Foreword

International Symposium on Mathematical Foundations of Computer Science (MFCS conference series) is a well-established venue for presenting research papers in theoretical computer science. The broad scope of the conference encourages interactions between researchers who might not meet at more specialized venues.

The first MFCS conference was organized in 1972 in Jabłonna (near Warsaw, Poland). Since then, the conference traditionally moved between the Czech Republic, Slovakia, and Poland. A few years ago, the conference started traveling around Europe (in 2013 it was held in Austria, then in 2014 in Hungary, and most recently, in 2015, in Italy), yet this year it visited Poland once again.

As compared to the previous editions, this year the conference featured several changes. The most prominent one regarded switching to publishing the proceedings in the Leibniz International Proceedings in Informatics (LIPIcs) series. In effect, there were more relaxed publishing requirements (in particular, the papers were limited to twelve pages, but excluding the references), registration fee was slightly lower, and – foremost – the authors kept the copyright for their papers (the proceedings are published under the Creative Commons CC-BY license; CC-BY 3.0 DE). A less significant change regarded partitioning the submission process. The authors first registered their papers' abstracts (by the 21st of April, 2016) and only then their content (by the 25th of April, 2016). This division has helped with the assignment of the papers to the PC members.

Over 220 abstracts were submitted, of which 195 materialized as papers, of which 84 were finally accepted. The authors of the submitted papers represent nearly 40 countries. Each paper was assigned to three PC members, who reviewed and discussed them thoroughly over a period of nearly seven weeks. As the co-chairs of the program committee, we would like to express our deep gratitude to all the committee members for their hard, dedicated work. The quality of the submitted papers was very high and many good papers had to be rejected.

The conference featured five invited talks, by Shai Ben-David (University of Waterloo, Canada), Mikołaj Bojańczyk (University of Warsaw, Poland), Patricia Bouyer-Decitre(LSV, CNRS & ENS de Cachan, France), Tobias Friedrich (Hasso Plattner Institute, Potsdam, Germany), and Virginia Vassilevska Williams (Stanford University, USA). We would like to thank them deeply for their contributions and their time.

These are the first MFCS proceedings published in the Dagstuhl/LIPIcs series. Thus we would like to particularly thank Marc Herbstritt and the LIPIcs team for all the help and support. We believe that the cooperation between MFCS and Dagstuhl/LIPIcs in the future will be as seamless and fruitful as ours.

How Far Are We From Having a Satisfactory Theory of Clustering?

Shai Ben-David[1]

1 **Universitys of Waterloo, Waterloo, Ontario, Canada**
shai@cs.uwaterloo.edu

Abstract

This is an overview of the invited talk delivered at the 41st International Symposium on Mathematical Foundations of Computer Science (MFCS-2016).

1998 ACM Subject Classification I.5.3 Clustering

Keywords and phrases clustering, theory, algorithm tuning, computational complexity

Category Invited Talk

1 Overview of the Talk

Unsupervised learning, utilizing the huge amounts of raw data available, is widely recognized as one of the most important challenges facing machine learning nowadays. For supervised tasks, machine learning theory has been successful in several respects; providing significant understanding of machine learning tasks (in terms of the informational and computational resources they require and in providing algorithmic tools to address them), insights about the pros and cons of alternative machine learning paradigms and their parameter settings, and initiating the development of new algorithmic approaches. However, no such successes had been achieved so far for the unsupervised ML domain.

My talk will focus on clustering, arguably the most fundamental unsupervised data processing task. I will discuss two aspects in which theory could play a significant role in guiding the use of clustering tools. The first is model selection - how should a user pick an appropriate clustering tool for a given clustering problem, and how should the parameters of such an algorithmic tool be tuned? In contrast with other common computational tasks, in clustering, different algorithms often yield drastically different outcomes. Therefore, the choice of a clustering algorithm may play a crucial role in the usefulness of an output clustering solution. Just the same, currently there exist no methodical guidance for clustering tool selection for a given clustering task. I will describe some recent proposals aiming to address this crucial lacuna.

The second aspect of clustering that I will address is the computational complexity of computing a cost minimizing clustering (given some clustering objective function). Once a clustering model (or objective) has been picked, the task becomes an optimization problem. While most of the clustering objective optimization problems are computationally infeasible, they are being carried out routinely in practice. This theory-practice gap has attracted significant research attention recently. I will describe some of the theoretical attempts to address this gap and discuss how close do they bring us to a satisfactory understanding of the computational resources needed for achieving good clustering solutions.

Decidable Extensions of MSO

Mikołaj Bojańczyk[1]

1 University of Warsaw, Warsaw, Poland
bojan@mimuw.edu.pl

Abstract

This is an overview of the invited talk delivered at the 41st International Symposium on Mathematical Foundations of Computer Science (MFCS-2016).

1998 ACM Subject Classification F.4.1 Mathematical Logic

Keywords and phrases monadic second-order logic, extensions, decidability, automata

Digital Object Identifier 10.4230/LIPIcs.MFCS.2016.2

Category Invited Talk

1 Overview of the Talk

Büchi's theorem says that it is decidable if a formula of MSO (monadic second-order logic) can be satisfied in an infinite word. Rabin generalised this to infinite trees. These are among the most powerful decidability results in computer science, and many other decidability results can be obtained as corollaries. In my talk, I will discuss how to go beyond these results and what features can be added to MSO so that it remains decidable. The added feature are going to be extra quantifiers, like the "unboundedness" quantifier or a probabilistic "almost surely" quantifier.

In the proofs of Büchi's and Rabin's theorems, the key role is played by automata. In the extensions from my talk, this will also be the case. The automata are going to be nondeterministic devices with new asymptotic acceptance conditions, which go beyond the classical Büchi or parity acceptance conditions.

Optimal Reachability in Weighted Timed Automata and Games*

Patricia Bouyer-Decitre[1]

1 LSV, CNRS & ENS Cachan, Université Paris-Saclay, France
bouyer@lsv.fr

Abstract

This is an overview of the invited talk delivered at the 41st International Symposium on Mathematical Foundations of Computer Science (MFCS-2016).

1998 ACM Subject Classification F.1.1 Models of Computation – D.2.4 Software/Program Verification

Keywords and phrases timed automata, model-checking, optimization

Digital Object Identifier 10.4230/LIPIcs.MFCS.2016.3

Category Invited Talk

1 Overview of the Talk

Toward the development of more reliable computerized systems, expressive models are designed, targetting application to automatic verification (model-checking). As part of this effort, timed automata have been proposed in the early nineties [2] as a powerful and suitable model to reason about (the correctness of) real-time computerized systems. Timed automata extend finite-state automata with several clocks, which can be used to enforce timing constraints between various events in the system. They provide a convenient formalism and enjoy reasonably-efficient algorithms (*e.g.* reachability can be decided using polynomial space), which explains the enormous interest that they provoked in the community of formal methods. Timed games [4] extend timed automata with a way of modelling systems interacting with external, uncontrollable components: some transitions of the automaton cannot be forced or prevented to happen. The reachability problem then asks whether there is a strategy (or controller) to reach a given state, whatever the (uncontrollable) environment does. This problem can also be decided, in exponential time.

Timed automata and games are not powerful enough for representing quantities like resources, prices, temperature, etc. The more general model of hybrid automata [14] allows for accurate modelling of such quantities using hybrid variables. The evolution of these variables follow differential equations, depending on the state of the system, and this unfortunately makes the reachability problem undecidable, even in the very restricted case of stopwatches (stopwatches are clocks that can be stopped, and hence, automata with stopwatches only are the simplest hybrid automata one can think of).

Weighted (or priced) timed automata [3, 5] and games [15, 1, 9] have been proposed in the early 2000's as an intermediary model for modelling resource consumption or allocation problems in real-time systems (*e.g.* optimal scheduling [6]). As opposed to (linear) hybrid

* This work was partially supported by ERC project EQualIS (308087).

systems, an execution in a weighted timed model is simply one in the underlying timed model: the extra quantitative information is just an observer of the system, and it does not modify the possible behaviours of the system.

In this talk, we will investigate the models of weighted timed automata and games, and we will mostly focus on the important optimal reachability problem: given a target location, we want to compute the optimal (*i.e.* smallest) cost for reaching a target location, and a corresponding strategy. We will survey the main results that have been obtained on that problem, from the primary results of [3, 5, 16, 13, 8, 17, 7] to the most recent developments [11, 10]. We will also mention our new tool TiAMo, which can be downloaded at `https://git.lsv.fr/colange/tiamo`. We will finally show that weighted timed automata and games have applications beyond that of model-checking [12].

Scale-Free Networks, Hyperbolic Geometry, and Efficient Algorithms

Tobias Friedrich

Hasso Plattner Institute, Potsdam, Germany

Abstract

The node degrees of large real-world networks often follow a power-law distribution. Such scale-free networks can be social networks, internet topologies, the web graph, power grids, or many other networks from literally hundreds of domains. The talk will introduce several mathematical models of scale-free networks (e.g. preferential attachment graphs, Chung-Lu graphs, hyperbolic random graphs) and analyze some of their properties (e.g. diameter, average distance, clustering). We then present several algorithms and distributed processes on and for these network models (e.g. rumor spreading, load balancing, de-anonymization, embedding) and discuss a number of open problems. The talk assumes no prior knowledge about scale-free networks, distributed computing or hyperbolic geometry.

1998 ACM Subject Classification F.2.2 Nonnumerical Algorithms and Problems

Keywords and phrases power-law graphs, scale-free graphs, random graphs, distributed algorithms

Digital Object Identifier 10.4230/LIPIcs.MFCS.2016.4

Category Invited Talk

1 Short Review of Network Models

There are numerous models for large complex networks. The talk reviews some popular scale-free random graph models. The most cited network model are preferential attachment graphs by Barabási and Albert [2]. A bit more accessible for a formal analysis is the model of graphs with fixed expected degree sequences by Chung and Lu [10]. Both models follow a power-law degree distribution, but show only an extremely small clustering coefficient. Other models like the small-world model by Watts and Strogatz [24] generate local clustering, but do not converge to a power-law degree distribution.

There are a number of variations of the aforementioned models to generate graphs with power-law degree distribution *and* local clustering, but most are very artificial and therefore do not give an explanation *why* large networks typically show both properties. In the last couple of years it has been observed that complex scale-free network topologies with high clustering coefficients emerge naturally from hyperbolic metric spaces [23]. There seems to be a close relationship between hyperbolic geometry and complex networks. This can be explained by observing that the nodes of real-world networks can be often organized hierarchically, in an approximate tree-like fashion. Based on this and other observations, hyperbolic random graphs have been suggested in [23] and experimentally studied in [21]. Boguñá, Papadopoulos, and Krioukov [6] describe how hyperbolic mappings can be used to improve internet routing. Hyperbolic networks seem to combine all desired features of real networks in a natural model.

2 Short Review of Algorithmic Results

The model of Chung and Lu [10] has been studied intensively. It has a giant connected component that contains a linear fraction of the nodes [10] and ultra-short average distances of $\mathcal{O}(\log\log n)$ [11, 12]. Algorithmically, these graphs have been examined in various contexts like information dissemination [14], bootstrap percolation [1], de-anonymization [7], and finding cliques [15]. Rumor spreading has also been studied on the preferential attachment model [13, 9]. Graphs can be generated from both models in linear time [22, 3].

For hyperbolic random graphs, much less is known so far. Besides the power-law degree distribution and high clustering [18, 21], the model generates larger cliques [16], polylogarithmic diameter [19, 17] and ultra-short average distances of order $\mathcal{O}(\log\log n)$ [8]. Hyperbolic random graphs can be generated in linear time [8]. In quasilinear runtime it is also possible to assign hyperbolic coordinates to large real-world graphs such that the hyperbolic metric approximates the graph distance [5]. Depending on the exponent β of the power-law degree distribution, the graphs have comparatively small separators and sublinear treewidth [4]. The model also allows fast bootstrap percolation [20].

Category Invited Talk

1 Overview of the Talk

A fundamental problem in computational biology is predicting the base-pairing of an RNA secondary structure. Most algorithms for this rely on an algorithm for a simplified version of this problem, RNA-folding, defined as follows: given a sequence S of letters over the alphabet $\{A, U, C, G\}$ where A can only be paired with U and C can only be paired with G, determine the best "folding" of S, i.e. a maximum size *nested* pairing of the symbols of S. For instance, in the sequence $ACUG$ the best pairing is either matching A with U, or matching C with G, but not both as that pairing wouldn't be nested.

A dynamic programming algorithm from 1980 by Nussinov and Jacobson [1] solves the RNA-folding problem on an n letter sequence in $O(n^3)$ time. Despite many efforts, until recently, the best algorithms for RNA-folding only shaved small logarithmic factors over this cubic running time. In this talk I will discuss our recent research on RNA-folding and related problems.

Our first result attempts to explain why it has been so difficult to obtain faster algorithms. We show that if one can solve RNA-folding on n length strings faster than one can currently multiply n by n matrices, then the Clique problem would have surprisingly fast algorithms. The current fastest algorithm to multiply n by n matrices runs in $O(n^{2.373})$ time and the fastest known Clique algorithms use this result. Obtaining an $O(n^{2.36})$ time algorithm for RNA-folding would thus be potentially difficult as it would imply a breakthrough for Clique algorithms and potentially also for matrix multiplication.

While this hardness result is appealing, it does not explain the seeming n^3 barrier. No better hardness seemed possible to us, and thus it became increasingly more plausible that RNA-folding should have a faster algorithm and in fact one using fast matrix multiplication. Indeed, this turned out to be true: we were recently successful in obtaining the first truly subcubic time algorithm for the problem. My talk will strive to give some insights into the hardness result and the new algorithm.

Abstract

Integer factoring is a curious number theory problem with wide applications in complexity and cryptography. The best known algorithm to factor a number n takes time, roughly, $\exp(2\log^{1/3} n \cdot \log^{2/3}\log n)$ (*number field sieve*, 1989). One basic idea used is to find two squares, possibly in a number field, that are congruent modulo n. Several variants of this idea have been utilized to get other factoring algorithms in the last century. In this work we intend to explore new ideas towards integer factoring. In particular, we adapt the AKS primality test (2004) ideas for integer factoring.

In the motivating case of semiprimes $n = pq$, i.e. $p < q$ are primes, we exploit the difference in the two Frobenius morphisms (one over $\mathbb{F}_p$ and the other over $\mathbb{F}_q$) to factor n in special cases. Specifically, our algorithm is polynomial time (on number theoretic conjectures) if we know a *small algebraic dependence* between p, q. We discuss families of n where our algorithm is significantly faster than the algorithms based on known techniques.

1 Introduction

Factoring a positive integer n is the process of finding a positive integer m $(1 < m < n)$ that divides n. Integer factorization has been fascinating mathematicians for centuries [8]. There has been continuous attempts to expand our abilities to factor larger and larger integers (see [13], [2]).

In general, factoring a composite number is widely believed to be a "hard" problem, with no efficient general purpose algorithms known. There are several *special* purpose factoring algorithms which can factor composites efficiently, provided some specific property is satisfied. Some of the algorithms being: Trial division (or Eratosthenes sieve, see [11]), Fermat's factorization [14], Euler's factorization [18][20], Pollard's rho algorithm [22], Pollard's $p-1$ algorithm [21], Williams' $p+1$ algorithm [28], Lenstra's elliptic curve factorization [17], quadratic sieve [9], and the number field sieve [5]. Sieve ideas have been the most successful ones in factoring, see an excellent survey in [24].

* N.S. is supported by DST/SJF/MSA-01/2013-14.

The “hardness” of integer factorization has no known proof, but, the belief hinges only on our inability to factor a general composite efficiently. However this belief is so strong, that the most widely used public key cryptosystems (eg. RSA [4]) are based on this “inherent” difficulty to factorize integers. Such applications in cryptography make integer factorization problem even more interesting. Giving a polynomial time algorithm to factorize any given integer, might result in breaking most widely used cryptosystems. On the other hand, proving (or giving evidence) that no efficient algorithm exists for factoring a general composite would further strengthen the trust on these cryptosystems.

This does not mean that no progress was made in the direction, to come up with a general purpose algorithm. Although there is no algorithm that can factor (even heuristically) all integers in “polynomial time" (i.e. polynomial in the bit-size of the input number), yet there are several algorithms that run in *subexponential* time (i.e. $\exp(O(\log^{\epsilon} n))$ time for $\epsilon < 1$). These are faster than the simple “high school” method (i.e. trial division algorithm, having exponential running time). The fastest general purpose algorithm for factoring a number n, is the general number field sieve (see [15]), with heuristic running time $\exp\left(\left(\sqrt[3]{64/9}+o(1)\right)(\log n)^{\frac{1}{3}}(\log\log n)^{\frac{2}{3}}\right)$. The other widely used algorithm in practice is the quadratic sieve algorithm [23], having running time $\exp\left((1+o(1))\sqrt{\log n \log\log n}\right)$, which is a modification of Dixon’s algorithm [7], that had a (rigorously provable) running time of $\exp\left((2\sqrt{2}+o(1))\sqrt{\log n \log\log n}\right)$.

In 1997, Peter Shor discovered the first polynomial time algorithm for factoring integers on a *quantum computer* [26]. To factor an integer n, it takes $O((\log n)^2 \log\log n \log\log\log n)$ time[1] on quantum computer and $O(\log n)$ post-processing time on classical computer for converting the output of quantum computer to factors of n. If one day quantum computation becomes feasible for large inputs, then this will have serious implications in cryptography [3].

One common thread in these, increasingly complex, algorithms is the trick of finding two squares in some number field, such that the *difference of the squares*, say $a^2 - b^2$, is a multiple of n. Then we can hope that the factors $(a-b), (a+b)$ would also lead us to the factors of n. The origins of this trick dates back atleast to Fermat, and was also exploited by Gauss, Seelhoff and Kraitchik (see the early history of factoring in [29]). One wonders whether other natural tricks or ideas could be discovered for factoring integers.

In this work we propose a method for factoring semiprimes $n = pq$ (i.e. $p < q$ are primes) using the difference in the Frobenius morphisms over the finite fields $\mathbb{F}_p$ and $\mathbb{F}_q$. We do this by working in a *cyclotomic* ring extension $(\mathbb{Z}/n\mathbb{Z})[\zeta] := \mathbb{Z}[X]/\left(n, \frac{X^r-1}{X-1}\right)$. We pick a random element $u(\zeta) \in (\mathbb{Z}/n\mathbb{Z})[\zeta]$ and compute the exponentiation u^e, for a carefully chosen positive integer e. For example, when $e = n$ we can invoke the Frobenius morphisms to deduce $u(\zeta)^n = u(\zeta^p)^q \pmod p$ and $u(\zeta)^n = u(\zeta^q)^p \pmod q$. A similar line of thought has been explored in [6], where they viewed the problem from the perspective of AKS [1] polynomial. Although no family of n was identified in that work to be particularly good. The asymptotic complexity of the algorithm was also not analyzed, but some supporting experimental data was included.

We identify certain families of n where this idea gives a fast factoring algorithm. Especially, in our main result we pick e corresponding to a *known* algebraic dependency of p and q. In this case, we show that the ring computations in $(\mathbb{Z}/n\mathbb{Z})[\zeta]$ are expected to factorize n. We believe that such computations in the cyclotomic ring have a good chance in further improving the state of the art in factoring. Similar techniques were utilized in [1] to give the

[1] We can shorten this using the soft-Oh notation as $\tilde{O}(\log^2 n)$.

first deterministic poly-time primality test. Moreover, for integer factoring even "heuristic" algorithms that are expected to run in poly-time (in the worst-case) would be of great interest.

Our notion of "small" algebraic dependence and the proof of its existence is captured in the following proposition. We say that a bivariate polynomial $f(X,Y)$ is *nondegenerate* if there appears, with a nonzero coefficient, a monomial X^iY^j in f such that $i \neq j$.

▶ Proposition 1.1 (Small dependency exists). For numbers $d, a < b \in \mathbb{N}$, there exists a degree $\leq d$ nondegenerate integral polynomial $f(X,Y)$ of sparsity 2γ and coefficients c_i's of magnitude at most $b^{d/(\gamma-1)}$ such that: $f(a,b) = \sum_{i=1}^{2\gamma} c_i\, a^{\alpha_i}\, b^{\beta_i} = 0$. (Note that $2\gamma \leq \binom{d+2}{2}$ as $0 \leq \alpha_i + \beta_i \leq d$.)

It is proven in Section 3. Recall that Fermat's factoring algorithm works fast when the primes p, q are really close[2]; formally, when there is an $f(x,y) = y - x - \alpha$, for a small α, such that $f(p,q) = 0$. We generalize the condition of Fermat's factoring algorithm to higher degree dependencies (and with more general coefficients). The above proposition gives the parameters for such f to exist. Our algorithms will require the *knowledge* of such an f (unfortunately, in general, it may be hard to find f given only n).

One such interesting dependence is addressed in Section 4.2. For $n = pq$, $p < q$, we represent q in base p as $q = a_0 + a_1.p + a_2.p^2 + a_3.p^3 + \cdots$. We define the *p^{th} norm of q* as $|q|_p := \prod_i (a_i + 1)$. Given a small bound B on $|q|_p$, our algorithm factors n in time $O(B^2 \log^2 n)$. This immediately gives us a family of n which can be factored efficiently (under certain number theory conjectures) using our algorithm. This family is a natural generalization of the family of numbers ($n = ab$, where $b - a$ is small) that can be factored efficiently using Fermat's factoring algorithm.

Our general approach works in polynomial time, assuming that a suitable dependency is provided (and that certain number theory conjectures hold). The algorithm presented in this paper runs in $\tilde{O}(\gamma^3 d \log^2 n)$ time, where d is the degree bound of the dependency, γ is its sparsity, and n is the number to be factored. Observe that once such a bivariate nondegenerate dependency $f(X,Y)$, of degree d is given, we can easily transform it to get a univariate polynomial $X^d f(X, n/X)$ which has p as a root. Notice, that it is important here that the dependency is nondegenerate. For degenerate dependency of the form $f(X,Y) = \sum_{i\leq d} a_i X^i Y^i$ the substitution $f(X, n/X)$ will give us a number instead of a univariate polynomial, and we could not proceed further.

Now, once we get a univariate polynomial $f' := X^d f(X, n/X)$ which has p as a root, we could simply try to find its integral roots by factoring it using Schönhage's algorithm [25] having time complexity $\tilde{O}(d^4 \cdot (d^2 + \log^2 |f'|))$, where $|f'|$ upper bounds the coefficients in f'. On the other hand, our new approach is sensitive to sparsity γ and tolerates bigger coefficients. So, for dependencies, having 'small' γ and 'large' d, our algorithm will outperform Schönhage's algorithm by several orders. For example, given dependence $f(x,y) = y + c_1 x^d + c_0$, where $|c_1| = |c_0| = n^{O(d)}$, our algorithm will factor it in time $\tilde{O}(d \log^2 n)$, whereas Schönhage's algorithm will take time $\tilde{O}(d^4 \cdot (d^2 + d^2 \log^2 n)) = \tilde{O}(d^6 \log^2 n)$.

The main result established is presented in Section 5. The section presents the algorithm to factor n when a small dependency is provided. The result is summarized by the following theorem.

▶ Theorem 1.2 (Main Result). For an integer $n = p{\cdot}q$ ($p < q$ are primes), given a nondegenerate integral (p,q) dependency of the form $f(X,Y) = \sum_{i=1}^{\gamma} c_i\, X^{\alpha_i}\, Y^{\beta_i}$, where $\forall i$, $0 \leq \alpha_i + \beta_i \leq d$,

[2] Essentially, one tries to find $q - p$ by brute-force.

$|c_i| = n^{O(d)} := A$ we can factor n in $\tilde{O}(\gamma^3 d \log^2 n)$ time. (Assuming Artin's conjecture & 3.)

We also present an alternate analysis of this algorithm in Section 6. This section also generalizes the result for integers of the form $n = p \cdot n'$, where p is a prime smaller than the largest prime factor of n. The following theorem presents the result of that section.

▶ Theorem 1.3. For an integer $n = p \cdot n'$ (where p is a prime smaller than the largest prime factor of n), given a nondegenerate integral (p, n') dependency of the form $f(X,Y) = \sum_{i=1}^{\gamma} c_i\, X^{\alpha_i}\, Y^{\beta_i}$, where $\forall i$, $0 \le \alpha_i + \beta_i \le d$, $|c_i| < n^d$, we can factor n in $\tilde{O}(\mu^3 \cdot \gamma d^4 \log^2 n)$ time. Here $\mu := \sum_i e_i$ for the prime factorization $n = \prod_i p_i^{e_i}$. (Assuming Artin's conjecture & 4.)

Here as well, for $\mu, \gamma = O(1)$ the time complexity is better than that of simply factoring $X^d f(X, n/X)$ by Schönhage's algorithm. Also, the algorithm seems simpler than the sophisticated lattice computations that underlie Schönhage's polynomial factoring algorithm (see [12]).

The paper is organized into following sections: Section 2 talks about the notations and results used in the paper. Section 3 proves the existence of small dependence. In Section 4, we discuss two simple dependencies as motivating examples, and explore the idea of exponentiation in the cyclotomic ring to factor n. Section 5 presents the main result of the paper. An alternate analysis of the algorithm is presented in Section 6.

2 Notation and Preliminaries

This section states the notations and number theory results that we will use later.

Polynomial notation. The form of polynomials that we compute in this work is exponentiation; motivated by the *AKS polynomial* (see [1]) used for primality testing:

$$\mathcal{P} = a(x)^e \pmod{n, x^r - 1}, \quad \text{where } a(x) \text{ is a polynomial.} \tag{1}$$

For technical reasons we will actually work modulo the r-th cyclotomic polynomial $\varphi_r(x)$. Then, we represent exponentiation by the following shorthand notation

$$\mathcal{P} = a(\zeta_r)^e \pmod{n}, \text{ and might drop } r \text{ when clear from the context.} \tag{2}$$

Formally, this arithmetic happens in the ring $(\mathbb{Z}/n\mathbb{Z})[\zeta_r] := \mathbb{Z}[X]/(n, \varphi_r(X))$, where every element can be written as a $(\mathbb{Z}/n\mathbb{Z})$-linear-combination of the monomials $\{X^i \mid 0 \le i \le \varphi(r) - 1\}$, where $\varphi(r)$ is the Euler totient function (also, the degree of the cyclotomic polynomial). This will be our standard representation.

In this paper we assume r to be a prime, mainly, to simplify the analysis since $\varphi_r(x) = (x^r - 1)/(x - 1)$. Also for composite r's the cyclotomic extension is quite well structured. For the basic properties of the cyclotomics see [27, Chap.2].

Artin's conjecture. Emil Artin (1927, see [19]) conjectured: For any non-square $a \in \mathbb{Q}\backslash\{-1\}$ there exist infinitely many primes p such that a is a *primitive root* modulo p, i.e. the multiplicative order $\mathrm{ord}_p(a) = p - 1$.

There has been impressive positive progress towards this conjecture [10]. Moreover, a quantitative version of this conjecture is also believed to be true.

▶ Conjecture (Artin's conjecture, see [19]). For any non-square $a \in \mathbb{Q} \setminus \{-1\}$, the number of primes $p \le x$ with $\mathrm{ord}_p(a) = p - 1$ is asymptotically at least $\mathcal{C}_{Artin} \cdot \pi(x)$. ($\pi(x)$ is the number of primes in the interval $[1, x]$ and $\mathcal{C}_{Artin} = 0.3739558136192\cdots$.)

Frobenius morphism. For a prime p consider the polynomial ring $R := \mathbb{F}_p[X]$ over the finite field $\mathbb{F}_p$. Consider the map $\phi : R \to R$ given by the exponentiation $a(X) \mapsto a(X)^p$. It is easy to see that ϕ is actually a (ring) endomorphism of R, and the trivial[3] automorphism of $\mathbb{F}_p$. In other words, we have the useful identity: $\forall a(X) \in R$, $a(X)^p = a(X^p)$.

Other notations. We use $[n]$ to denote the set $\{1, 2 \cdots, n\}$. The notation $\log_{q,r} p$ is used to denote, the *discrete log*, $\log_q p$ in the field $\mathbb{F}_r$, i.e. it is the exponent $i \in \{0, \ldots, r-2\}$ such that $p = q^i \pmod r$. Here, we assumed that r is a prime, and q is a primitive root modulo r. (We hope to get such an r corresponding to a q as the density of r's is high as per Artin's conjecture.) Bold faced symbols (e.g. $\boldsymbol{\alpha}$) represent vectors. $\mathbb{F}_q[\zeta]$ represents some ring $\mathbb{F}_q[X]/(\varphi_r(X))$.

We recall a useful standard property of cyclotomic polynomials. This is the main reason why Artin's conjecture appears in this work.

▶ Lemma 2.1. Let $q \neq r$ be primes. The integral polynomial $\varphi_r(x) = (x^r - 1)/(x - 1)$ is irreducible over $\mathbb{F}_q$ iff q is a primitive root modulo r.

Proof. Let q generate $\mathbb{F}_r^*$. Wlog assume $r > 2$, as $\varphi_r(x)$ is linear for $r = 2$. Suppose $\varphi_r(x)$ is reducible and has a degree d factor $g(x)$, where $d \in [r-2]$. Let α be a root of $g(x)$ in the (splitting) field $\mathbb{F}_q[x]/(g(x))$. As this is the field $\mathbb{F}_{q^d}$, the multiplicative order $\mathrm{ord}(\alpha)$ will divide $q^d - 1$. Since α is a root of $x^r - 1$, we also have $\mathrm{ord}(\alpha)|r$. Thus, $\mathrm{ord}(\alpha)$ is 1 or r. It cannot be 1 as $q \neq r$. So,

$$\mathrm{ord}(\alpha) = r.$$

$$\begin{aligned} \text{Consequently, } & r \,|\, q^d - 1 \\ q^d &= 1 \pmod r \\ (r-1) \,|\, d & \quad [\because q \text{ generates } \mathbb{F}_r^*] \,. \end{aligned}$$

This contradicts $d \in [r-2]$. Hence, $\varphi_r(x)$ is irreducible modulo q.

For the converse note that $\varphi_r(x)$ being irreducible modulo q, means that it divides $x^{q^{r-1}} - x$, and no other $x^{q^i} - x$ for a smaller i. Equivalently, $r \,|\, q^{r-1} - 1$ and no other $q^i - 1$ for a smaller i. Thus, q generates $\mathbb{F}_r^*$. ◀

3 Existence of small dependencies

Our basic idea is based on the following elementary property of numbers.

Proof for Proposition 1.1. Clearly, $2\gamma \leq \binom{d+2}{2} =: \gamma_0$ which is the upper bound for the number of exponents (α_i, β_i) in f.

Let $A := 2b^{d/(\gamma-1)}$. Consider a set $\mathcal{S}$ of nondegenerate combinations (i.e. $i_1 \neq i_2$ for at least one monomial in each sum),

$$\mathcal{S} := \left\{ \sum_{0 \leq i_1 + i_2 \leq d} \alpha_{i_1,i_2} \cdot a^{i_1} b^{i_2} \;\middle|\; \alpha_{i_1,i_2} \in \mathbb{Z}, |\alpha_{i_1,i_2}| \leq \frac{A}{2}, \text{ at most } \gamma \; \alpha_{i_1,i_2}\text{'s are nonzero} \right\}.$$

[3] Fermat's little theorem (1640).

Then, we have

$$\forall \beta \in \mathcal{S},\ |\beta| \leq \gamma \cdot \frac{A}{2} \cdot b^d .$$

Consider the set $\mathcal{V}$ comprising the coefficient-vectors $\boldsymbol{\alpha}$ corresponding to every element of $\mathcal{S}$. Then the cardinality of $\mathcal{V}$ can be lower bounded (by doing a sum over the possible supports of $\boldsymbol{\alpha}$) as,

$$\begin{aligned} |\mathcal{V}| &\geq \binom{\gamma_0}{\gamma} \cdot A^{\gamma} + \binom{\gamma_0}{\gamma-1} \cdot A^{\gamma-1} + \cdots + \binom{\gamma_0}{1} \cdot A + 1 \\ &> \left(\frac{\gamma_0}{\gamma}\right)^{\gamma} \cdot A^{\gamma} \qquad \text{[Simple binomial estimate]} \end{aligned}$$

Clearly, if $|\mathcal{V}| = |\mathcal{S}|$ is greater than $\max\{|\beta| \mid \beta \in \mathcal{S}\}$, then by the pigeon-hole principle there will be atleast two distinct vectors $\boldsymbol{\alpha}, \boldsymbol{\alpha'} \in \mathcal{V}$ that correspond to the same number $\beta \in \mathcal{S}$. This gives us the desired dependency,

$$0 = \sum_{0 \leq i_1 + i_2 \leq d} (\alpha_{i_1,i_2} - \alpha'_{i_1,i_2}) \cdot a^{i_1} b^{i_2} .$$

Hence, for the desired small dependency it suffices to ensure that,

$$\begin{aligned} |\mathcal{V}| &> \max\{|\beta|\} \\ \text{or } \left(\frac{\gamma_0 A}{\gamma}\right)^{\gamma} &\geq \gamma \cdot \frac{A}{2} \cdot b^d \\ \text{or } A^{\gamma-1} &\geq \left(\frac{\gamma}{\gamma_0}\right)^{\gamma} \cdot \frac{\gamma b^d}{2} \\ \text{or } A &\geq \left(\frac{\gamma}{\gamma_0}\right)^{\gamma/(\gamma-1)} \cdot \left(\frac{\gamma}{2}\right)^{1/(\gamma-1)} \cdot b^{d/(\gamma-1)} \\ \text{or } A &\geq 2 \cdot b^{d/(\gamma-1)} \end{aligned} \tag{3}$$

Clearly, for our A, Equation 3 is satisfied. Hence, the required dependency exists. ◀

Hence, there is a trade-off between the sparsity (γ) and the magnitude (c_i) of the dependency polynomial.

▶ Remark. This bound is not optimal. Eg. if we allow f to have sparsity γ_0 then a slightly better bound of $A = 2b^{d/(\gamma_0-1)}$ can be shown; which for $d = 1$ seems optimal.

For a nonconstant γ, or a superpolynomial coefficient-bound A, it would be quite expensive to search for such a dependency f in general. So, our algorithms would be interesting only for those $n = pq$ where it is relatively easy to find an f such that $f(p, q) = 0$.

4 Motivating Dependencies

In the previous section we have shown that a “small" dependency will always exist (Proposition 1.1). Although, in general this dependency could be hard to find, but in special cases there are several natural dependencies. Some of them have already been witnessed and worked upon. An example of one such naturally occurring dependency is, when the two factors are very close to each other. In other words, for $n = pq$, $q - p = \alpha$, where α is some *small*[4]

[4] The term “small" is used vaguely here. The running time of the algorithm is proportional to α. Hence, we could work with α according to the running time we aim for. For polynomial time algorithm, we want $\alpha = \text{poly} \log n$.

constant. Consequently, in such cases both p and q will be close to $\sqrt{n}$. Hence, to factor n, we can simply use the trial division algorithm, starting from $\sqrt{n}$, which would work efficiently as α is small. A more sophisticated and faster way to factor a number having such a dependency ($q - p = \alpha$) would be to use Fermat's factorization method. We propose a new method to factor numbers having such a dependency.

4.1 Factoring numbers having dependency of the form $q - p = \alpha$

Assuming that we have n and a bound B such that $q - p = \alpha \leq B$ the idea is to pick an element $(x + a) \in (\mathbb{Z}/n\mathbb{Z})[x]/(n, x^r - 1)$ and compute $\mathcal{P} := (x + a)^n$, for an r slightly bigger than B. The hope is that the two (underlying) polynomials, $\mathcal{P}_q = (x^q + a)^p \pmod{q, x^r - 1}$ and $\mathcal{P}_p = (x^p + a)^q \pmod{p, x^r - 1}$ would have different *supports* (i.e. there is a monomial x^i, $i \in [0, 1, \cdots, r - 1]$, that appears with zero coefficient in exactly one of the polynomials[5]). We can clearly see, that $r \leq q$ is the trivial upper bound. But we can likely improve this upper bound further.

For $r < p < q$ it seems likely that for most a's, $(x + a)^p \pmod{q, x^r - 1}$ will have each of the r monomials (i.e. x^i, $i \in [0, 1, \cdots, r - 1]$) appearing with nonzero coefficient[6]. We pose this formally.

▶ Conjecture 1. For primes $p < q$, $1 \leq r < p$ and a random $a \in \mathbb{Z}/q\mathbb{Z}$, $(x+a)^p \pmod{q, x^r - 1}$ is full support with high (i.e. constant) probability.

The rationale for this conjecture is that we expect $(x + a)^p$ to be a "random" element in the cyclotomic ring. So, it will be rare that there is a zero coefficient in its standard representation.

On the other hand $(x + a)^q \pmod{p, x^r - 1}$, for $r \geq 2B + 3$, has proper support as we now show.

▶ Theorem 4.1. For primes $p < q$ and $r \geq 2(q - p) + 3$, $(x + a)^q \pmod{x^r - 1, p}$ is proper support.

Proof. Consider the polynomial,

$$\begin{aligned}
\mathcal{P}_p &= (x + a)^q \pmod{p} \\
&= (x + a)^p (x + a)^{q-p} \pmod{p} \\
&= (x^p + a)(x + a)^{q-p} \pmod{p} \\
&= \underbrace{(x^p)(x + a)^{q-p}}_{\text{Sparsity} \leq q-p+1} \quad + \quad \underbrace{a \cdot (x + a)^{q-p}}_{\text{Sparsity} \leq q-p+1} \pmod{p}\,.
\end{aligned}$$

Hence, Sparsity$(\mathcal{P}_p) \leq 2(q - p + 1)$. So, taking $r \geq 2(q - p + 1) + 1$ will ensure that atleast one monomial in $(x + a)^q \pmod{x^r - 1, p}$ has the zero coefficient. ◀

These observations motivate the following algorithm.

[5] It is easy to see that this implies that one of the coefficients in $\mathcal{P}$ will share a nontrivial gcd with n.
[6] Such a polynomial we call *full* support, and its opposite is *proper* support.

Algorithm 1 Factoring Integer : $FAC_1(n, B)$

```
Require: Odd $n = pq$ ($p < q$ are primes) and a parameter $B \geq (q - p)$.
1: $r \leftarrow 2$
2: while $r \leq 2B + 3$ and $n$ is not factored do
3:     Choose a random number $a < n$
4:     Compute $\mathcal{P} = (x + a)^n \pmod{x^r - 1, n}$
5:     Take gcd of $n$ with $ra$, and with the coefficients of $\mathcal{P}$.
6:     if $n$ is factored then
7:         return $factor$
8: return 0
```

Time complexity. The polynomial computation in step 4, takes time $\tilde{O}(r \log^2 n)$ using fast arithmetic. Taking GCD in step 5, takes similar time. Hence, the overall time complexity of the algorithm is $\tilde{O}(B^2 \log^2 n)$. Note that it is a probabilistic algorithm based on Conjecture 1. It can be seen as an alternative (albeit slower) to Fermat's factoring algorithm.

4.2 Bound based on p^{th} norm of q

This subsection discusses a more general, yet natural, dependency and presents the algorithm to factor n in such cases.

Let us represent q in base p (so that a_i's are in $[0, \cdots, p-1]$),

$$q = a_0 + a_1.p + a_2.p^2 + a_3.p^3 + \cdots .$$

We define the p^{th} *norm of* q as $|q|_p := \prod_i (a_i + 1)$. It is defined as a 'measure' for the size of the coefficients in base p representation of q.

Can we factor $n = pq$ (primes $p < q$) if we have an upper bound B on $|q|_p$? We can generalize the methods of the last section.

By Conjecture 1 we expect $(x + a)^p \pmod{x^r - 1, q}$ to be full support, for random a. The other modulus is covered by the following simple observation.

▶ Theorem 4.2. For primes $p < q$ and $r > |q|_p$, $(x + a)^q \pmod{x^r - 1, p}$ is proper support.

Proof. By using the base-p representation of q we have,

$$\begin{aligned}
(x + a)^q &= (x + a)^{a_0 + a_1.p + a_2.p^2 + a_3.p^3 + \cdots} \\
&= \prod_i (x + a)^{a_i.p^i} \\
&= \prod_i (x^{p^i} + a)^{a_i} \pmod{p} \\
\therefore \text{Sparsity}((x + a)^q \mod p) &\leq \prod_i (a_i + 1) \\
&= |q|_p .
\end{aligned}$$

Hence, for $r > |q|_p$, $(x + a)^q \pmod{x^r - 1, p}$ is proper support. ◀

Remark. For dependency of the form $q - p = \alpha$, where $0 < \alpha < p$, the p^{th} norm of q is $2(\alpha + 1)$. Hence, we get a natural generalization of numbers n that are good for Fermat factorization.

These observations again motivate the following algorithm.

Algorithm 2 Factoring Integer : $FAC_2(n, B)$

```
Require: Odd $n = pq$ ($p < q$ are primes) and a parameter $B > |q|_p$.
1: $r \leftarrow 2$
2: while $r \leq B$ and $n$ is not factored do
3:     Choose a random number $a < n$
4:     Compute $\mathcal{P} = (x + a)^n \pmod{x^r - 1, n}$
5:     Take gcd of $n$ with $ra$, and with the coefficients of $\mathcal{P}$.
6:     if $n$ is factored then
7:         return $factor$
8: return 0
```

Time complexity. The overall time complexity of the algorithm is $\tilde{O}(B^2 \log^2 n)$, as in the previous subsection. Note that it is a probabilistic algorithm based on Conjecture 1. It can be seen as a natural generalization (albeit slower) of Fermat's factoring algorithm.

4.3 Relaxing conjecture 1

In the previous subsections the proofs of factoring depend on Conjecture 1. In this section we relax the conjecture; which might make it easier to prove.

The point is that we just need to prove, that for a random $a(x)$, with high probability there is a difference in the supports of the two polynomials:

$$\begin{aligned} &a(x^p)^q \pmod{x^r - 1, p} \quad \text{and,} \\ &a(x^q)^p \pmod{x^r - 1, q} \end{aligned} \tag{4}$$

in the case when $r > |q|_p$. The rationale is again that the first polynomial is proper support, while the second polynomial is likely to have a support *different* from the first.

▶ Conjecture 2. For primes $p < q$, $r > |q|_p$ and a random $a(x) \in (\mathbb{Z}/n\mathbb{Z})[x]/(x^r - 1, n)$, the two polynomials in Equation 4 have, with high probability, different support.

It can be seen that based on this conjecture, an algorithm similar to Algorithm 2 can be designed to factor n (in probabilistic time $\tilde{O}(B^2 \log^2 n)$).

5 General dependencies

The previous section addressed dependencies of specific forms. In this section, we move to the case of more general dependencies between the two factors. For $n = pq$, primes $p < q$, we consider a nondegenerate dependency $f(x, y)$ of degree bound d with at most γ nonzero coefficients. So, $0 = f(p, q) = \sum_{i=1}^{\gamma} c_i\, p^{\alpha_i}\, q^{\beta_i} = 0$, where $\forall i, 0 \leq \alpha_i + \beta_i \leq d$, $|c_i| = n^{O(d)}$. Proposition 1.1 gives the almost optimal parameters for its existence in general.

When we are given n and f, our idea is to compute AKS exponentiation (Eqn.2) in a cyclotomic ring extension over $\mathbb{Z}/n\mathbb{Z}$ and try distinguishing the two Frobenius morphisms. We give the details in the form of an algorithm and then the proof. The key step will be the computation of an expression $\prod_{i=1}^{\gamma} a(\zeta^{p^{\alpha_i - \beta_i}})^{c_i n^{\beta_i}}$, for a random element $a(\zeta)$. Note that modulo p it is the same as exponentiation by $\sum_{i=1}^{\gamma} c_i p^{\alpha_i} q^{\beta_i} = 0$. Also, note that $p^{\alpha_i - \beta_i}$ exists modulo r, when r and p are coprime.

Algorithm 3 Factoring Integer : $FAC_3(n, f)$

```
Require: Odd $n = pq$ ($p < q$ are primes), and a nondegenerate dependency $f = \sum_{i=1}^{\gamma} c_i x^{\alpha_i} y^{\beta_i}$, where $\forall i, 0 \le \alpha_i + \beta_i \le d$, $|c_i| = n^{O(d)}$.
1: Choose a random prime $r \le 10\gamma \log \gamma$ and verify that $\gcd(r, n) = 1$.
2: for $t \in [r-1]$ do
3:   $count \leftarrow 0$
4:   while $count < 5 \log\log n^r$ do
5:     Choose a random element $a(\zeta) := a(x) \in \mathbb{Z}[x]/(\varphi_r(x), n)$.
6:     Compute $\mathcal{P} := \prod_{i=1}^{\gamma} a(\zeta^{t^{\alpha_i - \beta_i}})^{c_i n^{\beta_i}}$.
7:     Take gcd of $n$ with the coefficients of $\mathcal{P}$.
8:     if $n$ is factored then
9:       return $factor$
10: return 0
```

To study this algorithm we would need a qualitative conjecture about the distribution of discrete logarithms.

▶ Conjecture 3. For a fixed p, q, f as before and $R > 10\gamma$, the function $\log_{q,r} p$ takes almost random values e as we vary $r \in [R]$ such that, with a constant probability,

$$\sum_{i=1}^{\gamma} c_i\, p^{\beta_i}\, q^{e\alpha_i + (1-e)\beta_i} \neq 0 \left(\bmod \frac{q^{r-1}-1}{q-1}\right).$$

The rationale for this conjecture is that as we vary r in a range bigger than $[\gamma]$ we expect e to be "random" enough so that the two γ-dimensional vectors $\left(c_i p^{\beta_i} \mid i \in [\gamma]\right)$ and $\left(q^{e\alpha_i+(1-e)\beta_i} \mid i \in [\gamma]\right)$ are not orthogonal $\pmod{(q^{r-1}-1)/(q-1)}$. One necessary condition for this is: $\{e\alpha_i + (1-e)\beta_i \mid i \in [\gamma]\}$ be a set of distinct functions in e, with at least one of them being nontrivially dependent on e. The *distinctness* holds because $e\alpha_i + (1-e)\beta_i = e\alpha_j + (1-e)\beta_j$ iff $(\alpha_i, \beta_i) = (\alpha_j, \beta_j)$ iff $i = j$. (*Note :* We use that, for some i, $\alpha_i \neq \beta_i$ as f is nondegenerate.)

Now we are ready to prove the correctness of the algorithm.

Proof for Theorem 1.2. By Artin's conjecture we can deduce that we will get a prime r, with constant probability, such that: q generates the unit group of $\mathbb{F}_r$. In this case Lemma 2.1 asserts that $\varphi_r(x)$ is irreducible over $\mathbb{F}_q$. Hence, $\mathbb{F}_q[\zeta] := \mathbb{F}_q[x]/(\varphi_r(x))$ is a field.

We are interested in the iteration when the variable t equals $p \pmod r$. Then we can write,

$$\mathcal{P} = \prod_{i=1}^{\gamma} a(\zeta^{p^{\alpha_i-\beta_i}})^{c_i n^{\beta_i}}. \tag{5}$$

Going modulo p, and using the "first" Frobenius morphism, we get:

$$\begin{aligned}\mathcal{P} &= \prod_{i=1}^{\gamma} a(\zeta)^{c_i p^{\alpha_i} q^{\beta_i}} \pmod p\\ &= a(\zeta)^{\sum_{i=1}^{\gamma} c_i p^{\alpha_i} q^{\beta_i}} \pmod p \;= a(\zeta)^0 \pmod p\\ &= 1 \pmod p.\end{aligned} \tag{6}$$

Now let $e := \log_{q,r} p$. So, we can replace p with q^e in Equation 5, to get

$$\mathcal{P} = \prod_{i=1}^{\gamma} a(\zeta^{q^{e(\alpha_i-\beta_i)}})^{c_i n^{\beta_i}}.$$

Going modulo q, and using the "second" Frobenius morphism, we get:

$$\begin{aligned}\mathcal{P} &= \prod_{i=1}^{\gamma} a(\zeta)^{c_i n^{\beta_i} q^{e(\alpha_i-\beta_i)}} \pmod q \\ &= \prod_{i=1}^{\gamma} a(\zeta)^{c_i p^{\beta_i} q^{e\alpha_i+(1-e)\beta_i}} \pmod q \\ &= a(\zeta)^{\sum_{i=1}^{\gamma} c_i p^{\beta_i} q^{e\alpha_i+(1-e)\beta_i}} \pmod q \qquad (7)\end{aligned}$$

Let us call the exponent $m := \sum_{i=1}^{\gamma} c_i\, p^{\beta_i}\, q^{e\alpha_i+(1-e)\beta_i}$.

If we can show that $a(\zeta)^m \notin \mathbb{F}_q$ then, by Equation 6, we get different supports in the polynomials $\mathcal{P} \pmod p$ and $\mathcal{P} \pmod q$. This means that step 7 would factor n. So, it suffices to ensure that $a(\zeta)^{m(q-1)} \neq 1 \pmod q$, in other words, the multiplicative order of $a(\zeta)$ in the field $\mathbb{F}_q[\zeta]$, denoted $\mathrm{ord}(a(\zeta), \mathbb{F}_q[\zeta])$ satisfies:

$$\mathrm{ord}(a(\zeta), \mathbb{F}_q[\zeta]) \not| \, m(q-1)\,. \qquad (8)$$

From step 5 (of the algorithm) we can treat $a(\zeta)$ as a random element in $\mathbb{F}_q[\zeta]$. From the initial discussion we have that $\mathbb{F}_q[\zeta]$ is the field $\mathbb{F}_{q^{r-1}}$. From this we can estimate the probability of $a(\zeta)$ having the largest multiplicative order.

▶ Claim 5.1. $\mathrm{ord}(a(\zeta), \mathbb{F}_q[\zeta]) = (q^{r-1}-1)$, with probability at least $\frac{1}{3\log\log(q^{r-1}-1)}$, when $r > 7$.

Proof. See full version of the paper. ◀

Thus, the repetitions in step 4 ensure that with a high probability we will pick a generator $a(\zeta)$ of $\mathbb{F}_q[\zeta]$. Now Equation 8 can be rewritten as:

$$\sum_{i=1}^{\gamma} c_i\, p^{\beta_i}\, q^{e\alpha_i+(1-e)\beta_i} \neq 0 \left(\mathrm{mod}\ \frac{q^{r-1}-1}{q-1}\right).$$

Conjecture 3 ensures this with high probability (for a random r). Hence, step 7 will factor with high (i.e. constant) probability.

Time Complexity. The 'for' loop of Step 2-9, runs for $r-1 = \tilde{O}(\gamma)$ times. The 'while' loop in Step 4-9, runs $O(\log\log(n^r)) = \tilde{O}(1)$ times.

The polynomial computation in step 6 is the expensive part. We would use repeated squaring and fast ring arithmetic. It multiplies γ many factors. The exponent of each factor can be bounded by An^d, so, by repeated squaring it takes $O(d\log n + \log A) = O(d\log n)$ time ($\because A := n^{O(d)}$). Also, in each step of repeated squaring there will be two polynomials multiplied in the cyclotomic ring; we can compute the product in $\tilde{O}(r\log n)$ time. Hence, step 6 takes $\tilde{O}(\gamma \cdot d\log n \cdot r\log n) = \tilde{O}(\gamma^2 d\log^2 n)$ time.

So, the overall time complexity of the Algorithm 3 is $\tilde{O}(\gamma^3 d\log^2 n)$.

◀

Clearly, the running time of the algorithm depends on the sparsity. For sparse dependency f, i.e. $\gamma = \tilde{O}(1)$, the running time becomes $\tilde{O}(d\log^2 n)$ which is only linear in d. If the given dependency has sparsity $\gamma = O(d^{1.6})$ then the running time is a much slower $\tilde{O}(d^{5.8}\log^2 n)$, but it is a simple algorithm and still faster than the known methods.

6 Alternate Analysis

In this section we present an alternate analysis and a corresponding algorithm to factor n. The algorithm presented is just a slightly modified version of Algorithm 3, and it will not need n/p to be a prime. The conjecture that our analysis relies on will be different from Conjecture 3.

Algorithm 4 Factoring Integer : $FAC_4(n, f, \mu)$

```
Require: Odd $n = pn'$ (prime $p$ is not the largest prime factor $q$ of $n$), and a nondegenerate
    $(p, n')$ dependency $f = \sum_{i=1}^{\gamma} c_i x^{\alpha_i} y^{\beta_i}$ where $\forall i, 0 \le \alpha_i + \beta_i \le d$, $|c_i| \le n^d$. Let $\mu := \sum_i e_i$
    for the prime factorization $n = \prod_i p_i^{e_i}$.
 1: $r \leftarrow 7\mu d$.
 2: while $r \le 10\mu d \log(d+1)$ do
 3:     Choose the next prime $r$, and verify that $\gcd(r, n) = 1$.
 4:     for $t$ in range $[r-1]$ do
 5:         Choose a random element $a(\zeta) := a(x) \in \mathbb{Z}[x]/(\varphi_r(x), n)$.
 6:         Compute $\mathcal{P} := \prod_{i=1}^{\gamma} a(\zeta^{t^{\alpha_i - \beta_i}})^{c_i n^{\beta_i}}$.
 7:         Take gcd of $n$ with the coefficients of $\mathcal{P}$.
 8:         if $n$ is factored then
 9:             return $factor$
10: return 0
```

To study this algorithm we will need a conjecture about discrete logarithm.

▶ Conjecture 4. For f, p, q, d, μ as before, there exists a prime $r \in [7\mu d, 10\mu d \log(d+1)]$ such that: $\mathrm{ord}_r(q) = r - 1$, $e := \log_{q,r} p < \frac{r}{2d}$ and $f(q^e, n/q^e) \neq 0$.

The rationale behind this conjecture is Artin's conjecture together with the feeling that the function $\log_{q,r} p$ should take "random" values in $\{0, \ldots, r-1\}$, in particular, values as small as $\frac{r}{2d}$. Also, since the interval is large enough we expect to get several such (r, e); one of these q^e is expected to not be a root of $f(X, n/X)$.

We now state our theorem.

Proof for Theorem 1.3. See full version of the paper. ◀

Given a sparse dependence of degree d, (small or constant γ and μ) our algorithm's performance is better than Schönhage's univariate polynomial factoring algorithm.

7 Conclusion

We initiate a new factoring idea using the AKS-type cyclotomic computation [1]. It uses the two Frobenius morphisms and we have been able to analyze it for specific families of n (based on some "reasonable" conjectures). It is a simple algorithm and, in special cases, it performs better than applying the previously known techniques. The outstanding question is what do we do when there is no dependency $f(x, y)$ readily available for n?

In this (general) case we could compute several (say, poly($\log n$)-many) AKS-type polynomials

$$S := \{a(\zeta_r)^e \mid r, a, e \text{ carefully chosen given } n\}$$

and try to apply easy algebraic operations on S. For example, view S as a lattice generator and apply the famous LLL basis reduction algorithm on it [16]. Or, compute other linear algebra operations on S. Do these operations lead us to a factor of n ?

Abstract

We study the version of the k-disjoint paths problem where k demand pairs $(s_1, t_1), \ldots, (s_k, t_k)$ are specified in the input and the paths in the solution are allowed to intersect, but such that no vertex is on more than c paths. We show that on directed acyclic graphs the problem is solvable in time $n^{O(d)}$ if we allow congestion $k - d$ for k paths. Furthermore, we show that, under a suitable complexity theoretic assumption, the problem cannot be solved in time $f(k)n^{o(d/\log d)}$ for any computable function f.

1 Introduction

The k-disjoint paths problem and related routing problems are among the central problems in combinatorial optimisation. In the most basic variant of the k-disjoint paths problem, a graph G is given with k pairs $(s_1, t_1), \ldots, (s_k, t_k)$ of vertices and the task is to find k pairwise vertex-disjoint paths linking each s_i to its corresponding target t_i.

The problem is well known to be NP-complete [14]. On undirected graphs with a fixed number k of source/terminal pairs, Robertson and Seymour proved in their monumental graph minor series [21] that the problem is polynomial-time solvable. In fact, they showed that it is fixed-parameter tractable with parameter k: it can be solved in cubic time for every fixed value of k.

For directed graphs, the problem is computationally much harder. Fortune et al. [15] proved that it is already NP-complete for only $k = 2$ source/terminal pairs. In particular,

[*] The research of Saeed Amiri, Stephan Kreutzer and Roman Rabinovich has been supported by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (ERC consolidator grant DISTRUCT, agreement No 648527).

[†] The research of Dániel Marx was supported by ERC Starting Grant PARAMTIGHT (No. 280152) and OTKA grant NK105645.

this also implies that it is not fixed-parameter tractable on directed graphs. Following this result a lot of work has gone into establishing more efficient algorithms on restricted classes of digraphs.

Fortune et al. [15] showed that the problem can be solved in time $n^{O(k)}$ on acyclic digraphs, that is, it is polynomial-time for every fixed k. However, as proved by Slivkins [22], the problem is $W[1]$-hard on acyclic digraphs, and therefore unlikely to be fixed-parameter tractable. On the other hand, Cygan et al. [11] proved that the problem is fixed-parameter tractable with parmeter k when restricted to planar digraphs. Related to this, Amiri et al. [1] proved that the problem remains NP-complete even in upward planar graphs, but admits a single exponential fixed-parameter algorithm.

Disjoint paths problems have also been studied intensively in the area of approximation algorithms, both on directed and undirected graphs (see, e.g., [9, 18, 2, 5, 8, 4, 6, 10, 7]). The goal is, given an input graph G and demands $(s_1, t_1), \dots, (s_k, t_k)$ to *route* as many pairs as possible in polynomial time. There are many variations what it means for a pair to be routable. In particular, a problem studied intensively in the approximation literature is a relaxed version of disjoint paths where the paths are no longer required to be fully disjoint. Instead, they may intersect but every vertex of the graph is allowed to be contained in at most c paths, for some fixed constant c. This is called *congestion c routing*. In particular, the well-linked decomposition framework developed in [10] for undirected graphs and later generalised to digraphs in [7] has proved to be very valuable for obtaining good approximation algorithms for disjoint paths problems on planar graphs and digraphs.

In this paper, we are interested in exact solutions for high congestion routing on acyclic digraphs. More precisely, we study the following problem.

▶ **Definition 1.** 1. Let G be a digraph and let $I := \{(s_1, t_1), \dots, (s_k, t_k)\}$ be a set of pairs of vertices. Let $c \geq 1$. A *c-routing* of I is a set $\{P_1, \dots, P_k\}$ of paths such that, for all $1 \leq i \leq k$, path P_i links s_i to t_i and no vertex $v \in V(G)$ appears in more than c paths from $\{P_1, \dots, P_k\}$.
2. Let $k, c \geq 1$. In the (k, c)-Congestion Routing problem, a digraph G is given in the input together with a set $I := \{(s_1, t_1), \dots, (s_k, t_k)\}$ of k pairs of vertices (the demands); the task is to decide whether there is a c-routing of I in G.

We consider (k, c)-Congestion Routing on acyclic digraphs. First, it is not very difficult to show that, for every fixed $c \geq 1$, we can generalise the $n^{O(1)}$ time algorithm of Fortune et al. [15] to (k, c)-Congestion Routing. By revisiting the W[1]-hardness proof of Slivkins [22] and making appropriate modifications, we can establish that the problem remains W[1]-hard for every fixed congestion $c \geq 1$. Moreover, by doing the proof in a more modern way (reducing from general subgraph isomorphism instead of maximum clique and invoking a lower bound of Marx [20]), we can show that the $n^{O(k)}$ time algorithm is essentially best possible with respect to the exponent of n. This lower bound is under the Exponential-Time Hypothesis (ETH), which can be informally stated as n-variable 3Sat cannot be solved in time $2^{o(n)}$ (see [16, 19, 12] for more background).

▶ **Theorem 2.** *For any fixed integer $c \geq 1$, (k, c)-*Congestion Routing *is* W[1]*-hard parameterised by k and, assuming ETH, cannot be solved in time $f(k)n^{o(k/\log k)}$ for any computable function f.*

Intuitively, one can expect the problem to become simpler if c is almost as large as k: after all, the problem is trivial if $c \geq k$. Therefore, we study the complexity of the problem in settings close to this extreme case. The main algorithmic result of this paper is to show that for any fixed value of $d \geq 1$, the $(k, k-d)$-Congestion Routing problem can be solved in time $n^{O(d)}$. That is, the exponent of the polynomial bounding the running time of the algorithm only depends on d but not on the number k.

▶ **Theorem 3.** *For every fixed $d \geq 1$ and for all $k \geq 1$ the $(k, k-d)$-*Congestion Routing *problem on acyclic digraphs can be solved in time $n^{O(d)}$.*

A simple corollary of Theorem 2 shows that $(k, k-d)$-Congestion Routing is unlikely to be fixed-parameter tractable and the running time of Theorem 3 essentially cannot be improved (assuming ETH). Observe that if we set $d := k-1$, then $(k, k-d)$-Congestion Routing is simply the standard k-disjoint path problem, thus any algorithmic result for $(k, k-d)$-Congestion Routing parameterised by d would imply the essentially same algorithmic result for the fully disjoint version parameterised by k.

▶ **Corollary 4.** $(k, k-d)$-Congestion Routing *is* W[1]*-hard parameterised by d (if k is part of the input) and, assuming ETH, cannot be solved in time $f(k)n^{o(d/\log d)}$ for any computable function f.*

Organisation. The paper is organised as follows. In Section 3 we fix some notation and prove our main algorithmic result. The corresponding lower bound is then proved in Section 4.

2 Preliminaries

We review basic notation and concepts of graph theory needed in the paper. We refer to [13, 3] for background.

Let G be a digraph. We write $V(G)$ and $E(G)$ for its set of vertices and edges, respectively. We assume that there is no edge with the same head and tail, i.e. there are no loops in the digraphs we consider in this paper. If $(u, v) \in E(G)$ is an edge, then u is its *tail* and v is its *head*. G is *simple* if there are no two distinct edges which have the same tail and the same head. Otherwise we call G a *multi digraph*.

A *path* P in a digraph G is determined by a sequence $(v_1, \dots, v_\ell)$ of vertices such that $v_i \neq v_j$ for all $1 \leq i < j \leq \ell$ and $(v_i, v_{i+1}) \in E(G)$ for all $1 \leq i < \ell$. We write $E(P)$ for the set $\{(v_i, v_{i+1}) : 1 \leq i \leq \ell - 1\}$ of edges appearing in P and $V(P)$ for the set $\{v_1, \dots, v_\ell\}$ of vertices. We say that P *links* v_1 to v_ℓ.

Two paths P_1 and P_2 are *edge disjoint* if $E(P_1) \cap E(P_2) = \emptyset$.

3 A polynomial-time algorithm on acyclic digraphs

In this section we prove the first main result of this paper, Theorem 3, which we repeat here for convenience.

Theorem 3. *For every fixed $d \geq 1$, the $(k, k-d)$-*Congestion Routing *problem on acyclic digraphs can be solved in time $n^{O(d)}$.*

We first need some additional notation and prove some auxiliary lemmas.

▶ **Definition 5.** Let G be a digraph and let $\mathcal{L}$ be a set of paths in G. For every $v \in V(G)$ we define the *congestion* of v with respect to $\mathcal{L}$ as the number of paths in $\mathcal{L}$ containing v.

The following lemma provides a simple extension of the algorithm from [15] for disjoint paths in acyclic digraphs.

▶ **Lemma 6.** *On acyclic digraphs G the (k,c)-*Congestion Routing *probem can be solved in time $n^{O(k)}$, where $n := |G|$.*

Proof. In [15], Fortune et al. proved that the k-disjoint paths problem can be solved in time $n^{O(k)}$ on any n-vertex acyclic digraph G.

Let G, $(s_1,t_1),\dots,(s_k,t_k)$ and c be given. We construct a new digraph H with $V(H) := V(G) \times \{1,\dots,c\}$ and $E(H) := \{\big((u,i),(v,j)\big) : (u,v) \in E(G), 1 \leq i,j \leq c\}$.

Then H contains k pairwise vertex disjoint paths $P_1,\dots,P_k$ such that P_i links $(s_i,1)$ to $(t_i,1)$ if, and only if, there is a positive solution to the (k,c)-Congestion Routing Problem on G. By the algorithm in [15] we can decide whether the paths $P_1,\dots,P_k$ exist in H in time $|V(H)|^{O(k)}$ and hence in time $(c \cdot n)^{O(k)} = n^{O(k)}$ as $c \leq n$. ◀

We will use this lemma in the form given in the next corollary.

▶ **Corollary 7.** *For $c,k \geq 0$ such that $k \in O(c)$, the (k,c)-*Congestion Routing *problem can be solved on any acyclic n-vertex digraph G in time $n^{O(c)}$.*

The next lemma provides the main reduction argument for proving Theorem 3.

▶ **Lemma 8.** *Let G be an acyclic directed graph and let $d \geq 1$ and $k > 3d$. Let $I := \{(s_1,t_1),\dots,(s_k,t_k)\} \subseteq V(G) \times V(G)$ be a set of source/terminal pairs. There exists a $(k-d)$-routing of I if, and only if, for every pair $(s,t) \in I$ there is a path in G from s to t and there is a subset $I' \subsetneq I$ of order $|I'| = k-1$ such that there is a $(k-d-1)$-routing of I'.*

Proof. The if direction is easy to see. Let $\mathcal{S}' := \{P_1,\dots,P_{k-1}\}$ be a $(k-d-1)$-routing of a set $I' \subseteq I$ of order $k-1$. Let s,t be such that $I = I' \cup \{(s,t)\}$. By assumption there is a simple path P from s to t in G. Then $\mathcal{S} := \mathcal{S}' \cup \{P\}$ is a $(k-d)$-routing of I.

For the reverse direction let $I := \{(s_1,t_1),\dots,(s_k,t_k)\}$ and let $\hat{\mathcal{S}} := \{\hat{P}_1,\dots,\hat{P}_k\}$ be a $(k-d)$-routing of I such that $\hat{P}_i$ links s_i to t_i, for all $1 \leq i \leq k$. We define a multi digraph G' on the same vertex set $V(G)$ as G as follows. For every pair $u,v \in V(G')$ such that $e = (u,v) \in E(G)$ and every $1 \leq i \leq k$, if e occurs on the path $\hat{P}_i \in \mathcal{S}$, then we add a new edge $e^i = (u,v)$ to G'. Hence, if any edge $e \in E(G)$ is used by ℓ different paths in $\hat{\mathcal{S}}$, then G' contains ℓ parallel edges between the endpoints of e. In the rest of the proof we will work on the multi digraph G'. We can now take a set $\mathcal{S} := \{P_1,\dots,P_k\}$ of pairwise edge disjoint paths, where P_i is the path from s_i to t_i induced by the edge set $\{e^i : e \in E(\hat{P}_i)\}$. That is, by using the parallel edges, we can turn the routing $\hat{\mathcal{S}}$ into a $(k-d)$-routing $\mathcal{S}$ of I where the paths are mutually edge disjoint.

In the remainder of the proof we will construct a subset $I' \subsetneq I$ of order $k-1$ and a $(k-d-1)$-routing of I' in G' which is pairwise edge disjoint. This naturally induces a $(k-d-1)$-routing of I' in G. Note that in G', if $\mathcal{L}$ is any set of pairwise edge disjoint paths, then the congestion of any vertex with respect to $\mathcal{L}$ is at most the congestion of the vertex with respect to $\mathcal{S}$ (and thus $\hat{\mathcal{S}}$) in G' (and G, respectively). Indeed, every edge in $\mathcal{L}$ has a corresponding path in $\mathcal{S}$, so no vertex can be contained in more paths from $\mathcal{L}$ than in $\mathcal{S}$.

Let $\sqsubseteq$ be a topological ordering of G' and let $A := \{a_1,\dots,a_\ell\}$ be the set of vertices of congestion $k-d$ with respect to $\mathcal{S}$ such that $a_i \sqsubseteq a_j$ whenever $i < j$. As $k > 3d$, for all $1 \leq i < \ell$ there is a path in G from a_i to a_{i+1}.

For $1 \leq i \leq k$, an *atomic subpath* of P_i (with respect to $\mathcal{S}$) is a subpath of P_i that starts and ends in a vertex of $A \cup \{s_i,t_i\}$ and is internally vertex disjoint from A. Hence, every path $P_i \in \mathcal{S}$ consists of the concatenation $P_1^1 \cdot \dots \cdot P_i^{\ell_i}$ of its atomic subpaths where we identify the last vertex of P_i^j with the first vertex of P_i^{j+1} for all $1 \leq j < \ell_i$. Note that any two atomic subpaths of paths P_i, P_j in $\mathcal{S}$ are pairwise edge disjoint.

Let $I' \subset I$ be a subset of order $k-1$. A routing $\mathcal{S}' := \{P'_1, \dots, P'_{k-1}\}$ of I' is *conservative with respect to* $\mathcal{S}$ if it consists of pairwise edge disjoint paths and every path in $\mathcal{S}'$ consists of a concatenation of atomic subpaths of paths in $\mathcal{S}$. In the sequel, whenever we speak of a conservative I'-routing we implicitly mean that it is conservative with respect to $\mathcal{S}$.

If $\mathcal{S}'$ is a conservative I'-routing with respect to $\mathcal{S}$, then it consists of pairwise edge disjoint paths and hence for every $v \in V(G)$ the congestion of v with respect to $\mathcal{S}'$ is at most the congestion of v with respect to $\mathcal{S}$.

Let $1 \leq i_1 < i_2 \leq \ell$ and let $1 \leq j \leq k$. Let $\mathcal{S}'$ be a conservative I'-routing. An (i_1, i_2)-*jump of colour* j is a subpath P' of P_j from a_{i_1} to a_{i_2} such that for all i with $i_1 < i < i_2$ the vertex a_i is not on P_j. Note that any jump is an atomic subpath. We call the jump P' *free with respect to* $\mathcal{S}'$ if P' is not used by any path in $\mathcal{S}'$.

We are now ready to complete the proof of the lemma. Note first that, as $k > 3d$, for any three vertices $b_1, b_2, b_3 \in A$ there is a path $P \in \mathcal{S}$ that contains b_1, b_2, b_3. Hence, we can choose an $h \in \{1, \dots, k\}$ such that $a_1, a_\ell \in V(P_h)$ and there is a vertex a_r with $1 < r < \ell$ such that $a_r \in V(P_h)$. Let $I' := I \setminus \{(s_h, t_h)\}$. If $A \subseteq V(P_h)$, then $\mathcal{S} \setminus \{P_h\}$ is a $(k-d-1)$-routing of I' and we are done. Otherwise, for every vertex $a_r \in A$ which has congestion $k-d$ with respect to $\mathcal{S} \setminus \{P_h\}$ there are i, j with $i < r < j$ and an (i,j)-jump P of colour h. This follows as $a_1, a_\ell \in V(P_h)$. Note also that a_1 and a_ℓ have congestion $k-d-1$ in $\mathcal{S} \setminus \{P_h\}$. Note that this jump P is free with respect to $\mathcal{S} \setminus \{P_h\}$.

Thus, it is easily seen that $\mathcal{S} \setminus \{P_h\}$ satisfies the following two properties:

1. For every vertex a_r of congestion $k-d$ with respect to $\mathcal{S} \setminus \{P_h\}$ there are indices $i < r < j$ such that there is a free (i,j)-jump P with respect to $\mathcal{S} \setminus \{P_h\}$.
2. For any three vertices b_1, b_2, b_3 of congestion $k-d$ with respect to $\mathcal{S} \setminus \{P_h\}$ there is a path $Q \in \mathcal{S} \setminus \{P_h\}$ with $\{b_1, b_2, b_3\} \subseteq V(Q)$.

Now let $\mathcal{S}'$ be a routing of I' which satisfies Condition 1 and 2 (with respect to $\mathcal{S}'$ instead of $\mathcal{S} \setminus \{P_h\}$) and, subject to this, the number of vertices of congestion $k-d$ with respect to $\mathcal{S}'$ is minimal.

We claim that $\mathcal{S}'$ is a $(k-d-1)$-routing of I'. Let $\mathcal{S}' := \{Q_1, \dots, Q_{k-1}\}$. Towards a contradiction, suppose there is a vertex a_r of congestion $k-d$ with respect to $\mathcal{S}'$. As $\mathcal{S}'$ is conservative, we have $a_r \in A$. Hence, by assumption, there are $i < r < j$ and a free (i,j)-jump P with respect to $\mathcal{S}'$.

Let Q_h be a path in $\mathcal{S}'$ that contains a_i, a_r and a_j, which exists by Condition 2. Let $Q_h := Q_h^1 \cup Q_h^2 \cup Q_h^3$ where

- Q_h^1 is the initial subpath of Q_h from its first vertex to a_i,
- Q_h^2 is the subpath starting at a_i and ending in a_j and
- Q_h^3 is the subpath starting in a_j and ending at the end of Q_h.

We define $Q'_h := Q_h^1 \cup P \cup Q_h^3$, i.e. Q'_h is the path obtained from Q_h by replacing the inner subpath Q_h^2 by the (i,j)-jump P. Let $\mathcal{L} := (\mathcal{S}' \setminus \{Q_h\}) \cup \{Q'_h\}$. Then $\mathcal{L}$ is a routing of I'. It is also conservative as we have only rerouted a single path along a free jump.

We need to show that for all b_1, b_2, b_3 of congestion $k-d$ with respect to $\mathcal{L}$ there is a path $Q \in \mathcal{L}$ containing b_1, b_2, b_3. By assumption, such a path Q' exists in $\mathcal{S}'$. If $Q' \neq Q_h$, then we are done. So suppose $Q_h = Q'$. But then this implies that $b_s \notin \{a_{i+1}, \dots, a_{j-1}\}$ for all $1 \leq s \leq 3$ as otherwise the congestion of b_s would have dropped to $k-d-1$ in $\mathcal{L}$. But then $b_1, b_2, b_3 \in V(Q'_h)$.

It remains to show that for every vertex a_s of congestion $k-d$ with respect to $\mathcal{L}$ there is a free (i,j)-jump for some $i < s < j$. As before, by assumption, there are $s_1 < s < s_2$ and a free (s_1, s_2)-jump with respect to $\mathcal{S}'$. If this jump is not P, then it still exists with respect to

$\mathcal{L}$ and we are done. So suppose this jump is P, which implies that $i < s < j$. Furthermore, $a_s \notin Q_h$ as otherwise the congestion of a_s in $\mathcal{L}$ would be $k - d - 1$. But then, there must be indices i_1, i_2 with $i \leq i_1 < s < i_2 \leq j$ such that $a_{i_1}, a_{i_2} \in V(Q_h)$ and $a_{s'} \notin V(Q_h)$ for all $i_1 < s' < i_2$. Hence, the atomic subpath Q'' of Q_h from a_{i_1} to a_{i_2} is an (i_1, i_2)-jump as required. As $Q'' \subseteq Q_h^2$, this jump is now free.

Finally, the vertex a_r now has congestion $k-d-1$ with respect to $\mathcal{L}$ as a_r is not contained in Q'_h. Hence, $\mathcal{L}$ has fewer vertices of congestion $k - d$ than $\mathcal{S}'$, contradicting the choice of $\mathcal{S}'$. Thus, $\mathcal{S}'$ must have been a $(k - d - 1)$-routing of I' as required. This completes the proof of the lemma. ◀

By repeatedly applying Lemma 8 we obtain the following corollary, which essentially implies Theorem 3.

▶ **Corollary 9.** *Let G be an acyclic digraph, $d \geq 0$, $k \geq 3d$ and let $I := \{(s_1, t_1), \ldots, (s_k, t_k)\}$ be a set of pairs of vertices such that for all $1 \leq i \leq k$ there is a path in G linking s_i to t_i. Then G contains a $(k - d)$-routing of I if, and only if, there is a subset $I' \subseteq I$ with $|I'| = 3d$ such that G contains a $2d$-routing of I'.*

We are now ready to prove Theorem 3.

Proof of Theorem 3. Let G, k, d and $I := \{(s_1, t_1), \ldots, (s_k, t_k)\}$ be given. Let $n := |G|$. If for some $1 \leq i \leq k$ there is no path in G from s_i to t_i, then the answer is no and we are done. If $k \leq 3d$, then we can apply Corollary 7 to compute the answer in time $n^{O(d)}$ as required.

Otherwise, by Corollary 9, there is a $(k - d)$-routing for I in G if, and only if, there is a subset $I' \subsetneq I$ of order $3d$ such that I' has a $2d$-routing. There are $\binom{k}{3d} \leq k^{3d} \leq n^{3d}$ subsets I' of order $3d$. By Corollary 7, we can decide for any such I' of order $3d$ in time $n^{O(d)}$ whether a $2d$-routing of I' exists. Hence, by iterating through all possible subsets I', we can decide in time $n^{O(d)}$ whether there is a $(k - d)$-routing of I in G. ◀

4 Lower Bounds

In this section, we prove Theorem 2 by a reduction from Partitioned Subgraph Isomorphism. The input of the Partitioned Subgraph Isomorphism problem consists of a graph H with vertex set $\{u_1, \ldots, u_k\}$ and a graph G whose vertex set is partitioned into k classes $V_1, \ldots, V_k$. The task is to find a mapping $\mu : V(H) \to V(G)$ such that $\mu(u_i) \in V_i$ for every $1 \leq i \leq k$ and μ is a subgraph embedding, that is, if u_i and u_j are adjacent in H, then $\mu(u_i)$ and $\mu(u_j)$ are adjacent in G.

▶ **Theorem 10** ([20]). *Assuming ETH,* Partitioned Subgraph Isomorphism *cannot be solved in time $f(k)n^{o(k/\log k)}$ (where $k = |V(H)|$) for any computable function f, even when H is assumed to be 3-regular and bipartite.*

To prove Theorem 2, we need a reduction from Partitioned Subgraph Isomorphism (for 3-regular bipartite graphs) to (k, c)-Congestion Routing, where the number k of demands is linear in the number of vertices of H.

Proof (of Theorem 2). We prove the theorem by a reduction from Partitioned Subgraph Isomorphism. Let H and G be two graphs, let $V(H) = \{u_1, \ldots, u_k\}$, and let $(V_1, \ldots, V_k)$ be a partition of $V(G)$. By copying vertices if necessary, we may assume that every V_i has the same size n; let us denote by $\{v_{i,1}, \ldots, v_{i,n}\}$ the vertices in V_i. By Theorem 10, we may assume that H is 3-regular and bipartite. This means that H has exactly $h = 3k/2$ edges

Figure 1 Part of the directed graph D constructed in the proof of Theorem 2 with $k = 4$, $h = 6$, and $n = 5$. For clarity, we consider only one edge e_4 of H, which connects u_1 and u_3, and assume that the only edge between V_1 and V_3 is between $v_{1,3}$ and $v_{3,5}$. The highlighted red paths show the paths P_1^v, P_3^v, and P_4^e of the solution.

and both partite classes contain $k/2$ vertices. Without loss of generality, we can assume that $U_1 = \{u_1, \ldots, u_{k/2}\}$ and $U_2 = \{u_{k/2+1}, \ldots, u_k\}$ are the two partite classes. Let us fix an arbitrary ordering e_1, …, e_h of the edges of H.

Construction. We construct an instance of (k, c)-Congestion Routing in the following way. We construct a directed graph D that contains, for every $1 \leq i \leq k$, two directed paths $\overline{Q}_i$ and $\underline{Q}_i$ (see Figure 1). Path $\overline{Q}_i$ has $n(h + 1) + 1$ vertices: it contains the vertices $\overline{q}_{i,0}$, …, $\overline{q}_{i,n}$ in this order and additionally, for every $1 \leq j \leq n$, the vertices $\overline{q}_{i,j,1}$, …, $\overline{q}_{i,j,h}$ are inserted between $\overline{q}_{i,j-1}$ and $\overline{q}_{i,j}$. The path $\underline{Q}_i$ is defined the same way, with vertices $\underline{q}$ instead of $\overline{q}$. For every $1 \leq \ell \leq h$, we introduce two vertices s_ℓ and t_ℓ. Then we complete the construction of the graph D by introducing further edges as follows.

- For every $1 \leq i \leq k$ and $1 \leq j \leq n$, we introduce the edge $(\overline{q}_{i,j-1}, \underline{q}_{i,j})$ (the curved bypass edges in Figure 1).
- For every $1 \leq i \leq k$, $1 \leq j \leq n$, and $1 \leq s \leq h$, we introduce the edge $(\overline{q}_{i,j,s}, \underline{q}_{i,j,s})$ (the vertical edges in Figure 1).
- For every $1 \leq \ell \leq h$, we do the following. Suppose that edge e_ℓ of H connects u_{i_a} and u_{i_b} for some $1 \leq i_a \leq k/2$ and $k/2 + 1 \leq i_b \leq k$. Then for every pair of vertices $v_{i_a,j_a} \in V_{i_a}$ and $v_{i_b,j_b} \in V_{i_b}$ that are adjacent in G, we introduce the following three edges into D:

$(s_\ell, \overline{q}_{i_a,j_a,\ell})$, $(\underline{q}_{i_a,j_a,\ell}, \overline{q}_{i_b,j_b,\ell})$, and $(\underline{q}_{i_b,j_b,\ell}, t_\ell)$.

To complete the construction of the (k,c)-Congestion Routing instance, we define the following set of $k + 2k(c-1) + h$ demands:

- For every $1 \leq i \leq k$, we introduce the demand $(\overline{q}_{i,0}, \underline{q}_{i,n})$ (vertex demands).
- For every $1 \leq i \leq k$, we introduce $c-1$ copies of the demand $(\overline{q}_{i,0}, \overline{q}_{i,n})$ (blocking demands).
- For every $1 \leq i \leq k$, we introduce $c-1$ copies of the demand $(\underline{q}_{i,0}, \underline{q}_{i,n})$ (blocking demands).
- For every $1 \leq \ell \leq h$, we introduce the demand (s_ℓ, t_ℓ) (edge demands).

Note that, for every fixed $c \geq 1$, the number of demands is $O(k)$. In the rest of the proof, we show that a routing with congestion c exists if and only if the Partitioned Subgraph Isomorphism instance has a solution. Then the W[1]-hardness and lower bound stated in Theorem 10 implies the same hardness results for the routing problem.

Subgraph embedding $\Rightarrow$ routing. Suppose first that vertices $v_{1,z_1} \in V_1$, …, $v_{k,z_k} \in V_k$ form a solution to the Partitioned Subgraph Isomorphism instance. We construct a routing that contains the following paths, satisfying the demands defined above:

- For every $1 \leq i \leq k$, the vertex demand $(\overline{q}_{i,0}, \underline{q}_{i,n})$ is satisfied by a path P_i^v that goes from $\overline{q}_{i,0}$ to $\overline{q}_{i,z_i-1}$ on $\overline{Q}_i$, uses the edge $(\overline{q}_{i,z_i-1}, \underline{q}_{i,z_i})$, and then goes from $\underline{q}_{i,z_i}$ to $\underline{q}_{i,n}$ on $\underline{Q}_i$.
- For every $1 \leq i \leq k$, each of the $c-1$ copies of the blocking demand $(\overline{q}_{i,0}, \overline{q}_{i,n})$ is satisfied by a path going on $\overline{Q}_i$.
- For every $1 \leq i \leq k$, each of the $c-1$ copies of the blocking demand $(\underline{q}_{i,0}, \underline{q}_{i,n})$ is satisfied by a path going on $\underline{Q}_i$.
- For every $1 \leq \ell \leq h$, the edge demand (s_ℓ, t_ℓ) is satisfied by a 5-edge path $P_\ell^e = (s_\ell, \overline{q}_{i_a,z_{i_a},\ell}, \underline{q}_{i_a,z_{i_b},\ell}, \overline{q}_{i_b,z_{i_b},\ell}, \underline{q}_{i_b,z_{i_b},\ell}, t_\ell)$.

It is easy to verify that these are indeed paths: all the required edges exist. We claim that each vertex of D is used by at most c of these paths. It is easy to see that two paths $P_{i'}^v$ and $P_{i''}^v$ with $i \neq i''$ satisfying vertex demands do not intersect, and this is also true for any two paths $P_{\ell'}^e$ and $P_{\ell''}^e$ with $\ell' \neq \ell''$ satisfying edge demands (note that each vertex of the path P_ℓ^e has ℓ in its index). The crucial observation is that the path P_i^v does not intersect the path P_ℓ^e for any ℓ. The only way this could possibly happen is if edge e_ℓ of H connects u_{i_a} with u_{i_b}, and i is equal to i_a or i_b. But the path P_ℓ^e uses only vertex $\overline{q}_{i_a,z_{i_a},\ell}$ from $\overline{Q}_{i_a}$ and vertex $\underline{q}_{i_a,z_{i_b},\ell}$ from $\underline{Q}_{i_b}$, while the path P_i^v does not use these vertices, as it jumps from $\overline{q}_{i,z_i-1}$ to $\underline{q}_{i,z_i}$. Thus each vertex is used by at most $c-1$ paths satisfying a blocking demand and at most one additional path satisfying a vertex or edge demand. We can conclude that each vertex is used by at most c of the paths, what we had to show.

Routing $\Rightarrow$ subgraph embedding. Next we show that given a routing with congestion c, it is possible to construct the required subgraph embedding from H to G. It is clear that the path satisfying the blocking demand $(\overline{q}_{i,0}, \overline{q}_{i,n})$ is exactly $\overline{Q}_i$: after leaving $\overline{Q}_i$, there is no way to return back to it. Similarly, the solution must use path $\underline{Q}_i$ to satisfying the blocking demand $(\underline{q}_{i,0}, \underline{q}_{i,n})$. It is also clear that the path P_i^v satisfying the vertex demand $(\overline{q}_{i,0}, \underline{q}_{i,n})$ has to be contained in the union of $\overline{Q}_i$ and $\underline{Q}_i$. Let $1 \leq z_i \leq n$ be the smallest value such that $\underline{q}_{i,z_i}$ is on path P_i^v (note that this value is positive, as vertex $\underline{q}_{i,0}$ cannot be reached from $\overline{q}_{i,0}$). Observe that path P_i^v uses every vertex of $\underline{Q}_i$ from $\underline{q}_{i,z_i}$ to $\underline{q}_{i,n}$ (as it cannot leave $\underline{Q}_i$). Moreover, since P_i^v does not use the part of $\underline{Q}_i$ from $\underline{q}_{i,0}$ to $\underline{q}_{i,z_i-1}$ by definition, it has to use the part of $\overline{Q}_i$ from $\overline{q}_{i,0}$ to $\overline{q}_{i,z_i-1}$.

We claim that mapping vertex u_i of H to vertex v_{i,z_i} of G is a correct subgraph embedding of H into G. To show this, suppose that edge e_i of H connects u_{i_a} and u_{i_b} with $1 \leq i_a \leq k/2$ and $k/2+1 \leq i_b \leq k$; we need to show that $v_{i_a,z_{i_a}} \in V_{i_a}$ and $v_{i_b,z_{i_b}} \in V_{i_b}$ are adjacent. Consider the path P^e_ℓ satisfying edge demand (s_ℓ, t_ℓ). By construction, the vertex of P^e_ℓ after s_ℓ has to be on the path $\overline{Q}_{i_a}$ and the vertex of P^e_ℓ before t_ℓ has to be on $\underline{Q}_{i_b}$. The only way to go from $\overline{Q}_{i_a}$ to $\underline{Q}_{i_b}$ is to use an edge of the form $(\underline{q}_{i_a,j_a,\ell}, \overline{q}_{i_b,j_b,\ell})$: the only way we can leave the union of $\overline{Q}_{i_a}$ and $\underline{Q}_{i_a}$ is to enter some $\overline{Q}_i$ with $k/2+1 \leq i \leq k$, and there is no edge connecting $\overline{Q}_{i_b}$ or $\underline{Q}_{i_b}$ with any $\overline{Q}_i$ with $k/2+1 \leq i \leq k$ and $i \neq i_b$ (this is the part of the proof where we use that H is bipartite). We claim that $j_a = z_{i_a}$. If $j > z_{i_a}$, then $\underline{q}_{i_a,j_a,\ell}$ is also used by the $c-1$ paths satisfying the blocking demand $(\underline{q}_{i_a,0}, \underline{q}_{i_a,n})$ and (as we have seen) the path $P^v_{i_a}$, contradicting the assumption that the routing has congestion c. If $j < z_{i_a}$, then there is no way for the path P^e_ℓ to reach $\underline{q}_{i_a,j_a,\ell}$ from s_ℓ: each vertex of the path $\overline{Q}_{i_a}$ from $\overline{q}_{i_a,0}$ to $\overline{q}_{i_a,j_a}$ is used by $c-1$ paths satisfying the blocking demand $(\underline{q}_{i_a,0}, \underline{q}_{i_a,n})$ and (as shown above) by the path $P^v_{i_a}$. This shows $j_z = z_{i_a}$ and a similar argument shows $j_b = z_{i_b}$. Now the existence of the edge $(\underline{q}_{i_a,z_a,\ell}, \overline{q}_{i_b,z_b,\ell})$ means, by construction, that G contains an edge between $v_{i_a,z_a} \in V_{i_a}$ and $v_{i_b,z_b} \in V_{i_b}$, what we had to show. ◀

5 Conclusion

In this paper we have studied the (k,c)-Congestion Routing problem on acyclic digraphs. It is easy to see that the $n^{O(k)}$ algorithm in [15] for solving the disjoint paths problem on acyclic digraphs can be extended to an $n^{O(k)}$ algorithm for (k,c)-Congestion Routing. As we proved in Theorem 2, the $n^{O(k)}$ time algorithm is essentially best possible with respect to the exponent of n, under the Exponential-Time Hypothesis (ETH). We therefore studied the extreme cases of relatively high congestion $k-d$ for some fixed value of d. In Theorem 3 we showed that in this case we can obtain an $n^{O(d)}$ algorithm on acyclic digraphs, i.e. the algorithm only depends on the offset d in $(k,k-d)$-Congestion Routing but not on the number k of demand pairs. The proof relied on a reduction argument that shows that as long as k is big enough compared to d, then a demand pair can be eliminated without changing the answer.

It will be interesting to see whether our result can be extended to larger classes of digraphs. In particular classes of digraphs of bounded directed tree width would be a natural target. On such classes, the k-disjoint paths problem can be solved in time $n^{O(k+w)}$, where w is the directed tree width of the input digraph (see [17]). It is conceivable that our results extend to bounded directed tree width classes and we leave this for future research.

Abstract

Stochastic timed games (STGs), introduced by Bouyer and Forejt, naturally generalize both continuous-time Markov chains and timed automata by providing a partition of the locations between those controlled by two players (Player Box and Player Diamond) with competing objectives and those governed by stochastic laws. Depending on the number of players – 2, 1, or 0 – subclasses of stochastic timed games are often classified as $2\frac{1}{2}$-player, $1\frac{1}{2}$-player, and $\frac{1}{2}$-player games where the $\frac{1}{2}$ symbolizes the presence of the stochastic "nature" player. For STGs with reachability objectives it is known that $1\frac{1}{2}$-player one-clock STGs are decidable for qualitative objectives, and that $2\frac{1}{2}$-player three-clock STGs are undecidable for quantitative reachability objectives. This paper further refines the gap in this decidability spectrum. We show that quantitative reachability objectives are already undecidable for $1\frac{1}{2}$ player four-clock STGs, and even under the time-bounded restriction for $2\frac{1}{2}$-player five-clock STGs. We also obtain a class of $1\frac{1}{2}$, $2\frac{1}{2}$ player STGs for which the quantitative reachability problem is decidable.

1 Introduction

Two-player zero-sum games over finite state-transition graphs are a natural framework for controller synthesis for discrete event systems. In this setting two players – say Player Box and Player Diamond (after necessity and possibility operators) – represent the controller and the environment, and control-program synthesis corresponds to finding a winning (or optimal) strategy of the controller for some given performance objective. Finite graphs, however, often do not satisfactorily model real-time safety-critical systems as they disregard not only the continuous dynamics of the physical environment but also the presence of stochastic behavior. Stochastic behavior in such systems stems from many different sources, e.g., faulty

or unreliable sensors or actuators, uncertainty in timing delays, the random coin flips of distributed communication and security protocols.

Timed automata [2] were introduced as a formalism to model asynchronous real-time systems interacting with a continuous physical environment. Timed automata and their two-player counterparts [3] provide an intuitive and semantically unambiguous way to model non-stochastic real-time systems, and a number of case-studies [23] demonstrate their application in the design and analysis of real-time systems. On the other hand, classical formalisms (discrete-time and continuous-time) Markov decision processes (MDPs) and stochastic games [22, 15] naturally model analysis and synthesis problems for stochastic systems, and have been applied in control theory, operations research, and economics.

For the formal analysis of stochastic real-time systems, a number of recent works considered a combination of stochastic features with timed automata, e.g. probabilistic timed automata [18], continuous probabilistic timed automata [17] and stochastic timed automata [9]. Probabilistic timed automata, respectively continuous probabilistic and stochastic timed automata can be considered as generalizations of timed automata with the features of discrete-time Markov decision processes, respectively continuous-time Markov chains [5] (or even generalized semi-Markov processes [13]). Stochastic timed games [12] form the most general formalism for studying controller-synthesis for stochastic real-time systems. These games can be considered as interactions between three players – Player Box, Player Diamond and the stochastic player (Nature) – such that Player Box and Player Diamond are adversarial and choose their delay and action so as to maximize and minimize probability to reach a given set of target states, while the stochastic player plays according to a given probability distribution. A key verification problem in this setting is that of games with reachability objectives, where the goal of Player Diamond is to reach a set of target states, while the goal of the Player Box is to avoid it.

Related Work. Probabilistic timed automata [18] and games [16] can be considered as subclasses of stochastic timed games where all of the locations controlled by stochastic players are *urgent* (no time delay allowed), while the decision-stochastic timed automata of [10] can be seen as a subclass of $1\frac{1}{2}$-player STGs where the locations of the rational players are urgent. The quantitative reachability problem for probabilistic timed automata is known to be decidable [18] with any number of clocks, while the best known decidability result for the quantitative reachability problem for $1\frac{1}{2}$-player STGs is using a single clock. $\frac{1}{2}$-player STGs, also called stochastic timed automata (STA) [9], have also received considerable attention: an abstraction based on the region abstraction has been proposed, which allows to solve the qualitative reachability problem under a *fairness* assumption on the STA (several subclasses of STAs have been proven to be fair). For quantitative reachability, the only decidability result is for a subclass of single-clock STA [8], but a recent approximability result has been shown in [7] for the class of *fair STA*.

Other variants of stochastic timed automata have been studied in the past. The model in [17] uses "countdown clocks" (which decrease from a set value) unlike the more timed-automata style of clock variables used in our model. The model in [11] (which is also called stochastic timed automata; we shall refer to them here as Modest-STA) is very general and encompasses most models with time and probabilities (and in particular the STA of [9]). However, Modest-STA is more aimed at capturing general languages (and providing a tool-set to simulate their runs) and less with decidability issues, and hence is orthogonal to our approach.

Table 1 Results in bold are contributions from this paper. "Conj" are conjectures.

Contributions. The scope of this paper is to investigate decidability of the reachability problem in STGs as defined in [12], for which the decidability picture is far from complete. In [12], the authors showed the decidability of qualitative reachability problem on 1-clock $1\frac{1}{2}$-player STGs, and the undecidability of quantitative reachability problem on STGs (with $2\frac{1}{2}$-players). This leaves a wide gap in the decidability horizon of STGs. In this paper, we study $1\frac{1}{2}$, $2\frac{1}{2}$-player games and contribute to a better understanding of the decidability status of STGs with quantitative reachability objectives.

Table 1 summarizes the results presented in this paper. We show that the quantitative reachability problem is already undecidable for $1\frac{1}{2}$-player games for systems with 4 or more clocks and for $2\frac{1}{2}$-player games the quantitative reachability problem remains undecidable even under the time-bounded restriction with 5 or more clocks. Another key contribution of this paper is the characterization of a previously unexplored subclass of stochastic timed games for which we recover decidability of quantitative reachability game for $1\frac{1}{2}$ (and even $2\frac{1}{2}$)-player stochastic timed games. We call a 1-clock stochastic timed game *initialized* if (i) all the transitions from non-stochastic states to stochastic states reset the clock, and (ii) in every bounded cycle, the clock is reset. The definition can be generalized to multiple clocks using the notion of strong reset where one resets all the clocks together. For some of the gaps in this spectrum, we provide our best conjectures as justified in the Discussion section:–the undecidability of time-bounded quantitative reachability for $1\frac{1}{2}$-player STG, and the decidability of qualitative reachability of 1-clock $2\frac{1}{2}$-player STG. Due to lack of space, details of some proofs can be found in [1].

2 Stochastic Timed Games

We use standard notations for the set of reals ($\mathbb{R}$), rationals ($\mathbb{Q}$), and integers ($\mathbb{Z}$), and add subscripts to indicate additional constraints (for instance $\mathbb{R}_{\geq 0}$ is for the set of non-negative reals). Let $\mathcal{C}$ be a finite set of real-valued variables called *clocks*. A *valuation* on $\mathcal{C}$ is a function $\nu : \mathcal{C} \to \mathbb{R}_{\geq 0}$. We assume an arbitrary but fixed ordering on the clocks and write x_i for the clock with order i. This allows us to treat a valuation ν as a point $(\nu(x_1), \nu(x_2), \ldots, \nu(x_n)) \in \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$. Abusing notations slightly, we use a valuation on $\mathcal{C}$ and a point in $\mathbb{R}_{\geq 0}^{|\mathcal{C}|}$ interchangeably. For a subset of clocks $X \subseteq \mathcal{C}$ and valuation $\nu \in \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$, we write $\nu[X{:=}0]$ for the valuation where $\nu[X{:=}0](x) = 0$ if $x \in X$, and $\nu[X{:=}0](x) = \nu(x)$ otherwise. For $t \in \mathbb{R}_{\geq 0}$, write $\nu + t$ for the valuation defined by $\nu(x) + t$ for all $x \in X$. The valuation $\mathbf{0} \in \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$ is a special valuation such that $\mathbf{0}(x) = 0$ for all $x \in \mathcal{C}$. A clock constraint over $\mathcal{C}$ is a subset of $\mathbb{R}_{\geq 0}^{|\mathcal{C}|}$ defined by a (finite) conjunction of constraints of the form $x \bowtie k$, where $k \in \mathbb{Z}_{\geq 0}$, $x \in \mathcal{C}$, and $\bowtie \in \{<, \leq, =, >, \geq\}$. We write $\varphi(\mathcal{C})$ for the set of clock constraints. For a constraint $g \in \varphi(\mathcal{C})$, and a valuation ν, we write $\nu \models g$ to represent the fact that valuation ν satisfies constraint g (defined in a natural way). A timed automaton (TA) [2] is a tuple $\mathcal{A} = (L, \mathcal{C}, E, \mathcal{I})$ such that (i) L is a finite set of locations, (ii) $\mathcal{C}$ is a finite set of clocks, (iii) $E \subseteq L \times \varphi(\mathcal{C}) \times 2^{\mathcal{C}} \times L$ is a finite set of edges, (iv) $\mathcal{I} : L \to \varphi(\mathcal{C})$ assigns an invariant to each location. A state s of a timed automaton is a pair $s = (\ell, \nu) \in L \times \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$ such that $\nu \models \mathcal{I}(\ell)$ (the clock valuation should satisfy the invariant of the location). If $s = (\ell, \nu)$, and $t \in \mathbb{R}_{\geq 0}$, we write $s + t$ for the state $(\ell, \nu + t)$. A transition (t, e) from a state $s = (\ell, \nu)$ to a state $s' = (\ell', \nu')$ is written as $s \xrightarrow{t,e} s'$ if $e = (\ell, g, C, \ell') \in E$, such that $\nu + t \models g$, and for every $0 \leq t' \leq t$ we have $\nu + t' \models \mathcal{I}(\ell)$ and $\nu' = \nu + t[C{:=}0](x)$. A run is a finite or infinite sequence of transitions $\rho = s_0 \xrightarrow{t_1,e_1} s_1 \xrightarrow{t_2,e_2} s_2 \ldots$ of states and transitions. An edge e is enabled from s whenever there is a state s' such that $s \xrightarrow{0,e} s'$. Given a state s of $\mathcal{A}$ and an edge e, we define $I(s, e) = \{t \in \mathbb{R}_{\geq 0} \mid s \xrightarrow{t,e} s'\}$ for some s' and $I(s) = \bigcup_{e \in E} I(s, e)$. We say that $\mathcal{A}$ is non-blocking iff for all states s, $I(s) \neq \emptyset$. Now we are ready to introduce stochastic timed games.

▶ **Definition 1** (Stochastic Timed Games [12]). A *stochastic timed game (STG)* is a tuple $\mathcal{G} = (\mathcal{A}, (L_\Box, L_\Diamond, L_\bigcirc), \omega, \mu)$ where

- $\mathcal{A}{=}(L, \mathcal{C}, E, \mathcal{I})$ is a timed automaton;
- $L_\Box, L_\Diamond$, and $L_\bigcirc$ form a partition of L characterizing the set of locations controlled by players $\Box$ and $\Diamond$ and the stochastic player, respectively;
- $\omega : E(L_\bigcirc) \to \mathbb{Z}_{>0}$ assigns some positive weight to each edge originating from $L_\bigcirc$ (notation $E(L_\bigcirc)$);
- μ is a function assigning a measure over $I(s)$ to all states $s \in L_\bigcirc \times \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$ satisfying the properties that $\mu(s)(I(s)) = 1$ and for Lebesgue measure λ, if $\lambda(I(s)) > 0$ then for each measurable set $B \subseteq I(s)$ we have $\lambda(B) = 0$ if and only if $\mu(s)(B) = 0$.

The timed automaton $\mathcal{A}$ is said equipped with uniform distributions over delays if for every state s, $I(s)$ is bounded, and $\mu(s)$ is the uniform distribution over $I(s)$. The timed automaton $\mathcal{A}$ is said equipped with exponential distributions over delays whenever, for every state s, either $I(s)$ has Lebesgue measure zero, or $I(s){=}\mathbb{R}_{\geq 0}$ and for every location l, there is a positive rational α_l such that $\mu(s)(I(s)){=}\int_{t \in I} \alpha_l e^{-\alpha_l t} dt$. For $s \in L_\bigcirc \times \mathbb{R}_{\geq 0}^{|\mathcal{C}|}$, both delays and discrete moves will be chosen probabilistically: from s, a delay t is chosen following the probability distribution over delays $\mu(s)$. Then, from state $s + t$, an enabled edge is selected following a discrete probability distribution that is given in a usual way with the weight function w: in state $s + t$, the probability of edge e (if enabled), denoted $p(s + t)(e)$ is $w(e) / \sum_{e'} \{w(e') \mid e'$ is enabled in $s + t\}$. This way of probabilizing behaviours in timed automata has been presented in [9].

If $L_\Box{=}\emptyset$ then the STGs are called $1\frac{1}{2}$ STGs or $1\frac{1}{2}$-player STGs while STGs with $L_\Box = L_\Diamond{=}\emptyset$ are called $\frac{1}{2}$ STGs or $\frac{1}{2}$-player STGs or STAs. We often refer to $l{\in}L_\bigcirc$ as stochastic nodes, $l \in L_\Box$ as box (or $\Box$) nodes and $l \in L_\Diamond$ as diamond (or $\Diamond$) nodes.

Fix a STG $\mathcal{G} = (\mathcal{A}, (L_\Box, L_\Diamond, L_\bigcirc), \omega, \mu)$ with $\mathcal{A} = (L, \mathcal{C}, E, \mathcal{I})$ for the rest of this section.

Strategies, Profiles, and Runs. A strategy for Player $\Box$ (resp. $\Diamond$) is a function that maps a finite run $\rho = s_0 \xrightarrow{t_0,e_0} s_1 \xrightarrow{t_1,e_1} \ldots s_n$ to a pair (t, e) such that $s_n \xrightarrow{t,e} s'$ for some state s', whenever $s_n = (\ell_n, \nu_n)$ and $\ell_n \in L_\Box$ (resp. $\ell_n \in L_\Diamond$). In this work we focus on deterministic strategies, though randomized strategies could also make sense; nevertheless understanding the case of deterministic strategies is already challenging. A strategy profile is a pair $\Lambda = (\lambda_\Diamond, \lambda_\Box)$ where $\lambda_\Diamond, \lambda_\Box$ respectively are strategies of players $\Diamond$ and $\Box$. In order to measure probabilities of certain sets of runs, the following measurability condition is imposed on strategy profiles $\Lambda = (\lambda_\Diamond, \lambda_\Box)$: for every finite sequence of edges $e_1, \ldots, e_n$ and every state s, the function $\kappa_s : (t_1, \ldots, t_n) \to (t, e)$ defined by $\kappa_s(t_1, \ldots, t_n) = (t, e)$ iff $\Lambda(s \xrightarrow{t_1,e_1} s_1 \xrightarrow{t_2,e_2} s_2 \ldots \xrightarrow{t_n,e_n} s_n) = (t, e)$, should be measurable.

Given a finite run ρ ending in state s_0, and a strategy profile Λ, define $\mathit{Runs}(\mathcal{G}, \rho, \Lambda)$ (resp. $\mathit{Runs}^\omega(\mathcal{G}, \rho, \Lambda)$) to be the set of all finite (resp. infinite) runs generated by Λ after prefix ρ; that is, the set of all runs of the automaton satisfying the following condition: If $s_i = (\ell_i, \nu_i)$ and $\ell_i \in L_\Diamond$ (resp. $\ell_i \in L_\Box$), then $\lambda_\Diamond$ (resp. $\lambda_\Box$) returns (t_{i+1}, e_{i+1}) when applied to $\rho \xrightarrow{t_1,e_1} s_1 \xrightarrow{t_2,e_2} \ldots \xrightarrow{t_i,e_i} s_i$. Given a finite sequence $e_1, \ldots, e_n$ of edges, a symbolic path $\pi_\Lambda(\rho, e_1 \ldots e_n)$ is defined as

$$\pi_\Lambda(\rho, e_1 \ldots e_n) = \{\rho' \in \mathit{Runs}(\mathcal{G}, \rho, \Lambda) \mid \rho' = \rho \xrightarrow{t_1,e_1} s_1 \xrightarrow{t_2,e_2} s_2 \ldots \xrightarrow{t_n,e_n} s_n, \text{ with } t_i \in \mathbb{R}_{\geq 0}\}.$$

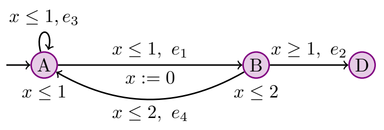
When Λ is clear, we simply write $\pi(\rho, e_1 \ldots e_n)$.

Probability Measure of a Strategy Profile. Given a strategy profile $\Lambda = (\lambda_\Diamond, \lambda_\Box)$, and a finite run ρ ending in $s = (\ell, \nu)$, a measure $\mathcal{P}_\Lambda$ can be defined on the set $\mathit{Run}(\mathcal{G}, \rho, \Lambda)$, following [12]: First, for the empty sequence ϵ, $\mathcal{P}_\Lambda(\pi(\rho, \epsilon)) = 1$, and

- If $\ell \in L_\Diamond$ (resp. $\ell \in L_\Box$), and $\lambda_\Diamond(\rho) = (t, e)$ (resp. $\lambda_\Box(\rho) = (t, e)$), then $\mathcal{P}_\Lambda(\pi(\rho, e_1 \ldots e_n))$ equals 0 if $e_1 \neq e$ and equals $\mathcal{P}_\Lambda(\pi(\rho \xrightarrow{t,e} s', e_2 \ldots e_n))$, otherwise.
- If $\ell \in L_\bigcirc$, $\mathcal{P}_\Lambda(\pi(\rho, e_1 \ldots e_n)) = \int_{t \in I(s,e_1)} p(s+t)(e_1) \cdot \mathcal{P}_\Lambda(\pi(\rho \xrightarrow{t,e_1} s', e_2 \ldots e_n))\, d\mu(s)(t)$ where $s \xrightarrow{t,e_1} s'$ for every $t \in I(s, e_1)$.

The cylinder generated by a symbolic path is defined as follows: an infinite run ρ'' is in the cylinder generated by $\pi_\Lambda(\rho, e_1, \ldots, e_n)$ denoted $\mathsf{Cyl}(\pi_\Lambda(\rho, e_1, \ldots, e_n))$ if ρ'' is in $\mathit{Runs}^\omega(\mathcal{G}, \rho, \Lambda)$ and there is a finite prefix ρ' of ρ'' such that $\rho' \in \pi_\Lambda(\rho, e_1, \ldots, e_n)$. It is routine to extend the above measure $\mathcal{P}_\Lambda$ to cylinders, and thereafter to the generated σ-algebra; extending [9], one can show this is a probability measure over $\mathit{Runs}^\omega(\mathcal{G}, \rho, \Lambda)$.

Example. An example of a STG is shown in the adjoining figure. In this example all the locations belong to stochastic player (this is an $\frac{1}{2}$ STG) and there is only one clock named x.



We explain here the method for computing probabilities. We assume uniform distribution over delays at all states, and initial state $s_0 = (A, 0)$. Let $d\mu_{(A,0)}$ be the uniform distribution over $[0, 1]$ and $d\mu_{(B,0)}$ uniform distribution over $[0, 2]$. Then $\mathcal{P}(\pi((A, 0), e_1e_2))$ equals $\frac{1}{8}$:

$$\int_0^1 \frac{\mathcal{P}(\pi((B,0), e_2))}{2} d\mu_{(A,0)}(t) = \int_0^1 \frac{1}{2}(\int_1^2 \frac{1}{2} d\mu_{(B,0)}(u))\, d\mu_{(A,0)}(t) = \frac{1}{2}\int_0^1 (\int_1^2 \frac{1}{2}\frac{1}{2} du))\, dt)$$

Reachability Problem. We study the reachability problem for STGs, stated as follows. Given a STG $\mathcal{G}$ with a set T of target locations, an initial state s_0 and a threshold $\bowtie p$ with $p \in [0, 1] \cap \mathbb{Q}$, decide whether there is a strategy $\lambda_\Diamond$ for Player $\Diamond$ such that for every strategy $\lambda_\Box$ for Player $\Box$, $\mathcal{P}_\Lambda(\{\rho \in \mathit{Run}(\mathcal{G}, s_0, \Lambda) \mid \rho \text{ visits } T\}) \bowtie p$, with $\Lambda = (\lambda_\Diamond, \lambda_\Box)$. There are two categories of reachability questions:

1. **Quantitative reachability**: The constraint on probability involves $0 < p < 1$.
2. **Qualitative reachability**: The constraint on probability involves $p \in \{0, 1\}$.

The key results of the paper are the following:

▶ **Theorem 2.** *The quantitative reachability problem is*
1. *Undecidable for $1\frac{1}{2}$ STGs with 4 or more clocks;*
2. *Undecidable for $2\frac{1}{2}$ STGs with 5 or more clocks even under the time-bounded semantics;*
3. *Decidable for $1\frac{1}{2}$ and $2\frac{1}{2}$* initialized *STGs with one clock.*

Mentioned restrictions (time-bounded semantics and initialized) will be introduced when needed. In Section 3, we deal with the quantitative reachability problem, where we show strengthened undecidability results. In Section 4, we explore a new model of STGs with a single clock and an initialized restriction to recover decidability for the quantitative reachability problem. In Section 5, we discuss the intrinsic difficulties and challenges ahead, summarize our key contributions and conjectures.

3 Undecidability Results for Quantitative Reachability

In this section, we focus on the quantitative reachability problem for STGs. We strengthen the existing undecidability result, which holds for $2\frac{1}{2}$ STGs [12], in two distinct directions. First, we show the undecidability of the quantitative reachability problem in $1\frac{1}{2}$ STGs, improving from $2\frac{1}{2}$. Second, we show the undecidability of the quantitative reachability problem for $2\frac{1}{2}$ STGs even in the time-bounded setting.

For both results, given a two-counter machine, we construct respectively, $1\frac{1}{2}$ and $2\frac{1}{2}$ STGs whose building blocks are the modules for the instructions in the two-counter machine. The objective of player $\Diamond$ is linked to a faithful simulation of various increment, decrement and zero-test instructions of the two-counter machine by choosing appropriate delays to adjust the clocks to reflect changes in counter values. However, the two proofs differ in how this verification is done and even in the problem from which the reduction is done, i.e., halting/non-halting for two-counter machines. This results in two quite different and non-trivial reductions as described in Subsection 3.1 and Subsection 3.2 respectively.

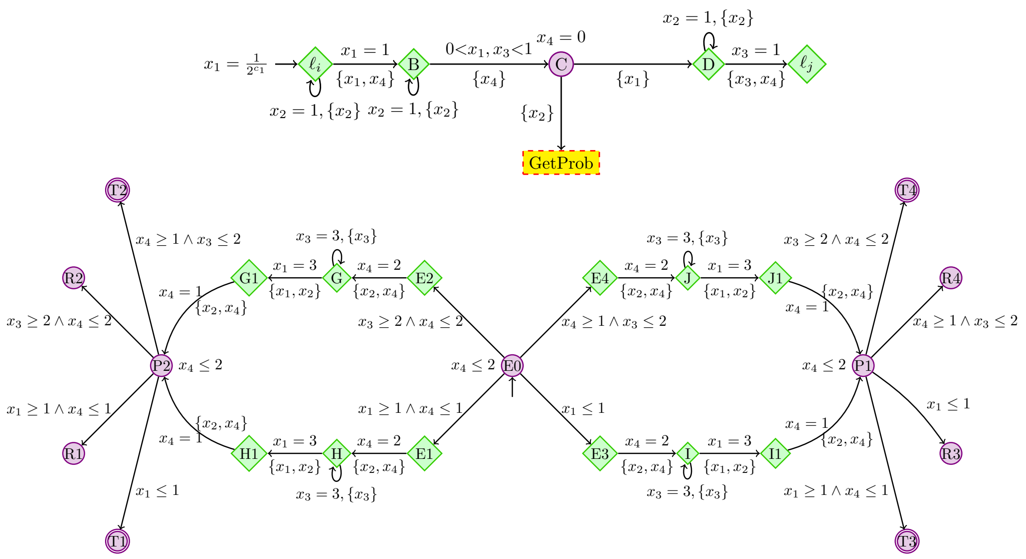
3.1 Quantitative reachability for $1\frac{1}{2}$ STGs

As mentioned above, in the case of $1\frac{1}{2}$ STGs we improve the corresponding result of [12] for $2\frac{1}{2}$ STGs. But unlike in [12], we reduce from the *non-halting problem* for two-counter machines to the existence of a winning strategy for Player $\Diamond$ with the desired objective. This crucial difference makes it possible for the probabilistic player to verify the simulation performed by player $\Diamond$.

▶ **Theorem 3.** *The quantitative reachability problem is undecidable for $1\frac{1}{2}$ STGs with ≥ 4 clocks.*

Let $\mathcal{M}$ be a two-counter machine. Our reduction uses a $1\frac{1}{2}$ player STG $\mathcal{G}$ with four clocks and uniform distributions over delays, and a set of target locations T such that player $\Diamond$ has a strategy to reach T with probability $\frac{1}{2}$ iff $\mathcal{M}$ does not halt. Each instruction (increment, decrement and test for zero value) is specified using a module. The main invariant in our reduction is that upon entry into a module, we have that $x_1 = \frac{1}{2^{c_1}}, x_2 = \frac{1}{2^{c_2}}$, $x_3 = x_4 = 0$, where c_1 (resp. c_2) is the value of counter C_1 (resp. C_2) in $\mathcal{M}$.

We outline the simulation of an increment instruction « ℓ_i : increment counter C_1, goto ℓ_j » in Figure 1 (top). The module is entered with values $x_1 = \frac{1}{2^{c_1}}, x_2 = \frac{1}{2^{c_2}}$, $x_3 = x_4 = 0$. A time $1 - \frac{1}{2^{c_1}}$ is spent at location ℓ_i, so that at location B we have $x_1 = 0$, $x_2 = \frac{1}{2^{c_2}} + 1 - \frac{1}{2^{c_1}}$ (or $\frac{1}{2^{c_2}} - \frac{1}{2^{c_1}}$, if $c_2 > c_1$ – we write in all cases $\frac{1}{2^{c_2}} + 1 - \frac{1}{2^{c_1}} \mod 1$), $x_3 = 1 - \frac{1}{2^{c_1}}$, $x_4 = 0$.



■ **Figure 1** The Increment c_1 module on the top and the GetProb gadget below

An amount of time $t \in (0, \frac{1}{2^{c_1}})$ is spent at B, which is decided by Player $\Diamond$. We rewrite this as $t = \frac{1}{2^{c_1+1}} \pm \epsilon$ for $-\frac{1}{2^{c_1+1}} < \epsilon < \frac{1}{2^{c_1+1}}$. This is because, ideally we want t to be $\frac{1}{2^{c_1+1}}$ and want to consider any deviation as an error.

Now at C, we have $x_1 = t$, $x_2 = \frac{1}{2^{c_2}} + 1 - \frac{1}{2^{c_1}} + t \bmod 1$, $x_3 = 1 - \frac{1}{2^{c_1}} + t$, $x_4 = 0$. The computation proceeds to D with probability $\frac{1}{2}$, and the location ℓ_j corresponding to the next instruction ℓ_j is reached with $x_1 = \frac{1}{2^{c_1}} - t$, $x_2 = \frac{1}{2^{c_2}}$, $x_3 = x_4 = 0$. On the other hand, with probability $\frac{1}{2}$, the gadget *GetProb* is reached. The gadget *GetProb* has 4 target locations $T1, T2, T3, T4$, which we will show are reached with probability $\frac{1}{2}$ from the start location $E0$ of *GetProb* iff $t = \frac{1}{2^{c_1+1}}$. Thus, in this case when $t = \frac{1}{2^{c_1+1}}$, we reach ℓ_j with the values $x_1 = \frac{1}{2^{c_1+1}}$, $x_2 = \frac{1}{2^{c_2}}$, $x_3 = x_4 = 0$ which implies that c_1 has been incremented correctly according to our encoding. We now look at the gadget *GetProb*.

▶ **Lemma 4.** *For any value $\epsilon \in (-\frac{1}{2^{c_1+1}}, \frac{1}{2^{c_1+1}})$, the probability to reach a target location in GetProb from $E0$ is $\frac{1}{2}(1-4\epsilon^2)$ $(\leq \frac{1}{2})$. Further this probability is equal to $\frac{1}{2}$ iff $\epsilon = 0$.*

Proof. Note that when the start location $E0$ of *GetProb* is reached, we have $x_1 = \frac{1}{2^{c_1+1}} + \epsilon$, $x_2 = 0$, $x_3 = 1 - \frac{1}{2^{c_1+1}} + \epsilon$, $x_4 = 0$. A total of 2 time units can be spent at $E0$. It can be seen that transitions to $E3$ and $E4$ are respectively enabled with the time intervals $[0, 1 - \frac{1}{2^{c_1+1}} - \epsilon]$ and $[1, 1 + \frac{1}{2^{c_1+1}} - \epsilon]$. Similarly, reaching $E1$ and $E2$ are enabled by the time intervals $[1 - \frac{1}{2^{c_1+1}} - \epsilon, 1]$ and $[1 + \frac{1}{2^{c_1+1}} - \epsilon, 2]$. The sum of probabilities of reaching either $E3$ or $E4$ is thus $\frac{1}{2}(1-2\epsilon)$. Similarly, the sum of probabilities for reaching $E1$ or $E2$ is $\frac{1}{2}(1+2\epsilon)$. The locations $P1, P2$ are then reached with the values $x_1 = \frac{1}{2^{c_1+1}} + \epsilon$, $x_2 = 0$, $x_3 = 1 - \frac{1}{2^{c_1+1}} + \epsilon$, $x_4 = 0$. The probability of reaching the target locations $T3$ or $T4$ (i.e., through $P1$) from $E0$ is hence $\frac{1}{2}(1+2\epsilon)\frac{1}{2}(1-2\epsilon) = \frac{1}{4}(1-4\epsilon^2)$, while the probability of reaching a target location $T1$ or $T2$ (i.e., through $P2$) from $E0$ is $\frac{1}{2}(1+2\epsilon)\frac{1}{2}(1-2\epsilon) = \frac{1}{4}(1-4\epsilon^2)$. Thus, the probability of reaching a target location (one of $T1, T2, T3, T4$) in *GetProb* is, $\frac{1}{2}(1-4\epsilon^2)$, which is always $\leq \frac{1}{2}$. This completes the first statement of the lemma. Further, from the expression, we immediately have that the probability to reach a target location in *GetProb* from $E0$ is $\frac{1}{2}$ iff $\epsilon = 0$. ◀

The decrement c_1, increment c_2 as well as decrement c_2 modules are similar and these as well as the zero test modules can be found in [1].

▶ **Lemma 5.** *Player $\diamond$ has a strategy to reach the (set of) target locations in $\mathcal{G}$ with probability $\frac{1}{2}$ iff the two-counter machine does not halt.*

Proof. Suppose the two-counter machine halts (say in k steps). Then there are two cases: (a) the simulations of all instructions are correct in $\mathcal{G}$. In this case, the target location can be reached in either of the first k steps. By Lemma 4, the probability of reaching a target location in the first k steps is the summation $\frac{1}{2}.\frac{1}{2} + (\frac{1}{2})^2.\frac{1}{2} + (\frac{1}{2})^3.\frac{1}{2} + \cdots + (\frac{1}{2})^k.\frac{1}{2} < \frac{1}{2}$. (b) Player $\diamond$ made an error in the computation in the first k steps. But then again by Lemma 4, the finite sum obtained is $< \frac{1}{2}$ (since in the error step(s), the probability to reach target locations is $\frac{1}{2} - 4\epsilon^2 < \frac{1}{2}$). Thus, if the two-counter machine halts, under any strategy of $\diamond$ player, the probability to reach the target locations is $< \frac{1}{2}$.

On the other hand, suppose the two-counter machine does not halt. Then, if Player $\diamond$ chooses the strategy which faithfully simulates all instructions of the two-counter machine, the probability to reach the (set of) target locations is given by the infinite sum $\sum_{i=0}^{\infty}(\frac{1}{2})^i\frac{1}{2} = \frac{1}{2}$. Any other strategy of Player $\diamond$ corresponds to performing at least one error in the simulation. In this case, the infinite sum obtained has at least one term of the form $(\frac{1}{2})^k(\frac{1}{2} - 4\epsilon^2)$, for $\epsilon^2 > 0$. Clearly, such an infinite sum does not sum to $\frac{1}{2}$. This concludes the proof. ◀

The previous proof can be changed for other thresholds and to use unbounded intervals and exponential distributions.

3.2 Time-bounded quantitative reachability for $2\frac{1}{2}$ STGs

In this section, we tackle the *time-bounded* version of the quantitative reachability problem. This strengthens the definition of reachability by considering a given time bound Δ, and requiring that $\mathcal{P}_\sigma(\{\rho \in Run(\mathcal{G}, s_0, \sigma) \mid \rho \text{ visits } T \text{ within } \Delta \text{ time units}) \bowtie p$.

In this new framework, we show the undecidability of the quantitative reachability problem for $2\frac{1}{2}$ STGs. We reduce from the *halting* problem for two-counter machines (unlike in the previous section, where our reduction was from the *non-halting* problem), using Player $\square$ to verify the correctness of the simulation. The complication here is that the total time spent should be bounded and hence we cannot allow arbitrary time elapses. We will in fact show a global time bound of $\Delta = 5$ for this reduction.

▶ **Theorem 6.** *The time-bounded quantitative reachability problem is undecidable for $2\frac{1}{2}$ STGs with ≥ 5 clocks.*

Proof. Let $\mathcal{M}$ be a two-counter machine. We construct an STG with 5 clocks such that the two-counter machine $\mathcal{M}$ halts iff Player $\diamond$ has a strategy to reach some desired locations with probability $\frac{1}{2}$, whatever Player $\square$ does, and such that the total time spent is bounded by $\Delta = 5$ units.

The main idea behind the proof is that the total time spent in the simulation of the k^{th} instruction will be $\frac{1}{2^k}$. We thus get a decreasing sequence of times $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8} \dots$ for simulating the instructions $1, 2 \dots$ and so on. In total, we will use five clocks x_1, x_2, z, a and b. The clocks x_1 and x_2 are used encode the counter values (along with the current instruction number) such that at the end of the k^{th} instruction, if k is even the values are encoded in x_1 and if k is odd they are encoded in x_2 as follows:

$(\boldsymbol{enc_{x_1}})$ k is even and $x_1 = \frac{1}{2^{k+c_1}3^{k+c_2}}$, $x_2 = 0$, $z = 1 - \frac{1}{2^k}$, $a = b = 0$;

$(\boldsymbol{enc_{x_2}})$ k is odd and $x_2 = \frac{1}{2^{k+c_1}3^{k+c_2}}$, $x_1 = 0$, $z = 1 - \frac{1}{2^k}$, $a = b = 0$;

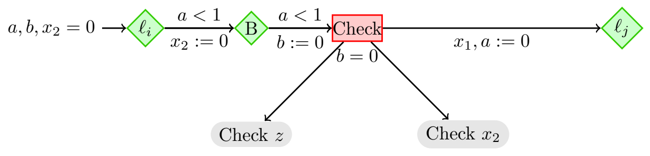


Figure 2 Module for incrementing C_1 (after an even number of steps)

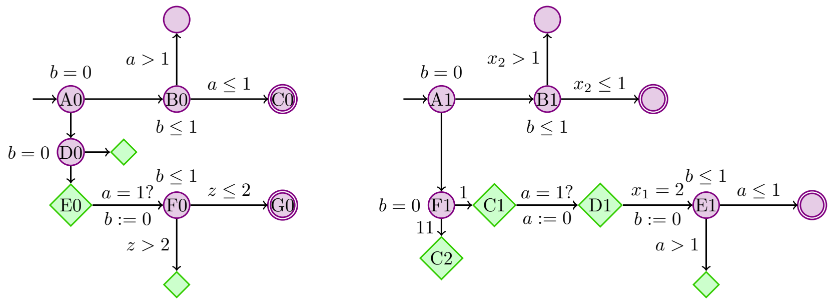

Figure 3 Widgets 'Check z' (left) and 'Check x_2' (right).

We start the simulation with $x_1 = 1, x_2 = z = 0 = a = b$ corresponding to the initial instruction ($k = 0$) and the fact that the values of C_1, C_2 are 0. Moreover, if $x_1 = \frac{1}{2^{k+c_1}3^{k+c_2}}$ at the end of the kth instruction, and if the $(k+1)$th instruction is an increment C_1 instruction, then at the end of the $(k+1)$th instruction, $x_2 = \frac{1}{2^{k+c_1+2}3^{k+c_2+1}}$. Clock z keeps a separate track of the number of instructions simulated so far, by having a value $1 - \frac{1}{2^k}$ after completing the simulation of k instructions. Clocks a and b are auxiliary clocks that we need for the simulation. We assume uniform distribution over delays in probabilistic locations. If no weight is written on an edge, it is assumed to be 1. We outline the simulation of a increment instruction « ℓ_i : increment counter C_1, goto ℓ_j » in Figure 2, assuming this is the $(k+1)$th instruction, where k is even. Thus, at the end of the k first instructions, we have $x_1 = \frac{1}{2^{k+c_1}3^{k+c_2}}$, $z = 1 - \frac{1}{2^k}$ and $a = b = x_2 = 0$ (the other case of odd k, i.e., (enc_{x_2}) encoding is symmetric). At the end of this $(k+1)$th instruction's simulation, the value of clock z should be $z = 1 - \frac{1}{2^{k+1}}$ to mark the end of the $(k+1)^{th}$ instruction. Also, we must obtain $x_2 = \frac{x_1}{2^2 \cdot 3} = \frac{x_1}{12}$, marking the successful increment of C_1.

Player $\diamond$ elapses times t_1, t_2 in locations ℓ_i, B. When the player $\Box$ location *Check* is reached, we have $a = t_1 + t_2 = t$ and $x_2 = t_2$, $z = 1 - \frac{1}{2^k} + t_1 + t_2$. Player $\Box$ has three possibilities : (1) to continue the simulation going to ℓ_{k+2}, (2) verify that $t_2 = \frac{1}{2^{k+c_1+2}3^{k+c_2+1}}$ by going to the widget 'Check x_2' or (3) verify that $t_1 + t_2 = \frac{1}{2^{k+1}}$ by going to the widget 'Check z'. These widgets are given in Figure 3. The probability of reaching a target location in widget 'Check z' is $\frac{1}{2}(1-t) + \frac{1}{4}\frac{1}{2^k} = \frac{1}{2}$ iff $t = \frac{1}{2^{k+1}}$. In widget 'Check x_2', the transitions from $F1$ to $C1$ and $F1$ to $C2$ are taken with probability $\frac{1}{12}$ and $\frac{11}{12}$, respectively since the weights of edges connecting F1,C1 and F1,C2 are respectively 1 and 11. With this, for $n = \frac{1}{2^{k+c_1}3^{k+c_2}}$, the probability of reaching a target location in 'Check x_2' is $\frac{1}{2}(1-t_2) + \frac{n}{24} = \frac{1}{2}$ iff $t_2 = \frac{n}{12}$.

Time elapse for Increment. If player $\Box$ goes ahead with the simulation, the time elapse for the $(k+1)$th instruction is $t_1 + t_2 = \frac{1}{2^{k+1}}$. Consider the case when player $\Box$ goes in to 'Check z'. The time elapse till now is $\frac{1}{2} + \cdots + \frac{1}{2^{k+1}}$. The time spent in the 'Check z' widget is as follows: one unit is spent at location $B0$, one unit at location $F0$, and $1 - t$ units at location

$E0$. Thus, ≤ 3 units are spent at the 'Check z' widget. Similarly, the time spent in the 'Check x_2' widget is one unit at $B1$, $1-t$ units at $C1$, $1-n$ units at $D1$ and one unit at $E1$. Thus a time ≤ 4 is spent in 'Check x_2'. Thus, the time spent till the $(k+1)$th instruction is $\leq \frac{1}{2} + \dots \frac{1}{2^{k+1}} + 4$ if player $\square$ goes in for a check, and otherwise it is $\frac{1}{2} + \dots + \frac{1}{2^{k+1}}$.

Other increment, decrement, zero-check Instructions. The main module corresponding to *increment* C_2 and decrement C_1, C_2 is the same as in Figure 2. The only change needed is in the 'Check x_2' widget. While incrementing c_2, we need $x_2 = \frac{x_1}{2 \cdot 3^2} = \frac{x_1}{18}$. This is done by changing the weights on the outgoing edges from $F1$ to $C1$ and $C2$ to 1 and 17 respectively. Similarly, while *decrementing* C_1, we need $x_2 = \frac{x_1}{3}$. This is done by changing the weights on the outgoing edges of $F1$ to $1, 2$ respectively. Lastly, to *decrement* C_2, we need $x_2 = \frac{x_1}{2}$, and in this case the weights are 1 each.

The zero check module is a bit more complicated. The broad idea is that we use a diamond node to guess whether the current clock (say C_1) value is zero and branch into two sides (zero and non-zero). Then we use a box node on each branch to verify that the guess was correct. If correct, we proceed with the next instruction, if not, we check this by going to a special widget. In this widget, we can reach a target node with probability $\frac{1}{2}$ iff the guess is correct. The details of this widget and the proof that all these simulations can be done in time bounded by $\Delta \leq 5$ units is given in [1]. ◀

4 Decidability results for quantitative reachability

We have seen in the previous section that the quantitative reachability problem is undecidable in $1\frac{1}{2}$ STGs with ≥ 4 clocks. In this section we study the *quantitative reachability* problem in the setting of $1\frac{1}{2}$ STGs *with a single clock*. In [8], the quantitative reachability problem in $\frac{1}{2}$ STGs with a single clock, under certain restrictions, was shown to be decidable by reducing it to the quantitative reachability problem for finite Markov chains. In our case, we lift this to $1\frac{1}{2}$ STGs with a single clock, under similar restrictions, by reducing to the quantitative reachability problem in finite Markov decision processes (MDPs in short).

For the rest of this section, we consider a $1\frac{1}{2}$ STG $\mathcal{G} = (\mathcal{A}, (L_\diamond, L_\bigcirc), \omega, \mu)$ with a single clock denoted x. We write $c_{\max}$ for the maximal constant appearing in a guard of $\mathcal{G}$. We assume w.l.o.g. that target locations belong to player $\diamond$ (a slight modification of the construction can be done if this is not the case). In the following, when we talk about regions, we mean the clock regions from the classical region construction for timed automata [2, 19]: since $\mathcal{G}$ has a single clock, regions in this case are simply either singletons $\{c\}$ with $c \in \mathbb{Z}_{\geq 0} \cap [0; c_{\max}]$, or open intervals $(c, c+1)$ with $c \in \mathbb{Z}_{\geq 0} \cap [0; c_{\max} - 1]$, or the unbounded interval $(c_{\max}; +\infty)$. While region automata are standardly finite automata, we build here from $\mathcal{G}$ a *region STG* $\mathcal{G}_\mathcal{R}$, which has only clock constraints defined by regions (that is, either $x = c$ or $c < x < c+1$ or $x > c_{\max}$), and such that each location of $\mathcal{G}_\mathcal{R}$ is indeed a pair (ℓ, R) where ℓ is a location of $\mathcal{G}$ and R a region (region R is for the region which is hit when entering the location). While it is not completely standard, this kind of construction has been already used in [9, 8, 12], and questions asked on $\mathcal{G}$ can be equivalently asked (and answered) on $\mathcal{G}_\mathcal{R}$. Now, we make the following restrictions on $\mathcal{G}_\mathcal{R}$ (which yields restrictions to $\mathcal{G}$), which we denote $(\star)$:

1. The TA $\mathcal{A}_\mathcal{R}$ is assumed to be structurally non-Zeno: any bounded cycle of $\mathcal{A}_\mathcal{R}$ (a cycle in which all edges have a non-trivial upper-bound) contains at least one location whose associated region is the zero region (i.e., edge leading to it, resets the clock).

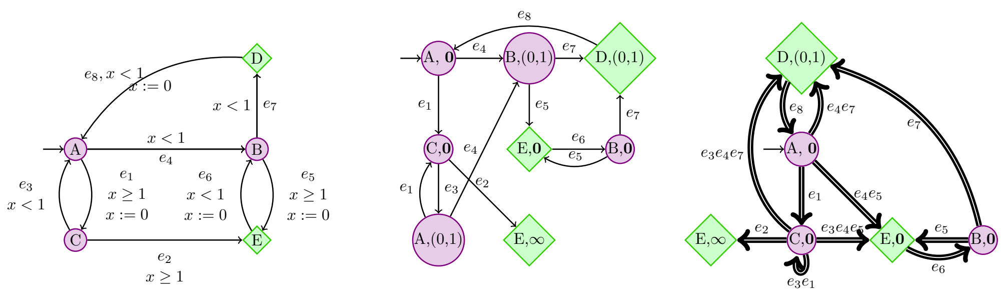

Figure 4 An initialized $1\frac{1}{2}$ player STG $\mathcal{G}$, its region game graph $\mathcal{G}_\mathcal{R}$ and the MDP abstraction $M_\mathcal{G}$.

2. For every state $s = ((\ell, r), \nu)$ of $\mathcal{G}_\mathcal{R}$ such that $\ell \in L_\bigcirc$, $I(s) = \mathbb{R}_{\geq 0}$, and μ_s is an exponential distribution; Furthermore the rate of μ_s only depends on location ℓ.
3. $\mathcal{G}_\mathcal{R}$ is *initialized*, that is, any edge from a non-stochastic location to a stochastic location resets the clock x.

While the first two assumptions are already made in [8], even in the $\frac{1}{2}$ player case, the third condition is new. In the following we denote $\mathbf{0}$ for the region $\{0\}$ and ∞ for the unbounded region $(c_{\max}; +\infty)$. We now show how to obtain an MDP from the STG $\mathcal{G}_\mathcal{R}$. The construction is illustrated on Figure 4. A node (ℓ, R) of $\mathcal{G}_\mathcal{R}$ with $\ell \in L_\bigcirc$ is *deletable* if R is neither the region 0 nor the region ∞. In Figure 4, $(B, (0,1))$ and $(A, (0,1))$ in $\mathcal{G}_\mathcal{R}$ are what we call deletable nodes. Then, we recursively remove all deletable nodes $\mathcal{G}_\mathcal{R}$ while labelling remaining paths with (finite) sequences of edges; each surviving edge is labelled by the probability of the (provably) finitely many sequences of edges appearing in the label. One can prove that this object is actually an MDP, which we denote $M_\mathcal{G}$. Target states in $M_\mathcal{G}$ are defined as the pairs (ℓ, R) where ℓ is a target location in $\mathcal{G}$. We can prove (see [1]) that:

▶ **Lemma 7.** *If $\mathcal{G}$ is an $1\frac{1}{2}$ player STG with one clock satisfying the hypotheses $(\star)$, then $M_\mathcal{G}$ is an MDP such that: (a) for every strategy $\lambda_\diamond$ of player $\diamond$ in $\mathcal{G}$, we can construct a strategy $\sigma_\diamond$ of player $\diamond$ in $M_\mathcal{G}$ such that the probability of reaching a target location in $\mathcal{G}$ is the same as the probability of reaching a target state in $M_\mathcal{G}$; and (b) for every strategy $\sigma_\diamond$ of player $\diamond$ in $M_\mathcal{G}$, we can construct a strategy $\lambda_\diamond$ of player $\diamond$ in $\mathcal{G}$ such that the probability of reaching a target location in $M_\mathcal{G}$ is the same as the probability of reaching a target state in $\mathcal{G}$.*

This lemma allows to reduce the quantitative reachability problem from the $1\frac{1}{2}$ STG $\mathcal{G}$ to the MDP $M_\mathcal{G}$.

As an example, in Figure 4, we show a $1\frac{1}{2}$ player STG $\mathcal{G}$, its region game graph $\mathcal{G}_\mathcal{R}$ (guards omitted for readability) and the MDP abstraction $M_\mathcal{G}$. Note that all $\diamond$ nodes remain, while only those stochastic nodes with regions $\mathbf{0}$ and ∞ are retained in $M_\mathcal{G}$. The stochastic nodes $(B, (0,1))$ as well as $(C, (0,1))$ are deleted in $M_\mathcal{G}$. On deleting nodes from the region graph, the probability on the edges of $M_\mathcal{G}$ is the probability of the respective paths from the region graph. For example, the edge from $(A, 0)$ to $(D, (0,1))$ is labelled with e_4e_7 by deleting $(B, (0,1))$.

Thus, the remaining thing that has to be addressed now is how to compute the probabilties and compare them with a rational threshold. The first thing to note is that the edges of the MDP are all labelled with polynomials over exponentials obtained using the delays from the underlying game with rational coefficients. For example, in Figure 4, in the MDP in the rightmost picture, we obtain: $\mathcal{P}(e_1)$=$\mathcal{P}(e_2)$=$\mathcal{P}(e_5)$=e^{-1}, $\mathcal{P}(e_6, e_7, e_8)$=$1-e^{-1}$,

$\mathcal{P}(e_4e_5)=e^{-1}-e^{-2}$, $\mathcal{P}(e_4e_7)=1-2e^{-1}$, $\mathcal{P}(e_3e_4e_7)=2-5e^{-1}+e^{-2}$, $\mathcal{P}(e_3e_4e_5)=1-e^{-1}+e^{-2}$, $\mathcal{P}(e_3e_1)=\frac{1}{2}(1-e^{-2})$. It can be seen that we can write each of these probabilities as a polynomial in e^{-1}. More generally, for any MDP with differing rates (of the exponential distribution) in each state, we get a set of rational functions in $e^{-\frac{1}{q}}$ for some $q \in \mathbb{Z}_{>0}$, where q is obtained as a function of the rates in each state. Thus, using standard algorithms for MDPs [6], and as done for Markov chains in [8], we get that we can compute expressions for the probability of reaching the targets, and decide the threshold problem.

▶ **Theorem 8.** *Quantitative reachability for 1-clock $1\frac{1}{2}$-player STGs satisfying ($\star$) is decidable.*

We can lift this construction to include $\Box$ player nodes, keeping the same initialized restriction with $\Box$ nodes as well. Then the region game graph $\mathcal{G}_{\mathcal{R}}$ includes $\Box$ nodes in the obvious way, and we consider strategy profiles of $\Box$ and $\Diamond$. The question then is to check if $\Diamond$ has a strategy to reach a target with probability $\sim c$ against all possible strategies of $\Box$ in $M_{\mathcal{G}}$. Hence we have that

▶ **Corollary 9.** *Quantitative reachability for 1-clock $2\frac{1}{2}$ player STGs satisfying ($\star$) is decidable.*

5 Discussion

In this paper, we have refined the decidability boundaries for STGs as summarized in the table in Introduction. The significance of our undecidability results for quantitative reachability (via different two-counter machine reductions) lies in the fact that they introduce ideas which could potentially help in settling other open problems. We highlight these below:

- for $1\frac{1}{2}$ player games, the crux is to cleverly encode the error ϵ made by player $\Diamond$ in such a way that it reflects as $\frac{1}{2} - \epsilon^2$ in the resulting probability. This ensures that the $\Diamond$ player can never cheat and the probability will be $< \frac{1}{2}$ as soon as there is an error (even when simulating a non-halting run of the two-counter machine). Indeed, this is why the reduction is from the non-recursively enumerable non-halting problem.
- for $2\frac{1}{2}$ player games in the *time-bounded setting*, we obtain undecidability by showing a reduction from halting problem for two-counter machines. This is surprising, as time-boundedness restores decidability in several classical undecidable problems like the inclusion problem in timed automata [20, 21]. In the case of priced timed games [14], time-boundedness gives undecidability; however, this can be attributed to the fact that price variables are not clocks, and can grow at different rates in different locations. Somehow, the combination of simple clocks and probabilities achieves the same.

Combining these ideas might allow us, for eg., to improve Theorem 6 by showing undecidability of time bounded, quantitative reachability in $1\frac{1}{2}$ player STGs with a larger number of clocks. The main challenge is to replace $\Box$ player nodes by stochastic nodes, and adapt the gadgets in such a way that, within a global time bound, the probability of reaching a target is $\frac{1}{2}$ iff all simulations are correct and the two-counter machine does not halt. As another example, if in the first item above, we obtain a probability of $1 - \epsilon^2$ (rather than $\frac{1}{2} - \epsilon^2$), this would settle the (currently open) *qualitative* reachability problem for $2\frac{1}{2}$ games [12].

Coming to decidability results, we have for the first time characterized a family of $1\frac{1}{2}$,$2\frac{1}{2}$ player STGs for whom the quantitative reachability is decidable. The use of exponential distributions is mandatory to get a closed form expression for the probability. It is unclear if this construction can be extended to some larger classes of STGs. Figure 9 in [9] shows an example of a two-clock $\frac{1}{2}$ player game for which the region abstraction fails to give any relevant information on the real "probabilistic" behaviour of the system (lack of so-called fairness); in particular it cannot be used for qualitative, and therefore quantitative, analysis of reachability properties. The decidability of qualitative reachability in $1\frac{1}{2}, 2\frac{1}{2}$, multi-clock STG seems then hard due to the same problem of unfair runs.

Abstract

We study a revenue maximization problem in the context of social networks. Namely, we consider a model introduced by Alon, Mansour, and Tennenholtz (EC 2013) that captures *inequity aversion*, i.e., prices offered to neighboring vertices should not be significantly different. We first provide approximation algorithms for a natural class of instances, referred to as the class of single-value revenue functions. Our results improve on the current state of the art, especially when the number of distinct prices is small. This applies, for example, to settings where the seller will only consider a fixed number of discount types or special offers. We then resolve one of the open questions posed in Alon et al., by establishing APX-hardness for the problem. Surprisingly, we further show that the problem is NP-complete even when the price differences are allowed to be relatively large. Finally, we also provide some extensions of the model of Alon et al., regarding the allowed set of prices.

1 Introduction

We study a differential pricing optimization problem in the presence of network effects. Differential pricing is a well known practice in everyday life and refers to offering a different price to potential customers for the same service or good. Examples include offering cheaper prices when launching a new product, making special offers to gold and silver members of an airline miles program, offering discounts at stores during selected periods, and several others.

We are interested in studying differential pricing in the context of a social network. Imagine a network connecting individuals (who are seen as potential clients here) with their friends, family, or colleagues, i.e., with people who can exert some influence on them. One can have in mind other forms of abstract networks as well, e.g., a node could represent a geographic region, a neighborhood within a city, a type of profession, a social class, and edges can represent interactions or proximity. The presence of such a network creates *externality*

[*] This research was supported by National Science Centre, Poland, 2015/17/N/ST6/03684. effects, meaning that the decision of a node to acquire a new product or a new service is affected by the fact that some other nodes within her social circle (her neighborhood in the graph) already did so. A typical example of positive externalities is when someone becomes more likely to buy a new product due to the positive reviews by a friend who already bought it in the past. Modeling positive externalities has led to a series of works that study marketing strategies for maximizing the diffusion of a new product, [7, 14], or the total revenue achieved, [13] (see also the Related Work section).

However, there also exist negative externality effects that can arise in a network. One example is the purchase of a product with the intention to show off and be a locally unique owner, e.g., a new type of expensive car, or clothes (also referred to as *invidious consumption*, see [5]). In such a case, a node may be deterred from buying the same product, if a neighboring node already did so. A second example of negative externalities, which is the focus of our work, and arises from differential pricing, is *inequity aversion*, see e.g., [4] and [8]. This simply means that a customer may experience dissatisfaction if she realizes that other people within her social circle, were offered a better deal for the same service. Hence, significant price differences, can create a negative response of some customers towards a product. Inequity aversion can also arise under a different, but equally applicable, interpretation: nodes may correspond to retail stores and an edge can signify proximity, so that clients could choose among these stores. Again, having significantly different prices to the same products is not desirable.

To capture the need for avoiding such phenomena, the relatively recent work of [2] introduced a model for pricing nodes over a social network. The main idea is to impose constraints on each edge, specifying that the price difference between two neighbors should be bounded by some (endogenous) parameter, determined by the two neighbors. On top of this, the seller is also allowed to not make a price offer to some nodes (referred to as introducing *discontinuities*, see the related discussion in Section 2), in which case the difference constraints do not apply for the edges incident to these nodes. Assuming a finite set of available prices, unit-demand users, and digital goods (i.e., the supply can cover all the demand) the problem is to find a feasible price vector that satisfies the edge constraints and maximizes the total revenue. In its more general form the problem was shown to be NP-complete, but exact or approximation algorithms were derived for some interesting cases.

Contribution: We revisit the model introduced by [2] (namely Model II of [2], which is the more general one), and study the approximability of the underlying revenue maximization problem. We resolve one of the open questions posed in [2], regarding the complexity of the problem under the natural class of the so-called *single-value* revenue functions. Simply put, this means that the revenue extracted by each node is exactly the price offered to her, as long as the price does not exceed her valuation for the product (the usual assumption made in auction settings as well). We first establish APX-hardness for this class answering the question of [2], and we also show that the problem is NP-complete even when the price differences are allowed to be relatively large (a case that could be thought easier to handle). We then provide approximation algorithms that improve some of the currently known results. Our improvement is stronger when the number of distinct prices is small. This applies for example to many settings where the seller will only consider a fixed number of discount types or special offers to selected customers. As the number of available price offers becomes large, the performance of our algorithm degrades to a logarithmic approximation. Finally, we provide an extension of these results to a more general model where the allowed prices come from a set of k arbitrary integers, instead of using price sets of the form $\{1, 2, \ldots, k\}$, as done in [2] (see Subsection 4.3).

Related Work: Price discrimination is well studied in various domains in economics and is also being applied to numerous real life scenarios. The algorithmic problem of differential pricing over social networks is a more recent topic, initiated by [13]. The work of [13] studied a model with positive externalities, where the valuation of a player may increase as more friends acquire a good, and analyzed the performance of a very intuitive class of pricing strategies. Further improvements on the performance of such strategies were obtained later on by [9]. The work of [1] also considers a pricing problem but in an iterative fashion, where the seller is allowed to reprice a good in future rounds. Revenue maximization under a mechanism design approach was also taken in [12] under positive network externalities. Finally, positive externalities have been used to model the diffusion of products on a network, see, among others, the exposition in [15].

Negative externalities within networks, as we focus on here, are less studied in the literature. For the concept of inequity aversion, see e.g., [4, 8]. The work most closely related to ours is [2], which introduced the model that we consider here. Efficient algorithms were obtained for the case where discontinuities are not allowed (even for more general revenue functions), and also for networks with bounded treewidth. An approximation ratio of $1/(\Delta + 1)$ was also provided, where Δ is the maximum degree. Similar results were shown for a stochastic version of the model. Finally, other types of negative externalities have been considered e.g., in [3, 5] which study the effects of invidious consumption.

2 Definitions and Preliminaries

The social network is represented as an undirected graph $G = (V, E)$, with $|V| = n$. We assume that a provider of some good or service has a finite set P of available prices that he could offer to the nodes. In most of our presentation, we assume as in [2], that the available prices are given by $P = \{1, 2, \ldots, k\}$. In Subsection 4.3, we show how to extend the analysis when P is an arbitrary set of k positive integers, i.e., $P = \{p_1, p_2, \ldots, p_k\}$.

We assume every node has a unit-demand for the same product and that the supply of the seller is enough to cover the demand of all nodes. For every node $v \in V$, we associate a revenue function $R_v : \{1, 2, \ldots, k\} \mapsto \mathbb{N}$ that maps an offered price p_v to the revenue that the provider gains from this offer. In this paper, we focus on a simple and intuitive class of revenue functions, also studied in [2]. In particular, for a node $v \in V$, R_v is called a *single value revenue function*, if there exists a value $val(v)$ such that when offered a price p_v:

$$R_v(p_v) = \begin{cases} p_v & \text{if } val(v) \geqslant p_v \\ 0 & \text{if } val(v) < p_v \end{cases}$$

We assume from now on that every node has a single value revenue function. We also assume that $val(v) \in P$, for every $v \in V$. This is because for revenue maximization, that we are interested in, nodes with $val(v) > k$, can only yield a revenue of k, and could be replaced by $val(v) = k$, i.e., the highest possible price. Also for values that are less than k, and not integers, we can again extract only an integer revenue, given the form of P. Finally, any node v with $val(v) < 1$ can be deleted without affecting the optimal revenue (see the concept of *discontinuity* defined below), so we can completely ignore such nodes to begin with. Thus, we consider only instances with $val(v) \in \{1, 2, \ldots, k\}, \forall v \in V$.

Given a vector $\mathbf{p} = (p_v)_{v \in V}$ of prices offered to the nodes, the total revenue is $R(\mathbf{p}) = \sum_{v \in V} R_v(p_v)$. Hence, our goal is to find a price vector that maximizes the total revenue. At the same time, however, we want to capture the effect of *inequity aversion* [4, 8] in social networks. This means that a node may experience dissatisfaction if she sees that other nodes within her social circle, were offered a better deal for the same service. Hence, significant price differences, create negative externalities among users.

To avoid such situations the model introduced in [2] has constraints on each edge, stating that the price difference between two neighbors u, v is bounded, i.e., $p_u - p_v \leqslant \alpha(u,v)$ and $p_v - p_u \leqslant \alpha(v,u)$, for every $(u,v) \in E$. Here, $\alpha(\cdot,\cdot) \geqslant 0$ is integer-valued (given that the prices are also integers) and note that in general is non-symmetric. Furthermore, the seller is also allowed not to make an offer to certain nodes. Formally, this is captured by having one more price option, which we denote by $\perp$, with $R_v(\perp) = 0$. Setting $p_v = \perp$ to a node, means that the provider does not make any offer to v, and there is no price restriction on the edges that are incident to v. We can essentially think about this as deleting these vertices from the graph. We will refer to setting $p_v = \perp$ to a node $v \in V$, as introducing a *discontinuity* on v. Avoiding making an offer can be thought of as choosing not to promote a product or service within a certain region or within a certain social group. In terms of optimization, allowing discontinuities can help the seller in producing much higher revenue (than without discontinuities) as Proposition 3 in Section 3 states.

Given this model, the set of feasible price vectors is then: $\mathcal{F} = \{\mathbf{p} : \forall\ v \in V, p_v \in P \cup \{\perp\}$, and $\forall\ (u,v) \in E,\ p_u \neq \perp\ \wedge\ p_v \neq \perp \Rightarrow p_u - p_v \leqslant \alpha(u,v)\ \wedge\ p_v - p_u \leqslant \alpha(v,u)\}$. Therefore, the problem we study is:

Inequity Aversion Pricing: Given a graph with edge constraints, and a single-value revenue function for each node, find a feasible price vector that maximizes the total revenue, i.e., find $\mathbf{p} \in \mathcal{F}$ that achieves $\max_{\mathbf{p} \in \mathcal{F}} \sum_{v \in V} R_v(p_v)$.

Some cases of this problem, as well as the variant where no discontinuities are allowed, are already known to be polynomial time solvable [2]. Regarding hardness, although the problem is NP-hard for more general revenue functions, it was posed as an open question whether NP-hardness still holds for single value revenue functions (the hardness result in [2] requires instances with revenue functions that cannot be captured by single value ones).

3 Warm-up: Basic Facts and Single-price Solutions

In this section, we present a simple algorithm and some basic observations, which we use later on, in Section 4.

Let $v_{\max} = \max_{v \in V} val(v) \leqslant k$, and $\text{MAX} = \sum_{v \in V} val(v)$. Given an instance of the problem, we denote by OPT the revenue of an optimal solution. The quantity MAX is clearly an upper bound on the optimal revenue, hence $\text{OPT} \leqslant \text{MAX}$.

We will refer to a solution as being a *single-price* solution, if it charges the same price to every node without introducing discontinuities. Note that this is always a feasible solution since all the edge constraints are satisfied. The revenue extracted by a single-price algorithm that uses the price of p for all nodes is equal to $p \cdot |\{v \in V : val(v) \geqslant p\}|$.

To understand whether single-price solution can be of any help for our setting, we can examine the performance of the best possible single price. The following observation suggests that we do not need to try too many values, even if v_{max} is very large.

▶ **Lemma 1.** *In order to find the optimal single-price solution, it suffices to check at most* $\min\{n, v_{\max}\}$ *possible prices.*

Proof. There are at most $min\{n, v_{\max}\}$ different values in the set $\{val(v) : v \in V\}$. It is never optimal to use any price $p \notin \{val(v) : v \in V\}$. Indeed, if $p \in (val(v_1), val(v_2))$, where $val(v_1)$ and $val(v_2)$ are two consecutive distinct values for some nodes $v_1, v_2 \in V$, then it is strictly better to set the price to $val(v_2)$. For the same reason, it is suboptimal to set a price that is less than the minimum value across nodes, while if we use a price $p > v_{\max}$ then we gain no revenue. ◀

Hence in $O(\min\{n, v_{\max}\})$ steps, we can select the best single-price solution. Let us denote by R_{SP} the revenue raised by this solution. The performance of R_{SP} has been analyzed in a different context[1] by [11], where it was shown that it achieves a $\Theta(\ln n)$-approximation. Here we give a slightly tighter statement, which we utilize in later sections for small values of v_{max}.

▶ **Theorem 2.** *For any number n of agents, the optimal single-price solution achieves a $1/H_r$-approximation, where $r = \min\{n, v_{\max}\}$, and H_ℓ is the ℓ-th harmonic number, i.e.,*

$$R_{\text{SP}} \geqslant \frac{\text{MAX}}{H_r} \geqslant \frac{\text{OPT}}{H_r}\,.$$

Furthermore, the approximation guarantee is tight.

The proof is deferred to the full version of the paper. One interesting point here, is that single-price solutions do not use any discontinuities. If R_{ND} is the maximum revenue without using any discontinuities, clearly $R_{\text{ND}} \geqslant R_{\text{SP}}$. And as we mentioned in Section 2, it is possible to find the optimal solution that does not use discontinuities in polynomial time; so why use something worse instead of R_{ND}? Actually, besides being harder to argue about, R_{ND} turns out to be as bad an approximation as R_{SP}, in the worst case. Hence, the proposition below reveals that introducing discontinuities can cause a significant increase in the optimal revenue achievable by the seller, compared to what can be achieved without discontinuities.

▶ **Proposition 3.** *The optimal solution with no discontinuities achieves a $1/H_r$-approximation, where $r = \min\{n, v_{\max}\}$, and this approximation guarantee is tight.*

The proof of Proposition 3 is deferred to the full version of the paper.

4 Approximation of Inequity Aversion Pricing

In this section we present new approximation algorithms for the problem by exploiting ways in which setting discontinuities in certain nodes can help. Our main result is an approximation algorithm, with a ratio of $(H_k - 0.25)^{-1}$. Even though asymptotically this is no better than the optimal single-price algorithm, it does yield better ratios for instances where k is a small constant. The motivation for studying cases where the set of available prices is a small constant is that a seller may be willing to offer only specific types of discount to selected customers, e.g., 20% or 30% off the regular price and so on, rather than using an arbitrary set of prices.

We start below with the case of $k = 2$, before we move to the more general case.

4.1 A 0.8-approximation Algorithm when $P = \{1, 2\}$ via Vertex Cover

In this subsection, we assume the available prices are 1, 2, or $\perp$. Despite this restriction, the problem still remains non-trivial, and it is currently not known if it is NP-complete

[1] The work of [11] studied an auction pricing problem without the presence of social networks.

Algorithm 1: A 0.8-approximation when $P = \{1, 2\}$

```
1 Given the graph $G = (V, E)$, construct the bipartite graph $G' = (V_1, V_2, E')$ with
  $V_i = \{v \in V : val(v) = i\}$ and $E' = \{(u, v) \in E : val(u) = 2, val(v) = 1, \alpha(u, v) = 0\}$
2 Find a minimum vertex cover on $G'$, say $S \subseteq V$
3 Set $\perp$ to all vertices of $S$
4 Set a price of 1 to every $v \in V_1 \setminus S$ and a price of 2 to every $v \in V_2 \setminus S$. Let $R^*$ be the revenue
  obtained by this solution
5 Compute the optimal single-price solution, as described in Section 3, with revenue $R_{\mathrm{SP}}$
6 Return the solution that achieves $\max\{R^*, R_{\mathrm{SP}}\}$
```

or not. Given the discussion in Section 2, we will also assume that for every node $v \in V$, $val(v) \in \{1, 2\}$. For such instances we already have a $\frac{2}{3}$-approximation by Theorem 2, that does not use discontinuities. The difficulty in improving this factor is in finding a way of selecting appropriate nodes to set to $\perp$.

Before we describe our algorithm, let us illustrate the main idea. Consider an instance of the problem on a graph $G = (V, E)$. Suppose we plan to find a feasible price vector, such that for each u, either $p_u = \perp$ or $p_u = val(u)$. Since the possible prices are only 1 and 2, if $val(u) = 1$, then for any $(u, v) \in E$, $\alpha(u, v)$ is not restrictive, while if $val(u) = 2$, then for any $(u, v) \in E$, $\alpha(u, v)$ is restrictive only if $\alpha(u, v) = 0$ and $val(v) = 1$. So, we could remove any edge except from edges in $E' = \{(u, v) \in E : val(u) = 2, val(v) = 1, \alpha(u, v) = 0\}$. Note that this defines a bipartite subgraph $G' = (V_1, V_2, E')$ of G, where $V_i = \{v \in V : val(v) = i\}$. Since this new instance has less restrictions, the optimal revenue OPT' is at least as good as the optimal revenue OPT of the original instance.

Consider a vertex cover S in G'. The crucial observation is that we can satisfy all the edge constraints regarding edges between V_1 and V_2, by introducing discontinuities on the vertices of S. Since S covers all the edges between V_1 and V_2, the edge constraints between V_1 and V_2 in the original graph G are now non-existent. If we also set a price of 1 on the remaining vertices of V_1 and a price of 2 on the remaining vertices of V_2, all the original constraints are satisfied. Thus, we have constructed a feasible solution for G.

The revenue of such a solution is $\mathrm{MAX} - val(S)$, where $\mathrm{MAX} = \sum_{v \in V} val(v) = |V_1| + 2 \cdot |V_2|$ and $val(S) = \sum_{v \in S} val(v)$. Hence, the best outcome of such an algorithm is achieved when S is a minimum weighted vertex cover (using the values as weights) rather than just any vertex cover. For the analysis however, it suffices to compute just a minimum vertex cover (see the Remark after the proof of Theorem 4). Moreover, by the Kőnig–Egerváry Theorem, we can compute this in polynomial time for bipartite graphs (e.g., see [16]).

Finally, the algorithm compares the best of two outcomes, the solution outlined above and the solution discussed in Section 3. Hence, we define $\mathrm{ALG} = \max\{R_{\mathrm{SP}}, \mathrm{MAX} - val(S)\}$, where R_{SP} is the maximum revenue achieved by setting a fixed price to every node.

▶ **Theorem 4.** *Algorithm 1 achieves a* 0.8*-approximation for the Inequity Aversion Pricing problem when* $P = \{1, 2\}$*. Furthermore, this ratio is tight.*

Proof. Let ALG denote the revenue obtained by Algorithm 1 and let β be its approximation ratio that we attempt to determine. Assume that $\beta < 0.8$. Then there exists some $\epsilon > 0$ such that $\beta = 0.8 - \epsilon$. To arrive at a contradiction, we are going to show that $\beta \geqslant \gamma = 0.8 - \epsilon/2$.

We will distinguish some cases, depending on the value of ALG. First of all, note that if $\mathrm{ALG} \geqslant \gamma \cdot \mathrm{MAX}$, then we trivially obtain a γ-approximation: $\frac{\mathrm{ALG}}{\mathrm{OPT}} \geqslant \frac{\gamma \cdot \mathrm{MAX}}{\mathrm{MAX}} \geqslant \gamma$. From now on, assume that $\mathrm{ALG} < \gamma \cdot \mathrm{MAX}$. The following turns out to be a very useful upper bound for OPT.

▶ **Claim 5.** *Let S denote a minimum vertex cover in the graph G' (defined in step 1 of Algorithm 1). Then,* $\mathrm{OPT} \leqslant \mathrm{OPT}' \leqslant \mathrm{MAX} - |S|$.

Proof of Claim 5. The first inequality is straightforward (see also the discussion before the theorem). For the second inequality, note that by the Kőnig–Egerváry Theorem, the maximum matching in G' has the same cardinality as S. Let M be such a maximum matching. By the definition of G', for each edge $(u, v) \in M$ the nodes u and v have different values, say $val(u) = 2$ and $val(v) = 1$. Because of (u, v), an optimal solution must lose at least one unit of revenue in comparison with MAX. Indeed, since $\alpha(u, v) = 0$, an optimal solution either sets a discontinuity on one of these two nodes, or it sets the same price. If this common price is 1, we lose one unit from node v, whereas if it is 2 we do not extract revenue from u. The claim follows. ◁

We know that $\mathrm{ALG} = \mathrm{MAX} - val(S)$ and also $val(S) \leqslant 2|S|$. Thus, $|S| \geqslant \frac{1}{2}(\mathrm{MAX} - \mathrm{ALG})$. If we combine this with Claim 5, we have

$$\mathrm{OPT} \leqslant \frac{1}{2}(\mathrm{MAX} + \mathrm{ALG})\,. \tag{1}$$

To proceed with the analysis, we divide the interval $[0, \gamma \cdot \mathrm{MAX}]$ into smaller subintervals of the form $\left[\frac{i-1}{m} \cdot \gamma \cdot \mathrm{MAX}\,,\ \frac{i}{m} \cdot \gamma \cdot \mathrm{MAX}\right)$ for some fixed large m and $i \in \{1, \cdots, m\}$. Notice that m is just a parameter in the analysis and has nothing to do with the input. We consider cases depending on where exactly the value of ALG falls. In particular, let i^* be the following interval index: $i^* = \left\lceil \frac{m+2}{2-\gamma} \right\rceil$.

Case (i): $\mathrm{ALG} \in \left[\frac{i-1}{m} \cdot \gamma \cdot \mathrm{MAX}, \frac{i}{m} \cdot \gamma \cdot \mathrm{MAX}\right)$ with $i \geqslant i^*$.
Using inequality (1), we have:

$$\frac{\mathrm{ALG}}{\mathrm{OPT}} \geqslant \frac{\frac{i-1}{m} \cdot \gamma \cdot \mathrm{MAX}}{\frac{1}{2}(\mathrm{MAX} + \mathrm{ALG})} \geqslant \frac{\frac{i-1}{m} \cdot \gamma \cdot \mathrm{MAX}}{\frac{1}{2}(\mathrm{MAX} + \frac{i}{m} \cdot \gamma \cdot \mathrm{MAX})} = \frac{\frac{i-1}{m} \cdot \gamma}{\frac{1}{2}(1 + \frac{i}{m} \cdot \gamma)}\,.$$

In order to ensure a γ-approximation, it suffices to have

$$\frac{\frac{i-1}{m} \cdot \gamma}{\frac{1}{2}(1 + \frac{i}{m} \cdot \gamma)} \geqslant \gamma \iff \frac{i-1}{m} \geqslant \frac{1}{2}\left(1 + \frac{i}{m} \cdot \gamma\right) \iff i \geqslant \frac{m+2}{2-\gamma}\,.$$

But this last inequality holds since $i \geqslant i^*$. Therefore, in this case, the algorithm achieves a γ-approximation.

Case (ii): $\mathrm{ALG} < \frac{i^*-1}{m} \cdot \gamma \cdot \mathrm{MAX}$.
Again, we use inequality (1), but now the lower bound of ALG comes from Theorem 2, which gives a guarantee for the optimal single-price solution:

$$\frac{\mathrm{ALG}}{\mathrm{OPT}} \geqslant \frac{R_{\mathrm{SP}}}{\frac{1}{2}(\mathrm{MAX} + \mathrm{ALG})} \geqslant \frac{\frac{1}{H_2}\mathrm{MAX}}{\frac{1}{2}\mathrm{MAX}\left(1 + \gamma \cdot \frac{i^*-1}{m}\right)} = \frac{4/3}{1 + \gamma \cdot \frac{i^*-1}{m}}\,.$$

Like in case (i), it suffices to have

$$\frac{4/3}{1 + \gamma \cdot \frac{i^*-1}{m}} \geqslant \gamma \iff 4 \geqslant 3\gamma\left(1 + \gamma \cdot \frac{i^*-1}{m}\right).$$

Using an obvious upper bound for i^*, it suffices for γ to satisfy the following:

$$4 \geqslant 3\gamma + 3\gamma^2 \cdot \frac{\frac{m+2}{2-\gamma} + 1 - 1}{m} \iff \frac{6}{m}\gamma^2 + 10\gamma - 8 \leqslant 0\,.$$

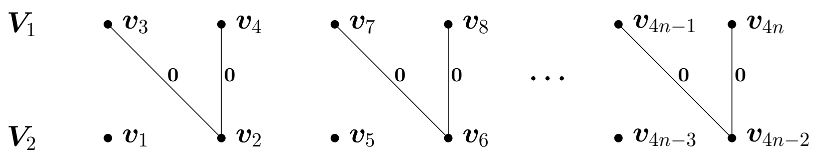

Figure 1 Algorithm 1 is tight on such instances. Only the relevant edges are shown.

Clearly, there is some $m^* \in \mathbb{N}$, such that

$$\frac{6}{m^*}(0.8 - \epsilon/2)^2 + 10(0.8 - \epsilon/2) - 8 \leqslant 0\,.$$

Thus, the approximation ratio β of Algorithm 1 is at least $0.8 - \epsilon/2$, which contradicts the choice of ϵ. Hence, $\beta \geqslant 0.8$.

To see why the ratio of the algorithm is tight, we can construct an infinite family of examples as follows: Consider a graph of 4 nodes $\{v_1, v_2, v_3, v_4\}$ such that $val(v_1) = val(v_2) = 2$, and $val(v_3) = val(v_4) = 1$. There are only two edges, namely (v_2, v_3) and (v_2, v_4). Suppose $\alpha(\cdot,\cdot) = 0$. The optimal revenue here is 5 by offering a price of 1 to v_2, v_3, v_4 and a price of 2 to v_1. On the other hand, the optimal single-price algorithm achieves a revenue of 4, either with a price of 1 or 2. Also, a minimum (weighted or not) vertex cover here is either $\{v_2\}$ or $\{v_3, v_4\}$. In both cases, the revenue by setting $\perp$ to the vertex cover is 4. We can add many copies of this construction (and possibly some extra edges with $\alpha(e) \geqslant 1$ for a connected example) to turn this into an infinite family of tight examples. For an illustration, see Figure 1. ◀

▶ Remark. It seems appealing to try to exploit the fact that we can solve the minimum weighted vertex cover problem in polynomial time for bipartite graphs. However, as our analysis shows, using the weighted version of vertex cover, instead of the unweighted one, does not yield any better approximation.

4.2 An Approximation Algorithm for $k > 2$

We now consider the case where there are more than two available prices. In order to improve the approximation guarantee of Theorem 2, we reduce the problem to the case of $k = 2$, and use the results of the previous subsection.

Consider an instance of the problem, with available prices in $\{\perp, 1, 2, \ldots, k\}$. As discussed in Section 2, we may assume that $val(v) \in \{1, 2, \ldots, k\}$ for every $v \in V$. We create another instance, where we set the value of every node with $val(v) > 1$ to be equal to 2. We can then run Algorithm 1 from Subsection 4.1 on this new instance. At the same time, we can also compute the optimal single-price solution for the original instance, and pick the best among these two solutions. This yields Algorithm 2, described below.

Clearly, Algorithm 2 runs in polynomial time. Note that the solution returned by the algorithm is feasible. Any single-price solution is always feasible, while Algorithm 1 will produce a price vector that is feasible for I', and therefore for I, since the edge restrictions in the two instances are the same. Even though asymptotically, this is still a logarithmic approximation, the algorithm achieves significantly better results for small values of k.

▶ **Theorem 6.** *Algorithm 2 achieves a $\frac{1}{H_{v_{\max}} - 0.25}$-approximation ratio for Inequity Aversion Pricing when the available prices are $\{\perp, 1, 2, \cdots, k\}$, with $k \geqslant 2$.*

```
Algorithm 2: An algorithm for $k > 2$
1 Given an instance $I$, construct a new instance $I'$, where for every $v \in V$,
  $val'(v) = \min\{val(v), 2\}$; everything else remains unchanged
2 Run Algorithm 1 from Subsection 4.1 on instance $I'$, and let $R_*$ be the revenue obtained
3 Compute the optimal single-price solution without discontinuities, on the original instance $I$,
  as described in Section 3, with revenue $R_{\mathrm{SP}}$
4 Return the solution that achieves $\max\{R_*, R_{\mathrm{SP}}\}$
```

Proof. The proof is by induction on $v_{\max}$. For $v_{\max} = 2$ the result follows from Theorem 4 since $0.8 = \frac{1}{H_2 - 0.25}$.

Now assume we have an instance I where $v_{\max} = j > 2$. As usual, let OPT denote the optimal revenue for I and ALG the revenue returned by Algorithm 2. Also, let R_j be the revenue extracted by setting price j at every node, and $V_j = \{v \in V : val(v) = j\}$. We consider two cases.

Case (i): $|V_j| \geqslant \frac{1}{(H_j - 0.25)j} \cdot \mathrm{OPT}$. Then, $\frac{\mathrm{ALG}}{\mathrm{OPT}} \geqslant \frac{R_j}{\mathrm{OPT}} = \frac{j \cdot |V_j|}{\mathrm{OPT}} \geqslant \frac{\frac{1}{H_j - 0.25} \cdot \mathrm{OPT}}{\mathrm{OPT}} = \frac{1}{H_j - 0.25}$.

Case (ii): $|V_j| < \frac{1}{(H_j - 0.25)j} \cdot \mathrm{OPT}$. Let I^* be an instance derived from I by setting $val^*(v) = \min\{val(v), j-1\}$, i.e., we only reduce the valuation of the nodes with $val(v) = v_{\max}$ by 1. Let OPT* denote the optimal revenue for I^*, and ALG* the revenue returned by Algorithm 2. By the inductive hypothesis we have $\mathrm{ALG}^* \geqslant \frac{1}{H_{j-1} - 0.25} \cdot \mathrm{OPT}^*$.

Furthermore, notice that the set of vertices with valuation greater than 1 is the same in both instances. So, Algorithm 2 on input I^* considers exactly the same price vectors as it does on input I, with the exception of the single-price solution that universally uses j. We conclude that $\mathrm{ALG}^* \leqslant \mathrm{ALG}$. Next, we prove the following useful claim.

▶ **Claim 7.** $\mathrm{OPT}^* \geqslant \mathrm{OPT} - |V_j|$.

Proof of Claim 7. Let $\mathbf{p}$ be an optimal price vector for I. Construct the price vector $\mathbf{p}^*$ by decreasing any price that is at least j to $j - 1$. It is straightforward to see that in instance I we have $R(\mathbf{p}^*) \geqslant R(\mathbf{p}) - |V_j| = \mathrm{OPT} - |V_j|$, while in both instances $R(\mathbf{p}^*)$ is the same. What is left to show is that $\mathbf{p}^*$ is feasible for I^*. Observe, however, that the two instances have exactly the same edge restrictions and that, by its definition, $\mathbf{p}^*$ did not increase the price difference between any two vertices compared to $\mathbf{p}$. Thus, $\mathrm{OPT}^* \geqslant R(\mathbf{p}^*) \geqslant \mathrm{OPT} - |V_j|$. ◁

Now, we can write

$$\begin{aligned}\frac{\mathrm{ALG}}{\mathrm{OPT}} &\geqslant \frac{\mathrm{ALG}^*}{\mathrm{OPT}} \geqslant \frac{\frac{1}{H_{j-1} - 0.25} \cdot \mathrm{OPT}^*}{\mathrm{OPT}} \geqslant \frac{\frac{1}{H_{j-1} - 0.25} \cdot (\mathrm{OPT} - |V_j|)}{\mathrm{OPT}} \\ &\geqslant \frac{1}{H_{j-1} - 0.25}\left(1 - \frac{\frac{1}{j(H_j - 0.25)} \cdot \mathrm{OPT}}{\mathrm{OPT}}\right) = \frac{1}{H_{j-1} - 0.25} \cdot \frac{jH_j - 0.25j - 1}{j(H_j - 0.25)} \\ &= \frac{1}{H_{j-1} - 0.25} \cdot \frac{j(H_{j-1} - 0.25)}{j(H_j - 0.25)} = \frac{1}{H_j - 0.25},\end{aligned}$$

which concludes the proof. ◀

4.3 Approximation Algorithms for General Price Sets

We end Section 4 by extending our results when P is an arbitrary set of k positive integers, i.e., $P = \{p_1, p_2, \ldots, p_k\}$. This can be seen as a more realistic model, especially for small values of k. In such a case, one could try to directly apply Theorems 2, 4, or 6 for $P' = \{1, 2, 3, \ldots, p_k\}$.

Table 1 Examples of obtained approximation ratios.

P	$\{1, 2\}$	$\{1, 2, 3\}$	$\{1, \ldots, 100\}$	$\{10, 20, 25\}$	$\{3, 6, 10, 11\}$
$1/H_k$	0.667	0.545	0.193	0.545	0.48
Alg. 2, general α	0.8	0.631	0.202	–	–
Thm. 10, general α || $\alpha = 0$	0.8	0.631	0.202	0.597 || 0.689	0.524 || 0.574

However, this may produce a very poor approximation when k is small but p_k is large, and feasibility is not guaranteed either. In what follows, P_j denotes $\sum_{i=1}^{j} \frac{p_i - p_{i-1}}{p_i}$, where $p_0 = 0$.

We begin with a generalization of Theorem 2.

▶ **Theorem 8.** *For any number n of agents and possible prices $p_1 < p_2 < \ldots < p_k$ the optimal single-price algorithm achieves a ρ-approximation, where $\rho = 1/\min\{H_n, P_k\}$, i.e.,*

$$R_{\text{SP}} \geqslant \frac{\text{MAX}}{\min\{H_n, P_k\}} \geqslant \frac{\text{OPT}}{\min\{H_n, P_k\}},$$

and this approximation guarantee is tight.

For $k = 2$, Theorem 8 yields an approximation ratio of $\frac{p_2}{2p_2 - p_1}$. We can still use the ideas of Theorem 4 to improve this factor. Notice, however, that although all of our results so far are independent of $\alpha(\cdot, \cdot)$, now the improvement will depend on the edge constraints. As in Algorithm 1, we can define a bipartite graph by using a restricted subset of the edges of G. In analogy to the set E' in section 4.1, we let $E' = \{(u, v) \in E : val(u) = p_2, val(v) = p_1,$ and $\alpha(u, v) < p_2 - p_1\}$, and $\alpha = \max_{(v_1, v_2) \in E'} \alpha(v_2, v_1)$. We have the following.

▶ **Theorem 9.** *When $P = \{p_1, p_2\}$ there is a polynomial time ρ-approximation algorithm for the Inequity Aversion Pricing problem, where $\rho = \frac{p_2^2}{2p_2^2 - p_1 p_2 - (p_2 - p_1)\min(p_1, p_2 - p_1 - \alpha)}$. Furthermore, this ratio is tight.*

Notice that Theorem 9 yields a 0.8-approximation when $P = \{1, 2\}$. Finally, based on the improved approximation for two prices, we can get an analog of Theorem 6 for any number of distinct prices. Given an instance I, let I' be the new instance where for every $v \in V$, $val'(v) = \min\{val(v), p_2\}$, while the constraints remain the same.

▶ **Theorem 10.** *Let $P = \{p_1, p_2, \cdots, p_k\}$, and suppose that on instance I' (described above) the algorithm implied by Theorem 9 gives a $\frac{1}{P_2 - x}$-approximate solution. Then, we can get a $\frac{1}{P_k - x}$-approximate solution for the original instance of the Inequity Aversion Pricing problem in polynomial time.*

The proofs of all results in this subsection are deferred to the full version of the paper. We note however, that the algorithms and the proofs for Theorems 9 and 10 are similar to the corresponding algorithms and proofs for Theorems 4 and 6 respectively.

Table 1 summarizes approximation ratios obtained by the optimal single price solution, Algorithm 2, as well as the algorithm implied by Theorem 10 for different sets of prices.

5 Hardness for Single Value Revenue Functions

In [2] there is an $n^{1-\epsilon}$ inapproximability result for Inequity Aversion Pricing, but for general revenue functions and $\alpha(u, v) = 1$ for every edge. An NP-hardness proof is also given for these edge constraints when single value and constant revenue functions are allowed. The NP-hardness of Inequity Aversion Pricing as we study it here, i.e., allowing only single value revenue functions, was left as an open question. We resolve this question by proving that the problem remains NP-complete even if we restrict the revenue functions to be single value. Our reduction implies that the result holds even when the price differences are allowed to be close to the maximum possible price k. Further, when $\alpha(u,v)=0$ for every edge, we are able to show APX-hardness.

The reduction, below, is from the decision version of *3-Terminal Node Cut*: Given a graph $G(V,E)$, a set $S=\{v_1,v_2,v_3\}\subseteq V$, and an integer q, is there a subset of q vertices that can be deleted, so that any two vertices of S are in different connected components of the resulting graph? The NP-completeness of the weighted version of 3-Terminal Node Cut is discussed in [6], while the APX-hardness of the unweighted version we use here is discussed in [10]; in either case no explicit proof is given. The NP-completeness result we need follows from Theorem 15 as well.

▶ **Theorem 11.** *Let $\epsilon>0$ be any small constant. The decision version of Inequity Aversion Pricing (for single value revenue functions) is NP-complete even when $\alpha(u,v)$ is as large as $k^{1-\epsilon}$ for all $(u,v)\in E(G)$, where k is the maximum possible price.*

Proof. It is immediate that the problem is in NP. To facilitate the presentation, we prove the NP-hardness when $\alpha(\cdot,\cdot)$ is upper bounded by $k^{1/3}/3$. As discussed at the end of the proof, the reduction can be easily adjusted when the upper bound of $\alpha(\cdot,\cdot)$ is $k^{1-\epsilon}$, for constant ϵ.

Let us consider an instance of 3-Terminal Node Cut, i.e., a graph $G(V,E)$, with $|V(G)|=n$, a set $S=\{v_1,v_2,v_3\}$ of non adjacent vertices of G, and an integer q. We may assume that $q\leqslant n-3$, otherwise the question is trivial. Next we give a construction of an appropriate instance for Inequity Aversion Pricing.

Let H be the graph obtained from G as follows. We replace every vertex $v\in S$ by n^3 vertices, where each such vertex has the same neighbors as v, i.e., if u_v is a vertex in the bundle of vertices replacing v, then for every edge $(v,x)\in E(G)$ we add the edge (u_v,x) to $E(H)$. For any $v\in S$, we call such a set of vertices in H a v-bundle. The set of prices is $\{\perp,1,2,\dots,k\}$, where $k=n^3+n^2$. Finally, for any $(u,v)\in E(H)$ we set $\alpha(u,v)$ and $\alpha(v,u)$ arbitrarily, as long as they are at most $k^{1/3}/3$. Note that $|V(H)|=n-3+3n^3$, and $|E(H)|\leqslant|E(G)|+3(n-1)n^3\leqslant 3n^4$.

Next we define the single value revenue functions for the vertices of H. For every $v\in V(G)\setminus S$, let $val(v)=n^3+n^2$, and for every $v_i\in S$, let $val(u_{v_i})=n^3+\frac{i-1}{2}n^2$ for all u_{v_i} in the v_i-bundle. We show below that G has a subset of at most q vertices that separate all the vertices of S, if and only if there is a feasible choice of prices for the vertices of H that gives revenue at least R_q, where $R_q=(n-3-q)\,n^3+\sum_{i=1}^{3}n^3\left(n^3+\frac{i-1}{2}n^2\right)$.

One direction is easy. Let A be a subset of at most q vertices of G that separate the three vertices of S. For all $v\in A$ we put a discontinuity on the corresponding v in H. If we think of these vertices as removed from H, this creates several connected components. For any other vertex $u\in V(H)$, if u is in the same component as some v_i-bundle (or itself is one of the vertices of the v_i-bundle), set its price to $n^3+\frac{i-1}{2}n^2$, otherwise set its price to n^3+n^2. Notice that any vertex without a discontinuity produces revenue at least n^3, while any vertex u_{v_i} in a v_i-bundle with $v_i\in S$ produces revenue exactly $n^3+\frac{i-1}{2}n^2$. Now, it is straightforward to check that this price vector $\mathbf{p}$ is feasible and gives enough revenue: $R(\mathbf{p})=\sum_{u\in V(H)}R(u)\geqslant(n-3-q)\,n^3+\sum_{i=1}^{3}n^3\left(n^3+\frac{i-1}{2}n^2\right)=R_q$.

For the opposite direction we begin with a couple of observations. Assume that there is a price vector $\mathbf{p}_*$ that gives revenue at least R_q. We claim that $\mathbf{p}_*$ can have only a few discontinuities.

▶ **Claim 12.** *There is no feasible price vector* $\mathbf{p}$ *with* $R(\mathbf{p}) \geqslant R_q$ *and more than* q *discontinuities.*

One immediate implication of Claim 12 is that for any $v \in S$ not every vertex in the v-bundle has price $\perp$. This holds because the v-bundle has n^3 vertices and only $q \leqslant n-3$ of them can get $\perp$. This is crucial, because if we think of the vertices with price $\perp$ as removed from H, then no two vertices are separated because of discontinuities in the v-bundles. In particular, we can completely ignore those discontinuities with respect to connectivity.

Let $D_{\mathbf{p}} = \{v \in V(G) \setminus S \mid \mathbf{p}_v = \perp\}$, i.e., $D_{\mathbf{p}}$ is the set of non terminal vertices in G that their corresponding vertices in H have discontinuities in $\mathbf{p}$. So far, by Claim 12, we have that $|D_{\mathbf{p}_*}| \leqslant q$. What is left to be shown is that these discontinuities separate the v-bundles, for any $v \in S$.

▶ **Claim 13.** *There is no feasible price vector* $\mathbf{p}$ *such that* $R(\mathbf{p}) \geqslant R_q$*, and for some* $v_i, v_j \in S$ *vertices from both the* v_i*-bundle and the* v_j*-bundle are in the same connected component of the graph* $H' = H - \{v \in V(H) \mid v \text{ is not in a bundle and } \mathbf{p}_v = \perp\}$*.*

We conclude that $D_{\mathbf{p}_*}$ is a set of at most q vertices of G that separate all the vertices of S. This completes the proof for the case where $\alpha(\cdot,\cdot)$ is upper bounded by $k^{1/3}/3$.

▶ **Claim 14.** *The above reduction generalizes for* $\alpha(\cdot,\cdot)$ *upper bounded by* $k^{1-\epsilon}$ *for any possitive constant* ϵ*.*

The proofs of Claims 12, 13, and 14 are deferred to the full version of the paper. ◀

For the special case where all the differences are 0, we show that the problem is APX-hard. In doing so, we prove that 3-Terminal Node Cut is MAX SNP-hard, and thus APX-hard. As noted already, MAX SNP-hardness of 3-Terminal Node Cut is discussed —but not explicitly proved— in [10]. Here, having this reduction is crucial, and we have therefore obtained an explicit construction, since eventually we need to show that 3-Terminal Node Cut restricted in a specific set of instances is MAX SNP-hard.

▶ **Theorem 15.** *Multi-Terminal Node Cut is MAX SNP-hard even for* 3 *terminals and all the weights equal to* 1*.*

▶ **Theorem 16.** *Inequity Aversion Pricing (for single value revenue functions) is APX-hard when* $\alpha(e) = 0$ *for all* $e \in E(G)$*.*

The proofs of Theorems 15 and 16 are deferred to the full version of the paper.

▶ Remark. The maximum price k in the instance constructed in the proof of Theorem 16 does not depend on the size of the problem. Given that there is some constant ρ beyond which it is hard to approximate 3-Terminal Node Cut, this means that there exists some constant k^* for which Inequity Aversion Pricing does not have a PTAS. Note that for such a k^* we do have a constant factor approximation, with factor $H_{k^*}^{-1}$.

6 Concluding remarks

We studied a revenue maximization problem under inequity aversion for the natural class of single-value revenue functions. Apart from establishing the first hardness results for this class, we also derived approximation algorithms based on combinatorial and graph-theoretic tools, which improve the state of the art when the set of available prices is small. We find this to be a realistic setting as special price offers are usually derived by specific discount and promotion policies. Several questions still remain open. Even for $k = 2$, it is not known if the problem is NP-hard, or whether we can have better approximation ratios. Clearly, it would also be interesting to resolve the approximability for general k, i.e., can we have a better than $O(1/H_k)$-approximation for large k? Exploring further models of negative externalities is another attractive direction that is not as well studied as the case of positive externalities.

Abstract

Savitch showed in 1970 that nondeterministic logspace (NL) is contained in deterministic $\mathcal{O}(\log^2 n)$ space but his algorithm requires quasipolynomial time. The question whether we can have a deterministic algorithm for every problem in NL that requires polylogarithmic space and simultaneously runs in polynomial time was left open.

In this paper we give a partial solution to this problem and show that for every language in NL there exists an unambiguous nondeterministic algorithm that requires $\mathcal{O}(\log^2 n)$ space and simultaneously runs in polynomial time.

1 Introduction

Deciding reachability between a pair of vertices in a graph is an important computational problem from the perspective of space bounded computations. It is well known that reachability in directed graphs characterizes the complexity class nondeterministic logspace (NL). For undirected graphs the problem was known to be hard for the class deterministic logspace (L) and in a breakthrough result Reingold showed that is contained in L as well [20]. Several other restrictions of the reachability problem are known to characterize other variants of space bounded complexity classes [12, 5, 6].

Unambiguous computations are a restriction of general nondeterministic computations where the Turing machine has at most one accepting computation path on every input. In the space bounded domain, unambiguous logspace (in short UL) is the class of languages for which there is a nondeterministic logspace bounded machine that has a unique accepting path for every input in the language and zero accepting path otherwise. UL was first formally defined and studied in [8, 2]. In 2000 Reinhardt and Allender showed that the class NL is contained in a non-uniform version of UL [21]. In a subsequent work it was shown that under the hardness assumption that deterministic linear space has functions that cannot be computed by circuits of size $2^{\epsilon n}$, it can be shown that NL = UL [1]. Although it is widely believed that NL and UL are the same unconditionally and in a uniform setting, the question still remains open.

Savitch's Theorem states that reachability in directed graphs is in $\mathsf{DSPACE}(\log^2 n)$, however the algorithm requires quasipolynomial time [22]. On the other hand standard graph traversal algorithms such as DFS and BFS can decide reachability in polynomial time (in fact linear time) but require linear space. Wigderson asked the question that can we solve reachability in $\mathcal{O}(n^{1-\epsilon})$ space and polynomial time simultaneously, for some $\epsilon > 0$ [26]. Barnes et. al. gave a partial answer to this question by giving a $\mathcal{O}(n/2^{\sqrt{\log n}})$ space and polynomial time algorithm for the problem [4]. Although this bound has been improved for several subclasses such as planar graphs [16], layered planar graphs [10], minor-free and bounded genus graphs [9], for general directed graphs (and hence for the class NL) we still do not have a better deterministic space upper bound simultaneously with polynomial time.

1.1 Main Result

In this paper we show that directed graph reachability can be decided by an unambiguous $\mathcal{O}(\log^2 n)$ space algorithm that simultaneously requires only polynomial time. Thus we get an improvement in the time required by Savitch's algorithm by sacrificing determinism. Formally, we show the following theorem.

▶ **Theorem 1.** $\mathsf{NL} \subseteq \mathsf{poly}{-}\mathsf{USPACE}(\log^2 n)$.

For the remainder of this paper all graphs that we consider are directed graphs unless stated otherwise.

1.2 Min-uniqueness of Graphs

An important ingredient of our proof is the *min-uniqueness* property of graphs. A graph G is said to be min-unique with respect to an edge weight function W if the minimum weight path between every pair of vertices in G is unique with respect to W. This turns out to be an important property and has been studied in earlier papers [27, 15, 21]. In fact, the fundamental component of Reinhardt and Allender's paper is a UL algorithm for testing whether a graph is min-unique and then deciding reachability in min-unique graphs in UL [21]. They achieve this by proposing a *double inductive counting* technique which is a clever adaptation of the inductive counting technique of Immerman and Szelepcsényi [17, 23]. As a result of Reinhardt and Allender's algorithm, in order to show that reachability in a class of graphs can be decided in UL, one only needs to design an efficient algorithm which takes as input a graph from this class and outputs an $\mathcal{O}(\log n)$ bit weight function with respect to which the graph is min-unique. This technique was successfully used to show a UL upper bound on the reachability problem in several natural subclasses of general graphs such as planar graphs [7], graphs with polynomially many paths from the start vertex to every other vertex [19], bounded genus graphs [11] and minor-free graphs [3]. For the latter two classes of graphs reachability was shown to be in UL earlier as well by giving reductions to planar graphs [18, 24]. Note that Reinhardt and Allender defines min-uniqueness for unweighted graphs where the minimum length path is unique, whereas we define it for weighted graphs where the minimum weight path is unique. However it can easily be seen that both these notions are equivalent.

1.3 Overview of the Proof

We prove Theorem 1 in two parts. We first show how to construct an $\mathcal{O}(\log^2 n)$ bit weight function W with respect to which the input graph G becomes min-unique. Our construction of the weight function W uses an iterative process to assign weights to the edges of G. We start by considering a subgraph of G having a fixed radius and construct an $\mathcal{O}(\log n)$ bit weight function with respect to which this subgraph becomes min-unique. For this we first observe that there are polynomially many paths in such a subgraph and then use the prime based hashing scheme of Fredman, Komlós and Szemerédi [14] to give distinct weights to all such paths. Thereafter, in each successive round of the algorithm, we construct a new weight function with respect to which a subgraph of double the radius of the previous round becomes min-unique and the new weight function has an additional $\mathcal{O}(\log n)$ bits. Hence in $\mathcal{O}(\log n)$ many rounds we get a weight function which has $\mathcal{O}(\log^2 n)$ bits and with respect to which G is min-unique. We show that this can be done by an unambiguous, polynomial time algorithm using $\mathcal{O}(\log^2 n)$ space. This technique is similar to the isolating weight construction in [13], but their construction is in $\mathsf{quasi{-}NC}$.

We then show that given a graph G and an $\mathcal{O}(\log^2 n)$ bit weight function with respect to which G is min-unique, reachability in G can be decided by an unambiguous, polynomial time algorithm using $\mathcal{O}(\log^2 n)$ space. Note that a straightforward application of Reinhardt and Allender's algorithm will not give the desired bound. This is because "unfolding" a graph with $\mathcal{O}(\log^2 n)$ bit weights will result in a quasipolynomially large graph. As a result we will not achieve a polynomial time bound. We tackle this problem by first observing that although there are $2^{\mathcal{O}(\log^2 n)}$ many different weight values, the weight of a shortest path can only use polynomial number of distinct such values. Using this observation we give a modified version of Reinhardt and Allender's algorithm that iterates over the "good" weight values and ignores the rest. This allows us to give a polynomial time bound.

The rest of the paper is organized as follows. In Section 2 we define the various notations and terminologies used in this paper. We also state prior results that we use in this paper. In Section 3 we give the proof of Theorem 1.

2 Preliminaries

For a positive integer n, let $[n] = \{1, 2, \ldots, n\}$. Let $G = (V, E)$ be a directed graph on n vertices and let $E = \{e_1, e_2, \ldots, e_m\}$ be the set of edges in G. Let s and t be two fixed vertices in G. We wish to decide whether there exists a path from s to t in G. The *length* of a path P is the number of edges in P and is denoted as $\mathrm{len}(P)$. The *center* of a path P is a vertex x in P such that the length of the path from either end point of P to x is at most $\lceil \mathrm{len}(P)/2 \rceil$ and x is no farther from the tail of P than from the head of P.

A *weight function* $w : E \to \mathbb{N}$ is a function which assigns a positive integer to every edge in G. The weight function w is said to be *polynomially bounded* if there exists a constant k such that $w(e) \leq \mathcal{O}(n^k)$ for every edge e in G. We use G_w to denote the weighted graph G with respect to a weight function w. For a graph G_w, the *weight of a path* P denoted by $w(P)$ is defined as the sum of weights of the edges in the path. A *shortest path* from u to v in G_w is a path from u to v with minimum weight. Let $\mathcal{P}^i_w(u, v)$ denote the set of shortest paths from u to v of length at most i in G_w. Thus in particular, the set of shortest paths from u to v in G_w, $\mathcal{P}_w(u, v) = \mathcal{P}^n_w(u, v)$.

We define the *distance* function with respect to a weight function and a nonnegative integer i as

$$\mathrm{dist}^i_w(u, v) = \begin{cases} w(P) & \text{for } P \in \mathcal{P}^i_w(u, v) \\ \infty & \text{if } \mathcal{P}^i_w(u, v) = \emptyset \end{cases}$$

Correspondingly we define the function l which represents the minimum length of such paths as

$$\mathrm{l}_w^i(u,v) = \begin{cases} \min_{P \in \mathcal{P}_w^i(u,v)} \{\mathrm{len}(P)\} & \text{if } \mathcal{P}_w^i(u,v) \neq \emptyset \\ \infty & \text{otherwise} \end{cases}$$

A graph G_w is said to be *min-unique* for paths of length at most i, if for any pair of vertices u and v, the shortest path from u to v with length at most i, is unique. G_w is said to be min-unique if G_w is min unique for paths of arbitrary length. Define weight function

$$w_0(e_i) := 2^{i-1}, \text{ where } i \in [m].$$

It is straightforward to see that for any graph G, w_0 is an n bit weight function and G_{w_0} is min-unique. Wherever it is clear from the context that there is only one weight function w, we will drop the subscript w in our notations.

For a graph G_w, vertex u in G, length i and weight value k, we define the quantities $c_k^i(u)$ and $D_k^i(u)$ as the number of vertices at a distance at most k from u, using paths of length at most i and the sum of the distances to all such vertices respectively. Formally,

$$c_k^i(u) = |\{v \mid \mathrm{dist}_w^i(u,v) \leq k\}|$$
$$D_k^i(u) = \sum_{v \mid \mathrm{dist}_w^i(u,v) \leq k} \mathrm{dist}_w^i(u,v).$$

An *unambiguous Turing machine* is a nondeterministic Turing machine that has at most one accepting computation path on every input [25]. We shall consider unambiguous computations in the context of space bounded computations. $\mathsf{USPACE}(s(n))$ denotes the class of languages decided by an unambiguous machine using $\mathcal{O}(s(n))$ space. In particular, $\mathsf{UL} = \mathsf{USPACE}(\log n)$. $\mathsf{TIME{-}USPACE}(t(n), s(n))$ denotes the class of languages decided by an unambiguous machine using $\mathcal{O}(s(n))$ space and $\mathcal{O}(t(n))$ time simultaneously. In particular, when $t(n)$ is a polynomial, we define

$$\mathsf{poly{-}USPACE}(s(n)) = \bigcup_{k \geq 0} \mathsf{TIME{-}USPACE}(n^k, s(n)).$$

For graphs having polynomially many paths, we use the well known hashing technique due to Fredman, Komlós and Szemerédi [14] to compute a weight function that assigns distinct weights to all such paths. We state the result below in a form that will be useful for our purpose.

▶ **Theorem 2.** *[14, 19] For every constant c there is a constant c' so that for every set S of n bit integers with $|S| \leq n^c$ there is a $c' \log n$ bit prime number p so that for all $x \neq y \in S$, $x \not\equiv y \bmod p$.*

Henceforth we will refer to Theorem 2 as the FKS hashing lemma.

3 Min-unique Weight Assignment

Reinhardt and Allender [21] showed that for every n there is a sequence of n^2 $\mathcal{O}(\log n)$ bit weight functions such that every graph G on n vertices is min-unique with respect to at least one of them. For each weight function they construct an unweighted graph (say G_w) by replacing every edge with a path of length equal to the weight of that edge. Since the weights are $\mathcal{O}(\log n)$ bit values therefore G_w is polynomially large in n. Next they show

Algorithm 1: Computes a min-unique weight function and checks for an $s-t$ path in G

```
   Input: (G, s, t)
   Output: weight function $W := W_q$, true if there is a path from $s$ to $t$ and false
           otherwise
1  begin
2      $q := \log n$; $W_0 := 0$
3      for $j \leftarrow 1$ to $q$ do
4          $i := 2^j$; $p := 2$
5          repeat
               /* By the FKS hashing lemma $p$ is bounded by a polynomial in $n$,
                  say $n^{c'}$.  We define $B := n^{c'+2}$.                        */
6              $W_j := B \cdot W_{j-1} + (w_0 \bmod p)$
7              Check whether $(G, W_j, i)$ is min-unique using Algorithm 2
8              $p :=$ next prime
9          until $(G, W_j, i)$ is min-unique
10     endfor
11     if $\mathrm{dist}^n_{W_q}(s,t) \leq B^q$ then return $(W_q, \mathsf{true})$
12     else return $(W_q, \mathsf{false})$
13 end
```

that using the double inductive counting technique one can check unambiguously using a logspace algorithm if G_w is min-unique, and if so then check if there is a path from s to t as well. They iterate over all weight functions until they obtain one with respect to which G_w is min-unique and use the corresponding graph G_w to check reachability. Since we use an $\mathcal{O}(\log^2 n)$ bit weight function with respect to which the input graph is min-unique, we cannot construct an unweighted graph by replacing every edge with a directed path of length equal to the corresponding edge weight.

In Section 3.1 we give an algorithm that computes an $\mathcal{O}(\log^2 n)$ bit, min-unique weight function and decides reachability in directed graphs. In Section 3.2 we check if a graph is min-unique. Although we use $\omega(\log n)$ bit weight functions, our algorithm still runs in polynomial time. In Section 3.3 we show how to compute the $\mathrm{dist}^i_w(u,v)$ function unambiguously.

3.1 Construction of the weight function

Theorem 3 shows how to construct the desired weight function.

▶ **Theorem 3.** *There is a nondeterministic algorithm that takes as input a directed graph G and outputs along a unique computation path, an $\mathcal{O}(\log^2 n)$ bit weight function W such that G_W is min-unique, while all other computation paths halt and reject. For any two vertices s and t the algorithm also checks whether there is a path from s to t in G. The algorithm uses $\mathcal{O}(\log^2 n)$ space and runs in polynomial time.*

Since directed graph reachability is complete for NL, Theorem 1 follows from Theorem 3.

Proof of Theorem 3. To prove Theorem 3 we design an algorithm that outputs the desired weight function. The formal description of the construction is given in Algorithm 1. The algorithm works in an iterative manner for $\log n$ number of rounds. Initially we consider all paths in G of length at most l where $l = 2^1$. The number of such paths is bounded by n^l and therefore by the FKS hashing lemma there exist a $c' \log n$ bit prime p_1 such that with respect to the weight function $W_1 := w_0 \bmod p_1$, G_{w_1} is min-unique for paths of length at most l. To find the right prime p_1 we iterate over all $c' \log n$ bit primes and use Lemma 7 to check whether G_{w_1} is min-unique for paths of length at most l.

We prove this by induction on the number of rounds, say j. Assume that $G_{W_{j-1}}$ is min-unique for paths of length at most 2^{j-1}. In the j-th round, the algorithm considers all paths of length at most 2^j. By applying Lemma 4 we get a weight function W_j from W_{j-1} which uses $\mathcal{O}(j \cdot \log n)$ bits and G_{W_j} is min-unique for paths of length at most 2^j. Hence in $\log n$ many rounds we get a weight function $W := W_{\log n}$ such that G_W is min-unique. Note that the inner **repeat-until** loop runs for at most $n^{c'}$ iterations due to the FKS hashing lemma.

Let p_j be the prime used in the j-th round of Algorithm 1. Define $p' := \max\{p_j \mid j \in [\log n]\}$. By the FKS hashing lemma p' is bounded by a polynomial in n, say $n^{c'}$. We set $B := n^{c'+2}$. This implies that for any weight function of the form $w = w_0 \bmod p_j$ and any path P in G, $w(P) < B$. Observe that with respect to the final weight function W, for any path P in G, $W(P) < B^q$.

Once we compute an $\mathcal{O}(\log^2 n)$ bit weight function W such that G_W is min-unique, there exist a path from s to t if and only if $\text{dist}^n_W(s,t) \leq B^q$. This can be checked using Algorithm 5 in $\mathcal{O}(\log^2 n)$ space and polynomial time. Also Algorithm 5 is a nondeterministic algorithm which returns true or false along a unique computation path while all other computation paths halt and reject.

In each round the size of W_j increases by $\mathcal{O}(\log n)$ bits and after $\log n$ rounds $W_{\log n}$ is an $\mathcal{O}(\log^2 n)$ bit weight function. By Lemma 7 checking whether a graph is min-unique with respect to an $\mathcal{O}(\log^2 n)$ bit weight function requires $\mathcal{O}(\log^2 n)$ space. Thus the total space complexity of Algorithm 1 is $\mathcal{O}(\log^2 n)$.

The FKS hashing lemma guarantees that in each round only a polynomial number of primes need to be tested to find a weight function which is min-unique for paths of length at most 2^j. By Lemma 7 checking whether a graph is min-unique for paths of length at most 2^j can be done in polynomial time. Thus each round runs in polynomial time. There are only $\log n$ many round and hence Algorithm 1 runs in polynomial time.

By Lemma 7, Algorithm 2 is a nondeterministic algorithm which outputs its answer along a unique computation path, while all other computation paths halt and reject. All other steps in Algorithm 1 are deterministic. This shows the unambiguity requirement of the theorem. ◀

▶ **Lemma 4.** *There is a nondeterministic algorithm $\mathcal{A}$, that takes as inputs (G, w) where G is a graph on n vertices and w is a k bit weight function such that G_w is min-unique for paths of length at most l. $\mathcal{A}$ outputs a $(k + \mathcal{O}(\log n))$ bit weight function w' such that $G_{w'}$ is min-unique for paths of length at most $2l$, along a unique computation path while all other computation paths halt and reject. $\mathcal{A}$ uses $\mathcal{O}(k + \mathcal{O}(\log n))$ space and runs in polynomial time.*

▶ Remark. The encoding of the output weight function w' is the concatenation of the k bit representation of the input weight function w and an $\mathcal{O}(\log n)$ bit prime number p. The output weight function w' is calculated as $w' := B \cdot w + w_0 \bmod p$, where B is the number defined in Algorithm 1. Multiplication using B is used just to left shift w and make room for the new function $w_0 \bmod p$.

Lemma 4 proves the correctness of each iteration of the outer **for** loop of Algorithm 1. Before proving the lemma, we will show that if G_w is min-unique for paths of length at most l, then the number of minimum weight paths with respect to w of length at most $2l$ is bounded by a polynomial independent of l. Hence it allows us to use the FKS hashing lemma to isolate such paths.

▶ **Lemma 5.** *Let G be a graph with n vertices and w be a weight function such the graph G_w is min-unique for paths of length at most l. Then for any pair of vertices u and v, $\left|\mathcal{P}_w^{2l}(u,v)\right|$ is at most n.*

Proof. Let P be a shortest path from u to v in G_w with length at most $2l$ with center vertex x. That is $P \in \mathcal{P}_w^{2l}(u,v)$. Let P_1 and P_2 be the subpaths from u to x and x to v. Since x is the center of P, P_1 has length at most l. Note that P_1 is the unique shortest path of length at most l from u to x in G_w. This is because if there exists another path of length at most l with a smaller weight than P_1 from u to x then replacing P_1 with this path in P will result in a path of length at most $2l$ from u to v with a lower weight than P. But this cannot happen since P is a shortest path from u to v.

▶ **Claim 6.** *There is only one shortest path of length at most $2l$ from u to v with x as its center.*

Proof. Assume there is another shortest path P' of length at most $2l$ from u to v with x as its center. Let P_1' be the subpath of P' from u to x. Since x is the center of P', P_1' is of length at most l. Similar to P_1, P_1' is a shortest path of length at most l from u to x. This means there are two shortest paths of length at most l from u to x. This is a contradiction since G is min-unique for paths of length at most l. ◀

Therefore each vertex can be the center of at most one path of length at most $2l$ from u to v. Thus the total number of shortest paths of length at most $2l$ from u to v in G_w is at most n. Hence $\left|\mathcal{P}_w^{2l}(u,v)\right| \leq n$. This completes the proof of Lemma 5. ◀

When we sum over all possible pairs of u and v, the total number of shortest paths of length at most $2l$ in G_w is at most n^3.

Proof of Lemma 4. G_w is min-unique for paths of length at most l. Therefore by Lemma 5 the number of shortest paths between all pairs of vertices with at most $2l$ edges in G is at most n^3. Let $\mathcal{S}$ be the set of these n^3 shortest paths. With respect to the weight function w_0 (see Section 2) each element of $\mathcal{S}$ gets a distinct weight. So by using the FKS hashing lemma we get a constant c' and a $c' \log n$ bit prime number p such that with respect to the weight function $\widehat{w}$ such that $\widehat{w} := w_0 \bmod p$, each element of $\mathcal{S}$ gets a distinct weight. Moreover, in G between any pair of vertices the shortest path in $\mathcal{S}$ is unique.

Let B be the number as defined in Algorithm 1. Now consider the weight function $w' := B \cdot w + \widehat{w}$. Since w is a k bit weight function and $\widehat{w}$ is an $\mathcal{O}(\log n)$ bit weight function therefore w' is a $(k + \mathcal{O}(\log n))$ bit weight function. Clearly w has higher precedence than $\widehat{w}$ in w'. So for any two paths P_1 and P_2 in G , we have if $w'(P_1) < w'(P_2)$ then either $w(P_1) < w(P_2)$ or both the predicates $w(P_1) = w(P_2)$ and $\widehat{w}(P_1) < \widehat{w}(P_2)$ are true. Additionally if $w'(P_1) = w'(P_2)$ then $w(P_1) = w(P_2)$ and $\widehat{w}(P_1) = \widehat{w}(P_2)$.

All the unique shortest paths of length at most $2l$ in G_w, will be unique shortest paths of length at most $2l$ in $G_{w'}$ also. If there are multiple shortest paths of length at most $2l$ from u to v in G_w, $\widehat{w}$ gives a unique weight to each of these paths. So $G_{w'}$ is min-unique for paths of length at most $2l$.

Algorithm 2: Check whether G is min-unique for paths of length at most i

```
Input: $(G, w, i)$

```

We can check whether a graph $G_{w'}$ is min-unique for paths of length at most $2l$ using Lemma 7. Since p is an $c' \log n$ bit prime number, we can iterate over all the $c' \log n$ bit primes and find p. ◀

3.2 Checking for min-uniqueness

The next lemma shows how to check whether G_w is min-unique for paths of length at most l in an unambiguous manner.

▶ **Lemma 7.** *There is a nondeterministic algorithm that takes as input a directed graph G, a k bit weight function w and a length i and outputs along a unique computation path whether or not the graph G_w is min-unique for paths of length at most i, while all other computation paths halt and reject. The algorithm uses $\mathcal{O}(k + \log n)$ space and runs in polynomial time.*

For every vertex v in the G_w we check whether there are two minimum weight paths of length at most i to some other vertex in G. Algorithm 2 gives a formal description of this process. The algorithm iterates over all shortest path weight values that can be achieved by some path of length at most i.

In the k-th stage of the algorithm it considers a ball of radius k consisting of vertices which have a shortest path of weight at most k from v and length at most i. $c_k^i(v)$ denotes the number of vertices in this ball and $D_k^i(v)$ denotes the sum of the weights of the shortest paths to all such vertices. Initially $k = 0$, $c_0^i(v) = 1$ (consisting of only the vertex v) and $D_0^i(v) = 0$.

A direct implementation of the double inductive counting technique of Reinhardt and Allender [21] does not work since this would imply that we cycle over all possible weight values, which we cannot afford. We bypass this hurdle by considering only the relevant

Algorithm 3: Find the next smallest weight value $k' > k$ among all paths of length at most i from u

```
Input: $(G, w, u, i, k, c_k^i(u), D_k^i(u))$
Output: $k' := \min\{\text{dist}_w^i(u,v) \mid \text{dist}_w^i(u,v) > k,\ v \in V\}$
begin
    $k' := \infty$
    for each vertex $v$ do
        if $\neg(\text{dist}_w^i(u,v) \le k)$ then
            $\text{min.dist}_w^i(u,v) := \infty$
            for each $x$ such that $(x,v)$ is an edge do
                if $\text{dist}_w^i(u,x) \le k$ and $\text{l}_w^i(u,x) + 1 \le i$ then
                    if $\text{min.dist}_w^i(u,v) > \text{dist}_w^i(u,x) + w(x,v)$ then
                        $\text{min.dist}_w^i(u,v) := \text{dist}_w^i(u,x) + w(x,v)$
                    endif
                endif
            endfor
            if $k' > \text{min.dist}_w^i(u,v)$ then $k' := \text{min.dist}_w^i(u,v)$
        endif
    endfor
    return $k'$
end
```

weight values. We compute the immediate next shortest path weight value k', and use k' as the weight value for the next stage of the algorithm. This computation is implemented in Algorithm 3). Lemma 8 proves the correctness of this process. Note that the number of shortest path weight values from a fixed vertex is bounded by the number of vertices in the graph. This ensure that the number of iterations of the inner **repeat-until** loop of Algorithm 2 is bounded by n.

▶ **Lemma 8.** *Given $(G, w, u, i, k, c_k^i(u), D_k^i(u))$, Algorithm 3 correctly computes the value $\min\{\text{dist}_w^i(u,v) \mid \text{dist}_w^i(u,v) > k,\ v \in V\}$.*

To see the correctness of Lemma 8 observe that for every vertex v such that $\text{dist}_w^i(u,v) > k$, the algorithm cycles through all vertices x such that there is an edge from x to v and the length of the path from u to x is at most $i-1$. It computes the minimum weight of such a path and store it in the variable $\text{min.dist}_w^i(u,v)$. It then computes the minimum value of $\text{min.dist}_w^i(u,v)$ over all possible vertices v and outputs it as k', as required.

After we get the appropriate weight value k', we then compute the values of $c_{k'}^i(v)$ and $D_{k'}^i(v)$ by using a technique similar to Reinhardt and Allender (implemented in Algorithm 4). Additionally we also maintain a shared flag value BAD.WEIGHT between Algorithms 2 and 4, which is set to true if G_w is not min-unique for paths of length at most i, else it is false.

3.3 Computing the $\text{dist}_w^i(u,v)$ function

In Algorithms 3 and 4, an important step is to check whether $\text{dist}_w^i(u,v) \le k$ and if so, get the values of $\text{dist}_w^i(u,v)$ and $\text{l}_w^i(u,v)$. These values are obtained from Algorithm 5. Algorithm 5 describes a nondeterministic procedure that takes as input a weighted graph G_w, which is min-unique for paths of length at most i and weight at most k from a source

Algorithm 4: Compute $c^i_{k'}(u)$ and $D^i_{k'}(u)$ and check whether G_w is min-unique for paths with length at most i and weight at most k' from u

```
   Input: $(G, w, u, i, k, c^i_k(u), D^i_k(u), k')$
   Output: $(c^i_{k'}(u), D^i_{k'}(u))$ and also flag BAD.WEIGHT
 1 begin
 2     $c^i_{k'}(u) := c^i_k(u)$; $D^i_{k'}(u) := D^i_k(u)$
 3     for each vertex $v$ do
 4         if $\neg(\mathrm{dist}^i_w(u,v) \leq k)$ then
 5             for each $x$ such that $(x,v)$ is an edge do
 6                 if $\mathrm{dist}^i_w(u,x) \leq k$ and $\mathrm{dist}^i_w(u,x) + w(x,v) = k'$ and $\mathrm{l}^i_w(u,x) + 1 \leq i$
                   then
 7                     $c^i_{k'}(u) := c^i_{k'}(u) + 1$; $D^i_{k'}(u) := D^i_{k'}(u) + k'$
 8                     for each $x' \neq x$ such that $(x',v)$ is an edge do
 9                         if $\mathrm{dist}^i_w(u,x') \leq k$ and $\mathrm{dist}^i_w(u,x') + w(x',v) = k'$ and
                           $\mathrm{l}^i_w(u,x') + 1 \leq i$ then
10                             BAD.WEIGHT := true
11                         endif
12                     endfor
13                 endif
14             endfor
15         endif
16     endfor
17     return $(c^i_{k'}(u), D^i_{k'}(u))$
18 end
```

vertex u and the values $c^i_k(u)$ and $D^i_k(u)$. For any vertex v, if $\mathrm{dist}^i_w(u,v) \leq k$ then it outputs true and the values of $\mathrm{dist}^i_w(u,v)$ and $\mathrm{l}^i_w(u,v)$ along a unique computation path. Otherwise it outputs false along a unique computation path with ∞ as the values of $\mathrm{dist}^i_w(u,v)$ and $\mathrm{l}^i_w(u,v)$. All other computation paths halt and reject. As a result we can compute the predicate $\neg(\mathrm{dist}^i_w(u,v) \leq k)$ along a unique path as well.

Note that Algorithm 5 is the only algorithm where we use non-determinism. The algorithm is similar to the unambiguous subroutine of Reinhardt and Allender [21] with the only difference being that here we consider weight of a path instead of length of a path. The algorithm assumes that the subgraph induced by all the paths of length at most i and weight at most k from u is min-unique.

In Line 5 of Algorithm 5, for each vertex x the routine non-deterministically guesses whether $\mathrm{dist}^i_w(u,x) \leq k$ and if the guess is 'true', it then guesses a path of length at most k from u to x. If the algorithm incorrectly guesses for some vertex x that $\mathrm{dist}^i_w(u,x) > k$, then the variable *count* will never reach $c^i_k(u)$ and the routine will reject. If it guesses incorrectly that $\mathrm{dist}^i_w(u,x) \leq k$ it will fail to guess a correct path in Line 7 and again reject that computation. Thus the only computation paths that exit the **for** loop in Line 16 and satisfy the first condition of the **if** statement in Line 17, are the ones that correctly guess exactly the set $\{x \mid \mathrm{dist}^i_w(u,x) \leq k\}$. If the algorithm ever guesses incorrectly the weight d of the shortest path to x, then if $\mathrm{dist}^i_w(u,x) > d$ no path of weight d will be found, and if $\mathrm{dist}^i_w(u,x) < d$ then the variable *sum* will be incremented by a value greater than $\mathrm{dist}^i_w(u,x)$. In the latter case, at the end of the algorithm, *sum* will be greater than $D^i_k(u)$, and the routine will reject.

Algorithm 5: An unambiguous routine to determine if $\mathrm{dist}_w^i(u,v) \leq k$ and find $\mathrm{dist}_w^i(u,v)$ and $\mathrm{l}_w^i(u,v)$

```
Input: $(G, w, u, i, k, c_k^i(u), D_k^i(u), v)$
Output: (true or false), $\mathrm{dist}_w^i(u,v)$, $\mathrm{l}_w^i(u,v)$
begin
    $count := 0$; $sum := 0$; $path.to.v :=$ false
    $\mathrm{dist}_w^i(u,v) := \infty$; $\mathrm{l}_w^i(u,v) := \infty$
    for each $x \in V$ do
        Guess non deterministically if $\mathrm{dist}_w^i(u,x) \leq k$ in $G_w$
        if the guess is $\mathrm{dist}_w^i(u,x) \leq k$ then
            Guess a path of weight $d \leq k$ and length $l \leq i$ from $u$ to $x$
            (If this fails then halt and reject)
            $count := count + 1$; $sum := sum + d$
            if $x = v$ then
                $path.to.v :=$ true
                $\mathrm{dist}_w^i(u,v) := d$
                $\mathrm{l}_w^i(u,v) := l$
            endif
        endif
    endfor
    if $count = c_k^i(u)$ and $sum = D_k^i(u)$ then
        return $(path.to.v, \mathrm{dist}_w^i(u,v), \mathrm{l}_w^i(u,v))$
    else
        halt and reject
    endif
end
```

Since G_w is min-unique for paths of length at most i and weight at most k from u, only for exactly one computation path *sum* and *count* will match with $c_k^i(u)$ and $D_k^i(u)$. So except one computation path which made all the guesses correct, all other paths halt and reject. If $\mathrm{dist}_w^i(u,v) \leq k$ then even though the algorithm uses non-deterministic choices, it outputs 'true' along a single computation path while all other paths halt and reject. Also if $\mathrm{dist}_w^i(u,v) > k$, the algorithm outputs 'false' along a single computation path while all other paths halt and reject. The space complexity of the algorithm is bounded by the size of the weight function w.

As a corollary of Theorem 1 we get the following result.

▶ **Corollary 9.** *For $s(n) \geq \log n$,* $\mathsf{NSPACE}(s(n)) \subseteq \mathsf{TIME{-}USPACE}(2^{\mathcal{O}(s(n))}, s^2(n))$.

Families of DFAs as Acceptors of ω-Regular Languages*

Abstract

Families of DFAs (FDFAs) provide an alternative formalism for recognizing ω-regular languages. The motivation for introducing them was a desired correlation between the automaton states and right congruence relations, in a manner similar to the Myhill-Nerode theorem for regular languages. This correlation is beneficial for learning algorithms, and indeed it was recently shown that ω-regular languages can be learned from membership and equivalence queries, using FDFAs as the acceptors.

In this paper, we look into the question of how suitable FDFAs are for defining ω-regular languages. Specifically, we look into the complexity of performing Boolean operations, such as complementation and intersection, on FDFAs, the complexity of solving decision problems, such as emptiness and language containment, and the succinctness of FDFAs compared to standard deterministic and nondeterministic ω-automata.

We show that FDFAs enjoy the benefits of deterministic automata with respect to Boolean operations and decision problems. Namely, they can all be performed in nondeterministic logarithmic space. We provide polynomial translations of deterministic Büchi and co-Büchi automata to FDFAs and of FDFAs to nondeterministic Büchi automata (NBAs). We show that translation of an NBA to an FDFA may involve an exponential blowup. Last, we show that FDFAs are more succinct than deterministic parity automata (DPAs) in the sense that translating a DPA to an FDFA can always be done with only a polynomial increase, yet the other direction involves an inevitable exponential blowup in the worst case.

1 Introduction

The theory of finite-state automata processing infinite words was developed in the early sixties, starting with Büchi [3] and Muller [13], and motivated by problems in logic and switching theory. Today, automata for infinite words are extensively used in verification and synthesis of *reactive systems*, such as operating systems and communication protocols.

An automaton processing finite words makes its decision according to the last visited state. On infinite words, Büchi defined that a run is accepting if it visits a designated set of states infinitely often. Since then several other accepting conditions were defined, giving rise to various ω-automata, among which are Muller, Rabin, Streett and parity automata.

* Research of the third author was supported by US NSF grant CCF-1138996

The theory of ω-regular languages is more involved than that of finite words. This was first evidenced by Büchi's observation that nondeterministic Büchi automata are more expressive than their deterministic counterpart. While for some types of ω-automata the nondeterministic and deterministic variants have the same expressive power, none of them possesses all the nice qualities of acceptors for finite words. In particular, none has a corresponding Myhill-Nerode theorem [16], i.e. a direct correlation between the states of the automaton and the equivalence classes corresponding to the canonical right congruence of the recognized language.

The absence of a Myhill-Nerode like property in ω-automata has been a major drawback in obtaining learning algorithms for ω-regular languages, a question that has received much attention lately due to applications in verification and synthesis, such as black-box checking [17], assume-guarantee reasoning [14], error localization [5], regular model checking [15] and more. The reason is that learning algorithms typically build on this correspondence between the automaton and the right congruence.

Recently, two algorithms for learning an unknown ω-regular language were proposed, both using non-conventional acceptors. One uses a reduction due to [4] named $L_{\$}$-automata of ω-regular languages to regular languages [6], and the other uses a representation termed *families of* DFA*s* [1]. Both representations are founded on the following well known property of ω-regular languages: two ω-regular languages are equivalent iff they agree on the set of ultimately periodic words. An ultimately periodic word uv^ω, where $u \in \Sigma^*$ and $v \in \Sigma^+$, can be represented as a pair of finite words (u, v). Both $L_{\$}$-automata and families of DFAs process such pairs and interpret them as the corresponding ultimately periodic words. Families of DFAs have been shown to be up to exponentially more succinct than $L_{\$}$-automata [1].

A family of DFAs (FDFA) is composed of a *leading automaton* $\mathcal{Q}$ with no accepting states and for each state q of $\mathcal{Q}$, a *progress* DFA $\mathcal{P}_q$. Intuitively, the leading automaton is responsible for processing the non-periodic part u, and depending on the state q reached when $\mathcal{Q}$ terminated processing u, the respective progress DFA $\mathcal{P}_q$ processes the periodic part v, and determines whether the pair (u, v), which corresponds to uv^ω, is accepted. (The exact definition is more subtle and is provided in Section 3.) If the leading automaton has n states and the size of the maximal progress DFA is k, we say that the FDFA is of size (n, k). An earlier definition of FDFAs, given in [9], provided a machine model for the *families of right congruences* of [10]. They were redefined in [1], where their acceptance criterion was adjusted, and their size was reduced by up to a quadratic factor. We follow the definition of [1].

In order for an FDFA to properly characterize an ω-regular language, it must satisfy the *saturation* property: considering two pairs (u, v) and (u', v'), if $uv^\omega = u'v'^\omega$ then either both (u, v) and (u', v') are accepted or both are rejected (cf. [4, 20]). Saturated FDFAs are shown to exactly characterize the set of ω-regular languages. Saturation is a semantic property, and the check of whether a given FDFA is saturated is shown to be in PSPACE. Luckily, the FDFAs that result from the learning algorithm of [1] are guaranteed to be saturated.

Saturated FDFAs bring an interesting potential – they have a Myhill-Nerode like property, and while they are "mostly" deterministic, a nondeterministic aspect is hidden in the separation of the prefix and period parts of an ultimately periodic infinite word. This gives rise to the natural questions of how "dominant" are the determinism and nondeterminism in FDFAs, and how "good" are they for representing ω-regular languages. These abstract questions translate to concrete questions that concern the succinctness of FDFAs and the complexity of solving their decision problems, as these measures play a key role in the usefulness of applications built on top of them.

Our purpose in this paper is to analyze the FDFA formalism and answer these questions.

Specifically, we ask: What is the complexity of performing the Boolean operations of complementation, union, and intersection on saturated FDFAs? What is the complexity of solving the decision problems of membership, emptiness, universality, equality, and language containment for saturated FDFAs? How succinct are saturated FDFAs, compared to deterministic and nondeterministic ω-automata?

We show that saturated FDFAs enjoy the benefits of deterministic automata with respect to Boolean operations and decision functions. Namely, the Boolean operations can be performed in logarithmic space, and the decision problems can be solved in nondeterministic logarithmic space. The constructions and algorithms that we use extend their counterparts on standard DFAs. In particular, complementation of saturated FDFAs can be obtained on the same structure, and union and intersection is done on a product of the two given structures. The correctness proof of the latter is a bit subtle.

As for the succinctness, which turns out to be more involved, we show that saturated FDFAs properly lie in between deterministic and nondeterministic ω-automata. We provide polynomial translations from deterministic ω-automata to FDFAs and from FDFAs to nondeterministic ω-automata, and show that an exponential state blowup in the opposite directions is inevitable in the worst case.

Specifically, a saturated FDFA of size (n, k) can always be transformed into an equivalent nondeterministic Büchi automaton (NBA) with $O(n^2k^3)$ states. As for the other direction, transforming an NBA with n states to an equivalent FDFA is shown to be in $2^{\Theta(n \log n)}$. This is not surprising since, as shown by Michel [12], complementing an NBA involves a $2^{\Omega(n \log n)}$ state blowup, while FDFA complementation requires no state blowup.

Considering deterministic ω-automata, a Büchi or co-Büchi automaton (DBA or DCA) with n states can be transformed into an equivalent FDFA of size $(n, 2n)$, and a deterministic parity automaton (DPA) with n states and k colors can be transformed into an equivalent FDFA of size (n, kn). As for the other direction, since DBA and DCA do not recognize all the ω-regular languages, while saturated FDFAs do, a transformation from an FDFA to a DBA or DCA need not exist. Comparing FDFAs to DPAs, which do recognize all ω-regular languages, we get that FDFAs can be exponentially more succinct: We show a family of languages $\{L_n\}_{n\geq 1}$, such that for every n, there exists an FDFA of size $(n+1, n^2)$ for L_n, but any DPA recognizing L_n must have at least 2^{n-1} states. (A deterministic Rabin or Streett automaton for L_n is also shown to be exponential in n, requiring at least $2^{\frac{n}{2}}$ states.)

Due to lack of space, some proofs are omitted and can be found in the full version, on the authors' home pages.

2 Preliminaries

An *alphabet* Σ is a finite set of symbols. The set of finite words over Σ is denoted by Σ^*, and the set of infinite words, termed ω-words, over Σ is denoted by Σ^ω. As usual, we use x^*, x^+, and x^ω to denote finite, non-empty finite, and infinite concatenations of x, respectively, where x can be a symbol, a finite word, or a langugae. We use ϵ for the empty word and Σ^+ for $\Sigma^* \setminus \{\epsilon\}$. An infinite word w is *ultimately periodic* if there are two finite words $u \in \Sigma^*$ and $v \in \Sigma^+$, such that $w = uv^\omega$. A *language* is a set of finite words, that is, a subset of Σ^*, while an ω-language is a set of ω-words, that is, a subset of Σ^ω. For natural numbers i and j and a word w, we use $[i..j]$ for the set $\{i, i+1, \ldots, j\}$, $w[i]$ for the i-th letter of w, and $w[i..j]$ for the subword of w starting at the i-th letter and ending at the j-th letter, inclusive.

An *automaton* is a tuple $\mathcal{A} = \langle \Sigma, Q, \iota, \delta \rangle$ consisting of an alphabet Σ, a finite set Q of states, an initial state $\iota \in Q$, and a transition function $\delta : Q \times \Sigma \to 2^Q$. A run of an automaton on a finite word $v = a_1a_2 \dots a_n$ is a sequence of states $q_0, q_1, \dots, q_n$ such that $q_0 = \iota$, and for each $i \geq 0$, $q_{i+1} \in \delta(q_i, a_i)$. A run on an infinite word is defined similarly and results in an infinite sequence of states. The transition function is naturally extended to a function $\delta : Q \times \Sigma^* \to 2^Q$, by defining $\delta(q, \epsilon) = \{q\}$, and $\delta(q, av) = \cup_{p\in\delta(q,a)}\delta(p, v)$ for $q \in Q$, $a \in \Sigma$, and $v \in \Sigma^*$. We often use $\mathcal{A}(v)$ as a shorthand for $\delta(\iota, v)$ and $|\mathcal{A}|$ for the number of states in Q. We use $\mathcal{A}^q$ to denote the automaton $\langle\Sigma, Q, q, \delta\rangle$ obtained from $\mathcal{A}$ by replacing the initial state with q. We say that $\mathcal{A}$ is *deterministic* if $|\delta(q, a)| \leq 1$ and *complete* if $|\delta(q, a)| \geq 1$, for every $q \in Q$ and $a \in \Sigma$. For simplicity, we consider all automata to be complete. (As is known, every automaton can be linearly translated to an equivalent complete automaton.)

By augmenting an automaton with an acceptance condition α, thereby obtaining a tuple $\langle\Sigma, Q, \iota, \delta, \alpha\rangle$, we get an *acceptor*, a machine that accepts some words and rejects others. An acceptor accepts a word if at least one of the runs on that word is accepting. For finite words the acceptance condition is a set $F \subseteq Q$ of *accepting states*, and a run on a word v is accepting if it ends in an accepting state, i.e., if $\delta(\iota, v)$ contains an element of F. For infinite words, there are various acceptance conditions in the literature; here we mention three: Büchi, co-Büchi, and parity. The Büchi and co-Büchi acceptance conditions are also a set $F \subseteq Q$. A run of a Büchi automaton is accepting if it visits F infinitely often. A run of a co-Büchi automaton is accepting if it visits F only finitely many times. A parity acceptance condition is a map $\kappa : Q \to [1..k]$ assigning each state a color (or rank). A run is accepting if the minimal color visited infinitely often is odd. We use $[\![\mathcal{A}]\!]$ to denote the set of words accepted by a given acceptor $\mathcal{A}$, and say that $\mathcal{A}$ *accepts* or *recognizes* $[\![\mathcal{A}]\!]$. Two acceptors $\mathcal{A}$ and $\mathcal{B}$ are *equivalent* if $[\![\mathcal{A}]\!] = [\![\mathcal{B}]\!]$.

