(v) an observation model $\Pr(o|\sigma)$, where $\sigma \in \Omega$ and $o \in \mathcal{O}$, (vi) a cost function $\mathrm{c} : \Omega \mapsto \mathbb{R}$ (or more generally a map from state-action pairs to the reals), and (vii) a desired criterion to minimize, e.g., expected total cumulative cost $\sum_{t=0}^{\infty} \mathbb{E}\left[\mathrm{c}(\sigma_t)\right]$, where σ_t is the random variable that equals the t-th state of the trajectory of the agent. Finally, various choices of controllers are possible. For instance, a *stochastic memoryless* controller is a map from the *current* observation to a probability distribution over actions, whereas a *belief-based* controller conditions its actions on probability distributions over the state space (i.e., beliefs) that are sequentially updated (using Bayes rule or some approximation of it) while the agent is interacting with the environment.

Unfortunately, the problem of computing an optimal policy for a POMDP, i.e., designing a controller that minimizes the expected cost, is highly intractable [27, 25] and, in general, undecidable [21]. Notably, the problem remains hard even if we severely restrict the class of controllers over which we optimize [27, 20, 12, 31]. As far as we know, the only tractable case [31] requires both the cost function and the class of controllers over which we optimize to be extremely restricted. In particular, the controller can not observe or remember anything and must apply the same distribution over actions in every step.

An important special case that has motivated our work is the *reachability* problem for POMPDs. Here, one has a set of *target* states $T \subseteq \Omega$, and the goal is to design a controller that starting from a distribution θ over Ω, guides the agent to a state in T (almost surely) with the optimal expected total cumulative cost. As shown in [8], the problem is undecidable in the general case. In the same work, for the case where the costs are positive integers and the observation model is deterministic, i.e., the observations induce a partition of the state space, the authors give an algorithm which runs in time doubly-exponential in $|\Omega|$ and returns doubly-exponential lower and upper bounds for the optimal expected total cumulative cost, using a belief-based controller. On the other hand, our work establishes a sufficient condition for a stochastic memoryless controller to reach the target set T rapidly (in time logarithmic in $|\Omega|$ and linear in $|F|$), in the case where each individual observation is binary valued (set membership) and the observation model is arbitrarily stochastic. To our knowledge, this is the first tractability result for a nontrivial class of POMDPs under stochastic memoryless controllers.

3.2 Focusing and Prioritization

To achieve our results the controller must be focused and prioritize. The idea of focusing was introduced by Papadimitriou [26] in the context of satisfiability algorithms, and amounts to "if it ain't broken don't fix it", i.e., state evolution should only happen by changing the values of variables that participate in at least one violated constraint. One way to implement this idea is to always first select a violated constraint (flaw) and then take actions that tend to get rid of it. This has been an extremely successful idea in practice [29, 4] and it is often materialized by selecting a *random* flaw to address in each step. We remark that our methods allow, in fact, also the analysis of controllers that address a random flaw in each step, but for simplicity of exposition we chose to only present the case of a fixed permutation (prioritization).

Focusing is not only a good algorithmic idea, but also enables proofs of termination. Specifically, at the foundation of the argument of Moser and Tardos [24] is the following observation: whenever an algorithm (focused or not) takes t or more steps to reach a flawless state, say through flawed states $\sigma_1, \sigma_2, \ldots, \sigma_t$, there exists, by definition, a sequence of flaws $w_1, w_2, \ldots, w_t$ such that $\sigma_i \in w_i$. Therefore, by establishing a (potentially randomized) rule for selecting a flaw present in the state at each step, we can construct a random variable

$W_t = w_1, w_2, \ldots, w_t$ to act as a *witness* of the fact that the algorithm took at least t steps. While, though, prima facie all constructions are equivalent, our capacity to bound the set of all possible such sequences is not. In particular, if the algorithm is focused and in each step we report the flaw on which the algorithm focused, then we can take advantage of the following observation: each appearance of a flaw f_i in the witness sequence, with the potential exception of the very first, must be preceded by a distinct appearance of a flaw f_j that causes f_i. This allows us to bound the rate at which the entropy of the set of t-witness sequences grows with t. Of course, in a general setting, there is good reason to believe that prioritization, i.e., focusing on the flaw determined by a fixed permutation, will be not be the best one can do. In particular, observe that for the same $D_{\rm po}$, different permutations π give rise to different causality graphs. On the other hand, at the level of generality of this work, i.e., without any assumptions about the system at hand, we can not really hope for a more intelligent choice.

3.3 LLL algorithmization

The Lovász Local Lemma (LLL) [11] is a non-constructive method for proving the *existence* of flawless states that has served as a cornerstone of the probabilistic method. To use the LLL one provides a probability measure μ on Ω, often the uniform measure, transforming flaws to ("bad") events, so that the existence of flawless states is equivalent to $\mu(\bigcup_{i=1}^{m} f_i) < 1$. The key quantity to control in order to prove this is negative dependence, i.e., the extent to which the probability of a bad event may be increased (boosted) by conditioning on the non-occurrence of other bad events. Roughly speaking, the LLL requires that for each bad event f, only a small number of other bad events should be able to boost $\mu(f)$ in this manner, whereas conditioning on the non-occurrence of all other bad events should not increase $\mu(f)$. Representing the boosting relationship in a graphical manner, with vertices corresponding to bad events pointing to their potential boosters, at a high level, the LLL requirement is that this digraph is sparse.

As one can imagine, whenever one proves that Ω contains flawless objects via the LLL it is natural to then ask if some such object can be found efficiently. Making the LLL constructive has been a long quest, starting with the work of Beck [6], with subsequent works of Alon [5], Molloy and Reed [22], Czumaj and Scheideler [10], Srinivasan [30] and others. Each of these works established a method for finding flawless objects efficiently, but with additional conditions relative to the LLL. A breakthrough was made by Moser [23] who gave a very elegant algorithmization of the LLL for satisfiability via entropy compression. Very shortly afterwards, Moser and Tardos in a landmark paper [24] made the LLL constructive for every product measure μ. Specifically, they proved that if one starts by sampling an initial state according to μ, and in every step selects an arbitrary occurring bad event and resamples its variables according to μ, then with high probability a flawless state will be reached within $O(m)$ steps.

Following [24], several works [18, 14, 3, 15, 2, 19] have extended the scope of LLL algorithmization beyond product measures. In these works, unlike [24], one has to also provide either an explicit algorithm [18, 14], or an algorithmic framework [3, 2, 15, 19], along with a way to capture the *compatibility* between the algorithm's actions for addressing each flaw f_i and the measure μ. As was shown in [15, 2, 19], one can capture compatibility by letting

$$d_i = \max_{\tau \in \Omega} \frac{\nu_i(\tau)}{\mu(\tau)} \geq 1 \ , \tag{3}$$

where $\nu_i(\tau)$ is the probability of ending up at state τ at the end of the following experiment: sample $\sigma \in f_i$ according to μ and address flaw f_i at σ. An algorithm achieving $d_i = 1$ is a *resampling oracle* for flaw f_i. If $d_i = 1$ for every $i \in [m]$, then it was proven in [15] that the causality digraph equals the boosting digraph mentioned above and the condition for success is identical to that of the LLL (observe that the resampling algorithm of Moser and Tardos [24] is trivially a resampling oracle for every flaw). More generally, ascribing to each flaw f_i the *charge* $\gamma(f_i) = d_i \cdot \mu(f_i)$, yields the following user-friendly algorithmization condition [2], akin to the asymmetric Local Lemma: if for every flaw $f_i \in F$,

$$\sum_{f_j \in \Gamma(f_i)} \gamma(f_j) < \frac{1}{4} \ , \tag{4}$$

then with high probability the algorithm will reach a sink after $O(\log |\Omega| + m)$ steps.

Even though the noiseless case is only tangential to the main point of this work, as an indication of the sharpness of our analysis, we point out that in the noiseless case, our condition (2) is identical to (4) with $\gamma(f_i)$ replaced by $\chi(f_i) := 2^{-\text{Potential}(f_i)+b^{f_i}_{\text{po}}}$. In general, $\gamma(f_i)$ and $\chi(f_i)$ are incomparable. Roughly speaking, settings where $b^{f_i}_{\text{po}}$ is small and d_i is large favor $\chi(f_i)$ over $\gamma(f_i)$ and vice versa, while the two meet when $b^{f_i}_{\text{po}} = 0$, μ is uniform, and the transition probabilities are uniform, as in [3].

In terms of techniques, as hinted in Section 3.2, proofs of LLL algorithmizations consist of two independent parts. In one part, one bounds from above the probability of any witness sequence occurring, or in the case of Moser's entropic argument, bounds from below the entropy injected to the system while addressing the sequence. In the other part, one has to estimate the [entropy of the] set of possible witness sequences, using syntactic properties mandated by causality: roughly speaking every occurrence of a flaw in a witness sequence, with the potential exception of the very first, must be preceded by an occurrence of some flaw that causes it. Finally, one compares the rate at which the probability of a t-step witness sequence decreases (or the rate at which entropy is increased) with the rate at which the [entropy of the] set of possible witness sequences increases, to establish that their product tends to 0 with t.

In this paper, exactly because we aim to capture the intensity of interactions between flaws under adversarial noise, we need to take a different approach. In particular, our proof can be thought of as entangling the two parts described above in order to establish that, while adversarial noise can make the imposed syntactic requirements inherited by the causality graph very weak (by making the graph extremely dense), the fact that the intensity of the noise is low, suffices to control the growth rate of the entropy of the set of witness sequences. The result is a carefully tuned argument that amortizes the entropy injected into the system against its effect on the entropy of the set of Break Forests. Key to the capacity to perform this amortization is the use of so-called Break Forests, introduced in [3], which localize in time the introduction of new flaws in the state. This property of Break Forests was not used in earlier works [3, 2] and allows us to use a different amortization for the flaws introduced by the principal vs. those introduced by noise.

4 Termination via Compression

Our analysis will not depend in any way on the distribution θ of the initial state. As a result, without loss of generality, we can assume that the process starts at an arbitrary but fixed state σ_{init}. We let $A(\sigma)$ denote the support of $\rho(\sigma, \cdot)$, i.e., $A(\sigma)$ is the set of all states reachable by the process in a single step from σ.

▶ **Definition 2.** We refer to the (random) sequence $\sigma_{\text{init}} = \sigma_1, \ldots, \sigma_{t+1}$, entailing the first t steps of the process, as the *t-trajectory*. A t-trajectory is *bad* iff $\sigma_1, \ldots, \sigma_{t+1}$ are all flawed.

We model the set of all possible trajectories as an infinite tree whose root is labelled by $\sigma_1 = \sigma_{\text{init}}$. The root has $|A(\sigma_{\text{init}})|$ children corresponding to (and labelled by) each possible value of σ_2. More generally, a vertex labeled by σ has $|A(\sigma)|$ children, each child labeled by a distinct element of $A(\sigma)$, i.e., a distinct possible value of σ_{i+1}. Every edge of this infinite vertex-labelled tree is oriented away from the root and labelled by the probability of the corresponding transition, i.e., $\rho(\sigma, \tau)$, where σ is the parent and τ is the child vertex. By our assumption, every such edge label is at least 2^{-B}.

We call the above labelled infinite tree the *process tree* and note that it is nothing but the unfolding of the Markov chain corresponding to the state-evolution of the process. In particular, for every vertex v of the tree, the probability, p_v, that an infinite trajectory will go through v equals the product of the edge-labels on the root-to-v path. In visualizing the process tree it will be helpful to draw each vertex v at Euclidean distance $-\log_2 p_v$ from the root. This way all trajectories whose last vertex is at the same distance from the root are equiprobable, even though they may entail wildly different numbers of steps (this also means that sibling vertices are not necessarily equidistant from the root). Finally, we color the vertices of the process tree as follows. For every infinite path that starts at the root determine its maximal prefix forming a bad trajectory. Color the vertices of the prefix red and the remaining vertices of the path blue.

In terms of the above picture, our goal will be to prove that there exist a critical radius x_0 and $\delta > 0$, such that the proportion of red states at distance x_0 from the root is at most $1 - \delta$. Crucially, x_0 will be polynomial, in fact linear, in $m = |F|$ and $\log_2 |\Omega|$. Since we will prove this for every possible initial state and the process is Markovian, it follows that the probability that the process reaches distance x from the root while going only through red states is at most $(1 - \delta)^{\lfloor x/x_0 \rfloor}$.

To prove that red vertices thin out as we move away from the root we stratify the process tree as follows. Fix any real number $x > 0$ and on each infinite path from the root mark the first vertex of probability 2^{-x} or less, i.e., the first vertex that has distance at least x from the root. Truncate the process tree so that the marked vertices become leaves of a finite tree. Let $L(x)$ be the set of all root-to-leaf paths (trajectories) in this finite tree and let $B(x) \subseteq L(x)$ consist of the bad trajectories. Now, let I be the random variable equal to an infinite trajectory of the process and let $\Sigma = \Sigma(x)$ be the random variable equal to the prefix of I that lies in $L(x)$. By definition, $\sum_{\ell \in L(x)} \Pr[\Sigma = \ell] = 1$, while $\Pr[\ell] \in (2^{-x-B}, 2^{-x}]$ for every $\ell \in L(x)$, since $-\log_2 \rho \geq B$. Let $P = P(\Sigma)$ be the maximal red prefix of Σ and observe that if $\Sigma \in B(x)$ then $P = \Sigma$. Therefore,

$$H[P] \;\geq\; \sum_{\ell \in B(x)} \Pr[\Sigma = \ell](-\log_2 \Pr[\Sigma = \ell]) \;\geq\; x \sum_{\ell \in B(x)} \Pr[\Sigma = \ell] \;=\; x \Pr[\Sigma \in B(x)] \;. \quad (5)$$

Assume now that there exist $M_0 > 0$ and $\lambda < 1$, such that $H[P] \leq \lambda x + M_0$, for every $x > 0$. Then (5) implies that for $x_0 = 2M_0/(1 - \lambda)$,

$$\Pr[\Sigma \in B(x_0)] \leq \frac{H[P]}{x_0} \leq \frac{\lambda x_0 + M_0}{x_0} = \lambda + \frac{1 - \lambda}{2} = \frac{1 + \lambda}{2} < 1 \;. \quad (6)$$

If $\Sigma \in B(x_0)$, we treat the reached state as the root of a new finite tree and repeat the same analysis, as it is independent of the starting state. It follows in this manner that for every integer $T \geq 1$, the probability that the process reaches a state at distance $T(x_0 + B)$

or more from the root by going only through red states is at most $((1+\lambda)/2)^T$. Thus, for any $s > 1/2$, the probability that the process reaches a state at distance

$$E = \left\lceil \frac{2s}{1+\lambda} \right\rceil (x_0 + B) = O\left(\frac{sM_0}{1-\lambda^2}\right)$$

or more from the root by going only through red states is at most $((1+\lambda)/2)^{\left\lceil \frac{2s}{1+\lambda} \right\rceil} < \exp(-s)$.

Since $\rho(\sigma,\tau) < 1-2^{-B}$, it follows that $-\log_2 \rho(\sigma,\tau) > 2^{-B}$, for every arc in D. Thus, after $2^B E$ steps the process is always at distance E or more from the root. Thus, the probability of not reaching a flawless state after $2^B E = O\left(\frac{sM_0}{1-\lambda^2}\right)$ steps is $\exp(-s)$. Therefore Theorem 1 follows from the following.

▶ **Theorem 3.** *Let* $\Xi = \max\{\mathrm{b_{ns}}, \mathrm{b_{po}}\}$ *and* $\Delta = \max_{j \in F} \Delta_j$. *If there exists* $\lambda < 1$ *such that for all* $j \in [m]$,

$$\sum_{f_i \in \Gamma_{\mathrm{po}}(f_j)} 2^{-(\lambda \mathrm{Potential}(f_i) - \mathrm{b}_{\mathrm{po}}^{f_i} - q_i(p))} < 2^{-(2+h(p))} \ ,$$

then $H[P] \le \lambda x + M_0$ *for every* $x > 0$, *where* $M_0 = \log_2 |\Omega| + m(\Delta+1)(\Xi+4) + \lambda B$.

The proof of Theorem 3 can be found in the full version of the paper [1]. To bound the entropy $H[P]$ we show how to represent trajectories as break sequences, described in the next section, and then show how to bound the entropy of break sequences by showing that they can be compressed in fewer bits, on average, than those consumed by the algorithm.

5 Break Sequences

Recall that π is an arbitrary but fixed ordering of the set of flaws F and that the highest flaw present in each state σ is denoted by $\pi(\sigma)$. We will refer to $\pi(\sigma)$ as the flaw *addressed* at state σ, i.e., as in the noiseless case, even though the action distribution $P(O(\sigma))$ may be "misguided" whenever $O(\sigma) \neq U(\sigma)$.

▶ **Definition 4.** Given a bad t-trajectory Σ, its *witness* sequence is $W(\Sigma) = w_1, \ldots, w_t = \{\pi(\sigma_i)\}_{i=1}^t$.

