least k, that is, all words of the form $a^k a^*$. It remains to check that all words up to length k are also accepted, which can be done in polynomial time. ◀

4 Restricted Partially Ordered NFAs

We now introduce restricted poNFAs, which are distinguished by the forbidden pattern of Figure 1. We relate them to the known class of $\mathcal{R}$-trivial languages, and we establish complexity results for deciding if a language falls into this class.

▶ **Definition 5.** A *restricted partially ordered NFA (rpoNFA)* is a poNFA such that, for every state q and symbol a, if $q \in q \cdot a$ then $q \cdot a = \{q\}$.

We will show below that rpoNFAs characterise $\mathcal{R}$-trivial languages [9]. To introduce this class of languages, we first require some auxiliary definitions. A word $v = a_1 a_2 \cdots a_n$ is a *subsequence* of a word w, denoted $v \preccurlyeq w$, if $w \in \Sigma^* a_1 \Sigma^* a_2 \Sigma^* \cdots \Sigma^* a_n \Sigma^*$. For $k \geq 0$, we write $sub_k(v) = \{u \in \Sigma^* \mid u \preccurlyeq v, |u| \leq k\}$ for the set of all subsequences of v of length up to k. Two words w_1, w_2 are *$\sim_k$-equivalent*, written $w_1 \sim_k w_2$, if $sub_k(w_1) = sub_k(w_2)$. Then $\sim_k$ is a congruence (for $\cdot$) of finite index (i.e., with finitely many equivalence classes) [32]. $\mathcal{R}$-trivial languages are defined by defining a related congruence $\sim_k^{\mathcal{R}}$ that considers subsequences of prefixes:

▶ **Definition 6.** Let $x, y \in \Sigma^*$ and $k \geq 0$. Then $x \sim_k^{\mathcal{R}} y$ if and only if

- for each prefix u of x, there exists a prefix v of y such that $u \sim_k v$, and
- for each prefix v of y, there exists a prefix u of x such that $u \sim_k v$.

A regular language is *k-$\mathcal{R}$-trivial* if it is a union of $\sim_k^{\mathcal{R}}$ classes, and it is *$\mathcal{R}$-trivial* if it is k-$\mathcal{R}$-trivial for some $k \geq 0$.

It is known that $x \sim_k^{\mathcal{R}} y$ implies $x \sim_k y$ and (if $k \geq 1$) $x \sim_{k-1}^{\mathcal{R}} y$ [9]. Therefore, every k-$\mathcal{R}$-trivial language is also $(k+1)$-$\mathcal{R}$-trivial. Moreover, it has been shown that a language L is $\mathcal{R}$-trivial if and only if the minimal DFA recognising L is partially ordered [9]. We can lift this result to characterise the expressive power of rpoNFAs. Namely, it is known that a language is $\mathcal{R}$-trivial if and only if it is a finite union of $\mathcal{R}$-expressions, i.e., expressions of the form $\Sigma_1^* a_1 \Sigma_2^* a_2 \cdots \Sigma_m^* a_m \Sigma_{m+1}^*$, for some $m \geq 0$, where $a_i \notin \Sigma_i$ for $1 \leq i \leq m$. The characterization goes back to Eilenberg and can be found, e.g., in [26]. Thus, we have the following.

▶ **Theorem 7.** *A regular language is $\mathcal{R}$-trivial if and only if it is accepted by an rpoNFA.*

This characterisation in terms of automata with forbidden patterns can be compared to results of Glaßer and Schmitz, who use DFAs with a forbidden pattern to obtain another characterisation of level $\frac{3}{2}$ of the Straubing-Thérien hierarchy [15, 29].

We can further relate the *depth* of rpoNFAs to k-$\mathcal{R}$-trivial languages. Recall that the depth of an atomaton $\mathcal{A}$, denoted $\mathit{depth}(\mathcal{A})$, is the number of input symbols on the longest simple path of $\mathcal{A}$ that starts in an initial state.

▶ **Theorem 8.** *The language recognised by a complete rpoNFA $\mathcal{A}$ is $\mathit{depth}(\mathcal{A})$-$\mathcal{R}$-trivial.*

Similar relationships have been studied for $\mathcal{J}$-trivial languages [18, 23], but we are not aware of any such investigation for $\mathcal{R}$-trivial languages.

Finally, we may ask how difficult it is to decide whether a given NFA $\mathcal{A}$ accepts a language that is $\mathcal{R}$-trivial or k-$\mathcal{R}$-trivial for a specific $k \geq 0$. For most levels of the ST hierarchy, it is not even known if this problem is decidable, and when it is, exact complexity bounds are often missing [27]. The main exception are $\mathcal{J}$-trivial languages – level 1 of the hiearchy – which have recently attracted some attention, motivated by applications in algebra and XML databases [16, 18, 24].

The following result is a special case of a more general result in [17, Theorem 3.1].

▶ **Theorem 9.** *Given an NFA $\mathcal{A}$, it is* PSPACE*-complete to decide if the language accepted by $\mathcal{A}$ is $\mathcal{R}$-trivial.*

To the best of our knowledge, the following complexity results for recognising $(k\text{-})\mathcal{R}$-trivial languages had not been obtained previously.

▶ **Theorem 10.** *Given an NFA $\mathcal{A}$ and $k \geq 0$, it is* PSPACE*-complete to decide if the language accepted by $\mathcal{A}$ is k-$\mathcal{R}$-trivial.*

In both previous theorems, hardness is shown by reduction from the universality problem for NFAs, hence it holds even for binary alphabets [14]. For a unary alphabet, we can obtain the following result.

▶ **Theorem 11.** *Given an NFA $\mathcal{A}$ over a unary alphabet, the problems of deciding if the language accepted by $\mathcal{A}$ is $\mathcal{R}$-trivial, or k-$\mathcal{R}$-trivial for a given $k \geq 0$, respectively, are both* coNP*-complete.*

5 Deciding Universality of rpoNFAs

In this section, we return to the universality problem for the case of rpoNFAs. We first show that we can indeed obtain the hoped-for reduction in complexity when using a fixed alphabet. For the general case, however, we can recover the same PSPACE lower bound as for poNFAs, albeit with a more involved proof. Even for fixed alphabets, we can get a coNP lower bound:

▶ **Lemma 12.** *The universality problem of rpoNFAs is* coNP*-hard even when restricting to alphabets with two letters.*

The proof proceeds by a direct reduction of propositional logic satisfiability to the emptiness of rpoNFAs. For a matching upper bound, we use some results from the literature.

▶ **Lemma 13** ([9]). *Every congruence class of $\sim_k^{\mathcal{R}}$ contains a unique element of minimal length. If $a_1, a_2, \ldots, a_n \in \Sigma$, then $a_1 a_2 \cdots a_n$ is minimal if and only if $sub_k(\varepsilon) \subsetneq sub_k(a_1) \subsetneq sub_k(a_1 a_2) \subsetneq \ldots \subsetneq sub_k(a_1 a_2 \ldots a_n)$.*

The maximal length of such a word has also been studied [24].

▶ **Lemma 14** ([24]). *Let Σ be an alphabet of cardinality $|\Sigma| \geq 1$, and let $k \geq 1$. The length of a longest word, w, such that $sub_k(w) = \{v \in \Sigma^* \mid |v| \leq k\}$, and, for any two distinct prefixes w_1 and w_2 of w, $sub_k(w_1) \neq sub_k(w_2)$, is $\binom{k+|\Sigma|}{k} - 1$. The bound is tight.*

Lemma 13 and 14 provide the main ingredients for showing that, if the size $|\Sigma|$ of the alphabet is bounded, then non-universality is witnessed by a word of polynomial length. Together with Lemma 12, this allows us to establish the following result, which we state in a more general form.

▶ **Theorem 15.** *Let Σ be a fixed alphabet, and let $\mathcal{A}$ and $\mathcal{B}$ be two complete rpoNFAs over Σ. Then the problem whether $L(\mathcal{A}) \subseteq L(\mathcal{B})$ is* coNP*-complete.*

Proof. Hardness follows from Lemma 12. To prove membership, we denote $|\Sigma| = m$. Let $k = \max\{depth(\mathcal{A}), depth(\mathcal{B})\}$; k is bounded by the number of states of $\mathcal{A}$ and $\mathcal{B}$. By Theorem 8, languages $L(\mathcal{A})$ and $L(\mathcal{B})$ are k-$\mathcal{R}$-trivial, which means that they are a finite union of $\sim_k^{\mathcal{R}}$ classes. According to Lemmas 13 and 14, the length of the unique minimal representatives of the $\sim_k^{\mathcal{R}}$ classes is at most $\binom{k+m}{k} - 1 < \frac{(k+m)^m}{m!}$. Since m is a constant, the bound is polynomial in k. Therefore, if the language $L(\mathcal{A})$ is not a subset of $L(\mathcal{B})$, then there exists a polynomial certificate, which can be guessed by a nondeterministic algorithm. ◀

▶ **Corollary 16.** *Let Σ be a fixed alphabet. Then the universality problem for rpoNFAs over Σ is* coNP*-complete.*

Without fixing the alphabet, universality remains PSPACE-hard even for rpoNFAs, but a proof along the lines of Theorem 3 is not straightforward. In essence, rpoNFAs lose the ability to navigate to an arbitrary position within a word for checking some pattern there. Expressions of the form $(\Sigma^* \cdots)$, which we frequently used, e.g., in (1), are therefore excluded. This is problematic since the run of a polynomially space-bounded Turing machine may be of exponential length, and we need to match patterns across the full length of our (equally exponential) encoding of this run. How can we navigate such a long word without using Σ^*? Our answer is to first define an rpoNFA that accepts all words except for a single, exponentially long word. This word will then be used as an rpoNFA-supported "substrate" for our Turing machine encoding, which again follows Theorem 3.

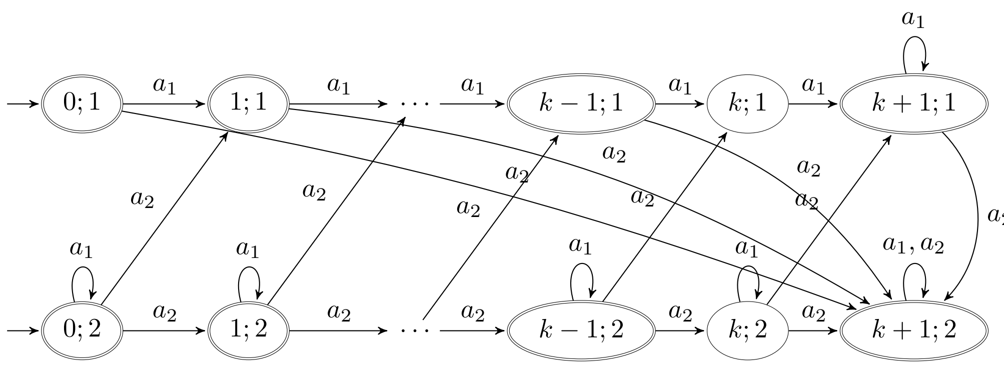

Figure 2 The rpoNFA $\mathcal{A}_{k,2}$ with $2(k+2)$ states.

Table 2 Recursive construction of words $W_{k,n}$ as used in the proof of Lemma 17.

$k\backslash n$	1	2	3
1	a_1	a_1a_2	$a_1a_2a_3$
2	a_1^2	$a_1^2a_2a_1a_2$	$a_1^2a_2a_1a_2a_3a_1a_2a_3$
3	a_1^3	$a_1^3a_2a_1^2a_2a_1a_2$	$a_1^3a_2a_1^2a_2a_1a_2a_3a_1^2a_2a_1a_2a_3a_1a_2a_3$
4	a_1^4	$a_1^4a_2a_1^3a_2a_1^2a_2a_1a_2$	$a_1^4a_2a_1^3a_2a_1^2a_2a_1a_2a_3a_1^3a_2a_1^2a_2a_1a_2a_3a_1^2a_2a_1a_2a_3a_1a_2a_3$

▶ **Lemma 17.** *For all positive integers k and n, there exists an rpoNFA $\mathcal{A}_{k,n}$ over an n-letter alphabet with $n(k+2)$ states such that the unique word not accepted by $\mathcal{A}_{k,n}$ is of length* $\binom{k+n}{k}-1$.

Proof sketch. For integers $k, n \geq 1$, we recursively define words $W_{k,n}$ over the alphabet $\Sigma_n = \{a_1, a_2, \ldots, a_n\}$. For the base cases, we set $W_{k,1} = a_1^k$ and $W_{1,n} = a_1a_2 \ldots a_n$. The cases for $k, n > 1$ are defined recursively by setting

$$\begin{aligned} W_{k,n} &= W_{k,n-1}\, a_n\, W_{k-1,n} \\ &= W_{k,n-1}\, a_n\, W_{k-1,n-1}\, a_n\, W_{k-2,n} \\ &= W_{k,n-1}\, a_n\, W_{k-1,n-1}\, a_n\, \cdots\, a_n\, W_{1,n-1}\, a_n\,. \end{aligned} \tag{5}$$

The recursive construction is illustrated in Table 2. The length of $W_{k,n}$ is $\binom{k+n}{n}-1$ [24]. We further set $W_{k,n} = \varepsilon$ whenever $kn = 0$, since this is useful for defining $\mathcal{A}_{k,n}$ below.

We construct an rpoNFA $\mathcal{A}_{k,n}$ over Σ_n that accepts the language $\Sigma_n^* \setminus \{W_{k,n}\}$. For $n = 1$ and $k \geq 0$, let $\mathcal{A}_{k,1}$ be the minimal DFA accepting the language $\{a_1\}^* \setminus \{a_1^k\}$. It consists of the $k+2$ states of the form $(i;1)$ in the upper part of Figure 2, together with the given transitions. All states but $(k;1)$ are final, and $(0;1)$ is initial.

Given $\mathcal{A}_{k,n-1}$, we recursively construct $\mathcal{A}_{k,n}$ as defined next. The construction for $n = 2$ is illustrated in Figure 2. We obtain $\mathcal{A}_{k,n}$ from $\mathcal{A}_{k,n-1}$ by adding $k+2$ states $(0;n), (1;n), \ldots, (k+1;n)$, where $(0;n)$ is added to the initial states, and all states other than $(k;n)$ are added to the final states. $\mathcal{A}_{k,n}$ therefore has $n(k+2)$ states.

The additional transitions of $\mathcal{A}_{k,n}$ consist of four groups: (1) self-loops $(i;n) \xrightarrow{a_j} (i;n)$ for every $i = 0, \ldots, k+1$ and $a_j = a_1, \ldots, a_{n-1}$. (2) transitions $(i;n) \xrightarrow{a_n} (i+1;n)$ for every $i = 0, \ldots, k$. (3) transitions $(i;n) \xrightarrow{a_n} (i+1;m)$ for every $i = 0, \ldots, k$ and $m = 1, \ldots, n-1$. (4) transitions $(i;m) \xrightarrow{a_n} (k+1;n)$ for every accepting state $(i;m)$ of $\mathcal{A}_{k,n-1}$.

The additional states of $\mathcal{A}_{k,n}$ and transitions (1) and (2) ensure acceptance of every word that does not contain exactly k occurrences of a_n. The transitions (3) ensure acceptance of all words in $(\Sigma_{n-1}^* a_n)^{i+1} L(\mathcal{A}_{k-(i+1),n-1}) a_n \Sigma_n^*$, for which the word between the $(i+1)$st and the $(i+2)$nd occurrence of a_n is not of the form $W_{k-(i+1),n-1}$, hence not a correct subword of $W_{k,n} = W_{k,n-1} a_n \cdots a_n W_{k-(i+1),n-1} a_n \cdots a_n W_{1,n-1} a_n$. The transitions (4) ensure that all words with a prefix $w \cdot a_n$ are accepted, where w is any word $\Sigma_{n-1}^* \setminus \{W_{k,n-1}\}$ accepted by $\mathcal{A}_{k,n-1}$. Together, these conditions ensure that $\mathcal{A}_{k,n}$ accepts every input other than $W_{k,n}$

It remains to show that $\mathcal{A}_{k,n}$ does not accept $W_{k,n}$, which we do by induction on (k,n). We start with the base cases. For $(0,n)$ and any $n \geq 1$, the word $W_{0,n} = \varepsilon$ is not accepted by $\mathcal{A}_{0,n}$, since the initial states $(0,m) = (k,m)$ of $\mathcal{A}_{0,n}$ are not accepting. Likewise, for $(k,1)$ and any $k \geq 0$, we find that $W_{k,1} = a_i^k$ is not accepted by $\mathcal{A}_{k,1}$ (the upper part of Figure 2).

For the inductive case $(k,n) \geq (1,2)$, assume $\mathcal{A}_{k',n'}$ does not accept $W_{k',n'}$ for any $(k',n') < (k,n)$. We have $W_{k,n} = W_{k,n-1} a_n W_{k-1,n}$, and $W_{k,n-1}$ is not accepted by $\mathcal{A}_{k,n-1}$ by induction. In addition, there is no transition under a_n from any non-accepting state of $\mathcal{A}_{k,n-1}$ in $\mathcal{A}_{k,n}$. Therefore, if $W_{k,n}$ is accepted by $\mathcal{A}_{k,n}$, it must be accepted in a run starting from the initial state $(0;n)$. Since $W_{k,n-1}$ does not contain a_n, we find that $\mathcal{A}_{k,n}$ can only reach the states $(0;n) \cdot W_{k,n-1} a_n = \{(1;m) \mid 1 \leq m \leq n\}$ after reading $W_{k,n-1} a_n$. These are the initial states of automaton $\mathcal{A}_{k-1,n}$, which does not accept $W_{k-1,n}$ by induction. Hence $W_{k,n}$ is not accepted by $\mathcal{A}_{k,n}$. ◀

As a corollary, we find that there are rpoNFAs $\mathcal{A} = \mathcal{A}_{n,n}$ for which the shortest non-accepted word is exponential in the size of $\mathcal{A}$. Note that $\binom{2n}{n} \geq 2^n$.

▶ **Corollary 18.** *For every integer $n \geq 1$, there is an rpoNFA $\mathcal{A}_n$ over an n-letter alphabet with $n(n+2)$ states such that the shortest word not accepted by $\mathcal{A}_n$ is of length at least $\binom{2n}{n} - 1$. Therefore, any minimal DFA accepting the same language has at least $\binom{2n}{n}$ states.*

To simulate exponentially long runs of a Turing machine, we start from an encoding of runs using words $\# w_1 \# \ldots \# w_m \#$ as in Theorem 3, but we combine every letter of this encoding with one letter of the alphabet of $\mathcal{A}_n$. We then accept all words for which the projection to the alphabet of $\mathcal{A}_n$ is accepted by $\mathcal{A}_n$, i.e., all but those words of exponential length that are based on the unique word not accepted by $\mathcal{A}_n$. We ensure that, if there is an accepting run, it will have an encoding of this length. It remains to eliminate (accept) all words that correspond to a non-accepting or wrongly encoded run. We can check this as in Theorem 3, restricting to the first components of our combined alphabet. The self-loop that was used to encode Σ^* in poNFAs is replaced by a full copy of $\mathcal{A}_n$, with an additional transition from each state that allows us to leave this "loop." This does not simulate the full loop, but it allows us to navigate the entirety of our exponential word, which is all we need.

▶ **Theorem 19.** *The universality problem for rpoNFAs is* PSPACE*-complete.*

Proof. The membership follows since universality is in PSPACE for NFAs. For hardness, we proceed as explained above. Consider a p-space-bounded DTM $M = \langle Q, T, I, \delta, \sqcup, q_o, q_f \rangle$ as in the proof of Theorem 3. We encode runs of M as words over $T \times (Q \cup \{\varepsilon\}) \cup \{\#\}$ as before. We can use an unrestricted alphabet now, so no binary encoding is needed, and the regular expressions can be simplified accordingly.

If M has an accepting run, then it has one without repeated configurations. For an input word x, there are $C(x) = (|T \times (Q \cup \{\varepsilon\})|)^{p(|x|)}$ distinct configuration words in our encoding. Considering separator symbols $\#$, the maximal length of the encoding of a run without repeated configurations therefore is $1 + C(x)(p(|x|) + 1)$. Let n be the least number such that $|W_{n,n}| \geq 1 + C(x)(p(|x|) + 1)$. Since $|W_{n,n}| + 1 = \binom{2n}{n} \geq 2^n$, it follows that n is smaller than $\lceil \log(1 + C(x)(p(|x|) + 1)) \rceil$ and hence polynomial in the size of M and x.

Consider the automaton $\mathcal{A}_{n,n}$ with alphabet $\Sigma_n = \{a_1, \ldots, a_n\}$ of Lemma 17, and define $\Delta_{\#\$} = T \times (Q \cup \{\varepsilon\}) \cup \{\#, \$\}$. We consider the alphabet $\Pi = \Sigma_n \times \Delta_{\#\$}$, where the second letter is used for encoding a run as in Theorem 3. Since $|W_{n,n}|$ may not be a multiple of $p(|x|) + 1$, we add \$ to fill up any remaining space after the last configuration. For a word $w = \langle a_{i_1}, \delta_1 \rangle \cdots \langle a_{i_\ell}, \delta_\ell \rangle \in \Pi^\ell$, we define $w[1] = a_{i_1} \cdots a_{i_\ell} \in \Sigma_n^\ell$ and $w[2] = \delta_1 \ldots \delta_\ell \in \Delta_{\#\$}^\ell$. Conversely, for a word $v \in \Delta_{\#\$}^*$, we write *enc*$(v)$ to denote the set of all words $w \in \Pi^{|v|}$ with $w[2] = v$. Similarly, for $v \in \Sigma_n^*$, *enc*(v) denotes the words $w \in \Pi^{|v|}$ with $w[1] = v$. We extend this notation to sets of words.

We say that a word w encodes an accepting run of M on x if $w[1] = W_{n,n}$ and $w[2]$ is of the form $\# w_1 \# \cdots \# w_m \# \$^j$ such that there is an $i \in \{1, \ldots, m\}$ for which we have that

- $\# w_1 \# \cdots \# w_i \#$ encodes an accepting run of M on x as in the proof of Theorem 3,
- $w_k = w_i$ for all $k \in \{i+1, \ldots, m\}$, and
- $j \leq p(|x|)$.

In other words, we extend the encoding by repeating the accepting configuration until we have less than $p(|x|) + 1$ symbols before the end of $|W_{n,n}|$ and fill up the remaining places with \$.

The modified encoding requires slightly modified expressions for capturing conditions (A)–(D) from the proof of Theorem 3. Condition (A) is not necessary, since we do not encode symbols in binary. Condition (B) can use the same expression as in (2), adjusted to our alphabet:

$$\left(\varepsilon + \Pi + \Pi^2 + \ldots + \Pi^{p(|x|)+1}\right) + \sum_{0 \leq j \leq p(|x|)+1} (\Pi^j \cdot \bar{E}_j \cdot \Pi^*) \tag{6}$$

where $\bar{E}_j$ is the set $\Sigma_n \times (\Delta_{\#\$} \setminus \{w_j\})$ where w_j encodes the jth symbol on the initial tape as in Theorem 3. All uses of Π^i in this expression encode words of polynomial length, which can be represented in rpoNFAs. Trailing expressions Π^* do not lead to the forbidden pattern of Figure 1.

Condition (C) uses the same ideas as in Theorem 3, especially the transition encoding function f, which we extend to $f : \Delta_{\#\$}^3 \to \Delta_{\#\$}$. For allowing the last configuration to be repeated, we define f as if the final state q_f of M had a self loop (a transition that does not modify the tape, state, or head position). Moreover, we generally permit \$ to occur instead of the expected next configuration symbol. We obtain:

$$\Pi^* \sum_{\delta_\ell, \delta, \delta_r \in \Delta_{\#\$}} \mathit{enc}(\delta_\ell \delta \delta_r) \cdot \Pi^{p(|x|)-1} \cdot \hat{f}(\delta_\ell, \delta, \delta_r) \cdot \Pi^* \tag{7}$$

where $\hat{f}(\delta_\ell, \delta, \delta_r)$ is $\Pi \setminus \mathit{enc}(\{f(\delta_\ell, \delta, \delta_r), \$\})$. Expression (7) is not readily encoded in an rpoNFA, due to the leading Π^*. To address this, we replace Π^* by the expression $\Pi^{\leq |W_{n,n}|-1}$, which matches every word $w \in \Pi^*$ with $|w| \leq |W_{n,n}| - 1$. Clearly, this suffices for our case. As $|W_{n,n}| - 1$ is exponential, we cannot encode this directly as for other expressions Π^i before and we use $\mathcal{A}(n,n)$ instead.

In detail, let E be the expression obtained from (7) when omitting the initial Π^*, and let $\mathcal{A}$ be an rpoNFA that accepts the language of E. We can construct $\mathcal{A}$ so that it has a single initial state. Moreover, let *enc*$(\mathcal{A}_{n,n})$ be the automaton $\mathcal{A}_{n,n}$ of Lemma 17 with each transition $q \xrightarrow{a_i} q'$ replaced by all transitions $q \xrightarrow{\pi} q'$ with $\pi \in \mathit{enc}(a_i)$. We construct an rpoNFA $\mathcal{A}'$ that accepts the language of $(\Pi^* \setminus \{W_{n,n}\}) + (\Pi^{\leq |W_{n,n}|-1} \cdot E)$ by merging *enc*$(\mathcal{A}_{n,n})$ with $n(n+1)$ copies of $\mathcal{A}$, where we identify the initial state of each such copy with a unique final state of *enc*$(\mathcal{A}_{n,n})$. The fact that *enc*$(\mathcal{A}_{n,n})$ alone already accepts $(\Pi^* \setminus \{\mathit{enc}(W_{n,n})\})$

was shown in the proof of Lemma 17. This also implies that it accepts all words of length $\leq |W_{n,n}| - 1$ as needed to show that $(\Pi^{\leq |W_{n,n}|-1} \cdot E)$ is accepted. Entering states of (a copy of) $\mathcal{A}$ after accepting a word of length $\geq |W_{n,n}|$ is possible, but all words accepted in such a way are longer than $W_{n,n}$ and hence in $(\Pi^* \setminus \{enc(W_{n,n})\})$.

Note that the acceptance of $(\Pi^* \setminus \{enc(W_{n,n})\})$, which is a side effect of this encoding, does not relate to expressing (7) but is still useful for our intended overall encoding.

The final condition (D) is minimally modified to allow for up to $p(|x|)$ trailing \$. For a word v, we use $v^{\leq i}$ to abbreviate $(\varepsilon + v + \ldots + v^i)$, and we define $\bar{E}_f = (T \times (Q \setminus \{q_f\}))$ as before. Since (C) does not accept words with too many trailing \$, we add this here instead. Moreover, we need to check that all the symbols \$ appear only at the end, that is, the last expression accepts all inputs where \$ is followed by a different symbol.

$$\begin{aligned}
&\Pi^* enc(\#)(\Pi + \ldots + \Pi^{p(|x|)})enc(\$)^{\leq p(|x|)} + \\
&\Pi^* enc(\bar{E}_f)(\varepsilon + \Pi + \ldots + \Pi^{p(|x|)-1})enc(\#)enc(\$)^{\leq p(|x|)} + \\
&\Pi^* enc(\$)^{p(|x|)+1} + \\
&(\Pi \setminus enc(\$))^* enc(\$)enc(\$)^*(\Pi \setminus enc(\$))\Pi^*
\end{aligned} \tag{8}$$

As before, we cannot encode the leading Π^* directly as an rpoNFA, but we can perform a similar construction as in (7) to overcome this problem.

The union of the rpoNFAs for (6)–(8) constitutes an rpoNFA that is polynomial in the size of M and x, and that is universal if and only if M does not accept x. ◀

6 Conclusion

Our results regarding the complexity of deciding universality for partially ordered NFAs are summarised in Table 1. We found that poNFAs over a fixed, two-letter alphabet are still powerful enough to recognise the language of all non-accepting computations of a PSPACE Turing machine. Restricting poNFAs further by forbidding the pattern of Figure 1, we could establish lower coNP complexity bounds for universality for alphabets of bounded size. We can view this as the complexity of universality of rpoNFAs in terms of the size of the automaton when keeping the alphabet fixed. Unfortunately, the complexity is PSPACE-complete even for rpoNFAs over arbitrary (unbounded) alphabets. The proof uses an interesting construction where the encoding of a Turing machine computation is "piggybacked" on an exponentially long word, for which a dedicated rpoNFA is constructed.

We have characterised the expressive power of rpoNFAs by relating them to the class of $\mathcal{R}$-trivial languages. It is worth noting that the complexity bounds we establish for recognising $\mathcal{R}$-triviality for a given NFA agrees with the complexity of the rpoNFA universality problem for both fixed and arbitrary alphabets. Our results on universality therefore extend beyond rpoNFAs to arbitrary NFAs that recognise $\mathcal{R}$-trivial languages.

Moreover, the results on universality further extend to the complexity of inclusion and equivalence, as explained in the introduction.

Our work can be considered as a contribution to the wider field of studying subclasses of star-free regular languages. The Straubing-Thérien hierarchy provides a large field for interesting future work in this area.

Eulerian Paths with Regular Constraints

Abstract

Labeled graphs, in which edges are labeled by letters from some alphabet Σ, are extensively used to model many types of relations associated with actions, costs, owners, or other properties. Each path in a labeled graph induces a word in Σ^* – the one obtained by concatenating the letters along the edges in the path. Classical graph-theory problems give rise to new problems that take these words into account. We introduce and study the *constrained Eulerian path* problem. The input to the problem is a Σ-labeled graph G and a specification $L \subseteq \Sigma^*$. The goal is to find an Eulerian path in G that satisfies L. We consider several classes of the problem, defined by the classes of G and L. We focus on the case L is regular and show that while the problem is in general NP-complete, even for very simple graphs and specifications, there are classes that can be solved efficiently. Our results extend work on Eulerian paths with edge-order constraints. We also study the *constrained Chinese postman* problem, where edges have costs and the goal is to find a cheapest path that contains each edge at least once and satisfies the specification. Finally, we define and study the *Eulerian language* of a graph, namely the set of words along its Eulerian paths.

1 Introduction

Many practical problems can be reduced to problems about graphs. A graph consists of vertices, which model objects, and edges, which model pairwise relations between the objects. Different settings call for different types of graphs. For example, when the relation between the objects is not symmetric, the graph is *directed*, and when it is not binary, the graph may have parallel edges or be *weighted*, say for modeling lengths or costs. In many applications, the edges of the graph carry information beyond weight. For example, edges may be associated with an action (say, in VLSI design), a query (say, in databases), properties like their owner or their security level (say, in a network of channels), and many more. Such applications require *labeled graphs*, in which each edge is labeled by a letter from some alphabet.[1]

Each path in a Σ-labeled graph induces a word in Σ^* – the one obtained by concatenating the letters along the edges in the path. Classical graph-theory problems give rise to new

[*] The research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP7/2007-2013) / ERC grant agreement no 278410, and from The Israel Science Foundation (grant no 1229/10).

[1] Alternatively, one could consider graphs with labels on vertices. It is not hard to alter our results to apply also for this setting.

problems that take these words into account. For example, rather than finding any *shortest path* between two given vertices in a graph [10], it is sometimes desirable, say in transportation planning [5], web searching [1], or network routing, to restrict attention to paths that satisfy some constraint [4]. The basic query mechanism in these applications retrieves all pairs of nodes connected by a path conforming to a given pattern. There have been plenty of theoretical and practical work on the subject of *regular path queries*, where we wish to find all objects reachable by paths whose labels form a word in a given regular language over the alphabet of the labels [8]. As another example, rather than finding a *maximal flow* along arbitrary routes in a graph [13], one may want to restrict the used routes to ones that satisfy some specification [23]. The specification may restrict the length of the routes, preventing long routes from consuming the system, it may restrict the number of different resources applied in a route, require an application of specific resources, require a specific event to trigger another specific event, and so on. As a third example, an extension of network formation games [2] assumes that the edges in the network are labeled and allows to lift the reachability objectives of the players to objectives that are arbitrary regular languages [3]. Paths constrained by regular languages were also considered in the context of finding efficient algorithms for processing database queries ([24, 1]). Finally, online algorithms for finding paths that satisfy regular constraints are given in [7].

An interesting question is how enriching the setting with labels and constrains influences the complexity of classical problems. Note that now there are two parameters to the problem: the graph itself, as well as a formal language $L \subseteq \Sigma^*$, which is usually regular and is given by means of a finite automaton or a regular expression. We refer to L as a *specification.* Existing work shows that the picture is diverse. For example, in the case of shortest paths, finding a shortest path that satisfies regular and even context-free specifications can still be done in polynomial time [4]. Their algorithm is generalized in [6] for graphs with both negative and positive edge weights (but without negative-weight cycles). However, research in regular path queries shows that the problem of finding a shortest simple path that satisfies a regular specification is NP-complete (note that a shortest path that satisfies a specification need not be simple, even when all weights are positive) [24]. In the context of maximal flow, it is shown in [23] that even simple regular restrictions on the routes make the problem APX-hard, namely it is even hard to approximate. Likewise, adding regular objectives to network formation games result in games that are much less stable: they need not have a Nash Equilibrium, and their Price of Stability is higher than in the case of reachability objective [3].

An *Eulerian path* in a graph is a path that traverses all the edges of the graph, each edge exactly once. The problem of deciding whether a given graph has an Eulerian path (the EP problem, for short) was introduced in 1736, in what is considered the first paper in the history of graph theory. The problem can be solved in linear time by examining the parity of the degree of the vertices. Back in 1736, the motivation to study the problem was the challenge of traversing the seven bridges of Königsberg. Nowadays, the problem and its many variants have applications in planning [21], coding [9], synchronization [19], DNA sequencing [27], and many more. In many of these applications, it is useful to restrict attention to Eulerian paths that satisfy some constraint. For example, [21] studies Eulerian paths that satisfy precedence constraints on the edges, specified by linear orders on subsets of the edges. In [27], the input to the EP problem contains a set of paths, and the goal is to find an Eulerian path that contains all the paths in the set as sub-paths. Another related problem is studied in [17]: each edge e in a graph with m edges is associated with an interval $I_e = [l_e, h_e]$ inside $[1, m]$, and the goal is to find an Eulerian path so that the position of every edge e in the path belongs to I_e.

Once we move to consider labeled graphs, the type of restrictions can be much richer. Eulerian paths in labeled graphs were considered in [25], where the problem of finding an Eulerian cycle with a lexicographically minimal label is shown to be NP-complete. Note that the constraint in [25] is not given by means of a specification $L \subseteq \Sigma^*$. Rather, the letters in Σ are ordered and the constraint refers to the lexicographic order between the Eulerian cycles, possibly with respect to a given word. In this work we study Eulerian paths with regular constraints. Formally, the *constrained Eulerian path* problem (CEP problem, for short) is defined as follows: given a Σ-labeled graph G and a regular language $L \subseteq \Sigma^*$, find an Eulerian path in G that satisfies L. We consider several classes of the problem, according to the classes of G and L. We first show that the general CEP problem is NP-complete, and that it is NP-hard already for very restricted graphs and specifications: when the graph does not have parallel edges or loops, and when the specification is a regular expression of a fixed size that can be expressed by a two-state deterministic automaton. In fact, the problem stays NP-hard even when the specification L is a singleton (that is, requiring the Eulerian path to be labeled with a specific given word). We then describe classes of regular languages for which the CEP problem can be solved in polynomial time. For this, we relate the CEP problem with the problem of finding edge-disjoint paths in a graph. In particular, we show that the CEP problem can be solved in polynomial time for regular expressions of the form $R = b_1 \ldots b_k$, where k is fixed, for every $1 \leq i \leq k$, we have $b_i = \sigma_i^*$ or $b_i = \sigma_i$ for some $\sigma_i \in \Sigma$, and for every $\sigma \in \Sigma$, the expression σ^* appears at most three times in R. Alternatively, $b_i = w_i^*$ or $b_i = w_i$ for some $w_i \in \Sigma^*$, and every $\sigma \in \Sigma$ appears at most once in R. We demonstrate the usefulness of such expressions in specifying desired behaviors of paths. We also consider multi-labeled graphs, where an edge may be labeled by several letters, and show that then, the problem is NP-hard even for specifications given by a regular expression of the form a^*b^*, which essentially partitions the path into two types of labels.

An optimization variant or the EP problem is the *Chinese postman problem*. There, each edge in the graph has a non-negative cost, and the goal is to find a *postman path* – one that contains each edge in the graph at least once, of a minimal cost. Clearly, when the graph has an Eulerian path, it induces an optimal postman path. Otherwise, the goal is to get as close as possible to an Eulerian path. Researchers have studied useful restrictions on the allowed postman paths [12]. In particular, a natural extension of the precedence restrictions studied for the EP problem is the *hierarchical Chinese postman problem* [11, 16, 22]. Here, the edges of the graph are partitioned into clusters $E_1, \ldots, E_k$, and a precedence relation $\prec$ specifies the order in which the clusters should be traversed. That is, we seek the cheapest path that visits each edge at least once and so that if $E_i \prec E_j$, then all the edges in E_i are visited for the first time before an edge in E_j is visited. The problem is NP-hard in general, but can be solved in polynomial time in some cases. We consider labeled graphs and study the *constrained Chinese postman* problem (the CCP problem, for short), where the postman path should satisfy a regular specification. We study the complexity of the CCP problem, show that it is in general NP-complete, but point to useful polynomial cases.

A labeled graph G can be viewed as a generator of formal languages. The traditional way to do this is to designate some of the vertices of G as initial and as final vertices. The language of the obtained *automaton* is then the set of words that label paths from some initial to some final vertex. We introduce and study the *Eulerian language* of G, denoted $EL(G)$, namely the set of words that label Eulerian paths in G. Clearly, deciding whether $EL(G) \neq \emptyset$ amount to deciding whether G has an Eulerian path, and can be done in linear time. More interesting questions about the Eulerian language of G relate it to nontrivial languages: whether $EL(G)$ is contained in some specification L, whether some set L of desired behaviors is contained in $EL(G)$, and the relation between the Eulerian languages of two different graphs. Since $EL(G)$ contains only words of a fixed length, we know that $EL(G)$ is finite and hence regular. On the other hand, given a regular language $L \subseteq \Sigma^*$ it is not clear whether there is a graph G such that $EL(G) = L$. We study all the above problems and show that they belong to different levels of the polynomial hierarchy.

Due to lack of space, detailed proofs can be found in the full version, in the authors' URLs.

2 Preliminaries

2.1 Graphs and Eulerian paths

A *graph* $G = \langle V, E\rangle$ consists of a set V of vertices and a set E of directed edges. The graph G may contain loops and parallel edges.[2] A graph is *simple* if it does not contain loops or parallel edges. A *path* P in G is a sequence of edges $e_1, \ldots, e_k$ such that there are $k+1$ vertices $v_0, \ldots, v_k$ and $e_i = (v_{i-1}, v_i)$ for all $1 \le i \le k$. We say that P is a path of length k from v_0 to v_k. If $v_0 = v_k$, then P is a *cycle*. We sometimes refer to P as a sequence of vertices, referring to the vertices $v_0, \ldots, v_k$. For an alphabet Σ, a Σ-*labeled graph* is a tuple $G = \langle V, E, l\rangle$, where $\langle V, E\rangle$ is a graph and $l : E \to \Sigma$ maps each edge to a letter in Σ. The label of a path $P = e_1, \ldots, e_k$, denoted $l(P)$, is the word $l(e_1) \cdot \ldots \cdot l(e_k)$ obtained by concatenating the labels of the edges along P. A *specification* for G is a language $L \subseteq \Sigma^*$. We say that P *satisfies* a specification L if $l(P) \in L$.

Consider a graph $G = \langle V, E\rangle$. For a vertex $v \in V$, the *in degree* and *out degree* of v, denoted *indeg*(v) and *outdeg*(v), are the number of edges entering and leaving v, respectively. An edge $(u_1, u_2) \in E$ is *incident to* v if $u_1 = v$ or $u_2 = v$. We say that G is *strongly connected* if for every two vertices $u, v \in V$ there is a path from u to v. An *undirected path* in G is a sequence of edges $e_1, \ldots, e_k$ such that there are $k+1$ vertices $v_0, \ldots, v_k$ and $e_i \in \{(v_{i-1}, v_i), (v_i, v_{i-1})\}$ for all $1 \le i \le k$. We say that G is *connected* if for every $u, v \in V$ there is an undirected path from u to v. The *size* of G, denoted $|G|$, is the number of vertices and edges in G.

A path in a graph $G = \langle V, E\rangle$ is *Eulerian* (EP, for short) if it visits every edge in E exactly once. We say that G is *Eulerian* if it has an Eulerian cycle. For two edges e_1 and e_2 in E, an EP with $e_1 \prec e_2$ is an EP in which the edge e_1 is visited before the edge e_2. The following is well known.

▶ **Theorem 1.** *Consider a directed graph $G = \langle V, E\rangle$.*

1. *The graph G is Eulerian iff G is connected and for every $v \in V$, we have indeg(v) = outdeg(v).*
2. *The graph G has an Eulerian path from s to t (with $s \neq t$) iff G is connected, outdeg(s) = indeg$(s) + 1$, indeg(t) = outdeg$(t) + 1$, and for every $v \notin \{s, t\}$, we have indeg(v) = outdeg(v).*

By Theorem 1, one can decide in time linear in $|G|$ whether G is Eulerian or has an EP between two given vertices. Furthermore, if G has an EP from s to t, then such path can be found as follows: Follow some path from s until reaching t. It is not possible to get stuck at any vertex other than t, because when the path enters another vertex v there must be an

[2] Since G may contain parallel edges, we do not refer to E as a subset of $V \times V$. However, for simplicity of notations, whenever there is no cause for confusion, we still denote an edge by a pair $(v_1, v_2) \in V \times V$.

unused edge leaving v. The path formed in this way may not cover all edges of the initial graph. As long as there exists a vertex v that belongs to the current path but that has incident edges not part of the path, start another path from v, following unused edges until returning to v (as above, this process does not get stuck), and join the path formed in this way to the previous path.

A path (cycle) in a graph $G = \langle V, E\rangle$ is *Hamiltonian* if it visits every vertex in V exactly once. The Hamiltonian path (cycle) problem, namely deciding whether a given graph has a Hamiltonian path (cycle), is NP-hard already when the graph is simple [15].

2.2 Regular languages and the constrained Eulerian path problem

A *nondeterministic finite automaton* (NFA, for short) is a tuple $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, F\rangle$, where Σ is a finite alphabet, Q is a finite set of states, $Q_0 \subseteq Q$ is a set of initial states, $\delta : Q \times \Sigma \to 2^Q$ is a transition function, and $F \subseteq Q$ is a set of final states. Given a word $w = \sigma_1 \cdot \sigma_2 \cdots \sigma_l \in \Sigma^*$, a *run* of $\mathcal{A}$ on w is a sequence $r = q_0, q_1, \ldots, q_l$ of states such that $q_0 \in Q_0$ and $q_{i+1} \in \delta(q_i, \sigma_{i+1})$ for all $i \geq 0$. The run is accepting if $q_l \in F$. The NFA $\mathcal{A}$ *accepts* the word w iff it has an accepting run on it. The language of $\mathcal{A}$, denoted $L(\mathcal{A})$ is the set of words that $\mathcal{A}$ accepts. If $|Q_0| = 1$ and $|\delta(q, \sigma)| \leq 1$ for all $q \in Q$ and $\sigma \in \Sigma$, then $\mathcal{A}$ is *deterministic*. Note that a deterministic finite automaton (DFA) has at most one run on each word.

A *regular expression* (RE, for short) over Σ is defined as follows.

- $\emptyset$, ϵ, and σ, for $\sigma \in \Sigma$, are REs.
- If R_1 and R_2 are REs, then so are $R_1 + R_2$, $R_1 \cdot R_2$, and R_1^*.

The language of an RE R, denoted $L(R)$, is defined inductively on the structure of R, where $+$, $\cdot$, and $*$ stand for union, concatenation, and Kleene star, respectively.

We say that R is a *chain* RE if it is of the form $b_1 \cdot b_2 \cdots b_k$, where for every $1 \leq i \leq k$, we have $b_i = w_i^*$ or $b_i = w_i$ for a word $w_i \in \Sigma^*$. We call every such b_i a *block*. Note that a chain RE does not contain the symbol “+" and does not contain nested Kleene stars. For $l \geq 1$, we say that a chain RE R is *l-wide* if $|w_i| \leq l$ for all $1 \leq i \leq k$ with $b_i = w_i^*$. Note that when R is 1-wide, then for all $1 \leq i \leq k$, we have that $b_i = \sigma^*$ or $b_i = \sigma$, for some $\sigma \in \Sigma$. For $d \geq 1$, we say that R is *d-diverse* if each letter in Σ appears in R at most d times. We say that R is *d-star-diverse* if for each letter $\sigma \in \Sigma$, the expression σ^* appears in R at most d times. Note that if R is d-diverse then it is also d-star-diverse. For example, $a^*(ba)^*c^*(bc)^*$ is a 2-wide, 2-diverse, 1-star-diverse chain RE. Then, $a^*b^*a^*$ is a 1-wide, 2-diverse, 2-star-diverse chain RE, and $(a + b)^*(b + c)^*$ is not a chain RE.

The *constrained Eulerian path* problem (CEP problem, for short) is defined as follows: given a labeled graph G and a regular language L, given by means of an NFA, DFA, or RE, find an Eulerian path in G that satisfies L.

▶ **Example 2.** We describe some chain REs that are useful specifications.

Zone patrolling and periodic checks. Consider a communication, social, or physical network. Let a, b, c, and d be labels of edges in different zones of the network. We may want to patrol the network in a certain pattern. For example, in security, one may want a guard to patrol the zones of a physical network in a certain order, and in commercial applications, one may want to do the same with an advertisement that traverses a social network. Likewise, several communication protocols are based on the fact that a message must patrol different zones of the network in some predefined order before reaching its destination; e.g., in Onion routing, where the message is encrypted in layers, or in *proof-of-work* protocols that are used to deter denial of service attacks and other service abuses such as spam. For this, REs of the form $(a^+b^+c^+d^+)^*$, where σ^+ stands for $\sigma\sigma^*$, may be useful. If the pattern of visits is of a known bounded length, it can be specified as a conjunction of 1-wide chain REs, say $a^+b^+c^+d^+a^+b^+c^+d^+$.

As another example, let s label edges in which a checksum is performed on the message, and let σ label all other edges. We may want a message to be periodically checked for corruptions. This can be specified by the chain RE $(\sigma^i s)^*$, for the duration i after which a check should be performed. If we want the specification to be more flexible, say allow different durations between successive checks, all bounded by i, this is possible, but the RE is no longer a chain RE.

Bounded-delay response and FIFO. Let r, r_1, and r_2 label edges in which requests are submitted, possibly parameterized by the user that submits them, and let g, g_1, and g_2 label edges in which requests are granted, again possibly parameterized by the granted user. The semantics of requests and grants depend on the type of the network. Suppose there can be at most one request in the graph and we want a request, if submitted, to be followed by a grant within 3 steps. Let σ label all edges that are not labeled r or g. This can be specified by $R = \sigma^* + \sigma^* r g \sigma^* + \sigma^* r \sigma g \sigma^* + \sigma^* r \sigma \sigma g \sigma^*$. Note that R is a union of 1-wide 4-diverse chain REs. In case of a grant bounded by k steps, the REs are 1-wide $(k+1)$-diverse chain REs. If there are two requests and we want them to be granted in a FIFO order, the specification is $R = \sigma^* + \sigma^* r_1 \sigma^* g_1 \sigma^* + \sigma^* r_1 \sigma^* r_2 \sigma^* g_1 \sigma^* g_2 \sigma^* + \sigma^* r_1 \sigma^* g_1 \sigma^* r_2 \sigma^* g_2 \sigma^*$, and dually when only r_2 is submitted or when r_2 is before r_1. Note that R is a union of 1-wide 5-diverse chain REs.

3 It Is Hard

In this section we study the general CEP problem and show that it is NP-complete for specifications given by NFAs, DFAs, or REs. The reductions in this section are simple. We give them here for completeness and as a warm-up before things get more complicated in the next sections.

▶ **Theorem 3.** *The CEP problem is NP-complete.*

Proof. We start with membership in NP. Checking the membership of a given word in the language of a given NFA, DFA, or RE can be done in polynomial time. Hence, given a labeled graph $G = \langle V, E, l \rangle$ and a regular language L given by means of an NFA, DFA, or RE, checking whether a sequence P of $|E|$ edges is an EP in G and that $l(P) \in L$ can be done in polynomial time.

We prove NP-hardness by a reduction from the Hamiltonian-path problem. We prove hardness for specifications given by DFAs. Hardness for NFAs follows immediately, and hardness for REs follows from the polynomial translation of DFAs to REs. Given a graph $G = \langle V, E \rangle$, we construct a labeled graph G' and a DFA $\mathcal{A}$ such that there is a Hamiltonian path in G iff there is an EP in G' that satisfies $L(\mathcal{A})$. The labeled graph G' is over the alphabet V. It consists of a single vertex u with $|V|$ parallel self loops, each labeled by a different vertex in V. That is, the EPs of G' correspond to permutations of V. We define the specification DFA $\mathcal{A}$ so that $L(\mathcal{A})$ includes exactly all words that label paths in G. It is easy to define $\mathcal{A}$ as above by adding to G an initial state that has a transition to all vertices, and labeling all transitions, including the new ones, by their destination vertex. All the states in $\mathcal{A}$ are final. Now, there is a Hamiltonian path in G iff there is a permutation of V that forms a path in G iff there is an EP in G' that satisfies $L(\mathcal{A})$. ◀

The graph G' used in the proof of Theorem 3 is not simple. It is easy, however, to add a new letter # to the alphabet V and obtain a simple graph G'' by replacing every (parallel) self-loop labeled v in G' by a (disjoint) cycle labeled $v\#$ in G''. Hence the following theorem.

▶ **Theorem 4.** *The CEP problem is NP-hard already for simple graphs.*

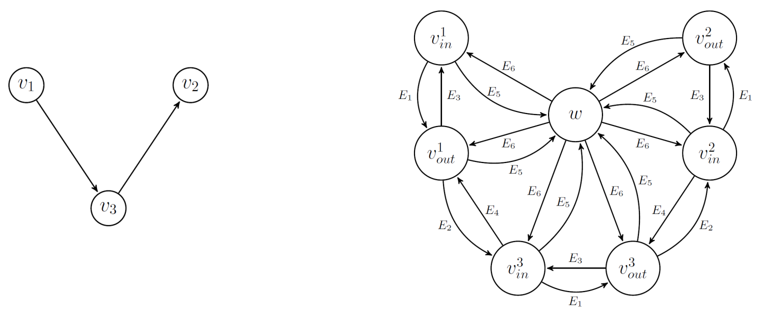

Figure 1 A graph and its Eulerian closure.

4 It Is Very Hard

While the graph G'' defined in the reduction in the proof of Theorem 4 is simple, the DFA $\mathcal{A}$ used in the proof is essentially the graph G. This suggests that we may do better with specifications of a constant size. In this section we show that the CEP problem is NP-hard already for more restricted cases, in particular for specification of a constant size. As we then show in Section 5, the cases we point to are tight, in the sense that tightening the restrictions makes the problem feasible.

We first define the *Eulerian closure* of a given graph – a construction that is going to be useful in some of our reductions. Given a graph $G = \langle V, E\rangle$, the *Eulerian closure of* G is the graph $\mathcal{G} = \langle \mathcal{V}, \mathcal{E}\rangle$, defined as follows (see an Example in Figure 1).

For each vertex $v \in V$ we include in $\mathcal{V}$ two vertices v_{in} and v_{out}. We also include in $\mathcal{V}$ a new vertex w. That is, $\mathcal{V} = \{v_{in} : v \in V\} \cup \{v_{out} : v \in V\} \cup \{w\}$. The set of edges of $\mathcal{G}$ is the union $\mathcal{E} = E_1 \cup E_2 \cup E_3 \cup E_4 \cup E_5 \cup E_6$, defined below:

- $E_1 = \{(v_{in}, v_{out}) : v \in V\}$. Thus, E_1 includes an edge for each vertex in G.
- $E_2 = \{(u_{out}, v_{in}) : (u, v) \in E\}$. Thus, E_2 includes an edge for every edge in G.
- $E_3 = \{(v_{out}, v_{in}) : v \in V\}$. Thus, E_3 includes an opposite edge for every edge in E_1.
- $E_4 = \{(v_{in}, u_{out}) : (u, v) \in E\}$. Thus, E_4 includes an opposite edge for every edge in E_2.
- $E_5 = \{(v, w) : v \in \mathcal{V} \setminus \{w\}\}$.
- $E_6 = \{(w, v) : v \in \mathcal{V} \setminus \{w\}\}$.

Note that, by Theorem 1, the graph $\mathcal{G}$ is Eulerian. Indeed, the edges in E_5 and E_6 guarantee that $\mathcal{G}$ is strongly connected regardless of the connectivity of G. Also, for every vertex $v \in \mathcal{V}$, we have $indeg(v) = outdeg(v)$. Finally, if G is simple, then so is $\mathcal{G}$.

▶ **Theorem 5.** *The CEP problem is NP-hard already for a simple graph and a specification given by fixed-size RE that can be expressed by a DFA with two states.*

Proof. We show a reduction from the problem of Hamiltonian path for simple graphs. Given a simple graph $G = \langle V, E\rangle$, we construct a simple labeled graph G' and a RE R that can be expressed by a DFA with two states, such that there is a Hamiltonian path in G iff there is an EP in G' that satisfies $L(R)$. The graph G' is defined by $G' = \langle \mathcal{V}, \mathcal{E}, l\rangle$ where $\langle \mathcal{V}, \mathcal{E}\rangle$ is the Eulerian closure of G, and $l(e)$ is $\{a\}$ if $e \in E_1$, is $\{b\}$ if $e \in E_2$, and is $\{c\}$ otherwise. Let $R = (a + b)^*(b + c)^*$. Note that $L(R)$ can be expressed by a DFA with two states. In the full version of the paper we prove that the reduction is correct. For this, we show that the way we have defined the Eulerian closure of G guarantees that if there is a Hamiltonian path in G, then it induces a path in G' that contains only edges labeled by a or b and can be extended to an Eulerian cycle by appending a path that contains only edges labeled by b or

c. Also, every EP in G' that satisfies $L(R)$ starts with a subpath that induces a Hamiltonian path in G. ◀

We continue and show that the CEP problem is NP-hard already for singleton specifications, namely when the specification consists of a single word, and for specifications given by a fixed-size RE without union and without nested Kleene star operators.

▶ **Theorem 6.** *The CEP problem is NP-hard for singleton specifications and for specifications given by a fixed-size* 2*-wide* 2*-diverse chain RE.*

Proof. In both cases, we show a reduction from the problem of Hamiltonian path for simple graphs. Let $G = \langle V, E\rangle$ be a simple graph, and let $V = \{v^1, \dots, v^n\}$. We define the simple graph $G' = \langle \mathcal{V}, \mathcal{E}, l\rangle$, where $\langle \mathcal{V}, \mathcal{E}\rangle$ is the Eulerian closure of G, and $l(e)$ is $\{a\}$ if $e \in E_1$, is $\{b\}$ if $e \in E_2 \cup E_6$, and is $\{c\}$ otherwise.

Consider the word $x = a(ba)^{n-1}c^{2n-1}(cb)^{|E|+n+1}$. We prove that there is a Hamiltonian path in G iff there is an EP in G' that is labeled by x. First, it is not hard to see that if G' has an EP labeled x, then the prefix $a(ba)^{n-1}$ of x induces a Hamiltonian path in G. Now, assume that there is a Hamiltonian path P in G from v^1 to v^n. We construct an Eulerian cycle in G' as follows: The Eulerian cycle starts with the path Q in G' corresponding to P. This path starts with the edge (v^1_{in}, v^1_{out}), ends with the edge (v^n_{in}, v^n_{out}), and visits the edge (v^i_{in}, v^i_{out}) for every i exactly once. Note that $l(Q) = a(ba)^{n-1}$. In the full version of the paper we show how the way the Eulerian closure is defined enables us to continue Q as required.

We continue to the second class. Let R be the RE $R = a(ba)^*c^*(cb)^*$. Note that R is indeed a fixed-size 2-wide 2-diverse chain RE. We show that there is a Hamiltonian path in G iff there is an EP in G' that satisfies $L(R)$. Again, it is not hard to see that if G' has an EP that satisfies $L(R)$, then the prefix $a(ba)^*$ of R induces a Hamiltonian path in G. Also, if there is a Hamiltonian path in G, then an Eulerian cycle in G' that satisfies $L(R)$ can be constructed as in the case of the word x.[3] ◀

5 But Sometimes It Is Easy

In this section we show classes of regular languages for which the CEP problem can be solved in polynomial time. By Theorem 6, the CEP problem is NP-hard for fixed-size 2-wide 2-diverse chain REs. We show that when one of the width and diversity parameters is tightened, the problem becomes feasible. We start with diversity and show that when a chain RE R is 1-diverse, we can solve the CEP problem for it in polynomial time even when R and its blocks are not of a fixed size.

▶ **Theorem 7.** *The CEP problem can be solved in polynomial time for specifications given by a* 1*-diverse chain RE.*

Proof. Let $G = \langle V, E, l\rangle$ be a labeled graph and let $R = b_1 \dots b_k$ be a RE, where for every i we have $b_i = w_i^*$ or $b_i = w_i$ for some $w_i \in \Sigma^*$, and every $\sigma \in \Sigma$ appears at most once in R. We assume that every letter that appears in G, appears also in R, because otherwise the CEP problem is trivial. We show how to find an EP that satisfies $L(R)$ and that starts in a vertex $v_1 \in V$. Note that since every $\sigma \in \Sigma$ appears at most once in R, then the subpath that

[3] Note that we could have defined the RE R to be $a^*(ba)^*c^*(cb)^*$, implying that NP-hardness applies already for fixed-size 2-wide 2-diverse chain REs in which all blocks have a Kleene star.

corresponds to a block b_i must be an EP in the subgraph G_i induced by the edges labeled by letters in w_i. Therefore, the first vertex in every subpath determines the last vertex in this subpath: if the degrees in every vertex in G_i are balanced, that is, the in degree is equal to the out degree for every vertex, then an EP must be a cycle; if the degrees are not balanced then an EP must start in the only vertex s_i where $outdeg(s_i) = indeg(s_i) + 1$ and end in the only vertex t_i where $indeg(t_i) = outdeg(t_i) + 1$. Thus, the algorithm checks whether G_1 has an EP from v_1 that corresponds to b_1, and if it does then it finds the vertex v_2 in which this EP ends. Then the algorithm checks whether G_2 has an EP from v_2 that corresponds to b_2 and continues similarly.

We now show how to find an EP in $G_i = \langle V_i, E_i, l\rangle$ that starts in a vertex v_i and corresponds to b_i. If $b_i = w_i$, then we check whether G_i contains every letter in w_i exactly once, and whether w_i induces a path in G_i from the vertex v_i. Assume now that $b_i = w_i^*$, and $w_i = \sigma_0 \ldots \sigma_{n-1}$. We construct a graph $G'_i = \langle V'_i, E'_i\rangle$, where $V'_i = \{\langle v, j\rangle : v \in V_i$ and $0 \le j \le n-1\}$ and $E'_i = \{(\langle u, j\rangle, \langle v, j+1 \ (mod\ n)\rangle) : (u, v) \in E_i$ and $l((u, v)) = \sigma_j\}$. Thus, G'_i includes n copies of G_i such that every edge (u, v) with $l((u, v)) = \sigma_j$ in G_i induces an edge from u in the j-th copy to v in the $(j+1)$-th copy in G'_i. Note that there is an EP in G_i from the vertex v_i that corresponds to b_i, iff there is an EP in G'_i from the vertex $\langle v_i, 0\rangle$ to some vertex $\langle u, 0\rangle$. Therefore, the problem is reduced to finding an EP from $\langle v_i, 0\rangle$ in G'_i. ◀

We continue and show that tightening the width also makes the problem solvable in polynomial time. We first describe another well-studied problem that we show to be strongly related to our problem. Let $G = \langle V, E\rangle$ be a directed or undirected graph and let (s_i, t_i), for $i = 1, \ldots, k$, be k ordered pairs of vertices. In the *edge-disjoint paths* problem (EDP problem, for short), we need to find, for every $1 \le i \le k$, a path in G from s_i to t_i such that the paths are edge-disjoint; that is, an edge cannot appear in more than one path. The EDP problem is NP-complete for both directed and undirected graphs [29]. When the graph is undirected and k is fixed, there is a polynomial-time algorithm ([28, 20]). For directed graphs, the problem is NP-complete already when $k = 2$ [14]. The directed graph $G_D = \langle V, E_D\rangle$ where $E_D = \{(t_i, s_i) : i = 1 \ldots k\}$ is called the *demand graph*.

Consider the graph $G + G_D = \langle V, E \cup E_D\rangle$ obtained by adding to G the edges from G_D. When $G + G_D$ is Eulerian, we say that there is an *Eulerian promise on the demand*. It is shown in [18] that when there is an Eulerian promise on the demand, there is a polynomial-time algorithm for the EDP problem with $k = 3$. It is also conjectured in [18] that when there is an Eulerian promise on the demand, there is a polynomial-time algorithm for the EDP problem for every fixed k. To the best of our knowledge, however, this problem is still open (it is also declared open in [29, 26]).

We first relate the EDP problem to the problem of finding an EP that respects a linear order on the subset of the edges.

▶ **Lemma 8.** *Consider a directed graph $G = \langle V, E\rangle$ and two vertices $s, t \in V$. Let $e_1, \ldots, e_k$ be some edges in E and $\tau = e_1 \prec \ldots \prec e_k$ be an order on them. If $k \le 2$, then finding an EP from s to t that respects τ can be done in polynomial time. If $k > 2$ is fixed, then finding an EP from s to t that respects τ can be solved in polynomial time iff the EDP problem for a directed graph with an Eulerian promise on the demand can be solved in polynomial time for $k + 1$ paths.*

We now relate the CEP problem for fixed-size 1-wide chain REs to the problem of finding an EP that respects a linear order on a subset of the edges. Lemma 8 then enables us to relate the former also to the EDP problem, implying that restricting the width also leads to a polynomial complexity.

▶ **Theorem 9.** *The CEP problem can be solved in polynomial time for specifications given by a fixed-size* 1*-wide* 3*-star-diverse chain RE. For specifications given by a fixed-size* 1*-wide* d*-star-diverse chain RE, the CEP problem can be solved in polynomial time iff the EDP problem for a directed graph with an Eulerian promise on the demand can be solved in polynomial time for* d *paths.*

Proof. Let $R = b_1 \dots b_k$ for a fixed k, where for every i we have $b_i = \sigma_i^*$ or $b_i = \sigma_i$ for some $\sigma_i \in \Sigma$. We assume that every letter that appears in G appears also in R. Indeed, otherwise the CEP problem is trivial. We run over all the options for choosing $k+1$ vertices $v_0, \dots, v_k \in V$ (there are $|V|^{k+1}$ such options), and check whether G has an EP from v_0 to v_k that satisfies $L(R)$ and can be partitioned into k subpaths, such that the i-th subpath starts in v_{i-1}, ends in v_i and corresponds to b_i. We now describe how to perform this check.

For every i such that $b_i = \sigma$ for some $\sigma \in \Sigma$, the graph G must have an edge $e = (v_{i-1}, v_i)$ with $l(e) = \sigma$. All the other subpaths corresponding to b_j for $j \neq i$, cannot use the edge e. In particular, if b_j with $j \neq i$ is a single-letter block, then it cannot use the edge e. In the rest of this proof we assume that for every single-letter block $b_n = \sigma_n$ there is an edge $e_n = (v_{n-1}, v_n)$ such that $l(e_n) = \sigma_n$, and that if b_m is a single-letter block with $m \neq n$ then e_m and e_n are different edges (they can be parallel edges). We denote the set of edges that correspond to a single-letter block by E_s.

Let $\sigma \in \Sigma$ and let $b_{i_1}, \dots, b_{i_m}$ be the blocks in R such that for every $1 \leq j \leq m$ we have $b_{i_j} = \sigma^*$. Let G_σ be the subgraph of G induced by the edges $\{e \in E \setminus E_s : l(e) = \sigma\}$. Let G'_σ be the graph obtained from G_σ by adding, for every $1 \leq j \leq m-1$, an edge $e_{i_j} = (v_{i_j}, v_{i_{j+1}-1})$; that is, we add for every i_j an edge from the end of the block i_j to the beginning of the block i_{j+1}. We check whether there is an EP in G'_σ from v_{i_1-1} to v_{i_m} such that $e_{i_1} \prec e_{i_2} \prec \dots \prec e_{i_{m-1}}$. In the full version we prove that such an EP exists in G'_σ for every σ iff the required EP in G exists.

Thus, we reduce the CEP problem to the problem of finding an EP that respects a linear order on a subset of the edges. By Lemma 8, the latter can be reduced to the EDP problem. Accordingly, we have a polynomial-time algorithm if for every $\sigma \in \Sigma$ the expression σ^*, appears at most three times in R (that is, R is 3-star-diverse). Also, if the EDP problem for a directed graph with an Eulerian promise on the demand can be solved in polynomial time for d paths, then, according to Lemma 8, we have a polynomial-time algorithm also if R is d-star-diverse.

Now, assume that there is a polynomial-time algorithm for the case R is d-star-diverse. Let $H = \langle V_H, E_H \rangle$ be a graph and let $e_1, \dots, e_{d-1} \in E_H$. Let H' be a labeled graph obtained from H by assigning a label σ_i for every edge e_i, and assigning a label σ for every other edge in E_H. Note that H has an EP with $e_1 \prec \dots \prec e_{d-1}$ iff H' has an EP that satisfies $L(R)$ for $R = \sigma^* \sigma_1 \sigma^* \sigma_2 \dots \sigma^* \sigma_{d-1} \sigma^*$. By our assumption, the latter problem can be solved in polynomial time. Therefore, by Lemma 8, the EDP problem for a directed graph with an Eulerian promise on the demand can be solved in polynomial time for d paths. ◀

We conclude that there is a polynomial-time algorithm for every specification that is a disjunction of polynomially many REs of the forms handled in Theorems 7 and 9. As demonstrated in Example 2, such disjuncts can specify useful behaviors. We note that with some additional ‘’technical acrobatics”, it is possible to squeeze the lemon some more and point to additional classes of chain REs that can be solved in polynomial time. For example, if $R = b_1 \dots b_k$, where k is a fixed number and for every $1 \leq i \leq k$ we have $b_i = w_i^*$ for some

$w_i \in \Sigma^*$, or $b_i = \sigma_i$ for some $\sigma_i \in \Sigma$, then it is possible to restrict the diversity of the letters, but allow repetitions of identical blocks, so that polynomial-time algorithms can be obtained by combining ideas used in the proofs of Theorems 9 and 7. We do not find, however, these special cases or technical acrobatics too interesting. A good intuitive and practical conclusion is that when the specification is a chain RE, it is recommended to use the ideas here in order to find the complexity of the CEP problem for it, and possibly to decompose or alter it to a disjunction of specifications of lower width and diversity for which a polynomial algorithm is possible.

6 Multi-Labeled Graphs

A *multi-labeled graph* is a tuple $G = \langle V, E, l \rangle$ where $\langle V, E \rangle$ is a graph and $l : E \to 2^{\Sigma}$ maps every edge to a subset of letters from the alphabet Σ. For a path $P = e_1, \ldots, e_k$ we define $l(P) = \{\sigma_1 \ldots \sigma_k : \sigma_i \in l(e_i)$ for every $1 \leq i \leq k\}$. We say that P satisfies a specification $L \subseteq \Sigma^*$ if $l(P) \cap L \neq \emptyset$. Note that we take here the existential approach in model checking, where satisfaction amounts to an existence of a correct path.

We show that if the graph is multi-labeled, the CEP problem is NP-hard already for the RE a^*b^*. Note that a^*b^* is a fixed-size 1-wide 1-diverse chain RE. Thus, by both Theorems 9 and 7, the CEP problem in graphs in which each edge is labeled by a single letter can be solved in polynomial time.

▶ **Theorem 10.** *The CEP problem for multi-labeled simple graphs is NP-hard already for the specification given by the RE $R = a^*b^*$.*

Proof. We show a reduction from the problem of Hamiltonian path for simple graphs. Given a simple graph $G = \langle V, E \rangle$, we construct a multi-labeled simple graph G', such that there is a Hamiltonian path in G iff there is an EP in G' that satisfies $L(R)$. The graph G' is defined by $G' = \langle \mathcal{V}, \mathcal{E}, l \rangle$ where $\langle \mathcal{V}, \mathcal{E} \rangle$ is the Eulerian closure of G, and $l(e)$ is $\{a\}$ if $e \in E_1$, is $\{a, b\}$ if $e \in E_2$, and is $\{b\}$ otherwise. In the full version of the paper we prove the correctness of the reduction. ◀

7 The Constrained Chinese Postman Problem

A *weighted graph* is a tuple $G = \langle V, E, c \rangle$, where $\langle V, E \rangle$ is a graph and $c : E \to \mathbb{R}^+$ maps every edge to a non-negative cost. The cost of a path $P = e_1, \ldots, e_k$, denoted $c(P)$, is $\sum_{i=1}^{k} c(e_i)$; that is, the sum of the costs of the edges along the path. A *postman path* in G is a path that visits every edge in E at least once. An *optimal postman path* is a least-cost postman path. Similar definitions apply to cycles. In the well-studied *Chinese postman problem*, we are given a weighted graph G and need to find an optimal postman path. Clearly, when G has an EP, it induces an optimal postman path. Otherwise, the goal is to get as close as possible to an EP. Thus, the Chinese postman problem can be viewed as an optimization variant of the EP problem. The combinatorial simplicity of the EP problem is carried over to the Chinese postman problem. In particular, it has a well-known polynomial-time algorithm [12].

A *labeled weighted graph* is a tuple $G = \langle V, E, l, c \rangle$, where $\langle V, E, l \rangle$ is a labeled graph and $\langle V, E, c \rangle$ is a weighted graph. For a regular language L, an *L-postman path* in G is a path that satisfies L and visits every edge in E at least once. An *optimal L-postman path* is a least-cost L-postman path. In the *constrained Chinese postman problem* (CCP problem, for short), we are given a labeled weighted graph G and a regular language L and need to find an optimal L-postman path in G. In this section we study the CCP problem.

First, we show that the corresponding decision problem is NP-complete, and is NP-hard already for restricted classes of graphs and specifications.

▶ **Theorem 11.** *Consider a labeled weighted graph G and a regular language L given by an NFA, DFA, or RE. For $k \in I\!R^+$, deciding whether there is an L-postman path P with $c(P) \leq k$ is NP-complete. Furthermore, it is NP-hard already when G is simple, when L is a singleton, when L is given by a DFA with two states, and when L is given by a fixed-size 2-wide 2-diverse chain RE.*

Proof. First, note that a labeled graph $H = \langle V_H, E_H, l_H \rangle$ has an EP that satisfies L iff the labeled weighted graph $H' = \langle V_H, E_H, l_H, c\rangle$ with $c(e) = 1$ for every $e \in E_H$ has an L-postman path with cost $|E|$. Thus, the lower bounds follow from Theorems 4, 5, and 6.

We prove the upper bound for L given by an NFA $\mathcal{A}$. The other cases follow. Let $G = \langle V, E, l, c\rangle$, $\mathcal{A} = \langle \Sigma, Q, Q_0, \delta, F\rangle$, and let $\mathcal{N}$ be the product NFA of $\mathcal{A}$ and G. Formally, $\mathcal{N} = \langle \Sigma, Q \times V, Q_0 \times V, \delta', F \times V\rangle$, where $\delta'(\langle q, v\rangle, \sigma) = \{\langle q', v'\rangle : q' \in \delta(q, \sigma), (v, v') \in E$, and $l((v, v')) = \sigma\}$. Note that $\mathcal{N}$ ignores parallel edges in G. Also, a path P in G satisfies $L(\mathcal{A})$ iff there is an accepting run in $\mathcal{N}$ whose projection on V corresponds to P. We claim that there is an $L(\mathcal{A})$-postman path P in G with $c(P) \leq k$ iff there is an $L(\mathcal{A})$-postman path $P' = e_1, \ldots, e_n$ in G with $c(P') \leq k$ of length $n \leq |E| \cdot |Q| \cdot |V|$. Let r be an accepting run in $\mathcal{N}$ whose projection on V corresponds to a path $P = e_1, \ldots, e_n$ in G, and assume that P includes every edge in G (including parallel edges) at least once. Let $i_1 < \ldots < i_{|E|}$ be the indices in which all edges appear for the first time in P. If for some j there are more than $|Q| \cdot |V|$ states between the appearance in r of the transition that corresponds to the edge e_{i_j} and the appearance of the transition that corresponds to the edge $e_{i_{j+1}}$, then r has a loop that can be avoided. By removing these loops we end up with a path of length $n \leq |E| \cdot |Q| \cdot |V|$. Thus, a witness for having an $L(\mathcal{A})$-postman path P in G with $c(P) \leq k$ is of size at most $n \leq |E| \cdot |Q| \cdot |V|$. ◀

Since the CCP problem is at least as hard as the CEP problem, we turn to consider cases for which the CEP problem is solvable in polynomial time. In particular, we restrict further the class of fixed-size 2-wide 2-diverse chain RE. First by restricting the width, and then the diversity.

▶ **Theorem 12.** *The CCP problem can be solved in polynomial time for specifications given by a fixed-size 1-wide 2-star-diverse chain RE.*

Proof. Let $G = \langle V, E, l, c\rangle$ and let $R = b_1 \ldots b_k$ be a 1-wide 2-star-diverse chain RE. We assume that every letter that appears in G, appears also in R. Indeed, otherwise the CCP problem is trivial. We run over all the (polynomially many) options for choosing $k+1$ vertices $v_0, \ldots, v_k \in V$, and find a least-cost path in G from v_0 to v_k that satisfies $L(R)$, contains all edges, and can be partitioned into k subpaths such that the i-th subpath starts in v_{i-1}, ends in v_i, and satisfies $L(b_i)$.

First, assume that $b_i = \sigma_i^*$ for every i; that is, R does not contain single-letter blocks. Let $\sigma \in \Sigma$. If σ^* appears exactly once in R and $\sigma = \sigma_i$, then we find an optimal postman path from v_{i-1} to v_i in the subgraph G_σ induced by the edges in G labeled by σ. If σ^* appears twice in R, let $\sigma = \sigma_i = \sigma_j$ with $i < j$. We construct a weighted graph G'_σ by adding to G_σ the edge (v_i, v_{j-1}) with a large cost. Now we need to find a least-cost path in G'_σ from v_{i-1} to v_j in which every edge appears at least once, and the new edge (v_i, v_{j-1}) appears exactly once. Since the edge (v_i, v_{j-1}) has a large cost, it can be done simply by finding an optimal postman path from v_{i-1} to v_j in G'_σ. Finally, as in Theorem 9, we construct a path

P by concatenating the corresponding paths for every block b_i in R. In the full version we describe how to handle the case where R contains single-letter blocks. ◀

The case of 1-diverse chain REs follows similar considerations and applies the ideas used in the proof of Theorem 7 in the case of the CEP problem.

▶ **Theorem 13.** *The CCP problem can be solved in polynomial time for specifications given by a* 1*-diverse chain RE with a fixed number of blocks.*

8 Eulerian Languages

The *Eulerian language* of a Σ-labeled graph G, denoted $EL(G)$, is the set of words read along Eulerian paths in G. Formally, $EL(G) = \{l(P) \in \Sigma^* : P \text{ is an EP in } G\}$. Clearly, the *nonemptiness problem*, namely deciding whether $EL(G) \neq \emptyset$, coincides with the EP problem and can thus be solved in polynomial time. Given a regular language $L \subseteq \Sigma^*$, the *satisfaction problem* for G and L is to decide whether $EL(G) \cap L \neq \emptyset$. It is easy to see that the satisfaction problem coincides with the CEP problem, and is thus NP-complete (Theorem 3). Given a word $w \in \Sigma^*$, the *membership problem* for G and w is to decide whether $w \in EL(G)$. By Theorem 6, the CEP problem is NP-complete also for singleton specifications, implying that so is the membership problem.

In this section we study additional problems about the Eulerian language of G. Problems that compare it with other languages, given by an NFA, DFA, or RE, or given as the Eulerian language of another graph. Not all our complexities are tight, but we are able to place all problems in different levels of the polynomial hierarchy.

▶ **Theorem 14.** *Consider a labeled graph G and a specification L given by an NFA, DFA, or RE. Deciding whether $EL(G) \subseteq L$ is co-NP-complete. Furthermore, it is co-NP-hard already for a fixed-size specification.*

Proof. For the upper bound, note that a witness for $EL(G) \not\subseteq L$, namely an EP in G that does not satisfy L, can be verified in polynomial time. For the lower bound, recall that the CEP problem is NP-hard already for fixed-size specifications (Theorem 5). Observe that there is an EP that satisfies L iff there is an EP that does not satisfy $\Sigma^* \setminus L$. Since L is given by a fixed-size NFA, DFA, or RE, the size of an NFA, DFA, or RE for its complement $\Sigma^* \setminus L$ is also fixed, and we are done. ◀

▶ **Theorem 15.** *Consider a labeled graph G and a specification L given by an NFA, DFA, or RE. Deciding whether $L \subseteq EL(G)$ is in Π_2^p and is NP-hard.*

Proof. The lower bound follows from the NP-hardness of the membership problem. The upper bound follows from the fact that deciding whether $L \not\subseteq EL(G)$ can be done with a nondeterministic polynomial-time Turing machine that uses an oracle for the membership problem. ◀

▶ **Theorem 16.** *Consider two labeled graphs G and G'. Deciding whether $EL(G') \subseteq EL(G)$ and deciding whether $EL(G') \cap EL(G) \neq \emptyset$ is in Π_2^p and Σ_2^p respectively, and is NP-hard.*

Proof. For the lower bound, we show a reduction from the membership problem. Given a word w and a graph G, we construct a graph G' such that $EL(G') = \{w\}$. Now, $w \in EL(G)$ iff $EL(G') \subseteq EL(G)$ iff $EL(G') \cap EL(G) \neq \emptyset$. For the upper bound, observe that deciding whether $EL(G') \not\subseteq EL(G)$ and whether $EL(G') \cap EL(G) \neq \emptyset$ can be done with a nondeterministic polynomial-time Turing machine that uses an oracle for the membership problem. ◀

Since $EL(G)$ contains only words of a fixed length, we know that $EL(G)$ is finite and hence regular. On the other hand, given a regular language $L \subseteq \Sigma^*$, even one all whose words are of the same length, it is not clear whether there is a graph G such that $EL(G) = L$. For example, it is possible to find a two-state labeled graph G such that $EL(G) = \{abcd, adbc, cbad, cdba\}$ (the reader is encouraged to search for it). but it is impossible to add $abdc$ to the Eulerian language. An upper bound for the problem follows from our ability to bound the number of edges in the candidate graph G. The tight complexity, however, is still open.

▶ **Theorem 17.** *For a language L given by an NFA, DFA, or RE, deciding whether there is a labeled graph G such that $EL(G) = L$ is in Σ_3^p.*

Proof. Follows from the fact that it can be done by a nondeterministic polynomial-time Turing machine with oracles for the problems described in Theorems 14 and 15. ◀

Abstract

We study the exact learnability of real valued graph parameters f which are known to be representable as partition functions which count the number of weighted homomorphisms into a graph H with vertex weights α and edge weights β. M. Freedman, L. Lovász and A. Schrijver have given a characterization of these graph parameters in terms of the k-connection matrices $C(f, k)$ of f. Our model of learnability is based on D. Angluin's model of exact learning using membership and equivalence queries. Given such a graph parameter f, the learner can ask for the values of f for graphs of their choice, and they can formulate hypotheses in terms of the connection matrices $C(f, k)$ of f. The teacher can accept the hypothesis as correct, or provide a counterexample consisting of a graph. Our main result shows that in this scenario, a very large class of partition functions, the rigid partition functions, can be learned in time polynomial in the size of H and the size of the largest counterexample in the Blum-Shub-Smale model of computation over the reals with unit cost.

1 Introduction

A graph *parameter* $f : \mathcal{G} \to \mathcal{R}$ is a function from all finite graphs $\mathcal{G}$ into a ring or field $\mathcal{R}$, which is invariant under graph isomorphisms.

In this paper we initiate the study of exact learnability of graph parameters with values in $\mathcal{R}$, which is assumed to be either $\mathbb{Z}, \mathbb{Q}$ or $\mathbb{R}$. As this question seems new, we focus here on the special case of graph parameters given as partition functions, [10, 14]. We adapt the model of exact learning introduced by D. Angluin [1]. Our research extends the work of [3, 11], where exact learnability of languages (set of words or labeled trees) recognizable by multiplicity automata (aka weighted automata) was studied, to graph parameters with values in $\mathcal{R}$.

1.1 Exact learning

In each step, the learner may make *membership queries* VALUE(x) in which they ask for the value of the target f on specific input x. This is the analogue of the MEMBERSHIP queries used in the original model of exact learning, [2]. The learner may also propose a hypothesis h by sending an EQUIVALENT(h) query to the teacher. If the hypothesis is correct, the teacher returns "YES" and if it is incorrect, the teacher returns a counterexample. A class of functions is *exactly learnable* if there is a learner that for each target function f, outputs a hypothesis h such that $f(x) = h(x)$ for all x and does so in time polynomial in the size of a shortest representation of f and the size of a largest counterexample returned by the teacher.

1.2 Formulating a hypothesis

To make sense one has to specify the formalism (language) $\mathfrak{L}$ in which a hypothesis has to be formulated. It will be obvious in the sequel, that the restriction imposed by the choice of $\mathfrak{L}$ will determine whether f is learnable or not.

Let us look at the seemingly simpler case of learning integer functions $f : \mathbb{Z} \to \mathbb{Z}$ or integer valued functions of words $w \in \Sigma^\star$ over an alphabet in Σ.

(i) If f can be any function $f : \mathbb{Z} \to \mathbb{Z}$ or $f : \Sigma^\star \to \mathbb{Z}$, there are uncountably many candidate functions as hypotheses, and no finitary formalism $\mathfrak{L}$ is suitable to formulate a hypothesis.

(ii) If f is known to be a polynomial $p(X) = \sum_i a_i X^i \in \mathbb{Z}[X]$, we can formulate the hypothesis as a vector $\mathbf{a} = (a_1, \ldots, a_m)$ in $\mathbb{Z}^m$. Learning is successful if the learner finds the hypothesis $h = \mathbf{a}$ in the required time. Here Lagrange interpolation will be used to formulate the hypotheses.

(iii) If f is known to satisfy some recurrence relation, the hypothesis will consist of the coefficients and the length of the recurrence relation, and exact learnability will depend on the class of recurrence relations one has in mind.

(iv) If $f : \Sigma^\star \to \mathbb{Z}$ is a word function recognizable by a multiplicity automaton MA, the hypotheses are given by the weighted transition tables of MA, cf. [3].

Looking now at a graph parameter $f : \mathcal{G} \to \mathcal{R}$ what can we expect? Again we have to restrict our treatment to a class of parameters where each member can be described by a finite string in a formalism $\mathfrak{L}$.

We illustrate the varying difficulty of the learning problem with the example of the chromatic polynomial $\chi(G; X \in \mathbb{N}[X])$ for a graph G. For $X = k$, the evaluation of $\chi(G; k)$ counts the number of proper colorings of G with at most k colors. It is well known that for fixed G, $\chi(G; k)$ is indeed a polynomial in k, [4, 7]. A graph parameter f is a *chromatic invariant over $\mathcal{R}$* if

(i) it is multiplicative, i.e., for the disjoint union $G_1 \sqcup G_2$ of G_1 and G_2, it holds that $f(G_1 \sqcup G_2) = f(G_1) \cdot f(G_2)$, and

(ii) there are $\alpha, \beta, \gamma \in \mathcal{R}$ such that $f(G) = \alpha \cdot f(G_{-e}) + \beta \cdot f(G_{/e})$ and $f(K_1) = \gamma$.

K_n denotes the complete graph on n vertices, and G_{-e} and $G_{/e}$ are, respectively, the graphs obtained from deleting the edge e from G and contracting e in G.

The parameter $\chi(G; k)$ is a chromatic invariant with $\alpha = 1, \beta = -1$ and $\gamma = k$. Finally, $\chi(G; k)$ has an interpretation by counting homomorphisms:

$$\chi(G; m) = \sum_{t: G \to K_m} 1,$$

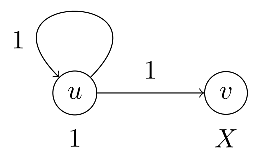

Figure 1 The weighted graph H_{indep}.

This is a special case of the homomorphism counting function for a fixed graph H:

$$\mathsf{hom}(G, H) = \sum_{t:G \to H} 1,$$

where t is a homomorphism $t : G \to H$.

Now, let a graph parameter $f : \mathcal{G} \to \mathcal{R}$ be the target of a learning algorithm.

(i) If f is known to be an instance of $\chi(G; X)$, a hypothesis consists of a value $X = a$. But in this case we know that $\chi(K_1; X) = X$, so it suffices to ask for $f(K_1) = a$.

(ii) If f is known to be a chromatic invariant, the hypothesis consists of the triple (α, β, γ). In this case a hypothesis can be computed from the values of $f(P_m)$ for undirected paths P_m for sufficiently many values of m.

(iii) If f is known to be an instance of $\mathsf{hom}(-, H)$, a hypothesis would consist of a target graph H.

1.3 Counting weighted homomorphisms aka partition functions

A *weighted graph* $H(\alpha, \beta)$ is a graph $H = (V(H), E(H))$ on $n = |V(H)|$ vertices together with a vertex weight function $\alpha : V(H) \to \mathbb{R}$, viewed as a vector of length n, and an edge weights function $\beta : V(H)^2 \to \mathbb{R}$ viewed as an $n \times n$ matrix, with $\beta(u, v) = 0$ if $(u, v) \notin E(H)$.

A *partition function*[1] $\mathsf{hom}(-, H(\alpha, \beta))$ is the generalization of $\mathsf{hom}(-, H)$ to weighted graphs, whose value on a graph G is defined as follows:

$$\mathsf{hom}(G, H(\alpha, \beta)) = \sum_{t:G \to H} \prod_{v \in V(G)} \alpha(t(v)) \prod_{(u,v) \in V(G)^2} \beta(t(u), t(v))$$

To illustrate the notion of a partition function, let H_{indep} be the graph with two vertices $\{u, v\}$ and the edges $\{(u, v), (u, u)\}$, shown in Figure 1. Let $\alpha(u) = 1, \alpha(v) = X$ and $\beta(u, v) = 1, \beta(u, u) = 1$. Then $\mathsf{hom}(-, H_{indep}(\alpha, \beta))$ is the *independence polynomial*,

$$\mathsf{hom}(G, H_{indep}(\alpha, \beta)) = I(G; X) = \sum_j ind_j(G) X^j$$

where $ind_j(G)$ is the number of independent sets of size j in the graph G.

We say a partition function $\mathsf{hom}(-, H(\alpha, \beta))$ is *rigid* aka *asymmetric* [2], if H has no proper automorphisms. Note that automorphisms in a weighted graph also respect vertex and edge weights. In our examples above, the evaluations of the independence polynomial are rigid partition functions, whereas the evaluations of the chromatic polynomial are not. It is known that almost all graphs are rigid:

[1] In the literature $\mathsf{hom}(-, H(\alpha, \beta))$ is also denoted by $Z_{H(\alpha,\beta)}(G)$, e.g., in [19]. We follow the notation of [14].

[2] Some authors say G is asymmetric if G has no proper automorphisms, and G is rigid if G has no proper endomorphisms, [12]. Wikipedia uses rigid as we use it here.

▶ **Theorem 1** ([9, 12]). *Let G be a uniformly selected graph on n vertices. The probability that G is rigid tends to 1 as $n \to \infty$.*

If the target f is known to be a (rigid) partition function $\mathsf{hom}(-, H(\alpha, \beta))$ then the hypothesis consists of a (rigid) weighted graph $H(\alpha, \beta)$.

In Section 2 we give the characterization of rigid and non-rigid partition functions from [10, 15, 14] in terms of connection matrices.

For technical reasons discussed in Section 5, in this paper we deal only with the learnability of rigid partition functions, and leave the general case to future work.

1.4 Main result

Our main result can now be stated:

▶ **Theorem 2.** *Let f be a graph parameter which is known to be a rigid partition function $f(G) = \mathsf{hom}(G, H(\alpha, \beta))$. Then f can be learned in time polynomial in the size of H and the size of the largest counterexample in the Blum-Shub-Smale model of computation over the reals with unit cost.*

▶ **Remark 3.** *If f takes values in $\mathbb{Q}$ rather than in $\mathbb{R}$ we can also work in the Turing model of computation with logarithmic cost for the elements in $\mathbb{Q}$.*

To prove Theorem 2 we will use the characterization of rigid partition functions in terms of connection matrices, [14, Theorem 5.54], stated as Theorem 4 and Corollary 6 in Section 2. The difficulty of our result lies not in finding a learning algorithm by carefully manipulating the counterexamples to meet the complexity constraints, but in proving the algorithm correct. In order to do this we had to identify and extract the suitable algebraic properties underlying the proof of Theorem 4 and Corollary 6.

The learning algorithm is given in pseudo-code as Algorithm 1. It maintains a matrix M used in the generation of the hypothesis h from VALUE and EQUIVALENT query results. After an initial setup of M, in each iteration the algorithm generates a hypothesis h, queries the teacher for equivalence between h and the target and either terminates, or updates M accordingly and moves on to the next iteration.

It uses three black-boxes; find basis which uses M to find a certain basis P of a graph algebra associated with the target function (see Section 2), generate hypothesis which uses this basis and VALUE queries to construct a hypothesis h, and augment M which augments the matrix M after a counterexample is received, using VALUE queries.

We briefly overview the complexity of the algorithm to illustrate that rigid partition functions are indeed exactly learnable. Proofs of validity and detailed analysis of the complexity are given in later sections. For a target $H(\alpha,\beta)$ on q vertices, the procedure find basis solves $O(q)$ systems of linear equations, and systems of linear matrix equations, all of dimension $O(\text{poly}(q))$. The procedure generate hypothesis performs $O(q)$ graph operations of polynomial time complexity on graphs of size $O(\text{poly}(q,|x|))$, where $|x|$ is the size of the largest counterexample, and $O(q^2)$ VALUE queries. The procedure augment M performs $O(q)$ VALUE queries. Thus, each iteration takes time $O(\text{poly}(q,|x|))$. Lemma 18 will show that there are $O(q)$ iterations, so the total run time of the algorithm is polynomial in the size q of $H(\alpha,\beta)$ and the size $|x|$ of the largest counterexample.

Organization

In Section 2 we give the necessary background on partition functions and the graph algebras induced by them. Section 3 presents the algorithm in detail and in Section 4 we prove its validity and analyze its time complexity. We discuss the results and future work in Section 5. Due to space limitations, the appendix is included in the arXiv version, [13].

2 Preliminaries

Let $k \in \mathbb{N}$. A *k-labeled graph* G is a finite graph in which k vertices, or less, are labeled with labels from $[k] = \{1,\dots,k\}$. We denote the class of k-labeled graphs by $\mathcal{G}_k$. The *k-connection* of two k-labeled graphs $G_1, G_2 \in \mathcal{G}_k$ is given by taking the disjoint union of G_1 and G_2 and identifying vertices with the same label. This produces a k-labeled graph $G = G_1G_2$. Note that k-connections are commutative.

2.1 Quantum graphs

A formal linear combination of a finite number of k-labeled graphs $F_i \in \mathcal{G}_k$ with coefficients from $\mathbb{R}$ is called a *k-labeled quantum graph*. $\mathcal{Q}_k$ denotes the set of k-labeled quantum graphs.

Let x, y be k-labeled quantum graphs: $x = \sum_{i=1}^n a_iF_i$, and $y = \sum_{i=1}^n b_iF_i$. Note that some of the coefficients may be zero. $\mathcal{Q}_k$ is an infinite dimensional vector space, with the operations: $x+y = (\sum_{i=1}^n a_iF_i)+(\sum_{i=1}^n b_iF_i) = \sum_{i=1}^n (a_i+b_i)F_i$, and $\alpha\cdot x = \sum_{i=1}^n (\alpha a_i)F_i$.

k-connections extend to k-labeled quantum graphs by $xy = \sum_{i,j=1}^n (a_ib_j)(F_iF_j)$. Any graph parameter f extends to k-labeled quantum graphs linearly: $f(x) = \sum_{i=1}^n a_if(F_i)$.

2.2 Equivalence relations for quantum graphs

The *k-connection matrix* $C(f,k)$ of a graph parameter $f : \mathcal{G} \to \mathcal{R}$ is a bi-infinite matrix over $\mathcal{R}$ whose rows and columns are labeled with k-labeled graphs, and its entry at the row labeled with G_1 and the column labeled with G_2 contains the value of f on G_1G_2:

$$C(f,k)_{G_1,G_2} = f(G_1G_2).$$

Given a connection matrix $C(f,k)$, we associate with a k-labeled graph $G \in \mathcal{G}_k$ the (infinite) row vector R_G^k appearing in the row labeled by G in $C(f,k)$. If k is clear from context we write R_G. Similarly, we associate an infinite row vector R_x with k-labeled quantum graphs

$x = \sum_{i=1}^{n} a_i F_i$, defined as $R_x = \sum_{i=1}^{n} a_i R_{F_i}$ where R_{F_i} is the row in $C(f,k)$ labeled by the k-labeled graph F_i.

We say $C(f,k)$ has *finite rank* if there are finitely many k-labeled graphs $\mathcal{B}_{C(f,k)} = \{B_1, \dots, B_n\}$ whose rows $\mathcal{R}_{C(f,k)} = \{R_{B_1}, \dots, R_{B_n}\}$ linearly span $C(f,k)$. Meaning, for any k-labeled graph G, there exists a linear combination of the rows in $\mathcal{R}_{C(f,k)}$ which equals the row vector R_G. We say that $C(f,k)$ has rank n and denote $r(f,k) = n$ if any set of less than n graphs does not linearly span $C(f,k)$.

The main result we use is the characterization of partition functions in terms of connection matrices. We do not need its complete power, so we state the relevant part:

▶ **Theorem 4** (Freedman, Lovász, Schrijver, [10]). *Let f be a graph parameter that is equal to $hom(-, H(\alpha,\beta))$ for some $H(\alpha,\beta)$ on q vertices. Then $r(f,k) \le q^k$ for all $k \ge 0$.*

The exact rank $r(f,k)$ was characterized in [15], but first we need some definitions. A weighted graph $H(\alpha,\beta)$ is said to be *twin-free* if β does not contain two separate rows that are identical to each other [3]. Let $H(\alpha,\beta)$ be a weighted graph on q vertices, and let $\mathrm{Aut}(H(\alpha,\beta))$ be the automorphism group of $H(\alpha,\beta)$. $\mathrm{Aut}(H(\alpha,\beta))$ acts on ordered k-tuples of vertices $[q]^k = \{\phi : [k] \to [q]\}$ by $(\sigma \circ \phi)(i) = \sigma(\phi(i))$ for $\sigma \in \mathrm{Aut}(H(\alpha,\beta))$. The *orbit* of ϕ is the set of ordered k-tuples ψ of vertices such that $\sigma \circ \phi = \psi$ for an automorphism $\sigma \in \mathrm{Aut}(H(\alpha,\beta))$. The *number of orbits* of $\mathrm{Aut}(H(\alpha,\beta))$ on $[q]^k$ is the number of different orbits for elements $\phi \in [q]^k$.

▶ **Theorem 5** (Lovász, [15]). *Let $f = hom(-, H(\alpha,\beta))$ for a twin-free weighted graph $H(\alpha,\beta)$ on q vertices. Then $r(f,k)$ is equal to the number of orbits of $\mathrm{Aut}(H(\alpha,\beta))$ on $[q]^k$ for all $k \ge 0$.*

We use the special case:

▶ **Corollary 6.** *Let $f = hom(-, H(\alpha,\beta))$ for a rigid twin-free weighted graph $H(\alpha,\beta)$ on q vertices. Then $r(f,k) = q^k$ for all $k \ge 0$.*

We define an equivalence relation $\equiv_{f,k}$ over $\mathcal{Q}_k$ where two k-labeled quantum graphs x and y are in the same equivalence class if and only if the infinite vectors R_x and R_y are identical: $x \equiv_{f,k} y \iff R_x^k = R_y^k$. Note that the set $\mathcal{Q}_k/f$ of equivalence classes of $\equiv_{f,k}$ is exactly the vector space $span(C(f,k))$ generated by linear combinations of rows in $C(f,k)$. k-connections extend to these vectors by: $R_x R_y = R_{xy}$.

Thus, if $r(f,k) = n$ with spanning rows $\mathcal{R}_{C(f,k)} = \{R_{B_1}, \dots, R_{B_n}\}$, they form a basis of $\mathcal{Q}_k/f = span(C(f,k))$. For brevity, we occasionally also refer to $\mathcal{B}_{C(f,k)}$ as a basis.

Let x be a k-labeled quantum graph whose equivalence class R_x is given as the linear combination $R_x = \sum_{i=1}^{n} \gamma_i R_{B_i}$. We call the column vector $\bar{c}_x = (\gamma_1, \dots, \gamma_n)^T$ the *coefficients vector* of x, or *representation* of x using $\mathcal{B}_{C(f,k)}$.

3 The learning algorithm in detail

In this section we present the learning algorithm in full detail. The commentary in this exposition foreshadows the arguments in Section 4, but otherwise validity is not considered here. We do not address complexity concerns in this section either, however, we reiterate

[3] If $H(\alpha,\beta)$ has twin vertices, they can be merged into one vertex by adding their vertex weights without changing the partition function. As the size of the target representation is the smallest possible, we assume all targets are twin-free.

for the sake of clarity that the algorithm runs on a Blum-Shub-Smale machine, [6, 5], over the reals. In such a machine, real numbers are treated as atomic objects; they are stored in single cells, and arithmetic operations are performed on them in a single step.

The objects the algorithm primarily works with are real matrices. In a context containing a basis $\mathcal{B}_{C(f,k)}$, we associate a real matrix A_x with each quantum graph x such that the following holds.

The coefficients vector $\bar{c}_{xy}$ of xy using $\mathcal{B}_{C(f,k)}$ is given by $A_x\bar{c}_y$. (*)

This device, as we will see in Section 4, will allow the algorithm to search for, and find, special quantum graphs that provide a translation of the answers of VALUE and EQUIVALENT queries into a hypothesis.

As mentioned earlier, Algorithm 1 maintains a matrix M which is a submatrix of $C(f,1)$. In each iteration the algorithm generates a hypothesis $h = (\alpha^{(h)}, \beta^{(h)})$ using M, and queries the teacher for equivalence between h and the target f. If the hypothesis is correct, the algorithm returns h, otherwise it augments M with a 1-labeled version of the counterexample, and moves on to the next iteration.

▶ **Remark 7.** *Strictly speaking, the teacher may be asked* VALUE *queries on (unlabeled) graphs, however, we freely write* VALUE(G) *for k-labeled graphs $G \in \mathcal{G}_k$. Additionally, the algorithm will need to know the value of the target on some quantum graphs. Since any graph parameter extend to quantum graphs linearly, for a quantum graph $x = \sum_{i=1}^{n} a_i F_i$ we write* VALUE(x) *as shorthand for $\sum_{i=1}^{n} a_i \cdot$* VALUE(F_i) *throughout the presentation.*

Incorporating counterexamples

The objective is to keep a non-singular submatrix M of $C(f,1)$. The first 1-labeled graph B_1 with which M is augmented is some arbitrarily chosen 1-labeled graph.

Upon receiving a B_n graph as counterexample, the 1-label is arbitrarily assigned to one of its vertices, making it a 1-labeled graph. Then augment M with(B_n) adds a row and a column to M labeled with the (now) 1-labeled graph B_n, and fills their entries with the values $f(B_nB_i) = f(B_iB_n)$, for $i \in [n]$, using VALUE queries.

The other functions are slightly more complex.

Finding an idempotent basis

The function find basis, given in pseudo-code as Algorithm 2, receives as input the matrix M. For reasons which will become apparent later, we are interested in finding a certain (idempotent) basis of the linear space generated by the rows of $C(f,1)$. For this purpose, in its first part find basis iteratively, over $k = 1, \ldots, n$, computes the entries of matrices A_x as in (*), where x are B_i, $i \in [n]$, by solving multiple systems $M\mathbf{x} = \mathbf{b}$ of linear equations, and using the solutions Γ of those systems to fill the entries of the matrices A_{B_i}, where the (k,j) entry of A_{B_i} is $\gamma^{ij}(k)$. Let p_i, $i \in [n]$ be those quantum graphs for which A_{p_i} is the $n \times n$ matrix with the value 1 in the entry (i,i) and zero in all other entries. Note that the matrices A_{p_i}, $i \in [n]$ are linearly independent. We will see that p_i, $i \in [n]$ are the idempotent basis, now we wish to find their representation using B_i, $i \in [n]$.

For $i \in [n]$, the representation $\bar{c}_{p_i}$ of the basic idempotent p_i using the basis elements $B_i, i \in [n]$ is found by solving a system $A\mathbf{X} = A_{p_i}$ of linear *matrix equations*, where A is a block matrix whose blocks are the matrices A_{B_i}, $i \in [n]$. Each solution is added to Δ.

Finally, find basis outputs the set Δ of these representations $\bar{c}_{p_i}$, $i \in [n]$. Then we have that $R_{p_i} = \sum_{k=1}^{n} \bar{c}_{p_i}(k) R_{B_k}$ where $\bar{c}_{p_i}$ is the coefficients vector of p_i using B_i, $i \in [n]$. The

Algorithm 2 find basis function

15:     $\bar{c}_{p_i} =$ solve linear matrix system$(A\mathbf{X} = A_{p_i})$
16:     $\Delta = \Delta \cup \{\bar{c}_{p_i}\}$
17: end for
18: return $\Delta$
```

representations $\bar{c}_{p_i} \in \Delta$ of the elements p_i, $i \in [n]$, are what will provide a translation from results of VALUE queries to weights.

Generating a hypothesis

The function generate hypothesis, given in pseudo-code as Algorithm 3, receives as input the representations $\bar{c}_{p_i}$ of the 1-labeled quantum graphs p_i, $i \in [n]$, which it uses to find the entries of the vertex weights vector $\alpha^{(h)}$ directly through VALUE queries.

Then generate hypothesis finds the 2-labeled analogues of these 1-labeled quantum graphs. Those 2-labeled analogues form a basis of of $\mathcal{Q}_2/f$.

Denote by K_2 the 2-labeled graph composed of a single edge with both vertices labeled. Next, generate hypothesis finds the representation of $R^2_{K_2}$, that is the row labeled with K_2 in $C(f,2)$, using the basis $\mathcal{R}_{C(f,2)}$. We find the representation of this specific graph K_2 as the coefficients in $\bar{c}_{K_2}$ constitute the entries of the edge weights matrix $\beta^{(h)}$ (see Section 4).

This representation is found by solving a linear system of equations, similarly to how find basis uses solve linear system, but here we use the diagonal matrix N whose entries correspond to the elements of $\mathcal{B}_{C(f,2)}$.

The solution of said system, i.e., the coefficients vector $\bar{c}_{K_2}$ of K_2, is used to fill the edge weights matrix $\beta^{(h)}$. If needed, $\beta^{(h)}$ is made twin-free by contracting the twin vertices into one and summing their weights in $\alpha^{(h)}$.

Finally, generate hypothesis returns the hypothesis $h = (\alpha^{(h)}, \beta^{(h)})$ as output.

▶ **Remark 8** (Algorithm 3). *Let q_i be the 1-labeled quantum graph p_i interpreted as a 2-labeled quantum graph, and let q_j be p_j with the labels of its components renamed to 2, and also interpreted as a 2-labeled quantum graph. The result of $p_i \otimes p_j$ is the 2-labeled quantum graph $q_i \sqcup_2 q_j$.*

10:    end for
11: end for
12: $\beta^{(h)} =$ solve linear system$(N\mathbf{x} = \mathbf{b})$
13: make twin-free$(\alpha^{(h)}, \beta^{(h)})$
14: $h = (\alpha^{(h)}, \beta^{(h)})$
15: return $h$
```

4 Validity and complexity

As stated earlier, a class of functions is exactly learnable if there is a learner that for each target function f, outputs a hypothesis h such that f and h identify on all inputs, and does so in time polynomial in the size of a shortest representation of f and the size of a largest counterexample returned by the teacher. The proof of Theorem 2 argues that Algorithm 1 is such a learner for the class of rigid partition functions, through Theorem 9, which proves validity, and Theorem 22, which proves the complexity constraints are met.

To prove validity, we first state existing results on properties of graph algebras induced by partition functions, then show, through somewhat technical algebraic manipulations, how our algorithm successfully exploits these properties to generate hypotheses. We then show our algorithm eventually terminates with a correct hypothesis.

For the rest of the section, let $H(\alpha, \beta)$ be a rigid twin-free weighted graph on q vertices, and denote $f = \mathsf{hom}(-, H(\alpha, \beta))$.

▶ **Theorem 9.** *Given access to a teacher for f, Algorithm 1 outputs a hypothesis h such that $f(G) = h(G)$ for all graphs $G \in \mathcal{G}$.*

The proof of the theorem follows from arguing that:

▶ **Theorem 10.** *If M is of rank q, then* generate hypothesis *outputs a correct hypothesis.*

and that the rank of M is incremented with every counterexample:

▶ **Theorem 11.** *In the n^{th} iteration of Algorithm 1 on f, M has rank n.*

First we confirm the hypotheses Algorithm 1 generates are indeed in the class of graph parameters we are trying to learn, namely, rigid partition functions $\mathsf{hom}(-, H(\alpha, \beta))$ for twin-free weighted graphs $H(\alpha, \beta)$.

Given Theorem 11, for the hypothesis h returned in the n^{th} iteration, the rank of $C(h, 1)$ is at least n, since M is a submatrix of $C(h, 1)$. Thus, from Theorem 5, h cannot have proper automorphisms, as it would imply that the rank of $C(h, 1) < n$. The fact that h is twin-free is immediate from the construction in generate hypothesis.

4.1 From the idempotent bases to the weights – proof of Theorem 10

Let $\mathcal{Q}_k/f$ be of finite dimension n. The *idempotent basis* $p_1, \ldots, p_n$ of $\mathcal{Q}_k/f$ consists of those k-labeled quantum graphs p_i for which $p_i p_i \equiv_{f,k} p_i$ and $p_i p_j \equiv_{f,k} 0$ for $i, j \in [n]$, $i \neq j$. Recall how find basis found those 1-labeled quantum graphs p_i, $i \in [n]$ whose matrices A_{p_i} behaved in this way.

In our setting of rigid twin-free weighted graphs, by [14, Chapter 6], we have that if $p_1, \ldots, p_q$ are the idempotent basis of Q_1/f, then the idempotent basis of $\mathcal{Q}_2/f$ is given by $p_i \otimes p_j$, $i, j \in [q]$. These are the 2-labeled analogues mentioned in the description of generate hypothesis.

Furthermore by [14, Chapter 6], the vertex weights α of H are given by $\alpha(i) = f(p_i)$, $i \in [q]$, and if the representation of K_2 using $p_i \otimes p_j$, $i, j \in [q]$ is $\sum_{i,j \in [q]} \beta_{ij}(p_i \otimes p_j)$, then the edge weights matrix β is given by $\beta_{i,j} = \beta_{ij}$.

Equipped with these useful facts, we show that:

▶ **Lemma 12.** *If M is of rank q, then find basis outputs the idempotent basis of $\mathcal{Q}_1/f$.*

Then obtain Theorem 10 by showing how, if generate hypothesis receives the idempotent basis of $\mathcal{Q}_1/f$ as input, it outputs a correct hypothesis.

Finding the idempotent basis – proof of Lemma 12

Recall that in the presence of a basis $\mathcal{B}_{C(f,k)}$ we associate a real matrix A_x with each quantum graph x such that the following holds.

The coefficients vector $\bar{c}_{xy}$ of xy using $\mathcal{B}_{C(f,k)}$ is given by $A_x \bar{c}_y$.

For reasons we cannot list here, A_x will be diagonal. Let $B_i, B_j \in \mathcal{B}_{C(f,1)}$, and denote by $\sum_{k=1}^{n} \gamma_k^{i,j} R_{B_k}$ the representation of the row $R_{B_i B_j}$ using $\mathcal{R}_{C(f,1)}$, i.e., the row in $C(f,1)$ labeled with the graph resulting from the product $B_i B_j$.

▶ **Claim 13.** *Let x be some 1-labeled quantum graph such that $R_x = \sum_{i=1}^{n} a_i R_{B_i}$. The matrix A_x is given by $(A_x)_{\ell,m} = \sum_{i=1}^{n} a_i \gamma_\ell^{im}$.*

Note that for a basis graph $B_k \in \mathcal{B}_{C(f,1)}$, we have that $(A_{B_k})_{i,j} = \gamma_i^{k,j}$. The proof of this claim appears in the appendix of [13].

▶ **Proposition 14.** *The matrices $A_{B_1}, \ldots, A_{B_n}$ of the graphs in $\mathcal{B}_{C(f,1)}$ are linearly independent and span all matrices of the form A_x for a quantum graph x.*

If we know what are the matrices $A_{p_1}, \ldots, A_{p_n}$ of the idempotent basis $p_1, \ldots, p_n$, we can find their representation using $A_{B_1}, \ldots, A_{B_n}$ by solving systems of linear matrix equations. Then, given a representation $A_{p_i} = \sum_{k=1}^{n} \delta_k^{(i)} A_{B_k}$, we will have the representation of the basic idempotents using $\mathcal{B}_{C(f,1)}$ as $p_i = \sum_{k=1}^{n} \delta_k^{(i)} B_k$.

The definitions of A_x and idempotence lead to the observation that for idempotent basics p_i, p_j, it holds that $A_{p_i} A_{p_i} = A_{p_i}$ and $A_{p_i} A_{p_j} = 0$. From Corollary 6 we know the dimension of $\mathcal{Q}_1/f$ is q, so we conclude:

▶ **Proposition 15.** *The idempotent basis for $\mathcal{Q}_1/f$ consists of the quantum graphs p_i, $i \in [q]$ for which A_{p_i} is the $q \times q$ matrix with the value 1 in the entry (i,i) and zero in all other entries. That is,*

$$A_{p_i}(k,j) = \begin{cases} 1, & \text{if } (k,j) = (i,i) \\ 0, & \text{otherwise} \end{cases}$$

As find basis solves the systems of linear matrix equations for these matrices, it remains to show that find basis correctly computes the matrices A_{B_i}, $i \in [q]$.

Since M is of full rank, the representations $\sum_{k=1}^{n} \gamma_k^{i,j} R_{B_k}$ of graphs B_iB_j, $i,j \in [q]$ using $\mathcal{B}_{C(f,1)}$ are correctly computed by the solve linear system calls. And as noted before, the coefficients $\gamma_k^{i,j}$ are the entries of the matrices A_{B_i}, $i \in [q]$. Thus they indeed are correctly computed, and we have Lemma 12.

Since generate hypothesis directly queries the teacher for the values of $\alpha^{(h)}$, we have:

▶ **Corollary 16.** *If M is of rank q, then* generate hypothesis *outputs a correct vertex weights vector $\alpha^{(h)}$.*

It remains to show this is true also for the edge weights:

▶ **Proposition 17.** *If M is of rank q, then* generate hypothesis *outputs a correct edge weights matrix $\beta^{(h)}$.*

Proof. As $p_{ij} = p_i \otimes p_j$, $i,j \in [q]$ are the idempotent basis for $\mathcal{Q}_2/f$ we have that $p_{ij}p_{ij} \not\equiv_{f,2} 0$, so the matrix N is a diagonal matrix of full rank, and solve linear system indeed finds the representation of K_2 using p_{ij}, $i,j \in [q]$. ◀

From Corollary 16 and Proposition 17 we have Theorem 10.

Now we show that Algorithm 1 reaches that point in the first place.

4.2 Augmentation results in larger rank – proof of Theorem 11

Theorem 11 is proved using the fact that A_x are linearly independent for k-labeled quantum graphs which are not equivalent in $\equiv_{f,k}$.

▶ **Lemma 18.** *In the n^{th} iteration of Algorithm 1, if the teacher returns a counterexample x, then R_x is not spanned by $R_{B_1}, \ldots, R_{B_n}$ where $B_1, \ldots, B_n$ are the graphs associated with the rows and columns of M.*

Proof. If $n = 1$, M has rank n. Now let M have rank n.

For contradiction, assume that $R_x = \sum_{i=1}^{n} a_i R_{B_i}$. Then $x \equiv_{f,1} \sum_{i=1}^{n} a_i B_i$ and we have that $\mathsf{hom}(x,H) = \sum_{i=1}^{n} a_i \mathsf{hom}(B_i,H)$ for the target graph H. Denote by $h^{(n)}$ the hypothesis generated in this iteration. If x is a counterexample, it must hold that

$$\mathsf{hom}(x, h^{(n)}) \neq \mathsf{hom}(x,H) = \sum_{i=1}^{n} a_i \mathsf{hom}(B_i,H)$$

The solution of the system of equations for $\mathbf{b}_x$ would give

$$\mathsf{hom}(x, h^{(n)}) = \sum_{i=1}^{n} a_i \mathsf{hom}(B_i, h^{(n)}) = \sum_{i=1}^{n} a_i \mathsf{hom}(B_i,H)$$

So we conclude that $\sum_{i=1}^{n} a_i \mathsf{hom}(B_i, h^{(n)}) \neq \sum_{i=1}^{n} a_i \mathsf{hom}(B_i,H)$.

Since M is of full rank, one can solve a system of linear equations using M for $\mathbf{b}_x$ defined as $\mathbf{b}_x(k) = \textsc{value}(xB_k)$, $k \in [n]$. Now recall that the matrix M contains *correct* values $\mathsf{hom}(B_iB_j, H(\alpha,\beta))$, as it was augmented using $\textsc{value}$ queries, therefore M is a submatrix of $C(f,1)$. Thus the coefficients of the solution $\mathbf{a}$ of $M\mathbf{a} = \mathbf{b}_x$ equal a_i, $i \in [k]$, and we reach a contradiction. Therefore we conclude $x \not\equiv_{f,1} \sum_{i=1}^{n} a_i B_i$ and its row R_x is linearly independent from $R_{B_1}, \ldots, R_{B_n}$. ◀

This also implies that the matrix A_x associated with x is not spanned by $A_{B_1}, \ldots, A_{B_n}$. Therefore the submatrix of $C(f, 1)$ composed of the entries of the rows and columns of $B_1, \ldots, B_n, x$ is of full rank $n+1$. This is exactly the matrix M augmented with x, and we have Theorem 11. Combining this with Corollary 6, we have:

▶ **Corollary 19.** *Let f be a rigid partition function of a twin-free weighted graph on q vertices. Then Algorithm 1 terminates in q iterations.*

4.3 Complexity analysis

As the algorithm runs on a Blum-Shub-Smale machine for the reals and mostly solves systems of linear equations, it is not difficult to show that it runs in time polynomial in the size of target and the largest counterexample. First we observe:

▶ **Proposition 20.** *Let $G_1, G_2 \in \mathcal{G}_1$. Then $G_1 G_2$ can be computed in time $O(\mathrm{poly}(|G_1|, |G_2|))$.*

▶ **Remark 21.** *B_1 is of fixed size, and all other B_i, $i = 2, \ldots, n$, used in Algorithm 1 are counterexamples provided by the teacher, therefore they are all of size polynomial in the size $|x|$ of the graph x.*

▶ **Theorem 22.** *Let $H(\alpha, \beta)$ be a rigid twin-free weighted graph on q vertices and denote $f = \mathsf{hom}(-, H(\alpha, \beta))$. Given access to a teacher for f, Algorithm 1 terminates in time $O(\mathrm{poly}(q, |x|))$, where $|x|$ is the size of the largest counterexample provided by the teacher.*

Proof. From Corollary 19 it is enough to show that each iteration of Algorithm 1 does not take too long (Lemma 23). ◀

▶ **Lemma 23** ([13]). *In the n^{th} iteration of Algorithm 1, augment M, find basis, and generate hypothesis all run in time $O(\mathrm{poly}(n, |x|))$.*

▶ Remark. We note that, from [14, Theorem 6.45], the counterexamples provided by the teacher may be chosen to be of size at most $2(1+q^2)q^6$ where q is the size of the target weighted graph.

5 Conclusion and future work

This paper presented an adaptation of the exact model of learning of Angluin, [1], to the context of graph parameters f representable as partition functions of weighted graphs $H(\alpha, \beta)$. We presented an exact learning algorithm for the class of *rigid* partition functions defined by twin-free $H(\alpha, \beta)$.

If a weighted graph has proper automorphisms, its connection matrices $C(f, k)$ may have rank smaller than q^k. In this case, the translation from query results to a weighted graph would involve the construction of a submatrix of $C(f, k)$ for a sufficiently large k, and then find an idempotent basis for $\mathcal{Q}_{k+1}/f$. We will study the learnability of non-rigid partition functions in a sequel to this paper.

Theorems similar to Theorem 4 have been proved for variants of partition functions and connection matrices, [16, 8, 17, 18]. It seems reasonable to us that similar exact learning algorithms exist for these settings, but it is unclear how to modify our proofs here for this purpose.

Acknowledgements. We thank M. Jerrum and M. Hermann for their valuable remarks while listening to an early version of the introduction of the paper, and A. Schrijver for his interest and encouragement. We also thank two anonymous referees for their helpful remarks.

Abstract

The *parameterized satisfiability problem* over a set of Boolean relations Γ ($\mathrm{SAT}(\Gamma)$) is the problem of determining whether a conjunctive formula over Γ has at least one model. Due to Schaefer's dichotomy theorem the computational complexity of $\mathrm{SAT}(\Gamma)$, modulo polynomial-time reductions, has been completely determined: $\mathrm{SAT}(\Gamma)$ is always either tractable or NP-complete. More recently, the problem of studying the relationship between the complexity of the NP-complete cases of $\mathrm{SAT}(\Gamma)$ with restricted notions of reductions has attracted attention. For example, Impagliazzo et al. studied the complexity of k-SAT and proved that the worst-case time complexity increases infinitely often for larger values of k, unless 3-SAT is solvable in subexponential time. In a similar line of research Jonsson et al. studied the complexity of $\mathrm{SAT}(\Gamma)$ with algebraic tools borrowed from clone theory and proved that there exists an NP-complete problem $\mathrm{SAT}(R^{\neq\neq\neq01}_{1/3})$ such that there cannot exist any NP-complete $\mathrm{SAT}(\Gamma)$ problem with strictly lower worst-case time complexity: the *easiest NP-complete* $\mathrm{SAT}(\Gamma)$ *problem*. In this paper we are interested in classifying the NP-complete $\mathrm{SAT}(\Gamma)$ problems whose worst-case time complexity is lower than 1-in-3-SAT but higher than the easiest problem $\mathrm{SAT}(R^{\neq\neq\neq01}_{1/3})$. Recently it was conjectured that there only exists three satisfiability problems of this form. We prove that this conjecture does not hold and that there is an infinite number of such $\mathrm{SAT}(\Gamma)$ problems. In the process we determine several algebraic properties of 1-in-3-SAT and related problems, which could be of independent interest for constructing exponential-time algorithms.

1 Introduction

The *parameterized satisfiability problem* ($\mathrm{SAT}(\Gamma)$) is the computational decision problem of, given a conjunctive formula over a constraint language Γ, determining whether this formula is satisfiable. Some notable examples of problems that can be formulated as $\mathrm{SAT}(\Gamma)$ problems include 1-in-3-SAT, k-SAT, SAT, and not-all-equal-SAT. For example, if we let $R_{1/3} = \{(0,0,1),(0,1,0),(1,0,0)\}$ then $\mathrm{SAT}(\{R_{1/3}\})$ can be seen as an alternative formulation of the monotone 1-in-3-SAT problem, i.e., 1-in-3-SAT without negation. Hence, $\mathrm{SAT}(\Gamma)$ is in general NP-complete. It is also known that $\mathrm{SAT}(\Gamma)$ is either tractable, i.e., solvable in polynomial time, or NP-complete, for all choices of Γ [25]. Assume that we instead are interested in a more fine-grained analysis of the worst-case time complexity of all

$$\begin{tikzcd}
\langle\{R_{1/3}\}\rangle_{\nexists} \\
\langle\{R^{01}_{1/3}\}\rangle_{\nexists} \arrow[u] \\
\langle\{R^{\neq 01}_{1/3}\}\rangle_{\nexists} \arrow[u] \\
\langle\{R^{\neq\neq 01}_{1/3}\}\rangle_{\nexists} \arrow[u] \\
\langle\{R^{\neq\neq\neq 01}_{1/3}\}\rangle_{\nexists} \arrow[u]
\end{tikzcd}$$

NP-complete SAT(Γ) problems. Clearly, the fact that two problems SAT(Γ) and SAT(Δ) are both NP-complete does not reveal a great amount of information about their respective worst case time complexity, except that they are both unlikely to be solvable in polynomial time. For example, the monotone 1-in-3-SAT problem is solvable in $O(1.0984^n)$ time [30], where n denotes the number of variables in a given instance. On the other hand, 3-SAT is only known to be solvable in $O(1.308^n)$ time [11], and more generally it is known that the worst-case time complexity of k-SAT increases infinitely often for increasing values of k [13] – assuming 3-SAT is not solvable in $O(c^n)$ time for arbitrary $c > 1$. Hence, the family of NP-complete SAT(Γ) problems seems to contain members with wildly distinct worst-case time complexity, and it is safe to say that we currently cannot provide a complete explanation of this phenomena. More generally, say that SAT(Γ) is *easier* than SAT(Δ) if SAT(Γ) is solvable in $O(c^n)$ time whenever SAT(Δ) is solvable in $O(c^n)$ time, where n denotes the number of variables in a given instance. In symbols, we denote this by $\text{SAT}(\Delta) \leq \text{SAT}(\Gamma)$. Jonsson et al. studied the complexity of SAT(·) viz a viz the ordering $\leq$ using *partial clone theory* [15]. The details of this approach is explained in greater detail in Section 2, but for the moment let us be content with the fact that there exists a lattice $\mathcal{X}$ such that every constraint language Γ can be mapped to an element $\langle\Gamma\rangle_{\nexists} \in \mathcal{X}$, such that $\text{SAT}(\Gamma) \leq \text{SAT}(\Delta)$ if $\langle\Gamma\rangle_{\nexists} \subseteq \langle\Delta\rangle_{\nexists}$. An element $\langle\Gamma\rangle_{\nexists} \in \mathcal{X}$ is usually referred to as a *weak system*, or a *weak partial co-clone*, and is a well-studied relational algebra known to consist of all relations definable by conjunctive logical formulas over Γ [23]. Hence, the lattice of weak partial co-clones can be used to compare SAT(Γ) problems with respect to worst-case time complexity. With the help of this algebraic approach Jonsson et al. gave a classification of the minimal element $\langle\{R^{\neq\neq\neq 01}_{1/3}\}\rangle_{\nexists}$ of this lattice and proved that $\text{SAT}(\{R^{\neq\neq\neq 01}_{1/3}\})$ results in the *easiest NP-complete* SAT(·) problem [15].

In this paper we continue the classification of NP-complete SAT(Γ) problems that in a certain precise sense are small elements in the ordering $\leq$. More specifically, we are interested in determining the structure of constraint languages resulting in NP-complete SAT(·) problems which are not computationally harder than monotone 1-in-3-SAT. In symbols, this can be rephrased as determining all constraint languages Γ such that $\text{SAT}(\{R^{\neq\neq\neq 01}_{1/3}\}) \leq \text{SAT}(\Gamma) \leq \text{SAT}(\{R_{1/3}\})$, or, in the language of clone theory, determining all constraint languages Γ satisfying $\langle\{R^{\neq\neq\neq 01}_{1/3}\}\rangle_{\nexists} \subset \langle\Gamma\rangle_{\nexists} \subset \langle\{R_{1/3}\}\rangle_{\nexists}$. We begin by recapitulating the necessary technical prerequisites in Section 2, and give a brief introduction to the algebraic approach for studying the complexity of satisfiability problems. In Section 3 we introduce novel methods for better understanding the structure of algebras of the form $\langle\Gamma\rangle_{\nexists}$, and in particular the structure of $\langle\{R_{1/3}\}\rangle_{\nexists}$. This classification is then used in Section 4 where we give a preliminary description of the satisfiability problems below $\text{SAT}(\{R_{1/3}\})$ in the ordering $\leq$. We prove that this is a rich and complicated structure and that the cardinality of the set $\{\langle\Gamma\rangle_{\not\exists} \mid \langle\{R^{\neq\neq\neq01}_{1/3}\}\rangle_{\not\exists} \subset \langle\Gamma\rangle_{\not\exists} \subset \langle\{R_{1/3}\}\rangle_{\not\exists}\}$ is at least countably infinite. We remark that this contradicts a recent conjecture that this set consists of only three elements [20]. See Figure 1 for a visualization of the conjectured structure between $\langle\{R_{1/3}\}\rangle_{\not\exists}$ and $\langle\{R^{\neq\neq\neq01}_{1/3}\}\rangle_{\not\exists}$, and Section 2.4 for definitions of the involved relations.

From an algebraical point of view our results are a natural investigation of the largely unexplored lattice of weak partial co-clones. We remark that weak partial co-clones are useful not only for studying the exact complexity of problems [16, 19], but also for complexity classifications of optimisation problems and non-standard logical reasoning problems [3, 4, 27]. So far one of the limiting factors of this approach is the fact that very little is known of the relationship between weak partial co-clones and their dual objects, *partial polymorphisms*, which is in stark contrast to the status of the currently flourishing research program of classifying finite domain constraint satisfaction problems by properties of polymorphisms [2]. Similar observations have been made by for example Börner et al. [7], by Schölzel [28], and by Bulatov in the context of counting problems [8].

From a more pragmatic point of view, our results show that even for extremely simple constraint languages such as $\{R_{1/3}\}$, trying to fully characterize $\text{SAT}(\Gamma)$ problems with a lower worst-case time complexity is an extremely difficult task. However, as we discuss in Section 5, even though we cannot hope to achieve a complete understanding of the complexity of $\text{SAT}(\{R_{1/3}\})$ with our algebraic approach, we believe that similar studies are likely to open up new possibilities for studying the complexity of $\text{SAT}(\{R_{1/3}\})$ and related problems.

2 Preliminaries

In this section we briefly review some basic concepts that will be needed later on, starting with a formal definition of the parameterized $\text{SAT}(\cdot)$ problem and ending with universal algebra and partial clone theory.

2.1 The Parameterized SAT(·) Problem

Let $\mathbb{B} = \{0, 1\}$ and let $BR = \bigcup_{i=1} \mathbb{B}^i$ denote the set of all Boolean relations. Given $R \in \mathbb{B}^k$ we let $\text{ar}(R) = k$. A *constraint language* is a set of relations $\Gamma \subseteq BR$. The *parameterized satisfiability problem* over a constraint language Γ ($\text{SAT}(\Gamma)$) is defined as follows.

INSTANCE: A set V of variables and a set C of constraint applications $R(v_1, \ldots, v_k)$ where $R \in \Gamma$, $\text{ar}(R) = k$, and $v_1, \ldots, v_k \in V$.
QUESTION: Is there a function $f : V \to \mathbb{B}$ such that $(f(v_1), \ldots, f(v_k)) \in R$ for each $R(v_1, \ldots, v_k)$ in C?

When $\Gamma = \{R\}$ we typically write $\text{SAT}(R)$ instead of $\text{SAT}(\{R\})$. As an example, if we let $R_{1/3} = \{(0, 0, 1), (0, 1, 0), (1, 0, 0)\}$ then the problem $\text{SAT}(R_{1/3})$ can be seen as an alternative formulation of monotone 1-in-3-SAT, i.e., the 1-in-3-SAT problem without negation.

2.2 Polymorphisms, Clones and Co-Clones

A Boolean function $f : \mathbb{B}^n \to \mathbb{B}$ is said to *preserve* a k-ary Boolean relation R if for every $t_1, \ldots, t_n \in R$ it holds that $(f(t_1[1], \ldots, t_n[1]), \ldots, f(t_1[k], \ldots, t_n[k])) \in R$. Here, $t_i[j]$ denotes the j-th element of the tuple t_i. If f preserves R we say that f is a *polymorphism* of R, and similarly we say that f is a polymorphism of a constraint language Γ if it preserves each relation in Γ. Given a constraint language Γ we let $\mathrm{Pol}(\Gamma)$ denote the set of all polymorphisms of Γ. Sets of the form $\mathrm{Pol}(\Gamma)$ are usually referred to as *clones* and it is well-known that clones are (1) closed under functional composition and (2) contain all functions which projects one of its arguments. To be a bit more precise, the first condition means that if $f, g_1, \ldots, g_m \in \mathrm{Pol}(\Gamma)$, where the f has arity m and the functions $g_1, \ldots, g_m$ all have the same arity n, then the *composition* $f \circ (g_1, \ldots, g_m)$, the function defined as $f \circ (g_1, \ldots, g_m)(x_1, \ldots, x_n) = f(g_1(x_1, \ldots, x_n), \ldots, g_m(x_1, \ldots, x_n))$ for all $x_1, \ldots, x_n \in \mathbb{B}$, is included in $\mathrm{Pol}(\Gamma)$. The second condition means that $\mathrm{Pol}(\Gamma)$ for each n and each $1 \leq i \leq n$ contains every function π^n_i defined as $\pi^n_i(x_1, \ldots, x_i, \ldots, x_n) = x_i$. Functions of the form π^n_i are called *projection functions*. We let $\Pi_{\mathbb{B}}$ denote the set of all Boolean projection functions.

There is also a similar notion to clones on the relational side. Say that a k-ary relation R has a *primitive positive definition* (p.p. definition) over a constraint language Γ if there exists a conjunctive formula over k variables $x_1, \ldots, x_k$ over Γ, possibly making use of existential quantification and the equality relation $\mathrm{Eq} = \{(0,0), (1,1)\}$, such that R is the set of models of this formula. In symbols, we denote such a p.p. definition as $R(x_1, \ldots, x_k) \equiv \exists y_1, \ldots, y_{k'} \,.\, R_1(\mathbf{x_1}) \wedge \ldots \wedge R_m(\mathbf{x_m})$, where each $R_i \in \Gamma \cup \{\mathrm{Eq}\}$ and each $\mathbf{x_i}$ is an $\mathrm{ar}(R_i)$-ary tuple of variables over $x_1, \ldots, x_k,\ y_1, \ldots, y_{k'}$. If we let $\langle \Gamma \rangle$ be the smallest set of relations containing Γ which is closed under p.p. definitions we obtain a *relational clone*, or a *co-clone*. The relationship between clones and co-clones is given in the following theorem.

▶ **Theorem 1** ([5, 6, 9]). *Let Γ and Γ' be two constraint languages. Then $\Gamma \subseteq \langle \Gamma' \rangle$ if and only if $\mathrm{Pol}(\Gamma') \subseteq \mathrm{Pol}(\Gamma)$.*

This inverse relationship between two closure operators is in general known as a *Galois connection*, and using Theorem 1 it is not difficult to prove the following result.

▶ **Theorem 2** ([14]). *Let Γ and Γ' be two finite constraint languages. If $\mathrm{Pol}(\Gamma') \subseteq \mathrm{Pol}(\Gamma)$, then $\mathrm{SAT}(\Gamma)$ is polynomial-time many-one reducible to $\mathrm{SAT}(\Gamma')$.*

Hence, the clone of a constraint language determines the complexity of a satisfiability problem up to polynomial time reductions. Unfortunately, as noted in Section 1, the mere fact that two $\mathrm{SAT}(\cdot)$ problems are polynomial-time equivalent does not offer any insight into their worst-case time complexity. To study this we need a more fine-grained algebra, which in our case consists of *partial functions* instead of total functions.

2.3 Partial Polymorphisms, Strong Partial Clones and Weak Partial Co-Clones

In this section we investigate clones based on partial functions instead of total functions, and show that Theorem 2 can be significantly strengthened with these notions. First, an n-ary Boolean partial function f is a map $f : X \to \mathbb{B}$ where $X \subseteq \mathbb{B}^n$. In other words f is a function that is allowed to be undefined for one or more sequences of arguments. Given a partial function $f : X \to \mathbb{B}$, $X \subseteq D^n$, we let $\mathrm{dom}(f) = X$ and $\mathrm{ar}(f) = n$. If $u = (x_1, \ldots, x_n) \in \mathrm{dom}(f)$ we use the shorthand notation $f(u)$ instead of $f(x_1, \ldots, x_n)$. A partial function g is said to be a *subfunction* of a partial function f if $\mathrm{dom}(g) \subseteq \mathrm{dom}(f)$ and $g(u) = f(u)$ for all $u \in \mathrm{dom}(g)$. A set of partial functions is *strong* if it is closed under taking subfunctions. If f is an n-ary partial function and $X \subseteq \mathrm{dom}(f)$ we write $f_{|X}$ for the subfunction of f satisfying $\mathrm{dom}(f_{|X}) = X$. Composition of partial functions is defined similarly to the case of total functions. Hence, if f is an m-ary partial function and $g_1, \ldots, g_m$ are n-ary partial functions then the composition is defined as $f \circ (g_1, \ldots, g_m)(x_1, \ldots, x_n) =$

$f(g_1(x_1,\ldots,x_n),\ldots,g_m(x_1,\ldots,x_n))$, and the resulting function is defined for every tuple $(x_1,\ldots,x_n) \in \bigcap_{i=1}^{m} \mathrm{dom}(g_i)$ such that $(g_1(x_1,\ldots,x_n),\ldots,g_m(x_1,\ldots,x_n)) \in \mathrm{dom}(f)$.

We now say that an n-ary partial function f is a *partial polymorphism* of a k-ary relation R if $(f(t_1[1],\ldots,t_n[1]),\ldots,f(t_1[k],\ldots,t_n[k])) \in R$ for all $t_1,\ldots,t_n \in R$ such that $\{(t_1[1],\ldots,t_n[1]),\ldots,(t_1[k],\ldots,t_n[k])\} \subseteq \mathrm{dom}(f)$. If we let $\mathrm{pPol}(\Gamma)$ denote the set of all partial polymorphisms of a constraint language Γ then the resulting set of partial functions is known as a *strong partial clone.* A strong partial clone $\mathrm{pPol}(\Gamma)$ is a set of partial functions which (1) is closed under composition of partial functions, i.e., if $f, g_1,\ldots,g_{\mathrm{ar}(f)} \in \mathrm{pPol}(\Gamma)$ then $f \circ (g_1,\ldots,g_{\mathrm{ar}(f)}) \in \mathrm{pPol}(\Gamma)$, (2) contains all projection functions, and (3) is closed under taking subfunctions. It is worth noting that the second and third conditions are equivalent to the condition that $\mathrm{pPol}(\Gamma)$ contains all partial projection functions, i.e., the total projection functions and all their possible subfunctions, and we let $\Pi_{\mathbb{B}}^{p}$ denote this set. Given a set of partial functions F we let $[F]_s$ denote the smallest strong partial clone which contains F. The set F is called a *base* of $[F]_s$. Similar to the relationship between clones and co-clones we can find a Galois connection between strong partial clones and sets of relation satisfying certain closure properties. In symbols, we say that a k-ary relation R has a *quantifier-free primitive positive definition* (q.f.p.p. definition) over a constraint language Γ if $R(x_1,\ldots,x_k) \equiv R_1(\mathbf{x_1}) \wedge \ldots \wedge R_m(\mathbf{x_m})$, where each $R_i \in \Gamma \cup \{\mathrm{Eq}\}$ and each $\mathbf{x_i}$ is an $\mathrm{ar}(R_i)$-ary tuple of variables over $x_1,\ldots,x_k$. We then let $\langle\Gamma\rangle_{\nexists}$ denote the smallest set of relations containing Γ which is closed under q.f.p.p. definitions, and as usual we write $\langle R\rangle_{\nexists}$ whenever $\Gamma = \{R\}$. Sets of the form $\langle\Gamma\rangle_{\nexists}$ are known as *weak partial co-clones*, or *weak systems.* We have the following Galois connection.

▶ **Theorem 3** ([9, 24]). *Let Γ and Γ' be two constraint languages. Then $\Gamma \subseteq \langle\Gamma'\rangle_{\nexists}$ if and only if $\mathrm{pPol}(\Gamma') \subseteq \mathrm{pPol}(\Gamma)$.*

Using this Galois connection Jonsson et al. [15] proved that the partial polymorphisms of a finite constraint language determines the complexity of the satisfiability problem up to $O(c^n)$ time complexity, where n denotes the number of variables in a given instance.

▶ **Theorem 4** ([15]). *Let Γ and Γ' be two finite constraint languages. If $\mathrm{pPol}(\Gamma) \subseteq \mathrm{pPol}(\Gamma')$ and $\mathrm{SAT}(\Gamma)$ is solvable in $O(c^n)$ time, then $\mathrm{SAT}(\Gamma')$ is solvable in $O(c^n)$ time, too.*

Hence, a better understanding of the lattice of Boolean strong partial clones could lead to a better understanding of the worst-case time complexity of satisfiability problems. Unfortunately, the cardinality of this lattice is equal to the continuum [1], and besides some minor results [18, 26], the details of this structure is largely unknown. In particular, it is known that the set $\{\mathrm{pPol}(\Gamma) \mid \mathrm{SAT}(\Gamma) \text{ is NP-complete}\}$ is of uncountably infinite cardinality. With a reformulation of Schaefer's dichotomy theorem [25] we can state this result even more precisely as follows (where $\neg x$ denotes the unary function $\neg x = 1 - x$).

▶ **Theorem 5** ([29]). *The sets $\{\mathrm{pPol}(\Gamma) \mid \mathrm{Pol}(\Gamma) = \Pi_{\mathbb{B}}\}$ and $\{\mathrm{pPol}(\Gamma) \mid \mathrm{Pol}(\Gamma) = [\neg x]\}$ are of uncountably infinite cardinality.*

Note that this theorem immediately implies that there exists strong partial clones of the form $\mathrm{pPol}(\Gamma)$ which does not admit a finite base. Perhaps more surprising is the following theorem which states that a strong partial clone of the form $\mathrm{pPol}(\Gamma)$ cannot have a finite base whenever Γ is a finite constraint language such that $\mathrm{Pol}(\Gamma) \subseteq [\neg x]$.

▶ **Theorem 6** ([21]). *Let Γ be a finite constraint language such that $\mathrm{Pol}(\Gamma) \subseteq [\neg x]$. Then $\mathrm{pPol}(\Gamma)$ does not admit a finite base.*

2.4 The Easiest NP-complete SAT(·) Problem

In Jonsson et al [15] it is proven that the "easiest" NP-complete SAT(·) problem can be seen as a variant of 1-in-3-SAT where each variable occurring in a constraint has a complementary variable and each constraint contains two variables forced to constant values. We can represent this problem as $\mathrm{SAT}(R_{1/3}^{\neq\neq\neq01})$ where $R_{1/3}^{\neq\neq\neq01}(x_1,x_2,x_3,x_4,x_5,x_6,c_0,c_1) \equiv R_{1/3}(x_1,x_2,x_3) \wedge R_{1/3}(c_0,c_0,c_1) \wedge R_{1/3}(x_1,x_4,c_0) \wedge R_{1/3}(x_2,x_5,c_0) \wedge R_{1/3}(x_3,x_6,c_0)$, where we have choosen the variable names c_0 and c_1 to indicate that they are forced constant values. Hence, we have that $R_{1/3}^{\neq\neq\neq01} = \{(0,0,1,1,1,0,0,1),(0,1,0,1,0,1,0,1),(1,0,0,0,1,1,0,1)\}$.

We are now interested in trying to determine the weak partial co-clones $\langle\Gamma\rangle_{\not\exists}$ such that $\langle R_{1/3}\rangle_{\not\exists} \supset \langle\Gamma\rangle_{\not\exists} \supset \langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists}$. In particular, is it possible to find a constraint language Γ such that $\langle\Gamma\rangle_{\not\exists}$ *covers* $\langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists}$? By this we mean that there does not exist any Δ such that $\langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists} \subset \langle\Delta\rangle_{\not\exists} \subset \langle\Gamma\rangle_{\not\exists}$. Since $R_{1/3}^{\neq\neq\neq01}$ has arity 8 and $R_{1/3}$ has arity 3, a reasonable first attempt to investigate this question is to gradually remove arguments from $R_{1/3}^{\neq\neq\neq01}$. Hence, let $R_{1/3}^{\neq\neq01}$, $R_{1/3}^{\neq01}$, and $R_{1/3}^{01}$ be the relations obtained from $R_{1/3}^{\neq\neq\neq01}$ by removing one, two, and three complemented arguments. That is, $R_{1/3}^{\neq\neq01} = \{(0,0,1,1,1,0,1),(0,1,0,1,0,0,1),(1,0,0,0,1,0,1)\}$, $R_{1/3}^{\neq01} = \{(0,0,1,1,0,1),(0,1,0,1,0,1),(1,0,0,0,0,1)\}$, and $R_{1/3}^{01} = \{(0,0,1,0,1),(0,1,0,0,1),(1,0,0,0,1)\}$. We remark that $\mathrm{Pol}(R_{1/3}^{\neq\neq\neq01}) = \mathrm{Pol}(R_{1/3}^{\neq\neq01}) = \mathrm{Pol}(R_{1/3}^{\neq01}) = \mathrm{Pol}(R_{1/3}^{01}) = \mathrm{Pol}(R_{1/3}) = \mathrm{II}_{\mathbb{B}}$, i.e., that the only total polymorphisms of these relations are the projections. In Lagerkvist [20] it was proven that $\langle R_{1/3}\rangle_{\not\exists} \subset \langle R_{1/3}^{01}\rangle_{\not\exists} \subset \langle R_{1/3}^{\neq01}\rangle_{\not\exists} \subset \langle R_{1/3}^{\neq\neq01}\rangle_{\not\exists} \subset \langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists}$. Hence, the inclusions in Figure 1 are correct. However, the question of whether these weak partial co-clones also cover one another was left open. We will see in Section 4 that there in fact exist an infinite number of weak partial co-clones between $\langle R_{1/3}\rangle_{\not\exists}$ and $\langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists}$.

3 The Partial Polymorphisms of $R_{1/3}$, $R_{1/3}^{01}$, $R_{1/3}^{\neq01}$, $R_{1/3}^{\neq\neq01}$ and $R_{1/3}^{\neq\neq\neq01}$

We now want to investigate the structure of weak partial co-clones between $\langle R_{1/3}\rangle_{\not\exists}$ and $\langle R_{1/3}^{\neq\neq\neq01}\rangle_{\not\exists}$, and determine to which extent the conjectured structure in Figure 1 is complete. Since investigating this problem purely from a relational perspective appears to be complicated, we in this section tackle the problem of characterizing the partial polymorphisms of $R_{1/3}$, $R_{1/3}^{01}$, $R_{1/3}^{\neq01}$, $R_{1/3}^{\neq\neq01}$, and $R_{1/3}^{\neq\neq\neq01}$. As a shorthand, we let $\vec{0}^n$ denote an n-ary tuple consisting only of zeroes, and similarly for $\vec{1}^n$. We write $\overline{x}$ for the complement of a tuple x. Recall that if $t_1,\ldots,t_n$ are k-ary tuples and f an n-ary partial function we by $f(t_1,\ldots,t_n)$ denote the k-ary tuple resulting from applying f componentwise to the elements of $t_1,\ldots,t_n$. To be able to more conveniently refer to the n-ary tuples of the form $(t_1[i],\ldots,t_n[i])$ we let $Cols(t_1,\ldots,t_n) = ((t_1[1],\ldots,t_n[1]),\ldots,(t_n[k],\ldots,t_n[k]))$, and $ColsSet(t_1,\ldots,t_n) = \{(t_1[1],\ldots,t_n[1]),\ldots,(t_n[k],\ldots,t_n[k])\}$. For example, we have that $Cols((0,0,1,0,1),(0,1,0,0,1),(1,0,0,0,1)) = ((0,0,1),(0,1,0),(1,0,0),(0,0,0),(1,1,1))$. We now introduce our method for describing domains of partial functions.

▶ **Definition 7.** We make the following definitions.

- A set $\{\omega_1,\ldots,\omega_k\} \subseteq \mathbb{B}^n$ is an *exact cover of* $R_{1/3}$ if (1) $2 \leq k \leq 3$ and (2) for every $i \in \{1,\ldots,n\}$ it holds that $\omega_1[i] + \ldots + \omega_k[i] = 1$.
- A set $C \cup \{\vec{0}^n, \vec{1}^n\} \subseteq \mathbb{B}^n$ is an *exact cover of* $R_{1/3}^{01}$ if C is an exact cover of $R_{1/3}$.
- A set $C \cup \{\omega, \vec{0}^n, \vec{1}^n\} \subseteq \mathbb{B}^n$ is an *exact cover of* $R_{1/3}^{\neq01}$ if (1) $\overline{\omega} \in C$ and (2) C is an exact cover of $R_{1/3}$.
- A set $C \cup \{\omega_1, \omega_2, \vec{0}^n, \vec{1}^n\} \subseteq \mathbb{B}^n$ is an *exact cover of* $R_{1/3}^{\neq\neq01}$ if (1) $\overline{\omega_1}, \overline{\omega_2} \in C$ and (2) C is an exact cover of $R_{1/3}$.
- A set $C \cup \{\omega_1, \omega_2, \omega_3, \vec{0}^n, \vec{1}^n\} \subseteq \mathbb{B}^n$ is an *exact cover of* $R_{1/3}^{\neq\neq\neq01}$ if (1) $\overline{\omega_1}, \overline{\omega_2}, \overline{\omega_3} \in C$ and (2) C is an exact cover of $R_{1/3}$.

For each $R \in \{R_{1/3}, R^{01}_{1/3}, R^{\neq 01}_{1/3}, R^{\neq\neq 01}_{1/3}, R^{\neq\neq\neq 01}_{1/3}\}$ we say that an exact cover C of R is *maximal* if there is no $C' \supset C$ which is an exact cover of R. Given $T \subseteq \mathbb{B}^n$ we let $\text{Cover}_R(T) = \{C \subseteq T \mid C \text{ is a maximal exact cover of } R\}$. We have the following link between exact covers and tuples from the relations $R_{1/3}, R^{01}_{1/3}, R^{\neq 01}_{1/3}, R^{\neq\neq 01}_{1/3}$, and $R^{\neq\neq\neq 01}_{1/3}$.

▶ **Lemma 8.** *Let $C \subseteq \mathbb{B}^n$. Then, for each $R \in \{R_{1/3}, R^{01}_{1/3}, R^{\neq 01}_{1/3}, R^{\neq\neq 01}_{1/3}, R^{\neq\neq\neq 01}_{1/3}\}$ it holds that C is maximal exact cover of R if and only if there exists $t_1, \dots, t_n \in R$ such that $ColsSet(t_1, \dots, t_n) = C$.*

Proof. We only prove the case when $R = R_{1/3}$ since the other relations can be proven with symmetrical arguments. Let $C \subseteq \mathbb{B}^n$ be a maximal exact cover of $R_{1/3}$. There are two cases to consider. First, assume that $|C| = 3$ and let $C = \{\omega_1, \omega_2, \omega_3\}$. For each $i \in \{1, \dots, n\}$ we by definition have that $\omega_1[i] + \omega_2[i] + \omega_3[i] = 1$, and hence, $(\omega_1[i], \omega_2[i], \omega_3[i]) \in R_{1/3}$. Therefore, it is easy to find $t_1, \dots, t_n \in R_{1/3}$ such that $ColsSet(t_1, \dots, t_n) = C$. Second, assume that $|C| = 2$. In this case $C = \{\vec{0}^n, \vec{1}^n\}$, from which it folows that $ColsSet(t_1, \dots, t_n) = \{\vec{0}^n, \vec{1}^n\}$ whenever $t_i = t_j$ for all $i, j \in \{1, \dots, n\}$. Now assume that $t_1, \dots, t_n \in R_{1/3}$. We must prove that $ColsSet(t_1, \dots, t_n) = \{\omega_1, \dots, \omega_k\}$ is an exact cover of $R_{1/3}$. But this is trivial since (1) $2 \leq |\{\omega_1, \dots, \omega_k\}| \leq 3$ and (2) $\omega_1[i] \dots + \omega_k[i] = 1$ for each $i \in \{1, \dots, n\}$. ◀

We now have everything in place to state the main results of this section.

▶ **Theorem 9.** *Let f be an n-ary function. Then $f \in \text{pPol}(R_{1/3})$ if and only if*
1. *$f_{|C} \in \Pi^p_{\mathbb{B}}$ for every $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$, or*
2. *$f(\vec{0}^n) = 1$, $\vec{1}^n \notin \text{dom}(f)$, and for every $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ either (1) $f(\omega) = f(\overline{\omega}) = 0$ if $C = \{\vec{0}^n, \omega, \overline{\omega}\}$ or (2) $f_{|C} \in \Pi^p_{\mathbb{B}}$ if $\vec{0}^n \notin C$.*

Proof. We begin with the completeness part of the proof. Let $f \in \text{pPol}(R_{1/3})$ be an n-ary partial function. We must prove that f satisfies condition (1) or condition (2). Assume first that there exists $\{\omega_1, \omega_2, \omega_3\} \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ such that $f_{|\{\omega_1, \omega_2, \omega_3\}}$ is not a partial projection function. Now assume that $\{\vec{0}^n, \omega, \overline{\omega}\} \notin \text{Cover}_{R_{1/3}}(\text{dom}(f))$. Then there exists $t_1, \dots, t_n \in R_{1/3}$ such that (1) $ColsSet(t_1, \dots, t_n) = \{\omega_1, \omega_2, \omega_3\}$ and (2) $|\{t_1, \dots, t_n\}| = 3$. This implies that $f_{|\{\omega_1, \omega_2, \omega_3\}}(t_1, \dots, t_n) = f(t_1, \dots, t_n) \notin R_{1/3}$. Since this contradicts the original assumption, it must be the case that $\vec{0}^n \in C$ for some $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$. Assume first that $f(\vec{0}^n) = 0$ and that $f(\omega) = f(\overline{\omega}) = 0$ for some $\{\vec{0}^n, \omega, \overline{\omega}\} \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$. In this case $f \notin \text{pPol}(R_{1/3})$, and similarly when $f(\vec{0}^n) = 0$ and $f(\omega) = f(\overline{\omega}) = 1$. Last, assume that $f(\vec{0}^n) = 0$ and that $f(\omega) = \overline{f(\overline{\omega})}$. In this case $f_{|\{\vec{0}^n, \omega, \overline{\omega}\}}$ is a partial projection, and, furthermore, $f_{|C}$ must be a partial projection for every $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$, i.e., we are in case (1). Assume now instead that $\vec{0}^n \in C$ for some $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ and that $f(\vec{0}^n) = 1$. In this case one can easily verify that if there exists $\{\vec{0}^n, \omega, \overline{\omega}\} \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ such that either $f(\omega) = 1$ or $f(\overline{\omega}) = 1$ then $f \notin \text{pPol}(R_{1/3})$. Hence, $f(\vec{0}^n) = 1$, $f(\omega) = f(\overline{\omega}) = 0$ for all $\{\vec{0}^n, \omega, \overline{\omega}\} \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$, and $f_{|C}$ is a partial projection for all $C \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ such that $\vec{0}^n \notin C$. This means that we are in case (2).

For the soundness part of the proof, assume that f is an n-ary partial function fullfiling condition (1). Let $t_1, \dots, t_n \in R_{1/3}$ and let $\{\omega_1, \omega_2, \omega_3\} = ColsSet(t_1, \dots, t_n)$. We must prove that either $(f(\omega_1), f(\omega_2), f(\omega_3)) \in R_{1/3}$ or that $f(\omega_i)$ is undefined for some $i \in \{1, 2, 3\}$. Clearly, if $\{\omega_1, \omega_2, \omega_3\} \in \text{Cover}_{R_{1/3}}(\text{dom}(f))$ then, by assumption, $(f(\omega_1), f(\omega_2), f(\omega_3)) \in R_{1/3}$ since $f_{|\{\omega_1, \omega_2, \omega_3\}}$ is a partial projection. Otherwise, if $\{\omega_1, \omega_2, \omega_3\} \notin \text{Cover}_{R_{1/3}}(\text{dom}(f))$, then $f(\omega_i)$ must be undefined for some $i \in \{1, 2, 3\}$. Now assume that f is an n-ary partial function fullfiling condition (2). Let $t_1, \dots, t_n \in R_{1/3}$. Observe that if $\vec{0}^n \notin ColsSet(t_1, \dots, t_n)$

then it directly follows that $f(t_1,\ldots,t_n) \in R_{1/3}$ or that $f(t_1,\ldots,t_n)$ is undefined, by recapitulating the proof of the preceding paragraph. Hence, assume that $ColsSet(t_1,\ldots,t_n) = \{\vec{0}^n,\omega,\overline{\omega}\}$. By assumption we have that either $f(t_1,\ldots,t_n) \in R_{1/3}$ (since $f(\vec{0}^n) = 1$ and $f(\omega) = f(\overline{\omega}) = 0$), or that $\omega \notin \mathrm{dom}(f)$ or that $\overline{\omega} \notin \mathrm{dom}(f)$. ◀

Similarly we can characterize the partial polymorphisms of $R^{01}_{1/3}$, $R^{\neq 01}_{1/3}$, $R^{\neq\neq 01}_{1/3}$, and $R^{\neq\neq\neq 01}_{1/3}$.

▶ **Theorem 10.** *Let $R \in \{R^{01}_{1/3}, R^{\neq 01}_{1/3}, R^{\neq\neq 01}_{1/3}, R^{\neq\neq\neq 01}_{1/3}\}$. Let f be an n-ary partial function. Then $f \in \mathrm{pPol}(R)$ if and only if*

1. *$\vec{0}^n \notin \mathrm{dom}(f)$, or*
2. *$\vec{1}^n \notin \mathrm{dom}(f)$, or*
3. *$\{\vec{0}^n, \vec{1}^n\} \subseteq \mathrm{dom}(f)$ and $f_{|C} \in \Pi^p_{\mathbb{B}}$ for every $C \in \mathrm{Cover}_R(\mathrm{dom}(f))$.*

Proof. We only prove the case when $R = R^{\neq 01}_{1/3}$ since the other cases are entirely analogous. For soundness, assume that f is an n-ary partial function satisfying condition (1), (2), or (3). Let $t_1,\ldots,t_n \in R^{\neq 01}_{1/3}$. We have two cases to consider: either (1) $ColsSet(t_1,\ldots,t_n) \not\subseteq \mathrm{dom}(f)$ in which case $f(t_1,\ldots,t_n)$ is undefined; or (2) $ColsSet(t_1,\ldots,t_n) \subseteq \mathrm{dom}(f)$ in which case $ColsSet(t_1,\ldots,t_n) \in \mathrm{Cover}_{R^{\neq 01}_{1/3}}(\mathrm{dom}(f))$ and $f(t_1,\ldots,t_n) \in R^{\neq 01}_{1/3}$.

For completeness, let $f \in \mathrm{pPol}(R^{\neq 01}_{1/3})$ be an n-ary partial function such that $\{\vec{0}^n, \vec{1}^n\} \subseteq \mathrm{dom}(f)$. First, it is easy to verify that $f(\vec{0}^n) = 0$ and that $f(\vec{1}^n) = 1$, since otherwise $f \notin \mathrm{pPol}(R^{\neq 01}_{1/3})$. Let $C \in \mathrm{Cover}_{R^{\neq 01}_{1/3}}(\mathrm{dom}(f))$. We prove that $f_{|C}$ must be a partial projection function. There are a few different cases depending on the size of C. First note that the size of a maximum exact $R^{\neq 01}_{1/3}$-cover of $\mathrm{dom}(f)$ is always either 6, 4, or 2.

First, assume that $|C| = 6$ and let $C = \{\omega_1, \omega_2, \omega_3, \overline{\omega_1}, \vec{0}^n, \vec{1}^n\}$, where $\{\omega_1,\omega_2,\omega_3\}$ is an exact cover of $R_{1/3}$. According to Lemma 8, there exists $t_1,\ldots,t_n \in R^{\neq 01}_{1/3}$ such that $ColsSet(t_1,\ldots,t_n) = C$ and such that $\{t_1,\ldots t_n\} = R^{\neq 01}_{1/3}$. If $f_{|C}$ is not a projection on C then $f_{|C}(t_1,\ldots,t_n) = f(t_1,\ldots,t_n) \notin R^{\neq 01}_{1/3}$.

Second, assume that $|C| = 4$ and let $C = \{\omega, \overline{\omega}, \vec{0}^n, \vec{1}^n\}$. Then, according to Lemma 8 there exists $t_1,\ldots,t_n \in R^{\neq 01}_{1/3}$ such that $ColsSet(t_1,\ldots,t_n) = C$. Now note that if $f_{|C}$ is not a projection, then either $f(\omega) = f(\overline{\omega}) = 0$ or that $f(\omega) = f(\overline{\omega}) = 1$, and in both these cases $f \notin \mathrm{pPol}(R^{\neq 01}_{1/3})$. Hence, $f(\omega) = \overline{f(\overline{\omega})}$, from which it follows that $f_{|C}$ is a partial projection.

Third, assume that $|C| = 2$, and observe that this implies that $C = \{\vec{0}^n, \vec{1}^n\}$, due to the assumption that C is maximal. Since, by assumption, $f(\vec{0}^n) = 0$ and $f(\vec{1}^n) = 1$, it follows that $f_{|C}$ is a projection. ◀

Hence, even though $\mathrm{pPol}(R_{1/3})$, $\mathrm{pPol}(R^{01}_{1/3})$, $\mathrm{pPol}(R^{\neq 01}_{1/3})$, $\mathrm{pPol}(R^{\neq\neq 01}_{1/3})$, and $\mathrm{pPol}(R^{\neq\neq\neq 01}_{1/3})$ cannot be described through finite bases (by Theorem 6), we could still obtain a complete understanding of the involved partial functions. We remark that the partial polymorphisms of 1-in-k-SAT has been described in earlier work [22], but in contrast to Theorem 9 and Theorem 10, the proposed classificaton only describes a finite subset of partial polymorphisms.

4 The Structure Between $\langle R_{1/3}\rangle_{\not\exists}$ and $\langle R^{\neq\neq\neq 01}_{1/3}\rangle_{\not\exists}$

In this section we use the results from Section 3 in order to investigate the structure of the weak partial co-clones between $\langle R_{1/3}\rangle_{\not\exists}$ and $\langle R^{\neq\neq\neq 01}_{1/3}\rangle_{\not\exists}$. Before delving deeper into the forthcoming proofs the reader is advised to first consult Figure 2 for a visualization of the main results. We concentrate on weak partial co-clones below $\langle R^{01}_{1/3}\rangle_{\not\exists}$ since it is readily seen that the problems $\mathrm{SAT}(R_{1/3})$ and $\mathrm{SAT}(R^{01}_{1/3})$ have the same worst-case time complexity. It is in fact not difficult to prove that there cannot exist any R such that $|R| \leq 3$ and such that $\langle R^{01}_{1/3}\rangle_{\not\exists} \subset \langle R\rangle_{\not\exists} \subset \langle R^{\neq 01}_{1/3}\rangle_{\not\exists}$, and the same also holds for weak partial co-clones between

$$\begin{tikzcd}
 & \langle R_{1/3}\rangle_{\nexists} & \\
 & \langle R^{01}_{1/3}\rangle_{\nexists} \arrow[u] & \\
\langle \alpha^5\rangle_{\nexists} \arrow[ur] & \langle \alpha^i\rangle_{\nexists} \arrow[u] \arrow[l, "/" marking] \arrow[r, "/" marking] & \langle \alpha^{i+1}\rangle_{\nexists} \arrow[ul] \\
 & \langle R^{\neq 01}_{1/3}\rangle_{\nexists} \arrow[ul] \arrow[u] \arrow[ur] & \\
\langle \beta^5\rangle_{\nexists} \arrow[ur] & \langle \beta^i\rangle_{\nexists} \arrow[u] \arrow[l, "/" marking] \arrow[r, "/" marking] & \langle \beta^{i+1}\rangle_{\nexists} \arrow[ul] \\
 & \langle R^{\neq\neq 01}_{1/3}\rangle_{\nexists} \arrow[ul] \arrow[u] \arrow[ur] & \\
\langle \gamma^5\rangle_{\nexists} \arrow[ur] & \langle \gamma^i\rangle_{\nexists} \arrow[u] \arrow[l, "/" marking] \arrow[r, "/" marking] & \langle \gamma^{i+1}\rangle_{\nexists} \arrow[ul] \\
 & \langle R^{\neq\neq\neq 01}_{1/3}\rangle_{\nexists} \arrow[ul] \arrow[u] \arrow[ur] &
\end{tikzcd}$$

Figure 2 The structure of weak partial co-clones below $\langle R_{1/3}\rangle_{\nexists}$. An arrow of the form $A \to B$ means that $A \subset B$. An arrow of the form $A \not\to B$ means that $A \not\subset B$.

all other cases. Hence, to find elements between we must consider relations of cardinality strictly larger than 3. With this as a guidance we define the following class of relations, where $\neq$ denotes the binary inequality relation $\{(0,1),(1,0)\}$ and $R_{1/k}$ denotes the k-ary relation $\{(x_1,\ldots,x_k) \in \mathbb{B}^k \mid \Sigma_{i=1}^k x_i = 1)\}$.

▶ **Definition 11.** Let $k \geq 5$. The relation α^k is defined as

$$\alpha^k(x_1,\ldots,x_k,y_1,\ldots,y_{k-3},z_1,\ldots,z_{k-3},w_1,\ldots,w_{k-4},c_0,c_1) \equiv R_{1/k}(x_1,\ldots,x_k)\wedge$$
$$\bigwedge_{i=1}^{k-3} R_{1/i+2}(x_1,\ldots,x_{i+1},y_i) \wedge \bigwedge_{i=1}^{k-3} y_i \neq z_i \wedge \bigwedge_{i=3}^{k-2} R_{1/3}(x_1,x_i,w_{i-2}) \wedge R_{1/3}(c_0,c_0,c_1).$$

The relation β^k for $k \geq 5$ is defined similarly but with $k-2$ additional arguments which are the complement of $x_1, x_3, \ldots, x_{k-1}$. Hence, let

$$\beta^k(x_1,\ldots,x_k,y_1,\ldots,y_{k-3},z_1,\ldots,z_{k-3},w_1,\ldots,w_{k-4},v_1,\ldots,v_{k-2},c_0,c_1) \equiv$$
$$\alpha^k(x_1,\ldots,x_k,y_1,\ldots,y_{k-3},z_1,\ldots,z_{k-3},w_1,\ldots,w_{k-4},c_0,c_1) \wedge x_1 \neq z_1 \wedge \bigwedge_{i=3}^{k-1} x_i \neq v_{i-1}.$$

Finally, the relation γ^k for $k \geq 5$ can be defined as

$$\gamma^k(x_1,\ldots,x_k,y_1,\ldots,y_{k-3},z_1,\ldots,z_{k-3},w_1,\ldots,w_{k-4},v_1,\ldots,v_k,c_0,c_1) \equiv$$
$$\alpha^k(x_1,\ldots,x_k,y_1,\ldots,y_{k-3},z_1,\ldots,z_{k-3},w_1,\ldots,w_{k-4},c_0,c_1) \wedge \bigwedge_{i=1}^{k} x_i \neq v_i.$$

Later in this section we will see that $\langle R^{\neq\neq\neq 01}_{1/3}\rangle_{\nexists} \subset \langle \gamma^k\rangle_{\nexists} \subset \langle R^{\neq\neq 01}_{1/3}\rangle_{\nexists} \subset \langle \beta^k\rangle_{\nexists} \subset \langle R^{\neq 01}_{1/3}\rangle_{\nexists} \subset \langle \alpha^k\rangle_{\nexists} \subset \langle R^{01}_{1/3}\rangle_{\nexists}$ for each $k \geq 5$. The intuition behind the relation α^k is as follows.

- The k first arguments $x_1,\ldots,x_k$ encode a 1-in-k-constraint.
- Since $R_{1/k} \notin \langle R^{01}_{1/3}\rangle_{\nexists}$ [20], we have to add arguments to make it q.f.p.p. definable by $R^{01}_{1/3}$.
- These arguments are $y_1,\ldots,y_{k-3}$, their complements $z_1,\ldots,z_{k-3}$, and the two constant arguments c_0 and c_1.

- To make sure that the resulting relation is not q.f.p.p. definable by $R^{\neq 01}_{1/3}$ we also need the additional arguments $w_1, \ldots, w_{k-4}$, which do not have any complementary arguments.

The relations β^k and γ^k can be understood in a similar way. We then have the following straightforward Lemma which states that the weak partial co-clones of the relations α^k, β^k and γ^k, are proper subsets of $\langle R^{01}_{1/3} \rangle_{\nexists}$, $\langle R^{\neq 01}_{1/3} \rangle_{\nexists}$, and $\langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists}$, respectively.