We use three letter acronyms to describe acceptors, where the first letter is either D or N depending on whether the automaton is *deterministic* or *nondeterministic*, respectively. The second letter is one of {F,B,C,P}: F if this is an acceptor over finite words, B, C, or P if it is an acceptor over infinite words with Büchi, co-Büchi, or parity acceptance condition, respectively. The third letter is always A for acceptor.

For finite words, NFA and DFA have the same expressive power. A language is said to be *regular* if it is accepted by an NFA. For infinite words, the theory is more involved. While NPAs, DPAs, and NBAs have the same expressive power, DBAs, NCAs, and DCAs are strictly weaker than NBAs. An ω-language is said to be *ω-regular* if it is accepted by an NBA.

3 Families of DFAs (FDFAs)

It is well known that two ω-regular languages are equivalent if they agree on the set of ultimately periodic words (this is a consequence of McNaughton's theorem [11]). An ultimately periodic word uv^ω, where $u \in \Sigma^*$ and $v \in \Sigma^+$, is usually represented by the pair (u, v). A canonical representation of an ω-regular language can thus consider only ultimately periodic words, namely define a language of pairs $(u, v) \in \Sigma^* \times \Sigma^+$. Such a representation $\mathcal{F}$ should satisfy the *saturation* property: considering two pairs (u, v) and (u', v'), if $uv^\omega = u'v'^\omega$ then either both (u, v) and (u', v') are accepted by $\mathcal{F}$ or both are rejected by $\mathcal{F}$.

A family of DFAs (FDFA) accepts such pairs (u, v) of finite words. Intuitively, it consists of a *leading automaton* $\mathcal{Q}$ with no acceptance condition that runs on the prefix-word u, and for each state q of $\mathcal{Q}$, a *progress automaton* $\mathcal{P}_q$, which is a DFA that runs on the period-word v.

A straightforward definition of acceptance for a pair (u, v), could have been that the run of the leading automaton $\mathcal{Q}$ on u ends at some state q, and the run of the progress automaton $\mathcal{P}_q$ on v is accepting. This goes along the lines of $L_\$$-automata [4]. However, such an acceptance definition does not fit well the saturation requirement, and might enforce very large automata [1]. The intuitive reason is that every progress automaton might need to handle the period-words of all prefix-words.

To better fit the saturation requirement, the acceptance condition of an FDFA is defined with respect to a *normalization* of the input pair (u, v). The normalization is a new pair (x, y), such that $xy^\omega = uv^\omega$, and in addition, the run of the leading automaton $\mathcal{Q}$ on xy^i ends at the same state for every natural number i. Over the normalized pair (x, y), the acceptance condition follows the straightforward approach discussed above. This normalization resembles the implicit flexibility in the acceptance conditions of ω-automata, such as the Büchi condition, and allows saturated FDFAs to be up to exponentially more succinct than $L_\$$-automata [1].

Below, we formally define an FDFA, the normalization of an input pair (u, v), and the acceptance condition. We shall use Σ^{*+} as a shorthand for $\Sigma^* \times \Sigma^+$, whereby the input to an FDFA is a pair $(u, v) \in \Sigma^{*+}$.

▶ **Definition 1** (A family of DFAs (FDFA)). [1]

- A *family of* DFA*s* (FDFA) is a pair $(\mathcal{Q}, \mathbf{P})$, where $\mathcal{Q} = (\Sigma, Q, \iota, \delta)$ is a deterministic *leading* automaton, and $\mathbf{P}$ is a set of $|\mathcal{Q}|$ DFAs, including for each state $q \in Q$, a *progress* DFA $\mathcal{P}_q = (\Sigma, P_q, \iota_q, \delta_q, F_q)$.
- Given a pair $(u, v) \in \Sigma^{*+}$ and an automaton $\mathcal{A}$, the *normalization* of (u, v) w.r.t $\mathcal{A}$ is the pair $(x, y) \in \Sigma^{*+}$, such that $x = uv^i$, $y = v^j$, and $i \geq 0$, $j \geq 1$ are the smallest numbers for which $\mathcal{A}(uv^i) = \mathcal{A}(uv^{i+j})$. (Since we consider complete automata, such a unique pair (x, y) is guaranteed.)
- Let $\mathcal{F} = (\mathcal{Q}, \mathbf{P})$ be an FDFA, $(u, v) \in \Sigma^{*+}$, and $(x, y) \in \Sigma^{*+}$ the normalization of (u, v) w.r.t $\mathcal{Q}$. We say that (u, v) is *accepted* by $\mathcal{F}$ iff $\mathcal{Q}(x) = q$ for some state q of $\mathcal{Q}$ and $\mathcal{P}_q(y)$ is an accepting state of $\mathcal{P}_q$.
- We use $[\![\mathcal{F}]\!]$ to denote the set of pairs accepted by $\mathcal{F}$.
- We define the *size* of $\mathcal{F}$, denoted $|\mathcal{F}|$, as the pair $(|\mathcal{Q}|, \max\{|\mathcal{P}_q|\}_{q \in \mathcal{Q}})$.
- An FDFA $\mathcal{F}$ is saturated if for every two pairs (u, v) and (u', v') such that $uv^\omega = u'v'^\omega$, either both (u, v) and (u', v') are in $[\![\mathcal{F}]\!]$ or both are not in $[\![\mathcal{F}]\!]$.

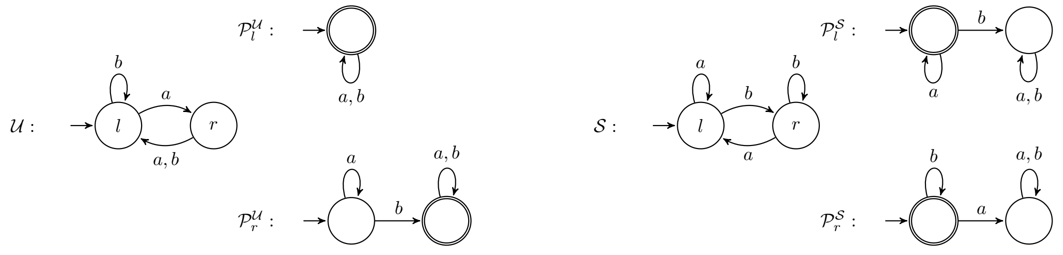
A saturated FDFA can be used to characterize an ω-regular language (see Theorem 10), while an unsaturated FDFA cannot.

An unsaturated FDFA is depicted in Figure 1 on the left. Consider the pairs (b, a) and (ba, aa). Though $b(a)^\omega = ba(aa)^\omega$, (b, a) is normalized to (b, aa) and $\mathcal{P}_l^U$ accepts aa but (ba, aa) is normalized to itself and $\mathcal{P}_r^U$ rejects aa. A saturated FDFA is depicted in Figure 1 on the right. It accepts pairs of the forms (Σ^*, a^+) and (Σ^*, b^+), and characterizes the ω-regular language $(a + b)^*(a^\omega + b^\omega)$.

4 Boolean Operations and Decision Procedures

We provide below algorithms for performing the Boolean operations of complementation, union, and intersection on saturated FDFAs, and deciding the basic questions on them, such as emptiness, universality, and language containment. All of these algorithms can be done in

[1] The FDFAs defined here follow the definition in [1], which is a little different from the definition of FDFAs in [9]; the latter provide a machine model for the families of right congruences introduced in [10]. The main differences between the two definitions are: i) In [9], a pair (u, v) is accepted by an FDFA $\mathcal{F} = (\mathcal{Q}, \mathbf{P})$ if there is some factorization (x, y) of (u, v), such that $\mathcal{Q}(u) = q$ and $\mathcal{P}_q$ accepts v; and ii) in [9], the FDFA $\mathcal{F}$ should also satisfy the constraint that for all words $u \in \Sigma^*$ and $v, v' \in \Sigma^+$, if $\mathcal{P}_{\mathcal{Q}(u)}(v) = \mathcal{P}_{\mathcal{Q}(u)}(v')$ then $\mathcal{Q}(uv) = \mathcal{Q}(uv')$.



$\mathcal{U}$:
$\mathcal{P}_l^{\mathcal{U}}$:
$\mathcal{P}_r^{\mathcal{U}}$:
$\mathcal{S}$:
$\mathcal{P}_l^{\mathcal{S}}$:
$\mathcal{P}_r^{\mathcal{S}}$:
l
r
a
b
a, b

Figure 1 Left: an unsaturated FDFA with the leading automaton $\mathcal{U}$ and progress DFAs $\mathcal{P}_l^{\mathcal{U}}$ and $\mathcal{P}_r^{\mathcal{U}}$. Right: a saturated FDFA with the leading automaton $\mathcal{S}$ and progress DFAs $\mathcal{P}_l^{\mathcal{S}}$ and $\mathcal{P}_r^{\mathcal{S}}$.

nondeterministic logarithmic space, taking advantage of the partial deterministic nature of FDFAs.[2] We conclude the section with the decision problem of whether an arbitrary FDFA is saturated, showing that it can be resolved in polynomial space.

Boolean operations

Saturated FDFAs are closed under Boolean operations as a consequence of Theorem 10, which shows that they characterize exactly the set of ω-regular languages. We provide below explicit algorithms for these operations, showing that they can be done effectively.

Complementation of an FDFA is simply done by switching between accepting and non-accepting states in the progress automata, as is done with DFAs.

▶ **Theorem 2.** *Let $\mathcal{F}$ be an* FDFA. *There is a constant-space algorithm to obtain an* FDFA *$\mathcal{F}^c$, such that $[\![\mathcal{F}^c]\!] = \Sigma^{*+} \setminus [\![\mathcal{F}]\!]$, $|\mathcal{F}^c| = |\mathcal{F}|$, and $\mathcal{F}^c$ is saturated iff $\mathcal{F}$ is.*

Union and intersection of saturated FDFAs also resemble the case of DFAs, and are done by taking the product of the leading automata and each pair of progress automata. Yet, the correctness proof is a bit subtle, and relies on the following lemma, which shows that for a normalized pair (x, y), the period-word y can be manipulated in a certain way, while retaining normalization.

▶ **Lemma 3.** *Let $\mathcal{Q}$ be an automaton, and let (x, y) be the normalization of some $(u, v) \in \Sigma^{*+}$ w.r.t. $\mathcal{Q}$. Then for every $i \geq 0$, $j \geq 1$ and finite words y', y'' such that $y = y'y''$, we have that $(xy^iy', (y''y')^j)$ is the normalization of itself w.r.t. Q.*

▶ **Theorem 4.** *Let $\mathcal{F}_1$ and $\mathcal{F}_2$ be saturated* FDFA*s of size (n_1, k_1) and (n_2, k_2), respectively. There exist logarithmic-space algorithms to obtain saturated* FDFA*s $\mathcal{H}$ and $\mathcal{H}'$ of size $(n_1n_2,\ k_1k_2)$, such that $[\![\mathcal{H}]\!] = [\![\mathcal{F}_1]\!] \cap [\![\mathcal{F}_2]\!]$ and $[\![\mathcal{H}']\!] = [\![\mathcal{F}_1]\!] \cup [\![\mathcal{F}_2]\!]$.*

Decision procedures

All of the basic decision problems can be resolved in nondeterministic logarithmic space, using the Boolean operations above and corresponding decision algorithms for DFAs.

The first decision question to consider is that of *membership*: given a pair (u, v) and an FDFA $\mathcal{F} = (\mathcal{Q}, \mathbf{P})$, does $\mathcal{F}$ accept (u, v)? The question is answered by normalizing (u, v)

[2] Another model that lies in between deterministic and nondeterministic automata are "semi-deterministic Büchi automata" [25], which are Büchi automata that are deterministic in the limit: from every accepting state onward, their behaviour is deterministic. Yet, as opposed to FDFAs, complementation of semi-deterministic Büchi automata might involve an exponential state blowup [2].

into a pair (x, y) and evaluating the runs of $\mathcal{Q}$ over x and of $\mathcal{P}_{\mathcal{Q}(x)}$ over y. A normalized pair is determined by traversing along $\mathcal{Q}$, making up to $|Q|$ repetitions of v. Notice that memory wise, x and y only require a logarithmic amount of space, as they are of the form $x = uv^i$ and $y = v^j$, where the representation of i and j is bounded by $\log |Q|$. The overall logarithmic-space solution follows from the complexity of algorithms for deterministically traversing along an automaton.

▶ **Proposition 5.** *Given a pair $(u, v) \in \Sigma^{*+}$ and an* FDFA *$\mathcal{F}$ of size (n, k), the membership question, of whether $(u, v) \in [\![\mathcal{F}]\!]$, can be resolved in deterministic space of $O(\log n + \log k)$.*

The next questions to consider are those of *emptiness* and *universality*, namely given an FDFA $\mathcal{F} = (\mathcal{Q}, \mathbf{P})$, whether $[\![\mathcal{F}]\!] = \emptyset$, and whether $[\![\mathcal{F}]\!] = \Sigma^{*+}$, respectively. Notice that the universality problem is equivalent to the emptiness problem over the complement of $\mathcal{F}$. For nondeterministic automata, the complement automaton might be exponentially larger than the original one, making the universality problem much harder than the emptiness problem. Luckily, FDFA complementation is done in constant space, as is the case with deterministic automata, making the emptiness and universality problems equally easy.

The emptiness problem for an FDFA $(\mathcal{Q}, \mathbf{P})$ cannot be resolved by only checking whether there is a nonempty progress automaton in $\mathbf{P}$, since it might be that the accepted period v is not part of any normalized pair. Yet, the existence of a prefix-word x and a period-word y, such that $\mathcal{Q}(x) = \mathcal{Q}(xy)$ and $\mathcal{P}_{\mathcal{Q}(x)}$ accepts y is a sufficient and necessary criterion for the nonemptiness of $\mathcal{F}$. This can be tested in NLOGSPACE. Hardness in NLOGSPACE follows by a reduction from graph reachability [8].

▶ **Theorem 6.** *Emptiness and universality for* FDFA*s are NLOGSPACE-complete.*

The complexity for *equality* and *containment* is easily derived from that of emptiness, intersection and complementation.

▶ **Proposition 7.** *Equality and containment for saturated* FDFA*s are NLOGSPACE-complete.*

Saturation check

All of the operations and decision problems above assumed that the given FDFAs are saturated. This is indeed the case when learning FDFAs via the algorithm of [1], and when translating ω-automata to FDFAs (see Section 5). We show below that the decision problem of whether an arbitrary FDFA is saturated is in PSPACE. We leave the question of whether it is PSPACE-complete open.

▶ **Theorem 8.** *The problem of deciding whether a given* FDFA *is saturated is in PSPACE.*

Proof Sketch. We first show that if an FDFA $\mathcal{F}$ of size (n, k) is unsaturated then there exist words u, v', v'' such that $|u| \leq n$ and $|v'|, |v''| \leq n^n k^{2k}$, and non-negative integers $l, r \leq k$ such that $(u, (v'v'')^l) \in \mathcal{F}$ while $(uv', (v''v')^r) \notin \mathcal{F}$.

Let $\mathcal{Q}$, $\mathcal{P}$, and $\mathcal{P}'$ be the leading automaton and two relevant progress automata, with state spaces Q, P and P', respectively. We achieve the bound on the length of v' and v'', by considering for every word $v \in \Sigma^*$, the function χ_v from (Q, P, P') to (Q, P, P') defined as $\chi_v(q, p, p') = (\delta_{\mathcal{Q}}(q, v), \delta_{\mathcal{P}}(p, v), \delta_{\mathcal{P}'}(p', v))$. Note that there are up to $n^n k^{2k}$ different such functions. Hence, if v' and v'' are longer than $n^n k^{2k}$, we can replace them with shorter words that are completely equivalent w.r.t. $\mathcal{Q}$, $\mathcal{P}$, and $\mathcal{P}'$.

A coNPSPACE algorithm guesses integers $l, r \leq k$ and, letter by letter, some words u, v', v'' such that $|u| \leq n$ and $|v'|, |v''| \leq n^n k^{2k}$. Along the way, it constructs $\chi_{v'v''}$ and $\chi_{v''v'}$.

It then verifies whether one of $(\chi_{v'v''})^l$ and $(\chi_{v''v'})^r$, applied to the relevant initial states, is accepting and the other is not. By Savitch's and Immerman–Szelepcsényi's theorems, the problem is in PSPACE. ◀

5 Translating To and From ω-Automata

As two ω-regular languages are equivalent iff they agree on the set of ultimately periodic words [11], an ω-regular language can be characterized by a language of pairs of finite words, and in particular by a saturated FDFA. We shall write $L \equiv L'$ to denote that a language $L \subseteq \Sigma^{*+}$ characterizes an ω-regular language L'. Formally:

▶ **Definition 9.** A language $L \subseteq \Sigma^{*+}$ *characterizes* an ω-regular language $L' \subseteq \Sigma^\omega$, denoted by $L \equiv L'$, if for every pair $(u, v) \in L$, we have $uv^\omega \in L'$, and for every ultimately periodic word $uv^\omega \in L'$, we have $(u, v) \in L$.

The families of DFAs defined in [9], as well as the analogous families of right congruences of [10], are known to characterize exactly the set of ω-regular languages [9, 10]. This is also the case with our definition of saturated FDFAs.

▶ **Theorem 10.** *Every saturated* FDFA *characterizes an ω-regular language, and for every ω-regular language, there is a saturated* FDFA *characterizing it.*

Proof. The two directions are proved in Theorems 12 and 16, below. ◀

5.1 From ω-Automata to FDFAs

We show that DBA, DCA, and DPA have polynomial translations to saturated FDFAs, whereas translation of NBAs to FDFAs may involve an inevitable exponential blowup.

From deterministic ω-automata. The constructions of a saturated FDFA that characterize a given DBA, DCA, or DPA $\mathcal{D}$ share the same idea: The leading automaton is equivalent to $\mathcal{D}$, except for ignoring the acceptance condition, and each progress automaton consists of several copies of $\mathcal{D}$, memorizing the acceptance level of the period-word. For a DBA or a DCA, two such copies are enough, memorizing whether or not a Büchi (co-Büchi) accepting state was visited. For a DPA with k colors, k such copies are required.

▶ **Theorem 11.** *Let $\mathcal{D}$ be a* DBA *or a* DCA *with n states. There exists a saturated* FDFA *$\mathcal{F}$ of size $(n, 2n)$, such that $[\![\mathcal{F}]\!] \equiv [\![\mathcal{D}]\!]$.*

▶ **Theorem 12.** *Let $\mathcal{D}$ be a* DPA *with n states and k colors. There exists a saturated* FDFA *$\mathcal{F}$ of size (n, kn), such that $[\![\mathcal{F}]\!] \equiv [\![\mathcal{D}]\!]$.*

From nondeterministic ω-automata. An NBA $\mathcal{A}$ can be translated into a saturated FDFA $\mathcal{F}$, by first determinizing $\mathcal{A}$ into an equivalent DPA $\mathcal{A}'$ [18, 7] (which might involve a $2^{O(n \log n)}$ state blowup and $O(n)$ colors [23]), and then polynomially translating $\mathcal{A}'$ into an equivalent FDFA (Theorem 12).

▶ **Proposition 13.** *Let $\mathcal{B}$ be an* NBA *with n states. There is a saturated* FDFA *that characterizes $[\![\mathcal{B}]\!]$ with a leading automaton and progress automata of at most $2^{O(n \log n)}$ states each.*

A $2^{O(n \log n)}$ state blowup in this case is inevitable, based on the lower bound for complementing NBAs [12, 26, 22], the constant complementation of FDFAs, and the polynomial translation of a saturated FDFA to an NBA:

▶ **Theorem 14.** *There exists a family of* NBA*s* $\mathcal{B}_1, \mathcal{B}_2, \ldots$, *such that for every* $n \in \mathbb{N}$, $\mathcal{B}_n$ *is of size* n, *while a saturated* FDFA *that characterizes* $[\![\mathcal{B}_n]\!]$ *must be of size* (m, k), *such that* $\max(m, k) \geq 2^{\Omega(n \log n)}$.

Proof. Michel [12] has shown that there exists a family of languages $\{L_n\}_{n \geq 1}$, such that for every n, there exists an NBA of size n for L_n, but an NBA for L_n^c, the complement of L_n, must have at least $2^{n \log n}$ states.

Assume, towards a contradiction, that exist $n \in \mathbb{N}$ and a saturated FDFA $\mathcal{F}$ of size (m, k) that characterizes L_n, such that $\max(m, k) < 2^{\Omega(n \log n)}$. Then, by Theorem 2, there is a saturated FDFA $\mathcal{F}^c$ of size (m, k) that characterizes L_n^c. Thus, by Theorem 16, we have an NBA of size smaller than $(2^{\Omega(n \log n)})^5 = 2^{\Omega(n \log n)}$ for L_n^c. Contradiction. ◀

5.2 From FDFAs to ω-Automata

We show that saturated FDFAs can be polynomially translated into NBAs, yet translations of saturated FDFAs to DPAs may involve an inevitable exponential blowup.

To nondeterministic ω-automata. We show below that every saturated FDFA can be polynomially translated to an equivalent NBA. Since an NBA can be viewed as a special case of an NPA, a translation of saturated FDFAs to NPAs follows. Translating saturated FDFAs to NCAs is not always possible, as the latter are not expressive enough.

The translation goes along the lines of the construction given in [4] for translating an $L_\$$-automaton into an equivalent NBA. We prove below that the construction is correct for saturated FDFAs, despite the fact that saturated FDFAs can be exponentially smaller than $L_\$$-automata.

We start with a lemma from [4], which will serve us for one direction of the proof.

▶ **Lemma 15** ([4]). *Let* $M, N \subseteq \Sigma^*$ *such that* $M \cdot N^* = M$ *and* $N^+ = N$. *Then for every ultimately periodic word* $w \in \Sigma^\omega$ *we have that* $w \in M \cdot N^\omega$ *iff there exist words* $u \in M$ *and* $v \in N$ *such that* $uv^\omega = w$.

We continue with the translation and its correctness.

▶ **Theorem 16.** *For every saturated* FDFA $\mathcal{F}$ *of size* (n, k), *there exists an* NBA $\mathcal{B}$ *with* $O(n^2 k^3)$ *states, such that* $[\![\mathcal{F}]\!] \equiv [\![\mathcal{B}]\!]$.

Proof. *Construction:* Consider a saturated FDFA $\mathcal{F} = (\mathcal{Q}, \mathbf{P})$, where $\mathcal{Q} = \langle \Sigma, Q, \iota, \delta \rangle$, and for each state $q \in Q$, $\mathbf{P}$ has the progress DFA $\mathcal{P}_q = \langle \Sigma, P_q, \iota_q, \delta_q, F_q \rangle$.

For every $q \in Q$, let M_q be the language of finite words on which $\mathcal{Q}$ reaches q, namely $M_q = \{u \in \Sigma^* \mid \mathcal{Q}(u) = q\}$. For every $q \in Q$ and for every accepting state $f \in F_q$, let $N_{q,f}$ be the language of finite words on which $\mathcal{Q}$ makes a self-loop on q, $\mathcal{P}_q$ reaches f, and $\mathcal{P}_q$ makes a self-loop on f, namely $N_{q,f} = \{v \in \Sigma^* \mid (\delta(q, v) = q) \wedge (\mathcal{P}_q(v) = f) \wedge (\delta_q(f, v) = f)\}$. We define the ω-regular language

$$L = \bigcup_{\{(q,f) \mid (q \in Q) \wedge (f \in F_q)\}} M_q \cdot N_{q,f}^\omega \tag{1}$$

One can construct an NBA $\mathcal{B}$ that recognizes L and has up to $O(n^2 k^3)$ states.

Correctness: Consider an ultimately periodic word $uv^\omega \in [\![\mathcal{B}]\!]$. By the construction of $\mathcal{B}$, $uv^\omega \in L$, where L is defined by Equation (1). Hence, $uv^\omega \in M_q \cdot N^\omega_{q,f}$, for some $q \in Q$ and $f \in F_q$. By the definitions of M_q and $N_{q,f}$, we get that M_q and $N_{q,f}$ satisfy the hypothesis of Lemma 15, namely $N^+_{q,f} = N_{q,f}$ and $M_q \cdot N^*_{q,f} = M_q$. Therefore, by Lemma 15, there exist finite words $u' \in M_q$ and $v' \in N_{q,f}$ such that $u'v'^\omega = uv^\omega$. From the definitions of M_q and $N_{q,f}$, it follows that the run of $\mathcal{Q}$ on u' ends in the state q, and $\mathcal{P}_q$ accepts v'. Furthermore, by the definition of $N_{q,f}$, we have $\delta(q, v') = q$, implying that (u', v') is the normalization of itself. Hence, $(u', v') \in [\![\mathcal{F}]\!]$. Since $\mathcal{F}$ is saturated and $u'v'^\omega = uv^\omega$, it follows that $(u, v) \in [\![\mathcal{F}]\!]$, as required.

As for the other direction, consider a pair $(u, v) \in [\![\mathcal{F}]\!]$, and let (x, y) be the normalization of (u, v) w.r.t. $\mathcal{Q}$. We will show that $xy^\omega \in L$, where L is defined by Equation (1), implying that $uv^\omega \in [\![\mathcal{B}]\!]$. Let $q = \mathcal{Q}(x)$, so we have that $\mathcal{P}_q(y)$ reaches some accepting state f of $\mathcal{P}_q$. Note, however, that it still does not guarantee that $y \in N_{q,f}$, since it might be that $\delta_q(f, y) \neq f$.

To prove that $xy^\omega \in L$, we will show that there is a pair $(x, y') \in \Sigma^{*+}$ and an accepting state $f' \in \mathcal{P}_q$, such that $y' = y^t$ for some positive integer t, and $y' \in N_{q,f'}$; namely $\delta(q, y') = q$, $\mathcal{P}_q(y') = f'$, and $\delta_q(f', y') = f'$. Note first that since $\mathcal{F}$ is saturated, it follows that for every positive integer i, $(x, y^i) \in [\![\mathcal{F}]\!]$, as $x(y^i)^\omega = xy^\omega$.

Now, for every positive integer i, $\mathcal{P}_q$ reaches some accepting state f_i when running on y^i. Since $\mathcal{P}_q$ has finitely many states, for a large enough i, $\mathcal{P}_q$ must reach the same accepting state $\hat{f}$ twice when running on y^i. Let h be the smallest positive integer such that $\mathcal{P}_q(y^h) = \hat{f}$, and r the smallest positive integer such that $\delta_q(\hat{f}, y^r) = \hat{f}$. Now, one can verify that choosing t to be an integer that is bigger than or equal to h and is divisible by r guarantees that $\delta(q, y^t) = q$ and $\delta_q(f', y^t) = f'$, where $f' = \mathcal{P}_q(y^t)$. ◀

To deterministic ω-automata. Deterministic Büchi and co-Büchi automata are not expressive enough for recognizing every ω-regular language. We thus consider the translation of saturated FDFAs to deterministic parity automata. A translation is possible by first polynomially translating the FDFA into an NBA (Theorem 16) and then determinizing the latter into a DPA (which might involve a $2^{O(n \log n)}$ state blowup [12]).

▶ **Proposition 17.** *Let $\mathcal{F}$ be a saturated* FDFA *of size (n, k). There exists a* DPA *$\mathcal{D}$ of size $2^{O(n^2k^3 \log n^2k^3)}$, such that $\mathcal{F} \equiv \mathcal{D}$.*

We show below that an exponential state blowup is inevitable. The family of languages $\{L_n\}_{n\geq 1}$ below demonstrates the inherent gap between FDFAs and DPAs; an FDFA for L_n may only "remember" the smallest and biggest read numbers among $\{1, 2, ..., n\}$, using n^2 states, while a DPA for it must have at least 2^{n-1} states.

We define the family of languages $\{L_n\}_{n\geq 1}$ as follows. The alphabet of L_n is $\{1, 2, ..., n\}$, and a word belongs to it iff the following two conditions are met:

- A letter i is always followed by a letter j, such that $j \leq i + 1$. For example, $533245\ldots$ is a bad prefix, since 2 was followed by 4, while $55234122\ldots$ is a good prefix.
- The number of letters that appear infinitely often is odd. For example, $2331(22343233)^\omega$ is in L_n, while $1(233)^\omega$ is not.

We show below how to construct, for every $n \geq 1$, a saturated FDFA of size polynomial in n that characterizes L_n.

▶ **Lemma 18.** *Let $n \geq 1$. There is a saturated* FDFA *of size $(n + 1, n^2)$ characterizing L_n.*

Proof Sketch. The leading automaton handles the safety condition of L_n, having $n+1$ states, and ensuring that a letter i is always followed by a letter j, such that $j \leq i+1$. The progress automata, which are identical, maintain the smallest and biggest number-letters that appeared, denoted by s and b, respectively. Since a number-letter i cannot be followed by a number-letter j, such that $j > i+1$, it follows that the total number of letters that appeared is equal to $b-s+1$. Then, a state is accepting iff $b-s+1$ is odd. ◀

A DPA for L_n cannot just remember the smallest and largest letters that were read, as these letters might not appear infinitely often. Furthermore, we prove below that the DPA must be of size exponential in n, by showing that its state space must be doubled when moving from L_n to L_{n+1}.

▶ **Lemma 19.** *Every* DPA *that recognizes L_n must have at least 2^{n-1} states.*

Proof. The basic idea behind the proof is that the DPA cannot mix between 2 cycles of n different letters each. This is because a mixed cycle in a parity automaton is accepting/rejecting if its two sub-cycles are, while according to the definition of L_n, the mixed cycle should reject if both its sub-cycles accept, and vice versa. Hence, whenever adding a letter, the state space must be doubled.

In the formal proof below, we dub a reachable state from which the automaton can accept some word a *live state*. Consider a DPA $\mathcal{D}_n$ that recognizes L_n, and let q be some live state of $\mathcal{D}_n$. Observe that $[\![\mathcal{D}_n^q]\!]$, namely the language of the automaton that we get from $\mathcal{D}_n$ by changing the initial state to q, is the same as L_n except for having some restriction on the word prefixes. More formally, if a word $w \in [\![\mathcal{D}_n^q]\!]$ then $w \in L_n$, and if $w \in L_n$ then there is a finite word u, such that $uw \in [\![\mathcal{D}_n^q]\!]$. For every $n \in \mathbb{N}$, and every $u \in \Sigma^*$, let $L_{n,u} = \{w \mid uw \in L_n\}$ and let $\mathfrak{L}_n$ denote the set of languages $\{L_{n,u} \mid u \in \Sigma^*\}$. Note that there is actually only a finite number of prefixes u to consider (this follows e.g. from [10, Thm. 22]). Moreover, for every state q of $\mathcal{D}_n$ there is a corresponding word u_q such that $[\![\mathcal{D}_n^q]\!] = L_{n,u_q}$.

We prove by induction on n the following claim, from which the statement of the lemma immediately follows: Let $\mathcal{D}_n$ be a DPA over $\Sigma = \{1, 2, \ldots, n\}$ that recognizes some language in $\mathfrak{L}_n$. Then there are finite words $u, v \in \Sigma^*$, such that:

(i) v contains all the letters in Σ;
(ii) the run of $\mathcal{D}_n$ on u reaches some live state p; and
(iii) the run of $\mathcal{D}_n$ on v from p returns to p, while visiting at least 2^{n-1} different states.

The base cases, for $n \in \{1, 2\}$, are trivial, as they mean a cycle of size at least 1 over v, for $n = 1$, and a cycle of size 2 for $n = 2$.

In the induction step, for $n \geq 2$, we consider a DPA $\mathcal{D}_{n+1}$ that recognizes some language $L \in \mathfrak{L}_{n+1}$. We shall define $\mathcal{D}'$ and $\mathcal{D}''$ to be the DPAs that result from $\mathcal{D}_{n+1}$ by removing all the transitions over the letter $n+1$ and by removing all the transitions over the letter 1, respectively.

Observe that for every state q that is live w.r.t. $\mathcal{D}_{n+1}$, we have that $[\![\mathcal{D}'^q]\!] \in \mathfrak{L}_n$, namely the language of the DPA that results from $\mathcal{D}_{n+1}$ by removing all the transitions over the letter $n+1$ and setting the initial state to q is in $\mathfrak{L}_n$. (Note that q might only be reachable via the letter $n+1$, yet it must have outgoing transitions over letters in $[2..n]$.) Analogously, $[\![\mathcal{D}''^q]\!]$ is isomorphic to a language in $\mathfrak{L}_n$ via the alphabet mapping of $i \mapsto (i-1)$. Hence, for every state q that is live w.r.t. $\mathcal{D}_{n+1}$, the induction hypothesis holds for $\mathcal{D}'^q$ and $\mathcal{D}''^q$.

We shall prove the induction claim by describing words $u, v \in \Sigma^*$, and showing that they satisfy the requirements above w.r.t. $\mathcal{D}_{n+1}$. We construct u by iteratively concatenating the words u'_i, v'_i, u''_i, and v''_i, which we define below, until the starting and ending states in some iteration k are the same. We then define the word v to be the last iteration, namely $u'_k\, v'_k\, u''_k\, v''_k$. Let q_1 be the initial state of $\mathcal{D}_{n+1}$. We define for every $i \in [1..k]$:

- u'_i and v'_i are the words that follow from the induction hypothesis on $\mathcal{D}'^{q_i}$, where q_i is the state that $\mathcal{D}_{n+1}$ reaches when reading $u'_1\, v'_1\, u''_1\, v''_1 \dots u'_{i-1}\, v'_{i-1}\, u''_{i-1}\, v''_{i-1}$.
- u''_1 and v''_1 are the words that follow from the induction hypothesis on $\mathcal{D}''^{q'_i}$, where q'_i is the state that $\mathcal{D}_{n+1}$ reaches when reading $u'_1\, v'_1\, u''_1\, v''_1 \dots u'_{i-1}\, v'_{i-1}\, u''_{i-1}\, v''_{i-1}\, u'_i\, v'_i$.

The word v obviously contains all the letters in Σ, as it is composed of subwords that contain all the letters in $\Sigma \setminus \{1\}$ and in $\Sigma \setminus \{n+1\}$. By the definition of u and v, we also have that the run of $\mathcal{D}_{n+1}$ on u reaches some live state p, and the run of $\mathcal{D}_{n+1}$ on v from p returns to p. Now, we need to prove that the run of $\mathcal{D}_{n+1}$ on v from p visits at least 2^n states.

We claim that when $\mathcal{D}_{n+1}$ runs on v from p, it visits disjoint set of states when reading v'_k and v''_k. This will provide the required result, as $\mathcal{D}_{n+1}$ visits at least 2^{n-1} states when reading each of v'_k and v''_k.

Assume, by way of contradiction, that $\mathcal{D}_{n+1}$ visits some state s both when reading v'_k and when reading v''_i. Let l' and r' be the parts of v'_k that $\mathcal{D}_{n+1}$ reads before and after reaching s, respectively, and l'' and r'' the analogous parts of v''_k. Now, define the infinite words $m' = u\, u'_k\, (l'\, r')^\omega$, $m'' = u\, u'_k\, l'\, (r''\, l'')^\omega$, and $m = u\, u'_k\, (l'\, r''\, l''\, r')^\omega$.

Observe that m' and m'' both belong or both do not belong to L, since there is the same number of letters (n) that appear infinitely often in each of them. The word m, on the other hand, belongs to L if m' and m'' do not belong to L, and vice versa, since $n+1$ letters appear infinitely often in it. However, the set of states that are visited infinitely often in the run of $\mathcal{D}_{n+1}$ on m is the union of the sets of states that appear infinitely often in the runs of $\mathcal{D}_{n+1}$ on m' and m''. Thus, if $\mathcal{D}_{n+1}$ accepts both m' and m'' it also accepts m, and if it rejects both m' and m'' it rejects m. (This follows from the fact that the minimal number in a union of two sets is even/odd iff the minimum within both sets is even/odd.) Contradiction. ◀

▶ **Theorem 20.** [3] *There is a family of languages $\{L_n\}_{n\geq 1}$ over the alphabet $\{1, 2, \dots, n\}$, such that for every $n \geq 1$, there is a saturated* FDFA *of size $(n+1, n^2)$ that characterizes L_n, while a* DPA *for L_n must be of size at least 2^{n-1}.*

Proof. By Lemmas 18 and 19. ◀

6 Discussion

The interest in FDFAs as a representation for ω-regular languages stems from the fact that they possess a correlation between the automaton states and the language right congruences, a property that traditional ω-automata lack. This property is beneficial in the context of

[3] A small adaptation to the proof of Lemma 19 shows an inevitable exponential blowup also when translating a saturated FDFA to a deterministic ω-automaton with a stronger acceptance condition of Rabin [19] or Streett [24]: A mixed cycle in a Rabin automaton is rejecting if its two sub-cycles are, and a mixed cycle in a Streett automaton is accepting if its two sub-cycles are. Hence, the proof of Lemma 19 holds for both Rabin and Streett automata if proceeding in the induction step from an alphabet of size n to an alphabet of size $n+2$, yielding a Rabin/Streett automaton of size at least $2^{\frac{n}{2}}$.

As for translating a saturated FDFA to a deterministic Muller automaton [13], it is known that translating a DPA of size n into a deterministic Muller automaton might require the latter to have an accepting set of size exponential in n [21]. (The family of languages in [21] uses an alphabet of size exponential in the number of states of the DPA, however it can easily be changed to use an alphabet of linear size.) Hence, by Theorem 12, which shows a polynomial translation of DPAs to FDFAs, we get that translating an FDFA to a deterministic Muller automaton entails an accepting set of exponential size, in the worst case.

learning, and indeed an algorithm for learning ω-regular languages by means of saturated FDFAs was recently provided [1]. Analyzing the succinctness of saturated FDFAs and the complexity of their Boolean operations and decision problems, we believe that they provide an interesting formalism for representing ω-regular languages. Indeed, Boolean operations and decision problems can be performed in nondeterministic logarithmic space and their succinctness lies between deterministic and nondeterministic ω-automata.

Abstract

What is the minimum amount of information and time needed to solve 2SAT? When the instance is known, it can be solved in polynomial time, but is this also possible without knowing the instance? Bei, Chen and Zhang (STOC '13) considered a model where the input is accessed by proposing possible assignments to a special oracle. This oracle, on encountering some constraint unsatisfied by the proposal, returns only the constraint index. It turns out that, in this model, even 1SAT cannot be solved in polynomial time unless P=NP. Hence, we consider a model in which the input is accessed by proposing probability distributions over assignments to the variables. The oracle then returns the index of the constraint that is most likely to be violated by this distribution. We show that the information obtained this way is sufficient to solve 1SAT in polynomial time, even when the clauses can be repeated. For 2SAT, as long as there are no repeated clauses, in polynomial time we can even learn an equivalent formula for the hidden instance and hence also solve it. Furthermore, we extend these results to the quantum regime. We show that in this setting 1QSAT can be solved in polynomial time up to constant precision, and 2QSAT can be learnt in polynomial time up to inverse polynomial precision.

1 Introduction

SAT has been a pivotal problem in theoretical computer science ever since the advent of the Cook-Levin Theorem [7, 13] proving its NP-completeness. It has a wide array of applications in operations research, artificial intelligence and bioinformatics. Moreover, it continues to be studied under various specialized models such as as random-SAT and building efficient SAT solvers for real-life scenarios. In the complexity theoretic setting, we know that while 3SAT is NP-complete [7, 13], 2SAT can be solved in linear time [12, 9, 3]. Given the fundamental nature of 2SAT, in this paper, we consider the following question:

What is the minimum amount of information needed to solve 2SAT *in polynomial time?*

More precisely, what happens if there is no direct access to the problem instance? Are there settings where one can *solve* 2SAT without ever *learning* the instance under consideration? We can also pose the same question for the quantum setting where the quantum analogue of SAT (QSAT) can be seen as a central problem in condensed matter physics. Complexity theoretically, we know that 2QSAT can be solved in linear time [2, 8] while 3QSAT is hard for QMA_1 [10], where QMA_1 is a quantum complexity class analogous to NP. We approach these questions through the "trial and error" model. In this model, one guesses a solution to an unknown constraint satisfaction problem and tests if it is valid. If so, then the problem is solved. Otherwise, the trial fails, and some information about what was wrong with the trial is revealed. This type of problem arises in a number of natural scenarios, in which one has incomplete or limited information about the problem they are trying to solve [4]. For example, the CSP may be instantiated by a complex biological or physical process to which one does not have access.

This approach to problem solving was first formalized by Bei, Chen and Zhang [4]. They considered several types of CSPs and analyzed the computational complexity in the "unknown input" setting. Specifically, they consider an oracle model where one can propose solutions to the CSP, and if the solution is not satisfying, then the oracle reveals the identity of a constraint which was violated. For example, if the CSP is an instance of Boolean satisfiability (SAT), then after an unsuccessful trial, one may learn that "clause 7 was violated", but not anything further. In particular, literals present in clause 7 will not be revealed - only the label of violated clause is known. Furthermore, if there are several violated constraints, then the oracle reveals only one of them, in a possibly adversarial manner. In this paper, we will refer to this as the "arbitrary violated constraint" oracle.

This model gives extremely limited access to the instance. In fact, Ivanyos et al. [11] showed that even if the underlying CSP is a 1SAT instance, accessing it with the BCZ oracle, one cannot determine if it is satisfiable in polynomial time unless $\text{P} = \text{NP}$. This drastically increases the difficulty of deciding a trivial problem like 1SAT (assuming $\text{P} \neq \text{NP}$). Interestingly, if there is access to a SAT solver, then 1SAT (and even generic SAT) in this setting can be solved with polynomially many trials [4]. So in some sense, their model reveals a sufficient amount of *information* to solve the 1SAT instance. However, *decoding* this information requires superpolynomial time (assuming $\text{P} \neq \text{NP}$). In short the information needed to solve the problem is present, but it is not accessible to poly-time algorithms.

In this paper, we ask if there are any meaningful modifications of their model which allow us to solve simple CSPs like 1SAT and 2SAT in polynomial time. A natural starting point is to randomize the "arbitrary violated constraints" model. One obvious way to do that is to consider allowing randomized queries to the oracle. This however does not significantly decrease the complexity of the problems. A second approach to randomize is to let the oracle return a violated clause at random. Contrary to the previous approach, this model trivializes the problem, since by repeating the same trial many times the oracle will reveal all violated clause indices with high probability. This in turn allows one to learn the entire instance, and therefore trivially, to solve 1SAT and 2SAT.

Motivated by these unfruitful approaches we consider a model which does not allow one to completely learn the underlying instance, but it still yields polynomial time algorithms for 1SAT and 2SAT. Specifically, in this model one can propose a probability distribution D over assignments, and the oracle reveals the index of the clause which is most likely to be violated by this trial. If there are multiple clauses with the same probability of violation under D, then the oracle can break ties arbitrarily. In particular, product distributions over the variables suffice for our application, so one merely specifies the probability p_i that each variable x_i is set to 1 in the assignment, to $1/\operatorname{poly}$ precision. We show that in this model, there exist cases where one cannot learn the underlying 1SAT or 2SAT instance. However, despite this limitation, one can still solve in polynomial time 1SAT and a restricted version of 2SAT where clauses are not repeated. In the course of the algorithm for the restricted version of 2SAT, we actually learn an equivalent formula with the same set of satisfying assignments. Furthermore, we are able extend this model to the quantum setting, and show that one can solve, in polynomial time, Quantum 1SAT (1QSAT) up to constant precision. We also show that in polynomial time we can learn Quantum 2SAT (2QSAT) up to inverse polynomial precision. This, however, seems insufficient to solve the hidden instance in polynomial time due to some subtle precision issues, which we discuss in Section 7.

Relation to prior work. As previously mentioned, Bei Chen and Zhang [4] introduced the trial and error model. They considered several examples of CSPs and analyzed their complexity under the unknown input model with the "arbitrary violated constraint" oracle. With regards to SAT, they showed an algorithm to solve hidden-SAT using polynomially many queries to the oracle (given access to a SAT oracle). Furthermore, they showed that one cannot efficiently learn generic SAT instances in this model, because it takes $\Omega(2^n)$ queries to the oracle to learn a clause involving all n variables of the instance.

Subsequently, Ivanyos *et al.* [11] characterized the complexity of classical CSPs in several hidden input models. In particular, they consider the "arbitrary violated constraint" model described above, as well as models which reveal more information such as the variables involved in the violated clause or the relation of the violated clause. They show a generic "transfer theorem" which classifies the complexity of hidden versions of CSPs given properties of the base CSP. In particular, their transfer theorem implies that the hidden version of 1SAT with arbitrary violated constraints cannot be solved in polynomial time unless P = NP. This indicates that the "arbitrary violated constraint" model is fairly restrictive.

In parallel, Bei, Chen and Zhang [5] considered a version of the trial and error model for linear programming. Suppose you have a linear program, and you are trying to determine whether or not it is feasible (By standard reductions this is as difficult as solving a generic LP). They consider a model in which one can propose a point, and the oracle will return the index of an arbitrary violated constraint (half-plane) in the linear program. They show that in this model, one requires exponentially many queries to the oracle to determine if an LP is feasible. However, they then consider a relaxation of this model, in which the oracle returns the index of the *worst-violated* constraint, i.e. the half-plane which is furthest (in Euclidean distance) from the proposed point. Surprisingly, they show (using a variant of the ellipsoid algorithm) that one can still solve linear programs in this model in polynomial time. Our model can be seen as an analogue of the "worst violated constraint" model of Bei, Chen and Zhang [5] for the case of hidden SAT (H–SAT).

Our Results. Our results can be broken into several sections. First, we consider a relaxation of the "arbitrary violated constraint" model of Bei, Chen and Zhang [4], in which the oracle reveals which subset of clauses are violated by each assignment[1]. We show that in some sense these models are almost "too easy"

▶ **Theorem** (Informal statement). *In the "all violated constraints" model, there is an algorithm which either learns an arbitrary* kSAT *instance on n variables and m clauses, or else finds a satisfying assignment to the instance, in time $O(mn^k)$.*

We then explore the "worst violated constraint" model for the rest of the paper. We provide an example for why this model is more powerful than the "arbitrary violated constraint" model of Bei, Chen and Zhang [4]. They showed that it requires $\Omega(2^n)$ time to learn a SAT clause involving all n variables. Our example states that

▶ **Proposition.** *Given a hidden* WIDESAT *instance on n variables and m distinct clauses where $m \leq n$, we can learn an equivalent instance in $O(\binom{n}{m-1}2^m + n)$ time.*

The proofs of the above results are omitted owing to space constraints[2]. Among our main results is the analysis of the computational complexity of H–1SAT and that of H–2SAT.

▶ **Theorem** (Informal statement). *Given a hidden* SAT *formula Φ on n variables and n clauses, it is possible to find a satisfying assignment for Φ in polynomial time if Φ is a*
(a) 1SAT *formula or*
(b) 2SAT *formula with no repeated clauses.*

Our algorithm for H–1SAT, in Section 3, works even when clauses are repeated multiple times in the instance, despite the fact that it's not possible to *learn* the instance in this setting. This is in sharp contrast to the "arbitrary violated constraint" model, where even H–1SAT cannot be solved in polynomial time unless P = NP [11]. The main difficulty in deriving our algorithm for H–1SAT comes from dealing with repeated clauses, which allow the oracle to obscure information about the instance. Unlike the H–1SAT case, the algorithm for H–2SAT discussed in Section 4, works by attempting to learn the instance; it either succeeds in learning an equivalent instance (in which case one can solve the problem using any 2SAT algorithm), or it accidentally stumbles upon a satisfying assignment in the meantime and aborts. The problem of solving H–2SAT with repeated clauses similar to H–1SAT is left for future work.

Following this we generalize these results to the quantum case. In this case the goal is to determine if a set of 1-qubit or a set of 2-qubit projectors is mutually satisfiable or not. We consider an analogue of this model in which one can propose a probability distribution over quantum states (i.e. a density matrix), and the oracle returns the index of the clause which is most likely to be violated. Our results for hidden QSAT (H–QSAT) show that

▶ **Theorem** (Informal statement). *Given a* H–QSAT *instance H defined on n qubits with m projectors and $\epsilon > 0$, it is possible to*

[1] This is equivalent to a model in which the oracle reveals a random violated clause - by repeating each query many times one can learn the set of violated clauses with high probability.
[2] Omitted details and proofs can be found in the full version of the paper at `http://arxiv.org/abs/1606.03585`.

(a) *solve H to a precision ϵ in time $O(n^{\log(1/\epsilon)})$ if H is a* 1QSAT *instance and*
(b) *learn each projector of H up to precision ϵ in time $O(n^4+n^2\log(1/\epsilon))$, if H is a* 2QSAT *instance as long as the interaction graph of H is not star-like.*

By star-like, we mean the interaction graph contains an edge that is incident to all other edges in the graph. At this point it is worth comparing the notions of *learning* and *solving* hidden instances both in the classical and quantum settings. The classical case is more straightforward where learning an instance means learning all the literals present in each clause, whereas solving means finding a satisfying assignment. For example, our algorithm for H–2SAT without repetitions learns the instance, while our algorithm for H–1SAT solves the instance without learning it. For hidden versions of 1SAT and 2SAT, learning the instance in polynomial time automatically triggers solving it in polynomial time as well.

However, in the quantum setting this simple relation between learning and solving breaks down. The continuous nature of QSAT means we can only learn a projector or find a satisfying assignment up to a specified precision ϵ. The latter is accomplished with our H–1QSAT algorithm in Section 6. However in the case of hidden 2QSAT learning the instance up to precision ϵ does not imply that one can solve the instance up to precision poly(n,ϵ) in polynomial time. This can be attributed to current algorithms for 2QSAT being very sensitive to precision errors. This issue of divergence between the notions of learning and solving H–2QSAT instances is further discussed in Section 7.

2 Notations and Preliminaries

Boolean Satisfiability. The Boolean satisfiability problem, generally referred to as SAT, is a constraint satisfaction problem defined on n variables $\mathbf{x} = \{x_1,\ldots,x_n\}$ where we are given a formula represented as a conjunction of m clauses and each clause is a disjunction of *literals* (variables, x_j, or negated variables, $\overline{x}_j$). The problem is solved if we can find an assignment to the variables (i.e. $\forall\ i,\ x_i \in \{0,1\}$) that sets the value of every clause to 1. In particular, if each clause involves at most k literals, then this problem is classified as kSAT. It is well known that while 2SAT can be solved in linear time [12, 9, 3], kSAT for $k \geq 3$ is NP-complete [7, 13]. A useful notion is that of *clause types* which is defined as the unordered set of literals present in the clause. Specifically, the clause type for $C_j = (x_a \vee \overline{x}_b \vee x_c)$ is denoted by $T(C_j) = \{x_a, \overline{x}_b, x_c\}$. So, all possible clause types for 2SAT would be $\{\{x_a,x_b\},\{x_a,\overline{x}_b\},\{\overline{x}_a,x_b\},\{\overline{x}_a,\overline{x}_b\} \mid a,b\in[n]$ and $a\neq b\}$, where $[n]$ denotes the set $\{1,\ldots,n\}$. From this definition, it is clear that 2SAT has $O(n^2)$ clause types and similarly, kSAT would have $\binom{2n}{k} = O(n^k)$ clause types. . Given a SAT formula ϕ, we say that the SAT formula ϕ' is *equivalent* to ϕ if for all assignments $\mathbf{x}\in\{0,1\}^n$, $\mathbf{x}$ satisfies ϕ if and only if it satisfies ϕ'. For any formula ϕ, SAT$(\phi) := \{\mathbf{x}\in\{0,1\}^n \mid \phi(\mathbf{x}) = 1\}$.

Hidden SAT. While considering the unknown input version of SAT (resp. kSAT), the boolean formula is considered as hidden and accessible only via an oracle that accepts an assignment and reveals some form of violation information. In our case, this is the "worst violated oracle" which accepts a *probabilistic* assignment and reveals a clause that has the *highest probability* of being violated with ties being broken arbitrarily. A probabilistic assignment for a set of n variables is a function $\mathbf{a} : [n] \to [0,1]$ such that $Pr[x_i = 1] = \mathbf{a}(i)$ and $Pr[x_i = 0] = Pr[\overline{x}_i = 1] = 1 - \mathbf{a}(i)$. For the sake of concise notation, these are usually written as $x_i = \mathbf{a}(i)$ and $\overline{x}_i = 1 - \mathbf{a}(i)$. This naturally translates to the notion of the probability of a clause C_j being violated which is defined as $Pr[C_j = 0] := \prod_{\ell\in T(C_j)} Pr[\ell = 0] = \prod_{\ell\in T(C_j)}(1-\ell)$ which allows the oracle to calculate the probability for each clause being violated. Here we are using ℓ to refer both to the identity of a literal as well as to the probability that literal ℓ is set to true. Now, the problem H–SAT (resp. H–kSAT) consists of finding a satisfying assignment for a hidden SAT (resp. kSAT) formula by proposing probabilistic assignments to the "worst violated oracle". One way we do this is also by *learning* an *equivalent formula* to the hidden instance and solve it to find a satisfying assignment. By learning we mean the process of using the information from a series of violations to determine what a clause in the hidden instance could be.

Note that it's possible for an instance to contain clauses which will never be returned by the oracle. For instance, given clauses C_i and C_j, if $T(C_i) \subset T(C_j)$, then clause C_i will always be at least as violated as C_j. Hence the oracle might never return clause C_j. For this reason we will say that C_i *obscures* C_j if $T(C_i) \subset T(C_j)$. An obscured clause might never be returned by the oracle.

The complexity of the algorithms in the following sections is in terms of the total running time where one query to the oracle takes unit time.

3 Hidden 1SAT

In this section, we will consider the problem of a hidden 1SAT instance Φ, possibly with repetitions. Our goal will be to determine whether or not Φ is satisfiable. A natural approach one might take to solve this problem would be to learn the identity of each clause in the instance Φ. Unfortunately, in the case that the 1SAT instance has repetitions, this is not possible.

▶ **Proposition 1.** *There is no algorithm which, given an instance Φ which is unsatisfiable, learns all the literals present in Φ (even granted arbitrary numbers of queries to the oracle).*

Here the difficulty in learning an unsatisfiable instance does not lie in the repetition of clauses, but rather in determining for which i do both x_i and $\overline{x}_i$ appear in Φ. This shows that no algorithm can learn the hidden 1SAT instance [3] (proof omitted owing to space constraints). Hence if there is an algorithm to solve 1SAT in this hidden setting, then it must solve the instance despite the fact that it cannot deduce the underlying instance. Surprisingly, this turns out to be possible.

▶ **Theorem 1.** *Given a hidden* 1SAT *instance Φ on n variables and m clauses, it is possible to determine if Φ is satisfiable in time $O(mn^2)$.*

Proof Consider an ordering of the variables $x_1 ... x_n$. The algorithm will work by inductively constructing a series of lists $L_1, L_2, \dots L_n$. Each list L_i will contain a list of partial assignments to the variables $x_1 \dots x_i$. Each list will be of size at most m, with the exception of L_n which will be of size at most $2m$. Let us call a partial assignment p to $x_1 \dots x_i$ *good* if there exists an assignment p' to the variables $x_{i+1} \dots x_n$ such that the assignment $p \cup p'$ satisfies Φ. Correspondingly, call p *bad* if it cannot be extended to a satisfying assignment of Φ. (Note in the case of 1SAT, every partial assignment is either good or bad.) Our algorithm will guarantee that, if Φ is satisfiable, then at least one assignment in each list is "good". Therefore, by constructing the list L_n, then trying all assignments in L_n, we will be guaranteed to find a satisfying assignment if one exists.

[3] Note, however, it is still possible that there exists an algorithm to learn the 1SAT instance when the instance is promised to be satisfiable.

We now describe how to construct the lists $\{L_i\}_{i\in[n-1]}$ by induction. The base case of L_1 is trivial - just add both $x_1 = 0$ and $x_1 = 1$ to the list. We now show how to construct L_{i+1} given L_i. First, let $\tilde{L}_{i+1}$ be all possible extensions of the assignments in L_i to the variable x_{i+1}. Clearly if one of the assignments in L_i was good, then one of the assignments in $\tilde{L}_{i+1}$ is good. However, when $i + 1 < n$, the size of $\tilde{L}_{i+1}$ could become too large - it is of size $2|L_i|$ which could at some point become larger than m. So we need to reduce the size of $\tilde{L}_{i+1}$ so that it contains at most m partial assignments. To decide which partial assignments to keep, we will perform the following oracle queries: for each partial assignment $y \in \tilde{L}_{i+1}$, propose the following query q_y to the oracle: set $x_1 ... x_{i+1}$ to 0 or 1 according to y, and set all other variables to value 1/2. The oracle will return the identity of a clause C_j which is worst violated by this fractional assignment. Now partition the elements of $\tilde{L}_{i+1}$ according to which clause C_j was returned by the query. This divides the elements of $\tilde{L}_{i+1}$ into at most m equivalence classes. To construct L_{i+1}, simply pick one element from each equivalence class of $\tilde{L}_{i+1}$.

Clearly L_{i+1} has size at most m by construction. To complete the proof, we need to show that at least one element of L_{i+1} is good. First, by the induction hypothesis, at least one element of L_i is good. This implies at least one element $y^* \in \tilde{L}_{i+1}$ is good as well. Consider what happens when we perform the query q_{y^*}. Since y^* is good, q_{y^*} must satisfy all clauses involving the variables $x_1 \dots x_{i+1}$. If there are no clauses involving the remaining variables $x_{i+2} \dots x_n$, then q_{y^*} satisfies the instance, so the oracle will tell us this and we can terminate the algorithm. Otherwise, there is a clause involving some variable in $\{x_{i+2} \dots x_n\}$. When we query q_{y^*}, the worst violated clause will be some clause C_k involving a variable in $\{x_{i+2} \dots x_n\}$, which will be violated with probability 1/2. So the equivalence class corresponding to C_k will contain a good assignment. Furthermore, since C_k involves one of the variables in $\{x_{i+2} \dots x_n\}$, it will never be returned as the worst violated clause for query $q_{y'}$ for any bad assignment $y' \in \tilde{L}_{i+1}$, because any bad assignment will violate a clause involving $\{x_1 \dots x_{i+1}\}$ by 1, while C_k will be violated only with probability 1/2. Therefore the equivalence class corresponding to C_k will contain only good assignments. So by picking one assignment from each equivalence class, we will ensure L_{i+1} contains at least one good assignment, as claimed.

The time to construct each list is $O(mn)$, and the algorithm constructs n lists. Hence the algorithm runs in time $O(mn^2)$. ☐

4 Hidden 2SAT without repetitions

In this section, we consider a hidden 2SAT formula Φ which is promised to contain no two clauses that are the same. Although Proposition 1 shows that we cannot always hope to learn Φ directly, it does not rule out the possibility of learning some Φ' such that $\mathrm{SAT}(\Phi') = \mathrm{SAT}(\Phi)$. In fact, this is exactly the approach we take. The full proof of this is omitted to conserve space, but the most interesting aspect is contained in the theorem below.

▶ **Theorem 2.** *Suppose Φ is a hidden repetition-free* 2SAT *instance on n variables. Then it is possible to generate a satisfying assignment in time $O(n^2)$.*

Proof The idea is to attempt to learn each clause present in the formula. Suppose we wish to determine if the clause $(x_i \vee x_j)$ is present in Φ (an analogous procedure works to determine if a 1SAT clause x_i is in Φ). We can assume that the clause is unobscured because the presence of an obscured clause does not affect the set of satisfying assignments. Run the following procedure:

Table 1 Violation of the clauses based on the fractional assignments of 1/4 and 3/4.

	$(x_i \vee x_j)$	$(x_i \vee x_k)$	$(x_j \vee x_k)$	$(x_{k_1} \vee x_{k_2})$	$(x_{k_1} \vee \bar{x}_{k_2})$	$(x_i \vee \bar{x}_k)$	$(x_j \vee \bar{x}_k)$	$(\bar{x}_{k_1} \vee \bar{x}_{k_2})$
1/4	1	3/4	3/4	9/16	3/16	1/4	1/4	1/16
3/4	1	1/4	1/4	1/16	3/16	3/4	3/4	9/16

1. First query the oracle with the assignment $x_i = 0$, $x_j = 0$, $x_k = 0$ for $k \neq i, j$. If this is a satisfying assignment, then we are done. Otherwise, we know that there must exist a clause of type:
   (a) $(x_i \vee x_j)$;
   (b) $(x_i \vee x_k)$ for $k \neq i, j$;
   (c) $(x_j \vee x_k)$ for $k \neq i, j$; or
   (d) $(x_{k_1} \vee x_{k_2})$ for $k_1, k_2 \neq i, j$.
5. Now query the oracle with the assignment $x_i = 0$, $x_j = 0$, $x_k = 1$ for $k \neq i, j$. As before, if this is satisfying, we are done. Otherwise, we know that there must exist a clause of type:
   (a) $(x_i \vee x_j)$;
   (b) $(x_i \vee \bar{x}_k)$ for $k \neq i, j$;
   (c) $(x_j \vee \bar{x}_k)$ for $k \neq i, j$; or
   (d) $(\bar{x}_{k_1} \vee \bar{x}_{k_2})$ for $k_1, k_2 \neq i, j$.
5. We can now construct an explicit test for the presence of the clause $(x_i \vee x_j)$. We will propose two fractional assignments to the oracle. If $(x_i \vee x_j)$ is present, then the clause returned each time will be the same. If it is not present, then the returned clause will be different. Formally, query the oracle with the assignment $x_i = 0$, $x_j = 0$, $x_k = \frac{1}{4}$ for $k \neq i, j$ and then with the assignment $x_i = 0$, $x_j = 0$, $x_k = \frac{3}{4}$ for $k \neq i, j$. Table 1 shows the accompanying violations.
   It is clear that if $(x_i \vee x_j)$ is present in the formula, then it is returned on both assignments. If it is not present, then from the table we can also see that one of the clauses known to exist from our first query must be returned on the 1/4 fractional assignment. However, one of the clauses known to exist from our second query must be returned on the 3/4 fractional assignment. Thus, the clause returned by the oracle changes when $(x_i \vee x_j)$ is not present.

Notice that the above procedure also works to detect all 1SAT and 2SAT clause types. Therefore, if we complete the above procedure with all $O(n^2)$ clause types without finding a satisfying assignment, then we have identified all unobscured clauses in the formula. It is clear that the conjunction of these clauses forms a formula Φ' such that $\text{SAT}(\Phi') = \text{SAT}(\Phi)$. Therefore, we can use any 2SAT algorithm which runs in time $O(n^2)$ on Φ' to find some satisfying assignment of Φ. ☐

While the above procedure may seem elementary, it acts as a stepping stone to tackle the harder problem of learning an unknown input instance of quantum 2SAT, which is introduced and discussed in the subsequent sections.

5 Quantum SAT Preliminaries

Notations. A quantum system of n qubits is described using a Hilbert space $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2 \otimes \ldots \otimes \mathcal{H}_n$ where each $\mathcal{H}_i$ is a two-dimensional Hilbert space of the i^{th} qubit. Vectors in $\mathcal{H}$ are called *pure states* and they describe a state of the system. By adding a subscript i to the vector $|\alpha\rangle$ we indicate that $|\alpha\rangle_i$ is defined in the local Hilbert space $\mathcal{H}_i$ of the i^{th}

qubit. Similarly, $|\psi\rangle_{ij}$ denotes a 2-qubit state $|\psi\rangle$ in $\mathcal{H}_i \otimes \mathcal{H}_j$. In any local qubit space $\mathcal{H}_i$, we pick an orthonormal basis $|0\rangle, |1\rangle$ so that every 1-qubit state $|\alpha\rangle$ can be expanded as $|\alpha\rangle = \alpha_0|0\rangle + \alpha_1|1\rangle$. We define its orthogonal state by $|\alpha^\perp\rangle := \alpha_1|0\rangle - \alpha_0|1\rangle$;[4] clearly, $\langle\alpha|\alpha^\perp\rangle = 0$. A standard geometrical representation of the state space of a single qubit is the Bloch sphere. The interested reader is referred to [14] for details on the exact correspondence between quantum states and points on the Bloch Sphere.

A more general way to describe a quantum state is by its *density matrix.* Density matrices can be viewed as statistical ensembles of pure states that are described by vectors. A density matrix representation a single pure state $|\psi\rangle$ is given by the matrix $\rho = |\psi\rangle\langle\psi|$. General density matrices are given as a convex sum of density matrices of the pure states with the coefficient summing up to 1: $\sigma = \sum_i p_i|\psi_i\rangle\langle\psi_i|$ where $\forall i, p_i \geq 0$ and $\sum_i p_i = 1$. Alternatively, they are defined as semi-definite operators whose trace is equal to 1. For instance, the density matrix $\frac{1}{2}\mathbb{I}$ can be written as $\frac{1}{2}\mathbb{I} = \frac{1}{2}|0\rangle\langle 0| + \frac{1}{2}|1\rangle\langle 1|$. The state of a quantum system can always be fully specified by a density matrix.

Observables in quantum mechanics are associated with Hermitian operators. The eigenvalues of such an operator correspond to the possible outcomes of a measurement. Given such a Hermitian operator A and a pure state $|\psi\rangle$, the expression $\langle\psi|A|\psi\rangle$ is the *expectation value* of A. It is the result we get if we measure A over many copies of the same state $|\psi\rangle$ and average the result. One can use the Chernoff bound to deduce that, with high probability, if we measure A over $\mathrm{poly}(n)$ copies of a state $|\psi\rangle$, we obtain an approximation to $\langle\psi|A|\psi\rangle$ with an additive error of $1/\mathrm{poly}(n)$.

The expectation value of A with respect to a state which is described by a density matrix ρ is given as $\mathrm{Tr}(\rho A)$. Note that if ρ is given by $\rho = \sum_i p_i|\psi_i\rangle\langle\psi_i|$ with $\sum_i p_i = 1$, then $\mathrm{Tr}(\rho A) = \sum_i p_i\langle\psi_i|A|\psi_i\rangle$, which justifies the interpretation of ρ as a statistical ensemble of pure states. Like in the pure state case, using $\mathrm{poly}(n)$ identical copies of ρ, one can estimate the expectation value $\mathrm{Tr}(\rho A)$ up to an additive error of $1/\mathrm{poly}(n)$.

Local Hamiltonians and Quantum SAT. While classically SAT is given as a CSP, quantum kSAT (kQSAT) is defined as a special case of the k-local Hamiltonian problem. A k-local Hamiltonian on n qubits is a Hermitian operator $H = \sum_{e=1}^m h_e$, where each h_e is a *local* Hermitian operator acting non-trivially on at most k qubits. Formally, it is written as $h_e = \hat{h}_e \otimes \mathbb{I}_{rest}$, where $\hat{h}_e$ is defined on the Hilbert space of k qubits, and $\mathbb{I}_{rest}$ is the identity operator on the Hilbert space of the rest of the qubits. When it is clear from the context, we often use h_e instead of $\hat{h}_e$, even while referring to its action on the local Hilbert space.

In physics, k-local Hamiltonians model the local interactions between particles in a many-body system and are the central tool for describing the physics of such systems. The *energy* of the system for every state $|\psi\rangle$ is defined by $E_\psi(H) := \langle\psi|H|\psi\rangle = \sum_e\langle\psi|h_e|\psi\rangle$. The lowest possible energy of the system is called the *ground energy* and is denoted by $E_0(H)$. It is easy to verify that $E_0(H)$ is the lowest eigenvalue of H. The corresponding eigenspace is called the *ground space* of the system, and its eigenvectors are called *ground states.* A central task in condensed matter physics is to understand the properties of the ground space, as it determines the low-temperature physics of the system.

There is a deep connection between the problem of approximating the ground energy of a local Hamiltonian and the classical problem of finding an assignment with minimal violations in a local CSP. In both cases, one tries to minimize a global function that is given

[4] There are, of course, continuously many orthogonal states for every $|\alpha\rangle$, so here we simply choose one in a canonical way.

in terms of local constraints. This connection is evident if we consider the special case when the local Hermitian operators h_e are given as local *projectors* Π_e. Then for any state $|\psi\rangle$, the local energy $\langle\psi|\Pi_e|\psi\rangle$ is a number between 0 and 1 that can be viewed as a measure to how much the state is 'violating' the quantum clause Π_e. When the local energy is 0, the state is inside the null space of the projector Π_e and is said to satisfy the constraint. The total energy of the system, $E_\psi = \langle\psi|H|\psi\rangle = \sum_e \langle\psi|\Pi_e|\psi\rangle$ then corresponds to the total violation of the state $|\psi\rangle$. When the ground energy of the system is 0, necessarily the ground space is the non-vanishing intersection of all the null spaces of the local projectors, and we say that the system is satisfiable. From a physical point of view, such a system is called *frustration-free*, since any ground state of the global system also minimizes the energy of every local term Π_e.

The quantum kQSAT problem is analogous to the classical kSAT problem. Whereas in the kSAT case we are asked to decide whether a k-local CSP is satisfiable or not, in the kQSAT problem we are asked to determine whether the ground energy of a k-local Hamiltonian made of projectors is 0 or not. Unlike the truth values of SAT clauses, however, the ground energy of a k-local Hamiltonian is a continuous function that is sensitive to any infinitesimal change in the form of the local projectors. To make the kQSAT problem more physically relevant, we define it using a promise: Given a k-local Hamiltonian of projectors over n qubits and a value $b > \frac{1}{n^\alpha}$ for some constant α, decide if the ground energy of H is 0 (the YES case) or the ground energy of H is at least b (the NO case). Bravyi [6] showed that kQSAT for $k \geq 4$ is QMA$_1$-complete while Gosset and Nagaj [10] showed that 3QSAT is also QMA$_1$-complete. The class QMA$_1$ stands for 'Quantum Merlin Arthur' with one-way error, and is the quantum generalization of the classical MA$_1$ class with one-way error. The differences are that the witness can be a quantum state over poly(n) qubits, and the verifier can be an efficient quantum machine. In Ref. [6] it was known that 2QSAT has an $O(n^4)$ classical algorithm, and is therefore in P. More recently linear time algorithms for the same problem have been constructed [2, 8].

As the Hamiltonian in a 2QSAT instance is a sum of 2-qubit projectors, every local projector is defined on a 4-dimensional Hilbert space and is of rank $1, 2$ or 3. The non-zero subspace of each projector (the subspace on which it projects) is commonly referred to as the *forbidden space* of that projector and the orthogonal subspace is its *solution space*. Finally, we say that H has *no repetitions* if there does not exist any pair of different projectors $\Pi_e, \Pi_{e'}$ which act non-trivially on the same set of qubits. In the case of repetition free 2QSAT, each projector can also be indexed by the qubit pairs it acts on and the instance can be written as $H = \sum_{(u,v)\in S} \Pi_{uv}$, where $S \subseteq [n] \times [n]$ and each Π_{uv} is non-zero. For any projector Π and a state $|\psi\rangle$, we say that $|\psi\rangle$ *satisfies* Π up to ϵ if $E_\psi(\Pi) := \langle\psi|\Pi|\psi\rangle \leq \epsilon^2$. The energy $E_\psi(\Pi)$ is the *violation energy* of $|\psi\rangle$ with respect to the projector Π. Notice that when the state of the system is described by a density matrix ρ, its violation energy with respect to Π is given by $E_\rho(\Pi) := \mathrm{Tr}(\rho\Pi)$

Finally, a 2QSAT Hamiltonian H is said to have a *Star-like* configuration if there exists a pair of qubits u, v with $\Pi_{u,v} \neq 0$ such that *all* projectors involve either u or v.

Hidden QSAT. The hidden version of QSAT is defined analogously to the classical case. Our task is to decide whether a k-local Hamiltonian $H = \sum_e \Pi_e$ that is made of m k-local projectors over n qubits is frustration-free with $E_0 = 0$ (YES instance) or $E_0 > m \cdot 2\epsilon^2$ (NO instance). Here, $\epsilon > 0$ is some threshold parameter that can be assumed to be inverse polynomially small in n. Moreover, as in H–SAT, here we do not know the Hamiltonian itself; instead we can only send *quantum* states to a "worst violated oracle", which will return the index e of the projector Π_e with the highest violation energy. Since we want to generalize the notion of a probabilistic assignment that is used in H–SAT, we allow ourselves to send the oracle qubits that hold a general quantum state ρ, which can only be described by a density matrix. Recall from the previous section that this can be regarded as an ensemble of pure quantum states. Then the oracle will return the the index e for which $\mathrm{Tr}(\Pi_e \rho)$ is maximized. If the total energy of the proposed state is $\leq m \cdot \epsilon^2$ then the oracle will indicate that a satisfying assignment has been found.

6 Hidden Quantum 1SAT

The algorithm used to solve H–1SAT can be extended to solve the H–1QSAT problem as well. A 1-local projector defined on $\mathbb{C}^2$ is satisfiable if it is of rank at most 1 and can be viewed as setting the direction of the qubit on the Bloch sphere. Unlike the classical case, where we may view the 1SAT clauses as either the $|0\rangle\langle 0|$ or $|1\rangle\langle 1|$ projectors, here the projectors can point in any direction in the Bloch sphere. To handle the continuous nature of the Bloch Sphere, we consider discretizing it by using an ϵ-net that covers the whole sphere. This allows us to generalize the lists of $0-1$ strings used in H–1SAT into lists of n-qubit product states where each qubit is assigned an element of the ϵ-net.

Given a 1-local projector $|\psi\rangle\langle\psi|$, its zero space is spanned by $|\psi^\perp\rangle$. We can divide the Bloch sphere into two hemispheres, one hemisphere containing states $|\phi\rangle$ having $|\langle\psi|\phi\rangle| \leq \frac{1}{2}$ and the other with states having $|\langle\psi|\phi\rangle| > \frac{1}{2}$. An n-qubit state $a = |a_1\rangle|a_2\rangle\ldots|a_n\rangle$ is called *good* if for each qubit i, where $|\psi_i\rangle$ is its forbidden state, $|\langle\psi_i|a_i\rangle| \leq \frac{1}{2}$ and *bad* if $\forall i, |\langle\psi_i|a_i\rangle| > \frac{1}{2}$. For the n-qubit state $a = |a_1\rangle|a_2\rangle\ldots|a_n\rangle$, let $a' := |a_1^\perp\rangle|a_2^\perp\rangle\ldots|a_n^\perp\rangle$.

Now, we can sketch the H–1QSAT algorithm. Adapting the process described in Theorem 1 for an arbitrary n-qubit state a gives a list of n-qubit states, $L_{a/a'}$, where at least one state is *good*. This is formally stated in Lemma 3 and the proof is omitted to owing to space constraints.

▶ **Lemma 3.** *Let $a = |a_1\rangle \otimes \ldots \otimes |a_n\rangle$ where $|a_i\rangle, |a_i^\perp\rangle$ is a basis for qubits i, for $i = 1, \ldots, n$. Then one can produce a list, $L_{a/a'} \subset \bigotimes_{i=1}^n \{|a_i\rangle, |a_i^\perp\rangle\}$ of at most $2mn$ states such that, if the instance is satisfiable, there is at least one* good *n-qubit state in the list. The time taken to produce this list is $O(n^2 m)$.*

However, this only gives us an assignment that violates each projector by $\leq \frac{1}{4}$ while we require assignments that violate each projector by $\leq \epsilon^2$. The key observation involves constructing two lists $L_{a/a'}$ and $L_{b/b'}$ where $b \neq a, a'$ and picking a state from each list. Consider the case when both states are good. Let the states on qubit i from each list be $|a_i\rangle$ and $|b_i\rangle$ respectively. Each state defines a hemisphere R_{i,a_i} and R_{i,b_i} containing all the states that are bad with respect to the forbidden state for qubit i, $|\psi_i\rangle$. Then, $|\psi_i\rangle$, should be contained in $R_{i,a_i b_i} := R_{i,a_i} \cap R_{i,b_i}$. The optimal choice for b_i, given a_i, would be one where $|R_{i,a_i b_i}| \leq \frac{|R_{i,a_i}|}{2}$. Then, similar to performing a binary search on the Bloch Sphere, repeating this process $\log_2\left(\frac{1}{\epsilon}\right)$ times, will give a region consisting of good approximations to the forbidden state.

▶ **Theorem 4.** *Let $\epsilon > 0$. Given a* H–1QSAT *on n qubits containing m projectors, there exists an an $O((2mn)^{2\log\frac{1}{\epsilon}} \cdot mn^2)$ time algorithm, with the property that*

(a) *for a frustration free instance, it outputs an assignment where for each projector, the forbidden state is violated with probability $\leq \epsilon^2$ and*

(b) *for a* NO *instance, the algorithm outputs* UNSAT.

Proof Initially, with no information, for each qubit i, R_i = Bloch sphere. Now the algorithm executes the following steps:

- Start by picking an arbitrary state, say $\bar{a} = |0\rangle^{\otimes n}$, and construct $L_{|0\rangle^{\otimes n}/|1\rangle^{\otimes n}}$ as per the procedure in Lemma 3. For each $a \in L_{|0\rangle^{\otimes n}/|1\rangle^{\otimes n}}$:
  - a defines the region R_{i,a_i} in this branch of the iteration.
  - For $i = 1, \ldots, n$ pick a basis $\{|b_i\rangle, |b_i^{\perp}\rangle\}$ such that their equator bisects R_{i,a_i}.
  - Set $\bar{b} = b_1 \ldots b_n$, construct $L_{\bar{b}/\bar{b}'}$ and for each $b \in L_{\bar{b}/\bar{b}'}$:
    - The tuples (a, b) define the region $R_{i,a_i b_i}$ in this branch.
    - Repeat the process to find $\bar{c}$ to bisect each $R_{i,a_i b_i}$;
    - Find a new region $R_{i,a_i b_i c_i}$ for each $c \in L_{\bar{c}/\bar{c}'}$.
    - Continue the recursion up to $\log_2\left(\frac{1}{\epsilon}\right)$ depth and let the last list be $L_{z/z^{\perp}}$.
    - Propose $|\phi^{\perp}\rangle = \bigotimes_{i=0}^{n} |\varphi_i^{\perp}\rangle$ where $\forall i, |\varphi_i\rangle \in R_{i,a_i b_i \ldots z_i}$ to the oracle. Output $|\phi^{\perp}\rangle$ if the oracle returns YES, otherwise continue.
- Output UNSAT if none of the trials satisfy the instance.

This algorithm essentially creates a recursion tree with each new string created where the width of the recursion at each point is $2mn$ and the depth is $\log_2\left(\frac{1}{\epsilon}\right)$. This leads to $(2mn)^{\log_2 \frac{1}{\epsilon}}$ trials to be proposed at the end and the number of lists created is also $(2mn)^{\log_2 \frac{1}{\epsilon}}$, each at a cost of $O(mn^2)$. Hence, the total running time of the algorithm is $O((2mn)^{\log \frac{1}{\epsilon}} \cdot mn^2)$.

To argue the correctness of this algorithm, we analyze region $R_{i,a_i b_i \ldots z_i}$ obtained at the leaf of the recursion tree. At the beginning, let $\forall\ i$, $|R_i| = 1$ (the complete Bloch sphere) and the only guarantee for each list is that there is at least one good string in it. Tracing the path in the recursion tree to the leaf, let us assume that each step of the recursion picks a good string i.e. $a, b, \ldots, z$ are all good strings. For a and $\forall i$, the forbidden state $|\psi_i\rangle$ is in the opposite hemisphere to $|a_i\rangle$ which reduces the size of the region to $|R_{i,a_i}| = 1/2$. Taking (a, b) at the next iteration, the region for each qubit is the over lap of two hemispheres $R_{i,a_i} \cap R_{i,b_i}$ and by construction, since b_i bisects R_{i,a_i}, the overlaps of the hemispheres also bisect R_{i,a_i} setting $|R_{i,a_i b_i}| = 1/4$. As this pattern continues, each step of the iteration halves the region for qubit i and we are left with regions of size at most ϵ at the end of the branch. If the instance is satisfiable, the state proposed will satisfy each projector up to ϵ resulting in the oracle to return YES. Of course, when one of the strings chosen is bad, the proposal $|\phi_j^{\perp}\rangle$ for some qubit j will end up having a large inner product with the forbidden state $|\psi_j\rangle$ and will result in the oracle returning the ID of the projector involving j. This concludes the proof. ☐

7 Hidden Quantum 2SAT

This section deals with a 2QSAT instance that is hidden and can only be accessed by a worst-violation oracle. We show how learn the underlying local Hamiltonian to precision ϵ by finding 2-local projectors Π'_e such that $\|\Pi_e - \Pi'_e\| \leq \epsilon$ for every projector Π_e. This yields an approximate local Hamiltonian $H' = \sum_e \Pi'_e$ whose ground energy is at most $m\epsilon$ away from the ground energy of the original Hamiltonian $H = \sum_e \Pi_e$. If ϵ is set such that $m\epsilon$ is much smaller than the promise gap of the initial Hamiltonian H (which merely requires $\epsilon < 1/\operatorname{poly}$), then the Hamiltonian H' will have a promise gap as well. This is stated in the theorem below with the proof and algorithm details omitted owing to space constraints.

▶ **Theorem 5.** *Given a* H–2QSAT *problem* $H = \sum_{(u,v)} \Pi_{uv}$ *on* n *qubits, and precision* ϵ*. If the interaction graph for* H *is not Star-like, then there is an* $O(n^4 + n^2 \log\left(\frac{1}{\epsilon}\right))$ *algorithm that can find an approximation* $H' = \sum_{(u,v)} \Pi'_{uv}$ *where* $\forall\ (u,v), \|\Pi'_{uv} - \Pi_{uv}\| \leq \epsilon$

The algorithm proceeds by:

1. Identifying two pairs of qubits $(i,j) \neq (k,\ell)$ on which two projectors are defined, Π_{ij} and $\Pi_{k\ell}$, and finding a constant approximation for these projectors;
2. Improving the constant approximation of the two projectors recursively so that the approximation improves by a factor of 2 in each iteration and
3. Using the ϵ-approximation of a projector to identify the rest of the independent projectors and approximating them to ϵ-precision.

Using the H' output by the above algorithm in a procedure which could find a good approximation to the ground energy of H' would completely solve H–2QSAT. At this time, though, existing 2QSAT algorithms [2, 6, 8] are not robust to such errors and seem to require $\frac{1}{\exp(n)}$ precision. Our algorithm for H–2QSAT does allow one to learn the projectors to exponential precision, since the dependence on ϵ in Theorem 5 is merely logarithmic. However, in this parameter regime our algorithm is somewhat unrealistic, as this would require the oracle to be able to distinguish between values that are exponentially close together[5]. If our oracle were constrained to be implementable in polynomial time by an experimenter, acting on polynomially many copies of the proposed state ρ, then one could only learn the instance up to error $\epsilon = \frac{1}{\text{poly}(n)}$. A natural open question is to determine whether one can still solve 2QSAT when one only knows the individual clauses to inverse polynomial precision; we believe this is a fundamental question about the nature of 2QSAT, which is left for future work.

Abstract

In this paper we study the complexity of the following problems:

1. Given a colored graph $X = (V, E, c)$, compute a minimum cardinality set of vertices $S \subset V$ such that no nontrivial automorphism of X *fixes* all vertices in S. A closely related problem is computing a minimum base S for a permutation group $G \le S_n$ given by generators, i.e., a minimum cardinality subset $S \subset [n]$ such that no nontrivial permutation in G fixes all elements of S. Our focus is mainly on the *parameterized complexity* of these problems. We show that when $k = |S|$ is treated as parameter, then both problems are MINI[1]-hard. For the dual problems, where $k = n - |S|$ is the parameter, we give FPT algorithms.
2. A notion closely related to fixing is called individualization. Individualization combined with the Weisfeiler-Leman procedure is a fundamental technique in algorithms for Graph Isomorphism. Motivated by the power of individualization, in the present paper we explore the complexity of individualization: what is the minimum number of vertices we need to individualize in a given graph such that color refinement "succeeds" on it. Here "succeeds" could have different interpretations, and we consider the following: It could mean the individualized graph becomes: (a) discrete, (b) amenable, (c) compact, or (d) refinable. In particular, we study the parameterized versions of these problems where the parameter is the number of vertices individualized. We show a dichotomy: For graphs with color classes of size at most 3 these problems can be solved in polynomial time, while starting from color class size 4 they become W[P]-hard.

1 Introduction

A permutation π on the vertex set V of a (vertex) colored graph $X = (V, E, c)$ is an *automorphism* if π preserves edges and colors. Uncolored graphs can be seen as the special case where all vertices have the same color. The automorphisms of X form the group $\mathrm{Aut}(X)$, which is a subgroup of the symmetric group $\mathrm{Sym}(V)$ of all permutations on V.

A *fixing set* for a colored graph $X = (V, E, c)$ is a subset S of vertices such that there is no nontrivial automorphism of X that fixes every vertex in S. The *fixing number* of X is the cardinality of a smallest size fixing set of X. This notion was independently studied in [10, 15, 16]. A nice survey on this and related topics is by Bailey and Cameron [8].

In this paper, one of the problems of interest is the computational complexity of computing the fixing number of graphs:

▶ **Problem 1.1.** k-Rigid

Input: A colored graph X and an integer k
Parameter: k
Question: Is there a subset S of k vertices in V such that there are no nontrivial automorphisms of X that fix each vertex of S?

There is a closely related problem that has received some attention. Let $G \leq S_n$ be a permutation group on $[n]$. A *base* of G is a subset $S \subset [n]$ such that no nontrivial permutation of G fixes each point in S, i.e., the pointwise stabilizer subgroup $G_{[S]} = \{g \in G \mid i^g = i \ \forall\, i \in S\}$ of G is the trivial subgroup $\{1\}$.

▶ **Problem 1.2.** k-Base-Size

Input: A generating set for a permutation group G on $[n]$ and an integer k
Parameter: k
Question: Is there a subset $S \subset [n]$ of size k such that no nontrivial permutation of G fixes each point in S?

Note that a graph X is in k-Rigid if and only if $\mathrm{Aut}(X)$ is in k-Base-Size.

Computing a minimum cardinality base for $G \leq S_n$ given by generators is shown to be NP-hard by Blaha [9]. The same paper also gives a polynomial-time $\log\log n$ factor approximation algorithm for the problem, i.e., the algorithm outputs a base of size bounded by $b(G)\log\log n$, where $b(G)$ denotes the optimal base size. We show that this approximation factor cannot be improved unless P = NP; see Theorem 2.7.

In this paper our focus is on the parameterized complexity of these problems. Arvind has shown that k-Base-Size is in FPT for transitive groups and groups with constant orbit size [2], and raised the question whether this can be extended to more general permutation groups. We show that both k-Rigid and k-Base-Size are MINI[1]-hard, even when the automorphism group of the given graph X (resp., the given group G) is an elementary 2-group; see Section 2.

We also consider the dual problems $(n-k)$-Rigid and $(n-k)$-Base-Size, which ask whether the given graph or group have a fixing set or base that consists of all but k vertices or points and k is the parameter. We show that these problems are fixed parameter tractable. More precisely, we give an $k^{O(k^2)} + n^{O(1)}$ time algorithm for $(n-k)$-Base-Size and an $k^{O(k^2)} n^{O(1)}$ time algorithm for $(n-k)$-Rigid in Section 3.

Color refinement and individualization. A broader question that arises is in the context of the Graph Isomorphism problem: Given two colored graphs $X = (V, E, c)$ and $X' =$

(V', E', c') the problem is to decide if they are *isomorphic*, i.e., whether there is a bijection $\pi\colon V \to V'$ such that for all $x \in V$, $c'(x^\pi) = c(x)$ and for all $x, y \in V$, $(x, y) \in E$ if and only if $(x^\pi, y^\pi) \in E'$. Color refinement is a classical heuristic for Graph Isomorphism, and in combination with other tools (group-theoretic/combinatorial) it has proven successful in Graph Isomorphism algorithms (e.g. in the two most important papers in the area [7, 6]). The basic color refinement procedure works as follows on a given colored graph $X = (V, E, c)$. Initially each vertex has the color given by c. The refinement step is to color each vertex by the tuple of its own color followed by the colors of its neighbors (in color-sorted order). The refinement procedure continues until the color classes become stable. If the multisets of colors are different for two graphs X and X', we can conclude that they are not isomorphic. Otherwise, more processing needs to be done to decide if the input graphs are isomorphic. One important approach in this area is to combine *individualization* of vertices with color refinement: Given a graph $X = (V, E)$ and k vertices $v_1, v_2, \dots, v_k \in V$, first these k vertices are assigned distinct colors $c_1, c_2, \dots, c_k$, respectively. Then, with this as initial coloring, the color refinement procedure is carried out as before. Individualization is used both in the algorithms with the best worst case complexity [7, 6] and in practical isomorphism solvers [21]. Note that individualizing a vertex v results in fixing v, as every automorphism must preserve the unique color of v.

In [5] we have examined several classes of colored graphs in connection with the color refinement procedure. They form a hierarchy:

$$\textsc{Discrete} \subsetneq \textsc{Amenable} \subsetneq \textsc{Compact} \subsetneq \textsc{Refinable} \tag{1}$$

- $X \in \textsc{Discrete}$ if running color refinement on X results in singleton color classes.
- $X \in \textsc{Amenable}$ if for any X' that is non-isomorphic to X, color refinement on X and X' results in different stable colorings [5].
- $X \in \textsc{Compact}$ if every fractional automorphism of X is a convex combination of automorphisms of X [25]. Here, automorphisms are viewed as permutation matrices that commute with the adjacency matrix A of X, and fractional automorphisms are doubly stochastic matrices that commute with A.
- $X \in \textsc{Refinable}$ if two vertices u and v of X receive the same color in the stable coloring if and only if there is an automorphism of X that maps u to v [5].

For these graph classes, various efficient isomorphism and automorphism algorithms are known. Motivated by the power of individualization in relation to color refinement, we consider the following type of problems.

▶ **Problem 1.3.** k-$\mathcal{C}$ (where $\mathcal{C}$ is a class of colored graphs)
Input: A colored graph $X = (V, E, c)$ and an integer k
Parameter: k
Question: Are there k vertices of X so that individualizing them results in a graph in $\mathcal{C}$?

It turns out that for each class $\mathcal{C}$ in the hierarchy (1), the problem k-$\mathcal{C}$ is W[P]-hard, even when the input graph has color class size at most 4. For color class size at most 3 however, the problems become polynomial time solvable. For the class $\textsc{Discrete}[\ell]$ of all colored graphs where ℓ rounds of color refinement turn all color classes into singletons, we show that k-$\textsc{Discrete}[\ell]$ is W[2]-hard. These results are in Section 4.

Additionally, we give an FPT algorithm for the dual problem $(n-k)$-$\textsc{Discrete}$ that asks whether there is a way to individualize all but k vertices so that the input graph becomes discrete; see Section 5.

Color valence. A beautiful observation due to Zemlyachenko [27], that plays a crucial role in [7], concerns the color valence of a graph. Given a colored graph $X = (V, E, c)$, the *color degree* $\deg_C(v)$ of a vertex v in a color class $C = \{v \in V \mid c(v) = c_0\}$ is the number of neighbors of v in C. The *color co-degree* of v in C is $\text{co-deg}_C(v) = |C| - \deg_C(v)$. The *color valence* of X is defined as $\max_{v,C} \min\{\deg_C(v), \text{co-deg}_C(v)\}$. Zemlyachenko has shown [27] that in any n-vertex graph $X = (V, E)$ we can individualize $O(n/d)$ vertices so that the vertex colored graph obtained after color refinement has color valence at most d. This gives rise to the following natural algorithmic problem:

▶ **Problem 1.4.** k-COLOR-VALENCE

Input: A colored graph $X = (V, E, c)$ and two numbers k and d
Parameter: k
Question: Is there a set of k vertices such that when these are individualized, the graph obtained after color refinement has color valence bounded by d?

We show that this problem is W[P]-complete; see Corollary 4.4.

2 The number of fixed vertices as parameter

In this section we show that the parameterized problems k-RIGID and k-BASE-SIZE are both MINI[1]-hard. The class MINI[1] contains all parameterized problems that are FPT-reducible to MINI-3SAT. Both were defined in [12, 14].

▶ **Problem 2.1** ([12, 14])**.** MINI-3SAT

Input: A formula F in 3-CNF of size bounded by $k \log n$ and the number n in unary
Parameter: k
Question: Is there a boolean assignment to the variables that satisfies the formula F?

It turns out that MINI[1] is contained in the class W[1] [14] and has a variety of complete problems in it. Moreover, it has been linked to the exponential time hypothesis.

▶ **Lemma 2.2** ([12, 14])**.** *If* MINI[1] = FPT *then there is a* $2^{o(n)}$ *time algorithm for* 3SAT.

▶ **Theorem 2.3.** *The problem k-BASE-SIZE is* MINI[1]*-hard, even for elementary* 2*-groups.*

Proof. It is easy to see that MINI-3SAT in which each variable occurs at most 3 times is also MINI[1]-complete, by modification of a standard NP-completeness proof. This only increases the size by a constant factor. We will give an FPT many-one reduction from this variant of MINI-3SAT to k-BASE-SIZE. Let $F = C_1 \wedge C_2 \wedge \cdots \wedge C_m$, and n in unary, be a MINI-3SAT instance with variable occurrences bounded by 3. Since the size of F is bounded by $k \log n$, we have $m \le k \log n$. Let V denote the set of distinct variables in F. We also have $|V| \le k \log n$. We partition V as $V = \bigsqcup_{i=1}^{k} V_i$, where $|V_i| \le \log n$ for $1 \le i \le k$. For each i, the set $T_i = \{0, 1\}^{V_i}$ consisting of all truth assignments to variables in V_i has size $|T_i| \le n$. Define the universe $U = \{1, 2, \ldots, m, m + 1, \ldots, m + k\}$. For each truth assignment $a \in T_i$ we define the subset $S_{i,a} \subset U$ consisting of $m + i$ along with all j such that a satisfies C_j, i.e.,

$$S_{i,a} = \{m + i\} \cup \{j \mid C_j \text{ contains a literal that is true under } a\}.$$

Clearly, since each variable occurs at most 3 times in F and since $|a| = |V_i| \le \log n$, it follows that $|S_{i,a}| \le 1 + 3 \log n$. The following claim is straightforward.

▶ **Claim 2.4.** The collection of sets $\{S_{i,a} \mid 1 \le i \le k, a \in T_i\}$ with universe U has a set cover of size k if and only if F is satisfiable.

We will now transform this special set cover instance into an instance of k-Base-Size. The group we shall consider is $\mathbb{F}_2^{m+k}$, i.e., the product of $m+k$ copies of the group on $\{0,1\}$ defined by addition modulo 2. Treating each set $S_{i,a}$ as a subset of the coordinates $1, 2, \ldots, m+k$, we can associate a copy of $\mathbb{F}_2^{|S_{i,a}|}$ with it. Consider the set $\Omega = \bigsqcup_{i,a} \mathbb{F}_2^{|S_{i,a}|}$. Note that $|\Omega| = \sum_{i,a} 2^{|S_{i,a}|} \le nk$. The group $\mathbb{F}_2^{m+k}$ acts faithfully on Ω as follows. Given an element $u \in \mathbb{F}_2^{m+k}$ and a point $v \in \mathbb{F}_2^{|S_{i,a}|}$, let $u_{i,a}$ denote the projection of u to the coordinates in $S_{i,a}$. Then u maps v to $v \oplus u_{i,a}$. Thus, $\mathbb{F}_2^{m+k}$ is a permutation group acting on Ω given by the standard basis of $m+k$ unit vectors as generating set. The following straightforward claim completes the reduction.

▶ **Claim 2.5.** The group $\mathbb{F}_2^{m+k}$ acting on Ω, as defined above, has a base of size k if and only if the set cover instance $(U, \{S_{i,a} \mid 1 \le i \le k, a \in T_i\})$ has a set cover of size k.

To see the claim, observe that $V \subseteq \Omega$ is a base if and only if the sets $S_{i,a}$ with $V \cap \mathbb{F}_2^{|S_{i,a}|} \neq \emptyset$ form a set cover for U. Indeed, a point $p \in U$ is covered by these sets if and only if all $u \in \mathbb{F}_2^{m+k}$ with $u_p = 1$ move an element of V. ◀

▶ **Theorem 2.6.** *The problem k-Rigid is* MINI[1]*-hard.*

Proof. It suffices to encode the k-Base-Size instance constructed in the proof of Theorem 2.3 as a k-Rigid instance (X, k) with the following properties. The graph X has $|\Omega| + 2(m+k)$ vertices and at most $|\Omega|(1 + 3\log n)$ edges. Further, the above k-Base-Size instance has a base of size k if and only if the graph X has a fixing set of size k.

We explain the construction of X. Let $l = m+k$. The vertex set of X is $\Omega \cup I_1 \cup \cdots \cup I_l$ where each set $I_j = \{a_j^0, a_j^1\}$ is a distinct color class of size 2. The edge set of X is defined as follows. Let $v = (b_1, \ldots, b_p) \in \mathbb{F}_2^{|S_{i,a}|}$ be a vertex in Ω and let $S_{i,a} = \{i_1, i_2, \ldots, i_p\}$ be the set of coordinates occurring in v. Then we connect v to the vertices $a_{i_q}^{b_q}$, for each $q = 1, \ldots, p$. This finishes the construction of X.

We claim a one-to-one correspondence between the permutation group $\mathbb{F}_2^{m+k}$ acting on Ω and $\mathrm{Aut}(X)$. Indeed, any vector $v = (b_1, \ldots, b_l) \in \mathbb{F}_2^{m+k}$ can be associated with a unique automorphism σ of X as follows. The automorphism σ flips the color class I_j if and only if $b_j = 1$. For a vertex $u \in \Omega$, define $\sigma(u) = v(u)$ using the action of $\mathbb{F}_2^{m+k}$ on Ω. It is easy to check that σ respects the adjacencies inside X. Note that the action of an automorphism of X is determined by its action on $I_1, \ldots, I_l$, so this is a one-to-one correspondence.

Consequently, a set $J \subset \Omega$ is a base for the original k-Base-Size instance if and only if J is a fixing set for the graph X. We observe that we can always avoid fixing a vertex u inside $I_1 \cup \cdots \cup I_l$ by instead fixing some neighbor of $u \in \Omega$. Therefore, the original k-Base-Size instance has a base of size k if and only if the graph X has a fixing set of size k. ◀

We end this section with some consequences of our hardness proofs on the approximability of the minimum base size of a group. There is a $\log\log n$ factor approximation algorithm due to Blaha [9] for the minimum base problem (in fact, a careful analysis yields a $\ln\ln n$-factor approximation). In this connection we have an interesting observation about the set cover problem instances that arise in Theorem 2.3 (Claim 2.4). A more general version is the B-Set-Cover problem: we are given a collection of subsets of size at most B of some universe U and the problem is to find a minimum size set cover. Trevisan [26] has shown that there is no approximation algorithm for this problem with approximation factor smaller than $\ln B - O(\ln\ln B)$ unless $\mathsf{P} = \mathsf{NP}$. This leads us to the following theorem.

▶ **Theorem 2.7.** *The approximation factor of $\ln\ln n$ in Blaha's approximation algorithm for minimum base cannot be improved, even for elementary abelian 2-groups, unless* $\mathsf{P} = \mathsf{NP}$.

Proof. The reduction from $(\log n)$-SET-COVER to the minimum base problem that is explained in the proof of Theorem 2.3 preserves the optimal solution size. Furthermore, it is easy to see that this reduction carries over to all $(\log n)$-SET-COVER instances. Combined with Trevisan's result, this completes the proof. ◀

3 The number of non-fixed vertices as parameter

In this section we show that the problems $(n-k)$-RIGID and $(n-k)$-BASE-SIZE are in FPT with running time $k^{O(k^2)}n^{O(1)}$. We will show this first for $(n-k)$-BASE-SIZE. We need some permutation group theory.

Let $G \leq \mathrm{Sym}(\Omega)$ be a permutation group acting on a set Ω. The *support* of a permutation $g \in G$ is $\mathrm{supp}(g) = \{i \in \Omega \mid i^g \neq i\}$. The *orbit* of a point $i \in \Omega$ is the set $i^G = \{i^g \mid g \in G\}$. The group G is *transitive* if it has a single orbit in Ω. Let $G \leq \mathrm{Sym}(\Omega)$ be transitive. A subset $\Delta \subseteq \Omega$ is a *block* if for every $g \in G$ its image $\Delta^g = \{i^g \mid i \in \Delta\}$ is either $\Delta^g = \Delta$ or $\Delta^g \cap \Delta = \emptyset$. Clearly, Ω and singleton sets are blocks for any G. All other blocks are called nontrivial. A transitive group G is *primitive* if it has no nontrivial blocks.

There are polynomial-time algorithms that take as input a generating set for some $G \leq \mathrm{Sym}(\Omega)$ and compute its orbits and maximal nontrivial blocks [19]. We can test if G is primitive in polynomial time. If G is transitive on Ω we can compute a maximal nontrivial block Δ_1. It is easy to see that Δ_1^g is also a block for each $g \in G$. This yields a partition of Ω into blocks (which are said to constitute a block system for G): $\Omega = \Delta_1 \sqcup \Delta_2 \sqcup \ldots \sqcup \Delta_\ell$. The group G acts transitively on the blocks $\{\Delta_1, \Delta_2, \ldots, \Delta_\ell\}$. Furthermore, since these are maximal blocks, the group action is primitive. The following classic result is useful for our algorithm.

▶ **Lemma 3.1.** [13, Lemma 3.3D] *Suppose $G \leq S_n$ is primitive and G is neither A_n nor S_n itself. If there is an element $g \in G$ such that $|\mathrm{supp}(g)| \leq k$, then $|\Omega| \leq (k-1)^{2k}$.*

Here, $A_n = \mathrm{Alt}([n])$ denotes the subgroup of S_n that consists of those permutations that can be written as the product of an even number of transpositions.

▶ **Theorem 3.2.** *There is a $k^{O(k^2)}+n^{O(1)}$ time algorithm for the $(n-k)$-BASE-SIZE problem.*

Proof. Let $G \leq S_n$ be the input group given by a generating set and let k be the parameter. We call a set $S \subseteq [n]$ a *co-base* for G, if $[n] \setminus S$ is a base for G. The algorithm finds a co-base S of size k if it exists. During its execution, the algorithm may decide to fix some points. Since in this case the actual group G is replaced by the pointwise stabilizer subgroup, there is no need to store these points. The algorithm proceeds as follows.

1. Let $O_1, O_2, \ldots, O_\ell$ be the orbits of the group G. If $\ell \geq k$ then the set S obtained by picking one point from each of the orbits $O_1, O_2, \ldots, O_k$ is a co-base for G.
2. Suppose $\ell < k$, and there is an orbit O_i of size more than k^{2k} on which G's action is not primitive. In this case compute a maximal block system of G in O_i, $O_i = \Delta_{i1} \sqcup \ldots \sqcup \Delta_{ir_i}$, and deal with the following subcases:
   a. If $r_i > k$, then the set S obtained by picking one point from each block $\Delta_{i1}, \ldots, \Delta_{ik}$ is a co-base for G.
   b. If $r_i \leq k$, then each block Δ_{ij} is of size at least k^{2k-1} which is strictly more than k. Thus any $n-k$ sized subset of $[n]$ intersects each block Δ_{ij} and hence the support of any permutation that moves the blocks. Let H be the subgroup of G that setwise stabilizes all blocks Δ_{ij}. The subgroup H can be computed from G in polynomial time

using the Schreier-Sims algorithm [19]. Replace G by H and go to Step 1. This step is invoked at most k times since each invocation increases the number of orbits.

3. Suppose $\ell < k$, and there is an orbit O_i of size more than k^{2k} such that G is primitive on O_i, but different from $\mathrm{Sym}(O_i)$ and $\mathrm{Alt}(O_i)$. Then any k points of O_i form a co-base for G (by Lemma 3.1).
4. Suppose there is an orbit O_i of size more than k^{2k} such that G restricted to O_i is either $\mathrm{Sym}(O_i)$ or $\mathrm{Alt}(O_i)$. Then fix the first $|O_i| - k$ elements of O_i (the choice of the subset of points fixed does not matter as both $\mathrm{Sym}(O_i)$ and $\mathrm{Alt}(O_i)$ are t-transitive for $t \le |O_i| - 2$). Replace G by the subgroup H that fixes the first $|O_i| - k$ elements of O_i and go to Step 1. This step is invoked at most once.
5. This step is only reached if all orbits are of size at most k^{2k}, implying that the entire domain size is at most k^{2k+1}. Hence, the algorithm can find a co-base S of size k by brute-force search in $k^{O(k^2)}$ time if it exists.

The brute-force computation (done in the last step), when the search space is bounded by k^{2k+1}, costs $k^{O(k^2)}$. The rest of the computation uses the standard group-theoretic algorithms [19] whose running time is polynomially bounded by n. Therefore, the overall running time of the algorithm is bounded by $k^{O(k^2)} + k\,n^{O(1)}$. As $k \le n$, the theorem follows.

We note that the algorithm is in fact a kernelization algorithm. It computes in $n^{O(1)}$ time a kernel of size k^{2k+1} (where size refers to the size of the domain on which the group acts). ◀

We now show the main result of this section, i.e., that $(n-k)$-Rigid is in FPT.

▶ **Theorem 3.3.** *There is a $k^{O(k^2)}n^{O(1)}$ time algorithm for the $(n-k)$-*Rigid *problem.*

Proof. Let $X = (V, E, c)$ be a colored n-vertex graph and k as parameter be an instance of $(n-k)$-Rigid. If we can use a subroutine for the Graph Isomorphism problem then we can compute a generating set for the automorphism group $\mathrm{Aut}(X)$ of X with polynomially many calls to this subroutine [20]. With this generating set as input we can then run the algorithm of Theorem 3.2 to compute an $(n-k)$ size fixing set for X, if it exists, in time $k^{O(k^2)}n^{O(1)}$.

However, it turns out that we can avoid using the Graph Isomorphism subroutine and still solve the problem in $k^{O(k^2)}n^{O(1)}$ time with the following observations:

1. We note that any set of size $n-k$ will intersect the support of any element $\sigma \in \mathrm{Aut}(X)$ if $|\mathrm{supp}(\sigma)| > k$. Thus, we only need to collect all elements of support bounded by k.
2. An automorphism $\sigma \in \mathrm{Aut}(X)$ is defined to be a *minimal support* automorphism of X if there is no nontrivial automorphism $\varphi \in \mathrm{Aut}(X)$ such that $\mathrm{supp}(\varphi) \subsetneq \mathrm{supp}(\sigma)$. For any nontrivial automorphism $\pi \in \mathrm{Aut}(X)$ such that $|\mathrm{supp}(\pi)| \le k$, there is a minimal support automorphism $\varphi \in \mathrm{Aut}(X)$ such that $|\mathrm{supp}(\varphi)| \le k$ and $\mathrm{supp}(\varphi) \subseteq \mathrm{supp}(\pi)$.
3. We observe that Schweitzer's algorithm in [24] can be used to compute, in $k^{O(k)}n^{O(1)}$ time, the set M of all minimal support automorphisms $\sigma \in \mathrm{Aut}(X)$ such that $|\mathrm{supp}(\sigma)| \le k$.
4. Let G' be the subgroup of $\mathrm{Aut}(X)$ generated by M. It follows from the above discussion that an $n-k$ sized subset of V is a base for $\mathrm{Aut}(X)$ (and thus a fixing set for X) if and only if it is a base for G'. We can apply the algorithm of Theorem 3.2 to compute such a base if it exists. ◀

4 The number of individualized vertices as parameter

In this section, we show that the problem k-$\mathcal{C}$ is W[P]-hard for all classes $\mathcal{C}$ of the color refinement hierarchy (1). To this end, we give a reduction from Weighted Monotone Circuit Satisfiability, which is known to be W[P]-complete [1].

▶ **Problem 4.1.** WEIGHTED MONOTONE CIRCUIT SATISFIABILITY

Input: A monotone boolean circuit C on n inputs and an integer k
Parameter: k
Question: Is there an assignment $x \in \{0,1\}^n$ of Hamming weight k so that $C(x) = 1$?

▶ **Theorem 4.2.** *For all classes $\mathcal{C}$ of the color refinement hierarchy* (1)*, k-$\mathcal{C}$ is* W[P]*-hard, even for graphs of color class size at most* 4*.*

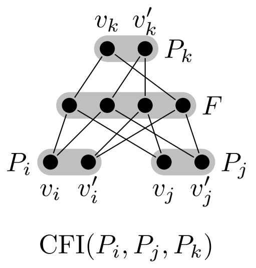
Proof. We will give a parameter-preserving reduction that maps positive instances of WEIGHTED MONOTONE CIRCUIT SATISFIABILITY to positive instances of k-DISCRETE, while negative instances are mapped to negative instances of k-REFINABLE. A similar reduction was used to show that the classes from the color refinement hierarchy (1) are all P-hard [5], which in turn builds on ideas of Grohe [17].

Let $\langle C, k\rangle$ be the given instance of WEIGHTED MONOTONE CIRCUIT SATISFIABILITY, and let n be the number of inputs of the circuit C. We define a graph X_C. For each gate g_k of C (including the input gates), X_C contains a vertex pair $P_k = \{v_k, v'_k\}$, which forms a color class. If a pair corresponds to an input gate, we call it an *input pair.* The intention is that setting an input g_i to 1 corresponds to individualizing the vertex v_i; we will add gadgets to X_C so that after color refinement it holds also for each non-input gate g_k that $g_k = 1$ if and only if v_k and v'_k have different colors.

To achieve this, we use the gadgets given in Figure 1. The basic building block is the gadget CFI(P_i, P_j, P_k) introduced by Cai, Fürer, and Immerman [11]. It connects the three pairs P_i, P_j, and P_k using four additional vertices as depicted. These four vertices form a color class F; each instance of the gadget uses its own copy of F. This gadget has the property that every automorphism flips either none or exactly two of the pairs P_i, P_j and P_k; thus the CFI-gadget implements the XOR function in the sense that any automorphism must flip P_k if and only if it flips exactly one of P_i and P_j. In our case, however, the CFI-gadget implements the AND function: If both P_i and P_j are distinguished (either by direct individualization or in previous rounds of color refinement), the vertices of the inner color class F and consequently P_k will be distinguished in two rounds of color refinement. Conversely, if at most one of the pairs P_i and P_j is distinguished, then the color class F is split into two color classes of size 2 and color refinement stops at this point, leaving the other two pairs non-distinguished. For each AND gate $g_k = g_i \wedge g_j$ in C, we add the gadget CFI(P_i, P_j, P_k) to X_C.

The second gadget we use is IMP(P_i, P_k). It consists of the gadget CFI(F', F'', P_k), where F' and F'' are vertex pairs that form color classes of size two, and perfect matchings that connect these pairs to P_i; see Fig. 1. Again, each instance of this gadget gets its own copy of the color classes F, F' and F''. There is an automorphism of IMP(P_i, P_k) that flips the vertices in P_i, but none that flips the vertices in P_k. In the color refinement setting, this gadget implements the IMPLICATION function: When P_i is distinguished, this will propagate to both F' and F'', and consequently also to F and P_k. Conversely, distinguishing P_k will only split F into two color classes of size 2 before color refinement stops. For each OR gate $g_k = g_i \vee g_j$ in C, we add the gadgets IMP(P_i, P_k) and IMP(P_j, P_k) to X_C. For the output gate g_ℓ of C, we add a second vertex pair Q and the gadget IMP(P_ℓ, Q) to X_C.

Our above analysis of the gadgets ensures that the following invariant holds when running color refinement on X_C after individualizing a subset of its input pairs: For each IMPLICATION gadget IMP(P_i, P_k) in X_C the pair P_k can only be distinguished if P_i is distinguished, and for each AND gadget CFI(P_i, P_j, P_k) the pair P_k can only be distinguished if both P_i and P_j are distinguished. This implies the following.



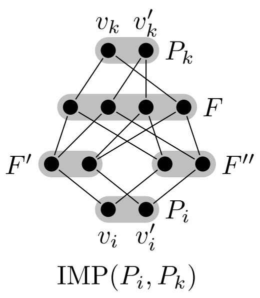


Figure 1 Gadgets used in the reduction of Theorem 4.2.

▶ **Claim 4.3.** Running color refinement on X_C after individualizing some input pairs will distinguish exactly those pairs P_k for which the gate g_k evaluates to 1 under the assignment that sets exactly those input gates to 1 whose corresponding pairs were initially individualized.

Let X'_C be the graph that is obtained from X_C by adding implication gadgets from Q to each pair P_i that corresponds to an input gate g_i. If C has a satisfying assignment $x \in \{0,1\}^n$ of weight k, individualizing the vertices v_i with $x_i = 1$ and subsequently running color refinement will assign distinct colors to all vertices of X_C. Indeed, the gadgets of X_C ensure that the pair Q becomes distinguished, the additional gadgets in X'_C propagate this to all input pairs P_i, and the gates of X_C in turn make sure that all remaining color classes become distinguished. Conversely, if C does not have a weight k satisfying assignment, there is no way to individualize k input vertices such that color refinement distinguishes Q. However, we already noted that there is no automorphism that transposes the output pair of the IMP(P_ℓ, Q) gadget, so no way of individualizing k input vertices makes X'_C refinable.

In X'_C, it always suffices to individualize one vertex from Q to make it discrete. To drop the assumption that each of the k individualized vertices must correspond to an input gate, we construct a graph X''_C. It consists of n input pairs $P_i = \{v_i, v'_i\}$ and n copies of X_C, to which we will refer to as $X_C^{(1)}, \ldots, X_C^{(n)}$. We also add the gadgets IMP$(P_i, P_i^{(j)})$ for all $i, j \in \{1, \ldots, n\}$ and the gadgets IMP$(Q^{(i)}, P_i)$ for all $i \in \{1, \ldots, n\}$. It is not hard to see that $\langle C, k\rangle \mapsto \langle X''_C, k\rangle$ is the desired reduction; see the full version [3] for its correctness. ◀

As a corollary to this proof we can derive the W[P]-hardness of the k-Color-Valence problem.

▶ **Corollary 4.4.** *k-Color-Valence is* W[P]*-hard.*

Proof. In the previous reduction we mapped instances of Weighted Monotone Circuit Satisfiability to instances of k-Discrete such that the given boolean circuit C has a satisfying assignment of weight k if and only if the resulting graph X''_C can be made discrete by individualizing k vertices. Note that individualizing k vertices in X''_C and subsequently running color refinement results in singleton color classes if and only if it brings the color valence down to 0. Thus, k-Color-Valence is W[P]-hard even for $d = 0$. ◀

4.1 Graphs of color class size at most 3

We call a vertex-colored graph *b-bounded* if all its color classes are of size at most b. In this section, we show that for any 3-bounded graph, we can compute in polynomial time the minimum number of vertices that have to be individualized so that the resulting colored graph becomes rigid, discrete, amenable, compact, or refinable. We will use the following two lemmas; their proofs can be found in the full version of this article [3].

▶ **Lemma 4.5.** *Let X be a 3-bounded graph whose color classes are stable. If $\mathrm{Aut}(X)$ restricted to any color class C_i of X is the full symmetric group on C_i, then X is compact.*

▶ **Lemma 4.6.** *Let X be a connected 3-bounded graph whose color classes are stable. If some $\sigma \in \mathrm{Aut}(X)$ is cyclic (i.e., σ acts cyclically on each color class C_i), then X is compact.*

▶ **Theorem 4.7.** *For any 3-bounded graph we can compute in polynomial time a vertex set S of minimum size such that individualizing (or fixing) all the vertices in S makes the graph discrete, amenable, compact, refinable (or rigid).*

Proof. Let $X = (V, E, c)$ be the given 3-bounded graph. We first compute the color partition $\{C_1, \dots, C_m\}$ of the stable coloring of X. We can assume that each induced graph $X_i = X[C_i]$ is empty and each induced bipartite graph $X_{ij} = X[C_i, C_j]$ has at most $|C_i| \cdot |C_j|/2$ edges, as otherwise we can complement these subgraphs. Since the partition $\{C_1, \dots, C_m\}$ is stable and the color classes have size at most 3, it follows that there are no edges between color classes having different sizes, and that between color classes C_i and C_j of the same size we either have a perfect matching or no edges at all.

We say that two color classes C_i and C_j are *linked* if there is a path between some vertex $u \in C_i$ and some vertex $v \in C_j$. Since this is an equivalence relation, it partitions the color classes into equivalence classes. This induces a partition $V = V_1 \sqcup \dots \sqcup V_l$ of the vertices such that each set V_i is a union of linked color classes having the same size and there are no edges between V_i and V_j whenever $i \neq j$. Hence, it suffices to solve the problem separately for each of the induced subgraphs $X[V_i]$.

If all color classes of $X[V_i]$ are of size 2, then $\mathrm{Aut}(X[V_i])$ contains exactly one non-trivial automorphism flipping all the color classes, implying that $X[V_i]$ is compact (see Lemma 4.5). In this case it suffices to individualize (or fix) an arbitrary vertex to make the graph discrete (or rigid). Further, $X[V_i]$ is already amenable if and only if it is a forest [4].

If all color classes of $X[V_i]$ are of size 3, then we compute its connected components as well as $\mathrm{Aut}(X[V_i])$ (which is even possible in logspace [18, 23]) and consider the following subcases.

- If $X[V_i]$ has 6 automorphisms (or, equivalently, consists of three connected components), then $X[V_i]$ is compact (see Lemma 4.5) and it suffices to individualize two vertices inside an arbitrary color class to make the graph discrete. On the other hand, if we individualize only one vertex, then the graph does not become discrete (not even rigid). Further, $X[V_i]$ is amenable if and only if it is a forest [4]. If $X[V_i]$ contains cycles then we need to individualize 2 vertices to make the graph amenable.
- If $X[V_i]$ has 3 automorphisms, then it follows that these automorphisms act cyclically on each color class and $X[V_i]$ is connected as well as compact (see Lemma 4.6). In this case it suffices to individualize an arbitrary vertex to make the graph discrete.
- If $X[V_i]$ has 2 automorphisms (or, equivalently, consists of two connected components), then $X[V_i]$ is not refinable and it suffices to individualize an arbitrary vertex in the larger of the two components to make the graph discrete.
- Finally, if $X[V_i]$ is rigid, then it follows that $X[V_i]$ is connected and not refinable. In this case it suffices to individualize an arbitrary vertex to make the graph discrete. ◀

We can actually strengthen Theorem 4.7 and show that these problems are in logspace. Since the case analysis in the proof can be done in logspace, it suffices to show that the stable color partition of a 3-bounded graph can be computed in logspace. The proof of this result is given in the full version of this article [3].

4.2 Bounded number of refinement steps

In this section, we consider (colored) graphs in which all color classes become singletons after ℓ rounds of color refinement. We denote the class of these graphs by DISCRETE[ℓ].

▶ **Theorem 4.8.** *The k-DISCRETE[ℓ] problem is* W[2]*-hard for any constant $\ell \geq 1$, even for uncolored and for 2-bounded graphs.*

Proof. We prove this by providing a reduction from the W[2]-complete problem DOMINATING SET that is inspired by [22, Theorem 7]. The input to this problem is a graph $X = (V, E)$ and a number k (treated as parameter) and the question is whether there exists a *dominating set* $D \subseteq V$ of size k in X, meaning that each vertex $v \in V \setminus D$ is adjacent to at least one vertex in D. We transform the DOMINATING SET instance (X, k) with $X = (V, E)$ into an equivalent instance (X', k) where $X = (V', E', c')$ for k-DISCRETE[ℓ]. For every $v \in V$, the colored graph X' contains the vertices $v_1, \dots, v_\ell$ and $v'_1, \dots, v'_\ell$ as well as the edges $\{v_i, v_{i+1}\}$ and $\{v'_i, v'_{i+1}\}$ for all i in $\{1, \dots, \ell - 1\}$. Furthermore, we add the edges $\{v_1, u_1\}$ and $\{v'_1, u'_1\}$ for every edge $\{u, v\}$ of X. We choose c' in such a way that for all $v \in V$ the set $\{v_1, v'_1\}$ is a color class and $c'(v_i) = c'(v'_i)$ for all $i \in \{2, \dots, \ell\}$.

Let D be a dominating set in X. Individualizing all the vertices v_1 in X' with $v \in D$ will distinguish the pairs $\{v_1, v'_1\}$ for all $v \in V$ after one round of color refinement. Thus after at most $\ell - 1$ more rounds all color classes of X' will be singletons.

For the converse direction, let I be a set of vertices in X', such that individualizing them and running ℓ rounds of color refinement produces singleton color classes. If I contains vertices v_i or v'_i for $i > 1$, we can replace them by v_1 and this still puts X' in DISCRETE[ℓ]. It is easy to see that this replacement does not decrease the number of color classes that become singletons after ℓ rounds. Hence, we can assume that I only contains vertices of the form v_1, implying that the set $D = \{v \in V \mid v_1 \in I\}$ is a dominating set of size at most $|I|$ in X. To see this it suffices to observe that the vertices u_ℓ and u'_ℓ can only be distinguished by color refinement within ℓ rounds if either u_1 is in I or u has a neighbor v for which v_1 is in I, implying that either u or some neighbor of u is in D.

For uncolored graphs we simulate the colors with degrees using a global gadget which in turn is distinguished from the rest by four special vertices of which two need to be individualized in any case. This increases the parameter from k to $k + 2$. See the full version [3] for details. ◀

5 The number of non-individualized vertices as parameter

In this section, we show that the problem $(n - k)$-DISCRETE is in FPT. In fact, we show a linear kernel and consequently, a $k^{O(k)} n^{O(1)}$ time algorithm for this problem.

▶ **Theorem 5.1.** *There exists a kernel of size $2k$ for $(n - k)$-DISCRETE that can be computed in polynomial time.*

We begin with some notation. Given a colored graph $X = (V, E, c)$, let S be a subset of vertices. Let $\mathcal{C}[S]$ denote the stable partition obtained by individualizing every vertex in $V \setminus S$ and performing color refinement. We denote the number of color classes in $\mathcal{C}[S]$ by $|\mathcal{C}[S]|$. We can partition the vertices u in $V \setminus S$ by their neighborhood $N(u) \cap S$ inside the set S. We denote this partition of $V \setminus S$ by $\mathcal{N}[S]$ and the number of sets in it by $|\mathcal{N}[S]|$. We call two vertices u and v *twins* if $N(u) \setminus \{v\} = N(v) \setminus \{u\}$. This relation is an equivalence relation and the corresponding equivalence classes are called *twin classes.* A graph is said to be *twin-free* if each twin class is of size 1.

The following lemma shows that sufficiently large twin-free graphs are YES instances of the $(n-k)$-DISCRETE problem.

▶ **Lemma 5.2.** *Let $X = (V, E)$ be a twin-free graph. Suppose $|V| > 2k$. There exists a set $S \subset V$ of size k such that $\mathcal{C}[S]$ is discrete. Moreover, we can compute such a set in $(nk)^{O(1)}$ time.*

Proof. We describe the algorithm for computing S. Initially, we pick an arbitrary subset $T_0 \subset V$ of size k and run color refinement to compute the stable partition $\mathcal{C}[T_0]$. Let $C_1, \dots, C_l$ be the color classes in $\mathcal{C}[T_0]$ that are contained in T_0. If $\mathcal{C}[T_0]$ is already discrete, we output the set $S = T_0$ and stop.

Otherwise we rename the color classes such that $|C_1| \geq |C_i|$ for $i = 2, \dots, l$. Then we compute the partition $\mathcal{N}[S] = \{B_1, \dots, B_m\}$ of $V \setminus S$, where we assume that $|B_1| \geq |B_i|$ for $i = 2, \dots, m$. If $m \geq k$, then we form S by picking an arbitrary vertex from each of the sets $B_1, \dots, B_k$. To see that $\mathcal{C}[S]$ is discrete it suffices to observe that individualizing all the vertices in $V \setminus S$ causes the separation of the sets $B_1, \dots, B_m$ and individualizing all but at most one vertex in each set B_i makes the graph discrete.

It remains to handle the case that $m < k$. We show that in this case it is possible to compute in polynomial time a set T_1 of size k such that $|\mathcal{C}[T_1]| > |\mathcal{C}[T_0]|$. By repeating this procedure $i \leq k-1$ times, we end up with a set T_i for which $\mathcal{C}[T_i]$ is discrete. Let u and v be two vertices inside the color-class C_1. Since X is twin-free, there must be a vertex a witnessing the fact that u and v are not twins. Since u and v have the same color, a cannot be individualized, implying that $a \in T_0$. Let C_j be the color class containing a. Since C_1 and C_j are stable color classes, there must exist a vertex $b \in C_j$ such that $\{u, a\}$ and $\{v, b\}$ are edges and $\{u, b\}$ and $\{v, a\}$ are non-edges. Clearly, individualizing a refines the color class C_1. Therefore, the set $T' = T_0 - \{a\}$ has the desired property $|\mathcal{C}[T']| > |\mathcal{C}[T_0]|$ but is of size $k-1$.

Since $|V| > 2k$ and $m < k$, it follows that $|B_1| \geq 2$. Let x and y be two vertices inside B_1. Since X is twin-free, there must be a vertex z witnessing the fact that x and y are not twins. Since all vertices in T_0 either have both vertices x and y as neighbors or none of them (otherwise, x and y would have different neighborhoods inside T_0, contradicting the fact that $x, y \in B_1$), it follows that $z \notin T_0$. We claim that the set $T_1 = T' \cup \{z\}$ yields the same stable partition as T', i.e., $\mathcal{C}[T_1] = \mathcal{C}[T']$. In fact, color refinement anyway assigns a unique color to z, since it is the only non-individualized vertex that is adjacent to exactly one of the two individualized vertices x and y. This completes the proof of the lemma. ◀

Proof of Theorem 5.1. We outline a simple kernelization algorithm for $(n-k)$-DISCRETE. Let X be the given graph and let k be the given parameter. The algorithm first makes the graph X twin-free by removing all but one vertex from each twin-class.

If the resulting graph X' has at most $2k$ vertices, it outputs the instance (X', k) as the kernel. Since in each twin class of X, all but one vertices have to be individualized to make the graph discrete, the two instances (X, k) and (X', k) are indeed equivalent with respect to the $(n-k)$-DISCRETE problem.

If X' has more than $2k$ vertices, the algorithm computes in polynomial time a set S of size k such that individualizing every vertex outside of S makes the graph X' discrete (see Lemma 5.2). Clearly this set S is also a solution for X, so the kernelization algorithm can output a trivial YES instance. ◀

Abstract

We study interactive proofs in the framework of real number complexity as introduced by Blum, Shub, and Smale. The ultimate goal is to give a Shamir like characterization of the real counterpart $\mathrm{IP}_{\mathbb{R}}$ of classical IP. Whereas classically Shamir's result implies $\mathrm{IP} = \mathrm{PSPACE} = \mathrm{PAT} = \mathrm{PAR}$, in our framework a major difficulty arises from the fact that in contrast to Turing complexity theory the real number classes $\mathrm{PAR}_{\mathbb{R}}$ and $\mathrm{PAT}_{\mathbb{R}}$ differ and space resources considered alone are not meaningful. It is not obvious to see whether $\mathrm{IP}_{\mathbb{R}}$ is characterized by one of them - and if so by which.

In recent work the present authors established an upper bound $\mathrm{IP}_{\mathbb{R}} \subseteq \mathrm{MA}\exists\mathbb{R}$, where $\mathrm{MA}\exists\mathbb{R}$ is a complexity class satisfying $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{MA}\exists\mathbb{R} \subseteq \mathrm{PAT}_{\mathbb{R}}$ and conjectured to be different from $\mathrm{PAT}_{\mathbb{R}}$. The goal of the present paper is to complement this result and to prove interesting lower bounds for $\mathrm{IP}_{\mathbb{R}}$. More precisely, we design interactive real protocols for a large class of functions introduced by Koiran and Perifel and denoted by $\mathrm{UniformVPSPACE}^0$. As consequence, we show $\mathrm{PAR}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$, which in particular implies $\text{co-NP}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$, and $\mathrm{P}_{\mathbb{R}}^{Res} \subseteq \mathrm{IP}_{\mathbb{R}}$, where *Res* denotes certain multivariate Resultant polynomials.

Our proof techniques are guided by the question in how far Shamir's classical proof can be used as well in the real number setting. Towards this aim results by Koiran and Perifel on $\mathrm{UniformVPSPACE}^0$ are extremely helpful.

1 Introduction

Shamir's famous theorem [18] characterizes the set IP of languages that can be verified by an interactive protocol performed between a polynomial time probabilistic verifier and a prover of unlimited power as being equal to PSPACE.

Around the same time of Shamir's result Blum, Shub, and Smale [5] introduced a model of computation over the real numbers (for short: BSS model in the sequel) and a complexity theory for it. Since then, among other things one line of activity in research on the BSS model was to figure out whether and by what reasons important classical results in Turing

[*] Both authors were partially supported under projects ME 1424/7-1 and ME 1424/7-2 by the Deutsche Forschungsgemeinschaft DFG. We gratefully acknowledge the support.

complexity theory hold as well over other computational structures. Following this line, in the present paper we are interested in deriving results about the real class $\mathrm{IP}_{\mathbb{R}}$ of languages verifiable by an interactive protocol over the reals; for precise definitions see next section.

It is well known that over the reals complexity classes that are classically defined or characterized using space resources turn out to have a more subtle relation among each other than they do classically. Taken alone, space resources have no meaning at all; each decision problem can be decided in linear space using an elementary coding trick [15]. As consequence, for many equivalent characterizations especially of the class PSPACE in classical complexity it is unclear what they should become in the real number framework. Recall that PAR, PSPACE, PAT, and IP, denoting the classes of languages acceptable in parallel polynomial time with exponentially many processors, in polynomial space, in polynomial alternating time, and by interactive proofs, respectively, all are the same in Turing complexity; see the textbook [1] for references and proofs. In contrast, over $\mathbb{R}$ it is known that the first three classes mentioned above satisfy $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{PSPACE}_{\mathbb{R}} \subseteq \mathrm{PAT}_{\mathbb{R}}$, where $\mathrm{PSPACE}_{\mathbb{R}}$ denotes the class of real decision problems decidable by an algorithm using both exponential time and polynomial space and the other two classes are defined by extending the classical definitions straightforwardly, see [7, 4]. As a consequence, if a new class like $\mathrm{IP}_{\mathbb{R}}$ is studied which classically gives yet another characterization of PSPACE via Shamir's result, it is not obvious where it can be located over the reals.

It is straightforward to see from the definitions that $\mathrm{NP}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$. But already the inclusion co-$\mathrm{NP}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$ is far from being obvious. Shamir's proof designs an interactive protocol for the PSPACE-complete Quantified Boolean Formulas problem QBF roughly as follows: First, the problem is arithmetized in form of giving a short formula representing an algebraic expression with exponentially many terms. This expression replaces Boolean quantifiers in the original formula by sums and products, respectively, in which the quantified variables run through all values in $\{0, 1\}$. The goal of the communication protocol is to evaluate this expression interactively and randomly. Towards this aim, certain canonical univariate polynomials are attached to this expression by eliminating one after the other the leftmost operator $\sum\limits_{x_i=0}^{1}$ or $\prod\limits_{x_i=0}^{1}$ in it. This results in a polynomial in x_i of polynomial degree whose value in a random point is verified interactively. Though a real variant of QBF can easily be defined and is complete for $\mathrm{PAT}_{\mathbb{R}}$, Shamir's proof cannot be transformed. An arithmetization of quantifiers ranging over the reals is not possible in the same way and immediately destroys the hope of following the above approach; however, see [2] for some attempts dealing with more restricted real decision problems.

In this paper we shall therefore follow a different approach. We still are guided by the question how far Shamir's technique might lead. Instead of dealing directly with an arithmetization of computationally hard real number problems we rely on results in BSS theory that figure out how much can be done using certain oracles in real computations. Such results have been obtained by several authors; crucial for us is work by Koiran and Perifel [12]. Therein a relatively huge class $\mathrm{UniformVPSPACE}^0$ of families of polynomial functions is introduced and studied. It is a kind of uniform extension of Valiant's class VNP and covers families of polynomials with exponential degree and integer coefficients computable in PSPACE. Crucial for us will be two observations: Firstly, verifying whether the result $f_n(x)$ of a member f_n of such a family on input x equals a given y can be done within the resources of $\mathrm{IP}_{\mathbb{R}}$. This result is obtained by showing that the discrete techniques used by Shamir are sufficient to deal with $\mathrm{UniformVPSPACE}^0$. This is important in order to circumvent the above mentioned problems. Secondly, as shown in [12] $\mathrm{UniformVPSPACE}^0$ is powerful enough to deal with interesting real number problems in classes like co-$\mathrm{NP}_{\mathbb{R}}$

and larger via polynomial time BSS algorithms that access an oracle for function families in UniformVPSPACE^0. That way, a real verifier can be designed that is able to deal with problems even from class $\mathrm{PAR}_{\mathbb{R}}$. This leads to our main result stating $\mathrm{PAR}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$. Taking into account previous results this will locate $\mathrm{IP}_{\mathbb{R}}$ much better within certain real number classes than it has been possible so far. It shows as well that also over the reals $\mathrm{IP}_{\mathbb{R}}$ under standard complexity theoretic assumptions is considerably larger than $\mathrm{NP}_{\mathbb{R}}$.

1.1 Previous results

Before summarizing previous results let us recall the formal definition of algebraic circuits and the class $\mathrm{PAR}_{\mathbb{R}}$. An algebraic circuit is a connected and directed acyclic graph having nodes either of indegree 0 (input nodes) , 1 (test nodes) or 2 (computation nodes). Nodes of indegree 2 are labelled with one of the operations $+, -, \bullet$, nodes of indegree 1 are labelled with $' \geq 0?'$ A circuit has one output node of outdegree 0. The size of a circuit is the number of its nodes, its depth is the length of the longest path from an input node to the output node. A circuit with n input nodes computes in the straightforward manner a function from $\mathbb{R}^n \mapsto \mathbb{R}$; on input $x \in \mathbb{R}^n$ it propagates values along the labels of nodes in the obvious way. The value of a test node is either 1 or 0, depending on whether its incoming value is ≥ 0 or not. We only consider circuits with one output node which is a test node. Thus, our circuits compute characteristic functions.

▶ **Definition 1.** A probem $L \subseteq \mathbb{R}^\infty := \bigsqcup_{i \geq 1} \mathbb{R}^i$ belongs to class $\mathrm{PAR}_{\mathbb{R}}$ iff there exists a family $\{C_n\}_{n \in \mathbb{N}}$ of algebraic circuits of depth polynomially bounded in n, a constant $s \in \mathbb{N}$, and a vector $c \in \mathbb{R}^s$ of real constants such that

(i) each C_n has $n + s$ input nodes;
(ii) for all $n \in \mathbb{N}$ the circuit C_n computes the characteristic function of $L \cap \mathbb{R}^n$, when the last s input nodes are assigned the constant values from c, i.e., $x \in L \cap \mathbb{R}^n \Leftrightarrow C_n(x, c) = 1$;
(iii) the family $\{C_n\}_n$ is PSPACE uniform, i.e., there is a Turing machine working in polynomial space which for each $n \in \mathbb{N}$ computes a description of C_n.

If no constant vector c is involved we obtain the constant free version of $\mathrm{PAR}_{\mathbb{R}}$ denoted by $\mathrm{PAR}^0_{\mathbb{R}}$.

The above definition basically is from [6]. There are equivalent ones explicitly involving BSS machines [4]. The vector c used above then plays the role of the machine constants of such a BSS algorithm.

There has so far not been much work on interactive proofs in the BSS model. It started with a paper by Ivanov and de Rougemont [11] where Shamir's result was shown to hold as well in the additive real number model. In this model, multiplications are not allowed. The interaction was restricted to exchanging bits. One side result in this paper was that the classes $\mathrm{PAR}_{\mathbb{R}}$ and $\mathrm{IP}_{\mathbb{R}}$ are provably different [1].

In [2] the real class $\mathrm{IP}_{\mathbb{R}}$ was introduced. The above mentioned problem in $\mathrm{IP}_{\mathbb{R}} \setminus \mathrm{PAR}_{\mathbb{R}}$ from [11] is one that can be formalized by using polynomially alternating existential quantifications over the reals and arbitrary Boolean quantifiers. It is therefore kind of natural trying to relate $\mathrm{IP}_{\mathbb{R}}$ to another real complexity class $\mathrm{MA}\exists\mathbb{R}$ introduced and studied by Cucker and

[1] in [11] $\mathrm{IP}_{\mathbb{R}}$ is not introduced formally, but it is shown that there exists a problem not in $\mathrm{PAR}_{\mathbb{R}}$ but within a class that easily is seen to be a subclass of $\mathrm{IP}_{\mathbb{R}}$ as defined below. However, this example does NOT show $\mathrm{PAR}_{\mathbb{R}} \subseteq \mathrm{IP}_{\mathbb{R}}$

Briquel in [8]. It is a class which does not make sense over finite alphabets and can be located between $\mathrm{PSPACE}_{\mathbb{R}}$ and $\mathrm{PAT}_{\mathbb{R}}$.

▶ **Definition 2.** ([8]) The class $\mathrm{MA}\exists\mathbb{R}$ consists of all decision problems $A \subseteq \mathbb{R}^{\infty}$ for which there exists a problem $L \in \mathrm{P}_{\mathbb{R}}$ together with a polynomial p such that an $x \in \mathbb{R}^{\infty}$ belongs to A if and only if the following formula holds:

$$\forall_B z_1 \exists_{\mathbb{R}} y_1 \ldots \forall_B z_{p(|x|)} \exists_{\mathbb{R}} y_{p(|x|)} (x, y, z) \in L \ .$$

Here, $y = (y_1, \ldots, y_{p(|x|)})$ and $z = (z_1, \ldots, z_{p(|x|)})$. The subscripts $B, \mathbb{R}$ for the quantifiers indicate whether a quantified variable ranges over $B := \{0, 1\}$ or $\mathbb{R}$, respectively.

Note that $\mathrm{MA}\exists\mathbb{R}$ contains the real polynomial hierarchy $\mathrm{PH}_{\mathbb{R}}$, i.e., problems with a fixed number of both existential and universal real quantifiers and even its supclasses $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{PSPACE}_{\mathbb{R}}$, see [8]. It is not known to capture $\mathrm{PAT}_{\mathbb{R}}$; however, $\mathrm{MA}\exists\mathbb{R}$ reflects the special structure of quantifiers mentioned above in relation to the problem that witnesses $\mathrm{PAR}_{\mathbb{R}} \neq \mathrm{IP}_{\mathbb{R}}$. In fact, we have

▶ **Theorem 3.** *([2])* $\mathrm{IP}_{\mathbb{R}} \subseteq \mathrm{MA}\exists\mathbb{R}$.

The main purpose of this paper is to complement this upper bound result by obtaining non-trivial lower bounds for $\mathrm{IP}_{\mathbb{R}}$ as well. In Section 2 we introduce the main concepts and define $\mathrm{IP}_{\mathbb{R}}$ and $\mathrm{UniformVPSPACE}^0$. Section 3 gives the result showing that all function families in $\mathrm{UniformVPSPACE}^0$ can be evaluated interactively within $\mathrm{IP}_{\mathbb{R}}$. The final section applies this theorem to prove our main result, namely that some further real complexity classes are included in $\mathrm{IP}_{\mathbb{R}}$, $\mathrm{PAR}_{\mathbb{R}}$ being the most interesting among them.

One remark concerning the contribution of this paper seems in charge. There is not one big new technical result presented here. Different variants of Theorem 10 below have been known before, see [16] and [14]; we present the proof again because of self-containment and because reformulating the results in the cited papers in the way we need them would not save much space. We believe the value of the present paper is the combination of several pieces of previous works in a way that has not been done so far. This in particular refers to using the class $\mathrm{UniformVPSPACE}^0$ in relation with interactive proofs and realizing that discrete techniques are sufficient to deal with it in a certain sense. That way, we obtain the strongest result on real interactive proofs so far. This result in our opinion definitely is interesting by itself and means significant progress concerning the question how a seminal result of classical complexity theory looks like in the real number framework.

2 Basic notions and results

In this section we recall the definitions of the two main complexity classes considered in this paper, namely $\mathrm{IP}_{\mathbb{R}}$ as well as $\mathrm{UniformVPSPACE}^0$. The former was defined in [2], the latter in [12].

2.1 The model for interaction and some variants

As underlying algorithm model we work in the Blum-Shub-Smale BSS model over $\mathbb{R}$ [4, 5]. Decision problems considered in this model are subsets of $\mathbb{R}^{\infty} := \bigsqcup_{i \geq 1} \mathbb{R}^i$. The model allows to perform the basic arithmetic operations $+, -, \bullet$ and test instructions of the form 'is $x \geq 0$?' at unit cost; an $x \in \mathbb{R}^i$ has (algebraic) size i. Below, in addition we allow both the verifier and the prover to exchange real numbers at unit cost.

The prover P is a BSS machine unlimited in computational power. The verifier V is a randomized polynomial time BSS algorithm. It is important to point out that randomization (still) is discrete, i.e., V generates a sequence of random bits $r = (r_1, r_2, \ldots)$ during its computation. The computation proceeds as follows:

- Given an input $x \in \mathbb{R}^n$ of size $|x| = n$ and (some of) the random bits of r the verifier V computes a real $V(x, r) =: w_1 \in \mathbb{R}$ and sends it to P;
- using x and w_1 the prover P sends a real $P(x, w_1) =: p_1 \in \mathbb{R}$ back to V;
- let $(w_1, p_1, w_2, \ldots, p_i)$ denote the information sent forth and back after i rounds, then in round $i + 1$ V computes a real $V(x, r, w_1, p_1, \ldots, p_i) =: w_{i+1}$ and sends it to P; P then computes a real $P(x, w_1, p_1, \ldots, p_i, w_{i+1}) =: p_{i+1}$ and sends it to V;
- the communication halts after a polynomial number $m = poly(|x|)$ of rounds. Then V computes its final result $V(x, r, w_1, \ldots, p_{m-1}) =: w_m \in \{0, 1\}$ representing its decision to reject or accept the input, respectively.

We denote the result of an interaction between V and P on input x and V using r as random string by $(P, V)(x, r)$. All computations by V have to be finished in (real) polynomial time; thus, in particular the number of random bits generated as well as the number of rounds is polynomially bounded in the size $|x|$ of x.

▶ **Definition 4.** a) A language $L \subseteq \mathbb{R}^\infty$ has an interactive protocol if there exists a polynomial time randomized verifier V such that
(i) if $x \in L$ there exists a prover P such that $\Pr\limits_{r \in \{0,1\}^*} \{(P, V)(x, r) = 1\} \geq \frac{2}{3}$ and
(ii) if $x \notin L$, then for all provers P it holds $\Pr\limits_{r \in \{0,1\}^*} \{(P, V)(x, r) = 1\} \leq \frac{1}{3}$.
Above, the length of r can be polynomially bounded in the length of x.
b) The class $\mathrm{IP}_\mathbb{R}$ contains all $L \subseteq \mathbb{R}^\infty$ which have an interactive protocol.

In the above definitions private coins are used, i.e., we do not allow the prover to know the outcome of V's random choices. One could change this requirement and let the verifier only send the random bits; what the verifier computes out of it then could be as well computed by the allmighty prover. Such protocols are called Arthur-Merlin protocols. Another modification uses one-sided instead of two-sided error in the acceptance condition for V. Then, for $x \in L$ there must be a prover such that V accepts with probability 1. For sake of completeness we show below that these modifications do not change the class $\mathrm{IP}_\mathbb{R}$. Both the result and its proof are the same as in the Turing model.

▶ **Definition 5.** The class $\widetilde{\mathrm{IP}_\mathbb{R}}$ is defined similar to $\mathrm{IP}_\mathbb{R}$, but with the following modifications:
(i) The verifier V uses *public coins*, i.e., it only sends the random bits r generated in each round to P.
(ii) The verifier accepts with one-sided error: A language L is in $\widetilde{\mathrm{IP}_\mathbb{R}}$ iff there is a verifier V such that $\forall x \in L$ there exists a prover P such that $\Pr\limits_{r \in \{0,1\}^*} \{(P, V)(x) = 1\} = 1$. And $\forall x \notin L$ $\forall P$ it holds $\Pr\limits_{r \in \{0,1\}^*} \{(P, V)(x) = 1\} \leq \frac{1}{3}$.

▶ Proposition 6. $\mathrm{IP}_\mathbb{R} = \widetilde{\mathrm{IP}_\mathbb{R}}$.

Proof. [2] The inclusion $\widetilde{\mathrm{IP}_\mathbb{R}} \subseteq \mathrm{IP}_\mathbb{R}$ being clear let $L \in \mathrm{IP}_\mathbb{R}$ and let V be a corresponding

[2] The fact that public coins are as powerful as private ones was first shown in [10]. An easier proof that also replaces two-sided by one-sided error was given by J. Kilian. We could not figure out whether the proof was published, it is however refered to in [9]. For sake of completeness we follow this proof below.

verifier accepting L with private coins and two-sided error. Without loss of generality in each communication round V generates one random bit. A new verifier $\tilde{V}$ using public coins and accepting L with one-sided error is obtained as follows. On input x $\tilde{V}$ expects from a prover to provide information about the communication between V and an optimal prover for it. More precisely, define a protocol tree T coding the protocol between V and an optimal prover on x as follows. An edge in T represents one communication round after a coin toss has been made by V. Since one bit is generated in each round T is binary, the outgoing edges of each node represent the communication for results 0 and 1, respectively. For m communication rounds the probability that V accepts x is $1/2^m$ times the number of accepting paths.

In its communication on x with a prover the new verifier $\tilde{V}$ descends a path of T top down as follows. Let r be the current node of T traversed, r_1, r_2 its left and right child, respectively. $\tilde{V}$ asks the prover for the numbers R, R_1, R_2 of accepting paths the communication between an optimal prover and V would generate when starting in r, r_1, and r_2, respectively. If r is the root and the number reported by the prover is $< \frac{2}{3} \cdot 2^m$ the verifier rejects right away. For an arbitrary node r it checks whether $R = R_1 + R_2$ and rejects if the equation is violated. Otherwise, $\tilde{V}$ moves to r_i with probability $\frac{R_i}{R}$ for $i = 1, 2$. The protocol continues until a leaf is reached. If the path traversed is accepting for the protocol followed by V, then $\tilde{V}$ accepts, otherwise it rejects.

$\tilde{V}$ obviously uses public coins; its random decisions are known to the prover because it is informed about the child of r that is picked by $\tilde{V}$. To see that $\tilde{V}$ accepts L with one-sided error first note that for $x \in L$ an optimal prover will always give the correct numbers R, R_1, R_2 and thus $\tilde{V}$ ends with probability 1 in an accepting leaf because there must exist such a leaf in T. Let us then assume $x \notin L$ and let P be an arbitrary prover.

Claim: For each node r in T the following holds: if there are R accepting paths from r on for an optimal prover and V, but the current prover P claims there are $R' > R$ accepting paths, then $\tilde{V}$ will realize an error with probability $\geq 1 - \frac{R}{R'}$.

Proof of claim: By induction on the height h of r. Let $h = 1$ and let r have children r_1, r_2 being leaves. If $R = 0$, then no matter whether $R' = 1$ or $R' = 2$ both paths are rejecting and $\tilde{V}$ realizes it with probability $1 = 1 - \frac{0}{R'}$. If $R = 1$ then $R' = 2$ and $\tilde{V}$ chooses the rejecting path with probability $\frac{1}{2} = 1 - \frac{1}{2}$.

For arbitrary h let the correct number of accepting paths from r, r_1, r_2 on be R, R_1, R_2, respectively. Let R', R'_1, R'_2 denote the (larger) numbers claimed by P. According to the induction hypothesis if the protocol starts in r_i the verifier $\tilde{V}$ realizes an error with probability $\geq (1 - \frac{R_i}{R'_i}), i = 1, 2$. In node r it chooses the left child with probability $\frac{R'_1}{R'}$ and the right one with probability $\frac{R'_2}{R'}$. The error probability thus is $(1 - \frac{R_1}{R'_1}) \cdot \frac{R'_1}{R'} + (1 - \frac{R_2}{R'_2}) \cdot \frac{R'_2}{R'} = 1 - \frac{R}{R'}$.

Finally, each $x \notin L$ is rejected by the original verifier V and any prover with probability $\geq \frac{2}{3}$, i.e., at most $\frac{1}{3}$ of all paths starting at the root of T are accepting. $\tilde{V}$ either rejects directly if the prover claims $R < \frac{2}{3} \cdot 2^m$ accepting paths or it rejects with probability $\geq 1 - \frac{1/3}{2/3} = \frac{1}{2}$ by the claim. Running the protocol for $\tilde{V}$ once more increases this probability to at least $\frac{3}{4} > \frac{2}{3}$ as required. ◻

2.2 UniformVPSPACE^0

The following class of functions was introduced and studied by Koiran and Perifel in [12] and kind of generalizes the famous Valiant class VNP. Informally, it consists of uniform families of polynomials with integer coefficients which depend on polynomially many variables, potentially an exponential degree and whose coefficients can be computed in PSPACE. Though originally defined over arbitrary fields we restrict ourselves to the real numbers.

▶ **Definition 7.** (see [12])

(a) A family $\{f_n\}_{n\in\mathbb{N}}$ of real polynomials belongs to UniformVPSPACE^0 iff the following conditions are satisfied: There exists a polynomial p such that

  (i) each f_n depends on $u(n)$ variables, where $u(n)$ is bounded from above by $p(n)$;

  (ii) the total degree of each f_n is bounded by $2^{p(n)}$;

  (iii) the coefficients of each f_n are integers which are bounded in their bitsize by $2^{p(n)}-1$;

  (iv) the coefficient function a is PSPACE computable. More precisely, a gets as arguments triples (n,α,i), where $n\in\mathbb{N}$ is given in unary, $\alpha=(\alpha_1,\ldots,\alpha_{u(n)})$ is a list of binary numbers representing a monomial $x^\alpha=x_1^{\alpha_1}\cdot x_2^{\alpha_2}\cdot\ldots\cdot x_{u(n)}^{\alpha_{u(n)}}$, and i is a binary number. Then $a(n,\alpha,i)\in\{0,1\}$ gives the i-th bit of the coefficient of monomial x^α in f_n. In particular, the value $a(n,\alpha,0)$ gives the sign of this monomial. [3]

The functions f_n thus have the following representation:

$$f_n(x_1,\ldots,x_{u(n)})=\sum_\alpha\left[(-1)^{a(n,\alpha,0)}\left(\sum_{i=1}^{2^{p(n)}}2^{i-1}a(n,\alpha,i)\right)x^\alpha\right].$$

(b) A family $\{f_n\}_{n\in\mathbb{N}}$ of polynomials belongs to class UniformVPAR iff it can be computed by a PSPACE-uniform family of arithmetic circuits of polynomial depth, compare Definition 1. If the family is constant free we obtain class UniformVPAR^0.

Again, the superscript '0' indicates that a class is defined without involving additional real constants. It is relatively straightforward to see that both notions above characterize the same set of families:

▶ **Lemma 8.** *([12]) It holds* UniformVPSPACE^0 = UniformVPAR^0.

The result implies in particular that if a family of functions $\{f_n\}\in$ UniformVPAR is defined by a family of circuits using a constant vector $c\in\mathbb{R}^s$, then one obtains another family of functions $\{g_n\}\in$ UniformVPSPACE^0 such that for all $x\in\mathbb{R}^{u(n)}$ of suitable input size we have $g_n(x,c)=f_n(x)$. This will be needed below.

3 Lower bound for IP$_\mathbb{R}$

In this section we prove our main technical theorem. Basically it shows that function families in UniformVPSPACE^0 can be represented by certain formulas having a very particular structure. The latter strongly resembles the structure of formulas arising via arithmetization of discrete quantified boolean formulas as outlined in the introduction. Of course, the new kind of formulas involve real variables. The special structure obtained allows to verify the values of such functions in a way similar to Shamir's original interactive proof for the QBF problem. Using additional results about class UniformVPSPACE^0 then makes it possible to derive real interactive proofs for interesting real number problems, foremost for all problems in PAR$_\mathbb{R}$.

We start with the definition of these specially structured formulas.

▶ **Definition 9.** Let $x_1,x_2,\ldots$ be a countable set of variable symbols.

(a) A *binary polynomial formula* over the reals is a formula p which can be built in finitely many steps according to the following rules:

[3] Note that since a only attains values in $\{0,1\}$ it can be seen as decision problem and thus the PSPACE requirement makes sense.

- **(i)** $p = 1$ and $p = x_i$ for $i = 1, 2, \ldots$ are binary polynomial formulas ;
- **(ii)** if p_1, p_2 are binary polynomial formulas, then so are $p_1 + p_2, p_1 - p_2, p_1 \cdot p_2$;
- **(iii)** if p is a binary polynomial formula depending freely on x_i, then both $\sum\limits_{x_i \in \{0,1\}} p(\ldots, x_i, \ldots)$ and $\prod\limits_{x_i \in \{0,1\}} p(\ldots, x_i, \ldots)$ are binary polynomial formulas (with x_i bounded by summation and multiplication, respectively).

All formulas - and no others - that can be obtained in finitely many steps applying the rules i) to iii) are binary polynomials formulas.

(b) The size of a binary polynomial formula is defined as the number of construction steps used in a) to generate it.

(c) A binary polynomial formula p in the canonical way represents a real polynomial function. It depends on the free variables, i.e., on those x_i that have been introduced via rule i) but have not been bound by a Boolean summation or multiplication applying rule iii).

The following theorem shows that families of functions in UniformVPSPACE^0 are basically the same as families of polynomials given via uniform families of binary polynomial formulas. Similar statements in different variants are already in [16] and [14]. We present the proof for sake of self-containment and because reformulating the results of those papers in the way we need them would likely not save much space.

▶ **Theorem 10.** *Let $\{f_n\}_n$ be a family of polynomial functions. Then $\{f_n\}_n$ belongs to class* UniformVPSPACE^0 *if and only if there exists a polynomial time Turing algorithm which on input $n \in \mathbb{N}$ (in unary) computes a binary polynomial formula p_n which represents f_n. By computing p_n we mean that the algorithm computes a scheme how to generate p_n according to the steps defined above.*

Proof. For the if-direction let $\{p_n\}_n$ be a family of binary polynomial formulas which are uniformly generated by a polynomial time Turing machine. Then it is easy to see that p_n can be computed by a PSPACE-uniform family of arithmetic circuits of polynomial depth. Since the formulas only involve the constant 1 the circuits are constant-free as well. The summation and multiplication operators in a formula can be simulated in parallel by the circuit, thus the polynomially many construction steps for the formula result in a polynomial depth for the circuit. It follows that the polynomial family $\{p_n\}_n$ belongs to class UniformVPAR^0. Lemma 8 now implies the 'if'-direction.

For the only-if direction, let a family $\{f_n\}_n \in$ UniformVPSPACE^0 be given and consider one of its members

$$f_n(x_1, \ldots, x_{u(n)}) = \sum_{\alpha} \left[(-1)^{a(n,\alpha,0)} \left(\sum_{i=1}^{2^{p(n)}} 2^{i-1} a(n, \alpha, i) \right) x^{\alpha} \right].$$

Without loss of generality we assume $u = p$. Our task is to show that the different parts in this representation can be rewritten in form of binary polynomial formulas.

Step 1: Let us start with constructing binary polynomial formulas for the numbers 2^{i-1}. To catch the necessary ideas we first give an unsuccessful approach: It is $2^{i-1} = \sum\limits_{j_1=0}^{1} \sum\limits_{j_2=0}^{1} \ldots \sum\limits_{j_{i-1}=0}^{1} 1$, but the length of this binary formula is i. Since parameter i in the above sum for representing f_n is running from 1 to $2^{p(n)}$ the corresponding formula becomes too long. Instead, consider the binary representation of $i =: (i_1, \ldots, i_{p(n)})$. We define a binary polynomial formula for $G_1(i_1, \ldots, i_{p(n)}) := 2^{i-1}$. Its main building block is a formula for the characteristic function

$$F_1(j_1,\ldots,j_{p(n)},i_1,\ldots,i_{p(n)}) = \begin{cases} 1 & \text{if } 0 \neq (j_1,\ldots,j_{p(n)}) < (i_1,\ldots,i_{p(n)}) \\ -1 & \text{if } 0 = i \\ 0 & \text{otherwise} \end{cases} \quad ,$$

where the ordering $<$ is to be understood as ordering of the integers represented in binary by the corresponding tuples. Once a binary polynomial formula for F_1 is available one for G_1 is obtained via

$$G_1(i_1,\ldots,i_{p(n)}) = \prod_{j_1=0}^{1} \cdots \prod_{j_{p(n)}=0}^{1} \left(F_1(j_1,\ldots,j_{p(n)},i_1,\ldots,i_{p(n)})+1\right);$$

this follows from the definition of F_1 since the above product contributes a factor 2 for each $0 \neq j < i$, a factor 0 if $i = 0$ and a factor 1 in the other cases.

Binary polynomial formulas for the cases $i = 0$ and $j = 0$ are easily obtained. The order relation $(j_1,\ldots,j_{p(n)}) < (i_1,\ldots,i_{p(n)})$ can be expressed as

$$\begin{array}{l} j_{p(n)} < i_{p(n)} \;\vee\; \left\{j_{p(n)} = i_{p(n)} \wedge j_{p(n-1)} < i_{p(n-1)}\right\} \;\vee \ldots \\ \left\{j_{p(n)} = i_{p(n)} \wedge \ldots \wedge j_2 = i_2 \wedge j_1 < i_1\right\} \end{array} .$$

A binary polynomial formula for the characteristic function $y < z$ of comparing two single input bits is given by $z \cdot (z - y)$; and a formula for the above Boolean combination is obtained by combining two characteristic functions χ_1, χ_2 via $\chi_1 \cdot \chi_2$ for conjunctions and via $\chi_1 + \chi_2$ for disjunctions (note here that at most one clause becomes true). That way a binary polynomial formula representing G_1 is obtained. Its length clearly is polynomially bounded in n.

Step 2: Next, a binary polynomial formula for the function

$$G_\alpha(x_1,\ldots,x_{p(n)}) := x_1^{\alpha_1} \cdot x_2^{\alpha_2} \cdot \ldots \cdot x_{p(n)}^{\alpha_{p(n)}} = x^\alpha$$

for given α is derived as follows. First, consider a single factor, for example $x_1^{\alpha_1}$, and let the binary representation of α_1 be $(\alpha_{11},\alpha_{12},\ldots,\alpha_{1p(n)})$. Now for $p(n)$ variables $t := (t_1,\ldots,t_{p(n)})$ consider the binary polynomial formula

$$\chi(\alpha_1 = 0) + (1 - \chi(\alpha_1 = 0)) \cdot \left(x_1 \cdot \prod_{t_1=0}^{1} \cdots \prod_{t_{p(n)}=0}^{1} \left(F_1(t_1,\ldots,t_{p(n)},\alpha_{11},\ldots,\alpha_{1p(n)}) \cdot (x_1 - 1) + 1\right) \right).$$

Here, $\chi(\alpha_1 = 0)$ denotes a binary polynomial formula for the characteristic function of the condition $\alpha_1 = 0$. A short moment of reflection now shows that for $\alpha_1 = 0$ the above formula results in $x_1^0 = 1$; if $\alpha_1 > 0$, then for each integer $0 < t < \alpha_1$ a factor x_1 is contributed whereas for $t = 0$ and $t \geq \alpha_1 > 0$ a factor 1 is obtained. Thus, the formula represents $x_1^{\alpha_1}$.

Since each monomial in f_n has $p(n)$ variables, the above construction can be repeated $p(n)$ many times to obtain

$$G_\alpha(x_1,\ldots,x_{p(n)}) = \prod_{j=1}^{p(n)} \Bigg[\chi(\alpha_j = 0) + (1 - \chi(\alpha_j = 0)) \cdot \left(x_j \prod_{t_1=0}^{1} \cdots \prod_{t_{p(n)}=0}^{1} \left(F_1(t_1,\ldots,t_{p(n)},\alpha_{j1},\ldots,\alpha_{jp(n)}) \cdot (x_j - 1) + 1\right) \right) \Bigg],$$

i.e., a binary polynomial formula for x^α of polynomial length. Note that in the above formula the first product results from applying a polynomial number of times construction step a),ii) of Definition 9, whereas the subsequent products result from step iii).

Step 3: The representation of the coefficients $a(n, \alpha, i)$ as binary polynomial formulas is based on PSPACE-completeness of the QBF problem, i.e., the question of deciding whether a quantified Boolean formula is true [19]. By assumption, computing $a(n, \alpha, i)$ can be done in PSPACE. Thus, for each n there exists a Boolean formula $\psi_n(\alpha, i) = \exists x_1 \forall x_2 \dots Q_m x_m \phi(n, \alpha, i)$ where the quantifiers range over $\{0, 1\}$, $Q_m \in \{\exists, \forall\}$, ϕ is quantifier free and $a(n, \alpha, i) = 1$ iff $\psi_n(\alpha, i)$ is true. Moreover, ψ_n can be computed uniformly in polynomial time in n. Next, arithmetize ψ_n in the folklore way (see, for example, [18]): first, compute in polynomial time a polynomial $q(x, \alpha, i), x = (x_1, \dots, x_m)$, that gives the truth value of the quantifier free formula $\phi(x, \alpha, i)$, then replace quantifiers of the form $\exists x_j q(..., x_j, ...)$ by $1 - \prod\limits_{x_j=0}^{1} (1 - q(..., x_j, ...))$ (this guarantees the result to stay in $\{0, 1\}$) and quantifiers of form $\forall x_j q(..., x_j, ...)$ by $\prod\limits_{x_j=0}^{1} q(..., x_j, ...)$. This gives uniformly a binary polynomial formula $G_2(n, \alpha, i)$ computing $a(n, \alpha, i)$.

Step 4: A binary formula for the sign $(-1)^{a(n,\alpha,0)}$ of a monomial x^α is given as $-2 \cdot G_2(n, \alpha, 0) + 1$.

Putting everything together, a binary polynomial formula representing $f_n(x_1, \dots, x_{p(n)})$ results from two further exponential sums, both expressed in our scheme via polynomially many applications of construction rule iii). Identifying as before $i = (i_1, \dots, i_{p(n)}), \alpha_j = (\alpha_{j1}, \dots, \alpha_{jp(n)})$ and $\alpha = (\alpha_1, \dots, \alpha_{p(n)})$ and recalling that $G_1(0) = 0$ this binary polynomial formula is

$$\sum_{j=1}^{p(n)} \sum_{\alpha_{j1}=0}^{1} \dots \sum_{\alpha_{jp(n)}=0}^{1} \left[(-2G_2(n, \alpha, 0) + 1) \cdot \left(\sum_{i_1=0}^{1} \dots \sum_{i_{p(n)}=0}^{1} G_1(i) \cdot G_2(n, \alpha, i) \right) \cdot G_\alpha(x_1, \dots, x_{p(n)}) \right] . \qquad \square$$

The theorem now can easily be applied to prove, maybe a bit surprisingly, that the classical technique by Shamir leads relatively far when designing interactive protocols also in the real number framework. More precisely, we have

▶ **Theorem 11.** *It holds* UniformVPSPACE$^0 \subseteq$ IP$_\mathbb{R}$ *in the following sense: Let* $\{f_n\}_n$ *be a family in* UniformVPSPACE^0 *such that* f_n *depends on* $u(n)$ *variables. Then there exists a real interactive protocol for the language* $\{(n, x, y) \in \mathbb{N} \times \mathbb{R}^{u(n)} \times \mathbb{R} \mid f_n(x) = y\}$.

Proof. The proof is an immediate application of Theorem 10 and the original proof of IP=PSPACE in [18]. Given an instance (n, x, y) the verifier first computes in polynomial time the binary polynomial formula obtained at the end of the proof of Theorem 10 representing $f_n(x)$. Note that it involves real numbers resulting from the input values x_j, has polynomial length and contains a polynomial number of operators of the form $\sum\limits_{t=0}^{1}$ and $\prod\limits_{t=0}^{1}$. This is the decisive observation; it implies that the technique used in Shamir's proof to verify interactively an equation $f_n(x) = y$ can be applied in our setting as well without major modifications: Once again, as briefly outlined in the introduction, the verification of $f_n(x) = y$ can be done by eliminating one after the other the leftmost of the operators. The fact that we deal with binary polynomial formulas of polynomial size guarantees that the univariate polynomials obtained with Shamir's construction have polynomially bounded degree. Therefore, the protocol runs in polynomial time.

□

4 Applications

In view of the difficulties described in the introduction when trying to design an interactive proof for problems in $\mathrm{PAR}_{\mathbb{R}}$ directly, an idea is to study oracle algorithms in the BSS model. More precisely, algorithms that are of interest use as information from an oracle different function evaluations. If f is a member of a family of functions such that for an argument x and a value y the equality $f(x) = y$ can be verified by an interactive protocol, then the outcome of a polynomial time BSS oracle computation having access to an oracle for values of f can be verified interactively as well; for each oracle query the verifier performs an interactive proof with the prover asking the latter to provide proofs of the correct oracle answers. Those are verified by the verifier. If it detects an error in any of the claimed oracle answers it rejects.

In order to obtain an interactive proof for interesting real complexity classes we can therefore consider such oracle computations. A typical classical example along this line is the computation of the permanent polynomial. In [13] an interactive protocol for verifying the value of a permanent of a 0-1-matrix was given (before Shamir's result was known). Together with Toda's theorem that the polynomial hierarchy PH is included in $P^{\#P}$ and the $\#P$-completeness of the permanent computation this implies the existence of an interactive protocol for all problems in the polynomial hierarchy. The protocol for the permanent, as for example described in [1], works as well for real matrices in the BSS model. This implies that real problems that can be decided by a polynomial time BSS algorithm having access to an oracle computing the permanent of real number matrices, i.e., all problems in class $\mathrm{P}_{\mathbb{R}}^{Perm}$, belong to $\mathrm{IP}_{\mathbb{R}}$. However, it is not known whether the permanent plays a similar role for real counting problems as it does in the Turing model. This is an active field of research. Basu and Zell [3] have given a real analogue of Toda's theorem. Instead of the permanent in this approach the computation of so-called Betti numbers of semi-algebraic sets plays a crucial role. The latter express certain topological properties of semi-algebraic sets. But they seem to be even more difficult to handle than permanent computations. And for the permanent itself a real variant of Toda's theorem is currently not known to hold.

In our context, Theorem 11 along the above lines has interesting consequences due to the strong relation the class $\mathrm{PAR}_{\mathbb{R}}$ has to $\mathrm{UniformVPSPACE}^0$. The main result of [12] is a transfer result which roughly states that if families in $\mathrm{UniformVPSPACE}^0$ can be evaluated efficiently, then there is a collapse of $\mathrm{PAR}_{\mathbb{R}}$ to $\mathrm{P}_{\mathbb{R}}$. On the way to prove this result the authors show a result most interesting for us; it witnesses the strength of oracle algorithms that query function evaluations of members of families in $\mathrm{UniformVPSPACE}^0$. We first state this result more precisely, starting with the following definition.

▶ **Definition 12** ([12]). A polynomial-time algorithm with $\mathrm{UniformVPSPACE}^0$-tests is a family $\{f_n(x_1, \ldots, x_{u(n)})\}_n \in \mathrm{UniformVPSPACE}^0$ together with a uniform family $\{C_n\}_n$ of constant-free algebraic circuits of polynomial size. The circuits in addition to their usual gates have special oracle gates of indegree $u(n)$. Those gates on input $x \in \mathbb{R}^{u(n)}$ output 1 if $f_n(x) \leq 0$ and 0 otherwise.

▶ **Theorem 13** ([12]). *For each $A \in \mathrm{PAR}_{\mathbb{R}}^0$ there is a polynomial-time algorithm with* $\mathrm{UniformVPSPACE}^0$*-tests deciding A.*

Given the remark following Lemma 8 the theorem holds analogously for all problems in $\mathrm{PAR}_{\mathbb{R}}$. Together with Theorem 11 we can now prove our main result.

▶ **Theorem 14.** $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{IP}_{\mathbb{R}}$

Proof. Let $A \in \mathrm{PAR}_{\mathbb{R}}$. Theorem 13 and the subsequent remark imply that there exists a family $\{f_n\}_n \in \mathrm{UniformVPSPACE}^0$ such that membership in A can be decided by a polynomial time BSS algorithm that has access to an oracle answering questions of the form: is $f_n(x) \leq 0$ for certain arguments x computed during the algorithm. Now each time such an oracle question is posed the verifier asks the prover for a $y \leq 0$ (or $y > 0$, respectively, if the answer should be $f_n(x) > 0$). Then, it applies the algorithm behind the proof of Theorem 11 to verify the result and to continue with the correct oracle answer. If no error occurs the given input is accepted to belong to A, otherwise it is rejected. Given the arguments at the beginning of this section the statement follows. ◻

Applying the same line of arguments and picking up the above discussion it also follows that $\mathrm{P}_{\mathbb{R}}^{Res} \in \mathrm{IP}_{\mathbb{R}}$, where $Res = \{Res_n\}_n$ denotes the family of resultant polynomials of $n+1$ homogeneous polynomials in $n+1$ variables. This follows from [12] because there it is shown that $\mathrm{Res} \in \mathrm{UniformVPSPACE}^0$.

Problem 1. How large is the class $\mathrm{P}_{\mathbb{R}}^{\mathrm{UniformVPSPACE}^0}$?

In this paper we have derived a first significant lower bound for the class $\mathrm{IP}_{\mathbb{R}}$. Summarizing the results already mentioned the current picture is $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{IP}_{\mathbb{R}} \subseteq \mathrm{MA}\exists\mathbb{R} \subseteq \mathrm{PAT}_{\mathbb{R}}$. There are some further immediate questions resulting from our lower bound. Given Shamir's characterization of classical IP it follows that IP is closed under complementation. However, without Shamir's result there seems no obvious way to prove this. Thus, in the real number setting we currently do not know whether the analogue statement holds.

Problem 2. Is it true that $\mathrm{IP}_{\mathbb{R}} = \text{co-}\mathrm{IP}_{\mathbb{R}}$?

Of course, we are still missing a characterization of $\mathrm{IP}_{\mathbb{R}}$. The work in [8] gives rise to conjecture $\mathrm{MA}\exists\mathbb{R} \subsetneq \mathrm{PAT}_{\mathbb{R}}$ which would imply that $\mathrm{IP}_{\mathbb{R}}$ is neither characterized by $\mathrm{PAR}_{\mathbb{R}}$ nor by $\mathrm{PAT}_{\mathbb{R}}$. Comparing our results with the different discrete characterizations of IP there seems to be only one more natural class left as a candidate, namely the class $\mathrm{PSPACE}_{\mathbb{R}}$ of problems being decidable by an algorithm using both exponential time and polynomially many registers. Note that requiring both conditions at the same time makes the coding argument from [15] not working. As mentioned above it is known that $\mathrm{PAR}_{\mathbb{R}} \subsetneq \mathrm{PSPACE}_{\mathbb{R}} \subseteq \mathrm{MA}\exists\mathbb{R} \subseteq \mathrm{PAT}_{\mathbb{R}}$. For establishing $\mathrm{PSPACE}_{\mathbb{R}}$ as a lower bound for $\mathrm{IP}_{\mathbb{R}}$ using the above techniques we should first get a similar result to Theorem 11 for a class like $\mathrm{UniformVPSPACE}^0$ such that using this class in oracle computations will cover $\mathrm{PSPACE}_{\mathbb{R}}$. We do not not know whether $\mathrm{UniformVPSPACE}^0$ itself or another similar class satisfies this. The upper bound $\mathrm{MA}\exists\mathbb{R}$ should then also be replaced by $\mathrm{PSPACE}_{\mathbb{R}}$.

Problem 3. What is the relation between $\mathrm{PSPACE}_{\mathbb{R}}$ and $\mathrm{IP}_{\mathbb{R}}$?

Abstract

Register automata (RAs) are finite automata extended with a finite set of registers to store and compare data. We study the concept of synchronizing data words in RAs: Does there exist a data word that sends all states of the RA to a single state?

For deterministic RAs with k registers (k-DRAs), we prove that inputting data words with $2k+1$ distinct data, from the infinite data domain, is sufficient to synchronize. We show that the synchronizing problem for DRAs is in general PSPACE-complete, and is NLOGSPACE-complete for 1-DRAs. For nondeterministic RAs (NRAs), we show that Ackermann(n) distinct data (where n is the size of RA) might be necessary to synchronize. The synchronizing problem for NRAs is in general undecidable, however, we establish Ackermann-completeness of the problem for 1-NRAs. Our most substantial achievement is proving NEXPTIME-completeness of the length-bounded synchronizing problem in NRAs (length encoded in binary). A variant of this last construction allows to prove that the bounded universality problem in NRAs is co-NEXPTIME-complete.

1 Introduction

Synchronizing words for finite automata have been studied since the 70's, see [8, 26, 32, 24]; such a word w drives the automaton from an unknown or unobservable state to a specific state q_w that only depends on w. The famous Černý conjecture on synchronizing words is a long-standing open problem in automata theory. The conjecture claims that the length of a shortest synchronizing data word for a deterministic finite automaton (DFA) with n states is at most $(n-1)^2$. There exists a family of DFAs, where the length of the shortest synchronizing word is exactly $(n-1)^2$, which attains the exact claimed bound in the conjecture. Despite all received attention in last decades, this conjecture has not been proved or disproved.

Synchronizing words have applications in planning, control of discrete event systems, biocomputing, and robotics [3, 32, 16]. Over the past few years, this classical notion has sparked renewed interest thanks to its generalization to games on transition systems [22, 29, 21], and to infinite-state systems [15, 10], which are more relevant for modelling complex systems such as distributed data networks or real-time embedded systems. These studies have inspired an elegant extension of temporal logics to capture synchronizing properties [9]; the proposed logic is more expressive than classical computation tree logic.

Figure 1 An RA $\mathcal{R}$ with single register r that models the interactive interfaces between a server and two users on the web. An *update*, denoted by $r\downarrow$, stores the input datum into r. Transitions labelled with $\neq$ are only taken if the datum of the current position of the input word and datum in register r are different. The data word $w = (a_1, \mathsf{password}_1)(a_2, \mathsf{password}_2)(b, \mathsf{restart})$ with the distinct datum restart is synchronizing; the set of successors after reading each input of w is shown on the right, where D is the infinite data domain. Observe that $\mathcal{R}$ is synchronized in (Server safe, restart).

In this paper, we are interested in *synchronizing data words* for *register automata. Data words* are sequences of pairs where the first element is taken from a finite alphabet and the second element is taken from *an infinite data domain* such as natural numbers or ASCII strings. In recent years, this structure has become an active subject of research thanks to applications in querying and reasoning about data models with complex structural properties, in XML, and lately also in graph databases [17, 2, 1, 5]. For reasoning about data words, various formalisms have been considered, ranging over first-order logic for data words [4, 6], extensions of linear temporal logic [23, 13, 12, 14], data automata [4, 7], register automata [20, 27, 25, 12] and extensions thereof, e.g. [31, 18, 11].

Register automata (RAs) are a natural generalization of finite automata over data words, and are equipped with a finite set of registers. When processing a data word, the automaton may store the data value of the current position in one or more registers. It may also test the data value of the current position for equality with the values stored in the registers, where the result of this test determines how the RA evolves. This allows for handling parameters like user names, passwords, identifiers of connections, sessions, etc., in a fashion similar to, and more expressive than, the class of data-independent systems. RAs come in different variants, e.g., one-way vs. two-way, deterministic vs. non-deterministic, alternating vs. non-alternating. For alternating RAs, classical decision problems like non-emptiness, universality and language inclusion are undecidable. We focus on the class of one-way RAs without alternation: They have a decidable non-emptiness problem [20], and the subclass of nondeterministic RAs with a single register has a decidable non-universality problem [12].

Semantically, an RA defines an infinite-state system, due to the unbounded domain for data stored in registers. Synchronizing words were introduced for infinite-state systems with infinite branching in [15, 29]; in particular, the notion of synchronizing words is motivated and studied for weighted automata and timed automata. In some infinite-state settings such as nested word automata (or equivalently visibly pushdown automata), finding the right definition of synchronizing words is however more challenging [10]. We define the synchronizing problem for RAs along the suggested framework in [15, 29]: Given an RA $\mathcal{R}$, does there exist a data word w that brings each of the infinitely many states of $\mathcal{R}$ to some specific state (depending only on w)? Such a data word is called a *synchronizing data word.*

Figure 1 depicts a web interface modelled by an RA $\mathcal{R}$ with register r. The RA models communications between a server and two users over an interactive interface. The server execute commands a_1, a_2 or b, and users locally attach private information as data to the input. The register r in each user's interface can be used to store local information such as the password, which implies the server has only partial information about the current state of the users' interfaces. When the server detects that an attacker is eavesdropping on the communication, it guides the system to a *safe* state. The data word $w = (a_1, \mathsf{password}_1)(a_2, \mathsf{password}_2)(b, \mathsf{restart})$ with the distinct datum restart, is synchronizing for the RA. We display the successive states after reading each input of w in Figure 1. The computation starts in the infinite set of all states in which the server and users might be; registers may have stored any datum from the data domain D, ranging over *infinitely many possible data values* (e.g. ASCII strings or numbers). The input $(a_1, \mathsf{password}_1)$ updates r in interface of the user 1 which synchronizes the infinite set of states of that user in the state $(\mathsf{User}_1, \mathsf{password}_1)$. However, no update has taken place in interface of the user 2. In fact, the register of that interface may still store any datum from D; this changes after inputting $(a_2, \mathsf{password}_2)$. Using the last input $(b, \mathsf{restart})$, the server accomplishes synchronizing $\mathcal{R}$ into $(\mathsf{Server\ safe}, \mathsf{restart})$. Now, the users can renew their passwords to prevent the attacker from future eavesdropping.

Contribution. The problem of finding synchronizing data words for RAs imposes new challenges in the area of synchronization. It is natural to ask how many distinct data are necessary and sufficient to synchronize an RA, which we refer to by the notion of *data efficiency* of synchronizing data words. We show this data efficiency to be polynomial in the number of registers for deterministic RAs (DRAs), and $\mathsf{Ackermann}(n)$ for nondeterministic RAs (NRAs), where n is the number of states. Remarkably, data efficiency is tightly related to the complexity of deciding the existence of a synchronizing data word.

For DRAs, we prove that for all automata $\mathcal{R}$ with k registers, if $\mathcal{R}$ has a synchronizing data word, then it also has one with data efficiency *at most* $2k + 1$. We provide a family $(\mathcal{R}_k)_{k\in\mathbb{N}}$ with k registers, for which indeed a polynomial data efficiency (in the size of k) is necessary to synchronize. This bound is the base of an (N)PSPACE-algorithm for DRAs; we prove a matching PSPACE lower bound by ideas carried over from timed settings [15]. We argue that, the synchronizing problems in DRAs with a single register (1-DRAs) and DFAs are NLOGSPACE-interreducible, implying that the problem is NLOGSPACE-complete for 1-DRAs.

For NRAs, a reduction from the non-universality problem yields the undecidability of the synchronization problem. For single-register NRAs (1-NRAs), we prove Ackermann-completeness of the problem by a novel construction proving that the synchronizing problem and the non-universality problem in 1-NRAs are polynomial-time interreducible. We believe that this technique is useful in studying synchronization in all nondeterministic settings, requiring careful analysis of the size of the construction.

Our most substantial achievement is proving NEXPTIME-completeness of the *length-bounded synchronizing problem* in NRAs: Does there exist a synchronizing data word with at most a given length (encoded in binary)?

For the lower bound, we present a non-trivial reduction from the bounded non-universality problem for *regular-like expressions with squaring*, which is known to be NEXPTIME-complete [30]. The crucial ingredient in this reduction is a family of RAs implementing binary counters. A variant of our construction yields a proof for co-NEXPTIME-completeness of the *bounded universality problem* in NRAs; the bounded universality problem asks whether all data words with at most a given length (encoded in binary) are in the language of the automaton.

2 Preliminaries

Deterministic finite-state automata (DFAs) are tuples $\mathcal{A} = \langle Q, \Sigma, \Delta\rangle$ where Q is a finite set of states, Σ is a finite alphabet and the transition function $\Delta : Q \times \Sigma \to Q$ is totally defined. The function Δ extends to finite words in a natural way: $\Delta(q, wa) = \Delta(\Delta(q, w), a)$ for all words $w \in \Sigma^*$ and letters $a \in \Sigma$; and it extends to all sets S by $\Delta(S, w) = \bigcup_{q\in S} \Delta(q, w)$.

Data Words and Register automata. Given an infinite data domain D, *data words* are finite words over $\Sigma \times \mathsf{D}$. For a data word $w = (a_1, d_1)(a_2, d_2)\ldots(a_n, d_n)$, the length of w is $|w| = n$. We use $\mathsf{data}(w) = \{d_1, \ldots, d_n\} \subseteq \mathsf{D}$ to refer to the set of data values occurring in w, and we say that the *data efficiency of* w is $|\mathsf{data}(w)|$.

Let reg be a finite set of *register variables*. We define *register constraints* ϕ over reg by the grammar $\phi ::= \mathsf{true} \mid \ =r \mid \phi \wedge \phi \mid \neg\phi$, where $r \in \mathsf{reg}$. We simply use $\neq r$ for the inequality constraint $\neg(=r)$; we denote by $\Phi(\mathsf{reg})$ the set of all register constraints over reg. A *register valuation* is a mapping $\nu : \mathsf{reg} \to \mathsf{D}$ that assigns a data value to each register; by a slight abuse of notation, we sometimes consider $\nu = \begin{pmatrix}\nu(r_1)\\ \cdots \\ \nu(r_k)\end{pmatrix} \in \mathsf{D}^k$ where $\mathsf{reg} = \{r_1, \cdots, r_k\}$. The satisfaction relation of register constraints is defined on $\mathsf{D}^k \times \mathsf{D}$ as follows: (ν, d) satisfies the constraint $= r$ if $\nu(r) = d$; the other cases follow. For example, $(\begin{pmatrix}d_1\\ d_2\\ d_1\end{pmatrix}, d_2)$ satisfies $((= r_1) \wedge (= r_2)) \vee (\neq r_3))$ where $d_1 \neq d_2$. For the set $\mathsf{up} \subseteq \mathsf{reg}$, we define the *update* $\nu[\mathsf{up} := d]$ of valuation ν by $\nu[\mathsf{up} := d](r) = d$ if $r \in \mathsf{up}$, and $\nu[\mathsf{up} := d](r) = \nu(r)$ otherwise.

Register automata (RAs) over infinite data domains D are tuples $\mathcal{R} = \langle\mathcal{L}, \mathsf{reg}, \Sigma, T\rangle$ where $\mathcal{L}$ is a finite set of locations, reg is a finite set of registers, Σ is a finite alphabet and $T \subseteq \mathcal{L} \times \Sigma \times \Phi(\mathsf{reg}) \times 2^{\mathsf{reg}} \times \mathcal{L}$ is a transition relation. We use $\ell \xrightarrow{\phi\ a\ \mathsf{up}\downarrow} \ell'$ to show transitions $(\ell, a, \phi, \mathsf{up}, \ell') \in T$. We call $\xrightarrow{\phi\ a\ \mathsf{up}\downarrow}$ an a-transition and ϕ the *guard*. We may omit ϕ when $\phi = \mathsf{true}$, and omit up if $\mathsf{up} = \emptyset$. We write $r\downarrow$ when $\mathsf{up} = \{r\}$ is singleton.

The *states* of $\mathcal{R}$ are pairs $(\ell, \nu) \in \mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}$ of locations ℓ and register valuations ν; since the data domains for registers are infinite, RAs are infinite-state transitions systems. We describe the behaviour of $\mathcal{R}$ as follows: Given that $\mathcal{R}$ is in state $q = (\ell, \nu)$, on inputting the letter a and datum d, an a-transition $\ell \xrightarrow{\phi\ a\ \mathsf{up}\downarrow} \ell'$ may be fired if (ν, d) satisfies the constraint ϕ; then $\mathcal{R}$ starts in *successor* state $q' = (\ell', \nu')$ where $\nu' = \nu[\mathsf{up} := d]$ is the update on registers. By $\mathsf{post}(q, (a, d))$, we denote all successor states q' of q, on inputting letter a and datum d. A run of $\mathcal{R}$ over the data word $w = (a_1, d_1)(a_2, d_2)\cdots(a_n, d_n)$ is a sequence of states $q_0q_1 \ldots q_n$ where $q_i \in \mathsf{post}(q_{i-1}, (a_i, d_i))$ for all $1 \leq i \leq n$.

We extend post to sets S of states by $\mathsf{post}(S, (a, d)) = \bigcup_{q\in S} \mathsf{post}(q, (a, d))$; and we extend post to words by $\mathsf{post}(S, w \cdot (a, d)) = \mathsf{post}(\mathsf{post}(S, w), (a, d))$ for all words $w \in (\Sigma \times \mathsf{D})^*$, letters $a \in \Sigma$ and datum $d \in \mathsf{D}$.

In the rest of paper, we consider *complete* RAs, meaning that for all states $q \in \mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}$ and all inputs $(a, d) \in \Sigma \times \mathsf{D}$, there is at least one successor: $|\mathsf{post}(q, (a, d))| \geq 1$. We also classify the RAs into *deterministic* (DRAs) and *nondeterministic* (NRAs), where an RA is deterministic if $|\mathsf{post}(q, (a, d))| \leq 1$ for all states q and all inputs (a, d).

Synchronizing words and synchronizing data words. The *synchronizing* words are a well-studied concept for DFAs; see [32]. Informally, a synchronizing word leads the automaton from every state to the same state: the word $w \in \Sigma^*$ is synchronizing for $\mathcal{A} = \langle Q, \Sigma, \Delta\rangle$ if there exists some state $\bar{q} \in Q$ such that $\Delta(Q, w) = \{\bar{q}\}$. The *synchronizing problem* in DFAs asks, given a DFA $\mathcal{A}$, whether there exists some synchronizing word for $\mathcal{A}$.

We introduce synchronizing data words for RAs: for an RA $\mathcal{R} = \langle \mathcal{L}, \mathsf{reg}, \Sigma, T \rangle$ over a data domain D, a data word $w \in (\Sigma \times \mathsf{D})^+$ is *synchronizing* if there exists some state $(\bar{\ell}, \bar{\nu})$ such that $\mathsf{post}(\mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}, w) = \{(\bar{\ell}, \bar{\nu})\}$. The *synchronizing problem* asks, given an RA $\mathcal{R}$ over a data domain D, whether $\mathcal{R}$ has some synchronizing data word. The *bounded synchronizing problem* decides, given an RA $\mathcal{R}$ and $\mathsf{length} \in \mathbb{N}$ encoded in binary, whether $\mathcal{R}$ has such synchronizing data word w with $|w| \leq \mathsf{length}$.

3 Synchronizing data words for DRAs

In this section, we first show that the synchronizing problems in 1-DRAs and DFAs are NLOGSPACE-interreducible, implying that the problem is NLOGSPACE-complete for 1-DRAs. Next, we prove that the problem for k-DRAs, in general, can be decided in PSPACE; a reduction similar to the timed settings, as in [15], provides the matching lower bound. To obtain the complexity upper bounds, we prove that inputting words with data efficiency $2|\mathsf{reg}| + 1$ is sufficient to synchronize a DRA.

The concept of synchronization requires that all runs of RAs, whatever the initial state (initial location and register valuations), end in the same state $(\ell_{\mathsf{synch}}, \nu_{\mathsf{synch}})$ that only depends on the data word w_{synch}: $\mathsf{post}(\mathcal{L} \times \mathsf{D}, w_{\mathsf{synch}}) = \{(\ell_{\mathsf{synch}}, \nu_{\mathsf{synch}})\}$. While processing a synchronizing data word, the infinite set of states in RAs must necessarily shrink to a finite set of states. The RA $\mathcal{R}$ with 3 registers depicted in Figure 2 illustrates this phenomenon. Considering the set $\{x_1, x_2, x_3\} \subseteq \mathsf{D}$ of distinct data values; starting from states in $\{\mathsf{init}\} \times \mathsf{D}^3$, the infinite set of runs of $\mathcal{R}$ over the data word $(a, x_1)(a, x_2)(a, x_3)$ is merged into the finite set $\{(\ell_3, \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}), (\ell_3', \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix})\}$. We use this observation to provide a linear bound on the sufficient number of required distinct data while synchronizing RAs.

In Lemma 1, we prove that data words over only $|\mathsf{reg}|$ distinct data values are sufficient to shrink states of RAs to a finite set. We establish this result based on the following two key facts: (1) to shrink the set $\mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}$, one can find a word w_ℓ that brings the RA from $\{\ell\} \times \mathsf{D}^{|\mathsf{reg}|}$ to some finite set for every $\ell \in \mathcal{L}$. Thanks to being deterministic, appending some prefix or suffix to w_ℓ would achieve the same objective; so the successor set of $\mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}$ and $(w_\ell)_{\ell \in \mathcal{L}}$ is a finite set. Moreover (2), when processing a synchronizing data word w_{synch} from a state (ℓ, ν) with $\nu(r) \notin \mathsf{data}(w_{\mathsf{synch}})$ for some $r \in \mathsf{reg}$, the register r must be updated. Observe that such updates must happen at inequality-guarded transitions, which themselves must be accessible by inequality-guarded transitions (possibly with no update).

For the RA $\mathcal{R}$ in Figure 2, assume that $d_1, d_2 \notin \mathsf{data}(w_{\mathsf{synch}})$. The two runs of $\mathcal{R}$ starting from $(\mathsf{init}, \begin{pmatrix} d_1 \\ d_1 \\ d_1 \end{pmatrix})$ and $(\mathsf{init}, \begin{pmatrix} d_2 \\ d_2 \\ d_2 \end{pmatrix})$ first take the transition $\mathsf{init} \xrightarrow{\neq r_1 \ a \ r_1\downarrow} \ell_1'$ updating register r_1. Next, the two runs must take $\ell_1' \xrightarrow{\mathsf{else} \ a \ r_2\downarrow} \ell_2'$ to update r_2 and $\ell_2' \xrightarrow{\mathsf{else} \ a \ r_3\downarrow} \ell_3'$ to update r_3; otherwise these two runs would never synchronize in a single state.

▶ **Lemma 1.** *For all DRAs for which there exist synchronizing data words, there exists some data word w with data efficiency $|\mathsf{reg}|$ such that* $\mathsf{post}(\mathcal{L} \times \mathsf{D}^{|\mathsf{reg}|}, w) \subseteq \mathcal{L} \times (\mathsf{data}(w))^{|\mathsf{reg}|}$.

After reading some word that shrinks the infinite set of states in RAs to a finite set S, one can apply the *pairwise synchronization* technique to synchronize states in S. This technique is the core to decide the synchronizing problem in DFAs in NLOGSPACE: Given a DFA $\mathcal{A} = \langle Q, \Sigma, \Delta \rangle$, it is known that it has a synchronizing word if and only if for all pairs of states $q, q' \in Q$, there exists a word v such that $\Delta(q, v) = \Delta(q', v)$ (see [32] for more details). The pairwise synchronization sets $S_{|Q|} = Q$, and for all $i = |Q| - 1, \cdots, 1$ repeats the following: find a word v_i such that $\Delta(q, v_i) = \Delta(q', v_i)$ for some pair $q, q' \in S_{i+1}$ and let

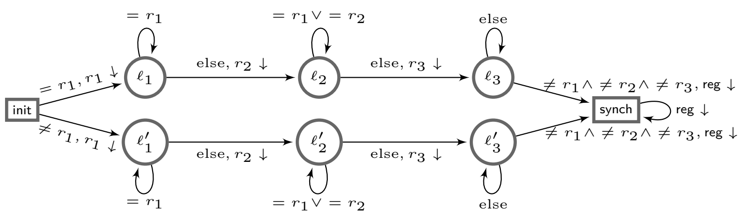

Figure 2 A DRA with three registers r_1, r_2, r_3 and single letter a (omitted from transitions) that can be synchronized in the state (synch, x_4) by the data word $w_{\mathsf{synch}} = (a, x_1)(a, x_2)(a, x_3)(a, x_4)$ if $\{x_1, x_2, x_3, x_4\} \subseteq \mathsf{D}$ is a set of 4 distinct data.

$S_i = \Delta(S_{i+1}, v_i)$. The word $w = v_{n-1} \cdots v_2 \cdot v_1$ is synchronizing for the DFA. We generalize the pairwise synchronization technique for DRAs to establish the following Lemma.

▶ **Lemma 2.** *For all DRAs for which there exist synchronizing data words, there exists a synchronizing data word with data efficiency* $2|\mathsf{reg}| + 1$.

Given a 1-DRA $\mathcal{R}$, the synchronizing problem can be solved by (1) ensuring that from each location ℓ an update on the single register is achieved by going through inequality-guarded transitions, which can be done in NLOGSPACE. Lemma 1 suggests that feeding $\mathcal{R}$ consecutively with a single datum $x \in \mathsf{D}$ is sufficient for this phase and the set of successors of $\mathcal{L} \times D$ would be a subset of $\mathcal{L} \times \{x\}$. Next (2) picking an arbitrary set $\{x, y, z\}$ of data including x, by Lemma 2 and the pairwise synchronization technique, the problem reduces to the synchronizing problem in DFAs where data in registers and input data extend locations and the alphabet: $Q = \mathcal{L} \times \{x, y, z\}$ and $\Sigma \times \{x, y, z\}$. Since a 1-DRA, where all transitions update the register and are guarded with true, models a DFA, we obtain the following result.

▶ **Theorem 3.** *The synchronization problem for* 1*-DRAs is in* NLOGSPACE*-complete.*

We provide a family of DRAs, for which a linear bound on the data efficiency of synchronizing data words, depending on the number of registers, is necessary. This necessary and sufficient bound is crucial to establish membership of synchronizing DRAs in PSPACE.

▶ **Lemma 4.** *There is a family of single-letter DRAs* $(\mathcal{R}_n)_{n \in \mathbb{N}}$*, with* $n = |\mathsf{reg}|$ *registers and* $\mathcal{O}(n)$ *locations, such that all synchronizing data words have data efficiency* $\mathcal{O}(n)$.

The synchronization problem for k-DRA is in PSPACE using the following co-(N)PSPACE algorithm: (1) picking a set $X = \{x_1, x_2, \cdots, x_{2k+1}\}$ of distinct data values, and (2) guessing some location $\ell \in \mathcal{L}$ and checking if there is no word $w \in (\Sigma \times \{x_1, x_2, \cdots, x_k\})^*$ with length $|w| \leq 2^{k|\mathcal{L}||\Sigma|}$ such that along firing inequality-guarded (on all k registers) transitions, some registers are not updated. Next (3) guessing two states $q_1, q_2 \in \mathcal{L} \times X^k$ such that there is no word $w \in (\Sigma \times X)^*$ with length $|w| \leq 2^{(2k+1)|\mathcal{L}||\Sigma|}$ such that $|\mathsf{post}(\{q_1, q_2\}, w)| = 1$.

▶ **Theorem 5.** *The synchronizing problem for k-DRAs is* PSPACE*-complete.*

4 Synchronizing data words for NRAs

In this section, we study the synchronizing problems for NRAs. We slightly update a result in [15] to present a general reduction from the *non-universality* problem to the synchronizing problem in NRAs. This reduction proves the *undecidability* result for the synchronizing problem in k-NRAs, and Ackermann-hardness in 1-NRAs. We then prove that in 1-NRA, the

synchronizing and non-universality problems are indeed interreducible, which completes the picture by Ackermann-completeness of the synchronizing problem in 1-NRAs.

In nondeterministic settings, we present two kinds of counting features while synchronizing. A family of 1-NRAs (with $\mathcal{O}(n)$ locations) where $\mathsf{Ackermann}(n)$ distinct data must be read and another family where an input datum $x \in \mathsf{D}$ must be read 2^n times to achieve synchronization. The second family can be captured by NFAs if the shortest length to synchronize is of interest. To give the intuition behind the constructions, we say an x-token is in location ℓ of an RA after reading a data word v if $(\ell, x) \in \mathsf{post}(\mathcal{L} \times \mathsf{D}, v)$.

The 1-NRA $\mathcal{R}_{\mathsf{counter}}$ shown in Figure 4 encodes a binary counter: In every synchronizing data word w, some datum $x \in \mathsf{data}(w)$ must appear at least 2^3 times. The location synch has self-loops on all letters, thus, $\mathcal{R}_{\mathsf{counter}}$ is only synchronized in synch. Generally speaking, the counting involves *resetting* and *incrementing*. The resetting places an x-token in the location zero by an unavoidable $\star$-transition (tokens in reset can only move out by $\star$-transitions). The numbers $m \le 2^3$ are represented by placing x-tokens in the locations corresponding to binary representation of m. An x-token in location 2^i (and in 2^i_c) means that the i-th least significant bit in binary representation is set to $\mathsf{1}$ (to $\mathsf{0}$). First, by resetting, a Bit_0-transition places x-tokens in $\{2^3_c, 2^2_c, 2^1_c, 2^0\}$ to represent $\mathsf{0001}$. Next, an incrementing process can be set off by inputting the datum x via equality guards. In each increment step the tokens are replaced by firing specific Bit_i-transitions $(0 \le i \le 3)$, following the standard procedure of binary addition. Figure 3 shows the three increment steps. At the end, $\#$-transitions takes the token in 2^3 to location synch and finally synchronize $\mathcal{R}_{\mathsf{counter}}$.

▶ **Lemma 6.** *There is a family of 1-NRAs $(\mathcal{R}_{\mathsf{counter}(n)})_{n \in \mathbb{N}}$ with $\mathcal{O}(n)$ locations, such that for all synchronizing data words w, some datum $d \in \mathsf{data}(w)$ appears in w at least 2^n times.*

We next remark that the data efficiency while synchronizing 1-NRAs can be a function in the *fast growing hierarchy* [28]. Recall that $\mathsf{tower} : \mathbb{N} \to \mathbb{N}$ is defined inductively by $\mathsf{tower}(0) = 1$ and $\mathsf{tower}(n+1) = 2^{\mathsf{tower}(n)}$.

Figure 4 shows the 1-NRA $\mathcal{R}_{\mathsf{tower}}$ over the data domain $\mathbb{N}$. We indicate that $|\mathsf{data}(w)| \in \mathcal{O}(\mathsf{tower}(3))$ for all synchronizing data words w. As in $\mathcal{R}_{\mathsf{counter}}$, synch is the location where the RA must be synchronized in, and an initial *reset* is enforced to reach the location Data_1. The main issue is that while synchronizing $\mathcal{R}_{\mathsf{tower}}$, some inequality-guarded transitions are unavoidable, which are the ones that may *replicate* the tokens. For example, if one token in Data_1, firing two transitions $\mathsf{Data}_1 \xrightarrow{\neq r \ \ \mathsf{rep}} \mathsf{Data}_{1,2}$ and $\mathsf{Data}_1 \xrightarrow{\neq r \ \ \mathsf{rep} \ \ r\downarrow} \mathsf{Data}_{1,2}$ replicates it to two tokens in $\mathsf{Data}_{1,2}$.

Since the question is the required data efficiency of synchronizing words, we always start from datum 1 and feed $\mathcal{R}_{\mathsf{tower}}$ with the smallest number i which contributes to synchronization.

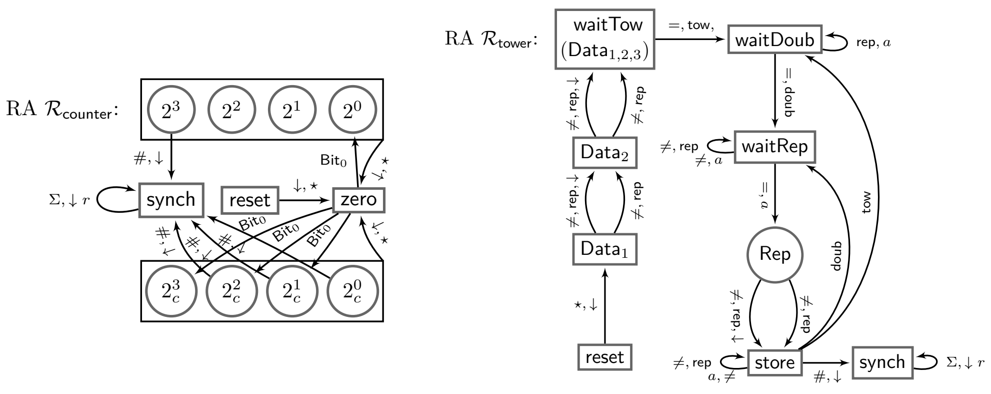

Figure 4 Bit$_i$-transitions in $\mathcal{R}_{\text{counter}}$ have equality guards. Most of the Bit$_i$-transitions are omitted; see Figure 3 for partial illustration of such transitions. Not-drawn $\star$-transitions activate a reset to zero in $\mathcal{R}_{\text{counter}}$, resp. to Data$_1$ in $\mathcal{R}_{\text{tower}}$. All inconsistent and inefficient transitions are omitted.

Moreover, when *resetting* we read datum 1. To synchronize $\mathcal{R}_{\text{tower}}$ with the least data efficiency, we go through the following steps:

▷ **resetting to** Data$_1$: the $\star$-transitions reset and place one token in Data$_1$ by $\ell \xrightarrow{\star\ r\downarrow}$ Data$_1$ for all $\ell \in \mathcal{L} \setminus \{$synch$\}$. Reading $\star$ is necessary for synchronizing since tokens in reset only move out by a $\star$-transition. Since another $\star$ eliminates all tokens and places one token in Data$_1$ again, resetting is inefficient; we call all transitions directed to reset *inefficient*.

▷ **replicating towering tokens**: after a reset with $(\star, 1)$ and having a 1-token in Data$_1$, the only efficient transitions are on $(\text{rep}, 2)(\text{rep}, 3)$, which results in replicating the 1-token in 3 tokens (shown as $\{1, 2, 3\}$-tokens) and placing them in waitTow.

▷ **towering the waiting i-token**: intuitively, the i-token in waitTow is waiting to trigger the tower(i)-process, right after the process of tower$(i-1)$ is accomplished. After the tower(i)-process, we see that $\{1, 2, \cdots, \text{tower}(i)\}$-tokens are in store. Next, if no more token is waiting in waitTow, the $\#$-transition synchronizes the RA into synch; otherwise, the inefficient $\#$-transition in waitTow resets. Below, we argue how, given a 3-token waiting in waitTow and $\{1, 2, \cdots, \text{tower}(2)\}$-tokens in store, the tower(3)-process proceeds. The first efficient transition is on $(\text{tow}, 3)$, which moves all those tokens to waitDoub. Recall that tower$(3) = 2^{\text{tower}(2)}$, simply doubling 1 for tower$(2) = 4$ times. Each i-token waiting in waitDoub (each in $\{1, 2, 3, 4\}$-tokens) is aimed to trigger a doubling,

▷ **1-token**: the only efficient transitions are on $(\text{doub}, 1)(a, 1)(\text{rep}, 2)$ which result in replicating $\{1, 2\}$-tokens in store.

▷ **2-token**: inputting $(\text{doub}, 2)$, which fires the only efficient transition, moves all the tokens obtained in the previous doubling process into waitRep. Then, both $\{1, 2\}$-tokens in waitRep will be replicated individually: note that while replicating, if a locally fresh datum from all data in waitRep, Rep and store is not read, an inefficient transition will be fired. After the second doubling by $(a, 1)(\text{rep}, 3)(a, 2)(\text{rep}, 4)$, the $\{1, 2, 3, 4\}$-tokens are produced in store.

▷ **3-token**: inputting $(\text{doub}, 3)$ moves $\{1, 2, 3, 4\}$-tokens into waitRep, which are indeed the tokens obtained in previous doubling process. For all $1 \leq i \leq 4$, the i-token is replicated into $\{i, 4+i\}$-tokens by $(a, i)(\text{rep}, 4+i)$. This results in storing $\{1, \cdots, 8\}$-tokens in store.

▷ **4-token**: it doubles the number of tokens in store for the 4-th time: $\{1, \cdots, 16\}$-tokens. So, tower$(3) = 2^{\text{tower}(2)} = 16$ distinct data are needed to synchronize $\mathcal{R}_{\text{tower}}$.

▶ **Lemma 7.** *There is a family of* 1*-NRAs* $(\mathcal{R}_{\mathsf{tower}(n)})_{n\in\mathbb{N}}$ *with* $O(n)$ *locations, such that* $|\mathsf{data}(w)| \in \mathcal{O}(\mathsf{tower}(n))$ *for all synchronizing data words* w*.*

We recall, from [28], that tower is at level 3 of the Ackermann-hierarchy. Using similar ideas as in Lemma 7, we can define a family of 1-NRAs $\mathcal{R}_n^m$ $(n, m \in \mathbb{N})$ such that all synchronizing data words have data efficiency at least $\mathsf{ack}_n(m)$, where ack_n is at level n of the Ackermann-hierarchy.

To define the language of a given RA $\mathcal{R}$, we equip it with an initial location ℓ_i and a set $\mathcal{L}_f$ of accepting locations, where, without loss of generality, we assume that all outgoing transitions from ℓ_i update all registers. The language $L(\mathcal{R})$ is the set of all data words $w \in (\Sigma \times \mathsf{D})^+$, for which there is a run from (ℓ_i, ν_i) to (ℓ_f, ν_f) such that $\ell_f \in \mathcal{L}_f$ and $\nu_i, \nu_f \in \mathsf{D}^{|\mathsf{reg}|}$. The universality problem asks, given an RA, whether $L(\mathcal{R}) = (\Sigma \times \mathsf{D})^+$. We adopt an established reduction in [15] to provide the following Lemma.

▶ **Lemma 8.** *The non-universality problem is reducible to the synchronizing problem for NRAs.*

As an immediate result of Lemma 8 and the undecidability of the non-universality problem for k-NRAs (Theorems 2.7 and 5.4 in [12]), we obtain the following theorem.

▶ **Theorem 9.** *The synchronizing problem for* k*-NRAs is undecidable.*

We present a reduction showing that, for 1-NRAs, the synchronizing problem is reducible to the non-universality problem, providing the tight complexity bounds for the synchronizing problem. We observe that Lemma 1 holds for 1-NRAs, meaning that for all 1-NRAs with some synchronizing data word, there exists some data word w with data efficiency 1 (for example, $\mathsf{data}(w) = \{x\}$) such that $\mathsf{post}(\mathcal{L} \times \mathsf{D}, w) \subseteq \mathcal{L} \times \mathsf{data}(w)$. Considering this fact as the skeleton, we define a language lang such that data words in this language are encodings of the synchronizing process. Let $\mathcal{L} = \{\ell_1, \ell_2, \cdots, \ell_n\}$ be the set of locations and x, y two distinct data. Each data word in lang, if there exists any, consists of

▷ **an initial block**: a delimiter $(\star, y)$ with distinct datum, the sequence $(\ell_1, x), (\ell_2, x)$, $\cdots, (\ell_n, x)$ and an input $(a, d) \in \Sigma \times \mathsf{D}$ as the first input of a synchronizing word. The initial block is followed by

▷ **a sequence of normal blocks**: the delimiter $(\star, y)$, successors reached from states and input in the previous block, and the next input of the synchronizing word. Finally, the data word ends with

▷ **a final block**: the delimiter $(\star, y)$, a single successor reached from states and input in the previous block and the delimiter $(\star, y)$.

We consider some further *membership conditions* for lang, which guarantee the correct semantics of the encoding of runs of $\mathcal{R}$. For instance, we impose the condition that for all (ℓ, d) and (a, d') with $d \neq d'$ in one block, if there exists a transition $\ell \xrightarrow{\neq r \;\; a \;\; r\downarrow} \ell'$, then (ℓ', d') must be in the next block.

We then construct a 1-NRA $\mathcal{R}_{\mathsf{comp}}$ that accepts the complement of lang; thus $\mathcal{R}$ has some synchronizing data word if, and only if, the language of $\mathcal{R}_{\mathsf{comp}}$ is not universal. The 1-NRA $\mathcal{R}_{\mathsf{comp}}$ is a finite union of smaller 1-NRAs, each of them violating one of the membership conditions for lang. For instance, the membership condition stated above is violated by the following 1-NRA.

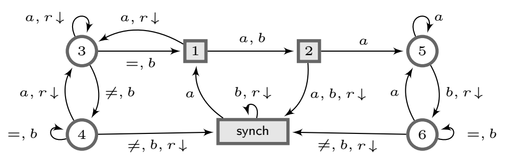

Figure 5 An RA where all synchronizing data words with length at most 3 require data efficiency 3 to shrink the infinite set of states to a finite subset.

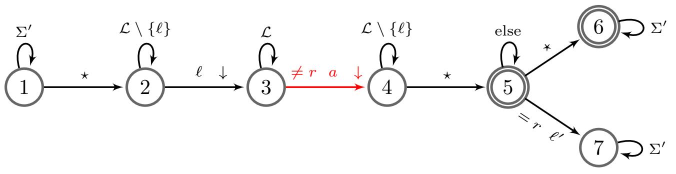

▶ **Lemma 10.** *The synchronizing problem is reducible to the non-universality problem for* 1*-NRAs.*

By Lemmas 8 and 10 and Ackermann-completeness of the non-universality problem for 1-NRA, which follows from Theorem 2.7 and the proof of Theorem 5.2 in [12], and the result for counter automata with incrementing errors in [19], we obtain the following theorem.

▶ **Theorem 11.** *The synchronizing problem for* 1*-NRAs is* Ackermann*-complete.*

5 Bounded synchronizing data words for NRAs

The synchronizing problem for NRAs is undecidable in general, due to the unbounded length of synchronizing data words; In the following, we study, for NRAs, the bounded synchronizing problem, that requires the synchronizing data words to have at most a given length.

To decide the synchronizing problem in 1-RAs, in both deterministic and nondeterministic settings, we hugely rely on Lemma 1. We thus assume that the RA inputs the same datum x (chosen arbitrary) as many times as necessary to have the successor set included in $\mathcal{L} \times \{x\}$; next, we synchronize this successor set in a singleton. The RA $\mathcal{R}$ shown in Figure 5 shows that this approach is not useful when the length of synchronizing words are asked to not exceed a given bound. Observe that the data word $(a, x)(b, y)(b, z)$ is synchronizing with length 3 (not exceeding the bound 3). All synchronizing data words that repeat a datum such as x, to first bring the RA to a finite set, have length at least 5.

We first present a NEXPTIME-hardness result based on the binary counting feature in NRAs. The proof is by a reduction from the bounded non-universality problem for *regular-like expressions*. A regular-like expression over an alphabet Σ is a well-parenthesized expression built by constants $a \in \Sigma$, two binary operations $\cdot$ (concatenation) and $+$ (union), and a unary operation ^{2} (squaring). The language $L(\mathsf{expr})$ of such expressions expr is defined inductively as in regular expressions, where $L(\mathsf{expr}^2) = L(\mathsf{expr}) \cdot L(\mathsf{expr})$. The *bounded universality problem* asks, given a regular-like expression expr and length $N \in \mathbb{N}$ written in binary, whether $L(\mathsf{expr})$ includes all strings with length at most N; in other words, if $\Sigma^{\leq N} \subseteq L(\mathsf{expr})$.

▶ Remark. The bounded universality problem of regular-like expressions is co-NEXPTIME-complete, where the membership in co-NEXPTIME comes by guessing a witness string u with length at most N, and checking in EXPTIME that $u \notin L(\mathsf{expr})$. We observe that the reduction presented in [30], for the inequivalence between two regular-like expressions, establishes the co-NEXPTIME-hardness for the bounded universality problem, even if $|\Sigma| = 2$.

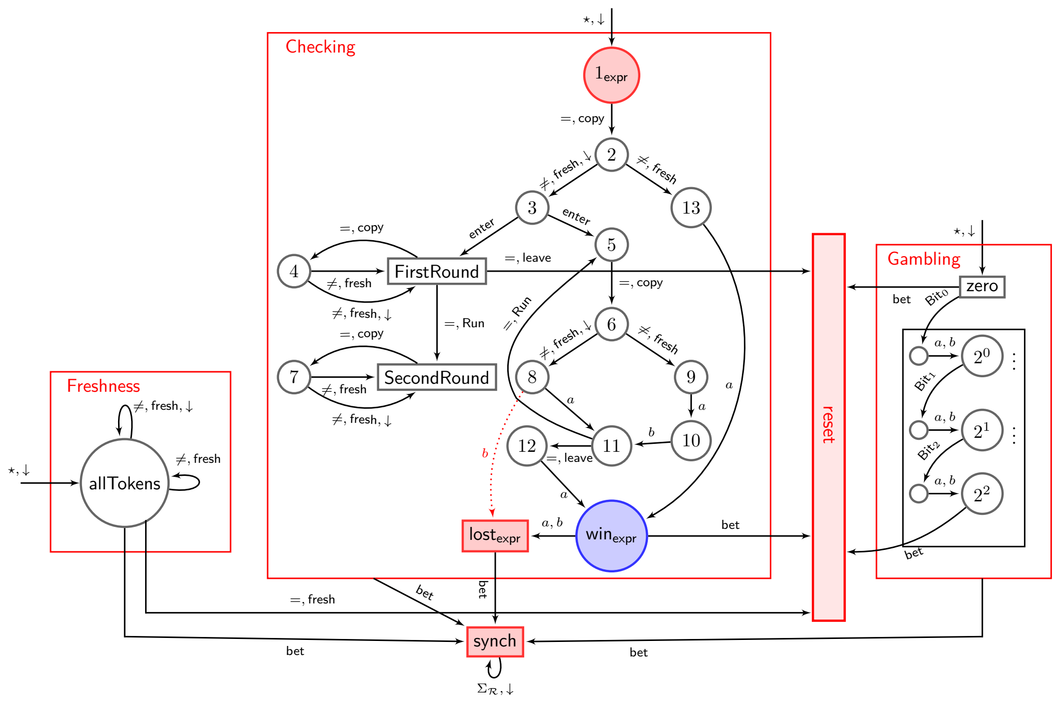

Figure 6 The $\star$-transitions reset $\mathcal{R}$, and all not-drawn a, b-transitions are inconsistent (except in allTokens). Other not-drawn transitions are self-loops.

Given a regular-like expression expr and length $N \in \mathbb{N}$, we construct a 1-NRA $\mathcal{R}$ and length $\in \mathbb{N}$, such that the language of expr is bounded universal if and only if $\mathcal{R}$ has no synchronizing data word with length at most length. The RA $\mathcal{R}$ consists of two distinguished locations reset, synch and three main gadgets: *Gambling*, *Freshness* and *Checking* gadget.

The RA $\mathcal{R}$ relies on the instincts of a *gambler* to synchronize. When feeding $\mathcal{R}$ with a data word w, we say that there is an x-token in location ℓ if $(\ell, x) \in \mathsf{post}(\mathcal{L} \times \mathsf{D}, w)$. Intuitively, whenever a token is in location reset, the gambler must restart; and $\mathcal{R}$ can only synchronize in synch. The reduction, roughly speaking, is such that the gambler guesses a string $u \in (a+b)^+$, letter-by-letter, and at some point places a *bet* that u is the witness for bounded non-universality. Gambling gadget discretely checks whether the bet makes sense: $|u| \leq N$. If *yes*, all tokens in Gambling gadget move to synch; otherwise, all tokens move to reset to give another chance to the gambler. On the other hand, meanwhile the gambler is hesitating to place the bet, Checking gadget tries to counter-attack the gambler by proving that expr generates u. To this aim, Checking gadget always follows all possible sub-expressions of expr which may produce u. This happens by replicating tokens and letting run computations for each sub-expression in parallel. As soon as one sub-expression fails in producing u, its token moves to lost$_{\mathsf{expr}}$ (of Checking gadget); and conversely, if a sub-expression definitely generates u, then its token moves to win$_{\mathsf{expr}}$ (of Checking gadget). The sub-expressions that have a string with prefix u keep their tokens in Checking gadget to follow the next computations (hoping that the gambler will not bet on u and continue guessing more letters). When a bet happens, all tokens in Checking gadget, except tokens in win$_{\mathsf{expr}}$, move to synch. In this way, $\mathcal{R}$ synchronizes in synch if $|u| \leq N$ and $u \notin L(\mathsf{expr})$.

Figure 6 depicts the constructed $\mathcal{R}$ for expr $= (a+ab)^2a + a$ and $N = 3$. Below, we give more intuitive explanations:

Gambler resets the guess: an initial *reset* is enforced while synchronizing since tokens in reset only move out by a $\star$-transition. When a reset happens, the gambler has the chance to change the guessed string u and to restart. Resetting eliminates all tokens in $\mathcal{R}$ and places tokens only to synch and the initial locations of all gadgets: zero, allTokens and 1_{expr}.

Gambler must only bet on $|u| \leq N$: after a reset, the sequence of read a, b is the guessed u by the gambler. Gambling gadget counts all a, b inputs to check whether $|u| \leq N$. This gadget is a chain of (modified) counting RAs $\mathcal{R}_{\mathsf{counter}(i)}$ described in Lemma 6, where $\mathcal{R}_{\mathsf{counter}(i)}$ counts until 2^i. We modify $\mathcal{R}_{\mathsf{counter}(i)}$ such that the *increment process*, triggered by Bit_i-transitions is executed after each occurrence of a or b. Gambling gadget in Figure 6 must count up to $N+1 = 2^2$ that is achieved by calling $\mathcal{R}_{\mathsf{counter}(2)}$.

Freshness gadget: after a reset, Checking gadget starts with a single token in 1_{expr}, say an x-token. This token moves along the gadget by reading u letter-by-letter and checking if the input prefix of u is in expr. For all unions, such as $a + ab$, the token replicates: x-token checks if a, and fresh y-token checks if ab contribute in generating u. Such tokens must move around individually, and thus must be distinctive. Freshness gadget guarantees the global freshness of such tokens: When replicating tokens by fresh-transitions, if the read datum is not fresh, the inconsistent transition $\mathsf{allTokens} \xrightarrow{=r\ \mathsf{fresh}} \mathsf{reset}$ happens.

Checking gadget: The checking is the gadget for expr that is built inductively from gadgets a, b, ab, $a+ab$, $(a+ab)^2$ and $(a+ab)^2a$. After a reset, it starts with a single token in 1_{expr}, if $u \in L(\mathsf{expr})$, then some token moves to $\mathsf{win}_{\mathsf{expr}}$ spoiling the gambler's plan in synchronizing. We explain the core of the sub-gadgets by following the scenario for $\mathcal{R}$ of $\mathsf{expr} = (a+ab)^2a+a$:

$\triangleright$ **When gambler bets on a wrong witness** $u \in L(\mathsf{expr})$, such as aaa. After a reset, assuming that an x-token is in 1_{expr}, it replicates by $(\mathsf{copy}, x)(\mathsf{fresh}, y)$ with $x \neq y$ to $\{x, y\}$-tokens. The x-token moves to 13 entering the a-gadget, and y-token to 3 entering the $(a+ab)^2a$-gadget. The only consistent transition is enter, the initial transition in the squaring. It makes a copy of the entering token in FirstRound to enforce the token to go through the gadget under squaring, two times. After (enter, y), there are y-tokens in FirstRound and in 5 as the initial location of the $(a+ab)$-gadget. For the union $a+ab$, inputting $(\mathsf{copy}, y)(\mathsf{fresh}, z)$ replicates the y-token in 5 to $\{y, z\}$-tokens where Freshness gadget guarantees that z is globally fresh. The z-token in 8 starts the a-gadget and y-token in 9 the ab-gadget. It is crucial that when union replicates tokens under squaring, their copy in FirstRound (and in SecondRound) must be replicated too: so $(\mathsf{copy}, y)(\mathsf{fresh}, z)$ replicates the y-token in FirstRound to $\{y, z\}$-tokens. Next a-transitions are consistent; observe that three tokens $\{x, y, z\}$ check if a is generated: as in $(a+ab)^2a + a$, the first produced a may be the result of three expressions: lonely a or a, ab under squaring.
The x-token from 13 moves to $\mathsf{win}_{\mathsf{expr}}$ meaning that $a \in L(\mathsf{expr})$; however, the gambler is betting on aaa, and the second a wastes this (fake) win by moving the token to $\mathsf{lost}_{\mathsf{expr}}$.
The y-token now must start the second round of squaring: inputting (run, y) brings back the y-token to 5, the initial of squaring, and also free the y-token in FirstRound to SecondRound (as a flag that y-token is ready to *leave* the squaring gadget). Due to the union again, the y-token, individually from z-token, must be replicated. By $(\mathsf{copy}, y)(\mathsf{fresh}, d)$ $(a, y)(\mathsf{leave}, y)(a, y)$, the y-token arrives in $\mathsf{win}_{\mathsf{expr}}$. The gambler places the bet with no more a, b, meaning that the y-token in $\mathsf{win}_{\mathsf{expr}}$ has no way to get synchronized, as it moves to reset by the bet-transition.
$\triangleright$ **When gambler bets on a right witness** $u \notin L(\mathsf{expr})$, such as bb. Observe that $(\star, x)(\mathsf{copy}, x)(\mathsf{fresh}, y)(\mathsf{enter}, x)(\mathsf{copy}, y)(\mathsf{fresh}, z)(b, x)(b, x)(\mathsf{bet}, x)$ synchronizes $\mathcal{R}$ into synch.

▷ **When gambler cheats** by betting on strings longer than N, such as *abbb*. The issue is when $abbb \notin L(\mathsf{expr})$, in these cases data words such as $(\star, x)(\mathsf{copy}, x)(\mathsf{fresh}, y)(\mathsf{enter}, x)$ $(\mathsf{copy}, y)(\mathsf{fresh}, z)(a, x)(\mathsf{run}, y)(\mathsf{copy}, y)(\mathsf{fresh}, d)(b, x)(\mathsf{run}, z)(\mathsf{copy}, z)(\mathsf{fresh}, m)(b, x)(b, x)$ would place all tokens of Checking gadget in $\mathsf{lost}_{\mathsf{expr}}$. Now, bet-transitions would move all tokens from Checking gadget to synch. However, Gambling gadget has counted 4, and thus location 2^2 has a token which goes to reset by placing the bet. This spoils synchronizing $\mathcal{R}$ when the gambler cheats by exceeding the bound $N = 3$. Note that tokens in zero, by bet-transitions, move to reset to forbid that the gambler cheats by the empty word too.

Note that $\mathsf{length} = 14$ of the synchronizing data word is computed inductively: here, $+1$ for resetting $\mathcal{R}$, $+2$ for the first union, $+(2 \cdot (2) + 3)$ for the squaring and union under it, $+1$ for the bet and $+N$ for Gambling gadget.

▶ **Lemma 12.** *The bounded synchronization problem for NRAs is* NEXPTIME*-hard.*

Guessing a data word w with $|(|w) \leq \mathsf{length}$ and checking in EXPTIME whether w is synchronizing yields NEXPTIME-membership. Altogether we obtain the following result:

▶ **Theorem 13.** *The bounded synchronization problem for NRAs is* NEXPTIME*-complete.*

The *bounded universality problem* asks, given an RA and $\mathsf{length} \in \mathbb{N}$ encoded in binary, whether all data words w with $|w| \leq \mathsf{length}$ are in the language of the automaton. We state that the bounded universality problem in NRAs is co-NEXPTIME-complete. The membership in co-NEXPTIME follows by guessing a witness w letter-by-letter; and checking if the successor states after reading w are all non-accepting. A variant of the presented reduction allows to prove that the bounded universality problem in NRAs is co-NEXPTIME-hard: equip $\mathcal{R}$ with the initial location reset and set $\mathcal{L}_f$ of accepting locations including all locations but synch.

▶ **Theorem 14.** *The bounded universality problem for NRAs is* co-NEXPTIME*-complete.*

Abstract

Various combinatorial/algebraic parameters are used to quantify the complexity of a Boolean function. Among them, *sensitivity* is one of the simplest and *block sensitivity* is one of the most useful. Nisan (1989) and Nisan and Szegedy (1991) showed that block sensitivity and several other parameters, such as certificate complexity, decision tree depth, and degree over $\mathbb{R}$, are all polynomially related to one another. The sensitivity conjecture states that there is also a polynomial relationship between sensitivity and block sensitivity, thus supplying the "missing link".

Since its introduction in 1991, the sensitivity conjecture has remained a challenging open question in the study of Boolean functions. One natural approach is to prove it for special classes of functions. For instance, the conjecture is known to be true for monotone functions, symmetric functions, and functions describing graph properties.

In this paper, we consider the conjecture for Boolean functions computable by read-k formulas. A read-k formula is a tree in which each variable appears at most k times among the leaves and has Boolean gates at its internal nodes. We show that the sensitivity conjecture holds for read-once formulas with gates computing symmetric functions. We next consider *regular* formulas with OR and AND gates. A formula is regular if it is a leveled tree with all gates at a given level having the same fan-in and computing the same function. We prove the sensitivity conjecture for constant depth regular read-k formulas for constant k.

1 Introduction

Sensitivity and block sensitivity are two important complexity parameters of Boolean functions. The sensitivity conjecture states that these two parameters are polynomially related. A long-standing open question is to prove (or disprove) this conjecture. In this paper, we prove the conjecture for several subclasses of functions computable by read-k formulas.

The sensitivity $\mathrm{s}(f)$ of a Boolean function f is the maximum (over all inputs) number of coordinate dimensions along which the value of the function changes. This notion was

* This work was done while the author was an intern at Microsoft Research, Bangalore, India.

first introduced by Cook et al. [9] to prove lower bounds on the parallel complexity (in the CREW PRAM model) of Boolean functions. Nisan [16] introduced the more general definition of *block sensitivity.* The block sensitivity $\mathrm{bs}(f)$ of a Boolean function f is the maximum (again, over all inputs) number of disjoint subsets of coordinate dimensions such that flipping all values of a given input in any of these subsets results in flipping the value of the function. Nisan proved that block sensitivity asymptotically captures the CREW PRAM complexity of all Boolean functions. Remarkably, Nisan also showed that several other complexity parameters of Boolean functions such as certificate complexity, decision tree depth, and randomized decision tree depth are polynomially related to block sensitivity. Subsequently, Nisan and Szegedy [17] showed that block sensitivity and degree of polynomials (approximately) representing a Boolean function over $\mathbb{R}$ are polynomially related.

Hence, a number of combinatorial/algebraic parameters describing complexity of Boolean functions are all polynomially related to each other, but sensitivity has so far resisted such a polynomial equivalence with any of these other parameters. In fact, Nisan and Szegedy posed this as the *sensitivity vs. block sensitivity* question and since then, this question has come to be known as the "sensitivity conjecture". More than two decades later, proving (or disproving) this conjecture still remains a foundational challenge in the study of Boolean functions. In recent times, this quest has become even more intriguing as other complexity parameters such as quantum query complexity (both exact and two-sided error versions) have been shown to be polynomially related to block sensitivity [5, 7]. At the same time, the sensitivity conjecture has been shown to be related to a number of other conjectures and open questions in Boolean function complexity, as illustrated in the survey [13].

The best known universal (applicable to all functions) upper bound on block sensitivity remains exponential in sensitivity [19] (see [14], [3], [21] for more refined upper bounds). In the other direction, Rubinstein [18] gives an example function where the gap between sensitivity and block sensitivity is quadratic (see [4] and references therein for improvements in constants). Thus the challenge is to close this gap between quadratic and exponential relations between block sensitivity and sensitivity.

Several approaches have been proposed in the literature to attack the sensitivity conjecture. Gotsman and Linial [12] showed that the degree vs. sensitivity problem is equivalent to a combinatorial problem on the maximum degree of induced subgraphs of the Boolean cube. Aaronson [1] (see also [6]) stated a problem about certain two-colorings of the integer lattice whose solution would imply the sensitivity conjecture. Recently, Gilmer et al. [10] formulated an approach to the degree vs. sensitivity problem using lower bounds on a two-party communication game. Even more recently, Gopalan et al. [11] prove an ℓ_2-approximate version of the degree vs. sensitivity conjecture (the original one needs an ℓ_∞-approximation). They also formulate the notion of tree sensitivity and a robust analog of the degree vs. sensitivity conjecture.

To make progress on our understanding of this problem, researchers also studied the conjecture on special classes of Boolean functions. It is trivial to see that the conjecture holds for monotone functions and symmetric functions. A natural question, then, is if the sensitivity conjecture holds when the function is invariant under other groups of symmetries. Turán [22] proved that for Boolean functions that describe graph properties (edges are the Boolean variables) sensitivity is $\Omega(\sqrt{n})$ and hence the conjecture holds for graph properties. Chakraborty [8] studied minterm-transitive Boolean functions and showed that for such functions sensitivity is $\Omega(n^{1/3})$, thus showing the conjecture for this class of functions. Sun [20] studied block sensitivity for Boolean functions invariant under any transitive permutation group and showed that such functions must have block sensitivity $\Omega(n^{1/3})$.

Our Results: We prove the sensitivity conjecture for another restricted class of Boolean functions, namely certain functions computed by read-k formulas. A *read-k formula* is a tree whose internal nodes are Boolean gates, e.g., AND and OR, and leaves are literals of input variables with the restriction that each variable (as negated or non-negated literal) appears at most k times among the leaves. Such a formula computes a Boolean function in a natural way from the leaves to the root. A formula is called *regular* if all gates at a given depth are the same type and have the same fan-in.

In what follows, we will mainly focus on formulas composed of OR and AND gates. In particular we show that the sensitivity conjecture is true for read-$\log n$ regular formulas whose bottom fanins are sufficiently large.

▶ **Theorem 1. Regular read-$\log n$ with large bottom fanin.** *Let f be a Boolean function, dependent on n variables, computed by a regular read-$(\log n)$ formula with bottom fan-in at least $\log^2 n$. Then $\mathrm{s}(f) \geq \tilde{\Omega}\left(\mathrm{bs}(f)^{1/4}\right)$, where the $\tilde{\Omega}$ notation hides some logarithmic terms.*

We would like to remove the condition on the bottom fanin. We succeed in doing so when the read and depth of the formula are constants.