To prove Theorem 3, i.e., to gain control of bad trajectories and thus of $H[P]$, we introduce the notion of *break sequences* (see also [3, 2]). Recall that $U(\sigma)$ denotes the set of flaws present in σ.

▶ **Definition 5.** Let $B_0 = U(\sigma_1)$. For $1 \le i \le t-1$, let $B_i = U(\sigma_{i+1}) \setminus (U(\sigma_i) \setminus w_i)$.

Thus, B_i is the set of flaws "introduced" during the i-th step, where if a flaw is addressed in a step but remains present in the resulting state we say that it "introduced itself". Each flaw $f \in B_i$ may or may not be addressed during the rest of the trajectory. For example, f may get fixed "collaterally" during some step taken to address some other flaw, before the controller had a chance to address it. Alternatively, it may be that f remains present throughout the rest of the trajectory, but in each step $i < j \le t-1$ some other flaw has greater priority than f. It will be crucial to identify and focus on the subset of flaws $B_i^* \subseteq B_i$ that *do* get addressed during the t-trajectory, causing entropy to enter the system. Per the formal Definition 6 below, the set of such flaws is $B_i^* = B_i \setminus \{O_i \cup N_i\}$, where O_i comprises any flaws in B_i that get eradicated collaterally, while N_i comprises any flaws in B_i that remain present in every subsequent state after their introduction without being addressed.

▶ **Definition 6.** The *Break Sequence* of a t-trajectory is $B_0^*, B_1^*, \ldots, B_t^*$, where for $0 \leq i \leq t$,

$$B_i^* = B_i \setminus \{O_i \cup N_i\} \text{ , where}$$
$$O_i = \{f \in B_i \mid \exists j \in [i+1, t] : f \notin U(\sigma_{j+1}) \wedge \forall \ell \in [i+1, j] : f \neq w_\ell\} \ ,$$
$$N_i = \{f \in B_i \mid \forall j \in [i+1, t] : f \in U(\sigma_{j+1}) \wedge \forall \ell \in [i+1, t] : f \neq w_\ell\} \ .$$

Given $B_0^*, B_1^*, \ldots, B_{i-1}^*$ we can determine the sequence $w_1, w_2, \ldots, w_i$ of flaws addressed inductively, as follows. Define $E_1 = B_0^*$, while for $i \geq 1$, let

$$E_{i+1} = (E_i - w_i) \cup B_i^* \ . \tag{7}$$

Observe that, by construction, $E_i \subseteq U(\sigma_i)$ and $w_i \in E_i$. Therefore, for every i, the highest flaw in E_i is w_i.

Abstract

We consider the following generalization of the binary search problem. A search strategy is required to locate an unknown target node t in a given tree T. Upon querying a node v of the tree, the strategy receives as a reply an indication of the connected component of $T \setminus \{v\}$ containing the target t. The cost of querying each node is given by a known non-negative weight function, and the considered objective is to minimize the total query cost for a worst-case choice of the target. Designing an optimal strategy for a weighted tree search instance is known to be strongly NP-hard, in contrast to the unweighted variant of the problem which can be solved optimally in linear time. Here, we show that weighted tree search admits a quasi-polynomial time approximation scheme (QPTAS): for any $0 < \varepsilon < 1$, there exists a $(1+\varepsilon)$-approximation strategy with a computation time of $n^{O(\log n/\varepsilon^2)}$. Thus, the problem is not APX-hard, unless NP $\subseteq$ DTIME$(n^{O(\log n)})$. By applying a generic reduction, we obtain as a corollary that the studied problem admits a polynomial-time $O(\sqrt{\log n})$-approximation. This improves previous $\widetilde{O}(\log n)$-approximation approaches, where the $\widetilde{O}$-notation disregards $O(\text{poly}\log\log n)$-factors.

1 Introduction

In this work we consider a generalization of the fundamental problem of searching for an element in a sorted array. This problem can be seen, using graph-theoretic terms, as a problem of searching for a target node in a path, where each query reveals on which 'side' of the queried node the target node lies. The generalization we study is two-fold: a more general structure of a tree is considered and we assume non-uniform query times. Thus,

Table 1 Computational complexity of the search problem in different graph classes, including our results for weighted trees. Completeness results refer to the decision version of the problem. In the case of unweighted paths, the solution is the classical binary search algorithm.

Graph class	*Unweighted*	*Weighted*
Paths:	exact in $O(n)$ time	exact in $O(n^2)$ time [4]
		strongly NP-complete [9]
Trees:	exact in $O(n)$ time [26, 28]	$(1+\varepsilon)$-approx. in $n^{O(\log n/\varepsilon)}$ time (Thm. 3.3)
		$O(\sqrt{\log n})$-approx. in poly-time (Thm. 3.4)
Undirected:	exact in $n^{O(\log n)}$ time [10]	PSPACE-complete [10]
	$O(\log n)$-approx. in poly-time [10]	$O(\log n)$-approx. in poly-time [10]
Directed:	PSPACE-complete [10]	PSPACE-complete [10]

our problem can be stated as follows. Given a node-weighted input tree T (in which the query time of a node is provided as its weight), design a search strategy (sometimes called a decision tree) that locates a hidden *target node* x by asking *queries*. Each query selects a node v in T and after the time that equals the weight of the selected node, a reply is given: the reply is either 'yes' which implies that v is the target node and thus the search terminates, or it is 'no' in which case the search strategy receives the edge outgoing from v that belongs to the shortest path between u and v. The goal is to design a search strategy that locates the target node and minimizes the search time in the worst case.

The vertex search problem is more general than its 'edge variant' that has been more extensively studied. In the latter problem one selects an edge e of an edge-weighted tree $T = (V, E, w)$ in a query and learns in which of the two components of $T - e$ the target node is located. Indeed, this edge variant can be reduced to our problem as follows: first assign a 'large' weight to each node of T (for example, one plus the sum of the weights of all edges in the graph) and then subdivide each edge e of T giving to the new node the weight of the original edge, $w(e)$. It is apparent that an optimal search strategy for the new node-weighted tree should never query the nodes with large weights, thus immediately providing a search strategy for the edge variant of T.

We also point out that the considered problem, as well as the edge variant, being quite fundamental, were historically introduced several times under different names: minimum height elimination trees [27], ordered colourings [15], node and edge rankings [13], tree-depth [25] or LIFO-search [11]. Table 1 summarizes the complexity status of the node-query model and places our result in the general context.

1.1 State-of-the-Art

In this work we focus on the worst case search time for a given input graph and we only remark that other optimization criteria has been also considered [3, 16, 17, 30]. For other closely related models and corresponding results see e.g. [1, 12, 19, 21, 29].

The node-query model. An optimal search strategy can be computed in linear-time for an unweighted tree [26, 28]. The number of queries performed in the worst case may vary from being constant (for a star one query is enough) to being at most $\log_2 n$ for any tree [26] (by

always querying a node that halves the search space). Several following results have been obtained in [10]. First, it turns out that $\log_2 n$ queries are always sufficient for general simple graphs and this implies a $O(m^{\log_2 n} n^2 \log n)$-time optimal algorithm for arbitrary unweighted graphs. The algorithm which performs $\log_2 n$ queries also serves as a $O(\log n)$-approximation algorithm, also for the weighted version of the problem. On the other hand, it is shown in the same work that an optimal algorithm (for unweighted case) with a running time of $O(n^{o(\log n)})$ would be in contradiction with the Exponential-Time-Hypothesis. When weighted graphs are considered, the problem becomes PSPACE-complete.

The edge-query model. In the case of unweighted trees, an optimal search strategy can be computed in linear time [20, 24]. (See [7] for a correspondence between edge rankings and the searching problem.) The computational complexity of the problem on weighted trees attracted a lot of attention. On the negative side, it has been proved that it is strongly NP-hard to compute an optimal search strategy [6] for bounded diameter trees, which has been improved by showing hardness for several specific topologies: trees of diameter at most 6, trees of degree at most 3 [4] and spiders [5] (trees having at most one node of degree greater than two). On the other hand, polynomial-time algorithms exist for weighted trees of diameter at most 5 and weighted paths [4]. We note that for weighted paths there exists a linear-time but approximate solution given in [16]. For approximate polynomial-time solutions, a simple $O(\log n)$-approximation has been given in [6] and a $O(\log n/\log\log\log n)$-approximate solution is given in [4]. Then, the best known approximation ratio has been further improved to $O(\log n/\log\log n)$ in [5].

Some bounds on the number of queries for unweighted trees have been developed. Observe that an optimal search strategy needs to perform at least $\log_2 n$ queries in the worst case. However, there exist trees of maximum degree Δ that require $\Delta \log_{\Delta+1} n$ queries [2]. On the other hand, $\Theta(\Delta \log n)$ queries are always sufficient for each tree [2], which has been improved to $(\Delta+1)\log_\Delta n$ [18], $\Delta \log_\Delta n$ [8] and $1 + \frac{\Delta-1}{\log_2(\Delta+1)-1}\log_2 n$ [10].

1.2 Organization of the Paper

The aim of Section 2 is to give the necessary notation and a formal statement of the problem (Sections 2.1 and 2.2) and to provide two different but equivalent problem formulations that will be more convenient for our analysis. As opposed to the classical problem formulation in which a strategy is seen as a *decision tree*, Section 2.3 restates the problem in such a way that with each vertex v of the input tree we associate a sequence of vertices that need to be iteratively queried when v is the root of the current subtree that contains the target node. In Section 2.4 we extend this approach by associating with each vertex a sequence of not only vertices to be queried but also time points of the queries.

The latter problem formulation is suitable for a dynamic programming algorithm provided in Section 3.1. In this section we introduce an auxiliary, slightly modified measure of the cost of a search strategy. First we provide a quasi-polynomial time dynamic programming scheme that provides an arbitrarily good approximation of the output search strategy with respect to this modified cost (the analysis is deferred to Section 4), and then we prove that the new measure is sufficiently close to the original one (the analysis is deferred to Section 5). These two facts provide the quasi-polynomial time scheme for the tree search problem, achieving a $(1+\varepsilon)$-approximation with a computation time of $n^{O(\log n/\varepsilon^2)}$, for any $0 < \varepsilon < 1$.

In Section 3.2 we observe how to use the above algorithm to derive a polynomial-time $O(\sqrt{\log n})$-approximation algorithm for the tree search problem. This is done by a divide and conquer approach: a sufficiently small subtree T^* of the input tree T is first computed

so that the quasi-polynomial time algorithm runs in polynomial (in the size of T) time for T^*. This decomposes the problem: having a search strategy for T^*, the search strategies for $T - T^*$ are computed recursively.

2 Preliminaries

2.1 Notation and Query Model

We now recall the problem of searching of an unknown target node x by performing queries on the vertices of a given node-weighted rooted tree $T = (V, E, w)$ with weight function $w\colon V \to \mathbb{R}_+$. Each *query* selects one vertex v of T and after $w(v)$ time units receives an answer: either the query returns *true*, meaning that $x = v$, or it returns a neighbor u of v which lies closer to the target x than v. Since we assume that the queried graph T is a tree, such a neighbor u is unique and is equivalently described as the unique neighbor of v belonging to the same connected component of $T \setminus \{v\}$ as x.

All trees we consider are rooted. Given a tree T, the root is denoted by $r(T)$. For a node $v \in V$, we denote by T_v the subtree of T rooted at v. For any subset $V' \subseteq V$ (respectively, $E' \subseteq E$) we denote by $T[V']$ (resp., $T[E']$) the minimal subtree of T containing all nodes from V' (resp., all edges from E'). For $v \in V$, $N(v)$ is the set of neighbors of v in T.

For $U \subseteq V$ and a target node $x \notin U$, there exists a unique maximal subtree of $T \setminus U$ that contains x; we will denote this subtree by $T\langle U, x\rangle$.

We denote $|V| = n$. We will assume w.l.o.g. that the maximum weight of a vertex is normalized to 1. (This normalization is immediately obtained by a proportional scaling of all units of cost.) We will also assume w.l.o.g. that the weight function satisfies the following *star condition*: for all $v \in V$, $w(v) \leq \sum_{u \in N(v)} w(u)$. Observe that if this condition is not fulfilled, i.e., for some vertex v will have $w(v) > \sum_{u \in N(v)} w(u)$, then vertex v will never be queried by any optimal strategy in v, since a query to v can then be replaced by a sequence of queries to all neighbors of v, obtaining not less information at strictly smaller cost. In general, given an instance which does not satisfy the star condition, we enforce it by performing all necessary weight replacements $w(v) \leftarrow \min\{w(v), \sum_{u \in N(v)} w(u)\}$, for $v \in V$. Replacements terminate definitely since no vertex will be replaced more than once.

For $a, \omega \in \mathbb{R}_{\geq 0}$, we denote the rounding of a down (up) to the nearest multiple of ω as $\lfloor a \rfloor_\omega = \omega \lfloor a/\omega \rfloor$ and $\lceil a \rceil_\omega = \omega \lceil a/\omega \rceil$, respectively.

2.2 Definition of a Search Strategy

A search strategy $\mathcal{A}$ for a rooted tree $T = (V, E, w)$ is an adaptive algorithm which defines successive queries to the tree, based on responses to previous queries, with the objective of locating the target vertex in a finite number of steps. Note that search strategies can be seen as decision trees in which each node represents a subset of vertices of T that contains x, with leaves representing singletons consisting of x.

Let $\mathtt{Q}_\mathcal{A}(T, x)$ be the time-ordering (sequence) of queries performed by strategy $\mathcal{A}$ on tree T to find a target vertex x, with $\mathtt{Q}_{\mathcal{A},i}(T, x)$ denoting the i-th queried vertex in this time ordering, $1 \leq i \leq |\mathtt{Q}_\mathcal{A}(T, x)|$.

We denote by $\mathtt{COST}_\mathcal{A}(T, x) = \sum_{i=1}^{|\mathtt{Q}_\mathcal{A}(T,x)|} w(\mathtt{Q}_{\mathcal{A},i}(T, x))$ the sum of weights of all vertices queried by $\mathcal{A}$ with x being the target node, i.e., the time after which $\mathcal{A}$ finishes. Let $\mathtt{COST}_\mathcal{A}(T) = \max_{x \in V} \mathtt{COST}_\mathcal{A}(T, x)$ be the *cost of* $\mathcal{A}$. We define the *cost of* T to be $\mathtt{OPT}(T) = \min\{\mathtt{COST}_\mathcal{A}(T) \mid \mathcal{A} \text{ is a search strategy for } T\}$. We say that a search strategy is *optimal* for T if its cost equals $\mathtt{OPT}(T)$.

Algorithm 2.1 Search strategy $\mathcal{A}_S$ for a query sequence assignment S.

```
1: v ← r(T)    // stores current root
2: U ← ∅
3: while |T⟨U, x⟩| > 1 do
4:     for u ∈ S(v) do
5:         if u ∈ T⟨U, x⟩ then    // u is the first vertex in S(v) that belongs to T⟨U, x⟩
6:             QueryVertex(u)
7:             U ← U ∪ {u}
8:             if v ≠ r(T⟨U, x⟩) then    // query reply is 'down'
9:                 v ← r(T⟨U, x⟩)
10:                break    // for loop
```

As a consequence of normalization and the star condition, we have the following bound.

▶ **Observation 2.1.** *For any tree T, we have* $1 \leq \mathtt{OPT}(T) \leq \lceil \log_2 n \rceil$.

All omitted proofs are provided in the full version.

We also introduce the following notation. If the first $|U|$ queried vertices by a search strategy $\mathcal{A}$ are exactly the vertices in U, $U = \{\mathtt{Q}_{\mathcal{A},i}(T, x) : 1 \leq i \leq |U|\}$, then we say that $\mathcal{A}$ *reaches* $T\langle U, x\rangle$ *through* U, and $w(U)$ is the *cost of reaching* $T\langle U, x\rangle$ *by* $\mathcal{A}$. We also say that we receive an 'up' reply to a query to a vertex v if the root of the tree remaining to be searched remains unchanged by the query, i.e., $r(T\langle U, x\rangle) = r(T\langle U \cup \{v\}, x\rangle)$, and we call the reply a 'down' reply when the root of the remaining tree changes, i.e., $r(T\langle U, x\rangle) \neq r(T\langle U \cup \{v\}, x\rangle)$.

2.3 Query Sequences and Stable Strategies

By a slight abuse of notation, we will call a search strategy *polynomial-time* if it can be implemented using a dynamic (adaptive) algorithm which computes the next queried vertex in polynomial time.

We give most of our attention herein to search strategies in trees which admit a natural (non-adaptive, polynomial-space) representation called a *query sequence assignment*. Formally, for a rooted tree T, the *query sequence assignment* S is a function $S : V \to V^*$, which assigns to each vertex $v \in V$ an ordered sequence of vertices $S(v)$, known as the *query sequence* of v. The query sequence assignment directly induces a strategy $\mathcal{A}_S$, presented as Algorithm 2.1. Intuitively, the strategy processes successive queries from the sequence $S(v)$, where v is the root vertex of the current search tree, $v = r(T\langle U, x\rangle)$, where U is the set of queries performed so far. This processing is performed in such a way that the strategy iteratively takes the first vertex in $S(v)$ that belongs to $T\langle U, x\rangle$ and queries it. As soon as the root of the search tree changes, the procedure starts processing queries from the sequence of the new root, which belong to the remaining search tree. The procedure terminates as soon as $T\langle U, x\rangle$ has been reduced to a single vertex, which is necessarily the target x.