▶ **Lemma 12.** *$\langle R^{01}_{1/3} \rangle_{\nexists} \supset \langle \alpha^k \rangle_{\nexists}$, $\langle R^{\neq 01}_{1/3} \rangle_{\nexists} \supset \langle \beta^k \rangle_{\nexists}$, and $\langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists} \supset \langle \gamma^k \rangle_{\nexists}$ for each $k \geq 5$.*

Proof. Let $k \geq 5$. We only consider the case $\langle R^{01}_{1/3} \rangle_{\nexists} \supset \langle \alpha^k \rangle_{\nexists}$ since the other cases are similar. We begin by proving that $\alpha^k \in \langle R^{01}_{1/3} \rangle_{\nexists}$ which implies that $\langle R^{01}_{1/3} \rangle_{\nexists} \supseteq \langle \alpha^k \rangle_{\nexists}$. The base case when $k = 5$ is simple:

$$\begin{aligned}
&\alpha^5(x_1, x_2, x_3, x_4, x_5, y_1, y_2, z_1, z_2, w_1, c_0, c_1) \equiv \\
&R^{01}_{1/3}(x_1, x_2, y_1, c_0, c_1) \land R^{01}_{1/3}(x_3, y_2, z_1, c_0, c_1) \land \\
&R^{01}_{1/3}(c_0, y_1, z_1, c_0, c_1) \land R^{01}_{1/3}(x_4, x_5, z_2, c_0, c_1) \land \\
&R^{01}_{1/3}(c_0, y_2, z_2, c_0, c_1) \land R^{01}_{1/3}(x_1, x_3, w_1, c_0, c_1).
\end{aligned}$$

For the inductive step assume that $\alpha^{k-1} \in \langle R^{01}_{1/3} \rangle_{\nexists}$. We can then implement α^k as follows.

$$\begin{aligned}
&\alpha^k(x_1, \ldots, x_k, y_1, y_2, \ldots, y_{k-4}, y_{k-3}, z_1, z_2, \ldots, z_{k-4}, z_{k-3}, w_1, \ldots, w_{k-5}, w_{k-4}, c_0, c_1) \equiv \\
&\quad \alpha^{k-1}(x_1, \ldots, x_{k-2}, y_{k-3}, y_1, \ldots, y_{k-4}, z_1, \ldots, z_{k-4}, w_1, \ldots, w_{k-5}, c_0, c_1) \land \\
&\quad R^{01}_{1/3}(z_{k-3}, x_{k-1}, x_k, c_0, c_1) \land R^{01}_{1/3}(c_0, y_{k-3}, z_{k-3}, c_0, c_1) \land R^{01}_{1/3}(x_1, x_{k-2}, w_{k-4}, c_0, c_1).
\end{aligned}$$

To prove the proper inclusion $\langle R^{01}_{1/3} \rangle_{\nexists} \supset \langle \alpha^k \rangle_{\nexists}$ we show that there exists $f \in \mathrm{pPol}(\alpha^k)$ such that $f \notin \mathrm{pPol}(R^{01}_{1/3})$. Consider the ternary partial function f defined such that $f(0,0,0) = 0$, $f(1,1,1) = 1$, and $f(0,0,1) = f(0,1,0) = f(1,0,0) = 0$. By Theorem 10 it follows that $f \notin \mathrm{pPol}(R^{01}_{1/3})$, but it is not difficult to verify that for any sequence of three tuples $t_1, t_2, t_3 \in \alpha^k$, the set $\mathit{ColsSet}(t_1, t_2, t_3)$ will either be of the form $\{(0,0,0), (1,1,1)\}$, or it will contain the complement of $(0,0,1)$, $(0,1,0)$, or $(1,0,0)$. Hence, $f(t_1, t_2, t_3)$ is either a projection or undefined, from which it follows that $f \in \mathrm{pPol}(\alpha^k)$. ◀

We now need to prove that it cannot be the case that $\langle \alpha^k \rangle_{\nexists} = \langle \alpha^{k'} \rangle_{\nexists}$ whenever $k \neq k'$, and similarly for the relations β^k and γ^k. Before proving this we need a slight generalisation of the concept of exact covers from Definition 7. A set $\{\omega_1, \ldots, \omega_{k'}\} \subseteq \mathbb{B}^n$ is a *exact k'-cover of $R_{1/k}$* if (1) $2 \leq k' \leq k$ and (2) for every $i \in \{1, \ldots, n\}$ it holds that $\omega_1[i] + \ldots + \omega_{k'}[i] = 1$. From Lagerkvist et al. [22] it follows that $t_1, \ldots, t_{k'} \in R_{1/k}$ if and only if $\mathit{ColsSet}(t_1, \ldots, t_{k'})$ is an exact k'-cover of $R_{1/k}$. This implies that $t_1, \ldots, t_{k'} \in \alpha^k$ if and only if $\{(t_1[1], \ldots, t_{k'}[1]), \ldots, (t_1[k], \ldots, t_{k'}[k])\}$ is an exact k'-cover of $R_{1/k}$.

▶ **Lemma 13.** *For each $k, k' \geq 5$ such that $k > k'$ there exists $f \in \mathrm{pPol}(\alpha^k)$, $f' \in \mathrm{pPol}(\beta^k)$, and $f'' \in \mathrm{pPol}(\gamma^k)$ such that $f \notin \mathrm{pPol}(\alpha^{k'})$, $f' \notin \mathrm{pPol}(\beta^{k'})$, and $f'' \notin \mathrm{pPol}(\gamma^{k'})$.*

Proof. We only consider the relations α^k and $\alpha^{k'}$ since the other cases are similar. We provide a partial function $f^{k'}$ such that $f^{k'} \in \mathrm{pPol}(\alpha^k)$ but $f^{k'} \notin \mathrm{pPol}(\alpha^{k'})$. Let $j = \mathrm{ar}(\alpha^{k'})$, let $\{t_1, \ldots, t_{k'}\} = \alpha^{k'}$, and define $f^{k'}$ such that $\mathrm{dom}(f^{k'}) = \mathit{ColsSet}(t_1, \ldots, t_{k'})$ and such that $f^{k'}(t_1, \ldots, t_{k'}) = (t_1[1], \ldots, t_1[j-3], c, 0, 1)$, where $c = t_1[1] \oplus t_1[k'-3]$. Note that, by definition, $f^{k'}(t_1, \ldots, t_{k'}) \notin \alpha^{k'}$ since any tuple $t \in \alpha^{k'}$ satisfies $t[1] + t[k'-3] + t[j-2] = 1$. Hence, $f^{k'} \notin \mathrm{pPol}(\alpha^{k'})$. Given a tuple $t \in \{0,1\}^k$ we let $\Sigma t = \Sigma_{i=1}^{k} t[i]$. Let $\mathbf{x} = (t_1[j-3], \ldots, t_{k'}[j-3])$, and note that due to the constraint $R^{01}_{1/3}(x_1, x_{k-2}, w_{k-4}, c_0, c_1)$ in Definition 11, $\Sigma\mathbf{x} = 2$, i.e., the sequence $\mathbf{x}$ contains exactly two zeroes. We now prove that $f^{k'} \in \mathrm{pPol}(\alpha^k)$. Let $u_1, \ldots, u_{k'} \in \alpha^k$ and assume, with the aim of reaching a contradiction, that $f^{k'}(u_1,\ldots,u_{k'}) \notin \alpha^k$. Since $f^{k'}(\mathbf{y}) = \pi_1^{k'}(\mathbf{y})$ for all $\mathbf{y} \in \mathrm{dom}(f^{k'}) \setminus \{\mathbf{x}\}$, it follows that $\mathbf{x}$ is included in the sequence $Cols(u_1,\ldots,u_{k'})$. There are now only three possible distinct cases to consider depending on where the sequence $\mathbf{x}$ occurs in $Cols(u_1,\ldots,u_{k'})$. We will show that for each of these cases $f^{k'}(u_1,\ldots,u_{k'})$ must be undefined, contradicting the assumption that $f^{k'}(u_1,\ldots,u_{k'}) \notin \alpha^k$. Let

$$(a_1,\ldots,a_k,b_1,\ldots,b_{k-3},c_1,\ldots,c_{k-3},d_1,\ldots,d_{k-4},\vec{0}^{k'},\vec{1}^{k'}) = Cols(u_1,\ldots,u_{k'}).$$

First assume that $\mathbf{x} = a_i$ for some $1 \leq i \leq k$. Since $\{a_1,\ldots,a_k\}$ must form an exact k'-cover and since $\Sigma\mathbf{x} = \Sigma a_i = k' - 2$ it follows that there exists a_j and $a_{j'}$ such that $\{a_i,a_j,a_{j'}\}$ is an exact k'-cover and that all other a_l sequences are equal to $\vec{0}^{k'}$. If $|\{a_i,a_j,a_{j'}\}| = 2$ then $\overline{a_j} = \overline{a_{j'}} = a_i$, which is a contradiction since $\overline{a_j} = \overline{\mathbf{x}} \notin \mathrm{dom}(f^{k'})$. Assume that $|\{a_i,a_j,a_{j'}\}| = 3$. This implies that $\Sigma a_j = \Sigma a_{j'} = 1$ and that there exists a tuple $u \in ColsSet(u_1,\ldots,u_{k'})$ such that either $u = \overline{a_i}, u = \overline{a_j}$, or $u = \overline{a_{j'}}$. In each of these cases it follows that $u \notin \mathrm{dom}(f)$, and we reach a contradiction.

Second, assume that $\mathbf{x} = b_i$ for some $i \in \{1,\ldots,k-3\}$. Then $c_i = \overline{\mathbf{x}}$. This is a contradiction since $\overline{\mathbf{x}} \notin \mathrm{dom}(f^{k'})$. The case when $\mathbf{x} = c_i$ for some $i \in \{1,\ldots,k-3\}$ is entirely analogous.

Third, assume that $\mathbf{x} = d_i$ for some $i \in \{1,\ldots,k-4\}$. Then, due to the constraint $R_{1/3}(x_1,x_{i-2},w_i)$ in Definition 11, it follows that $\Sigma a_1 = \Sigma a_{i-2} = 1$. Assume without loss of generality that $a_1[k'] = 1$. Now note that each constraint of the form $R_{1/3}(x_1,x_j,w_{j-2})$ for $j \in \{3,\ldots,k-2\}$ also implies that $\Sigma a_j \geq 1$. First, assume $\Sigma a_j = 1$ for $j \in \{1,\ldots,k-2\}$. Since $k' < k$ and since $\{a_1,\ldots,a_k\}$ must form an exact k'-cover, it follows that either $\Sigma a_{k-1} + \Sigma a_k = 1$ or that $\Sigma a_{k-1} + \Sigma a_k = 0$, and in both these cases $f^{k'}(u_1,\ldots,u_{k'})$ must be undefined. Assume that there exists some $a_{j'}$, $j' \in \{2,\ldots,i-1,i+1,\ldots,k\}$ such that $\Sigma a_{j'} > 1$. Since $\Sigma a_j \geq 1$ for each $j \in \{1,\ldots,k-2\}$ and since $\Sigma_{j=1}^{k} \Sigma a_j = k' < k$, it follows that $\Sigma a_{j'} = 2$, $k' = k-1$, and that $\Sigma a_j = 1$ for every $j \in \{1,\ldots,k-2\}$. This implies that $\Sigma a_{k-1} + \Sigma a_k = 1$, and, due to the constraint $R_{1/4}(x_{k-2},x_{k-1},x_k,z_{k-4})$, that $c_{k-4} = \overline{a_{k-2}}$. If $\Sigma a_{k-2} = 1$ then $\overline{a_{k-2}} \notin \mathrm{dom}(g)$. Hence, assume that $j' = k-2$ and that $\Sigma a_{k-2} = 2$. Due to the constraint $R_{1/3}(x_1,x_{k-2},w_{k-4})$ it follows that $\Sigma d_{k-4} = k-3$, and since $a_1[k'] = 1$, we have that $a_{k-2} \notin \mathrm{dom}(f^{k'})$ or that $d_{k-4} \notin \mathrm{dom}(f^{k'})$. ◀

Last, to get the inclusion structure in Figure 2, we need to prove that $\langle \alpha^k \rangle_{\nexists} \supset \langle R^{\neq 01}_{1/3} \rangle_{\nexists}$, $\langle \beta^k \rangle_{\nexists} \supset \langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists}$, and $\langle \gamma^k \rangle_{\nexists} \supset \langle R^{\neq\neq\neq 01}_{1/3} \rangle_{\nexists}$.

▶ **Lemma 14.** *$\langle \alpha^k \rangle_{\nexists} \supset \langle R^{\neq 01}_{1/3} \rangle_{\nexists}$, $\langle \beta^k \rangle_{\nexists} \supset \langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists}$, and $\langle \gamma^k \rangle_{\nexists} \supset \langle R^{\neq\neq\neq 01}_{1/3} \rangle_{\nexists}$, for each $k \geq 5$.*

Proof. We only consider α^k since the other cases are similar. To prove that $\langle \alpha^k \rangle_{\nexists} \supseteq \langle R^{\neq 01}_{1/3} \rangle_{\nexists}$, we use the q.f.p.p. definition

$$R^{\neq 01}_{1/3}(x_1,x_2,x_3,x_4,c_0,c_1) \equiv$$
$$\alpha^k(\underbrace{c_0,\ldots,c_0}_{k-3},x_1,x_2,x_3,\underbrace{c_1,\ldots,c_1}_{k-4},x_4,\underbrace{c_0,\ldots c_0}_{k-4},x_1,\underbrace{c_1,\ldots,c_1}_{k-5},x_4,c_0,c_1).$$

For the proper inclusion, simply note that the function f^k in the proof of Lemma 13 does not preserve α^k. An application of Theorem 10 shows that $f^k \in \mathrm{pPol}(R^{\neq 01}_{1/3})$. ◀

By combining Lemma 12, Lemma 13 and Lemma 14 we have thus proved the main result of the paper.

▶ **Theorem 15.** *The cardinalities of the sets $\{\langle \Gamma \rangle_{\nexists} \mid \langle R^{\neq 01}_{1/3} \rangle_{\nexists} \subset \langle \Gamma \rangle_{\nexists} \subset \langle R^{01}_{1/3} \rangle_{\nexists}\}$, $\{\langle \Gamma \rangle_{\nexists} \mid \langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists} \subset \langle \Gamma \rangle_{\nexists} \subset \langle R^{\neq 01}_{1/3} \rangle_{\nexists}\}$, and $\{\langle \Gamma \rangle_{\nexists} \mid \langle R^{\neq\neq\neq 01}_{1/3} \rangle_{\nexists} \subset \langle \Gamma \rangle_{\nexists} \subset \langle R^{\neq\neq 01}_{1/3} \rangle_{\nexists}\}$ are at least countably infinite.*

5 Concluding Remarks and Future Research

We have studied the structure of NP-complete satisfiability problems whose complexity is not higher than $\mathrm{SAT}(R_{1/3})$. By using partial clone theory we have proven that one can find an infinite number of such satisfiability problems, and in the process we have also obtained a complete description of the partial polymorphisms of $R_{1/3}$. These results raise two questions that we deem particularly interesting for future research.

Algorithms based on partial polymorphisms. There exist many examples in the literature of polynomial-time algorithms based on properties of polymorphisms of constraint languages. For example, one can use polynomial-time algorithms based on Gaussian elimination to solve constraint satisfaction problems whenever the constraint language contains a so-called k-edge polymorphism [12]. By Theorem 4 we know that the partial polymorphisms of a constraint language correlates to the worst-case complexity of the corresponding satisfiability problem. Is it possible to exploit the information given by the partial polymorphisms to construct better exponential-time algorithms for satisfiability problems? In particular, can the classification in Theorem 9 be used to improve algorithms for 1-in-3-SAT? For a concrete example, consider the following strategy: it is known that the *inverse satisfiability problem* for $R_{1/3}$, $\text{Inv-SAT}(R_{1/3})$, is co-NP-complete [17]. In our terminology this problem can be stated as determining whether a given relation R is included in $\langle R_{1/3} \rangle_{\nexists}$, and can therefore be restated as whether $\mathrm{pPol}(R_{1/3}) \subseteq \mathrm{pPol}(R)$. Hence, to solve $\mathrm{SAT}(R_{1/3})$ we can utilize a Turing reduction to $\text{Inv-SAT}(R_{1/3})$, which in turn can be solved by enumerating the partial polymorphisms of $R_{1/3}$ and checking if they preserve R. Would it be possible to transform this rather implicit algorithm into an efficient algorithm for 1-in-3-SAT?

Uncountably many weak partial co-clones? We have proven that there exists at least a countably infinite number of weak partial co-clones below $\langle R_{1/3} \rangle_{\nexists}$. Is it possible to strengthen this even further and prove that there exists an uncountably infinite number of such weak partial co-clones? A starting point for proving this is to first show that the converse of Lemma 13 also holds, i.e., that $\langle \alpha^{k} \rangle_{\nexists}$ and $\langle \alpha^{k'} \rangle_{\nexists}$ are always incomparable whenever $k \neq k'$.

Does $\langle R_{1/3} \rangle_{\nexists}$ cover $\langle R^{01}_{1/3} \rangle_{\nexists}$? In this paper we restricted ourselves to study weak partial co-clones below $\langle R^{01}_{1/3} \rangle_{\nexists}$ since the two problems $\mathrm{SAT}(R_{1/3})$ and $\mathrm{SAT}(R^{01}_{1/3})$ have the same worst-case time complexity. From an algebraical point of view, however, it would be interesting to prove or disprove that $\langle R_{1/3} \rangle_{\nexists}$ covers $\langle R^{01}_{1/3} \rangle_{\nexists}$, since only a handful of such results are known in the literature [10]. This question might not be as easy as one might believe at a first glance, since it is e.g. known that there exist an uncountably infinite number of weak partial co-clones between $\langle \mathrm{OR} \rangle_{\nexists}$ and $\langle \mathrm{OR}^{01} \rangle_{\nexists}$, where $\mathrm{OR} = \{(0,1),(1,0),(1,1)\}$ and $\mathrm{OR}^{01} = \{(0,1,0,1),(1,0,0,1),(1,1,0,1)\}$ [29]. Hence, even though the relations $R_{1/3}$ and $R^{01}_{1/3}$ might appear to be almost identical, it might indeed be very hard to prove that $\langle R_{1/3} \rangle_{\nexists}$ covers $\langle R^{01}_{1/3} \rangle_{\nexists}$.

Uniformization Problems for Tree-Automatic Relations and Top-Down Tree Transducers*

Christof Löding[1] **and Sarah Winter**[2]

Abstract

For a given binary relation of finite trees, we consider the synthesis problem of deciding whether there is a deterministic top-down tree transducer that uniformizes the relation, and constructing such a transducer if it exists. A uniformization of a relation is a function that is contained in the relation and has the same domain as the relation. It is known that this problem is decidable if the relation is a deterministic top-down tree-automatic relation. We show that it becomes undecidable for general tree-automatic relations (specified by non-deterministic top-down tree automata). We also exhibit two cases for which the problem remains decidable. If we restrict the transducers to be path-preserving, which is a subclass of linear transducers, then the synthesis problem is decidable for general tree-automatic relations. If we consider relations that are finite unions of deterministic top-down tree-automatic relations, then the problem is decidable for synchronous transducers, which produce exactly one output symbol in each step (but can be non-linear).

1 Introduction

A uniformization of a (binary) relation is a function that selects for each element in the domain of the relation a unique image that is in relation with this element. Originally, uniformization has been studied in set theory, where the complexity of a class of definable relations is related with the complexity of uniformizations for these relations (see [18] for results of this kind). The basic uniformization question for a class $\mathcal{C}$ of relations is whether each relation from $\mathcal{C}$ has a uniformization in $\mathcal{C}$.

Automata provide a natural framework for defining relations (over words or trees), and uniformization problems in this setting have been studied since the early days of automata theory. Word relations defined by asynchronous finite automata [8], also called rational relations, were first shown to have rational uniformizations in [13, Theorem 3] (with many alternative and simplified proofs following later). For relations of infinite words that are accepted by synchronous finite automata, or equivalently definable in monadic second-order logic (MSO) over the structure consisting of natural numbers equipped with the successor relation, the uniformization property is shown in [19]. Over infinite trees, the uniformization property fails for MSO definable relations (corresponding to synchronous tree automata) [10, 2], while it has been shown recently that uniformization is possible for synchronous

* This work was supported by the DFG grant "Transducer Synthesis from Automaton Definable Specifications" (LO 1174/3-1)

relations over finite trees [14, 4]. These relations defined by synchronous automata are usually referred to as automatic, ω-automatic, tree-automatic and ω-tree-automatic relations (for finite words, infinite words, finite trees, and infinite trees, respectively).

In a more algorithmic setting, uniformization is often referred to as synthesis: The relation is viewed as a specification between inputs and outputs, and the function is supposed to be realized by a device that produces the output while processing the input. This means, that the class for the uniformizations is usually different from the class of the specifications, and the problem of interest is now the decision problem whether a given relation admits a uniformization in the desired class.

The classical setting, originating from Church's synthesis problem [3], is the one of infinite words. The specification is given by an ω-automatic relation (orginally in MSO), and the question is whether it can be uniformized by a synchronous sequential transducer that produces, letter by letter, an infinite output word while reading an infinite input word. The seminal paper of Büchi and Landweber [1] shows the decidability of this problem, and has been extended later to uniformizations by asynchronous sequential transducers [12, 11]. A detailed study of the synthesis of sequential transducers for asynchronous automata on finite words is provided in [6].

Our aim is to study these uniformization questions for relations over finite trees. Tree automata are used in many fields, for example as a tool for analyzing and manipulating rewrite systems or XML Schema languages (see [7]). Tree transformations that are realized by finite tree transducers thus become interesting in the setting of translations from one document scheme into another [17]. As class for the uniformizations we consider deterministic top-down tree transducers (D↓TTs), which are a natural extension of sequential transducers on words. A first result in this setting was obtained in [16], where we show that it is decidable whether a tree-automatic relation that is defined by a deterministic top-down tree automaton (D↓TA) can be uniformized by a D↓TT. A representation of the specification by a deterministic automaton model is essential in many synthesis algorithms for automata. A standard approach is to build a game in which the two players produce input and output. The aim of the output player is to ensure that the pair of input and output produced along a play satisfies the specification. This property is ensured in the game by simulating a deterministic automaton for the specification on the moves of the players. A winning strategy for the output player then corresponds to a uniformizer.

In this paper, we show that the synthesis problem for D↓TT from nondeterministic tree-automatic relations is indeed undecidable, showing that the nondeterminism does not only destroy the game theoretic approach (as sketched above) but makes the problem intractable in general. On the positive side, we prove two decidability results for restricted classes of uniformizers and specifications:

1. For nondeterministic tree-automatic relations uniformization by path-preserving D↓TTs is decidable. Intuitively, we call a D↓TT path-preserving if every node of the output tree is produced from a node of the input tree that is above or below the output node (this implies that each path-preserving D↓TT is in particular linear). For this class of uniformizers we can adapt the game theoretic approach by using guidable automata [5, 15] instead of deterministic automata for the specification.
2. If we restrict the specifications to unions of D↓TAs with disjoint domain, we obtain decidability for uniformizations by synchronous D↓TTs. We call a D↓TT synchronous if it produces one output symbol in each transition (but the transitions can be non-linear). While this is a rather specific result, it is the first decidability result for synthesis of transducers in which in the synthesized transducer may need to be non-linear.

The paper is structured as follows. In Section 2 we fix some basic definitions and terminology. In Section 3 we show undecidability for synthesis of D↓TTs from tree-automatic specifications, and the decidability results are presented in Section 4.

2 Preliminaries

Words and trees. The set of natural numbers containing zero is denoted by $\mathbb{N}$. For a set S, the powerset of S is denoted by 2^S. An *alphabet* Σ is a finite non-empty set of letters. A finite *word* is a finite sequence of letters. The set of all finite words over Σ is denoted by Σ^*. The length of a word $w \in \Sigma^*$ is denoted by $|w|$, the empty word is denoted by ε. For $w = a_1 \dots a_n \in \Sigma^*$ for some $n \in \mathbb{N}$ and $a_1, \dots, a_n \in \Sigma$, let $w[i]$ denote the ith letter of w, i.e., $w[i] = a_i$. Furthermore, let $w[i,j]$ denote the infix from the ith to the jth letter of w, i.e., $w[i,j] = a_i \dots a_j$. We write $u \sqsubseteq w$ if there is some v such that $w = uv$ for $u, v \in \Sigma^*$. A subset $L \subseteq \Sigma^*$ is called *language* over Σ.

A *ranked alphabet* Σ is an alphabet where each letter $f \in \Sigma$ has a rank $rk(f) \in \mathbb{N}$. The set of letters of rank i is denoted by Σ_i. A tree domain *dom* is a non-empty finite subset of $(\mathbb{N} \setminus \{0\})^*$ such that *dom* is prefix-closed and for each $u \in (\mathbb{N} \setminus \{0\})^*$ and $i \in \mathbb{N} \setminus \{0\}$ if $ui \in dom$, then $uj \in dom$ for all $1 \leq j < i$. We speak of ui as successor of u for each $u \in dom$ and $i \in \mathbb{N} \setminus \{0\}$.

A (finite Σ-labeled) *tree* is a pair $t = (dom_t, val_t)$ with a mapping $val_t : dom_t \to \Sigma$ such that for each node $u \in dom_t$ the number of successors of u is a rank of $val_t(u)$. The height h of a tree t is the length of its longest path, i.e., $h(t) = max\{|u| \mid u \in dom_t\}$. The set of all Σ-labeled trees is denoted by T_Σ. A subset $T \subseteq T_\Sigma$ is called *tree language* over Σ.

A *subtree* $t|_u$ of a tree t at node u is defined by $dom_{t|_u} = \{v \in \mathbb{N}^* \mid uv \in dom_t\}$ and $val_{t|_u}(v) = val_t(uv)$ for all $v \in dom_{t|_u}$. In order to formalize concatenation of trees, we introduce the notion of special trees. A *special tree* over Σ is a tree over $\Sigma \uplus \{\circ\}$ such that $\circ$ occurs exactly once at a leaf. Given $t \in T_\Sigma$ and $u \in dom_t$, we write $t[\circ/u]$ for the special tree that is obtained by deleting the subtree at u and replacing it by $\circ$. Let S_Σ be the set of special trees over Σ. For $t \in S_\Sigma$ and $s \in T_\Sigma$ or $s \in S_\Sigma$ let the *concatenation* $t \cdot s$ be the tree that is obtained from t by replacing $\circ$ with s.

Let X_n be a set of n variables $\{x_1, \dots, x_n\}$ and Σ be a ranked alphabet. We denote by $T_\Sigma(X_n)$ the set of all trees over Σ which additionally can have variables from X_n at their leaves. We define X_0 to be the empty set, the set $T_\Sigma(\emptyset)$ is equal to T_Σ. Let $X = \bigcup_{n>0} X_n$. A tree from $T_\Sigma(X)$ is called *linear* if each variable occurs at most once. For $t \in T_\Sigma(X_n)$ let $t[x_1 \leftarrow t_1, \dots, x_n \leftarrow t_n]$ be the tree that is obtained by substituting each occurrence of $x_i \in X_n$ by $t_i \in T_\Sigma(X)$ for every $1 \leq i \leq n$.

A tree from $T_\Sigma(X_n)$ such that all variables from X_n occur exactly once and in the order $x_1, \dots, x_n$ when reading the leaf nodes from left to right, is called *n-context* over Σ. Given an n-context, the node labeled by x_i is referred to as ith hole for every $1 \leq i \leq n$. A special tree can be seen as a 1-context, a tree without variables can be seen a 0-context. If C is an n-context and $t_1, \dots, t_n \in T_\Sigma(X)$ we write $C[t_1, \dots, t_n]$ instead of $C[x_1 \leftarrow t_1, \dots, x_n \leftarrow t_n]$.

Tree automata. We fix our notations. For a detailed introduction to tree automata see e.g. [9] or [7]. Let $\Sigma = \bigcup_{i=0}^m \Sigma_i$ be a ranked alphabet. A *non-deterministic top-down tree automaton* (an N↓TA) over Σ is of the form $\mathcal{A} = (Q, \Sigma, Q_0, \Delta)$ consisting of a finite set of states Q, a set $Q_0 \subseteq Q$ of initial states, and $\Delta \subseteq \bigcup_{i=0}^m (Q \times \Sigma_i \times Q^i)$ is the transition relation. For $i = 0$, we identify $Q \times \Sigma_i \times Q^i$ with $Q \times \Sigma_0$. Let t be a tree and $\mathcal{A}$ be an N↓TA, a *run* of $\mathcal{A}$ on t is a mapping $\rho : dom_t \to Q$ compatible with Δ, i.e., $\rho(\varepsilon) \in Q_0$ and for each node $u \in dom_t$ with $i \geq 0$ successors $(\rho(u), val_t(u), \rho(u1), \ldots, \rho(ui)) \in \Delta$. A tree $t \in T_\Sigma$ is *accepted* if, and only if, there is a run of $\mathcal{A}$ on t. The tree language *recognized* by $\mathcal{A}$ is $T(\mathcal{A}) = \{t \in T_\Sigma \mid \mathcal{A} \text{ accepts } t\}$. A tree language $T \subseteq T_\Sigma$ is called *regular* if T is recognizable by a non-deterministic top-down tree automaton.

A top-down tree automaton $\mathcal{A} = (Q, \Sigma, Q_0, \Delta)$ is *deterministic* (a D↓TA) if the set Q_0 is a singleton set and for each $f \in \Sigma_i$ and each $q \in Q$ there is at most one transition $(q, f, q_1, \ldots, q_i) \in \Delta$. However, non-deterministic and deterministic top-down automata are not equally expressive. It is effectively decidable whether a regular tree language is top-down deterministic [9].

In Section 4.1 we use *guidable tree automata* [15]. The concept of guidable tree automata is that another tree automaton can act as a guide, meaning that a tree automaton $\mathcal{B}$ can guide a tree automaton $\mathcal{A}$ if an accepting run of $\mathcal{B}$ on a tree t can be translated deterministically into an accepting run of $\mathcal{A}$ on t.

Formally, an N↓TA $\mathcal{A}$ can be *guided by* an N↓TA $\mathcal{B}$ if there is a mapping $g : Q_\mathcal{A} \times \Delta_\mathcal{B} \to \Delta_\mathcal{A}$ such that $g(q, (p, a, p_1, \ldots, p_i)) = (q, a, q_1, \ldots, q_i)$ for some $q_1, \ldots, q_i \in Q_\mathcal{A}$, and for every accepting run ρ of $\mathcal{B}$ over a tree t, $g(\rho)$ is an accepting run of $\mathcal{A}$ over t, where $g(\rho) = \rho'$ is the unique run such that $\rho'(\varepsilon) = q_0^\mathcal{A}$, and for all $u \in dom_t : (\rho'(u), val_t(u), \rho'(u1), \ldots, \rho'(ui)) = g(\rho'(u), (\rho(u), val_t(u), \rho(u1), \ldots, \rho(ui)))$. An N↓TA $\mathcal{A}$ is called *guidable* if it can be guided by every N↓TA $\mathcal{B}$ such that $T(\mathcal{B}) \subseteq T(\mathcal{A})$.

Tree-automatic relations are defined by using tree automata over a product alphabet. For nodes that belong only to one of the trees one uses a padding symbol. Formally, let Σ, Γ be ranked alphabets and let $\Sigma_\perp = \Sigma \uplus \{\perp\}$, $\Gamma_\perp = \Gamma \uplus \{\perp\}$, where $\perp$ is a new symbol with rank 0. For an i-ary symbol $f \in \Sigma_\perp$ and a j-ary symbol $g \in \Gamma_\perp$, let $rk((f, g)) = max\{i, j\}$. The *convolution* of (t_1, t_2) with $t_1 \in T_\Sigma$, $t_2 \in T_\Gamma$ is the $\Sigma_\perp \times \Gamma_\perp$-labeled tree $t = t_1 \otimes t_2$ defined by $dom_t = dom_{t_1} \cup dom_{t_2}$, and $val_t(u) = (val^\perp_{t_1}(u), val^\perp_{t_2}(u))$ for all $u \in dom_t$, where $val^\perp_{t_i}(u) = val_{t_i}(u)$ if $u \in dom_{t_i}$ and $val^\perp_{t_i}(u) = \perp$ otherwise for $i \in \{1, 2\}$. As a special case, given $t \in T_\Sigma$, we define $t \otimes \perp$ to be the tree with $dom_{t \otimes \perp} = dom_t$ and $val_{t \otimes \perp}(u) = (val_t(u), \perp)$ for all $u \in dom_t$. Analogously, we define $\perp \otimes t$. We define the *convolution of a tree relation* $R \subseteq T_\Sigma \times T_\Gamma$ to be the tree language $T_R := \{t_1 \otimes t_2 \mid (t_1, t_2) \in R\}$.

We call a (binary) relation R *tree-automatic* if there exists a regular tree language T such that $T = T_R$. For ease of presentation, we say a tree automaton $\mathcal{A}$ recognizes R if it recognizes the convolution T_R and denote by $R(\mathcal{A})$ the induced relation R.

A *uniformization* of a relation $R \subseteq X \times Y$ is a function $f_R : X \to Y$ such that $(x, f_R(x)) \in R$ for all $x \in dom(R)$. We are interested in uniformizations of tree-automatic relations by deterministic top-down tree transducers.

Tree transducers. We consider top-down tree transducers, which read the tree from the root to the leaves and produce finite output trees in each step that are attached to the already produced output (see [7] for an introduction to tree transducers).

A *top-down tree transducer* (a ↓TT) is of the form $\mathcal{T} = (Q, \Sigma, \Gamma, q_0, \Delta)$ consisting of a finite set of states Q, a finite input alphabet Σ, a finite output alphabet Γ, an initial state $q_0 \in Q$, and Δ is a finite set of transition rules of the form $q(f(x_1, \ldots, x_i)) \to w[q_1(x_{j_1}), \ldots, q_n(x_{j_n})]$, or $q(x_1) \to w[q_1(x_1), \ldots, q_n(x_1)]$($\varepsilon$-transition), where $f \in \Sigma_i$, w is an n-context over Γ, $q, q_1, \ldots, q_n \in Q$ and variables $x_{j_1}, \ldots, x_{j_n} \in X_i$. A *deterministic* top-down tree transducer (a D↓TT) has no ε-transitions and no two rules with the same left-hand side.

A *configuration* of a top-down tree transducer is a triple $c = (t, t', \varphi)$ of an input tree $t \in T_\Sigma$, an output tree $t' \in T_{\Gamma \cup Q}$ and a function $\varphi : D_{t'} \to dom_t$, where

- $val_{t'}(u) \in \Gamma_i$ for each $u \in dom_{t'}$ with $i > 0$ successors, and

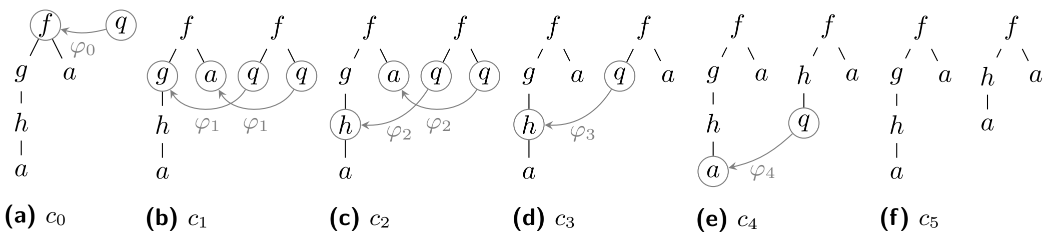

Figure 1 The configuration sequence c_0 to c_5 of $\mathcal{T}$ on t from Example 1.

- $val_{t'}(u) \in \Gamma_0$ or $val_{t'}(u) \in Q$ for each leaf $u \in dom_{t'}$, and
- $D_{t'} \subseteq dom_{t'}$ with $D_{t'} = \{u \in dom_{t'} \mid val_{t'}(u) \in Q\}$, i.e., φ maps every node from the output tree t' that has a state-label to a node of the input tree t.

Let $c_1 = (t, t_1, \varphi_1)$ and $c_2 = (t, t_2, \varphi_2)$ be configurations of a top-down tree transducer over the same input tree. We define a *successor relation* $\rightarrow_\mathcal{T}$ on configurations as usual by applying one rule. Figure 1 illustrates a configuration sequence explained in Example 1 below. Formally, for the application of a non-ε-rule, we define $c_1 \rightarrow_\mathcal{T} c_2 :\Leftrightarrow$

- There is a state-labeled node $u \in D_{t'}$ of the output tree t_1 that is mapped to a node $v \in dom_t$ of the input tree t, i.e., $\varphi_1(u) = v$, and
- there is a rule $val_{t_1}(u)\,(val_t(v)(x_1, \dots, x_i)) \rightarrow w[q_1(x_{j_1}), \dots, q_n(x_{j_n})] \in \Delta$ such that the output tree is correctly updated, i.e., $t_2 = t_1[\circ/u] \cdot w[q_1, \dots, q_n]$, and
- the mapping φ_2 is correctly updated, i.e., $\varphi_2(u') = \varphi_1(u')$ if $u' \in D_{t_1} \setminus \{u\}$ and $\varphi_2(u') = v.j_i$ if $u' = u.u_i$ with u_i is the ith hole in w.

Furthermore, let $\rightarrow^*_\mathcal{T}$ be the reflexive and transitive closure of $\rightarrow_\mathcal{T}$ and $\rightarrow^n_\mathcal{T}$ the reachability relation for $\rightarrow_\mathcal{T}$ in n steps. From here on, let φ_0 always denote the mapping $\varphi_0(\varepsilon) = \varepsilon$. A configuration (t, q_0, φ_0) is called *initial configuration* of $\mathcal{T}$ on t. A configuration $c = (t, t', \varphi)$ is said to be *reachable* in a computation of $\mathcal{T}$ on t, if $c_0 \rightarrow^*_\mathcal{T} c$, where c_0 is the initial configuration of $\mathcal{T}$ on t. The relation $R(\mathcal{T})$ induced by a top-down tree transducer $\mathcal{T}$ is $R(\mathcal{T}) = \{(t, t') \in T_\Sigma \times T_\Gamma \mid (t, q_0, \varphi_0) \rightarrow^*_\mathcal{T} (t, t', \varphi)\}$. For a (special) tree $t \in T_\Sigma$ or $t \in S_\Sigma$ let $\mathcal{T}(t) \subseteq T_{\Gamma \cup Q}$ be the set of *final transformed outputs* of a computation of $\mathcal{T}$ on t, that is the set $\{t' \mid (t, q_0, \varphi_0) \rightarrow^*_\mathcal{T} (t, t', \varphi)$ s.t. there is no successor configuration of $(t, t', \varphi)\}$. Note, we explicitly do not require that the final transformed output is a tree over Γ. In the special case that $\mathcal{T}(t)$ is a singleton set $\{t'\}$, we also write $\mathcal{T}(t) = t'$. The class of relations definable by ↓TTs is called the class of *top-down tree transformations*.

▶ **Example 1.** Let Σ be a ranked alphabet given by $\Sigma_2 = \{f\}$, $\Sigma_1 = \{g, h\}$, and $\Sigma_0 = \{a\}$. Consider the ↓TT $\mathcal{T}$ given by $(\{q\}, \Sigma, \Sigma, \{q\}, \Delta)$ with $\Delta = \{\ q(a) \rightarrow a,\ q(g(x_1)) \rightarrow q(x_1),\ q(h(x_1)) \rightarrow h(q(x_1)),\ q(f(x_1, x_2)) \rightarrow f(q(x_1), q(x_2))\ \}$. For each $t \in T_\Sigma$ the transducer deletes all occurrences of g in t. Consider $t := f(g(h(a)), a)$. A possible sequence of configurations of $\mathcal{T}$ on t is $c_0 \rightarrow^5_\mathcal{T} c_5$ such that $c_0 := (t, q, \varphi_0)$ with $\varphi_0(\varepsilon) = \varepsilon$, $c_1 := (t, f(q, q), \varphi_1)$ with $\varphi_1(1) = 1$, $\varphi_1(2) = 2$, $c_2 := (t, f(q, q), \varphi_2)$ with $\varphi_2(1) = 11$, $\varphi_2(2) = 2$, $c_3 := (t, f(q, a), \varphi_3)$ with $\varphi_3(1) = 11$, $c_4 := (t, f(h(q), a), \varphi_4)$ with $\varphi_4(11) = 111$, and $c_5 := (t, f(h(a), a), \varphi_5)$. A visualization of this sequence is shown in Figure 1.

We consider two restricted types of top-down tree transducers. The first type are *transducers with bounded (output) delay*. Intuitively, delay occurs in a computation of a transducer if there is a difference between the number of produced output symbols and read input symbols. If the output is behind this is called output delay. More formally, in a configuration (t, t', φ) occurs *delay* d w.r.t. a node $u \in D_{t'}$ if the absolute value of $|\varphi(u)| - |u|$

equals d. We speak of *output delay* if $|\varphi(u)| - |u|$ is a positive integer. We say the *delay* (resp. *output delay*) in a $\downarrow$TT $\mathcal{T}$ is *bounded* by k, if there is a $k \in \mathbb{N}$ such that for every reachable configuration c of $\mathcal{T}$ the maximal delay (resp. output delay) that occurs in c is at most k. We speak of *synchronous* $\downarrow$TTs if the delay is bounded by 0. Consider $\mathcal{T}$ from Example 1 and the configuration sequence of $\mathcal{T}$ given in Example 1. In c_2 occurs output delay 1 resp. 0 w.r.t. node 1 resp. 2 of the output tree. It is easy to see that the transducer has unbounded output delay, because it deletes all occurrences of g in an input tree.

The second restricted type of top-down tree transducer concerns the ability to copy and swap subtrees. A $\downarrow$TT is *linear* if all the trees in the transitions are linear. In Section 4.1, we consider a special case of linear $\downarrow$TTs called *path-preserving*. Intuitively, a $\downarrow$TT is said to be path-preserving if in every computation the read input and correspondingly produced output are always on the same path, i.e., every node of the output tree is produced from a node of the input tree that is above or below the output node. More formally, in every reachable configuration (t, t', φ) of the transducer it holds either $u \sqsubseteq \varphi(u)$ or $\varphi(u) \sqsubseteq u$ for every node $u \in D_{t'}$. We refer to this kind of $\downarrow$TTs as P$\downarrow$TTs for short.

3 Undecidability Results

▶ **Theorem 2.** *It is undecidable whether a given tree-automatic relation has a uniformization by a deterministic top-down tree transducer.*

Proof Sketch. We give a reduction from the halting problem for Turing machines (TM). Given a TM M, our goal is to describe a tree-automatic specification R_M which can only be realized by a deterministic top-down tree transducer if M does not halt on the empty input tape. In order to save space, we draw trees from left to right rather than from top to bottom. For explaining the idea, we provide for a given Turing machine a specification S and a uniformizer θ and a D$\downarrow$TT-realizable transformation θ such that θ uniformizes S if, and only if, M does not halt on the empty tape. For the full proof, the specification and the uniformizer have to be adapted such that θ becomes the only candidate for uniformizer of S, which then implies the undecidability of the existence of a uniformizer.

In the following, we explain the simple versions of S and θ. Let Q_M denote the state set of M, q_0 denote the initial state of M, and Γ_M denote the tape alphabet of M. We can represent a configuration c of M, as a unary tree, i.e., as a string, of the form $u_1 - \cdots - u_k - q - v_1 \cdots - u_\ell$, where $u_1, \ldots, u_k, v_1, \ldots, v_\ell \in \Gamma_M$, $u_1 \ldots u_k v_1 \ldots v_\ell$ is the content of the tape of M, $q \in Q_M$ is the current control state of M, and the head of M is on v_1.

We start with the first step. Concerning the specification S, we are interested in pairs (t, t') of trees over $Q_M \cup \Gamma_M \cup \{f, a\}$ which have the form

$$\left(\begin{array}{ccccccc} f & - & f & - \cdots - & f & - & a \\ | & & | & & | & & \\ c_0 & & c_1 & & c_n & & \end{array}\ ,\ \begin{array}{ccccccc} f & - & f & - \cdots - & f & - & a \\ | & & | & & | & & \\ k_1 & & k_2 & & k_m & & \end{array}\right),$$

where $m \geq n$, each c_i (resp. k_i) is a configuration of M, c_0 is the initial configuration of M on the empty tape and c_n is a halting configuration of M. Note that the numbering of the c_i starts with 0 and the numbering of the k_i with 1, this is intended. Such a pair of trees is part of the specification S if it additionally satisfies the following: There is an $i \in \{0, \ldots, n-1\}$ such that $succ(c_i) \neq k_{i+1}$, where $succ(c_i)$ is the successor configuration of c_i.

The specification S is tree-automatic. Note that for a pair (t, t') of the correct form, the configurations c_i and k_{i+1} overlap for each $i \in \{0, \ldots, n-1\}$ in $t \otimes t'$. A tree-automaton can guess a branch and verify that $succ(c_i) \neq k_{i+1}$ holds.

Now, we consider the function $\theta\colon dom(S) \to T_{Q_M \cup \Gamma_M \cup \{f,a\}}$ defined by

$$\begin{array}{ccccccc} f & - & f & - \cdots - & f & - & a \\ | & & | & & | & & \\ c_0 & & c_1 & & c_n & & \end{array} \quad \mapsto \quad \begin{array}{ccccccc} f & - & f & - \cdots - & f & - & a \\ | & & | & & | & & \\ c_1 & & c_2 & & c_n & & \end{array} .$$

Assuming that a transducer is only given input trees that have the desired form, this function is realizable by a deterministic top-down tree transducer, e.g., by some transducer that produces no output in the first step, continues at the right child and then simply copies the rest of the input tree.

Assume that M does not halt on the empty input tape and consider an input tree $t \in dom(S)$, then there are configurations c_i and c_{i+1} such that c_{i+1} is not the successor configuration of c_i. The transformation θ yields $c_{i+1} = k_{i+1}$, it follows that $succ(c_i) \neq k_{i+1}$, i.e., $(t, \theta(t)) \in S$. Conversely, assume that M halts on the empty input tape. Consider an input tree $t \in dom(S)$ such that $c_0 c_1 \cdots c_n$ is the halting configuration sequence. It follows that $k_{i+1} = succ(c_i) = c_{i+1}$ for all $i \in \{0, \ldots, n-1\}$, i.e., $(t, \theta(t)) \notin S$. Clearly, S is uniformized by θ if, and only if, M does not halt on the empty input tape.

However, the specification S does not suffice to enforce that this kind of transformation is the only possible uniformizer. This can be achieved by extending the alphabet and the specification. ◀

From the undecidability proof one can derive that the uniformization problems remain undecidable if we restrict the D↓TTs, as stated in the following two theorems. Together with the decidability result from Section 4.1 this gives an almost complete picture of the frontier between decidability and undecidability (for the case of all tree-automatic relations as specifications, and subclasses of D↓TTs as uniformizers).

▶ **Theorem 3.** *It is undecidable whether a given tree-automatic relation has a uniformization by a linear deterministic top-down tree transducer with delay bounded by 1.*

▶ **Theorem 4.** *It is undecidable whether a given tree-automatic relation has a uniformization by a synchronous deterministic top-down tree transducer.*

4 Decidability Results

In the previous section we have seen that the uniformization problem for general tree-automatic specifications is undecidable. In order to regain decidability of the uniformization problem for non-deterministic top-down specifications we present two approaches. In Section 4.1, we consider general non-deterministic top-down specifications and restrict the uniformizer, whereas in Section 4.2 we consider a restricted class of non-deterministic top-down specifications and ask whether there is a synchronous uniformizer.

4.1 Path-preserving uniformization

In this section, we consider general non-deterministic tree relations and restrict the uniformizer; we are looking for a uniformization by a deterministic path-preserving top-down transducer. We solve the following uniformization problem.

▶ **Theorem 5.** *It is decidable whether a given tree-automatic relation has a uniformization by a deterministic path-preserving top-down tree transducer.*

In the following we show that deciding whether a general non-deterministic top-down tree relation has a path-preserving uniformization reduces to deciding the winner in a safety game between two players. We show that the use of guidable tree automata [15] for the specifications makes it feasible to adapt a decision procedure presented in [16], where the uniformization problem for deterministic top-down tree relations was reduced to deciding the winner in a safety game.

Before we present the decision procedure, we need to fix some notations. Given $\Sigma = \bigcup_{i=0}^{m} \Sigma_i$, let $\mathrm{dir}_\Sigma = \{1, \dots, m\}$ be the set of directions compatible with Σ. For $\Sigma = \bigcup_{i=0}^{m} \Sigma_i$, the set Path_Σ of labeled paths over Σ is defined inductively by:

- ε is a labeled input path and each $f \in \Sigma$ is a labeled input path,
- given a labeled input path $\pi = x \cdot f$ with $f \in \Sigma_i$ $(i > 0)$ over Σ, then $\pi \cdot jg$ with $j \in \{1, \dots, i\}$ and $g \in \Sigma$ is a labeled input path.

For $\pi \in \mathrm{Path}_\Sigma$, we define the path $path(\pi) \in \mathrm{dir}_\Sigma^*$ and the word $labels(\pi) \in \Sigma^*$ induced by π inductively by:

- if $\pi = \varepsilon$ or $\pi = f$, then $path(\varepsilon) = path(f) = \varepsilon$, $labels(\varepsilon) = \varepsilon$ and $labels(f) = f$,
- if $\pi = x \cdot jf$ with $j \in \mathrm{dir}_\Sigma$, $f \in \Sigma$, then $path(\pi) = path(x) \cdot j$, $labels(\pi) = labels(x) \cdot f$.

The length $|| \; ||$ of a labeled path over Σ is the length of the word induced by its path, i.e., $||\pi|| = |labels(\pi)|$.

For $\pi \in \mathrm{Path}_\Sigma$ let $T_\Sigma^\pi := \{t \in T_\Sigma \mid val_t\big(path(\pi)[1, (i{-}1)]\big) = labels(\pi)[i]$ for $1 \leq i \leq ||\pi||\}$ be the set of trees t over Σ such that π is a prefix of a labeled path through t. For a tree-automatic relation $R \subseteq T_\Sigma \times T_\Gamma$ recognized by an N↓TA $\mathcal{A}$, $\pi \in \mathrm{Path}_\Sigma$ and $q \in Q_\mathcal{A}$ let $R^\pi := \{(t, t') \in R \mid t \in T_\Sigma^\pi\}$ and $R_q^\pi := \{(t, t') \in R(\mathcal{A}_q) \mid t \in T_\Sigma^\pi\}$.

Since we consider labeled paths through trees, it is convenient to define the notion of convolution also for labeled paths. For a labeled path $x \in \mathrm{Path}_\Sigma$ with $||x|| > 0$, let $dom_x := \{u \in \mathrm{dir}_\Sigma^* \mid u \sqsubseteq path(x)\}$ and $val_x : dom_x \to \Sigma$, where $val_x(u) = labels(x)[i]$ if $u \in dom_x$ with $|u| = i + 1$. Let $x \in \mathrm{Path}_\Sigma$, $y \in \mathrm{Path}_\Gamma$ with $path(y) \sqsubseteq path(x)$ or $path(x) \sqsubseteq path(y)$, then the *convolution* of x and y is $x \otimes y$ defined by $dom_{x \otimes y} = dom_x \cup dom_y$, and $val_{x \otimes y}(u) = (val_x^\perp(u), val_y^\perp(u))$ for all $u \in dom_{x \otimes y}$, where $val_x^\perp(u) = val_x(u)$ if $u \in dom_x$ and $val_x^\perp(u) = \perp$ otherwise, analogously defined for $val_y^\perp(u)$.

Furthermore, it is useful to relax the notion of runs to labeled paths. Let $x \in \mathrm{Path}_\Sigma$, $y \in \mathrm{Path}_\Gamma$ such that $x \otimes y$ is defined, i.e., $path(y) \sqsubseteq path(x)$ or $path(x) \sqsubseteq path(y)$. We define the run of $\mathcal{A}$ on $x \otimes y$ such that it maps all nodes from $dom_{x \otimes y}$ as well as all nodes that are a direct successor of a node from $dom_{x \otimes y}$ to a state of $\mathcal{A}$. Formally, let the (partial) *run* of $\mathcal{A}$ on $x \otimes y$ be the partial function $\rho : \mathrm{dir}_\Sigma^* \to Q_\mathcal{A}$ such that $\rho(\varepsilon) = q_0^\mathcal{A}$, and for each $u \in dom_{x \otimes y}$: if $q := \rho(u)$ is defined and there is a transition $(q, val_{x \otimes y}(u), q_1, \dots, q_i) \in \Delta_\mathcal{A}$, then $\rho(u.j) = q_j$ for all $j \in \{1, \dots, i\}$. Let $path(x \otimes y) = v$ and $i \in \mathrm{dir}_\Sigma$. Shorthand, we write $\mathcal{A} : q_0^\mathcal{A} \xrightarrow{x \otimes y}_i q$, if $q := \rho(vi)$ is defined. We write $\mathcal{A} : q_0^\mathcal{A} \xrightarrow{x \otimes y} Acc$ if $rk(val_{x \otimes y}(v)) = 0$ and $(\rho(v), val_{x \otimes y}(v)) \in \Delta_\mathcal{A}$ to indicate that the (partial) run ρ of $\mathcal{A}$ on $x \otimes y$ is accepting.

We explicitly state a simple lemma that is used in several places.

▶ **Lemma 6** ([16]). *Given a ↓TA $\mathcal{A}$ and a state q of $\mathcal{A}$, the following properties are decidable:*

1. $\forall t \in T_\Sigma : t \otimes \perp \in T(\mathcal{A}_q)$,
2. $\exists t' \in T_\Gamma : \perp \otimes t' \in T(\mathcal{A}_q)$,
3. $\exists t' \in T_\Gamma \, \forall t \in T_\Sigma : t \otimes t' \in T(\mathcal{A}_q)$.

Towards the decision procedure, we consider the relationship between the delay that a transducer introduces and uniformizability. Intuitively, if a specification is uniformized by a transducer such that the uniformizer introduces long delays between outputs, then only one path in an input tree is relevant in order to determine an output tree. We express this property by introducing the term path-recognizable function, meaning that there is a D↓TT that first deterministically reads a path from the root to a leaf in an input tree and then outputs a matching output tree. Note that such a uniformizer is always path-preserving.

Formally, we say a relation $R \subseteq T_\Sigma \times T_\Gamma$ is *uniformizable by a path-recognizable function*, if there exists a D↓TT $\mathcal{T}$ that uniformizes R such that $\Delta_\mathcal{T}$ only contains transitions of the following form:

1. $q(f(x_1,\dots,x_i)) \to q'(x_j)$, or
2. $q(a) \to t$,

where $f \in \Sigma_i$, $i > 0$, $a \in \Sigma_0$, $q, q' \in Q_\mathcal{T}$ and $j \in \{1,\dots,i\}$ and $t \in T_\Gamma$.

This notion was introduced in [16], where it was shown to be decidable whether a top-down deterministic relation can be uniformized by a path-recognizable function. Using guidable automata, the result carries over to general tree-automatic relations.

▶ **Theorem 7.** *It is decidable whether a given tree-automatic relation can be uniformized by a path-recognizable function.*

Given a specification, we can show that there exists a computable bound with the following property: If it is necessary for a D↓PTT to introduce delay that exceeds the bound in order to satisfy the specification, then either the remaining specification has a simple uniformization by a path-recognizable function, which is decidable by the above theorem, or is not D↓PTT-uniformizable.

Towards the definition of the game, we need one more notion. We introduce a relation that contains state transformations of a given specification automaton that a labeled path together with some output sequence on this path induces. However, we are only interested in the result of a state transformation if it suffices for a uniformizer to read this labeled path segment in an input tree to (partially) determine a matching output tree. Formally, let $x \in \mathrm{Path}_\Sigma$, $y \in \mathrm{Path}_\Gamma$ and $i \in \mathrm{dir}_\Sigma$ such that $x \otimes y$ is defined. We define the relation $\tau_{xi,y} \subseteq Q_\mathcal{A} \times Q_\mathcal{A}$ such that $(q,q') \in \tau_{xi,y}$ if there is a partial run ρ_q of $\mathcal{A}_q$ on $x \otimes y$ with $\mathcal{A}_q : q \xrightarrow{x\otimes y}_i q'$ and for each uj with $u \in dom_{x\otimes y}, uj \not\sqsubseteq path(x \otimes y)i$, and $j \in \{1,\dots,rk\big((val_x^\perp(u), val_y^\perp(u))\big)\}$ holds

- if $r := \rho_q(uj)$ and $j \leq rk(val_x^\perp(u)), rk(val_y^\perp(u))$, then there exists $t' \in T_\Gamma$ such that $t \otimes t' \in T(\mathcal{A}_r)$ for all $t \in T_\Sigma$, and
- if $r := \rho_q(uj)$ and $rk(val_y^\perp(u)) < j \leq rk(val_x^\perp(u))$, then $t \otimes \perp \in T(\mathcal{A}_r)$ for all $t \in T_\Sigma$, and
- if $r := \rho_q(uj)$ and $rk(val_x^\perp(u)) < j \leq rk(val_y^\perp(u))$, then there exists $t' \in T_\Gamma$ such that $\perp \otimes t' \in T(\mathcal{A}_r)$.

Lemma 6 implies that it is decidable whether $(q,q') \in \tau_{xi,y}$. Basically, if q is in the domain of $\tau_{xi,y}$, then there exists a fixed (partial) output tree $s' \in S_\Gamma^{yio}$ such that for each input tree $t \in T_\Sigma^x \cap dom(T(\mathcal{A}_q))$ there exists some $t' \in T_\Gamma$ such that $t \otimes (s' \cdot t') \in T(\mathcal{A}_q)$.

Now, we are ready to show that the uniformization problem posed in this section reduces to deciding the winner in a safety game, provided that the specification is given by a guidable automaton. The game is played between In and Out on a game graph parameterized by k, where In can follow any path from the root to a leaf in an input tree such that In plays one input symbol at a time. Out can either react with an output symbol, or delay the output a bounded number of times (at most $2k$ times) and react with a direction in which In should continue with his input sequence. As stated after Theorem 7, when the output delay increases to a computable bound, then uniformization is either impossible or can be realized by a path-recognizable function (Out then wins automatically, see o4. in the construction below). To make the decision procedure sound, the parameter k has to be chosen as this bound.

Given a tree-automatic relation $R \subseteq T_\Sigma \times T_\Gamma$, we assume its domain to be deterministic, otherwise no deterministic ↓TT can recognize the domain. Let R be recognized by a guidable

N↓TA $\mathcal{A}$ and let $dom(R)$ be recognized by a D↓TA $\mathcal{B}$. Formally, the game graph $G^k_{\mathcal{A},\mathcal{B}}$ is constructed as follows.

- $V_{\mathsf{In}} = \{(p, q, \pi j) \in Q_{\mathcal{B}} \times Q_{\mathcal{A}} \times \text{Path}_\Sigma \cdot \text{dir}_\Sigma \mid \|\pi\| \leq 2k+1, \pi \in \text{Path}_\Sigma, j \in \text{dir}_\Sigma\} \cup 2^{Q_{\mathcal{B}} \times Q_{\mathcal{A}}}$ is the set of vertices of player In including the initial vertex $\{(q_0^{\mathcal{B}}, q_0^{\mathcal{A}})\}$.
- $V_{\mathsf{Out}} = \{(p, q, \pi) \in Q_{\mathcal{B}} \times Q_{\mathcal{A}} \times \text{Path}_\Sigma \mid \|\pi\| \leq 2k+1\}$ is the set of vertices of player Out.
- From a vertex of In the following moves are possible:
  i1. $(p, q, \pi j) \to (p, q, \pi j f)$ for each $f \in \Sigma$ such that $\mathcal{B}\colon p \xrightarrow{\pi}_j p'$ and there exists $(p', f, p_1, \ldots, p_i) \in \Delta_{\mathcal{B}}$ if $\|\pi\| < 2k+1$ (delay; In chooses the next input symbol)
  i2. $\{(p_1, q_1), \ldots, (p_n, q_n)\} \to (p_j, q_j, f)$ for each $f \in \Sigma$ such that there is $(p_j, f, p_j^1, \ldots, p_j^i) \in \Delta_{\mathcal{B}}$ and each $j \in \{1, \ldots, n\}$ (no delay; In chooses the next direction and input symbol)
- From a vertex of Out the following moves are possible:
  o1. $(p, q, f) \xrightarrow{r} \{(p_1, q_1), \ldots, (p_i, q_i)\}$ if there is $r = (q, (f, g), q_1, \ldots, q_n) \in \Delta_{\mathcal{A}}$, $(p, f, p_1, \ldots, p_i) \in \Delta_{\mathcal{B}}$, $f \in \Sigma$ is i-ary, $g \in \Sigma_\perp$ is j-ary, $n = max\{i, j\}$, and if $j > i$ there exist trees $t_{i+1}, \ldots, t_j \in T_\Gamma$ such that $\perp \otimes t_\ell \in T(\mathcal{A}_{q_l})$ for all $i < \ell \leq j$.
  (no delay; Out applies a transition; Out can pick output trees for all directions where the input has ended; In can continue from the other directions)
  Note, if $f \in \Sigma_0$, i.e., the input symbol is a leaf, then the next reached vertex is $\emptyset \in V_{\mathsf{In}}$, which is a terminal vertex.
  o2. $(p, q, fj\pi) \xrightarrow{r} (p_j, q_j, \pi)$ if there is $r = (q, (f, g), q_1, \ldots, q_n) \in \Delta_{\mathcal{A}}$ such that $(q, q_j) \in \tau_{fj,g}$ and $(p, f, p_1, \ldots, p_i) \in \Delta_{\mathcal{B}}$.
  (delay; Out applies a transition, removes the leftmost input symbol and advances in direction of the labeled path ahead; Out can pick output trees for all divergent directions)
  o3. $(p, q, \pi j f) \to (p, q, \pi j f j')$ for each $j' \in \{1, \ldots, i\}$ for $f \in \Sigma_i$ if $\|\pi j f\| < k+1$
  (Out delays and chooses a direction from where In should continue)
  o4. $(p, q, \pi) \to (p, q, \pi)$ if R_q^π is uniformizable by a path-recognizable function.
  (Out stays in this vertex and wins)

Note that the game graph can effectively be constructed, because Lemma 6 and Theorem 7 imply that it is decidable whether the edge constraints are satisfied.

The desired winning condition expresses that player Out loses the game if the input can be extended, but no valid output can be produced. This is represented in the game graph by a set of bad vertices B that contains all vertices of Out with no outgoing edges. If one of these vertices is reached during a play, Out loses the game. Thus, we define $\mathcal{G}^k_{\mathcal{A},\mathcal{B}} = (G^k_{\mathcal{A},\mathcal{B}}, V \setminus B)$ as safety game for Out.

The following two lemmata show that from the existence of a winning strategy a top-down tree transducer that uniformizer the relation can be obtained and vice versa.

▶ **Lemma 8.** *Given k, if Out has a winning strategy in $\mathcal{G}^k_{\mathcal{A},\mathcal{B}}$, then R is D↓PTT-uniformizable.*

The key idea in order to lift the proof in [16] from deterministic to general non-deterministic specifications is, given a guidable automaton for the specification, to turn a uniformizer into a guide for the specification automaton in order to construct a winning strategy.

▶ **Lemma 9.** *If R is D↓PTT-uniformizable, then Out has a winning strategy in $\mathcal{G}^k_{\mathcal{A},\mathcal{B}}$, where k is a number effectively computable from $\mathcal{A}$.*

As a consequence of Lemmata 8 and 9 and the fact that a winning strategy for Out in $\mathcal{G}^k_{\mathcal{A},\mathcal{B}}$ can effectively be computed, together with the fact that for each tree-automatic relation a guidable N↓TA can effectively be constructed, see [15], we immediately obtain Theorem 5.

4.2 Union of top-down deterministic specifications

In this section, we assume that $R \subseteq T_\Sigma \times T_\Gamma$ is given as the union $\bigcup_{i=1}^{n} R_i$ of n relations with pairwise disjoint domains, where each R_i is recognized by a D↓TA $\mathcal{A}_i$ and its domain is recognized by a D↓TA $\mathcal{B}_i$. Furthermore, we assume that the domain of the relation is D↓TA-recognizable, otherwise there exists no uniformization by a deterministic top-down tree transducer.

▶ **Example 10.** Let Σ be an input alphabet given by $\Sigma_1 = \{h\}$ and $\Sigma_0 = \{c, d\}$ and let Γ be an output alphabet given by $\Gamma_2 = \{f\}$, $\Gamma_1 = \{h\}$ and $\Gamma_0 = \{c, d\}$. We consider the relation $R \subseteq T_\Sigma \times T_\Gamma$ defined by $\{(h(t), f(t, t')) \mid t, t' \in T_\Sigma$ such that t and t' have the same leaf symbol$\}$. This specification can be obtained by the union of two deterministic top-down specifications, one specification for each leaf symbol. Clearly, a deterministic top-down transducer can realize the specification by producing $f(t, t)$ for a unary input tree $h(t)$, e.g., by starting with $q_0(h(x_1)) \to f(q(x_1), q(x_1))$. However, there is no linear synchronous uniformizer for R, because in the first step a linear D↓TT would have to pick for either the right or the left subtree an output tree with a fixed leaf symbol. As the actual leaf symbol of the input tree is yet unknown it is not possible to fix a correct output tree.

We provide a decision procedure for the following problem.

▶ **Theorem 11.** *It is decidable whether the union of D↓TA-recognizable relations with pairwise disjoint D↓TA-recognizable domains has a uniformization by a synchronous deterministic top-down tree transducer.*

We show that the existence of a synchronous uniformizer for such a relation is a regular property over infinite trees that can be checked by a parity tree automaton. For an introduction to parity tree automata, see e.g. [20]. We define a regular infinite tree, given as the unfolding of a finite graph, such that each vertex of the infinite tree represents a node in an input tree together with a set of output nodes produced from this input node. Since the uniformizer might be non-linear, output at different positions in the output tree can depend on the same position in the input tree. Our construction bounds the number of required output choices by making the choice only depending on the state transformation that the current output sequences together with the input sequence induces.

Before we formally define the finite graph, we describe its components. Recall, $R = \bigcup_{i=1}^{n} R_i$, where R_i is recognized by a D↓TA $\mathcal{A}_i$ and $dom(R)$ is recognized by a D↓TA $\mathcal{D}$. The graph keeps track of the state of $\mathcal{D}$ on the input, and the states of $\mathcal{A}_1, \ldots, \mathcal{A}_n$ on the produced output. For the latter we use vectors with n elements. We define a function λ_ℓ that returns the ℓth element of a vector, for each $1 \leq \ell \leq n$. Let L denote such a vector, then $\lambda_\ell(L)$ stores the information w.r.t. $\mathcal{A}_\ell$. We model that read input and produced output can be on the same or on divergent paths as follows: In case that input and output are on the same path, $\lambda_\ell(L)$ is the state of $\mathcal{A}_\ell$ on the combined input sequence and output sequence. In case that the output is mapped to a divergent path, $\lambda_\ell(L)$ is a set of states of $\mathcal{A}_\ell$ that is obtained by combining all possible input sequences with the produced output sequence. Now we are ready to formally define the graph $\mathcal{G}$:

- From a vertex v of the form $(p, \{L_1, \ldots, L_m\})$, where p is a state of $\mathcal{D}$ and each L_j is a vector of states resp. sets of states over $\mathcal{A}_1, \ldots, \mathcal{A}_n$, the following edges exist:
  - $v \to (v, f)$ if there is $(p, f, p_1 \ldots, p_i) \in \Delta_\mathcal{D}$ (edges for every possible input symbol)
- An edge $((p, \{L_1, \ldots, L_m\}), f) \xrightarrow{o_1, \ldots, o_m} [(p_1, Q_1), \ldots, (p_i, Q_i)]$ defining output choices $o_1, \ldots, o_m$ exists if $(p, f, p_1 \ldots, p_i) \in \Delta_\mathcal{D}$ and the following conditions hold:
  - $o_j \in \Gamma(X_i)$ for each $1 \leq j \leq m$, and
    (for each L_j an output o_j consisting of one symbol and directions to continue is chosen)

- the set Q_d is constructed as follows for each $1 \leq d \leq i$:
  if for output $o_j = g(x_{j_1}, \dots, x_{j_r})$ there is $k \in \{1, \dots, r\}$ with $j_k = d$,
  (the kth child of the output o_j depends on the dth child of the input)
  we add a vector V_k to Q_d, where the component $\lambda_\ell(V_k)$ referring to $\mathcal{A}_\ell$ is build up from $\lambda_\ell(L_j)$ and o_j as follows:
  * if $\lambda_\ell(L_j) \in Q_{\mathcal{A}_\ell}$, say $q \in Q_{\mathcal{A}_\ell}$, (input and output are at the same position)
    and there is $(q, (f, g), q_1, \dots, q_{max\{rk(f),rk(g)\}}) \in \Delta_{\mathcal{A}_\ell}$,
    then $\lambda_\ell(V_k) = \begin{cases} q_k & \text{if } d = k, \quad \text{(input and output continue in the same direction)} \\ \{q_k\} & \text{otherwise. (input and output continue in divergent directions)} \end{cases}$
    (the corresponding transition in $\mathcal{A}_\ell$ is applied)
  * if $\lambda_\ell(L_j) \in 2^{Q_{\mathcal{A}_\ell}}$, (input and output are on divergent paths)
    then set $\lambda_\ell(V_k)$ to $\emptyset$ and for each $q \in \lambda_\ell(L_j)$ and each $f' \in \Sigma$ such that there is $(q, (f', g), q_1, \dots, q_{max\{rk(f'),rk(g)\}}) \in \Delta_{\mathcal{A}_\ell}$, add q_k to $\lambda_\ell(V_k)$.
    (all possibly reachable states in $\mathcal{A}_\ell$ are collected)
- From $[v_1, \dots, v_i]$ an edge to v_j exists for all $1 \leq j \leq i$. (edges to all directions)
- The initial vertex is $(p_0, \{L\})$, where $L = [q_0^{\mathcal{A}_1}, \dots, q_0^{\mathcal{A}_n}]$ and p_0 is the initial state of $\mathcal{D}$.

Now that we have defined $\mathcal{G}$, we consider the unfolding $\mathcal{H}$ of $\mathcal{G}$ which is a regular infinite tree. Consequently, each vertex of $\mathcal{H}$ is associated with a labeled path, interpreted as an input sequence π, and additionally it is associated with a bounded number of labeled paths, interpreted as output sequences produced by a transducer while reading the input sequence π. Note that different vertices of $\mathcal{H}$ may represent the same input sequence, but differ in the associated output sequences. This is a regular infinite tree that has the desired property, namely, each input sequence together with a (sufficiently large) number of possible output sequences is represented in the tree.

Our goal is to construct a parity tree automaton, whose tree language is non-empty iff R has a uniformization by a synchronous deterministic top-down tree transducer. The idea is to annotate $\mathcal{H}$ with an output strategy σ. The strategy selects for each node of the form (v, f) with $f \in \Sigma$ one child, i.e., σ fixes an output choice. Let $\mathcal{H}^\frown\sigma$ denote the tree $\mathcal{H}$ with annotations encoding σ. Given $\mathcal{H}^\frown\sigma$ and some input tree $t \in dom(R)$, the output choices defined by σ identify a unique output tree that a D↓TT can produce while reading t. For an input tree t, let $\sigma(t)$ denote the corresponding output tree. The strategy σ corresponds to a uniformizer if for all $t \in dom(R)$ holds that $(t, \sigma(t)) \in R$. The following lemma shows that the set of trees $\mathcal{H}^\frown\sigma$ such that σ corresponds to a uniformizer is a regular set of trees.

▶ **Lemma 12.** *There exists a parity tree automaton $\mathcal{C}$ that accepts exactly those trees $\mathcal{H}^\frown\sigma$ such that $(t, \sigma(t)) \in R$ for all $t \in dom(R)$.*

The next lemma shows that the uniformization problem posed in this section reduces to deciding the emptiness problem for $\mathcal{C}$. It directly implies Theorem 11 because emptiness of parity tree automata is decidable (see [20]).

▶ **Lemma 13.** *The tree language $T(\mathcal{C})$ is non-empty if, and only if, R has a uniformization by a synchronous deterministic top-down tree transducer.*

5 Conclusion

We have considered uniformization of tree-automatic relations by D↓TTs. Using the subclasses of bounded-delay, linear, and path-preserving D↓TTs, we have obtained an almost complete picture of the frontier between decidability and undecidability. We have also presented a class of tree-automatic relations for which the uniformization problem is decidable but requires, in general, non-linear uniformizers.

As further research questions it would be interesting to extend the class of specifications beyond those of tree-automatic relations. In [6] decidability results for word transformations have been obtained for deterministic rational relations, and for uniformization questions in which the delay of the uniformizer is related to the one of the specification. We plan to study extensions of these ideas from words to trees.

Abstract

We study the class of languages of finitely-labelled countable linear orderings definable in two-variable first-order logic. We give a number of characterisations, in particular an algebraic one in terms of circle monoids, using equations. This generalises the corresponding characterisation, namely variety DA, over finite words to the countable case. A corollary is that the membership in this class is decidable: for instance given an MSO formula it is possible to check if there is an equivalent two-variable logic formula over countable linear orderings. In addition, we prove that the satisfiability problems for two-variable logic over arbitrary, countable, and scattered linear orderings are NEXPTIME-complete.

1 Introduction

Countable linear orderings are linear orderings over countable domains. They are of primary interest in the context of satisfiability of logics due to a result of Shelah [24]: the satisfiability problem of monadic second-order (MSO) logic is undecidable over arbitrary linear orderings, and in particular over the Reals. But by Rabin's theorem [18] the problem remains decidable when considered over countable linear orderings. Thus the class of countable linear orderings sets a natural limit to the decidability of satisfiability problem for MSO over linear orderings. This is in sharp contrast with first-order (FO) logic, that has the corresponding question decidable over arbitrary linear orderings. A second and perhaps more important reason why the class of countable linear orderings are interesting is the logic-algebra connection on its subclasses – MSO definable languages over finite words (*resp.* ω-words) are precisely the class of languages definable by finite monoids (*resp.* ω-semigroups, equivalently Wilke algebras) – extends to countable linear orderings: the result due to Carton-Colcombet-Puppis [4] states that MSO definable languages of countable linear orderings are precisely the class of languages of countable linear orderings recognisable by $\circ$-monoids (recalled in the next section).

The principal import of such a connection is well displayed by the seminal theorem of Schützenberger [21]: over finite words, FO definable languages are precisely the languages recognisable by aperiodic finite monoids, in particular the syntactic monoids of FO definable languages are aperiodic. This immediately yields the decidability of membership in the class of FO definable languages: compute the syntactic monoid of the given language and check if it is aperiodic. Since the time of Schützenberger numerous logics have been characterised algebraically, over finite words, ω-words etc.

However, unlike finite words or ω-words, characterising a logic over countable linear orderings has the following added advantage: An algebraic, in particular decidable, characterisation of a class of languages of countable linear orderings (for instance languages definable by FO) in terms of $\circ$-monoids, immediately provides decidable characterisations over restricted classes of countable linear orderings that are equationally definable (for instance finite words, ω-words, bi-infinite words, rationals etc.). In that sense, characterising a logic algebraically over the class of countable linear orderings in *one shot* characterises it over all equationally definable subclasses.

An elaborate study over a variety of sublogics over countable linear orderings was done in [6] where FO, FO[cut], WMSO, WMSO[cut], MSO[ordinals], MSO[scattered] etc. were characterised algebraically. These characterisations show that WMSO with "cut" quantifiers are equivalent to those with "ordinal" quantifiers, whereas the rest of the logics are expressively different from each other. The study also gives decidability of membership for all these logics.

As a continuation, in this work we consider the class of languages of countable linear orderings that are definable in two-variable first-order logic (FO^2). Two-variable FO is the fragment of FO with at most two variables x, y. While over abritrary structures FO has an undecidable satisfiable problem, FO^2 has a decidable, low complexity satisfiability problem. Yet FO^2 is expressive enough to contain modal logics. This feature of FO^2 has been thoroughly studied and the decidability of satisfiability has been extended to special classes of structures as well as particular vocabularies. FO^2 has been of significant interest over words (and ω-words) as well. Over finite words, FO^2 definable languages have numerous characterisations [26, 25]: they are precisely the class of languages (1) definable in unary LTL [26, 8], (2) recognisable by 2-way partially ordered DFA [22], (3) definable by turtle expressions [27], and (4) whose syntactic monoids are in the variety DA [26] (a finite monoid is in DA if it is aperiodic and all its regular D-classes are subsemigroups) etc. The last characterisation also gives a decision procedure for membership in the class. Not only that FO^2 languages have numerous characterisations, they also have a rich structure inside them [17]– they form an infinite hierarchy under quantifier alternations that is also decidable as shown recently [12].

Though FO^2 is well understood algebraically over finite words, its algebraic characterisation over countable orderings, in particular over infinite ones, is not immediate. This is because even with two variables one can express a variety of "infinitary" conditions: clearly with two variables we can express that letter a has a minimum occurrence (for instance by the formula $\varphi_1 = \exists y \forall x\, (a(x) \wedge a(y) \wedge x \geq y))$, as well as its negation, that is there is an infinite descending chain of a's. Consider the following formula φ_2 that says that if an a-position has an a-position before it, then it has two a-positions before it.

$$\varphi_2 = \forall x\, (a(x) \wedge \exists y\ (a(y) \wedge x > y) \rightarrow \exists y\, (a(y) \wedge x > y \wedge \exists x\, (a(x) \wedge y > x)))$$

The word aa, as well as a^{ω^*} (the ordering $(\mathbb{Z}^-, <)$ labelled with a) does not satisfy $\varphi_1 \wedge \varphi_2$ while the words a and aa^{ω^*} satisfy $\varphi_1 \wedge \varphi_2$. Thus, as $\varphi_1 \wedge \varphi_2$ exemplifies, with two variables one can stipulate both a minimum occurrence as well as existence of a descending chain of a letter. Therefore for the algebraic characterisation of FO^2 one has to make an intricate analysis of whether the letters appear as a minimum or as an infinite chain at different factors of the word.

In the rest of the section, we mention works that are related to the present paper and our contributions.

Related Work

Algebraic characterisations, in particular for FO, for scattered linear orderings are given in [1, 2, 5]. The connection between MSO over countable linear orderings and $\circ$-monoids was proved in [4]. It showed that MSO is equivalent to $\circ$-monoids. This gives an alternate proof of decidability of MSO over countable linear orderings. Moreover it showed that MSO collapses to the second level of the quantifier alternation hierarchy. An algebraic classification of MSO under various forms of set quantifications, in particular corresponding to the sublogics FO, FO[cut], WMSO, WMSO[cut], MSO[ordinals], MSO[scattered], was done in [6].

The literature on FO^2 over arbitrary structures is extensive and we don't mention it here. FO^2 over finite words as well as ω-words has been studied extensively [22, 26, 8, 25, 27, 12, 17]. A survey of various characterisations of FO^2 is given in [25]. The quantifier alternation hierarchy on FO^2 was proved in [11] and the decidability of the hierarchy was shown in [12].

Satisfiability of FO^2 over arbitrary structures were shown to be NEXPTIME-complete in [10]. The corresponding results (also NEXPTIME-complete) was shown for ω-words in [8], and for ordinals in [15]. More recently the satisfiability problem was studied for words with additional linear orderings/preorderings [3, 23, 14, 13].

Satisfiability of LTL over countable linear orderings is PSPACE-complete [7, 19].

Contributions

We study the two variable fragment of first order logic over countable linear orderings and give a number of different characterisations. The simplest characterisation is in terms of temporal logic (TL): FO^2 is equivalent to TL with only the modalities *Future* ($\mathtt{F}$) and *Past* ($\mathtt{P}$). Our major contribution is an algebraic characterisation for FO^2. We show that it corresponds to a subclass of $\circ$-monoids and give two algebraic characterisations for this subclass: (1) by equations, and (2) as the class of $\circ$-monoids that are aperiodic and whose regular $\mathcal{J}$ classes are sub $\circ$-monoids. It follows that the membership in the class is decidable.

Next we study the satisfiability problem for FO^2 over countable linear orderings. The models of FO^2 formulas could be infinite, but we show that a satisfiable formula always admits a scattered model that has a finite representation of small (exponential in the size of the formula) size. Thus we prove that the satisfiability of FO^2 over countable linear orderings is NEXPTIME-complete. From this we also deduce that the satisfiability problems for FO^2 over arbitrary and scattered orderings are NEXPTIME-complete.

Structure of the paper

In Section 2, we introduce words over countable linear orderings, two-variable first-order logic, and the algebra required to characterise FO^2, namely $\circ$-monoids. In Section 3 we prove our main result (Theorem 8) which characterises FO^2. Section 4 deals with the satisfiability of FO^2 over countable linear orderings. Finally we conclude our results in Section 5.

2 Preliminaries

In this section we recall the basic facts about (countable) linear orderings, $\circ$-monoids, logics and related notions.

Words over countable linear orderings. A *linear ordering* $\alpha = (Z, <)$ is a set Z equipped with a total order $<$. For $X, Y \subseteq Z$ we write $X < Y$ if $x < y$ for each x in X and y in Y. In particular $\emptyset < X < \emptyset$ for any set X. Also if $X < Y$, $Y < Z$ and Y is nonempty, then

$X < Z$. A *cut* of the linear ordering α is a pair (Z_1, Z_2) such that $Z = Z_1 \cup Z_2$ and $Z_1 < Z_2$. The set of all cuts are linearly ordered and has the least upper bound property [2]. A set L is a *prefix* of X if $X = L \cup K$ and $L < K$ for some $K \subseteq X$. Similarly if $X = L \cup K$ and $L < K$, then K is a *suffix* of X. Element $z \in Z$ is an *upperbound* (*resp. lowerbound*) of a set $X \subseteq Z$ if $x \leq z$ (*resp.* $z \leq x$) for each x in X. A set X is *right-open* (*resp. left-open*) if it has no maximum element (*resp.* minimum element). Nonempty suffixes of right-open sets are right-open and nonempty prefixes of left-open sets are left-open. The set X is *dense* if between any two elements in the set there is another element; set X is *scattered* if it has no dense subsets. An ordering is a *countable* (scattered) linear ordering if the set Z is countable (scattered). See [20] for further details.

For a finite alphabet A and a linear ordering $\alpha = (Z, <)$, we define a *word* $w : \alpha \to A$ to be a mapping from the set Z to A. We call α the *domain* of w, $dom(w)$. For a word w, we say a point/position x to denote an element $x \in dom(w)$. The notation $w[x]$ denote the letter at the x^{th} position in w. A word has a minimal (respectively maximal) element if its domain has a minimal (maximal) element. The word u is a suffix (prefix) of w if $dom(u)$ is a suffix (prefix) of $dom(w)$. If u and v are words, then uv denotes the unique word w such that $(dom(u), dom(v))$ is a cut of $dom(w)$. This operation is naturally extended to a set of words $\{w_i\}_\alpha$ indexed by a linear ordering α as $\prod_{i\in\alpha} w_i$ (see [6] for more details). For a set $S \subseteq A$, and a word w, we denote the restriction of w to the positions labelled by S as $w_{|S}$. That is $w_{|S} = \{i \in dom(w) \mid w[i] \in S\}$.

The following words are of special interest. ϵ stands for the empty word (the word over an empty domain). The word $\{a\}^\omega$ (denoted in short as a^ω) denotes the word over the domain $(\mathbb{N}, <)$ such that every position is mapped to the letter a. Similarly a^{ω^*} denotes the word over the domain $(\mathbb{N}^-, <)$ where every position is mapped to letter a. A *perfect shuffle* over a nonempty set $S \subseteq A$ of letters, denoted by S^η, is the word over domain $(\mathbb{Q}, <)$ such that any nonempty open interval contains each of the letters in S. This is a unique word (up to isomorphism) (see [4]) and is an example of a dense word, i.e. a word whose domain is dense.

For an alphabet A, the set of all words over nonempty countable domains is denoted by A°. For a word w, we define *alphabet*(w) to be the set of all letters in w. A *language* over the alphabet A is a subset of A°. The language $\{a\}^\infty \subseteq \{a\}^\circ$ (or written as a^∞) denotes all words which are right open. Similarly for a set $S \subseteq A$, the language S^∞ is the set of all words whose letters come only from S and any letter from S can be seen arbitrarily towards the right. The sets $a^{-\infty}$ and $S^{-\infty}$ are defined analogously.

Circle monoids and algebras. A $\circ$-*semigroup* $\mathbf{M} = (M, \pi)$ consists of a set M with an operation $\pi : M^\circ \to M$ which satisfies the following two properties (1) $\pi(a) = a$ for all $a \in M$, (2) *generalised associativity property* – that is $\pi\big(\prod_{i\in\alpha} u_i\big) = \pi\big(\prod_{i\in\alpha} \pi(u_i)\big)$ for every countable linear ordering α. If $\mathbf{M}$ has an identity element, then it is called a $\circ$-*monoid*. An element $e \in \mathbf{M}$ is an *idempotent* if $\pi(ee) = e$.

For the rest of the paper, we assume that the monoid $\mathbf{M}$ is finite, that is M is a finite set. The product π is over countable linear orderings and hence it is not possible to finitely represent π. Fortunately, we are able to represent this by a $\circ$-algebra that uses only finite sets and finitely many operations. The following operations are derivable from a $\circ$-monoid $\mathbf{M} = (M, \pi)$:

- *Finite product*, $\cdot : M^2 \to M$ such that $\cdot(a, b) = \pi(ab)$
- *Omega*, $\omega : M \to M$ such that $\omega(a) = \pi(a^\omega)$
- *Omega**, $\omega^* : M \to M$ such that $\omega^*(a) = \pi(a^{\omega^*})$
- *Shuffle*, $\eta : \mathcal{P}(M) \to M$ such that $\{a_1, \ldots, a_k\}^\eta = \pi(\{a_1, \ldots, a_k\}^\eta)$

The resulting structure $(M, \cdot, \omega, \omega^*, \eta)$ is called a $\circ$-*algebra* if it satisfies some additional axioms relating the operations (for example $a \cdot a^\omega = a^\omega$, $(a^\eta)^\omega = a^\eta$ etc.). We skip these details and refer the reader to the paper by Carton et. al [4] for a detailed discussion. The relavant fact is that, for any $\circ$-monoid there exists a unique $\circ$-algebra and vice versa [4].

An important "tool" to understand finite monoids (in our case $\circ$-monoids) is *Green's relations*. In a $\circ$-monoid $\mathbf{M}$, we say that two elements $u \geq_{\mathcal{J}} v$ if there exists two elements $x, y \in \mathbf{M}$ such that $v = xuy$ and $u\mathcal{J}v$ (called J equivalent) if it is both $u \geq_{\mathcal{J}} v$ and $v \geq_{\mathcal{J}} u$. We also say that two elements are $u \geq_{\mathcal{R}} v$ (similarly $u \geq_{\mathcal{L}} v$) if there exists an element $x \in \mathbf{M}$ such that $v = ux$ $(v = xu)$. Also $u\mathcal{R}v$ if $u \geq_{\mathcal{R}} v$ and $v \geq_{\mathcal{R}} u$. Similarly we can define $u\mathcal{L}v$. The relations $\mathcal{L}$ and $\mathcal{R}$ are right and left congruences respectively. If a $\mathcal{J}$ class contains an idempotent then it is called a *regular* $\mathcal{J}$ class. All elements in a $\mathcal{J}$ class can be described by an "eggbox" structure, such that $u\mathcal{J}v$ iff there exists elements $x, y \in \mathbf{M}$ such that $u\mathcal{R}x\mathcal{L}y\mathcal{R}v$. For a more detailed elaboration on this subject see [16].

The class of $\circ$-monoids that satisfies the property – there exists an $n \in \mathbb{N}$ such that $a^n = a^{n+1}$ for all $a \in \mathbf{M}$ – are called *aperiodic*. It is precisely the class of $\circ$-monoids which do not contain any non-trivial group as a subsemigroup of $(M, \cdot)$ (by Schützenberger's theorem [21]).

One way to denote a class of $\circ$-monoids is by equations. For instance, we say that $\mathbf{M}$ satisfies the equation $x^* = x^\omega x^{\omega^*}$, if for all elements $a \in \mathbf{M}$, $a^* = a^\omega a^{\omega^*}$, where a^* is the unique idempotent power of a.

We say that a language $L \subseteq A^\circ$ is recognised by the $\circ$-monoid $\mathbf{M}$, if there is a morphism, $\gamma : A^\circ \to \mathbf{M}$ and a subset $S \subseteq \mathbf{M}$ such that $L = \gamma^{-1}(S)$. The *syntactic* $\circ$-*monoid* of a language L is the minimal $\circ$-monoid $\mathbf{M}$ recognising L that has the following universal property: any $\circ$-monoid recognising L has a morphism onto $\mathbf{M}$.

Logics. Monadic second-order logic (MSO) over a finite alphabet A is a logic which can be inductively built using the following operations.

$$a(x) \mid x < y \mid x = y \mid \alpha_1 \vee \alpha_2 \mid \neg\alpha \mid x \in X \mid \exists x\ \alpha \mid \exists X\ \alpha$$

Here $a \in A$. If we remove the second-order quantification, we get first-order logic (FO). If we further restrict the logic to use only two variables (but allowing repetitions) we get FO^2. Note that, we do not have the *successor* relation in our logic.

A formula with no free variables is called a sentence. The language of a sentence φ (denoted by $L(\varphi)$) is the set of all $u \in A^\circ$ that satisfies φ.

Over finite words, FO^2 can talk about occurrence of letters and also about the order in which they appear [8, 27]. Over countable linear orders, FO^2 can also talk about an infinite sequence of a letter. For example, the language a^∞ is definable in FO^2 by stating that, every position is labelled by a and there is no maximum position.

$$\big(\forall x\ \exists y > x\big) \wedge \big(\forall x\ a(x)\big)$$

Also, for a subset $S \subseteq A$, we can also express the language S^∞ in FO^2.

$$\big(\forall x \bigwedge_{a \in S} \exists y > x\ a(y)\big) \wedge \big(\forall x \bigvee_{a \in S} a(x)\big)$$

Analogously, FO^2 can also talk about left open words.

The temporal logic $\{\mathtt{F},\mathtt{P}\}$-TL over the alphabet A is the logic with the set of formulas – a when a is a letter in A, and $\mathtt{F}\varphi$ and $\mathtt{P}\varphi$ when φ is a formula – that is closed under Boolean operations. To state the semantics fix a word $u \in A^\circ$. A position $i \in dom(u)$ satisfies – the formula a if i is labelled with the letter a, and the formula $\mathtt{F}\varphi$ (*resp.* $\mathtt{P}\varphi$) if there is a position $i < j \in dom(u)$ (*resp.* $i > j \in dom(u)$) that satisfies the formula φ. The semantics for Boolean connectives are defined in the usual way. The word u satisfies the formula φ if there is a position $i \in dom(u)$ that satisfies the formula (see [8] for a detailed presentation). The language of the formula φ is the set of all $u \in A^\circ$ that satisfies φ.

3 Characterisation

In this section, we give the algebraic characterisation for FO^2($<$) over countable linear orderings. As we noted earlier, $\circ$-monoid captures MSO. Here we identify a subclass which will capture the two-variable first-order fragment. Our characterisation builds on the characterisation for FO^2 on finite words given in [26]. In particular, we crucially use a generalisation of the congruence given there.

▶ **Definition 1.** We define $\circ$-DA to be the subclass of $\circ$-monoids that satisfy the following equations.

1. $(xyz)^* y (xyz)^* = (xyz)^*$
2. $x^* = (x)^\omega (x)^{\omega^*}$
3. $\{x_1, \ldots, x_k\}^\eta = (x_1 \cdots x_k)^{\omega^*} (x_1 \cdots x_k)^\omega$

The first equation corresponds to the variety DA of finite monoids [25]. It identifies the constraints the product operation has to satisfy. The second equation corresponds to FO definable languages of countable linear orderings [6]. This equation states that a $\mathcal{J}$ class with an idempotent will also contain its omega and omega* powers. The last equation says that, $\circ$-DA cannot differentiate between dense and scattered orderings.

The connection between logic and algebra is established using the following congruence.

A congruence on words

Let $u \in A^\circ$ be an arbitrary word. *alphabet*(u) is defined as the set of all letters occurring in u. For a letter a in *alphabet*(u), let $P_u(a)$ denote the set of all positions in u labelled with a. Let $T_r^1(u) \subseteq alphabet(u)$ be the set of all letters a such that $P_u(a)$ has a maximal element. Furthermore, let $T_r^\omega(u)$ be the set $alphabet(u) \setminus T_r^1(u)$, i.e. the set of all letters that do not have a maximal occurrence. Similarly let $T_l^1(u) \subseteq alphabet(u)$ be the set of all letters a such that $P(a)$ has a minimal element, and let $T_l^{\omega^*}(u)$ be the set $alphabet(u) \setminus T_l^1(u)$.

▶ **Definition 2.** The relation $\lesssim_r$ over the set of letters $T_r^\omega(u)$ is defined as follows:

$a \lesssim_r b$ if each a-position i in u has a b-position j to its right (i.e. $j > i$).

▶ **Lemma 3.** *The relation $\lesssim_r$ is a total preorder on the set $T_r^\omega(u)$.*

We write $\sim_r$ to denote the equivalence relation associated with the preorder $\lesssim_r$. For a letter a in $T_r^\omega(u)$ we let $[a]_r \subseteq T_r^\omega(u)$ denote the equivalence class of a with respect to the total preorder $\lesssim_r$, i.e. $[a]_r = \{b \in T_r^\omega(u) : b \sim_r a\}$. Also, we extend the definition of P_u to equivalence classes by defining $P_u([a]_r) = \bigcup_{a \in [a]_r} P_u(a)$. We write $<_r$ to denote the total order on $\{[a]_r : a \in T_r^\omega(u)\}$.

By symmetry, the dual relation $\lesssim_l$ defined as,

$b \lesssim_l a$ if each a-position in u has a b-position to its left, is also a total preorder. The corresponding equivalence relation and strict order relation are denoted as $\sim_l$ and $<_l$. Given a circle word u the preorders $\lesssim_r$ and $\lesssim_l$ associated with u are called the *right preorder* and *left preorder* of u respectively. As before we define $P_u([a]_l) = \bigcup_{a \in [a]_l} P_u(a)$.

▶ **Example 4.** Let $S = \{a, b\}$ and let $u \in S^{-\infty}$ be an arbitrary word. Consider the word $v = ua^{\omega^*}a^\omega ab^\omega \in \{a, b\}^\circ$. Then $T_l^1(u) = T_l^1(v) = \emptyset$ and $T_l^{\omega^*}(u) = T_l^{\omega^*}(v) = \{a, b\}$, since a and b occur infinitely often towards left in both u and v. It also follows that $a \lesssim_l b$ and $b \lesssim_l a$. Since u is an arbitrary word, we do not know about $T_r^1(u)$ and $T_r^\omega(u)$. But, since a has a maximum point in v, we have $T_r^1(v) = \{a\}$ and $T_r^\omega(v) = \{b\}$. Moreover $b \lesssim_r b$.

Consider another word $w = a^\omega b^\omega$. Here we have $T_l^1(w) = \{a, b\}$ and $T_l^{\omega^*}(w) = T_r^1(w) = \emptyset$. We also have $T_r^\omega(w) = \{a, b\}$ and $a \lesssim_r b$ but $b \not\lesssim_r a$.

We will now introduce left/right decomposition of words. The idea is to factorise a word in a particular way to capture the "pivot" points for an FO^2 formula.

▶ **Definition 5.** Let $a \in \mathit{alphabet}(u)$. If $a \in T_l^1(u)$, then there exists a unique factorisation of u as (u_0, a, u_1) such that $u = u_0 a u_1$ and $a \notin \mathit{alphabet}(u_0)$. This is called the a-left decomposition of u. Similarly there is a unique factorisation of u as (u_0, a, u_1) such that $a \notin \mathit{alphabet}(u_1)$, if $a \in T_r^1(u)$. This is called the a-right decomposition of u.

We are also interested in left decomposition obtained by a set of positions $P_u([a]_l)$, where $[a]_l \in T_l^{\omega^*}(u)/\sim_l$. That is for a subset of positions $P_u([a]_l)$ of u, we define the $P_u([a]_l)$*-left decomposition of a word* u to be the unique maximal cut (u_0, u_1) such that $P_u([a]_l) \cap \mathit{dom}(u_0) = \emptyset$. Note that if $S = \{b \mid b \sim_l a\}$, then there is a prefix of u_1 such that $u_1 \in S^{-\infty}$. This follows from the fact that, the decomposition (u_0, u_1) is a maximal cut. Similarly the $P_u([a]_r)$*-right decomposition of a word* u is defined to be the unique minimal cut (u_0, u_1) such that $P_u([a]_r) \cap \mathit{dom}(u_1) = \emptyset$.

With the left/right decomposition defined, we can define the *congruence on words*, $\equiv_n$ which essentially captures a sequence of unique decompositions.

▶ **Definition 6.** For an alphabet A, a natural number $n \in \mathbb{N}$ and words $u, v \in A^\circ$, we define $u \equiv_n v$ by induction on $m = n + |A|$ as follows.

1. If $n = 0$ (the base case): $u \equiv_0 v$ for all $u, v \in A^\circ$.
2. If $n > 0$: We say $u \equiv_n v$ if the following conditions are satisfied:
   a. $\mathit{alphabet}(u) = \mathit{alphabet}(v)$, $T_r^1(u) = T_r^1(v)$, and $T_l^1(u) = T_l^1(v)$. (This condition implies that $T_r^\omega(u) = T_r^\omega(v)$ and $T_l^{\omega^*}(u) = T_l^{\omega^*}(v)$).
   b. The right preorders of u and v (both on the same set by the previous observation) are the same. Similarly the left preorders of u and v are the same. (We denote the left and right preorders as $\lesssim_l, \lesssim_r$ respectively).
   c. For each $a \in T_l^1(u) = T_l^1(v)$, let (u_0, a, u_1) be the a-left decomposition of u, and let (v_0, a, v_1) be the a-left decomposition of v, then $u_0 \equiv_n v_0$ and $u_1 \equiv_{n-1} v_1$. Note that the induction parameter has reduced in both cases: u_0 has at least one letter less than u; and we have a lesser congruence in u_1.
   d. Similarly, for each $a \in T_r^1(u) = T_r^1(v)$, let (u_0, a, u_1) be the a-right decomposition of u and let (v_0, a, v_1) be the a-right decomposition of v, then $u_0 \equiv_{n-1} v_0$ and $u_1 \equiv_n v_1$.
   e. For each class $[a]_l \in T_l^{\omega^*}(u)/\sim_l = T_l^{\omega^*}(v)/\sim_l$, let (u_0, u_1) be the $P_u([a]_l)$-left decomposition of u and let (v_0, v_1) be the $P_v([a]_l)$-left decomposition of v, then $u_0 \equiv_n v_0$ and $u_1 \equiv_{n-1} v_1$. Again, the induction parameter has reduced in both cases: u_0 has at least one letter less than u; and we have a lesser congruence in u_1.

f. Similarly for each class $[a]_r \in T^\omega_r(u)/\sim_r = T^\omega_r(v)/\sim_r$, let (u_0, u_1) be the $P_u([a]_r)$-right decomposition of u and let (v_0, v_1) be the $P_v([a]_r)$-right decomposition of v, then $u_0 \equiv_{n-1} v_0$ and $u_1 \equiv_n v_1$.

▶ **Lemma 7.** *The relation $\equiv_n$ is a congruence relation for every $n \in \mathbb{N}$.*

Main theorem

We are now in a position to state our main theorem.

▶ **Theorem 8.** *Let $L \subseteq A^\circ$. Then the following are equivalent:*
1. *L is definable in $\{\mathtt{F}, \mathtt{P}\}$-TL.*
2. *L is $\mathrm{FO}^2(A, \leq)$ definable.*
3. *L is a union of $\equiv_n$ congruent classes for some $n \in \mathbb{N}$.*
4. *L is recognised by a $\circ$-DA.*
5. *L is recognised by an aperiodic $\circ$-monoid where all regular $\mathcal{J}$ classes are sub $\circ$-monoids.*
6. *The syntactic $\circ$-monoid of L is in $\circ$-DA.*

The proof of $(1 \Leftrightarrow 2)$ follows easily (see [8, 7]).
In subsection 3.1 we show the equivalence of the different monoid views $(4 \Leftrightarrow 5 \Leftrightarrow 6)$.
In subsection 3.2 we show $(4 \Rightarrow 3)$.
To prove $(2 \Rightarrow 4)$, we use 2-pebble *Ehrenfeucht-Fraïssé* (EF) games [26]. The EF game gives a game congruence $\cong_n$ defined as: $u \cong_n v$ if the duplicator wins the n-round 2-pebble game on the pair of words (u, v). See [26] for the game congruence and its equivalence to FO^2. Thus it suffices to show that the game congruence satisfies the equations of $\circ$-DA.
To show direction $(3 \Rightarrow 2)$ we follow the proof in [26]. It suffices to show that if $L \subseteq A^\circ$ is a union of $\equiv_n$ congruent classes for some n, then it is definable in $\mathrm{FO}^2(<)$. More precisely we prove the following lemma (again using the equivalence of game congruence $\cong_n$ and FO^2).

▶ **Lemma 9.** *For words $u, v \in A^\circ$, If $u \not\equiv_n v$, then $u \not\cong_{n+alphabet(u)} v$ i.e. the spoiler has a winning strategy in the 2-pebble $n + alphabet(u)$-round EF game on u and v.*

Since the syntactic $\circ$-monoid (and its finite representation using $\circ$-algebra) is computable given an MSO formula [4], it follows that it is decidable to check whether the language is FO^2 definable.

▶ **Corollary 10.** *For a sentence ϕ in MSO$[<]$, it is decidable whether $L(\phi)$ is FO$^2[<]$ definable.*

In the next subsection we show the equivalence of the different monoid views. The subsection after that shows that if a language is accepted by a $\circ$-monoid, then it is a union of congruence classes $\equiv_n$ for some $n \in \mathbb{N}$.

3.1 The different Monoid views

In this subsection we show that the different views of $\circ$-DA are equivalent. That is, $(4 \Leftrightarrow 5 \Leftrightarrow 6)$ of Theorem 8. The direction $(4 \Rightarrow 5)$, follows from standard ideas in semigroup theory and the reverse direction $(5 \Rightarrow 4)$, follows from the below lemma:

▶ **Lemma 11.** *Let $\mathbf{M}$ be an aperiodic $\circ$-monoid such that all regular $\mathcal{J}$ classes of $\mathbf{M}$ are sub $\circ$-monoids. Let $\gamma : A^\circ \to \mathbf{M}$ be a morphism and $u \in A^\circ$, such that $\gamma(u) = e$ an idempotent. Then, for all words $v \in \{alphabet(u)\}^\circ$, we have $\gamma(uvu) = \gamma(u)$.*

To prove direction $(4 \Rightarrow 6)$, assume L is recognised by a monoid in $\circ$-DA. Since, $\circ$-DA is closed under quotienting, it follows that the syntactic monoid of L satisfies the equations of $\circ$-DA (see [6] for more details about syntactic congruence and monoids).

3.2 Algebra to Congruence

In this subsection we show direction $(4 \Rightarrow 3)$ of Theorem 8. The proof improves on the equivalence of the congruence and algebra given in [26]. We show that a language recognisable by a $\circ$-monoid in $\circ$-DA, satisfies the congruence relation $\equiv_n$ for some $n \in \mathbb{N}$. Let L be recognised by the morphism $\gamma : A^\circ \to \mathbf{M}$, where $\mathbf{M}$ is in $\circ$-DA. It suffices to show that there exists an $n \in \mathbb{N}$ such that $\equiv_n$ is a finer congruence than the monoid congruence. That is for $u, v \in A^\circ$, if $u \equiv_n v$, then $\gamma(u) = \gamma(v)$. Since $\mathbf{M}$ is an aperiodic monoid (follows from equations of $\circ$-DA) it is sufficient to show that $u\mathcal{R}v$ and $u\mathcal{L}v$.

The left/right decomposition of words are closely related to how the $\mathcal{R}$ classes fall in the word. The following definition identifies a sequence of $\mathcal{R}$-smooth factors (those factors where there is no $\mathcal{R}$ fall), and the subsequent lemma shows there exists such a unique sequence.

▶ **Definition 12.** Let $\gamma : A^\circ \to \mathbf{M}$. Let $w \in A^\circ$. Then the $\mathcal{R}$ decomposition of w is defined as the sequence $(w_0, a_1, w_1, a_2, \ldots, a_k, w_k)$ such that

1. $a_i \in A \cup \{\epsilon\}$ and $w_i \in A^*$, for all $i \leq k$.
2. $w = w_0 a_1 \ldots a_k w_k$.
3. For each $0 < i \leq k$, if a_i is empty, then the following conditions hold:
   - **a.** w_i does not have a left end point.
   - **b.** $(w_0 a_1 \ldots a_i w_i')$ $\mathcal{R}$ $\gamma(w_0 a_1 \ldots a_i w_i)$, for all nonempty prefix w_i' of w_i.
   - **c.** $\gamma(w_0 a_1 \ldots w_{i-1})$ $\not\mathcal{R}$ $\gamma(w_0 a_1 \ldots w_{i-1} a_i w_i)$.
4. For each $0 < i \leq k$, if a_i is not empty, then the following holds:
   - **a.** $\gamma(w_0 a_1 \ldots a_i)$ $\mathcal{R}$ $\gamma(w_0 a_1 \ldots a_i w_i)$.
   - **b.** $\gamma(w_0 a_1 \ldots w_{i-1})$ $\not\mathcal{R}$ $\gamma(w_0 a_1 \ldots w_{i-1} a_i)$.

▶ **Lemma 13.** *Let $w \in A^\circ$ be an arbitrary word. Then, there is a unique $\mathcal{R}$ decomposition $(w_0, a_1, \ldots, a_k, w_k)$ of w.*

The following Lemma connects $\mathcal{R}$ decompositions and left decompositions.

▶ **Lemma 14.** *Let $(w_0, a_1, \ldots, a_k, w_k)$ be the $\mathcal{R}$ decomposition of w. Then, for each $0 < i \leq k$,*

1. *If a_i is not empty, then $a_i \notin alphabet(w_{i-1})$.*
2. *If a_i is empty, then there exists an $a \notin alphabet(w_{i-1})$ such that $a \in T_l^{\omega^*}(w_i')$ for all nonempty prefix w_i' of w_i.*

We are now in a position to prove our claim.

Proof of Theorem 8, $(4 \Rightarrow 3)$**.** We show that if $u \equiv_m v$ for a sufficiently large m (depending only on $alphabet(u)$ and $\mathbf{M}$), then $\gamma(u)\mathcal{R}\gamma(v)$. The $\mathcal{L}$ equivalence can be shown symmetrically. As discussed in the beginning, this proves our claim. Our induction hypothesis is as follows:

$$\text{If } u \equiv_m v \text{ for an } m > |alphabet(u)| \times |\mathbf{M}|, \text{ then } \gamma(u) = \gamma(v).$$

The base case, when $m = 0$ is clearly true, since $u = v = \epsilon$ (note that, in this case $alphabet(u) = \emptyset$). Let us now consider the inductive step, for $m > 0$, we have $u \equiv_m v$. Our aim is to show that $\gamma(u) = \gamma(v)$. Consider the $\mathcal{R}$ decomposition of $u = (u_0, a_1, u_1, \ldots, a_k, u_k)$. We give a sequence $v = (v_0, a_1, v_1, \ldots, a_k, v_k)$ such that $\gamma(u_i) = \gamma(v_i)$ for all $i < k$ and hence $\gamma(u) \geq_\mathcal{R} \gamma(v)$.

Define $u_i' = u_i a_{i+1} \ldots u_k$, for all $i \leq k$. We do the following procedure for i ranging from $1, 2, \ldots, k$. During every iteration of i, we give v_i', a suffix of v_i such that the invariant $u_i' \equiv_{m-i} v_i'$ is maintained. To start the iteration we set $v_0' = v$ and $u_0' \equiv_m v_0'$

1. If a_i is non empty, then (u_{i-1}, a_i, u'_i) is the a_i-left decomposition of the word u'_{i-1} (follows from Lemma 14). Since $(u'_{i-1} \equiv_{m-(i-1)} v'_{i-1})$, there exists an a_i-left decomposition of $v'_{i-1} = (v_{i-1}, a_i, v'_i)$ such that $u_{i-1} \equiv_{m-(i-1)} v_{i-1}$ and $u'_i \equiv_{m-i} v'_i$.
2. If a_i is empty, then (u_{i-1}, u'_i) is an $[a]_l$-left decomposition of the word u'_{i-1} for an $[a]_l \in T_l^{\omega^*}(u'_{i-1})/\sim_l$ (follows from Lemma 14). Since $(u'_{i-1} \equiv_{m-(i-1)} v'_{i-1})$, there exists an $[a]_l$-left decomposition of $v'_{i-1} = (v_{i-1}, v'_i)$ such that $u_{i-1} \equiv_{m-(i-1)} v_{i-1}$ and $u'_i \equiv_{m-i} v'_i$.

Assign $v_k = v'_k$ obtained at the end of iteration.

Note that $k \leq |\mathbf{M}|$. For an $i < k$, we have $|alphabet(u_i)| = |alphabet(v_i)| < |alphabet(u)|$ (from Lemma 14) and therefore $m-i > |alphabet(u_i)| \times |\mathbf{M}|$. Since $u_i \equiv_{m-i} v_i$ from induction hypothesis, it follows $\gamma(u_i) = \gamma(v_i)$, for all $i < k$. Therefore $\gamma(u_0 \dots a_k) = \gamma(v_0 \dots a_k)$.

It remains to show that $\gamma(u) \geq_{\mathcal{R}} \gamma(v)$. Depending on whether a_k is empty or not, we get the following cases.

1. If a_k is non empty, then $\gamma(u_0a_1 \dots a_ku_k) \ \mathcal{R} \ \gamma(u_0a_1 \dots a_k) = \gamma(v_0a_1 \dots a_k) \geq_{\mathcal{R}} \gamma(v)$. The first condition follows from the fact that the sequence $(u_0a_1 \dots u_k)$ is an $\mathcal{R}$ decomposition, and the second condition follows from the fact that $\gamma(u_i) = \gamma(v_i)$ for all $i < k$.
2. If a_k is empty, then $(u_0 \dots u_{k-1}, u_k)$ and $(v_0 \dots v_{k-1}, v_k)$ are both S-left decomposition for an $S \in T_l^{\omega^*}(u_i)/\sim_l$. Hence there are prefixes u'_k of u_k and v'_k of v_k such that $u'_k, v'_k \in S^{-\infty}$. From Lemma 11 we know that $\gamma(u'_k)\mathcal{R}\gamma(v'_k)$. Therefore, $\gamma(u_0a_1 \dots a_ku_k) \ \mathcal{R} \ \gamma(u_0a_1 \dots u'_k) \ \mathcal{R} \ \gamma(v_0a_1 \dots v'_k) \ \geq_{\mathcal{R}} \ \gamma(v_0a_1 \dots a_kv_k) = \gamma(v)$.

We now have $\gamma(u) \geq_{\mathcal{R}} \gamma(v)$. By a symmetric argument we get $\gamma(v) \geq_{\mathcal{R}} \gamma(u)$ and therefore $\gamma(u) \ \mathcal{R} \ \gamma(v)$. By $\mathcal{L}$-$\mathcal{R}$ symmetry, $\gamma(u) \ \mathcal{L} \ \gamma(v)$ and since $\mathbf{M}$ is aperiodic $\gamma(u) = \gamma(v)$. ◀

4 Satisfiability

In this section we address the satisfiability problem of two-variable logic over countable linear orderings. The rest of the section is devoted to the proof of the below theorem. Take note of the fact that in this section Σ denotes a set of unary predicates (and not an alphabet). Our models are words over the alphabet $\mathcal{P}(\Sigma)$.

▶ **Theorem 15.** *The following problems are* NEXPTIME*-complete: Satisfiability of* FO$^2(\Sigma, <)$ *over*
1. *arbitrary linear orderings,*
2. *countable linear orderings,*
3. *scattered linear orderings.*

First we deal with the hardness part of the theorem. By downward Löwenheim-Skolem theorem, every satisfiable first-order formula has a countable model, and therefore (1) reduces to (2). Similary by Lemma 16 (given below), if a two-variable logic formula has a countable model, then it has a scattered model. Therefore (2) reduces to (3). Secondly, satisfiability of FO$^2(\Sigma)$ over arbitrary structures already is NEXPTIME-hard [9], and therefore (1), (2) and (3) are NEXPTIME-hard.

Next we prove that (2) and (3) are in NEXPTIME. The idea is to show that for any satisfiable formula there is a model of a particular form that admit at most exponentially big (in the size of the formula) description.

Let φ be a FO$^2(\Sigma, <)$ formula. Using standard ideas we obtain a formula $\varphi' \in$ FO$^2(\Sigma', <)$ in Scott normal form, i.e.

$$\varphi' = \forall x \forall y \, \psi(x, y) \wedge \bigwedge_i \forall x \exists y \, \chi_i(x, y) \, , \tag{1}$$

where $\Sigma' \supseteq \Sigma$, $|\Sigma'| = |\Sigma| + \mathcal{O}(|\varphi|)$, $|\varphi'| = \mathcal{O}(|\varphi|)$, $\psi(x, y)$ and $\chi_i(x, y)$ are quantifier free, such that φ and φ' are equisatisfiable (one is satisfiable if and only if the other is satisfiable). More precisely, the sets of models of φ and φ' are isomorphic upto the erasure of the unary predicates $\Sigma' \setminus \Sigma$.

We introduce some notation. Given a set of unary predicates P, we define a unary type over P to be a maximal conjunction of literals (i.e. $U(x)$ or $\neg U(x)$ where U is a unary predicate in P) over the same variable that is satisfiable. When the set P is clear from the context we just use types to refer to the unary types over P. We write $\mathrm{tp}(P)$ to denote the types over the predicates P. Each position of a $\circ$-word satisfies exactly one type, called the *type of the position.* Models of φ' are $\circ$-words over the alphabet $\mathrm{tp}(\Sigma')$.

Next we prove that formulas φ' in Scott normal form possess particular kind of models.

▶ **Lemma 16.** *If φ' is satisfiable, then it has a model of the form $u_1^{\lambda_1} \cdots u_n^{\lambda_n}$ where $n \geq 1$ is a natural number, for each $1 \leq i \leq n$, u_i is a finite word over the alphabet $\mathrm{tp}(\Sigma')$ and λ_i is in $\{1, \omega, \omega^*\}$, such that*

1. *every type occurs at most once in each u_i, and*
2. *every type occurs in at most two u_i's.*

A model of the form $u = u_1^{\lambda_1} \cdots u_n^{\lambda_n}$ is finitely represented as a sequence of pairs $(u_1, \lambda_1) \cdots (u_n, \lambda_n)$. Lemma 16 guarantees that for every satisfiable formula φ' there is a representation of size at most $3 \cdot \mathrm{tp}(\Sigma) \leq 3 \cdot 2^{|\varphi'|}$.

▶ **Lemma 17.** *Given a sequence of pairs $(u_1, \lambda_1) \cdots (u_n, \lambda_n)$ and a formula φ' checking if the $\circ$-word $u_1^{\lambda_1} \cdots u_n^{\lambda_n}$ satisfies the formula φ in Scott normal form is in* PTIME.

To complete the proof of the Theorem 15 we describe a NEXPTIME algorithm for FO^2 formulas over countable linear orders: The algorithm converts the input formula to Scott normal form and guesses an atmost exponentially large representation of a model of the form described by Lemma 16 and checks that it is indeed a model by Lemma 17.

5 Conclusion

In this paper we characterised first-order logic with two variables over countable linear orderings. It is equivalent to a fragment of temporal logic and is characterised by a subclass of $\circ$-monoids, called $\circ$-DA. The class $\circ$-DA is the class of $\circ$-monoids whose regular $\mathcal{J}$ classes are sub $\circ$-monoids. We also proved an alternate characterisation of this class using equations and this yields decidability of membership in this class. Next we considered the satisfiability problem for FO^2 over arbitrary, countable and scattered linear orderings and showed that all the problems are NEXPTIME-complete.

Finally we note that FO^2 with order and *successor* relation (position $j > i$ is the successor of position i if there is no position between them) is strictly more powerful that FO^2 with only the order relation. To see this it is enough to note that a^ω and $a^\omega a^\omega$ are indistinguishable by any formula in the latter class, while there is a formula, namely "there is exactly one position without a predecessor" that separates them. We leave as future work the question of extending the characterisation in the present paper to handle the successor relation.

Piecewise Testable Languages and Nondeterministic Automata[*]

tomas.masopust@tu-dresden.de

Abstract

A regular language is k-piecewise testable if it is a finite boolean combination of languages of the form $\Sigma^* a_1 \Sigma^* \cdots \Sigma^* a_n \Sigma^*$, where $a_i \in \Sigma$ and $0 \le n \le k$. Given a DFA $\mathcal{A}$ and $k \ge 0$, it is an NL-complete problem to decide whether the language $L(\mathcal{A})$ is piecewise testable and, for $k \ge 4$, it is coNP-complete to decide whether the language $L(\mathcal{A})$ is k-piecewise testable. It is known that the depth of the minimal DFA serves as an upper bound on k. Namely, if $L(\mathcal{A})$ is piecewise testable, then it is k-piecewise testable for k equal to the depth of $\mathcal{A}$. In this paper, we show that some form of nondeterminism does not violate this upper bound result. Specifically, we define a class of NFAs, called ptNFAs, that recognize piecewise testable languages and show that the depth of a ptNFA provides an (up to exponentially better) upper bound on k than the minimal DFA. We provide an application of our result, discuss the relationship between k-piecewise testability and the depth of NFAs, and study the complexity of k-piecewise testability for ptNFAs.

1 Introduction

A regular language L over an alphabet Σ is *piecewise testable* if it is a finite boolean combination of languages of the form

$$L_{a_1 a_2 \ldots a_n} = \Sigma^* a_1 \Sigma^* a_2 \Sigma^* \cdots \Sigma^* a_n \Sigma^*$$

where $a_i \in \Sigma$ and $n \ge 0$. If L is piecewise testable, then there exists a nonnegative integer k such that L is a finite boolean combination of languages L_u, where the length of $u \in \Sigma^*$ is at most k. In this case, the language L is called *k-piecewise testable*.

Piecewise testable languages are studied in semigroup theory [2, 3, 28] and in logic over words [10, 29] because of their close relation to first-order logic FO(<). They actually form the first level of the Straubing-Thérien hierarchy [27, 36]. This hierarchy is closely related to the dot-depth hierarchy [7], see more in [23]. They are indeed studied in formal languages and automata theory [20], recently mainly in the context of separation [29, 38]. Although the separability of context-free languages by regular languages is undecidable, separability by piecewise testable languages is decidable [9] (even for some non-context-free families). Piecewise testable languages form a strict subclass of star-free languages, that is, of the limit of the above-mentioned hierarchies or, in other words, of the languages definable by

[*] This work was supported by the by the German Research Foundation (DFG) in Emmy Noether grant KR 4381/1-1 (DIAMOND).

LTL logic. They are investigated in natural language processing [11, 30], in cognitive and sub-regular complexity [31], in learning theory [12, 21], and in databases in the context of XML schema languages [8, 14, 15]. They have been extended from words to trees [4, 13].

Recently, the complexity of computing the minimal k and/or bounds on k for which a piecewise testable language is k-piecewise testable was studied in [14, 19, 20], motivated by applications in databases and in algebra and logic. However, the knowledge of such a k that is either minimal or of reasonable size is of interest in many other applications as well, see, e.g., [24]. The complexity to test whether a piecewise testable language is k-piecewise testable was shown to be coNP-complete for $k \geq 4$ if the language is given as a DFA [19] and PSPACE-complete if the language is given as an NFA [25]. The complexity for DFAs and $k < 4$ is discussed in detail in [25]. The best upper bound on k known so far is given by the depth of the minimal DFA [20].

In this paper, we define a class of NFAs, called ptNFAs, that characterizes piecewise testable languages. This characterization is based on purely structural properties, therefore it is NL-complete to check whether an NFA is a ptNFA (Theorem 5). We show that the depth of ptNFAs also provides an upper bound on k-piecewise testability (Theorem 8) and that this new bound is up to exponentially lower than the one given by minimal DFAs (Section 3 and Theorem 15). We further show that this property does not hold for general NFAs, and that the gap between k-piecewise testability and the depth of NFAs can be arbitrarily large (Lemma 12). The opposite implication of Theorem 8 does not hold and a brief discussion is provided. We give a non-trivial application of our result in Section 5, where we also provide more discussion. Finally, in Section 6, we study the complexity of k-piecewise testability for ptNFAs.

The paper is organized as follows. Section 2 presents basic notions and definitions, fixes the notation, and defines the ptNFAs. Section 3 motivates and demonstrates Theorem 8 on a simple example. Section 4 then proves Theorem 8 and the related results. Section 5 provides a non-trivial application and further discussion. Section 6 recalls the known complexity results and studies the complexity of the related problems for ptNFAs. Section 7 concludes the paper.

2 Preliminaries and Definitions

We assume that the reader is familiar with automata theory, see, e.g., [1]. The cardinality of a set A is denoted by $|A|$ and the power set of A by 2^A. An alphabet, Σ, is a finite nonempty set; the elements of an alphabet are called symbols or letters. The free monoid generated by Σ is denoted by Σ^*. A word over Σ is any element of Σ^*; the empty word is denoted by ε. For a word $w \in \Sigma^*$, $\mathrm{alph}(w) \subseteq \Sigma$ denotes the set of all letters occurring in w, and $|w|_a$ denotes the number of occurrences of letter a in w. A language over Σ is a subset of Σ^*. For a language L over Σ, let $\overline{L} = \Sigma^* \setminus L$ denote the complement of L.

A *nondeterministic finite automaton* (NFA) is a quintuple $\mathcal{A} = (Q, \Sigma, \cdot, I, F)$, where Q is a finite nonempty set of states, Σ is an input alphabet, $I \subseteq Q$ is a set of initial states, $F \subseteq Q$ is a set of accepting states, and $\cdot : Q \times \Sigma \to 2^Q$ is the transition function that can be extended to the domain $2^Q \times \Sigma^*$ by induction. The language *accepted* by $\mathcal{A}$ is the set $L(\mathcal{A}) = \{w \in \Sigma^* \mid I \cdot w \cap F \neq \emptyset\}$. In what follows, we usually omit $\cdot$ and write simply Iw instead of $I \cdot w$.

A *path* π from a state q_0 to a state q_n under a word $a_1a_2 \cdots a_n$, for some $n \geq 0$, is a sequence of states and input symbols $q_0a_1q_1a_2 \ldots q_{n-1}a_nq_n$ such that $q_{i+1} \in q_i \cdot a_{i+1}$, for all $i = 0, 1, \ldots, n-1$. The path π is *accepting* if $q_0 \in I$ and $q_n \in F$. We use the notation

$q_0 \xrightarrow{a_1a_2\cdots a_n} q_n$ to denote that there exists a path from q_0 to q_n under the word $a_1a_2\cdots a_n$. A path is *simple* if all states of the path are pairwise distinct. The number of states on the longest simple path of $\mathcal{A}$, starting in an initial state, decreased by one (i.e., the number of transitions on that path) is called the *depth* of the automaton $\mathcal{A}$, denoted by $\mathit{depth}(\mathcal{A})$.

The NFA $\mathcal{A}$ is *complete* if for every state q of $\mathcal{A}$ and every letter a in Σ, the set $q \cdot a$ is nonempty, that is, in every state, a transition under every letter is defined.

Let $\mathcal{A} = (Q, \Sigma, \cdot, I, F)$ be an NFA, and let p be a state of $\mathcal{A}$. The sub-automaton of $\mathcal{A}$ induced by state p is the automaton $\mathcal{A}_p = (\mathit{reach}(p), \Sigma, \cdot_p, p, F \cap \mathit{reach}(p))$ with state p being the sole initial state and with only those states of $\mathcal{A}$ that are reachable from p; formally, $\mathit{reach}(p)$ denotes the set of all states reachable from state p in $\mathcal{A}$ and $\cdot_p$ is a restriction of $\cdot$ to $\mathit{reach}(p) \times \Sigma$.

The NFA $\mathcal{A}$ is *deterministic* (DFA) if $|I| = 1$ and $|q \cdot a| = 1$ for every state q in Q and every letter a in Σ. Then the transition function $\cdot$ is a map from $Q \times \Sigma$ to Q that can be extended to the domain $Q \times \Sigma^*$ by induction. Two states of a DFA are *distinguishable* if there exists a word w that is accepted from one of them and rejected from the other. A DFA is *minimal* if all its states are reachable and pairwise distinguishable.

Let $\mathcal{A} = (Q, \Sigma, \cdot, I, F)$ be an NFA. The reachability relation $\leq$ on the set of states is defined by $p \leq q$ if there exists a word w in Σ^* such that $q \in p \cdot w$. The NFA $\mathcal{A}$ is *partially ordered* if the reachability relation $\leq$ is a partial order. In other words, the automaton is acyclic, but self-loops are allowed. Therefore, partially ordered automata are sometimes also called acyclic automata. For two states p and q of $\mathcal{A}$, we write $p < q$ if $p \leq q$ and $p \neq q$. A state p is *maximal* if there is no state q such that $p < q$.

An NFA $\mathcal{A} = (Q, \Sigma, \cdot, I, F)$ can be turned into a directed graph $G(\mathcal{A})$ with the set of vertices Q, where a pair (p, q) in $Q \times Q$ is an edge in $G(\mathcal{A})$ if there is a transition from p to q in $\mathcal{A}$. For $\Gamma \subseteq \Sigma$, we define the directed graph $G(\mathcal{A}, \Gamma)$ with the set of vertices Q by considering all those transitions that correspond to letters in Γ. For a state p, let $\Sigma(p) = \{a \in \Sigma \mid p \in p \cdot a\}$ denote the set of all letters under which the NFA $\mathcal{A}$ has a self-loop in state p. Let $\mathcal{A}$ be a partially ordered NFA. If for every state p of $\mathcal{A}$, state p is the unique maximal state of the connected component of $G(\mathcal{A}, \Sigma(p))$ containing p, then we say that the NFA satisfies the *unique maximal state (UMS) property*.

An equivalent notion to the UMS property for minimal DFAs has been introduced in the literature. A DFA $\mathcal{A}$ over Σ is *confluent* if, for every state q of $\mathcal{A}$ and every pair of letters a, b in Σ, there exists a word w in $\{a, b\}^*$ such that $(qa)w = (qb)w$.

We adopt the notation $L_{a_1a_2\cdots a_n} = \Sigma^* a_1 \Sigma^* a_2 \Sigma^* \cdots \Sigma^* a_n \Sigma^*$ from [20]. For two words $v = a_1a_2\cdots a_n$ and $w \in L_v$, we say that v is a *subsequence* of w or that v can be *embedded* into w, denoted by $v \preccurlyeq w$. For $k \geq 0$, let $\mathit{sub}_k(v) = \{u \in \Sigma^* \mid u \preccurlyeq v, |u| \leq k\}$. For two words w_1, w_2, we define $w_1 \sim_k w_2$ if and only if $\mathit{sub}_k(w_1) = \mathit{sub}_k(w_2)$. Note that $\sim_k$ is a congruence with finite index.

The following is well known.

▶ **Fact 1** ([33]). *Let L be a regular language, and let $\sim_L$ denote the Myhill congruence [26]. A language L is k-piecewise testable if and only if $\sim_k \subseteq \sim_L$. Moreover, L is a finite union of $\sim_k$ classes.*

In what follows, we will use this fact in several proofs in the form that if L is not k-piecewise testable, then there exist two words u and v such that $u \sim_k v$ and $|L \cap \{u, v\}| = 1$.

▶ **Fact 2.** *Let L be a language recognized by the minimal DFA $\mathcal{A}$. The following is equivalent.*

1. *The language L is piecewise testable.*

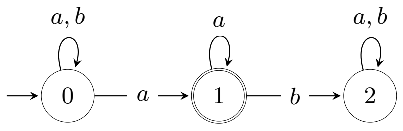

Figure 1 Confluent automaton accepting a non-piecewise testable language.

2. *The minimal DFA $\mathcal{A}$ is partially ordered and confluent [20].*
3. *The minimal DFA $\mathcal{A}$ is partially ordered and satisfies the UMS property [37].*

We now define a special class of nondeterministic automata called ptNFAs. The name comes from piecewise testable, since, as we show below, they characterize piecewise testable languages. And indeed include all minimal DFAs recognizing piecewise testable languages.

▶ **Definition 3.** An NFA $\mathcal{A}$ is called a *ptNFA* if it is partially ordered, complete, and satisfies the UMS property.

The reason why we use the UMS property in the definition of ptNFAs rather than confluence is simply because confluence does not naturally generalize to NFAs as shown in Example 4 below. Moreover, it is known that partially ordered NFAs characterize the level $\frac{3}{2}$ of the Straubing-Thérien hierarchy [32] and that partially ordered NFAs satisfying that $q \in q \cdot a$ implies $q \cdot a = \{q\}$ characterize $\mathcal{R}$-trivial languages [5, 22]. It can be shown that adding confluence and completeness on top of these properties results in ptNFAs.

▶ **Example 4.** Consider the automaton depicted in Figure 1. The notion of confluence is not clear for NFAs. If we consider the point of view that whenever the computation is split, a common state can be reached under a word over the splitting alphabet, then this automaton is confluent. However, it does not satisfy the UMS property and its language is not piecewise testable; there is an infinite sequence $a, ab, aba, abab, \ldots$ that alternates between accepted and non-accepted words, which implies that there is a non-trivial cycle in the corresponding minimal DFA and, thus, it proves non-piecewise testability by Fact 2.

Note that to check whether an NFA is a ptNFA requires to check whether the automaton is partially ordered, complete and satisfies the UMS property. The violation of these properties can be tested by several reachability tests, hence its complexity belongs to coNL=NL. On the other hand, to check the properties is NL-hard even for minimal DFAs [6]. Thus, we have the following.

▶ **Theorem 5.** *It is NL-complete to check whether an NFA is a ptNFA.*

3 Motivation and an Example

Considering applications, such as XML, where the alphabet can hardly be considered as fixed, the results of [19] (cf. Theorem 18 below) say that it is intractable to compute the minimal k for which a piecewise testable language is k-piecewise testable, unless P=NP. This leads to the investigation of reasonably small upper bounds. The result of [20] says that k is bounded by the depth of the minimal DFA. However, applications usually require to work with NFAs, which motivates the research of this paper. Another motivation comes from a simple observation that, given several DFAs, a result of an operation can lead to an NFA that in some sense still has the DFA-like properties, see more discussion below. Moreover, it seems to be a human nature to use a kind of nondeterminism, for instance, to reuse already defined parts as demonstrated here on a very simple example.

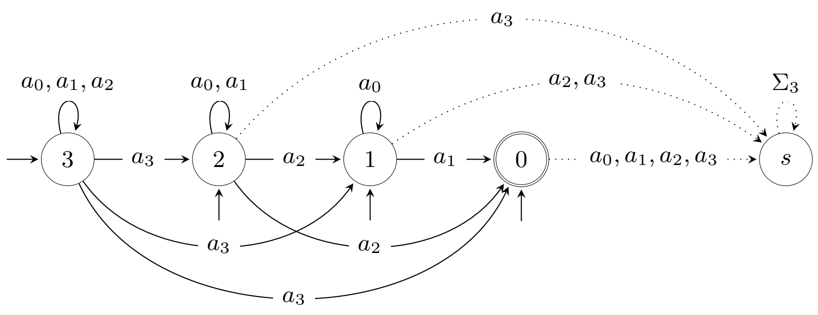

Figure 2 Automaton $\mathcal{A}_3$; the dotted transitions depict the completion of $\mathcal{A}_3$.

Let $L_0 = \{\varepsilon\}$ be a language over the alphabet $\Sigma_0 = \{a_0\}$. Assume that the language L_i over Σ_i is defined, and let $L_{i+1} = L_i \cup \Sigma_i^* a_{i+1} L_i$ over $\Sigma_{i+1} = \Sigma_i \cup \{a_{i+1}\}$, where a_{i+1} is a new symbol not in Σ_i. We now construct the NFAs for the languages L_i,

$$\mathcal{A}_i = (\{0, 1, \ldots, i\}, \{a_0, a_1, \ldots, a_i\}, \cdot, \{0, 1, \ldots, i\}, \{0\})$$

where $\ell \cdot a_j = \ell$ if $i \geq \ell > j \geq 0$ and $\ell \cdot a_\ell = \{0, 1, \ldots, \ell - 1\}$ if $i \geq \ell \geq 1$. The automaton $\mathcal{A}_3$ is depicted in Figure 2. The dotted transitions are to complete the NFA in the meaning that $\ell \cdot a \neq \emptyset$ for any state ℓ and letter a.

Although the example is very simple, the reader can see the point of the construction in nondeterministically reusing the existing parts.

Now, to decide whether the language is piecewise testable and, if so, to obtain an upper bound on its k-piecewise testability, a naive application of the known results for DFAs requires to compute the minimal DFA. Doing so shows that L_i is piecewise testable. However, the minimal DFA for the language L_i is of exponential size and its depth is $2^{i+1} - 1$, cf. [25], which implies that L_i is $(2^{i+1} - 1)$-piecewise testable. Another way is to use the PSPACE algorithm of [25] to compute the minimal k. Both approaches are basically of the same complexity.

This is the place, where our result comes into the picture. According to Theorem 8 proved in the next section, the easily testable structural properties say that the language L_i is $(i + 1)$-piecewise testable. This provides an exponentially better upper bound for every language L_i than the technique based on minimal DFAs. Finally, we note that it can be shown that L_i is not i-piecewise testable, so the bound is tight for L_i.

4 Piecewise Testability and Nondeterminism

In this section, we establish a relation between piecewise testable languages and nondeterministic automata and generalize the bound given by the depth of DFAs to ptNFAs. We first recall the known result for DFAs.

▶ **Theorem 6** ([20]). *Let $\mathcal{A}$ be a partially ordered and confluent DFA. If the depth of $\mathcal{A}$ is k, then the language $L(\mathcal{A})$ is k-piecewise testable.*

This result is currently the best known structural upper bound on k-piecewise testability. The opposite implication of the theorem does not hold and we have shown in [25] (see also Section 3) that this bound can be exponentially far from the minimal value of k.

This observation has motivated our investigation of the relationship between piecewise testability and the depth of NFAs. We have already generalized a structural automata characterization for piecewise testability from DFAs to NFAs as follows.

▶ **Theorem 7** ([25]). *A regular language is piecewise testable if and only if it is recognized by a ptNFA.*

We now generalize Theorem 6 to ptNFAs and discuss the relation between the depth of NFAs and k-piecewise testability in more detail. An informal idea behind the proof is that every ptNFA can be "decomposed" into a finite number of partially ordered and confluent DFAs. We now formally prove the theorem by generalizing the proof of Theorem 6 given in [20].

▶ **Theorem 8.** *If the depth of a ptNFA $\mathcal{A}$ is k, then the language $L(\mathcal{A})$ is k-piecewise testable.*

The proof of Theorem 8 follows directly from Lemmas 9 and 11 proved below.

▶ **Lemma 9.** *Let $\mathcal{A}$ be a ptNFA with I denoting the set of initial states. Then the language $L(\mathcal{A}) = \bigcup_{i\in I} L(\mathcal{A}_i)$, where every sub-automaton $\mathcal{A}_i$ is a ptNFA.*

Based on the previous lemma, it is sufficient to show the theorem for ptNFAs with a single initial state. We make use of the following lemma.

▶ **Lemma 10** ([20]). *Let $\ell \geq 1$, and let $u, v \in \Sigma^*$ be such that $u \sim_\ell v$. Let $u = u'au''$ and $v = v'av''$ such that $a \notin \mathrm{alph}(u'v')$. Then $u'' \sim_{\ell-1} v''$.*

▶ **Lemma 11.** *Let $\mathcal{A}$ be a ptNFA with a single initial state and depth k. Then the language $L(\mathcal{A})$ is k-piecewise testable.*

Proof. Let $\mathcal{A} = (Q, \Sigma, \cdot, i, F)$. If the depth of $\mathcal{A}$ is 0, then $L(\mathcal{A})$ is either $\emptyset$ or Σ^*, which are both 0-piecewise testable by definition. Thus, assume that the depth of $\mathcal{A}$ is $\ell \geq 1$ and that the claim holds for ptNFAs of depth less than ℓ. Let $u, v \in \Sigma^*$ be such that $u \sim_\ell v$. We prove that u is accepted by $\mathcal{A}$ if and only if v is accepted by $\mathcal{A}$.

Assume that u is accepted by $\mathcal{A}$ and fix an accepting path of u in $\mathcal{A}$. If $\mathrm{alph}(u) \subseteq \Sigma(i)$, then the UMS property of $\mathcal{A}$ implies that $i \in F$. Therefore, v is also accepted in i. If $\mathrm{alph}(u) \not\subseteq \Sigma(i)$, then $u = u'au''$ and $v = v'bv''$, where $u', v' \in \Sigma(i)^*$, $a, b \in \Sigma \setminus \Sigma(i)$, and $u'', v'' \in \Sigma^*$. Let $p \in i \cdot a$ be a state on the fixed accepting path of u. Let $\mathcal{A}_p = (\mathit{reach}(p), \Sigma, \cdot_p, p, F \cap \mathit{reach}(p))$ be a sub-automaton of $\mathcal{A}$ induced by state p. Note that $\mathcal{A}_p$ is a ptNFA. By assumption, $\mathcal{A}_p$ accepts u'' and the depth of $\mathcal{A}_p$ is at most $\ell - 1$.

If $a = b$, Lemma 10 implies that $u'' \sim_{\ell-1} v''$. By the induction hypothesis, u'' is accepted by $\mathcal{A}_p$ if and only if v'' is accepted by $\mathcal{A}_p$. Hence, $v = v'av''$ is accepted by $\mathcal{A}$.

If $a \neq b$, then $u = u'au_0''bu_1''$ and $v = v'bv_0''av_1''$, where $b \notin \mathrm{alph}(u'au_0'')$ and $a \notin \mathrm{alph}(v'bv_0'')$. Then

$$u'' = u_0''bu_1'' \sim_{\ell-1} v_0''av_1'' = v''$$

because, by Lemma 10,

$$\mathit{sub}_{\ell-1}(u_0''bu_1'') = \mathit{sub}_{\ell-1}(v_1'') \subseteq \mathit{sub}_{\ell-1}(v_0''av_1'') = \mathit{sub}_{\ell-1}(u_1'') \subseteq \mathit{sub}_{\ell-1}(u_0''bu_1'')\,. \qquad (*)$$

If $p \in i \cdot b$, the induction hypothesis implies that v'' is accepted by $\mathcal{A}_p$, hence $v = v'bv''$ is accepted by $\mathcal{A}$.

If $p \notin i \cdot b$, let $q \in i \cdot b$. By the UMS property of $\mathcal{A}$, there exists a word $w \in \{a, b\}^*$ such that $pw = qw = r$, for some state r with $a, b \in \Sigma(r)$. Indeed, there exists w_1 and a unique maximal state r with respect to $\{a,b\}$ such that $pw_1 = \{r\}$ and $a,b \in \Sigma(r)$. By the UMS property, there exists w_2 over $\{a,b\}$ such that $qw_1w_2 = \{r\}$. Let $w = w_1w_2$. We now show that $wu'' \sim_{\ell-1} u''$ by induction on the length of w. There is nothing to show for $w = \varepsilon$. Thus, assume that $w = xw'$, for $x \in \{a,b\}$, and that $w'u'' \sim_{\ell-1} u''$. Notice that (*) shows that $u'' \sim_{\ell-1} v_1'' \sim_{\ell-1} v'' \sim_{\ell-1} u_1''$. This implies that $sub_{\ell-1}(v_1'') \subseteq sub_{\ell-1}(av_1'') \subseteq sub_{\ell-1}(v_0''av_1'') = sub_{\ell-1}(v'') = sub_{\ell-1}(v_1'')$, which shows that $av_1'' \sim_{\ell-1} v_1''$. Analogously, we can show that $bu_1'' \sim_{\ell-1} u_1''$. If $x = a$, then $w'u'' \sim_{\ell-1} u'' \sim_{\ell-1} v_1''$ implies that $aw'u'' \sim_{\ell-1} av_1'' \sim_{\ell-1} v_1'' \sim_{\ell-1} u''$. If $x = b$, then $w'u'' \sim_{\ell-1} u'' \sim_{\ell-1} u_1''$ implies that $bw'u'' \sim_{\ell-1} bu_1'' \sim_{\ell-1} u_1'' \sim_{\ell-1} u''$. Therefore, $wu'' \sim_{\ell-1} u''$; similarly, $wv'' \sim_{\ell-1} v''$.

Finally, using the induction hypothesis (of the main statement) on $\mathcal{A}_p$, we get that u'' is accepted by $\mathcal{A}_p$ if and only if wu'' is accepted by $\mathcal{A}_p$, which is if and only if u'' is accepted by $\mathcal{A}_r$. Since $u'' \sim_{\ell-1} v''$, the induction hypothesis applied on $\mathcal{A}_r$ gives that u'' is accepted by $\mathcal{A}_r$ if and only if v'' is accepted by $\mathcal{A}_r$. However, this is if and only if wv'' is accepted by $\mathcal{A}_q$. Using the induction hypothesis on $\mathcal{A}_q$, we obtain that wv'' is accepted by $\mathcal{A}_q$ if and only if v'' is accepted by $\mathcal{A}_q$. Together, the assumption that u'' is accepted by $\mathcal{A}_p$ implies that v'' is accepted by $\mathcal{A}_q$. Hence $v = v'bv''$ is accepted by $\mathcal{A}$, which completes the proof. ◀

In other words, the previous theorem says that if k is the minimum number for which a piecewise testable language L is k-piecewise testable, then the depth of any ptNFA recognizing L is at least k.

It is natural to ask whether this property holds for any NFA recognizing the language L. The following result shows that it is not the case. Actually, for any natural number ℓ, there exists a piecewise testable language such that the difference between its k-piecewise testability and the depth of an NFA is at least ℓ.

▶ **Lemma 12.** *For every $k \geq 3$, there exists a k-piecewise testable language that is recognized by an NFA of depth at most $\lfloor \frac{k}{2} \rfloor$.*

Proof. For every $i \geq 1$, let $L_i = a^i + a^{2i+1} \cdot a^*$. We show that the language L_i is $(2i+1)$-piecewise testable and that there exists an NFA of depth at most i recognizing it.

The minimal DFA for L_i consists of $2i+1$ states $\{0,1,\ldots,2i+1\}$, where 0 is the initial state, i and $2i+1$ are accepting, $p \cdot a = p+1$ for $p < 2i+1$, and $(2i+1) \cdot a = 2i+1$. The depth is $2i+1$, which shows that L_i is $(2i+1)$-piecewise testable. Notice that $a^{2i} \sim_{2i} a^{2i+1}$, but a^{2i} does not belong to L_i, hence L_i is not $2i$-piecewise testable.

The NFA for L_i consists of two cycles of length $i+1$, the structure is depicted in Figure 3. The initial state is state 0 and the solely accepting state is state i. The automaton accepts L_i. Indeed, it accepts a^i and no shorter word. After reading a^i, the automaton is in state i or i'. In both cases, the shortest nonempty path to the single accepting state i is of length $i+1$. Thus, the automaton accepts a^{2i+1}, but nothing between a^i and a^{2i+1}. Finally, using the self-loop in state i', the automaton accepts $a^ia^*a^{i+1} = a^{2i+1}a^*$. The depth of the automaton is i. ◀

Piecewise testability and the depth of NFAs. Theorem 8 gives rise to a question whether the opposite implication holds true. This is not the case. Notice that although the depth of ptNFAs is more suitable to provide bounds on k-piecewise testability, the depth is significantly influenced by the size of the input alphabet. For instance, for an alphabet Σ, the language $L = \bigcap_{a\in\Sigma} L_a$ of all words containing all letters of Σ is a 1-piecewise testable language such that any NFA recognizing it requires at least $2^{|\Sigma|}$ states and is of depth $|\Sigma|$, cf. [25]. The

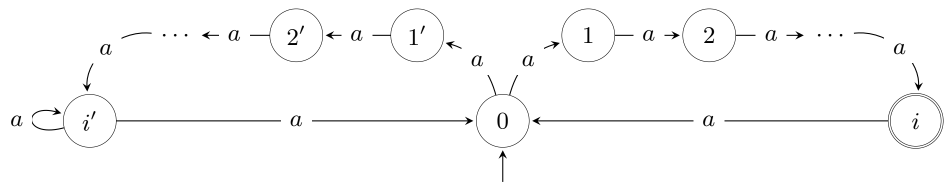

Figure 3 The NFA of depth i recognizing L_i.

depth follows from the fact that the shortest accepted word is of length $|\Sigma|$, hence any path from an initial state to an accepting state must be of length at least $|\Sigma|$.

The dependence on the alphabet is even stronger as shown below.

▶ **Lemma 13.** *For any alphabet of cardinality $n > 1$, there exists an n^2-piecewise testable language such that any NFA recognizing it is of depth at least n^{n-1}.*

Proof. Let $L_n(k)$ denote the maximal length of the shortest representatives of the $\sim_k$-classes over an n-element alphabet. It was shown in [18] that $(L_n(k) + 1)\log n > (\frac{k}{n})^{n-1}\log(\frac{k}{n})$. Setting $k = n^2$ then gives that $L_n(n^2) \geq n^{n-1}$. Let L be a language defined by a single $\sim_{n^2}$-class with shortest representatives of length $L_n(n^2)$. Then L is n^2-piecewise testable, since it is defined as a union of $\sim_{n^2}$ classes. Consider any NFA recognizing L. Since the shortest word of L is of length $L_n(n^2)$, any path from an initial state to an accepting state must be of length at least $L_n(n^2)$. ◀

Recall that it was independently shown in [19, 25] that, given a k-piecewise testable language over an n-letter alphabet, the tight upper bound on the depth of the minimal DFA recognizing it is $\binom{k+n}{k} - 1$. In other words, this formula gives the tight upper bound on the depth of the $\sim_k$-canonical DFA [25] over an n element alphabet. A related question on the size of this DFA is still open, see [18] for more details.

▶ **Theorem 14** ([19, 25])**.** *For any natural numbers k and n, the depth of the minimal DFA recognizing a k-piecewise testable language over an n-letter alphabet is at most $\binom{k+n}{k} - 1$. The bound is tight for any k and n.*

The lower bound for NFAs and ptNFAs remains open.

5 Application and Discussion

The reader might have noticed that the reverse of the automaton $\mathcal{A}_i$ constructed in Section 3 is deterministic and, when made complete, it satisfies the conditions of Fact 2. Since, by definition, a language is k-piecewise testable if and only if its reverse is k-piecewise testable, this observation provides the same upper bound $i+1$ on k-piecewise testability of the language $L(\mathcal{A}_i)$. However, this is just a coincidence and it is not difficult to find an example of a ptNFA whose reverse is not deterministic.

Since both the minimal DFA for L and the minimal DFA for L^R provide an upper bound on k, it could seem reasonable to compute both DFAs in parallel with the hope that (at least) one of them will be computed in a reasonable (polynomial) time. Although this may work for many cases (including the case of Section 3), we now show that there are cases where both the DFAs are of exponential size.

▶ **Theorem 15.** *For every $n \geq 0$, there exists a $(2n+1)$-state ptNFA $\mathcal{B}$ such that the depth of both the minimal DFA for $L(\mathcal{B})$ and the minimal DFA for $L(\mathcal{B})^R$ are exponential with respect to n.*

Proof sketch. The idea of the proof is to make use of the automaton $\mathcal{A}_i$ constructed in Section 3 to build a ptNFA $\mathcal{B}_i$ such that $L(\mathcal{B}_i) = L(\mathcal{A}_i) \cdot L(\mathcal{A}_i)^R$. Then $L(\mathcal{B}_i) = L(\mathcal{B}_i)^R$ and it can be shown that the minimal DFA recognizing the language $L(\mathcal{B}_i)$ requires an exponential number of states compared to $\mathcal{B}_i$. Namely, the depth of both the minimal DFA for $L(\mathcal{B}_i)$ and the minimal DFA for $L(\mathcal{B}_i)^R$ are of length at least $2^{i+1} - 1$. ◀

The previous proof provides another motivation to investigate nondeterministic automata for piecewise testable languages. Given several DFAs, the result of a sequence of operations may result in an NFA that preserves some good properties. Namely, the language $L(\mathcal{B}_i)$ from the previous proof is a result of the operation concatenation of a language L^R with L, where L is a piecewise testable language given as a DFA.

It immediately follows from Theorem 8 that the language $L(\mathcal{B}_i)$ is $(2i+1)$-piecewise testable. This result is not easily derivable from known results, which are either in PSPACE or require to compute an exponentially larger minimal DFA, which provides only the information that the language $L(\mathcal{B}_i)$ is k-piecewise testable for some $k \geq 2^{i+1} - 1$.

Even the information that the language $L(\mathcal{B}_i)$ is of the form $L^R \cdot L$, for a piecewise testable language L, does not seem very helpful, since piecewise testable languages are not closed under concatenation, even with its own reverse, as we show in the example below.

▶ **Example 16.** Let L be the language over the alphabet $\{a, b, c\}$ defined by the regular expression $ab^* + c(a+b)^*$. The reader can construct the minimal DFA for L and check that the properties of Fact 2 are satisfied. In addition, the depth of the minimal DFA is two, hence the language is 2-piecewise testable. Since the properties of Theorem 19 (see below) are not satisfied, the language L is not 1-piecewise testable.

On the other hand, the reader can notice that the sequence $ca, cab, caba, cabab, cababa, \ldots$ is an infinite sequence where every word on the odd position belongs to $L \cdot L^R$, whereas every word on the even position does not. This means that there exists a cycle in the minimal DFA recognizing $L \cdot L^R$, which shows that $L \cdot L^R$ is not a piecewise testable language according to Fact 2. The reader can also directly compute the minimal DFA for $L \cdot L^R$ and notice a non-trivial cycle in it.

To complete this part, we show that the language $L(\mathcal{B}_i)$ is not $(2i)$-piecewise testable. Thus, there are no ptNFAs recognizing the language $L(\mathcal{B}_i)$ with depth less than $2i+1$.

▶ **Lemma 17.** *For every $i \geq 0$, the language $L(\mathcal{B}_i)$ is not $2i$-piecewise testable.*

6 Complexity

In this section, we first give an overview of known complexity results and characterization theorems for DFAs and then discuss the related complexity for ptNFAs.

Simon [33] proved that piecewise testable languages are exactly those regular languages whose syntactic monoid is $\mathcal{J}$-trivial, which shows decidability of the problem whether a regular language is piecewise testable. Later, Stern proved that the problem is decidable in polynomial time for languages represented as minimal DFAs [34], and Cho and Huynh [6] showed that it is NL-complete for DFAs. Trahtman [37] improved Stern's result by giving an algorithm quadratic in the number of states of the minimal DFA, and Klíma and Polák [20] presented an algorithm quadratic in the size of the alphabet of the minimal DFA. If the language is represented as an NFA, the problem is PSPACE-complete [16] (see more details below).

By definition, a regular language is piecewise testable if there exists $k \geq 0$ such that it is k-piecewise testable. It gives rise to a question to find such a minimal k. The *k-piecewise testability problem* asks, given an automaton, whether it recognizes a k-piecewise testable language. The problem is trivially decidable because there are only finitely many k-piecewise testable languages over a fixed alphabet. The coNP upper bound on k-piecewise testability for DFAs was independently shown in [14, 25].[1] The coNP-completeness for $k \geq 4$ was recently shown in [19]. The complexity holds even if k is given as part of the input. The complexity analysis of the problem for $k < 4$ is provided in [25]. We recall the results we need later.

▶ **Theorem 18** ([19]). *For $k \geq 4$, to decide whether a DFA represents a k-piecewise testable language is coNP-complete. It remains coNP-complete even if the parameter $k \geq 4$ is given as part of the input. For a fixed alphabet, the problem is decidable in polynomial time.*

It is not difficult to see that, given a minimal DFA, it is decidable in constant time whether its language is 0-piecewise testable, since it is either empty or Σ^*.

▶ **Theorem 19** (1-piecewise testability DFAs, [25]). *Let $\mathcal{A} = (Q, \Sigma, \cdot, i, F)$ be a minimal DFA. Then $L(\mathcal{A})$ is 1-piecewise testable if and only if* (i) *for every $p \in Q$ and $a \in \Sigma$, $paa = pa$ and* (ii) *for every $p \in Q$ and $a, b \in \Sigma$, $pab = pba$. The problem is in AC^0.*

It is not hard to see that this result does not hold for ptNFAs. Indeed, one can simply consider a minimal DFA satisfying the properties and add a nondeterministic transition that violates them, but not the properties of ptNFAs. On the other hand, the conditions are still sufficient.

▶ **Lemma 20** (1-piecewise testability ptNFAs). *Let $\mathcal{A} = (Q, \Sigma, \cdot, i, F)$ be a complete NFA. If* (i) *for every $p \in Q$ and $a \in \Sigma$, $paa = pa$ and* (ii) *for every $p \in Q$ and $a, b \in \Sigma$, $pab = pba$, then the language $L(\mathcal{A})$ is 1-piecewise testable.*

Note that any ptNFA $\mathcal{A}$ satisfying (i) must have $|pa| = 1$ for every state p and letter a. If $pa = \{r_1, r_2, \ldots, r_m\}$ with $r_1 < r_2 < \ldots < r_m$, then $paa = pa$ implies that $\{r_1, \ldots, r_m\}a = \{r_1, \ldots, r_m\}$. Then $r_1 \in r_1 a$ and the UMS property says that $r_1 a = \{r_1\}$. By induction, we can show hat $r_i a = \{r_i\}$. Consider the component of $G(\mathcal{A}, \Sigma(r_1))$ containing r_1. Then $r_1, \ldots, r_m$ all belong to this component. Since r_1 is maximal, r_1 is reachable from every r_i under $\Sigma(r_1) \supseteq \{a\}$. However, the partial order $r_1 < \ldots < r_m$ implies that r_1 is reachable from r_i only if $r_i = r_1$. Thus, $|pa| = 1$. However, $\mathcal{A}$ can still have many initial states, which can be seen as a finite union of piecewise testable languages rather then a nondeterminism.

The 2-piecewise testability characterization for DFAs is as follows.

▶ **Theorem 21** (2-piecewise testability DFAs, [25]). *Let $\mathcal{A} = (Q, \Sigma, \cdot, i, F)$ be a minimal partially ordered and confluent DFA. The language $L(\mathcal{A})$ is 2-piecewise testable if and only if for every $a \in \Sigma$ and every state s such that $iw = s$ for some $w \in \Sigma^*$ with $|w|_a \geq 1$, $sba = saba$ for every $b \in \Sigma \cup \{\varepsilon\}$. The problem is NL-complete.*

It is again sufficient for ptNFAs.

[1] Actually, [14] gives the bound NEXPTIME for the problem for NFAs where k is part of the input. The coNP bound for DFAs can be derived from the proof omitted in the conference version. The problem is formulated in terms of separability, hence it requires the NFA for the language and for its complement.

▶ **Lemma 22** (2-piecewise testability ptNFAs). *Let $\mathcal{A} = (Q, \Sigma, \cdot, i, F)$ be a ptNFA. If for every $a \in \Sigma$ and every state s such that $iw = s$ for some $w \in \Sigma^*$ with $|w|_a \geq 1$, $sba = saba$ for every $b \in \Sigma \cup \{\varepsilon\}$, then the language $L(\mathcal{A})$ is 2-piecewise testable.*

Considering Theorem 18, the lower bound for DFAs is indeed a lower bound for ptNFAs. Thus, we immediately have that the k-piecewise testability problem for ptNFAs is coNP-hard for $k \geq 4$. We now show that it is actually coNP-hard for every $k \geq 0$. The proof is split into two lemmas.

The proof of the following lemma is based on the proof that the non-equivalence problem for regular expressions with operations union and concatenation is NP-complete, even if one of them is of the form Σ^n for some fixed n [17, 35].

▶ **Lemma 23.** *The 0-piecewise testability problem for ptNFAs is coNP-hard (even if the alphabet is binary).*

It seems natural that the $(k + 1)$-piecewise testability problem is not easier then the k-piecewise testability problem. We now formalize this intuition. We also point out that our reduction introduces a new symbol to the alphabet.

▶ **Lemma 24.** *For $k \geq 0$, k-piecewise testability is polynomially reducible to $(k+1)$-piecewise testability.*

Together, since the k-piecewise testability problem for NFAs is in PSPACE [25], we have the following result.

▶ **Theorem 25.** *For $k \geq 0$, the k-piecewise testability problem for ptNFAs is coNP-hard and in PSPACE.*

The case of a fixed alphabet. The previous discussion is for the general case where the alphabet is arbitrary and considered as part of the input. In this subsection, we assume that the alphabet is fixed. In this case, it is shown in the arxiv versions v1–v4 of [18] that the length of the shortest representatives of the $\sim_k$-classes is bounded by the number $\left(\frac{k+2c-1}{c}\right)^c$, where c is the cardinality of the alphabet. This gives us the following result for 0-piecewise testability for ptNFAs.

▶ **Lemma 26.** *For a fixed alphabet Σ with $c = |\Sigma| \geq 2$, the 0-piecewise testability problem for ptNFAs is coNP-complete.*

Proof. The hardness follows from Lemma 23, since it is sufficient to use a binary alphabet.

We now prove the membership. Let $\mathcal{A}$ be a ptNFA over Σ of depth d recognizing a nonempty language (this can be checked in NL). Then the language $L(\mathcal{A})$ is d-piecewise testable by Theorem 8. This means that if $v \sim_d u$, then either both u and v are accepted or both are rejected by $\mathcal{A}$. Now, the language $L(\mathcal{A}) \neq \emptyset$ is not 0-piecewise testable if and only if $L(\mathcal{A})$ is non-universal. Since Σ is fixed, the shortest representative of any of the $\sim_d$-classes is of length less than $\left(\frac{d+2c-1}{c}\right)^c = O(d^c)$, which is polynomial in the depth of $\mathcal{A}$. Thus, if the language $L(\mathcal{A})$ is not universal, then the nondeterministic algorithm can guess a shortest representative of a non-accepted $\sim_d$-class and verify the guess in polynomial time. ◀

We can now generalize this result to k-piecewise testability.

▶ **Theorem 27.** *Let Σ be a fixed alphabet with $c = |\Sigma| \geq 3$, and let $k \geq 0$. Then the problem to decide whether the language of a ptNFA $\mathcal{A}$ over Σ is k-piecewise testable is coNP-complete.*

Table 1 Complexity of k-piecewise testability – an overview.

	Unary alphabet	Fixed alphabet	Arbitrary alphabet	
			$k \leq 3$	$k \geq 4$
DFA	P	P [19]	NL-complete [25]	coNP-complete [19]
ptNFA	P	coNP-complete	PSPACE & coNP-hard	
NFA	coNP-complete	PSPACE-complete [25]	PSPACE-complete [25]	

Note that this is in contrast with the analogous result for DFAs, cf. Theorem 18, where the problem is in P for DFAs over a fixed alphabet. In addition, the hardness part of the proof of the previous theorem gives us the following corollary, which does not follow from the hardness proof of [19], since the proof there requires a growing alphabet.

► **Corollary 28.** *The k-piecewise testability problem for ptNFAs over an alphabet Σ is coNP-hard for $k \geq 0$ even if $|\Sigma| = 3$.*

The case of a unary alphabet. Lemma 26 (resp. Lemma 23) requires at least two letters in the alphabet to prove coNP-hardness. Thus, it remains to consider the case of a unary alphabet. We now show that the problem is simpler in the unary case, unless P=NP. Namely, a similar argument as in the proof of Lemma 26, improved by the fact that the length of the shortest representatives of $\sim_k$-classes is bounded by the depth of the ptNFA, gives the following result.

► **Theorem 29.** *The k-piecewise testability problem for ptNFAs over a unary alphabet is decidable in polynomial time. The result holds even if k is given as part of the input.*

In contrast to this, the problem is coNP-cotmplete for general NFAs.

► **Theorem 30.** *Both piecewise testability and k-piecewise testability problems for NFAs over a unary alphabet are coNP-complete.*

The complexity of k-piecewise testability for considered automata is summarized in Table 1. Note that the precise complexity of k-piecewise testability for ptNFAs is not yet known in the case the alphabet is considered as part of the input even for $k = 0$.

7 Conclusion

In this paper, we have defined a class of nondeterministic finite automata (ptNFAs) that characterize piecewise testable languages. We have shown that their depth (exponentially) improves the known upper bound on k-piecewise testability shown in [20] for DFAs. We have discussed several related questions, mainly in comparison with DFAs and NFAs, including the complexity of k-piecewise testability for ptNFAs. It can be noticed that the results for ptNFAs generalize the results for DFAs in the sense that the results for DFAs are consequences of the results presented here. This, however, does not hold for the complexity results.

The complexity of k-piecewise testability for the case where the alphabet is consider as part of the input is left open. Recall that the results of [18] give a lower bound on the maximal length of the shortest representative of a class. Specifically, let $L_n(k)$ denote the maximal length of the shortest representatives of the $\sim_k$-classes over an n-element alphabet. Then $L_n(n^2) \geq n^{n-1}$. Thus, the representative can be of exponential length with respect to the size of the alphabet.

However, we conjecture that the problem is PSPACE-complete. A partial evidence for this is that it is possible to construct, for an alphabet of cardinality n, an $O(n^2)$-state ptNFA such that the (unique) non-accepted word is of length $\binom{2n}{n} - 1$. We leave this for the future work and provide more details in an extended version.

Abstract

In this paper we initiate the study of populations of agents with very limited capabilities that are globally able to compute order statistics of their arithmetic input values via pair-wise meetings. To this extent, we introduce the *Arithmetic Population Protocol (APP)* model, embarking from the well known Population Protocol (PP) model and inspired by two recent papers [1, 11] in which states are treated as integer numbers. In the APP model, every agent has a state from a set $\mathcal{Q}$ of states, as well as a fixed number of registers (independent of the size of the population), each of which can store an element from a *totally ordered* set $\mathcal{S}$ of samples. Whenever two agents interact with each other, they update their states and the values stored in their registers according to a *joint transition function*. This transition function is also restricted; it only allows (a) comparisons and (b) copy / paste operations for the sample values that are stored in the registers of the two interacting agents. Agents can only meet in pairs via a fair scheduler and are required to eventually converge to the same output value of the function that the protocol globally and stably computes. We present two different APPs for stably computing the median of the input values, initially stored on the agents of the population. Our first APP, in which every agent has 3 registers and no states, stably computes (with probability 1) the median under *any* fair scheduler in *any* strongly connected directed (or connected undirected) interaction graph. Under the probabilistic scheduler, we show that our protocol stably computes the median in $O(n^6)$ number of interactions in a connected undirected interaction graph of n agents. Our second APP, in which every agent has 2 registers and $O(n^2 \log n)$ states, computes to the correct median of the input with high probability in $O(n^3 \log n)$ interactions, assuming the probabilistic scheduler and the complete interaction graph. Finally we present a third APP which, for any k, stably computes the kth smallest element of the input of the population under *any* fair scheduler and in *any* strongly connected directed (or connected undirected) interaction graph. In this APP

every agent has 2 registers and n states. Upon convergence every agent has a different state; all these states provide a *total ordering* of the agents with respect to their input values.

1 Introduction

The *population protocol (PP)* model [2, 5] was originally defined to represent sensor networks consisting of very limited mobile agents with no control over their own movement. It has been defined by analogy to population processes [8] in probability theory and has already been used in various fields, such as in statistical physics, genetics, epidemiology, chemistry and biology [6]. An exciting feature of such systems of simple agents is that, by exchanging information through local pairwise interactions (rendezvous), the entities can collectively perform significant global computational tasks. In the basic model, in each pairwise interaction both participating agents update their state according to a (pre-specified) joint transition function that only depends on the states of the two agents. Furthermore the interactions between agents happen under some kind of a *fairness* condition. Assuming the complete interaction graph, it is known that population protocols compute exactly the class of semilinear predicates [3], i.e., the predicates definable in first-order logic Presburger arithmetic. In addition, it is well known that population protocols do not compose, except for certain cases; for a survey we refer to [5, 10].

One limitation of the PP model is that, as every agent is characterized at every time point by its state, the predicates that can be stably computed are defined over variables that count the number of nodes having initially some specific state from the set of allowable states (see for example [4, 9]). However, in several circumstances, it is natural to assume that nodes may also store some *arithmetic* values, for instance a temperature or some other local measurement. Imagine for instance a huge network of elementary sensors that measure local temperature and want to compute some statistical function of the temperatures of the whole network. The computation of elementary functions (e.g. the median) of such arithmetic values by a population of autonomous agents requires an extension of the standard PP model. On the other hand, it is worth noting that computations of statistics in classical distributed network models have been already considered, e.g. [7].

In order to overcome such limitations, we introduce in this paper the *Arithmetic Population Protocols (APP)* model, which is inspired by the PP model and by two recent papers [1, 11]. Similarly to the spirit of population protocols, we still assume in arithmetic population protocols that agents are weak computational devices with very small local memory, thus still staying on the pragmatic side. In [11], the authors consider the problem of determining the exact difference between the majority and the minority type in a two-type population. The basic idea of their protocol generalizes an idea of [1], where the set of states available to each agent was a set of integers, thus implying a total ordering of the states. In particular, an agent at state i was considered to be more firm in supporting her type than another agent at state i', with $|i| > |i'|$.