▶ **Theorem 2. Regular read-constant and constant depth.** *Let f be computed by a regular read-k formula of depth-d for constants k and d such that all internal gates compute non-constant AND-OR functions. Then $\mathrm{s}(f) = \Omega_{k,d}(\sqrt{\mathrm{bs}(f)})$, where the hidden constant is a (rapidly decreasing) function of k and d.*

We present our main results (Theorem 1 and 2) on regular read-k formulas with AND and OR gates in Section 4. A crucial ingredient of our proofs is an application of the *Lovász Local Lemma* (LLL) to show that some literals can be assumed to occur in their positive form in such a formula without increasing the function's sensitivity and ensuring that any satisfying assignment of such a formula must have a large Hamming weight. However, in order to apply LLL, we need the bottom fan-in of such formulas to be large enough. So, we first prove the conjecture for formulas with large bottom fan-in. We then remove the restriction on the bottom fan-in by switching AND's of OR's to OR's of AND's (or vice versa). The idea is that if the formula is sufficiently large and the depth small, there has to be a layer L with large fanin. Then, by switching, we expand the layers under L and put L close to the bottom.

When specialized to read-once formulas with symmetric gates or to read-k DNF's our lower bounds on regular read-k formulas yield better dependence on k.

▶ **Theorem 3. Read-once with symmetric gates.** *Let f be a Boolean function dependent on n variables and computed by a read-once formula with symmetric gates. Then, $\mathrm{s}(f) \geq \sqrt{n}$.*

We note that Hiroki Morizumi [15] proved a similar lower bound for read-once AND-OR formulas.

▶ **Theorem 4. Read-k DNF.** *Let f be a Boolean formula dependent on n variables and computed by a read-k DNF. Then $\mathrm{s}(f) \geq n^{1/3}/(k+2)$. In particular, if $k \leq n^{\frac{1}{3}-\varepsilon} - 2$, then $\mathrm{s}(f) \geq n^{\varepsilon} \geq \mathrm{bs}(f)^{\varepsilon}$.*

Our proof of the conjecture for read-once formulas with symmetric gates appears in Section 3. The results on DNF's appear in Section 5.

2 Notations and Preliminaries

- In this paper, log will always denote the logarithm to base two.
- We will always assume that f is a Boolean function on n variables and moreover that it depends on all its variables.

2.1 Measures on Boolean functions

Let $f : \{0,1\}^n \to \{0,1\}$ be a Boolean function. For $x \in \{0,1\}^n$ and $S \subseteq [n]$, we denote by x^S the vector obtained by flipping all the coordinates on x in S. For $x \in \{0,1\}^n$ and $z \in \{0,1\}$, we denote by $|x|_z$ the number of coordinates of x with the value z.

▶ **Definition 5. Sensitivity:**

- The *sensitivity* of f at x is defined as the number of coordinates of x, which when flipped, will flip the value of f: $\mathrm{s}(f,x) := |\{i \in [n] : f(x) \neq f(x^i)\}|$.
- For $z \in \{0,1\}$, the *z-sensitivity* of f is defined as the maximum sensitivity of f at an input in $f^{-1}(z)$: $\mathrm{s}_z(f) := \max\{\mathrm{s}(f,x) : f(x) = z\}$.
- Finally, the *sensitivity of f* is the maximum sensitivity of f among all inputs: $\mathrm{s}(f) := \max\{\mathrm{s}(f,x) : x \in \{0,1\}^n\} = \max\{\mathrm{s}_0(f), \mathrm{s}_1(f)\}$.

▶ **Definition 6.** The *block sensitivity of f at x*, denoted $\mathrm{bs}(f,x)$ is the maximum number of *disjoint* subsets $S_1, \ldots, S_b$ of $[n]$ such that for every i, $f(x) \neq f(x^{S_i})$. The z-block sensitivity and block sensitivity of f are defined similar to the case of sensitivity. In particular, $\mathrm{bs}(f) := \max\{\mathrm{bs}(f,x) : x \in \{0,1\}^n\}$.

▶ **Definition 7.** A *certificate of f on x* is a subset $S \subseteq [n]$ such that $f(y) = f(x)$ whenever $y_i = x_i, \forall i \in S$. The size of the certificate S is $|S|$.

The *certificate complexity of f on x* denoted by $\mathrm{C}(f,x)$ is the size of a smallest certificate of f on x. The *certificate complexity of f* denoted by $\mathrm{C}(f)$ is $\max_x \mathrm{C}(f,x)$. For $z \in \{0,1\}$, the z-certificate complexity of f denoted by $\mathrm{C}_z(f)$, is $\max_{x \in f^{-1}(z)} \mathrm{C}(f,x)$.

We will use the following known results.

▶ **Lemma 8.** *For any Boolean function f and $z \in \{0,1\}$, $\mathrm{C}_z(f) \geq \mathrm{bs}_z(f) \geq \mathrm{s}_z(f)$.*

The first inequality above is from [16] and the second inequality is obvious from definitions.

▶ **Theorem 9** ([4]). *For any Boolean function f and $z \in \{0,1\}$, $\mathrm{C}_z(f) \geq \frac{3\mathrm{bs}_{1-z}(f)}{2\mathrm{s}_{1-z}(f)} - \frac{1}{2}$.*

2.2 Formulas

▶ **Definition 10. Regular Read-k Formulas:**

- A formula C is said to be *$(a_1, \ldots, a_d)$-regular* if it is a layered tree of depth d whose leaves are input variables or their negations and all internal nodes at a given layer i, $1 \leq i \leq d$, are gates of the same kind and the same fanin a_i. The layers are numbered 1 through $d+1$ from the root (output) to the leaves (inputs). We will often denote the gates at the layer d by *bottom gates*. In this paper, we only consider both formulas of alternating layers of AND and OR gates (we could start at the root with either gate and then alternate) and formulas with symmetric gates.
- A formula is *read-k* if each variable (either in its negated or non-negated form) appears at most k times among its leaves.
  One can argue that by replicating the arguments, we can always assume that the formula is in regular form. However, this idea does not work here because by doing this transformation, we would increase the read-multiplicity of the formula.

2.3 Lovász local lemma

We will make use of the Lovász Local Lemmas:

▶ **Lemma 11.** *[The Lovász Local Lemma: Symmetric Case] Let $A_1, \ldots, A_n$ be events in an arbitrary probability space. Suppose that each event A_i is mutually independent of a set of all the other events A_j but at most d and that $\Pr[A_i] \leq p$ for all $1 \leq i \leq n$.*

If $ep(d+1) < 1$, then $\Pr\left[\bigcap \overline{A_i}\right] > 0$.

We will also use the general version of this lemma. Both versions can be found, e.g., in [2].

3 Read-once formulas with symmetric gates

In this section, we prove the sensitivity conjecture for read-once formulas with *symmetric* gates. The read-multiplicity is more restrictive than the model we will consider later but the gates we allow are more powerful.

▶ **Definition 12.** Let g be a non-constant symmetric function on m inputs. We define $\tau(g)$ to be the minimal weight of an input $x \in \{0,1\}^m$ such that $g(x) \neq g(\vec{0})$:

$$\tau(g) := \min\left\{i \mid \ |x|_1 = i \implies g(x) \neq g(\vec{0})\right\}.$$

▶ **Theorem 13.** *Let f be a Boolean function computed by a read-once formula $\mathtt{C}$ with symmetric gates. Then, $\mathrm{s}_0(f)\mathrm{s}_1(f) \geq n$.*

Proof. We prove it by induction on the depth of the formula $\mathtt{C}$. If the depth of the formula is 1, then f is a symmetric function on n variables.

Let $z = f(\vec{0})$ and $t := \tau(f)$. By Definition 12, when $|x|_1 = t-1$, $f(x) = z$ and when $|y|_1 = t$, $f(y) = 1-z$. It follows immediately that $s_z(f,x) \geq n-t+1$ and $s_{1-z}(f,y) \geq t$. So $\mathrm{s}_0(f)\mathrm{s}_1(f) \geq t(n-t+1) \geq n$.

Now assume that the theorem is true for all depths $\leq d$. We prove it for depth $d+1$.

So $f = h(g_1, \ldots, g_m)$, where h is symmetric and each g_i is computed by a read-once formula with symmetric gates, of depth at most d. Let every g_i be a function on n_i variables with $a_i = \mathrm{s}_0(g_i)$ and $b_i = \mathrm{s}_1(g_i)$. By the inductive hypothesis, we know that $a_ib_i \geq n_i$. Since $n = \sum_{i=1}^m n_i$, we have that, $\sum_{i=1}^m a_ib_i \geq n$. Without loss of generality, we may assume that $a_1 \geq a_2 \geq \ldots \geq a_m$ and $b_{\pi(1)} \geq b_{\pi(2)} \geq \ldots \geq b_{\pi(m)}$ for a suitable permutation π of $[m]$. Let $A_j := \sum_{i=1}^j a_i$ and $B_j := \sum_{i=1}^j b_{\pi(i)}$. Let $t := \tau(h)$ so $h(x) = z$ for all x with $|x|_1 = t-1$ and $h(y) = 1-z$ for all y with $|y|_1 = t$.

Since the formula is read-once, the g_i depend on disjoint sets of variables, and so it is easy to see that for all S with $|S| = t-1$, we can find an assignment σ to all the variables of f such that (i) $g_i(\sigma_i) = 1$ for exactly those $i \in S$ and (ii) for $i \notin S$, $g_i(\sigma_i) = 0$ and g_i has $a_i = \mathrm{s}_0(g_i, \sigma_i)$ sensitive inputs.

It follows that $s_z(f) \geq \max_{\substack{S \subseteq [n] \\ |S| = m-t+1}} \{\sum_{i \in S} a_i\} = A_{m-t+1}$.

Similarly, $s_{1-z}(f) \geq \max_{\substack{S \subseteq [n] \\ |S| = t}} \{\sum_{i \in S} b_i\} = B_t$.

So, $\mathrm{s}_0(f)\mathrm{s}_1(f) \geq A_{m-t+1}B_t = (a_1 + \ldots + a_{m-t+1})(b_{\pi(1)} + \ldots + b_{\pi(t)})$.

Our proof is completed by the following claim whose proof is given in the full version.

▶ **Claim 14.** *For any t, $1 \leq t \leq m$, $A_{m-t+1}B_t \geq \sum_{i=1}^m a_ib_i$.*

We therefore conclude that $\mathrm{s}_0(f)\mathrm{s}_1(f) \geq A_{m-t+1}B_t \geq \sum_{i=1}^m a_ib_i \geq n$. ◀

▶ **Corollary 15.** *Let f be a Boolean function computed by a read once formula C with symmetric gates. Then, $s(f) \geq \sqrt{n} \geq \sqrt{bs(f)}$.*

Furthermore, this bound is tight whenever n is a perfect square. To see the tightness of the bound, consider an OR of fan-in $\sqrt{n}$ over $\sqrt{n}$ disjoint AND's on $\sqrt{n}$ variables each. It is easy to see that both 0-sensitivity and 1-sensitivity of this function are exactly $\sqrt{n}$.

4 Read-k formulas

In the following, we will only consider AND-OR formulas (with positive and negative literals). In this section, we prove the sensitivity conjecture for read-k formulas with certain restrictions.

▶ **Theorem 16.** *Let f be computed by a regular read-k formula of depth d with constants k and d such that any internal gate computes a non-constant function. Then, $\mathrm{s}(f) = \Omega_{k,d}(\sqrt{\mathrm{bs}(f)})$, where the hidden constant is a (rapidly decreasing) function of k and d.*

We prove this theorem in two stages:

- In Section 4.1, we first prove a lower bound for $\mathrm{s}(f)$ in terms of $\mathrm{bs}(f)$ when f is computed by a read-k regular formula with large bottom fanin.
- Then, in Section 4.2, we remove the condition on the bottom fanin by defining a normal form for formulas and then reducing a formula with small bottom fanin to one in the normal form where the previous step applies.

Notation: When $\mathtt{C}$ is an $(a_1, \ldots, a_d)$-regular formula with AND-OR gates we will use $A(\mathtt{C}, j)$ to denote the product,

$$A(\mathtt{C}, j) = \prod_{\substack{l \in [j] \\ l \text{ is a } \wedge\text{-gates level}}} a_l .$$

As most of the times, the function A will be used on the parameters $\mathtt{C}$ and $j = d - 2$, we will denote $A(\mathtt{C}, d-2)$ by A.

4.1 Large bottom fan-in

In this section, we give a lower bound for sensitivity in terms of block sensitivity for read-k regular formulas with large bottom fanin.

4.1.1 1-Sensitivity when bottom gates are AND gates

We will first prove a lower bound on the 1-sensitivity of such formulas. We will show that given a formula $\mathtt{C}$ it is possible to get an equivalent formula $\mathtt{C}'$ which has certain nice properties. Specifically, all inputs on which $\mathtt{C}'$ evaluates to 1 have large Hamming weight, which directly implies that the 1-sensitivity for this function is large.

▶ **Definition 17.** A parse tree P of a formula $\mathtt{C}$ computing f is a subcircuit which is recursively defined as follows:

- The output gate of $\mathtt{C}$ is in P.
- If an $\wedge$-gate belongs to P then all its children are also in P.
- If an $\vee$-gate belongs to P then exactly one of its children is in P.

It is easy to see that f evaluates to 1 on an input x if and only if $\mathtt{C}$ contains a parse tree all of whose gates evaluate to 1. A simple induction also shows that every parse tree of a regular formula has $A(\mathtt{C}, d-1)$ bottom gates.

▶ **Definition 18.** The parse-read of $\mathtt{C}$ is the maximum number of times any variable appears in any parse tree.

We will now consider two models. The first model is a (natural) restriction of our model of regular formulas: a variable can appear at most once under the same bottom gate. The second model is the general one without this restriction.

▶ **Lemma 19.** *Let $(a_1, \ldots, a_d) \in (\mathbb{N} \setminus \{0\})^d$ with $a_d \geq 2\log 4k$. Let f be a non-constant function computed by an $(a_1, \ldots, a_d)$-regular read-k and parse-read p formula such that the bottom gates are $\wedge$-gates and such that each variable appears at most once under any bottom gate. Then*

$$\mathrm{s}_1(f) \geq \left(\frac{a_d - 2\log 4k + 1}{2p\log 4k}\right) A.$$

Proof. By regularity, any bottom gate of $\mathtt{C}$ is the parent of a_d literals. Let us group these literals into groups of size α whose value will be chosen later. The last group will be of size a_d modulo α. So we get $\lfloor a_d/\alpha \rfloor$ groups of α literals under every bottom gate. We want to modify $\mathtt{C}$ to $\mathtt{C}'$ such that each group contains at least one positive literal.

Let us randomly negate each variable. Each variable is independently chosen as positive or negative with probability $\frac{1}{2}$. Let A_i be the event that the i^{th} group has no positive literals (where the i^{th} group is taken over all groups under all bottom gates). So $\Pr[A_i] = \frac{1}{2^\alpha}$. Every event A_i is dependent on at most $k\alpha$ other A_j's. Using the symmetric version of the Lovász Local Lemma we get that, if $e(k\alpha+1) \leq 2^\alpha$ then $\Pr\left[\bigcap \overline{A_i}\right] > 0$.

Notice that $\alpha = \lfloor 2\log(4k) \rfloor$ satisfies the previous inequality for all positive integers k. So there exists a new formula $\mathtt{C}'$ such that every group will have at least one positive literal. Let g be the function computed by $\mathtt{C}'$. Note that we now have a fixed σ such that for all x, $f(x \oplus \sigma) = g(x)$.

On any input $x \in g^{-1}(1)$ we get at least one parse tree in $\mathtt{C}'$ all of whose gates evaluate to 1. Consequently, on any input x in $g^{-1}(1)$, there are at least A bottom $\wedge$-gates of $\mathtt{C}'$ which evaluate to 1. As each variable can appear at most p times in any parse tree, we have that $\forall x \in g^{-1}(1)$, $|x|_1 \geq \left\lceil \frac{A}{p} \left\lfloor \frac{a_d}{\alpha} \right\rfloor \right\rceil \geq \frac{A(a_d - 2\log 4k + 1)}{2p\log 4k}$.

Taking the input $x \in g^{-1}(1)$ with least Hamming weight we get that,

$$\mathrm{s}_1(f, x \oplus \sigma) = \mathrm{s}_1(g, x) \geq |x|_1 \geq \left(\frac{a_d - 2\log 4k + 1}{2p\log 4k}\right) A.$$

◀

It is interesting to notice that the proof can be turned into an algorithm for finding an input which has high sensitivity given any 1-input x. Namely, one just have to run the algorithmic version of Lovász Local Lemma to get the above bijection $\oplus\sigma$. Then find (by flipping the 1's from x) a locally minimal weight (under $\oplus\sigma$) assignment that still gives the output 1.

We will now remove the condition that every variable can occur at most once under any bottom gate. In doing so we will lose a factor of k in the lower bound while also demanding a stronger constraint on the bottom fanin. This time around we use the general version of the Lovász Local Lemma to transform $\mathtt{C}$ to $\mathtt{C}'$. The rest of the proof then follows along similar lines to the proof of Lemma 19. The proof can be found in the full version.

▶ **Lemma 20.** *Let $(a_1, \ldots, a_d) \in (\mathbb{N} \setminus \{0\})^d$ with $a_d \geq k\log(3k)$. Let f be a non-constant function computed by an $(a_1, \ldots, a_d)$-regular read-k and parse-read p formula such that the bottom gates are $\wedge$-gates. Then*

$$\mathrm{s}_1(f) \geq \left(\frac{a_d - k\log(3k) + 1}{kp\log(3k)}\right) A.$$

4.1.2 The Sensitivity Conjecture for large bottom fan-in case

We will now combine previously known results with the statements proved in the section above to obtain some relations between sensitivity and block sensitivity.

The next lemma will help us relate the bound obtained for $\mathrm{s}_1(f)$ to $\mathrm{C}_1(f)$ of read-k regular formulas. The proof follows by induction and can be found in the full version.

▶ **Lemma 21.** *Let f be a Boolean function computed by an $(a_1, \ldots, a_d)$-regular formula $\mathtt{C}$. Then, $\mathrm{C}_1(f) \leq A(\mathtt{C}, d)$.*

▶ **Theorem 22.** *Let f be a non-constant Boolean formula computed by an $(a_1, \ldots, a_d)$-regular read-k formula with parse-read p such that its bottom fanin a_d is larger or equal to $(3\log 4k)$ and such that any variable appears at most one time under each bottom gate. Then*

$$\mathrm{s}(f) \geq \sqrt{\frac{\mathrm{bs}(f)}{10p\log 4k}}.$$

Moreover, when a variable can occur multiple times under each bottom gate and the bottom fan-in $a_d \geq 2k\log 3k$, we have

$$\mathrm{s}(f) \geq \sqrt{\frac{3\mathrm{bs}(f)}{10kp\log 3k}}.$$

Proof. Let us start by the first point of the theorem. By considering f or $\neg f$, we can assume that the bottom layer is composed of $\wedge$-gates. By Lemma 19, we have that,

$$\mathrm{s}_1(f) \geq \left(\frac{a_d - 2\log 4k + 1}{2p\log 4k}\right) A.$$

From Lemma 21 we have $C_1(f) \leq a_d A$. Since $a_d \geq 3\log 4k$, $a_d - 2\log 4k \geq a_d/3$,

$$\mathrm{s}_1(f) \geq \frac{3A + \mathrm{C}_1(f)}{6p\log 4k} \geq \frac{\mathrm{C}_1(f) + 1/2}{6p\log 4k}.$$

Using Lemma 8 we get, $\mathrm{s}(f) \geq \mathrm{s}_1(f) \geq \frac{\mathrm{bs}_1(f)}{6p\log 4k}$. We also get by Theorem 9,

$$\mathrm{s}(f)^2 \geq \mathrm{s}_1(f) \cdot \mathrm{s}_0(f) \geq \frac{\mathrm{bs}_0(f)}{4p\log 4k}.$$

Since $\mathrm{bs}(f) = \max(\mathrm{bs}_1(f), \mathrm{bs}_0(f))$, $5\mathrm{s}^2 \geq 2\mathrm{s}^2 + 3\mathrm{s} \geq \dfrac{\mathrm{bs}_0(f)}{2p\log 4k} + \dfrac{\mathrm{bs}_1(f)}{2p\log 4k} \geq \dfrac{\mathrm{bs}(f)}{2p\log 4k}$.

Consequently, $\mathrm{s} \geq \sqrt{\dfrac{\mathrm{bs}(f)}{10p\log 4k}}$, proving the first part. The second part of the theorem follows analogously using Lemma 20. ◀

The following corollary follows from the lower bound for sensitivity proved in [19]. A detailed proof can be found in the full version of the paper.

▶ **Corollary 23.** *Let f be a non-constant Boolean formula computed by an $(a_1, \ldots, a_d)$-regular read-$(\log n)$ formula with bottom fan-in at least $\log^2 n$. Then $\mathrm{s}(f) \geq \tilde{\Omega}\left(\mathrm{bs}(f)^{1/4}\right)$ where the $\tilde{\Omega}$ notation hides some logarithmic terms.*

4.2 Removing the condition on the bottom fan-in

In this section, we complete the proof of Theorem 16. We note that when the depth is constant but the size of the formula is large enough, there has to be a level at which the fanin is sufficiently large. If one of the last two fanins is large, we can apply an argument quite similar to the one in the previous section. Otherwise, we can switch these two layers while incurring a significant blow-up (but still only as a function of depth and read-multiplicity) in certain circuit parameters, while reducing the depth of the circuit. We continue switching the last two layers until one of their fanins is sufficiently large, which is ensured because the circuit is of constant depth.

4.2.1 Normal form by switching:

For notational convenience, we number the layers of a depth-d circuit as $L_1, \ldots, L_d$ with L_1 being just the root (output) gate and L_d the bottom layer (with inputs feeding into them) of gates. Also, we define the following function over $\mathbb{N}$ for later reference:

$$H(x) := 24 \cdot (3x)^{2x} x^4 \log 3x. \qquad (1)$$

As mentioned above, we will transform our formula into an equivalent formula where the fanin in the last or the last but one layer is sufficiently large. Such a representation for Boolean functions will be called a normal form:

▶ **Definition 24.** A formula is in $(k; a_1, \ldots, a_d)$-normal form if the following properties hold:

1. the formula is alternating and $(a_1, \ldots, a_d)$-regular, i.e., fanin of all gates in L_i is a_i,
2. the formula is read-k,
3. the bottom layer L_d is composed of $\wedge$-gates,
4. at least one of the two following conditions on the fanins of the two bottom layers L_{d-1} and L_d is true:
   - $a_d \geq 2k \log 3k$,
   - under each $\vee$-gate in L_{d-1}, i.e., one layer above the bottom layer, there are at least $H(k)$ non-constant $\wedge$-bottom gates.

As we will switch adjacent layers of the formula, let us start by bounding the increase we get by such a procedure. Let the size and width of a DNF (respectively CNF) be the fanin of its first layer and second layer respectively.

▶ **Lemma 25.** *If f is a function computed by a read-k regular DNF (respectively CNF) of size (top fanin) a and width b, then it is also computed by a read-$(kb^{(a-1)})$ CNF (respectively DNF) of size b^a and width a.*

Now we will focus on the last two layers we get after some number of switches in the formula. We will recursively define certain functions T_i below. Intuitively, T_1 is the fanin of the bottom layer without any switches and T_{i+2} is the fanin of the layer just above the bottom layer after i switching steps. Note that a depth d circuit becomes a depth $d - i$ circuit after i switches and merges of adjacent layers (after switching) of gates of the same type. Thus T_{i+2} is the fanin of layer L_{d-i-1} in the transformed circuit after i applications of switching and merging.

Formally, the family of functions $T_i : \mathbb{N}^i \to \mathbb{N}$, where i is a positive integer, is defined as

$$\begin{cases} T_0 = 1 \\ T_1(a) = a \\ T_p(a_1, \ldots, a_p) = a_1 \cdot (T_{p-2}(a_3, \ldots, a_p))^{T_{p-1}(a_2, \ldots, a_p)} & \text{if } p \geq 2. \end{cases}$$

In what follows, the function T_i will almost always be evaluated on the fanins of the last i layers of the formula. So, we will sometimes use the shorter notation $T_i(\mathbf{a})$ to designate $T_i(a_{d-i+1}, \ldots, a_d)$.

Observe that most of the non-regular formulas can be converted into a regular one by inserting gates or subtrees of gates that compute identically constant functions. Since we want to avoid this, we will define *purely regular formulas* as regular formulas in which each internal gate computes a non-constant Boolean function.

In the next claim, we compute the parameters of our new formula after several switches. The proof of the claim is by induction on the number of switchings i and the details can be found in the full version of the paper.

▶ **Claim 26.** *Suppose f is computed by a purely $(a_1, \ldots, a_d)$-regular read-k formula. Then for all integers $i \in [0, d-2]$, f is computable by an $(a_1, \ldots, a_{d-i-2}, u, v)$-regular read-$\Big(kuv/(\prod_{j=d-i-1}^{d} a_j)\Big)$ formula where*

$$u = T_{i+2}(a_{d-i-1}, \ldots, a_d) \quad \text{and} \quad v = T_{i+1}(a_{d-i}, \ldots, a_d)$$

such that under any gate in layer L_{d-i-1}, i.e., one layer above the bottom layer of gates, there are at least a_{d-i-1} non-constant bottom gates.

Recall the function $H(x)$ from (1). We inductively define $R_i(k)$ as

$$\begin{cases} R_0(k) = R_1(k) = k \\ R_p(k) = k \prod_{j=1}^{p-1} T_j(H(R_{j-1}(k)), \ldots, H(R_0(k)))^{T_{j+1}(H(R_j(k)), \ldots, H(R_0(k))) - 1} & \text{if } p \geq 2. \end{cases}$$

Intuitively, the $R_i(k)$'s bound the read value of the formula after $i-1$ switches of the bottom layers. As the functions R_p will always be used on the parameter k (the read value of the original formula), we will usually denote $R_p(k)$ by the simpler notation R_p.

We are now ready to prove that we can transform a sufficiently large regular formula into a formula in normal form. Proof of the following lemma appears in the full version.

▶ **Lemma 27.** *If f is computed by a purely $(a_1, \ldots, a_d)$-regular read-k formula with size larger than $H(R_d)$ then there exists $i \in [0, d-2]$ such that either f or $\neg f$ can be computed by a formula in $(R_{i+1}; a_1, \ldots, a_{d-i-2}, u, v)$-normal form with*

$$u = T_{i+2}(a_{d-i-1}, \ldots, a_d) \text{ and } v = T_{i+1}(a_{d-i}, \ldots, a_d).$$

Moreover,

- *the index i is such that for any $p \geq d-i$ we have $a_p \leq H(R_{d-p})$, and*
- *under each gate in one layer above the bottom one, i.e., L_{d-i-1}, there are at least a_{d-i-1} non-constant gates, where $a_{d-i-1} \geq H(R_{i+1})$.*

Now since our new formula's last or last but one fanin is sufficiently large, we can prove a lower bound on the sensitivity as was done in Theorem 22. The sketch of the proof is similar to the one of Theorem 22, but the fact that we now consider the last two layers (instead of the last layer only) makes details a bit more complicated.

▶ **Theorem 28.** *If f is computed by a purely $(a_1, \ldots, a_d)$-regular read-k formula with size larger than $H(R_d(k))$, then*

$$\mathrm{s}(f) \geq \sqrt{\frac{3\mathrm{bs}(f)}{5R_{d-1}(k)H(R_{d-1}(k))^{(d+1)/2}}} = \Omega_{k,d}(\sqrt{\mathrm{bs}(f)}).$$

Since the function $R_{d-1}(k)$ only depends on d and k, Theorem 16 immediately follows. One can notice that the hidden constant in this theorem is approximatively the inverse of the tetration ${}^{2d-2}k = \underbrace{k^{k^{\cdot^{\cdot^{k}}}}}_{2d-2}$.

Proof of Theorem 28. By Lemma 27, we know that f (or $\neg f$) can be computed by a $(k', a_1, \ldots, a_{d'-2}, u, v)$-regular formula in normal form where $k' = R_{d-d'+1}(k)$. Here d' is the depth of the new (equivalent) formula after applying $d - d'$ switches and merges. If the bottom fanin is larger than $2k' \log(3k')$ (the first condition for the fanins in the normal form) then using Theorem 22 we get that,

$$\mathrm{s}(f) \geq \frac{1}{k'}\sqrt{\frac{3\mathrm{bs}(f)}{10\log 3k'}} \geq \sqrt{\frac{3\mathrm{bs}(f)}{5R_{d-1}(k)H(R_{d-1}(k))^{(d+1)/2}}}.$$

Otherwise we have that under each gate in $L_{d'-1}$, there are at least $a_{d'-1} \geq H(R_{d-d'+1})$ non-constant bottom gates.

In this case, we want to give a similar argument as in proof of Lemma 19 for the last but one layer instead of the last layer. Hence, we would like to have $\wedge$-gates at the last but one layer. So we will consider $(\neg f)$ if necessary. By Lemma 27, such a bottom $\wedge$-gate of $\mathtt{C}$ is the parent of at least $a_{d'-1}$ non-constant bottom $\vee$-gates. Let us group these non-constant $\vee$-gates into groups of size $\alpha = \lfloor H(k')/2 \rfloor$. We now get $\mathtt{C}'$ from $\mathtt{C}$ so that each group contains at least one $\vee$-gate which has only positive literals under it. Let g be the function computed by $\mathtt{C}'$.

Using a similar argument as in proof of Lemma 19 (proved in the full version),

▶ **Claim 29.** *For all x in $g^{-1}(1)$*

$$|x|_1 \geq \left\lceil \frac{A'}{k'} \left\lfloor \frac{a_{d'-1}}{\alpha} \right\rfloor \right\rceil \geq \frac{A'(2a_{d'-1} - H(k') + 1)}{k'H(k')} \quad \textit{with } A' = A(\mathtt{C}, d'-2).$$

Taking the input $x \in g^{-1}(1)$ with least Hamming weight we get that,

$$\mathrm{s}_1(g, x) \geq |x|_1 \geq \frac{A'(2a_{d'-1} - H(k') + 1)}{k'H(k')} \geq \frac{A'a_{d'-1} + 1}{k'H(k')} \geq \frac{A(\mathtt{C}, d) + 1}{k'H(k')H(R_{d-3})^{(d-d'+1)/2}}$$

since for any $p \geq d' + 1$ we have that $a_p \leq H(R_{d-p}) \leq H(R_{d-3})$ and we only need to consider alternate layers in the definitions of A and A'.

Since the circuit is in normal form we know that $k' \leq R_{d-d'+1}(k) \leq R_{d-1}(k)$. Using a proof similar to Lemma 19 we get that, $s(f) \geq \sqrt{\frac{3\mathrm{bs}(f)}{5R_{d-1}(k)H(R_{d-1}(k))^{(d+1)/2}}}$. ◀

5 Sensitivity Lower Bounds for DNFs

In this section, we get sensitivity lower bounds for functions computed by read-restricted DNFs. A DNF is said to be *minimal* if no proper sub-formula of such a DNF computes the same function.

Notation: For a DNF $\mathtt{C}$ let a_1 denote its top fanin and $a_{21}, \ldots, a_{2a_1}$ its bottom fanins, with $a_2 = a_{21} \geq a_{22} \geq \ldots \geq a_{2a_1}$.

5.1 Regular read-k DNFs of large width

We can adapt Corollary 23 in the case where the DNF in question is regular and its width is sufficiently large:

▶ **Corollary 30.** *Let f be a Boolean function computed by a minimal regular DNF of size n^c, for some $c > 0$ with width larger than or equal to $6 + 3c \log n$. Then,* $\mathrm{s}(f) \geq \dfrac{\mathrm{bs}(f)^{1/3}}{2\sqrt{5}\max(2,c)}$.

5.2 Read-k DNFs of small size

In this section we will remove the constraints of regularity and large width for DNFs, thus proving the sensitivity conjecture for all functions computed by read-k DNFs.

The first lemma ensures a lower bound on $\mathrm{s}_0(f)$ for functions computed by read-k DNFs. The proof can be found in the full version.

▶ **Lemma 31.** *Let f be a Boolean formula computed by a minimal read-k DNF* $\mathtt{C}$. *Then* $\mathrm{s}_0(f) \geq \frac{a_1}{ka_2}$.

The second lemma states that the sensitivity of a read-k DNF is lower bounded by a function of its maximum bottom fanin.

▶ **Lemma 32.** *Let f be a Boolean function computed by a minimal read-k DNF* $\mathtt{C}$.
Then $\mathrm{s}_1(f) + (1+k)\mathrm{s}_0(f) \geq a_2$.

Proof. Let the bottom $\wedge-$gates be $W_1, \ldots, W_{a_1}$ with fanins $a_2 = a_{21} \geq \ldots \geq a_{2a_1}$ respectively. Let the variables under W_i be $x_{i1}, \ldots, x_{ia_{2i}}$.

Let us define two sets:
- $z \in P_1$ if and only if $W_1(z) = 1$ and for all $j > 1$, $W_j(z) = 0$,
- $y \in P_2$ if and only if $W_1(y) = 1$ and y is sensitive on the variable x_{11}.

By minimality of $\mathtt{C}$, we can find an input
- z_0 in P_1, otherwise removing the gate W_1 would not modify the function,
- y_0 in P_2, otherwise we can remove the leaf corresponding to x_{11} from W_1.

In fact it would be great to find an input which belongs to both P_1 and P_2, but unfortunately, it is not always possible. However, we show we can find such a pair (z, y) such that the Hamming distance between them is small. The next two claims are proved in the full version.

▶ **Claim 33.** *There exists a pair of inputs $(z_1, y_1) \in P_1 \times P_2$ such that the Hamming distance between z_1 and y_1 is at most $\mathrm{s}_0(f) - 1$.*

Let $J \subseteq [2, a_2]$ be the variables which appear under W_1 and which are sensitive on z_1, so $\mathrm{s}_1(f) \geq |J|$. Let $\bar{J} = [2, a_2] \setminus J$. Hence, it is sufficient to show:

▶ **Claim 34.** $\mathrm{s}_0 \geq |\bar{J}| - k\mathrm{s}_0 + 1$.

◀

▶ **Theorem 35.** *Let f be a Boolean formula computed by a read-k DNF.*
Then $(k+2)\mathrm{s}(f) \geq n^{1/3}$. In particular, if $k \leq n^{\frac{1}{3}-\varepsilon} - 2$, we get $\mathrm{s}(f) \geq n^{\varepsilon} \geq \mathrm{bs}(f)^{\varepsilon}$.

Proof. Using Lemma 32 we get that, $(k+2)\mathrm{s}(f) \geq \mathrm{s}_1(f) + (1+k)\mathrm{s}_0(f) \geq a_2$. By Lemma 31 we know that, $\mathrm{s}_0(f) \geq \frac{a_1}{ka_2} \geq \frac{n}{ka_2^2}$. Combining these two inequalities we get,

$$\mathrm{s}^3(f) \geq \left(\frac{a_2}{k+2}\right)^2 \frac{n}{ka_2^2} \geq \frac{n}{k(k+2)^2}$$

and so $(k+2)\mathrm{s}(f) \geq n^{1/3}$. In particular, when $k+2 \leq n^{\frac{1}{3}-\varepsilon}$, we get $\mathrm{s}(f) \geq n^{\varepsilon} \geq \mathrm{bs}(f)^{\varepsilon}$. ◀

Abstract

The query complexity of graph properties is well-studied when queries are on the edges. We investigate the same when queries are on the nodes. In this setting a graph $G = (V, E)$ on n vertices and a property $\mathcal{P}$ are given. A black-box access to an unknown subset $S \subseteq V$ is provided via queries of the form "Does i belong to S?". We are interested in the minimum number of queries needed in the worst case in order to determine whether $G[S]$ – the subgraph of G induced on S – satisfies $\mathcal{P}$.

Our primary motivation to study this model comes from the fact that it allows us to initiate a systematic study of breaking symmetry in the context of query complexity of graph properties. In particular, we focus on the hereditary graph properties – properties that are closed under deletion of vertices as well as edges. The famous Evasiveness Conjecture asserts that even with a minimal symmetry assumption on G, namely that of vertex-transitivity, the query complexity for any hereditary graph property in our setting is the worst possible, i.e., n.

We show that in the absence of any symmetry on G it can fall as low as $O(n^{1/(d+1)})$ where d denotes the minimum possible degree of a minimal forbidden sub-graph for $\mathcal{P}$. In particular, every hereditary property benefits at least quadratically. The main question left open is: Can it go exponentially low for some hereditary property? We show that the answer is no for any hereditary property with finitely many forbidden subgraphs by exhibiting a bound of $\Omega(n^{1/k})$ for a constant k depending only on the property. For general ones we rule out the possibility of the query complexity falling down to constant by showing $\Omega(\log n/ \log\log n)$ bound. Interestingly, our lower bound proofs rely on the famous Sunflower Lemma due to Erdös and Rado.

1 Introduction

1.1 The query model

The decision tree model (aka query model) has been extensively studied in the past and still remains a rich source of many fascinating questions. In this paper, we focus on Boolean functions, i.e., functions of the form $f : \{0,1\}^n \to \{0,1\}$ and their decision tree complexity. A deterministic decision tree D_f for f takes $x = (x_1, \dots, x_n)$ as an input and determines the value of $f(x_1, \dots, x_n)$ using queries of the form "is $x_i = 1$?". Let $C(D_f, x)$ denote the cost of the computation, that is the number of queries made by D_f on input x. The *deterministic decision tree complexity* (aka deterministic query complexity) of f is defined as

$$D(f) = \min_{D_f} \max_{x} C(D_f, x)$$

Randomized and the Quantum variants [6] of decision trees have also been extensively studied in the past. Several different variants such as parity decision trees have been studied in connection to communication complexity, learning, and property testing [25, 20, 4]. We refer the interested reader to the excellent survey by Buhrman and de Wolf [6] for more background on decision tree complexity.

Importance of query models

Variants of the decision tree model are fundamental for several reasons: Firstly, they occur naturally in connection to the other models of computation such as communication complexity [25], property testing [4], learning [20], circuit complexity [13] etc. Secondly, decision tree models are much simpler to analyse as compared to other models such as circuits. Thus one can actually hope to use them as a tool in the study of other models. Thirdly, these models are mathematically rich and beautiful – several connections to algebra, combinatorics, topology, Fourier analysis, and number theory [22, 2] make the decision tree models interesting in their own right. Finally, there remain some fascinating open questions [17] in query complexity that have attracted the attention of generations of researchers over the last few decades by their sheer elegance and notoriety.

1.2 Graph properties in node-query setting

In this paper , we investigate the query complexity of graph properties. In particular, we focus on the following setting: A graph $G = (V, E)$ and a property $\mathcal{P}$ are fixed. We have access to $S \subseteq V$ via queries of the form "Does i belong to S?". We are interested in the minimum number of queries needed in the worst case in order to determine whether $G[S]$ – the subgraph of G induced on S – satisfies $\mathcal{P}$, which we denote by $cost(\mathcal{P}, G)$. One may define a similar notion of cost for randomized and quantum models.

We call G the base graph for $\mathcal{P}$. We say that a vertex i of G is relevant for $\mathcal{P}$ if there exists some S containing i such that exactly one of $G[S]$ and $G[S - \{i\}]$ satisfies $\mathcal{P}$. We say that G is relevant for $\mathcal{P}$ if all its vertices are relevant for $\mathcal{P}$. The minimum possible cost of $\mathcal{P}$, denoted by[1] *min-cost*$(\mathcal{P})$, is defined as follows:

$$\textit{min-cost}_n(\mathcal{P}) = \min_{G} \{ cost(\mathcal{P}, G) \mid G \text{ is relevant for } \mathcal{P} \ \& \ |V(G)| = n \}.$$

[1] We slightly abuse this notation by omitting the subscript n.

Note that in the node-query settings the notion of *relevance of a graph G for the property* $\mathcal{P}$ is important because if any vertex $v \in G$ is *not* relevant then v cannot possibly influence the output of the function and hence any query algorithm does not need to query it.

Similarly one can define *max-cost*$(\mathcal{P})$, which is a more natural notion of complexity when one is interested in studying the universal upper bounds. Investigating the *max-cost* in our setting can indeed be a topic of an independent interest. However, for the purpose of this paper, the notion of *min-cost* will be more relevant as we are interested in finding how low can the universal lower bound on query complexity go under broken symmetry (Refer to Section 1.3 for more on symmetry). It turns out that in the presence of symmetry this bound is $\Omega(n)$ for most of the properties and it is conjectured to be $\Omega(n)$ for any hereditary property in our setting. Recall that a hereditary property is a property of graphs, which is closed under deletion of vertices as well as edges. For instance acyclicity, bipartiteness, planarity, and triangle-freeness are hereditary properties whereas connectedness and containing a perfect matching are not. Every hereditary property can be described by a (not necessarily finite) collection of its forbidden subgraphs.[2] [3]

It appears that the node-query setting is a natural abstraction of scenarios where one is interested in the properties of the subgraph induced by active nodes in a network. We discuss three such examples in the Appendix of the full version of this paper. To the best of our knowledge, no systematic study of node-query setting has been yet undertaken. Here we initiate such a line of inquiry for graph properties. In particular, we focus on the role of presence and absence of *symmetry*.

1.3 Effect of breaking symmetry

The primary reason why we are interested in the node-query model is that it allows us to study the effect of breaking symmetry on query complexities of graph properties. In particular, our setting provides a platform to compare the complexity of $\mathcal{P}$ when the base graph G has certain amount of symmetry with the complexity of $\mathcal{P}$ when G has no symmetry whatsoever. To formalize this, we define the notion of $\mathcal{G}$-*min-cost*$(\mathcal{P})$ for a class of graphs $\mathcal{G}$ by restricting ourselves only to graphs in $\mathcal{G}$.

$$\mathcal{G}\text{-}\mathit{min\text{-}cost}_n(\mathcal{P}) = \min_{G \in \mathcal{G}} \{\mathit{cost}(\mathcal{P}, G) \mid G \text{ is relevant for } \mathcal{P} \text{ \& } |V(G)| = n\}.$$

When $\mathcal{G}$ has the highest amount of symmetry, i.e., when $\mathcal{G}$ is the class of complete graphs, then it is easy to see that for every hereditary $\mathcal{P}$, $\mathcal{G}$-*min-cost*$(\mathcal{P})$ is nearly the worst possible, i.e., $\Omega(n)$. It turns out that one does not require the whole symmetry of the complete graph to guarantee the $\Omega(n)$ bound. Even weaker symmetry assumptions on graphs in $\mathcal{G}$, for instance being Cayley graphs of some group, indeed suffices. Thus it is natural to ask how much symmetry is required to guarantee the $\Omega(n)$ bound. In fact, the famous Evasiveness Conjecture implies that even under the weakest form of symmetry on $\mathcal{G}$, i.e., when $\mathcal{G}$ is the class of transitive graphs, for any hereditary property $\mathcal{P}$ the $\mathcal{G}$-*min-cost*$(\mathcal{P})$ would remain the highest possible, i.e., n. So for the complexity to fall down substantially we might have to let go of the transitivity of $\mathcal{G}$. This is exactly what we do. In particular we take $\mathcal{G}$ to be the class of all graphs, i.e., we assume no symmetry whatsoever. Note that in this case

[2] In our setting, every hereditary property is a monotone Boolean function.

[3] We would like to highlight that although we didn't explicitly define *min-cost*$(\mathcal{P})$ or *max-cost*$(\mathcal{P})$ for randomized query model, all our lower bound proofs are based on sensitivity arguments and hence work even for randomized case.

$\mathcal{G}$-*min-cost*$(\mathcal{P})$ = *min-cost*$(\mathcal{P})$ that we defined earlier. Now a natural question is how low can *min-cost*$(\mathcal{P})$ go in the absence of any symmetry? This is the main question addressed by our paper. In particular, we show that for any hereditary property $\mathcal{P}$, the *min-cost*$(\mathcal{P})$ falls down at least quadratically, i.e, to $O(\sqrt{n})$. For some properties, it can go even further below (polynomially down) with polynomials of arbitrary constant degree, i.e. to $O(n^{1/k})$ where k is a constant depending only on the property. The main question left open by our work is: does there exist a hereditary property $\mathcal{P}$ for which *min-cost*$(\mathcal{P})$ is exponentially low? In other words:

▶ Question 1. Is it true that for every hereditary property $\mathcal{P}$ there exists an integer $k_{\mathcal{P}} > 0$ such that

$$\textit{min-cost}(\mathcal{P}) = \Omega(n^{1/k_{\mathcal{P}}})?$$

1.4 Related work

Understanding the effect of symmetry on computation is a very well-studied theme in the past. Perhaps its roots can also be traced back to the non-solvability of quintic equations by radicals – the legendary work of Galois [1]. In the context of query complexity, again there has been a substantial amount of effort invested in understanding the role of symmetry. A recurrent theme here is to exploit the symmetry and some other structure [19] of the underlying functions to prove good lower bounds on their query complexity. For instance the famous Andera-Rosenberge-Karp Conjecture [15] asserts that every non-trivial monotone graph property of n vertex graphs (in the edge-query model) must be evasive, i.e., its query complexity is $\binom{n}{2}$. While a weaker bound of $\Omega(n^2)$ is known, the conjecture remains widely open to this date. Several special cases of the conjecture have also been studied [7]. The randomized query complexity of monotone graph properties is also conjectured to be $\Omega(n^2)$ [10]. The generalizations of these conjectures for arbitrary transitive Boolean functions are also studied: In particular, recently Kulkarni [16] has formulated the Weak-Evasiveness Conjecture for monotone transitive functions, which vastly generalize monotone graph properties. In the past, Lovász had conjectured [14] the evasiveness of checking independence of S exactly in our setting. Sun,Yao, and Zhang [24] study query complexity of graph properties and several transitive functions including the circulant ones. Their motivation was to investigate how low can the query complexity go if one drops the assumption of monotonicity or lower the amount of symmetry. In this paper, we follow their footsteps and ask the same question under no symmetry assumption whatsoever. The main difference between the past works and this one is that most of the previous work exploit the symmetry to prove (or to conjecture) a good lower bound, whereas we investigate the consequences of breaking the symmetry for the query complexity.

1.5 Our main results

In this section we summarize our main results. Let $\mathcal{P}$ be a hereditary graph property and $d_{\mathcal{P}}$ denote the minimum possible degree of a minimal forbidden subgraph for $\mathcal{P}$.

▶ **Theorem 2.** *For any hereditary graph property $\mathcal{P}$:*

$$\textit{min-cost}(\mathcal{P}) = O(n^{1/(d_{\mathcal{P}}+1)}).$$

Table 1 Summary of Results for Finite/Infinite Forbidden Subgraphs.

	Properties		With Symmetry[4]	Without Symmetry
Finite	Independence/Emptiness	[Full Version]	$\Theta(n)$	$\Theta(\sqrt{n})$
	Bounded Degree	[Full Version]	$\Theta(n)$	$\Theta(\sqrt{n})$
	Triangle-freeness	[Full Version]	$\Theta(n)$	$\Theta(n^{1/3})$
	Containing K_t	[Thm. 2][Thm. 4]	$\Theta(n)$	$\Theta(n^{1/t})$
	Containing P_t	[Thm. 2][Thm. 4]	$\Theta(n)$	$O(\sqrt{n})$,$\Omega(n^{1/t})$
	Containing C_t	[Thm. 2][Thm. 4]	$\Theta(n)$	$O(n^{1/3})$, $\Omega(n^{1/t})$
	Containing H: $V(H) = k$	[Thm. 13][Thm. 2][Thm. 4]	$\Theta(n)$	$O(n^{1/(d_{min}+1)})$, $\Omega(n^{1/k})$
Infinite	Acyclicity	[Thm. 15]	$\Theta(n)$	$O(n^{1/3})$
	Bi-partiteness	[Thm. 2]	Open	$O(n^{1/3})$
	3-colorability	[Thm. 2]	Open	$O(n^{1/4})$
	Planarity	[Thm. 17]	$\Theta(n)$[5]	$O(n^{1/4})$

▶ **Corollary 3.** *For any hereditary graph property $\mathcal{P}$:*

$$\textit{min-cost}(\mathcal{P}) = O(\sqrt{n}).$$

Theorem 2 and Corollary 3 show that in the absence of any symmetry on the graph G the query complexity can fall as low as $O(n^{1/(d+1)})$ where d denotes the minimum possible degree of a minimal forbidden sub-graph for $\mathcal{P}$. In particular, every hereditary property benefits at least quadratically.

We note that the above upper bound does not hold for general graph properties. For instance Connectivity has *min-cost* $\Theta(n)$, so does containment of a Perfect Matching, which are both non-hereditary properties (See Appendix of the full version of this paper).

As a partial answer to Question 1 we prove the following theorem.

▶ **Theorem 4.** *Let H be a fixed graph on k vertices and let $\mathcal{P}_H$ denote the property of containing H as a subgraph. Then,*

$$\textit{min-cost}(\mathcal{P}_H) = \Omega(n^{1/k}).$$

Interestingly our proof of Theorem 4 uses the famous Sunflower Lemma due to Erdös and Rado [9]. Moreover it generalizes to any fixed number of forbidden subgraphs each on at most k vertices. This implies that any hereditary property with *finitely many forbidden subgraphs* has a lower bound of $\Omega(n^{1/k})$, for a constant k depending only on the property.

We note that both Theorem 2 and Theorem 4 are not tight. However, we do prove tight bounds for several hereditary properties. We summarize a few such interesting bounds in the Table 1.

Finally we note a non-constant lower bound, which holds for *any* hereditary property. Our proof again relies on the Sunflower Lemma.

▶ **Theorem 5.** *For any hereditary graph property $\mathcal{P}$*

$$\textit{min-cost}(\mathcal{P}) = \Omega\left(\frac{\log n}{\log\log n}\right).$$

As we use sensitivity arguments all our lower bounds work for randomized case as well.

[4] assuming Weak Evasiveness
[5] when $d(G) \geq 7$

1.6 Organization

The rest of the paper is organized as follows: We introduce some preliminary notions in Section 2. We revisit some results on Weak Evasiveness under symmetry in Section 3. In Section 4, we provide proofs of Theorem 2 and Theorem 4. Proof of some tight bounds for Theorem 2 are deferred to Appendix. In Section 5 we state some results on restricted graph classes and their proofs are deferred to Appendix. Finally in Section 6 we discuss questions and directions that are naturally raised by our work.

The whole Appendix section of this paper can be found in the full version, which is available on the arXiv [3].

2 Preliminaries

▶ **Definition 6** (Randomized query complexity)**.** A randomized decision tree $\mathcal{T}$ is simply a probability distribution on the deterministic decision trees $\{T_1, T_2, \ldots\}$ where the tree T_i occurs with probability p_i. We say that $\mathcal{T}$ computes f correctly if for every input x: $\Pr_i[T_i(x) = f(x)] \geq 2/3$. The depth of $\mathcal{T}$ is the maximum depth of a T_i. The (bounded error) randomized query complexity of f, denoted by $R(f)$, is the minimum possible depth of a randomized tree computing f correctly on all inputs.

▶ **Definition 7** (Monotone, Transitive and Evasive Boolean functions)**.** A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is said to be *monotone* increasing if for any $x \leq y$, we have $f(x) \leq f(y)$, where $x \leq y$ means $x_i \leq y_i$ for all $i \in [n]$. Similarly one can define a monotone decreasing function. A Boolean function $f(x_1, \ldots, x_n)$ is said to be *transitive* if there exists a group G that acts transitively on the variables x_is such that f is invariant under this action, i.e., for every $\sigma \in G$: $f(x_{\sigma_1}, \ldots, f_{\sigma_n}) = f(x_1, \ldots, x_n)$. A Boolean function $f : \{0,1\}^n \to \{0,1\}$ is said to be *evasive* if $D(f) = n$.

▶ **Definition 8** (Hereditary graph properties)**.** A property $\mathcal{P}$ of graphs is simply a collection of graphs. The members of $\mathcal{P}$ are said to satisfy $\mathcal{P}$ and non-members are said to fail $\mathcal{P}$. A property is hereditary if it is closed under deletion of vertices as well as edges[6]. For instance: acyclicity, planarity, and 3-colorability are hereditary properties, whereas connectivity and containing a perfect matching are not. Every hereditary property $\mathcal{P}$ can be uniquely expressed as a (possibly infinite) family $\mathcal{F}_{\mathcal{P}}$ of its forbidden subgraphs. For instance: acyclicity can be described as forbidding all cycles. Given a graph G, a hitting set $S_{G,\mathcal{P}}$ for $\mathcal{P}$ is a subset of $V(G)$ such that removing $S_{G,\mathcal{P}}$ from G would make the property $\mathcal{P}$ present[7]. Hereditary graph properties in node-query setting are monotone decreasing Boolean functions. Sometimes we refer hereditary properties by their negation. For instance: containing triangle.

▶ **Definition 9** (Sensitivity and block-sensitivity [12])**.** The i^{th} bit of an input $x \in \{0,1\}^n$ is said to be sensitive for $f : \{0,1\}^n \to \{0,1\}$ if $f(x_1, \ldots, x_i, \ldots, x_n) \neq f(x_1, \ldots, 1 - x_i, \ldots, x_n)$. The sensitivity of f on x, denoted by $s_{f,x}$ is the total number of sensitive bits of x for f. The sensitivity of f, denoted by $s(f)$, is the maximum of $s_{f,x}$ over all possible choices of x. A block $B \subseteq [n]$ of variables is said to be sensitive for f on input x, if flipping the values of all x_i such that $i \in B$ and keeping the remaining x_i the same, results in flipping the output of f. The block sensitivity of f on an input x, denoted by $bs_{f,x}$ is the maximum

[6] on the other hand, vertex-hereditary is closed only under vertex-deletion (e.g. being chordal).
[7] such that every graph in $\mathcal{F}_{\mathcal{P}}$ shares a node with $S_{\mathcal{G},\mathcal{P}}$.

number of *disjoint* sensitive blocks for f on x. The block sensitivity of a function f, denoted by $bs(f)$, is the maximum value of $bs_{f,x}$ over all possible choices of x. It is known that $D(f) \geq R(f) \geq bs(f) \geq s(f)$. For monotone functions, $bs(f) = s(f)$.

3 Presence of symmetry in node-query setting: Does it guarantee weak-evasiveness?

In edge-query setting, Aanderaa-Rosenberg-Karp Conjecture [15, 7] asserts that any non-trivial monotone graph property must be evasive, i.e., one must query all $\binom{n}{2}$ edges in worst-case. The following generalization of the ARK Conjecture asserts that only monotonicity and modest amount of symmetry, namely transitivity, suffices to guarantee the evasiveness [21].

▶ Conjecture 10 (Evasiveness Conjecture). Any non-constant monotone transitive function f on n variables has $D(f) = n$.

This conjecture appears to be notoriously hard to prove even in several interesting special cases. Recently Kulkarni [16] formulates:

▶ Conjecture 11 (Weak Evasiveness Conjecture). If f_n is a sequence of monotone transitive functions on n variables then for every $\epsilon > 0$:

$$D(f_n) = \Omega(n^{1-\epsilon}).$$

Although Weak EC appears to be seemingly weaker, Kulkarni [16] observes that it is equivalent to the EC itself. His results hint towards the possibility that disproving Weak EC might be as difficult as separating TC^0 from NC^1. However: proving special cases of Weak EC appears to be relatively less difficult. In fact, Rivest and Vuillemin [23] confirm the Weak EC for graph properties and recently Kulkarni, Qiao, and Sun [18] confirm Weak EC for 3-uniform hyper graphs and Black [5] extends this result to k-uniform hyper graphs. All these results are studied in the edge-query setting. It is natural to ask whether the Weak EC becomes tractable in node-query setting. The monotone functions in node-query setting translate precisely to the hereditary graph properties. Here we show that it does become tractable for several hereditary graph properties. But first we need the following lemma [8, 24]:

▶ **Lemma 12.** *Let f be a non-trivial monotone transitive function. Let k be the size of a 1-input with minimal number of 1s. Then: $D(f) = \Omega(n/k^2)$.*

Let $\mathcal{G}_\mathcal{T}$ denote the class of transitive graphs. Let H be a fixed graph. Let $\mathcal{P}_H$ denote the property of containing H as a subgraph. The following theorem directly follows from Lemma 12.

▶ **Theorem 13.**

$$\mathcal{G}_\mathcal{T}\text{-}min\text{-}cost(\mathcal{P}_H) = \Omega(n).$$

The above result can be generalized for any finite family of forbidden subgraphs. We do not yet know how to prove it for infinite family in general. However below we illustrate a proof for one specific case when the infinite family is the family of cycles. First we need the following lemma:

▶ **Lemma 14.** *Let G be a graph on n vertices, m edges, and maximum degree d_{max}. Let $\mathcal{C}$ denote the property of being acyclic. Then,*

$$cost(\mathcal{C}, G) \geq (m - n)/d_{max}.$$

Proof. To make G acyclic one must remove at least $m-n$ edges. Removing one vertex can remove at most d_{max} edges. Thus the size of minimum feedback vertex set (FVS) is at least $(m-n)/d_{\max}$. The adversary answers all vertices outside this FVS to be present. Now the algorithm must query every vertex in the minimum FVS. ◀

▶ **Theorem 15.**

$$\mathcal{G}_{\mathcal{T}}\text{-}min\text{-}cost(\mathcal{C}) = \Omega(n).$$

Proof. Since G is transitive, G is d regular for some d [11]. Therefore $m = dn/2$ and $d_{max} = d$. Hence from Lemma 14 we get the desired bound. ◀

We also show similar bound for the property of being planar:

▶ **Lemma 16.** *Let G be a graph on n vertices, m edges, and maximum degree d_{max}. Let $\mathcal{P}'$ denote the property of being planar. Then,*

$$cost(\mathcal{P}', G) \geq (m - 3n + 6)/d_{max}.$$

Proof. To make G planar one has to remove at least $(m - 3n + 6)$ edges from the graph G. Removing one vertex can remove at most d_{max} edges. Thus the size of minimum hitting set of G is at least $(m - 3n + 6)/d_{\max}$. The adversary answers all vertices outside this minimum hitting set to be present. Now the algorithm must query every vertex in the minimum hitting set. ◀

▶ **Theorem 17.**

$$\mathcal{G}_{\mathcal{T}}\text{-}min\text{-}cost(\mathcal{P}') = \Omega(n).$$

Proof. Since G is transitive, G is d regular for some d [11]. Therefore $m = dn/2$ and $d_{max} = d$. Hence for $d \geq 7$ using Lemma 16 we get the desired bound[8]. ◀

Following special case of Weak EC remains open:

▶ Conjecture 18. For any hereditary property $\mathcal{P}$, for any $\epsilon > 0$:

$$\mathcal{G}_{\mathcal{T}}\text{-}min\text{-}cost(\mathcal{P}) = \Omega(n^{1-\epsilon}).$$

4 Absence of symmetry in node-query setting: How low can query complexity go?

4.1 A general upper bound

Let $\mathcal{P}$ be a hereditary graph property and $d_{\mathcal{P}}$ denote the minimum possible degree of a minimal forbidden subgraph for $\mathcal{P}$.

Proof of Theorem 2: Let $k = c{\cdot}n^{1/(d_{\mathcal{P}}+1)}$ where we choose the constant c appropriately. Construct a graph G on n vertices as follows (See Figure 1):

- Start with a clique on vertices $v_1, \ldots, v_k$.
- For every $S \subseteq [k]$ such that $|S| = d_{\mathcal{P}}$
  - add k new vertices $u_1^S, \ldots, u_k^S$ and
  - connect every vertex $v_i : i \in S$ to each of these new k vertices $u_1^S, \ldots, u_k^S$.

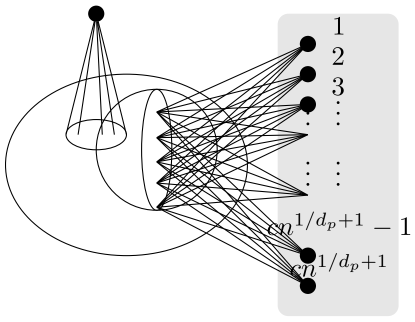

Figure 1 Construction of G for a general upper bound .

Algorithm 1:

```
- Query $v_1, \ldots, v_k$.
- If at least $c_{\mathcal{P}}$ of these vertices are present then $\mathcal{P}$ must fail.
- Otherwise there are at most $c_{\mathcal{P}} - 1$ vertices present
  (wlog: $v_1, \ldots, v_{c_{\mathcal{P}}-1}$).
    - For every subset $S \subseteq [c_{\mathcal{P}} - 1]$ such that $|S| = d_{\mathcal{P}}$, query $u_1^S, \ldots, u_k^S$.
    - If the graph induced on the nodes present (after all these
      $\binom{c_{\mathcal{P}}-1}{d_{\mathcal{P}}} \times k$ queries) satisfies $\mathcal{P}$ then answer Yes.
      Otherwise answer No.
```

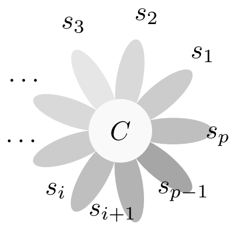
Now we describe an algorithm (See Algorithm 1) to determine $\mathcal{P}$ in $O(n^{1/(d_{\mathcal{P}}+1)})$ queries. Let $c_{\mathcal{P}}$ denote the smallest integer such that the clique on $c_{\mathcal{P}}$ vertices satisfies $\mathcal{P}$.

Note that any vertex that is not queried by the above algorithm can have at most $d_{\mathcal{P}} - 1$ edges to the vertices in the clique $v_1, \ldots, v_k$. Since $d_{\mathcal{P}}$ is the minimum degree of a minimal forbidden subgraph for $\mathcal{P}$, these vertices now become irrelevant for $\mathcal{P}$. Thus the algorithm can correctly declare the answer based on only the queries it has made. It is easy to check that the query complexity of the above algorithm is $O(k)$ which is $O(n^{1/(d_{\mathcal{P}}+1)})$. $\square$

This completes the proof of Theorem 2. Corollary 3 follows from this by observing that $d_{\mathcal{P}} \geq 2$ for any non-trivial $\mathcal{P}$.

4.2 General lower bounds

Now we show that any hereditary property with *finitely many forbidden subgraphs* has a lower bound of $\Omega(n^{1/k})$, for a constant k depending only on the property.



[8] Currently our proof works only when $d \geq 7$, but we believe that it can be extended for any degree d.

▶ **Definition 19** (Sunflower). A sunflower with core set C and p petals is a collection of sets $S_1, \ldots, S_p$ such that for all $i \neq j$: $S_i \cap S_j = C$.

We use the following lemma due to Erdös and Rado [9].

▶ **Lemma 20** (Sunflower Lemma). *Let $\mathcal{F}$ be a family of sets of cardinality k each. If $|\mathcal{F}| > k!(p-1)^k$ then $\mathcal{F}$ contains a sunflower with p petals.*

Proof of Theorem 4: Let G be a graph on n vertices such that every vertex of G is relevant for the property of containing H. Let

$$\mathcal{F} := \{S \mid |S| = k \ \& \ H \text{ is a subgraph of } G[S]\}.$$

Since every vertex of G is relevant for $\mathcal{P}_H$, we have: $|\mathcal{F}| \geq n/k$. Now from Lemma 20 we can conclude that $\mathcal{F}$ contains a sunflower on at least $|\mathcal{F}|^{1/k}/k = \Omega(n^{1/k})$ petals. Let C be the core of this sunflower. We consider the restriction of $\mathcal{P}_H$ on G where every vertex in C is present. Since $|C| < k$, $G[C]$ does not contain H. Now it is easy to check that one must query at least one vertex from each petal in order to determine $\mathcal{P}_H$.

□

Using similar technique we prove Theorem 5 showing that *min-cost*$(\mathcal{P})$ for any hereditary $\mathcal{P}$ can not fall to a constant.

▶ Theorem 5. (Restated) For any hereditary graph property $\mathcal{P}$

$$\textit{min-cost}(\mathcal{P}) = \Omega\left(\frac{\log n}{\log\log n}\right).$$

Proof. Let G be a graph on n vertices such that every vertex of G is relevant for $\mathcal{P}$. Let k be the largest integer such that G contains a minimal forbidden subgraph for $\mathcal{P}$ on k vertices. Note that we are concerned with vertex minimal certificates.

Case 1: $k \geq \frac{\log n}{2\log\log n}$.

Since one must query all the vertices of a minimal forbidden subgraph, we obtain a lower bound of $k = \Omega(\log n/\log\log n)$.

Case 2: $k < \frac{\log n}{2\log\log n}$.

Since every vertex of G is relevant for $\mathcal{P}$ and all the minimal forbidden subgraphs of $\mathcal{P}$ present in G are of size at most k, every vertex of G must belong to some minimal forbidden subgraph of size at most k. Consider the property $\mathcal{P}_k$ obtained from $\mathcal{P}$ by omitting the minimal forbidden subgraphs of $\mathcal{P}$ on k or more vertices. Our simple but crucial observation is that $\mathcal{P}$ and $\mathcal{P}_k$ are equivalent as far as G is concerned. Therefore, they have the same complexity. Now we define $\mathcal{F}_i$ for $i \leq k$ as follows:

$$\mathcal{F}_i := \{S \mid |S| = i \ \& \ G[S] \notin \mathcal{P} \ \& \ \forall T \subset S : G[T] \in \mathcal{P}\}.$$

Since every vertex of G is relevant for $\mathcal{P} \equiv \mathcal{P}_k$, we have: $|\bigcup_{i=1}^{k} \mathcal{F}_i| \geq n/k$. Since $\mathcal{F}_i$ and $\mathcal{F}_j$ are disjoint when $i \neq j$, we have $\sum_{i=1}^{k} |\mathcal{F}_i| \geq n/k$. Therefore one of the $\mathcal{F}_i$s must be of size at least n/k^2. We denote that $\mathcal{F}_i$ by $\mathcal{F}'$.

Now from Lemma 20 we can conclude that $\mathcal{F}'$ contains a sunflower on at least $|\mathcal{F}'|^{1/k}/k$ petals. Let C be the core of this sunflower. We consider the restriction of $\mathcal{P}$ on G where every vertex in C is present. Since $|C| < i$, by definition of $\mathcal{F}_i$ we must have $G[C] \in \mathcal{P}$. Now it is easy to check that one must query at least one vertex from each petal in order to determine $\mathcal{P}$. A simple calculation yields that one can obtain a lower bound of $\min\{k, \frac{2^{\Omega(\log n/k)}}{k}\}$. When $k = \log n/(2\log\log n)$, this gives us $\Omega(\log n/\log\log n)$ bound. ◀

4.3 Some tight bounds

We manage to show that Theorem 2 is tight for several special properties like Independence, Triangle-freeness, Bounded-degree etc. In the Appendix of the full version of this paper we present them in detail. In order to prove the tight bounds, we show several inequalities which might be of independent interest combinatorially. We present one such inequality below.

Lower bound based on the chromatic number

▶ **Theorem 21.** *Let $\mathcal{I}$ denote the property of being an independent subset of nodes (equivalently the property of being an empty graph). Then,*

$$\mathcal{G}\text{-}min\text{-}cost(\mathcal{I}) \geq n/\chi$$

where χ is the maximum chromatic number of a graph $G \in \mathcal{G}$.

Proof. Let $G \in \mathcal{G}$ be a graph on n vertices such that every vertex of G is relevant for $\mathcal{I}$, i.e., G does not contain any isolated vertices. Consider a coloring of vertices of G with χ colors. Let C_i denote the set of vertices colored with color i. We pick a coloring that maximizes $\max_{i \leq \chi}\{|C_i|\}$. Let C_{max} denote such a color class with maximum number of vertices in this coloring. Thus $|C_{\max}| \geq n/\chi$.

When $|C_{\max}| \leq (1 - \frac{1}{\chi})n$, the adversary answers all the vertices in $C_{\max}$ to be present. Since $C_{\max}$ is maximal and G does not contain any isolated vertices, every vertex outside $C_{\max}$ must be connected to some vertex in $C_{\max}$. As long as any of these outside vertices are present there will be an edge. Hence we get a lower bound of $n - |C_{\max}| \geq n/\chi$.

Now when $|C_{\max}| > (1 - \frac{1}{\chi})n$, since there are no isolated vertices in G, every vertex in $C_{\max}$ must have an edge to some vertex in $C_i \neq C_{\max}$. Furthermore as $|C_{\max}| > (1 - \frac{1}{\chi})n$, there are at least $(1 - \frac{1}{\chi})n$ edges incident on $C_{\max}$.

Now the vertices outside $C_{\max}$ are colored with $(\chi - 1)$ colors. Thus there must exists a C_i such that at least $\frac{(1-\frac{1}{\chi})n}{\chi-1} = n/\chi$ edges incident on $C_{\max}$ are also incident on C_i. Now the adversary answers all the vertices in that C_i to be present. Then one must check at least n/χ vertices from $C_{\max}$ because as soon as any one of them is present we have an edge in the graph. ◀

5 Results on restricted graph classes

5.1 Triangle-freeness in planar graphs

A graph G is called *inherently sparse* if every subgraph of G on k nodes contains $O(k)$ edges.

▶ **Theorem 22.** *Let $\mathcal{G}_s$ be a family of inherently sparse graphs on n vertices and $\mathcal{T}$ denote the property of being triangle-free. Then,*

$$\mathcal{G}_s\text{-}min\text{-}cost(\mathcal{T}) = \Omega(\sqrt{n}).$$

The proof of Theorem 22 is deferred to the Appendix of the full version of this paper. As a consequence we obtain the same for the class of planar graphs.

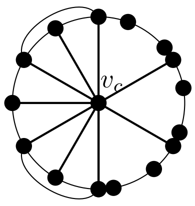


Figure 2 A wheel with d_{max} spokes.

5.2 Acyclicity in planar graphs

▶ **Theorem 23.** *Let $\mathcal{G}_{\mathcal{P}_3}$ be a family of 3-connected planar graphs and $\mathcal{C}$ denote the property of being acyclic. Then,*

$$\mathcal{G}_{\mathcal{P}_3} - min\text{-}cost(\mathcal{C}) = \Omega(\sqrt{n}).$$

Proof. Let $G \in \mathcal{G}_{\mathcal{P}_3}$ be a graph on n vertices and m edges such that every vertex is relevant for the acyclicity property. Let d_{max} denote the maximum degree of G.

Case 1: $d_{\max} > \sqrt{n}$: We use the following fact: In 3-connected planar graphs, removing any vertex leaves a facial cycle around it. We apply this for the maximum degree vertex. In other words, we have a (not necessarily induced) wheel with d_{max} spokes (some spokes might be missing). See Figure 2. The adversary answers the central vertex of the wheel to be present. We can find a matching of size $\Omega(n)$ among the vertices of the cycle. Hence we have $\Omega(n)$ sensitive blocks of length 2 each, which can not be left un-queried.

Case 2: $d_{\max} \leq \sqrt{n}$: We use the fact that every 3-connected graph must have at least $3n/2$ edges. Now using Lemma 14 we obtain a lower bound of $(m-n)/d_{max} \geq \Omega(\sqrt{n})$. ◀

We can generalize the above proof to any planar graph (See the Appendix of the full version of this paper).

6 Conclusion & open directions

- **Weak-evasiveness in the presence of symmetry:** Is it true that every hereditary graph property $\mathcal{P}$ in the node-query setting is weakly-evasive under symmetry, i.e., $\mathcal{G}_{\mathcal{T}}$-*min-cost*$(\mathcal{P}) = \Omega(n)$? What about the randomized case?
- **Polynomial lower bound in the absence of symmetry:** How low can *min-cost*$(\mathcal{P})$ go for a hereditary $\mathcal{P}$ in the absence of symmetry? Is it possible to improve the $\Omega(\log n/\log\log n)$ bound substantially?
- **Further restrictions on graphs:** How low can $\mathcal{G}$-*min-cost*$(\mathcal{P})$ go for hereditary properties $\mathcal{P}$ on restricted classes of graphs $\mathcal{G}$ such as social-network graphs, planar graphs, bipartite graphs, bounded degree graphs etc?
- **Tight bounds on *min-cost*:** What are the tight bounds for natural properties such as acyclicity, planarity, containing a cycle of length t, path of length t?
- **Extension to hypergraphs:** What happens for hereditary properties of (say) 3-uniform hypergraphs in node-query setting? We note that *min-cost*$(\mathcal{I}) = \Theta(n^{1/3})$ for 3-uniform hypergraphs. What about other properties?

- **Global vs local:** We note (See the Appendix of the full version of this paper) that global connectivity requires $\Theta(n)$ queries whereas the cost of s-t connectivity for fixed s and t can go as low as $O(1)$. What about other properties such as min-cut?
- **How about *max-cost* upper bounds? :** From algorithmic point of view, it might be interesting to obtain good upper bounds on the *max-cost*$(\mathcal{P})$ for some natural properties. It might also be interesting to investigate $\mathcal{G}$-*max-cost*$(\mathcal{P})$ for several restricted graph classes such as social-network graphs, planar graphs, bipartite graphs etc.

Abstract

Given an infinitesimal perturbation of a discrete-time finite Markov chain, we seek the states that are stable despite the perturbation, *i.e.* the states whose weights in the stationary distributions can be bounded away from 0 as the noise fades away. Chemists, economists, and computer scientists have been studying irreducible perturbations built with monomial maps. Under these assumptions, Young proved the existence of and computed the stable states in cubic time. We fully drop these assumptions, generalize Young's technique, and show that stability is decidable as long as $f \in O(g)$ is. Furthermore, if the perturbation maps (and their multiplications) satisfy $f \in O(g)$ or $g \in O(f)$, we prove the existence of and compute the stable states and the metastable dynamics at all time scales where some states vanish. Conversely, if the big-O assumption does not hold, we build a perturbation with these maps and no stable state. Our algorithm also runs in cubic time despite the weak assumptions and the additional work. Proving its correctness relies on new or rephrased results in Markov chain theory, and on algebraic abstractions thereof.

1 Introduction

Motivated by the dynamics of chemical reactions, Eyring [4] and Kramers [12] studied how infinitesimal perturbations of a Markov chain affect its stationary distributions. It has been further investigated by, *e.g.*, probability theorists, economists, and computer scientists. In fields of application such as learning and game theory, it is sometimes unnecessary to describe the exact values of the limit stationary distributions: it suffices to know whether these values are zero or not. Thus, the *stochastically stable states* ([5], [10], [17]) were defined in several contexts as the states with positive probability in the limit. We rephrase a definition below.

▶ **Definition 1** (Markov chain and stability)**.** A finite discrete-time Markov chain is a function $m : S \times S \to [0,1]$ such that $\sum_{y \in S} m(x,y) = 1$ for all x in finite state space S. A stationary distribution is a probability distribution over the states that is invariant under one step of the MC. Let I be a subset of positive real numbers with 0 as a limit point for the usual topology[1]. A perturbation is a function $p : I \times S \times S \to [0,1]$ such that p_ϵ is a discrete-time MC for all $\epsilon \in I$. If p_ϵ is irreducible for all $\epsilon \in I$, then p is said to be an irreducible perturbation.

A state $x \in S$ is stochastically stable if there is a family of corresponding stationary distributions $(\mu_\epsilon)_{\epsilon \in I}$ s.t. $\liminf_{\epsilon \to 0} \mu_\epsilon(x) > 0$, *i.e.* $1 \in O(\mu(x))$. It is stochastically fully vanishing if $\limsup_{\epsilon \to 0} \mu_\epsilon(x) = 0$ for all $(\mu_\epsilon)_{\epsilon \in I}$. Non-stable states are called vanishing.

* The second author was partly supported by the ERC inVEST (279499) project.
[1] This implies that I is infinite. $]0,1]$ and $\{\frac{1}{2^n} \mid n \in \mathbb{N}\}$ are typical I.

Let us motivate Definition 1: we want to find out which states of a real-world system are the most likely to occur a lot in the long run. The system behaves like a MC that we are unable to know exactly, but we know what it is likely to look like, *i.e.* we know a family of MC indexed by ϵ where it occurs for sure, most likely for a very small ϵ. This alone is far too weak to decide state likeliness in the long run, but assuming a good asymptotic behavior of the family for small ϵ implies the existence of a likely state. This is our main result below.

▶ **Theorem 2.** *Consider a perturbation with state space S such that $f \in O(g)$ or $g \in O(f)$ for all f and g in the multiplicative closure of the transition probability functions $\epsilon \mapsto p_\epsilon(x,y)$ with $x \neq y$. Then the perturbation has stable states. Furthermore, any oracle deciding $f \in O(g)$ in constant time allows us to decide stability in $O(|S|^3)$.*

The finiteness of the state space implies that all perturbations have non-fully vanishing states.

1.1 Related works and comparisons

In 1990 Foster and Young [5] defined the stochastically stable states of a general (continuous) evolutionary process, as an alternative to the evolutionary stable strategies [16]. Stochastically stable states were soon adapted in [10] for 2×2 evolutionary games. Then Young [17, Theorem 4] proved a "finite version of results obtained by Freidlin and Wentzel" in [6] and characterized the stochastically stable states if the perturbation satisfies the following assumptions: 1) the p_ϵ are aperiodic and irreducible; 2) the p_ϵ converge to some p_0 when ϵ approaches zero; 3) every transition probability is a function of ϵ that is equivalent to $c \cdot \epsilon^\alpha$ for some non-negative real numbers c and α. The main tool in Young's proof was proved in [11] and is the special case for irreducible chains of the Markov chain tree theorem (see [13] or [6]). Young's characterization involves minimum directed spanning trees, which can be computed in $O(n^2)$ [7] for graphs with n vertices. Since there are at most n roots for directed spanning trees in a graph with n vertices, Young can compute the stable states in $O(n^3)$.

In 2000 Ellison [3] studied the stable states *via* the alternative notion of the radius of a basin of attraction, and wrote that the major drawback of his work compared to Young's is that it is "not universally applicable". In 2005, Greenwald and Wicks [9] designed an algorithm expressing the exact values of the limit stationary distribution of a perturbation, which, as a byproduct, also computes the stable states. Like [17] they consider perturbations that are related to the functions $\epsilon \mapsto \epsilon^\alpha$, but they only require that the functions converge exponentially fast. Also, instead of requiring that the P^ϵ be irreducible for $\epsilon > 0$, they only require that they have exactly one essential class. They do not analyze the complexity of their algorithm, though. We improve upon [17], [3], and [9] in several ways.

1. The perturbations in the literature relate to the maps $\epsilon \mapsto \epsilon^\alpha$. Their specific form and their continuity, especially at 0, are used in the existing proofs. Theorem 2 relaxes this assumption. Continuity, even at 0, is irrelevant, which allows for aggressive, *i.e.*, non-continuous "perturbations". We show that our assumption is (almost) unavoidable.
2. The perturbations in the literature are irreducible (or almost in [9]). It is general enough for perturbations using the maps $\epsilon \mapsto \epsilon^\alpha$, since it suffices to process each sink (aka bottom) irreducible component independently, and gather the results. This trick does not work for general perturbation maps, but Theorem 2 still does not assume irreducibility.
3. The perturbation is abstracted into a weighted graph and shrunk by combining recursively a shortest-path algorithm (w.r.t. some tropical-like semiring) and a strongly-connected-component algorithm. Using tropical-like algebra to abstract over Markov chains has already been done before, *e.g.* in [8], but not to solve the stable state problem.

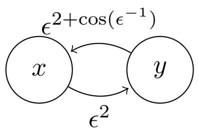

Figure 1

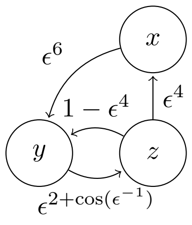

Figure 2

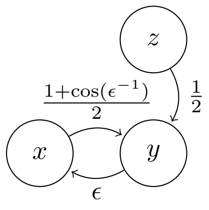

Figure 3

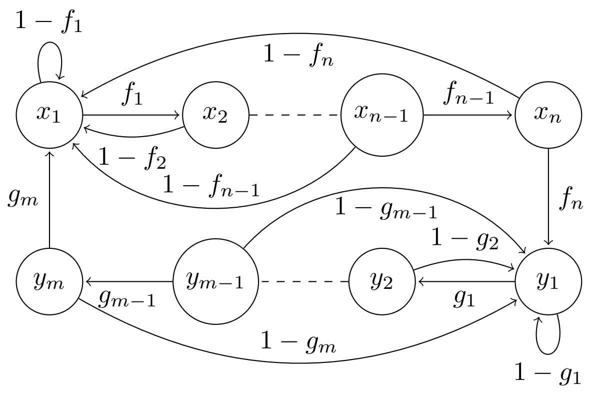

Figure 4

4. We compute the stable states in $O(n^3)$, the best known complexity as in [17], and the computation itself is a summary of the asymptotic behavior of the perturbation: it says at which time scales the vanishing states vanish, and the intermediate graph at each recursive stage of the algorithm accounts for the metastable dynamics at this time scale.

Section 1.2 analyses which assumptions are relevant for the existence of stable states; Section 2 proves the existential part of Theorem 2, *i.e.* it develops the probabilistic machinery to prove the existence of stable states; hinging on this, Section 3 proves the algorithmic part of Theorem 2, *i.e.* it abstracts the relevant objects using a new algebraic structure, presents the algorithm, and proves its correctness and complexity; Section 4 discusses two important special cases and an induction proof principle related to the termination of our algorithm. (Standard notations and proofs can be found in [1].)

1.2 Towards general assumptions

Even continuous perturbations that converge when ϵ approaches 0 may fail to have stable states. For instance let $S := \{x, y\}$ and for all $\epsilon \in]0, 1]$ let $p_\epsilon(x, y) := \epsilon^2$ and $p_\epsilon(y, x) := \epsilon^{2+\cos(\epsilon^{-1})}$ as in Figure 1, where the self-loops are omitted. In the unique stationary distribution x has a weight $\mu_\epsilon(x) = (1 + \epsilon^{-\cos(\epsilon^{-1})})^{-1}$. Since $\mu_{(2n\pi)^{-1}}(x) = \frac{2n\pi}{1+2n\pi} \rightarrow_{n\to\infty} 1$ and $\mu_{(2(n+1)\pi)^{-1}}(x) = \frac{1}{1+2(n+1)\pi} \rightarrow_{n\to\infty} 0$, neither x nor y is stable.

As mentioned above, the usual perturbations relate to the maps $\epsilon \mapsto \epsilon^\alpha$ with $\alpha \geq 0$, which rules out Figure 1 and implies the existence of stable states [17]. Here, however, we want to assume as little as possible about the perturbations, while still guaranteeing the existence of stable states. Towards it let us rephrase the big O notation as a binary relation. (Its useful and well-known algebraic properties are mentioned in [1].)

Figure 7

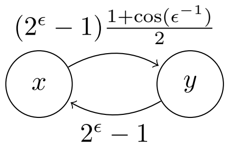

Figure 8

▶ **Definition 3** (Order). For $f, g : I \to [0,1]$, let us write $f \precsim g$ if there exist positive b and ϵ such that $f(\epsilon') \leq b \cdot g(\epsilon')$ for all $\epsilon' < \epsilon$; let $f \cong g$ stand for $f \precsim g \wedge g \precsim f$.

Requiring that every two transition probability maps f and g occurring in the perturbation satisfy $f \precsim g$ or $g \precsim f$ rules out the example from Figure 1, but not the one from Figure 2. There $\mu_\epsilon(z) \leq \mu_\epsilon(x) = \frac{\epsilon^{\cos(\epsilon^{-1})}}{1+\epsilon^{\cos(\epsilon^{-1})}(1+\epsilon^2)}$ and $\mu_\epsilon(y) = \frac{1}{1+\epsilon^{\cos(\epsilon^{-1})}(1+\epsilon^2)}$. So $\mu_\epsilon(z) \to_{\epsilon\to 0} 0$ and $\mu_{2n\pi}(y) \to_{n\to\infty} 0$ and $\mu_{2(n+1)\pi}(x) \to_{n\to\infty} 0$, no state is stable. Informally, z is not stable because it gives everything but receives at most ϵ; neither x nor y is stable since their interaction resembles Figure 1 due to ϵ^6 and $\epsilon^4 \cdot \epsilon^{2+\cos(\epsilon^{-1})}$. This remark is turned into a general Observation 4 below, which will motivate the "unavoidable" Assumption 5.

▶ **Observation 4.** *For $1 \leq i \leq n$ and $1 \leq j \leq m$ let $f_i, g_j : I \to [0,1]$ be s.t. $\prod_i f_i$ and $\prod_j g_j$ are not $\precsim$-comparable. Then there is a perturbation without stable states that is built only with the $f_1, \dots, f_n, g_1, \dots, g_m$ and the $1-f_1, \dots, 1-f_n, 1-g_1, \dots, 1-g_m$. See Figure 4.*

▶ **Assumption 5.** *The multiplicative closure of the maps $\epsilon \mapsto p_\epsilon(x,y)$ with $x \neq y$ is totally preordered by $\precsim$.*

E.g, the maps $\epsilon \mapsto c \cdot \epsilon^\alpha$ with $c > 0$ and $\alpha \in \mathbb{R}$ satisfy Assumption 5. We can afford such a weak Assumption 5 because we are not interested in the exact weights of some putative limit stationary distribution, but only whether the weights are bounded away from zero.

Let us show the significance of Assumption 5, which is satisfied in Figures 5 to 8: Young's result shows that y is the unique stable state of the perturbation in Figure 5, but it cannot say anything about Figures 6 to 8: Figure 6 is not regular, *i.e.*, $\frac{2+\cos(\epsilon^{-1})}{2-\cos(\epsilon^{-1})}$ does not converge, and neither do the weights $\mu_\epsilon(x)$ and $\mu_\epsilon(y)$, but it is possible to show that both limits inferior are $1/4$ nonetheless, so both x and y are stable; the transition probabilities in Figure 7 do not converge, and $\frac{1+\cos(\epsilon^{-1})}{2}$ and $1 - \frac{1+\cos(\epsilon^{-1})}{2}$ are not even comparable, but it is easy to see that $\mu_\epsilon(x) = \mu_\epsilon(y) = \frac{1}{2}$; and in Figure 8 the only stable state is x since its weight oscillates between $\frac{1}{2}$ and 1. Note that Assumption 5 rules out Figure 1 to 4 without stable states.

2 Existence of stable states

This section presents three transformations that simplify perturbations while retaining the relevant information about stability. Two of them are defined *via* the dynamics of the original perturbation. Their relevance relies on the close relation between the stationary distributions and the dynamics of MCs. Lemma 6 below pinpoints this relation, where $\mathbb{P}^x(\tau_y^+ < \tau_x^+)$ is the probability that starting from x the MC hits y before returning to x.

▶ **Lemma 6.** *A distribution μ of a finite Markov chain is stationary iff its support involves only essential states and for all states x and y we have $\mu(x)\mathbb{P}^x(\tau_y^+ < \tau_x^+) = \mu(y)\mathbb{P}^y(\tau_x^+ < \tau_y^+)$.*

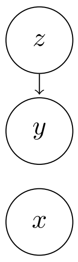

Figure 9

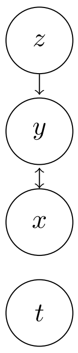

Figure 10

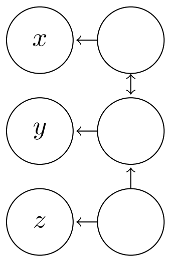

Figure 11

Lemma 6 can already help us find the stable states of small examples such as in Figures 1 and 6. In Figure 1 it says that $\mu_\epsilon(x)\epsilon^2 = \mu_\epsilon(y)\epsilon^{2+\cos(\epsilon^{-1})}$ so we find $\liminf \mu_\epsilon(x) = \liminf \mu_\epsilon(y) = 0$ without calculating the stationary distributions. In Figure 6 it says that $\mu_\epsilon(x)(2-\cos(\epsilon^{-1})) = \mu_\epsilon(y)(2+\cos(\epsilon^{-1}))$, so $\mu_\epsilon(x) \leq 3\mu_\epsilon(y)$ and $\frac{1}{4} \leq \mu_\epsilon(y)$, and likewise for x.

The dynamics, *i.e.*, terms like $\mathbb{P}^x(\tau_y^+ < \tau_x^+)$ are usually hard to compute, and so will be the two transformations that are defined *via* the dynamics, but Lemma 7 below shows that approximating them is safe as far as the stable states are concerned. *E.g.*, the coefficients in Figure 6 (19) can safely be replaced with ϵ (1), and Figure 13 with Figure 14. Lemma 7, where p, μ, *etc.* depend on ϵ, will simplify the computation of the stable states dramatically.

▶ **Lemma 7.** *Let p and $\tilde{p}$ be perturbations with the same state space, s.t. $x \neq y \Rightarrow p(x,y) \cong \tilde{p}(x,y)$. For all stationary distribution maps μ for p, there exists $\tilde{\mu}$ for $\tilde{p}$ such that $\mu \cong \tilde{\mu}$.*

2.1 Essential graph

The *essential graph* of a perturbation captures the non-infinitesimal flow between different states at the normal time scale. It is a very coarse yet useful description of the perturbation.

▶ **Definition 8** (Essential graph)**.** Given a perturbation with state space S, the essential graph is a binary relation over S and possesses the arc (x,y) if $x \neq y$ and $p(z,t) \precsim p(x,y)$ for all $z, t \in S$. The essential classes are the sink SCCs of the graph. The other SCCs are the transient classes. A state in an essential class is essential, the others are transient.

The essential classes will be named $E_1, \dots, E_k$. Observation 9 below implies that the essential graph is made of the arcs (x,y) such that $x \neq y$ and $p(x,y) \cong 1$, as expected.

▶ **Observation 9.** *Let p be a perturbation. There exist positive c and ϵ_0 such that for all $\epsilon < \epsilon_0$, for all simple paths γ in the essential graph, $c < p_\epsilon(\gamma)$.*

For example, the perturbations (with $I =]0,1]$) that are described in Figures 2, 3, 5, and 7 all have Figure 9 as essential graph, and $\{x\}$ and $\{y\}$ as essential class. Figure 10 (11) is the essential graph of Figure 12 (15), and $\{x,y\}$ and $\{t\}$ (x, y, z) are its essential classes. Note that the essential states of a perturbation and of the related MCs are not the same: in Figure 12, for all $\epsilon \in]0,1]$ all the states are essential for the related MCs. However, if $p_\epsilon = m$ for some m and all ϵ, the essential graph of p is the underlying graph of m. Thus the essential graphs generalize the underlying graphs like the perturbations generalize the MCs.

The essential graph alone cannot tell which states are stable: *e.g.*, swapping ϵ and ϵ^2 in Figure 5 yields the same graph, but then by Lemma 6 the only stable state is x instead of y.

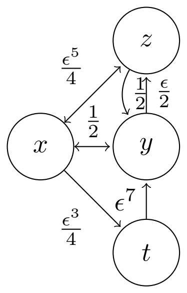

Figure 12

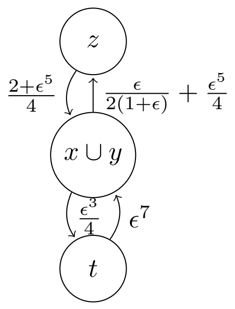

Figure 13

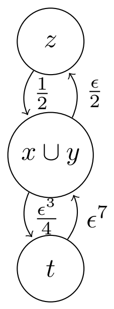

Figure 14

Yet, the graph makes the following case disjunction possible, along which we will either say that all states are stable, or perform one of the transformations from the next subsections.

1. Either the graph is empty (*i.e.* totally disconnected) and the perturbation is trivial, or
2. it is empty and the perturbation is non-trivial, or
3. it is non-empty and has a non-singleton essential class, or
4. it is non-empty and has only singleton essential classes.

Observation 9 motivates the convenient Assumption 10 below. Note that it is just made wlog, *i.e.*, up to focusing on a smaller neighborhood of 0 inside I, whereas Assumption 5 above is a key condition that will appear explicitly in our final result.

▶ **Assumption 10.** *There is $c > 0$ s.t. $p(\gamma) > c$ for all simple paths γ in the essential graph.*

2.2 Essential collapse

The essential collapse, defined below, amounts to merging one essential class of a perturbation into one meta-state and letting this state represent faithfully the whole class in terms of dynamics between the whole class and each of the outside states. ($\mathbb{P}^x(X_{\tau^+_{S \setminus E \cup \{x\}}} = y)$ is the probability that starting from x, the first state hit in $S \setminus E \cup \{x\}$ is y.)

▶ **Definition 11** (Essential collapse of a perturbation). Let p be a perturbation on state space S. Let x be a state in an essential class E, and let $\tilde{S} := (S \setminus E) \cup \{\cup E\}$. The essential collapse $\kappa(p,x) : I \times \tilde{S} \times \tilde{S} \to [0,1]$ of p around x is defined below.

$$\begin{aligned}
\kappa(p,x)(y,z) &:= p(y,z) && \text{for all } y,z \in S \setminus E\\
\kappa(p,x)(\cup E, \cup E) &:= \mathbb{P}^x(X_{\tau^+_{S\setminus E \cup \{x\}}} = x) &&\\
\kappa(p,x)(\cup E, y) &:= \mathbb{P}^x(X_{\tau^+_{S\setminus E \cup \{x\}}} = y) && \text{for all } y \in S \setminus E\\
\kappa(p,x)(y, \cup E) &:= \sum_{z \in E} p(y,z) && \text{for all } y \in S \setminus E
\end{aligned}$$

▶ **Observation 12.** *$\kappa(p,x)$ is again a perturbation, κ preserves irreducibility, and if $\{x\}$ is an essential class, $\kappa(p,x) = p$.*

For example, collapsing around x or y in Figure 6 has no effect. Figure 12 has essential classes $\{x,y\}$ and $\{t\}$. Figure 13 displays its essential collapse around x. It was calculated by noticing that $\mathbb{P}^x(X_{\tau^+_{\{x,z,t\}}} = t) = \frac{\epsilon^3}{4}$, and $\mathbb{P}^x(X_{\tau^+_{\{x,z,t\}}} = x) = \frac{1}{2} - \frac{\epsilon^3}{4} - \frac{\epsilon^5}{4} + \frac{1}{2} \cdot \mathbb{P}^y(X_{\tau^+_{\{x,z,t\}}} = x)$, and $\mathbb{P}^y(X_{\tau^+_{\{x,z,t\}}} = x) = \frac{1}{2} + \frac{1-\epsilon}{2} \cdot \mathbb{P}^y(X_{\tau^+_{\{x,z,t\}}} = x)$.

Proposition 16 will show that it suffices to compute the stable states of Figure 13 to compute those of Figure 12, and by Lemma 7 it suffices to compute those of the simpler

Figure 14. However, computing the exact values $\mathbb{P}^x(X_{\tau^+_{S\setminus E\cup\{x\}}} = y)$ can be difficult even on simple examples like above. Fortunately, Lemma 13 shows that they are $\cong$-equivalent to maxima that are easy to compute. *E.g.*, using Lemma 13 to approximate the essential collapse of Figure 12 around x yields Figure 14 directly, without Figure 13 as an intermediate.

▶ **Lemma 13.** *Let p be a perturbation with state space S satisfy Assumption 5, and let $\tilde{p}$ be the essential collapse $\kappa(p,x)$ of p around x in some essential class E. For all $y \in S \setminus E$, we have $\tilde{p}(\cup E, y) \cong \max_{z\in E} p(z,y)$ and $\tilde{p}(y, \cup E) \cong \max_{z\in E} p(y,z)$.*

Note that by Lemma 13, only the essential class is relevant during the essential collapse up to $\cong$, the exact state is irrelevant. Lemma 13 is also a tool used to prove, *e.g.*, Proposition 14 which shows that the essential graph may contain useful information about stability.

▶ **Proposition 14.** *Let a perturbation p with state space S satisfy Assumption 5, let μ be a corresponding stationary distribution map.*
1. *If y is a transient state, $\liminf_{\epsilon\to 0} \mu_\epsilon(y) = 0$.*
2. *If two states x and y belong to the same essential or transient class, $\mu(x) \cong \mu(y)$.*

Proposition 14.1 says that the transient states are vanishing, *e.g.* the nameless states in Figure 11. Proposition 14.2 says that two states in the same class are either both stable or both vanishing, *e.g.* $\{x\}$ and $\{y\}$ in Figure 10.

The essential collapse is useful since it preserves (non-)stability, as stated in Proposition 16. Its proof invokes Lemma 15 below, which shows that the essential collapse preserves the dynamics up to $\cong$, and Lemma 6, which relates the dynamics and the stationary distributions.

▶ **Lemma 15.** *Given a perturbation p with state space S, let $\tilde{p}$ be the essential collapse of p around x in some essential class E, and let $\tilde{x} := \cup E$. The following holds for all $y \in S \setminus E$.*
$\mathbb{P}^y(\tau_x < \tau_y) \cong \tilde{\mathbb{P}}^y(\tau_{\tilde{x}} < \tau_y) \quad \wedge \quad \mathbb{P}^x(\tau_y < \tau_x) \cong \tilde{\mathbb{P}}^{\tilde{x}}(\tau_y < \tau_{\tilde{x}})$

▶ **Proposition 16.** *Let a perturbation p with state space S satisfy Assumption 5, and let x be in an essential class E.*
1. *Let $\tilde{p}$ be the chain after the essential collapse of p around x. Let μ ($\tilde{\mu}$) be a stationary distribution map of p ($\tilde{p}$). There exists a stationary distribution map $\tilde{\mu}$ for $\tilde{p}$ (μ for p) such that $\tilde{\mu}(\cup E) \cong \mu(x)$ and $\tilde{\mu}(y) \cong \mu(y)$ for all $y \in S \setminus E$.*
2. *A state $y \in S$ is stable for p iff either $y \in E$ and $\cup E$ is stable for $\kappa(p,x)$, or $y \notin E$ and y is stable for $\kappa(p,x)$.*

By definition, collapsing an essential class preserves the structure of the perturbation outside of the class, so Proposition 16 implies that the collapse commutes up to $\cong$. Especially, the order in which the collapses are performed is irrelevant when computing the stable states.

2.3 Transient deletion

If all the essential classes of a perturbation are singletons, Observation 12 says that the essential collapse is useless. If in addition the essential graph has arcs, there are transient states, and Definition 17 below deletes them to shrink the perturbation further.

▶ **Definition 17** (Transient deletion). Let a perturbation p with state space S, transient states T, and singleton essential classes, satisfy Assumption 5. The function $\delta(p)$ over $S\setminus T$ is derived from p by transient deletion: for all distinct $x, y \in S \setminus T$ let $\delta(p)(x,y) := \mathbb{P}^x(X_{\tau^+_{S\setminus T}} = y)$

▶ **Observation 18.** *$\delta(p)$ is again a perturbation, δ preserves irreducibility, and if all states are essential, $\delta(p) = p$.*

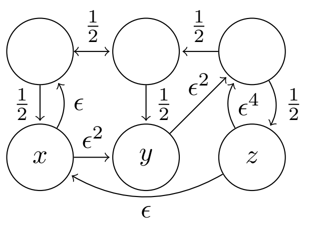

Figure 15

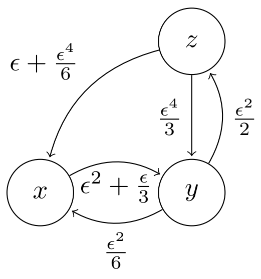

Figure 16

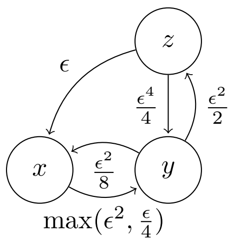

Figure 17

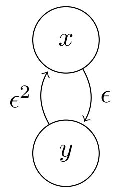

Figure 18

For example, in Figure 5 the essential classes are $\{x\}$ and $\{y\}$, z is transient, and the transient deletion yields Figure 18. Also, in Figure 15, the essential classes are $\{x\}$, $\{y\}$, and $\{z\}$, the transient states are nameless, and the transient deletion yields Figure 16. The transient deletion is useful thanks to Proposition 19 below.

▶ **Proposition 19.** *If a perturbation p satisfy Assumption 5 and has singleton essential classes, p and $\delta(p)$ have the same stable states.*

Like the essential collapse, the transient deletion is defined *via* the dynamics and is hard to compute. Like Lemma 13 did for the collapse, Lemma 20 approximates the transient deletion by an expression that is easy to compute. *E.g.*, Figure 15 yields Figure 17 without computing Figure 16. Note that $\max(\epsilon^2, \frac{\epsilon}{4})$ in Figure 17 may be simplified into ϵ by Lemma 7.

▶ **Lemma 20.** *If p with states S, transient states T, satisfies Assumption 5 and has singleton essential classes, then $\mathbb{P}^x(X_{\tau^+_{S\setminus T}} = y) \cong \max\{p(\gamma) : \gamma \in \Gamma_T(x, y)\}$ for all $x, y \in S \setminus T$.*

2.4 Outgoing scaling and existence of stable states

If the essential graph has no arc, the collapse and the deletion are useless to compute the stable states. This section says how to transform a non-trivial perturbation with empty (*i.e.* totally disconnected) essential graph into a perturbation with the same stable states but a non-empty essential graph, so that collapse or deletion may be applied. Intuitively, it is done by speeding up time until a first non-infinitesimal flow is observable between different states.

Towards it, the *ordered division* is defined in Definition 21. It allows us to divide a function by a function with zeros by returning a default value in the zero case. It is named ordered because we will "divide" f by g only if $f \precsim g$, so that only 0 may be "divided" by 0. Then Observation 22 further justifies the terminology.

▶ **Definition 21** (Ordered division). For $f, g : I \to [0, 1]$ and $n > 1$ let us define $(f \div_n g) : I \to [0, 1]$ by $(f \div_n g)(x) := \frac{f(x)}{g(x)}$ if $0 < g(x)$ and otherwise $(f \div_n g)(x) := \frac{1}{n}$.

▶ **Observation 22.** *$(f \div_n g) \cdot g = f$ for all n and $f, g : I \to [0, 1]$ such that $f \precsim g$.*

▶ **Definition 23** (Outgoing scaling). Let a perturbation p with state space S satisfy Assumption 5, let $m := |S| \cdot \max\{p(z, t) \mid z, t \in S \wedge z \neq t\}$, and let us define the following.

- $\sigma(p)(x, y) := p(x, y) \div_{|S|} m$ for all $x \neq y$
- $\sigma(p)(x, x) := (p(x, x) + m - 1) \div_{|S|} m$.

For example Figure 6 satisfies Assumption 5 and its essential graph is empty. Scaling it yields Figure 19, which satisfies Assumption 5 and whose essential graph has two arcs. Note that collapsing around x or y in Figure 6 has no effect, but in Figure 19 it yields a one-state perturbation. Proposition 24 below states how well the outgoing scaling behaves.

▶ **Proposition 24.** *1. If a perturbation p satisfies Assumption 5, so does $\sigma(p)$, and the essential graph of $\sigma(p)$ is non-empty.*
2. A state is stable for p iff it is stable for $\sigma(p)$.

The outgoing scaling divides the weights of the proper arcs by m, as if time were sped up by m^{-1}. The self-loops thus lose their meaning, but Proposition 24 proves it harmless. Note that the self-loops are also ignored in Assumption 5, Lemma 7, and Definition 8.

Let us describe a recursive computation of the stable states: if the perturbation is constant identity, all its states are stable; else, if the essential graph is empty, apply the outgoing scaling; else, apply one collapse or the transient deletion. This procedure is correct by Propositions 24.2, 16.2, and 19, hence Theorem 25 below (the existential part of Theorem 2).

▶ **Theorem 25.** *Let p be a perturbation such that $f \precsim g$ or $g \precsim f$ for all f and g in the multiplicative closure of the $p(x, y)$ with $x \neq y$. Then p has stable states.*

3 Abstract and quick algorithm

Following the procedure described before Theorem 25 but using the approximation Lemmas 13 and 20 instead of the precise collapse and deletion computes the stable states in $O(n^4)$, where n is the number of states. To improve the speed to $O(n^3)$ we split the deletion into two stages, depending on the lengths of the relevant paths. To improve it further by a multiplicative factor we merge the collapses into these two stages. It would have been cumbersome to define the collapse-deletion merge directly *via* the dynamics in Section 2, and to prove its correctness *via* probabilistic techniques, hence the usefulness of the rather atomic collapse and deletion in the first part of our work. Ensuring that they are safely performed up to $\cong$ is a straightforward sanity check, by Lemma 7, but handling the collapse-deletion merge requires particular attention. Also, the proof for the scaling involves a new algebraic structure accommodating the ordered division: we call it an order-division semiring $(F, 0, 1, \cdot, \leq, \div)$, where F is the quotient of the transition-probability maps by $\cong$, 0 is the zero function, $\div$ is the abstraction of the ordered division, *etc.*, and $[\chi]$ and $[\sigma]$ are the abstractions of the collapse-deletion merge and of the scaling, respectively. All this is well-defined thanks to Assumption 5. Definitions and proofs can be found in Section 3.1 in [1].

Based on these abstractions, this section presents the algorithm (computing the stable states and more), its correctness, and its complexity in $O(n^3)$. Algorithm 1 mainly consists in applying recursively the function $[\chi] \circ [\sigma]$ until a totally disconnected graph is produced. It does not explicitly refer to perturbations since this notion was abstracted on purpose. Instead, the algorithm manipulates digraphs with arcs labeled in an ordered-division semiring, in which inequality, multiplication and ordered division are implicitly assumed to be computable.

One call to the `FindHubRec` corresponds to $[\chi] \circ [\sigma]$, *i.e.* Lines 7 and 9 to $[\sigma]$, and Lines 10 till 18 to $[\chi]$. Before calling `FindHubRec`, Lines 2 and 3 produce an isomorphic copy of the input that is easier to handle when making unions and keeping track of the remaining vertices. Note that Line 9 does not update the $P(x, x)$: it would be useless indeed, since the self-loops are irrelevant by Observation 34 in [1]. Line 10 computes the essential graph up to self-loops, and Line 11 computes the essential classes by a modified Tarjan's algorithm. The computation of $[\chi](P)(\cup E_i, \cup E_j) := \max_{\leq}\{P(\gamma) : \gamma \in \Gamma_T(E_i, E_j)\}$ is performed in two stages: the first stage at Line 12 considers only paths of length one; the second stage at Line 18 considers the paths with a vertex in T. This case disjunction reduces the size of the graph on which the shortest path algorithm from Line 16 is run (and thus the complexity of `FindHub`). Note that it is called with laws $\cdot$ and max instead of $+$ and min. Moreover,

Algorithm 1: FindHub

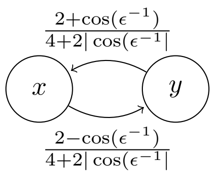
```
Function FindHub is
    input  : $(S, P)$, where $P : S \times S \to F$
    // $(F, 0, 1, \cdot, \leq, \div)$ is an ordered-division semiring.
    output : a subset of $S$
    $\hat{S} \leftarrow \{\{s\} | s \in S\}$;                                   // For bookkeeping.
    for $x, y \in S$ do $\hat{P}(\{x\}, \{y\}) \leftarrow P(x, y)$;             // For bookkeeping.
    return FindHubRec($\hat{S}$,$\hat{P}$);
end
Function FindHubRec is
    input  : $(S, P)$, where $S$ is a set of sets and $P : S \times S \to F$
    output : a subset of $S$
    $M \leftarrow \max\{P(x, y) \mid (x, y) \in S \times S \wedge x \neq y\}$;
    if $M = 0$ then return $\cup S$;                                        // Recursion base case
    for $x, y \in S$ and $x \neq y$ do $P(x, y) \leftarrow P(x, y) \div M$;      // Outgoing scaling.
    $A \leftarrow \{(x, y) \in S \times S \mid P(x, y) = 1\}$;                   // $A$ is a digraph.
    $(E_1, \dots, E_k) \leftarrow$TarjanSinkSCC($S$,$A$);          // Returns the sink SCCs of $A$.
    // Maximal labels of direct arcs, below.
    for $1 \leq i, j \leq k$ do $P'(\cup E_i, \cup E_j) \leftarrow \max\{P(x, y) \mid (x, y) \in E_i \times E_j\}$;
    // Maximal labels of all relevant paths, in the remainder.
    $T \leftarrow S \setminus (E_1 \cup \cdots \cup E_k)$;
    $P_T \leftarrow P$;                                                   // Initialisation.
    for $(x, y) \in (S \setminus T) \times S$ do $P_T(x, y) \leftarrow 0$;  // Drops arcs not starting in $T$.
    for $y \in T$ do $P_T(y, \_) \leftarrow$Dijkstra($S$,$P_T$,$y$, $\cdot$, max);
    // $P_T(y, \_)$ is the "distance" function from $y \in T$, using $\cdot$ and max.
    for $1 \leq i, j \leq k$ and $i \neq j$ and $(x_i, x_j, y) \in E_i \times E_j \times T$ do
        $P'(\cup E_i, \cup E_j) \leftarrow \max(P'(\cup E_i, \cup E_j), P(x_i, y) \cdot P_T(y, x_j))$;
    end for
    return FindHubRec($\{\cup E_1, \dots, \cup E_k\}, P'$)
end
```

since our weights are at most 1 we can use [14] or [2] (which assume non-negative weights) to implement Line 16. Proposition 26 below shows that our algorithm is fast, and our main algorithmic result follows, which is the algorithmic part of Theorem 2.

▶ **Proposition 26.** *The algorithm* FindHub *terminates within $O(n^3)$ computation steps, where n is the number of vertices of the input graph.*

▶ **Theorem 27.** *Let a perturbation p satisfy Assumption 5. A state is stochastically stable iff it belongs to* FindHub$(S, [p])$. *Provided that inequality, multiplication, and ordered division between equivalence classes of perturbation maps can be computed in constant time, stability can be decided in $O(n^3)$, where n is the number of states.*

One achievement of our algorithm is that it processes all weighted digraphs (*i.e.* abstractions of perturbations) uniformly: neither irreducibility nor any kind of connectedness is required. *E.g.* in Figures 20 to 25, the four-state perturbation is the disjoint union of two



$\frac{2+\cos(\epsilon^{-1})}{4+2|\cos(\epsilon^{-1}|}$
x
y
$\frac{2-\cos(\epsilon^{-1})}{4+2|\cos(\epsilon^{-1}|}$

Figure 19

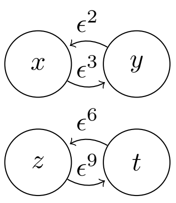


Figure 20 Initial perturbation.

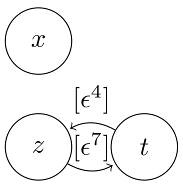

Figure 23 Transient deletion.

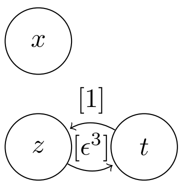

Figure 24 Outgoing scaling.

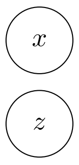

Figure 25 Transient deletion.

smaller perturbations. As expected the stable states of the union are the union of the stable states, *i.e.* $\{x, z\}$, but whereas the outgoing scaling applied to the bottom of Figure 21 (the perturbation restricted to $\{z, t\}$) would yield the bottom of Figure 24 directly by division by $[\epsilon^6]$, two rounds of ougtoing scaling lead to this stage when processing the four-state perturbations.

4 Discussion

This section studies two special cases of our setting: first, how assumptions that are stronger than Assumption 5 make not only some proofs easier but also one result stronger; second, how far Young's technique can be generalized. Then we notice that the termination of our algorithm defines an induction proof principle, which is used to show that the algorithm computes a well-known object when fed a strongly connected graph. Eventually, we discuss how to give the so-far-informal notion of time scale a formal flavor.

Stronger assumption

We consider Assumption 28, a stronger version of Assumption 5. It yields Proposition 29, a stronger version of Proposition 14.1. (The proofs are similar but the new one is simpler.)

▶ **Assumption 28.** *If $x \neq y$ and $p(x, y)$ is non-zero, it is positive; and $f \cong g$ or $f \in o(g)$ or $g \in o(f)$ for all f and g in the multiplicative closure of the $\epsilon \mapsto p_\epsilon(x, y)$ with $x \neq y$.*

▶ **Proposition 29.** *Let a perturbation p with state space S satisfy Assumption 28, and let μ be a stationary distribution map for p. If y is a transient state, $\lim_{\epsilon \to 0} \mu_\epsilon(y) = 0$.*

Under Assumption 5 some states may be neither stable nor fully vanishing: y in Figure 8 and x in Figure 1 where the bottom ϵ^2 is replaced with ϵ. Assumption 28 rules out such cases.

▶ **Corollary 30.** *States of perturbations under Assumption 28 are stable or fully vanishing.*

Generalization of Young's technique

Our proof of existence of and computation of the stable states of a perturbation are very different from Young's [17] who uses a finite version of the Markov chain tree theorem. Here we investigate how far Young's technique can be generalized. This will suggest that we were right to change approaches, but it will also yield a decidability result in Proposition 34.

Lemma 31 generalizes [17, Lemma 1]. Both proofs use the Markov chain tree theorem, but they are significantly different nonetheless. Let p be a perturbation with state space S. As in [17] or [8], for all $x \in S$ let $\mathcal{T}_x$ be the set of the spanning trees of (the complete graph of) $S \times S$ that are directed towards x. For all $x \in S$ let $\beta^x_\epsilon := \max_{T \in \mathcal{T}_x} \prod_{(z,t)\in T} p_\epsilon(z,t)$.

▶ **Lemma 31.** *A state x of irreducible p with state space S is stable iff $\beta^y \precsim \beta^x$ for all $y \in S$.*

Assumption 5 and Lemma 31 together yield Observation 32, a generalization of existing results about existence of stable states, such as [17, Theorem 4]. The underlying algorithm runs in time $O(n^3)$ where n is the number of states, just like Young's.

▶ **Observation 32.** *Let a perturbation p on state space S satisfy Assumption 5. If for all $x \neq y$ the map $p(x,y)$ is either identically zero or strictly positive, p has stable states.*

The stable states of a perturbation are computable even without the positivity assumption from Observation 32, but their existence is no longer guaranteed by the same proof. In this way, Observation 33 is like the existential part of Theorem 2, but with a bad complexity.

▶ **Observation 33.** *Let F be a set of perturbation maps of type $I \to [0,1]$ for some I. Let us assume that F is closed under multiplication by elements in F and by characteristic functions of decidable subsets of I, that $\precsim$ is decidable on $F \times F$, and that the supports of the functions in F are uniformly decidable. If $f \precsim g$ or $g \precsim f$ for all $f, g \in F$, stability is decidable in $O(n^5)$ for the perturbations p such that $x \neq y \Rightarrow p(x,y) \in F$.*

The assumption $f \precsim g$ or $g \precsim f$ for all $f, g \in F$ from Observation 33 relates to Assumption 5. Proposition 34 drops it while preserving decidability of stability, but at the cost of an exponential blow-up since the supports of the maps are no longer ordered by inclusion.

▶ **Proposition 34.** *Let F be a set of maps of type $I \to [0,1]$ for some I. Let us assume that F is closed under multiplication by elements in F and by characteristic functions of decidable subsets of I, that $\precsim$ is decidable on $F \times F$, and that the supports of the functions in F are uniformly decidable. Then stability is decidable for the p such that $x \neq y \Rightarrow p(x,y) \in F$.*

What does Algorithm 1 compute?

Applying sequentially the scaling, collapse, and deletion terminates, so it amounts to an *induction proof principle* for finite graphs with arcs labeled in an ordered-division semiring. Observation 35 is proved along this principle. It can also be proved by an indirect argument using Lemma 31 and Theorem 27, but the inductive proof is simple and from scratch.

▶ **Observation 35.** *Let $(F, 0, 1, \cdot, \leq, \div)$ be an ordered-division semiring, and let $P : S \times S \to F$ correspond to a strongly connected digraph, where an arc is absent iff its weight is 0. Then* `FindHub`(S, P) *returns the roots of the maximum directed spanning trees.*

Note that finding the roots from Observation 35 is also doable in $O(n^3)$ by computing the maximum spanning trees rooted at each vertex, by [7] which uses the notion of *heap*, whereas `FindHub` uses a less advanced algorithm.

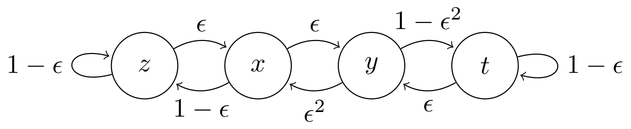

Figure 26 Vanishing time scale.

Vanishing time scales

Computing `FindHub` induces an order in which the states are found to be vanishing. Under the stronger Assumption 28, a notion of *vanishing time scale* may be defined, with the flavor of non-standard analysis [15]. Let $(\mathcal{T}, \cdot)$ be a group of functions $I \to]0, +\infty[$ such that $f \cong g$ or $f \in o(g)$ or $g \in o(f)$ for all f and g in $\mathcal{T}$. The elements of $[\mathcal{T}]$ are called the time scales. Let p over states S satisfy Assumption 28 and let $x \in S$ be deleted at the d-th recursive call of `FindHub`$(S, [p])$. Let $M_1, \dots, M_d$ be the maxima (*i.e.* M) from Line 7 in Algorithm 1 at the 1st,...,d-th recursive calls, respectively. We say that x vanishes at time scale $\prod_{1\leq i\leq d} M_i^{-1}$.

Figure 26 suggests that a similar account of vanishing times scales, even just a qualitative one, would be much more difficult to obtain by invoking the Markov chain tree theorem as in [17]. The only stable state is t; the state z vanishes at time scale $[\epsilon]^{-2}$; and x and y vanish at the same time scale [1] although the maximum spanning trees rooteed at x and y have different weights: ϵ^4 and ϵ^3, respectively.

Abstract

An important building block in all current asymptotically fast algorithms for matrix multiplication are tensors with low border rank, that is, tensors whose border rank is equal or very close to their size. To find new asymptotically fast algorithms for matrix multiplication, it seems to be important to understand those tensors whose border rank is as small as possible, so called tensors of minimal border rank.

We investigate the connection between degenerations of associative algebras and degenerations of their structure tensors in the sense of Strassen. It allows us to describe an open subset of $n \times n \times n$ tensors of minimal border rank in terms of smoothability of commutative algebras. We describe the smoothable algebra associated to the Coppersmith-Winograd tensor and prove a lower bound for the border rank of the tensor used in the "easy construction" of Coppersmith and Winograd.

1 Introduction

Let V_1, V_2, V_3 be vector spaces. The tensor product $V_1 \otimes V_2 \otimes V_3$ is spanned by tensors of the form $v_1 \otimes v_2 \otimes v_3$, which are called *decomposable* tensors, i. e., any tensor $T \in V_1 \otimes V_2 \otimes V_3$ can be represented as a sum

$$T = \sum_{s=1}^{r} v_{1,s} \otimes v_{2,s} \otimes v_{3,s}. \tag{1}$$

This representation is called a *polyadic decomposition* of T. The minimal number of summands in a polyadic decomposition of T is called the *rank* of T. Tensor rank is a direct generalization of the usual notion of matrix rank, which can be defined as a minimal number of summands in a representation of a matrix as a sum of rank one matrices. Unlike in the matrix case, the set $\mathbf{R}_r$ of all tensors of rank at most r is in general not closed, so it is useful to consider not only exact polyadic decompositions, but also approximations of tensors by sums of the form (1). Given a tensor T, the minimal number r such that T is contained in the closure of $\mathbf{R}_r$ is called the *border rank* of T.

Rank and border rank of tensors have diverse applications (see [3, 7, 9] for more information). Our motivation originates from computational complexity theory of bilinear maps. Any

bilinear map $\varphi\colon U \times V \to W$ between finite-dimensional vector spaces is a contraction with some tensor from $U^* \otimes V^* \otimes W$, called the *structural tensor* of φ. Polyadic decompositions of the structural tensor can be interpreted as algorithms of a certain kind for computing φ, and the rank of the structural tensor of a bilinear map is a measure of its computational complexity. See [1] for a detailed exposition of bilinear complexity theory.

One interesting problem in this area is the classification of concise tensors of minimal border rank. A tensor from $V_1 \otimes V_2 \otimes V_3$ is *concise* if it is not contained in any proper subspace $V_1' \otimes V_2' \otimes V_3' \subset V_1 \otimes V_2 \otimes V_3$. The border rank of a concise tensor is bounded from below by $\max\{\dim V_i\}$. Tensors for which this bound is exact are called tensors *of minimal border rank*.

Tensors of minimal border rank correspond to bilinear maps that have low complexity and can be used to construct efficient bilinear algorithms. For example, the famous Coppersmith-Winograd algorithm for matrix multiplication [4] (as well as its recent improvements [12]) uses a tensor of minimal border rank as a basic block. Such a tensor, like the Coppersmith-Winograd tensor, usually appears “out of the blue” and this starting tensor, which at a first glance has only very little to do with matrix multiplication, is then used to design a fast matrix multiplication algorithm by looking at high powers of the starting tensor. Therefore, to make further progress in the design of fast matrix multiplication algorithms, a systematic description of the tensors of minimal border rank seems to be very helpful. As our first result, we describe (an open subset) of the tensors of minimal border rank in terms of their structure. It turns out, that these tensors are the multiplication tensors of so-called smoothable commutative algebras. These algebras are studied in algebraic geometry in connection with Hilbert schemes of points, and have received quite some attention in the recent years, however, their structure is not fully understood.

Recently, Landsberg and Michałek [10] described tensors of minimal border rank in $\mathbb{C}^n \otimes \mathbb{C}^n \otimes \mathbb{C}^n$ that have a slice of rank n in terms of certain Lie algebras constructed from the slices of the tensor. In this paper we consider a slightly stronger condition, namely, existence of rank-n slices in two slicing directions, and prove that any tensor of minimal border rank satisfying this condition is equivalent to a structure tensor of a smoothable commutative algebra.

Furthermore, we describe a method which can be though of as a limiting version of the substitution method for the rank lower bounds (essentially the same method was independently described by Landsberg and Michałek [11]) and use it to prove a lower bound on the border rank of tensor powers of the restricted Coppersmith-Winograd tensor used in the “easy construction” of [4]. This easy tensor is not a tensor of minimal border rank. However, as pointed out in [1, Rem. 15.44], if this tensor had asymptotically minimal border rank, then the exponent of matrix multiplication would be 2. Asymptotically minimal border rank means that the border rank of the tensor powers converges to the size of the tensor. While our bound is nontrivial, it does not rule out that the easy tensor has asymptotically minimal border rank.

2 Preliminaries

2.1 Notation and basic definitions

All vector spaces are presumed to be finite-dimensional vector spaces over some fixed algebraically closed field k. Letters U, V, W, possibly indexed, denote vector spaces, A denotes algebras. ε usually denotes some indeterminate. Linear maps and tensors over $k(\varepsilon)$ are rendered in calligraphic font.

We do not distinguish between bilinear maps $U \times V \to W$ and corresponding tensors in $U^* \otimes V^* \otimes W$. When there is no confusion, multiplication in some algebra as a bilinear map is denoted by the same symbol as the algebra itself. In particular, k^r denotes the coordinate-wise multiplication of r-dimensional vectors.

A bilinear map $\varphi \in V^* \otimes V^* \otimes V$ is called *unital* if there is an *identity element* $e \in V$ such that $\varphi(e, x) = \varphi(x, e) = x$ for all $x \in V$.

Any tensor in $V_1 \otimes V_2 \otimes V_3$ with $\dim V_i = n_i$ is said to have *format* $n_1 \times n_2 \times n_3$. We are mostly interested in tensors of format $n \times n \times n$.

Rank and border rank of a tensor T are denoted by $R(T)$ and $\underline{R}(T)$ respectively.

The Zariski closure of a set $\mathbf{S}$ is denoted by $\overline{\mathbf{S}}$. We use the Zariski topology to define the border rank of tensors over k. However, over $\mathbb{C}$, the Zariski closure of the set of all tensors in $V_1 \otimes V_2 \otimes V_3$ of rank at most r coincides with its Euclidean closure, thus capturing the idea of approximation.

Let $T \in V_1 \otimes V_2 \otimes V_3$ and $T' \in V_1' \otimes V_2' \otimes V_3'$ be two tensors. T' is a *restriction* of T (denoted $T' \leq T$) if there exists a triple of linear maps $F_i \colon V_i \to V_i'$ such that $T' = (F_1 \otimes F_2 \otimes F_3)T$. We call the operator $(F_1 \otimes F_2 \otimes F_3)$ *a restriction operator* for $T' \leq T$.

Two tensors T_1 and T_2 are called *equivalent* ($T_1 \sim T_2$) if $T_1 \leq T_2$ and $T_2 \leq T_1$. If T_1 and T_2 have the same format, they are equivalent iff there is a bijective restriction operator for $T_1 \leq T_2$.

The tensor rank can be defined via restrictions of k^r (or, equivalently, diagonal tensors $\sum_{i=1}^r e_i \otimes e_i \otimes e_i$): polyadic decompositions of a tensor T are in one-to-one correspondence with restriction operators for $T \leq k^r$, so $R(T) \leq r$ iff $T \leq k^r$.

For more information, we refer to [1].

2.2 Degeneration of tensors

Degeneration of tensors was introduced by Strassen [15]. It is an approximate analogue of restriction: a tensor T' is a *degeneration* of T (denoted $T' \trianglelefteq T$) if

$$T' \in \overline{\{t \in V_1' \otimes V_2' \otimes V_3 \mid t \leq T\}}.$$

Strassen gives alternative descriptions of degeneration. One of these descriptions is in terms of representation theory. Consider the group $G = \mathrm{GL}(V_1) \times \mathrm{GL}(V_2) \times \mathrm{GL}(V_3)$. It acts on $V_1 \otimes V_2 \otimes V_3$ in a standard way:

$$(F_1, F_2, F_3) \cdot T = (F_1 \otimes F_2 \otimes F_3)T.$$

The orbits of this action are equivalence classes of tensors in $V_1 \otimes V_2 \otimes V_3$.

▶ **Lemma 2.1** (Strassen [15]). *Let $T \in V_1 \otimes V_2 \otimes V_3$ and $T' \in V_1' \otimes V_2' \otimes V_3'$ be two tensors. $T' \trianglelefteq T$ if and only if there exists a tensor $S \in V_1 \otimes V_2 \otimes V_3$ such that $T' \sim S$ and $S \in \overline{G \cdot T}$.*

Another description of degeneration uses base extension from k to $k(\varepsilon)$. For any vector space V over k its base extension $V(\varepsilon) = V \otimes k(\varepsilon)$ is a vector space over $k(\varepsilon)$. We have an injection $V \hookrightarrow V(\varepsilon)$ defined by $v \mapsto v \otimes 1$. Analogously, $V_1 \otimes V_2 \otimes V_3$ injects into $V_1(\varepsilon) \otimes_{k(\varepsilon)} V_2(\varepsilon) \otimes_{k(\varepsilon)} V_3(\varepsilon)$, so any tensor $T \in V_1 \otimes V_2 \otimes V_3$ can be viewed as a tensor over $k(\varepsilon)$, which we also denote by T.

Going in the other direction, we have a partial map from $k(\varepsilon)$ to k that takes a rational function regular at $\varepsilon = 0$ to its value at 0. It can be extended to partial maps from $V(\varepsilon)$ to V for each vector space V. If $\mathcal{T}|_{\varepsilon=0} = T$, we sometimes write $\mathcal{T} = T + O(\varepsilon)$, thinking of ε as an infinitesimal.

▶ **Lemma 2.2** (Strassen [15]). *Let $T \in V_1 \otimes V_2 \otimes V_3$ and $T' \in V_1' \otimes V_2' \otimes V_3'$ be two tensors. $T' \trianglelefteq T$ if and only if there exists $\mathcal{T} \in V_1(\varepsilon) \otimes_{k(\varepsilon)} V_2(\varepsilon) \otimes_{k(\varepsilon)} V_3(\varepsilon)$ such that $\mathcal{T}|_{\varepsilon=0} = T'$ and $\mathcal{T} \leq T$ as tensors over $k(\varepsilon)$.*

This lemma allows us to talk about specific ways in which T degenerates into T', which are represented by restriction operators for restrictions of the form $T' + O(\varepsilon) \leq T$ considered in the lemma. We call these operators *degeneration operators* for $T' \trianglelefteq T$.

Degenerations of k^r are related to border rank in the same way its restrictions are related to rank: since $R(\varphi) \leq r$ iff $\varphi \leq k^r$, by taking closures we have $\underline{R}(\varphi) \leq r$ iff $\varphi \trianglelefteq k^r$. In particular, Lemma 2.2 implies existence of *approximate polyadic decompositions*

$$T + O(\varepsilon) = \sum_{s=1}^{r} \mathcal{v}_{1,s} \otimes_{k(\varepsilon)} \mathcal{v}_{2,s} \otimes_{k(\varepsilon)} \mathcal{v}_{3,s}$$

2.3 Degeneration of algebras

Strassen's theory of tensor degenerations was inspired by the similar concept in the deformation theory of algebras.

Degeneration of algebras is usually restricted to associative or Lie algebras, but we define it for arbitrary bilinear maps in $V^* \otimes V^* \otimes V$, which can be thought of as nonassociative algebra structures on V. The group $\mathrm{GL}(V)$ acts on $V^* \otimes V^* \otimes V$ by change of basis:

$$(g \cdot \varphi)(x, y) = g\varphi(g^{-1}x, g^{-1}y).$$

The orbits of this action are isomorphism classes of nonassociative algebras.

Let $\varphi, \varphi' \in V^* \otimes V^* \otimes V$. We call φ' an *algebraic degeneration* of φ (denoted $\varphi' \trianglelefteq_{\mathrm{a}} \varphi$) if φ' lies in the orbit closure $\overline{\mathrm{GL}(V) \cdot \varphi}$. The name "algebraic degeneration" is used here to distinguish between two different notions of degeneration on $V^* \otimes V^* \otimes V$ and does not appear in the literature on degeneration of algebras. It is easy to see that $\varphi' \trianglelefteq_{\mathrm{a}} \varphi$ implies $\varphi' \trianglelefteq \varphi$.

We can extend the definition of algebraic degeneration to bilinear maps on different spaces of the same dimension by saying that if φ' is an algebraic degeneration of φ, then any ψ' isomorphic to φ' as a nonassociative algebra is also a algebraic degeneration of φ.

Since associativity and commutativity properties define closed subsets of $V^* \otimes V^* \otimes V$, degenerations of associative (resp. commutative) algebras are themselves associative (commutative).

▶ **Definition 2.3.** An unital algebra A of dimension n such that $A \trianglelefteq_{\mathrm{a}} k^n$ is called *smoothable*.

As follows from previous discussion, smoothable algebras are always associative and commutative.

In the geometric study of finite-dimensional commutative algebras they are sometimes studied as elements of a variety in $V^* \otimes V^* \otimes V$ or a similar scheme, and sometimes — as elements of a Hilbert scheme of points $\mathbf{Hilb}_n(\mathbb{A}_k^d)$, which parameterizes 0-dimensional schemes on d-dimensional affine plane, or, equivalently, ideals I in $R = k[x_1, \ldots, x_d]$ such that R/I is an n-dimensional algebra. The exact relationship between these two approaches is explored in [14]. We will only need the fact that topologies on $V^* \otimes V^* \otimes V$ and on $\mathbf{Hilb}_n(\mathbb{A}_k^d)$ give the same notion of smoothability, so we can use results from [2, 6] formulated in the language of Hilbert schemes.

There are analogues of Lemma 2.2 for algebraic degeneration (for example, [8, § 3.9] gives a geometric formulation of a similar statement). We only need the easier part of the equivalence which says that if φ' is approximated by bilinear maps isomorphic to φ, then it is an algebraic degeneration of φ.

▶ **Lemma 2.4.** *Let $\varphi, \varphi' \in V^* \otimes V^* \otimes V$ be two bilinear maps on V. If there exists an invertible $k(\varepsilon)$-linear map $\mathcal{F}\colon V(\varepsilon) \to V(\varepsilon)$ such that*

$$\mathcal{F}^{-1}\varphi(\mathcal{F}x, \mathcal{F}y)|_{\varepsilon=0} = \varphi'(x, y) \quad \textit{for all } x, y \in V,$$

then $\varphi' \trianglelefteq_{\mathrm{a}} \varphi$.

Proof. As ε varies, the bilinear map $\varphi^\varepsilon(x, y) = \mathcal{F}^{-1}\varphi(\mathcal{F}x, \mathcal{F}y)$ traces an algebraic curve in $V^* \otimes V^* \otimes V$. Since $\mathcal{F}$ is invertible, its values for Zariski almost all ε are also invertible, so an open subset of the curve $\{\varphi^\varepsilon\}$ lies in the orbit $\mathrm{GL}(V) \cdot \varphi$. Therefore, the value at $\varepsilon = 0$ lies in the closure of this orbit. ◀

We can rephrase this lemma as follows: tensor degeneration $\varphi' \trianglelefteq \varphi$ with a degeneration operator of the form $\mathcal{F}^* \otimes \mathcal{F}^* \otimes \mathcal{F}^{-1}$ implies algebraic degeneration $\varphi' \trianglelefteq_{\mathrm{a}} \varphi$.

3 Degenerations of associative algebras

In this section and later *algebra* means associative unital algebra over k.

3.1 Transformations of degeneration operators

Suppose $T \in V_1 \otimes V_2 \otimes V_3$ and $T' \in V_1' \otimes V_2' \otimes V_3'$ are two tensors such that $T' \trianglelefteq T$. Denote by $D(T' \trianglelefteq T)$ the set of all degeneration operators for $T' \trianglelefteq T$.

Let us describe some groups that act on $D(T' \trianglelefteq T)$. These groups are subgroups of $\mathrm{GL}(V_1(\varepsilon)) \times \mathrm{GL}(V_2(\varepsilon)) \times \mathrm{GL}(V_3(\varepsilon))$ and $\mathrm{GL}(V_1'(\varepsilon)) \times \mathrm{GL}(V_2'(\varepsilon)) \times \mathrm{GL}(V_3'(\varepsilon))$ which act on the domain and image of operators in $D(T' \trianglelefteq T)$ in the usual way (a triple $(\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3)$ acts via $\mathcal{F}_1 \otimes \mathcal{F}_2 \otimes \mathcal{F}_3$).

Let $T \in V_1 \otimes V_2 \otimes V_3$ be a tensor. Its *isotropy group* $\Gamma(T)$ is defined as the subgroup of $\mathrm{GL}(V_1) \times \mathrm{GL}(V_2) \times \mathrm{GL}(V_3)$ which leaves T fixed. Isotropy groups of bilinear maps and their action on the set of all bilinear algorithms were studied by de Groote [5]. Similarly, we define the *ε-isotropy group* $\Gamma^\varepsilon(T)$ of T as the subgroup of $\mathrm{GL}(V_1(\varepsilon)) \times \mathrm{GL}(V_2(\varepsilon)) \times \mathrm{GL}(V_3(\varepsilon))$ that fixes T considered as a tensor over $k(\varepsilon)$.

Suppose $\mathcal{F} \in \mathrm{GL}(V(\varepsilon))$ is a $k(\varepsilon)$-linear map such that $\mathcal{F} = \mathrm{id} + O(\varepsilon)$. Then for each $\nu \in V(\varepsilon)$ we have $\mathcal{F}\nu|_{\varepsilon=0} = \nu|_{\varepsilon=0}$, when $\nu|_{\varepsilon=0}$ is defined. Let $E(V_1, V_2, V_3)$ be the subgroup of $\mathrm{GL}(V_1(\varepsilon)) \times \mathrm{GL}(V_2(\varepsilon)) \times \mathrm{GL}(V_3(\varepsilon))$ consisting of all triples of such operators.

▶ **Lemma 3.1.** *The groups $\Gamma(T')$ and $E(V_1', V_2', V_3')$ act on $D(T' \trianglelefteq T)$ on the left and $\Gamma^\varepsilon(T)$ acts on the right via composition.*

Proof. Let $\mathcal{F} = \mathcal{F}_1 \otimes \mathcal{F}_2 \otimes \mathcal{F}_3$ be a degeneration operator for $T' \trianglelefteq T$, i. e., $T' + O(\varepsilon) = \mathcal{F}T$. The described actions preserve this relation, since if $G \in \Gamma(T')$, then $GT' = T'$ and $G(O(\varepsilon)) = O(\varepsilon)$; if $\mathcal{G} \in E(V_1', V_2', V_3')$, then $\mathcal{G}(T' + O(\varepsilon)) = T' + O(\varepsilon)$; and if $\mathcal{G} \in \Gamma^\varepsilon(T)$, then $\mathcal{G}T = T$. ◀

We use these transformations in case when T is the structure tensor of some algebra. Suppose A is an algebra and a, b, c are three invertible elements of A. Let L_x and R_x denote left and right multiplication by x respectively. Then $((L_a R_b)^*, (L_b^{-1} R_c)^*, L_a^{-1} R_c^{-1})$ is an element of the isotropy group $\Gamma(A)$ arising from the identity $xy = a^{-1}(axb)(b^{-1}yc)c^{-1}$. The use of this identity is sometimes called *sandwiching* in the literature. Since the tensor over $k(\varepsilon)$ corresponding to A is $A(\varepsilon) = A \otimes k(\varepsilon)$, an analogous expression with $a, b, c \in A(\varepsilon)$ can be used to construct elements of $\Gamma^\varepsilon(A)$.

3.2 Main theorem

▶ **Theorem 3.2.** *Let A be an algebra and $\varphi \in A^* \otimes A^* \otimes A$ be a unital bilinear map. Then $\varphi \trianglelefteq A$ iff $\varphi \trianglelefteq_{\mathrm{a}} A$.*

Proof. The implication $\varphi \trianglelefteq_{\mathrm{a}} A \Rightarrow \varphi \trianglelefteq A$ is obvious. Let us prove the opposite implication.

Let $\varphi \trianglelefteq A$ and $\mathcal{F}^* \otimes \mathcal{G}^* \otimes \mathcal{H}$ be a degeneration operator, i. e.,

$$\varphi(x, y) = \mathcal{H}(\mathcal{F}x \cdot \mathcal{G}y)|_{\varepsilon=0} \quad \text{for all } x, y \in A,$$

where the multiplication is in $A \otimes k(\varepsilon)$.

Let e be the identity element of φ. After the substitution $x = e$ we have

$$y = \varphi(e, y) = \mathcal{H}(\mathcal{F}e \cdot \mathcal{G}y)|_{\varepsilon=0} = \mathcal{H}L_{\mathcal{F}e}\mathcal{G}y|_{\varepsilon=0} \quad \text{for all } y \in A,$$

so $\mathcal{Q} := \mathcal{H}L_{\mathcal{F}e}\mathcal{G} = \mathrm{id} + O(\varepsilon)$. Applying $(\mathrm{id}, (\mathcal{Q}^{-1})^*, \mathrm{id}) \in E(A^*, A^*, A)$ to the degeneration operator $\mathcal{F}^* \otimes \mathcal{G}^* \otimes \mathcal{H}$, we obtain a new degeneration operator $\mathcal{F}^* \otimes \hat{\mathcal{G}}^* \otimes \mathcal{H}$ where $\hat{\mathcal{G}} = \mathcal{G}\mathcal{Q}^{-1} = L_{\mathcal{F}e}^{-1}\mathcal{H}^{-1}$.

Analogously, setting $y = e$ we get that $\mathcal{P} := \mathcal{H}R_{\hat{\mathcal{G}}e}\mathcal{F} = \mathrm{id} + O(\varepsilon)$ and using transformation $((\mathcal{P}^{-1})^*, \mathrm{id}, \mathrm{id}) \in E(A^*, A^*, A)$ we get another degeneration operator $\hat{\mathcal{F}}^* \otimes \hat{\mathcal{G}}^* \otimes \mathcal{H}$ where $\hat{\mathcal{F}} = \mathcal{F}\mathcal{P}^{-1} = R_{\hat{\mathcal{G}}e}^{-1}\mathcal{H}^{-1}$.

Finally, we use a sandwiching transformation $((L_{\mathcal{F}e}^{-1})^*, (R_{\hat{\mathcal{G}}e}^{-1})^*, L_{\mathcal{F}e}R_{\hat{\mathcal{G}}e})$ from $\Gamma^\varepsilon(A)$ and obtain a degeneration operator $\mathcal{S}^* \otimes \mathcal{S}^* \otimes \mathcal{S}^{-1}$ where

$$\mathcal{S} = (\mathcal{H}L_{\mathcal{F}e}R_{\hat{\mathcal{G}}e})^{-1}.$$

By Lemma 2.4 we have an algebraic degeneration $\varphi \trianglelefteq_{\mathrm{a}} A$. ◀

This theorem can be seen as an extension of the fact that associative algebras have equivalent structure tensors iff they are isomorphic ([1, Prop. 14.13]). The general idea of the proof — using symmetries of the tensors to transform maps that express the relationship between them — goes back to de Groote [5], but in our case some care needed to track the behaviour of degeneration operators as ε varies.

3.3 Tensors of minimal border rank

A special case of Theorem 3.2 when the algebra A is k^r can be used to study tensors of minimal border rank. First, we describe algebras of minimal border rank:

▶ **Corollary 3.3.** *A unital bilinear map on a vector space of dimension n is of minimal border rank iff it is a multiplication in a smoothable algebra.*

Proof. By Theorem 3.2 in the present case it is equivalent to $\varphi \trianglelefteq_{\mathrm{a}} k^n$, which is the definition of a smoothable algebra. ◀

For example, if $\operatorname{char} k \neq 2, 3$, the following algebras are smoothable [2], and, therefore, have minimal border rank:

1. any algebra generated by 2 elements;
2. any algebra of the form $k[x_1, \dots, x_d]/I$ where the ideal I is monomial;
3. any algebra with $\dim(R^2/R^3) = 1$ where $R = \operatorname{rad} A$;
4. any algebra with $\dim(R^2/R^3) = 2$, $\dim R^3 \leq 2$ and $R^4 = 0$ where $R = \operatorname{rad} A$;
5. any algebra of dimension 7 or less;

A description of smoothable algebras of dimension 8 is contained in [2, 6].

Using the description of algebras of minimal border rank, we can identify a certain open subset of tensors of minimal border rank.

▶ **Definition 3.4.** A tensor $T \in V_1 \otimes V_2 \otimes V_3$ of format $n \times n \times n$ is called *binding* if there are elements $\alpha_1 \in V_1^*$ and $\alpha_2 \in V_2^*$ such that the contractions $T\alpha_1 \in V_2 \otimes V_3$ and $T\alpha_2 \in V_1 \otimes V_2$ have rank n.

Note that a generic tensor of format $n \times n \times n$ is binding. In the terminology of [10] binding tensors are called 1_{V_1}- and 1_{V_2}-generic. We call these tensors binding because they allow us to relate spaces V_1 and V_2 to V_3 similarly to how a nondegenerate bilinear form allows to view spaces of its arguments as dual to each other. This is used in the proof of the following lemma.

▶ **Lemma 3.5.** *A binding tensor is equivalent to an unital bilinear map.*

Proof. Let $\dim V_1 = \dim V_2 = \dim V_3 = n$ and $T \in V_1 \otimes V_2 \otimes V_3$ be a binding tensor. Let $\alpha_1 \in V_1^*$ and $\alpha_2 \in V_2^*$ be as in Definition 3.4.

We can view $T\alpha_1$ and $T\alpha_2$ as linear isomorphisms $P_1 \colon V_1^* \to V_3$ and $P_2 \colon V_2^* \to V_3$. Applying $(P_2^{-1})^* \otimes (P_1^{-1})^* \otimes \mathrm{id}$ to T we get an equivalent bilinear map

$$\varphi(x_1, x_2) = T(P_2^{-1}x_1)(P_1^{-1}x_2).$$

This bilinear map is unital, since $\varphi(P_2\alpha_1, x) = x$ and $\varphi(x, P_1\alpha_2) = x$ for all $x \in V_1$, so

$$P_2\alpha_1 = \varphi(P_2\alpha_1, P_1\alpha_2) = P_1\alpha_2$$

is the identity element. ◀

▶ **Corollary 3.6.** *A binding tensor has minimal border rank iff it is equivalent to a smoothable algebra.*

These results suggest that structure tensors of smoothable algebras are possible candidates for basic blocks to construct fast matrix multiplication algorithms. We tried to use some of them in the same framework that is used by Coppersmith and Winograd (it is known as "laser method", see [1, 12] for more information). So far, these attempts did not lead to improved matrix multiplication algorithms.

3.4 Example: Coppersmith-Winograd tensor

Let $e^{[0]}, e_1^{[1]}, \ldots, e_q^{[1]}, e^{[2]}$ be a basis of a $(q+2)$-dimensional vector space, and $\alpha^{[0]}, \alpha_i^{[1]}, \alpha^{[2]}$ be the dual basis. The famous Coppersmith-Winograd algorithm [4] uses the tensor

$$\begin{aligned} T_{CW} = \sum_{i=1}^{q} &(e^{[0]} \otimes e_i^{[1]} \otimes e_i^{[1]} + e_i^{[1]} \otimes e^{[0]} \otimes e_i^{[1]} + e_i^{[1]} \otimes e_i^{[1]} \otimes e^{[0]}) + \\ &+ e^{[0]} \otimes e^{[0]} \otimes e^{[2]} + e^{[0]} \otimes e^{[2]} \otimes e^{[0]} + e^{[2]} \otimes e^{[2]} \otimes e^{[0]}, \end{aligned}$$

which we will call *Coppersmith-Winograd tensor*.

We can use the results of the previous section to exhibit a smoothable algebra with the structure tensor equivalent to the Coppersmith-Winograd tensor.

The Coppersmith-Winograd tensor is a tensor of minimal border rank, as witnessed by the approximate decomposition

$$\begin{aligned}T_{CW} + O(\varepsilon) = \varepsilon^{-2}\sum_{i=1}^{q}(e^{[0]} + \varepsilon e_i^{[1]}) \otimes (e^{[0]} + \varepsilon e_i^{[1]}) \otimes (e^{[0]} + \varepsilon e_i^{[1]}) - \\ - \varepsilon^{-3}(e^{[0]} + \varepsilon^2\sum_{i=1}^{q} e_i^{[1]}) \otimes (e^{[0]} + \varepsilon^2\sum_{i=1}^{q} e_i^{[1]}) \otimes (e^{[0]} + \varepsilon^2\sum_{i=1}^{q} e_i^{[1]}) + \\ + (\varepsilon^{-3} - q\varepsilon^{-2})(e^{[0]} + \varepsilon^3 e^{[2]}) \otimes (e^{[0]} + \varepsilon^3 e^{[2]}) \otimes (e^{[0]} + \varepsilon^3 e^{[2]}).\end{aligned} \tag{2}$$

The Coppersmith-Winograd tensor T_{CW} is binding (the layers corresponding to $\alpha^{[0]}$ have full rank). Applying Lemma 3.5, we obtain a bilinear map

$$\begin{aligned}\sum_{i=1}^{q}(\alpha^{[2]} \otimes \alpha_i^{[1]} \otimes e_i^{[1]} + \alpha_i^{[1]} \otimes \alpha^{[2]} \otimes e_i^{[1]} + \alpha_i^{[1]} \otimes \alpha_i^{[1]} \otimes e^{[0]}) + \\ + \alpha^{[2]} \otimes \alpha^{[2]} \otimes e^{[2]} + \alpha^{[2]} \otimes \alpha^{[0]} \otimes e^{[0]} + \alpha^{[0]} \otimes \alpha^{[0]} \otimes e^{[0]}\end{aligned}$$

which is unital with the identity $e^{[2]}$. By Corollary 3.6 this map is a multiplication in some smoothable algebra. Denote $e^{[2]}$ by 1 and $e_i^{[1]}$ by x_i. In this notation, $x_i x_j = 0$ for $i \neq j$ and $e^{[0]}$ corresponds to $x_1^2 = x_2^2 = \cdots = x_q^2$. To summarize,

▶ **Example 3.7.** The Coppersmith-Winograd tensors is equivalent to the smoothable algebra $A_{CW} \cong k[x_1, \ldots, x_q]/\left\langle x_i x_j, x_i^2 - x_j^2, x_i^3 \mid i \neq j \right\rangle$.

Performing transformations described in the proof of Theorem 3.2 for the decomposition (2), we can construct an algebraic degeneration of k^{d+2} to A_{CW} given by a degeneration operator $\mathcal{S}^* \otimes \mathcal{S}^* \otimes \mathcal{S}^{-1}$ where $\mathcal{S} \colon A_{CW}(\varepsilon) \to k(\varepsilon)^{q+2}$ has the following matrix relative to the basis $\{1, x_1, \ldots, x_q, x_1^2\}$ in A_{CW} and the standard basis in k^{q+2}:

$$\left[\begin{array}{c|ccccc|c} 1 & \varepsilon - (q-1)\varepsilon^2 & \varepsilon^2 & \varepsilon^2 & \cdots & \varepsilon^2 & -\varepsilon^3 \\ 1 & \varepsilon^2 & \varepsilon - (q-1)\varepsilon^2 & \varepsilon^2 & \cdots & \varepsilon^2 & -\varepsilon^3 \\ 1 & \varepsilon^2 & \varepsilon^2 & \varepsilon - (q-1)\varepsilon^2 & \cdots & \varepsilon^2 & -\varepsilon^3 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & \varepsilon^2 & \varepsilon^2 & \varepsilon^2 & \cdots & \varepsilon - (q-1)\varepsilon^2 & -\varepsilon^3 \\ 1 & \varepsilon^2 & \varepsilon^2 & \varepsilon^2 & \cdots & \varepsilon^2 & -\varepsilon^3 \\ 1 & 0 & 0 & 0 & \cdots & 0 & 0 \end{array}\right].$$

We may simplify this matrix by applying a certain linear map of the form id $+O(\varepsilon)$, obtaining a new degeneration corresponding to a matrix

$$\left[\begin{array}{c|ccccc|c} 1 & \varepsilon & 0 & 0 & \cdots & 0 & -\varepsilon^3 \\ 1 & 0 & \varepsilon & 0 & \cdots & 0 & -\varepsilon^3 \\ 1 & 0 & 0 & \varepsilon & \cdots & 0 & -\varepsilon^3 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 1 & 0 & 0 & 0 & \cdots & \varepsilon & -\varepsilon^3 \\ 1 & \varepsilon^2 & \varepsilon^2 & \varepsilon^2 & \cdots & \varepsilon^2 & -\varepsilon^3 \\ 1 & 0 & 0 & 0 & \cdots & 0 & 0 \end{array}\right]. \tag{3}$$

In the language of schemes this degeneration can be interpreted as follows: the 0-dimensional scheme $\mathbf{S}_{CW}$ with coordinate ring A_{CW} is the flat limit of the family (parameterized by ε) of schemes containing $q+2$ points in $(q+2)$-dimensional affine space with coordinates given by the rows of the matrix (3).

Since A_{CW} is generated by q elements, $\mathbf{S}_{CW}$ is contained in a q-dimensional affine subspace, so we can consider instead of schemes in $(q+2)$-dimensional space their projections to this subspace, which corresponds to the middle part of (3).

For those unfamiliar with the terminology of schemes, here is an algorithmic interpretation: to approximately multiply two elements of A_{CW}, evaluate the corresponding polynomials of the form $a^{[0]} + \sum a_i^{[1]} x_i + a^{[2]} x_1^2$ at the $q+2$ points given by the middle part of the matrix, multiply the corresponding values, and interpolate the products to get a resulting polynomial.

4 Substitution method for border rank

In this section we describe a method for obtaining lower bounds which can be seen as a border rank version of the substitution method for tensor rank. Let $T \in U^* \otimes V \otimes W$. We can view it as a linear map $U \to V \otimes W$ and consider the restriction $T|_{U'} \in (U')^* \otimes V \otimes W$ for any subspace $U' \subset U$. If the border ranks of $T|_{U'}$ are known, we can derive the bound on the border rank of T.

▶ **Theorem 4.1.** *Let $T \in U^* \otimes V \otimes W$ and $\dim U = n$. For any d we have*

$$\underline{R}(T) \geq n - d + \min\{\underline{R}(T|_{U'}) \mid U' \subset U, \dim U' = d\}.$$

Proof. Suppose $\underline{R}(T) = r$. We can assume that T is concise, considering it as an element of a smaller subspace $(U')^* \otimes V' \otimes W' \subset U^* \otimes V \otimes W$ otherwise. We need to show that there exists a subspace $U' \subset U$, $\dim U' = d$, such that $\underline{R}(T|_{U'}) \leq r - n + d$.

Note that this is true for tensors T of rank r. Indeed, let $T = \sum_{s=1}^r f_s \otimes v_s \otimes w_s$ be a polyadic decomposition. Without loss of generality, $f_1, \dots, f_n$ form a basis of U^*, and for the d-dimensional subspace $U' \subset U$ defined by the equations $f_i = 0$ for $1 \leq i \leq n - d$ we have $\underline{R}(T|_{U'}) \leq R(T|_{U'}) \leq r - n + d$, since the first $n - d$ terms of the decomposition vanish on U'.

Moreover, if we have an approximate decomposition

$$T + O(\varepsilon) = \sum_{s=1}^{r} f_s(\varepsilon) \otimes v_s(\varepsilon) \otimes w_s(\varepsilon) = \mathcal{T},$$

we can assume that $f_1(\varepsilon), \dots, f_n(\varepsilon)$ are linearly independent for almost all values of ε (because concise tensors form an open set), and obtain a family of subspaces U'_ε such that $\mathcal{T}(\varepsilon)|_{U'_\varepsilon}$ has rank at most $r - n + d$. The family U'_ε defines an algebraic curve in the Grassmannian $\mathbf{Gr}(d, U)$. Grassmannians are projective varieties, so U'_ε can be extended to $\varepsilon = 0$ (see, for example, [13, Rem. 7.12, Thm. 7.22]).

Given an isomorphism $F\colon k^d \to U' \subset U$ and a tensor T, we can define $\hat{T} \in (k^d)^* \otimes V \otimes W$ as $\hat{T}(p) = T(Fp)$ so that $\hat{T} \sim T|_{U'}$ and the map $Z\colon (T, F) \mapsto \hat{T}$ is algebraic. In the neighborhood of U'_0 we can choose isomorphisms $\mathcal{F}\colon k^d \to U'_\varepsilon$ which vary continuously with ε. Using these isomorphisms, we include $T|_{U'_0}$ in an algebraic family $Z(\mathcal{T}, \mathcal{F})$ of tensors of rank at most $r - n + d$, therefore, its border rank does not exceed this value. ◀

Essentially the same method was independently described by Landsberg and Michałek [11]. They prove this lower bound when U' is a hyperplane in U (from which the general version follows easily) and use it to obtain a lower bound on the rank of matrix multiplication. We consider the other extremal case where $U' = \langle u \rangle$ is 1-dimensional. In this case $T|_{U'}$ is essentially the matrix $Tu \in V \otimes W$ and, since for matrices rank and border rank coincide, we have

▶ **Corollary 4.2.** $\underline{R}(T) \geq n - 1 + m(T)$ *where* $m(T) = \min_{u \in U \setminus \{0\}} \operatorname{rk}(Tu)$.

4.1 Border rank of the easy Coppersmith-Winograd tensor

In [4], Coppersmith and Winograd first describe a simplified version of the main construction. This "easy version" uses the tensor

$$T_{cw} = \sum_{i=1}^{q} (e^{[0]} \otimes e_i^{[1]} \otimes e_i^{[1]} + e_i^{[1]} \otimes e^{[0]} \otimes e_i^{[1]} + e_i^{[1]} \otimes e_i^{[1]} \otimes e^{[0]}),$$

with $q \geq 2$, which we will call *easy Coppersmith-Winograd tensor.*

The easy Coppersmith-Winograd tensor is a restriction of the full Coppersmith-Winograd tensor obtained using the projection along $e^{[2]}$ onto $\left\langle e^{[0]}, e_i^{[1]} \right\rangle$, so its border rank is at most $q+2$. It is known that this is the exact value of $\underline{R}(T_{cw})$ (see [1, Exercise 15.14(3)]).

We can write a bilinear map equivalent to T_{cw} in terms of the algebra A_{CW} described in §3.4. Let X be the subspace of A_{CW} spanned by x_i, M be the subspace spanned by 1 and X, and R be the radical of A_{CW} (the subspace spanned by x_i and x_1^2). Denote by ρ the projection of A_{CW} onto R along 1. Then T_{cw} is equivalent to the bilinear map $\varphi_{cw} \in M^* \otimes M^* \otimes R$ defined as $\varphi_{cw}(a,b) = \rho(ab)$ (the multiplication is in A_{CW}).

▶ **Lemma 4.3.** *Let $q \geq 2$. For any $\psi \in U^* \otimes V^* \otimes W$, we have $m(\varphi_{cw} \otimes \psi) \geq 2m(\psi)$.*

Proof. For a bilinear map ψ, the value $m(\psi)$ is the minimum dimension of the space $\psi(u,V)$ among all nonzero $u \in U$.

Consider a nonzero element $a = 1 \otimes u_0 + \sum_{i=1}^{q} x_i \otimes u_i \in M \otimes U$. If all $u_i = 0$, then

$$(\varphi_{cw} \otimes \psi)(a, M \otimes V) = (\varphi_{cw} \otimes \psi)(1 \otimes u_0, M \otimes V) = \varphi_{cw}(1, M) \otimes \psi(u_0, V) = X \otimes \psi(u_0, V)$$

has dimension at least $qm(\psi)$. Otherwise, without loss of generality assume $u_1 \neq 0$. The space $(\varphi_{cw} \otimes \psi)(a, M \otimes V)$ contains subspaces

$$S_0 = (\varphi_{cw} \otimes \psi)(a, 1 \otimes V) = \{\sum_{i=1}^{q} x_i \otimes \psi(u_i, v) \mid v \in V\}$$
$$S_1 = (\varphi_{cw} \otimes \psi)(a, x_1 \otimes V) = \{x_1 \otimes \psi(u_0, v) + x_1^2 \otimes \psi(u_1, v) \mid v \in V\}$$

which have at least $2m(\psi)$ linearly independent elements, namely, for each of at least $m(\psi)$ linearly independent vectors $z_k \in \psi(u_1, V)$ we have $x_1 \otimes z_k + x_2 \otimes w_2 + \cdots + x_q \otimes w_q \in S_0$ and $x_1^2 \otimes z_k + x_1 \otimes w_1 \in S_1$ for some $w_1, w_2, \ldots, w_q \in W$.

In both cases we have $\dim(\varphi_{cw} \otimes \psi)(a, M \otimes V) \geq 2m(\psi)$ for all $a \in M \otimes U$. ◀

▶ **Corollary 4.4.** $\underline{R}(T_{cw}^{\otimes n}) \geqslant (q+1)^n + 2^n - 1$.

Proof. Use the previous Lemma to show that $m(T_{cw}^{\otimes n}) = m(\varphi_{cw}^{\otimes n}) = 2^n$ and Corollary 4.2. ◀

If $\lim_{n\to\infty}(\underline{R}(T_{cw}^{\otimes n}))^{1/n} = q+1$, then the exponent of matrix multiplication would be 2. While the bound above is nontrivial, it is yet not strong enough to rule this out.

Using Contracted Solution Graphs for Solving Reconfiguration Problems

Paul Bonsma[*1] **and Daniël Paulusma**[†2]

Abstract

We introduce a dynamic programming method for solving reconfiguration problems, based on *contracted solution graphs*, which are obtained from solution graphs by performing an appropriate series of edge contractions that decrease the graph size without losing any critical information needed to solve the reconfiguration problem under consideration. As an example, we consider a well-studied problem: given two k-colorings α and β of a graph G, can α be modified into β by recoloring one vertex of G at a time, while maintaining a k-coloring throughout? By applying our method in combination with a thorough exploitation of the graph structure we obtain a polynomial-time algorithm for $(k-2)$-connected chordal graphs.

1 Introduction

Given a search problem we may want to find out if one solution for a particular instance is "close" to another solution of that instance to get more insight into the solution space of the problem. Studying the solution space from this perspective could, for instance, be potentially interesting for improving the performance of corresponding heuristics [16]. Searching the solution space by making small "feasible" moves also turned out to be useful when analyzing randomized algorithms for sampling and counting k-colorings of a graph or when analyzing cases of Glauber dynamics in statistical physics (see Section 5 of the survey [19]).

In most general terms, the above situation can be modeled with solution graphs. We formalize this as follows: A *solution graph concept* $\mathcal{S}$ is obtained by defining a set of *instances*, *solutions* for these instances, and a (symmetric) *adjacency relation* between pairs of solutions. For every instance G of the problem, this gives a *solution graph* $\mathcal{S}(G)$, also called a *reconfiguration graph*, which has as node set all solutions of G, with edges as defined by the given adjacency relation. (If G has no solutions then $\mathcal{S}(G)$ is the empty graph.) The adjacency relation usually represents a smallest possible change (or *reconfiguration move*) between two solutions of the same instance. For example, the well-known *k-Color Graph concept* $\mathcal{C}_k$, related to the k-Colorability search problem, is defined as follows: instances are graphs G, and solutions are (proper) k-colorings of G. Two colorings are adjacent if and only if they differ in exactly one vertex. Note however that in general there may be more than one natural way to define the adjacency relation.

Solution graphs and their properties have been studied very intensively over the last couple of years for a variety of search problems, which include amongst others k-Coloring [3, 4, 8, 11, 12, 13, 15, 25], Satisfiability [16, 32], Independent Set [7, 9, 26], Shortest Path [5, 6, 26], List Coloring [18], List Edge Coloring [22, 23], $L(2,1)$-Labeling [24], H-Coloring [35] and Subset Sum [20]; see also the aforementioned survey [19]. The study of such solution graphs is commonly called *reconfiguration.*

Reconfiguration problems. Both algorithmic and combinatorial questions have been considered in the fast-growing area of reconfiguration. For instance, what is the diameter of $\mathcal{S}(G)$ (in terms of the size of the instance G) or if $\mathcal{S}(G)$ is not connected, what is the diameter of its (connected) components? In particular, is the diameter always polynomially bounded or not? This led to the introduction of the $\mathcal{S}$-Connectivity problem, which is that of deciding whether the solution graph $\mathcal{S}(G)$ of a given instance G is connected. Refining this problem leads to the following problem:

$\mathcal{S}$-Reachability.
Instance: an instance G with two solutions α and β.
Question: is there a path from α to β in $\mathcal{S}(G)$?

The $\mathcal{S}$-Reachability problem is a central problem in the area of reconfiguration, which has received much attention in the literature. The problem is sometimes called the *α-β-path* problem for $\mathcal{S}$ [19], whereas the specific case of $\mathcal{C}_k$-Reachability is also known as the k-Color Path problem [13]. It is known that $\mathcal{S}$-Reachability is PSPACE-complete for most of the aforementioned solution graph concepts even for special graph classes [8, 17, 21, 29, 34, 36]. For instance, $\mathcal{C}_k$-Reachability is PSPACE-complete even if $k = 4$ and instances are restricted to planar bipartite graphs [8]. This explains that efficient algorithms are only known for very restricted classes of instances. Hence, there is still a need for developing general algorithmic techniques for solving these problems in practice, and for sharpening the boundary between tractable and computationally hard instance classes. Our paper can be seen as the next step in these directions.

Method. One important algorithmic technique is *dynamic programming* (DP). In the area of reconfiguration, there are only relatively few successful examples of nontrivial DP algorithms (such as [5, 7, 18, 29]). In this paper, we focus on a DP technique based on the concept of *contracted solution graphs.* This method was first used by Bonsma [5] to obtain an efficient algorithm for a Shortest-Path-Reachability problem restricted to planar graphs. Recently, Hatanaka, Ito and Zhou [18] used this technique for proving that List-Coloring-Reachability is polynomial-time solvable for caterpillars. We will:

1. generalize the ideas of [5, 18] to a unified dynamic programming method,
2. introduce this method in a broader setting,
3. provide useful notation, terminology and basic lemmas, and
4. illustrate the method by giving a new application.

In Section 2 we give a detailed description of the general method of contracted solution graphs. Informally speaking, in dynamic programming one first computes the required information for parts of the instance, and combines/propagates this to compute the same information for ever larger parts of the instance, until the desired information is known for the entire instance. In our case, the instance G can be any relational structure on a ground set, such as (directed) graphs, hypergraphs, satisfiability formulas, or constraint satisfaction problems in general (see e.g. [10]). The order in which the information can be computed or in which parts should be considered is given by a *decomposition* of G. The elements of the ground set that are in a processed part H and that have incidences with the unexplored part are called *terminals*. The key idea behind the method is that reconfiguration moves in the processed part H that do not involve terminals are often irrelevant. The information that is relevant is captured by the notion of a *terminal projection*. These projections assign labels to solutions, yielding so-called *label components*, which are maximally connected subgraphs of $\mathcal{S}(H)$ induced by sets of solutions that all have the same label. A contracted solution graph is obtained from $\mathcal{S}(H)$ by contracting the label components into single vertices. We stress that the general method can readily be applied to *any kind of relational structure*, but in our example we focus on graphs, just as [5] and [18].

Relation to Other Results. In [18] dynamic programming was done over a *path decomposition* of the given caterpillar. In [5], a layer-based decomposition of the graph was used (for every $i \in \mathbb{N}$, the subgraph H_i consisted of all vertices at distance at most i of the given shortest path starting from a vertex s), which can also be viewed as a path decomposition. Here we focus on the more general *tree decompositions* instead. For our application, we give *full* dynamic programming rules for the $\mathcal{C}_k$-Reachability problem. In particular we introduce a join rule and we allow bags of size larger than 2. Our rules can be used directly for List-Coloring-Reachability as well and thus generalize the rules of [18].

Many well-studied $\mathcal{S}$-Reachability problems (including $\mathcal{C}_k$-Reachability for an appropriate constant k) are PSPACE-complete already for graphs of bounded bandwidth [29, 34], and therefore also for graphs of bounded treewidth. Recently, the PSPACE-completeness results from [29, 34] were strengthened to hold even for planar graphs of bounded bandwidth and low maximum degree [36]. Hence we cannot hope to obtain polynomial-time algorithms for graphs of treewidth w, for every constant w, and certainly not fixed parameter tractable (FPT) algorithms parameterized by w, although such results are common when working with decision problems that are only NP-complete instead of PSPACE-complete.

One way to cope with the above problem is to restrict the problem even further. For instance, in a number of recent papers [10, 25, 26, 32, 30, 31] the *length-bounded* version of the $\mathcal{S}$-Reachability problem was studied, that is the problem of finding a path of length at most ℓ in the solution graph between two given solutions, in particular with an aim to determine fixed-parameter tractability (observe that the length of a path between two solutions is a natural parameter). For instance, although $\mathcal{C}_k$-Reachability is PSPACE-complete for $k \geq 4$, the length-bounded version is FPT when parameterized by the length ℓ [10, 25] (in addition, it is polynomial-time solvable for $k \leq 3$ [25]). In this restricted context, other dynamic programming algorithms over tree decompositions for reconfiguration problems are known: in [29] FPT algorithms are given for various length-bounded reachability problems, parameterized by both the treewidth and the length bound ℓ. In [28], FPT algorithms are given for the reachability versions of different token reconfiguration problems for graphs of bounded degeneracy (and thus for bounded treewidth), when parameterized by the number of tokens.

Since we wish to solve $\mathcal{S}$-Reachability problems in general, we choose a different approach, and present a generally applicable method. However, because of the aforementioned PSPACE-completeness, we can obviously not guarantee that it terminates in polynomial time for all instances. Nevertheless, one can identify restricted instance classes for which it does yield polynomial-time algorithms, as illustrated by our new application and the two other examples [5, 18]. Moreover, our initial computational studies indicate that this method, with a few additions, performs well in practice for various instances of reconfiguration problems, for which the theoretical complexity status is not yet resolved.

Our Application. In Section 3 we illustrate the method by giving dynamic programming rules for the $\mathcal{C}_k$-Reachability problem, which describe how to compute new (larger) contracted solution graphs from smaller ones. Recall that similar dynamic programming rules can be given for other reconfiguration problems, as done already in [5, 18]. The given rules can be used when a tree decomposition of the graph is given. We emphasize that the rules solve the $\mathcal{C}_k$-Reachability problem correctly for *every* graph G (see e.g. [1, 27] for information on finding tree decompositions). Nevertheless, the algorithm is only *efficient* when the contracted solution graphs stay small enough (that is, polynomially bounded). As indicated by the PSPACE-hardness of the problem, this is not always the case. In the same section, we illustrate the DP rules and show that the size of the contracted solution graphs can grow exponentially, even for 2-connected 4-colorable unit interval graphs.

In Section 4 we apply our method to show that, for all $k \geq 3$, $\mathcal{C}_k$-Reachability is polynomially solvable for $(k-2)$-connected chordal graphs. As unit interval graphs are chordal, the result from Section 3 implies that we need to exploit the structure of chordal graphs to prove this. This is not surprising: although $\mathcal{C}_3$-Reachability can be solved in polynomial time for all graphs [13], $\mathcal{C}_k$-Reachability is PSPACE-complete even for bipartite graphs, and if $k \in \{4, 5, 6\}$ for planar graphs, and if $k = 4$ for planar bipartite graphs [8]. As the proof for the PSPACE-completeness result for bipartite graphs from [8] can be easily modified to hold for $(k-2)$-connected bipartite graphs, our result for $(k-2)$-connected chordal graphs cannot be extended to $(k-2)$-connected perfect graphs. On the positive side, $\mathcal{C}_k$-Connectivity is polynomial-time solvable on chordal graphs. This is due to a more general result of Bonamy et al. [4], which implies that for a chordal graph G, $\mathcal{C}_k(G)$ is connected if and only if G has no clique on more than $k-1$ vertices. Hence, our result can be seen as an extension of this result if in addition $(k-2)$-connectivity is imposed. Our result on $\mathcal{C}_k$-Reachability on $(k-2)$-connected chordal graphs is also the first time that dynamic programming over tree decompositions is used to solve the general version of a PSPACE-complete reachability problem in polynomial time for a graph class strictly broader than trees. In Section 5 we discuss possible directions for future work.

Preliminaries. For a connected graph G, a *vertex cut* is a set $S \subseteq V(G)$ such that $G - S$ is disconnected. Vertices in different components of $G - S$ are *separated* by S. For $k \geq 1$, a (connected) graph G is *k-connected* if $|V(G)| \geq k+1$ and every vertex cut S has $|S| \geq k$. The *contraction* of an edge uv of a graph G replaces u and v by a new vertex made adjacent to precisely those vertices that were adjacent to u or v in G (this does not create any multi-edges or loops). A graph is *chordal* if it has no induced cycle of length greater than 3.

Let G be a graph. A *k-color assignment* of G is a function $\alpha : V(G) \to \{1, \ldots, k\}$. For $v \in V(G)$, $\alpha(v)$ is called the *color* of v. It is a *k-coloring* if $\alpha(u) \neq \alpha(v)$ for every edge $uv \in E(G)$. A *coloring* of G is a k-coloring for some value of k. If α and β are colorings of G and a subgraph H of G, respectively, such that $\alpha|_{V(H)} = \beta$ (that is, α and β coincide on $V(H)$) then α and β are said to be *compatible.* For an integer k, the *k-color graph $\mathcal{C}_k(G)$* has as nodes all (proper) k-colorings of G, such that two colorings are adjacent if and only if they differ on one vertex. A *walk* from u to v in G is a sequence of vertices $v_0, \ldots, v_k$ with $u = v_0$, $v = v_k$, such that for all $i < k$, $v_iv_{i+1} \in E(G)$. A *pseudowalk* from u to v is a sequence of vertices $v_0, \ldots, v_k$ with $u = v_0$, $v = v_k$, such that for all $i < k$, either $v_i = v_{i+1}$, or $v_iv_{i+1} \in E(G)$. A *recoloring sequence* from a k-coloring α of G to a k-coloring β of G is a pseudowalk from α to β in $\mathcal{C}_k(G)$. A *labeled graph* is a pair G, ℓ where $G = (V, E)$ is a graph and $\ell : V \to X$ is a vertex labeling (which may assign the same label to different vertices). A *label preserving isomorphism* between two labeled graphs G_1, ℓ_1 and G_2, ℓ_2 is an isomorphism $\phi : V(G_1) \to V(G_2)$, such that $\ell_1(v) = \ell_2(\phi(v))$ for all $v \in V(G_1)$. Informally, two labeled graphs G_1, ℓ_1 and G_2, ℓ_2 are the same if there exists a label preserving isomorphism between them.

2 The Method of Contracted Solution Graphs

In this section we define the concept of *contracted solution graphs* (CSGs) for reconfiguration problems in general. Consider a solution graph concept $\mathcal{S}$, which for every instance G of $\mathcal{S}$ defines a solution graph that is denoted by $\mathcal{S}(G)$. A *terminal projection* for $\mathcal{S}$ is a function p that assigns a *label* to each tuple (G, T, γ) consisting of an instance G of $\mathcal{S}$, a set T of *terminals* for G and a solution γ for G. Terminal projections are used to decide which nodes are "equivalent" and can be contracted. We remark that G and T can be anything, but in our example and in previous examples in the literature [5, 18] G is always a graph, and T is a subset of its vertices. We also note that a terminal projection p can be seen as a node labeling for the solution graph $\mathcal{S}(G)$. So, for every instance G of $\mathcal{S}$, every choice of terminals T may give a different node labeling for the solution graph $\mathcal{S}(G)$. When G and T are clear from the context, we may write $p(\gamma)$ to denote the label of a node γ of $\mathcal{S}(G)$.

Example. Consider the k-color graph concept $\mathcal{C}_k$. Let G be a graph. We can define a terminal projection p as follows. Let T be a subset of $V(G)$. The nodes of $\mathcal{C}_k(G)$ are k-colorings and we give each node as label its restriction to T, that is, for every k-coloring γ of G, we set $p(\gamma) = p(G, T, \gamma) = \gamma|_T$. Note that $\gamma|_T$ is a k-coloring of $G[T]$.

Let p be a terminal projection for a solution graph concept $\mathcal{S}$. For an instance G of $\mathcal{S}$ and a terminal set T, a *label component* C of $\mathcal{S}(G)$ is a maximal set of nodes γ that all have the same label $p(\gamma)$ and that induce a connected subgraph of $\mathcal{S}(G)$. It is easy to see that every solution γ of G is part of exactly one label component, or in other words: the label components partition the node set of $\mathcal{S}(G)$. The *contracted solution graph (CSG)* $\mathcal{S}^c(G, T)$ is a labeled graph that has a node set that corresponds bijectively to the set of label components of G. For a node x of $\mathcal{S}^c(G, T)$, we denote by S_x the corresponding label component. Two distinct nodes x_1 and x_2 of $\mathcal{S}^c(G, T)$ are adjacent if and only if there exist solutions $\gamma_1 \in S_{x_1}$ and $\gamma_2 \in S_{x_2}$ such that γ_1 and γ_2 are adjacent in $\mathcal{S}(G)$. We define a label function ℓ^* for nodes of $\mathcal{S}^c(G, T)$ to denote the corresponding label in $\mathcal{S}(G)$. More precisely: for a node x of $\mathcal{S}^c(G, T)$, the label $\ell^*(x)$ is chosen such that $\ell^*(x) = p(\gamma)$ for all $\gamma \in S_x$. Note that the contracted solution graph $\mathcal{S}^c(G, T)$ can also be obtained from $\mathcal{S}(G)$ by contracting all label components into single nodes and choosing node labels appropriately.

Example. Figure 1(c) shows one component of $\mathcal{C}_4(G)$ for the (4-colorable) graph G from Figure 1(a). This is the component that contains all colorings of G whose vertices a, b, c, d are colored with colors $4, 3, 2, 1$, respectively (note that it is not possible to recolor any of these four vertices if one may recolor only one vertex at a time). So in Figure 1(c) the colors of the vertices a, b, c, d are omitted in the node labels, which only indicate the colors of e, f, g, in this order. For terminal set $T = \{f\}$, this component contains three label components (of equal size), and contracting them yields the CSG $\mathcal{C}_4^c(G, \{f\})$ shown in Figure 1(d). For $T = \{g\}$, there are seven label components, and the corresponding CSG $\mathcal{C}_4^c(G, \{g\})$ is shown in Figure 1(e). Note that $\mathcal{C}_4^c(G, \{g\})$ contains different nodes with the same label.

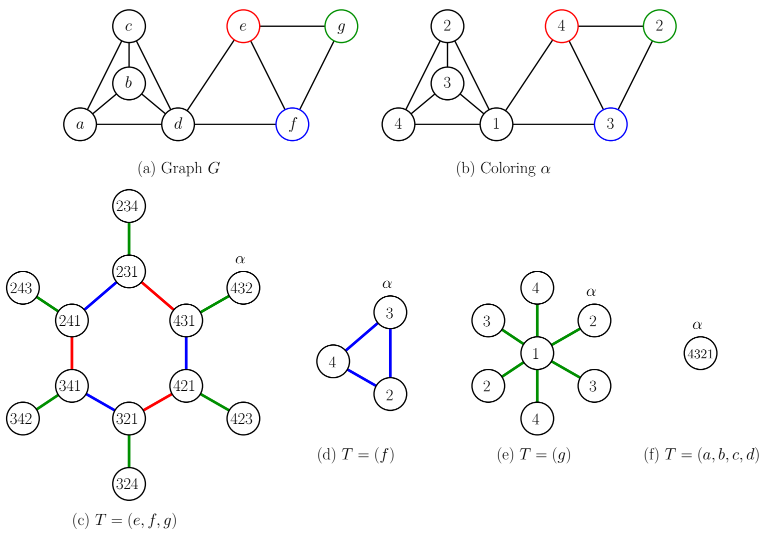

Figure 1 (a) A 4-colorable chordal graph G with $V(G) = \{a, b, c, d, e, f, g\}$. (b) a 4-coloring α, and one component of the CSGs of G for four different terminal sets T: (c) $\mathcal{C}_4^c(G, \{e, f, g\})$, (d) $\mathcal{C}_4^c(G, \{f\})$, (e) $\mathcal{C}_4^c(G, \{g\})$ and (f) $\mathcal{C}_4^c(G, \{a, b, c, d\})$. The $G[T]$-colorings in the node labels are given as sequences of colors, for the (ordered version of) T as indicated below each CSG. Example (c) can also be seen as the component of $\mathcal{C}_4(G)$ where vertices a, b, c, d receive colors $4, 3, 2, 1$.

We stress that the CSG $\mathcal{S}^c(G, T)$ is a labeled graph that includes the label function ℓ^* defined above. However, to keep its size reasonable, the CSG itself does not include the solution sets S_x for each node that were used to define it. For proving the correctness of dynamic programming rules for CSGs the following alternative characterization of CSGs (proof omitted) is useful; note that the sets S_x correspond exactly to the label components.

▶ **Lemma 1.** *Consider an instance G of a solution graph concept $\mathcal{S}$, terminal set T and terminal projection p. Let H, ℓ be a labeled graph. Then $H, \ell = \mathcal{S}^c(G, T)$ if and only if one can define nonempty sets of solutions S_x for each node $x \in V(H)$ such that the following properties hold:*

1. *$\{S_x \mid x \in V(H)\}$ is a partition of the nodes of $\mathcal{S}(G)$ (the solutions of G).*
2. *For every $x \in V(H)$ and every solution $\gamma \in S_x$: $p(G, T, \gamma) = \ell(x)$.*
3. *For every edge $xy \in E(H)$: $\ell(x) \neq \ell(y)$.*
4. *For every $x \in V(H)$: S_x induces a connected subgraph of $\mathcal{S}(G)$.*
5. *For every pair of distinct nodes $x, y \in V(H)$: $xy \in E(H)$ if and only if there exist solutions $\alpha \in S_x$ and $\beta \in S_y$ such that α and β are adjacent in $\mathcal{S}(G)$.*

A mapping S that assigns solution sets (or label components) S_x to each node x of $\mathcal{S}^c(G, T)$ that satisfies the properties given in Lemma 1 is called a *certificate* for $\mathcal{S}^c(G, T)$. Given such a certificate S and a solution γ for G, the *γ-node* of $\mathcal{S}^c(G, T)$ with respect to S is the node x with $\gamma \in S_x$. For readability, we will not always explicitly mention this certificate when talking about γ-nodes in $\mathcal{S}^c(G, T)$ (except in Lemma 2 below), but the reader should keep the following convention in mind: when γ-nodes are identified in $\mathcal{S}^c(G, T)$ for multiple solutions γ, *these are all chosen with respect to the same certificate.*

Example. In Figures 1(c)–(f), the α-node for the coloring α shown in Figure 1(b) is marked. In particular consider $\mathcal{C}_4^c(G, \{g\})$ in Figure 1(e). Since the certificate for $\mathcal{C}_4^c(G, \{g\})$ is not actually indicated in the figure, the other leaf with label 2 can also be chosen as the α-node (considering the nontrivial label-preserving automorphisms of the graph). Similarly, if we choose a coloring β that coincides with α except on nodes e and f, where we choose $\beta(e) = 3$ and $\beta(f) = 4$, then the same two leaves (the ones with label 2) of $\mathcal{C}_4^c(G, \{g\})$ can be chosen as the β-node. Nevertheless, if both an α-node and β-node are marked, then this will only be correct according to the above convention when they are distinct!

The main purpose of our definitions is the following key observation (we omit its proof).

▶ **Lemma 2.** *Let (G, T) be an instance of a solution graph concept $\mathcal{S}$. Let $\mathcal{S}^c(G, T)$ be the contracted solution graph for some terminal projection p. Let α and β be two solutions and let x and y be the α-node resp. β-node with respect to some certificate S. Then there is a path from α to β in $\mathcal{S}(G)$ if and only if there is a path from x to y in $\mathcal{S}^c(G, T)$.*

Lemma 2 implies that for a solution graph concept $\mathcal{S}$ and *any* terminal projection p and terminal set T, we can decide $\mathcal{S}$-Connectivity if we know $\mathcal{S}^c(G, T)$ (the answer is YES if and only if $\mathcal{S}^c(G, T)$ is connected) and the $\mathcal{S}$-Reachability problem if we know $\mathcal{S}^c(G, T)$ and the α-node and the β-node (the answer is YES if and only if these two nodes are in the same component). However, for obtaining an *efficient* algorithm using this strategy, we must choose the terminal projection p smartly: we need to throw away enough irrelevant information to ensure that $\mathcal{S}^c(G, T)$ will be significantly smaller than $\mathcal{S}(G)$, yet maintain enough information to ensure the efficient computation of $\mathcal{S}^c(G, T)$, without first constructing $\mathcal{S}(G)$. Our strategy for doing this is to use dynamic programming to compute $\mathcal{S}^c(H, T')$ for ever larger subgraphs H of G, while ensuring that all of the CSGs stay small throughout the process. The remainder of this paper shows a successful example of this strategy.

3 Dynamic Programming Rules for Recoloring

The following terminology is based on widely used techniques for dynamic programming over tree decompositions; see Section 4 and [2, 27, 33] for background information. A *terminal graph* (G, T) is a graph G together with a vertex set $T \subseteq V(G)$, whose vertices are called the *terminals*. If $T = V(G)$, then (G, T) is called a *leaf*. If $v \in T$, then we say that the new terminal graph $(G, T \setminus \{v\})$ is obtained from (G, T) by *forgetting* v (or *using a forget operation*). If $T \neq V(G)$, $v \in T$ and $N(v) \subseteq T$ then we say that (G, T) can be obtained from $(G - v, T \setminus \{v\})$ by *introducing* v (or *using an introduce operation*). Note that for a terminal graph (G', T') with $T' \neq \emptyset$, different graphs can be obtained from (G', T') by introducing a vertex v, whereas forgetting a terminal always yields a unique result. As we will see, the condition that each neighbor of the new vertex v must be in T is necessary. We say that (G, T) is the *join of* (G_1, T) *and* (G_2, T) (or *can be constructed using a join operation*) if

- G_1 and G_2 are induced subgraphs of G,
- $V(G_1) \cap V(G_2) = T$ and $V(G_1) \cup V(G_2) = V(G)$,
- $V(G_1) \neq T$ and $V(G_2) \neq T$, and
- for every $uv \in E(G)$, it holds that $uv \in E(G_1)$ or $uv \in E(G_2)$.

We will now focus on CSGs for the k-color graph concept $\mathcal{C}_k$, using the terminal projection $p(G, T, \gamma) = \gamma|_T$. We will show how to compute the CSG $\mathcal{C}_k^c(G, T)$ when (G, T) is obtained using a forget, introduce or join operation from a (pair of) graph(s) for which we know the CSG(s). We recall that a variant of these CSGs have been considered before by Hatanaka, Ito and Zhou [18], namely for the case that $|T| = 1$ in the context of list colorings of caterpillars. Similar dynamic programming rules were given in [18]: for the case that $|T| = 1$, they presented a combined introduce and forget rule, and a restricted type of join rule.

We start by stating a trivial rule for computing $\mathcal{C}_k^c(G,T)$ for leaves, which follows from the facts that $\mathcal{C}_k(G)$ has k-colorings of G as nodes and that the label $\ell(x)$ of a node x in $\mathcal{C}_k^c(G,T)$ is a k-coloring of $G[T]$.

▶ **Lemma 3** (Leaf). *Let (G,T) be a terminal graph with $T = V(G)$. Then $\mathcal{C}_k^c(G,T)$ is isomorphic to $\mathcal{C}_k(G)$ and its label function ℓ is the isomorphism from $\mathcal{C}_k^c(G,T)$ to $\mathcal{C}_k(G)$. Moreover, for every k-coloring γ of G, the γ-node of $\mathcal{C}_k^c(G,T)$ is the node v with $\ell(v) = \gamma$.*

We now give the rules for the forget, introduce and join operations. Figure 2 illustrates the first two rules. We show how Lemma 1 can be applied to prove Lemma 4; the other proofs are similar.

▶ **Lemma 4** (Forget). *Let (G,T) be a terminal graph. For every $v \in T$, it holds that $H', \ell' = \mathcal{C}_k^c(G, T \setminus \{v\})$ can be computed from $H, \ell = \mathcal{C}_k^c(G,T)$ as follows:*

- *For every node x in H with $\ell(x) = \gamma$, let $\ell'(x) = \gamma|_{T\setminus\{v\}}$.*
- *Iteratively contract every edge between two nodes x and y with $\ell'(x) = \ell'(y)$ and assign label $\ell'(z) := \ell'(x)$ to the resulting node z.*

Moreover, for any coloring γ of G, the γ-node of $\mathcal{C}_k^c(G, T \setminus \{v\})$ is the node that results from contracting the set of nodes that includes the γ-node of $\mathcal{C}_k^c(G,T)$.

Proof sketch: Let S denote the certificate for H, ℓ, so for every node x of H, S_x denotes the set of k-colorings of G (or *solutions*), such that these sets satisfy the properties stated in Lemma 1. In addition, for every coloring γ for which a γ-node x has been marked in H, we may assume that $\gamma \in S_x$. We will prove the statement using Lemma 1 again, by giving a certificate S' for H', ℓ', and proving that the five properties hold for these.

The graph H' is obtained by iteratively contracting edges of H, so every node y of H' corresponds to a connected set of nodes of H, which we will denote by M_y. So $\{M_y \mid y \in V(H')\}$ is a partition of $V(H)$. For every node $y \in V(H')$, we define $S'_y = \cup_{x \in M_y} S_x$. For every k-coloring γ of G such that the γ-node $x \in V(H)$ is marked, we define the γ-node of H' to be the node y with $x \in M_y$. Clearly, $\gamma \in S'_y$ then holds, so this is correct. One can now verify that the solution sets S'_x satisfy the five properties stated in Lemma 1. ◀

▶ **Lemma 5** (Introduce). *Let (G,T) be a terminal graph obtained from a terminal graph $(G - v, T \setminus \{v\})$ by introducing v. Then $H', \ell' = C_k^c(G,T)$ can be computed as follows from $H, \ell = \mathcal{C}_k^c(G - v, T \setminus \{v\})$:*

- *For every node x of H with label $\ell(x)$, and every color $c \in \{1, \ldots, k\}$: if the (unique) function $\delta : T \to \{1, \ldots, k\}$ with $\delta(v) = c$ and $\delta|_T = \ell(x)$ is a coloring of $G[T]$ then introduce a node x_c with label $\ell'(x_c) = \delta$.*
- *For every pair of distinct nodes x_c and y_d: add an edge between them if and only if (1) $x = y$ or (2) xy is an edge in H and $c = d$.*

Moreover, for every k-coloring γ of G, if x is the $\gamma|_{V(G)\setminus\{v\}}$-node in H and $\gamma(v) = c$, then x_c is the γ-node of H'.

▶ **Lemma 6** (Join). *Let (G,T) be a terminal graph that is the join of terminal graphs (G_1,T) and (G_2,T). Let $H_1, \ell_1 = C_k^c(G_1,T)$ and $H_2, \ell_2 = C_k^c(G_2,T)$. Then $H, \ell = C_k^c(G,T)$ can be computed as follows:*

- *For every pair of nodes $x \in V(H_1)$ and $y \in V(H_2)$: if $\ell_1(x) = \ell_2(y)$ then introduce a node (x,y) with $\ell((x,y)) = \ell_1(x)$.*
- *For two distinct nodes (x,y) and (x',y'), add an edge between them if and only if xx' is an edge in H_1 and yy' is an edge in H_2.*

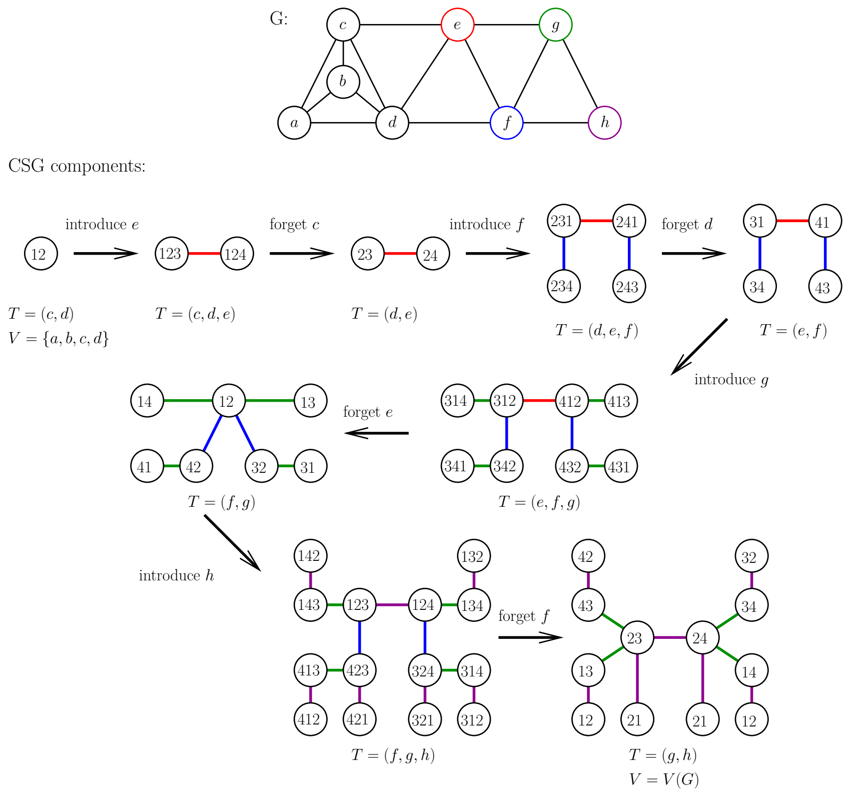

Figure 2 An example of computing CSGs using forget and introduce operations. A 4-colorable 2-connected chordal graph G with $V(G) = \{a, b, c, d, e, f, g, h\}$ is shown. Note that G is in fact unit interval and isomorphic to the graph G_8^I defined in Section 3. Starting with one component of the CSG $\mathcal{C}_4^c(G[\{a, b, c, d\}], \{c, d\})$, the corresponding component of $\mathcal{C}_4^c(G, \{g, h\})$ is computed, using four forget and introduce operations. The $G[T]$-colorings in the node labels are given as sequences of colors for the ordered version of T as indicated below each CSG. For instance, for $T = (c, d)$, the node label 12 indicates the coloring γ with $\gamma(c) = 1$ and $\gamma(d) = 2$.

Moreover, for every k-coloring γ of G, if x is the $\gamma|_{V(G_1)}$-node in H_1 and y is the $\gamma|_{V(G_2)}$-node in H_2, then (x, y) is the γ-node in H.

Remark 1. The DP rules in this section can be generalized further to capture the rules of [18] for the *list coloring* generalization $\mathcal{C}_L$ of $\mathcal{C}_k$. In this generalization, an instance G, L consists of a graph G together with color lists $L(v) \subseteq \{1, \dots, k\}$ for each $v \in V(G)$. Solutions are now list colorings, which are colorings α of G such that $\alpha(v) \in L(v)$ for each $v \in V(G)$. Adjacency is defined as before. So the *list coloring solution graph* $\mathcal{C}_L(G, L)$ is an induced subgraph of $\mathcal{C}_k(G)$. Hence, it is straightforward to generalize our DP rules to $\mathcal{C}_L$, namely by simply omitting all nodes that correspond to invalid vertex colors.

We now show that components of $\mathcal{C}_k^c(G)$ can grow exponentially even if G is chordal and $k = 4$. First, when considering 4-colorable chordal graphs with cut vertices, it is easy to obtain CSGs that have exponentially large components: take p copies of the graph shown in Figure 1(a), and identify the g-vertices of all of these graphs. Call the resulting graph G_p^*. We can show that, for every integer $p \geq 1$, $\mathcal{C}_4^c(G_p^*, \{g\})$ has a component with $1 + 3 \cdot 2^p$ nodes.

We can construct CSGs with exponentially large components for $(k-2)$-connected k-

colorable chordal graphs, or even 2-connected 4-colorable unit interval graphs, as follows. For $p \geq 4$, let the graph G^I_p have vertex set $\{v_0, \ldots, v_{p-1}\}$, and edge set $\{v_0v_3\} \cup \{v_iv_{i+1} \mid 0 \leq i \leq p-2\} \cup \{v_iv_{i+2} \mid 0 \leq i \leq p-3\}$. A graph isomorphic to G^I_8 is shown in Figure 2. Note that each G^I_p is unit interval. To state our claim more precisely, for every $p = 4q + 4$ with $q \in \mathbb{N}$, we can show that the CSG $\mathcal{C}^c_4(G^I_p, \{v_{p-2}, v_{p-1}\})$ has 4! components on at least 2^q nodes.

Both examples show that we need to do more than only computing CSGs to solve the problem for $(k-2)$-connected chordal graphs. Next, we will characterize the CSGs and show that it suffices to compute only a part of them.

4 Recoloring Chordal Graphs

We will show that CSGs can be used to efficiently decide the $\mathcal{C}_k$-Reachability problem for $(k-2)$-connected chordal graphs. To prove this we use the fact that for a chordal graph G and any clique T of G, the terminal graph (G,T) can recursively be constructed from simple cliques using a polynomial number of clique-based introduce, forget and join operations. We remark that some statements given here are similar to (and can alternatively be deduced from) well-known facts about tree decompositions [14] and nice tree decompositions [27]. However, for readability, and since we need to prove a new bound on the size of any tree decomposition, we give a self-contained presentation.

A *nice tree decomposition* of a terminal graph (G,T) (where G is not necessarily chordal and T may not be a clique) is a tuple $(\mathcal{T}, X, r)$, where $\mathcal{T}$ is a tree with root r and X is an assignment of *bags* $X_u \subseteq V(G)$ for each $u \in V(\mathcal{T})$ that can be defined recursively as follows:

1. If $T = V(G)$, then the tree $\mathcal{T}$ consists of one (root) node r with bag $X_r = T$.
2. If $v \in V(G) \setminus T$ and $(\mathcal{T}', X, r')$ is a nice tree decomposition of $(G, T \cup \{v\})$, then a nice tree decomposition for (G,T) can be obtained by adding a new root r with $X_r = T$, and adding the edge rr'.
3. If (G,T) can be obtained from $(G-v, T\setminus\{v\})$ using an introduce operation and $(\mathcal{T}', X, r')$ is a nice tree decomposition of $(G-v, T\setminus\{v\})$, then a nice tree decomposition for (G,T) can be obtained by adding a new root r with $X_r = T$, and adding the edge rr'.
4. If (G,T) can be obtained from (G_1,T) and (G_2,T) using a join operation, and $(\mathcal{T}_1, X, r_1)$ and $(\mathcal{T}_2, X, r_2)$ are nice tree decompositions of (G_1,T) and (G_2,T), then a nice tree decomposition for (G,T) can be obtained by adding a new root r with $X_r = T$ and adding edges rr_1 and rr_2.

We call a node $u \in V(\mathcal{T})$ a *leaf*, *forget node*, *introduce node* or *join node* if u is added as the root in case (1), (2), (3) or (4), respectively. The *width* of $(\mathcal{T}, X, r)$ is $\max_{u \in V(\mathcal{T})} |X_u| - 1$.

▶ **Lemma 7.** (proof omitted) *Let $(\mathcal{T}, X, r)$ be a nice tree decomposition of (G,T) of width at most $w \geq 1$, and let $n = |V(G)| \geq 1$. Then $|V(\mathcal{T})| \leq (w+4)n$.*

The bound from Lemma 7 holds for *any* nice tree decomposition, in contrast to the (stronger) bound of [27] which states that for any graph G, a nice tree decomposition of G of width at most $4n$ can be constructed (for an appropriate choice of the terminal set T). A nice tree decomposition $(\mathcal{T}, X, r)$ of (G,T) is *chordal* if for every node $u \in V(\mathcal{T})$, X_u is a clique of G. If $(\mathcal{T}, X, r)$ is a chordal nice tree decomposition of a k-colorable graph G, then the width of $(\mathcal{T}, X, r)$ is at most $k-1$. Hence, Lemma 7 shows that any chordal nice tree decomposition has at most $(k+3)n$ nodes. This bound is asymptotically sharp.

▶ **Theorem 8.** (proof omitted) *There are k-colorable chordal graphs G for which any chordal nice tree decomposition has at least $\Omega(kn)$ nodes.*

In order to show how to find a chordal nice tree decomposition in polynomial time we need the following lemma (proof omitted), which tells us how to select the proper type of root node when constructing such a tree decomposition. A terminal graph (G_1, T_1) is called *smaller* than another terminal graph (G_2, T_2) if $2|V(G_1)| - |T_1| < 2|V(G_2)| - |T_2|$.

▶ **Lemma 9.** *Let (G, T) be a terminal graph where $G = (V, E)$ is a chordal graph, and T is a clique with $T \neq V$. If $G - T$ is disconnected, then (G, T) can be obtained from a pair of smaller chordal terminal graphs (G_1, T) and (G_2, T) using a join operation. Otherwise, (G, T) can be obtained from a smaller chordal terminal graph (G', T') using either a forget or introduce operation, where T' is again a clique. For every such (G, T), the relevant operation and subgraph(s) can be found in polynomial time.*

By combining Lemmas 7 and 9 we obtain the following result.

▶ **Corollary 10.** *Let G be a chordal k-colorable graph on n vertices, and let T be a clique of G. In polynomial time, we can find a chordal nice tree decomposition of (G, T) on at most $(k + 3)n$ nodes.*

Proof. Lemma 9 shows how we can choose the proper type of root node. We can build the chordal nice tree decomposition by adding this node to the tree decomposition(s) of (a) smaller graph(s). The entire chordal nice tree decomposition is constructed by continuing this process recursively. Lemma 7 shows that the resulting chordal nice tree decomposition has at most $(w + 4)n$ nodes, where $w + 1$ is the maximum bag size. Since every bag is a clique of G and the graph is k-colorable, we have $w + 1 \leq k$, so there are at most $(k + 3)n$ nodes. Since we have a polynomial number of nodes, and for every node we spend polynomial time (Lemma 9), the entire process terminates in polynomial time. ◀

The precise complexity bound in Corollary 10 depends on implementation details beyond the scope of this paper.

Using an inductive proof based on Lemma 9, we will now characterize the shape of CSGs for $(k - 2)$-connected k-colorable chordal graphs. For integers m, k with $1 \leq m \leq k$, a labeled graph H, ℓ is an (m, k)-*color-complete graph* if there exists a set T with $|T| = m$ such that:

- for all vertices $v \in V(H)$, $\ell(v)$ is a k-coloring of a complete graph on vertex set T,
- every such k-coloring of T appears at exactly one vertex of H, and
- two vertices of H are adjacent if and only if their labels differ on exactly one element of T.

From this definition it follows that for every pair of integers m and k, there is a unique (m, k)-color complete graph, up to the choice of T. An (m, k)-color-complete graph has $k!/(k - m)!$ vertices (this is the number of ways to k-color a complete graph on m vertices), and every vertex has degree $m(k - m)$. In particular, if $m = k$ then the graph consists of $k!$ isolated vertices (which is a forest). A labeled graph H, ℓ is said to satisfy the *injective neighborhood property (INP)* if for every vertex $u \in V(H)$ and every pair of distinct neighbors $v, w \in N(u)$, it holds that $\ell(v) \neq \ell(w)$. Note that (m, k)-color-complete graphs trivially satisfy the INP. We prove Theorem 12 by first showing that for our graphs the following invariant (Theorem 11) is maintained by introduce, forget and join operations. This invariant can be proven by induction based on Lemma 9, using the rules from Section 3.

▶ **Theorem 11.** *Let $k \geq 3$. Let $G = (V, E)$ be a $(k - 2)$-connected k-colorable chordal graph, and let $T \subseteq V(G)$ be a clique of G with $m = |T| \geq k - 2$. Then $\mathcal{C}^c_k(G, T)$ is an (m, k)-color-complete graph, or it is a forest that satisfies the injective neighborhood property.*

Remark 2. Figure 1 shows that if we relax the connectivity requirement to $(k-3)$-connectedness, the above property does not necessarily hold anymore: the examples in Figure 1(c) and (d) are not forests, and the example in Figure 1(e) does not satisfy the INP.

The characterization of $\mathcal{C}_k^c(G,T)$ in Theorem 11 does not yet guarantee that simply keeping track of the (relevant component of the) CSG yields a polynomial-time algorithm, as shown by the second example in Section 3. However, we will now show that it suffices to only keep track of the following essential information, which remains polynomially bounded.

Let $G=(V,E)$ be a graph with $T\subseteq V$, and let α and β be k-colorings of a supergraph of G. (G should be viewed as a subgraph that occurs during the dynamic programming, while α and β are the colorings of the full graph.) Let $\alpha'=\alpha|_V$ and $\beta'=\beta|_V$. If $\mathcal{C}_k^c(G,T)$ is a forest with the α'-node x and β'-node y in the same component, then we define the *α-β-path* to be the unique path in $\mathcal{C}_k^c(G,T)$ with end vertices x and y (together with its vertex labels). Given the two colorings α and β, the *essential information* for $\mathcal{C}_k^c(G,T)$ consists of the following:

- whether the α' and β' nodes appear in the same component,
- whether $\mathcal{C}_k^c(G,T)$ is a forest, and
- in case the answers to both questions are yes: the α-β-path in $\mathcal{C}_k^c(G,T)$.

▶ **Theorem 12.** *For a k-colorable $(k-2)$-connected chordal graph G with two k-colorings α and β, we can decide in polynomial time whether $\mathcal{C}_k(G)$ contains an α-β path.*

Proof sketch: Corollary 10 shows that for every chordal k-colorable graph G on n vertices, we can find in polynomial time a chordal nice tree decomposition on at most $(k+3)n$ nodes. So every node of this tree decomposition corresponds to a $(k-2)$-connected chordal subgraph H of G with terminal set T, such that either H is a clique with $T=V(H)$ (leaf nodes), or (H,T) can be obtained from the graph(s) corresponding to its child node(s) using a forget, introduce or join operation. For every one of those terminal subgraphs, we compute the essential information, bottom up. If at any point, the α' and β' nodes are separated, the answer is NO. Forget, introduce and join operations maintain a forest. The lemmas from Section 3 show how the α-β-path can be computed. We return YES if in the root node, a color-complete graph or an α-β-path is obtained (Lemma 2). The total number of operations (tree decomposition nodes) is $O(kn)$. For every operation, the essential information can be computed in polynomial time (in the input size, which includes the path length). One can show that the maximum length of any α-β path that occurs during the computation is $O(kn)$. Hence, the algorithm terminates in polynomial time. ◀

We stress that (m,k)-color complete graphs, which have $k!/(k-m)!$ nodes, are not computed explicitly in our algorithm. So indeed, in order to obtain a polynomial-time algorithm, we do not need to assume that k is a constant.

5 Discussion

An obvious question is whether our polynomial-time algorithm for can be extended to all chordal graphs, or whether $\mathcal{C}_k$-Reachability is PSPACE-hard for chordal graphs. As $\mathcal{C}_3$-Reachability is polynomial-time solvable in general [13], the first open case is the complexity of $\mathcal{C}_4$-Reachability for chordal graphs (with at least one cut vertex). We refer to Remark 2 for a discussion on why our current proof technique does not work for this case. We also note that the complexity of $\mathcal{C}_4$-Reachability is open for proper interval graphs (initial experimental results for these graphs seem to suggest that even this problem is not straightforward to solve). The two most important future research goals are the following.

1. Explore for which other solution graph concepts $\mathcal{S}$ the DP method can be used to obtain polynomial-time algorithms for the $\mathcal{S}$-REACHABILITY problem. The DP method has now been used to obtain polynomial-time algorithms for several reconfiguration problems, but its true strength is not always revealed when using the viewpoint of worst-case algorithm analysis. For instance, when considering randomly generated k-colorable chordal or interval graphs, we observed that the method performs well on most instances, despite the fact that specialized examples can be constructed that exhibit exponential growth. As we noticed when considering other reconfiguration problems, this behavior seems to occur in general. Because of this, we will write a subsequent paper which will include computational studies, where we apply extensions of this method to various other reconfiguration problems such as well-studied variants of independent set reconfiguration problems (see e.g. [9, 26]).

2. Explore which known reconfiguration problems can be solved efficiently using CSGs. The method of using CSGs can easily be applied to solve the $\mathcal{S}$-CONNECTIVITY problem. Hence, this well-studied problem is a suitable candidate problem for the second research goal.

Abstract

The quantum PCP (QPCP) conjecture states that all problems in QMA, the quantum analogue of NP, admit quantum verifiers that only act on a constant number of qubits of a polynomial size quantum proof and have a constant gap between completeness and soundness. Despite an impressive body of work trying to prove or disprove the quantum PCP conjecture, it still remains widely open. The above-mentioned proof verification statement has also been shown equivalent to the QMA-completeness of the Local Hamiltonian problem with constant relative gap. Nevertheless, unlike in the classical case, no equivalent formulation in the language of multi-prover games is known.

In this work, we propose a new type of quantum proof systems, the Pointer QPCP, where a verifier first accesses a classical proof that he can use as a pointer to which qubits from the quantum part of the proof to access. We define the Pointer QPCP conjecture, that states that all problems in QMA admit quantum verifiers that first access a logarithmic number of bits from the classical part of a polynomial size proof, then act on a constant number of qubits from the quantum part of the proof, and have a constant gap between completeness and soundness. We define a new QMA-complete problem, the Set Local Hamiltonian problem, and a new restricted class of quantum multi-prover games, called CRESP games. We use them to provide two other equivalent statements to the Pointer QPCP conjecture: the Set Local Hamiltonian problem with constant relative gap is QMA-complete; and the approximation of the maximum acceptance probability of CRESP games up to a constant additive factor is as hard as QMA. Our new conjecture is weaker than the original QPCP conjecture and hence provides a natural intermediate step towards proving the quantum PCP theorem. Furthermore, this is the first equivalence between a quantum PCP statement and the inapproximability of quantum multi-prover games.

1 Introduction

The celebrated PCP theorem states that all languages in NP can be verified probabilistically by randomized verifiers that only check a constant number of bits of a polynomial size proof [6, 7, 10]. This theorem has far-reaching applications in complexity theory and especially in the inapproximability of certain optimization problems. This is because the PCP theorem can be recast in the following equivalent way: the approximation of MAX-SAT up to some constant additive factor is NP-complete. Let us also remark that the classical PCP

* This work was supported by the European Union (ERC project QCC 306537) and the ANR RDAM project.

theorem has a third very interesting equivalent formulation as approximation of the maximum acceptance probability of some polynomial size multi-prover interactive games [22]. This game formulation was fundamental in order to achieve better constants for the inapproximability results of a number of NP-hard problems.

One of the main questions in quantum complexity theory is whether one can prove an analogous statement for the class QMA, the quantum analogue of NP. The QPCP conjecture [2] has received a lot of attention due to its importance to both physics and theoretical computer science and an impressive body of work has provided either positive evidence [1, 11, 19] or negative [5, 3, 8]. There are many different ingredients that go into the proof of the classical PCP theorem, especially since there are two different ways of proving it, one through the proof system formulation and another more combinatorial way by looking directly at the inapproximability of constraint satisfaction problems. In the quantum setting, the positive and negative evidence has been mostly that certain techniques that had been used in the classical setting are applicable or not in the quantum setting. We note that the lack of a way of seeing the quantum PCP conjecture in a game context also prevents us from using some important techniques that are present in the classical case, such as the parallel repetition theorem. Overall, proving the quantum PCP theorem remains a daunting task.

The QPCP conjecture can be cast as a type of a proof system which we denote by $\mathsf{QPCP}(q, \alpha, \beta)$. Here a quantum verifier tosses a logarithmic number of classical coins and, based on the coin outcomes, decides on which q qubits from the polynomial-size quantum proof to perform a measurement. The measurement output decides on acceptance or rejection. A yes instance is accepted with probability at least α and a no instance is accepted with probability at most β, for some $\alpha > \beta$ [1, 2]. The formal conjecture is stated below.

▶ **Conjecture 1** (QPCP Conjecture – Proof verification version)**.** $\mathsf{QMA} = \mathsf{QPCP}(q, \alpha, \beta)$ *where* $q = O(1)$ *and* $\alpha - \beta = \Omega(1)$*.*

In quantum mechanics, the evolution of quantum systems are described by Hermitian operators called Hamiltonians. In nature, particles that are far apart tend not to interact so the global Hamiltonian can usually be described as a sum of local Hamiltonians. The Local Hamiltonian problem, denoted by $\textsc{LocalHam}(k, a, b)$, receives as input m Hamiltonians $H_1, \ldots, H_m$ where each one has norm at most 1 and describes the evolution of at most k qubits. The question is if there is a global state such that its energy is at most am or all states have energy at least bm for $b > a$. The area studying the above problem is called quantum Hamiltonian complexity [21, 13]. It began with Kitaev who showed that for $b - a \geq 1/\text{poly}(n)$, $\textsc{LocalHam}(5, a, b)$ is complete for the class QMA [4, 18]. It has subsequently been improved, reducing the locality of the Hamiltonians to two [16] and restricting their structure [17, 20, 9, 14]. These results imply that estimating the groundstate energy of a system within an inverse polynomial additive factor is hard. It is natural to ask if it still remains hard if we require only constant approximation. The physical interpretation of this problem is connected to the stability of entanglement in "room temperature".

The second version of the quantum PCP conjecture asks if $\textsc{LocalHam}(k, a, b)$ remains QMA-complete when $b - a$ is constant. It is stated formally in the conjecture below.

▶ **Conjecture 2** (QPCP Conjecture – Constraint satisfaction version)**.** *The Local Hamiltonian problem* $\textsc{LocalHam}(k, a, b)$ *is* QMA*-complete for* $k = O(1)$ *and* $b - a = \Omega(1)$*, where the* QMA*-hardness is with respect to quantum reductions.*

The two versions of the quantum PCP conjecture have been proven equivalent [2], and since Conjecture 2 is true for $b - a \geq 1/\text{poly}(n)$, we can also conclude that $\mathsf{QMA} = \mathsf{QPCP}(q, \alpha, \beta)$ with $q = O(1)$ and $\alpha - \beta \geq 1/\text{poly}(n)$.

Let us note that so far there is no multi-prover game equivalent to the QPCP conjecture, though the approximation of the maximum acceptance probability of certain multi-prover games up to an inverse-polynomial additive factor has been proven to be QMA-hard [12].

1.1 Our Results

In our work, we propose a new type of quantum proof systems, the Pointer QPCP, and formulate three equivalent versions of the Pointer QPCP conjecture. This may help towards proving or disproving the original QPCP conjecture. We start by describing a new proof system then we provide a new variant of the Local Hamiltonian problem and last we describe an equivalent polynomial size multi-prover game. Up to our knowledge, this is the first time a polynomial size multi-prover game has been proven equivalent to some QPCP conjecture.

Our new conjecture is a weaker statement than the original QPCP conjecture and hence it is an intermediate step which may be easier to prove. One may also try to prove the equivalence with the original conjecture, but despite being more structured than general QMA verifiers, Pointer QPCPs still have some characteristics, such as adaptiveness, which we do not know how to cast in term of the usual QPCPs. Moreover, having an equivalent game version of it might also lead to new methods that could potentially be relevant for attacking the original conjecture as well.

We now give some details of our results. We define a new quantum proof system, where the proof contains two separate parts, a classical and a quantum proof both of polynomial size. The verifier can first access a block from the classical proof and, depending on the content, he can then access a constant number of qubits from the quantum proof. Since the classical part can be seen as a pointer to the qubits that will be accessed, we denote this proof system by PointerQPCP(q, α, β). To be more specific, the verifier first reads a logarithmic number of bits from the classical part of the proof and then measures at most q qubits from the quantum part. He accepts a yes instance with probability at least α and a no instance with probability at most β. Since a Pointer QPCP is a generalization of QPCP, it follows that all problems in QMA have a PointerQPCP(q, α, β) proof system with $\alpha - \beta \geq 1/\text{poly}(n)$.

▶ **Conjecture 3** (Pointer QPCP Conjecture – Proof verification version). *It holds that* QMA $=$ PointerQPCP(q, α, β) *where* $q = O(1)$ *and* $\alpha - \beta = \Omega(1)$.

We note that quantum proof systems with classical and quantum parts have also appeared in [23]. There, the aim was to reduce the number of blocks being read in classical PCPs and hence, in the proposed model, a logarithmic size quantum proof is provided to the verifier who measures it and then reads only a single block from a polynomial size classical proof.

In addition to Pointer QPCPs, we also propose a "constraint satisfaction" version of the above conjecture which will turn out to be equivalent. We do this by defining a new variant of the Local Hamiltonian problem which we call the Set Local Hamiltonian problem. Here the input is m sets of a polynomial number of k-local Hamiltonians each, and we ask if there exists a representative Hamiltonian from each set such that the Hamiltonian corresponding to their sum has groundstate energy at most am or for every possible choice of representative Hamiltonians from each set, the Hamiltonian corresponding to their sum has groundstate energy at least bm. We denote the above problem by $\text{SLH}(k, a, b)$. Since the Local Hamiltonian problem is a special case of the Set Local Hamiltonian problem, where the sets are singletons, $\text{SLH}(k, a, b)$ is QMA-hard for $k \geq 2$ and $b - a \geq 1/\text{poly}(n)$.

▶ **Conjecture 4** (Pointer QPCP Conjecture – Constraint satisfaction version). *The* $\text{SLH}(k, a, b)$ *problem is* QMA*-complete for* $k = O(1)$ *and* $b - a = \Omega(1)$.

As mentioned earlier, the classical PCP theorem has another interesting equivalent formulation regarding the approximation of the maximum acceptance probability of multi-prover games [22], while the same is not known for the quantum case. We propose an equivalent multi-prover game formulation of the Pointer QPCP conjecture. Our game, which we call CRESP (Classical and Restricted-Entanglement Swapping-Provers) game, was inspired by the work of Fitzsimons and Vidick [12]. However, in order to prove an equivalence, we had to drastically change the game. In their work, a multi-prover game is proposed for the Local Hamiltonian problem in which the completeness-soundness gap is inverse polynomial. If we try to follow the same proof but with an instance of the Local Hamiltonian with constant gap, the gap does not survive and we end with an inverse-polynomial gap in the game. Hence we are not able to prove the equivalence with the standard QPCP conjecture.

We define our CRESP game to have one classical prover and logarithmically many quantum provers who are restricted both in the strategies they can perform and also in the initial quantum state they share. The verifier asks a single question of logarithmic length to all of them, the classical prover replies with logarithmically many bits, while the quantum provers reply with k 4-dimensional qudits. (For simplicity, we will omit the dimension of the qudit system in the rest of the paper.) The promise problem $\mathrm{CRESP}(k, \alpha, \beta)$ informally asks if we can distinguish between the cases when the provers win the game with probability at least α or at most β. Similarly to the previous problems, we will see that $\mathrm{CRESP}(k, \alpha, \beta)$ is QMA-complete for $\alpha - \beta \geq 1/\mathrm{poly}(n)$. See Theorem 22 for the precise statement.

▶ **Conjecture 5** (Pointer QPCP Conjecture – Game version). *The* $\mathrm{CRESP}(k, \alpha, \beta)$ *problem is* QMA*-complete for* $k = O(1)$ *and* $\alpha - \beta = \Omega(1)$*.*

Our main result is the equivalence of the above three formulations of the Pointer QPCP conjecture. It is stated formally in the following theorem.

▶ **Theorem 6** (Main theorem). *The three versions of the Pointer QPCP conjecture (Conjectures 3 to 5) are either all true or all false.*

The proof is divided into three steps: first, we show that Conjecture 3 implies Conjecture 4; second, we show that Conjecture 4 implies Conjecture 5; and finally, we prove that Conjecture 5 implies Conjecture 3.

The paper is organized as follows: In Section 2, we describe some standard definitions required for the rest of the paper. In Section 3, we present the definitions of our new notions, the Pointer QPCPs, the Set Local Hamiltonian problem, and the CRESP games. The proof of equivalence is presented in Section 4. We conclude the paper with some discussion and open problems in Section 5.

2 Preliminaries

In this section we provide some definitions that we use in the paper. We start by defining QMA, the quantum analogue of NP.

▶ **Definition 7** (Quantum Merlin-Arthur proof systems). Let $n \in \mathbb{Z}^+$ be the input size and p be a polynomial. A QMA protocol proceeds in the following steps.

1. The verifier receives an input x and a quantum proof $|\psi\rangle$ of size $p(n)$.
2. The verifier runs in polynomial time in n. He performs a general POVM measurement on $|\psi\rangle$ and decides on the acceptance or rejection of the input.

A promise problem $A = (A_{\mathrm{yes}}, A_{\mathrm{no}})$ belongs to QMA if it has a QMA proof system with the following properties.

Completeness. If $x \in A_{\text{yes}}$ then there is a $|\psi\rangle$ such that the verifier accepts w.p. at least $\frac{2}{3}$.
Soundness. If $x \in A_{\text{no}}$ then for all $|\psi\rangle$ the verifier accepts w.p. at most $\frac{1}{3}$.

Now we present the Local Hamiltonian problem, the quantum analogue of MAX-SAT.

▶ **Definition 8.** The *Local Hamiltonian* problem is denoted by $\textsc{LocalHam}(k, a, b)$ where $k \in \mathbb{Z}^+$ is called the locality and for $a, b \in \mathbb{R}$ it holds that $a < b$. It is the following promise problem. Let n be the number of the qubits of a quantum system. The input is a set of $m(n)$ Hamiltonians $H_1, \ldots, H_{m(n)}$ where m is a polynomial in n, $\forall i \in [m(n)] : 0 \leq H_i \leq \mathbb{1}$ and each H_i acts on k qubits out of the n qubit system. For $H \overset{\text{def}}{=} \sum_{j=1}^{m(n)} H_j$ the following two conditions hold.

- In a YES instance there exists a state $|\varphi\rangle \in \mathbb{C}^{2^n}$ such that $\langle\varphi| H |\varphi\rangle \leq a \cdot m(n)$.
- In a NO instance for all states $|\varphi\rangle \in \mathbb{C}^{2^n}$ it holds that $\langle\varphi| H |\varphi\rangle \geq b \cdot m(n)$.

Kitaev proved that for $k \geq 5$ and $b - a \geq 1/\mathit{poly}(n)$ the $\textsc{LocalHam}(k, a, b)$ problem is QMA-complete [18]. This completeness result was later improved for $k \geq 2$ [17].

We now define the quantum analogue of PCPs.

▶ **Definition 9** (Quantum Probabilistically Checkable Proofs). Let $n \in \mathbb{Z}^+$ be the input size and p be a polynomial. A QPCP protocol proceeds in the following steps.

1. The verifier receives an input x and a quantum proof $|\psi\rangle$ of size $p(n)$.
2. The verifier runs in time polynomial in n. He picks $O(\log n)$ bits uniformly at random, and based on the input and on the random bits, he performs a general POVM measurement on q qubits, and decides on acceptance or rejection of the input.

A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ belongs to $\mathsf{QPCP}(q, \alpha, \beta)$ if it has a QPCP proof system with the following properties.
Completeness. If $x \in A_{\text{yes}}$ then there is a $|\psi\rangle$ such that the verifier accepts w.p. at least α.
Soundness. If $x \in A_{\text{no}}$ then for all $|\psi\rangle$ the verifier accepts w.p. at most β.

We can easily prove the following statement:

▶ **Lemma 10.** *It holds that* $\mathsf{QMA} = \mathsf{QPCP}(q, \alpha, \beta)$ *where* $q = O(1)$ *and* $\alpha - \beta \geq 1/\text{poly}(n)$.

Proof. The containment $\mathsf{QPCP}(q, \alpha, \beta) \subseteq \mathsf{QMA}$ is trivial since the QMA verifier can read the whole proof and the power of QMA doesn't change if the gap is inverse-polynomial. The other direction of the containment follows from Kitaev's proof that the 5-Local Hamiltonian is QMA-complete [18, 4]. The QMA verifier in the proof is also a QPCP verifier. ◀

The quantum PCP conjecture has two equivalent versions:

▶ **Theorem 11** ([2]). *The class* QMA *is equal to the class* $\mathsf{QPCP}(q, \alpha, \beta)$ *with* $q = O(1)$ *and* $\alpha - \beta = \Omega(1)$ *(Conjecture 1) if and only if the Local Hamiltonian problem* $\textsc{LocalHam}(k, a, b)$ *is* QMA*-complete for* $k = O(1)$ *and* $b - a = \Omega(1)$*, where the* QMA*-hardness is with respect to quantum reductions (Conjecture 2).*

3 Pointer QPCPs, Set Local Hamiltonians, and CRESP Games

In this section, we present the definitions required for our conjectures. We start by defining Pointer QPCPs, a generalized version of QPCPs, in which the verifier can read a small number of bits from the classical part of the proof and then, based on that, read a constant number of qubits from the quantum part of the proof. Then we propose the Set Local Hamiltonian problem that can be thought of as a "constraint satisfaction" version of the conjecture. Finally, we define CRESP games which are restricted multi-prover games for which approximation of their value will turn out to be equivalent to the other two formulations.

3.1 Pointer QPCPs

▶ **Definition 12.** Let $n \in \mathbb{Z}^+$ be the input size, let q be a fixed parameter and let m, l, p be polynomials. A Pointer QPCP protocol proceeds in the following steps.

1. The verifier receives an input x and a two-part proof of size $m(n) + p(n)$ in the form $y_1...y_{m(n)} \otimes |\psi\rangle$, where where $y_i \in [l(n)]$ (i.e. each y_i can be written with $O(\log n)$ bits) and $|\psi\rangle$ is a state of $p(n)$ qubits. We refer to $y_1...y_{m(n)}$ as the classical part of the proof and $|\psi\rangle$ as the quantum part of the proof.
2. The verifier runs in time polynomial in n. He chooses uniformly at random a position $i \in [m(n)]$ of the classical proof to read. Then, based on his input, the random bits and the value of y_i, he chooses q qubits from the quantum proof, performs a general POVM measurement on them, and decides on acceptance or rejection of the input.

A promise problem $A = (A_{\text{yes}}, A_{\text{no}})$ belongs to $\mathsf{PointerQPCP}(q, \alpha, \beta)$ if it has a Pointer QPCP proof system with the following properties.

Completeness. If $x \in A_{\text{yes}}$ then there exists a $y_1...y_{m(n)} \otimes |\psi\rangle$ such that verifier accepts w.p. at least α.

Soundness. If $x \in A_{\text{no}}$ then for all $y_1...y_{m(n)} \otimes |\psi\rangle$ the verifier accepts w.p. at most β.

▶ **Lemma 13.** $\mathsf{QMA} = \mathsf{PointerQPCP}(q, \alpha, \beta)$ *where* $q = O(1)$ *and* $\alpha - \beta \geq 1/\text{poly}(n)$.

Proof. Since Pointer QPCPs are generalizations of QPCPs, we have that $\mathsf{QPCP}(q, \alpha, \beta) \subseteq \mathsf{PointerQPCP}(q, \alpha, \beta)$ for any values of q, α, and β. From Lemma 10, it follows that $\mathsf{QMA} \subseteq \mathsf{PointerQPCP}(q, \alpha, \beta)$. The other direction of the containment follows trivially since the QMA verifier can read the whole proof. ◀

Conjecture 3 asks whether QMA also has Pointer QPCPs with $q = O(1)$ and $\alpha - \beta = \Omega(1)$.

3.2 The Set Local Hamiltonian Problem

We define a new QMA-complete problem which is a generalization of the Local Hamiltonian problem and which will lead to another version of our conjecture.

▶ **Definition 14** (Set Local Hamiltonian Problem)**.** The *Set Local Hamiltonian* problem is denoted by $\text{SLH}(k, a, b)$ where $k \in \mathbb{Z}^+$ is called the locality and for $a, b \in \mathbb{R}$ it holds that $a < b$. It is the following promise problem. Let n be the number of the qubits of a quantum system, and m and l be two polynomials. The input for the problem are $m(n)$ sets of Hamiltonians. For all $i \in [m(n)]$ the set $\mathbf{H}_i$ contains $l(n)$ Hamiltonians, i.e., $\forall i \in [m(n)] : \mathbf{H}_i = \left\{H_{i,1}, \ldots, H_{i,l(n)}\right\}$. Each Hamiltonian is positive and has norm at most one, i.e., $\forall i \in [m(n)], \forall j \in [l(n)] : 0 \leq H_{i,j} \leq \mathbb{1}$. Each Hamiltonian acts non-trivially on at most k qubits out of the n qubits of the quantum system. The problem is to decide which one of the following two conditions hold.

- In a YES instance, there exists a function $f : [m(n)] \to [l(n)]$ and a state $|\varphi\rangle \in \mathbb{C}^{2^n}$ such that $\langle\varphi| \sum_{i=1}^{m(n)} H_{i,f(i)} |\varphi\rangle \leq a \cdot m(n)$.
- In a NO instance, for all functions $f : [m(n)] \to [l(n)]$ and for all states $|\varphi\rangle \in \mathbb{C}^{2^n}$, we have that $\langle\varphi| \sum_{i=1}^{m(n)} H_{i,f(i)} |\varphi\rangle \geq b \cdot m(n)$.

▶ **Lemma 15.** *The* $\text{SLH}(k, a, b)$ *problem is* QMA*-complete for* $k \geq 2$ *and* $b - a \geq 1/\text{poly}(n)$.

Proof. For the containment $\text{SLH}(k, a, b) \in \mathsf{QMA}$, let the witness have a classical part that contains the description of the function f and a quantum part that is supposed to be the state $|\varphi\rangle$. The quantum verifier can then apply the usual eigenvalue estimation on $\sum_{i=1}^{m(n)} H_{i,f(i)}$. The hardness of $\text{SLH}(k, a, b)$ comes trivially from the fact that Local Hamiltonian problem is a special case of the Set Local Hamiltonian problem with $l(n) = 1$. ◀

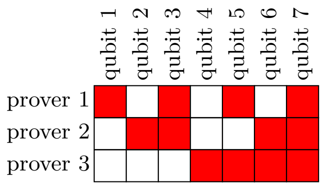

Figure 1 A possible distribution of the encoding of 7 qubits among 3 provers. The red cells correspond to the GHZ-like entangled states, while the white cells to $|0\rangle$ states.

Note that Conjecture 4 asks whether the Set Local Hamiltonian problem remains QMA-complete when the locality is constant and the gap between b and a is also constant.

3.3 CRESP Games

We now formally describe a new variant of quantum multi-prover games. These games are rather restricted but will allow us to state a third variant of our pointer QPCP conjecture.

3.3.1 Description of the Game

Let $n \in \mathbb{Z}^+$ be a parameter and m be a polynomial. The size of the game will be polynomial in n. The game is played by one classical prover, $\lceil \log(n+1) \rceil$ quantum provers, and a verifier. It is played as follows.

1. The quantum provers share the encoding of an arbitrary n-qubit state. (The encoding maps each qubit into a number of qudits and will be defined later.) They are not allowed to share any other resources.
2. The verifier picks a question i uniformly at random out of the $m(n)$ possible questions and sends the same question to all the provers (both quantum and classical).
3. The classical prover replies with $O(\log n)$ bits.
4. Each quantum prover replies by at most k qudits from their shared encoded state. All the quantum provers use the same strategy.
5. The verifier accepts or rejects, based on his question and the answers from the provers.

We denote these games by the acronym CRESP after the **C**lassical prover, the **R**estricted **E**ntanglement that the quantum provers can share and, since the only possible strategy the quantum provers can perform is to swap some of their qudits into the message register, we call them **S**wapping-**P**rovers.

3.3.2 Restriction on the Entanglement

The entangled state the provers share is of the following predefined form. First, the provers pick an arbitrary n-qubit state $|\phi\rangle \in \mathbb{C}^{2^n}$. The state $|\phi\rangle$ is encoded with a linear isometry $\mathcal{E} = \mathcal{E}_1 \otimes \mathcal{E}_2 \otimes \ldots \otimes \mathcal{E}_n$ where each qubit of $|\phi\rangle$ is encoded with $\mathcal{E}_i : \mathbb{C}^2 \to \bigotimes_{j=1}^{\lceil \log(n+1) \rceil} \mathcal{H}_{i,j}$. For all i and j, $\mathcal{H}_{i,j} \cong \mathbb{C}^4$, that is, $\mathcal{H}_{i,j}$ is a four-dimensional space which we simply call qudit. To define $\mathcal{E}_i$, let's fix some ordering on the non-empty subsets of $[\lceil \log(n+1) \rceil]$. Let Q_i be the i-th subset, $\mathcal{S}_i \overset{\text{def}}{=} \bigotimes_{j \in Q_i} \mathcal{H}_{i,j}$, and $\overline{\mathcal{S}_i} \overset{\text{def}}{=} \bigotimes_{j \notin Q_i} \mathcal{H}_{i,j}$. For each $i \in [n]$, we define

$\mathcal{E}_i$ by giving its action on the standard basis states.

$$\mathcal{E}_i(|0\rangle) \overset{\text{def}}{=} \frac{1}{\sqrt{2}} \left(|0\rangle^{\otimes|Q_i|} + |1\rangle^{\otimes|Q_i|}\right)_{\mathcal{S}_i} \otimes \left(|0\rangle^{\otimes\lceil\log(n+1)\rceil-|Q_i|}\right)_{\overline{\mathcal{S}_i}} \tag{1}$$

$$\mathcal{E}_i(|1\rangle) \overset{\text{def}}{=} \frac{1}{\sqrt{2}} \left(|2\rangle^{\otimes|Q_i|} + |3\rangle^{\otimes|Q_i|}\right)_{\mathcal{S}_i} \otimes \left(|0\rangle^{\otimes\lceil\log(n+1)\rceil-|Q_i|}\right)_{\overline{\mathcal{S}_i}} \tag{2}$$

We refer to the states in $\mathcal{S}_i$ as GHZ-like states. After $\mathcal{E}$ is applied, prover j receives the qudits that live in space $\bigotimes_{i=1}^{n} \mathcal{H}_{i,j}$. A possible distribution of the qudits is depicted in Figure 1.