In what follows, in order to show that our approximation strategies are polynomial-time, we will confine ourselves to presenting a polynomial-time algorithm which outputs an appropriate sequence assignment.

A sequence assignment is called *stable* if the replacement of line 9 in Algorithm 2.1 by any assignment of the form $v \leftarrow v''$, where v'' is an arbitrary vertex which is promised to lie on the path from $r(T\langle U, x\rangle)$ to the target x, always results in a strategy which performs a (not necessarily strict) subsequence of the sequence of queries performed by the original strategy $\mathcal{A}_S$. Sequence assignments computed on trees with a bottom-up approach usually have the stability property; we provide a proof of stability for one of our main routines in Section 4.

Without loss of generality, we will also assume that if $v \in S(v)$, then v is the last element of $S(v)$. Indeed, when considering a subtree rooted at v, after a query to v, if v was not the target, then the root of the considered subtree will change to one of the children of v, hence any subsequent elements of $S(v)$ may be removed without changing the strategy.

2.4 Strategies Based on Consistent Schedules

Intuitively, we may represent search strategies by a schedule consisting of some number of jobs, with each job being associated to querying a node in the tree (cf. e.g. [14, 22, 23]). Each job has a fixed processing time, which is set to the weight of a node. Formally, in this work we will refer to the schedule $\hat{S}$ only in the very precise context of search strategies $\mathcal{A}_S$ based on some query sequence assignment S. The *schedule assignment* $\hat{S}$ is the following extension of the sequence assignment S, which additionally encodes the starting time of any search query job. If the query sequence S of a node v is of the form $S(v) = (v_1, \ldots, v_k)$, $k = |S(v)|$, then the corresponding schedule for v will be given as $\hat{S}(v) = ((v_1, t_1), \ldots, (v_k, t_k))$, with $t_i \in \mathbb{R}_{\geq 0}$ denoting the starting time of the query for v_i. We will call $\hat{S}(v)$ the *schedule of node* v. We will call a schedule assignment $\hat{S}$ *consistent* with respect to search in a given tree T if the following conditions are fulfilled:

- **(i)** No two jobs in the schedule of a node overlap: for all $v \in V$, for two distinct jobs $(u_1, t_1), (u_2, t_2) \in \hat{S}(v)$, we have $|[t_1, t_1 + w(u_1)] \cap [t_2, t_2 + w(u_2)]| = 0$.
- **(ii)** If v is the parent of v' in T and $(u, t) \in \hat{S}(v')$, then we either also have $(u, t) \in \hat{S}(v)$, or the job $(v, t_v) \in \hat{S}(v)$ completes before the start of job (u, t): $t_v + w(v) \leq t$.

It follows directly from the definition that a consistent schedule assignment (and the underlying query sequence assignment) is uniquely determined by the collection of jobs $\{(v, t_v) : (v, t_v) \in \hat{S}(u), u \in V\}$. Note that not every vertex has to contain a query to itself in its schedule; we will occasionally write $t_v = \perp$ to denote that such a job is missing.

By extension of notation for sequence assignments, we will denote a strategy following a consistent schedule assignment $\hat{S}$ (i.e., executing the query jobs of schedule $\hat{S}$ at the prescribed times) as $\mathcal{A}_{\hat{S}}$. We will then have: $\texttt{COST}_{\mathcal{A}_{\hat{S}}}(T) = |\hat{S}|$, where $|\hat{S}|$ is the *duration* of schedule assignment $\hat{S}$, given as: $|\hat{S}| = \max_{v \in V} |\hat{S}(v)|$, with: $|\hat{S}(v)| = \max_{(u,t) \in \hat{S}(v)} (t + w(u))$.

We remark that there always exists an optimal search strategy which is based on a consistent schedule. By a well-known characterization (cf. e.g. [6]), tree T satisfies $\texttt{OPT}(T) = \tau \in \mathbb{R}$ if and only if there exists an assignment $I : V \to \mathcal{I}_\tau$ of intervals of time to nodes before deadline τ, $\mathcal{I}_\tau = \{[a, b] : 0 \leq a < b \leq \tau\}$, such that $|I(v)| = w(v)$ and if $|I(u) \cap I(v)| > 0$ for any pair of nodes $u, v \in V$, then the $u - v$ path in T contains a separating vertex z such that $\max I(z) \leq \min(I(u) \cup I(v))$. The corresponding schedule assignment of duration τ is obtained by adding, for each node $u \in V$, the job $(u, \min I(u))$ to the schedule of all nodes on the path from u towards the root, until a node v such that $\max I(v) \leq \min I(u)$ is encountered on this path. The consistency and correctness of the obtained schedule is immediate to verify.

▶ **Observation 2.2.** *For any tree T, there exists a query sequence assignment S and a corresponding consistent schedule $\hat{S}$ on T such that $|\hat{S}| = \texttt{OPT}(T)$.*

3 The Results

3.1 $(1 + \varepsilon)$-Approximation in $n^{O(\log n/\varepsilon^2)}$ Time

We first present an approximation scheme for the weighted tree search problem with $n^{O(\log n)}$ running time. The main difficulty consists in obtaining a constant approximation ratio for

the problem with this running time; we at once present this approximation scheme with tuned parameters, so as to achieve $(1+\varepsilon)$-approximation in $n^{O(\log n/\varepsilon^2)}$ time.

Our construction consists of two main building blocks. First, we design an algorithm based on a bottom-up (dynamic programming) approach, which considers exhaustively feasible sequence assignments and query schedules over a carefully restricted state space of size $n^{O(\log n)}$ for each node. The output of the algorithm provides us both with a lower bound on $\texttt{OPT}(T)$, and with a sequence assignment-based strategy $\mathcal{A}_S$ for solving the tree search problem. The performance of this strategy $\mathcal{A}_S$ is closely linked to the performance of $\texttt{OPT}(T)$, however, there is one type of query, namely a query on a vertex of small weight leading to a 'down' response, due to whose repeated occurrence the eventual cost difference between $\texttt{COST}_{\mathcal{A}_S}(T)$ and $\texttt{OPT}(T)$ may eventually become arbitrarily large. To alleviate this difficulty, we introduce an alternative measure of cost which compensates for the appearance of the disadvantageous type of query.

We start by introducing some additional notation. Let $\omega \in \mathbb{R}_+$, be an arbitrarily fixed value of weight and let $c \in \mathbb{N}$. The choice of constant $c \in \mathbb{N}$ will correspond to an approximation ratio of $(1+\varepsilon)$ of the designed scheme for $\varepsilon = 168/c$.

We say that a query to a vertex v is a *light down query* in some strategy if $w(v) < c\omega$ and $x \in V(T_v)$, i.e., it is also a 'down' query, where x is the target vertex.

For any strategy $\mathcal{A}$, we denote by $\texttt{COST}^{(\omega,c)}_{\mathcal{A}}(T,x)$ its modified cost of finding target x, defined as follows. Let d_x be the number of light down queries when searching for x: $d_x = \left|\{i : w(\mathtt{Q}_{\mathcal{A},i}(T,x)) < c\omega \text{ and } x \in V(T_{\mathtt{Q}_{\mathcal{A},i}(T,x)})\}\right|$. Then, the modified cost $\texttt{COST}^{(\omega,c)}_{\mathcal{A}}(T,x)$ is:

$$\texttt{COST}^{(\omega,c)}_{\mathcal{A}}(T,x) = \texttt{COST}_{\mathcal{A}}(T,x) - (2c+1)\omega d_x. \tag{1}$$

and by a natural extension of notation: $\texttt{COST}^{(\omega,c)}_{\mathcal{A}}(T) = \max_{x\in V} \texttt{COST}^{(\omega,c)}_{\mathcal{A}}(T,x)$.

The technical result which we will obtain in Section 4 may now be stated as follows.

▶ **Proposition 3.1.** *For any $c \in \mathbb{N}$, $L \in \mathbb{N}$, there exists an algorithm running in time $(cn)^{O(L)}$, which for any tree T constructs a stable sequence assignment S and computes a value of ω such that $\omega \le \frac{1}{L}\texttt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T)$ and: $\texttt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) \le \left(1+\frac{12}{c}\right)\texttt{OPT}(T)$.*

In order to convert the obtained strategy $\mathcal{A}_S$ with a small value of $\texttt{COST}^{(\omega,c)}$ into a strategy with small $\texttt{COST}$, we describe in Section 5 an appropriate strategy conversion mechanism. The approach we adopt is applicable to any strategy based on a stable sequence assignment and consists in concatenating, for each vertex $v \in V$, a prefix to the query sequence $S(v)$ in the form of a separately computed sequence $R(v)$, which does not depend on $S(v)$. The considered query sequences are thus of the form $R(v) \circ S(v)$, where the symbol "$\circ$" represents sequence concatenation. Intuitively, the sequences R, taken over the whole tree, reflect the structure of a specific solution to the unweighted tree search problem on a contraction of tree T, in which each edge connecting a node to a child with weight at least $c\omega$ is contracted. We recall that the optimal number of queries to reach a target in an unweighted tree is $O(\log n)$, and the goal of this conversion is to reduce the number of light down queries in the combined strategy to at most $O(\log n)$.

▶ **Proposition 3.2.** *For any fixed $\omega > 0$ there exists a polynomial-time algorithm which for a tree T computes a sequence assignment $R : V \to V^*$, such that, for any strategy $\mathcal{A}_S$ based on a stable sequence assignment S, the sequence assignment S^+, given by $S^+(v) = R(v) \circ S(v)$ for each $v \in V$, has the following property:*

$$\texttt{COST}_{\mathcal{A}_{S^+}}(T) \le \texttt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) + 4(2c+1)\omega \log_2 n.$$

The proof of Proposition 3.2 is provided in Section 5.

We are now ready to put together the two bounds. Combining the claims of Proposition 3.1 for $L = \lceil c^2 \log_2 n \rceil$ (with $\omega \leq \frac{1}{L}\mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) \leq \frac{\mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T)}{c^2 \log_2 n}$) and Proposition 3.2, we obtain:

$$\begin{aligned}\mathtt{COST}_{\mathcal{A}_{S^+}}(T) &\leq \mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) + 4(2c+1)\omega \log_2 n \leq \mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) + 12c\omega \log_2 n \;\leq \\ &\leq \mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) + 12c \log_2 n \frac{\mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T)}{c^2 \log_2 n} \leq \left(1 + \frac{12}{c}\right) \mathtt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) \leq \\ &\leq \left(1 + \frac{12}{c}\right)^2 \mathtt{OPT}(T) \leq \left(1 + \frac{168}{c}\right) \mathtt{OPT}(T).\end{aligned}$$

After putting $\varepsilon = \frac{168}{c}$ and noting that in stating our result we can safely assume $c = O(\mathrm{poly}(n))$ (beyond this, the tree search problem can be trivially solved optimally in $O(n^n)$ time using exhaustive search), we obtain the main theorem of the section.

▶ **Theorem 3.3.** *There exists an algorithm running in $n^{O(\frac{\log n}{\varepsilon^2})}$ time, providing a $(1+\varepsilon)$-approximation solution to the weighted tree search problem for any $0 < \varepsilon < 1$.*

3.2 Extension: A Poly-Time $O(\sqrt{\log n})$-Approximation Algorithm

We now present the second main result of this work. By recursively applying the previously designed QPTAS (Theorem 3.3) with $\varepsilon = 1$, we obtain a polynomial-time $O(\sqrt{\log n})$-approximation algorithm for finding search strategy for an arbitrary weighted tree. We start by informally sketching the algorithm – we follow here the general outline of the idea from [5]. The algorithm is recursive and starts by finding a minimal subtree T^* of an input tree whose removal disconnects T into subtrees, each of size bounded by $n/2^{\sqrt{\log n}}$. The tree T^* will be processed by our QPTAS algorithm described in Section 3.1. This results either in locating the target node, if it belongs to T^*, or identifying the component of $T - T^*$ containing the target, in which case the search continues recursively in the component. Subtrees considered at each level of recursion are disjoint, thus factors of approximation add up over recursion levels. However, for the final algorithm to have polynomial running time, the tree T^* needs to be of size $2^{O(\sqrt{\log n})}$. This is obtained by contracting paths in T^* (each vertex of the path has at most two neighbors in T^*) into single nodes having appropriately chosen weights. Since T^* has $2^{O(\sqrt{\log n})}$ leaves, this narrows down the size of T^* to the required level and we argue that an optimal search strategy for the 'contracted' T^* provides a search strategy for the original T^* that is within a constant factor from the cost of T^*.

A formal exposition and analysis of the obtained algorithm is provided in the full version.

▶ **Theorem 3.4.** *There is a $O(\sqrt{\log n})$-approximation polynomial time algorithm for the weighted tree search problem.*

4 Quasi-Polynomial Computation of Strategies with Small $\mathtt{COST}^{(\omega,c)}$

4.1 Preprocessing: Time Alignment in Schedules

We adopt here a method similar but arguably more refined than rounding techniques in scheduling problems of combinatorial optimization, showing that we could discretize the starting and finishing time of jobs, as well as weights of vertices, in a way to restrict the size of state space for each node to $n^{O(\log n)}$, without introducing much error.

Fix $c \in \mathbb{N}$ and $\omega = \frac{a}{cn}$ for some $a \in \mathbb{N}$. (In subsequent considerations, we will have $c = \Theta(1/\varepsilon)$, $a = O(\frac{n}{\log n})$ and $\omega = \Omega(\varepsilon/\log n)$.) Given a tree $T = (V, E, w)$, let $T' = (V, E, w')$ be a tree with the same topology as T but with weights rounded up as follows:

$$w'(v) = \begin{cases} \lceil w(v) \rceil_{\omega}, & \text{if } w(v) > c\omega, \\ \lceil w(v) \rceil_{\frac{1}{cn}}, & \text{otherwise.} \end{cases} \tag{2}$$

We will informally refer to vertices with $w(v) > c\omega$ (equivalently $w'(v) > c\omega$) as *heavy vertices* and vertices with $w(v) \leq c\omega$ (equivalently $w'(v) \leq c\omega$) as *light vertices*. (Note that $w(v) \leq c\omega$ if and only if $w'(v) \leq c\omega$.)

When designing schedules, we consider time divided into *boxes* of duration ω, with the i-th box equal to $[i\omega, (i+1)\omega]$. Each box is divided into a identical *slots* of length $\frac{1}{cn}$.

In the tree T', the duration of a query to a heavy vertex is an integer number of boxes, and the duration of a query to a light vertex is an integer number of slots. We next show that, without affecting significantly the approximation ratio of the strategy, we can align each query to a heavy vertex in the schedule so that it occupies an interval of full adjacent boxes, and each query to a light vertex in the schedule so that it occupies an interval of full adjacent slots (possibly contained in more than one box).

We start by showing the relationship between the costs of optimal solutions for trees T and T'.

▶ **Lemma 4.1.** $\texttt{OPT}(T) \leq \texttt{OPT}(T') \leq (1 + \frac{2}{c})\texttt{OPT}(T)$.

▶ **Lemma 4.2.** *There exists a consistent schedule assignment $\hat{S}$ for tree T' such that $\texttt{COST}_{\mathcal{A}_{\hat{S}}}(T') \leq (1 + \frac{3}{c})\texttt{OPT}(T')$ and for all $v \in V$ we have that*

- *if $w'(v) > c\omega$, (v is heavy), then the starting time t of any job (v, t) in the schedule $\hat{S}(u)$ of any $u \in V$ is an integer multiple of ω (aligned to a box),*
- *if $w'(v) \leq c\omega$, (v is light), then the starting time t of any query (v, t) in the schedule $\hat{S}(u)$ of any $u \in V$ is an integer multiple of $\frac{1}{cn}$ (aligned to a slot).*

A schedule on tree T' satisfying the conditions of Lemma 4.2, and the resulting search strategy, are called *aligned*. Subsequently, we will design an aligned strategy on tree T', and compare the quality of the obtained solution to the best aligned strategy for T'.

The intuition between the separate treatment of heavy vertices (aligned to boxes) and light vertices (aligned to slots) in aligned schedules is the following. Whereas the time ordering of boxes is essential in the design of the correct strategy, in our dynamic programming approach we will not be concerned about the order of slots within a single box (i.e., the order of queries to light vertices placed in a single box). This allows us to reduce the state space of a node. Whereas the ordering of slots in the box will eventually have to be repaired to provide a correct strategy, this will not affect the quality of the overall solution too much (except for the issue of light down queries pointed out earlier, which are handled separately in Section 5).