In our APP model, every agent has a state from a set $\mathcal{Q}$ of states, as well as $r \geq 1$ registers, each of which can store an element from a *totally ordered* set $\mathcal{S}$ of samples (e.g. $\mathcal{S} \subseteq \mathbb{N}$

or $\mathcal{S} \subseteq \mathbb{R}$). We assume that r is a fixed constant, i.e., independent of the population size. Furthermore, agents have limited knowledge of the set $\mathcal{S}$ and limited computational power over $\mathcal{S}$. In particular, no agent is aware of the whole set $\mathcal{S}$. Furthermore, whenever two agents interact with each other, they update their states and the values stored in their registers according to a *joint transition function*. This transition function only allows (a) comparisons and (b) copy / paste operations for values in $\mathcal{S}$ that are stored in the registers of the two interacting agents. Initially, each agent $v \in \mathcal{V}$ is given an element $x_v \in \mathcal{S}$ as input; her initial state and the initial values of her registers are then determined according to x_v. The goal is that eventually, after a sequence of local pairwise interactions (which are planned by a *scheduler* that satisfies a general "fairness" condition), every agent computes the same function on the input values in one of her registers. We assume that agents are oblivious of their own identity and of identities of other agents they interact with. Therefore, at any time, each agent is completely characterized by the values stored in its registers, together with its state.

1.1 Our model

More formally, let $\mathcal{S}$ denote a totally ordered set of *samples* and let $\mathcal{Q}$ be a totally ordered[1] set of states. We assume that there is a population $\mathcal{V}$ of computationally weak agents with limited memory. In particular, each agent can be in one of the states in $\mathcal{Q}$ and has r registers at its disposal, each one of which can store an element of $\mathcal{S}$.

For any $t \geq 0$ let $\mathbf{R}(t)$ be a $|\mathcal{V}| \times r$ matrix, such that $\mathbf{R}_{v,j}(t)$ is the value of the j-th register of agent $v \in \mathcal{V}$ at time t. Furthermore, for every $t \geq 0$, let $\mathbf{q}(t)$ be a $|\mathcal{V}|$-dimensional vector such that $\mathbf{q}_v(t)$ is the state of agent $v \in \mathcal{V}$ at time t. We refer to $\mathbf{C}(t) \overset{def}{=} (\mathbf{R}(t), \mathbf{q}(t))$ as the *configuration* at time t. We will assume that the number of registers r of each agent is a fixed constant independent of the population size, i.e., every agent has a limited number of registers available. For every agent $v \in \mathcal{V}$, we will refer to the first register of v as the *input register*; we also refer to $\mathbf{R}_{v,1}(t)$ as the *value of the input register* of v. Furthermore, we will say that $\mathbf{R}_{:,1}(0)$ (i.e., the first column of $\mathbf{R}(0)$) is the *population input* at time 0.

An *Arithmetic Population Protocol (APP)* is defined on a population $\mathcal{V}$ of agents and consists of an *input initialization function* $\iota : \mathcal{S} \to \mathcal{S}^r \times \mathcal{Q}$, an *output function* $\gamma : \mathcal{S}^r \times \mathcal{Q} \to \mathcal{D}$ ($\mathcal{D}$ is the set of output values; usually it is the same as the sample set $\mathcal{S}$), and a *joint transition function* $f : (\mathcal{S}^r \times \mathcal{Q}) \times (\mathcal{S}^r \times \mathcal{Q}) \to (\mathcal{S}^r \times \mathcal{Q}) \times (\mathcal{S}^r \times \mathcal{Q})$. In particular, if v interacts with u at time $t+1$, then the new values of their registers and states become $(\mathbf{R}_{v,:}(t+1), \mathbf{q}_v(t+1))$ and $(\mathbf{R}_{u,:}(t+1), \mathbf{q}_u(t+1))$ respectively, where $(\mathbf{R}_{v,:}(t+1), \mathbf{q}_v(t+1), \mathbf{R}_{u,:}(t+1), \mathbf{q}_u(t+1)) = f(\mathbf{R}_{v,:}(t), \mathbf{q}_v(t), \mathbf{R}_{u,:}(t), \mathbf{q}_u(t))$. As also mentioned earlier, the transition function f is *not arbitrary*: it only allows (a) comparisons and (b) copy / paste operations for values in $\mathcal{S}$ that are stored in the registers of the two interacting agents. Therefore, if agents v, u interact at time $t+1$, then for any register $j \in [r]$, we have $\mathbf{R}_{v,j}(t+1), \mathbf{R}_{u,j}(t+1) \in \{\mathbf{R}_{x,j'}(t) : x \in \{v,u\}, j' \in [r]\}$.

Initially, the values of the registers of each agent are determined by the input initialization function ι, i.e., for each agent $v \in \mathcal{V}$ that has input $x_v \in \mathcal{S}$, we initially set $(\mathbf{R}_{v,:}(0), \mathbf{q}_v(0)) = \iota(x_v)$, where $\mathbf{R}_{v,:}(0)$ denotes the row of $\mathbf{R}(0)$ corresponding to agent v. Subsequently, in every time step $t+1 \geq 1$, a pair of agents interacts and updates the values of their registers according to the transition function f.

[1] This assumption on $\mathcal{Q}$ is not necessary for our results, but is given for the sake of presentation.

Agent pairwise interactions are planned by a *scheduler* under a general "fairness" condition; the actual mechanism for choosing which agents interact each time is abstracted away. The fairness condition states that *the scheduler cannot postpone a possible finite sequence of agent interactions indefinitely.* The *direction of interaction* may or may not be relevant (see also the discussion below on the probabilistic scheduler); if it is not relevant, we say that the APP is *symmetric.*

Due to lack of coordination and storage restrictions, the agents in a population executing an APP cannot determine when the computation has finished. Instead, the values of the output registers of every agent is required to converge to a common (correct) value. More formally, we have the following:

▶ **Definition 1** (Stable computation)**.** Let $\mathcal{M}$ be the (infinite) set of multi-sets of a (finite or infinite) totally ordered set $\mathcal{S}$ and let $\mathcal{F} : \mathcal{M} \to \mathcal{D}$ be a function. We say that an APP *stably computes* the function $\mathcal{F}$ if and only if under *any fair scheduler*, for *any multi-set* $M \in \mathcal{M}$, and starting from *any configuration* where the elements in M are assigned bijectively to the input registers of the agents in a population $\mathcal{V}$ (where $|\mathcal{V}| = |M|$) we have that, after a finite time τ, $\gamma(\mathbf{R}_{v,:}(t), \mathbf{q}_v(t)) = \mathcal{F}(M)$, for all agents $v \in \mathcal{V}$ and for all $t \geq \tau$.

To allow for the comparison of our APPs in terms of the number of pairwise interactions needed to compute some function, we will consider in this paper a special case of a fair scheduler, namely the *probabilistic scheduler*, which is defined on directed interaction graphs as follows. In each time step a directed edge (v, u) of the interaction graph is chosen uniformly at random, where v (i.e., the tail of (v, u)) is called the *initiator* and u (i.e., the head of (v, u)) is called the *responder* of the interaction. Then, agents v and u update the values of their registers jointly according to the transition function f. The direction of interaction plays an important role in the general case, as the initiator will update its register values according to the first part of the outcome of f (consisting of r numeric values), while the responder will use the second part of the outcome (which also consists of r numeric values). The values of the registers of all other agents remain unchanged. The probabilistic scheduler is defined on undirected graphs similarly, by replacing every undirected edge $\{v, u\}$ by the two directed edges (v, u) and (u, v).

1.2 Our contribution

In this paper, we initiate the study of populations of agents with very limited capabilities that are globally able to compute order statistics of their input via pair-wise meetings. We initially focus on the fundamental problem of computing the *median* of the input values in a population of n agents, which is defined as the $\lceil n/2 \rceil$-th minimum element of the input values. We provide two different APPs for stably computing the median.

In our first APP (see Section 2) every agent has 3 registers and no states. This APP stably computes (with probability 1) the median under *any* fair scheduler in *any* strongly connected directed (or connected undirected) interaction graph. We also show that, under the probabilistic scheduler, our protocol stably computes the median in $O(n^6)$ number of interactions in a connected undirected interaction graph of n agents.

Our second APP for stably computing the median (see Section 3) is considerably faster than the first one, however it works with high probability (rather than with probability 1) and it requires additional assumptions on the scheduler and the structure of the underlying interaction graph. In particular, in our second APP for the median, every agent has 2 registers and $O(n^2 \log n)$ states. Assuming the probabilistic scheduler and the complete interaction graph, this APP converges to the correct median of the input of the population with high probability in $O(n^3 \log n)$ interactions. Additionally, agents are required to know the size of the population. The latter assumption can be dropped by assuming additional states and computational power for the agents.

As our final contribution, we present in Section 4 an APP which, for any k, stably computes the kth smallest element of the input of the population under *any* fair scheduler and in *any* strongly connected directed (or connected undirected) interaction graph. In this APP every agent has 2 registers and n states. Upon convergence every agent has a different state; all these states provide a *total ordering* of the agents with respect to their input values.

2 A 3-register APP for median

In this section we describe a APP using 3 registers and no states that stably computes the median of the input of a population of agents $\mathcal{V}$, i.e., the median of the (multi-) set of elements $\{x_v : v \in \mathcal{V}\} \in \mathcal{S}^n$. We will assume without loss of generality that the set of measurements $\mathcal{S}$ is the set of real numbers, i.e., $\mathcal{S} = \mathbb{R}$. Our protocol is not symmetric, hence in every interaction we distinguish between initiator and responder. For the sake of clarity of presentation, we will assume that the size $n = |\mathcal{V}|$ of the population is odd, so that the median is well (and uniquely) defined. In fact, without further modifications, our protocol may not converge if there is an even number of nodes (because in this case there are 2 candidates for the median).[2] Additionally, we will initially assume that the interaction graph is complete and we later show how this assumption can be dropped.

For every agent $v \in \mathcal{V}$, the first register will contain the (input) number x_v initially assigned to node v (i.e., $\mathbf{R}_{v,1}(0) = x_v$); the value of $\mathbf{R}_{v,1}(t)$ will remain unchanged throughout the computation. The third register of each agent v, i.e., $\mathbf{R}_{v,3}$, will eventually converge to median of the input of the population $\{x_v : v \in \mathcal{V}\}$. The first two registers (i.e., $\mathbf{R}_{v,1}, \mathbf{R}_{v,2}$) are used to make virtual connections between agents; upon convergence, the agent with the smallest number will be virtually connected to the agent with the largest number, the agent with the second smallest number will be virtually connected to the agent with the second largest number and so on. Furthermore, for any agent $v \in \mathcal{V}$, we will denote by $I_v(t) \overset{def}{=} \{s \in \mathbb{R} : \min(\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t)) \leq s \leq \max(\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t))\}$. For simplicity, we will write $I_v(t) = [\min(\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t)), \max(\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t))]$ and we will refer to $I_v(t)$ as the *closed interval* of v at time t (we use this term loosely, since in general the set of measurements may not be compact). Finally, we denote $\mathbf{C}_v(t) \overset{def}{=} (\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t), \mathbf{R}_{v,3}(t))$.

The initialization function of our protocol is given by $\iota_{\text{MDN}}(x_v) = \mathbf{C}_v(0) = [x_v, x_v, x_v]$, for any $x_v \in \mathcal{S}$ and $v \in \mathcal{V}$, and the output function is given by $\gamma_{\text{MDN}}(\mathbf{C}_v(t)) = \mathbf{R}_{v,3}(t)$, for any $v \in \mathcal{V}$. Consequently, for any $v \in \mathcal{V}$, the closed interval $I_v(0)$ contains just one point. The joint transition function is defined as follows: if agent v (the initiator) interacts with u (the responder) at time $t + 1 = 1, 2, \ldots$, then $(\mathbf{C}_v(t+1), \mathbf{C}_u(t+1)) = f_{\text{MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t))$, where f_{MDN} is given below.

[2] Nevertheless, it is not difficult to extend our APP so that it converges to one of the 2 candidate values (say the smallest) for the median in the case where n is even.

```
Transition function $f_{\mathrm{MDN}}$
Input: $\mathbf{C}_v(t), \mathbf{C}_u(t)$
```

Case I: $\mathbf{R}_{v,1}(t) = \mathbf{R}_{v,2}(t)$ AND $I_v(t) \subseteq I_u(t)$.

$$f_{\mathrm{MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = ([\mathbf{C}_v(t)], [x_u, \mathbf{R}_{u,2}(t), x_v])$$

Case II: $I_v(t) \nsubseteq I_u(t)$ AND $I_u(t) \nsubseteq I_v(t)$ AND $x_v \in \{r_2, r_3\}$ AND $x_u \in \{r_1, r_4\}$, where r_1, r_2, r_3 and r_4 are the first, second, third and fourth smallest value in the set $\{\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t), \mathbf{R}_{u,1}(t), \mathbf{R}_{u,2}(t)\}$ respectively.

$$f_{\mathrm{MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = ([x_v, \{r_2, r_3\} \backslash x_v, \mathbf{R}_{v,3}(t)], [x_u, \{r_1, r_4\} \backslash x_u, \mathbf{R}_{u,3}(t)])$$

Case III: Every other case.

$$f_{\mathrm{MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = (\mathbf{C}_v(t), \mathbf{C}_u(t))$$

We can prove the following:

▶ **Theorem 2** (Correctness). *The APP with initialization function ι_{MDN}, output function γ_{MDN} and transition function f_{MDN} stably computes the median function when the underlying interaction graph is the complete graph.*

Proof. Let $n = |\mathcal{V}|$ and define the potential function $\phi : \mathbb{R}^n \times \mathbb{R}^n \to \mathbb{R}$ as follows:

$$\phi(\mathbf{R}_{:,1}(t), \mathbf{R}_{:,2}(t)) = \sum_{v \in \mathcal{V}} (\mathbf{R}_{v,2}(t) - \mathbf{R}_{v,1}(t))^2.$$

Clearly, ϕ remains unchanged if two agents interact according to one of the cases I, or III, since the values of the first two registers of the agents remain unchanged. On the other hand, ϕ strictly increases in case II. Indeed, suppose that agent v (the initiator) interacts with agent u (the responder) at time $t+1$ according to case II, and let r_1, r_2, r_3 and r_4 be the first, second, third and fourth smallest value in the set $\{\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t), \mathbf{R}_{u,1}(t), \mathbf{R}_{u,2}(t)\}$. Then

$$\begin{aligned} &\phi(\mathbf{R}_{:,1}(t+1), \mathbf{R}_{:,2}(t+1)) - \phi(\mathbf{R}_{:,1}(t), \mathbf{R}_{:,2}(t)) \\ &\quad = \left[(r_3 - r_2)^2 + (r_4 - r_1)^2\right] - \left[(\mathbf{R}_{v,2}(t) - \mathbf{R}_{v,1}(t))^2 + (\mathbf{R}_{u,2}(t) - \mathbf{R}_{u,1}(t))^2\right] \\ &\quad = 2\left(\mathbf{R}_{v,1}(t)\mathbf{R}_{v,2}(t) + \mathbf{R}_{u,1}(t)\mathbf{R}_{u,2}(t) - r_2 r_3 - r_1 r_4\right) > 0. \end{aligned} \tag{1}$$

Notice also that, by the definition of ι_{MDN} and f_{MDN}, our protocol maintains the following invariant:

(INV) For any $v \in \mathcal{V}$ and any time $t \geq 0$, there are exactly 2 copies of x_v, one in $\mathbf{R}_{:,1}(t)$ and one in $\mathbf{R}_{:,2}(t)$ (obviously, if two or more nodes have the same input, there will be two copies for each).

Let $0 \leq i \leq \lceil \frac{n}{2} \rceil$. We say that a configuration $\mathbf{C}(t)$ is *non-crossing up to i* if, for every $1 \leq k \leq i$, the agent with the kth smallest input value is matched in an interval with the kth largest input value. That is, a configuration $\mathbf{C}(t)$ is non-crossing up to i if there are sets of distinct agents $L^{(i)}$ and $U^{(i)}$ for which the following conditions hold:

(C1) $L^{(i)} = \{z_1, \ldots, z_i\} \subseteq \mathcal{V}$, such that $x_{z_1} \leq \cdots \leq x_{z_i}$ and, for each $z \in L^{(i)}$ and $z' \in \mathcal{V} \backslash L^{(i)}$, we have $x_z \leq x_{z'}$.

(C2) $U^{(i)} = \{u_1, \ldots, u_i\} \subseteq \mathcal{V}$, such that $x_{u_1} \geq \cdots \geq x_{u_i}$ and, for each $u \in U^{(i)}$ and $u' \in \mathcal{V} \backslash U^{(i)}$, we have $x_u \geq x_{u'}$.

(C3) $I_{z_j}(t) = I_{u_j}(t) = [z_j, u_j]$, for all $j \in [i]$.

The sets $L^{(i)}, U^{(i)}$ will be called *witnesses* for the fact that $\mathbf{C}(t)$ is non-crossing up to i. We can prove the following:

▶ **Claim 3.** *Let $i < \lceil \frac{n}{2} \rceil$. If $\mathbf{C}(t)$ is non-crossing up to i but not up to $i+1$, then there is a pair of agents that can interact according to Case II. Equivalently, there is an interaction of agents that can strictly increase the value of ϕ.*

Proof. Let i be the maximum index such that $\mathbf{C}(t)$ is non-crossing up to i and let $L^{(i)}, U^{(i)}$ be witnesses of this fact. Let $L^+ \overset{def}{=} \{z : z \notin L^{(i)}, x_z \leq x_{z'}, \text{ for every } z' \in \mathcal{V} \backslash L^{(i)}\}$ and $U^- \overset{def}{=} \{u : u \notin U^{(i)}, x_u \geq x_{u'}, \text{ for every } u' \in \mathcal{V} \backslash U^{(i)}\}$. Notice that, by definition, x_z (respectively x_u) is the same for all $z \in L^+$ (respectively $u \in U^-$).

The fact that $\mathbf{C}(t)$ is non-crossing up to i (and not up to $i+1$) implies that at least one of the following holds:

(i) For all agents $z \in L^+$, there is no agent $u \in U^-$, such that $I_z(t) = [x_z, x_u]$.
(ii) For all agents $u \in U^-$, there is no agent $z \in L^+$, such that $I_u(t) = [x_z, x_u]$.

Assume without loss of generality that (i) holds; the case where (ii) holds is similar, by symmetry. Let $z_{\max} \in L^+$ be such that the length of the interval $I_{z_{\max}}(t)$ is maximal. In particular, this means that there is some agent w such that $I_{z_{\max}}(t) = [x_{z_{\max}}, x_w]$, with $x_{z_{\max}} \leq x_w < x_u$, for each $u \in U^-$. Indeed, by assumption we have that $x_w \neq x_u$, for each $u \in U^-$. But also, we cannot have $x_w > x_u$ or $x_w < x_{z_{\max}}$, by definition of the sets L^+, U^-.

Notice now that, by invariant (INV) there also exists a pair of agents $z', w' \notin L^{(i)} \cup U^{(i)}$, such that $I_{z'}(t) = [x_{z'}, x_{w'}]$, with $x_{w'} > x_w$ (and $x_{z'} \leq x_{w'}$). Indeed, let $I_w(t)$ be the interval of node w at time t. If $\max(\mathbf{R}_{w,1}(t), \mathbf{R}_{w,2}(t)) > x_w$, then we have $z' = w$. Otherwise, let x_y be the other endpoint of $I_w(t)$ (in fact $x_y = \min(\mathbf{R}_{w,1}(t), \mathbf{R}_{w,2}(t))$. Similarly, if $\max(\mathbf{R}_{y,1}(t), \mathbf{R}_{y,2}(t)) > x_w$, then we have $z' = y$. Proceeding inductively, we will eventually find an agent z' with $\max(\mathbf{R}_{z',1}(t), \mathbf{R}_{z',2}(t)) > x_w$. Notice also that z' does not belong to U^-, by construction, but also neither to L^+, by maximality of $I_{z_{max}}(t)$.

We can then see that the pair of agents $(z', z_{\max})$ is suitable for interaction according to Case II. Indeed, $\mathbf{R}_{z',1}(t) = x_{z'} > x_{z_{\max}} = \mathbf{R}_{z_{\max},1}(t)$, so $I_{z_{\max}}(t) \nsubseteq I_{z'}(t)$, $\mathbf{R}_{z',2}(t) = x_{w'} > x_w = \mathbf{R}_{z_{\max},2}(t)$, so $I_{z'}(t) \nsubseteq I_{z_{\max}}(t)$ and finally $x_{z'} \in \{r_2, r_3\} = \{x_{z'}, x_w\}$ and $x_{z_{max}} \in \{r_1, r_4\} = \{x_{z_{max}}, x_{w'}\}$. This completes the proof of the claim, since by equation (1), any interaction according to Case II strictly increases the value of ϕ. ◀

By the above claim, we can now show that the potential function ϕ is maximized whenever the system reaches a configuration $\mathbf{C}(t)$ that is non-crossing up to $\lceil \frac{n}{2} \rceil$. Indeed, by inequality (1), any interaction according to case II strictly increases the value of the potential ϕ, and since this increment is independent of t and the maximum value of ϕ is finite (e.g. it is at most $n(\max\{x_v\} - \min\{x_v\})^2$), we conclude that, in finite time (because of the fairness assumption of the scheduler) we will have reached the desired configuration. Finally, notice that in such a configuration, the node that corresponds to the median will have the same value stored in both its first two registers (by the assumption that n is odd). In particular, whenever it interacts as an initiator with another agent, it will do so according to case I. In fact, no agent with assigned value different than the median will be able to interact with other nodes according to this case after convergence of the protocol. This implies that, eventually, all agents will have the value of the correct median stored in their third register. This completes the proof. ◀

Notice that our protocol does not make any assumption on the uniqueness of assigned values to agents. For example, if there are several agents that have $\mathbf{R}_{v,1}(t) = \mathbf{R}_{v,2}(t)$ and ϕ is maximum, then this means that there are at least 3 nodes that are equal to the median; our protocol will still stably compute the correct median value. It is only required that nodes have registers that can store any element in the multi-set $\{x_v : x \in \mathcal{V}\}$.

Before moving on to the running time analysis of our protocol under the probabilistic scheduler, it is worth noting that we can slightly modify our transition function f_{MDN} so that the protocol works on arbitrary strongly connected directed interaction graphs. Indeed, we just need to guarantee that every two agents will eventually be able to compare their input. This can be achieved if agents that interact also exchange the values of their registers. Therefore, we have the following more general result:

▶ **Theorem 4.** *Let $f'_{MDN} : \mathcal{S}^3 \times \mathcal{S}^3 \to \mathcal{S}^3 \times \mathcal{S}^3$ be a transition function defined as follows: for any $\vec{x}, \vec{y}, \vec{x}', \vec{y}' \in \mathcal{S}^3$, $f'_{MDN}(\vec{x}, \vec{y}) = (\vec{y}', \vec{x}')$ if and only if $f_{MDN}(\vec{x}, \vec{y}) = (\vec{x}', \vec{y}')$. Then the APP with input initialization function ι_{MDN}, output function γ_{MDN} and transition function f'_{MDN} stably computes the median function under any strongly connected directed interaction graph.*

We note that the potential function ϕ defined for the proof of correctness of our protocol, together with inequality (1) can be used to give upper bounds on the expected time needed for the protocol to stably compute the median under the probabilistic scheduler. However, this bound will depend on the input of the population. Nevertheless, by using Claim 3 and the definition of non-crossing configurations from the proof of Theorem 2, we can also provide an upper bound that only depends on the population size.

▶ **Theorem 5.** *Assuming the probabilistic scheduler under any connected undirected interaction graph, the expected time needed for the APP with input initialization function ι_{MDN}, output function γ_{MDN} and transition function f'_{MDN} to stably compute the median of the input of a population $\mathcal{V}$ of n agents is $O(n^6)$.*

Proof. Let T_1 be the time until the population reaches a configuration that is non-crossing up to $\lceil \frac{n}{2} \rceil$ (see the definition in the proof of Theorem 2) and let T_2 be the additional time needed for the value of the median to be propagated to all agents in the population. Clearly, the expected time needed for the protocol to stably compute the correct median value is $\mathbb{E}[T_1 + T_2]$.

Notice that, by definition of f'_{MDN}, whenever two agents interact, they also exchange the values of their registers. Therefore, it is as if each agent is performing a random walk on the interaction graph $G = (V, E)$. Furthermore, these random walks performed by two agents are independent until those 2 agents interact with each other.

Remember that, (arguing as in the proof of Theorem 2) if at some time t the configuration reached is non-crossing up to i, but not up to $i + 1$, we have that at least one of the following holds:

(i) For all agents $z \in L^+$, there is no agent $u \in U^-$, such that $I_z(t) = [x_z, x_u]$.
(ii) For all agents $u \in U^-$, there is no agent $z \in L^+$, such that $I_u(t) = [x_z, x_u]$.

In particular, by definition of f_{MDN}, agents $z \in L^+ \cup U^-$ can never decrease the length of the interval $I_z(t')$, for any $t' \geq t$. But then, the proof of Claim 3 implies that there is a pair of agents z, z', with $z \in L^+ \cup U^-$, who can interact according to Case II, which will strictly increase the length of $I_z(t')$. By Corollary 1 of [12], the expectation of the maximum meeting time is $O(n^3)$. If we also take into account the interactions which do not involve agents z, z', we then have that the expected number of steps before some agent $z \in L^+ \cup U^-$ increases the length of its interval is at most $O(n^4)$, where we also used the fact that the expected number of steps between two interactions that involve z, z' is $O(n)$. Since the length of the interval of any $z \in L^+ \cup U^-$ can increase at most n times and there are at most n agents, we have that $\mathbb{E}[T_1] = O(n^6)$.

To bound $\mathbb{E}[T_2]$, we can use Theorem 3 of [12], which states that the expected number of steps needed for a single random walk to cover all vertices of a graph is $O(n^4)$. If we also take into account the interactions which do not involve the median (there are $O(n)$ such steps in expectation between any interaction involving the median), we have that $\mathbb{E}[T_2] = O(n^5)$, which completes the proof. ◀

3 A faster protocol for median using random walks

In this section we describe another APP for stably computing the median of the input of a population of agents $\mathcal{V}$. Our protocol is not symmetric (hence in every interaction we distinguish between initiator and responder) and it converges with high probability (rather than with probability 1) to the correct median faster than the one in Section 2, at the expense of additional assumptions on the scheduler and the structure of the underlying interaction graph; in particular, we assume the probabilistic scheduler, under the complete interaction graph. For the sake of clarity of presentation, we will assume that the size $n = |\mathcal{V}|$ of the population is known to all agents. However, it is worth noting that this assumption can be dropped if one combines the APP presented here with the APP described in the Remark at the end of Section 4 for stably computing the population size, provided that agents are able to locally compute the value of a certain function $p(n)$ (for any n) that will be defined later.

Our APP uses 2 registers and $3p(n) + 2$ states per agent; the value of $p(n)$ will be determined in Theorem 6 below. For every agent $v \in \mathcal{V}$, the value of the input register $\mathbf{R}_{v,1}(t)$ will be initialized to x_v and will remain unchanged throughout the computation. The second register $\mathbf{R}_{v,2}(t)$ will eventually contain the median, i.e., with high probability, $\mathbf{R}_{v,2}(t)$ will eventually converge to the median of the set $\{x_v : v \in \mathcal{V}\}$. We view the state space $\mathcal{Q}$ for each agent $v \in \mathcal{V}$ as two counters $\mathbf{q}_{v,1}(t)$ and $\mathbf{q}_{v,2}(t)$; the first one can store an integer between $-p(n)$ and $p(n)$, and the second an integer between 0 and $p(n)$. These counters are used as follows: whenever agent v (the initiator) interacts with another agent u (the responder) at time $t + 1$, it will increase (respectively decrease) the value of $\mathbf{q}_{v,1}(t)$ by 1 if $x_v \geq x_u$ (respectively if $x_v < x_u$). Therefore, for each agent v, $\mathbf{q}_{v,1}(t)$ describes a (possibly) biased random walk, the least biased (or ideally unbiased) of which will correspond to the median. This means that, with high probability, if we stop those random walks after a sufficient number of steps, the one closest to 0 will correspond to the median of the population. The total number of steps that the random walk for agent v takes are counted in $\mathbf{q}_{v,2}(t)$.

More precisely, let $p(n)$ be any large enough integer function of the size of the population, which will stand for the maximum number of steps that we allow each random walk to take. We denote $\mathbf{C}_v(t) \overset{def}{=} \left(\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t), \mathbf{q}_{v,1}(t), \mathbf{q}_{v,2}(t)\right)$. Also, for any agent v, we denote by $\mathbf{1}_v$ the indicator variable that is equal to 1 if $\mathbf{q}_{v,2}(t) < p(n)$ and 0 otherwise. The initialization function of our protocol is given by $\iota_{\text{RW-MDN}}(x_v) = \mathbf{C}_v(0) = [x_v, x_v, 0, 0]$, for any $x_v \in \mathcal{S}$ and $v \in \mathcal{V}$, and the output function is given by $\gamma_{\text{RW-MDN}}(\mathbf{C}_v(t)) = \mathbf{R}_{v,2}(t)$, for any $v \in \mathcal{V}$. The transition function is defined as follows: if agent v (the initiator) interacts with agent u (the responder) at time $t + 1 = 1, 2, \ldots$, then $(\mathbf{C}_v(t + 1), \mathbf{C}_u(t + 1)) = f_{\text{RW-MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t))$, where $f_{\text{RW-MDN}}$ is given below.

```
Transition function $f_{\text{RW-MDN}}$
Input: $\mathbf{C}_v(t), \mathbf{C}_u(t)$
Case I: $x_v \geq x_u$ AND $\mathbf{q}_{v,2}(t) < p(n)$.
    $f_{\text{RW-MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) =$
      $([x_v, \mathbf{R}_{v,2}(t), \mathbf{q}_{v,1}(t) + \mathbf{1}_v, \mathbf{q}_{v,2}(t) + \mathbf{1}_v], [x_u, \mathbf{R}_{u,2}(t), \mathbf{q}_{u,1}(t) - \mathbf{1}_u, \mathbf{q}_{u,2}(t) + \mathbf{1}_u])$
Case II: $x_v < x_u$ AND $\mathbf{q}_{v,2}(t) < p(n)$.
    $f_{\text{RW-MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) =$
      $([x_v, \mathbf{R}_{v,2}(t), \mathbf{q}_{v,1}(t) - \mathbf{1}_v, \mathbf{q}_{v,2}(t) + \mathbf{1}_v], [x_u, \mathbf{R}_{u,2}(t), \mathbf{q}_{u,1}(t) + \mathbf{1}_u, \mathbf{q}_{u,2}(t) + \mathbf{1}_u])$
Case III: $\mathbf{q}_{v,2}(t) = \mathbf{q}_{u,2}(t) = p(n)$ AND $|\mathbf{q}_{v,1}(t)| \leq |\mathbf{q}_{u,1}(t)|$.
    $f_{\text{RW-MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = (\mathbf{C}_v(t), [x_u, \mathbf{R}_{v,2}(t), \mathbf{q}_{u,1}(t), \mathbf{q}_{u,2}(t)])$
Case IV: Every other case.
    $f_{\text{RW-MDN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = (\mathbf{C}_v(t), \mathbf{C}_u(t))$
```

We can prove the following:

▶ **Theorem 6.** *If $p(n) \geq 16n^2 \ln n$, then the APP with input initialization function $\iota_{RW\text{-}MDN}$, output function $\gamma_{RW\text{-}MDN}(v)$ and transition function $f_{RW\text{-}MDN}$ stably computes the median of the input of a population of n agents with high probability (i.e., with probability tending to 0 as n goes to ∞), under the complete interaction graph, assuming the probabilistic scheduler.*

Proof. Consider an ordering $v_1, \ldots, v_n$ of the agents of the population $\mathcal{V}$ in non-decreasing order of their input, i.e., $x_{v_1} \leq x_{v_2} \leq \cdots \leq x_{v_n}$. For any agent v, we will denote by m_v the number of agents that have the same input as v (including v herself), i.e., $m_v \stackrel{def}{=} |\{u \in \mathcal{V} : x_u = x_v\}|$.

For any agent v, and $\ell = 1, 2, \ldots, p(n)$, define the random variable $X_\ell^{(v)}$ as follows: $X_\ell^{(v)} = 1$ if at the ℓ-th interaction of agent v (either as an initiator or responder) the value of $\mathbf{q}_{v,1}(t)$ increases and $X_\ell^{(v)} = -1$ otherwise. In particular, for any $\ell = 1, 2, \ldots, p(n)$, at the ℓ-th interaction of agent v, the following disjoint events may happen: (a) either v will interact with an agent u that has $x_v > x_u$, in which case $X_\ell^{(v)} = 1$, or (b) v will interact with an agent u that has $x_v < x_u$, in which case $X_\ell^{(v)} = -1$, or (c) v will interact with another agent u that has $x_v = x_u$, in which case if v is the initiator (which happens with probability $\frac{1}{2}$, by definition of the probabilistic scheduler) then $X_\ell^{(v)} = 1$, otherwise (i.e., if v is the responder of the interaction) $X_\ell^{(v)} = -1$.

Therefore, for any fixed agent $v \in \mathcal{V}$, the $p(n)$ random variables $X_\ell^{(v)}$, $1 \leq \ell \leq p(n)$ are independent and also

$$\Pr\left(X_\ell^{(v)} = 1\right) = 1 - \Pr\left(X_\ell^{(v)} = -1\right) = \frac{|\{u : x_v > x_u\}|}{n-1} + \frac{1}{2}\frac{(m_v - 1)}{n-1}.$$

For each agent $v_i, i \in [n]$, define now the discrete time stochastic process $\{Y_\ell^{(v_i)}\}_{\ell \geq 0}$ as follows:

(i) $Y_0^{(v_i)} = 0$

(ii) $Y_\ell^{(v_i)} = Y_{\ell-1}^{(v_i)} + X_\ell^{(v_i)} - \mathbb{E}[X_\ell^{(v_i)}] = \sum_{i=1}^{\ell} X_\ell^{(v_i)} - \ell \frac{n-2|\{u : x_{v_i} > x_u\}| - m_{v_i}}{n-1}$, for any $1 \leq \ell \leq p(n)$

(iii) $Y_\ell^{(v_i)} = Y_{\ell-1}^{(v_i)}$, for any $\ell > p(n)$

Since $X_\ell^{(v_i)}$ are independent, for every $1 \leq \ell \leq p(n)$, it is easy to prove that $\{Y_\ell^{(v_i)}\}_{\ell \geq 0}$ is a Martingale, that also satisfies $|Y_\ell^{(v_i)} - Y_{\ell-1}^{(v_i)}| \leq 2$, for all $\ell \geq 1$. Therefore, by Azuma's inequality, for any $x \geq 0$,

$$\Pr\left(\left|Y^{(v_i)}_{p(n)} - Y^{(v_i)}_0\right| \geq x\right) = \Pr\left(\left|Y^{(v_i)}_{p(n)}\right| \geq x\right) \leq 2e^{\frac{-x^2}{8p(n)}}.$$

Let now $t^*_{v_i}$ the time just after the $p(n)$-th interaction of v_i, i.e., the values of the counters $\mathbf{q}_{v_i,1}, \mathbf{q}_{v_i,2}$ remain unchanged after $t^*_{v_i}$. By the definition of $X^{(v_i)}_\ell, 1 \leq \ell \leq p(n)$, we then have that $\mathbf{q}_{v_i,1}(t^*_{v_i}) = \sum_{\ell=1}^{p(n)} X^{(v_i)}_\ell$. Furthermore, by the previous inequality and by definition of $\{Y^{(v_i)}_\ell\}_{\ell \geq 0}$, we have that

$$\Pr\left(\left|\mathbf{q}_{v_i,1}(t^*_{v_i}) - p(n)\frac{n - 2|\{u : x_{v_i} > x_u\}| - m_{v_i}}{n-1}\right| \geq x\right) = \Pr\left(\left|Y^{(v_i)}_{p(n)}\right| \geq x\right) \leq 2e^{\frac{-x^2}{8p(n)}}. \quad (2)$$

For any agent $v \in \mathcal{V}$, let $A_v = p(n)\frac{n-2|\{u:x_v>x_u\}|-m_v}{n-1}$. Notice now that, for any two agents v, v', such that $x_v \neq x'_v$, we have that $|(|\{u : x_v > x_u\}| - |\{u : x_{v'} > x_u\}|)| \geq 1$, since for one of v, v', the number of agents with strictly greater input must be larger. Similarly, $|(|\{u : x_v > x_u\}| + m_v) - (|\{u : x_{v'} > x_u\}| + m_{v'})| = |(|\{u : x_v \geq x_u\}| - |\{u : x_{v'} \geq x_u\}|)| \geq 1$. Therefore, we have proved the following separation inequality:

$$|A_v - A_{v'}| \geq 2\frac{p(n)}{n-1}, \quad \text{for every } v, v' \text{ with } x_v \neq x'_v.$$

Now set $x = \frac{p(n)}{n}$ in (2). Since $p(n) \geq 16n^2 \ln n$, we have that, for any $v_i, i \in [n]$,

$$\Pr\left(\left|\mathbf{q}_{v_i,1}(t^*_{v_i}) - A_{v_i}\right| \geq \frac{p(n)}{n}\right) \leq \frac{2}{n^2}$$

By the union bound, we conclude that, with probability at least $1 - \frac{2}{n}$, not only are the values $\mathbf{q}_{v_i,1}(t^*_{v_i})$, for all nodes v_i, concentrated around their mean values A_{v_i}, but they are also well separated, i.e., just by looking at $\mathbf{q}_{v_i,1}(t^*_{v_i})$, we can uniquely determine the value of A_{v_i}. Furthermore, node v_i will never change the value of its first register after time $t^*_{v_i}$.

Finally note that the smallest value of $|A_{v_i}|$ (hence also the smallest value of $|\mathbf{q}_{v_i,1}(t^*_{v_i})|$ whp, because of well separation) will correspond to agent $v_{\lceil n/2 \rceil}$, i.e., the agent with the median of $\{x_v, v \in \mathcal{V}\}$ as input. Indeed, it is not hard to see that, by definition, $|A_{v_i}|$ is a function of i, for which $|A_{v_i}| \leq |A_{v_{i-1}}|$ for every $i \leq \lceil \frac{n}{2} \rceil$, and $|A_{v_{i+1}}| \geq |A_{v_i}|$ for every $i \geq \lceil \frac{n}{2} \rceil$. Therefore, with high probability, the correct median will be propagated because of Case III of the protocol. This completes the proof. ◀

4 k-th minimum element

In this section, we present an APP with n states and 2 registers per agent (the first of which serves as the input register and does not change throughout the computation) that stably computes the k-th minimum element of the input values $x_v, v \in \mathcal{V}$. Our protocol is not symmetric, hence in every interaction we distinguish between initiator and responder. For simplicity, we first present a protocol that stably computes the k-minimum function assuming the complete interaction graph and then we generalize it for arbitrary interaction graphs.

The set of states of our protocol is $\mathcal{Q} = \{0, 1, \ldots, n-1\}$; without loss of generality, we treat the state of each agent v at time t as a counter $\mathbf{q}_v(t)$ which is initialized to the value 0 and can count up to $n-1$. For simplicity, we will denote $\mathbf{C}_v(t) \overset{def}{=} (\mathbf{R}_{v,1}(t), \mathbf{R}_{v,2}(t), \mathbf{q}_v(t))$.

The input initialization function of our protocol is given by $\iota_{k\text{-MIN}}(x_v) = \mathbf{C}_v(0) = (x_v, x_v, 0)$, for any $x_v \in \mathcal{S}$ and $v \in \mathcal{V}$, and the output function is given by $\gamma_{k\text{-MIN}}(\mathbf{C}_v(t)) =$

$\mathbf{R}_{v,2}(t)$, for any $v \in \mathcal{V}$. The transition function is defined as follows: if agent v (the initiator) interacts with agent u (the responder) at time $t+1 = 1, 2, \ldots$, then $(\mathbf{C}_v(t+1), \mathbf{C}_u(t+1)) = f_{k\text{-MIN}}(\mathbf{C}_v(t), \mathbf{C}_u(t))$, where $f_{k\text{-MIN}}$ is given below.

```
Transition function $f_{k\text{-MIN}}$
Input: $\mathbf{C}_v(t), \mathbf{C}_u(t)$
Case I: $\mathbf{q}_v(t) = \mathbf{q}_u(t)$ AND $\mathbf{R}_{v,1}(t) \geq \mathbf{R}_{u,1}(t)$.
    $f_{k\text{-MIN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = ([x_v, \mathbf{R}_{v,2}(t), \mathbf{q}_v(t)+1], [\mathbf{C}_u(t)])$
Case II: $\mathbf{q}_v(t) = \mathbf{q}_u(t)$ AND $\mathbf{R}_{v,1}(t) < \mathbf{R}_{u,1}(t)$.
    $f_{k\text{-MIN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = ([\mathbf{C}_v(t)], [x_u, \mathbf{R}_{u,2}(t), \mathbf{q}_u(t)+1])$
Case III: $\mathbf{q}_v(t) \neq \mathbf{q}_u(t)$ AND $\mathbf{q}_v(t) = k-1$.
    $f_{k\text{-MIN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = ([x_v, x_v, \mathbf{q}_v(t)], [x_u, x_v, \mathbf{q}_u(t)])$
Case IV: Every other case.
    $f_{k\text{-MIN}}(\mathbf{C}_v(t), \mathbf{C}_u(t)) = (\mathbf{C}_v(t), \mathbf{C}_u(t))$
```

▶ **Theorem 7.** *The APP with initialization function $\iota_{k\text{-MIN}}$, output function $\gamma_{k\text{-MIN}}$ and transition function $f_{k\text{-MIN}}$ stably computes the k-minimum of the set $\{x_v : v \in \mathcal{V}\}$.*

Proof. We first prove that, eventually, there will be exactly one agent in state i, for each $0 \leq i \leq n-1$. To this end, define t_i to be the earliest time when exactly one agent has state j, for each $j \leq i$. Note that, after time t_i, every agent v_j, $1 \leq j \leq i+1$, which has $\mathbf{q}_{v_j}(t_i) = j-1$, will never change her state. Indeed, by definition of $f_{k\text{-MIN}}$, for every $v \in \mathcal{V}$, $\mathbf{q}_v(t)$ never decreases; it can only increase if there is another agent $u \neq v$ with $\mathbf{q}_u(t) = \mathbf{q}_v(t)$. Thus we only need to prove that t_{n-1} is finite; we do this by induction on i.

For the base case of our inductive argument we need to prove that t_0 is finite. This is true because, if at some time t there are at least 2 agents at state 0, then, since the scheduler is fair, after finite time, two of these agents will eventually interact, which, by Cases I and II of $f_{k\text{-MIN}}$, will result in one of the agents increasing her state by 1. This will continue until there is only one agent in state 0.

For the inductive step, suppose that t_i is finite, for some i. By definition, at time t_i we have exactly one agent in state j, for each $j = 0, \ldots, i$. However, by definition of $f_{k\text{-MIN}}$, we also have that at time t_i some agent v set $\mathbf{q}_v(t_i) = i+1$ (i.e., either the one with the largest value stored in its first register, or the initiator in the interaction if both agents had the same value stored in their first registers). If this agent v was the only agent in state $i+1$ after t_i, then we also have that $t_i = t_{i+1}$. If not, then, similarly to the base case, after finite time the number of agents in state $i+1$ will decrease by 1, and this will continue until (within finite time) only one agent remains in state $i+1$. This completes the induction step, implying that t_i is finite, for every $i = 0, 1, \ldots, n-1$. In particular, in finite time t_{n-1}, there will be exactly one agent in state i, for each $i = 0, \ldots, n-1$ and these values will never change thereafter. Moreover, after time t_{n-1}, the agent in state $k-1$ will have the k-minimum of the set $\{x_v : v \in \mathcal{V}\}$ stored in its first register and this item will eventually appear in the second register of each agent in the population (because of Case III of $f_{k\text{-MIN}}$). ◀

We now slightly modify our transition function $f_{k\text{-MIN}}$ so that the protocol works on arbitrary strongly connected directed interaction graphs. Notice that we just need to guarantee that every two agents will eventually be able to exchange their local information.

This can be achieved if agents that interact also swap their register values and states. Therefore, we have the following more general result:

▶ **Theorem 8.** *Let $f'_{k\text{-}MIN} : (\mathcal{S}^2 \times \mathcal{Q}) \times (\mathcal{S}^2 \times \mathcal{Q}) \to (\mathcal{S}^2 \times \mathcal{Q}) \times (\mathcal{S}^2 \times \mathcal{Q})$ be a transition function defined as follows: for any $\vec{x}, \vec{y}, \vec{x}', \vec{y}' \in \mathcal{S}^2 \times \mathcal{Q}$, $f'_{k\text{-}MIN}(\vec{x}, \vec{y}) = (\vec{y}', \vec{x}')$ if and only if $f_{k\text{-}MIN}(\vec{x}, \vec{y}) = (\vec{x}', \vec{y}')$. Then the APP with initialization function $\iota_{k\text{-}MIN}$, output function $\gamma_{k\text{-}MIN}$ and transition function $f'_{k\text{-}MIN}$ stably computes the k-minimum of the set $\{x_v : v \in \mathcal{V}\}$ under any strongly connected interaction graph.*

Note that, upon convergence in this APP, each of the n agents has a different state which is an integer between 0 and $n-1$. Therefore all these states provide a *total ordering* of the agents with respect to their input values.

▶ Remark. This APP can be slightly modified to stably compute the population size $n = |\mathcal{V}|$, under any strongly connected interaction graph. Indeed, we only need that the second register of each agent $v \in \mathcal{V}$ is replaced by another counter $\mathbf{q}'_v(t)$, which stores the value n (instead of the k-minimum element). This can be achieved trivially by initializing $\mathbf{q}'_v(0)$ to 1, for each agent v and modifying $f'_{k\text{-MIN}}$ as follows: whenever agents v, u interact at time $t+1$, we set $\mathbf{q}'_v(t+1) = \mathbf{q}'_u(t+1) = \max\{\mathbf{q}_v(t)+1, \mathbf{q}_u(t)+1, \mathbf{q}'_v(t), \mathbf{q}'_u(t)\}$; the rest of $f'_{k\text{-MIN}}$, i.e., the part that affects the first registers and the states, remains unchanged.

Abstract

We consider the problem of answering shortest unique substring (SUS) queries on run-length encoded strings. For a string S, a unique substring $u = S[i..j]$ is said to be a *shortest unique substring* (*SUS*) of S containing an interval $[s,t]$ $(i \leq s \leq t \leq j)$ if for any $i' \leq s \leq t \leq j'$ with $j - i > j' - i'$, $S[i'..j']$ occurs at least twice in S. Given a run-length encoding of size m of a string of length N, we show that we can construct a data structure of size $O(m + \pi_s(N,m))$ in $O(m \log m + \pi_c(N,m))$ time such that queries can be answered in $O(\pi_q(N,m) + k)$ time, where k is the size of the output (the number of SUSs), and $\pi_s(N,m)$, $\pi_c(N,m)$, $\pi_q(N,m)$ are, respectively, the size, construction time, and query time for a predecessor/successor query data structure of m elements for the universe of $[1,N]$. Using the data structure by Beam and Fich (JCSS 2002), this results in a data structure of $O(m)$ space that is constructed in $O(m \log m)$ time, and answers queries in $O(\sqrt{\log m / \log\log m} + k)$ time.

1 Introduction

The *shortest unique substring* (*SUS*) problem is, given a string S of length N and query interval $[s,t] \subseteq [1,N]$ of positions in S, find the shortest substring $S[x..y]$ of S that contains $[s,t]$ (i.e., $[s,t] \subseteq [x,y]$) and is *unique* (i.e., occurs only once) in S. Finding SUSs has possible applications in various fields, including alignment free genome comparison [10], PCR primer design [17], and display of search results [17]. The problem was first introduced by Pei et al. [17], who considered only a single position (i.e., an interval of size 1) as the query input, and showed that the string can be preprocessed in $O(N^2)$ time and $O(N)$ space so that a single SUS for a query position can be returned in constant time. Again for the single position query, Tsuruta et al. [20], Ileri et al. [13], and Hon et al. [11] independently showed that the preprocessing can be improved to $O(N)$ time and space, with constant query time. Tsuruta et al. [20] and Ileri et al. [13] also showed that all SUSs that contain the query position can be answered in $O(k)$ time, where k is the number of SUSs to output. Hu et al. [12] further generalized the problem to interval queries, and showed that it can be solved in $O(N)$ time and space, and all SUSs that contain the query interval can be answered in $O(k)$ time.

In this paper, we consider the SUS problem for interval queries in the case where the string is given in *run-length encoding* (*RLE*). The RLE of a string is a natural compressed representation where each maximal character run of a character a of length e is encoded as a^e. String processing on the compressed representation of a string without explicit decompression [1] is a heavily studied topic, and can lead to time and space efficient processing [18]. There have been many studies on efficient algorithms for processing RLE strings [7, 8, 2, 3, 16, 14, 9, 15, 4]. We show that given a run-length encoding of size m of a string, we can construct a data structure of size $O(m + \pi_s(N, m))$ in $O(m \log m + \pi_c(N, m))$ time such that all SUSs that contain the query interval can be answered in $O(\pi_q(N, m) + k)$ time, where k is the number of such SUSs and $\pi_s(N, m)$, $\pi_c(N, m)$, $\pi_q(N, m)$ are, respectively, the size, construction time, and query time for a predecessor/successor query data structure of m elements for the universe of $[1, N]$. Using the data structure by Beam and Fich [5], this results in a data structure of size $O(m)$ space that is constructed in $O(m \log m)$ time, and answers queries in $O(\sqrt{\log m / \log \log m} + k)$ time. Thus, compared to previous work [12], our algorithm allows for more time and space efficient preprocessing for RLE compressible strings, with a slight increase in query time.

Our result is an outcome of a non-trivial mixed use of combinatorial properties of RLE strings and data structures built on RLE strings: All existing solutions [17, 20, 13, 12, 11] to the SUS problem precompute *minimal unique substrings* (*MUSs*) of a given string, which are minimal substrings of S occurring exactly once in S, and store them in $\Theta(N)$ space, since, in general, there can be $\Theta(N)$ MUSs in a given string. However, using combinatorial properties of MUSs and RLE strings, we show in this paper that any string of RLE size m contains at most $2m - 1$ MUSs, enabling our space-efficient $O(m)$-size data structure for the SUS problem. This bound is indeed tight, namely, some strings contain $2m - 1$ MUSs. In our algorithm, we separately treat MUSs that are completely contained in runs, those that start at the last characters of runs, and the rest. We then show that all the MUSs can be precomputed in $O(m \log m)$ time using a special type of suffix arrays for RLE strings [19]. Finally, we show how, given all MUSs, to efficiently compute all SUSs for any given query interval.

2 Preliminaries

2.1 Notations

Let $\Sigma = \{1, \ldots, \sigma\}$ be an *alphabet*. An element of Σ^* is called a *string*. The length of a string S is denoted by $|S|$. The empty string ε is the string of length 0, namely, $|\varepsilon| = 0$. The i-th character of a string S of length N is denoted by $S[i]$ for $1 \leq i \leq N$. For $1 \leq i \leq j \leq N$, let $S[i..j] = S[i] \cdots S[j]$, i.e., $S[i..j]$ is the *substring* of S starting at position i and ending at position j in S. For convenience, let $S[i..j] = \varepsilon$ if $j < i$. For any $1 \leq i \leq N$, non-empty strings $S[1..i]$ and $S[i..N]$ are respectively called *prefixes* and *suffixes* of S. Let $\mathit{suf}_S(i) = S[i..N]$. For any strings X and Y, let $\mathit{lcp}(X, Y)$ denote the length of the *longest common prefix* of X and Y. For any string S of length n and any $1 \leq i \leq j \leq N$, let $\mathit{lce}_S(i, j) = \mathit{lcp}(\mathit{suf}_S(i), \mathit{suf}_S(j))$. If a string X is lexicographically smaller than another string Y, then we write $X \prec Y$ or $Y \succ X$.

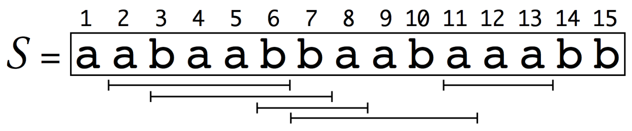

Figure 1 All the MUSs of string S = aabaabbaabaaabb are $S[2..6]$ = abaab, $S[3..7]$ = baabb, $S[6..8]$ = bba, $S[7..11]$ = baaba, and $S[11..13]$ = aaa.

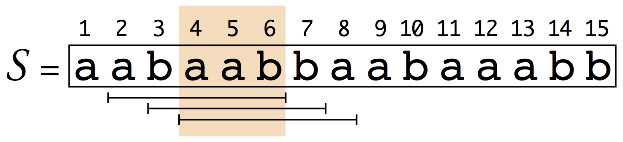

Figure 2 Consider the same string S = aabaabbaabaaabb as in Figure 1. All the SUSs that contain a query interval $[4, 6]$ are $S[2..6]$ = abaab, $S[3..7]$ = baabb, and $S[4..8]$ = aabba. The first two SUSs are also MUSs of S, while the last SUS is obtained by taking the beginning position 4 of the query interval $[4, 6]$ and the ending position of a MUS $S[6..8]$ that overlaps the query interval.

2.2 MUSs and SUSs

For any non-empty strings S and w, let $occ_S(w)$ denote the set of occurrences of w in S, namely, $occ_S(w) = \{i \mid 1 \leq i \leq |S| - |w| + 1, w = S[i..i + |w| - 1]\}$. A substring w of a string S is called a *unique substring* (resp. a *repeat*) of S if $|occ_S(w)| = 1$ (resp. $|occ_S(w)| \geq 2$). In the sequel, we will identify each unique substring w of S with its corresponding (unique) interval $[i, j]$ in S such that $w = S[i..j]$. A unique substring $u = S[i..j]$ is said to be *right minimal unique* if for any $i \leq j' < j$, $S[i..j']$ is a repeat of S. A unique substring $u = S[i..j]$ is said to be *left minimal unique* if for any $i < i' \leq j$, $S[i'..j]$ is a repeat of S. A substring $u = S[i..j]$ is said to be a *minimal unique substring* (*MUS*) of S if u is right minimal unique and left minimal unique. Let $\mathcal{M}_S$ denote the set of all MUSs of S. Also, a unique substring $u = S[i..j]$ is said to be a *shortest unique substring* (*SUS*) of S containing an interval $[s, t]$ $(i \leq s \leq t \leq j)$ if for any $i' \leq s \leq t \leq j'$ with $j - i > j' - i'$, $S[i'..j']$ is a repeat of S. Hu et al. [12] showed that precomputing all MUSs $\mathcal{M}_S$ in a given string S, later allows to efficiently answer all SUSs that contain any query range $[s, t]$. See Figures 1 and 2 for examples of MUSs and SUSs of a string.

2.3 Run-length encodings and our problem

The *run-length encoding* (*RLE*) of string S of length N is a compact representation of S which encodes each maximal character run $S[i..i + e - 1]$ by a^e, if (1) $S[j] = a$ for all $i \leq j \leq i + e - 1$, (2) $S[i - 1] \neq S[i]$ or $i = 1$, and (3) $S[i + e - 1] \neq S[i + e]$ or $i + e - 1 = N$. E.g., $RLE(\mathtt{aabbbbcccaaa\$}) = \mathtt{a}^2\mathtt{b}^4\mathtt{c}^3\mathtt{a}^3\$^1$. The *size* of $RLE(S) = a_1^{e_1} \cdots a_m^{e_m}$ is the number m of maximal character runs in S and is denoted by $|RLE(S)|$. For any $1 \leq i \leq m$, let $bpos_S(i)$, $epos_S(i)$, and $exp_S(i)$ respectively denote the beginning position, ending position, and exponent of the ith run of $RLE(S)$ in the original string S; namely, $bpos_S(i) = 1 + \sum_{k=1}^{i-1} e_k$, $epos_S(i) = \sum_{k=1}^{i} e_k$, and $exp_S(i) = e_i$.

In this paper, we will tackle the following problem:

▶ **Problem 1** (SUSs on RLE strings).
Preprocess: *$RLE(S) = a_1^{e_1} \cdots a_m^{e_m}$ of size m of string S of length N.*
Query: *An interval $[s, t] \in [1, N]$.*
Return: *All SUSs of S containing the query interval $[s, t]$.*

Figure 3 tRLESA_S, tRLESA_S^{-1}, $\mathsf{tRLELCP}_S$, and EXP_S for $RLE(S) = \mathtt{a}^3\mathtt{c}^2\mathtt{a}^1\mathtt{c}^2\mathtt{a}^2\mathtt{b}^2\mathtt{c}^3\$^1$ with $m = 8$ and $N = |S| = 16$. We remark that the exponents of the first runs in parentheses are all regarded as 1. For instance, consider the suffixes of lexicographical ranks 2 and 3. Although $\mathtt{a}^1\mathtt{c}^2\mathtt{a}^2\mathtt{b}^2\mathtt{c}^3\$^1$ is lexicographically greater than $\mathtt{a}^3\mathtt{c}^2\mathtt{a}^1\mathtt{c}^2\mathtt{a}^2\mathtt{b}^2\mathtt{c}^3\$^1$, $\mathtt{a}^1\mathtt{c}^2\mathtt{a}^2\mathtt{b}^2\mathtt{c}^3\$^1$ is lexicographically smaller than $\mathtt{a}^1\mathtt{c}^2\mathtt{a}^1\mathtt{c}^2\mathtt{a}^2\mathtt{b}^2\mathtt{c}^3\$^1$, and tRLESA_S builds on the latter ordering.

Our model of computation is a standard word RAM with machine word size $\Omega(\log N)$. The space complexity of our algorithm to solve Problem 1 will be evaluated by the number of words (rather than bits).

3 Tools

In this section, we list some data structure which we use to solve Problem 1.

3.1 Suffix arrays and related arrays for RLE strings

Let S be a string of length N and let $B \subseteq [1, N]$ be any subset of positions in S called sampled positions. The sparse suffix array SSA_B of a string S w.r.t. B is an array of size $|B|$ such that $\mathsf{SSA}_B[i] \in B$ for all $1 \le i \le |B|$ and $suf_S(\mathsf{SSA}_B[i]) \prec suf_S(\mathsf{SSA}_B[i+1])$ for all $1 \le i < N$.

We will use the following arrays in our algorithm for computing SUSs on RLE strings. These arrays were first introduced in [19]. Let $m = |RLE(S)|$ and $E = \{epos_S(i) \mid 1 \le i \le m\}$. The *truncated RLE suffix array* for $RLE(S)$, denoted tRLESA_S, is the sparse suffix array of S w.r.t. E. Namely, for any $1 \le i \le m$, $\mathsf{tRLESA}_S[i] = j$ iff $j \in E$ and the lexicographical rank of the suffix $S[j..N]$ is i among all suffixes of S that begin with positions in E. Let tRLESA_S^{-1} be an array of size m such that $\mathsf{tRLESA}_S[\mathsf{tRLESA}_S^{-1}[i]] = epos_S(i)$ for all $1 \le i \le m$. Let $\mathsf{tRLELCP}_S$ be an array of size $m+1$ such that $\mathsf{tRLELCP}_S[1] = \mathsf{tRLELCP}_S[m+1] = 0$ and $\mathsf{tRLELCP}_S[i] = lce_S(\mathsf{tRLESA}_S[i-1], \mathsf{tRLESA}_S[i]) = lcp(suf_S(\mathsf{tRLESA}_S[i-1]), suf_S(\mathsf{tRLESA}_S[i]))$ for all $2 \le i \le m$. Also, let EXP_S be an array of size m such that $\mathsf{EXP}_S[i] = exp_S(k)$ where $\mathsf{tRLESA}_S[i] = epos_S(k)$ for all $1 \le i \le m$, namely, $\mathsf{EXP}_S[i]$ stores the ignored exponent of the first run of the ith suffix in tRLESA_S. See Figure 3 for concrete examples of these arrays.

▶ **Lemma 2** ([19]). *Given $RLE(S)$ of size m, tRLESA_S, tRLESA_S^{-1}, $\mathsf{tRLELCP}_S$, and EXP_S can be computed in a total of $O(m \log m)$ time with $O(m)$ working space.*

The following is a simple observation of these arrays we will exploit.

▶ **Observation 3.** *For any* $1 \leq i \leq m$*, let*

$$l = \max\{\mathsf{tRLELCP}_S[p], \mathsf{tRLELCP}_S[p+1]\},$$

where $p = \mathsf{tRLESA}_S^{-1}[i]$*. If* $l \neq 0$*, then* l *is the length of the longest repeat of* S *that starts at* $epos_S(i)$*.*

For example of Observation 3, see Figure 3. There, for position $i = 3$, we have $p = \mathsf{tRLESA}_S^{-1}[3] = 2$. Then, observe that $l = \max\{1, 4\} = 4$ is the length of the longest repeat $\mathtt{ac}^2\mathtt{a}$ that starts at position $epos_S(3) = 6$. On the other hand, for position $i = 6$, we have $p = \mathsf{tRLESA}_S^{-1}[6] = 4$. Then, $l = \max\{0, 0\} = 0$, but this is not equal to the length 1 of the longest repeat $\mathtt{b}$ that starts at position $epos_S(6) = 12$. In our algorithm, we will use Observation 3 only the case where $l \neq 0$.

3.2 Range minimum/maximum query data structure

Let A be an integer array of size m. Give a query range $[i, j] \in [1, m]$, a *range minimum query* $\mathsf{RmQ}_A(i, j)$ returns the index of a minimum element in the subarray $A[i, j]$, namely, it returns one of $\arg\min_{i \leq k \leq j}\{A[k]\}$. Similarly, *range maximum query* $\mathsf{RMQ}_A(i, j)$ returns the index of a maximum element in the subarray $A[i, j]$, namely, it returns one of $\arg\max_{i \leq k \leq j}\{A[k]\}$. It is well-known (see e.g. [6]) that after an $O(m)$-time preprocessing over the input array A, $\mathsf{RmQ}_A(i, j)$ and $\mathsf{RMQ}_A(i, j)$ can be answered in $O(1)$ time for any query range $[i, j]$, using $O(m)$ space.

3.3 Some functions related to tRLESA

In this subsection, we introduce some functions related to tRLESA_S and the other arrays, which will be used in our algorithm to compute SUSs on RLE strings.

Consider $RLE(S)$ of size m. For any pair $(i, j) \in [1, m] \times [1, m]$, let $trle\_lce_S(i, j) = lce_S(\mathsf{tRLESA}_S[i], \mathsf{tRLESA}_S[j])$. Since

$$trle\_lce_S(i, j) = \begin{cases} \mathsf{RmQ}_{\mathsf{tRLELCP}_S}(i+1, j) & \text{if } i < j, \\ \mathsf{RmQ}_{\mathsf{tRLELCP}_S}(j+1, i) & \text{otherwise}, \end{cases}$$

after a linear-time preprocessing on $\mathsf{tRLELCP}_S$, we can answer $trle\_lce_S(i, j)$ in $O(1)$ time for any given pair (i, j).

For any $1 \leq q \leq m$ and $e \geq 1$, let $exp\_pos(q, e)$ denote a query which returns a position $q' \neq q$, if it exists, that satisfies $\mathsf{EXP}_S[q'] \geq e$ and $S[\mathsf{tRLESA}_S[q']] = S[\mathsf{tRLESA}_S[q]]$ while maximizing $trle\_lce(q, q')$, and *nil* otherwise. Thus, with $q' = exp\_pos(q, e)$, we can obtain the length of the longest repeating substring starting at position $\mathsf{tRLESA}_S[q] - e + 1$ as $e - 1 + trle\_lce(q, q')$.

▶ **Lemma 4.** *Given* EXP_S *for* $RLE(S)$ *of size* m*, we can preprocess* EXP_S *in* $O(m)$ *time so that subsequent* $exp\_pos(q, e)$ *queries can be answered in* $O(\log m)$ *time for any* $1 \leq q \leq m$ *and* $e \geq 1$*.*

Proof. We construct an RMQ data structure for EXP_S in $O(m)$ time. Since lexicographically close strings share a longer prefix, $exp\_pos(q, e)$ is one of the two closest neighbours of q in EXP_S that stores an exponent at least e, corresponding to a run of the same character. Thus, we can compute $exp\_pos(q, e)$ using two binary searches on EXP, by comparing e with the answer of the RMQ queries, starting with the initial range $[1, q-1]$ and $[q+1, m]$. Since the size of EXP_S is m and each RMQ query takes $O(1)$ time, it takes $O(\log m)$ time to locate $exp\_pos(q, e)$. ◀

For any $1 \le q \le m$ and $\ell \ge 0$, let $lce\_pos(q, \ell)$ denote a query which returns a position $q' \ne q$, if it exists, such that $trle\_lce(q, q') \ge \ell$ while maximizing $\mathsf{EXP}_S[q']$, and nil otherwise. In other words, $lce\_pos(q, \ell)$ corresponds to a suffix that has the maximum exponent out of suffixes which, have a common prefix of length ℓ with the suffix corresponding to q. Note that if $\ell > \max\{\mathsf{tRLELCP}[q], \mathsf{tRLELCP}[q+1]\}$, $lce\_pos(q, \ell) = nil$.

▶ **Lemma 5.** *Given* $\mathsf{tRLELCP}_S$ *for* $RLE(S)$ *of size* m*, we can preprocess* $\mathsf{tRLELCP}_S$ *in* $O(m)$ *time so that subsequent* $lce\_pos(q, \ell)$ *queries can be answered in* $O(\log m)$ *time for any* $1 \le q \le m$ *and* $\ell \ge 0$.

Proof. We construct an RmQ data structure on $\mathsf{tRLELCP}_S$. Since, as noted previously, lexicographically close strings share a longer prefix, values of $trle\_lce(q, q'')$ are larger when q'' is closer to q. Thus, similar to Lemma 4, we can conduct two binary searches on $\mathsf{tRLELCP}_S$ using RmQ and obtain the maximal range $[q_p, q_n]$ such that $trle\_lce(q, q'') \ge \ell$ if and only if $q'' \in [q_p, q_n]$. After finding the range, the larger of the two RMQ queries for the ranges $[q_p, q-1]$ and $[q+1, q_n]$ on EXP_S gives the answer. ◀

3.4 Predecessor/successor query data structure

Let $A[1..m]$ be an array containing positive integers less than or equal to N, in increasing order. The predecessor and successor queries on A are defined for any $1 \le d \le N$ as

$$\mathsf{Pred}_A(d) = \begin{cases} \max\{i \mid A[i] \le d\} & \text{if it exists,} \\ 0 & \text{otherwise.} \end{cases}$$

$$\mathsf{Succ}_A(d) = \begin{cases} \min\{i \mid A[i] \ge d\} & \text{if it exists,} \\ N+1 & \text{otherwise.} \end{cases}$$

There exists a data structure of $O(m)$ space that can be built in $O(m\sqrt{\log m / \log\log m})$ time, such that later, for any given $1 \le d \le N$, $\mathsf{Pred}_A(d)$ and $\mathsf{Succ}_A(d)$ can be answered in $O(\sqrt{\log m / \log\log m})$ time [5].

4 Computing MUSs from RLE strings

In this section we show how we can compute $\mathcal{M}_S$ given $RLE(S)$, which is the main part of our preprocessing. As will be seen in Section 4.1, we partition MUSs into three disjoint groups; those that are completely contained in runs, those that start at the last characters of runs, and the rest.

4.1 Size of $\mathcal{M}_S$

We begin with the analysis of the size of $\mathcal{M}_S$ in terms of $m = |RLE(S)|$. Let

$$\begin{aligned} \mathcal{M}^{(1)} &= \{[x, y] \in \mathcal{M}_S \mid bpos_S(i) \le x \le y \le epos_S(i) \text{ for some } 1 \le i \le m\}, \\ \mathcal{M}^{(2)} &= \{[x, y] \in \mathcal{M}_S \mid x = epos_S(i) < y \text{ for some } 1 \le i < m\}, \text{ and} \\ \mathcal{M}^{(3)} &= \{[x, y] \in \mathcal{M}_S \mid bpos_S(i) \le x < epos_S(i) < y \text{ for some } 1 \le i < m\}. \end{aligned}$$

Clearly, $\mathcal{M}_S = \mathcal{M}^{(1)} \cup \mathcal{M}^{(2)} \cup \mathcal{M}^{(3)}$. For example, for the same string $S = \mathtt{aaaccaccaabbccc\$}$ as in Figure 3, $\mathcal{M}_S = \{[1,3],[2,4],[5,7],[8,10],[10,11],[11,12],[12,13],[13,15],[16,16]\} = \{\mathtt{aaa}, \mathtt{aac}, \mathtt{cac}, \mathtt{caa}, \mathtt{ab}, \mathtt{bb}, \mathtt{bc}, \mathtt{ccc}, \$\}$, $\mathcal{M}^{(1)} = \{\mathtt{aaa}, \mathtt{bb}, \mathtt{ccc}, \$\}$, $\mathcal{M}^{(2)} = \{\mathtt{cac}, \mathtt{caa}, \mathtt{ab}, \mathtt{bc}\}$, and $\mathcal{M}^{(3)} = \{\mathtt{aac}\}$.

Since, by definition, a MUS cannot be a proper substring of another MUS, there can be at most one MUS that starts at any given position. Thus, it follows that $|\mathcal{M}^{(2)}| \leq m-1$.

For $|\mathcal{M}^{(3)}|$, we have the following lemma.

▶ **Lemma 6.** *For any $[x,y] \in \mathcal{M}^{(3)}$ and $p \in occ_S(S[x+1..y]) \setminus \{x+1\}$, we have that $p = bpos_S(i)$ for some $1 \leq i < m$.*

Proof. Since $S[x..y]$ is a MUS, $S[x+1..y]$ is not unique and thus $occ_S(S[x+1..y]) \setminus \{x+1\}$ is not empty. If $p \neq bpos_S(i)$ for any $1 \leq i < m$, then $S[p-1] = S[p]$ and thus gives another occurrence of $S[x..y]$ contradicting that it is unique. ◀

We now show $|\mathcal{M}^{(3)} \cup \mathcal{M}^{(1)}| \leq m$. Let $\mathcal{R} = \{bpos_S(i) \mid 1 \leq i \leq m\}$. From Lemma 6, we can define a function $f : \mathcal{M}^{(3)} \cup \mathcal{M}^{(1)} \to \mathcal{R}$ as follows:

$$f([x,y]) = \begin{cases} \min(occ_S(S[x+1..y]) \setminus \{x+1\}) & \text{if } [x,y] \in \mathcal{M}^{(3)} \\ x & \text{if } [x,y] \in \mathcal{M}^{(1)} \end{cases}$$

Suppose f is not an injective function, i.e., there exist distinct intervals $[x_1,y_1],[x_2,y_2] \in \mathcal{M}^{(3)} \cup \mathcal{M}^{(1)}$ such that $x_1 \neq x_2$ and $p = f([x_1,y_1]) = f([x_2,y_2])$. Note that by definition, $\mathcal{M}^{(3)} \cap \mathcal{M}^{(1)} = \emptyset$.

If $[x_1,y_1],[x_2,y_2] \in \mathcal{M}^{(3)}$, assume w.l.o.g. $y_1 - x_1 \leq y_2 - x_2$. By definition of f, we have $S[x_1+1..y_1] = S[p..p+y_1-x_1-1]$ and $S[x_2+1..y_2] = S[p..p+y_2-x_2-1]$. Also, from the definition of $\mathcal{M}^{(3)}$, we have $S[x_1] = S[x_1+1] = S[p] = S[x_2+1] = S[x_2]$. It follows that $S[x_1..y_1]$ is a prefix of $S[x_2..y_2]$, contradicting that $S[x_1..y_1]$ is unique. If $[x_1,y_1] \in \mathcal{M}^{(3)}$ and $[x_2,y_2] \in \mathcal{M}^{(1)}$, this implies that $S[x_2..y_2]$ is a prefix of $S[x_1+1..y_1]$ which is not unique, thus contradicting that $S[x_2..y_2]$ is unique. Finally, if $[x_1,y_1],[x_2,y_2] \in \mathcal{M}^{(1)}$, $p = f([x_1,y_1]) = f([x_2,y_2])$ implies that $p = x_1 = x_2$ contradicting that $x_1 \neq x_2$. Thus, f must be an injective function. Therefore, $|\mathcal{M}^{(3)} \cup \mathcal{M}^{(1)}| \leq |\mathcal{R}| = m$.

From the above arguments, we have:

▶ **Lemma 7.** $|\mathcal{M}_S| \leq 2m-1$.

We note that the upper bound of Lemma 7 is tight, and there exists a string S such that $|\mathcal{M}_S| = 2m-1$. Consider $S = a_1^{e_1}a_2^{e_2}\cdots a_m^{e_m}$ such that for any $1 \leq i,j \leq m$, $e_i \geq 2$, and $a_i \neq a_j$ when $i \neq j$. Clearly, $a_i^{e_i}$ is a MUS for all $1 \leq i \leq m$, and a_ia_{i+1} is a MUS for all $1 \leq i < m$, giving $2m-1$ MUSs.

4.2 Computing $\mathcal{M}_S$

We now show how to obtain $\mathcal{M}_S$ in $O(m \log m)$ time and $O(m)$ space, by computing the sets $\mathcal{M}^{(1)}, \mathcal{M}^{(2)}, \mathcal{M}^{(3)}$ as defined in Section 4.1.

4.2.1 Computing $\mathcal{M}^{(1)}$

To compute $\mathcal{M}^{(1)}$, we first show a necessary and sufficient condition for an interval $[x,y]$ to be in $\mathcal{M}^{(1)}$.

▶ **Lemma 8.** *For any string S where $RLE(S) = a_1^{e_1}\cdots a_m^{e_m}$, an interval $[x,y] \in \mathcal{M}^{(1)}$ if and only if there exists some $1 \leq i \leq m$ such that $bpos_S(i) = x$, $epos_S(i) = y$, and for any $j \in [1,m] \setminus \{i\}$, either $a_i \neq a_j$ or $e_j < e_i$.*

Proof. ($\Rightarrow$) Since $[x, y]$ is a MUS and any proper substring of $[x, y]$ is not unique, it must be that $x = \mathit{bpos}_S(i), y = \mathit{epos}_S(i)$ for some $1 \leq i \leq m$. Furthermore, it must be that $a_i \neq a_j$ or $e_j < e_i$ for any $j \in [1, m] \setminus \{i\}$, since otherwise, $[x, y]$ will not be unique. ($\Leftarrow$) The condition implies that $S[x..y]$ is the longest run of character a_i in S and is unique. Since any proper substring of $S[x..y]$ is not unique, $[x, y]$ is a MUS and is thus in $\mathcal{M}^{(1)}$. ◀

Let Σ_S be the subset of Σ consisting of letters occurring in S. Using Lemma 8, we can compute $\mathcal{M}^{(1)}$ by simply checking for each character $a \in \Sigma_S$, whether there exists a run of character a with a unique (w.r.t. runs of character a) maximum exponent, and if so, include the interval corresponding to the run in $\mathcal{M}^{(1)}$. Since $|\Sigma_S| \leq m$, this can be done in $O(m \log m)$ time and $O(m)$ space using any standard sorting algorithm.

4.2.2 Computing $\mathcal{M}^{(2)}$

To compute, $\mathcal{M}^{(2)}$, we check for each $1 \leq i \leq m-1$, whether there exists a MUS that starts at $\mathit{epos}_S(i)$ and insert it in $\mathcal{M}^{(2)}$ if there is. More specifically, we first compute y such that $S[\mathit{epos}_S(i)..y]$ is right minimal unique. Next, we check whether $S[\mathit{epos}_S(i) + 1..y]$ is unique or not, and if not, we have that $[\mathit{epos}_S(i), y]$ is also left minimal unique and thus is a MUS.

Let $r = \mathsf{tRLESA}_S^{-1}[i]$. By Observation 3, we have that $l = \max\{\mathsf{tRLELCP}_S[r], \mathsf{tRLELCP}_S[r+1]\}$ is the length of the longest repeat of S that starts at $\mathit{epos}_S(i)$. This implies that $S[\mathit{epos}_S(i)..\mathit{epos}_S(i) + l]$ is right minimal unique. Thus, given the $\mathsf{tRLELCP}_S$ array, $y = \mathit{epos}_S(i) + l$ can be computed in constant time. Next, to determine whether $S[\mathit{epos}_S(i) + 1..y]$ is unique or not, we compute y' such that $S[\mathit{epos}_S(i) + 1..y']$ is right minimal unique. Then, $[\mathit{epos}_S(i) + 1, y]$ is unique iff $y' \leq y$. Noticing that $\mathit{epos}_S(i) + 1 = \mathit{bpos}_S(i + 1)$, we can compute y' as follows. Let $q = \mathsf{tRLESA}_S^{-1}[i + 1]$ and $x = \mathsf{EXP}_S[q]$. We compute $l' = x - 1 + \mathit{trle\_lce}_S(q, q')$, where $q' = \mathit{exp\_pos}(q, x)$. By definition, we have that l' is the length of the longest repeat of S that starts at $\mathit{bpos}_S(i + 1)$. Thus, $y' = \mathit{bpos}_S(i + 1) + l'$. By Lemma 4, this can be computed in $O(m \log m)$ total time and $O(m)$ space for all i.

4.2.3 Computing $\mathcal{M}^{(3)}$

For each $1 \leq i < m$, we will compute the elements of $\mathcal{M}^{(3)}$ that start in the ith run. Let $s = \mathit{bpos}_S(i)$ and we repeat the following while $s < \mathit{epos}_S(i)$. First, compute y such that $S[s..y]$ is right minimal unique. If such y does not exists, i.e., $S[s..|S|]$ is not unique, then we are done. If y does exist, $y \geq \mathit{epos}_S(i)$ since, as noted earlier, no proper substring of a run can be unique. If $y = \mathit{epos}_S(i)$, we must have that $s = \mathit{bpos}_S(i)$ and $[s, y]$ is a MUS in $\mathcal{M}^{(1)}$ and not in $\mathcal{M}^{(1)}$; thus we simply increment s by 1 and repeat the process. Otherwise, if $y > \mathit{epos}_S(i)$, we try to find x such that $S[x..y]$ is left minimal unique. Then, by definition, $[x, y]$ is a MUS. If $x < \mathit{epos}_S(i)$, then we have that $[x, y]$ is a MUS in $\mathcal{M}^{(3)}$, and since there can be no other MUS that starts in the interval $[s, x]$, we set $s = x + 1$ and repeat the process. Otherwise, if $x \geq \mathit{epos}_S(i)$, then $[x, y]$ is either a MUS in $\mathcal{M}^{(2)}$ or does not start in the ith run, so we are finished for the current value of i. Because we obtain one distinct MUS each time we determine y and x, the above process is repeated for a total of $O(m)$ times for all i by Lemma 7. What remains is how to determine y and x.

Whether $y = \mathit{epos}_S(i)$ or not can be determined by checking if $[s, \mathit{epos}_S(i)]$ is a MUS in $\mathcal{M}^{(1)}$ as described in Section 4.2.1. Next, we assume $y \geq \mathit{epos}_S(i) + 1 = \mathit{bpos}_S(i + 1)$. Let $q = \mathsf{tRLESA}_S^{-1}[i]$, $q' = \mathit{exp\_pos}(q, \mathit{epos}_S(i) - s + 1)$. If q' is nil, this implies that no run other than the ith one contains a run of character $S[\mathit{epos}_S(i)]$ with length at least $\mathit{epos}_S(i) - s + 1$. Since $y > \mathit{epos}_S(i)$, we have that $S[s..\mathit{epos}_S(i)]$ is not unique but $S[s..\mathit{bpos}_S(i + 1)]$ is unique and thus, $y = \mathit{bpos}_S(i+1)$. Otherwise, if q' is not nil, then, we have that $\mathit{epos}_S(i) - s + l$, where

$l = \mathit{trle\_lce}_S(q, q')$, is the length of the longest repeat of S that starts at s. Therefore, we have $y = \mathit{epos}_S(i) + l$. From the above arguments and Lemma 4, y can be determined in $O(\log m)$ time. Whether $x \geq \mathit{epos}_S(i)$ or not can be determined by the arguments for checking whether $[\mathit{epos}_S(i), y]$ is a MUS in $\mathcal{M}^{(2)}$, as described in Section 4.2.2. Next, we assume $x < \mathit{epos}_S(i)$. Then, $S[\mathit{epos}_S(i)..y]$ is a repeat. Let $q = \mathsf{tRLESA}_S^{-1}(i)$, $q' = \mathit{lce\_pos}(q, y - \mathit{epos}_S(i) + 1)$. From the definition of $\mathit{lce\_pos}$, we have $x = \mathit{epos}_S(i) - \mathsf{EXP}_S[q'] + 1$. Thus, from the above arguments and Lemma 5, x can be determined in $O(\log m)$ time.

The arguments from Sections 4.2.1-4.2.3 lead to the following lemma.

▶ **Lemma 9.** *For any string S, the set $\mathcal{M}_S$ can be computed from $RLE(S)$ in $O(m \log m)$ time using $O(m)$ space, where $m = |RLE(S)|$.*

5 Solution to the SUS Problem

5.1 Data structure

Our data structure consists of three arrays: X_S, Y_S, and MUSlen_S. Arrays X_S and Y_S are arrays of size $|\mathcal{M}_S|$ such that for any $1 \leq i \leq |\mathcal{M}_S|$, $[\mathsf{X}_S[i], \mathsf{Y}_S[i]]$ is the ith MUS in order of their start position in S. Also, let the array $\mathsf{MUSlen}_S[i] = \mathsf{Y}_S[i] - \mathsf{X}_S[i] + 1$ hold the length of each MUS. Arrays X_S and Y_S are preprocessed for Succ and Pred queries, and MUSlen_S is preprocessed for RmQ queries. From arguments in previous sections, the preprocessing can clearly be done in a total of $O(m \log m)$ time and $O(m)$ space.

5.2 Answering queries

For any two intervals $[s, t]$ and $[x, y]$, let $\mathit{cover}([s, t], [x, y])$ be the smallest interval that contains both $[s, t], [x, y]$, i.e., $\mathit{cover}([s, t], [x, y]) = [\min\{s, x\}, \max\{t, y\}]$.

Given a query interval $[s, t]$, let $i = \mathsf{Pred}_{\mathsf{Y}_S}(t)$ and $j = \mathsf{Succ}_{\mathsf{X}_S}(s)$. Clearly, all SUSs that contain interval $[s, t]$ are contained in the set $\{|\mathit{cover}([s, t], [\mathsf{X}_S[r], \mathsf{Y}_S[r]])| \mid i \leq r \leq j\}$. Thus, it suffices to find the intervals of smallest size in this set, i.e., if $p \in \arg\min\{|\mathit{cover}([s, t], [\mathsf{X}[r], \mathsf{Y}[r]])| \mid i \leq r \leq j\}$, then $\mathit{cover}([s, t], [\mathsf{X}_S[p], \mathsf{Y}_S[p]])$ is a SUS. Notice that for all $i < r < j$, we have that $\mathit{cover}([s, t], [\mathsf{X}_S[r], \mathsf{Y}_S[r]]) = [\mathsf{X}_S[r], \mathsf{Y}_S[r]]$. Thus, the shortest of these can be found by considering $\mathit{cover}([s, t], [\mathsf{X}_S[i], \mathsf{Y}_S[i]])$, $\mathit{cover}([s, t], [\mathsf{X}_S[j], \mathsf{Y}_S[j]])$, and performing an RmQ query on MUSlen_S. An example is shown in Figure 4. For finding a single SUS, the query time is dominated by the Pred and Succ queries, and thus is $O(\pi_q(N, m))$ time. To output all SUSs that contain $[s, t]$, recursive RmQ on sub-intervals of MUSlen_S can be conducted in constant time per output, in order to find all the shortest intervals in the range $[i, j]$. Thus, the total query time is $O(\pi_q(N, m) + k)$, where k is the total number of SUSs that are output.

Putting everything together, we have proved the following theorem:

▶ **Theorem 10.** *Given $RLE(S)$ of size m representing a string S of length N, we can compute in $O(m \log m + \pi_c(N, m))$ time a data structure of size $O(m + \pi_s(N, m))$ which answers SUS queries for any interval $[s, t] \subseteq [1, N]$ in $O(\pi_q(N, m) + k)$ time, where k is the number of SUSs to output.*

Using known results for predecessor/successor queries [5], we obtain the following corollary.

▶ **Corollary 11.** *Given $RLE(S)$ of size m representing a string S of length N, we can compute in $O(m \log m)$ time a data structure of size $O(m)$ which answers SUSs queries for any interval $[s, t] \subseteq [1, N]$ in $O(\sqrt{\log m / \log \log m} + k)$ time, where k is the number of such SUSs.*

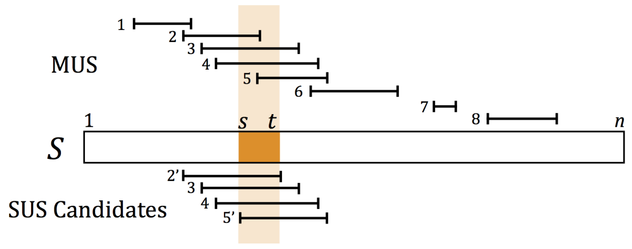

Figure 4 Finding SUSs that contains query interval $[s, t]$. The SUS must be either a MUS that completely contains $[s, t]$ (MUS 3,4), or, it must be an interval that covers both $[s, t]$ and the preceding MUS (MUS 2) or succeeding MUS (MUS 5). Of these, the intervals with shortest length are the SUSs that contain $[s, t]$.

6 Conclusions and open question

We considered the problem of finding all shortest unique substrings (SUSs) of a string S given as the run-length encoding (RLE) of size m. We showed that we can preprocess the RLE in $O(m \log m)$ time and $O(m)$ space so that subsequent SUS queries for S can be answered in $O(\sqrt{\log m / \log\log m} + k)$ time, where k is the number of outputs for the query interval. Notice that none of the preprocessing time, space requirement, or query time depends on the original length N of the string S. This efficiency was achieved by a non-trivial use of the suffix arrays for RLE strings and by revealing combinatorial properties of MUSs and SUSs on RLE strings.

The $\sqrt{\log m / \log\log m}$ term in our query time is due to the use of the $O(m)$-space dynamic predecessor/successor data structure by Beame and Fich [5]. They also showed that for a static set $\mathcal{A}$ of m integers from the universe $[1, N]$, any predecessor/successor data structure for $\mathcal{A}$ of polynomial size in m must use $\Omega(\sqrt{\log m / \log\log m})$ query time (Corollary 3.10 of [5]). Notice that once we build arrays X_S and Y_S, they will remain static. Hence, we cannot hope for faster SUS query time as long as we use predecessor/successor queries to find a MUS for a given interval. Thus, an interesting open question is whether there exists a data structure of size $O(m)$ that can efficiently answer SUS queries without using predecessor/successor queries.

Abstract

We study complexity measures on subsets of the boolean hypercube and exhibit connections between algebra (the Hilbert function) and combinatorics (VC theory). These connections yield results in both directions. Our main complexity-theoretic result demonstrates that a large and natural family of linear program feasibility problems cannot be computed by polynomial-sized constant-depth circuits. Moreover, our result applies to a stronger regime in which the hyperplanes are fixed and only the directions of the inequalities are given as input to the circuit. We derive this result by proving that a rich class of extremal functions in VC theory cannot be approximated by low-degree polynomials. We also present applications of algebra to combinatorics. We provide a new algebraic proof of the Sandwich Theorem, which is a generalization of the well-known Sauer-Perles-Shelah Lemma. Finally, we prove a structural result about downward-closed sets, related to the Chvátal conjecture in extremal combinatorics.

1 Introduction

Understanding the properties and structure of subsets of the boolean hypercube is a central theme in theoretical computer science and combinatorics. When studying a family of mathematical objects, endowing the objects with algebraic structure often sheds new light on interesting properties. This phenomena appears classically in areas such as algebraic topology and algebraic geometry. It also provides much utility when studying the boolean hypercube. Let $C \subseteq \{0,1\}^n$ be a subset of the boolean hypercube, and let $\mathbb{F}$ be a field. Consider the linear space of functions from C to $\mathbb{F}$, that is, $\mathbb{F}^C$. This is clearly a $|C|$-dimensional vector space over $\mathbb{F}$. Every function in this space can be represented as a multilinear polynomial with degree at most n. Interestingly, for certain sets C, smaller degree actually suffices. For example, when C is the standard basis, denoted $C = \{\vec{e}_1, \ldots, \vec{e}_m\}$, then any function $f : C \to \mathbb{F}$ can be expressed as the linear function $f(\vec{e}_1)x_1 + \ldots + f(\vec{e}_m)x_m$.

The Hilbert function, denoted $h_d(C, \mathbb{F})$, is the dimension of the space of functions $\{f : C \to \mathbb{F}\}$ that have representations as polynomials with degree at most d. This classical algebraic object will be useful in our study of how the structure of C affects the function space. In complexity theory, Smolensky [40] has used the Hilbert function to unify polynomial approximation lower bounds relating to bounded-depth circuits.

We establish new connections between the Hilbert function and VC theory. Our main technical contributions are bounds $h_d(C, \mathbb{F})$ in terms of basic concepts in VC theory, such as shattering, strong shattering, and down-shifts. Previous results on bounding the Hilbert function utilize a more intricate analysis and focus on symmetric sets, that is, unions of slices of the hypercube [40, 11]. In addition to giving new bounds on the Hilbert function, our connection between Algebra and Combinatorics allows us to derive results in both directions.

Our main complexity theoretical application is that determining feasibility of a large family of linear programs is hard for the class of bounded-depth circuits. More specifically, let $h_1, \dots, h_m$ be affine functions. Each sign vector s in $\{\pm\}^m$ defines the following feasibility problem: does there exist $x \in \mathbb{R}^d$ such that $h_i(x) > 0$ when $s_i = +$, and $h_i(x) < 0$ when $s_i = -$, for all $i \in [m]$? This defines a boolean function that takes an input s and outputs one if and only if the problem is feasible. We prove that if $m = 2d + 1$, and the affine functions h_i are in general position, then this function cannot be approximated by low-degree polynomials, over any field. This implies a lower bound on the computability of this function by constant-depth circuits, due to the polynomial approximation technique introduced by Razborov [37] and Smolensky [41]. The above linear programming problem relates to the study of hyperplane arrangements (see the books of Matoušek [30] and Stanley [43] for more details and applications). Our results implicitly provide algebraic proofs of some known facts regarding the combinatorics of hyperplane arrangements.

As a combinatorial application of our bounds on the Hilbert function, we provide a short algebraic proof of the Sandwich Theorem. This theorem comes from VC theory and is a well-studied generalization of the Sauer-Shelah-Perles Lemma [29, 36, 15, 14, 18, 5, 8, 33, 28, 32, 35]. Similar proofs of related upper bounds have appeared previously, due to Frankl and Pach [7], Gurvits [24], and Smolensky [42]. We contribute new lower bounds and applications.

Facts we prove about the function space $\mathbb{F}^C$ also lead to a new result about downward-closed sets. A family D of subsets is *downward-closed* if $b \subseteq a$ and $a \in D$ implies $b \in D$. A theorem of Berge [10] implies that for any downward-closed set D there exists a bijection $\pi : D \to D$ such that $a \cap \pi(a) = \emptyset$ for all $a \in D$. We generalize his result to arbitrary, prescribed intersections. Let $\phi : D \to D$ have the property $\phi(a) \subseteq a$ for all $a \in D$. We show that there always exists a bijection $\pi : D \to D$ such that $a \cap \pi(a) = \phi(a)$. Note that choosing $\phi(a) = \emptyset$ for all a implies Berge's result.

Our algebra-combinatorics connection fits within the framework of the polynomial method. This method has been successful in providing elegant proofs of fundamental results in many areas, such as circuit complexity [41, 6, 37, 9], discrete geometry [25, 19, 39, 44], extremal combinatorics [1, 26, 7], and more.

The paper is organized as follows. We state our main theorems in Section 2. In Section 3, we prove our bounds on the Hilbert function. In Section 4, we use our Hilbert function bounds to prove that linear program feasibility is hard for bounded-depth circuits. Finally, in Section 5, we prove results about downward-closed sets. We now review preliminaries.

1.1 Preliminaries

We begin with algebraic preliminaries. Let $C \subseteq \{0,1\}^n$ and $\mathbb{F}$ be a field. Every $f : C \to \mathbb{F}$ can be expressed as a multilinear polynomial over variables $x_1, \dots, x_n$ with coefficients in $\mathbb{F}$.

▶ **Definition 1.** For $d \in [n]$ the *Hilbert function* $h_d(C, \mathbb{F})$ is the dimension of the space of functions $f : C \to \mathbb{F}$ that can be represented as polynomials with degree at most d.

Notice that $h_d(C, \mathbb{F}) \le \min\{\sum_{j=0}^{d} \binom{n}{j}, |C|\}$. A basic fact about the Hilbert function is that

$$1 = h_0(C, \mathbb{F}) \le h_1(C, \mathbb{F}) \le \ldots \le h_n(C, \mathbb{F}) = |C|.$$

The final equality holds because all $f : C \to \mathbb{F}$ have representations with degree at most n.

It is natural to wonder when the Hilbert function attains its maximum and how the structure of C influences the Hilbert function. We introduce the following measure.

▶ **Definition 2.** The **interpolation degree of** C denoted $\mathsf{intdeg}(C, \mathbb{F})$ is the minimum d such that any $f : C \to \mathbb{F}$ can be expressed as a multilinear polynomial with degree at most d. In other words,

$$\mathsf{intdeg}(C, \mathbb{F}) = \min\{d \in [n] : h_d(C, \mathbb{F}) = |C|\}.$$

Intuitively, a smaller interpolation degree implies a less complex set.

We move on to combinatorial preliminaries. Our bounds on the Hilbert function use basic concepts in VC theory. We define these concepts now.

▶ **Definition 3.** A subset $I \subseteq [n]$ is **shattered** by $C \subseteq \{0, 1\}^n$ if for every pattern $s : I \to \{0, 1\}$ there is $c \in C$ that realizes s. In other words, the restriction of c to I equals s. A subset $I \subseteq [n]$ is **strongly shattered** by C if C contains all elements of some subcube on I. In other words, there exists a pattern $\bar{s} : ([n] \setminus I) \to \{0, 1\}$ such that all extensions of $\bar{s}$ to a vector in $\{0, 1\}^n$ are in C.

These definitions lead to natural families of sets, which will be important to our work.

▶ **Definition 4.** The **shattered sets** with respect to C are

$$\mathsf{str}(C) = \{I \subseteq [n] : I \text{ is shattered by } C\}.$$

The **strongly shattered sets** with respect to C are

$$\mathsf{sstr}(C) = \{I \subseteq [n] : I \text{ is strongly shattered by } C\}.$$

▶ **Definition 5.** The **VC dimension** of C is defined as $\mathsf{VC}(C) = \max\{|I| : I \in \mathsf{str}(C)\}$.

Note that $\mathsf{sstr}(C) \subseteq \mathsf{str}(C)$ and that both of these families are downward-closed.

We also lower bound the Hilbert function using down-shifts, a standard tool in extremal combinatorics. Let $C \subseteq \{0, 1\}^n$ and let $i \in [n]$. We denote as S_i the down-shift operator on the i'th coordinate. Obtain the set $S_i(C) \subseteq \{0, 1\}^n$ from C as follows. Replace every $c \in C$ such that both (i) $c_i = 1$, and (ii) the i'th neighbor[1] of c is not in C with the i'th neighbor of c. Authors have referred to this operation as "compression", "switching", and "polarization'. Previous works that use down-shifts include [27, 20, 13, 22, 23, 33].

An important property of down-shifts is that they transform an arbitrary subset of $\{0, 1\}^n$ into a downward-closed set, without changing cardinality. Specifically, if

$$D = S_n(S_{n-1}(\cdots S_1(C)))$$

is the result of sequentially applying S_i on C for each i, then D is downward-closed. It is also convenient in this context to think of D as a family of subsets of $[n]$ rather than a set of boolean vectors via the natural correspondence between boolean vectors and sets.

We move on to explaining our results in more formality and detail.

[1] Vectors $u, v \in \{0, 1\}^n$ are *i'th-neighbors* if they differ in coordinate i and are the same elsewhere.

2 Our Results

We start with the result about linear program feasibility. We then state the bounds on the Hilbert function in terms of shattered sets and down-shifts. We show this leads to bounded-depth circuit lower bounds. Finally, we state two combinatorial applications.

2.1 Linear Program Feasibility

We formalize and prove a strong version of the statement "linear programming feasibility can not be decided by polynomial-sized, constant-depth circuits." Clearly, linear programming being P-complete [17] implies a version of this statement for specific linear programs representing functions previously known not to have efficient bounded-depth circuits. We prove a stronger version stating that any linear feasibility problem, in which the number of constraints is roughly twice the number of variables and the constraints are non-degenerate, cannot be decided by an efficient bounded-depth circuit. For a set of hyperplanes $\mathcal{H}$ in $\mathbb{R}^k$ we will define a boolean function $f_{\mathcal{H}}$. It takes orientations as inputs and outputs one if and only if a certain polytope is nonempty. In particular, we establish hardness of this problem even when the hyperplanes are fixed in advance and only the orientations are given as input.

We express linear program feasibility as a boolean function as follows. Specify an arrangement of m hyperplanes $\mathcal{H} = \{h_1, \dots, h_m\}$ with normal vectors $\vec{n}_i$ and translation scalars b_i as

$$h_i = \{\vec{x} : \langle \vec{n_i}, \vec{x} \rangle = b_i\}.$$

A sign pattern $s \in \{-1,1\}^m$ encodes the following linear programming feasibility problem:

Does there exist $\vec{x} \in \mathbb{R}^k$ *satisfying* $\mathsf{sign}(\langle x, \vec{n}_i \rangle - b_i) = s_i$ *for all* $i \in [m]$*?*

This corresponds to checking the feasibility of a linear program with m constraints and k variables. Define $f_{\mathcal{H}} : \{-1,1\}^m \to \{0,1\}$ as the boolean function such that $f_{\mathcal{H}}(s) = 1$ if and only if the linear program encoded by s is feasible.

As an example, consider the following arrangement in $\mathbb{R}^2$. The three hyperplanes

$$h_1 = \{(x_1, x_2) : 5x_1 + 3x_2 = 3\},$$
$$h_2 = \{(x_1, x_2) : 8x_1 - x_2 = 8\},$$
$$h_3 = \{(x_1, x_2) : 4x_1 - 5x_2 = 0\}$$

form an arrangement of three lines in the plane. The vector $s = (+1, -1, +1)$ encodes the system

$$5x_1 + 3x_2 > 3 \qquad (s(1) = +1)$$
$$8x_1 - x_2 < 8 \qquad (s(2) = -1)$$
$$4x_1 + 5x_2 > 0 \qquad (s(3) = +1)$$

In the example, the system encoded by $(+1, -1, +1)$ is not satisfiable (see Figure 1). For more background material on hyperplane arrangements and related results, see the books by Stanley [43] and Matoušek [30].

We prove the following theorem.

▶ **Theorem 6.** *Let $\mathcal{H}$ be an arrangement of $2k+1$ hyperplanes in $\mathbb{R}^k$ that are in general position. Any $AC^0[p]$ circuit, for a prime p, with depth d computing $f_{\mathcal{H}}$ requires $exp(\Omega(k^{1/2d}))$ gates.*

We prove Theorem 6 in Section 4, using the framework of Razborov [37] and Smolensky [41].

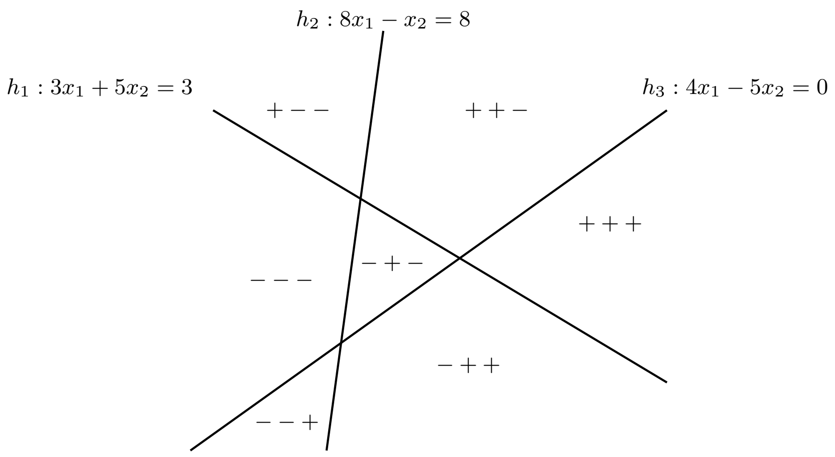

Figure 1 Three lines divide $\mathbb{R}^2$ into seven regions, each labeled by a feasible sign pattern.

Explicit Arrangements. The space of oriented hyperplanes is a rich and well-studied object. The books [30, 43] provide many facts and examples. The paper [2] and references therein give bounds on how many different boolean functions can be represented as $f_{\mathcal{H}}$ for some hyperplane arrangement $\mathcal{H}$.

General position hyperplane arrangements come from any $2k+1$ vectors in $\mathbb{R}^{k+1}$ such that every $k+1$ of them are linearly independent. For a vector $v \in \mathbb{R}^{k+1}$ the hyperplane has normal $(v_1, \ldots, v_k)$ and translation v_{k+1}. Explicit families of m vectors in $\mathbb{R}^d$ such that every d of them are independent are known for any m, d. For example, take the rows of an $m \times d$ Cauchy or Vandermonde matrix.

2.2 Hilbert Function Bounds

Our results are based on the following theorem.

▶ **Theorem 7.** *Any $C \subseteq \{0,1\}^n$ and any $d \in [n]$ satisfy the relationships*

$$|\{I \in \mathsf{sstr}(C) \ : \ |I| \le d\}| \ \le \ h_d(C, \mathbb{F}) \ \le \ |\{I \in \mathsf{str}(C) \ : \ |I| \le d\}|$$

and

$$\max\{|I| : I \in \mathsf{sstr}(C)\} \ \le \ \mathsf{intdeg}(C, \mathbb{F}) \ \le \ \max\{|I| : I \in \mathsf{str}(C)\}.$$

The upper bounds on interpolation degree are not new. Smolensky [42] derives the Sauer-Perles-Shelah Lemma using very similar polynomial-based arguments. The upper bounds on interpolation degree in terms of VC dimension also appear implicitly in the work of Frankl and Pach [7] and explicitly in Gurvits [24]. Our technical contributions center around the lower bounds and the applications. We prove Theorem 7 in Section 3.1.

We strengthen the lower bound on the Hilbert function in Theorem 7 using down-shifts.

▶ **Theorem 8.** *Let $C \subseteq \{0,1\}^n$ and let $D = S_n(S_{n-1}(\ldots S_1(C)))$. Then*

$$|\{I \in D \ : \ |I| \le d\}| \ \le \ h_d(C, \mathbb{F}) \quad \text{and} \quad \max\{|I| : I \in D\} \ \le \ \mathsf{intdeg}(C, \mathbb{F}).$$

In Section 3.2 we prove this theorem and show that the parity function provides a tight example over $GF(2)$. We also discuss how Theorem 8 implies the lower bound in Theorem 7.

2.3 Low-Degree Polynomial Approximations

Classic results in bounded-depth circuit complexity reduce the task of proving circuit lower bounds to showing that a boolean function has no low-degree approximation [37, 41, 6]. Smolensky shows in [40] how to express all known degree lower bounds in terms of the Hilbert function. For a boolean function f consider the set $S = f^{-1}(1)$ as a subset of the boolean cube. Smolensky shows that if $h_d(S, \mathbb{F})$ is large, then f is hard to approximate.

▶ **Theorem 9** ([40]). *Consider $f : \{0,1\}^n \to \{0,1\}$ and $p : \{0,1\}^n \to \mathbb{F}$. Define $S = f^{-1}(1)$ and fix $d = \lfloor (n - \deg_{\mathbb{F}}(p) - 1)/2 \rfloor$. Then,*

$$\Pr_x[p(x) \neq f(x)] \geq \frac{2 \cdot h_d(S, \mathbb{F}) - |S|}{2^n},$$

where x is uniform over $\{0,1\}^n$.

Theorem 7 implies the following corollary in terms of strongly shattered sets.

▶ **Corollary 10.** *Assume n is odd. Consider $f : \{0,1\}^n \to \{0,1\}$. If $|f^{-1}(1)| = 2^{n-1}$ and $\mathsf{sstr}(f^{-1}(1)) = \{I \subseteq [n] : |I| \leq \frac{n-1}{2}\}$, then for any polynomial $p \in \mathbb{F}[x_1, \ldots, x_n]$ we have*

$$\Pr_x[p(x) \neq f(x)] \geq \frac{1}{2} - \frac{10 \deg_{\mathbb{F}}(p)}{\sqrt{n}},$$

where x is uniform over $\{0,1\}^n$.

Proof. Since $\mathsf{sstr}(f^{-1}(1)) = \{I \subseteq [n] : |I| \leq \frac{n-1}{2}\}$, we have that

$$|\{I \in \mathsf{sstr}(C) \ : \ |I| \leq d\}| = \sum_{j=0}^{d} \binom{n}{j}$$

for all $d = 0, 1, \ldots, (n-1)/2$. Theorem 7 implies that $h_d(f^{-1}(1), \mathbb{F}) = \sum_{j=0}^{d} \binom{n}{j}$ as well. Plugging these into Theorem 9, along with $|f^{-1}(1)| = 2^{n-1}$, gives the corollary. ◀

Bernasconi and Egidi [11] thoroughly characterize the Hilbert function for symmetric sets and prove that any nearly-balanced, symmetric boolean function is hard to approximate. They leave as an open question deriving bounds for non-symmetric sets. Our connection to VC theory leads to new families of functions satisfying the conditions of Corollary 10. Many of these functions, such as the linear programming feasibility functions from Section 2.1, are non-monotone and non-symmetric. As a final remark, recent work shows that Smolensky's lower bound (and thus our result) extends to nonclassical polynomials [12].

2.4 The Sandwich Theorem

The following relationship which is a generalization of the Sauer-Perles-Shelah Lemma was discovered several times and independently [14, 36, 18, 5].

▶ **Theorem 11** (Sandwich Theorem). *For any $C \subseteq \{0,1\}^n$ we have $|\mathsf{sstr}(C)| \leq |C| \leq |\mathsf{str}(C)|$.*

Since $|\mathsf{str}(C)| \leq \sum_{i=0}^{\mathsf{VC}(C)} \binom{n}{i}$, this implies the Sauer-Perles-Shelah Lemma.

Theorem 7 yields a new algebraic proof of the Sandwich Theorem. Indeed, this follows from examining the case of $d = n$ and observing that $h_n(C, \mathbb{F}) = |C|$.

The Sandwich Theorem is tight in the sense that there are sets that achieve equality in both of its inequalities[2]. These sets are calles *shattering extremal sets*. For example, downward-closed sets are shattering extremal. Shattering extremal sets have been rediscovered and studied in different contexts [29, 15, 14, 18, 8, 33, 28, 32, 35]. In our context, Corollary 10 says that shattering extremal sets S of size $|S| = 2^{n-1}$ and VC dimension $\frac{n-1}{2}$ correspond to boolean functions that cannot be approximated by low-degree polynomials.

2.5 Downward-closed Sets and Chvátal's Conjecture

Downward-closed sets have a well-studied, rich combinatorial structure. A theorem of Berge [10] implies the following fact. For any downward-closed set D, there is a bijection $\pi : D \to D$ such that $a \cap \pi(a) = \emptyset$, for all $a \in D$. We refer to such a bijection as a *pseudo-complement*. We prove the following generalization of the existence of a pseudo-complement.

▶ **Theorem 12.** *Let D be any downward-closed set. Fix any mapping $\phi : D \to D$ with the property that $\phi(a) \subseteq a$ for all $a \in D$. Then there exists a bijection $\pi : D \to D$ satisfying the condition that $a \cap \pi(a) = \phi(a)$ for all $a \in D$.*

Note that choosing $\phi(a) = \emptyset$ for all a implies the existence of a pseudo-complement.

In topology, downward-closed sets correspond to simplicial complexes. We think of the ϕ as prescribing intersections. For simplicial complexes, this corresponds to prescribing that complexes intersect in certain faces. We prove Theorem 12 in Section 5. Our proof proceeds by proving that a certain matrix is invertible. A non-zero determinant implies that the matrix contains a permutation matrix that yields the desired bijection.

We next discuss the result by Berge for the existence of pseudo-complements and its connections with Chvátal's conjecture in extremal combinatorics [16]. Berge's result about pseudo-complements follows from the following stronger theorem that he proved.

▶ **Theorem 13** ([10]). *If D is a downward-closed set, then either D or $D \setminus \emptyset$ can be partitioned into pairs of disjoint sets.*

We need two definitions to explain Berge's motivation. A family B of subsets of $[n]$ is called a *star* if there is an element $x \in [n]$ such that $x \in b$ for all $b \in B$. It is called an *intersecting family* if every pair of sets in B intersects. Chvátal's conjecture is the following.

▶ **Conjecture 14** (Chvátal's conjecture). *If D is a downward closed set, then the cardinality of the largest star in D is equal to the cardinality of the largest intersecting family in D.*

This conjecture remains open, aside from partial results, such as the following corollary of Berge's theorem.

▶ **Corollary 15.** *In a downward-closed set D, any intersecting family has cardinality at most $|D|/2$.*

We contrast Berge's theorem and our Theorem 12. Berge's pair decomposition induces a permutation π such that $\pi(\pi(a)) = a$, whereas a permutation decomposes D into disjoint cycles with unspecified lengths. Many people have observed that the above corollary only needs the pseudo-complement result, instead of the stronger statement in Berge's theorem [4]. Indeed, consider each disjoint cycle in the guaranteed permutation, and note that at most half of the sets in the cycle may mutually intersect. Therefore, our Theorem 12 implies the above corollary.

[2] In fact, it is well known (see for example [33]) that any set achieving equality in one of the inequalities, also achieves equality in the other.

3 The Hilbert Function for Subsets of the Boolean Cube

We prove upper and lower bounds on the Hilbert function. First, we prove the bounds in Theorem 7 involving the shattered and the strongly shattered sets. Then, we prove the bounds in Theorem 8 using shifting. Finally we consider an example of applying these bounds to analyze the Hilbert function of the parity function.

3.1 Bounding the Hilbert Function Using Shattered Sets

The high-level idea of the proof of Theorem 7 is to define a vector space V with $\dim(V) = |C|$ and prove that $|\mathsf{sstr}(C)| \le \dim(V) \le |\mathsf{str}(C)|$. We sandwich the dimension $\dim(V)$ by finding a linearly independent set of size $|\mathsf{sstr}(C)|$ and a spanning set of size $|\mathsf{str}(C)|$.

We analyze the $|C|$-dimensional vector space $\{f : C \to \mathbb{F}\}$. Evaluation on C induces a natural mapping from $P \in \mathbb{F}[x_1, \dots, x_n]$ to the restriction $P|_C \in \{f : C \to \mathbb{F}\}$. The following lemma provides the desired sets of spanning monomials and linearly independent monomials.

▶ **Lemma 16.** *For all fields $\mathbb{F}$ and sets $C \subseteq \{0,1\}^n$ the following two facts hold.*
1. *The monomials $\prod_{i\in I} x_i$ for $I \in \mathsf{str}(C)$ span $\{f : C \to \mathbb{F}\}$.*
2. *The monomials $\prod_{i\in I} x_i$ for $I \in \mathsf{sstr}(C)$ are linearly independent in $\{f : C \to \mathbb{F}\}$.*

Proof. For $I \subseteq [n]$, let x_Y denote the monomial $x_I = \prod_{i\in I} x_i$. For the first item, we express every $f : C \to \mathbb{F}$ as a linear combination of monomials $(x_I)|_C$ where $I \in \mathsf{str}(C)$. It suffices to express the monomials $(x_I)|_C$ for all $I \subseteq [n]$. We prove this by induction. For the base case, if $I \in \mathsf{str}(C)$, we are done. Otherwise, I is not shattered by C and there exists $s \in \{0,1\}^I$ such that for all $c \in C$, we have $c|_I \ne s$. Consider

$$P = \prod_{i\in I} (x_i - (1 - s_i)) .$$

Note that $P(c) = 0$ for all $c \in C$ and hence $P|_C = 0|_C$. Specifically, by expanding the product $\prod_{i\in I} (x_i - (1 - s_i))$ we see

$$0|_C = P = (x_I)|_C + (Q)|_C,$$

where the degree of Q is smaller than $|I|$. By induction, we can write Q as a combination of $x_{I'}$ for $I' \in \mathsf{str}(C)$. Since $(x_I)|_C = (-Q)|_C$ we get that x_I is in this span as well.

We now prove the second item. Consider a linear combination

$$P = \sum_{I\in \mathsf{sstr}(C)} \alpha_I x_I$$

such that not all α_I are zero. We want to show that there is $c \in C$ such that $P(c) \ne 0$. Let $Z \in \mathsf{sstr}(C)$ be a maximal set such that $\alpha_Z \ne 0$. Since Z is strongly shattered by C, there is some $\bar{s} : ([n] \setminus Z) \to \{0,1\}$ such that all extensions of it in $\{0,1\}^n$ are in C. Let $Q(x_i)_{i\in Z}$ be the polynomial obtained by plugging in the values of $\bar{s}$ in the variables of $([n] \setminus Z)$. By maximality of Z it follows that the coefficient of x_Z in Q is $\alpha_Z \ne 0$, and so Q is not the 0 polynomial. Therefore there is $s \in \{0,1\}^Z$ such such that $Q(s) \ne 0$. Pick $c \in C$ such that

$$c_i = \begin{cases} s_i & i \in Z, \\ \bar{s}_i & i \in ([n] \setminus Z). \end{cases}$$

It follows that $P(c) = Q(s) \ne 0$, which finishes the proof. ◀

We use this lemma to prove bounds on the Hilbert function and interpolation degree.

Proof of Theorem 7. For the upper bound on $h_d(C,\mathbb{F})$, the above proof shows how to express all monomials of degree d using monomials of equal or smaller degree. For the lower bound on $h_d(C,\mathbb{F})$, linear independence still holds after restricting set size.

The upper bound on $\mathsf{intdeg}(C,\mathbb{F})$ is immediate. For the lower bound on $\mathsf{intdeg}(C,\mathbb{F})$, since $\mathsf{sstr}(C)$ is downward-closed, the linear independence of the monomials in $\mathsf{sstr}(C)$ implies any maximal degree monomial in $\{(x_I)|_C : I \in \mathsf{sstr}(C)\}$ cannot be expressed solely by lower degree monomials. ◀

3.2 Down-shifts, Downward-closed Bases, and the Hilbert Function

We prove Theorem 8. We also use the theorem to analyze the Hilbert function for the parity function. Theorem 8 is a direct corollary of the following theorem.

▶ **Theorem 17.** *Let $C \subseteq \{0,1\}^n$ and let $D = S_n(S_{n-1}(\ldots S_1(C)))$. Then the set of monomials $\{\prod_{i\in I} x_i : I \in D\}$ is a basis for the vector space of functions $\{f : C \to \mathbb{F}\}$.*

A theorem, equivalent in content, but expressed with respect to Gröbner bases, is proved in [31]. For completeness we include an elementary proof in the full version of this paper.

The lower bound given in Theorem 8 subsumes the lower bound in Theorem 7. This is a direct corollary of the following simple lemma.

▶ **Lemma 18.** *Let $C \subseteq \{0,1\}^n$ and let $D = S_n(S_{n-1}(\ldots S_1(C)))$. We have that $\mathsf{sstr}(C) \subseteq D$, where we associate $\{0,1\}^n$ with subsets of $[n]$ in the natural way.*

Proof. Since D is downward-closed, it follows that it is shattering extremal and therefore $\mathsf{sstr}(D) = D$. So, it is enough to show that $\mathsf{sstr}(C) \subseteq \mathsf{sstr}(D)$. To this end, it suffices to show that for every class C', $\mathsf{sstr}(C') \subseteq \mathsf{sstr}(S_i(C'))$. Let $I \in \mathsf{sstr}(C')$. Therefore C' contains a subcube B in coordinates I. During the down-shift, B is either shifted or stays in place, but in any case also $S_i(C')$ contains a subcube in coordinates I and therefore $I \in \mathsf{sstr}(S_i(C'))$. ◀

The Hilbert Function of Parity. A simple example which demonstrates an application of Theorem 8 is the parity function. Let P denote the set of all vectors of even hamming weight. Notice that P does not contain subcubes other than $\emptyset$. Therefore, $\mathsf{sstr}(P) = \{\emptyset\}$. As a consequence, the lower bound on the Hilbert function in Theorem 7 reveals no information in this case. In contrast, shifting gives a better bound. If we down-shift P, say on the first coordinate, we get the set $S_1(P) = D = \{v : v_1 = 0\}$. Therefore, as D is downward closed, shifting it on other coordinates does not change it. Thus, $S_n(S_{n-1}(\ldots S_1(P))) = D$. By Theorem 8 we have that $h_d(P,\mathbb{F}) \geq \binom{n-1}{\leq d} = \binom{n-1}{d} + \binom{n-1}{d-1} + \ldots + \binom{n-1}{0}$.

This lower bound is tight when the field has characteristic two and $d \leq n/2$. It suffices to show every polynomial q of degree at most d can be expressed by a polynomial of degree at most d that does not depend on x_1. Therefore the $\binom{n-1}{\leq d}$ multilinear monomials that do not depend on x_1 span the space of degree at most d polynomials with domain P. Note that $(x_1 + \ldots + x_n)|_P = 0$, and therefore every appearance of x_1 can be replaced by $x_2 + \ldots + x_n$. This transforms q to a polynomial that does not depend on x_1 without changing the represented function.

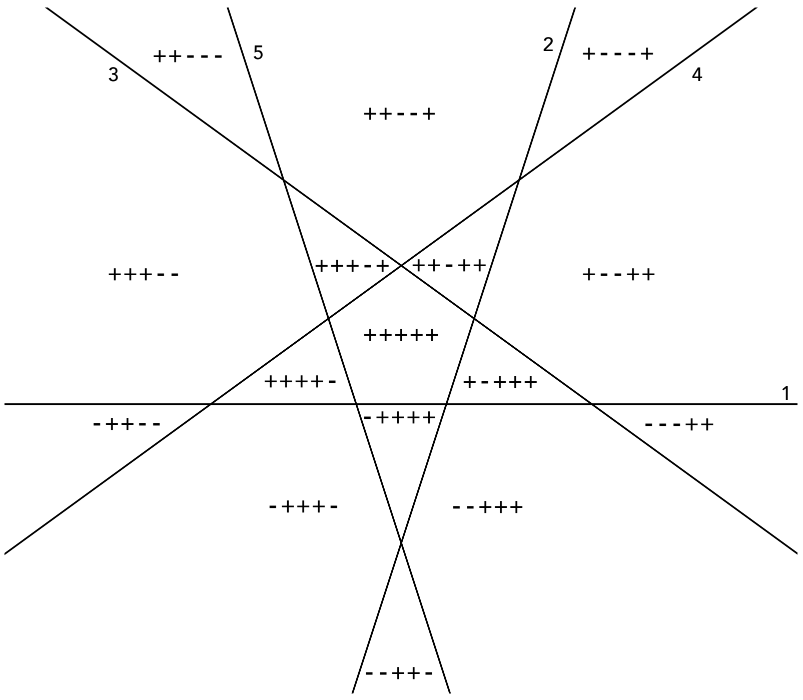

Figure 2 Five hyperplanes divide $\mathbb{R}^2$ into 16 cells. Cell labels in $\{-,+\}^5$ correspond to oriented hyperplane feasibility. Notice that every two coordinates are strongly shattered, but no three coordinates are shattered. This provides a proof-by-picture of Proposition 20 for $m = 5$ and $d = 2$.

4 Linear Programming and Low-degree Polynomial Approximations

We now prove Theorem 6. By the Razborov-Smolensky framework, it suffices to prove that $f_{\mathcal{H}}$ cannot be approximated by a low-degree polynomial over any field.[3]

▶ **Theorem 19.** *Let $\mathcal{H}$ be an arrangement of $2k+1$ hyperplanes in $\mathbb{R}^k$ that are in general position. For any any polynomial $p \in \mathbb{F}[x_1, \ldots, x_{2k+1}]$ we have*

$$\Pr_s[p(s) \neq f_{\mathcal{H}}(s)] \geq \frac{1}{2} - \frac{10 \deg_{\mathbb{F}}(p)}{\sqrt{2k+1}},$$

where s is uniform over $\{-1,1\}^{2k+1}$.

The proof of Theorem 19 proceeds via a reduction to Corollary 10. Let

$$S_{\mathcal{H}} = \{s \in \{-1,1\}^n : \ f_{\mathcal{H}}(s) = 1\}.$$

To apply Corollary 10 on $f_{\mathcal{H}}$ we will show $|S_{\mathcal{H}}| = 2^{2k}$ and $\mathsf{sstr}(S_{\mathcal{H}}) = \{I \subseteq [2k+1] : |I| \leq k\}$. We establish this by the following proposition. The facts we need about hyperplane arrangements follow from standard arguments [21, 43]. For intuition about the following proposition, see Figure 2 for a pictorial proof in $\mathbb{R}^2$.

▶ **Proposition 20.** *For any m hyperplanes $\mathcal{H}$ in $\mathbb{R}^d$ in general position*

$$\mathsf{sstr}(S_{\mathcal{H}}) = \mathsf{str}(S_{\mathcal{H}}) = \{I \subseteq [m] : |I| \leq d\}.$$

[3] We state the following theorem for $\{-1,1\}$ inputs to $f_{\mathcal{H}}$. This only makes sense for fields containing these elements. When $\mathbb{F} = \mathbb{F}_2$ simply replace $\{-1,1\}$ with $\{0,1\}$ in the definition of $f_{\mathcal{H}}$.

Proof. In the full version of the paper we include two lemmas that characterize the shattered and strongly shattered sets of $S_{\mathcal{H}}$ when $\mathcal{H}$ is in general position. The first lemma shows $\mathsf{str}(S_{\mathcal{H}}) \subseteq \{I \subseteq [m] : |I| \leq d\}$. The second lemma shows $\{I \subseteq [m] : |I| \leq d\} \subseteq \mathsf{sstr}(S_{\mathcal{H}})$. Since $\mathsf{sstr}(S_{\mathcal{H}}) \subseteq \mathsf{str}(S_{\mathcal{H}})$ these two lemmas combine to finish the proof. ◀

Proposition 20 implies Theorem 6. The equality $\mathsf{sstr}(S_{\mathcal{H}}) = \mathsf{str}(S_{\mathcal{H}})$ along with the Sandwich Theorem implies that $|S_{\mathcal{H}}| = |\mathsf{sstr}(S_{\mathcal{H}})|$. Let k be the ambient dimension in Theorem 6. The above proposition for $m = 2k+1$ and $d = k$ gives $|S_{\mathcal{H}}| = 2^{2k}$ and also $\mathsf{sstr}(S_{\mathcal{H}}) = \{I \subseteq [2k+1] : |Y| \leq k\}$. Thus $f_{\mathcal{H}}$ satisfies the premises of Corollary 10, and Theorem 6 follows.

5 Downward-closed Sets and Prescribed Intersections

We prove Theorem 12. Let $D \subseteq \{0,1\}^n$ be a downward-closed set. Fix $\phi : D \to D$ with the property that $\phi(a) \subseteq a$ for all $a \in D$. We will show that there exists a bijection $\pi : D \to D$ satisfying the condition that $a \cap \pi(a) = \phi(a)$ for all $a \in D$. We first prove two lemmas about the function space $\{f : D \to GF(2)\}$ and then use these to prove the existence of π. The first lemma holds for all subsets of the boolean cube.

▶ **Lemma 21.** *Let $C \subseteq \{0,1\}^n$ be a subset of the boolean hypercube. The monomials*

$$\prod_{i\in a} x_i \text{ for } a \in C$$

form a basis for $\{f : C \to GF(2)\}$.

Proof. We proceed using induction on $|C|$. When $C = \{a\}$ for $a \in \{0,1\}^n$ the function space has dimension one and the monomial $\prod_{i\in a} x_i$ represent the constant "1" function in this space, which spans it. Let $z \in C$ denote a maximal Hamming weight element in C. Notice $\prod_{i\in z} x_i$ is an indicator function in $\{f : C \to GF(2)\}$ for the input z. By the inductive hypothesis on $(C \setminus \{z\})$, we know the set of monomials $\prod_{i\in a} x_i$ for $a \in (C \setminus \{z\})$ form a basis for $\{f : (C \setminus \{z\}) \to GF(2)\}$. Since $\prod_{i\in z} x_i$ is an indicator function, we may add it to the basis for $\{f : (C \setminus \{z\}) \to GF(2)\}$ and achieve a basis for $\{f : C \to GF(2)\}$. ◀

We remark that if C is downward-closed, then it is shattering extremal, and the above lemma is a corollary of the Sandwich theorem. We prove the following stronger claim as well.

▶ **Lemma 22.** *Let $D \subseteq \{0,1\}^n$ be a downward-closed set. Fix any mapping $\phi : D \to D$ with the property that $\phi(a) \subseteq a$ for all $a \in D$. The functions*

$$\prod_{i\in\phi(a)} x_i \prod_{i\in a\setminus\phi(a)} (1 + x_i)$$

for $a \in D$ form a basis for $\{f : D \to GF(2)\}$.

Proof. Let $\mathcal{B}$ denote the set of polynomials that we wish to show is a basis. Since the cardinality of $\mathcal{B}$ is $|D|$ it is enough to show that it is a spanning set. By Lemma 21, it is enough to show that every monomial of the form $\prod_{i\in a} x_i$ for $a \in D$ can be expressed as a linear combination of polynomials in $\mathcal{B}$. We proceed by induction on the size of a. The case of $a = \emptyset$ is trivial. For the induction step, let $a \in D$ be non-empty. Expand the polynomial

$$\prod_{i\in\phi(a)} x_i \prod_{i\in a\setminus\phi(a)} (1 + x_i) = \left(\prod_{i\in a} x_i\right) + r,$$

where r is a linear combination of monomials $\prod_{i\in b} x_i$ for $b \subseteq a$ and $b \neq a$. Since D is downward-closed, by induction hypothesis r is in the span of $\mathcal{B}$. Thus,

$$\prod_{i\in a} x_i = \left(\prod_{i\in\phi(z)} x_i \prod_{i\in a\setminus\phi(a)} (1+x_i) \right) + r$$

is also in the span of $\mathcal{B}$, and we are done. ◀

Proof of Theorem 12. We show there exists a bijection $\pi : D \to D$ such that $a\cap\pi(a) = \phi(a)$ for all $a \in D$, for the given map ϕ. Consider the $|D|\times|D|$ boolean matrix M defined as follows. Index the rows and columns both by D, and define the element in location $(a, b) \in D \times D$ to be one if and only if $a \cap b = \phi(a)$. We claim that M is nonsingular. Indeed, the rows of M correspond to the functions in Lemma 22. Since they form a basis, the row space of M is $|D|$-dimensional. This implies the determinant of M is nonzero. There must exist a permutation $\pi : [n] \to [n]$ such that $\prod_{i=1}^{|D|} M_{i,\pi(i)} = 1$. By the definition of M, we found the bijection π we were looking for. ◀

6 Conclusion

We exhibited a connection between algebra and combinatorics. We provided a general way to lower bound the Hilbert function. We showed a new family of functions cannot be approximated by low-degree polynomials. We provided a polynomial method proof of the Sandwich theorem and for a new theorem about prescribed intersections.

6.1 Open Directions

Our work suggests that the interpolation degree is a useful complexity measure on subsets of the boolean hypercube. Therefore, an open direction is to better understand the structure of sets with low interpolation degree. As noted by Remscrim [38], one can equivalently define interpolation degree in terms of the rank of a certain incidence matrix. The matrix corresponds to the monomials in our Lemma 21 with a cut-off on the degree. For the case of interpolation degree one, this characterization is particularly simple.

▶ **Proposition 23.** *A set $C \subseteq \{0,1\}^n$ has $\mathsf{intdeg}(C, \mathbb{F}) = 1$ if and only if the boolean vectors corresponding to C are affinely independent in $\mathbb{F}^n$.*

We are curious if other properties of the vectors in C correspond to implications for the interpolation degree. Even for interpolation degree two, the algebraic/matrix description becomes more opaque and less intuitive than the characterization in the above proposition. Since $\mathsf{intdeg}(C, \mathbb{F}) \leq \mathsf{VC}(V)$, any combinatorial characterization may also shed new light on the structure of sets with VC dimension two, for which our understanding is lacking [3, 34].

Abstract

This paper analyzes to what extent it is possible to efficiently reduce the number of clauses in NP-hard satisfiability problems, without changing the answer. Upper and lower bounds are established using the concept of kernelization. Existing results show that if $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$, no efficient preprocessing algorithm can reduce n-variable instances of CNF-SAT with d literals per clause, to equivalent instances with $\mathcal{O}(n^{d-\varepsilon})$ bits for any $\varepsilon > 0$. For the Not-All-Equal SAT problem, a compression to size $\widetilde{\mathcal{O}}(n^{d-1})$ exists. We put these results in a common framework by analyzing the compressibility of binary CSPs. We characterize constraint types based on the minimum degree of multivariate polynomials whose roots correspond to the satisfying assignments, obtaining (nearly) matching upper and lower bounds in several settings. Our lower bounds show that not just the number of constraints, but also the encoding size of individual constraints plays an important role. For example, for Exact Satisfiability with unbounded clause length it is possible to efficiently reduce the number of constraints to $n+1$, yet no polynomial-time algorithm can reduce to an equivalent instance with $\mathcal{O}(n^{2-\varepsilon})$ bits for any $\varepsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

1 Introduction

The goal of sparsification is to make an object such as a graph or logical structure less dense, without changing the outcome of a computational task of interest. Sparsification can be used to speed up the solution of NP-hard problems, by sparsifying a problem instance before solving it. The notion of kernelization, originating in the field of parameterized complexity [8, 12, 13], facilitates a rigorous study of polynomial-time preprocessing for NP-hard problems and can be used to reason about (the impossibility of) sparsification. Over the last few years, our understanding of the power of polynomial-time data reduction has increased tremendously, as documented in recent surveys [4, 16, 23, 26]. By studying the kernelization complexity of a graph problem parameterized by the number of vertices, or of a logic problem parameterized by the number of variables, we can analyze its potential for sparsification.

* This work was supported by NWO Veni grant "Frontiers in Parameterized Preprocessing" and NWO Gravitation grant "Networks". This work was done in part while the first author was visiting the Simons Institute for the Theory of Computing.

The vast majority of the currently known results in this direction are negative [10, 18, 19, 20], stating that no nontrivial sparsification is possible under plausible complexity-theoretic assumptions. For example, Dell and van Melkebeek [10] obtained such a result for CNF-Satisfiability with clauses of size at most d (d-cnf-sat), for each fixed $d \geq 3$. Assuming $\mathsf{NP} \not\subseteq \mathsf{coNP/poly}$, there is no polynomial-time algorithm that compresses any n-variable instance of d-cnf-sat to an equivalent instance with $\mathcal{O}(n^{d-\varepsilon})$ bits for $\varepsilon > 0$. Since there are $\mathcal{O}(n^d)$ possible clauses of size at most d over n variables, the trivial compression scheme that outputs a bitstring of length $\mathcal{O}(n^d)$, denoting for each possible clause whether it occurs in the instance or not, is optimal up to $n^{o(1)}$ factors.

A problem for which nontrivial polynomial-time sparsification *is* possible was recently discovered by the current authors [20]. Any n-variable instance of the Not-All-Equal CNF-Satisfiability problem with clauses of size at most d (d-nae-sat) can efficiently be compressed to an equivalent instance with $\mathcal{O}(n^{d-1})$ clauses, which can be encoded in $\mathcal{O}(n^{d-1} \log n)$ bits. The preprocessing algorithm is based on a linear-algebraic lemma by Lovász [27] to identify clauses that are implied by others, allowing a reduction from $\Theta(n^d)$ clauses to $\mathcal{O}(n^{d-1})$. This sparsification for d-nae-sat forms the starting point for this work. Since d-cnf-sat and d-nae-sat can both be seen as constraint satisfaction problems (CSPs) with a binary domain, it is natural to ask whether the positive results for d-nae-sat extend to other binary CSPs. The difference between d-cnf-sat and d-nae-sat shows that the type of constraints that one allows, affects the compressibility of the resulting CSP. The goal of this paper is to understand how the optimal compression size for a binary CSP depends on the type of legal constraints, with the aim of obtaining matching upper and lower bounds.

Before presenting our results, we give an example to illustrate our methods. Consider the NP-complete Exact d-CNF-Satisfiability (Exact d-sat) problem, which asks whether there is a truth assignment that satisfies *exactly one* literal in each clause; the clauses have size at most d. While there are $\Theta(n^d)$ different clauses that can occur in an instance with n variables, the exact nature of the problem makes it possible to reduce any instance to an equivalent one with $n + 1$ clauses. A clause such as $x_1 \vee x_3 \vee \neg x_5$ naturally corresponds to an equality constraint of the form $x_1 + x_3 + (1 - x_5) = 1$, since a 0/1-assignment to the variables satisfies exactly one literal of the clause if and only if it satisfies the equality. To find redundant clauses, transform each of the m clauses into an equality to obtain a system of equalities $A\mathbf{x} = \mathbf{b}$ where A is an $m \times n$ matrix, $\mathbf{x}$ is the column vector $(x_1, \ldots, x_n)$, and $\mathbf{b}$ is an integer column vector. Using Gaussian elimination, one can efficiently compute a basis B for the row space of the extended matrix $(A|b)$: a set of equalities such that every equality can be written as a linear combination of equalities in B. Since $(A|b)$ has $n + 1$ columns, its rank is at most $n + 1$ and the basis B contains at most $n + 1$ equalities. To perform data reduction, remove all clauses from the Exact d-sat instance whose corresponding equalities do not occur in B. If an assignment satisfies $f_1(\mathbf{x}) = b_1$ and $f_2(\mathbf{x}) = b_2$, then it also satisfies their sum $f_1(\mathbf{x}) + f_2(\mathbf{x}) = b_1 + b_2$, and any linear combination of the satisfied equalities. Since any equality not in B can be written as a linear combination of equalities in B, a truth assignment satisfying all clauses from B must necessarily also satisfy the remaining clauses, which shows the correctness of the data reduction procedure. The resulting instance can be encoded in $\mathcal{O}(n \log n)$ bits, as each of the remaining $n + 1$ clauses has $d \in O(1)$ literals.

Our results

Our positive results are generalizations of the linear-algebraic data reduction tool for binary CSPs presented above. They reveal that the $\widetilde{\mathcal{O}}(n)$-bit compression for Exact d-sat, the $\widetilde{\mathcal{O}}(n^{d-1})$-bit compression for d-nae-sat, and the $\mathcal{O}(n^d)$-bit compression for d-cnf-sat are samples of a gliding scale of problem complexity: more tightly constrained problems can be compressed better. We formalize this idea by considering a generic CSP whose constraints are of the form $f(\mathbf{x}) = 0$, where f is a bounded-degree polynomial and the constraint demands that $\mathbf{x}$ is a root of f. The example given earlier shows that EXACT d-SAT can be expressed using degree-1 polynomials. We show that d-NAE-SAT and d-CNF-SAT can be expressed using equalities of polynomial expressions of degree $d-1$ and d. We study the following problem:

d-POLYNOMIAL ROOT CSP **Parameter:** The number of variables n.
Input: A list L of polynomial equalities over variables $V = \{x_1, \ldots, x_n\}$. An equality is of the form $f(x_1, \ldots, x_n) = 0$, where f is a multivariate polynomial of degree at most d.
Question: Does there exist an assignment of the variables $\tau\colon V \to \{0,1\}$ satisfying all equalities in L?

Using a generalization of the argument presented above, the number of constraints in an instance of d-POLYNOMIAL ROOT CSP can efficiently be reduced to $\mathcal{O}(n^d)$, even when the number of variables that occur in a constraint is not restricted. The latter implies, for example, that using degree-1 polynomials one can express the EXACT SAT problem with clauses of arbitrary size. When the number of variable occurrences in a constraint can be as large as n, it may take $\Omega(n)$ bits to encode a single constraint. After reducing the number of clauses in an EXACT SAT instance to $n+1$, one may therefore still require $\Theta(n^2)$ bits to encode the instance. This turns out to be unavoidable: we prove that EXACT SAT has no sparsification of size $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. In general, we compress instances of d-POLYNOMIAL ROOT CSP to bitsize $\widetilde{\mathcal{O}}(n^{d+1})$ when each constraint can be encoded in $\widetilde{\mathcal{O}}(n)$ bits. We prove that no compression to size $\mathcal{O}(n^{d+1-\varepsilon})$ is possible unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. When each constraint can be encoded in $\widetilde{\mathcal{O}}(1)$ bits, the constraint reduction scheme reduces the size of an instance to $\widetilde{\mathcal{O}}(n^d)$. As we will show that d-NAE-SAT can be modeled using polynomials of degree $d-1$, this method strictly generalizes our earlier results [20] for d-NAE-SAT.

The linear-algebraic data reduction tool described above works over arbitrary fields F, allowing us to capture constraints such as "the number of satisfied literals in the clause is exactly two, when evaluated modulo 3". We therefore extend our study to the d-POLYNOMIAL ROOT CSP problem over arbitrary fields F, and obtain similar positive and negative results.

Finally, we consider binary CSPs whose constraints are formed by *inequalities*, rather than equalities, of degree-d polynomials. This leads to the following generic problem:

d-POLYNOMIAL NON-ROOT CSP OVER F **Parameter:** The number of variables n.
Input: A list L of polynomial inequalities over variables $V = \{x_1, \ldots, x_n\}$. An inequality is of the form $f(x_1, \ldots, x_n) \neq 0$, where f is a multivariate polynomial of degree $\leq d$.
Question: Does there exist an assignment of the variables $\tau\colon V \to \{0,1\}$ satisfying all inequalities in L?

We present upper and lower bounds for problems of this type. When the polynomials are evaluated over a structure that is not a field, the situation changes significantly. For example, CSPs with constraints of the type "the number of satisfied literals in the clause is 1 or 2, when evaluated modulo 6" behave differently than the corresponding problem modulo 5, or modulo 7, because the integers modulo 6 do not form a field. Both our upper- and lower bound techniques fail when defining constraints with respect to composite moduli. We present connections to different areas of theoretical computer science where the distinction between prime and composite moduli plays a big role. More concretely, we show that obtaining polynomial sparsification upper bounds for d-Polynomial non-root CSP over the integers modulo a composite, would resolve a long-standing problem concerning the representation of the or-function using low-degree polynomials (cf. [2, 3, 29]).

Related work

Schaefer's Theorem [28] is a classic result relating the complexity of a binary CSP to the type of allowed constraints, separating the NP-complete from the polynomial-time solvable cases. A characterization of the kernelization complexity of min-ones CSPs parameterized by the number of variables was presented by Kratsch and Wahlström [25]. There are several parameterized complexity results for CSPs [7, 9, 24].

2 Preliminaries

A *parameterized problem* $\mathcal{Q}$ is a subset of $\Sigma^* \times \mathbb{N}$, where Σ is a finite alphabet. Let $\mathcal{Q}, \mathcal{Q}' \subseteq \Sigma^* \times \mathbb{N}$ be parameterized problems and let $h\colon \mathbb{N} \to \mathbb{N}$ be a computable function. A *generalized kernel for $\mathcal{Q}$ into $\mathcal{Q}'$ of size $h(k)$* is an algorithm that, on input $(x,k) \in \Sigma^* \times \mathbb{N}$, takes time polynomial in $|x| + k$ and outputs an instance (x',k') such that:

1. $|x'|$ and k' are bounded by $h(k)$, and
2. $(x',k') \in \mathcal{Q}'$ if and only if $(x,k) \in \mathcal{Q}$.

The algorithm is a *kernel* for $\mathcal{Q}$ if $\mathcal{Q} = \mathcal{Q}'$. It is a *polynomial (generalized) kernel* if $h(k)$ is a polynomial. Since a polynomial-time reduction to an equivalent sparse instance yields a generalized kernel, we use lower bounds for the sizes of generalized kernels to prove the non-existence of sparsification algorithms.

A *linear-parameter transformation* from a parameterized problem $\mathcal{Q}$ to a parameterized problem $\mathcal{Q}'$ is a polynomial-time algorithm that transforms any instance (x,k) of $\mathcal{Q}$ into an equivalent instance (x',k') of $\mathcal{Q}'$ such that $k' \in \mathcal{O}(k)$. It is easy to see (cf. [6]) that the existence of a linear-parameter transformation from $\mathcal{Q}$ to $\mathcal{Q}'$, together with a (generalized) kernel of size $\mathcal{O}(k^d)$ for $\mathcal{Q}'$, yields a generalized kernel of size $\mathcal{O}(k^d)$ for $\mathcal{Q}$. By contraposition, the existence of such a transformation implies that when $\mathcal{Q}$ does not have generalized kernels of size $\mathcal{O}(k^{d-\varepsilon})$, then $\mathcal{Q}'$ does not have generalized kernels of size $\mathcal{O}(k^{d-\varepsilon})$ either.

We use the framework of cross-composition [5] to establish kernelization lower bounds, requiring the definitions of polynomial equivalence relations [5, Def. 3.1] and or-cross-compositions [5, Def. 3.3].

▶ **Theorem 1** ([5, Theorem 6]). *Let $L \subseteq \Sigma^*$ be a language, let $\mathcal{Q} \subseteq \Sigma^* \times \mathbb{N}$ be a parameterized problem, and let d, ε be positive reals. If L is NP-hard under Karp reductions, has an* or*-cross-composition into $\mathcal{Q}$ with cost $f(t) = t^{1/d+o(1)}$, where t denotes the number of instances, and $\mathcal{Q}$ has a polynomial (generalized) kernelization with size bound $\mathcal{O}(k^{d-\varepsilon})$, then* NP $\subseteq$ coNP/poly.

For $d \in \mathbb{N}$ we will refer to an or-cross-composition of cost $f(t) = t^{1/d}\log(t)$ as a *degree-d cross-composition*. By Theorem 1, a degree-d cross-composition can be used to rule out generalized kernels of size $\mathcal{O}(k^{d-\varepsilon})$. Note that when studying sparsification, we use the number of vertices or variables in the instance (which is usually denoted by n) as the parameter value (which is usually denoted by k).

When interpreting truth assignments as elements of a field, we equate the value *true* with the 1 element in the field (multiplicative identity), and the value *false* with the 0 element (additive identity). Consequently, for a boolean variable x its negation $\neg x$ corresponds to $(1 - x)$. We let $\mathbb{Z}/m\mathbb{Z}$ denote the integers modulo m, which form a field if m is a prime number. The *degree* of a multivariate polynomial is the maximum degree of its monomials. Let $f(x_1,\ldots,x_d)$ be a d-variate polynomial over a field F. The *root set* of f is the algebraic variety $\{(e_1,\ldots,e_d)\in F^d \mid f(e_1,\ldots,e_d)=0\}$. For a field F and a finite set $S\subseteq F$ of elements, the univariate polynomial $f(x) := \prod_{s\in S}(x-s)$ over F of degree $|S|$ has root set exactly S. We say that a field F is *efficient* if the field operations and Gaussian elimination can be done in polynomial time in the size of a reasonable input encoding. The field of rational numbers $\mathbb{Q}$, and all finite fields, are efficient. We use $[n]$ to denote $\{1,\ldots,n\}$. The $\widetilde{\mathcal{O}}$-notation suppresses polylogarithmic factors: $\widetilde{\mathcal{O}}(n)=\mathcal{O}(n\log^c n)$ for a constant c. For statements marked with a (★), the proof can be found in the full version [21].

3 Kernel upper bounds

3.1 Polynomial root CSP

We start by showing how to reduce the number of constraints in instances of d-Polynomial root CSP, by extending the argument presented in the introduction.

▶ **Theorem 2.** *There is a polynomial-time algorithm that, given an instance (L,V) of d-*Polynomial root CSP *over an efficient field F, outputs an equivalent instance (L',V) with at most n^d+1 constraints such that $L'\subseteq L$.*

Proof. Given a list L of polynomial equalities over variables V for d-Polynomial root CSP, we use linear algebra to find redundant constraints. Observe that $(x_i)^c = x_i$ for all 0/1-assignments and $c\in\mathbb{N}_+$. As constraints are evaluated over 0/1-assignments, we may assume without loss of generality that the monomials in each of the polynomials are multilinear: each monomial consists of a coefficient from F multiplied by distinct variables.

Create a matrix A with $|L|$ rows and a column for every multilinear monomial of degree at most d over variables from V. Let position $a_{i,j}$ in A be the coefficient of the monomial corresponding to column j in the polynomial equality corresponding to row i.

Compute a basis B of the row space of matrix A, for example using Gaussian elimination [17], and let L' consist of the equalities in L whose corresponding row appears in the basis. Since $L'\subseteq L$, it follows that if the original instance has a satisfying assignment, the reduced instance has a satisfying assignment as well. The crucial part of the correctness proof is to establish the converse.

▶ **Claim 3.** *If an assignment $\tau\colon V\to\{0,1\}$ of the variables in V satisfies the equalities in L', then it satisfies all equalities in L.*

Proof. Consider any equality $(f(\mathbf{x})=0)\in L\setminus L'$, since equalities in L' are trivially satisfied, and assume it corresponds to the i'th matrix row. Let $f_j(\mathbf{x})$ be the polynomial represented in the j'th row of matrix A for $j\in[|L|]$. Without loss of generality, let the basis of A correspond to its first m rows $\mathbf{a}_1,\ldots,\mathbf{a}_m$. We then have $i>m$, and by the definition of basis there exist $\beta_1,\ldots,\beta_m\in F$ such that $\mathbf{a}_i=\sum_{j=1}^m \beta_j\mathbf{a}_j$. Let $\mathbf{t}$ be the column vector containing, for each multilinear monomial of degree $\leq d$ in variables $x_1,\ldots,x_n$, the evaluation under τ. For example, for monomial x_1x_3 it contains $\tau(x_1)\cdot\tau(x_3)$. By using the same order of monomials as in the construction of A, we obtain for all $j\in[|L|]$ that $f_j(\tau(x_1),\ldots,\tau(x_n))=\mathbf{a}_j\mathbf{t}$, the inner product of $\mathbf{a}_j$ and $\mathbf{t}$. It follows that $\mathbf{a}_j\mathbf{t}=0$ for all $j\in[m]$, since satisfying L' implies $f_j(\tau(x_1),\ldots,\tau(x_n))=0$. To conclude the proof, note that

$$f_i(\mathbf{x})=\mathbf{a}_i\mathbf{t}=\sum_{j=1}^m(\beta_j\mathbf{a}_j)\mathbf{t}=\sum_{j=1}^m\beta_j(\mathbf{a}_j\mathbf{t})=\sum_{j=1}^m\beta_j\cdot 0=0. \qquad ◀$$

▶ **Claim 4.** *The number of constraints in the resulting kernel is bounded by $n^d + 1$.*

Proof. The size of a basis of any matrix over a field equals its rank, which is bounded by the number of columns. As there is a column for each multilinear monomial of degree at most d, there are at most $\sum_{i=0}^{d} \binom{n}{i}$ constraints in the basis. Now observe that $\sum_{i=1}^{d} \binom{n}{i} \leq n^d$. The left side counts nonempty subsets of $[n]$ of size at most d, each of which can be mapped to a distinct d-tuple by repeating an element. Since there are n^d d-tuples, the claim follows. ◀

This concludes the proof of Theorem 2. ◀

When each constraint can be encoded in $\widetilde{\mathcal{O}}(n)$ bits, for example when each polynomial can be represented as an arithmetic circuit of size $\mathcal{O}(n)$, Theorem 2 gives a kernelization of size $\widetilde{\mathcal{O}}(n^{d+1})$. When constraints can be encoded in $\widetilde{\mathcal{O}}(1)$ bits, which may occur when constraints have constant arity, we obtain kernels of bitsize $\widetilde{\mathcal{O}}(n^d)$. For explicit examples consider the following problem, where optionally a prime p may be chosen.

Generalized d-Sat (mod p) **Parameter:** The number of variables n
Input: A set of clauses $\mathcal{C}$ over variables $V := \{x_1, \ldots, x_n\}$, and for each clause a set $S_i \subset \mathbb{N} \cup \{0\}$ with $|S_i| \leq d$. Each clause is a set of distinct literals of the form x_i or $\neg x_i$.
Question: Does there exist a truth assignment for the variables V such that the number of satisfied literals in clause i lies in $S_i \pmod p$ for all i?

▶ **Corollary 5.** Generalized d-Sat *and* Generalized d-Sat mod p *both have a kernel with $n^d + 1$ clauses that can be encoded in $\mathcal{O}(n^{d+1} \log n)$ bits.*

Proof. To reduce the number of clauses using Theorem 2, we only have to provide a polynomial of degree at most d to represent each constraint. Consider a clause involving k variables $x_{i_1}, \ldots, x_{i_k}$. Let $t_j = x_{i_j}$ if variable x_{i_j} occurs positively in the clause, and let $t_j = (1 - x_{i_j})$ if the variable occurs negatively. Then the number of satisfied literals in the clause is given by the degree-1 polynomial $f(x_{i_1}, \ldots, x_{i_k}) := \sum_{i=1}^{k} t_i$. Let $F(x)$ be a polynomial with root set $S_j \pmod p$ of degree at most $|S_j|$. We obtain $F(f(\mathbf{x})) \equiv 0 \pmod p$ if and only if $\mathbf{x}$ satisfies the clause. Note that the degree of $F(f(\mathbf{x}))$ is at most $|S_j| \leq d$.

Applying Theorem 2 to the resulting instance of d-Polynomial root CSP identifies a subset of at most $n^d + 1$ constraints which preserve the answer to the Sat problem. Each clause contains at most $2n$ literals, which can be encoded in $\mathcal{O}(\log n)$ bits each. Additionally, for each clause we need to store the set S_i of at most d integers, which have value at most $2n$ in relevant inputs. As d is a constant, the instance can be encoded in $\mathcal{O}(n^{d+1} \log n)$ bits. ◀

Corollary 5 yields a new way to get a nontrivial compression for d-nae-sat, which is conceptually simpler than the existing approach which requires an unintuitive lemma by Lovász [27]. The new approach gives the same size bound as given earlier [20].

▶ **Corollary 6.** d-nae-sat *has a kernel with $n^{d-1} + 1$ clauses and bitsize $\mathcal{O}(n^{d-1} \log n)$.*

Proof. A clause of size $k \leq d$ is not-all-equal satisfied if and only if the number of satisfied literals lies in $S := \{1, \ldots, k-1\}$. Using Corollary 5 we can reduce the number of clauses to $n^{d-1} + 1$. Each clause has $d \in O(1)$ variables and can thus be encoded in $\mathcal{O}(\log n)$ bits. ◀

3.2 Polynomial non-root CSP

In this section we consider d-Polynomial non-root CSP. In Section 4.2 we will show that, over the field of rational numbers, the problem cannot be compressed to size polynomial in n, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. We therefore consider the field $\mathbb{Z}/p\mathbb{Z}$ of integers modulo a prime p.

▶ **Theorem 7.** *There is a polynomial-time algorithm that, given an instance (L, V) of d-*Polynomial non-root CSP *over $\mathbb{Z}/p\mathbb{Z}$, outputs an equivalent instance (L', V) with $\mathcal{O}(n^{d(p-1)})$ constraints such that $L' \subseteq L$.*

Proof. Suppose we are given a list of polynomial inequalities L over variables V. Observe that an inequality $f(\mathbf{x}) \not\equiv 0 \pmod p$ is equivalent to $f(\mathbf{x}) \in \{1, \ldots, p-1\} \pmod p$.

Let $F\colon \mathbb{Z}/p\mathbb{Z} \to \mathbb{Z}/p\mathbb{Z}$ be a polynomial of degree $p-1$ with root set $\{1, \ldots, p-1\}$ modulo p, which exists since $\mathbb{Z}/p\mathbb{Z}$ is a field. Then $f(\mathbf{x}) \not\equiv 0 \pmod p$ can equivalently be stated as $F(f(\mathbf{x})) \equiv 0 \pmod p$. It is easy to see that $F(f(\mathbf{x}))$ is a polynomial of degree at most $d(p-1)$. Therefore, L can be written as an instance of $d(p-1)$-Polynomial root CSP by replacing every polynomial f by $F \circ f$. By Theorem 2, the proof follows. ◀

In Section 4.2 we will establish a nearly-matching lower bound counterpart to Theorem 7.

4 Kernel lower bounds

4.1 Polynomial root CSP

We now turn our attention to lower bounds, starting with d-Polynomial root CSP over $\mathbb{Q}$. We start by proving that Exact Red-Blue Dominating Set does not have generalized kernels of bitsize $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. The same lower bound for 1-Polynomial root CSP will follow by a linear-parameter transformation. We then show how to generalize this result to d-Polynomial root CSP. As a starting problem for the cross-composition we will use the NP-hard Red-Blue Dominating Set (rbds) [11, 22].

Red-Blue Dominating Set (rbds) **Parameter:** The number of vertices n
Input: A bipartite graph $G = (R \cup B, E)$ containing red (R) and blue (B) vertices, and an integer k.
Question: Does there exist a set $D \subseteq R$ with $|D| \leq k$ such that every vertex in B has at least one neighbor in D?

Exact Red Blue Dominating Set (erbds) is defined similarly, except that every vertex in B must have *exactly one* neighbor in D. Furthermore we will not bound the size of such a set, but merely ask for the existence of any erbds.

▶ **Theorem 8.** Exact Red-Blue Dominating Set *parameterized by the number of vertices n does not have a generalized kernel of size $\mathcal{O}(n^{2-\varepsilon})$, unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

Proof. We will prove this result by giving a degree-2 cross-composition from rbds to erbds. We start by giving a polynomial equivalence relation $\mathcal{R}$ on inputs of rbds. Let two instances of rbds be equivalent under $\mathcal{R}$ if they have the same number of red vertices, the same number of blue vertices, and the same maximum size of a rbds. It is easy to check that $\mathcal{R}$ is a polynomial equivalence relation.

Assume we are given t instances of rbds, labeled $X_{i,j}$ for $i, j \in [\sqrt{t}]$, from the same equivalence class of $\mathcal{R}$. If the number of instances given is not a square, we duplicate one of the input instances until a square number is reached. Since this changes the number of

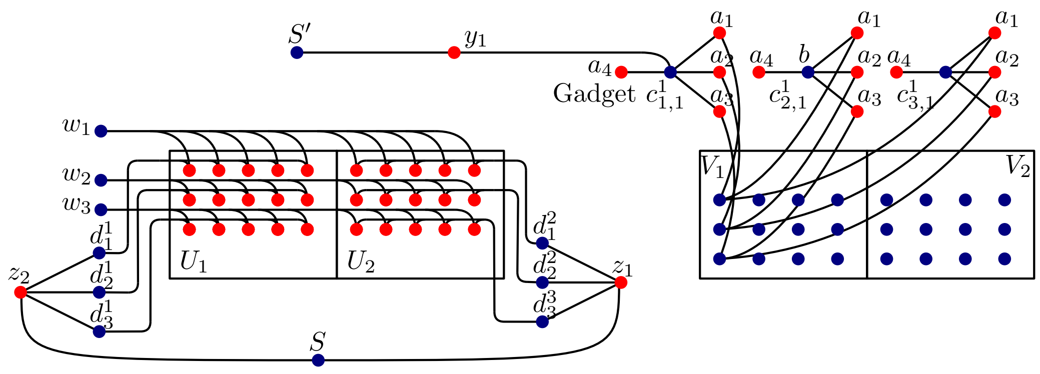

Figure 1 The graph G' created in the proof of Theorem 8, for $k = 3$, $m_R = 5$, $m_B = 4$, and $t = 4$. Edges between U and V are left out for simplicity. Of the 24 gadgets in C only $c^1_{1,1,}$, $c^1_{2,1}$, and $c^1_{3,1}$ are shown. Vertex y_2 is left out.

inputs by at most a factor four, this does not influence the cross-composition. Instance $X_{i,j}$ consists of graph $G_{i,j}$ with a set of red vertices $R_{i,j}$ and blue vertices $B_{i,j}$. Call the number of red vertices in every instance m_R, the number of blue vertices m_B, and the required size of the dominating set k. For each instance enumerate the red vertices as $r_1, \dots, r_{m_R}$ and the blue vertices as $b_1, \dots, b_{m_B}$, arbitrarily. Create instance G' for ERBDS by the following steps. Figure 1 shows a sketch of G'.

1. Create $\sqrt{t}$ sets $U_1, \dots, U_{\sqrt{t}}$ each consisting of $k \cdot m_R$ red vertices, such that for all $\ell \in [\sqrt{t}]$ $U_\ell := \{u^\ell_{i,j} \mid i \in [k], j \in [m_R]\}$.
2. Similarly create $\sqrt{t}$ sets $V_1, \dots, V_{\sqrt{t}}$, each consisting of $k \cdot m_B$ blue vertices, and define $V_\ell := \{v^\ell_{i,j} \mid i \in [k], j \in [m_B]\}$ for all $\ell \in [\sqrt{t}]$.
3. For each $i \in [k]$ add the edge from $u^\ell_{i,j}$ to $v^{\ell'}_{i,j'}$ if $\{r_j, b_{j'}\}$ is an edge in instance $X_{\ell,\ell'}$ with $\ell, \ell' \in [\sqrt{t}], j \in [m_R], j' \in [m_B]$.

By steps 1 to 3, the graph induced by the vertices in $U_\ell \cup V_{\ell'}$ consists of k vertex-disjoint copies of $G_{\ell,\ell'}$. The next steps are used to ensure that there are exactly k vertices from U in any ERBDS, which must all belong to the same set U_ℓ.

4. Create k blue vertices $W := \{w_i \mid i \in [k]\}$ and connect all vertices $\{u^\ell_{i,j} \mid j \in [m_R], \ell \in [\sqrt{t}]\}$ to w_i for $i \in [k]$.
5. Create blue vertices d^ℓ_i for $\ell \in [\sqrt{t}]$ and $i \in [k]$. Connect vertex d^ℓ_i to the vertices $u^\ell_{i,j}$ with $j \in [m_R]$. Add blue vertex S and red vertices $Z := \{z_j \mid j \in [\sqrt{t}]\}$ and connect z_j to d^ℓ_i for $i \in [k]$ and $\ell \neq j \in [\sqrt{t}]$. Connect all vertices in Z to vertex S.

The next steps ensure that some of the blue vertices in one set V_ℓ need to be dominated by vertices from U, while all other vertices in V can be dominated "for free".

6. Add sets of gadgets C_ℓ for $\ell \in [\sqrt{t}]$. Each set consists of $m_B \cdot k$ selector gadgets $c^\ell_{i,j}$. A selector gadget consists of $k+1$ red vertices labeled $a_1, \dots, a_{k+1}$ that are all connected to a blue vertex b that is private to the gadget. Furthermore, in gadget $c^\ell_{i,j}$, the vertex a_x for $x \in [k]$ is connected to $v^\ell_{x,j}$ for $j \in [m_B]$, $\ell \in [\sqrt{t}]$ and $i \in [k]$. By this construction an ERBDS uses at most one red vertex from each gadget, to dominate one vertex from V.
7. Add red vertices $Y := y_1, \dots, y_{\sqrt{t}}$ and connect y_ℓ to the blue vertices of gadgets $c^\ell_{1,j}$ for all $j \in [m_B]$, $\ell \in [\sqrt{t}]$. Connect $y_1, \dots, y_{\sqrt{t}}$ to the new blue vertex S'.

This concludes the construction of graph G', with red vertices ($U \cup Y \cup Z \cup$ vertices labeled $a_1, \dots, a_{k+1}$ in C), and blue vertices ($V \cup D \cup \{S, S'\} \cup$ vertices labeled b in C).

▶ **Claim 9.** *For any* ERBDS *E of G', there exists an index $\ell \in [\sqrt{t}]$ such that $U_x \cap E = \emptyset$ for all $x \neq \ell \in [\sqrt{t}]$ and $|E \cap \{u^{\ell}_{i,j} \mid j \in [m_R]\}| = 1$ for all $i \in k$.*

Proof. By Step 5, blue vertex S has neighborhood $\{z_\ell \mid \ \ell \in [\sqrt{t}]\}$. Exactly one of these vertices is contained in E; let this be z_ℓ. The neighborhood of z_ℓ contains $\{d^j_i \mid i \in [k], j \in [\sqrt{t}] \setminus \{\ell\}\}$. Thereby, no other neighbors from vertices in this set can be in E, implying no vertices from U_i for $i \neq \ell \in [\sqrt{t}]$ can be in E. In other words, $U_i \cap E = \emptyset$ for all $i \neq \ell \in [\sqrt{t}]$.

By Step 4, the neighborhood of blue vertex w_i for $i \in [k]$ is exactly $\{u^x_{i,j} \mid x \in [\sqrt{t}], j \in [m_R]\}$. It follows that exactly one vertex in this set is in E for all i. By the previous argument the vertex cannot be from U_x for $x \neq \ell$, hence it is from U_ℓ. ◀

▶ **Claim 10.** *For any* ERBDS *E of G', there exists ℓ such that $E \cap c^{\ell}_{1,j} = \emptyset$ for all $j \in [m_B]$.*

Proof. By Step 7, blue vertex S' has neighborhood $\{y_\ell \mid \ell \in [\sqrt{t}]\}$. Exactly one of these vertices is contained in E; let this be y_ℓ. It is connected to the blue vertex of all gadgets $c^\ell_{1,j}$ for $j \in [m_B]$. Since all red vertices in a gadget $c^\ell_{1,j}$ for $j \in [m_B]$ have a blue neighbor b that is also adjacent to $y_\ell \in E$, the red vertices in these gadgets are not present in E. ◀

▶ **Claim 11.** *For any* ERBDS *E of G', there exists an index ℓ such that for every $j \in [m_B]$ at least one of the vertices in $\{v^\ell_{i,j} \mid i \in [k]\}$ has a neighbor in $E \cap U$.*

Proof. By Claim 10 there exists $\ell \in [\sqrt{t}]$ such that $E \cap c^\ell_{1,j} = \emptyset$ for all $j \in [m_B]$. Consider an arbitrary $j \in [m_B]$. The k vertices in $\{v^\ell_{i,j} \mid i \in [k]\}$ are connected to k gadgets $c^\ell_{1,j}, c^\ell_{2,j}, \ldots, c^\ell_{k,j}$, and to some vertices in U. From each gadget, at most one red vertex is in E, since the red vertices have a common blue neighbor. Any red gadget vertex is connected to only one vertex in V. Since no vertex of gadget $c^\ell_{1,j}$ is in E, at most $k-1$ of the vertices in $\{v^\ell_{i,j} \mid i \in [k]\}$ have a neighbor in $E \cap C_\ell$. Consequently, at least one of these vertices has a neighbor in $E \cap U$ for each $j \in [m_B]$. ◀

▶ **Claim 12.** *If G' has an* ERBDS, *then some input $X_{i,j}$ has a* RBDS *of size at most k.*

Proof. Assume G' has an ERBDS, say E. By Claim 11, there exists $\ell_2 \in [\sqrt{t}]$, such that for every $j \in [m_B]$ at least one of the vertices in $\{v^\ell_{i,j} \mid i \in [k]\}$ has a neighbor in $E \cap U$. By Claim 9, there exists $\ell_1 \in [\sqrt{t}]$ with $U_i \cap E = \emptyset$ for all $i \neq \ell_1$, so these neighbors lie in U_{ℓ_1}.

We now construct a RBDS E' for instance X_{ℓ_1,ℓ_2}. For each $j \in [m_R]$, add r_j to E' if $E \cap \{u^{\ell_1}_{i,j} \mid i \in [k]\} \neq \emptyset$. By Claim 9, it follows that E' has size at most k, as required. It remains to show that every vertex in B_{ℓ_1,ℓ_2} has a neighbor in E'. If some vertex b_j from B_{ℓ_1,ℓ_2} does not have a neighbor in E', then none of the vertices $\{v^{\ell_2}_{i,j} \mid i \in [k]\}$ have a neighbor in $E \cap U_{\ell_1}$. This contradicts Claim 11. Hence E' is an RBDS of size at most k for B_{ℓ_1,ℓ_2}. ◀

▶ **Claim 13.** *If some input instance has a* RBDS *of size at most k, then G' has an* ERBDS.

Proof. Suppose instance X_{ℓ_1,ℓ_2} has a RBDS E' of size k consisting of vertices $r_{i_1}, \ldots, r_{i_k} \subseteq R_{\ell_1,\ell_2}$. We construct an ERBDS E for G'. Start by choosing vertices $u^{\ell_1}_{x,i_x}$ for $x \in [k]$, so for every vertex in E' we pick one vertex in the ERBDS for G'. Furthermore we choose the red vertices z_{ℓ_1} and y_{ℓ_2} to be in E. To exactly dominate the blue vertices in V, we use the gadgets in C as follows. For $\ell \neq \ell_2 \in [\sqrt{t}]$, add red vertex a_x of gadget $c^\ell_{x,j}$ if vertex $v^\ell_{x,j}$ does not yet have a neighbor in E, for $j \in [m_R]$. Else, add vertex a_{k+1} of gadget $c^\ell_{x,j}$ to E, in order to exactly dominate the blue vertex of this gadget.

To exactly dominate the vertices in V_{ℓ_2} we apply a similar procedure, except that gadget $c^\ell_{1,j}$ cannot be used since its blue vertex b is already dominated by y_{ℓ_2}. Since E' is a RBDS of instance X_{ℓ_1,ℓ_2}, for each $j \in [m_B]$ at least one vertex from set $\{v^{\ell_2}_{i,j} \mid i \in [k]\}$ has a neighbor in $E \cap U$. As such, the $k-1$ remaining gadgets can be used to each dominate one of the $k-1$ remaining vertices in this set, if they do not already have a neighbor in $E \cap U$. If no red vertex of a gadget is needed to dominate, we choose vertex a_{k+1} of the gadget in E to dominate the blue vertex in the gadget.