We remark that despite being forced to share a state in a specific encoded form, the Provers still have all the freedom to choose the original state to be encoded, which lives in a 2^n dimensional Hilbert space.

3.3.3 Description of the CRESP Problem

We are interested in the maximum acceptance probability the provers can achieve, which is called the value of the game. Here the maximum is taken over all legitimate shared states and all legitimate provers' strategies. We now define the promise problem that corresponds to the approximation of the value of CRESP games.

▶ **Definition 16.** Let $k \in \mathbb{Z}^+$ and $\alpha, \beta \in \mathbb{R}$ with $\alpha > \beta$. Then, CRESP(k, α, β) is the following promise problem. The input is the description of a CRESP game defined above where the quantum provers answer at most k qudits and the following conditions hold.

- In a YES instance the value of the game is at least α.
- In a NO instance the value of the game is at most β.

We will prove that the CRESP(k, α, β) problem is QMA-complete for $k = O(1)$ and $\alpha - \beta \geq 1/\text{poly}(n)$. We defer this proof to Section 4.2 as it needs results that we will establish later. Again, we note that Conjecture 5 asks whether CRESP(k, α, β) remains QMA-complete when $k = O(1)$ and $\alpha - \beta = \Omega(1)$.

4 Equivalence of Our QPCP Conjectures

In this section we prove Theorem 6, the equivalence of the three versions of our Pointer QPCP conjecture. The proof proceeds in the following three steps. In Section 4.1, we show that if Conjecture 3 is true then Conjecture 4 is also true. We do this by reducing any problem with a Pointer QPCP proof system to the Set Local Hamiltonian problem. In Section 4.2 we show that if Conjecture 4 is true then Conjecture 5 is also true by giving a reduction from the Set Local Hamiltonian problem to our decision problem involving CRESP games. To complete the cycle, we prove in Section 4.3 that if Conjecture 5 is true then Conjecture 3 is also true by giving a Pointer QPCP proof system for an arbitrary CRESP game.

4.1 From Pointer QPCP to the Set Local Hamiltonian Problem

In this section we show that if Conjecture 3 is true then Conjecture 4 is also true. We show that any problem $P \in$ PointerQPCP(q, α, β) is polynomial-time reducible to SLH$(q, 1-\alpha, 1-\beta)$. Assuming Conjecture 3, this means that the Set Local Hamiltonian problem is QMA-hard. The containment of the Set Local Hamiltonian problem in QMA is implied by Lemma 15.

▶ **Theorem 17.** *Any problem $P \in$ PointerQPCP(q, α, β) can be reduced to* SLH$(q, 1-\alpha, 1-\beta)$ *in polynomial time.*

Proof. Let $y_1, \ldots, y_m$ be the classical part of the proof where $m = m(n)$ for a polynomial m and $|\psi\rangle$ be the quantum part of the proof, which contains $p(n)$ qubits, for a polynomial p. Suppose that each y_i can take $l = l(n)$ different values, for a polynomial l. We construct an instance of the Set Local Hamiltonian problem that consists of m sets of Hamiltonians $\mathbf{H}_i$, for $i \in [m]$, where $\mathbf{H}_i = \{H_{i,j}\}_{j\in[l]}$ and the Hamiltonians act on a $p(n)$-qubit system. Let $H_{i,j}$ be the rejection POVM generated by the Pointer QPCP verifier (who runs in quantum polynomial time) over the constant number of qubits when he reads register i from the classical part of the proof and it contains the value j, i.e., $j = y_i$.

First we prove that if there is a proof that makes the Pointer QPCP verifier accept with probability greater than α then there is a function f such that the groundstate of $\sum_{i=1}^{m} H_{i,f(i)}$ has energy at most $(1-\alpha)m$. Let $y_1...y_m \otimes |\psi\rangle$ be such proof and let α_i be the acceptance probability of the Pointer QPCP verifier when the verifier queries i. Since the verifier picks an i uniformly at random, it follows that $\frac{1}{m}\sum_i \alpha_i = \alpha$. Let $f(i) \overset{\text{def}}{=} y_i$. In this case, the energy of $|\psi\rangle$ on $\sum_i H_{i,f(i)}$ is

$$\langle\psi| \left(\sum_i H_{i,y_i}\right) |\psi\rangle \leq \sum_i (1-\alpha_i) = (1-\alpha)m.$$

For the other direction of the proof, suppose that there is a function f and a state $|\psi\rangle$ such that $\langle\psi| \left(\sum_i H_{i,f(i)}\right) |\psi\rangle \leq (1-\beta)\,m$. Then there is a proof that makes the Pointer QPCP verifier accept with probability bigger than β. Let $(f(1), f(2), ..., f(m)) \otimes |\psi\rangle$ be the proof for the Pointer QPCP verifier, and in this case the acceptance probability is

$$\frac{1}{m}\sum_i (1 - \langle\psi| H_{i,f(i)} |\psi\rangle) = 1 - \frac{1}{m}\langle\psi| \left(\sum_i H_{i,f(i)}\right) |\psi\rangle \geq \beta.$$

This finishes the proof of the reduction. ◀

4.2 From the Set Local Hamiltonian Problem to CRESP Games

In this section we show that if Conjecture 4 is true then Conjecture 5 is also true. We do this by giving a reduction from the SLH(k,a,b) problem to the CRESP$(k, 1-a/2, 1-b/2)$ problem. Assuming Conjecture 4, this implies that the CRESP$(k, 1-a/2, 1-b/2)$ problem is QMA-hard. We prove the containment CRESP$(k, 1-a/2, 1-b/2) \in$ QMA in Theorem 22.

We construct a CRESP game for the Set Local Hamiltonian problem. The main idea in the construction is the following. In our game, the verifier picks an index $i \in [m]$ uniformly at random and sends i to all the provers. The classical prover tells the verifier the specific Hamiltonian that should be taken from set i, i.e., the value of $f(i)$. The quantum provers replies with the encoding of the qubits of groundstate of the Hamiltonian $\sum_i H_{i,f(i)}$.

First, the verifier checks if the received qudits lie in the codespaces of the qubits of $H_{i,f(i)}$, and if not he rejects. Using the definition of the encoding, the projector onto the codespace of the qubit q is described by

$$(\Pi_q)_{\mathcal{S}_q} \otimes |0\rangle\langle 0|_{\overline{\mathcal{S}_q}}, \text{ with } \Pi_q = \frac{1}{2}\left(\sum_{u,v\in\{0,1\}} \left|u^{|Q_q|}\right\rangle \left\langle v^{|Q_q|}\right| + \sum_{w,z\in\{2,3\}} \left|w^{|Q_q|}\right\rangle \left\langle z^{|Q_q|}\right|\right).$$

If the above test succeeds then the verifier picks a bit uniformly at random and if it is 0, he accepts. Otherwise, the verifier decodes the answered qudits by inverting the mapping $\mathcal{E}$, defined by Equations 1 and 2, for all the qubits in Hamiltonian $H_{i,f(i)}$. Then, he performs

Protocol 1 CRESP Game for SLH(k, a, b)

1. The provers pick an n-qubit state $|\phi\rangle$ and share its encoding $\mathcal{E}(|\phi\rangle)$. (In the honest case, $|\phi\rangle$ is supposed to be the groundstate of Hamiltonian H.)
2. The verifier picks $i \in [m]$ uniformly at random and sends it to all the provers.
3. The classical prover sends some $j \in [l]$.
4. Each quantum prover sends k qudits.
5. The verifier performs the following tests.
   - T_1. Check if the answered qudits lie in the codespaces of the qubits of $H_{i,f(i)}$ and reject if not. Otherwise, continue.
   - T_2. Pick $b \in \{0, 1\}$ uniformly at random and accept if $b = 0$. Otherwise, continue.
   - T_3. Decode the received qudits and perform the measurement specified by $H_{i,f(i)}$ and accept or reject depending on the outcome.

the measurement that corresponds to $H_{i,f(i)}$ on the decoded qubits and accepts or rejects based on the outcome.

If the Hamiltonian $\sum_i H_{i,f(i)}$ has an eigenstate with small eigenvalue then the provers will pass the test with high probability. Using the fact that the provers share a state in the predefined encoding and the restriction on the quantum provers' strategies, we also show that the verifier will reject with high probability if all states have high eigenvalues. The description of the game is in Protocol 1.

▶ **Theorem 18.** *The game defined by Protocol 1 has completeness $1 - a/2$ and soundness $1 - b/2$.*

Proof. Lemma 19 proves completeness while Lemma 21 proves soundness. ◀

▶ **Lemma 19** (Completeness)**.** *If there is a function f such that the groundstate of $\sum_i H_{i,f(i)}$ has eigenvalue at most am then the maximum acceptance probability of the game is at least $1 - a/2$.*

Proof. Let the quantum provers share $\mathcal{E}(|\psi\rangle)$, the encoding of the groundstate $|\psi\rangle$ of $H \stackrel{\text{def}}{=} \sum_i H_{i,f(i)}$. When the verifier queries i, the classical prover answers $f(i)$ and all quantum provers honestly reply with their shares of the encodings of the k qubits corresponding to $H_{i,f(i)}$. The verifier always measures Π_i, and hence he accepts with probability

$$\frac{1}{2} + \frac{1}{2}\left(1 - \frac{1}{m}\sum_{i=1}^{m} \langle\psi| H_{i,f(i)} |\psi\rangle\right) = 1 - \frac{1}{2m}\langle\psi| H |\psi\rangle \geq 1 - \frac{a}{2}.$$ ◀

The following technical lemma is the key to prove soundness. It establishes that when the provers reply with the qudits that belong to the encoding of a different qubit, the verifier will detect it with probability at least half. We defer the full proof of this lemma to the full version of the paper.

▶ **Lemma 20.** *If the provers are asked for the encoding of qubit i and they answer with the qudits that correspond to the encoding of a different qubit, then the answered state projects to the correct codespace, i.e., the subspace that corresponds to the projector Π_i, with probability at most $1/2$.*

Proof Sketch. Since the provers have the same strategy for a fixed question and they can only do swaps, the only cheating strategy for the provers is to answer the encoding of a qubit which is different from the one the verifier asked for. In this case, by the properties of the chosen encoding, the state that should be a GHZ-like state is actually separable and it projects to the correct codespace with probability at most half. ◀

We sketch now the proof of the soundness property and defer its full proof to the full version of the paper.

▶ **Lemma 21** (Soundness). *If, for all functions f, the groundstate of $\sum_i H_{i,f(i)}$ has eigenvalue at least bm then the maximum acceptance probability of the game is at most $1 - b/2$.*

Proof Sketch. We can prove, using Lemma 20 and tests T_1 and T_2, that the optimal strategy for the provers is to answer honestly the encoding of the asked qubits. In this case, we can bound the maximum acceptance probability in the game using the fact that the original Hamiltonian has no low-energy groundstate. ◀

We now show that even though our game seems very restricted, it is in fact QMA-hard to approximate its value to within an inverse-polynomial precision.

▶ **Theorem 22.** *The* CRESP(k, α, β) *problem is* QMA*-complete for $k = O(1)$ and $\alpha - \beta \geq 1/\mathrm{poly}(n)$.*

Proof. The containment in QMA is simple: The QMA proof is the state the provers choose before the encoding together with the classical information that describes the behavior of all the provers. Then the QMA verifier can create the encoding and simulate the game. This leads to the same acceptance probability as that of the game which means that there is an inverse-polynomial gap between completeness and soundness in the QMA protocol. The QMA-hardness follows from Lemma 15 and Theorem 18. ◀

4.3 From CRESP Games to Pointer QPCPs

In this section we show that if Conjecture 5 is true then Conjecture 3 is also true. We do this by proving that CRESP$(k, \alpha, \beta) \in$ PointerQPCP(k, α, β). Assuming Conjecture 5, this implies that QMA $\subseteq$ PointerQPCP(k, α, β). The inclusion PointerQPCP$(k, \alpha, \beta) \subseteq$ QMA follows trivially, the same way as in Lemma 13.

▶ **Theorem 23.** CRESP$(k, \alpha, \beta) \in$ PointerQPCP(k, α, β).

Proof. In CRESP games, the strategy of the quantum provers consists of the choice of the shared state and the choice of which qudits to answer for each one of the verifier's questions. For the classical prover, the strategy consists of the his answers for each one of the verifier's questions. Therefore, we can have a Pointer QPCP whose proof will be as follows: for the classical part, for each possible question of the verifier, we include the indices of the qudits answered by the quantum provers and the answer of the classical prover. The quantum part of the proof will be the shared state before the encoding. With this information, the Pointer QPCP verifier can simulate the provers and the verifier of the CRESP game.

Formally, the verifier of the Pointer QPCP protocol is provided a proof of the form $y_1 \ldots y_m \otimes |\psi\rangle$, where y_i can be seen as a pair (s_i, c_i). The verifier will do the following.

1. He picks a question i uniformly at random as the verifier of the game.
2. He reads the corresponding strategy of the provers, i.e., (s_i, c_i).
3. He creates the encoding of the qubits that are specified by strategy s_i.

4. He simulates the verifier of the game using the encoded qubits as the quantum provers' answers and c_i as the classical prover's answer.
5. He accepts if and only if the verifier of the game accepts.

In our construction, we crucially use the fact that each quantum prover has the same strategy, as otherwise, the QPCP verifier would need to read out the strategies of each prover, which would require $\Omega\left(\log^2(n)\right)$ bits of information. Note that we only read out k qubits from the quantum part of the proof. We are left to prove completeness and soundness.

For completeness, it is not hard to see that if there is a strategy for the provers in the game with acceptance probability p then there is a Pointer QPCP that accepts with probability p as well, just by providing the values of s_i, c_i, and $|\psi\rangle$ that lead to acceptance with probability p in the game.

For soundness, if there are values of $y_i = (s_i, c_i)$ and $|\psi\rangle$ that make the Pointer QPCP verifier accept with some probability then these values can be translated to strategies of the provers in the CRESP game that will achieve the same acceptance probability. ◀

5 Discussions and Open Problems

We defined a new variant of quantum proof systems, the Pointer QPCPs, and provided three equivalent versions of the Pointer QPCP conjecture. Our conjecture is weaker than the original QPCP conjecture and hence may be easier to prove, which might also be facilitated with its equivalent game formulation. On the contrary, proving its equivalence to the QPCP conjecture, and hence dealing with the adaptivity property, might provide some insight on proving the original QPCP conjecture.

It is an interesting question to see whether we can define a more natural game which is equivalent to the Pointer QPCP conjecture. For our equivalence, we were forced to impose stringent constraints on the game. Nevertheless, it seems that if we allow the quantum provers to either share some more general entangled state or apply any operator to the state they share other than swapping, then it is not clear how not to lose the constant gap when constructing the witness [12, 15] or not to increase the question size to exponential [19].

Even with our constraints, CRESP games remain equivalent to Pointer QPCPs. Since Pointer QPCPs are a superclass of QPCPs, finding a game that is equivalent to the original QPCP would potentially impose even further constraints. One of the main problems going from a game back to Local Hamiltonians or QPCPs, is that to simulate the game, the strategies of the provers must be somehow simulated and when we try to do this with Local Hamiltonians, the gap vanishes, while for QPCPs, we require the classical pointer queries. Note that, in the Set Local Hamiltonian problem the gap doesn't depend on the size of the sets, by definition. Whereas, if we want to go to the usual Local Hamiltonian problem then the absolute gap is divided by the total number of Hamiltonians and so the gap vanishes.

A Formal Exploration of Nominal Kleene Algebra

Paul Brunet[1] **and Damien Pous**[*2]

2 Univ Lyon, CNRS, ENS de Lyon, UCB Lyon 1, LIP

Abstract

An axiomatisation of Nominal Kleene Algebra has been proposed by Gabbay and Ciancia, and then shown to be complete and decidable by Kozen et al. However, one can think of at least four different formulations for a Kleene Algebra with names: using freshness conditions or a presheaf structure (types), and with explicit permutations or not. We formally show that these variations are all equivalent.

Then we introduce an extension of Nominal Kleene Algebra, motivated by relational models of programming languages. The idea is to let letters (i.e., atomic programs) carry a set of names, rather than being reduced to a single name. We formally show that this extension is at least as expressive as the original one, and that it may be presented with or without a presheaf structure, and with or without syntactic permutations. Whether this extension is strictly more expressive remains open.

All our results were formally checked using the Coq proof assistant.

1 Introduction

Gabbay and Ciancia introduced a nominal extension of Kleene algebra [3], as a framework for trace semantics with dynamic allocation of resources. The associated semantics extends formal languages into nominal languages, where words have a nominal structure. Kozen et al. recently proved the completeness of the proposed axiomatisation [6], and proposed a coalgebraic treatment [5] yielding decidability of the equational theory.

They use the following syntax for nominal regular expressions:

$$e, f ::= a \in \Sigma \mid 0 \mid 1 \mid e + f \mid e \cdot f \mid e^\star \mid \nu a.e \ ,$$

where Σ is the alphabet, and $\nu a.e$ makes it possible to generate a fresh letter (or name) a before continuing as e. For instance, the expression $\nu a.\nu b.(a{\cdot}b)$ denotes the language of all words of length two consisting of two distinct letters.

While such a syntax is natural from a nominal point of view, other choices are possible. For instance, one might expect expressions to be typed or classified according to their set of free names. Similarly, name permutations, which are available in any model, can be reified at the syntactic level. We first list four axiomatisations of the corresponding presentations—one

* This author was funded by the European Research Council (ERC) under the European Union's Horizon 2020 programme (CoVeCe, grant agreement No 678157); this work has also been supported by the project ANR 12IS02001 PACE.

of them corresponding to Gabbay and Ciancia's axiomatisation, and we prove that all choices are in fact equivalent. For the sake of the proofs, we need to introduce the *positive* fragments, where the constant 0 denoting the empty language is excluded; these fragments are interesting because they are *stable*: any proof of an equality whose members belong to the fragment only uses expressions from that fragment.

Kleene algebra are known to be complete not only with respect to language models, but also relational models. There, the letters from the alphabet are interpreted as binary relations, and the regular operations correspond to standard operations on binary relations: union, composition, reflexive transitive closure. This makes it possible to interpret imperative programs, seen as state transformers: binary relations between memory states. Kozen actually designed an extension of Kleene algebra, Kleene algebra with tests [4], which makes it possible to represent not only the control flow of such programs, but also the tests and conditions appearing in while loops and branching statements.

Extending Kleene algebra with names seems appropriate to model imperative programs with local variables, where parts of the memory is visible only locally. The previous notion of nominal Kleene algebra is however not really appropriate for this purpose: letters of the alphabet (i.e., atomic programs, instructions) are equated with names bound by the $\nu a.e$ construct (i.e., memory locations). In contrast, the instruction $x \leftarrow y$ that assigns to variable x the value of variable y should be an elementary construction depending on the names x and y. For this reason, we provide an extension of the syntax where letters carry a list of names. (We could use arbitrary nominal sets, but we restrict to a concrete representation in this work for the sake of simplicity.) The typed version of this extension is more appropriate for modelling imperative programs with local variables; like above for plain nominal Kleene algebra, we show that the various presentations are equivalent. We moreover show that the extension is conservative: plain nominal Kleene algebra can be encoded into the extended ones. Whether a converse encoding is possible remains open.

Outline. We define the various theories in Section 2 and we compare them in Section 3. In Section 4 we provide a relational interpretation for our extended model. We conclude in Section 5.

Notation. We write $\wp_f(A)$ for the set of finite subsets of A. The set of natural numbers is written $\mathbb{N}$. Composition of two functions f and g is written $f \circ g$; it maps x to $f(g(x))$.

2 Expressions and proofs

2.1 Atoms and letters

Let $\mathcal{A}$ be an infinite set of *atoms* with decidable equality. We consider in this paper *finitely supported permutations of atoms*, simply called permutations in the following. They are bijections π such that there is a finite set $A \subseteq \mathcal{A}$ such that $a \notin A \Rightarrow \pi(a) = a$. The *inverse* of a permutation π is written π^{-1}. The *identity permutation* is denoted by $()$, and the permutation exchanging a and b, and leaving every other atom unchanged, is written $(a\ b)$. Finally, if π is a permutation and A is a finite set of atoms, $\pi(A) := \{\pi(a) \mid a \in A\}$ is *the image of A under π*.

We consider as *letters* an arbitrary nominal set $\mathcal{L}$[2, 7], which we assume to be decidable. Such a set is specified through the data of its set of elements, a function $\natural() : \mathcal{L} \to \wp_f(\mathcal{A})$ mapping every element to its *support*, and an *action* of the group of permutations on $\mathcal{L}$.

These functions must satisfy the following axioms:

$$\forall x \in \mathcal{L}, \forall \pi, (\forall a \in \natural(x), \pi(a) = a) \Rightarrow \pi(x) = x. \quad (1)$$

$$\forall x \in \mathcal{L}, \forall \pi, \natural(\pi(x)) = \pi(\natural(x)). \quad (2)$$

$$\forall x \in \mathcal{L}, \forall \pi, \pi', \pi(\pi'(x)) = \pi \circ \pi'(x). \quad (3)$$

2.2 Expressions and sets of expressions

We define a single type for expressions, containing all possible operators, and we define several fragments of it afterwards. Doing so makes it possible to share several definitions, enabling important code-reuse in our proof scripts.

▸ **Definition 1** (Expressions). The set $\mathbb{E}$ of *expressions* is composed of terms formed over the following syntax, where the letter A is a finite set of atoms, π denotes a permutation, a is an atom and l is a letter:

$$e, f \coloneqq 0 \mid 1 \mid e+f \mid e\cdot f \mid e^\star \mid \nu_a.e \mid l \mid a \mid \langle\pi\rangle e \mid \bot_A \mid id_A \mid w_a.e.$$

Product $(\cdot)$, sum $(+)$ and Kleene star $(\cdot^\star)$ are the regular operations, together with the associated constants 0 and 1, ν_a is name restriction. Variables can be either letters l or atoms a. We include a syntactic construction for explicit permutations $\langle\pi\rangle$. The remaining entries ($\bot_A$, id_A, and w_a) are for the presheaf presentation; we discuss them in Section 2.2.2

2.2.1 Untyped expressions

▸ **Definition 2** (Untyped expression). An expression e is *untyped* if it neither contains the operator w_a nor the constants $\bot_A$ and id_A. The set of untyped expressions is written $\mathbb{U}$.

We define freshness only for untyped expressions:

▸ **Definition 3** (Freshness). An atom a *is fresh for* e if the judgement $a \# e$ can be inferred in the following system.

$$\frac{}{a \# 1} \qquad \frac{}{a \# 0} \qquad \frac{a \notin \natural(l)}{a \# l} \qquad \frac{a \neq b}{a \# b} \qquad \frac{a \# e \quad a \# f}{a \# e+f}$$

$$\frac{a \# e \quad a \# f}{a \# e\cdot f} \qquad \frac{a \# e}{a \# e^\star} \qquad \frac{}{a \# \nu_a.e} \qquad \frac{a \# e}{a \# \nu_b.e} \qquad \frac{\pi^{-1}(a) \# e}{a \# \langle\pi\rangle e}.$$

Accordingly, the *support* of an untyped expression e, written $\natural(e)$, is the unique set such that $\forall a,\ a \# e \Leftrightarrow a \notin \natural(e)$.

2.2.2 Typed expressions

For the presheaf approach, we replace freshness assumptions with type derivations. In order to enforce uniqueness of types, we replace the constants 0 and 1 from the untyped syntax by the annotated constants $\bot_A$ and id_A, and we use explicit weakenings (w_a).

▸ **Definition 4** (Typed expressions). For any $e \in E$ and $A \in \wp_f(\mathcal{A})$, e *has the type* A if the judgement $e : A$ can be inferred in the following system:

$$\frac{}{id_A : A} \qquad \frac{}{\bot_A : A} \qquad \frac{l \in \mathcal{L}}{l : \natural(l)} \qquad \frac{a \in \mathcal{A}}{a : \{a\}} \qquad \frac{e : A \quad f : A}{e+f : A}$$

$$\frac{e : A \quad f : A}{e\cdot f : A} \qquad \frac{e : A}{e^\star : A} \qquad \frac{e : A \cup \{a\} \quad a \notin A}{\nu_a.e : A} \qquad \frac{e : A \setminus \{a\} \quad a \in A}{w_a.e : A} \qquad \frac{e : \pi^{-1}(A)}{\langle\pi\rangle e : A}$$

If this is the case, then e is *typed.* The set of typed expressions is written $\mathbb{T}$.

▸ Remark. This type system is syntax directed and yields a simple decision procedure.

2.2.3 Expressions over letters or atoms

A significant motivation for this work was to study the differences between having atoms or letters as variables in expressions. Hence we define two other subsets.

▸ **Definition 5** (Atomic expressions, literate expressions)**.** An expression e is called *atomic* (respectively *literate*) if it does not contain letters (respectively atoms) as variables. The set of atomic expressions is $\mathbb{E}\langle\mathcal{A}\rangle$, and the set of literate expressions is $\mathbb{E}\langle\mathcal{L}\rangle$.

Intuitively, there are two main differences between having atoms or letters as variables. First, a letter may depend on many atoms. Second, two letters with the same support can still be different, whereas the following equivalence holds :

$$\forall a,b\in\mathcal{A},\ a=b\Leftrightarrow(\forall c\in\mathcal{A},\ c\# a\Leftrightarrow c\# b)\,.$$

2.2.4 Positive expressions

For the sake of proofs, we also define the classes of expressions without 0 or $\bot_A$ as a sub-expression. A motivation for excluding these is that in any reasonable system $0\equiv 0\cdot e$. Hence if there is an atom a not fresh for e, we would have two equivalent expressions with different sets of fresh variables.

▸ **Definition 6** (Positive expression)**.** An expression e is *positive* if it does not contain 0 nor $\bot_A$ as a sub-expression. The set of positive expressions is $\mathbb{E}^+$.

For concision, we write $\mathbb{E}^+\langle\mathcal{L}\rangle$ for $\mathbb{E}\langle\mathcal{L}\rangle\cap\mathbb{E}^+$, and $\mathbb{E}^+\langle\mathcal{A}\rangle$ for $\mathbb{E}\langle\mathcal{A}\rangle\cap\mathbb{E}^+$.

2.2.5 Explicit permutations

Our syntax includes for explicit permutations $\langle\pi\rangle$, while permutations are usually considered as external operations. This allows one to manipulate permutations inside the expressions, and we shall see that this addition does not raise the complexity of the problem.

Nevertheless, we need to formally define the semantics of permutations on expressions.

▸ **Definition 7** (Action of a permutation on an expression)**.** Let $e\in\mathbb{E}$ be an expression and π a permutation. The *action of* π *on* e, written $\pi\bowtie e$, is defined as follows:

$$\begin{array}{ccc}
\pi\bowtie 1:=1 & \pi\bowtie 0:=0 & \pi\bowtie(w_a.e):=w_{\pi(a)}.(\pi\bowtie e)\\
\pi\bowtie id_A:=id_{\pi(A)} & \pi\bowtie\bot_A:=\bot_{\pi(A)} & \pi\bowtie(\nu_a.e):=\nu_{\pi(a)}.(\pi\bowtie e)\\
\pi\bowtie a:=\pi(a) & \pi\bowtie l:=\pi(l) & \pi\bowtie(\langle\pi'\rangle e):=\langle\,()\,\rangle(\pi\circ\pi')\bowtie e\\
\pi\bowtie(e^\star):=(\pi\bowtie e)^\star & \pi\bowtie(e\cdot f):=\pi\bowtie e\cdot\pi\bowtie f & \pi\bowtie(e+f):=\pi\bowtie e+\pi\bowtie f
\end{array}$$

Expressions without explicit substitutions are called *clean.*

▸ **Definition 8** (Clean expressions)**.** An expression e is *clean* if it never uses the operator $\langle\pi\rangle$. The set of clean expressions is $\mathbb{C}$.

Applying permutations preserves all classes we have listed so far:

$$\frac{Ax \vdash f = e}{Ax \vdash e = f} \qquad \frac{Ax \vdash e = f \quad Ax \vdash f = g}{Ax \vdash e = f} \qquad \frac{}{Ax \vdash e = f}\;(e,f) \in Ax$$

(a) Equivalence and axiom rules.

$$\frac{}{Ax \vdash 0 = 0} \qquad \frac{}{Ax \vdash 1 = 1} \qquad \frac{}{Ax \vdash id_A = id_A} \qquad \frac{}{Ax \vdash \bot_A = \bot_A}$$

$$\frac{}{Ax \vdash l = l} \qquad \frac{}{Ax \vdash a = a} \qquad \frac{Ax \vdash e = g \quad Ax \vdash f = h}{Ax \vdash e + f = g + h} \qquad \frac{Ax \vdash e = g \quad Ax \vdash f = h}{Ax \vdash e \cdot f = g \cdot h}$$

$$\frac{Ax \vdash e = f}{Ax \vdash e^\star = f^\star} \qquad \frac{Ax \vdash e = f}{Ax \vdash \nu_a.e = \nu_a.f} \qquad \frac{Ax \vdash e = f}{Ax \vdash w_a.e = w_a.f} \qquad \frac{Ax \vdash e = f}{Ax \vdash \langle\pi\rangle\, e = \langle\pi\rangle\, f}$$

(b) Congruence rules.

$$\frac{}{Ax \vdash e + f = f + e} \qquad \frac{}{Ax \vdash e + (f + g) = (e + f) + g} \qquad \frac{}{Ax \vdash e + e = e}$$

$$\frac{}{Ax \vdash e \cdot (f + g) = (e \cdot f) + (e \cdot g)} \qquad \frac{}{Ax \vdash (e + f) \cdot e = (e \cdot g) + (f \cdot g)}$$

$$\frac{}{Ax \vdash e \cdot (f \cdot g) = (e \cdot f) \cdot g} \qquad \frac{Ax \vdash f + e \cdot g \leqslant g}{Ax \vdash e^\star \cdot f \leqslant g} \qquad \frac{Ax \vdash f + g \cdot e \leqslant g}{Ax \vdash f \cdot e^\star \leqslant g}$$

(c) Constant-free Kleene algebra axioms.

Figure 1 Modular deduction system.

▶ **Lemma 9.** *For any subset of expressions S chosen from $\{\mathbb{T}, \mathbb{U}, \mathbb{E}\langle\mathcal{A}\rangle, \mathbb{E}\langle\mathcal{L}\rangle, \mathbb{E}^+, \mathbb{C}\}$, for any permutation π, and for any expression $e \in \mathbb{E}$, $e \in S \Leftrightarrow \pi \bowtie e \in S$. Furthermore, if e has the type A then $\pi \bowtie e : \pi(A)$, and if a is fresh for e then $\pi(a) \# \pi \bowtie e$.*

(Note the equivalence in the first point, which is why we keep a residual empty permutation when we apply a permutation to an expression of the shape $\langle\pi\rangle\, e$.)

2.3 Proofs

A generic framework for proofs

We now describe a generic framework for defining equational theories over $\mathbb{E}$. Given a relation $Ax \subseteq \mathbb{E} \times \mathbb{E}$, we define the judgement $Ax \vdash e = f$ to hold if it can be inferred in the system displayed in Figure 1 (where $Ax \vdash e \leqslant f$ is a shorthand for $Ax \vdash e + f = f$).

Notice that we have "hardwired" some laws of Kleene Algebra (KA) in this system, on the basis that they should hold for any reasonable equational system for Nominal Kleene Algebra. However, as we have two sets of constants, we cannot put inside the generic system the Kleene Algebra laws dealing with them. For instance when we consider expressions over the untyped syntax, the fact that $e \cdot 1 = e$ will be stated inside Ax. It is a simple matter to check that whatever Ax, the relation $Ax \vdash \_ = \_$ is an equivalence relation and $Ax \vdash \_ \leqslant \_$ is a preorder.

Sets of axioms

In Figures 2-6, we present a number of possible sets of axioms, which may be combined to axiomatise the different subsets we consider. All the axioms displayed here are implicitly universally quantified.

The first groups of axioms correspond to the axioms of KA for 1, declined in a typed and an untyped fashion. We then do the same for 0 and $\bot_A$, first with the KA axioms, and then for its interactions with $\langle\pi\rangle$, ν_a and w_a, always separating between the typed and untyped cases. These sets of axioms for constants are presented in Figures 2 and 3.

We then introduce sets of axioms to handle permutations. The axiom propagating w_a is set apart, as it only makes sense for typed expressions. This group is displayed in Figure 4. Notice that no law speaks about zeros, as it already has been dealt with in (3a).

The sets of axioms in Figure 5 are simple distributive laws of the restriction and weakening operators.

The next group, displayed in Figure 6, constitutes the core of the nominal theory of expressions. The untyped axioms are mostly the classic nominal axioms, taken from [6]. The only new axiom here is (6b), where we use syntactic permutations rather than semantic ones. The typed axioms are for the most part straightforward reformulations of the previous ones. Notice that in the typed case, we do not need to use freshness conditions, but rather typing statements. The last law of the set (6f) reflects the fact that for an untyped expression e, if $a \neq b$ then $a \# e \Leftrightarrow a \# \nu_b.e$.

2.4 Theories

A *theory* is given by a relation Ax, listing the axioms, and a set S from which we take expressions. As expressions may be typed or untyped, atomic or literate, clean or not and positive or not, there are 16 theories, listed in Table 1.

Notice that every subset of expressions mentioned in this table is associated with a single theory. In the following, for concision, we may refer to a theory by simply giving its base set. It is also worth mentioning that for every set S, the theories for $\mathbb{E}\langle\mathcal{L}\rangle \cap S$ and $\mathbb{E}\langle\mathcal{A}\rangle \cap S$ use the same set of axioms.

The theory $\mathbb{E}\langle\mathcal{A}\rangle \cap \mathbb{U} \cap \mathbb{C}$ corresponds precisely to the axiomatisation of NKA given in [6]. In our view, the best theory for defining the interpretation of a program would be $\mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U} \cap \mathbb{C}$, but a relational interpretation is best defined in $\mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{T}$.

A difficulty is that if we have a theory (S, Ax), with two expressions $e, f \in S$ such that $Ax \vdash e = f$, it may be the case that the proof uses expressions outside of S. This is generally what happens in systems with 0 (or $\bot_A$): if $e \notin S$ and $0 \in S$, then:

$$\frac{Ax \vdash 0 = 0 \cdot e \qquad Ax \vdash 0 \cdot e = 0}{Ax \vdash 0 = 0}$$

This is a bad property when one wants to prove results by structural induction on proofs. This phenomenon disappears with stable theories:

▶ **Definition 10.** A theory (S, Ax) is *stable* if for any expressions $e, f \in \mathbb{E}$ such that $Ax \vdash e = f$, $e \in S$ if and only if $f \in S$.

All of our positive theories (those included in $\mathbb{E}^+$) are stable.

$$\begin{aligned} e\cdot 1 &= e\\ 1\cdot e &= e\\ 1+e\cdot e^\star &\leqslant e^\star\\ 1+e^\star\cdot e &\leqslant e^\star \end{aligned}$$

3 Ordering theories

3.1 Definitions

We define two preorders to compare theories. The first one is the strongest one:

▸ **Definition 11** (Embedding preorder)**.** A theory (S, Ax) *can be embedded into* (S', Ax'), written $(S, Ax) \preccurlyeq (S', Ax')$ if there is a function ϕ such that for any $e \in S$, $\phi(e) \in S'$, and for any $e, f \in S$, $Ax \vdash e = f \Leftrightarrow Ax' \vdash \phi(e) = \phi(f)$. In that case we say that ϕ *is an embedding of* (S, Ax) *into* (S', Ax').

When a theory can be embedded into a second one, then every model of the latter one gives rise to a model former one. However, some intuitively equivalent theory cannot be compared using this preorder. For instance, $\mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{T}$ cannot be embedded into $\mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$. Indeed, while the typed expressions $id_{\{a\}}$ and $id_{\{a,b\}}$ are not equal (they have different types), they have the same untyped behaviour and both of them should be mapped to the untyped constant 1. To this end, we introduce a slightly weaker preorder:

▸ **Definition 12** (Reduction preorder)**.** A theory (S, Ax) *reduces to* (S', Ax'), which we denote by $(S, Ax) \ll (S', Ax')$, if for any pair $(e, f) \in S \times S$ there is a pair of expressions $(e', f') \in S'$ such that $Ax \vdash e = f \Leftrightarrow Ax' \vdash e' = f'$.

▸ **Lemma 13.** *If* $(S, Ax) \ll (S', Ax')$ *and if* (S', Ax') *is decidable, then so is* (S, Ax)*.*

▸ Remark. This lemma assumes an effective proof of $(S, Ax) \ll (S', Ax')$: there must be a way to build the pair e', f' from the pair e, f. Our (Coq) proofs below have this property.

3.2 Embeddings

We summarise the results we obtained using Coq on Figure 7. (The scripts are available online [1]). A plain arrow is drawn between two theories if the source of the arrow can be embedded into the target of the arrow, and a dashed arrow when the source reduces to the target. Thanks to the decidability result for $\mathbb{E}\langle\mathcal{A}\rangle \cap \mathbb{U} \cap \mathbb{C}$ [5], this ensures that all atomic theories are decidable.

We discuss in more details how we obtained some of these results.

3.2.1 Reducing to positive fragments

The first step consists in getting rid of the constants 0 and $\bot_A$, so that we can focus on stable theories (Definition 10). We only present here the untyped case. In other words we choose a theory (S, Ax), with S taken from the set $\{\mathbb{E}\langle\mathcal{A}\rangle \cap \mathbb{U}, \mathbb{E}\langle\mathcal{A}\rangle \cap \mathbb{U} \cap \mathbb{C}, \mathbb{E}\langle\mathcal{L}\rangle \cap \mathbb{U}, \mathbb{E}\langle\mathcal{L}\rangle \cap \mathbb{U} \cap \mathbb{C}\}$, the corresponding positive theory being $(S \cap \mathbb{E}^+, Ax \smallsetminus (3a))$.

▸ **Definition 14.** If e is an untyped expression, $\mathit{extract}(e)$ is the unique normal form of e with respect to the following confluent rewriting system:

$$e + 0 \to e \qquad 0 + f \to f \qquad e \cdot 0 \to 0 \qquad 0 \cdot f \to 0 \qquad \nu_a.0 \to 0 \qquad \langle\pi\rangle\, 0 \to 0 \qquad 0^\star \to 1.$$

The interesting property of this function is that if $Ax \vdash e = 0$, then $\mathit{extract}(e)$ is syntactically equal to 0, and $\mathit{extract}(e) \in \mathbb{E}^+$ otherwise. Furthermore, for every $e \in S$, $Ax \vdash \mathit{extract}(e) = e$. The formal proof then relies on two key observations:
1. If $(e, f) \in Ax \smallsetminus (3a)$, then $Ax \smallsetminus (3a) \vdash \mathit{extract}(e) = \mathit{extract}(f)$.
2. If $(e, f) \in (3a)$, then $\mathit{extract}(e) = \mathit{extract}(f)$.

This allows to prove by induction on proofs that:

$$Ax \vdash e = f \Rightarrow Ax \smallsetminus (3a) \vdash \mathit{extract}(e) = \mathit{extract}(f).$$

Because the positive axiomatisation is included in Ax, we also get:

$$Ax \smallsetminus (3a) \vdash \mathit{extract}(e) = \mathit{extract}(f) \Rightarrow Ax \vdash \mathit{extract}(e) = \mathit{extract}(f).$$

The fact that $\mathit{extract}(e)$ is provably equal to e with the axioms Ax allows to close the proof of equivalence, with the entailment:

$$Ax \vdash \mathit{extract}(e) = \mathit{extract}(f) \Rightarrow Ax \vdash e = f.$$

However, if $Ax \vdash e = 0$ then $\mathit{extract}(e) \notin \mathbb{E}^+$. This means that we cannot directly use $\mathit{extract}()$ as an embedding between theories. We obtain the reduction as follows: when given the pair e, f, we compute $\mathit{extract}(e)$ and $\mathit{extract}(f)$. If both of these are equal to zero, then when map the pair to equal positive expressions, say $1, 1$. If both of them are non-zero, then we produce $\mathit{extract}(e), \mathit{extract}(f)$. Otherwise we produce different positive expressions, say $1, a$ in the atomic case and $1, l$ in the literate case.

3.2.2 From presheaves to freshness, and back

Let (S, Ax) be a positive untyped theory, meaning $S \subseteq \mathbb{E}^+ \cap \mathbb{U}$, and (S', Ax') be the corresponding positive typed theory. We show here how to transport S into S', and vice versa. This corresponds to the vertical arrows on Figure 7. The key tools in this case are the erasure and retyping functions.

▸ **Definition 15** (Erasure). The *erasure* of $e \in \mathbb{T}$, written $\lfloor e \rfloor$, is the expression obtained from e by removing all weakenings (w_a), and replacing all id_A with 1 and all $\bot_A$ with 0.

▸ **Lemma 16.** *If $e \in S'$ then $\lfloor e \rfloor \in S$, and if $e : A$ then $\natural(\lfloor e \rfloor) \subseteq A$.*

▸ **Definition 17** (Retyping). Let $e \in \mathbb{U}$, we define the retyping of e, written $\lceil e \rceil$, by structural induction:

$$\begin{array}{rlrlrll}
\lceil 0 \rceil &:= \bot_\varnothing & \lceil 1 \rceil &:= id_\varnothing & \lceil e + f \rceil &:= w_{\natural(f) \smallsetminus \natural(e)} \cdot \lceil e \rceil + w_{\natural(e) \smallsetminus \natural(f)} \cdot \lceil f \rceil & \\
\lceil a \rceil &:= a & \lceil l \rceil &:= l & \lceil e \cdot f \rceil &:= w_{\natural(f) \smallsetminus \natural(e)} \cdot \lceil e \rceil \cdot w_{\natural(e) \smallsetminus \natural(f)} \cdot \lceil f \rceil & \\
\lceil e^\star \rceil &:= \lceil e \rceil^\star & & & \lceil \nu_a.e \rceil &:= \nu_a \cdot \lceil e \rceil & (\text{if } a \in \natural(e)) \\
\lceil \langle\pi\rangle\, e \rceil &:= \langle\pi\rangle \lceil e \rceil & & & \lceil \nu_a.e \rceil &:= \nu_a.w_a \cdot \lceil e \rceil & (\text{if } a \notin \natural(e))
\end{array}$$

The notation $w_A.e$ is justified by the law $w_a.w_b.e = w_b.w_a.e$, holding in every typed theory.

▸ **Lemma 18.** *$e \in S$ entails $\lceil e \rceil \in S'$. Furthermore, $\lceil e \rceil$ has the type $\natural(e)$.*

These functions allow one to go back and forth between S and S':

▸ **Lemma 19.** *If $e \in S$, then $e = \lfloor \lceil e \rceil \rfloor$. If $e : A$, then:*

$$(6f)\ (5a)\ (4b) \vdash e = w_{A \smallsetminus \natural(\lfloor e \rfloor)} \cdot \lceil \lfloor e \rfloor \rceil .$$

Furthermore, if $S \subseteq \mathbb{C}$, we may remove the axiom $(4b)$.

From this lemma, we obtain that the retyping function is an embedding of S into S'. But it also shows a problem for the other direction. For instance the expressions e and $w_a.e$ have different types, and are thus different, but they will be mapped to the same expression. For this reason, we cannot use the erasure function to embed S' into S.

Nevertheless, we can use it to show that S' is simpler than S. Given a pair of expressions $e, f \in S'$, if e and f have the same type, then we produce the pair $\lfloor e \rfloor, \lfloor f \rfloor$ which is equiprovable. If it is not the case, we purposely produce different expressions, as in the previous section.

3.2.3 From atomic to literate

We assume there is an atom $\alpha \in \mathcal{A}$ and an element $\lambda \in \mathcal{L}$ with $\natural(\lambda) = \{\alpha\}$. We show the transformation from $\mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$ to $\mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U}$, which corresponds to the central horizontal top arrow on Figure 7. Let NKApu be the set of axioms $(2a), (4a), (5b), (6b), (6e)$ corresponding to the theory of these sets.

▸ **Definition 20** (From atoms to letters.)**.** Given an expression $e \in \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$, we obtain the expression $\downharpoonleft e \downharpoonright \in \mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U}$ by replacing every atomic variable a by $\langle (a\ \alpha) \rangle \lambda$. We write $\downharpoonleft \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U} \downharpoonright$ for the set of expressions $f \in \mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U}$, such that there is an expression $e \in \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$ such that $f = \downharpoonleft e \downharpoonright$.

For any expression e, $e \in \downharpoonleft \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U} \downharpoonright$ if and only if each literate variable in e has the identifier x. It is also worth noting that $\downharpoonleft \_ \downharpoonright$ preserves freshness: $a \# e \Leftrightarrow a \# \downharpoonleft e \downharpoonright$. As for typed and untyped expressions, we define an inverse operation.

▸ **Definition 21** (Going back)**.** The inverse operation is only defined on literate expressions whose variables carry the identifier x, and thus have a singleton support. The expression $\upharpoonleft e \upharpoonright$ is then obtained by replacing every variable by the single atom in its support.

The function $\upharpoonleft \_ \upharpoonright$ is the inverse of $\downharpoonleft \_ \downharpoonright$, $\downharpoonleft \_ \downharpoonright$ preserves NKApu-equality, and $\upharpoonleft \_ \upharpoonright$ preserves NKApu-equality on the image of $\downharpoonleft \_ \downharpoonright$.

▸ **Lemma 22.** *$\forall e \in \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$, NKApu $\vdash e = \upharpoonleft \downharpoonleft e \downharpoonright \upharpoonright$.*

▸ **Lemma 23.** *$\forall e, f \in \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$, NKApu $\vdash e = f \Rightarrow$ NKApu $\vdash \downharpoonleft e \downharpoonright = \downharpoonleft f \downharpoonright$.*

▸ **Lemma 24.** *$\forall e, f \in \mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U} \cap \downharpoonleft \mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U} \downharpoonright$, NKApu $\vdash e = f \Rightarrow$ NKApu $\vdash \upharpoonleft e \upharpoonright = \upharpoonleft f \upharpoonright$.*

By putting all together, we obtain that $\downharpoonleft \_ \downharpoonright$ is an embedding of $\mathbb{E}^+\langle\mathcal{A}\rangle \cap \mathbb{U}$ into $\mathbb{E}^+\langle\mathcal{L}\rangle \cap \mathbb{U}$.

4 Relational interpretation of literate expressions

Our main motivation for developing the typed syntax was to define a relational interpretation of expressions. As explained in the introduction, the classical way of interpreting a program as a relation is to consider memory states as functions, associating values to memory cells. A program is then simply a relation between memory states. Furthermore, in most high level programming languages, one cannot access every part of the memory: a variable should be declared before it is used. There are also constructs allowing one to declare a local variable, which is hidden from the rest of the program. Both of these considerations can be encoded by considering functions with a finite domain: the set of memory locations that are visible in the current scope.

Let us be more precise. Consider that the set $\mathcal{A}$ of atoms corresponds to memory locations, and that locations may contain values from an arbitrary set $\mathcal{V}$. A memory state of domain $A \in \wp_f(\mathcal{A})$ is then a function from A to $\mathcal{V}$, and an expression of type A will be interpreted as a binary relation over memory states of domain A (whence the presheaf structure).

Regular operations are interpreted using the standard operations on binary relations; in particular, id_A is interpreted as the identity relation on $\mathcal{V}^A$. To interpret letters, we need to fix an equivariant map ϕ that assign to a letter x a relation between memory states with domain $\natural(x)$. Several choices are possible for the operations of restriction (ν_a) and weakening (w_a), yielding slightly different theories. Here is a possibility which gives rise to a model of our theory: if R is a relation over $\mathcal{V}^A$, then we define

$$\nu_a.R := \{(f\restriction_A, g\restriction_A) \mid (f,g) \in R\} \quad ; \qquad \text{(if } a \in A)$$
$$w_a.R := \{(f,g) \mid (f\restriction_A, f\restriction_A) \in R \text{ and } f(a) = g(a)\} \quad . \qquad \text{(if } a \notin A)$$

(Where $f\restriction_A$ is the restriction of a function $f \in \mathcal{V}^B$ for some superset B of A.)

Note that this model is not free: for all relations R, S we have $\nu_a.(R \cdot S) \subseteq (\nu_a.R)\cdot(\nu_a.S)$, which is not an inequation provable from the axioms.

Example.

Consider the program $\texttt{swap}(x,y)$ that exchanges the contents of the variables x and y. The natural implementation of this program is the following: $\texttt{let}\ t\ \texttt{in}\ t \leftarrow x; x \leftarrow y; y \leftarrow t$.

The instruction $\texttt{x} \leftarrow \texttt{y}$ may be represented by a nominal element $\texttt{assign}(\texttt{x},\texttt{y})$ with support $\{\texttt{x},\texttt{y}\}$, and such that $\pi(\texttt{assign}(\texttt{x},\texttt{y})) = \texttt{assign}(\pi(\texttt{x}),\pi(\texttt{y}))$. Accordingly, the program $\texttt{swap}$ is represented by the following expression, where the location is hidden using a top-level restriction.

$$\nu_{\texttt{t}}.(\texttt{assign}(\texttt{t},\texttt{x})\cdot\texttt{assign}(\texttt{x},\texttt{y})\cdot\texttt{assign}(\texttt{y},\texttt{t})) \quad .$$

Alternatively, one can obtain an expression with a single letter using explicit permutations: let a_1 and a_2 be two atoms, and set $\mathbb{a} := \texttt{assign}(a_1,a_2)$. The instruction $\texttt{x} \leftarrow \texttt{y}$ may be represented by $\langle(\texttt{x}\ a_1)\ (\texttt{y}\ a_2)\rangle\mathbb{a}$, and the program swap by

$$\nu_t.(\langle(\texttt{t}\ a_1)\ (\texttt{x}\ a_2)\rangle\mathbb{a})\cdot(\langle(\texttt{x}\ a_1)\ (\texttt{y}\ a_2)\rangle\mathbb{a})\cdot(\langle(\texttt{y}\ a_1)\ (\texttt{t}\ a_2)\rangle\mathbb{a}).$$

5 Future work

We leave two questions for future work. First, is it possible to reduce the literate theory of nominal Kleene algebra to that of atomic nominal Kleene algebra? If not, is there a free language theoretic model for which we could obtain decidability?

Second, is there a free relational model for our literate theory?

On the Implicit Graph Conjecture

Maurice Chandoo

Leibniz Universität Hannover, Theoretical Computer Science, Appelstr. 4, 30167 Hannover, Germany
chandoo@thi.uni-hannover.de

Abstract

The implicit graph conjecture states that every sufficiently small, hereditary graph class has a labeling scheme with a polynomial-time computable label decoder. We approach this conjecture by investigating classes of label decoders defined in terms of complexity classes such as P and EXP. For instance, GP denotes the class of graph classes that have a labeling scheme with a polynomial-time computable label decoder. Until now it was not even known whether GP is a strict subset of GR where R is the class of recursive languages. We show that this is indeed the case and reveal a strict hierarchy akin to classical complexity. We also show that classes such as GP can be characterized in terms of graph parameters. This could mean that certain algorithmic problems are feasible on every graph class in GP. Lastly, we define a more restrictive class of label decoders using first-order logic that already contains many natural graph classes such as forests and interval graphs. We give an alternative characterization of this class in terms of directed acyclic graphs. By showing that some small, hereditary graph class cannot be expressed with such label decoders a weaker form of the implicit graph conjecture could be disproven.

1 Introduction

The class of interval graphs has at most $2^{\mathcal{O}(n \log n)}$ graphs on n vertices. Neither adjacency matrices nor lists are asymptotically space optimal to represent this class since only $\mathcal{O}(n \log n)$ bits should be used to store a graph on n vertices. However, due to the geometrical representation of this class every vertex of an interval graph can be assigned an interval on a discrete line with $2n$ points. Stated differently, every vertex can be labeled with two numbers between 1 and $2n$ and adjacency of two vertices can be determined by comparing the four numbers. Storing two such numbers for all n vertices requires $n \log 4n^2$ bits and thus is asymptotically optimal. Labeling schemes, also known as implicit representation, generalize this kind of representations by allowing to store a $\mathcal{O}(\log n)$ long binary label at every vertex such that adjacency between two vertices can be determined by running an algorithm on the two labels. We investigate what graph classes can or cannot be represented in such a way when restricting the computational complexity of the function that determines adjacency, also called label decoder.

Let us call a graph class that has at most $2^{\mathcal{O}(n \log n)}$ graphs on n vertices small. A simple counting argument shows that only small graph classes can have labeling schemes. The first question that springs to mind is whether all small graph classes have a labeling scheme. This is not the case as Spinrad shows by giving a small, non-hereditary graph class as counter-example in [12, Thm. 7]. Now, the question becomes whether all small, hereditary graph classes have a labeling scheme; this is known as implicit graph conjecture(IGC). This question was already posed more than two decades ago in 1992 by Kannan, Naor and Rudich [7] and has been brought up again by Spinrad [12]. But despite being such an old question not much is known in this regard. One such result is: every tiny, hereditary graph class admits a labeling scheme with labels of constant length [10]. Tiny means that there exist $n_0 \in \mathbb{N}$ and $k < \frac{1}{2}$ such that the class has at most $2^{kn \log n}$ labeled graphs on n vertices for all $n \geq n_0$. This follows from the insight that every tiny, hereditary graph class has only a constant number of twin-free graphs, which makes such classes rather uninteresting. On the other hand, small, hereditary graph classes such as planar or circular-arc graphs can have a rich structure. Candidates for the IGC, i.e. small, hereditary graph classes for which no labeling scheme is known, are line segment graphs, (unit) disk graphs, k-dot product graphs and k-sphere graphs [3, 9, 6]. It is interesting to note that the obvious labeling schemes for line segment and disk graphs using their geometrical representation does not work since coordinates and radii can require an exponential number of bits [9] unlike in the case of interval graphs.

A different aspect of labeling schemes that has been extensively studied are lower and upper bounds on the label length, i.e. the constant lurking in $\mathcal{O}(\log n)$, which is related to small universal graphs. A recent result shows that graphs of bounded arboricity k admit a labeling scheme with optimal label length $k \log n + \mathcal{O}(1)$ [1]. Besides, labeling schemes can be generalized in various ways. One variant are distance labeling schemes where one wants to infer the distance between two vertices given their labels [4]. In [8] it was proposed to consider multiple labels instead of only two. Another natural extension is to consider labeling schemes for graph classes that are not small by allowing longer labels while still maintaining the condition of being asymptotically space optimal [12]. However, here we shall investigate the original variant of this concept.

Our results. For a complexity class A let GA denote the class of graph classes that have a labeling scheme where the label decoder can be computed in A (precise definitions follow). In general, we investigate how choosing various complexity classes for A affects the class of graph classes GA that can be represented and how such classes of graph classes can be characterized. In section two we argue that $\mathsf{G}k\mathsf{EXP} \subsetneq \mathsf{G}(k+1)\mathsf{EXP}$ for all $k \geq 1$ by giving a diagonalization argument. A related result for distance labeling schemes can be found in section four of [4]. Additionally, we consider the graph class(es) constructed in the proof as candidate for the implicit graph conjecture. In the third section we show that for every reasonable complexity class A the class of graph classes GA can be exactly characterized in terms of a graph parameter. By graph parameter we mean a graph property which maps to the natural numbers such as clique number or tree width. Given such a characterizing graph parameter λ_{A} for GA the question of whether a graph class lies in GA then is equivalent to asking whether it is bounded by λ_{A}. Another consequence of such a characterization is that if for example determining the existence of a Hamiltonian cycle is fixed-parameter tractable under the parameterization λ_{A} then for every graph class in GA this problem can be decided in polynomial time. This means the existence of a labeling scheme can have algorithmic implications. In the last section we define a class of label decoders FO via first-order logic formulas with arithmetic, i.e. comparing order, addition and multiplication. Our motivation for introducing this class of label decoders is that the Turing machine model seems too strong to obtain lower bounds. We give upper bounds on the expressiveness of GFO and its quantifier-free variant. Even if quantifiers, addition and multiplication are disallowed the resulting class $\mathsf{GFO}_{\mathrm{qf}}(<)$ already contains many interesting graph classes such as forests, planar graphs and k-interval graphs(also known as multiple interval graphs [2]). Lastly, we describe an alternative characterization of $\mathsf{GFO}_{\mathrm{qf}}(<)$ in terms of directed acyclic graphs.

Terminology. Let $[n] = \{1, 2, \dots, n\}$. We write $\log n$ instead of $\lceil \log_2 n \rceil$ and $\exp(n) = 2^n$. Let $\exp^i(n) = \exp(\exp^{i-1}(n))$ for $i \geq 1$ and $\exp^0(n) = n$. The domain and image of a function f are abbreviated by $\mathrm{dom}(f)$ and $\mathrm{Im}(f)$ respectively. We consider only graphs without multiple edges and self-loops and regard undirected graphs as special case of directed ones. For a sequence of graphs $G, G_1, \dots, G_m$ on the same vertex set V let us say G is the edge-union of $G_1, \dots, G_m$ if $E(G) = \cup_{i \in [m]} E(G_i)$. For two graphs G, H we write $G \cong H$ to indicate that they are isomorphic. We speak of G as unlabeled graph to emphasize that we talk about the isomorphism class of G rather than a specific adjacency matrix of G. A graph class is a set of unlabeled graphs, i.e. closed under isomorphism. A graph class is hereditary if it is closed under taking induced subgraphs. Let $\mathcal{G}$ be the class of all graphs and $\mathcal{G}_n$ is the class of all graphs on n vertices. A language is a set of words over the binary alphabet $\{0, 1\}$. We use complexity class as informal term to mean a set of languages defined in terms of computation and assume that it is countable. The deterministic Turing machine (TM) is our model of computation when talking about time as resource bound. Let L denote the complexity class logspace, PH is the polynomial-time hierarchy, R is the class of recursive languages and $k\mathsf{EXP}$ is the class of languages computable in time $\exp^k(n^{\mathcal{O}(1)})$ for $k \geq 0$, e.g. $0\mathsf{EXP} = \mathsf{P}$. Let $\mathsf{ALL} = \mathcal{P}(\{0, 1\}^*)$ be the class of all languages.

▶ **Definition 1** (Labeling scheme). A label decoder F is a binary relation over words, i.e. $F \subseteq \{0, 1\}^* \times \{0, 1\}^*$. A labeling scheme is a tuple $S = (F, c)$ where F is a label decoder and $c \in \mathbb{N}$ is the label length. A graph G on n vertices is in the class of graphs spanned by S, denoted by $G \in \mathrm{gr}(S)$, if there exists a labeling $\ell \colon V(G) \to \{0, 1\}^{c \log n}$ such that for all $u, v \in V(G)$:

$$(u, v) \in E(G) \Leftrightarrow (\ell(u), \ell(v)) \in F$$

We say a graph class $\mathcal{C}$ is represented by (or has) a labeling scheme S if $\mathcal{C} \subseteq \mathrm{gr}(S)$.

▶ **Definition 2.** A language $L \subseteq \{0, 1\}^*$ induces a label decoder F_L where for all $x, y \in \{0, 1\}^*$ with $|x| = |y|$ it holds that $(x, y) \in F_L \Leftrightarrow xy \in L$.

Let A be a set of languages and $k \in \mathbb{N}$. A graph class $\mathcal{C}$ is in $\mathsf{G}_k\mathsf{A}$ if there exists a language $L \in \mathsf{A}$ such that $\mathcal{C}$ is represented by (F_L, c) for some $c \leq k$. Analogously, $\mathcal{C}$ is in GA if $\mathcal{C}$ is in $\mathsf{G}_k\mathsf{A}$ for some $k \in \mathbb{N}$.

A class of the form $\mathsf{G}\cdot$ is trivially closed under taking subsets, i.e. if $\mathcal{C} \subseteq \mathcal{C}'$ and $\mathcal{C}' \in \mathsf{G}\cdot$ then $\mathcal{C} \in \mathsf{G}\cdot$. It follows that $\mathsf{G}\cdot$ is closed under intersection as well. However, no $\mathsf{G}\cdot$ is closed under complement since the complement of a small graph class is not small. For many complexity classes such as L and P it is also not hard to show that the classes GL and GP are closed under union.

Here is an example of a language L whose label decoder F_L represents interval graphs: $x_1x_2y_1y_2 \in L$ iff x_1, x_2, y_1, y_2 are binary strings of equal length and neither $x_2 < y_1$ nor $y_2 < x_1$ holds where $<$ denotes the lexicographical order. Then the labeling scheme $S = (F_L, 2)$ represents interval graphs. Since L can be computed in logspace it follows that interval graphs are in $\mathsf{G}_2\mathsf{L}$.

Using our terminology the implicit graph conjecture can be rephrased as:

▶ **Conjecture 3** (IGC,[7]). *Let* H *denote the set of all small, hereditary graph classes.*

$$\mathsf{GP} \cap \mathrm{H} = \mathsf{GALL} \cap \mathrm{H} = \mathrm{H}$$

As of now it is far from clear whether even the second equality holds, i.e. can every small, hereditary graph class be represented by some labeling scheme, leaving computability issues aside? This is a graph-theoretic question dealing with the existence of polynomial-sized universal graphs that should be addressed before one can expect to prove the implicit graph conjecture.

2 Hierarchy of Implicit Representations

In the previous section we have seen that every language L can be interpreted as label decoder F_L. Therefore a set of languages A can be understood as set of label decoders and GA denotes the set of graph classes that can be represented by a labeling scheme (F, c) with $F \in \mathsf{A}$ and $c \in \mathbb{N}$. Inclusion carries over to this setting meaning $\mathsf{A} \subseteq \mathsf{B}$ implies $\mathsf{GA} \subseteq \mathsf{GB}$. For separations, however, this is not true, i.e. there exist A, B with $\mathsf{A} \subsetneq \mathsf{B}$ and $\mathsf{GA} = \mathsf{GB}$. Spinrad remarks that it is not known whether restricting the label decoder to be computable in polynomial time versus requiring it to be simply computable makes a difference in terms of the graph classes that can be represented [12, p. 22]. We resolve this question by applying diagonalization, which yields many of the separations known in the classical setting. For the sake of clarity we prove the following class of separations which we deem most interesting with respect to the IGC since it yields the smallest class($\mathsf{G2EXP}$) that can be separated from GP by this argument:

▶ **Theorem 4.** $\mathsf{G}k\mathsf{EXP} \subsetneq \mathsf{G}(k+1)\mathsf{EXP}$ *for all* $k \geq 1$.

The basic idea behind the proof of this statement is the following diagonalization argument. Let $\mathsf{A} = \{F_1, F_2, \dots\}$ be a set of label decoders. Then a labeling scheme in GA can be seen as pair of natural numbers, one for the label decoder and one for the label length. Let $\tau : \mathbb{N} \to \mathbb{N}^2$ be a surjective function and $S_{\tau(x)} = (F_y, z)$ with $\tau(x) = (y, z)$. It follows that for every labeling scheme S in GA there exists an $x \in \mathbb{N}$ such that $S = S_{\tau(x)}$. The following graph class cannot be in GA:

$$G \in \mathcal{C}_{\mathsf{A}} \Leftrightarrow G \text{ is the smallest graph on } n = |V(G)| \text{ vertices s.t. } G \notin \mathrm{gr}(S_{\tau(n)})$$

where smallest is meant w.r.t. some order such as the lexicographical one. Note that the order must be for unlabeled graphs. However, an order for labeled graphs can be easily adopted to unlabeled ones. Assume $\mathcal{C}_{\mathsf{A}}$ is in GA via the labeling scheme S. There exists an $n \in \mathbb{N}$ such that $S = S_{\tau(n)}$ and it follows that $\mathcal{C}_{\mathsf{A}}$ contains a graph on n vertices that cannot be in S per definition, contradiction. Then it remains to show that $\mathcal{C}_{\mathsf{A}}$ is in the class that we wish to separate from GA.

For the remainder of this section we formalize this idea in three steps. First, we state the requirements for a pairing function τ and show that such a function exists. We continue by arguing that the diagonalization graph class $\mathcal{C}_{\mathsf{A}}$ is not contained GA. In the last step we construct a label decoder for $\mathcal{C}_{k\mathsf{EXP}}$ and show that it can be computed in $(k+1)\mathsf{EXP}$.

▶ **Definition 5.** A surjective function $\tau : \mathbb{N} \to \mathbb{N}^2$ is an admissible pairing if

1. $|\tau^{-1}(y, z)|$ is infinite for all $y, z \in \mathbb{N}$,
2. $\tau_y(x), \tau_z(x) \in \mathcal{O}(\log x)$ with $\tau(x) = (\tau_y(x), \tau_z(x))$,
3. $\tau(x)$ is undefined if x is not a power of two, and
4. τ is computable in polynomial time given its input in unary.

Note, that a graph on n vertices gets assigned labels of the same length as a graph on m vertices whenever $\log n = \log m$ (rounded up). The third condition prevents this from happening, i.e. for all $G \neq H \in \mathcal{C}_{\mathsf{A}}$ it holds that their vertices must have labels of different length.

▶ **Lemma 6.** *There exists an admissible pairing function.*

Proof. Consider the function $\tau(x) = (y,z)$ iff $x = 2^{2^y \cdot 3^z \cdot 5^w}$ for some $w \geq 0$. ◀

▶ **Definition 7.** Let A be a set of languages, $\prec$ an order on unlabeled graphs and τ an admissible pairing. The diagonalization graph class of A is defined as:

$$\mathcal{C}_{\mathsf{A}} = \bigcup_{n \in \operatorname{dom}(\tau)} \left\{ G \in \mathcal{G}_n \;\middle|\; G \text{ is the smallest graph w.r.t. } \prec \text{ not in } \operatorname{gr}(S_{\tau(n)}) \right\}$$

When we consider the diagonalization graph class of a set of languages we assume the lexicographical order for $\prec$ and the function given in the proof of Lemma 6 for τ.

▶ **Lemma 8.** *For every countable set of languages* A *it holds that* $\mathcal{C}_{\mathsf{A}} \notin \mathsf{GA}$.

Proof. As argued in the paragraph after Theorem 4 it holds that for any labeling scheme S in GA there exists a graph G that is in $\mathcal{C}_{\mathsf{A}}$ but not in $\operatorname{gr}(S)$ and thus this lemma holds. Since the labeling scheme S is in GA there exists an $n \in \mathbb{N}$ such that $S = S_{\tau(n)}$ where $S_{\tau(n)} = (F_y, z)$, $\tau(n) = (y,z)$ and $\mathsf{A} = \{F_1, F_2, \dots\}$. Due to the fact that $|\tau^{-1}(y,z)|$ is infinite it follows that there exists an arbitrarily large $n \in \mathbb{N}$ such that $S = S_{\tau(n)}$. For $\mathcal{C}_{\mathsf{A}} \setminus \operatorname{gr}(S)$ to be non-empty it must hold that $\operatorname{gr}(S_{\tau(n)})$ does not contain all graphs on n vertices. By choosing n to be sufficiently large this is guaranteed since $\operatorname{gr}(S_{\tau(n)})$ is a small graph class. ◀

To show that $\mathcal{C}_{\mathsf{A}}$ is in some class GB we need to define a labeling scheme $S_{\mathsf{A}} = (F_{\mathsf{A}}, 1)$ that represents $\mathcal{C}_{\mathsf{A}}$ and consider the complexity of computing its label decoder.

▶ **Definition 9.** Let A be a set of languages. For $G \in \mathcal{C}_{\mathsf{A}}$ let G_0 denote the smallest labeled graph with $G_0 \cong G$. We define the label decoder F_{A} as follows. For every $m \in \mathbb{N}$ such that there exists $G \in \mathcal{C}_{\mathsf{A}}$ with $|V(G)| = 2^m$ and for all $x, y \in \{0,1\}^m$ let

$$(x,y) \in F_{\mathsf{A}} \Leftrightarrow (x,y) \in E(G_0)$$

It can be assumed that G_0 has $\{0,1\}^m$ as vertex set. Also, note that $\mathcal{C}_{\mathsf{A}}$ has at most one graph on n vertices for any n. Therefore the label decoder F_{A} is well-defined. It is easy to see that $(F_{\mathsf{A}}, 1)$ represents $\mathcal{C}_{\mathsf{A}}$, i.e. $\mathcal{C}_{\mathsf{A}} \subseteq \operatorname{gr}(F_{\mathsf{A}}, 1)$.

Up to this point the exact correspondence between $y \in \mathbb{N}$ and the label decoder F_y was not important. In fact, we only required the set of label decoders A to be countable. To show that the label decoder $F_{k\mathsf{EXP}}$ can be computed in $(k+1)\mathsf{EXP}$ it is important that given y the label decoder F_y from $k\mathsf{EXP}$ can be effectively computed. The following lemma grants this.

▶ **Lemma 10.** *For every* $k \geq 0$ *there exists a mapping* $f \colon \mathbb{N} \to \mathsf{ALL}$ *such that* $\operatorname{Im}(f) = k\mathsf{EXP}$ *and on input* $x \in \mathbb{N}$ *in binary and* $w \in \{0,1\}^*$ *the question* $w \in f(x)$ *can be decided in* $\exp^{k+1}(n^{\mathcal{O}(1)})$ *time with* $n = |w| + \log x$.

Proof. The lemma essentially states that all TMs running in $k\mathsf{EXP}$ can be simulated in $(k+1)\mathsf{EXP}$. Given the Gödelization of such a TM M and a word w as input the question whether M accepts x can be decided by a TM in $(k+1)\mathsf{EXP}$. Fix a reasonable encoding of TMs as natural numbers, i.e. given $z \in \mathbb{N}$ then M_z is a TM. Let $f(x) = (y,z) \Leftrightarrow x = 2^y 3^z$. It holds that $y \leq \log x$ for every $z \geq 0$. On input $x \in \mathbb{N}$ and $w \in \{0,1\}^*$ the reference input length is $n = |w| + \log x$. Compute $f(x) = (y,z)$ and then simulate M_z on w for $\exp^k(y|w|^y) \leq \exp^k(n^{n+1}) \in \mathcal{O}(\exp^{k+1}(n^2))$ steps. ◀

▶ **Lemma 11.** $F_{k\mathsf{EXP}} \in (k+1)\mathsf{EXP}$ *for every* $k \geq 1$.

Proof. On input xy with $x, y \in \{0,1\}^m$ and $m \geq 1$ compute $\tau(2^m) = (y, z)$. If it is undefined then reject. Otherwise there is a labeling scheme $S_{\tau(2^m)} = (F_y, z)$ and we need to compute the smallest graph G_0 on 2^m vertices such that $G_0 \notin \mathrm{gr}(S_{\tau(2^m)})$. If G_0 exists we assume that its vertex set is $\{0,1\}^m$ and accept iff $(x, y) \in E(G_0)$. If it does not exist then reject.

The graph G_0 can be computed as follows. Iterate over all labeled graphs H with 2^m vertices in order and over all bijections $\ell\colon V(H) \to \{0,1\}^{zm}$. Check if $H \in \mathrm{gr}(S_{\tau(2^m)})$ by checking for every pair of vertices $u, v \in V(H)$ if $(\ell(u), \ell(v)) \in F_y \Leftrightarrow (u, v) \in E(H)$. If this condition fails then $G_0 = H$. To query the label decoder F_y the previous lemma can be applied, i.e. y can be interpreted as encoding of a TM in kEXP that can be simulated.

Let us consider the time requirement w.r.t. m. To compute $\tau(2^m)$ we write down 2^m in unary and compute τ in polynomial time w.r.t. 2^m which is in the order $2^{\mathcal{O}(m)}$. To compute G_0 there are four nested loops. The first one goes over all labeled graphs on 2^m vertices which is bounded by $\exp^2(2m)$. The second loop considers all possible labelings ℓ of which there can be at most $\exp(zm)^{\exp(m)} = \exp(\exp(m)zm) \leq \exp^2(zm^2) \in \exp^2(m^{\mathcal{O}(1)})$; recall that z is polynomially bounded by m due to Definition 5. The other two loops go over all vertices of H meaning 2^m. By applying Lemma 10 the time required to compute $(\ell(u), \ell(v)) \in F_y$ is $\exp^{k+1}(n_0^{\mathcal{O}(1)})$ with $n_0 := 2zm + \log y$. Since $n_0 \in m^{\mathcal{O}(1)}$ this operation can be computed in $(k+1)$-exponential time. In summary, the runtime order of this algorithm is $\exp^{k+1}(m^{\mathcal{O}(1)})$. ◀

Now, Lemma 8 states that $\mathcal{C}_{k\mathsf{EXP}} \notin \mathsf{G}k\mathsf{EXP}$ and from Lemma 11 it follows that $\mathcal{C}_{k\mathsf{EXP}} \in \mathsf{G}(k+1)\mathsf{EXP}$ therefore proving Theorem 4. Notice, that this argument fails to show that $\mathsf{GP} \subsetneq \mathsf{GEXP}$ because the runtime to compute the label decoder F_{P} is at least double exponential due to the first two loops mentioned in the proof of Lemma 11. Can this argument be modified to separate these two classes as well? This seems rather unlikely. Nonetheless, we now know that there exist graph classes that have an implicit representation but a polynomial-time computable label decoder does not suffice to capture them.

▶ **Fact 12.** *If there exists a small, hereditary graph class $\mathcal{C}$ with $\mathcal{C}_{\mathsf{P}} \subseteq \mathcal{C}$ then the implicit graph conjecture is false.*

For two graph classes $\mathcal{C}$ and $\mathcal{D}$ let us call $\mathcal{D}$ the hereditary closure of $\mathcal{C}$ if $G \in \mathcal{D}$ iff G occurs as induced subgraph of some graph in $\mathcal{C}$. If the hereditary closure of $\mathcal{C}_{\mathsf{P}}$ is not a small graph class then it follows that the premise of Fact 12 is unsatisfiable. Recall that $\mathcal{C}_{\mathsf{P}}$ is not an unambiguous graph class but depends on the chosen order $\prec$ and pairing τ, which makes it difficult to analyze what kind of graphs are contained in such a class.

3 Parameter Characterization

We consider a graph parameter to be a total function $\lambda\colon \mathcal{G} \to \mathbb{N}$ and call it natural if the cardinality of its image is infinite. Examples of natural graph parameters are the chromatic number or the diameter. A graph class $\mathcal{C}$ is bounded by a graph parameter λ if there exists a $c \in \mathbb{N}$ such that for all $G \in \mathcal{C}$ it holds that $\lambda(G) \leq c$. We show that for every complexity class A such that GA is closed under union there exists a graph parameter that characterizes GA. One interesting aspect of such a characterization is that it might reveal algorithmic implications for graph classes that have a labeling scheme of certain complexity.

▶ **Definition 13.** Let $\mathbb{C}$ be a set of graph classes and λ is a graph parameter. We say λ characterizes $\mathbb{C}$ if for every graph class $\mathcal{C}$ it holds that $\mathcal{C} \in \mathbb{C}$ iff $\mathcal{C}$ is bounded by λ.

Let us say a set of graph classes $\mathbb{C}$ is complete if for every graph G there exists a $\mathcal{C} \in \mathbb{C}$ such that $G \in \mathcal{C}$.

▶ **Theorem 14.** *Let $\mathbb{C}$ be a complete set of graph classes closed under union and subsets with $\mathcal{G} \notin \mathbb{C}$. If there exists a countable subset of $\mathbb{C}$ such that its closure under subsets equals $\mathbb{C}$ then there exists a natural graph parameter that characterizes $\mathbb{C}$.*

Proof. Let $\mathbb{C}$ be a set of graph classes that satisfies the above premises and $\mathbb{C}' = \{\mathcal{C}_1, \mathcal{C}_2, \dots\}$ is the needed countable subset of $\mathbb{C}$. Let $\lambda(G)$ be the minimal $i \geq 1$ such that $G \in \mathcal{C}_i$. Since $\mathbb{C}$ is complete it follows that $\mathbb{C}'$ is complete and thus λ is total. Let us define $\mathcal{C}^{\lambda}_{\leq i}$ as $\{G \in \mathcal{G} \mid \lambda(G) \leq i\}$ and similarly $\mathcal{C}^{\lambda}_{=i}$. It follows that a class $\mathcal{C}$ is bounded by λ iff $\mathcal{C} \subseteq \mathcal{C}^{\lambda}_{\leq i}$ for some $i \in \mathbb{N}$. We now argue that λ characterizes $\mathbb{C}$.

If $\mathcal{C} \in \mathbb{C}$ then there exists an $i \in \mathbb{N}$ such that $\mathcal{C} \subseteq \mathcal{C}_i$. It follows that $\mathcal{C} \subseteq \mathcal{C}^{\lambda}_{\leq i}$. We show the other direction by induction: if $\mathcal{C} \subseteq \mathcal{C}^{\lambda}_{\leq i}$ then $\mathcal{C} \in \mathbb{C}$ for all $i \in \mathbb{N}$. For $i = 1$ it holds that $\mathcal{C} \subseteq \mathcal{C}^{\lambda}_{\leq 1} = \mathcal{C}^{\lambda}_{=1} = \mathcal{C}_1$. Since $\mathbb{C}$ is closed under subsets it follows that $\mathcal{C} \in \mathbb{C}$. For $i+1$ it holds that $\mathcal{C} \subseteq \mathcal{C}^{\lambda}_{\leq i+1}$ and $\mathcal{C}^{\lambda}_{\leq i+1} = \mathcal{C}^{\lambda}_{\leq i} \cup \mathcal{C}^{\lambda}_{=i+1}$. By induction hypothesis it follows that $\mathcal{C}^{\lambda}_{\leq i} \in \mathbb{C}$. Since $\mathbb{C}$ is closed under union it remains to argue that $\mathcal{C}^{\lambda}_{=i+1}$ is in $\mathbb{C}$. This follows by the observation $\mathcal{C}^{\lambda}_{=i+1} \subseteq \mathcal{C}_{i+1}$ and $\mathcal{C}_{i+1} \in \mathbb{C}$. ◀

Let us examine the premises of Theorem 14 with respect to the class of graph classes that we consider. Every class of the form G· is closed under subsets and for a lot of complexity classes A it also holds that GA is closed under union. For completeness a lookup table can be constructed for every singleton graph class. The required countable subset is given by the languages of A. In fact, every class of the form G· mentioned in this paper satisfies these premises and therefore has a parameter characterization with the only exception being the class GALL, which provably has no parameter characterization. Assume λ is a characterizing parameter for GALL and let $A = \{\mathcal{C}^{\lambda}_{\leq i} \mid i \in \mathbb{N}\}$. It must hold that for every graph class $\mathcal{C} \in$ GALL that it is a subset of some graph class in A. However, the diagonalization graph class $\mathcal{C}_A$ of A cannot be a subset of any graph class in A but has a labeling scheme and thus is in GALL, contradiction.

Consider the algorithmic relevance of such characterizations. Let $P \colon \mathcal{G} \to \{0,1\}$ be a graph property such as having a Hamiltonian cycle and λ is a graph parameter that characterizes the class GA. Assume that P can be decided in time $n^{f(k)}$ on input G with $k = \lambda(G)$ for some computable function $f \colon \mathbb{N} \to \mathbb{N}$. This can also be stated as P parameterized by λ being in the complexity class XP. Then it follows that the property P can be decided in polynomial time on every graph class in GA. The contra-position of this argument can be used to show that a graph class $\mathcal{C}$ is probably not in GA: if it is NP-hard to decide the property P on a graph class $\mathcal{C}$ then this implies that $\mathcal{C}$ cannot be in GA unless P = NP.

Of course, the characterizing parameter derived from the proof of Theorem 14 is not suitable for direct analysis but guarantees existence of such a characterization. However, there is room for different parameter characterizations of the same class as the following equivalence notion shows. For two graph parameters λ_1, λ_2 let us say that λ_2 bounds λ_1, in symbols $\lambda_1 \leq \lambda_2$, if every graph class $\mathcal{C}$ that is bounded by λ_1 is also bounded by λ_2. If $\lambda_1 \leq \lambda_2$ and $\lambda_2 \leq \lambda_1$ we say λ_1 and λ_2 are equivalent. For example, the maximum degree is bounded by clique number but not vice versa.

▶ **Fact 15.** *Let $\mathbb{C}_1, \mathbb{C}_2$ be two classes of graph classes and λ_1, λ_2 are respective characterizing graph parameters. $\mathbb{C}_1 \subseteq \mathbb{C}_2$ iff $\lambda_1 \leq \lambda_2$.*

It follows that two graph parameters are equivalent iff they characterize the same class of graph classes. For a complexity class A let λ_{A} be a characterizing graph parameter thereof. Hence, comparing the containment relation of two classes GA and GB is the same as examining whether λ_{A} bounds λ_{B} or vice versa. The interval number $\lambda_{\text{Intv}}(G)$ of a graph G is the smallest number $k \in \mathbb{N}$ such that G is a k-interval graph, see [2]. From this perspective some of our results can be stated as:

$$\lambda_{\text{Intv}} \lneq \lambda_{\mathsf{FO}_{\text{qf}}(<)} \leq \lambda_{\mathsf{L}} \leq \lambda_{\mathsf{P}} \leq \lambda_{\mathsf{EXP}} \lneq \lambda_{\mathsf{2EXP}} \lneq \cdots \lneq \lambda_{\mathsf{R}}$$

where $\lambda \lneq \lambda'$ means strict containment, i.e. $\lambda \leq \lambda'$ holds and $\lambda' \leq \lambda$ does not hold. The class $\mathsf{FO}_{\text{qf}}(<)$ is introduced in the next section.

4 First-Order Definable Label Decoders

For a given small, hereditary graph class there is no obvious way of showing that this class is not contained in GP or even GL as the fact that the IGC still stands open has shown. As a consequence, it is reasonable to look at a more restrictive model of computation for label decoders. From a complexity-theoretic view the circuit class AC^0 is probably among the first candidates. In this case uniformity issues have to be considered, i.e. the complexity of an algorithm computing the circuits for each input length. The strongest uniformity condition, which is the most suitable for lower bounds, leads to the class FO_{D} from descriptive complexity defined in terms of first-order logic [5]. However, the domain of discourse in this setting would be the positions of the labels, which is arguably not the most natural choice. Instead we propose the domain to be polynomially many natural numbers and a label consists of a constant number of elements of this domain. In this setting the labeling scheme for interval graphs can be stated as the formula $\varphi(x_1, x_2, y_1, y_2) = \neg(x_2 < y_1 \vee y_2 < x_1)$; compare this with the example given in the first section. It is also possible to describe k-interval graphs or any hereditary graph class with linearly many edges such as bounded arboricity graphs with such formulas.

For $n \geq 1$ let $\mathcal{N}_n$ be the structure that has $[n]$ as universe, the order relation $<$ on $[n]$ and addition as well as multiplication defined as functions:

$$+(x,y) = \begin{cases} x+y & \text{, if } x+y \leq n \\ 1 & \text{, if } x+y > n \end{cases} \quad , \quad \times(x,y) = \begin{cases} xy & \text{, if } xy \leq n \\ 1 & \text{, if } xy > n \end{cases}$$

For $\sigma \subseteq \{<, +, \times\}$ let $\mathsf{FO}_k(\sigma)$ be the set of first-order formulas with boolean connectives $\neg, \vee, \wedge$, quantifiers $\exists, \forall$ and k free variables using only equality and the relation and function symbols from σ. For $\sigma = \{<, +, \times\}$ we simply write FO_k. Let $\text{Vars}(\varphi)$ be the set of free variables in φ. Given $\varphi \in \mathsf{FO}_k(\sigma)$, $\text{Vars}(\varphi) = (x_1, \ldots, x_k)$ and an assignment $a_1, \ldots, a_k \in [n]$ we write $\mathcal{N}_n, (a_1, \ldots, a_k) \models \varphi$ if the interpretation $\mathcal{N}_n, (a_1, \ldots, a_k)$ satisfies φ under the usual semantics of first-order logic.

▶ **Definition 16.** A (quantifier-free) logical labeling scheme is a tuple $S = (\varphi, c)$ with a (quantifier-free) formula $\varphi \in \mathsf{FO}_{2k}$ and $c, k \in \mathbb{N}$. A (c,k)-labeling for a set V is a function $\ell \colon V \to [n^c]^k$ and induces the graph G_S^ℓ with vertex set V and edges (u,v) if $\mathcal{N}_{n^c}, (\ell(u), \ell(v)) \models \varphi$. Then a graph G is in $\text{gr}(S)$ if there exists a (c,k)-labeling ℓ for $V(G)$ such that $G = G_S^\ell$.

▶ **Definition 17.** Let $\sigma \subseteq \{<, +, \times\}$, $c, k \in \mathbb{N}$. A graph class $\mathcal{C}$ is in $\mathsf{G}_{c,k}\mathsf{FO}(\sigma)$ if there exists a logical labeling scheme (φ, c) with $\varphi \in \mathsf{FO}_{2k}(\sigma)$ such that $\mathcal{C} \subseteq \text{gr}(\varphi, c)$. And $\mathsf{GFO}(\sigma) = \cup_{c,k \in \mathbb{N}} \mathsf{G}_{c,k}\mathsf{FO}(\sigma)$. Let $\mathsf{GFO}_{\text{qf}}(\sigma)$ denote the quantifier-free analogue.

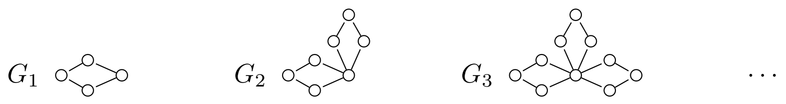

Figure 1 A family of graphs with unbounded interval number.

Notice, k numbers in $[n^c]$ can be encoded as string of length $ck \log n$. A logical labeling scheme can for instance express a system of polynomial inequalities on $2k$ variables and adjacency is determined by whether this system is satisfied when plugging in the values for two vertices. By disallowing multiplication these systems become linear. Quantified variables can be used to incorporate unknowns. For example, $\varphi(x, y) = \exists z : x \times z^2 = y$ means that there is an edge from u to v with labels x_u, y_v if y_v can be written as product of x_u and a square number.

▶ **Theorem 18.** $\mathsf{GFO} \subseteq \mathsf{GPH}$ *and* $\mathsf{GFO}_{\mathrm{qf}} \subseteq \mathsf{GL}$.

Proof sketch. It is known that the circuit class $\mathsf{TC}^0 \subseteq \mathsf{L}$ (assuming logspace-uniformity or stronger) and therefore $\mathsf{GTC}^0 \subseteq \mathsf{GL}$ [13]. We argue that $\mathsf{GFO}_{\mathrm{qf}} \subseteq \mathsf{GTC}^0$. Given a logical labeling scheme (φ, c) with $\varphi \in \mathsf{FO}_{2k}$ the label length in a graph with n vertices is $ck \log n$. The TC^0-circuit has $2ck \log n$ input bits and every block of $c \log n$ bits corresponds to the value of a free variable in φ. Every term in φ can be evaluated by implementing its syntax tree as part of the circuit since addition and multiplication can be computed in TC^0. The overflow condition, i.e. if the result is larger than n^c, has to be checked. Then for every atomic formula in φ it remains to test for equality or less than of the input terms. After replacing every atomic formula in φ by its truth value the formula becomes a propositional formula that can be seen as circuit since it is quantifier-free. If φ contains quantifiers assume that it is in prenex normal form, i.e. $\varphi = Q_1 z_1 \dots Q_q z_q \psi(x_1, \dots, x_{2k}, z_1, \dots, z_k)$ where $Q_i \in \{\exists, \forall\}$ and ψ is a quantifier-free formula. The values for $x_1, \dots, x_{2k}$ are determined by the input string and the value of a variable z_i corresponds to a binary word of length $k \log n$, which is linear in the size of the input string. Using the non-determinism of the polynomial-time hierarchy the values of the z_i's can be "guessed" and then evaluated using the TC^0-circuit described before, which can be simulated in polynomial time. ◀

Indeed, all of the graph classes mentioned in the beginning of this section are already contained in $\mathsf{GFO}_{\mathrm{qf}}(<)$. Therefore let us consider this class more closely.

▶ **Fact 19.** *The interval number λ_{Intv} is strictly bounded by a graph parameter that characterizes* $\mathsf{GFO}_{\mathrm{qf}}(<)$.

Proof. This statement is equivalent to saying that k-interval graphs are contained in $\mathsf{GFO}_{\mathrm{qf}}(<)$ and there exists a graph class $\mathcal{C} \in \mathsf{GFO}_{\mathrm{qf}}(<)$ that is no subclass of k-interval graphs for all $k \geq 1$. The containment of k-interval graphs in $\mathsf{GFO}_{\mathrm{qf}}(<)$ for every k follows by translating its geometrical representation into a logical labeling scheme as we have done for interval graphs previously. Consider the family of graphs shown in Figure 1 where G_{i+1} is obtained by appending a new 4-cycle to G_i.

Then the class $\{G_i \mid i \in \mathbb{N}\}$ lies in $\mathsf{GFO}_{\mathrm{qf}}(<)$ but can be verified to have unbounded interval number. This follows from the observation that the vertex with maximal degree in G_i cannot be represented with $i - 1$ intervals. ◀

A natural question is how do c and k affect the expressiveness of $\mathsf{G}_{c,k}\mathsf{FO}_{\mathrm{qf}}(<)$. Non-surprisingly, increasing k strictly enhances the graph classes that can be represented as we will see in a moment. The parameter c determines how large a number stored in a label can be, i.e. at most n^c. In fact, c is degenerate in the sense that it can be bounded in terms of k. It would be surprising if the same holds in the presence of addition.

▶ **Lemma 20.** $\mathsf{G}_{c,k}\mathsf{FO}_{\mathrm{qf}}(<) \subseteq \mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$ *for all* $c, k \geq 1$.

Proof. Consider why it suffices for an interval graph on n vertices to use only numbers between 1 and $2n$ to represent the intervals. For the same reason it makes no difference for a quantifier-free formula $\varphi \in \mathsf{FO}_{2k}(<)$ to be evaluated on a universe larger than kn in the sense that a labeling $\ell\colon V(G) \to \mathbb{N}^k$ can be converted to a labeling $\ell'\colon V(G) \to [kn]^k$ such that adjacency is preserved. More precisely, a (c,k)-labeling ℓ for a vertex set V can be transformed into a (k,k)-labeling ℓ' such that $G^{\ell}_{(\varphi,c)} = G^{\ell'}_{(\varphi,k)}$ holds for every quantifier-free formula $\varphi \in \mathsf{FO}_{2k}(<)$. Let $n = |V|$ be the number of vertices. Since k numbers are assigned to each vertex there are at most kn numbers in $A = \{x_i \mid u \in V, \ell(u) = (x_1,\dots,x_k), i \in [k]\}$. For an $a \in A$ let $\mathrm{ord}(a) = |\{b \in A \mid b < a\}| + 1$, i.e. the number of numbers in A that are smaller than a plus one. For $u \in V(G)$ we define $\ell'(u)$ as follows. Let $\ell(u) = (x_1,\dots,x_k)$. Then $\ell'(u) = (\mathrm{ord}(x_1),\dots,\mathrm{ord}(x_l))$. Notice that the maximal value for a component of $\ell'(u)$ is kn. It remains to check that the truth value of φ is invariant under this modified labeling, which follows from the fact that $x < y \Leftrightarrow \mathrm{ord}(x) < \mathrm{ord}(y)$. ◀

A consequence of this is that a logical labeling scheme in $\mathsf{GFO}_{\mathrm{qf}}(<)$ is solely determined by its formula φ. Therefore we consider a quantifier-free formula $\varphi \in \mathsf{FO}_{2k}(<)$ to be the logical labeling scheme (φ, k) as well. To check whether a graph G is in $\mathrm{gr}(\varphi)$ it suffices to find a labeling $\ell\colon V(G) \to \mathbb{N}^k$ with $2k = |\mathrm{Vars}(\varphi)|$ which can be regarded as (c,k)-labeling for a sufficiently large c. Stated differently, one does not need to worry about the numbers being polynomially bounded.

Also, it implies that for every k there exists a $k' > k$ such that $\mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<) \subsetneq \mathsf{G}_{k',k'}\mathsf{FO}_{\mathrm{qf}}(<)$. Assume the opposite, then $\mathsf{GFO}_{\mathrm{qf}}(<)$ collapses to $\mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$. It follows that every graph class in $\mathsf{GFO}_{\mathrm{qf}}(<)$ can be represented using $k^2 \log n$ bits and therefore has at most $\exp(k^2 \log n)$ graphs on n vertices, which obviously cannot be the case for any $k \in \mathbb{N}$.

▶ **Lemma 21.** *The graph class that is the union of every graph class in* $\mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$ *is contained in* $\mathsf{GFO}_{\mathrm{qf}}(<)$ *for all* $k \in \mathbb{N}$.

Proof. We argue that $\mathsf{GFO}_{\mathrm{qf}}(<)$ is closed under finite union and that there exists only a finite number of labeling schemes in $\mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$ such that they represent different graph classes. For closure under union consider two labeling schemes given by their quantifier-free formulas $\varphi, \psi \in \mathsf{FO}_{2k}(<)$. Then the graph class given by the following formula with $2k+2$ variables contains the union of $\mathrm{gr}(\varphi)$ and $\mathrm{gr}(\psi)$:

$$\big(x_{k+1} = x_{2k+2} \Rightarrow \varphi(x_1,\dots,x_k,x_{k+2},\dots,x_{2k+1})\big) \wedge$$
$$\big(x_{k+1} \neq x_{2k+2} \Rightarrow \psi(x_1,\dots,x_k,x_{k+2},\dots,x_{2k+1})\big)$$

The second claim follows from the fact that there are only finitely many semantically different quantifier-free formulas in $\mathsf{FO}_k(<)$ for every k. More precisely, there are at most $2k^2$ different atomic formulas ('$<$' and '$=$') on k variables and therefore at most $\exp^2(2k^2)$ semantically different formulas, which is the number of boolean functions on $2k^2$ variables. ◀

▶ **Definition 22.** For a graph G and $k \in \mathbb{N}$ we define the graph parameter $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}$ such that $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}(G) = k$ if k is the minimal number with $\{G\} \in \mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$.

▶ **Fact 23.** *The graph parameter* $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}(G)$ *characterizes* $\mathsf{GFO}_{\mathrm{qf}}(<)$.

Proof. One direction is trivial: if $\mathcal{C}$ is in $\mathsf{GFO}_{\mathrm{qf}}(<)$ then it is bounded by $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}$. For the other direction let $\mathcal{C}$ be bounded by $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}$ meaning that there exists a k such that for every $G \in \mathcal{C}$ it holds that $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}(G) \leq k$. Therefore $\mathcal{C}$ is a subset of the union of all graph classes in $\mathsf{G}_{k,k}\mathsf{FO}_{\mathrm{qf}}(<)$ which is in $\mathsf{GFO}_{\mathrm{qf}}(<)$ by Lemma 21. ◀

We remark that a similar construction using the label length does not yield a characterizing parameter for GP or GL. More specifically, the parameter defined by $\lambda(G)$ = minimal k such that $\{G\} \in \mathsf{G}_k\mathsf{P}$ does not characterize GP simply because the union of all graph classes in $\mathsf{G}_1\mathsf{P}$ already contains all graphs(the analogon of Lemma 21 fails).

4.1 Directed Acyclic Graph Characterization

The semantics of a logical labeling scheme given by a quantifier-free formula $\varphi \in \mathsf{FO}_{2k}(<)$ can be alternatively characterized by directed acyclic graphs (DAGs). Intuitively, an edge in the DAG corresponds to an atomic formula using '$<$'. The atomic formulas involving equality can be modeled by grouping variables together. This means the DAG has not the variables of φ as vertex set but rather a partition of these variables.

▶ **Definition 24.** Let $k \in \mathbb{N}$. We call a DAG $D = (X, E_D)$ a k-DAG if its vertex set X partitions $[2k]$. A k-labeling of a vertex set V is a function $\ell \colon V \to \mathbb{N}^k$. A k-DAG D and a k-labeling ℓ of a vertex set V define the graph G^ℓ_D on vertex set V with the following edges. For $u, v \in V$ let $(\ell(u), \ell(v)) = (x_1, \ldots, x_{2k})$. There is an edge (u, v) in G^ℓ_D if the following two conditions are satisfied:

1. For all $i, j \in [2k]$ it holds that $x_i = x_j$ whenever i, j are in the same part of X,
2. For all edges $(A, B) \in E_D$ it holds that $x_i < x_j$ for all $i \in A$ and $j \in B$.

▶ **Definition 25.** A graph $G = (V, E)$ is k-expressible for a $k \in \mathbb{N}$ if there exists a finite sequence of k-DAGs $D_1, \ldots, D_r$ and a k-labeling ℓ of V such that G is the edge-union of $G^\ell_{D_1}, \ldots, G^\ell_{D_r}$.

▶ **Theorem 26.** *For a graph G and $k \in \mathbb{N}$ it holds that $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}(G) = k$ iff k is the minimal number such that G is k-expressible.*

Proof. We show that there is a one-to-one correspondence between the semantics of a quantifier-free formula $\varphi \in \mathsf{FO}_{2k}(<)$ and k-DAGs. We can assume that φ contains no negation. To see that this can be done without loss of generality let φ be in negation normal form. Then $\neg x = y$ can be replaced by $x < y \vee y < x$ and $\neg x < y$ by $y < x \vee x = y$. Next, we assume that φ is in disjunctive normal form, i.e. $\varphi = C_1 \vee \cdots \vee C_p$ where C_i consists of atomic formulas linked by conjunction. Given a (c, k)-labeling ℓ for a vertex set V the formula φ induces the graph G^ℓ_S with $S = (\varphi, k)$ as described in Definition 16. Due to the observation given after the proof of Lemma 20 it is okay to consider a less restrictive k-labeling $\ell \colon V \to \mathbb{N}^k$ instead and additionally we write G^ℓ_φ instead of G^ℓ_S. Since every clause C_i is a formula as well it can be seen as logical labeling scheme, which induces the graph $G^\ell_{C_i}$. Then the correspondence between the graphs induced by φ and its clauses $C_1, \ldots, C_p$ is that G^ℓ_φ is the edge-union of $G^\ell_{C_1}, \ldots, G^\ell_{C_p}$. If a clause is unsatisfiable then its induced graph is the empty graph and thus removing this clause does not affect G^ℓ_S. Therefore we assume that every clause is satisfiable.

We now argue how to convert a clause C from φ into a k-DAG $D = (X, E_D)$ such that $G^\ell_C = G^\ell_D$ for every k-labeling ℓ. Consider the undirected graph H which has the variables of φ as vertices and two vertices x_i, x_j are adjacent iff the clause C contains $x_i = x_j$ or $x_j = x_i$. It follows that the connected components of H partition the variables of φ; let X be this partition. Now, consider the directed graph F which has the variables of φ as vertices again and there is an edge (x_i, x_j) in F iff C contains the atomic formula $x_i < x_j$. Since we can assume C to be satisfiable it follows that for every part A in the partition X (A is a subset of the variables of φ) the induced subgraph of F on the vertex set A yields the independent graph. Assume the opposite, then there exist two variables x_i, x_j in the same part of X such that (x_i, x_j) is an edge in F. This means that C contains the atomic formulas $x_i = x_j$ and $x_i < x_j$, which contradicts satisfiability of C. Let us define the operation of merging a set of vertices S in a graph G such that the resulting graph G' is the same as G except that all vertices in S are replaced by a single vertex v_s and there is an edge (u, v_s) in G' if there is a vertex $v \in S$ such that (u, v) is an edge in the old graph G; analogously for edges (v_s, u). Now, let F' be the graph obtained from F by merging each part of X. Then there is a natural one-to-one correspondence between the partition X and the vertex set of F'. We define D to have the same edges as F' via this correspondence. It remains to check that for this construction $G^\ell_C = G^\ell_D$ holds indeed. To prove the other direction a k-DAG can be converted into a conjunctive clause in a similar way. ◀

We conclude with the following two observations. By adding edge weights $w\colon E \to \mathbb{N}$ to the k-DAGs and adjusting the second condition of Definition 24 such that for all edges $(A, B) \in E_D$ it holds that $x_j - x_i \geq w(x_i, x_j)$ for all $x_i \in A, x_j \in B$ the semantics of existential quantifiers can be mimicked. Besides, given two k-DAGs D_1 and D_2 with identical vertex sets $V(D_1) = V(D_2)$ it holds that $G^\ell_{D_1} = G^\ell_{D_2}$ for every k-labeling ℓ whenever the transitive closures of D_1 and D_2 coincide.

5 Conclusions and Future Research

We have seen that limiting the computational resources for label decoders does indeed affect the class of graph classes that can be represented. Unfortunately, for a specific graph class the diagonalization argument from the second section does not help us determine whether it lies in GP. However, as of now it is not even clear whether any candidate of the IGC admits a labeling scheme at all as mentioned at the end of the first section. Therefore trying to place any of these classes in GP seems elusive. On the other side, proving lower bounds against GP or GL for small, hereditary graph classes might be just as futile given the lack of a suitable reduction notion. To counter this grim situation we have introduced a logical framework in the previous section that is much more restrictive than the TM model in its quantifier-free variant but still expressive enough to capture many of the implicit representations that we know. It appears to be a realistic goal to prove impossibility results in this setting, or more concretely refute the following weaker version of the IGC:

▶ **Conjecture 27** (Weak IGC). *Every small, hereditary graph class is in* $\mathsf{GFO}_{\mathrm{qf}}$.

As a first step in this direction we have investigated the fragment $\mathsf{GFO}_{\mathrm{qf}}(<)$ and made some structural observations. With the concept of parameter characterizations we have shown that the question of whether a certain graph class lies in $\mathsf{GFO}_{\mathrm{qf}}(<)$ can be answered by considering the k-expressibility property of every graph in this class independently. The directed acyclic graph characterization gives an alternative view on $\mathsf{GFO}_{\mathrm{qf}}(<)$, which is independent of the logical formalism. This could be a useful tool for proving lower bounds against this class. But even this small fragment seems to be surprisingly expressive as the following task shows. Give an example of a family of graphs that is not bounded by $\lambda_{\mathsf{FO}_{\mathrm{qf}}(<)}$. Recall that for the interval number this was quite simple, see Figure 1. Another interesting question is whether adding quantifiers enhances the expressiveness, i.e. $\mathsf{GFO}_{\mathrm{qf}}(<) = \mathsf{GFO}(<)$?

Abstract

While weighted automata provide a natural framework to express quantitative properties, many basic properties like average response time cannot be expressed with weighted automata. Nested weighted automata extend weighted automata and consist of a master automaton and a set of slave automata that are invoked by the master automaton. Nested weighted automata are strictly more expressive than weighted automata (e.g., average response time can be expressed with nested weighted automata), but the basic decision questions have higher complexity (e.g., for deterministic automata, the emptiness question for nested weighted automata is PSpace-hard, whereas the corresponding complexity for weighted automata is PTime). We consider a natural subclass of nested weighted automata where at any point at most a bounded number k of slave automata can be active. We focus on automata whose master value function is the limit average. We show that these nested weighted automata with bounded width are strictly more expressive than weighted automata (e.g., average response time with no overlapping requests can be expressed with bound $k = 1$, but not with non-nested weighted automata). We show that the complexity of the basic decision problems (i.e., emptiness and universality) for the subclass with k constant matches the complexity for weighted automata. Moreover, when k is part of the input given in unary we establish PSpace-completeness.

1 Introduction

Traditional to quantitative verification. In contrast to the traditional view of formal verification that focuses on Boolean properties of systems, such as "every request is eventually granted", quantitative specifications consider properties like "the long-run average success rate of an operation is at least one half" or "the long-run average response time is below a threshold." Such properties are crucial for performance related properties, for resource-constrained systems, such as embedded systems, and significant attention has been devoted to them [21, 14, 13, 22, 2].

Weighted automata. A classical model to express quantitative properties is *weighted automata* that extends finite automata where every transition is assigned a rational number called a *weight*. Each run results in a sequence of weights, and a *value function* aggregates the sequence into a single value. For non-deterministic weighted automata, the value of a word is the infimum value of all runs over the word. Weighted automata provide a natural and flexible framework to express quantitative[1] properties [14]. Weighted automata have been studied over finite words with weights from a semiring [21], and extended to infinite words with limit averaging or supremum as a value function [14, 13, 12]. While weighted automata over semirings can express several quantitative properties [27], they cannot express long-run average properties that weighted automata with limit averaging can [14]. However, even weighted automata with limit averaging cannot express the basic quantitative property of average response time [16, Example 5].

Nested weighted automata. To express properties like average response time, weighted automata were extended to *nested weighted automata (NWA)* [16]. An NWA consists of a master automaton and a set of slave automata. The master automaton runs over infinite input words. At every transition the master automaton can invoke a slave automaton that runs over a finite subword of the infinite word, starting at the position where the slave automaton is invoked. Each slave automaton terminates after a finite number of steps and returns a value to the master automaton. Each slave automaton is equipped with a value function for finite words, and the master automaton aggregates the returned values from slave automata using a value function for infinite words. For Boolean finite automata, nested automata are as expressive as the non-nested counterpart, whereas NWA are strictly more expressive than non-nested weighted automata [16]. It has been shown in [16] that NWA provide a specification framework where many basic quantitative properties, which cannot be expressed by weighted automata, can be expressed easily, and they provide a natural framework to study quantitative run-time verification.

The basic decision questions. We consider the basic automata-theoretic decision questions of emptiness and universality. The importance of these basic questions in the weighted automata setting is as follows: (1) Consider a system modeled by a finite-automaton recognizing traces of the system and a quantitative property given as a weighted automaton or an NWA. Then whether the worst-case (resp., best-case) behavior has the value at least λ is the emptiness (resp., universality) question on the product. (2) Problems related to model measuring (that generalizes model checking) and model repair also reduce to the emptiness problem [25, 16].

Complexity gap. In this work we focus on the following classical value functions: $\textsc{LimAvg}$ for infinite words, which is the long-run average property; and $\textsc{Sum}, \textsc{Sum}^+$ (where $\textsc{Sum}^+$ is the sum of absolute values) for finite words. While NWA are strictly more expressive than weighted automata, the complexity of the decision questions are either unknown or considerably higher. Table 1 (non-bold-faced results) summarizes the existing results for weighted automata [14] and NWA [16], for example, for NWA for $\textsc{Sum}^+$ the known bounds are $\textsc{ExpSpace}$ and $\textsc{PSpace}$-hard, and for $\textsc{Sum}$ even the decidability of the basic decision

[1] We use the term "quantitative" in a non-probabilistic sense, which assigns a quantitative value to each infinite run of a system, representing long-run average or maximal response time, or power consumption, or the like, rather than taking a probabilistic average over different runs.

Table 1 Decidability and complexity of emptiness and universality for weighted and nested weighted automata with LimAvg value function and Sum and Sum$^+$ value function for slave automata. Our results are bold faced. Moreover all PTime results become NLogSpace-complete when the weights are specified in unary.

	Deterministic (Emptiness/Universality)	Nondeterministic Emptiness	Nondeterministic Universality
Weighted aut.	PTime		Undecidable
NWA (LimAvg, Sum$^+$)	ExpSpace, PSpace-hard **PTime (width k is constant)** **PSpace-c. (bounded width)**		Undecidable
NWA (LimAvg, Sum)	Open **PTime (width k is constant)** **PSpace-c. (bounded width)**		Undecidable

questions is open (or undecidable). Thus, a fundamental question is whether there exist sub-classes of NWA that are strictly more expressive than weighted automata and yet have better complexity than general NWA. We address this question in this paper.

Nested weighted automata with bounded width. For NWA, let the maximum number of slave automata that can be active at any point be the *width* of the automaton. In this work we consider a natural special class of NWA, namely, NWA with bounded width, i.e., NWA where at any point at most k slave automata can be active. For example, the average response time with bounded number of requests pending at any point can be expressed by an NWA with bounded width, but not with a weighted automaton. Moreover, the class of NWA with bounded width is equivalent to automata with monitor counters [18], which are automata equipped with counters, where at each transition, a counter can be started, terminated, or the value of the counter can be increased or decreased. The transitions do not depend on the counter values, and hence they are referred to as monitor counters. The values of the counters when they are terminated give rise to the sequence of weights, which is aggregated into a single value with the LimAvg value function (see [18]). Automata with monitor counters are similar in spirit with the class of cost register automata of [2].

Our contributions. Our contributions are as follows (summarized as bold-faced results in Table 1):

1. *Constant width.* We show that the emptiness problem (resp., the emptiness and the universality problems) for non-deterministic (resp., deterministic) NWA with constant width (i.e., k is constant) can be solved in polynomial time and is NLogSpace-complete when the weights are specified in unary. Thus we achieve the same complexity as weighted automata for a much more expressive class of quantitative properties.
2. *Bounded width.* We show that the emptiness problem (resp., the emptiness and the universality problems) for non-deterministic (resp., deterministic) NWA with bounded width (i.e., k is a part of input given in unary) is PSpace-complete. Thus we establish precise complexity when k is a part of input given in unary.
3. *Deciding width.* We show that checking whether a given NWA has width k can be solved in polynomial time for constant k and in PSpace if k is given in the input (Theorem 6).

Technical contributions. Our main technical contributions for deterministic (LimAvg; Sum)-automata are as follows.

1. *Infinite infimum.* We first identify a necessary and sufficient condition for the infimum value over all words to be $-\infty$, and show that this condition can be checked efficiently.
2. *Lasso-approximation.* We show that if the above condition does not hold, then the infimum over all words can be approximated by lasso words, i.e., words of the form vu^ω. Moreover, we show that the infimum value is achieved with words where the slave automata run for short length relative to the point of the invocation, and hence the partial averages converge.
3. *Reduction to width* 1. Using the lasso-approximation we reduce the emptiness problem of width bounded by k to the corresponding problem of width 1. We show that the case of width 1 can be solved using standard techniques.

In the paper we present the key intuitions of the proofs, and due to space restrictions the technical details are in the full version [17].

Related works. Weighted automata over finite words have been extensively studied, the book [21] provides an excellent collection of results. Weighted automata on infinite words have been studied in [14, 13, 22]. The extension to weighted automata with monitor counters over finite words has been considered as cost register automata in [2]. A version of nested weighted automata over finite words has been studied in [6], and nested weighted automata over infinite words has been studied in [16]. Several quantitative logics have also been studied, such as [5, 7, 1]. In this work we consider a subclass of nested weighted automata which is strictly more expressive than weighted automata yet achieve the same complexity for the basic decision questions. Probabilistic models (such as Markov decision processes) with quantitative properties (such as limit-average or discounted-sum) have also been extensively studied for single objectives [23, 28], and for multiple objectives and their combinations [20, 10, 15, 8, 19, 9, 24, 11, 3, 4]. While NWA with bounded width have been studied under probabilistic semantics [18], the basic automata theoretic decision problems have not been studied for them.

2 Preliminaries

2.1 Words and automata

Words. We consider a finite *alphabet* of letters Σ. A *word* over Σ is a (finite or infinite) sequence of letters from Σ. We denote the i-th letter of a word w by $w[i]$, and for $i < j$ we have $w[i,j]$ is the word $w[i]w[i+1]\ldots w[j]$. The length of a finite word w is denoted by $|w|$; and the length of an infinite word w is $|w| = \infty$. For an infinite word w, thus $w[i,\infty]$ is the suffix of the word with first $i-1$ letters removed.

Labeled automata. For a set X, an *X-labeled automaton* $\mathcal{A}$ is a tuple $\langle \Sigma, Q, Q_0, \delta, F, C \rangle$, where (1) Σ is the alphabet, (2) Q is a finite set of states, (3) $Q_0 \subseteq Q$ is the set of initial states, (4) $\delta \subseteq Q \times \Sigma \times Q$ is a transition relation, (5) F is a set of accepting states, and (6) $C : \delta \mapsto X$ is a labeling function. A labeled automaton $\langle \Sigma, Q, \{q_0\}, \delta, F, C \rangle$ is *deterministic* if and only if δ is a function from $Q \times \Sigma$ into Q and Q_0 is a singleton. For deterministic labeled automata, we omit curly brackets for Q_0 and write $\langle \Sigma, Q, q_0, \delta, F, C \rangle$.

Semantics of (labeled) automata. A *run* π of a (labeled) automaton $\mathcal{A}$ on a word w is a sequence of states of $\mathcal{A}$ of length $|w|+1$ such that $\pi[0]$ belongs to the initial states of $\mathcal{A}$ and for every $0 \leq i \leq |w|-1$ we have $(\pi[i], w[i+1], \pi[i+1])$ is a transition of $\mathcal{A}$. A run π on a finite word w is *accepting* iff the last state $\pi[|w|]$ of the run is an accepting state of

$\mathcal{A}$. A run π on an infinite word w is *accepting* iff some accepting state of $\mathcal{A}$ occurs infinitely often in π. For an automaton $\mathcal{A}$ and a word w, we define $\mathsf{Acc}(w)$ as the set of accepting runs on w. Note that for deterministic automata, every word w has at most one accepting run ($|\mathsf{Acc}(w)| \leq 1$).

Weighted automata. A *weighted automaton* is a $\mathbb{Z}$-labeled automaton, where $\mathbb{Z}$ is the set of integers. The labels are called *weights*.

Semantics of weighted automata. We define the semantics of weighted automata in two steps. First, we define the value of a run. Second, we define the value of a word based on the values of its runs. To define values of runs, we will consider *value functions* f that assign real numbers to sequences of integers. Given a non-empty word w, every run π of $\mathcal{A}$ on w defines a sequence of weights of successive transitions of $\mathcal{A}$, i.e., $C(\pi) = (C(\pi[i-1], w[i], \pi[i]))_{1 \leq i \leq |w|}$; and the value $f(\pi)$ of the run π is defined as $f(C(\pi))$. We denote by $(C(\pi))[i]$ the weight of the i-th transition, i.e., $C(\pi[i-1], w[i], \pi[i])$. The value of a non-empty word w assigned by the automaton $\mathcal{A}$, denoted by $\mathcal{L}_{\mathcal{A}}(w)$, is the infimum of the set of values of all *accepting* runs; i.e., $\inf_{\pi \in \mathsf{Acc}(w)} f(\pi)$, and we have the usual semantics that infimum of an empty set is infinite, i.e., the value of a word that has no accepting run is infinite. Every run π on the empty word has length 1 and the sequence $C(\pi)$ is empty, hence we define the value $f(\pi)$ as an external (not a real number) value $\bot$. Thus, the value of the empty word is either $\bot$, if the empty word is accepted by $\mathcal{A}$, or ∞ otherwise. To indicate a particular value function f that defines the semantics, we will call a weighted automaton $\mathcal{A}$ an f-automaton.

Value functions. For finite runs we consider the following classical value functions: for runs of length $n+1$ we have

- *Sum, absolute sum:* the sum function $\textsc{Sum}(\pi) = \sum_{i=1}^{n} (C(\pi))[i]$, the absolute sum $\textsc{Sum}^{+}(\pi) = \sum_{i=1}^{n} \mathsf{Abs}((C(\pi))[i])$, where $\mathsf{Abs}(x)$ is the absolute value of x,

For infinite runs we consider:

- *Limit average:* $\textsc{LimAvg}(\pi) = \liminf_{k \to \infty} \frac{1}{k} \cdot \sum_{i=1}^{k} (C(\pi))[i]$.

Silent moves. Consider a $(\mathbb{Z} \cup \{\bot\})$-labeled automaton. We can consider such an automaton as an extension of a weighted automaton in which transitions labeled by $\bot$ are *silent*, i.e., they do not contribute to the value of a run. Formally, for every function $f \in \mathsf{InfVal}$ we define $\mathsf{sil}(f)$ as the value function that applies f on sequences after removing $\bot$ symbols. The significance of silent moves is as follows: it allows to ignore transitions, and thus provide robustness where properties could be specified based on desired events rather than steps.

2.2 Nested weighted automata

In this section we describe nested weighted automata introduced in [16], and closely follow the description of [16]. For more details and illustration of such automata we refer the reader to [16]. We start with an informal description.

Informal description. A *nested weighted automaton* (NWA) consists of a labeled automaton over infinite words, called the *master automaton*, a value function f for infinite words, and a set of weighted automata over finite words, called *slave automata*. A nested weighted automaton can be viewed as follows: given a word, we consider the run of the master automaton on the word, but the weight of each transition is determined by dynamically running slave automata; and then the value of a run is obtained using the value function f. That is, the master automaton proceeds on an input word as an usual automaton, except that before it takes a transition, it starts a slave automaton corresponding to the label of the current transition. The slave automaton starts at the current position of the word of the master automaton and works on some finite part of the input word. Once a slave automaton finishes, it returns its value to the master automaton, which treats the returned value as the weight of the current transition that is being executed. The slave automaton might immediately accept and return value $\bot$, which corresponds to *silent* transitions. If one of slave automata rejects, the nested weighted automaton rejects. We first present an example and then the formal definition.

▶ **Example 1** (Average response time). Consider an alphabet Σ consisting of requests r, grants g, and null instructions #. The average response time (ART) property asks for the average number of instructions between any request and the following grant. This property cannot be expressed by a non-nested automaton: a quantitative property is a function from words to reals, and as a function the range of non-nested LimAvg-automata is bounded, whereas the ART can have unbounded values (for details see [16]).

Nested weighted automata. A *nested weighted automaton* (NWA) is a tuple $\langle \mathcal{A}_{mas}; f; \mathfrak{B}_1, \ldots, \mathfrak{B}_l \rangle$, where (1) $\mathcal{A}_{mas}$, called the *master automaton*, is a $\{1, \ldots, l\}$-labeled automaton over infinite words (the labels are the indexes of automata $\mathfrak{B}_1, \ldots, \mathfrak{B}_l$), (2) f is a value function on infinite words, called the *master value function*, and (3) $\mathfrak{B}_1, \ldots, \mathfrak{B}_l$ are weighted automata over finite words called *slave automata*. Intuitively, an NWA can be regarded as an f-automaton whose weights are dynamically computed at every step by the corresponding slave automaton. We define an $(f; g)$*-automaton* as an NWA where the master value function is f and all slave automata are g-automata.

Semantics: runs and values. A *run* of $\mathbb{A}$ on an infinite word w is an infinite sequence $(\Pi, \pi_1, \pi_2, \ldots)$ such that (1) Π is a run of $\mathcal{A}_{mas}$ on w; (2) for every $i > 0$ we have π_i is a run of the automaton $\mathfrak{B}_{C(\Pi[i-1], w[i], \Pi[i])}$, referenced by the label $C(\Pi[i-1], w[i], \Pi[i])$ of the master automaton, on some finite word of $w[i, j]$. The run $(\Pi, \pi_1, \pi_2, \ldots)$ is *accepting* if all runs $\Pi, \pi_1, \pi_2, \ldots$ are accepting (i.e., Π satisfies its acceptance condition and each $\pi_1, \pi_2, \ldots$ ends in an accepting state) and infinitely many runs of slave automata have length greater than 1 (the master automaton takes infinitely many non-silent transitions). The value of the run $(\Pi, \pi_1, \pi_2, \ldots)$ is defined as $\mathsf{sil}(f)(v(\pi_1)v(\pi_2)\ldots)$, where $v(\pi_i)$ is the value of the run π_i in the corresponding slave automaton. The value of a word w assigned by the automaton $\mathbb{A}$, denoted by $\mathcal{L}_{\mathbb{A}}(w)$, is the infimum of the set of values of all *accepting* runs. We require accepting runs to contain infinitely many non-silent transitions as f is a value function over infinite sequences, hence the sequence $v(\pi_1)v(\pi_2)\ldots$ with $\bot$ removed must be infinite.

Deterministic nested weighted automata. An NWA $\mathbb{A}$ is *deterministic* if (1) the master automaton and all slave automata are deterministic, and (2) slave automata recognize prefix-free languages, i.e., languages $\mathcal{L}$ such that if $w \in \mathcal{L}$, then no proper extension of w belongs to $\mathcal{L}$. Condition (2) implies that no accepting run of a slave automaton visits an accepting state twice. Intuitively, slave automata have to accept the first time they encounter an accepting state as they will not visit an accepting state again.

▶ **Definition 2** (Width of NWA). An NWA has *width k* if and only if in every run at every position at most k slave automata are active.

▶ **Example 3** (Non-overlapping ART). We consider a variant of the ART property, called the 1-ART property, where after a request till it is granted additional requests are not considered. Formally, we consider the ART property over the language $\mathcal{L}_1$ defined by $(r\#^*g\#^*)^\omega$ (equivalently, given a request, the automata can check if the slave automaton is not active, and only then invoke it). An NWA $\mathbb{A}_1$ computing the ART property over $\mathcal{L}_1$ is obtained from the NWA for the ART property (see [16]) by taking the product of the master automaton $\mathcal{A}_{mas}$ with an automaton recognizing the language $\mathcal{L}_1$. The automaton $\mathbb{A}_1$ is a deterministic (LimAvg; Sum$^+$)-automaton. Indeed, the master automaton and the slave automata are deterministic and the slave automata recognize prefix-free languages. Moreover, in any (infinite) run at most one slave automaton is active, i.e., $\mathbb{A}_1$ has width 1. The dummy slave automata do not increase the width as they immediately accept, and hence they are not considered as active even at the position they are invoked. Finally, observe that the 1-ART property can return unbounded values, which implies that there exists no (non-nested) LimAvg-automaton expressing it. Also see Example 3 of the full version [17].

Decision problems. The classical questions in automata theory are language *emptiness* and *universality*. These problems have their counterparts in the quantitative setting of weighted automata and NWA. The (quantitative) emptiness and universality problems are defined in the same way for weighted automata and NWA; in the following definition the automaton $\mathcal{A}$ can be either a weighted automaton or an NWA.

- **Emptiness and universality**: Given an automaton $\mathcal{A}$ and a threshold λ, the *emptiness* (resp. *universality*) problem asks whether there exists a word w with $\mathcal{L}_{\mathcal{A}}(w) \leq \lambda$ (resp., for every word w we have $\mathcal{L}_{\mathcal{A}}(w) \leq \lambda$).

▶ Remark. In this work we focus on value functions Sum and Sum$^+$ for finite words, and LimAvg for infinite words. There are other value functions for finite words, such as Max, Min and bounded sum. However, it was shown in [16] that for these value functions, there is a reduction to non-nested weighted automata. Also for infinite words, there are other value functions such as Sup, LimSup, where the complexity and decidability results have been established in [16]. Hence in this work we focus on the most conceptually interesting case of LimAvg function for master automaton and Sum and Sum$^+$ value functions for the slave automata.

3 Examples

We present several examples of properties that can be specified with NWA of bounded width.

▶ **Example 4** (Variants of ART). Recall the ART property (Example 1) and its variant 1-ART property (Example 3). We present two variants of the ART property.

First, we extend Example 3 and consider the k-ART property over languages L_k defined by $(\#^*r(\#^*r\#^*)^{\leq k-1}g\#^*)^\omega$, i.e., the language where there are at most k-pending requests before each grant. As Example 3, an NWA $\mathbb{A}_k$ computing the k-ART property can be constructed from the NWA from Example. 3 by taking the product of the master automaton $\mathcal{A}_{mas}$ of the ART property with an automaton recognizing $\mathcal{L}_k$. The NWA $\mathbb{A}_k$ has width k.

Second, we consider the 1-ART[k] property, where $\Sigma = \{r_i, g_i : i \in \{1, \ldots, k\}\} \cup \{\#\}$, i.e., there are k-different types of "request-grant" pairs. The 1-ART[k] property asks for the average number of instructions between any request and the following grant of the corresponding type. Moreover, we consider as for 1-ART property that for every i, between a request r_i and the following grant of the corresponding type g_i, there is no request r_i of the same type. The 1-ART$[k]$ can be expressed with an $(\textsc{LimAvg}; \textsc{Sum}^+)$-automaton $\mathbb{A}_1^{[k]}$ of width bounded by k, which is similar to $\mathbb{A}_1$ from Example 3. Basically, the NWA $\mathbb{A}_1^{[k]}$ has k slave automata; for $i \in \{1, \ldots, k\}$ the slave automaton $\mathfrak{B}_i$ is invoked on letters r_i and it counts the number of steps to the following grant g_i. Additionally, the master automaton checks that for every i, between any two grants g_i, there is at most one request r_i.

In Examples 1, 3, and 4 we presented properties that can be expressed with $(\textsc{LimAvg}; \textsc{Sum}^+)$-automata. The following property of *average excess* can be expressed with slave automata with $\textsc{Sum}$ value functions that have both positive and negative weights, i.e., it can be expressed by an $(\textsc{LimAvg}; \textsc{Sum})$-automaton, but not $(\textsc{LimAvg}; \textsc{Sum}^+)$-automata.

▶ **Example 5** (Average excess). Consider the alphabet $\{r, g, \#\}$ from Example 1 with an additional letter \$. The *average excess* (AE) property asks for the average difference between requests and grants over blocks separated by \$. For example, for $\$(rr\#g\$)^\omega$ the average excess is 1. The AE property can be expressed by $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}_{\mathrm{AE}}$ of width 1 (presented below), but it cannot be expressed with $(\textsc{LimAvg}; \textsc{Sum}^+)$-automata; $(\textsc{LimAvg}; \textsc{Sum}^+)$-automata return values form the interval $[0, \infty)$, while AE ranges from $(-\infty, \infty)$. The automaton $\mathbb{A}_{\mathrm{AE}}$ invokes a slave automaton $\mathfrak{B}_1$ at positions of letter \$ and a dummy automaton $\mathfrak{B}_2$ on the remaining positions. The slave automaton $\mathfrak{B}_1$ runs until it sees \$ letter; it computes the difference between the number of r and g letters by taking transitions of weights $1, -1, 0$ respectively on letters $r, g, \#$. The master automaton as well as the slave automata of $\mathbb{A}_{\mathrm{AE}}$ are deterministic and the slave automata recognize prefix-free languages. Therefore, the NWA $\mathbb{A}_{\mathrm{AE}}$ is deterministic and has width 1.

4 Our Results

In this section we establish our main results. We first discuss complexity of checking whether a given NWA has width k. Next, we comment the results we need to prove.

Configurations. Let $\mathbb{A}$ be a non-deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton of width k. We define a *configuration* of $\mathbb{A}$ as a tuple $(q; q_1, \ldots, q_k)$ where q is a state of the master automaton and each $q_1, \ldots, q_k$ is either a state of a slave automaton of $\mathbb{A}$ or $\bot$. In the sequence $q_1, \ldots, q_k$ each state corresponds to one slave automaton, and the states are ordered w.r.t. the position when the corresponding slave automaton has been invoked, i.e., q_1 correspond to the least recently invoked slave automaton. If there are less than k slave automata active, then $\bot$ symbols follow the actual states (denoting there is no slave automata invoked). We define $\textsc{Conf}(\mathbb{A})$ as the number of configurations of $\mathbb{A}$.

Key ideas. NWA without weights are equivalent to Büchi automata [16]. The property of having width k is independent from weights. It can be decided with a construction of a (non-weighted) Büchi automaton, which tracks configurations $(q; q_1, \ldots, q_k)$ of a given NWA (assuming width k) and accepts only if the width-k condition is at some point violated.

▶ **Theorem 6.** *(1) Fix $k > 0$. We can check in polynomial time whether a given NWA has width k. (2) Given an NWA and a number k given in unary we can check in polynomial space whether the NWA has width k.*

Comment. We first note that for deterministic automata, emptiness and universality questions are similar. Hence we focus on the emptiness problem for non-deterministic automata (which subsumes the emptiness problem for deterministic automata) to establish the new results of Table 1. Moreover, the $\textsc{Sum}^+$ value function is a special case of the $\textsc{Sum}$ value function with only positive weights. Since our main results are algorithms to establish upper bounds, we will only present the result for the emptiness problem for non-deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automata. However, as a first step we show that without loss of generality, we can focus on the case of deterministic automata.

▶ **Lemma 7.** *Let $k > 0$. Given a non-deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}$ over alphabet Σ of width k, a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}_d$ of width k over an alphabet $\Sigma \times \Gamma$ such that $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) = \inf_{u' \in (\Sigma\times\Gamma)^\omega} \mathbb{A}_d(u')$ can be constructed in time exponential in k and polynomial in $|\mathbb{A}|$. Moreover, $\textsc{Conf}(\mathbb{A}_d)$ is polynomial in $\textsc{Conf}(\mathbb{A})$ and k and only the alphabet of $\mathbb{A}_d$ is exponential (in k) as compared to the alphabet of $\mathbb{A}$.*

Proof sketch. The main idea is that the part Γ of the alphabet encodes the possible non-deterministic choices, and the possible non-deterministic choices basically correspond to transitions between configurations.

Proof overview. We present our proof overview for the emptiness of deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automata. The proof consists of the following four key steps.

1. First, we identify a condition, and show in Lemma 9 that it is sufficient to ensure that the infimum value among all words is $-\infty$ (i.e., the least value possible). Moreover we show that the condition can be decided in $\textsc{PTime}$ if k is constant (even $\textsc{NLogSpace}$ if additionally the weights are in unary) and in $\textsc{PSpace}$ if k is given in unary.
2. Second, we show that if the above condition does not hold, then there is a family of lasso words (i.e., a finite prefix followed by an infinite repetition of another finite word) that approximates the infimum value among all words. This shows that the above condition is both necessary and sufficient. Moreover, we consider *dense* words, in which an i-th invoked slave automaton runs for at most for $O(\log(i))$ steps. We show that the infimum is achieved by a dense word. These results are established in Lemma 11.
3. Third, we show using the above result, that the problem for bounded width can be reduced to the problem of width 1, and the reduction is polynomial in the size of the original automaton, and only exponential in k. Thus if k is constant, the reduction is polynomial. This is established in Lemma 12.
4. Finally, we show that for automata with width 1, the emptiness problem can be solved in $\textsc{NLogSpace}$ if weights are in unary and otherwise in $\textsc{PTime}$ (Lemma 13).

The above four steps give our main result (Theorem 14). We start with the first item.

Intuition for the condition. We first illustrate with an example that for very similar automata, which just differ in order of invoking slave automata, the infima over the values are very different. For one automaton the infimum value is $-\infty$ and for the other it is 0. This example provides the intuition for the need of the condition to identify when the infimum value is $-\infty$.

▶ **Example 8.** Consider two deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automata $\mathbb{A}_1, \mathbb{A}_2$ defined as follows. The master automaton $\mathcal{A}_{mas}$ of $\mathbb{A}_1$ accepts the language $(12a^*\#)^\omega$. At letter 1 (resp., 2) it invokes an automaton $\mathfrak{B}_1$ (resp., $\mathfrak{B}_2$). The slave automaton $\mathfrak{B}_1$ increments its value at every a letter and it terminates once it reads $\#$. The slave automaton $\mathfrak{B}_2$ works as $\mathfrak{B}_1$ except that it decrements its value at a letters. NWA $\mathbb{A}_2$ is similar to $\mathbb{A}_1$ except that it accepts the language $(21a^*\#)^\omega$. It invokes the same slave automata as $\mathbb{A}_1$. Thus the two automata only differ in the order of invocation of the slave automata. Observe that the infimum over values of all words in $\mathbb{A}_1$ is 0. Basically, the values of slave automata are always the opposite, therefore the average of the values of slave automata is 0 infinitely often. However, the infimum over values of all words in $\mathbb{A}_2$ is $-\infty$. Indeed, consider a word $21a^1\# \ldots 21a^{2^i} \ldots$. At positions proceeding $1a^{2^i}$, the automaton $\mathfrak{B}_2$ returns the value -2^i and the average of all previous $2 \cdot i$ values is 0. Thus, the average at this position equals $-\frac{2^i}{2 \cdot i}$ (recall that the average is over the number of invocations of slave automata). Hence, the limit infimum of averages is $-\infty$.

Condition for infinite infimum. Let $k > 0$ and $\mathbb{A}$ be a deterministic ($\textsc{LimAvg}; \textsc{Sum}$)-automaton of width k. Let C be the minimal weight of slave automata of $\mathbb{A}$. Condition (*):

(*) $C < 0$ and there exists a word w accepted by $\mathbb{A}$ and infinitely many positions b such that the sum of weights, which automata active at position b accumulate while running on $w[b, \infty]$, is less than $C \cdot k^2 \cdot \textsc{Conf}(\mathbb{A})$.

Intuitively, condition (*) implies that there is a subword u which can be repeated so that the values of slave automata invoked before position b can be decreased arbitrarily. Note that pumping that word may not decrease the total average of the word. However, with $\textsc{LimAvg}$ value function, we need to ensure only the existence of a subsequence of positions at which the averages tend to $-\infty$, i.e., we only need to decrease the values of slave automata invoked before position b (for infinitely many positions).

Illustration of condition on example. Consider automata $\mathbb{A}_1, \mathbb{A}_2$ from Example 8. The automaton $\mathbb{A}_2$ satisfies condition (*), whereas $\mathbb{A}_1$ does not. In the word $21a^1\# \ldots 21a^{2^i} \ldots$, consider positions b, where $\mathfrak{B}_2$ is invoked by $\mathbb{A}_2$. The automaton $\mathfrak{B}_2$ works on the subword $21a^{2^i}$, where both automata $\mathfrak{B}_1, \mathfrak{B}_2$ are active and the sum of their values past any position is 0. However, the only slave automaton active at position b is $\mathfrak{B}_2$. These automaton accumulates the value -2^i past position b. Therefore, past some position N, all such positions b satisfy the statement from condition (*), and hence $\mathbb{A}_2$ satisfies condition (*). Now, for $\mathbb{A}_1$, at every position at which $\mathfrak{B}_2$ is active, $\mathfrak{B}_1$ is active as well, hence for any position b, the values accumulated by slave automaton active past this position is non-negative. Hence, $\mathbb{A}_1$ does not satisfy condition (*). We now present our lemma about the condition.

▶ **Lemma 9.** *Let $k > 0$ and $\mathbb{A}$ be a deterministic* ($\textsc{LimAvg}; \textsc{Sum}$)*-automaton of width k.*

1. *If condition (*) holds for $\mathbb{A}$, then* $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) = -\infty$.
2. *Condition (*) can be checked in* NLogSpace *for constant width and weights in unary,* PTime *for constant width, and in* PSpace *if the width is given in unary.*

Key intuitions. For (1), we show that the word from condition (*) can be pumped at some positions to achieve a word u' with $\mathbb{A}(u') = -\infty$. For (2), we show that condition (*) holds if and only if there exists a cycle in the graph of configurations of $\mathbb{A}$, which (a) can be visited infinitely often, and (b) for some $j \geq 1$, the sum of weights in this cycle of the j least recently invoked slave automata is negative. Recall that the order of invocation of slave automaton is encoded in the configuration, i.e., in $(q; q_1, \ldots q_j, q_{j+1}, \ldots, q_k)$ slave automata that correspond to the states $q_1, \ldots, q_j$ are the j least recently invoked.

▶ **Definition 10.** Let $\mathbb{A}$ be a deterministic ($\textsc{LimAvg}; \textsc{Sum}$)-automaton of width k. A word w is *dense* (w.r.t. $\mathbb{A}$) if in the run of $\mathbb{A}$ on w, for every $i > 0$, the i-th invoked slave automaton takes at most $O(\log(i))$ steps.

Intuitive explanation of dense words. In a deterministic ($\textsc{LimAvg}; \textsc{Sum}$)-automaton, the average is over the number of invoked slave automata, but in general, the returned values of

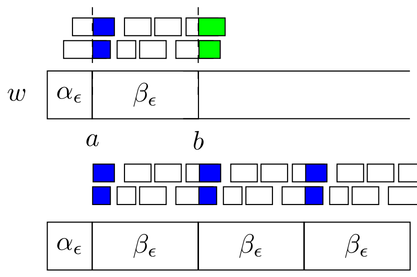

Figure 1 Explanation to Lemma 11; the blue part corresponds to H, while the green part corresponds to T.

the slave automata can be arbitrarily large as compared to the number of invocations, and hence the partial averages need not converge. Intuitively, in dense words, slave automata are invoked and terminated relatively densely, i.e., the length of their runs depends on the number of slave automata invoked till this position. In consequence, the value they can accumulate is small w.r.t. the average, i.e., their absolute contribution to the sum of the first n elements is $O(\log(n))$, and hence the contribution of the value a single slave automaton converges to 0 and the partial averages converge on dense words.

Illustration on example. Consider an automaton $\mathbb{A}_1$ from Example 8. We discuss the definition of density on an example of word $w = 12a^1\#12a^3\#\dots 12a^{2\cdot i+1}\#\dots$, which is not dense (w.r.t. $\mathbb{A}_1$). Observe that at the position of subword $12a^{2\cdot i+1}$, the partial average is 0. Once $\mathfrak{B}_1$ is invoked it returns value $2\cdot i+1$ and it is $(2\cdot i+1)$-th invocation of a slave automaton. Hence, the average increases to 1 only to be decreased to 0 after invocation of $\mathfrak{B}_2$. Now, word $w' = 12a^1\#(12a^2\#)^3\dots(12a^{2\cdot i+1}\#)^{2^i}\dots$ is dense. Indeed, before the slave automaton invoked at subword $12a^{2\cdot i+1}\#$ there are at least $\sum_{j=1}^{i-1} 2^j = 2^i - 1$ invoked slave automata. Therefore, the value $2\cdot i+1$ returned by $\mathfrak{B}_1$ invoked on $12a^{2\cdot i+1}$ is logarithmic in the number of invoked slave automata $2^i - 1$ and it changes the average by at most $\frac{2\cdot i+1}{2^i}$; as previously invoking $\mathfrak{B}_2$ in the next step bring the average back to 0. Thus, the sequence of partial averages of values returned by slave automata converges to 0.

▶ **Lemma 11.** *Let $k > 0$ and $\mathbb{A}$ be a deterministic* (LimAvg; Sum)*-automaton of width k. Assume that condition (*) does not hold. Then the following assertions hold:*
1. *For every $\epsilon > 0$ there exist finite words $\alpha_\epsilon, \beta_\epsilon$ such that $|\inf_{u\in\Sigma^\omega} \mathbb{A}(u) - \mathbb{A}(\alpha_\epsilon(\beta_\epsilon)^\omega)| < \epsilon$.*
2. *The value $\inf_{u\in\Sigma^\omega} \mathbb{A}(u)$ is greater than $-\infty$.*
3. *There exists a dense word w_d such that $\inf_{u\in\Sigma^\omega} \mathbb{A}(u) = \mathbb{A}(w_d)$.*

Proof sketch: We present the key ideas for each item (detailed proof in [17]). Assume that condition (*) fails.
1. We consider $\epsilon > 0$ and a word w_ϵ, which is $\frac{\epsilon}{4}$-close to the infimum over all values of $\mathbb{A}$. We show that w_ϵ contains a subword β_ϵ on which (a) the automaton $\mathbb{A}$ starts and ends with the same configuration, and (b) the average of the values returned by the slave automata is at most $\mathbb{A}(w_\epsilon) + \frac{\epsilon}{4}$. The existence of such a word follows from the fact that the partial averages are infinitely often $\frac{\epsilon}{4}$-close to the value of w_ϵ. We then show that β_ϵ together with α_ϵ, the prefix preceding β_ϵ, satisfy $|\inf_{u\in\Sigma^\omega} \mathbb{A}(u) - \mathbb{A}(\alpha_\epsilon(\beta_\epsilon)^\omega)| < \epsilon$. If we consider the sequence of values returned by slave automata on the word β_ϵ^ω, then it differs from the sequence of values returned when we consider the corresponding suffix in w_ϵ: this is because the values of slave automata in β_ϵ as a subword of w_ϵ depend on the following letters. The difference of partial averages can be bounded with an estimate

of $H - T$ which is defined below. Consider the subword $\alpha_\epsilon \cdot \beta_\epsilon$. Let X be the set of slave automata that are active when β_ϵ is invoked (i.e., after α_ϵ). Let H be the sum of weights of the active slave automata in X accumulated in the part of their respective runs on β_ϵ. Let Y be the set of active slave automata after $\alpha_\epsilon \cdot \beta_\epsilon$. Let T be the sum of weights of the active slave automata in Y accumulated in the part of their respective runs on w_ϵ past $\alpha_\epsilon \cdot \beta_\epsilon$. See Fig 1 for an illustration. We establish an estimate on $H - T$ using the fact that (*) does not hold.

2. Almost all slave automata invoked in the run of $\mathbb{A}$ on a word of the form $\alpha(\beta)^\omega$ take at most $|\beta|$ steps. Only slave automata invoked at α can take more steps without looping. Thus, the value $\mathbb{A}(\alpha(\beta)^\omega)$ is finite. Therefore, (1) implies that $\inf_{u \in \Sigma^\omega} \mathbb{A}(u)$ is finite (given some words are accepted and condition(*) fails.)
3. We construct w_d from a word $\beta_1^{k[1]}\beta_{\frac{1}{2}}^{k[2]}\beta_{\frac{1}{3}}^{k[3]}\ldots$ by choosing the sequence $k[0], k[1], \ldots$ to increase sufficiently fast. By repeating $k[n]$ times word $\beta_{\frac{1}{n}}$, we increase the number of invoked slave automata at least by $k[n]$, so the number of steps of slave automaton invoked in $\beta_{\frac{1}{n+1}}$, which is bounded by $|\beta_{\frac{1}{n+1}}|$, can be made arbitrarily small w.r.t. $k[n]$.

▶ Remark. Lemma 9 together with (2) of Lemma 11 imply that for a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}$ of width k condition (*) is both necessary and sufficient for the infimum over all values equal to $-\infty$. Moreover, this condition can be checked efficiently.

Lemma 12 reduces the emptiness problem for deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automata of width k to the same problem with automata of width 1.

▶ **Lemma 12.** *Let $k > 0$ and $\mathbb{A}$ be a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton of width k. Assume that condition (*) does not hold. Then, there exists a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}_1$ of width 1 over an alphabet Δ such that $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) = \inf_{u \in \Delta^\omega} \mathbb{A}_1(u)$. The size of $\mathbb{A}_1$ is $O(|\mathbb{A}|^k)$ and it can be constructed on-the-fly.*

Key intuitions. Consider a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton $\mathbb{A}$ of width k. We define the automaton $\mathbb{A}_1$, which uses a single slave automaton to keep track of all k automata of $\mathbb{A}$. This single slave automaton takes transitions whose weight is the sum of weights of transitions of tracked slave automata of $\mathbb{A}$. Therefore, $\mathbb{A}$ and $\mathbb{A}_1$ compute the averages of the same weights. Still, the way these weights are aggregated, i.e., their order in the sequence is different, and hence these automata may return different values on the same word. However, we show that on dense words the values of both automata coincide. This and Lemma 11 stating that there exists a dense word at which the automaton $\mathbb{A}_1$ realizes its infimum implies that the infimum over all values of $\mathbb{A}$ and $\mathbb{A}_1$ coincide.

▶ **Lemma 13.** *The emptiness problem for deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automata of width 1 is in $\textsc{PTime}$ and if the weights are in unary, then it is in $\textsc{NLogSpace}$.*

Key intuitions. We show that every transition of $\mathcal{A}_{mas}$, the master automaton of $\mathbb{A}$, at which a slave automaton is invoked, can be substituted by a transition whose weight is the minimal value the invoked slave automaton can achieve. More precisely, while a slave automaton is running on the input word, the master automaton $\mathcal{A}_{mas}$ is still active. Therefore, we substitute transitions (q, a, q', i) of $\mathcal{A}_{mas}$ by multiple transitions of the form $(q, (q, a, i, q''), q'')$, where (q, a, i, q'') is a new letter, q'' is a state of $\mathcal{A}_{mas}$ and the weight of this transition is the minimal value $\mathfrak{B}_i$ can achieve over words au such that $\mathcal{A}_{mas}$ moves from q to q'' upon reading au. Such a transformation preserves the infimum over all words and it transforms a deterministic $(\textsc{LimAvg}; \textsc{Sum})$-automaton of width 1 to a deterministic

LimAvg-automaton. The emptiness problem for LimAvg-automaton is decidable in PTime and even in NLogSpace provided that weights are given in unary.

We now present the algorithm and lower bound for our main result.

The algorithm. We present an algorithm, which, given a non-deterministic (LimAvg, Sum)-automaton $\mathbb{A}$ of width k and $\lambda \in \mathbb{Q}$, decides whether $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) \leq \lambda$.

1. Transform $\mathbb{A}$ into a deterministic (LimAvg, Sum)-automaton $\mathbb{A}_d$ of the same width such that $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) = \inf_{u \in (\Sigma \times \Gamma)^\omega} \mathbb{A}_d(u)$ (Lemma 7).
2. Check condition (*) for $\mathbb{A}_d$. If it holds, then $\inf_{u \in \Sigma^\omega} \mathbb{A}(u) = -\infty$ and return answer **YES**. Otherwise, continue the algorithm.
3. Transform $\mathbb{A}_d$ into a deterministic (LimAvg, Sum)-automaton $\mathbb{A}_1$ of width 1 such that $\inf_{u \in (\Sigma \times \Gamma)^\omega} \mathbb{A}_d(u) = \inf_{u \in \Delta^\omega} \mathbb{A}_1(u)$ (Lemma 12).
4. Compute $\inf_{u \in \Delta^\omega} \mathbb{A}_1(u)$ (Lemma 13), and return whether $\inf_{u \in \Delta^\omega} \mathbb{A}_1(u) \leq \lambda$.

Transformations in (1) and (3) are polynomial in the size of the automaton and exponential in k. Also, transformation from (1) does not increase k. Therefore, the size of $\mathbb{A}_1$ is polynomial in the size $\mathbb{A}$ and singly exponential in k. Moreover, these transformations can be done on-the-fly, i.e., there is not need to store the whole resulting automaton. Therefore, checks from (2) and (4), can be done in NLogSpace if k is constant and weights are in unary, PTime if k is constant, and PSpace if k is given in unary.

Hardness results. If k is constant, then the reachability problem on directed graphs, which is NLogSpace-complete, can be reduced to language emptiness of a finite automaton, which is a special case the emptiness problem for non-deterministic (LimAvg, Sum)-automata of width 1 with unary weights. If k is given in unary, consider the emptiness problem for the intersection of regular languages, which given k and regular languages $\mathcal{L}_1, \ldots, \mathcal{L}_k$, asks whether $\mathcal{L}_1 \cap \ldots \cap \mathcal{L}_k = \emptyset$. This problem is PSpace-complete [26] and reduces to the emptiness problem for deterministic (LimAvg, Sum)-automata of width given in unary: the PSpace-hardness result for emptiness of NWA given in [16] uses NWA of width $|\mathbb{A}|$.

▶ **Theorem 14.** *The emptiness problem for non-deterministic* (LimAvg, Sum)*-automata is (a)* NLogSpace*-complete in the size of $\mathbb{A}$ for constant width k with weights in unary; (b)* PTime *in the size of $\mathbb{A}$ for constant width k; and (c)* PSpace*-complete when the bounded width k is given as input in unary.*

Abstract

Games on graphs provide the appropriate framework to study several central problems in computer science, such as verification and synthesis of reactive systems. One of the most basic objectives for games on graphs is the liveness (or Büchi) objective that given a target set of vertices requires that some vertex in the target set is visited infinitely often. We study generalized Büchi objectives (i.e., conjunction of liveness objectives), and implications between two generalized Büchi objectives (known as GR(1) objectives), that arise in numerous applications in computer-aided verification. We present improved algorithms and conditional super-linear lower bounds based on widely believed assumptions about the complexity of (A1) combinatorial Boolean matrix multiplication and (A2) CNF-SAT. We consider graph games with n vertices, m edges, and generalized Büchi objectives with k conjunctions. First, we present an algorithm with running time $O(k \cdot n^2)$, improving the previously known $O(k \cdot n \cdot m)$ and $O(k^2 \cdot n^2)$ worst-case bounds. Our algorithm is optimal for dense graphs under (A1). Second, we show that the basic algorithm for the problem is optimal for sparse graphs when the target sets have constant size under (A2). Finally, we consider GR(1) objectives, with k_1 conjunctions in the antecedent and k_2 conjunctions in the consequent, and present an $O(k_1 \cdot k_2 \cdot n^{2.5})$-time algorithm, improving the previously known $O(k_1 \cdot k_2 \cdot n \cdot m)$-time algorithm for $m > n^{1.5}$.

1 Introduction

Games on graphs. Two-player games on graphs, between player 1 and the adversary player 2, are central in many problems in computer science, specially in formal analysis of reactive systems, where vertices of the graph represent states of the system, edges represent transitions, infinite paths of the graph represent behaviors (or non-terminating executions)

L. the research leading to these results has received funding from the European Research Council under the European Union's Seventh Framework Programme (FP/2007-2013) / ERC Grant Agreement no. 340506.

of the system, and the two players represent the system and the environment, respectively. Games on graphs have been used in many applications related to verification and synthesis of systems, such as, synthesis of systems from specifications and controller-synthesis [30, 54, 55], verification of open systems [8], checking interface compatibility [31], well-formedness of specifications [32], and many others. We will distinguish between results most relevant for *sparse graphs*, where the number of edges m is roughly proportional to the number of vertices n, and *dense graphs* with $m = \Theta(n^2)$. Sparse graphs arise naturally in program verification, as control-flow graphs are sparse [57, 28]. Graphs obtained as synchronous product of several components (where each component makes transitions at each step) [45, 23] can lead to dense graphs.

Objectives. Objectives specify the desired set of behaviors of the system. The most basic objective for reactive systems is the *reachability* objective, and the next basic objective is the *Büchi* (*also called liveness or repeated reachability*) objective that was introduced in the seminal work of Büchi [17, 18, 19] for automata over infinite words. Büchi objectives are specified with a target set T and the objective specifies the set of infinite paths in the graph that visit some vertex in the target set infinitely often. Since for reactive systems there are multiple requirements, a very central objective to study for games on graphs is the conjunction of Büchi objectives, which is known as generalized Büchi objective. Finally, currently a very popular class of objectives to specify behaviors for reactive systems is called the GR(1) (generalized reactivity (1)) objectives [53]. A GR(1) objective is an implication between two generalized Büchi objectives.

We present a brief discussion about the significance of the objectives we consider, for a detailed discussion see [26]. The conjunction of liveness objectives is required to specify progress conditions of mutual exclusion protocols, and deterministic Büchi automata can express many important properties of linear-time temporal logic (LTL) (the de-facto logic to specify properties of reactive systems) [47, 46, 9, 44]. The analysis of reactive systems with such objectives naturally gives rise to graph games with generalized Büchi objectives. Finally, graph games with GR(1) objectives have been used in many applications, such as the industrial example of synthesis of AMBA AHB protocol [14, 36] as well as in robotics applications [35, 21].

Basic problem and conditional lower bounds. In this work we consider games on graphs with generalized Büchi and GR(1) objectives, and the basic algorithmic problem is to compute the *winning set*, i.e., the set of starting vertices where player 1 can ensure the objective irrespective of the way player 2 plays; the way player 1 achieves that is called her *winning strategy.* These are core algorithmic problems in verification and synthesis. For the problems we consider, while polynomial-time algorithms are known, there are no super-linear lower bounds. Since for polynomial-time algorithms unconditional super-linear lower bounds are extremely rare in the whole of computer science, we consider *conditional lower bounds*, which assume that for some well-studied problem the known algorithms are optimal up to some lower-order factors. In this work we consider two such well-studied assumptions: (A1) there is no combinatorial[1] algorithm with running time of $O(n^{3-\varepsilon})$ for any $\varepsilon > 0$ to multiply two $n \times n$ Boolean matrices; or (A2) for all $\varepsilon > 0$ there exists a k such that there is no algorithm for the k-CNF-SAT problem that runs in $O(2^{(1-\varepsilon)\cdot n} \cdot \text{poly}(m))$ time, where n is the number of variables and m the number of clauses. These two assumptions have been used to establish

[1] Combinatorial here means avoiding fast matrix multiplication [48], see also the discussion in [38].

lower bounds for several well-studied problems, such as dynamic graph algorithms [3, 5], measuring the similarity of strings [4, 15, 16, 10, 2], context-free grammar parsing [49, 1], and verifying first-order graph properties [52, 61].

Our results. We consider games on graphs with n vertices, m edges, generalized Büchi objectives with k conjunctions, and target sets of size $b_1, b_2, \ldots, b_k$, and GR(1) objectives with k_1 conjunctions in the assumptions and k_2 conjunctions in the guarantee. Our results are as follows.

- *Generalized Büchi objectives.* The classical algorithm for generalized Büchi objectives requires $O(k \cdot \min_{1 \le i \le k} b_i \cdot m)$ time. Further there exists an $O(k^2 \cdot n^2)$-time algorithm via a reduction to Büchi games [13, 26].
  1. *Dense graphs.* Since $\min_{1 \le i \le k} b_i = O(n)$ and $m = O(n^2)$, the classical algorithm has a worst-case running time of $O(k \cdot n^3)$. First, we present an algorithm with worst-case running time $O(k \cdot n^2)$, which is an improvement for instances with $\min_{1 \le i \le k} b_i \cdot m = \omega(n^2)$. Second, for dense graphs with $m = \Theta(n^2)$ and $k = \Theta(n^c)$ for any $0 < c \le 1$ our algorithm is optimal under (A1); i.e., improving our algorithm for dense graphs would imply a faster (sub-cubic) combinatorial Boolean matrix multiplication algorithm.
  2. *Sparse graphs.* We show that for $k = \Theta(n^c)$ for any $0 < c \le 1$, for target sets of constant size, and sparse graphs with $m = \Theta(n^{1+o(1)})$ the basic algorithm is optimal under (A2). In fact, our conditional lower bound under (A2) holds even when each target set is a singleton. Quite strikingly, our result implies that improving the basic algorithm for sparse graphs even with singleton sets would require a major breakthrough in overcoming the exponential barrier for SAT.

  In summary, for games on graphs, we present an improved algorithm for generalized Büchi objectives for dense graphs that is optimal under (A1); and show that under (A2) the basic algorithm is optimal for sparse graphs and constant size target sets.

  The conditional lower bound for dense graphs means in particular that for unrestricted inputs the dependence of the runtime on n cannot be improved, whereas the bound for sparse graphs makes the same statement for the dependence on m. Moreover, as the graphs in the reductions for our lower bounds can be made acyclic by deleting a single vertex, our lower bounds also apply to a broad range of digraph parameters. For instance let w be the DAG-width [12] of a graph, then there is no $O(f(w) \cdot n^{3-\epsilon})$-time algorithm under (A1) and no $O(f(w) \cdot m^{2-\epsilon})$-time algorithm under (A2).
- *GR(1) objectives.* We present an algorithm for games on graphs with GR(1) objectives that has $O(k_1 \cdot k_2 \cdot n^{2.5})$ running time and improves the previously known $O(k_1 \cdot k_2 \cdot n \cdot m)$-time algorithm [43], for $m > n^{1.5}$. Note that since generalized Büchi objectives are special cases of GR(1) objectives, our conditional lower bounds for generalized Büchi objectives apply to GR(1) objectives as well but are not tight.

All our algorithms can easily be modified to also return the corresponding winning strategies for both players within the same time bounds.

Implications. We discuss the implications of our results.

1. *Comparison with related models.* We compare our results for game graphs to the special case of standard graphs (i.e., games on graphs with only player 1) and the related model of Markov decision processes (MDPs) (with only player 1 and stochastic transitions). First note that for reachability objectives, linear-time algorithms exist for game graphs [11, 39],

whereas for MDPs[2] the best-known algorithm has running time $O(\min(n^2, m^{1.5}))$ [29, 26]. For MDPs with reachability objectives, a linear or even $O(m \log n)$ time algorithm is a major open problem, i.e., there exist problems that seem harder for MDPs than for game graphs. Our conditional lower bound results show that under assumptions (A1) and (A2) the algorithmic problem for generalized Büchi objectives is strictly harder for games on graphs as compared to standard graphs and MDPs. More concretely, for $k = \Theta(n)$, (a) for dense graphs ($m = \Theta(n^2)$) and $\min_{1 \le i \le k} b_i = \Omega(\log n)$, our lower bound for games on graphs under (A2) is $\Omega(n^{3-o(1)})$, whereas both the graph and the MDP problems can be solved in $O(n^2)$ time [25, 26]; and (b) for sparse graphs ($m = \Theta(n^{1+o(1)})$) with $\min_{1 \le i \le k} b_i = O(1)$, our lower bound for games on graphs under (A1) is $\Omega(m^{2-o(1)})$, whereas the graph problem can be solved in $O(m)$ time and the MDP problem in $O(m^{1.5})$ time [7, 24]; respectively.

2. *Relation to SAT.* We present an algorithm for game graphs with generalized Büchi objectives and show that improving the algorithm would imply a better algorithm for SAT, and thereby establish an interesting algorithmic connection for classical objectives in game graphs and the SAT problem.

Due to the lack of space, some technical details are omitted. A full version is available at `http://eprints.cs.univie.ac.at/4708/`.

2 Preliminaries

2.1 Basic definitions for Games on Graphs

Game graphs. A *game graph* $\mathcal{G} = ((V, E), (V_1, V_2))$ is a directed graph $G = (V, E)$ with n vertices V and m edges E and a partition of V into *player 1 vertices* V_1 and *player 2 vertices* V_2. Given such a game graph $\mathcal{G}$, we denote with $\overline{\mathcal{G}}$ the game graph where the player 1 and player 2 vertices of $\mathcal{G}$ are interchanged, i.e, $\overline{\mathcal{G}} = ((V, E), (V_2, V_1))$. We use p to denote a player and $\bar{p}$ to denote its opponent. For a vertex $u \in V$, we write $Out(u) = \{v \in V \mid (u, v) \in E\}$ for the set of successor vertices of u and $In(u) = \{v \in V \mid (v, u) \in E\}$ for the set of predecessor vertices of u. If necessary, we refer to the successor vertices in a specific graph by using, e.g., $Out(G, u)$. We denote by $Outdeg(u) = |Out(u)|$ the number of outgoing edges from u, and by $Indeg(u) = |In(u)|$ the number of incoming edges. We assume for technical convenience $Outdeg(u) \ge 1$ for all $u \in V$.

Plays and strategies. A *play* on a game graph is an infinite sequence $\omega = \langle v_0, v_1, v_2, \ldots \rangle$ of vertices such that $(v_\ell, v_{\ell+1}) \in E$ for all $\ell \ge 0$. The set of all plays is denoted by Ω. Given a finite prefix $\omega \in V^* \cdot V_p$ of a play that ends at a player p vertex v, a *strategy* $\sigma : V^* \cdot V_p \to V$ of player p is a function that chooses a successor vertex $\sigma(\omega)$ among the vertices of $Out(v)$. We denote by Σ and Π the set of all strategies for player 1 and player 2 respectively. The play $\omega(v, \sigma, \pi)$ is uniquely defined by a start vertex v, a player 1 strategy $\sigma \in \Sigma$, and a player 2 strategy $\pi \in \Pi$ as follows: $v_0 = v$ and for all $j \ge 0$, if $v_j \in V_1$, then $v_{j+1} = \sigma(\langle v_1, \ldots, v_j \rangle)$, and if $v_j \in V_2$, then $v_{j+1} = \pi(\langle v_1, \ldots, v_j \rangle)$.

Objectives. An objective ψ is a set of plays that is winning for a player. We consider zero-sum games where for a player-1 objective ψ the complementary objective $\Omega \setminus \psi$ is winning

[2] For MDPs the winning set refers to the almost-sure winning set that requires that the objective is satisfied with probability 1.

for player 2. In this work we consider only *prefix independent objectives*, for which the set of desired plays is determined by the set of vertices $\mathrm{Inf}(\omega)$ that occur *infinitely often* in a play ω. Given a target set $T \subseteq V$, a play ω belongs to the *Büchi objective* Büchi (T) iff $\mathrm{Inf}(\omega) \cap T \neq \emptyset$. For the complementary *co-Büchi objective* we have $\omega \in$ coBüchi (T) iff $\mathrm{Inf}(\omega) \cap T = \emptyset$. A *generalized (or conjunctive) Büchi objective* is specified by a set of k target sets T_ℓ for $1 \leq \ell \leq k$ and is satisfied for a play ω iff $\mathrm{Inf}(\omega) \cap T_\ell \neq \emptyset$ for *all* $1 \leq \ell \leq k$. Its complementary objective is the *disjunctive co-Büchi objective* that is satisfied iff $\mathrm{Inf}(\omega) \cap T_\ell = \emptyset$ for *one of* the k target sets. A *generalized reactivity-1* (GR(1)) objective is specified by two generalized Büchi objectives, $\bigwedge_{t=1}^{k_1}$ Büchi (L_t) and $\bigwedge_{\ell=1}^{k_2}$ Büchi (U_ℓ), and is satisfied if whenever the first generalized Büchi objective holds, then also the second generalized Büchi objective holds; in other words, either $\bigvee_{t=1}^{k_1}$ coBüchi (L_t) holds, or $\bigwedge_{\ell=1}^{k_2}$ Büchi (U_ℓ) holds.

All the games in this paper will be given by a game graph $\mathcal{G}$ and an objective ψ for player 1 (player 2 has the complementary objective $\Omega \setminus \psi$).

Winning strategies and sets. A strategy σ is winning for player p at a start vertex v if the resulting play is winning for player p irrespective of the strategy of his opponent, player $\bar{p}$, i.e., $\omega(v, \sigma, \pi) \in \psi$ for all π. A vertex v belongs to the *winning set* W_p of player p if player p has a winning strategy from v. Every vertex is winning for exactly one of the two players [50]. When required for explicit reference of a specific game graph $\mathcal{G}$ and objective ψ, we use $W_p(\mathcal{G}, \psi)$ to refer to the winning sets.

Closed sets and attractors. A set $U \subseteq V$ is *p-closed* (in $\mathcal{G}$) if for all p-vertices u in U we have $Out(u) \subseteq U$ and for all $\bar{p}$-vertices v in U there exists a vertex $w \in Out(v) \cap U$. Note that player $\bar{p}$ can ensure that a play that currently ends in a p-closed set never leaves the p-closed set against any strategy of player p by choosing an edge (v, w) with $w \in Out(v) \cap U$ whenever the current vertex v is in $U \cap V_{\bar{p}}$ [62]. Given a game graph $\mathcal{G}$ and a p-closed set U, we denote by $\mathcal{G}[U]$ the game graph induced by the set of vertices U. Note that given that in $\mathcal{G}$ each vertex has at least one outgoing edge, the same property holds for $\mathcal{G}[U]$. We further use the shortcut $\mathcal{G} \setminus X$ to denote $\mathcal{G}[V \setminus X]$.

In a game graph $\mathcal{G}$, a *p-attractor* $Attr_p(\mathcal{G}, U)$ of a set $U \subseteq V$ is the set of vertices from which player p has a strategy to reach U against all strategies of player $\bar{p}$ [62]. We have that $U \subseteq Attr_p(\mathcal{G}, U)$. A p-attractor can be constructed inductively as follows: Let $R_0 = U$; and for all $j \geq 0$ let $R_{j+1} = R_j \cup \{v \in V_p \mid Out(v) \cap R_j \neq \emptyset\} \cup \{v \in V_{\bar{p}} \mid Out(v) \subseteq R_j\}$. Then $Attr_p(\mathcal{G}, U) = \bigcup_{j \geq 0} R_j$. The computation of attractors can be done in linear time [11, 39].

Dominions. A set of vertices $D \subseteq V$ is a player-p *dominion* if $D \neq \emptyset$ and player p has a winning strategy from every vertex in D that also ensures only vertices in D are visited. The notion of dominions was introduced by [42]. Note that a player-p dominion is also a $\bar{p}$-closed set and the p-attractor of a player-p dominion is again a player-p dominion.

▶ **Lemma 1.** *The following assertions hold for game graphs $\mathcal{G}$ where each vertex has at least one outgoing edge. The assertions referring to winning sets hold for graph games with prefix independent objectives. Let $X \subseteq V$.*

1. *The set $V \setminus Attr_p(\mathcal{G}, X)$ is p-closed on $\mathcal{G}$ [62, Lemma 4].*
2. *Let X be p-closed on $\mathcal{G}$. Then $W_{\bar{p}}(\mathcal{G}[X]) \subseteq W_{\bar{p}}(\mathcal{G})$ [42, Lemma 4.4].*
3. *Let X be a subset of the winning set $W_p(\mathcal{G})$ of player p and let A be its p-attractor $Attr_p(\mathcal{G}, X)$. Then the winning set $W_p(\mathcal{G})$ of the player p is the union of A and the winning set $W_p(\mathcal{G}[V \setminus A])$, and the winning set $W_{\bar{p}}(\mathcal{G})$ of the opponent $\bar{p}$ is equal to $W_{\bar{p}}(\mathcal{G}[V \setminus A])$ [42, Lemma 4.5].*

2.2 Conjectured Lower Bounds

While classical complexity results are based on complexity-theoretical assumptions about relationships between complexity classes, e.g., $\mathsf{P} \neq \mathsf{NP}$, polynomial lower bounds are often based on widely believed, conjectured lower bounds about well studied algorithmic problems. We next discuss the popular conjectures that will be the basis for our lower bounds.

First, we consider conjectures on Boolean matrix multiplication [58, 3] and triangle detection [3] in graphs, which build the basis for our lower bounds on dense graphs. A triangle in a graph is a triple x, y, z of vertices such that $(x, y), (y, z), (z, x) \in E$.

▶ **Conjecture 2** (Combinatorial Boolean Matrix Multiplication Conjecture (BMM))**.** *There is no $O(n^{3-\varepsilon})$ time combinatorial algorithm for computing the Boolean product of two $n \times n$ matrices for any $\varepsilon > 0$.*

▶ **Conjecture 3** (Strong Triangle Conjecture (STC))**.** *There is no $O(n^{3-\varepsilon})$ time combinatorial algorithm that can detect whether a graph contains a triangle for any $\varepsilon > 0$.*

BMM is equivalent to STC [58]. A weaker assumption, without the restriction to combinatorial algorithms, is that detecting a triangle in a graph takes super-linear time.

Second, we consider the Strong Exponential Time Hypothesis [40, 20] and the Orthogonal Vectors Conjecture [6], the former dealing with satisfiability in propositional logic and the latter with the *Orthogonal Vectors Problem.*

The Orthogonal Vectors Problem (OV). Given two sets S_1, S_2 of d-bit vectors with $|S_i| \leq N$ and $d \in \Theta(\log N)$, are there $u \in S_1$ and $v \in S_2$ such that $\sum_{i=1}^{d} u_i \cdot v_i = 0$?

▶ **Conjecture 4** (Strong Exponential Time Hypothesis (SETH))**.** *For each $\varepsilon > 0$ there is a k such that k-CNF-SAT on n variables and m clauses cannot be solved in time $O(2^{(1-\varepsilon)n} \operatorname{poly}(m))$.*

▶ **Conjecture 5** (Orthogonal Vectors Conjecture (OVC))**.** *There is no $O(N^{2-\varepsilon})$ time algorithm for the Orthogonal Vectors Problem for any $\varepsilon > 0$.*

SETH implies OVC [59], i.e., whenever a problem is hard assuming OVC, it is also hard when assuming SETH. Hence, it is preferable to use OVC for proving lower bounds. Finally, to the best of our knowledge, no such relations between the former two conjectures and the latter two conjectures are known.

▶ Remark. The conjectures that no *polynomial* improvements over the best known running times are possible do not exclude improvements by sub-polynomial factors such as poly-logarithmic factors or factors of, e.g., $2^{\sqrt{\log n}}$ as in [60].

3 Algorithms for Generalized Büchi Games

For generalized Büchi games we first present the basic algorithm that follows from the results of [33, 51, 62]. The basic algorithm runs in time $O(knm)$. We then improve it to an $O(k \cdot n^2)$-time algorithm by exploiting ideas from the $O(n^2)$-time algorithm for Büchi games in [25]. The basic algorithm is fast for instances where one Büchi set, say T_1, is small, i.e., the algorithm runs in time $O(k \cdot b_1 \cdot m)$ time, where $b_1 = |T_1|$. Generalized Büchi games can also be solved via a reduction to Büchi games [13], which yields an $O(k^2 n^2)$ time algorithm when combined with the $O(n^2)$-time Büchi algorithm [25].

Our algorithms iteratively identify sets of vertices that are winning for player 2, i.e., player-2 dominions, and remove them from the graph. We denote the sets in the jth-iteration with superscript j, in particular $\mathcal{G}^1 = \mathcal{G}$, where $\mathcal{G}$ is the input game graph, G^j is the graph of $\mathcal{G}^j$, V^j is the vertex set of G^j, and $T_\ell^j = V^j \cap T_\ell$. We also use $\{T_\ell^j\}$ to denote the list of Büchi sets $(T_1^j, T_2^j, \ldots, T_k^j)$, in particular when updating all the sets in a uniform way.

Algorithm GenBuchiGame: Algorithm for Generalized Büchi Games

```
Input  : Game graph $\mathcal{G} = ((V, E), (V_1, V_2))$ and objective $\bigwedge_{1 \le \ell \le k}$ Büchi $(T_\ell)$
Output : Winning set of player 1
$\mathcal{G}^1 \leftarrow \mathcal{G}$; $\{T_\ell^1\} \leftarrow \{T_\ell\}$; $j \leftarrow 0$
repeat
    $j \leftarrow j + 1$
    for $i \leftarrow 1$ to $\lceil \log_2 n \rceil$ do
        construct $G_i^j$
        $Z_i^j \leftarrow \{v \in V_2 \mid Outdeg(G_i^j, v) = 0\} \cup \{v \in V_1 \mid Outdeg(G_i^j, v) > 2^i\}$
        for $1 \le \ell \le k$ do
            $Y_{\ell,i}^j \leftarrow Attr_1(G_i^j, T_\ell^j \cup Z_i^j)$
            $S^j \leftarrow V^j \setminus Y_{\ell,i}^j$
            if $S^j \neq \emptyset$ then player 2 dominion found, continue with line 11
    $D^j \leftarrow Attr_2(G^j, S^j)$
    $\mathcal{G}^{j+1} \leftarrow \mathcal{G}^j \setminus D^j$;  $\{T_\ell^{j+1}\} \leftarrow \{T_\ell^j \setminus D^j\}$
until $D^j = \emptyset$
return $V^j$
```

Basic Algorithm. For each set U that is closed for player 1 we have that from each vertex $u \in U$ player 2 has a strategy to ensure that the play never leaves U [62]. Thus, if there is a Büchi set T_ℓ with $T_\ell \cap U = \emptyset$, then the set U is a player-2 dominion. Moreover, if U is a player-2 dominion, also the attractor $Attr_2(\mathcal{G}, U)$ of U is a player-2 dominion. The basic algorithm proceeds as follows. It iteratively computes vertex sets S^j closed for player 1 that do not intersect with one of the Büchi sets. If such a player-2 dominion S^j is found, then all vertices of $Attr_2(\mathcal{G}^j, S^j)$ are marked as winning for player 2 and removed from the game graph; the remaining game graph is denoted by $\mathcal{G}^{j+1}$. To find a player-2 dominion S^j, for each $1 \le \ell \le k$ the attractor $Y_\ell^j = Attr_1(\mathcal{G}^j, T_\ell^j)$ of the Büchi set T_ℓ^j is determined. If for some ℓ the complement of Y_ℓ^j is not empty, then we assign $S^j = V^j \setminus Y_\ell^j$ for the smallest such ℓ. The algorithm terminates if in some iteration j for each $1 \le \ell \le k$ the attractor Y_ℓ^j contains all vertices of V^j. In this case the set V^j is returned as the winning set of player 1. The winning strategy of player 1 from these vertices is then a combination of the attractor strategies to the sets T_ℓ^j.

▶ **Theorem 6.** *The basic algorithm for generalized Büchi games computes the winning set for player 1 in $O(k \cdot \min_{1 \le \ell \le k} b_\ell \cdot m)$ time, where $b_\ell = |T_\ell|$, and thus also in $O(knm)$ time.*

Our Improved Algorithm. The $O(k \cdot n^2)$-time Algorithm GenBuchiGame for generalized Büchi games combines the basic algorithm described above with the method used for the $O(n^2)$-time Büchi game algorithm [26], called *hierarchical graph decomposition* [37]. The hierarchical graph decomposition defines for a directed graph $G = (V, E)$ and integers $1 \le i \le \lceil \log_2 n \rceil$ the graphs $G_i = (V, E_i)$. Assume the incoming edges of each vertex in G are given in some fixed order in which first the edges from vertices of V_2 and then the edges from vertices of V_1 are listed. The set of edges E_i contains all the outgoing edges of each $v \in V$ with $Outdeg(G, v) \le 2^i$ and the first 2^i incoming edges of each vertex. Note that $G = G_{\lceil \log_2 n \rceil}$ and $|E_i| \in O(n \cdot 2^i)$. The runtime analysis uses that we can identify small player-2 dominions (i.e., player-1 closed sets that do not intersect one of the target sets) that contain $O(2^i)$ vertices by only looking at G_i. The algorithm first searches for such a set S^j in G_i for $i = 1$ and each target set and then increases i until the search is successful. In this way the time spent for the search is proportional to $k \cdot n$ times the number of vertices in the found dominion, which yields a total runtime bound of $O(k \cdot n^2)$. To obtain the $O(k \cdot n^2)$ running time bound, it is crucial to put the loop over the different Büchi sets as the innermost part of the algorithm. Given a game graph $\mathcal{G} = (G, (V_1, V_2))$, we denote by $\mathcal{G}_i$ the game graph where G was replaced by G_i from the hierarchical graph decomposition, i.e., $\mathcal{G}_i = (G_i, (V_1, V_2))$.

Properties of hierarchical graph decomposition. The following lemma identifies two essential properties of the hierarchical graph decomposition. The first is crucial for correctness: When searching in $\mathcal{G}_i$ for a player-1 closed set that does not contain one of the target sets, we can ensure that such a set is also closed for player 1 in $\mathcal{G}$ by excluding certain vertices that are missing outgoing edges in $\mathcal{G}_i$ from the search. The second is crucial for the runtime: Whenever the basic algorithm would remove (i.e., identify as winning for player 2) a set with at most 2^i vertices, then we can identify this set also by searching in $\mathcal{G}_i$ instead of $\mathcal{G}$.

▶ **Lemma 7.** *Let $\mathcal{G} = (G = (V, E), (V_1, V_2))$ be a game graph and $\{G_i\}$ its hierarchical graph decomposition. For $1 \le i \le \lceil \log_2 n \rceil$ let Z_i be the set consisting of the player 2 vertices that have no outgoing edge in $\mathcal{G}_i$ and the player 1 vertices with $> 2^i$ outgoing edges in $\mathcal{G}$.*
1. *If a set $S \subseteq V \setminus Z_i$ is closed for player 1 in $\mathcal{G}_i$, then S is closed for player 1 in $\mathcal{G}$.*
2. *If a set $S \subseteq V$ is closed for player 1 in $\mathcal{G}$ and $|Attr_2(\mathcal{G}, S)| \le 2^i$, then (i) $\mathcal{G}_i[S] = \mathcal{G}[S]$, (ii) the set S is in $V \setminus Z_i$, and (iii) S is closed for player 1 in $\mathcal{G}_i$.*

With the above lemma we can show that whenever a player-2 dominion is found in $\mathcal{G}_i$ but not in $\mathcal{G}_{i-1}$, then at least $\Omega(2^i)$ vertices are removed from the maintained game graph. Together with a runtime bound of $O(k \cdot 2^i \cdot n)$ for the search, this yields a total runtime of $O(k \cdot n)$ per vertex, i.e., time $O(k \cdot n^2)$ in total.

▶ **Theorem 8.** *Algorithm* GenBuchiGame *computes the winning set of player 1 in a generalized Büchi game in $O(k \cdot n^2)$ time.*

4 Conditional Lower bounds for Generalized Büchi Games

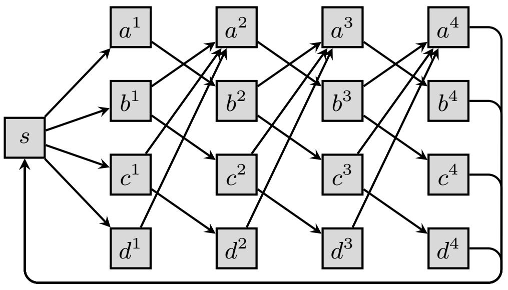
In this section we present two conditional lower bounds, one for dense graphs ($m = \Theta(n^2)$) based on STC & BMM, and one for sparse graphs ($m = \Theta(n^{1+o(1)})$) based on OVC & SETH.

▶ **Theorem 9.** *There is no combinatorial $O(n^{3-\epsilon})$ or $O((k \cdot n^2)^{1-\epsilon})$-time algorithm (for any $\epsilon > 0$) for generalized Büchi games under Conjecture 3 (i.e., unless STC & BMM fail).*

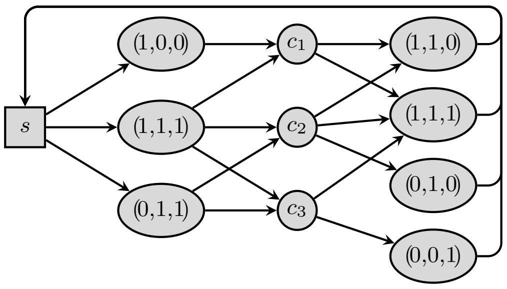
The result can be obtained from a reduction from triangle detection to disjunctive co-Büchi objectives on graphs in [22], and we present the reduction in terms of game graphs below and illustrate it on an example in Figure 1a.

▶ **Reduction 10.** *Given a graph $G = (V, E)$ (for triangle detection), we build a game graph $\mathcal{G}' = (G = (V', E'), (V_1, V_2))$ (for generalized Büchi objectives) as follows. As vertices V' we have four copies V^1, V^2, V^3, V^4 of V and a vertex s. A vertex $v^i \in V^i, i \in \{1, 2, 3\}$ has an edge to a vertex $u^{i+1} \in V^{i+1}$ iff $(v, u) \in E$. Moreover, s has an edge to all vertices of V^1 and all vertices of V^4 have an edge to s. All the vertices are owned by player 2, i.e., $V_1 = \emptyset$ and $V_2 = V$. Finally, we consider the generalized Büchi objective $\bigwedge_{v \in V}$ Büchi(T_v), with $T_v = (V^1 \setminus \{v^1\}) \cup (V^4 \setminus \{v^4\})$.*

We have that there is a triangle in the graph G if and only if the vertex s is winning for player 2 in the generalized Büchi game on $\mathcal{G}'$. Notice that the sets T_v in the above reduction are of linear size but can be reduced to logarithmic size using a construction from [22]. Next we present an $\Omega(m^{2-o(1)})$ lower bound for generalized Büchi objectives.



(a) Reduction 10 applied to $G = (\{a, b, c, d\}, \{(a, b), (b, a), (b, c), (c, a), (c, d), (d, a)\})$.



(b) Reduction 12 applied to $S_1 = \{(1, 0, 0), (1, 1, 1), (0, 1, 1)\}$ and $S_2 = \{(1, 1, 0), (1, 1, 1), (0, 1, 0), (0, 0, 1)\}$.

Figure 1 Illustration of Reductions 10 and 12.

▶ **Theorem 11.** *There is no $O(m^{2-\epsilon})$ or $O(\min_{1\leq i \leq k} b_i \cdot (k \cdot m)^{1-\epsilon})$-time algorithm (for any $\epsilon > 0$) for generalized Büchi games under Conjecture 5 (i.e., unless OVC & SETH fail).*

The above theorem is by a linear time reduction from OV provided below (cf. Figure 1b).

▶ **Reduction 12.** *Given two sets S_1, S_2 of d-dimensional vectors, we build the following game graph. The vertices V of the graph G are given by a start vertex s, vertices S_1 and S_2 representing the sets of vectors, and vertices $\mathcal{C} = \{c_i \mid 1 \leq i \leq d\}$ representing the coordinates. The edges E of G are defined as follows: the start vertex s has an edge to every vertex of S_1 and every vertex of S_2 has an edge to s; further for each $x \in S_1$ there is an edge to $c_i \in \mathcal{C}$ iff $x_i = 1$ and for each $y \in S_2$ there is an edge from $c_i \in \mathcal{C}$ iff $y_i = 1$. The set of vertices V is partitioned into player 1 vertices $V_1 = S_1 \cup S_2 \cup \mathcal{C}$ and player 2 vertices $V_2 = \{s\}$. Finally, the generalized Büchi objective is given by $\bigwedge_{v \in S_2}$ Büchi(T_v) with $T_v = \{v\}$.*

▶ **Lemma 13.** *Given two sets S_1, S_2 of d-dimensional vectors and the corresponding graph game $\mathcal{G}$ given by Reduction 12 with $T_v = \{v\}$ for $v \in S_2$, (1) there exist orthogonal vectors $x \in S_1$ and $y \in S_2$ if and only if (2) $s \notin W_1(\mathcal{G}, \bigwedge_{v \in S_2}$ Büchi$(T_v))$.*

Proof. W.l.o.g. we assume that the 1-vector, i.e., the vector with all coordinates being 1, is contained in S_2 (adding the 1-vector does not change the result of the OV instance), which guarantees that each vertex $c \in \mathcal{C}$ in the construction below has at least 1 outgoing edge. Then a play in the game graph $\mathcal{G}$ proceeds as follows. Starting from s, player 2 chooses a vertex $x \in S_1$; then player 1 first picks a vertex $c \in \mathcal{C}$ and then a vertex $y \in S_2$; then the play goes back to s (at each $y \in S_2$ player 1 has only this choice), starting another cycle of the play. (1)⇒(2): Assume there are orthogonal vectors $x \in S_1$ and $y \in S_2$. Now player 2 can satisfy coBüchi (T_y) by simply going to x whenever the play is in s. Then player 1 can choose some adjacent $c \in \mathcal{C}$ and then some adjacent vertex in S_2, but as x and y are orthogonal, this c is not connected to y. Thus the play will never visit y. (2)⇒(1): By the fact that $W_1 = V \setminus W_2$ [50] we have that (2) is equivalent to $s \in W_2(\mathcal{G}, \bigwedge_{v \in S_2}$ Büchi $(T_v))$. Assume $s \in W_2(\mathcal{G}, \bigwedge_{v \in S_2}$ Büchi $(T_v))$ and consider a corresponding strategy for player 2 that satisfies $\bigvee_{v \in S_2}$ coBüchi (T_v). Notice that the graph is such that player 2 has to visit at least one of the vertices v in S_1 infinitely often. Moreover, for such a vertex v then player 1 can visit all vertices $v' \in S_2$ that correspond to non-orthogonal vectors infinitely often. That is, if v has no orthogonal vector, player 1 can satisfy all the Büchi constraints, a contradiction to our assumption that $s \in W_2(\mathcal{G}, \bigwedge_{v \in S_2}$ Büchi $(T_v))$. Thus there must be a vector $x \in S_1$ such that there exists a vector $y \in S_2$ that is orthogonal to x. ◀

Let $N = \max(|S_1|, |S_2|)$. The number of vertices in the game graph, constructed by Reduction 12, is $O(N)$, the number of edges m is $O(N \log N)$ (recall that $d \in O(\log N)$), we have $k \in \Theta(N)$ target sets, each of size 1, and the construction can be performed in $O(N \log N)$ time. Thus, if we would have an $O(m^{2-\epsilon})$ or $O(\min_{1 \le i \le k} b_i \cdot (k \cdot m)^{1-\epsilon})$ time algorithm for any $\epsilon > 0$, we would immediately get an $O(N^{2-\epsilon})$ algorithm for OV, which contradicts OVC (and thus SETH).

▶ Remark. Notice that the lower bounds apply to instances with $k \in \Theta(n^c)$ for arbitrary $0 < c \le 1$, although the reductions produce graphs with $k \in \Theta(n)$. This is because of the specific type of the constructed instances, for which each $O((k \cdot f(n,m))^{1-\epsilon})$-time algorithm for $k \in \Theta(n^c)$ also implies an $O((k \cdot f(n,m))^{1-\epsilon})$-time algorithm for $k \in \Theta(n)$.

5 Generalized Reactivity-1 Games

GR(1) games deal with an objective of the form $\bigwedge_{t=1}^{k_1} \text{Büchi}(L_t) \to \bigwedge_{\ell=1}^{k_2} \text{Büchi}(U_\ell)$ and can be solved in $O(k_1 k_2 \cdot m \cdot n)$ time [43] with an extension of the progress measure algorithm of [41] and in $O((k_1 k_2 \cdot n)^{2.5})$ time by combining the reduction to one-pair Streett objectives by [13] with the algorithm of [27]. In this section we develop an $O(k_1 k_2 \cdot n^{2.5})$-time algorithm by modifying the algorithm of [43] to compute dominions. We further use our $O(k \cdot n^2)$-time algorithm for generalized Büchi games with $k = k_1$ as a subroutine.

We first describe a basic, direct algorithm for GR(1) games that is based on repeatedly identifying player-2 dominions in generalized Büchi games. We then show how the progress measure algorithm of [43] can be modified to identify player-2 dominions in generalized Büchi games with k_1 Büchi objectives in time proportional to $k_1 \cdot m$ times the size of the dominion. In the $O(k_1 k_2 \cdot n^{2.5})$-time algorithm we use the modified progress measure algorithm in combination with the hierarchical graph decomposition of [26, 27] to identify dominions that contain up to $\sqrt{n}$ vertices and our $O(k_1 \cdot n^2)$-time algorithm for generalized Büchi games to identify dominions with more than $\sqrt{n}$ vertices. Each time we search for a dominion we might have to consider k_2 different subgraphs.

We denote the sets in the jth-iteration of our algorithms with superscript j, in particular $\mathcal{G}^1 = \mathcal{G}$, where $\mathcal{G}$ is the input game graph, G^j is the graph of $\mathcal{G}^j$, V^j is the vertex set of G^j, $V_1^j = V_1 \cap V^j$, $V_2^j = V_2 \cap V^j$, $L_t^j = L_t \cap V^j$, and $U_\ell^j = U_\ell \cap V^j$.

Basic Algorithm. Similar to generalized Büchi games, the basic algorithm for GR(1) games identifies a player-2 dominion S^j, removes the dominion and its player-2 attractor D^j from the graph, and recurses on the remaining game graph $\mathcal{G}^{j+1} = \mathcal{G}^j \setminus D^j$. If no player-2 dominion is found, the remaining set of vertices V^j is returned as the winning set of player 1. Given the set S^j is indeed a player-2 dominion, the correctness of this approach follows from Lemma 1(3). A player-2 dominion in $\mathcal{G}^j$ is identified as follows: For each $1 \le \ell \le k_2$ first the player-1 attractor Y_ℓ^j of U_ℓ^j is temporarily removed from the graph. Then a generalized Büchi game with target sets $L_1^j, \ldots, L_{k_1}^j$ is solved on $\overline{\mathcal{G}^j \setminus Y_\ell^j}$. The generalized Büchi player in this game corresponds to player 2 in the GR(1) game and his winning set to a player-2 dominion in the GR(1) game. Note that $V^j \setminus Y_\ell^j$ is player-1 closed and does not contain U_ℓ^j. Thus if in the game induced by the vertices of $V^j \setminus Y_\ell^j$ player 2 can win w.r.t. the generalized Büchi objective $\bigwedge_{t=1}^{k_1} \text{Büchi}(L_t^j)$, then these vertices form a player-2 dominion in the GR(1) game. Further, we can show that when a player-2 dominion in the GR(1) games on $\mathcal{G}^j$ exists, then for one of the sets U_ℓ^j the winning set of the generalized Büchi game on $\overline{\mathcal{G}^j \setminus Y_\ell^j}$ is non-empty; otherwise we can construct a winning strategy of player 1 for the GR(1) game on $\mathcal{G}^j$. Note that this algorithm computes a player-2 dominion $O(k_2 \cdot n)$ often using our $O(k_1 \cdot n^2)$-time generalized Büchi Algorithm GenBuchiGame.

▶ **Theorem 14.** *The basic algorithm for GR(1) games computes the winning set for player 1 in $O(k_1 \cdot k_2 \cdot n^3)$ time.*

Improved Algorithm. The overall structure of our $O(k_1 k_2 \cdot n^{2.5})$-time algorithm for GR(1) games (see Algorithm GR(1)Game) is the same as for the basic algorithm: We search for a player-2 dominion S^j and if one is found, then its player-2 attractor D^j is determined and removed from the current game graph $\mathcal{G}^j$ (with $\mathcal{G}^1 = \mathcal{G}$) to create the game graph for the next iteration, $\mathcal{G}^{j+1}$. If no player-2 dominion exists, then the remaining vertices are returned as the winning set of player 1. The difference to the basic algorithm lies in the way player-2 dominions are searched. Two different procedures are used for this purpose: First we search for "small" dominions with the subroutine `kGenBüchiDominion`. If no small dominions exist, then we search for player-2 dominions as in the basic algorithm. The guarantee that we find a "large" dominion allows us to bound the number of times the second case can happen.

Progress Measure Algorithm. In the Procedure `kGenBüchiDominion` we use a subroutine that finds in a generalized Büchi game all dominions of the generalized Büchi player that have size at most h (where h is an input parameter). This subroutine is based on a so-called *progress measure* for generalized Büchi objectives which is a special instance of the progress measure for GR(1) objectives presented in [43, Section 3.1], which itself is based on [41]. We modify the progress measure to efficiently identify dominions of size at most h (instead of computing the whole winning set) by restricting the range of allowed values for the progress measure functions similar to [56]. Finally, we give an $O(k \cdot h \cdot m)$-time algorithm for computing the progress measure functions based on [34, 43] (details are provided in the full version).

▶ **Theorem 15.** *For a game graph $\mathcal{G}$ and objective $\psi = \bigwedge_{1 \le \ell \le k} \text{Büchi}(T_\ell)$, there is an $O(k \cdot h \cdot m)$ time procedure* `GenBüchiProgressMeasure`$(\mathcal{G}, \psi, h)$ *that either returns a player-1 dominion or the empty set, and, if there is at least one player-1 dominion of size $\le h$ then returns a player-1 dominion containing all player-1 dominions of size $\le h$.*

Procedure `kGenBüchiDominion`. The procedure `kGenBüchiDominion` searches for player-2 dominions in the GR(1) game, and returns some dominion if there exists a dominion D with $|Attr_2(\mathcal{G}, D)| \le h_{\max}$. To this end we again consider generalized Büchi games with target sets $L_1^j, \dots, L_{k_1}^j$, where the generalized Büchi player corresponds to player 2 in the GR(1) game. We use the same hierarchical graph decomposition as for Algorithm GenBuchiGame: Let the incoming edges of each vertex be ordered such that the edges from vertices of V_2 come first; for a given game graph $\mathcal{G}^j$ the graph G_i^j contains all vertices of $\mathcal{G}^j$, for each vertex its first 2^i incoming edges, and for each vertex with outdegree at most 2^i all its outgoing edges. The set Z_i^j contains all vertices of V_1 with outdegree larger than 2^i and all vertices of V_2 that have no outgoing edge in G_i^j. We start with $i = 1$ and increase i by one as long as no dominion was found. For a given i we perform the following operations for each $1 \le \ell \le k_2$: First the player 1 attractor $Y_{i,\ell}^j$ of $U_\ell^j \cup Z_i^j$ is determined. Then we search for player-1 dominions on $\overline{\mathcal{G}_i^j \setminus Y_{i,\ell}^j}$ w.r.t. the objective $\bigwedge_{t=1}^{k_1} \text{Büchi}(L_t)$ with the generalized Büchi progress measure algorithm and parameter $h = 2^i$, i.e., by Theorem 15 the progress measure algorithm returns all generalized Büchi dominions in $\overline{\mathcal{G}_i^j \setminus Y_{i,\ell}^j}$ of size at most h.

The following lemma shows how the properties of the hierarchical graph decomposition extend to GR(1) games. The first part is crucial for correctness: Every non-empty set found by the progress measure algorithm on $\overline{\mathcal{G}_i^j \setminus Y_{i,\ell}^j}$ for some i and ℓ is indeed a player-2 dominion in the GR(1) game. The second part is crucial for the runtime argument: Whenever the basic algorithm for GR(1) games would identify a player-2 dominion D with $|Attr_2(\mathcal{G}, D)| \le 2^i$, then D is also a generalized Büchi dominion in $\overline{\mathcal{G}_i^j \setminus Y_{i,\ell}^j}$ for some ℓ.

Algorithm GR(1)GAME: Algorithm for GR(1) Games

```

    return $\emptyset$
```

▶ **Lemma 16.** *Let the notation be as in Algorithm* GR(1)GAME*.*

1. *Every $X_{i,\ell}^j \neq \emptyset$ is a player-2 dominion in the GR(1) game on $\mathcal{G}^j$ with $X_{i,\ell}^j \cap U_\ell^j = \emptyset$.*
2. *If for player 2 there exists in $\mathcal{G}^j$ a dominion D w.r.t. the generalized Büchi objective $\bigwedge_{t=1}^{k_1}$ Büchi(L_t^j) such that $D \cap U_\ell^j = \emptyset$ for some $1 \le \ell \le k_2$ and $|Attr_2(\mathcal{G}^j, D)| \le 2^i$, then D is a dominion w.r.t. the generalized Büchi objective $\bigwedge_{t=1}^{k_1}$ Büchi$(L_t^j \setminus Y_{i,\ell}^j)$ in $\mathcal{G}_i^j \setminus Y_{i,\ell}^j$.*

From this we can draw the following two corollaries: (1) When we had to go up to i^* in the graph decomposition to find a dominion, then its attractor has size at least 2^{i^*-1} and (2) when `kGenBüchiDominion` returns an empty set, then all player-2 dominions in the current game graph have more than $h_{\max} = \sqrt{n}$ vertices. In the second case either no player-2 dominion exists or the subsequent call to `GenBüchiGame` returns one with more than $\sqrt{n}$ vertices, which can happen at most $O(\sqrt{n})$ times. Together with (1), this means we can (a) charge the time spent in `kGenBüchiDominion` to the vertices in the dominion identified in this iteration of the repeat-until loop (except for the last iteration) and (b) bound the number of calls to `GenBüchiGame` with $O(\sqrt{n})$.

▶ **Theorem 17.** *Algorithm* GR(1)GAME *computes the winning set of player 1 in a GR(1) game in $O(k_1 \cdot k_2 \cdot n^{2.5})$ time.*

6 Conclusion

In this work we present improved algorithms for generalized Büchi and GR(1) objectives, and conditional lower bounds for generalized Büchi objectives. The existing upper bounds and our conditional lower bounds are tight for (a) for dense graphs, and (b) sparse graphs with constant size target sets. Two interesting open questions are as follows: (1) For sparse graphs with $\theta(n)$ many target sets of size $\theta(n)$ the upper bounds are cubic, whereas the conditional lower bound is quadratic, and closing the gap is an interesting open question. (2) For GR(1) objectives we obtain the conditional lower bounds from generalized Büchi objectives, which are not tight in this case; whether better (conditional) lower bounds can be established also remains open.

Abstract

The Plane Subgraph (resp. Topological Minor) Completion problem asks, given a (possibly disconnected) plane (multi)graph Γ and a connected plane (multi)graph Δ, whether it is possible to add edges in Γ without violating the planarity of its embedding so that it contains some subgraph (resp. topological minor) that is topologically isomorphic to Δ. We give FPT algorithms that solve both problems in $f(|E(\Delta)|) \cdot |E(\Gamma)|^2$ steps. Moreover, for the Plane Subgraph Completion problem we show that $f(k) = 2^{\mathcal{O}(k \log k)}$.

1 Introduction

Completion problems on graphs are defined as follows: Consider a graph class $\mathcal{P}$ and ask whether we may add edges to a given graph G in order to obtain a graph G^+, where $G^+ \in \mathcal{P}$. Numerous results have appeared for the case where the objective is to minimize the number of edges added in G [13, 9, 11, 8, 3].

In this paper, we consider the Plane Subgraph (resp. Topological Minor) Completion (PSC) (resp. PTMC) problem which, given a (possibly disconnected) plane graph Γ, called the *host graph*, and a connected plane graph Δ, called the *pattern graph*, asks whether it is possible to add edges in Γ such that the resulting graph remains plane and contains some subgraph (resp. topological minor) that is topologically isomorphic to Δ. Both Γ and Δ are allowed to have multiple edges but not loops. When the input graph Γ is planar triangulated, both PSC and PTMC are NP-complete. Indeed, let G be any planar triangulated graph. Note here, that as any planar triangulated graph is 3-connected, G is 3-connected and from Whitney's Theorem [12] admits a unique embedding on the plane (up to equivalence), say Γ. Let also Δ be the cycle on $n = |V(G)|$ vertices. Then Δ also has unique embedding on the plane (up to equivalence). Since Γ is triangulated no edge can be added to it while preserving its planarity. Thus, both PSC and PTMC become equivalent to the Hamilton Cycle Problem which is NP-complete on planar triangulated graphs [4] (see also [7]). This observation further implies that PSC and PTMC parameterized by the number of added edges k, and in particular even for $k = 0$, are NP-complete. Thus, PSC and PTMC are not FPT when parameterized by the number of added edges unless P $=$ NP. Thus, in order to obtain a tractable algorithm, we need to find an alternative way to parameterize these problems. In particular, we will consider $|E(\Delta)|$ as our parameter. Our two main results are the following.

▶ **Theorem.** PSC *parameterized by the number of edges of the pattern graph Δ, say k, can be solved in $2^{\mathcal{O}(k \log k)} \cdot m^2$ time, where $m = |E(\Gamma)|$.*

▶ **Theorem.** PTMC *parameterized by the number of edges of the pattern graph Δ, say k, can be solved in $f(k) \cdot m^2$ time, where $m = |E(\Gamma)|$ and f is a computable function.*

For the PTMC algorithm our approach is the following. Let Γ and Δ be an input of the problem as above. We first apply a series of transformations on our input graph Γ that turn it into a combinatorial structure $\mathbf{G}$ whose treewidth is bounded by a function of $|E(\Delta)|$. Then, we apply a series of transformations on our input graph Δ that also turn it into a combinatorial structure $\mathbf{D}$. Finally, we show that (Δ, Γ) is a yes-instance of our problem if and only if an MSO-expressible relation holds for $\mathbf{G}$ and $\mathbf{D}$, thus translating our problem into a purely combinatorial one. Then by employing Courcelle's Theorem we prove our algorithm. We remark here that a similar approach could also solve the Plane Subgraph Completion problem. However, with a more careful analysis we are able to derive an algorithm with much better bounds on the dependence on the parameter.

Our approach towards solving PSC is the following. Let Γ and Δ be an input of PSC, where $|E(\Delta)| = k$ for some positive integer k. We construct a family $\mathcal{G}$ consisting of $\mathcal{O}(n)$ combinatorial structures depending only on Γ whose underlying graphs have treewidth $\mathcal{O}(k)$. We also construct a family $\mathcal{H}$ consisting of $2^{\mathcal{O}(k \log k)}$ combinatorial structures depending only on Δ, again by applying series of appropriate transformations on them (different than the transformations for PTMC). For the graphs Γ and Δ and the families $\mathcal{G}$ and $\mathcal{H}$, it holds that (Δ, Γ) is a yes-instance if and only if some structure $\mathbf{D} \in \mathcal{H}$ is contained as a *contraction* in a structure $\mathbf{G} \in \mathcal{G}$, denoted $\mathbf{D} \leq_c \mathbf{G}$. Therefore, we again translate our problem into one of combinatorial nature. Finally, for a fixed pair of structures $(\mathbf{D}, \mathbf{G}) \in \mathcal{H} \times \mathcal{G}$ with the above properties, we can decide in $2^{\mathcal{O}(k \log k)} \cdot m$ time whether $\mathbf{D} \leq_c \mathbf{G}$. Therefore, by testing for all pairs $(\mathbf{D}, \mathbf{G}) \in \mathcal{H} \times \mathcal{G}$ whether $\mathbf{D} \leq_c \mathbf{G}$, we decide in $2^{\mathcal{O}(k \log k)} \cdot m^2$ steps whether (Δ, Γ) is a yes-instance.

The paper is organized as follows. In Section 2 we give the necessary definitions. In Section 3 we present the algorithm for the PSC problem and in Section 4 we present the algorithm for the PTMC problem. In the concluding Section 5 we discuss about other completion problems that can be solved by modifying our results, such as the Plane Induced Subgraph Completion, the Plane Minor Completion, the Planar Rooted Topological Minor, and the Planar Disjoint Paths Completion problems. The lemmas whose proofs have been omitted due to lack of space are marked with $(\star)$.

2 Definitions

For a positive integer n, we denote $[n] = \{1, 2, \ldots, n\}$. Given a set S, a near-partition of S is a family of sets S_1, S_2, … , S_k, where $S_i \cap S_j = \emptyset$, for every $i \neq j$, and $\cup_{i \in [k]} S_i = S$ (note that by the definition it is possible that $S_i = \emptyset$ for some $i \in [k]$). Unless stated otherwise, the graphs considered do not have loops but may have multiple edges. In a graph G we will denote by $V(G)$ the set of its vertices and $E(G)$ the set of its edges. We denote by $\mathbf{dist}_G(u, v)$ the distance of two vertices u and v in the graph G. Also, given a graph G, a vertex $u \in V(G)$, and $V_0 \subseteq V(G)$, we denote by $N_G(u)$ the neighborhood of u in G and by $N_G(V_0) := \bigcup_{v \in V_0} N_G(v) \setminus V_0$. Given a vertex v with exactly two neighbors v_1 and v_2, the dissolution of v is the operation where we delete v and add an edge $\{v_1, v_2\}$ (even if one existed already).

Let G be a graph. A subset S of its vertices is a *separator* of G if the graph $G - S := (V(G) \setminus S, E[V(G) \setminus S])$ is not connected. The size of a separator S is equal to $|S|$. The vertex contained in a separator of size 1 will be called a *cut-vertex*, while the vertices of a separator of size 2 will be called a *cut-pair*. For every integer $k > 1$, a graph G with at least $k+1$ vertices is *k-connected* if G has no separators of size less than k. For definitions not explicitly stated on the paper as well as more details on general graphs, see [6]

We say that a graph is *plane* when it is embedded without crossings between its edges on the sphere $\Sigma = \{(x, y, z) \in \mathbb{R}^3 \mid x^2 + y^2 + z^2 = 1\}$. We treat a plane graph as its embedding in Σ and we simply refer to it as *plane graph*. That is, we do not distinguish between a vertex of the graph and the point of the sphere used in the drawing to represent the vertex or between an edge and the open line segment representing it. We often use the term "general graph" in order to stress that a graph is treated as a combinatorial structure and not as a topological (i.e., embedded) one. Also, given a plane graph Γ we use the term *general graph* of Γ to refer to Γ as a combinatorial structure. We use capital greek letters for plane graphs and capital latin letters for general graphs.

We denote by $\subseteq$, $\subseteq_{sp}$, $\subseteq_{in}$, $\leq_m$, and $\simeq$ the usual subgraph, spanning subgraph, induced subgraph, minor, and isomorphism relation between two graphs, respectively. Given a graph G and $V_0 \subseteq V(G)$, we denote by $G[V_0]$ the subgraph of G induced by V_0. We call V_0 *connected* if $G[V_0]$ is connected.

Let Γ be a plane graph and $u \in V(\Gamma)$. Then a tuple $(u_1, \ldots, u_k)$, with possible repetitions, will be called a *cyclic neighborhood* of u, and denoted by $\mathcal{N}_\Gamma(u)$, if $\{u, u_1\}, \ldots, \{u, u_k\}$ are exactly the edges incident to u, as we meet them starting from (u, u_1) and proceeding clockwise.

Let A be a subset of $\mathbb{R}^n$. We define $\mathbf{int}(A)$ to be the interior of A, $\mathbf{cl}(A)$ its closure and $\mathbf{bd}(A) = \mathbf{cl}(A) \setminus \mathbf{int}(A)$ its border. Given a plane graph Γ we denote its *faces* by $F(\Gamma)$, i.e.,

$F(\Gamma)$ is the set of the connected components of $\Sigma \setminus \Gamma$ (in the operation $\Sigma \setminus \Gamma$ we treat Γ as the set of points of Σ corresponding to its vertices and its edges). Given a graph G we denote by $\mathcal{C}(G)$ the set of the connected components of G. For every $f \in F(\Gamma)$ we denote by $B_\Gamma(f)$ the graph induced by the vertices and edges of Γ whose embeddings are subsets of $\mathbf{bd}(f)$ and we call it the *boundary* of f. We also denote by $V(B_\Gamma(f))$ and $E(B_\Gamma(f))$ the vertices and the edges of $B_\Gamma(f)$, respectively.

We define a *closed walk* of a graph G to be a cyclic ordering $w = (v_1, \dots, v_l, v_1)$ of vertices of $V(G)$ such that for any two consecutive vertices, say v_i, v_{i+1}, there is an edge between them in G, i.e., $\{v_i, v_{i+1}\} \in E(G)$. Note here that there may exist two distinct indices i, j such that $v_i, v_j \in w$ and $v_i = v_j$ (the walk can revisit a vertex). We will denote by $\ell_w = l$ the length of the respective closed walk w. We say that a walk w of a plane graph Γ is *facial* if there exists $f_i \in F(\Gamma)$ and $\Theta_j \in \mathcal{C}(B_\Gamma(f_i))$ such that the vertices of w are the vertices of $V(\Theta_j)$ and the cyclic ordering of w indicates the way these vertices are met when making a closed walk along Θ_j while always keeping f_i on the same side of the walk.

Given that Γ is a plane graph and $\mathbf{w} = \{w_1, \dots, w_p\}$ is a non-empty set of closed walks of Γ, we say that $\mathbf{w}$ is a *facial mapping* if there exists some face f of Γ such that $\mathcal{C}(B_\Gamma(f)) = \{\Theta_1, \Theta_2, \dots, \Theta_p\}$ and w_j is a facial walk of Θ_j, $j \in [p]$. We define the length of the facial mapping $\mathbf{w}$ to be $\ell_{\mathbf{w}} = \sum_{i=1}^{p} \ell_{w_i}$. Given a plane graph Γ and $f \in F(\Gamma)$, we define $\mathbf{w}(f)$ as the facial mapping of Γ corresponding to f and define its length ℓ_f to be the length $\ell_{\mathbf{w}}(f)$ of its corresponding facial mapping. Observe that for every face $f \in \Gamma(F)$, its facial mapping $\mathbf{w}(f)$ is unique (up to permutations). Let C_1, C_2 be two disjoint closed curves of Σ. Let also D_i be the open disk of $\Sigma \setminus C_i$ that does not contain points of C_{3-i}, $i \in [2]$. The *annulus between* C_1 and C_2 is the set $\Sigma \setminus (D_1 \cup D_2)$ and we denote it by $A[C_1, C_2]$. Notice that $A[C_1, C_2]$ is a closed set.

Let Γ and Δ be two plane graphs. We say that Γ and Δ are *topologically isomorphic* if they are isomorphic via a bijection $g : V(\Gamma) \to V(\Delta)$ and there exists a function $h : F(\Gamma) \to F(\Delta)$, such that for every $f \in F(\Gamma)$, $g(\mathbf{w}(f)) = \mathbf{w}(h(f))$ (where $g(\mathbf{w}(f))$ is the result of applying g to every vertex of every closed walk in $\mathbf{w}$). We call the function $\alpha : V(\Gamma) \cup F(\Gamma) \to V(\Delta) \cup F(\Delta)$ such that $\alpha = g \cup h$, a *topological isomorphism* between Γ and Δ.

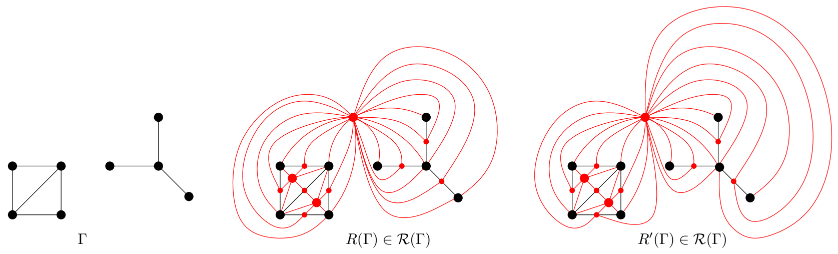
We say that a general graph G is *uniquely embeddable* if any two plane graphs Γ and Γ' that are embeddings of G in the sphere, are topologically isomorphic. We say that a plane graph Γ is *uniquely embedded* if its general graph G is uniquely embeddable, i.e., Γ is the unique embedding of G, up to topological isomorphism. Given two plane graphs Γ_1 and Γ_2 we say that they are the *same* graph if they are topologically isomorphic (and not just isomorphic).

Let Γ and Δ be two plane graphs and let $Z \subseteq V(\Gamma)$. We say that Δ is a *Z-embedded subgraph* of Γ, and write $\Delta \leq_{es}^{Z} \Gamma$, if Δ is topologically isomorphic to some subgraph of $\Gamma \setminus Z$. When $Z = \emptyset$, we say that Δ is an *embedded subgraph* of Γ and write $\Delta \leq_{es} \Gamma$.

Let Γ and Δ be two plane graphs and let $Z \subseteq V(\Gamma)$. We say that Δ is a *Z-embedded topological minor* of Γ, and write $\Delta \leq_{etm}^{Z} \Gamma$ if there exist a function $\rho_1 : V(\Delta) \to V(\Gamma)$ and a function $\rho_2 : E(\Delta) \to \mathcal{P}(\Gamma)$, where $\mathcal{P}(\Gamma)$ denotes the set of all paths of Γ such that

1. For every $v \in V(\Delta)$, $\rho_1(v) \notin Z$.
2. For every $e = \{u, v\} \in E(\Delta)$, the path $\rho_2(e)$ of Γ has $\rho_1(u)$ and $\rho_1(v)$ as its endpoints and if $e_1 \neq e_2$, then $\rho_2(e_1)$ and $\rho_2(e_2)$ are internally vertex-disjoint.
3. If $\Gamma\langle\rho_2\rangle$ is the graph obtained by the union of all paths in $\rho_2(E(\Delta))$ after we dissolve all vertices that are not vertices in $\rho_1(V(\Delta))$, then there is a topological isomorphism $\alpha : V(\Delta) \cup F(\Delta) \to V(\Gamma\langle\rho_2\rangle) \cup F(\Gamma\langle\rho_2\rangle)$ between Δ and $\Gamma\langle\rho_2\rangle$ where $\alpha|_{V(\Delta)} = \rho_1$.

When $Z = \emptyset$, we just write $\Delta \leq_{etm} \Gamma$.



Γ
$R(\Gamma) \in \mathcal{R}(\Gamma)$
$R'(\Gamma) \in \mathcal{R}(\Gamma)$

Figure 1 A disconnected plane graph Γ and two members of $\mathcal{R}_\Gamma$.

If in the 3rd condition of the above definition we replace topological isomorphism by isomorphism and consider general graphs, say H and G, we define the relation of H being a *Z-topological minor* of (G, Z).

For definitions not explicitly stated on the paper as well as more details on plane graphs, see [10].

2.1 Radial Enhancements

Let Γ be a plane graph. A *subdivided radial enhancement* of Γ is defined as a plane graph that can be constructed as follows: consider Γ, subdivide every edge once, add a vertex v_f inside each face f of Γ. Consider a permutation $(H_1, H_2, \ldots, H_s)$ of the connected components of $B_\Gamma(f)$ and a facial walk of each connected component. Then add edges connecting v_f with the vertices incident to $B_\Gamma(f)$ in such a way that the first vertices in the cyclic neighborhood of v_f are the vertices of H_1 and appear in the order of the fixed facial walk. Then the vertices of H_2 follow, etc. Observe that in the resulting embedding, every face that is incident to an edge of $E(\Gamma)$ is (planar) triangulated. This triangulation may have multiple edges unless the boundary of each face of Γ is a cycle, as can be seen in the two distinct examples of a subdivided radial enhancement of a disconnected plane graph Γ in Figure 1.

Notice that the vertices of the resulting plane graph can be partitioned into three independent sets: the *original vertices* of Γ denoted by $V_o(\Gamma)$, the *subdivision vertices* denoted by $V_s(\Gamma)$, which are the ones that were introduced after subdividing the edges, and the *radial vertices* denoted by $V_r(\Gamma)$, which are the ones that were added inside each face. Notice also that the edges of the resulting plane graph can be partitioned into two independent sets: the *subdivision edges* denoted by $E_s(\Gamma)$ and the *radial edges*, denoted by $E_r(\Gamma)$, that were introduced after adding the radial vertices.

We denote by $\mathcal{R}_\Gamma$ the set of all different (in terms of topological isomorphism) subdivided radial enhancements of Γ. Observe that if Γ is connected, then the boundary of each face of Γ is connected and we obtain the following.

▶ **Observation 1.** *For every connected plane graph Γ, $R(\Gamma)$ is uniquely defined and thus $\mathcal{R}_\Gamma$ contains only one member.*

From the subdivided radial enhancement's construction we obtain the following.

▶ **Observation 2.** *For every plane graph Γ and every $R(\Gamma) \in \mathcal{R}_\Gamma$ it holds that $|E(R(\Gamma)| = \mathcal{O}(|E(\Gamma)|)$.*

Given a plane graph Γ and a graph $R(\Gamma) \in \mathcal{R}_\Gamma$, for every integer $i > 1$, we denote by $R^i(\Gamma)$ the graph $R(R^{i-1}(\Gamma))$, where $R^1(\Gamma) = R(\Gamma)$. We define then $V_o^i(\Gamma) = V(R^{i-1}(\Gamma))$, $V_s^i = V_s(R^{i-1}(\Gamma))$, and $V_r^i = V_r(R^{i-1}(\Gamma))$. For notation consistency, we will denote by

$V_s^1(\Gamma) = V_s(\Gamma)$, $V_r^1(\Gamma) = V_r(\Gamma)$ and $V_o^1(\Gamma) = V_o(\Gamma)$. We also define the sets of edges $E_s^i(\Gamma)$ which are the edges obtained in $R^i(\Gamma)$ after subdiving the edges $E_s^{i-1}(\Gamma)$ and $E_r^i(\Gamma) = E(R^i(\Gamma)) \setminus E_s^i(\Gamma)$.

▶ **Lemma 2.1** (⋆). *For every plane graph Γ (with possibly multiple edges) every member of $\mathcal{R}_\Gamma$ is connected. Moreover, if Γ is i-connected, then $R(\Gamma)$ is $(i+1)$-connected, for $i \in [2]$.*

▶ Remark. If Γ is 2-connected then $R(\Gamma)$ can also be shown to be 4-connected. However, 3-connectivity is sufficient for our purposes.

2.2 Graph Structures

A key-concept in our algorithms is the notion of the vertex and the edge structure which is formally defined as follows. Let G be a simple planar graph, $k, l \in \mathbb{N}$, $(S_1, S_2, \dots, S_k)$ be a near-partition of $V(G)$ and $E_1, E_2, \dots, E_l$ be a near-partition of $E(G)$. A *vertex structure* $\mathbf{G}$ is a tuple $(G, S_1, S_2, \dots, S_k)$ and an edge structure $\mathbf{G}'$ is a tuple $(G, E_1, E_2, \dots, E_l)$.

Let $\mathbf{G} = (G, A, X_1, \dots, X_l)$ and $\mathbf{D} = (D, B, Y_1, \dots, Y_l)$ be vertex structures, where $l \in \mathbb{N}$. We say that $\mathbf{D}$ is a *contraction* of $\mathbf{G}$, denoted by $\mathbf{D} \leq_c \mathbf{G}$, if and only if there exists a function $\sigma : V(G) \to V(D)$ satisfying the following *contraction properties*:

1. if $u, v \in V(D)$, $u \neq v \Leftrightarrow \sigma^{-1}(u) \cap \sigma^{-1}(v) = \emptyset$,
2. for every $u \in V(D)$, $G[\sigma^{-1}(u)]$ is connected,
3. $\{u, v\} \in E(D) \Leftrightarrow G[\sigma^{-1}(u) \cup \sigma^{-1}(v)]$ is connected,
4. $\sigma(A) \subseteq B$, and
5. for every $i \in [l]$ and every $x \in Y_i$ it holds that $|\sigma^{-1}(x)| = 1$ and $\sigma^{-1}(x) \in X_i$.

In particular, a graph D is a *contraction* of a graph G if $(D, V(D)) \leq_c (G, V(G))$ and we write $D \leq_c G$. Notice that $\leq_c$ defined for graphs is the usual contraction relation where only conditions 1, 2, and 3 apply. Observe that for any two vertex structures $\mathbf{G}$ and $\mathbf{D}$, where G and D respectively are their associated planar graphs, $\mathbf{D} \leq_c \mathbf{G}$ implies that $D \leq_c G$.

We will also need the following proposition, which follows from the results in [1].

▶ **Proposition 1.** *There exists an algorithm that receives as input a vertex structure $\mathbf{G}$, whose graph has m edges and treewidth at most h, and a vertex structure $\mathbf{D}$, whose graph is connected and has k edges, and outputs whether $\mathbf{D} \leq_c \mathbf{G}$ in $2^{\mathcal{O}(k+h+k\log h)} \cdot m$ steps.*

Let $\mathbf{G} = (G, S_1, \dots, S_l)$ be a vertex structure on a planar graph G, where $l \in \mathbb{N}$. Given a possibly empty $Q \subseteq V(G)$, notice that the tuple $(Q, S_1 \setminus Q, \dots, S_l \setminus Q)$ also forms a near-partition of $V(G)$. Then, we can define the following operator on vertex structures:

$$\mathbf{d}(\mathbf{G}, Q) := (G, Q, S_1 \setminus Q, \dots, S_l \setminus Q).$$

Obviously, $\mathbf{d}(\mathbf{G}, Q)$ is also a vertex structure on G.

Let Γ be a plane graph and consider an $R(\Gamma) \in \mathcal{R}_\Gamma$. By Lemma 2.1 and Observation 1, the graph $R^3(\Gamma)$ is uniquely defined according to $R(\Gamma)$. The following operators on $(\Gamma, R(\Gamma))$ uniquely define a vertex and an edge structure:

$$\begin{aligned}\mathbf{p}(\Gamma, R(\Gamma)) &:= (R^3(\Gamma), V(\Gamma), V_s^1(\Gamma), V_r^1(\Gamma), V_s^2(\Gamma), V_r^2(\Gamma), V_s^3(\Gamma), V_r^3(\Gamma)) \\ \mathbf{e}(\Gamma, R(\Gamma)) &:= (R^3(\Gamma), E_s^3(\Gamma), E_r^3(\Gamma)).\end{aligned}$$

The underlying graph of the above structure is the general graph of $R^3(\Gamma)$ and the vertex sets that form the partition of $V(R^3(\Gamma))$ are the original vertices $V(\Gamma)$, followed by the sets of the subdivision and the radial vertices of each of the three subdivided radial enhancements.

Moreover, the edges are separated to those that have been obtain in $R^3(\Gamma)$ only by subdividing original edges of the graph and those that where obtained after adding radial vertices and edges and subdividing those edges.

Throughout the rest of the paper we will only use structures defined by those three operators. The main purpose is to associate three subdivided radial enhancements to a given plane graph so that (i) the resulting graph is 3-connected and therefore uniquely embeddable, so we can disregard the embedding and treat it as a combinatorial object, and (ii) the vertices and edges of the original graph and each subdivided radial enhancement are distinguishable. In addition, both in PSC and the PTMC problems we try to match the faces of the pattern graph to faces, or parts of faces, of the host graph, the radial enhancements and the corresponding structures seem to be the appropriate tool to use, since we actually only need to match the radial vertices that are added inside each face.

Given a graph G and a non-negative integer k, we define the *ball* around a vertex v of G as the subgraph $B^k_G(v)$ of G induced by the set of vertices at distance at most k from v. Consider now the subgraph $\tilde{G}$ of G induced by the set of vertices that lay outside a given ball $B^k_G(v)$, i.e., $\tilde{G} = G \setminus B^k_G(v)$, and consider the set $\mathcal{C}(\tilde{G})$ of all its connected components. Then by contracting all the edges of every $C \in \mathcal{C}(\tilde{G})$ to a single vertex in G, denoted v_C, we obtain the *k-contracted graph* around v, that will be denoted by G_v. Given a vertex structure $\mathbf{G} = (G, \emptyset, S_1, \ldots, S_l)$ and a non-negative integer k, we define the *k-contracted vertex structure* around a vertex v of the graph G as $\mathbf{G}^{(k)}_v := (G_v, \{v_C \mid C \in \mathcal{C}(\tilde{G})\}, S'_1, \ldots, S'_l)$, where $S'_i = S_i \cap B^k_G(v)$ for every $i \in [l]$.

3 An FPT algorithm for the PSC problem

Given a plane graph Γ we define *the set of non-edges of* Γ: $\overline{E(\Gamma)} = \binom{V(\Gamma)}{2} \setminus E(\Gamma)$. A set of non-edges $S \subseteq \overline{E(\Gamma)}$ will be called *insertable* if there is a way to add the edges to Γ such that no two edges of $E(\Gamma) \cup S$ intersect (apart from any common endpoints). Finally, we define the following relation between two plane graphs Γ and Δ. We say that $\Delta \preceq \Gamma$ if there exists a set $S \subseteq \overline{E(\Gamma)}$ of insertable edges of Γ such that $\Delta \leq_{es} \Gamma'$, where Γ' is obtained from Γ after adding S. Then PSC asks, given two plane graphs Γ and Δ, whether $\Delta \preceq \Gamma$.

The main idea of our algorithm is to create two families of vertex structures, one from the host graph Γ and the other from the pattern graph Δ, such that $\Delta \preceq \Gamma$ if and only if there are two structures $\mathbf{D}$ and $\mathbf{G}$ from each of the above families such that $\mathbf{D} \leq_c \mathbf{G}$. Then, we bound the size of these families and use the algorithm from Proposition 1 to check all pairs of their members for the required property. From now on, in this section, whenever we refer to a structure we will assume that it is a vertex structure.

We define the first family of structures based on the host graph. Given a plane graph Γ, a subdivided radial enhancement of it, $R(\Gamma)$, and a positive integer k, we define the following family of structures:

$$\mathcal{G}_{\Gamma,R(\Gamma),k} := \{\mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)^{(k)}_v | v \in V(\Gamma)\}.$$

Obviously, $|\mathcal{G}_{\Gamma,R(\Gamma),k}| = |V(\Gamma)|$, regardless of the choice of $R(\Gamma)$ and k.

▶ **Lemma 3.1** ($\star$). *Let Γ be a plane graph, $R(\Gamma)$ a subdivided radial enhancement of Γ, $k \in \mathbb{N}$, $v \in V(\Gamma)$, and $\mathbf{G}_v := \mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)^{(k)}_v \in \mathcal{G}_{\Gamma,R(\Gamma),k}$. Then the underlying graph G_v of the structure $\mathbf{G}_v$ has treewidth at most $3(k+1)$ and size $\mathcal{O}(|E(\Gamma)|)$.*

In order to define the second family of structures based on the pattern graph we need the following two definitions.

A *facial extension* of a connected plane graph Δ is a connected plane graph Δ^+ satisfying the following properties:

1. $\Delta \subseteq \Delta^+$,
2. $V(\Delta^+) \setminus V(\Delta)$ is an independent set in Δ^+, and
3. for every distinct $x, y \in V(\Delta^+) \setminus V(\Delta)$, $N_{\Delta^+}(x) \not\subseteq N_{\Delta^+}(y)$.

We will denote by $\mathcal{F}_\Delta$ the family of all facial extensions of the graph Δ.

Given a connected plane graph Δ and a subset $L \subseteq E(\Delta)$ of its edges, we denote by $\mathsf{span}(\Delta, L)$ the set of all spanning subgraphs of Δ that contain all the edges in $E(\Delta) \setminus L$. Note that such subgraphs could also contain some edges in L. A *pattern-guess* of a connected plane graph Δ is an element Δ^* of $\mathsf{span}(\Delta^+, E(\Delta))$, for $\Delta^+ \in \mathcal{F}_\Delta$. That is, a spanning subgraph of a facial extension Δ^+ of Δ containing at least all the edges in $E(\Delta^+) \setminus E(\Delta)$. The family of all possible pattern-guesses Δ^* of Δ will be denoted by $\mathcal{PG}_\Delta$.

Now, given a connected plane graph Δ we define the following family of structures: $\mathcal{H}_\Delta := \{\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), V(\Delta^*) \setminus V(\Delta)) | \Delta^* \in \mathcal{PG}_\Delta,\ R(\Delta^*) \in \mathcal{R}_{\Delta^*}\}$.

▶ **Lemma 3.2** ($\star$). *If Δ is a connected plane graph then $|\mathcal{H}_\Delta| = 2^{\mathcal{O}(|E(\Delta)| \cdot \log |E(\Delta)|)}$ and, for any structure $\mathbf{D} \in \mathcal{H}_\Delta$, the underlying graph D of $\mathbf{D}$ has size and diameter bounded by $\mathcal{O}(|E(\Delta)|)$.*

▶ **Lemma 3.3** ($\star$). *Let $\mathbf{G} = (G, \emptyset, S_1, \ldots, S_l)$ and $\mathbf{D} = (D, B, Z_1, \ldots, Z_l)$ be two structures, where B is an independent set and $l \in \mathbb{N}$. Then $\mathbf{D} \leq_c \mathbf{G}$ if and only if there exists some $v \in V(G)$ such that $\mathbf{D} \leq_c \mathbf{G}_v^{(k)}$, where $k := \mathbf{diam}(D)$.*

The next theorem ensures the correctness of our algorithm.

▶ **Theorem 3.4.** *Let Γ be a plane graph and Δ be a connected plane graph. It holds that $\Delta \preceq \Gamma$ if and only if for every $R(\Gamma) \in \mathcal{R}_\Gamma$ there exist two structures $\mathbf{G} \in \mathcal{G}_{\Gamma, R(\Gamma), c}$ and $\mathbf{D} \in \mathcal{H}_\Delta$, such that $\mathbf{D} \leq_c \mathbf{G}$, where c is a constant such that $\max\limits_{\Delta^*}\{\mathbf{diam}(R^3(\Delta^*))\} \leq c$.*

Proof. First of all, we know that such a constant c exists from Lemma 3.2 and that in fact $c = \mathcal{O}(|E(\Delta)|)$. Let us first assume that $\Delta \preceq \Gamma$. Then there exists an insertable set of non-edges $S \subseteq \overline{E(\Gamma)}$ and two plane graphs $\Gamma' = (V(\Gamma), E(\Gamma) \cup S)$ and Γ_0, such that $\Gamma_0 \subseteq \Gamma'$ and $\Delta \simeq_{tp} \Gamma_0$. Without loss of generality we may assume that all edges of S are also edges of Γ_0. Let then $\alpha : V(\Gamma_0) \cup F(\Gamma_0) \to V(\Delta) \cup F(\Delta)$ be a topological isomorphism between Γ_0 and Δ. For every edge $e = \{u, v\}$ of S let $e_\alpha = \{\alpha(u), \alpha(v)\}$. We define the sets $S_\alpha = \{e_\alpha \mid e \in S\}$, $S_\alpha^\Delta = S_\alpha \cap E(\Delta)$, and $S_\alpha^\Gamma = S_\alpha \setminus S_\alpha^\Delta$.

We first construct a graph $\Delta^+ \in \mathcal{F}_\Delta$. For this, we add a set of vertices and edges embedded inside some of the faces of Δ in such a way that edges intersect only at their common endpoints. In particular, for each face $f \in F(\Delta)$ with facial mapping $\mathbf{w}(f)$ do the following:

- For each edge $e = \{u, v\}$ that lies inside the region enclosed by $\alpha^{-1}(\mathbf{w}(f))$ in Γ and whose endpoints belong to Γ', add the edge $\{\alpha(u), \alpha(v)\}$ in the interior of f in Δ in such a way that (i) edges intersect only at their common endpoints and (ii) after we extend the mapping α so that it takes into account those edges of Γ that were added in Δ, the following must hold: for any connected component that was inside f and, after the addition of the edges, is in a face f', the preimages of the vertices of that connected component in Γ_0 are inside the region enclosed by $\alpha^{-1}(\mathbf{w}(f'))$.
- Consider the faces $f_1, f_2, \ldots, f_j$ that form the partition of f after the addition of the new edges. For every such face f_i let p_i be the region enclosed by $\alpha^{-1}(\mathbf{w}(f_i))$ in Γ'. Notice that since Δ^+ is connected, the boundary of $\alpha^{-1}(\mathbf{w}(f_i))$ is connected. For every $i \in [j]$

let $\mathcal{C}_{p_i}$ be the set of all connected components that lie entirely in the region enclosed by $\alpha^{-1}(\mathbf{w}(f_i))$ in Γ'. Let $\mathcal{C}_{p_i}^{\emptyset}$ denote the set of all connected components in $\mathcal{C}_{p_i}$ that do not have any neighbors in $B_{\Gamma'}(f_i)$. For every $C_w \in \mathcal{C}_{p_i}$, let S_w be its neighborhood in $B_\Gamma(f_i)$. Consider the Hasse diagram defined by the sets S_w and without loss of generality, let S_1, $S_2, \ldots, S_q$ be its maximal elements. Let then $O_t = \{C_l \in \mathcal{C}_{p_i} \setminus \mathcal{C}_{p_i}^{\emptyset} \mid S_l \subseteq S_t\}$, $t \in [q]$. For every $t \in [q]$, add a vertex u_t in f_i and make it adjacent to the vertices in $\alpha(S_t)$ (notice that since the boundary is again connected there is a unique way to construct the cyclic neighborhood of u_t up to cyclic permutations). We call O_t the *origin* of u_t.