4.2 Dynamic Programming Routine for Fixed Box Size

Let the values of parameter c and box size ω be fixed as before. Additionally, let $L \in \mathbb{N}$ be a parameter representing the time limit for the duration of the considered vertex schedules when measured in boxes, i.e., the longest schedule considered by the procedure will be of length $L\omega$ (we will eventually choose an appropriate value of $L = O(\log n)$ as required when showing Theorem 3.3).

In order to lower-bound the duration of the consistent aligned schedule assignment with minimum cost, we perform an exhaustive bottom-up evaluation of aligned schedules which

satisfy constraints on the occupancy of slots. However, instead of considering individual slots of a schedule which may be empty or full, for reasons of efficiency we consider the *load* $s_v[p]$ of each box, $0 \leq p < L$, in the same schedule, defined informally as the proportion of the duration of the occupied slots within the box to the duration ω of the box. In the full version, we formally show the following claim.

▶ **Lemma 4.3.** *Assume that the data structure $(s_v, t_v)_{v \in V}$ corresponds to a consistent schedule. Let $v \in V$ be an arbitrarily chosen node with set of children $\{v_1, \ldots, v_l\}$. Then the set of queried nodes forms an edge cover of the tree:*

$$\text{If } t_v = \perp, \text{ then } t_{v_j} \neq \perp, \text{ for all } 1 \leq j \leq l. \tag{3}$$

Moreover, let completion time t^v_{end} of the query to v given as:

$$t^v_{end} = \begin{cases} t_v + w'(v), & \text{if } t_v \neq \perp, \\ +\infty, & \text{if } t_v = \perp. \end{cases}$$

Let a_p be the contribution to the load of the p-th time box of the query job for vertex v, i.e.

$$a_p = \begin{cases} \frac{1}{\omega} |[t_v, t^v_{end}] \cap [p\omega, (p+1)\omega]| & \text{if } t_v \neq \perp, \\ 0 & \text{if } t_v = \perp. \end{cases}$$

Then, for any box $[p\omega, (p+1)\omega]$, $0 \leq p < L$, we have the following bounds on the amount of load which can be packed into the box:

$$\left.\begin{array}{ll} s_v[p] = a_p + \sum_{j=1}^{l} s_{v_j}[p] \in [0,1], & \text{when } t^v_{end} \geq (p+1)\omega, \\ s_v[p] \geq a_p, & \text{when } p\omega < t^v_{end} < (p+1)\omega, \\ s_v[p] = 0, & \text{when } t^v_{end} \leq p\omega. \end{array}\right\} \tag{4}$$

Moreover, for any box $[p\omega, (p+1)\omega]$, $0 \leq p < L$, we have that the total load of a query to v and queries propagated from any of the subtrees cannot exceed 1:

$$\text{For all } 1 \leq j \leq l, \text{ the following bound holds: } s_{v_j}[p] + a_p \leq 1. \tag{5}$$

We now show that the shortest schedule assignments satisfying the set of constraints (3), (4), and (5) can be found in $n^{O(\log n)}$ time. This is achieved by using the procedure BuildStrategy, presented in Algorithm 4.1, which returns for a node v a non-empty set of schedules $\hat{\mathcal{S}}[v]$, such that each $s_v \in \hat{\mathcal{S}}[v]$ can be extended into the sought assignment of schedules in its subtree, $(s_u, t_u)_{u \in V(T_v)}$. In the statement of Algorithm 4.1, we recall that, given a tree $T = (V, E, w)$, tree $T' = (V, E, w')$ is the tree with weights rounded up to the nearest multiple of the length of a slot (see Equation (2)).

The subsequent steps taken in procedure BuildStrategy can be informally sketched as follows. The input tree T' is processed in a bottom-up manner and hence, for an input vertex v, the recursive calls for its children $v_1, \ldots, v_l$ are first made, providing schedule assignments for the children (see lines 3–4). Then, the rest of the pseudocode is responsible for using these schedule assignments to obtain all valid schedule assignments for v. Lines 10–14 merge the schedules of the children in such a way that a set $\hat{S}^*_i$, $i \in \{1, \ldots, l\}$, contains all schedule assignments computed on the basis of the schedules for the children $v_1, \ldots, v_i$. Thus, the set $\hat{S}^*_l$ is the final product of this part of the procedure and is used in the remaining part. Note

Algorithm 4.1 Dynamic programming routine BUILDSTRATEGY for a tree T'. $L, c \in \mathbb{N}$ are global parameters. Subroutines MERGESCHEDULES and INSERTVERTEX are provided in the full version.

```
1: procedure BuildStrategy(vertex v, box size ω ∈ ℝ)
2:     l ← number of children of v in T'    // Denote by v_1, ..., v_l the children of v.
3:     for i = 1..l do
4:         Ŝ[v_i] ← BuildStrategy(v_i, ω);
5:     s ← 0^L
6:     s.max_child_load ← 0^L
7:     s.must_contain_v ← false
8:     Ŝ_0 ← {s}    // Ŝ_0 contains the schedule with no queries.
9:     // Inductively, Ŝ_i^* is based on merging schedules at v_1, ..., v_i.
10:    for i = 1..l do
11:        Ŝ_i^* ← ∅
12:        for each schedule s ∈ Ŝ_{i-1}^* do
13:            for each schedule s_add ∈ Ŝ[v_i] do
14:                Ŝ_i^* ← Ŝ_i^* ∪ MergeSchedules(s, s_add, ω);
15:    Ŝ[v] ← ∅
16:    for each s ∈ Ŝ_l^* do
17:        if w'(v) > cω then    // v is heavy
18:            for p = 0..L − 1 do    //attempt to insert (into s) query to v starting from time-box p
19:                Ŝ[v] ← Ŝ[v] ∪ InsertVertex(s, v, ω, p · ω)
20:        else    //v is light
21:            for real t = 0..L · ω step 1/(cn) do
22:                //attempt to insert (into s) query to v at a slot from time t
23:                Ŝ[v] ← Ŝ[v] ∪ InsertVertex(s, v, ω, t)
24:        if s.must_contain_v = false then
25:            Ŝ[v] ← Ŝ[v] ∪ InsertVertex(s, v, ω, ⊥)
26:    return Ŝ[v]
```

that a schedule assignment in $\hat{S}_l^*$ may not be valid since a query to v is not accommodated in it – the rest of the pseudocode is responsible for taking each schedule $s \in \hat{S}_l^*$ and inserting a query to v into s. More precisely, the subroutine INSERTVERTEX is used to place the query to v at all possible time points (depending whether v is heavy or light). We note that the subroutine MERGESCHEDULES, for each schedule s it produces, sets a Boolean 'flag' $s.must\_contain\_v$ that whenever equals $false$, indicates that querying v is not necessary in s to obtain a valid schedule for v (this happens if s queries all children of v). A detailed analysis of procedure BUILDSTRATEGY can be found in the full version.

▶ **Lemma 4.4.** *For fixed constants $L, c \in \mathbb{N}$, calling procedure* BUILDSTRATEGY$(r(T), \omega)$*, where $r(T)$ is the root of the tree, determines if there exists a tuple $(s_v, t_v)_{v \in V}$ which satisfies constraints* (3)*,* (4)*, and* (5)*, or returns an empty set otherwise.*

It follows directly from Lemma 4.4 that, for any value ω^*, tree T may only admit an aligned schedule assignment of duration at most $\omega^* L$ if a call to procedure BUILDSTRATEGY $(r(T), \omega^*)$ returns a non-empty set. Taking into account Lemmas 4.1 and 4.2, we directly obtain the following lower bound on the length of the shortest aligned schedule in tree T'.

▶ **Lemma 4.5.** *If* BUILDSTRATEGY$(r(T), \omega^*) = \emptyset$*, then:*

$$\omega^* L < \left(1 + \frac{3}{c}\right) \texttt{OPT}(T') \leq \left(1 + \frac{3}{c}\right)\left(1 + \frac{2}{c}\right) \texttt{OPT}(T) \leq \left(1 + \frac{11}{c}\right) \texttt{OPT}(T).$$

▶ **Lemma 4.6.** *The running time of procedure* BuildStrategy$(r(T), \omega)$ *is at most* $O((cn)^{\gamma L})$*, for some absolute constant* $\gamma = O(1)$*, for any* $\omega \leq n$*.*

To complete the proof of Proposition 3.1, we can now provide a strategy which achieves a small value of $\texttt{COST}^{(\omega,c)}$. This relies on procedure BuildStrategy$(r(T), \omega)$ as an essential subroutine, first determining the minimum value of $\omega = \frac{i}{cn}$, $i \in \mathbb{N}$, for which BuildStrategy produces a schedule. Details of the approach are provided in the full version.

5 Reducing the Number of Down-Queries

We start with defining a function $\ell\colon V \to \{1, \ldots, \lceil \log_2 n \rceil\}$ which in the following will be called a *labeling of* T and the value $\ell(v)$ is called the *label of* v. We say that a subset of nodes $H \subseteq V$ is an *extended heavy part* in T if $H = \{v\} \cup H'$, where all nodes in H' are heavy, no node in H' has a heavy neighbor in T that does not belong to H' and v is the parent of some node in H'. Let $H_1, \ldots, H_l$ be all extended heavy parts in T. Obtain a tree $T_C = (V_C, E_C)$ by contracting, in T, the subgraph H_i into a node denoted by h_i for each $i \in \{1, \ldots, l\}$. In the tree T_C, we want to find its labeling $\ell'\colon V_C \to \{1, \ldots, \lceil \log_2 |V_C| \rceil\}$ that satisfies the following condition: for each two nodes u and v in V_C with $\ell'(u) = \ell'(v)$, the path between u and v has a node z satisfying $\ell'(z) < \ell'(u)$. One can obtain such a labeling by a following procedure that takes a subtree T'_C of T_C and an integer i as an input. Find a central node v in T'_C, set $\ell'(v) = i$ and call the procedure for each subtree T''_C of $T'_C - v$ with input T''_C and $i + 1$. The procedure is initially called for input T and $i = 1$. We also remark that, alternatively, such a labeling can be obtained via vertex rankings [13, 28].

Once the labeling ℓ' of T_C is constructed, we extend it to a labeling ℓ of T in such a way that for each node v of T we set $\ell(v) = \ell'(v)$ if $v \notin H_1 \cup \cdots \cup H_l$ and $\ell(v) = \ell'(h_i)$ if $v \in H_i$, $i \in \{1, \ldots, l\}$.

Having the labeling ℓ of T, we are ready to define a query sequence $R(v)$ for each node $v \in V$. $R(v)$ contains all nodes u from T_v such that $\ell(u) < \ell(v)$ and each internal node z of the path connecting v and u in T satisfies $\ell(z) > \ell(u)$. Additionally, the nodes in $R(v)$ are ordered by increasing values of their labels.

By x we refer to the target node in T. Fix S to be a stable sequence assignment in the remaining part of this section and by R we refer to the sequence assignment constructed above. Then, we fix S^+ to be $S^+(v) = R(v) \circ S(v)$ for each $v \in V$. A query made by $\mathcal{A}_{S^+}$ to a node that belongs to $R(v)$ for some $v \in V$ is called an *R-query*; otherwise it is an *S-query*. In the full version we show that, in $\mathcal{A}_{S^+}$, the total number of R-queries does not exceed $2\log_2 n$. Moreover, since S is stable, for each target node x, the S-queries performed by $\mathcal{A}_{S^+}$ are a subsequence of the queries performed by $\mathcal{A}_S$. Therefore, the potentially additional queries made by $\mathcal{A}_{S^+}$ with respect to $\mathcal{A}_S$ are R-queries. We then formally show that each R-query is made on a light node and that any R-query increases the value of $\texttt{COST}^{(\omega,c)}$ of $\mathcal{A}_{S^+}$ with respect to the value of $\texttt{COST}^{(\omega,c)}$ of $\mathcal{A}_S$ by at most $(2c+1)\omega$. Hence we have: $\texttt{COST}^{(\omega,c)}_{\mathcal{A}_{S^+}}(T) \leq \texttt{COST}^{(\omega,c)}_{\mathcal{A}_S}(T) + 2(2c+1)\omega \log_2 n$.

Moreover, we show in the full version that the total number of queries in strategy $\mathcal{A}_{S^+}$ to light nodes receiving 'down' replies can be likewise bounded by $2\log_2 n$. Since each such query introduces a rounding difference of at most $(2c+1)\omega$ when comparing cost functions $\texttt{COST}$ and $\texttt{COST}^{(\omega,c)}$, we thus obtain: $\texttt{COST}_{\mathcal{A}_{S^+}}(T) \leq \texttt{COST}^{(\omega,c)}_{\mathcal{A}_{S^+}}(T) + 2(2c+1)\omega \log_2 n$.

Combining the above observations gives the claim of the Proposition.

Abstract

We construct uniquely satisfiable k-CNF formulas that are hard for the PPSZ algorithm, the currently best known algorithm solving k-SAT. This algorithm tries to generate a satisfying assignment by picking a random variable at a time and attempting to derive its value using some inference heuristic and otherwise assigning a random value. The "weak PPSZ" checks all subformulas of a given size to derive a value and the "strong PPSZ" runs resolution with width bounded by some given function. Firstly, we construct graph-instances on which "weak PPSZ" has savings of at most $(2+\epsilon)/k$; the *saving* of an algorithm on an input formula with n variables is the largest γ such that the algorithm succeeds (i.e. finds a satisfying assignment) with probability at least $2^{-(1-\gamma)n}$. Since PPSZ (both weak and strong) is known to have savings of at least $\frac{\pi^2+o(1)}{6k}$, this is optimal up to the constant factor. In particular, for $k=3$, our upper bound is $2^{0.333\ldots n}$, which is fairly close to the lower bound $2^{0.386\ldots n}$ of Hertli [SIAM J. Comput.'14]. We also construct instances based on linear systems over $\mathbb{F}_2$ for which *strong* PPSZ has savings of at most $O\left(\frac{\log(k)}{k}\right)$. This is only a $\log(k)$ factor away from the optimal bound. Our constructions improve previous savings upper bound of $O\left(\frac{\log^2(k)}{k}\right)$ due to Chen et al. [SODA'13].

1 Introduction

The k-SAT problem is one of the most fundamental NP-complete problems: given a k-CNF formula decide if there is an assignment to the variables that satisfies all the clauses. While a simple exhaustive search algorithm solves the problem, attempting to beat this trivial approach remains an active direction (see e.g. [11, 12, 4, 10]). Formalizing the true hardness of k-SAT, Impagliazzo and Paturi [7] presented two hypotheses: *Exponential Time Hypothesis (ETH)* which rules out any $2^{o(n)}$ time algorithm for k-SAT where n is the number of variables and *Strong Exponential Time Hypothesis (Strong ETH)* which says that for any $\epsilon > 0$ there exists $k > 0$ such that k-SAT cannot be solved in time $2^{(1-\epsilon)n}$. Both ETH and Strong ETH

have successfully been used to explain the hardness of many other problems; under ETH one can prove tight lower bounds for many fixed parameter tractable problems (see [8]), and under Strong ETH several lower bounds for polynomial time solvable problems are proved (see e.g. [1]). However the validity of both these hypotheses remains a matter of mystery and in particular regarding Strong ETH no consensus seems to be within reach any time soon.

In this paper we focus on Strong ETH and the problem of constructing hard instances for known classes of algorithms for k-SAT. Paturi, Pudlák, Saks and Zane [10] presented the currently best known randomized algorithm for k-SAT. The algorithm roughly does the following: pick uniformly at random a variable x from the input formula. Try to infer the value of x using some sound heuristic. If this check fails, pick a random value for x. Set x to be this value and repeat. A sound heuristic is an algorithm P that receives a formula F and a variable x such that $P(F,x)=0$ implies $F \models (x=0)$ and $P(F,x)=1$ implies $F \models (x=1)$. We will consider two heuristics, P_w^{weak} amd P_w^{strong}, where P_p^{weak} checks if the value of x can be derived from any set of w clauses of F, and P_w^{strong} checks if the value of x can be derived by a width-w resolution derivation from F. Note that if F is $O(1)$-CNF then both P_w^{weak} and P_w^{strong} run in subexponential time as long as $w = o(\frac{n}{\log n})$. The first result showing that even simple sound heuristics can yield non-trivial savings over exhaustive search was proved by Paturi, Pudlák and Zane.

▶ **Theorem 1** ([11]). *Let F be a k-CNF formula on n variable. Then*

$$\Pr[\texttt{ppsz}(F, P_1^{\text{weak}}) \in \text{sat}(F)] \geq 2^{-(1-\frac{1}{k})n}.$$

Naturally one can ask if stronger heuristics can improve the success probability. It was indeed shown in the following theorem that using $\omega(1)$-width resolution yields improvements.

▶ **Theorem 2** ([10]). *Let F be a k-CNF formula on n variables. Then*

$$\Pr[\texttt{ppsz}(F, P_{\omega(1)}^{\text{strong}}) \in \text{sat}(F)] \geq 2^{-(1-\frac{\pi^2}{6k}-o(1))n}.$$

Later Hertli [6] showed among other things that even $P_{\omega(1)}^{\text{weak}}$ yields the same improvement over the trivial P_1^{weak}.