It is straight-forward to verify that this results in an ERBDS for G'. ◀

From Claims 12 and 13 it follows that graph G' has an ERBDS if and only if at least one of the input instances has a RBDS of size at most k. The graph G' has $\mathcal{O}(\sqrt{t} \cdot (m_R + m_B)^3)$ vertices, which is suitably bounded for a cross-composition. By Theorem 1, it follows that ERBDS parameterized by the number of vertices n does not have a generalized kernel of size $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. ◀

Using Theorem 8 we provide lower bounds for constraint satisfaction problems.

▶ **Corollary 14.** *The problems* EXACT SATISFIABILITY *and* 1-POLYNOMIAL ROOT CSP *over $\mathbb{Q}$, parameterized by the number of variables n, do not have a generalized kernel of size $\mathcal{O}(n^{2-\varepsilon})$ for any $\varepsilon > 0$, unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

Proof. By Theorem 8 and the discussion in Section 2, it suffices to give linear-parameter transformations from ERBDS parameterized by the number of vertices to the two mentioned problems. Consider an instance $G = (R \cup B, E)$ of ERBDS. Create a binary variable x_r for each $r \in R$. For each blue vertex $b \in B$ create a clause of the form $\bigvee_{r \in N(b)} x_r$ (to build an instance of EXACT SAT), or create a constraint $\sum_{r \in N(b)} x_r = 1$ (to build an instance of CSP). The resulting instance has a satisfying 0/1-assignment if and only if G has an ERBDS. Since the number of variables is $|R| \leq n$, these are valid linear-parameter transformations. ◀

▶ **Theorem 15.** *d-*POLYNOMIAL ROOT CSP *over $\mathbb{Q}$ parameterized by the number of variables n does not have a generalized kernel of size $\mathcal{O}(n^{d+1-\varepsilon})$ for any $\varepsilon > 0$, unless* $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

Proof. The case $d = 1$ is covered by Corollary 14; we consider $d \geq 2$ and give a degree-$(d+1)$ cross-composition from RBDS, re-using some parts of the proof of Theorem 8. Suppose we are given $t = r^{d+1}$ instances of RBDS from the same equivalence class of $\mathcal{R}$, all having m_R red vertices and m_B blue vertices. By a similar padding argument as before, we may assume r is an integer. Split the inputs into groups of size r^2 and apply the cross-composition of Theorem 8 to each group, followed by the linear-parameter transformation in Corollary 14. We obtain r^{d-1} instances of 1-POLYNOMIAL ROOT CSP with $O(r \cdot \mathrm{poly}(m_R + m_B))$ variables each, such that the answer to each composed instance is the logical OR of the answers to the RBDS instances in its group. Label the instances resulting from the group compositions $X_{i_1,\ldots,i_{d-1}}$ with $i_1, \ldots, i_{d-1} \in [r]$. They all use the same number of variables; label the variables in each instance as $x_1, \ldots, x_q$. Create an instance L' of d-POLYNOMIAL ROOT CSP as follows:

1. Create variables $x_1, \ldots, x_q$. Create sets $Y_1, \ldots, Y_{d-1}$ of r variables each, where $Y_i := \{y^i_j \mid j \in [r]\}$. Add the requirement $\sum_{j \in [r]} y^i_j = 1$ to L' for each $i \in [d-1]$.
2. Let the list of equations of instance $X_{i_1,\ldots,i_{d-1}}$ be $L_{i_1,\ldots,i_{d-1}}$. For every equality $f(\mathbf{x}) = 1$ in $L_{i_1,\ldots,i_{d-1}}$ with $i_1, \ldots, i_d \in [r]$, add the following equality to L':

$$f(\mathbf{x}) \cdot \prod_{z \in [d-1]} y^z_{i_z} = \prod_{z \in [d-1]} y^z_{i_z}.$$

The polynomial equalities have degree $\leq d$ since $f(\mathbf{x})$ has degree 1. The number of variables is $q + (d-1) \cdot r \in \mathcal{O}(r \cdot d \cdot \mathrm{poly}(m_R + m_B)) \in \mathcal{O}(t^{1/(d+1)} \mathrm{poly}(m_R + m_B))$. It remains to show that L' is satisfiable if and only if one of the input instances has an ERBDS. Since Theorem 8 gives a correct cross-composition, it is sufficient to show that L' is satisfiable if and only if one of the r^{d-1} instances of 1-Polynomial root CSP has a solution.

($\Rightarrow$) Suppose L' is satisfied by some assignment. Then from each Y_i for $i \in [d-1]$, exactly one variable is set to 1. So suppose variables $y^z_{i_z}$ are set to 1 for $z \in [d-1], i_z \in [r]$. Then from instance $X_{i_1,\ldots,i_{d-1}}$, all polynomial equations are copied to L' and multiplied by 1 on both sides. Hence they are satisfied by the assignment to $\mathbf{x}$.

($\Leftarrow$) Suppose instance $X_{i_1,\ldots,i_{d-1}}$ of 1-Polynomial root CSP has a satisfying assignment. Set the $\mathbf{x}$-variables according to this assignment. Furthermore, set variables $y^z_{i_z}$ for $z \in [d-1]$ to 1, set all other variables to 0. Thereby the sum of variables in each set Y_i is 1, as required. Furthermore, any equation added in Step 2 of the construction is satisfied in the following way. If it belongs to instance $X_{i_1,\ldots,i_{d-1}}$, it is satisfied by definition. Equations belonging to any other instance are trivially satisfied since both sides are multiplied by zero. ◀

Observe that the polynomials constructed in Theorem 15 have a simple form: each polynomial is a product of $(d-1)$ Y-variables multiplied by a sum of distinct variables from $\mathbf{x}$. Each polynomial can therefore be encoded in $\widetilde{\mathcal{O}}(n)$ bits, where n is the number of variables in the constructed CSP. The sparsification of Theorem 2 therefore encodes such instances in $\widetilde{\mathcal{O}}(n^{d+1})$ bits. The lower bound shows that this is optimal up to $n^{o(1)}$ factors.

We expect the lower bound of Theorem 15 to extend to arbitrary finite fields of prime order, except for the case $d = 1$ over $\mathbb{Z}/2\mathbb{Z}$, which is polynomial-time solvable [28].

4.2 Polynomial non-root CSP

We start our lower bound discussion for d-Polynomial non-root CSP by considering polynomials over $\mathbb{Q}$. 1-Polynomial non-root CSP over $\mathbb{Q}$ does not have a generalized kernel of size bounded by any polynomial in n, unless NP $\subseteq$ coNP/poly. This follows from the fact that CNF-Satisfiability parameterized by the number of variables does not have a kernel of size polynomial in n unless NP $\subseteq$ coNP/poly [10, 14], together with the fact that a clause such as $(x_1 \vee \neg x_3 \vee x_4)$ is satisfied by a 0/1-assignment if and only if $x_1 + (1-x_3) + x_4 \neq 0$ over $\mathbb{Q}$. In the remainder of the section we investigate the behavior over finite fields.

In Theorem 7 we provided a kernel for d-Polynomial non-root CSP over $\mathbb{Z}/p\mathbb{Z}$ for primes p. It is natural to ask whether similar results can be obtained when working with polynomials modulo an arbitrary integer m. When m is composite, our kernelization fails. We can show that this is not a shortcoming of our proof strategy, but a necessity due to the fact that constraints expressed by equalities of degree-d polynomials modulo composite numbers can model more complex constraints than degree-d polynomials modulo a prime. For example, it is known (cf. [1, §2]) that there is a degree-3 polynomial f over the integers modulo 6 which represents a logical or of size 27 in the following way:

$$f(x_1, \ldots, x_{27}) \not\equiv 0 \pmod 6 \Leftrightarrow (x_1 \vee \ldots \vee x_{27}). \tag{1}$$

By this expressibility of a size-27 or by a polynomial of degree 3 over $\mathbb{Z}/6\mathbb{Z}$ using the same variables, it is easy to give a linear-parameter transformation from 27-cnf-sat to 3-Polynomial non-root CSP (mod 6). Using known lower bounds for d-cnf-sat [10, Theorem 1], this implies the latter problem has no kernel of $\mathcal{O}(n^{27-\varepsilon})$ bits, unless NP $\subseteq$ coNP/poly. Plugging in the degree of 3 and modulus 6 into the bound of Theorem 7 would give a reduction to $\mathcal{O}(n^{3\cdot(6-1)}) = \mathcal{O}(n^{15})$ constraints and would contradict the lower bound. The example therefore shows that the problem is more complex for composite moduli.

For more general non-primes, we can prove a lower bound using a general construction by Bhowmick *et al.* [3] of low-degree polynomials representing or in the sense of Equation 1.

▶ **Theorem 16** (★). *Let m be a non-prime with a prime factorization consisting of r distinct primes, such that $m = \prod_{i \in [r]} p_i$. Then d-*Polynomial non-root CSP (mod m) *parameterized by the number of variables n does not have a generalized kernel of size $\mathcal{O}(n^{(d^r)/2-\varepsilon})$ for any $\varepsilon > 0$, unless* NP ⊆ coNP/poly.

In case m does not have a prime factorization in which all primes are distinct, it is possible to obtain weaker a lower bound using a result by Barrington *et al.* [2], which proves that there exists a polynomial of degree $\mathcal{O}(\ell N^{1/r})$ that represents a logical OR when taken modulo m. Here ℓ is the largest prime factor of m. For prime moduli, we provide a lower bound almost matching the upper bound in Section 3.2.

▶ **Theorem 17** (★). *Let p be a prime. d-*Polynomial non-root CSP (mod p) *parameterized by the number of variables n does not have a generalized kernel of size $\mathcal{O}(n^{d(p-1)-\varepsilon})$ for any $\varepsilon > 0$, unless* NP ⊆ coNP/poly.

5 Conclusion

We have given upper and lower bounds on the kernelization complexity of binary CSPs that can be represented by polynomial (in)equalities, obtaining tight sparsification bounds in several cases. Our main conceptual contribution is to analyze constraints on binary variables based on the minimum degree of multivariate polynomials whose roots, or non-roots, capture the satisfying assignments. The ultimate goal of this line of research is to characterize the optimal sparsification size of a binary CSP based on easily accessible properties of the constraint language. To reach this goal, several significant hurdles have to be overcome.

For d-Polynomial non-root CSP (mod 6), we do not know of any way to reduce the number of constraints to polynomial in n. This difficulty is connected to longstanding questions regarding the minimum degree of a multivariate polynomial modulo 6 that represents the OR-function of n variables in the sense of Equation 1. As exploited in the construction of Theorem 16, if the OR-function with $g(d)$ inputs can be represented by polynomials of degree d, then d-Polynomial non-root CSP cannot be compressed to size $\mathcal{O}(n^{g(d)-\varepsilon})$ unless NP ⊆ coNP/poly. By contraposition, a kernelization with size bound $\widetilde{\mathcal{O}}(n^{h(d)})$ implies a lower bound of $h^{-1}(d)$ on the degree of a polynomial representing an OR of arity $h(d)$, assuming NP ⊈ coNP/poly. Kernel bounds where $h(d)$ is polynomially bounded in d, would therefore establish inverse polynomial lower bounds on the degree of polynomials representing an n-variable OR modulo 6. However, the current-best degree lower bound [29] is only $\Omega(\log n)$, which has not been improved in nearly two decades (cf. [3, §1.4]).

When it comes to CSPs whose constraints are of the form "the number of satisfied literals in the clause belongs to set S", many cases remain unsolved. We can prove (★) using the Green-Tao theorem [15] that for constraints of the form "the number of satisfied literals is a prime number", no generalized kernel of size polynomial in n exists unless NP ⊆ coNP/poly. On the other hand, Corollary 5 gives good compressions for problems of the type "the number of satisfied literals in the clause is a multiple of three". Is sparsification possible when a constraint requires the number of satisfied literals to be a square, for example?

A simple example of a CSP whose kernelization complexity is currently unclear has constraints of the form "the number of satisfied literals is one or two, modulo six". The approach of Theorem 2 fails, since there is no polynomial modulo six with root set $\{1, 2\}$.

Finally, we mention that all our results extend to the setting of min-ones and max-ones CSPs, in which one has to find a satisfying assignment that sets at least, or at most, a given number of variables to true. For example, our results easily imply that Exact Hitting Set parameterized by the number of variables n has a sparsification of size $\mathcal{O}(n^2)$, which cannot be improved to $\mathcal{O}(n^{2-\varepsilon})$ unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$.

Abstract

A Longest Common Extension (LCE) query on a text T of length N asks for the length of the longest common prefix of suffixes starting at given two positions. We show that the signature encoding $\mathcal{G}$ of size $w = O(\min(z \log N \log^* M, N))$ [Mehlhorn et al., Algorithmica 17(2):183-198, 1997] of T, which can be seen as a compressed representation of T, has a capability to support LCE queries in $O(\log N + \log \ell \log^* M)$ time, where ℓ is the answer to the query, z is the size of the Lempel-Ziv77 (LZ77) factorization of T, and $M \geq 4N$ is an integer that can be handled in constant time under word RAM model. In compressed space, this is the fastest deterministic LCE data structure in many cases. Moreover, $\mathcal{G}$ can be enhanced to support efficient update operations: After processing $\mathcal{G}$ in $O(wf_{\mathcal{A}})$ time, we can insert/delete any (sub)string of length y into/from an arbitrary position of T in $O((y + \log N \log^* M)f_{\mathcal{A}})$ time, where $f_{\mathcal{A}} = O(\min\{\frac{\log\log M \log\log w}{\log\log\log M}, \sqrt{\frac{\log w}{\log\log w}}\})$. This yields the first fully dynamic LCE data structure working in compressed space. We also present efficient construction algorithms from various types of inputs: We can construct $\mathcal{G}$ in $O(Nf_{\mathcal{A}})$ time from uncompressed string T; in $O(n \log\log(n \log^* M) \log N \log^* M)$ time from grammar-compressed string T represented by a straight-line program of size n; and in $O(zf_{\mathcal{A}} \log N \log^* M)$ time from LZ77-compressed string T with z factors. On top of the above contributions, we show several applications of our data structures which improve previous best known results on grammar-compressed string processing.

1 Introduction

A *Longest Common Extension (LCE)* query on a text T of length N asks to compute the length of the longest common prefix of suffixes starting at given two positions. This fundamental query appears at the heart of many string processing problems (see text book [11] for example), and hence, efficient data structures to answer LCE queries gain a great attention.

A classic solution is to use a data structure for lowest common ancestor queries [4] on the suffix tree of T. Although this achieves constant query time, the $\Theta(N)$ space needed for the data structure is too large to apply it to large scale data. Hence, recent work focuses on reducing space usage at the expense of query time. For example, time-space trade-offs of LCE data structure have been extensively studied [7, 24].

Another direction to reduce space is to utilize a compressed structure of T, which is advantageous when T is highly compressible. There are several LCE data structures working on grammar-compressed string T represented by a straight-line program (SLP) of size n. The best known deterministic LCE data structure is due to I et al. [13], which supports LCE queries in $O(h \log N)$ time, and occupies $O(n^2)$ space, where h is the height of the derivation tree of a given SLP. Their data structure can be built in $O(hn^2)$ time directly from the SLP. Bille et al. [5] showed a Monte Carlo randomized data structure which supports LCE queries in $O(\log N \log \ell)$ time, where ℓ is the output of the LCE query. Their data structure requires only $O(n)$ space, but requires $O(N)$ time to construct. Very recently, Bille et al. [6] showed a faster Monte Carlo randomized data structure of $O(n)$ space which supports LCE queries in $O(\log N + \log^2 \ell)$ time. The preprocessing time of this new data structure is not given in [6]. Note that, given the LZ77-compression of size z of T, we can convert it into an SLP of size $n = O(z \log \frac{N}{z})$ [22] and then apply the above results.

In this paper, we focus on the *signature encoding* $\mathcal{G}$ of T, which can be seen as a grammar compression of T, and show that $\mathcal{G}$ can support LCE queries efficiently. The signature encoding was proposed by Mehlhorn et al. for equality testing on a dynamic set of strings [19]. Alstrup et al. used signature encodings combined with their own data structure called anchors to present a pattern matching algorithm on a dynamic set of strings [2, 1]. In their paper, they also showed that signature encodings can support longest common prefix (LCP) and longest common suffix (LCS) queries on a dynamic set of strings. Their algorithm is randomized as it uses a hash table for maintaining the dictionary of $\mathcal{G}$. Very recently, Gawrychowski et al. improved the results by pursuing advantages of randomized approach other than the hash table [10]. It should be noted that the algorithms in [2, 1, 10] can support LCE queries by combining split operations and LCP queries although it is not explicitly mentioned. However, they did not focus on the fact that signature encodings can work in compressed space. In [9], LCE data structures on edit sensitive parsing, a variant of signature encoding, was used for sparse suffix sorting, but again, they did not focus on working in compressed space.

Our contributions are stated by the following theorems, where $M \geq 4N$ is an integer that can be handled in constant time under word RAM model. More specifically, $M = 4N$ if T is static, and $M/4$ is the upper bound of the length of T if we consider updating T dynamically. In dynamic case, N (resp. w) always denotes the current size of T (resp. $\mathcal{G}$). Also, $f_{\mathcal{A}}$ denotes the time for predecessor/successor queries on a set of w integers from an M-element universe, which is $f_{\mathcal{A}} = O(\min\{\frac{\log\log M \log\log w}{\log\log\log M}, \sqrt{\frac{\log w}{\log\log w}}\})$ by the best known data structure [3].

▶ **Theorem 1** (LCE queries). *Let $\mathcal{G}$ denote the signature encoding of size $w = O(\min(z \log N \log^* M, N))$ for a string T of length N. Then $\mathcal{G}$ supports LCE queries on T in $O(\log N + \log \ell \log^* M)$ time, where ℓ is the answer to the query, and z is the size of the LZ77 factorization of T.*

▶ **Theorem 2** (Updates). *After processing $\mathcal{G}$ in $O(w f_{\mathcal{A}})$ time, we can insert/delete any (sub)string Y of length y into/from an arbitrary position of T in $O((y + \log N \log^* M) f_{\mathcal{A}})$ time. If Y is given as a substring of T, we can support insertion in $O(f_{\mathcal{A}} \log N \log^* M)$ time.*

▶ **Theorem 3** (Construction). *Let T be a string of length N, Z be LZ77 factorization without self reference of size z representing T, and $\mathcal{S}$ be an SLP of size n generating T. Then, we can construct the signature encoding $\mathcal{G}$ for T in (1a) in $O(Nf_{\mathcal{A}})$ time and $O(w)$ working space from T, (1b) in $O(N)$ time and working space from T, (2) in $O(zf_{\mathcal{A}} \log N \log^* M)$ time and $O(w)$ working space from Z, (3a) in $O(nf_{\mathcal{A}} \log N \log^* M)$ time and $O(w)$ working space from $\mathcal{S}$, and (3b) in $O(n \log\log(n \log^* M) \log N \log^* M)$ time and $O(n \log^* M + w)$ working space from $\mathcal{S}$.*

The remarks on our contributions are listed in the following:

- We achieve an algorithm for the fastest deterministic LCE queries on SLPs, which even permits faster LCE queries than the randomized data structure of Bille et al. [6] when $\log^* M = o(\log \ell)$ which in many cases is true.
- We present the first fully dynamic LCE data structure working in compressed space.
- Different from the work in [2, 1, 10], we mainly focus on maintaining a single text T in compressed $O(w)$ space. For this reason we opt for supporting insertion/deletion as edit operations rather than split/concatenate on a dynamic set of strings. However, the difference is not much essential; our insert operations specified by a substring of an existing string can work as split/concatenate, and conversely, split/concatenate can simulate insert. Our contribution here is to clarify how to collect garbage being produced during edit operations, as directly indicated by a support of delete operations.
- The results (2) and (3a) of Theorem 3 immediately follow from the update operations considered in [2, 1], but others are nontrivial.
- Direct construction of $\mathcal{G}$ from SLPs is important for applications in compressed string processing, where the task is to process a given compressed representation of string(s) without explicit decompression. In particular, we use the result (3b) of Theorem 3 to show several applications which improve previous best known results. Note that the time complexity of the result (3b) can be written as $O(n \log\log n \log N \log^* M)$ when $\log^* M = O(n)$ which in many cases is true, and always true in static case because $\log^* M = O(\log^* N) = O(\log N) = O(n)$.

Proofs and examples omitted due to lack of space are in a full version of this paper [21].

2 Preliminaries

2.1 Strings

Let Σ be an ordered alphabet. An element of Σ^* is called a string. For string $w = xyz$, x, y and z are called a prefix, substring, and suffix of w, respectively. The length of string w is denoted by $|w|$. The empty string ε is a string of length 0. Let $\Sigma^+ = \Sigma^* - \{\varepsilon\}$. For any $1 \leq i \leq |w|$, $w[i]$ denotes the i-th character of w. For any $1 \leq i \leq j \leq |w|$, $w[i..j]$ denotes the substring of w that begins at position i and ends at position j. Let $w[i..] = w[i..|w|]$ and $w[..i] = w[1..i]$ for any $1 \leq i \leq |w|$. For any string w, let w^R denote the reversed string of w, that is, $w^R = w[|w|] \cdots w[2]w[1]$. For any strings w and u, let $\mathsf{LCP}(w, u)$ (resp. $\mathsf{LCS}(w, u)$) denote the length of the longest common prefix (resp. suffix) of w and u. Given two strings s_1, s_2 and two integers i, j, let $\mathsf{LCE}(s_1, s_2, i, j)$ denote a query which returns $\mathsf{LCP}(s_1[i..|s_1|], s_2[j..|s_2|])$. Our model of computation is the unit-cost word RAM with machine word size of $\Omega(\log_2 M)$ bits, and space complexities will be evaluated by the number of machine words. Bit-oriented evaluation of space complexities can be obtained with a $\log_2 M$ multiplicative factor.

▶ **Definition 4** (Lempel-Ziv77 factorization [25]). The Lempel-Ziv77 (LZ77) factorization of a string s without self-references is a sequence $f_1, \ldots, f_z$ of non-empty substrings of s such that $s = f_1 \cdots f_z$, $f_1 = s[1]$, and for $1 < i \leq z$, if the character $s[|f_1..f_{i-1}| + 1]$ does not occur in $s[|f_1..f_{i-1}|]$, then $f_i = s[|f_1..f_{i-1}| + 1]$, otherwise f_i is the longest prefix of $f_i \cdots f_z$ which occurs in $f_1 \cdots f_{i-1}$. The size of the LZ77 factorization $f_1, \ldots, f_z$ of string s is the number z of factors in the factorization.

2.2 Context free grammars as compressed representation of strings

Straight-line programs. A *straight-line program* (*SLP*) is a context free grammar in the Chomsky normal form that generates a single string. Formally, an SLP that generates T is a quadruple $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$, such that Σ is an ordered alphabet of terminal characters; $\mathcal{V} = \{X_1, \ldots, X_n\}$ is a set of positive integers, called *variables*; $\mathcal{D} = \{X_i \rightarrow \mathit{expr}_i\}_{i=1}^{n}$ is a set of *deterministic productions* (or *assignments*) with each expr_i being either of form $X_\ell X_r$ $(1 \leq \ell, r < i)$, or a single character $a \in \Sigma$; and $S := X_n \in \mathcal{V}$ is the start symbol which derives the string T. We also assume that the grammar neither contains *redundant* variables (i.e., there is at most one assignment whose righthand side is *expr*) nor *useless* variables (i.e., every variable appears at least once in the derivation tree of $\mathcal{G}$). The *size* of the SLP $\mathcal{G}$ is the number n of productions in $\mathcal{D}$. In the extreme cases the length N of the string T can be as large as 2^{n-1}, however, it is always the case that $n \geq \log_2 N$.

Let $\mathit{val} : \mathcal{V} \rightarrow \Sigma^+$ be the function which returns the string derived by an input variable. If $s = \mathit{val}(X)$ for $X \in \mathcal{V}$, then we say that the variable X *represents* string s. For any variable sequence $y \in \mathcal{V}^+$, let $\mathit{val}^+(y) = \mathit{val}(y[1]) \cdots \mathit{val}(y[|y|])$.

Run-length straight-line programs. We define *run-length SLPs* (*RLSLPs*), as an extension to SLPs, which allow *run-length encodings* in the righthand sides of productions, i.e., $\mathcal{D}$ might contain a production $X \rightarrow \hat{X}^k \in \mathcal{V} \times \mathcal{N}$. The *size* of the RLSLP is still the number of productions in $\mathcal{D}$ as each production can be encoded in constant space. Let $\mathit{Assgn}_\mathcal{G}$ be the function such that $\mathit{Assgn}_\mathcal{G}(X_i) = \mathit{expr}_i$ iff $X_i \rightarrow \mathit{expr}_i \in \mathcal{D}$. Also, let $\mathit{Assgn}_\mathcal{G}^{-1}$ denote the reverse function of $\mathit{Assgn}_\mathcal{G}$. When clear from the context, we write $\mathit{Assgn}_\mathcal{G}$ and $\mathit{Assgn}_\mathcal{G}^{-1}$ as Assgn and Assgn^{-1}, respectively.

Representation of RLSLPs. For an RLSLP $\mathcal{G}$ of size w, we can consider a DAG of size w as a compact representation of the derivation trees of variables in $\mathcal{G}$. Each node represents a variable X in $\mathcal{V}$ and store $|\mathit{val}(X)|$ and out-going edges represent the assignments in $\mathcal{D}$: For an assignment $X_i \rightarrow X_\ell X_r \in \mathcal{D}$, there exist two out-going edges from X_i to its ordered children X_ℓ and X_r; and for $X \rightarrow \hat{X}^k \in \mathcal{D}$, there is a single edge from X to $\hat{X}$ with the multiplicative factor k.

3 Signature encoding

Here, we recall the *signature encoding* first proposed by Mehlhorn et al. [19]. Its core technique is *locally consistent parsing* defined as follows:

▶ **Lemma 5** (Locally consistent parsing [19, 1]). *Let W be a positive integer. There exists a function $f : [0..W]^{\log^* W + 11} \rightarrow \{0, 1\}$ such that, for any $p \in [1..W]^n$ with $n \geq 2$ and $p[i] \neq p[i+1]$ for any $1 \leq i < n$, the bit sequence d defined by $d[i] = f(\tilde{p}[i - \Delta_L], \ldots, \tilde{p}[i + \Delta_R])$ for $1 \leq i \leq n$, satisfies: $d[1] = 1$; $d[n] = 0$; $d[i] + d[i+1] \leq 1$ for $1 \leq i < n$; and $d[i] + d[i+1] + d[i+2] + d[i+3] \geq 1$ for any $1 \leq i < n - 3$; where $\Delta_L = \log^* W + 6$, $\Delta_R = 4$,* *and $\tilde{p}[j] = p[j]$ for all $1 \leq j \leq n$, $\tilde{p}[j] = 0$ otherwise. Furthermore, we can compute d in $O(n)$ time using a precomputed table of size $o(\log W)$, which can be computed in $o(\log W)$ time.*

For the bit sequence d of Lemma 5, we define the function $\mathit{Eblock}_d(p)$ that decomposes an integer sequence p according to d: $\mathit{Eblock}_d(p)$ decomposes p into a sequence $q_1, \ldots, q_j$ of substrings called *blocks* of p, such that $p = q_1 \cdots q_j$ and q_i is in the decomposition iff $d[|q_1 \cdots q_{i-1}| + 1] = 1$ for any $1 \leq i \leq j$. Note that each block is of length from two to four by the property of d, i.e., $2 \leq |q_i| \leq 4$ for any $1 \leq i \leq j$. Let $|\mathit{Eblock}_d(p)| = j$ and let $\mathit{Eblock}_d(s)[i] = q_i$. We omit d and write $\mathit{Eblock}(p)$ when it is clear from the context, and we use implicitly the bit sequence created by Lemma 5 as d.

We complementarily use run-length encoding to get a sequence to which *Eblock* can be applied. Formally, for a string s, let $\mathit{Epow}(s)$ be the function which groups each maximal run of same characters a as a^k, where k is the length of the run. $\mathit{Epow}(s)$ can be computed in $O(|s|)$ time. Let $|\mathit{Epow}(s)|$ denote the number of maximal runs of same characters in s and let $\mathit{Epow}(s)[i]$ denote i-th maximal run in s.

The signature encoding is the RLSLP $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$, where the assignments in $\mathcal{D}$ are determined by recursively applying *Eblock* and *Epow* to T until a single integer S is obtained. We call each variable of the signature encoding a *signature*, and use e (for example, $e_i \rightarrow e_\ell e_r \in \mathcal{D}$) instead of X to distinguish from general RLSLPs.

For a formal description, let $E := \Sigma \cup \mathcal{V}^2 \cup \mathcal{V}^3 \cup \mathcal{V}^4 \cup (\mathcal{V} \times \mathcal{N})$ and let $\mathit{Sig} : E \rightarrow \mathcal{V}$ be the function such that: $\mathit{Sig}(x) = e$ if $(e \rightarrow x) \in \mathcal{D}$; $\mathit{Sig}(x) = \mathit{Sig}(\mathit{Sig}(x[1..|x| - 1])x[|x|])$ if $x \in \mathcal{V}^3 \cup \mathcal{V}^4$; or otherwise undefined. Namely, the function *Sig* returns, if any, the lefthand side of the corresponding production of x by recursively applying the Assgn^{-1} function from left to right. For any $p \in E^*$, let $\mathit{Sig}^+(p) = \mathit{Sig}(p[1]) \cdots \mathit{Sig}(p[|p|])$.

The signature encoding of string T is defined by the following *Shrink* and *Pow* functions: $\mathit{Shrink}^T_t = \mathit{Sig}^+(T)$ for $t = 0$, and $\mathit{Shrink}^T_t = \mathit{Sig}^+(\mathit{Eblock}(\mathit{Pow}^T_{t-1}))$ for $0 < t \leq h$; and $\mathit{Pow}^T_t = \mathit{Sig}^+(\mathit{Epow}(\mathit{Shrink}^T_t))$ for $0 \leq t \leq h$; where h is the minimum integer satisfying $|\mathit{Pow}^T_h| = 1$. Then, the start symbol of the signature encoding is $S = \mathit{Pow}^T_h$. We say that a node is in *level* t in the derivation tree of S if the node is produced by Shrink^T_t or Pow^T_t. The height of the derivation tree of the signature encoding of T is $O(h) = O(\log |T|)$. For any $T \in \Sigma^+$, let $\mathit{id}(T) = \mathit{Pow}^T_h = S$, i.e., the integer S is the signature of T.

In this paper, we implement signature encodings by the DAG of RLSLP introduced in Section 2.

4 Compressed LCE data structure using signature encodings

In this section, we show Theorem 1.

Space requirement of the signature encoding. It is clear from the definition of the signature encoding $\mathcal{G}$ of T that the size of $\mathcal{G}$ is less than $4N \leq M$, and hence, all signatures are in $[1..M - 1]$. Moreover, the next lemma shows that $\mathcal{G}$ requires only *compressed space*:

▶ **Lemma 6** ([23]). *The size w of the signature encoding of T of length N is $O(z \log N \log^* M)$, where z is the number of factors in the LZ77 factorization without self-reference of T.*

Common sequences of signatures to all occurrences of same substrings. Here, we recall the most important property of the signature encoding, which ensures the existence of common signatures to all occurrences of same substrings by the following lemma.

▶ **Lemma 7** (common sequences [23]). *Let $\mathcal{G}$ be a signature encoding for a string T. Every substring P in T is represented by a signature sequence $Uniq(P)$ in $\mathcal{G}$ for a string P.*

$Uniq(P)$, which we call the *common sequence* of P, is defined by the following.

▶ **Definition 8.** For a string P, let

$$XShrink^P_t = \begin{cases} Sig^+(P) & \text{for } t = 0, \\ Sig^+(Eblock_d(XPow^P_{t-1})[|L^P_t|..|XPow^P_{t-1}| - |R^P_t|]) & \text{for } 0 < t \leq h^P, \end{cases}$$

$$XPow^P_t = Sig^+(Epow(XShrink^P_t[|\hat{L}^P_t| + 1..|XShrink^P_t| - |\hat{R}^P_t|])|) \text{ for } 0 \leq t < h^P,$$

- L^P_t is the shortest prefix of $XPow^P_{t-1}$ of length at least Δ_L such that $d[|L^P_t| + 1] = 1$,
- R^P_t is the shortest suffix of $XPow^P_{t-1}$ of length at least Δ_R+1 such that $d[|d|-|R^P_t|+1] = 1$,
- $\hat{L}^P_t$ is the longest prefix of $XShrink^P_t$ such that $|Epow(\hat{L}^P_t)| = 1$,
- $\hat{R}^P_t$ is the longest suffix of $XShrink^P_t$ such that $|Epow(\hat{R}^P_t)| = 1$, and
- h^P is the minimum integer such that $|Epow(XShrink^P_{h^P})| \leq \Delta_L + \Delta_R + 9$.

Note that $\Delta_L \leq |L^P_t| \leq \Delta_L + 3$ and $\Delta_R + 1 \leq |R^P_t| \leq \Delta_R + 4$ hold by the definition. Hence $|XShrink^P_{t+1}| > 0$ holds if $|Epow(XShrink^P_t)| > \Delta_L + \Delta_R + 9$. Then,

$$Uniq(P) = \hat{L}^P_0 L^P_0 \cdots \hat{L}^P_{h^P-1} L^P_{h^P-1} XShrink^P_{h^P} R^P_{h^P-1} \hat{R}^P_{h^P-1} \cdots R^P_0 \hat{R}^P_0.$$

We give an intuitive description of Lemma 7. Recall the locally consistent parsing of Lemma 5. Each i-th bit of bit sequence d of Lemma 5 for a given string s is determined by $s[i - \Delta_L..i + \Delta_R]$. Hence, for two positions i, j such that $P = s[i..i + k - 1] = s[j..j + k - 1]$ for some k, $d[i + \Delta_L..i + k - 1 - \Delta_R] = d[j + \Delta_L..j + k - 1 - \Delta_R]$ holds, namely, "internal" bit sequences of the same substring of s are equal. Since each level of the signature encoding uses the bit sequence, all occurrences of same substrings in a string share same internal signature sequences, and this goes up level by level. $XShrink^P_t$ and $XPow^P_t$ represent signature sequences obtained from only internal signature sequences of $XPow^T_{t-1}$ and $XShrink^T_t$, respectively. This means that $XShrink^P_t$ and $XPow^P_t$ are always created over P. From such common signatures we take as short signature sequence as possible for $Uniq(P)$: Since $val^+(Pow^P_{t-1}) = val^+(L^P_{t-1} XShrink^P_t R^P_{t-1})$ and $val^+(Shrink^P_t) = val^+(\hat{L}^P_t XPow^P_t \hat{R}^P_t)$ hold, $|Epow(Uniq(P))| = O(\log |P| \log^* M)$ and $val^+(Uniq(P)) = P$ hold. Hence Lemma 7 holds [1].

The number of ancestors of nodes corresponding to $Uniq(P)$ is upper bounded by:

▶ **Lemma 9.** *Let $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$ be a signature encoding for a string T, P be a string, and let $\mathcal{T}$ be the derivation tree of a signature $e \in \mathcal{V}$. Consider an occurrence of P in s, and the induced subtree X of $\mathcal{T}$ whose root is the root of $\mathcal{T}$ and whose leaves are the parents of the nodes representing $Uniq(P)$, where $s = val(e)$. Then X contains $O(\log^* M)$ nodes for every level and $O(\log |s| + \log |P| \log^* M)$ nodes in total.*

LCE queries. In the next lemma, we show a more general result than Theorem 1, which states that the signature encoding supports (both forward and backward) LCE queries on a given arbitrary pair of signatures. Theorem 1 immediately follows from Lemma 10.

▶ **Lemma 10.** *Using a signature encoding $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$ for a string T, we can support queries $\mathsf{LCE}(s_1, s_2, i, j)$ and $\mathsf{LCE}(s^R_1, s^R_2, i, j)$ in $O(\log |s_1| + \log |s_2| + \log \ell \log^* M)$ time for given two signatures $e_1, e_2 \in \mathcal{V}$ and two integers $1 \leq i \leq |s_1|$, $1 \leq j \leq |s_2|$, where $s_1 = val(e_1)$, $s_2 = val(e_2)$ and ℓ is the answer to the LCE query.*

[1] The common sequences are conceptually equivalent to the *cores* [17] which are defined for the *edit sensitive parsing* of a text, a kind of locally consistent parsing of the text.

Proof. We focus on $\mathsf{LCE}(s_1, s_2, i, j)$ as $\mathsf{LCE}(s_1^R, s_2^R, i, j)$ is supported similarly.

Let P denote the longest common prefix of $s_1[i..]$ and $s_2[j..]$. Our algorithm simultaneously traverses two derivation trees rooted at e_1 and e_2 and computes P by matching the common signatures greedily from left to right. Recall that s_1 and s_2 are substrings of T. Since the both substrings P occurring at position i in $val(e_1)$ and at position j in $val(e_2)$ are represented by $Uniq(P)$ in the signature encoding by Lemma 7, we can compute P by at least finding the common sequence of nodes which represents $Uniq(P)$, and hence, we only have to traverse ancestors of such nodes. By Lemma 9, the number of nodes we traverse, which dominates the time complexity, is upper bounded by $O(\log |s_1| + \log |s_2| + Epow(Uniq(P))) = O(\log |s_1| + \log |s_2| + \log \ell \log^* M)$. ◀

5 Updates

In this section, we show Theorem 2. Formally, we consider a *dynamic signature encoding* $\mathcal{G}$ of T, which allows for efficient updates of $\mathcal{G}$ in compressed space according to the following operations: $INSERT(Y, i)$ inserts a string Y into T at position i, i.e., $T \leftarrow T[..i-1]YT[i..]$; $INSERT'(j, y, i)$ inserts $T[j..j+y-1]$ into T at position i, i.e., $T \leftarrow T[..i-1]T[j..j+y-1]T[i..]$; and $DELETE(j, y)$ deletes a substring of length y starting at j, i.e., $T \leftarrow T[..j-1]T[j+y..]$.

During updates we recompute $Shrink_t^T$ and Pow_t^T for some part of new T (note that the most part is unchanged thanks to the virtue of signature encodings, Lemma 9). When we need a signature for $expr$, we look up the signature assigned to $expr$ (i.e., compute $Assign^{-1}(expr)$) and use it if such exists. If $Assign^{-1}(expr)$ is undefined we create a new signature, which is an integer that is currently not used as signatures (say $e_{new} = \min([1..M] \setminus \mathcal{V})$), and add $e_{new} \rightarrow expr$ to $\mathcal{D}$. Also, updates may produce a useless signature whose parents in the DAG are all removed. We remove such useless signatures from $\mathcal{G}$ during updates.

Note that the corresponding nodes and edges of the DAG can be added/removed in constant time per addition/removal of an assignment. In addition to the DAG, we need dynamic data structures to conduct the following operations efficiently: (A) computing $Assgn^{-1}(\cdot)$, (B) computing $\min([1..M] \setminus \mathcal{V})$, and (C) checking if a signature e is useless.

For (A), we use Beame and Fich's data structure [3] that can support predecessor/successor queries on a dynamic set of integers.[2] For example, we consider Beame and Fich's data structure maintaining a set of integers $\{e_\ell M^2 + e_r M + e \mid e \rightarrow e_\ell e_r \in \mathcal{D}\}$ in $O(w)$ space. Then we can implement $Assgn^{-1}(e_\ell e_r)$ by computing the successor q of $e_\ell M^2 + e_r M$, i.e., $e = q \bmod M$ if $\lfloor q/M \rfloor = e_\ell M + e_r$, and otherwise $Assgn^{-1}(e_\ell e_r)$ is undefined. Queries as well as update operations can be done in deterministic $O(f_\mathcal{A})$ time, where $f_\mathcal{A} = O\left(\min\left\{\frac{\log\log M \log\log w}{\log\log\log M}, \sqrt{\frac{\log w}{\log\log w}}\right\}\right)$.

For (B), we again use Beame and Fich's data structure to maintain the set of maximal intervals such that every element in the intervals is signature. Formally, the intervals are maintained by a set of integers $\{e_i M + e_j \mid [e_i..e_j] \subseteq \mathcal{V}, e_i - 1 \notin \mathcal{V}, e_j + 1 \notin \mathcal{V}\}$ in $O(w)$ space. Then we can know the minimum integer currently not in $\mathcal{V}$ by computing the successor of 0.

For (C), we let every signature $e \in \mathcal{V}$ have a counter to count the number of parents of e in the DAG. Then we can know that a signature is useless if the counter is 0.

Lemma 11 shows that we can efficiently compute $Uniq(P)$ for a substring P of T.

[2] Alstrup et al. [1] used hashing for this purpose. However, since we are interested in the worst case time complexities, we use the data structure [3] in place of hashing.

▶ **Lemma 11.** *Using a signature encoding $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$ of size w, given a signature $e \in \mathcal{V}$ (and its corresponding node in the DAG) and two integers j and y, we can compute $Epow(Uniq(s[j..j+y-1]))$ in $O(\log|s| + \log y \log^* M)$ time, where $s = val(e)$.*

Proof of Theorem 2. It is easy to see that, given the static signature encoding of T, we can construct data structures (A)-(C) in $O(wf_{\mathcal{A}})$ time. After constructing these, we can add/remove an assignment in $O(f_{\mathcal{A}})$ time.

Let $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$ be the signature encoding before the update operation. We support $DELETE(j, y)$ as follows: (1) Compute the new start variable $S' = id(T[..j-1]T[j+y..])$ by recomputing the new signature encoding from $Uniq(T[..j-1])$ and $Uniq(T[j+y..])$. Although we need a part of d to recompute $Eblock_d(Pow_t^{T[..j-1]T[j+y..]})$ for every level t, the input size to compute the part of d is $O(\log^* M)$ by Lemma 5. Hence these can be done in $O(f_{\mathcal{A}} \log N \log^* M)$ time by Lemmas 11 and 9. (2) Remove all useless signatures Z from $\mathcal{G}$. Note that if a signature is useless, then all the signatures along the path from S to it are also useless. Hence, we can remove all useless signatures efficiently by depth-first search starting from S, which takes $O(f_{\mathcal{A}}|Z|)$ time, where $|Z| = O(y + \log N \log^* M)$ by Lemma 9.

Similarly, we can support $INSERT(Y, i)$ in $O(f_{\mathcal{A}}(y + \log N \log^* M))$ time by creating the new start variable S' from $Uniq(T[..i-1])$, $Uniq(Y)$ and $Uniq(T[i..])$. Note that we can naively compute $Uniq(Y)$ in $O(f_{\mathcal{A}}y)$ time. For $INSERT'(j, y, i)$, we can avoid $O(f_{\mathcal{A}}y)$ time by computing $Uniq(T[j..j+y-1])$ using Lemma 11. ◀

6 Construction

In this section, we give proofs of Theorem 3, but we omit proofs of the results (2) and (3a) as they are straightforward from the previous work [2, 1].

6.1 Theorem 3 (1a)

Proof of Theorem 3 (1a). Note that we can naively compute $id(T)$ for a given string T in $O(Nf_{\mathcal{A}})$ time and $O(N)$ working space. In order to reduce the working space, we consider factorizing T into blocks of size B and processing them incrementally: Starting with the empty signature encoding $\mathcal{G}$, we can compute $id(T)$ in $O(\frac{N}{B} f_{\mathcal{A}}(\log N \log^* M + B))$ time and $O(w + B)$ working space by using $INSERT(T[(i-1)B+1..iB], (i-1)B+1)$ for $i = 1, \ldots, \frac{N}{B}$ in increasing order. Hence our proof is finished by choosing $B = \log N \log^* M$. ◀

6.2 Theorem 3 (1b)

We compute signatures level by level, i.e., construct $Shrink_0^T, Pow_0^T, \ldots, Shrink_h^T, Pow_h^T$ incrementally. For each level, we create signatures by sorting signature blocks (or run-length encoded signatures) to which we give signatures, as shown by the next two lemmas.

▶ **Lemma 12.** *Given $Eblock(Pow_{t-1}^T)$ for $0 < t \leq h$, we can compute $Shrink_t^T$ in $O((b-a) + |Pow_{t-1}^T|)$ time and space, where b is the maximum integer in Pow_{t-1}^T and a is the minimum integer in Pow_{t-1}^T.*

Proof. Since we assign signatures to signature blocks and run-length signatures in the derivation tree of S in the order they appear in the signature encoding. $Pow_{t-1}^T[i] - a$ fits in an entry of a bucket of size $b - a$ for each element of $Pow_{t-1}^T[i]$ of Pow_{t-1}^T. Also, the length of each block is at most four. Hence we can sort all the blocks of $Eblock(Pow_{t-1}^T)$ by bucket sort in $O((b-a) + |Pow_{t-1}^T|)$ time and space. Since Sig is an injection and since we process the levels in increasing order, for any two different levels $0 \leq t' < t \leq h$, no elements of $Shrink^T_{t-1}$ appear in $Shrink^T_{t'-1}$, and hence no elements of Pow^T_{t-1} appear in $Pow^T_{t'-1}$. Thus, we can determine a new signature for each block in $Eblock(Pow^T_{t-1})$, *without* searching existing signatures in the lower levels. This completes the proof. ◀

▶ **Lemma 13.** *Given $Epow(Shrink^T_t)$, we can compute Pow^T_t in $O(x + (b - a) + |Epow(Shrink^T_t)|)$ time and space, where x is the maximum length of runs in $Epow(Shrink^T_t)$, b is the maximum integer in Pow^T_{t-1}, and a is the minimum integer in Pow^T_{t-1}.*

Proof. We first sort all the elements of $Epow(Shrink^T_t)$ by bucket sort in $O(b - a + |Epow(Shrink^T_t)|)$ time and space, ignoring the powers of runs. Then, for each integer r appearing in $Shrink^T_t$, we sort the runs of r's by bucket sort with a bucket of size x. This takes a total of $O(x + |Epow(Shrink^T_t)|)$ time and space for all integers appearing in $Shrink^T_t$. The rest is the same as the proof of Lemma 12. ◀

Proof of Theorem 3 (1b). Since the size of the derivation tree of $id(T)$ is $O(N)$, by Lemmas 5, 12, and 13, we can compute a DAG of $\mathcal{G}$ for T in $O(N)$ time and space. ◀

6.3 Theorem 3 (3b)

In this section, we sometimes abbreviate $val(X)$ as X for $X \in \mathcal{S}$. For example, $Shrink^X_t$ and Pow^X_t represents $Shrink^{val(X)}_t$ and $Pow^{val(X)}_t$ respectively.

Our algorithm computes signatures level by level, i.e., constructs incrementally $Shrink^{X_n}_0$, $Pow^{X_n}_0$, $\ldots$, $Shrink^{X_n}_h$, $Pow^{X_n}_h$. Like the algorithm described in Section 6.2, we can create signatures by sorting blocks of signatures or run-length encoded signatures in the same level. The main difference is that we now utilize the structure of the SLP, which allows us to do the task efficiently in $O(n \log^* M + w)$ working space. In particular, although $|Shrink^{X_n}_t|, |Pow^{X_n}_t| = O(N)$ for $0 \le t \le h$, they can be represented in $O(n \log^* M)$ space.

In so doing, we introduce some additional notations relating to $XShrink^P_t$ and $XPow^P_t$ in Definition 8. By Lemma 7, there exist $\hat{z}^{(P_1,P_2)}_t$ and $z^{(P_1,P_2)}_t$ for any string $P = P_1P_2$ such that the following equation holds: $XShrink^P_t = \hat{y}^{P_1}_t \hat{z}^{(P_1,P_2)}_t \hat{y}^{P_2}_t$ for $0 < t \le h^P$, and $XPow^P_t = y^{P_1}_t z^{(P_1,P_2)}_t y^{P_2}_t$ for $0 \le t < h^P$, where we define $\hat{y}^P_t$ and y^P_t for a string P as:

$$\hat{y}^P_t = \begin{cases} XShrink^P_t & \text{for } 0 < t \le h^P, \\ \varepsilon & \text{for } t > h^P, \end{cases} \qquad y^P_t = \begin{cases} XPow^P_t & \text{for } 0 \le t < h^P, \\ \varepsilon & \text{for } t \ge h^P. \end{cases}$$

For any variable $X_i \to X_\ell X_r$, we denote $\hat{z}^{X_i}_t = \hat{z}^{(val(X_\ell),val(X_r))}_t$ (for $0 < t \le h^{val(X_i)}$) and $z^{X_i}_t = z^{(val(X_\ell),val(X_r))}_t$ (for $0 \le t < h^{val(X_i)}$). Note that $|z^{X_i}_t|, |\hat{z}^{X_i}_t| = O(\log^* M)$ because $z^{X_i}_t$ is created on $\hat{R}^{X_\ell}_t \hat{z}^{X_i}_t \hat{L}^{X_r}_t$, similarly, $\hat{z}^{X_i}_t$ is created on $R^{X_\ell}_{t-1} z^{X_i}_{t-1} L^{X_r}_{t-1}$. We can use $\hat{z}^{X_1}_t, \ldots, \hat{z}^{X_n}_t$ (resp. $z^{X_1}_t, \ldots, z^{X_n}_t$) as a compressed representation of $XShrink^{X_n}_t$ (resp. $XPow^{X_n}_t$) based on the SLP: Intuitively, $\hat{z}^{X_n}_t$ (resp. $z^{X_n}_t$) covers the middle part of $XShrink^{X_n}_t$ (resp. $XPow^{X_n}_t$) and the remaining part is recovered by investigating the left/right child recursively (see also Fig. 1). Hence, with the DAG structure of the SLP, $XShrink^{X_n}_t$ and $XPow^{X_n}_t$ can be represented in $O(n \log^* M)$ space.

In addition, we define $\hat{A}^P_t$, $\hat{B}^P_t$, A^P_t and B^P_t as follows: For $0 < t \le h^P$, $\hat{A}^P_t$ (resp. $\hat{B}^P_t$) is a prefix (resp. suffix) of $Shrink^P_t$ which consists of signatures of $A^P_{t-1} L^P_{t-1}$ (resp. $R^P_{t-1} B^P_{t-1}$); and for $0 \le t < h^P$, A^P_t (resp. B^P_t) is a prefix (resp. suffix) of Pow^P_t which consists of signatures of $\hat{A}^P_t \hat{L}^P_t$ (resp. $\hat{R}^P_t \hat{B}^P_t$). By the definition, $Shrink^P_t = \hat{A}^P_t XShrink^P_t \hat{B}^P_t$ for $0 \le t \le h^P$, and $Pow^P_t = A^P_t XPow^P_t B^P_t$ for $0 \le t < h^P$. See Fig. 2 for the illustration.

Since $Shrink^{X_n}_t = \hat{A}^{X_n}_t XShrink^{X_n}_t \hat{B}^{X_n}_t$ for $0 < t \le h^{X_n}$, we use $\hat{\Lambda}_t = (\hat{z}^{X_1}_t, \ldots, \hat{z}^{X_n}_t, \hat{A}^{X_n}_t, \hat{B}^{X_n}_t)$ as a compressed representation of $Shrink^{X_n}_t$ of size $O(n \log^* M)$. Similarly, for $0 \le$

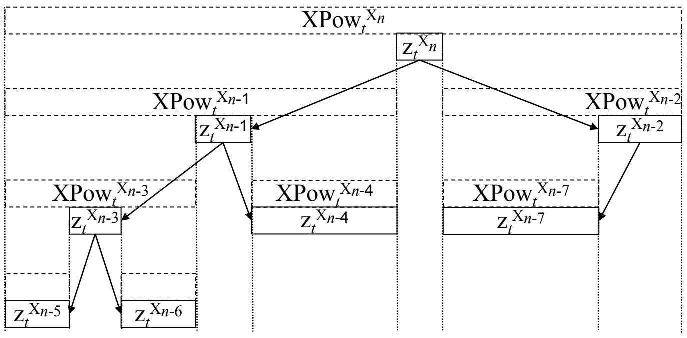

Figure 1 $XPow_t^{X_n}$ can be represented by $z_t^{X_1}, \ldots, z_t^{X_n}$. In this example, $XPow_t^{X_n} = z_t^{X_{n-5}} z_t^{X_{n-3}} z_t^{X_{n-6}} z_t^{X_{n-1}} z_t^{X_{n-4}} z_t^{X_n} z_t^{X_{n-7}} z_t^{X_{n-2}}$.

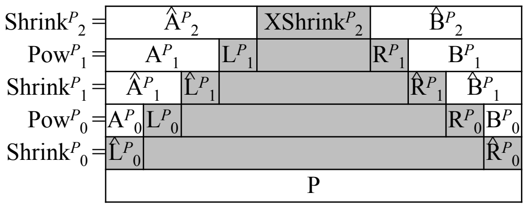

Figure 2 An abstract image of $Shrink_t^P$ and Pow_t^P for a string P. For $0 \leq t < h^P$, $A_t^P L_t^P$ (resp. $R_t^P B_t^P$) is encoded into $\hat{A}_{t+1}^P$ (resp. $\hat{B}_{t+1}^P$). Similarly, for $0 < t < h^P$, $\hat{A}_t^P \hat{L}_t^P$ (resp. $\hat{R}_t^P \hat{B}_t^P$) is encoded into A_t^P (resp. B_t^P).

$t < h^{X_n}$, we use $\Lambda_t = (z_t^{X_1}, \ldots, z_t^{X_n}, A_t^{X_n}, B_t^{X_n})$ as a compressed representation of $Pow_t^{X_n}$ of size $O(n \log^* M)$.

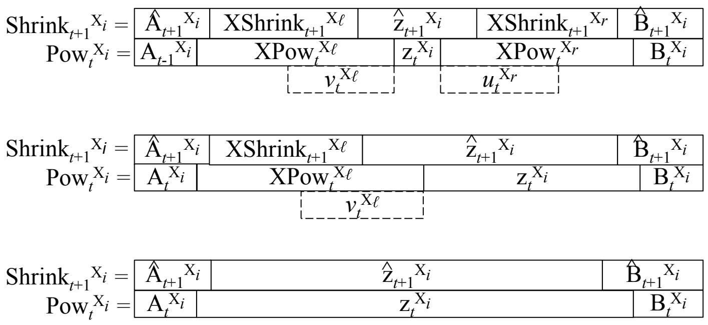
Our algorithm computes incrementally $\Lambda_0, \hat{\Lambda}_1, \ldots, \hat{\Lambda}_{h^{X_n}}$. Given $\hat{\Lambda}_{h^{X_n}}$, we can easily get $Pow_{h^{X_n}}^{X_n}$ of size $O(\log^* M)$ in $O(n \log^* M)$ time, and then $id(val(X_n))$ in $O(\log^* M)$ time from $Pow_{h^{X_n}}^{X_n}$. Hence, in the following three lemmas, we show how to compute $\Lambda_0, \hat{\Lambda}_1, \ldots, \hat{\Lambda}_{h^{X_n}}$.

▶ **Lemma 14.** *Given an SLP of size n, we can compute Λ_0 in $O(n \log\log(n \log^* M) \log^* M)$ time and $O(n \log^* M)$ space.*

Proof. We first compute, for all variables X_i, $Epow(XShrink_0^{X_i})$ if $|Epow(XShrink_0^{X_i})| \leq \Delta_L + \Delta_R + 9$, otherwise $Epow(\hat{L}_0^{X_i})$ and $Epow(\hat{R}_0^{X_i})$. The information can be computed in $O(n \log^* M)$ time and space in a bottom-up manner, i.e., by processing variables in increasing order. For $X_i \to X_\ell X_r$, if both $|Epow(XShrink_0^{X_\ell})|$ and $|Epow(XShrink_0^{X_r})|$ are no greater than $\Delta_L + \Delta_R + 9$, we can compute $Epow(XShrink_0^{X_i})$ in $O(\log^* M)$ time by naively concatenating $Epow(XShrink_0^{X_\ell})$ and $Epow(XShrink_0^{X_r})$. Otherwise $|Epow(XShrink_0^{X_i})| > \Delta_L + \Delta_R + 9$ must hold, and $Epow(\hat{L}_0^{X_i})$ and $Epow(\hat{R}_0^{X_i})$ can be computed in $O(1)$ time from the information for X_ℓ and X_r.

The run-length encoded signatures represented by $z_0^{X_i}$ can be obtained by using the above information for X_ℓ and X_r in $O(\log^* M)$ time: $z_0^{X_i}$ is created over run-length encoded signatures $Epow(XShrink_0^{X_\ell})$ (or $Epow(\hat{R}_0^{X_\ell})$) followed by $Epow(XShrink_0^{X_r})$ (or $Epow(\hat{R}_0^{X_r})$). Also, by definition $A_0^{X_n}$ and $B_0^{X_n}$ represents $Epow(\hat{L}_0^{X_n})$ and $Epow(\hat{R}_0^{X_n})$, respectively.

Hence, we can compute in $O(n \log^* M)$ time $O(n \log^* M)$ run-length encoded signatures to which we give signatures. We determine signatures by sorting the run-length encoded signatures as Lemma 13. However, in contrast to Lemma 13, we do not use bucket sort for sorting the powers of runs because the maximum length of runs could be as large as N and we cannot afford $O(N)$ space for buckets. Instead, we use the sorting algorithm of Han [12]



■ **Figure 3** Abstract images of the needed signature sequence $v_t^{X_\ell} z_t^{X_i} u_t^{X_r}$ ($v_t^{X_\ell}$ and $u_t^{X_r}$ are not shown when they are empty) for computing $\hat{z}_{t+1}^{X_i}$ in three situations: Top for $0 \le t < h^{X_\ell}, h^{X_r}$; middle for $h^{X_r} \le t < h^{X_\ell}$; and bottom for $h^{X_\ell}, h^{X_r} \le t < h^{X_i}$.

which sorts x integers in $O(x \log\log x)$ time and $O(x)$ space. Hence, we can compute Λ_0 in $O(n \log\log(n \log^* M) \log^* M)$ time and $O(n \log^* M)$ space. ◀

▶ **Lemma 15.** *Given $\hat{\Lambda}_t$, we can compute Λ_t in $O(n \log\log(n \log^* M) \log^* M)$ time and $O(n \log^* M)$ space.*

Proof. The computation is similar to that of Lemma 14 except that we also use $\hat{\Lambda}_t$. ◀

▶ **Lemma 16.** *Given Λ_t, we can compute $\hat{\Lambda}_{t+1}$ in $O(n \log^* M)$ time and $O(n \log^* M)$ space.*

Proof. In order to compute $\hat{z}_{t+1}^{X_i}$ for a variable $X_i \to X_\ell X_r$, we need a signature sequence on which $\hat{z}_{t+1}^{X_i}$ is created, as well as its context, i.e., Δ_L signatures to the left and Δ_R to the right. To be precise, the needed signature sequence is $v_t^{X_\ell} z_t^{X_i} u_t^{X_r}$, where $u_t^{X_j}$ (resp. $v_t^{X_j}$) denotes a prefix (resp. suffix) of $y_t^{X_j}$ of length $\Delta_L + \Delta_R + 4$ for any variable X_j (see also Figure 3). Also, we need $A_t u_t^{X_n}$ and $v_t^{X_n} B_t$ to create $\hat{A}_{t+1}^{X_n}$ and $\hat{B}_{t+1}^{X_n}$, respectively.

Note that by Definition 8, $|z_t^X| > \Delta_L + \Delta_R + 9$ if $z_t^X \neq \varepsilon$. Then, we can compute $u_t^{X_i}$ for all variables X_i in $O(n \log^* M)$ time and space by processing variables in increasing order on the basis of the following fact: $u_t^{X_i} = u_t^{X_\ell}$ if $z_t^{X_\ell} \neq \varepsilon$, otherwise $u_t^{X_i}$ is the prefix of $z_t^{X_i}$ of length $\Delta_L + \Delta_R + 4$. Similarly $v_t^{X_i}$ for all variables X_i can be computed in $O(n \log^* M)$ time and space.

Using $u_t^{X_i}$ and $v_t^{X_i}$ for all variables X_i, we can obtain $O(n \log^* M)$ blocks of signatures to which we give signatures. We determine signatures by sorting the blocks by bucket sort as in Lemma 12 in $O(n \log^* M)$ time. Hence, we can get $\hat{\Lambda}_{t+1}$ in $O(n \log^* M)$ time and space. ◀

Proof of Theorem 3 (3b). Using Lemmas 14, 15 and 16, we can get $\hat{\Lambda}_{h^{X_n}}$ in $O(n \log\log (n \log^* M) \log N \log^* M)$ time by computing $\Lambda_0, \hat{\Lambda}_1, \dots, \hat{\Lambda}_{h^{X_n}}$ incrementally. Note that during the computation we only have to keep Λ_t (or $\hat{\Lambda}_t$) for the current t and the assignments of $\mathcal{G}$. Hence the working space is $O(n \log^* M + w)$. By processing $\hat{\Lambda}_{h^{X_n}}$ in $O(n \log^* M)$ time, we can get the DAG of $\mathcal{G}$ of size $O(w)$. ◀

7 Applications

Theorem 17 is an application to text compression. Theorems 19-23 are applications to compressed string processing, where the task is to process a given compressed representation of string(s) without explicit decompression. We believe that only a few applications are listed here, considering the importance of LCE queries. As one example of unlisted applications, there is a paper [14] in which our LCE data structure was used to improve an algorithm of computing the Lyndon factorization of a string represented by a given SLP.

▶ **Theorem 17.** (1) *Given a dynamic signature encoding $\mathcal{G}$ for $\mathcal{G} = (\Sigma, \mathcal{V}, \mathcal{D}, S)$ of size w which generates T, we can compute an SLP $\mathcal{S}$ of size $O(w \log |T|)$ generating T in $O(w \log |T|)$ time.* (2) *Let us conduct a single INSERT or DELETE operation on the string T generated by the SLP of (1). Let y be the length of the substring to be inserted or deleted, and let T' be the resulting string. During the above operation on the string, we can update, in $O((y + \log |T'| \log^* M)(f_{\mathcal{A}} + \log |T'|))$ time, the SLP of (1) to an SLP $\mathcal{S}'$ of size $O(w' \log |T'|)$ which generates T', where w' is the size of updated $\mathcal{G}$ which generates T'.*

We can get the next lemma using Theorem 3 (3b) and Theorem 2:

▶ **Lemma 18.** *Given an SLP of size n representing a string of length N, we can sort the variables of the SLP in lexicographical order in $O(n \log n \log N \log^* N)$ time and $O(n \log^* N + w)$ working space.*

Lemma 18 has an application to an SLP-based index of Claude and Navarro [8]. In the paper, they showed how to construct their index in $O(n \log n)$ time if the lexicographic order of variables of a given SLP is already computed. However, in order to sort variables they almost decompressed the string, and hence, needs $\Omega(N)$ time and $\Omega(N \log |\Sigma|)$ bits of working space. Now, Lemma 18 improves the sorting part yielding the next theorem.

▶ **Theorem 19.** *Given an SLP of size n representing a string of length N, we can construct the SLP-based index of [8] in $O(n \log n \log N \log^* N)$ time and $O(n \log^* N + w)$ working space.*

▶ **Theorem 20.** *Given an SLP $\mathcal{S}$ of size n generating a string T of length N, we can construct, in $O(n \log\log n \log N \log^* N)$ time, a data structure which occupies $O(n \log N \log^* N)$ space and supports $\mathsf{LCP}(val(X_i), val(X_j))$ and $\mathsf{LCS}(val(X_i), val(X_j))$ queries for variables X_i, X_j in $O(\log N)$ time. The $\mathsf{LCP}(val(X_i), val(X_j))$ and $\mathsf{LCS}(val(X_i), val(X_j))$ query times can be improved to $O(1)$ using $O(n \log n \log N \log^* N)$ preprocessing time.*

▶ **Theorem 21.** *Given an SLP $\mathcal{S}$ of size n generating a string T of length N, there is a data structure which occupies $O(w + n)$ space and supports queries $\mathsf{LCE}(val(X_i), val(X_j), a, b)$ for variables X_i, X_j, $1 \leq a \leq |X_i|$ and $1 \leq b \leq |X_j|$ in $O(\log N + \log \ell \log^* N)$ time, where $w = O(z \log N \log^* N)$. The data structure can be constructed in $O(n \log\log n \log N \log^* N)$ preprocessing time and $O(n \log^* N + w)$ working space, where $z \leq n$ is the size of the LZ77 factorization of T and ℓ is the answer of LCE query.*

Let h be the height of the derivation tree of a given SLP $\mathcal{S}$. Note that $h \geq \log N$. Matsubara et al. [18] showed an $O(nh(n + h \log N))$-time $O(n(n + \log N))$-space algorithm to compute an $O(n \log N)$-size representation of all palindromes in the string. Their algorithm uses a data structure which supports in $O(h^2)$ time, LCE queries of a special form $\mathsf{LCE}(val(X_i), val(X_j), 1, p_j)$ [20]. This data structure takes $O(n^2)$ space and can be constructed in $O(n^2 h)$ time [16]. Using Theorem 21, we obtain a faster algorithm, as follows:

▶ **Theorem 22.** *Given an SLP of size n generating a string of length N, we can compute an $O(n \log N)$-size representation of all palindromes in the string in $O(n \log^2 N \log^* N)$ time and $O(n \log^* N + w)$ space.*

Our data structures also solve *the grammar compressed dictionary matching problem* [15].

▶ **Theorem 23.** *Given a DSLP $\langle \mathcal{S}, m\rangle$ of size n that represents a dictionary $\Pi_{\langle \mathcal{S}, m\rangle}$ for m patterns of total length N, we can preprocess the DSLP in $O((n \log\log n + m \log m) \log N \log^* N)$ time and $O(n \log N \log^* N)$ space so that, given any text T in a streaming fashion, we can detect all occ occurrences of the patterns in T in $O(|T| \log m \log N \log^* N + occ)$ time.*

It was shown in [15] that we can construct in $O(n^4 \log n)$ time a data structure of size $O(n^2 \log N)$ which finds all occurrences of the patterns in T in $O(|T|(h+m))$ time, where h is the height of the derivation tree of DSLP $\langle \mathcal{S}, m\rangle$. Note that our data structure of Theorem 23 is always smaller, and runs faster when $h = \omega(\log m \log N \log^* N)$.

Abstract

Robot game is a two-player vector addition game played on the integer lattice $\mathbb{Z}^n$. Both players have sets of vectors and in each turn the vector chosen by a player is added to the current configuration vector of the game. One of the players, called Eve, tries to play the game from the initial configuration to the origin while the other player, Adam, tries to avoid the origin. The problem is to decide whether or not Eve has a winning strategy. In this paper we prove undecidability of the robot game in dimension two answering the question formulated by Doyen and Rabinovich in 2011 and closing the gap between undecidable and decidable cases.

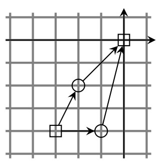
1 Introduction

In the modern world the reliability of a software code and verification of the correct functionality of complex technological devices require the analysis of various interactive processes and open systems, where it is important to take into account the effects of uncontrollable adversaries, such as environment or malicious users. Computational games provide a good framework to model interactive processes and the extensions of classical reachability problems to game schemes, studied in different contexts and settings, have recently garnered considerable interest [2, 3, 5, 6, 8, 10, 19].

In this paper we study two-player games where the main problem is to decide which of the players wins based on a given set of eligible moves, a computational environment and reachability objectives. Following early results for games on VASS (Vector Addition Systems with States)[1] [1, 6], Doyen and Rabinovich formulated an open problem about the simplest version of games (*robot games*) for which the decidability was unknown [9]. Robot games are two-player games played by updating a vector of n integer counters. Each of the players, called Adam and Eve, has a finite set of vectors in $\mathbb{Z}^n$. A play starts from a given initial vector $\mathbf{x}_0 \in \mathbb{Z}^n$, and proceeds in rounds. During each round, first Adam adds a vector from his set, followed by Eve doing the same. Eve wins when, after her turn, the vector is the zero vector. A simple example of the game is illustrated in Figure 1.

We say that Eve has a winning strategy if she eventually can reach the zero vector regardless of the moves Adam plays. As a consequence of [15], robot games are determined,

[1] A game is played on a graph with states of player 1 and states of player 2, with $\mathbb{N}^2$ as the vector space.



Adam's moves: $\{(1,2),(2,0)\}$

Eve's moves: $\{(2,2),(1,4)\}$

Figure 1 An example of a robot game.

that is, Adam has a winning strategy if Eve does not. Thus a winning strategy gives a way for a player to win, regardless of the way the opponent plays. Previously, it has been proved that deciding the winner in one-dimensional robot games, where integers are given in binary, is EXPTIME-complete [4].

In this paper we consider the open problem of deciding the winner of robot games for dimension $n = 2$ and show that it is undecidable to check which of the players has a winning strategy in a two-dimensional robot game, i.e., in a very restricted fragment of counter reachability games with stateless players playing in integer grid $\mathbb{Z}^2$. The basis of proofs are 2-counter Minsky machines (2CM) for which the halting problem is undecidable. For a 2-counter machine, we construct a game where Eve has to simulate the machine and Adam verifies that Eve does not cheat. The intuition is that the counters of the machine are multiplied by constants and represented by two-dimensional vectors. Additionally, the states of the machine are encoded in the least significant digits of the vectors. We analyse all the possible deviations from simulating the counter machine and show that the opponent has a winning strategy in that case. The biggest challenge is to ensure that all possible ways to cheat can be caught without introducing new ways to cheat for the other player.

We prove the main theorem by considering the undecidable problem of determining whether a 2CM $\mathcal{M}$ reaches a configuration where both counters are zero. In Section 3, we construct a robot game with states that follows the computation of $\mathcal{M}$. To simulate zero checks present in 2CM, Adam has a move allowing him to check whether a counter is positive or not leading, deterministically, either to his victory with a correct guess or to his loss otherwise. In the fourth section, we map the states and state transitions into integers and embed them into the least significant digits in vectors of a two-dimensional robot game. Our proof uses two successive reductions making the proof shorter and more intuitive in contrast to a direct reduction from 2CM that would lead to a longer proof with significantly more cases to consider. All proofs omitted due to length constrain can be found in [17].

Apart from the solution of the open problem, the main contribution of this paper is a collection of new, original encodings and constructions that allow simulating zero-checks and state space of a universal machine within a minimalistic two-dimensional system of two non-deterministic stateless players.

Previous research: Robot games are subfamily of counter reachability games where the game is played on a graph with vertices partitioned between players. It has been proved that deciding the winner in two-dimensional counter reachability games is undecidable [19]. Our result can be seen as strengthening of this as our arena is a graph without self-loops and with one vertex for each player, i.e., both players are stateless.

In [2] and [6], VASS games, where the game is played on a graph and counters are always positive, were considered. It was proven that already in two dimensions it is undecidable who wins if Eve's goal is to reach a particular vertex with counter $(0,0)$. On the other hand, if it can be any vertex, then the problem is $(k-1)$-EXPTIME for a game with k counters. Later, the result was improved to PTIME for $k = 2$ [7]. In [19], the possible counter values were extended to all integers and it was proven that the problem remains undecidable. Hunter considered the variants of games, where updates on the counters are done in binary, and showed that one-dimensional games are EXPSPACE-complete [13]. While these games have reachability objectives, it is also possible to extend the objectives of the games to energy constrains [10] or parity constrains [3, 8].

The proofs of undecidability of VASS games and counter reachability in two dimensions in [1, 6] use the state structure of the game to embed the state structure of a 2-counter machine. In this sense, our result on robot games with states is comparable, as Eve simulates the state transitions of a 2-counter machine with her underlying automaton. On the other hand, the stateless game is essentially different as we have to represent state transitions with integers. When simulating a two-counter machine, it is possible for Eve to make a wrong move and then Adam is able to ensure his victory from this point onward. In robot games, Eve's state is dependent only on her previous moves, while in VASS games or counter reachability games, Adam's moves effect which state Eve enters. Because of this, Adam's cheat catching ability is implemented in a different way.

2 Notation and definitions

We denote the set of all integers by $\mathbb{Z}$ and the set of all non-negative integers by $\mathbb{N}$. By 0_n we denote a n-dimensional zero vector.

A *counter reachability game* (CRG) consists of a directed graph $G = (V, F)$, where the set of vertices is partitioned into two parts, V_1 and V_2, each edge $e \in F \subseteq V \times \mathbb{Z}^n \times V$ is labelled with vectors in $\mathbb{Z}^n$. A *configuration* of the game is $(v, \mathbf{x})$, a successive configuration is $(v', \mathbf{x} + \mathbf{x}')$, where an edge $(v, \mathbf{x}', v') \in E$ is chosen by player 1 if $v \in V_1$ or by player 2 if $v \in V_2$. A *play* is a sequence of successive configurations. The goal of the first player, called *Eve*, is to reach the *final configuration* $(v_f, 0_n)$ for some $v_f \in V$ from a given initial configuration $(v_0, \mathbf{x}_0)$, while the goal of the second player, called *Adam*, is to keep Eve from reaching $(v_f, 0_n)$. A *strategy* for a player is a function that maps a configuration to an edge that can be applied. We say that Eve has a *winning strategy* if she can reach the final configuration regardless of the strategies of Adam. The determinacy result of [15] holds for counter reachability games and thus Adam has a winning strategy if Eve does not have a winning strategy. In the figures we use ◯ for Eve's states and □ for Adam's states.

A *robot game* (RG) [9] is a special case of the counter reachability games, where the graph consists of only two vertices, v_0 of Adam and v of Eve. The goal of the game is the configuration $(v_0, 0_n)$. That is, a robot game consists of two players, *Eve* and *Adam*, having a set of vectors E, A over $\mathbb{Z}^n$, respectively, and an *initial vector* $\mathbf{x}_0$. Starting from $\mathbf{x}_0$ players add a vector from their respective sets to the current configuration of the game in turns. As in counter reachability games, Eve tries to reach the origin while Adam tries to keep Eve from reaching the origin. The decision problem concerning robot games is, for a given robot game (A, E) and $\mathbf{x}_0$, to decide whether Eve has a winning strategy to reach 0_n from $\mathbf{x}_0$. The problem is EXPTIME-complete in dimension one [4] and was open for dimension two.

An extension of robot games where players have control states is called *robot games with states* (RGS). We consider only the games where Adam's state structure is trivial, i.e., he has only one state and all moves are self-loops. RGS consists of (A, E) where A is a finite subset of $\mathbb{Z}^n$ that Adam can apply during his turn and E is a finite subset of $V \times \mathbb{Z}^n \times V$ of Eve. The configuration is now a pair $(s, \mathbf{v})$ consisting of Eve's control state s and a counter vector $\mathbf{v} \in \mathbb{Z}^n$. Eve updates her control state when she makes a move: in the configuration $(s, \mathbf{v})$, for any vector $\mathbf{v}$, only moves of the form $(s, \mathbf{x}, t)$ are enabled, and with one such move the new configuration is $(t, \mathbf{v} + \mathbf{x})$. Eve wins if, and only if, after her turn, the configuration is $(s, (0, 0))$ for any $s \in V$. The decision problem associated with robot games with states asks whether Eve has a winning strategy from a given configuration.

A *Minsky machine*, introduced in [16], is a simple computation model that is crucial in our proof. A *deterministic two-counter Minsky machine* (2CM) is a pair (Q, T), where Q is a finite set of states and $T \subseteq Q \times \{c_{i++}, c_{i--}, c_i{=}{=}0 \mid i = 1, 2\} \times Q$ is a finite set of labelled transitions to increment, decrement or test for zero one of the counters. In a deterministic two-counter Minsky machine, the set Q contains an initial state s_0 and a sink state $\perp$, such that there is no outgoing transition from $\perp$. Moreover, from all $s \in Q \setminus \{\perp\}$, either there is only one outgoing transition with the label c_{1++} or c_{2++}, or there are exactly two outgoing transitions with respective labels c_{1--} and $c_1{=}{=}0$, or c_{2--} and $c_2{=}{=}0$. A configuration of a 2CM is a pair $(s, (y, z)) \in Q \times \mathbb{N}^2$, representing a state and a pair of counter values. The run of a 2CM is a finite or infinite sequence of configurations that starts from $(s_0, (0, 0))$ and follows the transitions of the machine incrementing and decrementing the counters according to the labels. As usual, a transition with a label $c_i{=}{=}0$ can only be taken when the counter i is zero and a transition with a label c_{i--} can only be taken when the counter i is positive.

Note that there is only one possible run in a deterministic two-counter Minsky machine. Indeed, when there are two outgoing transitions, only one of them can be executed, depending on the value of the counter that the transitions update or test for zero. The halting problem of 2CM is to decide, given a 2CM, whether the run reaches a configuration with state $\perp$, in other words whether the run halts. This problem is known to be undecidable for deterministic two-counter machines [16]. Another well-known undecidable problem for 2CM is whether a configuration where both counters are zero is reachable. The undecidability follows from the halting problem by modifying a 2CM to ensure that both counters are zero only in the halting state; see for example [18] for a proof.

▶ **Theorem 1.** *Let (Q, T) be a deterministic two-counter machine. It is undecidable whether in the run of (Q, T), a configuration in $Q \times \{(0, 0)\} \setminus \{(s_0, (0, 0))\}$ appears.*

We can assume that the first move of a 2CM is an increment of either c_1 or c_2. Indeed, otherwise the problem is trivial as the second configuration is in $Q \times \{(0, 0)\}$.

3 Robot games with states in two dimensions

In this section we prove that the decision problem for robot games with states is undecidable. We show that for each two-counter machine, there exists a corresponding robot game with states where Eve has a winning strategy if and only if the machine reaches a configuration where both counters are zero. To simulate zero checks present in two-counter machines, Adam has a move allowing him to check whether a counter is positive or not.

▶ **Theorem 2.** *Let (Q, T) be a two-counter machine. There exists a two-dimensional robot game with states (A, E) where Eve has a winning strategy if and only if (Q, T) reaches a configuration in $Q \times \{(0, 0)\}$.*

The idea is that in the robot game with states, Eve simulates the computation of the 2CM while Adam does not interfere with the computation. If one of the players deviates from the computation, the opponent has a winning strategy from that point on.

Essentially, there are four ways the game can progress. These ways are depicted in the Figure 2. Three of the outcomes have a predetermined winner which does not depend on the 2CM. In the last case where Eve correctly simulates the 2CM and Adam does not interfere

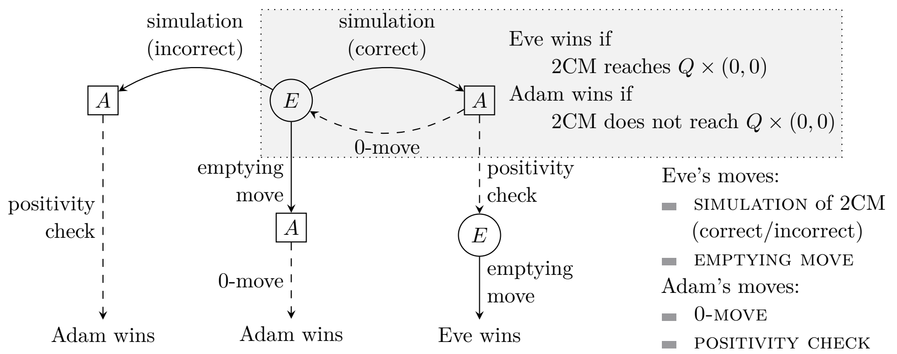


Figure 2 Progress of 2RGS.

(plays only a 0-MOVE), the winner depends on whether the 2CM reaches $(s, (0, 0))$ for some $s \in Q$ or not.

- If Eve's move corresponds to the SIMULATION of the 2CM and Adam replies with a 0-MOVE (a move that does not modify the counters), then iteratively applying only this turn-based interaction, Eve wins if and only if the 2CM reaches $(s, (0, 0))$ for some $s \in Q$ (Lemma 3).
- If Eve's move incorrectly simulates the 2CM, then Adam has a winning strategy from this moment on, starting with a POSITIVITY CHECK that makes Eve's target unreachable (Lemma 4).
- On the other hand, if Adam plays his POSITIVITY CHECK following a correct simulating move of Eve, then Eve has a winning strategy from this moment on, starting with an EMPTYING MOVE allowing Eve to empty both counters and reach $(0, 0)$ (Lemma 5).
- Finally, if Eve plays an EMPTYING MOVE instead of a SIMULATING MOVE, in that case Adam has a winning strategy starting by playing his 0-MOVE (Lemma 6).

Before presenting the detailed constructions of Eve's and Adam's state spaces, we consider a simple modification to a 2CM, making it non-deterministic. For any 2CM (Q, T), we construct a 2CM (Q', T') where Q' is Q with additional information on positivity of the both counters and T' is like T with guards ensuring that the extra information in states of Q' correspond to the actual values of the counters. We denote the states of Q' by s_{ab} where $s \in Q$ and $a, b \in \{0, +\}$ are flags indicating whether the value of a counter is positive or equal to 0, i.e., a (b) is $+$ if the first (second) counter is positive or 0 if the counter is zero. The transition set T' consists of the following sets

$$\begin{aligned}
&\{(s_{ab}, c_1{+}{+}, t_{+b}) \mid (s, c_1{+}{+}, t) \in T, a, b \in \{0, +\}\}, \{(s_{ab}, c_2{+}{+}, t_{a+}) \mid (s, c_2{+}{+}, t) \in T, a, b \in \{0, +\}\},\\
&\{(s_{+b}, c_1{-}{-}, t_{ab}) \mid (s, c_1{-}{-}, t) \in T, a, b \in \{0, +\}\}, \{(s_{a+}, c_2{-}{-}, t_{ab}) \mid (s, c_2{-}{-}, t) \in T, a, b \in \{0, +\}\},\\
&\{(s_{0b}, c_1{=}{=}0, t_{0b}) \mid (s, c_1{=}{=}0, t) \in T, b \in \{0, +\}\}, \{(s_{a0}, c_2{=}{=}0, t_{a0}) \mid (s, c_2{=}{=}0, t) \in T, a \in \{0, +\}\}.
\end{aligned}$$

Now, after decrementing counters from a state with $+$ flag, a state will be changed to a state with $+$ or 0 flag depending on the current counter value.

counter value	flag		flag	
$c_i > 1$	$+$	$\rightarrow$	$+$	**correct flag**
$c_i > 1$	$+$	$\rightarrow$	0	wrong flag
$c_i = 1$	$+$	$\rightarrow$	$+$	wrong flag
$c_i = 1$	$+$	$\rightarrow$	0	**correct flag**

At the moment we assume that the machine moves to a state with the correct flag (correct simulation) and does not move to incorrect flag (incorrect simulation). Later in the robot

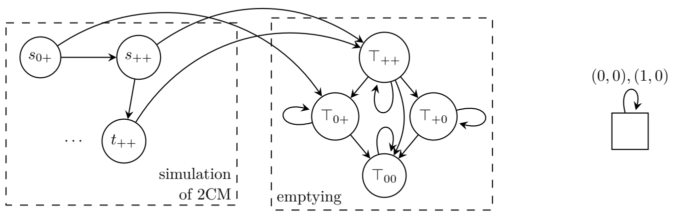

Figure 3 An illustration of state transitions of Eve and Adam.

game with states, Adam will act as guards (i.e., checks whether $c_i > 1$ or $c_i = 1$) using his POSITIVITY CHECK if Eve picks a wrong transition resulting in a state with the wrong flag.

Now we present the moves of the players. Eve's states are the states of Q', corresponding to the simulation of the 2CM, together with emptying states $\{\top_{00}, \top_{+0}, \top_{0+}, \top_{++}\}$, associated with EMPTYING MOVES. The moves of Eve correspond to transitions in T' where incrementing and decrementing of the first counter is by 4 rather than by 1. We call these moves SIMULATING MOVES.

Transition with c_1	Eve's move
$(s, c_1{+}{+}, t)$	$(s, (4,0), t)$
$(s, c_1{-}{-}, t)$	$(s, (-4,0), t)$
$(s, c_1{=}{=}0, t)$	$(s, (0,0), t)$

Transition with c_2	Eve's move
$(s, c_2{+}{+}, t)$	$(s, (0,1), t)$
$(s, c_2{-}{-}, t)$	$(s, (0,-1), t)$
$(s, c_2{=}{=}0, t)$	$(s, (0,0), t)$

The other type of moves, EMPTYING MOVES, are related to the new states and are used to empty the counters. Note that there is hierarchy in the emptying states — Eve cannot move from a state with 0 to a state with +. Let us define the emptying partition of Eve's automaton where for every possible move of Adam there is a cancelling move with additional decrementing of the counters eventually leading to the sink state $\top_{00}$.

- $\{(\top_{++}, (-4-e, -1), t) \mid e \in \{0,1\}, t \in \{\top_{++}, \top_{+0}, \top_{0+}, \top_{00}\}\}$;
- $\{(\top_{+0}, (-4-e, 0), t) \mid e \in \{0,1\}, t \in \{\top_{+0}, \top_{00}\}\}$;
- $\{(\top_{0+}, (-e, -1), t) \mid e \in \{0,1\}, t \in \{\top_{0+}, \top_{00}\}\}$;
- $\{(\top_{00}, (-e, 0), \top_{00}) \mid e \in \{0,1\}\}$.

Finally, we define transitions connecting the simulating partition of Eve's automaton with the emptying partition. For each state $s_{ab} \in Q'$, Eve has a transition $(s_{ab}, (-1,0), \top_{ab})$.

Adam is stateless, i.e., he has one state and his moves are self-loops. There are two types of moves: the 0-MOVE, $(0,0)$, with which Adam agrees that Eve simulated the 2CM correctly and the POSITIVITY CHECK, $(1,0)$, with which Adam checks whether a flag matches the counter (i.e., Eve simulated incorrectly). Control states of the players are depicted in Figure 3.

To avoid Eve winning trivially every play in the robot game with states, we do not use $(s'_{00}, (0,0))$ as an initial configuration, but instead consider the configuration that is reached in (Q', T') after one step of the run of the machine. We write the configuration after one step as $(s_{\overline{a}\overline{b}}, (y,z))$ and we define $\overline{a} = +, \overline{b} = 0$ if $y = 1$ and $\overline{a} = 0, \overline{b} = +$ if $y = 0$. The initial configuration in the robot game with states is then $(s_{\overline{a}\overline{b}}, (4y, z))$. The effect of simulating moves, emptying moves and positivity check modulo four is depicted in Figure 4.

Next we prove which player has a winning strategy in the scenarios presented previously.

▶ **Lemma 3.** *In a sequence where Adam plays only the* 0-MOVE *and Eve plays only correct* SIMULATING MOVES*, Adam wins if the 2-counter machine does not reach a configuration with zeros in both counters and Eve wins otherwise.*

Proof. It easy to see that correct moves of Eve simulate the 2CM and that a configuration $(s, (0,0))$ of the 2CM is reachable if and only if it is reachable in 2RGS. ◀

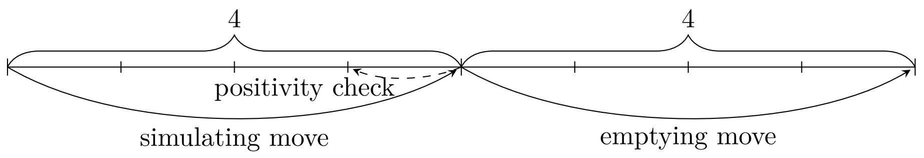

Figure 4 An illustration of changes in an interval when simulating or emptying moves of Eve or positivity check of Adam is applied.

▶ **Lemma 4.** *If Eve plays an incorrect move, i.e., after her turn a flag does not match the counter value (i.e., the flag is + while the counter is 0 or vice versa), then Adam has a winning strategy starting with the* POSITIVITY CHECK.

Proof. Assume that Eve made a mistake regarding the positivity of the first counter. As noted previously, there are two ways she can make a mistake. Either the configuration is $(s_{0b}, (4x, y))$, where $x \geq 1$ or $(s_{+b}, (0, y))$. In both cases Adam plays his POSITIVITY CHECK which changes the parity of the first counter. That is, after Adam's turn, the first counter is $1 \pmod 4$. It is easy to see that if Eve does not change the parity of the counter back to zero with her following turn, then Adam has a winning strategy. Indeed in this case, he will play his POSITIVITY CHECK if and only if the first counter is not $3 \pmod 4$. Eve cannot make the counter 0, as she cannot even make it $0 \pmod 4$. Thus Eve has to play a move adding -1 to the first counter. The only move for that is $(s_{ab}, (-1, 0), \top_{ab})$ which takes Eve to an emptying state. In the first case the emptying state is $\top_{0b}$ and all the transitions from it do not modify the first counter, i.e., Eve cannot reach $(0, 0)$. In the second case the emptying state is $\top_{+b}$ where the next transition subtracts 4 from the first counter making it negative and there are no moves that increment the counters. Again, Eve cannot reach $(0, 0)$. The case where Eve makes a mistake with the second counter is proven analogously and, in fact, Adam's strategy is the same. ◀

▶ **Lemma 5.** *Assume that Eve plays only correct* SIMULATING MOVES *before Adam plays the* POSITIVITY CHECK *for the first time. If Adam plays the* POSITIVITY CHECK, *then Eve has a winning strategy starting with an* EMPTYING MOVE.

Proof. Similarly as in the previous proof, if Eve does not play an EMPTYING MOVE, then Adam has a winning strategy. Now, the configuration is $(s_{ab}, (4x + 1, y))$ after Adam's turn and Eve plays $(s_{ab}, (-1, 0), \top_{ab})$. From that point onward, Eve can empty the counters ensuring that the first counter is $0 \pmod 4$ and that the flags match the positivity of the counters. That is, every time Adam plays his POSITIVITY CHECK, Eve plays an EMPTYING MOVE subtracting one from the first counter. Eventually, Eve will reach the configuration $(\top_{00}, (0, 0))$ and win the game. ◀

▶ **Lemma 6.** *If Adam plays only the* 0-MOVE *and Eve plays an* EMPTYING MOVE. *Adam has a winning strategy starting with the* 0-MOVE.

Proof. After Eve's move, the first counter is $3 \pmod 4$. As in proof of Lemma 4, Adam ensures that the first counter stays non-zero modulo four and wins the game. ◀

Proof of Theorem 2. Let (A, E) be the robot game with states constructed in this section. Assume first that (Q, T) reaches a configuration in $Q \times \{(0, 0)\}$. Now by Lemma 3, Eve's winning strategy is to respond with the correct SIMULATING MOVES if Adam plays the 0-MOVE, and if Adam plays a POSITIVITY CHECK, then Eve has a sequence of moves described in Lemma 5 that leads to the configuration $(\top_{00}, (0, 0))$.

Assume then that (Q, T) never reaches a configuration in $Q \times \{(0,0)\}$. We show that Eve does not have a winning strategy. If Adam plays only the 0-MOVE, then, by Lemma 3, Eve does not win by responding with just the correct SIMULATING MOVES. Alternatively, if at some point, she plays either an incorrect SIMULATING MOVE or an EMPTYING MOVE, then by Lemmas 4 and 6, respectively, Adam has winning strategies making sure that a configuration with counter values $(0,0)$ is not reachable. As we analysed all the possible moves of Eve, we have shown that Eve does not have a winning strategy. ◀

By Theorems 1 and 2, we have the following corollary regarding decidability of 2-dimensional robot games with states.

▶ **Corollary 7.** *Let (A, E) be a robot game with states and $\mathbf{x}_0$ be the initial vector. It is undecidable whether Eve has a winning strategy to reach $(0,0)$ from $\mathbf{x}_0$. In particular, Adam is stateless and does not modify the second counter.*

4 Stateless robot games in two dimensions

In this section we prove the main result that it is undecidable whether Eve has a winning strategy in a two-dimensional robot game. We prove the claim by constructing a robot game that simulates a robot game with states. In some ways the construction is similar to the construction of a game with states in the previous section as can be seen in similarities of figures 2 and 5. On the other hand, the construction of the stateless game is more complex as the information on two counters, states and state transitions has to be embedded into two-dimensional vectors.

▶ **Theorem 8.** *Let (A_1, E_1) be a 2-dimensional robot game with states where Adam is stateless and does not modify the second counter. There exists a two-dimensional robot game (A, E) where Eve has a winning strategy if and only if Eve has a winning strategy in (A_1, E_1).*

Similarly to the construction of Section 3, the idea is that in the robot game, Eve and Adam simulate a play of the 2RGS. If one of the players deviates from the play, the opponent has a winning strategy from that point onward. In Figure 5, we present a schematic similar to Figure 2 depicting the possible ways two-dimensional robot games can go. Three of the outcomes have a predetermined winner which does not depend on the 2RGS. In the last case where Eve and Adam correctly simulate the 2RGS, the winner depends on the winner of the 2RGS, i.e., whether Eve has a winning strategy to reach $(s, (0,0))$, for any state s, or not.

- If Eve's move corresponds to a move in a play of the 2RGS, that we call a REGULAR MOVE, and Adam replies with his REGULAR MOVE, then iteratively applying only this turn-based interaction, Eve has a winning strategy if and only if she has a winning strategy in the corresponding 2RGS (Lemma 10).
- If Eve's move incorrectly simulates the 2RGS, then Adam has a winning strategy from this moment on starting with a STATE-CHECK that makes Eve's target unreachable (Lemma 11).
- On the other hand, if Adam plays his STATE-CHECK following a correct REGULAR MOVE of Eve, then Eve has a winning strategy from this moment on starting with a STATE-DEFENCE MOVE allowing Eve to empty both counters and reach $(0,0)$ (Lemma 12).
- Finally, if Eve plays a STATE-DEFENCE MOVE instead of a REGULAR MOVE, in that case Adam has a winning strategy starting by playing his REGULAR MOVE (Lemma 13).

Intuitively, we encode the states as powers of 8 such that the coefficient of 8^i is 1 if and only if Eve's state in robot games with states is s_i. When the state changes from

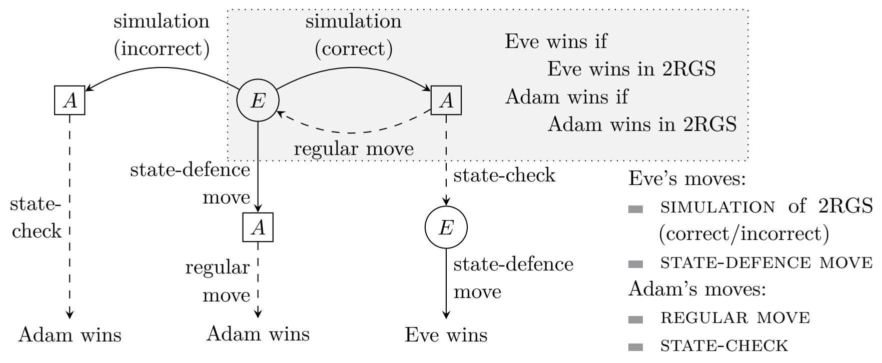

Figure 5 Progress of 2RG.

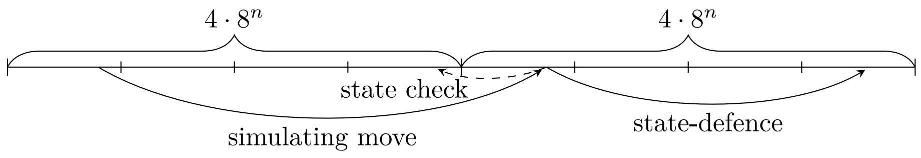

Figure 6 An illustration of changes in interval when simulating or state-defence moves of Eve or state check of Adam is applied.

s_i to s_j, $-8^i + 8^j$ is added to the second counter. Let $(s_i, (x, y))$ be a configuration in a two-dimensional robot game with m states. Let us represent the state s_i with m-dimensional characteristic vector $\mathbf{s_i} = (s_1, \dots, s_m)$ where s_i is 1 and $s_j = 0$ for all $j \neq i$. We can now map $\mathbf{s_i}$ to an integer defined by the sum $\sum_{k=1}^{m} s_k 8^k$. A transition from s_i to s_j can be simulated by adding $\sum_{k=1}^{m} s_k 8^k$, where $s_k = -1$ if $k = i$, $s_k = 1$ if $k = j$, and zero otherwise. We represent states as coefficients of powers of eight because we need the extra space smaller bases do not possess.

It is easy to see that this is not enough as incorrect transitions can result in a correct configuration. For example, if the configuration of the 2RGS is $(s_i, (x, y))$ and moves corresponding to $(s_j, (a, b), s_k)$ and $(s_k, (c, d), s_j)$ are used, the resulting configuration corresponds to $(s_i, (x + a + c, y + b + d))$. Another way to cheat is to use carries as incrementing the coefficient of 8^i eight times is indistinguishable from incrementing the coefficient of 8^{i+1} once. Both types of cheating can be countered with Adam's STATE-CHECKS.

We now show how we embed the states and state transitions into the second counter of the game. Similarly to how in the previous section we created additional space in the first counter by multiplying the moves modifying the first counter by four, we multiply the second counter by $4 \cdot 8^n$, where $n = m + 7$ and m is the number of states, creating enough space to store all the needed information of the underlying automaton. The multiplication by $4 \cdot 8^n$ rather than just 8^n has two purposes. The first one is similar to multiplying the first counter by four in the Section 3. Namely, certain moves will move between different intervals modulo $4 \cdot 8^n$ ensuring the correct response from the opponent. This is illustrated in Figure 6. The second purpose is to ensure that above described cheating with carries is not possible. A configuration in $Q \times \mathbb{Z}^2$ is mapped to a vector in $\mathbb{Z}^2$ by $(s_i, (c_1, c_2)) \mapsto (c_1, c_2 \cdot 4 \cdot 8^n + 8^i)$.

Before presenting the detailed constructions of Eve's and Adam's moves, we note that we can assume that the 2RGS has the information on the positivity of the counters and players have to update the information correctly. Indeed, this was done in the previous section by using flags 0 and $+$. Recall that because of this, the first counter is incremented and decremented by 4. By this assumption, we can denote the states of Eve by s_{ab} as before. We also assume that Eve's automaton is without self-loops as they would allow Eve to modify the counters without modifying coefficients of the states. Let Q be the set of states of Eve in 2RGS. We create an emptying gadget for Eve similar to the one constructed in the previous reduction. To avoid self-loops, there are seven emptying states, $\{\top_{ab}, \top'_{ab} \mid a, b \in \{0, +\}\} \setminus \{\top'_{00}\}$. The state $\top'_{00}$ is not needed as $\top_{00}$ will not have any moves from it. The moves in the emptying gadget are as in the emptying gadget constructed in Section 3 but instead of self-loops, the transitions are between primed and unprimed versions of the states.

- $\{(\top_{++}, (-4, -1) - \alpha, t) \mid \alpha \in A_1, t \in \{\top'_{++}, \top_{+0}, \top'_{+0}, \top_{0+}, \top'_{0+}, \top_{00}\}\}$;
  $\{(\top'_{++}, (-4, -1) - \alpha, t) \mid \alpha \in A_1, t \in \{\top'_{++}, \top_{+0}, \top'_{+0}, \top_{0+}, \top'_{0+}, \top_{00}\}\}$;
- $\{(\top_{+0}, (-4, 0) - \alpha, t) \mid \alpha \in A_1, t \in \{\top'_{+0}, \top_{00}\}\}$;
  $\{(\top'_{+0}, (-4, 0) - \alpha, t) \mid \alpha \in A_1, t \in \{\top_{+0}, \top_{00}\}\}$;
- $\{(\top_{0+}, (0, -1) - \alpha, t) \mid \alpha \in A_1, t \in \{\top'_{+0}, \top_{00}\}\}$;
  $\{(\top'_{0+}, (0, -1) - \alpha, t) \mid \alpha \in A_1, t \in \{\top_{+0}, \top_{00}\}\}$;

We denote $\mathcal{T} = \{\top_{++}, \top'_{++}, \top_{0+}, \top'_{0+}, \top_{+0}, \top'_{+0}\}$. We think of elements of $Q \cup \mathcal{T} \cup \{\top_{00}\}$ as integers in $\{0, \ldots, n-1\}$ such that $\top_{00} = 0, \top'_{0+} = n-6, \top_{0+} = n-5, \top'_{+0} = n-4, \top_{+0} = n-3, \top'_{++} = n-2, \top_{++} = n-1$. We give names for update vectors that we often use:

$$\begin{aligned}
&\textsc{Add}(1, x) := (x, 0); && \textsc{Move}(j, k) := (0, -8^j + 8^k), \text{ for } 0 \le j, k \le n-1;\\
&\textsc{Add}(2, x) := (0, 4x \cdot 8^n); && \textsc{Check}(i) := (0, -5 \cdot 8^i - 8^n), \text{ for } n-6 \le i \le n-1.
\end{aligned}$$

The initial vector of the robot game is $\textsc{Add}(1, x) + \textsc{Add}(2, y) + \textsc{Move}(\top_{00}, s)$, that is, $(x, 4y \cdot 8^n + 8^s - 8^0)$, where $(s, (x, y))$ is the initial configuration in the robot game with states. In the next example we illustrate how the update vectors modify the counters.

▶ **Example 9.** Let (A_1, E_1) be a two-dimensional robot game with states where Eve has two states, $s = 1$ and $t = 2$, and the initial configuration $(s, (1, 0))$. Next we present a set of configurations in 2RG obtained from the corresponding initial configuration when we apply $\textsc{Add}(1, -1)$, $\textsc{Add}(2, 1)$, $\textsc{Move}(s, t)$, $\textsc{Check}(8)$ in succession:

$$\begin{aligned}
&(\overbrace{1, 0 \cdot 4 \cdot 8^9}^{\text{2RGS counters}} + \overbrace{0 \cdot 8^8 + 0 \cdot 8^7 + 0 \cdot 8^6 + 0 \cdot 8^5 + 0 \cdot 8^4 + 0 \cdot 8^3}^{\mathcal{T}} + \overbrace{0 \cdot 8^2 + 1 \cdot 8^1}^{\text{states of 2RGS}} \overbrace{-1 \cdot 8^0}^{\top_{00}}) \xrightarrow{\textsc{Add}(1,-1)}\\
&(0, 0 \cdot 4 \cdot 8^9 + 0 \cdot 8^8 + 0 \cdot 8^7 + 0 \cdot 8^6 + 0 \cdot 8^5 + 0 \cdot 8^4 + 0 \cdot 8^3 + 0 \cdot 8^2 + 1 \cdot 8^1 - 1 \cdot 8^0) \xrightarrow{\textsc{Add}(2,1)}\\
&(0, 4 \cdot 8^9 + 0 \cdot 8^8 + 0 \cdot 8^7 + 0 \cdot 8^6 + 0 \cdot 8^5 + 0 \cdot 8^4 + 0 \cdot 8^3 + 0 \cdot 8^2 + 1 \cdot 8^1 - 1 \cdot 8^0) \xrightarrow{\textsc{Move}(s,t)}\\
&(0, 4 \cdot 8^9 + 0 \cdot 8^8 + 0 \cdot 8^7 + 0 \cdot 8^6 + 0 \cdot 8^5 + 0 \cdot 8^4 + 0 \cdot 8^3 + 1 \cdot 8^2 + 0 \cdot 8^1 - 1 \cdot 8^0) \xrightarrow{\textsc{Check}(8)}\\
&(0, 3 \cdot 8^9 - 5 \cdot 8^8 + 0 \cdot 8^7 + 0 \cdot 8^6 + 0 \cdot 8^5 + 0 \cdot 8^4 + 0 \cdot 8^3 + 1 \cdot 8^2 + 0 \cdot 8^1 - 1 \cdot 8^0).
\end{aligned}$$

Now we present the moves of the players. Adam has two types of moves: REGULAR MOVES that correspond to the moves in the 2RGS and STATE-CHECK MOVES, $\{\textsc{Check}(i) \mid i \in \mathcal{T}\}$. The moves of Eve correspond to moves in E_1 where incrementing and decrementing of the second counter is by $4 \cdot 8^n$ rather than by 1. Let $(s, (x, y), t) \in E_1$, then $\textsc{Add}(1, x) + \textsc{Add}(2, y) + \textsc{Move}(s, t) = (x, 4y \cdot 8^n - 8^s + 8^t) \in E$. We call these moves REGULAR MOVES. We also need a move for Eve to finish the simulation by removing any values corresponding to the automaton if the state is s_{00}. That is, we add moves $\{\textsc{Move}(s_{00}, \top_{00}) - \alpha \mid \alpha \in A_1\}$. The other type of moves, STATE-DEFENCE MOVES, are used to empty the counters. As in the previous construction, Eve will be able to cancel every Adam's move and decrement the counters at the same time.

Finally, we define moves connecting the simulating partition of Eve's automaton with the emptying partition. For each state $s_{ab} \in Q$ where a, b are not both zero, Eve has a move $\{\textsc{Move}(s_{ab}, k) - \textsc{Check}(i) \mid (a, b) \in \{0, +\}^2 \setminus \{(0, 0)\}, k \in \{\top_{ab}, \top'_{ab}\}, k \neq i, i \in \mathcal{T}\}$. For s_{00}, Eve has a move $\{\textsc{Move}(s_{00}, \top_{00}) - \textsc{Check}(i) \mid i \in \mathcal{T}\}$.

Adam's move	Eve's move
$\alpha \in A_1$	$\{\textsc{Add}(1, -4) + \textsc{Add}(2, -1) - \textsc{Move}(j, k) - \alpha \mid j, k \in \{\top_{++}, \top'_{++}\}, j \neq k\}$ $\{\textsc{Add}(1, -4) - \textsc{Move}(j, k) - \alpha \mid j, k \in \{\top_{+0}, \top'_{+0}\}, j \neq k\}$ $\{\textsc{Add}(2, -1) - \textsc{Move}(j, k) - \alpha \mid j, k \in \{\top_{0+}, \top'_{0+}\}, j \neq k\}$
	$\{\textsc{Add}(1, -4) + \textsc{Add}(2, -1) + \textsc{Move}(j, k) - \alpha \mid j \in \{\top_{++}, \top'_{++}\}, k \in \mathcal{T}, j \neq k\}$
	$\{\textsc{Add}(1, -4) + \textsc{Add}(2, -1) + \textsc{Move}(j, 1) - \alpha \mid j \in \{\top_{++}, \top'_{++}\}\}$
	$\{\textsc{Add}(1, -4) + \textsc{Move}(j, 1) - \alpha \mid j \in \{\top_{+0}, \top'_{+0}\}\}$
	$\{\textsc{Add}(2, -1) + \textsc{Move}(j, 1) - \alpha \mid j \in \{\top_{0+}, \top'_{0+}\}\}$
$\textsc{Check}(i)$	$\{\textsc{Add}((1, -4e_1) + \textsc{Add}(2, -e_2) - \textsc{Check}(i) \mid e_1, e_2 \in \{0, 1\}\}$
	$\{\textsc{Add}(1, -4) + \textsc{Add}(2, 1) + \textsc{Move}(j, k) - \textsc{Check}(i) \mid i, j \neq k,$ $j \in \{\top_{++}, \top'_{++}\}, k \in \mathcal{T}\}$
	$\{\textsc{Add}(1, -4) + \textsc{Add}(2, -1) + \textsc{Move}(j, 1) - \textsc{Check}(i) \mid j \in \{\top_{++}, \top'_{++}\}\}$
	$\{\textsc{Add}(1, -4) + \textsc{Move}(j, 1) - \textsc{Check}(i) \mid j \in \{\top_{+0}, \top'_{+0}\}\}$
	$\{\textsc{Add}(2, -1) + \textsc{Move}(j, 1) - \textsc{Check}(i) \mid j \in \{\top_{0+}, \top'_{0+}\}\}$

Next we prove which player has a winning strategy in the scenarios presented previously.

▶ **Lemma 10.** *If both players only play* REGULAR MOVES *and Eve plays only correct* REGULAR MOVES*, then Eve has a winning strategy if and only if she has a winning strategy in two-dimensional robot games with states.*

Proof. It easy to see that REGULAR MOVES of the players simulate the 2RGS and that Eve has a winning strategy to reach a configuration $(s_{00}, (0, 0))$ of the 2RGS if and only if she has a winning strategy to reach the vector $(0, 0 \cdot 4 \cdot 8^n + 8^{s_{00}} - 8^{\top_{00}})$ in 2RG after which Eve wins by playing $\textsc{Move}(s_{00}, \top_{00}) - \alpha$, where α is the REGULAR MOVE played by Adam. ◀

▶ **Lemma 11.** *If Eve plays an incorrect move, i.e., after her turn the coefficient of some 8^s is -1 or the coefficient of $8^{\top_{00}}$ is zero, then Adam has a winning strategy starting with a* STATE-CHECK*.*

Proof. First, we prove that Eve loses if a coefficient corresponding to a state of 2RGS is negative after one of her turns. A coefficient corresponding to a state of 2RGS can only be increased, namely incremented, by Eve's REGULAR MOVES. Hence, if one of the coefficients becomes negative, then Adam wins by playing a STATE-CHECK move. The reasoning is now similar to the usage of the POSITIVITY CHECK in Lemma 4. We consider the second counter modulo $4 \cdot 8^n$. Before Adam's STATE-CHECK, the configuration is in $[0, 8^n) \pmod{4 \cdot 8^n}$ and after the check in $[3 \cdot 8^n, 4 \cdot 8^n) \pmod{4 \cdot 8^n}$. If Eve does not play a STATE-DEFENCE MOVE (a move containing a $\textsc{Check}(i)$), then Adam has a winning strategy by playing a STATE-CHECK if the second counter is not in $[3 \cdot 8^n, 4 \cdot 8^n) \pmod{4 \cdot 8^n}$ and a REGULAR MOVE otherwise (recall that Adam's REGULAR MOVES do not modify the second counter). Thus Eve has to play a STATE-DEFENCE MOVE which does not make the negative coefficient non-negative. Now at least one of the coefficients in $\mathcal{T}$ is non-zero, say i. Adam will play $\textsc{Check}(i)$ forcing Eve to play a move containing $-\textsc{Check}(i)$ which will make another coefficient in $\mathcal{T}$ non-zero. As long as Adam keeps playing the correct STATE-CHECK, Eve cannot make all the coefficients zero and thus cannot win.

The second case where a coefficient of some state in $\mathcal{T}$ is negative has been proven above. For the final case, where the coefficient of $8^{\top_{00}}$ is zero, we consider the next move of Eve. During her next turn, Eve has to play a move containing $\textsc{Move}(s,t)$ making the coefficient of 8^s negative, which has been covered previously. ◀

▶ **Lemma 12.** *Assume that Eve plays only correct* REGULAR MOVES *before Adam plays a* STATE-CHECK *for the first time. If Adam plays a* STATE-CHECK, *then Eve has a winning strategy starting with a* STATE-DEFENCE MOVE.

Proof. Similarly as in the previous proof, if Eve does not play a STATE-DEFENCE MOVE, then Adam has a winning strategy. Now, Eve plays the STATE-DEFENCE MOVE $\textsc{Move}(s_{ab},k) - \textsc{Check}(i)$ where s_{ab} is the non-zero coefficient, $\textsc{Check}(i)$ is the STATE-DEFENCE MOVE Adam played and $k \in \{\top_{ab}, \top'_{ab}\}$, $k \neq i$. From that point onward, Eve can empty the counters ensuring as she has emptying moves with an opposite move of Adam. Eventually, Eve will reach the configuration $(0,0)$ and win the game. ◀

▶ **Lemma 13.** *If Adam plays only* REGULAR MOVES *and Eve plays a* STATE-DEFENCE MOVE, *then Adam has a winning strategy starting with a* REGULAR MOVE.

Proof. Since all STATE-DEFENCE MOVES subtract -8^n from the second counter, after Eve's move, the counter is in $[8^n, 2\cdot 8^n) \pmod{4\cdot 8^n}$. As in proof of Lemma 11, Adam ensures that the second counter does not return to the interval $[0, 8^n) \pmod{4\cdot 8^n}$. ◀

Proof of Theorem 8. Let (A,E) be the robot game constructed in this section. Assume first that Eve has a winning strategy in (A_1,E_1). Now, Eve's winning strategy in two-dimensional robot games is to follow the strategy of (A_1,E_1) as long as Adam plays REGULAR MOVES which is a winning strategy by Lemma 10. If Adam plays a STATE-CHECK, then Eve responds according to the winning strategy of Lemma 12.

Assume then that Adam has a winning strategy in (A_1,E_1) and Eve has a winning strategy in (A,E). If Adam plays only REGULAR MOVES, then by Lemma 10, Eve does not win by playing just the correct the correct SIMULATING MOVES. That is, Eve has to, at some point, either play an incorrect SIMULATION MOVE or play a STATE-DEFENCE MOVE. By Lemmas 11 and 13, Adam has winning strategies for both cases. As we analysed all the possible moves of Eve, we have shown that Eve does not have a winning strategy. ◀

▶ **Corollary 14.** *Let (A,E) be a two-dimensional robot game and an initial vector $\mathbf{x}_0$. It is undecidable whether Eve has a winning strategy to reach $(0,0)$ from $\mathbf{x}_0$.*

Corollary 14 follows from Corollary 7 and Theorem 8. It is possible to apply it to matrix games introduced in [11] to show undecidability in $\mathbb{Z}^{3\times 3}$.

Final remarks: The construction of robot games with states was first presented in the PhD thesis of one of the authors, [18], where it was also proved that robot games in dimension three are undecidable. The undecidability of 2RG is proved by a new technique of embedding state transitions of a 2CM into integers. It would be interesting to see whether the same approach can be applied to other automata and games, such as stateless VASS games.

Korec showed in [14] that there exists a universal Minsky machine with 32 instructions. The natural question of a universal game arises: Is it possible to construct a fixed robot game simulating a universal 2CM? This game would have fixed moves and only the initial vector would affect the result. In [12], it was proven that two-dimensional robot games where both players have two moves are decidable in polynomial time. Consider the machine with

32 instructions. We can construct a robot game from it and count the number of moves. Thus it is undecidable whether Eve has a winning strategy in a two-dimensional robot game where Eve has at least 2083 moves and Adam has 8 moves.

Abstract

The motivation for this work comes from two problems– test algebraic independence of arithmetic circuits over a field of small characteristic, and generalize the structural property of algebraic dependence used by (Kumar, Saraf CCC'16) to arbitrary fields.

It is known that in the case of zero, or large characteristic, using a classical criterion based on the Jacobian, we get a randomized poly-time algorithm to test algebraic independence. Over small characteristic, the Jacobian criterion fails and there is no subexponential time algorithm known. This problem could well be conjectured to be in RP, but the current best algorithm puts it in $\mathrm{NP}^{\#\mathsf{P}}$ (Mittmann, Saxena, Scheiblechner Trans.AMS'14). Currently, even the case of two bivariate circuits over $\mathbb{F}_2$ is open. We come up with a natural generalization of Jacobian criterion, that works over all characteristic. The new criterion is efficient if the underlying *inseparable degree* is promised to be a constant. This is a modest step towards the open question of fast independence testing, over finite fields, posed in (Dvir, Gabizon, Wigderson FOCS'07).

In a set of linearly dependent polynomials, any polynomial can be written as a linear combination of the polynomials forming a basis. The analogous property for algebraic dependence is false, but a property approximately in that spirit is named as "functional dependence" in (Kumar, Saraf CCC'16) and proved for zero or large characteristic. We show that functional dependence holds for *arbitrary* fields, thereby answering the open questions in (Kumar, Saraf CCC'16). Following them we use the functional dependence lemma to prove the first exponential lower bound for *locally low algebraic rank* circuits for *arbitrary* fields (a model that strongly generalizes homogeneous depth-4 circuits). We also recover their quasipoly-time hitting-set for such models, for fields of characteristic smaller than the ones known before.

Our results show that approximate functional dependence is indeed a more fundamental concept than the Jacobian as it is field independent. We achieve the former by first picking a "good" transcendence basis, then translating the circuits by new variables, and finally approximating them by truncating higher degree monomials. We give a tight analysis of the "degree" of approximation needed in the criterion. To get the locally low algebraic rank circuit applications we follow the known shifted partial derivative based methods.

1 Introduction

Algebraic dependence is a fundamental concept in algebra that captures algebraic/polynomial relationship of objects like numbers, polynomials, rational functions or power series, over some field. Here we define algebraic dependence of polynomials, since in this work we deal only with polynomials. Polynomials $f_1, \ldots, f_m \in \mathbb{F}[x_1, \ldots, x_n]$ are called *algebraically dependent* over field k if and only if there exists a nonzero polynomial $A(y_1, \ldots, y_m) \in \mathbb{F}[y_1, \ldots, y_m]$ such that $A(f_1, \ldots, f_m) = 0$ and such an A is called an *annihilating polynomial* of $f_1, \ldots, f_m$. If no such nonzero polynomial A exists, the given polynomials are called *algebraically independent* over k.

For example, $f_1 = (x + y)^2$ and $f_2 = (x + y)^3$ are algebraically dependent over any field, as $y_1^3 - y_2^2$ is an annihilating polynomial. Polynomials $x + y$ and $x^p + y^p$ are dependent over $\mathbb{F}_p$, but independent over $\mathbb{Q}$. Monomials $x_1, \ldots, x_n$ are examples of algebraically independent polynomials over any field.

Algebraic dependence can be viewed as a generalization of linear dependence as the former captures algebraic relationships of any degree, whereas the latter captures linear relationships. Algebraic dependence shares a few combinatorial properties (known as matroid properties [30]) with linear dependence. For example, if a set of polynomials are algebraically independent then any subset of them are algebraically independent. The *transcendence degree* (trdeg or algRank) of a set of polynomials is defined as the maximal number of algebraically independent polynomials and it is well defined thanks to the matroid properties. The concepts of rank and basis in linear algebra have analogs here as transcendence degree and *transcendence basis* respectively.

The concept of algebraic independence is useful in several areas of mathematics: field theory, commutative algebra, algebraic geometry, invariant theory, theory of algebraic matroids. It has found interesting applications in computer science as well. For example, [28] used algebraic dependence in analysis of program invariants of arithmetic straight line programs. To prove lower bounds on the formula size of determinant, [21] also used transcendence degree as a tool. [7, 9] constructed explicit deterministic randomness extractors for sources which are polynomial maps over finite fields. [8] gives a cryptography application, using algebraic characterization of entropy of low degree polynomials. [4, 1, 27] used it for designing faster deterministic hitting-sets for some interesting cases of the polynomial identity testing problem (PIT) and proving circuit lower bounds. [5] used algebraic independence of polynomials to show the hardness of a parameterized counting problem.

An example relevant to computer science is to compute the "entropy" of a given polynomial map $\phi : (x_1, \ldots, x_n) \mapsto (f_1, \ldots, f_n)$ in the space $\mathbb{F}_q^n$, where q is a power of $p = 2$ (more, generally, p grows as a polynomial in the input size). This turns out to be a question of computing the transcendence degree of the polynomials $f_1, \ldots, f_n$ [7]. For constant p, there are no good methods known. Our work improves the state of the art in this regime.

To discuss the complexity of algebraic independence testing, we have to specify the representation of input polynomials. An *arithmetic circuit* is a directed acyclic graph consisting of addition $(+)$ and multiplication $(\times)$ gates as nodes, takes variables $x_1, \ldots, x_n$ and field constants as input (leaves), and outputs a polynomial $f(x_1, \ldots, x_n)$. This is a succinct representation of multivariate polynomials, as polynomials of high degree (or having many monomials) can be represented by small circuits.

Perron [31, 32] gave a bound on the degree of the minimal annihilating polynomial, proving that it is bounded by the product of the degrees of the input polynomials. This bound was subsequently slightly improved in [22, 4]. Perron's bound gives us the brute-force approach.

It reduces the problem of computing annihilating polynomial to solving an exponential sized system of linear equations and this can be done in PSPACE. Thus, PSPACE is the "trivial" complexity upper bound for algebraic independence testing, over any field.

The degree bound on the minimal annihilating polynomial happens to be tight. We can give examples of n quadratic polynomials, such that the degree of their minimal annihilating polynomial is 2^n [22]. There is a hardness result known [22], that shows that computing even the constant term of the annihilating polynomial is NP-hard, and that annihilating polynomial is not of polynomial size in general, unless the polynomial hierarchy collapses.

It turns out that the decision version, i.e. checking if the polynomials are algebraically independent, is much more efficient over zero or large characteristic, even when the polynomials are succinctly represented as circuits. The key idea is a classical result, known as the Jacobian criterion [20, 4]. It says that if the characteristic of the field is zero, or large enough (compared to the product of degrees of the given polynomials), then the transcendence degree equals the linear rank of the Jacobian matrix of the polynomials. This leads to a simple randomized poly-time algorithm for checking algebraic independence, as we can get the circuits of the partial derivatives efficiently [3] and then use random evaluations to compute the rank of the Jacobian matrix. This final step of randomized evaluation is possible due to the Schwartz-Zippel-DeMillo-Lipton lemma [36, 6, 40].

One direction of the Jacobian criterion (if the polynomials are algebraically dependent, then their Jacobian matrix is not full rank) holds true for any characteristic. But the converse fails if the characteristic is small compared to the product of the degrees of input polynomials. For example, x^p is algebraically independent of $\mathbb{F}_p$, yet its derivative vanishes. We remark here that if two algebraically independent polynomials over characteristic p have zero Jacobian, then it does not mean that one of them is a p power. Consider, for example, $\{x^{p-1}y, xy^{p-1}\}$ over $\mathbb{F}_p$ for prime $p > 2$.

There are infinitely many input instances (set of polynomials), where the Jacobian criterion fails, i.e. Jacobian vanishes even though the given polynomials are independent. Those instances can be characterized by the notion of *inseparable extension*, that appears in Galois theory, and is formally defined in Sec.2.1. For example, the field extension $\mathbb{F}_p(x)/\mathbb{F}_p(x^p)$ has inseparable degree p as that many *conjugates* of $\sqrt[p]{x^p}$ in the splitting field are equal. This is a hard algebraic situation with no good geometric interpretation. Such behavior is absent over zero characteristic fields. So, positive characteristic requires inventing new concepts.

Naturally, we would like to come up with an efficient (randomized poly-time) algorithm over small characteristic. Though the failure of Jacobian criterion over small characteristic is known for long [12, 15], owing to the interest in algebraic independence from computer science perspective, several recent papers [7, 22, 4] posed the complexity status of this problem (whether it is in RP) as an open question. One curious aspect is that this problem is one of the rare ones in computer science where the gap between the known time complexity (EXP) and the conjectured one (RP) is that stark!

Talking about the two degrees. Let us consider a case where Jacobian criterion fails and certifying independence gets tricky. Let m_1m_2 be coprime to p, and $f_1 = x_1^{pm_1}, f_2 = x_2^{m_2}$. It is easy to deduce that the degree of the extension $\mathbb{F}_p(x_1, x_2)/\mathbb{F}_p(f_1, f_2)$ is pm_1m_2. In fact, the degree of the annihilating polynomial of $\{x_1, f_1, f_2\}$ (resp. $\{x_2, f_1, f_2\}$) is pm_1 (resp. m_2). However, the inseparable degree of the extension is only p, as the former annihilating polynomial (i.e. $y_1^{pm_1} - y_2$) is a polynomial in y_1^p but not in $y_1^{p^2}$. Thus, there are cases when the inseparable degree can be much smaller, even $O(1)$, compared to the extension degree. Notice that, in general, the inseparable degree is a p-power that divides the extension degree, which in turn is upper bounded by $\prod_i \deg(f_i)$ (by Perron's bound)– usually an exponentially large parameter. The methods developed in this work only depend on the underlying inseparable degree, thus, our algorithm is expected to be much better than brute-force (in many cases).

A criterion that works for all characteristic for a natural problem like testing algebraic independence would be mathematically interesting. Computational implications of an efficient Jacobian like criterion would include a possible generalization (to small characteristic) of PIT or lower bound results [1], and algebraic extractors or entropy concepts [7].

Work done in case of finite fields. [29] gave a criterion that works over all fields, which they named *Witt-Jacobian* criterion. One key idea of the Witt-Jacobian criterion is to lift the input polynomials from characteristic $p \geq 2$ to a field of p-adics, which is zero characteristic. Witt-Jacobian polynomial can be seen as a scaled up p-adic lift of Jacobian polynomial and the criterion involves checking certain monomials (degeneracy testing; which looks hard) rather than zero testing. The main object underlying the proof is the de Rham-Witt pro-complex; a tool from modern algebraic-geometry (an excellent survey is [18]).

Witt-Jacobian criterion improved the complexity of independence testing problem, over positive characteristic, from PSPACE to $\mathrm{NP}^{\#\mathsf{P}}$. In the hierarchy of complexity classes, $\mathrm{NP}^{\#\mathsf{P}}$ is far above RP; thus there is a huge gap between what we have and what we want.

Partial derivative (defined as formal operators on polynomials), that played a key role in Jacobian criterion, behaves strangely over positive characteristic. Though it satisfies the usual rules of derivatives like linearity, product rule and chain rule, one important difference here is the fact that a non-constant polynomial can have a zero derivative. Another difference is that the higher derivatives of order $k \geq p$ are zero for all polynomials over characteristic p. Hasse-Schmidt derivatives are variants of usual derivatives, that were originally defined by [17], and independently by [38], to tackle this problem. In computer science literature, Hasse derivatives were used recently in coding theory (see [10] and the references therein), and PIT or lower bounds via generalized versions of shifted partial derivatives [14, 13].

Background on PIT and circuit lower bounds. The problems of derandomization of PIT and proving lower bounds, for explicit family of polynomials, are two fundamental questions in complexity theory. The question of PIT asks to test whether the polynomial computed by an arithmetic circuit is identically zero. This question can be studied in two settings. In the whitebox setting we are allowed to see inside the circuit, whereas in the blackbox setting we can only evaluate the circuit at some field points. The problem of blackbox PIT is equivalent to the problem of designing *hitting-sets* efficiently. Hitting-set is defined as follows. Let $\mathcal{C}$ be a class of polynomials in N variables over a field $\mathbb{F}$. Then, a set $\mathcal{H} \subseteq \mathbb{F}^N$ is called a *hitting-set* for the class $\mathcal{C}$, if for every nonzero polynomial $C \in \mathcal{C}$, there exists an $x \in \mathcal{H}$ such that $C(x) \neq 0$. PIT has a randomized poly-time algorithm, thanks to Schwartz-Zippel-DeMillo-Lipton lemma [36, 40, 6]. Derandomization of PIT is an outstanding open question in complexity theory with several implications, including proving arithmetic circuit lower bounds (refer to [2] & the survey [37]).

In the world of arithmetic complexity, we have strong structural results like *depth reductions* [16, 2]. These results show that strong enough lower bound, or PIT, results for homogeneous depth-4 (or general depth-3) circuits would give us exponential lower bounds and quasipoly-time derandomized PIT for general circuits (up to VP). Recent years have seen a fast growth in papers giving lower bound and PIT results for several special cases of small depth arithmetic circuits [34, 35]. Although there are strong (almost exponential, [26, 23]) lower bounds for homogeneous depth-4 circuits, the best known lower bounds for non-homogeneous depth-4 circuits are only superlinear (see [33] & the references therein).

Circuits with locally low algebraic rank. Kumar & Saraf [27] defined a *locally low algebraic rank* circuit of degree n in N variables over $\mathbb{F}$, denoted $\Sigma\Gamma^{(k)}\Sigma\Pi^{d}$, as: $C = \sum_{i\in[T]} \Gamma_i(Q_{i1},\ldots,Q_{it})$, where Q_{ij} is a sparse polynomial (all monomials are given explicitly) of degree at most d, algRank of $\{Q_{ij} \mid j \in [t]\}$ is at most k, and Γ_i is an arbitrary t-variate polynomial, for $i \in [T]$.

The *size* of C comprises N, n, T and the maximum sparsity of Q_{ij}'s. Note that $k \le N$, and we will be interested in the cases when kd is somewhat restricted.

Interestingly, $\Sigma\Gamma^{(n)}\Sigma\Pi$ subsumes homogeneous depth-4 circuits computing a degree n polynomial, as for homogeneous circuits $k \le t \le n$ and Γ_i is merely the product gate. Since this class includes non-homogeneous circuits as well (where t can be arbitrarily larger than k, n), it can be seen as a significant generalization of homogeneous depth-4.

This model subsumes certain other interesting models that were studied by [14, 1, 4] in the context of lower bounds and PIT. Invariably, their methods need to assume that $\mathbb{F}$ has characteristic zero or exponentially large (since partial derivatives are involved). Our goal in this paper is to overcome such restrictions.

1.1 Our contribution and relation with previous works

Broadly, in this paper, we prove two main technical theorems, one about the algebraically dependent polynomials and the other about algebraically independent polynomials. We apply these two theorems to obtain an algebraic independence testing algorithm, an arithmetic circuit lower bound over arbitrary field and a PIT algorithm (over fields of characteristic larger than the individual-degree of the polynomial). We now describe each of the results.

Algebraic dependence to approximate functional dependence. We show that over arbitrary fields, algebraic dependence of polynomials $f_1,\ldots,f_m$ imply the existence of a transcendence basis such that all the polynomials $f_1,\ldots,f_m$ can be obtained (upto a random shift and a truncation) as a polynomial function of the basis elements (Thm.10). Essentially, to obtain the desired polynomial, say f_k, we truncate a polynomial function in the elements of the basis upto the degree of f_k. This generalizes the functional dependence result of [27, Lem.3.1] which asserted the same over fields of zero (or large) characteristic.

We use a proof approach which is different from [27] to achieve the more general results. In the case of fields of zero characteristic, the subtle strength that this functional dependence property possesses is that *any* transcendence basis serves the purpose, which in general is false over positive characteristic. Our result explains this subtlety using the concept of *separating transcendence basis* from Galois theory (Sec.2.1). With this, a simple algebraic manipulation on the annihilating polynomial, and subspace of polynomial products (Lem.12), yields a functional dependence up to *any* desired degree of approximation. (This is a bit simpler than the approach of [27, Lem.2.4] where they approximate the roots of any multivariate polynomial using [11, Lem.3.1]. Such methods also appear in classical analysis under *Implicit Function Theorems*, see [25].)

Eg. $\{x_1, x_2, x_1x_2^2\}$ are algebraically dependent over $\overline{\mathbb{F}}_2$. Pick random field elements a_1, a_2. The shifted polynomials are $\{x_1 + a_1, x_2 + a_2, (x_1 + a_1)(x_2^2 + a_2^2)\}$. Clearly, $(x_2 + a_2)$ is not a function of the other two modulo the ideal $\langle \mathbf{x}\rangle^2$. However, $(x_1 + a_1)$ is trivially a function of the other two, namely, $(x_1 + a_1) \equiv a_2^{-2} \cdot (x_1 + a_1)(x_2^2 + a_2^2) \mod \langle \mathbf{x}\rangle^2$.

Algebraically independent polynomials – Criterion. The above example shows that over fields of positive characteristic, an approximate functional dependence may exist even in the case of algebraically independent polynomials. We overcome this issue and show that the independence can be captured by truncating the polynomial function in the basis elements upto a precise parameter, i.e. if we choose the truncation point to be greater than that parameter, then algebraically independent polynomials *cannot* exhibit functional dependence (Thm.13). This parameter is actually the *inseparable degree* of an appropriate field extension, which is a well studied concept in Galois theory (Sec.2.1).

Continuing the above example– $\{x_1, x_1x_2^2\}$ are algebraically independent over $\overline{\mathbb{F}}_2$. Pick random field elements a_1, a_2. The shifted polynomials are $\{x_1 + a_1, (x_1 + a_1)(x_2^2 + a_2^2)\}$. It can be verified that neither is a polynomial function of the other modulo the ideal $\langle \mathbf{x} \rangle^3$. This becomes a certificate of algebraic independence. (Note that the inseparable degree of $\mathbb{F}_2(x_1, x_2)/\mathbb{F}_2(x_1, x_1x_2^2)$ is 2.)

When the inseparable degree is 1 (which means a *separable extension*), then looking at the truncation upto the linear term of shifted basis elements would suffice. So, our result implies that *separable extension* is precisely the case when the Jacobian works (an exposition can be found in the full version). For higher inseparable degree t, our result can be reinterpreted as giving a Jacobian like result: algebraically independent polynomials have $\mathbb{F}(\mathbf{z})$-linearly independent higher differentials (Sec.2.2), modulo a carefully chosen subspace $\mathcal{U}_t$ (Rmk.11). This follows by considering the Taylor series, around a "generic" point $\mathbf{z}$, whence, the functional independence of polynomials shifted by $\mathbf{z}$, implies the linear independence of shifted polynomials modulo $\mathcal{U}_t$. As shifted polynomials contain all the Hasse-Schmidt higher derivatives (wrt $\mathbf{x}$ and evaluated at the point $\mathbf{z}$), we deduce their $\mathbb{F}(\mathbf{z})$-linear independence modulo $\mathcal{U}_t$.

Again, a key technical lemma used in finishing the proof is Lem.12 (*subspace reduction*), which concerns the ideal theoretic properties of the subspace $\mathcal{U}_t$. Basically, it helps us prove that if $\{h_1, \ldots, h_n\}$ are polynomials with their degree($\leq t$)-part having algebraically independent leading monomials, and g_n functionally depends on $\{g_1, \ldots, g_{n-1}\}$ (with truncation beyond t), then some h_i is functionally independent of $\{g_1, \ldots, g_n\}$.

Application 1: Testing algebraic independence. An easy consequence of Thm.10 and Thm.13 is that we get a randomized poly-time algorithm for testing algebraic independence of polynomials over finite fields (say, $\mathbb{F}_q$ of characteristic p) in the cases when the inseparable degree is constant. Since the latter is a p-power (Sec.2.1), our algorithm is interesting when p is a constant. (Whenever required, we can assume wlog that the input is n circuits in n variables over an algebraically closed field; see full version for simple proofs.)

▶ **Theorem 1** (Independence testing). *For circuits $\mathbf{f} \in \mathbb{F}_q[\mathbf{x}]$, we have a randomized poly(s, $\binom{t+n}{n}$)-time algebraic independence testing algorithm, where the inseparable degree of the field extension $\mathbb{F}_q(\mathbf{x})/\mathbb{F}_q(\mathbf{f})$ is t (assuming $\mathbf{f}$ algebraically independent) & input size is s.*

This covers a lot of interesting cases as the inseparable degree can be quite small even in case of polynomials with exponential degree. As a simple example, take two bivariate circuits of exponential degree over $\mathbb{F}_2$. Suppose they are independent and their Jacobian is nonzero. Now if we square any one of these two, then Jacobian would fail as the inseparable degree becomes 2. Previously known algorithms cannot deal with even such a simple case, whereas we easily handle the case by trying our test with $t = 2$. In general, the inseparable degree is upper bounded by Perron's degree bound (product of degrees of given polynomials, [32]), so in the worst-case our algorithm is exponential-time. (Witt-Jacobian criterion [29] is exponential-time in all cases.) We illustrate the overall idea, and its comparison with Jacobian criterion, in the figure in the conclusion (Sec.4).

An interesting by-product of the algorithm is that it computes the inseparable degree, of the given independent polynomials, in the same time.

Application 2: Lower bound for locally low algebraic rank circuits. Using the functional dependence result, we give an explicit family of polynomials in VNP of degree n in N variables, where $N = n^{O(1)}$ such that any $\Sigma\Gamma^{(n)}\Sigma\Pi$ circuit computing it has size $N^{\Omega(\sqrt{n})}$. We obtain this lower bound over *arbitrary* fields. This generalizes the lower bound of [27, Thm.1.4] which itself was a strong generalization of the shifted partials based homogeneous depth-4 lower bounds [23] and Jacobian based lower bounds [1] (all over zero or large characteristic). Since our functional dependence generalizes the key technical ingredient of [27] to arbitrary fields, we are able to get the same lower bound (for the same model and hard polynomial family) over arbitrary fields. Formally,

▶ **Theorem 2.** *Let $\mathbb{F}$ be any field. There exists a family $\{P_n\}$ of polynomials in VNP, such that P_n is a polynomial of degree n in $N = n^{O(1)}$ variables with $0, 1$ coefficients, and for any $\Sigma\Gamma^{(k)}\Sigma\Pi$ circuit C, if $k \leq n$ and if C computes P_n over $\mathbb{F}$, then Size$(C) \geq N^{\Omega(\sqrt{n})}$.*

▶ Remark. As remarked by [27], the above model is challenging even for $k = 2$ (& was open before us for small characteristic fields). Also, the proof goes through for any $k = n^{O(1)}$, as long as one picks N as an appropriately large polynomial in n.

The proof of this theorem closely follows [27], and is sketched in the full version.

Application 3: Hitting-set for $\Sigma\Gamma^{(k)}\Sigma\Pi^d$ circuits. We show that for any size-s circuit $C \in \Sigma\Gamma^{(k)}\Sigma\Pi^d$, where $k, d = \text{polylog}(s)$, over fields of characteristic $p >$ individual-degree(C), there exists a quasipoly(s)-time hitting-set.

▶ **Theorem 3.** *Let $\mathbb{F}$ be any field of characteristic p. There exists an $\exp(\log^{O(1)} s)$-time constructible hitting-set $\mathcal{H} \subseteq \overline{\mathbb{F}}^N$ for size-s circuit $C \in \Sigma\Gamma^{(k)}\Sigma\Pi^d$ with $kd = \log^{O(1)} s$, assuming $p >$ individual-degree(C) or $p = 0$.*

Again, the proof follows [27]. For PIT, algebraic rank based models have already been considered by [4, 1, 27]. Our result generalizes some of these results to smaller positive characteristic (only requiring $p >$ individual-degree(C)). The previous results required $p > d^k$, which is super-polynomial in the above regime. Our inability to remove this restriction lies in the nature of shifted partials [14, Lem.4.13]. Eg. the dimension of shifted partials of a p-power monomial $x_1^{p^{e1}} \cdots x_n^{p^{en}}$ is not that large over $\mathbb{F}_p$.

2 Preliminaries: Jacobi, Galois and Hasse-Schmidt

We define the central object related to the testing of algebraic independence is the Jacobian.

▶ **Definition 4** (Jacobian). The *Jacobian* of polynomials $\mathbf{f} = \{f_1, \cdots, f_m\}$ in $\mathbb{F}[x_1, \cdots, x_n]$ is the matrix $\mathcal{J}_{\mathbf{x}}(\mathbf{f}) = (\partial_{x_j} f_i)_{m \times n}$, where $\partial_{x_j} f_i := \partial f_i / \partial x_j$.

We state the classical Jacobian criterion [20, 4].

▶ **Lemma 5** (Jacobian criterion). *Let $\mathbf{f} \subset \mathbb{F}[\mathbf{x}]$ be a finite set of polynomials of degree at most d, and $\text{trdeg}_{\mathbb{F}} \mathbf{f} \leq r$. If $\text{char}(\mathbb{F}) = 0$, or $\text{char}(\mathbb{F}) > d^r$, then $\text{trdeg}_{\mathbb{F}} \mathbf{f} = \text{rank}_{\mathbb{F}(\mathbf{x})} \mathcal{J}_{\mathbf{x}}(\mathbf{f})$.*

Previously, we saw some examples of polynomials over fields of smaller characteristic where the Jacobian *fails*. Here is another nontrivial example: $\mathbf{f} = \{x_1^2x_2 + x_1^3,\ x_1x_2^2 + x_1x_2^5\}$ in $\mathbb{F}_3[x_1, x_2]$ is a set of algebraically independent polynomials, but $\operatorname{rank}_{\mathbb{F}_3(\mathbf{x})}\mathcal{J}_{\mathbf{x}}(\mathbf{f}) = 1$, and hence the criterion fails.

2.1 Inseparability & separating transcendence basis

For this section, let $\mathbb{E} \supseteq \mathbb{F}$ be fields. Failure of the Jacobian criterion can be explained using the fundamental concept of inseparability from Galois theory [19].

▶ **Definition 6.** An $f \in \mathbb{F}[x]$ is *separable* if it has no multiple roots in its splitting field.

It is easy to prove that. For an irreducible f, separability is implied by the non-zeroness of $\partial_x f$. Thus, if $\operatorname{char}(\mathbb{F}) = 0$, then any irreducible polynomial is separable. It further implies that if $\operatorname{char}(\mathbb{F}) = p > 0$ then, an irreducible f is separable if and only if $f \notin \mathbb{F}[x^p]$. We have this notion of separability in case of field extensions as well. An algebraic extension $\mathbb{E}/\mathbb{F}$ is said to be *separable* if every element $\alpha \in \mathbb{E}$ has a minimal polynomial over $\mathbb{F}$ that is separable.

For polynomials $f_1, \ldots, f_m \in \mathbb{F}[x_1, \ldots, x_n]$, we deal with the extension $\mathbb{F}(x_1, \ldots, x_n)/\mathbb{F}(f_1, \ldots, f_m)$. This extension is algebraic iff $\operatorname{trdeg}(\mathbf{f}) = n$ (as every x_j depends on $\mathbf{f}$). In which case, the extension $\mathbb{F}(\mathbf{x})/\mathbb{F}(\mathbf{f})$ is separable iff the minimal polynomial of x_j over $\mathbb{F}(\mathbf{f})$ is separable, for all $j \in [n]$. The latter, clearly, is the case when $\operatorname{char}(\mathbb{F}) = 0$. When $\operatorname{char}(\mathbb{F}) = p > 0$, the extension is inseparable if there exists $j \in [n]$, such that the minimal polynomial of x_j over $\mathbb{F}(\mathbf{f})$ lives in $\mathbb{F}(\mathbf{f})[y^p]$. Thus for every x_j, we have an m_j such that $x_j^{p^{m_j}}$ has a separable minimal polynomial over $\mathbb{F}(\mathbf{f})$.

The *inseparable degree of the extension* $\mathbb{F}(\mathbf{x})/\mathbb{F}(\mathbf{f})$ is defined as the minimum p^m such that the minimal polynomial of $x_j^{p^m}$ over $\mathbb{F}(\mathbf{f})$ is separable, for all $j \in [n]$. We also associate this inseparable degree with the set $\mathbf{f}$.

In the case when $\mathbf{f}$ are algebraically dependent, we would like to use a "good" transcendence basis. This is captured by:

▶ **Definition 7** (Separating transcendence basis)**.** A field extension $\mathbb{E}/\mathbb{F}$ is called *separably generated* if there exists an algebraically independent set (i.e. transcendence basis) $S = \{f_1, \ldots, f_r\} \subset \mathbb{E}$ such that $\mathbb{E}/\mathbb{F}(S)$ is algebraic and separable.

S is called a *separating transcendence basis* of $\mathbb{E}/\mathbb{F}$.

It is a classical result that such bases exist for fields that we are interested in.

▶ **Theorem 8.** *Consider a finite set of polynomials* $\mathbf{f} \subset \mathbb{F}[\mathbf{x}]$. *If* $\mathbb{F}$ *is a finite field (resp. an algebraically closed field) then there exists a separating transcendence basis, of* $\mathbb{F}(\mathbf{f})/\mathbb{F}$*, in* $\mathbf{f}$.

In case $\mathbb{F}$ *is a zero characteristic field then* every *transcendence basis of* $\mathbf{f}$ *is a separating one of the extension* $\mathbb{F}(\mathbf{f})/\mathbb{F}$.

Proof. It is clear that if $\mathbb{F}$ has characteristic zero then there is no possibility of inseparability.

Let $\mathbb{F}$ be a finite (resp. algebraically closed) field. [24, Thm.7.20] shows that the extension $\mathbb{F}(\mathbf{f})/\mathbb{F}$ is separably generated. Furthermore, [24, Thm.7.18] shows that $\mathbf{f}$ contains a subset that is a separating transcendence basis of the extension. ◀

Examples. Extension $\mathbb{F}_3(x^3)/\mathbb{F}_3$ has $\{x^3\}$ as a separating transcendence basis. Consider the two transcendence bases of the extension $\mathbb{F}_3(x^2, x^3)/\mathbb{F}_3$ – $\{x^3\}$ and $\{x^2\}$. The latter is a separating transcendence basis, but the former is not.

2.2 Taylor expansion at $\mathbf{z}$, higher derivatives & differentials

We consider the application of shift (or translation) to our polynomials. We view this as writing the Taylor expansion of a polynomial $f(\mathbf{x})$ at a "generic" point $\mathbf{z}$ [13, Sec.C.1]. A second view is that of computing the Hasse-Schmidt higher derivatives of f at the point $\mathbf{z}$ [14, 10]. A third view is seeing the shifted polynomial as a Hasse-Schmidt differential [39]. We collect these equivalent viewpoints in a single definition.

▶ **Definition 9** (Formal shift)**.** We see $f(\mathbf{x}+\mathbf{z})$ as a polynomial in $R := \mathbb{F}_p(\mathbf{z})[\mathbf{x}]$ where the variables $x_1, \dots, x_n$ are *shifted* respectively by the function field elements $z_1, \dots, z_n$.

Now the coefficient of $m := x_1^{\ell_1} \cdots x_n^{\ell_n}$ in the Taylor-series expansion of $f(\mathbf{x}+\mathbf{z})$ can be written as $\frac{1}{\ell_1! \cdots \ell_n!} \frac{\partial^{(\ell_1+\cdots+\ell_n)} f}{\partial x_1^{\ell_1} \cdots \partial x_n^{\ell_n}}(\mathbf{z})$.

This is called the *Hasse-Schmidt derivative of f wrt m evaluated at the point* $\mathbf{z}$. It can be denoted, by some abuse of notation, as $\partial_m f(\mathbf{x})|_{\mathbf{z}}$.

Finally, we can see the formal shift as a *Hasse-Schmidt differential*, namely, $f(\mathbf{x}+\mathbf{z}) = \sum_m m \cdot \partial_m f(\mathbf{x})|_{\mathbf{z}}$ (sum over all monomials m in $\mathbf{x}$).

Example. We have $\partial^2 x^2/\partial x^2 = 0$ over $\mathbb{F}_2$, but $\partial^2 x^2/2!\partial x^2 = 1$. Thus, Hasse-Schmidt derivatives offer a natural solution to this vanishing problem.

This connection between the shifts and Hasse-Schmidt higher derivatives/ differentials is what motivated us to search for the right framework to study algebraic independence.

Now the Jacobian criterion is given in terms of the first order derivatives of the polynomials and the failure of Jacobian essentially exposes the inability of first order derivative in capturing independence. Intuitively, it seems that going to higher derivatives may help. The above connection points out that perhaps we need to look at higher degree terms (wrt $\mathbf{x}$) of $f(\mathbf{x}+\mathbf{z})$ to get an algebraic independence criterion in cases where Jacobian fails. Eventually, we will see that the intuition is indeed true.

Operator $\mathcal{H}$. For notational convenience, we define the non-constant part of $f(\mathbf{x}+\mathbf{z})$ up to degree$\le t$ wrt $\mathbf{x}$, as $\mathcal{H}_t f := f^{\le t}(\mathbf{x}+\mathbf{z}) - f(\mathbf{z})$.

This is easier to work with when we do manipulations modulo the ideal $\langle \mathbf{x} \rangle_R^{t+1}$.

3 Main structure theorems

We use the following standard notation in the paper:

1. $\mathbb{F}$ is an arbitrary field. $\overline{\mathbb{F}}$ is its algebraic closure.
2. $\mathbb{F}_q$ is a finite field of size q and characteristic $p \ge 2$.
3. Let $R \supseteq S$ be a commutative ring extension over a field $\mathbb{F}$, let $v_1, \dots, v_m \in R$ and $r \ge 1$. Then $\langle v_1, \dots, v_m \rangle_S^r$ is simply the set of all S-linear combinations of products $v_{i_1} \cdots v_{i_r}$ (i_j's in $[m]$). It is both an S-module and an $\mathbb{F}$-vector space. (It is an ideal when $R = S$.)
4. For a polynomial $h \in \mathbb{F}[\mathbf{x}]$, $h^{\le d}$ extracts out the degree$\le d$ part of h and returns it as an element in $\mathbb{F}[\mathbf{x}]$ again.
5. For a polynomial $h \in \mathbb{F}[\mathbf{x}]$, $h^{[\le d]}$ extracts out the degree$\le d$ part of h and returns it as a $d+1$ tuple, where for $i \in [0 \dots d]$, i-th entry of the tuple contains $h^{=i}$ which is defined as the homogeneous component of h of degree i.

3.1 Functional dependence for algebraically dependent polynomials

A fact about linear independence is that if $f_1, \ldots, f_m \in \mathbb{F}[\mathbf{x}]$ are linearly dependent, it also implies that every polynomial can be written as a linear combination of the polynomials in the basis. The question is whether the same can be extended to algebraic dependence: Does algebraic dependence imply that all the polynomials can be written as a function of the polynomials in the transcendence basis? It was shown in [27, Lem.3.1] that it is indeed true (approximately) over fields of zero (and large) characteristic.

We generalize the property using a different proof approach and show that algebraic dependence implies functional dependence over arbitrary fields (to arbitrary degree of approximation t).

▶ **Theorem 10** (Functional dependence over arbitrary fields). *Let $\mathbf{f} = \{f_1, \ldots, f_m\} \subset \mathbb{F}[x_1, \ldots, x_n]$ be a set of polynomials, where $\mathbb{F}$ is any field, and $t \in \mathbb{N}$. If trdeg of $\{f_1, \ldots, f_m\}$ is k, then there exist algebraically independent $\{g_1, \ldots, g_k\} \subset \mathbf{f}$, such that for random $\mathbf{a} \in \overline{\mathbb{F}}^n$, there are polynomials $h_i \in \overline{\mathbb{F}}[Y_1, \ldots, Y_k]$ satisfying, $\forall i \in [m]$, $f_i^{\leq t}(\mathbf{x}+\mathbf{a}) = h_i^{\leq t}(g_1(\mathbf{x}+\mathbf{a}), \ldots, g_k(\mathbf{x}+\mathbf{a}))$.*

▶ Remark. Clearly, $\overline{\mathbb{F}}^n$ is an infinite space. What we mean here by a *random* $\mathbf{a}$ is "random point in any sufficiently large, but finite, subset of the space". It will be clear from the proof that it would suffice to sample from any set of size at most exponential in the input size. We skip the detailed estimate as in this paper merely existence of $\mathbf{a}$ is needed.

We will use $\mathbf{z}$ as a formal variable (n-tuple) and can fix it later to a suitable constant $\mathbf{a}$. To prove the theorem, we consider the ring $R := \overline{\mathbb{F}}(\mathbf{z})[\mathbf{x}]$ and its ideal $\mathcal{I}_0 := \langle \mathbf{x} \rangle_R$. The ideal collects the non-constant linear polynomials. Now, define the ideal $\mathcal{I}_t := \mathcal{I}_0^{t+1}$ and the quotient algebra $\mathcal{Q}_t := R/\mathcal{I}_t$, i.e. we are filtering out, or *truncating*, all the terms of degree $> t$. Now $\mathcal{Q}_t$ can also be seen as a finite $\binom{n+t}{n}$ dimensional vector space over $\overline{\mathbb{F}}(\mathbf{z})$ whose basis is monomials in $\mathbf{x}$ of degree at most t. In our theorems and proofs, most of the operations happen in this quotient ring $\mathcal{Q}_t$ for increasing t's.

In our analysis, we plan to use the shifting of the variables in the evaluated annihilating polynomial of $\{f_i, g_1, \ldots, g_k\}$, and it is clear that on applying the shifts, we will end up having terms of the form $(\mathcal{H}_t f_i)^{j_0} (\mathcal{H}_t g_1)^{j_1} \cdots (\mathcal{H}_t g_k)^{j_k}$ (recall that in Q_t, $f(\mathbf{x}+\mathbf{z}) = f(\mathbf{z}) + \mathcal{H}_t f(\mathbf{x})$). Now, note that due to the filtration in $\mathcal{Q}_t$, some of these terms will be equivalent to terms involving $\mathcal{H}_r$ with $r < t$. We consider an appropriate subspace $\mathcal{U}_t \subset \mathcal{Q}_t$ generated by such "higher" products, which we formally define as: $\mathcal{U}_1 := \{0\}$ and

$$\mathcal{U}_t := \langle \mathcal{H}_{t-1} f_i, \mathcal{H}_{t-1} g_1, \ldots, \mathcal{H}_{t-1} g_k \rangle^2_{\overline{\mathbb{F}}(\mathbf{z})} + \cdots + \langle \mathcal{H}_1 f_i, \mathcal{H}_1 g_1, \ldots, \mathcal{H}_1 g_k \rangle^t_{\overline{\mathbb{F}}(\mathbf{z})}, \quad t \geq 2.$$

▶ Remark 11. In $\mathcal{Q}_t$, observe that, this is the same subspace as $\langle \mathcal{H}_t f_i, \mathcal{H}_t g_1, \ldots, \mathcal{H}_t g_k \rangle^2_{\overline{\mathbb{F}}(\mathbf{z})} + \cdots + \langle \mathcal{H}_t f_i,\, \mathcal{H}_t g_1, \ldots, \mathcal{H}_t g_k \rangle^t_{\overline{\mathbb{F}}(\mathbf{z})}$

Proof of Theorem 10. Consider the set $\mathbf{f} := \{f_1, \ldots, f_m\} \subset \mathbb{F}[\mathbf{x}]$ with algebraic rank k. If we work over $\overline{\mathbb{F}}$, then Thm.8 guarantees the existence of a separating transcendence basis $\{g_1, \ldots, g_k\} \subseteq \mathbf{f}$. Let $g_0 := f_i$ for a fixed $i \in [m]$. Now we consider the separable annihilating polynomial $A(\mathbf{y}) = \sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \mathbf{y}^{\mathbf{e}_\ell}$ of the set $\mathbf{g} := \{g_0, g_1, \ldots, g_k\}$, and $a_{\mathbf{e}_\ell}$'s are in $\overline{\mathbb{F}}$ ($\mathbf{e}_\ell$ is a $(k+1)$-tuple $(e_{j\ell} \mid j \in [0 \ldots k])$). Thus, $A(\mathbf{g}) = \sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \prod_{j=0}^{k} g_j(\mathbf{x})^{e_{j\ell}} = 0$. We now apply the formal shift $\mathbf{x} \mapsto \mathbf{x} + \mathbf{z}$ to get $A(g_0(\mathbf{x}+\mathbf{z}), \ldots, g_k(\mathbf{x}+\mathbf{z})) = 0$, i.e. $\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \prod_j g_j(\mathbf{x}+\mathbf{z})^{e_{j\ell}} = 0$.

We now study this relation in the algebra $\mathcal{Q}_t$. By Taylor series expansion, we know that $f(\mathbf{x}+\mathbf{z}) \equiv f(\mathbf{z}) + \mathcal{H}_t f(\mathbf{x})$ in $\mathcal{Q}_t$, so we get $\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \prod_j (g_j(\mathbf{z}) + \mathcal{H}_t g_j)^{e_{j\ell}} \equiv 0$. The binomial expansion gives a compact expression:

$$\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \sum_{\mathbf{0}\le\mathbf{s}\le\mathbf{e}_\ell} \binom{\mathbf{e}_\ell}{\mathbf{s}} \cdot (\mathcal{H}_t\mathbf{g})^{\mathbf{s}} \cdot \mathbf{g}^{\mathbf{e}_\ell-\mathbf{s}} \equiv 0\,.$$

Note that the contribution by $\mathbf{s}=\mathbf{0}$ terms sum up to $\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} \prod_{j=0}^{k} g_j(\mathbf{z})^{e_{j\ell}}$ which is zero. This implies that an $\overline{\mathbb{F}}(\mathbf{z})$-linear combination of the products of the form $(\mathcal{H}_t g_0)^{s_0}\cdots(\mathcal{H}_t g_k)^{s_k}$, $\sum_j s_j \ge 1$, vanishes in $\mathcal{Q}_t$. Now the key step is to separate out the terms *linear* in $\mathcal{H}_t g_j$ and switch the sums, to obtain

$$\mathcal{H}_t g_0 \cdot g_0(\mathbf{z})^{-1}\left(\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell}\cdot e_{0\ell} g_0^{e_{0\ell}}\cdots g_k^{e_{k\ell}}\right) + \sum_{j\in[k]} \mathcal{H}_t g_j \cdot g_j(\mathbf{z})^{-1}\left(\sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell}\cdot e_{j\ell} g_0^{e_{0\ell}}\cdots g_k^{e_{k\ell}}\right)$$
$$+\,(\text{higher terms with } \sum_j s_j \ge 2) \equiv 0\,. \qquad (1)$$

Further, we argue using the minimality and separability of A (in terms of the first variable) that the "linear" term $\mathcal{H}_t g_0$ in the vanishing sum above has a non-zero coefficient: as it would either mean a lower degree annihilating polynomial $A := \sum_{\mathbf{e}_\ell} a_{\mathbf{e}_\ell} e_{0\ell} y_0^{e_{0\ell}-1}\cdot y_1^{e_{1\ell}}\cdots y_k^{e_{k\ell}}$ i.e. contradicting the minimality, or that all the $e_{0\ell}$'s are divisible by p (when $\mathbb{F}$ has characteristic p) which means that f_i does not depend separably on $\{g_1,\ldots,g_k\}$; which contradicts the fact that $\{g_1,\ldots,g_k\}$ is a separating transcendence basis.

Thus, we get that $\mathcal{H}_t g_0$ lives in the $\overline{\mathbb{F}}(\mathbf{z})$-linear span of $\mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k$ modulo the subspace generated by the higher terms of the summation in Eqn.1. So, $\mathcal{H}_t g_0$ lives in the $\overline{\mathbb{F}}(\mathbf{z})$-linear span of $\mathcal{H}_t g_1\ldots,\mathcal{H}_t g_k$ modulo the subspace $\mathcal{U}_t$ (Rmk.11) in $\mathcal{Q}_t$.

We got $\mathcal{H}_t f_i \in \langle \mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k\rangle_{\overline{\mathbb{F}}(\mathbf{z})} + \mathcal{U}_t$. Now, we are in a position to apply Lemma 12, which essentially says that if $\mathcal{H}_r f_n$ depends on higher order terms (in the sense of Equation 1) then it can be "dropped" from the ideal manipulations. Thus, we get that $\mathcal{H}_t f_i \in \langle \mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k\rangle_{\overline{\mathbb{F}}(\mathbf{z})} + \langle \mathcal{H}_{t-1} g_1,\ldots,\mathcal{H}_{t-1} g_k\rangle^2_{\overline{\mathbb{F}}(\mathbf{z})} + \cdots + \langle \mathcal{H}_1 g_1,\ldots,\mathcal{H}_1 g_k\rangle^t_{\overline{\mathbb{F}}(\mathbf{z})}$. The latter (by Rmk.11) is exactly $\langle \mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k\rangle_{\overline{\mathbb{F}}(\mathbf{z})} + \langle \mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k\rangle^2_{\overline{\mathbb{F}}(\mathbf{z})} + \cdots + \langle \mathcal{H}_t g_1,\ldots,\mathcal{H}_t g_k\rangle^t_{\overline{\mathbb{F}}(\mathbf{z})}$.

This implies $f_i(\mathbf{x}+\mathbf{z}) \in \langle 1, g_1(\mathbf{x}+\mathbf{z}),\ldots,g_k(\mathbf{x}+\mathbf{z})\rangle^t_{\overline{\mathbb{F}}(\mathbf{z})}$ in $\mathcal{Q}_t$, which yields the approximate functional dependence around a generic point $\mathbf{z}$.

Fixing $\mathbf{z}$ (avoiding some bad choices that make certain $\mathbf{z}$-polynomials in the above proof zero) to an element $\mathbf{a}\in\overline{\mathbb{F}}^n$ finishes the proof. ◀

We now formally state our subspace reduction lemma:

▶ **Lemma 12** (Subspace reduction). *Let $\mathbb{F}$ be any field, $R := \mathbb{F}(\mathbf{z})[\mathbf{x}]$, $\mathcal{Q}_r := R/\langle\mathbf{x}\rangle^{r+1}$ for $r\ge 1$, and $\mathbf{f}\subset\mathbb{F}[\mathbf{x}]$. Define $\mathcal{U}_1=\mathcal{V}_1=\{0\}$, and for $u\in\langle\mathbf{x}\rangle_R$, $r\ge 2$, define the subspaces (in the quotient algebra $\mathcal{Q}_r$),*

$$\mathcal{U}_r := \langle \mathcal{H}_{r-1}f_1,\ldots,\mathcal{H}_{r-1}f_n\rangle^2_{\mathbb{F}(\mathbf{z})} + \cdots + \langle \mathcal{H}_1 f_1,\ldots,\mathcal{H}_1 f_n\rangle^r_{\mathbb{F}(\mathbf{z})}\,,$$
$$\mathcal{V}_r := \langle \mathcal{H}_{r-1}f_1,\ldots,\mathcal{H}_{r-1}f_{n-1},u\rangle^2_{\mathbb{F}(\mathbf{z})} + \cdots + \langle \mathcal{H}_1 f_1,\ldots,\mathcal{H}_1 f_{n-1},u\rangle^r_{\mathbb{F}(\mathbf{z})}\,.$$

If $\mathcal{H}_t f_n \in \langle \mathcal{H}_t f_1,\ldots,\mathcal{H}_t f_{n-1},u\rangle_{\mathbb{F}(\mathbf{z})} + \mathcal{U}_t$, then $\mathcal{U}_t\subseteq\mathcal{V}_t$ (for any $t\in\mathbb{N}$).

▶ Remark. If $u=0$ then the lemma "reduces" the n polynomial generators, of the subspace $\mathcal{U}_t$, by one. Hence, the name "subspace reduction". A simple inductive proof of the lemma is given in the full version.

3.2 Algebraically independent polynomials: Criterion

Having proved the functional dependence for algebraically dependent polynomials, one naturally asks whether a converse exists (for arbitrary fields? to what degree?). We will characterize this completely.

It's all about the inseparable degree- We show that if f is algebraically independent of $\{g_1, \ldots, g_k\}$ then, under a random shift, f cannot be written as a function of $\{g_1, \ldots, g_k\}$ when chosen to truncate at (or beyond) the inseparable degree of the extension $\mathbb{F}_q(\mathbf{x})/\mathbb{F}_q(f, g_1, \ldots, g_k)$. Moreover, for each truncation at lower degrees we get functional dependence.

▶ **Theorem 13** (Algebraic to functional independence). *Let $\mathbf{f} \subset \mathbb{F}_q[\mathbf{x}]$ be algebraically independent polynomials (wlog n-variate n polynomials) with inseparable degree p^i. Then,*

1. *for all $t \geq p^i$, for random $\mathbf{a} \in \overline{\mathbb{F}}_q^n$, $f_n^{\leq t}(\mathbf{x}+\mathbf{a})$ cannot be written as $h^{\leq t}(f_1(\mathbf{x}+\mathbf{a}), \ldots, f_{n-1}(\mathbf{x}+\mathbf{a}))$, for any $h \in \overline{\mathbb{F}}_q[Y_1, \ldots, Y_{n-1}]$.*
2. *for all $1 \leq t < p^i$, $\exists j \in [n]$, for random $\mathbf{a} \in \overline{\mathbb{F}}_q^n$, $f_j^{\leq t}(\mathbf{x}+\mathbf{a})$ can be written as $h_{jt}^{\leq t}(f_1(\mathbf{x}+\mathbf{a}), \ldots, f_{j-1}(\mathbf{x}+\mathbf{a}), f_{j+1}(\mathbf{x}+\mathbf{a}), \ldots, f_n(\mathbf{x}+\mathbf{a}))$, for some $h_{jt} \in \overline{\mathbb{F}}_q[\mathbf{Y}]$.*

▶ Remark. Our proof works for any field $\mathbb{F}$ (manipulate in $\overline{\mathbb{F}}$). In case of characteristic $p \geq 2$ we get the above statement and in characteristic zero use inseparable degree $= 1$.

Proof idea: By the hypothesis we have that each monomial $x_j^{p^i}$, $j \in [n]$, algebraically depends on $\mathbf{f}$ with a *separable* annihilating polynomial over $\mathbf{F}_q$. Consider ring $R := \overline{\mathbb{F}}_q(\mathbf{z})[\mathbf{x}]$. The basic idea is to consider the minimal annihilating polynomial A_j of $\{x_j^{p^i}, \mathbf{f}\}$ and formally shift the relevant polynomials by $\mathbf{z}$. From the proof of Thm.10 we get a functional dependence of $x_j^{p^i}$ on $\mathbf{f}(\mathbf{x}+\mathbf{z})$ up to any degree t.

Interestingly, when we take $t < p^i$ the monomial $x_j^{p^i}$ vanishes mod $\langle \mathbf{x} \rangle^{t+1}$. This means that the above yields, in fact, a functional dependence among $\mathbf{f}(\mathbf{x}+\mathbf{z})$.

On the other hand, for $t \geq p^i$, we get a nontrivial functional dependence of $x_j^{p^i}$ on $\mathbf{f}(\mathbf{x}+\mathbf{z})$, for all $j \in [n]$. In this case, one can give an argument using monomial ordering that there exists no functional dependence among $\mathbf{f}(\mathbf{x}+\mathbf{z})$.

We can see the classical Jacobian criterion as a special case of Theorems 10 and 13. The detailed discussions and missing proofs are given in the full version.

4 Conclusion

We give a criterion for testing algebraic independence over positive characteristic, in the spirit of Jacobian criterion, that works for any field. Its complexity is parameterized by the inseparable degree bound. It is also strong enough to give the inseparable degree at the same time. We give applications to locally low algebraic rank circuits in the cases that were open before.