The resulting graph Δ^+ is, by definition, a member of $\mathcal{F}_\Delta$.

To construct Δ^* from Δ^+, for every edge $\{u, v\} \in S$, we remove the edge $\{\alpha(u), \alpha(v)\}$ from Δ^+. Since $\{\alpha(u), \alpha(v)\} \in E(\Delta)$, it follows that

$$\Delta^* \in \mathsf{span}(\Delta^+, E(\Delta)).$$

We now define a function $g_0 : E(\Delta^*) \cup F(\Delta^*) \mapsto E(\Gamma) \cup F(\Gamma)$. Let $f \in F(\Delta^*)$ with facial mapping $\mathbf{w}(f)$. Observe that there is at least one face $f' \in F(\Gamma)$ with facial mapping $\mathbf{w}(f')$, such that for every facial walk $w = (u_1, \ldots, u_k) \in \mathbf{w}(f)$ there is a facial walk $w' \in \mathbf{w}(f')$ of length at least k and a subsequence $(v_1, \ldots, v_k)$ of w' (up to cyclic permutations) with the following properties: $v_i = \alpha(u_i)$ if $v_i \in \Delta$ and $v_i \in V(C)$, for some C in the origin of u_i, if $u_i \in V(\Delta^*) \setminus V(\Delta)$.

Notice that due to planarity the regions defined by those walks (unless the walks are trivial) are mutually nested. Of all such faces (if there are multiple), let f' be the one whose region contains all other regions. Then, $g_0(f) = f'$. We will call the connected component whose vertices belong to that walk the *outermost connected component*.

Recall that, by construction, the new vertices of $V(\Delta^*) \setminus V(\Delta)$ form an independent set. Thus, for each edge $e = \{u, v\} \in E(\Delta^*)$ at most one of its endpoints belongs in $V(\Delta^*) \setminus V(\Delta)$. If both endpoints u, v of e belong to $V(\Delta)$, then we define $g_0(e) = \{\alpha^{-1}(u), \alpha^{-1}(v)\} \in E(\Gamma)$. Otherwise exactly one of u and v, say v, belongs to $V(\Delta^*) \setminus V(\Delta)$. In this case, we define $g_0(e) = \{\alpha^{-1}(u), v'\} \in E(\Gamma)$, where v' is a neighbor of $\alpha^{-1}(u)$ in the outermost connected component in the origin of v.

Let now $R(\Gamma)$ be an arbitrary subdivided radial enhancement of Γ. In order to construct a subdivided radial enhancement $R(\Delta^*)$ of Δ recall that we first subdivide all edges of $R(\Delta^*)$ and then add a radial vertex u_f inside each face $f \in F(\Delta^*)$. For every f let $r_{g_0}(f)$ be the radial vertex of $R(\Gamma)$ that was added in $g_0(f)$. Consider the cyclic neighborhood of $r_{g_0}(f)$ in $R(\Gamma)$. Notice that it can be broken down in $s_1, s_2, \ldots, s_l$ segments where s_i is a facial walk w_i of $\mathbf{w}(g_0(f))$. Let w_i' be the subsequence of the walk that corresponds to a walk z_i in $\mathbf{w}(f)$. Add edges between the u_f and the vertices of the boundary of u_f in such a way that the cyclic neighborhood of u_f is $(z_1, z_2, \ldots, z_l)$. Notice that for every subdivision vertex x of $R(\Delta^*)$ that appears between u_i and u_{i+1} in the facial walk of w, there is a subdivision vertex v_x appearing between v_i and v_{i+1} in the walk w of $\mathbf{w}(f)$. We add an edge $\{u_f, v_x\}$ so that v_x appears between u_i and u_{i+1} in the cyclic neighborhood of u_f (this can be done in a unique way). We extend the mapping g_0 restricted to $E(\Delta^*)$ to the mapping g_1 by mapping every edge $\{u_f, u_i\}$ to the edge $\{r_{g_0}(f), v_i\}$. We also map the edges $\{u_f, x\}$ to the edges $\{r_{g_0(f)}, v_x\}$. Notice that g_1 can be extended to $F(R(\Delta^*))$ similarly to g_0. In the same fashion we extend g_1 to the function g_2 on the graphs $R^2(\Gamma)$ and $R^2(\Delta^*)$ and then to g_3 on the graphs $R^3(\Gamma)$ and $R^3(\Delta^*)$. Recall that

$$\mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset) = (R^3(\Gamma), \emptyset, V(\Gamma), V_s^1(\Gamma), V_r^1(\Gamma), \ldots, V_s^3(\Gamma), V_r^3(\Gamma)),$$

and that

$$\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), B) =$$
$$= (R^3(\Delta^*), V(\Delta^*) \setminus V(\Delta), V(\Delta), V_s^1(\Delta^*), V_r^1(\Delta^*), \ldots, V_s^3(\Delta^*), V_r^3(\Delta^*)).$$

Let now $\sigma : V(R^3(\Gamma)) \to V(R^3(\Delta^*))$ such that:

$$\sigma(v) = \begin{cases} u & \text{if } v \in V(\Gamma), u \in V(\Delta), \text{ and } \alpha^{-1}(u) = v \in V(\Gamma) \\ z & \text{if } v \in V_s^i(\Gamma) \text{ and there exists } u \in V_s^i(\Delta^*) \text{ with } g^i(e) = e', i \in [3], \\ & \text{where } z \text{ (resp. } v\text{) is the subdivision vertex of the edge } e \text{ (resp. } e'\text{)} \\ w & \text{if } v \in V_r^i(\Gamma) \text{ and there exists } u \in V_r^i(\Delta^*) \text{ with } g^i(f) = f', i \in [3], \\ & \text{where } w \text{ (resp. } v\text{) is the radial vertex added in face } f \text{ (resp. } f'\text{)} \\ x & \text{where } x \in B \text{ such that the distance between } v \text{ and the vertices in} \\ & O_x \text{ in } R^3(\Gamma) \text{ is minimized} \end{cases}$$

It is quite straightforward to verify that σ satisfies the five required contraction properties and thus $\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), B) \leq_c \mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)$. Therefore, since these two structures satisfy the conditions of Lemma 3.3, we conclude that there exists some $v \in V(\Gamma)$ such that $\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), B) \leq_c \mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)_v^{\mathbf{diam}(R^3(\Delta^*))}$. Notice now that $\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), B) \in \mathcal{H}_\Delta$ and that $\mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)_v^{\mathbf{diam}(R^3(\Delta^*))}$ is a minor of $\mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)_v^c \in \mathcal{G}_{\Gamma, R(\Gamma), c}$ and we have proven the first direction.

Suppose now that for every $R(\Gamma) \in \mathcal{R}_\Gamma$ there exist two structures $\mathbf{G} \in \mathcal{G}_{\Gamma,R(\Gamma),c}$ and $\mathbf{D} \in \mathcal{H}_\Delta$, such that $\mathbf{D} \leq_c \mathbf{G}$. This is the same as saying that for every $R(\Gamma) \in \mathcal{R}_\Gamma$ there exist a $\Delta^+ \in \mathcal{F}_\Delta$, a $\Delta^* \in \mathsf{span}(\Delta^+, E(\Delta))$, and an $R(\Delta^*) \in \mathcal{R}_{\Delta^*}$ such that $\mathbf{d}(\mathbf{p}(\Delta^*, R(\Delta^*)), B) \leq_c \mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), \emptyset)$. Let then Γ' be the plane graph that results from $R^3(\Gamma)$ if we contract all connected components of $R^3(\Gamma)[\sigma^{-1}(B)]$. It follows immediately that $\Gamma' \simeq_{tp} R^3(\Delta^*)$. Let

$$\alpha : V(\Gamma') \cup F(\Gamma') \to V(R^3(\Delta^*)) \cup F(R^3(\Delta^*))$$

be a topological isomorphism between Γ' and $R^3(\Delta^*)$. Then, for each edge $\{u, v\} \in E(\Delta) \setminus E(\Delta^*)$ there is a face $f \in F(\Gamma)$ such that both $\alpha^{-1}(u)$ and $\alpha^{-1}(v)$ belong to a member of the facial mapping of f. Hence, the set $S = \{\{\alpha^{-1}(u), \alpha^{-1}(v)\} \mid \{u, v\} \in E(\Delta) \setminus E(\Delta^*)\}$ is insertable in Γ. Hence, $\Delta \preceq \Gamma$. ◀

▶ **Theorem 3.5** (⋆). *There exists an algorithm that, given as input an n-edge plane graph Γ and a connected k-edge plane graph Δ, decides whether $\Delta \preceq \Gamma$ in $2^{\mathcal{O}(k \log k)} \cdot n^2$ steps.*

4 An FPT algorithm for the PTMC problem

We need the following definitions and results before we are ready to prove the main result of this section.

Given a plane graph Γ and a non-negative integer k, we say that a graph Γ' is a k-face completion of Γ if it can be obtained from Γ in the following way; for every $f \in F(\Gamma)$ we add a set E_f of at most k edges to Γ such that the endpoints of the edges in E_f are vertices of Γ that belong to the boundary of f, all the edges E_f lie inside f, they do not intersect Γ in any points other than their endpoints, and finally they do not intersect each other.

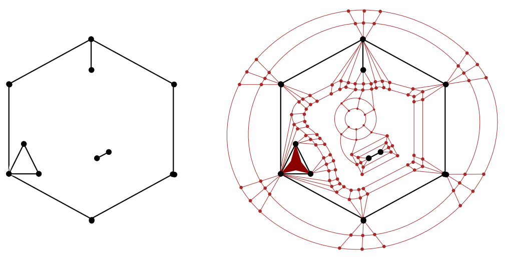


Figure 2 This figure depicts the construction of $\Gamma_{3,2}$ from Γ (Γ is the graph on the left).

Let r and q be integers such that $r \in \mathbb{N}_{\geq 3}, q \in \mathbb{N}_{\geq 1}$. A (r, q)-*cylinder*, denoted by $C_{r,q}$, is the Cartesian product of a cycle on r vertices and a path on q vertices. We will refer to r as the *length* and q as the *width* of $C_{r,q}$. Note here that $C_{r,q}$ is a 3-connected graph and thus, by Whitney's Theorem, it is uniquely embeddable (up to homeomorphism) in the sphere. Furthermore, $C_{r,q}$ has exactly two non-square faces f_1 and f_2 that are incident only with vertices of degree 3. We call one of the faces f_1 and f_2 the *interior* of $C_{r,q}$ and the other the *exterior* of $C_{r,q}$. We call the vertices incident to the interior (exterior) of $C_{r,q}$ *base* (*roof*) of $C_{r,q}$.

Let Γ be a plane graph. We give the definition of the graph $\Gamma_{r,q}$ for $r \in \mathbb{N}_{\geq 3}$ and $q \in \mathbb{N}_{\geq 3}$. Let $f_i \in F(\Gamma)$ and let $\Theta^i_1, \ldots, \Theta^i_{\rho_i}$ be the connected components of $B_\Gamma(f_i)$. For each Θ^i_j, we denote by $\sigma_{j,i}$ the length of a facial walk of Θ^i_j. We then add a copy C^i_j of $(\sigma_{j,i} \cdot r, q)$-cylinder in the embedding of Γ such that Θ^i_j is contained in the interior of C^i_j and all $\Theta^i_1, \ldots, \Theta^i_{j-1}, \ldots, \Theta^i_{j+1} \ldots, \Theta^i_{\rho_i}$ are contained in the exterior of C^i_j. Then we partition the base of C^i_j into $\sigma_{j,i}$ parts Q_l, $l \in \sigma_{j,i}$ each consisting of r consecutive base vertices. Let $(u^1_{j,i}, u^2_{j,i}, \ldots, u^{\sigma_{j,i}}_{j,i}, u^1_{j,i})$ be a facial walk of $\Theta_{j,i}$. We join by r edges the vertex $u^x_{j,i}$ to all the vertices of the set Q_l, $l \in \sigma_{j,i}$. We apply this enhancement for each connected component of the boundary of each face of Γ and we denote the resulting graph by $\widehat{\Gamma}_{r,q}$.

We call a face f_i of $\widehat{\Gamma}_{r,q}$ non-trivial if $B_{\widehat{\Gamma}_{r,q}}(f_i)$ has more than one connected components $\Theta^i_1, \ldots, \Theta^i_{\rho_i}$. Notice that if f_i is non-trivial, each Θ^i_j is the roof of some previously added cylinder. For each such cylinder, let J^i_j be a set of r consecutive vertices of its roof. We add inside f_i a copy C_{f_i} of $C_{\rho_i \cdot r,q}$ such that its base is a subset of f_i and let $\{I_1, \ldots, I_{\rho_i}\}$ be a partition of its roof in ρ_i parts, each consisting of r consecutive base vertices. For each $x \in \{1, \ldots, \rho_i\}$ we add r edges each connecting a vertex of J^i_j with some vertex of I_x in a way that the resulting embedding remains plane (there is a unique way for this to be done). We apply this enhancement for each non-trivial face of $\widehat{\Gamma}_{r,q}$ and the resulting graph is the graph $\Gamma_{r,q}$. Notice that $\Gamma_{r,q}$ is not uniquely defined as its definition depends on the choice of the sets J_x. From now on, we always consider an arbitrary choice for $\Gamma_{r,q}$ and we call $\Gamma_{r,q}$ the (r, q)-*cylindrical enhancement of* Γ. Finally, given a plane graph Γ and $r, q \in \mathbb{N}_{\geq 3}$. Let $V^0_{\Gamma,r,q} = V(\Gamma)$ and $V^n_{\Gamma,r,q} = V(\Gamma_{r,q}) \setminus V(\Gamma)$ and notice that $\deg_{\Gamma_{r,q}}(v) \leq 4$, for every $v \in V^n_{\Gamma,r,q}$. (For an example, see Figure 2.) Given a positive integer k, we denote by $\tilde{\Gamma}_k$ the graph $\Gamma_{2\cdot k, 8\cdot k}$.

We are now ready to state one of the main results of this section.

▶ **Theorem 4.1** ($\star$). *Let* Γ *and* Δ *be plane graphs where* Δ *is connected and* $k = |E(\Delta)|^{2^{|E(\Delta)|}}$. *There exists a* k*-face completion* Γ^+ *of* Γ *such that* $\Delta \leq_{etm} \Gamma^+$ *if and only if* $\Delta \leq^S_{etm} \tilde{\Gamma}_k$ *where* $S = V(\tilde{\Gamma}_k) \setminus V(\Gamma) = V^n_{\Gamma,2\cdot k,8\cdot k}$.

Moreover, we have the following.

▶ **Theorem 4.2** ($\star$). *There exists an algorithm that given two plane graphs Γ and Δ and a set $V \subseteq V(\Gamma)$ with $\deg_\Gamma(z) \leq c$, for every $z \in V$ outputs a graph Γ', with $\Gamma' \subseteq_{sp} \Gamma$ and $\mathbf{tw}(\Gamma') = \mathcal{O}(f(|E(\Delta)|))$, for some computable function f such that $\Delta \leq^V_{etm} \Gamma$ if and only if $\Delta \leq^V_{etm} \Gamma'$. This algorithm runs in $\mathcal{O}_{|E(\Delta)|}(|E(\Gamma)|)$ steps.*

Let Γ be a connected plane graph and $Z \subseteq V(\Gamma)$, we define the following pair of vertex and edge structures:

$$\mathbf{G}_{\Gamma,Z} := (\mathbf{d}(\mathbf{p}(\Gamma, R(\Gamma)), Z), \mathbf{e}(\Gamma, R(\Gamma))).$$

Given two connected plane graphs Δ and Γ and $Z \subseteq V(\Gamma)$ we say that $\mathbf{G}_{\Delta,\emptyset}$ is a *restricted topological minor* of $\mathbf{G}_{\Gamma,Z}$, denoted by $\mathbf{G}_{\Delta,\emptyset} \leq_{rtm} \mathbf{G}_{\Gamma,Z}$, if and only if there exist two functions $f_1 : V(R^3(\Delta)) \to 2^{V(R^3(\Gamma))}$ and $f_2 : E(R^3(\Delta)) \to 2^{E(R^3(\Gamma))}$ satisfying the following:

1. for every $x \in V(\Delta)$, $f_1(x) \in V(\Gamma) \setminus Z$ and $|f_1(x)| = 1$,
2. for every $x \in \cup_{i\in[3]} V(R^i_s(\Delta))$, $f_1(x) \notin \cup_{i\in[3]}(V(R^i_r(\Gamma)))$ and $|f_1(x)| = 1$,
3. for every $x, y \in \cup_{i\in[3]} V(R^i_r(\Delta))$ is connected and $f_1(x) \cap f_1(y) = \emptyset$,
4. for every $xy \in E^3_s(\Delta)$, $G[f_2(xy)]$ is a path between $f_1(x)$ and $f_1(y)$ and $f_2(xy) \subseteq E^3_s(\Gamma)$, and
5. for every $xy \in E^3_r(\Delta)$, $G[f_2(xy)]$ is a path between some vertex of $f_1(x)$ and some vertex of $f_1(y)$.

▶ **Theorem 4.3.** *Let Γ, Δ be two connected plane graphs and $Z \subseteq V(\Gamma)$. Then $\Delta \leq^Z_{etm} \Gamma$ if and only if $\mathbf{G}_{\Delta,\emptyset} \leq_{rtm} \mathbf{G}_{\Gamma,Z}$.*

Our algorithm for PTMC . Let Γ and Δ be two plane graphs, where Δ is connected. From Therorem 4.1 we construct a cylindrical enhancement $\tilde{\Gamma}_k$ of Γ, where the vertices of the set $S = V^n_{\Gamma,2\cdot k,8\cdot k}$ have degree bounded by a constant such that Δ, Γ are a yes instance if and only if $\Delta \leq^S_{etm} \tilde{\Gamma}_k$. Then, the algorithm of Theorem 4.1 with inputs $\tilde{\Gamma}_k, \Delta, S$ outputs a graph Γ' with $\Gamma' \subseteq_{sp} \Gamma$ and $\mathbf{tw}(\Gamma') = \mathcal{O}(f(|E(\Delta)|))$. Moreover, Theorem 4.3 translates Γ', Δ, and S to two structures $\mathbf{G}_{\Delta,\emptyset}$ and $\mathbf{G}_{\Gamma,S}$, for which $\Delta \leq^S_{etm} \Gamma$ if and only if $\mathbf{G}_{\Delta,\emptyset} \leq_{rtm} \mathbf{G}_{\Gamma,S}$. Notice that the relation $\mathbf{G}_{\Delta,\emptyset} \leq_{rtm} \mathbf{G}_{\Gamma,S}$ can be expressed in Monadic Second Order Logic. Finally, by observing that $\mathbf{tw}(R^3(\Gamma)) = \mathcal{O}(f(|E(\Delta)|))$ we can employ Courcelle's Theorem [5] to obtain an $f(|E(\Delta)|) \cdot m^2$ time algorithm, for some computable function f.

5 Extensions

Our approach for the PSC problem can also solve the Plane Induced Subgraph Completion problem, with the same running time, where instead of an embedded subgraph we ask for an embedded *induced subgraph*. The only modification would be at the definition of a facial extension of Δ where we would additionally require that every connected graph Δ^+ contains Δ as an *induced* subgraph.

In the PTMC problem the connectivity of Δ is only required in the proof of Theorem 4.1 (that has been omitted). We would like to remark here that if we disregard the embedding of Δ then the Proposition holds for disconnected graphs as well. In this case by modifying the algorithm for PTMC we may obtain an FPT algorithm that given a plane graph Γ and a *planar* graph D decides whether there exists a face completion of Γ, say Γ^+, such that D is a rooted topological minor of Γ. That is, each vertex of D is mapped to a specified vertex of Γ. Notice that this approach also permits us to solve the Planar Disjoint Paths Completion problem where we allow edge additions inside all faces of Γ (in contrast to [2] where edge additions are allowed only inside a specified face of Γ).

Finally, with the same cylindrical enhancement that we apply for PTMC and the extra restriction that the sets of vertices of the enhanced graph that are contracted to a vertex of the pattern graph Δ contain only vertices of the initial graph we can solve the Plane Minor Completion problem. In these last two cases, however, only the existence of an FPT algorithm is verified (since both would be derived by Courcelle's Theorem).

Abstract

We demonstrate some lower bounds for parameterized problems via parameterized classes corresponding to the classical AC^0. Among others, we derive such a lower bound for all fpt-approximations of the parameterized clique problem and for a parameterized halting problem, which recently turned out to link problems of computational complexity, descriptive complexity, and proof theory. To show the first lower bound, we prove a strong AC^0 version of the planted clique conjecture: AC^0-circuits asymptotically almost surely can not distinguish between a random graph and this graph with a randomly planted clique of any size $\leq n^{\xi}$ (where $0 \leq \xi < 1$).

1 Introduction

For $k \in \mathbb{N}$ the k-clique problem asks, given a graph G, whether it contains a clique of size k. In [20], Rossman showed that the k-clique problem has no bounded-depth and unbounded-fan-in circuits of size $O(n^{k/4})$. Therefore, there doesn't exist a family $(\mathsf{C}_{n,k})_{n,k\in\mathbb{N}}$ of circuits such that for some functions $d, f : \mathbb{N} \to \mathbb{N}$,

- every $\mathsf{C}_{n,k}$ has depth at most $d(k)$ and size bounded by $f(k) \cdot n^{k/4}$,
- an n-vertex graph G has a k-clique if and only if $\mathsf{C}_{n,k}(G) = 1$.

If the constraint on the depth of the circuits could be removed, then we would immediately obtain that the *parameterized clique problem*

p-CLIQUE	
Instance:	A graph G and $k \in \mathbb{N}$.
Parameter:	k.
Problem:	Does G contain a clique of size k?

cannot be solved in time $f(k) \cdot n^{O(1)}$. Thus, p-CLIQUE would not be fixed-parameter tractable and hence, FPT $\neq$ W[1] since p-CLIQUE is in the parameterized class W[1]. Therefore, Rossman's result may be viewed as an AC^0 version of FPT $\neq$ W[1], an inequality conjectured by most experts in the field (recall that the complexity class AC^0 contains all problems that can be computed by bounded-depth and unbounded fan-in circuits of polynomial size).

* This research is partially supported by the Sino-German Center for Research Promotion (CDZ 996) and National Nature Science Foundation of China (Project 61373029).

In [11] Elberfeld et al. introduced the parameterized class para-AC^0 as the AC^0 analog of the class FPT: A problem is in para-AC^0 if it can be computed by *dlogtime-uniform* AC^0-circuits after an (arbitrarily complex) *precomputation* [12] on the parameter. Later in [3] it was shown that para-AC^0 contains the *parameterized vertex cover problem*, one of the archetypal fixed-parameter tractable problems. For various other problems the authors of [3] also proved their membership in para-AC^0. Concerning nonmembership, a result in [6] shows that the parameterized *st*-connectivity problem (p-stConn), i.e., the problem of deciding whether there is a path of length at most k between vertices s and t in a graph G, parameterized by k, is not in para-AC^0. It is worth noting that *st*-connectivity is solvable in polynomial time, and hence, p-stConn $\in$ FPT.

The class AC^0 is one of the best understood classical complexity classes. Already in [1, 13] it was shown that Parity, the problem of deciding whether a binary string contains an even number of 1's, is not in AC^0. Since Parity has a very low complexity, for many other problems, including Vertex-Cover and Clique, the AC^0-lower bound can be easily derived by reductions from Parity. Similarly, as p-Clique $\notin$ para-AC^0, it is not very hard to see, using some appropriate weak parameterized reductions, that many other parameterized problems, including the dominating set problem, are not in para-AC^0.

It is well known that the class AC^0 is intimately connected to first-order logic (FO). In fact, the problems decidable by a dlogtime-uniform AC^0-family of circuits are precisely those definable in FO$(<, +, \times)$, that is, in first-order logic for ordered structures with built-in predicates of addition and multiplication.

Now we can also study various parameterized classes based on fragments of FO$(<, +, \times)$. Let us emphasize that this is not merely an academic exercise. Logic and parameterized complexity are surprisingly intertwined with each other, which, among others, is witnessed by various algorithmic meta-theorems (see e.g. [15]). Moreover, the problem whether there is a logic for PTIME, a central problem of descriptive complexity, turned out (see [9] for a thorough discussion) to be related to the complexity of the parameterized halting problem

p-Halt	
Instance:	$n \in \mathbb{N}$ in *unary* and a nondeterministic Turing machine (NTM) $\mathbb{M}$.
Parameter:	$\lvert\mathbb{M}\rvert$, the size of the machine $\mathbb{M}$.
Problem:	Does $\mathbb{M}$ accept the empty input tape in at most n steps?

In fact, already in [19] it was shown that PTIME has a logic if p-Halt has an algorithm with running time $n^{f(|\mathbb{M}|)}$ for some function f. We get a family $(\mathsf{C}_{n,k})_{n,k\in\mathbb{N}}$ of circuits such that

- every $\mathsf{C}_{n,k}$ has depth 2 and size $g(k) \cdot n$ for some function $g : \mathbb{N} \to \mathbb{N}$,
- an NTM $\mathbb{M}$ accepts the empty input tape in at most n steps if and only if $\mathsf{C}_{n,|\mathbb{M}|}(n, \mathbb{M}) = 1$

by hard-wiring into $\mathsf{C}_{n,k}$ the NTMs of size k which halt on empty input in $\leq n$ steps. Therefore, p-Halt belongs to a *nonuniform* version of para-AC^0. The question arises whether p-Halt $\in$ para-AC^0. A positive answer will yield that p-Halt $\in$ FPT, which is considered to be highly unlikely [9]. Hence, the goal is to show *unconditionally* that p-Halt $\notin$ para-AC^0. To the best of our knowledge, all existing AC^0 lower bounds for natural problems apply to both uniform and nonuniform circuits. Perhaps, in order to settle the complexity of p-Halt with respect to para-AC^0, a better understanding of the uniformity conditions of circuits is really required.

1.1 Our work

In this paper, we investigate lower bounds in terms of para-AC^0. We show that a number of problems are not in this class or in some of its proper subclasses.

Following the framework proposed in [12], we first compare two possible definitions of para-AC^0 depending on different ways to obtain parameterized classes from classical ones. We already mentioned the first one, in which an arbitrary precomputation can be performed on the parameter before a standard computation according to the corresponding classical class. The second approach requires the parameterized problem to be in the classical class if we restrict to instances where the parameter is far smaller than the size of the input. We show that both views lead to the same para-AC^0.

Then we derive a first set of lower bound results: We show that many natural W[1]-hard problems are not in para-AC^0 by arguing that the corresponding reductions from p-Clique can be made in AC^0. Among others, they include the weighted satisfiability problems for classes of propositional formulas, which define the W-hierarchy.

We present a modeltheoretic tool, based on the color-coding method, which allows to show membership in AC^0 (similarly as done in [3] via circuits).

We generalize Rossman's result mentioned at the beginning of this introduction and show that any fpt-approximation of p-Clique is not in para-AC^0. To get this result we prove that AC^0-circuits asymptotically almost surely can not distinguish between a random graph and this graph with a randomly planted clique of any size $\leq n^{\xi}$ with $0 \leq \xi < 1$. Our first proof of the last two results used the sophisticated machinery in [20]. Here we outline a proof, suggested to us anonymously, which is directly built on Beame's *Clique Switching Lemma* [5]. The fpt-approximation lower bound of p-Clique again can be transferred to the weighted satisfiability problems, provided the propositional formulas are of odd depth.

Finally we turn to p-Halt. We are not able to show p-Halt $\notin$ para-AC^0, however, using the decidability of Presburger's arithmetic we prove that p-Halt is not in para-FO$(<,+)$, not even in XFO$(<,+)$. On the other hand, p-Halt $\in$ nonuniform-para-FO$(<,+)$.

Due to space limitations for some proofs we refer to the full version of the paper.

2 Preliminaries

By $\mathbb{N}$ we denote the set of nonnegative integers. For every $n \in \mathbb{N}$ we let $[n] := \{1, \ldots, n\}$. Let $\mathbb{R}$ be the set of real numbers, $\mathbb{R}_{+} := \{r \in \mathbb{R} \mid r > 0\}$, and $\mathbb{R}_{\geq 1} := \{r \in \mathbb{R} \mid r \geq 1\}$. For any set A and $k \in \mathbb{N}$ we define $\binom{A}{k}$ as the class of k-element subsets of A, i.e., $\{S \subseteq A \bigm| |S| = k\}$.

A (simple) graph $G = (V(G), E(G))$ (for short, $G = (V, E)$) is undirected and has no loops and multiple edges. Here, $V(G)$ is the vertex set and $E(G)$ the edge set, respectively. A subset $C \subseteq V(G)$ is a *clique* of G if for every $u, v \in C$ either $u = v$ or $\{u, v\} \in E(G)$. And $D \subseteq V(G)$ is a *dominating set* of G if for every $v \in V(G)$ either $v \in D$ or there exists $u \in D$ with $\{u, v\} \in E(G)$.

2.1 Relational structures and first-order logic

A *vocabulary* τ is a finite set of relation symbols. Each relation symbol has an *arity*. A *structure* $\mathcal{A}$ of vocabulary τ, or simply structure, consists of a finite set A called the *universe*, and an interpretation $R^{\mathcal{A}} \subseteq A^r$ of each r-ary relation symbol $R \in \tau$. For example, a graph G can be identified with a structure $\mathcal{A}(G)$ of vocabulary $\{E\}$ with binary relation symbol E such that $A(G) := V(G)$ and $E^{\mathcal{A}(G)} := \{(u, v) \mid \{u, v\} \in E(G)\}$.

Formulas of first-order logic of vocabulary τ are built up from atomic formulas $x = y$ and $Rx_1 \ldots x_r$, where $x, y, x_1, \ldots, x_r$ are variables and $R \in \tau$ is of arity r, using the boolean connectives and existential and universal quantification. For example, for every $k \geq 1$ let

$$\mathit{clique}_k := \exists x_1 \ldots \exists x_k \Big(\bigwedge_{1 \leq i < j \leq k} (\neg x_i = x_j \wedge E x_i x_j) \Big).$$

Then a graph G has a k-clique if and only if $\mathcal{A}(G) \models \mathit{clique}_k$.

2.2 Parameterized complexity

We fix an alphabet $\Sigma := \{0,1\}$. A *parameterized problem* (Q, κ) consists of a classical problem $Q \subseteq \Sigma^*$ and a function $\kappa : \Sigma^* \to \mathbb{N}$, the *parameterization*, computable in polynomial time. As an example, we have already seen p-CLIQUE in the Introduction. A similar problem is the *parameterized dominating set problem.*

p-DOMINATING-SET	
Instance:	A graph G and $k \in \mathbb{N}$.
Parameter:	k.
Problem:	Does G contain a dominating set of size k?

Both, p-CLIQUE and p-DOMINATING-SET, play an important role in parameterized complexity, mainly because they are complete for the classes W[1] and W[2], respectively. Recall that the classes of the W-hierarchy are defined by taking the closure under fpt-reductions of the following weighted satisfiability problem for suitable classes Γ of propositional formulas.

p-WSAT(Γ)	
Instance:	$\gamma \in \Gamma$ and $k \in \mathbb{N}$.
Parameter:	k.
Problem:	Does γ have a satisfying assignment of Hamming weight k?

▶ **Definition 1.** Let (Q, κ) and (Q', κ') be two parameterized problems. An *fpt-reduction* from (Q, κ) to (Q', κ') is a mapping $R : \Sigma^* \to \Sigma^*$ such that:

- For $x \in \Sigma^*$ we have $(x \in Q \iff R(x) \in Q')$.
- For $x \in \Sigma^*$, $R(x)$ is computable in time $f(\kappa(x)) \cdot |x|^{O(1)}$ for some computable $f : \mathbb{N} \to \mathbb{N}$.
- There is a computable function $g : \mathbb{N} \to \mathbb{N}$ such that $\kappa'(R(x)) \leq g(\kappa(x))$ for all $x \in \Sigma^*$.

If there is an fpt-reduction from (Q, κ) to (Q', κ'), then we write $(Q, \kappa) \leq^{\text{fpt}} (Q', \kappa')$.

For $t \geq 0$ and $d \geq 1$ we inductively define the classes $\Gamma_{t,d}$ and $\Delta_{t,d}$ of propositional formulas: $\Gamma_{0,d}$ and $\Delta_{0,d}$ are the class of conjunctions of at most d literals and the class of disjunctions of at most d literals, respectively.

$$\Gamma_{t+1,d} := \Big\{ \bigwedge_{i \in I} \delta_i \mid I \text{ finite and } \delta_i \in \Delta_{t,d} \text{ for all } i \in I \Big\},$$
$$\Delta_{t+1,d} := \Big\{ \bigvee_{i \in I} \gamma_i \mid I \text{ finite and } \gamma_i \in \Gamma_{t,d} \text{ for all } i \in I \Big\}.$$

▶ **Definition 2.** Let $t \geq 1$. The class W[t] of the W-*hierarchy* is defined by

$$\mathrm{W}[t] := \bigcup_{d \geq 1} \big\{ (Q, \kappa) \mid (Q, \kappa) \leq^{\text{fpt}} p\text{-WSAT}(\Gamma_{t,d}) \big\}.$$

Circuit Complexity

A circuit C with n input gates is a directed acyclic graph in which every node (i.e., gate) is labelled by $\bigwedge$, $\bigvee$, $\neg$, or by one of the variables, or by $0, 1$. All $\bigwedge$ and $\bigvee$ gates may have arbitrarily many inputs, i.e., C is of *unbounded fan-in.* The *depth* of C is the length of a longest directed path in C. The *size* of C, denoted by $|\mathsf{C}|$, is the number of gates in C. We often tacitly identify C with the function $\mathsf{C} : \{0,1\}^n \to \{0,1\}^m$ it computes. Here, n is the number of variables of C and m the number of its *output gates*.

AC^0 is the class of problems that can be computed by circuits of bounded-depth and polynomial size. More precisely:

▶ **Definition 3.** Let $Q \subseteq \Sigma^*$. We say that $Q \in \mathrm{AC}^0$ if there exists a family of boolean circuits $(\mathsf{C}_n)_{n\in\mathbb{N}}$ such that:

(A1) The depth of every C_n is bounded by a fixed constant.

(A2) $|\mathsf{C}_n| = n^{O(1)}$.

(A3) Let $x \in \Sigma^*$. Then ($x \in Q$ if and only if $C_{|x|}(x) = 1$). In particular, every C_n has n input gates.

(A4) $(\mathsf{C}_n)_{n\in\mathbb{N}}$ is *dlogtime-uniform*, that is: there is a *deterministic logtime Turing machine* $\mathbb{M}$ which on input 1^n outputs the circuit C_n. More precisely, $\mathbb{M}$ recognizes the language $\big\{(b, i, 1^n) \bigm| \text{the } i\text{th bit of the binary encoding of } C_n \text{ is } b\big\}$ (cf. Section 6 of [4]).

Often, $(\mathsf{C}_n)_{n\in\mathbb{N}}$ are called AC^0*-circuits*.

We remark that most lower bounds in our paper still hold without the requirement (A4). Therefore, (A4) is irrelevant for most of our results. However, with this uniformity condition, AC^0 characterizes precisely the class of problems that are definable in $\mathrm{FO}(<, +, \times)$ [4].

3 The class para-AC^0 and some natural examples

▶ **Definition 4** ([3])**.** Let (Q, κ) be a parameterized problem. Then (Q, κ) is in para-AC^0 if there exists a family $(\mathsf{C}_{n,k})_{n,k\in\mathbb{N}}$ of circuits such that:

(P1) The depth of every $\mathsf{C}_{n,k}$ is bounded by a fixed constant.

(P2) $|\mathsf{C}_{n,k}| \le f(k) \cdot n^{O(1)}$ for every $n, k \in \mathbb{N}$, where $f : \mathbb{N} \to \mathbb{N}$ is a computable function.

(P3) Let $x \in \Sigma^*$. Then ($x \in Q$ if and only if $\mathsf{C}_{|x|,\kappa(x)}(x) = 1$).

(P4) There is a deterministic Turing machine that on input $(1^n, 1^k)$ computes the circuit $\mathsf{C}_{n,k}$ in time $g(k) + O(\log n)$, where $g : \mathbb{N} \to \mathbb{N}$ is a computable function.

For future reference, we restate Rossman's main result [20] as follows.

▶ **Theorem 5.** *Let $k \in \mathbb{N}$. Then there is no family $(\mathsf{C}_n)_{n\in\mathbb{N}}$ of circuits such that:*

- *The depth of every C_n is bounded by a fixed constant.*
- *The size of C_n is $n^{O(k/4)}$.*
- *Let G be a graph and $n := |V(G)|$. Then G has a k-clique if and only if $\mathsf{C}_n(G) = 1$.*

*In particular, p-*CLIQUE* $\notin$ para-AC^0.*

▶ Remark. Recall that Chen et al. [7] showed that p-CLIQUE has no algorithms of running time $f(k) \cdot |n|^{o(k)}$ unless the Exponential Time Hypothesis (ETH) fails. ETH is apparently stronger than $\mathrm{FPT} \neq \mathrm{W}[1]$. Theorem 5 establishes an AC^0 version of $\mathrm{FPT} \neq \mathrm{W}[1]$.

Next, we give two equivalent characterizations of para-AC^0 (for a proof see the full version). The first one (i.e., between (i) and (ii)) was already mentioned in [11]. Note that in [11] it is required that a problem in para-AC^0 has an AC^0 computable parameterization.

▶ **Proposition 6.** *Let (Q, κ) be a parameterized problem. Consider the following statements.*

(i) $(Q, \kappa) \in$ para-AC^0.

(ii) *There is a computable function $pre : \mathbb{N} \to \Sigma^*$ (i.e., a precomputation) and AC^0-circuits $(\mathsf{C}_n)_{n\in\mathbb{N}}$ such that for $x \in \Sigma^*$,*

$$x \in Q \iff \mathsf{C}_{|(x, pre(\kappa(x)))|}(x, pre(\kappa(x))) = 1.$$

(iii) *Q is decidable and there is a computable function, $h : \mathbb{N} \to \mathbb{N}$ and AC^0-circuits $\big(\mathsf{C}_n\big)_{n\in\mathbb{N}}$ such that for every $x \in \Sigma^*$ with $|x| \geq h(\kappa(x))$,*

$$x \in Q \iff C_{|x|}(x) = 1.$$

Then (iii) ⇒ (i) ⇔ (ii). If, in addition, the parameterization κ can be computed by AC^0-circuits, then (i) ⇒ (iii), i.e., they are all equivalent.

In order to use Theorem 5 to show para-AC^0 lower bounds for other problems, we introduce a more restricted form of fpt-reductions.

▶ **Definition 7.** Let (Q, κ) and (Q', κ') be two parameterized problems. A *para-*AC^0*-reduction* from (Q, κ) to (Q', κ') is a mapping $R : \Sigma^* \to \Sigma^*$ such that:
(R1) For all $x \in \Sigma^*$ we have $(x \in Q \iff R(x) \in Q')$.
(R2) There is a family $(\mathsf{C}_{n,k})_{n,k\in\mathbb{N}}$ of circuits, whose depth is bounded by a fixed constant, such that
1. for all $x \in \Sigma^*$, $\mathsf{C}_{|x|,\kappa(x)}(x)$ outputs $R(x)$;
2. every $|\mathsf{C}_{n,k}| \leq f(k) \cdot |x|^{O(1)}$ for a computable function $f : \mathbb{N} \to \mathbb{N}$;
3. there is a deterministic Turing machine that on input $(1^n, 1^k)$ computes the circuit $\mathsf{C}_{n,k}$ in time $g(k) + O(\log\, n)$, where $g : \mathbb{N} \to \mathbb{N}$ is a computable function.

(R3) There is a computable function $h : \mathbb{N} \to \mathbb{N}$ such that $\kappa'(R(x)) \leq h(\kappa(x))$ for all $x \in \Sigma^*$.
If there is a para-AC^0-reduction from (Q, κ) to (Q', κ'), then we write $(Q, \kappa) \leq^{\mathrm{pac}} (Q', \kappa')$.

However, in general para-AC^0 is *not* closed under para-AC^0-reductions:

▶ **Example 8.** Define $Q := \big\{(x, b) \;\big|\; x \in \{0, 1\}^* \text{ and } b = \sum_{i\in[|x|]} x_i \mod 2\big\}$. Clearly, Q is equivalent to the classical Parity problem of deciding whether there is an even number of 1's in x. Thus $Q \notin \mathrm{AC}^0$. We define polynomial time computable parameterizations of Q by $\kappa_1(x, b) := 0$ and $\kappa_2(x, b) := \sum_{i\in[|x|]} x_i \mod 2$. Then it is easy to see that $(Q, \kappa_1) \notin$ para-AC^0 and $(Q, \kappa_2) \in$ para-AC^0; yet $(Q, \kappa_1) \leq^{\mathrm{pac}} (Q, \kappa_2)$ by the identity mapping $R(x, b) = (x, b)$.

Note (Q, κ_2) also serves as a counterexample for the direction from (i) to (iii) in Proposition 6.

Therefore we need a further requirement on pac-reductions. The previous example suggests to require the AC^0-computability of the parameterization (as done in [11]). In fact, para-AC^0 is closed under those reductions. However, we choose another requirement, which is simpler to verify and is satisfied by almost all natural reductions.

▶ **Definition 9.** Let (Q, κ) and (Q', κ') be two parameterized problems. A *weak para-*AC^0*-reduction* from (Q, κ) to (Q', κ') is a *para-*AC^0*-reduction* which satisfies:
(R3') There is a computable function $h : \mathbb{N} \to \mathbb{N}$ such that $\kappa'(R(x)) = h(\kappa(x))$ for all $x \in \Sigma^*$.
$(Q, \kappa) \leq^{\mathrm{pwac}} (Q', \kappa')$ means that there is a weak para-AC^0-reduction from (Q, κ) to (Q', κ').

It is straightforward to verify that para-AC^0 is closed under weak para-AC^0-reductions.

▶ **Lemma 10.** *Let (Q, κ) and (Q', κ') be parameterized problems with $(Q, \kappa) \leq^{pwac} (Q', \kappa')$. If $(Q', \kappa') \in$ para-AC^0, then $(Q, \kappa) \in$ para-AC^0, too.*

It is well known that p-Clique is fpt-reducible to p-Dominating-Set. The reduction presented in the full version of this paper is a weak para-AC^0-reduction. Thus, by Theorem 5 and Lemma 10:

▶ **Proposition 11.** p-Dominating-Set $\notin$ para-AC^0.

▶ **Corollary 12.** *Let $t, d \geq 1$ with $t + d \geq 3$. Then p-WSAT$(\Gamma_{t,d}) \notin$ para-AC^0.*

Proof. For every graph $G = (V, E)$ we define a propositional formula

$$\delta_G := \bigwedge_{\substack{u,v \in V \text{ with} \\ u \neq v \text{ and } \{u,v\} \notin E}} \neg X_u \vee \neg X_v.$$

Clearly, for every $k \in \mathbb{N}$,

$$G \text{ has a } k\text{-clique} \iff \delta_G \text{ has a satisfying assignment of weight } k \tag{1}$$

This gives a weak para-AC^0-reduction from p-CLIQUE to p-WSAT$(\Gamma_{1,2})$, or p-WSAT$(\Gamma_{t,1})$ in case $t \geq 2$. ◀

Similarly, one can show that basic problems like p-SUBGRAPH-ISOMORPHISM, p-HOM, p-EMB, and p-MC(Σ_1^1) are not in para-AC^0 (we use the notations of [12]).

In view of Corollary 12 the reader might wonder about the status of p-WSAT$(\Gamma_{1,1})$. Using the color-coding technique as in [3], one can show that the problem is in fact solvable in para-AC^0. We present a more logic-oriented technique for such proofs. It is based on Proposition 13. It uses FO$(<, +, \times)$ instead of dlogtime-uniform AC^0. We defer the proofs of this proposition and of Proposition 14 to the full version of the paper.

For $n \in \mathbb{N}$ denote by $<^{[n]}$ the natural ordering on $[n]$. If $\mathcal{A}$ is any ordered structure, then $(A, <^{\mathcal{A}})$ is isomorphic to $([|A|], <^{[|A|]})$ and the isomorphism is unique. For ternary relation symbols $+$ and $\times$ we consider the ternary relations $+^{[n]}$ and $\times^{[n]}$ on $[n]$ that are the relations underlying the addition and the multiplication of $\mathbb{N}$ restricted to $[n]$. That is,

$$+^{[n]} := \{(a,b,c) \mid a,b,c \in [n],\ c = a + b\}, \quad \times^{[n]} := \{(a,b,c) \mid a,b,c \in [n],\ c = a \cdot b\}.$$

Let τ be a vocabulary which does not contain $<, +, \times$ and set $\tau_{<,+,\times} := \tau \cup \{<, +, \times\}$. We say that a $\tau_{<,+,\times}$-structure $\mathcal{A}$ *has built-in addition and built-in multiplication* if $(A, <^{\mathcal{A}}, +^{\mathcal{A}}, \times^{\mathcal{A}})$ is isomorphic to $([|A|], <^{[|A|]}, +^{[|A|]}, \times^{[|A|]})$. Sometimes we write $\varphi \in$ FO$(<, +, \times)$ to emphasize that φ is a first-order formula in a vocabulary containing the symbols $<, +, \times$.

▶ **Proposition 13.** *There is a computable function which associates every $k \in \mathbb{N}$ with a structure $\mathcal{C}(k)$ and every FO-formula $\varphi(x)$ with an FO$(<, +, \times)$-sentence χ_φ such that for every structure $\mathcal{A}$,*

$$[\mathcal{A} : \mathcal{C}(k)] \models \chi_\varphi \tag{2}$$
$$\iff \text{there are pairwise distinct } x_1, \dots, x_k \in A \text{ with } \mathcal{A} \models \varphi(x_i) \text{ for every } i \in [k].$$

Here, $[\mathcal{A} : \mathcal{C}(k)] := \mathcal{B} = \big(\mathcal{A} \,\dot\cup\, \mathcal{C}(k), U^{\mathcal{B}}, <^{\mathcal{B}}, +^{\mathcal{B}}, \times^{\mathcal{B}}\big)$ is defined as follows.

- *$\mathcal{A} \,\dot\cup\, \mathcal{C}(k)$ is the disjoint union of $\mathcal{A}$ and $\mathcal{C}(k)$ (see the full version of the paper for the definition of the disjoint union of structures).*
- *$U^{\mathcal{B}} := A$ and $<^{\mathcal{B}}$ is an ordering of B and every element of A precedes all elements of $C(k)$. Furthermore $<^{\mathcal{B}}$ extends the ordering $\prec^{\mathcal{C}(k)}$ given in $\mathcal{C}(k)$.*
- *$\mathcal{B}$ has built-in addition and multiplication.*

▶ **Proposition 14.** *p-WSAT$(\Gamma_{1,1}) \in$ para-AC^0.*

4 Inapproximability of p-Clique by para-AC^0

We recall the notion of fpt approximation introduced in [10]. We present the definition for p-Clique, the problem which interests us. It can easily be generalized to any maximization problem.

If not stated otherwise, $\rho : \mathbb{N} \to \mathbb{R}_{\geq 1}$ is always a computable function such that the mapping $k \mapsto k/\rho(k)$ is nondecreasing and unbounded.

▶ **Definition 15.** An algorithm $\mathbb{A}$ is a *parameterized approximation for* p-Clique *with approximation ratio* ρ if for every graph G and $k \in \mathbb{N}$ with $\omega(G) \geq k$ the algorithm $\mathbb{A}$ computes a clique C of G such that $|C| \geq k/\rho(k)$. Here the clique number $\omega(G)$ is the size of a maximum clique of G. If the running time of $\mathbb{A}$ is bounded by $f(k) \cdot |G|^{O(1)}$ where $f : \mathbb{N} \to \mathbb{N}$ is computable, then $\mathbb{A}$ is an *fpt approximation algorithm.*

We tend to believe that p-Clique has no fpt approximation algorithm for any ratio ρ. Since para-AC^0 is a class of decision problems, in order to prove a lower bound it is more convenient to deal with decision algorithms instead of algorithms computing a clique.

▶ **Definition 16** ([10]). A decision algorithm $\mathbb{A}$ is a *parameterized cost approximation for* p-Clique *with approximation ratio* ρ if for every graph G and $k \in \mathbb{N}$,
- if $k \leq \omega(G)/\rho(\omega(G))$, then $\mathbb{A}$ accepts (G, k);
- if $k > \omega(G)$, then $\mathbb{A}$ rejects (G, k).

In other words, $\mathbb{A}$ decides the *promise* problem:

p-Gap$_\rho$-Clique	
Instance:	A graph G and $k \in \mathbb{N}$ such that either $k \leq \omega(G)/\rho(\omega(G))$ or $k > \omega(G)$.
Parameter:	k.
Problem:	Is $k \leq \omega(G)/\rho(\omega(G))$?

The intuition behind this definition: If G contains a clique far bigger than k, detecting a k-clique might become easier. It is straightforward to verify that if p-Clique has no fpt cost approximation of ratio ρ, then it has no fpt approximation of ratio ρ either [10].

▶ **Theorem 17.** p-Gap$_\rho$-Clique $\notin$ para-AC^0.

Our original proof of this result was based on a generalization of the machinery developed in [20], a generalization we first used to prove that AC^0 circuits are not sensitive to planted cliques of a reasonable size, see Theorem 21. The much simpler proof of Theorem 21 we present here is based on Beame's Clique Switching Lemma [5] (see Section 4.1) and was suggested to us anonymously. In the full version of the paper we apply Theorem 21 to derive Theorem 17.

First we prove a consequence of Theorem 17. For $t \geq 0$, $d \geq 1$ we denote by $\Gamma^-_{t,d}$ the subset of subformulas of $\Gamma_{t,d}$ with only negative literals. Clearly, if $\gamma \in \Gamma^-_{t,d}$ has a satisfying assignment of Hamming weight k, then it has one of weight k' for every $k' < k$. Denote by $\omega(\gamma)$ the maximum Hamming weight of assignments satisfying γ. Then p-Gap$_\rho$-WSat$(\Gamma^-_{t,d})$ can be defined similarly as p-Gap$_\rho$-Clique.

▶ **Proposition 18.** *Let $t, d \geq 1$ with $t + d \geq 3$. Then* p-Gap$_\rho$-WSat$(\Gamma^-_{t,d}) \notin$ para-AC^0.

Proof. Consider the reduction from p-Clique to p-Gap$_\rho$-WSat$(\Gamma_{t,d})$ in the proof of Corollary 12. Clearly $\delta_G \in \Gamma^-_{t,d}$ and δ_G is independent of k. Thus, the equivalence (1) preserves the approximation ratio. The result then follows immediately. ◀

4.1 Beame's Clique Switching Lemma

Let $n \in \mathbb{N}$. We consider graphs with vertex set $[n]$. To represent functions on those graphs, every potential edge $e \in \binom{[n]}{2}$ is encoded by a boolean variable X_e. We set

$$\mathcal{X}_n := \left\{ X_e \;\middle|\; e \in \binom{[n]}{2} \right\}.$$

In particular, $X_e = 1$ means that e is present in the given graph, otherwise $X_e = 0$. Sometimes, it is convenient to understand e as a natural number with $e \in \left[\binom{n}{2}\right]$. Then, e is the eth potential edge in an n-vertex graph, and X_e is the eth variable in $\mathcal{X}_n$.

For every $\ell \in [n]$ and $q \in \mathbb{R}$ with $0 \le q \le 1$ let $\mu \in \mathcal{C}_n^{\ell,q}$ be a *random restriction*, $\mu : \mathcal{X}_n \to \{0, 1, \star\}$ generated as follows:

- Choose $U \in \binom{[n]}{\ell}$ uniformly at random and then set $\mu(X_e) := \star$ for every $e \in \binom{U}{2}$.
- For $e \notin \binom{U}{2}$ we set $\mu(X_e) := 1$ with probability q and $\mu(X_e) := 0$ with probability $1 - q$.

Let F be a boolean function defined on the set of assignments from $\mathcal{X}_n$ to $\{0, 1\}$ and $\mu \in \mathcal{C}_n^{\ell,q}$. The function $F{\restriction_\mu}$ is defined on the set of assignments from $\mu^{-1}(\star)$ to $\{0, 1\}$ by: For $S : \mu^{-1}(\star) \to \{0, 1\}$, we set $F{\restriction_\mu}(S) := F(S \cup \mu)$, where $S \cup \mu : \mathcal{X}_n \to \{0, 1\}$ is the assignment:

$$(S \cup \mu)(X_e) := S(X_e), \text{ if } X_e \in \mu^{-1}(\star) \quad \text{and} \quad (S \cup \mu)(X_e) := \mu(X_e), \text{ otherwise.}$$

Recall that a rooted binary tree is a *decision tree* on some variable set $\mathcal{X} \subseteq \mathcal{X}_n$ if every leaf is labeled either 0 or 1, every internal node is labelled by a variable of $\mathcal{X}$, and the edges between an internal node and its two children are labelled 0 and 1. The *vertex height* of a path P in T is the number of distinct vertices occurring in edges e such that the corresponding X_e appears in P. The *vertex height* $|T|_v$ of T is the maximum vertex height of a path in T.

For any boolean function F as above, we set

$$\text{DTdepth}_{\text{vertex}}(F) = \min\{|T|_v \mid T \text{ a decision tree computing } F\}.$$

The following lemma is the imbalanced version of [5, Lemma 3] mentioned in the first paragraph of page 12 of that paper. The *vertex length* of a clause is the number of distinct vertices in edges e with X_e appearing in this clause.

▶ **Lemma 19** ([5]). *Let $n, r \in \mathbb{N}$ and $0 \le q \le 1/2$. Moreover, let F be a* DNF*-formula of variable set $\mathcal{X}_n$ with conjunctive clauses of vertex length at most r. For $s, \ell \in \mathbb{N}$ with $\ell := pn$, where $s \ge 0$ and $\ell := pn$ with $p \le 1/(r(2/q)^{(r+s)/2})$, we have*

$$\Pr_{\mu \in \mathcal{C}_n^{\ell,q}} \left[\text{DTdepth}_{\text{vertex}}(F{\restriction_\mu}) > s \right] < \frac{8\left((2/q)^{(s+r-1)/2} pr\right)^s}{3}.$$

In the full version of the paper we apply Lemma 19 inductively on bounded-depth circuits and show

▶ **Lemma 20.** *Assume*

- *$k : \mathbb{N} \to \mathbb{R}_+$ with $k(n) \le \log_2 n$ for all sufficiently large n and $\lim_{n\to\infty} k(n) = \infty$,*
- *$S, d : \mathbb{N} \to \mathbb{N}$ with $S(n) \ge n$.*

Define $q : \mathbb{N} \to \mathbb{R}_+$ and $s : \mathbb{N} \to \mathbb{N}$ by

$$q(n) := n^{-1/k(n)} \quad \text{and} \quad s(n) := \left\lfloor \sqrt{k(n)(\log_n S(n) d(n))} \right\rfloor, \tag{3}$$

and $\ell_i : \mathbb{N} \to \mathbb{N}$ *inductively by*

$$\ell_0(n) := n \quad \textit{and} \quad \ell_{i+1}(n) := \left\lfloor \frac{\ell_i(n)}{n^{5s(n)/k(n)}} \right\rfloor . \tag{4}$$

Then, $\ell_{d(n)}(n) = n^{1-\Theta\left(5d(n)\sqrt{(\log_n S(n)d(n))/k(n)}\right)}$ *and for every circuit* C *with variable set* $\mathcal{X}_n$*, size bounded by* $S(n)$*, and depth bounded by* $d(n)$*,*

$$\Pr_{\mu \in \mathfrak{C}_n^{\ell_{d(n)}(n),q(n)}} \left[\mathsf{C}{\restriction_\mu} \textit{ is constant} \right] = 1 - o(1).$$

4.2 A strong AC^0 version of the planted clique conjecture

In the standard planted clique problem, we are given a graph G whose edges are generated by starting with a random graph with universe $[n]$ and edge probability $1/2$, then "planting" (adding edges to make) a random clique on k vertices; the problem asks for efficient algorithms finding such a clique of size k. The problem was addressed in [17, 18, 2], among many others. It is conjectured that no such algorithm exists. Here, as a consequence of Lemma 20, we prove a statement considerably stronger than the AC^0 version of this conjecture.

Let us be more precise. The Erdős-Rényi probability space $\mathrm{ER}(n,p)$, where $n \in \mathbb{N}$ and $0 \le p \le 1$, is obtained as follows. We start with the set $[n]$ of vertices. Then we choose every $e \in \binom{[n]}{2}$ as an edge of G with probability p, independently of the choices of other edges.

For $G \in \mathrm{ER}(n,1/2)$ the expected size of a maximum clique is approximately $2 \log\, n$. Therefore G almost surely has no clique of size, say, $4 \log\, n$. For any graph G with vertex set $[n]$ and any $A \subseteq [n]$ we denote by $G + C(A)$ the graph obtained from G by adding edges such that the subgraph induced on A is a clique. For $n, c \in \mathbb{N}$ with $c \in [n]$ and $p \in \mathbb{R}$ with $0 \le p \le 1$ we consider a second distribution $\mathrm{ER}(n,p,c)$: Pick a random graph $G \in \mathrm{ER}(n,p)$ and a uniformly random subset A of $[n]$ of size c and plant in G a clique on A, thus getting the graph $G + C(A)$. The notation $(G,A) \in \mathrm{ER}(n,p,c)$ should give the information that the random graph was G and that the random subset of $[n]$ of size c was A.

▶ **Theorem 21.** *Let* $k : \mathbb{N} \to \mathbb{R}^+$ *with* $\lim_{n\to\infty} k(n) = \infty$*, and* $c : \mathbb{N} \to \mathbb{N}$ *with* $c(n) \le n^\xi$ *for some* $0 \le \xi < 1$*. Then for all* AC^0 *circuits* $(\mathsf{C}_n)_{n\in\mathbb{N}}$*,*

$$\lim_{n\to\infty} \Pr_{(G,A)\in \mathrm{ER}(n,n^{-1/k(n)},\ c(n))} \left[\mathsf{C}_n(G) = \mathsf{C}_n(G + C(A)) \right] = 1.$$

Proof. We assume that $k(n) \le \log_2\, n$ for all sufficiently large n. The general case can be reduced to it by standard techniques from probability theory.

Let $(\mathsf{C}_n)_{n\in\mathbb{N}}$ be a family of circuits such that for some $\bar{d}, t \in \mathbb{N}$ every C_n has depth at most $\bar{d}$ and size bounded by n^t. In order to apply Lemma 20, we set for $n \in \mathbb{N}$,

$$S(n) = n^t \text{ and } d(n) = \bar{d}. \tag{5}$$

By Lemma 20, it follows that (recall that $q(n) = n^{-1/k(n)}$)

$$\Pr_{\mu \in \mathfrak{C}_n^{\ell_{\bar{d}}(n),q(n)}} \left[\mathsf{C}_n{\restriction_\mu} \text{ is constant} \right] = 1 - o(1). \tag{6}$$

Furthermore, $\ell_{\bar{d}}(n) = n^{1-\Theta\left(5d(n)\sqrt{(\log_n S(n)d(n))/k(n)}\right)} = n^{1-o(1)}$; the first equality holds by Lemma 20 and the second by (5). The key step consists of the following random process, which generates $(G,A) \in \mathrm{ER}(n, n^{-1/k(n)},\ c(n))$ from $\mu \in \mathfrak{C}_n^{\ell_{\bar{d}}(n),q(n)}$.

(a) Let $V(G) := [n]$.
(b) Add edges $e \in \binom{[n]}{2}$ with $\mu(e) = 1$ to $E(G)$.
(c) Recall that $\mu^{-1}(\star) = \binom{U}{2}$, where $U \in \binom{[n]}{\ell_{\bar{d}}(n)}$ was chosen uniformly at random. For every $e \in \binom{U}{2}$, add e to $E(G)$ with probability $q(n)$.
(d) Choose $A \in \binom{U}{c(n)}$ uniformly at random. Note that this is possible as $|U| = \ell_{\bar{d}}(n) = n^{1-o(1)} > n^{\xi} \geq c(n)$ for sufficiently large n.

By (b)–(d), G and $G + C(A)$ contain the same edges from $\binom{[n]}{2} \setminus \mu^{-1}(\star)$. Thus, by (6), $\mathsf{C}_n(G) = \mathsf{C}_n(G + C(A))$ with high probability. By (c) and (d), A can be viewed as being chosen in $\binom{[n]}{c(n)}$ uniformly at random. ◀

5 The complexity of p-Halt

We already mentioned in the abstract of this article that the complexity of the parameterized halting problem p-HALT is linked to open problems in computational complexity, descriptive complexity, and proof theory [9]. For example, p-HALT $\in$ XP is equivalent to the existence of an almost optimal algorithm for the set of tautologies of propositional logic, or to the fact that a certain logic, presented in [16], is a logic for PTIME. Both statements are conjectured to be false. The origin of our interest in para-AC^0 was our hope to get a lower bound on the complexity of p-HALT in terms of para-AC^0, that is, to show p-HALT $\notin$ para-AC^0. But also this problem remains open. We know that AC^0 corresponds to FO$(<, +, \times)$, first-order logic with an ordering relation and built-in addition and multiplication. In this section we prove that p-HALT $\notin$ para-FO$(<, +)$, even p-HALT $\notin$ XFO$(<, +)$, hold unconditionally, to our knowledge the best known lower bound for the complexity of p-HALT.

Recall that in the paragraph preceding Proposition 13 we defined the natural ordering $<^{[n]}$ on $[n]$ and the ternary relations $+^{[n]}$ and $\times^{[n]}$ of addition and multiplication, respectively, on $[n]$. Now we address the definition of XFO$(<, +, \times)$. For this purpose we view inputs to parameterized problems as structures.

Any string $x \in \Sigma^*$ with $|x| = n$ can be identified with the $\{<, +, \times, One\}$-structure $\langle x \rangle^{<,+,\times} := ([n], <^{[n]}, +^{[n]}, \times^{[n]}, One^{[n]})$. Here $i \in [n]$ is in $One^{[n]}$, the interpretation of the unary relation symbol One, if and only if the ith bit of x is a '1'. The structures $\langle x \rangle^{<,+}$ and $\langle x \rangle^{<}$ are reducts of $\langle x \rangle^{<,+,\times}$ over the vocabularies $\{<, +, One\}$ and $\{<, One\}$, respectively.

▶ **Definition 22.** Let (Q, κ) be a parameterized problem. Then $(Q, \kappa) \in$ XFO$(<, +, \times)$ if there is a computable function that assigns to every $k \in \mathbb{N}$ a first-order sentence φ_k such that for every instance x of (Q, κ) we have $\big(x \in Q \iff \langle x \rangle^{<,+,\times} \models \varphi_{\kappa(x)}\big)$. Analogously, the class XFO$(<, +)$ is defined.

▶ **Theorem 23.** p-HALT $\notin$ XFO$(<, +)$.

Proof. For a contradiction we assume that p-HALT $\in$ XFO$(<, +)$ and show that then the halting problem for Turing machines would be decidable.

Assume that there is a computable function that assigns to every $k \in \mathbb{N}$ a first-order sentence φ_k such that $\big((1^n, \mathbb{M}) \in p\text{-HALT} \iff \langle(1^n, \mathbb{M})\rangle^{<,+} \models \varphi_{|\mathbb{M}|}\big)$ for every instance $(1^n, \mathbb{M})$. Fix $\mathbb{M}$. There is a first-order interpretation I that for every $n \in \mathbb{N}$ defines an isomorphic copy of $\langle(1^n, \mathbb{M})\rangle^{<,+}$ in $([n], <^{[n]}, +^{[n]})$: Let $c(n) := |(1^n, \mathbb{M})|$ be the length of the string $(1^n, \mathbb{M})$. We define the interpretation stepwise. As $\mathbb{M}$ is fixed, it is easy to see that we can define in $([n], <^{[n]}, +^{[n]})$ a subset S of $c(n)$ elements of $[n]^s$ for suitable s, the universe of the structure defined by the intended interpretation. We order S by the lexicographical order on s-tuples with respect to $<^{[n]}$. Now it is easy to define, using $+^{[n]}$, the corresponding built-in addition.

Then, from $\mathbb{M}$ we can compute $\varphi_{|\mathbb{M}|}$ and $\varphi^I_{|\mathbb{M}|}$ such that $(1^n, \mathbb{M})^{<,+} \models \varphi_{|\mathbb{M}|}$ if and only if $([n], <^{[n]}, +^{[n]}) \models \varphi^I_{|\mathbb{M}|}$, and thus,

$$(1^n, \mathbb{M}) \in p\text{-}\textsc{Halt} \iff \big([n], <^{[n]}, +^{[n]}\big) \models \varphi^I_{|\mathbb{M}|}. \tag{7}$$

By the Ginsburg-Spanier [14] improvement of Presburger's Theorem we know that for $\varphi^I_{|\mathbb{M}|}$ we may compute $n_0, p_0 \in \mathbb{N}$ such that for all $n \geq n_0$ we have $\big([n], <^{[n]}, +^{[n]}\big) \models \varphi^I_{\mathbb{M}}$ if and only if $\big([n+p_0], <^{[n+p_0]}, +^{[n+p_0]}\big) \models \varphi^I_{\mathbb{M}}$. By this equivalence and (7) we see that

$$\mathbb{M} \text{ does not hold on empty input tape} \iff \big([n_0], <^{[n_0]}, +^{[n_0]}\big) \models \neg\varphi^I_{\mathbb{M}}.$$

We can decide the halting problem by checking whether $\big([n_0], <^{[n_0]}, +^{[n_0]}\big) \models \neg\varphi^I_{\mathbb{M}}$. ◀

For the proof it was essential that the function assigning to every $k \in \mathbb{N}$ the FO$(<,+)$-sentence φ_k is *computable.* The class obtained if we drop the requirement of computability is called nonuniform-XFO$(<,+)$. We will see that p-Halt $\in$ nonuniform-XFO$(<,+)$ by the even stronger statement of part 1 of Proposition 24, a proposition we prove in the full version of the paper.

We note in passing that by standard modeltheoretic techniques one can show that the parameterized vertex cover problem, a fixed-parameter tractable problem, is not in the subclass nonuniform-XFO$(<)$ of nonuniform-XFO$(<,+)$. Thus we get a lower bound for the parameterized complexity of this problem.

We come back to our claim p-Halt $\in$ nonuniform-XFO$(<,+)$. We even show p-Halt $\in$ nonuniform-para-FO$(<,+)$. By definition, a parameterized probelm (Q,κ) belongs to nonuniform-para-FO$(<,+)$ (to para-FO$(<,+)$) if there are a sentence $\varphi \in$ FO$(<,+)$ and a (computable) function $pre : \mathbb{N} \to \Sigma^*$ such that for all x,

$$x \in Q \iff \langle (x, pre(\kappa(x))) \rangle^{<,+} \models \varphi.$$

So, in the nonuniform version we allow noncomputable precomputations. Note that para-FO$(<,+) \subseteq$ XFO$(<,+)$ as the role of the precomputation (in the definition of para-FO$(<,+)$) can be taken over by the sentences φ_k (in the definition of XFO$(<,+)$).

▶ **Proposition 24.** ***1.*** p-Halt $\in$ nonuniform-para-FO$(<,+)$.
2. p-Halt $\notin$ nonuniform-para-FO$(<)$.

Let τ be a vocabulary which does not contain the reation symbols $<, +, \times$ and set $\tau_{<,+,\times} := \tau \cup \{<,+,\times\}$. Recall that a $\tau_{<,+,\times}$-structure $\mathcal{A}$ *has built-in addition and built-in multiplication* if $(A, <^{\mathcal{A}}, +^{\mathcal{A}}, \times^{\mathcal{A}})$ is isomorphic to $([|A|], <^{[|A|]}, +^{[|A|]}, \times^{[|A|]})$.

A first-order sentence φ of vocabulary $\tau_{<,+,\times}$, shortly $\varphi \in$ FO$(<,+,\times)$, is *invariant* (more precisely, $<$-*invariant*) if for every τ-structure $\mathcal{A}$ and any expansions $(\mathcal{A}, <_1, +_1, \times_1)$ and $(\mathcal{A}, <_2, +_2, \times_2)$ of $\mathcal{A}$ to structures with built-in addition and multiplication, we have:

$$(\mathcal{A}, <_1, +_1, \times_1) \models \varphi \quad\iff\quad (\mathcal{A}, <_2, +_2, \times_2) \models \varphi.$$

It should be clear what we mean if we say that a $\varphi \in$ FO$(<,+)$ or a $\varphi \in$ FO$(<)$ is *invariant.*

Along the lines of [8, Theorem 10] one can show:

▶ **Proposition 25.** *Assume that p-*Halt *$\in$ XFO$(<,+,\times)$. Let τ be any vocabulary not containing the symbols $<$, $+$, and $\times$. Then there is a computable function F defined on the class of* FO$(<,+,\times)$*-sentences of vocabulary $\tau \cup \{<,+,\times\}$ such that*

- *for every $\varphi \in \mathrm{FO}(<,+,\times)$ the sentence $F(\varphi)$ is invariant;*
- *if φ is an invariant $\mathrm{FO}(<,+,\times)$-sentence, then φ and $F(\varphi)$ are equivalent.*

Thus, $\{F(\varphi) \mid \varphi$ an invariant $\mathrm{FO}(<,+,\times)\}$ is the class of sentences of vocabulary τ of a logic for the invariant fragment of $\mathrm{FO}(<,+,\times)$.

In view of Theorem 23, we tried, without success, to show that for $\mathrm{FO}(<,+)$ there is no computable function F with the properties mentioned in the preceding result for $\mathrm{FO}(<,+,\times)$, or even to show that there is no effective enumeration of the invariant sentences of $\mathrm{FO}(<,+,\times)$.

Abstract

We present a Logspace Approximation Scheme (LSAS), i.e. an approximation algorithm for maximum matching in planar graphs (not necessarily bipartite) that achieves an approximation ratio arbitrarily close to one, using only logarithmic space. This deviates from the well known Baker's approach for approximation in planar graphs by avoiding the use of distance computation - which is not known to be in Logspace. Our algorithm actually works for any "recursively sparse" graph class which contains a linear size matching and also for certain other classes like bounded genus graphs.

The scheme is based on an LSAS in bounded degree graphs which are not known to be amenable to Baker's method. We solve the bounded degree case by parallel augmentation of short augmenting paths. Finding a large number of such disjoint paths can, in turn, be reduced to finding a large independent set in a bounded degree graph. The bounded degree assumption allows us to obtain a Logspace algorithm.

1 Introduction

Historically, matching problems have played a central role in Algorithms and Complexity Theory. Edmond's blossom algorithm [14] for maximum matching was one of the first examples of a non-trivial polynomial time algorithm. It had a considerable share in initiating the study of efficient computation, including the class P itself; Valiant's #P-hardness [32] for counting perfect matchings in bipartite graphs provided surprising insights into the counting complexity classes. The rich combinatorial structure of matching problems combined with their potential to serve as central problems in the field invites their study from several perspectives.

The study of whether matching is parallelizable has yielded powerful tools, such as the isolating lemma [27], that have found numerous other applications. The RNC bound remains the best known parallel complexity for maximum matching till date. The best known upper bound for Perfect-Matching is non-uniform SPL[1] whereas the best hardness known is NL-hardness [8].

Matching in Planar Graphs

A well known example where planarity is a boon is that of counting perfect matchings. The problem in planar graphs is in P [21] and can in fact be done in NC[33]; thus Perfect-Matching (Decision) in planar graphs is in NC. "Is the construction version of Perfect-Matching in planar graphs in NC ?" remains an outstanding open question, whereas the bipartite planar case is known to be in NC [26, 25, 23, 11].

* The third author was partially supported by a TCS PhD fellowship. The first and the third authors were partially funded by a grant from Infosys foundation.

The space complexity of matching problems in planar graphs was first studied by Datta, Kulkarni, and Roy [11] where it is shown that minimum weight Perfect-Matching (Min-Wt-PM) in bipartite planar graphs is in SPL. Computing a maximum matching for bipartite planar graphs is shown to be in NC by Hoang [16]. Kulkarni [22] shows that Min-Wt-PM in planar graphs (not necessarily bipartite) is NL-hard. The only known hardness for Perfect-Matching in planar graphs is L-hardness (cf. [10]).

1.1 Motivation

Time efficient approximation algorithms are well studied and have a lot of applications. Space is arguably the second most important resource other than time. Although there is an abundance of work on time efficient approximation, work on space efficient approximation seems limited. To the best of our knowledge even some basic problems such as maximum matching have not been considered. Notice that for (the construction version of) this well studied problem we know of no better complexity bound than $\mathsf{P} \cap \mathsf{RNC}$ [14, 27, 20] even in the planar case. In particular we do not know if it is in SC or NC.

Bounded space approximation algorithms in the presence of non-determinism can be obtained by using Baker's approach [4] for some problems in certain sparse graphs, the most prominent being planar graphs. Dispensing with non-determinism in algorithms even for reachability (not to say matching) leads to either a quasipolynomial blow-up in the time requirement via Savitch's theorem [30] or a large space footprint ($O(\sqrt{n})$) if we want to simultaneously keep the algorithms in polynomial time (see e.g. [19, 3] for reachability in planar graphs). For general graphs the tradeoff at the low space side is even worse, with $O(\frac{n}{2^{\sqrt{\log n}}})$ space and polynomial time [5].

In the context of simultaneous polylogarithmic space and polynomial time (i.e. the class SC), Logspace is the gold-standard and therefore a Logspace Approximation Scheme is the desired result we are able to achieve for planar graphs. An LSAS for bounded degree graphs and a plethora of related graph classes is a serendipitous side effect.

1.2 Previous Work

The problem of approximating maximum matching has been considered both in time and parallel complexity model. [13] gives a linear-time approximation scheme for maximum matching which has the best known time complexity. An NC approximation scheme for maximum matching is given in [18].

Two papers [31, 36] have strived to rephrase Logspace approximation algorithms in the general approximation framework. Their well directed efforts need to be augmented with more concrete problems.

In this direction [9] studied planar MaxCut and related problems in the context of approximation but had to be satisfied with a $\mathsf{UL} \cap \mathsf{co}\text{-}\mathsf{UL}$ approximation scheme which closely follows Baker's approach and is unsatisfactory since it uses non-determinism.

The folklore randomized algorithm for a 1/2-approximation to MaxCut and which can be derandomized in L, with the help of pair-wise independence, is another example in the same spirit.

1.3 Our Results

In this work we first show that there is a Logspace Approximation Scheme for maximum matching in bounded degree graphs.

▶ **Theorem 1.** *Let G be a graph with degrees bounded by a constant d then for any fixed $\epsilon > 0$, we can find a $(1 - \epsilon)$ factor approximation to the maximum matching in Logspace.*

The main fact we use here is that any bounded degree graphs (assuming it's connected) always contains a linear size matching. Many planar graph classes are known to have the property of containing a large matching. Such classes include 3−connected planar graphs [7]. In fact our algorithm works for any *recursively sparse* graph containing a large matching.

Next we show that we can actually give Logspace Approximation Scheme for maximum matching in any planar graph by reducing it to the bounded degree graphs by suitable modifications.

▶ **Theorem 2.** *Let G be a planar graph then for any fixed $\epsilon > 0$, we can find a $(1-\epsilon)$ factor approximation to the maximum matching in Logspace.*

This result extends to many other graph classes, namely for classes which are "biparted" i.e. sparse graphs with bipartite graphs in the class being even *significantly sparser* such as: in bounded genus graphs, k-Apex graphs, (g, k)-Apex graphs, 1-planar graphs, k-page graphs.

Notice that while some of our ideas are similar to the classical sequential algorithm of Hopcroft and Karp [17] for maximum matching in bipartite graphs, we consider graphs which are not necessarily bipartite. Our algorithm trades off Logspace and non-bipartiteness for approximation and sparsity.

1.4 Our Techniques

The primary algorithmic tool is augmentation along short augmenting paths. We prove that in a bounded degree graph, if there are many unmatched but matchable vertices remaining there exist precisely linearly many short augmenting paths. We need to pick a large subset of independent ones from these.

This prompts us to find a large independent set in a bounded degree graph *that works in Logspace*. Notice that the simple greedy strategy that removes a least degree vertex and its neighbourhood will find a linear sized independent set but the algorithm is not implementable in Logspace.

The above method needs the graph to be bounded degree. To convert a planar graph to a bounded degree graph we simply delete high degree vertices and show that this does not affect the size of the matching considerably since the number of high degree vertices is small though possibly still linear in the graph size. This will work if we are sure that the size of the maximum matching is at least linear.

Next we work to whittle the graph down to one containing a linear sized matching without reducing the matching size. We show that removing some small number of vertices ensures this. The proof of this part is based on a lengthy case analysis.

1.5 Organization

After some preliminaries in Section 2, we describe in Section 3 the approximation algorithm for bounded degree graphs where they contain a large (linear in the number of vertices) matching. In Section 4 we then show that our algorithm can be extended for planar graphs also. We conclude in Section 5 with some open ends.

2 Preliminaries

A graph $G = (V, E)$ consists of a finite set of vertices $V(G) = V$ and edges $E(G) = E \subseteq V \times V$.

The class L is the class of languages accepted by deterministic logspace Turing machines. We know that undirected graph connectivity is in L[29]. For the definition of other complexity classes we refer the reader to any standard text book, for example [34, 2]. The concept of Logspace transducer is implicit in Definition 4.16 of [2] and is made explicit in Exercise 4.8 from the same text.

A matching in G is a set $M \subseteq E$, such that no two edges in M have a vertex in common. A matching M is called *perfect* if M covers all vertices of G, M of maximum size is called *maximum* matching. Vertices not incident to an M edge are *free*. An alternating path is one whose edges alternate between M and $E \setminus M$. An alternating path P is augmenting if P begins and ends at free vertices, that is, $M \oplus P = (M \setminus P) \cup (P \setminus M)$ is a matching with cardinality $|M \oplus P| = |M| + 1$. For a complete treatment on matching see [24].

An *independent set* is a set of vertices in a graph, no two of which are adjacent. A *maximum* independent set is an independent set of largest possible size in a given graph. A (vertex) colouring of a graph is an assignment of labels (called "colours") to the vertices of a graph such that no two adjacent vertices share the same color.

An *induced* subgraph of a graph is another graph, formed from a subset of the vertices of the graph and all of the edges connecting pairs of vertices in that subset. An *induced path* is a path that is an induced subgraph. A graph is called *recursively sparse* if every subgraph of it is a sparse graph.

▶ **Definition 3** (Approximation Ratio)**.** We call an algorithm A a β-approximation algorithm if, on every instance I, the algorithm outputs a set I_A such that $1/\beta \cdot I_A \leq I_{Opt} \leq \beta \cdot I_A$ where I_{Opt} is the optimal result on the instance I. The β is called the approximation ratio (or approximation factor) of the algorithm.

▶ **Definition 4** (Approximation Scheme)**.** Let X be a minimization (respectively, maximization) problem.

- An approximation scheme is a family of $(1+\epsilon)$-approximation algorithms A_ϵ (respectively, $(1-\epsilon)$-approximation algorithms A_ϵ) for problem X for any $0 < \epsilon < 1$.
- A Logspace approximation scheme (LSAS) for problem X is an approximation scheme which runs in Logspace.

For a more general treatment of LSAS, consult [36, 31].

A planar graph is a graph that can be embedded in the plane, i.e., the edges can be drawn on the plane in such a way that no edges cross each other (i.e.the edges intersect only at their endpoints). A graph G is said to have *genus* g if G has a minimal embedding (an embedding where every face of G is homeomorphic to a disc) on a genus g surface. Euler's formula for a genus g graph states that $\chi(g) = |V| - |E| + |F|$ where $\chi(g) = 2 - 2g$ and $|F|$ is the number of faces of G. For planar graphs, this implies $|E| \leq 3n - 6$ and so the *average degree* of a planar graph is at most 6. See standard texts on Graph theory (e.g. [12, 35]) for further information. Consult [28] for definitions and properties of various other sparse graph classes.

3 Approximating maximum matching in bounded degree graphs

In this section we show that given any bounded degree graph, we can give a Logspace approximation scheme for the maximum matching.

Our strategy is to design a Logspace transducer that takes in a bounded degree graph and a matching therein as input and while the matching has size significantly smaller than the size of the maximum matching finds a number of disjoint augmenting paths that can then be augmented in parallel in Logspace. The output of the transducer is thus a somewhat larger matching - in fact a matching which is larger than the previous matching by a constant fraction of the maximum matching. We are of course assuming that we are not already very close to the optimal matching. Since we can compose constantly many Logspace transducers to yield another Logspace transducer we are done.

All the augmenting paths we deal with are short i.e. of length at most $2k+1$ for some constant k. This is because such paths can be found in Logspace by say exhaustively listing all $(2k+1)$-tuples of vertices and checking if they form valid augmenting paths.

These short augmenting paths are at most linearly many in n, at most $n(2k+1)^2d^{2k+1}$ to be more precise where d is an upper bound on the maximum degree. Now suppose that the current matching cardinality differs significantly from the maximum matching size $|M_{opt}|$ (by a factor $\Omega(1/k)$ of the maximum matching) then we show that there are at least $\Omega(|M_{opt}|/k)$ many augmenting paths of length $2k+1$ (which happen to be disjoint - though this fact is not used subsequently).

Having demonstrated that there exist lots of paths, we have to find a large fraction in Logspace, which are mutually disjoint. If we form an intersection graph of these short augmenting paths by making two paths adjacent if they have a vertex in common, then we are looking for a large independence set in this intersection graph. We would be done if we can colour the paths with $O(1)$ colours (so that no two intersecting paths get the same colour) because then the largest colour class serves as the desired constant fraction independence set. Since the original graph is bounded degree so is the intersection graph - so it is, at least existentially, $O(1)$-colourable. We in fact show how to constant colour this graph in Logspace.

3.1 Lower bounding the number of short paths

Let $G = (V, E)$ (where $n = |V|$) be the given bounded degree graph with an upper bound of d on the degrees. Let M_{opt} be an optimal maximum matching contained in G. Let M be any other matching which is not necessarily maximum. We assume that the gap $|M_{opt}| - |M|$ is sufficiently large so that lot of augmenting paths exist since the number of unmatched but matchable vertices is large. Yet conceivably very few or none of these paths may be short. Because we can only hope to explore augmenting paths of a constant length in L such a possibility would be very injurious to the approach. Fortunately, we can show that as long as we are not very close to the maximum matching there are *many* short augmenting paths that survive. The following lemma is an adaptation of Corollary 2 of [17] tailored for augmenting paths of constant length where the number of such paths is also important to us.

▶ **Lemma 5.** *If $|M| < (1-\frac{3}{k})|M_{opt}|$ for some positive integer k then there are at least $3|M_{opt}|/2k$ augmenting paths consisting of at most $2k+1$ edges.*

Proof. The maximum number of vertices that can be matched in any matching is precisely, $2|M_{opt}|$. The symmetric difference $M \oplus M_{opt}$ consists of $|M_{opt}| - |M|$ augmenting paths and a number of alternating cycles, which are all mutually disjoint. Suppose the length of the i-th augmenting path is ℓ_i. Then $\sum_{i=1}^{|M_{opt}|-|M|}(\ell_i - 1) \leq 2|M_{opt}|$. This is because an augmenting path of length ℓ contains $\ell - 1$ matched vertices which are distinct across other paths. Thus, $(|M_{opt}| - |M|)\ell_{avg} \leq 3|M_{opt}| - |M| \leq 3|M_{opt}|$ where ℓ_{avg} is the average path length. Thus, $\ell_{avg} \leq k$.

Since at least half fraction of the paths have length at most double the average, we get that at least $3|M_{opt}|/2k$ paths have length at most $2k$. ◀

3.2 Approximating Maximum Independent Set

As graph G still contains a large set of (linearly many) disjoint augmenting paths, we find a constant factor approximation to the maximum independent set in intersection graph of bounded length augmenting paths of G.

Let H be the intersection graph of augmenting paths of length at most $2k+1$ in G.

▶ **Lemma 6.** *A β-factor approximation to the maximum independent set in the graph H can be computed in L where $\beta = 2^{-(2k+1)^2d^{2k+1}}$*

Proof. The graph H has maximum degree upper bounded by $D = (2k+1)^2 d^{2k+1}$ since there are at most $d^i d^{2k+1-i} = d^{2k+1}$ paths in which a fixed vertex appears as the i-th vertex[1]. Since d, k are constants D is also a constant. If we can colour the intersection graph by at most $f(D)$ colours then we would be done because the largest colour class will be a constant (say β) factor approximation to the maximum independent set. Now we give a simple procedure to do this.

For a graph with maximum degree bounded by D, we can find at most D disjoint forests that partition the edge set. This can be done by running Reingold's algorithm for undirected connectivity [29] at most D times on the graph. Now we colour each forest with 2 colours and it gives D bit colours to every node (1 bit for every colouring). This yields an $f(D) = 2^D$ colouring of the graph because two vertices that are adjacent must belong to at least one common forest. ◀

▶ **Theorem 7.** *Let G be a graph with degrees bounded by a constant d then for any fixed $\epsilon > 0$, we can find a $(1-\epsilon)$ factor approximation to the maximum matching in Logspace.*

Proof. Fix integer $k = \lceil \frac{3}{\epsilon} \rceil$. If the current matching is of size at most $(1-3/k)$ fraction of the maximum matching there are a lot (at least $|M_{opt}|/2k$ from Lemma 5) of augmenting paths of length $2k+1$ remaining. Thus the number of vertices in H is at least linear in $|M_{opt}|$.

By Lemma 6 we can find an independent set of size at least $\beta|V(H)| = \beta|M_{opt}|/2k$. This yields a linear number in the size of the maximum matching, of short (length $\leq 2k+1$) augmenting paths which are vertex disjoint and thus are augmentable in parallel. In fact a L-transducer can do the augmentation and output the new matching (it just has to interchange the matched and the unmatched edges in every picked augmenting path).

At every step we increase the matching size by an additive term of $|M_{opt}|/(2k/\beta)$ (unless we get closer than a factor of $(1-3/k)$ to the maximum matching). We chain $(1-3/k)2k/\beta$ such transducers. Note that since we start with an empty matching, after K rounds the approximation ratio would be at least $(1-3/k)$. Thus we get an approximation ratio of at least $(1-3/k) \leq 1-\epsilon$. ◀

4 Approximating Planar Maximum Matching

In this section we show that we can give Logspace Approximation Scheme for finding maximum matching in planar graphs using the LSAS for bounded degree graphs. We first show that a *tame* graph and so a minimum degree 3 planar graph contains a linear size matching in Subsection 4.1. In Subsection 4.2 we describe the Logspace Approximation Scheme.

4.1 Existence of a linear matching subgraph

We say that a maximal induced path is k-isolated if its length is $k > 1$ edges and each of its $(k-1)$-internal vertices have degree precisely two in G. A k-isolated path is long if $k > 2$. An endpoint of an isolated path is called a branch vertex if its degree is G is at least 3 and a pendant vertex if its degree is 1.

Consider the set P of all isolated paths in a graph G. Let P_0 represent the paths in P which contain an even number of edges. Let B_0 represent the set of pairs of endpoints of all the paths in P_0 which support at least two paths from P_0. For each pair in B_0 pick exactly two paths from P_0 supported by vertices of B_0 to yield set P'_0. Let E_0 be the set of extreme[2] edges of all paths in $P_0 \setminus P'_0$.

▶ **Definition 8.** A graph is *tame* if all pairs in B_0 support exactly two paths from P_0.

[1] This is a very crude upper bound which does not take into account that the $2k+1$ length length path is augmenting so the bound of $k^2 d^k$ is closer to truth. Our bound however suffices for the purpose at hand

[2] i.e. the first and the last

We can use the following Lemma to compress the graph preserving maximum matching size:

▶ **Lemma 9.** *The size of the maximum matching in $G - E_0$ is the same as in G.*

Proof. Every matching in $G - E_0$ is a matching in G. Thus we just need to prove that for any maximum matching in G there is a matching in in $G - E_0$ of the same cardinality. To see this notice that for any pair $\{u, v\} \in B_0$ in any matching M it is the case that $0, 1$ or 2 edges from E_0 are used. If 1 or 2 edges of E_0 are used in the matching then 1 or 2 paths, respectively, in P'_0 which are incident on u, v have at least one unmatched vertex (because they contain odd number of vertices apart from their externally matched endpoints). Switching the $1, 2$ matched edges incident on u, v to these $1, 2$ paths in P'_0 so that the unmatched vertices on these paths are matched we reach a matching with the same cardinality as M. ◀

Notice that for a tame graph there may be zero, one or two isolated even length paths between any pair of vertices. Removing the edges in E_0 ensures that we are left with a tame graph. The following is the property of tame graphs that we plan to exploit:

▶ **Lemma 10.** *A tame planar graph has a linear sized maximum matching.*

Proof. Let N_0 be a yet to be fixed threshold[3]. We use a case analysis:

1. The total length of long isolated paths $N \geq N_0$. We have a matching of size at least $N_0/4$ in this case by Lemma 11.
2. The total length of long isolated paths $N < N_0$: In this case for every pair of endpoints of long paths.
   a. We replace each such long path by a path of length 2 or 3 depending on whether the path was even and odd. This reduces the max matching size by at most $N/2$ without increasing the number of vertices.
   b. If there are more than 2 paths of length 3 between u, v then delete all but 2. This further reduces the max matching size by at most 2ν without increasing the number of vertices. Here ν is the number of odd paths in the initial graph. Thus the loss in matching in this step is at most $2N/3$.
   c. Attach the Lollipop graph (i.e. a K_4 with a pendant edge attached to one of the vertices) to each of the 2 internal vertices of the 3-isolated paths. This does not decrease the matching size. The number of vertices goes up by at most $4N$. In the resulting graph only 2-isolated paths have degree 2 vertices.
      i. If there are at least $N' \geq N'_0$ isolated 2-paths in the graph.
         A. Consider the subgraph of this graph where all edges not incident on vertices of degree 2 have been deleted and all isolated vertices formed as a result have been deleted. The resulting subgraph has at least $2N'$ edges and N' (degree 2) vertices.
         B. Find a spanning forest of this graph and root every tree in the forest at a vertex which wasn't a degree 2 vertex in G. It is easy to see that all the vertices of degree 2 in G are matchable in the forest - just match them to their unique child in the rooted forest. Thus a matching size of $N' \geq N'_0$ is guaranteed in G.
      ii. If there are at most $N' < N'_0$ isolated 2-paths in the graph.
         A. Attach the Lollipop graph to each degree 2 vertex of the graph. This does not decrease the matching size and increases the number of vertices by at most $4N'$. We obtain a min degree 3 graph.

[3] which will turn out to be $n/35$

Thus we have a matching of size at least $\min(N_0/4, N_0', m - (N_0/2 + 2N_0/3))$ and the number of vertices is at most $n + 4N_0 + 4N_0'$ in the last case of the minimum. Since the ratio of matching edges and vertices cannot be better than 1/140 from Lemma 12, we just need to assume that: $N_0/4 \geq n/140, N_0' \geq n/140, (m - 5N_0/6) \geq (n + 4N_0 + 4N_0')/140$. Taking $N_0 = 4n/140 = n/35$ and $N_0' = n/140$, we get:

$$m - n/42 \geq (n + n/7)/140$$

or

$$m \geq n/42 + n/140 + n/980 > n/140.$$

Thus, overall, $m \geq n/140$. ◀

▶ **Lemma 11.** *A graph in which the total length of long isolated paths is N has a matching of size at least $N/4$.*

Proof. Let the sum of lengths, number of odd, even isolated paths be denoted by respectively N_{odd}, N_{even} and ν_{odd}, ν_{even} An isolated path of odd length N_i has a matching of size at least $(N_i - 1)/2$ (leaving out the two extreme edges). Similarly, an even length isolated path has a matching of size at least $N_i/2 - 1$. Thus the size of a matching from long odd isolated paths is at least $N_{odd}/2 - \nu_{odd}/2$ and from even isolated paths is at least $N_{even}/2 - \nu_{even}$. Now each long even isolated path has length at least 4 so $4\nu_{even} \leq N_{even}$ and each long odd isolated path has length at least 3 so that $3\nu_{odd} \leq N_{odd}$. Thus the total size of matchings is at least

$$\sum_i N_i/2 - \nu_{odd}/2 - \nu_{even} \geq N/2 - N_{odd}/6 - N_{even}/4 \geq N/2 - N_{odd}/4 - N_{even}/4 = N/4$$

◀

▶ **Lemma 12.** *A minimum degree 3 planar graph has a matching of size at least $n/140$.*

Proof. Consider the set S of all vertices of degree at least d in G. Let S_0 be the isolated vertices in $G - S$ i.e. those vertices in $V(G) - S$ all whose neighbours are in S. Consider the bipartite graph G' with bipartitions S_0, S where we connect a vertex $u \in S_0$ to all $v \in S$ such that $(u, v) \in E(G)$. Now the number of edges incident on S_0 is at least $3|S_0|$ (because every edge incident on $u \in S_0$ is still present in G'). On the other hand, the number of edges from average degree is at most $2(|S| + |S_0|)$. Thus $|S_0| \leq 2|S|$. But $|S| \leq 6n/d$. thus together the number of vertices deleted is at most $3|S| = 18n/d$. Hence the number of remaining vertices is at least $(1 - 18/d)n$.

Now suppose the graph has c components. Find a spanning forest of this graph. Vertices in each spanning tree have degree at most $d - 1$. Then,

▶ Claim 1. Any tree on n vertices and maximum degree d supports a matching of size at least $(n - 1)/d$.

Proof. To see this fix a root to the tree and consider a deepest leaf v in the tree. Remove the other endpoint w of the pendant edge (v, w) leads to a tree containing d lesser vertices. Since at the end we might be left with just the root as an isolated vertex, the claimed bound follows. ◀

Thus the tree supports a matching of size at least $(n'' - 1)/(d - 1)$ where n'' is the number of vertices in the component. Therefore the total size of the matching is at least $(n' - c)/(d - 1)$ where $n' \geq (1 - 18/d)n$ is the number of vertices spanned by the forest. Since none of the components is a singleton it must be that $c \leq n'/2$. So the size of the maximum matching is at least $(1 - 18/d)(1/(2d - 2))n$. Putting $d = 36$, we get that the size of the maximum matching is at least $n/140$. ◀

4.2 Finding a large planar matching

▶ **Theorem 13.** *There is a Logspace Approximation Scheme for maximum matching in planar graphs.*

Proof. We first convert the original graph G into a tame graph G' by using Lemma 9. This preserves the maximum matching size. Suppose there are least αn matching edges in G' for some $\alpha < 1/2$. Fix a positive $\epsilon < \alpha$.

We will delete all vertices of degrees greater than d from G' to yield graph G'' which is of degree bounded by d. Since the number of vertices of degree at least d in G' is at most $6n/d$, the number of matching edges removed by deleting the high degree vertices is at most $6n/d$. So we will have a large $= (\alpha - 6/d)n$ sized matching remaining after this if $\alpha - 6/d = \epsilon/2$ i.e. $d = \frac{12}{2\alpha-\epsilon}$. Thus it suffices to find a $(1 - \epsilon/2)$ factor approximation to the maximum matching using Theorem 7 in Logspace. ◀

Notice that, here we had to tame the graph only to ensure the existence of a linear size matching. But given promise that the graph contains a linear size matching, we can get a approximation scheme, for any recursively sparse graph, without taming it.

▶ **Corollary 14.** *There is a Logspace Approximation Scheme for maximum matching in recursively graphs which contains a linear size matching.*

▶ Note 1. We require only the following properties of planar graphs in proving Lemma 12:

- Sparsity: The average degree is upper bounded by 6.
- Bipartite sparsity: The average degree of every bipartite subgraph is even lower i.e. 4.
- Min-degree: The minimum degree is at least 3 i.e. at least half the average degree.

Thus the proof of Lemma 12 goes through for any family of graphs satisfying these properties. Also notice that Lemma 9 works for arbitrary graphs and Lemma 10 works for any family of graphs satisfying the first two properties above. Hence we also get Logspace Approximation Schemes for the following families of graphs [15]:

1. Genus g graphs: graphs that are embeddable on a surface of genus $g = O(1)$.
2. k-Apex graphs: graphs such that deleting k vertices leads to planar graphs.
3. (g, k)-Apex graphs: graphs such that deleting k vertices leads to genus g graphs.
4. 1-planar graphs: graphs that can be drawn with at most one crossing per edge.
5. k-page graphs: graphs such that all edges can be accommodated on a k-page book with vertices on the spine.

4.3 The Algorithm

Here we present the full algorithm for finding the approximate maximum matching. First we present the algorithms for finding the approximate maximum matching in bounded degree graphs in Algorithm 1 and then we present our main algorithm, describing the *taming* procedure and using the previous algorithm as subroutine, in Algorithm 2.

5 Conclusion and Open-Ends

The main open question which remains is to show that whether we can devise an LSAS for maximum matching in *general* graphs or at least in arbitrary sparse graphs. In this work, we have been able to resolve this for bounded degree graphs, planar graphs and some related classes of sparse graphs.

Algorithm 1 (Matching in Bounded Degree Graphs)

Input : (G, ϵ, M) where $G = (V, E)$ is bounded degree graph with $deg(v) \leq d$ for all $v \in V, \epsilon > 0$ and M is a set of matched edges.
Output : A set $M' \subseteq E$ of matched edges.

```
1: Fix integer $k = \lceil \frac{3}{\epsilon} \rceil$.
2: Construct the intersection graph of augmenting paths of length at most $2k + 1$ in $G$.
3: Let the graph be $H$ with maximum degree $\leq D = (2k + 1)^2 d^{2k+1}$
4: Find at most $D$ disjoint forests that partition the edge set.
5: Colour each forest with 2 colours, giving $D$ bit colours to every node
6: Augment the vertex disjoint augmenting paths in parallel using L-transducer
7: Add the new matching to $M$
8: return $M$
```

Biedl [6] showed that there exists a linear-time (also in Logspace) reduction from maximum matching in arbitrary graphs to maximum matching in 3-regular graphs, though it is not immediate that it is approximation preserving. It will interesting to show such a reduction which is also approximation preserving.

Proving lower bounds for maximum matching in the context of approximation is another important goal. Currently we do not know of any non-trivial hardness results including NC^1-hardness or even TC^0-hardness let alone a L-hardness for approximation to any factor.

Abstract

In recent years the study of probabilistic transition systems has shifted to transition relations over distributions to allow for a smooth adaptation of the standard non-probabilistic apparatus. In this paper we study transition relations over probability distributions in a setting with internal actions. We provide new logics that characterize probabilistic strong, weak and branching bisimulation. Because these semantics may be considered too strong in the probabilistic context, Eisentraut et al. recently proposed weak distribution bisimulation. To show the flexibility of our approach based on the framework of van Glabbeek for the non-deterministic setting, we provide a novel logical characterization for the latter probabilistic equivalence as well.

1 Introduction

Labeled transition systems (LTS) are a standard way of modeling processes. To verify processes, process theory has embraced two related lines of research, viz. *behavioral equivalences* and *modal logics*. Behavioral equivalences state when two processes present the same behavior. Corresponding minimization algorithms facilitate, e.g., state space reduction. On the other hand, modal logics allow to express extensional properties of processes to be used, for example, in formal specification and verification of systems. In classical cases, a logic characterizes a particular equivalence; two processes are equivalent precisely when they satisfy the same logical formula. In such a situation, when two processes are not equivalent, the logic has a formula that is only satisfied by one of the processes. In a way, the particular formula provides an explanation why the two processes do not have the same behavior.

The introduction of probabilistic transition systems called for an extension of the results known for the non-probabilistic context to the probabilistic one. In [10], Hennessy takes *"a*

fresh look at strong probabilistic bisimulation for processes which exhibit both non-determinism and probabilistic behavior". In his view a process is not in a single state of a probabilistic LTS, but control is spread over a distribution of states. Operationally, this makes sense, because after the execution of an action, a process reaches a set of states with a particular distribution. Thus, transitions of the shape $s \xrightarrow{a} \mu$ are replaced by transitions of the shape $\mu \xrightarrow{a} \mu'$, where s is a state and μ and μ' are distributions over states. This underlies the smooth adaptation of many results for strong bisimulation to probabilistic strong bisimulation in [10].

In this paper we study transitions over distributions in the context of *weak semantics*, i.e. semantics that allow to abstract from internal actions, and the logical characterization of these semantics. We present two concrete enhancements w.r.t. earlier works. First, we do not require processes to be *divergence-free*, i.e. processes may execute infinite τ-actions. Second, we do not focus our attention on weak simulation and bisimulation only; our goal is provide a framework to deal with more general weak semantics. Key for this development is to define what constitutes a transition between two distributions. Following [14, 9], we opt for *hyper-transitions*. Different alternatives and variations of hyper-transitions appear in the literature, e.g. [6, 20, 5, 2]. In [2] also provides a comparison. Given a notion of transitions over distributions, there is a natural way to adapt the relational definition of a semantics from the state-based context to the distributions-based context: just take the standard definition and replace states by distributions.

We discuss *probabilistic strong bisimulation*, *probabilistic weak bisimulation* and *probabilistic branching bisimulation*. For each semantics we propose a logical characterization. These characterizations follow the set-up for the non-deterministic context of van Glabbeek presented in [21]. However, we add in particular the modal operator $[\cdot]_{\geq q}$ to measure probabilities. Because probabilistic weak bisimulation, as one can argue, may be considered too strong, [9] introduces a variant of weak bisimulation, so-called weak distribution bisimulation. We also introduce a logical characterization for this semantics. The peculiarity of this logic is the way probabilities are measured, for which the modal operator $\oplus_q$ is used as introduced in [10]. However, the semantics of $[\cdot]_{\geq q}$ and $\oplus_q$ are rather different: $[\cdot]_{\geq q}$ governs the support of a distribution, while $\oplus_q$ concerns decomposition of a distribution.

Related work on logics for distributions includes [17, 7, 18, 10, 2]. In [17, 2], the idea of transitions over sets of states or distributions does not appear. There, the semantics of the prefix operator depends on the actions that can be executed by the states in the support of the distribution rather than the distribution itself. In addition, in [17] the relational characterization is given for a probabilistic LTS and not for transition relation over distributions. Inspired by the different logics, [2] introduces relations over distributions. On the other hand, [10] takes into account the idea of transitions over set of states but it only focuses on probabilistic strong bisimilarity. Also [7, 18] deal with logics over distributions. The logics introduced in [7] are variants of the probabilistic μ-calculus. Two of these variants, that do not use fix-point operators, characterize weak and strong bisimulation. In [18] only extensions of HML logics are considered. The main difference between [7, 18] and our work lies in the definition of hyper-transitions; in [7, 18], only divergence-free processes are considered. Moreover, they only consider logics to characterize weak (bi)similarity and the approach cannot be uniformly extended other weak semantics as in our case. Specific details on the relation relating to the work mentioned are discussed throughout the paper.

Since the seminal work of [13] on the logical characterization of probabilistic strong bisimulation many extensions have been presented. Work on the logical characterization of weak bisimulation in the probabilistic setting includes [8, 19]. In [8], Desharnais et al. prove that, for the alternating model, PCTL* is sound and complete with respect to weak bisimulation. Song et al. do a similar study taking into account probabilistic automata, see [19]. First, they show that the logic is sound but not complete for strong bisimulation. For this reason, they introduce a variant of the semantics such that PCTL* is complete too. This new semantics relaxes the transfer property: existence of a matching (combined) transition is replaced by existence of a transition of at least the same weight on downward closed sets. Along the same lines a variant for weak bisimulation is obtained. A counterexample in [19] shows that the results for the alternating model in [8] do not hold for probabilistic automata.

The remainder of the paper is organized as follows. In Section 2, following [9], we review *probabilistic automata*, the model used to formalize probabilistic LTS, and transitions between two distributions, so-called *hyper-transitions*, taking into account both visible and internal actions. In Section 3, we introduce the relational characterizations of the various semantics and their logical characterization. Section 4 collects concluding remarks.

2 Preliminaries

For a set X, we denote by $\mathit{SubDisc}(X)$ the set of discrete sub-probability distributions over X. Given $\varrho \in \mathit{SubDisc}(X)$, we denote by $\mathit{spt}(\varrho)$ the support of ϱ, i.e. the set $\{ x \in X \mid \varrho(x) > 0 \}$, by $\varrho(\bot)$ the value $1 - \varrho(X)$, for a distinguished symbol $\bot \notin X$. For $x \in X$, we use $\delta(x)$ to denote the *Dirac* distribution of x given by $\delta(x)(y) = 1$ for $y = x$, 0 otherwise; $\delta_\bot$ represents the empty distribution with $\delta_\bot(X) = 0$. We call a distribution a *probability* distribution if $\varrho(X) = 1$. The set of all discrete probability distributions over X is denoted by $\mathit{Disc}(X)$. Given $\{x_1, \ldots, x_n\} \subseteq X$ and $p_1, \ldots, p_n > 0$ such that $p_1 + \cdots + p_n = 1$, we write $\sum_{i=1}^n p_i x_i$ to denote the distribution that assigns probability p_i to x_i, for $i = 1, \ldots, n$. In addition, given distributions $\mu_1, \ldots, \mu_n \in \mathit{Disc}(X)$, the distribution $\sum_{i=1}^n p_i \mu_i$ is called a convex combination of μ_1 to μ_n. If $n = 2$, we may write $\mu_1 \oplus_p \mu_2$ where $p = p_1$ instead of $p_1\mu_1 + p_2\mu_2$.

We reserve the symbol τ to denote the silent action. For a set X with $\tau \notin X$ we write X_τ for $X \cup \{\tau\}$.

▶ **Definition 1.** A *probabilistic automaton* or PA $\mathcal{A}$ is a tuple (S, Σ_τ, D), where S is the finite set of states, Σ_τ is the set of actions, and $D \subseteq S \times \Sigma_\tau \times \mathit{Disc}(S)$ is the transition relation.

For the rest of the paper we assume that a PA $\mathcal{A} = (S, \Sigma_\tau, D)$ is given. Moreover, $\mathcal{A}$ is *image-finite*, i.e. for all $a \in \Sigma_\tau$ and $s \in S$, the set $\{ \mu \mid (s, a, \mu) \in D \}$ is finite. We write $s \xrightarrow{a} \mu$ for $(s, a, \mu) \in D$. We write $D(a)$ for the set of transitions with label a and $D(s)$ for the set of transitions with source s.

An *execution fragment* $\alpha = s_0 a_1 s_1 a_2 s_2 \ldots$ of $\mathcal{A}$ is a finite or infinite alternating sequence of states and actions such that for each $i > 0$ there exists a transition $(s_{i-1}, a_i, \mu_i) \in D$ with $\mu_i(s_i) > 0$. We say, α is starting from $\mathit{fst}(\alpha) = s_0$, and in case the sequence is finite, ending in $\ell\mathit{st}(\alpha)$. We use $\mathit{frags}(\mathcal{A})$ to denote the set of execution fragments of $\mathcal{A}$, and by $\mathit{ffrags}(\mathcal{A})$ the set of finite execution fragments of $\mathcal{A}$. An execution fragment α is a prefix of an execution fragment α', notation $\alpha \preccurlyeq \alpha'$, if the sequence α is a prefix of the sequence α'. The trace $\mathit{trace}(\alpha)$ of α is the subsequence of non-silent actions of α. We use ε to denote the empty trace. Thus, $\mathit{trace}(a) = a$ for $a \in \Sigma$ and $\mathit{trace}(\tau) = \varepsilon$.

A *scheduler* for $\mathcal{A}$ is a map $\sigma\colon \mathit{ffrags}(\mathcal{A}) \to \mathit{SubDisc}(D)$ with $\sigma(\alpha) \in \mathit{SubDisc}(D(\ell\mathit{st}(\alpha)))$ for every finite execution fragment α. The scheduler is *deterministic* if for every α, $\sigma(\alpha)$ is a Dirac distribution or $\delta_\bot$. Note that by using sub-probability distributions, it is possible that with non-zero probability no transition is chosen after α, that is, the computation stops after α with probability $\sigma(\alpha)(\bot)$. Given a scheduler σ and a finite execution fragment α, the

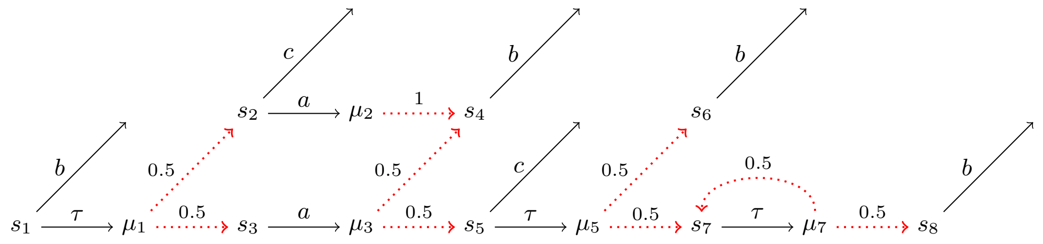

Figure 1 Example probabilistic automaton $\mathcal{A}$.

distribution $\sigma(\alpha)$ describes how transitions are chosen to move on from $\ell st(\alpha)$. A scheduler σ and a state s induce a probability distribution $\mu_{\sigma,s}$ over execution fragments as follows.

The cone C_α of a finite fragment α is the set $\{\, \alpha' \in \mathit{frags}(\mathcal{A}) \mid \alpha \preccurlyeq \alpha' \,\}$. Given a scheduler σ and states s and t, the distribution $\mu_{\sigma,s}$ on cones C_α is recursively defined by

$$\mu_{\sigma,s}(C_t) = \delta(s)(t) \qquad \mu_{\sigma,s}(C_{\alpha a t}) = \mu_{\sigma,s}(C_\alpha) \cdot \textstyle\sum_{\ell st(\alpha) \xrightarrow{a} \mu} \sigma(\alpha)\big(\ell st(\alpha) \xrightarrow{a} \mu\big) \cdot \mu(t)$$

For a finite execution fragment α, the *probability* $\mu_{\sigma,s}(\alpha)$ *of executing* α *(and stop)* based on σ and s is defined as $\mu_{\sigma,s}(\alpha) = \mu_{\sigma,s}(C_\alpha) \cdot \sigma(\alpha)(\perp)$.

A state s can execute a combined weak transition for an action $a \in \Sigma$ if there is a scheduler σ such that with probability 1 the action a is executed once while no other visible action is executed. After a is executed, a state t will be reached with probability $\mu_{\sigma,s}(\{\, \alpha \in \mathit{ffrags}(\mathcal{A}) \mid \ell st(\alpha) = t \,\})$. If $a = \tau$, we have a similar definition but with probability 1 no visible action is executed. Definition 2 takes both cases into account. As usual, $\hat{a} = a$ if $a \in \Sigma$ and $\hat{a} = \varepsilon$ if $a = \tau$

▶ **Definition 2.** Let $s \in S$ and $a \in \Sigma_\tau$. A transition $s \overset{\hat{a}}{\Longrightarrow}_c \mu$ is called a *weak combined transition* if there exists a scheduler σ such that $\mu_{\sigma,s}$ satisfies the following:
1. $\mu_{\sigma,s}(\mathit{ffrags}(\mathcal{A})) = 1$,
2. for each $\alpha \in \mathit{ffrags}(\mathcal{A})$, if $\mu_{\sigma,s}(\alpha) > 0$, then $\mathit{trace}(\alpha) = \mathit{trace}(a)$,
3. for each state t, $\mu_{\sigma,s}(\{\, \alpha \in \mathit{ffrags}(\mathcal{A}) \mid \ell st(\alpha) = t \,\}) = \mu(t)$.

Occasionally we want to make reference to the scheduler σ underlying a weak combined transition $s \overset{\hat{a}}{\Longrightarrow}_c \mu$. We do so by writing $s \overset{\hat{a}}{\Longrightarrow}_\sigma \mu$. For execution fragment α, let $\ell gt(\alpha) = n$ in case $\alpha = s_0 a_1 s_1, \ldots a_n s_n$ is finite, and $\ell gt(\alpha) = \infty$ if α is infinite. We define the length of a scheduler σ with respect to a state s by $\ell gt_s(\sigma) = \sup\{\, \ell gt(\alpha) \mid \mathit{fst}(\alpha) = s, \sigma(\alpha) = \delta_\perp \,\}$.

▶ **Example 3.** Let $\mathcal{A}$ be the PA in Fig. 1. The state s_1 can execute the following weak combined transitions:
(i) $s_1 \overset{\varepsilon}{\Longrightarrow}_c \nu_0$ with $\nu_0(s_1) = 0.5$, $\nu_0(s_2) = 0.25$ and $\nu_0(s_3) = 0.25$;
(ii) $s_1 \overset{a}{\Longrightarrow}_c \nu_1$ with $\nu_1(s_4) = 0.75$ and $\nu_1(s_5) = 0.25$;
(iii) $s_1 \overset{a}{\Longrightarrow}_\sigma \nu_2$ with $\nu_2(s_4) = 0.75$, $\nu_2(s_5) = 0.05$ and $\nu_2(s_6) = \nu_2(s_7) = 0.1$, where σ stops at state s_5 with probability 0.2 and selects the transition $s_5 \xrightarrow{\tau} \mu_5$ with probability 0.8;
(iv) $s_7 \overset{\varepsilon}{\Longrightarrow}_\sigma \delta(s_8)$ where σ is such that $\ell gt(\sigma) = \infty$.

Notice there is no combined transition from s_1 that executes an action c, since from s_1, there is no scheduler that allows to execute this action with probability 1.

A *weak hyper-transition* is a linear combination of weak combined transitions with the same label, see [9]. The weight of each weak combined transition is defined by a distribution μ. The notion of a weak hyper-transition allows to work with transitions over distributions.

▶ **Definition 4.** Given $\mu, \mu' \in \mathit{Disc}(S)$ and $a \in \Sigma_\tau$, there is a *weak hyper-transition* $\mu \overset{\hat{a}}{\Longrightarrow}_c \mu'$ if there exists a family of weak combined transitions $\{s \overset{\hat{a}}{\Longrightarrow}_c \mu_s\}_{s \in spt(\mu)}$ such that $\mu' = \sum_{s \in spt(\mu)} \mu(s) \cdot \mu_s$.

Given a scheduler σ, the scheduler σ_n is such that $\sigma_n(\alpha) = \sigma(\alpha)$ if $\ell gt(\alpha) \leqslant n$, otherwise $\sigma_n(\alpha) = \delta_\perp$. For $a \in \Sigma_\tau$, we write $s \xrightarrow{a}_c \mu$ if there is a scheduler σ of length 1 such that $s \overset{\hat{a}}{\Longrightarrow}_\sigma \mu$. Schedulers of length 1 induce the notion of a *one-step transition*.

▶ **Definition 5.** Let $\mu, \mu' \in \mathit{Disc}(S)$ and $a \in \Sigma_\tau$. For $a \neq \tau$, a *one-step transition* $\mu \xrightarrow{a}_c \mu'$ is a weak hyper-transition $\mu \overset{a}{\Longrightarrow}_c \mu'$ for $\{s \overset{a}{\Longrightarrow}_c \mu_s\}_{s \in spt(\mu)}$ such that $s \xrightarrow{a}_c \mu_s$. A *one-step transition* $\mu \xrightarrow{\tau}_c \mu'$ is a weak hyper-transition $\mu \overset{\varepsilon}{\Longrightarrow}_c \mu'$ for $\{s \overset{\varepsilon}{\Longrightarrow}_c \mu_s\}_{s \in spt(\mu)}$ such that either $\mu_s = \delta(s)$ or $s \xrightarrow{\tau}_c \mu_s$, for $s \in spt(\mu)$, and $s \xrightarrow{\tau}_c \mu_s$ for at least one $s \in spt(\mu)$.

The definition of a one-step transition for a visible action requires that each state in the support of μ executes the visible action. On the other hand, if the action is not visible, we require that at least one state executes a τ-transition.

▶ **Example 6.** Consider again Example 3. Because of $s_1 \xrightarrow{a}_c \nu_1$ and $s_2 \xrightarrow{a}_c \mu_2$, $0.5\delta(s_1) + 0.5\delta(s_2) \xrightarrow{a}_c 0.5\nu_1 + 0.5\mu_2$. Since $s_1 \xrightarrow{\tau}_c 0.5\delta(s_1) + 0.5\mu_1$, we have $\delta(s_1) \xrightarrow{\varepsilon}_c 0.5\delta(s_1) + 0.5\mu_1$. Notice that this target distribution cannot be reached from $\delta(s_1)$ by a one-step transition with a deterministic scheduler. Definition 5 does not allow to split the state s_1. Finally, notice that $\delta(s_1) \overset{\varepsilon}{\Longrightarrow}_c \delta(s_1)$ but $\delta(s_1) \xrightarrow{\tau}_c \delta(s_1)$ is not a valid one-step hyper-transition.

We have used the notion of a hyper-transition of [14] to define transitions over distributions because of its clear operational intuition.

3 Semantics for Transitions Over Distributions and their Logical Characterizations

In this section we present four different semantics. First we treat probabilistic strong bisimulation. Here we present the main results to deal with probabilities. The second semantics is probabilistic weak bisimulation. The key point is how to define a logic that characterizes the relation in such a way that the modal operators can be reused for characterizing other semantics that abstract from internal behavior. For this we follow the framework defined by van Glabbeek in [21]. Additionally, we have to introduce a number of properties satisfied by our definitions of combined and hyper-transitions (Lemma 19). We also recall why probabilistic weak bisimulation may be considered too tight. Next we cover probabilistic branching bisimulation. Defining a logic and proving that it characterizes the process equivalence is straightforward given the definitions and results gathered already. We also provide a stuttering lemma for the probabilistic context. Finally, we discuss weak distribution bisimulation [9] and its logical characterization.

3.1 Probabilistic strong bisimulation

Generally, approaches to define behavioral equivalences for probabilistic transition systems provide a relation over states and a lifting to distributions over states, by means of, for example, *weight functions* [20] or *closed sets* [3]. We follow a different approach and will directly define relations over distributions that satisfy the *decomposability* condition of [10].

▶ **Definition 7.** A symmetric relation $\mathcal{R} \subseteq \mathit{Disc}(S) \times \mathit{Disc}(S)$ is *decomposable* if $\mu \,\mathcal{R}\, \nu$ and $\mu = \mu_1 \oplus_p \mu_2$ imply there are $\nu_1, \nu_2 \in \mathit{Disc}(S)$ s.t. $\nu = \nu_1 \oplus_p \nu_2$, $\mu_1 \,\mathcal{R}\, \nu_1$ and $\mu_2 \,\mathcal{R}\, \nu_2$.

Figure 2 The decomposability condition is needed – Only considering deterministic schedulers is too strong.

In Definition 8, we introduce the notion of a *probabilistic strong bisimulation* for transition relations over probability distributions. Then we will explain why the decomposability condition is needed. We also show that a variant of strong bisimulation for transitions over distributions that only considers deterministic schedulers is too strong. For this reason we will not consider one-step transitions for deterministic schedulers further.

▶ **Definition 8.** A decomposable relation $\mathcal{R} \subseteq \mathit{Disc}(S) \times \mathit{Disc}(S)$ is called a *probabilistic strong bisimulation* if, for every $a \in \Sigma_\tau$, $\mu \,\mathcal{R}\, \nu$ and $\mu \xrightarrow{a}_c \mu'$ imply $\nu \xrightarrow{a}_c \nu'$ and $\mu' \,\mathcal{R}\, \nu'$ for some ν'. *Probabilistic strong bisimilarity*, notation $\approx_{ps}$, is defined as the union of all probabilistic strong bisimulations.

Figure 2 illustrates the need for the decomposability condition. Suppose we remove the condition, therefore μ_1 and μ_2 should be consider equivalent since they execute no transition, see Def. 5; therefore $\delta(t_1)$ and $\delta(t_2)$ are also equivalent. The condition ensures that distributions that are related by $\approx_{ps}$ assign the same weight to equivalence classes. Note that $\mu_1 = 0.6\delta(u) + 0.4\delta(u')$ and there are no μ'_2 and μ''_2 such that $\mu_2 = 0.6\mu'_2 + 0.4\mu''_2$, $\delta(u) \approx_{ps} \mu'_2$ and $\delta(u') \approx_{ps} \mu''_2$. Thus $\mu_1 \not\approx_{ps} \mu_2$ and therefore $\delta(t_1) \not\approx_{ps} \delta(t_2)$.

We explain the problem with deterministic schedulers. Consider state t_3, t'_3 and t''_3 in Figure 2. It is clear that $\delta(t_3) \approx_{ps} \delta(t'_3)$, $\delta(t'_3) \approx_{ps} \delta(t''_3)$ and $\delta(t_3) \approx_{ps} \delta(t''_3)$. If we would consider only deterministic schedulers to define one-step transitions we have the transition $0.5\delta(t'_3) + 0.5\delta(t''_3) \xrightarrow{b} 0.5\mu_3 + 0.5\mu'_3$ and this transition cannot be mimicked by $\delta(t_3)$ in the restricted setting. However, since we consider arbitrary schedulers, $\delta(t_3) \xrightarrow{b}_c 0.5\mu_3 + 0.5\mu'_3$.

Definition 9 introduces a logic that characterizes $\approx_{ps}$ (Theorem 15).

▶ **Definition 9.** The logic $\mathcal{L}_{ps}$ is defined by

$$\psi := \top \mid \bigwedge_{i\in I} \psi_i \mid \neg\psi \mid a\psi \mid \tau\psi \mid [\psi]_{\geq q}$$

for $a \in \Sigma$, $q \in \mathbb{Q}$ and possibly infinite index sets I. The *satisfiability of an $\mathcal{L}_{ps}$-formula for $\mu \in \mathit{Disc}(S)$* is defined by the following clauses:

$(\top)$	$\mu \models \top$	for all μ	(a)	$\mu \models a\psi$	if $\mu \xrightarrow{a}_c \mu'$ and $\mu' \models \psi$
$(\wedge)$	$\mu \models \bigwedge_{i\in I} \psi_i$	if $\mu \models \psi_i$ for all $i \in I$	(τ)	$\mu \models \tau\psi$	if $\mu \xrightarrow{\tau}_c \mu'$ and $\mu' \models \psi$
$(\neg)$	$\mu \models \neg\psi$	if $\mu \not\models \psi$	$(\geq q)$	$\mu \models [\psi]_{\geq q}$	if $\mu(\{s \in S \mid \delta(s) \models \psi\}) \geqslant q$

We denote by $\models_{ps}$ the satisfiability relation of $\mathcal{L}_{ps}$.

Recall that a one-step transition with an action a different from τ requires that all states in the support of the distribution execute the action a. This is not the case for a τ action. See Definition 5.

In [10], Hennessy introduces the logic pHML that also characterizes probabilistic strong bisimulation. The difference with this logic is the modality used to measure probabilities. The logic pHML uses a modal operator $\oplus_q$ and its validity, in contrast to $[\psi]_{\geq q}$, does not depend on the support of the distribution. Instead, it depends on how the distribution can be decomposed. The quantitative modal operators of [7, 18] are defined similarly. We do not follow this approach because it does not fit well for weak semantics. We explain this in more detail in the next subsection.

Parma and Segala [17] have introduced a distribution-based logic to characterize state-based probabilistic strong bisimulation, the logic $\mathcal{L}_p^N$. In this setting, states s and t are bisimilar iff $\delta(s)$ and $\delta(t)$ satisfy the same set of formulas. If we compare $\models_{ps}$ with $\mathcal{L}_p^N$, we see that clause (a) of Definition 9 is different: they have $\mu \models a\psi$ if for all $s \in spt(\mu)$, $s \xrightarrow{a}_c \mu_s$ and $\mu_s \models \psi$. In this case, the modal operator refers to the transitions that can be executed by the states underlying the distribution instead of the transitions of the distribution itself.

Theorem 15 states that $\mathcal{L}_{ps}$ characterizes $\approx_{ps}$. To prove the theorem we need a number of auxiliary results.

▶ **Lemma 10.** *Let $\mathcal{R}$ be a decomposable relation. For all μ, ν with $\mu \, \mathcal{R} \, \nu$, there is a finite index set K such that*
1. $\mu = \sum_{k \in K} p_k \cdot \delta(s_k)$.
2. $\nu = \sum_{k \in K} p_k \cdot \delta(t_k)$.
3. $\delta(s_k) \, \mathcal{R} \, \delta(t_k)$ *for all* $k \in K$.

In the following three lemmas $\mathcal{L}$ indicates a sublogic (of the logic at hand, here $\mathcal{L}_{ps}$).

▶ **Lemma 11.** *Let $\hat{s} \in S$ and $\psi \in \mathcal{L}$. If $\delta(\hat{s}) \models \psi$ then it holds that $\delta(\hat{s})(\{ \, s \mid \delta(s) \models \psi \, \}) = 1$.*

Note that the last result does not work for arbitrary μ and ψ such that $\mu \models_s \psi$. Referring to Figure 1, $0.5\delta(s_2) + 0.5\delta(s_3) \models_s a[b]_{\geq 0.75}$. However, $\delta(s_3) \not\models_s a[b]_{\geq 0.75}$, and therefore it holds that $0.5\delta(s_2) + 0.5\delta(s_3)(\{ \, s \mid \delta(s) \models \psi \, \}) < 1$.

▶ **Lemma 12.** *Let $\mathcal{L}$ be a logic containing $\neg$ and $\bigwedge$. Then there is a formula ψ_C for each $C \in \{\pi \mid \pi \in Disc(S)$ is a Dirac distribution$\}/{\approx_{\mathcal{L}}}$ s.t. for all $s \in S$, $\delta(s) \models \psi_C$ iff $\delta(s) \in C$.*

▶ **Lemma 13.** *Let $\mathcal{L}$ be a logic containing $\bigwedge$, $\neg$, and $[\cdot]_{\geq q}$ for $q \in \mathbb{Q}$. For all $\mu, \nu \in Disc(S)$ with $\mu \approx_{\mathcal{L}} \nu$ there is a finite index set K such that*
1. $\mu = \sum_{k \in K} p_k \cdot \delta(s_k)$.
2. $\nu = \sum_{k \in K} p_k \cdot \delta(t_k)$.
3. $\delta(s_k) \approx_{\mathcal{L}} \delta(t_k)$ *for all* $k \in K$.

▶ **Lemma 14.** *Suppose $\sum_{k \in K} p_k = 1$ for some index finite set K. If $\mu_k \approx_{\mathcal{L}_{ps}} \nu_k$ for $k \in K$, then $\sum_{k \in K} p_k \mu_k \approx_{\mathcal{L}_{ps}} \sum_{k \in K} p_k \nu_k$.*

▶ **Theorem 15.** *Let $\mu, \nu \in Disc(S)$, then $\mu \approx_{ps} \nu$ iff $\mu \approx_{\mathcal{L}_{ps}} \nu$.*

Sketch. To prove ($\Rightarrow$) we show that $\mu \approx_{ps} \nu$ and $\mu \models_{ps} \psi$ implies $\nu \models_{ps} \psi$. This goes by structural induction on ψ. Cases $\top, \bigwedge_{i \in I} \psi_i$, $\neg\psi$ and $a\psi$ follow [21]. The case $[\psi]_{\geq q}$ follows by Lemmas 10 and 11. To prove ($\Leftarrow$) we show that $\approx_{\mathcal{L}_{ps}}$ is a probabilistic strong bisimulation. The check of the transfer property follows [21]. To prove that $\approx_{\mathcal{L}_{ps}}$ is decomposable we use Lemmas 13 and 14. ◀

3.2 Probabilistic weak bisimulation

Transition relations over distributions allow to introduce straightforwardly a notion of weak bisimulation. Moreover, the discussion of the previous subsection applies here as well. Then, after the definition of weak bisimulation, we can focus on defining a corresponding logic.

▶ **Definition 16.** A decomposable relation $\mathcal{R} \subseteq \mathit{Disc}(S) \times \mathit{Disc}(S)$ is a *probabilistic weak bisimulation* if given $\mu \, \mathcal{R} \, \nu$, for every $a \in \Sigma_\tau$, $\mu \xrightarrow{a}_c \mu'$ implies there is ν' such that $\nu \overset{\hat{a}}{\Longrightarrow}_c \nu'$ and $\mu' \, \mathcal{R} \, \nu'$. *Probabilistic weak bisimilarity*, notation $\approx_{pw}$, is defined as the union of all probabilistic weak bisimulations.

The logic that characterizes $\approx_{pw}$ uses many of the operators of the logic for $\approx_{ps}$, but also adds new features to deal with internal behavior. The logic $\mathcal{L}_{pw}$ will be defined using a new modality ε, and two new clauses, $(\vec{\varepsilon})$ and $(\overleftarrow{\varepsilon})$ in the satisfiability relation. Because internal transitions cannot be observed, the clause (τ) is removed. First, we introduce the syntax and explain the intuition of the modality ε.

▶ **Definition 17.** The *logic* $\mathcal{L}_{pw}$ is defined by

$$\psi := \top \mid \bigwedge_{i \in I} \psi_i \mid \neg\psi \mid a\varepsilon\psi \mid \varepsilon\psi \mid [\psi]_{\geq q}$$

for $a \in \Sigma$, $q \in \mathbb{Q}$ and possibly infinite index sets I.

The modality ε is introduced to encode that internal behavior (zero or more τ's) can happen. In addition, we shall assume that some internal behavior can happen before the execution of any action. For example, $\varepsilon[c\varepsilon\top]_{\geq 0.5}$ encodes that after some internal behavior, with probability at least 0.5, an action c can be executed and the observation terminates; because the assumption and the modality ε, before and after the execution of c, some internal behavior can happen. This behavior is present in state s_1 in Figure 1. Also in Figure 1, notice that states s_2 and s_3 satisfy $a\varepsilon\top$. Because s_1 can reach both states with probability 1 via internal behavior, then $\delta(s_1)$ should also satisfy $a\varepsilon\top$. These ideas are modeled by clauses $(\vec{\varepsilon})$ and $(\overleftarrow{\varepsilon})$, which follow a phrasing of [21], in the following definition.

▶ **Definition 18.** The *satisfiability* of an $\mathcal{L}_{pw}$-formula is defined by the clauses $(\top)$, $(\bigwedge)$, $(\neg)$, $[\cdot]_{\geq q}$, (a) together with the following two:

$(\vec{\varepsilon})$ $\mu \models \varepsilon\psi$ if $\mu \models \psi$. $(\overleftarrow{\varepsilon})$ $\mu \models \psi$ if $\mu \overset{\varepsilon}{\Longrightarrow}_c \mu'$, $\mu' \models \psi$ and the outermost operator of ψ is neither $\neg$, $\bigwedge$ nor $[\cdot]_{\geq q}$.

We write $\models_{pw}$ to denote the satisfiability relation of $\mathcal{L}_{pw}$.

Figures 3 and 4, corresponding to the example in Figure 1, illustrates these clauses. Moreover, Figure 4 shows their interaction. Notice that it is possible to infer that some internal behavior can or cannot happen in a state. For instance, $\delta(s_1) \models \varepsilon[c\varepsilon\top]_{\geq 0.5}$, but $\delta(s_1) \not\models [c\varepsilon\top]_{\geq 0.5}$. The two formulas confirm that an internal transition for s_1 will change the equivalence class of the process for s_1 of Figure 1.

The condition "*the outermost operators of ψ is not $\neg$, $\bigwedge$ nor $[\cdot]_{\geq q}$*" of Definition 18 is needed for $(\overleftarrow{\varepsilon})$ because operators $\neg$ and $[\cdot]_{\geq q}$ give information about the current distribution. We use an example to explain this. See Figure 1: distribution μ_1 is such that $\mu_1 \models_{pw} \neg b\varepsilon\top$. If the restriction is not present, given that $\delta(s_1) \overset{\varepsilon}{\Longrightarrow} \mu_1$, one has $\delta(s_1) \models_{pw} \neg b\varepsilon\top$. This is inconsistent with the fact that $s_1 \xrightarrow{b}$. Similar reasoning is in place for the modality $[\cdot]_{\geq q}$. Operator $\bigwedge$ is also restricted to take into account the recursive case, for example, $\neg b\varepsilon\top \wedge \top$.

1. $\delta(s_2) \models_{pw} a\varepsilon\top$ and $\delta(s_3) \models_{pw} a\varepsilon\top$
2. $0.5\delta(s_2) + 0.5\delta(s_3) \models_{pw} a\varepsilon\top$ by (a)
3. $\delta(s_1) \xRightarrow{\varepsilon}_c 0.5\delta(s_2) + 0.5\delta(s_3)$
4. $\delta(s_1) \models_{pw} a\varepsilon\top$ by $(\overleftarrow{\varepsilon})$ and 3.

Figure 3 $(\overleftarrow{\varepsilon})$ allows to take into account the formula that are satisfied after an internal hyper-transition with a probabilistic scheduler.

(i) $\delta(s_2) \models_{pw} c\varepsilon\top$.
(ii) $0.5\delta(s_2) + 0.5\delta(s_3) \models_{pw} [c\varepsilon\top]_{\geq 0.5}$ by $(\geq q)$
(iii) $0.5\delta(s_2) + 0.5\delta(s_3) \models_{pw} \varepsilon[c\varepsilon\top]_{\geq 0.5}$ by $(\overrightarrow{\varepsilon})$
(iv) $\delta(s_1) \models_{pw} \varepsilon[c\varepsilon\top]_{\geq 0.5}$ by $(\overleftarrow{\varepsilon})$, 3. and 3

Figure 4 $(\overrightarrow{\varepsilon})$ concerns the current probability measure. Then $(\overleftarrow{\varepsilon})$ can be used for backward propagation. Notice $\delta(s_1) \not\models_{pw} [c\varepsilon\top]_{\geq 0.5}$.

In addition, in the following sections, we will use the same definition to define other logics that characterize other weak semantics.

In [17], Parma and Segala also introduce a logic that characterizes probabilistic weak bisimulation, the logic $\mathcal{L}_w^N$. This logic is the logic $\mathcal{L}_p^N$ where the modality a is replaced by a modality that considers weak combined transitions. Similarly, [7, 18] consider weak hyper-transitions. In comparison with other logics characterizing probabilistic weak bisimulation, $\mathcal{L}_{pw}$ looks more complex because of the modalities ε and the clauses $(\overleftarrow{\varepsilon})$ and $(\overrightarrow{\varepsilon})$. This complexity is needed to extend the logic to other semantics. See the next section.

It has been argued that probabilistic weak bisimulation is too strong [9, 5]: Consider Figure 5 and assume that states $\frownie$ and $\smiley$ are such that $\frownie \not\approx_{pw} \smiley$. State s_1 does not add any behavior to the system represented by the state s, and the probabilities of reaching states $\frownie$ and $\smiley$ from s are, respectively, 0.25 and 0.75. Then it is plausible to consider the distributions $\delta(s)$ and $\delta(t)$ weakly bisimilar, but in fact they are not. Notice there is no matching for the transition $\delta(s) \xrightarrow{\tau} \mu_s$. In [9], a variant of weak bisimulation is introduced to deal with this problem. We study the logic characterization of this variant in Subsection 3.4.

We explain why the approach of Hennessy [10] to define the measure modality does not fit well for weak bisimilarity. Let $\psi_{\frownie}$ and $\psi_{\smiley}$ be the characteristic formula of $\frownie$ and $\smiley$. Then

$$\delta(s_1) \models_{pw} \varepsilon([\psi_{\frownie}]_{\geq 0.5} \wedge [\psi_{\smiley}]_{\geq 0.5}) \qquad \delta(s) \models_{pw} \varepsilon([\varepsilon([\psi_{\frownie}]_{\geq 0.5} \wedge [\psi_{\smiley}]_{\geq 0.5}]_{\geq 0.5} \wedge [\psi_{\smiley}]_{\geq 0.5}))$$

Let $\hat{\psi}$ be the last formula, then $\delta(t) \not\models_{pw} \hat{\psi}$. In case we had used the approach used by Hennessy [10], we would replace the measure modality $[\,\cdot\,]_{\geq q}$ by $\oplus_q$ with clause

$$(\oplus) \quad \mu \models \psi_1 \oplus_q \psi_2 \quad \text{if } \mu = \mu_1 \oplus_q \mu_2 \text{ and } \mu_i \models \psi_i \text{ for } i = 1, 2$$

In the new setting, the formula analogous to $\hat{\psi}$ is $\varepsilon((\varepsilon(\psi_{\frownie} \oplus_{0.5} \psi_{\smiley})) \oplus_{0.5} \psi_{\smiley})$. This formula is satisfied by $\delta(t)$ because $\mu_t = (\frownie \oplus_{0.5} \smiley) \oplus_{0.5} \smiley$. Then $\delta(s)$ and $\delta(t)$ would not be distinguished by the logic in the new setting.

Theorem 21 states $\mathcal{L}_{pw}$ characterizes $\approx_{pw}$. To prove the result, we reuse the results for probabilistic strong bisimulation regarding probabilities. In addition, we need to introduce technical properties of weak transitions, see Lemma 19, and to recast Lemma 14 for $\mathcal{L}_{pw}$.

▶ **Lemma 19.** *Let $s \in S$, $\mu, \mu', \nu, \mu_i, \mu_i' \in Disc(S)$, where $i \in I$, and σ be a scheduler. Then*
1. *$\mu \xRightarrow{\varepsilon}_c \nu$ and $\nu \xRightarrow{\varepsilon}_c \mu'$ imply $\mu \xRightarrow{\varepsilon}_c \mu'$. [14, Prop. 3.6]*
2. *$s \xRightarrow{\hat{a}}_c \mu_i$, $i \in I$, $a \in \Sigma_\tau$ and $\sum_{i \in I} p_i = 1$ imply $s \xRightarrow{\hat{a}}_c \sum_{i \in I} p_i\mu_i$ [14, Prop. 3.4].*

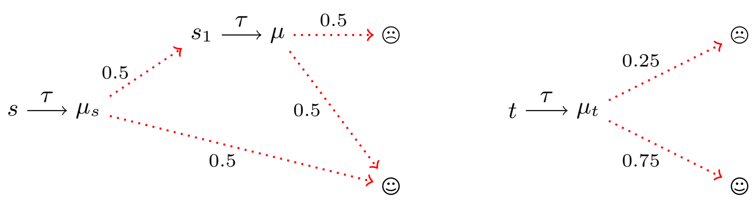

Figure 5 Probabilistic weak bisimulation is too strong.

3. $\mu_i \overset{\hat{a}}{\Longrightarrow}_c \mu_i'$, $i \in I$, $a \in \Sigma_\tau$ *and* $\sum_{i\in I} p_i = 1$ *imply* $\sum_{i\in I} p_i\mu_i \overset{\hat{a}}{\Longrightarrow} \sum_{i\in I} p_i\mu_i'$.
4. *For* $a \in \Sigma$, $\mu \overset{a}{\Longrightarrow}_c \mu'$ *iff there are* $\nu, \nu' \in Disc(S)$ *such that* $\mu \overset{\varepsilon}{\Longrightarrow}_c \nu \xrightarrow{a}_c \nu' \overset{\varepsilon}{\Longrightarrow}_c \mu'$.
5. $\sigma = \lim_{n\to\infty} \sigma_n$ *pointwise. Moreover,* $\mu_{s,\sigma}(\alpha) = \lim_{n\to\infty} \mu_{s,\sigma_n}(\alpha)$ *[20, Prop. 5.3.22].*
6. *If* $\ell gt(\sigma) > n$, $s \overset{\varepsilon}{\Longrightarrow}_{\sigma_n} \mu_n$ *and* $s \overset{\varepsilon}{\Longrightarrow}_{\sigma_{n+1}} \mu_{n+1}$ *then* $\mu_n \xrightarrow{\tau}_c \mu_{n+1}$.
7. *If* $\mu \approx_{pw} \nu$ *and* $\mu \overset{\varepsilon}{\Longrightarrow}_c \mu'$, *there is* $\nu' \in Disc(S)$ *such that* $\nu \overset{\varepsilon}{\Longrightarrow}_c \nu'$ *and* $\mu' \approx_{pw} \nu'$.
8. *For* $a \in \Sigma$, *if* $\mu \approx_{pw} \nu$ *and* $\mu \overset{a}{\Longrightarrow}_c \mu'$, *there is* $\nu' \in Disc(S)$ *such that* $\nu \overset{a}{\Longrightarrow}_c \nu'$ *and* $\mu' \approx_{pw} \nu'$.

▶ **Lemma 20.** *Suppose* $\sum_{k\in K} p_k = 1$, *for some finite index set* K. *If* $\mu_k \approx_{\mathcal{L}_{pw}} \nu_k$ *for* $k \in K$, *then* $\sum_{k\in K} p_k\mu_k \approx_{\mathcal{L}_{pw}} \sum_{k\in K} p_k\nu_k$.

▶ **Theorem 21.** *Let* $\mu, \nu \in Disc(S)$. *Then* $\mu \approx_{pw} \nu$ *iff* $\mu \approx_{\mathcal{L}_{pw}} \nu$.

The proofs of Lemma 20 and Theorem 21 strongly depend on the properties of Lemma 19. The proof of these statements are intricate, because of the definitions of combined and hyper-transitions considering schedulers of infinite length. These chedulers are needed, e.g., to distinguish between distributions $\delta(s_7)$ and $\delta(s_8)$ in Figure 1, i.e. $\delta(s_7) \approx_{pw} \delta(s_8)$. Note, state s_8 executes a transition with action b and this transition can be mimicked by s_7 only using a weak hyper-transition defined by a scheduler of infinite length. The variant of weak bisimulation of [7, 18] does not relate $\delta(s_7)$ and $\delta(s_8)$, because the relation $\overset{\varepsilon}{\Longrightarrow}_c$ is defined as the reflexive and transitive closure of $\xrightarrow{\hat{\tau}}_c$. This way of defining hyper-transition is sufficient in the context of [7, 18], because they deal with divergence-free PA. Notice, $\mathcal{A}$ in Figure 1 is not divergence-free.

3.3 Probabilistic branching bisimulation

We discuss probabilistic branching bisimilarity and its logical characterization. We remark that for the correspondence result we only need to add one new auxiliary result, a lemma analogous to Lemma 20.

▶ **Definition 22.** A decomposable relation $\mathcal{R} \subseteq Disc(S) \times Disc(S)$ is a *probabilistic branching bisimulation* if given $\mu \,\mathcal{R}\, \nu$, for every $a \in \Sigma_\tau$, $\mu \xrightarrow{a}_c \mu'$ implies

- $a = \tau$ and $\mu' \,\mathcal{R}\, \nu$, or
- there are $\tilde{\nu}$ and ν' such that $\nu \overset{\varepsilon}{\Longrightarrow}_c \tilde{\nu} \xrightarrow{a}_c \nu'$ with $\mu \,\mathcal{R}\, \tilde{\nu}$ and $\mu' \,\mathcal{R}\, \nu'$.

Probabilistic branching bisimilarity, notation $\approx_{pb}$, is defined as the union of all probabilistic branching bisimulations.

For the logic $\mathcal{L}_{pb}$ for probabilistic branching bisimulation we include binary operators $\_a\_$, for $a \in \Sigma$, and $\_\tau\_$ replacing $a\varepsilon$ and ε.

▶ **Definition 23.** The *logic* $\mathcal{L}_{pb}$ is defined by

$$\psi := \top \mid \bigwedge_{i\in I}\psi_i \mid \neg\psi \mid \psi a\psi' \mid \psi\tau\psi' \mid [\psi]_{\geq q}$$

for $a \in \Sigma$, $q \in \mathbb{Q}$ and possibly infinite index sets I. The satisfiability of an $\mathcal{L}_{pb}$-formula is defined by the clauses ($\top$), ($\bigwedge$), ($\neg$), ($\geq q$), ($\overleftarrow{\varepsilon}$) and

(η) $\quad \mu \quad \models \psi a\psi'$ $\quad$ if $\mu \xrightarrow{a}_c \mu'$, $\mu \models \psi$ and $\mu' \models \psi'$.

(η_τ) $\quad \mu \quad \models \psi\tau\psi'$ $\quad$ if, $\mu = \mu'$ or $\mu \xrightarrow{\tau}_c \mu'$, $\mu \models \psi$ and $\mu' \models \psi'$.

As in the non-probabilistic context [22, 21], the modality $\psi a\psi'$ (based on the notion of η-replication) allows to observe ψ' after an execution of action a that is preceded by the observation of ψ. This modality generalizes $a\psi$. A similar meaning for $\psi\tau\psi'$. These two modalities allow to check the branching of a process. Notice that _a_ does not force using ε, because of this, it is possible to check the branching after the execution of the action a.

▶ **Lemma 24.** *Suppose $\sum_{k\in K} p_k = 1$ for some finite index set K.*

1. *If $\mu_k \approx_{pb} \nu_k$ for $k \in K$, then $\sum_{k\in K} p_k\mu_k \approx_{pb} \sum_{k\in K} p_k\nu_k$.*
2. *If $\mu_k \approx_{\mathcal{L}_{pb}} \nu_k$ for $k \in K$, then $\sum_{k\in K} p_k\mu_k \approx_{\mathcal{L}_{pb}} \sum_{k\in K} p_k\nu_k$.*

▶ **Theorem 25.** *Let $\mu, \nu \in Disc(S)$, $\mu \approx_{pb} \nu$ iff $\mu \approx_{\mathcal{L}_{pb}} \nu$.*

3.4 Probabilistic weak bisimulation with sloppy probabilities

We have argued that weak bisimulation may be considered too strong. To deal with this problem, Eisentraut and co-workers introduced in [9] a notion called *weak distribution bisimulation*. We recall this process equivalence in Definition 27. Our presentation slightly differs from the original because we build on the notion of a weak decomposable relation (see Definition 26). In line with the nomenclature used in [21] for the global testing variants, we refer to our notion as *probabilistic weak bisimulation with sloppy probabilities*. We will motivate this further after the presentation of the logic that characterizes the semantics.

▶ **Definition 26.** A symmetric relation $\mathcal{R} \subseteq Disc(S) \times Disc(S)$ is called a *weak decomposable relation* if $\mu\,\mathcal{R}\,\nu$ and $\mu = \mu_1 \oplus_p \mu_2$ implies there are ν_1 and ν_2 such that $\nu \overset{\varepsilon}{\Longrightarrow}_c \nu_1 \oplus_p \nu_2$, $\mu_1\mathcal{R}\nu_1$ and $\mu_2\mathcal{R}\nu_2$.

Next we define for a weak decomposable relation when it is called a probabilistic weak bisimulation with sloppy probabilities.

▶ **Definition 27.** A weak decomposable relation $\mathcal{R} \subseteq Disc(S)\times Disc(S)$ is a called *probabilistic weak bisimulation with sloppy probabilities* if, for every $a \in \Sigma_\tau$, $\mu\mathcal{R}\nu$ and $\mu \xrightarrow{a}_c \mu'$ imply there is $\nu' \in Disc(S)$ s.t. $\nu \overset{\hat{a}}{\Longrightarrow}_c \nu'$ and $\mu'\,\mathcal{R}\,\nu'$. *Probabilistic weak bisimilarity with sloppy probabilities*, notation $\approx_{spw}$, is defined as the union of all the probabilistic weak bisimulations with sloppy probabilities.

The single difference of Definition 16 and Definition 27 is that the former uses a decomposable relation while the latter requires it to be weakly decomposable. However, this change is sufficient to capture $\delta(s) \approx_{spw} \delta(t)$ in Figure 5. Notice, $\mu_s \approx_{spw} \mu_t$ and these distributions are weakly decomposable because $\delta(s) \approx_{spw} \mu$.

In Figure 5 we have seen how the modal operator $[\cdot]_{\geq q}$ can be used to distinguish $\delta(s)$ and $\delta(t)$. We have argued that the approach of Hennessy does not differentiate between $\delta(s)$ and $\delta(t)$. However, to characterize the new semantics we only need to push his approach a little forward. The extra subtlety is this: Recall $\mu_s \approx_{spw} \mu_t$ and take into account the operator $\oplus_p$ with clause ($\oplus$). Then $\mu_t \models \psi_☹ \oplus_{0.25} \psi_☺$, but there are no μ_1 and μ_2 such that

$\mu_s = \mu_1 \oplus_{0.25} \mu_2$, $\mu_1 \models \psi_{☹}$ and $\mu_2 \models \psi_{☺}$. On the other hand, $\mu_s \overset{\varepsilon}{\Longrightarrow}_c 0.5\mu + 0.5\delta(☺)$ and $0.5\mu + 0.5\delta(☺) \models \psi_{☹} \oplus_{0.25} \psi_{☺}$. Therefore, in order to achieve $\mu_s \models \psi_{☹} \oplus_{0.25} \psi_{☺}$, we will allow a distribution to observe the measuring that is done after some internal behavior. This can be arranged 'for free', because the constraint that "*the outermost operator of ψ is not $\neg$, $\bigwedge$ nor $[\cdot]_{\geq q}$*" in the clause $(\overleftarrow{\varepsilon})$ does not concern the operator $\oplus_p$.

▶ **Definition 28.** The logic $\mathcal{L}_{spw}$ is defined by

$$\psi := \top \mid \bigwedge_{i \in I} \psi_i \mid \neg\psi \mid a\varepsilon\psi \mid \varepsilon\psi \mid \psi_1 \oplus_q \psi_2$$

for $a \in \Sigma$ and $q \in \mathbb{Q}$. The *satisfiability* of an $\mathcal{L}_{spw}$ formula is defined by clauses $(\top)$, $(\bigwedge)$, $(\neg)$, (a), $(\overleftarrow{\varepsilon})$, $(\overrightarrow{\varepsilon})$, and

$(\oplus)$ $\quad \mu \models \psi_1 \oplus_p \psi_2 \quad$ if $\mu = \mu_1 \oplus_p \mu_2$ and $\mu_i \models \psi_i$ for $i = 1, 2$.

We write $\models_{spw}$ to denote the satisfiability relation of $\mathcal{L}_{spw}$.

▶ **Theorem 29.** *For $\mu, \nu \in Disc(S)$, it holds that $\mu \approx_{spw} \nu$ iff $\mu \approx_{\mathcal{L}_{spw}} \nu$.*

4 Concluding remarks

In this paper we studied various behavioral equivalences for transitions systems over distributions in the presence of internal actions. An important contribution of our work is that we have consider weak hyper-transitions that deal with schedulers of infinite length. This allows to avoid the divergence-free condition for processes. Led by van Glabbeek's framework for the non-deterministic setting, we considered various ways to deal with τ-moves and provide logical characterizations for distribution-based probabilistic bisimulations. Moreover, we gave new characterization results following a uniform framework. The logics and axioms derive from the step-based behaviour encounter in the transfer conditions of the underlying bisimulation relation. The approach to prove correspondence results is the same for all notions of bisimulations considered. Crucial is the technical treatment of decomposable relations for weak combined and weak hyper-transitions (see Lemma 19). The uniform set-up allows to extend the results presented here to other semantics of the probabilistic branching-time spectrum without significantly more effort. Examples of this are η-bisimulation [1, 22] and delay bisimulation [22, 20].

▶ **Definition 30.** Let $\mathcal{R} \subseteq Disc(S) \times Disc(S)$ be a decomposable relation.

- $\mathcal{R}$ is a *probabilistic η-bisimulation* if given $\mu \mathrel{\mathcal{R}} \nu$, for every $a \in \Sigma_\tau$, $\mu \xrightarrow{a} \mu'$ implies
  1. $a = \tau$ and $\mu' \mathrel{\mathcal{R}} \nu$, or
  2. there are $\tilde{\nu}$, $\hat{\nu}$ and ν' such that $\nu \overset{\varepsilon}{\Longrightarrow}_c \tilde{\nu} \xrightarrow{a}_c \hat{\nu} \overset{\varepsilon}{\Longrightarrow}_c \nu'$ with $\mu \mathrel{\mathcal{R}} \tilde{\nu}$ and $\mu' \mathrel{\mathcal{R}} \nu'$.
- $\mathcal{R}$ is a *probabilistic delay bisimulation* if given $\mu \mathcal{R} \nu$, for every $a \in \Sigma_\tau$, $\mu \xrightarrow{a} \mu'$ implies
  1. $a = \tau$ and $\mu' \mathrel{\mathcal{R}} \nu$, or
  2. there are $\tilde{\nu}$ and ν' such that $\nu \overset{\varepsilon}{\Longrightarrow}_c \tilde{\nu} \xrightarrow{a}_c \nu'$ with $\mu' \mathrel{\mathcal{R}} \nu'$.

Probabilistic η-bisimilarity is defined as the union of all probabilistic η-bisimulations. *Probabilistic delay bisimilarity* is defined as the union of all probabilistic delay bisimulations.

We claim that the logics that characterize probabilistic η-bisimilarity and delay bisimilarity have the following syntax (using formulas ψ and φ for η and delay bisimulation, respectively).

$$\psi := \top \mid \textstyle\bigwedge_{i \in I} \psi_i \mid \neg\psi \mid \psi a \varepsilon \psi' \mid \psi \tau \psi' \mid [\psi]_{\geq q} \qquad \varphi := \top \mid \textstyle\bigwedge_{i \in I} \varphi_i \mid \neg\varphi \mid a\varphi \mid [\varphi]_{\geq q}$$

In the first logic, adding the modality ε in $\psi a \varepsilon \psi'$ does not allow anymore to check the branching of a process after the execution of a visible action. In the second logic, because the modalities $\psi a \psi'$ and $\psi \tau \psi'$ are removed, it is no longer possible to check the branching of a process before the execution of a visible action. We also remark that the problem presented in Figure 5 for probabilistic weak bisimulation is also present for these two new semantics. Then, one may also consider variants of the semantics with sloppy probabilities.

A decomposable relation $\mathcal{R} \subseteq \mathit{Disc}(S) \times \mathit{Disc}(S)$ straightforwardly induces a relation $\mathcal{S}$ over states just by putting $\mathcal{S} = \{ \, (s,t) \mid \delta(s) \, \mathcal{R} \, \delta(t) \, \}$. For distributions μ and ν with $\mu \mathcal{R} \nu$ we can define a weight function w for μ and ν with respect to $\mathcal{S}$ using the decompositions of μ and ν given by Lemma 10. Then the lifting of $\mathcal{S}$ to distributions agrees with $\mathcal{R}$. On the other hand, we expect that the approach based on *preserving* transitions used in [9] to give a state-based characterization of weak bisimulation with sloppy probabilities can be generalized to any weak decomposable relation. We have not studied this so far.

The probabilistic linear-time branching-time spectrum contains many more equivalences besides the ones discussed above. In [20] different types of combined transitions have been defined, each of which may potentially yield a new variant of a particular weak semantics. Alternatively, one can relax the condition over distributions, such as the variant of weak bisimulation of [19], or the variants of abstract probability bisimulation of [4]. The study of transition relations over distributions with internal actions can also be extended in other directions. We have considered image-finite relations, but this condition could be dropped, cf. [12]. Another interesting direction of future work considers relations over distributions with internal actions for uncountable state spaces, both regarding states and labels, as studied in [11]. Finally, it would be interesting to study how other probabilistic logics (like PCTL* [19] or variants of the probabilistic μ-calculus [15, 16]) behave in the distribution-based approach.

Abstract

For a finitely presented group, the word problem asks for an algorithm which declares whether or not words on the generators represent the identity. The Dehn function is a complexity measure of a direct attack on the word problem by applying the defining relations. Dison and Riley showed that a "hydra phenomenon" gives rise to novel groups with extremely fast growing (Ackermannian) Dehn functions. Here we show that nevertheless, there are efficient (polynomial time) solutions to the word problems of these groups. Our main innovation is a means of computing efficiently with enormous integers which are represented in compressed forms by strings of Ackermann functions.

1998 ACM Subject Classification F.2.2 Geometrical problems and computations, E.4 Data compaction and compression

Keywords and phrases Ackermann functions, hydra, word problem

1 Ackermann functions, compressed integers, and our first theorem

Let $\mathbb{N} = \{0, 1, 2, \ldots\}$. For $i \in \mathbb{N}$, the Ackermann functions $A_i : \mathbb{N} \to \mathbb{N}$ are a family of recursively defined increasingly fast-growing functions:

(i) $A_0(n) = n + 1$ for all $n \in \mathbb{Z}$,
(ii) $A_1(n) = 2n$ for all $n \in \mathbb{Z}$,
(iii) $A_i(0) = 1$ for all $i \geq 2$, and
(iv) $A_{i+1}(n + 1) = A_i A_{i+1}(n)$ for all $n \geq 0$ and all $i \geq 1$.

The following table, showing some values of $A_i(n)$, can be constructed by first inserting the $i = 0, 1$ rows and then $n = 0$ column, and then filling in the subsequent rows left-to-right according to the recurrence relation.

	0	1	2	3	4	$\cdots$	n	$\cdots$
A_0	1	2	3	4	5	$\cdots$	$n+1$	$\cdots$
A_1	0	2	4	6	8	$\cdots$	$2n$	$\cdots$
A_2	1	2	4	8	16	$\cdots$	2^n	$\cdots$
A_3	1	2	4	16	65536	$\cdots$	$\left.2^{2^{\cdot^{\cdot^{\cdot^{2}}}}}\right\}n$	$\cdots$
A_4	1	2	4	65536	$\left.2^{2^{\cdot^{\cdot^{\cdot^{2}}}}}\right\}65536$	$\cdots$		
$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$	$\vdots$			

Due to the increasing nesting of the recursion, the A_i represent the successive graduations in a hierarchy of all primitive recursive functions due to Grzegorczyk (see e.g. [30]).

The functions A_i are all strictly increasing and hence injective, so have partial inverses:

(I) $A_0^{-1} : \mathbb{Z} \to \mathbb{Z}$ mapping $n \mapsto n-1$,
(II) $A_1^{-1} : 2\mathbb{Z} \to \mathbb{Z}$ mapping $n \mapsto n/2$, and
(III) $A_i^{-1} : \operatorname{Img} A_i \to \mathbb{N}$ for all $i > 1$.

Starting with zero and successively applying a few Ackermann functions and their inverses can produce an enormous integer. For example,

$$A_3A_0A_1^2A_0(0) \;=\; A_3A_0A_1^2(1) \;=\; A_3A_0A_1(2) \;=\; A_3A_0(4) \;=\; A_3(5) \;=\; 2^{65536}$$

because

$$A_3(5) \;=\; A_2^5A_3(0) \;=\; A_2^5(1) \;=\; 2^{2^{2^{2^{2}}}} \;=\; 2^{65536}.$$

Thus Ackermann functions give highly compact representations for some very large numbers.

More precisely, here is how a string w of Ackermann functions may represent an integer $w(0)$. For $x_1, \ldots, x_n \in \{A_0^{\pm 1}, \ldots, A_k^{\pm 1}\}$, we say the word $w = x_nx_{n-1}\cdots x_1$ is *valid* if $x_mx_{m-1}\cdots x_1(0)$ is defined for all $0 \le m \le n$. That is, if we evaluate $w(0)$ by starting with 0 and proceeding through w from right to left applying successive x_i, we never encounter the problem that we are trying to apply x_i to an integer outside its domain.

For example, $w := A_2^{-1}A_1A_1A_0$ is valid, and $w(0) = \log_2(2 \cdot 2 \cdot (0+1)) = 2$. But $A_2A_0^{-1}$ and $A_1A_1^{-1}A_0$ are not valid because $A_0^{-1}(0) = -1$ is not in $\mathbb{N}$ (the domain of A_2) and because $A_0(0) = 1$ is not in $2\mathbb{Z}$ (the domain of A_1^{-1}).

Motivated by applications in group theory that we will describe in the next section, we wish to compute with these representations in an efficient manner. (Our choices of $\mathbb{Z}$ as the domains for A_0 and A_1 and our definition of A_0 represent small variations on the standard definitions of Ackermann functions, which are convenient for our applications.) One could just evaluate $w(0)$ using standard integer arithmetic, but this can be monumentally inefficient because of the sizes of the integers involved. Our first theorem is that is it possible to calculate efficiently in a rudimentary way with these representations of integers:

▶ **Theorem 1.** *Fix an integer $k \ge 0$. There is a polynomial-time algorithm, which on input a word w on $A_0^{\pm 1}, \ldots, A_k^{\pm 1}$, declares whether or not $w(0)$ represents an integer, and if so whether $w(0) < 0$, $w(0) = 0$ or $w(0) > 0$.*

(In fact our algorithm halts in time bounded above by a polynomial of degree $4 + k$. We have not attempted to optimize the degrees of the polynomial bounds on time complexity here or elsewhere in this work.)

2 The word problem, Dehn functions, and our second theorem

Elements of a group Γ with a generating set A can be represented by words—that is, products of elements of A and their inverses. To work with Γ, it is useful to have an algorithm which, on input a word, declares whether that word represents the identity element in Γ. After all, if we can recognize when a word represents the identity, then we can recognize when two words represent the same group element, and thereby begin to compute in Γ. The issue of whether there is such an algorithm is known as the *word problem* for (Γ, A) and was first posed by Dehn [9, 10] in 1912. (He did not precisely ask for an algorithm, of course, rather '*eine Methode angeben, um mit einer endlichen Anzahl von Schritten zu entscheiden...*'—that is, '*specify a method to decide in a finite number of steps...*')

Suppose a group Γ has a finite presentation $\langle a_1, \ldots, a_m \mid r_1, \ldots, r_n \rangle$. The *Dehn function* Area : $\mathbb{N} \to \mathbb{N}$ quantifies the difficulty of a *direct attack* on the word problem: roughly speaking Area(n) is the minimal N such that if a word of length at most n represents the identity, then it does so 'as a consequence of' at most N defining relations.

Here is some notation that we will use to make this more precise. Associated to a set $\{a_1, a_2, \ldots\}$ (an *alphabet*) is the set of inverse letters $\{a_1^{-1}, a_2^{-1}, \ldots\}$. The inverse map is the involution defined on $\{a_1^{\pm 1}, a_2^{\pm 1}, \ldots\}$ that maps $a_i \mapsto a_i^{-1}$ and $a_i^{-1} \mapsto a_i$ for all i. The inverse map extends to words by sending $w = x_1 \cdots x_s \mapsto x_s^{-1} \cdots x_1^{-1} = w^{-1}$ when each $x_i \in \{a_1^{\pm 1}, a_2^{\pm 1}, \ldots\}$. Words u and v are *cyclic conjugates* when $u = \alpha\beta$ and $v = \beta\alpha$ for some subwords α and β. *Freely reducing* a word means removing all $a_j^{\pm 1} a_j^{\mp 1}$ subwords. For Γ presented as above, *applying a relation* to a word $w = w(a_1, \ldots, a_m)$ means replacing some subword τ with another subword σ such that some *cyclic conjugate* of $\tau\sigma^{-1}$ is one of $r_1^{\pm 1}, \ldots, r_n^{\pm 1}$.

For a word w representing the identity in Γ, Area(w) is the minimal $N \geq 0$ such that there is a sequence of *freely reduced* words $w_0, \ldots, w_N$ with w_0 the freely reduced form of w, and w_N is the empty word, such that for all i, w_{i+1} can be obtained from w_i by *applying a relation* and then *freely reducing*. The *Dehn function* Area : $\mathbb{N} \to \mathbb{N}$ is defined by

$$\mathrm{Area}(n) \; := \; \max \{ \, \mathrm{Area}(w) \mid \text{words } w \text{ with } \ell(w) \leq n \text{ and } w = 1 \text{ in } \Gamma \, \}.$$

This is one of a number of equivalent definitions of the Dehn function. While a Dehn function is defined for a particular finite presentation for a group, its growth type—quadratic, polynomial, exponential etc.—does not depend on this choice. Dehn functions are important from a geometric point-of-view and have been studied extensively. There are many places to find background, for example [4, 5, 6, 10, 15, 16, 29, 31].

If Area(n) is bounded above by a recursive function $f(n)$, then it is possible to solve the word problem by an exhaustive search: to tell whether or not a given word w represents the identity, try all the possible ways of applying at most $f(n)$ defining relations and see whether one reduces w to the empty word. (There are finitely presented groups for which there is no algorithm to solve the word problem [3, 27].) Conversely, when a finitely presented group admits an algorithm to solve its word problem, Area(n) is bounded above by a recursive function (in fact Area(n) *is* a recursive function) [14].

There are finitely presented groups for which an extrinsic algorithm is far more efficient than this intrinsic brute-force approach. A simple example is $\mathbb{Z}^2 = \langle a, b \mid ab = ba \rangle$ (which has Dehn function Area$(n) \simeq n^2$). Given a word on $a^{\pm 1}, b^{\pm 1}$, the extrinsic approach amounts to searching exhaustively through all the ways of shuffling letters $a^{\pm 1}$ past letters $b^{\pm 1}$ to see if there is one which brings each $a^{\pm 1}$ together with an $a^{\mp 1}$ to be cancelled, and likewise each $b^{\pm 1}$ together with a $b^{\mp 1}$. It is much more efficient to read through the word and check that the number of a is the same as the number of a^{-1}, and the number of b is the same as the number of b^{-1}.

There are more dramatic examples of groups where Area(n) is a fast growing recursive function (so the 'brute force' algorithm succeeds but is extremely inefficient), but there are efficient ways to solve the word problem. Cohen, Madlener & Otto built extraordinary examples in a series of papers [7, 8, 25] where Dehn functions were first introduced (under then name *derivational complexity*). They designed their groups in such a way that the 'intrinsic' method of solving the word problem involves running a very slow algorithm which has been suitably 'embedded' in the presentation. But running this algorithm to see whether it halts on a given input is pointless as it is constructed to halt (eventually) on all inputs and so presents no obstacle to the word representing the identity. Their examples all admit algorithms to solve the word problem in running times that are at most $n \mapsto \exp^{(\ell)}(n) := \underbrace{\exp(\exp(\ldots\exp(n)))}_{\ell \text{ compositions of } \exp}$ for some ℓ. But for each $k \in \mathbb{N}$ they have examples which have Dehn functions growing like $n \mapsto A_k(n)$. Indeed, better, they have examples with Dehn function growing like $n \mapsto A_n(n)$.

Recently, yet more extreme examples were constructed by Kharlampovich, Miasnikov & Sapir [20]. By simulating Minsky machines in groups, for every recursive function $f : \mathbb{N} \to \mathbb{N}$, they construct a finitely presented group (which also happens to be residually finite and solvable of class 3) with Dehn function growing faster than f, but with word problem solvable in polynomial time.

There are also 'naturally arising' groups which have fast growing Dehn function but an efficient (that is, polynomial-time) solution to the word problem. A first example is $\langle\, a, b \mid b^{-1}ab = a^2 \,\rangle$. Its Dehn function grows exponentially (see, for example, [4]), but the group admits a faithful matrix representation

$$a \mapsto \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad b \mapsto \begin{pmatrix} 1/2 & 0 \\ 0 & 1 \end{pmatrix},$$

so it is possible to check efficiently when a word on $a^{\pm 1}$ and $b^{\pm 1}$ represents the identity by multiplying out the corresponding string of matrices.

A celebrated 1-relator group due to Baumslag [1] provides a more dramatic example:

$$\langle\ a, b \ \mid\ (b^{-1}a^{-1}b)\, a\, (b^{-1}ab) = a^2\ \rangle.$$

Platonov [28] proved its Dehn function grows like $n \mapsto \overbrace{\exp_2(\exp_2 \cdots (\exp_2}^{\lfloor \log_2 n \rfloor}(1)) \cdots)$, where $\exp_2(n) := 2^n$. (Earlier results in this direction are in [2, 14, 15].) Nevertheless, Miasnikov, Ushakov & Won [26] solve its word problem in polynomial time. (In unpublished work I. Kapovich and Schupp showed it is solvable in exponential time [33].)

Higman's group

$$\langle\ a, b, c, d \ \mid\ b^{-1}ab = a^2,\ c^{-1}bc = b^2,\ d^{-1}cd = c^2,\ a^{-1}da = d^2\ \rangle$$

from [19] is another example. Diekert, Laun & Ushakov [11] recently gave a polynomial time algorithm for its word problem and, citing a 2010 lecture of Bridson, claim it too has Dehn function growing like a tower of exponentials.

The groups we focus on here are yet more extreme 'natural examples.' They arose in the study of *hydra groups* by Dison & Riley [13] . Let $\theta : F(a_1, \ldots, a_k) \to F(a_1, \ldots, a_k)$ be the automorphism of the free group of rank k such that $\theta(a_1) = a_1$ and $\theta(a_i) = a_i a_{i-1}$ for $i = 2, \ldots, k$. The family

$$G_k \ := \ \langle\ a_1, \ldots, a_k, t \ \mid\ t^{-1}a_i t = \theta(a_i)\ \ \forall i > 1\ \rangle,$$

are called *hydra groups*. Define

$$\Gamma_k \ := \ \langle\, a_1, \ldots, a_k, t, p \ \mid \ t^{-1}a_it = \theta(a_i), \ [p, a_it] = 1 \ \forall i \geq 1 \,\rangle,$$

which is an *HNN-extension* of G_k in which an additional *stable letter* p commutes with all elements of the subgroup $H_k := \langle a_1t, \ldots, a_kt\rangle$. It is shown in [13] that for $k = 1, 2, \ldots$, the subgroup H_k is free of rank k and Γ_k has Dehn function growing like $n \mapsto A_k(n)$. Our second theorem is that nevertheless:

▶ **Theorem 2.** *For all k, the word problem of Γ_k is solvable in polynomial time.*

(In fact, our algorithm halts in time at most a polynomial of degree $3k^2 + k + 2$.)

3 The membership problem, subgroup distortion, and our third theorem

A geometric feature known as *distortion* is the root cause of the Dehn function of the group Γ_k of the previous section growing like $n \mapsto A_k(n)$. The massive gap described in Theorem 2 between Dehn function and the time-complexity of the word problem for Γ_k is attributable to a similarly massive gap between a *distortion function* and the time-complexity of a *membership problem*. Here are more details.

Suppose H is a subgroup of a group G and G and H have finite generating sets S and T, respectively. So G has a *word metric* $d_S(g, h)$, the length of a shortest word on $S^{\pm1}$ representing $g^{-1}h$, and H has a word metric d_T similarly. The *distortion* of H in G is

$$\mathrm{Dist}_H^G(n) \ := \ \max\{\, d_T(1, g) \mid g \in H \text{ with } d_S(1, g) \leq n \,\}.$$

(Distortion is defined here with respect to specific S and T, but their choices do not affect the qualitative growth of $\mathrm{Dist}_H^G(n)$.) A fast growing distortion function signifies that H 'folds back on itself' dramatically as a metric subspace of G.

The *membership problem* for H in G is to find an algorithm which, on input of a word on $S^{\pm1}$, declares whether or not it represents an element of H.

If the word problem of G is decidable (as it is for all G_k, because, for instance, they are free-by-cyclic) and we have a recursive upper bound on $\mathrm{Dist}_H^G(n)$, then there is a brute-force solution to the membership problem for H in G. If the input word w has length n, then search through all words on $T^{\pm1}$ of length at most $\mathrm{Dist}_H^G(n)$ for one representing the same element as w. This is, of course, likely to be extremely inefficient, and especially so for H_k in G_k as the distortion $\mathrm{Dist}_{H_k}^{G_k}$ grows like $n \mapsto A_k(n)$. Nevertheless:

▶ **Theorem 3.** *For all k, the membership problem for H_k in G_k is solvable in polynomial time.*

(The algorithm we construct to prove this halts in time at most polynomial of degree $3k^2 + k$.)

Reducing Theorem 2 to Theorem 3 is straight-forward, requiring little more than a standard result about HNN-extensions. We detail this in Section 5 of [12].

4 Comparing our methods for Theorem 1 with power circuits and straight-line programs

Our strategy compares and contrasts with those used to solve the word problem for Baumslag's group in [26] and Higman's group in [11], where *power circuits* are the key tool. Power circuits provide concise representations of integers: power circuits of 'size' n represent (some) integers up to a height-n tower of powers of 2. There are efficient algorithms to perform addition, subtraction, and multiplication and division by 2 with power-circuit representations of integers, and to declare which of two power circuits represents the larger integer.

We too use concise representations of large integers, but in place of power circuits we use strings of Ackermann functions. These have the advantage that they may represent much larger integers. After all, $A_3(n) = \exp_2^{(n-1)}(1)$ already produces a tower of exponents, and the higher rank Ackermann functions grow far faster. However, we are aware of fewer efficient algorithms to perform operations with strings of Ackermann functions than are available for power circuits: we only have Theorem 1.

Our methods also bear comparison with the work of Lohrey, Schleimer and their coauthors [17, 18, 21, 22, 23, 24, 32] on efficient computation in groups and monoids where words are given in compressed forms using *straight-line programs* and are compared and manipulated using polynomial-time algorithms due to Hagenah, Plandowski and Lohrey. For instance Schleimer obtained polynomial-time algorithms solving the word problem for free-by-cyclic groups and automorphism groups of free groups and the membership problem for the handlebody subgroup of the mapping class group in [32].

5 The hydra phenomenon: connecting the group theory to Ackermann's functions

The reason G_k are named *hydra groups* is that the extreme distortion of H_k in G_k stems from a string-rewriting phenomenon which is a reimagining of the battle between Hercules and the Lernean Hydra, a mythical beast which grew two new heads for every one Hercules severed. Think of a *hydra* as a word w on $a_1, a_2, a_3, \ldots$. Hercules fights w as follows. He removes its first letter, then the remaining letters regenerate in that for all $i > 1$, each remaining a_i becomes $a_i a_{i-1}$ (and each remaining a_1 is unchanged). This repeats. An induction on the highest index present shows that every hydra eventually becomes the empty word. (Details are in [13].) Hercules is then declared victorious. For example, the hydra $a_2a_3a_1$ is annihilated in 5 steps:

$$a_2a_3a_1 \;\to\; a_3a_2a_1 \;\to\; a_2a_1a_1 \;\to\; a_1a_1 \;\to\; a_1 \;\to\; \textit{empty word.}$$

Define $\mathcal{H}(w)$ to be the number of steps required to reduce a hydra w to the empty word. (So $\mathcal{H}(a_3a_3a_1) = 5$.) Then, for $k = 1, 2, \ldots$, define functions $\mathcal{H}_k : \mathbb{N} \to \mathbb{N}$ by $\mathcal{H}_k(n) = \mathcal{H}(a_k^n)$. It is shown in [13] that $\mathcal{H}_k$ and A_k grow at the same rate for all k, since the two families of functions exhibit a similar recursion relation.

Here is an outline of the argument from [13] as to why $\mathrm{Dist}_{H_k}^{G_k}$ grows at least as fast as $n \mapsto \mathcal{H}_k(n)$ (and so as fast as $n \mapsto A_k(n)$). When $k \geq 2$ and $n \geq 1$, there is a reduced word $u_{k,n}$ on $\{a_1t, \ldots, a_kt\}^{\pm1}$ of length $\mathcal{H}_k(n)$ representing $a_k^n t^{\mathcal{H}_k(n)}$ in G_k on account of the hydra phenomenon. (For example, $u_{2,3} = (a_2t)^2(a_1t)(a_2t)(a_1t)^3$ equals $a_2^3t^7$ in G_2 since a_2, a_2, a_1, a_2, a_1, a_1, and a_1 are the $\mathcal{H}_2(3) = 7$ initial letters removed by Hercules as he vanquishes the hydra a_2^3.) It follows that in G_k

$$a_k^n a_2 \; ta_1 \; a_2^{-1} a_k^{-n} \;=\; u_{k,n} \, (a_2t) \, (a_1t) \, (a_2t)^{-1} \, {u_{k,n}}^{-1}.$$

The word on the left is a product of length $2n + 4$ of the generators $a_1^{\pm1}, \ldots, a_n^{\pm1}, t^{\pm1}$ of G_k and that on the right is a product of length $2\mathcal{H}_k(n) + 3$ of the generators $(a_1t)^{\pm1}, \ldots, (a_kt)^{\pm1}$ of H_k. As H_k is free of rank k and this word is reduced, it is not equal to any shorter word on these generators.

Hydra functions and Ackermann functions grow at the same rates, but do not precisely agree. So for Theorem 3 we, in fact, need a variation of Theorem 1, namely Proposition 3.4 in [12] which concerns a recursively defined family of functions ψ_i we call *ψ-functions*. Like strings of Ackermann functions, strings of ψ-functions (which we call *ψ-words*) can concisely represent extremely large integers. We do not have a direct proof of the equivalence of this proposition to Theorem 1, but they can be proved in essentially the same ways as the defining recurrence for the ψ_i is very similar to that for the A_i. We prefer to highlight Theorem 1 here because Ackermann functions have a long history and so are of intrinsic interest.

6 An outline of our strategy for Theorem 1

Here is a sketch of the algorithm we construct in Section 2 of [12] to prove Theorem 1. A more detailed high-level description is in Section 2.2 of [12].

Suppose we have a word w on $A_0^{\pm 1}, \ldots, A_k^{\pm 1}$ and we seek to determine in polynomial time whether it is valid and, if so, whether the integer $w(0)$ is negative, zero, or positive.

We will attempt to pass to successive new words $w = w_0, w_1, \ldots$ that are *equivalent* to w (denoted $w \sim w_j$) in that each w_j is valid if and only if w is, and when they both are, $w(0) = w_j(0)$. These words are obtained by making substitutions such as replacing a letter A_{i+1} in w by a subword $A_i A_{i+1} A_0^{-1}$ (the recursion defining the Ackermann functions), or deleting a subword $A_i A_i^{-1}$ or $A_i^{-1} A_i$. The lengths of these w_j will all be at most a constant times the length of w, which is important for our proof that our algorithm halts in polynomial time. The aim of the substitutions is to reach a $w' \sim w$ which contains no $A_1^{-1}, \ldots, A_k^{-1}$. Eliminating these letters represents progress because they denote functions which have sparse domains and so present the greatest obstacle to checking whether a word is valid.

We will look at how to make these substitutions momentarily, but first here's what happens when we have reached such a w'. Consider calculating a succession of integers beginning with 0 and ending with $w'(0)$ by evaluating $w'(0)$ letter-by-letter starting from the right. Only $A_0^{\pm 1}$ can trigger decreases in absolute value. So, to determine the sign of $w'(0)$, we can stop our evaluation if the integer calculated ever exceeds the length of w': after all, whatever sign our evaluation then has will be the sign of $w'(0)$. This threshold for the integers in our calculation allow for a polynomial time bound.

So how do we reach this w'? The rough idea is to 'cancel' each A_i^{-1} (where $i \geq 1$) in w with some A_i (if present) further to the right in w'. We do this inductively on i by manipulating suffixes of the form $\sigma = A_i^{-1} u A_i v$ such that u is a word on $A_0^{\pm 1}, \ldots, A_{i-1}^{\pm 1}$ and v a word on $A_0, \ldots, A_k$. A number of complications may arise. For instance, there are exceptional cases when substituting a A_{i+1} with $A_i A_{i+1} A_0^{-1}$ fails to preserve validity. Another issue is that we may have to introduce an A_i 'artificially' to cancel with an A_i^{-1}.

It is only possible to give a few details of our algorithm in the space available here. We choose to present a subroutine **BasePinch**, which serves as the base case of this inductive process of manipulating suffixes (the instance where u only contains letters $A_0^{\pm 1}$). It displays the crucial idea that allows us to operate within polynomial time: because the gaps between elements of $\mathrm{Img} A_i$ are large, we can either recognize efficiently that σ (and hence w) is invalid on account of u not being able to carry $A_i v(0) \in \mathrm{Img} A_i$ to another element of $\mathrm{Img} A_i$ (this is what the commentary on line 12 below is about), or σ is long enough that computing letter-by-letter by usual integer arithmetic is possible in polynomial time.

BasePinch will call two other subroutines (from Section 2.3 of [12]):

- **Bounds** which, on input $\ell \in \mathbb{N}$ (expressed in binary), returns in time $O(\ell)$ a list of all the (at most $(\log_2 \ell)^2$) triples of integers $(r, n, A_r(n))$ such that $r \geq 2$, $n \geq 3$, and $A_r(n) \leq \ell$.

Algorithm 1 BasePinch.

- Input a word $\sigma = A_r^{-1} u A_r v$ where $r \geq 1$, u is a word on $A_0^{\pm 1}$, and v is a word on $A_0^{\pm 1}, \ldots, A_k$.
- Either return that σ is invalid, or return a valid word $\sigma' = A_0^{l'} v \sim \sigma$ such that $\ell(\sigma') \leq \ell(\sigma) - 2$.
- Halt in time $O(\ell(\sigma)^4)$.

```
1    $l := u(0)$  (so  $A_r^{-1} A_0^l A_r v \sim w$)
     if Positive($A_r v$) $=$ Invalid, halt and return invalid
     run Positive($v$) to determine whether $v(0) < 0$
4    if $r \geq 2$ and $v(0) < 0$, halt and return invalid
     if $l = 0$, halt and return $\sigma' := v$
     if $r = 1$, halt and return $\sigma' := A_0^{l/2} v$ if $i$ is even or invalid otherwise
7
     we now have $l \neq 0$ and $r > 1$
     run Positive($A_0^l A_r v$) to determine if $A_0^l A_r v(0) \leq 0$ (so $\notin$ domain of $A_r^{-1}$)
10           if so, halt and return invalid
     run Positive($A_0^{-2|l|} A_r v$) to determine whether $A_r v(0) > 2|l|$
             if so, halt and return invalid
13
     we now have that $0 \leq v(0) \leq |l|$ and $0 < A_r v(0) \leq 2|l|$ and $A_r v(0) + l \leq 3|l|$
     calculate $v(0)$ by running Positive($A_0^{-i} v$) for $i = 0, 1, \ldots, |l|$
16   run Bounds($3\,|l|$)
     search the output of Bounds($3\,|l|$) to find $A_r v(0)$
     set $m := A_r v(0) + l$
19   search the output of Bounds($3\,|l|$) for $c$ with $A_r(c) = m$
                                                (so $c = A_r^{-1} A_0^l A_r v(0) = \sigma(0)$)
             if such a $c$ exists, halt and return $\sigma' := A_0^{c - v(0)} v$
22           else halt and return invalid
```

- **Positive** which, on input a word w on $A_0^{\pm 1}, A_1, \ldots, A_k$ in time $O(\ell(w)^3)$ either declares w invalid or declares whether $w(0) < 0$, $w(0) = 0$, or $w(0) > 0$.

  We use these properties of Ackermann functions:

Lemma 4.

$$A_i(n) + m \leq A_i(n+m) \qquad \forall i, n, m \geq 0, \tag{1}$$

$$|A_i(n) - A_i(m)| \geq \frac{1}{2} A_i(n) \qquad \forall i \geq 2 \textit{ and } n \neq m. \tag{2}$$

The proofs follow by inductive arguments applied to the definition of an Ackermann function. Refer to Lemma 2.1 of [12] for details.

Correctness of BasePinch. Here are the salient points line-by-line.

4: If $v(0) < 0$, then σ is invalid.

5: If $r < 2$ or $v(0) \geq 0$, $A_r^{-1} A_r v \sim v$.

6: Since A_1 is the function $n \mapsto 2n$, the parity of $A_0^l A_r v(0)$ is the parity of l when $r = 1$, and determines the validity of σ.

9, 11: We know $A_0^l A_r v$ and $A_0^{-2|l|} A_r v$ are valid at these points because $A_r v$ is valid.

12: Let $q = v(0)$. For all $p \neq q$ we have $|A_r(q) - A_r(p)| \geq \frac{1}{2} A_r(q)$ by Lemma 4, and so $|A_r(q) - A_r(p)| > |l|$. If $A_r^{-1} A_0^l A_r v$ is valid, then there exists $p \in \mathbb{N}$ such that $A_r(p) = A_0^l A_r v(0) = l + A_r(q)$, but then $|A_r(p) - A_r(q)| = |l|$ for some $p \neq q$ (since $l \neq 0$), contradicting $|A_r(q) - A_r(p)| > l$. Thus w is invalid.

14: The reason $0 < A_r v(0)$ is that $r > 1$ and so $\mathrm{Img} A_r$ contains only positive integers. And $A_r v(0) \leq 2\,|l|$ because of lines 11 and 12. It follows that $v(0) \leq |l|$ because $2v(0) = A_1 v(0) \leq A_r v(0) \leq 2\,|l|$. And $v(0) \geq 0$ since $v(0)$ is in the domain of A_r, which is $\mathbb{N}$ when $r > 1$. We have $A_0^l A_r v(0) \leq 3|l|$ here because $A_r v(0) \leq 2\,|l|$ and so $A_0^l A_r v(0) \leq l + 2\,|l|$.
20: If $m = A_r v(0) + l = A_0^l A_r v(0)$ is in the domain of A_r^{-1}, then $m > 0$. And, from line 14, we know $m \leq 3\,|l|$, so this will find c if it exists. If no such c exists, σ is invalid.
21: $A_0^{c-v(0)} v(0) = c = A_r^{-1}(l + A_r v(0)) = A_r^{-1} A_0^l A_r v(0)$.

We must show that $\ell(\sigma') \leq \ell(\sigma) - 2$. In the cases of lines 5 and 6, this is immediate, so suppose $r \geq 2$. As for line 21, by Lemma 4:

$$|c - v(0)| \leq |A_r(v(0) + c - v(0)) - A_r v(0)| = |A_r(c) - A_r(v(0)| = |l|$$

from which $\ell(\sigma') \leq \ell(\sigma) - 2$ follows immediately.

The integer calculations performed by the algorithm involve integers of absolute value at most $3\ell(\sigma)$. See [12] for details.

That **BasePinch** halts in time $O(\ell(\sigma)^4)$ follows the following. **Positive** and **Bounds** halt in cubic and linear time, respectively. **BasePinch** may add a pair of positive binary numbers each at most $2\ell(\sigma)$, may determine the parity of a number of absolute value at most $\ell(\sigma)$, and may halve an even positive number less than $\ell(\sigma)$. It calls **Positive** at most $|l| + 3 \leq \ell(\sigma) + 3$ times, always on a word of length at most $2\ell(\sigma)$. It calls **Bounds** at most once and on a non-negative integer that is at most $3\ell(\sigma)$. The output of **Bounds** is then searched at most twice and has size $O((\log_2 \ell(\sigma))^2)$. ◀

7 An outline of our strategy for Theorem 3

Here is an outline of our algorithm solving the membership problem for H_k in G_k from Section 4 of [12], proving Theorem 3. For a more detailed high-level description, see Section 4.1 of [12].

Suppose w is a word on $a_1^{\pm1}, \ldots, a_k^{\pm1}, t^{\pm1}$, so represents an element of G_k. To tell whether or not w represents an element of H_k, first collect all the $t^{\pm1}$ at the front by shuffling them to the left through the word, applying $\theta^{\pm1}$ as appropriate to the intervening a_i so that the element of G_k represented does not change. The result is a word $t^r v$ where $|r| \leq \ell(w)$ and v, a word on $a_1^{\pm1}, \ldots, a_k^{\pm1}$ has length at most a constant times $\ell(w)^k$ since θ is a free group automorphism of such polynomial growth.

Here is an example (one of a number in Section 4.2 of [12]). Suppose $w = a_3^4 a_2 t a_1 a_2^{-1} a_3^{-4}$. This equals tv in G_3 where $v = (a_3 a_2)^4 a_2 a_1^2 a_2^{-1} a_3^{-4}$ because $a_2 t = a_2 a_1$ and $a_3 t = a_3 a_2$.

We next look to carry the t^r back through v working from left to right, converting (if possible) what lies to the left of the power of t to a word on the generators $(a_1 t)^{\pm1}, \ldots, (a_k t)^{\pm1}$ of H_k. However the power of t being carried along will vary as this proceeds and, in fact, can get extremely large as a result of the hydra phenomenon. Similarly, the length of the word on the generators of H_k appearing to the left can be impractically long. For instance, in our example, the calculation outlined in Section 5 shows that w equals an element of the subgroup H_3 of G_3 which has length $2^{47} \cdot 3 - 1$ as a reduced word on the generators $(a_1 t)^{\pm1}$, $(a_2 t)^{\pm1}$, $(a_3 t)^{\pm1}$ of H_3.

So, instead of keeping track of the power of t directly, we record it as a word on ψ-functions (the functions that are analogues of Ackermann functions, as we explained in Section 5). Roughly speaking, checking whether this process ever gets stuck (in which case $w \notin H_k$) amounts to checking whether an associated ψ-word is valid. If the end of the word is reached, we then have a word on $(a_1 t)^{\pm 1}, \ldots, (a_k t)^{\pm 1}$ times some power of t, where the power is represented by a ψ-word whose length is at most a polynomial function of the length of w. We then determine whether or not $w \in H_k$ by checking whether or not that ψ-word represents 0. Both tasks can be accomplished suitably efficiently thanks to Proposition 3.4 in [12] (a variation of Theorem 1 as we explained in Section 5).

A complication is that we do not carry the power of t through from left to right one letter at a time. Rather, we partition v into subwords we call *rank k-pieces* and are determined by the locations of the a_k and a_k^{-1} in v. Each contains at most one a_k and at most one a_k^{-1}, and if the a_k is present in a piece, it is the first letter of that piece, and if the a_k^{-1} is present, it is the last letter. For instance, in our example $k = 3$ and $v = (a_3a_2)(a_3a_2)(a_3a_2)(a_3a_2^2a_1^2a_2^{-1}a_3^{-1})(a_3^{-1})(a_3^{-1})(a_3^{-1})$. We look to carry the power of t through v one piece at a time. Lemma 6.2 of [13] details how $v \in \bigcup_{s\in\mathbb{Z}} H_k t^s$ if and only if this is possible.

Whether the power of t can be carried through a piece $a_k^{\varepsilon_1} u a_k^{-\varepsilon_2}$ (here, $\varepsilon_1, \varepsilon_2 \in \{0,1\}$ and u is a reduced word on $a_1^{\pm 1}, \ldots, a_{k-1}^{\pm 1}$) depends on u in a manner that can be recursively analyzed by decomposing u into pieces with respect to the locations of the $a_{k-1}^{\pm 1}$ it contains. The main technical result behind our algorithm is our ‘Piece Criterion’ (Proposition 4.10 in [12]). This determines whether a power t^r can pass through a piece π—that is, whether $t^r\pi \in H_k t^s$ for some $s \in \mathbb{Z}$—and, if it can, how to represent s by a ψ-word. The way this plays out in our example is:

$$\begin{aligned}
t(a_3a_2) &\in H_k t^{f_1(0)} &&\text{where} && f_1 = \psi_1\psi_1^{-1},\\
t^{f_1(0)}(a_3a_2) &\in H_k t^{f_2(0)} &&\text{where} && f_2 = \psi_2\psi_3 f_1,\\
t^{f_2(0)}(a_3a_2) &\in H_k t^{f_3(0)} &&\text{where} && f_3 = \psi_2\psi_3 f_2,\\
t^{f_3(0)}(a_3a_2^2a_1^2a_2^{-1}a_3^{-1}) &\in H_k t^{f_4(0)} &&\text{where} && f_4 = \psi_3^{-1}\psi_2^{-1}(\psi_1)^2\psi_2^2\psi_3 f_3.\\
t^{f_4(0)}(a_3^{-1}) &\in H_k t^{f_5(0)} &&\text{where} && f_5 = \psi_3^{-1} f_4,\\
t^{f_5(0)}(a_3^{-1}) &\in H_k t^{f_6(0)} &&\text{where} && f_6 = \psi_3^{-1} f_5,\\
t^{f_6(0)}(a_3^{-1}) &\in H_k t^{f_7(0)} &&\text{where} && f_7 = \psi_3^{-1} f_6.
\end{aligned}$$

(The integers encoded here are $f_1(0) = 0$, $f_2(0) = -3$, $f_3(0) = -45$, $f_4(0) = -46$, $f_5(0) = -4$, $f_6(0) = -1$, and $f_7(0) = 0$. The conclusion is that $w \in H_3$ since $f_7(0) = 0$.)

Like in the previous section, we do not have space here to present many of the details, and so will only give an illustrative subroutine, namely ‘$\mathbf{Back}_m$.’ This attempts to pass a power t^r through a rank m-piece which has the special form $ua_m^{-\epsilon_2}$ where $\epsilon_2 \in \{0,1\}$, u is a word $a_1^{\pm 1} \cdots a_{m-1}^{\pm 1}$ and $m \geq 3$. There are several precursors to the construction of $\mathbf{Back}_m$:

- The construction is inductive on m. $\mathbf{Back}_m$ calls an algorithm $\mathbf{Push}_{m-1}$ (of Section 4.5 of [12]) which takes as input a word v on $a_0^{\pm 1}, \ldots, a_{m-1}^{\pm 1}$ and a ψ-word f representing an integer, and declares whether $t^{f(0)}v \in H_k t^s$ for some $s \in \mathbb{Z}$; if so, $\mathbf{Push}_{m-1}$ also returns a ψ-word g so that $t^{f(0)}v \in H_k t^{g(0)}$.
- The Piece Criterion (Proposition 4.10 in [12]) stipulates (in particular) that if $t^r ua_m^{-\epsilon_2} \in H_k t^s$ for some $s \in \mathbb{Z}$, exactly one of the following three conditions must hold:
  - **(a)** $\epsilon_2 = 0$ and $t^r ua_m^{-\epsilon_2} = t^r u \in H_k t^s$ (the trivial case).
  - **(b)** $\epsilon_2 = 1$, $s \leq 0$ and $t^r u \in H_k t^{\psi_m(s)}$.
  - **(c)** $\epsilon_2 = 1$, $s > 0$, $t^r ua_m^{-1}\theta^s(a_m) \in H_k t^{s-1}$ and $\theta^{s-1}(a_m^{-1})$ is a suffix of $ua_m^{-\epsilon_2}$.

  (Here, θ is the free group automorphism we defined in Section 2.)
- A routine $\mathbf{Prefix}_m$ (of Section 4.5 of [12]) inputs a rank-m piece $\pi = a_m u a_m^{-\epsilon_2}$ where $m \geq 3$. It returns the largest integer $i > 0$ (if any) such that $\theta^{i-1}(a_m)$ is a prefix of π and halts in time in $O(\ell(\pi)^2)$.

Algorithm 2 Back$_m$.

∘ Input a rank-m piece $\pi = ua_m^{-\epsilon_2}$ with $m \geq 3$ (so u is a reduced word on $a_1^{\pm 1}, \ldots, a_{m-1}^{\pm 1}$ and $\epsilon_2 \in \{0,1\}$) and a valid ψ-word f on $\psi_1^{\pm 1}, \ldots, \psi_k^{\pm 1}$. Let $r := f(0)$.
∘ Declare whether or not $t^r \pi \in \bigcup_{s \in \mathbb{Z}} H_k t^s$. And, if it is, return a valid ψ-word f' such that $t^{f(0)}\pi \in H_k t^{f'(0)}$, $\ell(f') \leq \ell(f) + 2(m-1)\ell(\pi) + 1$ and rank $(f') \leq \max\{\text{rank } (f), m\}$.
∘ Halt in time $O((\ell(\pi) + \ell(f))^{2m+k})$.

```
   run Push$_{m-1}(u,f)$ to test whether or not $t^r u \in \bigcup_{s\in\mathbb{Z}} H_k t^s$
2    if so, let $g$ be the valid $\psi$-word it outputs such that $t^r u \in H_k t^{g(0)}$
   if $\epsilon_2 = 0$,
     if $t^r u \in H_k t^{g(0)}$ (so, (a) of the Piece Criterion holds with $s = g(0)$),
5            return $f' := g$
     else declare  $t^r \pi \notin \bigcup_{s\in\mathbb{Z}} H_k t^s$
     halt
8
   we now have that $\epsilon_2 = 1$
   run Psi($\psi_m^{-1} g$) to check validity of $\psi_m^{-1} g$ (so whether $g(0) \in$ Img $\psi_m$)
11   and, if so, to check  $\psi_m^{-1} g(0) \leq 0$
             (i.e. whether (2) of the Criterion holds with $s = \psi_m^{-1} g(0)$)
     if so, halt and return $f' := \psi_m^{-1} g$
14
   run Prefix$_m(\pi^{-1})$ to determine the maximum $i$ (if any)
         such that $a_{m-1}^{-1}\theta^{i-1}(a_m^{-1})$ is a suffix of $\pi$
17   if there is no such $i$, halt and declare $t^r \pi \notin \bigcup_{s\in\mathbb{Z}} H_k t^s$
   for $s = 1$ to $i$:
     run Push$_{m-1}(u', f)$ where $u'$ is the reduced word representing $u a_m^{-1}\theta^s(a_m)$
20     if it outputs a $\psi$-word $h$, run Psi($\psi_1^{s-1} h$) to check if $h(0) = s - 1$
         if so halt and return $f' := \psi_1 h$
   declare that $t^{f(0)} w \notin \bigcup_{s\in\mathbb{Z}} H_k t^s$
```

- **Psi** is our algorithm (of Section 3.3 of [12]) determining in polynomial time whether a ψ-word is valid and, if so, whether the integer it represents is negative, zero, or positive. We discussed its Ackermann-function analogue in the previous section.

Proof of correctness. Here is our justification line-by-line.

2: It follows from the workings of **Push**$_{m-1}$ (proved in Section 4.5 of [12]) that $\ell(g) \leq \ell(u) + \ell(f)$ and **rank** $(g) \leq \max\{$**rank** $(f), m\}$.

3–6: **Push**$_{m-1}$ in lines 1–2 tests whether or not $t^r u$ is in $\bigcup_{s\in\mathbb{Z}} H_k t^s$ and, if so, it identifies the s such that $t^r u \in H_k t^s$. The Piece Criterion then tells us that the answer to whether $t^r \pi \in \bigcup_{s\in\mathbb{Z}} H_k t^s$ is the same, and if affirmative the s agrees. By our comment on line 2, $\ell(f') \leq \ell(f) + \ell(u) = \ell(f) + \ell(\pi)$, and rank$(f') \leq \max\{\text{rank}(f), m\}$, as required.

10–13: Again, we refer back to lines 1–2 for whether or not $t^r u$ is in $\bigcup_{s_0\in\mathbb{Z}} H_k t^{s_0}$. Assuming that it is, in fact, in $H_k t^{g(0)}$, then Condition *2*, is satisfied if and only if $g(0) = \psi_m(s)$ for some $s \leq 0$. And that is checked in line 10. The Piece Criterion then tells us that the answer to this is the same as the answer to whether $t^r u \in \bigcup_{s\in\mathbb{Z}} H_k t^s$, and, if affirmative, the s agrees. By our comment on line 2, $\ell(f') = \ell(g) + 1 \leq \ell(f) + \ell(u) + 1 = \ell(f) + \ell(\pi)$ and rank$(f') \leq \max\{\text{rank}(f), m\}$, as required.

16–21: The aim here is to determine whether Condition *3* holds—that is, whether

$$t^r u a_m^{-1} \theta^s(a_m) \in H_k t^{s-1}$$

and $a_{m-1}^{-1}\theta^{s-1}(a_m^{-1})$ is a suffix of π for some $s > 0$—and, if so, output a ψ-word f' such that $f'(0) = s$. (This s must be unique, if it exists, because, by the Criterion, it is the s such that $t^r\pi \in H_k t^s$, and we know that is unique.)

The possibilities for s are limited to the range $1, \ldots, i$ by the suffix condition and the requirement that $s > 0$, where i is as found in line 16 and must be at most $\ell(\pi)$. If there is such a suffix $a_{m-1}^{-1}\theta^{i-1}(a_m^{-1})$ of π, then $a_{m-1}^{-1}\theta^{s-1}(a_m^{-1})$ is a suffix of π for all $s \in \{1, \ldots, i\}$. If there is no such suffix, then Condition *3* fails, and, as we know at this point that Conditions *1* and *2* also fail, we declare in line 17 that (by the Criterion), $t^r\pi \notin \bigcup_{s\in\mathbb{Z}} H_k t^s$.

For each s in the range $1, \ldots, i$, lines 18–21 address the question of whether or not $t^r u a_m^{-1}\theta^s(a_m) \in H_k t^{s-1}$. First $\mathbf{Push}_{m-1}$ is called, which can be done because, on freely reducing $u a_m^{-1}\theta^s(a_m)$, the a_m^{-1} cancels with the a_m at the start of $\theta^s(a_m)$ to give a word of rank at most $m-1$. $\mathbf{Push}_{m-1}$ either tells us that $t^r u a_m^{-1}\theta^s(a_m) \notin \bigcup_{s'\in\mathbb{Z}} H_k t^{s'}$, or it gives a ψ-word h such that $t^r u a_m^{-1}\theta^s(a_m) \in H_k t^{h(0)}$. In the latter case, **Psi** is then used to test whether or not $h(0) = s - 1$.

By the specifications of $\mathbf{Push}_{m-1}$, $\ell(h) \le \ell(f) + 2(m-1)\ell(u')$. And, as $\pi = u a_m^{-1}$ has suffix $\theta^{s-1}(a_m^{-1})$, when we form u' by freely reducing $u a_m^{-1}\theta^s(a_m)$, at least half of $\theta^s(a_m) = \theta^{s-1}(a_m)\theta^{s-1}(a_{m-1})$ cancels into π. So $\ell(u') \le \ell(\pi)$, and

$$\ell(f') \;=\; \ell(h) + 1 \;\le\; \ell(f) + 2(m-1)\ell(u') + 1 \;\le\; \ell(f) + 2(m-1)\ell(\pi) + 1,$$

as required. Also, it is immediate that $\operatorname{rank}(f') \le \max\{\operatorname{rank}(f), m\}$, as required.

22: At this point, we know *1*, *2* and *3* fail for all $s \in \mathbb{Z}$, so $t^r\pi \notin \bigcup_{s\in\mathbb{Z}} H_k t^s$.

$\mathbf{Back}_m$ runs $\mathbf{Push}_{m-1}(u, f)$ once (with $\ell(u) \le \ell(\pi)$), $\mathbf{Psi}(\psi_m^{-1}g)$ at most once (with $\ell(g) \le \ell(\pi) + \ell(f)$), $\mathbf{Prefix}_m(\pi^{-1})$ at most once, $\mathbf{Push}_{m-1}(u', f)$ at most $i \le \ell(\pi)$ times (with $\ell(u') < \ell(\pi)$), and $\mathbf{Psi}(\psi_1^{s-1}h)$ at most $i \le \ell(\pi)$ times (with $1 \le s \le \ell(\pi)$ and $\ell(h) < \ell(f) + \ell(\pi)$). Other operations such as free reductions of words etc. do not contribute significantly to the running time. Referring to the specifications of $\mathbf{Push}_{m-1}$, **Psi**, and $\mathbf{Prefix}_m$, we see that they (respectively) contribute:

$$\begin{aligned}\ell(\pi)O((\ell(\pi) + \ell(f))^{2(m-1)+k+1}) + \ell(\pi)O((\ell(f) + 2\ell(\pi))^{4+k}) + O(\ell(\pi)^2)\\ = O((\ell(\pi) + \ell(f))^{2m+k})\end{aligned}$$

which is the claimed bound on the halting time of $\mathbf{Back}_m$. ◀

There is also an algorithm $\mathbf{Front}_m$ which takes a rank-m-piece π and a ψ-word f and determines (in a manner similar to $\mathbf{Back}_m$, see [12] Algorithm 4.2 for details) whether $t^{f(0)}$ can efficiently pass an initial a_m (if it exists) in π. If so, $\mathbf{Front}_m$ outputs a word of the form $u a_m^{-1}$ suitable for input into $\mathbf{Back}_m$ and a valid ψ word g such that checking whether $t^{f(0)}\pi \in Ht^s$ for some $s \in \mathbb{Z}$ is equivalent to checking whether $t^{g(0)} u a_m^{-1} \in Ht^s$ for some $s \in \mathbb{Z}$. If $t^{f(0)}$ does not pass through an initial a_m of π in one of three ways, Proposition 4.10 in [12] says that $t^{f(0)}\pi \notin H_k t^S$ for all $s \in \mathbb{Z}$. Putting together the algorithm $\mathbf{Front}_m$ with $\mathbf{Back}_m$ and implicitly $\mathbf{Push}_{m-1}$, we can construct the algorithm $\mathbf{Push}_m$. That way, given a word v on $a_1^{\pm1}, \ldots, a_m^{\pm1}$ and a ψ-word f, we have a polynomial time algorithm to determine whether or not $t^{f(0)}v \in H_k t^s$ and if so, to give a ψ-word g such that $g(0) = s$. We can then use **Psi** to determine whether g represents zero, and so whether $t^{f(0)}v$ represents an element of H_k.

A Reference to the technical details

The technical details are set out in full in *Taming the hydra: the word problem and extreme integer compression* [12], which is available from the arXiv repository at `http://arxiv.org/abs/1509.02557`.

Abstract

Investigating the complexity of randomized space-bounded machines that are allowed to make *multiple passes over the random tape* has been of recent interest. In particular, it has been shown that derandomizing such probabilistic machines yields a weak but new derandomization of probabilistic time-bounded classes.

In this paper we further explore the complexity of such machines. In particular, as our main result we show that for any $\epsilon < 1$, every language that is accepted by an $O(n^{\epsilon})$-pass, randomized logspace machine can be simulated in deterministic logspace with *linear amount of advice*. This result extends an earlier result of Fortnow and Klivans who showed that RL is in deterministic logspace with linear advice.

1 Introduction

In the standard definition of probabilistic space-bounded computations, a probabilistic machine accesses its random tape in a *one-way*, read-only manner. In particular, the machine cannot reread the random bits unless they are stored in its work tapes. This model captures machines that can toss coins and hence is the most natural and this leads to well-studied space-bounded probabilistic classes BPL and RL [7].

While one-way access to the random tape is the most natural notion for probabilistic space-bounded computations, researchers have explored space-bounded models where the base machines are allowed to read contents of the random tape multiple times. An interesting earlier result is due to Nisan who showed that two-sided error logspace machines with one-way access to the random tape can be simulated by zero-error logspace machines that have two-way access to the random tape (BPL $\subseteq$ 2-*way*ZPL) [12]. However, the progress in understanding such machines and corresponding complexity classes has been sporadic and

* Research Supported in part by NSF grants 1421163 and 1422668.

many relations are unknown. For example, while we know that BPL is in P, we do not know whether 2-*way*BPL is even in deterministic sub-exponential time (note that it is in BPP). A key issue is that allowing two-way access to the random tape for space-bounded machines brings the corresponding nonuniform classes closer to randomized circuit complexity classes, where progress is known to be difficult.

Allowing the probabilistic machine to have *multiple passes* over the random tape is an access mechanism that is in between one-way and two-way. In particular, a $k(n)$-pass probabilistic machine is allowed to make $k(n)$ passes over the random tape for deciding an input of length n. Such probabilistic space-bounded machines were first considered by David, Papakonstantinou, and Sidiropoulos [5]. They showed that any pseudorandom generator that fools traditional $k(n)s(n)$ space-bounded machines can also fool $k(n)$-pass $s(n)$ space-bounded machines. As a corollary, they obtain that polylog-pass, randomized logspace is contained in deterministic polylog-space. Very recently, Mandal, Pavan, and Vinodchandrian [10] showed that such multipass probabilistic machines are interesting from a derandomization point of view. In particular, they showed the following theorem.

▶ **Theorem 1** ([10]). *For some constant $k > 0$, if every language decided by a probabilistic logspace machine that uses $O(\log n \log^{(k+3)} n)$ random bits and makes $O(\log^{(k)} n)$ passes over its random tape is in* P*, then* $\mathrm{BPTIME}(n) \subseteq \mathrm{DTIME}(2^{o(n)})$.

Here $\log^{(k)} n$ denotes log function applied k times iteratively. Note that showing $\mathrm{BPTIME}(n)$ is a subset of $\mathrm{DTIME}(2^{o(n)})$ is a significant open problem. Thus derandomizing a slightly non-constant pass probabilistic space-bounded machine yields a non-trivial derandomization of $\mathrm{BPTIME}(n)$.

The Main Result

This note considers the *advice complexity* of multipass probabilistic machines. Using standard techniques, it can be shown that 2-*way*RL[1] is in L/poly. Can this simulation be improved for multipass machines? Indeed, for RL, Fortnow and Klivans established that RL is in $\mathrm{L}/O(n)$. Thus one-pass logspace probabilistic machines can be simulated deterministically in logspace using *linear* advice. Our main contribution is to show that even if the base probabilistic machine is allowed n^δ passes over the random tape, the corresponding complexity class can still be simulated in $\mathrm{L}/O(n)$. More formally,

▶ **Main Theorem.** *For any $\delta < 1$, n^δ-pass* RL *is in* $\mathrm{L}/O(n)$.

This result extends Fortnow and Klivans' result and improves a result in [10] where it is shown that n^δ-pass RL is in deterministic $\log^2(n)$ space with linear advice.

2 Preliminaries

We refer the reader to [3] for standard notions and definitions of complexity theory. We first define probabilistic space-bounded computations. A probabilistic $s(n)$ space-bounded Turing Machine M has a *random tape* in addition to its input and work tapes. The machine has read-only access to both input and random tapes and it is allowed to read the contents on the random tape in a one-way manner. The total space used by the work tapes is bounded

[1] In this paper we consider one-sided error classes. Similar results can be obtained for two-sided error classes also.

by $s(n)$ and the machine can read at most $2^{s(n)}$ cells of the random tape. Thus the total number of random bits used by such machines is bounded by $2^{s(n)}$. The complexity class RL is the class of languages accepted by $O(\log n)$ space-bounded machines with one-sided error. We can relax the restriction on the machine's access to the random tape so that the machine M is allowed to read the contents of the random tape in a two-way manner. We use 2-*way*RL to denote the class that is analogous to RL but the base machine has two-way access to the random tape. In this paper, we use two-way, probabilistic machines that use limited amount of randomness. Let 2-*way*RL$[r(n)]$ denote the class of languages that are in 2-*way*RL and the base machine uses only $r(n)$ random bits on inputs of length n.

Next we define multipass, probabilistic, space-bounded machines.

▶ **Definition 2.** A probabilistic Turing machine M is a *$k(n)$-pass, $s(n)$ space-bounded machine* if

- M has read-only, two-way access to the input tape,
- total space used by the work tapes is bounded by $s(n)$,
- M is allowed to make $k(n)$ passes (on inputs of length n) over the random tape and during each pass it accesses the tape in a one-way, read only manner, and
- the total number of random bits used by the machine is bounded by $2^{s(n)}$.

▶ **Definition 3.** We say that a language L belongs to *$k(n)$-pass* RL if there exists a $k(n)$-pass, $O(\log n)$ space-bounded probabilistic Turing machine M such that for every input x, if $x \in L$, M accepts x with probability at least $1/2$ and if $x \notin L$, then the probability that M accepts x is 0.

Next we define the notion of advice [9].

▶ **Definition 4.** Let f be a function from natural numbers to natural numbers. A language L is in $\mathrm{L}/f(n)$, if there is a logspace machine M and a sequence of strings $a_1, a_2, \cdots$ such that $|a_n| \leq f(n)$ and for every input x of length n, $M(x, a_n)$ accepts if and only if $x \in L$.

For a probabilistic machine M and an input x, we use $M(x; r)$ to denote the computation of M on x, where r is the contents of the random tape. We now define the notion of *pseudorandom generators* for space-bounded machines.

▶ **Definition 5.** A family of functions $G = \{G_n\}_{n\geq 0}$ is an $(m(n), r(n), \epsilon)$ pseudorandom generator for space $s(n)$ if for every probabilistic $s(n)$ space-bounded machine M that uses $r(n)$ random bits (on inputs of length n) and for every input x of length n,

$$\big|\Pr[M(x; r) = 1] - \Pr[M(x; G_n(y)) = 1]\big| \leq \epsilon,$$

where r is chosen uniformly at random from $\Sigma^{r(n)}$ and y is chosen uniformly at random from $\Sigma^{m(n)}$.

We can define a similar notion of *pseudorandom generators* for $k(n)$-pass, $s(n)$-space.

The following theorem of David *et al.* [5] connects pseudorandom generators for multipass machines to pseudorandom generators for single pass machines.

▶ **Theorem 6** ([5]). *Let $G = \{G_n\}_{n\geq 0}$ be an $(m(n), r(n), \epsilon)$ PRG for space $k(n)s(n)$. Then G is an $(m(n), r(n), \epsilon 2^{k(n)})$ PRG for $k(n)$-pass, $s(n)$-space.*

Our proofs use the pseudorandom generator of Babai, Nisan, and Szegedy [4] which is based on lowerbounds for multiparty communication complexity. We now define the necessary notions that are needed.

▶ **Definition 7.** Let f be a Boolean function which takes k r-bit strings $x_1, \dots, x_k$ as inputs. Suppose k people wish to collectively compute $f(x_1, \dots, x_k)$ with the constraint that the i^{th} person does not know x_i. The k-party, ϵ-distributional communication complexity of f, denoted by $C_\epsilon(f)$, is the minimum number of bits that must be communicated among the k people (by, say, writing on a public whiteboard) in order to compute the function f on at least $\frac{1+\epsilon}{2}$ fraction of inputs (from Σ^{kr}).

▶ **Definition 8.** The Generalized Inner Product of r k-bit strings, denoted by $\mathrm{GIP}_{r,k}(x_1, \dots, x_k)$, is 0 if there is an even number of indices i, $1 \le i \le r$, at which all of $x_1[i], \dots, x_k[i]$ are 1; otherwise $\mathrm{GIP}_{r,k}(x_1, \dots, x_k)$ is 1.

Babai, Nisan, and Szegedy obtained the following bound on the communication complexity of GIP.

▶ **Theorem 9** ([4]).

$$C_\epsilon(\mathrm{GIP}_{r,k}) = \Omega\left(\frac{r}{4^k} + \log \epsilon\right)$$

3 Two-way Simulation and Linear Advice

In this section, we prove the main result of the paper which is stated below.

▶ **Theorem 10.** *Let $0 \le \delta < 1$ be a constant. Every language L that is in n^δ-pass* RL *is in* $\mathrm{L}/O(n)$.

The proof proceeds in two steps. We first show that any n^δ-pass randomized logspace machine can be simulated by a two-way randomized logspace machine that uses only n^γ ($\delta < \gamma < 1$) random bits. We then prove that such two-way machines can be decided in deterministic logspace with a linear amount of advice. The first step is proved in Theorem 11 and the second step is proved in Theorem 13.

▶ **Theorem 11.** *For every $0 \le \delta < 1$, there exists a γ, where $\delta < \gamma < 1$, such that for every language L in n^δ-pass* RL, *L is in 2-way*RL *with n^γ random bits.*

Before we present a formal proof, we give an overview of the proof. Consider the class RL. The well-known result of Nisan [11] states that there exists a PRG for logspace that stretches an $O(\log^2 n)$-length seed to $p(n)$ bits, where $p(n)$ is a polynomial in n. Moreover, the generator can be computed in *logspace*. The logspace machine that computes the PRG accesses the seed in a two-way manner. Thus using this generator we obtain that RL is in 2-*way*RL$[O(\log^2 n)]$. In fact, this is the first step in the work of Fortnow and Klivans [6]. A natural approach to Theorem 11 is to use a PRG for multipass, space-bounded machines. Let M be an n^δ-pass, logspace machine. By Theorem 6, any PRG for $O(n^\delta \log n)$-space will also be a PRG for M. Since M uses at most polynomially many random bits, we only need a PRG for $O(n^\delta \log n)$-space machines that use a polynomial number of random bits (as opposed to potentially $2^{O(n^\delta \log n)}$ random bits). A natural candidate is a generalized version of Nisan's generator that uses $O(S \log R)$ seed length for space S machines that use R random bits. This leads to a PRG that stretches $O(n^{\delta'})$ bits to polynomially many bits (for some $\delta' > \delta$), and this PRG fools the multipass machine M. Thus M can be simulated by a two-way randomized machine that uses $O(n^{\delta'})$ random bits. However, there is a small caveat in this argument. The space needed to compute this PRG is $O(\log^2 n)$. Thus this simulation of M using a two-way probabilistic machine takes $O(\log^2 n)$ space, whereas our goal is to simulate M using a two-way probabilistic machine that only uses $O(\log n)$ space.

We get around this problem by using the generator due to Babai, Nisan, and Szegedy [4]. They exhibited a PRG for space S that stretches $2^{\sqrt{S}}$-bits to 2^S bits and this PRG can be computed in $O(S)$ space. More specifically, when applied to logspace, their generator uses $O(2^{\sqrt{\log n}})$ seed length and is inefficient compared to Nisan's generator (in seed length). However, we observe that their generator is much easier to compute than Nisan's generator. We show that the BNS generator for $O(n^\delta \log n)$-space machines that use only polynomially many random bits has a seed length of n^γ ($\delta < \gamma < 1$) and can be computed in $O(\log n)$ space.

We now provide a formal proof.

Proof. Let M be an n^δ-pass, RL machine that accepts a language L. Assume that M uses n^ℓ random bits on inputs of length n. We will use the BNS generator to reduce the number of random bits used by M.

▶ **Theorem 12** ([4]). *Let $f_{r,k} : \Sigma^{rk} \to \{0,1\}$ be a Boolean function, $t > k$, and $N \leq \binom{t}{k}$. There is an $(rt, N, N\epsilon)$-pseudorandom generator G for s space-bounded machines that use N random bits, where $s < C_\epsilon(f)/k$. Also, the space required to compute G is the space required to compute the bits of f in antilexicographic order.*

We invoke this theorem for our choice of parameters. By Theorem 6, any $(m(n), n^\ell, \frac{1}{4\times 2^{n^\delta \log n}})$ generator for space $n^\delta \log n$ is an $(m(n), n^\ell, 1/4)$ generator for machine M. Note that we need a generator for $n^\delta \log n$ space-bounded machines that uses only n^ℓ random bits. Let $1 > \delta'$ be a constant that is greater than δ. We choose $r = n^{\delta'}$, $k = 2\ell\sqrt{\log n}$, $t = 2^k$, $N = n^\ell$, and the function f to be $\mathrm{GIP}_{k,r}$. By Theorem 9, the ϵ-distributional communication complexity of f is at least $\frac{r}{4^k} + \log \epsilon$. We pick ϵ as $\frac{1}{n^\ell} \times \frac{1}{4\times 2^{n^\delta \log n}}$. Thus $C_\epsilon(f)$ is at least

$$c\left(\frac{n^{\delta'}}{4^{2\ell\sqrt{\log n}}} - \ell \log n - 2 - \delta \log^2 n\right)$$

for some constant $c > 0$. With this we have $C_\epsilon(f)/k > c\left(\frac{n^{\delta'}}{4^{2\sqrt{\log n}}} - \ell \log n - 2 - \delta \log^2 n\right)/k > n^\delta \log n$ and $n^\ell < \binom{t}{k}$. Thus, by Theorem 12, there is an $(n^{\delta'} \times 2^{2\ell\sqrt{\log n}}, n^\ell, \frac{1}{4\times 2^{n^\delta \log n}})$-generator G for $n^\delta \log n$-space that uses n^ℓ random bits. Let γ be a constant that is greater than δ' (and less than 1). By theorem 6, G is an $(n^\gamma, n^\ell, 1/4)$-generator for n^δ-pass RL machines and hence fools M.

Our 2-*way*RL machine that simulates M works as follows. On any input x of length n, it has n^γ-bits written on its random tape. Let r denote the random string. It keeps track of the index of the random bit that M attempts to read. When M asks for ith random bit, it invoke the BNS generator on r, compute the ith bit of the generator, and continue the simulation of M. Note that the space needed by this machine is bounded by space needed by M plus the space needed to compute a bit of the BNS generator. We now claim that each bit of the generator can be computed in $O(\log n)$ space.

▶ **Claim 12.1.** *Each bit of the BNS generator can be computed in $O(\log n)$ space.*

Proof. The input to the BNS generator is an rt bit string which is viewed as t strings each of length r. Let $x_1, x_2, \cdots, x_t$ be these strings. We will describe the i^{th} bit of BNS generator. Consider the first $N = n^\ell$ k-subsets of $\{1, 2, \cdots, t\}$ in antilexicographic order: for two sets A and B, $A < B$ iff the largest element in $A \triangle B$ is an element of B. Let $S_1, S_2, \cdots, S_N$ be these subsets. Let $S_i = \{i_1, i_2, \cdots, i_k\}$. Then the i^{th} bit of BNS generator is $\mathrm{GIP}_{k,r}(x_{i_1}, x_{i_2}, \cdots, x_{i_k})$. Note that each S_i can be stored in $O(k \times \log t) = O(\log n)$ bits.

Also, $\mathrm{GIP}_{k,r}$ is computable in $\log k + \log r = O(\log n)$ space. We will describe an $O(\log n)$ space algorithm that takes set A and outputs B which is the next set in the antilexicographic order. Given A, initialize B with the maximal k-set. It generates all N k-subsets one by one and replaces B with the current set C if $A < C < B$. Note that given A and B, checking whether $A < B$ can be done in logspace. This leads to a logspace algorithm for generating the next set in the antilexicographic order. ◀

Thus we can simulate the n^{δ}-pass machine M using n^{γ} random bits in $O(\log n)$ space. Note that the simulating machine needs to access the random tape in a two-way manner. This completes the proof of the theorem. ◀

▶ **Theorem 13.** $2\text{-}way\mathrm{RL}[O(n)] \subseteq \mathrm{L}/O(n)$.

Proof. Let L be a language in $2\text{-}way\mathrm{RL}[O(n)]$ and let M be a machine that witnesses this with error probability $\leq 1/2$. The idea is to reduce the error probability of M to $1/2^{2n}$ using additional $O(n)$ random bits. Then a standard counting argument implies that there exists an $O(n)$-length string y for which $M(x; y)$ is correct on all strings x of length n. Thus y can be used as an advice. For reducing the error probability, we will use a *space-efficient expander walk* given by Gutfreund and Viola [8].

The general technique of using constant degree expander graphs to reduce the error probability of probabilistic machines is due to Ajtai, Komlos, and Szemeredi [1]. Let $r(n)$ denotes the number of random bits used by M on inputs on length n. Let G be a constant degree expander over $2^{r(n)}$ vertices. Consider the following process of producing k vertices: randomly pick a node v_0. For $1 \leq i \leq k-1$, v_i is a random neighbor of v_{i-1}. Note that each v_i is described using an $r(n)$ bit string. Also, the total random bits used in this process is $r(n) + O(k)$.

Consider the following simulation of M by M': on input x of length n, M' simulates M k times where the i^{th} simulation uses the encoding of v_i as the random string. If one of the simulations accept, M' accepts. It is well known that for any constant degree expander, there is a k where $k = O(n)$ so that the error probability of M' is $1/2^{2n}$.

▶ **Theorem 14** ([1]). *Given a constant degree expander G, there is a k where $k = O(n)$ so that the error probability of the above simulation is $\leq 1/2^{2n}$.*

To make this work we need be able to perform the random walk in logspace. The following theorem due to Allender, Jiao, Mahajan, and Vinay shows that random walk on certain constant degree expanders can be done in logspace. In a latter work, Gutfreund and Viola show that random walks on certain constant degree expanders can be done in AC_0[2].

▶ **Theorem 15** ([2, 8]). *There exist an infinite family $\{G_n\}_{n\geq 0}$ of expander graphs where G_n has 2^n nodes and constant degree D, and an $O(\log n)$-space algorithm A such that A on input $v_0 \in \{0,1\}^n$ and indices $\ell_1, \cdots, \ell_k$ where $1 \leq \ell_i \leq D$, outputs $v_0, v_1, \cdots, v_k$ where v_i is the ℓ_i^{th} neighbor of v_{i-1}. The algorithm runs in space $O(\log n + \log k)$.*

Proof of Theorem 13 follows from Theorem 14 and Theorem 15. ◀

Complexity of Constraint Satisfaction Problems over Finite Subsets of Natural Numbers

Titus Dose

dose@informatik.uni-wuerzburg.de

Abstract

We study the computational complexity of constraint satisfaction problems that are based on integer expressions and algebraic circuits. On input of a finite set of variables and a finite set of constraints the question is whether the variables can be mapped onto finite subsets of $\mathbb{N}$ (resp., finite intervals over $\mathbb{N}$) such that all constraints are satisfied. According to the operations allowed in the constraints, the complexity varies over a wide range of complexity classes such as L, P, NP, PSPACE, NEXP, and even Σ_1, the class of c.e. languages.

1 Introduction

The problems investigated in this paper are motivated by constraint satisfaction problems and integer expressions. We first introduce these notions and then explain their connection.

Constraint satisfaction problems. A constraint satisfaction problem (CSP) is a computational problem that on input of a finite set of variables and a finite set of constraints asks whether there is a mapping from the variables to some fixed domain such that all constraints are satisfied.

An example of a classical CSP is 3-Colorability, i.e., the question of whether there is a mapping α from a graph's vertices onto $\{0, 1, 2\}$ such that for adjacent nodes u and v it holds that $\alpha(u) \neq \alpha(v)$.

The set of relations permitted in the constraints is called *constraint language*. Obviously CSPs over finite domains permitting arbitrary constraints belong to NP. The question of which constraint languages lead to CSPs even decidable in polynomial time has been a topic of intensive research over the past decades.

Feder and Vardi [4] conjectured a dichotomy for CSPs over finite domains such that these CSPs are either in P or NP-complete. This conjecture is still open.

In the past years there has been an increasing interest in CSPs over *infinite* domains. Here much higher complexities are obtained, and some problems are even undecidable.

Integer expressions and algebraic circuits. In 1973, Meyer and Stockmeyer [14] asked for the complexity of decision problems regarding so-called integer expressions. An integer expression is a term built by singleton sets of natural numbers, the pairwise addition, and set operations like union, intersection, or complement. Meyer and Stockmeyer investigated the membership problem, i.e., the question of whether a given natural number is contained in the subset of ℕ described by an integer expression. Moreover, they studied the inequality problem, i.e., the question of whether two given integer expressions describe the same subset of ℕ.

For some constant $m \in \mathbb{N}$ the integer expression $(0 \cup 2^1) + (0 \cup 2^2) + \cdots + (0 \cup 2^{m-1})$ describes the set of all even natural numbers $< 2^m$ in a succinct way. Note that here the natural number n is an abbreviation for the set $\{n\}$.

McKenzie and Wagner [11] considered generalized integer expressions and the complexity of membership problems for circuits over finite subsets of ℕ.

Here a circuit is a directed, acyclic graph with two kinds of nodes: on the one hand, there are input nodes containing a single natural number. On the other hand all remaining nodes, so-called operation nodes, perform one of the following operations: union, intersection, complement, pairwise addition, and pairwise multiplication. Each operation node has an indegree equal to the number of operands required by the operation.

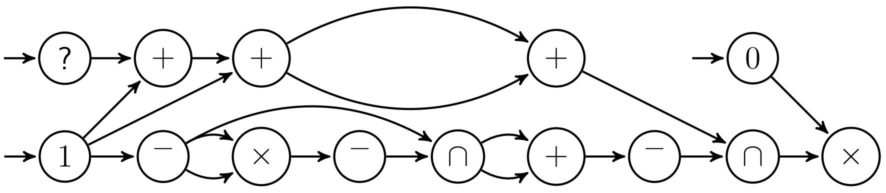
So each of the nodes computes a set of natural numbers: the input nodes compute singletons, and each operation node computes the corresponding set obtained from its predecessors. The set computed by the circuit overall is defined as the set computed by some fixed output node.

In contrast to integer expressions, these circuits are able to store intermediate results and reuse them several times. Thus, it is possible to describe large numbers and sets in a succinct way.

Similar to Meyer and Stockmeyer, who investigated the inequality problem for integer expressions, Glaßer et al. [5] considered the equivalence problem for circuits.

Moreover, Glaßer et al. [7] studied the satisfiability problem for circuits where the corresponding circuits are allowed to have unassigned input nodes. Now the problem is to decide for a given natural number b whether there exists an assignment for the input nodes such that b is contained in the set computed by the circuit. This modification makes the circuits even more similar to CSPs.

Consider the following circuit. Goldbach's conjecture fails if and only if there is an assignment for the ?-node in the circuit below such that the set computed by the rightmost node contains 0. Note that $\overline{\overline{1} \times \overline{1}} \cap \overline{1} = \mathbb{P}$ where $\mathbb{P}$ is the set of all primes.



Hence, if the satisfiability problem for circuits is decidable, then Goldbach's conjecture can be proven or refuted. Up to now it is not known whether this is possible.[1]

Connection of circuits and CSPs. Glaßer et al. [6] combined CSPs and integer circuits, and investigated CSPs over the domain of singletons of natural numbers and with operations from $\{+, \times, \cup, \cap, ^-\}$.

[1] Knuth [9] even assumes that Goldbach's conjecture is a problem that will never be solved. He mentions that "it might very well be that the conjecture happens to be true, but there is no rigorous way to prove it".

As we will see later, each CSP-instance can be represented by a primitive positive fo-sentence such as $\exists X\ (X+X+4)\cap\big(\mathbb{P}+\mathbb{P}\big)=0\cap 1$, where $\mathbb{P}$ can be expressed by $\overline{\overline{1}\times\overline{1}\cap\overline{1}}$. Here we use natural numbers as abbreviations for singletons. Since each variable stands for a singleton, this sentence is true if and only if Goldbach's conjecture fails.

However, the set of singletons of natural numbers is not closed under the mentioned operations. As it can be seen in the example above, variables and constants are singletons, whereas there are terms that describe bigger and even infinite sets. Therefore, we consider CSPs over the domain $\mathcal{P}_{\text{fin}}(\mathbb{N})=\{A\subseteq\mathbb{N}\mid A \text{ is finite}\}$, and replace the complement with the set difference. Thus, compared to the CSPs considered by Glaßer et al. [6] we consider problems that allow a straighter definition (i.e., variables and terms have the same domain), but that is more distant to the satisfiability problem for circuits.

Some results of the mentioned papers can be translated to our situation, but in general the questions for the enlarged domain turn out to be different ones.

Once an arithmetical and a set operation are permitted, we are not able to show the (un)decidability of the corresponding problems.

Therefore, we also consider a restricted version of the described CSPs, in which the domain is the set of all finite intervals over $\mathbb{N}$, denoted by $[\mathbb{N}]$. Note that this domain is not closed under all permitted operations anymore, but in several cases it is easier to obtain completeness results for this domain.