▶ **Theorem 3** ([6]). *Let F be a k-CNF formula on n variables. Then*

$$\Pr[\texttt{ppsz}(F, P_{\omega(1)}^{\text{weak}}) \in \text{sat}(F)] \geq 2^{-(1-\frac{\pi^2}{6k}-o(1))n}.$$

The first construction of hard instances for PPSZ was given by Chen, Scheder, Talebanfard and Tang [3]. These instances are hard even for $P_{\omega(1)}^{\text{strong}}$.

▶ **Theorem 4** ([3]). *For any large enough $k, n > 0$ there are k-CNF formulas F such that*

$$\Pr[\texttt{ppsz}(F, P_{n/k}^{\text{strong}}) \in \text{sat}(F)] \leq 2^{-(1-O(\log^2 k/k))n}.$$

In this paper we improve this upper bound. For $P_{\omega(1)}^{\text{weak}}$ we give completely different constructions for which we can show that the success probability of PPSZ is essentially tight. For $P_{\omega(1)}^{\text{strong}}$ we can improve the asymptotics of k from $O(\log^2 k/k)$ to $O(\log k/k)$.

▶ **Theorem 5.** *For every $k \geq 3$ and every large enough n there exists a uniquely satisfiable k-CNF formula F on n variables such that*

1. $\Pr[\texttt{ppsz}(F, P_w^{\text{weak}}) \in \text{sat}(F)] \leq 2^{-(1-\frac{2}{k})n}$ *for some* $w = \Theta(\log n)$,
2. *for any* $\epsilon > 0$, $\Pr[\texttt{ppsz}(F, P_w^{\text{weak}}) \in \text{sat}(F)] \leq 2^{-(1-\frac{2(1+\epsilon)}{k})n}$ *for some* $w = n^{\Theta(\epsilon)}$.

In particular, for $k = 3$, our upper bound is $2^{0.333\ldots n}$, which is fairly close to the lower bound $2^{0.386\ldots n}$ of [6].

▶ **Theorem 6.** *For every $k \geq 3$ and every large enough n, there exists a k-CNF formula F on n variables with a unique satisfying assignment such that $\texttt{ppsz}(F, P^{\text{strong}}_{n/k})$ is successful with probability at most $2^{(-1+\epsilon)n}$, where $\epsilon = O\left(\frac{\log(k)}{k}\right)$.*

Unfortunately we fail to obtain $2^{-(1-O(1/k))n}$ upper bounds for strong PPSZ. Is this possible at all or indeed strong PPSZ succeeds with probability at least $2^{-(1-\omega(1/k))n}$?

The analysis of our hard instances is based on an encoding view of PPSZ. Given a formula F on variables $x_1, \ldots, x_n$ and a satisfying assignment $\mathbf{b}$, PPSZ produces an encoding of the assignment with respect to a given permutation π of the variables in the following way.

```
encode(b, π, F, P)
c := empty string
for i = 1, ..., n do
    if P(F, x_π(i)) ∉ {0, 1} then
        append b_π(i) to c;
    end
    F := F|_{x_π(i) → b_π(i)};
end
```

It is not hard to see that we can express the success probability of PPSZ in terms of expected code lengths as follows.

▶ **Lemma 7** ([10]). *Let F be a k-CNF and let P be a sound heuristic. We have* $\Pr[\texttt{ppsz}(F, P) \in \text{sat}(F)] = \sum_{\mathbf{b} \in \text{sat}(F)} \mathbb{E}_\pi \, 2^{-|\texttt{encode}(\mathbf{b}, \pi, F, P)|}$.

Thus our goal is to construct instances having a few satisfying assignments, all of which admitting only long encodings. Defining the optimal encoding length a satisfying assignment $\mathbf{b}$ to be $\text{codelength}(F, P, \mathbf{b}) := \min_\pi |\texttt{encode}(\mathbf{b}, \pi, F, P)|$ we get

$$\Pr[\texttt{ppsz}(F, P) \in \text{sat}(F)] \quad \leq \quad \sum_{\mathbf{b} \in \text{sat}(F)} 2^{-\text{codelength}(\mathbf{b}, F, P)} \, .$$

The formulas in Theorem 5 and Theorem 6 have the unique satisfying assignment $\mathbf{0}$. Thus our goal will be to prove a lower bound on $\text{codelength}(F, P, \mathbf{0})$.

2 Notation and Preliminaries

Let F be a CNF formula with variable set V. A restriction (or partial assignment) is a partial function $\rho : V \to \{0, 1\}$. For $\mathbf{b} \in \{0, 1\}^n$, the notation $S \mapsto \mathbf{b}$ is the restriction that maps $x \in S$ to $\mathbf{b}_x$ and is undefined on $V \setminus S$. By $F|_\rho$ we denote the formula arising from fixing the variables according to ρ and then simplifying the resulting formula by removing unsatisfied literals and satisfied clauses. For a matrix $A \in \mathbb{F}_2^{m \times n}$ and $U \subseteq [n]$ we denote by A_U the $(m \times |U|)$ submatrix formed by taking all columns indexed by some $i \in U$. By $\mathbf{0}$ we denote the all-0-assignment as well as the null vector in $\mathbb{F}_2^n$.

We will identify a vector $\mathbf{a} \in \mathbb{F}_2^n$ with its support $\{i \in [n] \mid a_i = 1\}$. Thus we will liberally write things like $\mathbf{a} \cup \mathbf{b}$, $\mathbf{a} \setminus \mathbf{b}$, $|\mathbf{a}|$, and so on.

We list some key observations relating PPSZ and resolution. The (easy) proofs can be found in the appendix.

▶ **Definition 8.** Let F be a formula with a unique satisfying assignment, which without loss of generality is $\mathbf{0}$, and let P be a proof heuristic. We say F *collapses under* P if there is an ordering $x_1, \ldots, x_n$ of the variables in F such that $F|_{(x_1,\ldots,x_{i-1}\mapsto 0)} \vdash_P (x_i = 0)$ for all $1 \le i \le n$.

▶ **Proposition 9.** *If* $\mathrm{codelength}(F, P, \mathbf{b}) \le m$ *then there is a set* S *of* m *variables such that* $F|_{S\mapsto\mathbf{b}}$ *collapses under* P.

The next lemma states that if F collapses "sequentially" under bounded-width resolution, then it collapses "simultaneously" as well.

▶ **Proposition 10.** *Let* F *be a* k*-CNF formula with the unique satisfying assignment* $\mathbf{0}$*, and let* $w \ge k$*. If* F *collapses under* P_w^{strong} *then* $F \vdash_w^{\mathrm{strong}} (x = 0)$ *for all variables* x *of* F.

The next proposition connects logical implication and collapse under P^{weak} to linear algebra.

▶ **Proposition 11.** *Let* $A \in \mathbb{F}_2^{m\times n}$ *and* F_A *be its linear formula. If* $\vdash_w^{\mathrm{weak}} (F, x_i) \in \{0, 1\}$ *then there is a row vector* $\mathbf{r} \in \mathbb{F}_2^m$ *of Hamming weight at most* w *such that* $\mathbf{r} \cdot A = \mathbf{e}_i$.

3 Hard Instances for Weak PPSZ: Proof of Theorem 5

The construction in this section is based on a modification of satisfiable Tseitin formulas. Unsatisfiable Tseitin formulas are extensively studied in proof complexity (see e.g. [13, 14]). Given a graph $G = (V, E)$, the girth of G is defined as the size of the shortest cycle in G. We denote this by $g(G)$. For every pair $e, e' \in E(G)$ of edges we define the distance between e and e' by $\min_{u\in e, v\in e'}\{d(u, v)\}$. We will need graphs of bounded degree with large girth. According to a well-known result of Erdős and Sachs [5], for every $k \ge 3$ and every sufficiently large n, there exists a k-regular graph with n vertices and girth $> \log_{k-1} n$. Explicit constructions for infinitely many values of k with a better constant are also known [9].

Given a degree-k graph $G = (V, E)$, the Tseitin formula $T(G)$ is defined as follows. For each edge $e \in E$, there is a propositional variable x_e. For each vertex $v \in V$ we add the constraint $\sum_{e\ni v} x_e = 0 \pmod 2$, which can be written as a conjunction of 2^{k-1} k-clauses. [1] In our formulas we assume that the girth of the graph is at least $\log_{k-1} n$, where n denotes the number of vertices. Furthermore, we add a clause $\neg x_e \vee \neg x_{e'}$ for each pair of edges e, e' of distance at least $\frac{g(G)}{2} - 1$ (which is $\ge \frac{1}{2}\log_{k-1} n - 1$). We call these clauses *bridges* and we denote the conjunction of all of them by B. Define $F_G := T(G) \wedge B$. Note that F_G has $N = kn/2$ variables.

The following proposition follows readily.

▶ **Proposition 12.** F_G *has the unique satisfying assignment* $\mathbf{0}$.

Proof. For an assignment α let G_α denote the spanning subgraph of G containing the edges e with $\alpha(e) = 1$. Note that α satisfies $T(G)$ if and only if G_α is *even*, i.e., every vertex has even degree. There are two cases: either G_α is the empty graph, in which case $\alpha = \mathbf{0}$ and satisfies F_G, too. Or G_α contains a cycle C, which has length at least $g(G)$ and therefore contains a bridge. In this case, α violates B. ◀

[1] The original Tseitin tautologies express the fact that the system $\sum_{e\ni v} x_e = a_v \pmod 2$ is unsatisfiable if $\sum_v a_v = 1 \pmod 2$.

We will consider PPSZ with P_w^{weak} when $w = O(\log n)$

▶ **Lemma 13.** *In F_G any encoding of the all-0 assignment has length at least $(1 - \frac{2}{k})N$ under $w \leq \frac{1}{2}\log_{k-1} n - 1$.*

Proof. Suppose for contradiction that $\text{codelength}(F, P_w^{\text{weak}}) \leq \left(1 - \frac{2}{k}\right) N$ collapses. Then there is a restriction ρ that sets some $\left(1 - \frac{2}{k}\right) N$ variables to 0 such that $F_G|_\rho$ collapses under P_w^{weak}. Note that ρ leaves at least $\frac{2}{k}N = n$ variables (i.e., edge) unset. Obviously this set of edges contains a cycle C. Let $\sigma := (E \setminus C \mapsto \mathbf{0})$. Clearly $F_G|_\sigma$ also collapses. This contradicts the next lemma:

▶ **Lemma 14.** *Let $C \subseteq E$ be a cycle and $\sigma := (E \setminus C \mapsto \mathbf{0})$. Then $F_G|_\sigma$ does not collapse under P_w^{weak}.*

Proof. Suppose it does collapse. Then there exists an edge $e \in C$ and a set $F' \subseteq F|_\sigma$ of at most w clauses such that $F' \models \neg x_e$.

The clauses in F' are either coming from the Tseitin part or from the bridges. Consider a path $P = v_1, \ldots, v_s$ of maximum length on which e appears and the vertices of P are mentioned by Tseitin clauses in F'. Note that P cannot contain the whole cycle, since otherwise there would be too many clauses in F'. Let v_0 and v_{s+1} be vertices on $C \setminus P$ connected to v_1 and v_s, respectively. We extend P by v_0 and v_{s+1}. Since $w \leq \frac{1}{2}\log_{k-1} n - 1$, there is no bridge between any pair of edges appearing on P. We can now simply set all the variables in P to 1 and all other variables to 0. This would satisfy F' and yet it sets x_e to 1, contradicting that $F' \models \neg x_e$. ◀

This concludes the proof of Lemma 13. ◀

Below we show that it is possible to obtain similar lower bounds even when w is some function in $n^{O(\epsilon)}$.

▶ **Lemma 15.** *For every $\epsilon > 0$ and every sufficiently large n, any encoding of the all-0 assignment with $w < n^{\frac{\epsilon}{8(k-1)}}$ has length at least $(1 - \frac{2(1+\epsilon)}{k})N$.*

Proof. Let S be the set of edges appearing in any encoding of the all-0 assignment. We will show that $|E \setminus S| < (1+\epsilon)n$. Assume for a contradiction that $|E \setminus S| \geq (1+\epsilon)n$. We will show that $E \setminus S$ contains a large subgraph which is expanding in a certain sense.

▶ **Definition 16.** In a graph G we say that a path $P = v_1, \ldots, v_t$ is *slender* if for all $1 \leq i \leq t$ we have $d(v_i) \leq 2$.

▶ **Lemma 17.** *Let $G = (V, E)$ be a graph on n vertices such that $|E| \geq (1+\epsilon)n$ for some $\epsilon > 0$. There exists an induced subgraph $H \subseteq G$ on at least $\Omega(\epsilon^{3/4} n^{1/4})$ vertices with $\delta(G) \geq 2$ with no slender path of length $\geq 2/\epsilon$.*

Proof. Let $r = 2/\epsilon$. We first find a subgraph of minimum degree at least 2 on at least $\Omega(\sqrt{n/r})$ vertices with many edges. To do this we can remove vertices of degree at most 1 at a time. Having removed t vertices we are left with a graph on $n - t$ vertices and at least $(1 + \frac{2}{r})n - t$ edges. It holds that $(1 + \frac{2}{r})n - t \geq (1 + \frac{2}{r})(n - t)$. As the remaining graph has at most $\binom{n-t}{2}$ edges we have $(1 + 2/r)n \leq \binom{n-t}{2} + t$. This implies $t \leq n - \Omega(\sqrt{n/r})$. Let $n' = n - t$. We thus have $n' \geq \Omega(\sqrt{n/r})$.

If the remaining graph has no slender path of length r we are done. Otherwise let $v_1, \ldots, v_{t_1}$ be a maximal slender path, i.e., $d(v_i) = 2$ for all $1 \leq i \leq t_1$ and v_1 and v_{t_1} have a neighbor (possibly the same) outside P of degree at least 3. We remove $v_1, \ldots, v_{t_1}$ from the

graph. If there are any vertices of degree 1 we remove them one at a time until there are no more such vertices. Let the total number removed vertices be t'_1. We repeat this for d rounds until there are no more slender paths of length r and all vertices have degree at least 2. Let t_i and t'_i be defined similarly for the ith iteration. We have $t'_i \geq r$ and thus $d \leq n'/r$. Note that the total number of removed edges is $t'_1 + \ldots + t'_d + d$ and hence at most $n' + n'/r$. We are left with a graph with at least n'/r edges and hence at least $\Omega(\sqrt{n'/r}) = \Omega(\epsilon^{3/4} n^{1/4})$ vertices. ◀

Applying Lemma 17 on $E \setminus S$ we obtain a subgraph H with minimum degree at least 2 which does not contain any slender path of length $\geq 2/\epsilon$. Setting all edges outside of H to 0, we obtain that there exists a set of at most w clauses F' in the restricted formula which implies $x_e = 0$ for some $e \in H$. Let $e = (u, v)$. We will construct a tree T_{uv} in H by growing two disjoint rooted trees T_u and T_v, starting at u and v, respectively. The crucial requirement is that in both T_u and T_v any path of length $\geq 2/\epsilon$ that goes downwards in the rooted tree there exists a vertex of degree ≥ 3. We call such a vertex a *branching* vertex. Furthermore, in T_{uv} the distance between the first branching vertices in T_u and T_v is at most $2/\epsilon$. Using the fact that the minimum degree in H is at least 2 and it does not contain any slender path of length $2/\epsilon$ and that the girth is at least $\log_{k-1} n$, we can easily construct T_{uv} so that each root to leaf path in both T_u and T_v has $\frac{\epsilon}{8} \log_{k-1} n$ branching vertices. Since the horizon $w < n^{\frac{\epsilon}{8(k-1)}}$, there are vertices u' and v' in T_u and T_v, respectively, that are not mentioned in F'. Consider the unique path between u' and v' in T_{uv}. Note that this path has length at most $\frac{1}{2} \log_{k-1} n$. However, since we put bridges only between edges of distance more that $\frac{1}{2} \log_{k-1} n$, there is no bridge between any pair of edges on this path. Setting all edges on the path including e to 1 and everything else to 0 satisfies F', contradicting to $F' \models \neg x_e$. ◀

Lemma 13 implies that $\text{codelength}(F_G, P_w^{\text{weak}}) \geq (1 - \frac{2}{k})N$ for $w \leq \frac{1}{2} \log_{k-1} n - 1$. Similarly, Lemma 15 implies that $\text{codelength}(F_G, P_w^{\text{weak}}) \geq (1 - \frac{2(1+\epsilon)}{k})N$ for $w < n^{\frac{\epsilon}{8(k-1)}}$. This completes the proof of Theorem 5.

4 Hard Linear Formulas for Strong PPSZ: Proof of Theorem 6

Suppose $A \in \mathbf{F}^{m \times n}$ is a matrix in which every row has Hamming weight at most k. Then the system $A \cdot \mathbf{x} = \mathbf{0}$ consists of m linear equations over n variables, each of which involves at most k variables. One can encode it as a k-CNF formula with $2^{k-1} \cdot m$ clauses. Let us denote this formula by F_A. A CNF formula which in this way encodes a system of linear equations will be called a *linear CNF* formula.