	Jacobian Criterion	**Our Criterion**
The approach:	reduces algebraic independence to linear independence testing	reduces algebraic independence to linear independence testing
Related "approximate" shift :	$\mathbf{f}(\mathbf{x}) \mapsto \mathbf{f}(\mathbf{x}+\mathbf{z}) \mod \langle \mathbf{x} \rangle^2_{\mathbb{F}(\mathbf{z})[\mathbf{x}]}$	$\mathbf{f}(\mathbf{x}) \mapsto \mathbf{f}(\mathbf{x}+\mathbf{z}) \mod \mathcal{U}_t$
Vectors for $\mathbb{F}(\mathbf{z})$-dependence:	$\mathcal{H}_1\mathbf{f} \mod \mathcal{U}_1$	$\mathcal{H}_t\mathbf{f} \mod \mathcal{U}_t$
Certifies alg.independence if:	$\mathbb{F}(\mathbf{x})/\mathbb{F}(\mathbf{f})$ is separable	separable or inseparable $\mathbb{F}(\mathbf{x})/\mathbb{F}(\mathbf{f})$
Efficiency in char$(\mathbb{F}) = 0$:	randomized poly-time algorithm	$t = 1$, (same as Jacobian criterion)
Efficiency in char$(\mathbb{F}) = p$, inseparable degree $\leq p^e$:	fails	randomized poly$\binom{n+p^e}{n}$-time algorithm

The main open problem is to investigate whether we can improve the criterion to get a randomized poly-time algorithm for circuits over a finite field. We mention a few special cases based on different restrictions on input. None of these cases are (efficiently) solved by presently known techniques.

- the polynomials are *supersparse*, i.e. sparse polynomials with possibly exponential degree.
- two bivariate circuits, with an exponentially large inseparable degree, over $\mathbb{F}_2$.
- n quadratic polynomials over $\mathbb{F}_2$.

Our hitting-set result, for locally low algebraic rank circuits, still has a mild assumption on the characteristic. Can this be eliminated?

Abstract

For fixed integers $r, \ell \geq 0$, a graph G is called an (r, ℓ)*-graph* if the vertex set $V(G)$ can be partitioned into r independent sets and ℓ cliques. Such a graph is also said to have *cochromatic number* $r + \ell$. The class of (r, ℓ) graphs generalizes r-colourable graphs (when $\ell = 0$) and hence not surprisingly, determining whether a given graph is an (r, ℓ)-graph is NP-hard even when $r \geq 3$ or $\ell \geq 3$ in general graphs.

When r and ℓ are part of the input, then the recognition problem is NP-hard even if the input graph is a perfect graph (where the Chromatic Number problem is solvable in polynomial time). It is also known to be fixed-parameter tractable (FPT) on perfect graphs when parameterized by r and ℓ. I.e. there is an $f(r + \ell) \cdot n^{\mathcal{O}(1)}$ algorithm on perfect graphs on n vertices where f is a function of r and ℓ. Observe that such an algorithm is unlikely on general graphs as the problem is NP-hard even for constant r and ℓ.

In this paper, we consider the parameterized complexity of the following problem, which we call Vertex Partization. Given a perfect graph G and positive integers r, ℓ, k decide whether there exists a set $S \subseteq V(G)$ of size at most k such that the deletion of S from G results in an (r, ℓ)-graph. This problem generalizes well studied problems such as Vertex Cover (when $r = 1$ and $\ell = 0$), Odd Cycle Transversal (when $r = 2$, $\ell = 0$) and Split Vertex Deletion (when $r = 1 = \ell$).

1. Vertex Partization on perfect graphs is FPT when parameterized by $k + r + \ell$.
2. The problem, when parameterized by $k + r + \ell$, does not admit any polynomial sized kernel, under standard complexity theoretic assumptions. In other words, in polynomial time, the input graph cannot be compressed to an equivalent instance of size polynomial in $k + r + \ell$. In fact, our result holds even when $k = 0$.
3. When r, ℓ are universal constants, then Vertex Partization on perfect graphs, parameterized by k, has a polynomial sized kernel.

1 Introduction

For fixed integers $r, \ell \geq 0$, a graph G is called an (r, ℓ)-*graph* if the vertex set $V(G)$ can be partitioned into r independent sets and ℓ cliques. Many special subclasses of this graph class, such as bipartite, chordal, interval, split and permutation, are well studied in various areas of algorithm design and intractability. For example, $(2, 0)$- and $(1, 1)$-graphs correspond to bipartite graphs and split graphs respectively. A $(3, 0)$-graph is a 3-colourable graph. Hence, there is a rich dichotomy even with respect to recognition algorithms for (r, ℓ)-graphs. It is well known that we can recognize $(2, 0)$- and $(1, 1)$-graphs, on n vertices and m edges, in $\mathcal{O}(m + n)$ time. In fact, one can show that recognizing whether a graph G is an (r, ℓ)-graph, when $r, \ell \leq 2$, can be done in polynomial time [4, 9]. On the other hand, when either $r \geq 3$ or $\ell \geq 3$, the recognition problem is as hard as the celebrated 3-Colouring problem, which is NP-complete [12]. Thus, the following problem is NP-hard when r or ℓ are at least 3:

Partization Recognition
Input: A graph G and positive integers r, ℓ
Question: Is G an (r, ℓ)-graph?

Partization Recognition has also been studied when the input is restricted to be a chordal graph. This restricted problem has a polynomial time algorithm [10]. On the other hand, when the input graphs are restricted to perfect graphs, Partization Recognition is NP-complete [23]. It was shown in [15], that the problem, when parameterized by $r + \ell$, has an FPT algorithm, i.e, an algorithm that runs in time $f(r + \ell) \cdot n^{\mathcal{O}(1)}$ for a computable function f. A natural extension to Partization Recognition is the Vertex Partization problem. The problem is formally stated below:

Vertex Partization **Parameter:** r, ℓ, k
Input: A graph G and positive integers r, ℓ, k
Question: Is there a vertex subset $S \subseteq V(G)$ of size at most k such that $G - S$ is an (r, ℓ)-graph?

Because of the NP-hardness of the 3-Colouring problem, we do not expect to obtain an FPT algorithm on general graphs, parameterized by $k + r + \ell$, for Vertex Partization, when $r \geq 3$ or $\ell \geq 3$. It has been shown in [16, 2] that, for all other combinations of r and ℓ, namely when $0 \leq r, \ell \leq 2$, Vertex Partization has an FPT algorithm with running time $3.3146^k n^{\mathcal{O}(1)}$. Various special cases of this problem are very well studied. When $r = 1$ and $\ell = 0$, the problem is the same as the celebrated Vertex Cover problem, which has been extensively studied in parameterized complexity, and the current fastest algorithm runs in time $1.2738^k n^{\mathcal{O}(1)}$ and has a kernel with $2k$ vertices [5] (A brief overview of paramaterized complexity is given in the preliminaries).

For $r = 2$ and $\ell = 0$, the problem is the same as Odd Cycle Transversal (OCT) whose parameterized complexity was settled by Reed et al. [22] by using the iterative compression technique (which is also the technique we use to show that Vertex Partization on perfect graphs has an FPT algorithm in this paper) for the first time. The current best algorithm for the problem is by Lokshtanov et al. [20] with a running time of $2.3146^k n^{\mathcal{O}(1)}$ that uses a branching algorithm based on linear programming.

When $r = \ell = 1$, the Vertex Partization problem is the same as Split Vertex Deletion (SVD) for which Ghosh et al. [13] designed an algorithm with running time $2^k n^{\mathcal{O}(1)}$. They also gave the best known polynomial kernel for SVD. Later, Cygan and Pilipczuk [7] designed an algorithm for SVD running in time $1.2738^{k+o(k)} n^{\mathcal{O}(1)}$.

As in the case of Partization Recognition, the Vertex Partization problem has also been studied when the input graph is restricted to a non-trivial graph class. By a celebrated result of Lewis and Yannakakis [19], this problem is NP-complete even when restricted to the perfect graph class. In fact, Odd Cycle Transversal (OCT) restricted to perfect graphs is NP-hard, because of this result. Thus, we cannot expect an FPT algorithm for Vertex Partization parameterized by $r + \ell$, unless P = NP. Moreover, because of the NP-hardness of Partization Recognition on perfect graphs, we do not expect Vertex Partization on perfect graphs to be FPT when parameterized by k alone, again under the assumption that P $\neq$ NP. Krithika and Narayanaswamy [17] studied Vertex Partization problems on perfect graphs, and among several results, they obtain an $(r+1)^k n^{\mathcal{O}(1)}$ algorithm for Vertex $(r, 0)$-Partization on perfect graphs. In this paper, we generalize this for all values of r and ℓ. In other words, we show that Vertex Partization on perfect graphs, parameterized by $k + r + \ell$, is FPT.

Our Results and Methods. For Vertex Partization on perfect graphs, parameterized by $k + r + \ell$, we give an FPT algorithm using the method of iterative compression. This algorithm is inspired by the FPT algorithm for Cochromatic Number on Perfect Graphs, given in [15].

Then, we obtain a negative result for *kernelization* for Vertex Partization on perfect graphs. We show that Vertex Partization cannot have a polynomial kernel unless NP $\subseteq$ co-NP/poly. This is shown by exhibiting a polynomial parameter transformation from CNF-SAT. In fact, our result holds even when $k = 0$ and either r or ℓ is one. Thus, we show that Partization Recognition, parameterized by r, ℓ (also known as the Cochromatic Number problem [15]), does not admit a polynomial kernel on perfect graphs unless NP $\subseteq$ co-NP/poly. See Section 2 for the definition of polynomial parameter transformation and kernelization.

Finally, we consider the following parameterized problem:

Vertex (r, ℓ) Partization **Parameter:** k
Input: A graph G and a positive integer k
Question: Is there a vertex subset $S \subseteq V(G)$ of size at most k such that $G - S$ is an (r, ℓ)-graph?

For each pair of constants r and ℓ, we give a polynomial kernelization algorithm for the above parameterized problem. To arrive at the kernelization algorithm, we consider a slightly larger class of graphs called (r, ℓ)-*split graphs*. A graph G is an (r, ℓ)-split graph if its vertex set can be partitioned into V_1 and V_2, such that the size of a largest clique in $G[V_1]$ is bounded by r and the size of a largest independent set in $G[V_2]$ is bounded by ℓ. Such a two-partition for the graph G is called as (r, ℓ)-split partition. The notion of (r, ℓ)-split graphs was introduced in [14]. For any fixed r and ℓ, there is a finite forbidden set $\mathbb{F}_{r,\ell}$ of graphs for (r, ℓ)-split graphs [14]. That is, a graph G is an (r, ℓ)-split graph if and only if G does not contain any graph $H \in \mathbb{F}_{r,\ell}$ as an induced subgraph. The size of the largest forbidden graph is bounded by $f(r, \ell)$, for some function f depending only on r and ℓ [14]. We use this to design the kernelization algorithm.

2 Preliminaries

We use $[n]$ to denote $\{1, \ldots, n\}$. We use standard notations from graph theory [8]. The vertex set and edge set of a graph are denoted as $V(G)$ and $E(G)$ respectively. The complement of the graph G, denoted by $\overline{G}$, has $V(G)$ as its vertex set and $\binom{V(G)}{2} \setminus E(G)$ as its edge set. Here, $\binom{V(G)}{2}$ denotes the family of two sized subsets of $V(G)$. The neighbourhood of a vertex v is represented as $N_G(v)$, or, when the context of the graph is clear, simply as $N(v)$. An induced subgraph of G on the vertex set $V' \subseteq V$ is written as $G[V']$. For a vertex subset $V' \subseteq V$, $G[V \setminus V']$ is also denoted as $G - V'$. We denote by $\omega(G)$ the size of a maximum clique in G. Similarly, $\alpha(G)$ denotes the size of a maximum independent set in G. The chromatic number of G is denoted by $\chi(G)$. In this paper, we consider the class of (r, ℓ)-graphs, The following is the formal definition of this graph class.

▶ **Definition 1** ((r, ℓ)-graph)**.** A graph G is an (r, ℓ)-graph if its vertex set can be partitioned into r independent sets and ℓ cliques. We call such a partition of $V(G)$ an (r, ℓ)-partition.

For a graph G, we say $S \subseteq V(G)$ is an (r, ℓ)-*vertex deletion set*, if $G - S$ is an (r, ℓ)-graph.

▶ **Definition 2** (IC-partition)**.** An IC-partition, of an (r, ℓ)-graph G, is a partition (V_1, V_2) of $V(G)$ such that $G[V_1]$ can be partitioned into r independent sets and $G[V_2]$ can be partitioned into ℓ cliques.

A graph G is a *perfect graph* if, for every induced subgraph H, $\chi(H) = \omega(H)$. We also need the following characterisation of perfect graphs – also known as strong perfect graph theorem.

▶ **Proposition 3** ([6])**.** *A graph G is perfect if and only if G does not have, as an induced subgraph, an odd cycle of length at least* 5 *or its complement.*

This tells us that perfect graphs are closed under complementation. However, this was proved earlier and was called weak perfect graph theorem.

▶ **Lemma 4** ([21])**.** *G is a perfect graph if and only if $\overline{G}$ is a perfect graph.*

Moreover, this class is well known for its tractability for several NP-hard problems.

▶ **Proposition 5** ([15, Lemma 3])**.** *Given a perfect graph G and an integer ℓ, there is a polynomial time algorithm to output*

(a) *either a partition of $V(G)$ into at most ℓ independent sets or a clique of size $\ell + 1$, and*
(b) *either a partition of $V(G)$ into at most ℓ cliques or an independent set of size $\ell + 1$.*

Parameterized Complexity. A parameterized problem Π is a subset of $\Gamma^* \times \mathbb{N}$, where Γ is a finite alphabet. An instance of a parameterized problem is a tuple (x, k), where x is a classical problem instance, and k is called the parameter. A central notion in parameterized complexity is *Fixed Parameter Tractability (FPT)*. A parameterized problem Π is in FPT if there is an algorithm that takes an instance (x, k) and decides if $(x, k) \in \Pi$ in time $f(k) \cdot |x|^{\mathcal{O}(1)}$. Here, f is an arbitrary function of k. Such an algorithm is called a *Fixed Parameter Tractable* algorithm and, in short, an FPT algorithm.

Kernelization. A kernelization algorithm for a parameterized problem $\Pi \subseteq \Gamma^* \times \mathbb{N}$ is an algorithm that, given $(x, k) \in \Gamma^* \times \mathbb{N}$, outputs, in time polynomial in $|x| + k$, a pair $(x', k') \in \Gamma^* \times \mathbb{N}$ such that (a) $(x, k) \in \Pi$ if and only if $(x', k') \in \Pi$ and (b) $|x'|, k' \leq g(k)$, where g is some computable function. The output instance x' is called the kernel, and the function g is referred to as the size of the kernel. If $g(k) = k^{\mathcal{O}(1)}$ then we say that Π has a polynomial kernel.

Lower bounds in Kernelization. In recent years, several techniques have been developed to show that certain parameterized problems cannot have any polynomial sized kernel unless some classical complexity assumptions are violated. One such technique is the *polynomial parameter transformation.*

▶ **Definition 6.** Let Π, Γ be two parameterized problems. A polynomial time algorithm $\mathcal{A}$ is called a polynomial parameter transformation (or ppt) from Π to Γ if , given an instance (x, k) of Π, $\mathcal{A}$ outputs in polynomial time an instance (x', k') of Γ such that $(x, k) \in \Pi$ if and only if $(x', k') \in \Gamma$ and $k' \leq k^{\mathcal{O}(1)}$.

We use the following theorem together with ppt reductions to rule out polynomial kernels.

▶ **Proposition 7** ([3]). *Let Π, Γ be two parameterized problems such that Π is* NP*-hard, $\Gamma \in$ NP and there exists a polynomial parameter transformation from Π to Γ. Then, if Π does not admit a polynomial kernel neither does Γ.*

▶ **Proposition 8** ([11]). CNF-SAT *is* FPT *parameterized by the number of variables; however, it does not admit a polynomial kernel unless* NP $\subseteq$ co-NP*/poly.*

3 FPT algorithm for Vertex Partization

In this section, we show that Vertex Partization on perfect graphs is FPT, using the iterative compression technique. Let (G, r, ℓ, k) be an input instance of Vertex Partization on perfect graphs, and let $V(G) = \{v_1, \ldots, v_n\}$. We define, for every $1 \leq i \leq n$, the vertex set $V_i = \{v_1, \ldots, v_i\}$. Let G_i denote $G[V_i]$. Let $i_0 = r + \ell + k + 1$. We iterate through the instances (G_i, r, ℓ, k) starting from $i = i_0$. Given the i^{th} instance and a known (r, ℓ)-vertex deletion set S'_i of size at most $k+1$, our objective is to obtain an (r, ℓ)-vertex deletion set S_i of size at most k. The formal definition of this compression problem is as follows.

Vertex Partization Compression **Parameter:** r, ℓ, k
Input: A perfect graph G, non-negative integers r, ℓ, k and a $k+1$-sized vertex subset S' such that $G - S'$ is an (r, ℓ)-graph, along with an IC-partition (Q_1, Q_2) of $G - S'$.
Output: A vertex subset $S \subseteq V(G)$ of size at most k such that $G - S$ is an (r, ℓ)-graph, and an IC-partition (P_1, P_2) of $G - S$.

Before we solve Vertex Partization Compression, we explain how to reduce the Vertex Partization problem to $n-(r+\ell+k+1)+1$ instances of the Vertex Partization Compression problem on G_i, from $i = i_0$ to $i = n$. For the graph G_{i_0}, the set V_{k+1} is a (r, ℓ)-vertex deletion set, S'_i, of size $k+1$. The graph $G_{i_0} - V_{k+1}$ has $r + \ell$ vertices. We set $Q_1^{i_0}$ to be a set of any r vertices of $V_{i_0} - V_{k+1}$ and $Q_2^{i_0}$ to be the remaining set of ℓ vertices; that is, $Q_2^{i_0} = V_{i_0} - V_{k+1} - Q_1^{i_0}$. Now, let $I_i = (G_i, r, \ell, k, S'_i, (Q_1^i, Q_2^i))$ be the i^{th} instance of Vertex Partization Compression. If S_{i-1} is a k-sized solution for I_{i-1}, then $S_{i-1} \cup \{v_i\}$ is a $(k+1)$-sized (r, ℓ)-vertex deletion set for G_i. So, the iteration begins with the instance $I_{i_0} = (G_{i_0}, r, \ell, k, V_{k+1}, (Q_1^{i_0}, Q_2^{i_0}))$ and we try to obtain an (r, ℓ)-vertex deletion set of size at most k. If such a solution S_{i_0} exists, we set $S'_{i_0+1} = S_{i_0} \cup \{v_{i_0+1}\}$ and ask for a k-sized solution for the instance I_{i_0+1}. We continue in this manner. If, during any iteration, the corresponding instance does not have an (r, ℓ)-vertex deletion set of size at most k, then this implies that the original instance (G, r, ℓ, k) is a NO instance for Vertex Partization. If S_n is a k-sized (r, ℓ)-vertex deletion set for G_n, where $G_n = G$, then clearly (G, r, ℓ, k) is YES instance of Vertex Partization. Since there are at most $n - (r + \ell + k + 1) + 1$ iterations, the total time taken by the algorithm to solve Vertex Partization is at most

$n - (r + \ell + k + 1) + 1$ times the time taken to solve Vertex Partization Compression. Thus, if Vertex Partization Compression is FPT, it follows that Vertex Partization is FPT.

We can also *view* the input graph G of an instance of Vertex Partization Compression as an $(r+k+1, \ell)$-graph with IC-partition $(Q_1 \cup S', Q_2)$. Equivalently, Vertex Partization Compression has an input positive integers r, ℓ, k and a graph G that is an $(r + k + 1, \ell)$-graph and the objective is to decide whether there is a k-sized set $S \subseteq V(G)$ such that $G - S$ is an (r, ℓ)-graph. This view point allows us to design an FPT algorithm for Vertex Partization Compression. Towards that we first define some notations. Let G be a graph and $V(G) = \{v_1, \ldots, v_n\}$. For partition $P = (A, B)$ of $V(G)$ we define an n-length bit vector B_P^G corresponding to P as follows. We set the i^{th} bit to 0 if $v_i \in A$ and to 1 otherwise. For two n-length bit vectors $a = a_1 \ldots a_n$ and $b = b_1 \ldots b_n$, the Hamming distance between a and b, denoted by $\mathcal{H}(a, b)$, is the number of indices on which a and b mismatches. That is, $\mathcal{H}(a, b) = |\{(a_i, b_i) \; | a_i \neq b_i, i \in [n] \; \}|$. The Hamming distance for the bitvectors corresponding to two IC-partitions, of a graph, is bounded as given by the following proposition.

▶ **Proposition 9** ([15]). *Let G be a graph. Let Q be an IC-partition of G that realizes G as an (r', ℓ')-graph and P is an IC-partition of G that realizes G as an (r, ℓ)-graph. Then $\mathcal{H}(B_Q^G, B_P^G) \leq r'\ell + r\ell'$.*

The following lemma follows from Proposition 9.

▶ **Lemma 10.** *Let G be a perfect graph and (Q_1, Q_2) be an IC-partition that realizes G as an (r', ℓ')-graph. Let S be an (r, ℓ)-vertex deletion set for G such that P is an IC-partition of G that realizes $G - S$ as an (r, ℓ)-graph and let $Q = (Q_1 \setminus S, Q_2 \setminus S)$. Then $\mathcal{H}(B_Q^{G-S}, B_P^{G-S}) \leq r'\ell + r\ell'$.*

Lemma 10 implies that to solve Vertex Partization Compression it is enough to solve the following problem.

Short Vertex Partization **Parameter:** r, ℓ, k, ρ
Input: A perfect graph G, positive integers r, ℓ, k, ρ, and a partition $Q = (Q_1, Q_2)$ of $V(G)$.
Output: A vertex subset $S \subseteq V(G)$ of size at most k such that $G - S$ is a (r, ℓ)-graph, and an IC-partition (P_1, P_2) of $G - S$ such that $\mathcal{H}(B_P^{G-S}, B_{Q'}^{G-S}) \leq \rho$ where $Q' = (Q_1 \setminus S, Q_2 \setminus S)$.

▶ **Lemma 11.** Short Vertex Partization *is* FPT.

Proof. We design a recursive algorithm $\mathcal{A}$ for Short Vertex Partization which takes a tuple $(G, r, \ell, k, \rho, Q = (Q_1, Q_2))$ as input, where G is a graph, Q is a partition of $V(G)$ and r, ℓ, k, ρ are integers. It outputs a k-sized (r, ℓ)-vertex deletion set S of G and an IC-partition P that realizes that $G - S$ is (r, ℓ)-graph such that $\mathcal{H}(B_P^{G-S}, B_{Q'}^{G-S}) \leq \rho$, where $Q' = (Q_1 \setminus S, Q_2 \setminus S)$, if such a tuple (S, P) exists, otherwise returns NO. The following are the steps of the recursive algorithm $\mathcal{A}$ on input $(G, r, \ell, k, Q = (Q_1, Q_2), \rho)$.

1. If $k < 0$ or $\rho < 0$ then output NO.
2. If $G[Q_1]$ is r-colorable and $\overline{G}[Q_2]$ is ℓ-colorable, then return $(\emptyset, Q)$.
3. If $G[Q_1]$ is not r-colorable, then there is an $r + 1$-sized clique in $G[Q_1]$. By Proposition 5, we can find such a $r + 1$-sized clique C in polynomial time. Make the following recursive calls to $\mathcal{A}$:

(a) For every vertex $v \in V(C)$, do a recursive call $\mathcal{A}(G-v, r, \ell, k-1, \rho, (Q_1 \setminus \{v\}, Q_2 \setminus \{v\}))$ and if the recursive call returns (S', P) then return $(S' \cup \{v\}, P)$ as output.
(b) For every vertex $v \in V(C)$, do a recursive call $\mathcal{A}(G, r, \ell, k, \rho - 1, (Q_1 \setminus \{v\}, Q_2 \cup \{v\}))$ and if the recursive call returns (S', P) then return (S', P) as output.

If all the recursive calls above (in Step 3) return NO, then return NO.

4 If $\overline{G}[Q_2]$ is not ℓ-colorable, then there is clique of size $\ell + 1$ in $\overline{G}[Q_2]$. Thus, using Proposition 5, we can find an $\ell + 1$-sized independent set I in $G[Q_2]$. Make the following recursive calls of the algorithm:
(a) For every vertex $v \in V(I)$, do a recursive call $\mathcal{A}(G-v, r, \ell, k-1, \rho, (Q_1 \setminus \{v\}, Q_2 \setminus \{v\}))$ and if the recursive call returns (S', P) then return $(S' \cup \{v\}, P)$ as output.
(b) For every vertex $v \in V(I)$, do a recursive call $\mathcal{A}(G, r, \ell, k, \rho - 1, (Q_1 \cup \{v\}, Q_2 \setminus \{v\}))$ and if the recursive call returns (S', P) then return (S', P) as output.

If all the recursive calls above (in Step 4) return NO, then return NO.

We now prove that the recursive algorithm $\mathcal{A}$ is correct. We show that if $(G, r, \ell, k, \rho, (Q_1, Q_2))$ is a YES instance of Short Vertex Partization, then the algorithm $\mathcal{A}$ will output correct solution. We prove this by induction on $k + \rho$.

1. Base case: $k = 0$ and $\rho = 0$. Since $(G, r, \ell, k, \rho, (Q_1, Q_2))$ is a YES instance, (Q_1, Q_2) is an IC-partition which realizes that G is an (r, ℓ)-graph. In Step 2 of the algorithm $\mathcal{A}$ we output $(\emptyset, (Q_1, Q_2))$ as the output.
2. By induction hypothesis we assume that $\mathcal{A}$ outputs the correct answer when $k + \rho < \gamma$, where $\gamma \geq 0$. Now we need to show that $\mathcal{A}$ outputs correct answer when $k + \rho = \gamma$. Let $(G, r, \ell, k, \rho, Q = (Q_1, Q_2))$ be the input of $\mathcal{A}$ such that $k + \rho = \gamma$. Let $(S, (P_1, P_2))$ be a solution of Short Vertex Partization. If $S = \emptyset$ and $(P_1, P_2) = (Q_1, Q_2)$ then in Step 2, algorithm $\mathcal{A}$ will output $(\emptyset, Q)$. Otherwise either $G[Q_1]$ is not r-colorable or $\overline{G}[Q_2]$ is not ℓ-colorable.
3. Case 1: Suppose $G[Q_1]$ is not r-colorable. Then there is a clique C of size $r + 1$ in $G[Q_1]$. In this case at least one vertex v from C either belongs to S or does not belong to P_1. If $v \in S$, then consider the recursive call $\mathcal{A}(G - v, r, \ell, k - 1, \rho, (Q_1 \setminus \{v\}, Q_2 \setminus \{v\})$. By induction hypothesis $\mathcal{A}(G-v, r, \ell, k-1, \rho, (Q_1 \setminus \{v\}, Q_2 \setminus \{v\})$ will return (S', P') such that S' is a $k - 1$ sized (r, ℓ)-vertex deletion set of $G - \{v\}$ such that $\mathcal{H}(B_{P'}^{G-S'}, B_{Q'}^{G-S'}) \leq \rho$, where $Q' = (Q_1 \setminus (S' \cup \{v\}), Q_2 \setminus (S' \cup \{v\}))$. Hence in Step $3(a)$, algorithm $\mathcal{A}$ will output $(S' \cup \{v\}, P)$ and this is a solution for Short Vertex Partization on input $(G, r, \ell, k, \rho, (Q_1, Q_2))$.
If $v \notin S$, then $v \notin P_1$ as well. Now consider the recursive call $\mathcal{A}(G, r, \ell, k, \rho - 1, (Q_1 \setminus \{v\}, Q_2 \cup \{v\})$. By induction hypothesis $\mathcal{A}(G, r, \ell, k, \rho - 1, (Q_1 \setminus \{v\}, Q_2 \cup \{v\})$ will return (S'', P'') such that S'' is a k sized (r, ℓ)-vertex deletion set of G such that $\mathcal{H}(B_{P''}^{G-S''}, B_{Q'}^{G-S''}) \leq \rho - 1$, where $Q' = ((Q_1 \setminus \{v\}) \setminus S'', (Q_2 \cup \{v\}) \setminus S'')$. Hence in Step $3(b)$, algorithm $\mathcal{A}$ will output (S'', P''). Clearly S'' is a k sized (r, ℓ)-vertex deletion set of G''. Now we show that $\mathcal{H}(B_{P''}^{G-S''}, B_{Q''}^{G-S''}) \leq \rho$, where $Q'' = (Q_1 \setminus S'', Q_2 \setminus S'')$. Note that $\mathcal{H}(B_{Q'}^{G-S''}, B_{Q''}^{G-S''}) \leq 1$. Since $\mathcal{H}(B_{P''}^{G-S''}, B_{Q'}^{G-S''}) \leq \rho - 1$ and $\mathcal{H}(B_{Q'}^{G-S''}, B_{Q''}^{G-S''}) \leq 1$, we have that
$\mathcal{H}(B_{P''}^{G-S''}, B_{Q''}^{G-S''}) \leq \rho$
4. Case 2: $\overline{G}[Q_2]$ is not ℓ-colorable. This case is symmetric to Case 1.

In the reverse direction we need to show that if the algorithm $\mathcal{A}$ returns YES then indeed the given instance is a YES instance. The proof of reverse direction is similar to the proof of forward direction. Again, we induct on $k + \rho$. The algorithm returns a bipartition as evidence of a YES instance. We show that this bipartition is the required IC-partition. Such a bipartition is returned in Steps 2, $3(a), (b)$ and $4(a), (b)$. By description of the algorithm, both $k, \rho \geq 0$ in order for the algorithm to return YES. In the base case, $k = \rho = 0$. Here, it must be the case that Step 2 is executed and the output bipartition is Q itself, while the output vertex deletion set is $\emptyset$. In this case, by definition Q is an IC-partition. Hence, Q is evidence that the input graph G is already an (r, ℓ)-graph and does not require any vertex to be deleted. Thus, in the base case, we correctly determine that the given input instance is a YES instance.

By induction hypothesis we assume that $\mathcal{A}$ outputs the correct answer when $k + \rho < \gamma$, where $\gamma \geq 0$. Now we need to show that if $\mathcal{A}$ outputs a bipartition P and a vertex set S when $k + \rho = \gamma$, then the vertex set S is an (r, ℓ)-vertex deletion set while the bipartition is an IC-partition of $G - S$. If the bipartition is output in Step 2, then by definition the input graph is already an (r, ℓ)-graph. Otherwise, a recursive call is made to an instance where $k + \rho$ is strictly smaller. By induction hypothesis, the recursive call returns an (r, ℓ)-vertex deletion set S' and a witnessing IC-partition of $G - S'$. It follows that the vertex set S and the bipartition output by the algorithm, on the current input instance, is an (r, ℓ)-vertex deletion set of size at most k, and an IC-partition respectively for the input instance. This completes the proof of correctness of the algorithm.

What remains is the running time analysis. Note that when $k < 0$ or $\rho < 0$, then the algorithm will stop in a single step. Each recursive call either decreases k by 1 or ρ by 1. Hence the depth of the recursion tree is bounded by $k + \rho + 1$. Note that in Step 3 we make at most $2(r + 1)$ recursive calls and in Step 4 we make at most $2(\ell + 1)$ recursive calls. Hence the total running time of the algorithm $\mathcal{A}$ is bounded by $\mathcal{O}(\max\{(2(r+1))^{k+\rho+1} n^{\mathcal{O}(1)}, (2(\ell + 1))^{k+\rho+1} n^{\mathcal{O}(1)}\})$. ◀

Vertex Partization Compression is a special case of Short Vertex Partization when $\rho = (r + k + 1)\ell + r\ell$. Therefore, we have the following theorem.

▶ **Theorem 12.** Vertex Partization *on perfect graphs has an* FPT *algorithm with running time* $2^{\mathcal{O}((k+r)\ell \log(r+\ell))} n^{\mathcal{O}(1)}$.

4 Kernel lower bound for Vertex Partization

In this section, we show that Vertex Partization on perfect graphs does not have polynomial kernels. Partization Recognition on perfect graphs, when parameterized by $r + \ell$, was shown to be FPT in [15]. Our proof implies that Partization Recognition on perfect graphs cannot have a polynomial kernel, when parameterized by $r + \ell$, unless NP $\subseteq$ co-NP/poly.

▶ **Theorem 13.** Partization Recognition *on perfect graphs, when parameterized by* $r + \ell$, *does not have a polynomial kernel unless* NP $\subseteq$ co-NP*/poly.*

Proof. We prove the theorem by giving a polynomial parameter transformation from CNF-SAT parameterized by the number of variables. From Proposition 8, we know that CNF-SAT, parameterized by the number of variables, does not have a polynomial kernel unless NP $\subseteq$ co-NP/poly [11]. Then the proof of the theorem follows from Proposition 7. We start with an instance (ϕ, n) of CNF-SAT, where ϕ is a CNF formula with m clauses and n variables. Without loss of generality, we assume that there is no clause where both literals of a variable appear together, since such a clause will be satisfied by any assignment and hence can be removed. The polynomial parameter transformation produces an instance $(G, n, 1)$ of

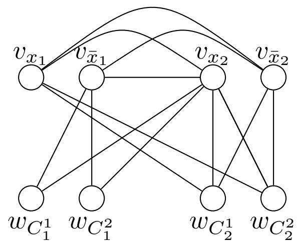

Figure 1 An illustration of the construction of the graph G in Theorem 13 for the formula $\phi = (x_1 \vee \overline{x}_2) \wedge (\overline{x}_1)$. Here $C_1 = (x_1 \vee \overline{x}_2)$ and $C_2 = (\overline{x}_1)$.

Partization Recognition, where G is a perfect graph, such that (ϕ, n) is a YES instance of CNF-SAT if and only if $(G, n, 1)$ is a YES instance of Partization Recognition. Let $\mathcal{C} = \{C_1, \ldots, C_m\}$, $X = \{x_1, \ldots, x_n\}$ and $L = \{x_1, \bar{x}_1, \ldots, x_n, \bar{x}_n\}$ be the set of clauses, variables and literals of ϕ respectively. The construction of the graph G from the formula ϕ is as follows (illustrated in Figure 1):

1. For each variable x, we create two vertices $v_x, v_{\bar{x}}$ which represent the literals $x, \bar{x}$. We call them the literal vertices. More specifically, we call v_x the positive literal vertex and $v_{\bar{x}}$ the negative literal vertex.
2. For each clause C, we create two vertices w_C^1, w_C^2. We call these the clause vertices corresponding to the clause C.
3. For each pair of variables x, y, we add the edges $(v_x, v_y), (v_{\bar{x}}, v_y), (v_x, v_{\bar{y}})$, and $(v_{\bar{x}}, v_{\bar{y}})$. Notice that $(v_x, v_{\bar{x}})$ and $(v_y, v_{\bar{y}})$ are non-edges.
4. For each clause C and each literal $q \in L$, if $q \notin C$, we add edges (x_q, w_C^1) and (x_q, w_C^2). In other words if a literal q' belongs to a clause C, then $(q', w_C^1), (q', w_C^2) \notin E(G)$ So, there is a complete bipartite graph between $L \setminus C$ and $\{w_C^1, w_C^2\}$.

In short, the vertex set and edge set of G is defined as follows (note that for a literal x, if $x = \bar{y}$, then $y = \bar{x}$).

$$\begin{aligned} V(G) &= \{v_x, v_{\bar{x}} \mid x \in X\} \cup \{w_C^1, w_C^2 \mid C \in \mathcal{C}\} \\ E(G) &= \{(v_x, v_y) \mid x, y \in L, x \neq \bar{y}\} \cup \{(w_C^1, v_x), (w_C^2, v_x) \mid x \in L, x \notin C, C \in \mathcal{C}\} \end{aligned}$$

Let $V_X = \{v_x, v_{\bar{x}} \mid x \in X\}$ and $V_{\mathcal{C}} = \{w_C^1, w_C^2 \mid C \in \mathcal{C}\}$. Note that the set of vertices $V_{\mathcal{C}}$ corresponding to the clauses forms an independent set in G. First we show that G is a perfect graph.

▶ **Claim 14.** *The graph $\overline{G}$ does not contain an induced odd cycle of length ≥ 5.*

Proof. We first prove that there is no path of length 2 (path on 3 vertices) in $\overline{G}[V_X]$. Note that $E(\overline{G}[V_X]) = \{(v_x, v_{\bar{x}}) \mid x \in X\}$. This implies that the degree of each vertex in the graph $\overline{G}[V_X]$ is exactly equal to 1. Hence, there is no path of length 2 in $\overline{G}[V_X]$. Also, since $V_{\mathcal{C}}$ forms a clique in $\overline{G}$, any induced cycle of length at least 5 in $\overline{G}$ will either contain a vertex or an edge from $V_{\mathcal{C}}$.

Let C' be an induced odd cycle of length at least 5 in $\overline{G}$. There will be at most two vertices from $V_{\mathcal{C}}$ which are part of C' and these vertices will appear consecutively in C'. This implies that C' contains a path of length at least 2 using only vertices from V_X in $\overline{G}$, which is a contradiction. ◀

▶ **Claim 15.** *The graph G does not contain an induced odd cycle of length ≥ 5.*

Proof. We first show that any induced odd cycle of length at least 5 can contain at most 3 vertices from V_X. Suppose not. Let C' be an induced odd cycle of length at least 5 such that $|V(C') \cap V_X| \geq 4$. Let v_w, v_x, v_y, v_z be four distinct vertices from $V(C') \cap V_X$ appearing in that order, if we go around the cycle in a clockwise manner. That is, there are paths $v_w - v_x$, $v_x - v_y$, $v_y - v_z$ in C'. Since C' is an induced cycle, there is no edge (v_w, v_y) in $E(G)$. This implies that $y = \bar{w}$. By similar arguments, we can show that $x = \bar{z}$. This implies that $v_w v_x v_y v_z v_w$ form a cycle of length 4 in G, contradicting the fact that C' is induced odd cycle containing v_w, v_x, v_y and v_z. Hence any induced odd cycle of length at least 5 can contain at most 3 vertices from V_X.

Since $V_{\mathcal{C}}$ is an independent set in G, no two vertices from $V_{\mathcal{C}}$ can occur as consecutive vertices in any cycle. Let C' be an induced odd cycle of length at least 5 in G. Since $|V(C') \cap V_X| \leq 3$ and no two vertices from $V_{\mathcal{C}}$ appear as consecutive vertices in C', it must be the case that $|V(C') \cap V_{\mathcal{C}}| \leq 2$. This implies that the length of C' is exactly equal to 5 and C' is of the form $v_x w^i_{C_1} v_y w^j_{C_2} v_z v_x$, where $i, j \in \{1, 2\}$. Since C' is an induced cycle $(v_x, v_y), (v_y, v_z) \notin E(G)$. This implies that $y = \bar{x} = z$ and hence $v_y = v_z$. This contradicts the fact that C' is a cycle. This completes the proof of the claim. ◀

Proposition 3 and Claims 14 and 15 imply that G is a perfect graph. We now show that (ϕ, n) is a YES instance of CNF-SAT if and only if $(G, n, 1)$ is a YES instance of Partization Recognition.

First, suppose that (ϕ, n) is a YES instance of CNF-SAT. Then there is an assignment τ, such that every clause has at least one literal set to 1. Let $f : \mathcal{C} \to X$ be a map that arbitrarily maps one such satisfying literal to each clause. Note that for a clause C, $(w^1_C, v_{f(C)}), (w^2_C, v_{f(C)}) \notin E(G)$, because $f(C) \in C$. Now we construct n independent sets as follows. For each literal y, if $\tau(y) = 1$, let $I_y = \{w^1_C, w^2_C \mid f(C) = y\} \cup \{v_y\}$. Since $V_{\mathcal{C}}$ is an independent set $I_y \setminus \{v_y\}$ is an independent set. Note that for all $w^i_C \in I_y$, $i \in \{1, 2\}$ we have that $(w^i_C, v_y) \notin E(G)$, because $f(C) = y$ and $y \in C$. This implies that I_y is an independent set. Since τ is an assignment, exactly one of the literals of each variable is assigned 1 by τ. Thus, in this way we form n independent sets. Since τ is a satisfying assignment for ϕ, the function f maps each clause C to a literal which is assigned 1 by τ. This implies that all vertices in $V_{\mathcal{C}}$ are covered by the independent sets constructed above. The vertices in the graph G, which are not covered by the independent sets constructed, correspond to the literals that have been set to 0 by τ. By construction of G and by the definition of an assignment τ, these vertices form a clique. Hence, $(G, n, 1)$ is an YES instance of Partization Recognition.

Conversely, suppose $(G, n, 1)$ is a YES instance of Partization Recognition. Then there is an (r, ℓ)-partition $\mathcal{P}$ of G. Let $I_1, \ldots, I_n$ be n independent sets and K be a clique in the (r, ℓ)-partition $\mathcal{P}$. It is not possible, by construction of G, that there is a variable x such that both v_x and $v_{\bar{x}}$ belong to the clique K, because $(v_x, v_{\bar{x}}) \notin E(G)$. As there is only one clique in $\mathcal{P}$, at most one literal of each variable can be contained in the clique K of $\mathcal{P}$. Hence, for each variable x either v_x or $v_{\bar{x}}$ is part of an independent set in $\mathcal{P}$. Furthermore, since for two literals p and q such that $p \neq \bar{q}$, $(v_p, v_q) \in E(G)$, any independent set I in $\mathcal{P}$ cannot contain both v_p and v_q. This implies that each of the n independent sets can be identified by a variable $x \in X$. Since there are only n independent sets in $\mathcal{P}$, there cannot be a variable x such that both v_x and $v_{\bar{x}}$ are part of distinct independent sets in $\mathcal{P}$. Thus the construction of G forces only two possibilities for each variable:

(a) there is exactly one literal vertex that is part of an independent set while the other one belong to the clique K, or

(b) both literals together form an independent set.

Now we construct an assignment τ and show that τ is a satisfying assignment for ϕ. For a literal z, if $v_z \in K$, then we set $\tau(z) = 0$. If for a variable x, both vertices v_x and $v_{\bar{x}}$ do not belong to K then we set $\tau(x) = 1$. Now we show that τ is a satisfying assignment for ϕ. Let C be a clause in the formula ϕ. Since $(w_C^1, w_C^2) \notin E(G)$ at least one of w_C^1 or w_C^2 belongs to an independent set I in $\mathcal{P}$. Let $w_C^i \in I$, where $i \in \{1, 2\}$. We have shown that each independent set contains at least one vertex corresponding to a literal y. Since v_y and w_C^i belong to I, we have that $(v_z, w_C^i) \notin E(G)$. This implies that $y \in C$. Furthermore, this implies that $v_{\bar{y}} \notin I$ as no clause contains both y and $\bar{y}$. Hence, $v_{\bar{y}}$ is in K and $\tau(\bar{y}) = 0$. This implies that y is set to 1 and hence the clause C is satisfied. This proves that τ is a satisfying assignment for ϕ. ◀

Note that Partization Recognition is same as Vertex Partization, when $k = 0$. Hence we get the following corollary.

▶ **Corollary 16.** Vertex Partization *parameterized by* $k + r + \ell$ *on perfect graphs does not have a polynomial kernel unless* NP $\subseteq$ co-NP*/poly.*

5 Polynomial kernel when r and ℓ are constants

We saw that there is no polynomial kernel for Vertex Partization, unless NP $\subseteq$ co-NP/poly. The parameter for this problem is $k+r+\ell$, where the size of the deletion set is at most k and the final graph is an (r, ℓ)-graph. In this section, we consider the Vertex (r, ℓ) Partization problem on perfect graphs, which is a special case of Vertex Partization on perfect graphs. Here, for a given pair of fixed positive constants (r, ℓ), we take a perfect graph G and a positive integer k as input and decide whether there is a vertex set S of size at most k the deletion of which results in an (r, ℓ)-graph. This simplified problem has a polynomial kernel, as shown below.

We first observe that when perfect graphs are (r, ℓ)-graphs, this class coincides with another graph class, namely the class of perfect graphs that are (r, ℓ)-split graphs. The notion of (r, ℓ)-split graphs was introduced in [14].

▶ **Definition 17** ((r, ℓ)-split graph). A graph G is an (r, ℓ)-split graph if its vertex set can be partitioned into V_1 and V_2 such that the size of a largest clique in $G[V_1]$ is bounded by r and the size of a largest independent set in $G[V_2]$ is bounded by ℓ. We call such a partition, (V_1, V_2), an (r, ℓ)-split partition.

From the definition of (r, ℓ)-split graph, it follows that any (r, ℓ)-graph is also an (r, ℓ)-split graph.

▶ **Lemma 18.** *Let G be a perfect graph. If G is an (r, ℓ)-split graph, then G is also an (r, ℓ)-graph.*

Proof. Since G is a perfect graph, for any induced subgraph G' of G, the chromatic number of G' ($\chi(G')$) is equal to the cardinality of a maximum sized clique of G' ($\omega(G')$). We know that G is an (r, ℓ)-split graph. Let (P_1, P_2) be an (r, ℓ)-split partition with $\omega(G[P_1]) \leq r$ and $\alpha(G[P_2]) \leq \ell$ Now we show that (P_1, P_2) is indeed an (r, ℓ)-partition of G. Since G is a perfect graph, the graphs $G[P_1]$ and $\overline{G}[P_2]$ are perfect graphs. Since $G[P_1]$ is a perfect graph and $w(G[P_1]) \leq r$, $\chi(G[P_1]) \leq r$. This implies that P_1 can be partitioned into r independent sets. Since $\overline{G}[P_2]$ is a perfect graph and $\alpha(G[P_2]) \leq \ell$, $w(\overline{G}[P_2]) \leq \ell$ and hence $\chi(\overline{G}[P_2]) \leq \ell$. This implies that P_2 can be partitioned into ℓ sets such that each set is independent in $\overline{G}[P_2]$. Hence P_2 can be partitioned into ℓ cliques in $G[P_2]$. So (P_1, P_2) is an (r, ℓ)-partition of G. This completes the proof of the lemma. ◀

For any fixed r and ℓ, there is a finite forbidden set $\mathbb{F}_{r,\ell}$ for (r, ℓ)-split graphs [14]. That is, a graph G is an (r, ℓ)-split graph if and only if G does not contain any graph $H \in \mathbb{F}_{r,\ell}$ as an induced subgraph. The size of the largest forbidden graph is bounded by $f(r, \ell)$, f being a function given in [14]. In [18], a bound was given for the number of minimal forbidden perfect graphs. This function, say $g(r, \ell)$, has a bound of $2(\ell+1)(R(r(\ell+1), (r(l+1))^2+r(l+1)+3)+1)$. Since $g(r, \ell)$ is a constant, it is possible to compute the forbidden set $\mathbb{F}'_{r,\ell}$ of perfect forbidden graphs in polynomial time. Thus, the class of perfect (r, ℓ)-graphs has a refined finite forbidden characterization. This implies that Vertex (r, ℓ) Partization on perfect graphs reduces to the d-Hitting Set problem, where d is the constant $g(r, \ell)$. In an equivalent d-Hitting Set instance, the universe will be the set of vertices of the input graph G, while the family of sets will be the vertex sets of induced subgraphs of G that are isomorphic to a forbidden graph. The set sizes are bounded by $g(r, \ell)$. Hence, by [1], this problem has a polynomial kernel. This gives us the following theorem.

▶ **Theorem 19.** Vertex (r, ℓ) Partization *on perfect graphs admits a kernel of size* $k^{\mathcal{O}(d)}$ *and has an algorithm with running time* $d^k n^{\mathcal{O}(d)}$. *Here,* $d = g(r, \ell)$.

6 Conclusion

In this paper we studied the Vertex Partization problem on perfect graphs, and showed that it is FPT and does not admit a polynomial kernel. Furthermore, we observed that Vertex (r, ℓ) Partization has an induced finite forbidden characterization and utilized that to give a faster FPT algorithm and a polynomial kernel for the problem. However, the algorithms for Vertex (r, ℓ) Partization has a factor of $n^{\mathcal{O}(d)}$, where d depends on the size of a largest graph in the finite forbidden set. It would be interesting to replace the factor $n^{\mathcal{O}(d)}$ by $\tau(d) \cdot n^{\mathcal{O}(1)}$.

Abstract

The ZX-calculus is a powerful diagrammatic language for quantum mechanics and quantum information processing. We prove that its $\frac{\pi}{4}$-fragment is not complete, in other words the ZX-calculus is not complete for the so called "Clifford+T quantum mechanics". The completeness of this fragment was one of the main open problems in *categorical quantum mechanics*, a programme initiated by Abramsky and Coecke. The ZX-calculus was known to be incomplete for quantum mechanics. On the other hand, its $\frac{\pi}{2}$-fragment is known to be complete, i.e. the ZX-calculus is complete for the so called "stabilizer quantum mechanics". Deciding whether its $\frac{\pi}{4}$-fragment is complete is a crucial step in the development of the ZX-calculus since this fragment is approximately universal for quantum mechanics, contrary to the $\frac{\pi}{2}$-fragment.

To establish our incompleteness result, we consider a fairly simple property of quantum states called supplementarity. We show that supplementarity can be derived in the ZX-calculus if and only if the angles involved in this equation are multiples of $\pi/2$. In particular, the impossibility to derive supplementarity for $\pi/4$ implies the incompleteness of the ZX-calculus for Clifford+T quantum mechanics. As a consequence, we propose to add the supplementarity to the set of rules of the ZX-calculus.

We also show that if a ZX-diagram involves antiphase twins, they can be merged when the ZX-calculus is augmented with the supplementarity rule. Merging antiphase twins makes diagrammatic reasoning much easier and provides a purely graphical meaning to the supplementarity rule.

1 Introduction

The ZX-calculus has been introduced by Coecke and Duncan [7] as a graphical language for pure state qubit quantum mechanics where each diagram can be interpreted as a linear map or a matrix in a typical way (so-called *standard interpretation*). Intuitively, a ZX-diagram

* This work was partially supported by Région Lorraine.

is made of three kinds of vertices: , , and , where each green or red vertex is parameterised by an angle.

Unlike the quantum circuit notation which has no transformation rules, the ZX-calculus combines the advantages of being intuitive with a built-in system of rewrite rules. These rewrite rules make the ZX-calculus into a formal system with nontrivial equalities between diagrams. As shown in [7], the ZX-calculus can be used to express any operation in pure state qubit quantum mechanics, i.e. it is *universal*. Furthermore, any equality derived in the ZX-calculus can also be derived in the standard matrix mechanics, i.e. it is *sound*.

The converse of soundness is *completeness*. Informally put, the ZX-calculus would be complete if any equality that can be derived using matrices can also be derived graphically. It has been shown in [15] that the ZX-calculus is incomplete for the overall pure state qubit quantum mechanics, and there is no way on how to complete it by now. However, some fragments of the ZX-calculus are known to be complete. The $\frac{\pi}{2}$-fragment, which corresponds to diagrams involving angles multiple of $\pi/2$, is complete [1]. This fragment corresponds to the so called stabilizer quantum mechanics [14]. The π-fragment is also complete [12] and corresponds to real stabilizer quantum mechanics. Meanwhile, the stabilizer completeness proof in [1] carries over to a ZX-like graphical calculus for Spekkens′ toy theory [4].

While it is an important and active area of research, stabilizer quantum mechanics is only a small part of all quantum mechanics. In particular stabilizer quantum mechanics is not universal, even approximately. This fragment is even efficiently simulatable on a classical computer. On the contrary, the $\frac{\pi}{4}$-fragment, which corresponds to the so-called "Clifford+T quantum mechanics" is approximately universal [6]: any unitary transformation can be approximated with an arbitrary precision by a diagram involving angles multiple of $\pi/4$ only. The $\frac{\pi}{4}$-fragment corresponds actually to the post selected Clifford+T quantum mechanics: any diagram of the $\frac{\pi}{4}$-fragment can be interpreted as a composition of: (*i*) preparations of qubits in the computational basis; (*ii*) "Clifford+T" unitary transformations; (*iii*) post selected measurements in the computational basis. Post selected measurements, which are noting but projections, are useful to compute the probability that a given computation produces a given output. An actual quantum measurement which, roughly speaking, consists in applying with some probability a projector among a complete set of projectors, can also be represented as a ZX-diagram using formal variables as described in [11].

The completeness of the $\frac{\pi}{4}$-fragment is a crucial property and has even been stated as one of the major open question in the categorical approach to quantum mechanics [1, 2, 17]. A partial result has been proved in [2]: the fragment composed of path diagrams involving angles multiple of $\pi/4$ is complete.

Our main contribution is to prove that the $\frac{\pi}{4}$-fragment of the ZX-calculus is incomplete. In other words, we prove that the ZX-calculus is not complete for the "Clifford+T quantum mechanics". To this end, we consider a simple equation called supplementarity. This equation is inspired by a work by Coecke and Edwards [8] on the structures of quantum entanglement. We show that supplementarity can be derived in the ZX-calculus if and only if the angles involved in this equation are multiples of $\pi/2$. In particular, the impossibility to derive this equation for $\pi/4$ implies the incompleteness of the ZX-calculus for Clifford+T quantum mechanics.

We also show that in the ZX-calculus augmented with the supplementarity rule, antiphase twins can be merged. A pair of antiphase twins is a pair of vertices which have: the same colour; the same neighbourhood; and antiphase angles (the difference between their angles is π). Merging antiphase twins makes diagrammatic reasoning much easier and provides a purely graphical meaning to the supplementarity rule.

Notice that various slightly different notions of soundness/completeness have been used so far in the context of the ZX-calculus, depending on whether the rules of the language should strictly preserve the standard interpretation (as used in this paper), or up to a global phase, or even up to a (non-zero) scalar. Our result of incompleteness applies to any of these variants. However, we believe that the recent attempts to treat carefully the scalars and in particular the zero scalar are valuable, that is why we consider in this paper the strict notion of soundness and completeness. It should also be noticed that the notion of completeness used in the context of the ZX-calculus is different from a related one used in [16] to prove that finite dimensional Hilbert spaces are complete for dagger compact closed categories. The difference lies in that the concept of completeness used in the present paper is only concerned with the standard interpretation in finite dimensional Hilbert spaces, whereas, roughly speaking, in [16] it is considered for every possible interpretation (of object variables as spaces and morphism variables as linear maps).

This paper is structured as follows: the ZX-calculus (diagrams, standard interpretation, and rules) is presented in Section 2. Section 3 is dedicated to the supplementarity equation. In Section 4 we show that supplementarity involving angles which are not multiples of $\pi/2$ cannot be derived in the ZX-calculus which implies the incompleteness of the $\frac{\pi}{4}$-fragment. In Section 5, we identify an infinite family of equations which derivations require the supplementarity rule, and given a graphical interpretation of supplementarity by means of antiphase twins. Finally, in Section 6, we discuss the simplification of the ZX-calculus augmented with the supplementarity rule and its completeness.

2 ZX-calculus

2.1 Diagrams and standard interpretation

A ZX-diagram $D : k \to l$ with k inputs and l outputs is generated by:

$R_Z^{(n,m)}(\alpha) : n \to m$		$R_X^{(n,m)}(\alpha) : n \to m$	$H : 1 \to 1$		$e : 0 \to 0$	$\mathbb{I} : 1 \to 1$		$\sigma : 2 \to 2$	$\epsilon : 2 \to 0$		$\eta : 0 \to 2$	
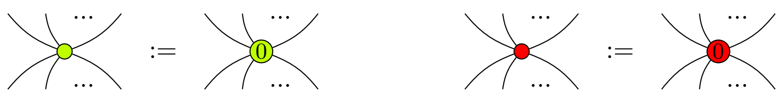
where $m, n \in \mathbb{N}$ and $\alpha \in [0, 2\pi)$.

- Spacial composition: for any $D_1 : a \to b$ and $D_2 : c \to d$, $D_1 \otimes D_2 : a + c \to b + d$ consists in placing D_1 and D_2 side-by-side, D_2 on the right of D_1.
- Sequential composition: for any $D_1 : a \to b$ and $D_2 : b \to c$, $D_2 \circ D_1 : a \to c$ consists in placing D_1 on the top of D_2, connecting the outputs of D_1 to the inputs of D_2.

When equal to 0 modulo 2π the angles of the green and red dots are omitted:



The standard interpretation of the ZX-diagrams associates with any diagram $D : n \to m$ a linear map $[\![D]\!] : \mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$ inductively defined as follows:

$[\![D_1 \otimes D_2]\!] := [\![D_1]\!] \otimes [\![D_2]\!]$ $\quad [\![D_2 \circ D_1]\!] := [\![D_2]\!] \circ [\![D_1]\!]$  $:= 1$  $:= \begin{pmatrix}10\\01\end{pmatrix}$

 $:= \frac{1}{\sqrt{2}}\begin{pmatrix}1 & 1\\1 & \text{-}1\end{pmatrix}$  $:= \begin{pmatrix}1000\\0010\\0100\\0001\end{pmatrix}$  $:= (1001)$  $:= \begin{pmatrix}1\\0\\0\\1\end{pmatrix}$

$[\![R_Z^{(0,0)}(\alpha)]\!] := 1{+}e^{i\alpha}$, and when $a{+}b > 0$, $[\![R_Z^{(a,b)}(\alpha)]\!]$ is a matrix with 2^a columns and 2^b rows such that all entries are 0 except the top left one which is 1 and the bottom right one which is $e^{i\alpha}$, e.g.:

 $= 1 + e^{i\alpha}$  $= \begin{pmatrix}1\\e^{i\alpha}\end{pmatrix}$  $= \begin{pmatrix}1 & 0\\0 & e^{i\alpha}\end{pmatrix}$  $= \begin{pmatrix}1 & 0 & 0 & 0\\0 & 0 & 0 & e^{i\alpha}\end{pmatrix}$

For any $a, b \geq 0$, $[\![R_X^{a,b}(\alpha)]\!] := [\![H]\!]^{\otimes b} \times [\![R_Z^{a,b}(\alpha)]\!] \times [\![H]\!]^{\otimes a}$, where $M^{\otimes 0} = 1$ and for any $k > 0$, $M^{\otimes k} = M \otimes M^{\otimes k-1}$. E.g.,

 $= 1 + e^{i\alpha}$  $= \sqrt{2}e^{i\frac{\alpha}{2}}\begin{pmatrix}\cos(\alpha/2)\\ \text{-}i\sin(\alpha/2)\end{pmatrix}$  $= e^{i\frac{\alpha}{2}}\begin{pmatrix}\cos(\alpha/2) & \text{-}i\sin(\alpha/2)\\ \text{-}i\sin(\alpha/2) & \cos(\alpha/2)\end{pmatrix}$

ZX-diagrams are universal in the sense that for any $m, n \geq 0$ and any linear map $U : \mathbb{C}^{2^n} \to \mathbb{C}^{2^m}$, there exists a diagram $D : n \to m$ such that $[\![D]\!] = U$ [7]. In particular, any unitary quantum evolution on a finite number of qubits can be represented by a ZX-diagram. Notice that universality implies working with a uncountable set of angles. As a consequence, the approximate version of universality, i.e. the ability to approximate with arbitrary accuracy any linear map, is generally preferred in quantum information processing. The $\frac{\pi}{4}$-fragment of language, which consists of all diagrams which angles are multiples of $\pi/4$, is approximately universal, whereas the $\frac{\pi}{2}$-fragment is not.

2.2 Calculus

The representation of a matrix in this graphical language is not unique. We present in this section the rules of the ZX calculus. These rules are sound in the sense that if two diagrams D_1 and D_2 are equal according to the rules of the ZX calculus, denoted $ZX \vdash D_1 = D_2$, then $[\![D_1]\!] = [\![D_2]\!]$. The rules of the language are given in Figure 1, and detailed bellow. The colour-swapped version and upside-down version of each rule given in Figure 1 also apply.

Spider. According to the (S1) rule any two directly connected green dots can be merged. Moreover, a dot with a single input, single output and angle 0 can be removed according to the (S2) rule. These rules have their origins in the axiomatisation of orthonormal bases by means of dagger special Frobenius algebras (see [9] for details). According to the standard interpretation $[\![.]\!]$, the green dots are associated with the so-called standard basis $\{\binom{1}{0}, \binom{0}{1}\}$, whereas the red dots (which also satisfies the spider property since colour-swapped rules also apply) are associated with the so-called diagonal basis $\{\frac{1}{\sqrt{2}}\binom{1}{1}, \frac{1}{\sqrt{2}}\binom{1}{\text{-}1}\}$.

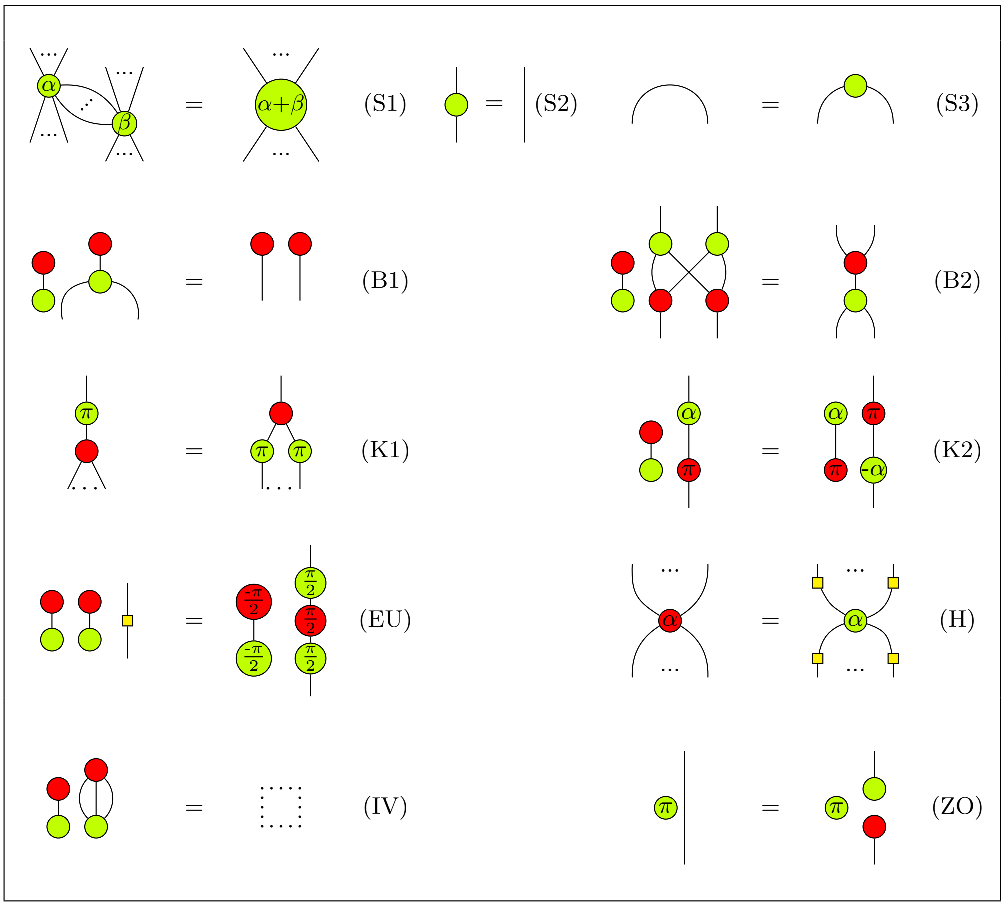


Figure 1 Rules of ZX-calculus. The colour-swapped and/or upside-down versions of each rule also applies. Horizontal dots (. . .) mean ‘arbitrary number’, whereas diagonal dots (⋰) mean ‘at least one’.

Green-Red Interactions. Monochromatic diagrams are lax: according to the (S1) rule any (green- or red-) monochromatic connected diagram is equivalent to a single dot with the appropriate number of legs and which angle is the sum of the angles. Thus the interesting structures arises when the two colours interact. The bialgebra rule (B1) and the copy rule (B2), imply that the red and the green bases are complementary, which roughly speaking capture the notion of uncertainty principle and of unbiasedness a fundamental property in quantum information (see [7] for details).

Parallel wires and Hopf law. (B1) and (B2) rules imply the following Hopf law [7, 10]:  =  where  :=  is the called the antipode. The (S3) rule trivialises the antipode and simplifies the Hopf law:

 **(Hopf Law)**

Hopf law has then a simple graphical meaning: two parallel wires between dots of distinct colours can be removed (up to the scalar). Notice that any pair of complementary basis in arbitrary finite dimension satisfies the rules (S1), (S2), (B1) and (B2). However the (S3) rule implies that the dimension of the corresponding Hilbert space is a power of two. As a consequence the ZX-calculus is a language dedicated to *qubit quantum mechanics*.

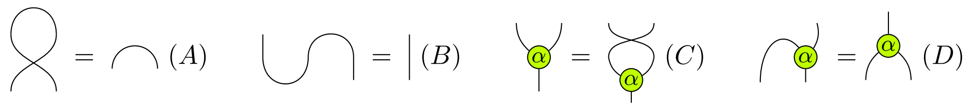
Classical point. In the context of complementary basis, the rules (K1) and (K2) imply that is a classical point. Intuitively, it means that together with are two elements of the red basis, so in dimension 2 they form an orthogonal basis.

Colour change. According to the (H) rule, can be used to change the colour of a dot. The (EU) rule corresponds to the Euler decomposition of the Hadamard matrix into three elementary rotations.

Scalar and zero. A scalar is a diagram with no input and no output. The standard interpretation of such a diagram is a complex number. While for simplicity, scalars have been ignored in several versions of the ZX calculus [7, 1], recently several rules have been introduced for scalars [3] and then simplified in [5], leading to the two rules (IV) and (ZO) presented in Figure 1. As the interpretation of the empty diagram is 1, the (IV) rule implies that is the inverse of . The interpretation of is 0, as a consequence for any diagrams D_1 and D_2, $[\![$ $\otimes D_1]\!] = [\![$ $\otimes D_2]\!]$. This absorbing property is captured by the (ZO) rule.

Context. The axioms of the language presented in Figure 1 can be applied to any subdiagram. In other word, if $ZX \vdash D_1 = D_2$ then, for any D (with the appropriate number of inputs/ouputs), $ZX \vdash D \otimes D_1 = D \otimes D_2$; $ZX \vdash D_1 \otimes D = D_2 \otimes D$; $ZX \vdash D \circ D_1 = D \circ D_2$; and $ZX \vdash D_1 \circ D = D_2 \circ D$.

Only topology matters. A ZX-diagram can be deformed without changing its interpretation. This property is known as "only topology matters" in [7]. E.g.



"Only topology matters" is a consequence of the underlying dagger compact closed structure (e.g. Eq. A and B), together with the ability to interchange any two legs (Eq. C) and to turn inputs into outputs (Eq D) and vice-versa. Equations C and D are non standard in dagger compact closed categories, and are consequences of the other rules of the ZX-calculus [5].

2.3 Soundness and Completeness

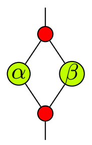
(In-)Completeness. All the rules of the ZX calculus are sound with respect to the standard interpretation, i.e. if $ZX \vdash D_1 = D_2$ then $[\![D_1]\!] = [\![D_2]\!]$. The converse of soundness is completeness: the language would be complete if $[\![D_1]\!] = [\![D_2]\!]$ implies $ZX \vdash D_1 = D_2$. The completeness would imply that one can forget matrices and do graphical reasoning only. Completeness would also imply that all the fundamental properties of qubit quantum mechanics are graphically captured by the rules of the ZX-calculus. This desirable property is one of the main open questions in categorical quantum mechanics. In the following , we review the known results about the completeness of the ZX-calculus, which are essentially depending on the considered fragment (restriction on the angles) of the language.

The very first result of incompleteness was about the original ZX-calculus in which the Euler decomposition[1] of H, the (EU) rule in Figure 1 was not derivable. This equation is now part of the language. Backens [1] proved that the $\frac{\pi}{2}$ fragment is complete. Schröder and Zamdzhiev proved that the language is not complete in general. Their argument is also based on some Euler decomposition, but contrary to the previous case this decomposition involves non rational multiples of π. The most natural – and actually the only known way – to bypass this incompleteness result is to consider a fragment of the language. Indeed, irrational multiple of π are not necessary for approximate universality. As the $\frac{\pi}{2}$-fragment is not approximately universal, the most interesting candidate for completeness is the $\frac{\pi}{4}$-fragment which is approximately universal. The completeness for the $\frac{\pi}{4}$-fragment has been conjectured in [2] and actually proved in the single qubit case, i.e. for path diagrams. The use of path diagrams (diagrams with all dots of degree two) is rather restrictive, but the completeness for this class of diagrams is not trivial and is sufficient to show that any argument based on some Euler decomposition cannot be applied in the $\pi/4$ case. However, we disprove the conjecture: the $\frac{\pi}{4}$-fragment of the ZX-calculus is not complete (Corollary 3), using a novel approach not based on Euler decompositions.

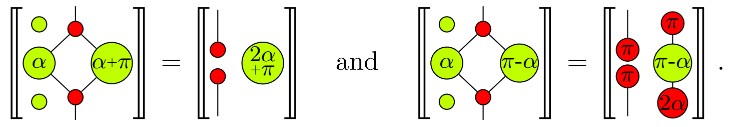
Scalars and completeness. In several versions of the ZX-calculus scalars are ignored, leading to a slightly different notion of soundness and completeness involving proportionality. Roughly speaking, ignoring the scalars consists in an additional rule which allows one to freely add or remove diagram with no input/output. A particular attention has to be paid to 'zero' diagrams, i.e. diagrams whose interpretations are zero, like π. When scalars are ignored, the notion of soundness is modified as follows: if $D_1 = D_2$ then $[\![D_1]\!]$ and $[\![D_2]\!]$ are proportional. The definition of completeness is modified likewise. Notice that in [15] yet another notion of soundness is considered where scalars are not ignored in general but global phases are, i.e. if $D_1 = D_2$ then $\exists\theta, [\![D_1]\!] = e^{i\theta}[\![D_2]\!]$. Our main result of incompleteness (Theorem 2) applies for any of these variants of soundness/completeness. However, we believe that the recent attempts to treat carefully the scalars and in particular the zero scalar are valuable that is why we consider in this paper the strict notion of soundness and completeness.

3 Supplementarity

In [8], Coecke and Edwards introduced the notion of *supplementarity* by pointing out that when $\alpha \neq 0 \bmod \pi$ the standard interpretation of the following diagram is proportional to the projector $\left(\begin{smallmatrix}10\\00\end{smallmatrix}\right)$ if $\alpha - \beta = \pi$ and to the projector $\left(\begin{smallmatrix}00\\01\end{smallmatrix}\right)$ if $\alpha + \beta = \pi$.



Putting back the scalars, one gets the following equations, which are true for any angle α, even when $\alpha = 0$:

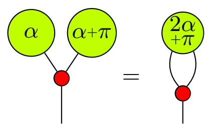


[1] By Euler decomposition we mean the existence, for any 1-qubit unitary U, of 4 angles $\alpha, \beta, \gamma, \delta$ s.t. $U = e^{i\alpha} R_x(\beta) R_z(\gamma) R_x(\delta)$ where $R_x(.)$ and $R_z(.)$ are elementary rotations about orthogonal axis.

Coecke and Edwards showed that the concept of supplementarity is related to the entanglement of quantum states. Up to stochastic local operations and classical communications (SLOCC), there are only two kinds of three-qubit states with genuine tripartite entanglement: those which are SLOCC-equivalent to a GHZ state, and those which are SLOCC-equivalent to a W state. A GHZ-state is a particular instance of a graph state which can be easily represented with a ZX-diagram [13]. On the other hand this is more involved to represent a W-type entangled states. The concept of supplementarity allowed Coecke and Edwards to characterise inhabitants of the W-class.

Albeit Coecke and Edwards did not address explicitly the question of proving whether the above equations can be derived in the ZX-calculus or not, these equations were known to be candidates for proving the incompleteness of the language[2]. We prove in Section 4 that these equations can be derived in the ZX-calculus only when $\alpha = 0 \bmod \frac{\pi}{2}$.

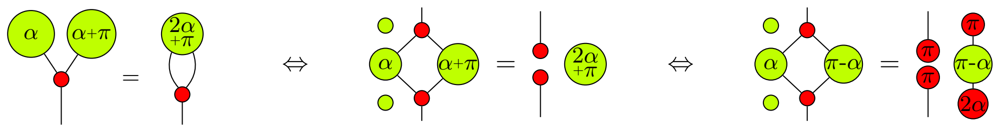
Inspired by the property pointed out by Coecke and Edwards we introduce the following equation that we call *supplementarity*:



(1)

Supplementarity is sound in the sense that both diagrams of (Eq. 1) have the same standard interpretation $\frac{1}{\sqrt{2}}\binom{1-e^{2i\alpha}}{0}$. It is provable in the ZX-calculus that supplementarity (Eq. 1) is equivalent to the equations pointed out by Coecke and Edwards:

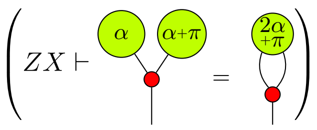
▶ **Lemma 1.** *In the ZX calculus, for any $\alpha \in [0, 2\pi)$:*



4 Supplementarity is necessary

In this section, we prove the main result of the paper: supplementarity involving angles which are not multiples of $\frac{\pi}{2}$ cannot be derived using the rules of the ZX-calculus, and as a corollary the $\frac{\pi}{4}$-fragment of ZX-calculus is incomplete.

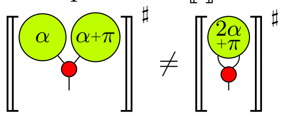
▶ **Theorem 2.** *Supplementarity can be derived in the ZX-calculus only for multiples of $\pi/2$:*



$$\Leftrightarrow \qquad \alpha = 0 \bmod \frac{\pi}{2}$$

▶ **Corollary 3.** *The $\frac{\pi}{4}$-fragment of ZX-calculus is not complete. In other words, ZX-calculus is not complete for the so-called "Clifford+T quantum mechanics".*

The rest of the section is dedicated to the proof of Theorem 2. To do so, we introduce an alternative interpretation $[\![.]\!]^\sharp$ for the diagrams, that we prove to be sound (Lemma 5) but for which

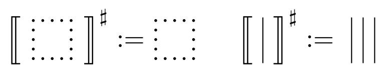


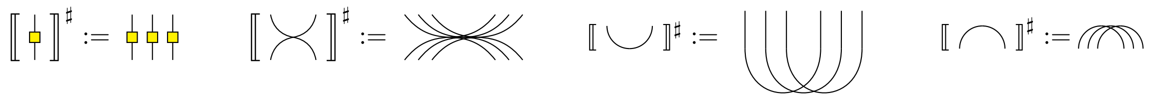
when $\alpha \neq 0 \bmod \frac{\pi}{2}$.

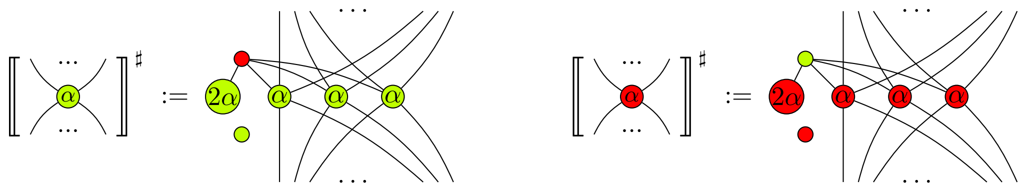
[2] Personal communications with Miriam Backens and Aleks Kissinger.

▶ **Definition 4.** For any diagram $D : n \to m$, let $[\![D]\!]^\sharp : 3n \to 3m$ be a diagram defined as follows:

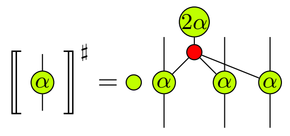
$[\![D_1 \otimes D_2]\!]^\sharp := [\![D_1]\!]^\sharp \otimes [\![D_2]\!]^\sharp \qquad [\![D_2 \circ D_1]\!]^\sharp := [\![D_2]\!]^\sharp \circ [\![D_1]\!]^\sharp$



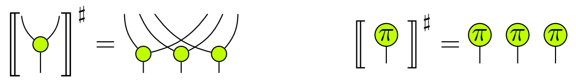




Roughly speaking, $[\![D]\!]^\sharp$ consists of three copies of D together with, for each dot of angle α, a *gadget* parameterized by the angle 2α connecting the three copies of the dot. E.g.

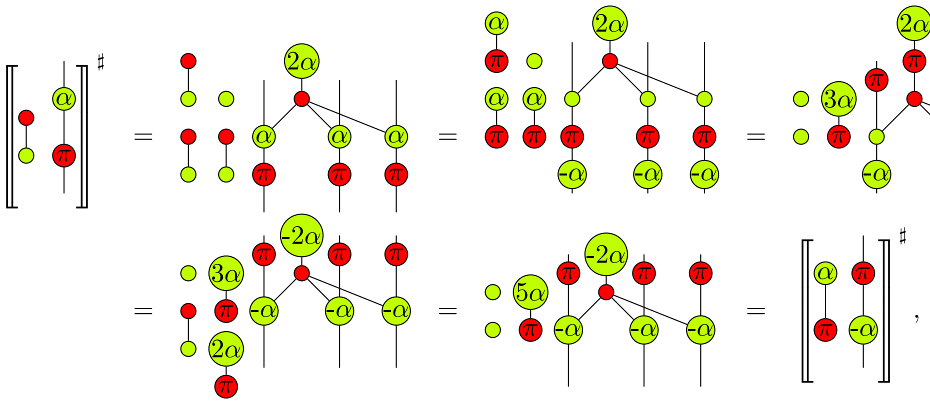


Simple calculations show that the gadget disappears when $\alpha = 0 \bmod \pi$, e.g.:



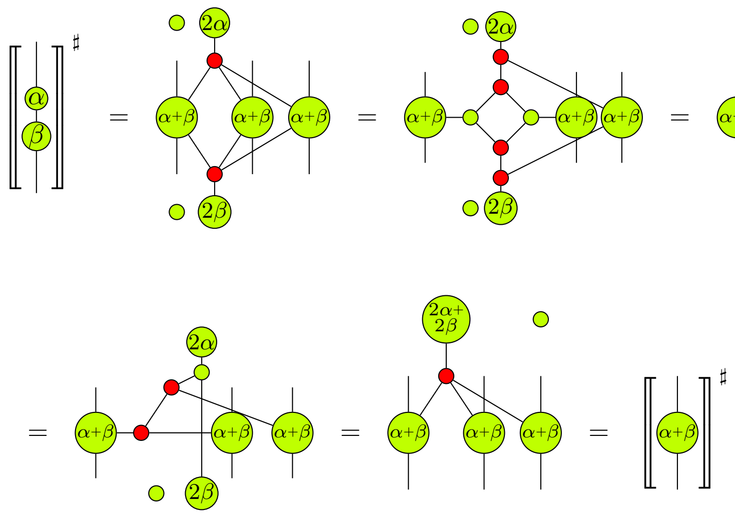
▶ **Lemma 5** (Soundness). *$[\![.]\!]^\sharp$ is a sound interpretation: if $ZX \vdash D_1 = D_2$ then $ZX \vdash [\![D_1]\!]^\sharp = [\![D_2]\!]^\sharp$.*

Proof. Soundness is trivial for the π-fragment of the language (i.e. when angles are multiples of π). Thus, it remains the four rules $(S1)$, $(K2)$, (EU), and (H) to complete the proof. We give the proof of $(K2)$ and a particular case of $(S1)$ to illustrate the proof, the other cases are omitted.
[(K2)]



The first equality is nothing but the definition of $[\![.]\!]^\sharp$. The second step is based on the (K2) rule. The third step consists in (i) grouping the 3 scalars depending on α into a single one, to do so rules (B1), (K1) and finally (S1) are combined; (ii) applying the (K1) rule on the non scalar part of the diagram. Fourth step consists in applying the (K2) rule on the gadget. The fifth step is combining the scalars depending on α. Finally for the last step we use .

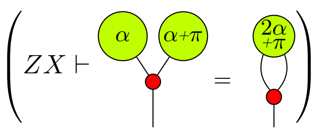
[(S1)] In the following we consider a particular case of the (S1) rule where the two dots are of degree 2. The following derivation essentially consists in applying the bialgebra rule (B2) twice:



◀

▶ Remark (1). The interpretation $[\![.]\!]^\sharp$ can be naturally extended to an interpretation $[\![.]\!]^\sharp_{k,\ell}$ which associates with every diagram $D : n \to m$ a diagram $[\![D]\!]^\sharp_{k,\ell} : k \times n \to k \times m$ which consists in k copies of D where the k copies of each dot are connected by a "gadget" parameterized by an angle ℓ times larger than the angle of the original dot. Moreover $[\![D]\!]^\sharp_{k,\ell}$ has additional scalars, namely $k-1$ times  per dot in D. Notice that the interpretation $[\![.]\!]^\sharp$ used in this section is nothing but $[\![.]\!]^\sharp_{3,2}$. The interpretation $[\![.]\!]^\sharp_{k,\ell}$ is sound if and only if $k = 1 \bmod 2$ and $\ell = 0 \bmod 2$, indeed $(K1)$ forces k to be odd while (EU) and (ZO) force $\ell = 0 \bmod 2$. All the other rules are sound for any k, ℓ. When $k = 1$, $[\![.]\!]^\sharp_{1,\ell}$ is nothing but an interpretation which multiplies the angles by $\ell + 1$, without changing the structure of the diagrams: $[\![.]\!]^\sharp_{1,0}$ is the identity, while $[\![.]\!]^\sharp_{1,-1}$ has been used to prove that the (EU) rule is necessary [13] and $[\![.]\!]^\sharp_{1,-2}$ has been used to prove that the ZX-calculus is incomplete [15].

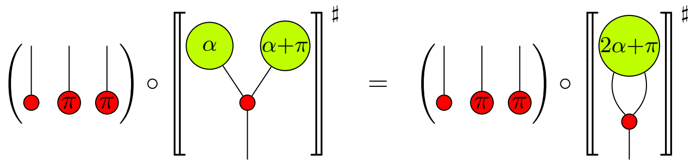
Proof of Theorem 2. In the following we prove that supplementarity can be derived in the ZX-calculus if and only if the involved angles are multiples of $\pi/2$:



$$\Leftrightarrow \qquad \alpha = 0 \bmod \frac{\pi}{2}$$

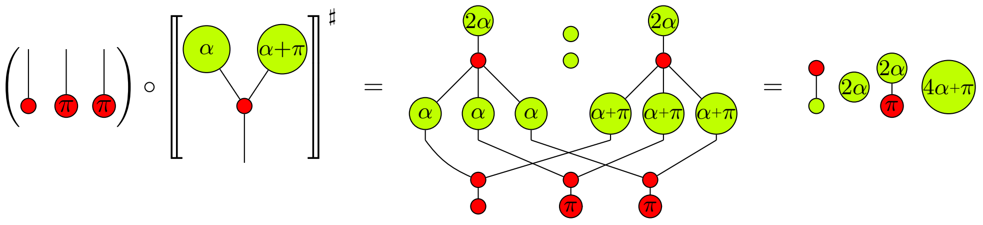
[⇐] Since both diagrams of the supplementarity equation have the same standard interpretation $\frac{1}{\sqrt{2}}\binom{1-e^{2i\alpha}}{0}$, by completeness of the $\frac{\pi}{2}$-fragment of the ZX-calculus, supplementarity can be derived when α is a multiple of $\frac{\pi}{2}$.

[$\Rightarrow$] Let $\alpha \in [0, 2\pi)$, and assume that supplementarity (1) can be derived in the ZX-calculus. Since $[\![.]\!]^\sharp$ is sound, the following equation must be derivable in the ZX-calculus:

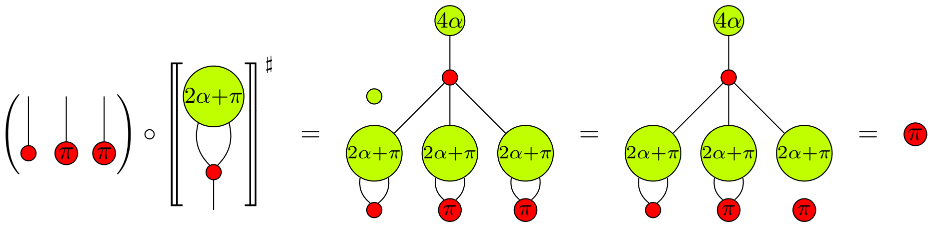


(2)

The LHS diagram is as follows.



The RHS diagram of Eq. 2 is:



which is obtained first by applying the Hopf law and then thanks to the absorbing property of . Thus, Eq. 2 is equivalent to  $=$ which can be simplified, leading to  $=$. Finally, since $[\![.]\!]$ is sound, it implies  $= [\![$ $]\!]$, thus $(1 + e^{2i\alpha})(1 - e^{4i\alpha}) = 0$ which is equivalent to $\alpha = 0 \bmod \frac{\pi}{2}$. ◀

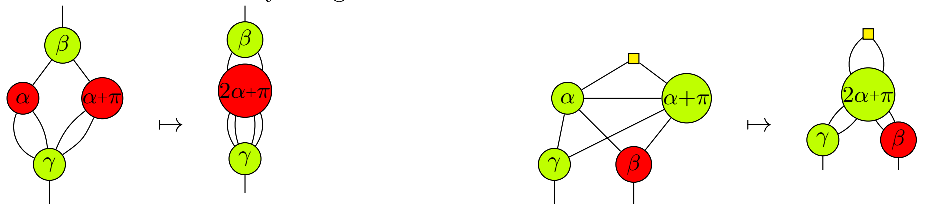
5 Supplementarity as an axiom

As supplementarity cannot be derive from the other rules of the language, we propose to add this equation as an axiom, a rule of the ZX-calculus. We identify an infinite class of equations that cannot be derived without the supplementarity rule. This class of equations also provides a graphical meaning to the supplementarity equation. Graphically, the supplementarity equation (Eq. 1) can be interpreted as merging two dots in a particular configuration: they are antiphase (i.e. same colour and the difference between the two angles is π); of degree one; and they have the same neighbour. While antiphase is a necessary condition, the other conditions can be relaxed to any "twins" as follows:

▶ **Definition 6** (Antiphase Twins). Two dots u and v in a ZX-diagram are antiphase twins if:

- they have the same colour;
- the difference between their angles is π;
- they have the same neighbourhood: for any other vertex (,  or) w, the number of wires connecting u to w, and v to w are the same.

Notice that antiphase twins might be directly connected or not. Here two examples of antiphase twins and how they merge:



▶ **Theorem 7** (Antiphase Twins and Supplementarity). *In ZX-calculus, any pair of antiphase twins can be merged if and only if* $\forall\alpha$, .

▶ **Corollary 8.** *In the ZX-calculus augmented with the supplementarity rule, any pair of antiphase twins can be merged.*

6 Discussions

Simplified ZX-calculus. Adding a new rule to the language may lead to a simplification of the other rules of the language. Indeed the (ZO) rule can be replaced by a simpler rule:

▶ **Lemma 9.** *In the ZX-calculus augmented with the supplementarity rule, the (ZO) rule can be replaced by the following (ZO') rule:* .

Proof.  ◀

However, it seems that the language cannot be simplified much. Actually, the two most interesting candidates for simplification are the (EU) rule – which is the only one which is specific to the $\pi/2$ angle and thus may lack generality – and the (K2) rule. Even in the presence of the supplementarity rule, the (EU) rule cannot be derived from the other rules:

▶ **Lemma 10.** *In the ZX-calculus augmented with the supplementary rule, the (EU) rule cannot be derived from the other rules.*

Proof. Let $[\![.]\!]^\flat$ be defined as $[\![.]\!]^\sharp_{2,0}$ (see Remark 1) for all generators but ; and $[\![$ $]\!]^\flat$ = . So intuitively, $[\![.]\!]^\flat$ 'doubles' the diagram, and each 'swaps' the two copies. This interpretation is sound for all rules, including the supplementarity rule, but is not sound for the (EU) rule. ◀

Regarding the (K2) rule, it has been shown recently that (K2) instantiated with an angle multiple of $\frac{\pi}{2}$ can be derived from the other rules [5], without using the supplementarity rule. We leave its necessity for arbitrary angles and in the presence of the supplementarity rule as an open question.

Completeness. Even augmented with the supplementarity rule the ZX-calculus is incomplete in general since the argument of [15] still applies. Indeed, the cornerstone of the incompleteness argument is the soundness of the interpretation which consists in multiplying the angles by -3 ($[\![.]\!]^\sharp_{1,-4}$ according to the notation of Remark 1). This interpretation is also sound with respect to the supplementarity rule, and thus the ZX-calculus is still incomplete, even augmented with the supplementarity rule. However, the second ingredient of the incompleteness result of [15] is based on the Euler decomposition of some unitary transformation which diagrammatic representation involves irrational multiples of π. As a consequence, the completeness of the ZX-calculus augmented with the supplementarity is an open question for any fragment which does not contain rational multiples of π. In particular, the completeness of the $\frac{\pi}{4}$-fragment – i.e. for Clifford+T quantum mechanics – is open.

7 Conclusion

We have proved that the ZX-calculus is not complete, even for Clifford+T quantum mechanics, which corresponds to the $\frac{\pi}{4}$-fragment of the language. We have identified an infinite set of equations that cannot be derived in the language. Moreover, we have shown that a single simple rule, called supplementarity, is sufficient to derive these equations. Supplementarity has been introduced as fundamental structure of multipartite entanglement by Coecke and Edwards. In addition to this physical interpretation, we provide a graphical meaning to the supplementarity rule by means of antiphase twins.

Abstract

An important endeavor in computer science is to precisely understand the expressive power of logical formalisms over discrete structures, such as words. Naturally, "understanding" is not a mathematical notion. Therefore, this investigation requires a concrete objective to capture such a notion. In the literature, the standard choice for this objective is the *membership problem*, whose aim is to find a procedure deciding whether an input regular language can be defined in the logic under study. This approach was cemented as the "right" one by the seminal work of Schützenberger, McNaughton and Papert on first-order logic and has been in use since then.

However, membership questions are hard: for several important fragments, researchers have failed in this endeavor despite decades of investigation. In view of recent results on one of the most famous open questions, namely the quantifier alternation hierarchy of first-order logic, an explanation may be that membership is too restrictive as a setting. These new results were indeed obtained by considering more general problems than membership, taking advantage of the increased flexibility of the enriched mathematical setting. This opens a promising avenue of research and efforts have been devoted at identifying and solving such problems for natural fragments. However, until now, these problems have been *ad hoc*, most fragments relying on a specific one. A unique new problem replacing membership as the right one is still missing.

The main contribution of this paper is a suitable candidate to play this role: the Covering Problem. We motivate this problem with three arguments. First, it admits an elementary set theoretic formulation, similar to membership. Second, we are able to reexplain or generalize all known results with this problem. Third, we develop a mathematical framework as well as a methodology tailored to the investigation of this problem.

1 Introduction

One of the most successful applications of the notion of regularity in computer science is the investigation of logics on discrete structures such as words or trees. The story began in the 60s when Büchi [5], Elgot [10] and Trakhtenbrot [36] proved that the *regular languages* of

* This study has been carried out with financial support from the French State, managed by the French National Research Agency (ANR) in the frame of the "Investments for the future" Programme IdEx Bordeaux – CPU (ANR-10-IDEX-03-02).

finite words are those that can be defined in monadic second order logic (MSO). This result has since been exploited to study the expressive power of important fragments of MSO by relying on a decision problem: the *membership problem.* Given a regular language as input, this problem asks if it can be defined by a sentence of the fragment under investigation.

Getting membership algorithms is difficult. In fact, this is still open on finite trees for the most natural fragment of MSO, namely first-order logic (FO). On words however, this question was solved in the 70s by Schützenberger, McNaughton and Papert [30, 14]. This theorem was very influential and has often been revisited [38, 9, 7, 20]. It paved the way to a series of results of the same nature. A famous example is Simon's Theorem [31], which yields an algorithm for the first level of the quantifier alternation hierarchy of FO. Other examples include [4, 13, 39, 33] which consider fragments of FO where the linear order on positions is replaced by the successor relation or [34] which considers the 2-variable fragment of FO. The relevance of this approach is nowadays validated by a wealth of results.

The reason for this success is twofold. First, these results cemented membership as the "right" question: a solution conveys a deep intuition on the investigated logic. In particular, most results include a *generic method for building a canonical sentence* witnessing membership of an input language in the logic. Second, Schützenberger's solution established a suitable framework and a methodology to solve membership problems. This methodology is based on a canonical algebraic abstraction of a regular language which is finite and computable, the *syntactic monoid.* The core of the approach is to translate the semantic question (*is the language definable in the fragment?*) into a purely syntactical, easy question to be tested on the syntactic monoid (*does the syntactic monoid satisfy some equation?*).

Unfortunately, this methodology seems to have reached its limits for the hardest questions. An emblematic example is the *quantifier alternation hierarchy of first-order logic* which classifies sentences according to the number of alternations between $\exists$ and $\forall$ quantifiers in their prenex normal form. A sentence is Σ_i if its prenex normal form has $(i-1)$ alternations and starts with a block of existential quantifiers. A sentence is $\mathcal{B}\Sigma_i$ if it is a boolean combination of Σ_i sentences. Obtaining membership algorithms for all levels in this hierarchy is a major open question and has been given a lot of attention (see [37, 35, 15, 16, 17, 18, 27, 19] for details and a complete bibliography). However, progress on this question has been slow: until recently, only the lowest levels were solved: Σ_1 [3, 21], $\mathcal{B}\Sigma_1$ [31] and Σ_2 [3, 21].

It took years to solve higher levels. Recently, membership algorithms were obtained for Σ_3 [25], $\mathcal{B}\Sigma_2$ [25] and Σ_4 [22]. This was achieved by introducing new ingredients into Schützenberger's methodology: problems that are *more general than membership.* For each result, the strategy is the same: first, a well-chosen more general problem is solved for a lower level in the hierarchy, then, this result is transferred into a membership algorithm for the level under investigation. Let us illustrate what we mean by "more general problem" and present the simplest of them: the *separation problem.* It takes *two* regular languages as input and asks whether there exists a third one which is definable in the logic, contains the first, and is disjoint from the second. Being more general, such problems are also more difficult than membership. However, this generality also makes them more rewarding in the insight they give on the investigated logic. This motivated a series of papers on the separation problem [28, 8, 23, 24, 26] which culminated in the three results above [25, 22]. However, while this avenue of research is very promising, it presently suffers three important flaws:

1. The family of problems that have been considered up until now is a jungle: each particular result relies on a specific ad-hoc problem. For example, the results of [25, 22] rely on three different problems. In fact, even if one is only interested in separation, the actual solution often considers an even more general problem (see [28, 25, 22] for example).

2. Among the problems that have been investigated, separation is the only one that admits a simple and generic set-theoretic definition (which is why it is favored as an example). On the other hand, for all other problems, the definition requires to introduce additional concepts such as semigroups and Ehrenfeucht-Fraïssé games.
3. In contrast to membership solutions, the solutions that have been obtained for these more general problems are non-constructive. For example, most of the separation solutions do not include a generic method for building a separator language when it exists (the algorithms are built around the idea of proving that the two inputs are *not* separable).

Contributions. Our objective in this paper is to address these three issues. Our first contribution is the presentation of a single general problem, the "*covering problem*", which admits a purely set-theoretic definition and generalizes all problems that have already been considered. Furthermore, its definition is modular: the covering problem is designed so that it can easily be generalized to accommodate future needs. Its design is based on an analysis of the methods used to solve membership and separation. In both cases, the algorithms almost always exploit the fact that an input regular language L is *not isolated*: its recognizer defines a *set* of regular languages from which L is built. This set has a structure upon which the algorithms are based. The covering problem takes this observation into account: an input of the problem is directly *any finite set* of regular languages. Given such a set $\mathbf{L}$, the problem asks to compute the "best possible approximation" (called *optimal cover*, hence the name "covering") of this set of languages by languages belonging to the investigated fragment. In particular, the separation problem is just the special case when the input set is of size 2.

The main advantage of the covering problem is that it comes with a generic framework and a generic methodology designed for solving it. This framework is our second contribution. It generalizes the original framework of Schützenberger for membership in a natural way and lifts all its benefits to a more general setting. In particular, we recover *constructiveness*: a solution to the covering problem associated to a particular fragment yields a generic way for building an actual optimal cover of the input set.

Finally, the relevance of our new framework is supported by the fact that we are able to obtain covering algorithms for the fragments that were already known to enjoy a decidable separation problem. In contrast to the previous algorithms, these more general ones are presented within a single unified framework. This is our third contribution. We present actual covering algorithms for four particular logics: first-order logic (FO), two-variables FO (FO^2) and two logics within the quantifier alternation hierarchy of FO ($\mathcal{B}\Sigma_1$ and Σ_2). As explained, the payoff is that we obtain *effective* solutions to the covering problem. Hence, we obtain an effective method for building separators in the weaker separation problem.

Historical note. As observed by Almeida [1], separation is tied to a purely algebraic problem of Henckell and Rhodes (see [11, 12]): computing the "pointlike sets of a given finite semigroup with respect to a variety $\mathbf{V}$". This can probably be lifted to covering. However, there are two main advantages to our approach. First, it is more general: pointlike sets are restricted to classes and inputs that are both more specific than ours. Second, covering admits a simple set theoretic definition that pointlike sets obfuscate with heavy terminology.

Organization. We define the covering problem in Section 2 (for arbitrary input sets of languages, *i.e.*, not necessarily made of regular languages). We present our framework for the particular case of regular inputs in Sections 3 and 4. Four examples of covering algorithms are presented in Section 5. Due to lack of space, proofs are deferred to the journal version.

2 The Covering Problem

In this section, we define the covering problem. For the whole paper, we fix a finite alphabet A and work with finite words over A (*i.e.*, elements of A^*). A *language* is a subset of A^*. Note that we restrict ourselves to words for the sake of simplifying the presentation. However, the covering problem makes sense for *any structure* (such as infinite words or trees).

We focus on two kinds of classes of languages. We say that a class of languages $\mathscr{C}$ is a *lattice* when it contains the empty and universal languages ($\emptyset$ and A^*) and it is closed under finite union and finite intersection: $K, L \in \mathscr{C}$ implies $K \cup L, K \cap L \in \mathscr{C}$. Furthermore, $\mathscr{C}$ is a *boolean algebra* when $\mathscr{C}$ is a lattice that is closed under complement: $L \in \mathscr{C}$ implies $\{w \in A^* \mid w \notin L\} \in \mathscr{C}$. The covering problem then comes into two variants:

- a variant that can be associated to any class of languages that is a lattice. We call this variant the *pointed covering problem.*
- a weaker variant that can be associated to any class of languages that is a boolean algebra. We call it the *covering problem.* While weaker than the first one, this variant enjoys simpler terminology, which makes it our choice when working with boolean algebras.

We now define these two variants. In the definition, we use the separation problem as a foundation to motivate and explain our design choices. As we explained, given a class of languages $\mathscr{C}$, solutions to membership and separation exploit the fact that the recognizer of an input regular language L recognizes a *set* of regular languages from which L is built. The covering problem is based on this observation: its input is any finite set of languages $\mathbf{L}$.

▶ Remark. A "set of languages" is a purely mathematical object. An actual input is a set of recognizing devices for these languages. In particular, it may happen that two such devices recognize the same language. Therefore our inputs are actually finite sets of languages *names* (which may contain "several copies" of the same language). This is harmless: two sets of names for the same underlying set of languages are equivalent for both covering problems.

2.1 The Covering Problem for Boolean Algebras

We begin with the simpler covering problem. Let $\mathscr{C}$ be a boolean algebra[1]. Given a finite set of languages names $\mathbf{L} = \{L_1, \dots, L_n\}$, a *$\mathscr{C}$-cover* of $\mathbf{L}$ is a finite set of languages $\mathbf{K} = \{K_1, \dots, K_m\}$ such that $K_i \in \mathscr{C}$ for all $i \leq n$ and:

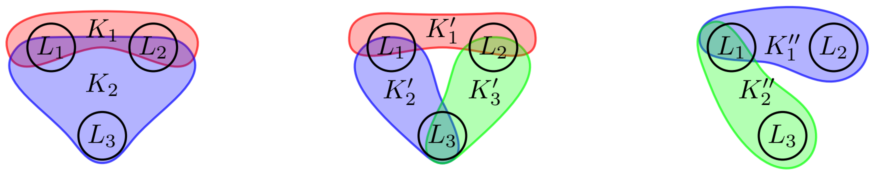
$$L_1 \cup \dots \cup L_n \subseteq K_1 \cup \dots \cup K_m.$$

Note that since $\mathscr{C}$ is a boolean algebra, there always exists a $\mathscr{C}$-cover of $\mathbf{L}$: the singleton $\{A^*\}$. When we have a $\mathscr{C}$-cover $\mathbf{K}$ of $\mathbf{L}$ in hand, our main interest will be to know how good $\mathbf{K}$ is at separating languages in $\mathbf{L}$: what languages in $\mathbf{L}$ are separated by unions of languages in $\mathbf{K}$? What are the "best $\mathscr{C}$-covers" of $\mathbf{L}$ (called optimal $\mathscr{C}$-covers)? This information is captured by a new object that we associate to any cover of $\mathbf{L}$, its imprint on $\mathbf{L}$.

Filterings and Imprints. Imprints are based on filterings. Given a finite set of names $\mathbf{L}$ and a language K, the *filtering of* $\mathbf{L}$ *by* K, measures the "interaction" between $\mathbf{L}$ and K. More precisely, the filtering of $\mathbf{L}$ by K, denoted by $\langle \mathbf{L} | K \rangle$, is defined as the following set:

$$\langle \mathbf{L} | K \rangle = \{L \in \mathbf{L} \mid L \cap K \neq \emptyset\} \subseteq \mathbf{L}\,.$$

[1] The problem actually makes sense for any class that contains the universal language and is closed under intersection. However, we need $\mathscr{C}$ to be a boolean algebra for the connection with separation.



Cover $\mathbf{K} = \{K_1, K_2\}$ $\mathcal{I}[\mathbf{L}](\mathbf{K}) =$ $\downarrow\{\{L_1, L_2, L_3\}\}$ | Cover $\mathbf{K}' = \{K'_1, K'_2, K'_3\}$ $\mathcal{I}[\mathbf{L}](\mathbf{K}') =$ $\downarrow\{\{L_1, L_2\}, \{L_1, L_3\}, \{L_2, L_3\}\}$ | Cover $\mathbf{K}'' = \{K''_1, K''_2\}$ $\mathcal{I}[\mathbf{L}](\mathbf{K}'') =$ $\downarrow\{\{L_1, L_2\}, \{L_1, L_3\}\}$

Figure 1 Some $\mathscr{C}$-covers of $\mathbf{L} = \{L_1, L_2, L_3\}$ and their imprint on $\mathbf{L}$.

▶ Remark. This notion is what makes the problem modular. It can be strengthened to define harder variants of the problem and accommodate future needs.

We may now define imprints. Given a subset E of $2^{\mathbf{L}}$, we write $\downarrow E$ to denote the *downset of* E, *i.e.*, the set $\downarrow E = \{\mathbf{H} \mid \exists \mathbf{H}' \in E \text{ such that } \mathbf{H} \subseteq \mathbf{H}'\}$. If $\mathbf{K}$ is a finite set of languages, the *imprint of* $\mathbf{K}$ *on* $\mathbf{L}$ is the set,

$$\mathcal{I}[\mathbf{L}](\mathbf{K}) \quad = \quad \downarrow\{\langle \mathbf{L}|K\rangle \mid K \in \mathbf{K}\} \subseteq 2^{\mathbf{L}} .$$

Note that we shall mainly use this definition when $\mathbf{K}$ is a $\mathscr{C}$-cover of $\mathbf{L}$. However, in some proofs, it will be convenient to have it for an arbitrary set of languages $\mathbf{K}$. We present examples of imprints when $\mathbf{K}$ is a $\mathscr{C}$-cover of $\mathbf{L}$ in Figure 1.

Let us make a few observations about imprints. An imprint on $\mathbf{L}$ is a subset of $2^{\mathbf{L}}$. Therefore, for a fixed *finite* set $\mathbf{L}$, there are *finitely many* possible imprints on $\mathbf{L}$, even though there are infinitely many finite sets $\mathbf{K}$ of languages. Another simple observation is that all imprints are closed under downset: $\mathcal{I}[\mathbf{L}](\mathbf{K}) = \downarrow\mathcal{I}[\mathbf{L}](\mathbf{K})$. Also notice that if $\mathbf{K}$ is a $\mathscr{C}$-cover of $\mathbf{L}$, its imprint captures separation-related information: if $\{L_1, L_2\} \notin \mathcal{I}[\mathbf{L}](\mathbf{K})$, then L_1 (resp. L_2) can be separated from L_2 (resp. L_1) by a union (in $\mathscr{C}$) of languages in $\mathbf{K}$.

▶ Remark. Imprints capture more than just separation-related information. From the separation point of view, the $\mathscr{C}$-covers $\mathbf{K}$ and $\mathbf{K}'$ of Figure 1 are equivalent: they cannot separate any pair of languages in $\mathbf{L}$. However, their imprints on $\mathbf{L}$ tell us that $\mathbf{K}'$ is "better" as it covers $\mathbf{L}$ without containing a language that intersects all languages in $\mathbf{L}$ at the same time.

Finally, observe that if $\mathbf{K}$ is a $\mathscr{C}$-cover of a finite set $\mathbf{L}$, then its imprint on $\mathbf{L}$ always contains some trivial elements. To any finite set of names $\mathbf{L}$, we associate the following set:

$$\mathcal{I}_{triv}[\mathbf{L}] = \downarrow\{\langle \mathbf{L}|\{w\}\rangle \mid w \in A^*\} = \{\mathbf{H} \subseteq \mathbf{L} \mid \cap_{H \in \mathbf{H}} H \neq \emptyset\} .$$

▶ **Fact 1.** *For any $\mathscr{C}$-cover $\mathbf{K}$ of $\mathbf{L}$, we have $\mathcal{I}_{triv}[\mathbf{L}] \subseteq \mathcal{I}[\mathbf{L}](\mathbf{K})$.*

Optimal $\mathscr{C}$-covers. We now use imprints to define our notion of "best" $\mathscr{C}$-cover of $\mathbf{L}$ which we call *optimal $\mathscr{C}$-covers*. A necessary (but not sufficient) property for a $\mathscr{C}$-cover of $\mathbf{L}$ to be optimal will be that $L_1, L_2 \in \mathbf{L}$ are $\mathscr{C}$-separable if and only if they can be separated by a union of languages in the $\mathscr{C}$-cover. Formally, we say that a $\mathscr{C}$-cover $\mathbf{K}$ of $\mathbf{L}$ is *optimal* when,

$$\mathcal{I}[\mathbf{L}](\mathbf{K}) \subseteq \mathcal{I}[\mathbf{L}](\mathbf{K}') \quad \text{for any } \mathscr{C}\text{-cover } \mathbf{K}' \text{ of } \mathbf{L}.$$

In general, there can be infinitely many optimal $\mathscr{C}$-covers of a given finite set of names $\mathbf{L}$. We now state that for any $\mathbf{L}$, there always exists an optimal $\mathscr{C}$-cover of $\mathbf{L}$. Note that the proof only requires $\mathscr{C}$ to be closed under finite intersection.

▶ **Lemma 2.** *For any finite set of languages names* $\mathbf{L}$*, there exists an optimal* $\mathscr{C}$*-cover of* $\mathbf{L}$*.*

Note that the proof of Lemma 2 is non-constructive. Given a finite set of names $\mathbf{L}$, computing an actual optimal $\mathscr{C}$-cover is a difficult problem in general. In fact, as seen in Theorem 4 below, this is more general than solving $\mathscr{C}$-separability for any pair of languages in $\mathbf{L}$. Before we present this theorem, let us make a key observation about optimal $\mathscr{C}$-covers.

By definition, given a boolean algebra $\mathscr{C}$ and a finite set of names $\mathbf{L}$, all optimal $\mathscr{C}$-covers of $\mathbf{L}$ have the same imprint on $\mathbf{L}$. Hence, this unique imprint on $\mathbf{L}$ is a *canonical* object for $\mathscr{C}$ and $\mathbf{L}$. We call it the *optimal imprint with respect to* $\mathscr{C}$ *on* $\mathbf{L}$ and we denote it by $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$:

$$\mathcal{I}_{\mathscr{C}}[\mathbf{L}] = \mathcal{I}[\mathbf{L}](\mathbf{K}) \quad \text{for any optimal } \mathscr{C}\text{-cover } \mathbf{K} \text{ of } \mathbf{L}.$$

We can now state the *covering problem.* We parametrize it by two classes of languages, a class $\mathscr{D}$ constraining the input, and a boolean algebra $\mathscr{C}$.

▶ **Definition 3.** The Covering problem for $\mathscr{C}$ inside $\mathscr{D}$ is as follows:

INPUT:	A finite set of languages $\mathbf{L} \subseteq \mathscr{D}$.
QUESTION:	Compute $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$.

As expected, we only consider the covering problem when the input class $\mathscr{D}$ is the class of regular languages (in particular we will often simply say "covering problem" for this particular variant). There are two stages when solving the covering problem.

1. *Stage One*: find an algorithm that, given a finite set of regular languages $\mathbf{L}$ as input, computes $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ (we call such an algorithm a covering algorithm for $\mathscr{C}$). In Theorem 4 below, we prove that this generalizes separation as a *decision problem.*
2. *Stage Two*: find an algorithm that, given a finite set of regular languages $\mathbf{L}$ as input, computes an optimal $\mathscr{C}$-cover of $\mathbf{L}$ (*i.e.*, one whose imprint is $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$). We prove below that this generalizes separation as a *computational problem*: if one has an optimal $\mathscr{C}$-cover of $\mathbf{L}$, one may build a separator in $\mathscr{C}$ for any two separable languages in $\mathbf{L}$.

▶ **Theorem 4.** *Let* $\mathscr{C}$ *be a boolean algebra and let* $\mathbf{L}$ *be a finite set of languages names. Given any two language name' 's* $L_1, L_2 \in \mathbf{L}$*, the following properties are equivalent:*
1. L_1 *and* L_2 *are* $\mathscr{C}$*-separable.*
2. $\{L_1, L_2\} \notin \mathcal{I}_{\mathscr{C}}[\mathbf{L}]$.
3. *For any optimal* $\mathscr{C}$*-cover* $\mathbf{K}$ *of* $\mathbf{L}$*,* L_1 *and* L_2 *are* $\mathscr{C}$*-separable by a union of languages in* $\mathbf{K}$*.*

Theorem 4 will be proved in the journal version of this paper. It entails that 'covering' is a more general problem than 'separation'. It is actually *strictly* more general as $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ captures more information than which pairs of languages in $\mathbf{L}$ are $\mathscr{C}$-separable.

2.2 The Pointed Covering Problem for Lattices

So far, we connected the separation problem to the more general *covering problem.* Unfortunately, while the definition of the covering problem makes sense for all lattices, the connection with separation stated in Theorem 4 requires the investigated class $\mathscr{C}$ to be a boolean algebra. When $\mathscr{C}$ is not closed under complement, the optimal imprint $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ does not capture enough information to decide whether two languages in $\mathbf{L}$ are $\mathscr{C}$-separable.

▶ **Example 5.** Let $\mathscr{C}$ be the class of languages which are unions and intersections of languages of the form A^*aA^* for some $a \in A$. Observe that $L_1 = A^*aA^* \cap A^*bA^*$ is $\mathscr{C}$-separable from $L_2 = a^*$ (L_1 belongs to $\mathscr{C}$ and $L_1 \cap L_2 = \emptyset$). However, it can be verified that the optimal imprint with respect to $\mathscr{C}$ on $\{L_1, L_2\}$ is $\mathcal{I}_{\mathscr{C}}[\{L_1, L_2\}] = \{\emptyset, \{L_1\}, \{L_2\}, \{L_1, L_2\}\}$.

We solve this issue with a new problem generalizing separation for any lattice of languages $\mathscr{C}$: the *pointed $\mathscr{C}$-covering problem.* The main idea behind this new problem is to replace the notion of cover of a finite set of languages names $\mathbf{L}$ with a more general one: *pointed covers.* When a class of languages $\mathscr{C}$ is a lattice but not a boolean algebra (*i.e.*, $\mathscr{C}$ is *not closed under complement*), the associated separation problem is asymmetric: given $L_1, L_2 \subseteq A^*$, the two following problems are non-equivalent:

- finding $K_1 \in \mathscr{C}$ such that $L_1 \subseteq K_1$ and $K_1 \cap L_2 = \emptyset$.
- finding $K_2 \in \mathscr{C}$ such that $L_2 \subseteq K_2$ and $K_2 \cap L_1 = \emptyset$.

From the point of view of $\mathscr{C}$-covers, this means that we have to define a notion of "$\mathscr{C}$-cover of $\{L_1, L_2\}$" making a distinction between the languages used to cover L_1 and those used to cover L_2. This is what pointed $\mathscr{C}$-covers are designed for.

Pointed $\mathscr{C}$-covers. Let $\mathbf{L}$ be a finite set of names. An $\mathbf{L}$-*pointed set of languages* is a *finite* set $\mathbb{P} \subseteq \mathbf{L} \times 2^{A^*}$ (i.e., elements of $\mathbb{P}$ are pairs (L, K) where L is a name in $\mathbf{L}$ and K is an arbitrary language). Furthermore, we call *support* of $\mathbb{P}$ the set $\mathbf{K} = \{K \mid (L, K) \in \mathbb{P} \text{ for some } L \in \mathbf{L}\}$. In other words the support of $\mathbb{P}$ is the smallest set of languages such that $\mathbb{P} \subseteq \mathbf{L} \times \mathbf{K}$. Finally, when we have an $\mathbf{L}$-pointed set of languages $\mathbb{P}$ with support $\mathbf{K}$ in hand, for all $L \in \mathbf{L}$, we will denote by $\mathbb{P}(L) \subseteq \mathbf{K}$ the set of all $K \in \mathbf{K}$ such that $(L, K) \in \mathbb{P}$.

We may now define *pointed $\mathscr{C}$-covers.* Let $\mathscr{C}$ be a lattice. Given a finite set of languages names $\mathbf{L}$, a *pointed $\mathscr{C}$-cover* of $\mathbf{L}$ is an $\mathbf{L}$-pointed set of languages $\mathbb{P}$ such that all K in the support of $\mathbb{P}$ belong to $\mathscr{C}$ and for all $L \in \mathbf{L}$,

$$L \subseteq \bigcup_{K \in \mathbb{P}(L)} K \quad (\textit{i.e.}, \mathbb{P}(L) \text{ is a cover of } \{L\})$$

Note that since $\mathscr{C}$ is a lattice, we have $A^* \in \mathscr{C}$. Hence, for all finite sets $\mathbf{L}$, there always exists a pointed $\mathscr{C}$-cover of $\mathbf{L}$: the set $\{(L, A^*) \mid L \in \mathbf{L}\}$.

▶ Remark. Pointed $\mathscr{C}$-covers are more general than $\mathscr{C}$-covers: if $\mathbb{P}$ is a pointed $\mathscr{C}$-cover of $\mathbf{L}$, then the support $\mathbf{K}$ of $\mathbb{P}$ is a $\mathscr{C}$-cover of $\mathbf{L}$. Intuitively, pointed $\mathscr{C}$-covers capture more information: they record for each $L \in \mathbf{L}$ which languages in $\mathbf{K}$ are needed to cover L. We use this additional information to define a finer notion of optimality.

Pointed Imprints. We now generalize imprints to pointed covers with the notion of pointed imprint (also based on the notion of filtering which is unchanged). To define pointed imprints, we first have to generalize the notion of downset to our new setting. If $\mathbf{L}$ is a finite set of language names and $E \subseteq \mathbf{L} \times 2^{\mathbf{L}}$, we denote by $\downarrow E$ the set,

$$\downarrow E = \{(L, \mathbf{H}) \mid \text{there exists } (L, \mathbf{H}') \in E \text{ such that } \mathbf{H} \subseteq \mathbf{H}'\}$$

We may now define pointed imprints. Let $\mathbf{L}$ be a finite set of language names and let $\mathbb{P}$ be an $\mathbf{L}$-pointed set of languages. The *pointed imprint of* $\mathbb{P}$ *on* $\mathbf{L}$ is the set,

$$\mathcal{P}[\mathbf{L}](\mathbb{P}) \quad = \quad \downarrow\{(L, \langle \mathbf{L} | K \rangle) \mid (L, K) \in \mathbb{P}\} \subseteq \mathbf{L} \times 2^{\mathbf{L}}$$

This new notion of pointed imprint has similar properties to those of the original notion of imprint. For a fixed $\mathbf{L}$, any pointed imprint on $\mathbf{L}$ is a subset of $\mathbf{L} \times 2^{\mathbf{L}}$, so there are finitely many pointed imprints on $\mathbf{L}$. Furthermore, pointed imprints are closed under downset.

Moreover, as for imprints, pointed imprints contain some trivial elements. If $\mathbf{L}$ is a finite set of languages, we let

$$\mathcal{P}_{triv}[\mathbf{L}] = \downarrow\{(L, \langle \mathbf{L} | \{w\} \rangle) \mid L \in \mathbf{L} \text{ and } w \in L\} = \{(L, \mathbf{H}) \mid (\cap_{H \in \mathbf{H}} H) \cap L \neq \emptyset\}$$

▶ **Fact 6.** *For any pointed $\mathscr{C}$-cover $\mathbb{P}$ of $\mathbf{L}$, we have $\mathcal{P}_{triv}[\mathbf{L}] \subseteq \mathcal{P}[\mathbf{L}](\mathbb{P})$.*

Optimal Pointed $\mathscr{C}$-Covers. We can now define optimal pointed $\mathscr{C}$-covers. The definition is similar to that of optimal $\mathscr{C}$-covers. We say that a pointed $\mathscr{C}$-cover $\mathbb{P}$ of $\mathbf{L}$ is *optimal* when,

$$\mathcal{P}[\mathbf{L}](\mathbb{P}) \subseteq \mathcal{P}[\mathbf{L}](\mathbb{P}') \quad \text{for any pointed } \mathscr{C}\text{-cover } \mathbb{P}' \text{ of } \mathbf{L}\,.$$

▶ **Lemma 7.** *For any finite set of languages names $\mathbf{L}$, there exists an optimal pointed $\mathscr{C}$-cover of $\mathbf{L}$.*

As Lemma 2, Lemma 7 is based on closure under intersection. We now generalize the notion of optimal imprint. By definition, all optimal pointed $\mathscr{C}$-covers of $\mathbf{L}$ share the same pointed imprint on $\mathbf{L}$. Hence, this unique pointed imprint is a *canonical object* for $\mathscr{C}$ and $\mathbf{L}$. We call it the *optimal pointed imprint with respect to $\mathscr{C}$ on* $\mathbf{L}$ denoted by $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$:

$$\mathcal{P}_{\mathscr{C}}[\mathbf{L}] = \mathcal{P}[\mathbf{L}](\mathbf{K}) \quad \text{for any optimal pointed } \mathscr{C}\text{-cover } \mathbf{K} \text{ of } \mathbf{L}\,.$$

We are now ready to state the pointed covering problem. As before, it is parametrized by a class $\mathscr{D}$ constraining the input, and a lattice $\mathscr{C}$.

▶ **Definition 8.** The Pointed covering problem for $\mathscr{C}$ inside $\mathscr{D}$ is as follows:

INPUT:	A finite set of languages $\mathbf{L} \subseteq \mathscr{D}$.
QUESTION:	Compute $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$.

Similarly to the covering problem, there are two stages when solving the pointed covering problem for a given lattice $\mathscr{C}$. The first one is to find an algorithm that computes $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$ from $\mathbf{L}$ and the second one is to find a generic method for constructing optimal pointed $\mathscr{C}$-covers. We now make the connection with the $\mathscr{C}$-separation problem in the following theorem.

▶ **Theorem 9.** *Let $\mathscr{C}$ be a lattice and let $\mathbf{L}$ be a finite set of languages. Given any two languages $L_1, L_2 \in \mathbf{L}$, the following properties are equivalent:*

1. *L_1 is $\mathscr{C}$-separable from L_2.*
2. *$(L_1, \{L_2\}) \notin \mathcal{P}_{\mathscr{C}}[\mathbf{L}]$.*
3. *For any optimal pointed $\mathscr{C}$-cover $\mathbb{P}$ of $\mathbf{L}$, the language $\bigcup_{K \in \mathbb{P}(L_1)} K$ separates L_1 from L_2.*

Let us make two remarks. The first one is that for any lattice $\mathscr{C}$, pointed covering is more general than covering. The second is that while this relation can be strict (see Example 5), this only happens when the class $\mathscr{C}$ is not closed under complement: if $\mathscr{C}$ is a boolean algebra, then the two problems are equivalent. In other words, when $\mathscr{C}$ is a boolean algebra, there is no point in considering pointed covering: the covering problem (which relies on simpler terminology) suffices. We refer to the journal version of this paper for details.

Now that we have defined both covering problems, the remaining sections are devoted to presenting their benefits. In particular, we present a general methodology for regular inputs in Sections 3 and 4 and use it in Section 5 on specific examples. Note that in contrast to this section which was generic to all types of structures and inputs, the remainder of the paper is specific to words and regular languages: we will rely on the fact that our inputs are sets of regular languages of finite words in our methodology.

3 Tame Sets of Languages

We now present a special class of input sets for the covering problem that we call the class of *tame* sets of languages names. A tame set contains only regular languages and has a specific algebraic structure (which is connected to language concatenation). While not all finite sets of regular languages are tame, we will be able to restrict our algorithms to such inputs without loss of generality. This restriction is central: we rely heavily on the properties of tame inputs in all our algorithms. The typical example of a tame set is the following.

▶ **Example 10.** Given a nondeterministic finite automaton (NFA) $\mathscr{A} = (A, Q, I, F, \delta)$, the set $\{L_{q,r} \mid (q, r) \in Q^2\}$ is tame (where $L_{q,r}$ is a name for the language $\{w \mid q \xrightarrow{w} r\}$).

3.1 Definition

A finite set of languages names is said to be *tame* if it can be given a *partial semigroup structure*. Let us first define *partial semigroups*. A partial semigroup is a set S equipped with a partial multiplication (*i.e.*, st may not be defined for all $s, t \in S$) such that for all $r, s, t \in S$, if rs and st are both defined, then $(rs)t$ and $r(st)$ are defined and equal.

We may now define tame sets. Let $\mathbf{L}$ be a finite set of languages names. A *tame multiplication* for $\mathbf{L}$ is a partial semigroup multiplication "$\odot$" (we use this notation to avoid confusion with language concatenation) that satisfies the following properties:

1. for all $L, L' \in \mathbf{L}$, if $L \odot L'$ is defined then $LL' \subseteq L \odot L'$.
2. for all $H \in \mathbf{L}$ and all words $w \in H$, if w may be decomposed as $w = uu'$, then there exist $L, L' \in \mathbf{L}$ such that $u \in L$, $u' \in L'$ and $H = L \odot L'$.

We say that a finite set of languages names $\mathbf{L}$ is *tame* if it can be equipped with a *tame multiplication*. Note that when working with tame sets, we will implicitly assume that we have a tame multiplication "$\odot$" for this set. Furthermore, since $\mathbf{L}$ is a finite partial semigroup, it is known that there exists an integer $\omega(\mathbf{L})$ (denoted by ω when $\mathbf{L}$ is understood) such that if $L \odot L$ is defined, then L^ω is defined and idempotent (*i.e.*, $L^\omega \odot L^\omega = L^\omega$).

An important observation is that tame sets of languages names may only contain *regular languages*, as stated in the following lemma (proved in the journal version).

▶ **Lemma 11.** *Any language in a tame set of languages is regular.*

Unfortunately, the converse of Lemma 11 is not true: there are finite sets of regular languages that are not tame. For example, the set $\mathbf{L} = \{\{ab\}\}$ fails Condition 2. However, this issue is easily solved with the following proposition.

▶ **Proposition 12.** *Let* $\mathbf{H} = \{H_1, \dots, H_n\}$ *be a finite set of languages given by* n NFAs $\mathscr{A}_1, \dots, \mathscr{A}_n$. *There exists a tame set of languages names* $\mathbf{L}$ *such that for any lattice* $\mathscr{C}$,

- $\mathcal{I}_{\mathscr{C}}[\mathbf{H}]$ *(resp.* $\mathcal{P}_{\mathscr{C}}[\mathbf{H}]$*) can be computed from* $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ *(resp.* $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$*).*
- *any optimal (pointed)* $\mathscr{C}$*-cover of* $\mathbf{L}$ *is an optimal (pointed)* $\mathscr{C}$*-cover of* $\mathbf{H}$*.*
- $\mathbf{L}$ *and its tame multiplication can be computed from* $\mathscr{A}_1, \dots, \mathscr{A}_n$ *in polynomial time and has size* $|\mathscr{A}_1|^2 + \cdots + |\mathscr{A}_n|^2$ *(where* $|\mathscr{A}_i|$ *stands for the number of states of* $\mathscr{A}_i$*).*

Proposition 12 is proved in the journal version (the construction is based on Example 10). From now on, we will assume that our inputs are tame. We finish the section by explaining the benefits of considering tame inputs in the covering and pointed covering problems.

3.2 Tame Sets of Languages and the Covering Problems

As explained, we will restrict our inputs to tame sets. We now have to explain the benefits of such a restriction. In order to get these benefits, we need the investigated class $\mathscr{C}$ to satisfy a new property in addition to being a boolean algebra or a lattice. The *left quotient* of a language L by a word w is the language $w^{-1}L = \{u \in A^* \mid wu \in L\}$. The *right quotient* Lw^{-1} is defined symmetrically. A class of languages is a *quotienting boolean algebra* if it is a boolean algebra of regular languages closed under left and right quotient. A *quotienting lattice* is a lattice of regular languages closed under left and right quotients.

When $\mathbf{L}$ is tame, the partial semigroup multiplication $\odot$ over $\mathbf{L}$ can be extended as a semigroup multiplication over $2^{\mathbf{L}}$: $\mathbf{S} \odot \mathbf{R} = \{S \odot R \mid S \in \mathbf{S},\ R \in \mathbf{R} \text{ and } S \odot R \text{ is defined}\}$. Hence, $2^{\mathbf{L}}$ is a semigroup and $\mathbf{L} \times 2^{\mathbf{L}}$ a partial semigroup. It turns out that when $\mathscr{C}$ is a quotienting lattice these structures are transferred to $\mathcal{I}_{\mathscr{C}}[\mathbf{L}] \subseteq 2^{\mathbf{L}}$ and $\mathcal{P}_{\mathscr{C}}[\mathbf{L}] \subseteq \mathbf{L} \times 2^{\mathbf{L}}$.

▶ **Lemma 13.** *Let $\mathscr{C}$ be a quotienting lattice and let $\mathbf{L}$ be a tame set of languages. Then the two following properties holds:*

1. *$\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$ is closed under multiplication: for all $(L_1, \mathbf{L}_1)$, $(L_2, \mathbf{L}_2)$ in $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$, if $L_1 \odot L_2$ is defined, then $(L_1 \odot L_2, \mathbf{L}_1 \odot \mathbf{L}_2) \in \mathcal{P}_{\mathscr{C}}[\mathbf{L}]$.*
2. *$\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ is closed under multiplication: for all $\mathbf{L}_1$ and $\mathbf{L}_2$ in $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$, $\mathbf{L}_1 \odot \mathbf{L}_2 \in \mathcal{I}_{\mathscr{C}}[\mathbf{L}]$.*

Lemma 13 will be proved in the full version. Let us explain why it is crucial. We do it in the setting of the covering problem, which is simpler. We start with the following statement.

▶ **Lemma 14.** *Let $\mathbf{L}$ be a tame set of languages and let K_1, K_2 be two languages, then $\langle \mathbf{L} | K_1 \rangle \odot \langle \mathbf{L} | K_2 \rangle = \langle \mathbf{L} | K_1 K_2 \rangle$.*

Let $\mathscr{C}$ be a boolean algebra and $\mathbf{L}$ be a finite set of names. A natural method for building an optimal $\mathscr{C}$-cover $\mathbf{K}$ of $\mathbf{L}$ is to start from $\mathbf{K} = \mathcal{I}_{triv}[\mathbf{L}]$ and to add new languages K in $\mathscr{C}$ to $\mathbf{K}$ until $\mathbf{K}$ covers $\mathbf{L}$. By definition of imprints, for $\mathbf{K}$ to be optimal, we need all such candidate languages K to satisfy $\langle \mathbf{L} | K \rangle \in \mathcal{I}_{\mathscr{C}}[\mathbf{L}]$. It follows from Lemma 13 and Lemma 14 that when $\mathscr{C}$ is a quotienting boolean algebra and $\mathbf{L}$ is tame, these K may be built with concatenation: if we already have K_1 and K_2 such that $\langle \mathbf{L} | K_1 \rangle, \langle \mathbf{L} | K_2 \rangle \in \mathcal{I}_{\mathscr{C}}[\mathbf{L}]$, then we may add $K_1 K_2$ as well since by Lemmas 13 and 14, $\langle \mathbf{L} | K_1 K_2 \rangle = \langle \mathbf{L} | K_1 \rangle \odot \langle \mathbf{L} | K_2 \rangle \in \mathcal{I}_{\mathscr{C}}[\mathbf{L}]$.

This is central for classes of languages defined through logic (such as first-order logic). Indeed, concatenation is a fundamental process for building new languages in such classes.

4 General Approach

In this section, we present a natural methodology for attempting to solve the covering or pointed covering problem for a particular input class $\mathscr{C}$. This is the methodology that we use for all examples of Section 5.

Let $\mathscr{C}$ be a quotienting boolean algebra or a quotienting lattice. Recall that since we restrict ourselves to tame sets, the two objectives of the covering (resp. pointed covering) problem are as follows. Given as input a tame set $\mathbf{L}$,

1. we want an algorithm that computes $\mathcal{I}_{\mathscr{C}}[\mathbf{L}]$ (resp. $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$).
2. we want an algorithm that computes optimal $\mathscr{C}$-covers (resp. pointed $\mathscr{C}$-covers).

We now detail our methodology for the pointed covering problem (the case of the weaker covering problem is similar, see Section 5). This methodology consists in three steps.

Step 1: Presentation of the Pointed Covering Algorithm. The first step presents a solution to stage one: an algorithm that takes as input a tame set $\mathbf{L}$ and computes $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$. This step only presents the algorithm: the second and third steps are devoted to its proof.

A key point is that pointed covering algorithms are designed as *lowest fixpoint algorithms*. Since $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$ is a pointed imprint on $\mathbf{L}$, we have $\mathcal{P}_{triv}[\mathbf{L}] \subseteq \mathcal{P}_{\mathscr{C}}[\mathbf{L}]$ (Fact 6). All our algorithms start from $\mathcal{P}_{triv}[\mathbf{L}]$, and then add new elements using finitely many operations until a fixpoint is reached. Among these operations, some are specific to the particular quotienting lattice $\mathscr{C}$ that we consider, and some are *generic* to all quotienting lattices. In particular, the set of operations that we use will always include downset and multiplication (see Lemma 13). To sum up, our algorithms compute $\mathcal{P}_{\mathscr{C}}[\mathbf{L}]$ as a the smallest set $Sat_{\mathscr{C}}(\mathbf{L}) \subseteq \mathbf{L} \times 2^{\mathbf{L}}$ (*Sat* means 'saturation'), containing $\mathcal{P}_{triv}[\mathbf{L}]$ and closed under the following operations:

1. Downset: $Sat_{\mathscr{C}}(\mathbf{L}) = \downarrow Sat_{\mathscr{C}}(\mathbf{L})$.
2. Multiplication: if $(L, \mathbf{H}), (L', \mathbf{H}') \in Sat_{\mathscr{C}}(\mathbf{L})$, then $(L \odot L', \mathbf{H} \odot \mathbf{H}') \in Sat_{\mathscr{C}}(\mathbf{L})$ (if defined).
3. $\cdots$ (additional operation(s) specific to $\mathscr{C}$).

Step 2: Soundness. The second step is devoted to proving that the covering algorithm of Step 1 is sound, *i.e.*, that $Sat_{\mathscr{C}}(\mathbf{L}) \subseteq \mathcal{P}_{\mathscr{C}}[\mathbf{L}]$: for any pointed $\mathscr{C}$-cover $\mathbb{P}$ of $\mathbf{L}$, $Sat_{\mathscr{C}}(\mathbf{L}) \subseteq \mathcal{P}[\mathbf{L}](\mathbb{P})$. This is the "easy" direction and it involves Ehrenfeucht-Fraïssé arguments.

Step 3: Completeness. The third step is devoted to proving that the covering algorithm of Step 1 is complete, *i.e.*, that $\mathcal{P}_{\mathscr{C}}[\mathbf{L}] \subseteq Sat_{\mathscr{C}}(\mathbf{L})$. While usually difficult, this proof is of particular interest as it yields a solution to second stage of the pointed covering problem as a byproduct: an algorithm that computes optimal pointed $\mathscr{C}$-covers.

The proof of this step should be presented as a generic construction for building an actual pointed $\mathscr{C}$-cover $\mathbb{P}$ of $\mathbf{L}$ whose imprint on $\mathbf{L}$ is included in $Sat_{\mathscr{C}}(\mathbf{L})$. This proves that $\mathcal{P}_{\mathscr{C}}[\mathbf{L}] \subseteq \mathcal{P}[\mathbf{L}](\mathbb{P}) \subseteq Sat_{\mathscr{C}}(\mathbf{L})$, and therefore completeness. However, by combining this with the knowledge that the algorithm is also sound (this is proved in Step 2), we obtain that $\mathcal{P}_{\mathscr{C}}[\mathbf{L}] = \mathcal{P}[\mathbf{L}](\mathbb{P})$. In other words the proof builds an *optimal pointed $\mathscr{C}$-cover* $\mathbb{P}$ of $\mathbf{L}$.

5 Examples of Covering Algorithms

We now present examples of covering algorithms for several classical logical fragments, all based on first-order logic on words. Let us first briefly recall the definition of first-order logic over finite words. A word is viewed as logical structure made of a sequence of positions labeled over A. In first-order logic over words (FO), for each $a \in A$, one is allowed to use a unary predicate "$a(x)$" which selects positions x labeled with an a, as well as a binary predicate "$<$" for the linear order. A language L is said to be *first-order definable* if there is an FO sentence φ such that $L = \{w \mid w \models \varphi\}$. Also denote by FO the class of all first-order definable languages. We present algorithms for FO itself and its fragments $\mathcal{B}\Sigma_1$, FO^2, Σ_2.

Note that we only present Step 1 of our methodology in the main text, *i.e.*, algorithms without their proofs. An important remark is that these proofs are all difficult: while we have a generic template, proving a covering algorithm always requires arguments specific to the investigated class. We present proofs for $\mathcal{B}\Sigma_1$, FO^2 and Σ_2 in the full version of this paper. The proof for FO is omitted as it is close to proof of [28] (which is based on a prototype of the present framework). On the other hand, the algorithms and proofs for $\mathcal{B}\Sigma_1$, FO^2 and Σ_2 are new.

First-Order Logic: FO. The first algorithm that we present is for FO itself, which is among the most famous classes of regular languages in the literature. The decidability of the membership problem for FO was proved by Schützenberger, McNaughton and Papert [30, 14] and the result is among those that started this line of research. Separation was later proved to be decidable as well [11, 12, 28]. As explained the covering algorithm is a generalization of that of [28] (which is based on a prototype of this framework). As FO is known to be a quotienting boolean algebra, we use the covering problem.

▶ **Theorem 15.** *Let* $\mathbf{L}$ *be a tame set of languages. Then* $\mathcal{I}_{\mathrm{FO}}[\mathbf{L}]$ *is the smallest subset of* $2^{\mathbf{L}}$ *containing* $\mathcal{I}_{triv}[\mathbf{L}]$*, closed under downset, multiplication and such that for all* $\mathbf{S} \in \mathcal{I}_{\mathrm{FO}}[\mathbf{L}]$*, we have* $\mathbf{S}^{\omega} \cup \mathbf{S}^{\omega+1} \in \mathcal{I}_{\mathrm{FO}}[\mathbf{L}]$*.*

Boolean Combinations of Σ_1: $\mathcal{B}\Sigma_1$. The next class that we use as an example is $\mathcal{B}\Sigma_1$, which is the restriction of FO to sentences that are boolean combinations of Σ_1 sentences. A sentence is Σ_1 if its prenex normal form uses only existential quantifiers. The class $\mathcal{B}\Sigma_1$ is famous in the literature. the decidability of $\mathcal{B}\Sigma_1$-membership was proved by Simon [31]. $\mathcal{B}\Sigma_1$-separation is also known to be decidable [8, 23]. As $\mathcal{B}\Sigma_1$ is known to be a quotienting boolean algebra, we use the covering problem. Given a word $w \in A^*$, we denote by $\mathbf{alph}(w)$ the set of letters occurring in w, i.e. the smallest subset of B of A such that $w \in B^*$.

▶ **Theorem 16.** *Let* $\mathbf{L}$ *be a tame set of languages.* $\mathcal{I}_{\mathcal{B}\Sigma_1}[\mathbf{L}]$ *is the smallest subset of* $2^{\mathbf{L}}$ *containing* $\mathcal{I}_{triv}[\mathbf{L}]$*, closed under downset, multiplication and such that for all* $B \subseteq A$*, if* $\mathbf{H} = \{L \in \mathbf{L} \mid \exists w \in L,\ s.t.\ \mathbf{alph}(w) = B\}$*, then* $\mathbf{H}^{\omega} \in \mathcal{I}_{\mathcal{B}\Sigma_1}[\mathbf{L}]$*.*

Two-variable First-Order Logic: FO^2. The logic FO^2 is the restriction of FO to sentences that use at most two distinct variables (which may be reused). That the associated membership problem is decidable is due to Thérien and Wilke [34]. The separation problem was proved to be decidable in [23]. As FO^2 is known to be a quotienting boolean algebra, we use the covering problem. Our algorithm requires the input to satisfy a new condition in addition to being tame: *alphabet compatibility* (this may be assumed without loss of generality, as will be shown in the full version). A set $\mathbf{L}$ is said to be *alphabet compatible* if for all languages $L \in \mathbf{L}$, there exists a unique $B \subseteq A$ such that for any $w \in L$, $\mathbf{alph}(w) = B$. Note that when $\mathbf{L}$ is alphabet compatible, then $\mathbf{alph}(L)$ is well-defined for all $L \in \mathbf{L}$ as this unique alphabet.

▶ **Theorem 17.** *Let* $\mathbf{L}$ *be a tame and alphabet compatible set of languages.* $\mathcal{I}_{\mathrm{FO}^2}[\mathbf{L}]$ *is the smallest subset of* $2^{\mathbf{L}}$ *containing* $\mathcal{I}_{triv}[\mathbf{L}]$*, closed under downset, multiplication and such that for all* $B \subseteq A$ *and* $\mathbf{S}, \mathbf{T} \in \mathcal{I}_{\mathrm{FO}^2}[\mathbf{L}]$ *containing* S, T *with* $\mathbf{alph}(S) = \mathbf{alph}(T) = B$*,*

$$\mathbf{S}^{\omega} \odot \langle \mathbf{L} | B^* \rangle \odot \mathbf{T}^{\omega} \in \mathcal{I}_{\mathrm{FO}^2}[\mathbf{L}].$$

One Quantifier Alternation: Σ_2. Our third example is Σ_2, which is the restriction of FO to sentences whose prenex normal form have a quantifier prefix of the form '$\exists^*\forall^*$'. It was proved that Σ_2-membership is decidable in [3, 21] and the same was proved for separation in [25]. As Σ_2 is a quotienting lattice but not a boolean algebra, we use the pointed covering problem. Our algorithm requires the input to be tame and alphabet compatible.

▶ **Theorem 18.** *Let* $\mathbf{L}$ *be a tame and alphabet compatible set of languages* $\mathcal{P}_{\Sigma_2}[\mathbf{L}]$ *is the smallest subset of* $\mathbf{L} \times 2^{\mathbf{L}}$ *containing* $\mathcal{P}_{triv}[\mathbf{L}]$*, closed under downset, multiplication and such that for any* $B \subseteq A$*, and* $(S, \mathbf{S}) \in \mathcal{P}_{\Sigma_2}[\mathbf{L}]$ *satisfying* $\mathbf{alph}(S) = B$ *and* $S \odot S$ *is defined,*

$$(S^{\omega}, \mathbf{S}^{\omega} \odot \langle \mathbf{L} | B^* \rangle \odot \mathbf{S}^{\omega}) \in \mathcal{P}_{\Sigma_2}[\mathbf{L}].$$

6 Conclusion

We introduced the covering and pointed covering problems which are designed to investigate quotienting boolean algebras and quotienting lattices respectively. We also presented a methodology outlining how these problems should be approached. Furthermore, we presented four examples of algorithms for the instances associated to FO, $\mathcal{B}\Sigma_1$, FO^2 and Σ_2.

It is worth noting that while our examples include the most significant logics for which separation is known to be decidable, an important one is missing: Σ_3. This is not surprising as the algorithm of [22] considers an *ad hoc* problem which is associated to two logics at the same time: Σ_2 and Σ_3. However, it is possible to generalize this result as well within our framework: this is where the modularity of our problems comes into play. Using a stronger notion of filtering, one can reformulate and generalize the problem of [22] as an instance of the pointed covering problem (we leave the presentation of this instance for further work).

Our results raise several questions. The most natural is to apply our framework to classes for which no membership or separation algorithm is known yet. Another one is related to the classical membership algorithms. These algorithms are usually stated as equations on the syntactic monoid of the language which share similarities with fixpoint operations of our (pointed) covering algorithms. An interesting question would be to find a criterion under which membership equations can be lifted as a fixpoint operation for the covering problem.

Abstract

Infinite duration games with regular conditions are one of the crucial tools in the areas of verification and synthesis. In this paper we consider a branching variant of such games – the game contains branching vertices that split the play into two independent sub-games. Thus, a play has the form of an infinite tree. The winner of the play is determined by a winning condition specified as a set of infinite trees. Games of this kind were used by Mio to provide a game semantics for the probabilistic μ-calculus. He used winning conditions defined in terms of parity games on trees. In this work we consider a more general class of winning conditions, namely those definable by finite automata on infinite trees. Our games can be seen as a branching-time variant of the stochastic games on graphs.

We address the question of determinacy of a branching game and the problem of computing the optimal game value for each of the players. We consider both the stochastic and non-stochastic variants of the games. The questions under consideration are parametrised by the family of strategies we allow: either mixed, behavioural, or pure.

We prove that in general, branching games are not determined under mixed strategies. This holds even for topologically simple winning conditions (differences of two open sets) and non-stochastic arenas. Nevertheless, we show that the games become determined under mixed strategies if we restrict the winning conditions to open sets of trees. We prove that the problem of comparing the game value to a rational threshold is undecidable for branching games with regular conditions in all non-trivial stochastic cases. In the non-stochastic cases we provide exact bounds on the complexity of the problem. The only case left open is the 0-player stochastic case, i.e. the problem of computing the measure of a given regular language of infinite trees.

1 Introduction

Since the seminal works of Büchi and Landweber [3], and of McNaughton [17], the infinite duration games are widely used to model interaction between a system and an environment. One of the fundamental questions about such games is the question of determinacy – does always one of the players has a winning strategy? In a more general case of valued zero-sum

games, determinacy amounts to the equality

$$\sup_{\sigma} \inf_{\pi} \ val(\sigma, \pi) = \inf_{\pi} \sup_{\sigma} \ val(\sigma, \pi), \tag{1}$$

where σ and π range over strategies of the respective players. It is often crucial to provide a specific information about the strategies that are enough to win a given game. Büchi and Landweber proved that if the winning condition of a game is a regular language of infinite words then the game is determined under finite memory strategies. Further results have established more precise bounds for the amount of memory needed [9, 10]. Also, the stochastic variant of the question was considered [7].

In this work we study a branching variant of stochastic games on graphs – a variant called *branching games* (also known as *tree games*, c.f. [20, Chapter 4]), played on *branching boards*. A play of a branching game consists of a number of threads, each thread develops independently. When a thread reaches a vertex marked as *branching*, it is split into two separate threads. Thus, a play of a branching game has the shape of an infinite tree. The winner of the play is determined by a winning condition specified as a regular set of infinite trees. Since the choices made by players in separate threads are independent, branching games are not games of perfect information, nor of perfect recall in the meaning of [2]. Games of this kind were used by Mio [21] to provide a game semantics for the probabilistic μ-calculus, with the *meta-parity* winning condition defined in terms of parity games on trees. The author called them *meta-parity games* and established their pure determinacy subject to some set-theoretic assumptions, that were later eliminated [13]. This result is interesting, because, as the author notices in conclusion, determinacy results for imperfect information games are not frequent in game theory.

In this article we address the question of determinacy of branching games and the problem of computing the game value for a more general class of winning conditions than the meta-parity conditions studied by Mio, namely those definable by finite automata on infinite trees. We believe that this extension is motivated by the role tree automata play in verification theory. Recall that these automata, introduced by Rabin in his proof of decidability of the Monadic Second-Order theory of the full k-ary tree [23], constitute a general formalism subsuming most of temporal logics of programs. The first step was made by the first author who extended the results of Mio [21] to winning conditions given by game automata [22].

We consider both the stochastic and non-stochastic variants of the games. The questions under consideration are parametrised by the family of strategies we allow, either mixed, behavioural, or pure. The goal of this work is to provide answers to two questions:

- When a branching game is determined in the sense of (1)?
- When the optimal value for a given player can be effectively computed?

Both questions can be asked for stochastic and non-stochastic variants of games, which usually yields different answers, see e.g. [7]; and for different sets of allowed strategies. The distinction between the sets of pure, behavioural, and mixed strategies can significantly alter the techniques and expected outcomes, see e.g. [5].

The answers we provide create an almost complete picture from the point of view of topological complexity of sets:

- non-stochastic branching games are not determined under pure nor behavioural strategies even for winning conditions that are topologically both closed and open,
- non-stochastic branching games are not determined under mixed strategies for winning conditions that are a difference of two open sets,
- non-stochastic branching games are determined under mixed strategies for winning conditions that are open (equivalently, closed) sets,

- the problem of comparing the value of a branching game to a rational number is undecidable in all the non-trivial stochastic cases,
- in the non-stochastic case, when we ask about the existence of a pure winning strategy, the problem is decidable and we provide precise bounds on its complexity.

The only remaining question is whether the value of a 0-player stochastic branching game can be effectively computed. This is equivalent to asking about computability of the measure of a given regular language of infinite trees.

Although the results of this paper show intractability of branching games, it is still possible that they are determined for a reasonable class of winning conditions. These ideas are discussed in Conclusions.

1.1 Related work

It is known that games with arbitrary pay-off functions are not determined. The celebrated result of Martin [15] states that *Gale-Steward games* with Borel payoffs are determined under pure strategies. His later result establishes an analogous result for the so-called *Blackwell games* and mixed strategies (cf. [16]). In this work we show that branching games are determined only for topologically simplest winning conditions – open or closed sets; even allowing a difference of two open sets leads to indeterminacy.

Since the branching games are not games of *perfect recall* the Kuhn's theorem (cf. e.g. [2]) does not hold; and the behavioural strategies are weaker than the mixed strategies. An example of such a situation was provided by Mio in [20, Chapter 4]. Therefore, there are three variants of the question of determinacy: pure, behavioural, and mixed determinacy.

The concept of branching games is a natural extension of the *meta-parity games* introduced by Mio [21] to provide a game semantics for the probabilistic μ-calculus. The first author proved in [22] that non-stochastic branching games with winning conditions given by the so-called *game automata* are determined under pure strategies. In this work we study determinacy of branching games from the perspective of the topological complexity of the winning condition.

Recently Asarin et al. considered the so-called *entropy games*, cf. [1], which can be easily embedded in our framework. In the authors' own words, an entropy game is played on a finite arena by two-and-a-half players: Despot, Tribune, and the non-deterministic People. The pay-off function is the entropy of the language formed by paths of the resulting tree. The authors of [1] prove that the entropy games are determined under pure strategies and can be solved in $NP \cap coNP$, extending the class of objectives for which branching games are determined.

The question of computing the coin-flipping measure of a given regular languages of infinite trees is one of the crucial open problems about probabilistic logics on infinite trees. Chen, Dräger, and Kiefer proved in [8] that the problem is decidable for regular languages recognisable by deterministic automata. The result was later strengthened by Michalewski and Mio [19] to the so-called game automata. The question of computing the value of a branching game is a natural extension of the above problem obtained by allowing interplay between the players. The first author implicitly provided bounds on the complexity of the problem in the non-stochastic case. In this paper we complete those bounds by proving *2-EXP*-hardness of the problem. Additionally, we prove that the problem becomes undecidable if any form of randomisation is allowed (either by considering randomised or behavioural strategies; or by adding stochastic positions). The only remaining open question is the original one – when there are only stochastic positions and no players.

Branching games fall into a general category of games of *imperfect information*, i.e. games where the full information about the state of the game is not assumed: the definitions assure that the players have no information about the execution of separate threads. The area of imperfect information games is rich and not fully understood, see e.g. [7, 4, 6], see also [5]. In this context, branching games with regular objectives can be seen as a natural extension of *imperfect information games with ω-regular objectives* to the branching-time case.

2 Definitions

In this section we will define the objects studied in the paper. The crucial definitions are those of a *branching game* and *game values*. By ω we denote the set of natural numbers and $\mathbb{R}$ stands for the set of reals.

Words and trees. An *alphabet* Γ is a finite non-empty set. A *word* over Γ is any, possibly infinite, sequence $w = a_0 a_1 \cdots a_n \cdots$ where $a_i \in \Gamma$. By $w[i]$ we denote the i-th letter of w, i.e. a_i. ε stands for the empty sequence. Words are either *finite* (Γ^*) or *infinite* (Γ^ω). $|w|$ is the length of a finite word w. The prefix order on words is denoted $\sqsubseteq$.

A *tree* over an alphabet Γ is any partial function $t\colon \{\mathtt{L},\mathtt{R}\}^* \rightharpoonup \Gamma$ with a non-empty prefix-closed domain $\mathit{Dom}(t) \subseteq \{\mathtt{L},\mathtt{R}\}^*$. The elements $d \in \{\mathtt{L},\mathtt{R}\}$ are called *directions*, $\bar{d}$ is the direction opposite to d. Elements of the set $\{\mathtt{L},\mathtt{R}\}^*$ are called *nodes*. We say that a node u of a tree t is *fully branching* if it has two children in the tree, is *uniquely branching* if it has exactly one child in the tree. The set $\mathcal{T}_\Gamma$ is the set of all trees over an alphabet Γ. This set can naturally be enhanced with a topology in such a way that it becomes a homeomorphic copy of the Cantor set [25]. We say that a tree t_1 is a *prefix* of a tree t_2 if $t_1 \subseteq t_2$, i.e. $\mathit{Dom}(t_1) \subseteq \mathit{Dom}(t_2)$ and for every $u \in \mathit{Dom}(t_1)$ we have $t_1(u) = t_2(u)$.

Regular languages. In this work we use the standard notions of non-deterministic and alternating parity automata over infinite trees. Together with Monadic Second-Order logic, these automata form equivalent formalisms for defining *regular* languages of infinite trees. For an introduction to this area see for instance [24].

Branching games. This paper is about branching games. The two adversaries of our games are called Eve and Adam (or shortly E and A). Since we consider stochastic games, we additionally introduce *Nature* denoted $\mathcal{N}$. A *branching board* is a tuple $\mathtt{B} = \langle V, \Gamma, s_\mathtt{L}, s_\mathtt{R}, \rho, \eta, \lambda, v_\mathrm{I}\rangle$, where V is the set of *vertices*; Γ is the *alphabet*; $s_\mathtt{L}, s_\mathtt{R}\colon V \to V$ are the *successor functions*; $\lambda\colon V \to \Gamma$ is the *labelling* of the vertices; $\rho\colon V \to \{A, E, \mathcal{N}, \mathcal{B}\}$ is a partition of the vertices between Adam's, Eve's, *Nature*'s, and branching vertices; $\eta\colon \rho^{-1}\big(\{\mathcal{N}\}\big) \to \mathit{Dist}(\{\mathtt{L},\mathtt{R}\})$ maps *Nature*'s vertices to random distributions over the successors; $v_\mathrm{I} \in V$ is the *initial vertex*. We extend the assignment s to arbitrary sequences of directions in the natural way: $s_\varepsilon(v) = v$ and $s_{u\cdot d}(v) = s_d\big(s_u(v)\big)$.

For $P \in \{A, E, \mathcal{N}, \mathcal{B}\}$, by V_P we denote the set of vertices belonging to P, i.e. $\rho^{-1}\big(\{P\}\big)$. We say that $\mathtt{B}$ is *finitary* if the set of vertices V is finite and the values used to define η are rational. For $\mathcal{P} \subseteq \{A, E, \mathcal{N}, \mathcal{B}\}$ we say that $\mathtt{B}$ is $\mathcal{P}$-*branching* if $\mathit{Range}(\rho) \subseteq \mathcal{P}$. Every board $\mathtt{B}$ defines the tree $t^\lambda_\mathtt{B}\colon \{\mathtt{L},\mathtt{R}\}^* \to \Gamma$ as the unfolding of the adequate labelled sub-graph of the board, i.e. $t^\lambda_\mathtt{B}(u) = \lambda\big(s_u(v_\mathrm{I})\big)$. $\mathtt{B}$ is *non-stochastic* if it is $\{E, A, \mathcal{B}\}$-branching.

Intuitively, a play over a branching board $\mathtt{B}$ proceeds in threads, each thread has one token located in a vertex of the board. Initially, there is one thread with the token located in v_I. Consider a thread with a token located in a vertex v. If $\rho(v) = \mathcal{B}$ then the thread is duplicated into two separate threads with tokens located in $s_{\mathtt{L}}(v)$ and $s_{\mathtt{R}}(v)$. If $\rho(v) = \mathcal{N}$ then the token is moved either to $s_{\mathtt{L}}(v)$ or to $s_{\mathtt{R}}(v)$ depending on an independent random event with distribution $\eta(v)$. If $\rho(v) \in \{E, A\}$ then the respective player can make her/his choice depending on the history of the current thread. However, she/he cannot take into account positions of tokens from other threads in the current play. After all the threads moved infinitely many times, a tree-like play has been created. The winning condition of a branching game will indicate which plays are winning for which player. Figure 1 depicts a branching board and a play on this board.

We will now formalise the notions of a play and a pure strategy of a player. Consider a non-empty set $\mathcal{P} \subseteq \{A, E, \mathcal{N}, \mathcal{B}\}$. We say that a tree $t \subseteq t^{\lambda}_{\mathtt{B}}$ is *$\mathcal{P}$-branching* if it is fully branching in the nodes $u \in \{\mathtt{L},\mathtt{R}\}^*$ such that $\rho\big(s_u(v_{\mathrm{I}})\big) \in \mathcal{P}$ and uniquely branching in the remaining nodes. A *play* on a board $\mathtt{B}$ is a tree $t \subseteq t^{\lambda}_{\mathtt{B}}$ that is $\{\mathcal{B}\}$-branching. The set of all plays on a board $\mathtt{B}$ is denoted $\mathrm{plays}(\mathtt{B})$. For $P \in \{E, A, \mathcal{N}\}$ we say that a tree $t \subseteq t^{\lambda}_{\mathtt{B}}$ is a *pure strategy* of P over $\mathtt{B}$ if t is $\big(\{E, A, \mathcal{N}, \mathcal{B}\} \setminus \{P\}\big)$-branching. The set of pure strategies of P over $\mathtt{B}$ is denoted $\Sigma^P_{\mathtt{B}}$. Notice that the sets $\mathrm{plays}(\mathtt{B})$ and $\Sigma^P_{\mathtt{B}}$ for $P \in \{E, A, \mathcal{N}\}$ are closed sets of Γ-labelled trees. If V is finite then all these sets are regular.

Given three pure strategies $\sigma \in \Sigma^E_{\mathtt{B}}$, $\pi \in \Sigma^A_{\mathtt{B}}$, and $\eta \in \Sigma^{\mathcal{N}}_{\mathtt{B}}$ the *play resulting from σ, π, and η* (denoted $\mathrm{eval}_{\mathtt{B}}(\sigma, \pi, \eta)$) is the tree $\sigma \cap \pi \cap \eta \in \mathrm{plays}(\mathtt{B})$. Thus, $\mathrm{eval}_{\mathtt{B}} \colon \Sigma^E_{\mathtt{B}} \times \Sigma^A_{\mathtt{B}} \times \Sigma^{\mathcal{N}}_{\mathtt{B}} \to \mathrm{plays}(\Gamma)$. Notice that the function $\mathrm{eval}_{\mathtt{B}}$ is continuous.

Measure theory. For an introduction to measure theory we refer to [14, Chapter 17]. Measure properties of regular sets of trees are discussed in [13]. Let μ be a Borel measure on a topological space X. We say that μ is a *probability measure* if $\mu(X) = 1$. A function $f \colon X \to \mathbb{R}$ is μ-measurable if the pre-image of any measurable set in $\mathbb{R}$ is μ-measurable in X. $f \colon X \to \mathbb{R}$ is *universally measurable* if it is μ-measurable for every Borel measure μ on X. If $f \colon X \to \mathbb{R}$ is μ-measurable then by $\int_X f(x)\ \mu(\mathrm{d}x)$ we denote the integral of f with respect to the measure μ.

Branching games. A *branching game* is a pair $G = \langle \mathtt{B}, \Phi\rangle$ where $\mathtt{B}$ is a branching board and Φ is a universally measurable bounded real function $\Phi \colon \mathrm{plays}(\mathtt{B}) \to \mathbb{R}^+$. The notions of a *$\mathcal{P}$-branching* game and a *finitary* game refer to the respective properties of the board.

Mixed strategies. A mixed strategy of a player $P \in \{E, A\}$ is a Borel probability measure over the set $\Sigma^P_{\mathtt{B}}$. The set of all mixed strategies of P is denoted by $\Sigma^{MP}_{\mathtt{B}}$.

There is a natural way of defining a Borel probability measure $\eta^*_{\mathtt{B}}$ on the set $\Sigma^{\mathcal{N}}_{\mathtt{B}}$ of strategies of $\mathcal{N}$. This measure represents the intuition, that after a sequence of directions $u \in \{\mathtt{L},\mathtt{R}\}$ corresponding to a vertex $v = s_u(v_{\mathrm{I}}) \in V$ such that $\rho(v) = \mathcal{N}$, *Nature* chooses to move to a direction $d \in \{\mathtt{L},\mathtt{R}\}$ with the probability $\eta(v)(d)$ and is called *behavioural.*

Behavioural strategies. We say that a mixed strategy of P is *behavioural* if it is a "coin flipping" measure, i.e. a measure induced by supplying some of the nodes of $t^{\lambda}_{\mathtt{B}}$ corresponding to vertices of P with a probability distribution over the successors. To produce a pure strategy from a behavioural one, the directions are chosen independently according to the fixed probability distributions.

More formally, a mixed strategy τ of P is *behavioural* if it is, as a measure over $\Sigma^P_{\mathtt{B}}$, the measure $\eta^*_{\mathtt{B}'}$ for some (possibly not finitary) board $\mathtt{B}'$. The set of all behavioural strategies of P is denoted by $\Sigma^{BP}_{\mathtt{B}}$. Clearly we can treat every pure strategy in $\Sigma^P_{\mathtt{B}}$ as a Dirac delta function in $\Sigma^{MP}_{\mathtt{B}}$ (in fact in $\Sigma^{BP}_{\mathtt{B}}$). Thus, we can assume that $\Sigma^P_{\mathtt{B}} \subseteq \Sigma^{BP}_{\mathtt{B}} \subseteq \Sigma^{MP}_{\mathtt{B}}$.

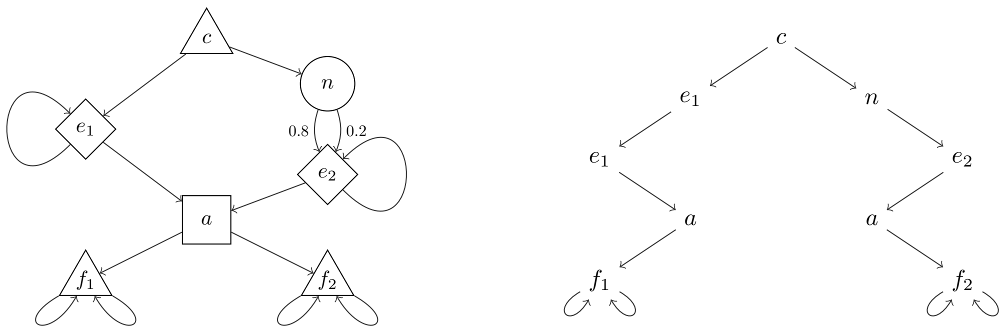

Figure 1 An example of a branching board and a play on this board. We denote Eve's, Adam's, *Nature*'s, and branching vertices by diamonds, squares, circles, and triangles respectively. *Nature*'s vertices are equipped with a probability distribution over the successors. The successors L and R agree with the directions on the picture, i.e. L moves to the left.

Strategies as functions. There is a different way to define the three types of strategies that may give more intuition to the behaviour and expressive power of the strategies. A pure strategy $\sigma \in \Sigma^P$ can be seen as a function $\sigma\colon \{\mathtt{L},\mathtt{R}\}^* \to \{\mathtt{L},\mathtt{R}\}$; a behavioural strategy $\sigma_b \in \Sigma^{BP}$ as a function $\sigma_b\colon \{\mathtt{L},\mathtt{R}\}^* \to \mu(\{\mathtt{L},\mathtt{R}\})$; and a mixed strategy $\sigma_m \in \Sigma^{MP}$ as a measure $\sigma_m \in \mu(\Sigma^P)$, where $\mu(X)$ dentotes some Borel probability mesure on the set X.

An example. Figure 1 depicts a branching board $\mathtt{B}$ and a play t on this board. We identify the vertices with their labels. A pure strategy of Adam can make different choices in a depending on the history of the thread that lead to this vertex (there are infinitely many such histories). A pure strategy of Eve can make different choices in e_2 depending on the edge taken by *Nature* in n. A mixed strategy of Eve can synchronise: with probability $\frac{1}{2}$ move to L in both vertices e_1, e_2; and with probability $\frac{1}{2}$ move to R in both of them. A behavioural strategy cannot make such a synchronisation: the probability distribution over the successors depends only on the history of the current thread.

Values of strategies. Assume that $\sigma_m \in \Sigma_{\mathtt{B}}^{ME}$ and $\pi_m \in \Sigma_{\mathtt{B}}^{MA}$ are two mixed strategies of the respective players. Our aim is to define the value $val_{\mathrm{G}}(\sigma_m, \pi_m)$. Intuitively, $val_{\mathrm{G}}(\sigma_m, \pi_m)$ should be the expected value of $\Phi\big(\mathrm{eval}_{\mathrm{G}}(\sigma, \pi, \eta)\big)$ where the pure strategies σ, π, and η are chosen according to the probability distributions σ_m, π_m, and $\eta_{\mathtt{B}}^*$ respectively. This is formalised as follows.

$$val_{\mathrm{G}}(\sigma_m, \pi_m) \overset{\mathrm{def}}{=} \int_{\Sigma_{\mathtt{B}}^E, \Sigma_{\mathtt{B}}^A, \Sigma_{\mathtt{B}}^N} \Phi\big(\mathrm{eval}_{\mathrm{G}}(\sigma, \pi, \eta)\big)\ \sigma_m(\mathrm{d}\sigma)\, \pi_m(\mathrm{d}\pi)\, \eta_{\mathtt{B}}^*(\mathrm{d}\eta) \tag{2}$$

If σ and π are pure strategies and the board is non-stochastic then $val_{\mathrm{G}}(\sigma, \pi) = \Phi(\pi \cap \sigma)$.

Values of a game. The aim of Eve in a branching game is to maximise the value $val_{\mathrm{G}}(\sigma, \pi)$. Let us define the *partial values* of the game. Consider $X \in \{\varepsilon, B, M\}$ (i.e. X stands for respectively *pure*, *behavioural*, and *mixed* strategies). The X *value of* G *for Eve* (resp. Adam) is defined as

$$val_{\mathrm{G}}^{XE} \overset{\mathrm{def}}{=} \sup_{\sigma \in \Sigma_{\mathtt{B}}^{XE}} val_{\mathrm{G}}(\sigma) \quad \text{where} \quad val_{\mathrm{G}}(\sigma) \overset{\mathrm{def}}{=} \inf_{\pi \in \Sigma_{\mathtt{B}}^{A}} val_{\mathrm{G}}(\sigma, \pi),$$

$$val_{\mathrm{G}}^{XA} \overset{\mathrm{def}}{=} \inf_{\pi \in \Sigma_{\mathtt{B}}^{XA}} val_{\mathrm{G}}(\pi) \quad \text{where} \quad val_{\mathrm{G}}(\pi) \overset{\mathrm{def}}{=} \sup_{\sigma \in \Sigma_{\mathtt{B}}^{E}} val_{\mathrm{G}}(\sigma, \pi).$$

Notice, that the second inf/sup is taken over the pure strategies of the opponent. This is explained by the following simple lemma.

▶ **Lemma 1.** *Let* G *be a branching game. If* σ_m *is Eve's mixed strategy then*

$$\inf_{\pi_m \in \Sigma_{\mathtt{B}}^{MA}} val_{\mathrm{G}}(\sigma_m, \pi_m) = \inf_{\pi_b \in \Sigma_{\mathtt{B}}^{BA}} val_{\mathrm{G}}(\sigma_m, \pi_b) = \inf_{\pi \in \Sigma_{\mathtt{B}}^{A}} val_{\mathrm{G}}(\sigma_m, \pi)$$

Dually, the same holds for mixed strategies of Adam if we replace inf *with* sup *and* A *with* E*.*

Determinacy. As a simple consequence of Lemma 1 we obtain the following inequalities

$$val_{\mathrm{G}}^{A} \geq val_{\mathrm{G}}^{BA} \geq val_{\mathrm{G}}^{MA} \geq val_{\mathrm{G}}^{ME} \geq val_{\mathrm{G}}^{BE} \geq val_{\mathrm{G}}^{E}. \qquad (3)$$

The first two (resp. the last two) inequalities hold by the fact that we take inf (resp. sup) over greater (reps. smaller) sets of strategies. The third inequality holds by Lemma 1 and the fact that $\inf_x \sup_y f(x,y) \geq \sup_y \inf_x f(x,y)$.