Our contribution. In the first part we consider all CSPs that only permit set operations. Here, for each problem we are able to show the $\leq_{\mathrm{m}}^{\log}$-completeness for one of the complexity classes L, P, and NP. We observe that there is a case in which the problem over $[\mathbb{N}]$ is more difficult than the corresponding problem over $\mathcal{P}_{\text{fin}}(\mathbb{N})$.

When also admitting arithmetical operations, the complexity is much higher. Each of the problems is $\leq_{\mathrm{m}}^{\log}$-hard for NP, and once both arithmetical operations are permitted, we obtain Σ_1-completeness.

The case with the addition as the only operation is particularly interesting. Here for CSPs over arbitrary finite sets we obtain only NP-hardness and membership in NEXP, and one of this paper's open questions is to close this gap. In contrast, the corresponding CSP over $[\mathbb{N}]$ turns out to be NP-complete. For the variant over $\mathcal{P}_{\text{fin}}(\mathbb{N})$ we even do not know whether the problem admitting addition and intersection is decidable. The corresponding problem over $[\mathbb{N}]$ is shown to be NP-complete again.

Furthermore, we consider the multiplication of intervals, and show that the CSP over $[\mathbb{N}]$ permitting only multiplication belongs to Σ_3^{p}. This result can be improved if the problem of testing whether two products of intervals are equal can be shown to belong to some class of the polynomial hierarchy lower than Π_2^{p}.

An overview over all results received in this paper can be found on pages 7 and 12. The technical report [3] provides a more comprehensive version of this paper.

2 Preliminaries

Let $\mathbb{N}$ (resp., $\mathbb{N}^+$) denote the set of non-negative (resp., positive) integers. $\mathcal{P}_{\text{fin}}(\mathbb{N})$ is the set of finite subsets of $\mathbb{N}$. For $A,B\in\mathcal{P}_{\text{fin}}(\mathbb{N})$ we define $A+B=_{\text{def}}\{a+b\mid a\in A,b\in B\}$ and $A\times B=_{\text{def}}\{ab\mid a\in A,b\in B\}$. By "$-$" we denote the set difference. Furthermore, $[\mathbb{N}]$ denotes the set of finite intervals over $\mathbb{N}$. An interval $\{x\mid a\leq x\leq b\}$ for non-negative integers a and b is represented by $[a,b]$. For $a>b$ it holds that $[a,b]=\emptyset$.

The set $f(A) = \{f(x) \mid x \in A\}$ for a function $f : A \to B$ and arbitrary sets A and B is also denoted by W_f.

We denote by L, P, NP, Σ_i^{p} and Π_i^{p} for $i \in \mathbb{N}$, PSPACE, and NEXP the standard complexity classes whose definitions can be found in textbooks on computational complexity [12]. The class of c.e. languages is denoted by Σ_1.

Note that commonly known $\leq_{\mathrm{m}}^{\mathrm{p}}$-complete problems for NP like SAT, 3SAT, or SOS are even $\leq_{\mathrm{m}}^{\log}$-complete for NP where $\leq_{\mathrm{m}}^{\log}$ (resp., $\leq_{\mathrm{m}}^{\mathrm{p}}$) denotes the many-one reduction computable in logarithmic space (resp., polynomial time).

We presume that finite subsets of natural numbers $\{a_1, \dots, a_k\}$ for $k \in \mathbb{N}^+$ are encoded such that the encoding's length is in $\Theta(\sum_{i=1}^{k} |a_k|)$, where $|a_k|$ denotes the length of the binary representation of a_k. An interval $[a, b]$ for $a < b$ is encoded such that the length of the encoding is in $\Theta(|a| + |b|)$. Note that all problems studied in this paper should be interpreted as subsets of $\mathbb{N}$ although for the sake of simplicity problems might be defined differently.

We successively define the CSPs this paper deals with. Let $\mathcal{O} \subseteq \{+, \times, \cup, \cap, -\}$ and X be a variable or a constant, where constants are finite subsets of $\mathbb{N}$.

Then X is a **term**. For terms β and γ as well as $\oplus \in \{+, \times, \cup, \cap, -\}$ the expression $(\beta \oplus \gamma)$ is a **term.** $X = Y$ for terms X and Y is an **atom**.

Let $a_1 = (t_{1,1} = t_{1,2}), \dots, a_m = (t_{m,1} = t_{m,2})$ for $m \in \mathbb{N}$ be atoms. Furthermore, let $X_1, \dots, X_n$ be the variables in the mentioned atoms. Then $\varphi = \exists X_1 \dots \exists X_n \; a_1 \wedge \dots \wedge a_m$ (or more shortly $\varphi = a_1 \wedge \dots \wedge a_m$) is an **$\mathcal{O}$-sentence**. If $\mathcal{O}$ is apparent from the context, we also write **sentence** instead of $\mathcal{O}$-sentence.

Let Var_φ denote the set of variables in φ, and let Const_φ denote the set of constants in φ. Moreover, we denote the set of all terms occurring in φ by T_φ.

We define the semantics of terms. A mapping $\alpha : T_\varphi \to \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ is an **assignment of terms** if the following conditions are satisfied.

- For constants C it holds that $\alpha(C) = C$.
- For variables X it holds $\alpha(X) \in \mathcal{P}_{\mathrm{fin}}(\mathbb{N})$.
- For $\oplus \in \{+, \times, \cup, \cap, -\}$ and all terms $X \oplus Y$ it holds that $\alpha(X \oplus Y) = \alpha(X) \oplus \alpha(Y)$.

φ is **true** if and only if there is an assignment of terms α with $\alpha(t_{i,1}) = \alpha(t_{i,2})$ for all $i = 1, \dots, m$. We call such an α **satisfying**.

The restriction of an assignment of terms to Var_φ (resp., in some cases $\mathrm{Var}_\varphi \cup \mathrm{Const}_\varphi$) is called **assignment of variables** or **assignment**.

Moreover, an assignment of variables β is **satisfying** if the assignment of terms induced by β is satisfying. Note that for each assignment of variables β there is exactly one assignment of terms α such that $\beta(X) = \alpha(X)$ for all $X \in \mathrm{Var}_\varphi$.

▶ **Definition 1.** Let $\mathcal{O}$ denote an arbitrary subset of $\{+, \times, \cup, \cap, -\}$. Then we define $\mathrm{CSP}\Big(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \mathcal{O}\Big) =_{\mathrm{def}} \{\varphi \mid \varphi \text{ is a true } \mathcal{O}\text{-sentence}\}$.

Furthermore, we define

$$\mathrm{CSP}\Big([\mathrm{N}], \mathcal{O}\Big) =_{\mathrm{def}} \{\varphi \mid \varphi \text{ is an } \mathcal{O}\text{-sentence, all constants in } \varphi \text{ are intervals,}$$
$$\text{there is a satisfying assignment } \alpha \text{ with } \alpha(\mathrm{Var}_\varphi) \subseteq [\mathrm{N}]\}.$$

Here all constants are encoded as intervals. Hence, the length of the encoding of a constant $[a, b]$ for $a, b \in \mathbb{N}$ and $a \leq b$ is in $\Theta(|a| + |b|)$.

We also consider a slightly different problem. This enables us to simplify numerous proofs.

▶ **Definition 2.** Let $\mathcal{O} \subseteq \{+, \times, \cup, \cap, -\}$. We define

$$\mathrm{CSP}'\big(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \mathcal{O}\big) =_{\mathrm{def}} \{\varphi \,|\, \varphi \text{ is true, and each atom in } \varphi \text{ is of the form } X \oplus Y = Z \\ \text{for } X, Y, Z \in \mathrm{Const}_\varphi \cup \mathrm{Var}_\varphi \text{ and } \oplus \in \mathcal{O}\},$$

where we identify the atoms $X \oplus Y = Z$ and $Z = X \oplus Y$. $\mathrm{CSP}'\big([\mathbb{N}], \mathcal{O}\big)$ for $\mathcal{O} \subseteq \{\cap, +\}$ is defined analogously to $\mathrm{CSP}'\big(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \mathcal{O}\big)$.

The following lemma often allows us to presume that an input sentence is of the described simpler form. This is so because we can resolve a bigger term into several smaller terms by storing intermediate results in new variables. For CSPs over intervals, however, this works only when the set $[\mathbb{N}]$ is closed under the permitted operations.

▶ **Lemma 3.** $\mathrm{CSP}'\big(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \mathcal{O}\big) \equiv_m^{\log} \mathrm{CSP}\big(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \mathcal{O}\big)$ *for* $\mathcal{O} \subseteq \{+, \times, \cup, \cap, -\}$.
For $\mathcal{O} \subseteq \{+, \cap\}$ *it holds that* $\mathrm{CSP}'\big([\mathbb{N}], \mathcal{O}\big) \equiv_m^{\log} \mathrm{CSP}\big([\mathbb{N}], \mathcal{O}\big)$.

3 CSPs Permitting Set Operations Exclusively

We firstly focus on CSPs permitting only set operations.

Here all problems belong to NP, which is not the case when also arithmetic operations are allowed. In Section 4 we will see that some CSPs also permitting arithmetic operations are hard for PSPACE or even Σ_1.

Furthermore, when admitting only set operations it is much easier to prove CSPs to be complete for particular complexity classes. For each $\mathcal{O} \subseteq \{\cup, \cap, -\}$ and for $M \in \{\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), [\mathbb{N}]\}$ we show that $\mathrm{CSP}(\mathrm{M}, \mathcal{O})$ is $\leq_{\mathrm{m}}^{\log}$-complete for one of the classes L, P, and NP. Thus, all the problems studied in this section are considered exhaustively.

It can be proven: if an $\mathcal{O}$-sentence φ for $\mathcal{O} \subseteq \{\cup, \cap, -\}$ is true, then there is a satisfying assignment α with $W_\alpha \subseteq \bigcup_{C \in \mathrm{Const}_\varphi} C$. Hence, we obtain the following upper bound for all CSPs admitting only set operations.

▶ **Lemma 4.** *Let* $\mathcal{O} \subseteq \{-, \cup, \cap\}$ *and* $M \in \{[\mathbb{N}], \mathcal{P}_{\mathrm{fin}}(\mathbb{N})\}$. *Then* $\mathrm{CSP}\big(\mathrm{M}, \mathcal{O}\big) \in \mathrm{NP}$.

If we do not allow any operations at all, the corresponding CSP belongs to L. This can be proven by a Turing reduction to the problem USTCON, i.e., the question of whether two nodes in an undirected, finite graph are connected. This problem was shown to be in L by Reingold [13].

▶ **Lemma 5.** $\mathrm{CSP}\big(\mathrm{M}, \emptyset\big) \in \mathrm{L}$.

Thus, $\overline{\mathrm{CSP}(\mathrm{M}, \emptyset)}$ is trivially $\leq_{\mathrm{m}}^{\log}$-complete for L. Nevertheless, we remark that the reduction $\overline{\mathrm{USTCON}} \leq_{\mathrm{m}}^{\log} \mathrm{CSP}(\mathrm{M}, \emptyset)$ is simple. This shows that a direct proof of $\mathrm{CSP}(\mathrm{M}, \emptyset) \in \mathrm{L}$ is as difficult as a proof for $\mathrm{USTCON} \in \mathrm{L}$.

Problems admitting union only

▶ **Theorem 6.** $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\cup\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* P.

Proof. We first show $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\cup\}) \in \mathrm{P}$. According to lemma 3 it is sufficient to decide $\mathrm{CSP}'((\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\cup\})$ in polynomial time.

The following algorithm decides whether there is a satisfying assignment of variables for an input sentence φ of the form described in definition 2. For this purpose it successively computes an assignment α. Let $K = \bigcup_{C \in \mathrm{Const}_\varphi} C$.

1. For each constant C set $\alpha(C) = C$. For variables X set $\alpha(X) = K$.
2. Apply the following rules to every atom $X \cup Y = Z$.
   a. Set $\alpha(Z) = \alpha(Z) \cap (\alpha(X) \cup \alpha(Y))$.
   b. Set $\alpha(X) = \alpha(X) \cap \alpha(Z)$ and analogously $\alpha(Y) = \alpha(Y) \cap \alpha(Z)$.
   c. If $\alpha(C)$ for a constant C has been changed, return 0.
3. If $\alpha(X)$ for an $X \in \mathrm{Var}_\varphi$ has been changed in step 2, execute step 2 again.
4. Return 1.

Since the sets $\alpha(X)$ are decreased monotonically regarding the inclusion relation, there are at most $\mathrm{Var}_\varphi \cdot |\mathrm{K}|$ changes of values $\alpha(X)$ for variables X. Hence, the algorithm can be executed in polynomial time. Moreover, it can be proven that the algorithm returns 1 if and only if φ is true.

It remains to prove that $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\cup\})$ is $\leq_{\mathrm{m}}^{\log}$-hard for P: let MCVE be the problem of whether a monotone Boolean circuit, i.e., a Boolean circuit with solely OR- and AND-gates, outputs 1 on some fixed input. According to Greenlaw et al. [8] this problem is $\leq_{\mathrm{m}}^{\log}$-complete for P.

We simulate such a circuit by a $\{\cup\}$-sentence such that the set $\{1\}$ stands for the truth value 1, and $\emptyset$ stands for the truth value 0.

Each OR-gate can be simulated by an atom $X \cup Y = Z$ where X and Y stand for the gate's inputs, and Z stands for the gate's output.

Now we describe how AND-gates can be simulated. For an AND-gate consider the atoms $Z \cup H = X \wedge Z \cup H' = Y$ where X and Y stand for the gate's inputs, Z stands for the gate's output, and H and H' are auxiliary variables. These atoms are satisfied by an assignment α only if $\alpha(Z) = \{1\} \Rightarrow (\alpha(X) = \{1\} \wedge \alpha(Y) = \{1\})$. Note that there might indeed be an assignment of terms β with $\beta(Z) = \emptyset$ and $\beta(X) = \beta(Y) = \{1\}$. But as the circuit is monotone, this is no problem.

Finally, if G is the variable standing for the circuit's output value, we add the atom $G = \{1\}$. This completes the proof. ◀

Contrary to expectation the problem $\mathrm{CSP}([\mathbb{N}], \{\cup\})$ is – in case $\mathrm{P} \neq \mathrm{NP}$ – more difficult than the problem $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\cup\})$. Since the CSP over $[\mathbb{N}]$ might appear to be a restriction of the CSP over $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$, one might at first view rather expect the opposite. The $\{\cup\}$-sentences over $[\mathbb{N}]$ are indeed a restricted version of sentences over $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ because the constants belong to a strict subset of $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$.

However, since for the CSP over $[\mathbb{N}]$ also the variables are mapped onto intervals only, we obtain greater expressive power in this specific situation.

For instance, the atom $\{0\} \cup \{2\} = X \cup Y$ expresses that X is mapped onto $\{0\}$ (resp., $\{2\}$) by a satisfying assignment if and only if Y is mapped onto $\{2\}$ (resp., $\{0\}$). Furthermore, for $X, Y \in \{\{0\}, \{2\}\}$ the atoms $\{0\} \cup X \cup Y = \{0\} \cup Z \wedge Z \cup Z' = \{0\} \cup \{2\}$ express that Z is mapped onto $\{2\}$ by any satisfying assignment if and only if X or Y is mapped onto $\{2\}$. Otherwise Z is mapped onto $\{0\}$. Hence, interpreting $\{2\}$ (resp., $\{0\}$) as the truth value 1 (resp., 0), the logical disjunction and negation can be expressed. Thus, 3SAT is reducible to $\mathrm{CSP}([\mathbb{N}], \{\cup\})$ and we obtain the following theorem.

▶ **Theorem 7.** $\mathrm{CSP}([\mathbb{N}], \{\cup\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP.

Further CSPs admitting set operations only. The methods and results for all other CSPs permitting only set operations are similar.

So we obtain the P-completeness for $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\cap\})$. Yet, as $[\mathbb{N}]$ is not closed under union, but under intersection, $\mathrm{CSP}([\mathbb{N}], \{\cap\})$ is – in contrast to $\mathrm{CSP}([\mathbb{N}], \{\cup\})$ – not NP-complete, but P-complete.

▶ **Theorem 8.** $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\cap\})$ *and* $\mathrm{CSP}([\mathbb{N}], \{\cap\})$ *are* $\leq_{\mathrm{m}}^{\log}$*-complete for* P.

By use of sentences in $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\cup, \cap\})$ and $\mathrm{CSP}([\mathbb{N}], \{\cup, \cap\})$ arbitrary propositional formulas can be described. Thus we obtain the following theorem.

▶ **Theorem 9.** $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\cup, \cap\})$ *and* $\mathrm{CSP}([\mathbb{N}], \{\cup, \cap\})$ *are* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP.

As $X = A \cup B$ can be expressed by $(X - A) - B = \emptyset \wedge A - X = \emptyset \wedge B - X = \emptyset$, and as $X = A \cap B$ holds if and only if $X = (A - (A - B))$, we obtain the first statement of the following theorem.

▶ **Theorem 10.** *Let* $\mathcal{O} \subseteq \{-, \cap, \cup\}$ *with* $- \in \mathcal{O}$.
1. $\mathrm{CSP}\big(\mathcal{P}_{\text{fin}}(\mathbb{N}), \mathcal{O}\big)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP.
2. $\mathrm{CSP}\big([\mathbb{N}], \mathcal{O}\big)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP.

Overview. The following table provides an overview over the results obtained in this section.

$\mathrm{CSP}\big(\mathrm{M}, \mathcal{O}\big)$ with	$M = \mathcal{P}_{\text{fin}}(\mathbb{N})$		$M = [\mathbb{N}]$	
	$\leq_{\mathrm{m}}^{\log}$-hard for	belongs to	$\leq_{\mathrm{m}}^{\log}$-hard for	belongs to
$\mathcal{O} = \emptyset$	L	L, 5	L	L, 5
$\mathcal{O} = \{\cup\}$	P, 6	P, 6	NP, 7	NP, 4
$\mathcal{O} = \{\cap\}$	P, 8	P, 8	P, 8	P, 8
$\mathcal{O} = \{\cup, \cap\}$	NP, 9	NP, 4	NP, 9	NP, 9
$\mathcal{O} \supseteq \{-\}$	NP, 10	NP, 4	NP, 10	NP, 4

For each of the problems the $\leq_{\mathrm{m}}^{\log}$-completeness for one of the complexity classes L, P, and NP is proven.

Additionally, it can be seen that in both situations we receive the same results for all $\mathcal{O} \subseteq \{\cup, \cap, -\}$ but $\mathcal{O} = \{\cup\}$. If it holds $\mathrm{P} \neq \mathrm{NP}$, then $\mathcal{O} = \{\cup\}$ is the only case throughout this paper where deciding a problem over $[\mathbb{N}]$ is more difficult than deciding the corresponding problem over $\mathcal{P}_{\text{fin}}(\mathbb{N})$. Contrary to that, in Section 4 there is an example for which – under the assumption $\mathrm{PSPACE} \neq \mathrm{NEXP}$ – the opposite is true.

4 CSPs Permitting Arithmetic Operations

Before we move to the consideration of some concrete problems, we prove an upper bound for all CSPs investigated in this paper:

▶ **Lemma 11.** *Let* $M \in \{\mathcal{P}_{\text{fin}}(\mathbb{N}), [\mathbb{N}]\}$ *and* $\mathcal{O} \subseteq \{+, \times, \cup, \cap, -\}$. *Then* $\mathrm{CSP}(\mathrm{M}, \mathcal{O}) \in \Sigma_1$.

Proof. The set $\{(\varphi, \alpha) \mid \varphi \in \mathrm{CSP}(\mathrm{M}, \mathcal{O}),\ \alpha$ is a satisfying assignment of variables for $\varphi\}$ is decidable. Hence, the problem $\mathrm{CSP}(\mathrm{M}, \mathcal{O})$ is a projection of a decidable set. ◀

4.1 CSPs over a Single Arithmetical Operation

In this section we consider the problems $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+\})$ and $\mathrm{CSP}([\mathbb{N}], \{+\})$ as well as $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\times\})$ and $\mathrm{CSP}([\mathbb{N}], \{\times\})$. All these problems turn out to be $\leq_{\mathrm{m}}^{\log}$-hard for NP. This shows that all CSPs permitting an arithmetical operation are $\leq_{\mathrm{m}}^{\log}$-hard for NP.

▶ **Definition 12.** Let $\mathrm{MSOS} =_{\mathrm{def}} \{x_1, \ldots, x_n, b \mid \exists a_1, \ldots, a_n \in \mathbb{N} : \sum_{i=1}^{n} a_i x_i = b\}$.

▶ **Lemma 13** ([1])**.** *MSOS is $\leq_{\mathrm{m}}^{\log}$-complete for NP.*

Let $M \in \{\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), [\mathbb{N}]\}$. In order to see that $\mathrm{MSOS} \leq_{\mathrm{m}}^{\log} \mathrm{CSP}(\mathrm{M}, \{+\})$, consider a $\{+\}$-sentence in which the factors a_i are guessed. Using the shift-and-add technique it can be made sure that some variable S_i in that sentence is mapped onto $\{a_i x_i\}$ by each satisfying assignment. Obviously $(x_1, \ldots, x_n, b) \in \mathrm{MSOS}$ if and only if the a_i can be chosen such that $\sum_{i=1}^{n} S_i = \{b\}$.

$\sum_{i \in I} a_i x_i = b$ is equivalent to $\prod_{i=1}^{n} 2^{a_i x_i} = 2^b$. Thus, with a similar approach using the square-and-multiply technique $\mathrm{MSOS} \leq_{\mathrm{m}}^{\log} \mathrm{CSP}(\mathrm{M}, \{\times\})$ can be shown.

▶ **Theorem 14.** *The following statements hold:*

1. $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{+\})$ *and* $\mathrm{CSP}([\mathbb{N}], \{+\})$ *are $\leq_{\mathrm{m}}^{\log}$-hard for* NP.
2. $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\times\})$ *and* $\mathrm{CSP}([\mathbb{N}], \{\times\})$ *are $\leq_{\mathrm{m}}^{\log}$-hard for* NP.

Yet we find different upper bounds. The problems over $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ belong to NEXP, whereas $\mathrm{CSP}([\mathbb{N}], \{\times\}) \in \Sigma_3^{\mathrm{p}}$ and even $\mathrm{CSP}([\mathbb{N}], \{+\}) \in \mathrm{NP}$ hold. We start with the consideration of CSPs that permit the addition only.

At first we show: if there is a satisfying assignment of variables for a given $\{+\}$-sentence φ, then there is also a satisfying assignment for φ that is "small" in some sense.

▶ **Lemma 15.** *Let $\varphi \in \mathrm{CSP}'\big(\mathrm{M}, \{+\}\big)$ for $M \in \{\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), [\mathbb{N}]\}$ and $n =_{def} |\varphi|$. Furthermore, let $x = \max(\bigcup_{C \in \mathrm{Const}_\varphi} C \cup \{0\})$. Then there is a satisfying assignment of variables α for φ with $\forall X \in \mathrm{Var}_\varphi : \ \max(\alpha(\mathrm{X}) \cup \{0\}) \leq \mathrm{x}2^{\mathrm{n}}$.*

Proof. The following non-deterministic algorithm successively constructs an assignment α.

1. Set $\alpha(C) = C$ for each constant C.
2. For each variable X with undefined $\alpha(X)$ occurring in an atom $Y + Z = X$ such that $\alpha(Y)$ and $\alpha(Z)$ are already defined, set $\alpha(X) = \alpha(Y) + \alpha(Z)$.
3. For each variable X with undefined $\alpha(X)$ occurring in an atom $X + Z_1 = Z_2$ such that $\alpha(Z_2)$ is defined and unequal to $\emptyset$, guess a set $S \in M$ with $\max\{S\} \leq \max(\alpha(Z_2))$ non-deterministically, and set $\alpha(X) = S$.
4. If there is a variable X such that $\alpha(X)$ has been defined in the last execution of the steps 2 and 3, then go to step 2.
5. For all variables X with undefined $\alpha(X)$ set $\alpha(X) = \emptyset$.
6. If α is a satisfying assignment, then return α.

It can be shown inductively that on at least one computation path the algorithm returns a satisfying assignment. Let $X_1, \ldots, X_{|\mathrm{Var}_\varphi|}$ denote the variables such that for $i < j$ the value $\alpha(X_i)$ is defined before $\alpha(X_j)$. Then it holds $\max(\alpha(X_i)) \leq x \cdot 2^i$ for $1 \leq i \leq |\mathrm{Var}_\varphi|$. ◀

Through this result we can proceed as follows: guess all assignments whose range is a subset of the power set of $\{0, 1, \ldots, x \cdot 2^n\}$. Test whether the respective assignment is satisfying, and return the corresponding return value.

Note that for CSPs over $[\mathbb{N}]$ only assignments with range $\subseteq \{[a, b] \mid a, b \leq x \cdot 2^n\}$ have to be considered. Hence, we obtain the following results.

▶ **Theorem 16.** *It holds that*

1. $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{+\}) \in \mathrm{NEXP}$
2. $\mathrm{CSP}([\mathbb{N}], \{+\}) \in \mathrm{NP}$.

▶ Remark. It is also possible to show $\mathrm{CSP}([\mathbb{N}], \{+\}) \in \mathrm{NP}$ by using ILP (the problem of whether an integer linear program has a solution) as an oracle. With that approach one can even show $\mathrm{CSP}([\mathbb{N}], \{+, \cap\}) \in \mathrm{NP}$ (theorem 24).

Now we consider $\mathrm{CSP}([\mathbb{N}], \{\times\})$. Contrary to $\mathrm{CSP}([\mathbb{N}], \{+\})$ we are only able to show $\mathrm{CSP}([\mathbb{N}], \{\times\})$ belonging to Σ_3^{p}. The reason for this difference is that $[\mathbb{N}]$ is not closed under multiplication. In particular, we may not assume that the input sentences are of the simplified form described in definition 2.

Nevertheless, by investigating the multiplication of intervals we find some properties that significantly simplify deciding $\mathrm{CSP}([\mathbb{N}], \{\times\})$.

▶ **Lemma 17.** *Let $A_1, \dots, A_m, B_1, \dots, B_n$ be finite intervals over $\mathbb{N}$ such that it holds $\emptyset \neq \prod_{i=1}^m A_i = \prod_{i=1}^n B_i \neq \{0\}$.*
Then $\prod_{1 \leq i \leq m, |A_i|=1} A_i = \prod_{1 \leq i \leq n, |B_i|=1} B_i$ and $\prod_{1 \leq i \leq m, |A_i| \neq 1} A_i = \prod_{1 \leq i \leq n, |B_i| \neq 1} B_i$.

▶ **Lemma 18.** *Let $A_1, \dots, A_m, B_1, \dots, B_n$ be intervals with at least two elements each such that $\max(A_1) \leq \max(A_2) \leq \dots \leq \max(A_m)$ and $\max(B_1) \leq \max(B_2) \leq \dots \leq \max(B_n)$. Let furthermore $\prod_{i=1}^m A_i = \prod_{i=1}^n B_i$. Then $\max(A_m) = \max(B_n)$.*

Proof. Let $L =_{\mathrm{def}} \prod_{i=1}^m A_i$ and $R =_{\mathrm{def}} \prod_{i=1}^n B_i$. In addition, let the greatest elements of A_i (resp., B_i) be denoted by a_i (resp., b_i). Because of $L = R$ the second greatest elements of L and R are equal. Thus $\max(L - \{\max(L)\}) = \max(R - \{\max(R)\})$.

We show $\max(L - \{\max(L)\}) = \big(\prod_{i=1}^{m-1} a_i\big) \cdot (a_m - 1) = \max(L) - \prod_{i=1}^{m-1} a_i$: the right equation is obvious. Furthermore, it apparently holds that $\big(\prod_{i=1}^{m-1} a_i\big) \cdot (a_m - 1) \in L - \{\max(L)\}$.

Let $x \in L - \{\max(L)\}$. There are $x_i \in A_i$ for $i = 1, \dots, m$ such that $x = \prod_{i=1}^m x_i$. Due to $x \neq \max(L)$ there is a j such that $x_j < a_j$. Then

$$x \leq \big(\prod_{1 \leq i \leq m, i \neq j} a_i\big) \cdot (a_j - 1) = \max(L) - \prod_{1 \leq i \leq m, i \neq j} a_i \leq \max(L) - \prod_{i=1}^{m-1} a_i.$$

Analogously it can be seen that $\max(R - \{\max(R)\}) = \max(R) - \prod_{i=1}^{n-1} b_i$. Hence $\max(L) - \prod_{i=1}^{m-1} a_i = \max(L - \{\max(L)\}) = \max(R - \{\max(R)\}) = \max(R) - \prod_{i=1}^{n-1} b_i$.

Because of $\max(L) = \max(R)$ we obtain $\prod_{i=1}^{m-1} a_i = \prod_{i=1}^{n-1} b_i$ and as a consequence $a_m = \frac{\max(L)}{\prod_{i=1}^{m-1} a_i} = \frac{\max(R)}{\prod_{i=1}^{n-1} b_i} = b_n$. ◀

We roughly describe a non-deterministic polynomial time algorithm satisfying the following properties: on input of a $\mathrm{CSP}([\mathbb{N}], \{\times\})$-instance the algorithm simplifies this sentence until no variables are left, and finally returns it. If and only if the input sentence is in $\mathrm{CSP}([\mathbb{N}], \{\times\})$, then there is a computation path on which a true sentence is returned.

After some preprocessing we obtain a possibly modified sentence and may neglect the sets $\emptyset$ and $\{0\}$ henceforth. Then we guess which variables stand for singletons. According to lemma 17 each atom can be split in two atoms: one for the "singleton variables and constants" and one for the other variables and constants. Hence, we obtain two sets of atoms, which can be considered independently.

For singletons we only store the exponents occurring in the prime decomposition. Two singletons are multiplied by adding the vectors of exponents componentwise. Hence, testing whether there is a satisfying assignment for the "singleton-atoms" can be done the same way as deciding $\mathrm{CSP}([\mathbb{N}], \{+\})$, which we have shown to be in NP. If there is a satisfying assignment, all "singleton-atoms" can be deleted. Otherwise return $[0, 1] = [1, 2]$ for instance.

Now consider the remaining atoms. Without loss of generality there is an atom $A_1 \times \cdots \times A_m = B_1 \times \cdots \times B_n$ such that all A_i are constants (if for each atom there are variables on both sides, then the remainig sentence is obviously true). For each variable B_j we guess an interval whose upper endpoint is $\leq \max(\bigcup_{i=1}^{m} A_i)$, and replace each occurrence of B_j with this interval. This approach is backed up by lemma 18 and can be repeated until no variable is left.

▶ **Lemma 19.** *There is a non-deterministic polynomial time algorithm $\mathcal{A}$ satisfying the following properties:*

- *As input $\mathcal{A}$ receives a $\{\times\}$-sentence φ whose constants are intervals.*
- *On each computation path $\mathcal{A}$ returns a $\{\times\}$-sentence ψ without any variables such that all constants are finite intervals with at least two elements each.*
- *If and only if $\varphi \in \mathrm{CSP}([\mathbb{N}], \{\times\})$, then on at least one computation path $\mathcal{A}$ returns a sentence $\psi \in \mathrm{CSP}([\mathbb{N}], \{\times\})$.*

Since $\mathcal{A}$ is a polynomial time algorithm, it holds that $|\psi| \in O(p(|\varphi|))$ for each ψ returned by the algorithm and some polynomial p.
It remains to test whether two products of intervals are equal.

▶ **Definition 20.** Let EPI be the set

$$\{(([a_1, a'_1], \ldots, [a_k, a'_k]), ([b_1, b'_1], \ldots, [b_n, b'_n])) \mid a_i < a'_i,\ b_i < b'_i,\ \prod_{i=1}^{k} [a_i, a'_i] = \prod_{i=1}^{n} [b_i, b'_i]\}\,.$$

▶ **Lemma 21.** $\mathrm{EPI} \in \Pi_2^{\mathrm{p}}$.

Proof. Let $A_1, \ldots, A_m, B_1, \ldots, B_n$ be non-empty intervals with $|A_i|, |B_j| \geq 2$.
It holds

$$\begin{aligned}\prod_{i=1}^{m} A_i = \prod_{i=1}^{n} B_i \Leftrightarrow & \forall x_1 \in A_1 \ldots \forall x_m \in A_m \forall y_1 \in B_1 \ldots \forall y_n \in B_n \\ & \exists x'_1 \in B_1 \ldots \exists x'_n \in B_n \exists y'_1 \in A_1 \ldots \exists y'_m \in A_m \\ & \prod_{i=1}^{m} x_i = \prod_{i=1}^{n} x'_i \wedge \prod_{i=1}^{n} y_i = \prod_{i=1}^{m} y'_i.\end{aligned}$$

Thus $\mathrm{EPI} \in \forall^{\mathrm{p}}\exists^{\mathrm{p}}\mathrm{P} = \Pi_2^{\mathrm{p}}$. ◀

▶ **Theorem 22.** $\mathrm{CSP}([\mathbb{N}], \{\times\}) \in \Sigma_3^{\mathrm{p}}$.

Proof. According to theorem 19 and lemma 21 the problem $\mathrm{CSP}([\mathbb{N}], \{\times\})$ can be decided by an NP-algorithm with Π_2^{p}-oracle. ◀

▶ Remark. Our decision algorithm for EPI tests whether two products of intervals are equal by considering all elements of the two products. Maybe this can be done more efficiently. In lemma 18 we have shown that a necessary condition for the equality of two products of intervals is that the greatest upper interval endpoint is the same in both products. If this condition can be extended to a sufficient condition that can still be tested efficiently, we would obtain a better upper bound for $\mathrm{CSP}([\mathbb{N}], \{\times\})$.

For the variant over $\mathcal{P}_{\mathrm{fin}}(\mathbb{N})$ we obtain membership in NEXP, which can be proven similarly to $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{+\}) \in \mathrm{NEXP}$.

▶ **Theorem 23.** $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\times\}) \in \mathrm{NEXP}$.

4.2 Addition and Intersection

Whereas we are not able to show $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{+, \cap\})$ to be decidable, the NP-hardness for the problem $\mathrm{CSP}([\mathbb{N}], \{+, \cap\})$ can be proven by use of integer linear programs.

Furthermore, due to the NP-hardness of $\mathrm{CSP}([\mathbb{N}], \{+\})$ also $\mathrm{CSP}([\mathbb{N}], \{+, \cap\})$ is NP-hard.

▶ **Theorem 24.** $\mathrm{CSP}([\mathbb{N}], \{+, \cap\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* NP.

Proof. According to the lemmata 3 and 14 it suffices to show $\mathrm{CSP}'([\mathbb{N}], \{+, \cap\}) \in \mathrm{NP}$. Hence, let φ be a $\{+, \cap\}$-sentence whose constants are solely intervals such that each atom is of the form $X \oplus Y = Z$ for $X, Y, Z \in \mathrm{Var}_\varphi \cup \mathrm{Const}_\varphi$ and $\oplus \in \{+, \cap\}$.

During a polynomial time computable preprocessing step φ is modified non-deterministically such that the following holds: $\varphi \in \mathrm{CSP}'([\mathbb{N}], \{+, \cap\})$ if and only if on at least one computation path a sentence φ' satisfying the following conditions has been computed: there is a satisfying assignment α for φ' with $\emptyset \notin W_\alpha$, and if there is an atom $X \oplus Y = Z$ in φ' containing $\emptyset$ as a constant, then $\oplus = \cap$, $Z = \emptyset$, and $X, Y \neq \emptyset$.

The problem of testing these conditions can be solved with the help of integer linear programs (ILP). For each $R \in (\mathrm{Var}_\varphi \cup \mathrm{Const}_\varphi) - \{\emptyset\}$ we introduce two ILP-variables r_0, r_1. If R is a constant and $R = [l, u]$, set $r_0 = l$ and $r_1 = u$.

1. For each atom $X + Y = Z$ we set up the equations $x_0 + y_0 = z_0$ and $x_1 + y_1 = z_1$.
2. For each atom $X \cap Y = Z$ with $Z \neq \emptyset$ use four further variables d, e, d', e'. We express $z_0 = \max(x_0, y_0)$ and $z_1 = \min(x_1, y_1)$:
   - On $z_0 = \max(x_0, y_0)$: Add $x_0 \leq z_0$, $y_0 \leq z_0$, $z_0 = dx_0 + ey_0$, and $d + e = 1$.
   - On $z_1 = \min(x_1, y_1)$: Add $x_1 \geq z_1$, $y_1 \geq z_1$, $z_1 = d'x_1 + e'y_1$, and $d' + e' = 1$.
3. For each atom $X \cap Y = Z$ with $Z = \emptyset$ we want to express $y_1 < x_0 \vee x_1 < y_0$. Hence, we guess a bit b. If $b = 0$, we add the inequation $y_1 < x_0$. Otherwise we add $x_1 < y_0$.
4. Furthermore, for every two ILP-variables x_0 and x_1 that describe the lower and upper endpoint of some interval we add the inequation $x_0 \leq x_1$.

If and only if one of the ILPs has a solution, it holds $\varphi \in \mathrm{CSP}([\mathbb{N}], \{+, \cap\})$. ◀

4.3 Lower Bounds for CSPs Permitting One Arithmetical and One Set Operation

We present two lower bounds obtained from literature. It should be possible to improve them in at least some cases.

By use of some results by Meyer and Stockmeyer [14] the following lower bound can be proven.

▶ **Theorem 25.**
1. $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{+, \cup\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* Π_2^{P}.
2. $\mathrm{CSP}(\mathcal{P}_{\mathrm{fin}}(\mathbb{N}), \{\times, \cup\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* Π_2^{P}.

These results can be shown by a reduction not making use of CSP-variables. This yields evidence that probably a better lower bound – such as the $\leq_{\mathrm{m}}^{\log}$-hardness for Σ_3^{P} – can be proven.

If beside one arithmetical operation there is also one of the two operations intersection and set difference available, we can revisit some results by McKenzie and Wagner [11] and show the corresponding problem to be PSPACE-hard.

▶ **Theorem 26.**
1. $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+, \cap\})$ *is* $\leq_{\mathrm{m}}^{\mathrm{p}}$*-hard for* PSPACE*.*
2. $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\times, \cap\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE*.*
3. $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+, -\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE*.*
4. $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{\times, -\})$ *is* $\leq_{\mathrm{m}}^{\log}$*-hard for* PSPACE*.*

In Section 3 we observed that under the assumption $\mathrm{P} \neq \mathrm{NP}$ there are CSPs for which the variant over $[\mathbb{N}]$ is more difficult than the variant over $\mathcal{P}_{\text{fin}}(\mathbb{N})$. Here we have the opposite situation.

According to corollary 24 $\mathrm{CSP}([\mathbb{N}], \{+, \cap\})$ belongs to NP. According to theorem 26, however, $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+, \cap\})$ is $\leq_{\mathrm{m}}^{\mathrm{p}}$-hard for PSPACE. Hence, under the assumption $\mathrm{NP} \neq \mathrm{PSPACE}$ deciding $\mathrm{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+, \cap\})$ is more difficult than deciding $\mathrm{CSP}([\mathbb{N}], \{+, \cap\})$.

4.4 Undecidability Results

As soon as both addition and multiplication are permitted, we receive undecidable, but computably enumerable problems.

More precisely, it can be shown that the problem of solving Diophantine equations, which was proven to be undecidable by Matiyasevich [2, 10], can be reduced to $\mathrm{CSP}(\mathrm{M}, \mathcal{O})$ for $M \in \{\mathcal{P}_{\text{fin}}(\mathbb{N}), [\mathbb{N}]\}$ and $\{+, \times\} \subseteq \mathcal{O}$.

▶ **Theorem 27.** *Let* $M \in \{\mathcal{P}_{\text{fin}}(\mathbb{N}), [\mathbb{N}]\}$ *and* $\mathcal{O} \subseteq \{\cup, \cap, -\}$*. Then* $\mathrm{CSP}\big(\mathrm{M}, \{+, \times\} \cup \mathcal{O}\big)$ *is* $\leq_{\mathrm{m}}^{\log}$*-complete for* Σ_1*.*

4.5 Overview

The following tables yield an overview over the results obtained in this section. For both tables there are sets of operations which do not occur in the list. For these problems we only know those bounds that follow directly from other entries in the corresponding tables (recall that whenever the set difference is permitted, then one may assume without loss of generality that also union and intersection are allowed).

The first table deals with the CSPs over $\mathcal{P}_{\text{fin}}(\mathbb{N})$.

$\mathrm{CSP}\big(\mathcal{P}_{\text{fin}}(\mathbb{N}), \mathcal{O}\big)$ with	hardness	member of
$\mathcal{O} = \{+\}$	$\leq_{\mathrm{m}}^{\log}$-hard for NP, 14	NEXP, 16
$\mathcal{O} = \{\times\}$	$\leq_{\mathrm{m}}^{\log}$-hard for NP, 14	NEXP, 23
$\mathcal{O} = \{+, \cup\}$	$\leq_{\mathrm{m}}^{\log}$-hard for Π_2^{p}, 25	Σ_1, 11
$\mathcal{O} = \{+, \cap\}$	$\leq_{\mathrm{m}}^{\mathrm{p}}$-hard for PSPACE, 26	Σ_1, 11
$\mathcal{O} = \{+, -\}$	$\leq_{\mathrm{m}}^{\log}$-hard for PSPACE, 26	Σ_1, 11
$\mathcal{O} \supseteq \{+, \times\}$	$\leq_{\mathrm{m}}^{\log}$-hard for Σ_1, 27	Σ_1, 11

The following tabular contains the results concerning CSPs over $[\mathbb{N}]$.

$\mathcal{O} = \mathrm{CSP}\big([\mathbb{N}], \mathcal{O}\big)$ with	$\leq_{\mathrm{m}}^{\log}$-hard for	member of
$\mathcal{O} = \{+\}$	NP, 14	NP, 16
$\mathcal{O} = \{\times\}$	NP, 14	Σ_3^{p}, 22
$\mathcal{O} = \{+, \cap\}$	NP, 14	NP, 24
$\mathcal{O} \supseteq \{+, \times\}$	Σ_1, 27	Σ_1, 11

The bounds for CSPs over $[\mathbb{N}]$ are in general lower than those for the corresponding CSPs over $\mathcal{P}_{\text{fin}}(\mathbb{N})$. If $[\mathbb{N}]$ is closed under all allowed operations, then we know the corresponding CSP to be complete for one of the classes L, NP, and Σ_1.

For the variant over $\mathcal{P}_{\text{fin}}(\mathbb{N})$ there are in almost all cases gaps between the lower and upper bound. It seems to be difficult to close these gaps.

In contrast to the section before, here remain several open questions. The following are particularly interesting:

Is $\text{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+, \cap\})$ decidable? Is $\text{CSP}(\mathcal{P}_{\text{fin}}(\mathbb{N}), \{+\})$ complete for some class between NP and NEXP? Does EPI belong to some class of the polynomial hierarchy lower than Π_2^{p}?

Abstract

The maximum common subtree isomorphism problem asks for the largest possible isomorphism between subtrees of two given input trees. This problem is a natural restriction of the maximum common subgraph problem, which is NP-hard in general graphs. Confining to trees renders polynomial time algorithms possible and is of fundamental importance for approaches on more general graph classes. Various variants of this problem in trees have been intensively studied. We consider the general case, where trees are neither rooted nor ordered and the isomorphism is maximum w.r.t. a weight function on the mapped vertices and edges. For trees of order n and maximum degree Δ our algorithm achieves a running time of $\mathcal{O}(n^2\Delta)$ by exploiting the structure of the matching instances arising as subproblems. Thus our algorithm outperforms the best previously known approaches. No faster algorithm is possible for trees of bounded degree and for trees of unbounded degree we show that a further reduction of the running time would directly improve the best known approach to the assignment problem. Combining a polynomial-delay algorithm for the enumeration of all maximum common subtree isomorphisms with central ideas of our new algorithm leads to an improvement of its running time from $\mathcal{O}(n^6 + Tn^2)$ to $\mathcal{O}(n^3 + Tn\Delta)$, where n is the order of the larger tree, T is the number of different solutions, and Δ is the minimum of the maximum degrees of the input trees. Our theoretical results are supplemented by an experimental evaluation on synthetic and real-world instances.

1 Introduction

The maximum common subgraph isomorphism problem (MCS) asks for an isomorphism between induced subgraphs of two given graphs that is of maximum weight w.r.t. a weight function on the mapped vertices and edges. The problem is of fundamental importance in applications like pattern recognition [5] or bio- and cheminformatics [9, 18]. MCS naturally generalizes the subgraph isomorphism problem (SI), where the task is to decide if one graph

[*] This work was supported by the German Research Foundation (DFG), priority programme "Algorithms for Big Data" (SPP 1736).

is isomorphic to a subgraph of another graph. Both problems are known to be NP-hard for general graphs.

It is not astonishing that these problems have been extensively studied for restricted graph classes. Polynomial time algorithms for SI and MCS in trees have been pioneered by Edmonds and Matula in the 1960s. They rely on solving a series of maximum bipartite matching instances, see [15]. These early results focused on the polynomial time complexity of the problem; since then considerable progress has been achieved in improving the running time of SI algorithms (also see [1] and references therein): Reyner [17, 23] and Matula [15] both showed a running time of $\mathcal{O}(n^{2.5})$ for rooted trees. Chung [4] later obtained the same bound for unrooted trees. Further improvements were made by Shamir and Tsur [19] who obtained time $\mathcal{O}(n^{2.5}/\log n)$ and $\mathcal{O}(n^{\omega})$, where ω is the exponent of matrix multiplication.

MCS on trees seems to be harder. For two rooted trees of size n, it is known that the problem can be solved, roughly speaking, in the same time as the associated maximum weight matching problem in a bipartite graph on n vertices: Gupta and Nishimura [11] presented an $\mathcal{O}(n^{2.5}\log n)$ algorithm for MCS in rooted trees by assuming weights to be in $\mathcal{O}(n)$, which allows to employ a scaling approach to the matching problem [10]. The running time can be improved to $\mathcal{O}(\sqrt{\Delta}n^2\log\frac{2n}{\Delta})$, where Δ denotes the maximum degree [12]. Allowing a real weight function to determine the similarity of mapped vertices gives rise to bipartite matching instances with unrestricted weights. Solving these with the Hungarian method leads to cubic running time, see e.g. [22]. Since the the size of the matching instances is bounded by the maximum degree Δ, the result can be improved to $\mathcal{O}(n^2\Delta)$ time [20]. Various related concepts for the comparison of rooted trees, either ordered or unordered, have been proposed and were studied in detail, see [22] and references therein, where the *tree edit distance* is a prominent example [3, 6].

In this article we consider the problem of finding a common subtree isomorphism in unrooted, unordered trees that is maximum w.r.t. a weight function on the mapped vertices and edges. This problem is directly relevant in various applications, where real-world objects like molecules or shapes are represented by (attributed) trees [16, 20]. Moreover, it forms the basis for several recent approaches to solve MCS in more general graph classes, see [2, 13, 14, 18]. Methods directly based on algorithms for rooted trees result in time $\mathcal{O}(n^4\Delta)$ by considering all pairs of possible roots. An improvement to $\mathcal{O}(n^3\Delta)$ has been reported in [20], which is limited to non-negative weight functions. Schietgat, Ramon and Bruynooghe [18] suggested an approach for MCS in outerplanar graphs, which solves the considered problem when applied to trees. The approach is stated to have a running time of $\mathcal{O}(n^{2.5})$, but in fact leads to a running time of $\Omega(n^4)$ in the worst case.[1]

Our contribution. We show that for arbitrary weights a maximum common subtree isomorphism between two trees G and H of order n with $\Delta(G) \leq \Delta(H)$ can be computed in time $\mathcal{O}(n^2(\Delta(G) + \log\Delta(H))$. We obtain the improvement by (i) considering only a specific subset of subproblems that we show to be sufficient to guarantee an optimal solution; (ii) exploiting the close relation between the emerging matching instances. We show that for general trees any further improvement of this time bound would allow to solve the assignment problem in $o(n^3)$, and hence improve over the best known approach to this famous problem for more than 30 years. For trees of bounded degree the running time bound of $\mathcal{O}(n^2)$ is

[1] The analysis of the algorithm appears to be flawed. An Erratum to [18] has been submitted to the *Annals of Mathematics and Artificial Intelligence*, see Appendix of `https://arxiv.org/abs/1602.07210`. Our experimental study of their implementation actually suggests a time bound of $\Omega(n^5)$.

tight. We apply our new techniques to the problem of enumerating all maximum common subtree isomorphisms, thus improving the state-of-the-art running times. Finally, we present an experimental evaluation on synthetic and real-world instances showing that our new algorithm is faster than existing approaches.

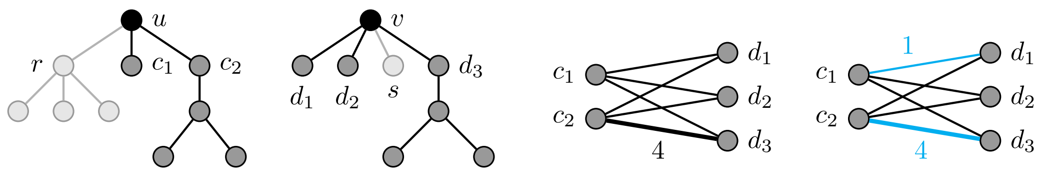
2 Preliminaries

In this paper, $G = (V, E)$ is a *simple undirected graph.* We call $v \in V$ a *vertex* and $uv = vu \in E$ an *edge* of G. For a graph $G = (V, E)$ we define $V(G) := V_G := V$, $E(G) := E_G := E$ and $|G| := |V(G)|$. For a subset of vertices $V' \subseteq V$ the graph $G[V'] := (V', E')$, $E' := \{uv \in E \mid u, v \in V'\}$, is called *induced* subgraph. A connected graph with a unique path between any two vertices is a *tree.* A tree G with an explicit root vertex $r \in V_G$ is called *rooted* tree, denoted by G^r. In a rooted tree G^r we denote the children of a vertex v by $C(v)$ and its parent by $p(v)$, where $p(r) = r$. The *depth* $\text{depth}(v)$ of a vertex v is the number of edges on the path from v to r. The *neighbors* of a vertex v are defined as $N(v) := \{u \in V_G \mid vu \in E_G\}$. The *degree* of a vertex $v \in V_G$ is $\delta(v) := |N(v)|$, the *degree* $\Delta(G)$ of a graph G is the maximum degree of its vertices.

For a graph $G = (V, E)$ a *matching* $M \subseteq E$ is a set of edges, such that no two edges share a vertex. A matching M of G is said to be *perfect*, if $2|M| = |V|$. A *weighted graph* is a graph endowed with a function $w : E \to \mathbb{R}$. The weight of a matching M in a weighted graph is $W(M) := \sum_{e \in M} w(e)$. We call a matching M of a weighted bipartite graph G a *maximum weight matching* (MWM) if there is no other matching M' of G with $W(M') > W(M)$. The *assignment problem* asks for a matching with maximum weight among all perfect matchings and we refer to a solution by MWPM.

An *isomorphism* between two graphs G and H is a bijective function $\phi : V_G \to V_H$ such that $uv \in E_G \Leftrightarrow \phi(u)\phi(v) \in E_H$; if such an isomorphism exists, G and H are said to be *isomorphic.* We call a graph G *subgraph isomorphic* to a graph H, if there is an induced subgraph $H' \subseteq H$ isomorphic to G. In this case, we write $G \preceq_\phi H$, where $\phi : V_G \to V_{H'}$ is an isomorphism between G and H'. A *common subgraph* of G and H is a graph I, such that $I \preceq_\phi G$ and $I \preceq_{\phi'} H$. The isomorphism $\varphi := \phi' \circ \phi^{-1}$ is called *common subgraph isomorphism* (CSI). For a function $f : X \to Y$ let $\text{dom}(f) := X$ be the domain of f. If there is no other CSI φ' with $|\text{dom}(\varphi')| > |\text{dom}(\varphi)|$, we call φ *maximum* common subgraph isomorphism (MCSI).

We generalize the above definitions to a pair of graphs G, H under a commutative weight-function $\omega : (V_G \times V_H) \cup (E_G \times E_H) \to \mathbb{R} \cup \{-\infty\}$. The weight $\mathcal{W}(\phi)$ of an isomorphism ϕ between G and H under ω is the sum of the weights $\omega(v, \phi(v))$ and $\omega(vu, \phi(v)\phi(u))$ of all vertices and edges mapped by ϕ. A maximum common subgraph isomorphism ϕ under a weight function is one of maximum weight $\mathcal{W}(\phi)$ instead of maximum size $|\text{dom}(\phi)|$. Note, this is less restrictive than a common approach for isomorphisms on labeled graphs, where the labels must match. By defining ω such that mapped vertices and mapped edges add 1 and 0, respectively, to the weight, we obtain an isomorphism of maximum size. Therefore, in the following we consider graphs under a weight function unless stated otherwise and refer to the corresponding solution as MCSI. For convenience we replace the word *graph* by *tree* in the above definitions when appropriate. The *maximum common subtree isomorphism problem* (MCST) is to determine the weight of an MCSI, where the input graphs and the common subgraph are trees. We further define $[1..k] := \{1, \ldots, k\}$ for $k \in \mathbb{N}$.



(a) Rooted subtree G^r_u. **(b)** Rooted subtree H^s_v. **(c)** Matching problem. **(d)** MWM.

Figure 1 Two rooted subtrees (a) and (b), the associated weighted matching instance (c), and an MWM on that instance (d). Light gray vertices and edges are not part of the rooted subtrees, root vertices are shown in solid black. The maximum weight matching is shown in blue. We assume a weight function ω with $\omega(u, v) = 1$ for all $(u, v) \in V_G \times V_H$ and $\omega(e, f) = 0$ for all $(e, f) \in E_G \times E_H$. The edges without label in (c) have weight 1.

3 Problem Decomposition and Fundamental Algorithms

We introduce the basic techniques for solving MCST following the ideas of Edmonds and Matula [15]. The approach requires to compute MWMs in bipartite graphs as a subroutine. We discuss the occurring matching instances in detail in Section 4.

By fixing the roots of both trees we can develop an algorithm solving MCST on this restricted setting. It is easy to generalize this solution by considering all possible pairs of roots. We then show that it is sufficient to fix the root of one tree while still obtaining a maximum solution.

Rooted trees. We first consider the problem restricted to rooted trees under the assumption that the roots of the two trees must be mapped to each other. For a rooted tree G^r we define the *rooted subtree* G^r_u as the subtree induced by u and all its descendants in G^r that is rooted at u, cf. Figures 1a and b. Note that $G^r_r = G^r$ and that G^r_u and G^s_u both refer to the same subtree unless s is contained in G^r_u. The key to solving MCST for two rooted trees G^r and H^s is the following recursive formulation:

$$\mathrm{MCS}_{\mathrm{root}}(G^r, H^s) = \omega(r, s) + W(M), \tag{1}$$

where M is an MWM of the complete bipartite graph on the vertex set $C(r) \uplus C(s)$ with weights $w(uv) = \omega(ru, sv) + \mathrm{MCS}_{\mathrm{root}}(G^r_u, H^s_v)$ for all $u \in C(r)$ and $v \in C(s)$. Hence, each edge weight corresponds to the solution of a problem of the same type for a pair of smaller rooted subtrees and the recursion naturally stops at the leaves. Each subproblem, the initial one as well as those arising in recursive calls, is uniquely defined by a pair of rooted subtrees and essentially consists of solving a matching instance.

Figure 1 illustrates the two rooted subtrees G^r_u and H^s_v and the corresponding matching problem under the weight function as given in the figure. For rooted trees G^r and H^s this problem arises on the second level in the recursion of Eq. (1). We obtain $\mathrm{MCS}_{\mathrm{root}}(G^r_u, H^s_v) = \omega(u, v) + W(M) = 1 + 5 = 6$, where M is an MWM of Figure 1c, depicted in Figure 1d.

In order to compute Eq. (1) the subproblems defined by the pairs of rooted subtrees $\mathcal{S}_{\mathrm{root}}(G^r, H^s) := \{(G^r_u, H^s_v) \mid \mathrm{depth}(u) = \mathrm{depth}(v)\}$ have to be solved.

▶ **Proposition 1.** *A maximum common subtree isomorphism for two rooted trees G^r and H^s can be computed in time $\mathcal{O}(n^3)$, where $n = |G| + |H|$.*

Proof. The bipartite graph for the subproblem (G^r_u, H^s_v) contains $k_u + l_v$ vertices, where $k_u := |C(u)|$ and $l_v := |C(v)|$. For the total running time we distinguish the cases $k_u \le l_v$

and $k_u > l_v$. For the first case we obtain a MWM in time $\mathcal{O}(k_u l_v(k_u + \log l_v))$ according to Lemma 5. The second case is analog. Since $\mathcal{S}_{\text{root}}(G^r, H^s) \subseteq \{(G^r_u, H^s_v) \mid u \in V_G, v \in V_H\}$ the total running time is bounded by $\mathcal{O}(n^3)$ as

$$\sum_{u \in V_G} \sum_{v \in V_H, k_u \leq l_v} k_u l_v(k_u + \log l_v) \leq \sum_{u \in V_G} k_u \sum_{v \in V_H} l_v(l_v + \log l_v) \leq n \cdot 2n^2 \in \mathcal{O}(n^3)$$

◀

Unrooted trees. We now consider the problem for unrooted trees. An immediate solution is to solve the rooted problem variant for all possible pairs of roots, i.e., by computing

$$\text{MCS}(G, H) := \max \{\text{MCS}_{\text{root}}(G^r, H^s) \mid r \in V(G), s \in V(H)\}. \tag{2}$$

Clearly, this yields the optimal solution in time $\mathcal{O}(n^5)$ with Proposition 1. Note that several recursive calls involve solving the same subproblem. Repeated computation can easily be avoided by means of a lookup table. Let $\text{Rt}(G^r) := \{G^r_u \mid u \in V(G)\}$ and $\text{Rt}(G) := \bigcup_{r \in V(G)} \text{Rt}(G^r)$. Note that we may uniquely associate the subtree G^r_u with G^p_u, where p is the parent of u in G^r. Hence, each rooted subtree $G^u_v \in \text{Rt}(G)$ either is the whole tree G with root $u = v$ or is the subtree rooted at v of some edge $uv \in E(G)$, where u is not contained in the subtree. Thus, $\text{Rt}(G) = \{G^u_v \mid v \in V(G) \wedge u \in N(v) \cup \{v\}\}$ is the set of all rooted subtrees of G. In total the subproblems defined by $\mathcal{S}(G, H) := \text{Rt}(G) \times \text{Rt}(H)$ have to be solved.

However, ensuring that each subproblem is solved only once does not allow to improve the bound on the running time, since $\mathcal{S}(G, H)$ still may contain a quadratic number of subproblems of linear size: Let G and H be two star graphs on n vertices, i.e., trees with all but one vertex of degree one. Each of the $(n-1)^2$ pairs of leaves can be selected as root pair and leads to a different subproblem of size $n - 1$.

We show that it is sufficient to consider only a subset of the subproblems to guarantee that an optimal solution is found. Let

$$\text{MCS}_{\text{fast}}(G^r, H) := \max \{\text{MCS}_{\text{root}}(G^r_u, H^s) \mid u \in V(G), s \in V(H)\}, \tag{3}$$

where $r \in V(G)$ is an arbitrary but fixed root of G. To compute Eq. (3), only the subproblems $\mathcal{S}_{\text{fast}}(G^r, H) := \text{Rt}(G^r) \times \text{Rt}(H) \subseteq \mathcal{S}(G, H)$ need to be solved.

▶ **Lemma 2.** *Let* MCS_{fast} *and* MCS *be defined as above and* $r \in V(G)$ *arbitrary but fixed, then* $\text{MCS}_{\text{fast}}(G^r, H) = \text{MCS}(G, H)$ *for all trees* G, H.

Proof. Let ϕ be an MCSI. If r is in the domain of ϕ, then $\omega(\phi) = \text{MCS}_{\text{root}}(G^r, H^{\phi(r)}) = \text{MCS}_{\text{fast}}(G^r, H)$. Otherwise the domain of ϕ is contained in the subtree rooted at one child of r. Let u be the unique vertex that is closest to r and mapped by ϕ. Then $\omega(\phi) = \text{MCS}_{\text{root}}(G^r_u, H^{\phi(u)}) = \text{MCS}_{\text{fast}}(G^r, H)$. ◀

Algorithm 1 implements this strategy, where the postorder traversal on G^r (line 2) ensures that the solutions to smaller subproblems are always available when required (line 9). The lookup table contains one entry for each subproblem in $\mathcal{S}_{\text{fast}}(G^r, H)$ and hence requires space $\mathcal{O}(n^2)$. Note that it is also possible to compute a concrete isomorphism from the MWMs associated with the computed optimal solution. The restriction of the considered subproblems allows to improve the bound on the running time.

▶ **Proposition 3.** *Algorithm 1 solves the maximum common subtree isomorphism problem for two trees* G *and* H *in time* $\mathcal{O}(n^4)$*, where* $n = |G| + |H|$.

```
Algorithm 1: Maximum Common Subtree Isomorphism
   Input  : Trees $G$ and $H$ under a weight function $\omega$
   Output : Weight of an MCSI between $G$ and $H$.
   Data   : Table $D(u, s, v)$ storing solutions $\mathrm{MCS}_{\mathrm{root}}(G^r_u, H^s_v)$ of subproblems.
 1 Select an arbitrary root vertex $r \in V_G$.
 2 foreach $u \in V_G$ in postorder traversal on $G^r$ do          ▷ All possible $G^r_u \in \mathrm{RT}(G^r)$
 3     $U \leftarrow C(u)$ in $G^r$
 4     foreach $v \in V_H$ do
 5         foreach $s \in N(v) \cup \{v\}$ do                     ▷ All possible $H^s_v \in \mathrm{RT}(H)$
 6             $V \leftarrow C(v)$ in $H^s$
 7             if $\omega(u, v) \neq -\infty$ then
 8                 foreach pair $(u', v') \in U \times V$ do
 9                     $w(u'v') \leftarrow \omega(uu', vv') + D(u', v, v')$
10                 $M \leftarrow$ MWM of the complete graph on $U \uplus V$ with weights $w$.
11                 $D(u, s, v) \leftarrow \omega(u, v) + W(M)$
12             else $D(u, s, v) \leftarrow -\infty$
13 return the maximum entry in $D$
```

Proof. According to Lemma 2 computing Eq. (3) yields the optimal solution and it suffices to solve the subproblems $\mathcal{S}_{\text{fast}}(G^r, H)$ as realized by Algorithm 1. Let k_u be the number of children of u in G^r_u, l^s_v the number of children of v in H^s, $s \in V(H)$, and $l_v = |N(v)|$. For all s we have $l^s_v \leq l_v$. Similar to Proposition 1 the subproblems $\mathcal{S}_{\text{fast}}(G, H)$ can be solved in a total time of

$$\mathcal{O}\left(\sum_{u \in V_G} \sum_{s \in V_H} \sum_{v \in V_H} (k_u l^s_v)(\min\{k_u, l^s_v\} + \log \max\{k_u, l^s_v\})\right) \subseteq \mathcal{O}\left(\sum_{s \in V_H} n^3\right) \subseteq \mathcal{O}\left(n^4\right).$$

◀

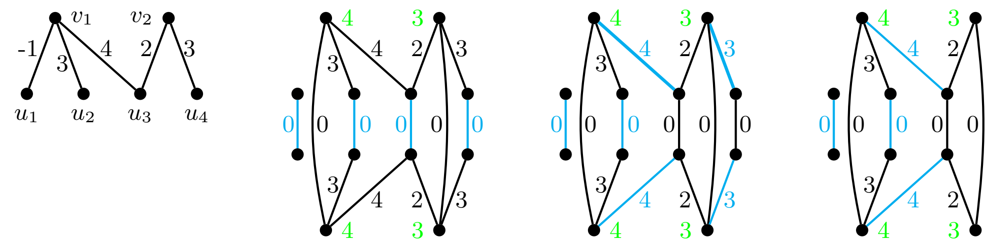
Further improvement of the running time is possible by no longer considering the MWM subroutine as a black box. We pursue this direction in the next section. Our findings there yield the following theorem.

▶ **Theorem 4.** *An MCSI between two unrooted trees G and H can be computed in time $\mathcal{O}(|G||H|(\min\{\Delta(G), \Delta(H)\} + \log \max\{\Delta(G), \Delta(H)\}))$.*

Proof. The MWM computations in Algorithm 1 are dominating, thus we obtain the above running time directly from Theorem 7 of the following section. ◀

4 Computing All Maximum Weight Matchings

In this section we improve the total time bound for solving all the matching instances arising in Algorithm 1. First, we provide a time bound to compute an MWM in a single bipartite graph $(V \uplus U, E)$, where possibly $|V| \neq |U|$. In the following, we exploit the fact that during the run of our algorithm, we get sets of "similar" bipartite graph instances. After computing an MWM on one graph in one of the sets, we can derive MWMs for all the other bipartite graphs in that set very efficiently. Finally, we provide an upper bound to compute an MWM in all the occurring bipartite graphs.



(a) Input graph B. **(b)** Reduced graph B'. **(c)** MWMs M', M. **(d)** B'_4 with M'_4.

Figure 2 Weighted bipartite graph B (a); reduced graph B' with initial duals in green (vertices without label have dual value 0) and initial matching M'' in blue (b); MWM M' of B' in blue, M of B in thick blue c; B'_4 with matching M'_4 in blue (d). - cf. proofs of Lemma 5 and Lemma 6.

Computing an MWM is closely related to finding an MWPM and there is extensive literature on both problems [8]. Gabow and Tarjan [10] describe a reduction to solve the MWM problem using any algorithm for MWPM, without altering the algorithm's asymptotic time bound, which we will make use of. For computing an MWPM, we use the well known Hungarian method, which has at most n iterations in its outer loop and a total running time of $\mathcal{O}(n^3)$ or $\mathcal{O}(n(m + n \log n))$ using Fibonacci heaps, where n and m denote the number of vertices and edges of the bipartite graph. We denote this algorithm by $\mathcal{A}_{\text{PM}}$.

The Hungarian method is a primal-dual algorithm. It starts with an empty matching and computes a new matching with one more edge in each iteration, maintaining a feasible dual solution of a primal linear program. The complementary slackness theorem ensures, that the obtained perfect matching after n iterations is a MWPM. Note, by using the reduction in [10], we always have at least one perfect matching.

▶ **Lemma 5.** *Let $B = (V \uplus U, E)$ be a bipartite graph with edge weights $w : E \to \mathbb{R}$. Let $k := |V|$, $l := |U|$, and $k \leq l$. An MWM M on B can be computed in time $\mathcal{O}(kl(k + \log l))$.*

Proof. Let $\{v_1, \ldots, v_k\} = V, \{u_1, \ldots, u_l\} = U$ be the two vertex sets of B. First, we remove all edges from B with negative edge weight, because they never contribute to an MWM. Then, we add a copy B^{C} of B to the graph. For each vertex $v \in V \uplus U$ we denote its copy v^{C} and for each edge $e \in E$ we denote its copy e^{C}. We then copy the edge weights, i.e., $w(e^{\text{C}}) := w(e)$ for each edge $e \in E$. Next we insert a new edge of weight 0 between each vertex $v \in V \uplus U$ and its copy v^{C}. This graph is called *reduced graph* B'. Figures 2a and b show an example of B and B'. An MWPM M' of B' yields an MWM M of B: $vu \in M \Leftrightarrow vu \in M'$ and $v \in V, u \in U$. This follows from the construction of B'.

In the following, we prove an upper time bound to compute M'. An initial feasible dual solution $d : V_{B'} \to \mathbb{R}$, i.e., $d(v) + d(u) \geq w(vu)$ for all edges $vu \in E_{B'}$, including l matching edges vu with $d(v) + d(u) = w(vu)$, is computed as follows: We set $d(u) = 0$ for all $u \in U$ and $d(v) := \max\{w(vu) \mid u \in U\}$ for all $v \in V$. Next, for each $v \in V \uplus U$ the vertex v^{C} obtains the dual value $d(v^{\text{C}}) := d(v)$. We define an initial matching $M'' := \{uu^{\text{C}} \mid u \in U\}$. Note, $d(u) + d(u^{\text{C}}) = 0 = w(uu^{\text{C}})$.

The dual solution d is feasible and can be computed in time $\mathcal{O}(kl)$. Let $n := |V_{B'}| = 2(k+l) \in \Theta(l)$ and $m := |E_{B'}| \leq 2kl+k+l \in \mathcal{O}(kl)$. Increasing the number of matching edges by one using a single iteration of $\mathcal{A}_{\text{PM}}$ is possible in time $\mathcal{O}(m + n \log n) = \mathcal{O}(l(k + \log l))$. To obtain an MWPM M' form M'' in B' we need to increase the number of matching edges by k, therefore the time to compute M' and thus M is $\mathcal{O}(kl(k + \log l))$. ◀

Algorithm 2: Computing MWMs on B and B_j, cf. Lemmas 5, 6

```
Input  : Bipartite graph $B = (V \uplus U, E), |U| \geq 2, U = \{u_1, u_2, \ldots\}$ with edge weights
         $w : E \to \mathbb{R}$
Output : MWMs $M, M_j$ on $B, B_j := G[V \uplus U \setminus \{u_j\}]$ for each $j \in [1..|U|]$.
if $|V| \leq |U|$ then                                          ▷ Compute MWM $M$ of $B$
    Let $B' := (V', E')$, where $V' := V \cup U \cup \{v^{\mathrm{C}} \mid v \in V \cup U\}$ and
    $E' := E \cup \{e^{\mathrm{C}} \mid e \in E\} \cup \{vv^{\mathrm{C}} \mid v \in V \cup U\}$.
    $w(e^{\mathrm{C}}) \leftarrow w(e)$ for all $e \in E$              ▷ Weights of additional edges
    $w(vv^{\mathrm{C}}) \leftarrow 0$ for all $v \in V \cup U$
    $d(u^{\mathrm{C}}) \leftarrow d(u) \leftarrow 0$ for all $u \in U$                  ▷ Dual values
    $d(v^{\mathrm{C}}) \leftarrow d(v) \leftarrow \max\{w(vu) \mid u \in U\}$ for all $v \in V$
    $M'' \leftarrow \{uu^{\mathrm{C}} \mid u \in U\}$                       ▷ Initial matching edges
    Starting with $M''$ and $d$, compute an MWPM $M'$ on $B'$ using $|V|$ iterations of $\mathcal{A}_{\mathrm{PM}}$
    $M \leftarrow \{vu \mid vu \in M', v \in V, u \in U\}$
else
    Exchange the vertices of $V$ and $U$.
    Compute $M$ as in lines 2 to 9 and exchange $V$ and $U$ back.
$d \leftarrow$ The dual values obtained while computing $M'$.
foreach $j \in [1..|U|]$ do                                    ▷ MWMs $M_j$ on $B_j$
    if $u_j$ is not matched by $M$ then
        $M_j \leftarrow M$
    else
        $B'_j \leftarrow B' \setminus \{u_j, u_j^{\mathrm{C}}\}$
        $M'_j \leftarrow M'$ without the matching edges incident to $u_j, u_j^{\mathrm{C}}$   ▷ Initial matching
        Compute an MWPM $M'_j$ on $B'_j$ using $d$ and a single iteration of $\mathcal{A}_{\mathrm{PM}}$.
        $M_j \leftarrow \{vu \mid vu \in M'_j, v \in V, u \in U\}$
```

▶ **Lemma 6.** *Let $B = (V \uplus U, E)$ be a weighted bipartite graph with $k := |V|, U = \{u_1, \ldots, u_l\}, l \geq 2$. Let $B_j := G[V \uplus U \setminus \{u_j\}]$ for each $j \in [1..l]$. Computing MWMs for all graphs $B, B_1, \ldots, B_l$ is possible in total time $\mathcal{O}(kl(\min\{k,l\} + \log \max\{k,l\}))$.*

Proof. According to Lemma 5 we obtain an MWM M of B in time $\mathcal{O}(kl(\min\{k,l\} + \log \max\{k,l\}))$. We compute an MWM on each B_j as follows: Let d be an optimal dual solution obtained while computing M' (on B', see proof of Lemma 5). If u_j is not matched by M, i.e., $u_j \notin e$ for all $e \in M$, then $M_j := M$ is an MWM of B_j. Otherwise let B'_j be the reduced graph as explained in the proof of Lemma 5. We obtain a feasible dual solution d_j on the bipartite graph B'_j by taking the dual values from d, i.e., $d_j(v) := d(v)$ for all $v \in V(B'_j)$. Note, we have $2(k + l)$ vertices in B', and exactly two less in B'_j, i.e., a perfect matching in B'_j consists of $k + l - 1$ matching edges.

We can derive an initial matching M'_j on B'_j with $k+l-2$ edges from M'; M'_j contains the matching edges that are not incident to the two removed vertices from B' to B'_j. Therefore only one more iteration of $\mathcal{A}_{\mathrm{PM}}$ is needed, which is possible in time $\mathcal{O}(\max\{k,l\}(\min\{k,l\} + \log \max\{k,l\}))$, cf. proof of Lemma 5. We then obtain M_j from M'_j as previously described. The complementary slackness conditions ensure M'_j and therefore M_j is of maximum weight. An example of M' and B'_j ($j = 4$) is shown in Figures 2c and d.

We need to compute an MWM different from M for at most $\min\{k,l\}$ of the l graphs $B_1, \ldots, B_l$, because at most k vertices of U are matched by M, cf. Figure 2c: only u_3

and u_4 of U are matched by M. Therefore the time bound to compute MWMs for all the graphs $B_1, \ldots, B_l$ is $\mathcal{O}(\min\{k,l\}\max\{k,l\}(\min\{k,l\} + \log\max\{k,l\})) = \mathcal{O}(kl(\min\{k,l\} + \log\max\{k,l\}))$. ◀

We call B and the graphs $B_j, j \in [1..l]$, a set of "similar" bipartite graph instances. Algorithm 2 shows how we compute an MWM for each graph in this set. Next, we apply Lemma 6 to Algorithm 1. For each pair $u \in V_G, v \in V_H$ of vertices, selected in line 2 and 4, respectively, the algorithm computes up to $|N(v)| + 1$ MWMs, cf. lines 5, 10. A close look at Algorithm 1 reveals this as a set of "similar" bipartite graph instances. The first graph B is obtained by selecting $s = v$ in line 5. The other graphs B_j are obtained by selecting all the vertices $s \in N(v)$. This observation allows to prove the following theorem.

▶ **Theorem 7.** *All the MWMs in Algorithm 1 can be computed in total time* $\mathcal{O}(kl(\min\{\Delta(G), \Delta(H)\} + \log\max\{\Delta(G), \Delta(H)\}))$*, where* $k = |G|$ *and* $l = |H|$*.*

Proof. For each pair $(v, u) \in V_G \times V_H$ we compute an MWM on each of the "similar" graphs, where $B = (C(v) \uplus N(u), E)$ and edge weights as determined by Eq. (1). Let $d_{\min} := \min\{\Delta(G), \Delta(H)\}$ and $d_{\max} := \max\{\Delta(G), \Delta(H)\}$. For all the pairs (v, u) we obtain a time complexity of

$$\begin{aligned}
&\mathcal{O}\left(\sum_v \sum_u \delta(v)\delta(u)(\min\{\delta(v), \delta(u)\} + \log\max\{\delta(v), \delta(u)\})\right)\\
\subseteq\ &\mathcal{O}\left(\sum_v \delta(v) \sum_u \delta(u)(d_{\min} + \log d_{\max})\right)\\
=\ &\mathcal{O}\left((d_{\min} + \log d_{\max}) \sum_v \delta(v) l\right)\\
=\ &\mathcal{O}((d_{\min} + \log d_{\max})kl).
\end{aligned}$$

◀

5 Lower Bounds on the Time Complexity and Optimality

Providing a tight lower bound on the time complexity of a problem is generally a non-trivial task. We obtain this for trees of bounded degree and reason why the existence of an algorithm with subcubic running time for unrestricted trees is unlikely. In order to solve MCST with an arbitrary weight function ω for two trees G and H, all values $\omega(u, v)$ for $u \in V(G)$ and $v \in V(H)$ must be considered. This directly leads the lower bound of $\Omega(|G||H|)$ for the time complexity of MCST. For trees of bounded degree our approach achieves running time $\mathcal{O}(|G||H|)$ according to Theorem 4 and, thus, has an optimal worst-case running time in the considered setting.

For unrestricted trees of order n our approach has a running time of $\mathcal{O}(n^3)$ according to Theorem 4. In the next paragraph we present a linear time reduction from the assignment problem to MCST, which preserves the time complexity. Therefore solving MCST in time $o(n^3)$ yields an algorithm to solve the assignment problem in time $o(n^3)$. The Hungarian method solves the assignment problem in $\mathcal{O}(n^3)$, which is the best known time bound for bipartite graphs with $\Theta(n^2)$ edges of unrestricted weight for more than 30 years.

Let $B = (U \uplus V, E, w)$ be a weighted bipartite graph on which we want to solve the assignment problem, i.e., to find an MWPM. We assume weights to be non-negative, which can be achieved by adding a sufficiently large constant to every edge weight to obtain an assignment problem that is equivalent w.r.t. the MWPMs. We construct a star graph G with center c and leaves U and another star graph H with center c' and leaves V. Let $n = |U| = |V|$ and $N = \max_{e\in E} w(e)$. We define ω such that $\omega(u, v) = w(uv) + nN$ for all $uv \in E$, $\omega(c, c') = nN$ and $\omega(u, v) = -\infty$ for all other pairs of vertices. For all pairs of edges we define $\omega(e, e') = 0$. Let ϕ be an MCSI between G and H w.r.t. w and $p := |\operatorname{dom}(\phi)|$. It directly follows from the construction that $M := \{uv \in E \mid \phi(u) = v\}$ is an MWM in B with $W(M) = \mathcal{W}(\phi) - pnN$. Furthermore, the incremented weights ensure that M is perfect, i.e., $p = n + 1$, whenever B admits a perfect matching. Therefore we obtain:

▶ **Proposition 8.** *Only if we can solve the assignment problem on a graph with n vertices and $\Theta(n^2)$ edges of unrestricted weight in time $o(n^3)$, we can solve MCST on two unrooted trees of order $\Theta(n)$ in time $o(n^3)$.*

6 Output-Sensitive Algorithms for Listing All Solutions

Algorithm 1 can easily be modified to not only output the weight of an MCSI, but also an associated isomorphism. Let $D(u, s, v)$ be a maximum entry in D. Then $\phi(u) = v$. Further mappings are defined by the matching edges occurring in Eq. (1). In the example of Figure 1d we obtain $\phi(c_1) = d_1$ and $\phi(c_2) = d_3$. Since in general there is no single unique MCSI, it is of interest to find and list all of them. In this section we show how our techniques can be combined with the enumeration algorithm from [7], which lists all the different MCSIs of two trees exactly once. We obtain the best known time bound for listing all solutions by an improved analysis.

Since the number of MCSIs is not polynomially bounded in the size of the input trees, we cannot expect polynomial running time. An algorithm is said to be *output-sensitive* if its running time depends on the size of the output in addition to the size of the input.

The basic idea to enumerate all MCSIs is to first compute the weight of an MCSI. Then for each maximum table entry $D(u, v, v), u \in V_G, v \in V_H$, all the different rooted MCSIs on the rooted subtrees G^r_u, H^v_v are listed. Note, we omit maximum table entries $D(u, s, v)$, where $s \neq v$. We do this, because every MCSI of G^r_u, H^s_v is also an MCSI of G^r_u, H^v_v. As an example let u be the root of G in Figure 1. Then $D(u, v, v) = D(u, s, v) = 7$. For both table entries we obtain the same MCSI ϕ with $\phi(u) = v, \phi(r) = d_1, \phi(c_1) = d_2, \phi(c_2) = d_3, \ldots$.

We enumerate the MCSIs on a pair of rooted subtrees by enumerating all MWMs of the associated bipartite graphs of Eq. (1) and then expanding ϕ recursively along all the different MWMs of the mapped children. For the problem depicted in Figure 1c there are two different MWMs: $M_1 = \{c_1d_1, c_2d_3\}$ and $M_2 = \{c_1d_2, c_2d_3\}$. Therefore we first expand along M_1 as explained in the first paragraph of this section and then along M_2. We do this recursively for each occurring matching instance. The enumerated isomorphisms of each maximum entry are pairwise different, based on the different MWMs. They are also pairwise different between two different maximum entries. The proof of the latter claim is similar to the proof of Lemma 2. Thus we do not enumerate an MCSI twice. Further we do not omit an MCSI, because we consider all necessary maximum table entries and their rooted subtrees, as well as all possible expansions along the MWMs.

Note, the enumeration algorithm of [7] uses a somewhat different table to store maximum solutions. The basic idea to list all solutions is the same. For trees of sizes $k := |G|$ and $l := |H|$, $k \le l$, their enumeration algorithm requires total time $\mathcal{O}(k^2l^4 + Tl^2)$, where T is the number of different MCSIs. The $\mathcal{O}(k^2l^4)$ term of the running time is caused by computing the weight of an MCSI in time $\mathcal{O}(kl^4)$ and repeated deletions of single edges in one tree and recalculations of the weight of an MCSI to avoid outputting an MCSI twice. We have improved the time bound to compute the weight of an MCSI, cf. Theorem 4. Therefore we can improve the $\mathcal{O}(k^2l^4)$ term to $\mathcal{O}(kl(\min\{\Delta(G), \Delta(H)\} + \log \max\{\Delta(G), \Delta(H)\}))$.

The $\mathcal{O}(Tl^2)$ term in the original running time is caused by the enumeration of MWMs. For each MCSI ϕ several MWMs have to be enumerated, let this number be m_ϕ. The time to do this can be bounded by $\mathcal{O}(l^2)$, when using a variant of the enumeration algorithm for perfect matchings presented in [21]. The running time follows from the fact, that for each MWM two depth first searches (DFS) in a directed subgraph of B', cf. Figure 2, are computed. The running time of DFS is linear in the number of edges and vertices. Let k_i, l_i be the sizes of the disjoint vertex sets of the i-th bipartite graph, on which we enumerate the MWMs, $i \in [1..m_\phi]$. Then $\sum_i k_i \leq k$ and $\sum_i l_i \leq l$, because all the vertices in all the m_ϕ bipartite graphs are pairwise disjoint. The running time of DFS in the directed subgraphs of the i-th bipartite graph is $\mathcal{O}(k_il_i)$, cf. Figure 2b or d. For all m_ϕ DFS runs we have $\sum_i k_il_i \leq \sum_i k_i\Delta(H) \leq k\Delta(H)$ as well as $\sum_i k_il_i \leq \sum_i \Delta(G)l_i \leq \Delta(G)l$. Hence, the time to enumerate ϕ is bounded by $\mathcal{O}(\min\{k\Delta(H), \Delta(G)l\})$.

Both improvements combined together, the initial computation of the weight of an MCSI and the MWM enumeration, improve the enumeration time from $\mathcal{O}(n^6 + Tn^2)$ to $\mathcal{O}(n^3 + Tn \min\{\Delta(G), \Delta(H)\})$. More precisely we obtain the following theorem.

▶ **Theorem 9.** *Enumerating all MCSIs of two unrooted trees G and H is possible in time $\mathcal{O}(\,|G|\,|H|\,(\,\min\{\Delta(G), \Delta(H)\} + \log \max\{\Delta(G), \Delta(H)\}\,) + T(\,\min\{|G|\Delta(H), \Delta(G)|H|\}\,)\,)$, where T is the number of different MCSIs.*

7 Experimental Comparison

In this section we experimentally evaluate the running time of our approach (DKM) on synthetic and real-world instances. We compare our algorithm to the approach of [18] which also solves MCST when the input graphs are trees. The corrected analysis of the approach yields a running time of $\mathcal{O}(n^4)$, which aligns better with our experimental findings of $\Omega(n^5)$. The implementation was provided by the authors as part of the FOG package.[2] Both algorithms were implemented in C++ and compiled with GCC v.4.8.4. Running times were measured on an Intel Core i7-3770 CPU with 16 GB of RAM using a single core only. We generated random trees by iteratively adding edges to a randomly chosen vertex and averaged over 40 to 100 pairs of instances depending on their size. The weight function ω was set to 1 for each pair of vertices and edges, i.e., we compute isomorphisms of maximum size. This matches the setting in FOG.

Table 1 summarizes our results and we observe that the running time of our approach aligns with our theoretical analysis. In comparison, FOG's running time is much higher and increases to a larger extent with the input size. The running times of both algorithms show a low standard deviation for random trees, cf. Tables 1a, b. Table 1c shows the running time in star graphs, which are worst-case examples for some approaches, see Sec. 3. Our theoretical proven cubic running time matches the experimental results, while FOG's running time increases drastically. Table 1d summarizes the computation time under different weight functions. We defined ω such that different labels are simulated, i.e., vertices and edges with different labels have weight $-\infty$, which again matches FOG's setting. Both algorithms clearly benefit from the fact that less MWMs have to be computed. The results on random trees are also shown in Figure 3.

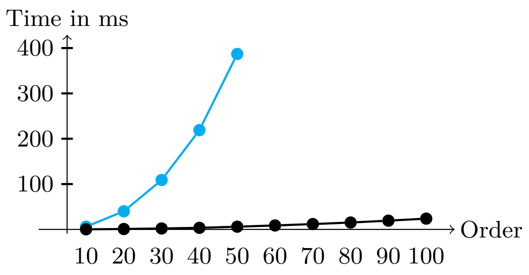

Figure 3 Average running time in ms (y-axis) for MCSI computation on random trees of order n (x-axis). Black = Our implementation (DKM). Blue = FOG implementation.

From a chemical database of thousands of molecules[3] we extracted 100 pairs of graphs with block-cut trees (BC-trees) consisting of more than 40 vertices. BC-trees are a representation of graphs, where each maximal biconnected component is represented by a B-vertex. If two such components share a vertex, the corresponding B-vertices are connected through a C-vertex representing this shared vertex. The running time for MCST on BC-trees is an important factor for the total running time of MCS algorithms for outerplanar and series-parallel graphs like [2, 13, 18]. The average running time of our algorithm was 11.2 ms, compared to FOG's 481.3 ms. The speedup factor ranges from 24 to 59, with an average of 43. This indicates that the above mentioned approaches could greatly benefit from the techniques presented in this paper.

8 Conclusions

We have presented a novel algorithm for MCST which (i) considers only the subproblems required to guarantee that an optimal solution is found and (ii) solves groups of related matching instances efficiently in one pass. Rigorous analysis shows that the approach achieves cubic time in general trees and quadratic time in trees of bounded degree. Our analysis of the

[3] NCI Open Database, GI50, `http://cactus.nci.nih.gov`

problem complexity reveals that there is only little room for possible further improvements. The practical efficiency is documented by an experimental comparison.

If the weight function is restricted to integers of a bounded value, scaling approaches [8] to the corresponding matching problems become applicable. It remains future work to improve the running time for this case.

Abstract

Vertex deletion problems ask whether it is possible to delete at most k vertices from a graph so that the resulting graph belongs to a specified graph class. Over the past years, the parameterized complexity of vertex deletion to a plethora of graph classes has been systematically researched. Here we present the first single-exponential fixed-parameter algorithm for vertex deletion to distance-hereditary graphs, a well-studied graph class which is particularly important in the context of vertex deletion due to its connection to the graph parameter rank-width. We complement our result with matching asymptotic lower bounds based on the exponential time hypothesis.

1 Introduction

Vertex deletion problems include some of the best studied NP-hard problems in theoretical computer science, including Vertex Cover or Feedback Vertex Set. In general, the problem asks whether it is possible to delete at most k vertices from a graph so that the resulting graph belongs to a specified graph class. While these problems are studied in a variety of contexts, they are of special importance for the parameterized complexity paradigm [11, 9], which measures the performance of algorithms not only with respect to the input size but also with respect to an additional numerical parameter. Vertex deletion problems allow a highly natural choice of the parameter (specifically, k), and many vertex deletion problems are known to admit so-called *single-exponential fixed-parameter algorithms*, which are algorithms running in time $\mathcal{O}(c^k \cdot n^{\mathcal{O}(1)})$ for input size n and some constant c.

Over the past years, the parameterized complexity of vertex deletion to a plethora of graph classes has been systematically researched. However, there still remain a few important classes where the existence of a single-exponential fixed-parameter algorithm remains open. One such class has, until now, been the class of *distance-hereditary graphs* [17] (also called *completely separable graphs* [15]). Distance-hereditary graphs have several equivalent

* The authors acknowledge support by ERC Starting Grant PARAMTIGHT (No. 280152) and the Austrian Science Fund (FWF, projects P26696 and W1255-N23). Robert Ganian is also affiliated with FI MU, Brno, Czech Republic.

characterizations; for instance, they are the graphs where every induced path is a shortest path. But perhaps the main reason why distance-hereditary graphs are particularly important in the context of vertex deletion problems is their connection to the structural parameter *rank-width* [24, 23]. While TREEWIDTH-t VERTEX DELETION[1] is known to admit a single-exponential fixed-parameter algorithm for every fixed t [12, 22], the existence of such algorithms for the analogous RANK-WIDTH-t VERTEX DELETION is a challenging open problem. Since distance-hereditary graphs are exactly the graphs of rank-width 1 [23], a single-exponential fixed-parameter algorithm for DISTANCE-HEREDITARY VERTEX DELETION represents the first step towards handling RANK-WIDTH-t VERTEX DELETION.

DISTANCE-HEREDITARY VERTEX DELETION
Instance : A graph G and an integer k.
Parameter : k.
Task : Is there a vertex set $Q \subseteq V(G)$ with $|Q| \leq k$ such that $G-Q$ is distance-hereditary?

The main result of this paper is an $\mathcal{O}(37^k \cdot |V(G)|^7(|V(G)| + |E(G)|))$-time algorithm for DISTANCE-HEREDITARY VERTEX DELETION, solving an open problem of Kanté, Kim, Kwon, and Paul [20]. The core of our approach exploits two distinct characterizations of distance-hereditary graphs: one by forbidden induced subgraphs (obstructions), and the other by admitting a special kind of split decomposition [7].

The algorithm can be conceptually divided into three parts. First, we use the well-known iterative compression technique [25] to reduce the problem to the easier DISJOINT DISTANCE-HEREDITARY VERTEX DELETION, where we assume that the instance additionally contains a certain form of advice to aid us in our computation. Specifically, this advice is a vertex deletion set S to distance-hereditary graphs which is disjoint from and slightly larger than the desired solution. Then we exhaustively apply two branching rules to simplify the given instance of DISJOINT DISTANCE-HEREDITARY VERTEX DELETION. At a high level, these branching rules allow us to assume that the resulting instance contains no small obstructions and furthermore that certain connectivity conditions hold on $G[S]$. Lastly, we compute the split decomposition of $G - S$ and exploit the properties of our instance G guaranteed by branching to prune the decomposition. In particular, we show that the connectivity conditions and non-existence of small obstructions mean that S must interact with the split decomposition of $G - S$ in a special way, and this allows us to identify irrelevant vertices in $G - S$. This is by far the most technically challenging part of the algorithm.

A more detailed explanation of our algorithm is provided in Section 3, after the definition of required notions. We complement this result with an algorithmic lower bound which rules out a subexponential fixed-parameter algorithm for DISTANCE-HEREDITARY VERTEX DELETION under well-established complexity assumptions.

The set of induced subgraph obstructions for distance-hereditary graphs consists of three small graphs, and induced cycles of length at least 5. We remark that Heggernes et al. [16] showed that the problem asking whether it is possible to delete k vertices so that the resulting graph has no induced cycles of length at least 5 is W[2]-hard. Therefore, one cannot simply obtain a single-exponential fixed-parameter algorithm for DISTANCE-HEREDITARY VERTEX DELETION using the problem of hitting induced cycles of length at least 5.

The paper is organized as follows. Section 2 contains the necessary preliminaries and notions required for our results. In Section 3, we set the stage for the process of simplifying

[1] TREEWIDTH-t VERTEX DELETION asks whether it is possible to delete k vertices so that the resulting graph has treewidth at most t.

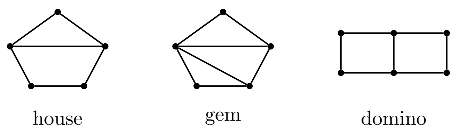

Figure 1 Small DH obstructions which are not cycles.

the split decomposition, which entails the definition of Disjoint Distance-Hereditary Vertex Deletion, introduction of our branching rules, and a few technical lemmas which will be useful throughout the later sections. Section 4 then introduces and proves the safeness of 8 polynomial-time reduction rules; crucially, the exhaustive application of these rules guarantees that the resulting instance will have a certain "inseparability" property. In Section 5, we introduce and prove the safeness of our final reduction rule using this inseparability property. Finally, the proof of our main result as well as the corresponding lower bound are presented in Section 6.

2 Preliminaries

For a graph G, let $V(G)$ and $E(G)$ denote the vertex set and the edge set of G, respectively. For $S \subseteq V(G)$, let $G[S]$ denote the subgraph of G induced on S. For $v \in V(G)$ and $S \subseteq V(G)$, let $G - v$ be the graph obtained from G by removing v, and let $G - S$ be the graph obtained by removing all vertices in S. For $v \in V(G)$, the set of neighbors of v in G is denoted by $N_G(v)$. For $A \subseteq V(G)$, let $N_G(A)$ denote the set of all vertices in $G - A$ that have a neighbor in A. The *length* of a path is the number of edges on the path. For $v \in V(G)$ and a subgraph H of $G - v$, we say v is adjacent to H if it has a neighbor in H.

Two vertices v, w in a graph G are called *twins* if they have the same set of neighbors on $V(G) \setminus \{v, w\}$. For two vertex sets A and B, we say that

- A is *complete* to B if for every $a \in A$, $b \in B$, a is adjacent to b,
- A is *anti-complete* to B if for every $a \in A$, $b \in B$, a is not adjacent to b.

2.1 Distance-Hereditary Graphs

A graph G is called *distance-hereditary* if for every connected induced subgraph H of G and every $v, w \in V(H)$, the distance between v and w in H is the same as the distance between v and w in G. This graph class was first introduced by Howorka [17], and deeply studied by Bandelt and Mulder [3].

The house, the gem, the domino graphs are depicted in Figure 1. A graph isomorphic to one of the house, the gem, the domino, and induced cycles of length at least 5 will be called a *distance-hereditary obstruction* or shortly a *DH obstruction.* A DH obstruction with at most 6 vertices will be called a *small DH obstruction.* Note that every DH obstruction does not contain any twins.

It is known that distance-hereditary graphs are precisely the graphs not containing any DH obstruction as an induced subgraph [3]. The following lemma will be used to find DH obstructions later on.

▶ **Lemma 1** (Kantè, Kim, Kwon, and Paul [20]). *Let G be a graph obtained from an induced path of length at least 3 by adding a vertex v adjacent to its end vertices where v may be adjacent to some internal vertices of the path. Then G has a DH obstruction containing v.*

In particular, if the given path has length at most 4*, then* G *has a small DH obstruction containing* v*.*

2.2 Split decompositions

We follow the notations in [4]. A *split* of a connected graph G is a vertex partition (X, Y) of G such that $|X| \geq 2, |Y| \geq 2$, and $N_G(Y)$ is complete to $N_G(X)$. Splits are also called *1-joins*, or simply *joins* [13]. A connected graph G is called a *prime graph* if $|V(G)| \geq 5$ and it has no split.

A connected graph D with a distinguished set of edges $M(D)$ is called a *marked graph* if the edges in $M(D)$ form a matching and each edge in $M(D)$ is a cut edge. An edge in $M(D)$ is called a *marked edge*, and every other edge is called an *unmarked edge*. A vertex incident with a marked edge is called a *marked vertex*, and every other vertex is called an *unmarked vertex*. Each connected component of $D - M(D)$ is called a *bag* of D.

When G admits a split (X, Y), we construct a marked graph D on the vertex set $V(G) \cup \{x', y'\}$ such that

- for vertices x, y with $\{x, y\} \subseteq X$ or $\{x, y\} \subseteq Y$, $xy \in E(G)$ if and only if $xy \in E(D)$,
- $x'y'$ is a new marked edge,
- X is anti-complete to Y,
- $\{x'\}$ is complete to $N_G(Y) \cap X$ and $\{y'\}$ is complete to $N_G(X) \cap Y$ (with unmarked edges).

The marked graph D is called a *simple decomposition of* G. A *split decomposition* of a connected graph G is a marked graph D defined inductively to be either G or a marked graph defined from a split decomposition D' of G by replacing a connected component H of $D' - M(D')$ with a simple decomposition of H. See Figure 2 for an example of a split decomposition. We note that when D is a split decomposition of a graph G and u, v are two vertices in G, $uv \in E(G)$ if and only if there is a path from u to v in D where its first and last edges are unmarked, and an unmarked edge and a marked edge alternatively appear in the path [1, Lemma 2].

Naturally, we can define a reverse operation of decomposing into a simple decomposition; for a marked edge xy of a split decomposition D, *recomposing* xy is the operation of removing two vertices x and y and making $N_D(x) \setminus \{y\}$ complete to $N_D(y) \setminus \{x\}$ with unmarked edges. It is not hard to observe that if D is a split decomposition of G, then G can be obtained from D by recomposing all marked edges.

Note that there are many ways of decomposing a complete graph or a star, because every its non-trivial vertex partition is a split. Cunningham and Edmonds [8] developed a canonical way to decompose a graph into a split decomposition by not allowing to decompose a bag which is a star or a complete graph. A split decomposition D of G is called a *canonical split decomposition* if each bag of D is either a prime graph, a star, or a complete graph, and D cannot be obtained from a split decomposition with the same property by recomposing a marked edge. It is not hard to observe that every canonical split decomposition has no marked edge linking two complete bags, and no marked edge linking a leaf of a star bag and the center of another star bag [4]. Furthermore, for each pair of twins a, b in G, it holds that a, b must both be located in the same bag of the canonical split decomposition.

▶ **Theorem 2** (Cunningham and Edmonds [8])**.** *Every connected graph has a unique canonical split decomposition, up to isomorphism.*

▶ **Theorem 3** (Dahlhaus [10])**.** *The canonical split decomposition of a graph* G *can be computed in time* $\mathcal{O}(|V(G)| + |E(G)|)$*.*

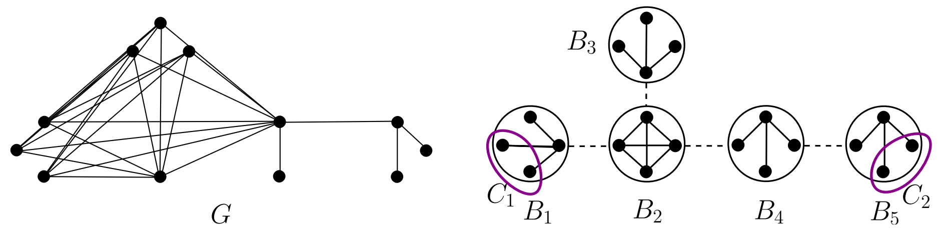

Figure 2 A graph G and its canonical split decomposition. Marked edges are represented by dashed edges, and bags are indicated by circles. Note that path$(B_1, B_5) = \{B_1, B_2, B_4, B_5\}$, bags B_4, B_5 are (C_1, C_2)-separator bags, and B_4 is a (B_1, B_5)-separator bag.

We can now give the second characterization of distance-hereditary graphs that is crucial for our results. For convenience, we call a bag a *star bag* or a *complete bag* if it is a star or a complete graph, respectively.

▶ **Theorem 4** (Bouchet [4]). *A graph is a distance-hereditary graph if and only if every bag in its canonical split decomposition is either a star bag or a complete bag.*

We will later on also need a little bit of additional notation related to split decompositions. Let D be a canonical split decomposition. For two distinct bags B_1 and B_2, we denote by comp(B_1, B_2) the connected component of $D - V(B_1)$ containing B_2. Technically, when $B_1 = B_2$, we define comp(B_1, B_2) to be the empty set. For two bags B_1 and B_2, we denote by path(B_1, B_2) the set of all bags containing a vertex in a shortest path from B_1 to B_2 in D. Note that path(B_1, B_2) contains B_1 and B_2. See Figure 2 for an example.

Let C_1, C_2 be two disjoint vertex subsets of D such that each C_1, C_2 is a set of unmarked vertices contained in (not necessarily distinct) bags B_1, B_2, respectively. A bag B is called *a* (C_1, C_2)*-separator bag* if B is a star bag contained in path(B_1, B_2) whose center is adjacent to neither comp(B, B_1) nor comp(B, B_2). We remark that B can be B_i for some $i \in \{1, 2\}$, and especially when $B_1 = B_2$ and it is a star bag and each C_i consists of leaves of B, B_1 is a (C_1, C_2)-separator bag. For convenience, we also say that a bag B is *a* (B_1, B_2)*-separator bag* if B is a star bag contained in path$(B_1, B_2) \setminus \{B_1, B_2\}$ whose center is adjacent to neither comp(B, B_1) nor comp(B, B_2). For this notation, B cannot be B_1 nor B_2. It is not hard to check that the length of the shortest path from C_1 to C_2 in the original graph is exactly the same as one plus the number of (C_1, C_2)-separator bags.

3 Setting the Stage

We begin by applying the *iterative compression technique* [25]. This technique allows us to transform our problem to a simpler problem called DISJOINT DISTANCE-HEREDITARY VERTEX DELETION. Our goal for the majority of the paper will be to obtain a single-exponential fixed-parameter algorithm for DISJOINT DISTANCE-HEREDITARY VERTEX DELETION; this is then used to obtain the sought after algorithm for DISTANCE-HEREDITARY VERTEX DELETION in Section 6.

DISJOINT DISTANCE-HEREDITARY VERTEX DELETION
Instance : A graph G, an integer k, and $S \subseteq V(G)$ with $|S| \leq k+1$ such that $G - S$ is distance-hereditary.
Parameter : k.
Task : Is there $Q \subseteq V(G) \setminus S$ with $|Q| \leq k$ such that $G - Q$ is distance-hereditary?

We will denote instances of Disjoint Distance-Hereditary Vertex Deletion as a tuple (G, S, k). By Theorem 4, every connected component of $G - S$ admits a canonical split decomposition whose bags are either a star or a complete graph.

Before explaining the general approach for solving Disjoint Distance-Hereditary Vertex Deletion, it will be useful to introduce a few definitions. Since the canonical split decomposition guaranteed by Theorem 4 only helps us classify twins in $G - S$ and not in G, we explicitly define an equivalence $\sim$ on the vertices of $G - S$ which allows us to classify twins in G: for two vertices $u, v \in V(G - S)$, $u \sim v$ iff they are twins in G.

We denote by $\mathbf{tc}(G - S)$ the set of equivalence classes of $\sim$ on $V(G - S)$, and each individual equivalence class will be called a *twin class* in $G - S$. We can observe that if $U \in \mathbf{tc}(G - S)$ lies in a single connected component of $G - S$, then U must be contained in precisely one bag of the split decomposition of this connected component of $G - S$, as U is a set of twins in $G - S$ as well. A twin class is *S-attached* if it has a neighbor in S, and *non-S-attached* if it has no neighbors in S. Similarly, we say that a bag in the canonical split decomposition of $G - S$ is *S-attached* if it has a neighbor in S, and *non-S-attached* otherwise.

3.1 Overview of the Approach

Now that we have introduced the required terminology, we can provide a high-level overview of our approach for solving Disjoint Distance-Hereditary Vertex Deletion.

1. We exhaustively apply the branching rules described in Section 3.2. Branching rules will be applied when G has a small subset $X \subseteq V(G - S)$ such that $S \cup X$ induces a DH obstruction, or there is a small connected subset $X \subseteq V(G - S)$ such that adding X to S decreases the number of connected components in $G[S]$.
2. We exhaustively apply the initial reduction rules described in Section 4. Each of these rules runs in polynomial time, finds a part in the canonical split decomposition of a connected component of $G - S$ that can be simplified, and modifies the decomposition. Each application of a reduction rule from Section 4 either reduces the number of vertices in $G - S$ or reduces the total number of bags in the canonical split decomposition (of a connected component of $G - S$). It is well known that the total number of bags in the canonical split decomposition of a graph is linear in the number of vertices. Therefore, the total number of applications of these initial reduction rules will also be at most linear in the number of vertices.
3. We say that G and the canonical split decompositions of $G - S$ are *reduced* if the branching rules in Section 3.2 and reduction rules in Section 4 cannot be applied anymore. We will obtain the following simple structure of the decompositions in the reduced instance:
   - Each canonical split decomposition D of a connected component of $G - S$ contains at least two distinct S-attached twin classes (Reduction Rule 1).
   - Each bag contains at most one S-attached twin class (Reduction Rule 3).
   - When B is a bag and D' is a connected component of $D - V(B)$ containing no bags having a neighbor in S, D' consists of one bag and B is a star bag whose center is adjacent to D' (Lemma 8).
   - When B is a bag and D' is a connected component of $D - V(B)$ such that D' contains exactly one S-attached bag B', there is no (B', B)-separator bag (Lemma 10).
4. We choose a canonical split decomposition D of a connected component of $G - S$ and assign any bag as a root bag of D. We choose a bag farthest from the root bag such that there are two descendant bags having S-attached twin classes C_1 and C_2, respectively. Then the length of every shortest path from C_1 to C_2 in $G - S$ is at most 2, and we

introduce a special polynomial-time reduction rule in Section 5 which simplifies this configuration.

Whenever we introduce a new rule, we need to show that it is *safe*; for branching rules this means that there exists at least one subinstance resulting from the rule which is a YES-instance iff the original graph was a YES-instance, while for reduction rules this means that the application of the rule preserves the property of being a YES-instance.

A vertex v in $G - S$ is called *irrelevant* if (G, S, k) is a YES-instance if and only if $(G - v, S, k)$ is a YES-instance. We will be identifying and removing irrelevant vertices in several of our reduction rules. When removing a vertex v from $G - S$, it is easy to modify the canonical split decomposition containing v, and thus it is not necessary to recompute the canonical split decomposition of the resulting graph from scratch [14].

3.2 Branching Rules

We state our two branching rules below.

▶ Branching Rule 1. For every vertex subset X of $G - S$ with $|X| \leq 5$, if $G[S \cup X]$ is not distance-hereditary, then we remove one of the vertices in X, and reduce k by 1.

▶ Branching Rule 2. For every vertex subset X of $G - S$ with $|X| \leq 5$ such that $G[X]$ is connected and the set $N_G(X) \cap S$ is not contained in a connected component of $G[S]$, then we either remove one of the vertices in X and reduce k by 1, or put all of them into S (which reduces the number of connected components of $G[S]$).

The safeness of Branching Rules 1 and 2 are clear, and these rules can be performed in polynomial time. The exhaustive application of these branching rules guarantees the following structure of the instance.

▶ **Lemma 5.** *Let (G, S, k) be an instance reduced under Branching Rules 1 and 2.*

1. *G has no small DH obstructions.*
2. *Let $v \in V(G - S)$. For every two vertices $x, y \in N_G(v) \cap S$, they are contained in the same connected component of $G[S]$ and there is no induced path of length at least 3 from x to y in $G[S]$. Specifically, if $xy \notin E(G)$, then there is an induced path xpy for some $p \in S$.*
3. *There is no induced path $v_1 \cdots v_5$ of length 4 in $G - S$ where v_1 and v_5 have neighbors in S but v_2 and v_4 have no neighbors in S.*
4. *There is no induced path $v_1 \cdots v_4$ of length 3 in $G - S$ where v_1 and v_4 have neighbors on S but v_2 has no neighbors on S.*

Lemma 5, and especially point (2) in the lemma, is used in many parts of our proofs. Since we will apply the branching rules exhaustively at the beginning and also after each new application of a reduction rule, these properties will be implicitly assumed to hold in subsequent sections.

4 Reduction Rules in Split Decompositions

In this section, we assume that the given instance (G, S, k) is reduced under Branching Rules 1 and 2. The reduction rules introduced here either remove some irrelevant vertex, or move some vertex into S, or reduce the number of bags in the decomposition by modifying the instance into an equivalent instance. After we apply any of these reduction rules, we will run the two branching rules from Section 3 again.

Before we move on to the reduction rules themselves, we introduce a generic way of finding an irrelevant vertex which will be used in many reduction rules. For a vertex v in $G - S$ and an induced cycle H of length at least 5 in G containing a vertex v and two neighbors w, z of v in H, a vertex v' in S is called a *bad vertex* for H and v if v' is adjacent to w and z. If such a vertex v' exists, it is clear that v' is not contained in H because $vwv'zv$ is a cycle of length 4. More importantly, since $H - v$ is an induced path of length at least 3 from w to z and v' is adjacent to both of its endpoints, by Lemma 1, $G[(V(H) \setminus \{v\}) \cup \{v'\}]$ contains a DH obstruction. This implies that one of the vertices in $V(H) \setminus \{v\}$ must be contained in every solution (note that $v' \in S$ and so v' itself cannot be part of a solution). This property results in the following two lemmas.

▶ **Lemma 6.** *Let (G, S, k) be an instance reduced under Branching Rule 1. Let v be a vertex in $G - S$ such that for every induced cycle H of length at least 7 containing v, there is a bad vertex for H and v. Then v is irrelevant.*

▶ **Lemma 7.** *Let (G, S, k) be an instance reduced under Branching Rules 1 and 2. Let v be a vertex in $G - S$ and H be an induced cycle of length at least 7 containing v, and let w, z be the two neighbors of v in H. If $w, z \in S$, then there is a bad vertex for H and v, and thus $G[(V(H) \setminus \{v\}) \cup S]$ contains a DH obstruction.*

We are now ready to start with our reduction rules. For the remainder of this section, let us fix a canonical split decomposition D of a connected component of $G - S$.

▶ Reduction Rule 1. If D has at most one S-attached twin class, then we remove all unmarked vertices of D from G.

▶ Reduction Rule 2. Let B be a star bag whose center is unmarked, and let v be a leaf unmarked vertex in B. If v has no neighbor in S, then we remove v. If v has a neighbor in S, then we move v into S.

We remark that when we move v into S in Reduction Rule 2, $k + cc(G[S])$ does not increase. Next, we introduce an important rule which reduces the number of S-attached twin classes in each bag.

▶ Reduction Rule 3. Let B be either a complete bag or a star bag whose center is marked. Let C_1, C_2 be two distinct S-attached twin classes in B such that $(N_G(C_1) \setminus N_G(C_2)) \cap S$ is non-empty. Then we remove C_1.

We proceed by introducing a reduction rule which sequentially arranges non-S-attached bags in a canonical split decomposition. The number of bags in D is strictly reduced when applying Reduction Rule 4.

▶ Reduction Rule 4. Let B be a leaf bag and B' be the neighbor bag of B.
1. If B is a complete bag having exactly one twin class and B' is a star bag whose leaf is adjacent to B, then we transform B into a star whose center is adjacent to B', and recompose the marked edge connecting B and B'.
2. If B is a star bag having exactly one twin class, the center of B is adjacent to B', and B' is a complete bag, then we transform B into a complete graph, and recompose the marked edge connecting B and B'.

The next reduction rule allows us to remove a non-S-attached twin class under certain conditions (see Figure 3).

▶ Reduction Rule 5. Let B_1 be a leaf bag containing at most one S-attached twin class and B_2 be a bag distinct from B_1 such that

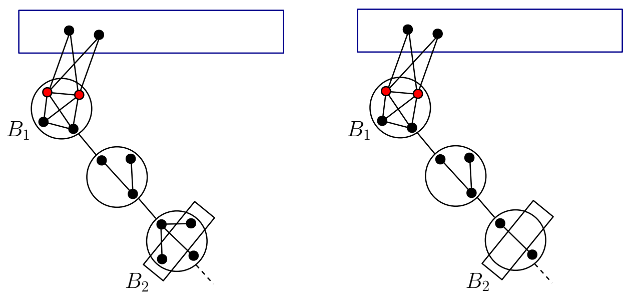

Figure 3 Reduction Rule 5.

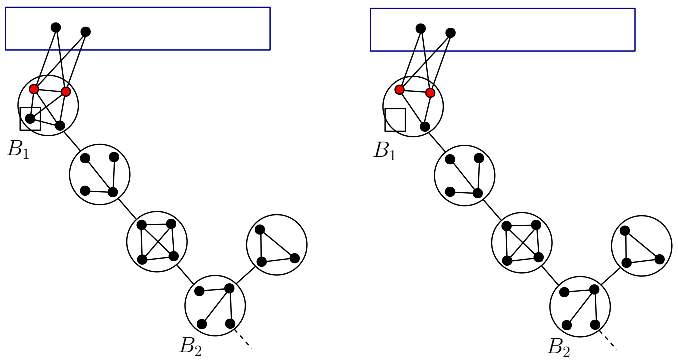

Figure 4 Reduction Rule 6.

- every bag in path$(B_1, B_2) \setminus \{B_1, B_2\}$ is non-S-attached, not a (B_1, B_2)-separator bag, and has exactly two neighbor bags, and
- B_2 is a star bag whose center is adjacent to comp(B_2, B_1).

If B_2 contains a non-S-attached twin class C, then we remove C.

We can now show that after the exhaustive application of the reduction rules introduced up to this point, every connected component of $D - V(B)$ containing no S-attached bags is "simple", as formalized in the next lemma.

▶ **Lemma 8.** *Let D be the canonical split decomposition of a connected component of $G - S$ reduced under Reduction Rules 1–5. Let B be a bag and D' be a connected component of $D - V(B)$ containing no S-attached bags. Then D' consists of one bag and B is a star bag whose center is adjacent to D'.*

Next, we introduce some rules simplifying connected components of $D - V(B)$ for some bag B containing one S-attached twin class. The following rule is depicted in Figure 4.

▶ Reduction Rule 6. Let B_1 be a leaf bag having exactly one S-attached twin class and B_2 be a bag distinct from B_1 such that

- B_1 is not a star whose leaf is adjacent to a neighboring bag,
- every bag in path$(B_1, B_2) \setminus \{B_1, B_2\}$ is non-S-attached, not a (B_1, B_2)-separator bag and has exactly two neighbor bags, and
- B_2 is a star whose center is either an unmarked vertex, or adjacent to a connected component of $D - V(B_2)$ consisting of one non-S-attached bag.

If B_1 contains a non-S-attached twin class C, then we can safely remove C.

By applying Reduction Rules 4, 5, and 6, we can simplify the decomposition near an S-attached leaf containing one S-attached twin class; for instance, in Figure 4, B_1 will be

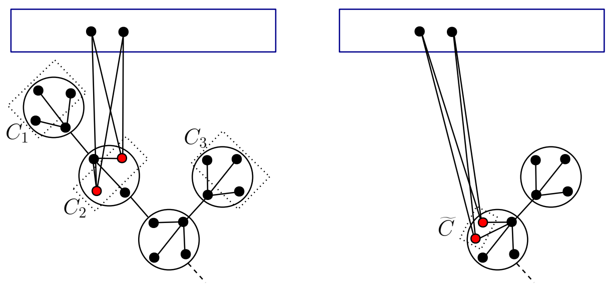

Figure 5 Reduction Rule 8.

eventually merged with B_2. We state the properties that are guaranteed by the reduction rules introduced up to this point in the following lemma.

▶ **Lemma 9.** *Let D be the canonical split decomposition of a connected component of $G - S$ reduced under Reduction Rules 1–6. Let B be a star bag whose center is unmarked or adjacent to a connected component of $D - V(B)$ consisting of one non-S-attached bag. Let D' be a connected component of $D - V(B)$ such that*

- *D' contains exactly one S-attached bag B', and*
- *there is no (B', B)-separator bag.*

Then B' is a star whose leaf is adjacent to $\text{comp}(B', B)$ *and there is a leaf bag B'' where the center of B' is adjacent to B''.*

The final two rules in this section help us simplify the configuration specified in Lemma 9; using Reduction Rule 7 we can remove all unmarked vertices in $\text{path}(B, B') \setminus \{B, B'\}$, and then Reduction Rule 8 allows us to merge B' with B.

▶ Reduction Rule 7. Let B_1 and B_2 be two star bags in D such that

- for each i, either the center of B_i is an unmarked vertex, or the center of B_i is adjacent to a connected component of $D - V(B_i)$ consisting of one non-S-attached bag,
- every bag in $\text{path}(B_1, B_2) \setminus \{B_1, B_2\}$ is a non-S-attached bag, has two neighbor bags, and is not a (B_1, B_2)-separator bag.

Then we remove every unmarked vertex in every bag in $\text{path}(B_1, B_2) \setminus \{B_1, B_2\}$.

▶ Reduction Rule 8. Let B_1, B_2, B_3 be distinct bags in D such that

- B_1 is a non-S-attached leaf bag whose neighbor bag is B_2, and it is not a star whose leaf is adjacent to B_2,
- B_2 has exactly two neighbor bags B_1 and B_3, it is a star whose center is adjacent to B_1, and the set of unmarked vertices in B_2 is the unique S-attached twin class C_2 in B_2, and
- B_3 is a star whose center is either an unmarked vertex, or adjacent to a connected component of $D - V(B_3)$ consisting of one non-S-attached bag.

Let C_1 be the set of unmarked vertices in B_1. Then we remove B_1 and B_2, and add a leaf set of unmarked vertices $\widetilde{C}$ with $\min(|C_1|, |C_2|)$ vertices to B_3, that is complete to $N_G(C_2) \cap S$ and has no other neighbors in S.

We provide an illustration of Reduction Rule 8 in Figure 5.

Finally, after applying all the reduction rules in this section, our instance has the desired inseparability property. We formalize and prove this property below.

▶ **Lemma 10.** *Let D be the canonical split decomposition of a connected component of $G - S$ reduced under Reduction Rules 1–8. Let B be a bag and let D' be a connected component of $D - V(B)$ such that D' contains exactly one S-attached bag B'. Then there is no (B', B)-separator bag.*

▶ **Proposition 11.** Let (G, S, k) be an instance reduced under Branching Rules 1 and 2. Given a canonical split decomposition D of a connected component of $G - S$, we can in time $\mathcal{O}(|V(G)|^2)$ either apply one of Reduction Rules 1–8, or correctly answer that Reduction Rules 1–8 cannot be applied anymore.

5 Twin Class Reduction Rule

In this section, we introduce our last, but perhaps most important, reduction rule. Later on in the proof of Theorem 13, we will show that whenever the other rules cannot be applied, we can either apply Reduction Rule 9 or our instance is trivial.

▶ Reduction Rule 9. Suppose that (G, S, k) and all canonical split decompositions of connected components of $G-S$ are reduced under Branching Rules 1–2 and Reduction Rules 1–8. Let D be the canonical split decomposition of a connected component of $G - S$, and let B be a bag, and B_1, B_2 be two distinct S-attached bags (possibly $B_i = B$ for some $i \in \{1, 2\}$). Furthermore, let C_1, C_2 be two distinct S-attached twin classes in B_1, B_2, respectively, such that for each $i \in \{1, 2\}$, either $B_i = B$ or C_i is the unique S-attached twin class in $\text{comp}(B, B_i)$. Then we apply one of the following:

1. If the distance from C_1 to C_2 in $G - S$ is 2 and the unique (C_1, C_2)-separator bag is contained in $\text{comp}(B, B_2)$, then we remove C_2. (We show that B cannot be the (C_1, C_2)-separator bag.)
2. If C_1 is complete to C_2, $B \neq B_2$, and B is a star bag whose center is adjacent to $\text{comp}(B, B_2)$, then we remove C_1.
3. If C_1 is complete to C_2, $B \neq B_1$, and B is a complete bag, then B_1 contains a non-S-attached twin class C_1' and we remove C_1'.

▶ **Proposition 12.** Reduction Rule 9 is safe.

Sketch of Proof. Here we prove the proposition for one important special case. Suppose that C_1 is anti-complete to C_2 and the (C_1, C_2)-separator bag is contained in $\text{comp}(B, B_2)$. We claim that every vertex in C_2 is irrelevant. For each $i \in \{1, 2\}$, let $c_i \in C_i$ and let $T_i = N_G(C_i)$. Let B' be the (C_1, C_2)-separator bag. We first confirm that $B_2 = B'$. If not, then B' is a (B_2, B)-separator bag. However, since $\text{comp}(B, B_2)$ has exactly one S-attached bag B_1, by Lemma 10, there is no (B_2, B)-separator bag, a contradiction. We conclude that $B' = B_2$. There is a leaf bag B_2' where the center of B_2 is adjacent to B_2', otherwise, we can apply Reduction Rule 2.

Let $v \in C_2$. We claim that for every induced cycle H of length at least 7 containing v, there is a bad vertex for H and v. If this is true, then the result follows from Lemma 6. Let w and z be the two neighbors of v in H. If w and z are contained in S, then by Lemma 7, there is a bad vertex. On the other hand, w and z cannot be contained in $V(G-S)$ together, because the vertices in B_2' form a twin class. We may assume that $w \in (T_1 \cap T_2) \cap V(G - S)$ and $z \in S$. We actually show that this is not possible. Note that since $w \in V(B_2')$, w has no neighbors in S.

We divide cases depending on the location of z: specifically, to conclude the proof, we separately consider the case of $z \in (T_2 \setminus T_1) \cap S$ and $z \in (T_1 \cap T_2) \cap S$. We show that the former case always leads to a contradiction with w having no neighbors in S. On the other hand, it can be shown that the latter case necessarily implies the existence of a small DH obstruction, contradicting the exhaustive application of Branching Rules 1–2. ◀

6 The Algorithm and Lower Bounds

Our goal in this section is to give a proof of our main result, Theorem 14, and prove corresponding lower bounds.

▶ **Theorem 13.** Disjoint Distance-Hereditary Vertex Deletion *can be solved in time* $\mathcal{O}(36^k \cdot |V(G)|^6(|V(G)| + E(G)))$.

Sketch of Proof. The main argument in the proof is that whenever we cannot apply one of Branching Rules 1–2 and Reduction Rules 1–8, either we have a trivial instance, or we run into a situation where we can apply Reduction Rule 9. Suppose that D is the canonical split decomposition of a connected component of $G - S$ such that G and D are reduced under those rules. If D contains at most one S-attached twin class, then we can apply Reduction Rule 1. Thus, we know that D contains at least two distinct S-attached twin classes.

We choose a root bag of D, and choose a bag B that is farthest from the root bag such that there are two descendant bags B_1, B_2 of B having distinct S-attached twin classes C_1, C_2, respectively. By Reduction Rule 3, we have $B_1 \neq B_2$. Using the structure that if $B_i \neq B$, then there is no (B_i, B)-separator bag by Lemma 10, we can observe that the distance between C_1 and C_2 in $G - S$ is at most 2, and then C_1 and C_2 satisfy one of the conditions in Reduction Rule 9.

We can notice that each branching rule reduces either k or the number of connected components in S and branch into at most 6 subinstances. Since none of the reduction rules change k or the number of components in S, branching rules are applied at most $2k$ times. Due to the application of reduction rules (which we also consider as nodes of the branching tree and which may be applied independently in different branches), the branching tree will have at most $\mathcal{O}(36^k \cdot |V(G)|)$ nodes, and the runtime in every node will not exceed $\mathcal{O}(|V(G)|^5(|V(G)| + |E(G)|))$. Hence, the whole algorithm for Disjoint Distance-Hereditary Vertex Deletion can be implemented in time $\mathcal{O}(36^k \cdot |V(G)|^6(|V(G)| + |E(G)|))$. ◀

▶ **Theorem 14.** Distance-Hereditary Vertex Deletion *can be solved in time* $\mathcal{O}(37^k \cdot |V(G)|^7(|V(G)| + |E(G)|))$.

Sketch of Proof. Let $n := |V(G)|$ and $m := |E(G)|$. Fix an arbitrary labeling $v_1, \dots, v_n$ of $V(G)$ and let $G_i := G[\{v_1, \dots, v_i\}]$ for $1 \leq i \leq n$. From $i = 1$ up to n, given a graph G_i and $S_i \subseteq V(G_i)$ with $|S_i| \leq k + 1$ such that $G_i - S_i$ is distance-hereditary, we aim to find a set $S_i' \subseteq V(G_i)$ with $|S_i'| \leq k$ such that $G_i - S_i'$ is distance-hereditary if one exists. We further guess all possible $S_i' \cap S_i$ as I, and we aim to find a deletion set S_i'' of size at most $k - |I|$ in $G_i - I$ where $S_i'' \cap (S_i \setminus I) = \emptyset$ if one exists. We can recursively resolve this problem using Disjoint Distance-Hereditary Vertex Deletion. As we iterate the subproblem n times, we obtain the runtime $n \cdot \sum_{i=0}^{k} \binom{k+1}{i} \cdot \mathcal{O}(36^{k-i} \cdot n^6(n+m)) = \mathcal{O}(37^k \cdot n^7(n+m))$. ◀

Our lower bound result is based on the well-established exponential time hypothesis [19], and specifically uses the fact that there is no $2^{o(k)} \cdot |V(G)|^{\mathcal{O}(1)}$ algorithm for Vertex Cover, unless ETH fails [5]. The proof relies on a reduction which is similar to the one used for vertex deletion to graphs of linear rank-width 1 [20].

▶ **Theorem 15.** *There is no* $2^{o(k)} \cdot |V(G)|^{\mathcal{O}(1)}$ *algorithm for* Distance-Hereditary Vertex Deletion *unless ETH fails.*

7 Concluding Notes

We conclude with a few remarks on why we believe that the presented algorithm is of high interest. First, it intrinsically exploits the properties guaranteed by distinct, seemingly unrelated characterization of distance-hereditary graphs; this approach can likely be used to design or improve algorithms for other vertex deletion problems. Second, it uses highly nontrivial reduction rules which simplify canonical split decompositions, and an adaptation or extension of the presented rules could be highly relevant for other graph classes characterized by special canonical split decompositions, such as parity graphs [6] or circle graphs [13]. Third, it is the first of its kind which targets a "full" class of graphs of bounded rank-width (contrasting previous results for specific subclasses of graphs of rank-width 1 [18, 2, 21, 20]).

It is worth noting that there remains a number of interesting open problems in this general area. Perhaps the most prominent one is the question of whether vertex deletion to graphs of rank-width c, for any constant c, admits a single-exponential fixed-parameter algorithm. Our algorithm represents the first steps in this general direction. The existence of a polynomial kernel or an approximation algorithm for such vertex deletion problems also remains open, even for the case of distance-hereditary graphs.

Abstract

We continue the study of preprocessing under uncertainty that was initiated independently by Assadi et al. (FSTTCS 2015) and Fafianie et al. (STACS 2016). Here, we are given an instance of a tractable problem with a large static/known part and a small part that is dynamic/uncertain, and ask if there is an efficient algorithm that computes an instance of size polynomial in the uncertain part of the input, from which we can extract an optimal solution to the original instance for all (usually exponentially many) instantiations of the uncertain part.

In the present work, we focus on the MATROID INTERSECTION problem. Amongst others we present a positive preprocessing result for the important case of finding a largest common independent set in two linear matroids. Motivated by an application for intersecting two gammoids we also revisit MAXIMUM FLOW. There we tighten a lower bound of Assadi et al. and give an alternative positive result for the case of low uncertain capacity that yields a MAXIMUM FLOW instance as output rather than a matrix.

1 Introduction

Recently, Assadi et al. [2] and, independently, Fafianie et al. [12] initiated a study of problems where part of the input is *dynamic* or *uncertain*. While the introduced concepts are differently named, i.e., *dynamic sketching* [2] and *preprocessing under uncertainty* [12], and are rooted in different areas, i.e., *streaming algorithms* and *parameterized complexity* respectively, the fundamental goal is the same: Given an instance x that is largely static/known and a small specified part, say of k bits, that is dynamic/uncertain. Can we extract from x in polynomial time an instance (or just any string) x' of size polynomial in k such that optimal solutions for x for any instantiation of the k bits of dynamic/uncertain part can also be computed just from x' and the k bits? Since there are 2^k instantiations of k bits this is clearly nontrivial, as we can afford neither the time nor the space to simply precompute and store 2^k solutions, even for polynomial-time solvable problems (which are the focus of this work). Arguably, this parallel development of essentially the same goal in different contexts speaks to the generality and importance of the question. Let us anyway recall some of the motivation.[1]

We are often faced with inputs that appear over time or that are subject to changes. The areas of *online algorithms* and *streaming algorithms* deal with the extreme case that the entire input is only revealed right before or during the computation, or that the data is continuously changing. What if we already hold "most" of the input and there is only a small amount of data that is uncertain or subject to changes? Can we do better than under the strict settings of online or streaming algorithms? Canonical examples are machine scheduling in a factory with only few irregularly occurring jobs, or routing in a network when there is a small set of links that are frequently congested. Unlike online algorithms, the goal is to obtain optimal solutions rather than approximate ones. To make this possible, we do not insist on committing to (parts of) a solution without knowing the uncertain part and only require to preprocess and shrink the given part to size polynomial in the amount of uncertain information. In other words, we do not desire a solution that is (approximately) robust to uncertainty, but to do as much work as possible before receiving the uncertain part (and then compute a solution). In the introduction of [12] this is sketched for the simple case of computing a shortest s,t-path in a road network when the transit times of some k roads is not known in advance; let us discuss a different straightforward example for illustration.

Consider the Closest Pair problem where we are given a set P of points in the Euclidean plane such that for k points $P' \subseteq P$ it is not known beforehand whether they appear in the final input. For any instantiation of availability of points in P' we know that the closest pair of points is either contained entirely in $P \setminus P'$ or P', or one point is in $P \setminus P'$ while the other is in P'. Accordingly, it suffices to store the closest pair in $P \setminus P'$, the set P', and for each point $p' \in P'$ its closest point in P. Thus, we obtain an equivalent instance with at most $2|P'| + 2$ points such that, after removing any subset of P', the closest pair of points has the same distance as it would have in the input instance.

The example shows that such a preprocessing can be quite simple and fast, and be feasible even for larger amounts of uncertain data. On the other end of the spectrum, there are problem settings where even an arbitrary amount of preprocessing time does not suffice to obtain a polynomially large sketch of the instance. Conveniently, the lower bound proofs do not require any complexity assumptions, but rely on fundamental information-theoretic arguments that are implicit in the well-known lower bound for the membership game: Therein, Alice holds any subset $S \subseteq [n]$ unknown to Bob, whereas Bob holds an integer $i \in [n]$ unknown to Alice, and communication is only allowed from Alice to Bob. How many bits of information does Alice need to send to Bob in order for Bob to be able to answer whether $i \in S$? The answer is that n bits are necessary and (obviously) sufficient. Note that the sent information necessarily works for all $i \in [n]$ that Bob could hold, and hence must represent the entire set S. In other words, the lower bound also gives us an incompressibility argument for n bits of information. Fafianie et al. [12] give lower bounds for small connected vertex cover and linear programming under various forms of uncertainty by showing that the existence of an efficient preprocessing algorithm would lead to a violation of the aforementioned bounds.

Assadi et al. [2] explore graph problems where uncertainty is restricted to a set T of k *terminal* vertices, e.g., their adjacency is uncertain. Their main positive result is on the maximum matching problem. Using the *Tutte matrix* of the input graph with n vertices, they show that storing only a $2k \times 2k$ matrix whose entries are in $\mathbb{Z}_p$ (p is any prime of

[1] In the following we will stick to the terms as used in [12].

magnitude $\Theta(\frac{n}{\delta})$ with $0 < \delta < 1$) and an integer suffices to extract the rank of the Tutte matrix for each instantiation/change to the adjacency of the terminals; this yields the size of a maximum matching of G. This result then gives rise to a *cut-preserving sketch* result where the value of all $(S, T \setminus S)$-cuts in G is preserved for $S \subseteq T$ in a sketch of size $\mathcal{O}(kC^2)$ where C is the total capacity of edges incident on T. They obtain this result by constructing a bipartite graph and creating a dynamic sketch for the maximum matching problem. In addition, they prove a lower bound of $\Omega(C/\log C)$ bits which implies a lower bound of $2^{\Omega(k)}$ bits. Furthermore, they show how to obtain a sketch of size $\mathcal{O}(k^4)$ for s,t-CONNECTIVITY, by again using the dynamic sketch for the maximum matching problem. These results extend to MAXIMUM FLOW as well: it follows that the maximum flow problem has a sketch of size $\mathcal{O}((k+C')^4)$ (in the form of a $8(k+C')^2 \times 8(k+C')^2$) matrix); here C' is the total capacity of edges between terminals, which is arguably an advantage over the dependency on C. They also point out that the maximum flow problem has a $2^{\Omega(k)}$ lower bound on size of dynamic sketches which follows from the lower bound for the cut-preserving sketch. Finally, they give an $\mathcal{O}(k)$ size dynamic sketch for the MINIMUM SPANNING TREE problem.

The result for MINIMUM SPANNING TREE was obtained independently by Fafianie et al. [12], where it is generalized to the problem of finding a minimum weight basis of a matroid when the presence of k ground set elements is uncertain. (The MST problem is the same as finding a minimum weight basis of a *graphic matroid*.) If the matroid is given by a matrix respectively by oracle access then the output is a smaller matroid given by a (smaller) matrix respectively by restricted access to the original oracle (e.g., smaller ground set). These results work also in the more general setting where the *weights* of k edges/elements are not known beforehand. Furthermore, for the BIPARTITE MATCHING problem with k uncertain vertices or edges, Fafianie et al. [12] show how to efficiently reduce to a new graph G' whose maximum matchings, relative to availability of the uncertain vertices, differ from those of the input graph G by a fixed (and known) amount. In other words, the output in all three cases is an equivalent instance of the same problem.

The known results leave different directions for further study. The main direction would be to study other polynomial-time solvable regarding preprocessing under uncertainty respectively dynamic sketching. There were several positive results, but the lower bounds for MAXIMUM FLOW and LINEAR PROGRAMMING show limitations for more general problems. Among other fundamental polynomial-time problems there are certainly MATROID INTERSECTION, LINEAR MATROID PARITY, STABLE MARRIAGE, and problem families such as string matching or scheduling. We note that the same problem may have several interesting variants for making parts of its input uncertain. Due the importance of MAXIMUM FLOW and LINEAR PROGRAMMING also restrictions of the problems, e.g., restricted input graphs or special types of LPs, seem reasonable in order to obtain positive results for them. Another question would be how important it is to have the output be an instance of the same problem. This is arguably beneficial for applications, especially if existing algorithms for the underlying problem can be applied as-is. Likely, lower bounds will be unaffected by this decision since we only know how to get lower bounds for the bit size of the encoding; this is similar to the situation of lower bounds for kernelization in parameterized complexity (cf. [6, 10]).

Our work. We focus mainly on preprocessing under uncertainty for the MATROID INTERSECTION problem (Section 4) and present three positive results, including the important case of intersecting two linear matroids. We also revisit MAXIMUM FLOW (Section 3) where we tighten a lower bound of Assadi et al. [2] and give a positive result that is used as a subroutine for GAMMOID INTERSECTION. We conclude with a brief discussion and point out some open problems (Section 5). Let us discuss the results in some more detail.

Matroid Intersection. In the Matroid Intersection problem we are given as input two matroids over the same ground set E, and the goal is to find a set of maximum cardinality which is independent in both matroids. This is a classical optimization problem studied since the early 1970s, e.g., in [1, 11, 18], and generalizes a wide range of concrete problems such as the bipartite matching problem and the colorful spanning tree problem. There are also applications of matroid intersection outside of combinatorial optimization [9, 20]. For many algorithms the independent sets of a matroid are given by an independence oracle, i.e., a blackbox algorithm which answers whether a given subset of the ground set is independent or not. Another common way is to represent a matroid by a matrix over some field: Matroids which can be represented in this way are called *linear matroids.* One can obtain more efficient algorithms for linear matroid intersection that work directly on a matrix rather than via an oracle; e.g., Gabow and Xu [13] make use of fast matrix multiplication. It is also possible to provide matroids implicitly, e.g., by the underlying graphs (*gammoids, graphic matroids*). Finding a maximum common independent set of two matroids is solvable in polynomial time [11] but finding a maximum common independent set of three matroids is NP-hard; e.g. the DIRECTED HAMILTON PATH problem can be formulated as the intersection of three matroids [26]. We study the LINEAR MATROID INTERSECTION problem in the setting that the presence of k elements in the ground set is uncertain. Solving all possible 2^k instantiations in polynomial time is impossible; but we will show how to construct a small encoding from which we can compute the size of a maximum common independent set for all instantiations.

To get the result for LINEAR MATROID INTERSECTION we use a result of Harvey [15], which determines the size of a maximum common independent set by computing the rank of a matrix Z that contains the matrix representations of the two linear matroids as sub-matrices. We use this matrix Z to compute a $2k \times 2k$ matrix and an integer from which we can compute the size of a maximum common independent set for all 2^k instantiations. The construction of the $2k \times 2k$ matrix uses similar ideas as the construction of the $2k \times 2k$ matrix for the dynamic sketching scheme for the maximum matching problem of Assadi et al. [2] and the compression for the K-set-cycle problem of Wahlström [25]. However, we have to be much more careful during row and column operations because our initial matrix has entire rows and columns whose presence is uncertain in the final instance; the uncertain part in the paper of Assadi et al. [2] is contained in a $k \times k$ sub-matrix of the initial matrix.

Since the output of our preprocessing is not an instance of LINEAR MATROID INTERSECTION, this poses the question of whether special cases of the problem permit a preprocessing whose output is an equivalent instance of the same problem. We prove this for the fairly general case of the intersection of two *gammoids*, which contains several classes of well-studied matroids (e.g., *transversal matroids*) and for the ROOTED ARBORESCENCE problem, where we want to determine the existence of a rooted arborescence in a directed graph with some uncertain arcs; note that the ROOTED ARBORESCENCE problem can be described as the intersection of a *partition matroid* and a *graphic matroid.* For the gammoid intersection problem, we show how to compute two new gammoids over the same ground set of size $\mathcal{O}(|T|^3)$ and an offset value from which we can compute the size of a maximum common independent set for all 2^k instantiations. For the ROOTED ARBORESCENCE problem we compute a graph with $k+1$ vertices from which we can decide for all 2^k instantiations whether the input instance has a rooted arborescence. We complement this by a lower bound of $\binom{k}{\lceil k/2 \rceil}$ bits for the case of k uncertain vertices.

Maximum Flow. The problem of finding a maximum flow is one of the most important problems besides the more general problem of solving linear programs and has been explicitly studied in graph theory and combinatorial optimization. We show that if there is an arc set

F of unit-capacity arcs whose presence is uncertain (equivalently: there is a total of $|F|$ units of uncertain capacity), while capacity of other arcs is arbitrary, then we can efficiently reduce to an equivalent unit-capacity flow network with $\mathcal{O}(|F|^3)$ vertices. If we are only interested in any encoding of small size, then instead of the obvious $\mathcal{O}(|F|^6)$ bits encoding size this can also be represented as a gammoid, using $\mathcal{O}(|F|^3)$ bits, which follows from results from Kratsch and Wahlström [17]. This improves the upper bound of Assadi et al. [2] who give a dynamic sketching scheme with sketch size $\mathcal{O}((k+C')^4)$ for the maximum flow problem (represented as a $\mathcal{O}((k+C')^2) \times \mathcal{O}((k+C')^2)$ matrix); since the size of a sketch is measured by the number of machine words of length $\mathcal{O}(\log(n))$, their sketch needs $\mathcal{O}((k+C')^4 \log(n))$ bits. Recall that C' is the total capacity of all edges between the k terminals; by small modifications to the graph $|F|$ and C' become comparable. We complement this by a lower bound of 2^k bits for the case of k uncertain arcs with large capacity which slightly improves the lower bound of $2^{\Omega(k)}$ of Assadi et al. [2]. Furthermore we show that our lower bound is tight, even when the encoding only preserves the parity of the maximum flows.

Further related work. Generally, apart from the areas of online and streaming algorithms, there are several models of optimization problems on uncertainty, such as *stochastic optimization* or *robust optimization*. We refer interested readers to some papers [3, 4, 5, 7] for more information. Some ideas of our work come from the area of kernelization from parameterized complexity, which is about preprocessing algorithms for NP-hard problems. Some particular results from this field inspired our work, namely a result of Pilipczuk et al. [22] on Steiner trees connecting terminals on the outer face of a plane graph, and a result of Kratsch and Wahlström [16] on cut-covering sets (which is also used in Section 3).

2 Preliminaries

Let $[n]$ denote the set $\{1, 2, \ldots, n\}$. If U is a set, then $\binom{U}{k}$ are all its subsets of size k.

We mostly use graph notation as given by Diestel [8]. For a graph $G = (V, E)$ and set of edges $F \subseteq E$, let $V(F)$ denote the vertices incident with F. For a vertex $v \in V$ we denote by $\delta(v)$ the set of edges that are incident to v; thus $\delta(v) = \{e \in E \mid v \in e\}$. Let $D = (V, A)$ be a directed graph and $v \in V$ be a vertex of D. For a vertex $v \in V$ we denote by $\delta^-(v)$ (resp. $\delta^+(v)$) the set of arcs $(u, v) \in A$ (resp. $(v, u) \in A$) with $u \in V$. Let $N^-(v)$ (resp. $N^+(v)$) denote the in-neighbors (resp. out-neighbors) of v. If F is a subset of V then we use $D - F$ to denote the graph obtained from D by deleting all vertices in F and $D[F]$ to denote the graph induced in D by F. If F is a subset of A then we use $D - F$ to refer the graph obtained from D by removing all edges in F. If f is a flow in D then we use $|f|$ to denote the value of f.

We use standard matroid notation as given by Oxley [21]. A *matroid* is a pair $(E, \mathcal{I})$, where E is a finite set of elements, called *ground set*, and $\mathcal{I}$ is a family of subsets of E which are called *independent sets* such that:

1. $\emptyset \in \mathcal{I}$.
2. If $A \in \mathcal{I}$, then for every subset $B \subseteq A$ we have $B \in \mathcal{I}$.
3. If A and B are two independent sets in $\mathcal{I}$ and $|A| > |B|$, then there is an element $e \in A \setminus B$ such that $B \cup \{e\} \in \mathcal{I}$.

Given a matroid $\mathcal{M} = (E, \mathcal{I})$ and $F \subseteq E$, we denote by $\mathcal{M}/F$ the matroid obtained from $\mathcal{M}$ by contracting F. The *rank function* corresponding to $\mathcal{M}$ is a function $r\colon 2^E \to \mathbb{N}$ which is defined by $r(S) := \max\{|I| : I \subseteq S, I \in \mathcal{I}\}$.

Let us recall some well-known types of matroids. For any matrix A over some field F there is an associated matroid $\mathcal{M}$ on the set of columns with independence defined by linear independence of the column vectors. We then say that A *represents* $\mathcal{M}$, and representable matroids are also called *linear matroids*. Let $U_1, \dots, U_m$ be a collection of pairwise disjoint sets and $d_1, \dots, d_m$ be integers with $0 \leq d_i \leq |U_i|$ for each $i = 1, \dots, m$. If we set $E = \cup_{i=1}^m U_i$ and $\mathcal{I} = \{I \subseteq E \colon |I \cap U_i| \leq d_i \text{ for all } i = 1, \dots, m\}$ then $(E, \mathcal{I})$ becomes a matroid, and matroids of this form are called *partition matroids*. The family of forests in a graph $G = (V, E)$ forms a matroid on E. Matroids that can be represented in this way are called *graphic matroids*. Let $G = (V, E)$ be a graph and S and T be two subsets of V. In the set T, we define a subset $U \subseteq T$ to be independent if there are $|U|$ vertex-disjoint paths from S onto U in G. Then this constructs a matroid on T, and matroids of this type are called *gammoids*.

3 Maximum flow

In the MAXIMUM FLOW problem we are given a directed graph $G = (V, A)$, capacities $c \colon A \to \mathbb{N}$, and two vertices $s, t \in V$; the task is to find a flow $f \colon A \to \mathbb{N}$ of maximum value. We consider preprocessing for the MAXIMUM FLOW problem for the case that capacity respectively presence of arcs in a set $F \subseteq A$ is not yet known. Results of this type were previously obtained by Assadi et al. [2]. We tighten one of their lower bounds and give a variant for the case of preserving the parity of the maximum flow. Moreover, we obtain a positive result for the case of $|F|$ uncertain arcs of unit capacity, which is a subroutine for our result for GAMMOID INTERSECTION. Crucially, the output of the latter is again an instance of MAXIMUM FLOW; it also implies a slightly improved encoding size in bits when represented by a matrix. In this section all capacities are integers, implying that there always exists an integral maximum flow. We tacitly assume that all considered maximum flows are integral.

▶ **Theorem 1.** *There is no algorithm that, given an instance $G = (V, A)$, $c \colon A \to \mathbb{N}^+$, and vertices $s, t \in V$ of* MAXIMUM FLOW *together with a set $F \subseteq A$, returns an encoding that requires fewer than $2^{|F|}$ bits, from which we can correctly extract the value of a maximum s,t-flow in $G - (F \setminus F')$ for all $F' \subseteq F$.*

It can be checked that the theorem is tight for the family of graphs used for the lower bound construction. The point is that the relevant information about each graph consists only of $2^{|F|}$ bits, and all flow values can be computed once the graph is known. In general, the lower bound should not be seen as the question of outright storing the $2^{|F|}$ results but regarding any way of storing enough information to compute requested values.

For an arbitrary graph with uncertain arcs F it is not clear whether $2^{|F|}$ bits are sufficient information to compute all flow values. Nevertheless, it is clearly enough space to store the *parities* of the maximum flows, and we can show that this is tight: By reinspecting our proof we can see that it can be adapted to the parity question. The key point is that the matrix used in the proof of Theorem 1 also has full rank over $GF(2)$, which can be easily verified.

▶ **Corollary 2.** *The lower bound of Theorem 1 is tight for* MAXIMUM FLOW PARITY, *i.e., given a graph $G = (V, A)$, $c \colon A \to \mathbb{N}^+$, and vertices $s, t \in V$, there is an encoding of $2^{|F|}$ bits, from which we can correctly extract the parity of the value of a maximum s,t-flow in $G - (F \setminus F')$ for all $F' \subseteq F$. There is no algorithm that returns a smaller encoding.*

The construction in the proof of Theorem 1 relies on uncertain edges with a high capacity. The following positive result shows that this is necessary since we can achieve an encoding to size polynomial in $|F| + l$ where l is the maximum capacity of any uncertain edge. Moreover, this also works if the capacity of edges in F can be instantiated to any value in $\{0, 1, \dots, l\}$. The preprocessing can be performed by a randomized polynomial-time algorithm.

Let us first observe that we may easily reduce this question to the case that $l = 1$, which is equivalent to having a set $\hat{F}$ of edges of capacity 1 each that may or may not be present in the final instance: It suffices to replace each edge of F by l parallel edges of capacity 1 in $\hat{F}$. Setting the capacity of some $e \in F$ to a value $c(e) \in \{0, 1, \ldots, l\}$ is equivalent to making exactly $c(e)$ copies of e in $\hat{F}$ available (We can avoid getting a multigraph by subdividing the edges and putting one of the newly obtained edges in $\hat{F}$). Note that we make no assumption about the capacity of other edges, but the returned graph will have unit capacities.

▶ **Theorem 3.** *Let $G = (V, A)$ be a directed graph, $s, t \in V$, $F \subseteq A$, and $c\colon A \to \mathbb{N}$ be a capacity function such that $c(F) \equiv 1$. There exists a randomized polynomial-time algorithm that, given a network (G, s, t, c) and a set $F \subseteq A$ as above, returns a network $(G' = (V', A'), s, t, c')$ with $F \subseteq A'$, $c' \equiv 1$, $|V'| \in \mathcal{O}(|F|^3)$, and an integer $\alpha \in \mathbb{N}$ such that for any $F' \subseteq F$, the network $(G - F', s, t, c|_{A \setminus F'})$ has a maximum s,t-flow of value β if and only if the network $(G' - F', s, t, c'|_{A' \setminus F'})$ has maximum s,t-flow of value $\beta' = \beta - \alpha$. Here, α is the value of a maximum s,t-flow in $G - F$.*

As mentioned before, differing from the work of Assadi et al. [2] we are interested in finding a small instance of the same problem. In the full version we discuss how our resulting network (G', s, t, c') can be compressed into size $\mathcal{O}(|F|^3)$ bits which improves upon the upper bound of Assadi et al. [2].

The result is obtained by analyzing the *residual graph* with respect to any maximum flow f of $G - F$, i.e., not using any arc of F. We transform this graph in such a way that the cut-covering results of Kratsch and Wahlström [16] can be applied. Crucially, the residual graph has a small minimum s,t-cut size and its maximum flow with respect to deletion of $F' \subseteq F$ is equal to the possible additional flow in $G - F'$ as compared to f. Using the cut-covering set, a small equivalent instance can be obtained. A special case of Theorem 3, which is used for the gammoid intersection result, is the following.

▶ **Corollary 4.** *There exists a randomized polynomial-time algorithm that, given a directed graph $D = (V, A)$, two vertices $s, t \in V$ and a set $F \subseteq V \setminus \{s, t\}$, returns a directed graph $D' = (V', A)$ with $F \subseteq V'$, $|V'| \in \mathcal{O}(|F|^3)$ and an integer $\alpha \in \mathbb{N}$ such that $F \cup \{s, t\} \subseteq V'$ and for any $F' \subseteq F$, the maximum number of internally vertex-disjoint s,t-paths in $D - F'$ is β if and only if the maximum number of internally vertex-disjoint s,t-paths in $D' - F'$ is $\beta - \alpha$. Here, α is the maximum number of vertex-disjoint paths in $D - F$.*

4 Matroid intersection

In this section, we consider the well-known Matroid Intersection problem. In this problem, we are given two matroids $\mathcal{M}_1 = (E, \mathcal{I}_1)$ and $\mathcal{M}_2 = (E, \mathcal{I}_2)$ over the same ground set E. Our task is to determine the largest size of a set $I \subseteq E$ which is independent in both $\mathcal{M}_1$ and $\mathcal{M}_2$. We are interested in the case where the availability of a set of elements $F \subseteq E$ is uncertain and we want to know how much we can compress the input without knowing F. We obtain a positive result for the linear matroid intersection problem, where we construct a matrix from which we can compute the size of a common independent set. Furthermore, for two special cases of matroid intersection, gammoid intersection and rooted arborescence, we show how to obtain small instances of the same problem.

4.1 Linear matroid intersection

In this section we discuss preprocessing for the intersection problem of linear matroids over the same ground set $E = \{e_1, e_2, \ldots, e_m\}$ with respect to a set $F = \{e_1, e_2, \ldots, e_k\} \subseteq E$ of elements whose presence in the final instance is uncertain. Throughout, we will refer to the two matroids in question as M_1 and M_2, and let A and B be $r \times m$ matrices over some field $\mathbb{F}$ that represent M_1 and M_2; here $r \leq m$ is an upper bound on the ranks of M_1 and M_2.

In previous work, e.g., for MINIMUM SPANNING TREE, it was possible to compute for each $F' \subseteq F$ an optimal solution that avoids F': The preprocessing would identify a set $X \subseteq E$ such that there exist solutions $X \cup Y_{F'}$ for each $F' \subseteq F$ where $Y_{F'}$ can be obtained from the outcome of the preprocessing. Unfortunately, this can be easily ruled out for LINEAR MATROID INTERSECTION: Let $G = (A \dot{\cup} B, E)$ be a bipartite graph and $M_1 = (E, \mathcal{I}_1)$ and $M_2 = (E, \mathcal{I}_2)$ be two linear matroids over E with $\mathcal{I}_1 = \{E' \subseteq E \colon |\delta(v) \cap E'| \leq 1 \, \forall v \in A\}$ and $\mathcal{I}_2 = \{E' \subseteq E \colon |\delta(v) \cap E'| \leq 1 \, \forall v \in B\}$. It can be checked that a set E' is independent in M_1 and M_2 if and only if E' is a matching in G. Consider the bipartite graph that is a cycle of length $2n$. This graph has two disjoint maximum matchings E_1 and E_2. Let $F = \{e_1, e_2\}$ with $e_2 \in E_1$ and $e_1 \in E_2$. Now, the unique maximum common independent set in $M_1 - \{e_i\}$ and $M_2 - \{e_i\}$ is E_i for $i = 1, 2$. Thus, we cannot hope to identify $X \subseteq E$ that is shared by optimal solutions. Generally, the size of E cannot be bounded in terms of $|F|$ and as just seen the union of two maximum independent sets in two different instantiations can be the set E; hence we cannot hope to report for each $F' \subseteq F$ a largest common independent set $I \subseteq E \setminus F'$ from any preprocessed instance of size bounded in terms of $|F|$.

Instead, we will show that the *size* of a maximum common independent set in $M_1 - F'$ and $M_2 - F'$, for all $F' \subseteq F$, can be computed from (the rank of) an appropriate $2|F| \times 2|F|$ matrix M that is derived from A and B, which represent M_1 and M_2. To construct M we use a theorem due to Harvey [15]. Before stating the theorem, we need to introduce some notation. For each $J \subseteq E$ we define an $|E| \times |E|$ matrix $T(J)$ by

$$T(J)_{ij} := \begin{cases} 0 & \text{if } i \neq j \text{ or } i = j \in J, \\ t_i & \text{if } i = j \notin J, \end{cases}$$

where each t_i is an indeterminate. Next we define the matrix $Z(J)$ as

$$Z(J) := \begin{pmatrix} 0 & A \\ B^T & T(J) \end{pmatrix}.$$

By $\lambda(J)$ we denote the maximum cardinality of a set that is independent in the contracted matroids M_1/J and M_2/J. Later we consider these two matrices for the case that $J = \emptyset$; we define the shorthands $T = T(\emptyset)$, $Z = Z(\emptyset)$, and $\lambda = \lambda(\emptyset)$.

▶ **Theorem 5** (Harvey [15]). *Let M_1 and M_2 two linear matroids of rank r over the same ground set E. Let A (resp. B) be the $r \times m$ matrix that represents M_1 (resp. M_2). Let $r_1 \colon E \to \mathbb{N}$ and $r_2 \colon E \to \mathbb{N}$ the rank functions of M_1 (resp. M_2). For any $J \subseteq E$, we have* $\operatorname{rank}(Z(J)) = m + r_1(J) + r_2(J) - |J| + \lambda(J)$.

To determine the maximum cardinality of a set that is independent in M_1 and M_2, we use Theorem 5 for the case where $J = \emptyset$. For this case it implies $\operatorname{rank}(Z) = m + \lambda$. For $J = \emptyset$, this result was also obtained by Geelen [14] and it follows from the connection between matroid intersection and the Cauchy-Binet formula [24] (see also Murota [20, Remark 2.3.37]).

During the construction of the desired $2|F| \times 2|F|$ matrix M, we will perform many elementary row and column operations. This can lead to entries which are polynomials of large degree, because matrix T contains m indeterminates. To avoid this we replace some indeterminates by random elements from a field $\mathbb{F}$; this was also used in previous work [2, 25]. Performing row and column operations on the resulting matrix can cause elements to vanish over $\mathbb{F}$, which can reduce the rank and thus lead to a wrong result. We bound the resulting error probability by using the Zippel-Schwartz lemma [23, 27].

Essentially, the idea of the proof is to derive an equivalent matrix whose rank can easily be computed from the rank of a couple of submatrices, where one of the submatrices is small and captures the uncertainty. Thus, we only need to keep the latter and store the rank of the other submatrices. A similar idea is used by Wahlström [25] and by Assadi et al. [2]. In the dynamic sketching scheme of Assadi et al. they have as initial matrix the Tutte matrix, where the uncertainty is contained in a $k \times k$ sub-matrix that contains indeterminates which can be set to zero in the final instance. In our case the initial matrix the is matrix Z which contains the sub-matrices A and B^T. The crucial difficulty is that we need the matrix Z from Harvey's theorem for each choice of $F' \subseteq F$ (or at least a matrix of same rank relative to an offset). Since each F' corresponds to a deletion of pairs of rows and columns, this is not simply handled by a small number of indeterminates that can be set to zero. Also, we cannot avoid using elements of these rows and columns for cancellation. We have to prove that our construction is *independent of the choice of* $F' \subseteq F$. This means, that taking the matrix Z for the matroids without elements of F' (which is same as deleting those rows and columns from Z) and applying our transformation yields the same result as first applying the transformation and then deleting rows and columns corresponding to F'.

To formally state our theorem and to describe the transformation steps let us denote by $W[F'^C, F'^C]$ the sub-matrix of W that contains all rows and columns that do not correspond to elements in $F' \subseteq F$, where W is the matrix in the current step; this means we delete the rows and columns that contain an indeterminate t_i with $e_i \in F'$.

▶ **Theorem 6.** *Let M_1 and M_2 be two linear matroids of rank r over the same ground set $E = \{e_1, e_2, \ldots, e_m\}$. Let A and B be $r \times m$ matrices over the same field $\mathbb{F}$ with $|\mathbb{F}| \geq N = 2^p(r+k)2^k$ that represent M_1 and M_2. Let $F = \{e_1, e_2, \ldots, e_k\} \subseteq E$ be the set of uncertain elements. There exists a randomized polynomial-time algorithm that, given the representations A and B of matroids M_1 and M_2 and $F \subseteq E$, returns a $2k \times 2k$ matrix M, and $\alpha \in \mathbb{N}$ such that with probability at least $1 - 2^{-p}$ for all $F' \subseteq F$, the maximum cardinality of a set that is independent in $M_1 - F'$ and $M_2 - F'$ is equal to* $\operatorname{rank}(M[F'^C, F'^C]) + \alpha - |F \setminus F'|$.

Proof sketch. In our case columns of A (resp. B) correspond to elements in E. For a set $X \subseteq E$ we denote by $A[X, \cdot]$ (resp. $B^T[\cdot, X]$) the matrix that contains the columns (resp. rows) that correspond to set X. Note that both row i and column i of matrix T correspond to the element $e_i \in E$, since $T[i,i] = t_i$. Therefore, by $T[X,X]$ we denote the submatrix of T that is induced by the rows an columns that correspond to the set X. To make sure that our preprocessing works for all choices of $F' \subseteq F$ we have to treat columns from A and B that correspond to elements in F differently from the remaining ones. To this end let $A_F = A[\cdot, F]$, $A_{E\setminus F} = A[\cdot, F^C]$, $B_F = B[\cdot, F]$, $B_{E\setminus F} = B[\cdot, F^C]$, $T_F = T[F,F]$ and $T_{E\setminus F} = T[F^C, F^C]$, i.e., $A = (A_F\, A_{E\setminus F})$, $B = (B_F\, B_{E\setminus F})$ and $T = \operatorname{diag}(T_F, T_{E\setminus F})$. We construct the matrix M in five steps, which we outline below. Due to space constrains, we only show how the construction of matrix M looks like; the crucial point of the proof, which is to show that the construction is independent on the choice of $F' \subseteq F$, is deferred to full version.

$$Z = \begin{pmatrix} 0 & A_F & A_{E\setminus F} \\ B_F^T & T_F & 0 \\ B_{E\setminus F}^T & 0 & T_{E\setminus F} \end{pmatrix} \qquad \xrightarrow{\text{step 1}} Z_1 = \begin{pmatrix} T_F & B_F^T \\ A_F & -A_{E\setminus F} T_{E\setminus F}^{-1} B_{E\setminus F}^T \end{pmatrix}$$

$$\xrightarrow{\text{step 2}} Z_2 = \begin{pmatrix} T_F & B_F^T \\ A_F & \widetilde{X} \end{pmatrix} \qquad \xrightarrow{\text{step 3}} Z_3 = \begin{pmatrix} T_F & {B_F}^T C \\ RA_F & D \end{pmatrix}$$

$$\xrightarrow{\text{step 4}} Z_4 = \begin{pmatrix} T_F - {B'}^T A' & {B''}^T \\ A'' & 0 \end{pmatrix} \qquad \xrightarrow{\text{step 5}} Z_5 = \begin{pmatrix} T_F - {B'}^T A' & \widetilde{B}^T \\ \widetilde{A} & 0 \end{pmatrix}$$

Step 1 In the first step, we reduce Z to an $(r+k)\times(r+k)$ matrix Z_1 such that the uncertain rows and columns remain unaffected; furthermore it holds that the rank of matrix Z equals the rank of matrix Z_1 plus $m-k$. We obtain matrix Z_1 by zeroing out the matrices $A_{E\setminus F}$ and $B_{E\setminus F}^T$ using the invertible matrix $T_{E\setminus F}$. Afterwards, we delete the rows and columns that contain matrix $T_{E\setminus F}$; this reduces the rank by $m-k$.

Step 2: We replace the indeterminate t_i for $k < i \leq m$ by random elements to avoid polynomials of large degree; the entries of matrix Z_1 are polynomials of degree at most one and this leads to an error probability of at most 2^{-p}. Denote the resulting sub-matrix by $\widetilde{X}$ and the complete matrix by Z_2. Note that we could replace the indeterminates before Step 1; but then we have to choose elements from a set of size at least $2^p(r+m)2^k$ to obtain the same error probability (instead of a set of size $N = 2^p(r+k)2^k$).

Step 3: Let $h = \operatorname{rank}(\widetilde{X})$. We apply elementary row and column operations to turn $\widetilde{X}$ into a diagonal matrix $D = \operatorname{diag}(1,\ldots,1,0,\ldots,0)$ with only h non-zero entries. It is well known that there exist two matrices R and C such that $D = R\widetilde{X}C$, where R is the product of all row operations and C the product of all column operations. Let Z_3 be the matrix after applying these row and column operations to Z_2. Matrix Z_2 and Z_3 have the same rank, because we only apply elementary row and column operations. Note that neither matrix R nor matrix C depend on the choice of $F' \subseteq F$, because $\widetilde{X}$ does not depend on the choice of $F' \subseteq F$. One can show that a column j of $R \cdot A_F$ (resp. $C^T \cdot B_F$) only depends on entries of column j of A_F (resp. B_F) and matrix entries that do not depend on the choice of $F' \subseteq F$; thus this transformation is independent on the choice of $F' \subseteq F$.

Step 4: Let $A' = (R\cdot A_F)[[h],\cdot]$ and let $A'' = (R\cdot A_F)[\{h+1,h+2,\ldots,r\},\cdot]$, i.e. $R\cdot A_F = \begin{pmatrix} A' & A'' \end{pmatrix}^T$. Analog we define the $h\times k$ sub-matrix B' and the $(r-h)\times k$ sub-matrix B'' of $B_F^T \cdot C$, i.e. $B_F^T \cdot C = \begin{pmatrix} B'^T & B''^T \end{pmatrix}$. Note that A' (resp. ${B'}^T$) correspond to the rows (resp. columns) where matrix D has a non-zero entry. We zero-out matrices A' and B'^T using the identity matrix I_h. Afterwards, we delete the rows and columns that contain matrix I_h. We denote the resulting matrix by Z_4. By a well-known fact from linear algebra we have that matrix Z_4 has rank l if and only if matrix Z_3 has rank $l+h$.

Step 5: Since A'' (resp. B'') is an $(r-h)\times k$ matrix, at most k rows can be linear independent. We pick a maximum set of linear independent rows from A'' (resp. B''); if less than k rows are independent, then we arbitrarily pick from the remaining rows or add zero rows until we have k rows. Denote this matrix by $\widetilde{A}$ (resp. $\widetilde{B}$). This results in the $2k \times 2k$ matrix Z_5. Note that matrix Z_4 and matrix Z_5 have the same rank, because deleting rows that are dependent on the rows in $\widetilde{A}$ (resp. columns in $\widetilde{B}^T$) corresponds to row (resp. column) operations that zero-out these rows (resp. columns) and this does not change the rank of a matrix.

Altogether, we have constructed a $2|F| \times 2|F|$ matrix $M = Z_5$ and, as we show in the full version, for all $F' \subseteq F$ the equation $\operatorname{rank}(M[{F'}^C, {F'}^C]) + \beta = \operatorname{rank}(Z[{F'}^C, {F'}^C])$ holds with an error probability of at most 2^{-p} where $\beta = h + m - k$. Since the matroid $M_1 - F'$ (resp.

the matroid $M_2 - F'$) is represented by the matrix $A[\cdot, {F'}^C]$ (resp. the matrix $B[\cdot, {F'}^C]$), and the matroids M_1 and M_2 are defined over the same ground set of size $m - |F'|$ it follows from Theorem 5 that $\mathrm{rank}(Z[{F'}^C, {F'}^C]) = (m - |F'|) + \lambda_{F'}$, where $\lambda_{F'}$ denotes the maximum cardinality of a set that is independent in $M_1 - F'$ and $M_2 - F'$. Combining these two equations result in equation $\lambda_{F'} = \mathrm{rank}(M[{F'}^C, {F'}^C]) + h - |F \setminus F'|$. All operations required to obtain the matrix M can be performed in polynomial time and the matrix M together with integer $\alpha = h$ satisfy the required properties in Theorem 6. This completes the proof. ◀

4.2 Gammoid intersection

In this section, we consider the Matroid Intersection problem for the case that both matroids are gammoids. Since gammoids are also linear matroids (cf. [19]) we could apply Theorem 6 to obtain an encoding of size polynomial in the uncertain part. We show how to compute an instance of the gammoid intersection problem instead of an arbitrary encoding. In the same way, the following preprocessing result for the problem of intersecting two gammoids can also be applied to special cases of gammoids such as *transversal matroids* and *partition matroids*, but extra work would be needed to ensure that the output is again, e.g., a pair of transversal matroids rather than general gammoids.

▶ **Theorem 7.** *There exists a randomized polynomial-time algorithm that, given two gammoids $\mathcal{M}_1 = \mathcal{M}(G_1, S_1, T)$ and $\mathcal{M}_2 = \mathcal{M}(G_2, S_2, T)$ together with a subset $F \subseteq T$, returns two new gammoids $\mathcal{M}'_1 = \mathcal{M}(G'_1, S'_1, T')$ and $\mathcal{M}'_2 = \mathcal{M}(G'_2, S'_2, T')$ over a ground set T' of size $\mathcal{O}(|F|^3)$ together with an integer $\alpha \in \mathbb{N}$ such that $F \subseteq T'$ and for every $F' \subseteq F$, $\mathcal{M}_1 - F'$ and $\mathcal{M}_2 - F'$ have a maximum common independent set of size l if and only if $\mathcal{M}'_1 - F'$ and $\mathcal{M}'_2 - F'$ have a maximum common independent set of size $l - \alpha$.*

Proof. Because T appears in both graphs, G_1 and G_2, for each vertex $v \in T$ we rename it in G_1 by v_1 and G_2 by v_2 respectively. We obtain two sets T_1, T_2 where $T_i = \{v_i : v \in T\}$ plays the role of T in G_i and $\mathcal{M}_i$. In order to apply Corollary 4, we construct a graph G as follows. We first reverse all arcs in G_2 to obtain $\overleftarrow{G_2}$ and take the union of G_1 and $\overleftarrow{G_2}$. For each $v \in T$, we create a new vertex in G, also named v, and add two arcs $(v_1, v), (v, v_2)$ to G. Then we create a source s and a sink t together with arcs from s to each vertex in S_1 and arcs from each vertex in S_2 to t. Thus, we obtain a graph $G = (V, E)$ such that $T \subseteq V$ is an (s,t)-cut and there is no arc from $\overleftarrow{G_2}$ to G_1 in G.

▶ **Claim 1.** *For all $F' \subseteq F$, the maximum cardinality of a common independent set of $\mathcal{M}_1 - F'$ and $\mathcal{M}_2 - F'$ is equal to the maximum number of internally vertex-disjoint s,t-paths in $G - F'$.*

We apply the algorithm given by Corollary 4 for G and F to compute a graph $G' = (V', A')$ with $\mathcal{O}(|F|^3)$ vertices and an integer $\alpha' \in \mathbb{N}$ such that $F \subseteq V'$ and for any $F' \subseteq F$, the maximum number of internally vertex-disjoint s,t-paths in $G - F'$ is l if and only if the maximum number of internally vertex-disjoint s,t-paths in $G' - F'$ is $l - \alpha'$. Using graph G' we construct the two new gammoids $\mathcal{M}'_1$ and $\mathcal{M}'_2$. We obtain the graph G'_1 by adding two new vertices $s_v, \hat{v}$ as well as the arcs $(s_v, v), (s_v, \hat{v})$ to G' for all vertices $v \in F$. Let $S_F := \{s_v : v \in F\}$, and let N^+ (resp. N^-) denote the out-neighbors of s (resp. in-neighbors of t). The first gammoid $\mathcal{M}'_1 = \mathcal{M}(G'_1, S'_1, T')$ is defined by the graph G'_1, the set of sources $S'_1 = N^+ \cup S_F$ and the ground set $T' = N^- \cup F \cup \hat{F}$ and the second gammoid $\mathcal{M}'_2 = \mathcal{M}(G'_2, S'_2, T')$ is defined by the graph $G'_2 = (S'_2 \cup T', \{(s_v, v), (s_v, \hat{v}) : v \in F\})$, the set of sources $S'_2 = S_F \cup N^-$ and the ground set T'. For each $F' \subseteq F$, let $\hat{F}' := \{\hat{v} : v \in F'\}$.

▶ **Claim 2.** *For every $F' \subseteq F$, the maximum number of internally vertex-disjoint s,t-paths in $G' - F'$ is h if and only if the maximum cardinality of a common independent set of $\mathcal{M}'_1 - \hat{F}'$ and $\mathcal{M}'_2 - \hat{F}'$ is $h + |F|$.*

We conclude that for every $F' \subseteq F$, the maximum cardinality of a common independent set in $\mathcal{M}_1 - F'$ and $\mathcal{M}_2 - F'$ is l if and only if the maximum cardinality of a common independent set in $\mathcal{M}'_1 - \hat{F}'$ and $\mathcal{M}'_2 - \hat{F}'$ is $l - \alpha' + |F|$. Note that in the construction of $\mathcal{M}'_1$ and $\mathcal{M}'_2$, $\hat{F}$ is a copy of F, so if we identify $\hat{F}$ with the set F in the input gammoids and set $\alpha = \alpha' - |F|$, then we obtain the desired result. ◀

4.3 Rooted arborescence

In this subsection we consider the Rooted Arborescence problem, where we are given a directed graph $D = (V, A)$ with root r and we need to determine whether there exists an r-arborescence in D. An *arborescence* with root $r \in V$, or an *r-arborescence*, is an arc set $A' \subseteq A$ such that A' is a spanning tree if considered as an undirected subgraph and every $v \in V$ is reachable from r via arcs of A', i.e., there is a directed path from r to v using only arcs of A'. We are again interested in the case that there is uncertainty in the input, more precisely, that there are some arcs or vertices whose presence is not known. Rooted Arborescence can be considered as a special case of Matroid Intersection. Indeed, let $\mathcal{M}_1$ be the graphic matroid defined on the undirected underlying graph corresponding to D and $\mathcal{M}_2 = (A, \mathcal{I})$ where $\mathcal{I} = \{S \subseteq A : |S \cap \delta^-(v)| \leq 1 \text{ for all } v \in V \setminus r\}$. It can be checked that D has an r-arborescence if and only if $\mathcal{M}_1$ and $\mathcal{M}_2$ have a common independent set of size $|V| - 1$. Uncertainty of some elements in the two matroids corresponds to uncertain appearance of some arcs in D. By constructing reduction rules based on a well-known property of arborescences, we obtain the following result.

▶ **Theorem 8.** *There exists a polynomial-time algorithm that, given a directed graph $D = (V, A)$ with a root $r \in V$ and an arc set $F \subseteq A$, returns a directed graph $D' = (V(F) \cup \{r\}, A')$ with $F \subseteq A'$ such that for every $F' \subseteq F$, the graph $D - F'$ has an r-arborescence if and only if $D' - F'$ has an r-arborescence.*

In the next theorem, we consider the case that there are some uncertain vertices in our input graph and prove a lower bound for it. The construction is similar to the one used for maximum flow by Assadi et al. [2]. Note that this is not a special case of Matroid Intersection with uncertainty about ground set elements.

▶ **Theorem 9.** *There is no algorithm that, given an instance of* Rooted Arborescence *with k uncertain vertices, returns an encoding that requires fewer than $\binom{k}{\lceil k/2 \rceil}$ bits from which we can correctly extract the answer for all 2^k instantiations of the input instance.*

5 Conclusion

We have continued the study of preprocessing under uncertainty initiated by Assadi et al. [2] (who called their notion *dynamic sketching*) and Fafianie et al. [12]. Our main focus was on preprocessing for matroid intersection problems when the presence of certain ground set elements is uncertain. We obtained positive results for (i) intersecting two linear matroids, (ii) intersecting two gammoids, and (iii) the Rooted Arborescence problem. For the latter two problems our preprocessing returns an instance of the respective problem; for the former, the output is in form of a matrix. Additionally, we have revisited maximum flow, also studied by Assadi et al. [2]. We have tightened a lower bound construction and gave a variant of the result for preserving the parity of maximum flows. Furthermore, we obtained a positive result for the case that a small amount of capacity is uncertain, with output again an instance of MAXIMUM FLOW, which is used for the gammoid intersection result. Deriving a matrix encoding from this yields bitsize $\mathcal{O}(|F|^3)$, improving slightly over $\mathcal{O}((k+C')^4 \log n)$ [2].

It would be interesting whether our result for LINEAR MATROID INTERSECTION can be generalized to the weighted case, possibly with uncertain weights. Similarly, one can try to extend the result to arbitrary matroids that are given by an independence oracle. Generally, preprocessing under uncertainty (or dynamic sketching) in the oracle setting is interesting, as the presence of oracles precludes the lower bounds based on MEMBERSHIP.

Abstract

A ride sharing problem is considered where we are given a graph, whose edges are equipped with a travel cost, plus a set of objects, each associated with a transportation request given by a pair of origin and destination nodes. A vehicle travels through the graph, carrying each object from its origin to its destination without any bound on the number of objects that can be simultaneously transported. The vehicle starts and terminates its ride at given nodes, and the goal is to compute a minimum-cost ride satisfying all requests. This ride sharing problem is shown to be tractable on paths by designing a $O(h \log h + n)$ algorithm, with h being the number of distinct requests and with n being the number of nodes in the path. The algorithm is then used as a subroutine to efficiently solve instances defined over cycles, hence covering all graphs with maximum degree 2. This traces the frontier of tractability, since **NP**-hard instances are exhibited over trees whose maximum degree is 3.

1 Introduction

Ride Sharing. Vehicle routing problems have been drawn to the attention of the research community in the late 50's [8]. Since then, they have attracted much attention in the literature due to their pervasive presence in real-world application scenarios, till becoming nowadays one of the most studied topics in the field of operation research and combinatorial optimization (see, e.g., [24, 29, 10] and the references therein).

Within the broad family of vehicle routing problems, a noticeable class is constituted by the pickup and delivery problems, where a given set of objects, such as passengers or goods, have to be picked at certain nodes of a transportation network and delivered at certain destinations [11]. Pickup and delivery problems can be divided in two main groups [27]. The first group refers to situations where we have a single type of object to be transported, so that pickup and delivery locations are unpaired (see, e.g., [21]). The second group deals, instead, with problems where each transportation request is associated with a specific origin and a specific destination, hence resulting in paired pickup and delivery points (see, e.g., [22, 9]).

* This work was partially supported by the project ANR-14-CE24-0007-01 *"CoCoRICo-CoDec"*. G. Greco's work was also supported by a Kurt Gödel Research Fellowship, awarded by the Kurt Gödel Society. We thank Jérôme Lang, from Université Paris-Dauphine, for introducing the subject to us.

In the paper, we focus on problems of the latter kind, and we deal with the most basic setting where *one vehicle* is available only. The vehicle is initially located at some given source node and it must reach a given destination node by means of a *feasible* ride, that is, of a ride satisfying all requests. The edges of the network are equipped with weights, and the goal is to compute an *optimal* ride, that is, a feasible ride minimizing the sum of the weights of the edges traversed by the vehicle.

Vehicles of Limited Capacity. Ride sharing with one vehicle has attracted much research in the literature and most of the foundational results in the area of vehicle routing precisely refer to this setting. In fact, earlier works have mainly focused on the case where the capacity of the vehicle is bounded by some given constant. In particular, based on whether or not we allow objects to be temporarily unloaded at some vertex of the transportation network, two versions of ride sharing problems emerge: *preemptive* (where drops are allowed) and *non-preemptive* (where drops are not allowed). An orthogonal classification comes, moreover, from the capacity c of the given vehicle. The setting with *unit* capacity ($c = 1$) has received much attention in the literature, where it often comes in the form of a *stacker crane problem* (see [15, 28] and the references therein). A natural generalization is then when the vehicle can carry more than one object at time, that is, when c is any given natural number possibly larger than 1.

Given these two orthogonal dimensions, a total of four different configurations can be studied (cf. [19]). In all the possible configurations, vehicle routing is known to be **NP**-hard [15, 16] when the underlying transportation network is an arbitrary graph. In fact, motivated by applications in a wide range of real-world scenarios, complexity and algorithms for ride sharing problems have been studied for networks with specific topologies, such as path, cycles, and trees. Consider first the unit capacity setting. In this case, ride sharing is known to be polynomial time solvable on both paths [2] and cycles [13], no matter of whether drops are allowed. Moving to trees, instead, the preemptive case remains efficiently solvable [14], while the non-preemptive case becomes **NP**-hard [12]. Consider now the case where $c \geq 1$ holds. Clearly enough, the intractability result over trees established for $c = 1$ still holds in this more general setting. In fact, in this setting, ride sharing appears to be intrinsically more complex. Indeed, it has been shown that the non-preemptive version of the problem is **NP**-hard on all the considered network topologies and that the preemptive version is **NP**-hard even on trees [18]. Good news comes instead when the problem is restricted over paths and cycles in the preemptive case. Indeed, the problem has been shown to be feasible in polynomial time on paths [19]. Moreover, the algorithm by [19] is also applicable to cycles, under the constraint that, for each object, the direction of the transportation (either clockwise, or anticlockwise) is a-priori given. More efficient algorithms are know for paths when the ride starts from one endpoint [18, 23].

Vehicles of Unlimited Capacity. There are application scenarios where the capacity of the vehicle can be better thought as being *unlimited*, as it happens, for instance, when we are transporting intangible objects, such as messages. More generally, we might know beforehand that the number of objects to be transported is less than the capacity of the vehicle; and, accordingly, we would like to use solution algorithms that are more efficient than those proposed in the literature and designed in a way that this knowledge is not suitably taken into account. In fact, the **NP**-hardness results discussed above exploit a given constant bound on the capacity and, hence, they do not immediately apply to the unbounded setting. However, specific reductions have been exhibited showing the **NP**-hardness on general graphs (cf. [30, 3]). Moreover, heuristic methods (see, e.g., [17, 25]) and approximation algorithms (see, e.g., [1, 20]) have been defined, too. On the other hand, a number of tractability results for vehicles with unlimited capacity transporting objects of the same type can be inherited even in the paired context we are considering. Indeed, for cases where such identical objects are initially stored at the same node (or, equivalently, have to be transported to the same destination) [3, 4, 6, 5], efficient algorithms have been designed for transportation networks that are trees and cycles [30]. Moreover, the algorithm for paths proposed by [19] can be still applied over the unlimited capacity scenario. But, it was not explored so far whether better performances can be obtained by means of algorithms specifically designed for vehicles with unlimited capacity.

Contributions. The goal of the paper is to address the above research question, and to study complexity and algorithmic issues arising with ride sharing problems in presence of one vehicle of unlimited capacity. The analysis has been conducted by considering different kinds of undirected graph topologies, which have been classified on the basis of the degree of their nodes. Let n be the number of nodes in the underlying graph, let q be the number of requests (hence, of objects to be transported), and let h denote the number of distinct requests (so, $h \leq q$ and $h \leq n^2$). Then, our results can be summarized as follows:

- In Section 3, we show that optimal rides can be computed in polynomial time over graphs that are *paths*. In particular, an algorithm is exhibited to compute an optimal ride in $O(h \log h + n)$. This improves the $O(qn + n^2)$ bound that we obtain with the state-of-the-art algorithm by Guan and Zhu [19] for vehicles with limited capacity, by naïvely setting the limit to k.
- The design and the analysis of the above algorithm is the main technical achievement of the paper. By using the algorithm as a basic subroutine, we are then able to show in Section 4 that optimal rides can be computed in polynomial time over *cycles* too, formally in $O(m^2 \cdot (h \log h + n))$, with m being the number of distinct nodes that are endpoints of some request, so that $m \leq 2h$ and $m \leq n$. The result has no counterpart in the limited capacity setting, since differently from [19], we do not require that the direction of the transportation of the objects is fixed beforehand.
- Path and cycles completely cover all graphs whose maximum degree is 2. In fact, this value precisely traces the frontier of tractability for the ride sharing problem we have considered, as **NP**-hard instances are exhibited over graphs whose maximum degree is 3 and which are moreover trees.

2 Ride Sharing Scenarios

Let $G = (V, E, w)$ be an undirected weighted graph, where V is a set of nodes and E is a set of edges. Each edge $e \in E$ is a set $e \subseteq V$ with $|e| = 2$, and it is equipped with a cost $w(e) \in \mathbb{Q}^+$. A *ride* π in G is a sequence of nodes $\pi_1, \ldots, \pi_k$ such that $\pi_i \in V$ is the node reached at the *time step* i and $\{\pi_i, \pi_{i+1}\} \in E$, for each i with $1 \leq i \leq k-1$. The time step $k > 0$ is called the *length* of π, hereinafter denoted by $len(\pi)$. The value $\sum_{i=1}^{k-1} w(\{\pi_i, \pi_{i+1}\})$ is the *cost* of π (w.r.t. w) and is denoted by $w(\pi)$. Moreover, $nodes(\pi)$ denotes the set of all nodes $v \in V$ occurring in π.

A *request* on $G = (V, E, w)$ is a pair (s, t) such that $\{s, t\} \subseteq V$. Note that s and t are not necessarily distinct, and they are called the starting and terminating nodes, respectively, of the request. We say that a ride π in G *satisfies* the request (s, t) if there are two time steps i and i' such that $1 \leq i \leq i' \leq len(\pi)$, $\pi_i = s$ and $\pi_{i'} = t$. If $\mathcal{C}$ is a set of requests on G, then

$V_\mathcal{C}$ is the set of all starting and terminating nodes occurring in it. A *ride-sharing* scenario consists of a tuple $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$, where $G = (V, E, w)$ is an undirected weighted graph, (s_0, t_0) is a request on G and $\mathcal{C}$ is a non-empty set of requests.

A ride $\pi = \pi_1, \ldots, \pi_k$ in G is *feasible* for $\mathcal{R}$ if $\pi_1 = s_0$, $\pi_k = t_0$, and π satisfies each request in $\mathcal{C}$. The set of all feasible rides for $\mathcal{R}$ is denoted by $\mathit{feasible}(\mathcal{R})$. A feasible ride π is *optimal* if $w(\pi') \geq w(\pi)$, for each feasible ride π'. The set of all optimal rides for $\mathcal{R}$ is denoted by $\mathit{opt}(\mathcal{R})$.

Let $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$ be a ride-sharing scenario, and let π be a ride in G. Let i and i' be two time steps such that $1 \leq i \leq i' \leq \mathit{len}(\pi)$. Then, we denote by $\pi[i, i']$ the ride $\pi_i, \ldots, \pi_{i'}$ obtained as the sequence of the nodes occurring in π from time step i to time step i'. If π and π' are two rides on G, then we write $\pi' \preceq \pi$ if either $\pi' = \pi$ or, recursively, if there are two time steps i and i' such that $1 \leq i < i' \leq \mathit{len}(\pi)$, $\pi_{i+1} = \pi_{i'}$ or $\pi_i = \pi_{i'-1}$, and $\pi' \preceq \pi[1, i], \pi[i', \mathit{len}(\pi)]$ (informally speaking, π' can be obtained from π by removing a subsequence of nodes).

▶ **Fact 1.** *Let π and π' be two rides such that $\pi' \preceq \pi$. Then: $w(\pi') \leq w(\pi)$; if π' satisfies a request $(s, t) \in \mathcal{C}$, then π satisfies (s, t), too; if π is feasible (resp., optimal) and $V_\mathcal{C} \cap (\mathit{nodes}(\pi) \setminus \mathit{nodes}(\pi')) = \emptyset$, then π' is feasible (resp., optimal), too.*

It is easily seen that computing optimal rides is an intractable problem (**NP**-hard), for instance, by exhibiting a reduction from the well-known traveling salesman problem (see, e.g., [16]). Actually, we can strengthen this result, in a way that suggest to focus our subsequent analysis on ride-sharing scenarios over graphs whose maximum degree is 2 (at most). In fact, these graphs must be either paths or cycles.

▶ **Theorem 2.** *Computing optimal rides is* **NP***-hard over trees whose maximum degree is 3.*

3 Optimal Rides on Paths

In this section we describe an algorithm that, given as input a ride-sharing scenario $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$ where $G = (V, E, w)$ is a *path*, returns an optimal ride for $\mathcal{R}$. In order to keep notation simple, we assume that nodes in V are (indexed as) natural numbers, so that $V = \{1, \ldots, n\}$. Hence, for each node $v \in V \setminus \{n\}$, the edge $\{v, v+1\}$ is in E; and no further edge is in E. Moreover, let us define $\mathsf{left}(\mathcal{R}) = \mathsf{min}_{v \in V_\mathcal{C}} v$ and $\mathsf{right}(\mathcal{R}) = \mathsf{max}_{v \in V_\mathcal{C}} v$, as the extreme (left and right) endpoints of any request in $\mathcal{C}$.

Based on these notions, we distinguish two mutually exclusive cases:

"outer": where either $s_0 \leq \mathsf{left}(\mathcal{R}) \leq \mathsf{right}(\mathcal{R}) \leq t_0$ or $t_0 \leq \mathsf{left}(\mathcal{R}) \leq \mathsf{right}(\mathcal{R}) \leq s_0$; that is, the starting and the terminating nodes s_0 and t_0 are not properly included in the range $\{\mathsf{left}(\mathcal{R}), ..., \mathsf{right}(\mathcal{R})\}$.

"inner": where $\{s_0, t_0\} \cap \{v \in V \mid \mathsf{left}(\mathcal{R}) < v < \mathsf{right}(\mathcal{R})\} \neq \emptyset$; in particular, in this case, $\mathsf{left}(\mathcal{R}) < \mathsf{right}(\mathcal{R})$ necessarily holds.

In the following two subsections we describe methods to address the two different cases, while their complexity will be later analyzed in Section 3.3. A basic ingredient for both methods is the concept of concatenation of rides. Let $\pi = \pi_1, \ldots, \pi_k$ and $\pi' = \pi'_1, \ldots, \pi'_h$ be two rides. Their *concatenation* $\pi \mapsto \pi'$ is the ride inductively defined as follows: if $\pi_k = \pi'_1$ and $h > 1$, then $\pi \mapsto \pi' = \pi_1, \ldots, \pi_k, \pi'_2, \ldots, \pi'_h$; if $\pi_k = \pi'_1$ and $h = 1$, then $\pi \mapsto \pi' = \pi$; if

Algorithm 1: RideOnPath_Outer

```
Input: A scenario $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$, where $G = (V, E, w)$ is a path,
and with $s_0 \leq \mathsf{left}(\mathcal{R}) \leq \mathsf{right}(\mathcal{R}) \leq t_0$ or $t_0 \leq \mathsf{left}(\mathcal{R}) \leq \mathsf{right}(\mathcal{R}) \leq s_0$;
Output: An optimal ride for $\mathcal{R}$;
1 if $s_0 > t_0$ then
2     $\pi \leftarrow$ RideOnPath_Outer($\mathsf{sym}(\mathcal{R})$);
3     return $\mathsf{sym}(\pi)$;
4 else
5     $\mathcal{C}^* = \{(s_1, t_1), \ldots, (s_h, t_h)\} \leftarrow$Normalize($\mathcal{C}$);        /* $s_1 \leq s_2 \cdots \leq s_h$ */
6     return $s_0 \mapsto s_1 \mapsto t_1 \mapsto s_2 \mapsto \ldots \mapsto s_h \mapsto t_h \mapsto t_0$;
```

$\pi_k \neq \pi'_1$, then $\pi \mapsto \pi'$ is defined as the concatenation[1] $\pi \mapsto \bar{\pi} \mapsto \pi'$, where $\bar{\pi} = \pi_k, \ldots, \pi'_1$ is the ride obtained as the sequence of nodes connecting π_k and π'_1 with the smallest length. Note that $\bar{\pi}$ is univocally determined on paths.

3.1 Solution to the "outer" case

Consider Algorithm 1, named RideOnPath_Outer. In the first step, it distinguishes the case $s_0 > t_0$ from the case $s_0 \leq t_0$. Indeed, the former can be reduced to the latter by introducing the concept of *symmetric* scenario. For every node $v \in V$, let $\mathsf{sym}(v) = n - v + 1$. Denote by $\mathsf{sym}(\pi)$ and $\mathsf{sym}(\mathcal{C})$ the ride and the set of requests derived from the ride π and the set of requests $\mathcal{C}$, respectively, by replacing each node v with its "symmetric" counterpart $\mathsf{sym}(v)$. Finally, denote by $\mathsf{sym}(\mathcal{R})$ the scenario $\langle G, (\mathsf{sym}(s_0), \mathsf{sym}(t_0)), \mathsf{sym}(\mathcal{C})\rangle$, referred to as the symmetric scenario of $\mathcal{R}$. Then, the following is immediately seen to hold.

▶ **Fact 3.** *Let π be a ride. Then, π is optimal for $\mathcal{R}$ if, and only if, $\mathsf{sym}(\pi)$ is optimal for $\mathsf{sym}(\mathcal{R})$.*

According to the previous observation, step 5 and step 6 are the core of the computation by addressing the case $s_0 \leq t_0$, where hence $s_0 \leq \mathsf{left}(\mathcal{R}) \leq \mathsf{right}(\mathcal{R}) \leq t_0$. The idea is to reduce the set of requests $\mathcal{C}$ to an "equivalent" set of requests $\mathcal{C}^*$, which presents a simpler structure that we call *normal form*. Formally, let $\mathcal{C}^* = \{(s_1, t_1), \ldots, (s_h, t_h)\}$, and let us say that $\mathcal{C}^*$ is in normal form if $t_i < s_i$ for each $i \in \{1, \ldots, h\}$, and $s_i < t_{i+1}$ for each $i \in \{1, \ldots, h-1\}$. The reduction is performed at step 5, where Normalize is invoked.

The definition of Normalize is shown in Algorithm 2: Step 1 is responsible of filtering out all requests (s, t) such that $s \leq t$. Steps 2 and 3 iteratively "merge" all pairs of requests (s, t) and (s', t') such that $t < s$, $t' < s'$ and $t' \leq t \leq s' \leq s$. Finally, steps 4 and 5 remove all requests (s, t) with $t < s$ and for which there is a request (s', t') such that $t' \leq t < s \leq s'$. It can be shown that the set of requests $\mathcal{C}^*$ returned by Normalize is in normal form and that the optimal ride for the ride-sharing scenario $\langle G, (s_0, t_0), \mathcal{C}^*\rangle$ is an optimal ride also for $\mathcal{R}$. In particular, it can be shown that an optimal ride for $\langle G, (s_0, t_0), \mathcal{C}^*\rangle$ can be obtained by concatenating the rides connecting s_i to t_i, incrementally from $i = 1$ to $i = h$, as it is implemented in step 6 of RideOnPath_Outer. Thus, the following can be established.

▶ **Theorem 4.** *Algorithm* RideOnPath_Outer *is correct.*

[1] The specific order of application of the operator $\mapsto$ is immaterial. Hence, we often avoid the use of parenthesis.

Algorithm 2: NORMALIZE

```
Input: A set $\mathcal{C}$ of requests with $s_0 \le \mathsf{left}(\mathcal{R}) \le \mathsf{right}(\mathcal{R}) \le t_0$;
Output: A set of requests $\mathcal{C}^*$ in normal form and such that $opt(\langle G, (s_0, t_0), \mathcal{C}^* \rangle) \subseteq opt(\mathcal{R})$;
1 $\mathcal{C}^* \leftarrow \mathcal{C} \setminus \{(s,t) \mid s \le t\}$;
2 while exist $(s,t), (s',t') \in \mathcal{C}^*$ such that $t < s$, $t' < s'$, and $t' \le t \le s' \le s$ do
3     $\mathcal{C}^* \leftarrow \mathcal{C}^* \setminus \{(s,t), (s',t')\} \cup \{(s,t')\}$;
4 while exist $(s,t), (s',t') \in \mathcal{C}^*$ such that $t' \le t < s \le s'$ do
5     $\mathcal{C}^* \leftarrow \mathcal{C}^* \setminus \{(s,t)\}$;
6 return $\mathcal{C}^*$;
```

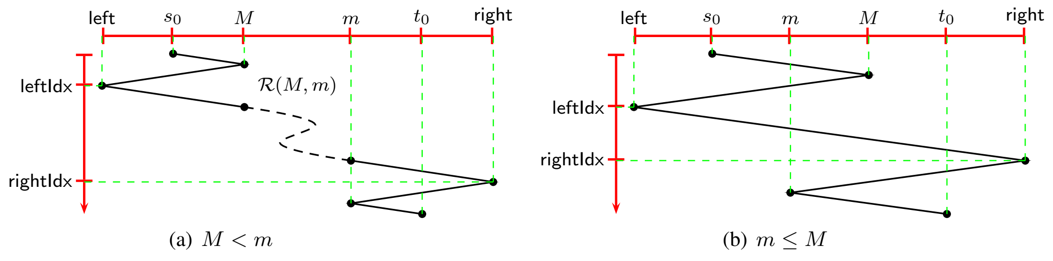

Figure 1 Example of (M,m)-canonical rides.

3.2 Solution to the "inner" case

Let us now move to analyze the "inner" case, where $\{s_0, t_0\} \cap \{v \in V \mid \mathsf{left}(\mathcal{R}) < v < \mathsf{right}(\mathcal{R})\} \neq \emptyset$ holds. Let us introduce some notation. For any feasible ride π, denote by $\mathsf{leftIdx}(\pi)$ (resp., $\mathsf{rightIdx}(\pi)$) the minimum time step i such that $\pi_i = \mathsf{left}(\mathcal{R})$ (resp., $\pi_i = \mathsf{right}(\mathcal{R})$). Note that $\mathsf{leftIdx}(\pi)$ and $\mathsf{rightIdx}(\pi)$ are well defined and, in particular, $\mathsf{leftIdx}(\pi) \neq \mathsf{rightIdx}(\pi)$ holds, since $\mathsf{left}(\mathcal{R}) < \mathsf{right}(\mathcal{R})$. Moveover, for every pair of nodes $x, y \in V$ with $x < y$, define $\mathcal{R}(x,y) = \langle G, (x,y), \{(s,t) \in \mathcal{C} \mid x \le s, t \le y\} \rangle$, that is, the scenario which inherits from $\mathcal{R}$ the graph G and every request with both starting and terminating nodes in the interval $\{x, ..., y\}$, and where the vehicle is asked to start from x and to terminate at y. Notice that, by definition, the set of all nodes occurring in any optimal ride for $\mathcal{R}(x,y)$ is a subset of $\{x, ..., y\}$.

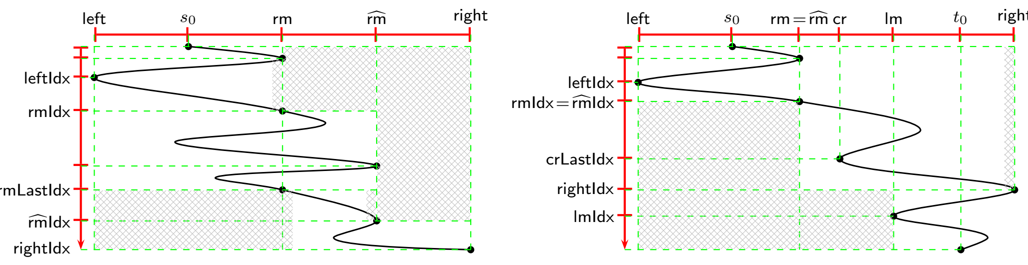
3.2.1 Canonical rides

A crucial role in our analysis is played by the concept of canonical ride, which is illustrated below.

▶ **Definition 5.** *Let $M, m \in V_{\mathcal{C}} \cup \{s_0, t_0\}$ be two nodes. A ride π^{c} in $\mathcal{R}$ is said to be (M,m)-*canonical *if $\pi^{\mathsf{c}} = \pi' \mapsto \pi'' \mapsto \pi'''$ where: $\pi' = s_0 \mapsto M \mapsto \mathsf{left}(\mathcal{R}) \mapsto M$; $\pi'' = M \mapsto \mathsf{right}(\mathcal{R})$ (resp., $\pi'' = \bar{\pi} \mapsto \mathsf{right}(\mathcal{R})$, with $\bar{\pi}$ being an optimal ride for $\mathcal{R}(M,m)$) if $m \le M$ (resp., $m > M$); $\pi''' = \mathsf{right}(\mathcal{R}) \mapsto m \mapsto t_0$.* ☐

Two examples of canonical rides are in Figure 1. Note that if $m \le M$ holds, we can refer without ambiguities to *the* (M,m)-canonical ride, as there is precisely one ride enjoying the properties in Definition 5.

▶ **Fact 6.** *If $m \le M$, then the (M,m)-canonical ride is $s_0 \mapsto M \mapsto \mathsf{left}(\mathcal{R}) \mapsto \mathsf{right}(\mathcal{R}) \mapsto m \mapsto t_0$.*



(a) Some critical steps on a ride π^*

(b) Some critical steps on a ride π^{h+1}

Figure 2 Some critical steps of any feasible ride on a path. The gray areas denote the space that no feasible ride can cross for a given time interval.

Instead, whenever $m > M$, there can be more than one canonical ride. In this case, to compute a (M, m)-canonical ride, we need to compute an optimal ride for $\mathcal{R}(M, m)$, which is a scenario fitting the "outer" case and which can be hence addressed via the RideOnPath_Outer algorithm.

As claimed by the following theorem, the notion of canonical ride characterizes the optimal rides for $\mathcal{R}$. In particular, observe that in the following result, we focus on optimal rides π^* such that $\mathsf{leftIdx}(\pi^*) < \mathsf{rightIdx}(\pi^*)$. Indeed, the case where $\mathsf{leftIdx}(\pi^*) \geq \mathsf{rightIdx}(\pi^*)$ will be eventually addressed by working on the symmetric scenario $\mathsf{sym}(\mathcal{R})$, according to the approach discussed in Section 3.1 (see Fact 3).

▶ **Theorem 7.** *Assume that π^* is an optimal ride with $\mathsf{leftIdx}(\pi^*) < \mathsf{rightIdx}(\pi^*)$. Then, there are two nodes $M, m \in V_{\mathcal{C}} \cup \{s_0, t_0\}$, with $s_0 \leq M$ and $m \leq t_0$, such that any (M, m)-canonical ride is optimal, too.*

The proof of the result is rather involved, and we provide an overview here. We repeatedly use *exchange arguments* to gradually transform a given optimal ride without hurting its quality. Hence, let us assume that π^* is a given optimal ride such that $\mathsf{leftIdx}(\pi^*) < \mathsf{rightIdx}(\pi^*)$.

We first define a number of critical time steps and nodes of the path which are useful to analyze the properties of any optimal ride π. To help the intuition, the reader is referred to Figure 2(a). Let $\mathsf{rm}(\pi) = \mathsf{max}_{1 \leq i \leq \mathsf{leftIdx}(\pi)} \pi_i$. Note that $\mathsf{rm}(\pi) < \mathsf{right}(\mathcal{R})$ necessarily holds. Let $\mathsf{rmIdx}(\pi)$ be the minimum time step $i \geq \mathsf{leftIdx}(\mathcal{R})$ such that $\pi_i = \mathsf{rm}(\pi)$. Note that that $\mathsf{rmIdx}(\pi)$ is well defined, because $\mathsf{leftIdx}(\pi) < \mathsf{rightIdx}(\pi)$ and, hence, the ride π has to cross the node $\mathsf{rm}(\pi)$ at least once between the time step $\mathsf{leftIdx}(\pi)$ and the time step $\mathsf{rightIdx}(\pi)$. In fact, it actually holds that $\mathsf{rmIdx}(\pi) < \mathsf{rightIdx}(\pi)$, since $\mathsf{rm}(\pi) < \mathsf{right}(\mathcal{R})$. Then, define $\mathsf{rmLastIdx}(\pi)$ as the maximum time step $i \leq \mathsf{rightIdx}(\pi)$ such that $\pi_i = \mathsf{rm}(\pi)$. Note that $\mathsf{rmLastIdx}(\pi)$ coincides with $\mathsf{rmIdx}(\pi)$ if, and only if, there is no time step i such that $\mathsf{rmIdx}(\pi) < i \leq \mathsf{rightIdx}(\pi)$ with $\pi_i = \mathsf{rm}(\pi)$. Again, observe that $\mathsf{rmLastIdx}(\pi) < \mathsf{rightIdx}(\pi)$ holds. Now, define $\widehat{\mathsf{rm}}(\pi) = \mathsf{max}_{\mathsf{rmIdx}(\pi) \leq i \leq \mathsf{rmLastIdx}(\pi)} \pi_i$. Since $\mathsf{rmLastIdx}(\pi) < \mathsf{rightIdx}(\pi)$ and since $\mathsf{rightIdx}(\pi)$ is the minimum time step where the ride reaches the extreme node $\mathsf{right}(\mathcal{R})$, we have that $\widehat{\mathsf{rm}}(\pi) < \mathsf{right}(\mathcal{R})$. Moreover, $\widehat{\mathsf{rm}}(\pi) \geq \mathsf{rm}(\pi)$ clearly holds. Therefore, there is some time step between $\mathsf{rmLastIdx}(\pi)$ and $\mathsf{rightIdx}(\pi)$ where π crosses $\widehat{\mathsf{rm}}(\pi)$. So, we can define $\widehat{\mathsf{rm}}\mathsf{Idx}(\pi)$ as the minimum index $i \geq \mathsf{rmLastIdx}(\pi)$ such that $\pi_i = \widehat{\mathsf{rm}}(\pi)$, by noticing that $\widehat{\mathsf{rm}}\mathsf{Idx}(\pi) < \mathsf{rightIdx}(\pi)$ holds.

A basic transformation preserving optimality is illustrated in the following lemma.

▶ **Lemma 8.** *Assume there is an optimal ride $\pi \in opt(\mathcal{R})$ such that $\mathsf{leftIdx}(\pi) < \mathsf{rightIdx}(\pi)$. Then, the ride $s_0 \mapsto \widehat{\mathsf{rm}}(\pi) \mapsto \mathsf{left}(\mathcal{R}) \mapsto \widehat{\mathsf{rm}}(\pi) \mapsto \pi[\widehat{\mathsf{rm}}\mathsf{Idx}(\pi), len(\pi)]$ is also optimal.*

Consider now the optimal ride π^*, and the succession of optimal rides π^j, with $j \geq 0$, obtained by repeatedly applying Lemma 8. First, we set $\pi^0 = \pi^*$. Then, for each $j \geq 0$, we define π^{j+1} as the optimal ride having the form: $s_0 \mapsto \widehat{\mathsf{rm}}(\pi^j) \mapsto \mathsf{left}(\mathcal{R}) \mapsto \widehat{\mathsf{rm}}(\pi^j) \mapsto \pi^j[\widehat{\mathsf{rm}}\mathsf{Idx}(\pi^j), len(\pi^j)]$.

In the above succession, there must exists an optimal ride π^h, with $h \geq 0$, such that $\widehat{\mathsf{rm}}(\pi^h) = \mathsf{rm}(\pi^h)$. Indeed, note that $\mathsf{rm}(\pi^{j+1}) = \widehat{\mathsf{rm}}(\pi^j)$ holds, for each $j \geq 0$, and we know that, for any optimal ride π, $\mathsf{rm}(\pi) \leq \widehat{\mathsf{rm}}(\pi) < \mathsf{right}(\mathcal{R})$. For this optimal ride π^h, we have that $\mathsf{rmLastIdx}(\pi^h) = \widehat{\mathsf{rm}}\mathsf{Idx}(\pi^h)$, by definition of these two time steps. Therefore, $\pi^{h+1} = s_0 \mapsto \mathsf{rm}(\pi^h) \mapsto \mathsf{left}(\mathcal{R}) \mapsto \mathsf{rm}(\pi^h) \mapsto \pi^h[\mathsf{rmLastIdx}(\pi^h), len(\pi^h)]$. It is possible to prove that π^{h+1} satisfies a number of desirable properties, which can informally be summarised as follows: after time step $\widehat{\mathsf{rm}}\mathsf{Idx}(\pi^h)$ and before reaching $\mathsf{right}(\mathcal{R})$, π^{h+1} never crosses $\widehat{\mathsf{rm}}(\pi^h)$ anymore; moreover, let $\mathsf{lm}(\pi^{h+1}) = \mathsf{min}_{\mathsf{rightIdx}(\pi^{h+1}) \leq i \leq len(\pi^{h+1})} \pi_i$, there is no request $(s,t) \in \mathcal{C}$ such that $t < \mathsf{lm}(\pi^{h+1})$, $t < \widehat{\mathsf{rm}}(\pi^h)$, and $\widehat{\mathsf{rm}}(\pi^h) < s$. For $\mathsf{lm}(\pi^{h+1}) \geq \mathsf{rm}(\pi^h)$, π^{h+1} is depicted in Figure 2(b). Note that, under such condition, π^{h+1} has an addition critical node $\mathsf{cr}(\pi^{h+1})$. Informally speaking, $\widehat{\mathsf{rm}}(\pi^h)$ is the largest node v, such that it is smaller than $\mathsf{lm}(\pi^{h+1})$ and does not admit any crossing request, i.e., a request (s,t) with $t < v \leq s$.

The properties of π^{h+1} allow us to apply a final improving transformation. In particular, we are able to show that, if $\mathsf{lm}(\pi^{h+1}) < \mathsf{rm}(\pi^h)$ then, by setting $M = \mathsf{rm}(\pi^h)$ and $m = \mathsf{lm}(\pi^{h+1})$, π^{h+1} can be reduced to the (M,m)-canonical ride depicted in Figure 2(b); otherwise, by setting $M = \mathsf{rm}(\pi^h)$ and $m = \mathsf{cr}(\pi^{h+1})$, π^{h+1} can be reduced to any of the (M,m)-canonical ride depicted in Figure 2(a).

3.2.2 An algorithm for the "inner" case

It is not difficult to see that the result in Theorem 7 immediately provides us with an algorithm to compute an optimal ride, which is based on exhaustively enumerating all possible pairs M, m of elements, by computing the associated canonical ride for each of them (either by exploiting Fact 6 if $m \leq M$, or using the RIDEONPATH_OUTER algorithm on $\mathcal{R}(M,m)$ of $m > M$), and by eventually returning the feasible one having minimum cost. Actually, in order to deal with the case where all optimal rides π^* are such that $\mathsf{leftIdx}(\pi^*) > \mathsf{rightIdx}(\pi^*)$, we can just apply the approach over the symmetric scenario $\mathsf{sym}(\mathcal{R})$ too (see Fact 3), and return the best over the rides computed for $\mathcal{R}$ and $\mathsf{sym}(\mathcal{R})$.

Note that the approach sketched above requires the enumeration of $|V_\mathcal{C}|^2$ canonical rides. However, we can do better than a naïve enumeration. To this end, we explore the properties enjoyed by canonical rides that are optimal applying to the cases where $M < m$ and $M \geq m$, respectively, hold in Theorem 7.

▶ **Theorem 9.** *Assume that there are two nodes $M, m \in V_\mathcal{C} \cup \{s_0, t_0\}$, with $s_0 \leq M$, $m \leq t_0$ and $M < m$, such that a (M,m)-canonical ride is an optimal ride. Consider the two sets $\hat{X} = \{x \in \{s_0\} \cup V_\mathcal{C} \mid x \geq s_0 \ \wedge \nexists (s,t) \in \mathcal{C}$ with $t \leq x < s\}$ and $\hat{Y} = \{y \in \{t_0\} \cup V_\mathcal{C} \mid y \leq t_0 \ \wedge \nexists (s,t) \in \mathcal{C}$ with $t < y \leq s\}$. It holds that $\hat{X} \neq \emptyset$ and $\hat{Y} \neq \emptyset$. Moreover, let $\hat{M} = \mathsf{min}_{\hat{x} \in \hat{X}} \hat{x}$ and $\hat{m} = \mathsf{max}_{\hat{y} \in \hat{Y}} \hat{y}$, then $s_0 \leq \hat{M}$, $\hat{m} \leq t_0$, $\hat{M} < \hat{m}$ and any $(\hat{M}, \hat{m})$-canonical ride is an optimal ride, too.*

▶ **Theorem 10.** *Assume that there are two nodes $M, m \in V_\mathcal{C} \cup \{s_0, t_0\}$, with $s_0 \leq M$, $m \leq t_0$ and $m \leq M$, such that the (M,m)-canonical ride π^c is an optimal ride. Consider the set $\hat{Z}_m = \{z \in \{s_0, t_0\} \cup V_\mathcal{C} \mid m \leq z$ and $s_0 \leq z \ \wedge \nexists (s,t) \in \mathcal{C}$ with $t < m$ and $z < s\}$. It holds that $\hat{Z} \neq \emptyset$. Moreover, let $\hat{M}_m = \mathsf{min}_{\hat{z} \in \hat{Z}_m} \hat{z}$, then $s_0 \leq \hat{M}$, $m \leq \hat{M}_m$ and the $(\hat{M}_m, m)$-canonical ride $\hat{\pi}^\mathsf{c}$ is optimal, too.*

```
Algorithm 3: RideOnPath_Inner
Input: A ride-sharing scenario $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$, where $G$ is a path and with
       $\{s_0, t_0\} \cap \{v \in V \mid \mathsf{left}(\mathcal{R}) < v < \mathsf{right}(\mathcal{R})\} \neq \emptyset$;
       Optionally, a Boolean value symmetric—set to false, if not provided;
Output: An optimal ride for $\mathcal{R}$;
    /* PHASE I: implementation of Theorem 9                                    */
 1  Compute $\hat{M}$ and $\hat{m}$, as defined in Theorem 9;   // note that $\hat{M} < \hat{m}$
 2  $\pi^* \leftarrow$ any $(\hat{M}, \hat{m})$-canonical ride;   // use RideOnPath_Outer as a subroutine for
    $\mathcal{R}(\hat{M}, \hat{m})$
    /* PHASE II: implementation of Theorem 10                                  */
 3  for each node $m \in V_\mathcal{C} \cup \{s_0, t_0\}$ with $m \leq t_0$ do
 4      Compute $\hat{M}_m$, as defined in Theorem 10;   // note that $\hat{M}_m \geq \hat{m}$
 5      $\pi \leftarrow$ the $(\hat{M}_m, m)$-canonical ride;   // $s_0 \mapsto \hat{M}_m \mapsto \mathsf{left}(\mathcal{R}) \mapsto \mathsf{right}(\mathcal{R}) \mapsto m \mapsto t_0$
 6      if $w(\pi) < w(\pi^*)$ then
 7          $\pi^* \leftarrow \pi$;
    /* PHASE III: working on the symmetric scenario                            */
 8  if symmetric is false then
 9      $\pi^*_{\mathsf{sym}} \leftarrow$ RideOnPath_Inner($\mathsf{sym}(\mathcal{R})$, true);
10      if $w(\pi^*_{\mathsf{sym}}) < w(\pi^*)$ then
11          $\pi^* \leftarrow \mathsf{sym}(\pi^*_{\mathsf{sym}})$;
12  return $\pi^*$;
```

In the light of Theorem 7, Theorem 9 and Theorem 10, consider then Algorithm 3, named RideOnPath_Inner. It computes an optimal ride π^* for the "inner" case, by proceeding in three phases.

In Phase I, the algorithm computes the values $\hat{M}$ and $\hat{m}$ defined in Theorem 9 (step 1), it builds a $(\hat{M}, \hat{m})$-canonical ride, and it assigns it to π^* (step 2). Note that, according to Definition 5 and given that $\hat{M} < \hat{m}$, in order to build a $(\hat{M}, \hat{m})$-canonical ride we need to compute an optimal ride for $\mathcal{R}(\hat{M}, \hat{m})$, which is a task that we can accomplish by exploiting RideOnPath_Outer as a subroutine—indeed, note that $\mathcal{R}(\hat{M}, \hat{m})$ fits the "outer" case. In Phase II, the algorithm iterates over all possible values for m in $V_\mathcal{C} \cup \{s_0, t_0\}$ with $m \leq t_0$. For each node m, the value $\hat{M}_m$, defined in Theorem 10, is calculated (step 4). Then, the $(\hat{M}_m, m)$-canonical ride π is built. In particular, since $\hat{M}_m \geq m$ holds, the ride π is completely determined by Fact 6. Eventually, if the cost of π is smaller than the cost of the current value of π^*, it updates π^* to π (step 7). Finally, Phase III is devoted to deal with the symmetric scenario $\mathsf{sym}(\mathcal{R})$. The idea is that the first two phases are executed again on $\mathsf{sym}(\mathcal{R})$. Let π^*_{sym} be the result of this computation (step 9). Then, we consider the symmetric ride $\mathsf{sym}(\pi^*_{\mathsf{sym}})$, which is a ride for $\mathcal{R}$, and we compare its cost with the cost of the current value of π^* (step 10). As usual, we keep the ride with the associated minimum cost, which is eventually returned as output (step 12).

Concerning the correctness, note that if $\mathcal{R}$ admits an optimal ride π with $\mathsf{leftIdx}(\pi) < \mathsf{rightIdx}(\pi)$, then by combining Theorem 7 with Theorem 9 and Theorem 10, we get that either any $(\hat{M}, \hat{m})$-canonical ride is optimal, or there is a node $m \in V_\mathcal{C} \cup \{s_0, t_0\}$ for which the $(\hat{M}_m, m)$-canonical ride is optimal. Instead, if every optimal ride π for $\mathcal{R}$ is such that $\mathsf{leftIdx}(\pi) > \mathsf{rightIdx}(\pi)$, then $\mathsf{sym}(\mathcal{R})$ admits an optimal ride that meets the fits the previous case. We can conclude that an optimal ride for $\mathcal{R}$ is one with the smallest cost among any $(\hat{M}, \hat{m})$-canonical ride and every $(\hat{M}_m, m)$-canonical ride, for every value of m in $V_\mathcal{C} \cup \{s_0, t_0\}$, both for $\mathcal{R}$ and for $\mathsf{sym}(\mathcal{R})$. Note that RideOnPath_Inner exhaustively searches among all the possible candidate optimal rides listed above. So, the algorithm is correct.

3.3 Implementation issues and running time

Note that checking whether an instance fits the "outer" or the "inner" case is feasible in $O(|\mathcal{C}|)$. Our goal is to show that both RideOnPath_Outer and RideOnPath_Inner can be made to run in $O(|\mathcal{C}|\log|\mathcal{C}|+|V|)$. So, we eventually establish the following result.

▶ **Theorem 11.** *Let $\mathcal{R}=\langle G,(s_0,t_0),\mathcal{C}\rangle$ be a ride-sharing scenario where $G=(V,E,w)$ is a path. Then, an optimal ride for $\mathcal{R}$ (together with its cost) can be computed in time $O(|\mathcal{C}|\log|\mathcal{C}|+|V|)$.*

In the implementation, we propose to sort these requests in order of starting node and, accordingly, we shall assume that $\hat{\mathcal{C}}=\{(s_1,t_1),(s_2,t_2),\dots,(s_{|\hat{\mathcal{C}}|},t_{|\hat{\mathcal{C}}|})\}$ holds with $s_i\le s_j$ whenever $i<j$. Similarly, we sort the nodes in $V_{\mathcal{C}}\cup\{s_0,t_0\}$, and hence we assume that $V_{\mathcal{C}}\cup\{s_0,t_0\}=\{w_1,w_2,\dots,w_r\}$ holds with $w_i\le w_j$ whenever $i<j$. Moreover, for each node $w_i\in V_{\mathcal{C}}\cup\{s_0,t_0\}$, we define the set $F(w_i)=\{j\mid(s_j,t_j)\in\hat{\mathcal{C}}\wedge(w_i=s_j \text{ or } w_i=t_j)\}$, maintained as linked list. And, finally, for each element j in $F(w_i)$ we keep a label $l_{ij}\in\{\mathsf{s},\mathsf{t}\}$ denoting whether w_i is a starting (s) or a terminating (t) node of request j. This is feasible in $O(|\mathcal{C}|\log|\mathcal{C}|)$. Given the pre-processing, it is not difficult to show that RideOnPath_Outer can be implemented in $O(|\mathcal{C}|\log|\mathcal{C}|+|V|)$, where the extra $O(|V|)$ factor comes from the need of explicitly building the ride and computing the associated cost.

Let us then analyze RideOnPath_Inner and let us focus on Phase I and Phase II, since it is immediate to check that Phase III has the same complexity.

Concerning Phase I, we first need to compute $\hat{M}$ and $\hat{m}$. To this end, we iterate through the nodes in $V_{\mathcal{C}}\cup\{s_0,t_0\}$ in order of increasing index, starting from w_1. Throughout the iteration, we maintain a set S of indexes of requests in $\hat{\mathcal{C}}$. Initially $S=\emptyset$; during the k-th iteration, we add to S every $j\in F(w_k)$ with $l_{kj}=\mathsf{t}$, and we remove from S every $j\in F(w_k)$ with $l_{kj}=\mathsf{s}$. Note that, at the end of the iteration, S contains all the elements in P_{w_k}, so that if $w_k\ge s_0$ and $S=\emptyset$, then we terminate by concluding that w_k is the smallest element in $\hat{X}$. Given the existence of $\hat{M}$, such procedure always terminates. For the complexity analysis, observe that every request in $\hat{\mathcal{C}}$ is added and removed from S exactly once. Hence, the time taken by the procedure is at most $O(|\hat{\mathcal{C}}|)$ times the maximum cost for performing each operation. If the set S is maintained as a binary min-heap, where the key of each request is its starting node, removing an element from S with label s corresponds to extract the element with smallest key, and both the insertion and the removal can be made to run in time $O(\log|\hat{\mathcal{C}}|)$. A similar approach can be used to compute $\hat{m}$. Thus, Phase I takes total time $O(|\hat{\mathcal{C}}|\log|\hat{\mathcal{C}}|)$, hence $O(|\mathcal{C}|\log|\mathcal{C}|)$, to define the pair $\hat{M},\hat{m}$. A canonical ride with its associated cost can be then computed in $O(|\mathcal{C}|\log|\mathcal{C}|+|V|)$, since the dominant operation is the invocation of the algorithm for the outer case.

Concerning Phase II, let $m\in V_{\mathcal{C}}\cup\{s_0,t_0\}$ with $m\le t_0$, and let $\hat{M}_m$ be the node as defined in Theorem 10. Consider the set $Q_m=\{(s',t')\in\mathcal{C}\mid t'<m<s'\}$, and let $u_m=\mathsf{max}\{m,\ s_0\}$ if $Q_m=\emptyset$, and $u_m=\mathsf{max}\{s_0,\ \mathsf{max}_{(s',t')\in Q_m}s'\}$ otherwise. Then, we can show that $\hat{M}_m=u_m$.

Therefore, for every node $w_i\in V_{\mathcal{C}}\cup\{s_0,t_0\}$, $\hat{M}_{w_i}$ is defined as the maximum between w_i and s_0, if Q_{w_i} is not empty, or the maximum between s_0 and $\mathsf{max}_{(s',t')\in Q_{w_i}}s'$, otherwise. So, the dominant operation is the computation of Q_{w_i}. To this end, for every $w_i\in V_{\mathcal{C}}\cup\{s_0,t_0\}$, we iterate through the nodes in $V_{\mathcal{C}}\cup\{s_0,t_0\}$ in order of increasing index. Note that $Q_{w_i}\subseteq\hat{\mathcal{C}}$, hence equivalently we can write $Q_{w_i}=\{(s',t')\in\hat{\mathcal{C}}\mid t'<w_i<s'\}$; this implies that, in order to compute Q_{w_i}, we need of only the requests in $\hat{\mathcal{C}}$ and we can use the usual data structures. More specifically, we iterate through the nodes in $V_{\mathcal{C}}\cup\{s_0,t_0\}$ in order of increasing index, starting from w_1. Initially, we define a set $S=\emptyset$. During the k-th iteration, we remove from S every $j\in F(w_k)$ with $l_{kj}=\mathsf{s}$, and if $k\ge2$ we add to S every $j\in F(w_{k-1})$ with

$l_{(k-1)j} = \mathsf{t}$. Note that, at the end of the iteration, S contains all the elements in Q_{w_k}. Thus, if $S = \emptyset$, then we set M_{w_k} to $\max\{m, s_0\}$, otherwise we set M_{w_k} to $\max\{s_0, \max_{(s',t')\in S} s'\}$. In the latter case, we need to calculate $\max_{(s',t')\in S} s'$, i.e., to search in S for the request with the largest starting node. We continue in this fashion until we run out of nodes. For the complexity analysis, observe that every request in $\hat{\mathcal{C}}$ is added and removed from S exactly once. Moreover, at the end of each iteration, we need to search in S for the request with the largest starting node, in order to calculate $\max_{(s',t')\in S} s'$. Hence, the time taken by the procedure is at most $O(|\hat{\mathcal{C}}|)$ times the maximum cost for performing each operation. If the set S is maintained as a binary min-max-heap, where the key of each request is its starting node, removing an element from S with label s corresponds to extract the element with smallest key, hence both the insertion and the removal can be made to run in time $O(\log |\hat{\mathcal{C}}|)$; moreover, calculating $\max_{(s',t')\in S} s'$ corresponds to search for the element with largest key, which takes only constant time. Thus, the computation of $\hat{M}_{w_i}$, for every node $w_i \in V_{\mathcal{C}} \cup \{s_0, t_0\}$, takes a total time $O(|\hat{\mathcal{C}}| \log |\hat{\mathcal{C}}|)$, hence $O(|\mathcal{C}| \log |\mathcal{C}|)$.

Now, note that the computation of the $(\hat{M}_m, m)$-canonical ride takes constant time, since by Fact 6, we know that this ride has the form $s_0 \mapsto \hat{M}_m \mapsto \mathsf{left}(\mathcal{R}) \mapsto \mathsf{right}(\mathcal{R}) \mapsto m \mapsto t_0$. Then, the remaining operation in Phase II is the comparison between the cost of the given best ride and cost of the current ride. We have already seen that the computation of the cost of rides built in Phase I can be accommodated in the overall $O(|\mathcal{C}| \log |\mathcal{C}| + |V|)$ cost. Now, we claim that the computation of the cost of the $(\hat{M}_m, m)$-canonical ride takes constant time, provided a suitable pre-processing. Indeed, observe that the $(\hat{M}_m, m)$-canonical ride is succinctly represented by a constant number of nodes. The idea is then to associate each node $x \in V$ with the value $cw(x) = \sum_{i=2}^{x} w(\{i, i+1\})$, which is overall feasible in $O(|V|)$. Then, the cost for a rides moving from a node x to a node y, along the unique path as defined in the notion of canonical ride, is just given by the value $|cw(y) - cw(x)|$. Therefore, with a constant overhead, the cost of the $(\hat{M}_m, m)$-canonical ride can be computed. Putting it all together, Phase II can be implemented in $O(|\mathcal{C}| \log |\mathcal{C}| + |V|)$, too.

4 Optimal Rides on Cycles

In this section, we consider scenarios $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C}\rangle$ such that the underlying graph $G = (V, E, w)$, with $V = \{1, \ldots, n\}$, is a *cycle*. Formally, for each node $v \in V \setminus \{n\}$, the edge $\{v, v+1\}$ is in E; moreover, the edge $\{n, 1\}$ is in E; and no further edge is in E. Without loss of generality, we assume $s_0 = 1$.

The solution approach we shall propose is to reuse the methods we have already developed to deal with scenarios over paths. In this section, we define the key technical ingredients, and based on them an algorithm will be subsequently illustrated. Let π be a ride on $\mathcal{R}$, and let us associate each of its time steps i with a "virtual" node $\tau_\pi(i) = \pi_i + (\ell_\pi(i) - \mathsf{min}_{j\in\{1,\ldots,len(\pi)\}}\ell_\pi(j)) \cdot n$, where $\ell_\pi(1) = 0$ and where, for each $i \in \{2, \ldots, len(\pi)\}$, $\ell_\pi(i)$ is an integer defined as follows: $\ell_\pi(i) = \ell_\pi(i-1)+1$ if $\pi_{i-1} = n$ and $\pi_i = 1$; $\ell_\pi(i) = \ell_\pi(i-1)-1$ if $\pi_{i-1} = 1$ and $\pi_i = n$; and $\ell_\pi(i) = \ell_\pi(i-1)$ otherwise.

Intuitively, the function τ_π keeps track of the number of times in which the cycle is completely traversed by the ride, either clockwise or anti clockwise. Note that $\tau_\pi(i) \texttt{ mod } n = \pi_i$.

Let $\mathsf{cw}(\pi)$ (resp., $\mathsf{acw}(\pi)$) be the maximum (resp., minimum) value of $\tau_\pi(i)$ over all time steps $i \in \{1, \ldots, len(\pi)\}$. Let $\mathsf{cwIdx}(\pi)$ (resp., $\mathsf{acwIdx}(\pi)$) be the minimum time step $i \in \{1, \ldots, len(\pi)\}$ such that $\tau_\pi(i) = \mathsf{acw}(\pi)$ (resp., $\tau_\pi(i) = \mathsf{cw}(\pi)$). Note that $1 \leq \mathsf{acw}(\pi) \leq n$ always hold, by definition of τ_π. In fact, over optimal rides, useful characterizations and bounds can be derived for both $\mathsf{acw}(\pi)$ and $\mathsf{cw}(\pi)$.

Algorithm 4: RideOnCycle

```
Input: A ride-sharing scenario $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C} \rangle$, where $G$ is a cycle;
Output: An optimal ride for $\mathcal{R}$ ;
1 for each tuple $\langle \alpha, \beta, v_{s_0}, v_{t_0}, s^\circ, t^\circ \rangle$ of elements as in Theorem 14 do
2     Let $\pi^\circ$ be an optimal ride for $\langle G^\circ, (v_{s_0}, v_{t_0}), \mathcal{C}^\circ_{\alpha,\beta} \cup \{(s^\circ, t^\circ)\} \rangle$;
3     if $\pi^*$ is not yet defined or $w^\circ(\pi^\circ) < w^\circ(\pi^*)$ then
4         $\pi^* \leftarrow \pi^\circ$;
5 return $\pi^*_1$ mod $n, \ldots, \pi^*_{len(\pi^*)}$ mod $n$;
```

▶ **Lemma 12.** *An optimal ride π exists with $\mathsf{cw}(\pi) \leq 3n$ and $\{\mathsf{cw}(\pi) \texttt{ mod } n, \mathsf{acw}(\pi) \texttt{ mod } n\} \subseteq V_\mathcal{C} \cup \{s_0, t_0\}$.*

Now, consider the path $G^\circ = (V^\circ, E^\circ, w^\circ)$, where $V^\circ = \{1, \ldots, 3n\}$ and where w° is the function such that $w^\circ(\{v, v+1\}) = w(\{v \texttt{ mod } n, (v+1)\texttt{mod } n\})$. For each pair of nodes $\alpha, \beta \in V^\circ$ with $\alpha \leq \beta$, let us define $V^\circ_{\alpha,\beta}$ as the set of nodes $v \in \{\alpha, \ldots, \beta\}$ for which no other distinct node $v' \in \{\alpha, \ldots, \beta\}$ exists such that $v \texttt{ mod } n = v' \texttt{ mod } n$. Note that if $\beta < \alpha + n$, then $V^\circ_{\alpha,\beta} = \{\alpha, \ldots, \beta\}$; if $\beta \geq \alpha + 2n - 1$, then $V^\circ_{\alpha,\beta} = \emptyset$; if $\alpha + n \leq \beta < \alpha + 2n - 1$, then $V^\circ_{\alpha,\beta} = \{\beta - n + 1, \ldots, \alpha + n - 1\}$. Moreover, define $\mathcal{C}^\circ_{\alpha,\beta} = \{(v_s, v_t) \mid (v_s \texttt{ mod } n, v_t \texttt{ mod } n) \in \mathcal{C}, v_s \in V^\circ_{\alpha,\beta}, v_t \in V^\circ_{\alpha,\beta}\}$.

▶ **Theorem 13.** *Let π be a feasible ride for $\mathcal{R}$ with $\mathsf{cw}(\pi) \leq 3n$ and such that $\mathsf{acwIdx}(\pi) \leq \mathsf{cwIdx}(\pi)$ (resp., $\mathsf{acwIdx}(\pi) > \mathsf{cwIdx}(\pi)$). Let $\alpha = \mathsf{acw}(\pi)$ and $\beta = \mathsf{cw}(\pi)$, and let $(s^\circ, t^\circ) = (\alpha, \beta)$ (resp., $(s^\circ, t^\circ) = (\beta, \alpha)$). Then, the ride $\tau_\pi(1), ..., \tau_\pi(len(\pi))$ is feasible for $\langle G^\circ, (\tau_\pi(1), \tau_\pi(len(\pi))), \mathcal{C}^\circ_{\alpha,\beta} \cup \{(s^\circ, t^\circ)\} \rangle$.*

Intuitively, the result tells us that feasible rides for $\mathcal{R}$ are mapped into feasible rides for a suitable defined scenario over a path. Below, we show that the converse also holds, under certain technical conditions.