4.1 Robust Expanding Matrices

As often in the realm of resolution, our proof of hardness relies on a certain notion of expansion. Loosely speaking, a matrix A is a *robust expander* if for every "sufficiently large" submatrix A_U and every "sufficiently diverse" set of row vectors $\mathbf{u}_1, \ldots, \mathbf{u}_\ell$ at least one of the vectors $\mathbf{u}_i \cdot A_U$ has "large" Hamming weight. We will now define this notion formally. Throughout this section, let $k \in \mathbb{N}$ be arbitrary but fixed (this is the k for which we want to construct hard k-CNF formulas). A sequence $\mathbf{u}_1, \ldots, \mathbf{u}_\ell \in \mathbb{F}_2^n$ is *well-increasing* if $n/k \leq |\mathbf{u}_i \setminus (\mathbf{u}_1 \cup \cdots \cup \mathbf{u}_{i-1})| \leq 4n/k$ for every $1 \leq i \leq \ell$. This is what we mean by "sufficiently diverse".

▶ **Definition 18** (Robust Expanders). A matrix $A \in \mathbb{F}_2^{n\times n}$ is called a t-robust (ℓ, w)-expander if for every $U \subseteq [n]$ of size t and well-increasing sequence $\mathbf{u}_1 \ldots, \mathbf{u}_\ell$, there is some $1 \leq i \leq \ell$ such that $|\mathbf{u}_i \cdot A_U| > w$.

▶ **Theorem 19** (Robust Expanders Are Hard). *Let $t, w \in \mathbb{N}$, $w \geq 2n/k$, and $\ell := \lfloor \frac{k\cdot t}{4n} \rfloor$. If A is a t-robust (ℓ, w)-expander, then* $\mathrm{codelength}(F, P_w^{\mathrm{strong}}, \mathbf{0}) \geq n - t$.

▶ **Theorem 20** (Robust Expanders Exist). *For every sufficiently large n, there is a matrix $A \in \mathbb{F}_2^{n\times n}$ such that (1) every row of A has Hamming weight at most $k+1$; (2) the rank of A is at least $n - 2\log(n)$; (3) A is a t-robust (ℓ, w)-expander for $t = \frac{60\cdot\log(k)}{k} \cdot n$, $\ell = \lfloor \frac{k\cdot t}{4n} \rfloor$, and $w = 2n/k$.*

With these theorems we can prove Theorem 6 for strong PPSZ. Write $t = \frac{60\cdot\log(k)}{k} \cdot n$ and let A be a matrix as promised by Theorem 20. By Theorem 19 we know that $\mathrm{codelength}(F_A, P_{2n/k}^{\mathrm{strong}}, \mathbf{0}) \geq n - t$. The Steinitz exchange lemma from linear algebra gives us $2\log(n)$ unit row vectors that we can add to A to obtain a matrix $A' \in F_2^{(n+2\log(n))\times n}$ of row rank n. This means that $F_{A'}$ has the unique satisfying assignment $\mathbf{0}$. Each added unit row vector in A' is a unit clause in $F_{A'}$. It can easily be verified that adding a unit clause reduces codelength by at most 1. Therefore $\mathrm{codelength}(F_{A'}, P_{n/k}^{\mathrm{weak}}, \mathbf{0}) \geq \mathrm{codelength}(F_A, P_{n/k}^{\mathrm{weak}}, \mathbf{0}) - 2\log(n) \geq n - t - 2\log(n)$. This proves Theorem 6.

Proof of Theorem 19. Let P be the strong proof heuristic which performs resolution of width up to w. We assume that $\mathrm{codelength}(F_A, P, \mathbf{0}) \leq n - t$ and will derive a contradiction to the assumption that A is a robust expander.

By Proposition 9 and 10, $\mathrm{codelength}(F_A, P, \mathbf{0}) \leq n - t$ means that there is a partition $[n] = U \uplus S$ with $|U| = t$ such that $F' \vdash_P (x_i = 0)$ for every $i \in U$, where $F' := F_A|_{S\mapsto\mathbf{0}}$ is the formula obtained from F by setting every variable in S to 0. For notational simplicity assume $U = \{1, \ldots, t\}$. By a connection between resolution and linear algebra which is folklore by now (see e.g. [2]), the fact that $F' \vdash_P (x_i = 0)$ means the following:

▶ **Proposition 21** (Connection Between Resolution and Linear Algebra). *For every $i \in U$ there exists a binary tree T_i in which every node v is labeled with a row vector $\mathbf{r}_v \in \mathbb{F}_2^n$ such that:*

1. *for a leaf v, the label $\mathbf{r}_v$ is a unit vector,*
2. *if v is an inner node and v_0, v_1 are its children then $\mathbf{r}_v = \mathbf{r}_{v_0} + \mathbf{r}_{v_1}$.*
3. *$|\mathbf{r}_v \cdot A_U| \leq w$ for every node v of T_i,*
4. *$\mathbf{r}_{\mathrm{root}} \cdot A_U = \mathbf{e}_i$.*

We call T_i the resolution tree of x_i.

For $i \in \{1, \ldots, t\}$ let $\mathbf{r}_i$ be the root labels of the tree T_i. Since $\mathbf{r}_i \cdot A_U = \mathbf{e}_i$ we conclude that the vectors $\mathbf{r}_1, \ldots, \mathbf{r}_t$ are linearly independent. In particular this means that $|\mathbf{r}_1 \cup \cdots \cup \mathbf{r}_t| \geq t$. Equipped with these observations and the previous proposition, we can now construct a well-increasing sequence $\mathbf{u}_1, \ldots, \mathbf{u}_{\ell^*}$ with $\ell^* := \lfloor \frac{k\cdot t}{4n} \rfloor$ and $|\mathbf{u}_i \cdot A_U| \leq w$ for all $1 \leq i \leq \ell^*$. This will be a contradiction to the assumption that A is a robust expander.

Start with the empty sequence and $\ell = 0$. While $\ell < \ell^*$, we try to extend the current well-increasing sequence $\mathbf{u}_1, \ldots, \mathbf{u}_\ell$ by considering two cases. For convenience let $\mathbf{u} = \mathbf{u}_1 \cup \cdots \cup \mathbf{u}_\ell$. Note that $\frac{\ell\cdot n}{k} \leq |\mathbf{u}| \leq \frac{4\ell\cdot n}{k}$.

Case 1. Suppose some vector $\mathbf{r}_i$ among $\mathbf{r}_1, \ldots, \mathbf{r}_t$ satisfies $|\mathbf{r}_i \setminus \mathbf{u}| > 2n/k$. Recall that $\mathbf{r}_i$ is the root label of the tree T_i. We walk from the root of T_i to a leaf by always choosing the child v for which the "weight" $|\mathbf{r}_v \setminus \mathbf{u}|$ is largest. Note that this weight is more than $2n/k$ at

the root and at most 1 at a leaf. Also, in every step the weight decreases by at most a factor of 2. Thus we find a node v on the path for which $n/k \leq |\mathbf{r}_v \setminus \mathbf{u}| \leq 2n/k$. We set $\mathbf{u}_{\ell+1} := \mathbf{r}_v$ and see that the sequence $\mathbf{u}_1, \dots, \mathbf{u}_{\ell+1}$ is well-increasing by the choice of $\mathbf{u}_{\ell+1}$. Also, since $\mathbf{u}_{\ell+1}$ is the label of a node in a resolution tree, it holds that $|\mathbf{u}_{\ell+1} \cdot A_U| \leq w$.

Case 2. Suppose $|\mathbf{r}_i \setminus \mathbf{u}| \leq 2n/k$ for all $1 \leq i \leq t$. Since $|(\mathbf{r}_1 \cup \dots \cup \mathbf{r}_t) \setminus \mathbf{u}| \geq t - |\mathbf{u}| \geq t - \frac{4\ell \cdot n}{k} \geq t - \frac{4\ell^* \cdot n}{k} + \frac{4n}{k} \geq \frac{4n}{k}$, we can find a subset $I \subseteq [t]$ with $|I| \leq 2n/k$ such that $2n/k \leq \left|\bigcup_{i \in I} \mathbf{r}_i \setminus \mathbf{u}\right| \leq 4n/k$. If we let v be a random linear combination of the $\mathbf{r}_i, i \in I$, we see that $\mathbb{E}[|\mathbf{v} \setminus \mathbf{u}|] \geq n/k$. Thus, there is some vector $\mathbf{v}$ which is a linear combination of the $\mathbf{r}_i, i \in I$ and $n/k \leq |\mathbf{v} \setminus \mathbf{u}| \leq 4n/k$. Furthermore, since $|\mathbf{r}_i \cdot A_U| = |\mathbf{e}_i| = 1$ we get $|\mathbf{v} \cdot A_U| \leq \sum_{i \in I} |\mathbf{r}_i \cdot A_U| = |I| \leq 2n/k \leq w$. We can extend the sequence $\mathbf{u}_1, \dots, \mathbf{u}_\ell$ by setting $\mathbf{u}_{\ell+1} = \mathbf{v}$.

To summarize, this iteratively constructs a well-increasing sequence $\mathbf{u}_1, \dots, \mathbf{u}_{\ell^*}$ with $|\mathbf{u}_i \cdot A_U| \leq w$. We obtain a contradiction to the assumption that A is a robust expander, which completes the proof. ◀

4.2 Robust Kernel Expanders Exist – Proof of Theorem 20

Proof of Theorem 20. We will show that a matrix A sampled from a suitable probability distribution is a t-robust (ℓ, w) expander with high probability, for $t = \frac{60 \cdot \log(k)}{k} \cdot n$, $\ell = 5\log(k)$, and $w = 2n/k$. Note that by definition, this will also be a t-robust (ℓ', w)-expander for every $\ell' \geq \ell$, thus also for $\ell' = \left\lfloor \frac{k \cdot t}{4n} \right\rfloor = \left\lfloor \frac{60}{4} \cdot \log(k) \right\rfloor \geq 5\log(k) = \ell$.

Take a step k random walk in the Hamming cube $\{0,1\}^n$ and let $\mathbf{X}$ be its endpoint. We view $\mathbf{X}$ as a row vector in $\mathbb{F}_2^n$. Repeating this experiment n times independently gives n row vectors that form a matrix $B \in \mathbb{F}_2^{n \times n}$. Surely each row of B has Hamming weight at most k, and B turns out to be a robust expander. Unfortunately its kernel will have dimension $\Theta\left(\frac{\log^2(k) n}{k}\right)$ on expectation—too large for our purposes. We introduce a nice trick that boosts the rank of B.

▶ **Lemma 22.** *Let $B \in \mathbb{F}_2^{n \times n}$ be a matrix and let P be a random permutation matrix. Then $\mathbb{E}[|\ker(B+P)|] \leq n+1$.*

Proof. The kernel of a matrix $A \in \mathbb{F}_2^{n \times n}$ is the set $\{\mathbf{x} \in \mathbb{F}_2^n \mid A \cdot \mathbf{x} = \mathbf{0}\}$. With linearity of expectation we calculate:

$$\begin{aligned}\mathbb{E}[|\ker(B+P)|] &= \sum_{\mathbf{x} \in \mathbb{F}_2} \Pr[(B+P) \cdot \mathbf{x} = 0] \\ &= \sum_{\mathbf{x} \in \mathbb{F}_2} \Pr[B \cdot \mathbf{x} = P \cdot \mathbf{x}]\end{aligned}$$

Note that $B \cdot \mathbf{x}$ is a fixed vector whereas $P \cdot \mathbf{x}$ is a uniformly distributed over all vectors of weight $|x|$. Thus, the probability that this happens to be $B \cdot \mathbf{x}$ is exactly $\binom{n}{|\mathbf{x}|}^{-1}$ if $|B \cdot \mathbf{x}| = |\mathbf{x}|$ and 0 otherwise. Thus the above is at most

$$\sum_{w=0}^{n} \sum_{\mathbf{x} \in \mathbb{F}_2^n : |\mathbf{x}| = w} \binom{n}{w}^{-1} = n+1 \ . \qquad \blacktriangleleft$$

We set $A := B + P$. By Markov's inequality, $|\ker(A)| \leq n^2$ with high probability, and therefore also $\operatorname{rank}(A) \geq n - 2\log(n)$ with high probability. Also, each row of A has Hamming weight at most $k+1$.

It remains to show that A has the desired expansion properties. First we fix a set U of size t and a well-increasing sequence $\mathbf{u}_1, \ldots, \mathbf{u}_\ell$ and estimate the probability that $|\mathbf{u}_i \cdot A_U| \leq w$ for all i. For this we need the following fact about random walks in the Hamming cube which we will prove later.

▶ **Lemma 23** (Hamming Cube Mixing Lemma). *Let $U \subseteq [n]$ and $\mathbf{z} \in \{0,1\}^U$. Let $\mathbf{x}$ be the endpoint of a length d random walk in $\{0,1\}^n$ starting at $\mathbf{0}$. Then*

$$\Pr[\mathbf{x}_U = \mathbf{z}] \leq 2\left(\frac{1+(1-2/n)^d}{2}\right)^{|U|}.$$

In particular if $d \geq n$ and $|U| = t$ is sufficiently large, then this probability is at most $2^{-2t/3}$. From this lemma it is easy to show the following:

▶ **Lemma 24.** *Let $\mathbf{u}_1, \ldots, \mathbf{u}_\ell$ be a well-increasing sequence. Then the probability that $|\mathbf{u}_i \cdot A_U| \leq w$ for all i is at most $2^{-\frac{2\cdot\ell\cdot t}{3}} \cdot \binom{t}{\leq w}^\ell$.*

Proof. Let $\mathcal{E}_j$ be the event that $|\mathbf{u}_i \cdot A_U| \leq 2n/k$ for all $1 \leq i \leq j$. We want to bound $\Pr[\mathcal{E}_\ell] = \prod_{j=1}^{\ell} \Pr[|\mathbf{u}_j \cdot A_U| \leq 2n/k \mid \mathcal{E}_{j-1}]$. We claim that for each $1 \leq j \leq \ell$ the probability $\Pr[|\mathbf{u}_j \cdot A_U| \leq 2n/k \mid \mathcal{E}_{j-1}]$ is at most $2^{-2t/3} \cdot \binom{t}{\leq 2n/k}$.

We divide $\mathbf{u}_i$ into an "old part" v_i and a "new part" w_i. Formally, we write $\mathbf{v}_i = \mathbf{u}_i \cap (\mathbf{u}_1 \cup \ldots \mathbf{u}_{i-1})$ and $\mathbf{w}_i = \mathbf{u}_i \setminus (\mathbf{u}_1 \cup \ldots \mathbf{u}_{i-1})$. We know that $|\mathbf{w}_i| \geq n/k$ since the sequence is well-increasing. Also, $\mathbf{u}_i = \mathbf{v}_i + \mathbf{w}_i$. Let $\mathbf{y} \in \mathbb{F}_2^t$ be a fixed vector. Note that

$$\Pr[\mathbf{u}_j \cdot A_U = \mathbf{y} \mid \mathcal{E}_{j-1}] = \Pr[\mathbf{w}_j \cdot A_U = \mathbf{v}_j \cdot A_U + \mathbf{y} \mid \mathcal{E}_{j-1}]$$

Now $\mathbf{v}_j \cdot A_U$ and $\mathcal{E}_{j-1}$ both only depend on the rows $\mathbf{a}_h$ of A with $h \in \mathbf{v}_j$, and $\mathbf{w}_j \cdot A_U$ is independent these. Thus, it suffices to bound $\Pr[\mathbf{w}_j \cdot A_U = \mathbf{z}]$ for some unknown but fixed vector $\mathbf{z}$. Remember that $A = B + P$ where P is a random $n \times n$ permutation matrix.

$$\Pr[\mathbf{w}_j \cdot A_U = \mathbf{z}] = \Pr[\mathbf{w}_j \cdot B_U = \mathbf{z} + P_U \cdot \mathbf{w}_j]$$

What is the distribution of $\mathbf{w}_j \cdot B_U$? It is the sum of $|\mathbf{w}_j|$ rows of B_U and thus distributed like the endpoint of a $|\mathbf{w}_j| \cdot k \geq n$ step random walk in $\{0,1\}^n$ starting at $\mathbf{0}$ and then projected to the coordinates in U. By the Hamming Cube Mixing Lemma (Lemma 23) with $d = n$ we get

$$\Pr[\mathbf{w}_j \cdot A_U = \mathbf{z}] \leq 2\left(\frac{1+\left(1-\frac{2}{n}\right)^n}{2}\right)^t \leq 2^{-2t/3}.$$

We conclude that $\Pr[\mathbf{u}_j \cdot A_U = \mathbf{y} \mid \mathcal{E}_{j-1}] \leq 2^{-2t/3}$ for every fixed $\mathbf{y} \in \mathbb{F}_2^t$. Therefore

$$\Pr[|\mathbf{u}_j \cdot A_U| \leq 2n/k \mid \mathcal{E}_{j-1}] \leq 2^{-2t/3} \cdot \binom{t}{\leq 2n/k}.$$

This proves the claim. Via the chain rule, the claim immediately implies the lemma. ◀

To prove the theorem, it remains to do a union bound over the choices of $U \subseteq [n]$ and the well-increasing sequence. The number of ways to choose $U \subseteq [n]$ of size t is $\binom{n}{t} \leq \left(\frac{en}{t}\right)^t \leq k^t$. Bounding the number of well-increasing sequences is more subtle.