We will say that a branching game G is *determined*

- *under pure strategies* if $val_{\mathrm{G}}^{A} = val_{\mathrm{G}}^{E}$,
- *under behavioural strategies* if $val_{\mathrm{G}}^{BA} = val_{\mathrm{G}}^{BE}$,
- *under mixed strategies* if $val_{\mathrm{G}}^{MA} = val_{\mathrm{G}}^{ME}$.

Clearly, Equation (3) shows that pure determinacy implies behavioural determinacy and behavioural determinacy implies mixed determinacy. In general, the opposite implications do not hold. The questions of determinacy of branching games are discussed in Section 3.

Regular branching games. The following theorem implies that we can take as Φ an indicator of a regular language of trees $L \subseteq \mathrm{plays}(\mathtt{B})$, i.e. $\Phi(t) = 1$ if $t \in L$ and $\Phi(t) = 0$ otherwise. In that case we say that a game G has L *as a winning condition* and we write $G = \langle \mathtt{B}, L\rangle$ instead of $G = \langle \mathtt{B}, \Phi\rangle$.

▶ **Theorem 2** (Michalewski et al. [13]). *Every regular language* L *of infinite trees is universally measurable, i.e. for every Borel measure* μ *on the set of trees, we know that* L *is* μ*-measurable.*

3 Determinacy

In this section we study determinacy of branching games in the three variants: pure, behavioural, and mixed; see (3). We will show that for general regular winning conditions all three variants fail. However, when we restrict to closed regular winning sets we can recover the mixed determinacy.

Notice that if a branching game is not branching, i.e. it is a $\{E, A, \mathcal{N}\}$-branching game then the determinacy is well-understood [16, 7]. Similarly, if there are no positions of one of the players then the game is purely determined by Lemma 1. Therefore, the simplest case specific for the branching games are the $\{E, A, \mathcal{B}\}$-branching games.

3.1 Behavioural indeterminacy

We start by proving the following theorem.

▶ **Theorem 3.** *There is a* $\{E, A, \mathcal{B}\}$*-branching game* G *with a regular winning condition that is both closed and open such that* G *is not determined under behavioural strategies.*

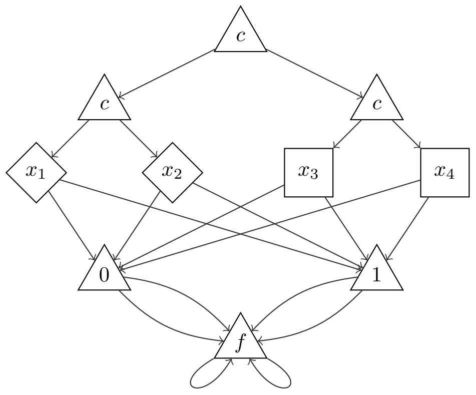

Figure 2 A branching board that is not determined under behavioural strategies.

The board B of the game G is depicted in Figure 2. A play $t \in \text{plays}(\mathtt{B})$ over B starts by splitting into four separate threads by the $\mathcal{B}$-vertices labelled with c. Then, each of the players can perform two separate choices, E in the two vertices labelled x_1 and x_2, and A in the two vertices labelled x_3 and x_4. Their choices lead to vertices labelled by either 0 or 1. The rest of the play stays forever in the branching vertex labelled by f. For $i = 1, 2, 3, 4$ let $x_i(t) \in \{0, 1\}$ be label chosen by the respective player in the vertex labelled by x_i, i.e. the label of the unique child of the unique node labelled by x_i in t. Consider a winning set $L \subseteq \text{plays}(\mathtt{B})$ defined as follows

$$L \overset{\text{def}}{=} \{t \in \text{plays}(\mathtt{B}) \mid x_1(t) = x_2(t) = x_3(t) = x_4(t) \ \vee \ x_3(t) \neq x_4(t)\} \tag{4}$$

In other words, Eve wins a play t if either Adam has chosen two different labels in x_3 and x_4 or all the chosen labels are equal. Since the vertices labelled x_i lie at a fixed depth of every play $t \in \text{plays}(\mathtt{B})$, L is a closed and open regular language of infinite trees.

▶ **Example 4.** The game $\mathrm{G} = \langle \mathtt{B}, L\rangle$ has the following partial values:

$$val_{\mathrm{G}}^{A} = 1; \qquad val_{\mathrm{G}}^{BA} = \frac{3}{4}; \qquad val_{\mathrm{G}}^{MA} = \frac{1}{2} = val_{\mathrm{G}}^{ME}; \qquad val_{\mathrm{G}}^{BE} = \frac{1}{4}; \qquad val_{\mathrm{G}}^{E} = 0.$$

We first argue about the pure values – a pure strategy over the board from Figure 2 needs to declare in advance the two values $x_i(t)$ and $x_{i+1}(t)$ for $i = 1, 3$ depending on the player.

If such a strategy is fixed, the opponent can choose his values in such a way to win.

We now consider the mixed value. Let σ_m randomly choose with equal probability between the following two pure strategies σ_i for $i = 0, 1$: the strategy σ_i satisfies $x_1(\sigma_i) = x_2(\sigma_i) = i$. π_m is defined analogously. It is easy to check that these strategies are optimal and witness that the mixed value of the game is $\frac{1}{2}$ for both players.

Consider a behavioural strategy σ_b of Eve (the case of Adam is entirely dual). Such a strategy can be described by two independent random choices:

1. σ_b chooses x_1 to be 0 with probability p_1,
2. σ_b chooses x_2 to be 0 with probability p_2.

Thus, each behavioural strategy of Eve is characterised by a pair of numbers $p_1, p_2 \in [0, 1]$. A simple computation shows that no matter how Eve chooses her values p_1, p_2, Adam can find a counter-strategy guaranteeing the value of at most $\frac{1}{4}$.

Since $val_{\mathrm{G}}^{BA} = \frac{3}{4} \neq \frac{1}{4} = val_{\mathrm{G}}^{BE}$ the proof of Theorem 3 is concluded.

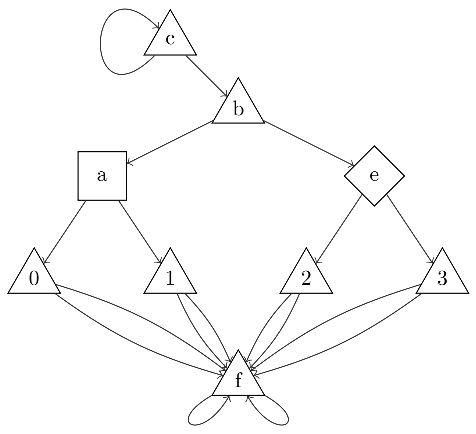

Figure 3 A branching board that is not determined under mixed strategies.

3.2 Mixed indeterminacy

We will now show that the mixed determinacy fails for relatively simple regular sets, as expressed by the following theorem.

▶ **Theorem 5.** *There is a* $\{E, A, \mathcal{B}\}$*-branching game with a regular winning set being a difference of two open sets that is not determined under mixed strategies.*

To prove this theorem we will encode the following game as a $\{E, A, \mathcal{B}\}$-branching game G. Assume that ∞ is an additional symbol such that for every $n \in \omega$ we have $n < \infty$.

▶ **Example 6** (Folklore)**.** Consider the following game: Adam and Eve simultaneously and independently choose two numbers: Eve chooses $e \in \omega \cup \{\infty\}$, Adam chooses $a \in \omega \cup \{\infty\}$. Eve wins if $e < \infty$, and either $a = \infty$ or $a \leq e$.

It is easy to see that this game is not determined under mixed strategies. Intuitively, it follows from the fact that both players try to choose a finite number as big as possible.

The board $\mathtt{B}$ of the game G is depicted in Figure 3. A play $t \in \mathrm{plays}(\mathtt{B})$ consists of infinitely many independent sub-games that start in the vertices labelled by b. More precisely, the k-th sub-game starts in the node $\mathtt{L}^k\mathtt{R}$ in the tree t. Such a sub-game is split into two independent choices: Adam chooses a label, either 0 or 1, for the successor of the node labelled by a; Eve chooses a label, either 2 or 3, for the successor of the node labelled by e.

Let $a(t)$ (resp. $e(t)$) be the smallest number $k \in \omega$ such that Eve (resp. Adam) has chosen an odd label in the k-th sub-game, i.e. $\mathtt{L}^k\mathtt{RLR} \in \mathit{Dom}(t)$ (resp. $\mathtt{L}^k\mathtt{RRR} \in \mathit{Dom}(t)$). If no such number exists then $a(t)$ (resp. $e(t)$) equals ∞.

Let the winning condition L of the game G be defined as follows

$$L \overset{\text{def}}{=} \big\{t \in \mathrm{plays}(\mathtt{B}) \mid e(t) < \infty \text{ and not } (e(t) < a(t) < \infty)\big\}. \tag{5}$$

It is easy to see that L is a regular language of infinite trees (to compare $a(t)$ with $e(t)$ it is enough to notice that each of these values corresponds to a node on the left-most branch of the play t). Moreover, both the conditions $e(t) < \infty$ and $e(t) < a(t) < \infty$ are open sets of plays.

Hence, the game $\mathrm{G} = \langle \mathtt{B}, L\rangle$ is a game as required in Theorem 5. Moreover, there is a clear correspondence between the pure strategies in G and the pure strategies in the game from Example 6. This correspondence extends to the mixed strategies what implies the following claim.

▶ **Claim 7.** *We have that* $val^{MA}_{\mathrm{G}} = 1$ *and* $val^{ME}_{\mathrm{G}} = 0$.

This concludes the proof of Theorem 5.

3.3 Mixed determinacy for closed sets

In this section we use Glicksberg's minimax theorem to prove that if a winning condition is a closed set of plays then the game is determined under mixed strategies.

▶ **Theorem 8.** *If* $\mathrm{G} = \langle \mathtt{B}, L\rangle$ *is a* $\{E, A, \mathcal{N}, \mathcal{B}\}$*-branching game and* L *is an arbitrary closed subset of* $\mathrm{plays}(\mathtt{B})$ *then* G *is determined under mixed strategies.*

Before we recall the statement of Glicksberg's minimax theorem, let us introduce some relevant notions. Assume that X is a metrisable topological space. We say that a function $f\colon X \to \mathbb{R}$ is *upper semi-continuous* if for every $x_0 \in X$ we have $\limsup_{x\to x_0} \leq f(x_0)$. Clearly, if $C \subseteq X$ is a closed subset of X then the characteristic function of C is upper semi-continuous. Also, a composition of a continuous function and an upper semi-continuous function is upper semi-continuous.

▶ **Theorem 9** (Glicksberg's minimax theorem [12], see also [18, pages 299–306])**.** *Let* A*,* B *be compact metrisable spaces and* $f\colon A \times B \to \mathbb{R}$ *be an upper semi-continuous function. Then the following holds*

$$\sup_{\mu} \inf_{\nu} \int_{A,B} f(a,b)\ \mu(\mathrm{d}a)\,\nu(\mathrm{d}b) = \inf_{\nu} \sup_{\mu} \int_{A,B} f(a,b)\ \mu(\mathrm{d}a)\,\nu(\mathrm{d}b), \tag{6}$$

where μ*,* ν *range over the Borel probability measures on the sets* A*,* B *respectively.*

It remains to prove that if $\mathrm{G} = \langle \mathtt{B}, L\rangle$ with $L \subseteq \mathrm{plays}(\mathtt{B})$ closed then the function $val_{\mathrm{G}}\colon \Sigma^{E}_{\mathtt{B}} \times \Sigma^{A}_{\mathtt{B}} \to \mathbb{R}$ is upper semi-continuous. This function can be written as a composition of two functions. The first one maps a pair of pure strategies (σ, π) to a measure on $\mathrm{plays}(\mathtt{B})$ defined as $\mu_{(\sigma,\pi)}(T) \overset{\text{def}}{=} \nu^{*}_{\mathtt{B}}\big(\{t \in \Sigma^{\mathcal{N}}_{\mathtt{B}} \mid \sigma \cap \pi \cap t \in T\}\big)$, i.e. the $\nu^{*}_{\mathtt{B}}$ measure of the pre-image of the set T under the function that intersects the three strategies. This mapping is continuous, as proved by Mio in [20, Lemma 4.1.4]. The second one applies the measure $\mu_{(\sigma,\pi)}$ to the winning set $L \subseteq \mathrm{plays}(\mathtt{B})$. For a closed set L this function is upper semi-continuous by [14, Corollary 17.21].

4 Computing game values

In this section we will discuss the computational complexity of determining the partial values of branching games. To be more precise, we consider the following family of problems, parametrised by the set of available positions $\mathcal{P} \subseteq \{A, E, \mathcal{N}, \mathcal{B}\}$ and the type of the value $V \in \{val^{A}, val^{BA}, val^{MA}, val^{ME}, val^{BE}, val^{E}\}$.

▶ **Problem 10** (The value V of a regular $\mathcal{P}$-branching game)**.**

- **Input:** *A finitary* $\mathcal{P}$*-branching game* G *with the winning condition given by a non-deterministic tree automaton.*
- **Output:** *Does* $V > \frac{1}{2}$?

4.1 The non-stochastic case

If no random choice is involved, i.e. the board has no *Nature*'s positions and we consider pure strategies, the values belong to the set $\{0, 1\}$ and we can compute them, as expressed by the following theorem.

▶ **Theorem 11.** *The value val^E problem of a regular $\{A, E, \mathcal{B}\}$-branching game is in 2-EXP, the value val^A problem of a regular $\{A, E, \mathcal{B}\}$-branching game is EXP-complete.*

Moreover, the value val^E problem of a regular $\{A, E, \mathcal{B}\}$-branching game is 2-EXP-complete if the winning condition is given by an alternating tree automaton.

This theorem follows from the constructions in [22], performed in a bit different language. The asymmetry in this theorem comes from the fact that in Problem 10 we assume that the winning condition of a game is given as a non-deterministic automaton. In this work we strengthen the second part of the above theorem by proving that the value val^E problem of a regular $\{A, E, \mathcal{B}\}$-branching game is *2-EXP*-hard also for non-deterministic automata. This is achieved by using the completeness result from [22] together with the following reduction. It is somehow surprising to notice that in the context of branching games one can de-alternate an automaton in polynomial time.

▶ **Theorem 12.** *There exists a polynomial time reduction that inputs a $\{A, E, \mathcal{B}\}$-branching game G with the winning condition given as an alternating tree automaton and constructs a $\{A, E, \mathcal{B}\}$-branching game G' with the winning condition given by a non-deterministic tree automaton, such that $val^E_{\mathrm{G}} = val^E_{\mathrm{G}'}$.*

The proof is straightforward, its main idea is to split the alternation of the given automaton into two parts: the choices of Adam and the choices of Eve. In the game G' the former choices will be done explicitly on the board while the latter choices will be performed by the non-deterministic automaton that recognises the winning condition of G'.

▶ **Corollary 13.** *val^E problem of a regular $\{A, E, \mathcal{B}\}$-branching game is 2-EXP-complete.*

4.2 The stochastic cases

The above decidability results hold for non-stochastic games and pure strategies. Restoring any of those features yields undecidability, as expressed by the two theorems of this section.

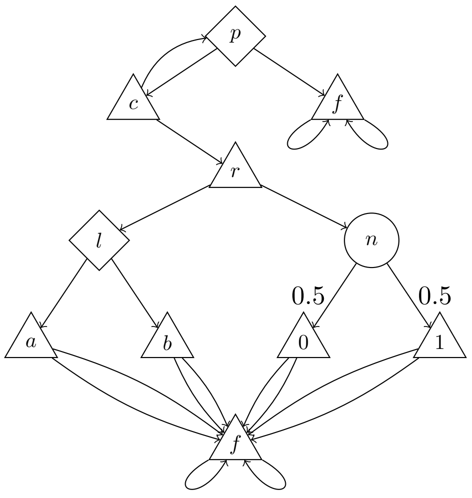
▶ **Theorem 14.** *For every $V \in \{val^A, val^{BA}, val^{MA}, val^{ME}, val^{BE}, val^E\}$ and $P \in \{E, A\}$, the value V problem of a regular $\{P, \mathcal{N}, \mathcal{B}\}$-branching game is undecidable.*

Observe that by Lemma 1 a $\{P, \mathcal{N}, \mathcal{B}\}$-branching game is determined under pure strategies. It means that all the six partial values are the same for such games. Thus, by the symmetry we can assume that $P = E$ and $V = val^E$.

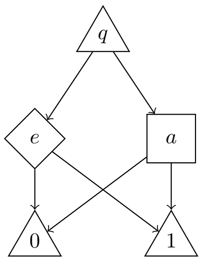
To prove Theorem 14 we reduce the following undecidable problem, cf. [11]. It can be shown that the word problem is undecidable even if we restrict our attention to a two-letters alphabet and the so-called *very simple* automata: a non-deterministic automaton is *very simple* if from every state and every letter there are exactly two possible transitions leading to two distinct states.

▶ **Problem 15** (Word problem for VSNA).

- **Input:** *A very simple non-deterministic automaton $\mathcal{A}$ on finite words over $\{a, b\}$.*
- **Output:** *Does there exist a finite word such that more than half of the runs of $\mathcal{A}$ on this word is accepting?*



(a) A branching board used in the proof of Theorem 14.



(b) A gadget used in the proof of Theorem 16. to replace *Nature*'s vertex in the board

Figure 4 Boards used in undecidability proofs.

We will now sketch the proof of Theorem 14. Let us take a very simple non-deterministic automaton $\mathcal{A}$ and assume that the two transitions over a letter $l \in \{a, b\}$ from a state $q \in Q^{\mathcal{A}}$ lead to the states $\delta_0(q, l)$ and $\delta_1(q, l)$. Assume that $l_0, l_1, \ldots, l_k$ is a sequence of letters $l_i \in \{a, b\}$ and $n_0, n_1, \ldots, n_k$ is a sequence of numbers $n_i \in \{0, 1\}$. These two sequences allow us to naturally define a run $\rho = \mathrm{run}(\vec{l}, \vec{n})$ of $\mathcal{A}$ over the word $l_0, \ldots, l_k$ that follows the respective transitions of $\mathcal{A}$: $\rho[0] = q_{\mathrm{I}}$ and $\rho[i + 1] = \delta_{n_i}(\rho[i], l_i)$.

Consider the board $\mathtt{B}$ depicted on Figure 4a. A play on this board consists of a sequence of decisions made by Eve, whether to move from the vertex labelled l to a or to b. At every moment Eve can stop this sequence by choosing the right successor of the vertex labelled p. For every choice of a or b by Eve, the *Nature* simultaneously chooses a number 0 or 1. Thus, a play t results in two finite or infinite sequences of the same length: $l_0, l_1, \ldots$ with $l_i \in \{a, b\}$ and $n_0, n_1, \ldots$ with $n_i \in \{0, 1\}$. Consider the following winning condition

$$L \overset{\text{def}}{=} \{t \in \mathrm{plays}(\mathtt{B}) \mid \text{the sequences } \vec{l} \text{ and } \vec{n} \text{ are finite and } \mathrm{run}(\vec{l}, \vec{n}) \text{ is accepting}\}. \tag{7}$$

Now let $\mathrm{G} = \langle \mathtt{B}, L\rangle$. It is easy to see that the winning condition L can be represented as a regular language of infinite trees. A pure strategy of Eve in G either never moves from the vertex labelled p to the vertex labelled f (in that case its value is 0) or in the opposite case it corresponds to a finite word $l_0, l_1, \ldots, l_k$. The value of such a strategy is the probability that the choices of *Nature* will represent an accepting run of $\mathcal{A}$ over the word $\vec{l}$. Thus, Eve has a pure strategy σ with $val^{E}_{\mathrm{G}}(\sigma) > \frac{1}{2}$ if and only if more than half of the runs of $\mathcal{A}$ over the word $\vec{l}$ produced by σ is accepting.

To complete the landscape of decidability we state.

▶ **Theorem 16.** *For every $V \in \{val^{BA}, val^{MA}, val^{ME}, val^{BE}\}$ the value V problem of a regular $\{E, A, \mathcal{B}\}$-branching game is undecidable.*

The theorem follows from the fact that the game used in the proof of Theorem 14 can be simulated on the board with *Nature*'s position replaced by the gadget depicted in Figure 4b.

5 Conclusions

In this work we have studied questions of determinacy and decidability of regular branching games. We have shown that the games are not determined even for topologically simple regular conditions. In the case of mixed determinacy, the frontier lies in the first level of the difference hierarchy of closed sets. Additionally, we have shown that the question whether the value of a given game is greater than a fixed threshold is undecidable in all non-trivial stochastic cases. In the non-stochastic cases (i.e. when the board is non-stochastic and we ask about pure strategies) we have given exact bounds on the complexity of the problem. The only remaining case is the 0-player stochastic case, i.e. the problem of computing the measure of a regular language of infinite trees.

Further work. It seems interesting to understand for which classes of regular winning conditions, the branching games are determined. It was proved by the first author in [22] that the non-stochastic branching games with winning conditions given by *game automata* are determined under pure strategies. We believe that the proof can be naturally extended to the stochastic case. However, there are regular languages of infinite trees L that are not recognisable by game automata, but still all the branching games with the winning condition L are purely determined. The characterisation of such objectives poses an interesting research direction as it could give a broader class of games with decidable value problem.

On the frontier of mixed determinacy, it seems that allowing the objective to check local consistency at arbitrary depths of the tree is the cause of both the indeterminacy and the undecidability. This intuition suggests the following conjecture. We say that L is a *path language* if L is a Boolean combination of languages of the form

$$\{t \mid \text{there exists a branch of } t \text{ belonging to a regular language of infinite words } K \subseteq \Gamma^\omega\}.$$

▶ **Conjecture 17.** *If* $\mathrm{G} = \langle \mathtt{B}, L\rangle$ *is a branching game and* L *is a path language then the game* G *is determined under mixed strategies.*

Symbolic Lookaheads for Bottom-Up Parsing

Paola Quaglia

University of Trento, Italy
`paola.quaglia@unitn.it`

Abstract

We present algorithms for the construction of LALR(1) parsing tables, and of LR(1) parsing tables of reduced size. We first define specialized characteristic automata whose states are parametric w.r.t. variables symbolically representing lookahead-sets. The propagation flow of lookaheads is kept in the form of a system of recursive equations, which is resolved to obtain the concrete LALR(1) table. By inspection of the LALR(1) automaton and of its lookahead propagation flow, we decide whether the grammar is LR(1) or not. In the positive case, an LR(1) parsing table of reduced size is computed by refinement of the LALR(1) table.

1 Introduction

Various classes of grammars can be parsed bottom-up by applying the same shift/reduce algorithm driven by different parsing tables (e.g., SLR(1) [4], LALR(1) [3], LR(1) [2]). Parsing tables are defined on top of deterministic finite state characteristic automata whose size is crucial to the applied parsing technique: the finer the information encoded by automata, the larger the class of parsed grammars, and the bigger the size of parsing tables.

LR(1)-automata are the richer structures in LR(1) parsing. The number of states of these automata has the striking upper bound $O(2^{n(t+1)})$ in the size of the grammar and in the number of terminal symbols (n and t, resp.) [12]. LALR(1) grammars have been defined as a technical compromise between the abundance of syntactic constructs of the generated languages and the size of the associated parsing tables. All the states of the LR(1)-automaton sharing the same LR(0) projection are collapsed into a single state of the LALR(1)-automaton. So, the size of LALR(1) parsing tables is much smaller than that of the corresponding LR(1) tables, and definitely tractable, as widespread parser generators clearly show [9, 2, 6]. At the same time, though, either debugging an LALR(1) grammar or choosing the appropriate directives for resolving conflicts is made harder by the fact that the user is compelled to reason about the propagation of LR(1) lookaheads modulo the – technical, and not necessarily intuitive - merging of LR(1)-states.

In this setting, and especially for large automata, it can be beneficial having some sort of explicit representation of the lookahead propagation flow among the states of the underlying automaton. We work towards this direction and propose a technique for the construction of LALR(1)-automata which provides a compact encoding of the propagation of lookaheads from one state to the other. The approach is based on the definition of symbolic characteristic automata that use items with two components: an LR(0)-item, and a symbolic lookahead-set. When a new state P is added to the automaton, each kernel LR(0)-item is associated with a variable that is propagated to the closure items of P. All the contributions to the lookahead-sets of the items in P are recorded by equations over the variables owned by the kernel items of the state. The propagation flow of lookaheads is embedded by defining equations for variables. For instance, a plausible equation for the variable x can look like $x \doteq \{b, x'\}$, meaning that x can take the value b and all the values that x' can take. To disclose the actual values of lookahead-sets, we resolve the system of equations. We reduce this problem to a reachability problem on the dependency graph of a propagation relation over equivalence classes of variables.

Once symbolic lookahead-sets are instantiated to ground elements, we construct the LALR(1) parsing table for the given grammar. We prove that the algorithm for the LALR(1) construction is correct. The proof of the assertion is based on two auxiliary results. One of them is the symbolic correspondence between the proposed automata and the merged LR(1)-automata used in the simplest algorithm for the construction of LALR(1) parsing tables. The other intermediate result is the correctness of the actualization of lookahead-sets.

Further, we describe an algorithm for the construction of LR(1) parsing tables. Such an algorithm is itself an example of use of the explicit representation of the lookahead propagation in LALR(1)-automata. The table for the larger class is obtained by refining the LALR(1) table. We look after reduce/reduce conflicts of the LALR(1) table and check whether they can be eliminated by unrolling the relevant LALR(1) mergings of states. This by-need strategy has the further benefit of providing opportunities for the early detection that the grammar at hand is not LR(1).

The rest of the paper is organized as follows. Basic definitions and conventions are introduced in Sec. 2. Sec. 3 presents symbolic automata, and their properties. The construction of LALR(1) parsing tables is the subject of Sec. 4, and the algorithm for the construction of LR(1) parsing tables is sketched in Sec. 5. Sec. 6 concludes this extended abstract.

2 Preliminaries

In this section we will introduce the basic definitions and the conventions which will be used in this manuscript. Some familiarity with the theory of LR(1)-parsing is assumed.

A context-free grammar is a tuple $\mathcal{G} = (V, T, S, \mathcal{P})$ whose elements represent, respectively, the vocabulary, the set of terminal symbols in the vocabulary, the start symbol, and the set of productions. Productions are written $A \to \beta$ where $A \in V \setminus T$, and $\beta \in V^*$. The reflexive and transitive closure of the one-step rightmost derivation relation is denoted by '$\Rightarrow^*$'.

We assume that grammars are reduced, and the following notational conventions are adopted. Members of V are denoted by $Y, Y_0, \ldots$; members of V^* by $\alpha, \beta, \ldots$; members of $(V \setminus T)$ by $A, B, \ldots$; members of T by $a, b, \ldots$; and members of T^* by $w, w_0, \ldots$. The empty string is denoted by ϵ. For every $\alpha \in V^*$, first(α) denotes the set of terminals that begin strings w such that $\alpha \Rightarrow^* w$. Moreover, if $\alpha \Rightarrow^* \epsilon$ then $\epsilon \in$ first(α).

Given any context-free grammar $\mathcal{G}$, parsing is applied to strings followed by the endmarker symbol $\$ \notin V$. Also, the parsing table refers to an augmented version of $\mathcal{G}$, denoted by $\mathcal{G}' = (V', T, S', \mathcal{P}')$ where, for a fresh symbol S', $V' = V \cup \{S'\}$, and $\mathcal{P}' = \mathcal{P} \cup \{S' \to S\}$. An LR(0)-item of $\mathcal{G}'$ is a production of $\mathcal{G}'$ with the marker "$\cdot$" at some position of its body. An LR(1)-item of $\mathcal{G}'$ is a pair consisting of an LR(0)-item of $\mathcal{G}'$ and of a symbol in the set $T \cup \{\$\}$. The LR(0)-item $A \to \alpha \cdot \beta$ is called *kernel item* if either $\alpha \neq \epsilon$ or $A = S'$, *closure item* if it is not kernel, *reducing item* if $\beta = \epsilon$, and *bypassing item* if it is not reducing. The same terminology is naturally extended to the LR(1)-items with first projection $A \to \alpha \cdot \beta$. For a set L of LR(1)-items, prj(L) is the set of LR(0)-items occurring as first components of the elements of L, and kernel(L) is the set of the kernel items of L.

We will call *LR(0)-automata*, and *LR(1)-automata* respectively, the characteristic automata constructed by collecting sets of LR(0)-items, and sets of LR(1)-items respectively. Also, we will call *LRm(1)-automata* the characteristic "merged" LR(1)-automata which are at the basis of the simplest, although inefficient, algorithm for the construction of LALR(1) parsing tables. We assume that LR(1)-automata and LRm(1)-automata are constructed after the methodology fully detailed in [1] and in its previous editions.

Below, we will denote the above mentioned characteristic automata by tuples of the form $(\mathcal{Q}, V, \tau, Q_0, \mathcal{F})$ where $\mathcal{Q}$ is the set of states, V the vocabulary, $\tau : (\mathcal{Q} \times V) \to \mathcal{Q}$ the transition function, $Q_0 \in \mathcal{Q}$ the initial state, and $\mathcal{F} \subseteq \mathcal{Q}$ the set of final states, i.e. of the states containing at least one reducing item. In particular, we will use the tuple $(St_l, V, \tau_l, L_0, F_l)$, called $\mathscr{A}_l$ for short, to stand for the LR(1)-automaton for $\mathcal{G}$. The tuple $(St_m, V, \tau_m, M_0, F_m)$, named $\mathscr{A}_m$, will denote the LRm(1)-automaton for $\mathcal{G}$.

Bottom-up parsing tables are filled in after an algorithm which is shared by various techniques (SLR(k), LALR(k), etc.). *Shift* and *goto* moves are determined after the transition function of the appropriate characteristic automaton. Further, the reducing items in the final states of the automaton, and the lookahead-sets associated with them, are used to set up *reduce* moves. By that, we will call *parsing table* the pair consisting of a characteristic automaton and of the collection of lookahead-sets for the reducing items of its final states.

3 Symbolic characteristic automata

In this section we will present the construction of the symbolic characteristic automaton that is central to further developments. In what follows, the prototypical LALR(1) grammar $\mathcal{G}_1$ with start symbol S_1 and production set $\mathcal{P}_1 = \{S_1 \to L = R \mid R,\ L \to *R \mid \text{id},\ R \to L\}$ [2] will be used as running example.

We let $\mathbb{V}$ be a set of symbols disjoint from $V' \cup \{\$\}$. Elements of $\mathbb{V}$ stand for *variables* and are ranged over by $x, x', \ldots$. We use $\Delta, \Delta', \ldots, \Gamma, \Gamma', \ldots$ to denote subsets of $\mathbb{V} \cup T \cup \{\$\}$. Also, we let $\text{ground}(\Delta) = \Delta \cap (T \cup \{\$\})$, and $\text{var}(\Delta) = \Delta \cap \mathbb{V}$. A *symbolic item* of $\mathcal{G}'$ is a pair of the shape $[A \to \alpha \cdot \beta, \Delta]$, whose second component is called *lookahed-set*. Below, symbolic items will be shortly called items when no confusion may arise. We assume the existence of a function newVar() which returns a fresh symbol of $\mathbb{V}$ at any invocation. This assumption on newVar() induces a strict total order over the generated variables, and we write $x \prec x'$ if the call to newVar() which returns x precedes the invocation of newVar() whose response is x'.

The definitions of kernel, closure, reducing, and bypassing items are extended to symbolic items in the natural way. Also, functions prj(_) and kernel(_) are overloaded to be applied to sets of symbolic items. Function first(_) is extended to arguments of the form $\beta\Delta$ as follows:

$$\text{first}(\beta\Delta) = \begin{cases} \text{first}(\beta) & \text{if } \epsilon \notin \text{first}(\beta) \\ (\text{first}(\beta) \setminus \{\epsilon\}) \cup \Delta & \text{otherwise.} \end{cases}$$

The closure of a set of symbolic items P, written closure(P), is defined as the smallest set of items, with smallest lookahead-sets, that satisfies the following equation:

$$\begin{aligned} \text{closure}(P) = P \cup \{[B \to \cdot\gamma, \Gamma] \text{ such that} \\ [A \to \alpha \cdot B\beta, \Delta] \in \text{closure}(P) \text{ and } B \to \gamma \in \mathcal{P} \text{ and first}(\beta\Delta) \subseteq \Gamma\}. \end{aligned}$$

The symbolic characteristic automaton for $\mathcal{G}$ is a tuple $(St_s, V, \tau_s, P_0, F_s, \mathit{Vars}, \mathit{Eqs})$, that we will shortly denote by $\mathscr{A}_s$. The first five elements of the tuple represent the set of states, the vocabulary, the transition function, the initial state, and the set of final states. *Vars* is a set of variables, and *Eqs* is a queue of defining equations of the form $x \doteq \Delta$ for the variables in *Vars*. When the actual ordering of the enqueued equations is irrelevant, we will interpret *Eqs* just as a set.

```
$x_0 \longleftarrow \mathrm{newVar}()$; $Vars \longleftarrow \{x_0\}$; $P_0 \longleftarrow \mathrm{closure}(\{[S' \to \cdot S, \{x_0\}]\})$;
initialize $Eqs$ to contain the equation $x_0 \doteq \{\$\}$; initialize $St_s$ to contain $P_0$;
set $P_0$ unmarked;
while there is some unmarked state in $St_s$ do
    foreach unmarked state $P$ in $St_s$ do
        foreach grammar symbol $Y$ do
            $tmp \longleftarrow \emptyset$;
            foreach $[A \to \alpha \cdot Y\beta, \Delta]$ in $P$ do
                add $[A \to \alpha Y \cdot \beta, \Delta]$ to $tmp$;
            if $tmp \neq \emptyset$ then
                if $\mathrm{prj}(tmp) = \mathrm{prj}(\mathrm{kernel}(Q))$ for some $Q$ in $St_s$ then /* Refine */
                    foreach pair
                    $([A \to \alpha Y \cdot \beta, \Gamma] \in \mathrm{kernel}(Q)$ , $[A \to \alpha Y \cdot \beta, \Delta] \in tmp)$ do
                        if $\beta = \epsilon$ then
                            update $[A \to \alpha Y \cdot, \Gamma]$ to $[A \to \alpha Y \cdot, \Gamma \cup \Delta]$ in $\mathrm{kernel}(Q)$;
                        else if $\Gamma = \{x\}$ and $(x \doteq \Delta_1) \in Eqs$ then
                            update $(x \doteq \Delta_1)$ to $(x \doteq \Delta_1 \cup \Delta)$ in $Eqs$;
                        $\tau_s(P, Y) \longleftarrow Q$;
                else /* Generate */
                    foreach $[A \to \alpha Y \cdot \beta, \Delta] \in tmp$ such that $\beta \neq \epsilon$ do
                        $x \longleftarrow \mathrm{newVar}()$;
                        $Vars \longleftarrow Vars \cup \{x\}$;
                        enqueue $(x \doteq \Delta)$ into $Eqs$;
                        change $[A \to \alpha Y \cdot \beta, \Delta]$ into $[A \to \alpha Y \cdot \beta, \{x\}]$ in $tmp$;
                    $\tau_s(P, Y) \longleftarrow \mathrm{closure}(tmp)$;
                    add $\tau_s$(P , Y ) to $St_s$ as an unmarked state;
        mark state $P$ ;
```

Algorithm 1: Construction of $\mathscr{A}_s$ for $\mathcal{G} = (V, T, S, \mathcal{P})$

The algorithm for the construction of the symbolic characteristic automaton for $\mathcal{G}$ is reported as Alg. 1. The collection of states is initialized to contain the initial state P_0, which is defined as the closure of $\{[S' \to \cdot S, \{x_0\}]\}$ where x_0 is a fresh variable. Correspondingly, *Eqs* is let to contain the equation $x_0 \doteq \{\$\}$. The generation of further states goes together with the incremental definition of the transition function. For every state P already found, and for all the grammar symbols Y such that some bypassing item $[A \to \alpha \cdot Y\beta, \Delta]$ is in P, a temporary set *tmp* is computed. Such a set represents, in the LR(0) sense, the kernel of $\tau_s(P, Y)$, and is used to check – irrespectively of lookahead-sets – whether the target state for the Y-transition from P has already been collected or not.

If the wanted target $\tau_s(P, Y)$ has not been collected yet, then a new state, say P', is created by closing up a set which is derived from *tmp* as follows. Reducing items of *tmp* are left untouched. On the other hand, each bypassing item is given a lookahead-set containing a fresh variable. Also, an equation for each such variable is installed in *Eqs* to record the lookahead-set carried by *tmp* from the corresponding item of P. The closure procedure is then applied to the modified instance of the kernel set *tmp*. This ensures the possible propagation of variables, and hence of symbolic lookaheads, to the closure items of P'. As an example, when we start running the algorithm for $\mathcal{G}_1$, we get $[S_1 \to \cdot L = R, \{x_0\}], [L \to \cdot * R, \{=, x_0\}] \in P_0$. By that, $[S_1 \to L \cdot = R, \{x_1\}] \in \tau_s(P_0, L)$, and $[L \to * \cdot R, \{x_2\}] \in \tau_s(P_0, *)$, with *Eqs* provisionally containing the equations $x_0 \doteq \{\$\}$, $x_1 \doteq \{x_0\}$, and $x_2 \doteq \{=, x_0\}$.

Either the states already generated or the equations which have been installed for them can still undergo refinements. This happens when the collected state P' is recognized, again in the LR(0) sense, as the target of the Y-transition from yet another state, say P''. If this is the case, then both the reducing kernel items of P' and the right-hand sides of the equations installed for the kernel bypassing items of P' are treated as accumulators, to record the contributions coming from the items in P''. No further modification is applied to P', nor a closure procedure invoked. Essentially, multiple incoming edges to the same state bring in multiple contributions, and all of them are encoded either by equations over variables or in the lookahead-sets of reducing kernel items. For instance, upon termination of the construction of the automaton for $\mathcal{G}_1$, *Eqs* is given by $E_1 = \langle x_0 \doteq \{\$\}, x_1 \doteq \{x_0\}, x_2 \doteq \{=, x_0, x_2, x_3\}, x_3 \doteq \{x_1\}\rangle$, where x_3 is the variable installed for the kernel item $[S \to L = \cdot R, \{x_3\}]$ of the state generated as $\tau_s(\tau_s(P_0, L), =)$.

A few basic properties of symbolic characteristic automata follow. An easy consequence of the technique used for the construction of symbolic automata is that, seen as graphs, $\mathscr{A}_s$ and the LR(0)-automaton for $\mathcal{G}$ are isomorphic. Moreover, the items contained in each state of the LR(0)-automaton are just the projections of the symbolic items in the corresponding state of $\mathscr{A}_s$. Lemma 1 below characterizes the rôle of variables in the symbolic construction. The lookahead-set of every bypassing kernel item of every state is a singleton set consisting of a distinct variable. Hence, each variable implicitly identifies a pair consisting of a bypassing kernel item and of the state the item belongs to.

▶ **Lemma 1.** *Let $\mathscr{A}_s$ be the symbolic characteristic automaton for $\mathcal{G}$, and let $P, P' \in St_s$. Also, assume that $[A \to \alpha \cdot Y\beta, \Delta] \in P$ and $[A' \to \alpha' \cdot Y'\beta', \Delta'] \in P'$ are such that $A \to \alpha \cdot Y\beta = A' \to \alpha' \cdot Y'\beta'$ implies $P \neq P'$. Then, for some x, x' with $x \neq x'$, $\Delta = \{x\}$ and $\Delta' = \{x'\}$.*

We observe that, by Lemma 1 and by definition of closure, if the lookahead-sets of the items not in the kernel contain any variable, then such a variable must be one of those installed for the bypassing items in the kernel of the same state.

The next lemma accounts for the properties of the equations for the variables identifying bypassing kernel items. The single equation installed for the initial state P_0 remains unchanged throughout the computation of the whole automaton. Hence, there is at least one equation with a ground right-hand side in *Eqs*. Moreover, every equation $x \doteq \Delta$ installed for the bypassing kernel item of a state $P \neq P_0$ is such that Δ collects contributions from all the predecessors of P. The set Δ can contain x itself, due, e.g., to a self-loop on P in the graph. By construction, however, the first provisional versions of every state P and of the relative equations are generated when processing the possible transitions of a state collected before P. So, even if Δ can contain x, it can never contain x alone.

▶ **Lemma 2.** *Let $\mathscr{A}_s$ be the symbolic characteristic automaton for $\mathcal{G}$.*

1. *If $[S' \to \cdot S, \{x\}] \in P_0$ then the equation for x in Eqs is $x \doteq \{\$\}$.*

2. *Assume that $P \in St_s \setminus \{P_0\}$, and that $[A \to \alpha Y \cdot \beta, \{x\}] \in \mathrm{kernel}(P)$ is a bypassing item. Also, let $x \doteq \Delta$ be the equation for x in Eqs. Then the following holds.*
   - *Let $\mathbb{D} = \{\Delta_i \mid [A \to \alpha \cdot Y\beta, \Delta_i] \in Q_i$ for $Q_i \in St_s$ such that $\tau_s(Q_i, Y) = P\}$. Then $\Delta = \bigcup_{\Delta_i \in \mathbb{D}} \Delta_i$.*
   - *$\Delta \setminus \{x\} \neq \emptyset$. Also, if $\Delta \setminus \{x\} = \{x'\}$ then $x' \prec x$.*

The following lemma, dual to Lemma 2, states the main properties of the lookahead-sets of kernel reducing items.

▶ **Lemma 3.** *Let $\mathscr{A}_s$ be the symbolic characteristic automaton for $\mathcal{G}$. Assume that $P \in St_s$, and that $[A \to \alpha Y \cdot, \Delta] \in \mathrm{kernel}(P)$. Also, let $\mathbb{D} = \{\Delta_i \mid [A \to \alpha \cdot Y, \Delta_i] \in Q_i$ for $Q_i \in St_s$ such that $\tau_s(Q_i, Y) = P\}$. Then $P \neq P_0$, $\Delta \neq \emptyset$, and $\Delta = \bigcup_{\Delta_i \in \mathbb{D}} \Delta_i$.*

4 LALR(1) tables

In this section we will first focus on the symbolic correspondence existing between $\mathscr{A}_s$ and the LRm(1)-automaton for the given grammar $\mathcal{G}$. Then, to make this correspondence concrete, we will show how *Eqs* can be resolved.

A key point for the proof of the symbolic correspondence between $\mathscr{A}_s$ and $\mathscr{A}_m$ is the relation between the states of the symbolic automaton and those of the LR(1)-automaton for $\mathcal{G}$. In order to capture such a relation, an appropriate handle on the propagation flow of ground lookaheads through the defining equations in *Eqs* is needed. To this end, we introduce a notion of reachability which relates ground lookaheads to lookahead-sets via equations. Intuitively, we say that the lookahead l reaches Δ if either $l \in \Delta$ or if l is in the right-hand side of the equation for some x, and x propagates, through a chain of uses and definitions, to a variable belonging to Δ. Consider for instance the system of equations $E_1 = \langle x_0 \doteq \{\$\}, x_1 \doteq \{x_0\}, x_2 \doteq \{=, x_0, x_2, x_3\}, x_3 \doteq \{x_1\}\rangle$ mentioned in Sec. 3. In E_1 the ground lookahead \$ reaches $\{\$\}$ simply because it is contained in the set. Moreover, there is a sequence of hops from right-hand sides to left-hand sides of equations which takes, e.g., \$ to x_3. In fact, \$ is used in the definition of x_0, which is used in the definition of x_1, which is used in the definition of x_3. By that, we conclude that \$ reaches, among the rest, every lookahead-set Δ containing x_3. Def. 4 below captures this intuition.

▶ **Definition 4.** Let $E = \{x_i \doteq \Delta_i\}_i$ be a set of defining equations for the variables in the finite subset $\{x_i\}_i$ of $\mathbb{V}$. Also, let $l \in T \cup \{\$\}$. Then:
- x_j gets x_k in E, written $x_j \text{ gets}_E\, x_k$, iff $x_j, x_k \in \{x_i\}_i$ and $x_k \in \Delta_j$;
- Δ takes l in E, written $\Delta \text{ takes}_E\, l$, iff $l \in \Delta$ or $x_j, x_k \in \{x_i\}_i$ exist such that $x_j \in \Delta$ and $x_j \text{ gets}^*_E\, x_k$ and $l \in \Delta_k$.

Next, we show in what respect the membership of the LR(1)-item $[A \to \alpha \cdot \beta, l]$ in a state of $\mathscr{A}_l$ is related to the membership of $[A \to \alpha \cdot \beta, \Delta]$, with l taken to Δ in *Eqs*, in a state of $\mathscr{A}_s$. The asymmetry of the statements of Lemma 5 and Lemma 6 below is due to the existence of a one-to-many correspondence between the states of $\mathscr{A}_s$ and those of $\mathscr{A}_l$. In fact, each state of $\mathscr{A}_l$ is simulated by an appropriate cut of *Eqs* and of the lookahead-sets of the reducing items of a state of $\mathscr{A}_s$. On the other hand, however, each state $P \in \mathscr{A}_s$, together with *Eqs*, stands for all the states of $\mathscr{A}_l$ whose projection is the same as the projection of P. So, if $[A \to \alpha \cdot \beta, \Delta] \in P$, then not all the states of the LR(1)-automaton with projection $\mathrm{prj}(P)$ necessarily contain the pairing of $A \to \alpha \cdot \beta$ with each of the lookahead l that are taken to Δ.

The proofs of the lemmata below crucially rely upon the following key issue. Both in $\mathscr{A}_l$ and in $\mathscr{A}_s$, the lookahead \$ is generated by the single kernel item of their initial state. All the other lookaheads show up by the application of the closure procedure, and this depends, in either automata and in corresponding ways, on the projection of the item undergoing closure. Once a lookahead has been generated, it propagates along the paths of the two automata in lock-step fashion.

▶ **Lemma 5.** *Let $\mathscr{A}_l$ and $\mathscr{A}_s$ be the LR(1)-automaton and the symbolic automaton for $\mathcal{G}$, respectively. Then for every $L \in St_l$ there exists $P \in St_s$ such that $\text{prj}(P) = \text{prj}(L)$, and, for every $[A \to \alpha \cdot \beta, l] \in L$, if $[A \to \alpha \cdot \beta, \Delta] \in P$ then Δ takes_{Eqs} l.*

Proof sketch. By construction of $\mathscr{A}_s$ and of $\mathscr{A}_l$, if we walk on both automata a path starting from the initial state and labelled by some γ, we reach states with equal projections. Also, given any $L \in St_l$, there is a unique state $P \in St_s$ such that $\text{prj}(P) = \text{prj}(L)$. Hence, all the lookaheads carried to the items of L are also carried, through the corresponding paths, to the relevant items of that state P. ◀

▶ **Lemma 6.** *Let $\mathscr{A}_s$ and $\mathscr{A}_l$ be the symbolic automaton and the LR(1)-automaton for $\mathcal{G}$, respectively. Also, let $[A \to \alpha \cdot \beta, \Delta] \in P \in St_s$, and let l be such that Δ takes_{Eqs} l. Then there exists $L \in St_l$ such that $\text{prj}(L) = \text{prj}(P)$ and $[A \to \alpha \cdot \beta, l] \in L$.*

Proof sketch. By the assumption that Δ takes_{Eqs} l, there is at least one state $P_g \in St_s$ which contains an item, precisely related to $[A \to \alpha \cdot \beta, \Delta]$, that generates l. If $l = \$$, then $P_g = P_0$ and the generating item is the kernel item of P_0. Otherwise, the generating item has the form $[B \to \cdot\delta, \Gamma]$ and $l \in \Gamma$. In either case, for some γ_1, there is a γ_1-path from P_g to P. The string γ_1 can be traced backwards from P to P_g, and depends both on the chain of hops among variables which takes l to Δ, and on the structure of the items found along the way. Now, let γ be a path from P_0 to P_g. By construction of $\mathscr{A}_l$, the state L reached from L_0 by the path $\gamma\gamma_1$ has the same projection as that of P, and contains the item $[A \to \alpha \cdot \beta, l]$. ◀

The relation between the states of $\mathscr{A}_s$ and of $\mathscr{A}_l$ is at the basis of the symbolic correspondence between $\mathscr{A}_s$ and $\mathscr{A}_m$ which is stated by the following theorem.

▶ **Theorem 7.** *Let $\mathscr{A}_s$ and $\mathscr{A}_m$ be the symbolic automaton and the LRm(1)-automaton for $\mathcal{G}$, respectively. Then the following holds.*

- *For every $P \in St_s$ there exists $M \in St_m$ such that $\text{prj}(M) = \text{prj}(P)$, and, for every Y, if $\tau_s(P, Y) = P'$ then $\tau_m(M, Y) = M'$ with M' such that $\text{prj}(M') = \text{prj}(P')$.*
- *For every $M \in St_m$ there exists $P \in St_s$ such that $\text{prj}(P) = \text{prj}(M)$, and, for every Y, if $\tau_m(M, Y) = M'$ then $\tau_s(P, Y) = P'$ with P' such that $\text{prj}(P') = \text{prj}(M')$.*
- *If $P \in St_s$ and $M \in St_m$ are such that $\text{prj}(P) = \text{prj}(M)$, then $[A \to \alpha \cdot \beta, l] \in M$ iff $[A \to \alpha \cdot \beta, \Delta] \in P$ and Δ takes_E l.*

Proof. The first two assertions are consequences of the construction procedures used to obtain $\mathscr{A}_s$ and $\mathscr{A}_m$, which can both be projected into the LR(0)-automaton for $\mathcal{G}$. The third assertion comes from Lemma 5 and Lemma 6, by construction of $\mathscr{A}_m$ from $\mathscr{A}_l$. ◀

To set up the the LALR(1) parsing table that we want to construct, we still need to compute the actual lookahead-set of reducing items. Suppose that $Vars = \{x_0, \ldots, x_n\}$ and $Eqs = \{x_i \doteq \Delta_i\}_{i=0,\ldots,n}$. Our goal is to compute the set of actual instantiations of $x_0, \ldots, x_n$, hereby called $val(x_0), \ldots, val(x_n)$. By definition of takes_{Eqs}, $val(x_i)$ is given by the union of ground(Δ_i) with $val(x_k)$, for all the variables x_k such that x_i gets$_{Eqs}$ x_k. Hence, we actually look for the solution of a system of recursive equations of the form

$$val(x_i) = \text{ground}(\Delta_i) \cup \bigcup_{x_k \,:\, x_i \text{gets}_{Eqs} x_k} val(x_k)\,.$$

We observe that $D = (2^{T \cup \{\$\}})^{n+1}$ is a cpo with least element, and that $val : D \to D$ is a monotone function. Relying on standard approximation techniques, we can prove that the least solution of the system of recursive equations for $val(x_i)$ is given by

$$val(x_i) = \bigcup_{x_k \,:\, x_i \text{gets}^*_{Eqs} x_k} \text{ground}(\Delta_k)\,.$$

To gain in efficiency, instead of computing the above solution for all the variables in *Vars*, we first partition variables into equivalence classes. This allows us to define a reduced system of equations *REqs* which induces a reachability relation of smaller size over a relevant subset *RVars* of *Vars*. The intuition behind this reduction is that characteristic automata are typically quite sparse, and lookahead propagation is usually preponderant over lookahead generation. So, in general *Eqs* is expected to contain many equations of the shape $x_i \doteq \{x_j\}$. An obvious optimization is computing only one of $val(x_i)$ and $val(x_j)$ and then, by need, copying it into the other.

```
inizialize $RVars$ and $REqs$ to $\emptyset$ ;
while  $Eqs$ not empty do
    $x \doteq \Delta \longleftarrow$ dequeue($Eqs$) ;
    if  $\Delta \setminus \{x\} = \{x'\}$ then
        $class(x) \longleftarrow class(x')$ ;
    else
        $class(x) \longleftarrow x$ ;
        add $x$ to $RVars$ ;
foreach  $x \in RVars$ such that $x \doteq \Delta \in Eqs$ do
    update each $x'$ in $\Delta$ to $class(x')$ ;
    add $x \doteq \Delta \setminus \{x\}$ to $REqs$ ;
```
Algorithm 2: Reduced system of equations *REqs* for the variables in $RVars \subseteq Vars$

The algorithm for the computation of *REqs* is reported as Alg. 2. For every $x \in Vars$ we record the membership of the variable into an equivalence class. The equations in *Eqs* are processed one at a time exploiting the generation order of the variables in *Vars*. We first check whether $\Delta \setminus \{x\} = \{x'\}$. If so, then the equation at hand has either the shape $x \doteq \{x'\}$ or the shape $x \doteq \{x', x\}$. Hence the variable x is reached, in *Eqs*, exactly by the same ground values that reach x', and we let both variables belong to same equivalence class. Moreover, by Lemma 2, if $\Delta \setminus \{x\} = \{x'\}$ then $x' \prec x$. Hence, by the ordering of equation processing, $class(x')$ has already been set when handling the equation for x. Once the set of representative variables *RVars* has been identified, we start populating *REqs*. Suppose $x \in RVars$, and assume that $x \doteq \Delta \in Eqs$. Then the equation installed into *REqs* for x is obtained by updating Δ as follows. First, non-representive variables in var(Δ) are replaced by the corresponding class representative. Second, the possible occurrence of x is removed from the resulting set. This is a further optimization that, as done above, amounts to disregard a possible self-recurrence in the computation of $val(x)$. As an example, the system of equations $E_1 = \langle x_0 \doteq \{\$\}, x_1 \doteq \{x_0\}, x_2 \doteq \{=, x_0, x_2, x_3\}, x_3 \doteq \{x_1\}\rangle$ for grammar $\mathcal{G}_1$ is reduced to $\langle x_0 \doteq \{\$\}, x_2 \doteq \{=, x_0\}\rangle$.

The following theorem is a consequence of the resolution strategy for Eqs that we have illustrated so far.

▶ **Theorem 8.** *Let $\mathscr{A}_s$ be the symbolic automaton for $\mathcal{G}$, $x \in Vars = \{x_i\}_i$, and $Eqs = \{x_i \doteq \Delta_i\}_i$. Also, let $RVars$, $REqs$, and $class(x)$ be as computed by Alg. 2. Then, for every $x_i \in RVars$, $val(x_i) = \bigcup_{x_k \,:\, x_i \mathrm{gets}^*_{REqs} x_k} \mathrm{ground}(\Delta_k)$, and, for every $x_i \in Vars \setminus RVars$, $val(x_i) = val(class(x_i))$.*

Commenting on the complexity of the resolution of Eqs, we notice that Alg. 2 is linear in the size of $Vars$, and that $val(x_i)$ can be efficiently computed by a depth-first search algorithm run on the dependency graph of the relation gets_{REqs}. Briefly, each node x_i of the graph can be initially associated with the value $\mathrm{ground}(\Delta_i)$. Then the graph is visited and the values associated with the farthest nodes are accumulated with the values of the nodes found along the way back to the origin of the path. The visit can be organized in such a way that strongly connected components, if any, are recognized on-the-fly and traversed only once (see, e.g., [13, 8, 5]). By that, the search algorithm is linear in the size of the dependency graph of the relation gets_{REqs}. Referring again to $\mathcal{G}_1$, the computation of the actual lookahead-sets goes through the depth-first visit of the dependency graph

$$\begin{tikzcd} \llbracket x_2 \rrbracket \arrow[r] & \llbracket x_0 \rrbracket \end{tikzcd}$$

where $\llbracket x_0 \rrbracket$ and $\llbracket x_2 \rrbracket$ stand for the equivalence classes of x_0 and of x_2, respectively.

The following result, which is a consequence of Theorem 7 and of Theorem 8, concludes the section by concretizing the symbolic correspondence between $\mathscr{A}_s$ and $\mathscr{A}_m$.

▶ **Theorem 9.** *Let $\mathscr{A}_s$ be the symbolic automaton for $\mathcal{G}$. Also, for $P \in F_s$ and $[A \to \beta\cdot, \Delta] \in P$, let*

$$\mathcal{LA}(P, [A \to \beta\cdot, \Delta]) = \mathrm{ground}(\Delta) \cup \bigcup_{x \,:\, x' \in \Delta \text{ and } x = class(x')} val(x)\,.$$

Then the pair consisting of $\mathscr{A}_s$ and of $\{\mathcal{LA}(P, [A \to \beta\cdot, \Delta])\}_{P \in F_s, [A \to \beta\cdot, \Delta] \in P}$ is an LALR(1) parsing table for $\mathcal{G}$.

5 LR(1) tables

Below we will briefly overview the strategy we propose for deciding whether the grammar at hand is LR(1), and for constructing a compact LR(1) parsing table in the positive case.

We adopt an optimistic approach, and build an LR(1) parsing table by appropriately expanding the LALR(1) table. The cases when the LALR(1) table does not contain any conflict, or only contains shift/reduce (s/r) conflicts are equally not relevant for our argument. Indeed, in the first case the grammar is LALR(1), and in the second case it is surely not LR(1). So, we focus on the reduce/reduce (r/r) conflicts of the LALR(1) table. If the grammar at hand is not LR(1), then at least one of these conflicts is a genuine LR(1) conflict. This is the case, e.g., for the r/r conflict of the table for the ambiguous grammar $\mathcal{G}_2$ with start symbol S_2 and productions in the set $\{S_2 \to Ab \mid Bb, A \to a, B \to a\}$. If instead the grammar is LR(1), then the r/r conflicts in the LALR(1) table depend on the fact that the procedure for the construction of $\mathscr{A}_s$ caused the merging of states which would have remained separated in the construction of the LR(1)-automaton. Our goal

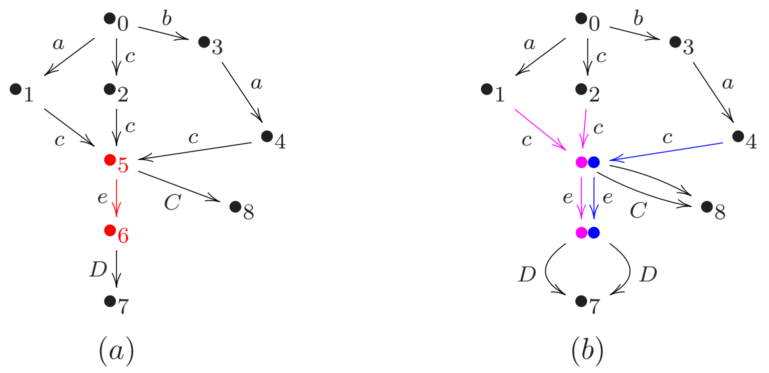

Figure 1 Partial layout of the symbolic automaton for $\mathcal{G}_3$ before (a) and after (b) the splitting due to the r/r conflict at state 6.

is eliminating that sort of r/r conflicts by appropriately splitting the *critical states* that cause those spurious r/r conflicts. Suppose that the symbolic state P is one of such merged states of $\mathscr{A}_s$, and that P stands for the union of the LR(1)-states $L_1, \ldots, L_k$. Also, assume that $P = \{[A_i \to \alpha_i \cdot \beta_i, \Delta_i]\}_i$, and that the instantiation of variables in the lookahead-sets transforms P to $P_{val} = \{[A_i \to \alpha_i \cdot \beta_i, \Sigma_i]\}_i$. Then, there exist k cuts of P_{val} of the form $P_{val_j} = \{[A_i \to \alpha_i \cdot \beta_i, \Sigma_{ij}]\}_i$ where $\bigcup_{j=1,\ldots,k} \Sigma_{ij} = \Sigma_i$, and each P_{val_j} plays the LR(1)-state L_j. Modulo an appropriate tuning of the automaton transition function, a way out for the elimination of the original r/r conflict would be exploding P_{val} in $P_{val_1}, \ldots, P_{val_k}$, and accordingly replicating the subgraph rooted at P_{val}. Two observations are in place here, both related to the space complexity of the resulting structure. Splitting P_{val} in k states might be an overkill, because, e.g., the conflict would be eliminated as well by letting P_{val_1} be still merged with P_{val_2}. For analogous reasons, replicating the whole subgraph rooted at P_{val} can be a waste, too.

We aim at applying the procedure hinted above while limiting the replication of states as much at possible. In the overall, we take the following steps. We start analyzing the r/r conflicts of the LALR(1) table, and check whether the conditions to eliminate them are met or not. If we find any r/r conflict that cannot be eliminated, we infer that the grammar is not LR(1) and conclude. Otherwise, we apply an optimized state splitting procedure to the states involved in the r/r conflicts. Operationally, this is performed by replicating some of the rows of the LALR(1) table, up to minor modifications to their contents. At worst, the resulting table has the same size as the LR(1) table built from the LR(1)-automaton.

A crucial issue in the application of the procedure is the ability to identify critical states. Also, when a state P is recognized as critical, a key point is how we actually split it under the guarantee that the intended LR(1) behaviour is preserved. The lookahead propagation flow embedded by gets_{Eqs} provides the needed support. We describe below the technique for the identification of critical states. The very first step towards this end is locating the states where the lookaheads leading to conflicts, called *critical lookaheads*, are actually generated. Assume we are considering an r/r conflict at state Q for the critical lookahead d. Also, suppose that the symbolic lookahead-sets associated with the conflicting reducing items get instantiated to Σ and to Σ'. There are various combinations here, depending on whether d is a ground element of one or both of the symbolic lookahead-sets, or it is the by-product of variable instantiation. Here we consider this last case which is the most intricate one. An example of this scenario is given by the LR(1) grammar $\mathcal{G}_3$ with start symbol S_3 and production set $\mathcal{P}_3 = \{S_3 \to aAd \mid aBc \mid baAe \mid baBd \mid cAd \mid cBc,\ A \to ce,\ B \to cC,\ C \to eD, D \to \epsilon\}$. The relevant portion of the layout of the symbolic automaton for $\mathcal{G}_3$ is drawn in Fig. 1(a), where 0 is the initial state. The r/r conflict for d is at state 6 and is induced by the reducing items $[A \to ce\cdot, \{x_7\}]$ and $[D \to \cdot, \{x_{11}\}]$ where $x_7 \doteq \{d, e\}$, $x_{11} \doteq \{x_8\}$, and $x_8 \doteq \{c, d\}$ are the relevant equations in Eqs. So, for this specific instance of state Q, $\Sigma = \{d, e\}$ and $\Sigma' = \{c, d\}$. By an analysis of gets^*_{Eqs}, we infer that the lookaheads d and e for $A \to ce\cdot$ come from the kernel item which owns x_7, say i_7, and the lookaheads c and d for $D \to \cdot$ come from the kernel item which owns x_8, say i_8 (both i_7 and i_8 are located at state 5). The items that actually generate the critical lookaheads are located in the predecessors of the state containing i_7 and i_8 (states 1, 2, and 4), and their identity can be inferred by inspection of the projections of i_7 and i_8.

Once the states generating the critical lookaheads have been identified, we check whether the r/r conflict in Q is either genuine or spurious. In the second case, we also decide which is the best possible split of Q. First, we set up two sets of pairs, say $loc(\Sigma)$ and $loc(\Sigma')$, to associate each lookahead in Σ and in Σ' with the state where the lookahead is actually generated. Then, for all the pairs in $loc(\Sigma)$ and $loc(\Sigma')$ that share the same lookahead, we deduce that the associated source states Q_1 and Q_2 are in conflict, written $Q_1 \# Q_2$. E.g., for the running example, $loc(\Sigma) = \{(d, 1), (d, 2), (e, 4)\}$, $loc(\Sigma') = \{(c, 1), (c, 2), (d, 4)\}$, and, by $(d, 1), (d, 2) \in loc(\Sigma)$ and $(d, 4) \in loc(\Sigma')$, we infer $1\#4$, and $2\#4$. The conflict relation $\#$ is the basic tool for deciding whether the r/r conflict at hand is a genuine LR(1) conflict or not. The intuition here is that if the r/r conflict at state Q is spurious, then, as discussed above, it must be possible finding cuts of Q that match the lookaheads contributed by the various merged states. Operationally, we check whether the source states occurring in $loc(\Sigma)$ and in $loc(\Sigma')$ can be partitioned in at least two groups of maximal size so that each group G of the partition meets the following requirements: (i) G contains non-conflicting states; (ii) the restriction of $loc(\Sigma)$ to the pairs whose second component is in G, written $loc(\Sigma)\restriction G$, is non empty; (iii) $loc(\Sigma')\restriction G$ is non empty either. For the example at hand, we end up partitioning $\{1, 2, 4\}$ in the two groups $\{1, 2\}$ and $\{4\}$.

If the above partition cannot be found, then the analyzed r/r conflict in P is a genuine LR(1) conflict, and we conclude that the grammar is not LR(1). This is always the case, e.g., if the conflict relation contains a pair $R\#R$. This conflict reveals that a critical lookahead is generated by distinct items of the state R. Hence this particular lookahead directly depends on the projection of R, which is the same either in $\mathscr{A}_s$ or in $\mathscr{A}_l$. (An instance of this scenario is found in the analysis of the ambiguous grammar $\mathcal{G}_2$ for the critical lookahead b that is generated in the initial state for either $A \to \cdot a$ or $B \to \cdot a$.)

If the source states of the actual lookahead-sets of Q can be partioned into the groups $G_1, \ldots, G_j$, then Q is split in j replica. For each actualized lookahead-set Σ_i, the jth replica of Q is assigned the lookahead-set containing the first elements of the pairs in $\Sigma_i\restriction G_j$. At the same time, relying upon gets^*_{Eqs} we identify the paths $\gamma_1, \ldots, \gamma_m$ that start at the states where the critical lookaheads are sourced and that lead to Q. Such paths share at least one state that is Q at latest. Among the states traversed by $\gamma_1, \ldots, \gamma_m$, those states which are shared by paths from conflicting source states are all critical (states in red in Fig. 1(a)). We split them to grant distinct and parallel routes to the contributions from the states of each group G_j to the corresponding replica of Q. As for the elimination of the spurious r/r conflict at hand, no other state needs to be replicated.

Looking at the splitting procedure from the perspective of the parsing table, the modifications performed are as follows. The row for state Q is copied j times, and each copy retains only the reduction steps for the represented group. The row for each replica of the other critical states is copied from the row of the replicated state. The shift moves of the non-conflicting predecessors of critical states (edges in magenta and in blue in Fig. 1(b)) are redirected to the replica for the appropriate group. Here we notice that each new row of the table has shift moves exactly for the same symbols as the old copy of the row, and fewer reduce moves. So, each pass of the splitting procedure cannot generate neither new s/r conflict nor new r/r conflicts.

The described approach for the construction of LR(1) tables guarantees the early detection that the grammar is not LR(1). In the opposite case, when all the r/r conflicts are eliminated, we get a table for LR(1) parsing where all the states whose merging is not critical are still merged as in an LALR(1) table. The generated table is then expected to be generally smaller than the table constructed on top of LR(1)-automata. An easy example of this is the size of the LR(1) table that we obtain by applying the above algorithm to the grammar $\mathcal{G}_4$ with start symbol S_4 and with production set $\{S_4 \to S_1 \mid S_3\} \cup \mathcal{P}_1 \cup \mathcal{P}_3$. The symbolic automaton for $\mathcal{G}_4$ has two separated sub-graphs corresponding to the symbolic automata for $\mathcal{G}_1$ and for $\mathcal{G}_3$, respectively. The subgraph representing the symbolic automaton for $\mathcal{G}_3$ is refined as described above. The sub-graph for $\mathcal{G}_1$, though, remains untouched, and hence definitely smaller than the LR(1)-automaton for $\mathcal{G}_1$.

6 Concluding remarks

We defined symbolic characteristic automata, and used them as the basis for the construction of LALR(1) parsing tables, for the construction of LR(1) parsing tables, and for early detecting that grammars are non LR(1).

Among the algorithms for the construction of LALR(1) parsing tables, the most popular ones are the `Yacc` algorithm [9, 2], and the algorithm by DeRemer and Pennello [5]. The algorithm we proposed is more similar to the `Yacc` algorithm than to the algorithm by DeRemer and Pennello. In fact, our technique retains, although making it symbolic, the `Yacc` strategy of generating/propagating LR(1) lookaheads. The approach taken by DeRemer and Pennello is instead a refinement of the SLR(1) technique. In a nutshell, the algorithm by DeRemer and Pennello elaborates on the state of the LR(0)-automaton where $A \to \beta\cdot$ is located, and infers which precise subset of the productions of the grammar should be considered when computing the follow-set of that specific occurrence of A.

In [11], Pager presented an algorithm that is used in the implementation of Menhir [7], the parsing engine of OCaml [10]. The algorithm by Pager generates on-the-fly a compact LR(1)-automaton by checking whether already generated states can be the target of the processed transition. We adopt a quite different strategy. Driven by local reasoning on r/r conflicts, we construct LR(1) parsing tables as refinements of the corresponding LALR(1) tables. This delays as much as possible any sort of check on the content of states.

In the algorithms for the construction of parsing tables, the number of set-union operations on lookahead-sets is typically taken as performance measure. Distinct algorithms execute those operations on different kinds of auxiliary structures, and the size of these structures is often grammar-dependent. So, even statistical reasoning about performance, which in many cases is likely as much as we can do, has to be very carefully tuned. Precise comparisons between our algorithms and those mentioned above are untimely at this stage, as they should be based on large test-sets.

The symbolic techniques we presented can be extended to produce parsing tables for grammars in classes bigger than LALR(1). E.g., we used it to define LALR(k) parsing tables for $k > 1$. The major benefit of the symbolic structures we proposed is, however, that equations over variables, together with the fact that each variable uniquely identifies an item, provide a compact and synthetic feedback on the origin of lookaheads, on their flow, and on their inter-dependency. The explicit representation of lookahead propagation can be most useful in the design phase of grammars, i.e. especially when the grammar under investigation is not yet in the wanted class. Orthogonally, the algorithm we presented for upgrading LALR(1) tables to LR(1) tables shows another sort of application of the explicit encoding of lookahead propagation in LALR(1)-automata.

Abstract

Inspired by the study of control scenarios in elections and complementing manipulation and bribery settings in cooperative games with transferable utility, we introduce the notion of structural control in weighted voting games. We model two types of influence, adding players to and deleting players from a game, with goals such as increasing a given player's Shapley–Shubik or probabilistic Penrose–Banzhaf index in relation to the original game. We study the computational complexity of the problems of whether such structural changes can achieve the desired effect.

1 Introduction

A major task in computational social choice [42, 12, 13] is the complexity analysis of the question of whether a certain form of influence is possible in an election under some voting rule (see, e.g., [42, 13]). Bartholdi et al. [5] introduced and analyzed the notion of manipulation in elections, where one or more voters strategically change their true preference in order to make a distinguished candidate a winner. In a bribery scenario, on the other hand, an external agent tries to pay voters for them to change their votes such that a certain candidate becomes a winner, and the question is whether the briber can be successful within a given budget. This idea has been introduced and analyzed by Faliszewski et al. [24, 25]. In a third model, control, the chair of an election changes the structure of an election by adding, deleting, or partioning either voters or candidates, with the aim of making a distinguished candidate a winner [6]. In addition to these constructive types of control, destructive control – the problem of whether a given candidate can be prevented from being a winner – has also been introduced and studied by Hemaspaandra et al. [32]. Manipulation, bribery, and control have been studied for many voting systems, and we refer the reader to the book chapters by Baumeister and Rothe [10], Conitzer and Walsh [15], and Faliszewski and Rothe [27] for an overview of numerous related results. In a nutshell, whenever successful manipulative actions are possible, a high computational complexity may provide some protection against them, or at least against detecting whether such actions are possible or not for an election.

* A two-page extended abstract of this paper appeared in the proceedings of AAMAS 2016 and has been presented at the workshops CoopMAS 2016 and LOFT 2016, both with informal proceedings.

† This work was supported in part by DFG grant RO-1202/14-2.

Similar ideas have been adapted to other fields, such as manipulation in preference aggregation [21] and manipulation, bribery, and control in judgement aggregation [23, 8, 7] (see the book chapters by Endriss [22] and Baumeister et al. [9] for an overview). In algorithmic game theory, the question of influencing the outcome of a game has also been studied extensively. In particular, for weighted voting games, manipulation by merging a coalition of players to a single player, or by splitting a player into several players in order to increase a player's power, have been introduced by Elkind et al. [2]. Here, "power" refers to the notion of power indices, such as the Penrose–Banzhaf [37, 4, 17] and the Shapley–Shubik index [43], measuring the significance of a player in a game (formal definitions will be given in Section 2). The complexity of beneficial merging, splitting, and annexation[1], e.g., for the Shapley–Shubik index, have been studied by Aziz et al. [1] who show NP-hardness. Faliszewski and Hemaspaandra [26] show that the beneficial merging problem is in PP. Rey and Rothe [40] prove PP-hardness for beneficial merging and splitting. Other forms of manipulation have been studied in weighted voting games. For example, Zuckerman et al. [48] study manipulation of the quota. From an algorithmic point of view, this is different from our model: In their model, the number of players and thus the denominator in a power index (see Equations (1) and (2) in Section 2) remains the same but the same coalitions can have different success due to different quotas, whereas with structural control the number of players varies but all coalitions that remain in the game are equally successful before and after the change. Relatedly, Zick et al. [46, 47] study algorithmic properties of the quota. In dynamic weighted voting games, as presented by Elkind et al. [18], the quota is changed as well, but dynamically over time. The notion of bribery has been adapted from voting theory to a model in cooperative game theory, so-called path-disruption games [3], where an external player tries to bribe a coalition of players so as to reach a target node in a graph [41]. Another perspective of persuasion for weighted voting games has been studied by Freixas and Pons [30].

Inspired by the notion of control in elections, we consider control scenarios in weighted voting games. We define the problems of whether it is possible to change the structure of a game by either *adding* or *deleting* players in order to achieve certain goals. One could, for instance, think of a committee that needs a certain quota of votes so as to decide upon an issue. In order to increase the significance of some participant, an organizer might invite further participants or might choose a certain meeting schedule to make sure that originally existing participants are excluded. These structural changes could also be viewed as a change of the players' participation over time without malicious intentions. Goals include *increasing* and *decreasing* the power of a distinguished player, in relation to the player's power in the original game. Increasing and decreasing power in a game by adding or deleting players can be seen as analogues of, respectively, constructive and destructive control in elections by adding or deleting either candidates or voters. Moreover, if an *exact* number of players is to be added, it might be desirable to *maintain* an original player's power index (or to keep it upper-bounded or lower-bounded by the original value – we will say the index is *nonincreasing* or *nondecreasing*).

Note that power indices in weighted voting games can be used to model decision processes in legislative bodies such as the EU Commission, national parliaments, or the United Nations Security Council. For a real-world example, suppose there is a discussion on whether a new member will join the EU, or an old member will leave the EU. What impact does this change

[1] While merging is an action of a manipulative coalition, annexation describes one manipulative player who takes over other players. This goes back to the bloc paradox [28].

Table 1 Overview of complexity results of control problems in weighted voting games with respect to the Shapley–Shubik and the probabilistic Penrose–Banzhaf index. Key: k is the number of players to be added or deleted, respectively; *PI* stands for *power index* (either *SS* or *PB*); *SS* (respectively, *PB*) indicates that these results are only known to hold for the Shapley–Shubik index (respectively, for the probabilistic Penrose–Banzhaf index); the other results each hold for both indices.

Goal	Control type		
	Adding players		Deleting players
	k fixed	k given	$k = 1$
Increase *PI*	PP-complete (Thm. 9)	PP-hard (Thm. 8)	NP-hard *(SS)* (Thm. 10)
Nondecrease *PI*	PP-complete (Thm. 9)	PP-hard (Thm. 8)	?
Decrease *PI*	PP-complete (Thm. 9)	PP-hard (Thm. 8)	coNP-hard *(PB)* (Thm. 11)
Nonincrease *PI*	PP-complete (Thm. 9)	PP-hard (Thm. 8)	coNP-hard *(PB)* (Thm. 13)
Maintain *PI*	coNP-hard, in PP (Thm. 12)	PP-hard (Thm. 8)	coNP-hard (Thm. 13)

have on the power of the existing, or remaining, EU members? Will they benefit from adding or deleting other members? Or, when it has been decided already that some new members will join the EU, an old member may be interested in maintaining the same power as before the new members have joined the game. We will show that all control types to be defined are possible in weighted voting games, and we will therefore analyze the computational complexity of whether control by structural changes can be exerted successfully in a given game. The complexity depends on the control type, the goal, and on whether the number of players that can be added or deleted is fixed or is given in the problem instance. Table 1 gives an overview.

2 Preliminaries

A *cooperative game with transferable utility* $\mathcal{G} = (N, v)$ consists of a set of players N and a coalitional function $v : 2^N \to \mathbb{R}$ assigning a value to each subset of players, called a *coalition*. $\mathcal{G}$ is called *simple* if v it is *monotonic* (i.e., $v(C) \leq v(D)$ whenever $C \subseteq D \subseteq N$) and if a coalition C is either *winning* ($v(C) = 1$) or *losing* ($v(C) = 0$).

Power indices are a common concept to measure a player's significance in a simple game $\mathcal{G} = (N, v)$. Two popular indices are the Penrose–Banzhaf index [37, 4] and the Shapley–Shubik index [43]. Let n be the number of players in $\mathcal{G}$ and $i \in N$. Define i's *raw Penrose–Banzhaf power index in* $\mathcal{G}$ by $\text{PenroseBanzhaf}^*(\mathcal{G}, i) = \sum_{C \subseteq N \smallsetminus \{i\}} (v(C \cup \{i\}) - v(C))$ and i's *probabilistic Penrose–Banzhaf power index in* $\mathcal{G}$ (proposed by Dubey and Shapley [17]) by

$$\text{PenroseBanzhaf}(\mathcal{G}, i) = \frac{\text{PenroseBanzhaf}^*(\mathcal{G}, i)}{2^{n-1}}. \tag{1}$$

We say that i is *critical for a coalition* C if the marginal contribution $v(C \cup \{i\}) - v(C)$ of player i to coalition C in the definition above is 1, i.e., if C is losing but, after i has joined, $C \cup \{i\}$ is winning. On the other hand, $v(C \cup \{i\}) - v(C) = 0$ means that i is not critical for C. Player i's *raw Shapley–Shubik power index in* $\mathcal{G}$ is $\text{ShapleyShubik}^*(\mathcal{G}, i) =$

$\sum_{C \subseteq N \smallsetminus \{i\}} \|C\|!(n-1-\|C\|)!(v(C \cup \{i\}) - v(C))$, which is then normalized by

$$\text{ShapleyShubik}(\mathcal{G}, i) = \frac{\text{ShapleyShubik}^*(\mathcal{G}, i)}{n!} \tag{2}$$

to obtain i's *Shapley–Shubik power index in* $\mathcal{G}$.

Some simple games $\mathcal{G} = (N, v)$ can be compactly represented as *weighted voting games* $(w_1, \ldots, w_n;\, q)$, where w_i, $1 \leq i \leq n$, is player i's *weight* and q is a *quota*, and a coalition $C \subseteq N$ *wins* if $\sum_{i \in C} w_i \geq q$ and otherwise it *loses*. Note that this representation is not fully expressive, i.e., there are simple games that cannot be represented by weighted voting games. For further background on cooperative game theory, see, e.g., the textbooks by Shoam and Leyton-Brown [44] and Peleg and Sudhölter [36] and, for computational aspects, the book by Chalkiadakis et al. [14] and the book chapters by Elkind et al. [19, 20].

For some background on computational complexity, see, e.g. the textbook by Papadimitriou [35]. We use the standard notions of *hardness* and *completeness* for a complexity class with respect to *many-one polynomial-time reducibility*. NP is the class of decision problems that can be solved in nondeterministic polynomial time, and coNP is the class of problems whose complements are in NP. Partition is the following well-known NP-complete problem:

	Partition
Given:	A set $A = \{1, \ldots, n\}$ and a function $a : A \to \mathbb{N} \smallsetminus \{0\}$, $i \mapsto a_i$, such that $\sum_{i=1}^{n} a_i$ is even.
Question:	Does there exist a partition into two subsets of equal weight, that is, does there exist a subset $A' \subseteq A$ such that $\sum_{i \in A'} a_i = \sum_{i \in A \smallsetminus A'} a_i$?

SubsetSum is also a well-known NP-complete problem:

	SubsetSum
Given:	A set $A = \{1, \ldots, n\}$, a function $a : A \to \mathbb{N} \smallsetminus \{0\}$, $i \mapsto a_i$, and a positive integer q.
Question:	Is there a subset $A' \subseteq A$ such that $\sum_{i \in A'} a_i = q$?

Let $(a_1, \ldots, a_n;\, q)$ and $(a_1, \ldots, a_n)$ denote SubsetSum and Partition instances, respectively. A third well-known NP-complete problem that we will need is

	Exact Cover By 3-Sets (X3C)
Given:	A set $B = \{1, \ldots, 3k\}$, $k > 0$, and a collection $\mathcal{S} = \{S_1, \ldots, S_n\}$ of subsets $S_i \subseteq B$ with $\|S_i\| = 3$ for $1 \leq i \leq n$.
Question:	Is there an exact cover of B in $\mathcal{S}$, that is, is there a subcollection $\mathcal{S}' \subseteq \mathcal{S}$ such that $\bigcup_{S \in \mathcal{S}'} S = B$ and $S_i \cap S_j = \emptyset$, for each $S_i, S_j \in \mathcal{S}'$, $i \neq j$?

We furthermore consider the function class #P, the class of functions that give the number of solutions of NP problems. A function is #P-*many-one-hard* if there exists a polynomial-time reduction from each function in #P; it is #P-*parsimonious-hard* if there exists such a reduction from each function in #P that preserves the number of solutions. If a #P function is #P-many-one-hard (#P-parsimonious-hard) it is said to be #P-*many-one-complete* (#P-*parsimonious-complete*). For instance, #SubsetSum and #X3C are known to be #P-parsimonious-complete functions. #P is closed under addition, i.e., if $f, g \in$ #P then $f + g \in$ #P. From the literature [38, 16, 26] we obtain the following lemma.

▶ **Lemma 1** ([38, 16, 26]). *Computing the raw Penrose–Banzhaf index is* #P*-parsimonious-complete. Computing the raw Shapley–Shubik index is* #P*-many-one-complete.*

The complexity class PP (*probabilistic polynomial time*) was introduced by Gill [31] via probabilistic Turing machines; equivalently, it can be defined as the class of all decision problems X for which there exist a function $f \in \#\mathrm{P}$ and a polynomial p such that for all instances x: $x \in X \iff f(x) \geq 2^{p(|x|)-1}$. PP is considered to be a rather large complexity class, since it contains both NP and coNP (and even $\mathrm{P}_{\parallel}^{\mathrm{NP}}$ as shown by Beigel et al. [11]) and since it is known to be at least as hard (in terms of polynomial-time Turing reductions) as the polynomial hierarchy (i.e., $\mathrm{PH} \subseteq \mathrm{P}^{\mathrm{PP}}$) by Toda's theorem [45]. PP is closed under complement (which is easy to see) and, far from being trivial, it is also closed under union and intersection [29]. We make use of the following lemma by Faliszewski and Hemaspaandra [26, Lemma 2.3] in the context of comparing a player's power in weighted voting games with respect to the probabilistic Penrose–Banzhaf and the Shapley–Shubik index.

▶ **Lemma 2** ([26]). *Let F be a* #P*-parsimonious-complete function. Then, the problem* Compare-$F = \{(x, y) \mid F(x) > F(y)\}$ *is* PP*-complete.*

Since #X3C and #SubsetSum are #P-parsimonious-complete, Compare-#SubsetSum and Compare-#X3C are PP-complete. Moreover, we will use the following lemma due to Faliszewski and Hemaspaandra [26] that has been slightly adapted by Rey and Rothe [40].

▶ **Lemma 3.** *Every* X3C instance $(B', \mathcal{S}')$ can be transformed into an X3C instance $(B, \mathcal{S})$ where $\|B\| = 3k$ and $\|\mathcal{S}\| = n$, such that $k/n = 2/3$ without changing the number of solutions (i.e., $\#\mathrm{X3C}(\mathrm{B}, \mathcal{S}) = \#\mathrm{X3C}(\mathrm{B}', \mathcal{S}')$). Consequently, we can assume that the size of each solution in a SubsetSum instance is $2n/3$, that is, each subsequence summing up to the given quota contains the same number of elements.

We consider a restricted variant of the Compare-#SubsetSum problem, namely Compare-#SubsetSum-RR as defined in [40]: Given a set $A = \{1, \ldots, n\}$ and a function $a : A \to \mathbb{N} \smallsetminus \{0\}$, $i \mapsto a_i$, is the number of subsets of A with values summing up to $(\alpha/2) - 2$, where $\alpha = \sum_{i=1}^{n} a_i$, greater than the number of subsets of A with values summing up to $(\alpha/2) - 1$, i.e., is it true that

$$\#\textsc{SubsetSum}((a_1, \ldots, a_n;\ (\alpha/2) - 2)) \ > \ \#\textsc{SubsetSum}((a_1, \ldots, a_n;\ (\alpha/2) - 1))? \qquad (3)$$

Let $(a_1, \ldots, a_n)$ denote an instance of Compare-#SubsetSum-RR. From [40, Lemma 4.5] we obtain the following lemma.

▶ **Lemma 4** ([40]). Compare-#SubsetSum-RR *is* PP*-hard.*

Likewise, the analogous problem of whether $<$ holds in (3), denoted by Compare-#SubsetSum-ЯЯ, is PP-hard [40]. The following lemma differentiates between players that are not part of a weighted voting game and those who are but do not have any weight.

▶ **Lemma 5.** *For both the probabilistic Penrose–Banzhaf index and the Shapley–Shubik index, given a weighted voting game, adding a player with weight zero does not change the original players' power indices, and the new player's power index is zero.*

3 Control Types and Goals

We define control by adding and by deleting players in weighted voting games. For each control type, we consider goals, such as increasing or decreasing a distinguished player's power, in relation to the original game. We first define how adding and deleting a player affects the coalitional function for weighted voting games: For control by adding players, from a given weighted voting game $\mathcal{G} = (w_1, \dots, w_n;\, q)$ with $N = \{1, \dots, n\}$ and a set $M = \{n+1, \dots, n+m\}$ of m unregistered players with weights $w_{n+1}, \dots, w_{n+m}$, we obtain a new game $\mathcal{G}_{\cup M} = (w_1, \dots, w_{n+m};\, q)$.

For example, we consider the following decision problem for a power index PI:

Control by Adding Players to Increase PI

Given: A weighted voting game $\mathcal{G}$ with players $N = \{1, \dots, n\}$, a set M of unregistered players with weights $w_{n+1}, \dots, w_{n+m}$, a distinguished player $p \in N$, and a positive integer k.

Question: Can at most k players $M' \subseteq M$ be added to $\mathcal{G}$ such that for the new game $\mathcal{G}_{\cup M'}$ it holds that $\mathrm{PI}(\mathcal{G}_{\cup M'}, p) > \mathrm{PI}(\mathcal{G}, p)$?

Analogously, we can ask whether the game can be controlled so as to gain the opposite effect, and decrease a certain player's index. In these cases, hardness in terms of complexity can be seen as a shield to prevent a game from being controlled to improve a player's significance or to worsen a player's significance. On the other hand, we also consider the following control question: Is it possible to add players to a game without changing the distribution of power among the original players?

We can ask analogous questions with the same aims for removing players from the game. Deleting a subset $M \subseteq N$ of m players from a weighted voting game $\mathcal{G} = (w_1, \dots, w_n;\, q)$ yields a weighted voting game $\mathcal{G}_{\smallsetminus M} = (w_{j_1}, \dots, w_{j_{n-m}};\, q)$ with $\{j_1, \dots, j_{n-m}\} = N \smallsetminus M$.[2]

For instance, we define the following decision problem for a power index PI:

Control by Deleting Players to Increase PI

Given: A weighted voting game $\mathcal{G}$ with players $N = \{1, \dots, n\}$, a distinguished player $p \in N$, and a positive integer $k < \|N\|$.

Question: Can at most k players $M' \subseteq N \smallsetminus \{p\}$ be deleted from $\mathcal{G}$ such that in the new game $\mathcal{G}_{\smallsetminus M'}$ it holds that $\mathrm{PI}(\mathcal{G}_{\smallsetminus M'}, p) > \mathrm{PI}(\mathcal{G}, p)$?

Again, we can analogously define the variations of this problem where the goal is not to increase some player's power index but to decrease or to maintain it.

▶ **Example 6.** Let $\mathcal{G} = (N, v)$ be a weighted voting game with six players in $N = \{1, 2, 3, 4, 5, 6\}$ represented by $(1, 2, 2, 3, 4, 5;\, 10)$. Let $k = 1$, that is, one player can be removed from the game. Table 2 lists the players' probabilistic Penrose–Banzhaf and Shapley–Shubik power indices for the resulting games. Note that fractions are sometimes expanded or reduced to a comparable denominator.

Consider the Penrose–Banzhaf index. Player 1, 4, 5 and 6 with indices of $1/8$, $5/16$, $3/8$, and $9/16$, respectively, cannot improve from any other player being deleted. However, e.g., player 1's index can be decreased to $1/16$ when removing player 5 and is maintained in the other cases. Players 2 and 3 can benefit from the other one being removed, as the index increases from $3/16$ to $1/4$.

[2] One might also think of different ways to reasonably model the new game, and we will eloborate on that in Section 6. Here, we focus on the notion just presented.

Table 2 Power distribution in the games of Example 6.

Player i		1	2	3	4	5	6
$\mathrm{PenroseBanzhaf}(\mathcal{G}, i)$	$\cdot 32$	4	6	6	10	12	18
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{1\}}, i)$	$\cdot 32$		6	6	10	10	18
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{2\}}, i)$	$\cdot 32$	4		8	8	12	16
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{3\}}, i)$	$\cdot 32$	4	8		8	12	16
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{4\}}, i)$	$\cdot 32$	4	4	4		12	16
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{5\}}, i)$	$\cdot 32$	2	6	6	10		14
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{6\}}, i)$	$\cdot 32$	4	4	4	8	8	
$\mathrm{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{1,2\}}, i)$	$\cdot 32$			8	8	8	16
$\mathrm{ShapleyShubik}(\mathcal{G}, i)$	$\cdot 60$	4	6	6	11	13	20
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{1\}}, i)$	$\cdot 60$		7	7	12	12	22
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{2\}}, i)$	$\cdot 60$	5		10	10	15	20
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{3\}}, i)$	$\cdot 60$	5	10		10	15	20
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{4\}}, i)$	$\cdot 60$	5	5	5		15	30
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{5\}}, i)$	$\cdot 60$	3	8	8	13		28
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{6\}}, i)$	$\cdot 60$	6	6	6	21	21	
$\mathrm{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{1,2\}}, i)$	$\cdot 60$			10	10	10	30

For the Shapley–Shubik index, due to normalization over the permutations of participating players, an increase of power is expected when deleting a player. As an example, player 5 has an index of $13/60$ in $\mathcal{G}$ which increases to $1/4$ if either one of the players 2, 3, or 4 is deleted, and even to $7/20$ if 6 is deleted. However, players can also have a disadvantage, if a player leaves the game. For instance, player 1 loses power if 5 is deleted, 2 and 3 lose power if 4 is deleted, 4 loses power if 2 or 3 are deleted, and 5 loses power if 1 is deleted. This suggests a symmetric dependence of the players. In the same way, the power of players 2 and 3 remains the same if 6 is removed, and the other way around.

From the opposite view, consider the weighted voting game represented by $(2, 3, 4, 5; 10)$, two unregistered players with weights 1 and 2, and $k = 2$ (see the bottom rows for the two indices). Note that adding them both ends up in $\mathcal{G}$. Here, the four players have probabilistic Penrose–Banzhaf indices of $1/4$, $1/4$, $1/4$, and $1/2$. The first player (with weight 2) can only be worse off when adding any of the two players. The player with weight 3 as well as the player with weight 5 can benefit from adding both players or only the one with weight 2. The former keeps the same index, while the latter loses power if the player with weight 1 is added. Finally, the player with weight 4 improves in every situation when adding one or two players. The first and the fourth player (with weight 2 and 5, respectively) cannot benefit from adding players with respect to the Shapley–Shubik index. The other two can take advantage in the same cases as for the probabilistic Penrose–Banzhaf index.

In particular, the example shows that these types of control are each possible. We therefore turn to the question of how hard it is to find out whether they can be exerted successfully in a given game. Next to goals in relation to the old game, we can also compare an index either in relation to the other players' power, or in relation to a constant number. See Section 6 for initial results for this idea. If a player i is deleted from a weighted voting game, any other player j gains the same amount of power that i would gain if j were deleted [33].

The changes of power indices by deletion of players are bounded as follows.

▶ **Theorem 7.** *After deleting the players of a subset $M \subseteq N \setminus \{i\}$ of size $m \geq 1$ from a weighted voting game $\mathcal{G} = (N, v)$, the difference between player i's old and new*
1. *Penrose–Banzhaf index is at most $1 - 2^{-m}$ and is at least $-1 + 2^{-m}$;*
2. *Shapley–Shubik index is at most $1 - {}^{(n-m+1)!}/{}_{2n!}$ and is at least $-1 + {}^{(n-m-1)!}/{}_{2(n-2)!}$.*

In particular, if $m = 1$ player is deleted, both the Penrose–Banzhaf index and the Shapley–Shubik index of any other player can increase by at most $1/2$ and will decrease by at most $-1/2$. These bounds are tight.

4 Increasing or Decreasing an Index

Similarly to control by adding or deleting voters or candidates in elections, adding and deleting players are not merely inverse operations. This is due to the fact that when adding players all original players are guaranteed to be part of the game before and after the structural change, whereas when deleting players each player except the distinguished one can be removed from the game. Hardness in terms of complexity can be seen as a shield to prevent a game from being controlled to improve or worsen a player's significance.

4.1 Control by Adding Players

From a computational complexity point of view, we distinguish the cases where an upper bound of new players is given as defined above and where the number of new players is fixed.

▶ **Theorem 8.** *Control by adding a given number of players in order to increase (decrease) a distinguished player's probabilistic Penrose–Banzhaf or Shapley–Shubik index in a weighted voting game is* PP*-hard.*

Proof. We show PP-hardness via the techniques used by Rey and Rothe [40], Faliszewski and Hemaspaandra [26], and Zuckerman et al. [48]. By Lemma 4, Compare-#SubsetSum-RR is PP-hard. Reducing from this problem, we map an instance $(a_1, \ldots, a_n)$ with $\alpha = \sum_{i=1}^{n} a_i$ to a weighted voting game $\mathcal{G}$ represented by $(1, a_1, \ldots, a_n;\ \alpha/2)$, an unregistered player with weight $w_{n+2} = 1$, $k = 1$, and distinguished player $p = 1$. There is only one possible new game obtained by adding the unregistered player to the game $\mathcal{G}_{\cup\{n+1\}}$. We show that

$$\begin{aligned}&\text{PenroseBanzhaf}(\mathcal{G}_{\cup\{n+2\}}, 1) - \text{PenroseBanzhaf}(\mathcal{G}, 1) > 0\\ &\quad\iff\quad \#\textsc{SubsetSum}((a_1, \ldots, a_n;\ \alpha/2 - 2)) > \#\textsc{SubsetSum}((a_1, \ldots, a_n;\ \alpha/2 - 1)).\end{aligned}$$

It holds that

$$\begin{aligned}&\text{PenroseBanzhaf}(\mathcal{G}_{\cup\{n+1\}}, 1) - \text{PenroseBanzhaf}(\mathcal{G}, 1) && (4)\\ &\quad = 1/2^n (\|\{C \subseteq \{2, \ldots, n+1\} \mid 2 + \textstyle\sum_{i \in C} a_{i-1} \geq \alpha/2,\ 1 + \sum_{i \in C} a_{i-1} < \alpha/2\}\| && (5)\\ &\qquad\quad - \|\{C \subseteq \{2, \ldots, n+1\} \mid 1 + \textstyle\sum_{i \in C} a_{i-1} \geq \alpha/2,\ \sum_{i \in C} a_{i-1} < \alpha/2\}\|). && (6)\end{aligned}$$

If for some $C \subseteq \{2, \ldots, n+1\}$ the conditions of the set in (6) are satisfied (i.e., $\sum_{i \in C} a_{i-1} < \alpha/2$ but $1 + \sum_{i \in C} a_{i-1} \geq \alpha/2$), then $\alpha/2 - 1 = \sum_{i \in C} a_{i-1}$, since the weights and the quota are integers. If for some $C \subseteq \{2, \ldots, n+1\}$ the conditions of the set in (5) are satisfied, then $\alpha/2 - 2 = \sum_{i \in C} a_{i-1}$. Therefore, the term in (4) is positive if and only if the number of solutions that sum up to $\alpha/2 - 2$ is greater than $\alpha/2 - 1$. Thus it is PP-hard to verify whether the Penrose–Banzhaf index of a player can be increased by adding players.

Analogously, for the goal of decreasing an index we can reduce from the PP-hard problem Compare-#SubsetSum-ЯЯ, which is defined in [40] by switching $\alpha/2 - 2$ and $\alpha/2 - 1$ in the definition of Compare-#SubsetSum-RR.

Likewise, with Lemma 3 these results can be adapted to the Shapley–Shubik index. ◀

▶ Remark. An upper bound of $\mathrm{NP}^{\mathrm{PP}}$ can be established whenever the number of players to be added is given. We can guess the subset of new players to be added nondeterministically. Verifying whether the different goals are satisfied is encoded in the PP-oracle. We conjecture that this problem is complete for this class.

▶ **Theorem 9.** *Control by adding a fixed number of players in order to increase (decrease) a distinguished player's probabilistic Penrose–Banzhaf or Shapley–Shubik index in a weighted voting game is* PP*-complete.*

Proof. Since the number of players to be added is fixed, there are polynomially many combinations to be added. Therefore, we have polynomially many comparisons of power indices. No matter which goal we consider, the comparison can be done in PP by Lemmas 1 and 2 and by the facts that #P is closed under addition and PP is closed under complement. The problem belongs to PP, since PP is closed under union.

Hardness is implied by the case of $k = 1$ player to be added in the proof of Theorem 8. By Lemma 5, this also holds for any other fixed number of players to be added. ◀

4.2 Control by Deleting Players

Recall that although deleting a previously added player results in the same game, the possibility to fulfill a certain goal by adding a player is not the complement of the possiblity to fulfill the complement goal by deleting a player. Initially, we obtain the following.

▶ **Theorem 10.** *Control by deleting players to increase a distinguished player's Shapley–Shubik index in a weighted voting game is* NP*-hard (even if only one player is deleted).*

Proof. We show NP-hardness by means of a reduction from SubsetSum. By Lemma 3 we can assume that the satisfying solutions all have the same size ℓ. Let $(a_1, \ldots, a_n; q)$ be a SubsetSum instance, consider the weighted voting game $\mathcal{G}$ represented by $(1, a_1, \ldots, a_n, q+1; q+1)$, and consider player 1 as our distiguished player. Let $k = 1$ and let $\xi = \#\text{SubsetSum}((a_1, \ldots, a_n; q))$ denote the number of solutions for the SubsetSum instance. Then, for the raw Shapley–Shubik index it holds that $\xi \geq 1$ if and only if deleting some player but 1 can lead to an increase of 1's index.

If: If $\xi = 0$, $\text{ShapleyShubik}^*(\mathcal{G}, 1)$ is and remains 0 no matter which player is deleted.

Only if: Assume that $\xi \geq 1$. Then $\text{ShapleyShubik}^*(\mathcal{G}, 1) = \xi/2 \cdot \ell!(n+1-\ell)! + \xi/2 \cdot (n-\ell)!(\ell+1)!$. If player $n+2$ is deleted, player 1's new raw index is $\text{ShapleyShubik}^*(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) = \xi \cdot \ell!(n-\ell)!$. This leads to

$$\begin{aligned}
&\text{ShapleyShubik}(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) - \text{ShapleyShubik}(\mathcal{G}, 1)\\
&= \frac{1}{(n+1)!} \cdot \xi \cdot \ell!(n-\ell)! \cdot \frac{2}{2} - \frac{1}{(n+2)!} \cdot \frac{\xi}{2} \cdot \ell!(n-\ell)!(n+1-\ell+\ell+1)\\
&= \frac{1}{(n+1)!} \cdot \frac{\xi}{2}(2-1)\ell!(n-\ell)!,
\end{aligned}$$

which is greater than 0 because $\ell!$ and $(m-\ell)!$ are positve. ◀

▶ **Theorem 11.** *Control by deleting players to decrease a distinguished player's Penrose–Banzhaf index in a weighted voting game is* coNP*-hard (even if only one player can be deleted).*

Proof. We show coNP-hardness by means of a reduction from the complement of PARTITION, denoted by $\overline{\text{PARTITION}}$. Letting $(a_1, \dots, a_n)$ be a PARTITION instance with $\alpha = \sum_{i=1}^{n} a_i$ and $\xi = \#\text{PARTITION}((a_1, \dots, a_n))$, we construct the control instance consisting of $\mathcal{G} = (1, a_1, \dots, a_n, \alpha/2; \alpha/2 + 1)$, $p = 1$, and $k = 1$. We show that $\xi = 0$ if and only if there exists a player whose removal from the game causes player 1's Penrose–Banzhaf power to decrease.

Only if: Assume that $\xi = 0$. Then $\text{PenroseBanzhaf}^*(\mathcal{G}, 1) = 1$. However, if player $n+2$ with weight $\alpha/2$ is removed, there is no coalition left player 1 is critical for. Therefore, control in order to decrease player 1's Penrose–Banzhaf index is possible.

If: Assume that $\xi \geq 0$. Then $\text{PenroseBanzhaf}^*(\mathcal{G}, 1) = \xi + 1$. If player $n+2$ is deleted, $\text{PenroseBanzhaf}^*(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) = \xi$ and

$$\text{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) - \text{PenroseBanzhaf}(\mathcal{G}, 1) = \frac{\xi}{2^n} - \frac{\xi+1}{2^{n+1}} = \frac{\xi-1}{2^{n+1}} \geq 0.$$

Note that this difference is even greater than 0, since ξ is even. If a player j, $2 \leq j \leq n+1$, is deleted, $\text{PenroseBanzhaf}^*(\mathcal{G}_{\smallsetminus\{j\}}, 1) = 1 + \xi/2$ and

$$\text{PenroseBanzhaf}(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) - \text{PenroseBanzhaf}(\mathcal{G}, 1) = \frac{1+\frac{\xi}{2}}{2^n} - \frac{\xi+1}{2^{n+1}} = \frac{1}{2^{n+1}} > 0.$$

Consequently, a decrease of player 1's Penrose–Banzhaf index is not possible by deleting any other player than 1. ◀

5 Maintaining an Index

In addition to constructive or destructive goals, we now consider situations in which an exact number of players is to be added and the goal is to either maintain a distinguished player's power index in this new game, or at least to ensure that this player's power does not increase or decrease, compared with this player's power in the old game.

For instance, control by adding players with the goal to maintain a given player's power index PI is defined as follows. The other goals of nonincreasing or nondecreasing a given player's power by adding or deleting players can be defined analogously.

CONTROL BY ADDING PLAYERS TO MAINTAIN PI	
Given:	A weighted voting game $\mathcal{G}$ with players $N = \{1, \dots, n\}$, a set M of unregistered players with weights $w_{n+1}, \dots, w_{n+m}$, a distinguished player $p \in N$, and a positive integer k.
Question:	Can exactly k players $M' \subseteq M$ be added to $\mathcal{G}$ such that for the new game $\mathcal{G}_{\cup M'}$ it holds that $\text{PI}(\mathcal{G}_{\cup M'}, p) = \text{PI}(\mathcal{G}, p)$?

5.1 Control by Adding Players

Analogously to Theorem 8, since PP is closed under complement and by an alternative reduction from the complement of COMPARE-#SUBSETSUM-ЯЯ, control by adding a given number of players in order to maintain a distinguished player's probabilistic Penrose–Banzhaf or Shapley–Shubik index in a weighted voting game is PP-hard. Similarly, whenever the number of players to be added is given in unary, these problems are in NP^{PP}.

▶ **Theorem 12.** *Control by adding a fixed number of players to maintain a distinguished player's probabilistic Penrose–Banzhaf or Shapley–Shubik index in a weighted voting game is* coNP*-hard and in* PP*.*

Proof. The upper bound holds by the same argument as in Theorem 9. We can show coNP-hardness by reducing from $\overline{\text{PARTITION}}$. By Lemma 5, the arguments also hold for any other fixed number of players to be added. ◀

5.2 Control by Deleting Players

Note again that deleting players in order to increase a power index is not the inverse of adding players in order to nonincrease the same index.

▶ **Theorem 13.** *Control by deleting a player in order to maintain a distinguished player's probabilistic Penrose–Banzhaf index in a weighted voting game is* coNP*-hard (even if only one player can be deleted).*

Proof. Again, we show coNP-hardness by means of a reduction from $\overline{\text{PARTITION}}$. Letting $(a_1, \dots, a_n)$ be a PARTITION instance with $\alpha = \sum_{i=1}^{n} a_i$, we construct the game $\mathcal{G}$ represented by $(1, a_1, \dots, a_n, \alpha/2, \alpha/2; \alpha/2 + 1)$ and consider player 1 as our distigiuished player. Let $k = 1$ and let $\xi = \#\text{PARTITION}((a_1, \dots, a_n))$ denote the number of solutions to the PARTITION instance. Then, for the raw Penrose–Banzhaf, it holds that $\xi \geq 1$ if and only if deleting any player but 1 does not maintain the index of player 1.

If: Assume that $\xi = 0$. Then PenroseBanzhaf$^*(\mathcal{G}, 1) = 2$. If player $n + 2$ with weight $\alpha/2$ is deleted, the raw index of player 1 is PenroseBanzhaf$^*(\mathcal{G}_{\smallsetminus\{n+2\}}, 1) = 1$, which results in the same probabilistic Penrose–Banzhaf index. The factor of 2 is due to the fact that the raw index is twice as significant in the new game with one player less than in the old game.

Only if: Assume that $\xi \geq 1$. Then PenroseBanzhaf$^*(\mathcal{G}, 1) = \xi + 2$. If player $n + 2$ or $n + 3$ is deleted, player 1's new raw index is $\xi + 1$. This leads to a higher index since $\xi + 2 < 2(\xi + 1)$. Deleting player j, $2 \leq j \leq n + 1$, leads to a raw index of $\xi/2 + 2$, which means that in comparison to the old game, player 1's index is increased: $\xi + 2 < 2(\xi/2 + 2) = \xi + 4$.

Hence, the problem of whether it is possible to maintain a player's probabilistic Penrose–Banzhaf index is coNP-hard. ◀

In particular, if $\xi \geq 1$ in the above proof, then deleting any player cannot lead to a nonincrease. Therefore, it also holds that $\xi \geq 1$ if and only if deleting any player but 1 does not nonincrease the probabilistic Penrose–Banzhaf index of player 1. Therefore, we get coNP-hardness for the problem where the goal is to nonincrease the probabilistic Penrose–Banzhaf by essentially the same proof. Observe that from these constructions we cannot draw further conclusion about the complexity of structural control by deleting players for neither the Shapley–Shubik nor the probabilistic Penrose–Banzhaf index.

6 Conclusions and Future Work

For weighted voting games, we have studied two types of control, combined with the following variants of goals: Strictly increasing or strictly decreasing a player's power index by adding or deleting at most a given number of players as well as maintaining, nondecreasing, and nonincreasing a player's power index by adding or deleting an exact number of players. As a measure of a player's power we have analyzed the well-known Shapley–Shubik power index and the probabilistic Penrose–Banzhaf power index. If the number of players to be added is given, the problems of adding players in order to obtain a change in a player's index (or at least allow a change in one direction) is PP-hard. And if the number of players to be added is fixed, a corresponding PP upper bound is valid, so we have PP-completeness. In the case of deleting players, we have established NP- and coNP-hardness lower bounds, even for the case of deleting exactly one player. The complexity results are summed up in Table 1.

The complexity of some control problems is left open; for instance, interesting gaps remain, e.g., between NP-hardness and PP membership as well as PP-hardness and $\mathrm{NP}^{\mathrm{PP}}$ membership, and we do not know the complexity of control by deleting players in order to nondecrease a player's index. Also, considering other measures of voter power may provide further insights into the problem of structurally controlling a game. Next to classic worst-case complexity results, it would be interesting to study approximations and average cases to understand the occurrence of computationally hard instances. Especially, it is interesting to find out how frequent the occurrence of a player gaining power by adding other players (or, likewise decreasing and deleting) is. This case would not to be expected intuitively but, as we have seen in Example 6, it is possible.

So far we have only obtained results for goals in *relation to the original game*. Alternatively, one might think of a situation where the goal is to increase a player's significance in *comparison to the other players*, which can also be achieved if players are added or deleted; the distinguished player's power index remains the same, but all remaining players' indices are distributed so that they are below this value. Besides this, we can also model a scenario where a player is required to exceed a certain *constant power index*, and we ask whether it is possible to control a game by adding or deleting players in order to reach this index. So far, we can tell that if the number of players to be added or deleted is $k = 0$, our value is $1/2$, and the considered power index is the Penrose–Banzhaf index, the problem is PP-complete. This might change if $k > 0$ is required. We might also study the variant of obtaining an exact value. Further, there seems to be a close connection to the notion of *synergies* in cooperative games (see, e.g., [39]), and it will be interesting to have a closer look at related results here.

In addition to weighted voting games, other classes of cooperative games with transferable utility might of course be affected by control scenarios as well. In each case, adding and deleting players has to be well-defined. As an example, consider general (weighted) majority games. Let $\mathcal{G} = (w_1, w_2, \ldots, w_n;\ \alpha(n))$ be a majority game, that is, $v(C) = 1$ if $\sum_{i \in C} w_i \geq \lfloor \alpha(n) \rfloor + 1$, and $v(C) = 0$ otherwise, for each $C \subseteq N$. Now, if a player is deleted, the number of players n is decremented, which changes the threshold $\alpha(n)$. The new coalitional function is computed as above. Adding a player requires a set of unregistered players given by their weights, and n is increased. For (weighted) threshold games, the new coalitional function is determined similarly, with the difference that the threshold does not change. One could alternatively think of weights as a percentage, and change the weights of the remaining players proportionally. Thus the new game $\mathcal{G}_{\cup M}$ is defined differently, by normalizing the sum of weights to the original value. Similarly to majority games, players now do not make an absolute but a relative contribution to the game.

Adding and deleting players can be viewed as a change over time and analyzing to what extent this influences power indices is an interesting task for future work (previously, only changing the quota over time has been studied [18]). Other games that will be interesting to study in this context include games in which the Shapley–Shubik index is easy to compute, such as weighted graph games [16]. In such games, two indices in two games can be compared in polynomial time and, therefore, if the coalition that is added to or removed from a game is known, the possibility of control is easy to detect, rendering the problems trivial. If, on the other hand, there are several possible coalitions to be added, this problem might become interesting again. Eventually, if players correspond to an edge in a game, deleting an edge may be interesting in the context of Braess's paradox for noncooperative congestion games (see, e.g., [34, pp. 464–465]) where, informally, an extra fast lane might lead to congestion, whereas without this lane traffic may split up to equally slower paths. Can we find a connection to control by deleting a player in a cooperative game with transferable utility?

Every Binary Pattern of Length Greater Than 14 Is Abelian-2-Avoidable

Matthieu Rosenfeld

Abstract

We show that every binary pattern of length greater than 14 is abelian-2-avoidable. The best known upper bound on the length of abelian-2-unavoidable binary pattern was 118, and the best known lower bound is 7.

We designed an algorithm to decide, under some reasonable assumptions, if a morphic word avoids a pattern in the abelian sense. This algorithm is then used to show that some binary patterns are abelian-2-avoidable. We finally use this list of abelian-2-avoidable pattern to show our result. We also discuss the avoidability of binary patterns on 3 and 4 letters.

1 Introduction

The avoidability of patterns in words has been widely studied since the work of Thue on avoidability of repetitions [22, 23]. Thue wanted to know whether, for any word u and long enough word w, there is always a non-erasing morphism h such that $h(u)$ is a factor of w. He answered negatively to the question by constructing an infinite word over three letters that does not contain any image of AA, and an infinite word over two letters that does not contain any image of AAA.

The formal notion of pattern was introduced in [2]. For two words P and w, we say that w avoids the pattern P if there is no non-erasing morphism h such that $h(P)$ is a factor of w, or equivalently if there is no factor $w_1w_2\dots w_{|P|}$ in w such that $\forall i,j,\ P_i = P_j \implies w_i = w_j$. The avoidability of patterns was studied by Zimin [24] and many other authors worked on the classification of avoidable patterns [4, 14, 15, 20, 21]. In particular Roth proved in [20] that binary patterns of length greater than 6 are avoidable over the binary alphabet and in [1] authors showed the existence of a pattern avoidable over 4 letters, but not avoidable over 3 letters. More recently it has been showed that patterns with m different letters of length at least $3(2^{m-1})$ are 2-avoidable [3, 16].

Erdős proposed a commutative version of the results of Thue [8, 9]. An *abelian square* is any non-empty word uv where u and v are permutations of each other. Erdős asked whether there is an infinite abelian-square-free word over an alphabet of size 4 [8, 9]. After some intermediary results (alphabet of size 25 by Evdokimov [10] and size 5 by Pleasant [17]), Keränen answered positively to Erdős's question by giving a 85-uniform morphism (found with the assistance of a computer) whose fixed point is abelian-square-free [11]. Moreover, Dekking showed that it is possible to avoid abelian cubes on a ternary alphabet and abelian-4-powers over a binary alphabet [7].

Following the question of Erdős we say that two words u and v are *abelian equivalent*, denoted $u \approx_a v$, if they are permutations of each other, for example: *listen* $\approx_a$ *silent*. Let $P = P_1P_2 \ldots P_n$ be a pattern, where the P_i are letters. Then we say that a word $w \in \Sigma^*$ *realizes* P *in the abelian sense* if there are $w_1, \ldots, w_n \in \Sigma^+$ such that $w = w_1w_2 \ldots w_n$ and $\forall i, j,\ P_i = P_j \implies w_i \approx_a w_j$. If a word w has no factor that realizes a pattern P in the abelian sense, then w *avoids* P in the abelian sense, w is *abelian-P-free*. In Section 2 we show that one can decide if the fixed point of a morphism avoids a given pattern. This generalizes a result from [5] that tells that under some conditions one can decide if the fixed point of a morphism avoids abelian-k-powers.

We say that a pattern is *abelian-k-avoidable* if there is a word from an alphabet of size k that avoids this pattern. For any pattern $P \in \Delta^*$, the *abelian-avoidability index* of P (denoted by $\lambda_a(P)$) is the smallest integer k such that P is abelian-k-avoidable or ∞ if there is no such k. It is an abelian analog of the usual avoidability index of a pattern P. For example $\lambda_a(ABA) = \lambda_a(ABACABA) = \infty$, $\lambda_a(AA) = 4$ [11], $\lambda_a(AAA) = 3$ and $\lambda_a(AAAA) = 2$ [7]. In [6] authors showed that binary pattern of length greater than 118 are abelian-2-avoidable and asked for a more precise characterization. We can use the algorithm of Section 2 to show that every binary pattern of length greater than 14 are abelian-2-avoidable.

In Section 2 we explain how to decide, under some conditions, whether a morphic word avoids a given pattern in the abelian sense. In Section 3 we show that binary patterns of length greater than 14 are abelian-2-avoidable. We also discuss the avoidability of binary patterns over any finite alphabet and we raise some open questions.

2 Proving the decidability

In this part we explain how to decide, under some conditions, if the fixed point of a morphism avoids some given pattern in the abelian sense.

We use terminology and notations of Lothaire [13]. For any morphism $h : \Sigma^* \mapsto \Sigma^*$, if there is $a \in \Sigma$ and $w \in \Sigma^*$ such that $h(a) = aw$, then the sequence $(h^n(a))_{n\geq 0}$ converges for the usual topology on $\Sigma^* \cup \Sigma^\omega$ and we denote by $h^\omega(a) = \lim_{n\to 0} h^n(a)$. Note that $h^\omega(a)$ is a fixed point of h. To any pattern P we associate the function $\varphi_P : [1, |P|] \mapsto [1, |P|]$ such that $\varphi_P(i) = \min\{j : P_j = P_i\}$ is the position of the first occurrence of the letter P_i in P.

For any word w, we denote by $[w]_i$ the letter at position i in w (or w_i if it is clear in the context). For any word w, we denote by $|w|$ the length of w and for any letter $a \in \Sigma$, $|w|_a$ is the number of occurrences of a in w. The *Parikh vector* of a word $w \in \Sigma^*$, denoted by $\Psi(w)$, is the vector indexed by Σ such that for every $a \in \Sigma$, $\Psi(w)[a] = |w|_a$. Note that by definition for any two words u and v, $u \approx_a v$ iff $\Psi(u) = \Psi(v)$.

We associate to any morphism $h : \Sigma^* \mapsto \Sigma^*$ a matrix M_h on $\Sigma \times \Sigma$ such that $(M_h)_{a,b} = |h(b)|_a$. Note that from the definition we can deduce for any morphism h and any word u the formula:

$$\Psi(h(u)) = M_h\Psi(u).$$

The induced norm of a matrix $M \in \mathbb{R}_{m\times m}$ is given by $\|M\|_2 = sup_{x\in\mathbb{R}^m} \frac{\|Mx\|_2}{\|x\|_2}$ where $\|v\|_2$ is the Euclidean norm of v.

We generalize the notion of k-templates introduced in [5] in order to show Theorem 1. Let Δ and Σ be two alphabets, and let P be a pattern over Δ, then a *P-template* over Σ is a $2(|P|+1)$-tuple of the form: $[w_0, v_1, w_1, v_2 \ldots, v_{|P|}, w_{|P|}]$ where for all i, $w_i \in \Sigma^*$, $v_i \in \mathbb{Z}^{|\Sigma|}$. A word $w \in \Sigma^*$ *realizes* (or *is a realization* of) a P-template $t = [w_0, v_1, \ldots, v_{|P|}, w_{|P|}]$ if there are $u_1, \dots, u_{|P|} \in \Sigma^+$ such that $w = w_0u_1w_1u_2w_2 \dots u_{|P|}w_{|P|}$ and $\forall i,j\ P_i = P_j \implies \Psi(u_i) - \Psi(u_j) = v_i - v_j$.

Each template can be associated to its set of realizations, but many templates are associated to the same set. We say that a P-template is *normalized* if for all $i \in [1, |P|]$, $\varphi_P(i) = i \implies v_i = \overrightarrow{0}$. For any P-template, we can compute a normalized template that is realized by the same set of words. Since one doesn't change the set of realizations by adding the same vector to all vectors corresponding to the same letter, one get the *normalization* of a template by taking for all i $v'_i = v_i - v_{\varphi_P(i)}$ and $w'_i = w_i$. Note that there is a natural bijection between the set of k-templates from [5] and the set of normalized A^k-templates. In the following we only use normalized templates.

We say that a morphism $h : \Sigma^* \to \Sigma^*$ is *convenient* if its associated matrix M_h is invertible, $\|M_h^{-1}\|_2 < 1$ and $\forall a \in \Sigma$, $|h(a)| > 1$. We can now state the main theorem:

▶ **Theorem 1.** *For any alphabets Δ and Σ, pattern $P \in \Delta^*$, P-template t, convenient morphism $h : \Sigma^* \mapsto \Sigma^*$ and any letter $a \in \Sigma$ such that $h(a) = as$ for some s, it is possible to decide if $h^\omega(a)$ avoids t.*

By definition, w avoids P if and only if w avoids the P-template $[\varepsilon, \overrightarrow{0}, \varepsilon, \dots, \overrightarrow{0}, \varepsilon, \overrightarrow{0}, \varepsilon]$. From that we can deduce the following corollary:

▶ **Corollary 2.** *For any alphabets Δ and Σ, pattern $P \in \Delta^*$, any convenient morphism $h : \Sigma^* \mapsto \Sigma^*$ and any letter $a \in \Sigma$ such that $h(a) = as$ for some s, it is possible to decide if $h^\omega(a)$ is abelian-P-free.*

The rest of this section is devoted to the proof of Theorem 1. The main idea of the proof is that we can compute S, a set of templates, such that $t \in S$ and $h^{n+1}(a)$ avoids any template of S if and only if $h^n(a)$ avoids any template of S. Thus $h^\omega(a)$ avoids t if and only if a avoids any template of S which is easy to check. The set S corresponds to what we call *the set of special ancestors*. In the following Δ will always be the alphabet of patterns and Σ the alphabet of words and templates.

2.1 Parents and ancestors of a template

Let $t = [w_0, v_1, \dots, v_{|P|}, w_{|P|}]$ and $t' = [w'_0, v'_1, \dots, v'_{|P|}, w'_{|P|}]$ be two normalized P-templates. We say that t' *is a parent of* t *by* h if there are $p_0, s_0, \dots, p_{|P|}, s_{|P|} \in \Sigma^*$ such that:

- $\forall i \in [0, |P|]$, p_i is a prefix of the image of the first letter of w'_i (a prefix of $h([w'_i]_1)$), s_i is a suffix of the image of the last letter of w'_i and $h(w'_i) = p_iw_is_i$,
- $\forall i,j \in [1, |P|]$, $P_i = P_j \implies v_i - v_j = (\Psi(s_{i-1}) + M_hv'_i + \Psi(p_i)) - (\Psi(s_{j-1}) + M_hv'_j + \Psi(p_j))$.

For any normalized template t we denote $\mathrm{Par}_h(t)$ the set of parents of t by h. The *ancestors of* t *by* h is the set $\mathrm{Ancestors}_h(t) = \cup_{i=0}^{\infty} \mathrm{Par}_h^i(t)$. The relation "is an ancestor" is the transitive and reflexive closure of the relation "is a parent".

Lemmas 3, 4 and 5 tell us that the set of ancestors of a template is computable.

▶ **Lemma 3.** *For any convenient morphism $h : \Sigma^* \mapsto \Sigma^*$ and normalized P-template t, the set $\mathrm{Par}_h(t)$ is finite and computable.*

Proof. Since the template t is normalized we know that:

$$M_hv'_i = \begin{cases} 0 & \text{if } \varphi_P(i) = i \\ v_i - \Psi(s_{i-1}) - \Psi(p_i) + \Psi(s_{\varphi_P(i)-1}) + \Psi(p_{\varphi_P(i)}) & \text{if } \varphi_P(i) \neq i. \end{cases}$$

Since M_h is invertible, there is at most one parent for a given valuation of $(w'_i)_{0\leq i\leq|P|}$, $(s_i)_{0\leq i\leq|P|}$ and $(p_i)_{0\leq i\leq|P|}$. Moreover the possibilities for the s_i, p_i and hence for the w'_i are finite (if h is injective there is at most one possibility for each w'_i). So we can try all the valuations for $(w'_i)_{0\leq i\leq|P|}$, $(s_i)_{0\leq i\leq|P|}$ and $(p_i)_{0\leq i\leq|P|}$ and we get all the parents. ◀

▶ **Lemma 4.** *For any convenient morphism $h : \Sigma^* \mapsto \Sigma^*$ and normalized P-template t there are $(r_1, \dots, r_{|P|}) \in \mathbb{R}^+$ such that if $t' = [w'_0, v'_1, w'_1, v'_2 \dots, v_{|P|}, w_{|P|}]$ is an ancestor of t by h then for all i $\|v'_i\|_2 < r_i$.*

We omit the details of the proof of Lemma 4 which is similar to the proof of Lemma 4 in [5]. Let v_i be the i-th vector of t, then $v'_i = M^{-n}v_i + \sum_{j=0}^{n-1} M^{-j}(\Psi(s_j) + \Psi(p_j) - \Psi(s'_j) - \Psi(p'_j))$ for some s_j, s'_j and p_j, p'_j being respectively suffixes and prefixes of images of letters by h. Moreover $\|M_h^{-1}\|_2 < 1$, so $\|v'_i\|_2$ is bounded.

▶ **Lemma 5.** *For any normalized P-template t the set of ancestors of t by h is finite and computable.*

Proof. Let $t' = [w_0, v_1, w_1, v_2 \dots, v_{|P|}, w_{|P|}]$ be an ancestor of t by h. From Lemma 4, each of the v_i is bounded and since $v_i \in \mathbb{Z}^{|\Sigma|}$ there are finitely many choices for each of the v_i. Moreover, since for all $a \in \Sigma$, $|h(a)| > 1$, the length of the w_i is bounded and there are finitely many different values for the w_i. It implies that there are only finitely many possible ancestors.

In order to compute the set of ancestors, one starts with the singleton $S = \{t\}$ and repeats the operation $S = S \cup \mathrm{Par}_h(S)$ (computable thanks to Lemma 3) until S reaches a fixed point, which will eventually happen since the set of ancestors is finite. ◀

▶ **Lemma 6.** *For any word w and any P-templates t and $t' \in \mathrm{Par}_h(t)$, if w is a realization of t' then $h(w)$ contains a realization of t.*

Proof. Let $t = [w_0, v_1, \dots, v_{|P|}, w_{|P|}]$ and $t' = [w'_0, v'_1, \dots, v'_{|P|}, w'_{|P|}] \in \mathrm{Par}_h(t)$. Then by definition there are $p_0, s_0, \dots, p_{|P|}, s_{|P|} \in \Sigma^*$ such that:

- $\forall i \in [1, |P|]$, $h(w'_i) = p_i w_i s_i$,
- $\forall i, j \in [1, |P|]$, $P_i = P_j \implies v_i - v_j = (\Psi(s_{i-1}) + M_h v'_i + \Psi(p_i)) - (\Psi(s_{j-1}) + M_h v'_j + \Psi(p_j))$.

Assume there is a word w realizing t'. Then there are $u'_1, \dots, u'_{|P|} \in \Sigma^+$ such that $w = w'_0 u'_1 w'_1 u'_2 w'_2 \dots u'_{|P|} w'_{|P|}$ and $\forall i, j$ $P_i = P_j \implies \Psi(u'_i) - \Psi(u'_j) = v'_i - v'_j$. Then $h(w) = p_0 w_0 s_0 h(u'_1) p_1 w_1 \dots s_{|P|-1} h(u'_{|P|}) p_{|P|} w_{|P|} s_{|P|}$. For all i let $u_i = s_{i-1} h(u'_i) p_i$, then $W = w_0 u_1 w_1 u_2 w_2 \dots u_{|P|} w_{|P|}$ is a factor of $h(w)$.

Moreover for all $i, j \in [1, |P|]$, if $P_i = P_j$ then:

$$\begin{aligned}
\Psi(u_i) - \Psi(u_j) &= \Psi(s_{i-1} h(u'_i) p_i) - \Psi(s_{j-1} h(u'_j) p_j) \\
&= (\Psi(s_{i-1}) + \Psi(h(u'_i)) + \Psi(p_i)) - (\Psi(s_{j-1}) + \Psi(h(u'_j)) + \Psi(p_j)) \\
&= (\Psi(s_{i-1}) + M_h v'_i + \Psi(p_i)) - (\Psi(s_{j-1}) + M_h v'_j + \Psi(p_j)) \\
&= v_i - v_j
\end{aligned}$$

So W realizes t and is a factor of $h(w)$. ◀

It tells us that if one of the ancestors of t is not avoided by $h^n(a)$ for some $n \in \mathbb{N}$, then there is $m > n$ such that t is not avoided by $h^m(a)$.

2.2 Specializations of a template

Let $P \in \Delta^*$ and $L \subseteq \Delta$ then we denote by $P_{|L}$ the pattern which is obtained by deleting from P every letter from $\Delta - L$. For example $ABCBBCCA_{|\{A,C\}} = ACCCA$.

Let $\mathrm{Pos}_{(P,L)} : [1, |P_{|L}|] \mapsto [1, |P|]$ be such that $\mathrm{Pos}_{(P,L)}(i) = \min\{j : |(P_1 \dots P_j)_{|L}| = i\}$, where P_i is the i-th letter of P. $\mathrm{Pos}_{(P,L)}(i)$ is the position of the letter in P that is sent to position i in $P_{|L}$.

Let $t = [w_0, v_1, w_1, \dots, v_{|P|}, w_{|P|}]$ be a P-template and $t_{|L} = [w'_0, v'_1, w'_1, \dots, v'_{|P_{|L}|}, w'_{|P_{|L}|}]$ be a $P_{|L}$-template. We say that $t_{|L}$ is a *L-specialization* of t if there are $(u_i)_{i:P_i \notin L} \in \Sigma^+$ such that:

- $\forall i \; v'_i = v_{\mathrm{Pos}_{(P,L)}(i)}$,
- $\forall i, j, \; P_i = P_j \notin L \implies \Psi(u_i) - \Psi(u_j) = v_i - v_j$,
- $\forall i \; w'_i = w_{i_b} u_{i_b+1} w_{i_b+1} \dots w_{i_e-1} u_{i_e} w_{i_e}$, where $i_b = \mathrm{Pos}_{(P,L)}(i)$ and $i_e = \mathrm{Pos}_{(P,L)}(i{+}1){-}1$.

▶ **Lemma 7.** *Let $P \in \Delta^*$ be a pattern and $L \subseteq \Delta$. For any P-template t and any L-specialization $t_{|L}$ of t if there is a word w realizing $t_{|L}$ then w realizes t.*

We omit the proof of Lemma 7 which is technical but straightforward.

With this definition a P-template t has infinitely many L-specializations, but in most cases the parents of a given L-specialization are included in the L-specializations of the parents. Thus we need to introduce the set of *small L-specializations* in order to keep a finit subset of them. A L-specialization of a P-template t is a *small L-specialization* if, with the notations from the definition of L-specialization, for any $A \in \Delta - L$ there is $i \in [1, |P|]$ such that $P_i = A$ and $|u_i| \leq 2 \cdot \max_{a \in \Sigma} |h(a)|$.

▶ **Lemma 8.** *For any pattern $P \in \Delta^*$, P-template t and $L \subseteq \Delta$ the set of small L-specializations of t is finite and computable.*

Proof. Let $P \in \Delta^*$, $t = [w_0, v_1, w_1, \dots, v_{|P|}, w_{|P|}]$ be a P-template and $L \subseteq \Delta$. Let $t_{|L} = [w'_0, v'_1, w'_1, \dots, v_{|P_{|L}|}, w_{|P_{|L}|}]$ be a small L-specialization of t. Since $t_{|L}$ is a small L-specialization of t, for any letter $A \notin L$ there is an index i_A such that $P_{i_A} = A$ and $|u_{i_A}| \leq 2 \cdot max_{a \in \Sigma} |h(a)|$, and there are only finitely many possible values for the u_{i_A}. Then from the definition for all j, $(P_j = A \text{ and } j \neq i_A) \implies \Psi(u_j) = \Psi(u_{i_A}) + v_{P_j} - v_{P_{i_A}}$. So there are only finitely many possible values for each u_j.

Once we have chosen the $(u_i)_{i:P_i \notin L}$ the w'_i and v'_i are fixed. Hence by trying all the possible values for $(u_i)_{i:P_i \notin L}$ we can compute the set of all small L-specializations of t. ◀

We denote by $\mathrm{SmallSpec}_L(t)$ the set of small L-specializations of a P-template t.

2.3 Special ancestors of a template

The set of *special ancestors* of a P-template t by h is the smallest set of templates containing t and any ancestor or small-L-specialization of any of its element. Let us first show that we can compute this set:

▶ **Theorem 9.** *For any alphabets Δ and Σ, pattern $P \in \Delta^*$, normalized P-template t and convenient morphism $h : \Sigma^* \mapsto \Sigma^*$, one can compute the set of special ancestors of t by h.*

Proof. The following algorithm computes this set for any P, t and h.

```
Input  : $P$, $t$, $h$.
Output: The set $S$ of special ancestors of $t$.
$S = \text{Ancestors}_h(t)$;
for $i = |\Delta| - 1 \dots 0$ do
    for $L \subseteq \Delta$, $|L| = i$ do
        $S = S \cup \text{SmallSpec}_L(S)$;
    end
    $S = S \cup \text{Ancestors}_h(S)$;
end
```

Algorithm 1: How to compute special ancestors.

This algorithm halts because if S is finite at some point then by Lemmas 5 and 8 one can execute $S = S \cup \text{Ancestors}(S)$ and $S = S \cup \text{SmallSpec}_L(S)$ and keep S finite.

For any $D \subseteq L \subseteq \Delta$ and any pattern $P \in \Delta^*$, $(P_{|D})_{|L} = P_{|D}$. So for any L-specialization t_{DL} of a D-specialization t_D of a P-template t, $t_{DL} = t_D$. It implies that at the end for any $L \subseteq \Delta$, every element of S has all of its small L-specializations in S. Since the last operation of the algorithm adds the ancestors, every ancestor of any element of S is in S. ◀

In some reasonable implementation of the algorithm, it is important to use for S a data-structure that allows to check if a template is already in S in logarithmic time. Moreover, we are careful with specialization so that we do not obtain twice the same template by two different paths of specialization (dropping the letter A and then the letter B is the same than dropping B and then A).

2.4 Using special ancestors to decide

Under the conditions of Theorem 1, one can compute the set of special ancestors of a template, thanks to Theorem 9. Now we show that this set allows us to decide if the morphism's fixed point avoids the template.

▶ **Theorem 10.** *For any pattern $P \in \Delta^+$, any normalized P-template t, any convenient morphism h and any word $w \in \Sigma^+$, if there is a factor f of $h(w)$ that realizes t, then there is a factor f' of w that realizes a special ancestor of t.*

In fact we show that f' realizes the parent of an L-specialization of t for some well chosen set L. The only thing we do is to unfold the definitions with this set L.

Proof. Let $t = [w_0, v_1, w_1, \dots, v_{|P|}, w_{|P|}]$ be a normalized P-template and assume there is a factor f of $h(w)$ that realizes t. Then by definition there are $u_1, \dots, u_{|P|} \in \Sigma^+$ such that $f = w_0 u_1 w_1 u_2 w_2 \dots u_{|P|} w_{|P|}$ and

$$\forall i, j \; P_i = P_j \implies \Psi(u_i) - \Psi(u_j) = v_i - v_j. \tag{1}$$

Let us introduce the set L:

$$L = \left\{ A \in \Delta : \forall i, P_i = A \implies |u_i| > 2 \cdot \max_{a \in \Sigma} |h(a)| \right\}. \tag{2}$$

Take the $P_{|L}$-template $t_{|L} = [w'_0, v'_1, w'_1, \dots, v_{|P_{|L}|}, w_{|P_{|L}|}]$ such that:

- $\forall i,\ v'_i = v_{\text{Pos}_{(P,L)}(i)}$,
- $\forall i,\ w'_i = w_{i_b} u_{i_b+1} w_{i_b+1} \dots w_{i_e-1} u_{i_e} w_{i_e}$, where $i_b = \text{Pos}_{(P,L)}(i)$ and $i_e = \text{Pos}_{(P,L)}(i{+}1){-}1$.

From the equality (1) and the definition of L, $t_{|L}$ is a small L-specialization of t. Let $(u'_i)_{1\leq i\leq |P_{|L}|}$ be such that for all i, $u'_i = u_{\mathrm{Pos}_{(P,L)}(i)}$. Then $f = w'_0u'_1w'_1\dots u'_{|P_{|L}|}w'_{|P_{|L}|}$. Then from the equality (1) we can deduce:

$$\forall i,j\ [P_{|L}]_i = [P_{|L}]_j \implies \Psi(u'_i) - \Psi(u'_j) = v'_i - v'_j. \tag{3}$$

So f is a realization of the $P_{|L}$-template $t_{|L}$.

Since f is a factor of $h(w)$ there is a factor f' of w such that $h(f') = p_0fs_{|P_{|L}|}$, where $p_0 \in \text{prefixes}(h(f'_1))$ and $s_{|P_{|L}|} \in \text{suffixes}(h(f'_{|f'|}))$. By construction, for all i, $|u'_i| > 2\cdot \max_{a\in\Sigma}|h(a)|$ so we know that each of the u'_i contains at least the full image of one letter. So there are $u''_1,\dots,u''_{|P_{|L}|}\in\Sigma^+$, $w''_0,\dots,w''_{|P_{|L}|}\in\Sigma^*$ and $s_0,p_1,s_1,\dots,s_{|P_{|L}|-1},p_{|P_{|L}|}\in\Sigma^*$ such that $f' = w''_0u''_1w''_1u''_2\dots u''_{|P_{|L}|}w''_{|P_{|L}|}$ and for all $i\in[0,|P|]$:

- p_i is a prefix of the image of the first letter of w''_i,
- s_i is a suffix of the image of the last letter of w''_i,
- $h(w''_i) = p_iw'_is_i$,
- $u'_i = s_{i-1}h(u''_i)p_i$.

For all $i\in[1,|P_{|L}|]$, let $v''_i = \Psi(u''_i) - \Psi(u''_{\varphi_{P_{|L}}(i)})$ and let t'' be the $P_{|L}$-template $t'' = [w''_0, v''_1, w''_1, v''_2,\dots,v''_{|P_{|L}|}, w''_{|P_{|L}|}]$. Then t'' is the normalization of the $P_{|L}$-template $[w''_0,\Psi(u''_1),w''_1,\Psi(u''_2),\dots,\Psi(u''_{|P_{|L}|}),w''_{|P_{|L}|}]$ which is realized by f', thus f' is a realization of t''.

From $u'_i = s_{i-1}h(u''_i)p_i$ we get:

$$\Psi(u'_i) = \Psi(s_{i-1}) + M_h\Psi(u''_i) + \Psi(p_i). \tag{4}$$

Let $i,j\in[1,|P_{|L}|]$ such that $[P_{|L}]_i = [P_{|L}]_j$ then $\varphi(i)=\varphi(j)$ and hence

$$\Psi(u''_{\varphi(i)}) = \Psi(u''_{\varphi(j)}). \tag{5}$$

Now if we put all of that together we get:

$$\begin{aligned}v'_i - v'_j =&\Psi(u'_i) - \Psi(u'_j)\text{ (from (3))}\\ =&(\Psi(s_{i-1}) + M_h\Psi(u''_i) + \Psi(p_i)) - (\Psi(s_{j-1}) + M_h\Psi(u''_j) + \Psi(p_j))\text{ (from (4))}\\ =&(\Psi(s_{i-1}) + M_hv''_i + \Psi(p_i)) - (\Psi(s_{j-1}) + M_hv''_i + \Psi(p_j))\text{ (from (5))}\end{aligned}$$

Thus t'' is a parent of $t_{|L}$. So t'' is a parent of a specialization of t and is realized by a factor f' of w. ◀

Theorem 10 together with the fact that, by definition, a special ancestor of a special ancestor of t is itself a special ancestor of t gives:

▶ **Theorem 11.** *For any pattern $P\in\Delta^*$, any normalized P-template t, any convenient morphism h and any letter $a\in\Sigma$, if there is a positive integer n and a factor of $h^n(a)$ that realizes t, then a realizes a special ancestor of t.*

We also need the converse, that is:

▶ **Theorem 12.** *For any pattern $P\in\Delta^*$, any normalized P-template t, any convenient morphism h and any letter $a\in\Sigma$, if a realizes a special ancestor t' of t, then there is a positive integer n and a factor of $h^n(a)$ that realizes t'.*

Proof. We first take the sequence of parent and L-specialization that reaches t' from t. Then we use Lemmas 6 and 7 to reverse operations on a and we reach the factor of $h^n(a)$ that realizes t. ◀

From Theorems 11 and 12 we deduce the following one:

▶ **Theorem 13.** *For any pattern $P \in \Delta^*$, any normalized P-template t, any convenient morphism h and any letter $a \in \Sigma$, $h^\omega(a)$ avoids t if and only if a does not realize any special ancestor of t.*

Since we can compute the set of special ancestors and compare it to the letter a, we can decide if $h^\omega(a)$ avoids t. We implemented this algorithm in c++ and thus we can check if a pattern is avoided by the fixed point of a morphism.

3 Abelian avoidability of patterns

Patterns are words so we can say that a pattern avoids another pattern in the abelian sense. Moreover, for two patterns P, P' and word w, if P' is not abelian-P-free and the word w is abelian-P-free, then w is abelian-P'-free. It means that if P' is not abelian-P-free, then $\lambda_a(P') \leq \lambda_a(P)$. For instance, since $\lambda_a(AA) = 4$ for any $P \in \{A, B\}^*$, if $P \notin \{A, B, AB, BA, ABA, BAB\}$, then $\lambda_a(P) \leq 4$ because all the other binary patterns are not abelian-AA-free. So every binary pattern is either abelian-4-avoidable or abelian unavoidable. It is interesting to know which of them have avoidability index 2 or 3.

▶ **Theorem 14.** *Binary patterns of length greater than 8 are abelian-3-avoidable. More precisely every pattern that does not appear up to symmetry on the following list is abelian-3-avoidable:*
A, AA, AB, AAB, ABA, $AABA$, $AABB$, $ABAB$, $ABBA$, $AABAA$, $AABAB$, $AABBA$, $ABAAB$, $ABABA$, $AABAAB$, $AABABA$, $AABABB$, $AABBAA$, $ABAABA$, $AABAABA$, $AABABAA$, $ABBABBA$, $AABAABAA$, $ABAABAAB$.

Proof. It is well known that AAA is abelian-3-avoidable [7] and it is already enough to show the upper bound. Moreover, we can use the algorithm from Theorem 1 to show that any fixed point of $a \mapsto aabaac$, $b \mapsto cbbbab$, $c \mapsto cbccac$ is abelian-$AABBAB$-free. So we only need to find exhaustively all the words that avoid AAA, $AABBAB$ and $ABAABB$. This gives the list of Theorem 14. ◀

Conversely, if there is a word that avoids $AABAA$, there is also a recurrent word w that avoids $AABAA$ and then w avoids AA, thus $\lambda_a(AABAA) = 4$. So the patterns $A, AA, AB, AAB, ABA, AABA, AABAA$ are not abelian-3-avoidable. But, for the rest of the list, we do not know which of them are abelian-3-avoidable

▶ **Problem 1.** *Which of the following patterns are abelian-3-avoidable?*
$ABAB$, $ABBA$, $AABAB$, $AABBA$, $ABAAB$, $ABABA$,$AABAAB$, $AABABA$, $AABABB$, $AABBAA$, $ABAABA$, $AABAABA$, $AABABAA$, $ABBABBA$, $AABAABAA$, $ABAABAAB$.

There is a direct link with the following question:

▶ **Problem 2** (Mäkelä (see [12])). *Can you avoid abelian squares of the form uv where $|u| \geq 2$ over three letters ? - Computer experiments show that you can avoid these patterns at least in words of length 450.*

If the answer to the question from Mäkelä is positive then all the patterns from Problem 1 are abelian-3-avoidable. In [18] we showed that abelian squares of the form uv where $|u| \geq 6$ are avoidable over three letters.

Abelian-2-avoidability. For the binary case it was showed in [6] that:

▶ **Theorem 15** (J. D. Currie, T. I. Visentin). *Binary patterns of length greater than 118 are abelian-2-avoidable.*

They also asked:

▶ **Problem 3** (J. D. Currie, T. I. Visentin). *Characterize which binary patterns are abelian-2-avoidable.*

Using the algorithm from Theorem 1 we can improve this result and lower the 118 to 14. First we use the algorithm to check that:

▶ **Lemma 16.** *The fixed point of the morphisms on the left avoid in the abelian sense the corresponding patterns in the right:*

morphisms	*avoided patterns*
$a \mapsto aabaa$ $b \mapsto bbabb$	$AABBBAAAB$, $ABAAABBBA$, $AAABABABBB$, $AAABABBABB$,$AAABABBBAB$, $AABBBABAAB$, $AABBBABABA$, $ABAABABBBA$, $ABAABBBABA$, $ABABAABBBA$, $ABBBABAAAB$, $AABAABBBAB$, $AABBBAABAB$, $AABBBAABAAB$, $AAABABBAAAB$, $AABBBABBBAA$, $ABABABBBABA$, $ABABBABBABA$, $AAABAAABBAB$, $AAABBABAAAB$, $AAABAABAABAB$, $AAABABAAABAB$, $AABAAABABAAB$, $AAABAAABABBA$, $AAABAABABAAB$, $AAABABAABAAB$, $ABBABAAABAAB$, $ABABBBABBBABA$.
$a \mapsto aaaab$ $b \mapsto abbab$	$ABAABBBAAB$, $AAABBABABB$, $AAABBABBAB$, $AABAABBABB$, $AABABABBBA$, $AABABBABBA$, $AABABBBAAB$, $AABABBBABA$, $AABBAABBBA$, $AABBABABBA$, $AABBABBAAB$, $AABBABBABA$, $AABBBAABBA$, $ABAABBABBA$, $AABBABABBBA$, $AABABBBABBBA$,
$a \mapsto abb$ $b \mapsto aaab$	$AAAA$, $AAABAABBB$, $AAABBBABB$, $AABBABBBA$, $AABBBABBA$, $AAABBAAABB$, $AABABAAABB$, $ABBBAABBBA$, $AAABAABBAB$, $AAABAABAABB$, $AAABBAABAAB$, $AABAABAABBA$, $AABAABBAAAB$, $AABABABAAAB$, $AAABBAAABAB$, $AABAAABABAB$, $AABAAABBAAB$, $AAABAABAAABAB$,
$a \mapsto aaab$ $b \mapsto bbba$	$AAABABBBAA$, $AAABBAABBB$, $AAABBABBAA$, $ABABAAABBB$, $ABABBBAABBA$, $AABABBAAABA$, $AABBABAAABA$,
$a \mapsto abaa$ $b \mapsto babb$	$AABBABBABBA$, $AABABBABBBA$, $AABBBABBBABA$, $ABABBABBABBA$, $ABABBABBBABA$, $ABABBBABABBA$, $ABBABABBABBA$,
$a \mapsto aaaba$ $b \mapsto babbb$	$ABAABBBAAA$, $AABABBBAAA$,
$a \mapsto aababbaaaba$ $b \mapsto babbbaababb$	$AABAAABAAABAB$, $ABBBABBBABBBA$, $AAABAAABAAABAAA$,

It implies that, if a pattern contains any of the pattern from Lemma 16, then it can be avoided by a binary word. One can easily check that any binary pattern of length greater than 14 contains at least one of the patterns from the Lemma 16. It implies:

▶ **Theorem 17.** *Binary patterns of length greater than 14 are abelian-2-avoidable.*

In fact, up to symmetry, there are only 284 patterns that avoid all patterns of Lemma 16.

▶ **Theorem 18.** *The patterns from the following list are abelian-2-unavoidable: A, AA, AB, AAA, AAB, ABA, $AAAB$, $AABA$, $AABB$, $ABAB$, $ABBA$, $AAABA$, $AAABB$, $AABAA$, $AABAB$, $AABBA$, $ABAAB$, $ABABA$, $ABBBA$, $AAABAA$, $AAABAB$, $AABAAB$, $ABAAAB$, $AAABAAA$.*

Proof. Let assume that $AAABAAA$ is abelian-2-avoidable, then we can find a recurrent word that avoids $AAABAAA$ in the abelian sense and this words necessarily avoids AAA which is not possible. Thus $AAABAAA$ is abelian-2-unavoidable.

For all the other patterns one can do an exhaustive search and check that they are abelian-2-unavoidable. ◀

For the 260 other patterns we don't know which are abelian-2-avoidable and which are not. For most of them there is probably no fixed point of a binary morphism avoiding them, but they could be avoided by the image of a fixed point by a second morphism.

We are left with some interesting questions:

▶ **Problem 4.** *What is the length of the longest abelian-2-unavoidable binary pattern?*

We know that the answer is between 7 and 14.

▶ **Problem 5.** *What is the exact list of the abelian-2-unavoidable binary patterns?*

It is probably related somehow to the question 6 which seems really hard.

▶ **Problem 6** (Mäkelä (see [12])). *Can you avoid abelian-cubes of the form uvw where $|u| \geq 2$, over two letters ? - You can do this at least for words of length 250.*

It was showed in [19] that the answer to Problem 6 is negative. But we can replace the 2 in the question by any integer. In particular a proof that abelian cubes of the form uvw where $|u| \geq 3$ are avoidable over two letters would imply that many of the 284 patterns are also abelian-2-avoidable.

Finally we have some more general questions:

▶ **Problem 7.** *For any finite alphabet Δ is it true that:*
- $\exists n \in \mathbb{N}$ *such that any pattern over Δ of length greater than n is abelian-avoidable?*
- $\exists n \in \mathbb{N}$ *such that any pattern over Δ of length greater than n is abelian-$|\Delta|$-avoidable?*
- $\exists n \in \mathbb{N}$ *such that any pattern over Δ of length greater than n is abelian-2-avoidable?*

Acknowledgements. The author would like to thank Pascal Ochem and Michaël Rao for valuable discussions.

Abstract

A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *weighted symmetric* if there exist a function $g : \mathbb{Z} \to \{0,1\}$ and integers $w_0, w_1, \ldots, w_n$ such that $f(x_1, \ldots, x_n) = g(w_0 + \sum_{i=1}^{n} w_i x_i)$ holds.

In this paper, we present algorithms for the circuit satisfiability problem of bounded depth circuits with AND, OR, NOT gates and a limited number of weighted symmetric gates. Our algorithms run in time super-polynomially faster than 2^n even when the number of gates is super-polynomial and the maximum weight of symmetric gates is nearly exponential. With an additional trick, we give an algorithm for the maximum satisfiability problem that runs in time $\mathrm{poly}(n^t) \cdot 2^{n-n^{1/O(t)}}$ for instances with n variables, $O(n^t)$ clauses and *arbitrary* weights. To the best of our knowledge, this is the first moderately exponential time algorithm even for Max 2SAT instances with arbitrary weights.

Through the analysis of our algorithms, we obtain average-case lower bounds and compression algorithms for such circuits and worst-case lower bounds for majority votes of such circuits, where all the lower bounds are against the generalized Andreev function. Our average-case lower bounds might be of independent interest in the sense that previous ones for similar circuits with arbitrary symmetric gates rely on communication complexity lower bounds while ours are based on the restriction method.

1 Introduction

We are concerned with bounded depth circuits with AND, OR, NOT and (weighted) symmetric gates. Let $\mathbb{Z}$ be the set of integers and $x_1, x_2 \ldots, x_n$ be Boolean variables. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *weighted symmetric* if there exist a function $g : \mathbb{Z} \to \{0,1\}$ and integers $w_0, w_1, \ldots, w_n$ such that $f(x_1, \ldots, x_n) = g(w_0 + \sum_{i=1}^{n} w_i x_i)$ holds. If $w_1 = w_2 = \cdots = w_n = 1$ holds, then f is *symmetric*.

For example, if we set $g(z) = \mathrm{sgn}(z)$, where $\mathrm{sgn}(z) = 1$ if and only if $z \geq 0$, we obtain *majority* functions as symmetric functions and *linear threshold* functions as weighted symmetric functions. If we define $g(z) = 1$ if and only if $z \equiv 0 \bmod m$ for an integer $m \geq 2$, then we obtain *modulo* m functions as symmetric functions.

A (weighted) symmetric gate is a logic gate that computes a (weighted) symmetric function. We denote by $\mathbf{SYM}_w$ the set of weighted symmetric gates such that $\max_i |w_i| \leq w$ holds. When we consider satisfiability and compression algorithms, we assume that $g(z)$ can be evaluated in time polynomial in $\log_2 |z|$, where $|z|$ denotes the absolute value of z. When we consider circuit lower bounds, we assume that g is computable, i.e., there exists a Turing machine that computes g.

1.1 Our contribution

Satisfiability Algorithms: In the *circuit satisfiability problem* (Circuit SAT), our task is, given a Boolean circuit C, to decide whether there exists a 0/1 assignment to the input variables such that C evaluates 1. If input instances are restricted to a class of Boolean circuits $\mathcal{C}$, the problem is called $\mathcal{C}$-SAT. A naïve algorithm can solve Circuit SAT in time $O(\mathrm{poly}(|C|) \cdot 2^n)$, where we denote by $|C|$ the size of C and by n the number of input variables of C respectively. We say an algorithm for $\mathcal{C}$-SAT is *moderately exponential time* if it checks the satisfiability of every $C \in \mathcal{C}$ in time $\mathrm{poly}(|C|) \cdot 2^{n-\omega(\log n)}$, i.e., super-polynomially faster than 2^n. We are interested in for which class $\mathcal{C}$ moderately exponential time satisfiability algorithms exist.

Let $\mathbf{SYM}_w \circ \mathbf{AND}(n,m)$ be the set of n-variate depth 2 circuits with a weighted symmetric gate in $\mathbf{SYM}_w$ at the top and at most m AND gates at the bottom. Let $\mathbf{SYM}_w \circ \mathbf{AC}^0_d(n,m)$ be the set of n-variate unbounded fan-in depth $d+1$ layered circuits with AND, OR, NOT gates and a weighted symmetric gate in $\mathbf{SYM}_w$ such that the top gate is the weighted symmetric gate and each layer contains at most m gates. Let $\mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)$ be the set of n-variate unbounded fan-in depth d layered circuits with AND, OR, NOT gates and at most t weighted symmetric gates in $\mathbf{SYM}_w$ such that each layer contains at most m gates.

In this paper, we show moderately exponential time algorithms for the counting version of $\mathcal{C}$-SAT, where $\mathcal{C} \in \{\mathbf{SYM}_w \circ \mathbf{AND}(n,m), \mathbf{SYM}_w \circ \mathbf{AC}^0_d(n,m), \mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)\}$, as follows.

▶ **Theorem 1** (depth 2, weighted symmetric gate at the top, AND gates at the bottom)**.** *We can count the number of satisfying assignments for $C \in \mathbf{SYM}_w \circ \mathbf{AND}(n,m)$ deterministically in time*

$$\mathrm{poly}(n,m,\log w) \cdot 2^{n-\Omega\left((n/\log(mw))^{\log n/4\log(nm)}\right)}$$

and exponential space.

The running time is super-polynomially faster than 2^n when, e.g., $m = n^{o(\log n/\log\log n)}$ and $w = 2^{n^{0.99}}$. Note that $\mathbf{SYM}_{2^n}$ contains all Boolean functions (if we ignore the assumption that $g(z)$ can be evaluated in time polynomial in $\log_2 |z|$). The heart of our algorithms is a (seemingly new) *bottom fan-in reduction* technique inspired by recent developments on the analysis of "greedy restriction" by "concentrated shrinkage" [51, 54, 17, 49]. With an additional trick, we give an algorithm for the maximum satisfiability problem that runs in time $\mathrm{poly}(n^t) \cdot 2^{n-n^{1/O(t)}}$ for instances with n variables, $O(n^t)$ clauses and *arbitrary* weights. To the best of our knowledge, this is the first moderately exponential time algorithm even for Max 2SAT instances with arbitrary weights.

We extend the above algorithm with the help of the depth reduction algorithm due to Beame, Impagliazzo and Srinivasan [7].

▶ **Theorem 2** (depth d, weighted symmetric gate only at the top)**.** *We can count the number of satisfying assignments for $C \in \mathbf{SYM}_w \circ \mathbf{AC}^0_d(n,m)$ deterministically in time*

$$\mathrm{poly}(n,m,\log w) \cdot 2^{n-\Omega\left((n/2^{2d(\log m)^{4/5}}\log(mw))^{\log n/9\log m}\right)}$$

and exponential space.

The running time is super-polynomially faster than 2^n when, e.g., $m = 2^{(\log n/4d)^{5/4}}$ and $w = 2^{n^{0.49}}$.

We further extend the above algorithm relying on the circuit transformation techniques due to Beigel, Reingold and Spielman [9] and Beigel [8].

▶ **Theorem 3** (depth d, $t(n)$ weighted symmetric gates)**.** *We can count the number of satisfying assignments for $C \in \mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)$ deterministically in time*

$$\mathrm{poly}(n,m,d,t,\log w) \cdot 2^{n+O(t\log mw)-\Omega\left((n/2^{4d(\log m)^{4/5}}t\log(mw))^{\frac{\log n}{18\log m}}\right)}$$

and exponential space.

The running time is super-polynomially faster than 2^n when, e.g., $m = n^c$, $w = 2^{n^{\frac{1}{40c}}}$ and $t = n^{\frac{1}{40c}}$, where $c \leq \frac{\log^{1/4} n}{2(4d)^{5/4}}$.

Although our algorithms run in time super-polynomially faster than 2^n instead of exponentially faster than 2^n ($2^{(1-\varepsilon)n}$ for a universal constant $\varepsilon > 0$), this seems unavoidable due to the Strong Exponential Time Hypothesis (SETH) [12, 32, 34]: The hypothesis states that for all k, there exists $\varepsilon_k > 0$ such that the satisfiability problem of k-CNF formulas cannot be solved in time $2^{(1-\varepsilon_k)n}$. SETH has been used in proving conditional time lower bounds for several exponential time and polynomial time algorithms, see, e.g., [21, 37, 40].

Circuit Lower Bounds: Through the analysis of our satisfiability algorithms, we obtain the following average-case lower bounds.

▶ **Theorem 4** (depth 2, weighted symmetric gate at the top, AND gates at the bottom)**.** *There exists a constant $\alpha > 0$ such that for every m, w and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w}$ such that for every $C \in \mathbf{SYM}_w \circ \mathbf{AND}(n,m)$, it holds that*

$$\Pr_{x\in\{0,1\}^n}[f(x) = C(x)] \leq \frac{1}{2} + 2^{-\Omega\left((n/\log(mw))^{\alpha\log n/\log(nm)}\right)}.$$

We also obtain similar average-case lower bounds for $\mathbf{SYM}_w \circ \mathbf{AC}^0_d(n,m)$ and $\mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)$, see Theorems 12 and 13 in Section 5.

Our average-case lower bounds might be interesting in the sense that (1) previous ones for similar circuits with arbitrary symmetric gates rely on communication complexity lower bounds while ours are based on the restriction method and (2) we are not aware of (even worst-case) lower bounds for $\mathbf{SYM}_w \circ \mathbf{AND}$ with $w = n^{\omega(\log n)}$.

Let $\mathcal{C}$ be a set of Boolean circuits and $\mathbf{MAJ} \circ \mathcal{C}$ be the set of Boolean circuits, where $C \in \mathbf{MAJ} \circ \mathcal{C}$ is a majority vote of $\mathcal{C}$ circuits, i.e., $C(x) = \mathrm{sgn}(C_1(x) + \cdots + C_s(x) + w_0)$ holds for some $C_1, \ldots, C_s \in \mathcal{C}$ and an integer w_0.

Combining the above average-case lower bounds and the discriminator lemma due to Hajnal, Maass, Pudlák, Szegedy and Turán [27], we obtain the following worst-case lower bounds.

▶ **Theorem 5** (majority vote of depth 2, weighted symmetric gate at the top, AND gates at the bottom). *There exists a constant $\alpha > 0$ such that for every m, w and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w}$ such that any $C \in \mathbf{MAJ} \circ \mathbf{SYM}_w \circ \mathbf{AND}(n, m)$ cannot compute $f_{n,m,w}$ if the majority gate at the top of C has fan-in at most $2^{o\left((n/\log(mw))^{\alpha \log n/\log(nm)}\right)}$.*

We also obtain similar worst-case lower bounds for $\mathbf{MAJ} \circ \mathbf{SYM}_w \circ \mathbf{AC}^0_d(n, m)$, $\mathbf{MAJ} \circ \mathbf{AC}^0_d[\mathbf{SYM}_w](n, m, t)$ (and $\mathbf{AC}^0_d[\mathbf{SYM}_w](n, m, t)$ with different parameters), see Theorems 24, 25 and 26 in Section 6.

Compression Algorithms: In the *circuit compression problem* (Circuit CMP), our task is, given the truth table of an s-sized Boolean circuit C and an integer $s' \geq s$, to construct a Boolean circuit C' that is at most s'-sized and computes the same function as C. If input instances are restricted to a class of Boolean circuits $\mathcal{C}$, the problem is called $\mathcal{C}$-CMP. In $\mathcal{C}$-CMP, we do not have to construct C' as a circuit in $\mathcal{C}$. Since every n-variate Boolean function can be represented as a $\frac{(1+o(1))2^n}{n}$-sized circuit [39][1], the problem is interesting if $s' \ll 2^n/n$ and in particular we consider the case $s' = 2^{n-\omega(\log n)}$.

A compression algorithm is *efficient* if it runs in time $2^{O(n)}$ given the truth table of an n-variate Boolean function. Note that input length is 2^n and an efficient algorithm runs in polynomial time. The running time analyses of our satisfiability algorithms imply efficient compression algorithms. Let $\mathcal{C} \in \{\mathbf{SYM}_w \circ \mathbf{AND}(n, m), \mathbf{SYM}_w \circ \mathbf{AC}^0_d(n, m), \mathbf{AC}^0_d[\mathbf{SYM}_w](n, m, t)\}$. We obtain deterministic efficient algorithms for $\mathcal{C}$-CMP if parameters n, m, w, d, t are such that the corresponding algorithms for $\mathcal{C}$-SAT run in time $2^{n-\omega(\log n)}$.

1.2 Background

Bounded Depth Circuits with (Weighted) Symmetric Gates: Let $\mathbf{AC}^0$ be the set of bounded depth circuits with AND, OR and NOT gates, $\mathbf{AC}^0[m]$ be the set of $\mathbf{AC}^0$ circuits with modulo m gates, $\mathbf{AC}^0[\mathbf{MAJ}]$ be the set of $\mathbf{AC}^0$ circuits with majority gates (also known as $\mathbf{TC}^0$), $\mathbf{AC}^0[\mathbf{THR}]$ be the set of $\mathbf{AC}^0$ circuits with linear threshold gates and $\mathbf{AC}^0[\mathbf{SYM}_w]$ be the set of $\mathbf{AC}^0$ circuits with gates in $\mathbf{SYM}_w$. Note that for every linear threshold gate, there exists a polynomial size depth 2 majority circuit that computes it [24].

In their seminal work, Razborov [46] and Smolensky [55] showed exponential lower bounds on the size of $\mathbf{AC}^0[m]$ circuits computing majority or mod q functions when m, q are prime powers and relatively prime. Since then, people have been trying to obtain super-polynomial size lower bounds against stronger circuit classes such as $\mathbf{AC}^0[m]$ with arbitrary m or $\mathbf{AC}^0[\mathbf{MAJ}]$. Despite much effort of researchers, super-polynomial size lower bounds have been only shown for such circuit classes with some restriction, see,

[1] Such a representation can be obtained in time $2^{O(n)}$.

e.g., [4, 9, 14, 22, 23, 26, 27, 28] (here we consider circuits computing "explicit" Boolean functions, i.e., functions in NP).

One of the best studied restriction is limiting the number of (weighted) symmetric gates. The following lower bounds are known:

- (Worst-case lower bounds) Exponential lower bounds for $\mathbf{AC}^0[\mathbf{MAJ}]$ circuits with $n^{o(1)}$ majority gates [6, 8] and $\mathbf{AC}^0[\mathbf{THR}]$ circuits with $o(\log n)$ linear threshold gates [44].
- (Average-case lower bounds) super-polynomial lower bounds for $\mathbf{AC}^0[\mathbf{SYM}_1]$ circuits with $o(\log^2 n)$ symmetric gates [58]; arbitrary large polynomial lower bounds for $\mathbf{AC}^0[\mathbf{SYM}_1]$ circuits with $n^{1-o(1)}$ symmetric gates and $\mathbf{AC}^0[\mathbf{THR}]$ circuits with $n^{1/2-o(1)}$ linear threshold gates [38].

The above average-case lower bounds are based on the results of Håstad and Goldmann [29] and Razborov and Wigderson [48] that show average-case lower bounds for $\mathbf{SYM}_1 \circ \mathbf{AND}$ circuits from the communication complexity lower bounds due to Babai, Nisan and Szegedy [5] and also show worst-case lower bounds for $\mathbf{MAJ} \circ \mathbf{SYM}_1 \circ \mathbf{AND}$ circuits using the discriminator lemma.

Circuit Satisfiability: Studying moderately exponential time algorithms for Circuit SAT is motivated by not only the importance in practice, e.g., logic circuit design and constraint satisfaction but also the viewpoint of Boolean circuit complexity. As pointed out by several papers such as [60, 65], there are strong connections between proving circuit lower bounds for $\mathcal{C}$ and designing moderately exponential time algorithms for $\mathcal{C}$-SAT; see also excellent surveys [52, 43, 62]. Typical such connections are:

(1) Some proof techniques such as deterministic/random restriction (shrinkage analysis/switching lemma) simultaneously prove circuit lower bounds for $\mathcal{C}$ and provides $\mathcal{C}$-SAT algorithms [51, 31, 7, 54, 17, 16, 15, 20, 25].

(2) Williams [60, 64] showed that if we obtain a moderately exponential time algorithm for $\mathcal{C}$-SAT and $\mathcal{C}$ satisfies some closure property, then we also have a separation of complexity classes such as $\mathrm{E}^{\mathrm{NP}} \not\subseteq \mathcal{C}$ or $\mathrm{NE} \not\subseteq \mathcal{C}$, where E^{NP} is the set of languages decidable by exponential time Turing machines with NP oracles and NE is the set of languages decidable by non-deterministic exponential time Turing machines; see also [59, 61, 63, 10, 35] for the improvement of such connections. Since then, people have developed moderately exponential time satisfiability algorithms for various circuit classes [33, 18, 30, 1, 3, 2, 42, 19, 57]. In particular, one of the current best lower bounds, $\mathrm{NE} \not\subseteq \mathbf{ACC}^0 \circ \mathbf{THR}$ (also $\mathrm{NE} \not\subseteq \mathbf{ACC}^0 \circ \mathbf{SYM}_1$), was obtained through satisfiability algorithms [63], where $\mathbf{ACC}^0 := \bigcup_m \mathbf{AC}^0[m]$.