▶ **Theorem 14.** *Assume that: **(i)** $\alpha, \beta \in V^\circ$ is a pair of nodes such that $\{\alpha \texttt{ mod } n, \beta \texttt{ mod } n\} \subseteq V_\mathcal{C} \cup \{s_0, t_0\}$, $1 \leq \alpha, \beta \leq 3n$, and such that, for each $x \in V_\mathcal{C} \cup \{s_0, t_0\}$, there is a node $v_x \in V^\circ$ with $\alpha \leq v_x \leq \beta$ and $x = v_x \texttt{ mod } n$. **(ii)** $v_{s_0}, v_{t_0} \in V^\circ$ is a pair of nodes such that $\alpha \leq v_{s_0} \leq \beta$, $\alpha \leq v_{t_0} \leq \beta$, $v_{s_0} \texttt{ mod } n = s_0$, and $v_{t_0} \texttt{ mod } n = t_0$. **(iii)** (s°, t°) is a request such that $(s^\circ, t^\circ) \in \{(\alpha, \beta), (\beta, \alpha)\}$. Let π° be a feasible ride for $\langle G^\circ, (v_{s_0}, v_{t_0}), \mathcal{C}^\circ_{\alpha,\beta} \cup \{(s^\circ, t^\circ)\} \rangle$. Then, $\pi^\circ_1 \texttt{ mod } n, \ldots, \pi^\circ_{len(\pi^\circ)} \texttt{ mod } n$ is a feasible ride for $\mathcal{R}$.*

Armed with the above technical ingredients, we can now illustrate Algorithm 4, which we refer to as RideOnCycle. This algorithm computes an optimal ride for any ride-sharing scenario $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C} \rangle$, with G being a cycle. The algorithm founds on the idea of enumerating each possible tuple $\langle \alpha, \beta, v_{s_0}, v_{t_0}, s^\circ, t^\circ \rangle$ of elements as in Theorem 14. For each given configuration, the optimal ride π° over the scenario $\langle G^\circ, (v_{s_0}, v_{t_0}), \mathcal{C}^\circ_{\alpha,\beta} \cup \{(s^\circ, t^\circ)\} \rangle$ is computed. Eventually, π^* is defined (see step 3) as the ride with minimum cost (w.r.t. w°) over such rides π°. The ride $\pi^*_1 \texttt{ mod } n, \ldots, \pi^*_{len(\pi^*)} \texttt{ mod } n$ is then returned. Now, we claim the following.

▶ **Theorem 15.** *Let $\mathcal{R} = \langle G, (s_0, t_0), \mathcal{C} \rangle$ be a ride-sharing scenario where $G = (V, E, w)$ is a cycle. Then, an optimal ride for $\mathcal{R}$ can be computed in time $O(|V_\mathcal{C}|^2 \cdot (|\mathcal{C}| \log |\mathcal{C}| + |V|))$.*

In order to analyze the correctness, observe that by Theorem 14, the ride returned as output, say $\Lambda^* = \pi^*_1 \texttt{ mod } n, \ldots, \pi^*_{len(\pi^*)} \texttt{ mod } n$, is necessarily feasible for $\mathcal{R}$. Therefore, assume for the sake of contradiction that there is an optimal ride π for $\mathcal{R}$ such that $w(\pi) < w(\Lambda^*)$. In particular, by construction of w°, we derive that $w(\pi) < w(\Lambda^*) = w^\circ(\pi^*)$. Now, by Lemma 12, we can actually assume, w.l.o.g., that $\mathtt{cw}(\pi) \leq 3n$ and $\{\mathtt{cw}(\pi) \bmod n, \mathtt{acw}(\pi) \bmod n\} \subseteq V_\mathcal{C} \cup \{s_0, t_0\}$ hold. So, we can apply Theorem 13 and derive the existence of a tuple $\langle \alpha, \beta, v_{s_0}, v_{t_0}, s^\circ, t^\circ \rangle$ of elements, with $v_{s_0} = \tau_\pi(1)$ and $v_{t_0} = \tau_\pi(len(\pi))$, satisfying properties *(i)*, *(ii)*, and *(iii)* in Theorem 14 and such that $\Upsilon = \tau_\pi(1), ..., \tau_\pi(len(\pi))$ is feasible for $\langle G^\circ, (v_{s_0}, v_{t_0}), \mathcal{C}^\circ_{\alpha,\beta} \cup \{(s^\circ, t^\circ)\}\rangle$. In particular, by construction of w°, we derive that $w^\circ(\Upsilon) = w(\pi)$. However, the algorithm has compared the weight of Υ and π^*, and hence we know that $w(\pi) = w^\circ(\Upsilon) \geq w^\circ(\pi^*)$, which is impossible.

Let us finally discuss about the implementation and running time of the algorithm. Before starting the loop, we first compute the sets $W = \{w \in V^\circ \mid 1 \leq w \leq 3n \text{ and } (w \bmod n) \in V_\mathcal{C} \cup \{s_0, t_0\}\}$ and $\mathcal{C}^\circ = \{(s,t) \in W \mid (s \bmod n, t \bmod n) \in \mathcal{C}\}$; this can be done in time $O(|\mathcal{C}|)$ by iterating through the requests in $\mathcal{C}$. Note that $|W| = O(|V_\mathcal{C}|)$ and $\mathcal{C}^\circ| = O(|\mathcal{C}|)$. Now, note that the number of iterations of RideOnCycle corresponds to the number tuples $\langle \alpha, \beta, v_{s_0}, v_{t_0}, s^\circ, t^\circ \rangle$ which satisfy the conditions of Theorem 14. The number of possible pairs (α, β) is $W^2 = O(|V_\mathcal{C}|^2)$. Checking whether condition *(i)* in Theorem 14 holds on them can be simply accomplished by checking that every element $x \in V_\mathcal{C} \cup \{s_0, t_0\}\}$ is such that $\alpha \bmod n \leq x \leq \beta \bmod n$. So, it can be done in constant time after that, in a pre-processing step costing $O(|V_C|)$, the minimum and maximum element in $V_\mathcal{C} \cup \{s_0, t_0\}\}$ have been computed. Moreover, note that since $1 \leq \alpha, \beta \leq 3n$, according to Theorem 14, there are at most 3 possible choices for s_0 (resp, t_0); in addition, there are just two alternatives for the pair s°, t°. Hence, summarizing we have that all tuples satisfying the conditions of Theorem 14 can be enumerated in $O(|V_\mathcal{C}|^2)$. Then, by inspecting the operations performed at each iteration, for each tuple $\langle \alpha, \beta, v_{s_0}, v_{t_0}, s^\circ, t^\circ \rangle$, we have to compute the set $\mathcal{C}^\circ_{\alpha,\beta}$. To this end, we search among the elements in $\mathcal{C}^\circ$ for the pairs (s,t) having both nodes in $V^\circ_{\alpha,\beta}$; this step takes $O(|\mathcal{C}|)$. Finally, on the resulting scenario defined on a path, we apply the algorithm for computing an optimal ride, which costs $O(|\mathcal{C}| \log |\mathcal{C}| + |V|)$. Hence the result in the theorem follows.

Abstract

The Chain Pair Simplification problem (CPS) was posed by Bereg et al. who were motivated by the problem of efficiently computing and visualizing the structural resemblance between a pair of protein backbones. In this problem, given two polygonal chains of lengths n and m, the goal is to simplify both of them simultaneously, so that the lengths of the resulting simplifications as well as the discrete Fréchet distance between them are bounded. When the vertices of the simplifications are arbitrary (i.e., not necessarily from the original chains), the problem is called General CPS (GCPS).

In this paper we consider for the first time the complexity of GCPS under both the discrete Fréchet distance (GCPS-3F) and the Hausdorff distance (GCPS-2H). (In the former version, the quality of the two simplifications is measured by the discrete Fréchet distance, and in the latter version it is measured by the Hausdorff distance.) We prove that GCPS-3F is polynomially solvable, by presenting an $\widetilde{O}((n+m)^6 \min\{n, m\})$ time algorithm for the corresponding minimization problem. We also present an $O((n+m)^4)$ 2-approximation algorithm for the problem. On the other hand, we show that GCPS-2H is **NP**-complete, and present an approximation algorithm for the problem.

1 Introduction

Polygonal curves play an important role in many applied areas, such as 3D modeling, map matching, and protein backbone structural alignment and comparison. There exist many methods for comparing curves in these (and in many other) applications, where one of the more prevalent methods is the Fréchet distance.

* Work by O. Filtser was supported by the Ministry of Science, Technology & Space, Israel, and by the Lynn and William Frankel Center.

The *Fréchet distance* between two curves is often described through the man-dog analogy. Imagine a man and a dog connected by a leash, each walking along his own curve from its starting point to its end point. Both of them can control their speed, but they can only move forward. The Fréchet distance between the two curves is the length of a minimum-length leash that allows them to reach the end point of their curves.

In the *discrete Fréchet distance* we are given finite sequences of points instead of continuous curves. The same rules apply, but now the man and the dog are hopping between the points of their sequence. The discrete Fréchet distance is a simpler version, and is considered a good approximation of the continuous distance.

Recently, the discrete Fréchet distance was used to align and compare protein backbones, yielding favorable results in many instances [11, 12]. A protein backbone may consists of as many as 500$\sim$600 α-carbon atoms, which are the vertices (i.e., points) of our chain. Thus, a natural approach to accelerate computations is to use a simplification of the chain. In general, given a chain A of n vertices, a simplification of A is a chain A' such that A' is "close" to A and the number of vertices in A' is significantly smaller than n. The vertices of the simplification A' can be arbitrary, or restricted to the vertices of A (in order).

Simplifying two aligned chains independently does not necessarily preserve the resemblance between them. Thus, the following question arises: Is it possible to simplify both chains in a way that will retain the resemblance between them? This question has led Bereg et al. [3] to pose the Chain Pair Simplification problem (CPS). In this problem, the goal is to simplify both chains simultaneously, so that the discrete Fréchet distance between the resulting simplifications is bounded. More precisely, given two chains A and B of lengths n and m, respectively, an integer k and three real numbers δ_1,δ_2,δ_3, one needs to find two chains A',B' with vertices from A,B, respectively, each of length at most k, such that $d_1(A, A') \le \delta_1$, $d_2(B, B') \le \delta_2$, $d_{dF}(A', B') \le \delta_3$ (d_1 and d_2 can be any similarity measures and d_{dF} is the discrete Fréchet distance).

When the chains are simplified using the Hausdorff distance, i.e., d_1, d_2 is the Hausdorff distance (CPS-2H), the problem becomes **NP**-complete [3]. When the chains are simplified using the Fréchet distance, i.e., d_1, d_2 is the Fréchet distance (CPS-3F), the problem is polynomially solvable, as shown by Fan et al. [9] who presented an $O(m^2n^2 \min\{m, n\})$-time algorithm for the minimization problem of CPS-3F.

In this paper we consider, for the first time, the problem where the vertices of the simplifications A', B' may be arbitrary points, Steiner points, i.e., they are not necessarily from A, B, respectively. Since this problem is more general, we call it General CPS, or GCPS for short. Our main contribution, see below, is a (relatively) efficient polynomial-time algorithm for GCPS, or more precisely, for its corresponding optimization problem. As a first step towards devising such an algorithm, we had to characterize the structure of a solution to the problem. This was quite difficult, since on the one hand, we have full freedom in determining the vertices of the simplifications, but, on the other hand, the definition of the problem induces an implicit dependency between the two simplifications. The second challenge in devising such an algorithm, is to reduce its time complexity (which is unavoidably high), by making some non-trivial observations on the combinatorial complexity of an arrangement of complex objects that arises, and by applying some sophisticated tricks.

Since the time complexity of our algorithm is still rather high, it makes sense to resort to more realistic approximation algorithms. See below for a detailed description of our results in this direction and of the rest of our results.

Related work

The Fréchet distance and its variants have been studied extensively in the past two decades. Given two polygonal curves of lengths m and n, Alt and Godau [2] gave an $O(mn \log mn)$-time algorithm for computing the Fréchet distance between them. This result in the plane was recently improved by Buchin et al [6]. The discrete Fréchet distance was originally defined by Eiter and Mannila [8], who also presented an $O(mn)$-time algorithm for computing it. A slightly sub-quadratic algorithm was given recently by Agarwal et al. [1]. Bringmann [4], and later Bringmann and Mulzer [5], presented a conditional lower bound implying that strongly subquadratic algorithms for the discrete Fréchet distance are unlikely to exist, even in the one-dimensional case and even if the solution may be approximated up to a factor of 1.399.

Bereg et al. [3] were the first to study simplification problems under the discrete Fréchet distance. They considered several versions of the problem, and presented polynomial-time exact algorithms. Driemel and Har-Peled [7] presented an algorithm for finding an approximate simplification in near linear time.

Our results

In Section 3, we show that GCPS-3F is polynomially solvable by presenting a sophisticated polynomial-time algorithm for the corresponding optimization problem. In Section 4 we give an $O(m+n)^4$-time 2-approximation algorithm for the problem. In Section 5 we consider the 1-sided version of the problem and present a simpler and more efficient algorithm for this problem. Finally, in Section 6 we investigate GCPS-2H, showing that it is **NP**-complete and presenting an approximation algorithm for the problem.

2 Preliminaries

There are several equivalent definitions for the discrete Fréchet distance. In this paper, we use the one that is based on the notion of a paired walk, following [10], [3] and [7].

Let $A = (a_1, \dots, a_n)$ and $B = (b_1, \dots, b_m)$ be two sequences of points in $\mathbb{R}^d$. We denote by $d(a, b)$ the distance between two points $a, b \in \mathbb{R}^d$. For $1 \le i \le j \le n$, we denote by $A[i, j]$ the subchain $a_i, a_{i+1}, \dots, a_j$ of A.

A *paired walk* along A and B is a sequence of pairs (or matchings) $W = \{(A_i, B_i)\}_{i=1}^{k}$, such that $A = A_1 \cdot A_2 \cdots A_k$ and $B = B_1 \cdot B_2 \cdots B_k$, and for any i it holds that $|A_i| = 1$ or $|B_i| = 1$ (where $|A_i|, |B_i| \ge 1$). The *cost of a paired walk* W along A and B is $d_{dF}^{W}(A, B) = \max_i \max_{(a,b)\in A_i \times B_i} d(a, b)$.

The *discrete Fréchet distance* between A and B is $d_{dF}(A, B) = \min_W d_{dF}^{W}(A, B)$. A *Fréchet walk* along A and B is a paired walk W along A and B for which $d_{dF}^{W}(A, B) = d_{dF}(A, B)$.

A δ-simplification of A w.r.t. distance d_1, is a sequence of points $A' = (a'_1, \dots, a'_k)$, such that $k \le n$ and $d_1(A, A') \le \delta$. The points of A' can be arbitrary (the *general* case), or a subset of the points in A appearing in the same order as in A, i.e., $A' = (a_{i_1}, \dots, a_{i_k})$ and $i_1 \le \cdots \le i_k$ (the *restricted* case).

The different versions of the chain pair simplification problem are defined as follows.

▶ **Problem 1.**
Instance: Given a pair of polygonal chains A and B of lengths n and m, respectively, an integer k, and three real numbers $\delta_1, \delta_2, \delta_3 > 0$.
Problem: Does there exist a pair of chains A',B', each of at most k vertices, such that A'

is a δ_1-simplification of A w.r.t. d_1 ($d_1(A, A') \leq \delta_1$), B' is a δ_2-simplification of B w.r.t. d_2 ($d_2(B, B') \leq \delta_2$), and $d_{dF}(A', B') \leq \delta_3$?

When the vertices of the simplifications are from A and B (restricted simplifications), the problem is called CPS, and when the vertices of the simplifications are not necessarily from A and B (arbitrary simplifications), we call the problem GCPS. For each problem, we distinguish between two versions:

1. When $d_1 = d_2 = d_H$, the problems are called CPS-2H and GCPS-2H, respectively.
2. When $d_1 = d_2 = d_{dF}$, the problems are called CPS-3F and GCPS-3F, respectively.

▶ Remark. We sometimes say that a set D of disks of radius δ covers a chain C. By this we mean that there exists a partition of C into consecutive subchains $C = C_1 \cdot C_2 \cdots C_t$, such that for each $1 \leq i \leq t$ there exists a disk in D that contains all the points of C_i.

3 GCPS under the Fréchet distance

In order to solve GCPS-3F, we consider the optimization problem: Given a pair of polygonal chains A and B of lengths n and m, respectively, and three real numbers $\delta_1, \delta_2, \delta_3 > 0$, what is the smallest number k such that there exist a pair of chains A',B', each of at most k (arbitrary) vertices, for which $d_{dF}(A, A') \leq \delta_1$, $d_{dF}(B, B') \leq \delta_2$, and $d_{dF}(A', B') \leq \delta_3$?

We begin by describing some properties that are required from an optimal solution to the problem. Then, based on these properties, we are able to refine our search for the optimal solution.

3.1 What does an optimal solution look like?

Let (A', B') be an optimal solution, that is, let A' and B' be two arbitrary simplifications of A and B respectively, such that $d_{dF}(A, A') \leq \delta_1$, $d_{dF}(B, B') \leq \delta_2$, $d_{dF}(A', B') \leq \delta_3$, and $\max\{|A'|, |B'|\}$ is minimum. Moreover, we assume that the shorter of the chains A', B' is as short as possible.

Let $W_{A'B'} = \{(A'_i, B'_i)\}_{i=1}^{t}$ be a Fréchet walk along A' and B'. Notice that, by definition, for any i it holds that $|A'_i| = 1$ or $|B'_i| = 1$.

Let $W_{AA'}$ be a Fréchet walk along A and A'. Notice that unlike in regular (one-sided) simplifications, the pairs in $W_{AA'}$ may match several points from A' to a single point from A, because A' does not depend only on A but also on B' and B. Similarly, let $W_{BB'}$ be a Fréchet walk along B and B' (see Figure 1).

With each pair $(A'_i, B'_i) \in W_{A'B'}$, we associate a pair of subchains A_i of A and B_i of B, which we call a *pair component*. Assume $A'_i = A'[p, q]$, then A_i is defined as follows:

1. If $p \neq q$, then each $a'_k \in A'[p, q]$ appears as a singleton in $W_{AA'}$ (since otherwise A' can be shortened). Let A^k be the subchain of A that is matched to a'_k, i.e., $(A^k, a'_k) \in W_{AA'}$, for $k = p, \ldots, q$. Then, we set $A_i = A^p A^{p+1} \cdots A^q$.
2. If $p = q$ and a'_p appears as a singleton in $W_{AA'}$, then we set $A_i = A^p$.
3. If $p = q$ and a'_p belongs to some subchain of A' of length at least two that is matched (in $W_{AA'}$) to a single element $a_l \in A$, we set $A_i = a_l$.

The subchains $B_1, \ldots, B_t$ are defined analogously.

We need two observations. The first one is that A_i and B_i are indeed subchains (consecutive sets of points). This is simply because the matchings of the points from A'_i and B'_i in $W_{AA'}$ and $W_{BB'}$, respectively, are sub-chains, and by definition $A_i = A^p A^{p+1} \cdots A^q$ is also a consecutive set of points. The second observation is that the subchains $A_1, \ldots, A_t$ (resp. $B_1, \ldots, B_t$) are almost-disjoint, in the sense that there can be only one point a_x that belongs

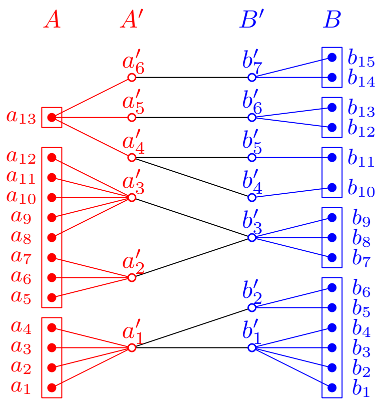

Figure 1 How does an optimal solution look like? a composition of pair-components: $W_{A'B'} = \{(\{a'_1\},\{b'_1,b'_2\}), (\{a'_2,a'_3\},\{b'_3\}), (\{a'_4\},\{b'_4,b'_5\}), (\{a'_5\},\{b'_6\}), (\{a'_6\},\{b'_7\})\}$
$(A_1 = A[1,4], B_1 = [1,6])$, $(A_2 = A[5,12], B_2 = B[7,9])$, $(A_3 = A[13], B_3 = B[10,11])$, $(A_4 = A[13], B_4 = B[12,13])$, $(A_5 = A[13], B_5 = B[14,15])$.

to both A_i and A_{i+1}, and in that case $A_i = A_{i+1} = (a_x)$. This is because if there were more than one point in common, or, if one of A_i, A_{i+1} contained more points, then the sets in $W_{AA'}$ (resp. $W_{BB'}$) were not disjoint.

So what does an optimal solution look like? It is composed of such almost-disjoint *pair-components*. A pair-component is a pair of sub-chains, (A_i, B_i), $A_i \subseteq A$, $B_i \subseteq B$, such that the points of A_i (resp. B_i) can be covered by one disk c of radius δ_1 (resp. δ_2), the points of B_i (resp. A_i) can be covered by a set C of disks of radius δ_2 (resp. δ_1), and for any $c' \in C$, the distance between the center of c and c' is at most δ_3.

The idea of the algorithm is to compute all the possible components (and that there are not too many of them), and then use dynamic programming to compute the optimal solution that is composed of pair-components.

3.2 The algorithm

For any two sub-chains $A[i,i']$ and $B[j,j']$ there are two possible types of pair-components. In the first type, there is only one disk that covers $A[i,i']$, and in the second type, there is only one disk that covers $B[j,j']$.

We denote by $PC_1[i,i',j,j']$ the size of the minimum-cardinality set C of disks of radius δ_2 needed in order to cover $B[j,j']$, such that there exists a disk c of radius δ_1 that covers $A[i,i']$, and for any $c' \in C$, the distance between the centers of c and c' is at most δ_3. Symmetrically, we define $PC_2[i,i',j,j']$. For any 4-tuple of indices (i,i',j,j') we need to compute $PC_1[i,i',j,j']$ and $PC_2[i,i',j,j']$.

Now, in order to compute an optimal solution, we need to combine pair-components in a way that will result in a simplification of minimum size. We use dynamic programming.

Let $OPT[i,j][r]$ be the minimum number of points in a simplification of $B[1,j]$ in an optimal solution for $A[1,i], B[1,j]$ in which the number of points in the simplification of $A[1,i]$ is at most r. Then we have the following dynamic programming algorithm: $OPT[1,1][r] = 1$ if and only if $||a_1 - b_1|| \le \delta_1 + \delta_2 + \delta_3$, and

$$OPT[1,j][r] = \min_{q \le j}\{OPT[1,q-1][r-1] + PC_1[1,1,q,j]\},$$

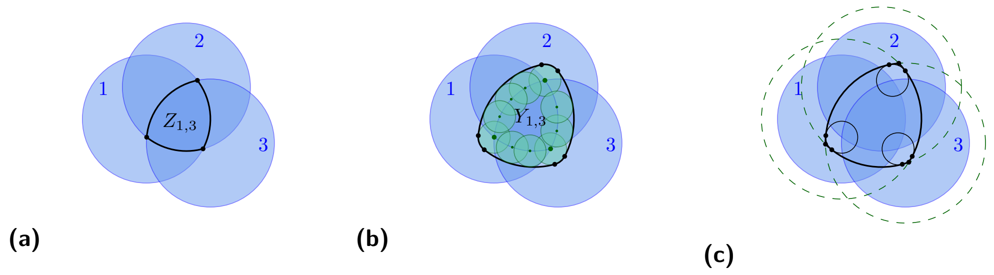

Figure 2 The blue filled disks represent $D(b_j, \delta_2)$ and the empty dashed green disks represent $D(b_j, \delta_2 + \delta_3)$. The small disks has radius δ_3.

$$OPT[i,1][r] = \min_{p \leq i}\{OPT[p-1,1][r - PC_2[p,i,1,1]] + 1\},$$

$$\begin{aligned} OPT[i,j][r] = \min_{p \leq i, q \leq j}\{&OPT[p-1,q-1][r-1] + PC_1[p,i,q,j], \\ &OPT[i,q-1][r-1] + PC_1[i,i,q,j], \\ &OPT[p-1,q-1][r - PC_2[p,i,q,j]] + 1, \\ &OPT[p-1,j][r - PC_2[p,i,j,j]] + 1\}. \end{aligned}$$

▶ **Theorem 1.** *For any i,j and r, $OPT[i,j][r]$ is the minimum number of points in a simplification of $B[1,j]$ in an optimal solution for $A[1,i], B[1,j]$ in which the number of points in the simplification of $A[1,i]$ is at most r.*

Proof. The proof is by induction on i, j, and r. For $i = 1$ and $j = 1$ the theorem holds by definition. Let A' and B' be an optimal solution for $A[1,i], B[1,j]$, s.t. $|A'| \leq r$. Let $[p,i,q,j]$ be the last pair-component in this solution. If $[p,i,q,j]$ is of type 1, i.e. there is one disk that covers $A[p,i]$ and $PC_1[p,i,q,j]$ disks that cover $B[q,j]$, then there are two possibilities: if $p = i$ and the pair-component that came before $[p,i,q,j]$ is $[i,i,q',q-1]$ for some $q' \leq q-1$, then $OPT[i,j][r] = OPT[i,q-1][r-1] + PC_1[i,i,q,j]$, else, $OPT[i,j][r] = OPT[p-1,q-1][r-1] + PC_1[p,i,q,j]$. If $[p,i,q,j]$ is of type 2, i.e. there is one point that covers $B[q,j]$ and $PC_2[p,i,q,j]$ points that cover $A[p,i]$, then again we have two possibilities, $OPT[i,j][r] = OPT[p-1,j][r - PC_2[p,i,j,j]] + 1$ or $OPT[i,j][r] = OPT[p-1,q-1][r - PC_2[p,i,q,j]] + 1$. ◀

3.3 Computing the components

Let $D(p, \delta)$ denote the disk centred at p with radius δ.

Recall that $PC_1[i,i',j,j']$ is the size of a minimum-cardinality set C of disks of radius δ_2 needed in order to cover $B[j,j']$, such that there exists a disk c of radius δ_1 that covers $A[i,i']$, and for any $c' \in C$, the distance between the centers of c and c' is at most δ_3.

We show how to find $PC_1[i,i',j,j']$ for all $1 \leq i \leq i' \leq n$ and $1 \leq j \leq j' \leq m$ ($PC_2[i,i',j,j']$ is symmetric). We begin with a few observations to give an intuition for the algorithm.

Consider $PC_1[i,i',j,j']$. First, notice that the center of c is in the region $X_{i,i'} = \bigcap_{i \leq k \leq i'} D(a_k, \delta_1)$, because the distance from c to any point in $A[i,i']$ is at most δ_1.

Any $c' \in C$ is covering a consecutive subchain of $B[j,j']$. Thus, for any $j \leq t \leq t' \leq j'$, the center of a disk c' that covers the subsequence $B[t,t']$ (if exists) is in the region $Z_{t,t'} = \bigcap_{t \leq k \leq t'} D(b_k, \delta_2)$ (see Figure 2(a)). There are $O((j'-j)^2) = O(m^2)$ such regions.

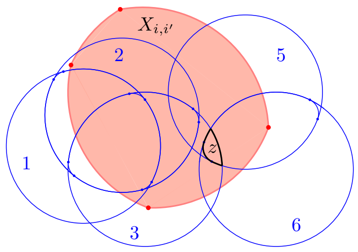

Figure 3 The arrangement $\mathcal{A}(D_A)$. After computing $Size_A(X_{1,4}, j, j')$, we know that $Size_A(X_{1,3}, j, j')$ is the minimum between $Size_A(X_{1,4}, j, j')$ and the values of the cells in $O_{1,3}$.

Each such region is convex and composed of linear number of arcs. Any point placed inside $Z_{t,t'}$ can cover $B[t, t']$, and we need a point with distance at most δ_3 to the center of c. For each $Z_{t,t'}$, consider the Minkowski sum $Y_{t,t'} = Z_{t,t'} \oplus \delta_3$ (see Figure 2(b)).

Now, consider the arrangement obtained by the intersection of $X_{i,i'}$ and the arrangement of $\{Y_{t,t'} \mid j \leq \ t \leq t' \leq j'\}$ (see Figure 3). Each cell in this arrangement corresponds to a set of $Y_{t,t'}$'s, each has some point with distance at most δ_3 to the same points in $X_{i,i'}$. Each cell corresponds to a possible choice of the center of c, or, in other words, a possible pair-component of type 1.

We now describe an algorithm for computing $PC_1[i, i', j, j']$ for all $1 \leq i \leq i' \leq n$ and $1 \leq j \leq j' \leq m$. The algorithm is quite complex and has several sub-procedures.

Let $X = \{X_{i,i'} = \bigcap\limits_{i \leq k \leq i'} D(a_k, \delta_1) \mid 1 \leq i \leq i' \leq n\}$. The number of shapes in X is $O(n^2)$.

Let $Y = \{Y_{j,j'} \mid 1 \leq j \leq j' \leq m,\ Z_{j,j'} \neq \emptyset\}$. The number of shapes in Y is $O(m^2)$, each shape is of complexity $O(m)$.

Consider the arrangement $\mathcal{A}(Y)$ of the shapes in Y.

▶ **Lemma 2.** *The number of cells in $\mathcal{A}(Y)$ is $O(m^4)$.*

Proof. Let P be the set of intersection points between the disks in $\{D(b_j, \delta_2) \mid 1 \leq j \leq m\}$. Consider the following set of disks: $D = \{D(b_i, \delta_2 + \delta_3) \mid 1 \leq i \leq m\} \cup \{D(p, \delta_3) \mid p \in P\}$. Notice that the arcs and vertices of $\mathcal{A}(Y)$ are a subset of the arcs and vertices of $\mathcal{A}(D)$ (see Figure 2(c)). Since the number of points in P is $O(m^2)$, we get that the number of disks in $\mathcal{A}(D)$ is $O(m^2)$, and thus the complexity of $\mathcal{A}(D)$ is $O(m^4)$. ◀

Notice that for any shape $Y_{j,j'} \in Y$ and a cell $z \in \mathcal{A}(Y)$ it holds that $Y_{j,j'} \cap z \neq \emptyset$ if and only if $z \subseteq Y_{j,j'}$. For each cell $z \in \mathcal{A}(Y)$, let Y_z be the set of $O(m^2)$ shapes from Y that contain z. The algorithm has two main steps:

1. For each cell $z \in \mathcal{A}(Y)$, and for any two indices $1 \leq j \leq j' \leq m$, compute $Size_B(z, j, j')$ – the minimum number of shapes from Y_z needed in order to cover the points of $B[j, j']$. Recall that a shape $Y_{t,t'} \in Y_z$ covers the subsequence $B[t, t']$, in other words, there exists a point q in $Y_{t,t'}$ s.t. $d(q, b_k) \leq \delta_2$ for any $t \leq k \leq t'$.
2. For each shape $X_{i,i'} \in X$, and for any two indices $1 \leq j \leq j' \leq m$, compute $Size_A(X_{i,i'}, j, j') = \min\limits_{z \cap X_{i,i'} \neq \emptyset} Size_B(z, j, j')$.

Note that $Size_A(X_{i,i'}, j, j') = PC_1[i, i', j, j']$.

Algorithm 1 $Size_B(Y_z)$

```
For $j$ from 1 to $m$:
  1. Set $counter \leftarrow 1$
  2. Set $j' \leftarrow j$.
  3. Set $p \leftarrow \max\{next(Y_{j,j'}), max(j'+1)\}$.
  4. While $p \neq -\infty$:
       For $k$ from $j'$ to $p$: Set $Size_B(z,j,k) \leftarrow counter$.
       Set $counter \leftarrow counter + 1$
       Set $p \leftarrow \max\{next(Y_{j',k}), max(k+1)\}$.
       Set $j' \leftarrow k$.
```

Step 1

First we have to find the set Y_z for each cell $z \in \mathcal{A}(Y)$. We start by computing Y: for any j, j' we check whether $\bigcap_{j \le k \le j'} D(b_k, \delta_2) \neq \emptyset$. If yes, we add $Y_{j,j'}$ to Y. This can be done in $O(m^3)$ time. Then we compute the arrangement $\mathcal{A}(Y)$, while maintaining the lists Y_z for any cell $z \in \mathcal{A}(Y)$. This can be done in $O(m^4)$ as the complexity of $\mathcal{A}(Y)$ is $O(m^4)$.

Now, for each cell $z \in \mathcal{A}(Y)$ we compute $Size_B(z, j, j')$ for all $1 \le j \le j' \le m$ as follows: Notice that the problem of finding a minimum cover to $B[j, j']$ from a set of subsequences, is actually an interval-cover problem. We refer to the shapes in Y_z as intervals (between 1 and m), and the goal is to find the minimum number of intervals from Y_z needed in order to cover the interval $[j, j']$.

First, for every $1 \le j \le n$ we find $max(j)$ - the largest interval from Y_z that starts at j. This can be done simply in $O(m^2 \log m)$ time, by sorting the intervals first by their lower bound and then by their upper bound.

Next, for an interval $Y_{t,t'} \in Y_z$, consider the intervals in Y_z whose lower bound lies in $[t, t']$ and whose upper bound is greater than t'. Let $next(Y_{t,t'})$ be the largest upper bound among the upper bounds of these intervals. We can find $next(Y_{t,t'})$, for each $Y_{t,t'} \in Y_z$, in total time $O(m^2 \log m)$, using a segment tree as follows: Let $S = \{s_1, \ldots, s_n\}$ be a set of line segments on the x-axis, $s_i = [a_i, b_i]$. Construct a segment tree for the set S. With each vertex v of the tree, store a variable r_v, whose initial value is $-\infty$. Query the tree with each of the left endpoints. When querying with a_i, in each visited vertex v with non-empty list of segments do: if $b_i > r_v$, then set r_v to b_i. Finally, for each segment s, let $next(s)$ be the maximum over the values r_v of the vertices storing s.

After computing $next(Y_{t,t'})$ for all $Y_{t,t'} \in Y_z$ (assume $next(Y_{t,t'}) = -\infty$ for $Y_{t,t'} \notin Y_z$), we use Algorithm 1 to compute $Size_B(z, j, j')$ for all $1 \le j \le j' \le m$. The running time of Algorithm 1 is $O(m^2)$. Thus, computing $Size_B(z, j, j')$ for all cells $z \in \mathcal{A}(Y)$ and all indices $1 \le j \le j' \le m$ takes $O(m^6 \log m)$ time.

Step 2

Recall that $\mathcal{A}(Y)$ is the arrangement obtained from the shapes in Y. Let $\mathcal{A}(D_A)$ be the arrangement of the disks $D_A = \{D(a_k, \delta_1) \mid 1 \le k \le n\}$. The number of cells in $\mathcal{A}(D_A)$ is $O(n^2)$.

A trivial algorithm to compute the value $Size_A(X_{i,i'}, j, j')$ is by considering the values $Size_B(z, j, j')$ of $O(m^4)$ cells from $\mathcal{A}(Y)$. Since there are $O(n^2)$ shapes $X_{i,i'} \in X$ and $O(m^2)$ pairs of indices $1 \le j \le j' \le m$, the running time will be $O(n^2 m^6)$. We manage to reduce

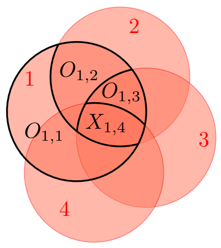

Figure 4 The arrangement $\mathcal{A}(D_A)$. After computing $Size_A(X_{1,4}, j, j')$, we know that $Size_A(X_{1,3}, j, j')$ is the minimum between $Size_A(X_{1,4}, j, j')$ and the values of the cells in $O_{1,3}$.

the running time by a factor of $O(n)$, using some properties of the arrangement of disks.

Let $\mathcal{U}$ be the arrangement of the shapes in Y and the disks in D_A. Notice that $\mathcal{U}$ is a union of the arrangements $\mathcal{A}(D_A)$ and $\mathcal{A}(Y)$.

▶ **Lemma 3.** *The number of cells in $\mathcal{U}$ is $O((m^2 + n)^2)$.*

The proof is similar to the proof of Lemma 2.

We make a few quick observations:

▶ **Observation 1.** For any two cells $w \in \mathcal{U}, x \in \mathcal{A}(D_A)$, $x \cap w \neq \emptyset$ if and only if $w \subseteq x$. Similarly, for any cell $z \in \mathcal{A}(Y)$, $z \cap w \neq \emptyset$ if and only if $w \subseteq z$.

▶ **Observation 2.** For any cell $x \in \mathcal{A}(D_A)$, if $X_{i,i'} \cap x \neq \emptyset$, then $x \subseteq X_{i,i'}$.

▶ **Observation 3.** For any $1 \leq i \leq i' \leq n$ we have $X_{i,i'+1} \subseteq X_{i,i'}$.

Given $w \in \mathcal{U}$, let z_w be the cell from $\mathcal{A}(Y)$ that contains w. We have $Size_B(w, j, j') = Size_B(z, j, j')$.

Let $O_{i,i'}$ be the set of cells $w \in \mathcal{U}$ s.t. $w \subseteq X_{i,i'}$ and $w \nsubseteq X_{i,i'+1}$.

For fixed $1 \leq j \leq j' \leq m$ and $1 \leq i \leq n$, the idea is to compute the values $Size_A(X_{i,n}, j, j'), Size_A(X_{i,n-1}, j, j'), \ldots, Size_A(X_{i,i}, j, j')$ in this order, so we can use the value of $Size_A(X_{i,i'+1}, j, j')$ in order to compute $Size_A(X_{i,i'}, j, j')$, adding only the values of the cells in $O_{i,i'}$ (see Figure 4). This way, any cell in $\mathcal{U}$ will be checked only once (for any fixed $1 \leq j \leq j' \leq m$ and $1 \leq i \leq n$), and the running time will be $O(m^2 n(n + m^2)^2)$.

Now we have to show how to find the sets $O_{i,i'}$.

First, for any cell $x \in \mathcal{A}(D_A)$ we find all the cells $w \in \mathcal{U}$ such that $w \subseteq x$. There are $O(n^2)$ cells in $\mathcal{A}(D_A)$, but from Observation 1 we keep a total of $O((m^2 + n)^2)$ cells from $\mathcal{U}$.

Then, for any shape $X_{i,i'} \in X$ we find the set of cells $P_{i,i'}\{x \in \mathcal{A}(D_A) \mid x \subseteq X_{i,i'}\}$. There are $O(n^2)$ shapes in X, and for each shape we keep $O(n^2)$ cells from $\mathcal{A}(D_A)$.

Now we have $O_{i,i'} = P_{i,i'} \setminus P_{i,i'+1}$. The size of $P_{i,i'}$ is $O(n^2)$, so computing $O_{i,i'}$ for all $1 \leq i \leq i' \leq n$ takes $O(n^4)$ time.

The total running time for all $PC_1[i, i', j, j']$ is $O(m^6 \log m + m^2 n(n + m^2)^2)$

Total running time

For computing $PC_2[i, i', j, j']$ we get symmetrically a total running time of $O(n^6 \log n + n^2 m(m + n^2)^2)$, so the running time for computing all the components is $\widetilde{O}((m + n)^6 \min\{m, n\})$. Calculating $OPT[i, j][r]$ takes $O(m^2 n^2 \min\{m, n\})$ time, all together takes $\widetilde{O}((m + n)^6 \min\{m, n\})$ time.

Algorithm 2

```
Find $X_{i,i'} = \bigcap_{i \le k \le i'} D(a_k, \delta_1)$.
Set $R \leftarrow \mathbb{R}$.
Set $counter \leftarrow 1$.
Set $k \leftarrow j$.
While $k \le j'$ and $counter \neq \infty$:
  1. Set $R \leftarrow R \cap D(b_k, \delta_2)$.
  2. If $(X_{i,i'} \oplus \delta_3) \cap R \neq \emptyset$, set $APC_1[i,i',j,k] \leftarrow counter$.
  3. Else,
       Set $R \leftarrow D(b_k, \delta_2)$.
       If $(X_{i,i'} \oplus \delta_3) \cap R \neq \emptyset$, set $counter \leftarrow counter + 1$.
       Else, set $counter \leftarrow \infty$.
       Set $APC_1[i,i',j,k] \leftarrow counter$.
  4. Set $k \leftarrow k + 1$.
```

4 Approximating GCPS

All the missing proofs of this section can be found in the full version of the paper.

To approximate GCPS, we use approximated pair-components which are easier to compute.

Let $APC_1[i,i',j,j']$ be the minimum number of disks with radius δ_2 needed in order to cover the points of $B[j,j']$ (in order), and whose centers are located in $X_{i,i'} \oplus \delta_3$. Similarly, let $APC_2[i,i',j,j']$ be the minimum number of disks with radius δ_1 needed in order to cover the points of $A[i,i']$ (in order), and whose centers are located in $Z_{j,j'} \oplus \delta_3$.

▶ **Lemma 4.** *For any $1 \le i \le i' \le n, 1 \le j \le j' \le m$, $APC_1[i,i',j,j'] \le PC_1[i,i',j,j']$.*

4.1 Computing the approximated components

We present a greedy algorithm that given $1 \le i \le i' \le n, 1 \le j \le j' \le m$, computes $APC_1[i,i',j,k]$ for all $j \le k \le j'$ (resp. $APC_2[i,k,j,j']$ for all $i \le k \le i'$). The algorithm runs in $O((j'-j)(j'-j+i'-i))$ time (See Algorithm 2).

Running time

Finding $X_{i,i'}$ takes $O(i'-i)$ time, and step 1 takes $O(j'-j)$ time. Step 2 takes $O(j'-j+i'-i)$ time, since the complexity of $X_{i,i'} \oplus \delta_3$ is $O(i'-i)$, the complexity of R is $O(j'-j)$, and both regions are convex. The while loop runs $O(j'-j)$ times, so the total running time is $O((j'-j)(j'-j+i'-i))$.

Computing all the approximated pair components using Algorithm 2 takes $O(n^2m^2(m+n))$ time. The idea of our algorithm is to compute only a small part of the components, and then approximate the others using the ones that were computed.

▶ **Lemma 5.** *Fix $1 \le i \le i' \le n, 1 \le j \le j' \le m$, then for any $i \le x \le i'$ and $j \le y \le j'$:*
1. *$APC_1[i,x,j,j'] \le APC_1[i,i',j,j']$ and $APC_1[x,i',j,j'] \le APC_1[i,i',j,j']$.*
2. *$APC_1[i,i',j,y] + APC_1[i,i',y,j'] \le APC_1[i,i',j,j'] + 1$.*
3. *$APC_1[i,x,j,y] + APC_1[x,i',y,j'] \le APC_1[i,i',j,j'] + 1$.*

We only compute $APC_1[i,i,j,j']$,$APC_2[i,i,j,j']$ for all $1 \le i \le n$ and $1 \le j \le j' \le m$, and $APC_1[i,i',j,j]$,$APC_2[i,i',j,j]$ for all $1 \le i \le i' \le n$ and $1 \le j \le m$. This takes $O(nm^3 + n^2m^2)$ time using Algorithm 2.

4.2 Composing the approximated solution

Let $AAPC_1[i,i',j,j'] = APC_1[i,i,j,j'] + APC_1[i,i',j',j']$. By Lemma 5(3), choosing $x = i$ and $y = j'$, we have $APC_1[i,i,j,j'] + APC_1[i,i',j',j'] \leq APC_1[i,i',j,j'] + 1$, and by Lemma 4 we have $AAPC_1[i,i',j,j'] \leq PC_1[i,i',j,j'] + 1$.

Now let $APX[i,j]$ be the approximate solution for $A[1,i]$ and $B[1,j]$. We set

$$APX[i,j] = \min_{p<i,q<j} APX[p,q] + \min\{AAPC_1[p+1,i,q+1,j], AAPC_2[p+1,i,q+1,j]\}$$

Obviously, given the values of $AAPC_1$ and $AAPC_2$, $APX[n,m]$ can be computed in $O(m^2n^2)$ time.

▶ **Lemma 6.** *Let OPT be the size of an optimal solution, i.e. OPT is the smallest number such that there exists a pair of chains A',B' each of at most OPT (arbitrary) vertices, such that $d_1(A,A') \leq \delta_1$, $d_2(B,B') \leq \delta_2$, and $d_{dF}(A',B') \leq \delta_3$. Then $APX[n,m] \leq 2 \cdot OPT$.*

Thus we have the following theorem:

▶ **Theorem 7.** *A 2-approximation for GCPS can be computed in $O(nm^3 + n^2m^2 + n^3m)$ time.*

▶ Remark. Notice that we do not have to actually compute a solution to GCPS, just to return the minimum k. A solution of size $2 \cdot OPT$ can be computed as follows: for each approximated component $APC_1[i,i',j,j']$ (or $APC_2[i,i',j,j']$) keep the set C_1 of centers of disks that are located in $X_{i,i'} \oplus \delta_3$. For each such center $c_1 \in C_1$, find a point c_2 in $X_{i,i'}$ s.t. $d(c_1,c_2) \leq \delta_3$, and put c_2 in a new set C_2. If our solution $APX[n,m]$ uses the approximated component $APC_1[i,i',j,j']$, then the points of C_1 will be used to cover $B[j,j']$ and the points of C_2 will be used to cover $A[i,i']$.

5 1-Sided GCPS

As in [9], we consider the 1-sided variant of GCPS. In this variant we can imagine there are two dogs, one is walking on a path A and the other on a path B, and a man has to walk both of them, one with a leash of length δ_1 and the other with a leash of length δ_2. We have to find a minimum-size polygonal path for the man, such that he can walk both dogs together.

▶ **Problem 2** (1-Sided General Chain Pair Simplification).
Instance: Given a pair of polygonal chains A and B of lengths n and m, respectively, an integer k, and two real numbers $\delta_1, \delta_2 > 0$.
Problem: Does there exist a chain C of at most k (arbitrary) vertices, such that $d_{dF}(A,C) \leq \delta_1$ and $d_{dF}(B,C) \leq \delta_2$?

Denote $X_{i,i'} = \bigcap_{i \leq k \leq i'} D(a_k, \delta_1)$ and $Z_{j,j'} = \bigcap_{j \leq k \leq j'} D(b_k, \delta_2)$ as before.

For any $1 \leq i \leq i' \leq n$ and $1 \leq j \leq j' \leq m$, let $I[i,i',j,j'] = \begin{cases} 1, & X_{i,i'} \cap Z_{j,j'} \neq \emptyset \\ 0, & otherwise \end{cases}$.
Notice that $I[i,i',j,j'] = 1$ if and only if there exists one point that covers both $A[i,i']$ and $B[j,j']$. The values of $I[i,i',j,j']$ can be computed in $O((n+m)^4)$ time (the details can be found in the full version of the paper).

Now we use a dynamic programming algorithm as follows: Let $OPT[i,j]$ be the length of the minimum-length sequence C such that $d_{dF}(A[1,i],C) \leq \delta_1$ and $d_{dF}(B[1,j],C) \leq \delta_2$. Fix $i,j > 1$, we have $OPT[i,j] = \min_{p,q:I[p,i,q,j]=1} \{OPT[p-1,q-1]+1\}$.

Running time

The values of $I[i,i',j,j']$ can be computed in $O((n+m)^4)$ time. For each $i,j>1$, we have $O(mn)$ values to check. Thus, the running time is $O((m+n)^4)$.

6 GCPS under the Hausdorff distance

The Hausdorff distance between two sets of points A and B is defined as follows:

$$d_H(A,B) = \max\{\max_{a\in A}\min_{b\in B} d(a,b),\ \max_{b\in B}\min_{a\in A} d(a,b)\}.$$

As mentioned above, the chain pair simplification under the Hausdorff distance (CPS-2H) is **NP**-complete. In this section we investigate the general version of this problem. We prove that it is also **NP**-complete, and give an approximation algorithm for the problem.

6.1 GCPS-2H is NP-complete

We show that GCPS under Hausdorff distance (GCPS-2H) is **NP**-complete, we use a simple reduction from geometric set cover: Given a set P of n points, and a radius δ, find the minimum number of disks with radius δ that cover P.

Let the sequence A be the points of P in some order (the order does not matter), and the sequence B be one point b with distance 2δ from P. Let $\delta_1=\delta_2=\delta$ and $\delta_3=4\delta+diam(P)$. Now a simplification for B is just one point anywhere in $D(b,\delta)$, and finding a simplification for A is equivalent to finding the minimum-cardinality set of disks that covers P.

▶ **Theorem 8.** *GCPS-2H is* ***NP****-complete.*

6.2 An approximation algorithm for GCPS-2H

Consider the variant of GCPS-2H where $d_1=d_2=d_H$ and the distance between the simplifications A' and B' is measured with Hausdorff distance and not Fréchet distance (i.e. $d_H(A',B')\le\delta_3$ instead of $d_{dF}(A',B')\le\delta_3$). We call this variant GCPS-3H, and show that GCPS-3H=GCPS-2H.

▶ **Lemma 9.** *Given two sets of points A and B, if $d_H(A,B)\le\delta$, then there exist an ordering A' of the points in A and an ordering B' of the points in B, such that $d_{dF}(A',B')\le\delta$.*

Proof. We construct a bipartite graph $G(V=A\cup B,E)$, where $E=\{(a,b)\mid a\in A,\ b\in B,\ d(a,b)\le\delta\}$. Notice that since $d_H(A,B)\le\delta$, there are no isolated vertices. Now, while there exists a path with three edges in the graph, delete the middle edge. The maximal path in the resulting graph G' has at most two edges, and there are still no isolated vertices (because we only delete the middle edge). Let $C_1,\dots,C_t$ be the connected components of G'. Notice that each C_i has exactly one point from A or exactly one point from B. Let A' be the sequence of points $C_1\cap A,\dots,C_t\cap A$, and B' be the sequence $C_1\cap B,\dots,C_t\cap B$. We get that $C_1,\dots,C_t$ are a paired walk along A' and B' with cost at most δ. ◀

Since we can choose the order of points in the simplifications A' and B' in the GCPS-2H problem, we get by the above lemma that any solution for GCPS-3H is also a solution for GCPS-2H. Now, since for any two sequence P,Q we have $d_H(P,Q)\le d_{dF}(P,Q)$, we get that any solution for GCPS-2H is also a solution for GCPS-3H.

Let $S_1=\{p_1,\dots,p_k\}$ be the smallest set of points such that for each $a_i\in A$ there exists some $p_j\in S_1$ s.t. $d(a_i,p_j)\le\delta_1$ and for each $p_j\in S_1$ there exists some $b_i\in B$ s.t.

$d(p_j, b_i) \le \delta_2 + \delta_3$. Notice that since S_1 is minimum, we also know that for each $p_j \in S_1$ there exists some $a_i \in A$ s.t. $d(a_i, p_j) \le \delta_1$ (or, we can just delete the points of S_1 that do not cover any points from A).

We can find a c-approximation for S_1, using a c-approximation algorithm for discrete unit disk cover (DUDC). The DUDC problem is defined as follows: Given a set P of t points and a set D of k unit disks on a 2-dimensional plane, find a minimum-cardinality subset $D' \subseteq D$ such that the unit disks in D' cover all the points in P. We denote by $T_c(k, t)$ the running time for a c-approximation algorithm for the DUDC problem with k unit disks and t points.

▶ **Lemma 10.** *Given a c-approximation algorithm for the DUDC problem that runs in $T_c(k, t)$ time, we can find a c-approximation for S_1 in $T_c(n, (m + n)^2) + O((m + n)^2)$ time.*

Proof. Compute the arrangement of $\{D(a_i, \delta_1)\}_{1 \le i \le m} \cup \{D(b_j, \delta_2 + \delta_3)\}_{1 \le j \le n}$ (there are $(m + n)^2$ disjoint cells in the arrangement). Clearly, it is enough to choose one candidate from each cell. Now we can use the c-approximation algorithm for the DUDC problem. ◀

Symmetrically, let $S_2 = \{q_1, \dots, q_l\}$ be the smallest set of points such that for each $b_i \in B$ there exists some $q_j \in S_2$ s.t. $d(b_i, q_j) \le \delta_2$ and for each $q_j \in S_2$ there exists some $a_i \in A$ s.t. $d(q_j, a_i) \le \delta_1 + \delta_3$.

For each point $p_j \in S_1$ there exists some $b_i \in B$ s.t. $d(p_j, b_i) \le \delta_2 + \delta_3$, so we can find a point p'_j such that $d(p'_j, b_i) \le \delta_2$ and $d(p'_j, p_j) \le \delta_3$. Denote $S'_1 = \{p'_1, \dots, p'_k\}$. We do the same for the points of S_2, and find a set $S'_2 = \{q'_1, \dots, q'_k\}$ such that for any $q'_j \in S'_2$,$d(q'_j, q_j) \le \delta_3$ and there exists some $a_i \in A$ s.t. $d(q'_j, a_i) \le \delta_1$.

Now, we know that for each $a_i \in A$ there exists some $p \in S_1 \cup S'_2$ s.t. $d(a_i, p) \le \delta_1$, and, on the other hand, for each $p \in S_1 \cup S'_2$ there exists some $a_i \in A$ s.t. $d(a_i, p) \le \delta_1$. So we have $d_H(A, S_1 \cup S'_2) \le \delta_1$. Similarly, we have $d_H(B, S_2 \cup S'_1) \le \delta_2$. We also know that for each $p_j \in S_1$ we have a point $p'_j \in S'_1$ s.t. $d(p'_j, p_j) \le \delta_3$, and for each $q'_j \in S'_2$ we have a point $q_j \in S_2$ s.t. $d(q'_j, q_j) \le \delta_3$. So we also have $d_H(S_1 \cup S'_2, S_2 \cup S'_1) \le \delta_3$, and since CPS-2H=CPS-3H, we get that $S_1 \cup S'_2$ and $S_2 \cup S'_1$ is a possible solution for CPS-2H.

The size of the optimal solution OPT is at least $\max\{|S_1|, |S_2|\}$. Using a c-approximation algorithm for finding S_1 and S_2, the size of the approximate solution will be $c(|S_1| + |S_2|) \le 2c \max\{|S_1| + |S_2|\} = 2c \cdot OPT$.

▶ **Theorem 11.** *Given a c-approximation algorithm for the DUDC problem that runs in $T_c(k, t)$ time, our algorithm gives a $2c$-approximation for the GCPS-2H problem, and runs in $T_c(n, (m + n)^2) + T_c(m, (m + n)^2) + O((m + n)^2)$ time.*

Abstract

The *directed acyclic word graph* (*DAWG*) of a string y is the smallest (partial) DFA which recognizes all suffixes of y and has only $O(n)$ nodes and edges. We present the first $O(n)$-time algorithm for computing the DAWG of a given string y of length n over an integer alphabet of polynomial size in n. We also show that a straightforward modification to our DAWG construction algorithm leads to the first $O(n)$-time algorithm for constructing the *affix tree* of a given string y over an integer alphabet. Affix trees are a text indexing structure supporting bidirectional pattern searches. As an application to our $O(n)$-time DAWG construction algorithm, we show that the set $MAW(y)$ of all minimal absent words of y can be computed in *optimal* $O(n + |MAW(y)|)$ time and $O(n)$ working space for integer alphabets.

1 Introduction

Text indexes are fundamental data structures that allow for efficient processing of string data, and have been extensively studied. Although there are several alternative data structures which can be used as an index, such as suffix trees [18] and suffix arrays [11], in this paper, we focus on *directed acyclic word graphs* (*DAWGs*) proposed by Blumer et al. [3]. Intuitively, the DAWG of string y, denoted $DAWG(y)$, is an edge-labeled DAG obtained by merging isomorphic subtrees of the trie representing all suffixes of string y, called the suffix trie of y. Hence, $DAWG(y)$ can be seen as an automaton recognizing all suffixes of y. Let n be the length of the input string y. Despite the fact that the number of nodes and edges of the suffix trie can be as large as $O(n^2)$, Blumer et al. [3] proved that, surprisingly, $DAWG(y)$ has at most $2n - 1$ nodes and $3n - 4$ edges for $n > 2$. Crochemore [5] showed that $DAWG(y)$ is the smallest (partial) automaton recognizing all suffixes of y, namely, the sub-tree merging operation which transforms the suffix trie to $DAWG(y)$ indeed minimizes the automaton.

Since $DAWG(y)$ is a DAG, in general, more than one string can be represented by its node. It is known that every string represented by the same node of $DAWG(y)$ has the

Table 1 Space requirements and construction times for text indexing structures for input strings of length n over an alphabet of size σ.

	space (in words)	construction time		
		ordered alphabet	integer alphabet	constant alphabet
suffix tries	$O(n^2)$	$O(n^2)$	$O(n^2)$	$O(n^2)$
suffix trees	$O(n)$	$O(n \log \sigma)$ [12]	$O(n)$ [8]	$O(n)$ [18]
suffix arrays	$O(n)$	$O(n \log \sigma)$ [12]+[11]	$O(n)$ [8]+[11]	$O(n)$ [18]+[11]
DAWGs	$O(n)$	$O(n \log \sigma)$ [3]	$O(n)$ [this work]	$O(n)$ [3]
CDAWGs	$O(n)$	$O(n \log \sigma)$ [4]	$O(n)$ [14]	$O(n)$ [4]
affix trees	$O(n)$	$O(n \log \sigma)$ [10]	$O(n)$ [this work]	$O(n)$ [10]

same set of ending positions in the string y. Due to this property, if z is the longest string represented by a node v of $DAWG(y)$, then any other string represented by the node v is a proper suffix of z. Hence, the *suffix link* of each node of $DAWG(y)$ is well-defined; if ax is the shortest string represented by node v where a is a single character and x is a string, then the suffix link of ax points to the node of $DAWG(y)$ that represents string x.

One of the most intriguing properties of DAWGs is that the suffix links of $DAWG(y)$ for any string y forms the suffix tree [18] of the reversed string of y. Hence, $DAWG(y)$ augmented with suffix links can be seen as a *bidirectional* text indexing data structure. This line of research was followed by other types of bidirectional text indexing data structures such as *symmetric compact DAWGs* (*SCDAWGs*) [4] and *affix trees* [15, 10]. DAWGs with suffix links also have applications to other kinds of string processing problems which are not always easily solvable by using suffix trees or arrays, such as: finding *minimal absent words* for a given string [7, 16], finding *α-gapped repeats* that occur in a given string [17], finding *maximal-exponent repeats* in a given overlap-free string [1], computing the *Lempel-Ziv 77 factorization* [20] of a given string in an online manner and with compact space [19].

Time complexities for constructing text indexing data structures depend on the underlying alphabet. See Table 1. For a given string y of length n over an ordered alphabet of size σ, the suffix tree [12], the suffix array [11], the DAWG, and the *compact DAWGs* (*CDAWGs*) [4] of y can all be constructed in $O(n \log \sigma)$ time. These immediately lead to $O(n)$-time construction algorithms for a constant alphabet.

In this paper, we are particularly interested in input strings of length n over an *integer alphabet* of polynomial size in n. Farach-Colton et al. [8] proposed the first $O(n)$-time suffix tree construction algorithm for integer alphabets. Since the out-edges of every node of the suffix tree constructed by McCreight's [12] and Farach-Colton et al.'s algorithms are lexicographically sorted, and since sorting is an obvious lower-bound for constructing edge-sorted suffix trees, the above-mentioned suffix-tree construction algorithms are optimal for ordered and integer alphabets, respectively. Since the suffix array of y can be easily obtained in $O(n)$ time from the edge-sorted suffix tree of y, suffix arrays can also be constructed in optimal time. In addition, since the edge-sorted suffix tree of y can easily be constructed in $O(n)$ time from the edge-sorted CDAWG of y, and since the edge-sorted CDAWG of y can be constructed in $O(n)$ time from the edge-sorted DAWG of y [4], sorting is also a lower-bound for constructing edge-sorted DAWGs and edge-sorted CDAWGs. Using the technique of Narisawa et al. [14], edge-sorted CDAWGs can be constructed in optimal $O(n)$ time for integer alphabets. On the other hand, the only known algorithm to construct DAWGs was Blumer et al.'s $O(n \log \sigma)$-time online algorithm [3] for ordered alphabets of size σ, which results in $O(n \log n)$-time DAWG construction for integer alphabets.

In this paper, we close the gap between the upper and lower bounds for DAWG construction, by proposing the first $O(n)$-time algorithm to construct edge-sorted DAWGs for integer alphabets. Our algorithm also computes the suffix links, and can thus be applied to various kinds of string processing problems. Our algorithm builds $\mathit{DAWG}(y)$ for a given string y by transforming the suffix tree of y to $\mathit{DAWG}(y)$. In other words, our algorithm simulates the minimization of the suffix trie of y to $\mathit{DAWG}(y)$ using only $O(n)$ time and space.

A simple modification to our $O(n)$-time DAWG construction algorithm also leads us to the first $O(n)$-time algorithm to construct affix trees for integer alphabets. We remark that the previous best known affix-tree construction algorithm of Maaß [10] requires $O(n \log n)$ time for integer alphabets.

As an application of our $O(n)$-time DAWG construction algorithm, we present the first optimal time algorithm to compute *minimal absent words* for a given string. Let $\mathit{MAW}(y)$ be the set of minimal absent words of y. Crochemore et al. [7] proposed an algorithm to compute $\mathit{MAW}(y)$ in $\Theta(n\sigma)$ time and $O(n)$ working space. Their algorithm first constructs $\mathit{DAWG}(y)$ with suffix links in $O(n \log \sigma)$ time and compute $\mathit{MAW}(y)$ in $O(n\sigma)$ time using $\mathit{DAWG}(y)$ and its suffix links. Since $|\mathit{MAW}(y)| = O(n\sigma)$, the output size $|\mathit{MAW}(y)|$ is hidden in the running time of their algorithm. In this paper, we show that $\mathit{MAW}(y)$ can be computed in *output-sensitive* $O(n + |\mathit{MAW}(y)|)$ optimal time for integer alphabets. We first construct edge-sorted $\mathit{DAWG}(y)$ in $O(n)$ time using the algorithm we propose in this paper. Then, we show that a slight modification to Crochemore et al.'s algorithm [7] finds $\mathit{MAW}(y)$ in $O(n + |\mathit{MAW}(y)|)$ time. We emphasize that for non-constant alphabets Crochemore et al.'s algorithm takes super-linear time in terms of the input string length independently of the output size $|\mathit{MAW}(y)|$, and thus our results greatly improves the efficiency for integer alphabets. Belazzougui et al. [2] showed that using a representation of the bidirectional BWT of the input string y, $\mathit{MAW}(y)$ can be computed in $O(n + |\mathit{MAW}(y)|)$ time. However, the construction time for the representation of the bidirectional BWT is not given in [2].

Our result can also be applied to recent work by Crochemore et al. [6] for string comparison with minimal absent words, resulting in a more efficient algorithm for string comparison with minimal absent words for integer alphabets.

2 Preliminaries

2.1 Strings

Let Σ denote the alphabet. An element of Σ^* is called a *string*. Let ε denote the empty string, and let $\Sigma^+ = \Sigma^* \setminus \{\varepsilon\}$. For any string y, we denote its length by $|y|$. For any $1 \leq i \leq |y|$, we use $y[i]$ to denote the ith character of y. If $y = uvw$ with $u, v, w \in \Sigma^*$, then u, v, and w are said to be a *prefix*, *substring*, and *suffix* of y, respectively. For any $1 \leq i \leq j \leq |y|$, $y[i..j]$ denotes the substring of y which begins at position i and ends at position j. For convenience, let $y[i..j] = \varepsilon$ if $i > j$. Let $\mathit{Substr}(y)$ and $\mathit{Suffix}(y)$ denote the set of all substrings and that of all suffixes of y, respectively.

Throughout this paper, we will use y to denote the input string. For any string $x \in \Sigma^*$, we define $\mathit{BegPos}(x) = \{i \mid i \in [1, |y| - |x| + 1], y[i..i + |x| - 1] = x\}$, $\mathit{EndPos}(x) = \{i \mid i \in [|x|, |y|], y[i - |x| + 1..i] = x\}$, i.e., the set of beginning and end positions of occurrences of x in y. For any strings u, v, we write $u \equiv_L v$ (resp. $u \equiv_R v$) when $\mathit{BegPos}(u) = \mathit{BegPos}(v)$ (resp. $\mathit{EndPos}(u) = \mathit{EndPos}(v)$). For any string $x \in \Sigma^*$, the equivalence classes with respect to $\equiv_L$ and $\equiv_R$ that x belongs to, are respectively denoted by $[x]_L$ and $[x]_R$. Also, $\overrightarrow{x}$ and $\overleftarrow{x}$ respectively denote the longest elements of $[x]_L$ and $[x]_R$.

For any set S of strings where no two strings are of the same length, let $\mathrm{long}(S) = \arg\max\{|x| \mid x \in S\}$ and $\mathrm{short}(S) = \arg\min\{|x| \mid x \in S\}$.

In this paper, we assume that the input string y of length n is over the integer alphabet $[1, n^c]$ for some constant c, and that the last character of y is a unique character denoted by \$ that does not occur elsewhere in y. Our model of computation is a standard word RAM of machine word size $\log_2 n$. Space complexities will be evaluated by the number of words (not bits).

2.2 Suffix trees and DAWGs

Suffix trees [18] and directed acyclic word graphs (*DAWGs*) [3] are fundamental text data structures. Both of these data structures are based on suffix tries. The *suffix trie* for string y, denoted $\mathit{STrie}(y)$, is a trie representing $\mathit{Substr}(y)$, formally defined as follows.

▶ **Definition 1.** $\mathit{STrie}(y)$ for string y is an edge-labeled rooted tree (V_T, E_T) such that

$$\begin{aligned} V_T &= \{x \mid x \in \mathit{Substr}(y)\} \\ E_T &= \{(x, b, xb) \mid x, xb \in V_T, b \in \Sigma\}. \end{aligned}$$

The second element b of each edge (x, b, xb) is the label of the edge. We also define the set L_T of labeled "reversed" edges called the *suffix links* of $\mathit{STrie}(y)$ by

$$L_T = \{(ax, a, x) \mid x, ax \in \mathit{Substr}(y), a \in \Sigma\}.$$

As can be seen in the above definition, each node v of $\mathit{STrie}(y)$ can be identified with the substring of y that is represented by v. Assuming that string y terminates with a unique character that appears nowhere else in y, for each suffix $y[i..|y|] \in \mathit{Suffix}(y)$ there is a unique leaf ℓ_i in $\mathit{STrie}(y)$ such that the suffix $y[i..|y|]$ is spelled out by the path from the root to ℓ_i.

It is well known that $\mathit{STrie}(y)$ requires $O(n^2)$ space. One idea to reduce its space to $O(n)$ is to contract each path consisting only of non-branching edges into a single edge labeled with a non-empty string. This leads to the suffix tree $\mathit{STree}(y)$ of string y. Following conventions from [4, 9], $\mathit{STree}(y)$ is defined as follows.

▶ **Definition 2.** $\mathit{STree}(y)$ for string y is an edge-labeled rooted tree (V_S, E_S) such that

$$\begin{aligned} V_S &= \{\overrightarrow{x} \mid x \in \mathit{Substr}(y)\} \\ E_S &= \{(x, \beta, x\beta) \mid x, x\beta \in V_S, \beta \in \Sigma^+, b = \beta[1], \overrightarrow{xb} = x\beta\}. \end{aligned}$$

The second element β of each edge $(x, \beta, x\beta)$ is the label of the edge. We also define the set L_S of labeled "reversed" edges called the *suffix links* of $\mathit{STree}(y)$ by

$$L_S = \{(ax, a, x) \mid x, ax \in V_S, a \in \Sigma\},$$

and denote the tree (V_S, L_S) of the suffix links by $\mathit{SLT}(y)$.

Observe that each internal node of $\mathit{STree}(y)$ is a branching internal node in $\mathit{STrie}(y)$. Note that for any $x \in \mathit{Substr}(y)$ the leaves in the subtree rooted at $\overrightarrow{x}$ correspond to $\mathit{BegPos}(x)$. By representing each edge label β with a pair of integers (i, j) such that $y[i..j] = \beta$, $\mathit{STree}(y)$ can be represented with $O(n)$ space.

An alternative way to reduce the size of $\mathit{STrie}(y)$ to $O(n)$ is to regard $\mathit{STrie}(y)$ as a partial DFA which recognizes $\mathit{Suffix}(y)$, and to minimize it. This leads to the directed acyclic word graph $\mathit{DAWG}(y)$ of string y. Following conventions from [4, 9], $\mathit{DAWG}(y)$ is defined as follows.

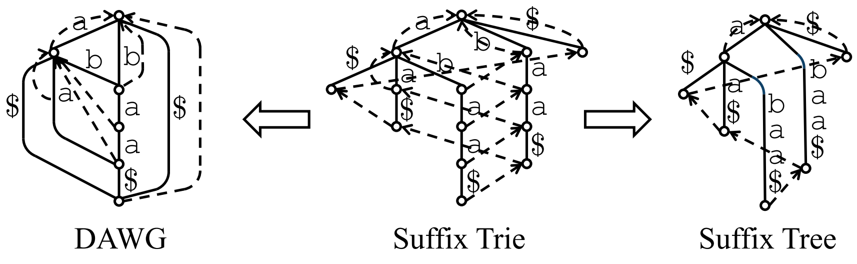

Figure 1 $STrie(y)$, $STree(y)$, and $DAWG(y)$ for string $y = \mathtt{abaa\$}$. The solid arcs represent edges, and the broken arcs represent suffix links.

▶ **Definition 3.** $DAWG(y)$ of string y is an edge-labeled DAG (V_D, E_D) such that

$$\begin{aligned} V_D &= \{[x]_R \mid x \in Substr(y)\} \\ E_D &= \{([x]_R, b, [xb]_R) \mid x, xb \in Substr(y), b \in \Sigma\}. \end{aligned}$$

We also define the set L_D of labeled "reversed" edges called the *suffix links* of $DAWG(y)$ by

$$L_D = \{([ax]_R, a, [x]_R) \mid x, ax \in Substr(y), a \in \Sigma, [ax]_R \neq [x]_R\}.$$

See Figure 1 for examples of $STrie(y)$, $STree(y)$, and $DAWG(y)$.

▶ **Theorem 4** ([3]). *For any string y of length $n > 2$, the number of nodes in $DAWG(y)$ is at most $2n - 1$ and the number of edges in $DAWG(y)$ is at most $3n - 4$.*

Minimization of $STrie(y)$ to $DAWG(y)$ can be done by merging isomorphic subtrees of $STrie(y)$ which are rooted at nodes connected by a chain of suffix links of $STrie(y)$. Since the substrings represented by these merged nodes end at the same positions in y, each node of $DAWG(y)$ forms an equivalence class $[x]_R$. We will make an extensive use of this property in our $O(n)$-time construction algorithm for $DAWG(y)$ over an integer alphabet.

2.3 Minimal Absent Words

A string x is said to be an *absent word* of another string y if $x \notin Substr(y)$. An absent word x of y is said to be a *minimal absent word* (*MAW*) of y if $Substr(x) \setminus \{x\} \subset Substr(y)$. The set of all MAWs of y is denoted by $MAW(y)$. For example, if $\Sigma = \{\mathtt{a}, \mathtt{b}, \mathtt{c}\}$ and $y = \mathtt{abaab}$, then $MAW(y) = \{\mathtt{aaa}, \mathtt{aaba}, \mathtt{bab}, \mathtt{bb}, \mathtt{c}\}$.

▶ **Lemma 5** ([13]). *For any string $y \in \Sigma^*$, $\sigma \leq |MAW(y)| \leq (\sigma_y - 1)(|y| - 1) + \sigma$, where $\sigma = |\Sigma|$ and σ_y is the number of distinct characters occurring in y. This bound is tight.*

The next lemma follows from the definition of MAWs.

▶ **Lemma 6.** *Let y be any string. For any characters $a, b \in \Sigma$ and string $x \in \Sigma^*$, $axb \in MAW(y)$ iff $axb \notin Substr(y)$, $ax \in Substr(y)$, and $xb \in Substr(y)$.*

By Lemma 6, we can encode each MAW axb of y in $O(1)$ space by (i, j, b), where $ax = y[i..j]$.

3 Constructing DAWGs in $O(n)$ Time for Integer Alphabet

In this section, we present an optimal $O(n)$-time algorithm to construct $DAWG(y)$ with suffix links L_D for a given string y of length n over an integer alphabet. Our algorithm constructs $DAWG(y)$ with suffix links L_D from $STree(y)$ with suffix links L_S. The following result is known.

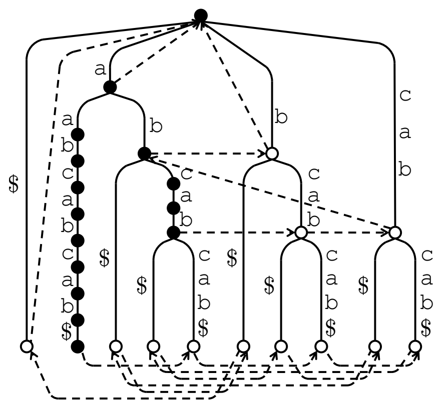

Figure 2 An example of $STree'(y)$ with string $y =$ aabcabcab\$.

▶ **Theorem 7** ([8]). *Given a string y of length n over an integer alphabet, edge-sorted $STree(y)$ with suffix links L_S can be computed in $O(n)$ time.*

Let $\mathcal{L}$ and $\mathcal{R}$ be, respectively, the sets of longest elements of all equivalence classes on y w.r.t. $\equiv_L$ and $\equiv_R$, namely, $\mathcal{L} = \{\overrightarrow{x} \mid x \in Substr(y)\}$ and $\mathcal{R} = \{\overleftarrow{x} \mid x \in Substr(y)\}$. Let $STree'(y) = (V'_S, E'_S)$ be the edge-labeled rooted tree obtained by adding extra nodes for strings in $\mathcal{R}$ to $STree(y)$, namely,

$$\begin{aligned} V'_S &= \{x \mid x \in \mathcal{L} \cup \mathcal{R}\}, \\ E'_S &= \{(x, \beta, x\beta) \mid x, x\beta \in V'_S, \beta \in \Sigma^+, \\ &\quad 1 \leq \forall i < |\beta|, x \cdot \beta[1..i] \notin V'_S\}. \end{aligned}$$

Notice that the size of $STree'(y)$ is $O(n)$, since $|\mathcal{L} \cup \mathcal{R}| \leq |V_S| + |V_D| = O(n)$, where V_S and V_D are respectively the sets of nodes of $STree(y)$ and $DAWG(y)$.

A node $x \in V'_S$ of $STree'(y)$ is called *black* iff $x \in \mathcal{R}$. See Figure 2 for an example of $STree'(y)$.

▶ **Lemma 8.** *For any $x \in Substr(y)$, if x is represented by a black node in $STree'(y)$, then every prefix of x is also represented by a black node in $STree'(y)$.*

Proof. Since x is a black node, $x = \overleftarrow{x}$. Assume on the contrary that there is a proper prefix z of x such that z is not represented by a black node. Let $zu = x$ with $u \in \Sigma^+$. Since $z \equiv_R \overleftarrow{z}$, we have $x = zu \equiv_R \overleftarrow{z}u$. On the other hand, since z is not black, we have $|\overleftarrow{z}| > |z|$. However, this contradicts that x is the longest member $\overleftarrow{x}$ of $[x]_R$. Thus, every prefix of x is also represented by a black node. ◀

▶ **Lemma 9.** *For any string y, let $BT(y)$ be the trie consisting only of the black nodes of $STree'(y)$. Then, every leaf ℓ of $BT(y)$ is a node of the original suffix tree $STree(y)$.*

Proof. Assume on the contrary that some leaf ℓ of $BT(y)$ corresponds to an internal node of $STree'(y)$ that has exactly one child. Since any substring in $\mathcal{L}$ is represented by a node of the original suffix tree $STree(y)$, we have $\ell \in \mathcal{R}$. Since $\ell = \overleftarrow{\ell}$, ℓ is the longest substring of y which has ending positions $EndPos(\ell)$ in y. This implies one of the following situations: (1) occurrences of ℓ in y are immediately preceded by at least two distinct characters $a \neq b$, (2) ℓ occurs as a prefix of y and all the other occurrences of ℓ in y are immediately preceded by a unique character a, or (3) ℓ occurs exactly once in y as its prefix. Let u be the only

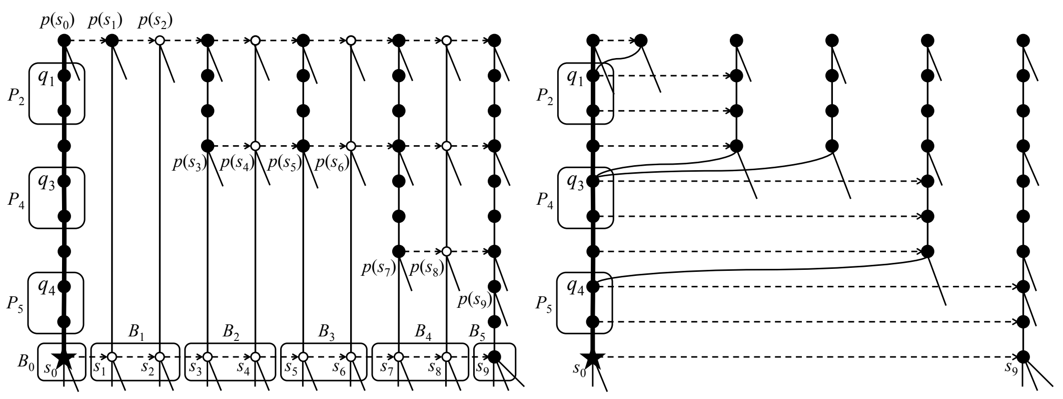

Figure 3 (Left): Illustration for a part of $STree'(y)$, where the branching nodes are those that exist also in the original suffix tree $STree(y)$. Suppose we have just visited node $x = s_0$ (marked by a star) in the post-order traversal on $STree'(y)$. Here, $s_0, \ldots, s_9$ are connected by a chain of the suffix links starting from s_0, and s_9 is the first black node after s_0 in the chain. In the corresponding DAG D, we will add in-coming edges to the black nodes in the path from $p(x)$ to x, and will add suffix links from these black nodes in the path. The sequence $s_0, \ldots, s_m$ of nodes in $STree'(y)$ is partitioned into blocks, such that that the parents of the nodes in the same block belong to the same equivalence class w.r.t. $\equiv_R$. (Right): The in-coming edges and the suffix links have been added to the nodes in the path from $p(x)$ to $x = s_0$.

child of ℓ in $STree'(y)$, and let $\ell z = u$, where $z \in \Sigma^+$. By the definition of ℓ, u is not black. On the other hand, in any of the situations (1)-(3), $u = \ell z$ is the longest substring of y which has ending positions $EndPos(u)$ in y. Hence we have $u = \overleftarrow{u}$ and u must be black, a contradiction. Thus, every leaf ℓ of $BT(y)$ is a node of the original suffix tree $STree(y)$. ◀

▶ **Lemma 10** ([14]). *For any node $x \in V_S$ of the original suffix tree $STree(y)$, its corresponding node in $STree'(y)$ is black iff (1) x is a leaf of the suffix link tree $SLT(y)$, or (2) x is an internal node of $SLT(y)$ and for any character $a \in \Sigma$ such that $ax \in V_S$, $|BegPos(ax)| \neq |BegPos(x)|$.*

Using Lemma 9 and Lemma 10, we can compute all leaves of $BT(y)$ in $O(n)$ time by a standard traversal on the suffix link tree $SLT(y)$. Then, we can compute all internal black nodes of $BT(y)$ in $O(n)$ time using Lemma 8. Now, by Theorem 7, the next lemma holds:

▶ **Lemma 11.** *Given a string y of length n over an integer alphabet, edge-sorted $STree'(y)$ can be constructed in $O(n)$ time.*

We construct $DAWG(y)$ with suffix links L_D from $STree'(y)$, as follows. First, we construct a DAG D, which is initially equivalent to the trie $BT(y)$ consisting only of the black nodes of $STree'(y)$. Our algorithm adds edges and suffix links to D, so that the DAG D will finally become $DAWG(y)$. In so doing, we traverse $STree'(y)$ in post-order. For each black node x of $STree'(y)$ visited in the post-order traversal, which is either an internal node or a leaf of the original suffix tree $STree(y)$, we perform the following: Let $p(x)$ be the parent of x in the *original suffix tree* $STree(y)$. It follows from Lemma 8 that every prefix x' of x with $|p(x)| \leq |x'| \leq |x|$ is represented by a black node. For each black node x' in the path from $p(x)$ to x in the DAG D, we compute the in-coming edges to x' and the suffix link of x'.

Let $s_0, \ldots, s_m$ be the sequence of nodes connected by a chain of suffix links starting from $s_0 = x$, such that $|BegPos(s_i)| = |BegPos(s_0)|$ for all $0 \leq i \leq m-1$ and $|BegPos(s_m)| > |BegPos(s_0)|$ (see the left diagram of Figure 3). In other words, s_m is the first black node after s_0 in the chain of suffix links (this is true by Lemma 10). Since $|s_i| = |s_{i-1}| + 1$ for every $1 \leq i \leq m-1$, $\mathit{EndPos}(s_i) = \mathit{EndPos}(s_0)$. Thus, $s_0, \ldots, s_{m-1}$ form a single equivalence class w.r.t. $\equiv_R$ and are represented by the same node as $x = s_0$ in the DAWG.

For any $0 \leq i \leq m-1$, let $d(s_i) = |s_i| - |p(s_i)|$. Observe that the sequence $d(s_0), \ldots, d(s_m)$ is monotonically non-increasing. We partition the sequence $s_0, \ldots, s_m$ of nodes into blocks so that the parents of all nodes in the same block belong to the same equivalence class w.r.t. $\equiv_R$. Let r be the number of such blocks, and for each $0 \leq k \leq r-1$, let $B_k = s_{i_k}, \ldots, s_{i_{k+1}-1}$ be the kth such block. Note that for each block B_k, $p(s_{i_k})$ is the only black node among the parents $p(s_{i_k}), \ldots, p(s_{i_{k+1}-1})$ of the nodes in B_k, since it is the longest one in its equivalence class $[p(s_{i_k})]_R$. Also, every node in the same block has the same value for function d. Thus, for each block B_k, we add a new edge $(p(s_{i_k}), b_k, q_k)$ to the DAG D, where q_k is the (black) ancestor of x such that $|q_k| = |x| - d(s_{i_k}) + 1$, and b_k is the first character of the label of the edge from $p(s_{i_k})$ to s_{i_k} in $\mathit{STree}'(y)$. Notice that this new edge added to D corresponds to the edges between the nodes in the block B_k and their parents in $\mathit{STree}'(y)$. We also add a suffix link $(p(q_k), a, p(s_{i_k}))$ to D, where $a = s_{i_k - 1}[1]$. See also the right diagram of Figure 3.

For each $2 \leq k \leq r-1$, let P_k be the path from q_{k-1} to g_k, where $g_k = p(p(q_k))$ for $2 \leq k \leq r-2$ and $g_{r-1} = x = s_0$. Each P_k is a sub-path of the path from $p(s_0)$ to s_0, and every node in P_k has not been given their suffix link yet. For each node v in P_k, we add the suffix link from v to the ancestor u of s_{i_k} such that $|s_{i_k}| - |u| = |s_0| - |v|$. See also the right diagram of Figure 3.

Repeating the above procedure for all black nodes of $\mathit{STree}'(y)$ that are either internal nodes or leaves of the original suffix tree $\mathit{STree}(y)$ in post order, the DAG D finally becomes $\mathit{DAWG}(y)$ with suffix links L_D. We remark however that the edges of $\mathit{DAWG}(y)$ might not be sorted, since the edges that exist in $\mathit{STree}'(y)$ were firstly inserted to the DAG D. Still, we can easily sort all the edges of $\mathit{DAWG}(y)$ in $O(n)$ total time after they are constructed: First, extract all edges of $\mathit{DAWG}(y)$ by a standard traversal on $\mathit{DAWG}(y)$, which takes $O(n)$ time. Next, radix sort them by their labels, which takes $O(n)$ time because we assumed an integer alphabet of polynomial size in n. Finally, re-insert the edges to their respective nodes in the sorted order.

▶ **Theorem 12.** *Given a string y of length n over an integer alphabet, we can compute edge-sorted $\mathit{DAWG}(y)$ with suffix links L_D in $O(n)$ time and space.*

Proof. The correctness can easily be seen if one recalls that minimizing $\mathit{STrie}(y)$ based on its suffix links produces $\mathit{DAWG}(y)$. The proposed algorithm simulates this minimization using only the subset of the nodes of $\mathit{STrie}(y)$ that exist in $\mathit{STree}'(y)$. The out-edges of each node of $\mathit{DAWG}(y)$ are sorted in lexicographical order as previously described.

We analyze the time complexity of our algorithm. We can compute $\mathit{STree}'(y)$ in $O(n)$ time by Lemma 11. The initial trie for D can easily be computed in $O(n)$ time from $\mathit{STree}'(y)$. Let x be any node visited in the post-order traversal on $\mathit{STree}'(y)$ that is either an internal node or a leaf of the original suffix tree $\mathit{STree}(y)$. The cost of adding the new in-coming edges to the black nodes in the path from $p(x)$ to $x = s_0$ is linear in the number of nodes in the sequence $s_0, \ldots, s_m$ connected by the chain of suffix links starting from $s_0 = x$. Since s_0 and s_m are the only black nodes in the sequence, it follows from Lemma 10 that the chain of suffix links from s_0 to s_m is a non-branching path of the suffix link tree $\mathit{SLT}(y)$. This implies that the suffix links in this chain are used only for node x during the post-order traversal of $\mathit{STree}'(y)$. Since the number of edges in $\mathit{SLT}(y)$ is $O(n)$, the amortized cost of adding each edge to D is constant. Also, the total cost to sort all edges is $O(n)$, as was previously explained. Now let us consider the cost of adding the suffix links from the nodes in each sub-path P_k. For each node v in P_k, the destination node v can be found in constant time by simply climbing up the path from s_{i_k} in the chain of suffix links. Overall, the total time cost to transform the trie for D to $\mathit{DAWG}(y)$ is $O(n)$.

The working space is clearly $O(n)$. ◀

Figure 4 shows an example of DAWG construction by our algorithm.

In some applications such as bidirectional pattern searches, it is preferable that the in-coming suffix links at each node of $\mathit{DAWG}(y)$ are also sorted in lexicographical order, but our algorithm described above does not sort the suffix links. However, we can sort the suffix links in $O(n)$ time by the same technique applied to the edges of $\mathit{DAWG}(y)$.

4 Constructing Affix Trees in $O(n)$ Time for Integer Alphabet

Let y be the input string of length n over an integer alphabet. Recall the sets $\mathcal{L} = \{\overrightarrow{x} \mid x \in \mathit{Substr}(y)\}$ and $\mathcal{R} = \{\overleftarrow{x} \mid x \in \mathit{Substr}(y)\}$ introduced in Section 3. For any set $S \subseteq \Sigma^* \times \Sigma^*$ of ordered pairs of strings, let $S[1] = \{x_1 \mid (x_1, x_2) \in S$ for some $x_2 \in \Sigma^*\}$ and $S[2] = \{x_2 \mid (x_1, x_2) \in S$ for some $x_1 \in \Sigma^*\}$. For any string x, let $\hat{x}$ denote the reversed string of x.

The affix tree [15] of string y, denoted $\mathit{ATree}(y)$, is a *bidirectional* text indexing structure defined as follows:

▶ **Definition 13.** $\mathit{ATree}(y)$ for string y is an edge-labeled DAG $(V_A, E_A) = (V_A, E_A^F \cup E_A^B)$ which has two mutually distinct sets E_A^F, E_A^B of edges such that

$$\begin{aligned}
V_A &= \{(x, \hat{x}) \mid x \in \mathcal{L} \cup \mathcal{R}\},\\
E_A^F &= \{((x, \hat{x}), \beta, (x\beta, \hat{\beta}\hat{x})) \mid x, x\beta \in V_A[1],\\
&\qquad \beta \in \Sigma^+, 1 \leq \forall i < |\beta|, x \cdot \beta[1..i] \notin V_A[1]\},\\
E_A^B &= \{((x, \hat{x}), \hat{\alpha}, (\alpha x, \hat{x}\hat{\alpha})) \mid \hat{x}, \hat{x}\hat{\alpha} \in V_A[2],\\
&\qquad \alpha \in \Sigma^+, 1 \leq \forall i < |\alpha|, \hat{x} \cdot \hat{\alpha}[1..i] \notin V_A[2]\}.
\end{aligned}$$

E_A^F is the set of forward edges labeled by substrings of y, while E_A^B is the set of backward edges labeled by substrings of $\hat{y}$.

▶ **Theorem 14.** *Given a string y of length n over an integer alphabet, we can compute edge-sorted $\mathit{ATree}(y)$ in $O(n)$ time and space.*

Proof. Clearly, there is a one-to-one correspondence between each node $(x, \hat{x}) \in V_A$ of $\mathit{ATree}(y) = (V_A, E_A^F \cup E_A^B)$ and each node $x \in V_S'$ of $\mathit{STree}'(y) = (V_S', E_S')$ of Section 3 (see also Figure 2 and Figure 5). Moreover, there is a one-to-one correspondence between each forward edge $(x, \beta, x\beta) \in E_A^F$ of $\mathit{ATree}(y)$ and each edge $(x, \beta, x\beta) \in E_S'$ of $\mathit{STree}'(y)$. Hence, what remains is to construct the backward edges in E_A^B for $\mathit{ATree}(y)$. A straightforward modification to our DAWG construction algorithm of Section 3 can construct the backward edges of $\mathit{ATree}(y)$; instead of working on the DAG D, we directly add the suffix links to the black nodes of $\mathit{STree}'(y)$ whose suffix links are not defined yet (namely, those that are neither branching nodes nor leaves of the suffix link tree $\mathit{SLT}(y)$). Since the suffix links are reversed edges, by reversing them we obtain the backward edges of $\mathit{ATree}(y)$. The labels of the backward edges can be easily computed in $O(n)$ time by storing in each node the length of the string it represents. Finally, we can sort the forward and backward edges in lexicographical order in overall $O(n)$ time, using the same idea as in Section 3. ◀

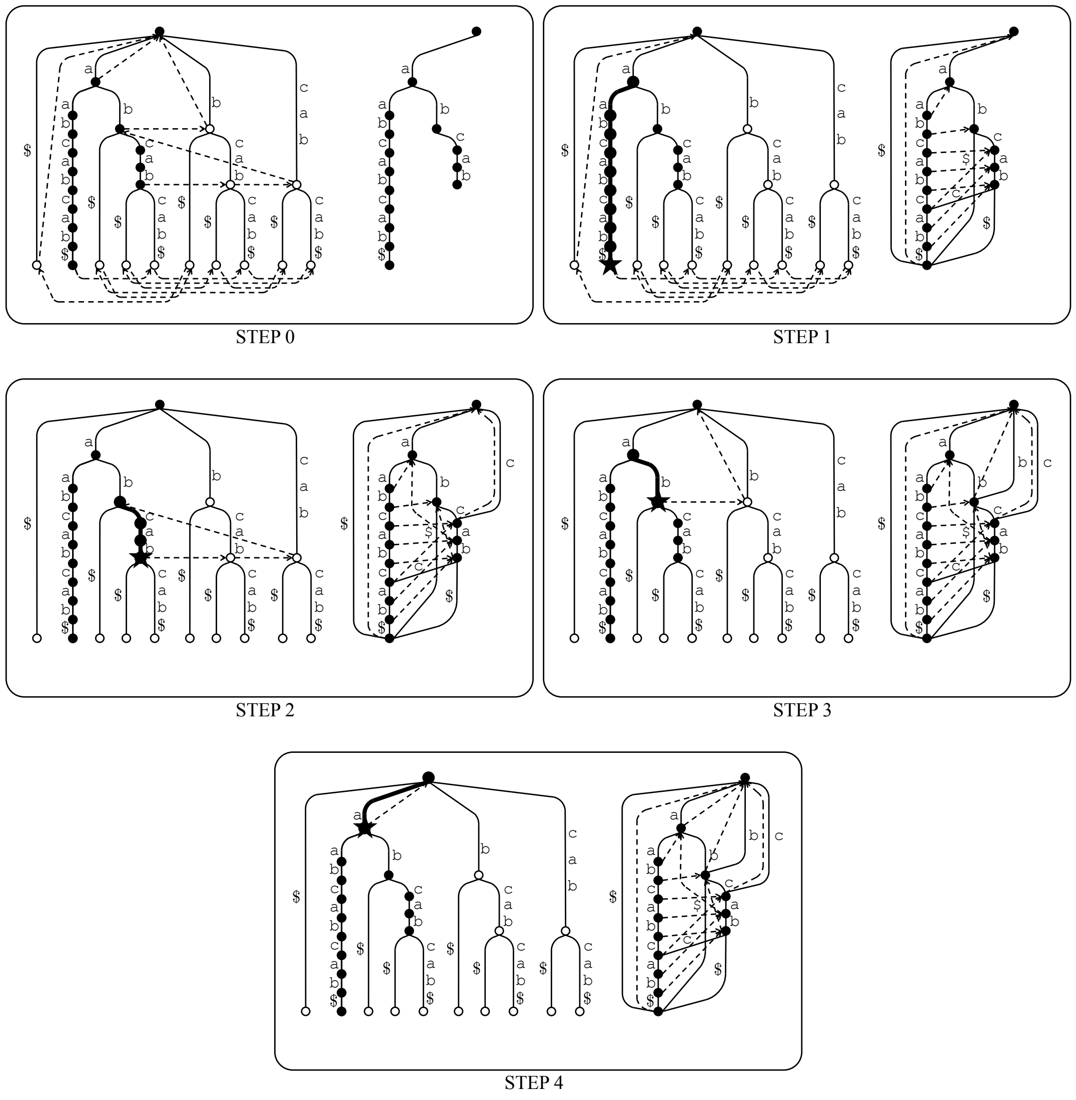

Figure 4 Snapshots during the construction of $DAWG(y)$ for $y = \texttt{aabcabcab\$}$. Step 0: (Left): $STree'(y)$ with suffix links L_S and (Right): the initial trie for D. We traverse $STree'(y)$ in post order. Step 1: We arrived at black leaf node $x_1 = \texttt{aabcabcab\$}$ (indicated by a star). We determine the in-coming edges and suffix links for the black nodes in the path from $p(x_1) = \texttt{a}$ and x_1 (indicated by thick black lines). To the right is the resulting DAG D for this step. Step 2: We arrived at black branching node $x_2 = \texttt{abcab}$ (indicated by a star). We determine the in-coming edges and suffix links for the black nodes in the path from $p(x_2) = \texttt{ab}$ and x_2 (indicated by thick black lines). To the right is the resulting DAG D for this step. Step 3: We arrived at black branching node $x_3 = \texttt{ab}$ (indicated by a star). We determine the in-coming edges and suffix links for the black nodes in the path from $p(x_3) = \texttt{a}$ and x_3 (indicated by thick black lines). To the right is the resulting DAG D for this step. Step 4: We arrived at black branching node $x_4 = \texttt{a}$ (indicated by a star). We determine the in-coming edges and suffix links for the black nodes in the path from $p(x_4) = \varepsilon$ and x_4 (indicated by thick black lines). To the right is the resulting DAG D for this step. Since all branching and leaf black nodes have been processed, the final DAG D is $DAWG(y)$ with suffix links.

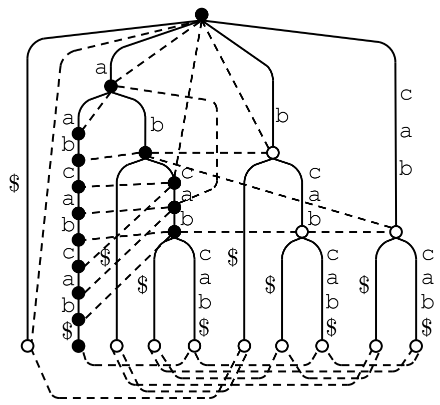

Figure 5 An example of $ATree(y)$ with string $y =$ `aabcabcab$`. The solid arcs represent the forward edges in E_A^F, while the broken arcs represent the backward edges in E_A^B. For simplicity, the labels of backward edges are omitted.

5 Computing Minimal Absent Words in $O(n + |MAW(y)|)$ Time

As an application to our $O(n)$-time DAWG construction algorithm of Section 3, in this section we show an optimal time algorithm to compute the set of all minimal absent words of a given string over an integer alphabet.

Finding minimal absent words of length 1 for a given string y (i.e., the characters not occurring in y) is easy to do in $O(n+\sigma)$ time and $O(1)$ working space for an integer alphabet, where σ is the alphabet size. In what follows, we concentrate on finding minimal absent words of y of length at least 2.

Crochemore et al. [7] proposed a $\Theta(\sigma n)$-time algorithm to compute $MAW(y)$ for a given string y of length n. The following two lemmas, which show tight connections between $DAWG(y)$ and $MAW(y)$, are implicitly used in their algorithm but under a somewhat different formulation. Since our $O(n + |MAW(y)|)$-time solution is built on the lemmas, we give a proof for completeness.

▶ **Lemma 15.** *Let $a, b \in \Sigma$ and $x \in \Sigma^*$. If $axb \in MAW(y)$, then $x = \overleftarrow{x}$, namely, x is the longest string represented by node $[x]_R \in V_D$ of $DAWG(y)$.*

Proof. Assume on the contrary that $x \neq \overleftarrow{x}$. Since x is not the longest string of $[x]_R$, there exists a character $c \in \Sigma$ such that $cx \in Substr(y)$ and $[x]_R = [cx]_R$. Since $axb \in MAW(y)$, it follows from Lemma 6 that $xb \in Substr(y)$. Since $[x]_R = [cx]_R$, c always immediately precedes x in y. Thus we have $cxb \in Substr(y)$.

Since $axb \in MAW(y)$, $c \neq a$. On the other hand, it follows from Lemma 6 that $ax \in Substr(y)$. However, this contradicts that c always immediately precedes x in y and $c \neq a$. Consequently, if $axb \in MAW(y)$, then $x = \overleftarrow{x}$. ◀

For any node $v \in V_D$ of $DAWG(y)$ and character $b \in \Sigma$, we write $\delta_D(v, b) = u$ if $(v, b, u) \in E_D$ for some $u \in V_D$, and write $\delta_D(v, b) = nil$ otherwise. For any suffix link $(u, a, v) \in L_D$ of $DAWG(y)$, we write $sl_D(u) = v$. Since there is exactly one suffix link coming out from each node $u \in V_D$ of $DAWG(y)$, the character a is unique for each node u.

▶ **Lemma 16.** *Let $a, b \in \Sigma$ and $x \in \Sigma^*$. Then, $axb \in MAW(y)$ iff $x = \overleftarrow{x}$, $\delta_D([x]_R, b) = [xb]_R$, $sl_D([ax]_R) = [x]_R$, and $\delta_D([ax]_R, b) = nil$.*

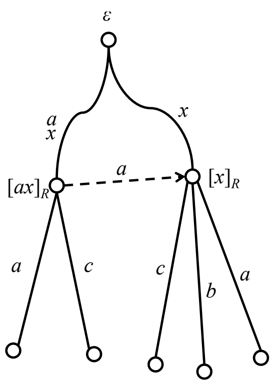

Figure 6 Computing minimal absent words from a DAWG. In this case, axb is a MAW since it does not occur in the string while ax and xb do.

Algorithm 1: $\Theta(n\sigma)$-time algorithm (MF-TRIE) by Crochemore et al. [7]

```
Input: String $y$ of length $n$
Output: All minimal absent words for $y$
1 $MAW \leftarrow \emptyset$;
2 Construct $DAWG(y)$ augmented with suffix links $L_D$;
3 for each non-source node $u$ of $DAWG(y)$ do
4     for each character $b \in \Sigma$ do
5         if $\delta_D(u, b) = nil$ and $\delta_D(sl_D(u), b) \neq nil$ then
6             $MAW \leftarrow MAW \cup \{axb\}$ ;        // $(u, a, sl_D(u)) \in L_D$, $x = \text{long}(sl_D(u))$
7 Output $MAW$;
```

Proof. ($\Rightarrow$) From Lemma 15, $x = \overleftarrow{x}$. From Lemma 6, $axb \notin Substr(y)$. However, $ax, xb \in Substr(y)$, and thus we have $\delta_D([ax]_R, b) = nil$, $\delta_D([x]_R, b) = [xb]_R$, and $sl_D([ax]_R) = [x]_R$, where the last suffix link exists since $x = \overleftarrow{x}$.

($\Leftarrow$) Since $\delta_D([x]_R, b) = [xb]_R$ and $sl_D([ax]_R) = [x]_R$, we have that $xb, ax \in Substr(y)$. Since $ax \in Substr(y)$ and $\delta_D([ax]_R, b) = nil$, we have that $axb \notin Substr(y)$ Thus from Lemma 6, $axb \in MAW(y)$. ◀

From Lemma 16 all MAWs of y can be computed by traversing all the states of $DAWG(y)$ and comparing all out-going edges between nodes connected by suffix links. A pseudo-code of the algorithm MF-TRIE by Crochemore et al. [7], which is based on this idea, is shown in Algorithm 1. Since all characters in the alphabet Σ are tested at each node, the total time complexity becomes $\Theta(n\sigma)$. The working space is $O(n)$, since only the DAWG and its suffix links are needed.

Next we show that with a simple modification in the for loops of the algorithm and with a careful examination of the total cost, the set $MAW(y)$ of all MAWs of the input string y can be computed in $O(n + |MAW(y)|)$ time and $O(n)$ working space. Basically, the only change is to move the "$\delta_D(sl_D(u), b) \neq nil$" condition in Line 5 to the for loop of Line 4. Namely, when we focus on node u of $DAWG(y)$, we test only the characters which label the out-edges from node $sl_D(u)$. A pseudo-code of the modified version is shown in Algorithm 2.

▶ **Theorem 17.** *Given a string y of length n over an integer alphabet, we compute $MAW(y)$ in optimal $O(n + |MAW(y)|)$ time with $O(n)$ working space.*

Algorithm 2: Proposed $O(n + |MAW(y)|)$-time algorithm

```
Input: String $y$ of length $n$
Output: All minimal absent words for $y$
1 $MAW \leftarrow \emptyset$;
2 Construct edge-sorted $DAWG(y)$ augmented with suffix links $L_D$;
3 for each non-source node $u$ of $DAWG(y)$ do
4     for each character $b$ such that $\delta_D(sl_D(u), b) \neq nil$ do
5         if $\delta_D(u, b) = nil$ then
6             $MAW \leftarrow MAW \cup \{axb\}$ ;          // $(u, a, sl_D(u)) \in L_D$, $x = \mathrm{long}(sl_D(u))$
7 Output $MAW$;
```

Proof. First, we show the correctness of our algorithm. For any node u of $DAWG(y)$, $EndPos(sl_D(u)) \supset EndPos(u)$ holds since every string in $sl_D(u)$ is a suffix of the strings in u. Thus, if there is an out-edge of u labeled c, then there is an out-edge of $sl_D(u)$ labeled c. Hence, the task is to find every character b such that there is an out-edge of $sl_D(u)$ labeled b but there is no out-edge of u labeled b. The for loop of Line 4 of Algorithm 2 tests all such characters and only those. Hence, Algorithm 2 computes $MAW(y)$ correctly.

Second, we analyze the efficiency of our algorithm. As was mentioned above, minimal absent words of length 1 for y can be found in $O(n + \sigma)$ time and $O(1)$ working space. By Lemma 5, $\sigma \leq |MAW(y)|$ and hence the σ-term is dominated by the output size $|MAW(y)|$. Now we consider the cost of finding minimal absent words of length at least 2 by Algorithm 2. Let b be any character such that there is an out-edge e of $sl_D(u)$ labeled b. There are two cases: (1) If there is no out-edge of u labeled b, then we output an MAW, so we can charge the cost to check e to an output. (2) If there is an out-edge e' of u labeled b, then the trick is that we can charge the cost to check e to e'. Since each node u has exactly one suffix link going out from it, each out-edge of u is charged only once in Case (2). Since the out-edges of every node u and those of $sl_D(u)$ are both sorted, we can compute their difference for every node u in $DAWG(y)$, in overall $O(n)$ time. Edge-sorted $DAWG(y)$ with suffix links can be constructed in $O(n)$ time for an integer alphabet as in Section 3. Overall, Algorithm 2 runs in $O(n + |MAW(y)|)$ time. The space requirement is clearly $O(n)$. ◀

Abstract

We study the computational complexity of planar valued constraint satisfaction problems (VCSPs). First, we show that intractable *Boolean* VCSPs have to be *self-complementary* to be tractable in the planar setting, thus extending a corresponding result of Dvořák and Kupec [ICALP'15] from CSPs to VCSPs. Second, we give a complete complexity classification of *conservative* planar VCSPs on arbitrary finite domains. As it turns out, in this case planarity does not lead to any new tractable cases, and thus our classification is a sharpening of the classification of conservative VCSPs by Kolmogorov and Živný [JACM'13].

1 Introduction

The valued constraint satisfaction problem (VCSP) is a far-reaching generalisation of many natural satisfiability, colouring, minimum-cost homomorphism, and min-cut problems [18, 21]. It is naturally parametrised by its domain and a valued constraint language. A *domain* D is an arbitrary finite set. A *valued constraint language*, or just a language, Γ is a (usually finite) set of weighted relations; each weighted relation $\gamma \in \Gamma$ is a function $\gamma : D^{\mathrm{ar}(\gamma)} \to \overline{\mathbb{Q}}$, where $\mathrm{ar}(\gamma) \in \mathbb{N}^{+}$ is the *arity* of γ and $\overline{\mathbb{Q}} = \mathbb{Q} \cup \{\infty\}$ is the set of extended rationals.

An *instance* $I = (V, D, C)$ of the VCSP on domain D is given by a finite set of n variables $V = \{x_1, \dots, x_n\}$ and an objective function $C : D^n \to \overline{\mathbb{Q}}$ expressed as a weighted sum of *valued constraints* over V, i.e. $C(x_1, \dots, x_n) = \sum_{i=1}^{q} w_i \cdot \gamma_i(\mathbf{x}_i)$, where γ_i is a weighted relation, $w_i \in \mathbb{Q}_{\geq 0}$ is the *weight* and $\mathbf{x}_i \in V^{\mathrm{ar}(\gamma_i)}$ the *scope* of the ith valued constraint. Given an instance I, the goal is to find an assignment $s : V \to D$ of domain labels to the variables that *minimises* C. Given a language Γ, we denote by VCSP(Γ) the class of all instances I that use only weighted relations from Γ in their objective function.

We now provide a few examples of languages on $D = \{0, 1\}$. If $\Gamma_{\mathsf{nae}} = \{\rho\}$ with $\rho(x, y, z) = \infty$ if $x = y = z$ and $\rho(x, y, z) = 0$ otherwise, then VCSP(Γ_{nae}) captures precisely the NAE-3-Sat (Not-All-Equal 3-Satisfiability) problem. If $\Gamma_{\mathsf{cut}} = \{\gamma\}$ with $\gamma(x, y) = 1$ if $x = y$ and $\gamma(x, y) = 0$ otherwise, then VCSP(Γ_{cut}) captures precisely the Min-UnCut problem. If $\Gamma_{\mathsf{is}} = \{\rho, \gamma\}$ with $\rho(x, y) = \infty$ if $x = y = 1$ and $\rho(x, y) = 0$ otherwise, and $\gamma(x) = 1 - x$, then VCSP(Γ_{is}) captures precisely the Maximum Independent Set problem.

[*] The authors were supported by a Royal Society Research Grant. The work was done while the authors were visiting the Simons Institute for the Theory of Computing at UC Berkeley. Stanislav Živný was supported by a Royal Society University Research Fellowship.

Minimisation of bounded-arity submodular functions (or equivalently, submodular pseudo-Boolean polynomials of bounded degree) corresponds to VCSP(Γ_{sub}) for Γ_{sub} consisting of all weighted relations γ that satisfy $\gamma(\min(\mathbf{x}, \mathbf{y})) + \gamma(\max(\mathbf{x}, \mathbf{y})) \leq \gamma(\mathbf{x}) + \gamma(\mathbf{y})$, where min and max are applied componentwise.

We will be concerned with *exact* solvability of VCSPs. A language Γ is called *tractable* if VCSP(Γ') can be solved (to optimality) in polynomial time for every finite subset $\Gamma' \subseteq \Gamma$, and Γ is called *intractable* if VCSP(Γ') is NP-hard for some finite $\Gamma' \subseteq \Gamma$. For instance, Γ_{sub} is tractable [8] whereas Γ_{nae}, Γ_{cut}, Γ_{is} are intractable [15].

1.1 Contribution

Languages on a two-element domain are called *Boolean.* The complexity of Boolean valued constraint languages is well understood and eight tractable cases have been identified [8]. Suppose that a Boolean language Γ is intractable. We are interested in restrictions that can be imposed on input instances of VCSP(Γ) that make the problem tractable. A natural way is to restrict the *incidence graph* of the instance (the precise definition is given in Section 2). In this paper we initiate the study of the *planar* variant of the VCSP.

We denote by $\mathrm{VCSP}_{\mathrm{p}}(\Gamma)$ the class of instances I of VCSP(Γ) with planar incidence graph (with an additional requirement that leads to a finer classification, as discussed in detail in Section 2). Language Γ is called *planarly-tractable* if $\mathrm{VCSP}_{\mathrm{p}}(\Gamma')$ can be solved (to optimality) in polynomial time for every finite subset $\Gamma' \subseteq \Gamma$, and it is called *planarly-intractable* if $\mathrm{VCSP}_{\mathrm{p}}(\Gamma')$ is NP-hard for some finite $\Gamma' \subseteq \Gamma$. For instance, while Γ_{nae}, Γ_{cut}, and Γ_{is} are intractable, it is known that Γ_{nae} and Γ_{cut} are planarly-tractable [28, 17] whereas Γ_{is} is planarly-intractable [14]. The problem of classifying all intractable languages as planarly-tractable and planarly-intractable is challenging and open even for Boolean valued constraint languages.

A Boolean valued constraint language Γ is called *self-complementary* if every $\gamma \in \Gamma$ satisfies $\gamma(\mathbf{x}) = \gamma(\overline{\mathbf{x}})$ for every $\mathbf{x} \in D^{\mathrm{ar}(\gamma)}$, where $\overline{\mathbf{x}} = (1 - x_1, \ldots, 1 - x_{\mathrm{ar}(\gamma)})$ for $\mathbf{x} = (x_1, \ldots, x_{\mathrm{ar}(\gamma)})$. As our first contribution, we show in Section 3 that intractable Boolean valued constraint languages that are *not* self-complementary are planarly-intractable. We prove this by carefully constructing planar NP-hardness gadgets for any intractable Boolean valued constraint language that is not self-complementary, relying on the fact that all tractable Boolean valued constraint languages are known [8]. Our result subsumes the analogous result obtained for $\{0, \infty\}$-valued languages [10]. We remark that focusing on Boolean languages is natural as it avoids a number of difficulties intrinsic to the planar setting. Let $\Gamma_{\mathsf{col}} = \{\gamma\}$ with $\gamma(x, y) = 0$ if $x \neq y$ and $\gamma(x, y) = \infty$ otherwise. Then Γ_{col} on domain D with $|D| = 3$ is planarly intractable (since $\mathrm{VCSP}_{\mathrm{p}}(\Gamma_{\mathsf{col}})$ captures precisely the 3-Colouring problem on planar graphs) [15] but is tractable on D with $|D| = 4$ for highly nontrivial reasons, namely the Four Colour Theorem.

A valued constraint language Γ on D is called *conservative* if Γ contains all $\{0, 1\}$-valued unary weighted relations. The complexity of conservative valued constraint languages is well understood: a complete complexity classification has been obtained in [26], with a recent simplification of both the algorithmic and the hardness part [35]. As our second contribution, we give a complete complexity classification of conservative valued constraint languages on arbitrary finite domains with respect to planar-tractability. In particular, we show that every intractable conservative valued constraint language is also planarly-intractable. Hence there are no new tractable cases in the conservative planar setting. This may seem unsurprising but the proof is not trivial.

Note that for Boolean valued constraint languages that are conservative the claim follows immediately from our first result: any intractable Boolean language containing both $\gamma_0(x) = x$

and $\gamma_1(x) = 1 - x$ (guaranteed by the conservativity assumption) is not self-complementary, and thus is planarly-intractable. This shows that $\Gamma = \Gamma_{\mathsf{cut}} \cup \{\gamma_0, \gamma_1\}$ is intractable, a result originally obtained in [1] since $\mathrm{VCSP_p}(\Gamma)$ captures precisely the planar Min-UnCut problem with unary weights. (In fact, the same argument shows that both $\Gamma_{\mathsf{cut}} \cup \{\gamma_0\}$ and $\Gamma_{\mathsf{cut}} \cup \{\gamma_1\}$ are planarly-intractable.)

As it is common in the world of CSPs, dealing with non-Boolean domains is considerably more difficult than the case of Boolean domains. For valued constraint languages we have a Galois connection with certain algebraic objects [6, 13] but no Galois connection is known for valued constraint languages in the planar setting. Moreover, it is unclear how to use the recent relatively simple proof of the complexity classification of conservative valued constraint languages [35] and make it work in the planar setting since the proof depends on linear programming duality. (This is related to the lack of a Galois connection in the planar setting. In particular, [35, Lemma 2], which relates (non-planar) expressibility and operator Opt, is proved via LP duality, and it is unclear how to prove it in the planar setting.)

Our approach is to follow the original proof of the classification of conservative valued constraint languages [26]. In order to adapt the proof for the planar setting, we significantly simplify it and generalise necessary parts. Details on proof differences as well as challenges that we needed to overcome to make the proof work are outlined in Section 4. We believe that our proof techniques, and in particular the now simplified and generalised technique from [26], will be useful in future work on planar (V)CSPs.

1.2 Related work

VCSPs with $\{0, \infty\}$-valued weighted relations are just (ordinary) decision CSPs [11]. There has been a lot of work on decision CSPs, see [5] for a recent survey. Most results have been obtained for CSPs parametrised by a constraint language, see [2] for a recent survey. Some of the algebraic methods developed for CSPs [3] have been extended to VCSPs [6, 34, 13, 27] and successfully used in classifying various fragments of VCSPs [20, 25, 33, 23, 35]. However, it is unclear how to use algebraic methods for instance-restricted classes of VCSPs (sometimes called *hybrid* [5]), even though there are some recent investigations in this direction [24, 32].

Planar restrictions have been studied for Boolean (decision) CSPs [10], for Boolean symmetric counting CSPs with real [4] and complex [16] weights, and also for Boolean CSPs with respect to polynomial-time approximation schemes [22, 9].

2 Preliminaries

2.1 Planar VCSPs

Let I be a VCSP instance with variables V and valued constraints S. The *incidence graph* of I is the bipartite multigraph with vertex set $S \cup V$ and edges (γ, x_i) for every $\gamma(x_1, \ldots, x_{\mathrm{ar}(\gamma)}) \in S$ and $1 \leq i \leq \mathrm{ar}(\gamma)$.

We are interested in VCSP instances with *planar* incidence graphs. Following [10], we additionally require the order of edges around constraint vertices in the plane drawing of the incidence graph respect the order of arguments of the corresponding constraint. Note that the variant without this additional restriction can be easily modelled by replacing each weighted relation γ in a language by all weighted relations obtained from γ by permuting the order of its inputs. Hence, this choice leads to a finer classification.

Following [10], rather than working with the incidence graph, we equivalently define the problem in terms of a related plane graph where variables correspond to vertices and valued constraints to faces. We note that our graphs are allowed to have loops, possibly several at a single vertex, and parallel edges.

For a connected plane graph G, we denote by $F(G)$ the set of its faces. For any face $f \in F(G)$, let $b(f)$ denote a closed walk bounding f, enumerated in the clockwise order around f.

▶ **Definition 1.** A *plane* VCSP *instance* (I, G, ϕ) is given by a VCSP instance I with variables V and objective function C with q valued constraints, a connected plane graph G over vertices V, and an injective mapping $\phi : \{1, \dots, q\} \to F(G)$ such that for every valued constraint $\gamma_i(x_1, x_2, \dots, x_{\mathrm{ar}(\gamma_i)})$ it holds $b(\phi(i)) = x_1 x_2 \dots x_{\mathrm{ar}(\gamma_i)} x_1$.

We note that the definition of a *planar* VCSP *instance*, in which case the graph G and mapping ϕ are not given, is equivalent to Definition 1. This is because, as mentioned in [10], checking whether a VCSP instance I has a planar representation, and if so then finding (I, G, ϕ), can be done in polynomial time [19]. For simplicity of presentation, we will assume that graph G and mapping ϕ are given.

We denote by $\mathrm{VCSP}_\mathrm{p}(\Gamma)$ the class of plane VCSP instances over the language Γ.

2.2 Planar Weighted Relational Clones

In this section, we define planar weighted relational clones, which are closures of valued constraint languages that do not change the tractability of corresponding planar VCSPs.

Relations can be seen as a special case of weighted relations with range $\{0, \infty\}$ (also called *crisp*). For a weighted relation $\gamma : D^r \to \overline{\mathbb{Q}}$, we denote by $\mathrm{Feas}(\gamma) = \{\mathbf{x} \in D^r \mid \gamma(\mathbf{x}) < \infty\}$ the underlying *feasibility relation*, and by $\mathrm{Opt}(\gamma) = \{\mathbf{x} \in \mathrm{Feas}(\gamma) \mid \gamma(\mathbf{x}) \le \gamma(\mathbf{y})$ for every $\mathbf{y} \in D^r\}$ the relation of minimal-value (or *optimal*) tuples. We also write $\mathrm{Feas}(\gamma) = 0 \cdot \gamma$ and see the Feas operator as scaling a weighted relation by zero, where we define $0 \cdot \infty = \infty$.

An assignment $s : V \to D$ for a VCSP instance (V, D, C) with $V = \{x_1, \dots, x_n\}$ is called *feasible* if $C(s(x_1), \dots, s(x_n)) < \infty$.

▶ **Definition 2.** Let (I, G, ϕ) be a plane VCSP instance such that ϕ does not map any i to the outer face f_o of G, and let $\mathbf{v} = (v_1, \dots, v_r)$ be an r-tuple of variables from V such that $b(f_o) = v_r v_{r-1} \dots v_1 v_r$. We denote by $\pi_\mathbf{v}(I)$ the r-ary weighted relation mapping any $\mathbf{x} \in D^r$ to the minimum objective value obtained by feasible assignments s of I with $s(\mathbf{v}) = \mathbf{x}$, or ∞ if no such feasible assignment exists.

An r-ary weighted relation γ is *planarly expressible* from a valued constraint language Γ if there exists a plane instance I over Γ and an r-tuple $\mathbf{v}$ of its variables such that $\pi_\mathbf{v}(I) = \gamma$.

▶ **Definition 3.** A *planar weighted relational clone* is a non-empty set of weighted relations over the same domain that is closed under planar expressibility, scaling by non-negative rational constants, addition of rational constants, and operator Opt. We will denote the smallest planar weighted relational clone containing a valued constraint language Γ by $\mathrm{wClone}_\mathrm{p}(\Gamma)$.

An analogous notion of weighted relational clones closed under *general* (i.e. not necessarily planar) expressibility [6, 13] has been used to study the complexity of VCSPs.

▶ **Lemma 4.** *For any domain D and language Γ on D, the binary equality relation $\rho_=$ on D belongs to* $\mathrm{wClone}_\mathrm{p}(\Gamma)$.

Proof. Relation $\rho_=$ is planarly expressible by a plane instance consisting of a single variable x with two self-loops, and $\mathbf{v} = (x, x)$. ◀

▶ **Theorem 5.** *For any valued constraint language* Γ, Γ *is planarly-tractable if, and only if,* $\mathrm{wClone_p}(\Gamma)$ *is planarly-tractable, and* Γ *is planarly-intractable if, and only if,* $\mathrm{wClone_p}(\Gamma)$ *is planarly-intractable.*

Proof. We show that $\mathrm{VCSP_p}(\mathrm{wClone_p}(\Gamma))$ is polynomial-time reducible to $\mathrm{VCSP_p}(\Gamma)$. Given an instance I over $\mathrm{wClone_p}(\Gamma)$, we replace in it all weighted relations planarly expressible from Γ by their plane instances. Scaling, which includes Feas, can be achieved by adjusting the weights of the valued constraints. Adding a constant to a weighted relation affects the value of every feasible assignment by the same amount, and therefore can be ignored.

Relation $\mathrm{Opt}(\gamma)$ can be simulated by scaling γ by a sufficiently large constant. Let W equal an upper bound on the maximum objective value of a feasible assignment of I. Without loss of generality, we may assume that no weighted relation of I assigns a negative value and that the smallest value assigned by γ is 0. Let d equal the second smallest value assigned by γ. We replace $\mathrm{Opt}(\gamma)$ with $(W/d+1)\cdot\gamma$, so that any assignment of I that would incur an infinite value from $\mathrm{Opt}(\gamma)$ has now objective value exceeding W. ◀

2.3 Algebraic Properties

For any r-tuple $\mathbf{x} \in D^r$, we write x_i for its ith component. We apply a k-ary operation $f : D^k \to D$ to k r-tuples componentwise; that is, if $\mathbf{x}^1 = (x^1_1,\dots,x^1_r), \mathbf{x}^2 = (x^2_1,\dots,x^2_r),\dots,\mathbf{x}^k = (x^k_1,\dots,x^k_r)$, then

$$f(\mathbf{x}^1,\dots,\mathbf{x}^k) \;=\; (f(x^1_1,x^2_1,\dots,x^k_1), f(x^1_2,x^2_2,\dots,x^k_2),\dots,f(x^1_r,x^2_r,\dots,x^k_r))\,.$$

The following notion is at the heart of the algebraic approach to decision CSPs [3].

▶ **Definition 6.** Let γ be a weighted relation on D. A k-ary operation $f : D^k \to D$ is a *polymorphism* of γ (and γ is *invariant under* or *admits* f) if, for every $\mathbf{x}^1,\dots,\mathbf{x}^k \in \mathrm{Feas}(\gamma)$, we have $f(\mathbf{x}^1,\dots,\mathbf{x}^k) \in \mathrm{Feas}(\gamma)$. We say that f is a polymorphism of a language Γ if it is a polymorphism of every $\gamma \in \Gamma$. We denote by $\mathrm{Pol}(\Gamma)$ the set of all polymorphisms of Γ.

A k-ary *projection* is an operation of the form $\pi^{(k)}_i(x_1,\dots,x_k) = x_i$ for some $1 \le i \le k$. Projections are (trivial) polymorphisms of all valued constraint languages.

The following notion, which involves a collection of k k-ary polymorphisms, played an important role in the complexity classification of Boolean valued constraint languages [8].

▶ **Definition 7.** Let γ be a weighted relation on D. A list $\langle f_1,\dots,f_k\rangle$ of k-ary polymorphisms of γ is a k-ary *multimorphism* of γ (and γ *admits* $\langle f_1,\dots,f_k\rangle$) if, for every $\mathbf{x}^1,\dots,\mathbf{x}^k \in \mathrm{Feas}(\gamma)$, we have

$$\sum_{i=1}^{k} \gamma(f_i(\mathbf{x}^1,\dots,\mathbf{x}^k)) \;\le\; \sum_{i=1}^{k} \gamma(\mathbf{x}^i)\,. \tag{1}$$

We say that $\langle f_1,\dots,f_k\rangle$ is a multimorphism of a language Γ if it is a multimorphism of every $\gamma \in \Gamma$.

It is known that weighted relational clones preserve polymorphisms and multimorphisms [6] and thus planar weighted relational clones do as well.

▶ **Example 8.** The class of submodular functions on $D = \{0,1\}$ [30] can be defined as the valued constraint language Γ_{sub} that admits $\langle \min,\max\rangle$ as a multimorphism; that is, for every $\gamma \in \Gamma_{\mathsf{sub}}$, we have $\gamma(\min(\mathbf{x},\mathbf{y})) + \gamma(\max(\mathbf{x},\mathbf{y})) \le \gamma(\mathbf{x}) + \gamma(\mathbf{y})$.

3 Boolean Valued CSPs

In this section, we will consider only languages on a Boolean domain $D = \{0, 1\}$. Our first result is that self-complementarity is necessary for planar-tractability of intractable Boolean languages.

▶ **Theorem 9.** *Let Γ be a Boolean valued constraint language that is intractable. If Γ is not self-complementary then it is planarly-intractable.*

We start with some notation for important operations on D. For any $a \in D$, c_a is the constant unary operation such that $c_a(x) = a$ for all $x \in D$. Operation $\neg$ is the unary negation, i.e. $\neg(0) = 1$ and $\neg(1) = 0$. Binary operation min (max) is the minimum (maximum) operation with respect to the order $0 < 1$. Ternary operation Mn (Mj) is the unique minority (majority) operation.

Next we define some useful relations. For any $a \in D$, we denote by ρ_a the unary constant relation $\{(a)\}$. Relation $\rho_{\neq}$ is the binary disequality relation, i.e. $\rho_{\neq} = \{(0, 1), (1, 0)\}$. Ternary relation $\rho_{\text{1-in-3}}$ corresponds to the 1-in-3 Positive 3-Sat problem, i.e. $\rho_{\text{1-in-3}} = \{(0, 0, 1), (0, 1, 0), (1, 0, 0)\}$. Weighted relations $\gamma_0, \gamma_1, \gamma_{\neq}$ are defined as soft-constraint variants of $\rho_0, \rho_1, \rho_{\neq}$ assigning value 0 to allowed tuples and 1 to disallowed tuples.

Note that Γ is self-complementary if, and only if, Γ admits multimorphism $\langle\neg\rangle$. The proof of Theorem 9 is based on the following four lemmas.

▶ **Lemma 10.** *Let Γ be a valued constraint language that admits neither of the multimorphisms $\langle c_0\rangle$, $\langle c_1\rangle$. Then $\rho_0, \rho_1 \in \mathrm{wClone_p}(\Gamma)$ or $\rho_{\neq} \in \mathrm{wClone_p}(\Gamma)$.*

▶ **Lemma 11.** *Let Γ be a valued constraint language that admits neither of the multimorphisms $\langle \min, \min\rangle$, $\langle \max, \max\rangle$, $\langle \min, \max\rangle$. If $\rho_0, \rho_1 \in \mathrm{wClone_p}(\Gamma)$, then $\rho_{\neq} \in \mathrm{wClone_p}(\Gamma)$.*

▶ **Lemma 12.** *Let Γ be a valued constraint language that does not admit multimorphism $\langle\neg\rangle$. If $\rho_{\neq} \in \mathrm{wClone_p}(\Gamma)$, then $\rho_0, \rho_1 \in \mathrm{wClone_p}(\Gamma)$.*

▶ **Lemma 13.** *Let Γ be a valued constraint language that admits neither of the multimorphisms $\langle \mathrm{Mn}, \mathrm{Mn}, \mathrm{Mn}\rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mj}\rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn}\rangle$. If $\rho_0, \rho_1, \rho_{\neq} \in \mathrm{wClone_p}(\Gamma)$, then $\rho_{\text{1-in-3}} \in \mathrm{wClone_p}(\Gamma)$.*

Proof (of Theorem 9). Since Γ is intractable we know, by [8, Theorem 7.1], that Γ admits neither of the multimorphisms $\langle c_0\rangle$, $\langle c_1\rangle$, $\langle \min, \min\rangle$, $\langle \max, \max\rangle$, $\langle \min, \max\rangle$, $\langle \mathrm{Mn}, \mathrm{Mn}, \mathrm{Mn}\rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mj}\rangle$, $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn}\rangle$. By assumption, Γ is not self-complementary and hence does not admit the $\langle\neg\rangle$ multimorphism.

By Lemmas 10, 11, and 12, we have $\rho_0, \rho_1, \rho_{\neq} \in \mathrm{wClone_p}(\Gamma)$ and hence by Lemma 13 $\rho_{\text{1-in-3}} \in \mathrm{wClone_p}(\Gamma)$. Planar 1-in-3 Positive 3-Sat problem is NP-complete [29], and therefore Γ is planarly-intractable by Theorem 5. ◀

4 Conservative Valued CSPs

A valued constraint language Γ is called *conservative* if Γ includes all $\{0, 1\}$-valued unary weighted relations. As our second result, we prove that planarity does not add any tractable cases for conservative valued constraint languages.

▶ **Theorem 14.** *Let Γ be an intractable conservative valued constraint language. Then Γ is planarly-intractable.*

Consequently, we obtain a complexity classification of all conservative valued constraint languages in the planar setting, thus sharpening the classification of conservative valued constraint languages [26, 35]. As mentioned in Section 1, for Boolean domains Theorem 14 follows from Theorem 9. Thus, the only tractable Boolean conservative languages in the planar setting are given by the multimorphisms $\langle \min, \max \rangle$ and $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn} \rangle$ [8].

We now define certain special types of multimorphisms.

A k-ary operation $f : D^k \to D$ if called *conservative* if $f(x_1, \ldots, x_k) \in \{x_1, \ldots, x_k\}$ for every $x_1, \ldots, x_k \in D$. A multimorphism $\langle f_1, \ldots, f_k \rangle$ is called *conservative* if applying $\langle f_1, \ldots, f_k \rangle$ to $(x_1, \ldots, x_k)$ returns a permutation of $(x_1, \ldots, x_k)$.

▶ **Definition 15.** A binary multimorphism $\langle f, g \rangle$ of Γ is called a *symmetric tournament pair* (STP) if it is conservative and both f and g are commutative operations.

It was shown in [7] that languages admitting an STP multimorphism are tractable.

A ternary operation $f : D^3 \to D$ is called a *majority* operation if $f(x, x, y) = f(x, y, x) = f(y, x, x) = x$ for all $x, y \in D$, and a *minority* operation if $f(x, x, y) = f(x, y, x) = f(y, x, x) = y$ for all $x, y \in D$.

▶ **Definition 16.** A ternary multimorphism $\langle f, g, h \rangle$ is called an MJN if f and g are (possibly equal) majority operations and g is a minority operation.

It was shown in [26] that languages admitting an MJN multimorphism are tractable.

▶ **Theorem 17** ([26]). *Let Γ be a conservative valued constraint language on D. Then either Γ admits a conservative binary multimorphism $\langle f, g \rangle$ and a conservative ternary multimorphism $\langle f', g', h' \rangle$ and there is a family M of 2-element subsets of D, such that*

- *for every $\{a, b\} \in M$, $\langle f, g \rangle$ restricted to $\{a, b\}$ is a symmetric tournament pair, and*
- *for every $\{a, b\} \notin M$, $\langle f', g', h' \rangle$ restricted to $\{a, b\}$ is an MJN multimorphism,*

in which case Γ is tractable, or else Γ is intractable.

The idea of the proof of Theorem 17 is as follows: given a conservative valued constraint language Γ, we define a certain graph G_Γ whose vertices are pairs of different labels from D and an edge $(a, b) - (c, d)$ is present if there is a binary weighted relation $\gamma \in \mathrm{wClone}(\Gamma)$ that is "non-submodular with respect to the order $a < b$ and $c < d$". The edges of G_Γ are then classified as soft and hard. It is shown that a soft self-loop implies intractability of Γ. Otherwise, the vertices of G_Γ are partitioned into $M \cup \overline{M}$, where M denotes the set of loopless vertices and $\overline{M}$ denotes the rest (i.e. vertices with hard loops). It is then shown that G_Γ restricted to M is bipartite, which is in turn used to construct a binary multimorphism and a ternary multimorphism of Γ such that the binary multimorphism is an STP on M and the ternary multimorphism is an MJN on $\overline{M}$. (Proving that the constructed objects are multimorphisms of Γ is the most technical part of the proof.) Any such language is then tractable via an involved algorithm from [26] that relies on [7], or by an LP relaxation [35].

Our approach is to follow the above-described proof and adapt it to the planar setting. It is natural to replace $\mathrm{wClone}(\Gamma)$ by $\mathrm{wClone}_{\mathrm{p}}(\Gamma)$ in the definition of G_Γ. But this simple change does not immediately yield the desired result. There are two main obstacles. First, the proof of Theorem 17 from [26] heavily relies on [31], which guarantees the existence of a majority polymorphism. However, this is proved in [31] using (functional) clones and depends on the Galois connection between clones and relational co-clones; such a connection is not known for planar expressibility! Second, some of the gadgets (and in particular the "i-expansion" from [26, Section 6.4]) are not necessarily planar.

To avoid these obstacles, we modify, significantly simplify, and generalise the proof so that it works in the planar setting. The key changes are the following. (i) We use a closure of a language, denoted Γ^* below, that is a subset of the planar weighted relational clone of a conservative language. (ii) We do *not* rely on Takhanov's result on the existence of a majority polymorphism [31] but instead prove directly without using [31] that (the closure of) Γ is 2-decomposable. (iii) We define different STP and MJN multimorphisms that allow us to simplify the proof that these are indeed multimorphisms of Γ. In particular, we will prove modularity of weighted relations on $\overline{M}$ and show that the ternary multimorphism satisfies Inequality (1) with equality, thus obtaining a better structural understanding of tractable languages. The main simplification is that we define MJN as close to projection operations as possible, and in particular not depending on the STP multimorphism as in [26].

We now define a few operations on weighted relations.

▶ **Definition 18.** Let γ be an r-ary weighted relation on D. A *domain restriction* of γ to $D' \subseteq D$ at coordinate i is the r-ary weighted relation defined as $\gamma'(x_1, \dots, x_r) = \gamma(x_1, \dots, x_r) + \rho_{D'}(x_i)$, where $\rho_{D'}(x) = 0$ if $x \in D'$ and $\rho_{D'}(x) = \infty$ otherwise. A *pinning* of γ to $a \in D$ at coordinate i is the $(r-1)$-ary weighted relation defined as $\gamma'(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_r) = \min_{x_i \in D} \gamma(x_1, \dots, x_r) + \rho_{\{a\}}(x_i)$. A *minimisation* of γ at coordinate i is the $(r-1)$-ary weighted relation defined as $\gamma'(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_r) = \min_{x_i \in D} \gamma(x_1, \dots, x_r)$.

A *join* of two binary weighted relations γ_1 and γ_2 is the weighted relation $\gamma(x, y) = \min_{z \in D} \gamma_1(z, x) + \gamma_2(z, y)$.

We will make use only of a limited subset of $\mathrm{wClone_p}(\Gamma)$, which is defined below.

▶ **Definition 19.** For a conservative valued constraint language Γ on D, we define Γ^* to be the smallest set containing Γ, all unary weighted relations and the binary equality relation on D, and closed under operators Feas and Opt, addition of unary weighted relations to weighted relations of arbitrary arity, minimisation, and join.

Note that $\Gamma^* \subseteq \mathrm{wClone_p}(\Gamma)$, as any unary weighted relation can be obtained from the set of all $\{0, 1\}$-valued unary weighted relations by addition of unary weighted relations, scaling, addition of constants, and operator Opt. It is easy to show that addition of unary weighted relations, minimisation, and join are planarly-expressible. Set Γ^* is also closed under domain restriction and pinning, as these operations can be achieved by adding unary weighted relations and minimisation. By Theorem 5, Γ^* has the same complexity as Γ.

▶ **Definition 20.** Let Γ be a conservative language. We define an undirected graph G_Γ on vertices (a, b) for all $a, b \in D, a \neq b$. For any vertex $v = (a, b)$, we will denote by $\overline{v}$ vertex (b, a). Graph G_Γ is allowed to have self-loops. It contains edge $(a_1, b_1) - (a_2, b_2)$ if there is a binary weighted relation $\gamma \in \Gamma^*$ such that $(a_1, b_2), (b_1, a_2) \in \mathrm{Feas}(\gamma)$ and

$$\gamma(a_1, b_2) + \gamma(b_1, a_2) < \gamma(a_1, a_2) + \gamma(b_1, b_2)\,. \tag{2}$$

If there exists such a weighted relation γ with at least one of $(a_1, a_2), (b_1, b_2)$ belonging to $\mathrm{Feas}(\gamma)$, we will call the edge *soft*, otherwise the edge is *hard*. We denote by $\overline{M}$ and M the set of vertices with and without self-loops respectively.

We will show in Theorem 25, proved in Section 5, that if G_Γ has a soft self-loop then Γ is planarly-intractable. Our goal, assuming G_Γ has no soft self-loops, is to prove the following.

▶ **Theorem 21.** *If G_Γ has no soft self-loop, then Γ admits a binary multimorphism $\langle \sqcap, \sqcup \rangle$ that is an STP on M, and a ternary multimorphism $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ that is an MJN on $\overline{M}$.*

5 Proof of Theorem 21

We will need the following definition.

▶ **Definition 22.** Let ρ be an r-ary relation. For any $i, j \in \{1, \ldots, r\}$, we will denote by $\mathrm{Pr}_{i,j}(\rho)$ the projection of ρ on coordinates i and j, i.e. the binary relation defined as

$$(a_i, a_j) \in \mathrm{Pr}_{i,j}(\rho) \iff (\exists \mathbf{x} \in \rho)\ x_i = a_i \wedge x_j = a_j\,. \tag{3}$$

Relation ρ is *2-decomposable* if

$$\mathbf{x} \in \rho \iff \bigwedge_{1 \le i,j \le r} (x_i, x_j) \in \mathrm{Pr}_{i,j}(\rho)\,. \tag{4}$$

The following lemma will be useful in proving results about both Boolean and conservative valued constraint languages. For any r-tuple $\mathbf{z}$ and a subset of coordinates $I \subseteq \{1, \ldots, r\}$, we denote by $\mathbf{z}_I$ the projection of $\mathbf{z}$ onto I. For any partition of coordinates $I, J \subseteq \{1, \ldots, r\}$, we then write $\cdot$ for the inverse operation, i.e. $\mathbf{z}_I \cdot \mathbf{z}_J = \mathbf{z}$.

▶ **Lemma 23.** *Let γ be an r-ary weighted relation and $I, J \subseteq \{1, \ldots, r\}$ a partition of its coordinates. If $\mathbf{x}, \mathbf{y} \in \mathrm{Feas}(\gamma)$ and*

$$\gamma(\mathbf{x}) + \gamma(\mathbf{y}) < \gamma(\mathbf{x}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J)\,, \tag{5}$$

then there exist coordinates $i \in I, j \in J$ and a binary weighted relation $\gamma_{i,j} \in \{\gamma\}^*$ such that $(x_i, x_j), (y_i, y_j) \in \mathrm{Feas}(\gamma_{i,j})$ and

$$\gamma_{i,j}(x_i, x_j) + \gamma_{i,j}(y_i, y_j) < \gamma_{i,j}(x_i, y_j) + \gamma_{i,j}(y_i, x_j)\,. \tag{6}$$

Moreover, if every relation in $\{\gamma\}^*$ is 2-decomposable, then $\mathbf{x}_I \cdot \mathbf{y}_J \in \mathrm{Feas}(\gamma)$ implies $(x_i, y_j) \in \mathrm{Feas}(\gamma_{i,j})$ and $\mathbf{y}_I \cdot \mathbf{x}_J \in \mathrm{Feas}(\gamma)$ implies $(y_i, x_j) \in \mathrm{Feas}(\gamma_{i,j})$.

The following lemma gives a useful alternative characterisation of an edge in G_Γ.

▶ **Lemma 24.** *Graph G_Γ contains edge $(a_1, b_1) - (a_2, b_2)$ if, and only if, binary relation $\{(a_1, b_2), (b_1, a_2)\}$ belongs to Γ^*. The edge is soft if, and only if, at least one of binary relations $\{(a_1, a_2), (a_1, b_2), (b_1, a_2)\}$, $\{(b_1, b_2), (a_1, b_2), (b_1, a_2)\}$ belongs to Γ^*.*

▶ **Theorem 25.** *If G_Γ has a soft self-loop, language Γ is planarly-intractable.*

Proof. Let (a, b) be a vertex of G_Γ with a soft self-loop. Without loss of generality, we have $\rho = \{(a, a), (a, b), (b, a)\} \in \Gamma^*$ by Lemma 24. We denote by γ_a, γ_b the unary weighted relations defined as $\gamma_a(a) = \gamma_b(b) = 0$, $\gamma_a(b) = \gamma_b(a) = 1$, and $\gamma_a(x) = \gamma_b(x) = \infty$ for $x \notin \{a, b\}$. Set $\Gamma' = \{\rho, \gamma_a, \gamma_b\} \subseteq \Gamma^*$ can be viewed as a conservative language over a Boolean domain $\{a, b\}$. Observe that Γ' is intractable (via checking that it does not fall into either of the two tractable cases for Boolean conservative valued constraint languages [8] corresponding to the $\langle \min, \max \rangle$ and $\langle \mathrm{Mj}, \mathrm{Mj}, \mathrm{Mn} \rangle$ multimorphisms) and not self-complementary (neither of its weighted relations is self-complementary), and hence planarly-intractable by Theorem 9. Alternatively, just take the obvious encoding of the planar Maximum Independent Set problem as discussed in Section 1. ◀

In order to prove Theorem 21, we now introduce several lemmas. From now on we will assume that G_Γ has no soft self-loop.

▶ **Lemma 26.** *For any vertex v, graph G_Γ contains edge $v - \overline{v}$. There is no edge between M and $\overline{M}$, no odd cycle in M, and no soft edge in $\overline{M}$.*

Proof. As the binary equality relation belongs to Γ^*, we have edge $v - \overline{v}$ for all vertices v.

Consider any sequence of vertices v_1, v_2, v_3, v_4 such that there is an edge between every two consecutive ones, and denote $v_i = (a_i, b_i)$. By Lemma 24, there exist binary relations $\rho_i = \{(a_i, b_{i+1}), (b_i, a_{i+1})\} \in \Gamma^*$ for $i \in \{1, 2, 3\}$. Their join equals $\{(a_1, b_4), (b_1, a_4)\} \in \Gamma^*$, and hence G_Γ contains edge $v_1 - v_4$. If any of edges $v_1 - v_2, v_2 - v_3, v_3 - v_4$ is soft, we can replace the corresponding relation ρ_i with $\{(a_i, a_{i+1}), (a_i, b_{i+1}), (b_i, a_{i+1})\}$ or $\{(b_i, b_{i+1}), (a_i, b_{i+1}), (b_i, a_{i+1})\}$ to show that $v_1 - v_4$ is also soft.

Suppose that there is an edge between $s \in M$ and $t \in \overline{M}$. Then we have edges $s - t, t - t, t - s$, and hence also self-loop $s - s$, which is a contradiction.

If there is an odd cycle in M, let us choose a shortest one and denote its vertices $v_1, \ldots, v_k$ ($k \geq 3$). We have a sequence of adjacent vertices v_k, v_1, v_2, v_3, and hence v_3 and v_k are also adjacent. But that means there is a shorter odd cycle (or a self-loop) $v_3, \ldots, v_k$; a contradiction.

Finally, suppose that $s, t \in \overline{M}$ and edge $s - t$ is soft. Then we have edges $s - t, t - t, t - s$, and hence a soft self-loop at s, which is a contradiction. ◀

▶ **Lemma 27.** *Every relation in Γ^* is 2-decomposable.*

Proof. Let $\rho \in \Gamma^*$ be an r-ary relation. By definition, $\mathbf{x} \in \rho$ implies $\bigwedge_{1 \leq i,j \leq r} (x_i, x_j) \in \mathrm{Pr}_{i,j}(\rho)$ for every relation. We prove the converse implication by induction on r. If $r \leq 2$, relation ρ is trivially 2-decomposable. Let $r = 3$. Suppose for the sake of contradiction that $(x_1, x_2, x_3) \notin \rho$ even though $(y_1, x_2, x_3), (x_1, y_2, x_3), (x_1, x_2, y_3) \in \rho$ for some $y_1, y_2, y_3 \in D$. Let $\rho_1 \in \Gamma^*$ be the binary relation obtained from ρ by pinning it at the first coordinate to label x_1; we have $(x_2, y_3), (y_2, x_3) \in \rho_1$, $(x_2, x_3) \notin \rho_1$, and thus graph G_Γ contains edge $(x_2, y_2) - (x_3, y_3)$. Analogously, the graph contains edges $(x_3, y_3) - (x_1, y_1)$ and $(x_1, y_1) - (x_2, y_2)$. This is an odd cycle, so it must hold $(x_1, y_1), (x_2, y_2), (x_3, y_3) \in \overline{M}$. Let γ be a unary weighted relation with $\gamma(x_1) = 0, \gamma(y_1) = 1$ and $\gamma(z) = \infty$ for all $z \in D \setminus \{x_1, y_1\}$. By adding γ to ρ at the first coordinate and then minimising over it we show that edge $(x_2, y_2) - (x_3, y_3)$ is soft, which is a contradiction.

It remains to prove the lemma for $r \geq 4$. Let $\rho_1 \in \Gamma^*$ be the relation obtained from ρ by minimisation over the first coordinate. Relation ρ_1 is 2-decomposable by the induction hypothesis, so $(x_2, \ldots, x_r) \in \rho_1$, and hence $(y_1, x_2, \ldots, x_r) \in \rho$ for some $y_1 \in D$. Analogously, we have $(x_1, y_2, x_3, \ldots, x_r), (x_1, x_2, y_3, x_4, \ldots, x_r) \in \rho$ for some $y_2, y_3 \in D$. Pinning ρ at every coordinate $k \geq 4$ to its respective label x_k gives a ternary 2-decomposable relation ρ' such that $(x_i, x_j) \in \mathrm{Pr}_{i,j}(\rho')$ for all $i, j \in \{1, 2, 3\}$. Therefore, $(x_1, x_2, x_3) \in \rho'$ and $\mathbf{x} \in \rho$. ◀

The following lemma involves a generalisation of the definition of an edge in G_Γ to non-binary weighted relations.

▶ **Lemma 28.** *Let $\gamma \in \Gamma^*$ be an r-ary weighted relation and $I, J \subseteq \{1, \ldots, r\}$ a partition of its coordinates. If $\mathbf{x}, \mathbf{y} \in \mathrm{Feas}(\gamma)$ and*

$$\gamma(\mathbf{x}) + \gamma(\mathbf{y}) < \gamma(\mathbf{x}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J), \tag{7}$$

then graph G_Γ contains edge $(x_i, y_i) - (y_j, x_j)$ for some $i \in I, j \in J$. If at least one of $\mathbf{x}_I \cdot \mathbf{y}_J, \mathbf{y}_I \cdot \mathbf{x}_J$ belongs to $\mathrm{Feas}(\gamma)$, the edge is soft.

Proof. By Lemma 23, there are coordinates $i \in I, j \in J$ and a binary weighted relation $\gamma_{i,j} \in \Gamma^*$ such that $(x_i, x_j), (y_i, y_j) \in \mathrm{Feas}(\gamma_{i,j})$ and $\gamma_{i,j}(x_i, x_j) + \gamma_{i,j}(y_i, y_j) < \gamma_{i,j}(x_i, y_j) +$

$\gamma_{i,j}(y_i, x_j)$, so graph G_Γ contains edge $(x_i, y_i) - (y_j, x_j)$. If $\mathbf{x}_I \cdot \mathbf{y}_J$ or $\mathbf{y}_I \cdot \mathbf{x}_J$ belongs to Feas(γ), then (x_i, y_j) or (y_i, x_j) belongs to Feas($\gamma_{i,j}$) (as Feas(γ) is 2-decomposable by Lemma 27), and hence the edge is soft. ◀

▶ **Lemma 29.** *Let $\gamma \in \Gamma^*$ be an r-ary weighted relation and $I, J \subseteq \{1, \dots, r\}$ a partition of its coordinates. If $\mathbf{x}, \mathbf{y}, \mathbf{x}_I \cdot \mathbf{y}_J, \mathbf{y}_I \cdot \mathbf{x}_J \in$ Feas(γ) and, for all $i \in I$, $(x_i, y_i) \in \overline{M}$, then*

$$\gamma(\mathbf{x}) + \gamma(\mathbf{y}) = \gamma(\mathbf{x}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J)\,. \tag{8}$$

Proof. Suppose for the sake of contradiction that the equality does not hold. Without loss of generality, we may assume that $\gamma(\mathbf{x}) + \gamma(\mathbf{y}) < \gamma(\mathbf{x}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J)$. By Lemma 28, graph G_Γ contains a soft edge incident to (x_i, y_i) for some $i \in I$, which contradicts Lemma 26. ◀

Graph G_Γ does not have any odd cycle on vertices M. Therefore, there is a partition of M into two independent sets M_1, M_2. (In fact, it can be shown that every connected component of G_Γ restricted to M is a complete bipartite graph but we do not need this fact here.) Note that $(a, b) \in M_1$ if, and only if, $(b, a) \in M_2$, as every vertex $v \in M$ is adjacent to $\overline{v}$. We define multimorphism $\langle \sqcap, \sqcup \rangle$ as follows:

$$\langle \sqcap, \sqcup \rangle(x, y) = \begin{cases} (x, y) & \text{if } (x, y) \in M_1, & (9a)\\ (y, x) & \text{if } (x, y) \in M_2, & (9b)\\ (x, y) & \text{otherwise.} & (9c) \end{cases}$$

By definition, $\langle \sqcap, \sqcup \rangle$ is commutative on M.

▶ **Theorem 30.** *$\langle \sqcap, \sqcup \rangle$ is a multimorphism of Γ.*

Proof. Let $\gamma \in \Gamma$ be an r-ary weighted relation and $\mathbf{x}, \mathbf{y} \in$ Feas(γ). Suppose for the sake of contradiction that (1) does not hold. We partition set $\{1, \dots, r\}$ into I and J: Set J consists of all coordinates j such that case (9b) applies to (x_j, y_j); set I covers the other two cases. For any $i \in I$, either $x_i = y_i$ or $(x_i, y_i) \in M_1 \cup \overline{M}$. For any $j \in J$, $(x_j, y_j) \in M_2$ and hence $(y_j, x_j) \in M_1$. $\langle \sqcap, \sqcup \rangle$ maps $\mathbf{x}, \mathbf{y}$ to $\mathbf{x}_I \cdot \mathbf{y}_J, \mathbf{y}_I \cdot \mathbf{x}_J$, so we have $\gamma(\mathbf{x}) + \gamma(\mathbf{y}) < \gamma(\mathbf{x}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J)$. By Lemma 28, graph G_Γ contains edge $(x_i, y_i) - (y_j, x_j)$ for some $i \in I, j \in J$, which contradicts Lemma 26. ◀

The following definition corresponds to the "μ function" from [26, Section 6].

▶ **Definition 31.** For any $a, b, c \in D$, we say that $ab|c$ holds if a, b, c are all different labels and there exist $(s, t) \in \overline{M}$ such that binary relation $\{(a, s), (b, s), (c, t)\}$ belongs to Γ^*.

The intuition is that if $ab|c$ holds, then any minority operation on $\overline{M}$ must map any permutation of $\{a, b, c\}$ to c.

▶ **Lemma 32.** *For any $a, b, c \in D$, at most one of $ab|c$, $ca|b$, $bc|a$ holds. If $ab|c$, then $(a, c), (b, c) \in \overline{M}$.*

Proof. Suppose that both $ca|b$ and $bc|a$ hold. Then there are $(s_1, t_1), (s_2, t_2) \in \overline{M}$ and binary relations $\rho_1, \rho_2 \in \Gamma^*$ such that $\rho_1 = \{(c, s_1), (a, s_1), (b, t_1)\}$, $\rho_2 = \{(b, s_2), (c, s_2), (a, t_2)\}$. We construct binary relation ρ as $\rho(x, y) = \min_{z \in D} \rho_1(z, x) + \rho_2(z, y)$. We have $\rho \in \Gamma^*$ and $\rho = \{(s_1, s_2), (s_1, t_2), (t_1, s_2)\}$, which implies a soft edge in $\overline{M}$ and hence a contradiction.

If $ab|c$, then there are $(s, t) \in \overline{M}$ such that $\{(a, s), (b, s), (c, t)\} \in \Gamma^*$. By restricting this relation at the first coordinate to labels $\{a, c\}$ we get edge $(a, c) - (t, s)$ and thus $(a, c) \in \overline{M}$; analogously by restricting to $\{b, c\}$ we get $(b, c) \in \overline{M}$. ◀

We define multimorphism $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ as follows:

$$\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle(x,y,z) = \begin{cases} (x,y,z) & \text{if } x = y \wedge (y,z) \in \overline{M} \text{ or } xy|z, & \text{(10a)} \\ (z,x,y) & \text{if } z = x \wedge (x,y) \in \overline{M} \text{ or } zx|y, & \text{(10b)} \\ (y,z,x) & \text{if } y = z \wedge (z,x) \in \overline{M} \text{ or } yz|x, & \text{(10c)} \\ (x,y,z) & \text{otherwise.} & \text{(10d)} \end{cases}$$

Note that the operations of $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ are majorities and a minority on $\overline{M}$. Also note that in the subcase $x = y \wedge (y,z) \in \overline{M}$ of case (10a), the output has to be (x,y,z) for $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ to be an MJN multimorphism of Γ on $\overline{M}$ (and similarly for the first subcase of case (10b) and case (10c)). It is the other cases where there is some freedom and where we differ from [26].

▶ **Theorem 33.** $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ *is a multimorphism of* Γ.

We will actually prove that (1) holds with *equality.*

Proof. Suppose for the sake of contradiction this is not true for some r-ary weighted relation $\gamma \in \Gamma^*$ and $\mathbf{x}, \mathbf{y}, \mathbf{z} \in \mathrm{Feas}(\gamma)$; we choose γ so that it has the minimum arity among such counterexamples. We denote the r-tuples to which $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ maps $(\mathbf{x}, \mathbf{y}, \mathbf{z})$ by $(\mathbf{f}, \mathbf{g}, \mathbf{h})$.

First we show that case (10b) does not occur. Let I be the set of coordinates i such that case (10b) applies to (x_i, y_i, z_i) and let J cover the remaining cases. Suppose that I is non-empty, and note that $\mathbf{f}_I = \mathbf{z}_I, \mathbf{g}_I = \mathbf{x}_I, \mathbf{h}_I = \mathbf{y}_I$. For every $i \in I$, it holds $(x_i, y_i), (z_i, y_i) \in \overline{M}$ (directly or by Lemma 32), and either $z_i = x_i$ or $z_i x_i | y_i$.

We claim that $\{x_i, y_i, z_i\} \times \{x_j, y_j, z_j\} \subseteq \mathrm{Pr}_{i,j}(\mathrm{Feas}(\gamma))$ for all $i \in I, j \in J$. (A detailed proof of the claim is given in the full version of this paper [12].)

Because $\mathrm{Feas}(\gamma)$ is 2-decomposable by Lemma 27, we have $\mathbf{u}_I \cdot \mathbf{v}_J \in \mathrm{Feas}(\gamma)$ for any $\mathbf{u}, \mathbf{v} \in \{\mathbf{x}, \mathbf{y}, \mathbf{z}\}$. It must hold

$$\gamma(\mathbf{y}_I \cdot \mathbf{x}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{y}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{z}_J) = \gamma(\mathbf{y}_I \cdot \mathbf{f}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{g}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{h}_J)\,, \tag{11}$$

otherwise we would obtain a smaller counterexample by pinning γ at every coordinate $i \in I$ to its respective label y_i. This gives $\mathbf{y}_I \cdot \mathbf{f}_J, \mathbf{y}_I \cdot \mathbf{g}_J, \mathbf{y}_I \cdot \mathbf{h}_J \in \mathrm{Feas}(\gamma)$ and hence $\mathbf{u}_I \cdot \mathbf{v}_J \in \mathrm{Feas}(\gamma)$ for any $\mathbf{u}, \mathbf{v} \in \{\mathbf{x}, \mathbf{y}, \mathbf{z}, \mathbf{f}, \mathbf{g}, \mathbf{h}\}$. By Lemma 29, it holds

$$\gamma(\mathbf{x}_I \cdot \mathbf{x}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{g}_J) = \gamma(\mathbf{x}_I \cdot \mathbf{g}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{x}_J)\,, \tag{12}$$
$$\gamma(\mathbf{z}_I \cdot \mathbf{z}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{f}_J) = \gamma(\mathbf{z}_I \cdot \mathbf{f}_J) + \gamma(\mathbf{y}_I \cdot \mathbf{z}_J)\,. \tag{13}$$

Adding (11), (12), and (13) shows that (1) holds as equality, which is a contradiction. Therefore, case (10b) does not apply at any coordinate.

Suppose that case (10c) applies at some coordinate i. $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ maps $(\mathbf{y}, \mathbf{x}, \mathbf{z})$ to $(\mathbf{g}, \mathbf{f}, \mathbf{h})$, which gives us another smallest counterexample to the theorem. However, at coordinate i is now applied case (10b), which was proved impossible.

Finally, we have that only cases (10a) and (10d) may occur in a smallest counterexample. But then $\langle \mathrm{Mj}_1, \mathrm{Mj}_2, \mathrm{Mn}_3 \rangle$ maps $(\mathbf{x}, \mathbf{y}, \mathbf{z})$ to $(\mathbf{x}, \mathbf{y}, \mathbf{z})$, and hence the stated equality holds. ◀

Abstract

A word is quasiperiodic if it can be obtained by concatenations and overlaps of a smaller word, called a quasiperiod. Based on links between quasiperiods, right special factors and square factors, we introduce a method to determine the set of quasiperiods of a given right infinite word. Then we study the structure of the sets of quasiperiods of right infinite words and, using our method, we provide examples of right infinite words with extremal sets of quasiperiods (no quasiperiod is quasiperiodic, all quasiperiods except one are quasiperiodic, . . .). Our method is also used to provide a short proof of a recent characterization of quasiperiods of the Fibonacci word. Finally we extend this result to a new characterization of standard Sturmian words using a property of their sets of quasiperiods.

1 Introduction

Many studies around words focus on the task of measuring regularities of strings. Various notions were introduced to that end, the strongest one being *periodicity*. Recall that an infinite word is *periodic* if it is obtained by infinite concatenation of occurrences of a word u, called a *period*.

In the context of text algorithms, Apostolico and Ehrenfeucht introduced [1] the notion of *quasiperiodicity*, which is a generalization of periodicity for finite words. A word $w = w_1 w_2 \dots w_n$ is *quasiperiodic* if there exists another word $q \neq w$ (called a *cover* or a *quasiperiod* of w) such that w is covered with occurrences of q. More precisely, for all $i \in \{1, \dots, n\}$, there exists $k \in \{0, \dots, |q| - 1\}$ such that $w_{i-k} w_{i-k+1} \dots w_{i-k+|q|-1}$ is an occurrence of q. For instance, the string "*ababa abababa ababababa ababa*" has quasiperiods *aba* and *ababa*, but it is not periodic.

This definition generalizes immediately to right infinite words (see [18]). As finite words may have several quasiperiods, infinite words may have infinitely many quasiperiods. Words with infinitely many quasiperiods are called *multi-scale quasiperiodic* (see [19]). In Section 2 we state a characterization of the set of quasiperiods of an infinite aperiodic word showing links between some extremal quasiperiods and some square factors and right special factors. An important consequence of this result is to provide a general method to determine the set of quasiperiods of any infinite word. Next we describe several examples of uses of this method.

In [6], Christou, Crochemore and Iliopoulos provide characterizations of quasiperiods of Fibonacci strings. One of their motivations was that “Fibonacci strings are important in many concepts [3] and are often cited as a worst case example for many string algorithms.” However, Fibonacci strings are not always the best words for this purpose. For example, Groult and Richomme [11] proved that the algorithms provided by Brodal and Pedersen [5] and by Iliopoulos and Mouchard [12] to compute all the quasiperiods of a word do not reach their worst case on Fibonacci strings. They proved that those algorithms were optimal, and provided a family of strings reaching the worst case. Nevertheless, the study of finite Fibonacci strings is indeed of great interest: see, e.g., references in [6].

Some of the results from [6] were recently reformulated by Mousavi, Schaeffer and Shallit as a new characterization of quasiperiods of the infinite Fibonacci word [21] (another one was given in [14]). They use this result, among many others, to show how to build automated proofs of some results about the Fibonacci word. Using the method to determine the set of quasiperiods of any infinite word described in Section 2, we provide a short proof of the above mentioned characterization (Section 4.1).

The infinite Fibonacci word is a special case of Sturmian words (and therefore Fibonacci strings are special cases of factors of Sturmian words). A natural question is whether the previous characterization of quasiperiods of the Fibonacci word can be extended to other Sturmian words. Unfortunately, some Sturmian words are not quasiperiodic [15]; more precisely, a Sturmian word is quasiperiodic if and only if it is not a Lyndon word. However, we can still extend our characterization to *standard* Sturmian words, i.e. Sturmian words having all their left special factors as prefixes (Section 4.3).

Sturmian words are not necessarily quasiperiodic, but their bi-infinite counterparts are always multi-scale quasiperiodic. This result can be extended to subshifts, i.e. topological spaces generated from languages by the shift operation. A subshift is *quasiperiodic* (resp. *multi-scale quasiperiodic*) if and only if it is generated by a word which is quasiperiodic (resp. multi-scale quasiperiodic). Monteil and Marcus proved [19] that all Sturmian subshifts are multi-scale quasiperiodic. They also proved that multi-scale quasiperiodic shifts have zero topological entropy, are minimal (their words are uniformly recurrent), and that all of their factors have frequencies (see [9] for a generalization to two-dimensional words).

The main tool of [19] is a so-called *derivation* operation, which takes the inverse image of a word by a well-chosen morphism. The derivative of a quasiperiodic word $\mathbf{w}$ is another word which describes the lengths of the overlaps in $\mathbf{w}$ between each two consecutive occurrences of its quasiperiods. While reading [19], one naturally asks whether the derivation operation preserves multi-scale quasiperiodicity. In other terms, given a multi-scale quasiperiodic word, does its derivative still has infinitely many quasiperiods? In Section 3, we show this is not the case. We provide a right infinite multi-scale quasiperiodic word whose derivative is non-quasiperiodic. While discussing properties of the derivation operation, we also provide a word such that each quasiperiod has the previous (in terms of length) one as a quasiperiod. This nested effect can be avoided; we provide a multi-scale quasiperiodic word with only non-quasiperiodic quasiperiods. The proof of properties of our examples all involve our general method.

Let us summarize the main parts of our paper. In Section 2, we present general properties of quasiperiods of right infinite words and a general method to determine them. In Section 3, we present our results around the derivation operation. In Section 4, we provide our proof of the characterization of the quasiperiods of the Fibonacci word and its generalization to the new characterization of standard Sturmian words.

We assume readers are aware of general results and definitions in Combinatorics on Words (see for instance [16, 17]). Let us recall basic definitions. All infinite words we consider are right infinite words over finite alphabet. Given an alphabet A, A^* (resp. A^ω) denotes the set of finite (resp. infinite) words. The empty word is denoted by ε. The length of a finite word u is denoted $|u|$. A word u is a *factor* of a word v if $v = pus$ for some words p and s. When p is empty (resp. s is empty), u is a *prefix* (resp. a *suffix*) of v. When p and s are not empty, u is an *internal factor* of v. If there exists at least two different letters α and β such that $u\alpha$ and $u\beta$ are factors of v, u is a *right special factor* of v. When αu and βu are factors of v, u is a *left special factor* of v. A *bispecial factor* is a factor which is both left and right special.

2 Basic properties of sets of quasiperiods

Here we provide materials that help to determine quasiperiods of an infinite word poiting first the two main results of this section. Our first result characterizes periodic infinite words using their sets of quasiperiods. We give its proof later, as a consequence of Proposition 2.3, an intermediate result to show Theorem 2.2.

▶ **Proposition 2.1.** *An infinite word is periodic if and only if all its sufficiently long prefixes belong to its set of quasiperiods.*

Consider an infinite word $\mathbf{w}$. As any quasiperiod of $\mathbf{w}$ is one of its prefixes, $\mathbf{w}$ has at most one quasiperiod of length n for each integer n. Thus the knowledge of the lengths of quasiperiods is equivalent to the knowledge of the quasiperiods themselves. After Proposition 2.1, it is clear that lengths of quasiperiods of an aperiodic infinite word, if there are any, are distributed into intervals of integers which are finite and disjoint (possibly singletons). The next theorem characterizes these intervals.

▶ **Theorem 2.2.** *Let $\mathbf{w}$ be an infinite aperiodic word and, for any integer i, let p_i denote the prefix of length i of $\mathbf{w}$. The set of lengths of quasiperiods of $\mathbf{w}$ is an union (possibly empty) of disjoint intervals of integers. If $[i, j]$ is such an interval, then there are no quasiperiods of lengths $i - 1$ nor $j + 1$. Moreover,*

- *p_ip_i is a factor of $\mathbf{w}$;*
- *p_{i-1} is not an internal factor of p_ip_{i-1};*
- *p_j is a right special factor of $\mathbf{w}$;*
- *for all k such that $i \le k < j$, the word p_k is not a right special factor of $\mathbf{w}$.*

This theorem induces a method to determine the quasiperiods of an aperiodic infinite word $\mathbf{w}$. This method consists in determining first among all prefixes p such that pp is a factor of $\mathbf{w}$ or such that p is right special, those such that $\mathbf{w}$ is p-quasiperiodic. With this information, using Theorem 2.2, we can deduce that:

- for any prefix p of $\mathbf{w}$ such that $\mathbf{w}$ is p-quasiperiodic and pp is a factor of $\mathbf{w}$, if q is the smallest right special prefix of $\mathbf{w}$ longer than p, then all prefixes π such that $|p| \le |\pi| \le |q|$ are quasiperiods of $\mathbf{w}$;
- for any prefix q of $\mathbf{w}$ which is a quasiperiod and right special, if p is the smallest prefix such that $|p| > |q|$ and pp is a factor of $\mathbf{w}$, then all prefixes π such that $|q| < |\pi| < |p|$ are *not* quasiperiods of $\mathbf{w}$ (observe that when $\mathbf{w}$ has finitely many quasiperiods, p does not exist).

Moreover, any multi-scale quasiperiodic word which is not periodic has infinitely many quasiperiods which are right special factors. If an infinite word has finitely many quasiperiods, then the longest one is right special. The converse is not true: some multi-scale quasiperiodic words have infinitely many right special factors which are not quasiperiods. Construction of such counter-examples is left to the readers.

In Theorem 2.2, the existence of disjoint intervals is ensured by aperiodicity and Proposition 2.1. The first two items are consequence of Proposition 2.4 below, and the last two items are a consequence of Proposition 2.3. The end of this section is dedicated to the proof of these propositions.

▶ **Proposition 2.3.** *Let* $\mathbf{w}$ *be an infinite word with a quasiperiod* q*. Let* a *be the letter such that* qa *is a prefix of* $\mathbf{w}$*. The word* qa *is a quasiperiod of* $\mathbf{w}$ *if and only if* q *is not right special.*

Proof. If q is not a right special factor of $\mathbf{w}$ then each of its occurrences is followed by the letter a and so, since q is a quasiperiod of $\mathbf{w}$, qa is also a quasiperiod of $\mathbf{w}$.

Conversely assume that qa is a quasiperiod of $\mathbf{w}$ and let b be a letter such that qb is a factor of $\mathbf{w}$. Then qb is a factor of a qa-quasiperiodic factor u of $\mathbf{w}$. For a length reason, we can assume that u is the overlap of two occurrences of qa. Therefore there exist words p_1, p_2, s_1 and s_2 such that $u = p_1\, qb\, s_1 = qa\, s_2 = p_2\, qa$ with $0 < |p_2| \leq |qa|$ and $0 < |s_2| \leq |qa|$. If either p_1 or s_1 is the empty word then $a = b$, so assume these words are not empty. By a classical result (see for instance [16, Prop. 1.3.4]), the equation $p_2\, qa = qa\, s_2$ implies that there exist words x and y and an integer k such that $p_2 = xy$ and $qa = (xy)^k x$ and $s_2 = yx$. In particular, qa is a factor of the periodic word $(xy)^\omega$. Equation $p_1\, qb\, s_1 = p_2\, qa$ implies that qb is also a factor of $(xy)^\omega$. As $|qa| = |qb| \geq |xy|$ (recall that $xy = p_2$ and $|qa| \geq |p_2|$), we conclude that $a = b$, so the word q is not right special factor of $\mathbf{w}$. ◀

As shown below, Proposition 2.1 is a corollary of Proposition 2.3.

Proof of Proposition 2.1. Let $\mathbf{w}$ be an infinite word. If $\mathbf{w}$ is periodic with period of length n, then any prefix of $\mathbf{w}$ with length at least n is a quasiperiod of $\mathbf{w}$.

Conversely assume that, for an integer n, all prefixes with length at least n are quasiperiods of $\mathbf{w}$. For $i \geq 0$, let p_i be the prefix of length i. As $\mathbf{w}$ is p_n-quasiperiodic, $\mathbf{w}$ has at least two occurrences. There exists a word u such that both p_n and up_n are prefixes of $\mathbf{w}$. By hypothesis and Proposition 2.3, p_n is not right special. Each of its occurrences extend to p_{n+1}. Hence both p_{n+1} and up_{n+1} are prefixes of $\mathbf{w}$. Iterating this argument, for all $i \geq n$, both p_i and up_i are prefixes of $\mathbf{w}$. Thus $\mathbf{w} = u\mathbf{w}$: $\mathbf{w}$ is periodic with period u. ◀

Proposition 2.3 provides a first piece of information on some extremal quasiperiods of a word. The next result provides further information. It generalizes an observation made in [14] for the smallest quasiperiod of a word.

▶ **Proposition 2.4.** *Assume that* qa *is a quasiperiod of an infinite word* $\mathbf{w}$ *for some word* q *and some letter* a*. The word* q *is not a quasiperiod of* $\mathbf{w}$ *if and only if the word* qaq *is a factor of* $\mathbf{w}$ *and* q *is not an internal factor of* qaq*.*

Proof. If qaq is not a factor of $\mathbf{w}$, then each occurrence of qa is properly overlapped by the next occurrence of qa. This implies that each occurrence of q is overlapped by or concatenated to the next occurrence of q, that is $\mathbf{w}$ is q-quasiperiodic.

The converse is immediately true. If a word $\mathbf{w}$ contains qaq as a factor and if q is not an internal factor of qaq, then q cannot be a quasiperiod of $\mathbf{w}$. ◀

It should be observed for understanding Theorem 2.2 that under the hypotheses "qa is a quasiperiod of $\mathbf{w}$" and "q is not an internal factor of qaq", the word qaq is a factor of $\mathbf{w}$ if and only if $qaqa$ is a factor of $\mathbf{w}$.

3 On multiscale properties

As explained in the introduction, the goal of this section is threefold. First we provide examples to illustrate the usage of Theorem 2.2. Second we want to show that the derivation operation introduced in [19] does not preserve multiscale quasiperiodicity. Third we aim to study the structure of the relation "is a quasiperiod of" for multiscale quasiperidic words.

A finite word u is said to be *superprimitive* if it is not quasiperiodic. It can be seen (for instance as a consequence of the study made in [14]) that the Fibonacci word has both infinitely many superprimitive quasiperiods and infinitely many non-superprimitive quasiperiods. Moreover, due to its morphic structure, the Fibonacci word has an infinite sequence of *nested quasiperiods*. In other terms, it has a sequence of quasiperiods $(q_n)_{n\geq 0}$ such that, for each $n \geq 0$, q_{n+1} is q_n-quasiperiodic. There are many possible structures for the relation "is a quasiperiod of" inside multiscale quasiperiodic words. We provide several extremal examples throughout this section.

3.1 A multiscale quasiperiodic word with only one superprimitive quasiperiod

▶ **Proposition 3.1.** *There exists a multiscale quasiperiodic word having only one superprimitive quasiperiod.*

This proposition is a direct corollary of the next lemma.

Recall that a morphism between two sets of words A^* and B^* (with A, B finite alphabets) is an application which commutes with concatenation. A morphism is entirely defined by the images of the letters. A morphism is called *non-erasing* if no image of letters is the empty word. As usual, for a word u and a morphism h, we denote $h^\omega(u)$ the word $\lim_{n\to\infty} h^n(u)$ when it exists.

▶ **Lemma 3.2.** *Let h be the morphism from $\{a,b\}^*$ to $\{a,b\}^*$ defined by $h(a) = abaaba$ and $h(b) = bababa$. The quasiperiods of $h^\omega(a)$ are exactly the words $h^n(aba)$ for $n \geq 0$, and all these words are aba-quasiperiodic.*

Proof. This lemma is a direct consequence of Theorem 2.2 and the following four steps. Indeed Steps 1 to 3 determine the prefixes p of $h^\omega(a)$ such that pp is a factor of $h^\omega(a)$ and $h^\omega(a)$ is p-quasiperiodic. Step 4 and Theorem 2.2 allow to conclude that words $h^n(aba)$ are the only quasiperiods of $h^\omega(a)$.

Step 1: The prefixes p such that pp is a factor of $h^\omega(a)$ are $h^n(a)$, $h^n(ab)$ and $h^n(aba)$.

Let p be such a word. If $|p| \leq 6$, it can be checked that $p \in \{a, ab, aba, h(a)\}$. Assume $|p| > 6$. The word p has $abaabab$ as a prefix. Observe that if $\pi abaabab$ is a prefix of $h^\omega(a)$ for a word π, then necessarily $\pi \in h(A^*)$. As pp is a factor of $h^\omega(a)$, there exist words π and p' such that $h(\pi)pp$ is a prefix of $h^\omega(a)$ and $p = h(p')$. Hence $h(\pi p'p')$ is a prefix of $h^\omega(a)$. As $h(a)$ and $h(b)$ are not prefixes of one another, $\pi p'p'$ is a prefix of $h^\omega(a)$. As $|\pi p'p'| < |h(\pi p'p')|$, the proof of this step ends by induction.

Step 2: Words $h^n(a)$ and $h^n(ab)$ are not quasiperiods of $h^\omega(a)$.

Assume $h^n(a)$ is a quasiperiod of $h^\omega(a)$ for a smallest integer n. Observe $n \neq 0$ and $n \neq 1$. Let $(\pi_k)_{k\geq 0}$ be a sequence of words such that $\pi_k h^n(a)$ is a prefix of $h^\omega(a)$ and, for $k \geq 0$, $|\pi_{k+1}| - |\pi_k| \leq |h^n(a)|$. Since $abaabab$ is a prefix of $h^n(a)$ (as $n \geq 2$), for each $k \geq 0$, $\pi_k = h(\pi'_k)$ for a word π'_k. Observe that $(\pi'_k h^{n-1}(a))_{k\geq 0}$ is a sequence of prefixes of $h^\omega(a)$ and $|\pi'_{k+1}| - |\pi'_k| = \frac{|\pi_{k+1}|-|\pi_k|}{6} \leq \frac{|h^n(a)|}{6} = |h^{n-1}(a)|$. Hence $h^{n-1}(a)$ is a quasiperiod of $h^\omega(a)$. This contradicts the choice of n.

Similarly one can prove that words $h^n(ab)$ are not quasiperiods of $h^\omega(a)$.

Step 3: Words $h^n(aba)$ are quasiperiods of $h^\omega(a)$.

This is a direct consequence of the fact that aba is a quasiperiod of any word in $h(a\{a,b\}^\omega)$ and so of $h^\omega(a)$.

Step 4: Words $h^n(aba)$ are right special factors of $h^\omega(a)$.

This is direct consequence of the fact that aba is a right special factor of $h^\omega(a)$ and $h(a)$ and $h(b)$ begin with different letters.

By the previous steps and Theorem 2.2, factors $h^n(aba)$ are both beginnings and endings of intervals of quasiperiods. Therefore, they are the only quasiperiods of $h^\omega(a)$. ◀

Let us observe that, as aba is a quasiperiod of $h(aba)$, for any $n \geq 1$, $h^n(aba)$ is $h^{n-1}(aba)$-quasiperiodic. Thus not only $h^\omega(a)$ has a unique superprimitive quasiperiod but its sequence of quasiperiods (sorted by increasing length) is a sequence of nested quasiperiods.

3.2 About normal form and derivation

In [20], Mouchard introduced two normal forms to decompose a quasiperiodic (finite) word. A *border* of a nonempty word u is a factor different from u which is both a prefix and a suffix of u. Let $\mathcal{B}(q)$ be the set of borders of q; let $\mathcal{L}(q)$ be the set of words u such that $q = uv$ with $v \in \mathcal{B}(q)$; and let $\mathcal{R}(q)$ be the set of words u such that $q = vu$ with $v \in \mathcal{B}(q)$. Note that the empty word belongs to $\mathcal{B}(q)$ and q belongs to $\mathcal{L}(q) \cap \mathcal{R}(q)$. Any q-quasiperiodic finite word can be decomposed as a concatenation of elements of $\mathcal{L}(q)$ (or as a concatenation of elements of $\mathcal{R}(q)$). Mouchard proved that if q is superprimitive then the decomposition over $\mathcal{L}(q)$ (resp. over $\mathcal{R}(q)$) is unique. This decomposition is called the *left normal form* (resp. *right normal form*) of the word.

As observed by Marcus and Monteil [19] this result extends naturally to infinite words. They introduced a derivation operation. Observe that any word has at most one element of $\mathcal{L}(q)$ of each length. If $\mathbf{w}$ is decomposed over $\mathcal{L}(q)$ and if $(\ell_n)_{n\geq 0}$ is the decomposition, then the *left derivated word* is the word $(|q| - |\ell_n|)_{n\geq 0}$ (written over the alphabet $\{0, \ldots, |q| - 1\}$). Marcus and Monteil showed that this derivation operation is a desubstitution operation, that is, the inverse operation of taking the image of an infinite word under a morphism. This morphism, that we called (following the idea of [19]) the *left integrating morphism*, is defined from $\{0, \ldots, |q| - 1\}^*$ to A^* by mapping i on the prefix of length $|q| - i$ of q.

For instance, consider the *Fibonacci word* $\mathbf{F}$, that is the fixed point of the *Fibonacci morphism* φ defined by $\varphi(a) = ab$ and $\varphi(b) = a$. We know it is aba-quasiperiodic (as $\mathbf{F}$ does not contain aaa and bb as factors and starts with ab - see also [14]). With this quasiperiod $q = aba$, the morphism used to derivate any q-quasiperiodic word is the morphism defined by $0 \mapsto aba$, $1 \mapsto ab$ which, up to a renaming of letters, is φ^2. Hence $\mathbf{F}$ is its own derivative word, and therefore can be derivated arbitrarily many times.

Because of this terminology of "derivation", one could expect that, if a word is multiscale quasiperiodic, then it could be derivated infinitely many times. The next result, combined with Lemma 3.2, disproves this intuition.

▶ **Proposition 3.3.** *Let $\mathbf{w}$ be a quasiperiodic word such that for all quasiperiods q there is no quasiperiod of length $|q| + 1$. Given any quasiperiod q of $\mathbf{w}$, the corresponding left derivated word is not quasiperiodic.*

Proof. Let q be any quasiperiod of $\mathbf{w}$ and let $\mathbf{x}$ be the corresponding left derivated word. We denote by ν the morphism underlying the derivation: $\mathbf{w} = \nu(\mathbf{x})$. By construction of ν, for all letters α in $\{0, \ldots, |q| - 1\}$, $\nu(\alpha)$ begins with the first letter, say a, of $\mathbf{w}$. Assume that Q is a quasiperiod of $\mathbf{x}$. Then $\nu(Q)$ is a quasiperiod of $\mathbf{w}$ (as ν is a non-erasing morphism - basic fact mentioned in [15]). As $\nu(Q)$ is always followed by the letter a: $\nu(Q)a$ is a quasiperiod of $\mathbf{w}$, a contradiction with the hypothesis. ◀

As the derivation operation is associated to the left normal form, one can ask whether a similar definition associated to the right normal form could give a better behavior. To any q-quasiperiodic word, we call *right derivated word*, the word $(|q| - |r_n|)_{n\geq 0}$ where $(r_n)_{n\geq 0}$ is the decomposition of $\mathbf{w}$ over $\mathcal{R}(q)$. We call *right integrating morphism*, the morphism defined by mapping i on the suffix of length $|q| - i$ of q. The example of the Fibonacci word, developed below, shows that right derivation does not preserve multiscale quasiperiodicity.

The smallest quasiperiod of the Fibonacci word is aba. The corresponding right integrating morphism is the morphism μ defined by $\mu(a) = aba$; $\mu(b) = ba$. One can observe that $\varphi^2(a)aba = aba\mu(a)$ and $\varphi^2(b)aba = aba\mu(b)$. Thus $\varphi^2(u)aba = aba\mu(u)$ for any word u. Applying the previous formula for arbitrary large prefixes of $\mathbf{F}$, we get $\varphi^2(\mathbf{F}) = aba\mu(\mathbf{F})$, that is $\mathbf{F} = \mu(a\mathbf{F})$. The right derivated word of $\mathbf{F}$ is the word $a\mathbf{F}$. This word is a Lyndon infinite word and consequently it is not quasiperiodic (see [15]).

We end this section with an example of word for which both left and right derivation does not provide a multiscale quasiperiodic word. The proof of these properties is omitted (but still can be done using our general method). Let us consider the following four morphisms f, g, λ, χ, and the word $\mathbf{w}_{fg}$ defined by $\mathbf{w}_{fg} = f(g^\omega(a))$ and

$$f : \begin{cases} a \mapsto aba \\ b \mapsto ba \end{cases} \qquad g : \begin{cases} a \mapsto aba \\ b \mapsto bba \end{cases} \qquad \lambda : \begin{cases} a \mapsto aba \\ b \mapsto ab \end{cases} \qquad \chi : \begin{cases} a \mapsto baa \\ b \mapsto bab \end{cases}$$

▶ **Lemma 3.4.** *The word $\mathbf{w}_{fg}$ is equal to $\lambda(\chi^\omega(b))$. It is multiscale quasiperiodic and its quasiperiods are the words $f(g^n(a)) = \lambda(\chi^n(a))$. For any quasiperiod q of $\mathbf{w}_{fg}$, the right derivated word of $\mathbf{w}_{fg}$ is $g^\omega(a)$ and its left derivated word is $\chi^\omega(b)$. Both words $g^\omega(a)$ and $\chi^\omega(b)$ are not quasiperiodic.*

By lack of place, the proof of this lemma is omitted.

One can verify that $\mathbf{w}_{fg}$ is a fixed point of the morphism defined by $h(a) = a$ and $h(b) = babaab$ (this property is a consequence of $h(f(u)) = f(g(u))$ for all words u). This opens a new question: can any multiscale quasiperiodic word $\mathbf{w}$ be desubstituted into another multiscale quasiperiodic word?

3.3 A multiscale quasiperiodic word with all quasiperiods superprimitive

Let $q = abbababba$ and consider morphism ψ defined by:

$$\begin{cases} \psi(a) = (abbab)^7 = abbababbababbababbababbababbababbab \\ \psi(b) = bababba(q)^2(abbab)^2 = bababbaabbababbaabbababbaabbababbab \end{cases}$$

▶ **Proposition 3.5.** *The quasiperiods of the infinite word $\psi^\omega(a)$ are the words $\psi^n(q)$ with $n \geq 0$. Moreover each of these quasiperiods is superprimitive.*

This proposition is a synthesis of the next three lemmas.

▶ **Lemma 3.6.** *The word $\psi^\omega(a)$ is $\psi^n(q)$-quasiperiodic for each $n \geq 0$.*

Proof. As already recalled in the proof of Proposition 3.3, for any non-erasing morphism f and any infinite word $\mathbf{w}$, if $\mathbf{w}$ is q-quasiperiodic then $f(\mathbf{w})$ is $f(q)$-quasiperiodic. Hence to prove the lemma, we just need to prove that $\psi^\omega(a)$ is q-quasiperiodic.

As both words obtained from $\psi(a)$ and $ab\psi(b)$ removing their last b are q-quasiperiodic, for any infinite word $\mathbf{w}$, $\psi(a\mathbf{w})$ is q-quasiperiodic. In particular $\psi^\omega(a)$ is q-quasiperiodic. ◀

▶ **Lemma 3.7.** *For any $n \geq 0$, the word $\psi^n(q)$ is superprimitive.*

Proof. Assume by contradiction that n is the least integer such that $\psi^n(q)$ is quasiperiodic, and let Q be one of its quasiperiods. Necessarily $n \geq 1$. The word $\psi(a)ba$ is a prefix of $\psi^n(q)$. An exhaustive verification shows that a prefix of $\psi(a)ba$ is a border of $\psi^n(q)$ if and only if this prefix is of the form $(abbab)^\ell$ with $\ell \in [1;7]$ when $n = 1$ and $\ell \in \{1, 2\}$ when $n \geq 2$. As any $abbab$-quasiperiodic word cannot contain the word aa as a factor, no prefix of $\psi(a)ba$ can be a quasiperiod of $\psi^n(q)$. It follows that $\psi(a)ba$ must be a prefix of Q.

Observe that if $\psi(a)ba$ is a factor of the image by ψ of a word (finite or infinite) u, then any occurrence of $\psi(a)ba$ in $\psi(u)$ corresponds to a prefix of the image of a suffix of u. Consequently, considering the last occurrence of Q in $\psi^n(q)$, we then deduce that $Q = \psi(Q')$ for some word Q'. That Q is a quasiperiod of $\psi^n(q)$ means there exists a double sequence of words $(p_i, s_i)_{1 \leq i \leq k}$ such that $\psi^n(q) = p_i Q s_i$ for each i in $[1; k]$, $p_1 = \varepsilon = s_k$ and, for each i in $[1; k-1]$, $|p_i Q| \geq |p_{i+1}| > |p_i|$. The observation at the beginning of the paragraph implies that, for each i in $[1; k]$, $p_i = \psi(p'_i)$ for some word p'_i. As $Q = \psi(Q')$ and as images of letters by ψ have all the same length, for each i in $[1; k]$ $s_i = \psi(s'_i)$ for some word s'_i. Injectivity of ψ implies that for each i in $[1; k]$, $\psi^{n-1}(q) = p'_i Q' s'_i$. Moreover $p'_1 = \varepsilon = s'_k$. Observe for each i in $[1; k]$, $|p_i| = 35|p'_i|$ and $|q| = 35|Q'|$. Hence for each i in $[1; k-1]$ $|p'_i Q| \geq |p'_{i+1}| > |p'_i|$. Hence $\psi^{n-1}(a)$ is Q'-quasiperiodic. This contradicts the minimality in the choice of n. ◀

▶ **Lemma 3.8.** *If Q is a quasiperiod of $\psi^\omega(a)$ then $Q = \psi^n(q)$ for some integer $n \geq 0$.*

Proof. Observe that q is right special in $\psi^\omega(a)$, and so, as $\psi(a)$ and $\psi(b)$ begin with different letters, for all $n \geq 0$, the word $\psi^n(q)$ is right special. Thus by Theorem 2.2, we just have to prove that, if Q is a quasiperiod of $\psi^\omega(a)$ and QQ is a factor of $\psi^\omega(a)$, then $Q = \psi^n(q)$ for some integer $n \geq 0$. We use arguments similar to those used in the proof of Lemma 3.7.

The word $\psi(a)ba$ is a prefix of $\psi^\omega(a)$. An exhaustive verification shows that among all prefixes of this word, only q is a quasiperiod of $\psi^\omega(a)$. Let us assume that Q is a quasiperiod of $\psi^\omega(a)$ with $|Q| \geq |\psi(a)ba|$ and QQ a factor of $\psi^\omega(a)$. As in the proof of Lemma 3.7, we observe that if $u\psi(a)ba$ is a prefix of $\psi^\omega(a)$ then $u = \psi(v)$ for some word v. Thus this also holds if uQ is a prefix of $\psi^\omega(a)$. From the fact that QQ is a factor of $\psi^\omega(a)$, we deduce $Q = \psi(Q')$ for a word Q'. Moreover, possibly acting more precisely as in the proof of Lemma 3.7, we can see that Q' must be a quasiperiod of $\psi^\omega(a)$ with $Q'Q'$ a factor of $\psi^\omega(a)$. Hence by induction on $|Q|$, we can deduce that $Q = \psi^n(q)$ for some integer $n \geq 0$. ◀

To end this section, we emphasize the interest of the previous examples by mentioning that when there are arbitrarily large intervals of lengths of quasiperiods, then there exists arbitrarily large quasiperiods that are not superprimitive.

▶ **Lemma 3.9.** *Let $\mathbf{w}$ be an aperiodic multiscale quasiperiodic word for which there exist arbitrary large intervals $[i, j]$ of lengths of quasiperiods. This word $\mathbf{w}$ admits an infinite sequence of nested quasiperiods.*

Proof. Let q_0 be any quasiperiod of $\mathbf{w}$. By hypothesis, there exists an interval $[i, j]$ with $j - i \geq |q_0|$ such that for all integers k in $[i, j]$, the prefix of length k of $\mathbf{w}$ is one of its quasiperiods. As $j - i \geq |q_0|$, there exists an integer k in $[i, j]$ such that the prefix of length k of $\mathbf{w}$ is q_0-quasiperiodic. By iterating that reasoning, we can construct a sequence of nested quasiperiods of $\mathbf{w}$. ◀

4 Quasiperiods of standard Sturmian words

The starting result of this section is the recent characterization of the Fibonacci word of [21] mentioned in the introduction. We provide a short proof using the general method of Section 2. We also reformulate this result in such a way it could be generalized to all standard Sturmian words. This is done in Section 4.2 before showing in Section 4.3 this is a characteristic property of this family of words.

4.1 Fibonacci example

We denote by $(F_n)_{n\geq 0}$ the sequence of Fibonacci integers ($F_0 = 1$, $F_1 = 1$, $F_{n+2} = F_{n+1} + F_n$ for $n \geq 0$) and by $(f_n)_{n\geq 1}$ the sequence of finite Fibonacci words ($f_1 = a$, $f_2 = ab$, $f_{n+2} = f_{n+1}f_n$ for $n \geq 1$). It is well-known that the infinite Fibonacci word $\mathbf{F} = \lim_{n\to\infty} f_n$ is also the fixed point of the morphism φ defined by $\varphi(a) = ab$ and $\varphi(b) = a$.

▶ **Lemma 4.1** (see [21]). *For all $n \geq 0$, the prefix of length n of $\mathbf{F}$ is a quasiperiod of $\mathbf{F}$ if and only if $n \notin \{F_p - 1 \mid p \geq 0\}$.*

Proof. It is well-known that left special factors of $\mathbf{F}$ coincide with its prefixes (see for instance [4, Prop. 4.10.3]). Thus determining prefixes of $\mathbf{F}$ that are right special is equivalent to determining the bispecial factors of $\mathbf{F}$. Let us denote by $(g_n)_{n\geq 2}$ the sequence of prefixes of $\mathbf{F}$ of length $(F_{n+1} - 2)_{n\geq 2}$. These words are exactly the bispecial factors of $\mathbf{F}$ ($\mathbf{F}$ is a standard Sturmian word; by [7] palindromic prefixes of standard Sturmian word are its bispecial factors; lengths of palindromic prefixes of $\mathbf{F}$ are computed in [8]).

For any $n \geq 3$, f_nf_n is a prefix of $\mathbf{F}$ (indeed $abaaba = (\varphi^2(a))^2$ is a prefix of $\mathbf{F}$ which is the fixed point of φ). Moreover as $\mathbf{F}$ is $\varphi^2(a)$-quasiperiodic, $\mathbf{F}$ is f_n-quasiperiodic.

By Theorem 2.2, for all $n \geq 3$, for each prefix π of $\mathbf{F}$ with $F_n \leq |\pi| \leq |g_n| = F_{n+1} - 2$, π is a quasiperiod of $\mathbf{F}$. Moreover the prefix of length $|g_n| + 1 = F_{n+1} - 1$ is not a quasiperiod of $\mathbf{w}$. Finally prefixes of $\mathbf{F}$ of length $F_0 - 1 = F_1 - 1 = 0$, $F_2 - 1 = 1$ or $F_3 - 1 = 2$ are not quasiperiods of $\mathbf{F}$. ◀

As mentioned in the previous proof, bispecial factors of the Fibonacci word are its prefixes of length $F_{n+1} - 2$ for $n \geq 2$.

▶ **Corollary 4.2.** *For all $n \geq 0$, the prefix of length $n + 1$ of $\mathbf{F}$ is a quasiperiod of $\mathbf{F}$ if and only if the prefix of length n of $\mathbf{F}$ is not bispecial.*

4.2 Quasiperiods of standard Sturmian words

The study of quasiperiods in Sturmian words dates back to an original question of Marcus [18]: "Is every Sturmian word quasiperiodic?" This question was completely answered in [15]: a Sturmian word is quasiperiodic if and only if it is not a Lyndon word. In other words, in any Sturmian shift, all but two words are quasiperiodic. Episturmian words, a family of words that include Sturmian words, were also considered and a characterization of all quasiperiods of any episturmian word was provided (see [10, Th. 4.19]). This characterization is quite elaborate and uses the so-called directive word of the studied episturmian word. With a bit of work, Lemma 4.1 could be deduced from this characterization. This is also the case of the next result, which generalizes Corollary 4.2.

Let us recall that an infinite word is *Sturmian* if and only if it has exactly $n + 1$ factors of length n for all n. By the well-known Morse-Hedlund theorem, Sturmian words are the aperiodic words with the least possible number of factors. These words have exactly one left special factor and one right special factor of each length. A Sturmian word is called *standard Sturmian* if its left special factors coincide with its prefixes. By [15], they are multiscale quasiperiodic.

▶ **Proposition 4.3.** *Let* $\mathbf{w}$ *be a standard Sturmian word and* n *a positive integer. Then the prefix of length* n *of* $\mathbf{w}$ *is a quasiperiod if and only if its prefix of length* $n-1$ *is* not *bispecial.*

This proposition could be proved using [10, Th. 4.19]. We rather provide another argument, which may be reused in other contexts. We work with *graphs of words* and *return words*, for which we recall the definitions.

Let n be an integer and $\mathbf{w}$ be an infinite word. The *n-th order graph of words of* $\mathbf{w}$, denoted by $\mathcal{G}_{\mathbf{w}}(n)$, is the directed graph whose vertices are the factors of length n of $\mathbf{w}$, such that there is an edge between two vertices x and y if and only if $\mathbf{w}$ has a factor of length $n+1$ which has x as a prefix and y as a suffix. Observe that a factor v of $\mathbf{w}$ is right special if and only if its vertex in $\mathcal{G}_{\mathbf{w}}(|v|)$ has at least two outgoing edges. Therefore the graph of words allows to visualize right special factors, so it can help searching for quasiperiods using Proposition 2.3.

Let u be a factor of $\mathbf{w}$. A word v is a *return word* for u in $\mathbf{w}$ if and only if uv is a factor of $\mathbf{w}$ which has exactly two occurrences of u, one as a prefix and one as a suffix. A factor of $\mathbf{w}$ is *recurrent* if and only if it occurs infinitely many times in $\mathbf{w}$. Each return word v of u in $\mathbf{w}$ corresponds to a path of length $|v|$ starting from u in $\mathcal{G}_{\mathbf{w}}(|u|)$ (but not all such paths induce return words). The introduction of return words to study quasiperiodicity stems from the following lemma.

▶ **Lemma 4.4.** *[10, Lem. 4.3] A finite word* v *is a quasiperiod of an infinite word* $\mathbf{w}$ *if and only if* v *is a recurrent prefix of* $\mathbf{w}$ *such that any return to* v *in* $\mathbf{w}$ *has length at most* $|v|$.

The graphs of words of Sturmian words are well-known since works from Arnoux and Rauzy [2]. We exploit this information to characterize quasiperiods of Sturmian words.

Let $\mathbf{w}$ be a Sturmian word. It has exactly one left special factor and one right special factor of each length. Let $\ell_n(\mathbf{w})$ and $r_n(\mathbf{w})$ denote respectively the left and right special factors of length n of $\mathbf{w}$. Since $\mathbf{w}$ is on a binary alphabet, $\ell_n(\mathbf{w})$ has exactly two incoming edges and all other vertices have only one incoming edge. Likewise, $r_n(\mathbf{w})$ has exactly two outgoing edges and all other vertices have only one outgoing edge. There are only two possible shapes for such a graph. If $r_n(\mathbf{w}) = \ell_n(\mathbf{w})$ then $G_n(\mathbf{w})$ is the union of two edge-disjoint paths who only share one vertex, $r_n(\mathbf{w})$. Otherwise, $G_n(\mathbf{w})$ is the union of three edge-disjoint paths, one from $\ell_n(\mathbf{w})$ to $r_n(\mathbf{w})$ and two from $r_n(\mathbf{w})$ to $\ell_n(\mathbf{w})$. These paths do not share vertices other than $\ell_n(\mathbf{w})$ and $r_n(\mathbf{w})$.

The path going from $\ell_n(\mathbf{w})$ to $r_n(\mathbf{w})$, and which might be empty if these two vertices are equal, is called the *special path.* The other two paths are called the *short path* and the *long path*, according to their respective lengths. If both are of the same length, we arbitrarily choose which one is the short path (this does not matter). Although the special path might be of length 0, the short and the long path have always at least 1 edge.

The length of a return word to $\ell_n(\mathbf{w})$ is the sum of the length of the special path and of one of the short or long paths. As a Sturmian word has $n+2$ factors of length $n+1$, the graph $G_n(\mathbf{w})$ has $n+2$ edges (recall that each edge corresponds to a factor of length $n+1$). Lemma 4.4 implies that $\ell_n(\mathbf{w})$ is a quasiperiod of $\mathbf{w}$ if and only if the short path of $G_n(\mathbf{w})$ is not of length 1 and the special path is not empty.

This situation is well-known; see for instance the description of evolution of graphs of words in [2]. It occurs exactly for integers n such that $r_{n-1}(\mathbf{w}) = \ell_{n-1}(\mathbf{w})$. This ends the proof of Proposition 4.3.

4.3 Standard Sturmian words : a new characterization

The converse of Proposition 4.3 holds and allows to provide the following new characterization of standard Sturmian words.

▶ **Theorem 4.5.** *Let* $\mathbf{w}$ *be an aperiodic word. The word* $\mathbf{w}$ *is standard Sturmian if and only if it is multiscale quasiperiodic and satisfies the following condition: for each positive integer* n*, the prefix of length* n *of* $\mathbf{w}$ *is a quasiperiod if and only if the prefix of length* $n-1$ *is not right special.*

Proof. The “only if” part corresponds to Proposition 4.3. Let us prove the “if” part. Let $\mathbf{w}$ be an aperiodic word such that, for each $n > 0$, the prefix of length n of $\mathbf{w}$ is a quasiperiod if and only if the prefix of length $n-1$ is not right special. Let a be the first letter of $\mathbf{w}$ and let $B = \mathrm{alph}(\mathbf{w}) \setminus \{a\}$ with $\mathrm{alph}(\mathbf{w})$ the set of letters occurring in $\mathbf{w}$. The size of $\mathrm{alph}(\mathbf{w})$ may be arbitrary, but is at least two (so B is not empty) since $\mathbf{w}$ is not periodic.

Step 1: The word $\mathbf{w}$ has no factor in B^* of length at least 2.

First, observe that factors of $\mathbf{w}$ belonging to B^* have bounded length. Indeed, $\mathbf{w}$ is quasiperiodic and any quasiperiod contains occurrences of the letter a and of letters from B. Hence lengths of factors belonging to B^* are bounded by the length of the smallest quasiperiod. Let x be a factor of $\mathbf{w}$ of maximal length among all factors belonging to B^*. As B is not empty, $|x| \geq 1$. Let p be the smallest prefix of $\mathbf{w}$ ending with x. By maximality in the definition of x, p is not right special: it is always followed by the letter a. Thus by hypothesis on $\mathbf{w}$, pa is a quasiperiod of $\mathbf{w}$.

By definition, p begins with a and ends with x. By maximality in the definition of x, p ends with ax and, by construction, does not contain any other occurrence of x. It follows that borders of pa are the words ε and a. Thus $\mathbf{w} \in p\{p, ap\}^\omega$.

Let π be the prefix of $\mathbf{w}$ of length $|p|-1$ and let b be the last letter of p. We have $p = \pi b$ and $\mathbf{w} \in \pi b\{\pi b, a\pi b\}^\omega$. As x has only one occurrence in p as a suffix, it has no occurrence in π. Moreover a is the first letter of π. Assume that π is not right special. By hypothesis, it follows that p is a quasiperiod of $\mathbf{w}$. By the choice on x and definition of p, p cannot be an internal factor of pap. Thus $\mathbf{w} = p^\omega$: a contradiction with aperiodicity of $\mathbf{w}$. Thus π is right special. There exists a letter c different from b such that πc is a factor of $\mathbf{w}$. This word πc occurs in a factor $a\pi$. Hence $a\pi = \pi c$ which implies $a = c$ and π is a power of a. Thus $|x| = 1$.

First corollary of Step 1: There exists an aperiodic word $\mathbf{w}'$ such that $\mathbf{w} = L_a(\mathbf{w}')$, where L_a is the morphism defined by $L_a(a) = a$, $L_a(x) = ax$ for any letter $x \neq a$.

The existence of $\mathbf{w}'$ is a reformulation of the result of Step 1. Aperiodicity of $\mathbf{w}'$ is a consequence of aperiodicity of $\mathbf{w}$.

Second corollary of Step 1: $\mathbf{w}$ is a binary word.

Indeed assume that $\mathbf{w}$ contains at least three different letters a (its first letter), b and c, with the first occurrence of b occurring before the first occurrence of c. Any quasiperiod of $\mathbf{w}$ must contain b and c. By Step 1, b is always followed by the letter a. Let π be smallest prefix of $\mathbf{w}$ ending with b. The word πa is a prefix of $\mathbf{w}$. As it does not contains c, πa cannot be a quasiperiod of $\mathbf{w}$. By the properties of $\mathbf{w}$, π is right special. This contradicts the fact that b is not right special.

Step 2: The smallest quasiperiod of $\mathbf{w}$ is its prefix $a^k ba$ ($k \geq 1$).

Indeed by Step 1 (and its second corollary), each occurrence of b is followed by the letter a. In particular the prefix $a^k b$ is not right special. By the properties of $\mathbf{w}$, $a^k ba$ is a quasiperiod of $\mathbf{w}$. As $\mathbf{w}$ is aperiodic, $a^k b$ is not a quasiperiod of $\mathbf{w}$. Clearly $\mathbf{w}$ has no quasiperiod that are powers of the letter a. Hence $a^k ba$ is the smallest quasiperiod of $\mathbf{w}$.

Step 3: For each integer n, the prefix of $\mathbf{w}'$ of length $n+1$ is a quasiperiod of $\mathbf{w}'$ if and only if the prefix of $\mathbf{w}'$ of length n is not right special.

Let p be a prefix of $\mathbf{w}'$ and c be the letter such that pc is a prefix of $\mathbf{w}'$. We have to prove that pc is a quasiperiod of $\mathbf{w}'$ if and only if p is not right special in $\mathbf{w}'$. This is a direct consequence of the next four properties (the third one is an hypothesis on $\mathbf{w}$, the proof of the others are omitted by lack of place):

1. Let $\mathbf{x} \in \{a, b\}^\omega$. A word q is a quasiperiod of $\mathbf{x}$ if and only if both words $L_a(q)$ and $L_a(q)a$ are quasiperiods of $L_a(\mathbf{x})$.
2. $L_a(p)ac$ is a quasiperiod of $\mathbf{w}$ if and only if $L_a(pc)$ and $L_a(pc)a$ are quasiperiods of $\mathbf{w}$.
3. $L_a(p)ac$ is a quasiperiod of $\mathbf{w}$ if and only if $L_a(p)a$ is not right special in $\mathbf{w}$.
4. Let $\mathbf{x} \in \{a, b\}^\omega$. A word u is right special in $\mathbf{x}$ if and only if $L_a(u)a$ is right special in $L_a(\mathbf{x})$.

Step 4: $\mathbf{w}'$ is multi-scale quasiperiodic.

By Step 2, a^kba is a quasiperiod of $\mathbf{w}$. Hence $\mathbf{w} \in a^kb\{a^kb, a^{k+1}b\}^\omega$. As $\mathbf{w}$ is aperiodic, there exists an integer $i \geq 1$ such that $(a^kb)^ia^{k+1}b$ is a prefix of $\mathbf{w}$. Let j be the greatest integer such that of $((a^kb)^ia^{k+1}b)^j$ is a factor of $\mathbf{w}$ (aperiodicity of $\mathbf{w}$ implies the existence of j). Let p be any prefix of $\mathbf{w}$ beginning with $(a^kb)^ia^{k+1}b$ and ending with $((a^kb)^ia^{k+1}b)^{j-1}(a^kb)^ia^{k+1}$ (multiscale quasiperiodicity of $\mathbf{w}$ implies there exist infinitely many such p). As a^{k+2} is not a factor of $\mathbf{w}$, each occurrence of p in $\mathbf{w}$ is always followed by the letter b. Hence p is not right special and pb is a quasiperiod of $\mathbf{w}$. By maximality of j, $pbpb$ is not a factor of $\mathbf{w}$. Thus two consecutive occurrences of pb must overlap by a factor at least as long as $(a^kb)^ia^{k+1}b$. Let p' be the unique (by the properties of L_a) word such that $L_a(p') = pb$. The word p' is a quasiperiod of $\mathbf{w}'$. As there are infinitely many possible words p, and so p', $\mathbf{w}'$ is multiscale quasiperiodic.

Conclusion. We have proven that:

- $\mathbf{w}$ is a binary word (let $\{a, b\}$ be the alphabet of $\mathbf{w}$);
- for an aperiodic multi-scale quasiperiodic word $\mathbf{w}'$ and a letter x, $\mathbf{w} = L_x(\mathbf{w}')$;
- the word $\mathbf{w}'$ satisfies the condition which links its quasiperiods and its right special factors, like $\mathbf{w}$.

Hence we can iterate this argument on $\mathbf{w}'$ and so on. Thus $\mathbf{w}$ is $\{L_a, L_b\}$-adic, that is, there exists an infinite sequence $(s_i)_{i\geq 0}$ and an infinite sequence of letters $(\alpha_i)_{i\geq 1}$ such that $s_0 = \mathbf{w}$ and, for $i \geq 1$, $s_{i-1} = L_{\alpha_i}(s_i)$. By [13, Cor. 2.7], $\mathbf{w}$ is standard episturmian. As it is a binary word, $\mathbf{w}$ is Sturmian. ◀

5 Conclusion

Proposition 2.1 and Theorem 4.5 show that multiscale quasiperiodicity is an interesting combinatorial notion as it allows to characterize some families of right infinite words. These characterizations can be extended to biinfinite words. For instance a biinfinite word is Sturmian if and only if it is multiscale quasiperiodic and satisfies: for each positive integer n, $\mathbf{w}$ has a quasiperiod of length n if and only if $\mathbf{w}$ has no bispecial factor of length $n-1$. Nevertheless, the structure of sets of quasiperiods of biinfinite words still needs to be studied, because it is more complex as there may exist several quasiperiods having the same length.

Another important problem is left open at the end of Section 3.2. What is the exact link between desubstitution and multiscale quasiperiodicity? Can any multiscale quasiperiodic word $\mathbf{w}$ be desubstituted into another multiscale quasiperiodic word? If the answer is negative, what additional conditions does this property imply?

Abstract

Given an n-vertex graph G and a function $f : V(G) \to \{0, \dots, n-1\}$, an f-factor is a subgraph H of G such that $deg_H(v) = f(v)$ for every vertex $v \in V(G)$; we say that H is a *connected f-factor* if, in addition, the subgraph H is connected. A classical result of Tutte (1954) is the polynomial time algorithm to check whether a given graph has a specified f-factor. However, checking for the presence of a *connected* f-factor is easily seen to generalize Hamiltonian Cycle and hence is NP-complete. In fact, the Connected f-Factor problem remains NP-complete even when $f(v)$ is at least n^ϵ for each vertex v and $\epsilon < 1$; on the other side of the spectrum, the problem was known to be polynomial-time solvable when $f(v)$ is at least $\frac{n}{3}$ for every vertex v.

In this paper, we extend this line of work and obtain new complexity results based on restricting the function f. In particular, we show that when $f(v)$ is required to be at least $\frac{n}{(\log n)^c}$, the problem can be solved in quasi-polynomial time in general and in randomized polynomial time if $c \leq 1$. We also show that when $c > 1$, the problem is NP-intermediate.

1 Introduction

f-factors are a fundamental concept of graph theory dating back to the 19th century, specifically to the work of Petersen [13]. In modern terminology, an f-factor is defined as a spanning subgraph which satisfies degree constraints (given in terms of the degree function f) placed on each vertex of the graph [22]. Some of the most fundamental results on f-factors were obtained by Tutte, who gave sufficient and necessary conditions for the existence of f-factors [19]. Tutte also developed a method for reducing the existence of an f-factor

Table 1 The table depicting the known as well as new results in the complexity landscape of theConnected f-Factor problem.

$f(v) \geq$	Complexity Class
$n^\epsilon, \forall \epsilon > 0$	NPC [4]
$\frac{n}{\texttt{polylog}n}$	QP (Theorem 2)
$\frac{n}{\log n}$	RP (Theorem 3)
$\frac{n}{c}, \forall c \geq 3$	P (Theorem 1)

to the existence of a perfect matching [18], which gives a straightforward polynomial time algorithm for the problem of deciding whether an f-factor exists. There are also several detailed surveys on f-factors of graphs, for instance by Chung and Graham [3], Akiyama and Kano [1].

Aside from work on general f-factors, substantial attention has been devoted to the variant of f-factors where we require the subgraph to be connected (see for instance the survey articles by Kouider and Vestergaard [20] and Plummer [16]). Unlike the general variant, deciding the existence of a connected f-factor (the Connected f-Factor problem) is an NP-complete problem [6, 2]. It is easy to see that Connected f-Factor generalizes Hamiltonian Cycle (set $f(v) = 2$ for every vertex v), and even the existence of a deterministic single-exponential (in the number of vertices) algorithm is open for the problem [15].

The NP-completeness of this problem has motivated several authors to study the Connected f-Factor problem for various restrictions of the function f. Cornelissen et al. [4] showed that Connected f-Factor remains NP-complete even when $f(v)$ is at least n^ϵ for each vertex v and any constant ϵ between 0 and 1. At the other end of the spectrum, it has been shown that the problem is polynomial-time solvable when $f(v)$ is at least $\frac{n}{3}$ [12] for every vertex v. Aside from these two fairly extreme cases, the complexity landscape of this problem based on lower bounds on the function f has largely been left uncharted.

Our results and techniques. In this paper, we provide new results for solving the Connected f-Factor problem based on lower bounds on the range of f, both positive and negative. Since we will study the complexity landscape of Connected f-Factor through the lens of the function f, it will be useful to formally capture bounds on the function f via an additional "bounding" function g. To this end, we introduce the Connected g-Bounded f-Factor problem below:

Connected g-Bounded f-Factor
Instance: An n-vertex graph G and a mapping $f : V \to \mathbb{N}$ such that $f(v) \geq \frac{n}{g(n)}$.
Task: Find a connected subgraph H of G such that each vertex $v \in V(G)$ satisfies $d_H(v) = f(v)$.

First, we obtain a polynomial time algorithm for Connected f-Factor when $f(v)$ is at least $\frac{n}{c}$ for every vertex v and any constant $c \geq 1$. This result improves upon the previously known polynomial-time algorithm for the case when $f(v)$ is at least $\frac{n}{3}$. This is achieved thanks to a novel approach for the problem, which introduces a natural way of converting one f-factor to another by exchanging a set of edges. Here we formalize this idea using the notion of *Alternating Circuits*. These allow us to focus on a simpler version of the problem, where we merely need to ensure connectedness across a coarse partition of the vertex set. Furthermore, we extend this approach to obtain a quasi-polynomial time algorithm for the CONNECTED f-FACTOR problem when $f(v)$ is at least $\frac{n}{polylog(n)}$. To be precise, we prove the following two theorems (see the next page for an explanation of the function g used in the formal statements).

▶ **Theorem 1.** *For every function $g(n) = \mathcal{O}(1)$,* CONNECTED g-BOUNDED f-FACTOR *can be solved in polynomial time.*

▶ **Theorem 2.** *For every $c > 0$ and function $g(n) = \mathcal{O}((\log n)^c)$,* CONNECTED g-BOUNDED f-FACTOR *can be solved in time $n^{(\log n)^{\mathcal{O}(1)}}$.*

Second, we build upon these new techniques to obtain a *randomized polynomial-time* algorithm which solves CONNECTED f-FACTOR in the more general case when $f(v)$ is lower-bounded by $\frac{n}{\mathcal{O}(\log n)}$ for every vertex v. For this, we also require algebraic techniques that have found several applications in the design of fixed-parameter and exact algorithms for similar problems [5, 21, 7, 14]. Precisely, we prove the following theorem.

▶ **Theorem 3.** *For every function $g(n) = \mathcal{O}(\log n)$,* CONNECTED g-BOUNDED f-FACTOR *can be solved in polynomial time with constant error probability.*

We remark that the randomized algorithm in the above theorem has one-sided error with 'Yes' answers always being correct. Finally, we also obtain a lower bound result for CONNECTED f-FACTOR when $f(n)$ is at least $\frac{n}{(\log n)^c}$ for $c > 1$. Specifically, in this case we show that the problem is in fact NP-intermediate, assuming the Exponential Time Hypothesis [8] holds. Formally speaking, we prove the following theorem.

▶ **Theorem 4.** *For every $c > 1$, for every $g(n) = \Theta((\log n)^c)$,* CONNECTED g-BOUNDED f-FACTOR *is neither in* P *nor* NP*-hard unless the Exponential Time Hypothesis fails.*

We detail the known as well as new results on the complexity landscape of CONNECTED f-FACTOR in Table 1.

Organization of the paper. After presenting required definitions and preliminaries in Section 2, we proceed to the key technique and framework used for our algorithmic results, which forms the main part of Section 3. In the next Section 3.2, we obtain both of our deterministic algorithms, which are formally given as Theorem 1 (for the polynomial-time algorithm) and Theorem 2 (for the quasipolynomial-time algorithm). Section 4 then concentrates on our randomized polynomial-time algorithm, presented in Theorem 3. Finally, Section 5 focuses on ruling out (under established complexity assumptions) both NP-completeness and inclusion in P for all polylogarithmic functions g where we do not already have a polynomial-time algorithm.

2 Preliminaries

2.1 Basic Definitions and Graphs

We use standard definitions and notations from West [22]. $d_G(v)$ denotes the **degree** of a vertex v in a graph G. A **component** in a graph is a maximal subgraph that is connected. Note that the set of components in a graph uniquely determines a partition of the vertex set. A **circuit** in a graph is a cyclic sequence $v_0, e_1, v_1, \cdots, e_k, v_k = v_0$ where each e_i is of the form $\{v_{i-1}, v_i\}$ and occurs at most once in the sequence. An **Eulerian circuit** in a graph is a circuit in which each edge in the graph appears exactly once.

Let V' be a subset of the vertices in the graph G. The **induced subgraph** $G[V']$ is the graph over vertex set V' containing all the edges in G whose endpoints are both in V'.

Given a partition $\mathcal{Q} = \{Q_1, Q_2, \ldots, Q_r\}$ of the vertex set of G, the graph $G/\mathcal{Q}$ is constructed as follows: The vertex set of $G/\mathcal{Q}$ is $\mathcal{Q}$. Corresponding to each edge (u, v) in G where u in Q_i, v in Q_j, $i \neq j$, there exists an edge (Q_i, Q_j) in $G/\mathcal{Q}$. Thus, $G/\mathcal{Q}$ is a multigraph without loops. For a subgraph G' of G, we say G' **connects** a partition $\mathcal{Q}$ if $G'/\mathcal{Q}$ is connected. A **refinement** $\mathcal{Q}'$ of a partition $\mathcal{Q}$ is a partition of V where each part Q' in $\mathcal{Q}'$ is a subset of some part Q in $\mathcal{Q}$. This notion of partition refinement was used, e.g., by Kaiser [9]. A **spanning tree of** $G/\mathcal{Q}$ refers to a subgraph T of G with $|\mathcal{Q}|$-1 edges that connects $\mathcal{Q}$.

2.2 Colored Graphs, (Minimal) Alternating Circuits, and f-Factors

Recall the definition of the Connected g-Bounded f-Factor problem. Given an instance (G, f) of Connected g-Bounded f-Factor, a subgraph H of G is an *f-factor* if $d_H(v) = f(v)$ for each $v \in V(G)$; sometimes we also use the term f-factor to refer to $E(H)$.

A colored graph G is one in which each edge is assigned a color from the set $\{red, blue\}$. In a colored graph G, we use R and B to denote subgraphs of G whose edges are the set of red edges ($E(R)$) and blue edges ($E(B)$) of G, respectively, and $V(R) = V(B) = V(G)$. We will use this coloring in our algorithm to distinguish between edge sets of two distinct f-factors of the same graph G. A crucial computational step in our algorithms is to consider the symmetric difference between edge sets of two distinct f-factors and perform a sequence of edge exchanges preserving the degree of each vertex. The following definition is used extensively in our algorithms.

▶ **Definition 5.** A colored graph A is called an **alternating circuit** if there exists an Eulerian circuit in A where every pair of consecutive edges are of different colors.

Clearly, an alternating circuit has an even number of edges and is connected. Furthermore, $d_R(v) = d_B(v)$ for each v in A, where $d_R(v)$ and $d_B(v)$ denote the number of red and blue edges incident to v, respectively. A **minimal alternating circuit** M is an alternating circuit where each vertex v in M has at most two red edges incident to v. By definition, an empty graph is an alternating circuit.

We will also use the following lemma.

▶ **Lemma 6** ([12, Lemma 5]). *Let $S \subseteq E(G)$. An f-factor H containing all the edges in S, if one exists, can be computed in polynomial time.*

3 A Generic Algorithm for Finding Connected g-Bounded f-Factors

Our goal in this section is to present a generic algorithm for Connected g-Bounded f-Factor. In particular, we will in a certain sense reduce the question of solving Connected g-Bounded f-Factor to solving a related problem which we call Partition Connector. This can be viewed as a relaxed version of the original problem, since instead of a connected f-factor it merely asks for an f-factor which connects a specified partitioning of the vertex set. A formal definition is provided below.

PARTITION CONNECTOR
Instance: An n-vertex graph G, $f : V \to \mathbb{N}$, and a partition $\mathcal{Q}$ of $V(G)$.
Task: Find an f-factor of G that connects $\mathcal{Q}$.

The algorithms for solving PARTITION CONNECTOR will then be presented in the later parts of this article—specifically, a deterministic algorithm that runs in quasipolynomial time whenever $g(n) = \mathcal{O}(\texttt{polylog}(n))$ (Section 3.2) and a randomized polynomial-time algorithm for the case when $g(n) = \mathcal{O}(\log n)$ (Section 4).

The majority of this section is devoted to proving the key Theorem 7 stated below, which establishes the link between PARTITION CONNECTOR and CONNECTED g-BOUNDED f-FACTOR.

▶ **Theorem 7.** **(a)** *Let $g(n) = \mathcal{O}(\texttt{polylog}(n))$. If there is a deterministic algorithm running in time $\mathcal{O}(n^{2(|\mathcal{Q}|-1)})$ for* PARTITION CONNECTOR*, then there is a deterministic quasi-polynomial time algorithm for* CONNECTED g-BOUNDED f-FACTOR *with running time $\mathcal{O}(g(n) \cdot n^{2g(n)})$.*
(b) *Let $g(n) = \mathcal{O}(\log n)$. If there is a randomized algorithm running in time $\mathcal{O}(2^{|\mathcal{Q}|}n^{\mathcal{O}(1)})$ with error probability $\mathcal{O}(|\mathcal{Q}|^2/n^2)$ for* PARTITION CONNECTOR*, then there is a randomized polynomial-time algorithm for* CONNECTED g-BOUNDED f-FACTOR *that has a constant error probability.*

3.1 A generic algorithm for Connected g-Bounded f-Factor

The starting point of our generic algorithm is the following observation.

▶ **Observation 8.** Let G be an undirected graph and f be a function $f : V \to \mathbb{N}$. The graph G has a connected f-factor if and only if for each partition $\mathcal{Q}$ of the vertex set V, there exists an f-factor H of G that connects $\mathcal{Q}$.

We remark that for the running time analysis for our generic algorithm we will assume that we are only dealing with instances of CONNECTED g-BOUNDED f-FACTOR, where the number of vertices exceeds $6g(n)^4$. As $g(n)$ is in $\mathcal{O}(\texttt{polylog}(n))$, this does not reduce the applicability of our algorithms, since there is a constant n_0 such that $n \geq 6g(n)^4$ for every $n \geq n_0$; because $g(n)$ is part of the problem description, n_0 does not depend on the input instance. Consequently, we can solve instances of CONNECTED g-BOUNDED f-FACTOR where $n < n_0$ by brute-force in constant time. We will therefore assume without loss of generality in the following that $n \geq n_0$ and hence $n \geq 6g(n)^4$.

Our algorithm constructs a *maximal* sequence of pairs $(H_0, \mathcal{Q}_0), \ldots, (H_k, \mathcal{Q}_k)$ satisfying the following properties:

(M1) Each $\mathcal{Q}_i, 0 \leq i \leq k$ is a partition of the vertex set V, and $\mathcal{Q}_0 = \{V(G)\}$.
(M2) Each $H_i, 0 \leq i \leq k$ is an f-factor of G, and H_i connects $\mathcal{Q}_i$.
(M3) For each $1 \leq i \leq k$, $\mathcal{Q}_i$ is a refinement of $\mathcal{Q}_{i-1}$ satisfying the following:
  (a) Each part Y in $\mathcal{Q}_i$ induces a component $H_{i-1}[Y]$ in $H_{i-1}[Q]$, for some Q in $\mathcal{Q}_{i-1}$.
  (b) $\mathcal{Q}_i \neq \mathcal{Q}_{i-1}$.

The following lemma links the existence of a connected f-factor to the properties of maximal sequences satisfying (M1)–(M3).

▶ **Lemma 9.** *Let (G, f) be an instance of* CONNECTED g-BOUNDED f-FACTOR *and let $(H_0, \mathcal{Q}_0), \ldots, (H_k, \mathcal{Q}_k)$ be any maximal sequence satisfying Properties (M1)–(M3). Then G has a connected f-factor if and only if H_k is a connected f-factor of G.*

The above lemma shows that if we had an algorithm for constructing a maximal sequence satisfying (M1)–(M3), then we could solve the f-factor problem by testing whether the last f-factor in that sequence is connected. However, if the number of parts of the partitions $\mathcal{Q}_i$ is allowed to grow to n, then such an algorithm would eventually have to solve the connected f-factor problem. Hence, to employ the idea for an efficient algorithm, we first need to establish an upper bound on the number of parts in any partition $\mathcal{Q}_i$ of a maximal sequence. The following lemma, which shows a lower bound on the minimum degree and hence a lower bound on the size of any part in $\mathcal{Q}_i$, is crucial for estabilishing such an upper bound.

▶ **Lemma 10.** *Let $(H, \mathcal{Q})$, $(H', \mathcal{Q}')$ be two consequitive pairs occuring in a sequence satisfying properties (M1)–(M3). Then there is an f-factor H'' of G connecting $\mathcal{Q}'$ such that $|N_{H''}(v) \cap Q'| \geq |N_H(v) \cap Q'| - 2(|\mathcal{Q}'| - 1)$ for every $Q' \in \mathcal{Q}'$ and $v \in Q'$. Moreover, H'' can be computed from $\mathcal{Q}'$, H, and H' in polynomial time.*

Our algorithm will employ the above lemma to construct a maximal sequence $(H_0, \mathcal{Q}_0)$, $\dots, (H_k, \mathcal{Q}_k)$ that satisfies the following additional property:

(M4) For every $1 \leq i \leq k$, every $Q \in \mathcal{Q}_i$ and $v \in Q$ it holds that $|N_{H_i}(v) \cap Q| \geq |N_{H_{i-1}}(v) \cap Q| - 2(|\mathcal{Q}_i| - 1)$.

This property will be key for the analysis of our algorithm because it allows us to bound the number of parts in each partition $\mathcal{Q}_i$. Towards this aim we require the following auxirilliary lemma.

▶ **Lemma 11.** *Let $\mathcal{S} = (H_0, \mathcal{Q}_0), \dots, (H_k, \mathcal{Q}_k)$ be a sequence satisfying Properties (M1)–(M4). Then $|N_{H_i}(v) \cap Q| \geq f(v) - \sum_{1 \leq j \leq i} 2(|\mathcal{Q}_j| - 1)$ for every i with $1 \leq i \leq k$, $Q \in \mathcal{Q}_i$ and $v \in Q$.*

We are now ready to show that the number of parts in any partition $\mathcal{Q}_i$ in a maximal sequence does not exceed $g(n) + 1$.

▶ **Lemma 12.** *Let $\mathcal{S} = (H_0, \mathcal{Q}_0), \dots, (H_k, \mathcal{Q}_k)$ be a maximal sequence satisfying Properties (M1)–(M4). Then $|\mathcal{Q}_i| \leq g(n) + 1$ for every i with $0 \leq i \leq k$. Moreover, the length of $\mathcal{S}$ is at most $g(n) + 1$.*

We are now ready to prove the main theorem of this section.

Sketch of Proof of Theorem 7. Let (G, f) be an instance of CONNECTED g-BOUNDED f-FACTOR. The algorithm constructs a maximal sequence satisfying Properties (M1)–(M4). The first pair $(H_0, \mathcal{Q}_0)$ is obtained by computing an arbitrary f-factor of G and setting $\mathcal{Q}_0 = \{V(G)\}$. The crucial ingredient of the algorithm is then a procedure that given the i-th pair $(H_i, \mathcal{Q}_i)$ of a maximal sequence computes a $(i+1)$-th pair $(H_{i+1}, \mathcal{Q}_{i+1})$ that can be appended to the sequence without violating any of the Properties (M1)–(M4). Informally, this is achieved by first setting $\mathcal{Q}_{i+1}$ to be the refinement of $\mathcal{Q}_i$ containing one part for every part $Q \in \mathcal{Q}_i$ and every component of $H_i[Q]$. Then an f-factor connecting $\mathcal{Q}_{i+1}$ is computed using the given algorithm for PARTITION CONNECTOR. If no such f-factor exists, the algorithm returns failure (which is correct due to Observation 8). If such an f-factor exists, the procedure uses the given f-factor and Lemma 10 to compute an f-factor H_{i+1} connecting $\mathcal{Q}_{i+1}$ such that the pair $(H_{i+1}, \mathcal{Q}_{i+1})$ satisfies Property (M4). Clearly, if any of the computed f-factors are connected f-factors of G the procedure returns the corresponding f-factor as a solution. Otherwise, the procedure now tries to find a successor of $(H_{i+1}, \mathcal{Q}_{i+1})$ in the already computed sequence satisfying (M1)–(M4). ◀

3.2 A Quasipolynomial Time Algorithm for Polylogarithmic Bounds

In this section, we prove Theorem 1 and Theorem 2. In fact, we prove a more general result, from which both theorems directly follow.

▶ **Theorem 13.** *For every $c > 0$ and function $g(n) = \mathcal{O}((\log n)^c)$, the* Connected g-Bounded f-factor *problem can be solved in $\tilde{\mathcal{O}}(n^{g(n)})$ time.*

We will make use of the following simple lemma.

▶ **Lemma 14.** *Let G be a graph having a connected f-factor. Let $\mathcal{Q}$ be a partition of the vertex set V. There exists a spanning tree T of $G/\mathcal{Q}$ such that for some f-factor H of G, $E(T) \subseteq E(H)$. Furthermore, H can be computed from T in polynomial time.*

Proof. Let G' be a connected f-factor of G. For any partition $\mathcal{Q}$ of the vertex set, it follows from Theorem 8 that $G'/\mathcal{Q}$ is connected. Consider a spanning tree T of $G'/\mathcal{Q}$. Clearly, there exists at least one f-factor H containing $E(T)$ and hence $H/\mathcal{Q}$ is connected. Once we have $E(T)$, H can be computed in polynomial time using Lemma 6. ◀

In light of Theorem 7, it now suffices to prove the following Lemma 15, from which Theorem 13 immediately follows.

▶ **Lemma 15.** Partition Connector *can be solved in time $\mathcal{O}(n^{2(|\mathcal{Q}|-1)})$.*

Proof. It follows from Lemma 14 that we can solve Partition Connector by going over all spanning trees T of $G/\mathcal{Q}$ and checking for each of them whether there is an f-factor of G containing the edges of T. The lemma now follows because the number of spanning trees of $G/\mathcal{Q}$ is at most $\binom{|E(G)|}{|\mathcal{Q}|-1}$, which is upper bounded by $\mathcal{O}(n^{2(|\mathcal{Q}|-1)})$, and for every such tree T we can check the existence of an f-factor containing T in polynomial time. ◀

4 A Randomized Polynomial Time Algorithm for Logarithmic Bounds

In this section we prove Theorem 3. Due to Theorem 7, it is sufficient for us to provide a randomized algorithm for Partition Connector with running time $\mathcal{O}(2^{|\mathcal{Q}|}n^{\mathcal{O}(1)})$ and error probability $\mathcal{O}(g(n)^2/n^2)$. This is precisely what we do in the rest of this section (Lemma 28). As a first step, we will design an algorithm for the "existential version" of the problem which we call ∃-Partition Connector and define as follows.

∃-Partition Connector
Input: A graph G with n vertices, $f : V \to \mathbb{N}$, and a partition $\mathcal{Q}$ of $V(G)$.
Question: Is there an f-factor of G that connects $\mathcal{Q}$?

We will then describe how to use our algorithm for this problem as a subroutine in our algorithm to solve Partition Connector.

4.1 Solving ∃-Partition Connector in Randomized Polynomial Time

The objective of this subsection is to prove the following lemma which implies a randomized polynomial time algorithm for ∃-Partition Connector when $g(n) = \mathcal{O}(\log n)$.

▶ **Lemma 16.** *There exists an algorithm that, given a graph G, a function $f : V \to \mathbb{N}$, and a partition $\mathcal{Q}$ of $V(G)$, runs in time $\mathcal{O}(2^{|\mathcal{Q}|}|V(G)|^{\mathcal{O}(1)})$ and outputs*

- NO *if G has no f-factor connecting $\mathcal{P}$*
- YES *with probability at least $1 - \frac{1}{n^2}$ otherwise.*

We design this algorithm by starting from the exact-exponential algorithm in [14] and making appropriate modifications. During the description, we will point out the main differences between our algorithm and that in [14]. We now proceed to the details of the algorithm. We begin by recalling a few important definitions and known results on f-factors. These are mostly standard and are also present in [14], but since they are required in the description and proof of correctness of our algorithm, we will state them here.

▶ **Definition 17** (f-Blowup)**.** Let G be a graph and let $f : V(G) \to \mathbb{N}$ be such that $f(v) \leq deg(v)$ for each $v \in V(G)$. Let H be the graph defined as follows

1. For each vertex v of G, we add a vertex set $A(v)$ of size $f(v)$ to H.
2. For each edge $e = \{v, w\}$ of G we add to H vertices v_e and w_e and edges (u, v_e) for every $u \in A(v)$ and (w_e, u) for every $u \in A(w)$. Finally, we add the edge (v_e, w_e).