▶ **Lemma 25.** *The number of well-increasing sequences is at most $k^{\frac{4\ell n}{k}} \cdot 2^{\frac{4\ell^2}{k} \cdot n}$.*

Proof. First, write $\mathbf{u} := \mathbf{u}_1 \cup \cdots \cup \mathbf{u}_\ell$ and note that $|\mathbf{u}| \leq \frac{4\ell n}{k}$. Thus, the number of possible $\mathbf{u}$ is at most $\binom{n}{\leq \frac{4\ell n}{k}} \leq k^{\frac{4\ell n}{k}}$ Once we have chosen $\mathbf{u}$, there are at most $2^{|\mathbf{u}|}$ choices for each individual $\mathbf{u}_i$ and at most $2^{\ell \cdot |\mathbf{u}|} \leq 2^{\frac{4\ell^2}{k} \cdot n}$ well-increasing sequences. ◀

Let us now multiply (1) the number of choices for U, (2) the number of well-increasing sequences, and (3) for a fixed U and well-increasing sequence $\mathbf{u}_1, \ldots, \mathbf{u}_\ell$, the probability that $|\mathbf{u}_i \cdot A_U| \leq w$. We see that this is at most

$$k^t \cdot k^{\frac{4\ell n}{k}} \cdot 2^{\frac{4\ell^2}{k} \cdot n} \cdot 2^{-\frac{2 \cdot \ell \cdot t}{3}} \cdot \binom{t}{\leq w}^\ell$$
$$= 2^{\frac{\log^2(k) \cdot n}{k} \cdot \left(60 + 4 \cdot 5 + 4 \cdot 5^2 - \frac{2}{3} 5 \cdot 60 + 2 \cdot 5\right)} = o(1) \ .$$

Here we used $\binom{t}{\leq w} \leq \left(\frac{et}{w}\right)^w \leq k^{2n/k}$. We conclude that A has the desired expansion properties with high probability. In addition, it has rank at least $n - 2\log(n)$, and every row has Hamming weight at most $k + 1$. This concludes the proof. ◀

5 Proof of Lemma 23

Let Q be the random walk matrix of the n-dimensional Hamming cube. That is, $Q_{\mathbf{x},\mathbf{y}} = 1/n$ if $\mathbf{x}$ and $\mathbf{y}$ have Hamming distance 1, and 0 otherwise. Note that Q is a $(2^n \times 2^n)$-matrix, i.e., it takes as input vectors of dimension 2^n, or equivalently, functions from $\mathbb{F}_2^n$ to $\mathbf{R}$. If $f : \mathbb{F}_2^n \to [0, 1]$ is a probability distribution over $\mathbb{F}_2^n$, then $Q^d f$ is the distribution that we get when sampling $\mathbf{x} \sim f$ and performing a random walk of length d. Let f be the function that is 1 at $\mathbf{0}$ and 0 elsewhere. For $\mathbf{X}$ being the endpoint of an d-step random walk starting at $\mathbf{0}$, it holds that

$$\Pr[\mathbf{X} = \mathbf{y}] = (Q^t f)(\mathbf{y}) \ .$$

Fortunately, we can understand $Q^t f$, since we know the eigenvalues of Q: The Hamming cube is the Cayley graph of the additive group of $\mathbb{F}_2^n$ with generating set $\{\mathbf{e}_1, \ldots, \mathbf{e}_n\}$. The reader who could not make sense of this last sentence may read the next couple of paragraphs. The reader who is familiar with Cayley graphs and the discrete Fourier transform can skip them.

▶ **Definition 26.** For $S \subseteq [n]$, define $\chi_S : \mathbb{F}_2^n \to \mathbb{R}$ by

$$\chi_S(\mathbf{x}) := (-1)^{\sum_{i \in S} x_i} \ .$$

One checks that the χ_S form an orthonormal basis of the space of functions $\mathbb{F}_2^n \to \mathbb{R}$ when we choose the following inner product:

$$\langle f, g \rangle := \mathop{\mathbb{E}}_{\mathbf{x} \in \mathbb{F}_2^n} [f(\mathbf{x}) g(\mathbf{x})] \ .$$

Each χ_S is an eigenvector of Q:

$$\begin{aligned}
(Q \cdot \chi_S)(\mathbf{x}) &= \sum_{\mathbf{y}} Q_{\mathbf{x},\mathbf{y}} \chi_S(\mathbf{y}) = \sum_{\mathbf{y} : d_H(\mathbf{x},\mathbf{y}) = 1} \frac{1}{n} \chi_S(\mathbf{y}) \\
&= \sum_{i=1}^n \frac{1}{n} \chi_S(\mathbf{x} + \mathbf{e}_i) = \sum_{i=1}^n \frac{1}{n} \chi_S(\mathbf{x}) \chi_S(\mathbf{e}_i) \\
&= \chi_S(\mathbf{x}) \frac{1}{n} \sum_{i=1}^n \chi_S(\mathbf{e}_i) \ .
\end{aligned}$$

So $\lambda_S := \frac{1}{n}\sum_{i=1}^n \chi_S(\mathbf{e}_i)$ is the eigenvector of χ_S. Let us evaluate λ_S:

$$\lambda_S \quad = \quad \frac{1}{n}\sum_{i=1}^n \chi_S(\mathbf{e}_i) = \frac{1}{n}\sum_{i=1}^n (-1)^{[i\in S]} = \frac{1}{n}(n-2|S|) = 1 - \frac{2|S|}{n} \ .$$

Let $f : \mathbb{F}_2^n \to \mathbb{R}$ be the function that is 1 on $\mathbf{0}$ and 0 otherwise. To understand $Q^t f$, we write f in the basis of the eigenvectors of Q. Since the χ_S are orthonormal under the scalar product $\langle \cdot, \cdot \rangle$, we can write

$$f = \sum_{S\subseteq[n]} \hat{f}_S \chi_S \ ,$$

where the coefficients $\hat{f}_S$ are

$$\hat{f}_S := \langle f, \chi_S \rangle = \mathop{\mathbb{E}}_{\mathbf{x}\in\mathbb{F}_2^n}[f(\mathbf{x})\chi_S(\mathbf{x})] = 2^{-n},$$

since $\mathbf{x} = \mathbf{0}$ is the only element that contributes to the expectation. Thus,

$$Q^t f \quad = \quad Q^t\left(\sum_S \hat{f}_S\chi_S\right) = Q^t\left(\sum_S 2^{-n}\chi_S\right) = 2^{-n}\sum_S \lambda_S^t \chi_S \ .$$

For $\mathbf{y} \in \mathbb{F}_2^n$, let us bound the probability $\Pr[\mathbf{X} = \mathbf{y}]$: With the above equation, we get

$$\begin{aligned}
(Q^t f)(\mathbf{y}) &= 2^{-n}\sum_S \lambda_S^t \chi_S(\mathbf{y}) = 2^{-n}\sum_S \left(1 - \frac{2|S|}{n}\right)^t \chi_S(\mathbf{y}) \\
&\le 2^{-n}\sum_{s=0}^n \binom{n}{s}\left|1-\frac{2s}{n}\right|^t \quad \text{(since } |\chi_S(\mathbf{y})| = 1\text{)} \\
&\le 2^{-n}\sum_{s=0}^{\lfloor n/2\rfloor}\binom{n}{s}\left|1-\frac{2s}{n}\right|^t + 2^{-n}\sum_{s=\lceil n/2\rceil}^{n}\binom{n}{s}\left|1-\frac{2s}{n}\right|^t \\
&= 2^{-n}\sum_{s=0}^{\lfloor n/2\rfloor}\binom{n}{s}\left|1-\frac{2s}{n}\right|^t + 2^{-n}\sum_{r=0}^{\lfloor n/2\rfloor}\binom{n}{n-r}\left|1-\frac{2(n-r)}{n}\right|^t \\
&= 2\cdot 2^{-n}\sum_{s=0}^{\lfloor n/2\rfloor}\binom{n}{s}\left(1-\frac{2s}{n}\right)^t \\
&\le 2\cdot 2^{-n}\sum_{s=0}^{\lfloor n/2\rfloor}\binom{n}{s}\left(1-\frac{2}{n}\right)^{st} \le 2\cdot 2^{-n}\sum_{s=0}^{n}\binom{n}{s}\left(1-\frac{2}{n}\right)^{st} \\
&= 2\left(\frac{1+\left(1-\frac{2}{n}\right)^t}{2}\right)^n \ .
\end{aligned}$$

This proves the lemma for $U = [n]$. In general, however, we are interested in the distribution of $\mathbf{X}_U$, i.e., $\mathbf{X}$ projected to the coordinates in U.

▶ **Observation 27.** *Perform a "lazy" random walk on $\{0,1\}^{|U|}$ as follows: Start at $\mathbf{0}$. At each step, take each edge with probability $1/n$. With the remaining probability $1 - |U|/n$, don't move in this step. Then the end point of this walk after t steps has distribution $\mathbf{X}_U$.*

Let Q be transition matrix of the random walk on $\{0,1\}^{|U|}$. Then

$$\tilde{Q} := \frac{|U|}{n}Q + \frac{n-|U|}{n}I$$

is the transition matrix of the lazy random walk described above. For each $S \subseteq U$, χ_S is an eigenvector of Q, and the corresponding eigenvalue is $\lambda_S = 1 - \frac{2|S|}{|U|}$. The matrix $\tilde{Q}$ has the same eigenvectors as Q, and its eigenvalues are

$$\tilde{\lambda}_S = \frac{|U|}{n}\lambda_S + \frac{n-|U|}{n} \cdot 1 = 1 - \frac{2|S|}{n} \ .$$

Let $f : \{0,1\}^{|U|} \to \mathbb{R}$ be the function that is 1 at $\mathbf{0}$ and 0 elsewhere. We write $f = \sum_{S \subseteq U} \hat{f}_S \chi_S$. Let $u := |U|$. By the same calculation as above, $\hat{f}_S = 2^{-u}$. Thus, for $\mathbf{y} \in \{0,1\}^u$ we get

$$\begin{aligned}(\tilde{Q}^t f)(\mathbf{y}) &= 2^{-u} \sum_S \lambda_S^t \chi_S(\mathbf{y}) = 2^{-u} \sum_S \left(1 - \frac{2|S|}{n}\right)^t \chi_S(\mathbf{y}) \\ &\leq 2^{-u} \sum_{s=0}^{u} \binom{u}{s} \left|1 - \frac{2s}{n}\right|^t \quad (\text{siuce } |\chi_S(\mathbf{y})| = 1)\,.\end{aligned}$$

If $u \leq n/2$, we observe that all eigenvalues $1 - 2s/n$ are non-negative.[2] In this case we continue:

$$2^{-u} \sum_{s=0}^{u} \binom{u}{s} \left(1 - \frac{2s}{n}\right)^t \leq 2^{-u} \sum_{s=0}^{u} \binom{u}{s} \left(1 - \frac{2}{n}\right)^{st} = \left(\frac{1 + \left(1 - \frac{2}{n}\right)^t}{2}\right)^u \tag{1}$$

and we are done. If $u > n/2$, things get more tricky. We split the sum in two parts:

$$2^{-u} \sum_{s=0}^{\lfloor n/2 \rfloor} \binom{u}{s} \left(1 - \frac{2s}{n}\right)^t + 2^{-u} \sum_{s=\lfloor n/2 \rfloor + 1}^{u} \binom{u}{s} \left(\frac{2s}{n} - 1\right)^t \ . \tag{2}$$

We can bound the first sum exactly similar as in (1):

$$\begin{aligned}2^{-u} \sum_{s=0}^{\lfloor n/2 \rfloor} \binom{u}{s} \left(1 - \frac{2s}{n}\right)^t &\leq 2^{-u} \sum_{s=0}^{\lfloor n/2 \rfloor} \binom{u}{s} \left(1 - \frac{2}{n}\right)^{st} \leq 2^{-u} \sum_{s=0}^{u} \binom{u}{s} \left(1 - \frac{2}{n}\right)^{st} \\ &= \left(\frac{1 + \left(1 - \frac{2}{n}\right)^t}{2}\right)^u \ .\end{aligned}$$

Let us bound the second sum in (2). For notational convenience, we let it run from $\lceil n/2 \rceil$ to u, only making it larger. We change the parameter s to $r := u - s$. Thus

$$\begin{aligned}2^{-u} \sum_{s=\lceil n/2 \rceil}^{u} \binom{u}{s} \left(\frac{2s}{n} - 1\right)^t &= 2^{-u} \sum_{r=0}^{u-\lceil n/2 \rceil} \binom{u}{u-r} \left(\frac{2(u-r)}{n} - 1\right)^t \\ &= 2^{-u} \sum_{r=0}^{u-\lceil n/2 \rceil} \binom{u}{r} \left(\frac{2u-n}{n} - \frac{2r}{n}\right)^t \\ &\leq 2^{-u} \sum_{r=0}^{u-\lceil n/2 \rceil} \binom{u}{r} \left(1 - \frac{2r}{n}\right)^t \qquad (\text{since } u \leq n) \\ &\leq 2^{-u} \sum_{r=0}^{u-\lceil n/2 \rceil} \binom{u}{r} \left(1 - \frac{2}{n}\right)^{rt} \\ &\leq 2^{-u} \sum_{r=0}^{u} \binom{u}{r} \left(1 - \frac{2}{n}\right)^{rt} = \left(\frac{1 + \left(1 - \frac{2}{n}\right)^t}{2}\right)^u \ .\end{aligned}$$

Thus, both sums in (2) are bounded by (1) and the lemma follows.

[2] The reader might observe that in our application indeed $|U| \ll n/2$.

Abstract

Subspace designs are a (large) collection of high-dimensional subspaces $\{H_i\}$ of $\mathbb{F}_q^m$ such that for any low-dimensional subspace W, only a small number of subspaces from the collection have non-trivial intersection with W; more precisely, the sum of dimensions of $W \cap H_i$ is at most some parameter L. The notion was put forth by Guruswami and Xing (STOC'13) with applications to list decoding variants of Reed-Solomon and algebraic-geometric codes, and later also used for explicit rank-metric codes with optimal list decoding radius.

Guruswami and Kopparty (FOCS'13, Combinatorica'16) gave an explicit construction of subspace designs with near-optimal parameters. This construction was based on polynomials and has close connections to folded Reed-Solomon codes, and required large field size (specifically $q \geqslant m$). Forbes and Guruswami (RANDOM'15) used this construction to give explicit constant degree "dimension expanders" over large fields, and noted that subspace designs are a powerful tool in linear-algebraic pseudorandomness.

Here, we construct subspace designs over any field, at the expense of a modest worsening of the bound L on total intersection dimension. Our approach is based on a (non-trivial) extension of the polynomial-based construction to algebraic function fields, and instantiating the approach with cyclotomic function fields. Plugging in our new subspace designs in the construction of Forbes and Guruswami yields dimension expanders over $\mathbb{F}^n$ for any field $\mathbb{F}$, with logarithmic degree and expansion guarantee for subspaces of dimension $\Omega(n/(\log\log n))$.

1 Introduction

An emerging theory of "linear-algebraic pseudorandomness" studies the linear-algebraic analogs of fundamental Boolean pseudorandom objects where the rank of subspaces plays the role of the size of subsets. A recent work [4] studied the interrelationships between several such algebraic objects such as subspace designs, dimension expanders, rank condensers, and rank-metric codes, and highlighted the fundamental unifying role played by *subspace designs* in this web of connections.

Informally, a subspace design is a collection of subspaces of a vector space $\mathbb{F}_q^m$ (throughout we denote by $\mathbb{F}_q$ the finite field with q elements) such that any low-dimensional subspace W intersects only a small number of subspaces from the collection. More precisely:

▶ **Definition 1.** A collection $H_1, H_2, \ldots, H_M$ of b-dimensional subspaces of $\mathbb{F}_q^m$ form an (s, L)-(strong) subspace design, if for every s-dimensional subspace $W \subset \mathbb{F}_q^m$, $\sum_{i=1}^{M} \dim(W \cap H_i) \leqslant L$.

In particular, this implies that at most L subspaces H_i have non-trivial intersection with W. A collection meeting this weaker requirement is called a *weak* subspace design; unless we mention otherwise, by subspace design we always mean a strong subspace design in this paper. One would like the dimension b of each subspace in the subspace design to be large, typically $\Omega(m)$ for applications of interest, L to be small, and the number of subspaces M to be large.