Circuit Compression: Circuit CMP is a relaxed version of the circuit minimization problem. Chen, Kabanets, Kolokolova, Shaltiel and Zuckerman [17] established a connection between compression algorithms and circuit lower bounds as follows: If there exists a deterministic efficient algorithm for $\mathcal{C}$-CMP, then $\mathrm{NEXP} \not\subseteq \mathcal{C}$. They also gave efficient compression algorithms for $\mathbf{AC}^0$ circuits, Boolean formulas and branching programs of certain size range. Srinivasan [56] showed an efficient compression algorithm for $\mathbf{AC}^0[m]$ with a prime power m. Carmosino, Impagliazzo, Kabanets and Kolokolova [13] established interesting connections between the tasks of compression/learning and "natural properties" in the sense of Razborov and Rudich [47].

2 Preliminaries

We use random access machines as our computation model. For a set S, we denote by $|S|$ the cardinality of S.

A *literal* is either a Boolean variable or its negation. A *term* is a conjunction of literals. A *Boolean circuit* is a directed acyclic graph whose source nodes are labeled by literals or constants and internal and sink nodes are labeled by logic gates such as AND, OR, NOT, or weighted symmetric gates. A Boolean circuit with a single sink node computes a Boolean function in a natural way. We call source nodes and a sink node *input nodes* and *output node* respectively. The *depth* of a node is defined as the length of the longest path from it to the output node. The *depth* of a Boolean circuit is the maximum value of the depth over all nodes. A Boolean circuit is *layered* if for every edge (u, v), u and v have depth d and $d + 1$ for some d.

A Boolean circuit $C : \{0,1\}^n \to \{0,1\}$ is *satisfiable* if there exists a *satisfying assignment* for C, i.e., an assignment $a \in \{0,1\}^n$ such that $C(a) = 1$ holds. For two Boolean functions (or circuits) f, g in the same variables, we write $f \equiv g$ if $f(a) = g(a)$ holds for all $a \in \{0,1\}^n$. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *k-junta* if it depends on at most k variables, i.e., there exist $g : \{0,1\}^k \to \{0,1\}$ and $1 \le i_1 < \cdots < i_k \le n$ such that $f(x_1, \ldots, x_n) = g(x_{i_1}, \ldots, x_{i_k})$ holds.

Let $V = \{x_1, \ldots, x_n\}$. A *restriction* is a mapping $\rho : V \to \{0, 1, *\}$. The meaning of ρ is that if $\rho(x_i) \in \{0,1\}$, then we assign the value $\rho(x_i)$ to x_i, and if $\rho(x_i) = *$, then we leave x_i as it is. Thus, when we *apply* a restriction ρ to a Boolean function f, we obtain the Boolean function $f|_\rho$ defined over the variables $\rho^{-1}(*)$. We also apply a restriction ρ to a Boolean circuit C and obtain a Boolean circuit $C|_\rho$. When we apply a restriction ρ to a Boolean circuit C, we *simplify* a Boolean circuit C using the identities $0 \wedge f \equiv 0$, $1 \wedge f \equiv f$ repeatedly (each appearance of L.H.S. is replaced by R.H.S.).

A *restriction decision tree* T over $x_1, \ldots, x_n$ is an ordinary decision tree except that leaves are not necessarily labeled by 0 or 1. The *height* of T is defined as the number of nodes on the longest path from the root to a leaf and the *size* of T is defined as the number of nodes in T. We identify a path from the root to a leaf with a restriction. A *random root-to-leaf path* is sampled by repeatedly selecting a child of the current node uniformly at random from the root. Note that a path of length ℓ is chosen with probability $2^{-\ell}$.

3 A Dynamic Programming Algorithm for $\mathrm{SYM}_w \circ \mathrm{AND}_k$

We denote by $g \circ \mathbf{AND}_k(n, m, w)$ the set of n-variate Boolean circuits of the form $g(w_0 + \sum_{i=1}^{s} w_i t_i)$, where $g : \mathbb{Z} \to \{0,1\}$, $s \le m$, $w_0, w_1, \ldots, w_s \in \mathbb{Z}, \max_{0 \le i \le s} |w_i| \le w$, and $t_1, \ldots, t_s$ are terms that contain at most k-literals such that $t_i \ne t_j$ holds for $i \ne j$. We define

$$\mathbf{SYM}_w \circ \mathbf{AND}_k(n, m) := \bigcup_{g:\mathbb{Z}\to\{0,1\}} g \circ \mathbf{AND}_k(n, m, w).$$

We specify an element C in $\mathbf{SYM}_w \circ \mathbf{AND}_k(n, m)$ as $C = \{g, w_0, (t_1, w_1), \ldots, (t_s, w_s)\}$ and call s and $\max_{0 \le i \le s} |w_i|$ the *size* and the *maximum weight* of C respectively.

For a restriction ρ, we simplify $C|_\rho = \{g, w_0, (t_1|_\rho, w_1), \ldots, (t_s|_\rho, w_s)\}$ repeatedly if there exists a pair (i, j), $1 \le i < j \le s$ such that $t_i|_\rho \equiv t_j|_\rho$ holds. That is, we delete $(t_j|_\rho, w_j)$ and replace $(t_i|_\rho, w_i)$ by $(t_i|_\rho, w_i + w_j)$. If there are multiple such pairs, we may handle them in arbitrary order.

Our first satisfiability algorithm for $\mathbf{SYM}_w \circ \mathbf{AND}_k(n, m)$ is described in Fig. 1. The algorithm involves two parameters n', m' that are specified in the proof of Theorem 6.

The basic idea is as follows:

Step 1: We construct a table T that contains pairs of the form $(C, \#\mathrm{sat}(C))$ for every circuit C in $g \circ \mathbf{AND}_k(n', m', w')$, where $\#\mathrm{sat}(C)$ denotes the number of satisfying assignments

```
Algorithm1($C = \{g, w_0, (t_1, w_1), \ldots, (t_s, w_s)\}$: instance, $n, m, k, w$: integer)
01: if $C \notin \mathbf{SYM}_w \circ \mathbf{AND}_k(n, m)$, return $\perp$.
02: $T \leftarrow \emptyset$. /* table for dynamic programming */
03: for each $C \in g \circ \mathbf{AND}_k(n', m', (s+1) \cdot w)$, /* lexicographical order */
04:     $T \leftarrow T \cup \{(C, \#\mathrm{sat}(C))\}$. /* brute force search */
05: $N \leftarrow 0$.
06: for each $\rho : V \to \{0, 1, *\}$ such that $\rho^{-1}(*) = \{x_1, \ldots, x_{n'}\}$,
07:     $N \leftarrow N + \#\mathrm{sat}(C|_\rho)$. /* binary search in $T$ */
08: return $N$.
```

Figure 1 A Dynamic Programming Algorithm for $\mathbf{SYM}_w \circ \mathbf{AND}_k$.

for C and n', m', w' are appropriately chosen parameters. Furthermore, pairs are sorted in the lexicographical order with respect to the first coordinate C so that we can use binary search. To do so, we check the number of satisfying assignments for every circuit in $g \circ \mathbf{AND}_k(n', m', w')$ one by one in the lexicographical order using brute force search.

Step 2: Let C be an input instance in $g \circ \mathbf{AND}_k(n, m, w)$. For each restriction ρ that assigns $*$ to the first n' variables of C, we check the number of satisfying assignments for $C|_\rho$ using binary search in T and output the sum of them.

We will show the following theorem.

▶ **Theorem 6.** *We can count the number of satisfying assignments for $C \in \mathbf{SYM}_w \circ \mathbf{AND}_k(n, m)$ deterministically in time*

$$\mathrm{poly}(n, m, \log w) \cdot 2^{n - \Omega((n/\log(mw))^{1/k})}$$

and exponential space.

Proof. We denote by $|g \circ \mathbf{AND}_k(n, m, w)|$ the cardinality of $g \circ \mathbf{AND}_k(n, m, w)$. To evaluate the running time of (Step 1), we upper bound the size of the table T using the following fact.

▶ **Fact 7.** *For all m, we have*

$$|g \circ \mathbf{AND}_k(n, m, w)| \leq (2w+1)^{\sum_{i=0}^{k} 2^i \binom{n}{i}} \leq 2^{(k+1)(2n)^k \log(2w+1)}.$$

Proof. Note that $\sum_{i=0}^{k} 2^i \binom{n}{i}$ is the number of different terms that consist of at most k-literals (including a constant function 1). Each term has a weight in $\{-w, -w+1, \ldots, w-1, w\}$. Thus, we have the first inequality. The second inequality follows from an elementary calculation. ◀

Thus, we can bound the running time of Lines 03-04 from above by

$$2^{(k+1)(2n')^k \log(2(m+1)w+1)} \times \mathrm{poly}(m', \log(mw)) \cdot 2^{n'},$$

where we set $m' = \sum_{i=0}^{k} 2^i \binom{n'}{i} \leq (k+1)(2n')^k$.

Next we evaluate the running time of (Step 2). Note that the following guarantees that every $C|_\rho$ in Line 06 belongs to $g \circ \mathbf{AND}_k(n', m', (m+1) \cdot w)$.

▶ **Fact 8.** *Let $C = \{g, w_0, (t_1, w_1), \ldots, (t_m, w_m)\}$. If $C \in g \circ \mathbf{AND}_k(n, m, w)$ holds, then for all restriction ρ with $|\rho^{-1}(*)| = n'$, we have $C|_\rho \in g \circ \mathbf{AND}_k(n', m', (m+1) \cdot w)$.*

Proof. By the definition of $\mathbf{SYM}_w \circ \mathbf{AND}_k(n,m)$, we have $\sum_{i=0}^{s} |w_i| \le (m+1)w$. This implies the maximum weight of $C|_\rho$ is at most $(m+1)w$. ◀

For each $C|_\rho$, binary search in Line 07 takes time at most

$$\log_2 |g \circ \mathbf{AND}_k(n', m', (m+1)\cdot w)| \times \mathrm{poly}(m', \log(mw)) = \mathrm{poly}(m', \log(mw)).$$

Thus, we can bound the running time of Lines 06-07 above by

$$\mathrm{poly}(m, m', \log(mw)) \cdot 2^{n-n'}.$$

If we set $n' = \left(\frac{n}{(k+1)2^{k+1}\log(2(m+1)w+1)}\right)^{1/k} = \Theta((n/\log(mw))^{1/k})$, the total running time of **Algorithm1** is bounded from above by $\mathrm{poly}(n, m, \log w) \cdot 2^{n-\Omega((n/\log(mw))^{1/k})}$. This completes the proof. ◀

▶ Remark. In the case when $g(z) = \mathrm{sgn}(z)$, we can reduce the weight of the top gate of $C|_\rho$ from $(m+1)w$ to $2^{n'^{O(k)}}$ efficiently by Theorem 16 in [41]. With this trick, we can handle Max SAT instances with arbitrary weights.

4 A Greedy Restriction Algorithm for $\mathrm{SYM}_w \circ \mathrm{AND}_k$

For a term t, we denote by $|t|$ the width of t, i.e., the number of literals in t and by $\mathrm{var}(t)$ the set of variables that appear in t (possibly negated). Let $C \in \mathbf{SYM}_w \circ \mathbf{AND}_k(n,m)$ be a circuit $\{g, w_0, (t_1, w_1), \ldots, (t_s, w_s)\}$. We define $\mathrm{var}_\ell(C) := \cup_{i:|t_i|\ge \ell}\mathrm{var}(t_i)$, $\mathrm{freq}_\ell(C, x) := |\{t_i \in C \mid x \in \mathrm{var}(t_i), |t_i| \ge \ell\}|$, and $L_\ell(C) := \sum_{i:|t_i|\ge\ell} |t_i|$.

Our second satisfiability algorithm for $\mathbf{SYM}_w \circ \mathbf{AND}_k(n,m)$ is described in Fig. 2. The basic idea is as follows:

Step 1: Choose a positive integer ℓ according to the input. We seek for a variable, say x, that occurs most frequently in terms of width at least ℓ. We recursively run the algorithm for $C|_{x=0}$ and $C|_{x=1}$. Here $C|_{x=a}$ denotes the circuit obtained from C by applying a restriction ρ such that $\rho(x) = a \in \{0,1\}$ and $\rho(x') = *$ for $x' \ne x$.

Step 2: If there is no term of width at least ℓ, we call **Algorithm1**.

We will show the following theorem which implies Theorem 1 by setting $k = n$.

▶ **Theorem 9.** *We can count the number of satisfying assignments for* $C \in \mathbf{SYM}_w \circ \mathbf{AND}_k(n,m)$ *deterministically in time*

$$\mathrm{poly}(n, m, \log w) \cdot 2^{n-\Omega\left((n/\log(mw))^{\log n/4\log(km)}\right)}$$

and exponential space.

Proof. Let us define a sequence of random variables $\{C_i\}$ inductively as $C_0 := C$ and $C_{i+1} := C_i|_{x=a}$, where $x = \arg\max_{x\in\mathrm{var}(C_i)} \mathrm{freq}_\ell(C_i, x)$ and a is a uniform random bit.

We can think of the computation of **Algorithm2** as a rooted binary tree. That is, the root node is labeled with C_0, the left and right children of the root are labeled with $C_0|_{x=0}$ and $C_0|_{x=1}$, and so on. Then, if we pick a node of depth $n - n'$ uniformly at random, the distribution of its label is identical to that of the random variable $C_{n-n'}$.

We would like to bound the running time of **Algorithm2**$(C_{n-n'}, n', n', \ell)$. It is obviously bounded from above by $\mathrm{poly}(n, m, \log w) \cdot 2^{n'}$. Furthermore, if $L_\ell(C_{n-n'}) < \frac{n'}{2}$ holds, the

```
Algorithm2($C = \{g, w_0, (t_1, w_1), \ldots, (t_s, w_s)\}$: instance, $n, n', \ell$: integer)
01: if $n > n'$,
02:     $x = \arg\max_{x \in \mathrm{var}(C)} \mathrm{freq}_\ell(C, x)$.
03:     $N_0 \leftarrow$ Algorithm2($C|_{x=0}, n-1, n', \ell$).
04:     $N_1 \leftarrow$ Algorithm2($C|_{x=1}, n-1, n', \ell$).
05:     return $N_0 + N_1$.
06: else
07:     $N \leftarrow 0$.
08:     for each $\rho : \mathrm{var}(C) \to \{0, 1, *\}$ such that $\rho^{-1}(\{0,1\}) = \mathrm{var}_\ell(C)$,
09:       $w' \leftarrow$ the maximum weight of $C|_\rho$.
10:       $N \leftarrow N+$ Algorithm1($C|_\rho, n - |\mathrm{var}_\ell(C)|, m', \ell - 1, w'$).
11:     return $N$.
```

Figure 2 A Greedy Restriction Algorithm for $\mathbf{SYM}_w \circ \mathbf{AND}_k$.

running time can be bounded by $2^{n'/2}\times$ (the running time of **Algorithm1**$(C', n'/2, m', \ell - 1, w')$) for $C' \in \mathbf{SYM}_{w'} \circ \mathbf{AND}_{\ell-1}(n'/2, m')$ with $m' = \ell \cdot (n')^{\ell-1}$ and $w' = (m+1)w$. We need the following lemma.

▶ **Lemma 10** (Greedy bottom fan-in reduction). *Let $C \in \mathbf{SYM}_w \circ \mathbf{AND}_k(n, m)$. For all $n' \geq 4$, we have*

$$\Pr\left[L_\ell(C_{n-n'}) \geq 2^\ell \cdot L_\ell(C) \cdot \left(\frac{n'}{n}\right)^{\frac{\ell+2}{2}}\right] < 2^{-n'}.$$

Since $L_\ell(C) \leq km$, if we set $n' = \frac{1}{16}\left(\frac{n}{km}\right)^{2/\ell} \cdot n$ in the above lemma, we have

$$2^\ell \cdot L_\ell(C) \cdot \left(\frac{n'}{n}\right)^{\frac{\ell+2}{2}} \leq \frac{n'}{2},$$

that is, we have $L_\ell(C_{n-n'}) < n'/2$ with probability at least $1 - 2^{-n'}$. If we set $\ell = \frac{4\log(km)}{\log n}$, then the total running time of **Algorithm2** is bounded from above by the sum of

$$\mathrm{poly}(n, m, \log w) \cdot 2^{n-n'} \cdot 2^{-n'} \cdot 2^{n'}$$

and

$$\mathrm{poly}(n, m, \log w) \cdot 2^{n-n'} \cdot (1 - 2^{-n'}) \cdot 2^{n'/2} \cdot 2^{n'/2 - \Omega((n'/(\log(m'w')))^{1/\ell})}$$

according to whether $L_\ell(C_{n-n'}) \geq n'/2$ holds or not. An elementary calculation completes the proof. ◀

▶ Remark. The novelty of our algorithm and its analysis is a new way of reducing the bottom fan-in of circuits in a greedy manner. Intuitively, given a $\mathbf{SYM}_w \circ \mathbf{AND}_k$ circuit with m gates, greedy restriction produces a collection of $\mathbf{SYM}_{w'} \circ \mathbf{AND}_{k'}$ circuits with $k' = O(\log(km)/\log n)$ such that at least one of the circuits in the collection is satisfiable if and only if so is the original circuit. Note that previous techniques such as Schuler's width reduction [53, 11] or the standard random restriction achieve $k' = O(\log(m/n))$ and this bound is not sufficient for our purpose.

5 Average-Case Circuit Lower Bounds

Through the analysis of our satisfiability algorithms, we obtain the following average-case lower bounds.

▶ **Theorem 11** (depth 2, weighted symmetric gate at the top, AND gates at the bottom)**.** *There exists a constant $\alpha > 0$ such that for every m, w and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w}$ such that for every $C \in \mathbf{SYM}_w \circ \mathbf{AND}(n, m)$, it holds that*

$$\Pr_{x \in \{0,1\}^n}[f_{n,m,w}(x) = C(x)] \leq \frac{1}{2} + 2^{-\Omega\left((n/\log(mw))^{\alpha \log n/\log(nm)}\right)}.$$

▶ **Theorem 12** (depth d, weighted symmetric gate only at the top)**.** *There exists a constant $\alpha > 0$ such that for every m, w, d and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w,d}$ such that for every $C \in \mathbf{SYM}_w \circ \mathbf{AC}^0_d(n, m)$, it holds that*

$$\Pr_{x \in \{0,1\}^n}[f_{n,m,w,d}(x) = C(x)] \leq \frac{1}{2} + 2^{-\Omega\left((n/2^{2d(\log m)^{4/5}}\log(mw))^{\alpha \log n/\log m}\right)}.$$

▶ **Theorem 13** (depth d, $t(n)$ weighted symmetric gates)**.** *There exists a constant $\alpha > 0$ such that for every m, w and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w,d,t}$ such that for every $C \in \mathbf{AC}^0_d[\mathbf{SYM}_w](n, m, t)$, it holds that*

$$\Pr_{x \in \{0,1\}^n}[f_{n,m,w,d,t}(x) = C(x)] \leq \frac{1}{2} + 2^{-\Omega\left((n/2^{2d(\log m')^{4/5}}\log(m'w'))^{\alpha \log n/\log m'}\right)},$$

where $m' = m2^{t+1}$ and $w' = (mw)^{2^{t+1}}$.

In the rest of this section, we give a proof of Theorem 11. The proof of Theorem 12 is similar and we omit proof. Theorem 13 immediately follows from Theorem 12 with the idea of the proof of Theorem 5.1 in [8].

5.1 Generalized Andreev function

In this section, we review the construction of average-case hard Boolean functions due to [17, 36]. We begin with some definitions.

▶ **Definition 14** (Statistical distance)**.** Two distributions X, Y over a set E are *ε-close* if $|\mathbf{Pr}[X \in A] - \mathbf{Pr}[Y \in A]| \leq \varepsilon$ holds for every $A \subseteq E$.

▶ **Definition 15.** A set $A \subseteq \{0,1\}^n$ is a *subcube of dimension k* if there exist $1 \leq i_1 < \cdots < i_k \leq n$ and $a_{i_1}, \ldots, a_{i_k} \in \{0,1\}$ such that $A = \{x \in \{0,1\}^n \mid x_{i_1} = a_{i_1}, \ldots, x_{i_k} = a_{i_k}\}$.

▶ **Definition 16** (Bit-fixing extractor)**.** A function $f : \{0,1\}^n \to \{0,1\}^m$ is an (n, k, m, ε)-*bit-fixing extractor* if $f(X)$ and the uniform distribution over $\{0,1\}^m$ are ε-close for every distribution X that is uniform over a subcube of $\{0,1\}^n$ of dimension at least k.

We need the following explicit construction due to Rao.

▶ **Lemma 17** (Efficient bit-fixing extractor [45])**.** *There exist constants $\alpha, \beta > 0$ such that for every $k \geq (\log n)^\alpha$, there exists a polynomial time computable $\mathrm{Ext}_{n,k} : \{0,1\}^n \to \{0,1\}^m$ that is an (n, k, m, ε)-bit-fixing extractor with $m = 0.9k$ and $\varepsilon \leq 2^{-k^\beta}$.*

We also need an efficient and explicit construction of list decodable codes.

▶ **Definition 18** (List-Decodable Code). A function $f : \{0,1\}^k \to \{0,1\}^n$ is (p, L)-list-decodable if $|\{y \in \{0,1\}^k \mid \Delta(f(x), f(y)) \le pn\}| \le L$ holds for every $x \in \{0,1\}^k$, where $\Delta(a,b)$ denotes the Hamming distance between a and b.

▶ **Lemma 19** (Efficient List-Decodable Code (Folklore), see Theorem 6.4 in [17]). *There exists a function* $\mathrm{Enc}_{n,r} : \{0,1\}^{4n} \to \{0,1\}^{2^r}$ *that is* (p, L)*-list-decodable with* $p = 1/2 - O(2^{-r/4})$ *and* $L = O(2^{r/2})$*. Furthermore, there exists an algorithm that, given* $x \in \{0,1\}^{4n}$ *and* $z \in \{0,1\}^{2^r}$*, computes* $(\mathrm{Enc}_{n,r}(x))_z$ *in polynomial time.*

We are ready to define the average-case hard Boolean functions: The generalized Andreev function $A_{n,k} : \{0,1\}^{4n} \times \{0,1\}^n \to \{0,1\}$ is defined as $A_{n,k}(x,y) := (\mathrm{Enc}_{n,0.9k}(x))_{\mathrm{Ext}_{n,k}(y)}$. Let $K(x)$ denote the *Kolmogorov complexity* of a string $x \in \{0,1\}^*$. The following lemma plays an important role in the proofs of our average-case lower bounds.

▶ **Lemma 20** (Theorem 6.5 in [17]). *There exist constants* $\alpha, \gamma > 0$ *such that the following holds. Let* $k \ge (\log n)^\alpha$ *and* C *be a* k*-variate circuit whose binary description length is at most* n *in a some fixed encoding scheme. Let* $\rho : \{x_1, \dots, x_n\} \to \{0, 1, *\}$ *be a restriction with* $|\rho^{-1}(*)| = k$*. Fix* $a \in \{0,1\}^{4n}$ *with* $K(a) \ge 3n$ *and define* $f(y) := A_{n,k}(a, y)$*. Then, we have*

$$\Pr_{y' \in \{0,1\}^k}[C(y') = f|_\rho(y')] \le \frac{1}{2} + \frac{1}{2^{k^\gamma}}.$$

The following fact can be shown by a counting argument.

▶ **Fact 21.** *For every* $0 < p < 1$, $\mathbf{Pr}_{x \in \{0,1\}^n}[K(x) \le (1-p)n] \le 2^{-pn+1}$.

5.2 Proof of Theorem 11

Fix n, m, w and let $n' = (n/\log(mw))^{\log n / 4 \log(nm)}$. Select any $a \in \{0,1\}^{4n}$ with $K(a) \ge 3n$ and let $f(y) := A_{n,n'}(a, y)$. We show the following lemma.

▶ **Lemma 22.** *For every* $C \in \mathbf{SYM}_w \circ \mathbf{AND}(n,m)$*, it holds that*

$$\Pr_{y \in \{0,1\}^n}[C(y) = f(y)] \le \frac{1}{2} + 2^{-\Omega(n'^\gamma)},$$

where $\gamma > 0$ *is a universal constant from Lemma 20.*

Assuming this, the proof of Theorem 11 is complete since by Fact 21, we have

$$\begin{aligned}
\Pr_{x,y}[A_{n,n'}(x,y) = C(x,y)] &\le \Pr_x[K(x) < 3n] + \Pr_x[K(x) \ge 3n] \\
&\times \Pr_{x,y}[A_{n,n'}(x,y) = C(x,y) \mid K(x) \ge 3n] \\
&\le 2^{-\Omega(n)} + \max_{x : K(x) \ge 3n} \Pr_y[A_{n,n'}(x,y) = C(x,y)] \\
&\le 2^{-\Omega(n)} + \frac{1}{2} + 2^{-\Omega(n'^\gamma)}.
\end{aligned}$$

.

Proof of Lemma 22. We can see that from the proofs of Theorems 6 and 9, C can be computed by a restriction decision tree T of height $n - n'$ such that (1) each leaf is labeled by a circuit in $\mathbf{SYM}_{w'} \circ \mathbf{AND}_{k'}(n', m')$ for some m', k', w' and (2) except for a $2^{-n^{\Omega(1)}}$ fraction of leaves, such a circuit can be described by using at most n bits (due to Fact 7). Let $\sigma(C)$

denote the description length of a circuit C in a fixed encoding scheme. Let ρ be a random restriction sampled by selecting a leaf of T uniformly at random and y_ρ be a uniform random element of $\{0,1\}^{\rho^{-1}(*)}$. Then, we have

$$\begin{aligned}\mathop{\mathbf{Pr}}_{y}[C(y)=f(y)] &\leq \mathop{\mathbf{Pr}}_{\rho}[\sigma(C|_\rho)>n]+\mathop{\mathbf{Pr}}_{\rho}[\sigma(C|_\rho)\leq n] \\ &\times \mathop{\mathbf{Pr}}_{\rho,y_\rho}[C|_\rho(y_\rho)=f|_\rho(y_\rho)\mid \sigma(C|_\rho)\leq n]\leq 2^{-n^{\Omega(1)}}+\frac{1}{2}+2^{-\Omega(n'^{\gamma})},\end{aligned}$$

where the last inequality is by Item (2) above and Lemma 20. This completes the proof. ◀

6 Worst-Case Lower Bounds

From the average-case lower bounds in Section 5, we obtain the following worst-case lower bounds.

▶ **Theorem 23** (majority vote of depth 2, weighted symmetric gate at the top, AND gates at the bottom). *There exists a constant $\alpha>0$ such that for every m,w and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w}$ such that $C\in\mathbf{MAJ}\circ\mathbf{SYM}_w\circ\mathbf{AND}(n,m)$ cannot compute $f_{n,m,w}$ if the majority gate at the top of C has fan-in at most $2^{o\left((n/\log(mw))^{\alpha\log n/\log(nm)}\right)}$.*

▶ **Theorem 24** (majority vote of depth d, weighted symmetric gate only at the top). *There exists a constant $\alpha>0$ such that for every m,w,d and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w,d}$ such that any $C\in\mathbf{MAJ}\circ\mathbf{SYM}_w\circ\mathbf{AC}^0_d(n,m)$ cannot compute $f_{n,m,w,d}$ if the majority gate at the top of C has fan-in at most $2^{o\left((n/2^{2d(\log m)^{4/5}}\log(mw))^{\alpha\log n/\log m}\right)}$.*

▶ **Theorem 25** (majority vote of depth d, $t(n)$ weighted symmetric gates). *There exists a constant $\alpha>0$ such that for every m,w,d,t and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w,d,t}$ such that any $C\in\mathbf{MAJ}\circ\mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)$ cannot compute $f_{n,m,w,d,t}$ if the majority gate at the top of C has fan-in at most $2^{o\left((n/2^{2d(\log m')^{4/5}}\log(m'w'))^{\alpha\log n/\log m'}\right)}$, where $m'=m2^{t+1}$ and $w'=(mw)^{2^{t+1}}$.*

▶ **Theorem 26** (depth d, $t(n)$ weighted symmetric gates). *There exists a constant $\alpha>0$ such that for every m,w,d,t and sufficiently large n, there exists a polynomial time computable function $f_{n,m,w,d,t}$ such that any $C\in\mathbf{AC}^0_d[\mathbf{SYM}_w](n,m,t)$ cannot compute $f_{n,m,w,d,t}$ if*

$$t=o\left((n/2^{2d(\log m')^{4/5}}\log(m'w'))^{\alpha\log n/\log m'}\right)$$

holds, where $m'=m(t+1)$ and $w'=m^tw^{t+1}$.

We need a corollary of the discriminator lemma.

▶ **Lemma 27** (Discriminator Lemma [27]). *If a circuit $C\in\mathbf{MAJ}\circ\mathcal{C}$ is a majority vote of k circuits $C_1,\ldots,C_k\in\mathcal{C}$, then for some $1\leq i\leq k$, we have*

$$|\Pr_x[C_i(x)=1\mid C(x)=1]-\Pr_x[C_i(x)=1\mid C(x)=0]|\geq\frac{1}{k}.$$

For $f,g:\{0,1\}^n\to\{0,1\}$, let $\mathrm{Corr}(f,g):=|\mathbf{Pr}_x[f(x)=g(x)]-\mathbf{Pr}_x[f(x)\neq g(x)]|$.

▶ **Corollary 28.** *For $\varepsilon \geq 0$, if C in Lemma 27 also satisfies that*

$$|\Pr_x[C(x)=0] - \Pr_x[C(x)=1]| = 2\varepsilon,$$

then we have $\mathrm{Corr}(f,g) \geq \frac{1}{k} - 2\varepsilon$.

Theorems 23, 24 and 25 immediately follow from Theorems 11, 12 and 13 with Corollary 28. Theorem 26 can be shown by combining the relation of circuit classes, Theorem 12 and Corollary 28.

Transducer-Based Rewriting Games for Active XML

Martin Schuster

TU Dortmund, Dortmund, Germany
martin.schuster@tu-dortmund.de

Abstract

Context-free games are two-player rewriting games that are played on nested strings representing XML documents with embedded function symbols. These games were introduced to model rewriting processes for intensional documents in the *Active XML* framework, where input documents are to be rewritten into a given target schema by calls to external services.

This paper studies the setting where dependencies between inputs and outputs of service calls are modelled by transducers, which has not been examined previously. It defines transducer models operating on nested words and studies their properties, as well as the computational complexity of the winning problem for transducer-based context-free games in several scenarios. While the complexity of this problem is quite high in most settings (ranging from NP-complete to undecidable), some tractable restrictions are also identified.

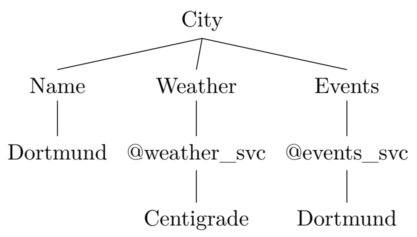
1 Introduction

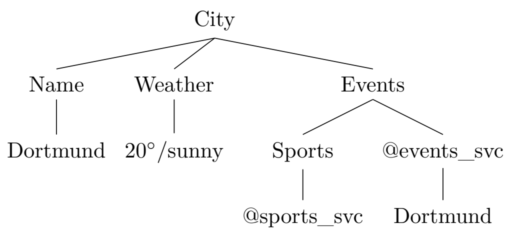
Scientific context

Context-free games on strings are two-player games extending context-free grammars, with the first player (called JULIET) choosing the non-terminal to be replaced and the second player (called ROMEO) choosing a replacement for that non-terminal. The winning condition for JULIET is reaching, at some point during the game, some string in a given target language over the combined alphabet of non-terminals and terminals.

These games were first introduced in [7] to model the rewriting process of *Active XML (AXML)* [1] documents. The intention of AXML is modelling *intensional* documents, i.e. documents that do not store all required information explicitly but instead contain references to external services, from which current information may be materialised on demand, as illustrated in the example below. To this end, AXML extends standard XML with *function nodes* referring to external web services that may be called to insert data into the AXML document when the document is requested. Context-free games abstract from AXML to model the uncertainty inherent in using external data.

A standard example (cf. [6, 7]) of an application for AXML is depicted in Figure 1. In this example, we consider (part of) an AXML document retained by a local online news site providing information about current weather and events. Initially, the server-side document looks like the one in Figure 1a. The nodes labelled @weather_svc and @events_svc are function nodes referring to external weather and event services.





(a) Example document before rewriting. **(b)** Same document after function calls.

Figure 1 Example of Active XML rewriting. After calls to function nodes @weather_svc and @events_svc in Fig. 1a, external data is materialised to yield the document in Fig. 1b.

Figure 1b shows the document from Figure 1a after both function nodes have been called, replacing them by the external services' results. As exemplified by the function node labelled @weather_svc, call results replace the entire subtree rooted at the called function node, with that subtree being passed to the external service as a parameter. Concretely, the @weather_svc node's child tells the weather service that temperatures returned should be in centigrade. As the call result of the @event_svc node shows, returns of external services may contain further function nodes, even copies of the called function node.

The *safe rewriting problem* [6] of determining whether a given AXML document can always be rewritten into a target schema was abstracted in [7] into the problem of determining whether JULIET has a winning strategy in a given context-free game on strings, with JULIET representing a rewriting algorithm and ROMEO representing the uncertainty inherent in function calls. This research assumed DTDs as schema formalisms. Allowing more expressive schema languages such as XML Schema [10] then led to research into context-free games on *nested strings* (i.e. XML-like linearisations of trees) [3]. Even though none of these previous works modelled dependencies between parameters and outputs of function calls, they already showed that the winning problem for JULIET can be undecidable or of a very high complexity, unless strategies for JULIET and allowed schema languages are seriously restricted.

The impact of service call parameters has so far only been studied in a limited fashion. In [10] (and in [6], for AXML rewriting with DTDs), external services were modelled by *input* (or *validation*) and *output* (or *replacement*) schemas, the semantics being that a function node could only be called if its parameter subtree was valid with regard to its corresponding input schema, which would then yield a return conforming to its output schema. This is a purely syntactic handling of input parameters which models a rather simple relationship between input and output of function calls; for instance, an @event_svc call reproducing its input parameters in its output as shown in Figure 1 cannot be enforced in this model.

While dependencies between parameters and outputs of service calls have always been implicit in the AXML model, they have not been studied in detail so far. Therefore, we extend the context-free games on nested words from [10] by (generally non-deterministic) transformations relating function parameters to possible outputs. We define *nested word transducers* (NWT) as a comparatively simple finite representation for transformations on nested words that naturally extends the nested word automata used in [10]. We then study the complexity of the winning problem for JULIET in various restrictions of context-free games with transducer-based replacement. As auxiliary results of potentially independent interest, we also examine closure properties and basic algorithmic problems of NWT.

Contributions

In light of prior undecidability and complexity results, the main objective of this paper is finding suitable restrictions to transducer-based context-free games that render the winning problem for Juliet decidable with as low complexity as possible. The two basic types of restrictions we examine are strategy restrictions (i.e. restrictions to Juliet's capabilities of calling function symbols) and restrictions to the type of NWT used for rewriting. To avoid undecidability, we only allow left-to-right strategies, i.e. once a function node has been called, no function calls to nodes preceding it (in post-order) are possible (cf. [7]).

The most important class of strategy restrictions considered here are restrictions to games with limited *replay*. In general context-free games, after a function call, Juliet continues her rewriting on that function call's result; we call this the *unbounded replay* case, as Juliet may continue rewriting function call results for as long as new function nodes are returned. In the *replay-free* case, Juliet is instead forbidden to call any function nodes inside results of function calls. As an intermediate case between unbounded replay and replay-free games, we also consider *bounded replay* games, where Juliet may only call functions returned by function calls up to a fixed maximum recursion depth. For instance, in a replay-free game, Juliet could call neither of the function nodes labelled @sports_svc and @events_svc in the situation of Figure 1b; in a bounded replay game of depth 2, on the other hand, she could call these nodes, but not any function nodes returned by those secondary calls.

The second type of restrictions comes from limiting expressiveness of the transducer used in games. Generally, transducers are allowed to be *non-functional*, i.e. any input string, may have several transducts (to model the fact that function call results are dependent upon, but not uniquely determined by, input parameters). The main types of transducers examined here are the following:

- *Nested word transducers (NWT)* allow for transforming input strings into output strings that are arbitrarily long, regardless of the input string's size.
- *Nested word transducers without ϵ-transitions (ϵ-free NWT)* may only increase the size of an input string by no more than a linear factor.
- *Relabelling transducers* may only change labels of input strings, not their structure.
- As a special case, *functional relabelling transducers* are relabelling transducers whose output string is uniquely determined by their input.

This paper's main complexity results are summarised in Table 1. The central insight here is that the least restricted settings yield an undecidable or non-elementary winning problem, and even for strong restrictions, the complexity of the winning problem is generally quite high, with no tractable case among the standard settings. For this reason, we also study several limitations of these settings, derived from our lower bound proofs, in order to reduce complexity:

- *Depth-bounded NWT* lower the complexity of the replay-free case to EXPSPACE-complete (in comparison to 2-EXPTIME for general NWT).
- Strategies with *bounded Call width* lower the complexity of the bounded-replay case for ϵ-free NWT from non-elementary to co-NEXPTIME-complete or co-NP-complete, depending on the precise formalisation of bounded Call width.
- *Write-once* strategies yield a tractable case for functional relabelling transducers in a setting even more restrictive than the replay-free one.

Table 1 Summary of complexity results. All results are completeness results.

	No replay	Bounded	Unbounded
NWT	2-EXPTIME	undecidable	undecidable
ϵ-free NWT	co-NEXPTIME	non-elementary	undecidable
Relabelling	PSPACE	PSPACE	EXPTIME
Functional relabelling	NP	NP	PSPACE

Related Work

Beyond the work already discussed, further complexity and decidability results for context-free games can be found in [2, 4], and [7] contains further references to related work.

Our concept of nested word transducers is based on Visibly Pushdown Transducers [8, 12], specifically the well-nested VPT of [5]. The original definitions of VPT in [8, 12] included ϵ-transitions, which were dropped from later definitions, as they caused several algorithmic problems, such as functionality and equivalence, to become undecidable (cf. [11]). Different from these approaches, this paper combines ϵ-transitions with the restriction to well-nested words, which is (to the best of the author's knowledge) new research.

Organisation

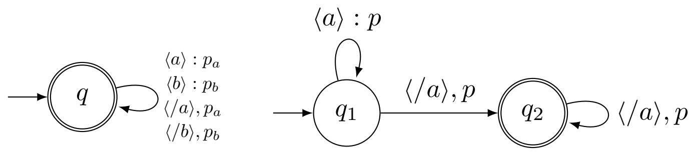
Section 2 gives basic notation and definitions. Section 3 defines nested word transducers and examines their structural and algorithmic properties. The next three sections give results on the complexity of the winning problem for games with transducer-based replacement, from most to least expressive – general nested word transducers (Section 4), nested word transducers without ϵ-transitions (Section 5), and relabelling transducers (Section 6). Each of these sections also discusses one of the restrictions with reduced complexity mentioned above. Section 7 concludes the paper. Due to space limitations, proofs and technical definitions are omitted here; for more details, an extended version is available online [9]. The author is grateful to Gaetano Geck and Thomas Schwentick for careful proof-reading and valuable suggestions, and to the anonymous reviewers for their insightful and constructive comments.

2 Preliminaries

For any natural number $n \in \mathbb{N}$, we denote by $[n]$ the set $\{1, \dots, n\}$. For finite sets M, $\mathcal{P}(M)$ denotes the powerset of M, i.e. the set of all subsets of M. For an alphabet Σ, we denote the set of finite strings over Σ by Σ^* and ϵ denotes the empty string.

Nested words

For a finite alphabet Σ, $\langle\Sigma\rangle \overset{\text{def}}{=} \{\langle a\rangle \mid a \in \Sigma\}$ denotes the set of all *opening* Σ*-tags* and $\langle/\Sigma\rangle \overset{\text{def}}{=} \{\langle/a\rangle \mid a \in \Sigma\}$ the set of all *closing* Σ*-tags*. We denote by $\hat{\Sigma} \overset{\text{def}}{=} \langle\Sigma\rangle \cup \langle/\Sigma\rangle$ the set of all Σ-tags. The set $\mathrm{NW}(\Sigma) \subseteq \hat{\Sigma}^*$ of *(well-)nested words* (or *(well-)nested strings*) over Σ is the smallest set such that $\epsilon \in \mathrm{NW}(\Sigma)$, and if $u, v \in \mathrm{NW}(\Sigma)$ and $a \in \Sigma$, then also $u\langle a\rangle v\langle/a\rangle \in \mathrm{NW}(\Sigma)$. We (informally) associate with every nested word w its *canonical forest representation*, such that words $\langle a\rangle\langle/a\rangle$, $\langle a\rangle v\langle/a\rangle$ and uv correspond to an a-labelled leaf, a tree with root a (and subforest corresponding to v), and the forest of u followed by the forest of v, respectively. A nested string w is *rooted* if its corresponding forest is a tree. We denote the set of rooted nested strings over Σ by $\mathrm{rNW}(\Sigma)$. In a string $w = w_1 \dots w_n \in \hat{\Sigma}^*$, two tags $w_i \in \langle\Sigma\rangle$ and $w_j \in \langle/\Sigma\rangle$ with $i < j$ are *associated* if the substring $w_i \dots w_j$ of w is a rooted nested string. An opening (closing) tag w_i in w is *unmatched*, if it has no associated



(a) NWA A_1 **(b)** NWA A_2

Figure 2 NWAs A_1 and A_2 from Example 2.1.

closing (opening) tag in w. To stress the distinction from nested strings in $\mathrm{NW}(\Sigma)$, we refer to strings in Σ^* as *flat strings*.

Nested word automata

A *nested word automaton (NWA)* $A = (Q, P, \Sigma, \delta, q_0, F)$ [3] is basically a pushdown automaton which performs a push operation on every opening tag and a pop operation on every closing tag, and in which the pushdown symbols are just states. More formally, A consists of a set Q of *linear states*, a set P of *hierarchical states*, an alphabet Σ, a *transition relation* δ, an *initial state* $q_0 \in Q$, and a set $F \subseteq Q$ of *accepting (linear) states*. The relation δ is a subset of the union of sets $(Q \times \langle\Sigma\rangle \times Q \times P)$ and $(Q \times P \times \langle/\Sigma\rangle \times Q)$. We sometimes interpret δ as the union of two functions from $(Q \times \langle\Sigma\rangle)$ to $\mathcal{P}(Q \times P)$ and from $(Q \times P \times \langle/\Sigma\rangle)$ to $\mathcal{P}(Q)$ and write accordingly $(q', p) \in \delta(q, \langle a\rangle)$ for $(q, \langle a\rangle, q', p) \in \delta$ and $q' \in \delta(q, p, \langle/a\rangle)$ for $(q, p, \langle/a\rangle, q') \in \delta$. The semantics of NWA as well as the language $L(A)$ decided by a NWA A are defined in the natural way, with a NWA accepting if it reaches a configuration with an accepting state and empty stack. If A is a NWA, we call $L(A)$ a *regular language* (of nested words). A NWA is *deterministic* (or DNWA) if $|\delta(q, \langle a\rangle)| = 1 = |\delta(q, p, \langle/a\rangle)|$ for all $q \in Q$, $p \in P$ and $a \in \Sigma$. In this case, we simply write $\delta(q, \langle a\rangle) = (q', p')$ instead of $\delta(q, \langle a\rangle) = \{(q', p')\}$ (and accordingly for $\delta(q, p, \langle/a\rangle)$).

▶ **Example 2.1.** The NWA A_1 (Fig. 2a) checks that its input string is well-nested by pushing hierarchical state p_a (resp. p_b) to the stack on each opening $\langle a\rangle$ (resp. $\langle b\rangle$) tag and popping an according hierarchical state with each matching closing tag. In this manner, A_1 decides the set of all well-nested strings over $\{a, b\}$. The NWA A_2 (Fig. 2b) initially pushes a hierarchical state p each time it reads $\langle a\rangle$ in linear state q_1, then changes linear state to q_2 on reading the first $\langle/a\rangle$ and accepts iff each initial $\langle a\rangle$ is matched by a $\langle/a\rangle$. In this manner, it decides the language $\{\langle a\rangle^n \langle/a\rangle^n \mid n \geq 1\}$.

Context-free games

A *context-free game (with transduction) on nested words (cfG)* $G = (\Sigma, \Gamma, R, T)$ consists of a finite alphabet Σ, a set $\Gamma \subseteq \Sigma$ of *function symbols*, a *(replacement) rule set* $R \subseteq \mathrm{rNW}(\Sigma) \times \mathrm{NW}(\Sigma)$ and a *target language* $T \subseteq \mathrm{NW}(\Sigma)$. We will only consider the case where T is a non-empty regular nested word language and replacement rules are given by nested word transducers, to be defined in Section 3. A play of G is played by two players, Juliet and Romeo, on a word $w \in \mathrm{NW}(\Sigma)$. In a nutshell, Juliet moves the focus along w from left to right and decides for each closing tag $\langle/a\rangle$, whether she plays a *Read* or, in case $a \in \Gamma$, a *Call* move. In the latter case, Romeo then replaces the rooted word u ending at the position of $\langle/a\rangle$ with some word v with $(u, v) \in R$ and the focus is set on the first symbol of v. If no such word v exists, Romeo immediately wins the play. In case of a Read move, the focus just moves further on. Juliet wins a play if the word obtained at its end is in T.

Strategies

A *strategy* for player $p \in \{\mathrm{J}, \mathrm{R}\}$ maps game states where player p is to move into allowed moves for player p, i.e. strategies σ for JULIET return moves in $\{\text{Read}, \text{Call}\}$ while strategies τ for ROMEO return replacement strings in $\mathrm{NW}(\Sigma)$. Given an initial word w and strategies σ, τ the play $\Pi(\sigma, \tau, w)$ according to σ and τ on w is uniquely determined. A *winning strategy* for JULIET is a strategy σ such that JULIET wins the play $\Pi(\sigma, \tau, w)$, for every τ of ROMEO. By $\mathrm{JWin}(G)$ we denote the set of all words for which JULIET has a winning strategy in G.

The *Call depth* of a play Π is the maximum nesting depth of Call moves in Π, if this maximum exists. That is, the Call depth of a play is zero, if no Call is played at all, and one, if no Call is played inside a string yielded by a replacement move. For a strategy σ of JULIET and a string $w \in \mathrm{NW}(\Sigma)$, the *Call depth* $\mathrm{Depth}^G(\sigma, w)$ of σ on w is the maximum Call depth in any play $\Pi(\sigma, \tau, w)$. A strategy σ has *k-bounded Call depth* if $\mathrm{Depth}^G(\sigma, w) \leq k$ for all $w \in \mathrm{NW}(\Sigma)$. As a more intuitive formulation, we use the concept of *replay*: Strategies for JULIET of Call depth one are called *replay-free*, and strategies of k-bounded Call depth, for any k, have *bounded replay.*

Algorithmic problems

In this paper, we study the following algorithmic problem $\mathrm{JWIN}(\mathcal{G})$ for various classes $\mathcal{G}$ of context-free games with replacement transducers.

$\mathrm{JWIN}(\mathcal{G})$	
Given:	A context-free game $G \in \mathcal{G}$ and a string w.
Question:	Is $w \in \mathrm{JWin}(G)$?

A class $\mathcal{G}$ of context-free games in $\mathrm{JWIN}(\mathcal{G})$ generally comes with three parameters:

- the representation of the target language T,
- the representation of the replacement relation R, and
- to which extent replay is restricted.

We generally assume target languages to be represented by DNWAs, because the complexity of the winning problem is already quite high under that assumption, and our main interest is in finding classes $\mathcal{G}$ for which $\mathrm{JWIN}(\mathcal{G})$ is tractable. Replacement relations will be given as different types of nested word transducers (defined in Section 3). By a slight abuse of notation, the replacement transducer implementing a replacement relation R will also be referred to as R.

In each setting, we consider the cases of unrestricted replay, bounded replay (Call depth k, for some k), and no replay (Call depth 1). We note that replay depth is formally not an actual game parameter, but the algorithmic problem can be restricted to strategies of JULIET of the stated kind. If the class $\mathcal{G}$ of games is clear from the context, we often simply write JWIN instead of $\mathrm{JWIN}(\mathcal{G})$.

3 Nested Word Transducers

In this section, we define nested word transducers and examine their closure properties and complexities of algorithmic problems. Thanks to our definition putting some rather severe restrictions on the use of ϵ-transitions and the allowed output of transducers, we obtain advantageous closure properties and comparatively low complexities.

Intuitively, a NWT T works much like a NWA with output and additional ϵ-transitions – T reads its input from left to right and decides nondeterministically which available transition

to use; on an opening (resp. closing) transition, it reads an opening (closing) input tag, changes its linear state and pushes (pops) a hierarchical state while producing an output. Opening (closing, internal) ϵ-transitions do not consume input symbols but induce state changes and outputs. T only produces an output string if it accepts the input string.

▶ **Definition 3.1.** A *nested word transducer* (or *NWT*) is a tuple $T = (Q, P, P_\epsilon, \Sigma, \delta, q_0, F)$ consisting of a set Q of *linear states*, a set P of *hierarchical states*, a set $P_\epsilon \subseteq P$ of *hierarchical ϵ-states*, an alphabet Σ, a *transition relation* δ, which is the union of three relations from $(Q \times (\langle\Sigma\rangle \cup \{\langle\epsilon\rangle\}) \times Q \times P \times \hat{\Sigma}^*)$ (called *opening* transitions), $(Q \times \{\epsilon\} \times Q \times \mathrm{NW}(\Sigma))$ (called *internal* transitions) and $(Q \times P \times (\langle/\Sigma\rangle \cup \{\langle/\epsilon\rangle\}) \times Q \times \hat{\Sigma}^*)$ (called *closing* transitions), an *initial state* $q_0 \in Q$, and a set of *accepting states* $F \subseteq Q$, such that for all $q, q', r, r' \in Q$, $p \in P$, $a \in \Sigma \cup \{\epsilon\}$ and $u, v \in \hat{\Sigma}^*$ it holds that[1]

- $(q, \langle\epsilon\rangle, q', p, u) \in \delta$ or $(q, p, \langle/\epsilon\rangle, q', u) \in \delta$ if and only if $p \in P_\epsilon$ (*ϵ-consistency*),
- if $(q, \langle a\rangle, q', p, u) \in \delta$ and $(r, p, \langle/a\rangle, r', v) \in \delta$, then $uv \in \mathrm{NW}(\Sigma)$ (*well-formedness*), and
- for each $(q, \langle a\rangle, q', p, u) \in \delta$ (resp. $(r, p, \langle/a\rangle, r', u) \in \delta$) with $u \neq \epsilon$, u contains at least one unmatched opening (resp. closing) tag (*synchronisation*).

As for standard NWA, we also write $(q', p, u) \in \delta(q, \langle a\rangle)$ (resp. $(q', u) \in \delta(q, p, \langle/a\rangle)$, $(q', u) \in \delta(q, \epsilon)$) instead of $(q, \langle a\rangle, q', p, u) \in \delta$ (resp. $(q, p, \langle/a\rangle, q', u), (q, \epsilon, q', u) \in \delta$).

A detailed semantics definition can be found in the extended version.

▶ **Example 3.2.** Figure 3 shows a NWT T_{ab}, with linear states displayed as circles and transitions as arrows. From the initial state i, T_{ab} branches nondeterministically into either state a_1 or b_1. In state a_1, T_{ab} checks that the input string is well-nested just as the NWA A_1 from Example 2.1. During this check, T_{ab} outputs $\langle a\rangle$ (resp. $\langle/a\rangle$) for each opening (resp. closing) input tag, effectively relabelling the input string to consist exclusively of a-labelled tags. In state a_2, T_{ab} inserts into the output string an arbitrary number of opening $\langle a\rangle$ tags, for which a matching number of $\langle/a\rangle$ tags are inserted in state f before T_{ab} accepts. The behaviour of T_{ab} in states b_1 and b_2 is analogous, but outputs consist only of b-labelled tags. Altogether, T_{ab} chooses nondeterministically some $x \in \{a, b\}$, relabels all tags of a well-nested input string into x-labelled tags and then appends a string of the form $\langle x\rangle^n \langle/x\rangle^n$.

The *image* $T(w)$ of a well-nested string $w \in \mathrm{NW}(\Sigma)$ under T is the set of all outputs of T on w according to some accepting run of T on w. This definition extends to sets of input strings in the natural way: For a set $S \subseteq \mathrm{NW}(\Sigma)$, we define $T(S) = \bigcup_{w \in S} T(w)$. The

[1] These three conditions make NWT roughly correspond to *synchronized visibly pushdown transducers* [8]; we mainly require them to ensure closure of regular nested word languages under NWT transduction.

domain $\mathcal{D}(T)$ of T is the set of all strings w such that $T(w) \neq \emptyset$, and the *range* $\mathcal{R}(T)$ of T is the set of all strings u such that there exists a $w \in \mathrm{NW}(\Sigma)$ with $u \in T(w)$, i.e. the set of all possible outputs of T.

We next define several restrictions on the expressiveness of NWT.

▶ **Definition 3.3.** Let $T = (Q, P, P_\epsilon, \Sigma, \delta, q_0, F)$ be a NWT. We call T

- *ϵ-free* if $P_\epsilon = \emptyset$ and δ contains no ϵ-transitions.
- *non-deleting* if the output component of every non-internal transition in δ is a non-empty string;
- *deterministic* (or a DNWT) if for every $q \in Q, p \in P$ and $a \in \Sigma$, it holds that $|\delta(q, \langle a\rangle)| = |\delta(q, p, \langle /a\rangle)| = 1$;
- a *relabelling* transducer if it is ϵ-free and for every $q, q' \in Q, p \in P$, $a \in \Sigma$ and $u \in \Sigma^*$, if $(q', p, u) \in \delta(q, \langle a\rangle)$, then $u \in \langle\Sigma\rangle$, and if $(q', u) \in \delta(q, p, \langle /a\rangle)$, then $u \in \langle /\Sigma\rangle$;
- *functional*, if for every $w \in \mathrm{NW}(\Sigma)$, it holds that $|T(w)| = 1$.

It is easy to see that the length of any output of an ϵ-free NWT is at most linear in the length of the input string, while outputs of general NWT may grow to an arbitrary length. We note that functionality, unlike the other restrictions defined here, is a *semantic* condition. We do not investigate in this paper the decidability or complexity of determining whether a NWT is functional; likely, techniques for Visibly Pushdown Transducers in [5] could be adapted for this purpose. Also, while determinism implies functionality, the converse does not hold.

The following lemma shows that we can assume without loss of generality that each transition of a NWT involves at most one input and at most one output symbol, i.e. each opening (closing) transition outputs at most one opening (closing) tag and each internal ϵ-transition outputs nothing.

▶ **Lemma 3.4.** *Each NWT $T = (Q, P, P_\epsilon, \Sigma, \delta, q_0, F)$ can be transformed in polynomial time into an NWT $T' = (Q', P', P'_\epsilon, \Sigma, \delta', q_0, F)$ with $T(w) = T'(w)$ for each $w \in NW(\Sigma)$, such that for any transition in δ' with output u, it holds that $|u| \leq 1$.*

We say that a NWT of this shape is in normal form.

In most of this paper, we restrict our attention to non-deleting transducers. This is because regular nested word languages are closed under transduction by non-deleting NWT, which does not hold in the presence of deletions (consider, for instance, a NWT deleting all matched opening and closing c-labelled tags on the regular input language $\{(\langle a\rangle\langle /a\rangle\langle c\rangle)^n(\langle /c\rangle\langle b\rangle\langle /b\rangle)^n \mid n \geq 0\}$). The practical motivation for desiring this property is the fact that the AXML setting assumes that function call results can be specified by standard XML schema languages, which are subclasses of regular nested word languages.

Moreover, for most of the transducer models examined here, non-deleting transducers are not a significant restriction when it comes to context-free games, as the following result states.

▶ **Lemma 3.5.** *Any context-free game $G = (\Sigma, \Gamma, R, T)$ with NWT R can be transformed in polynomial time into a game $G' = (\Sigma', \Gamma, R', T')$ such that R' is non-deleting and it holds that $JWin(G') \cap NW(\Sigma) = JWin(G)$.*

Using Lemma 3.4, it is comparatively easy (if tedious) to prove that non-deleting NWTs are closed under composition. This proof, like most proofs for properties of NWT in this section, follows proof ideas used in [5, 8] adapted to the specifics of NWT.

▶ **Proposition 3.6.** *Let T_1, T_2 be non-deleting NWT. Then there exists a non-deleting NWT T such that for all $w \in NW(\Sigma)$, it holds that $T(w) = (T_2 \circ T_1)(w) \overset{def}{=} T_2(T_1(w))$. This NWT T can be computed from T_1 and T_2 in polynomial time and is of size $\mathcal{O}(|T_1| \cdot |T_2|)$.*

Since we are solely interested in NWTs operating on well-nested strings, we restrict our attention to NWTs with well-nested domains. The following corollary to Proposition 3.6 justifies this restriction.

▶ **Corollary 3.7.** *Let T be a non-deleting NWT and A a NWA over alphabet Σ. Then, there exists a non-deleting NWT T' of size $\mathcal{O}(|T| \cdot |A|)$ such that $\mathcal{D}(T') = \mathcal{D}(T) \cap L(A)$ and $T'(w) = T(w)$ for each $w \in \mathcal{D}(T) \cap L(A)$.*

In order to prove closure of regular nested word languages under transduction by non-deleting NWT, we observe another helpful property of these transducers.

▶ **Lemma 3.8.** *Let T be a non-deleting NWT with $\mathcal{D}(T) \subseteq NW(\Sigma)$. Then $\mathcal{R}(T)$ is a regular language of nested words.*

▶ **Corollary 3.9.** *Regular nested word languages are closed under transduction by non-deleting NWT, i.e. if $L \subseteq NW(\Sigma)$ is regular and T an NWT, then $T(L)$ is regular.*

We now turn to the complexity of standard decision problems for NWT. The upper bounds use relatively simple constructions based on Proposition 3.6, while lower bounds follow from comparable results for NWA.

▶ **Theorem 3.10.** *The membership problem for non-deleting NWT (Given a non-deleting NWT T and strings $w, u \in NW(\Sigma)$, is $u \in T(w)$?) is in* PTIME.

▶ **Theorem 3.11.** *The nonemptiness problem for non-deleting NWT (Given a non-deleting NWT T, is there a string $w \in NW(\Sigma)$ with $T(w) \neq \emptyset$?) is* PTIME*-complete with regard to logspace reductions.*

▶ **Theorem 3.12.** *The type checking problem for non-deleting NWT (Given a non-deleting NWT T and NWA A_1, A_2, is $T(L(A_1)) \subseteq L(A_2)$?) is*
(a) EXPTIME*-complete in general, and*
(b) PTIME*-complete (w.r.t. logspace reductions) if A_2 is a DNWA.*

4 Games with general NWT replacement

Having laid the foundation with basic results on NWT, we now examine context-free games with NWT-based replacement. The main characteristic distinguishing general NWT from ϵ-free NWT is the fact that, for any input string w and NWT T, transducts in $T(w)$ may be arbitrarily large in the size of w. This behaviour is necessary if we want to simulate games with regular replacement languages (in the sense of [10]) by transducer-based games. As it turns out, however, NWT-based replacement is much more complex than that: the winning problem in games with replay becomes undecidable (as opposed to 2-EXPTIME with regular replacement languages), which may be proven by a rather straightforward reduction from the complement of the halting problem for Turing machines.

▶ **Theorem 4.1.** *For the class of games with NWT and Call depth $k \geq 2$,* JWin *is not recursively enumerable.*

Even the replay-free winning problem for JULIET is quite hard when using NWT for replacement – we show that this problem is complete for doubly exponential time. The lower bound uses a rather intricate reduction from a two-player tiling problem, while the upper bound is proven by reduction to the purely NWT-based problem of *alternating iterated transduction*, which can be proven to be in 2-EXPTIME.

▶ **Theorem 4.2.** *For the class of replay-free games with NWT,* JWIN *is* 2-EXPTIME-*complete.*

The lower bound proofs for both of these results require replacement transducers to output nested words of arbitrary depth. Considering our practical motivation, it is rarely required that function calls in Active XML documents return arbitrarily deep trees. Therefore, we now investigate the impact of limiting replacement transducers' output depth.

For simplicity's sake, we assume depth-boundedness as a *semantic* restriction, i.e. we assert that all outputs in $R(w)$ produced by a depth-bounded replacement transducer R on a string w obey a given upper bound on their depth, without examining the decidability and complexity of determining whether or not a given transducer is depth-bounded.

We note that NWT with an output depth linear in the size of the input string are already strictly more expressive than ϵ-free NWT, so the lower bounds from Section 5 also hold for NWT with linear output depth. As these lower bounds are already quite high, we focus only on transducers whose output depth is bounded by a constant.

▶ **Definition 4.3.** An NWT R is called *depth-bounded* if there is some constant $d \geq 0$ such that for any $w \in \mathrm{NW}(\Sigma)$ and any $w' \in R(w)$, the depth of w' is at most d.

Using depth-bounded NWT as replacement transducers places the complexity of the winning problem between those for general NWT and for ϵ-free NWT. The upper and lower bounds are proven similarly to those of Theorem 4.2, but use the fact that the stack size of a depth-bounded NWT on a fixed input is bounded by a constant.

▶ **Theorem 4.4.** *For the class of replay-free games with depth-bounded NWT,* JWIN *is* EXPSPACE-*complete.*

5 Games with ϵ-free NWT replacement

In this section, we examine context-free games with replacement relations given by ϵ-free NWT. As we shall see, this leads to a decidable winning problem for games with bounded replay, but non-elementary complexity in all but the easiest case. For the unbounded replay case, we can construct a rather straightforward reduction from the halting problem for TMs.

▶ **Theorem 5.1.** *For the class of games with ϵ-free NWT and unbounded replay,* JWIN *is undecidable.*

Different from games with general NWT, the winning problem for JULIET in games with ϵ-free NWT and fixed Call depth is decidable; however, the complexity of deciding JWIN is already non-elementary for Call depth 2.

▶ **Theorem 5.2.** *For the class of games with ϵ-free NWT and Call depth bounded by $d \geq 2$,* JWIN *is decidable, but not decidable in elementary time.*

Even for replay-free games with ϵ-free NWT, the complexity of deciding the winning problem for JULIET is still rather high. The lower bound is proven by reduction from a tiling problem, and the CO-NEXPTIME algorithm uses non-determinism to guess moves for ROMEO while trying out all possible strategies for JULIET by backtracking.

▶ **Theorem 5.3.** *For the class of replay-free games with ϵ-free NWT,* JWin *is complete for* co-NEXPTIME*.*

The non-elementary lower bound in Theorem 5.2 follows from the fact that, in each string returned by Romeo, Juliet may play Call arbitrarily often. On a return string corresponding to a path of length n, Juliet may play Call on all n nodes bottom-up, with each such Call doubling the number of nodes below the called node, inducing a non-elementary blow-up.

To avoid this, we now examine games with bounded *Call width*, where, intuitively, Juliet may only play Call for a bounded number of times in each replacement string given by Romeo. Note that Call width is counted within each individual replacement string – so, in a game of Call depth 3 and Call width c, if Juliet plays Call on some position of the input string, she may then place up to c calls within the string returned by Romeo, and again up to c calls in *each* of the depth-2 replacement strings resulting from those calls.

More formally, the Call width of a play Π is the maximum number of times Juliet plays Call in any replacement string given by Romeo in Π. This definition extends naturally into that of Call width of a strategy. Note that Call width only applies to *replacement* strings, so Juliet may still call arbitrarily many positions of the *input* string, even for games with Call width 0. For this reason, replay-free strategies always have bounded Call width.

The proof of Theorem 5.1 shows that JWin remains undecidable for games with unbounded Call depth, even with Call width bounded by 1. For bounded replay, though, the complexity of JWin collapses to that of the replay-free case if Call width is bounded.

▶ **Theorem 5.4.** *For the class of games with ϵ-free NWT, Call depth bounded by $d \geq 1$ and Call width bounded by $k \geq 1$,* JWin *is* co-NEXPTIME*-complete.*

As mentioned above, bounded Call width does not affect Juliet's options for Call moves on the input string, as we generally want Juliet to be able to at least process *all* function symbols in the input. Dropping this requirement (i.e. bounding *Call width including input*) yields at least an exponential improvement in complexity.

▶ **Theorem 5.5.** *For the class of games with ϵ-free NWT, Call depth bounded by d and Call width including input bounded by k,* JWin *is*

(a) co-NP*-complete for $d \geq 1$ and $k \geq 2$,*
(b) co-NP*-complete for $d \geq 2$ and $k \geq 1$, and*
(c) *in* PTIME *for $d = k = 1$.*

The upper bounds in Theorems 5.4 and 5.5 use a backtracking algorithm like the one for Theorem 5.3; in this case, however, bounded Call width reduces the size of both the decision tree for Juliet and the occurring replacement strings.

6 Games with relabelling replacement

As seen before, even the limited amount of insertion allowed by ϵ-free NWT renders the winning problem for Juliet quite complex. We now examine how this changes if we disallow insertion entirely. First, we show that the winning problem is greatly simplified by the fact that transducts of relabelling transducers do not require any additional space beyond that provided by the input. In fact, the upper bounds of Theorems 6.1 to 6.4 all use a nigh-trivial (alternating or nondeterministic) algorithm that simply simulates the game. Lower bounds, on the other hand, are proven by reduction from the word problem for linearly bounded (alternating) Turing machines (Theorems 6.1 and 6.3) and from standard logic-based problems (Theorems 6.2 and 6.4).

▶ **Theorem 6.1.** *For the class of games with relabelling transducers and unbounded replay,* JWin *is* EXPTIME*-complete.*

With limited or no replay, the complexity decreases even further.

▶ **Theorem 6.2.** *For any $k \geq 1$, for the class of games with relabelling transducers and bounded Call depth k,* JWin *is* PSPACE*-complete.*

As the winning problem for Juliet remains intractable (assuming PTIME $\neq$ PSPACE) for replay-free games with relabelling transducers, we now turn to the even more limited class of functional relabellings. Note that games with functional transducers are essentially "solitaire games" for Juliet, as they do not allow for any choice of transducts by Romeo.

▶ **Theorem 6.3.** *For the class of games with functional relabelling transducers and unbounded replay,* JWin *is* PSPACE*-complete.*

As for general relabelling transducers, the complexity of JWin is the same for games with bounded replay and no replay when restricted to functional relabelling transducers.

▶ **Theorem 6.4.** *For any $k \geq 1$, for the class of games with functional relabelling transducers and bounded Call depth k,* JWin *is* NP*-complete.*

We see that even in this very simple class of games, we still fail to obtain a PTIME upper bound. Careful examination of lower bound proofs shows that our semantics for replay-free games still allows for a sort of "hidden replay": On a string of the form $\langle a\rangle\langle b\rangle v\langle /b\rangle\langle /a\rangle$, if Juliet plays Call first on $\langle /b\rangle$ then on $\langle /a\rangle$, the substring v undergoes *two* transductions – one from the Call to $\langle /b\rangle$, another from the Call to $\langle /a\rangle$. This allows us to perform any number d of transductions on a given string by enclosing it inside d nested function symbols.

Excluding this hidden replay yields a very narrow restriction of context-free games, which we call *write-once* games. In these, no substring may be transduced more than once, i.e. Juliet may only play Call on any closing tag $\langle /a\rangle$ if the substring enclosed in it does not contain a substring on which Juliet has played Call before. Note that write-once games are always replay-free, but even weaker as far as Juliet's rewriting capabilities are concerned.

A slight adaptation of the proof of Theorem 6.2 shows that JWin remains PSPACE-hard for write-once games with arbitrary relabelling transducers; for functional (and deterministic) relabelling transducers, however, we can prove tractability. The proof constructs from a given game G a NWT R_{J} such that for each $w \in \text{NW}(\Sigma)$, the set of all strings into which Juliet way rewrite w in G is given by $R_{\text{J}}(w)$.

▶ **Theorem 6.5.** *For the class of write-once games with functional relabelling transducers,* JWin *is in* PTIME*.*

7 Conclusion

The research presented in this paper shows that a major challenge in using transducers for context-free games is finding sensible transducer models and strategy restrictions that do not cause a prohibitive increase in the complexity of the winning problem compared to context-free games without parameter transformation. This paper has made a first step towards identifying what suitable restrictions may look like; however, the few tractable cases identified here are still so restricted that they may be only of limited practical interest.

It is possible that the complexity of the winning problem in games with replacement transducers may be further reduced by restricting relevant schemas to be closer to practical schema specifications for XML (such as DTDs or XML Schema). However, since research in [10] indicates that specifications of input schemas for external services influence the complexity of the safe rewriting problem, further research might be necessary to find transducer models whose input and output schemas can be described by DTDs or XML Schema.

Abstract

The decision problems on matrices were intensively studied for many decades as matrix products play an essential role in the representation of various computational processes. However, many computational problems for matrix semigroups are inherently difficult to solve even for problems in low dimensions and most matrix semigroup problems become undecidable in general starting from dimension three or four.

This paper solves two open problems about the decidability of the vector reachability problem over a finitely generated semigroup of matrices from $\mathrm{SL}(2,\mathbb{Z})$ and the point to point reachability (over rational numbers) for fractional linear transformations, where associated matrices are from $\mathrm{SL}(2,\mathbb{Z})$. The approach to solving reachability problems is based on the characterization of reachability paths between points which is followed by the translation of numerical problems on matrices into computational and combinatorial problems on words and formal languages. We also give a geometric interpretation of reachability paths and extend the decidability results to matrix products represented by arbitrary labelled directed graphs. Finally, we will use this technique to prove that a special case of the scalar reachability problem is decidable.

1 Introduction

Decision problems on matrices were intensively studied from 1947 when A. Markov showed the connection between classical computations and problems for matrix semigroups [24]. Moreover matrix products play an essential role in the representation of various computational processes, i.e., linear recurrent sequences [18, 27, 28], arithmetic circuits [14], hybrid and dynamical systems [26, 3], probabilistic and quantum automata [7], stochastic games, broadcast protocols [13], optical systems, etc. New algorithms for solving reachability problems in matrix semigroups can be incorporated into software verification tools and used for analysis of mathematical models in physics, chemistry, biology, ecology, and economics.

However, many computational problems for matrix semigroups are inherently difficult to solve even when the problems are considered in dimension two, and most of these problems become undecidable in general starting from dimension three or four. Examples of such problems are the Membership problem (including the special cases of the Mortality and

[*] This work was supported by EPSRC grant "Reachability problems for words, matrices and maps" (EP/M00077X/1).

Identity problems), vector reachability, scalar reachability, freeness problem and the emptiness problem of matrix semigroups intersection [6]. All above problems are tightly connected, including three central problems:

- **The membership problem:** Let $S = \langle G \rangle$ be a semigroup generated by a finite set G of $n \times n$ matrices. Determine whether a given matrix M belongs to S, that is, determine whether there exists a sequence of matrices $M_1, M_2, \ldots, M_k$ in G such that $M = M_1 \cdot M_2 \cdot \ldots \cdot M_k$
- **The vector reachability problem:** Let $\mathbf{x}$ and $\mathbf{y}$ be two vectors and S be a given finitely generated semigroup of $n \times n$ matrices. Determine whether there is a matrix $M \in S$ such that $M\mathbf{x} = \mathbf{y}$.
- **The scalar reachability problem:** Let $\mathbf{x}$ and $\mathbf{y}$ be two vectors, λ be a scalar, and S be a given finitely generated semigroup of $n \times n$ matrices. Determine whether there is a matrix $M \in S$ such that $\mathbf{x}^\top M\mathbf{y} = \lambda$.

The vector reachability problem can be seen as a parameterized version of the membership problem, where some elements of a matrix M are either independent variables or variables linked by some equations. In contrast to the original membership problem, where all values of M are constants, in vector reachability we may have an infinite set of matrices that can transform a vector $\mathbf{x}$ to $\mathbf{y}$. Thus the decidability results for the membership cannot be directly applied to the vector reachability problem.

The scalar reachability can be viewed as a vector to hyperplane reachability problem. Indeed, we can rewrite the equation $\mathbf{x}^\top M\mathbf{y} = \lambda$ as a system of two equations: $M\mathbf{y} = \mathbf{z}$ and $\mathbf{x}^\top\mathbf{z} = \lambda$. So, the question becomes if there is a matrix $M \in S$ that maps a given vector $\mathbf{y}$ to a vector $\mathbf{z}$ that lies on a hyperplane $\mathbf{x}^\top\mathbf{z} = \lambda$. Because there are infinitely many vectors on a hyperplane, decidability of the scalar reachability problem does not follow directly from the decidability of the vector reachability problem.

Most of the problems such as membership, vector reachability and freeness are undecidable for 3×3 integer matrices. The undecidability proofs in matrix semigroups are mainly based on various techniques and methods of embedding universal computations into three and four dimensional matrices and their products. The case of dimension two is the most intriguing one since there is some evidence that if these problems are undecidable, then this cannot be proved using a construction similar to the one used for dimensions 3 and 4. In particular, there is no injective semigroup morphism from pairs of words over any finite alphabet (with at least two elements) into complex 2×2 matrices [8], which means that the coding of independent pairs of words in 2×2 complex matrices is impossible and the exact encoding of the Post Correspondence Problem or a computation of a Turing Machine cannot be used directly for proving undecidability in 2×2 matrix semigroups over $\mathbb{Z}$, $\mathbb{Q}$ or $\mathbb{C}$. The only undecidability result in dimension two for the vector reachability and the membership problems has been shown in the case of 2×2 matrices over quaternions [4].

The main hypothesis is that problems for 2×2 matrix semigroups over integers, rationals or complex numbers could be decidable, but not much is known about the status of these problems. Recently, there was some progress on the *Membership problem*, which was shown to be decidable in $\mathrm{SL}(2,\mathbb{Z})$, and the *Identity problem*, which was shown to be decidable in $\mathbb{Z}^{2\times 2}$ [11]. Later the decidability of the *Freeness problem* (that is, to decide whether each element can be expressed uniquely as a product of generating matrices) was shown for $\mathrm{SL}(2,\mathbb{Z})$ [9]. On the other hand, the Mortality, Identity and vector reachability problems were shown to be at least NP-hard for $\mathrm{SL}(2,\mathbb{Z})$ in [5, 6], but for the modular group the membership was shown to be decidable in polynomial time by Gurevich and Schupp [16].

The algorithmic properties of $\mathrm{SL}(2,\mathbb{Z})$ are important in the context of many fundamental problems in hyperbolic geometry [34, 10, 12], dynamical systems [29], Lorenz/modular knots [22], braid groups [30], particle physics, high energy physics [33], M/string theories [15], ray tracing analysis, music theory [25] and can lead to further decidability results in $\mathbb{Z}^{2\times 2}$ using matrix presentation in the Smith normal form.

This paper solves two open problems about the decidability of the vector reachability problem for finitely generated semigroups of matrices from $\mathrm{SL}(2,\mathbb{Z})$ and the point to point reachability (over rational numbers) for fractional linear transformations $f_M(x) = \frac{ax+b}{cx+d}$, where the associated matrix $M = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ belongs to $\mathrm{SL}(2,\mathbb{Z})$. The approach to solving these reachability problems for 2×2 matrix semigroups is based on the analysis of reachability paths between vectors or points. This analysis is then used to translate the numerical reachability problems into computational problems on words and regular languages. We also present several extensions of our main results, give a geometric interpretation of reachability paths, and use this technique to solve a special case of the scalar reachability problem.

The decidability proof of the vector reachability problem in dimension two presented in this paper is the first nontrivial new result for solving vector reachability problems since 1996 when it was shown that the problem is decidable for any commutative matrix semigroup in any dimension [1] and for a special case of non-commuting matrices [20]. On the other hand, in the general case of non-commuting matrices the problem is known to be undecidable already for integer matrices in dimension three [17].

2 Preliminaries

The integers and rationals are denoted by $\mathbb{Z}$ and $\mathbb{Q}$, respectively, and $\mathrm{SL}(2,\mathbb{Z})$ is a group of 2×2 integer matrices with determinant 1. The notation $a \mid b$ means that a divides b, and $a \nmid b$ means that a does not divide b, when a and b are integer numbers.

▶ **Definition 1.** With each matrix $M = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathrm{SL}(2,\mathbb{Z})$ we associate a fractional linear map (also called Möbius transformation) $f_M : \mathbb{Q} \to \mathbb{Q}$ defined as $f_M(x) = \frac{ax+b}{cx+d}$. This definition can be extended to $f : \mathbb{Q}\cup\{\infty\} \to \mathbb{Q}\cup\{\infty\}$ in a natural way by setting $f_M(\infty) = \frac{a}{c}$ if $c \neq 0$, $f_M(\infty) = \infty$ if $c = 0$, and $f_M(x) = \infty$ if $cx + d = 0$.

Note that we have $f_{M_1} \circ f_{M_2} = f_{M_1 M_2}$ for any matrices M_1 and M_2.

Let $M_1, \dots, M_n$ be a finite collection of matrices. Then $\langle M_1, \dots, M_n\rangle$ denotes the multiplicative semigroup (including the identity matrix) generated by $M_1, \dots, M_n$.

▶ **Definition 2.** The *vector reachability problem* in $\mathrm{SL}(2,\mathbb{Z})$ is defined as follows: Given two vectors $\mathbf{x}$ and $\mathbf{y}$ with integer coefficients and a finite collection of matrices $M_1, \dots, M_n$ from $\mathrm{SL}(2,\mathbb{Z})$, decide whether there exists a matrix $M \in \langle M_1, \dots, M_n\rangle$ such that $M\mathbf{x} = \mathbf{y}$.

▶ **Definition 3.** The *reachability problem by fractional linear transformations* in $\mathrm{SL}(2,\mathbb{Z})$ is defined as follows: Given two rational numbers x and y and a finite collection of matrices $M_1, \dots, M_n$ from $\mathrm{SL}(2,\mathbb{Z})$, decide whether there exists a matrix $M \in \langle M_1, \dots, M_n\rangle$ such that $f_M(x) = y$.

The main result of our paper is that the vector reachability problem and the reachability problem by fractional linear transformations for $\mathrm{SL}(2,\mathbb{Z})$ are decidable (Theorem 14). Both proofs follow the same pattern. We will use the fact that any matrix M from $\mathrm{SL}(2,\mathbb{Z})$ can be expressed as product of matrices $S = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$ and $R = \begin{bmatrix} 0 & -1 \\ 1 & 1 \end{bmatrix}$. So we can represent any $M \in \mathrm{SL}(2,\mathbb{Z})$ by a word w in the alphabet $\Sigma = \{S, R\}$.

The main idea of the proof is to show that the solution set of the equation $M\mathbf{x} = \mathbf{y}$ has the form $\left\{ B \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}^t C \;:\; t \in \mathbb{Z} \right\}$, where B and C are some matrices from $\mathrm{SL}(2,\mathbb{Z})$ that can be computed in PTIME from $\mathbf{x}$, $\mathbf{y}$ (Theorem 8). Similarly, the solution set of the equation $f_M(x) = y$ can be presented as a union of two sets of such form (Theorem 10). After translating matrices into words, these sets become regular languages. On the other hand, the language that corresponds to the semigroup $\langle M_1, \dots, M_n \rangle$ is also regular. Indeed, if M_i corresponds to the word w_i, then the semigroup $\langle M_1, \dots, M_n \rangle$ translates into the language $(w_1 + \dots + w_n)^*$. The last step of the proof is to show that the emptiness problem of the intersection of two such languages is decidable (Proposition 13).

Here is a more detailed description of our proofs. Let $M = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$, $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ and $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$. To show that the equation $M\mathbf{x} = \mathbf{y}$ defines a regular language we must solve the following system of three equations in four unknown variables:

$$x_1 a + x_2 b = y_1 \qquad x_1 c + x_2 d = y_2 \qquad ad - bc = 1$$

Choosing b as a free parameter, we can reduce it to the following system of linear congruence equations:

$$x_2 b \equiv y_1 \pmod{x_1} \qquad y_2 b \equiv -x_1 \pmod{y_1} \qquad x_2 y_2 b \equiv y_1 y_2 - x_1 x_2 \pmod{x_1 y_1}$$

It can be shown that the above system either has no solutions or it has a solution of the form $b = b_1 t + b_2$, where $t \in \mathbb{Z}$, and hence all coefficients of the matrix M are linear functions of t. In Proposition 7 we will show that such matrices can be written in the form $M = B \begin{bmatrix} 1 & k \\ 0 & 1 \end{bmatrix}^t C$, where B, C are some matrices from $\mathrm{SL}(2,\mathbb{Z})$, k is a fixed integer number and $t \in \mathbb{Z}$ is a free parameter. After that it is not hard to see that such solution translates into a regular language.

We will use a similar approach to prove that the equation $f_M(x) = y$ also defines a regular language. In fact, we will do it by showing that the solution set of $f_M(x) = y$ is equal to the union of the solution sets of the equations $M\mathbf{x} = \mathbf{y}$ and $M\mathbf{x} = -\mathbf{y}$ for suitable vectors $\mathbf{x}$ and $\mathbf{y}$.

The final step is to show that there is an algorithm that decides whether the intersection of two regular subsets of $\mathrm{SL}(2,\mathbb{Z})$ is empty or not. Our idea relies on the fact that the intersection of two regular languages is regular, and that the emptiness problem for regular languages is decidable. The problem here is that we cannot apply these facts directly because for each matrix $M \in \mathrm{SL}(2,\mathbb{Z})$ there are infinitely many words $w \in \{S, R\}^*$ that correspond to M, and only some of them may appear in the given language. However there is only one *reduced* word that corresponds to M, that is, the word that does not have a substring of the form SS or RRR. So, our solution is to take any automaton $\mathcal{A}$ and turn it into a new automaton $\widetilde{\mathcal{A}}$ that accepts the same language as $\mathcal{A}$ plus all reduced words w that correspond to non-reduced words w' accepted by $\mathcal{A}$.

The construction of the automaton $\widetilde{\mathcal{A}}$ was inspired by a similar construction from [11]. Note that in $\mathrm{SL}(2,\mathbb{Z})$ we have an equality $S^2 = R^3 = -I$. Thus to construct $\widetilde{\mathcal{A}}$ we add to $\mathcal{A}$ a new ε-transition from a state q_1 to a state q_2 if there is a run of $\mathcal{A}$ from q_1 to q_2 labelled by SS or RRR. We will apply this procedure iteratively until no new ε-transitions can be added. However we need to keep track of sign changes when we add new ε-transitions. To achieve this we will use *signed automata*, which are slight modifications of the usual finite automata but they take into account such sign changes.

Now to solve the emptiness problem for the intersection of two regular languages L_1 and L_2, we take the signed automata $\mathcal{A}_1$ and $\mathcal{A}_2$ that accept L_1 and L_2, respectively, and construct new automata $\widetilde{\mathcal{A}}_1$ and $\widetilde{\mathcal{A}}_2$ as described above. After that we can check whether $L(\widetilde{\mathcal{A}}_1) \cap L(\widetilde{\mathcal{A}}_2) \neq \emptyset$.

In the Section 4 we will show how to extend these decidability results to arbitrary regular subsets of $\mathrm{SL}(2,\mathbb{Z})$, i.e., subsets that are defined by finite automata. Using this technique we will show how to algorithmically solve the equation $M_1^{x_1} \cdots M_k^{x_k}\mathbf{x} = N_1^{y_1} \cdots N_l^{y_l}\mathbf{y}$, where $\mathbf{x}, \mathbf{y}$ are given vectors from $\mathbb{Z} \times \mathbb{Z}$, the matrices $M_1, \dots, M_k$ and $N_1, \dots, N_l$ are from $\mathrm{SL}(2,\mathbb{Z})$, and $x_1, \dots, x_k$ and $y_1, \dots, y_l$ are unknown non-negative integers. Furthermore, we will show how to apply this method to prove that a special case of the scalar reachability problem is decidable.

All missing proofs can be found in the extended version of this paper, which is available online on arXiv.org [31].

3 Main results

The characterization of the solution set of the equation $M\mathbf{x} = \mathbf{y}$ given in Theorem 8 will follow from Propositions 5 and 7. First, we prove one simple lemma which we will use several times in our arguments.

▶ **Lemma 4.** *Let* $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ *and* $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$ *be vectors from* $\mathbb{Z} \times \mathbb{Z}$ *and* M *be a matrix from* $\mathrm{SL}(2,\mathbb{Z})$ *such that* $M\mathbf{x} = \mathbf{y}$. *Then* $\gcd(x_1, x_2) = \gcd(y_1, y_2)$.

Proof. Take any $k \in \mathbb{Z}$ such that $k \mid x_1, x_2$ and let $M = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$. Then from $M\mathbf{x} = \mathbf{y}$ we have $y_1 = ax_1 + bx_2$ and $y_2 = cx_1 + dx_2$. Thus $k \mid y_1, y_2$. Now since $M \in \mathrm{SL}(2,\mathbb{Z})$, M^{-1} is also in $\mathrm{SL}(2,\mathbb{Z})$, and $M\mathbf{x} = \mathbf{y}$ is equivalent to $M^{-1}\mathbf{y} = \mathbf{x}$. So, if $k \in \mathbb{Z}$ is any number such that $k \mid y_1, y_2$, then $k \mid x_1, x_2$. Therefore, $\gcd(x_1, x_2) = \gcd(y_1, y_2)$. ◀

▶ **Proposition 5.** *Let* $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ *and* $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$ *be two vectors from* $\mathbb{Z} \times \mathbb{Z}$, *such that* $\mathbf{x}$ *is not equal to the zero vector* $\mathbf{0}$, *and consider the matrix equation* $M\mathbf{x} = \mathbf{y}$, *where* M *is an unknown matrix from* $\mathrm{SL}(2,\mathbb{Z})$. *Then either this equation does not have a solution or all its solutions are given by* $M = tA_1 + A_2$, *where* t *is any integer number,* A_1, A_2 *are some matrices from* $\mathbb{Z}^{2\times 2}$ *such that* A_1 *is a nonzero matrix. Moreover, there is a polynomial time algorithm that determines whether such an equation has a solution and if so, finds it.*

Proof. See Section A of the Appendix in [31]. ◀

For the next proposition we will need the following theorem about the Smith normal form of a matrix.

▶ **Theorem 6** (Smith normal form [19])**.** *For any nonzero matrix* $A \in \mathbb{Z}^{2\times 2}$, *there are matrices* B, C *from* $\mathrm{SL}(2,\mathbb{Z})$ *such that* $A = B\begin{bmatrix} t_1 & 0 \\ 0 & t_2 \end{bmatrix}C$ *for some* $t_1, t_2 \in \mathbb{Z}$ *such that* $t_1 \neq 0$ *and* $t_1 \mid t_2$. *Moreover,* B, C, t_1, t_2 *can be computed in polynomial time.*

▶ **Proposition 7.** *Let A_1 and A_2 be matrices from $\mathbb{Z}^{2\times 2}$ such that A_1 is a nonzero matrix and, for every $t \in \mathbb{Z}$, we have $tA_1 + A_2 \in \mathrm{SL}(2,\mathbb{Z})$. Then there are matrices B and C from $\mathrm{SL}(2,\mathbb{Z})$ and $k \in \mathbb{Z}$ such that*

$$tA_1 + A_2 = BT^{kt}C \quad \textit{for every } t \in \mathbb{Z},$$

where $T = \begin{bmatrix}1 & 1\\ 0 & 1\end{bmatrix} \in \mathrm{SL}(2,\mathbb{Z})$. Moreover, B, C, and k can be computed in polynomial time.

Proof. Let $A_1 = \begin{bmatrix}a_1 & b_1\\ c_1 & d_1\end{bmatrix}$ and $A_2 = \begin{bmatrix}a_2 & b_2\\ c_2 & d_2\end{bmatrix}$. By the assumption, for every $t \in \mathbb{Z}$,

$$\begin{vmatrix}a_1t + a_2 & b_1t + b_2\\ c_1t + c_2 & d_1t + d_2\end{vmatrix} = 1.$$

That is $(a_1t+a_2)(d_1t+d_2)-(b_1t+b_2)(c_1t+c_2) = 1$ or $(a_1d_1 - b_1c_1)t^2 + (a_1d_2 + a_2d_1 - b_1c_2 - b_2c_1)t + a_2d_2 - b_2c_2 = 1$ for all $t \in \mathbb{Z}$. Therefore, $a_1d_1 - b_1c_1 = 0$, $a_1d_2 + a_2d_1 - b_1c_2 - b_2c_1 = 0$, and $a_2d_2 - b_2c_2 = 1$. In particular, $\det(A_1) = 0$ and $\det(A_2) = 1$.

By Theorem 6, there are matrices $F, G \in \mathrm{SL}(2,\mathbb{Z})$ such that $A_1 = F\begin{bmatrix}k & 0\\ 0 & l\end{bmatrix}G$ for some $k, l \in \mathbb{Z}$ such that $k \mid l$. Since $\det(A_1) = 0$ we have that $kl = 0$. However if $k = 0$ and $l = 0$, then A_1 is equal to the zero matrix, contrary to the assumption. Hence we must have that $k \neq 0$ and $l = 0$.

Now $F^{-1}(tA_1 + A_2)G^{-1} = \begin{bmatrix}kt + a & b\\ c & d\end{bmatrix}$, for some $a, b, c, d \in \mathbb{Z}$. Note that since $\det(F) = \det(G) = \det(tA_1 + A_2) = 1$, we have $\begin{vmatrix}kt + a & b\\ c & d\end{vmatrix} = dkt + ad - bc = 1$ for every $t \in \mathbb{Z}$. Hence $dk = 0$ and so $d = 0$. Substituting $d = 0$ in the above equation, we obtain $bc = -1$. Since b and c are integers, there are only two possibilities: $b = 1$, $c = -1$, or $b = -1$, $c = 1$. So the above matrix actually looks like $F^{-1}(tA_1 + A_2)G^{-1} = \begin{bmatrix}kt + a & \mp 1\\ \pm 1 & 0\end{bmatrix}$. Therefore, $T^{-c(kt+a)}F^{-1}(tA_1 + A_2)G^{-1} = D$, where $c = \pm 1$ and $D = \begin{bmatrix}0 & \mp 1\\ \pm 1 & 0\end{bmatrix} \in \mathrm{SL}(2,\mathbb{Z})$. Hence $tA_1 + A_2 = FT^{(ck)t}T^{ca}DG$. Note that F and $T^{ca}DG$ are in $\mathrm{SL}(2,\mathbb{Z})$. This completes the proof. The bound on complexity follows from the fact that F and G can be computed in PTIME by Theorem 6. ◀

As a corollary of Propositions 5 and 7 we obtain the following theorem.

▶ **Theorem 8.** *Let $\mathbf{x} = \begin{bmatrix}x_1\\ x_2\end{bmatrix}$ and $\mathbf{y} = \begin{bmatrix}y_1\\ y_2\end{bmatrix}$ be vectors from $\mathbb{Z} \times \mathbb{Z}$ such that $\mathbf{x} \neq \mathbf{0}$, and consider the matrix equation $M\mathbf{x} = \mathbf{y}$, where M is an unknown matrix from $\mathrm{SL}(2,\mathbb{Z})$. Then either this equation does not have a solution or all its solutions are given by the following formula $M = B\begin{bmatrix}1 & k\\ 0 & 1\end{bmatrix}^t C$, where $t \in \mathbb{Z}$.*

In the above expression B and C are some matrices from $\mathrm{SL}(2,\mathbb{Z})$, and k is an integer number. Moreover, there is a polynomial time algorithm that determines whether such an equation has a solution and if so, finds the suitable matrices B, C and the integer k.

In Section 4 we will give a geometric interpretation of reachability paths (Figure 1 and Proposition 16), using which we can prove the following corollary.[1] The proof itself can be found in Section D of the Appendix in [31].

▶ **Corollary 9.** *The value of the parameter k in Theorem 8 is equal to 1.*

Theorem 8 provides us with a characterization of the matrices $M \in \mathrm{SL}(2,\mathbb{Z})$ that map vector $\mathbf{x}$ to vector $\mathbf{y}$. This characterization will be used later to prove the decidability of the vector reachability problem. We now give a similar characterization of the matrices $M \in \mathrm{SL}(2,\mathbb{Z})$ for which the fractional linear transformation f_M maps a number x to number y. In fact, we will do this by reducing the problem to finding the solutions of the equation $M\mathbf{x} = \mathbf{y}$ which we discussed above.

▶ **Theorem 10.** *Let x and y be rational numbers and let $\mathcal{F}(x,y)$ be the following set of matrices from* $\mathrm{SL}(2,\mathbb{Z})$:

$$\mathcal{F}(x,y) = \{M \in \mathrm{SL}(2,\mathbb{Z}) \ :\ f_M(x) = y\}.$$

Then $\mathcal{F}(x,y) = \mathcal{F}_1(x,y) \cup \mathcal{F}_2(x,y)$, where each $\mathcal{F}_i(x,y)$ is either empty or has the form

$$\mathcal{F}_i(x,y) = \{B_i T^t C_i \ :\ t \in \mathbb{Z}\},$$

where B_i and C_i are some matrices from $\mathrm{SL}(2,\mathbb{Z})$*. Moreover, there is a polynomial time algorithm that determines whether each $\mathcal{F}_i(x,y)$ is empty or not and in the latter case finds corresponding matrices B_i and C_i.*

Proof. Let us write the numbers x and y as $x = \frac{x_1}{x_2}$ and $y = \frac{y_1}{y_2}$, where we assume that $\gcd(x_1,x_2) = \gcd(y_1,y_2) = 1$. Consider the equation $f_M(x) = y$, where $M = \begin{bmatrix} a & b \\ c & d \end{bmatrix}$ is an unknown matrix from $\mathrm{SL}(2,\mathbb{Z})$. We can rewrite it as

$$\frac{a\frac{x_1}{x_2} + b}{c\frac{x_1}{x_2} + d} = \frac{y_1}{y_2} \quad \text{or} \quad \frac{ax_1 + bx_2}{cx_1 + dx_2} = \frac{y_1}{y_2}. \tag{1}$$

Consider the vectors $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$, $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$, and $\mathbf{z} = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix}$, where $\mathbf{z}$ is the vector with coordinates $z_1 = ax_1 + bx_2$ and $z_2 = cx_1 + dx_2$. So we have that $\mathbf{z} = M\mathbf{x}$. In this notation Equation (1) is equivalent to the fact that vector $\mathbf{z} = M\mathbf{x}$ belongs to the set $\{k\mathbf{y} \ :\ k \in \mathbb{Z}\}$.

Recall that $\gcd(x_1,x_2) = 1$ and hence, by Lemma 4, we also have that $\gcd(z_1,z_2) = 1$. Thus if $\mathbf{z} = k\mathbf{y}$ for some $k \in \mathbb{Z}$, then we must have that $k = \pm 1$. In other words, we showed that Equation (1) is equivalent to two matrix equations: $M\mathbf{x} = \mathbf{y}$ and $M\mathbf{x} = -\mathbf{y}$. So we have that $\mathcal{F}(x,y) = \mathcal{F}_1(x,y) \cup \mathcal{F}_2(x,y)$, where

$$\mathcal{F}_1(x,y) = \{M \in \mathrm{SL}(2,\mathbb{Z}) \ :\ M\mathbf{x} = \mathbf{y}\} \quad \text{and} \quad \mathcal{F}_2(x,y) = \{M \in \mathrm{SL}(2,\mathbb{Z}) \ :\ M\mathbf{x} = -\mathbf{y}\}.$$

Note that $\mathbf{x} \neq \mathbf{0}$ because $x_2 \neq 0$. Hence by Theorem 8 and Corollary 9, each $\mathcal{F}_i(x,y)$ is either empty or has the form $\mathcal{F}_i(x,y) = \{B_i T^t C_i \ :\ t \in \mathbb{Z}\}$ for some B_i and C_i from $\mathrm{SL}(2,\mathbb{Z})$ which can be computed in polynomial time. ◀

[1] Even though we use Corollary 9 in the proofs of Theorem 10 and Proposition 18, it is not essential there for proving decidability. Namely, all references to Corollary 9 in these proofs can be replaced by references to Theorem 8, at the same time replacing T with T^k where appropriate.

Now we will use signed automata to prove that the emptiness problem for the intersection of two regular subsets of $\mathrm{SL}(2,\mathbb{Z})$ is decidable.

Consider an alphabet $\Sigma = \{S, R\}$ consisting of two symbols S and R and define the mapping $\varphi : \Sigma \to \mathrm{SL}(2,\mathbb{Z})$ as follows: $\varphi(S) = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$ and $\varphi(R) = \begin{bmatrix} 0 & -1 \\ 1 & 1 \end{bmatrix}$. We can extend this mapping to the morphism $\varphi : \Sigma^* \to \mathrm{SL}(2,\mathbb{Z})$ in a natural way. The matrices $\varphi(S)$ and $\varphi(R)$ are in fact generators of $\mathrm{SL}(2,\mathbb{Z})$, so φ is surjective. We call a word $w \in \Sigma^*$ *reduced* if it does not have substrings of the form SS or RRR. In our proof we will make use of the following well-known fact.

▶ **Theorem 11** ([21, 23, 32]). *For every $M \in \mathrm{SL}(2,\mathbb{Z})$, there exists a unique reduced word $w \in \Sigma^*$ such that either $M = \varphi(w)$ or $M = -\varphi(w)$.*

▶ **Definition 12.** A *signed automaton* $\mathcal{A} = (\Sigma, Q, I, \Delta, F^+, F^-)$ is a (non-deterministic) finite automaton whose final states are divided into two (not necessarily disjoint) subsets F^+ and F^-.

A *signed language* accepted by a signed automaton $\mathcal{A}$ is a pair $L(\mathcal{A}) = (L(\mathcal{A})^+, L(\mathcal{A})^-)$, where $L(\mathcal{A})^+$ and $L(\mathcal{A})^-$ consists of the words $w \in \Sigma^*$ for which there is a run of $\mathcal{A}$ that ends in the set F^+ or F^-, respectively. Note that we do not assume that $L(\mathcal{A})^+$ and $L(\mathcal{A})^-$ are disjoint.

Let $L = (L^+, L^-)$ be a signed language, then we define a regular subset of $\mathrm{SL}(2,\mathbb{Z})$ corresponding to this language as $\varphi(L) = \{\varphi(w) : w \in L^+\} \cup \{-\varphi(w) : w \in L^-\}$.

The following proposition is an important ingredient of our main results.

▶ **Proposition 13.** *There is an algorithm that for any given regular signed languages L_1 and L_2 over the alphabet Σ, decides whether $\varphi(L_1) \cap \varphi(L_2)$ is empty or not.*

Proof. See Section B of the Appendix in [31]. ◀

We are now ready to prove our main results.

▶ **Theorem 14.** *The vector reachability problem and the reachability problem by fractional linear transformations in $\mathrm{SL}(2,\mathbb{Z})$ are decidable.*

Proof. Suppose $M_1, \dots, M_n$ is a given finite collection of matrices from $\mathrm{SL}(2,\mathbb{Z})$. Let $w_1, \dots, w_n \in \Sigma^*$ be some words, not necessarily reduced, such that $M_i = \varphi(w_i)$, for $i = 1, \dots, n$. Define the language $\mathcal{L}_{semigr}$ that corresponds to the semigroup $\langle M_1, \dots, M_n \rangle$ as $\mathcal{L}_{semigr} = (w_1 + w_2 + \cdots + w_n)^*$.

Recall that in the vector reachability problem we are given two vectors $\mathbf{x}$ and $\mathbf{y}$ from $\mathbb{Z} \times \mathbb{Z}$, and we ask if there is a matrix $M \in \langle M_1, \dots, M_n \rangle$ such that $M\mathbf{x} = \mathbf{y}$. We want to construct a regular language $\mathcal{L}^{\mathrm{vrp}}_{\mathbf{x},\mathbf{y}}$ that corresponds to these matrices.

If $\mathbf{x} = \mathbf{0}$ and $\mathbf{y} \neq \mathbf{0}$, then we set $\mathcal{L}^{\mathrm{vrp}}_{\mathbf{x},\mathbf{y}} = \emptyset$ because in this case the equation $M\mathbf{x} = \mathbf{y}$ does not have a solution. On the other hand, if $\mathbf{x} = \mathbf{0}$ and $\mathbf{y} = \mathbf{0}$, then we set $\mathcal{L}^{\mathrm{vrp}}_{\mathbf{x},\mathbf{y}} = \{S, R\}^*$ because any matrix $M \in \mathrm{SL}(2,\mathbb{Z})$ satisfies the equation $M\mathbf{0} = \mathbf{0}$.

Now assume that $\mathbf{x} \neq \mathbf{0}$. Then by Theorem 8, the matrix equation $M\mathbf{x} = \mathbf{y}$ either has no solution, or its solution has the form $\{BT^tC : t \in \mathbb{Z}\}$, where $T = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$, and B and C are some matrices from $\mathrm{SL}(2,\mathbb{Z})$. Moreover, B and C can be computed from $\mathbf{x}$ and $\mathbf{y}$ in PTIME. In the case when $M\mathbf{x} = \mathbf{y}$ has no solution, we set $\mathcal{L}^{\mathrm{vrp}}_{\mathbf{x},\mathbf{y}} = \emptyset$. If the solution set in non-empty, then we can rewrite it as

$$\{BT^tC : t \in \mathbb{Z}\} = \{BT^tC : t \geq 0\} \cup \{BT^{-t}C : t \geq 0\}.$$

Let u and v be words from Σ^* such that $B = \varphi(u)$ and $C = \varphi(v)$. It is easy to check that $T = \varphi(S^3R)$ and $T^{-1} = \varphi(R^5S)$. Hence $\mathcal{L}^{\text{vrp}}_{\mathbf{x},\mathbf{y}} = u(S^3R)^*v + u(R^5S)^*v$ is a regular language that describes the solutions of the equation $M\mathbf{x} = \mathbf{y}$ in $\mathrm{SL}(2,\mathbb{Z})$.

In a similar way we can construct a regular language $\mathcal{L}^{\text{flt}}_{x,y}$ that corresponds to the reachability problem by fractional linear transformations from x to y. By Theorem 10, the set $\mathcal{F}(x,y)$ of matrices from $\mathrm{SL}(2,\mathbb{Z})$ that satisfy the equation $f_M(x) = y$ is equal to $\mathcal{F}(x,y) = \mathcal{F}_1(x,y) \cup \mathcal{F}_2(x,y)$, where each $\mathcal{F}_i(x,y)$ is either empty or has the form $\mathcal{F}_i(x,y) = \{B_iT^tC_i : t \in \mathbb{Z}\}$, where T is as above, and B_i and C_i are some matrices from $\mathrm{SL}(2,\mathbb{Z})$. All these matrices can be computed in PTIME from x and y.

We define $\mathcal{L}^{\text{flt}}_{x,y}$ as the union $\mathcal{L}^{\text{flt}}_{x,y} = \mathcal{L}_1 \cup \mathcal{L}_2$ of two regular languages $\mathcal{L}_1$ and $\mathcal{L}_2$. If $\mathcal{F}_i(x,y)$ is empty, then we set $\mathcal{L}_i = \emptyset$. Otherwise, let u_i and v_i be words from Σ^* such that $B_i = \varphi(u_i)$ and $C_i = \varphi(v_i)$. Then we can define $\mathcal{L}_i$ as $\mathcal{L}_i = u_i(S^3R)^*v_i + u_i(R^5S)^*v_i$. Thus we defined a regular language $\mathcal{L}^{\text{flt}}_{x,y}$ that corresponds the solution set of the equation $f_M(x) = y$ in $\mathrm{SL}(2,\mathbb{Z})$.

We remind that in Proposition 13 we work with signed languages. Therefore, in what follows we convert every regular language L that we have constructed so far into a corresponding signed language $(L, \emptyset)$.

Finally, the vector reachability problem for $\mathbf{x}$ and $\mathbf{y}$ has a solution if and only if

$$\varphi\big((\mathcal{L}^{\text{vrp}}_{\mathbf{x},\mathbf{y}}, \emptyset)\big) \cap \varphi\big((\mathcal{L}_{semigr}, \emptyset)\big) \neq \emptyset.$$

Similarly, the reachability problem by fractional linear transformations for x and y has a solution if and only if

$$\varphi\big((\mathcal{L}^{\text{flt}}_{x,y}, \emptyset)\big) \cap \varphi\big((\mathcal{L}_{semigr}, \emptyset)\big) \neq \emptyset.$$

By Proposition 13 these questions are algorithmically decidable. ◀

A characterization of the matrices M from $\mathrm{SL}(2,\mathbb{Z})$ that satisfy the equation $M\mathbf{x} = \mathbf{y}$, which is given in Theorem 8, can be computed in polynomial time. However the overall complexity of the algorithm is EXPTIME if the entries of the matrices are given in binary presentation. This is due to the fact that a reduced word w that corresponds to a given matrix M, i.e., such that $M = \pm\varphi(w)$, has length exponential in the binary presentation of M. So computing symbolic presentations of given matrices and constructing automata for the languages $\mathcal{L}_{semigr}$, $\mathcal{L}^{\text{vrp}}_{\mathbf{x},\mathbf{y}}$ and $\mathcal{L}^{\text{flt}}_{x,y}$ takes exponential time. The next steps of the algorithm take only polynomial time in the size of these automata. However the PTIME algorithm for computing all mappings from $\mathbf{x}$ to $\mathbf{y}$ could be combined with the result of Gurevich and Schupp [16] to produce a polynomial time algorithm for the vector reachability problem over the modular group.

4 Geometric interpretation and extensions

Consider a semigroup generated by matrices $M_1, \dots, M_n$ from $\mathrm{SL}(2,\mathbb{Z})$. As we showed above, this semigroup can be described by a regular language which we called $\mathcal{L}_{semigr}$. It's not hard to see that the proof of Theorem 14 remains valid if we replace $\mathcal{L}_{semigr}$ by any other regular language, that is, a language defined by a finite automaton or a labelled transition system.

▶ **Proposition 15.** *Suppose that we are given a finite collection of matrices $M_1, \dots, M_n$ from $\mathrm{SL}(2,\mathbb{Z})$ and a regular language $L \subseteq \{1, \dots, n\}^*$. Consider the following generalized reachability problems:*

- **Generalized vector reachability problem.** *Given two vectors* $\mathbf{x}$ *and* $\mathbf{y}$ *with integer coefficients, decide whether there exists a word* $i_1 \ldots i_k$ *from the language* L *such that* $M_{i_1} \cdots M_{i_k}\mathbf{x} = \mathbf{y}$.
- **Generalized reachability problem by fractional linear transformations.** *Given two rational numbers* x *and* y*, decide whether there exists a word* $i_1 \ldots i_k$ *from* L *such that* $f_{M_{i_1} \cdots M_{i_k}}(x) = y$.

Then the above generalized reachability problems are decidable.

Proof. The proof of this proposition is similar to the proof of Theorem 14. Namely, it follows from the fact that a regular language L defines a regular subset in $\mathrm{SL}(2,\mathbb{Z})$ and Proposition 13, where we proved that the emptiness problem for the intersection of two regular subsets in $\mathrm{SL}(2,\mathbb{Z})$ is decidable. ◀

As an application of Proposition 15 let us consider the follow matrix equation

$$M_1^{x_1} \cdots M_k^{x_k}\mathbf{x} = N_1^{y_1} \cdots N_l^{y_l}\mathbf{y}, \tag{2}$$

where $x_1, \ldots, x_k$ and $y_1, \ldots, y_l$ are non-negative integers. In [1] it was proved that if $M_1, \ldots, M_k$ and $N_1, \ldots, N_l$ are commuting $n \times n$ matrices over algebraic numbers and $\mathbf{x}, \mathbf{y}$ are vectors with algebraic coefficients, then it is decidable in polynomial time whether the Equation (2) has a solution. On the other hand, in [2] it was shown that there is no algorithm for solving the equation $M_1^{x_1} \cdots M_k^{x_k} = Z$, where $M_1, \ldots, M_k$ are integer $n \times n$ matrices and Z is the zero matrix. Using the construction of Kronecker (or tensor) product of matrices, it is possible to show that the above-mentioned result implies that Equation (2) is algorithmically undecidable in general for non-commuting integer matrices $M_1, \ldots, M_k$ and $N_1, \ldots, N_l$.

However with the help of Proposition 15 we can algorithmically solve Equation (2) in the case when $M_1, \ldots, M_k$ and $N_1, \ldots, N_l$ are matrices from $\mathrm{SL}(2,\mathbb{Z})$ and the vectors $\mathbf{x}, \mathbf{y}$ have integer coefficients. Indeed, since the matrices from $\mathrm{SL}(2,\mathbb{Z})$ are invertible, we can rewrite (2) as $(N_l^{-1})^{y_l} \cdots (N_1^{-1})^{y_1} M_1^{x_1} \cdots M_k^{x_k}\mathbf{x} = \mathbf{y}$. It is not hard to see that $\{(N_l^{-1})^{y_l} \cdots (N_1^{-1})^{y_1} M_1^{x_1} \cdots M_k^{x_k} : x_1, \ldots, x_k,\, y_1, \ldots, y_l \in \mathbb{N} \cup \{0\}\}$ is a regular subset of $\mathrm{SL}(2,\mathbb{Z})$, and hence the problem is decidable. Using the same idea we can algorithmically solve Equation (2) also in the case when $x_1, \ldots, x_k$ and $y_1, \ldots, y_l$ are arbitrary integers and the matrices are from $\mathrm{SL}(2,\mathbb{Z})$.

In the rest of this section we will give a geometric interpretation of both reachability problems (Figure 1), which we will use later to solve a special case of the scalar reachability problem (Proposition 18).

▶ **Proposition 16.** *According to Theorem 8, the set of matrices* M *from* $\mathrm{SL}(2,\mathbb{Z})$ *that transform a vector* $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ *to a vector* $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$ *has the form* $\mathcal{F} = \{BT^{kt}C \ : \ t \in \mathbb{Z}\}$.

Consider the equation $BT^{kt}C\mathbf{x} = \mathbf{y}$ *and let us make the following change of variables:* $\mathbf{u} = C\mathbf{x}$ *and* $\mathbf{v} = B^{-1}\mathbf{y}$: $\mathbf{x} \xrightarrow{C} \mathbf{u} \xrightarrow{T^{kt}} \mathbf{v} \xrightarrow{B} \mathbf{y}$. *Then* $\mathbf{u} = \mathbf{v} = \begin{bmatrix} d \\ 0 \end{bmatrix}$*, where* $|d| = \gcd(x_1, x_2) = \gcd(y_1, y_2)$.

Proof. In the new notations, the equation $BT^{kt}C\mathbf{x} = \mathbf{y}$ can be written as $T^{kt}\mathbf{u} = \mathbf{v}$, and this equality holds for any $t \in \mathbb{Z}$. Now let $\mathbf{u} = \begin{bmatrix} u_1 \\ u_2 \end{bmatrix}$ and $\mathbf{v} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$. Hence we have $\begin{bmatrix} 1 & kt \\ 0 & 1 \end{bmatrix} \begin{bmatrix} u_1 \\ u_2 \end{bmatrix} = \begin{bmatrix} v_1 \\ v_2 \end{bmatrix}$, which is equivalent to $u_2 = v_2$ and $u_1 + ktu_2 = v_1$, for any $t \in \mathbb{Z}$. So, we must have $u_2 = v_2 = 0$ and hence $u_1 = v_1$.

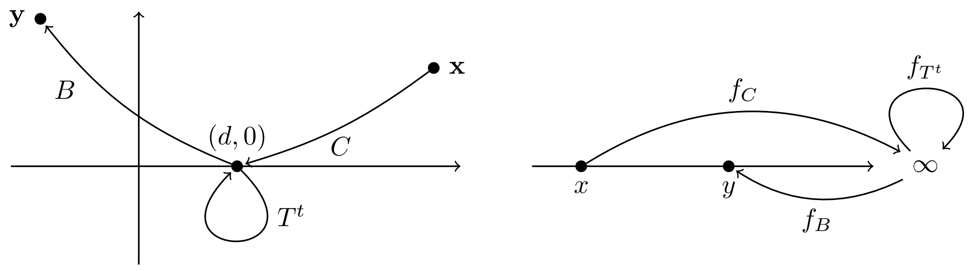

Figure 1 Geometric interpretation of the linear transformation $\mathbf{y} = BT^tC\mathbf{x}$ (left) and of the fractional linear transformation $y = f_{BT^tC}(x)$ (right).

Therefore, the vectors $\mathbf{u}$ and $\mathbf{v}$ have the form $\mathbf{u} = \mathbf{v} = \begin{bmatrix} d \\ 0 \end{bmatrix}$ for some $d \in \mathbb{Z}$. Moreover, since $\mathbf{u} = C\mathbf{x}$, we obtain from Lemma 4 that $|d| = \gcd(x_1, x_2) = \gcd(y_1, y_2)$. ◀

We can give the following geometric interpretation of the transformation $BT^tC\mathbf{x} = \mathbf{y}$: first, we apply C to $\mathbf{x}$ and arrive at $\mathbf{u} = \begin{bmatrix} d \\ 0 \end{bmatrix}$, then we loop at $\mathbf{u}$ for t many times using T, and finally apply B to move from $\mathbf{u}$ to $\mathbf{y}$ (see Figure 1 on the left).

Similarly, we have the following geometric interpretation of the fractional linear transformation $y = f_{BT^tC}(x) = f_B \circ f_{T^t} \circ f_C(x)$: first it maps x to ∞ using f_C, then loops at ∞ for t many times using f_T, and finally maps ∞ to y using f_B (see Figure 1 on the right).

We now show how to apply the geometric interpretation of the vector reachability problem to solve a special case of the scalar reachability problem.

▶ **Definition 17.** The *scalar reachability problem* in $\mathrm{SL}(2,\mathbb{Z})$ is stated as follows: Let $[z_1, z_2]$ and $\begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ be vectors from $\mathbb{Z} \times \mathbb{Z}$ and let λ be an integer number. We are also given a finite collection of matrices $M_1, \dots, M_n$ from $\mathrm{SL}(2,\mathbb{Z})$. The question is to decide whether there exists a matrix $M \in \langle M_1, \dots, M_n \rangle$ which satisfies the equation $[z_1, z_2]\, M \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \lambda$.

We will consider a special case of this problem when $z_2 = 1$ and $\lambda = 1$. Our proof relies on the characterization from Theorem 8 and Corollary 9 and on Proposition 13 in which we showed that the emptiness problem for the intersection of two regular subsets in $\mathrm{SL}(2,\mathbb{Z})$ is decidable.

▶ **Proposition 18.** *Suppose that the above equation has the form*

$$[a, 1]\, M \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = 1, \tag{3}$$

where a, x_1 and x_2 are some integer numbers. Then this special case of the scalar reachability problem is decidable.

Proof. The general idea of the proof is the same as in Theorem 14, that is, we will show that the set of matrices $M \in \mathrm{SL}(2,\mathbb{Z})$ that satisfy Equation (3) can be described by a regular language. First, let us consider a geometric interpretation of this problem. We can rewrite Equation (3) as a system of two equations: $M \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$ and $ay_1 + y_2 = 1$. So, M satisfies Equation (3) if and only if it maps a fixed vector $\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$ to some vector $\mathbf{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}$ that lies

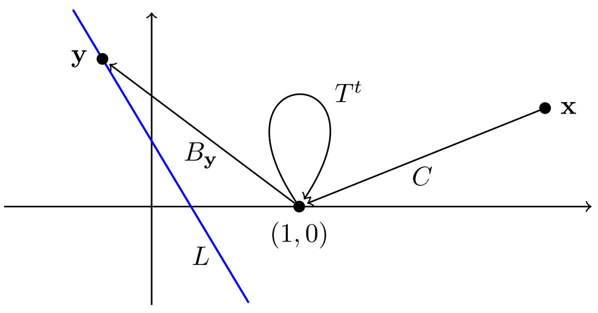

Figure 2 Geometric interpretation of the scalar reachability problem.

on the line L described by the equation $ay_1 + y_2 = 1$. In other words, we have a *vector to line reachability problem* for the line L that is defined by the equation $ay_1 + y_2 = 1$.

Note that if a vector $\mathbf{y}$ lies of the line $ay_1 + y_2 = 1$, then $\gcd(y_1, y_2) = 1$. Hence by Lemma 4, Equation (3) has a solution only if $\gcd(x_1, x_2) = 1$. So, from now on we assume that $\gcd(x_1, x_2) = 1$.

By Corollary 9, any $M \in \mathrm{SL}(2,\mathbb{Z})$ that maps $\mathbf{x}$ to a vector $\mathbf{y}$ on the line L has the form $M = BT^tC$, where B and C are some matrices from $\mathrm{SL}(2,\mathbb{Z})$ and $t \in \mathbb{Z}$. Geometrically, the transformation $\mathbf{y} = BT^tC\mathbf{x}$ goes via the point $(1,0)$ as shown in Figure 2.

Note that the matrices B and C above depend on the vector $\mathbf{y}$ as a parameter. Here we prove a useful lemma which will imply that we can choose only one matrix C that maps $\mathbf{x}$ to $\begin{bmatrix}1\\0\end{bmatrix}$ independently of the vector $\mathbf{y}$.

▶ **Lemma 19.** *Let* $\mathbf{x} = \begin{bmatrix}x_1\\x_2\end{bmatrix}$ *and* $\mathbf{y} = \begin{bmatrix}y_1\\y_2\end{bmatrix}$ *be any vectors from* $\mathbb{Z}\times\mathbb{Z}$ *such that* $\gcd(x_1, x_2) = \gcd(y_1, y_2) = d$. *Let* d_1 *and* d_2 *be any integer numbers with* $|d_1| = |d_2| = d$ *and let* A_1, B_1 *and* A_2, B_2 *by any matrices from* $\mathrm{SL}(2,\mathbb{Z})$ *such that* $B_i\mathbf{x} = \begin{bmatrix}d_i\\0\end{bmatrix}$ *and* $A_i\begin{bmatrix}d_i\\0\end{bmatrix} = \mathbf{y}$, *for* $i = 1, 2$. *Then* $\{A_1T^tB_1 \ : \ t \in \mathbb{Z}\} = \{A_2T^tB_2 \ : \ t \in \mathbb{Z}\}$. *In other words, the following diagrams define the same set of matrices that map* $\mathbf{x}$ *to* $\mathbf{y}$.

$$\begin{tikzcd} \mathbf{x} \arrow[r, "B_1"] & \left[\begin{smallmatrix}d_1\\0\end{smallmatrix}\right] \arrow[r, "A_1"] \arrow[loop below, "T^t"] & \mathbf{y} \end{tikzcd} \qquad \begin{tikzcd} \mathbf{x} \arrow[r, "B_2"] & \left[\begin{smallmatrix}d_2\\0\end{smallmatrix}\right] \arrow[r, "A_2"] \arrow[loop below, "T^t"] & \mathbf{y} \end{tikzcd}$$

Proof. See Section C of the Appendix in [31]. ◀

By Lemma 19, we can choose any matrix C from $\mathrm{SL}(2,\mathbb{Z})$ that maps a vector $\mathbf{x}$ to the vector $\begin{bmatrix}1\\0\end{bmatrix}$, and for each $\mathbf{y}$ on the line L we can choose any matrix $B_{\mathbf{y}}$ that maps $\begin{bmatrix}1\\0\end{bmatrix}$ to the vector $\mathbf{y}$. Then the solution of Equation (3) will be described by the following set $\mathcal{F} = \{B_{\mathbf{y}}T^tC \ : \ \mathbf{y} \in L \text{ and } t \in \mathbb{Z}\}$. Figure 2 gives geometric interpretation of this solution.

We need to choose $B_{\mathbf{y}}$ in such a way that $\mathcal{F}$ becomes a regular set. Let $\mathbf{y} = \begin{bmatrix}y_1\\y_2\end{bmatrix} \in L$, then we have $ay_1 + y_2 = 1$. As one can check, if we let $B_{\mathbf{y}} = \begin{bmatrix}y_1 & -1\\-ay_1+1 & a\end{bmatrix}$ then $B_{\mathbf{y}} \in \mathrm{SL}(2,\mathbb{Z})$ and $B_{\mathbf{y}}\begin{bmatrix}1\\0\end{bmatrix} = \mathbf{y}$.

Since every entry of $B_{\mathbf{y}}$ is a linear function of y_1, we obtain by Proposition 7 that $B_{\mathbf{y}} = AT^{ky_1}D$, where A and D are some matrices from $\mathrm{SL}(2,\mathbb{Z})$ and k is some integer number (in fact, one can show that $k = 1$). Finally, we can write all solutions of Equation (3) as $\mathcal{F} = \{AT^{ky_1}DT^tC \ : \ y_1 \in \mathbb{Z} \text{ and } t \in \mathbb{Z}\}$. This is clearly a regular set and, therefore, the scalar reachability problem is decidable. ◀

Abstract

The generalised colouring numbers $\mathrm{adm}_r(G)$, $\mathrm{col}_r(G)$, and $\mathrm{wcol}_r(G)$ were introduced by Kierstead and Yang as generalisations of the usual colouring number, also known as the degeneracy of a graph, and have since then found important applications in the theory of bounded expansion and nowhere dense classes of graphs, introduced by Nešetřil and Ossona de Mendez. In this paper, we study the relation of the colouring numbers with two other measures that characterise nowhere dense classes of graphs, namely with uniform quasi-wideness, studied first by Dawar et al. in the context of preservation theorems for first-order logic, and with the splitter game, introduced by Grohe et al. We show that every graph excluding a fixed topological minor admits a universal order, that is, one order witnessing that the colouring numbers are small for every value of r. Finally, we use our construction of such orders to give a new proof of a result of Eickmeyer and Kawarabayashi, showing that the model-checking problem for successor-invariant first-order formulas is fixed parameter tractable on classes of graphs with excluded topological minors.

1 Introduction

The *colouring number* $\mathrm{col}(G)$ of a graph G is the minimum k for which there is a linear order $<_L$ on the vertices of G such that each vertex v has *back-degree* at most $k-1$, that is, v has at most $k-1$ neighbours u with $u <_L v$. The colouring number is a measure for uniform sparseness in graphs: we have $\mathrm{col}(G) = k$ if and only if every subgraph H of G has a vertex

[*] This work was initiated during Sebastian Siebertz's visit at the Institute of Informatics of the University of Warsaw, which was supported by the Warsaw Centre of Mathematics and Computer Science. Michał Pilipczuk is supported by the Foundation for Polish Science (FNP) via the START stipend programme. Stephan Kreutzer, Roman Rabinovich and Sebastian Siebertz's research has been supported by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (ERC Consolidator Grant DISTRUCT, grant agreement No 648527).

of degree at most $k-1$. Hence, provided $\mathrm{col}(G)=k$, not only G is sparse, but also every subgraph of G is sparse. The colouring number minus one is also known as the *degeneracy*.

Recently, Nešetřil and Ossona de Mendez introduced the notions of *bounded expansion* [12] and *nowhere density* [14] as very general formalisations of uniform sparseness in graphs. Since then, several independent and seemingly unrelated characterisations of these notions have been found, showing that these concepts behave robustly. For example, nowhere dense classes of graphs can be defined in terms of excluded shallow minors [14], in terms of uniform quasi-wideness [2], a notion studied in model theory, or in terms of a game [8] with direct algorithmic applications. The *generalised colouring numbers* adm_r, col_r, and wcol_r were introduced by Kierstead and Yang [11] in the context of colouring and marking games on graphs. As proved by Zhu [17], they can be used to characterise both bounded expansion and nowhere dense classes of graphs.

The invariants adm_r, col_r, and wcol_r are defined similarly to the classic colouring number: for example, the *weak r-colouring* number $\mathrm{wcol}_r(G)$ of a graph G is the minimum integer k for which there is a linear order of the vertices such that each vertex v can reach at most $k-1$ vertices w by a path of length at most r in which w is the smallest vertex on the path.

The generalised colouring numbers found important applications in the context of algorithmic theory of sparse graphs. For example, they play a key role in Dvořák's approximation algorithm for minimum dominating sets [4], or in the construction of sparse neighbourhood covers on nowhere dense classes, a fundamental step in the almost linear time model-checking algorithm for first-order formulas of Grohe et al. [8].

In this paper we study the relation between the colouring numbers and the above mentioned characterisations of nowhere dense classes of graphs, namely with uniform quasi-wideness and the splitter game. We use the generalised colouring numbers to give a new proof that every bounded expansion class is uniformly quasi-wide. This was first proved by Nešetřil and Ossona de Mendez in [13]; however, the constants appearing in the proof of [13] are huge. We present a very simple proof which also improves the appearing constants. Furthermore, for the splitter game introduced in [8], we show that splitter has a very simple strategy to win on any class of bounded expansion, which leads to victory much faster than in general nowhere dense classes of graphs.

Every graph G from a fixed class $\mathcal{C}$ of bounded expansion satisfies $\mathrm{wcol}_r(G) \leq f(r)$ for some function f and all positive integers r. However, the order that witnesses this inequality for G may depend on the value r. We say that a class $\mathcal{C}$ admits *uniform orders* if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that for each $G \in \mathcal{C}$ there is one linear order that witnesses $\mathrm{wcol}_r(G) \leq f(r)$ for every value of r. We show that every class that excludes a fixed topological minor admits uniform orders that can be computed efficiently.

Finally, based on our construction of uniform orders for graphs that exclude a fixed topological minor, we provide an alternative proof of a very recent result of Eickmeyer and Kawarabayashi [6], that the model-checking problem for successor-invariant first-order (FO) formulas is fixed-parameter tractable on such classes (we obtained this result independently of, but later than, [6]). Successor-invariant logics have been studied in database theory and finite model theory, and successor-invariant FO is known to be more expressive than plain FO [15]. The model-checking problem for successor-invariant FO is known to be fixed-parameter tractable parameterized by the size of the formula on any graph class that excludes a fixed minor [7]. Very recently, this result was lifted to classes that exclude a fixed topological minor by Eickmeyer and Kawarabayashi [6]. The key point of their proof is to use the decomposition theorem for graphs excluding a fixed topological minor, due to Grohe and Marx [9]. Our approach is similar to that of [6]. However, we employ new constructions based on the generalised colouring numbers and use the decomposition theorem of [9] only implicitly. In particular, we do not construct a graph decomposition in order to solve the model-checking problem. Therefore, we believe that our approach may be easier to extend further to classes of bounded expansion, or even to nowhere dense classes of graphs.

2 Preliminaries

Notation. We use standard graph-theoretical notation; see e.g. [3] for reference. All graphs considered in this paper are finite, simple, and undirected. For a graph G, by $V(G)$ and $E(G)$ we denote the vertex and edge sets of G, respectively. A graph H is a *subgraph* of G, denoted $H \subseteq G$, if $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. For any $M \subseteq V(G)$, by $G[M]$ we denote the subgraph induced by M. We write $G - M$ for the graph $G[V(G) \setminus M]$ and if $M = \{v\}$, we write $G - v$ for $G - M$. For a non-negative integer ℓ, a *path of length* ℓ in G is a sequence $P = (v_1, \ldots, v_{\ell+1})$ of pairwise different vertices such that $v_iv_{i+1} \in E(G)$ for all $1 \leq i \leq \ell$. We write $V(P)$ for the vertex set $\{v_1, \ldots, v_{\ell+1}\}$ of P and $E(P)$ for the edge set $\{v_iv_{i+1} : 1 \leq i \leq \ell\}$ of P and identify P with the subgraph of G with vertex set $V(P)$ and edge set $E(P)$. We say that the path P *connects* its *endpoints* $v_1, v_{\ell+1}$, whereas $v_2, \ldots, v_\ell$ are the *internal vertices* of P. The *length* of a path is the number of its edges. Two vertices $u, v \in V(G)$ are *connected* if there is a path in G with endpoints u, v. The *distance* $\mathrm{dist}(u, v)$ between two connected vertices u, v is the minimum length of a path connecting u and v; if u, v are not connected, we put $\mathrm{dist}(u, v) = \infty$. The *radius* of G is $\min_{u\in V(G)} \max_{v\in V(G)} \mathrm{dist}(u, v)$. The set of all neighbours of a vertex v in G is denoted by $N^G(v)$, and the set of all vertices at distance at most r from v is denoted by $N_r^G(v)$. A graph G is c-*degenerate* if every subgraph $H \subseteq G$ has a vertex of degree at most c. A c-degenerate graph of order n contains an independent set of order at least $n/(c + 1)$.

A graph H with $V(H) = \{v_1, \ldots, v_n\}$ is a *minor* of G, written $H \preccurlyeq G$, if there are pairwise disjoint connected subgraphs $H_1, \ldots, H_n$ of G, called *branch sets*, such that whenever $v_iv_j \in E(H)$, then there are $u_i \in H_i$ and $u_j \in H_j$ with $u_iu_j \in E(G)$. We call $(H_1, \ldots, H_n)$ a *minor model* of H in G. The graph H is a *topological minor* of G, written $H \preccurlyeq^t G$, if there are pairwise different vertices $u_1, \ldots, u_n \in V(G)$ and a family of paths $\{P_{ij} : v_iv_j \in E(H)\}$, such that each P_{ij} connects u_i and u_j, and paths P_{ij} are pairwise internally vertex-disjoint.

Generalised colouring numbers. Let us fix a graph G. By $\Pi(G)$ we denote the set of all linear orders of $V(G)$. For $L \in \Pi(G)$, we write $u <_L v$ if u is smaller than v in L, and $u \leq_L v$ if $u <_L v$ or $u = v$. Let $u, v \in V(G)$. For a non-negative integer r, we say that u is *weakly* r-*reachable* from v with respect to L, if there is a path P of length ℓ, $0 \leq \ell \leq r$, connecting u and v such that u is minimum among the vertices of P (with respect to L). By $\mathrm{WReach}_r[G, L, v]$ we denote the set of vertices that are weakly r-reachable from v w.r.t. L.

Vertex u is *strongly* r-*reachable* from v with respect to L, if there is a path P of length ℓ, $0 \leq \ell \leq r$, connecting u and v such that $u \leq_L v$ and such that all internal vertices w of P satisfy $v <_L w$. Let $\mathrm{SReach}_r[G, L, v]$ be the set of vertices that are strongly r-reachable from v w.r.t. L. Note that we have $v \in \mathrm{SReach}_r[G, L, v] \subseteq \mathrm{WReach}_r[G, L, v]$.

For a non-negative integer r, we define the *weak* r-*colouring number* $\mathrm{wcol}_r(G)$ of G and the r-*colouring number* $\mathrm{col}_r(G)$ of G respectively as follows:

$$\begin{aligned} \mathrm{wcol}_r(G) &:= \min_{L\in\Pi(G)} \max_{v\in V(G)} \big|\mathrm{WReach}_r[G, L, v]\big|, \\ \mathrm{col}_r(G) &:= \min_{L\in\Pi(G)} \max_{v\in V(G)} \big|\mathrm{SReach}_r[G, L, v]\big|. \end{aligned}$$

For a non-negative integer r, the *r-admissibility* $\mathrm{adm}_r[G, L, v]$ of v w.r.t. L is the maximum size k of a family $\{P_1, \ldots, P_k\}$ of paths of length at most r that start in v, end at a vertex w with $w \leq_L v$, and satisfy $V(P_i) \cap V(P_j) = \{v\}$ for all $1 \leq i < j \leq k$. As for $r > 0$ we can always let the paths end in the first vertex smaller than v, we can assume that the internal vertices of the paths are larger than v. Note that $\mathrm{adm}_r[G, L, v]$ is an integer, whereas $\mathrm{WReach}_r[G, L, v]$ and $\mathrm{SReach}_r[G, L, v]$ are vertex sets. The *r-admissibility* $\mathrm{adm}_r(G)$ of G is

$$\mathrm{adm}_r(G) \quad = \quad \min_{L \in \Pi(G)} \max_{v \in V(G)} \mathrm{adm}_r[G, L, v].$$

The generalised colouring numbers were introduced by Kierstead and Yang [11] in the context of colouring and marking games on graphs. The authors also proved that the generalised colouring numbers are related by the following inequalities:

$$\mathrm{adm}_r(G) \leq \mathrm{col}_r(G) \leq \mathrm{wcol}_r(G) \leq (\mathrm{adm}_r(G))^r. \tag{1}$$

Shallow minors, bounded expansion, and nowhere denseness. A graph H with $V(H) = \{v_1, \ldots, v_n\}$ is a *depth-r minor* of G, denoted $H \preccurlyeq_r G$, if there is a minor model $(H_1, \ldots, H_n)$ of H in G such that each H_i has radius at most r. We write $d(H)$ for the *average degree* of H, that is, for the number $2|E(H)|/|V(H)|$. A class $\mathcal{C}$ of graphs has *bounded expansion* if there is a function $f\colon \mathbb{N} \to \mathbb{N}$ such that for all non-negative integers r we have $d(H) \leq f(r)$ for every $H \preccurlyeq_r G$ with $G \in \mathcal{C}$. A class $\mathcal{C}$ of graphs is *nowhere dense* if for every real $\epsilon > 0$ and every non-negative integer r, there is an integer n_0 such that if H is an n-vertex graph with $n \geq n_0$ and $H \preccurlyeq_r G$ for some $G \in \mathcal{C}$, then $d(H) \leq n^\epsilon$.

Bounded expansion and nowhere dense classes of graphs were introduced by Nešetřil and Ossona de Mendez as models for uniform sparseness of graphs [12, 14]. As proved by Zhu [17], the generalised colouring numbers are tightly related to densities of low-depth minors, and hence they can be used to characterise bounded expansion and nowhere dense classes.

▶ **Theorem 1** (Zhu [17]). *A class $\mathcal{C}$ of graphs has bounded expansion if and only if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that $\mathrm{wcol}_r(G) \leq f(r)$ for all $r \in \mathbb{N}$ and all $G \in \mathcal{C}$.*

Due to (1), we may equivalently demand that there is a function $f : \mathbb{N} \to \mathbb{N}$ such that $\mathrm{adm}_r(G) \leq f(r)$ or $\mathrm{col}_r(G) \leq f(r)$ for all non-negative integers r and all $G \in \mathcal{C}$.

Similarly, from Zhu's result one can derive a characterisation of nowhere dense classes of graphs, as presented in [14]. A class $\mathcal{C}$ of graphs is called *hereditary* if it is closed under induced subgraphs, that is, if H is an induced subgraph of $G \in \mathcal{C}$, then $H \in \mathcal{C}$.

▶ **Theorem 2** (Nešetřil and Ossona de Mendez [14]). *A hereditary class $\mathcal{C}$ of graphs is nowhere dense if and only if for every real $\epsilon > 0$ and every non-negative integer r, there is a positive integer n_0 such that if $G \in \mathcal{C}$ is an n-vertex graph with $n \geq n_0$, then $\mathrm{wcol}_r(G) \leq n^\epsilon$.*

As shown in [4], for every non-negative integer r, computing $\mathrm{adm}_r(G)$ is fixed-parameter tractable on any class of bounded expansion (parameterized by $\mathrm{adm}_r(G)$). For $\mathrm{col}_r(G)$ and $\mathrm{wcol}_r(G)$ this is not known; however, by (1) we can use admissibility to obtain approximations of these numbers. On nowhere dense classes of graphs, for every $\epsilon > 0$ and every non-negative integer r, we can compute an order that witnesses $\mathrm{wcol}_r(G) \leq n^\epsilon$ in time $\mathcal{O}(n^{1+\epsilon})$ if G is sufficiently large [8], based on Nešetřil and Ossona de Mendez's augmentation technique [12].

3 Uniform quasi-wideness and the splitter game

In this section we discuss the relation between weak r-colouring numbers and two notions that characterise nowhere dense classes: uniform quasi-wideness and the splitter game.

For a graph G, a vertex subset $A \subseteq V(G)$ is called *r-independent* in G, if $\mathrm{dist}_G(a,b) > r$ for all different $a, b \in V(G)$. A vertex subset is called *r-scattered*, if it is $2r$-independent, that is, if the r-neighbourhoods of different elements of A do not intersect.

Informally, uniform quasi-wideness means the following: in any large enough subset of vertices of a graph from $\mathcal{C}$, one can find a large subset that is r-scattered in G, possibly after removing from G a small number of vertices. Formally, a class $\mathcal{C}$ of graphs is *uniformly quasi-wide* if there are functions $N : \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ and $s : \mathbb{N} \to \mathbb{N}$ such that for all $m, r \in \mathbb{N}$, if $W \subseteq V(G)$ for a graph $G \in \mathcal{C}$ with $|W| > N(m,r)$, then there is a set $S \subseteq V(G)$ of size at most $s(r)$ such that W contains a subset of size at least m that is r-scattered in $G - S$.

The notion of quasi-wideness was introduced by Dawar [2] in the context of homomorphism preservation theorems. It was shown in [13] that classes of bounded expansion are uniformly quasi-wide and that uniform quasi-wideness characterises nowhere dense classes of graphs.

▶ **Theorem 3** (Nešetřil and Ossona de Mendez [13])**.** *A hereditary class $\mathcal{C}$ of graphs is nowhere dense if and only if it is uniformly quasi-wide.*

It was shown by Atserias et al. in [1] that classes that exclude K_k as a minor are uniformly quasi-wide. In fact, in this case we can choose $s(r) = k - 1$, independent of r (if such a constant function for a class $\mathcal{C}$ exists, the class is called *uniformly almost wide*). However, the function $N(m,r)$ that was used in the proof is huge: it comes from an iterated Ramsey argument. The same approach was used in [13] to show that every nowhere dense class, and in particular, every class of bounded expansion, is uniformly quasi-wide. We present a new proof that every bounded expansion class is uniformly quasi-wide, which gives us a much better bound on $N(m,r)$ and which is much simpler than the previously known proof.

▶ **Theorem 4.** *Let G be a graph and let $r, m \in \mathbb{N}$. Let $c \in \mathbb{N}$ be such that $\mathrm{wcol}_r(G) \le c$ and let $A \subseteq V(G)$ be a set of size at least $(c+1) \cdot 2^m$. Then there exists a set S of size at most $c(c-1)$ and a set $B \subseteq A$ of size at least m which is r-independent in $G - S$.*

Proof. Let $L \in \Pi(G)$ be such that $|\mathrm{WReach}_r[G,L,v]| \le c$ for every $v \in V(G)$. Let H be the graph with vertex set $V(G)$, where we put an edge $uv \in E(H)$ if and only if $u \in \mathrm{WReach}_r[G,L,v]$ or $v \in \mathrm{WReach}_r[G,L,u]$. Then L certifies that H is c-degenerate, and hence we can greedily find an independent set $I \subseteq A$ of size 2^m in H. By the definition of the graph H, we have that $\mathrm{WReach}_r[G,L,v] \cap I = \{v\}$ for each $v \in I$.

▶ **Claim 5.** *Let $v \in I$. Then deleting $\mathrm{WReach}_r[G,L,v] \setminus \{v\}$ from G leaves v at a distance greater than r (in $G - (\mathrm{WReach}_r[G,L,v] \setminus \{v\})$) from all the other vertices of I.*

Proof. Let $u \in I$ and let P be a path in G that has length at most r and connects u and v. Let $z \in V(P)$ be minimal with respect to L. Then $z <_L v$ or $z = v$. If $z <_L v$, then $z \in \mathrm{WReach}_r[G,L,v]$ and hence the path P no longer exists after the deletion of $\mathrm{WReach}_r[G,L,v] \setminus \{v\}$ from G. On the other hand, if $z = v$, then $v \in \mathrm{WReach}_r[G,L,u]$, contradicting the fact that both $u, v \in I$. ⌟

We iteratively find sets $B_0 \subseteq \ldots \subseteq B_m \subseteq I$, sets $I_0 \supseteq \ldots \supseteq I_m$, and sets $S_0 \subseteq \ldots \subseteq S_m$ such that B is r-independent in $G - S$, where $B := B_m$ and $S := S_m$. We maintain the invariant that sets B_i, I_i, and S_i are pairwise disjoint for each i. Let $I_0 = I$, $B_0 = \emptyset$ and $S_0 = \emptyset$. In one step $i = 1, 2, \ldots, m$, we delete some vertices from I_i (thus obtaining I_{i+1}), shift one vertex from I_i to B_i (obtaining B_{i+1}) and, possibly, add some vertices from $V(G) \setminus I_i$ to S_i (obtaining S_{i+1}). More precisely, let v be the vertex of I_i that is the largest in the order L. We set $B_{i+1} = B_i \cup \{v\}$, and now we discuss how I_{i+1} and S_{i+1} are constructed.

We distinguish two cases. First, suppose v is connected by a path of length at most r in $G - S_i$ to at most half of the vertices of I_i (including v). Then we remove these reachable vertices from I_i, and set I_{i+1} to be the result. We also set $S_{i+1} = S_i$. Note that $|I_{i+1}| \geq |I_i|/2$.

Second, suppose v is connected by a path of length at most r in $G - S_i$ to more than half of the vertices of I_i (including v). We proceed in two steps. First, we add the at most $c - 1$ vertices of $\mathrm{WReach}_r[G, L, v] \setminus \{v\}$ to S_{i+1}, that is, we let $S_{i+1} = S_i \cup (\mathrm{WReach}_r[G, L, v] \setminus \{v\})$. (Recall here that $\mathrm{WReach}_r[G, L, v] \cap I = \{v\}$.) By Claim 5, this leaves v at a distance greater than r from every other vertex of I_i in $G - S_{i+1}$. Second, we construct I_{i+1} from I_i by removing the vertex v and all the vertices of I_i that are not connected to v by a path of length at most r in $G - S_i$, hence we have $|I_{i+1}| \geq \lfloor |I_i|/2 \rfloor$.

Observe the construction above can be carried out for m steps, because in each step, we remove at most half of the vertices of I_i (rounded up) when constructing I_{i+1}. As $|I_0| = |I| = 2^m$, it is easy to see that the set I_i cannot become empty within m iterations. Moreover, it is clear from the construction that we end up with a set $B = B_m$ that has size m and is r-scattered in $G - S$, where $S = S_m$. It remains to argue that $|S_m| \leq c(c - 1)$. For this, it suffices to show that the second case cannot apply more than c times in total.

Suppose the second case was applied in the ith iteration, when considering a vertex v. Every vertex $u \in I_i$ with $u <_L v$ that was connected to v by a path of length at most r in $G - S_i$ satisfies $\mathrm{WReach}_r[G, L, v] \cap \mathrm{WReach}_r[G, L, u] \neq \emptyset$. Thus, every remaining vertex $u \in I_{i+1}$ has at least one of its weakly r-reachable vertices deleted (that is, included in S_{i+1}). As the number of such vertices is at most $c - 1$ at the beginning, and it can only decrease during the construction, this implies that the second case can occur at most c times. ◀

As shown in [16], if $K_k \not\preccurlyeq G$, then $\mathrm{wcol}_r(G) \in \mathcal{O}(r^{k-1})$. Hence, for such graphs we have to delete only a polynomial (in r) number of vertices in order to find an r-independent set of size m in a set of vertices of size single exponential in m.

We now implement the same idea to find a very simple strategy for splitter in the splitter game, introduced by Grohe et al. [8] to characterise nowhere dense classes of graphs. Let $\ell, r \in \mathbb{N}$. The *simple ℓ-round radius-r splitter game* on G is played by two players, *connector* and *splitter*, as follows. We let $G_0 := G$. In round $i + 1$ of the game, connector chooses a vertex $v_{i+1} \in V(G_i)$. Then splitter picks a vertex $w_{i+1} \in N_r^{G_i}(v_{i+1})$. We let $G_{i+1} := G_i[N_r^{G_i}(v_{i+1}) \setminus \{w_{i+1}\}]$. Splitter wins if $G_{i+1} = \emptyset$. Otherwise the game continues at G_{i+1}. If splitter has not won after ℓ rounds, then connector wins.

A *strategy* for splitter is a function σ that maps every partial play $(v_1, w_1, \ldots, v_s, w_s)$, with associated sequence $G_0, \ldots, G_s$ of graphs, and the next move $v_{s+1} \in V(G_s)$ of connector, to a vertex $w_{s+1} \in N_r^{G_s}(v_{s+1})$ that is the next move of splitter. A strategy σ is a *winning strategy* for splitter if splitter wins every play in which she follows the strategy f. We say that splitter *wins* the simple ℓ-round radius-r splitter game on G if she has a winning strategy.

▶ **Theorem 6** (Grohe et al. [8]). *A class $\mathcal{C}$ of graphs is nowhere dense if and only if there is a function $\ell : \mathbb{N} \to \mathbb{N}$ such that splitter wins the simple $\ell(r)$-round radius-r splitter game on every graph $G \in \mathcal{C}$.*

More precisely, it was shown in [8] that $\ell(r)$ can be chosen as $N(2s(r), r)$, where N and s are the functions that characterise $\mathcal{C}$ as a uniformly quasi-wide class of graphs. We present a proof that on bounded expansion classes, splitter can win much faster.

▶ **Theorem 7.** *Let G be a graph, let $r \in \mathbb{N}$ and let $\ell = \mathrm{wcol}_{2r}(G)$. Then splitter wins the ℓ-round radius-r splitter game.*

Proof. Let L be a linear order that witnesses $\mathrm{wcol}_{2r}(G) = \ell$. Suppose in round $i+1 \leq \ell$, connector chooses a vertex $v_{i+1} \in V(G_i)$. Let w_{i+1} (splitter's choice) be the minimum vertex of $N_r^{G_i}(v_{i+1})$ with respect to L. Then for each $u \in N_r^{G_i}(v_{i+1})$ there is a path between u and w_{i+1} of length at most $2r$ that uses only vertices of $N_r^{G_i}(v_{i+1})$. As w_i is minimum in $N_r^{G_i}(v_{i+1})$, w_{i+1} is weakly $2r$-reachable from each $u \in N_r^{G_i}(v_{i+1})$. Now let $G_{i+1} := G_i[N_r^{G_i}(v_{i+1}) \setminus \{w_{i+1}\}]$. As w_{i+1} is not part of G_{i+1}, in the next round splitter will choose another vertex which is weakly $2r$-reachable from every vertex of the remaining r-neighbourhood. As $\mathrm{wcol}_{2r}(G) = \ell$, the game must stop after at most ℓ rounds. ◀

4 Uniform orders for graphs excluding a topological minor

If $\mathcal{C}$ is a class of bounded expansion such that $\mathrm{wcol}_r(G) \leq f(r)$ for all $G \in \mathcal{C}$ and all $r \in \mathbb{N}$, the order L that witnesses this inequality for G may depend on the value r. We say that a class $\mathcal{C}$ *admits uniform orders* if there is a function $f : \mathbb{N} \to \mathbb{N}$ such that for each $G \in \mathcal{C}$, there is a linear order $L \in \Pi(G)$ such that $|\mathrm{WReach}_r[G, L, v]| \leq f(r)$ for all $v \in V(G)$ and all $r \in \mathbb{N}$. In other words, there is one order that simultaneously certifies the inequality $\mathrm{wcol}_r(G) \leq f(r)$ for all r.

It is implicit in [16] that every class that excludes a fixed minor admits uniform orders, which can be efficiently computed. We are going to show that the same holds for classes that exclude a fixed topological minor. Our construction is similar to the construction of [16], in particular, our orders can be computed quickly in a greedy fashion. The proof that we find an order of high quality is based on the decomposition theorem for graphs with excluded topological minors, due to Grohe and Marx [9]. Note however, that for the construction of the order we do not have to construct a tree decomposition according to Grohe and Marx [9].

Construction. Let G be a graph. We present a construction of an order of $V(G)$ of high quality. We iteratively construct a sequence $H_1, \ldots, H_\ell$ of pairwise disjoint and connected subgraphs of G such that $\bigcup_{1 \leq i \leq \ell} V(H_i) = V(G)$. For $0 \leq i < \ell$, let $G_i := G - \bigcup_{1 \leq j \leq i} V(H_j)$. We say that a component C of G_i is *connected* to a subgraph H_j, $j \leq i$, if there is a vertex $u \in V(H_j)$ and a vertex $v \in V(C)$ such that $uv \in E(G)$. For all i, $1 \leq i < \ell$, we will maintain the following invariant. If C is a component of G_i, then the subgraphs $H_{i_1}, \ldots, H_{i_s} \in \{H_1, \ldots, H_i\}$ that are connected to C form a minor model of the complete graph K_s, where s is their number.

To start, we choose an arbitrary vertex $v \in V(G)$ and let H_1 be the connected subgraph $G[\{v\}]$. Clearly, H_1 satisfies the above invariant. Now assume that for some i, $1 \leq i < \ell$, the sequence $H_1, \ldots, H_i$ has already been constructed. Fix some component C of G_i and, by the invariant, assume that the subgraphs $H_{i_1}, \ldots, H_{i_s} \in \{H_1, \ldots, H_i\}$ with $1 \leq i_1 < \ldots < i_s \leq i$ that have a connection to C form a minor model of K_s. For a vertex $v \in V(C)$, let $m(v)$ be the maximum cardinality of a family $\mathcal{P}$ of paths with the following properties: each path of $\mathcal{P}$ connects v with a different subgraph H_{i_j}, the internal vertices of each path from $\mathcal{P}$ belong to G_i, and the paths of $\mathcal{P}$ are pairwise disjoint apart from sharing v. Note that $m(v)$ can be computed in polynomial time using any maximum flow algorithm. Pick v to be a vertex of C with maximum $m(v)$. Let T be the tree of the breadth-first search in $G[C]$ that starts in v; thus, T is rooted at v. We choose H_{i+1} to be a minimal connected subtree of T that contains v and, for each j with $1 \leq j \leq s$, at least one neighbour of H_{i_j} in C.

From the construction it is easy to see that for every component C' of G_{i+1}, the subgraphs $H'_{i_1}, \ldots, H'_{i_{s'}} \in \{H_1, \ldots, H_{i+1}\}$ that are connected to C' form the minor model of a complete graph, hence the invariant is again established. Having chosen H_{i+1}, we proceed to the next iteration. The construction stops when all vertices are part of some H_i, $1 \leq i \leq \ell$.

We construct an order L of $V(G)$ as follows. Let $v <_L u$ if $v \in V(H_i)$ and $u \in V(H_j)$ for some $i < j$. Furthermore, we order the vertices within each H_i arbitrarily. Obviously, the construction does not depend on r, hence the produced order is uniform for G.

Analysis. From now on we assume that G excludes K_k as a topological minor, for some constant k. Furthermore, assume that the graphs $H_1, \ldots, H_\ell$ and a corresponding order L have been constructed, as described above. We now show that the constructed order has good qualities. Our proof is based on the following two key lemmas. The first lemma states that for every component C of G_i arising after the construction of $H_1, \ldots, H_i$, every vertex v of C can reach only a bounded number of subgraphs among $H_1, \ldots, H_i$ by disjoint paths.

► **Lemma 8.** *There is a constant α (depending only on k) such that for all integers i, $1 \le i < \ell$, if C is a component of G_i, then for every vertex $v \in V(C)$, we have $m(v) \le \alpha$, where $m(v)$ is defined as in the construction.*

The second lemma states that from a vertex of H_{i+1}, we can reach only a bounded number of vertices of each H_j, $1 \le j \le i+1$, by short disjoint paths in G_i.

► **Lemma 9.** *There is a constant β (depending only on k) such that for all integers i, j, where $1 \le j \le i \le \ell$, and all positive integers r, the following holds. Suppose $v \in V(H_i)$, and let $\mathcal{P}$ be any family of paths of length at most r with the following properties: each path from $\mathcal{P}$ connects v with a different vertex of H_j, the internal vertices of $\mathcal{P}$ belong to G_j, and paths from $\mathcal{P}$ are internally vertex disjoint. Then $\mathcal{P}$ has size not larger than $\beta \cdot r$.*

It is easy to show that the above two lemmas guarantee that L has the required properties. The proof of this fact, as well as all the other facts marked with $*$, is in the appendix.

► **Corollary 10** ($*$). *If $K_k \not\preccurlyeq^t G$, then there exists a constant γ (depending only on k) and a uniform order L that witnesses $\mathrm{adm}_r(G) \le \gamma \cdot r$ for all non-negative integers r.*

The proof of Lemma 8 is based on the decomposition theorem for graphs with excluded topological minors of Grohe and Marx [9]. Recall that a *tree decomposition* of a graph G is a pair (T, β), where T is a tree and $\beta : V(T) \to 2^{V(G)}$, such that for every vertex $v \in V(G)$ the set $\beta^{-1}(v) = \{t \in V(T) : v \in \beta(t)\}$ is non-empty and connected in T, and for every edge $e \in E(G)$ there is a node $t \in V(T)$ such that $e \subseteq \beta(t)$. The *width* of (T, β) is $\max\{|\beta(t)| - 1 : t \in V(T)\}$ and the *adhesion* of (T, β) is $\max\{|\beta(s) \cap \beta(t)| : st \in E(T)\}$.

For a node $t \in T$, we call $\beta(t)$ the *bag at t*. If $T' \subseteq T$, we write $\beta(T')$ for $\bigcup_{t' \in V(T')} \beta(t')$ and if $M \subseteq V(G)$, we write $\beta^{-1}(M)$ for $\bigcup_{v \in M} \beta^{-1}(v)$. Denote by $K[X]$ the complete graph on a vertex set X. The *torso at t* is the graph $\tau(t) := G[\beta(t)] \cup \bigcup_{st \in E(T)} K[\beta(s) \cap \beta(t)]$.

► **Theorem 11** ([9]). *For every $k \in \mathbb{N}$, there exist constants $a(k), c(k), d(k)$ and $e(k)$ such that the following holds. Let H be a graph on k vertices. Then for every graph G with $H \not\preccurlyeq^t G$ there is a tree decomposition (T, β) of adhesion at most $a(k)$ such that for all $t \in V(T)$ one of the following two alternatives hold.*

1. *The torso $\tau(t)$ has at most $c(k)$ vertices of degree larger than $d(k)$, which we call the* apex vertices *of $\tau(t)$. Such a node t will be called a* bounded degree node*.*
2. *The torso $\tau(t)$ excludes the complete graph $K_{e(k)}$ as a minor. Such a node t will be called an* excluded minor node*.*

We will need the following well-known properties of trees and tree decompositions.

► **Lemma 12** (Helly-property for trees). *Let T be a tree and let $(T_i)_{i \in I}$ be a family of subtrees of T. If $V(T_i) \cap V(T_j) \neq \emptyset$, for all $i, j \in I$, then $\bigcap_{i \in I} V(T_i) \neq \emptyset$.*

▶ **Lemma 13.** *Let (T, β) be a tree decomposition of a graph G. Let $e = st$ be an edge of T and let T_1, T_2 be the components of $T - e$. Then $\beta(s) \cap \beta(t)$ separates $\beta(T_1)$ from $\beta(T_2)$, that is, every path from a vertex of $\beta(T_1)$ to a vertex of $\beta(T_2)$ traverses a vertex of $\beta(s) \cap \beta(t)$.*

▶ **Lemma 14.** *If $H \subseteq G$ is a connected subgraph of G, then $\beta^{-1}(V(H))$ is connected in T.*

For the proof of Lemma 8, assume that G is decomposed as described by Theorem 11. Assume that $H_1, \ldots, H_i$ have been constructed and let C be a component of G_i that has a connection to the subgraphs $H_{i_1}, \ldots, H_{i_s}$. Recall that throughout the construction we guarantee that the subgraphs $H_{i_1}, \ldots, H_{i_s}$ form the minor model of a complete graph K_s. We first identify one bag of the decomposition as a bag which intersects many distinct branch sets of this minor model. The following lemma follows easily from the separator properties of tree decompositions, in particular Lemma 13.

▶ **Lemma 15 (∗).** *There can be at most one node t such that $\beta(t)$ intersects strictly more than $a(k)$ of the branch sets H_{i_j}, for $1 \leq j \leq s$.*

We now show that there is a bag that intersects every branch set. The proof is a simple application of the Helly property of trees (Lemma 12) and Lemma 14.

▶ **Lemma 16 (∗).** *There is a node t such that $\beta(t)$ intersects each H_{i_j}, for $1 \leq j \leq s$.*

Hence, provided $s > a(k)$, there is a node t with $\beta(t)$ intersecting at least $a(k)+1$ branch sets H_{i_j}. By Lemma 15, this node is unique. We call it the *core node* of the minor model. Next we show that if the model is large, then its core node must be a bounded degree node. Shortly speaking, this is because the model $H_{i_1}, \ldots, H_{i_s}$ trimmed to the torso of the core node is already a minor model of K_s in this torso.

▶ **Lemma 17 (∗).** *If $s > \max\{a(k), e(k)\}$, then the core node of the minor model is a bounded degree node.*

For vertices outside the bag of the core node, the bound promised in Lemma 8 can be proved similarly as Lemma 15.

▶ **Lemma 18 (∗).** *Let C be a component of G_i that has a connection to the subgraphs $H_{i_1}, \ldots, H_{i_s}$. If $s > a(k)$, then for every vertex $v \in V(C) \setminus \beta(t)$, where t is the core node of the model, we have that $m(v) \leq a(k)$.*

We now complete the proof of Lemma 8 by looking at the vertices inside the core bag.

Proof of Lemma 8. We set $\alpha := a(k) + c(k) + d(k) + e(k)$. Assume towards a contradiction that for some i, $1 \leq i < \ell$, we have that some component C of G_i contains a vertex v_1 with $m(v_1) > \alpha$. Denote the branch sets that have a connection to C by $H_{i_1}, \ldots, H_{i_s}$, where $i_1 < i_2 < \ldots < i_s$. Let $\mathcal{P}$ be a maximum-size family of paths that pairwise share only v_1 and connect v_1 with different branch sets H_{i_j}. As $m(v_1) > \alpha$, we have that $|\mathcal{P}| > \alpha$, and in particular $s > \alpha$. As $\alpha > a(k)$, by Lemmas 15 and 16 we can identify the unique core node t of the minor model. As $s > \max\{a(k), e(k)\}$, by Lemma 17 the core node is a bounded degree node. As $m(v_1) > a(k)$, by Lemma 18 we have $v_1 \in \beta(t)$. As $\mathcal{P}$ contains more than $d(k)$ disjoint paths from v to distinct branch sets, the degree of v_1 in G must be greater than $d(k)$, hence v_1 is an apex vertex of $\tau(t)$.

Since $i_1 < i_2 < \ldots < i_s$, we have that the component C was created when H_{i_s} was removed from G_{i_s-1}. Let C' be the component of G_{i_s-1} that contains C and H_{i_s} (and thus v_1). Observe that C' is still connected to $H_1, \ldots, H_{i_{s-1}}$, and possibly to some other branch sets. Recall that H_{i_s} was constructed as a subtree of the breadth-first search tree in G_{i_s} that started in a vertex $v_2 \in V(C')$ which, at this point of the construction, had maximum $m(v_2)$ among vertices in C'. However, at this point vertex v_1 was also present in C', and $\mathcal{P}$ certifies that it could send at least $\alpha - 1$ disjoint paths to different branch sets among $H_1, \ldots, H_{i_{s-1}}$ (in $\mathcal{P}$, at most one path leads to H_{i_s}, and all the other paths are also present in C'). We infer that it held that $m(v_2) \geq \alpha - 1$ at the moment v_2 was taken. Since $\alpha > a(k) + c(k) + d(k) + e(k) \geq a(k) + d(k) + e(k) + 1$, the same reasoning as above shows that t is also the core vertex of the minor model formed by branch sets connected to C'. Thus, by exactly the same reasoning we obtain that v_2 is also an apex vertex of $\tau(t)$.

Since $\alpha > a(k)+c(k)+d(k)+e(k)$, we can repeat this reasoning $c(k)+1$ times, obtaining vertices $v_1, \ldots, v_{c(k)+1}$, which are all apex vertices of $\tau(t)$. This contradicts the fact that $\tau(t)$ contains at most $c(k)$ apex vertices. ◀

At last, we come to the proof of Lemma 9

Proof of Lemma 9. We set β so that $\beta \cdot r \geq (2r+1) \cdot \alpha$, where α is the constant given by Lemma 8. For the sake of contradiction, suppose there is a family of paths $\mathcal{P}$ as in the statement, whose size is larger than $(2r+1) \cdot \alpha$.

Recall that H_j was chosen as a subtree of a breadth-first search tree in G_{j-1}; throughout the proof, we treat H_j as a rooted tree. As H_j is a subtree of a BFS tree, every path from a vertex w of the tree to the root v' of the tree is an isometric path in G_{j-1}, that is, a shortest path between w and v' in the graph G_{j-1}. If P is an isometric path in a graph H, then $|N_r^H(v) \cap V(P)| \leq 2r+1$ for all $v \in V(H)$ and all $r \in \mathbb{N}$. As the paths from $\mathcal{P}$ are all contained in G_{j-1}, and they have lengths at most r, this implies that the path family $\mathcal{P}$ cannot connect v with more than $2r+1$ vertices of H_j which lie on the same root-to-leaf path in H_j. Since $|\mathcal{P}| > (2r+1) \cdot \alpha$, we can find a set $X \subseteq V(H_j)$ such that $|X| > \alpha$, each vertex of X is connected to v by some path from $\mathcal{P}$, and no two vertices of X lie on the same root-to-leaf path in H_j. Recall that, by the construction, each leaf of H_j is connected to a different branch set $H_{j'}$ for some $j' < j$. Consequently, we can take the paths of $\mathcal{P}$ leading to X and extend them within H_j to obtain a family of more than α disjoint paths in G_{j-1} that connect v with different branch sets $H_{j'}$ for $j' < j$. This contradicts Lemma 8. ◀

Observe that the order can be computed in time $\mathcal{O}(n^5)$: for each vertex, we compute by a standard flow algorithm in time $\mathcal{O}(n^3)$ whether it should be chosen as the next tree root to form a subgraph H_{i_j}. This choice has to be made at most n times.

Finally, we state one property of the construction that follows immediately from Lemma 8.

▶ **Lemma 19.** *Each constructed subgraph H_i has maximum degree at most $\alpha+1$, where α is the constant given by Lemma 8.*

5 Model-checking for successor-invariant first-order formulas

A *finite and purely relational signature* τ is a finite set $\{R_1, \ldots, R_k\}$ of relation symbols, where each relation symbol R_i has an associated arity a_i. A finite τ-structure $\mathfrak{A}$ consists of a finite set A, the universe of $\mathfrak{A}$, and a relation $R_i(\mathfrak{A}) \subseteq A^{a_i}$ for each relation symbol $R_i \in \tau$. If $\mathfrak{A}$ is a finite τ-structure, then the *Gaifman graph* of $\mathfrak{A}$, denoted $G(\mathfrak{A})$, is the graph with $V(G(\mathfrak{A})) = A$ and there is an edge $uv \in E(G(\mathfrak{A}))$ if and only if $u \neq v$ and u and v appear together in some relation $R_i(\mathfrak{A})$ of $\mathfrak{A}$. We say that a class $\mathcal{C}$ of finite τ-structures has *bounded expansion* if the graph class $G(\mathcal{C}) := \{G(\mathfrak{A}) : \mathfrak{A} \in \mathcal{C}\}$ has bounded expansion. Similarly, for $r \in \mathbb{N}$, we write $\mathrm{adm}_r(\mathfrak{A})$ for $\mathrm{adm}_r(G(\mathfrak{A}))$ etc.

Let V be a set. A successor relation on V is a binary relation $S \subseteq V \times V$ such that (V, S) is a directed path of length $|V| - 1$. Let τ be a finite relational signature. A formula $\varphi \in \mathrm{FO}[\sigma \cup \{S\}]$ is *successor-invariant* if for all τ-structures $\mathfrak{A}$ and for all successor relations S_1, S_2 on $V(\mathfrak{A})$ it holds that $(\mathfrak{A}, S_1) \models \varphi \iff (\mathfrak{A}, S_2) \models \varphi$.

Successor-invariant logics have been studied in database theory and finite model theory in the past. It was shown by Rossman [15] that successor-invariant FO is more expressive than FO without access to a successor relation. It is known that successor-invariant FO (in fact even order-invariant FO) can express only local queries [10], however, the proof does not translate formulas into local FO-formulas which could be evaluated algorithmically. It was shown in [7] that the model-checking problem for successor-invariant first-order formulas is fixed-parameter tractable on any proper minor closed class of graphs. Very recently, the same result was shown for classes with excluded topological minors [6]. We give a new proof of the model-checking result of [6] which is based on the nice properties of the order we have constructed for graphs that exclude a topological minor.

Eickmeyer et al. [7] showed that on well-behaved classes of graphs one can apply the following reduction from the model-checking problem for successor-invariant formulas to the model-checking problem for plain first-order formulas.

▶ **Lemma 20** (Eickmeyer et al. [7]). *Let $\mathcal{C}$ be a class of τ-structures such that for each $\mathfrak{A} \in \mathcal{C}$ one can compute in polynomial time a graph $H(\mathfrak{A})$ such that*

1. *$V(H(\mathfrak{A})) = V(G(\mathfrak{A}))$ and $E(H(\mathfrak{A})) \supseteq E(G(\mathfrak{A}))$.*
2. *H contains a spanning tree T which can be computed in polynomial time and which is of maximum degree d for some fixed integer d depending on $\mathcal{C}$ only.*
3. *The model-checking problem for first-order formulas on the graph class $\{H(\mathfrak{A}) : \mathfrak{A} \in \mathcal{C}\}$ is fixed-parameter tractable.*

Then the model-checking problem for successor-invariant first-order formulas is fixed-parameter tractable on $\mathcal{C}$.

We remark that the original lemma from [7] refers to k-walks in H, which are easily seen to be equivalent to spanning trees of maximum degree k. In our view, spanning trees are more intuitive to handle in our graph theoretic context.