This completes the construction. The graph H is called the *f-blowup* of graph G. We use $\mathcal{B}_f(G)$ to denote the f-blowup of G. We omit the subscript when there is no scope for ambiguity.

▶ **Definition 18** (Induced f-blowup)**.** For a subset $S \subseteq V(G)$, we define the f-blowup of G *induced* by S as follows. Let the f-blowup of G be H. Begin with the graph H and for every edge $e = (v, w) \in E(G)$ such that $v \in S$ and $w \notin S$, delete the vertices v_e and w_e. Let the graph H' be the union of those connected components of the resulting graph which contain the vertex sets $A(v)$ for vertices $v \in S$. Then, the graph H' is called the f-blowup of G *induced* by the set S and is denoted by $\mathcal{B}_f(G)[S]$.

We now recall the relation between perfect matchings in the f-blowup and f-factors (see Figure 1).

▶ **Lemma 19** ([10])**.** *A graph G has an f-factor if and only if the f-blowup of G has a perfect matching.*

The relationship between the Tutte matrix and perfect matchings is well-known and this has already been exploited in the design of fixed-parameter and exact algorithms [21, 7].

▶ **Definition 20** (Tutte matrix)**.** The *Tutte matrix* of a graph G with n vertices is an $n \times n$ skew-symmetric matrix T over the set $\{x_{ij} | 1 \leq i < j \leq |V(G)|\}$ of indeterminates whose $(i, j)^{th}$ element is defined to be

$$T(i,j) = \begin{cases} x_{ij} & \text{if } \{i,j\} \in E(G) \text{ and } i < j \\ -x_{ij} & \text{if } \{i,j\} \in E(G) \text{ and } i > j \\ 0 & \text{otherwise} \end{cases}$$

We use $\mathcal{T}(G)$ to denote the Tutte matrix of the graph G.

Following terminology in [14], when we refer to expanded forms of *succinct* representations (such as summations and determinants) of polynomials, we use the term *naive expansion* (or summation) to denote that expanded form of the polynomial which is obtained by merely writing out the operations indicated by the succinct representation. We use the term *simplified expansion* to denote the expanded form of the polynomial which results after we apply all possible simplifications (such as cancellations) to a naive expansion. We call a monomial m which has a non-zero coefficient in a simplified expansion of a polynomial P, a *surviving* monomial of P in the simplified expansion.

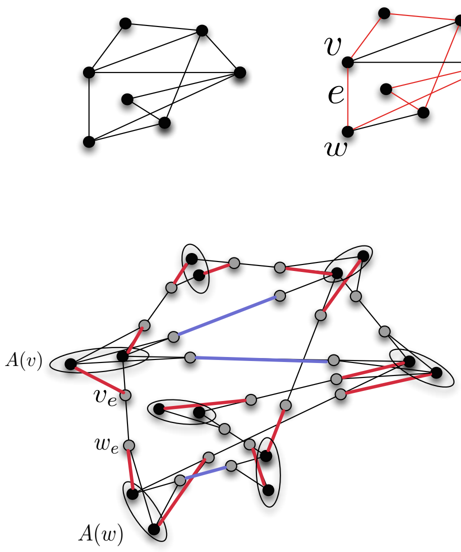

Figure 1 An illustration of a graph G with a 2-factor H (the red edges) and one possible corresponding perfect matching in $\mathcal{B}(G)$. It is important to note that an edge $e = (v, w)$ is *not* in H if and only if the edge (v_e, w_e) is present in the corresponding perfect matching.

The following basic facts about the Tutte matrix $\mathcal{T}(G)$ of a graph G are well-known. When evaluated over any field of characteristic two, the determinant and the permanent of the matrix $\mathcal{T}(G)$ (indeed, of any matrix) coincide. That is,

$$\det \mathcal{T}(G) = \mathrm{perm}(\mathcal{T}(G)) = \sum_{\sigma \in S_n} \prod_{i=1}^{n} \mathcal{T}(G)(i, \sigma(i)), \qquad (1)$$

where S_n is the set of all *permutations* of $[n]$. Furthermore, there is a one-to-one correspondence between the set of all *perfect matchings* of the graph G and the *surviving monomials* in the above expression for $\det \mathcal{T}(G)$ when its simplified expansion is computed over any field of characteristic two.

▶ **Proposition 21** ([11])**.** If $M = \{(i_1, j_1), (i_2, j_2), \ldots, (i_\ell, j_\ell)\}$ is a perfect matching of a graph G, then the product $\prod_{(i_k, j_k) \in M} x_{i_k j_k}^2$ appears exactly once in the naive expansion and hence as a surviving monomial in the sum on the right-hand side of Equation 1 when this sum is expanded and simplified over any field of characteristic two. Conversely, each surviving monomial in a simplified expansion of this sum over a field of characteristic two is of the form $\prod_{(i_k, j_k) \in M} x_{i_k j_k}^2$ where $M = \{(i_1, j_1), (i_2, j_2), \ldots, (i_\ell, j_\ell)\}$ is a perfect matching of G. In particular, $\det \mathcal{T}(G)$ is identically zero when expanded and simplified over a field of characteristic two if and only if the graph G does not have a perfect matching.

▶ **Lemma 22** (Schwartz-Zippel Lemma, [17, 23])**.** *Let $P(x_1, \ldots, x_n)$ be a multivariate polynomial of degree at most d over a field $\mathbb{F}$ such that P is not identically zero. Furthermore, let $r_1, \ldots, r_n$ be chosen uniformly at random from $\mathbb{F}$. Then, Prob$[P(r_1, \ldots, r_n) = 0] \leq \frac{d}{|\mathbb{F}|}$.*

▶ **Definition 23.** For a partition of $V(G)$, $\mathcal{Q} = \{Q_1, \ldots, Q_\ell\}$ and a subset $I \subseteq [\ell]$, we denote by $\mathcal{Q}(I)$ the set $\bigcup_{i \in I} Q_i$. Furthermore, with every set $\emptyset \neq I \subset [\ell]$, we associate a specific monomial m_I which is defined to be the product of the terms x_{ij}^2 where $i < j$

and $\{i,j\} = \{v_e, w_e\}$, $e = (v,w) \in E(G)$ crosses the cut $(\mathcal{Q}(I), \overline{\mathcal{Q}(I)})$ and v_e, w_e, are as in Definition 17 of the f-blowup $\mathcal{B}(G)$ of G. For $I = [\ell]$, we define $m_I = 1$.

From now on, for a set $X \subseteq V(G)$, we denote by $\overline{X}$ the set $V(G) \setminus X$. Also, since we always deal with a fixed graph G and function f, for the sake of notational convenience, we refer to the graph $\mathcal{B}_f(G)$ simply as $\mathcal{B}$. We now define a polynomial $P_{\mathcal{Q}}(\bar{x})$ over the indeterminates from the Tutte matrix $\mathcal{T}(\mathcal{B})$ of the f-blowup of G, as follows:

$$P_{\mathcal{Q}}(\bar{x}) = \sum_{\{1\} \subseteq I \subseteq [\ell]} (\det \mathcal{T}(\mathcal{B}[\mathcal{Q}(I)])) \cdot (\det \mathcal{T}(\mathcal{B}[\overline{\mathcal{Q}(I)}])) \cdot m_I, \tag{2}$$

where if a graph H has no vertices or edges then we set $\det \mathcal{T}(H) = 1$. In future, we will always deal with a fixed partition $\mathcal{Q} = \{Q_1, \ldots, Q_\ell\}$ of $V(G)$.

▶ Remark. The definition of the polynomial $P_{\mathcal{Q}}(\bar{x})$ is the main difference between our algorithm and the algorithm in [14]. The rest of the details are identical. The main algorithmic consequence of this difference is the time it takes to evaluate this polynomial at a given set of points. This is captured in the following lemma whose proof follows from the fact that determinant computation is a polynomial time solvable problem.

▶ **Lemma 24.** *Given values for the variables x_{ij} in the matrix $\mathcal{T}(\mathcal{B})$, the polynomial $P_{\mathcal{Q}}(\bar{x})$ can be evaluated over a field $\mathbb{F}$ of character 2 and size $\Omega(n^6)$ in time $\mathcal{O}(2^\ell n^{\mathcal{O}(1)})$.*

Having shown that this polynomial can be efficiently evaluated, we will now turn to the way we use it in our algorithm. Our algorithm for $\exists$-Partition Connector takes as input $G, f, \mathcal{Q}$, evaluates the polynomial $P_{\mathcal{Q}}(\bar{x})$ at points chosen independently and uniformly at random from a field $\mathbb{F}$ of size $\Omega(n^6)$ and characteristic 2 and returns Yes if and only if the polynomial does not vanish at the chosen points. In what follows we will prove certain properties of this polynomial which will be used in the formal proof of correctness of this algorithm. We need another definition before we can state the main lemma capturing the properties of the polynomial. Recall that for every $v \in V(G)$, the set $A(v)$ is the set of 'copies' of v in the f-blowup of G. Furthermore, for a set $X \subseteq V(G)$, we say that an edge $e \in E(G)$ *crosses* the cut $(X, \overline{X})$ if e has exactly one endpoint in X.

▶ **Definition 25.** We say that an f-factor H of G *contributes* a monomial $x^2_{i_1 j_1} \ldots x^2_{i_r j_r}$ to the naive expansion of the right-hand side of Equation 2 if and only if the following conditions hold.

1. For every $e = (v,w) \in E(H)$, there is a $u \in A(v)$, $u' \in A(w)$ and $1 \le p, q \le r$ such that $\{u, v_e\} = \{i_p, j_p\}$ and $\{u', w_e\} = \{i_q, j_q\}$.
2. For every $e = (v,w) \in E(G) \setminus E(H)$, there is a $1 \le p \le r$ such that $\{v_e, w_e\} = \{i_p, j_p\}$.
3. For every $1 \le p, q \le r$, if $\{u, v_e\} = \{i_p, j_p\}$ and $\{u', w_e\} = \{i_q, j_q\}$ for some $e \in E(G)$, then $e \in E(H)$.
4. For every $1 \le p \le r$, if $\{i_p, j_p\} = \{v_e, w_e\}$ for some $e \in E(G)$, then $e \notin E(H)$.
5. For every $1 \in I \subseteq [\ell]$ such that H has no edge crossing the cut $(\mathcal{Q}(I), \overline{\mathcal{Q}(I)})$, there is a pair of monomials m_1 and m_2 such that m_1 is a surviving monomial in the simplified expansion of $\det \mathcal{T}(\mathcal{B}[\mathcal{Q}(I)])$, m_2 is a surviving monomial in the simplified expansion of $\det \mathcal{T}(\mathcal{B}[\overline{\mathcal{Q}(I)}])$, and $m_1 \cdot m_2 \cdot m_I = x^2_{i_1 j_1} \ldots x^2_{i_r j_r}$.

Having set up the required notation, we now state the main lemma which allows us to show that monomials contributed by f-factors that do not connect $\mathcal{Q}$, do not survive in the simplified expansion of the right hand side of Equation 2.

▶ **Lemma 26.** *Every monomial in the polynomial $P_{\mathcal{Q}}(\bar{x})$ which is a surviving monomial in the simplified expansion of the right-hand side of Equation 2 is contributed by an f-factor of G to the naive expansion of the right-hand size of Equation 2. Furthermore, for any f-factor of G, say H, the following statements hold.*

1. *If H does not connect $\mathcal{Q}$ then every monomial contributed by H occurs an* even *number of times in the polynomial $P_{\mathcal{Q}}(\bar{x})$ in the naive expansion of the right-hand side of Equation 2.*
2. *If H connects $\mathcal{Q}$, then every monomial contributed by H occurs exactly once in the polynomial $P_{\mathcal{Q}}(\bar{x})$ in the naive expansion of the right-hand side of Equation 2.*

This implies the following result, which is the last ingredient we need to prove Lemma 16.

▶ **Lemma 27.** *The polynomial $P_{\mathcal{Q}}(\bar{x})$ is not identically zero over $\mathbb{F}$ if and only if G has an f-factor connecting $\mathcal{Q}$.*

Proof of Lemma 16. It follows from the definition of $P(\bar{x})$ that its degree is $\mathcal{O}(n^4)$ since the number of vertices in the f-blowup of G is $\mathcal{O}(n^2)$. As mentioned earlier, our algorithm for ∃-Partition Connector takes as input $G, f, \mathcal{Q}$, evaluates the polynomial $P_{\mathcal{Q}}(\bar{x})$ at points chosen independently and uniformly at random from a field $\mathbb{F}$ of size $\Omega(n^6)$ and characteristic 2 and returns Yes if and only if the polynomial does not vanish at the chosen points. Due to Lemma 27, we know that the polynomial $P_{\mathcal{Q}}(\bar{x})$ is identically zero if and only if G has an f-factor containing $\mathcal{Q}$ and by the Schwartz-Zippel Lemma, the probability that the polynomial is not identically zero and still vanishes upon evaluation is at most $\frac{1}{n^2}$. This completes the proof of the lemma. ◀

Having obtained the algorithm for ∃-Partition Connector, we now return to the algorithm for the computational version, Partition Connector.

4.2 Solving Partition Connector in Randomized Polynomial Time

▶ **Lemma 28.** *The* Partition Connector *problem can be solved by a randomized algorithm with running time $\mathcal{O}(2^{|\mathcal{Q}|}n^{\mathcal{O}(1)})$ and error probability $\mathcal{O}(1-(1-\frac{1}{n^2})^{|\mathcal{Q}|})$.*

Sketch of Proof. Consider the following algorithm $\mathcal{A}$. Algorithm $\mathcal{A}$ takes as input an n-vertex instance of Partition Connector with the partition $\mathcal{Q} = \{Q_1, \ldots, Q_\ell\}$, along with a separate set of edges F which will store the edges that have been previously selected to be included in the partition connector. Let F be initialized as $\emptyset$. As its first step, Algorithm $\mathcal{A}$ checks if $\ell = 1$; if this is the case, then it computes an arbitrary f-factor H, and outputs $H \cup F$. To proceed, let us denote the algorithm of Lemma 16 as $\mathcal{B}$. If $\ell > 1$, then $\mathcal{A}$ first calls $\mathcal{B}$ and outputs NO if $\mathcal{B}$ outputs NO. Otherwise, it fixes an arbitrary ordering $E^{\leq}$ of the edge set E and recursively proceeds as follows.

$\mathcal{A}$ constructs the set E_1 of all edges with precisely one endpoint in Q_1, and loops over all edges in E_1 (in the ordering given by $E^{\leq}$). For each processed edge e between Q_1 and some Q_i with endpoints c and d, it will compute a subinstance $(G^e, f^e, \mathcal{Q}^e)$ defined by setting:

- $G^e = G - e$, and
- $f^e(c) = f(c) - 1$, $f^e(d) - f(d) - 1$ and $f^e = f$ for all other vertices of G, and
- $\mathcal{Q}^e$ is obtained from $\mathcal{Q}$ by merging Q_1 and Q_i into a new set; formally, $\mathcal{Q}^e = (\mathcal{Q} \setminus \{Q_1, Q_i\}) \cup \{Q_1 \cup Q_i\}$.

Intuitively, each such new instance corresponds to us forcing the f-factor to choose the edge e. $\mathcal{A}$ then queries $\mathcal{B}$ on $(G^e, f^e, \mathcal{Q}^e)$. If $\mathcal{B}$ answers NO for each such tuple $(G^e, f^e, \mathcal{Q}^e)$ obtained from each edge in E_1, then $\mathcal{A}$ immediately terminates and answers NO. Otherwise let e be the first edge where $\mathcal{B}$ answered YES; then $\mathcal{A}$ will add e into F. If $|\mathcal{Q}^e| = 1$ then the algorithm computes an arbitrary f-factor H of (G^e, f^e) and outputs $H \cup F$. On the other hand, if $|\mathcal{Q}| > 1$ then $\mathcal{A}$ restarts the recursive procedure with $(G, f, \mathcal{Q}) := (G^e, f^e, \mathcal{Q}^e)$; observe that $|\mathcal{Q}^e| \leq |\mathcal{Q}| - 1$. To complete the proof, it suffices to verify the correctness and the running time. ◀

5 Classification Results

In this section, we prove Theorem 4 which we restate for the sake of completeness.

▶ **Theorem 4.** *For every $c > 1$, for every $g(n) = \Theta((\log n)^c)$,* Connected g-Bounded f-Factor *is neither in* P *nor* NP*-hard unless the Exponential Time Hypothesis fails.*

The result relies on the established Exponential Time Hypothesis, which we recall below.

▶ **Definition 29** (Exponential Time Hypothesis (ETH), [8]). There exists a constant $s > 0$ such that 3-SAT with n variables and m clauses cannot be solved in time $2^{sn}(n+m)^{\mathcal{O}(1)}$.

We first show that the problem is not NP-hard unless the ETH fails. We remark that we can actually prove a stronger statement here by weakening the premise to "NP is not contained in Quasi-Polynomial Time". However, since we are only able to show the other part of Theorem 4 under the ETH, we phrase the statement in this way.

▶ **Lemma 30.** *For every $c > 1$, for every $g(n) = \Theta((\log n)^c)$,* Connected g-Bounded f-Factor *is not* NP*-hard unless the Exponential Time Hypothesis fails.*

Proof. Due to Theorem 2, we know that when $g(n) = \Theta((\log n)^c)$, Connected g-Bounded f-Factor can be solved in quasi-polynomial time. Hence, this problem cannot be NP-hard unless NP is contained in the complexity-class Quasi-Polynomial Time, QP. Furthermore, observe that $NP \subseteq QP$ implies that the ETH is false. Hence, we conclude that Connected g-Bounded f-Factor is not NP-hard unless the Exponential Time Hypothesis fails. ◀

Next, we use a reduction from Hamiltonian Cycle to obtain:

▶ **Lemma 31.** *For every $c > 1$, for every $g(n) = \Theta((\log n)^c)$,* Connected g-Bounded f-Factor *is not in* P *unless the Exponential Time Hypothesis fails.*

Lemmas 30 and 31 together give us Theorem 4.

6 Concluding remarks

We obtained new complexity results for Connected f-Factor with respect to lower bounds on the function f. As our main results, we showed that when $f(v)$ is required to be at least $\frac{n}{(\log n)^c}$, the problem can be solved in quasi-polynomial time in general and in randomized polynomial time if $c \leq 1$. Consequently, we show that the problem can be solved in polynomial-time when $f(v)$ is at least $\frac{n}{c}$ for any constant c. We complement the picture with matching classification results.

As a by-product we obtain a generic approach reducing Connected f-Factor to the "simpler" Partition Connector problem. Hence future algorithmic improvements of Partition Connector carry over to the Connected f-Factor problem. Finally, it would be interesting to investigate the possibility of derandomizing the polynomial-time algorithm for the case that $g(n) = \mathcal{O}(\log n)$.

Acknowledgments. The authors wish to thank the anonymous reviewers for their helpful comments.

Abstract

Impagliazzo *et al.* proposed a framework, based on the logic fragment defining the complexity class SNP, to identify problems that are equivalent to k-CNF-Sat modulo subexponential-time reducibility (serf-reducibility). The subexponential-time solvability of any of these problems implies the failure of the Exponential Time Hypothesis (ETH). In this paper, we extend the framework of Impagliazzo *et al.*, and identify a larger set of problems that are equivalent to k-CNF-Sat modulo serf-reducibility. We propose a complexity class, referred to as Linear Monadic NP, that consists of all problems expressible in existential monadic second order logic whose expressions have a linear *measure* in terms of a complexity parameter, which is usually the universe size of the problem.

This research direction can be traced back to Fagin's celebrated theorem stating that NP coincides with the class of problems expressible in existential second order logic. Monadic NP, a well-studied class in the literature, is the restriction of the aforementioned logic fragment to existential *monadic* second order logic. The proposed class Linear Monadic NP is then the restriction of Monadic NP to problems whose expressions have linear measure in the complexity parameter.

We show that Linear Monadic NP includes many natural complete problems such as the satisfiability of linear-size circuits, dominating set, independent dominating set, and perfect code. Therefore, for any of these problems, its subexponential-time solvability is equivalent to the failure of ETH. We prove, using logic games, that the aforementioned problems are inexpressible in the monadic fragment of SNP, and hence, are not captured by the framework of Impagliazzo *et al.* Finally, we show that Feedback Vertex Set is inexpressible in existential monadic second order logic, and hence is not in Linear Monadic NP, and investigate the existence of certain reductions between Feedback Vertex Set (and variants of it) and 3-CNF-Sat.

1 Introduction

Motivation and related work

The area of exact algorithms seeks moderately exponential-time algorithms for NP-hard problems that improve on the trivial brute-force algorithms. This area of research has been gaining a lot of traction in the last two decades. Nowadays, there is a large set of important NP-complete problems such that for each problem there is a long list of exact algorithms, each improving slightly on the running time of the preceding one; we refer the interested reader to [19] for exposure to the area of exact algorithms. Perhaps the most well-known—and important—NP-hard problem is the satisfiability of Boolean formulas in conjunctive normal form, abbreviated CNF-Sat. Its importance stems from its practical relevance as well as from the canonical role it plays for the complexity class NP, being the first problem shown to be complete for this class. Despite all the exercised efforts over the last several decades, the best algorithms remain equivalent (in terms of the upper bound on their running time) to the trivial brute-force algorithm that solves CNF-Sat in time $\mathcal{O}^*(2^n)$,[1] where n is the number of Boolean variables in the input formula. It has become a common belief among a significant number of researchers in the area of exact algorithms that no $\mathcal{O}^*(2^{cn})$-time algorithm, for any constant $c < 1$, exists for CNF-Sat. If we restrict the clause-width to be at most k (where $k \geq 3$) in the instances of CNF-Sat, we obtain the k-CNF-Sat problem, for which there is a long list of moderately exponential-time algorithms culminating in the currently-best deterministic algorithm (for a general value of k) running in time $\mathcal{O}((2 - 2/(k+1))^n)$ [12].

The sequence of improvements in the running time of moderately exponential-time algorithms for k-CNF-Sat, as well as for other NP-complete problems, led researchers to ask whether we can "indefinitely" keep improving the running time of exact algorithms for these problems. More formally, it triggered the question of whether an algorithm solving k-CNF-Sat in time $\mathcal{O}(2^{o(n)})$, or equivalently in time $\mathcal{O}(2^{\varepsilon n})$ for every $\varepsilon > 0$, exists; an algorithm with such running time is referred to as a *subexponential-time algorithm.* In their seminal paper, Impagliazzo *et al.* [22] investigated this question. They proved that the existence of a subexponential-time algorithm for k-CNF-Sat, for any integer-constant $k \geq 3$, is related to its membership in the class SNP, introduced in [30]. The class SNP consists of all search problems expressible by second-order existential formulas whose first-order part is universal; we shall refer to the aforementioned logic fragment as *SNP logic.* For a problem in SNP, they defined a complexity parameter based on its SNP logic expression. They introduced the notion of completeness for the class SNP under serf-reductions, which are subexponential-time complexity preserving reductions with respect to the aforementioned complexity parameter, and identified a class of problems that are complete for SNP under serf-reducibility; the subexponential-time solvability of any of these problems with respect to its corresponding complexity parameter implies the subexponential-time solvability of all problems in SNP. They proved that many well-known NP-hard problems are SNP-complete under serf-reducibility with respect to a complexity parameter that is linear in the natural universe size of the problem, including k-CNF-Sat (universe is the Boolean variables in the formula), Vertex Cover, Independent Set, and c-Colorability ($c \geq 3$) (universe is the vertex set of the graph), for which extensive efforts to develop subexponential-time

[1] The $\mathcal{O}^*$ notation suppresses a polynomial factor in the input length.

algorithms have been made in the last three decades with no success. This led them to formulate the Exponential Time Hypothesis (ETH), stating that k-CNF-Sat is not solvable in subexponential-time, which is equivalent to the statement that not all SNP problems are solvable in subexponential time. ETH has become a standard hypothesis in complexity theory for proving hardness results that is closely related to the computational intractability of a large class of well-known NP-hard problems, measured from a number of different angles, such as subexponential-time complexity, fixed-parameter tractability, and approximation [6, 7, 10, 28, 29].

Our results

The SNP logic framework developed by Impagliazzo *et al.* [22] captures some well-known NP-complete problems that are serf-reducible to k-CNF-Sat with respect to their universe size, but fails to capture many others. Using logic games, we prove in Section 3 that there are many natural NP-complete problems that are not captured by this SNP logic framework, and yet are serf-reducible to k-CNF-Sat. Examples of such problems include the satisfiability problem for linear-size circuits (Linear Circuit-Sat), Dominating Set, Independent Dominating set, and Perfect Code. The restrictedness of the SNP-based framework, due to the restrictedness of SNP logic to allowing only universal quantifiers in the first order part, prevents the expressibility of problems such as the aforementioned ones, as we show in this paper that none of these problems can be expressed in SNP logic with a complexity parameter that is linear in the natural universe size of the problem.

We propose a complexity class, referred to as Linear Monadic NP, that captures more problems than the SNP-based framework of Impagliazzo *et al.* [22]. Fagin's celebrated theorem [15] states that NP coincides with the class of properties expressible in existential second-order logic. The class monadic NP, introduced by Fagin *et al.* [16], is the restriction of NP to problems expressible in monadic second-order logic in which the second-order part is existential, that is, all second-order variables have arity at most one (*i.e.*, set variables), and no universal quantification is allowed over these relations. The class monadic NP is a well-studied complexity class, and several properties have been shown to be inexpressible in the logic fragment defining this class [2, 3, 16, 23, 25]. We show in this paper that the class monadic NP plays an important role as well in identifying problems that are equivalent to k-CNF-Sat under serf-reducibility. We define a measure (for expressions), and use it to define a logic fragment, *Linear Existential Monadic Second-Order Logic* (LEMSO), consisting of the restriction of existential monadic second-order logic to expressions whose measure is linear in the complexity parameter, where the complexity parameter is defined as in Impagliazzo *et al.* [22]. The class Linear Monadic NP consists of all search problems expressible in LEMSO. All natural problems described in [22] including k-CNF-Sat, Independent Set, Vertex Cover, c-Colorability, which are complete for SNP under serf-reducibility with respect to their natural universe size (number of variables/vertices), are also complete for Linear Monadic NP under serf-reducibility. In fact, each problem in the class of problems defined by Impagliazzo *et al.* [22] consisting of all problems expressible in the SNP logic with a linear complexity parameter (as defined in [22]) is in Linear Monadic NP. We prove that problems such as Linear Circuit-Sat, Dominating Set, and Independent Dominating set are in Linear Monadic NP (and are actually complete for Linear Monadic NP), but *are not* expressible in the SNP logic, thus showing that the set of problems expressible in the SNP logic with a linear complexity parameter is a proper subset of Linear Monadic NP. This implies that the subexponential-time solvability of any of the aforementioned problems is equivalent to the failure of ETH. Our inexpressibility proofs use the framework of logic games, namely the Ajtai-Fagin game and the Ehrenfeucht-Fraïssé game.

Finally, we show using logic games that Feedback Vertex Set is inexpressible in EMSO, and hence is not in Linear Monadic NP. Whereas it can be easily shown that 3-CNF-Sat is serf-reducible to Feedback Vertex Set (by composing the two folklore polynomial-time reductions from 3-CNF-Sat to Vertex Cover and from Vertex Cover to Feedback Vertex Set), it is open whether a serf-reduction exists in the other direction. We show that there is a polynomial-time reduction from Feedback Vertex Set to 3-CNF-Sat with a quasi-linear increase in the universe size, and define a variant of Feedback Vertex Set that is equivalent to 3-CNF-Sat under serf-reducibility.

2 Preliminaries

2.1 Satisfiability

The CNF-Satisfiability problem, shortly CNF-Sat, is given a formula F in the CNF form, decide whether or not F is satisfiable. The *width* of a clause in a CNF formula F is the number of literals in the clause. The k-CNF-Sat problem, where $k \geq 2$, is the restriction of the CNF-Sat problem to instances in which the width of each clause is at most k. It is well known that the k-CNF-Sat problem for $k \geq 3$ is NP-complete [20]. Linear CNF-Sat is the restriction of CNF-Sat to formulas with a linear number of clauses with respect to the number of variables.

A *circuit* is a directed acyclic graph. The vertices of indegree 0 are called the *variables* or *input gates*, and are labeled either by *positive literals* x_i or by *negative literals* $\overline{x}_i$. The vertices of indegree larger than 0 are called the *gates* and are labeled with Boolean operators $\wedge$ or $\vee$. A special gate of outdegree 0 is designated as the *output* gate. We do not allow negation gates in the circuit since, by De Morgan's laws, a general circuit can be efficiently converted into the above circuit model. The *size* of a circuit C, denoted $|C|$, is the number of gates in it. A circuit C is *satisfiable* if there is a truth assignment to the input variables of C that makes C evaluate to 1. The Circuit-Satisfiability problem, shortly Circuit-Sat, is given a circuit C, decide whether or not C is satisfiable. Linear Circuit-Sat is the restriction of Circuit-Sat to circuits of linear size with respect to the number of variables.

2.2 Subexponential time and SNP

For any $n \in \mathbb{N}$, by $[n]$ we denote the set $\{1, 2, \ldots, n\}$. The time complexity functions used in this paper are assumed to be proper complexity functions.

It is clear that CNF-Sat is solvable in time $2^n|F|^{\mathcal{O}(1)}$, where F is the input instance and n is the number of variables in F. We say that CNF-Sat is solvable in *subexponential time* if there exists an algorithm that solves the problem in time $2^{o(n)}|F|^{\mathcal{O}(1)}$. Using the results of [8] and [17], the above definition is equivalent to the following: CNF-Sat is solvable in *subexponential time* if there exists an algorithm that for all $\varepsilon = 1/\ell$, where ℓ is a positive integer, solves the problem in time $2^{\varepsilon n}|I|^{\mathcal{O}(1)}$.

Let Q and Q' be two problems, and let μ and μ' be two parameter functions defined on instances of Q and Q', respectively. In the case of CNF-Sat, μ and μ' will be the number of variables in the instances of these problems. A *subexponential-time Turing reduction family* [22], see also [17], shortly a *serf-reduction*[2], is an algorithm A with an oracle to Q' such that there are computable functions $f, g : \mathbb{N} \longrightarrow \mathbb{N}$ satisfying: (1) given a pair (I, ε)

[2] Serf-reductions were introduced in [22]. Here we use the definition given in [17]. There is a slight difference between the two definitions, and the latter definition is more flexible for our purposes.

where $I \in Q$ and $\varepsilon = 1/\ell$ (ℓ is a positive integer), A decides I in time $f(1/\varepsilon)2^{\varepsilon\mu(I)}|I|^{\mathcal{O}(1)}$; and (2) for all oracle queries of the form "$I' \in Q'$" posed by A on input (I, ε), we have $\mu'(I') \leq g(1/\varepsilon)(\mu(I) + \log |I|)$.

The class SNP consists of all search problems expressible by second-order existential formulas whose first-order part is universal [30]; that is, search problems expressible by second-order formulas of the form $\exists R_1 \ldots \exists R_q \, \forall z_1 \ldots \forall z_r \; \Phi(S, R_1, \ldots, R_q, z_1, \ldots, z_r)$, where S is the input structure, $R_1, \ldots, R_q$ are (bound) relations, $z_1, \ldots, z_r$ are first-order variables, and Φ is a quantifier-free Boolean formula. We will refer to the preceding logic fragment as the *SNP logic*. Impagliazzo *et al.* [22] defined a complexity parameter for each such expression equal to $\sum_{i=1}^{q} |R_i|^{\alpha_i}$, where $|R_i|$ and α_i, $i = 1, \ldots, q$, are the encoding length of R_i and its arity, respectively. For monadic relations, the number of bits needed to describe R_i, is the size of the universe on which R_i is interpreted, and hence, as noted in [22], the complexity parameter in this case is linear in the universe size. They formulated the *Exponential Time Hypothesis* (ETH) stating that k-CNF-Sat (for any $k \geq 3$) cannot be solved in subexponential time $2^{o(n)}$, where n is the number of variables in the input formula. Therefore, there exists $c > 0$ such that k-CNF-Sat cannot be solved in time $\mathcal{O}(2^{cn})$. ETH is equivalent to the statement that not all SNP problems are solvable in subexponential time.

3 Linear Monadic NP and Serf-Reducibility to Linear Circuit-Sat

In this section, we present a fragment of existential second-order logic that extends the SNP logic introduced by Impagliazzo *et al.* [22] in the sense that it captures a larger set of problems that are serf-reducible to 3-CNF-Sat. The logic fragment we propose is a restriction of the well-studied existential monadic second-order logic (EMSO) that defines the complexity class Monadic NP (modulo standard syntactic augmentations to allow the expression of optimization problems). To define this logic fragment, we introduce a measure/function that associates with each expression in EMSO a value in terms of the complexity parameter of the expression, and we define Linear Monadic NP to be the restriction of Monadic NP to those expressions whose measure is linear in the complexity parameter. The complexity parameter of the expression we use is the same parameter defined by [22] for expressions in SNP: If $R_1, \ldots, R_q$ are the existentially-quantified second-order relations in the expression, where R_i has arity α_i, for $i = 1, \ldots, q$, then the complexity parameter of the expression is $\sum_{i=1}^{q} |R_i|^{\alpha_i}$.

We note that the SNP logic does not restrict the existentially quantified relations to be monadic, and we could have opted to do the same in this paper (*i.e.*, not restrict ourselves to monadic relations and Monadic NP), and the results in this paper would not have been affected. However, observe that the aforementioned complexity parameter defined by [22] and also used by us, when interpreted on a given structure (graph, CNF-formula, etc.) yields a parameter that is equal to $\sum_{i=1}^{q} |U|^{\alpha_i}$, where U is the natural universe on which the relations $R_1, \ldots, R_q$ are interpreted. Hence, this parameter can only be linear in the universe size (number of vertices in a graph, number of variables in a formula, etc.) if all relations in the expression are monadic; otherwise, the complexity parameter will be at least quadratic. To be able to use serf-reductions to claim that a subexponential-time algorithm for 3-CNF-Sat yields a subexponential-time algorithm for the search problem under consideration with respect to a complexity parameter that is linear in the universe size of the problem, the existentially-quantified relations in the SNP logic expression of the problem need to be monadic. We will refer to this fragment of SNP logic as *monadic SNP logic*, which, by the above, is the fragment of interest in the framework of Impagliazzo *et al.* [22] when studying the equivalence between natural problems modulo serf-reducibility.

We refer to the corresponding complexity class as Monadic SNP. By the same token, and without loss of generality, in this paper we restrict ourselves to Monadic NP.

3.1 Linear Monadic NP

The fragment of existential second-order logic that we consider is based on an inductively defined measure. Intuitively, this measure captures the size of the Boolean circuit that can be constructed for a concrete instance of the problem that is satisfiable if and only if there is an assignment to the second-order variables that makes the first-order part of the formula true.

We consider EMSO formulas with a single free monadic second-order variable, to be able to express optimization problems where solutions of a given (exact) size are sought.

In particular, let $\varphi(S) = \exists R_1 \dots \exists R_q \; Q_1 z_1 \dots Q_r z_r \; \Phi(S, R_1, \dots, R_q, z_1, \dots, z_r)$ be an existential second-order logic formula, where S is a free monadic second-order variable, where $R_1, \dots, R_q$ are (bound) monadic second-order variables, where $z_1, \dots, z_r$ are first-order variables and $Q_1, \dots, Q_r \in \{\exists, \forall\}$, and where Φ is quantifier-free.

Moreover, let A be an optimization problem consisting of inputs (I, N), where I is a relational structure over the same relational vocabulary as Φ, and where N is a positive integer.

We say that $\varphi(S)$ expresses the problem A if for each input (I, N) it holds that $(I, N) \in A$ if and only if there is an interpretation S_0 of S in I of size exactly N such that $I \models \varphi(S_0)$.

More generally, we also consider existential second-order logic formulas $\varphi(S)$ where the first-order part does not need to be in prenex form, that is, first-order quantifications and Boolean connectives can freely alternate.

Without loss of generality, we suppose that formulas $\varphi(S)$ are in negation normal form.

For search problems that do not involve an optimization component (*e.g.*, 3-CNF-Sat), we can simply omit the free variable S in the logic expression and the integer N in the problem input. All definitions and results extend straightforwardly to this setting.

For optimization problems where solutions of a given minimum or maximum size are sought, it suffices to investigate the variant of the problem involving solutions of exactly the given size, because it can easily be shown that there is a serf-reduction between these different problem variants.

Our size measure s is based on inductively defined measures, $s_\forall$ and $s_\exists$, that we define below. All measures take as input a second-order logic formula, and return an arithmetic expression over the single variable n. For any formula $\varphi(S)$ that expresses a search problem A, intuitively, the expression $s(\varphi(S)) = f(n)$ denotes an upper bound on the size of the Boolean circuit that expresses a given instance in terms of the input size n.

We inductively define these measures as follows. Here we let Q range over $\{\forall, \exists\}$, and we let $\overline{Q}$ denote the unique quantifier in $\{\forall, \exists\} \backslash \{Q\}$. Moreover, we let $\circ$ range over $\{\wedge, \vee\}$, and we let a denote any atom.

$$s(\exists R_i\ \psi) = s(\psi); \qquad (1) \qquad s(\psi_1 \circ \psi_2) = 1 + s(\psi_1) + s(\psi_2); \qquad (2)$$

$$s(Qz_i\ \psi) = \begin{cases} n & \text{if } \psi \text{ does not contain any occurrence of } \overline{Q}; \\ 1 + s_Q(Qz_i\ \psi) & \text{otherwise;} \end{cases} \qquad (3)$$

$$s_Q(\overline{Q}z_i\ \psi) = 1 + n \cdot s_{\overline{Q}}(\psi); \qquad (4) \qquad s_Q(a) = s_Q(\neg a) = 0; \qquad (6)$$

$$s_Q(Qz_i\ \psi) = n \cdot s_Q(\psi); \qquad (5)$$

$$s_Q(\psi_1 \circ \psi_2) = s_Q(\psi_2) \quad \text{if } \psi_1 \text{ contains no occurrences of second-order variables;} \qquad (7)$$

$$s_Q(\psi_1 \circ \psi_2) = s_Q(\psi_1) \quad \text{if } \psi_2 \text{ contains no occurrences of second-order variables;} \qquad (8)$$

for the case where both ψ_1 and ψ_2 contain second-order variables, we let:

$$s_\exists(\psi_1 \vee \psi_2) = s_\exists(\psi_1) + s_\exists(\psi_2); \qquad (9) \qquad s_\forall(\psi_1 \vee \psi_2) = 1 + s_\exists(\psi_1) + s_\exists(\psi_2); \qquad (11)$$

$$s_\forall(\psi_1 \wedge \psi_2) = s_\forall(\psi_1) + s_\forall(\psi_2); \qquad (10) \qquad s_\exists(\psi_1 \wedge \psi_2) = 1 + s_\forall(\psi_1) + s_\forall(\psi_2). \qquad (12)$$

The intuition behind the definition of the measure is that $s(\varphi(S))$ measures the size of the Boolean circuit C that is needed to express the formula $\varphi(S)$ when interpreted over the input I; $s(\varphi(S))$ returns an arithmetic expression with a single symbol, n, that is interpreted as the size of the universe U of the relational structure I. The variables of C are of the form $x_{T,e}$, representing whether an element e in the domain of I is chosen to be part of the interpretation of the monadic second-order variable T. The circuit C then encodes the first-order part of φ.

The computation of $s(\varphi)$ works as follows. The existential second-order quantifiers are disregarded, and the outermost Boolean connectives are dealt with in a straightforward inductive manner.

For every maximal subformula ψ that starts with a first-order quantifier Q, there are two options. Either ψ contains only first-order quantifiers of a single type—in which case the measure s returns n for this subformula—or ψ contains quantifiers of both types. In the latter case, the size of the (sub)circuit to represent ψ is measured inductively using s_Q.

The measure s_Q keeps track of what logic gate is the parent of the subcircuit representing the subformula ψ (*i.e.*, $Q = \forall$ corresponds to an $\wedge$-gate as parent and $Q = \exists$ corresponds to an $\vee$-gate as parent), and increases the size only if the subcircuit cannot be integrated/merged with its parent gate. For example, if the output gate of the subcircuit is an $\wedge$-gate, and its parent is also an $\wedge$-gate, these two gates can be merged into a single large $\wedge$-gate.

▶ **Definition 1.** We define Linear Monadic NP to be the class of NP search problems such that each is expressible using an EMSO formula $\varphi(S)$ with $s(\varphi(S)) = \mathcal{O}(n)$.

The following theorem shows that Linear Circuit-Sat can serve as the canonical satisfiability problem for Linear Monadic NP:

▶ **Theorem 2.** *Let A be a problem in Linear Monadic NP, and suppose that A is expressible using an EMSO formula $\varphi(S)$, where $s(\varphi(S)) = \mathcal{O}(n)$. Then A is serf-reducible to* Linear Circuit-Sat*, where the parameter of A is the size of the universe of the input structure, and that for* Linear Circuit-Sat *is the number of variables of the circuit.*

Sketch of Proof. Let A be a search problem with input of the form (I, N), where I is a relational structure with universe U, and $N \in \mathbb{N}$, such that A is expressed by the EMSO formula $\varphi(S) = \exists R_1, \dots, R_q\ \Phi(R_1, \dots, R_q, S)$, with $s(\varphi(S)) = \mathcal{O}(n)$.

We know that Φ consists of first-order formulas $\psi_1, \dots, \psi_k$—each starting with a first-order quantifier—that are combined using the connectives $\wedge$ and $\vee$, and that $s(\psi_i) = \mathcal{O}(n)$ for each $i \in [k]$.

We reduce the problem to Linear Circuit-Sat by transforming each such formula ψ_i into a sequence of (subexponentially many) circuits $C_{i,1}, \dots, C_{i,b_i}$ where each such circuit C_{i,b_i} is of size linear in $|U|$.

If ψ_i contains only universal first-order quantifiers, or only existential first-order quantifiers, constructing such a sequence of circuits can be done using known results [22, Theorems 1 and 2].

Otherwise, if ψ_i contains both universal and existential first-order quantifiers, we transform ψ_i into a single circuit C_i inductively, breaking the formula ψ_i into its subformulas and constructing subcircuits for each subformula.

Intuitively, this circuit C_i is constructed by 'unfolding' universal quantifiers into $\wedge$-gates and existential quantifiers into $\vee$-gates. Using the inductive definition of the measure s in Equations (1)–(12), and by our assumption that $s(\psi_i)$ is a linear function in n, we can derive that this construction yields a circuit C_i that is of size linear in $|U|$. ◀

▶ **Definition 3.** A problem A is *Linear Monadic NP-complete under serf-reducibility* if (1) it is in Linear Monadic NP and (2) every problem in Linear Monadic NP is serf-reducible to A.

▶ **Corollary 4.** Linear Circuit-Sat *is Linear Monadic NP-complete under serf-reducibility.*

Note that all problems in Monadic SNP [22] are in Linear Monadic NP. This is because every EMSO expression (in negation normal form) that contains no first-order quantifier alternations has a linear measure—due to Equation (3). Because Linear Circuit-Sat is serf-reducible to 3-CNF-Sat [24], Corollary 4 implies the following:

▶ **Corollary 5.** *Every Monadic SNP-complete problem is Linear Monadic NP-complete under serf-reducibility. Therefore, a Linear Monadic NP-complete problem is solvable in subexponential time if and only if ETH fails.*

The above implies that the well-known SNP-complete problems k-CNF-Sat ($k \geq 3$), c-Colorability, Independent Set, Clique, and Vertex Cover, among others, are Linear Monadic NP-complete. (Note that every problem that is complete for Linear Monadic NP under serf-reducibility is clearly hard for SNP under serf-reducibility.)

3.2 Applications: Expressing Natural Optimization Problems

We saw in the previous subsection that Linear Circuit-Sat is in Linear Monadic NP. We prove in Subsection 3.3 that Linear Circuit-Sat is not in monadic SNP. The same can be shown for problems that are serf-equivalent to Linear Circuit-Sat, such as Linear Hitting Set and Linear Set Cover. In this subsection, we give several examples of natural graph problems that are in Linear Monadic NP, but are inexpressible in monadic SNP logic as will be shown in Subsection 3.3. The definition of these natural problems can be found in [14].

Our first example is Dominating Set, with the number of vertices as the complexity parameter. This problem can be expressed using the following formula $\varphi_{\mathrm{DS}}(S)$:

$$\varphi_{\mathrm{DS}}(S) = \forall x \ (S(x) \vee \exists y(S(y) \wedge E(x,y))).$$

From Equations (1)–(12), we get that $s(\varphi_{\mathrm{DS}}(S)) = n + 1$. In effect:

$$\begin{aligned}
s(\varphi_{\mathrm{DS}}(S)) &= s[\forall x \ (S(x) \vee \exists y(S(y) \wedge E(x,y)))] && = 1 + s_\forall[\forall x \ (S(x) \vee \exists y(S(y) \wedge E(x,y)))] \\
&= 1 + n \cdot s_\forall[(S(x) \vee \exists y(S(y) \wedge E(x,y)))] && = 1 + n \cdot (1 + s_\exists[S(x)] + s_\exists[\exists y(S(y) \wedge E(x,y))]) \\
&= 1 + n \cdot (1 + 0 + n \cdot s_\exists[S(y) \wedge E(x,y)]) && = 1 + n \cdot (1 + 0 + n \cdot s_\exists[S(y)]) \\
&= 1 + n \cdot (1 + 0 + n \cdot 0) && = n + 1.
\end{aligned}$$

It follows that Dominating Set is in Linear Monadic NP. Our second example is the Red-Blue Dominating Set problem [11], with the number of vertices as the complexity parameter. The expression is $\varphi_{\text{RB-DS}}(S) = \forall x\,(\neg S(x) \vee R(x)) \wedge \forall y(\neg B(y) \vee \exists z(S(z) \wedge E(z,y)))$, for which it can be easily verified that $s(\varphi_{\text{RB-DS}}(S)) = 2n+2$.

Similarly, we can express the problem Non-Blocker [14], with the number of vertices as complexity parameter, using the following formula $\varphi_{\text{NB}}(S) = \forall x\,(\neg S(x) \vee \exists y\,(\neg S(y) \wedge E(x,y)))$. It can be easily verified that $s(\varphi_{\text{NB}}(S)) = n+1$, and hence Non-Blocker is in Linear Monadic NP.

The Independent Dominating Set problem [11] is also in Linear Monadic NP because it can be expressed as a conjunction of the two expressions for Dominating Set and Independent Set. Specifically, the formula $\varphi_{\text{IDS}}(S) = \varphi_{\text{DS}}(S) \wedge [\forall x \forall y\,(\neg E(x,y) \vee \neg S(x) \vee \neg S(y))]$ expresses the problem and $s(\varphi_{\text{IDS}}(S)) = 2n+2$.

A similar expression to the above shows that the Dominating Clique problem [9] is also in Linear Monadic NP.

Further examples of problems that are in Linear Monadic NP are Distance-r Dominating Set [21], r-Threshold Dominating Set [14], and r-Domatic Partition [32], for any integer-constant r.

We give the expression for r-Dominating Set below, whose measure can verified to be $\mathcal{O}(n)$. The expressions for the other two problems are omitted.

$$\varphi_{r\text{-DS}}(S) = \forall x\ \exists y_1 \exists y_2 \ldots \exists y_r\ [((x = y_1) \vee E(x,y_1)) \wedge \ldots \wedge ((y_{r-1} = y_r) \vee E(y_{r-1},y_r)) \wedge S(y_r)].$$

Finally, the Perfect Code problem [11] is in Linear Monadic NP because it can be expressed using the following formula $\varphi_{\text{PC}}(S)$, for which it can be verified that $s(\varphi_{\text{PC}}(S)) = 3n+3$:

$$\begin{aligned}\varphi_{\text{PC}}(S) = \quad & [\forall x \forall y\,(\neg E(x,y) \vee \neg S(x) \vee \neg S(y))] \wedge [\forall z\,(S(z) \vee \exists y\,(S(y) \wedge E(z,y)))] \wedge \\ & [\forall z \forall x \forall y\,(\neg S(x) \vee \neg S(y) \vee \neg E(x,z) \vee \neg E(y,z))].\end{aligned}$$

Via standard reductions from 3-CNF-Sat, it can be easily shown that all the problems discussed above are complete for Linear Monadic NP under serf-reducibility. Therefore, we have the following:

▶ **Corollary 6.** *For any of the problems* Dominating Set, Red-Blue Dominating Set, Independent Dominating Set, Dominating Clique, r-Threshold Dominating Set, Distance-r Dominating Set, r-Domatic Partition, *and* Perfect Code, *the following holds: the problem is solvable in subexponential time if and only if ETH fails.*

3.3 Inexpressibility in Monadic SNP Logic

We prove in this subsection that Dominating Set is inexpressible in monadic SNP logic, and show how the proof can be straightforwardly adapted to other considered problems. In particular, we show that there exists no formula φ in this logic with one free set variable such that $(G,S) \models \varphi(S)$ if and only if S is a dominating set in G. This shows that the greater freedom in quantifier alternation offered by our new logic fragment is necessary to express this problem. Before we give a formal proof of this result, we will need several notions from the area of logic; we refer the reader to Libkin's book [26]. The key tool we use to prove inexpressibility is the so-called Ajtai-Fagin game [1, 26], defined below.

▶ **Definition 7.** Let $\mathcal{P}$ be a property of graphs equipped with a single set, let Γ be a fragment of FO logic, and let $\ell, k \in \mathbb{N}$. Then the $(\mathcal{P}, \ell, k, \Gamma)$-Ajtai-Fagin game is a 2-player game between the duplicator and the spoiler which proceeds in the following 4 steps:

1. The duplicator selects a graph G equipped with a set S such that $(G, S) \in \mathcal{P}$.
2. The spoiler selects ℓ subsets $U_1, \ldots, U_\ell$ of $V(G)$.
3. The duplicator selects a graph G' equipped with a set S' and also ℓ subsets $U'_1, \ldots, U'_\ell$ of $V(G')$.
4. The duplicator wins if and only if he can prove that $(G, S, U_1, \ldots, U_\ell)$ and $(G', S', U'_1, \ldots, U'_\ell)$ agree on $\Gamma[k]$.

▶ **Proposition 8** ([1, 26])**.** The duplicator has a winning strategy in the $(\mathcal{P}, \ell, k, \Gamma)$-Ajtai-Fagin game if and only if $\mathcal{P}$ is not definable by any formula with a single free set variable S of the form $\exists X_1, \ldots, \exists X_\ell \chi(S, X_1, \ldots, X_\ell)$, where χ is a formula in Γ.

The final ingredient we need is a result which links the number of quantifier alternations in an FO formula to the moves of the Ehrenfeucht-Fraïssé game. The *j-alternations k-round Ehrenfeucht-Fraïssé game* is a restriction of the standard Ehrenfeucht-Fraïssé game to at most j alternations (“switches”) of the structure where the spoiler makes his moves. As a special case of a result by Pezzoli [31], it follows that the duplicator wins the 0-alternations k-round Ehrenfeucht-Fraïssé game on $(\mathcal{A}, \mathcal{B})$ if and only if $\mathcal{A}$ and $\mathcal{B}$ agree on all universal first-order formulas of quantifier rank at most k. We are now ready to prove our inexpressibility result.

▶ **Lemma 9.** Dominating Set *is inexpressible in monadic SNP logic.*

Sketch of Proof. We use the Ajtai-Fagin game and describe a winning strategy for the duplicator for every fixed $\ell, k \in \mathbb{N}$. In Step 1, the duplicator selects a graph G which consists of $2^{2\ell} \cdot k + 1$ copies of K_2, and a set S which contains a single vertex from each copy of K_2; observe that S is a dominating set of G. In Step 2, the spoiler arbitrarily selects his subsets $U_1, \ldots, U_\ell$ of vertices of G.

Before proceeding to Step 3, we need to find a “sufficiently frequent” configuration in $(G, U_1, \ldots, U_\ell)$ for the duplicator to exploit. Let the *type* $T(v)$ of a vertex $v \in G$ be defined as $T(v) = \{i \mid v \in U_i\}$. Let a, b be vertices of G which form a K_2 such that $b \in S$. Then the *configuration* $C(a, b)$ of a, b is the tuple $(T(a), T(b))$. Since the number of distinct types is upper-bounded by 2^ℓ, the number of distinct configurations is upper-bounded by $2^{2\ell}$. By construction, there must exist some configuration which occurs at least $k + 1$ times in G; let us now fix an arbitrary such configuration (T_1, T_2).

In Step 3, the duplicator selects a graph H equipped with a set Q. The graph H consists of a copy of G and one isolated vertex p. Let f be a bijection witnessing the isomorphism from $H - p$ to G; then the duplicator selects H and also the vertex-subsets $W_1, \ldots, W_\ell$ of H as follows: (1) for each vertex $w \in H - p$, $w \in Q$ if and only if $f(w) \in S$; (2) for each vertex $w \in H - p$ and each $i \in [\ell]$, $w \in W_i$ if and only if $f(w) \in U_i$; and (3) $p \in W_i$ if and only if $i \in T_1$.

In Step 4, it suffices to prove that $(G, S, U_1, \ldots, U_\ell)$ and $(H, Q, W_1, \ldots, W_\ell)$ agree on all first-order formulas with alternation number 0 and quantifier rank at most k. This is done by giving a winning strategy for the duplicator in the 0-alternations k-round Ehrenfeucht-Fraïssé game. On a high level, if the spoiler chooses to play on G, then the duplicator can precisely copy the spoiler's moved on H. On the other hand, if the spoiler decides to play on H then the duplicator can also precisely copy all spoiler's moves on G with the exception of a move on p; there, the duplicator uses the fact that the configuration (T_1, T_2) is sufficiently frequent to find a suitable replacement for p in G. ◀

The same technique can be applied to prove the inexpressibility of other problems considered in Subsection 3.2. For some, it suffices to merely adapt the above construction, while for others, such as Linear Circuit-Sat, new constructions are required.

4 Feedback Vertex Set

In the previous section, we gave a logic fragment such that every problem that is expressible in this logic fragment is serf-reducible to 3-CNF-Sat. A natural question to ask is whether there exist NP-complete problems that are not serf-reducible to 3-CNF-Sat, under some plausible complexity-theoretic hypothesis. This question has been answered by several works. For instance, Calabro *et al.* [4] showed that, unless ETH fails, the restriction of CNF-Sat to instances in which the number of clauses is super-linear in the number of variables is not serf-reducible to 3-CNF-Sat. More unlikely complexity-theoretic consequences befall if we replace CNF-Sat restricted to instances with super-linear number of clauses with "harder" satisfiability problems (*e.g.*, general CNF-Sat or Circuit-Sat). While the aforementioned problems are all expressible in EMSO, their expressions yield super-linear measures.

We also saw in the previous section that many natural graph problems, such as c-Colorability (for any integer-constant $c > 0$), Independent Set, Vertex Cover and Dominating Set are serf-reducible to 3-CNF-Sat, which raises the question of whether there is any natural graph problem that is not serf-reducible to 3-CNF-Sat. While it is not difficult to define a graph problem that, unless ETH fails, is not serf-reducible to 3-CNF-Sat, we do not know of any natural graph problem for which the aforementioned statement can be proved. In this section, we propose Feedback Vertex Set as a possible such candidate problem. The reason we believe that Feedback Vertex Set might be such a problem is that Feedback Vertex Set implicitly embodies a Hitting Set problem [5] (or a satisfiability problem) with possibly exponentially-many cycles to hit. Whereas in CNF-Sat and in Hitting Set the sets/clauses are given explicitly (*i.e.*, are part of the input), which allows us to quantify over the set of all sets/clauses, and hence, express these problems in monadic NP, the cycles in an instance of Feedback Vertex Set are implicitly encoded in the input graph. Moreover, enumerating all the cycles in a graph may require exponential time, which surpasses the allowed time in a serf-reduction.

While we are unable to prove that Feedback Vertex Set is not serf-reducible to 3-CNF-Sat (assuming ETH does not fail), we could prove that Feedback Vertex Set is inexpressible in EMSO, which rules out the possibility of using the proposed framework in this paper to show that Feedback Vertex Set is serf-reducible to 3-CNF-Sat. We leave it as an open problem whether Feedback Vertex Set is serf reducible to 3-CNF-Sat. We also show in this section that there is a polynomial-time reduction from Feedback Vertex Set to 3-CNF-Sat that maps an instance of Feedback Vertex Set with n vertices to an equivalent instance of 3-CNF-Sat with $\mathcal{O}(n \lg n)$ variables, and define a variant of Feedback Vertex Set that is equivalent to 3-CNF-Sat under serf-reducibility.

4.1 Inexpressibility of Feedback Vertex Set in EMSO

Recall that, by Theorem 2, we could obtain a serf-reduction from Feedback Vertex Set to 3-CNF-Sat if there existed an EMSO formula $\varphi(X)$ with linear measure such that $(G, S) \models \varphi(S)$ if and only if S is a feedback vertex set in G. In this subsection, we will prove that this approach cannot work; in particular, we show that feedback vertex set is not even expressible in EMSO. Our first step lies in showing that acyclicity is inexpressible by an EMSO sentence. However, instead of using the Ajtai-Fagin game (which would require a highly technical specification of a strategy for the duplicator), our proof will rely on the classical notion of *Hanf-locality.* We refer to Libkin's book [26] for the omitted definitions.

▶ **Lemma 10.** *Acyclicity is inexpressible in EMSO.*

Sketch of Proof. Suppose for a contradiction that acyclicity is definable by an EMSO sentence $\Psi = \exists Z_1 \dots Z_\ell\ \psi$. Since ψ is a first-order sentence, it is Hanf-local. Let G be a path of length at least r. Since G is acyclic, we have $G \models \Psi$. Let $U_1, \dots, U_m$ witness this fact, that is, $(G, U_1, \dots, U_m) \models \psi$. Let a, b be vertices of distance at least $2d+2$ from each other such that $N_d^{(G,U_1,\dots,U_m)}(a)$ is isomorphic to $N_d^{(G,U_1,\dots,U_m)}(b)$. Let p be the unique endpoint of the path that is closer to b than to a, and let a' be the unique neighbor of a which is closer to p (than the other neighbor of a), and let b' be that of b. We construct a new graph G' by removing edges aa' and bb' from G and adding edges ab' and ba' into G. We have that, for every vertex c, $N_d^{(G,U_1,\dots,U_m)}(c) \approx N_d^{(G',U_1,\dots,U_m)}(c)$. Observe that G' is not acyclic. To complete the proof, we use the Hanf-locality to prove that G' also satisfies Ψ. ◀

▶ **Lemma 11.** Feedback Vertex Set *is inexpressible in EMSO logic.*

4.2 Reductions between 3-CNF-Sat and Feedback Vertex Set

We now examine the existence of polynomial-time serf-reductions between 3-CNF-Sat and Feedback Vertex Set. Based on the framework in [13], we can show that it is unlikely that 3-CNF-Sat is polynomial-time serf-reducible to Feedback Vertex Set:

▶ **Proposition 12.** Unless the polynomial-time hierarchy collapses to its third level, 3-CNF-Sat is not polynomial-time serf-reducible to Feedback Vertex Set.

While we are unable to rule out—under plausible conditions—the existence of a polynomial-time serf-reduction from Feedback Vertex Set to 3-CNF-Sat, we give a polynomial-time reduction from Feedback Vertex Set to 3-CNF-Sat at the cost of a logarithmic factor increase in the number of variables in the 3-CNF-Sat instances. This reduction relies on the following characterization of Feedback Vertex Set that we prove: A graph G has a feedback vertex set of cardinality k if and only if there is a bijection $\varphi : V(G) \longrightarrow [n]$ such that, for all $uv, uw \in E(G)$, we have

$$(\varphi(u) > k) \wedge (\varphi(v) > k) \wedge (\varphi(w) > k) \implies (\varphi(v) > \varphi(u)) \vee (\varphi(w) > \varphi(u)).$$

Using the above characterization, we can reduce Feedback Vertex Set to 3-CNF-Sat by encoding each vertex using a block of $\lg n$ Boolean variables, and adding polynomially-many 3-CNF clauses, each of logarithmic width, encoding the existence of a function φ satisfying the above property. We have:

▶ **Theorem 13.** *There is a polynomial-time many-one reduction that takes an instance* (G, k) *of* Feedback Vertex Set *and produces an equivalent instance* F *of* CNF-Sat *such that* F *has* $\mathcal{O}(n \lg n)$ *variables,* $n^{\mathcal{O}(1)}$ *clauses, and width* $\mathcal{O}(\lg n)$*, where* $n = n(G)$*.*

We now define a variant of Feedback Vertex Set, denoted Monochromatic 3-Feedback Vertex Set, that we show to be equivalent under serf-reducibility to 3-CNF-Sat. An instance of Monochromatic 3-Feedback Vertex Set consists of a graph G and a nonnegative integer k. Each edge $e \in E(G)$ is associated with a set of colors, denoted Colors(e). The question is to decide if there exists a subset $Q \subseteq V(G)$ of vertices of cardinality at most k such that, for every 3-cycle C in G satisfying $\bigcap_{e \in E(C)} \text{Colors}(e) \neq \emptyset$, C contains at least one vertex of Q. That is, Q breaks every 3-cycle in G whose edges can all be assigned the same color from their color lists. It can be easily shown that Monochromatic 3-Feedback Vertex Set is NP-complete by adapting the standard reduction from Vertex Cover to Feedback Vertex Set (the color lists of all edges are singletons and consist of the same color). By d-Monochromatic 3-Feedback Vertex Set, where $d \geq 1$, we denote the restriction of MONOCHROMATIC 3-FEEDBACK VERTEX SET to instances in which the total number of colors assigned is at most d (that is, $|\bigcup_{e \in E(G)} \text{Colors}(e)| \leq d$). We have:

▶ **Theorem 14.** *For any integer $d \geq 10$, 3-CNF-SAT and d-MONOCHROMATIC 3-FEEDBACK VERTEX SET are equivalent under serf-reductions. Therefore, d-MONOCHROMATIC 3-FEEDBACK VERTEX SET is solvable in subexponential time if and only if ETH fails.*

▶ Remark. A natural question to ask is whether serf-reducibility to 3-CNF-SAT is equivalent to the notion of self-sparsification (as in the sparsification lemma for 3-CNF-SAT): The existence of a subexponential-time self-reduction that reduces an instance of the problem to an equivalent instance whose (instance) size is linear in the designated parameter. These two notions, in general, seem to be orthogonal. On one hand, it can be shown that FEEDBACK VERTEX SET is self-sparsifiable [18, 27], but this does not seem to imply that FEEDBACK VERTEX SET is serf-reducible to 3-CNF-SAT. On the other hand, CLIQUE is serf-reducible to 3-CNF-SAT, but unless ETH fails, CLIQUE is not self-sparsifiable since this would imply that CLIQUE is solvable in subexponential time.

Abstract

We introduce and study the computational power of Oritatami, a theoretical model to explore greedy molecular folding, by which a molecule begins to fold before awaiting the end of its production. This model is inspired by a recent experimental work demonstrating the construction of shapes at the nanoscale by folding an RNA molecule during its transcription from an engineered sequence of synthetic DNA.

An important challenge of this model, also encountered in experiments, is to get a single sequence to fold into different shapes, depending on the surrounding molecules. Another big challenge is that not all parts of the sequence are meaningful for all possible inputs. Hence, to prevent them from interfering with subsequent operations in the Oritatami folding pathway we must structure the unused portions of the sequence depending on the context in which it folds.

Next, we introduce general design techniques to solve these challenges and program molecules. Our main result in this direction is an algorithm that is time linear in the sequence length that finds a rule for folding the sequence deterministically into a prescribed set of shapes, dependent on its local environment. This shows that the corresponding problem is fixed-parameter tractable, although we also prove it NP-complete in the number of possible environments.

1 Introduction

The process by which one-dimensional sequences of nucleotides or amino-acids acquire their complex three-dimensional geometries, which are key to their *function*, is a major puzzle of biology today. Understanding molecular folding will not only shed light on the origin and functions of the molecules existing in nature, it will also enable us to *control* the process

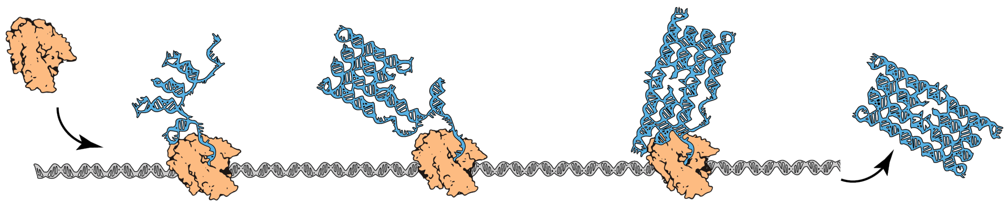

Figure 1 An RNA molecule folding over itself while being transcribed, as the experiments in [14].

more finely, and engineer artificial molecules with a wide range of uses, from performing missing functions inside living organisms, to producing precisely targeted drugs.

Biomolecular nano-engineering includes DNA self-assembly, which gave rise to an impressive number of successful experimental realizations, from arbitrary 2D shapes [23] to molecule cyclic machines [28], or counters [11]. First pioneered by Seeman [24], DNA nanotechnologies only really started to take off once a computer science model was devised by Winfree [26] to *program* molecular self assembly in a computer science way.

Since then, many models have been designed to refine different features of experiments: hierarchical self-assembly [4, 5], modeling the absence of a *seed*, kinetic tile assembly [26, 13], 3D and probabilistic tile assembly [6], among others.

The applications of DNA are limited by the high-fidelity of DNA base-pairing. The elaborate structures that researchers are able to produce with DNA are typically formed by the thermodynamically-driven assembly process of *annealing*, where many DNA strands are brought near equilibrium by heating them up to a high temperature and then cooling them down at a controlled rate, a folding process that is essentially incompatible with living cells.

By contrast, the RNA nanostrutures are designed to mimic the natural folding process, and are designed to fold under conditions that are cell-like. However, their assembly process is harder to program: intuitively, the shape depends on both the sequence and the environment, and the sequence is read *linearly*, independent from the environment. This contrasts with more classical programming models such as Turing machines, or even tile assembly, which are able to *jump* to different parts of the program depending on the input.

Another important difficulty is that even predicting the final shape of a sequence is still the center of active research, especially for proteins [29, 17, 18, 8, 21, 22, 16]

In particular, a large body of computer science literature focused on energy optimization, one of the main drivers of folding. For example, in different variants of the *hydrophobic-hydrophilic (HP) model* [9], it has been shown that the problem of predicting the most likely geometry (or *conformation*) of a sequence is NP-complete [25, 20, 2, 3, 7, 1], both in two and three dimensions, and in different variants of the model.

A few years ago, the *kinetics* of folding, which is the step-by-step dynamics of the reaction, has been demonstrated by biochemists to play a role in the final shape of molecules [15], even a *prevalent role* in the case of RNA [12]. In recent experimental results [14], researchers have even been able to *control* this mechanism to engineer their own shapes out of RNA.

This paper introduces a new model of RNA folding, intended to capture the kinetics of folding and model the experiments in [14]. In particular, it focuses on the *co-transcriptional* nature of RNA folding, which is the fact that, in real conditions, molecules fold while being transcribed (see Figure 1): in computer science terms, the folding process is a *local energy optimization*, or otherwise put, a *greedy algorithm*.

The first experimental results have used a standard benchmark: making simple shapes, such as squares (as shown for instance on Figure 2). With the new model introduced in

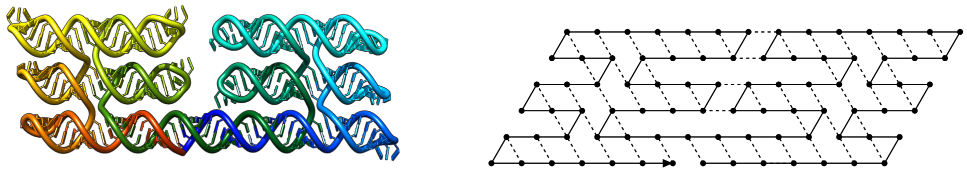

Figure 2 The design of a rectangle, co-transcriptionally folded with RNA, and the corresponding path on the triangular lattice, where each bead corresponds to two to four nucleotides.

this paper, our goal is twofold: first, explore the engineering possibilities of this mechanism, in order to make arbitrary shapes and structures. Then, the other aim of our study is to understand the complexity of sequence operations, to understand the computational processes which led to the creation of complex molecular networks.

Main contributions. In our model, called Oritatami, we consider a sequence of "beads", which are abstract basic components, standing for nucleotides or even sequences of nucleotides (also called *domains*). In Oritatami, only the latest produced beads of the molecules are allowed to move in order to adopt a more favorable configuration. The folding is driven by the respective attraction between the beads.

Our main construction is a *binary counter.* Counters are an essential component of many sophisticated constructions in biological computing, in particular in tile assembly [10, 19]. Counters are also an important benchmark in experiments [11].

▸ **Theorem 1.** *There is a fixed periodic sequence* $0, 1, \ldots, 59, 0, 1, \ldots$ *of period 60 whose rule is given in Fig. 11, which, when started from a seed encoding an integer* x *in binary with at most* $2k+1$ *bits for some* k*, folds into a structure encoding* $x+1$*,* $x+2$*,* $\ldots$*,* $2^{2k+1}-1$*, on the successive rows of the triangular grid.*

We *prove the correctness* of this construction by designing an abstract module system to handle the complexity of the base mechanism of the model, which is about as low-level as assembly code in more standard computing models.

We then show a generic construction method in this model, which we applied to automate parts of the design of the counter. Moreover, this result helps understanding the computational complexity of sequence programming. Precisely, we prove two results in this direction:

▸ **Theorem 2.** *Designing a single sequence that folds into different target shapes in a set of surrounding environments, is NP-complete in the number of environments.*

More surprisingly, it turns out that there is an algorithm to solve this problem in time *linear in the length of the sequence.* This algorithm is also practical, as we were able to use it to find sequences for our main construction:

▸ **Theorem 3.** *The sequence design problem is FPT with respect to the length* ℓ *of the sequence: there is an algorithm linear in* ℓ *(but exponential in the number of environments) to design a single sequence that folds into the target shapes in the given environments.*

2 Model and Main Results

2.1 Model

Oritatami system. Oritatami is about the folding of finite sequences of beads, each from a finite set B of *bead types*, using an attraction rule ♥, on the triangular lattice graph $\mathbb{T} = (\mathbb{Z}^2, \sim)$

where $(x,y) \sim (u,v)$ if and only if $(u,v) \in \{(x-1,y),(x+1,y),(x,y+1),(x+1,y+1),(x-1,y-1),(x,y-1)\}$.

A *conformation* c of a sequence $w \in B^*$ is a self-avoiding path of length ℓ labelled by w in $\mathbb{T}$, i.e. a path whose vertices $c_1,\dots,c_\ell$ are pairwise distinct and labelled by the letters of w. A *partial conformation* of a sequence w is a conformation of a prefix of w. For any partial conformation c of some sequence w, an *elongation* of c by k beads is a partial conformation of w of length $|c|+k$. We denote by $\mathcal{C}_w$ the set of all partial conformations of w (the index w will be omitted when the context is clear). We denote by $c^{\rhd k}$ the set of all elongations by k beads of a partial conformation c of a sequence w and by $c^{\lhd k}$ the singleton containing the prefix of length $|c|-k$ of c.

An *Oritatami system* $\mathcal{O} = (p, \heartsuit, \delta)$ is composed of (1) a (possibly infinite) *primary structure* p, which is a sequence of *beads*, of a type chosen from a finite set B, (2) an *attraction rule*, which is a symmetric relation $\heartsuit \subseteq B^2$ and (3) a parameter δ called the *delay time*.

Given an attraction rule $\heartsuit$ and a conformation c of a sequence w, we say that there is a *bond* between two adjacent positions c_i and c_j of c in $\mathbb{T}$ if $w_i \heartsuit w_j$. The *energy* of a conformation c of w, written $\mathrm{E}(c)$, is the negation of the number of bonds within c: formally, $\mathrm{E}(c) = -|\{(i,j) : c_i \sim c_j,\ j > i+1, \text{ and } w_i \heartsuit w_j\}|$.

Oritatami dynamics. A *dynamics* for a sequence w is a function $\mathcal{D} : 2^{\mathcal{C}} \to 2^{\mathcal{C}}$ such that for all subset S of partial conformations of length ℓ of w, $\mathcal{D}(S)$ is a subset of the elongations by one bead of the partial conformations in S (thus, partial conformations of length $\ell+1$).

Given an Oritatami system $\mathcal{O} = (p, \heartsuit, \delta)$ and a *seed conformation* σ of a seed sequence s of length ℓ, the set of partial conformations of the primary structure p at time t under dynamics $\mathcal{D}$ is $\mathcal{D}^t_{sp}(\{\sigma\})$, [1] i.e. the set of all elongations by t beads of the seed conformation prolongated by the primary structure according to dynamics $\mathcal{D}$.

We explore greedy folding dynamics where only the most recently transcribed beads can move, all other beads remain in place. These are controlled by integer parameter δ (in this article, $\delta \leqslant 4$). Several dynamics could model the "greedy" nature of the process. We choose the following dynamics, called the *hasty dynamics*:

The hasty dynamics does not question previous choices but chooses the energy-minimal positions for the δ last beads among all elongations of the previously adopted partial conformations. It lets the $\delta - 1$ already placed last beads where they are and abandons the extension of a conformation if no extension with the newly transcribed bead allows to reach a lowest energy conformation available for the δ last beads. Formally, $\mathcal{H}$ starts from a set of partial conformations, elongates each of them by one bead, and keeps the elongated conformations that have minimal energy among those who share the same prefix of length $|\sigma| + t - \delta$:

$$\mathcal{H}(S) = \bigcup_{\gamma \in S^{\lhd(\delta-1)}} \left(\operatorname*{arg\,min}_{c \in (S^{\rhd 1}) \cap (\gamma^{\rhd \delta})} \mathrm{E}(c) \right)$$

An Oritatami system $\mathcal{O} = (p, \heartsuit, \delta)$ is *deterministic* for dynamics $\mathcal{D}$ and seed σ of sequence s if for all $i \geqslant 1$, the position of the i-th bead of p is deterministic at time $i - 1 + \delta$, i.e. if for all $i \geqslant 1$, $|\{c_{|\sigma|+i} : c \in \mathcal{D}^{i-1+\delta}_{sp}(\{\sigma\})\}| = 1$. We say that $\mathcal{O}$ *stops* at time t with seed σ and dynamics $\mathcal{D}$ if $D^t_{sp}(\{\sigma\}) = \varnothing$ and $\mathcal{D}^z_{sp}(\{\sigma\}) \neq \varnothing$ for $z < t$. The folding process may

[1] Given two words $a, b \in B^*$, we denote by ab their concatenation.

only stop because of a geometric obstruction (no more elongation are possible because the conformation gets trapped in a closed area).

3 Folding a binary counter

3.1 General idea of the construction

Our construction works with $\delta = 4$. The counter is implemented by folding the periodic sequence of bead types $0, 1, \ldots, 58, 59, 0, 1, \ldots$ with period 60. Our construction proceeds in zig-zags as the classic implementation of a counter with a sweeping Turing machine whose head goes back and forth between the two ends of the coding part of the tape. Each pass is 3-rows thick and folds each part of the molecule into a parallelogram of size 4×3 or 6×3 except for the last and the first parts of each pass which are folded into parallelograms of size 3×6 to accomplish the U-turn downwards and start the next pass. The *zig pass*, folding three rows at a time from right to left, computes the carry propagation in the current value of the counter. The *zag pass*, folding three rows at a time from left to right, writes down the bits of the newly incremented value, and gets the folding to resume at the right-hand side of the conformation.

The molecule is semantically divided into 4 parts, called *modules*:

- Module A (beads 0–11, in blue in all figures): the First Half-Adder
- Module B (beads 12–29, in red in all figures): the Left-Turn module
- Module C (beads 30–41, in blue in all figures): the Second Half-Adder
- Module D (beads 42–59, in red in all figures): the Right-Turn module

Encoding. The current value of the counter is encoded in standard binary with the most significant bit to the left. Each bit is encoded into a specific folding of the modules A and C of the molecule in the rows corresponding to a zag pass: namely folding A0 and C0 for 0, and A1 and C1 for 1. During the zig pass, the *value of the carry* is encoded by the position of the molecule when it starts to fold Module A or C: `carry` $= 0$ if Module A or C starts to fold in the top row; `carry` $= 1$ if Module A or C starts to fold from the bottom row.

In the zig pass ($\leftarrow$), modules A and C "read" from the row above the value encoded into the folding in the row above during the previous zag-phase (or in the seed conformation for the first zig pass), and fold into a shape (called a *brick*, see Section 4) A00, A10, A01, A11 or C00, C10, C01, C11 accordingly where Axc is the brick corresponding to the case where x is the bit read in the row above and c is the carry. In the zig pass, modules B and D just propagate the carry value (0 or 1, i.e. start from top or bottom row) output by the preceding module A or C to the next.

When the zig pass reaches the leftmost part of the row on top, the beads there forces the module B to adopt the Left-turn shape which reverses the folding direction and starts the next zag pass.

In the zag pass ($\rightarrow$), modules A and C "read" the bricks above Axc or Cxc and folds into the bricks that encodes the corresponding bits, namely Ay or Cy where $y = (x + c) \mod 2$. There are no carry propagation and all the modules B and D fold into the same brick B2 or D2 in this pass.

When the molecule reaches the rightmost part of the row on top of it, the special beads there force the module D to fold into the Right-turn brick which reverses the folding direction and starts the next zig pass.

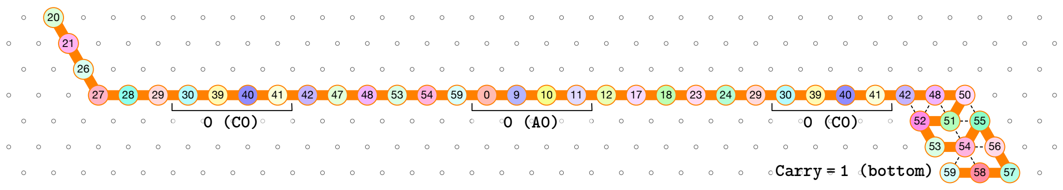

Figure 3 The seed conformation for the 3-bits counter encoding the three bits 000 as the initial value of the counter.

3.2 The first two passes of the folding

Let's run the first passes of the 3 bits counter to get acquainted with the process.

The seed conformation. is shown in Fig. 3. The seed conformation for the $(2k+1)$-bit counter is composed of $4k+3$ parts:

- The first part $20 \underset{\mathrm{SE}}{\searrow} 21 \underset{\mathrm{SE}}{\searrow} 26 \underset{\mathrm{SE}}{\searrow} 27 \underset{\mathrm{E}}{\rightarrow} 28 \underset{\mathrm{E}}{\rightarrow} 29$, made of beads from Module B, encodes a sequence that will trigger the carriage return at the end of the next zig pass.
- The central part consists in k repetitions of the same sequence of 4 patterns, plus an extra repetition of the first pattern at the end (the central part consists thus in $4k+1$ parts in total):
  - $30 \underset{\mathrm{E}}{\rightarrow} 39 \underset{\mathrm{E}}{\rightarrow} 40 \underset{\mathrm{E}}{\rightarrow} 41$ encoding a bit 0 using beads from Module C,
  - followed by $42 \underset{\mathrm{E}}{\rightarrow} 47 \underset{\mathrm{E}}{\rightarrow} 48 \underset{\mathrm{E}}{\rightarrow} 53 \underset{\mathrm{E}}{\rightarrow} 54 \underset{\mathrm{E}}{\rightarrow} 59$ encoding nothing but padding using beads from Module B,
  - followed by $0 \underset{\mathrm{E}}{\rightarrow} 9 \underset{\mathrm{E}}{\rightarrow} 10 \underset{\mathrm{E}}{\rightarrow} 11$ encoding a bit 0 using beads from Module A,
  - followed by $12 \underset{\mathrm{E}}{\rightarrow} 17 \underset{\mathrm{E}}{\rightarrow} 18 \underset{\mathrm{E}}{\rightarrow} 23 \underset{\mathrm{E}}{\rightarrow} 24 \underset{\mathrm{E}}{\rightarrow} 29$ encoding nothing but padding using beads from Module D.

  Note the symmetry by a shift of 30 of the beads values in the patterns involving Modules A and C, and Modules B and D.
- The last part $42 \underset{\mathrm{E}}{\rightarrow} 48 \underset{\mathrm{E}}{\rightarrow} 50 \underset{\mathrm{SW}}{\swarrow} 51 \underset{\mathrm{W}}{\leftarrow} 52 \underset{\mathrm{SE}}{\searrow} 53 \underset{\mathrm{E}}{\rightarrow} 54 \overset{\mathrm{NE}}{\nearrow} 55 \underset{\mathrm{SE}}{\searrow} 56 \underset{\mathrm{SE}}{\searrow} 57 \underset{\mathrm{W}}{\leftarrow} 58 \underset{\mathrm{W}}{\leftarrow} 59$, made of beads from Module D, encodes a sequence that will first initiate the next zig pass and later trigger the carriage return at the end of the next zag pass.

Note that the seed conformation ends at the bottom row of the upcoming zig pass, which encodes thus that initially the carry is 1.

The first zig pass (←). Each zig pass starts with a carry equal to 1, i.e. starts folding from the bottom row. In the first zig pass, the first module A (see Figure 4) folds into the brick A01, encoding the bit $1 = 0 + 1$ with no carry propagation, as a consequence of the carry being 1 and of reading the first bit, 0, from the seed above. Note that the folding A01 ends at the top row, encoding that the carry is now 0. The reading of the bit from the seed is accomplished by the way the module binds to the seed which shapes the module accordingly as we will see in details in Section 3.3.

Then, as illustrated in Fig. 5, the next modules B, C, D, and A fold into shapes B0, C00, D0 and A00 respectively: B0 and D0 meaning that no carry is propagated (they start and end on the top row); and C00 and A00 meaning that the (input) carry is 0 and the bit read from the seed is 0.

Finally, as illustrated in Fig. 6, the last module, B, of the zig pass binds to the 3-beads long carriage-return pattern at the leftmost part of the seed and folds into the shape BT

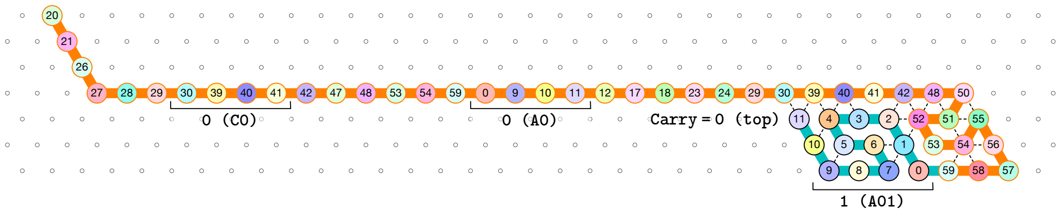

Figure 4 The folding of the first module, A: starting with a carry 1, encoded by the position of the first bead (on the bottom row), this module "reads" a 0 from the seed by binding to the seed, and folds into A01, encoding a 1 with no carry propagation, as encoded by the position of the last bead (on the top row of the module).

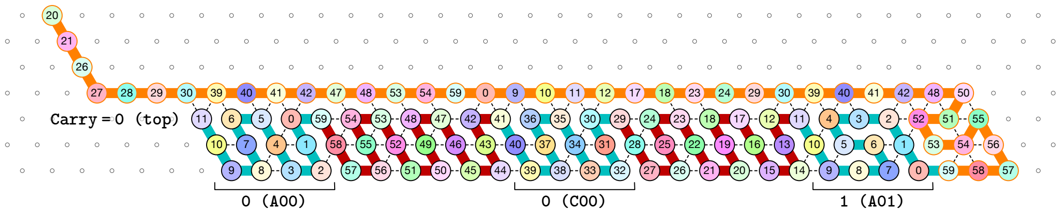

Figure 5 The folding of the central part of the first zig pass in the 3-bits counter.

conducing the molecule to go down by 6 rows, reverse direction and start the following zag pass. Note that the bottom of the shape BT contains the exact same carriage-return pattern.

The first zag pass (→). The zag pass is mostly a normalization pass as illustrated in Fig. 7–8. It progresses from left to right and computes the new value of each bit by rewriting each shape A00 and A11 as C0, C00 and C11 as A0, A10 and A01 as C1, and C10 and C10 as A0. Shapes A0 and C0 encode 0, and Shapes A1 and C1 encode 1, both to be read during the upcoming zig pass. Modules B and D just fold into the shapes B2 and D2 respectively, encoding nothing but padding.

Finally, as illustrated in Fig. 9, the last module, D, of the zag pass binds to the 3-beads long carriage-return pattern in the rightmost part of the seed and folds into the shape DT conducing the molecule to go down by 6 rows, reverse direction and start the next zig pass. Note that, as for the shape BT, the bottom of the shape DT contains the exact same carriage-return pattern.

Figure 10 shows the 3-bits counter folded upto the value $3 = 011$ in binary. One can observe the shape A11 in the second zig pass. A11 corresponds to reading a 1 with a carry 1 which propagates the carry: indeed, the folding ends at the bottom row which propagates the carry to the next module C which folds into C01 as it reads a 0 from above with carry 1. Note that shape A11 is then rewritten as C0 in the following zag pass below.

3.3 How does computation take place: modules, functions, states and environment

Each module A, B, C and D implement various "functions" that are "called" when the molecule is folded. Which function is called depends on two things:

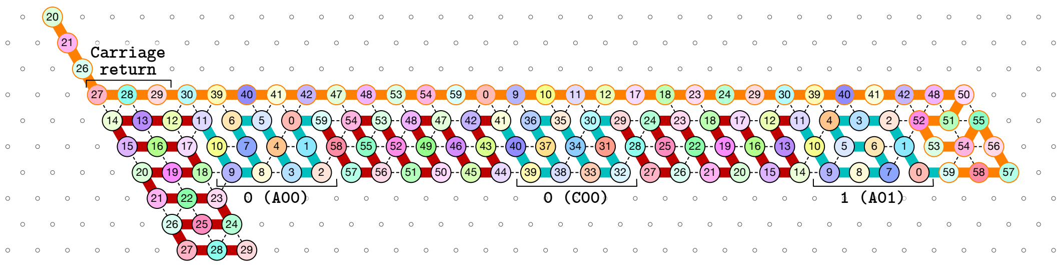

Figure 6 In our construction, the leftmost three beads of any conformation are different from the other beads the left U-turn module binds to inside the zig or zag pass: when the left U-turn module folds next to these bead types, it “triggers” the production of an actual U-turn.

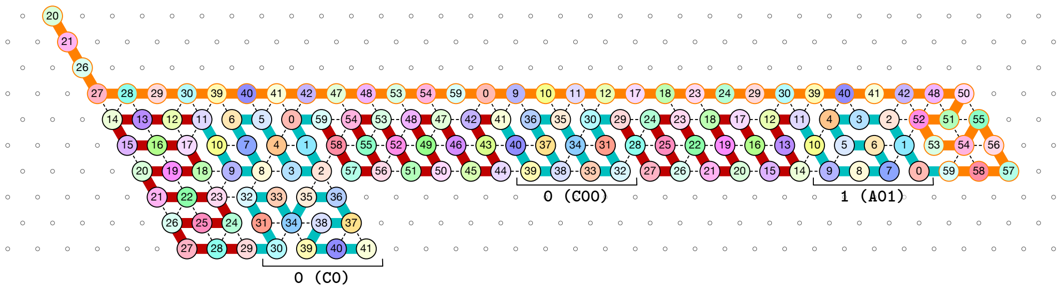

Figure 7 During the zag pass, all modules start from the bottom row, computing the value of each new bit by rewriting shapes A00 and A11 as C0, C00 and C11 as A0, A10 and A01 as C1, and C10 and C10 as A1.

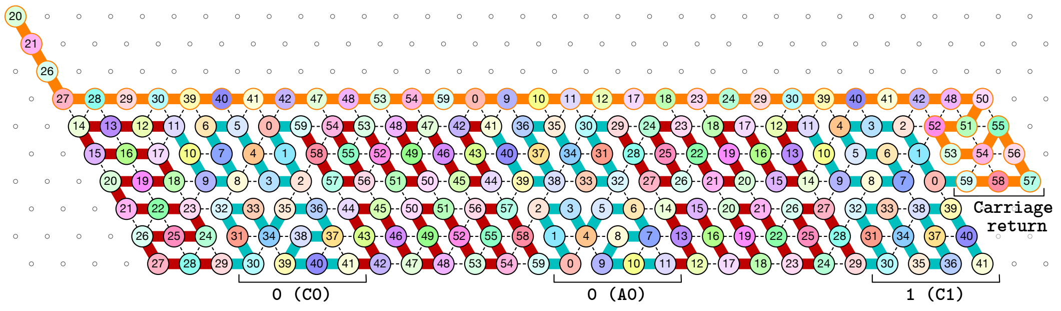

Figure 8 At the end of the first zag pass, the new value of each bit have been encoded into shapes: A0 or C0 for bits equal to 0, A1 or C1 for bit equal to 1.

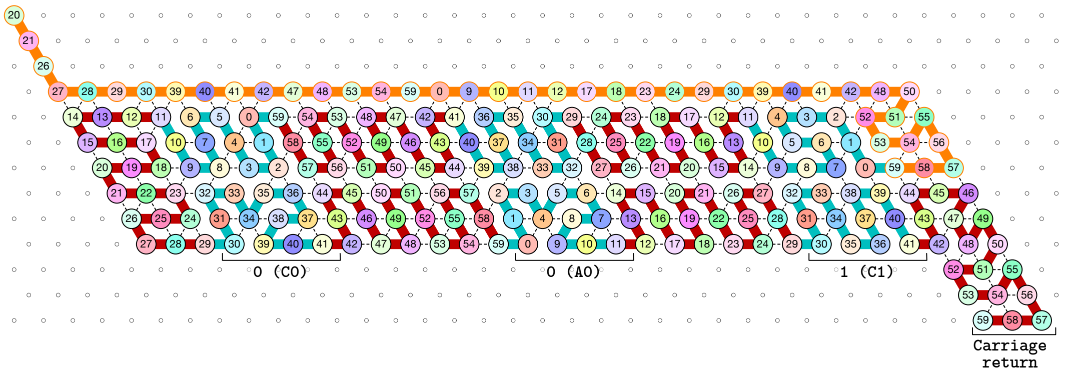

Figure 9 Finally, at the end of the first zag pass, the last module D binds to the carriage-return pattern in the seed and fold into the shape DT to accomplish the right U-turn from which the next zig pass can start.

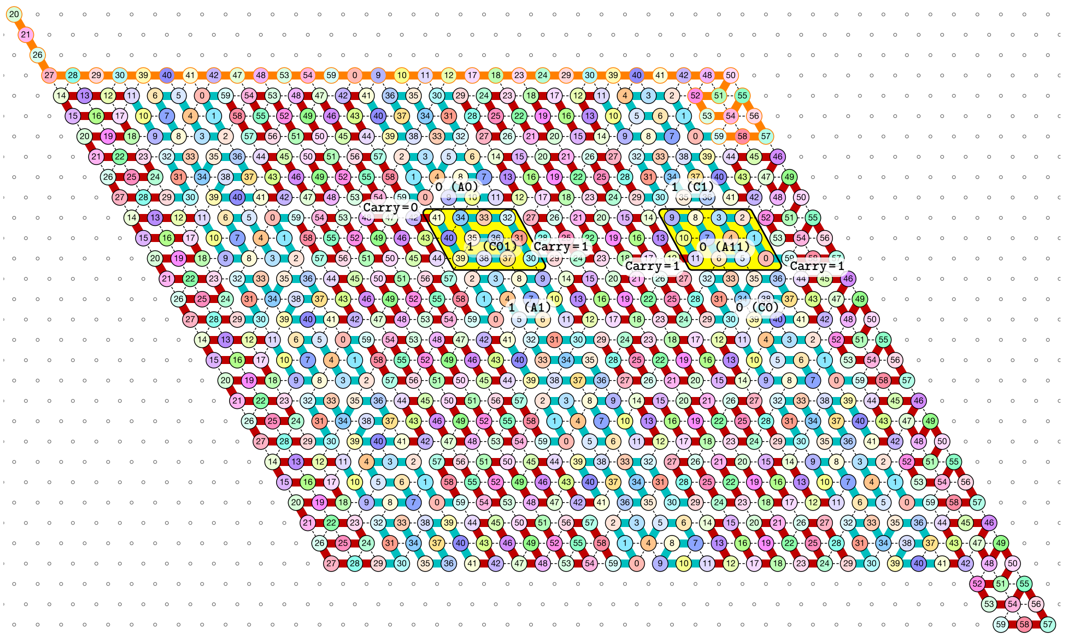

Figure 10 The folding of the 3-bits counter upto value 4 = 100 in binary. Observe the carry propagation in the second zig pass.

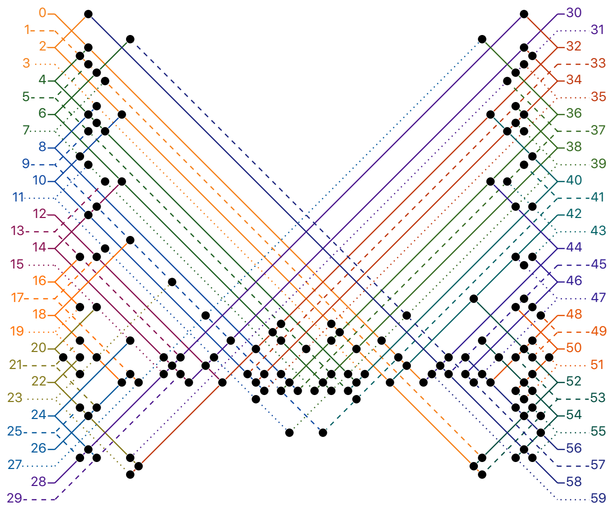

Figure 11 *The rule ♥ of the Counter Oritatami system*: in this diagram, we have b ♥ b' iff there is a bullet • at the intersection of one the two lines coming from b and from b'; for instance, we have 4 ♥ 8 but not 4 ♥ 7.

the current "state" of the molecule: here, the *state* is whether the carry is 0 or 1. As mentionned earlier this is encoded in the position of the molecule when the module starts to fold: it starts in the top row if the carry is 0; in the bottom row if the carry is 1.

the local environment of the molecule: the *environment*, i.e. the beads already placed around the current area where the folding take place, acts as the memory in the computation.

The position where the folding of a module starts, determines which beads of a given module will be exposed to and interact with the environment. Then, by creating bonds (or not) with the environment, each module will adopt a specific shape. Therefore, the possible binding schemes will be different depending of this initial position. Similarly, depending on the beads already placed in the environment, the part of the module exposed to it will adopt one form or another depending on how many bonds it can create with the environment. Adopting the language of computer science: the position at which a module starts to fold, determines which *function* of the module is called; the function then *reads the input* encoded by the beads already placed in the environment.

Fig. 12 provides a precise description on how the function of the Half-Adder Module C are implemented in the zig pass. As the zig pass goes from right to left, the figure is meant to be read from right to left. In the zig pass, Module C implements two functions: 1) Add 1 to the bit above and propagate the carry if needed, or 2) Copy the bit above unchanged. Add is called if the carry is 1 at the beginning of the folding and Copy is called if the carry is 0. The following step-by-step description of the folding explains how:

Beads 30-33 (rightmost column in Fig. 12): *if the carry is* 0 *at start,* then bead 30 is able to bind with beads 11 and 12 from the environment and depending on whether the input encodes a bit 0 or 1, bead 32 will be able to bind to bind either to 28 or to 5 and 6 respectively. *Whereas if the carry is* 1*,* then bead 30 cannot reach beads 11 and 12. Thus, these are beads 31 and 32 that will bind with beads 10 and 12 from the environment, giving to the molecule a completely different shape.

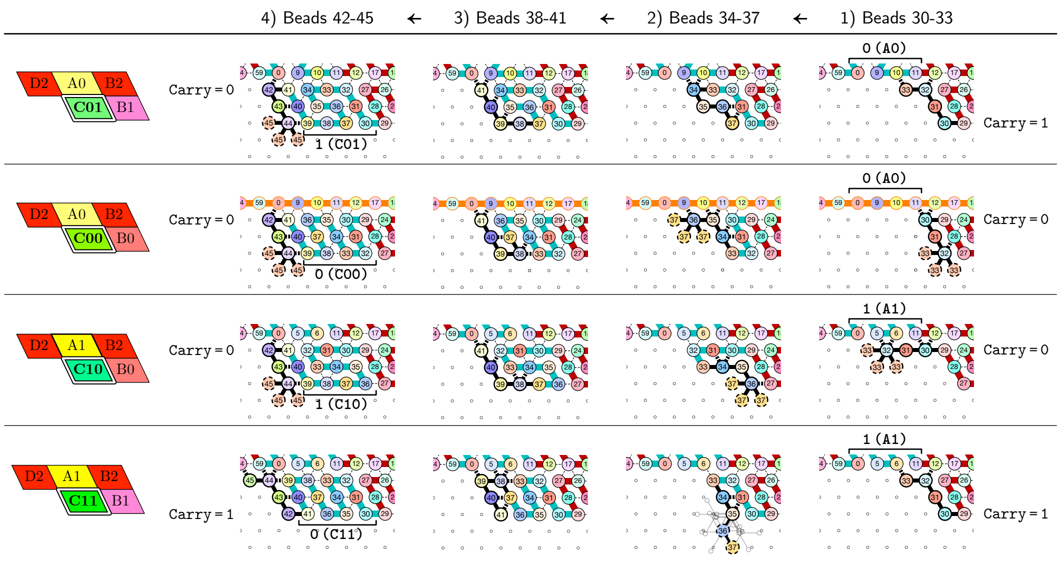

Figure 12 An illustration of how the module C applies a different function which results in different foldings according to the initial state of the molecule (carry = 0 or 1) at the beginning of the folding of the module, and to the environment (the bit 0 or 1 encoded) read above by the function. This figure is meant to be read from right to left (zig pass ←).

Beads 34-37 with carry = 0 at start: as bead 34 is attracted by both beads 30 and 31, the molecule folds upon itself similarly but with a different rotation depending on whether it had read a 0 or a 1 in the environement above: vertically if it has read a 0, horizontally if it has read a 1. Bead 36 attracted by beads 9 and 27 fixes the end of the tip in place leaving bead 37 free to move for now.

Beads 34-37 with carry = 1 at start: Bead 34 is attracted by beads 9 and 10 encoding a bit 0 above which allows beads 36 and 37 to bind with 31 as well, and but prefers to bind with 31 together with 35 otherwise. This induces two different shapes: the beginning of a "wave" pattern ( ) if the bit read above is 0; or the beginning of a "switchback" pattern ( ) if the bit read is 1.

Beads 38-41, without carry propagation (carry = 0, or carry = 1 and bit read = 0): in these three cases the folding of the beads 38-41 starts from the same position. As the environment is different for each of them, we could design the rule so that this part of the module prefers to adopt the same shape, climing along the part already folded to the top row to start the next module with a carry = 0.

Beads 38-41, with carry propagation (carry = 1 and bit read = 1): because the switchback pattern is upside down in this case, bead 37 stays low and bead 38 can firmly attach to the top with beads 5, 6 and 33, and the tip of the module folds downwards as 40 and 41 are attracted by 37. This ensures that the folding of the module ends at the bottom row, propagating the carry = 1 to the next module.

Note that the bottom rows of the four resulting foldings differ significantly: 39–38–37–30 for C01, 39–38–33–32 for C00, 39–38–37–36 for C10, and 41–36–35–30 for C11. This will allow to distinguish between them in the following zag pass to write the correct bit for the new value of the counter.

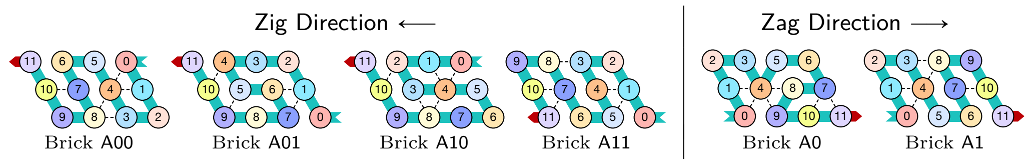

Figure 13 The six different bricks for Module A, First Half-Adder (beads 0–11).

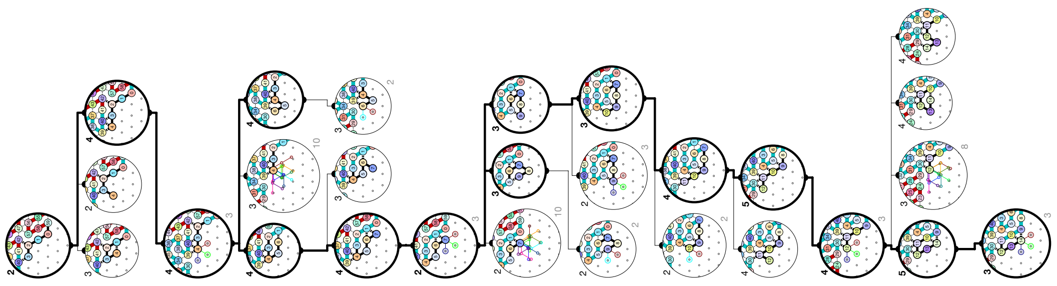

Figure 14 The folding certificate for the brick A01 in the environment:

4 Proof Sketch of Theorem 1

We call *bricks* the various conformations each module will adopt in the final folding, as they are the bricks upon which the whole folding is built. Designing the bricks is one of the biggest challenges when programming Oritatami. There are six bricks for Modules A and C: Axc and Cxc in the zig pass where $x, c \in \{0,1\}$ are the bit read from the brick above (Ax or Cx) and the (input) carry from the preceding module (Bc or Dc); and Ay and Cy in the zag pass where y is the bit written: namely $y = x + c \bmod 2$ if the brick above is Axc or Cxc. There are four bricks for Modules B and D: Bc' and Dc' in the zig pass where $c' \in \{0,1\}$ is the carry output by the preceding brick Cxc or Axc, namely $c' = x \wedge c$; B2 and D2 in the zag pass. Figure 13 lists the six bricks for Module A.

The proof works in two stages. First, we describe the final target folding and show that it implements correctly a binary counter: i.e. that the bricks implement correctly the relationships between the y, x, c and c' described above. Second, we show that indeed, each module folds into the expected brick in each given environment. For that matter, we produce a *folding certificate*, which shows for each step all the possible extension of the current conformation together with the number of bonds created (the number in the north-east corner), grouping together several extensions when they share a common path (the number of paths groupes are in the south-east corner). Figure 14 displays the folding certificate for Brick A01 surrounded by the bricks B2, C0, D2 and D1.

5 Rule design is NP-hard and FPT

Once we have agreed on the desired conformations in our construction, an important issue is to find an attraction rule such that a primary structure folds into its correct functions. The *rule design problem* consists in: given a delay time δ, a list of $n > 0$ seeds $\sigma_1, \sigma_2, \ldots, \sigma_n$, and a list of n conformations $c_1, c_2, \ldots, c_n$ of the same length ℓ, output an attraction rule ♥ such that for all $i \in \{1, 2, \ldots, n\}$, Oritatami system $\mathcal{O}_i = (s, \sigma_i, ♥, \delta)$ deterministically folds into conformation c_i, where $s = \langle 0, 1, \ldots, \ell - 1\rangle$.

Theorem 2 (proof omitted) shows by a reduction from 3-SAT that this problem is NP-hard. However, Theorem 3 (proof omitted) shows using the locality of the bindings that it is fixed-parameter tractable with respect to the length of the sequence ℓ. Then, as n and δ are usually small for the designs we considered, we could use this algorithm to help us designing an attraction rule compatible with our brick designs.

6 Perspectives

The purpose of our new model is not to be entirely accurate with respect to phenomena observed in nature, but instead to start developing an intuition about the *kind of problem* that need to be solved in order to engineer RNA shapes, and later, even proteins.

In the future, a number of extensions of this model seem natural. In particular, extending it with a more realistic notion of *thermodynamics and molecular agitation*. Using existing works in molecular dynamics [27], would allow to explore stochastic optimization processes.

Abstract

The simplest example of an infinite Burnside group arises in the class of automaton groups. However there is no known example of such a group generated by a reversible Mealy automaton. It has been proved that, for a connected automaton of size at most 3, or when the automaton is not bireversible, the generated group cannot be Burnside infinite. In this paper, we extend these results to automata with bigger stateset, proving that, if a connected reversible automaton has a prime number of states, it cannot generate an infinite Burnside group.

1 Mealy automata and the General Burnside problem

The Burnside problem is a famous, long-standing question in group theory. In 1902, Burnside asked if a *finitely generated* group whose all elements have finite order –henceforth called a *Burnside group*– is necessarily finite [3].

The question stayed open until Golod and Shafarevitch exhibit in 1964 an infinite group satisfying Burnside's conditions [8, 9], hence solving the general Burnside problem. In the early 60's, Glushkov suggested using automata to attack the Burnside problem [6]. Later, Aleshin [2] in 1972 and then Grigorchuk [10] in 1980 gave simple examples of automata generating infinite Burnside groups. Over the years, automaton groups have been successfully used to solve several other group theoretical problems and conjectures such as Atiyah, Day, Gromov or Milnor problems; the underlying automaton structure can indeed be used to better understand the generated group.

It is remarkable that every known examples of infinite Burnside automaton groups are generated by non reversible Mealy automata, that is, Mealy automata where the input letters do not all act like permutations on the stateset. We conjecture that it is in fact impossible for a reversible Mealy automaton to generate an infinite Burnside group. Our past work with several co-authors has already given some partial results to this end. In [7] it is proven that non bireversible Mealy automata cannot generate Burnside groups. For the whole class of reversible automata, it has been proved in [12] that 2-state reversible Mealy automata cannot generate infinite Burnside groups. This result has later been extended in [13] to 3-state

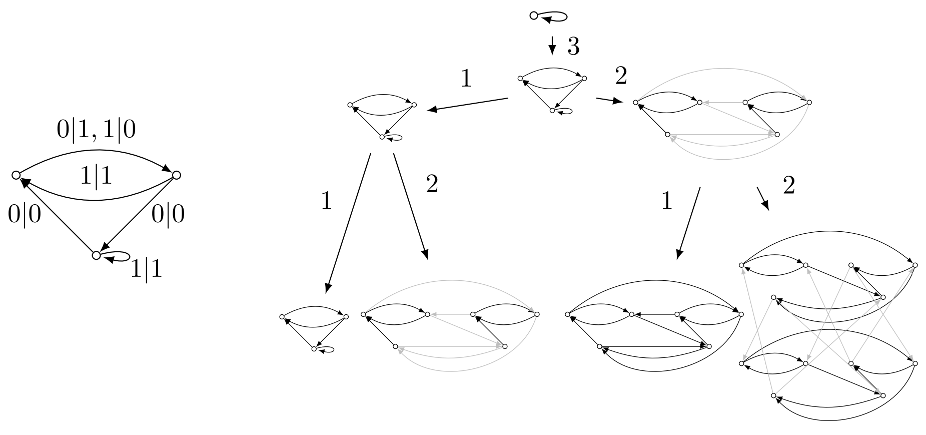

Figure 1 The Bellaterra automaton $\mathcal{B}$ and four levels of the orbit tree $\mathfrak{t}(\mathcal{B})$.

connected reversible automata. In this paper we generalize these results to any connected revertible automaton with a prime number of states:

▶ **Theorem.** *A connected invertible-reversible Mealy automaton of prime size cannot generate an infinite Burnside group.*

Our proof is inspired by the former work in the 3-state case of the second author with Picantin and Savchuk [13]. However the extension from 3 to any prime p required the introduction of a new machinery. This constitutes the main part of our paper, see Section 5.

The paper is organized as follows. In Section 2 we set up notations and recall useful facts on Mealy automata, automaton groups, and rooted trees. Then in Section 3 we link some characteristics of an automaton group to the connected components of the powers of the generating automaton. In Section 4 we introduce a tool developed in [13], the labeled orbit tree, that is used in Section 5 to define our main tool, the *jungle tree*. In this former section we also present some constructions and properties connected to this jungle tree. At last, in Section 6, we gather our information and prove our main result.

2 Basic notions

2.1 Groups generated by Mealy automata

We first recall the formal definition of an automaton. A *(finite, deterministic, and complete) automaton* is a triple $\big(Q, \Sigma, \delta = (\delta_i \colon Q \to Q)_{i\in\Sigma}\big)$, where the *stateset* Q and the *alphabet* Σ are non-empty finite sets, and the δ_i are functions.

A *Mealy automaton* is a quadruple $\mathcal{A} = (Q, \Sigma, \delta, \rho)$, where both (Q, Σ, δ) and (Σ, Q, ρ) are automata. In other terms, it is a complete, deterministic, letter-to-letter transducer with the same input and output alphabet. Its *size* $\#\mathcal{A}$ is the cardinality of its stateset.

The graphical representation of a Mealy automaton is standard, see Figure 1 left.

A Mealy automaton $(Q, \Sigma, \delta, \rho)$ is *invertible* if the functions ρ_x are permutations of Σ and *reversible* if the functions δ_i are permutations of Q.

In a Mealy automaton $\mathcal{A} = (Q, \Sigma, \delta, \rho)$, the sets Q and Σ play dual roles. So we may consider the *dual (Mealy) automaton* defined by $\mathfrak{d}(\mathcal{A}) = (\Sigma, Q, \rho, \delta)$. Obviously, a Mealy automaton is reversible if and only if its dual is invertible.

An invertible Mealy automaton is *bireversible* if it is reversible (i.e. the input letters of the transitions act like permutations on the stateset) and the output letters of the transitions act like permutations on the stateset.

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a Mealy automaton. Each state $x \in Q$ defines a mapping from Σ^* into itself recursively defined by:

$$\forall i \in \Sigma,\ \forall \mathbf{s} \in \Sigma^*, \qquad \rho_x(i\mathbf{s}) = \rho_x(i)\rho_{\delta_i(x)}(\mathbf{s})\ .$$

The mapping ρ_x for each $x \in Q$ is length-preserving and prefix-preserving: it is the function *induced* by x. For $\mathbf{x} = x_1 \cdots x_n \in Q^n$ with $n > 0$, set $\rho_{\mathbf{x}} : \Sigma^* \to \Sigma^*, \rho_{\mathbf{x}} = \rho_{x_n} \circ \cdots \circ \rho_{x_1}$.

Denote dually by $\delta_i : Q^* \to Q^*, i \in \Sigma$, the functions induced by the states of $\mathfrak{d}(\mathcal{A})$. For $\mathbf{s} = s_1 \cdots s_n \in \Sigma^n$ with $n > 0$, set $\delta_{\mathbf{s}} : Q^* \to Q^*,\ \delta_{\mathbf{s}} = \delta_{s_n} \circ \cdots \circ \delta_{s_1}$.

The semigroup of mappings from Σ^* to Σ^* generated by $\{\rho_x, x \in Q\}$ is called the *semigroup generated by* $\mathcal{A}$ and is denoted by $\langle \mathcal{A} \rangle_+$. When $\mathcal{A}$ is invertible, the functions induced by its states are permutations on words of the same length and thus we may consider the group of mappings from Σ^* to Σ^* generated by $\{\rho_x, x \in Q\}$. This group is called the *group generated by* $\mathcal{A}$ and is denoted by $\langle \mathcal{A} \rangle$.

2.2 Terminology on trees

Throughout this paper, we will use different sorts of labeled trees. Here we set up some common terminology for all of them.

All our trees are rooted, *i.e.* with a selected vertex called the *root*. We visualize the trees traditionally as growing down from the root. A *path* is a (possibly infinite) sequence of adjacent edges without backtracking from top to bottom. A path is *initial* if it starts at the root of the tree. A *branch* is an infinite initial path. The lead-off vertex of a non-empty path $\mathbf{e}$ is denoted by $\top(\mathbf{e})$ and its terminal vertex by $\bot(\mathbf{e})$ whenever the path is finite.

The *level of a vertex* is its distance to the root and the *level of an edge* or *a path* is the level of its initial vertex.

If the edges of a rooted tree are labeled by elements of some finite set, the *label* of a (possibly infinite) path is the ordered sequence of labels of its edges.

Extending the notions of children, parents and descendent to the edges, we will say that an edge f is the *child* of an edge e if $\bot(e) = \top(f)$ (*parent* being the converse notion, and *descendent* the transitive closure).

All along this article we will follow walks on some trees. A *walk* is just a path in a tree, which is build gradually. In particular if $\mathbf{e}$ is a finite path (or can identify one), to say that it can be followed by f in some tree means that $\mathbf{e}f$ is (or identifies) also a path in that tree.

3 Connected components of the powers of an automaton

In this section we detail the basic properties of the connected components of the powers of a reversible Mealy automaton, as it has been done in [13]. The link between these components is central in our construction.

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a reversible Mealy automaton.

By reversibility, all the connected components of its underlying graph are strongly connected.

Consider the powers of $\mathcal{A}$: for $n > 0$, its *n-th power* $\mathcal{A}^n$ is the Mealy automaton

$$\mathcal{A}^n = \left(Q^n, \Sigma, (\delta_i : Q^n \to Q^n)_{i \in \Sigma}, (\rho_{\mathbf{x}} : \Sigma \to \Sigma)_{\mathbf{x} \in Q^n} \right)\ .$$

By convention, $\mathcal{A}^0$ is the trivial automaton on the alphabet Σ.

As $\mathcal{A}$ is reversible, so are its powers and the connected components of $\mathcal{A}^n$ coincide with the orbits of the action of $\langle \mathfrak{d}(\mathcal{A}) \rangle$ on Q^n.

Since $\mathcal{A}$ is reversible, there is a very particular connection between the connected components of $\mathcal{A}^n$ and those of $\mathcal{A}^{n+1}$ as highlighted in [12]. More precisely, take a connected component $\mathcal{C}$ of some $\mathcal{A}^n$, and let $\mathbf{u} \in Q^n$ (also written $|\mathbf{u}| = n$) be a state of $\mathcal{C}$. Take also $x \in Q$ a state of $\mathcal{A}$, and let $\mathcal{D}$ be the connected component of $\mathcal{A}^{n+1}$ containing the state $\mathbf{u}x$. Then, for any state $\mathbf{v}$ of $\mathcal{C}$, there exists a state of $\mathcal{D}$ prefixed with $\mathbf{v}$:

$$\exists \mathbf{s} \in \Sigma^* \mid \delta_{\mathbf{s}}(\mathbf{u}) = \mathbf{v} \quad \text{and so} \quad \delta_{\mathbf{s}}(\mathbf{u}x) = \mathbf{v}\delta_{\rho_{\mathbf{u}}(\mathbf{s})}(x) \ .$$

Furthermore, if $\mathbf{u}y$ is a state of $\mathcal{D}$, for some state $y \in Q$ different from x, then $\delta_{\mathbf{s}}(\mathbf{u}x)$ and $\delta_{\mathbf{s}}(\mathbf{u}y)$ are two different states of $\mathcal{D}$ prefixed with $\mathbf{v}$, because of the reversibility of $\mathcal{A}^{n+1}$: the transition function $\delta_{\rho_{\mathbf{u}}(\mathbf{s})}$ is a permutation. Hence $\mathcal{D}$ can be seen as consisting of several copies of $\mathcal{C}$ and $\#\mathcal{C}$ divides $\#\mathcal{D}$. They have the same size if and only if, for each state $\mathbf{u}$ of $\mathcal{C}$ and any different states $x, y \in Q$, $\mathbf{u}x$ and $\mathbf{u}y$ cannot simultaneously lie in $\mathcal{D}$.

The connected components of the powers of a Mealy automaton and the finiteness of the generated group or of a monogenic subgroup are closely related, as shown in the following propositions (obtained independently in [13, 4]).

▶ **Proposition 1.** *A reversible Mealy automaton generates a finite group if and only if the connected components of its powers have bounded size.*

▶ **Proposition 2.** *Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be an invertible-reversible Mealy automaton and let $\mathbf{u} \in Q^+$ be a non-empty word. The following conditions are equivalent:*

(i) *$\rho_{\mathbf{u}}$ has finite order,*

(ii) *the sizes of the connected components of $(\mathbf{u}^n)_{n\in\mathbb{N}}$ are bounded,*

(iii) *there exists a word $\mathbf{v}$ such that the sizes of the connected components of $(\mathbf{v}\mathbf{u}^n)_{n\in\mathbb{N}}$ are bounded,*

(iv) *for any word $\mathbf{v}$, the sizes of the connected components of $(\mathbf{v}\mathbf{u}^n)_{n\in\mathbb{N}}$ are bounded.*

4 The Labeled Orbit Tree and the Order Problem

Most of the notions of this section have been introduced in [13]. We refer the reader to this reference for the proofs of the results in this section.

We build a tree capturing the links between the connected components of consecutive powers of a reversible Mealy automaton. See an example in Figure 1. As recalled at the end of this section, the existence of elements of infinite order in the semigroup generated by an invertible-reversible automaton is closely related to some path property of this tree.

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a reversible Mealy automaton. Consider the tree with vertices the connected components of the powers of $\mathcal{A}$, and the incidence relation built by adding an element of Q: for any $n \geq 0$, the connected component of $\mathbf{u} \in Q^n$ is linked to the connected component(s) of $\mathbf{u}x$, for any $x \in Q$. This tree is called the *orbit tree* of $\mathfrak{d}(\mathcal{A})$ [5, 11]. It can be seen as the quotient of the tree Q^* under the action of the group $\langle \mathfrak{d}(\mathcal{A}) \rangle$.

We label any edge $\mathcal{C} \to \mathcal{D}$ of the orbit tree by the ratio $\frac{\#\mathcal{D}}{\#\mathcal{C}}$, which is always an integer (less than or equal to $\#\mathcal{A}$) by the reversibility of $\mathcal{A}$. We call this labeled tree the *labeled orbit tree* of $\mathfrak{d}(\mathcal{A})$ [13]. We denote by $\mathfrak{t}(\mathcal{A})$ the labeled orbit tree of $\mathfrak{d}(\mathcal{A})$. Note that for each vertex of $\mathfrak{t}(\mathcal{A})$, the sum of the labels of all edges going down from this vertex always equals to $\#Q$, the size of $\mathcal{A}$.

Each vertex of $\mathfrak{t}(\mathcal{A})$ is labeled by a connected automaton with stateset in Q^n, where n is the level of this vertex in the tree. By a minor abuse, we can consider that each vertex is labeled by a finite language in Q^n, or even by a word in Q^n.

Let $\mathbf{u}$ be a (possibly infinite) word over Q. The *path of* $\mathbf{u}$ in the orbit tree $\mathfrak{t}(\mathcal{A})$ is the unique initial path going from the root through the connected components of the prefixes of $\mathbf{u}$; $\mathbf{u}$ can be called *a representative* of this initial path (we can say equivalently that this path is *represented* by $\mathbf{u}$ or that the word $\mathbf{u}$ *represents* the path).

▶ **Definition 3.** Let $\mathcal{A}$ be a reversible Mealy automaton and $\mathfrak{s}$ be a subtree of $\mathfrak{t}(\mathcal{A})$. An $\mathfrak{s}$-*word* is a word in $Q^* \cup Q^\infty$ representing an initial path of $\mathfrak{s}$. A *cyclic* $\mathfrak{s}$-*word* is a word in Q^* whose all powers are $\mathfrak{s}$-words (equivalently, it is an $\mathfrak{s}$-word viewed as a cyclic word).

The structure of an orbit tree is not arbitrary and it is possible to identify some similarities inside this tree.

▶ **Definition 4.** Let e and f be two edges in the orbit tree $\mathfrak{t}(\mathcal{A})$. We say that e *is liftable to* f if each word of $\bot(e)$ admits some word of $\bot(f)$ as a suffix.

Consider $\mathbf{u}$ in $\top(e)$ and its suffix $\mathbf{v}$ in $\top(f)$: any state $x \in Q$ such that $\mathbf{u}x \in \bot(e)$ satisfies $\mathbf{v}x \in \bot(f)$. Informally, "e liftable to f" means that what can happen after $\top(e)$ by following e can also happen after $\top(f)$ by following f. This condition is equivalent to a weaker one:

▶ **Lemma 5.** *Let $\mathcal{A}$ be a reversible Mealy automaton, and let e and f be two edges in the orbit tree $\mathfrak{t}(\mathcal{A})$. If there exists a word of $\bot(e)$ which admits a word of $\bot(f)$ as suffix, then e is liftable to f.*

Obviously if e is liftable to f, then f is closer to the root of the orbit tree. The fact that an edge is liftable to another one reflects a deeper relation stated below. The following lemma is one of the key observations.

▶ **Lemma 6.** *Let e and f be two edges in the orbit tree $\mathfrak{t}(\mathcal{A})$. If e is liftable to f, then the label of e is less than or equal to the label of f.*

The notions of children of an edge and of being liftable to it are not linked, but it is interesting to consider their intersection.

▶ **Definition 7.** Let e and f be two edges in an orbit tree: e is a *legitimate child* of f if f is its parent and e is liftable to f.

The notion of liftability can be generalized to paths:

▶ **Definition 8.** Let $\mathbf{e} = (e_i)_{i\in I}$ and $\mathbf{f} = (f_i)_{i\in I}$ be two paths of the same (possibly infinite) length in the orbit tree $\mathfrak{t}(\mathcal{A})$. The path $\mathbf{e}$ *is liftable to* the path $\mathbf{f}$ if, for any $i \in I$, the edge e_i is liftable to the edge f_i.

▶ **Definition 9.** Let $\mathcal{A}$ be a bireversible Mealy automaton and $\mathfrak{s}$ be a (possibly infinite) path or subtree of $\mathfrak{t}(\mathcal{A})$. For $k > 0$, $\mathfrak{s}$ is k-*self-liftable* whenever any path in $\mathfrak{s}$ starting at level $i + k$ is liftable to a path in $\mathfrak{s}$ starting at level i, for any $i \geq 0$. A path or a subtree is *self-liftable* if it is k-self-liftable for some $k > 0$.

The path represented by x^ω, for some state x, is an example of an infinite initial 1-self-liftable path.

▶ **Lemma 10.** *Let* $\mathbf{e}$ *be a non-empty finite initial* 1*-self-liftable path of some orbit tree* $\mathfrak{t}(\mathcal{A})$*, with last edge* e*. The edge* e *has at least one legitimate child. The sum of the labels of the legitimate children of* e *is equal to the label of* e*.*

Proof. Denote by k the label of e. Let $\mathbf{u}$ be some state in $\top(e)$ and x some state of $\mathcal{A}$ such that $\mathbf{u}x$ is a state of $\bot(e)$ —this is possible by the definition of an orbit tree. We decompose $\mathbf{u}$ in its first letter and some suffix: $\mathbf{u} = z\mathbf{v}$. As $\mathbf{e}$ is a 1-self-liftable path and $z\mathbf{v}x$ is a state in $\bot(\mathbf{e}) = \bot(e)$, we know that $\mathbf{v}x$ is a state in $\top(e)$. Hence by the construction of a label orbit tree, there exist exactly k states $(y_i)_{1\leq i\leq k}$ such that $(\mathbf{v}xy_i)_i$ are states of $\bot(e)$. So the connected components of the $(z\mathbf{v}xy_i)_i$ label legitimate children of e. Clearly e cannot have another legitimate child. ◀

We recall here a characterization of the existence of elements of infinite order in the semigroup generated by a reversible Mealy automaton $\mathcal{A}$ in terms of path properties of the associated orbit tree $\mathfrak{t}(\mathcal{A})$ [13].

▶ **Definition 11.** Any branch labeled by a word not suffixed by 1^ω is called *active.*

▶ **Theorem 12.** *[13] The semigroup generated by an invertible-reversible automaton* $\mathcal{A}$ *admits elements of infinite order if and only if the orbit tree* $\mathfrak{t}(\mathcal{A})$ *admits an active self-liftable branch.*

5 Jungle Trees

Our main result being known for non bireversible automata [7], we focus on the bireversible case. All the tools introduced in this section are new. They are used to get rid of the particularity of the stateset of size 3 in [13].

Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a connected bireversible Mealy automaton with no active self-liftable branch. From Theorem 12, all the elements of the semigroup $\langle\mathcal{A}\rangle_+$ have finite order. In this section we introduce the tools to prove that such an automaton of prime size generates a finite group (Theorem 32).

5.1 Jungle trees and stems

We focus on some particular subtrees of $\mathfrak{t}(\mathcal{A})$:

▶ **Definition 13.** Let $\mathbf{e}$ be a finite initial 1-self-liftable path such that:
- $\bot(\mathbf{e})$ has at least two legitimate children;
- every legitimate child of $\bot(\mathbf{e})$ has label 1.

The *jungle tree* $\mathfrak{j}(\mathbf{e})$ of $\mathbf{e}$ is the subtree of $\mathfrak{t}(\mathcal{A})$ build as follows:
- it contains the path $\mathbf{e}$ — its *trunk*;
- it contains the regular tree rooted by $\bot(\mathbf{e})$, and formed by all the edges which are descendant of $\bot(\mathbf{e})$ and liftable to the lowest (*i.e.* the last) edge of $\mathbf{e}$.

The *arity* of this jungle tree is the number of legitimate children of $\bot(\mathbf{e})$. Since every legitimate child has label 1, it is also the label of the last edge of $\mathbf{e}$.

Words in $\bot(\mathbf{e})$ are called *stems.* They have all the same length which is the length of the trunk of $\mathfrak{j}(\mathbf{e})$.

A tree is a *jungle tree* if it is the jungle tree of some finite initial 1-self-liftable path. An example of such a tree is depicted in Figure 3.

Graphically, a jungle tree starts with a linear part whose labels decrease (its trunk) and eventually ends as a regular tree with all labels 1. Any jungle tree is 1-self-liftable.

Note that: (i) there exists at least one jungle tree, from Lemma 10 and the hypothesis that $\mathcal{A}$ has no active self-liftable branch; (ii) there are finitely many jungle trees.

From now on, $\mathfrak{j}$ **denotes a jungle tree of** $\mathcal{A}$**, whose trunk has length** n**.**

As shown below, any cyclic $\mathfrak{j}$-words has finite order.

▶ **Remark 14.** *If* $\mathbf{uv}$ *is a* $\mathfrak{j}$*-word, with* $|\mathbf{v}| \geq n$*, what can follow* $\mathbf{uv}$ *in* $\mathfrak{j}$ *is independent from* $\mathbf{u}$*. In particular, if* $\mathbf{vw}$ *is also a* $\mathfrak{j}$*-word, then so is* $\mathbf{uvw}$*.*

The existence of cyclic $\mathfrak{j}$-words is ensured by the simple fact that any $\mathfrak{j}$-word of length $n \times (1 + \#Q^n)$ admits at least two identical factors of length n, and hence has a cyclic $\mathfrak{j}$-word as a factor by Remark 14.

▶ **Proposition 15.** *Every cyclic* $\mathfrak{j}$*-word induces an action of finite order, bounded by a uniform constant depending on* $\mathfrak{j}$*.*

Proof. Let $\mathbf{u}$ be a cyclic $\mathfrak{j}$-word, then, for any integer $k > n$, $\mathbf{u}^k$ is a $\mathfrak{j}$-word. By the definition of a jungle tree, the label of the path of $\mathbf{u}^\omega$ is ultimately 1 and, by Proposition 1, the action induced by $\mathbf{u}$ has finite order, bounded by a constant which depends on the connected component at the end of the trunk of $\mathfrak{j}$. ◀

Because of the self-liftability of $\mathfrak{j}$, any factor of a $\mathfrak{j}$-word is itself a $\mathfrak{j}$-word. Hence any factor of length n of a $\mathfrak{j}$-word is a stem. And by the construction of $\mathfrak{j}$, the end of its trunk has only one vertex whose label is hence a connected component, and all the stems are states of that same connected component.

▶ **Definition 16.** Let $\mathfrak{j}$ be a jungle tree of trunk of length n. A *liana covering up* $\mathfrak{j}$ is a language of $\mathfrak{j}$-words, of the form $\mathbf{w}L_\mathbf{w}$, where $\mathbf{w} \in Q^n$ is a stem, and $L_\mathbf{w} \subseteq Q^* \cup Q^\infty$ is a prefix-preserving language which, seen as a tree, is regular of the same arity than $\mathfrak{j}$.

Each vertex of $\mathfrak{j}$ has exactly one representative in $\mathbf{w}L_\mathbf{w}$. For each stem $\mathbf{w}$ there is exactly one suitable $L_\mathbf{w}$.

▶ **Remark 17.** *Let* $\mathbf{w}L_\mathbf{w}$ *be a liana covering up a jungle tree* $\mathfrak{j}$ *and* $\mathbf{uv}$ *be a finite* $\mathfrak{j}$*-word such that* $|\mathbf{v}| = n$*: if* $L_\mathbf{v}$ *is the greatest language such that* $\mathbf{uv}L_\mathbf{v} \subseteq \mathbf{w}L_\mathbf{w}$*, then* $\mathbf{v}L_\mathbf{v}$ *is also a liana covering up* $\mathfrak{j}$*.*

In what follows, we try to better understand the stucture of jungle trees and lianas. Let $S = \mathbf{s}L_\mathbf{s}$ be a liana covering up $\mathfrak{j}$ ($\mathbf{s} \in Q^n$). Our goal is to prove the following result:

▶ **Theorem 18.** *Let* $\mathbf{u}$ *be a factor in* S*. Then* $\mathbf{u}$ *has the following property:*

If $\mathbf{uv} \in Q^*$ *is a factor in* S*, then* $\mathbf{u}$ *exists further in* S*.* (**Ubiquity**)

More formally: if $\mathbf{tuv} \in S$*, there exists* $\mathbf{w} \in Q^*$ *such that* $\mathbf{tuvwu} \in S$*.*

The graphical sense of this theorem is that if you are walking on a $\mathfrak{j}$-word and you have already seen some factor, you can find eventually this same factor.

Proof. First, remember that if $\mathbf{u}$ is a stem (*i.e.* $\mathbf{u}$ is a factor in S of length n), what can follow $\mathbf{u}$ (in S) does not depend either of the choice of the liana (as long as you are in a liana covering up the same jungle tree), or of the location of $\mathbf{u}$ in this liana. Hence it is sufficient to prove Theorem 18 for $|\mathbf{u}| = n$.

We start by proving that there is at least one stem $\mathbf{u}_0$ with Property (**Ubiquity**). To obtain this word, we travel along $S = \mathbf{s}L_\mathbf{s}$ in the following way, starting with $\mathbf{u}_0 = \mathbf{s}$:

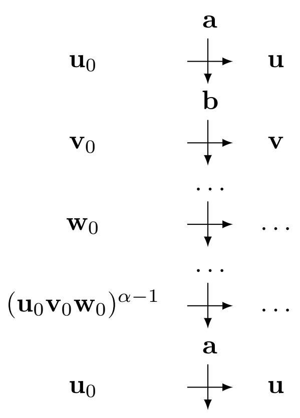

Figure 2 Extension of Property (**Ubiquity**) from $\mathbf{u}_0$ to $\mathbf{u}$.

- if $\mathbf{u}_0$ answers to the question, our journey is over;
- otherwise, at the end of $\mathbf{u}_0$ we follow some finite path such that $\mathbf{u}_0$ does not exist anymore after this path; then we replace $\mathbf{u}_0$ by the next word of length n in S, and back to the previous step.

Since S is infinite but has a finite arity and a finite number of factors of length n, the previous algorithm ends returning a stem $\mathbf{u}_0$ satisfying Property (**Ubiquity**). By Remark 17, the jungle tree $\mathfrak{j}$ is covered up by a liana of the form $\mathbf{u}_0 L_{\mathbf{u}_0}$.

The extension of Property (**Ubiquity**) to other words is illustrated by Figure 2. Let $\mathbf{uv}$ be a factor in S, with $|\mathbf{u}| = n$. In particular $\mathbf{u}$ is a stem, hence $\mathbf{u}_0$ and $\mathbf{u}$ are states of the same connected component, and there exists a path in this component from $\mathbf{u}_0$ to $\mathbf{u}$, say by the action of some $\mathbf{a} \in \Sigma^*$. The automaton being reversible, $\mathbf{v}$ is the image of some $\mathbf{v}_0 \in Q^{|\mathbf{v}|}$ by $\mathbf{b} = \delta_{\mathbf{u}_0}(\mathbf{a})$ (see Figure 2).

Now, we know that on the left part of Figure 2 we can find eventually $\mathbf{u}_0$, after some $\mathbf{w}_0$ (because $\mathbf{u}_0$ has Property (**Ubiquity**)). And by the invertibility of the automaton, there exists some power α of $\mathbf{u}_0\mathbf{v}_0\mathbf{w}_0$ which stabilizes $\mathbf{a}$ (see Figure 2).

Hence $\mathbf{u}$ can be seen again eventually. Furthermore, the vertical word on the right of Figure 2 is a $\mathfrak{j}$-word, as it is in the same connected component than the vertical $\mathfrak{j}$-word on the left of this same figure, and so it is a factor of S because, by hypothesis, its prefix of length n is a factor of S. Hence $\mathbf{u}$ has Property (**Ubiquity**). ◀

▶ **Remark 19.** *Note that, from Theorem 18, if $\mathbf{u}$, $\mathbf{v}$ are two stems such that $\mathbf{v}$ is a factor of some word in $\mathbf{u}L_{\mathbf{u}}$, then $\mathbf{u}$ is a factor of some word in $\mathbf{v}L_{\mathbf{v}}$.*

5.2 An equivalence on stems

Remember that $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ is a connected bireversible Mealy automaton such that $\mathfrak{t}(\mathcal{A})$ has no active self-liftable branch (and as a consequence all the elements of the semigroup $\langle \mathcal{A} \rangle_+$ have finite order). Let $\mathfrak{j}$ be a jungle tree of $\mathfrak{t}(\mathcal{A})$ with trunk of length n. All the stems considered from now on are stems of $\mathfrak{j}$.

In this subsection we prove several properties for the stems of the jungle tree $\mathfrak{j}$. Stems are used then in Section 6 to build a $\mathfrak{j}$-word inducing the same action than some given word.

Let us first introduce an equivalence relation on the set of stems.

▶ **Definition 20.** Let $\mathbf{u}$, $\mathbf{v}$ be two stems. We say that $\mathbf{u}$ is *equivalent* to $\mathbf{v}$, denoted by $\mathbf{u} \sim \mathbf{v}$, whenever there exists $\mathbf{s} \in Q^*$ such that $\mathbf{usv}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{us}}$ acts like the identity on Σ^*.

▶ **Lemma 21.** *The relation $\sim$ is an equivalence relation on stems.*

Proof. Let $\mathbf{u}$, $\mathbf{v}$, and $\mathbf{w}$ be three stems.

transitivity Suppose that $\mathbf{u} \sim \mathbf{v}$ and $\mathbf{v} \sim \mathbf{w}$: there exists $\mathbf{s}, \mathbf{t} \in Q^*$ such that $\mathbf{usv}$ and $\mathbf{vtw}$ are $\mathfrak{j}$-words, and $\rho_{\mathbf{us}}$ and $\rho_{\mathbf{vt}}$ act like the identity. As $\mathbf{v}$ is a stem, we obtain by Remark 14 that $\mathbf{usvtw}$ is a $\mathfrak{j}$-word, and $\rho_{\mathbf{usvt}}$ acts like the identity, so $\mathbf{u} \sim \mathbf{w}$.

reflexivity From Theorem 18, there exists $\mathbf{s} \in Q^*$ such that $\mathbf{usu}$ is a $\mathfrak{j}$-word (in fact from Theorem 18 one can even chose the beginning of $\mathbf{s}$, as long as we keep a $\mathfrak{j}$-word). As $\mathbf{u}$ is a stem, $\mathbf{usus}$ is also a $\mathfrak{j}$-word, and so are all the powers of $\mathbf{us}$. Now, by hypothesis and Theorem 12, $\mathbf{us}$ is of finite order, say α: $\mathbf{u}(\mathbf{su})^{\alpha-1}\mathbf{su}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{u}(\mathbf{su})^{\alpha-1}\mathbf{s}} = \rho_{(\mathbf{us})^{\alpha}}$ acts like the identity.

symmetry Suppose that $\mathbf{u} \sim \mathbf{v}$: there exists $\mathbf{s} \in Q^*$ such that $\mathbf{usv}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{us}}$ acts like the identity. From the reflexivity proof, there exists $\mathbf{t} \in Q^*$ such that $\mathbf{usvtu}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{usvt}}$ acts like the identity. Hence $\mathbf{vtu}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{vt}}$ acts like the identity, which proves the symmetry.

◀

Note that from reflexivity of $\sim$ and Theorem 18, if $\mathbf{u}$ and $\mathbf{v}$ are equivalent stems and $\mathbf{uw}$ is a $\mathfrak{j}$-word for some $\mathbf{w} \in Q^*$, then there exists $\mathbf{s} \in Q^*$ such that $\mathbf{uwsv}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{uws}}$ acts like the identity. So not only $\mathbf{v}$ can be reached from $\mathbf{u}$ by producing first the identity, but even if you walk in $\mathfrak{j}$ after reading $\mathbf{u}$, you can still reach $\mathbf{v}$ and produce first the identity.

We can now consider the equivalence classes induced by $\sim$. The aim of this subsection is to prove that if $\mathcal{A}$ has a prime size, then for a given state q there is in each $\sim$-class a stem with prefix q (Theorem 30).

▶ **Proposition 22.** *All the equivalence classes of $\sim$ have the same size.*

Proof. Let $\mathbf{u}_0$ and $\mathbf{v}_0$ be two stems of $\mathfrak{j}$: they are states of the same connected component and so there exists $\mathbf{a} \in \Sigma^*$ such that $\delta_{\mathbf{a}}(\mathbf{u}_0) = \mathbf{v}_0$. Denote by $\{\mathbf{u}_0, \dots, \mathbf{u}_k\}$ the $\sim$-class of $\mathbf{u}_0$: for any i, $1 \leq i \leq k$, there exists $\mathbf{s}_i \in Q^*$ such that $\mathbf{u}_0\mathbf{s}_i\mathbf{u}_i$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{u}_0\mathbf{s}_i}$ acts like the identity. Define the words $\mathbf{v}_i \in Q^{|\mathbf{u}_i|}$ and $\mathbf{t}_i \in Q^{|\mathbf{s}_i|}$ in the following way: $\delta_{\mathbf{a}}(\mathbf{u}_0\mathbf{s}_i\mathbf{u}_i) = \mathbf{v}_0\mathbf{t}_i\mathbf{v}_i$. Note that $\mathbf{v}_0\mathbf{t}_i\mathbf{v}_i$ is also a $\mathfrak{j}$-word: any factor of size n of $\mathbf{v}_0\mathbf{t}_i\mathbf{v}_i$ is the image of a stem (the corresponding factor in $\mathbf{u}_0\mathbf{s}_i\mathbf{u}_i$) and therefore belongs to the connected component of $\mathbf{u}_0$ and $\mathbf{v}_0$, hence every prefix of $\mathbf{v}_0\mathbf{t}_i\mathbf{v}_i$ is on a 1-self-liftable path. Now $\rho_{\mathbf{v}_0\mathbf{t}_i}$ acts like the identity by the reversibility of $\mathcal{A}$, so $\mathbf{v}_i$ is $\sim$-equivalent to $\mathbf{v}_0$. Furthermore, as $\rho_{\mathbf{u}_0\mathbf{s}_i}$ acts like the identity, we know that $\mathbf{v}_i = \delta_{\mathbf{a}}(\mathbf{u}_i)$, and all the $\mathbf{v}_i$ are different. ◀

5.3 Combinatorial properties of stems

We now state several combinatorial properties for stems. Let $k_1, k_2, \dots, k_n$ be the labels, from root to $\perp(\mathbf{e})$, of the jungle tree $\mathfrak{j} = \mathfrak{j}(\mathbf{e})$. Recall that, since $\mathcal{A}$ is connected, $k_1 = p$ and by construction of the jungle tree $k_n \geq 2$. For instance in Figure 3, $n = 4$, $k_1 = k_2 = 3$, and $k_3 = k_4 = 2$.

First if we consider no restriction then we can directly count stems by looking to the labels of the trunk:

▶ **Lemma 23.** *The number of stem with a given prefix depends only on length i of the prefix and is $k_{i+1}k_{i+2}\dots k_n$.*

We are now interested in two somehow dual questions. Fix a $\mathfrak{j}$-word $\mathbf{u}$ of length less than n: (i) if $\mathbf{u}$ is the prefix of a stem in some $\sim$-class γ, in how many way can $\mathbf{u}$ be completed in γ (Proposition 24)? (ii) in how many $\sim$-classes is $\mathbf{u}$ the prefix of a stem (Corollary 29)?

▶ **Proposition 24.** *Fix some $\mathfrak{j}$-word $\mathbf{u}$ of length less than n, a $\sim$-class γ of stems including an element with prefix $\mathbf{u}$, and some integer k such that $|\mathbf{u}| + k \leq n$. The number of $\mathbf{v} \in Q^k$ such that $\mathbf{uv}$ is a prefix of a stem of γ depends only on $|\mathbf{u}|$ and k.*

Proof. By the same argument than in the proof of Proposition 22. ◀

Let $\mathbf{u} \in Q^*$ be a prefix of a stem in some $\sim$-class γ. Denote by $\mathcal{S}_{\text{eq}}(|\mathbf{u}|+1)$ the cardinality of the set $\{q \in Q \mid \mathbf{u}q \text{ is a prefix of some stem in } \gamma\}$ (from Proposition 24 it depends only of $|\mathbf{u}|$ and so it is well-defined).

In order to obtain a minimal bound on the size of a $\sim$-class, we introduce another equivalence relation between stems which is finer than $\sim$, as proved in Lemma 26:

▶ **Definition 25.** Let $\mathbf{u}, \mathbf{v}$ be two stems. Define the relation $\mathbf{u} \wedge_0 \mathbf{v}$ whenever there exists a stem $\mathbf{s}$ such that both $\mathbf{su}$ and $\mathbf{sv}$ are $\mathfrak{j}$-words. The equivalence relation $\wedge$ is defined as the transitive closure of $\wedge_0$.

Note that by the construction of the jungle tree, a $\wedge_0$-class contains k^n elements, where k stands for the arity of this jungle tree.

▶ **Lemma 26.** *The relation $\wedge$ is finer than the relation $\sim$: $\mathbf{u} \wedge \mathbf{v} \Rightarrow \mathbf{u} \sim \mathbf{v}$.*

Proof. By transitivity it is enough to prove that: $\mathbf{u} \wedge_0 \mathbf{v} \Rightarrow \mathbf{u} \sim \mathbf{v}$. Let $\mathbf{u}$ and $\mathbf{v}$ be two stems such that $\mathbf{u} \wedge_0 \mathbf{v}$: there exists a stem $\mathbf{s}$ such that $\mathbf{su}$ and $\mathbf{sv}$ are $\mathfrak{j}$-words. From Theorem 18, there exists a word $\mathbf{w} \in Q^*$ such that $\mathbf{uws}$ is a $\mathfrak{j}$-word. As $\mathbf{u}$ and $\mathbf{s}$ are stems, and $\mathbf{su}$ is a $\mathfrak{j}$-word, $(\mathbf{uws})^2$ is a $\mathfrak{j}$-word by Remark 14, and so are all the powers of $\mathbf{uws}$. Now, by hypothesis and Theorem 12, the word $\mathbf{uws}$ has finite order, say α: $(\mathbf{uws})^\alpha\mathbf{v}$ is a $\mathfrak{j}$-word and $\rho_{(\mathbf{uws})^\alpha}$ acts like the identity. ◀

▶ **Corollary 27.** *For any i, $\mathcal{S}_{eq}(i) \geq 2$.*

Proof. For a stem $\mathbf{u}$, the set of words in $\wedge_0$-relation with $\mathbf{u}$, seen as a tree, has the same arity than $\mathfrak{j}$; so, by Lemma 26, for any i, $\mathcal{S}_{\text{eq}}(i)$ is greater than or equal to the arity of $\mathfrak{j}$. ◀

▶ **Proposition 28.** *Fix a $\mathfrak{j}$-word $\mathbf{u}$ of length less than n. The number of stems prefixed by $\mathbf{u}$ in a $\sim$-class is either 0 or depends only on $|\mathbf{u}|$.*

Proof. By the same argument than in the proof of Proposition 22. ◀

From Propositions 24 and 28 we obtain:

▶ **Corollary 29.** *Fix a $\mathfrak{j}$-word $\mathbf{u}$ of length less than n. The number of $\sim$-classes where $\mathbf{u}$ is the prefix of some stem depends only on $|\mathbf{u}|$.*

Denote by $\mathcal{P}_{\text{eq}}(|\mathbf{u}|+1)$ the number of $\sim$-classes containing a stem prefixed by $\mathbf{u}$ (it is correctly define by Corollary 29).

We can now prove the main result of this section:

▶ **Theorem 30.** *Let $\mathcal{A}$ be a connected bireversible Mealy automaton of prime size and without any active self-liftable branch. The set of states which appear as first letter of a stem in a fixed $\sim$-class is the whole stateset.*

Proof. Suppose $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ has prime size p, and let $\mathfrak{j}$ be a jungle tree of $\mathfrak{t}(\mathcal{A})$ whose trunk $\mathbf{e}$ has length n. We denote by $k_1,\ldots,k_n$ the label of the edges of $\mathbf{e}$ (from top to bottom). By the connectivity of $\mathcal{A}$, $k_1 = p$.

Let γ be a $\sim$-class of stems for $\mathfrak{j}$ and $\mathbf{u} \in Q^*$ of length $i \leq n$ be the prefix of some stem in γ. Consider all the stems in γ with prefix $\mathbf{u}$.

From Lemma 23, the number of stems of $\mathfrak{j}$ prefixed by $\mathbf{u}$ is $k_{i+1} \times k_{i+2} \times \ldots \times k_n$. On the other hand, it is also the number of stems with prefix $\mathbf{u}$ in γ, *i.e.* $\mathcal{S}_{\text{eq}}(i+1) \times \cdots \times \mathcal{S}_{\text{eq}}(n)$, times the number of $\sim$-classes which has a stem prefixed by $\mathbf{u}$, *i.e.* $\mathcal{P}_{\text{eq}}(i+1) \times \cdots \times \mathcal{P}_{\text{eq}}(n)$. Hence

$$k_{i+1} \times k_{i+2} \times \ldots \times k_n = \mathcal{S}_{\text{eq}}(i+1) \times \mathcal{P}_{\text{eq}}(i+1) \times \mathcal{S}_{\text{eq}}(i+2) \times \mathcal{P}_{\text{eq}}(i+2) \times \ldots \times \mathcal{S}_{\text{eq}}(n) \times \mathcal{P}_{\text{eq}}(n) .$$

It is straightforward that $k_n = \mathcal{P}_{\text{eq}}(n) \times \mathcal{S}_{\text{eq}}(n)$ and by induction $\mathcal{P}_{\text{eq}}(\ell) \times \mathcal{S}_{\text{eq}}(\ell) = k_\ell$ for all ℓ. In particular for $\ell = 1$, we get that $\mathcal{S}_{\text{eq}}(1)$ devides k_1. Since $k_1 = p$ and, from Corollary 27, $\mathcal{S}_{\text{eq}}(1) \geq 2$, we obtain then $\mathcal{S}_{\text{eq}}(1) = p$. ◀

▶ **Corollary 31.** *Let $\mathcal{A} = (Q, \Sigma, \delta, \rho)$ be a connected bireversible Mealy automaton of prime size, with no active self-liftable branch. Let $\mathfrak{j}$ be a jungle tree of $\mathfrak{t}(\mathcal{A})$ and $\mathbf{u}$ some $\mathfrak{j}$-word. Then for any state $x \in Q$, there exists $\mathbf{w} \in Q^*$ such that $\mathbf{uw}x$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{w}}$ acts like the identity of Σ^*.*

Proof. Let $\mathbf{s}$ be a stem such that $\mathbf{us}$ is a $\mathfrak{j}$-word: there exists a stem $\mathbf{x}$ with first letter x in the $\sim$-class of $\mathbf{s}$, from Theorem 30, *i.e.* there exists $\mathbf{v} \in Q^*$ such that $\mathbf{svx}$ is a $\mathfrak{j}$-word and $\rho_{\mathbf{sv}}$ acts like the identity of Σ^*. Conclusion comes from Remark 14. ◀

Note that in the previous corollary, the word $\mathbf{u}$ can be empty.

6 Proof of the main theorem

We now have all elements to prove our main result.

▶ **Theorem 32.** *A connected invertible-reversible Mealy automaton of prime size cannot generate an infinite Burnside group.*

Proof. Let $\mathcal{A}$ be a connected invertible-reversible Mealy automaton of prime size. If $\mathcal{A}$ is not bireversible we can apply [1, 7] and we get that, on one hand, $\langle \mathcal{A} \rangle$ is necessarily infinite, but on the other hand, it cannot be Burnside. If $\mathcal{A}$ is bireversible and $\mathfrak{t}(\mathcal{A})$ has an active self-liftable branch, then $\langle \mathcal{A} \rangle$ has an element of infinite order by Theorem 12.

Therefore we can assume that $\mathcal{A}$ is bireversible and $\mathfrak{t}(\mathcal{A})$ has no active self-liftable branch. Let us show that $\langle \mathcal{A} \rangle$ is finite. Let $\mathfrak{j}$ be some jungle tree of $\mathfrak{t}(\mathcal{A})$. As in [13] we prove that for any word $\mathbf{u} \in Q^*$, $\rho_{\mathbf{u}}$ has some uniformly bounded power which acts like some cyclic $\mathfrak{j}$-word.

Let $\mathbf{u} \in Q^*$. We prove by induction that any prefix $\mathbf{u}$ induces the same action than some $\mathfrak{j}$-word. It is obviously true for the empty prefix. Fix some $k < |\mathbf{u}|$ and suppose that the prefix $\mathbf{v}$ of length k of $\mathbf{u}$ induces the same action than some $\mathfrak{j}$-word $\mathbf{s}$. Let $x \in Q$ be the $(k+1)$-th letter of $\mathbf{u}$. By Corollary 31, there exists a $\mathfrak{j}$-word $\mathbf{w}$ inducing the identity, such that $\mathbf{sw}x$ is a $\mathfrak{j}$-word. But $\mathbf{v}x$ and $\mathbf{sw}x$ induce the same action ; the result follows. Hence we obtain a $\mathfrak{j}$-word $\mathbf{u}^{(1)}$ inducing the same action than $\mathbf{u}$.

By the very same process, we can construct, for any $i \in \mathbb{N}$, a j-word $\mathbf{u}^{(i)}$ inducing the same action than $\mathbf{u}$, such that $\mathbf{u}^{(1)}\mathbf{u}^{(2)}\ldots\mathbf{u}^{(i)}$ is a j-word. Since the set Q^n is finite there exist $i < j$, $j - i \leq |Q|^n$, such that $\mathbf{u}^{(i)}$ and $\mathbf{u}^{(j)}$ have the same prefix of length n. Take $\mathbf{v} = \mathbf{u}^{(i)}\mathbf{u}^{(i+1)}\ldots\mathbf{u}^{(j-1)}$: $\mathbf{v}$ is a cyclic j-word and induces the same action than $\mathbf{u}^{j-i}$. By Proposition 15, the order of $\rho_{\mathbf{v}}$ is bounded by a constant depending only on j, hence so is the order of $\rho_{\mathbf{u}}$ (with a different constant, but still depending only on j). Consequently, every element of $\langle\mathcal{A}\rangle$ has a finite order, uniformly bounded by a constant, whence, as $\langle\mathcal{A}\rangle$ is residually finite, by Zelmanov's theorem [14, 15], $\langle\mathcal{A}\rangle$ is finite, which concludes the proof. ◀

The tools and techniques we have developed here enabled to bridge the gap between 3 and the set of all prime numbers. The next step is the extension of our result to any connected automaton. However, experiments suggest that there are strong similarities between the non prime case and the non connected case, bringing the hope to solve entirely the question of the (im)possible generation of an infinite Burnside group by a reversible Mealy automaton. Note that the primality of the stateset is not used here before Theorem 30. It is likely that the extension of Theorem 32 to more general statesets will require to choose carefully some k-self-liftable branches, with $k > 1$. In fact, there exist examples of automata for which the set of first letters in a $\sim$-class is not the whole stateset. However the $\sim$-classes seem to still play a crucial role in these examples. So our construction will certainly be a key element for a more general result.

Abstract

Most of the known *lower bounds* for binary Boolean circuits with unrestricted depth are proved by the gate elimination method. The most efficient known *algorithms* for the #SAT problem on binary Boolean circuits use similar case analyses to the ones in gate elimination. Chen and Kabanets recently showed that the known case analyses can also be used to prove *average case circuit lower bounds*, that is, lower bounds on the size of approximations of an explicit function.

In this paper, we provide a general framework for proving worst/average case lower bounds for circuits and upper bounds for #SAT that is built on ideas of Chen and Kabanets. A proof in such a framework goes as follows. One starts by fixing three parameters: a class of circuits, a circuit complexity measure, and a set of allowed substitutions. The main ingredient of a proof goes as follows: by going through a number of cases, one shows that for any circuit from the given class, one can find an allowed substitution such that the given measure of the circuit reduces by a sufficient amount. This case analysis immediately implies an upper bound for #SAT. To obtain worst/average case circuit complexity lower bounds one needs to present an explicit construction of a function that is a disperser/extractor for the class of sources defined by the set of substitutions under consideration.

We show that many known proofs (of circuit size lower bounds and upper bounds for #SAT) fall into this framework. Using this framework, we prove the following new bounds: average case lower bounds of $3.24n$ and $2.59n$ for circuits over U_2 and B_2, respectively (though the lower bound for the basis B_2 is given for a quadratic disperser whose explicit construction is not currently known), and faster than 2^n #SAT-algorithms for circuits over U_2 and B_2 of size at most $3.24n$ and $2.99n$, respectively. Here by B_2 we mean the set of all bivariate Boolean functions, and by U_2 the set of all bivariate Boolean functions except for parity and its complement.

1 Introduction

1.1 Background

In this paper, we study binary Boolean circuits with no restriction on the depth. This is a natural model for computing Boolean functions that can be viewed as a simple program where each instruction is just a binary Boolean operation. Shannon [56] showed that for almost all Boolean functions of n variables the size of a smallest circuit (equivalently, the minimal number of instructions) computing this function is $\Omega(2^n/n)$. The proof is based on a counting argument (the number 2^{2^n} of all functions of n variables is larger than the number of circuits of size $o(2^n/n)$) and, for this reason, does not give an explicit function of high circuit complexity. By saying "explicit" one usually means a function from NP. Showing a superpolynomial lower bound for an explicit function would imply P $\neq$ NP. However, despite of many efforts [53, 47, 57, 8, 20, 26, 66, 3], currently we have only small linear lower bounds: $(3 + 1/86)n$ for the full binary basis B_2 consisting of all binary Boolean functions [25] and $5n - o(n)$ for the basis U_2 consisting of all binary Boolean functions except for parity and its complement [38, 32].

Going to larger complexity classes, it is known that the classes MA/1 [50], O_2^p [10], and $\mathrm{P}^{\mathrm{prMA}}$ [11] require circuits of superlinear size and the class MAEXP [9] has superpolynomial circuit complexity. Proving a superlinear lower bound on the circuit complexity of E^{NP} remains to be a major open problem.

Recently, Williams [60, 64] presented the following approach to prove circuit size lower bounds against E^{NP} or NE using SAT-algorithms: a super-polynomially faster than 2^n algorithm for the circuit satisfiability problem of a "reasonable" circuit class $\mathcal{C}$ implies either $\mathrm{E}^{\mathrm{NP}} \not\subseteq \mathcal{C}$ or $\mathrm{NE} \not\subseteq \mathcal{C}$, depending on $\mathcal{C}$ and the running time of the algorithm. The approach has been strengthened and simplified by subsequent work [59, 61, 63, 7, 33], see also excellent surveys [52, 45, 62] on this topic.

Williams' result inspired lots of work on satisfiability algorithms for various circuit classes [30, 63, 15, 2, 1, 43, 16, 58]. In addition to satisfiability algorithms, several papers [51, 29, 4, 54, 14, 12, 17, 49] also obtained average-case lower bounds (also known as correlation bounds, see [35, 36, 28]) by investigating the analysis of algorithms instead of just applying Williams' result that yields worst-case lower bounds. In particular, Chen and Kabanets [13] presented algorithms that count the number of satisfying assignments of circuits over U_2 and B_2 and run in time exponentially faster than 2^n if input instances have at most $2.99n$ and $2.49n$ gates, respectively (improving also the previously best known #SAT-algorithm by Nurk [44]). At the same time, they showed that $2.99n$ sized circuits over U_2 and $2.49n$ sized circuits over B_2 have exponentially small correlations with the parity function and affine extractors having "good" parameters, respectively.

To prove a lower bound of ζn on the circuit size, one usually shows that for any circuit there is a substitution $x_i \leftarrow f$ eliminating at least ζ gates from the circuit. For example, to prove a lower bound of $3n - 3$ on the circuit size over U_2 of the parity function, Schnorr [53] shows how to make a bit-fixing substitution (i.e., $f = c$ for $c \in \{0, 1\}$) eliminating at least 3 gates from any U_2-circuit. Demenkov and Kulikov [20] prove a lower bound of $3n - o(n)$ on the circuit size over B_2 of an affine disperser by showing that for any B_2-circuit there is an affine substitution ($f = \oplus_{j \in J} x_j \oplus c$) eliminating at least three gates from the circuit. Chen and Kabanets proved new average case lower bounds and #SAT upper bounds by analyzing what happens in the complementary branch $x_i \leftarrow f \oplus 1$ of proofs by Schnorr and by Demenkov and Kulikov.

1.2 Our Techniques and Results

The main qualitative contribution of this paper is a general framework for proving circuit worst/average case lower bounds and #SAT upper bounds. This framework is separated into conceptual and technical parts. The conceptual part is a proof that for a given circuit complexity measure and a set of allowed substitutions, for any circuit, there is a substitution that reduces the complexity of the circuit by a sufficient amount. This is usually shown by analyzing the structure of the top of a circuit. The technical part is a set of lemmas that allows us to derive worst/average case circuit size lower bounds and #SAT upper bounds as one-line corollaries from the corresponding conceptual part. The technical part can be used in a black-box way: given a proof that reduces the complexity measure of a circuit (conceptual part), the technical part implies circuit lower bounds and #SAT upper bounds. For example, by plugging in the proofs by Schnorr and by Demenkov and Kulikov, one immediately gets the bounds given by Chen and Kabanets. We also give new proofs that lead to the quantitatively better results. The main quantitative contribution of the paper is the following new bounds which are currently the strongest known bounds:

- average case lower bounds of $3.24n$ and $2.59n$ for circuits over U_2 and B_2 (though the lower bound for the basis B_2 is given for a quadratic disperser whose explicit construction is not currently known), respectively, improving upon the bounds of $2.99n$ and $2.49n$ [13];
- faster than 2^n #SAT-algorithms for circuits over U_2 and B_2 of size at most $3.24n$ and $2.99n$, respectively, improving upon the bounds of $2.99n$ and $2.49n$ [13].

These bounds are obtained by using non-standard circuit complexity measures and sets of substitutions. We also show that obtaining non-linear lower bounds through a weak version of this framework is unlikely as it would violate the Exponential Time Hypothesis [31] that states the following: The satisfiability problem of 3-CNF formulas with n variables cannot be solved in time $2^{o(n)}$. ETH is widely used as a hardness assumption to prove the optimality of many algorithms, see, e.g., [41, 42].

1.3 Framework

We prove circuit lower bounds (both in the worst case and in the average case) and upper bounds for #SAT using the following four step framework.

Initial setting We start by specifying the three main parameters: a class of circuits $\mathcal{C}$, a set $\mathcal{S}$ of allowed substitutions, and a circuit complexity measure μ. A set of allowed substitutions naturally defines a class of "sources". For the circuit lower bounds we consider functions that are non-constant (dispersers) or close to uniform (extractors) on corresponding sets of sources. In this paper we focus on the following four sets of substitutions where each set extends the previous one:

1. Bit fixing substitutions, $\{x_i \leftarrow c\}$: substitute variables by constants.
2. Projections, $\{x_i \leftarrow c, x_i \leftarrow x_j \oplus c\}$: substitute variables by constants and other variables and their negations.

3. Affine substitutions, $\{x_i \leftarrow \bigoplus_{j \in J} x_j \oplus c\}$: substitute variables by affine functions of other variables.
4. Quadratic substitutions, $\{x_i \leftarrow p \colon \deg(p) \le 2\}$: substitute variables by degree two polynomials of other variables.

Case analysis We then prove the main technical result stating that for any circuit from the class $\mathcal{C}$ there exists (and can be constructed efficiently) an allowed substitution $x_i \leftarrow f \in \mathcal{S}$ such that the measure μ is reduced by a sufficient amount under both substitutions $x_i \leftarrow f$ and $x_i \leftarrow f \oplus 1$.

#SAT upper bounds As an immediate consequence, we obtain an upper bound on the running time of an algorithm solving #SAT for circuits from $\mathcal{C}$. The corresponding algorithm takes as input a circuit, branches into two cases $x_i \leftarrow f$ and $x_i \leftarrow f \oplus 1$, and proceeds recursively. When applying a substitution $x_i \leftarrow f \oplus c$, it replaces all occurrences of x_i by a subcircuit computing $f \oplus c$. The case analysis provides an upper bound on the size of the resulting recursion tree.

Circuit size lower bounds Then, by taking a function that survives under sufficiently many allowed substitutions, we obtain lower bounds on the average case and worst case circuit complexity of the function. Below, we describe such functions, i.e., dispersers and extractors for the classes of sources under consideration.

1. The class of bit fixing substitutions generates the class of *bit-fixing sources* [18]. Extractors for bit-fixing sources find many applications in cryptography (see [22] for an excellent survey of the topic). The standard function that is a good disperser and extractor for such sources is the parity function $x_1 \oplus \cdots \oplus x_n$.
2. Projections define the class of *projection sources* [46]. Dispersers for projections are used to prove lower bounds for depth-three circuits [46]. It is shown [46] that a binary BCH code with appropriate parameters is a disperser for $n - o(n)$ substitutions. See [48] for an example of extractor with good parameters for projection sources.
3. Affine substitutions give rise to the class of *affine sources*. Dispersers for affine sources find applications in circuit lower bounds [19, 20, 25]. There are several known constructions of dispersers [6, 55] and extractors [65, 39, 5, 40] that are resistant to $n - o(n)$ substitutions.
4. The class of quadratic substitutions generates a special case of *polynomial sources* [24, 5] and *quadratic varieties sources* [23]. An explicit construction of disperser for quadratic varieties sources would imply new circuit lower bounds [26]. Although an explicit construction of a function resistant to sufficiently many quadratic substitutions is not currently known, it is easy to show that a random function is resistant to any $n - o(n)$ quadratic substitutions.

Due to the page limit of this extended abstract, we have to omit many proofs, which can be found in the full version [27].

2 Preliminaries

2.1 Boolean functions

We denote by B_n the set of all n-variate Boolean functions and define $U_2 = B_2 \setminus \{\oplus, \equiv\}$ as the set of all *binary* Boolean functions except for parity and its complement.

The set of all sixteen binary Boolean functions $f(x, y) \in B_2$ can be classified as follows: 1) two constant functions: 0 and 1; we also call them *trivial*; 2) four functions that depend essentially on one of the arguments only: x, $x \oplus 1$, y, $y \oplus 1$; we call them *degenerate*; 3) eight *and-type* functions: $(x \oplus a) \cdot (y \oplus b) \oplus c$ where $a, b, c \in \{0, 1\}$; 4) two *xor-type* functions: $x \oplus y \oplus a$, where $a \in \{0, 1\}$.

Hence U_2 consists of all binary functions except for xor-type functions. An important property of binary and-type functions $(x \oplus a) \cdot (y \oplus b) \oplus c$, useful for case analyses, is the following: one can turn this function into a constant c by assigning $x \leftarrow a$ or $y \leftarrow b$.

2.2 Dispersers and Extractors

Let $x_1, \ldots, x_n$ be Boolean variables, and $f \in B_{n-1}$ be a function of $n-1$ variables. We say that $x_i \leftarrow f(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)$ is a substitution to the variable x_i.

Let $g \in B_n$ be a function, then the *restriction* of g under the substitution f is a function $h = (g|x_i \leftarrow f)$ of $n-1$ variables, such that $h(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) = g(x_1, \ldots, x_{i-1}, x_i, x_{i+1}, \ldots, x_n)$, where $x_i = f(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)$. Similarly, if $K \subseteq \{0, 1\}^n$ is a subset of the Boolean cube, then the *restriction* of K under this substitution is $K' = (K|x_i \leftarrow f)$, such that $(x_1, \ldots, x_n) \in K'$ if and only if $(x_1, \ldots, x_n) \in K$ and $x_i = f(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n)$.

For a family of functions $\mathcal{F} = \{f : \{0, 1\}^* \to \{0, 1\}\}$ we define a set of corresponding substitutions $\mathcal{S}(\mathcal{F})$ that contains the following substitutions: for every $1 \le i \le n, c \in \{0, 1\}, f \in \mathcal{F}$, $\mathcal{S}$ contains the substitution $x_i \leftarrow f(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_n) \oplus c$.

Let $\mathcal{S}$ be a set of substitutions. We say that a set $K \subseteq \{0, 1\}^n$ is an $(\mathcal{S}, n, r)$-*source*[1] if it can be obtained from $\{0, 1\}^n$ by applying at most r substitutions from $\mathcal{S}$.

A function $f \in B_n$ is called an $(\mathcal{S}, n, r)$-*disperser*[2] if it is not constant on every $(\mathcal{S}, n, r)$-source. A function $f \in B_n$ is called an $(\mathcal{S}, n, r, \varepsilon)$-*extractor* if $|\Pr_{x \leftarrow K}[f(x) = 1] - 1/2| \le \varepsilon$ for every $(\mathcal{S}, n, r)$-source K.

2.3 Circuits

A circuit over the basis $\Omega \subseteq B_2$ is a directed acyclic graph with the following properties: 1) the indegree of each node is either zero or two; 2) each node of zero indegree is labeled by a variable and is called an *input* or an *input gate*; 3) each node of indegree two is labeled with a binary Boolean function from Ω called an *operation* of this gate; the node itself is called an *internal gate* or just a *gate*; 4) there is a unique node of outdegree zero and it is called an *output*. Such a circuit computes in a natural way a function from B_n, where n is the number of input gates of the circuit. In this paper, we consider circuits over the bases $\Omega = B_2$ and $\Omega = U_2$.

An *xor-gate* (*and-gate*) is a gate computing an xor-type (and-type, respectively) operation. A k-*gate* (k^+-*gate*) is a gate of outdegree exactly k (at least k, respectively).

For a circuit C, by $s(C)$ we denote the *size* of C, that is, the number of internal gates of C. By $i(C)$ and $i_1(C)$ we denote the total number of input gates of C and the number of input 1-gates, respectively. For a function $f \in B_n$, by $C_\Omega(f)$ we denote the minimal size of a circuit over Ω computing f.

For two Boolean functions $f, g \in B_n$, the correlation between them is defined as

$$\mathrm{Cor}(f, g) = \left| \Pr_{x \leftarrow \{0,1\}^n}[f(x) = g(x)] - \Pr_{x \leftarrow \{0,1\}^n}[f(x) \neq g(x)] \right| = 2\left| \frac{1}{2} - \Pr_{x \leftarrow \{0,1\}^n}[f(x) \neq g(x)] \right|.$$

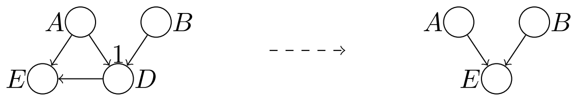
[1] Usually in the literature a source corresponds to a distribution over a subset of $\{0, 1\}^n$. In this paper, we focus only on uniform distributions, so we associate a source with its support.

[2] In this paper, we consider only dispersers and extractors with one bit outputs.

For a function $f \in B_n$, and $0 \leq \varepsilon \leq 1$, by $C_\Omega(f, \varepsilon)$ we denote the minimal size of a circuit over Ω computing function g such that $\operatorname{Cor}(f, g) \geq \varepsilon$.

2.4 Circuit normalization

A gate is called *useless* if it is a 1-gate and is fed by a predecessor of its successor:



In this case E actually computes a binary operation of A and B and this operation can be computed in the gate E directly. This might require to change an operation at E (if this circuit is over U_2 then E still computes an and-type operation of A and B as an xor-type binary function requires three gates in U_2).

By *normalizing* a circuit we mean removing all gates that compute trivial or degenerate operations and removing all useless gates. Note that normalization does not change the function computed by a circuit. It might however change the operations at some gates and outdegrees of some gates (in particular, input gates).

In the proofs of the paper we implicitly assume that if two gates are fed by the same variable then either there is no wire between them or each of the gates feed also some other gate (otherwise, one of the gates would be useless) and hence we do not care about this wire between the gates.

2.5 Circuit complexity measures

A function μ mapping circuits to non-negative real values is called a *circuit complexity measure* if for any circuit C,

- normalization of C does not increase its measure, and
- if $\mu(C) = 0$ then C has no gates.

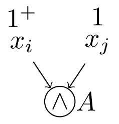
For a fixed circuit complexity measure μ, and function $f \in B_n$, we define $\mu(f)$ to be the minimum value of $\mu(C)$ over circuits C computing f. Similarly, we define $\mu(f, \varepsilon)$ to be the minimum value of $\mu(C)$ over circuits C computing g such that $\operatorname{Cor}(f, g) \geq \varepsilon$.

In this paper, we focus on the following two circuit complexity measures:

- $\mu(C) = s(C) + \alpha \cdot i(C)$ where $\alpha \geq 0$ is a constant;
- $\mu(C) = s(C) + \alpha \cdot i(C) - \sigma \cdot i_1(C)$ where $\alpha \geq 0, \sigma \leq 1$ are constants.

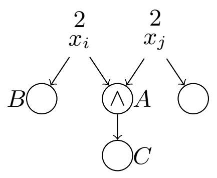
It is not difficult to see that these two functions are indeed circuit complexity measures if $\alpha \geq 0$ and $\sigma \leq 1$. The condition $\sigma \leq 1$ is needed to guarantee that if by removing a degenerate gate we increase the outdegree of a variable, the measure does not increase (an example is given on the next page).

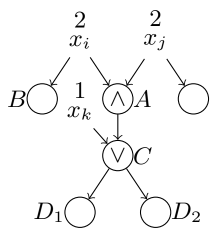
Intuitively we include the term $i(C)$ into the measure to handle cases like the one below (throughout the paper, we use labels above the gates to indicate their outdegree):



In this case, by assigning $x_i \leftarrow 0$ we make the circuit independent of x_j, so the measure is reduced by at least 2α. Usually, our goal is to show that we can find a substitution to a variable that eliminates at least some constant number k of gates, that is, to show a complexity decrease of at least $k + \alpha$. Thus, by choosing a large enough value of α we can always guarantee that $2\alpha \geq \alpha + k$. Thus, in the case above we do not even need to count the number of gates eliminated under the substitution.

The measure $\mu(C) = s(C) + \alpha \cdot i(C) - \sigma \cdot i_1(C)$ allows us to get an advantage of new 1-variables that are introduced during splitting.





For example, by assigning $x_i \leftarrow 0$ in a situation like the one in the left picture we reduce the measure by at least $3 + \alpha + \sigma$. As usual, the advantage comes with a related disadvantage. If, for example, a closer look at the circuit from the left part reveals that it actually looks like as shown on the right, then by assigning $x_i \leftarrow 0$ we introduce a new 1-variable x_j, but also loose one 1-variable (namely, x_k is now a 2-variable). Hence, in this case μ is reduced only by $(3 + \alpha)$ rather than $(3 + \alpha + \sigma)$. That is, our initial estimate was too optimistic. For this reason, when use a measure with $i_1(C)$ we check carefully for each eliminated gate if this elimination increases the degree of a 1-variable.

2.6 Splitting numbers and splitting vectors

Let μ be a circuit complexity measure and C be a circuit. Consider a recursive algorithm solving #SAT on C by repeated substitutions. Assume that at the current step the algorithm chooses k variables $x_1, \dots, x_k$ and k functions $f_1, \dots, f_k$ to substitute these variables and branches into 2^k possible situations: $x_1 \leftarrow f_1 \oplus c_1, \dots, x_k \leftarrow f_k \oplus c_k$ for all possible $c_1, \dots, c_k \in \{0, 1\}$ (in other words, it partitions the Boolean hypercube $\{0, 1\}^n$ into 2^k subsets).[3] For each substitution, we normalize the resulting circuit. Let us call the 2^k circuits $C_1, \dots, C_{2^k}$. We say that the current step has a *splitting vector* $v = (a_1, \dots, a_{2^k})$ w.r.t. μ if for all $i \in [2^k]$, $\mu(C) - \mu(C_i) \geq a_i > 0$. That is, the splitting vector gives a lower bound on the complexity decrease under the considered substitution. The *splitting number* $\tau(v)$ is the unique positive root of the equation $\sum_{i \in [2^k]} x^{-a_i} = 1$.

Splitting vectors and numbers are heavily used to estimate the running time of recursive algorithms. Below we assume that k is bounded by a constant. In all the proofs of this paper either $k = 1$ or $k = 2$, that is, we always estimate the effect of assigning either one or two variables. If an algorithm always splits with a splitting number at most β then its running time is bounded by $O^*(\beta^{\mu(C)})$.[4] To show this one notes that the recursion tree of this algorithm is 2^k-ary and $k = O(1)$ so it suffices to estimate the number of leaves. The

[3] Sometimes it is easier to consider vectors of length that is not a power of 2 too. For example, we can have a branching into three cases: one with one substituted variable, and two with two substituted variables. All the results from this paper can be naturally generalized to this case. For simplicity, we state the results for splitting vectors of length 2^k only.

[4] O^* suppresses factors polynomial in the input length.

number of leaves $T(\mu)$ satisfies the recurrence $T(\mu) \leq \sum_{i\in[2^k]} T(\mu - a_i)$ which implies that $T(\mu) = O(\tau(v)^\mu)$ (we assume also that $T(\mu) = O(1)$ when $\mu = O(1)$). See, e.g., [37] for a formal proof.

For a splitting vector $v = (a_1, \dots, a_{2^k})$ we define the following related quantities:

$$\overline{v}_{\max} = \max_{i\in[2^k]} \left\{\frac{a_i}{k}\right\}, \quad \overline{v}_{\min} = \min_{i\in[2^k]} \left\{\frac{a_i}{k}\right\}, \quad \overline{v}_{\text{avg}} = \frac{\sum_{i\in[2^k]} a_i}{k2^k}.$$

Intuitively, $\overline{v}_{\max}$ ($\overline{v}_{\min}$, $\overline{v}_{\text{avg}}$) is a (lower bound for) the maximum (minimum, average, respectively) complexity decrease per single substitution.

We will need the following estimates for the splitting numbers. It is known that a balanced binary splitting vector is better than an unbalanced one: $2^{1/a} = \tau(a, a) < \tau(a + b, a - b)$ for $0 < b < a$ (see, e.g., [37]). There is a known upper bound on $\tau(a, b)$.

▶ **Lemma 1.** $\tau(a, b) \leq 2^{1/\sqrt{ab}}$.

In the following lemma we provide an asymptotic estimate of their difference.

▶ **Lemma 2** (Gap between $\tau(a_1+b, a_2+b)$ and $\tau((a_1+a_2)/2+b, (a_1+a_2)/2+b) \leq 2^{\frac{1}{(a_1+a_2)/2+b}}$). *Let $a_1 > a_2 > 0$, $a' = (a_1 + a_2)/2$ and $\delta(b) = \tau(a_1 + b, a_2 + b) - 2^{\frac{1}{a'+b}}$. Then, $\delta(b) = O((a_1 - a_2)^2/b^3)$ as $b \to \infty$.*

2.7 Azuma's inequality

Following the approach from [13], we use a variant of Azuma's inequality with one-sided boundedness condition in order to obtain average case lower bounds. The standard version of Azuma's inequality requires the difference between two consecutive variables to be bounded, [13] considers the case when the difference takes on only two values but is bounded only from one side. For our results, we need a slightly more general variant of the inequality: the difference between two consecutive variables takes on up to k values and is bounded from one side.

A sequence $X_0, \dots, X_m$ of random variables is a *supermartingale* if for every $0 \leq i < m$, $\mathrm{E}[X_{i+1}|X_i, \dots, X_0] \leq X_i$.

▶ **Lemma 3.** *Let $X_0, \dots, X_m$ be a supermartingale, let $Y_i = X_i - X_{i-1}$. If $Y_i \leq c$ and for fixed values of $(X_0, \dots, X_{i-1})$, the random variable Y_i is distributed uniformly over at most $k \geq 2$ (not necessarily distinct) values, then for every $\lambda \geq 0$:*

$$\Pr[X_m - X_0 \geq \lambda] \leq \exp\left(\frac{-\lambda^2}{2mc^2(k-1)^2}\right).$$

Note that we have an extra factor of $(k-1)^2$ comparing with the normal form of Azuma's inequality, but we do not assume that $X_i - X_{i-1}$ is bounded from below.

3 Toolkit

3.1 Main theorem

In this subsection we prove the main technical theorem that allows us to get circuit complexity lower bounds and #SAT upper bounds.

▶ **Definition 4.** Let $\{v_1, \dots, v_m\}$ be splitting vectors, and each v_i is a splitting vector of length $2^{t_i} \geq 2$. For a class of circuits Ω (e.g., $\Omega = B_2$ or $\Omega = U_2$), a set of substitutions $\mathcal{S}$, and a circuit complexity measure μ, we write

$$\mathrm{Splitting}(\Omega, \mathcal{S}, \mu) \preceq \{v_1, \dots, v_m\}$$

as a shortcut for the following statement: For any normalized circuit C from the class Ω one can find in time $\mathrm{poly}(|C|)$ either a substitution[5] from $\mathcal{S}$ whose splitting vector with respect to μ belongs to the set $\{v_1, \dots, v_m\}$ or a substitution that trivializes the output gate of C. A substitution always trivializes at least one gate (in particular, when we assign a constant to a variable we trivialize an input gate) and eliminates at least one variable.

▶ **Theorem 5.** *If Splitting$(\Omega, \mathcal{S}, \mu) \preceq \{v_1, \dots, v_m\}$ and the longest splitting vector has length 2^k, then*

1. *There exists an algorithm solving #SAT for circuits over Ω in time $O^*(\gamma^{\mu(C)})$, where*

$$\gamma = \max_{i \in [m]} \{\tau(v_i)\}\,.$$

2. *If $f \in B_n$ is an $(\mathcal{S}, n, r)$-disperser, then*

$$\mu(f) \geq \beta_w \cdot (r - k + 1)\,, \text{ where } \beta_w = \min_{i \in [m]} \{\overline{v_i}_{\max}\}\,.$$

3. *If $f \in B_n$ is an $(\mathcal{S}, n, r, \varepsilon)$-extractor, then for every $\mu < \beta_a \cdot r$,*

$$\mu\,(f, \delta) \geq \mu, \text{ where } \beta_a = \min_{i \in [m]} \left\{\overline{v_i}_{\mathrm{avg}}\right\} \text{ and } \beta_m = \min_{i \in [m]} \{\overline{v_i}_{\min}\}\,,$$

$$\delta = \varepsilon + \exp\left(\frac{-(r \cdot \beta_a - \mu)^2}{2r(\beta_a - \beta_m)^2(2^k - 1)^2}\right)\,.$$

3.2 Discussion

Many known lower bounds for circuits with unrestricted depth can be proved using this framework, in particular, the strongest known lower bounds over B_2 and U_2. Schnorr [53] proved a $2n - \Theta(1)$ on C_{B_2} for a wide class of functions using $\mu(C) = s(C)$ and bit fixing substitutions. Stockmeyer [57] proved a $2.5n - \Theta(1)$ lower bound for symmetric functions using $\mu(C) = s(C)$ and a special case of projections: $\{x_i \leftarrow c, \{x_i \leftarrow f, x_j \leftarrow f \oplus 1\}\}$ (the latter "double" substitution essentially fixes $x_i \oplus x_j$ to 1; by applying such a substitution to, say, the majority function one gets the majority function of fewer inputs). Kojevnikov and Kulikov [34] improved the bound by Schnorr to $7n/3 - \Theta(1)$ using the measure $\mu(C) = 3x(C) + 2a(C)$ assigning different weights to xor-gates and and-gates. Demenkov and Kulikov [20] proved a $3n - o(n)$ lower bound for an affine disperser for sublinear dimension using $\mu(C) = s(C) + i(C)$ and affine substitutions. Recently, Find et al. [25] extended this approach to get a $(3 + 1/86)n$ lower bound for the same function using a few additional tricks (while the measure and the set of allowed substitutions are not easy to describe).

For the basis U_2, Schnorr [53] proved that the circuit size of parity is $3n - 3$ using bit fixing substitutions. Zwick [66] proved a $4n - \Theta(1)$ lower bound for symmetric functions using

[5] Here we assume that the circuit obtained from C by the substitution and normalization belongs to Ω too.

bit-fixing substitutions and $\mu(C) = s(C) - i_1(C)$. His measure was then used by Lachish and Raz [38] and by Iwama and Morizumi [32] to prove $4.5n - o(n)$ and $5n - o(n)$ lower bounds for strongly two-dependent functions. Recently, Demenkov et al. [21] gave a simpler proof of a $5n - o(n)$ lower bound for a linear function with $o(n)$ outputs. All these proofs use bit fixing substitutions only, however the case analysis can be simplified using also projections and a measure of the form $\mu = s + \alpha \cdot i$.

At the same time, there are known lower bound proofs that use additional tricks. E.g., Blum [8] to prove a $3n - o(n)$ lower bound over B_2 first considers a few cases when it is easy to remove three gates, and for all the remaining circuits shows a lower bound directly by counting the number of gates using some particular properties of the function under consideration.

Also, upper bounds for SAT and #SAT for various circuits classes (and for many other NP-hard problems) are proved by making substitutions recursively and using a carefully chosen measure to estimate the complexity decrease after substitutions.

The whole framework is a formalization of the following simple idea. To prove a lower bound ζn on circuit size one usually shows that there always exists a substitution $x_i \leftarrow f$ eliminating at least ζ gates from the circuit. By analysing also the complexity decrease under the substitution $x_i \leftarrow f \oplus 1$ one gets an upper bound for #SAT and an average case lower bound. Below we show an easy consequence of this: if one gets a very strong lower bound via short splitting vectors in this framework, then the corresponding #SAT-algorithm is also quite fast. That is, a superlinear circuit lower bound that uses only short splitting vectors in the framework implies a subexponential time (with respect to the size) algorithm for #SAT, which contradicts the Exponential Time Hypothesis.

▶ **Theorem 6.** *If for some set of substitutions $\mathcal{S}$, Splitting$(\Omega, \mathcal{S}, s + \alpha i) \preceq \{(a_1, b_1), \dots, (a_m, b_m)\}$, such that $\beta_w = \min_{i\in[m]} \max\{a_i, b_i\} = \omega(1)$ then #SAT can be solved in time $O^*(2^{o(s)})$.*

Note that due to the Sparsification Lemma [31] such an algorithm even over the basis U_2 contradicts the Exponential Time Hypothesis.

Although our "positive" results from Theorem 5 hold for splitting vectors of any length, this "negative" result from Theorem 6 holds only for splitting vectors of length 2. The authors do not know how to generalize this result to longer splitting vectors, and leave it as an open question.

4 Bounds for the basis U_2

4.1 Bit fixing substitutions: substituting variables by constants

We start with a well-known case analysis of a $3n - 3$ lower bound for the parity function over U_2 due to Schnorr [53]. Using this case analysis we reprove the bounds given recently by Chen and Kabanets [13] in our framework. The analysis is basically the same though the measure is slightly different. We provide these results mostly as a simple illustration of using the framework.

▶ **Lemma 7.** *Splitting$(U_2, \{x_i \leftarrow c\}, s + \alpha i) \preceq \{(\alpha, 2\alpha), (3 + \alpha, 3 + \alpha), (2 + \alpha, 4 + \alpha)\}$.*

▶ **Corollary 8.** *1. For any $\epsilon > 0$ there exists $\delta = \delta(\epsilon) > 0$ such that #SAT for circuits over U_2 of size at most $(3-\epsilon)n$ can be solved in time $(2-\delta)^n$.*

2. $C_{U_2}(x_1 \oplus \cdots \oplus x_n \oplus c) \geq 3n - 6$.

3. $C_{U_2}\left(x_1 \oplus \cdots \oplus x_n \oplus c, \exp\left(\frac{-(t-9)^2}{18(n-1)}\right)\right) \geq 3n - t$. *This, in particular, implies that* $\mathrm{Cor}(x_1 \oplus \cdots \oplus x_n \oplus c, C)$ *is negligible for any circuit C of size $3n - \omega(\sqrt{n}\log n)$.*

4.2 Projections: substituting variables by constants and other variables

In this subsection, we prove new bounds for the basis U_2.

▶ **Lemma 9.** *For $0 \leq \sigma \leq 1/2$,*

$$\textit{Splitting}(U_2, \{x_i \leftarrow c, x_i \leftarrow x_j \oplus c\}, s + \alpha i - \sigma i_1) \preceq \{(\alpha, 2\alpha), (2\alpha, 2\alpha, 2\alpha, 3\alpha), (3+\alpha+\sigma, 3+\alpha), (4+\alpha+\sigma, 2+\alpha)\}.$$

▶ **Corollary 10.** *1. For any $\epsilon > 0$ there exists $\delta = \delta(\epsilon) > 0$ such that #SAT for circuits over U_2 of size at most $(3.25-\epsilon)n$ can be solved in time $(2-\delta)^n$.*

2. Let $f \in B_n$ be an $\left(n, r(n) = n - \log^{O(1)}(n)\right)$-projections disperser from [40]. Then $C_{U_2}(f) \geq 3.5n - \log^{O(1)}(n)$.

3. Let $f \in B_n$ be an $\left(n, r(n) = n - \sqrt{n}, \varepsilon(n) = 2^{-n^{\Omega(1)}}\right)$-projections extractor from [48]. Then $C_{U_2}(f, \delta) \geq 3.25n - t$, where $\delta = 2^{-n^{\Omega(1)}} + \exp\left(\frac{-(t-10.25\sqrt{n})^2}{190.125(n-\sqrt{n})}\right)$. This, in particular, implies that $\mathrm{Cor}(f, C)$ is negligible for any circuit C of size $3.25n - \omega(\sqrt{n}\log n)$.

5 Bounds for the basis B_2

5.1 Affine substitutions: substituting variables by linear sums of other variables

Here, we again start by reproving the bounds for B_2 by Chen and Kabanets [13] by using the case analysis by Demenkov and Kulikov [20].

▶ **Lemma 11.** $\textit{Splitting}(B_2, \{x_i \leftarrow \oplus_{j \in J} x_j \oplus c\}, \mu = s + \alpha i) \preceq \{(\alpha, 2\alpha), (2+\alpha, 3+\alpha)\}$.

▶ **Corollary 12.** *1. For any $\epsilon > 0$ there exists $\delta = \delta(\epsilon) > 0$ such that #SAT for circuits over B_2 of size at most $(2.5-\epsilon)n$ can be solved in time $(2-\delta)^n$.*

2. Let $f \in B_n$ be an $\left(n, r(n) = n - \log^{O(1)}(n)\right)$-affine disperser from [40]. Then $C_{B_2}(f) \geq 3n - \log^{O(1)}(n)$.

3. Let $f \in B_n$ be an $\left(n, r(n) = n - O(n/\log\log n), \varepsilon(n) = 2^{-n^{\Omega(1)}}\right)$-affine extractor from [39]. Then $C_{B_2}(f, \delta) \geq 2.5n - t$, where $\delta = 2^{-n^{\Omega(1)}} + \exp\left(\frac{-(t-O(n/\log\log n))^2}{O(n)}\right)$. This, in particular, implies that $\mathrm{Cor}(f, C)$ is negligible for any circuit C of size $2.5n - \omega(n/\log\log n)$.

5.2 Quadratic substitutions: substituting variables by degree 2 polynomials of other variables

▶ **Lemma 13.** *For $0 \le \sigma \le 1/5$,*

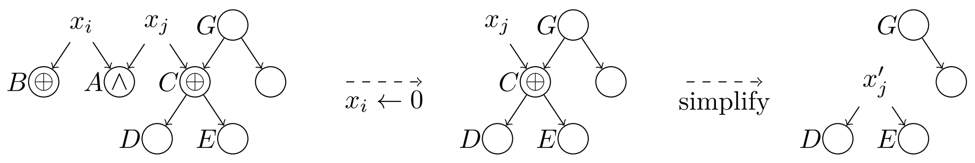
$$\text{Splitting}(B_2, \{x_i \leftarrow p\colon \deg(p) \le 2\}, s + \alpha i - \sigma i_1) \preceq \{(\alpha, 2\alpha), (2\alpha, 2\alpha, 2\alpha, 3\alpha), (3+\alpha-2\sigma, 3+\alpha-2\sigma), (3+\alpha+\sigma, 2+\alpha)\}\,.$$

▶ **Corollary 14.** *1. For any $\epsilon > 0$ there exists $\delta = \delta(\epsilon) > 0$ such that #SAT for circuits over B_2 of size at most $(2.6 - \epsilon)n$ can be solved in time $(2-\delta)^n$.*
2. Let $f \in B_n$ be an $(n, r(n) = n - o(n))$-quadratic disperser. Then $C_{B_2}(f) \ge 3n - o(n)$.
3. Let $f \in B_n$ be an $\left(n, r(n) = n - o(n), \varepsilon(n) = 2^{-\omega(\log n)}\right)$-quadratic extractor. Then $C_{B_2}(f, \delta) \ge 2.6n - t$, where $\delta = 2^{-n^{\Omega(1)}} + \exp\left(\frac{-(t-7.8(n-r(n)))^2}{121.68r(n)}\right)$. This, in particular, implies that $\operatorname{Cor}(f, C)$ is negligible for any circuit C of size $2.6n - g(n)$ for some $g(n) = o(n)$.

▶ Remark 1. Note that it is an open problem to find an explicit construction of quadratic disperser or extractor over $\mathbb{F}_2$ with $r = n - o(n)$. Any disperser for a slightly more general definition of quadratic varieties would also imply a new worst case lower bound [26].

▶ Remark 2. Note that the upper bound for #SAT can be improved using the following "forbidden trick", that is, a simplification rule that reduces the size of a circuit without changing the number of its satisfying assignments, but changes the function computed by the circuit.

In the proof of Lemma 13 set $\sigma = 0$ (that is, do not account for 1-variables). The set of splitting vectors then turn into By inspecting all the cases, we see that the splitting vector $(3 + \alpha, 2 + \alpha)$ only appears in one case. We can handle this case differently: split on x_i. When A is trivialized, x_j becomes a 1-variable feeding an xor-gate. It is not difficult to show that by replacing this gate with a new variable x'_j one gets a circuit with the same number of satisfying assignments.



This additional trick gives us the following set of splitting vectors: $\{(\alpha, 2\alpha), (2\alpha, 2\alpha, 2\alpha, 3\alpha), (3+\alpha, 3+\alpha), (4+\alpha, 2+\alpha)\}$. These splitting numbers give an algorithm solving #SAT in $(2-\delta(\epsilon))^n$ for B_2-circuits of size at most $(3 - \epsilon)n$ for $\epsilon > 0$.

Note that such a simplification rule does not fit into our framework since it *changes the function computed by a circuit.* It would be interesting to adjust the framework to allow such kind of simplifications (probably, by incorporating some new parameter to the measure).

6 Open problems

There are three natural questions left open in this paper.

1. Prove that a superlinear circuit lower bound in this framework violates the Exponential Time Hypothesis.

2. Give an explicit construction of quadratic dispersers (see Remark 1).
3. Adjust the framework to allow using natural simplification rules like replacing an xor gate fed by a 1-variable for both upper bounds for #SAT and lower bounds for circuit size (see Remark 2).

Abstract

Although a simple counting argument shows the existence of Boolean functions of exponential circuit complexity, proving superlinear circuit lower bounds for *explicit* functions seems to be out of reach of the current techniques. There has been a (very slow) progress in proving linear lower bounds with the latest record of $3\frac{1}{86}n - o(n)$. All known lower bounds are based on the so-called gate elimination technique. A typical gate elimination argument shows that it is possible to eliminate several gates from an optimal circuit by making one or several substitutions to the input variables and repeats this inductively. In this note we prove that this method cannot achieve linear bounds of cn beyond a certain constant c, where c depends only on the number of substitutions made at a single step of the induction.

1 Introduction

One of the most important and at the same time most difficult questions in theoretical computer science is proving circuit lower bounds. A binary Boolean circuit is a directed acyclic graph with nodes of in-degree either 0 or 2. Nodes of in-degree 0 are called inputs and are labeled by variables $x_1, \ldots, x_n$. Nodes of in-degree 2 are called gates and are labeled by binary Boolean functions. One of the nodes is additionally labeled as the output of the circuit. The output gate computes a Boolean function $\{0,1\}^n \to \{0,1\}$ in a natural way. The size of a circuit C is defined as the number of gates in C and is denoted by $\texttt{gates}(C)$. By $\texttt{inputs}(C)$ we denote the number of inputs of C. A circuit complexity measure μ is a function assigning each circuit a non-negative real number. In particular, `gates` and `inputs` are circuit complexity measures.

By B_n we denote the set of all Boolean functions $f\colon \{0,1\}^n \to \{0,1\}$. For a circuit complexity measure μ and a function $f \in B_n$, by $\mu(f)$ we denote the minimum value of $\mu(C)$ over all circuits C computing f. For example, $\texttt{gates}(f)$ is the miniumum size of a circuit computing f.

* This research is partially supported by NSF grant 1319051.

By comparing the number of small size circuits with the total number 2^{2^n} of Boolean functions of n variables, one concludes that almost all such functions have circuit size at least $\Omega(\frac{2^n}{n})$. This was shown by Shannon in 1949 [30]. However we still do not have an example of a function from NP that requires circuits of superlinear size. The currently strongest known lower bound is $(3 + \frac{1}{86})n - o(n)$ [11].

The lack of strong lower bounds is a consequence of the lack of methods for proving lower bounds for general circuits. Practically, the only known method for proving lower bounds is the gate elimination method. We illustrate this method with a simple example. Consider the function $\mathrm{MOD}^n_{3,r}\colon \{0,1\}^n \to \{0,1\}$ which outputs 1 if and only if the sum of n input bits is congruent to r modulo 3. One can prove that $\texttt{gates}(\mathrm{MOD}^n_{3,r}) \geq 2n - 4$ for any $r \in \{0,1,2\}$ by induction on n. The base case $n \leq 2$ clearly holds. Assume that $n \geq 3$ and consider an optimal circuit C computing $\mathrm{MOD}^n_{3,r}$ and its topologically first (with respect to some topological ordering) gate G. This gate is fed by two different variables x_i and x_j (if they were the same variable, the circuit would not be optimal). A crucial observation is that it cannot be the case that the out-degrees of both x_i and x_j are equal to 1. Indeed, in this case the whole circuit would depend on x_i and x_j through the gate G only. In particular, the four ways of fixing the values of x_i and x_j would give at most two different subfunctions (corresponding to $G = 0$ and $G = 1$), while $\mathrm{MOD}^n_{3,r}$ has three such different subfunctions: $\mathrm{MOD}^{n-2}_{3,0}$, $\mathrm{MOD}^{n-2}_{3,1}$, and $\mathrm{MOD}^{n-2}_{3,2}$. Assume, without loss of generality, that x_i has out-degree at least 2. We then substitute $x_i \leftarrow 0$, eliminate the gates fed by x_i from the circuit and proceed by induction. The eliminated gates are those fed by x_i. After the substitution, each such gate computes either a constant or a unary function of the other input of the gate, so can be eliminated. The resulting function computes $\mathrm{MOD}^{n-1}_{3,r}$. Thus we get by induction: $\texttt{gates}(\mathrm{MOD}^n_{3,r}) \geq \texttt{gates}(\mathrm{MOD}^{n-1}_{3,r}) + 2 \geq (2(n-1) - 4) + 2 = 2n - 4$. This proof was given by Schnorr in 1984 [29]. In fact, it works for a wider class of functions $Q^n_{2,3}$ containing functions that have at least three different subfunctions with respect to any two variables.

This example reveals the main idea of the gate elimination process: a lower bound is proved inductively by finding at each step an appropriate substitution that eliminates many gates from the given circuit. At the same time, using just bit-fixing substitutions is not enough for proving even stronger than $2n$ lower bounds: the class $Q^n_{2,3}$ contains, in particular, a function THR^n_2 that outputs 1 iff $\sum_{i=1}^n x_i \geq 2$ whose circuit complexity is known to be at most $2n + o(n)$ [10] (see also Theorem 2.3 in [35]). For this reason, known proofs of stronger lower bounds use various additional tricks.

- One can use amortized analysis of the number of eliminated gates. For example, one can show that at each step one can either find a substitution that eliminates 3 gates *or* a pair of consecutive substitutions, the first one eliminating 2 gates and the next one eliminating 4 gates.
- They also substitute variables not just by constants but by affine functions, quadratic functions, and even arbitrary functions of other variables.
- In order to amortize for steps that eliminate too few gates, they also use more intricate complexity measures that combine the number of gates with the number of variables or other quantities.

We give an overview of known lower bounds and used tricks in Section 2.

One can guess that the gate elimination method changes only the top of a circuit in few places and thus cannot eliminate many gates. In general, this intuition fails (it is easy to present examples where a single substitution greatly simplifies a function, in particular, every substitution to a function of the highest possible complexity $2^n/n$ (see Theorem 2.1

and below in [35]) lowers the complexity of this function almost twice as for a function of $n-1$ variables it cannot exceed $2^{n-1}/(n-1)+o(2^{n-1}/(n-1))$. However, in this paper we manage to make this intuition work for specially designed functions that compose gadgets satisfying certain rather general properties with arbitrary base functions. We show that certain formalizations of the gate elimination method cannot prove superlinear lower bounds. We prove that one cannot reduce the complexity of the designed functions by more than a constant using any constant number of substitutions of any type (that is, we allow to substitute variables by arbitrary functions). The complexity of a function may be counted as any complexity measure (i.e., a nonnegative function of a circuit) varying from the number of gates to any subadditive function. For recently popular measures that combine the number of gates with the number of inputs we prove a stronger result (namely, one cannot prove lower bounds beyond cn for a certain specific constant c; this constant may depend on the number m of consecutive substitutions made in one step of the induction but does not depend on the substitutions themselves, $m = 1$ or 2 in modern proofs).

The paper is organized as follows. In Section 2 we list known proofs based on gate elimination, we discuss their differences and limits. Section 3 presents several examples that lead us to the main questions of this work. This section contains main results of the paper: provable limits of the gate elimination method for various complexity measures. Section 4 contains a brief overview of the known barriers for proving circuit lower bounds. Finally, Section 5 concludes the work with open questions.

2 Known Lower Bounds Proofs

Improving Schnorr's $2n$ lower bound proof mentioned above is already a non-trivial task. It can be the case that all variables in the given circuit feed two parity gates. In this case, substituting any variable by any constant eliminates just two gates from this circuit. In 1977, Stockmeyer [31] used the following clever trick to prove a $2.5n-\Theta(1)$ lower bound for many symmetric functions including all MOD_m^n functions for constant $m \geq 3$. The idea is to eliminate five gates by *two* consecutive substitutions. This time, instead of substituting $x_i \leftarrow c$ where $c \in \{0,1\}$ we substitute $x_i \leftarrow f, x_j \leftarrow f \oplus 1$ where f is an *arbitrary function* that does not depend on x_i and x_j. One should be careful with such substitutions as they potentially might produce a subfunction outside of the class of functions for which we are currently proving a lower bound by induction. At the same time, one can see that, for example, $\mathrm{MOD}_{3,0}^n$ function turns into $\mathrm{MOD}_{3,2}^{n-2}$ function under the substitution $x_i \leftarrow f, x_j \leftarrow f \oplus 1$. Indeed, this substitution just forces the sum of x_i and x_j to be equal to 1 (both over integers and over the field of size two).

In 1984, Blum [5], following the work by Paul [25], proved a $3n-o(n)$ lower bound for an artificially constructed Boolean function of $n+3\log n+3$ variables. The input of this function consists of n variables $X = \{x_1,\ldots,x_n\}$ and $3\log n+3$ variables A. The following "universality" property of this function is essential for Blum's proof: for any two variables $x_i, x_j \in X$ one can assign constants to variables from A to turn the output of the function to be equal to both $x_i \wedge x_j$ and $x_i \oplus x_j$. Blum first applies the standard gate elimination procedure to variables from X using a carefully chosen induction hypothesis that states a circuit size lower bound in terms of the number of variables from X that are still "alive": if there is a substitution $x_i \leftarrow f$ that eliminates at least three gates, perform this substitution and proceed inductively. Note that the used function allows to substitute variables from X by arbitrary functions, but at the same time one is allowed to substitute variables from X, but not from A. In the remaining case, Blum counts the number of gates of out-degree at least 2: he shows that due to the special properties of the function, any circuit computing it must contain many such gates. This gives a lower bound on the size of a circuit.

In 2011, Demenkov and Kulikov [7] presented a different proof of essentially the same $3n - o(n)$ lower bound for a different function. The function they use is an affine disperser for dimension $d = o(n)$, which is by definition non-constant on any affine subspace of dimension at least d. This property allows to make at least $n - o(n)$ affine substitutions (that is, substitutions of the form $x_i \leftarrow \bigoplus_{j \in J} x_j \oplus c$ where $i \notin J \subseteq [n]$ and $c \in \{0, 1\}$) before the function trivializes. The proof also uses a non-standard circuit complexity measure: for a circuit C, $\mu(C) = \texttt{gates}(C) + \texttt{inputs}(C)$. This trick is used to amortize the case when by substituting one variable one also removes the dependence on another variable. One shows that for any circuit there is a substitution that reduces μ by at least 4 (or makes the whole circuit a constant). This implies, by induction, that for any circuit C computing an affine disperser for dimension $o(n)$,

$$\texttt{gates}(C) + \texttt{inputs}(C) \geq 4(n - o(n)), \tag{1}$$

which in turn implies that $\texttt{gates}(C) \geq 3n - o(n)$. To find an appropriate affine substitution, one considers the topologically first gate A that computes a non-linear binary operation. If A is fed by two variables x_i and x_j of out-degree 1, we substitute $x_i \leftarrow c$ to make A constant. This eliminates A and its successor from the circuit as well as the dependence on both x_i and x_j. Hence both $\texttt{gates}$ and $\texttt{inputs}$ are reduced by at least 2, and μ is reduced by at least 4. If, say, x_i has out-degree at least 2, we just substitute x_i by the constant that makes A constant: this eliminates the gates fed by x_i and all successors of A (at least three gates in total) and the dependence on x_i, hence μ is reduced by 4 again. In the remaining case, one of the inputs to A is a gate computing an affine function $\bigoplus_{j \in J} x_j \oplus c$. We make it constant by substituting $x_i \leftarrow \bigoplus_{j \in J \setminus \{i\}} x_j \oplus c'$. This eliminates this gate, the gate A, and the successors of A. Thus, μ is reduced by at least 4 again.

Find et al. [11] pushed the lower bound $3n - o(n)$ for affine dispersers further to $(3 + \frac{1}{86})n - o(n)$ by using several new tricks. They generalize the computational model to allow cycles in circuits, use quadratic substitutions (that are turned into affine substitutions in the end of the gate elimination process), and use a carefully chosen circuit complexity measure which besides the number of gates and inputs also depends on the number of certain local bottleneck configurations and the number of quadratic substitutions.

The first explicit construction of an affine disperser for sublinear dimension ($d = o(n)$) was presented relatively recently by Ben-Sasson and Kopparty [4]. While such constructions of higher degree dispersers for sublinear dimension are not yet known, these dispersers do exist, and a lower bound of $3.1n$ has been shown for them in [13] using the circuit complexity measure $\mu_\alpha(C) = \texttt{gates}(C) + \alpha \cdot \texttt{inputs}(C)$ ($\alpha > 0$ is a constant) and quadratic substitutions.

We summarize the discussed lower bounds proofs in the table below.

Bound	Class of functions	Measure	Substitutions
$2n$ [29]	$Q^n_{2,3}$	$\texttt{gates}$	$x_i \leftarrow c$
$2.5n$ [31]	symmetric	$\texttt{gates}$	$x_i \leftarrow c$, $\{x_i \leftarrow f, x_j \leftarrow f \oplus 1\}$
$3n$ [5]	artificial	$\texttt{gates}$	arbitrary: $x_i \leftarrow f$
$3n$ [7]	affine dispersers	$\texttt{gates} + \texttt{inputs}$	linear: $x_i \leftarrow \bigoplus_{j \in J} x_j \oplus c$
$3.01n$ [11]	affine dispersers	$\texttt{gates} + \alpha\texttt{inputs} + \cdots$	quadratic: $x_i \leftarrow f$, deg ≤ 2
$3.1n$ [13]	quadratic dispersers	$\texttt{gates} + \alpha\texttt{inputs}$	quadratic: $x_i \leftarrow f$, deg ≤ 2

It is also interesting to note that there is a trivial limitation for the first three proofs in the table above: the corresponding classes of functions contain functions of linear circuit complexity. The class $Q^n_{2,3}$ contains the function THR^n_2 (that outputs 1 iff the sum of n input bits is at least 2) of circuit size $2n + o(n)$. The class of symmetric functions used by Stockmeyer contains the function MOD^n_4 whose circuit size is at most $2.5n + \Theta(1)$. The circuit size of Blum's function is upper bounded by $6n + o(n)$. At the same time it is not known whether there are affine dispersers of sublinear dimension that can be computed by linear size circuits.

3 Limits of Gate Elimination

3.1 Notation

Let $X = \{x_1, \dots, x_n\}$ be a set of Boolean variables. A *substitution* ρ of a set of variables $R \subseteq X$ is a set of $|R|$ restrictions of the form

$$r_i = f_i(x_1, \dots, x_n),$$

one restriction for each variable $r_i \in R$, where f_i depends only on variables from $X \setminus R$. The degree of a substitution is the maximum degree of f_i's represented as Boolean polynomials. The size of a substitution is $|R|$. Substitutions of size m are called m-substitutions.

Given an m-substitution ρ and a function f, one can naturally define a new function $f|_\rho$ that has m fewer arguments than f.

A function f *depends* on a variable x if there is a substitution ρ of constants to all other variables such that $f|_\rho(0) \neq f|_\rho(1)$.

As we saw in Section 2, gate elimination proofs sometimes track sophisticated *complexity measure* μ rather than just number of gates, for example, the measure $\mu(f) = \mathtt{gates}(f) + \alpha \cdot \mathtt{inputs}(f)$ for a constant α.

A gate elimination argument uses a certain nonnegative complexity measure μ, a family of substitutions $\mathcal{S}$, a family of functions $\mathcal{F}$, a function $\mathtt{gain}\colon \mathbb{N} \to \mathbb{R}$, and a certain predicate $\mathtt{stop}$, and includes proofs of the following statements:

1. (Measure usefulness.) If $\mu(f)$ is large, then $\mathtt{gates}(f)$ is large.
2. (Invariance.) For every $f \in \mathcal{F}$ and $\rho \in \mathcal{S}$, either $f|_\rho \in \mathcal{F}$ or $\mathtt{stop}(f|_\rho)$.
3. (Induction step.) For every $f \in \mathcal{F}$ with $\mathtt{inputs}(f) = n$, there is a substitution $\rho \in \mathcal{S}$ such that $\mu(f|_\rho) \le \mu(f) - \mathtt{gain}(n)$. (In known proofs, $\mathtt{gain}(n)$ is constant.)

The family must contain functions f such that $\mathtt{stop}(f|_{\rho_1,\dots,\rho_s})$ is not reached for sufficiently many substitutions from $\mathcal{S}$ (for example, for $s = 0.999 \cdot \mathtt{inputs}(f)$ substitutions).

In what follows, we prove that every gate elimination argument fails to prove a strong lower bound, for many functions of (virtually) arbitrarily large complexity.

3.2 Introductory Example

We start by providing an elementary construction of functions that are resistant with respect to any constant number of arbitrary substitutions, i.e., such substitutions eliminate only a constant number of gates. In the next sections, we generalize this construction to capture other complexity measures.

Consider a function $f\colon \{0,1\}^n \to \{0,1\}$ and let $f \diamond \mathrm{MAJ}_3$ be a function of $3n$ variables resulting from f by replacing each of its input variables x_i by the majority function of three fresh variables x_{i1}, x_{i2}, x_{i3}:

$$(f \diamond \mathrm{MAJ}_3)(x_{11}, x_{12}, \dots, x_{n3}) = f(\mathrm{MAJ}_3(x_{11}, x_{12}, x_{13}), \dots, \mathrm{MAJ}_3(x_{n1}, x_{n2}, x_{n3}))\,,$$

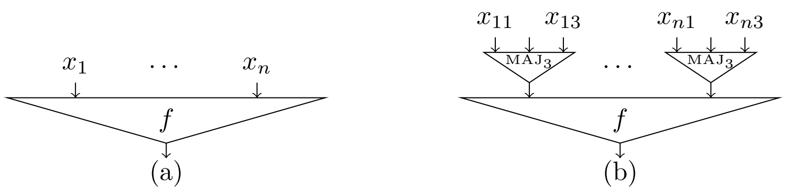

Figure 1 (a) A circuit for f. (b) A circuit for $f \diamond \mathrm{MAJ}_3$.

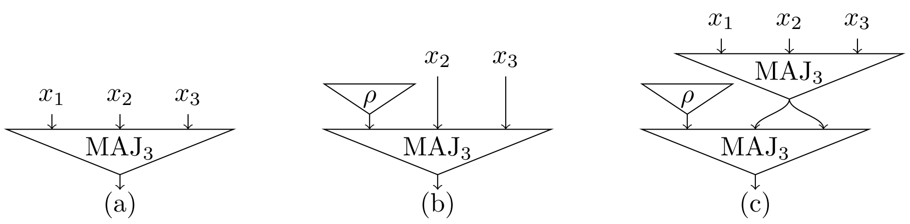

Figure 2 (a) A circuit computing the majority of three bits x_1, x_2, x_3. (b) A circuit resulting from substitution $x_1 \leftarrow \rho$. (c) By adding another gadget to a circuit with x_1 substituted, we force it to compute the majority of x_1, x_2, x_3.

see Fig. 1. Consider a circuit C of the smallest size computing $f \diamond \mathrm{MAJ}_3$. We claim that no substitution $x_{ij} \leftarrow \rho$, where ρ is any function of all the remaining variables, can remove from C more than 5 gates: $\texttt{gates}(C) - \texttt{gates}(C|_{x_{ij} \leftarrow \rho}) \leq 5$. We are going to prove this by showing that one can attach a gadget of size 5 to the circuit $C|_{x_{ij} \leftarrow \rho}$ and obtain a circuit that computes f. This is explained in Fig. 2. Formally, assume, without loss of generality, that the substituted variable is x_{11}. We then take a circuit C' computing $f|_{x_{11} \leftarrow \rho}$ and use the value of a gadget computing $\mathrm{MAJ}_3(x_{11}, x_{12}, x_{13})$ instead of x_{12} and x_{13}. This way we suppress the effect of the substitution $x_{11} \leftarrow \rho$, and the resulting circuit C'' computes the initial function $f \diamond \mathrm{MAJ}_3$. Since the majority of three bits can be computed in five gates, we get:

$$\texttt{gates}(C) \leq \texttt{gates}(C'') \leq \texttt{gates}(C|_{x_{11} \leftarrow \rho}) + 5\,.$$

This trick can be extended from 1-substitution to m-substitutions in a natural way. For this, we use gadgets computing the majority of $2m+1$ bits instead of just three bits. We can then suppress the effect of substituting any m variables by feeding the values to $m+1$ of the remaining variables. Taking into account the fact that the majority of $2m+1$ bits can be computed by a circuit of size $4.5(2m+1)$ [8], we get the following result.

▶ **Lemma 1.** *For any $m > 0$, for any function h of n inputs, there exists a function $f = h \diamond \mathrm{MAJ}_{2m+1}$ of $n(2m+1)$ variables, such that*

- *Circuit complexity of f is close to that of h: $\texttt{gates}(h) \leq \texttt{gates}(f) \leq \texttt{gates}(h) + 4.5(2m+1)n$,*
- *For any m-substitution ρ, $\texttt{gates}(f) - \texttt{gates}(f|_\rho) \leq 4.5(2m+1)m$.*

▶ Remark. Note that from the Circuit Hierarchy Theorem (see, e.g., [18]), one can find h of virtually any circuit complexity from n to $2^n/n$.

3.3 Subadditive Measures

In this section we generalize the result of Lemma 1 to *arbitrary* subadditive measures. A function $\mu\colon B_n \to \mathbf{R}$ is called a *subadditive complexity measure*, if for all functions f and g, $\mu(h) \le \mu(f) + \mu(g)$, where $h(\bar{x}, \bar{y}) = f(g(\bar{x}), \ldots, g(\bar{x}), \bar{y})$. That is, if h can be computed by application some function g to some of the the inputs, and then evaluating f, then the measure of h must not exceed the sum of measures of f and g. Clearly, the measures $\mu(f) = \texttt{gates}(f)$ and $\mu_\alpha(f) = \texttt{gates}(f) + \alpha \cdot \texttt{inputs}(f)$ are subadditive, and so are many other natural measures.

Let $f \in B_n$ and $g \in B_k$. Then by $h = f \diamond g$ we denote the function of nk variables resulting from f by replacing each of its input variables by h applied to k fresh variables.

Our main construction is such a composition of a function f (typically, of large circuit complexity) and a gadget g that is chosen to satisfy certain combinatorial properties. Note that since we show a limitation of the proof method rather than a proof of a lower bound, we do not necessarily need to present explicit functions.

In this section we use gadgets that satisfy the following requirement: For every set of variables Y of size m, we can force the value of the gadget to be 0 and 1 by assigning constants only to the remaining variables.

▶ **Definition 2** (weakly m-stable function)**.** A function $g(X)$ is weakly m-stable if, for every $Y \subseteq X$ of size $|Y| \le m$, there exist two assignments $\tau_0, \tau_1\colon X \setminus Y \to \{0,1\}$ to the remaining variables, such that $g|_{\tau_0}(Y) \equiv 0$ and $g|_{\tau_1}(Y) \equiv 1$. That is, after the assignment τ_0 (τ_1), the function does not depend on the remaining variables Y.

It is easy to see that MAJ_{2m+1} is a weakly m-stable function. In Lemma 6 we show that almost all Boolean functions satisfy an even stronger requirement of stability.

▶ **Theorem 3.** *Let μ be a subadditive measure, f be a Boolean function, g be a weakly m-stable function, and $h = f \diamond g$. Then for every m-substitution ρ, $\mu(h) - \mu(h|_\rho) \le m \cdot \mu(g)$.*

Proof. Similarly to Lemma 1, we use a circuit H for the function $h|_\rho$ to construct a circuit C for h. Let

$$h(x_{11}, x_{12}, \ldots, x_{nk}) = f(g(x_{11}, \ldots, x_{1k}), \ldots, g(x_{n1}, \ldots, x_{nk})).$$

Let us focus on the variables $x_{11}, \ldots, x_{1k}$. Assume, without loss of generality, that the variables $x_{11}, \ldots, x_{1r}$ are substituted by ρ. Since ρ is an m-substitution, $r \le m$. From the definition of weakly m-stable function, there exist substitutions τ_0 and τ_1 to the variables $x_{1r+1}, \ldots, x_{1k}$, such that $g|_{\rho\tau_0} = 0$ and $g|_{\rho\tau_1} = 1$. We take the circuit H and add a circuit computing $g(x_{11}, \ldots, x_{1k})$. Now, for every variable $x \in \{x_{1r+1}, \ldots, x_{1k}\}$ in the circuit H, we wire $g(x_{11}, \ldots, x_{1k}) \oplus \tau_0(x)$ instead of x if $\tau_0(x) \ne \tau_1(x)$, and wire $\tau_0(x)$ otherwise. That is, we set $x_{1r+1}, \ldots, x_{1k}$ in such a way that $g|_\rho(x_{1r+1}, \ldots, x_{1k}) = b = g(x_{11}, \ldots, x_{1k})$. Thus, we added one instance of a circuit computing the gadget g and "repaired" $g(x_{11}, \ldots, x_{1k})$.

Now we repeat this procedure for each of the n inner functions g that have at least one variable substituted by ρ. Since ρ is an m-substitution, there are at most m gadgets we need to repair. Thus, we can compute h using the circuit H and m instances of a circuit computing g. From subadditivity of μ, $\mu(h) - \mu(h|_\rho) \le m \cdot \mu(g)$. ◀

3.4 Measures that count inputs

The results of the previous section prove that no subadditive complexity measure can prove a lower bound of more than $n\mu(g)$, where the gadget g depends only on m. For $g = \mathrm{MAJ}_{2m+1}$

and measure $\mu(g) = \texttt{gates}(g)$ Lemma 1 gives $4.5(2m+1)n$ as a specific linear bound barrier that gate elimination cannot overcome. However, since $\mu(g)$ depends on the measure μ, it does not exclude a possibility that there is a sequence of complexity measures allowing to prove better and better bounds. One such natural sequence is based on the circuit measure $\mu_\alpha(C) = \texttt{gates}(C) + \alpha \cdot \texttt{inputs}(C)$ for a constant $\alpha \geq 0$ (used, for example, in [7, 13]). Indeed, for growing α, the method of the previous section gives growing bounds, and if one proves that it is possible to eliminate, say, $c_1 > 0$ gates and $c_2 > 1$ variables per substitution, then after $n - o(n)$ substitutions that would give us $\mu(C) \geq (n - o(n))(c_1 + \alpha c_2) = n(c_1 + \alpha c_2) - o(n)$. This would imply that $\texttt{gates}(C) \geq n(c_1 + \alpha(c_2 - 1)) - o(n)$, an arbitrary linear lower bound. Note that does not require a sequence of gate elimination proofs, just a single proof and a sequence of complexity measures.

In this section in order to show that such a measure cannot prove growing linear bounds, we construct a function f such that any m-substitution reduces the measure by a constant number c_m of gates and at most m inputs. This prevents anyone from proving a better than $c_m n$ bound with it.

▶ **Definition 4** (m-stable function)**.** A function $g(X)$ is m-stable if, for every $Y \subseteq X$ of size $|Y| \leq m+1$ and every $y \in Y$, there exists an assignment $\tau \colon X \setminus Y \to \{0,1\}$ to the remaining variables such that $g|_\tau(Y) \equiv y$ or $g|_\tau(Y) \equiv \neg y$. That is, after the assignment τ, the function depends only on the variable y.

It is now easy to see that every m-stable function is a weakly m-stable function.

▶ **Theorem 5.** *Let f be a Boolean function, g be an m-stable function, and $h = f \diamond g$. Then for every m-substitution ρ, $\mu_\alpha(h) - \mu_\alpha(h|_\rho) \leq m \cdot (\texttt{gates}(g) + \alpha)$.*

Proof. Since g is m-stable, Theorem 3 implies that $\texttt{gates}(h) - \texttt{gates}(h|_\rho) \leq m \cdot \texttt{gates}(g)$. It remains to show that $\texttt{inputs}(h) - \texttt{inputs}(h|_\rho) \leq m$. Thus, it suffices to prove that if f depends on x_i and ρ does not substitute $x_{i,j}$, then $h|_\rho$ depends on $x_{i,j}$. Let

$$h(x_{11}, x_{12}, \ldots, x_{nk}) = f(g(x_{11}, \ldots, x_{1k}), \ldots, g(x_{n1}, \ldots, x_{nk})).$$

Assume f depends on its first input. Since g is not constant, there exists a substitution η to the variables $\{x_{21}, \ldots, x_{2k}, \ldots, x_{n1}, \ldots, x_{nk}\}$ such that $h|_\eta(x_{11}, \ldots, x_{1k})$ is not constant.

Let us consider the variables $x_{11}, \ldots, x_{1k}$. Assume, without loss of generality, that the variables $x_{11}, \ldots, x_{1r}$ are substituted by ρ. Since ρ is an m-substitution, $r \leq m$. Now we want to show that for every $j > r$, $h|_\rho$ depends on x_{1j}. From the definition of an m-stable function, there exists a substitution τ to $\{x_{1,r+1}, \ldots, x_{1k}\} \setminus \{x_{ij}\}$ such that $g|_{\rho\tau}(x_{1j})$ is not constant ($g|_{\rho\tau} = x_{1j}$ or $g|_{\rho\tau} = \neg x_{1j}$). Now, we compose the substitutions η and τ, which gives us that $h|_{\rho\tau\eta}(x_{1j})$ is not constant. This implies that the function $h|_\rho$ depends on the variable x_{1j}. ◀

Now we show that for a fixed m, almost all Boolean functions are m-stable.

▶ **Lemma 6.** *For $m \geq 1$ and $k = \Omega(2^m)$, a random $f \in B_k$ is m-stable almost surely.*

Proof. Let X denote the set of k input variables. Let us fix a set Y, $|Y| \leq m+1$, and a variable $y \in Y$. Now let us count the number of functions that do not satisfy the definition of m-stable function for this fixed choice of Y and y. Thus, for each assignment to the variables from $X \setminus Y$, the function must not be y nor $\neg y$. There are 2^{k-m-1} assignments to the variables $X \setminus Y$, and at most $(2^{2^{m+1}} - 2)$ functions of $(m+1)$ variables that are not y nor $\neg y$. Thus, there are at most $(2^{2^{m+1}} - 2)^{2^{k-m-1}}$ functions that do not satisfy the definition of

m-stable function for this fixed choice of Y and y. Now, since there are $\binom{k}{m+1} \cdot (m+1)$ ways to choose Y and y, the union bound implies that a random function is not m-stable with probability at most

$$\frac{\binom{k}{m+1}(m+1)(2^{2^{m+1}}-2)^{2^{k-m-1}}}{2^{2^k}} \le k^{m+2} \cdot \left(\frac{2^{2^{m+1}}-2}{2^{2^{m+1}}}\right)^{2^{k-m-1}} \le$$
$$\exp\left((m+2)\ln k - 2^{k-m-2^{m+1}}\right) = o(1)$$

for $k = \Omega(2^m)$. ◀

Lemma 6, together with Theorem 5, provides a class of functions such that any m-substitution decreases the measure μ_α by at most a fixed constant (which may depend on m but not on α).

▶ **Corollary 7.** *For any $m > 0$, there exists $k > 0$ and a function g of k inputs, such that for any function h of n inputs, the function $f = h \diamond g$ of nk inputs satisfies:*

- *Circuit complexity of f is close to that of h: $\mathtt{gates}(h) \le \mathtt{gates}(f) \le \mathtt{gates}(h) + \mathtt{gates}(g) \cdot n$,*
- *For any m-substitution ρ and real $\alpha > 0$, $\mu_\alpha(f) - \mu_\alpha(f|_\rho) \le \mathtt{gates}(g) \cdot m + \alpha m$.*

Thus, for many functions gate elimination with m-substitutions and μ_α measures can prove only $O(n)$ lower bounds.

▶ Remark. Although Lemma 6 proves the existence of m-stable functions, their circuit complexities might be large (though constant). To optimize these constants, one can use explicit constructions of m-stable functions. For example, for $m = 1$ one can use an error correcting code $C\colon \{1, \dots, 7\} \to \{0,1\}^8$ with distance 4. Let us define a function $g_C\colon \{0,1\}^8 \to \{0,1\}$ as follows:

1. $g_C(C(i)) = 0$ and $g_C(C(i)^{\oplus i}) = 0$ for all i, where $x^{\oplus i}$ inverts the i-th coordinate of the vector x;
2. $g_C(C(i)^{\oplus j}) = 1$ and $g_C(C(i)^{\oplus i,j}) = 1$ for all $j \ne i$.

It is easy to see that g_C is 1-stable. This construction can also be easily generalized to larger m.

A computer-assisted search gives a 1-stable function of 5 inputs that can be computed with 11 gates, which means that for 1-substitutions one cannot prove a lower bound stronger than $11n$.

4 Known Limitations for Various Circuit Models

Although there is no known argument limiting the power of gate elimination, there are many known barriers in proving circuit lower bounds. In this section we list some of them. This list does not pretend to cover all known barriers in proving lower bounds, but we try to show both fundamental barriers in proving strong bounds and limits of specific techniques.

Baker, Gill, and Solovay [3, 12] present the *relativization* barrier that shows that any solution to the P versus NP question must be non-relativizing. In particular, they show that the classical diagonalization technique is not powerful enough to resolve this question. Aaronson and Wigderson [1] present the *algebrization* barrier that generalizes relativization. For instance, they show that any proof of superlinear circuit lower bound requires non-algebrizing techniques. The *natural proofs* argument by Razborov and Rudich [28] shows that a "natural" proof of a circuit lower bound would contradict the conjecture that strong one-way functions exist. In particular, this argument shows that the *random restrictions* method [14] is unlikely to prove superpolynomial lower bounds. The natural proofs argument implies the following limitation for the gate elimination method. If subexponentially strong one-way functions exist, then for any large class $\mathcal{P}$ of functions (fraction of elements of $\mathcal{P}$ is greater than $\frac{1}{n}$), for any effective measure (computable in time $2^{O(n)}$) and effective family of substitutions $\mathcal{S}$ (the family of substitutions used by the gate elimination algorithm is enumerable in time $2^{O(n)}$), gate elimination cannot prove lower bounds better than $O(n)$. Note that there are currently no known algorithms computing the measures considered in this paper in time $2^{O(n)}$.

Let $\mathcal{F}$ be a family of Boolean functions of n variables. Let X and Y be disjoint sets of input variables, and $|X| = n$. Then a Boolean function $UF(X, Y)$ is called *universal* for the family $\mathcal{F}$ if for every $f(X) \in \mathcal{F}$, there exists an assignment c of constants to the variables Y, such that $UF(X, c) = f(X)$. For example, it can be shown that the function used by Blum [5] is universal for the family $\mathcal{F} = \{x_i \oplus x_j, x_i \wedge x_j | 1 \le i, j \le n\}$. Nigmatullin [23, 24] shows that many known proofs can be stated as lower bounds for universal functions for families of low-complexity functions. At the same time, Valiant [34] proves a linear upper bound on the circuit complexity of universal functions for these simple families.

Vadhan and Williams [33] note that the inequality (1) is tight for the inner product function. This implies that the approach from [7] described in Section 2 cannot yield stronger bounds.

There are known linear upper bounds on circuit complexity of some specific functions and even classes of functions. For example, Demenkov et al. [6] show that each *symmetric function* (i.e., a function that depends only on the sum of its inputs over the integers) can be computed by a circuit of size $4.5n + o(n)$. This, in turn, implies that no gate elimination argument for a class of functions that contains a symmetric function can lead to a superlinear lower bound.

The basis U_2 is the basis of all binary Boolean functions without parity and its negation. The strongest known lower bound for circuits over the basis U_2 is $5n - o(n)$. This bound is proved by Iwama and Morizumi [17] for $(n - o(n))$-*mixed* functions. Amano and Tarui [2] construct an $(n - o(n))$-mixed function whose circuit complexity over U_2 is $5n + o(n)$.

A formula is a circuit where each gate has out-degree one. The best known lower bound of $n^{2-o(1)}$ on formula size is proved by Nechiporuk [21]. The proof of Nechiporuk is based on counting different *subfunctions* of given function. It is known that this argument cannot lead to a superquadratic lower bound (see, e.g., Section 6.5 in [18]).

A De Morgan formula is a formula with AND and OR gates, whose inputs are variables and their negations. The best known lower bound for De Morgan formulas is $n^{3-o(1)}$ (Håstad [15], Tal [32], Dinur and Meir [9]). The original proof of this lower bound by Håstad is based on showing that the shrinkage exponent Γ is at least 2. This cannot be improved since Γ is also at most 2 as can be shown by analyzing the formula size of the parity function.

Paterson introduces the notion of formal complexity measures for proving De Morgan formula size lower bounds (see, e.g., [35]). A formal complexity measure is a function $\mu\colon B_n \to \mathbb{R}$ that maps Boolean functions to reals, such that

1. for every literal x, $\mu(x) \le 1$;
2. for all Boolean functions f and g, $\mu(f \wedge g) \le \mu(f) + \mu(g)$ and $\mu(f \vee g) \le \mu(f) + \mu(g)$.

It is known that De Morgan formula size is the largest formal complexity measure. Thus, in order to prove a lower bound on the size of De Morgan formula, it suffices to define a formal complexity measure and show that an explicit function has high value of measure. Khrapchenko [19] uses this approach to prove an $n^{2-o(1)}$ lower bound on the size of DeMorgan formulas for parity. Unfortunately, many natural classes of formal complexity measures cannot lead to stronger lower bounds. Hrubes et al. [16] prove that *convex* measures (including the measure used by Khrapchenko) cannot lead to superquadratic bounds. A formula complexity measure μ is called *submodular*, if for all functions f, g it satisfies $\mu(f \vee g) + \mu(f \wedge g) \leq \mu(f) + \mu(g)$. Razborov [26] uses a submodular measure based on matrix parameters to prove superpolynomial lower bounds on the size of monotone formulas. In a subsequent work, Razborov [27] shows that submodular measures cannot yield superlinear lower bounds for non-monotone formulas. The *drag-along principle* [28, 20] shows that no useful formal complexity measure can capture specific properties of a function. Namely, it shows that if a function has measure m, then a random function with probability $1/4$ has measure at least $m/4$. Measures based on graph entropy (Newman and Wigderson [22]) are used to prove a lower bound of $n \log n$ on DeMorgan formula size, but it is proved that these measures cannot lead to stronger bounds.

5 Conclusion and Further Directions

In this paper we have demonstrated that there are functions of virtually arbitrary complexity that even after several substitutions do not allow to reduce their complexity more than by a constant number of gates (and at most one variable they depend upon), or a constant amount of a subadditive complexity measure.