▶ **Lemma 21.** *Let $k \in \mathbb{N}$. There is a constant δ, depending only on k, and a function $f : \mathbb{N} \to \mathbb{N}$ such that the following holds. For every graph G with $K_k \not\preccurlyeq^t G$ we can compute in polynomial time a supergraph H with $V(H) = V(G)$ and $E(H) \supseteq E(G)$ such that $\mathrm{adm}_r(H) \le f(r)$ for all $r \in \mathbb{N}$ and such that H contains a spanning tree T with maximum degree at most δ; furthermore, such a spanning tree T can be also computed in polynomial time.*

Proof. Without loss of generality, we assume that G is connected. Otherwise, we may apply the construction in each connected component separately, and then connect the components arbitrarily using single edges (added to H) in a path-like manner. It is easy to see that including the additional edges to the spanning tree increases its maximum degree by at most 2, while the admissibility of the graph also increases by at most 2.

We perform the construction of the subgraphs $H_1, \ldots, H_\ell$ almost exactly as in Section 4. However, when constructing the H_i's and the order L, we put some additional restrictions that do not change the quality of L. First, recall that when we defined H_{i+1}, for some $0 \le i < \ell$, we considered a tree of breadth-first search starting at v_{i+1} in a connected component C of G_i. Suppose that the subgraphs that C is connected to are $H_{i_1}, \ldots, H_{i_s}$, where $1 \le i_1 < \ldots < i_s \le i$. Then H_{i+1} was defined as a minimal subtree of the considered BFS tree that contained, for each $1 \le j \le s$, some vertex of H_{i_j} that is adjacent to C.

Observe that in the construction we were free to choose which neighbour of H_{i_j} will be picked to be included in H_{i+1}. For $j < s$ we make an arbitrary choice as before, but the neighbour of H_{i_s} (if exists; note that this is the case for $i > 0$) is chosen as follows. We first select the vertex $w'_{i+1} \in V(H_{i_s})$ that is the largest in the order L among those vertices of H_{i_s} that are adjacent to C (the vertices of H_j for $j \leq i$ are already ordered by L at this point). Then, we select any its neighbour w_{i+1} in C as the vertex that is going to be included in H_{i+1} in its construction. Finally, recall that in the construction of L, we could order the vertices of H_{i+1} arbitrarily. Hence, we fix an order of H_{i+1} so that w_{i+1} is the smallest among $V(H_{i+1})$. This concludes the description of the restrictions applied to the construction.

We now construct H by taking G and adding some edges. During the construction, we will mark some edges of H as *spanning edges*. We start by marking all the edges of all the trees H_i, for $1 \leq i \leq \ell$, as spanning edges. At the end, we will argue that the spanning edges form a spanning tree of H with maximum degree at most δ.

For each i with $1 \leq i < \ell$, let us examine the vertex w_{i+1}, and let us *charge* it to w'_{i+1}. Note that in this manner every vertex w_{i+1} is charged to its neighbour that lies before it in the order L. For any $w \in V(G)$, let $D(w)$ be the set of vertices charged to w. Now examine the vertices of G one by one, and for each $w \in V(G)$ do the following. If $D(w) = \emptyset$, do nothing. Otherwise, if $D(w) = \{u_1, u_2, \ldots, u_h\}$, mark the edge wu_1 as a spanning edge, and add edges $u_1u_2, u_2u_3, \ldots, u_{h-1}u_h$ to H, marking them as spanning edges as well.

▶ **Claim 22** (∗). *The spanning edges form a spanning tree of H of maximum degree at most $\alpha + 4$, where α is the constant given by Lemma 8.*

It remains to argue that H has small admissibility. For this, it suffices to prove the following claim. The proof uses the additional restrictions we introduced in the construction.

▶ **Claim 23** (∗). *Let r be a positive integer. If the order L certifies that $\mathrm{col}_{2r}(G) \leq m$, that is, $\max_{v \in V(G)} |\mathrm{SReach}_{2r}[G, L, v]| \leq m$, then $\mathrm{adm}_r(H) \leq m + 2$.*

The statement of the lemma now directly follows from Claims 22 and 23. ◀

Given a graph G that excludes K_k as a topological minor, let us write $H(G)$ for a graph constructed according to Lemma 21.

▶ **Corollary 24.** *The class $\{H(G) : K_k \not\preccurlyeq^t G\}$ has bounded expansion.*

We can now use Theorem 20 to combine the following result of Dvořak et al. [5] with Lemma 21, to prove fixed-parameter tractability of successor-invariant FO on classes that exclude a fixed topological minor.

▶ **Lemma 25** (Dvořák et al. [5]). *The model-checking problem for first-order formulas is fixed-parameter tractable on any class of bounded expansion.*

▶ **Corollary 26.** *The model-checking problem for successor-invariant first-order formulas is fixed parameter tractable on any class of graphs that excludes a fixed topological minor.*

6 Conclusions

In this work we gave several new applications of the generalised colouring numbers on classes of bounded expansion. In particular, we have shown that whenever a graph class $\mathcal{C}$ excludes some fixed topological minor, then any graph from $\mathcal{C}$ admits one ordering of vertices that certifies the boundedness of the generalised colouring numbers for all radii r at once. It is tempting to conjecture that such an ordering exists for any graph class of bounded expansion.

Our construction of the uniform ordering proved to be useful in showing that model-checking successor-invariant FO is FPT on any graph class that excludes a fixed topological minor. We believe that our construction may be helpful in extending this result to any graph class of bounded expansion, since both the construction of the order, and the reasoning of Section 5, are oblivious to the fact that the graph class excludes some topological minor. The only place where we used this assumption is the analysis of the constructed order.

Abstract

We study the interaction between polynomial space randomness and a fundamental result of analysis, the Lebesgue differentiation theorem. We generalize Ko's framework for polynomial space computability in $\mathbb{R}^n$ to define *weakly pspace-random* points, a new variant of polynomial space randomness. We show that the Lebesgue differentiation theorem characterizes weakly pspace random points. That is, a point x is weakly pspace random if and only if the Lebesgue differentiation theorem holds for a point x for every pspace L_1-computable function.

1 Introduction

The theory of computing allows for a meaningful definition of an individual point of Euclidean space being “random". Classically, such a notion would seem paradoxical, as any singleton set (indeed, any countably infinite set) has measure zero. Martin-Löf used computability to give the first mathematically robust definition of a point being random [10]. Since Martin-Löf's original definition, many notions of randomness have been introduced. In addition to Martin-Löf randomness, two of the most prominent variants are Schnorr randomness and computable randomness [4]. By developing a theory of resource-bounded measure, Lutz initiated the study of resource-bounded randomness [12, 13]. This allowed for research in algorithmic randomness to extend to resource-bounded computation [21].

Recently, research in algorithmic randomness has used computable analysis to study the connection between randomness and classical analysis [1, 5, 6, 7, 14, 15, 20]. With the rise of measure theory, many fundamental theorems of analysis have been “almost everywhere" results. Theorems of this type state that a certain property holds for almost every point; i.e., the set of points that does not satisfy the property is of measure zero. However, almost everywhere theorems typically give no information about which points satisfy the stated property. By adding computability restrictions, tools from algorithmic randomness are able to strengthen a theorem from a property simply holding almost everywhere, to one that holds for all random points. For example, an important classical result of analysis is Lebesgue's theorem on nondecreasing functions. Lebesgue showed that every nondecreasing continuous function $f : [0, 1] \to \mathbb{R}$ is differentiable almost everywhere. Brattka, Miller and

* This research was supported in part by National Science Foundation Grants 1247051 and 1545028.

Nies characterized computable randomness using Lebesgue's theorem by proving the following result [2].

▶ **Theorem.** *Let $z \in [0,1]$. Then z is computably random if and only if $f'(z)$ exists for every nondecreasing computable function $f : [0,1] \to \mathbb{R}$.*

This paper concerns a related theorem, also due to Lebesgue [9].

▶ **Lebesgue Differentiation Theorem.** *For each $f \in L_1([0,1]^n)$,*

$$f(x) = \lim_{Q \to x} \frac{\int_Q f d\mu}{\mu(Q)}$$

for almost every $x \in [0,1]^n$. The limit is taken over all open cubes Q containing x as the diameter of Q tends to 0.

Pathak first studied the Lebesgue differentiation theorem in the context of Martin-Löf randomness [18]. Under the assumption that the function is L_1-computable, Pathak showed that the Lebesgue differentiation theorem holds for every Martin-Löf random point. Subsequently, Pathak, Rojas and Simpson improved this theorem [19]. They showed that the Lebesgue differentiation theorem holds at a point z for every L_1 computable function if and only if z is Schnorr random [19]. Independently, and using very different techniques, Rute also showed that the Lebesgue differentiation theorem holds for Schnorr random points [20].

This paper concerns the connection between *resource-bounded* randomness and analysis. While there has been work on this interaction [3, 11, 17], resource-bounded randomness in analysis is still poorly understood. Recently, Nies extended the result of Brattka, Miller and Nies to the polynomial time domain [17]. Specifically, Nies characterized polynomial time randomness using the differentiability of nondecreasing polynomial time computable functions. In this paper, we extend this research of the Lebesgue differentiation theorem to the context of resource-bounded randomness. We show that the Lebesgue differentiation theorem characterizes *weakly polynomial space randomness.* We note that the polynomial space variant of Nies' result implies our result in one dimension. However, as in classical analysis, the proof for arbitrary dimension requires significantly different tools.

In order to work with resource bounded computability over continuous domains, we use the framework for polynomial space computability in $\mathbb{R}^n$ developed by Ko [8]. Using generalizations of Ko's *polynomial space approximable* sets, we define weakly polynomial space randomness, a new variant of polynomial space randomness. We prove that Lutz's notion of polynomial space randomness implies weakly polynomial randomness. Weakly polynomial space randomness uses open covers, similar to Martin-Löf's original definition, unlike the martingale definitions commonly used in resource-bounded randomness. The use of open covers lends itself better to adapting many theorems of classical analysis. We believe that the notion of weakly polynomial space randomness will be useful in further investigations of resource-bounded randomness in analysis.

Using this definition of randomness, we extend the result of Pathak, et al, and Rute to polynomial space randomness. Specifically, we prove that a point x is weakly polynomial space random if and only if the Lebesgue differentiation theorem holds at x for every polynomial space L_1-computable function. Structurally, the proof of this theorem largely follows that of Pathak, et al. However, the restriction to polynomial space forces significant changes to the internal methods. To prove the converse of our theorem, we introduce *dyadic tree decompositions.* Intuitively, a dyadic tree decomposition partitions an open cover randomness test into a tree structure. This allows for the construction of a polynomial space

L_1-computable function so that the Lebesgue differentiation theorem fails for any point covered by the test. We believe that dyadic tree decompositions will be useful in further research.

2 Preliminaries

Throughout the paper, μ will always denote the Lebesgue measure on $\mathbb{R}^n$. We denote the set of all Lebesgue integrable functions $f : [0,1]^n \to \mathbb{R}$ by $L_1([0,1]^n)$. A *dyadic rational number* d is a rational number that has a finite binary expansion; that is $d = \frac{m}{2^r}$ for some integers m, r with $r \geq 0$. We denote the set of all dyadic rational numbers by $\mathbf{D}$. We denote the set of all dyadic rationals d of precision r by $\mathbf{D}_r$. Formally,

$$\mathbf{D}_r = \{\frac{m}{2^r} \,|\, m \in \mathbb{Z}\}.$$

We denote the set of dyadic rationals in the interval $[0,1]$ by $\mathbf{D}[0,1]$. We denote the set of dyadic rationals of precision r in the interval $[0,1]$ by $\mathbf{D}_r[0,1]$. An *open dyadic cube of precision* r is a subset $Q \subseteq \mathbb{R}^n$ such that

$$Q = (\frac{a_1}{2^r}, \frac{a_1+1}{2^r}) \times \ldots \times (\frac{a_n}{2^r}, \frac{a_n+1}{2^r}),$$

where $a_i \in \mathbb{Z}$, and $r \in \mathbb{N}$. We say that the points $\{\frac{a_1}{2^r}, \frac{a_1+1}{2^r}, \ldots \frac{a_n}{2^r}, \frac{a_n+1}{2^r}\}$ are the *endpoints of* Q. In the same manner, we define closed dyadic cubes, and half-open dyadic cubes. We denote the set of all open dyadic cubes of precision r by

$$\mathbf{B}_r = \{Q \,|\, Q \text{ is an open dyadic cube of precision } r\}.$$

For an open set $Q \subseteq \mathbb{R}^n$ and $t \in \mathbb{R}^n$, define the translation of Q by t to be the set

$$t + Q = \{t + x \,|\, x \in Q\}.$$

2.1 Resource-Bounded Randomness in Euclidean Space

Lutz and Lutz recently adapted resource-bounded randomness to arbitrary dimension [11]. In this section, we review their definition of polynomial space randomness in $\mathbb{R}^n$.

Let $r \in \mathbb{N}$, $\mathbf{u} = (u_1, \ldots, u_n) \in \mathbb{Z}^n$. Define the *$r$-dyadic cube at* $\mathbf{u}$ to be the half-open dyadic cube of precision r,

$$Q_r(\mathbf{u}) = [u_1 \cdot 2^{-r}, (u_1+1) \cdot 2^{-r}) \times \ldots \times [u_n \cdot 2^{-r}, (u_n+1) \cdot 2^{-r}).$$

Define the family

$$\mathcal{Q}_r = \{Q_r(\mathbf{u}) \mid \mathbf{u} \in \{0, \ldots, 2^r - 1\}^n\}.$$

So then $\mathcal{Q}_r$ is a partition of the unit cube $[0,1)^n$. The family

$$\mathcal{Q} = \bigcup_{r=0}^{\infty} \mathcal{Q}_r,$$

is the set of all half-open dyadic cubes in $[0,1)^n$.

A *martingale* on $[0,1)^n$ is a function $d : \mathcal{Q} \to [0,\infty)$ satisfying

$$d(Q_r(\mathbf{u})) = 2^{-n} \sum_{\mathbf{a} \in \{0,1\}^n} d(Q_{r+1}(2\mathbf{u} + \mathbf{a})), \tag{1}$$

for all $Q_r(\mathbf{u}) \in \mathcal{Q}$. We may think of a martingale d as a strategy for placing successive bets on which cube contains x. After r bets have been placed, the bettor's capital is

$$d^{(r)}(\mathbf{x}) = d(Q_r(\mathbf{u})),$$

where $\mathbf{u}$ is the unique element of $\{0, \dots, 2^r - 1\}^n$ such that $\mathbf{x} \in Q_r(\mathbf{u})$. A martingale d *succeeds* at a point $\mathbf{x} \in [0,1)^n$ if

$$\limsup_{r \to \infty} d^{(r)}(\mathbf{x}) = \infty.$$

Let

$$J = \{(r, \mathbf{u}) \in \mathbb{N} \times \mathbf{Z}^n \mid \mathbf{u} \in \{0, \dots, 2^r - 1\}^n\}.$$

We say that a martingale $d : \mathcal{Q} \to [0, \infty)$ is *computable* if there is a computable function $\hat{d} : \mathbb{N} \times J \to \mathbb{Q} \cap [0, \infty)$ such that for all $(s, r, \mathbf{u}) \in \mathbb{N} \times J$,

$$|\hat{d}(s, r, \mathbf{u}) - d(Q_r(\mathbf{u}))| \leq 2^{-s}. \tag{2}$$

A martingale $d : \mathcal{Q} \to [0, \infty)$ is *p-computable* (resp. *pspace-computable*) if there is a function $\hat{d} : \mathbb{N} \times J \to \mathbb{Q} \cap [0, \infty)$ that satisfies (2) and is computable in $(s + r)^{O(1)}$ time (resp. space). A point $x \in \mathbb{R}^n$ is *p-random* (resp. *pspace-random*) if no p-computable (resp. pspace-computable) martingale succeeds at x.

2.2 Polynomial Space Computability in Euclidean Space

In this section, we review Ko's framework for complexity theory in $\mathbb{R}^n$ [8]. For the remainder of the paper, we include the write tape when considering polynomial space bounds of Turing machines.

We first introduce the polynomial space L_1-computable functions, the class of functions we will be using in the proof of the Lebesgue differentiation theorem. This definition is equivalent to Ko's notion of *pspace approximable functions*. It is a direct analog of the L_1-computable functions used in computable analysis.

A function $f : [0,1]^n \to \mathbb{R}$ is a *simple step function* if f is a step function such that

1. $f(x) \in \mathbf{D}$ for all $x \in [0,1]^n$ and
2. there exists a finite number of (disjoint) dyadic boxes $Q_1, \dots, Q_k$ and dyadic rationals $d_1, \dots, d_k$ such that $f(x) = \sum_{i=1}^{k} d_i \chi_{Q_i}(x)$, where χ_Q is the characteristic function of a set Q.

A function $f \in L_1([0,1]^n)$ is *polynomial space L_1-computable* if there exists a sequence of simple step functions, $\{f_m\}_{m \in \mathbb{N}}$, and a polynomial p such that for all $d \in \mathbf{D}^n$,

1. $f_m(x) = \sum_{i=1}^{k} d_i \chi_{Q_i}(x)$, such that the endpoints of each Q_i are in $\mathbf{D}^n_{p(m)}$,
2. there is a polynomial space TM M computing f_m in the sense that
$$M(0^m, d) = \begin{cases} f_m(d) & \text{if } d \text{ is not a breakpoint of } f_m \\ \# & \text{otherwise} \end{cases}$$
3. $\|f - f_m\|_1 \leq 2^{-n}$.

Note that we may assume that the polynomial p is increasing. We will frequently use the following nice property of polynomial space L_1-computable functions. If $f \in L_1([0,1]^n)$ is approximated by sequence of simple step function $\{f_m\}$ at precision p, then for every $i > 0$, f_i is a constant function on every $Q \in \mathbf{B}_{p(i)}$.

An infinite sequence $\{S_m\}_{m\in\mathbb{N}}$ of finite unions of open boxes is *polynomial space computable* if there exists a polynomial space TM M such that for all $m > 0$, and all $d \in \mathbf{D}^n$,

$$M(0^m, d) = \begin{cases} 1 & \text{if } d \in S_m \\ -1 & \text{if } d \text{ is a boundary point of } S_m \\ 0 & \text{otherwise} \end{cases}$$

A set $S \subseteq [0,1]^n$ is *polynomial space approximable* if S is measurable and there exists a polynomial space computable sequence of sets $\{S_m\}_{m\in\mathbb{N}}$ such that, for every $m > 0$,

1. there is a polynomial p such that all endpoints of S_m are in $\mathbf{D}^n_{p(m)}$ and
2. $\mu(S\Delta S_m) \leq 2^{-m}$.

Note that we may assume that the polynomial p is increasing; that is $p(i) \leq p(i+1)$, for all $i \in \mathbb{N}$.

3 Uniformly Approximable Sequences

We now generalize Ko's definition of approximable sets to approximable *arrays* of sets. We follow Ko in first defining computability, then leveraging this to define approximability.

▶ **Definition 1.** An infinite array $\{S^k_m\}_{k,m\in\mathbb{N}}$ of finite unions of open boxes is *uniformly polynomial space computable* if there exists a polynomial space TM M such that for all $k, m > 0$, and all $d \in \mathbf{D}^n$,

$$M(0^m, 0^k, d) = \begin{cases} 1 & \text{if } d \in S^k_m \\ -1 & \text{if } d \text{ is an boundary point of } S^k_m \\ 0 & \text{otherwise} \end{cases}$$

If $\{S^k_m\}$ is uniformly polynomial space computable and M is a TM satisfying the definition, we say M *computes* $\{S^k_m\}$.

▶ **Definition 2.** A sequence of sets $\{U_m\}_{m\in\mathbb{N}}$ is *uniformly polynomial space approximable* if there exists a uniformly polynomial space computable array of sets $\{S^k_m\}$ and a polynomial p such that

1. all endpoints of S^k_m are in $\mathbf{D}^n_{p(m+k)}$ and
2. $\mu(U_m \Delta S^k_m) \leq 2^{-k}$.

If a polynomial p and a uniformly polynomial space computable sequence $\{S^k_m\}$ satisfies (1) and (2), we say that $\{S^k_m\}_{k,m\in\mathbb{N}}$ *approximates* $\{U_m\}$ *at precision* p. Note that we may assume that the polynomial p is increasing.

We now show that we can construct *uniformly* pspace computable sequences from pspace computable sequences. This lemma will be useful, as polynomial space computability is an easier property to verify than its uniform counterpart.

▶ **Lemma 3.** *Let $\{T_i\}_{i\in\mathbb{N}}$ be a pspace computable sequence, and q_1, q_2 be polynomials. For every k, $m > 0$, define the set S^k_m by*

$$S^k_m = \bigcup_{i=q_1(m)}^{q_2(k)} T_i.$$

Then the array $\{S^k_m\}$ is uniformly polynomial space computable.

Similarly, we are able to construct uniformly pspace approximable sequences from other uniformly approximable sequences.

▶ **Lemma 4.** *Let q be a polynomial, $j \in \mathbb{N}$, and $\{V_i\}_{i\in\mathbb{N}}$ be a uniformly pspace approximable sequence, such that $\mu(V_i) \leq 2^{-i+j}$. Define the sequence $\{U_m\}_{m\in\mathbb{N}}$ by*

$$U_m = \bigcup_{i=q(m)}^{\infty} V_i.$$

Then $\{U_m\}_{m\in\mathbb{N}}$ is a uniformly pspace approximable sequence.

4 Weakly Polynomial Space Randomness

Using uniformly polynomial space approximable sequences, we give an open-cover definition of polynomial space randomness. This variant is intended to be similar to the open-cover definitions of the various computable randomness notions. However, the resource bounds force us to replace the typical enumerability requirements with approximability.

▶ **Definition 5.** Let $a, b \in \mathbb{Z}$. An infinite sequence of open sets $\{U_m\}_{m\in\mathbb{N}} \subseteq [a,b]^n$ is a *polynomial space $\mathcal{W}$-test (pspace $\mathcal{W}$-test)* if the following hold.

1. For every m, $\mu(U_m) \leq 2^{-m}$.
2. There is a uniformly pspace computable array $\{S_m^k\}$ approximating $\{U_m\}$ such that, for all m,

$$U_m \subseteq \liminf_{k\to\infty} S_m^k,$$

A point x *passes* a polynomial space $\mathcal{W}$-test $\{U_m\}_{m\in\mathbb{N}}$ if $x \notin \bigcap_{m=1}^{\infty} U_m$. We say that x is *weakly pspace random* if x passes every polynomial space $\mathcal{W}$-test.

The approximability of pspace $\mathcal{W}$-tests allows us to estimate the measure of the open covers in polynomial space.

▶ **Lemma 6.** *If $\{U_m\}_{m\in\mathbb{N}}$ is a pspace $\mathcal{W}$-test, then there exists a polynomial space TM M such that for every s, r, $m \in \mathbb{N}$ and $\mathbf{u} \in \{0,\ldots,2^r-1\}^n$*

$$|M(0^s, 0^r, \mathbf{u}, 0^m) - \mu(U_m \cap Q_r(\mathbf{u}))| \leq 2^{-s}.$$

We are now able to relate weakly polynomial space randomness with Lutz's pspace randomness. The following lemma shows that pspace randomness implies weakly pspace randomness.

▶ **Theorem 7.** *Let $\{U_m\}_{m\in\mathbb{N}}$ be a polynomial space $\mathcal{W}$-test. Then there exists a pspace martingale d succeeding on all points $x \in \bigcap_{m=1}^{\infty} U_m \bigcap [0,1]^n$.*

5 Randomness and the Lebesgue Differentiation Theorem

In this section we prove our main theorem, that the Lebesgue differentiation theorem characterizes weakly pspace-randomness. Recall the statement of Lebesgue's theorem.

▶ **Lebesgue Differentiation Theorem.** *For each $f \in L_1([0,1]^n)$,*

$$f(x) = \lim_{Q \to x} \frac{\int_Q f d\mu}{\mu(Q)}$$

for almost every $x \in [0,1]^n$. The limit is taken over all open cubes Q containing x as the diameter of Q tends to 0.

A point x that satisfies the Lebesgue differentiation theorem is called a *Lebesgue point*. We will prove the following theorem,

▶ **Main Theorem.** *A point x is weakly pspace-random if and only if for every polynomial space L_1-computable $f \in L_1([0,1]^n)$, and every polynomial space computable sequence of simple functions $\{f_m\}_{m\in\mathbb{N}}$ approximating f,*

$$\lim_{m\to\infty} f_m(x) = \lim_{Q \to x} \frac{\int_Q f d\mu}{\mu(Q)} \tag{3}$$

where the limit is taken over all cubes Q containing x as the diameter of Q tends to 0.

We first make several remarks regarding the form of our main theorem. The use of polynomial space L_1-computability is not simply for the sake of generality. It is well-known that if a function is continuous, the Lebesgue differentiation theorem holds for *every* point. Thus, to get a non-trivial randomness result, we must allow the function to be discontinuous. Our second remark concerns the limit of the approximating functions. In the statement of the classical theorem, the integral limit is equal to $f(x)$; whereas in our main theorem, it is equal to $\lim_{m\to\infty} f_m(x)$. This concession is necessary. For any point x, it is trivial to construct a polynomial space L_1-computable function f such that

$$f(x) \neq \lim_{Q \to x} \frac{\int_Q f d\mu}{\mu(Q)}.$$

Consider the function f which is 0 for all points, except at the given point x, $f(x) = 1$. Clearly, f is polynomial space L_1-computable, but x does not satisfy the Lebesgue differentiation theorem.

5.1 Random points satisfy the Lebesgue differentiation theorem

The outline of our proof roughly follows that of the classical proof of the Lebesgue differentiation theorem [19, 22]. However, the restriction to polynomial space computation significantly changes the internal methods. We first show that if a point $x \in [0,1]^n$ is weakly pspace-random, then it must be contained in an open dyadic cube. This is a useful property of weakly pspace-random points that we take advantage of in later theorems.

▶ **Lemma 8.** *Let $x = (x_1, \dots, x_n) \in [0,1]^n$ be weakly pspace-random. Then, for every i, x_i is not a dyadic rational.*

Let f be a polynomial space L_1-computable function, approximated by the pspace computable sequence of simple step functions $\{f_m\}_{m\in\mathbb{N}}$. We now show that for every weakly pspace-random point x, the limit $\lim\limits_{m\to\infty} f_m(x)$ exists. We will need the following inequality due to Chebyshev. For every $f \in L_1([0,1]^n)$ and $\epsilon > 0$, define the set

$$S(f, \epsilon) = \{x \mid |f(x)| > \epsilon\}.$$

▶ **Chebyshev's Inequality.** *Let $f \in L_1([0,1]^n)$ and $\epsilon > 0$. Then $\mu(S(f,\epsilon)) \le \frac{\|f\|_1}{\epsilon}$.*

▶ **Lemma 9.** *Let $f \in L_1([0,1]^n)$ be polynomial space L_1 computable, approximated by the polynomial space computable sequence of simple step functions $\{f_m\}_{m\in\mathbb{N}}$. If x is weakly pspace-random, the limit $\lim\limits_{m\to\infty} f_m(x)$ exists.*

We now focus on the limit

$$\lim_{Q\to x} \frac{\int_Q f d\mu}{\mu(Q)}$$

on the right hand side of our main theorem (equation (3)). The restriction to polynomial space computation creates difficulties in considering arbitrary open cubes. Intuitively, we overcome this obstacle through the use of translations of dyadic cubes, which are more amenable to polynomial space computation. Formally, for $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$, define the set

$$\mathbf{B}_r^t = \{I_r^t \mid I_r^t = t + Q, \text{ where } Q \in \mathbf{B}_r\}.$$

That is, $\mathbf{B}_r^t$ is the set of all translations of dyadic cubes of precision r by points $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$. For every $x \in [0,1]^n$, let $I_r^t(x)$ denote the (unique) element of $\mathbf{B}_r^t$ containing x. The following theorem of Rute [20], using results due to Morayne and Solecki [16], shows that it suffices to prove that the right hand limit of equation (3) exists for these translations.

▶ **Theorem 10** ([20])**.** *Let $f \in L_1([0,1]^n)$, and $x \in [0,1]^n$. Then the following are equivalent,*

1. *the limit $\lim\limits_{Q\to x} \frac{\int_Q f d\mu}{\mu(Q)}$ exists, where the limit is taken over all cubes containing x, as the diameter goes to* 0
2. *the limit $\lim\limits_{k\to\infty} \frac{\int_{I_k^t(x)} f d\mu}{\mu(I_k^t(x))}$ exists, for all $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$.*

We now show that the limit

$$\lim_{m\to\infty} \frac{\int_{I_r^t(x)} |f - f_m| d\mu}{\mu(I_r^t(x))}$$

exists, for every $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$ and $r > 0$. We will need the following inequality due to Hardy and Littlewood. For every $f \in L_1([0,1]^n)$ and $\epsilon > 0$, define the set

$$T(f,\epsilon) = \{x \mid \sup_{r,t} \frac{\int_{I_r^t(x)} f d\mu}{\mu(I_r^t)} > \epsilon\},$$

where the supremum is taken over all $r > 0$ and $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$.

▶ **Hardy/Littlewood Inequality.** *There is a constant c such that, for every $f \in L_1([0,1]^n)$ and $\epsilon > 0$, $\mu(T(f,\epsilon)) \le \frac{c\|f\|_1}{\epsilon}$.*

▶ **Lemma 11.** *Let $f \in L_1([0,1]^n)$ be polynomial space L_1 computable, approximated by the polynomial space computable sequence of step functions $\{f_m\}_{m\in\mathbb{N}}$. If x is weakly pspace-random, then*

$$\lim_{m\to\infty} \frac{\int_{I_r^t(x)} |f - f_m| d\mu}{\mu(I_r^t(x))} = 0,$$

for every $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$ and $r > 0$.

We are now able to prove that weakly pspace random points satisfy the Lebesgue differentiation theorem.

▶ **Theorem 12.** *If x is weakly pspace-random, then for every polynomial space L_1-computable $f \in L_1([0,1]^n)$, and every polynomial space computable sequence of simple functions $\{f_m\}_{m\in\mathbb{N}}$ approximating f,*

$$\lim_{m\to\infty} f_m(x) = \lim_{Q\to x} \frac{\int_Q f d\mu}{\mu(Q)}$$

where the limit is taken over all cubes Q containing x as the diameter of Q tends to 0.

Proof. Let x be weakly pspace-random. By Theorem 10, it suffices to show that

$$\lim_{m\to\infty} f_m(x) = \lim_{k\to\infty} \frac{\int_{I_k^t(x)} f d\mu}{\mu(I_k^t(x))}$$

for all $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$.

Let $\epsilon > 0$. By Lemmas 9 and 11, there exists an N such that for all $i > N$,

$$|f_i(x) - \lim_{m\to\infty} f_m(x)| < \frac{\epsilon}{2}, \tag{4}$$

and

$$\frac{\int_{I_k^t(x)} |f - f_i| d\mu}{\mu(I_k^t(x))} < \frac{\epsilon}{2}, \tag{5}$$

for every $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$ and $k > 0$. Let $i > N$. Then, using (4) we obtain

$$|\lim_{m\to\infty} f_m(x) - \lim_{k\to\infty} \frac{\int_{I_k^t(x)} f d\mu}{\mu(I_k^t(x))}| < \frac{\epsilon}{2} + |f_i(x) - \lim_{k\to\infty} \frac{\int_{I_k^t(x)} f d\mu}{\mu(I_k^t(x))}|. \tag{6}$$

By Lemma 8, for every $r > 0$, $x \in Q$ for some $Q \in \mathbf{B}_r$. Since f_i is a simple step function, f_i is constant on every $Q \in \mathbf{B}_{p(i)}$. So there exists an N' so that for all $r > N'$,

$$f_i(x) = \frac{\int_{I_r^t(x)} f_i d\mu}{\mu(I_r^t(x))},$$

for every $t \in \{-\frac{1}{3}, 0, \frac{1}{3}\}^n$. Therefore, by inequality (5), for every $r > N'$,

$$\begin{aligned}
|f_i(x) - \frac{\int_{I_r^t(x)} f d\mu}{\mu(I_r^t(x))}| &= |\frac{\int_{I_r^t(x)} f_i d\mu}{\mu(I_r^t(x))} - \frac{\int_{I_r^t(x)} f d\mu}{\mu(I_r^t(x))}| && (7)\\
&\leq \frac{\int_{I_r^t(x)} |f - f_i| d\mu}{\mu(I_r^t(x))} && (8)\\
&< \frac{\epsilon}{2}. && (9)
\end{aligned}$$

Combining inequalities (6) and (9) we have

$$|\lim_{m\to\infty} f_m(x) - \lim_{k\to\infty} \frac{\int_{I_k^t(x)} f d\mu}{\mu(I_k^t(x))}| < \epsilon.$$

Since ϵ was arbitrary, the proof is complete. ◀

5.2 Non-random points are not Lebesgue points

We now show that converse of our main theorem holds. That is, we show that if a point x is not weakly pspace random, the limit $\lim\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu$ does not exist. Our approach is largely similar from the construction of Pathak, et al [19]. However, due to the restriction of polynomial space computation, the implementation is significantly different. To adapt the construction of Pathak et al, we first introduce a notion that will partition a pspace $\mathcal{W}$-test $\{U_m\}$ into a tree of dyadic cubes.

Recall that the *level* of a node in a rooted tree is the length of the (unique) path from the root to the node. We denote the set of all nodes of a tree $\mathbf{T}$ at level i by $Level_i(\mathbf{T})$.

▶ **Definition 13.** A *dyadic tree decomposition of* $[0,1]^n$ is a tree $\mathbf{T}$ of dyadic cubes rooted at $[0,1]^n$ such that the following hold:

1. For every cube $Q \in \mathbf{T}$, the children of Q, are subsets of Q.
2. For any two cubes $Q_1, Q_2 \in \mathbf{T}$, either Q_1 and Q_2 are disjoint, or one contains the other.
3. For any cube $Q \in \mathbf{T}$,

$$\mu(\bigcup_{B\in Child(Q)} B) \leq \frac{\mu(Q)}{4}.$$

A dyadic tree decomposition $\mathbf{T}$ is *polynomial space approximable* if there exists a polynomial p and uniformly pspace computable array $\{T_m^k\}_{k,m\in\mathbb{N}}$ such that the following hold.

1. For every $k, m \in \mathbb{N}$, T_m^k is a finite union of disjoint dyadic cubes.
2. For every $\mu(Level_m(\mathbf{T})\Delta T_m^k) \leq 2^{-(k+m)}$.

Intuitively, for every k and m, T_m^k is a good approximation of the mth level of the tree $\mathbf{T}$.

We now show that every pspace $\mathcal{W}$-test admits a pspace approximable dyadic tree decomposition. We build the tree inductively, using the uniformly pspace computable sequence of the previous lemma.

▶ **Lemma 14.** *Let $\{U_m\}_{m\in\mathbb{N}}$ be a pspace $\mathcal{W}$-test. Then there exists a pspace approximable dyadic tree decomposition $\mathbf{T}$ such that, for every non-dyadic $x \in \bigcap U_m$, x is contained in an infinite path in $\mathbf{T}$.*

We are now able to prove the converse of Theorem 12, thereby completing the proof of our main theorem. The proof of this theorem involves constructing a function that takes advantage of the dyadic tree decomposition of a pspace W-test succeeding on x. We construct the function so that it assigns different values to alternating levels of the tree. As we are guaranteed that x is in an infinite path of the tree, the function oscillates around x.

▶ **Theorem 15.** *If $x \in [0,1]^n$ is not weakly pspace random, then there exists a pspace L_1 computable function f such that the limit $\lim\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu$ does not exist.*

Proof. We first assume that $x = (x_1, \ldots, x_n)$ so that some component x_i of x is a dyadic rational. Without loss of generality assume that $x_1 = d \in \mathbf{D}$. Define the function $f : [0,1]^n \to \mathbb{R}$ to be

$$f(y) = \begin{cases} 1 & \text{if } y \in [0,d] \times [0,1] \times \ldots \times [0,1] \\ 0 & \text{otherwise} \end{cases}$$

It is clear that f is pspace L_1-computable, and that the limit $\lim\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu$ does not exist.

Assume that $x = (x_1, \ldots, x_n)$ so that x_i is not a dyadic rational for all $i \le n$. Let $\{U_m\}_{m\in\mathbb{N}}$ be a pspace $\mathcal{W}$-test succeeding on x. Let $\mathbf{T}$ be a pspace computable dyadic tree partition of $\{U_m\}_{m\in\mathbb{N}}$ given by Lemma 14. Define $f : [0,1]^n \to \mathbb{R}$ as follows. For every $Q \in \mathbf{T}$,

$$f(Q - \bigcup_{B \in Child(Q)} B) = \begin{cases} 1 & \text{if the level of } Q \text{ in } \mathbf{T} \text{ is even} \\ 0 & \text{if the level of } Q \text{ in } \mathbf{T} \text{ is odd} \end{cases}$$

It is clear that f is integrable and well defined for all points that are not in the intersection $\bigcap U_m$. We now show that f is pspace L_1-computable. Let $\{T_m^k\}_{k,m\in\mathbb{N}}$ be the uniformly pspace computable array approximating $\mathbf{T}$. For every $m \in \mathbb{N}$, define

$$\mathbf{T}_m = \bigcup_{i=1}^{m} T_i^{m+2}.$$

We can consider $\mathbf{T}_m$ as a finite subtree of $\mathbf{T}$ which well approximates $\mathbf{T}$. For every $m \in \mathbf{N}$ and every $Q \in \mathbf{T}_m$, define the set of children of Q in the approximation $\mathbf{T}_m$ by

$$C_m(Q) = Child(Q) \cap \mathbf{T}_m.$$

For every $m \in \mathbb{N}$, define $f_m : [0,1]^n \to \mathbb{R}$ as follows.

$$f_m(Q - \bigcup_{B \in C_m(Q)} B) = \begin{cases} 1 & \text{if the level of } Q \text{ in } \mathbf{T}_m \text{ is even} \\ 0 & \text{if the level of } Q \text{ in } \mathbf{T}_m \text{ is odd} \end{cases}$$

It is clear that f_m is a simple step function. Since the array $\{T_m^k\}$ approximating $\mathbf{T}$ is uniformly pspace computable, on input $(0^m, d)$ we are able to compute the level of the largest dyadic cube in $\mathbf{T}$ containing d in polynomial space. Therefore the sequence of functions $\{f_m\}$ is pspace computable.

We now prove that $\{f_m\}_{m\in\mathbb{N}}$ approximates f. For $m \in \mathbb{N}$, define the set $A = \mathbf{T} - \mathbf{T}_m$, the set of all cubes in $\mathbf{T}$ that are not in the approximation $\mathbf{T}_m$. We now bound the error of our approximation $\mathbf{T}_m$. From the definition of tree decompositions, we have

$$\begin{aligned} \mu(A) &= \mu(\mathbf{T} - \mathbf{T}_m) \\ &= \mu(\bigcup_{i=1}^{m} Level_i(\mathbf{T}) - T_i^{m+2}) + \mu(\bigcup_{i=m+1}^{\infty} Level_i(\mathbf{T})) \\ &\le \sum_{i=1}^{m} \mu(Level_i(\mathbf{T}) - T_i^{m+2}) + \sum_{i=m+1}^{\infty} \mu(Level_i(\mathbf{T})) \\ &\le \sum_{i=1}^{m} 2^{-(i+m+2)} + \sum_{i=m+1}^{\infty} 2^{-2i} \\ &\le 2^{-m}. \end{aligned}$$

Therefore, we have

$$\begin{aligned} \|f - f_m\|_1 &= \int_0^1 |f - f_m| \\ &= \int_A |f - f_m| \\ &\le \mu(A) \\ &\le 2^{-m}. \end{aligned}$$

Hence, f is a pspace L_1 computable function.

Finally, we show that the limit $\lim\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu$ does not exist. We first show that $\limsup\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu \geq \frac{3}{4}$. Let $N \in \mathbb{N}$. By Lemma 14, x is contained in an infinite path of $\mathbf{T}$. Choose a dyadic cube $Q \in \mathbf{T}$ containing x so that $\mu(Q) < 2^{-N}$ and the level of Q in $\mathbf{T}$ is even. Then, by our construction of f,

$$\begin{aligned}\frac{1}{\mu(Q)} \int_Q f d\mu &\geq \frac{1}{\mu(Q)} \int_{Q-Child(Q)} 1 d\mu \\ &= \frac{1}{\mu(Q)} \mu(Q - Child(Q)) \\ &\geq \frac{3}{4}. \end{aligned} \tag{10}$$

Similarly, we show that $\liminf\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu \leq \frac{1}{4}$. Let $N \in \mathbb{N}$. Choose a dyadic cube $Q \in \mathbf{T}$ containing x so that $\mu(Q) < 2^{-N}$ and the level of Q in $\mathbf{T}$ is odd. Then, by our construction of f,

$$\begin{aligned}\frac{1}{\mu(Q)} \int_Q f d\mu &\leq \frac{1}{\mu(Q)} \int_{Child(Q)} 1 d\mu \\ &= \frac{1}{\mu(Q)} \mu(Child(Q)) \\ &\leq \frac{1}{4}. \end{aligned} \tag{11}$$

Combining the equalities (10) and (11), we see that the limit $\lim\limits_{Q\to x} \frac{1}{\mu(Q)} \int_Q f d\mu$ does not exist. ◀

Finally, by Theorems 12 and 15, the Lebesgue differentiation theorem characterizes weakly pspace randomness.

6 Conclusion and Open Problems

In the computable setting, there is a strong connection between randomness and classical theorems of analysis. However, this interaction is not as well understood in the context of resource-bounded randomness. An interesting direction is to characterize randomness for different computational resource bounds using the Lebesgue differentiation theorem. For example, what notion of polynomial time randomness is characterized by the Lebesgue differentiation theorem?

We believe the notion of weakly polynomial space randomness will be useful in further investigations into resource-bounded randomness in analysis. An interesting avenue of future research is to relate weakly pspace-randomness with other notions of polynomial space randomness. We showed that Lutz's definition of pspace-randomness implies weakly pspace randomness, but the converse is not known. We conjecture that weakly pspace randomness is strictly weaker than Lutz's notion of pspace-randomness.

Finding a Maximum 2-Matching Excluding Prescribed Cycles in Bipartite Graphs

Abstract

We introduce a new framework of restricted 2-matchings close to Hamilton cycles. For an undirected graph (V, E) and a family $\mathcal{U}$ of vertex subsets, a 2-matching F is called $\mathcal{U}$-feasible if, for each $U \in \mathcal{U}$, F contains at most $|U| - 1$ edges in the subgraph induced by U. Our framework includes $C_{\leq k}$-free 2-matchings, i.e., 2-matchings without cycles of at most k edges, and 2-factors covering prescribed edge cuts, both of which are intensively studied as relaxations of Hamilton cycles. The problem of finding a maximum $\mathcal{U}$-feasible 2-matching is NP-hard. We prove that the problem is tractable when the graph is bipartite and each $U \in \mathcal{U}$ induces a Hamilton-laceable graph. This case generalizes the $C_{\leq 4}$-free 2-matching problem in bipartite graphs. We establish a min-max theorem, a combinatorial polynomial-time algorithm, and decomposition theorems by extending the theory of $C_{\leq 4}$-free 2-matchings. Our result provides the first polynomially solvable case for the maximum $C_{\leq k}$-free 2-matching problem for $k \geq 5$. For instance, in bipartite graphs in which every cycle of length six has at least two chords, our algorithm solves the maximum $C_{\leq 6}$-free 2-matching problem in $\mathrm{O}(n^2 m)$ time, where n and m are the numbers of vertices and edges, respectively.

1 Introduction

The Hamilton cycle problem is one of the most fundamental NP-hard problems in various research fields such as graph theory, computational complexity, and combinatorial optimization. One successful approach to the Hamilton cycle problem is to utilize matching theory. In a graph $G = (V, E)$, an edge set $F \subseteq E$ is a 2-*matching* (resp., 2-*factor*) if it has at most (resp., exactly) two edges incident to each vertex in V. Since a Hamilton cycle is a special kind of 2-matching (or 2-factor) and a 2-matching of maximum size can be found in polynomial time, it is reasonable to put restrictions on 2-matchings to provide a tight relaxation of Hamilton cycles to which matching theory can be applied. Examples include the following two kinds of restricted 2-matchings:

$C_{\leq k}$-free 2-matchings. For a positive integer k, a 2-matching is called $C_{\leq k}$-*free* if it contains no cycles of length at most k. The larger k becomes, the closer a $C_{\leq k}$-free 2-factor becomes to a Hamilton cycle. If $k \geq |V|/2$, a $C_{\leq k}$-free 2-factor is a Hamilton cycle, whereas a $C_{\leq 2}$-free 2-matching is nothing other than a 2-matching.

[*] This work was partially supported by JSPS KAKENHI Grant Number 16K16012.

2-factors covering prescribed edge cuts. An *edge cut* is a minimal set of edges whose removal makes the graph disconnected. Given a family $\mathcal{K}$ of edge cuts, an edge subset is called $\mathcal{K}$*-covering* if it intersects every edge cut in $\mathcal{K}$. A Hamilton cycle is exactly a $\mathcal{K}$-covering 2-factor, where $\mathcal{K}$ is the family of all edge cuts.

Recently both $C_{\leq k}$-free and $\mathcal{K}$-covering 2-factors have been intensively studied and applied to designing approximation algorithms for NP-hard problems related to the Hamilton cycle problem, such as the graph-TSP and the minimum 2-edge connected spanning subgraph problem [4, 5, 8, 12, 20, 30, 32, 33].

1.1 Previous Work

In general graphs, the $C_{\leq k}$-free 2-matching problem is much more difficult than the 2-matching problem. For the cases $k \geq 3$, no algorithm is known other than Hartvigsen's $C_{\leq 3}$-free 2-matching algorithm [14]. NP-hardness for the case $k \geq 5$ is proved by Papadimitriou (see [7]). More generally, Hell et al. [17] proved that the problem is NP-hard, unless the excluded length of a cycle is a subset of $\{3, 4\}$. The case $k = 4$ is still open, and conjectured to be solvable in polynomial time [9]. Discrete convexity shown in [22] supports this conjecture.

While only a few positive results are known for the $C_{\leq k}$-free 2-matching problem in general graphs, in bipartite graphs the $C_{\leq 4}$-free 2-matching problem is efficiently solvable, and fundamental theorems in matching theory are extended. Motivated by a stimulating paper of Hartvigsen [15], Király [21] gave a min-max theorem for the $C_{\leq 4}$-free 2-matching problem in bipartite graphs, followed by a different min-max theorem by Frank [11]. Comparison of these two theorems is discussed in [31], together with decomposition theorems corresponding to the Dulmage-Mendelsohn and Edmonds-Gallai decompositions. Polynomial combinatorial algorithms are designed by Hartvigsen [16] and Pap [25], which are again slightly different and followed by an improvement in time complexity by Babenko [1]. For the weighted version, while the NP-hardness of the weighted $C_{\leq 4}$-free 2-matching problem in bipartite graphs is proved by Király (see [11]), positive results such as a linear programming formulation with dual integrality [23], a combinatorial algorithm [29], and discrete convexity [22] are established when the edge weights satisfy a certain property. Since the $C_{\leq 6}$-free 2-matching problem is NP-hard even in bipartite graphs [13], the $C_{\leq 4}$-free 2-matching problem in bipartite graphs is one of the few cases where the $C_{\leq k}$-free 2-matching problem is tractable.

For a set of positive integers $A \subseteq \mathbf{Z}$, denote the set of edge cuts whose sizes belong to A by $\mathcal{K}_A$. Kaiser and Škrekovski [18] proved that every bridgeless planar cubic graph has a $\mathcal{K}_{\{3,4\}}$-covering 2-factor, which is extended to a stronger result that every bridgeless cubic graph has a $\mathcal{K}_{\{3,4\}}$-covering 2-factor [19]. While the proof in [19] was not algorithmic, Boyd, Iwata, and Takazawa [4] designed a combinatorial algorithm for finding a $\mathcal{K}_{\{3,4\}}$-covering 2-factor in bridgeless cubic graphs, together with a combinatorial algorithm for finding a minimum-weight $\mathcal{K}_{\{3\}}$-covering 2-factor in bridgeless cubic graphs. Čada et al. [6] exhibited a family of graphs which has no $\mathcal{K}_{\{4,5\}}$-covering edge subset with even degree at every vertex, disproving a conjecture in [19].

1.2 Our Contribution

In the present paper, we introduce a new framework of restricted 2-matchings which commonly generalizes $C_{\leq k}$-free 2-matchings and $\mathcal{K}$-covering 2-factors. Let $G = (V, E)$ be a graph. For $U \subseteq V$, let $G[U] = (U, E[U])$ denote the subgraph induced by U, i.e., $E[U] = \{uv \in E\colon u, v \in U\}$. For $F \subseteq E$, let $F[U] = F \cap E[U] = \{uv \in F\colon u, v \in U\}$.

▶ **Definition 1** ($\mathcal{U}$-feasible 2-matching)**.** Let $\mathcal{U} \subseteq 2^V$ be a family of vertex subsets. A 2-matching $F \subseteq E$ is called *$\mathcal{U}$-feasible* if $|F[U]| \leq |U| - 1$ for each $U \in \mathcal{U}$.

Equivalently, a 2-matching F is $\mathcal{U}$-feasible if and only if F does not contain a 2-factor in $G[U]$ for each $U \in \mathcal{U}$. We remark that F does not only excludes a Hamilton cycle in $G[U]$, but also any 2-factor in $G[U]$ consisting of possibly multiple cycles.

If F is a 2-factor, then F is $\mathcal{U}$-feasible if and only if $F \cap \delta(U) \neq \emptyset$ for every $U \in \mathcal{U}$, where $\delta(U)$ denotes the set of edges having exactly one endpoint in U. From these viewpoints, it is not difficult to see that Hamilton cycles, $C_{\leq k}$-free 2-matchings, and $\mathcal{K}$-covering 2-factors are special cases of $\mathcal{U}$-feasible 2-factors or 2-matchings. That is, if we put $\mathcal{U} = \{U \subseteq V \colon |U| \leq |V|/2\}$ and $\mathcal{U} = \{U \subseteq V \colon \delta(U) \in \mathcal{K}\}$, then the set of $\mathcal{U}$-feasible 2-factors are exactly that of Hamilton cycles and $\mathcal{K}$-covering 2-factors, respectively. If putting $\mathcal{U} = \{U \subseteq V \colon |U| \leq k\}$, then the set of $\mathcal{U}$-feasible 2-factors is exactly that of $C_{\leq k}$-free 2-matchings.

The *$\mathcal{U}$-feasible 2-matching problem* is defined as a problem of finding a $\mathcal{U}$-feasible 2-matching of maximum size for given G and $\mathcal{U}$. In order to discuss the time complexity of the $\mathcal{U}$-feasible 2-matching problem, we should notice how $\mathcal{U}$ is given. In some cases, the size of $\mathcal{U}$ might be exponential in $|V|$, e.g., $\mathcal{U} = \{U \subseteq V \colon |U| \leq |V|/2\}$. Nevertheless, in many cases it is efficiently determined whether a given edge set is $\mathcal{U}$-feasible, such as the $C_{\leq k}$-free 2-matching case and the $\mathcal{K}$-covering 2-factor case. Therefore, we denote by γ the time for determining whether an edge set is $\mathcal{U}$-feasible, and we seek an algorithm with running time polynomial in $|V|$ and γ.

Since the Hamilton cycle problem is a special case of the $\mathcal{U}$-feasible 2-matching problem, the $\mathcal{U}$-feasible 2-matching problem is NP-hard in general. Thus, we need some assumption in order to obtain a tractable class of the $\mathcal{U}$-feasible 2-matching problem, such as the cases where G is bipartite and $\mathcal{U} = \{U \subseteq V \colon |U| \leq 4\}$, and G is bridgeless cubic and $\mathcal{U} = \{U \subseteq V \colon \delta(U) \in \mathcal{K}_{\{3,4\}}\}$.

A main objective of this paper is to provide a broader tractable class of the $\mathcal{U}$-feasible 2-matching problem by extending the theory of $C_{\leq 4}$-free 2-matchings in bipartite graphs. For this purpose, we exploit a graph-theoretic concept of *Hamilton-laceable graphs.* For a bipartite graph (V, E), we denote the two color classes by V^+ and V^-. For $X \subseteq V$, let $X^+ = X \cap V^+$ and $X^- = X \cap V^-$.

▶ **Definition 2** (Hamilton-laceable graph [26])**.** A bipartite graph $G = (V, E)$ is *Hamilton-laceable* if (i) $|V^+| = |V^-|$ and G has a Hamilton path between an arbitrary pair of $u \in V^+$ and $v \in V^-$, or (ii) $|V^+| = |V^-| - 1$ and G has a Hamilton path between an arbitrary pair of distinct vertices $u, v \in V^-$.

In what follows, we work on the $\mathcal{U}$-feasible 2-matching problem under the assumption that G is bipartite and $G[U]$ is Hamilton-laceable for each $U \in \mathcal{U}$. We note that, for a 2-factor F, $|F[U]| = |U|$ implies that $|U^+| = |U^-|$. Thus, we assume $|U^+| = |U^-|$ for each $U \in \mathcal{U}$, and hence only the case (i) in Definition 2 occurs in our arguments.

If we take into account the original motivation, i.e., finding a 2-factor close to a Hamilton cycle, then $\mathcal{U}$ should be a vertex set family as large as possible. Thus a natural setting would be to define $\mathcal{U}$ as the family of all vertex sets $U \subseteq V$ such that $G[U]$ is Hamilton-laceable. This indeed provides a new framework of 2-matchings closer to Hamilton cycles.

Furthermore, several types of the $C_{\leq k}$-free 2-matching problem are described as the $\mathcal{U}$-feasible 2-matching problem under our assumption. The smallest nontrivial example of a Hamilton-laceable graph would be a cycle of length four, and hence the $C_{\leq 4}$-free 2-matching problem in bipartite graphs is a special case of the $\mathcal{U}$-feasible 2-matching problem under our assumption. As for $C_{\leq 6}$-free-free 2-matchings, a cycle of length six is Hamilton-laceable if it has at least two chords. Thus, the $C_{\leq 6}$-free 2-matching problem in bipartite graphs in which every cycle of length six has at least two chords is described as the $\mathcal{U}$-feasible 2-matching problem under our assumption. In other words, in our setting a solution (a $\mathcal{U}$-feasible 2-matching) might contain a cycle of length six with at most one chord, but it can exclude all the cycles of length six with at least two chords. Further examples and previous work of Hamilton-laceable graphs are exhibited in § 2.

In the present paper, we exhibit that the theory of $C_{\leq 4}$-free 2-matching problem in bipartite graphs satisfactorily extends when $G[U]$ is Hamilton-laceable for each $U \in \mathcal{U}$. We first present a min-max theorem extending Király's min-max theorem [21]. We then design a combinatorial algorithm for finding a maximum $\mathcal{U}$-feasible 2-matching, which provides a constructive proof for our min-max theorem. In the design of our algorithm, we make use of both of Hartvigsen's and Pap's algorithms [16, 25]: the shrinking technique comes from Pap's algorithm; and the construction of a minimizer of the min-max theorem derives from Hartvigsen's method. Finally, we describe decomposition theorems extending those in [31] and corresponding to the Dulmage-Mendelsohn and Edmonds-Gallai decompositions.

Here we summarize our algorithmic results. We denote the number of vertices and edges in the input graph by n and m, respectively. Recall that γ is the time for determining whether an edge set is $\mathcal{U}$-feasible.

▶ **Theorem 3.** *Let $G = (V, E)$ be a bipartite graph and $\mathcal{U} \subseteq 2^V$ be a family of vertex subsets such that $G[U]$ is Hamilton-laceable for each $U \in \mathcal{U}$. Then a $\mathcal{U}$-feasible 2-matching of maximum size in G can be found in $\mathrm{O}(n^3\gamma + n^2 m)$ time.*

We remark that, when our algorithm is applied to the $C_{\leq k}$-free 2-matching case, i.e., the case $\mathcal{U} = \{U \subseteq V : |U| \leq k,\ G[U] \text{ is Hamilton-laceable}\}$, γ becomes the time for determining if a specified edge is contained in a cycle of length at most k in a given 2-matching, and thus $\gamma = \mathrm{O}(k)$. (The detail is described in § 4.3.) Therefore, the following theorem is established.

▶ **Theorem 4.** *The $C_{\leq k}$-free 2-matching problem in bipartite graphs is solvable in $\mathrm{O}(kn^3 + n^2 m)$ time if every cycle of length at most k induces a Hamilton-laceable graph.*

In particular, it holds that $\gamma = \mathrm{O}(1)$ if k is a constant. By setting $\mathcal{U} = \{U \subseteq V : |U| \leq 4,\ G[U] \text{ is Hamilton-laceable}\}$, we can see that Theorem 3 extends the solvability of the $C_{\leq 4}$-free 2-matching problem in bipartite graphs. Moreover, setting $\mathcal{U} = \{U \subseteq V : |U| \leq 6,\ G[U] \text{ is Hamilton-laceable}\}$ in Theorem 3 leads to the following corollaries on the $C_{\leq 6}$-free 2-matching problem in bipartite graphs.

▶ **Corollary 5.** *In a bipartite graph, a maximum 2-matching excluding any cycle of length six with at least two chords and any cycle of length four can be found in $\mathrm{O}(n^2 m)$ time.*

▶ **Corollary 6.** *In a bipartite graph in which every cycle of length six has at least two chords, the $C_{\leq 6}$-free-free 2-matching problem can be solved in $\mathrm{O}(n^2 m)$ time.*

To the best of our knowledge, Corollary 6 is the first polynomially solvable case of the $C_{\leq 6}$-free 2-matching problem. Furthermore, combined with Lemma 8 in § 2, Theorem 3 leads to the following corollary, an extension of Corollary 6.

▶ **Corollary 7.** *The $C_{\leq k}$-free 2-matching problem in bipartite graphs is solvable in $\mathrm{O}(kn^3 + n^2 m)$ time if every cycle of length $2t$ such that $2t \leq k$ has at least $(t-1)(t-2)$ chords.*

Note that Corollary 6 is exactly the case $k = 6$ of Corollary 7.

It is noteworthy that, unlike the literature of $C_{\leq k}$-free 2-matchings and $\mathcal{K}$-covering 2-factors, our assumption that each $G[U]$ is Hamilton-laceable does not depend on the size of the forbidden structures. As stated above, one benefit of this is that our result provides the first polynomially solvable case of the $C_{\leq k}$-free 2-matching problem for $k \geq 5$, and thus has a potential to provide better approximation ratios for the graph-TSP and the minimum 2-edge connected subgraph problem.

We further remark that our framework contains the both cases where multiplicities on edges are forbidden and allowed. That is, in the former case we only deal with simple 2-matchings and one edge can only contribute one to the degree of its endpoints. In the latter case, we can put multiplicity two on some edges. In the literature of the $C_{\leq k}$-free 2-matching problem, these two cases have formed different streams. The aforementioned results are of the former case, and results for the latter case include [2, 7, 24]. To the best of our knowledge, not much connection between these two cases is found. In our framework, forbidding multiplicity on an edge $uv \in E$ corresponds to having $\{u, v\}$ in $\mathcal{U}$, and it is clear that $G[\{u, v\}]$ is Hamilton-laceable if $uv \in E$. While in this paper we mainly keep the former case in mind, we note that our framework can represent both cases.

1.3 Organization of the Paper

The rest of the paper is organized as follows. In § 2, we present some previous work, observations, and examples of Hamilton-laceable graphs. After that, we exhibit our contribution on $\mathcal{U}$-feasible 2-matchings in bipartite graphs where $G[U]$ is Hamilton-laceable for each $U \in \mathcal{U}$. We present a min-max theorem in § 3. Section 4 is devoted to describing a combinatorial algorithm for finding a maximum $\mathcal{U}$-feasible 2-matching, which provides a constructive proof for the min-max theorem. In § 5, we exhibit decomposition theorems corresponding to the Dulmage-Mendelsohn and Edmonds-Gallai decompositions. In § 6, we demonstrate an application of our framework by showing that a regular bipartite graph admit a certain kind of $\mathcal{U}$-feasible 2-factor. Section 7 concludes this paper.

2 Hamilton-Laceable Graph

This section is devoted to a discussion on Hamilton-laceable graphs. We first note that the concept of Hamilton-laceable graphs is a bipartite analogue of that of *Hamilton-connected graphs*, which is well-known in the field of graph theory [3]. A graph is *Hamilton-connected* if it has a Hamilton path between an arbitrary pair of distinct vertices. Thus, a Hamilton-connected graph is nonbipartite if it has at least three vertices.

In what follows, we always assume that $G = (V, E)$ is bipartite. Trivial examples of a Hamilton-laceable graph are a graph of a single vertex, and a graph of two vertices connected by an edge. It is also clear that a complete bipartite graph on $2t$ vertices, denoted by $K_{t,t}$, is Hamilton-laceable. Recall that a special case $K_{2,2}$, a cycle of length four, is an example of a Hamilton-laceable graph.

If $G = (V, E)$ is Hamilton-laceable, a graph $(V, \tilde{E})$ satisfying $\tilde{E} \supseteq E$ is also Hamilton-laceable. Thus, it would be of interest to find Hamilton-laceable graphs with as few edges as possible. Indeed, the concept of Hamilton-laceable graphs was introduced as a generalized property of Hamiltonicity of *d-dimensional rectangular lattices* by Simmons [26]. A d-dimensional rectangular lattice is a graph (V, E) represented by d positive integers $a_1, \ldots, a_d$ as $V = \{x \in \mathbf{Z}^d \colon 0 \leq x_i \leq a_i,\ i = 1, \ldots, d\}$ and $E = \{xy \colon x, y \in V,\ \sum_{i=1}^{d} |x_i - y_i| = 1\}$. Simmons [26] proved that all d-dimensional rectangular lattices are Hamilton-laceable except for the two-dimensional lattices of order $2 \times r$ ($r \neq 2$) and $3 \times 2r$. This result provides a class of Hamilton-laceable graphs (V, E) with $|E| \approx d|V|$. For instance, every hypercube is

Hamilton-laceable. The following lemma also provides a sufficient condition for a graph to be Hamilton-laceable.

▶ **Lemma 8** (Simmons [28]). *Deleting fewer than $t-1$ edges from $K_{t,t}$ or $K_{t,t+1}$ maintains Hamilton-laceability.*

Furthermore, Simmons [27] discussed the minimum number l_t of the edges of Hamilton-laceable graphs with $|V^+| = t$. It holds that $3t - \lceil t/3 \rceil \leq l_t \leq 3t - 1$ for the case (i) in Definition 2, and $l_t = 3t + 1$ for the case (ii) in Definition 2.

The motivation of introducing Hamilton-laceable graph in this paper comes from an analysis in [31], which reveals that cycles of length four in the $C_{\leq 4}$-free 2-matching problem in bipartite graphs serve as factor-critical components for the nonbipartite matching problem: if $U \subseteq V$ induces a cycle of length four in a bipartite graph, for an arbitrary pair $u \in U^+$ and $v \in U^-$, $G[U]$ contains a 2-matching of size three in which only u and v have degree one. Indeed, this is the property which makes it possible to execute the shrinking and expanding procedures in the algorithms in [16, 25], which is shed light on by a decomposition theorem [31] resembling the Edmonds-Gallai decomposition. Observe that the definition of Hamilton-laceable graphs generalizes the above property of C_4. In the following sections we reveal that the property in Definition 2(i) plays a key role to provide a tractable class of restricted 2-matchings in bipartite graphs.

3 Min-Max Theorem

In this section, we describe a min-max theorem for the $\mathcal{U}$-feasible 2-matching problem in bipartite graphs where each $U \in \mathcal{U}$ induces a Hamilton-laceable graph. Our theorem is an extension of Király's min-max theorem [21] for the $C_{\leq 4}$-free 2-matching problem in bipartite graphs. For $X \subseteq V$, let $\bar{X} = V \setminus X$ and $c'(X)$ denote the number of components in $G[X]$ consisting of a single vertex, a single edge, or a single cycle of length four.

▶ **Theorem 9** ([21]). *Let $G = (V, E)$ be a bipartite graph. Then, it holds that*

$$\max\{|F| \colon F \textit{ is a } C_{\leq 4}\textit{-free } 2\textit{-matching}\} = \min\{|V| + |X| - c'(\bar{X}) \colon X \subseteq V\}.$$

Observe that every component contributing to $c'(\bar{X})$ is Hamilton-laceable. We now exhibit our theorem extending Theorem 9. For $X \subseteq V$, let $c(X)$ denote the number of components in $G[X]$ whose vertex set belongs to $\mathcal{U}$.

▶ **Theorem 10.** *Let $G = (V, E)$ be a bipartite graph and $\mathcal{U} \subseteq 2^V$ be a family of vertex subsets in G such that $G[U]$ is Hamilton-laceable for each $U \in \mathcal{U}$. Then, it holds that*

$$\max\{|F| \colon F \textit{ is a } \mathcal{U}\textit{-feasible } 2\textit{-matching}\} = \min\{|V| + |X| - c(\bar{X}) \colon X \subseteq V\}. \tag{1}$$

It is not difficult to see that Theorem 9 is indeed a special case of Theorem 10 where $\mathcal{U} = \{U \subseteq V \colon |U| \leq 4,\ G[U] \text{ is Hamilton-laceable}\}$.

Before proving Theorem 10, we first show that the inequality max $\leq$ min in (1) holds for an arbitrary G and $\mathcal{U}$, i.e., G may not be bipartite and $G[U]$ may not be Hamilton-laceable for $U \in \mathcal{U}$. For disjoint vertex sets $X, Y \subseteq V$, let $E[X, Y]$ denote the set of edges connecting X and Y, $G[X, Y] = (X \cup Y, E[X, Y])$, and $F[X, Y] = F \cap E[X, Y]$ for $F \subseteq E$.

▶ **Lemma 11.** *Let $G = (V, E)$ be a graph and $\mathcal{U} \subseteq 2^V$ be a family of vertex subsets in G. For an arbitrary $\mathcal{U}$-feasible 2-matching F and $X \subseteq V$, it holds that $|F| \leq |V| + |X| - c(\bar{X})$.*

Proof. Since F is a 2-matching, $2|F[X]| + |F[X, \bar{X}]| \leq 2|X|$ follows. Moreover, since F is $\mathcal{U}$-feasible, it holds that $|F[\bar{X}]| \leq |\bar{X}| - c(\bar{X})$. Therefore, $|F| = |F[X]| + |F[X, \bar{X}]| + |F[\bar{X}]| \leq 2|F[X]| + |F[X, \bar{X}]| + |F[\bar{X}]| \leq 2|X| + |\bar{X}| - c(\bar{X}) = |V| + |X| - c(\bar{X})$. ◀

The following lemma directly follows from the proof for Lemma 11. For $F \subseteq E$ and $u \in V$, denote the number of edges in F incident to u by $\deg_F(u)$.

▶ **Lemma 12.** *If a $\mathcal{U}$-feasible 2-matching F and $X \subseteq V$ attain the equality in* (1)*, it holds that*

- $F[X] = \emptyset$,
- $\deg_{F[\{u\}, \bar{X}]}(u) = 2$ *for each* $u \in X$*, and*
- *for each component* Q *in* $G[\bar{X}]$,

$$|F[V(Q)]| = \begin{cases} |V(Q)| - 1 & \text{if } V(Q) \in \mathcal{U}, \\ |V(Q)| & \text{otherwise.} \end{cases}$$

Proof. By the above proof for Lemma 11, it should hold that $|F[X]| = 0$, $|F[X, \bar{X}]| = 2|X|$, and $|F[\bar{X}]| = |\bar{X}| - c(\bar{X})$ for a $\mathcal{U}$-feasible 2-matching F and $X \subseteq V$ attaining the equality in (1). These respectively lead to the statements in the lemma. ◀

In § 4, we complete a proof of Theorem 10 by establishing an algorithm for finding a $\mathcal{U}$-feasible 2-matching F and $X \subseteq V$ attaining equality in (1). It should be noted that the bipartiteness of G and Hamilton-laceability of $G[U]$ for each $U \in \mathcal{U}$ play an important role in the algorithm, and thus they are key properties to achieving equality in (1) as well.

4 Combinatorial Algorithm

In this section, we describe a combinatorial polynomial-time algorithm for finding a maximum $\mathcal{U}$-feasible 2-matching in bipartite graphs where each $U \in \mathcal{U}$ induces a Hamilton-laceable graph. Our algorithm employs ideas of both of the $C_{\leq 4}$-free 2-matching algorithms of Hartvigsen [16] and Pap [25].

4.1 Algorithm Description

Roughly speaking, our algorithm resembles Edmonds' algorithm for nonbipartite matchings [10]. One main feature in our algorithm comes from Pap's algorithm [25]: we shrink $U \in \mathcal{U}$ after we find an alternating path, whereas in Edmonds' and Hartvigsen's algorithms shrinking occurs in the middle of construction of alternating forests. Another feature derives from Hartvigsen's algorithm [16]. A minimizer $X \subseteq V$ of the right-hand side of (1) is basically determined as the set of vertices reachable from the deficient vertices, vertices having at most one incident edge in the optimal solution. In Hartvigsen's and our algorithms, if a vertex resulting from shrinking $U \in \mathcal{U}$ satisfies certain properties, it is regarded as reachable even if it is not reachable.

Before describing the entire algorithm, we present how to shrink and expand $U \in \mathcal{U}$. In order to provide concise notation, in the rest of this section we denote the input of the algorithm by $\hat{G} = (\hat{V}, \hat{E})$ and $\hat{\mathcal{U}} \subseteq 2^{\hat{V}}$, and the graph obtained by repeated shrinkings by $G = (V, E)$. Following standard notation, for a vector $b \in \mathbf{Z}^V$, an edge set $F \subseteq E$ is called a *b-matching* if every vertex $v \in V$ is incident to at most $b(v)$ edges in F. If every vertex $v \in V$ is incident to exactly $b(v)$ edges in F, then F is called a *b-factor*. If $b(v) = t$ for every $v \in V$,

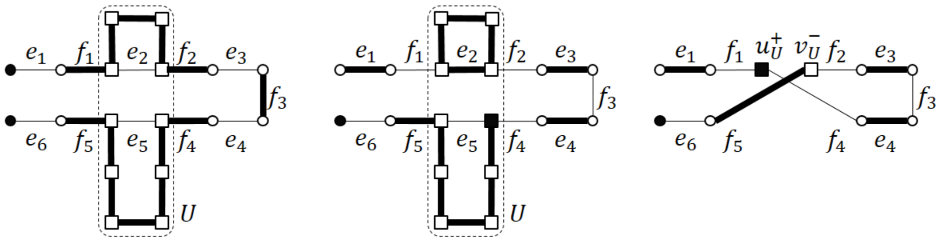

Figure 1 $b_v = 2$ for each v. The thick edges are in F, thin edges in $E \setminus F$, and the vertices in black are in S^+ or S^-. The ten vertices represented by squares form $U \in \mathcal{U}$. In the figure on the left, we have found P consisting of $e_1, f_1, e_2, \ldots, e_5, f_5, e_6$, and $F \triangle (E(P))$ contains a 2-factor in $G[U]$ for $U \in \mathcal{U}$. In this case $i^* = 5$, and the figure in the middle shows $F \triangle (E(P_4))$. The figure on the right shows the graph after $\mathsf{Shrink}(F, P)$.

then a b-matching is simply referred to as a t-matching. Note that this notation is compatible with our definition of 2-matchings.

In the algorithm, we maintain a $\mathcal{U}$-feasible b-matching F in G, where $\mathcal{U} \subseteq 2^V$ and $b \in \{1,2\}^V$, which can be extended to a $\hat{\mathcal{U}}$-feasible 2-matching in $\hat{G}$. For $b \in \{1,2\}^V$, a b-matching F is *$\mathcal{U}$-feasible* if $F[U]$ is not a b_U-factor in $G[U]$ for every $U \in \mathcal{U}$, where b_U is the restriction of b to U. Initially, $G = \hat{G}$, $\mathcal{U} = \hat{\mathcal{U}}$, $b_v = 2$ for each $v \in V$, and F is an arbitrary $\mathcal{U}$-feasible b-matching, e.g., $F = \emptyset$.

For $F_1, F_2 \subseteq E$, denote the symmetric difference of F_1 and F_2 by $F_1 \triangle F_2$, i.e., $F_1 \triangle F_2 = (F_1 \setminus F_2) \cup (F_2 \setminus F_1)$. Define the set of source vertices by $S^+ = \{u \in V^+ \colon \deg_F(u) < b_u\}$ and sink vertices $S^- = \{v \in V^- \colon \deg_F(v) < b_v\}$. Suppose that we have found an alternating path P with respect to F and $E \setminus F$ such that P starts in S^+ and ends in S^-, and $F \triangle (E(P))$ is not a $\mathcal{U}$-feasible b-matching. We then apply the following shrinking procedure.

Procedure Shrink(F, P). Denote $E(P) = \{e_1, f_1, e_2, \ldots, e_l, f_l, e_{l+1}\}$, where the edges are sorted by the order of appearance in P. Note that $e_j \in E \setminus F$ $(j = 1, \ldots, l+1)$ and $f_j \in F$ $(j = 1, \ldots, l)$. Let P_i be the path consisting of $\bigcup_{j=1}^{i} \{e_j, f_j\}$ for $i = 1, \ldots, l$, P_0 be an empty graph, and $P_{l+1} = P$. Let i^* be the smallest index i such that $F \triangle (E(P_i))$ contains a b-factor in $G[U]$ for some $U \in \mathcal{U}$, and let $F' = F \triangle (E(P_{i^*-1}))$. If more than one such $U \in \mathcal{U}$ exists, choose an arbitrary U. We then update G, b, $\mathcal{U}$, and F as follows. Let u_U^+ and v_U^- be new vertices obtained by contracting the vertices in U^+ and U^-, respectively. Then, reset

$$V := \bar{U} \cup \{u_U, v_U\}, \quad b_v := \begin{cases} 1 & \text{if } v = u_U^+, v_U^-, \\ b_v & \text{otherwise,} \end{cases}$$

$$E := E[\bar{U}] \cup \{u_U^+ v \colon uv \in E, u \in U^+, v \in \bar{U}^-\} \cup \{u v_U^- \colon uv \in E, u \in \bar{U}^+, v \in U^-\},$$

$$F := F'[\bar{U}] \cup \{u_U^+ v \colon uv \in F', u \in U^+, v \in \bar{U}^-\} \cup \{u v_U^- \colon uv \in F', u \in \bar{U}^+, v \in U^-\},$$

$$\mathcal{U} := \{U' \colon U' \in \mathcal{U}, U' \cap U = \emptyset\} \cup \{(U' \setminus U) \cup \{u_U^+, v_U^-\} \colon U' \in \mathcal{U}, U \subsetneq U'\}.$$

See Figure 1 for an illustration. Observe that the update preserves that G is bipartite and F is still a b-matching in G. We then repeat the above procedure.

If an alternating path P from S^+ to S^- is found such that $F \triangle (E(P))$ is a $\mathcal{U}$-feasible b-matching, then we reset $F := F \triangle (E(P))$ to augment the current solution, and expand the shrunk vertex sets to return to the original graph $\hat{G}$ as follows. First note that the shrunk vertex sets in $\hat{\mathcal{U}}$ form a laminar family, and it suffices to expand the maximal shrunk vertex sets. Let $\mathcal{U}^* \subseteq 2^{\hat{V}}$ be the family of maximal shrunk vertex sets. For a maximal shrunk

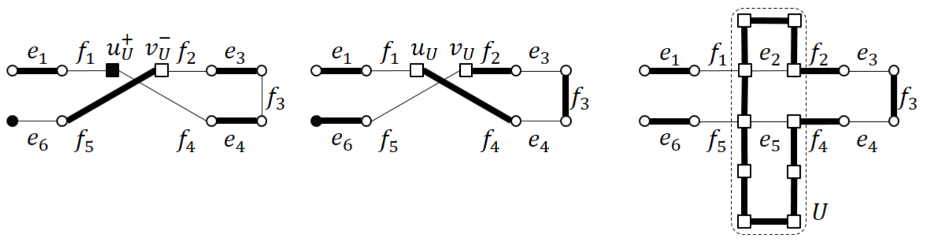

Figure 2 The graph in the middle results from an augmentation in the graph on the left, where the augmenting path P consists of $f_4, e_4, f_3, e_3, f_2, f_5, e_6$. We then expand U, where $\hat{f}_U^+ = f_4$ and $\hat{f}_U^- = f_2$. to obtain the graph on the right.

vertex set $U \subseteq \hat{V}$, denote the unique edge in F incident to u_U^+ by f_U^+, and to v_U^- by f_U^-, if exist. Let $\hat{f}_U^+, \hat{f}_U^- \in \hat{E}$ be the edges corresponding to $f_U^+, f_U^- \in E$, respectively. Denote the vertex in U^+ incident to $\hat{f}_U^+$ by $\hat{u}_U^+$, and that in U^- incident to $\hat{f}_U^-$ by $\hat{v}_U^-$. If f_U^+ (resp., f_U^-) does not exist, let $\hat{u}_U^+$ (resp., $\hat{v}_U^-$) be an arbitrary vertex in U^+ (resp., U^-). Now, since $\hat{G}[U]$ is Hamilton-laceable, $\hat{G}[U]$ has a Hamilton path P_U between $\hat{u}_U^+$ and $\hat{v}_U^-$. In expanding U, we add $E(P_U)$ to F. That is, $\hat{F} := F \cup \bigcup_{U \in \mathcal{U}^*} E(P_U)$. See Figure 2 for an illustration of augmentation and expansion. It is not difficult to see that $\hat{F}$ is a $\mathcal{U}$-feasible 2-matching.

The entire algorithm is described as follows.

Input: A bipartite graph $\hat{G} = (\hat{V}, \hat{E})$ and $\hat{\mathcal{U}} \subseteq 2^{\hat{V}}$ such that $\hat{G}[U]$ is Hamilton-laceable for each $U \in \hat{\mathcal{U}}$.

Output: A maximum $\hat{\mathcal{U}}$-feasible 2-matching $\hat{F}$ in $\hat{G}$.

Step 0: Put $G = \hat{G}$ and $\mathcal{U} = \hat{\mathcal{U}}$. Let F be an arbitrary $\mathcal{U}$-feasible 2-matching in G. Let F be an arbitrary $\mathcal{U}$-feasible 2-matching in G and then go to Step 1.

Step 1: Let $S^+ = \{u \in V^+ : \deg_F(u) < b_u\}$ and $S^- = \{v \in V^- : \deg_F(v) < b_v\}$. Orient each edge in $E \setminus F$ from V^+ to V^- and each edge in F from V^- to V^+ to obtain a directed graph D. If D has a directed path P from S^+ to S^-, then go to Step 2. Otherwise, go to Step 5.

Step 2: Let $E_P \subseteq E$ be the set of edges corresponding to the directed edges in P. If $F' = F \triangle E_P$ is a $\mathcal{U}$-feasible b-matching, then go to Step 3. Otherwise, go to Step 4.

Step 3 (Augmentation): Reset $F := F'$, expand all maximal shrunk vertex sets, and then go back to Step 1.

Step 4 (Shrinking): Apply Shrink(F, P), and then go back to Step 1.

Step 5 (Termination): Expand all maximal shrunk vertex sets and return $\hat{F}$.

4.2 Proof for Correctness

At the termination of the algorithm, we have a digraph D in which no directed path from S^+ to S^- exists. Let $R \subseteq V$ denote the set of vertices reachable from S^+ in D, and define $R' \subseteq V$ by

$$\begin{aligned} R' = R &\cup \{v \in (\bar{R})^- : v \text{ is not a shrunk vertex}, \deg_{F[R^+, \{v\}]}(v) = 2\} \\ &\cup \{v \in (\bar{R})^- : v = v_U^- \text{ for some } U \in \mathcal{U},\ uv \in F \text{ for some } u \in R^+\}. \end{aligned}$$

Finally, define $X \subseteq \hat{V}$ by the set of vertices corresponding to $(\overline{R'})^+ \cup (R')^-$, i.e.,

$$\begin{aligned} X = &\{u \in \hat{V}^+ : u \in (\overline{R'})^+ \text{ or } u \in U \text{ for some } U \in \mathcal{U} \text{ with } u_U \in (\overline{R'})^+\} \\ &\cup \{v \in \hat{V}^- : v \in (R')^- \text{ or } v \in U \text{ for some } U \in \mathcal{U} \text{ with } v_U \in (R')^-\}. \end{aligned}$$

▶ **Lemma 13.** *The output $\hat{F}$ and X defined above attain the equality in* (1).

Proof. It is not difficult to see that $\hat{F}[X] = \emptyset$. Moreover, since every $v \in X$ satisfies $\deg_{\hat{F}[\{v\},\bar{X}]} = 2$, we have that $|\hat{F}[X, \bar{X}]| = 2|X|$. Finally, since R is defined by reachability from S^+ in D, all edges in $E[\bar{X}]$ belong to F in G. Thus, each edge in $\hat{E}[\bar{X}]$ is in $\hat{F}$ or belongs to $\hat{E}[U]$ for some $U \in \mathcal{U}$ shrunk in G. By the definition of R', it holds that v_U^- has no adjacent edge in $E[\bar{X}]$, which implies that $\hat{G}[U]$ forms a component in $\hat{G}[\bar{X}]$. Thus, it follows that $|\hat{F}[\bar{X}]| = |\bar{X}| - c(\bar{X})$. Therefore, $|\hat{F}| = |\hat{F}[X]| + |\hat{F}[X, \bar{X}]| + |\hat{F}[\bar{X}]| = 2|X| + |\bar{X}| - c(\bar{X}) = |V| + |X| - c(\bar{X})$. ◀

Now Theorem 10 immediately follows from Lemmas 11 and 13. Thus, our algorithm provides a constructive proof for Theorem 10.

4.3 Complexity

Recall that $n = |\hat{V}|$, $m = |\hat{E}|$, and γ is the time for determining if an edge set is $\hat{\mathcal{U}}$-feasible. It is not difficult to see that shrinkings occur $\mathrm{O}(n)$ times between augmentations. Since augmentations occur $\mathrm{O}(n)$ times, shrinkings occur $\mathrm{O}(n^2)$ times in total.

After each shrinking, we search an alternating path, which takes $\mathrm{O}(m)$ time. Moreover, we determine if $F \triangle (E(P_i))$ is $\mathcal{U}$-feasible $\mathrm{O}(n)$ times for each shrinking. The time for this determination is γ in general. If we consider the $C_{\leq k}$-free 2-matching problem, then it suffices to determine if e_i is contained in a cycle of length at least k in $F \triangle (E(P_i))$, which takes $\mathrm{O}(k)$ time. Thus, the time complexity between shrinkings is $\mathrm{O}(n\gamma + m)$ in general, and is $\mathrm{O}(kn + m)$ for the $C_{\leq k}$-free 2-matching case. Therefore, Theorems 3 and 4 are established.

5 Decomposition Theorems

This section is devoted to decomposition theorems for the $\mathcal{U}$-feasible 2-matching problem in bipartite graphs where each $U \in \mathcal{U}$ induces a Hamilton-laceable graph. These theorems correspond to the Dulmage-Mendelsohn and Edmonds-Gallai decompositions, and extend decomposition theorems for the $C_{\leq 4}$-free 2-matchings in bipartite graphs [31]. Proofs for the theorems in this section will appear in a full version of this paper.

Let $X_1 \subseteq V$ be a minimizer of (1) obtained by the algorithm in § 4. By exchanging the roles of V^+ and V^-, i.e., searching alternating paths from S^- to S^+, we obtain another minimizer $X_2 \subseteq V$ of (1). Now partition V into three sets $D, A, C \subseteq V$, where $D = \bar{X}_1^+ \cup \bar{X}_2^-$, $A = X_2^+ \cup X_1^-$, and $C = V \setminus (D \cup A)$.

Now the following theorems are established. Theorem 14 provides a characterization of D. Note that such a characterization appears in both of the Dulmage-Mendelsohn and Edmonds-Gallai decompositions. Theorem 15 corresponds to the Dulmage-Mendelsohn decomposition, and suggests that X_1 and X_2 are canonical minimizers of (1). Finally, Theorem 16 corresponds to the Edmonds-Gallai decomposition. Figure 3 should help in understanding the statements in Theorem 16.

▶ **Theorem 14.** $D = \{v \colon \exists a$ *maximum* $\mathcal{U}$*-feasible* 2*-matching* F *with* $\deg_F(v) \leq 1\}$.

▶ **Theorem 15.** *For an arbitrary minimizer* $Y \subseteq V$ *of* (1), *it holds that* $X_2^+ \subseteq Y^+ \subseteq X_1^+$ *and* $X_1^- \subseteq Y^- \subseteq X_2^+$.

▶ **Theorem 16.**
1. *For each* $e \in E[D, A]$, *there exists a maximum* $\mathcal{U}$*-feasible* 2*-matching containing* e.
2. *The vertex set of each component in* $G[D]$ *and* $G[D, C]$ *is a singleton or belongs to* $\mathcal{U}$.

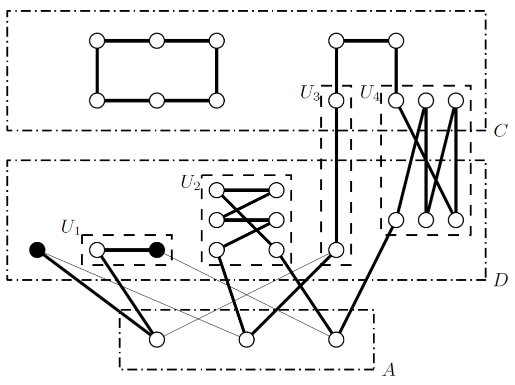

Figure 3 The thick lines are edges in a maximum $\mathcal{U}$-feasible 2-matching F, and the thin lines are edges in $E \setminus F$. The two vertices in black are those at which the degree of F is not two. The vertex sets U_1, U_2, U_3, and U_4 are in $\mathcal{U}$. Some edges in $E \setminus F$ are omitted.

3. *Shrink the components in $G[D]$ and $G[D, C]$ in the manner of* $\mathsf{Shrink}(F, P)$ *to obtain a new graph $G' = (V', E')$, denote the vertex subsets of V' corresponding to D, C by D', C', and define $b' \in \{1, 2\}^{D' \cup C'}$ by*

$$b'_v = \begin{cases} 1 & \text{if } v = u^+_U \text{ or } v = v^-_U \text{ for some } U \in \mathcal{U}, \\ 2 & \text{otherwise.} \end{cases}$$

   Then,
   a. *$G'[U']$ has a $b'_{U'}$-factor, and*
   b. *for arbitrary $A' \subseteq A$, it holds that $b'(\Gamma(A') \cap D') > 2|A'|$, where $\Gamma(A')$ is the set of vertices in $V \setminus A'$ adjacent to some vertex in A'.*
4. *An arbitrary maximum $\mathcal{U}$-feasible 2-matching F is composed of the following edges.*
   a. *In $G[D]$ and $G[D, C]$, F contains $|V(Q)| - 1$ edges in $E[V(Q)]$ for each component Q.*
   b. *For $u \in A$, F contains two edges connecting u and distinct components in $G[D]$.*
   c. *In $G[U]$, $F[U]$ corresponds to a $b'_{U'}$-factor in $G'[U']$.*
5. *Both $A \cup C^+$ and $A \cup C^-$ minimize* (1).

6 Applications

One main motivation of the restricted 2-matching problem is its application to designing approximation algorithms for NP-hard problems related to the TSP. Indeed, several recent work [20, 30, 32, 33] provide improved approximation ratios for the graph-TSP and the minimum 2-edge connected subgraph problem in cubic bipartite graphs, and these approximation algorithms are based on a property that ever cubic bipartite graph admits a $C_{\leq 4}$-free 2-factor. More generally, a d-regular bipartite graph with $d \geq 3$ admits a $C_{\leq 4}$-free 2-factor.

▶ **Theorem 17** ([30], see also [20, 33]). *Every d-regular bipartite graph such that $d \geq 3$ has a $C_{\leq 4}$-free 2-factor.*

Here we exhibit an extension of Theorem 17 by utilizing our min-max theorem (Theorem 10) for $\mathcal{U}$-feasible 2-matchings. That is, we prove that every regular bipartite graph admits a 2-factor which excludes not only every C_4 but also the longer cycles inducing Hamilton-laceable graphs. For a graph $G = (V, E)$ and a positive even integer k, define

$\mathcal{U}_{\le k} \subseteq 2^V$ by $\mathcal{U}_{\le k} = \{U \subseteq V : |U| \le k,\ |U| \text{ is even},\ G[U] \text{ is Hamilton-laceable}\}$. We now establish the following theorem.

▶ **Theorem 18.** *Let k be a positive even integer and G be a d-regular bipartite graph such that $d \ge k/2 + 1$. Then G has a $\mathcal{U}_{\le k}$-feasible 2-factor and it can be found in $\mathrm{O}(kn^3 + n^2 m)$ time.*

Proof. By (1) in Theorem 10, it suffices to show that $|X| \ge c(\bar{X})$ holds for an arbitrary $X \subseteq V$. The time-complexity is straightforward from Theorem 3.

For $\ell = 1, \ldots, k/2$, denote by $c_\ell(\bar{X})$ the number of components in $G[\bar{X}]$ whose vertex set U satisfies that $U \in \mathcal{U}_k$ and $|U| = 2\ell$. Also denote the number of isolated vertices in $G[\bar{X}]$ by $c_0(\bar{X})$. Note that $c(\bar{X}) = \sum_{\ell=0}^{k/2} d \cdot c_\ell(\bar{X})$. Then, for $\ell = 1, \ldots, k/2$, a component in $G[\bar{X}]$ contributing to $c_\ell(\bar{X})$ has at least $2\ell(d-\ell)$ incident edges in $E[X, \bar{X}]$, and it follows that $2\ell(d-\ell) \ge 2(d-1) \ge d$ from $d \ge k/2 + 1$. Therefore, we have that

$$|E[X,\bar{X}]| \ge d \cdot c_0(\bar{X}) + \sum_{\ell=1}^{k/2} 2\ell(d-\ell) c_\ell(\bar{X}) \ge d \cdot c_0(\bar{X}) + \sum_{\ell=1}^{k/2} d \cdot c_\ell(\bar{X}) = d \cdot c(\bar{X}).$$

Since G is d-regular, it also follows that $|E[X,\bar{X}]| \le d|X|$. We thus conclude $|X| \ge c(\bar{X})$. ◀

It is notable that the $\mathcal{U}_{\le k}$-feasibility of a 2-matching is a relaxed condition of $C_{\le k}$-freeness, and they coincide when $k = 4$. Thus, Theorem 17 is a special case of Theorem 18 where $k = 4$. For the case $k = 6$, while determining whether a bipartite graph admits a $C_{\le k}$-free 2-factor is NP-complete [13], Theorem 18 provides a sufficient condition for the existence of a 2-factor obeying a relaxed property.

The following corollary on $C_{\le 6}$-free 2-factors is a special case $k = 6$ of Theorem 18.

▶ **Corollary 19.** *In every d-regular bipartite graph such that $d \ge 4$, there exists a 2-factor excluding any cycle of length six and with at least two chords and any cycle of length four, and such a 2-factor can be found in $\mathrm{O}(n^2 m)$ time.*

7 Conclusion

We have introduced the concept of $\mathcal{U}$-feasible 2-matchings, which is a new framework of restricted 2-matchings. This concept includes those of $C_{\le k}$-free 2-matchings and 2-factors covering prescribed edge cuts. We then extended the theory of $C_{\le 4}$-free 2-matchings in bipartite graphs: a min-max theorem (Theorem 10), a polynomial combinatorial algorithm (Theorems 3 and 4), and decomposition theorems (Theorems 14, 15, and 16). Immediate consequences of these theorems are Corollaries 5, 6, and 7, which are, to the best of our knowledge, the first positive results on the $C_{\le k}$-free 2-matching problem for $k \ge 6$. We have further provided an application of Theorem 10 to prove the existence of a certain kind of $\mathcal{U}$-feasible 2-factor in regular bipartite graphs (Theorem 18). Further direction of research shall include more applications of the theory established here, in particular to designing approximation algorithms for NP-hard problems related to the TSP.

Abstract

We propose a new definition of regular expressions for describing languages of ω-words, called ∞-regular expressions. These expressions are obtained by adding to the standard regular expression on finite words an operator ∞ that acts similar to the Kleene-star but can be iterated finitely or infinitely often (as opposed to the ω-operator from standard ω-regular expressions, which has to be iterated infinitely often). We show that standard constructions between automata and regular expressions for finite words can smoothly be adapted to infinite words in this setting: We extend the Glushkov construction yielding a simple translation of ∞-regular expressions into parity automata, and we show how to translate parity automata into ∞-regular expressions by the classical state elimination technique, where in both cases the nesting of the $*$ and the ∞ operators corresponds to the priority range used in the parity automaton. We also briefly discuss the concept of deterministic expressions that directly transfers from standard regular expressions to ∞-regular expressions.

1 Introduction

Regular expressions play a central role in formal language theory. They are a widespread formalism for specifying patterns, and the tight connection to finite automata provides many algorithmic techniques for dealing with regular expressions (see any standard textbook on formal language theory, e.g., [7, 8]). The theory of regular languages can be lifted to languages of infinite words with a richer landscape of automaton models (see, e.g., [15, 16, 12, 8]). The basic model of Büchi automata, which accept if a run visits an accepting state infinitely often, is more expressive in its nondeterministic variant than in its deterministic one. To obtain a determinization theorem as in the case of finite words, one needs to introduce more complex acceptance conditions like the parity, Rabin, or Muller conditions. There are also regular expressions for infinite words, called ω-regular expressions. These are of the form $r_1 \cdot s_1^\omega + \cdots + r_n \cdot s_n^\omega$ for standard regular expressions r_i, s_i. An infinite word α matches such an expression if there is an index i such that α has a finite prefix matching r_i, followed by an infinite concatenation of finite words matching s_i. While this definition makes the translation between Büchi automata and ω-regular expressions easy, it appears to be ad hoc and made with this very purpose in mind. In particular, the non-inductive definition makes it difficult to embed ω-regular expressions into other specification formalisms for infinite words (or trees). Such formalisms usually rely on standard regular expressions like, e.g., PDL with regular programs [5], regular temporal logic that extends LTL by regular expressions [10], or the industrial specification language PSL that also combines temporal logic with regular expressions [13].

In this paper, we propose a simple inductive definition of regular expressions for infinite words, which we refer to as ∞-regular expressions. These are obtained by adding to the standard regular expressions an operator ∞ that behaves similar to the Kleene-star $*$ but can be iterated both finitely or infinitely often. Consequently, our expressions define mixed sets of finite and infinite words. This also solves the problem of the concatenation of two expressions defining infinite words. In a concatenation $r \cdot s$ of two ∞-regular expressions, we keep the infinite words defined by r, and concatenate the finite words defined by r with all words defined by s. This combined use of finite and infinite words is certainly not new. For example, in [11] the rational subsets of the set of finite and infinite words are defined from the single letters by closure under union, concatenation, finite, and infinite iteration (applied to the correct type of words, respectively). However, we are not aware of any simple inductive definition of regular expressions for infinite words as we propose it here.

We show that constructions between regular expressions and finite automata smoothly extend to ∞-regular expressions and parity automata. The acceptance condition of a parity automaton is defined by assigning priorities (natural numbers) to the states. By convention, the even priorities represent "good" states and the odd priorities represent "bad" states. The highest priority that is visited infinitely often decides about acceptance: the run is rejecting if it is odd, and accepting if it is even. These priorities naturally reflect the nesting of the $*$-operator and the ∞-operator in our expressions, where the $*$-operators correspond to odd priorities (because they can only be iterated finitely often), and the ∞-operators to even priorities (because they can be iterated finitely or infinitely often).

Based on this idea, we adapt the Glushkov construction (see [1]) to ∞-regular expressions and parity automata. The Glushkov construction translates regular expressions into automata using the occurrences of letters in the expressions as states, and inserting the transitions between these occurrences according to the operators of the expression. We use the same transition structure, assigning priorities to the transitions that reflect the nesting of the iteration operators.

For the other direction, from automata into expressions, we adapt the classical state elimination technique (as described, e.g., in [14]) to parity automata. In order to capture the semantics of the priorities in this translation, the elimination of the states has to be done in order of increasing priorities. Otherwise the construction is the same as for finite words.

We also consider the class of deterministic (or one-unambiguous) ∞-regular expressions. As for the case of finite words [2], these are, intuitively speaking, expressions for which matching can be done deterministically without lookahead on the input. As for finite words, deterministic ∞-regular expressions are precisely those for which the Glushkov automaton is deterministic. While we do not have deep results on deterministic ∞-regular expressions, we believe that this class of expressions could be of interest, for example, as specification formalism in synthesis problems. In the automata-theoretic approach to reactive synthesis, determinization of automata on infinite words is one of the main bottlenecks (see [9]). So, it could be interesting to write at least parts of the specification in a formalism that easily translates into deterministic automata.

The paper is structured as follows. In Section 2 we introduce the ∞-regular expressions and define a hierarchy of expressions corresponding to the nesting of the iteration operators. In Section 3 we present the adaption of the Glushkov construction to our setting. In Section 4 we show how state elimination can be used to translate parity automata into ∞-regular expressions. In Section 5 we define deterministic ∞-regular expressions, and we conclude in Section 6. Detailed proofs can be found in [17].

2 Definitions and Examples

We use Γ to denote an alphabet, that is, a finite set of symbols. As usual, Γ^* and Γ^ω denote the set of finite and infinite words over Γ. Furthermore, we let $\Gamma^\infty := \Gamma^* \cup \Gamma^\omega$ be the set of all finite and infinite words over Γ. Regular expressions are defined in the standard way, that is, they are built up inductively from single letters $a \in \Gamma$, the empty word ε, and $\emptyset$ by the operators $+$ (union), $\cdot$ (concatenation), and * (finite iteration). Since we consider different classes of regular expressions, we explicitly refer to these regular expressions as $*$*-regular expressions*.

The usual definition of regular expressions for infinite words uses expressions of the form $r_1 s_1^\omega + \cdots + r_n s_n^\omega$ (see [15]). We refer to these expressions as ω*-regular expressions*. An infinite word α matches such an expression if there is an index i such that α has a finite prefix matching r_i, followed by an infinite concatenation of finite words matching s_i.

We introduce a new class of expressions that define mixed sets of finite and infinite words.

▶ **Definition 1** (∞ regular expressions)**.** The set of ∞*-regular expressions* over the alphabet Γ is defined inductively as follows: ε, $\emptyset$, and every $a \in \Gamma$ is an expression. Given two expressions r and s, then the following are ∞-regular expressions as well: $r + s$, $r \cdot s$, r^*, r^∞.

The semantics of such an expression r is a language $L(r) \subseteq \Gamma^\infty$ of both finite and infinite words, defined as follows.

- $L(a) = \{a\}$, $L(\varepsilon) = \{\varepsilon\}$, $L(\emptyset) = \emptyset$
- $L(r + s) = L(r) \cup L(s)$
- $L(r \cdot s) = L_\omega(r) \cup (L_*(r) \cdot L(s))$
- $L(r^*) = (L_*(r))^* \cdot (L_\omega(r) \cup \{\varepsilon\})$
- $L(r^\infty) = L(r^*) \cup (L_*(r))^\omega$

Here, L_* and L_ω denote the subset of finite and infinite words of L, respectively, i.e. $L_*(r) = L(r) \cap \Gamma^*$ and $L_\omega(r) = L(r) \cap \Gamma^\omega$.

The following examples give an idea how ∞-expressions can be used. Trying to write ω-regular expressions for the corresponding sets of infinite words shows that ∞-regular expressions can express some natural properties more directly.

- $L_\omega((a^*b)^\infty)$ = the set of words which contain infinitely many b
- $L_\omega((a^\infty b)^*)$ = the set of words which contain finitely many b
- $L_\omega(\,((b+c)^\infty a(a+c)^*b)^\infty\,)$ = the set of words in which every a is followed by a b

It is not very difficult to see that ∞-regular expressions subsume the expressive power of the other two classes of regular expressions, as stated in the next proposition.

▶ **Proposition 2.**

1. *A language $L \subseteq \Gamma^*$ is regular iff there is an ∞-regular expression describing it.*
2. *A language $L \subseteq \Gamma^\omega$ is ω-regular iff there is an ∞-regular expression describing it.*
3. *A language $L \subseteq \Gamma^\infty$ is described by some ∞-regular expression iff $L \cap \Gamma^*$ is regular and $L \cap \Gamma^\omega$ is ω-regular*

Proof.

1. If a language is regular, then there is a $*$-regular expression r describing it. ∞-regular expressions are a generalization of $*$-expressions, so r is also an ∞-regular expression describing the language. Given an ∞-expression describing a language $L \subseteq \Gamma^*$, we can

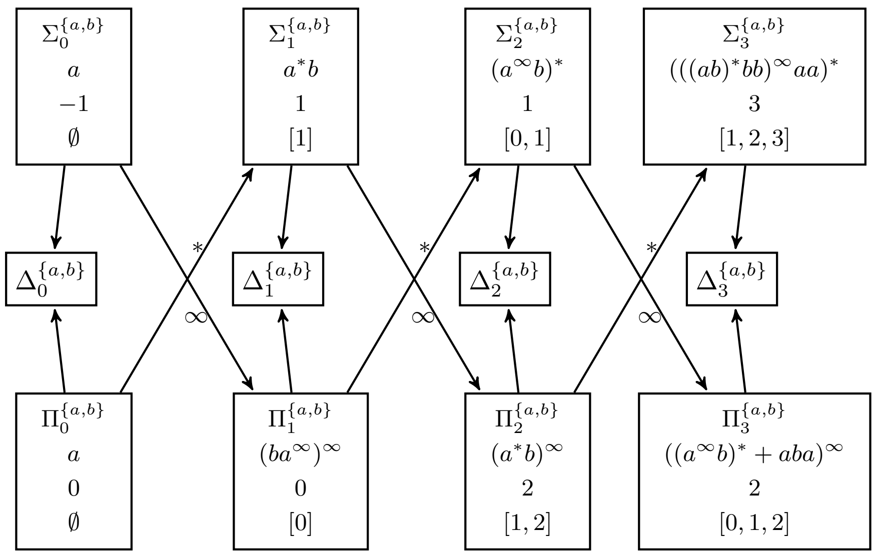

Figure 1 Illustration of the first four levels of the hierarchy $\mathcal{H}$. The second row is an example expression of the set and the third row shows the corresponding rank. The fourth row shows the interval of priorities which is used in the construction of a parity automaton from a regular expression in Section 3.

easily transform it into a $*$-regular expression by replacing every symbol r^∞ by r^*. This transformation does not change the set of finite words defined by the expression.

2. If $L \subseteq \Gamma^\omega$ is ω-regular, there is an ω-expression $r_1 s_1^\omega + \cdots + r_n s_n^\omega$ for it. By definition of the semantics of regular expressions, one can see that e^ω is equivalent to $e^\infty \cdot \emptyset$. Thus, L can be described by the ∞-expression $r_1 s_1^\infty \emptyset + \cdots + r_n s_n^\infty \emptyset$.
To convert an ∞-regular expression into an ω-expression, one has to replace the different operators inductively. The proof is technical and is therefore left out. This result also follows directly from Theorem 10.
3. The third result is a consequence of the first two. Given an ∞-regular expression, we can transform it to obtain expressions for both $L \cap \Gamma^*$ and $L \cap \Gamma^\omega$ as shown above. If we know expressions r and s for $L \cap \Gamma^*$ and $L \cap \Gamma^\omega$, we can transform them to ∞-regular expression. Their union then describes L. ◀

For the translation between ∞-regular expressions and automata, the alternation of the two unary operators $*$ and ∞ plays a central role. Thus, we consider the hierarchy resulting from the nesting of these operators. The use of the names Π and Σ for the classes is borrowed from hierarchies like the Borel hierarchy or arithmetic hierarchy.

Let $\Sigma_0^\Gamma = \Pi_0^\Gamma = \{r \mid r \text{ is an } \infty\text{-regular expression over } \Gamma \text{ and contains no } * \text{ nor } \infty\}$, which are the "lowest" levels in this hierarchy as they do not use any degree of alternation. Inductively, we define Π_{n+1}^Γ to be the closure of Σ_n^Γ w.r.t. the operators $+$, $\cdot$, and ∞. Analogously, Σ_{n+1}^Γ is the closure of Π_n^Γ w.r.t. $+$, $\cdot$, and $*$. Finally, we set $\Delta_n^\Gamma = \Sigma_n^\Gamma \cap \Pi_n^\Gamma$.

The structure of the hierarchy is shown in Figure 1. The arrows indicate how the classes are built from other classes. For further illustration, here are some examples.

- Every $*$-regular expression lies in Σ_1^Γ.
- The expression $(a^*b)^\infty$ is in $\Pi_2^{\{a,b\}}$ but in no lower level.
- The expression $(a^\infty b)^*$ is in $\Sigma_2^{\{a,b\}}$ but in no lower level.
- The expression $a^* + b^\infty$ is in $\Delta_2^{\{a,b\}}$ but in no lower level.

Since the levels of the hierarchy are strictly growing, each expression is contained in infinitely many levels. We refer to the lowest level as the stage of an expression, as detailed in the following definition.

▶ **Definition 3** (Stage). For every ∞-regular expression r, there is a unique set Σ_n^Γ, Π_n^Γ or Δ_n^Γ, which is the lowest set in the hierarchy that contains r (Δ_n being lower than Σ_n and Π_n). We call that set the *stage* of r ($\mathrm{stg}(r)$).

For example, $(a^\infty b)^*$ is contained in $\Sigma_3^{\{a,b\}}$. Its stage, however, is $\Sigma_2^{\{a,b\}}$, as it is not the element of any level 1 set or $\Delta_2^{\{a,b\}}$.

Note that this hierarchy, which we call $\mathcal{H}$ in the following, only describes the expressions as syntactical objects, without regard to the semantic language. In fact, a semantic hierarchy of the same kind would collapse down to two levels (the hierarchy becomes strict in the context of deterministic expressions, as explained in Section 5).

▶ **Proposition 4.** *Let $L \subseteq \Gamma^\infty$ be ∞-regular. Then there is an ∞-regular expressions r describing L with $r \in \Pi_2^\Gamma$.*

Proof. This result is implied by the construction used in point 3 of Proposition 2. ◀

To better "categorize" the complexity of an expression in the hierarchy $\mathcal{H}$, we assign a single number to each class. Basically, this number corresponds to the highest priority that is used in Section 3 in the construction of parity automata from expressions of the corresponding level of the hierarchy.

▶ **Definition 5** (Rank). We assign a *rank* to every set in $\mathcal{H}$ (see also Figure 1)

$$\mathrm{rk}(\Sigma_n^\Gamma) = 2 \cdot \left\lceil \frac{n+1}{2} \right\rceil - 1, \quad \mathrm{rk}(\Pi_n^\Gamma) = 2 \cdot \left\lfloor \frac{n}{2} \right\rfloor, \quad \text{and} \quad \mathrm{rk}(\Delta_n^\Gamma) = \min\{\mathrm{rk}(\Sigma_n^\Gamma), \mathrm{rk}(\Pi_n^\Gamma)\}.$$

We also define the rank of an expression r to be $\mathrm{rk}(r) = \mathrm{rk}(\mathrm{stg}(r))$. Note that every set Π_n^Γ has an even rank, and every Σ_n^Γ has an odd rank.

3 Glushkov Automaton

To convert a given ∞-regular expression to an automaton, we generalize the Glushkov construction which can be found in [1, 2] for finite words. We focus only on the set of ω-words defined by ∞-regular expression here. Since the automaton that we construct uses the same transition structure as the one from the classical construction for finite words, one can simply add a set of final states if one is interested in automata accepting both finite and infinite words. We start with the definition of parity automata, which is the model of automata for infinite words that we use (see, e.g., [6] for more information on parity automata).

▶ **Definition 6** (Parity automaton). A *parity automaton* is a tuple $\mathcal{A} = (Q, \Gamma, q_0, \delta, \gamma)$, where Q is the finite set of states, Γ is the alphabet, $q_0 \in Q$ is the initial state, $\delta : Q \times \Gamma \to 2^Q$ is the transition function, and γ is the priority assignment function. We use two different variants for γ; either $\gamma : Q \to \mathbb{N}$ assigns priorities to states, or $\gamma : Q \times Q \to \mathbb{N}$ assigns priorities to pairs of states, which corresponds to priority $\gamma(p, q)$ on all transitions from p to q.

A run of $\mathcal{A}$ on some word $w \in \Gamma^\infty$ is a word $\rho \in Q^\infty$ which "follows" δ, meaning $\rho(n+1) \in \delta(\rho(n), w(n))$ for all relevant n. $\mathcal{A}$ accepts an infinite word w if there is a run ρ on w which is accepting, meaning that the *highest* priority occurring infinitely often in ρ is *even*.

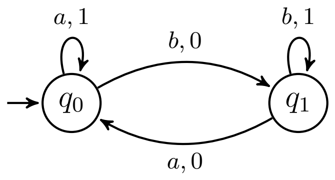

Figure 2 An automaton using transition priorities for the language $(a+b)^*(ab)^\omega$.

While the assignment of priorities to states is the usual definition, we use the assignment to transitions (pairs of states) in this section. An example of such an automaton is shown in Figure 2. It is easy to see that the two definitions of the priority function γ can be transformed into one another. From states to transitions, one can simply move the priorities to the outgoing transitions of a state. If the priorities are assigned to pairs of states, one can obtain an equivalent automaton with priorities on states by increasing the automaton by a factor of at most $|Q|$.

The states of the Glushkov automaton are the occurrences of letters in the expression. This is formalized using the definition of marking, given below.

▶ **Definition 7** (Marking). Let r be an ∞-regular expression over Γ. We call $\sharp(r)$ a *marking of* r. It is defined as an ∞-regular expression over some subset $\Gamma' \subset \Gamma \times \mathbb{N}$ by replacing every $a \in \Gamma$ in r by a *unique* pair $(a, n) \in \Gamma \times \mathbb{N}$. We also write a_n instead of (a, n).

For the transitions of the Glushkov automaton the following definitions are used.

▶ **Definition 8.** Let $L \subseteq \Gamma^\infty$ be a language. We define
- $\text{first}_L = \{a \in \Gamma \mid \text{There is a } w \in L \text{ which begins with } a\}$
- $\text{last}_L = \{a \in \Gamma \mid \text{There is a } w \in L \text{ which ends with } a\}$
- $\text{follows}_L(b) = \{a \in \Gamma \mid \text{There is a } w \in L \text{ in which } a \text{ occurs directly after } b\}$

▶ **Definition 9** (Glushkov automaton). Let r be an ∞-regular expression over the alphabet Γ. We define the *Glushkov automaton* $\mathcal{G}_r = (Q, \Gamma, q_0, \delta, \gamma)$. For that, let $\Gamma' \subset \Gamma \times \mathbb{N}$ be the set of symbols in $\sharp(r)$. The set of states $Q = \{q_0\} \cup \Gamma'$ contains one state for every symbol in r, as well as a distinct initial state. The transition function is defined as

$$\delta(q, a) = \begin{cases} \{a_n \in \Gamma' \mid a_n \in \text{first}_{L(\sharp(r))}\} & \text{if } q = q_0 \\ \{a_n \in \Gamma' \mid a_n \in \text{follows}_{L(\sharp(r))}(q)\} & \text{else.} \end{cases}$$

It allows the automaton to move from one symbol of $\sharp(r)$ to any succeeding symbol which matches with the read letter a. Note that for the case $q \neq q_0$, we use the fact that $\Gamma' \subset Q$, which is why follows(q) is well-defined. This definition of δ aligns with that for finite words from [2].

For the priority function, we use an assignment on edges: $\gamma : Q \times Q \to \mathbb{N}$. For any pair $p, q \in Q$ such that p or q equals q_0, or there is no transition between the two states, we can set $\gamma(p, q)$ to an arbitrary value, as it will occur at most once in any run. We will simply leave out the priority for these transitions in examples.

For the other cases, the priority is intuitively determined by the operators that induce the transition. To capture this formally, we need a few definitions that are illustrated with an example below. Let $a_n, b_m \in \Gamma'$ such that $b_m \in \delta(a_n, b)$. Let $R_* \ / \ R_\infty$ be the set of all sub-expressions of r of the form $s^* \ / \ s^\infty$, and

$$S = \{s \mid s \text{ is a sub-expression of } r \text{ with } a_n \in \text{last}_{L(\sharp(s))} \text{ and } b_m \in \text{first}_{L(\sharp(s))}\} .$$

Let $R'_* = \{s^* \in R_* \mid s \in S\}$, $R'_\infty = \{s^\infty \in R_\infty \mid s \in S\}$, and $R' = R'_* \cup R'_\infty$. These sets R'_* and R'_∞ can be seen as the "looping" expressions of the transition. The order $\prec$ on R' defined by $s \prec t$ if s is a sub-expression of t is a linear order because a_n and b_m exist exactly once in r.

We then set $\gamma(a_n, b_m) = \begin{cases} \blacklozenge & \text{if } R' = \emptyset \\ \mathrm{rk}(\max_\prec R'_\infty) & \text{if } R'_\infty \neq \emptyset \\ \mathrm{rk}(\min_\prec R'_*) & \text{else.} \end{cases}$

We use $\blacklozenge$ here as a dummy symbol for the minimal priority. These transitions never occur in a loop without a transition with $R' \neq \emptyset$.

This definition of γ ensures that the automaton always uses the "best looping transition" in r, meaning the highest even priority if possible, or the lowest odd priority otherwise.

We demonstrate the construction of $\mathcal{G}_r$ on the following example. Let the alphabet be $\Gamma = \{a, b, c\}$ and $r = (a((a+\varepsilon)b^\infty)^*)^\infty$. We want to note here that this is semantically not a useful expression and is only constructed to illustrate the definition. We use the marking $\sharp(r) = (a_1((a_2+\varepsilon)b_1^\infty)^*)^\infty$. $\mathcal{G}_r$ is displayed in Figure 3.

This expression yields the sets $R_* = \{((a_2+\varepsilon)b_1^\infty)^*\}$ and $R_\infty = \{(a_1((a_2+\varepsilon)b_1^\infty)^*)^\infty, b_1^\infty\}$, which are all sub-expressions with a $*$ or an ∞ as the outermost operator.

Let $p = a_1$ and $q = a_2$. The set S for this pair of states is $S = \emptyset$, as there is no sub-expression of r that can start with a_2 and end with a_1. Hence, R' is empty as well and we set $\gamma(p, q) = \blacklozenge$. The intuitive explanation for this is that moving from a_1 to a_2 in the expression corresponds to a concatenation operation and not a looping operator.

Let $p = q = b_1$. In this case, $S = \{b_1, b_1^\infty, (a_2+\varepsilon)b_1^\infty, ((a_2+\varepsilon)b_1^\infty)^*\}$. This also gives non-empty sets $R'_* = \{((a_2+\varepsilon)b_1^\infty)^*\}$ and $R'_\infty = \{b_1^\infty\}$. By definition, we assign $\gamma(p, q) = \mathrm{rk}(\max_\prec R'_\infty) = \mathrm{rk}(b_1^\infty) = 0$. The intuition is that there are two possible operators one could use to loop within the expression and follow a b_1 by another b_1. In this case, the priority reflects the "best" choice among these operators.

For the other priorities, note that moving back to a_1 from a_2 or b_1 is only possible via the outermost ∞-operator, hence these transitions have priority 2. Moving back between b_1 and a_2 is done through the $*$-operator, leading to priority 1. The transitions corresponding to concatenation operations and are assigned $\blacklozenge$ (which would be replaced by the minimal priority 0 used in the automaton).

Another significant example is the transition from a_2 to b_1. It might look like it would assigned the value $\blacklozenge$ as it corresponds to a concatenation operator but in fact the definition gives $\gamma(a_2, b_1) = 1$. That is because the transition can also be completed by the $*$-operator as follows: Read an a as a_2, skip b_1^∞ because it contains the empty word, use the $*$-operator to "loop around" to the beginning of the sub-expression, skip $(a_2+\varepsilon)$ because it contains the empty word, finally read b as part of b_1^∞.

Not only does the Glushkov automaton accept the correct language, we can also find a relation between the rank of the expression r and the number of priorities in $\mathcal{G}_r$. This is captured by the following theorem.

▶ **Theorem 10.** *Let r be an ∞-regular expression.*

- *$\mathcal{G}_r$ accepts exactly $L_\omega(r)$*
- *$\mathcal{G}_r$ uses priorities up to at most $\mathrm{rk}(r)$*
- *$\mathcal{G}_r$ uses $\mathcal{O}(|r|)$ many states*

Proof. The only idea of this proof is to convince oneself that the usage of "loops" in the expression, as it is described in the construction and the example, is correct. The formal

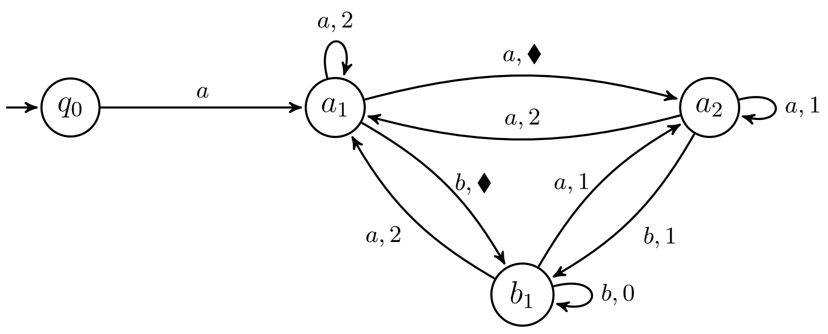

Figure 3 $\mathcal{G}_r$ for $r = (a((a+\varepsilon)b^\infty)^*)^\infty$.

proof is carried out by an equivalent inductive definition of the Glushkov automaton, which then admits an inductive correctness proof. The technical details are lengthy and can be found in [17]. ◀

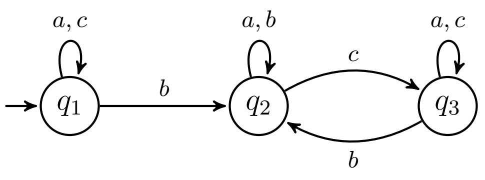
4 State Elimination

We now establish an algorithm for the reverse operation, i.e. converting a parity automaton to an equivalent ∞-regular expression. We use a variation of the *state elimination algorithm* which is known for regular languages of finite words [3] (see also [14]). In this section we work with priorities assigned to states.

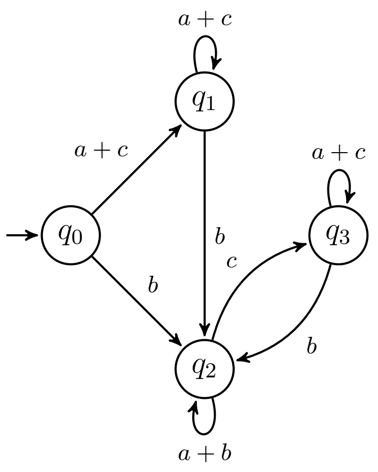
```
// Initialize new automaton
$Q_0 := Q \,\dot\cup\, \{q_0'\}$ ;
$R_0 : Q_0 \times Q_0 \to \{r \mid r \text{ is an } \infty\text{-reg.exp.}\}$ ;
for $p, q \in Q_0$ do
    $R_0(p,q) := \begin{cases} \sum\{a \in \Gamma \mid q \in \delta(p,a)\} & \text{if } p,q \in Q \\ \sum\{a \in \Gamma \mid q \in \delta(q_0,a)\} & \text{if } p = q_0', q \in Q \\ \emptyset & \text{if } q = q_0' \end{cases}$
end
Let $\prec \subseteq Q \times Q$ be a linear order such that $x \prec y$ implies $\gamma(x) \leq \gamma(y)$ ;
for $i = 0$ to $|Q| - 1$ do
    // Eliminate state with minimal priority
    $q_e := \min_\prec(Q_i \setminus \{q_0'\})$ ;
    $r_e := \begin{cases} (R_i(q_e,q_e))^\infty & \text{if } \gamma(q_e) \text{ is even} \\ (R_i(q_e,q_e))^* & \text{if } \gamma(q_e) \text{ is odd} \end{cases}$ ;
    $Q_{i+1} := Q_i \setminus \{q_e\}$ ;
    $R_{i+1} : Q_{i+1} \times Q_{i+1} \to \{r \mid r \text{ is an } \infty\text{-reg.exp.}\}$ ;
    for $p, q \in Q_{i+1}$ do
        $R_{i+1}(p,q) := R_i(p,q) + (R_i(p,q_e) \cdot r_e \cdot R_i(q_e,q))$
    end
end
return $R_{|Q|}(q_0', q_0')$ ;
```

Algorithm 1: State elimination algorithm

The formal algorithm is described as Algorithm 1. It takes as input a parity automaton



(a) Automaton for the language of words which contain at least one b and after every c, there is a b later on. The priorities are $\gamma(q_1) = \gamma(q_3) = 1$ and $\gamma(q_2) = 2$.



(b) The initialized transition structure defined by Q_0 and R_0.

Figure 4 Initialization step of Algorithm 1.

$\mathcal{A} = (Q, \Gamma, q_0, \delta, \gamma)$ with priorities assigned to states and returns an ∞-regular expression r with $L_\omega(r) = L(\mathcal{A})$. We explain its operations by an example.

The state elimination for parity automata is shown in Algorithm 1. It computes intermediate automata in which the transitions are labeled by ∞-regular expressions. These transitions are represented by mappings R_i that assign ∞-regular expressions to pairs of states. In the initialization, the algorithm adds a new initial state to the automaton, and R_0 maps each pair (p, q) of states to the disjunction of labels of transitions from p to q.

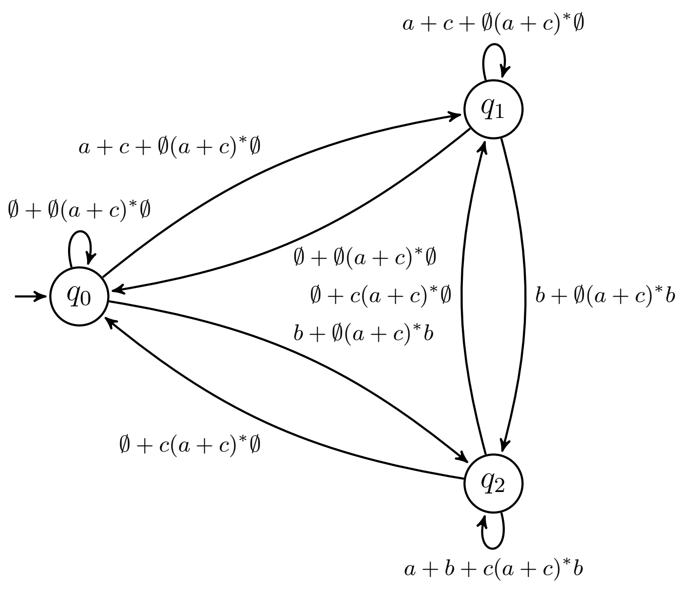
Consider the parity automaton shown in Figure 4a with priorities $\gamma(q_1) = \gamma(q_3) = 1$ and $\gamma(q_2) = 2$. It recognizes the language of words which contain at least one b and after every c, there is a b later on. The result of the initialization is shown in Figure 4b, where transitions labeled $\emptyset$ are omitted. The new initial state is called q_0 in the picture.

After this initialization, all states except for q_0 (q_0' in the algorithm) are eliminated in order of ascending priority. Here our algorithm differs from the original one for NFAs, for which the order of elimination is arbitrary. The resulting expression is then the label on the remaining loop on the new initial state.

The first step of this elimination process can be found in Figure 5, in which q_3 has been eliminated. As q_3 had odd priority, the $*$-operator was used for the iteration of $R_0(q_3, q_3) = a + c$. If the priority was even, all occurrences of $(a + c)^*$ would have to be replaced by $(a + c)^\infty$ instead. This is the second difference of our algorithm from the known one. The new function of expressions is then called R_1. A specific example is $R_1(q_1, q_2) = R_0(q_1, q_2) + R_0(q_1, q_3) \cdot R_0(q_3, q_3)^* \cdot R_0(q_3, q_2) = b + \emptyset \cdot (a + c)^* \cdot b$. Note here that unlike state elimination of NFAs, it is important to consider $\emptyset$-transitions in the calculation because $r^\infty\emptyset$ is the set of infinite words defined by r^∞, and thus $r^\infty\emptyset \neq \emptyset$.

The algorithm would continue by deleting q_1 followed by q_2 to create R_2 and R_3 respectively. The result is then found in $R_3(q_0, q_0)$, the self-loop of the new initial state.

The state elimination algorithm allows us to establish a similar relation between operator nesting and number of priorities like the Glushkov construction did. Concerning the complexity, the expression can be exponential in the size of the automaton, just like in the classical counterpart of the algorithm.



$a + c + \emptyset(a + c)^*\emptyset$
q_1
$a + c + \emptyset(a + c)^*\emptyset$
$\emptyset + \emptyset(a + c)^*\emptyset$
$\emptyset + \emptyset(a + c)^*\emptyset$
q_0
$\emptyset + c(a + c)^*\emptyset$
$b + \emptyset(a + c)^*b$
$b + \emptyset(a + c)^*b$
$\emptyset + c(a + c)^*\emptyset$
q_2
$a + b + c(a + c)^*b$

Figure 5 The transition structure defined by Q_1 and R_1, after the elimination of the first state q_3.

▶ **Theorem 11.** *Let $\mathcal{A} = (Q, \Gamma, q_0, \delta, \gamma)$ be a parity automaton with $\gamma(Q) = \{0, \ldots, n\}$ or $\gamma(Q) = \{1, \ldots, n\}$ and let r be the result of the state elimination algorithm with input $\mathcal{A}$.*

- *$\mathcal{A}$ accepts exactly $L_\omega(r)$*
- *$rk(r)$ is at most n*
- $|r| \in \mathcal{O}(4^{|\Gamma| \cdot |Q|})$

Proof. The statement about the size of r can be seen directly from the definition. In the first iteration, all edges are marked by regular expressions of size at most Γ. In every step, each expression is replaced by the concatenation of four expressions from the previous round, giving the bound on the size.

For the correctness proof one shows that after each step the automata accept the same language (with an appropriate definition of the semantics for parity automata with ∞-regular expressions on transitions). Details are available in [17]. ◀

5 Deterministic Regular Expressions

Deterministic regular expressions for finite words play a role in specification languages for XML documents. They have been studied in detail in [2] (where they are called one-unambiguous expressions). We extend the definition to ∞-regular expressions and state some basic properties for this class of expressions.

▶ **Definition 12** (Deterministic expressions)**.** Let r be an ∞-regular expression over Γ and let $\sharp(r)$ be a marking (see Definition 7) over an alphabet $\Gamma' \subset \Gamma \times \mathbb{N}$. We call r *deterministic* if it satisfies the following property: Let $u \in (\Gamma')^*$, $v, w \in (\Gamma')^\infty$, and $x = a_n, y = b_m \in \Gamma'$, such that $uxv, uyw \in L(\sharp(r))$. If $a = b$, then $n = m$.

A more natural description of this subclass defines it as those expressions, such that after every occurrence of some symbol a in the expression r and every $b \in \Gamma$, there is at most one occurrence of b in r which can succeed this occurrence of a.

For example, let $r_1 = aa^*$ and $r_2 = a^*a$. Possible markings are $\sharp(r_1) = a_1a_2^*$ and $\sharp(r_2) = a_1^*a_2$. That shows that r_1 is deterministic, but r_2 is not. For every word $u \in \{a\}^*$, it is clear which letter in u is mapped to which occurrence of a in r_1. However, that is not the case for r_2, as $u = \varepsilon$ is both a prefix of a_2 and a_1a_2. In other words, the first a of an input string could be mapped to the first or the second occurrence of a in r_2.

It is notable that these expressions are strictly less powerful than the class of all ∞-regular expressions, and they are also distinct from the deterministic Büchi-definable languages, which define a proper subclass of the ω-regular languages (see [15]). The proof is just a simple extension of a similar result for finite words: The language $(a + b)^*b(a + b)$ cannot be described by a deterministic $*$-regular expression. This is stated in [2], and can be verified using their decision procedure for definability by deterministic $*$-regular expressions.

▶ **Proposition 13.** *The language $(a + b)^*b(a + b)c^\omega$ can be recognized by a deterministic Büchi automaton but not by a deterministic ∞-regular expression.*

Proof. Assume there is a deterministic expression r for this language. We can replace every occurrence of c with ε to obtain a deterministic $*$-regular expression r' for $(a + b)^*b(a + b)$, which is not possible, as shown in [2]. The determinism of r' easily follows from the fact that the c only appear at the end of words. It is easy to specify a deterministic Büchi automaton for the language. ◀

Furthermore, a direct consequence of the definition of deterministic expressions is the following relation to the Glushkov automaton.

▶ **Proposition 14.** *Let r be an ∞-regular expression. r is deterministic iff the Glushkov automaton $\mathcal{G}_r$ is deterministic.*

Proof. As the transition structure is the same as for $*$-regular expressions, the same proof from [2] is valid here. ◀

There is however no such relation between the deterministic structure of a parity automaton and the resulting expression from the state elimination algorithm. In fact, the state elimination algorithm will produce a non-deterministic expression for almost all input automata.

In the context of deterministic ∞-regular expressions, the hierarchy $\mathcal{H}$ as defined in Section 2 becomes more interesting, as shown by the following results.

▶ **Proposition 15.** *For every $n > 0$, there is an alphabet Γ and deterministic ∞-regular expressions $r \in \Sigma_n^\Gamma$ and $s \in \Pi_n^\Gamma$ such that there are no deterministic ∞-regular expressions for $L(r)$ or $L(s)$ in $\Sigma_{n-1}^\Gamma \cup \Pi_{n-1}^\Gamma$.*

Proof. For all $0 \leq i < j$ we define $\Gamma_{i,j} = \{i, \dots, j\} \subset \mathbb{N}$ and

$$L_{i,j} = \{\alpha \in \Gamma_{i,j}^\omega \mid \text{The highest number occurring infinitely often in } \alpha \text{ is even}\}.$$

Let $r_{i,i} = \begin{cases} i^\infty & \text{if } i \text{ is even} \\ i^* & \text{if } i \text{ is odd} \end{cases}$ and $r_{i,j} = \begin{cases} (r_{i,j-1} \cdot j)^\infty & \text{if } j \text{ is even} \\ (r_{i,j-1} \cdot j)^* & \text{if } j \text{ is odd} \end{cases}$.

These regular expressions contain every symbol only once and are therefore deterministic. Their subset of ω-words also describes the corresponding language $L_{i,j}$. We use the well-known result that there is no deterministic parity automaton $\mathcal{A}$ such that $\mathcal{A}$ uses at most $j - i$ many priorities and $L(\mathcal{A}) = L_{i,j}$. A proof of this statement is given in [17].

For the claim stated in the proposition itself, let $n > 0$. We use $\Gamma = \{0, \dots, n+1\}$, $r = r_{1,n+1}$, and $s = r_{0,n}$. Assume there is a deterministic ∞-regular expression $t \in \Sigma^{\Gamma}_{n-1} \cup \Pi^{\Gamma}_{n-1}$ with $L_\omega(r) = L_\omega(t)$. (Argumentation for s is analogous.) Then $\mathrm{rk}(t) \leq n - 1$ by definition of the rank function, so the Glushkov construction finds a deterministic parity automaton for $L(r)$ which uses only priorities from 0 to $n-1$, i.e. at most n many priorities. This is a contradiction as $L(r) = L_{1,n+1}$ which we established not to be recognizable by any deterministic parity automaton with at most n priorities. ◀

As a consequence of the proof of Proposition 15 we obtain that in particular the languages of deterministic ∞-regular expressions are not captured by deterministic Büchi automata (more generally by deterministic parity automata with a fixed number of priorities). The language $L_{0,1} = \{\alpha \in \{0,1\}^\omega \mid \alpha \text{ contains only finitely many ones}\}$ is such an example.

▶ **Corollary 16.** *There are ω-languages which can be described by a deterministic ∞-regular expression but cannot be recognized by a deterministic Büchi automaton.*

The result gives more meaning to the hierarchy $\mathcal{H}$. While the class of all ∞-regular expressions breaks down to the set Π_2, the restriction of the hierarchy to deterministic expressions is strict.

6 Conclusion

We have given a simple inductive definition of the class of ∞-regular expressions that can be used to define languages of infinite words (or mixed languages of finite and infinite words). We adapted two classical algorithms for the transformation between automata and expressions such that the nesting of the two looping operators in the expressions corresponds to the priorities of an equivalent parity automaton. We have also shown that the hierarchy obtained from the nesting of the two operators, while collapsing to the second level in the general case, becomes strict for deterministic expressions.

Concerning deterministic expressions, there are some interesting questions for future research. For finite words it is decidable whether a given regular language can be defined by a deterministic expression [2]. Since the decision procedure uses the existence of a unique minimal DFA for each regular language, the methods cannot be adapted directly, and it is an open question whether the decidability result carries over to infinite words. The strictness of the deterministic hierarchy of operator nestings also naturally induces the problem of deciding whether a given deterministic ∞-regular expression has an equivalent one on a given level. For deterministic parity automata the corresponding question is decidable [4] but the exact relation between the hierarchy for deterministic ∞-regular expression and deterministic parity automata needs to be understood in more detail.

Abstract

The Traveling Tournament Problem is a complex combinatorial optimization problem in tournament timetabling, which asks a schedule of home/away games meeting specific feasibility requirements, while also minimizing the total distance traveled by all the n teams (n is even). Despite intensive algorithmic research on this problem over the last decade, most instances with more than 10 teams in well-known benchmarks are still unsolved. In this paper, we give a practical approximation algorithm for the problem with constraints such that at most two consecutive home games or away games are allowed. Our algorithm, that generates feasible schedules based on minimum perfect matchings in the underlying graph, not only improves the previous approximation ratio from $(1 + 16/n)$ to about $(1 + 4/n)$ but also has very good experimental performances. By applying our schedules on known benchmark sets, we can beat all previously-known results of instances with n being a multiple of 4 by 3% to 10%.

1 Introduction

In the field of tournament timetabling, the Traveling Tournament Problem is a well-known and practically difficult optimization problem inspired by Major League Baseball. This problem asks for a double round-robin schedule that minimizes the sum of distances traveled by all teams. Since the first introduction of this problem [6], several variants have been proposed, with a significant amount of research [13, 16]. Before introducing more background, we give the precise definition of the Traveling Tournament Problem.

The Traveling Tournament Problem (TTP-k):
Input:An $n \times n$ distance matrix D to indicate the distance between each pair of n teams, and an integer k;
Output:A double round-robin tournament on the n teams such that the total distance traveled by all the teams is minimized, subject to the following three conditions:

* This work is supported by National Natural Science Foundation of China, under the grant 61370071, and the Fundamental Research Funds for the Central Universities, under the grant ZYGX2015J057.

- *each-venue*: Each pair of teams plays twice, once in each other's home venue.
- *at-most-k*: No team may have a home stand or a road trip lasting more than k games.
- *no-repeat*: A team cannot play against the same opponent in two consecutive games.

When calculating the total distance, we assume that each team begins the tournament at home and returns home after playing its last away game. Furthermore, whenever a team has a road trip consisting of multiple away games, the team does not return to its home city but rather proceeds directly to its next away venue. There are two commonly used assumptions: each team has a game scheduled on each time slot with no time slots off and then the number n of teams must be even. The distances in D satisfy symmetry and triangle inequality, i.e.,$D_{i,j} = D_{j,i}$ and $D_{i,j} \leq D_{i,h} + D_{h,j}$ for all i, j, h. We also require that $D_{i,i} = 0$ for each i.

The integer k in the input defines the tradeoff between distance traveled and the length of the home stands and road trips. For the case that $k = \infty$, there is no constraint on the number of consecutive home stands or road trips and a team can be scheduled with its traveling length as short as that of the traveling salesman tour of the cities. The smaller k, the more often teams have to return to their home cities.

TTP-k can be regarded as a variant of the well-known Traveling Salesman Problem. The NP-hardness of TTP-k with $k = \infty$ or $k = 3$ has been proved [17, 2]. There is a large number of contributions on approximation algorithms [22, 12, 15, 21, 11] and heuristic algorithms [7, 14, 1, 5, 9].

There is an online set of benchmark data sets [19] with the list of best-known results for TTP-3. For most benchmark problems, instances are often completely solved or improved after weeks of computation on high-performance machines using parallel computing, see, e.g. [20]. Since the search space of TTP-k is very large, no instance with more than 10 teams in [19] has been completely solved even on high-performance machines. Goerigk *et al.* [9] used a technique of packing P_3 paths to find feasible solutions as initial inputs for some hybrid algorithms and then improved five benchmark instances of TTP-3. New techniques become more important to get further improvements.

In this paper, we focus on TTP-2. TTP-2 was first mentioned by Campbell and Chen [3], who scheduled a basketball conference of ten teams. In this problem, all away trips consist of either a single team or pairs of teams. It is reasonable that each team has at most two consecutive home stands or road trips in practice. In a schedule, we hope that home stands and road trips alternate as regularly as possible for each team. We can see that the perfect schedule with $k = 1$ can not be achieved [4]. It is natural to consider TTP-2. However, compared to the case that $k \geq 3$, TTP-2 did not attract much attention. A significant contribution to approximation algorithms for TTP-2 is due to Thielen and Westphal [18]. They first gave an approximation algorithm with ratio $3/2 + O(1/n)$ and then improved the ratio to $1 + 16/n$ for the case that $n \geq 12$ and n is a multiple of 4. Their algorithms also get the current best results on the benchmark instances listed on the website [19].

The main contribution of this paper is an improved approximation algorithm for TTP-2. Our algorithm generates a feasible solution to TTP-2 for n being a multiple of 4 with a traveling distance at most $(1 + 2/(n-2) + 2/n)$ times of the optimal distance, improving the previous approximation ratio of $(1 + 16/n)$ by an addition of almost $12/n$. Our algorithm takes only 2.6 seconds on a standard laptop to compute all the instances with n being a multiple of 4 (half of all the benchmark instances) in the benchmark [19], and beat the previously best-known upper bounds by 3% to 10%.

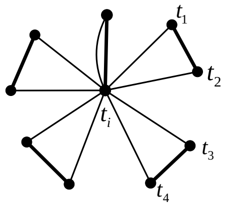

Figure 1 the itinerary graph of team t_i.

The remaining parts of the paper are organized as follows: We first introduce a simple lower bound of the problem, then introduce our methods of constructing schedule, and finally prove the approximation ratio and demonstrate the performance of the algorithm on benchmark instances.

2 A Lower Bound

Most lower bounds for the Traveling Tournament Problem are obtained by a relaxation technique called "independent". It is to compute the minimum distance of a "feasible" traveling for each team independently and then sum all of them together to get a bound. Here "feasible" means that the traveling satisfies the three conditions in the definition of TTP-k. This bound is known as the "independent lower bound".

The independent lower bound for TTP-2 was firstly obtained by Campbell and Chen [3]. It can be computed by finding a minimum perfect matching in a complete undirected graph G on the set of teams with edge weight being the distance between the homes of two teams. By triangle inequality, we know that an optimal feasible traveling for a team contains at most one away trip of a single team and all other away trips of a pair of teams. According to the definition of the problem, the number n of teams is even. So each team contains exactly one away trip consisting of a single site (team) and all other away trips consisting of a pair of sites (teams). The itinerary graph of a team t_i is as shown in Figure 1.

Each team t_i must travel to or from each other team for at least once. See the light lines in Figure 1. The total length of all light lines is a constant. It is the total distance from a team t_i to all other teams, which is also denoted by D_i. We have that $D_i = \sum_{j \neq i} D_{i,j}$.

The dark lines in Figure 1 form a perfect matching of G. We use M to denote a minimum perfect matching (a perfect matching with minimum total edge weight) of G and use D_M to denote the total edge weight of M. We can observe that the traveling distance of team t_i is at least

$$LB_i = D_i + D_M,$$

which is called the *independent lower bound* for team t_i. We use D_G to denote the sum of the weights of all edges in G. A lower bound for the Traveling Tournament Problem, obtained by summing up the independent lower bound of each team, is given as follows.

$$LB = \sum_{i=1}^{n} LB_i = \sum_{i=1}^{n}(D_i + D_M) = 2D_G + nD_M. \tag{1}$$

If we can find a feasible tournament schedule such that all teams achieve the independent lower bound synchronously, then the Traveling Tournament Problem is solved optimally. However, it is impossible for all teams to reach the independent lower bound synchronously in any feasible tournament schedule [18]. It is also worthy to mention that for $k \geq 3$ it is even NP-hard to compute the independent lower bound for a team, since it will involve the problem of finding an optimal k-path packing in a graph.

3 Techniques for Construction

It is nontrivial to obtain a feasible tournament schedule for TTP-2 even without considering the traveling distance. "Expander construction" is an effective method used to construct feasible schedules for TTP-3 [10, 9]. We will modify this method for TTP-2 to construct an initial solution. After obtaining a feasible tournament schedule, we use some techniques based on minimum perfect matchings to arrange the order of teams and then we can obtain a solution with the traveling distance quite near to the independent lower bound.

To make the traveling distance small, we hope that an away trip of a team consists of a pair in a minimum perfect matching of G. This gives us an idea to consider the teams in the tournament as pairs corresponding to a minimum perfect matching. After scheduling the pairs, we "expand" by replacing each pair with two original teams to get the final schedule. This is the main idea of the initial construction.

The construction contains two steps. Step 1 is to create a single round-robin tournament U_m on $m = n/2$ teams (each of which will represent a pair of original teams). Step 2 is to expand U_m to a double round-robin tournament Z_n on n teams. Note that the construction only works for $m = n/2$ being even, i.e., $n \equiv 0 \pmod 4$. Next, we always assume that m is even.

Step 1. Constructing a single round-robin tournament U_m: The single round-robin tournament U_m on m teams is built by using a variation of the Modified Circle Method [8, 10]. We use $\{u_1, u_2, \cdots, u_{m-1}, x\}$ to denote the m teams. Each team plays with each of the other $m-1$ teams on $m-1$ time slots according to the following rule: for each $1 \le i \le m-1$, team u_i plays with team u_j on time slot r such that

$$r - i \equiv j - 1 \pmod{m-1},$$

where we interpret the case that a team u_i plays with itself as that u_i plays with team x on the time slot. This assignment can guarantee a feasible schedule, i.e., each of the m teams plays with another team on each of the $m-1$ time slots.

The construction is not finished yet. We still designate a home team and a road team for each game not involving team x: for each $1 \le i \le m/2$, u_i plays only road games until it meets team x, before finishing the remaining games at home; for each $m/2+1 \le i \le m-1$, we have the opposite scenario, where u_i plays only home games until it meets team x, before finishing the remaining games on the road. Please see Table 1 for an illustration of the single round-robin schedule with $m = 8$, where items in bold font indicate that the corresponding teams (on the left of the table) are home teams in this game.

Step 2. Constructing a double round-robin tournament Z_n: We have four substeps to construct a double round-robin tournament Z_n on n teams from the single round-robin tournament U_m on $m = n/2$ teams. Recall that each team u_i in U_m is represented with a pair of original teams in the tournament. So we will replace u_i (where x is interpreted as u_m) with two original teams $\{t_{2i-1}, t_{2i}\}$ in this step. Thus, the set of the original n teams in Z_n is denoted by $\{t_1, t_2, ..., t_{n-1}, t_n\}$.

In U_m, a game on the last time slot is called a *last game* and a game not on the last time slot is called a *normal game*. To construct Z_n, we distinguish four kinds of games in U_m according to the game being a last game or not and involving team x or not.

	$4r-3$	$4r-2$	$4r-1$	$4r$
t_{2i-1}	$\boldsymbol{t_{2j-1}}$	$\boldsymbol{t_{2j}}$	t_{2j-1}	t_{2j}
t_{2i}	$\boldsymbol{t_{2j}}$	$\boldsymbol{t_{2j-1}}$	t_{2j}	t_{2j-1}
t_{2j-1}	t_{2i-1}	t_{2i}	$\boldsymbol{t_{2i-1}}$	$\boldsymbol{t_{2i}}$
t_{2j}	t_{2i}	t_{2i-1}	$\boldsymbol{t_{2i}}$	$\boldsymbol{t_{2i-1}}$

Case 1. Normal games not involving team x: We consider a game in U_m, where a home team u_i plays against a road team u_j on time slot r ($1 \le i, j \le m-1$ and $1 \le r \le m-2$). We will expand this game to $2 \times 4 = 8$ games on four consecutive time slots in Z_n. The corresponding four time slots are from $4r-3$ to $4r$. Recall that u_i will be replaced with $\{t_{2i-1}, t_{2i}\}$ and u_j will be replaced with $\{t_{2j-1}, t_{2j}\}$. Figure 2 demonstrates how the four teams play on the four time slots, where an arc from a to b means a road team a playing against a home team b.

The eight games in Figure 2 determine 16 items in Z_n, which correspond to the eight games between four teams $\{t_{2i-1}, t_{2i}, t_{2j-1}, t_{2j}\}$ on the four time slots from $4r-3$ to $4r$. The matching assignments in Z_n are presented in Table 2.

Note that in this scheduling, each of $\{t_{2i-1}, t_{2i}\}$ has an away trip consisting of two teams in $\{t_{2j-1}, t_{2j}\}$, and also each of $\{t_{2j-1}, t_{2j}\}$ has an away trip consisting of two teams in $\{t_{2i-1}, t_{2i}\}$. Furthermore, there is no conflict to assign the games in Z_n corresponding to all games of Case 1 in U_m, i.e., the three conditions in the definition of TTP-k hold.

Case 2. Normal games involving team x: We consider a game in U_m, where a team u_i plays against the team x in time slot r ($1 \le i \le m-1$ and $1 \le r \le m-2$). For the purpose of presentation, we use x_1 and x_2 to denote the two teams in Z_n corresponding to x, i.e., $x_1 = t_{n-1}$ and $x_2 = t_n$. We also expand this game to $2 \times 4 = 8$ games on four consecutive time slots in Z_n. However, the expansions are different according to the time slot r being odd or even.

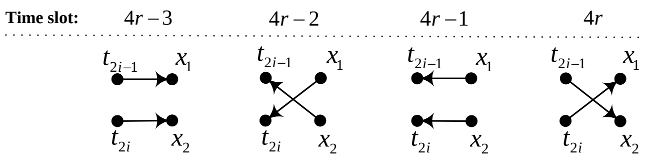

Figure 3 Expansion of Case 2 on an odd time slot.

	$4r-3$	$4r-2$	$4r-1$	$4r$
t_{2i-1}	$\boldsymbol{x_1}$	x_2	x_1	$\boldsymbol{x_2}$
t_{2i}	$\boldsymbol{x_2}$	x_1	x_2	$\boldsymbol{x_1}$
x_1	t_{2i-1}	$\boldsymbol{t_{2i}}$	$\boldsymbol{t_{2i-1}}$	t_{2i}
x_2	t_{2i}	$\boldsymbol{t_{2i-1}}$	$\boldsymbol{t_{2i}}$	t_{2i-1}

On an odd time slot r, a team u_i with $1 \leq i \leq m/2$ plays against the team x. We assign the games among four teams $\{t_{2i-1}, t_{2i}, x_1, x_2\}$ on time slots from $4r-3$ to $4r$ according to Figure 3.

The corresponding 16 items in Z_n determined by the games in Figure 3 are given in Table 3.

On an even time slot r, a team u_i with $m/2+1 \leq i \leq m-1$ plays against the team x. The schedule is almost the same as that in Table 3. We just need to switch the designation of home team and road team in each game. The corresponding part in Z_n is shown in Table 4.

For Case 2, we use a construction strategy different from that in Case 1 so that we are able to satisfy the condition of "at-most-k". From this schedule, we can see that each of $\{t_{2i-1}, t_{2i}\}$ has two away trips consisting of a single team, which are x_1 and x_2, and each of $\{x_1, x_2\}$ has an away trip consisting of two teams in $\{t_{2i-1}, t_{2i}\}$.

After expanding games of Cases 1 and 2, only last games on the last time slot in U_m are left unexpanded. If we expand last games according to the rules in Cases 1 and 2, superficially it will not cause trouble. However, after this there are still two games not assigned for each team, which are between two teams t_{2i-1} and t_{2i} corresponding to u_i in U_m. These two games cannot be assigned on two consecutive time slots by the "no-repeat" condition. It will be hard to find a place to schedule these two games. To solve this problem, our idea is to expand the last time slot in U_m into six (instead of four) time slots in Z_n, two of which will schedule the last two games. Then we have the following two cases.

Case 3. Last games not involving team x: We consider a game in U_m, where a home team u_i plays against a road team u_j in time slot $m-1$ $(1 \leq i, j \leq m-1)$. We expand this game to $2 \times 6 = 12$ games on six consecutive time slots, from $2n-7$ to $2n-2$, in Z_n. Figure 4 demonstrates the 12 games on the six time slots.

The corresponding part in Z_n is shown in Table 5.

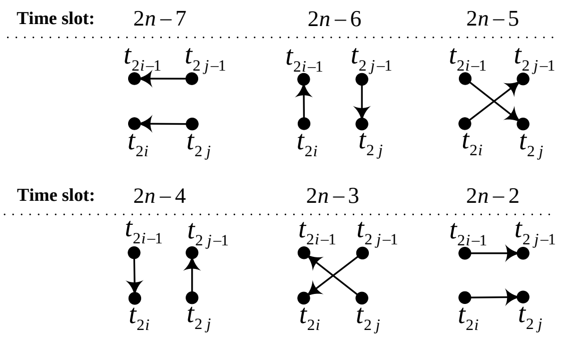

Figure 4 Expansion of Case 3.

t_{2i}	$\boldsymbol{t_{2j}}$	t_{2i-1}	t_{2j-1}	$\boldsymbol{t_{2i-1}}$	$\boldsymbol{t_{2j-1}}$	t_{2j}
t_{2j-1}	t_{2i-1}	t_{2j}	$\boldsymbol{t_{2i}}$	$\boldsymbol{t_{2j}}$	t_{2i}	$\boldsymbol{t_{2i-1}}$
t_{2j}	t_{2i}	$\boldsymbol{t_{2j-1}}$	$\boldsymbol{t_{2i-1}}$	t_{2j-1}	t_{2i-1}	$\boldsymbol{t_{2i}}$

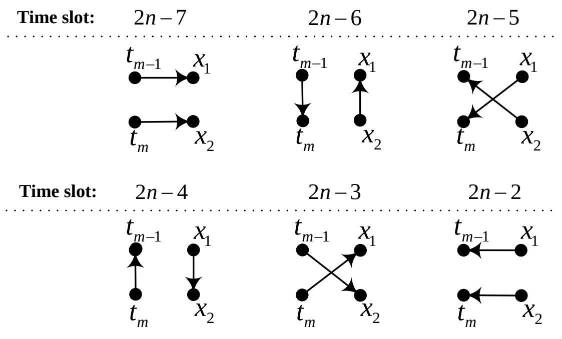

Figure 5 Expansion of Case 4.

Case 4. Last games involving team x: After Case 3, there is only one game in U_m left unexpanded. It is the game where team $u_{m/2}$ plays against x on time slot $m-1$. We expand this game to $2 \times 6 = 12$ games on six consecutive time slots in Z_n according to a strategy similar to that in Figure 4. We only need to replace x_1 and x_2 with t_{2j-1} and t_{2j}, respectively, and switch the designation of home team and road team in each game in Figure 4. Figure 5 demonstrates the 12 games on the six time slots. The corresponding part in Z_n is given in Table 6.

It is not hard to see that the construction can be implemented in $O(n^2)$ time. The complete tournament schedule for Z_8 is given in Table 7, where time slots 1-4 and 5-8 for teams t_3 and t_4 correspond to Case 1, time slots 1-4 for teams t_1 and t_2 correspond to Case 2, time slots 9-14 for teams t_5 and t_6 correspond to Case 3, time slots 9-14 for teams t_3 and t_4 correspond to Case 4.

4 Schedule based on Perfect Matchings

The above strategy provides a feasible tournament schedule for any order on the n teams. There are $n!$ permutations of n teams. To minimize the total traveling distance, we order the teams according to a minimum perfect matching M of G, where G is a complete undirected graph on the set of teams with edge weight representing the distance between teams.

An order $\{t_1, t_2, \cdots, t_n\}$ of teams is *consistent* with a minimum perfect matching M if for each odd i, teams t_i and t_{i+1} are in a pair in M, i.e., each pair of teams corresponding to a team in U_m is also a pair in M. There are many orders of teams consistent with matching M. We will introduce a way to find a good order of teams consistent with M, which can yield tournament schedules with good performances in both theory and practice. Our algorithm contains five steps.

Step 1. Construct the complete undirected graph G and compute a minimum perfect matching M of G. Note that G has n vertices and M has $n/2$ edges.

Step 2. Construct another complete undirected graph H based on G and M. The graph H has $n/2$ vertices $\{u_{i_1}, u_{i_2}, \cdots, u_{i_m}\}$. Each vertex u_i is corresponding to an edge $t_{2i-1}t_{2i}$ in M (also a team in U_m). The weight of each edge u_iu_j between two vertices u_i and u_j in H, denoted by $w_H(u_iu_j)$, is the total weight of the four edges between $\{t_{2i-1}, t_{2i}\}$ and $\{t_{2j-1}, t_{2j}\}$ in G.

Step 3. Find a vertex, denoted by u_m, in H such that the weight of all edges incident on it is minimized.

Step 4. Find a minimum perfect matching M_H in H. We let

$$M_H = \{u_1u_{m-1}, u_2u_{m-2}, \cdots, u_{m/2-1}u_{m/2+1}, u_{m/2}u_m\}.$$

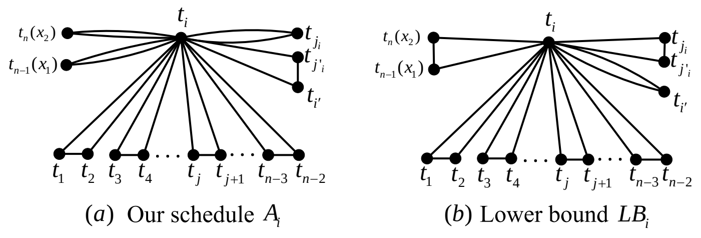

Figure 6 Itinerary of team t_i in Case (i).

Step 5. Order the n teams according to M_H. We get an order $\{t_1, t_2, \cdots, t_n\}$ of the teams such that: t_{2i-1} and t_{2i} are two teams in the edge in M corresponding to u_i for $1 \leq i \leq m$.

This algorithm mainly computes two minimum perfect matchings and runs in $O(n^3)$ time. From the analysis in the next section, we will see the advantages of taking this permutation of teams.

5 Analysis of The Approximation Ratio

We use A_i to denote the traveling distance of team t_i in our schedule. The total traveling distance in the tournament under our schedule is $A_{ALL} = \sum_{i=1}^{n} A_i$. To evaluate the performance of our schedule, we will analyze the ratio of A_{ALL}/LB. Let $\Delta = A_{ALL} - LB$.

First of all, we compare A_i with the independent lower bound LB_i. Let $\Delta_i = A_i - LB_i$. We analyze Δ_i for different cases according to the value of i.

Case (i). Teams t_i with $1 \leq i \leq n/2-2$: These teams in the double round-robin tournament Z_n are expanded from the first $m/2-1$ lines (teams) in the single round-robin tournament U_m. We look at the line of team t_i in Z_n. For the part expanded from U_m of Case 1 (normal games not involving team x), t_i has one away trip consisting of two teams in an edge in the matching M. For the part expanded from U_m of Case 2 (normal games involving team x on odd time slots), t_i has two away trips consisting of a single team of $x_1 = t_{n-1}$ and $x_2 = t_n$ respectively. For the part expanded from U_m of Case 3 (last games not involving team x), t_i has an away trip consisting of a single team t_{j_i} and an away trip consisting of two teams $t_{i'}$ and $t_{j'_i}$, where t_i and $t_{i'}$ (resp., t_{j_i} and $t_{j'_i}$) correspond to the same team u_q (resp., u_p) in U_m, and $p+q=m$. The itinerary graph of team t_i is shown in Figure 6 (a). Compared to the optimal itinerary to achieve the independent lower bound, shown in Figure 6 (b), we get the following by triangle inequality

$$\begin{array}{rcl}\Delta_i & = & (D_{i,n-1} + D_{i,n}) - D_{n-1,n} \\ & & +(D_{i,j_i} + D_{j'_i,i'}) - (D_{i,i'} + D_{j_i,j'_i}) \\ & \leq & (D_{i,n-1} + D_{i,n}) + (D_{i,j_i} + D_{i,j'_i}).\end{array}$$

Recall that we use $w_H(u_i u_j)$ to denote the weight of the edge between two vertices u_i and u_j in H. We have that

$$\sum_{i=1}^{\frac{n}{2}-2} \Delta_i \leq \sum_{i=1}^{\frac{m}{2}-1} w_H(u_i u_m) + \sum_{i=1}^{\frac{m}{2}-1} w_H(u_i u_{m-i}). \tag{2}$$

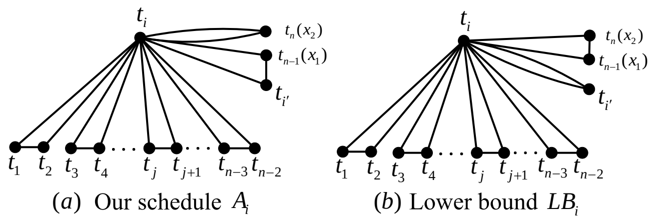

Figure 7 Itinerary of team t_i in Case (ii).

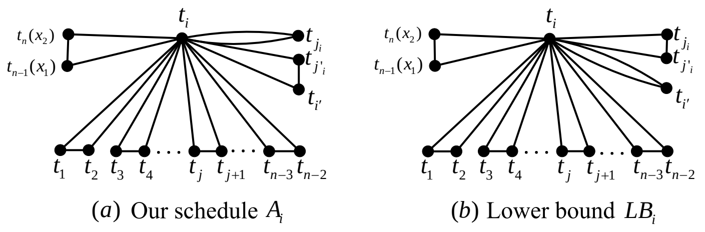

Figure 8 Itinerary of team t_i in Case (iii).

Case (ii). Teams t_i with $i \in \{n/2-1, n/2\}$: These teams in Z_n are expanded from the $\frac{m}{2}$-th line in U_m. There are only two kinds of expansions: Case 1 and Case 4. Analogously to Case (i), we have the itinerary of $t_{n/2-1}$ as shown in Figure 7. The itinerary graph for $t_{n/2}$ is similar.

We get that

$$\begin{aligned}\Delta_{n/2-1} &= (D_{n/2-1,n} + D_{n/2,n-1}) \\ &\quad -(D_{n/2-1,n/2} + D_{n-1,n}) \\ &\leq D_{n/2-1,n-1} + D_{n/2-1,n}\end{aligned}$$

and also $\Delta_{n/2} \leq D_{n/2,n-1} + D_{n/2,n}$. Then

$$\Delta_{n/2-1} + \Delta_{n/2} \leq w_H(u_{m/2}u_m). \tag{3}$$

Case (iii). Teams t_i with $n/2+1 \leq i \leq n-2$: These teams in Z_n are expanded from the lines from $m/2+1$ to $m-1$ in U_m. There are three kinds of expansions: Case 1, Case 2 and Case 3, where the expansions of Case 2 are on even time slots. Then t_i has an away trip consisting of two teams x_1 and x_2. The itinerary graph for t_i is shown in Figure 8. We get that

$$\begin{aligned}\Delta_i &= (D_{i,j_i} + D_{j'_i,i'}) - (D_{i,i'} + D_{j_i,j'_i}) \\ &\leq D_{i,j_i} + D_{i,j'_i},\end{aligned}$$

where t_i and $t_{i'}$ (resp., t_{j_i} and $t_{j'_i}$) correspond to the same team u_q (resp., u_p) in U_m, and $p+q=m$.

By summing up i's in this case, we get

$$\sum_{i=n/2+1}^{n-2} \Delta_i \leq \sum_{i=m/2+1}^{m-1} w_H(u_i u_{m-i}). \tag{4}$$

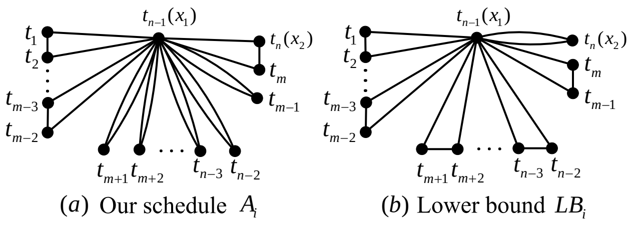

Figure 9 Itinerary of team x_1 in Case (iv).

Case (iv). Teams t_i with $i \in \{n-1, n\}$: The last two teams in Z_n are expanded from the last line in U_m. There are two kinds of expansions involving x: Case 2 and Case 4. The itinerary graph for $x_1 = t_{n-1}$ is shown in Figure 9.

We get that

$$\begin{aligned}\Delta_{n-1} &= \sum_{j=m/2+1}^{m-1}((D_{n-1,2j-1} + D_{n-1,2j}) - D_{2j-1,2j}) \\ &\quad +(D_{m-1,n-1} + D_{m,n}) - (D_{m-1,m} + D_{n-1,n}) \\ &\leq \sum_{j=m/2+1}^{m-1}(D_{n-1,2j-1} + D_{n-1,2j}) \\ &\quad +(D_{m,n-1} + D_{m-1,n-1}) \\ &= \sum_{j=m/2}^{m-1}(D_{n-1,2j-1} + D_{n-1,2j})\end{aligned}$$

and also $\Delta_n \leq \sum_{j=m/2}^{m-1}(D_{n,2j-1} + D_{n,2j})$. Then

$$\Delta_{n-1} + \Delta_n \leq \sum_{j=m/2}^{m-1} w_H(u_m u_j). \tag{5}$$

By summing up (2), (3), (4) and (5), we get

$$\begin{aligned}\Delta &= \sum_{i=1}^{n} \Delta_i \leq \sum_{j=1}^{m-1} w_H(u_m u_j) \\ &\quad +2\sum_{i=1}^{\frac{m}{2}-1} w_H(u_i u_{m-i}) + w_H(u_{m/2} u_m) \\ &\leq w_H(E(u_m)) + 2w_H(M_H),\end{aligned} \tag{6}$$

where $w_H(E(u_m))$ is the total weight of all edges incident on u_m in H and $w_H(M_H)$ is weight of all edges in the matching M_H. Let D_H denote the weight of all edges in H. Then

$$D_H = D_E - D_M. \tag{7}$$

Since we select u_m as the vertex in H such that the weight of all edges incident on it is minimized, we know that

$$w_H(E(u_m)) \leq \frac{2}{m} D_H. \tag{8}$$

Note that a complete graph of m vertices can be partitioned into $m-1$ perfect matchings. We select M_H as a perfect matching of minimum weight. Then we have that

$$w_H(M_H) \leq \frac{1}{m-1} D_H. \tag{9}$$

By (1), (6), (7), (8), (9) and $n = 2m$, we get

$$\Delta \leq (\frac{2}{m} + \frac{2}{m-1}) D_H \leq (\frac{2}{n} + \frac{2}{n-2}) LB,$$

which implies

▶ **Theorem 1.** *For TTP-2 with n teams such that $n \equiv 0 \pmod 4$, the above algorithm runs in $O(n^3)$ time and finds a feasible schedule such that the traveling distance is at most $1 + \frac{2}{n-2} + \frac{2}{n}$ times of the optimal traveling distance.*

Table 8 The results for real-world instances.

6 Local Search by Swapping

Some simple local search techniques can still be applied to our schedule. These techniques may not be able to improve approximation ratio in theory. However, in practice, for most benchmark instances they still can slightly improve our results by about 1%. We use only two simple search rules:

- Swap two pairs of teams in the matching M_H;
- Swap any pair of teams.

7 Applications to Benchmark Sets

To show the efficiency of our algorithm in practice, we apply it to the benchmark instances provided on the website of Trick [19], most of which are real-world instances. The website of Trick [19] displays the best results to TTP-3 on these instances, while we focus on the results to TTP-2. Table 8 lists our results and the best-known results [18] for all 17 instances with $n \equiv 0 \pmod 4$ and $n > 8$, where "lower bound" is the independent lower bound, "before search" and "after search" mean our results before and after applying local search by swapping respectively, and "our gap" is defined to be Δ/LB. Our results beat all previously best-known upper bounds, most by about 3% to 10%. It is also worthy to note that our algorithm computes all instances together within 2.6 seconds on a standard laptop with a 2.40GHz Intel(R) Core(TM) i5-2430 CPU and 4 gigabytes of memory.

8 Conclusion

Our tournament schedule generates a feasible solution to TTP-2 with $n \equiv 0 \pmod 4$. Our solution is at most $1 + \frac{2}{n-2} + \frac{2}{n}$ times of the optimal, improving the previous approximation ratio of $1 + \frac{16}{n}$ by an addition of almost $\frac{12}{n}$. By applying our algorithm on several benchmark sets of TTP, our tournament schedules beat best-known solutions for all instances with $n \equiv 0 \pmod 4$.

The number n of teams in TTP is required to be even. When we construct a double round-robin tournament from a single round-robin tournament, we further require that the number $m = n/2$ of teams in the single round-robin tournament is even. Thus, our constructive algorithm requires $n \equiv 0 \pmod 4$. The only left case not considered in this paper is $n \equiv 2 \pmod 4$. For this case, the previously-known approximation ratio is $\frac{3}{2} + \frac{6}{n-4}$ [18], and the gaps between upper and lower bounds on benchmark instances are large. A natural question is whether there is a $(1 + O(1/n))$-approximation algorithm for the case that $n \equiv 2 \pmod 4$.