Subspace designs were introduced by the first two authors in [11], where they used them to improve the list size and efficiency of list decoding algorithms for algebraic-geometric codes, yielding efficiently list-decodable codes with optimal redundancy over fixed alphabets and small output list size. A standard probabilistic argument shows that a random collection of subspaces forms a good subspace design with high probability. Subsequently, Guruswami and Kopparty [7] gave an explicit construction of subspace designs, nearly matching the parameters of random constructions, albeit over large fields.

Intriguingly, the construction in [7] was based on algebraic list-decodable codes (specifically folded Reed-Solomon codes). Recall that improving the list-decodability of such codes was the motivation for the formulation of subspace designs in the first place! This is yet another compelling example of the heavily intertwined nature of error-correcting codes and other pseudorandom objects. The following states one of the main trade-offs achieved by the construction in [7].

▶ **Theorem 2** (Folded Reed-Solomon based construction [7]). *For every $\varepsilon \in (0, 1)$, positive integers s, m with $s \leqslant \varepsilon m/4$, and a prime power $q > m$, there exists an explicit*[1] *collection of $M = q^{\Omega(\varepsilon m/s)}$ subspaces in $\mathbb{F}_q^m$, each of dimension at least $(1 - \varepsilon)m$, which form a $(s, \frac{2s}{\varepsilon})$-(strong) subspace design.*

Note the requirement of the field size q being larger than the ambient dimension m in their construction. To construct subspace designs over small fields, they use a construction over a large extension field $\mathbb{F}_{q^r}$, and view b-dimensional subspaces of $\mathbb{F}_{q^r}^{m'}$ as br-dimensional subspaces of $\mathbb{F}_q^{rm'}$. However, this transformation need not preserve the "strongness" of the subspace design, and an (s, L)-subspace design over the extension field only yields an (s, L)-weak subspace design over $\mathbb{F}_q$.

[1] By explicit, we mean a deterministic construction that runs in time $\text{poly}(q, m, M)$ and outputs a basis for each of the subspaces in the subspace design.

The strongness property is crucial for all the applications of subspace designs in [4]. In particular, the strongness is what drives the construction of dimension expanders (defined below) of low degree. The weak subspace design property does *not* suffice for these applications.

▶ **Definition 3.** A collection of linear maps $A_1, A_2, \ldots, A_d : \mathbb{F}^n \to \mathbb{F}^n$ is said to be a (b, α)-dimension expander if for every subspace V of $\mathbb{F}^n$ of dimension at most b, $\dim(\sum_{i=1}^{d} A_i(V)) \geqslant (1+\alpha)\cdot\dim(V)$. The number of maps d is the "degree" of the expander, and α is the expansion factor.

Using the subspace designs constructed in Theorem 2 in a black-box fashion, Forbes and Guruswami [4] gave explicit $(\Omega(n), \Omega(1))$-dimension expanders of $O(1)$ degree when $|\mathbb{F}| \geqslant \text{poly}(n)$. Here explicit means that the maps A_i are specified explicitly, say by the matrix representing their action with respect to some fixed basis. Extending Theorem 2 to smaller fields will yield constant-degree $(\Omega(n), \Omega(1))$-dimension expanders over all fields. The only known constructions of such dimension expanders over finite fields rely on monotone expanders [3, 2], a rather complicated (and remarkable) form of bipartite vertex expanders whose neighborhood maps are monotone. Even the existence of constant-degree monotone expanders does not follow from standard probabilistic methods, and the only known explicit construction is a sophisticated one using the group $\text{SL}_2(\mathbb{R})$ by Bourgain and Yehudayoff [1]. (Earlier, Dvir and Shpilka [2] constructed monotone expanders of logarithmic degree using Cayley graphs over the cyclic group, yielding logarithmic degree $(\Omega(n), \Omega(1))$-dimension expanders.)

In light of this, it is a very interesting question to remove the field size restriction in Theorem 2 above, as it will yield an arguably simpler construction of constant-degree dimension expanders over every field, and which might also offer a quantitatively better trade-off between the degree and expansion factor. We note that probabilistic constructions achieve similar parameters (in fact a slightly larger sized collection with $q^{\Omega(\varepsilon m)}$ subspaces) with no restriction on the field size (one can even take $q = 2$).

Our construction. The large field size in Theorem 2 was inherited from Reed-Solomon codes, which are defined over a field of size at least the code length. Our main contribution in this work is a construction of subspace designs based on algebraic function fields, which permits us to construct subspace designs over small fields. By instantiating this approach with a construction based on cyclotomic function fields, we are able to prove the following main result in this work:

▶ **Theorem 4** (Main Theorem). *For every $\varepsilon \in (0, 1)$, a prime power q and positive integers s, m such that $s \leq \varepsilon m/4$, there exists an explicit construction of $M = \Omega(q^{\lfloor \varepsilon m/(2s) \rfloor}/\varepsilon)$ subspaces in $\mathbb{F}_q^m$, each of dimension at least $(1-\varepsilon)m$, which form an $\left(s', \frac{2s'\lceil \log_q(m) \rceil}{\varepsilon}\right)$-strong subspace design for all $s' \leqslant s$.*

Note that we state a slightly stronger property that the bound on intersection size improves for subspaces of lower dimension $s' \leqslant s$. This property also holds for Theorem 2 and in fact is important for the dimension expander construction in [4], and so we make it explicit.

The bound on intersection size we guarantee above is worse than the one from the random construction by a factor of $\log_q m$. The result of Theorem 2 can be viewed as a special case of Theorem 4 since $\log_q m \leqslant 1$ when $q > m$. The factor $\log_q m$ comes out as a trade-off of the explicit construction vs the random construction given in [11]. The extension field based construction using Theorem 2 would yield an $(s, O(s^2/\varepsilon))$-subspace design (since an

(s, L)-weak subspace design is trivially an (s, sL)-(strong) subspace design). The bound we achieve is better for all $s = \Omega(\log_q m)$. In the use of subspace designs in the dimension expander construction of [4], s governs the dimension of the subspaces which are guaranteed to expand, which we would like to be large (and ideally $\Omega(m)$). The application of subspace designs to list decoding [11, 9] employs the parameter choice $m = O(s)$ in order keep the alphabet size q^m small. Therefore, our improvement applies to a meaningful setting of parameters that is important for the known applications of (strong) subspace designs.

Application to dimension expanders over small fields. By plugging in the subspace designs of Theorem 4 into the dimension expander construction of [4], we can get the following:

▶ **Theorem 5.** *For every prime power q and positive integer $n \geqslant q$, there exists an explicit construction of a $\left(b = \Omega\left(\frac{n}{\log_q \log_q n}\right), 1/3\right)$-dimension expander with $O(\log_q n)$ degree.*

For completeness, let us very quickly recap how such dimension expanders may be obtained from the subspace designs of Theorem 4, using the "tensor-then-condense" approach in [4]. We begin with linear maps $T_1, T_2 : \mathbb{F}^n \to \mathbb{F}^{2n}$, where $T_1(v) = (v; 0)$ and $T_2(v) = (0; v)$ – these trivially achieve expansion factor 2 by doubling the ambient dimension. Then we take the subspace design of Theorem 4 with $m = 2n$, $\varepsilon = 1/2$, $s = 2b$, and $M = 12\lceil \log_q m \rceil$ subspaces H_i (if $b = \beta n/(\log_q \log_q n)$ for small enough absolute constant $\beta > 0$, Theorem 4 guarantees these many subspaces). Let $E_i : \mathbb{F}^{2n} \to \mathbb{F}^n$ be linear maps such that $H_i = \ker(E_i)$. The dimension expander consists of the $2M$ composed maps $E_i \circ T_j$ for $i = 1, 2, \ldots, M$ and $j = 1, 2$. Briefly, the analysis of the expansion in dimension proceeds as follows. Let V be a subspace of $\mathbb{F}^n$ with $\dim(V) = \ell \leqslant b$, and let $W = T_1(V) + T_2(V)$ be the 2ℓ-dimensional subspace of $\mathbb{F}^{2n}$ after the tensoring step. The strong subspace design property implies that the number of maps E_i for which $\dim(E_i W) < 4\ell/3$ – which is equivalent to $\dim(W \cap H_i) > 2\ell/3$ – is less than $12\lceil \log_q m \rceil = M$. So there must be an i for which $\dim(E_i W) \geqslant 4\ell/3$, and this E_i when composed with T_1 and T_2 will expand V to a subspace of dimension at least $\frac{4}{3}\dim(V)$.

By using a method akin to the conversion of Reed-Solomon codes over extension fields to BCH codes over the base field, applied to the large field subspace designs of Theorem 2, Forbes and Guruswami [4] constructed $(\Omega(n/\log n), \Omega(1))$-dimension expanders of $O(\log n)$ degree. In contrast, our construction here guarantees expansion for dimension up to $\Omega(n/(\log \log n))$. The parameters offered by Theorem 5 are, however, weaker than both the construction given in [2], which has logarithmic degree but expands subspaces of dimension $\Omega(n)$, as well as the one in [1], which further gets constant degree. However, we do not go through monotone expanders which are harder to construct than vertex expanders, and our construction works fully within the linear-algebraic setting. We hope that the ideas in this work pave the way for a subspace design similar to Theorem 2 over small fields, and the consequent construction of constant-degree $(\Omega(n), \Omega(1))$-dimension expanders over all fields. In fact, all that is required for this is an $(s, O(s))$-subspace design with a sufficiently large constant number of subspaces, each of dimension $\Omega(m)$.

Construction approach. The generalization of the polynomials-based subspace design from [7] to take advantage of more general algebraic function fields is not straightforward. The natural approach would be to replace the space of low-degree polynomials by a Riemann-Roch space consisting of functions of bounded pole order ℓ at some place. We prove that such a construction can work, provided the degree ℓ is less than the degree of the field extension (and some other mild condition is met). However, this degree restriction is a severe one, and the dimension of the associated Riemann-Roch space will typically be too small (as

the "genus" of the function field, which measures the degree minus dimension "defect," will be large), unless the field size is large. Therefore, we don't know an instantiation of this approach that yields a family of good subspace designs over a fixed size field.

Let us now sketch the algebraic crux of the polynomial based construction in [7], and the associated challenges in extending it to other function fields. The core property of a dimension s subspace W of polynomials underlying the construction of Theorem 2 is the following: If $f_1, f_2, \ldots, f_s \in \mathbb{F}_q[X]$ of degree less than $q-1$ are linearly independent over $\mathbb{F}_q$ (these s polynomials being a basis of the subspace W), then the "folded Wronskian," which is the determinant of the matrix $M(f_1, f_2, \ldots, f_s)$ whose i,j'th entry is $f_j(\gamma^{i-1}X)$, is a *nonzero* polynomial in $\mathbb{F}_q[X]$. Here γ is an arbitrary primitive element of $\mathbb{F}_q$. One might compare this with the classical Wronskian criterion for linear dependence over characteristic zero fields (and also holds when characteristic is bigger than the degree of the f_i's), based on the singularity of the $s \times s$ matrix whose i,j'th entry is $\frac{d^{i-1} f_j}{dX^{i-1}}$.

One approach is to prove this claim about the folded Wronskian is via a "list size" bound from list decoding: one can prove that for any $A_1, \ldots, A_s \in \mathbb{F}_q[X]$, not all 0, the space of solutions $f \in \mathbb{F}_q[X]_{<(q-1)}$ to

$$A_1(X)f(X) + A_2(X)f(\gamma X) + \cdots + A_s(X)f(\gamma^{s-1}X) = 0 \tag{1}$$

has dimension at most $s-1$. (This was the basis of the linear-algebraic list decoding algorithm for folded Reed-Solomon codes [6, 8].) Stating the contrapositive, if $f_1, f_2, \ldots, f_s$ are linearly independent over $\mathbb{F}_q[X]$, then the rows of the matrix $M(f_1, f_2, \ldots, f_s)$ are linearly independent, and therefore its determinant, the folded Wronskian, is a nonzero polynomial. On the other hand, being the determinant of an $s \times s$ matrix whose entries are degree m polynomials, the folded Wronskian has degree at most ms. To prove the subspace design property, one then establishes that for each subspace H_i in the collection that intersects $W = \mathrm{span}(f_1, \ldots, f_s)$, the determinant picks up a number of distinct roots each with $\dim(W \cap H_i)$ multiplicity, the set of roots for different intersecting H_i being disjoint from each other. The total intersection bound then follows because the folded Wronskian has at most ms roots, counting multiplicities.

One can try to mimic the above approach for folded algebraic-geometric (AG) codes, with f^σ for some suitable automorphism σ playing the role of the shifted polynomial $f(\gamma X)$. This, however, runs into significant trouble, as the bound on number of solutions f to the functional equation analogous to (1), $A_1 f + A_2 f^\sigma + \cdots + A_s f^{\sigma^{s-1}} = 0$, is much higher. The list of solutions is either exponentially large and needs pruning via pre-coding the folded AG codes with subspace-evasive sets [10], or it is much bigger than q^{s-1} in the constructions based on cyclotomic function fields and narrow ray class fields where the folded AG codes work directly [5, 12].

Let F/K be a function field where the extension is Galois with Galois group generated by an automorphism σ. We choose the m-dimensional ambient space $\mathcal{V} \cong \mathbb{F}_q^m$ to be a carefully chosen subspace of a Riemann-Roch space in F of degree $\ell \gg m$ (specifically, we require $\ell \geqslant m + 2\mathfrak{g}$ where $\mathfrak{g}$ is the genus). We then establish that if $f_1, f_2, \ldots, f_s \in \mathcal{V}$ are linearly independent over $\mathbb{F}_q$, a certain "automorphism Moore matrix" $M_\sigma(f_1, f_2, \ldots, f_s)$ is non-singular. The determinant of this Moore matrix is thus a non-zero function in F, and this generalizes the folded Wronskian criterion for polynomials mentioned above.

This non-singularity result is proved in two steps. First, we show that for functions in $\mathcal{V}$, linear independence over $\mathbb{F}_q$ implies linear independence over K. Then we show that for any $f_1, \ldots, f_s \in F$ that are linearly independent over $K = F^\sigma$, the automorphism Moore matrix associated with σ is non-singular. With our hands on the non-zero function

$\Delta = \mathsf{det}(M_\sigma(f_1, f_2, \ldots, f_s))$, we can proceed as in the folded Reed-Solomon case – the part about Δ picking up many zeroes whenever a subspace in the collection intersects $\mathrm{span}(f_1, \ldots, f_s)$ also generalizes. The pole order of Δ, however, is now ℓs instead of ms in the polynomial-based construction. This is the cause for the worse bound on total intersection dimension in our Theorem 4. The detailed analysis of the above function field generalization will be presented in a full version of this paper. In the current version, we present only constructions without proof and hence "automorphism Moore matrix" is not introduced.

Organization. We begin with a quick review of background on algebraic function fields in general and cyclotomic function fields in particular in Section 2. We presentour constructions of subspace designs from function fields in Section 3 In Section 4, we instantiate our construction with specific cyclotomic function fields and derive our main consequence for subspace designs and establish Theorem 4.

2 Preliminaries on function fields

Background on function fields. Throughout this paper, $\mathbb{F}_q$ denotes the finite field of q elements. A function field F over $\mathbb{F}_q$ is a field extension over $\mathbb{F}_q$ in which there exists an element z of F that is transcendental over $\mathbb{F}_q$ such that $F/\mathbb{F}_q(z)$ is a finite extension. $\mathbb{F}_q$ is called the full constant field of F if the algebraic closure of $\mathbb{F}_q$ in F is $\mathbb{F}_q$ itself. In this paper, we always assume that $\mathbb{F}_q$ is the full constant field of F, denoted by $F/\mathbb{F}_q$.

Each discrete valuation ν from F to $\mathbb{Z} \cup \{\infty\}$ defines a local ring $O = \{f \in F : \nu(f) \geqslant 0\}$. The maximal ideal P of O is called a *place*. We denote the valuation ν and the local ring O corresponding to P by ν_P and O_P, respectively. The residue class field O_P/P, denoted by F_P, is a finite extension of $\mathbb{F}_q$. The extension degree $[F_P : \mathbb{F}_q]$ is called *degree* of P, denoted by $\deg(P)$.

Let $\mathbb{P}_F$ denote the set of places of F. A divisor D of F is a formal sum $\sum_{P \in \mathbb{P}_F} m_P P$, where $m_P \in \mathbb{Z}$ are equal to 0 except for finitely many P. The degree of D is defined to be $\deg(D) = \sum_{P \in \mathbb{P}_F} m_P \deg(P)$. We say that D is positive, denoted by $D \geqslant 0$, if $m_P \geqslant 0$ for all $P \in \mathbb{P}_F$. For a nonzero function f, the principal divisor (f) is defined to be $\sum_{P \in \mathbb{P}_F} \nu_P(f) P$. Then the degree of the principal divisor (f) is 0. The Riemann-Roch space associated with a divisor D, denoted by $\mathcal{L}(D)$, is defined by

$$\mathcal{L}(D) := \{f \in F \setminus \{0\} : (f) + D \geqslant 0\} \cup \{0\}. \tag{2}$$

Then $\mathcal{L}(D)$ is a finite dimensional space over $\mathbb{F}_q$. By the Riemann-Roch theorem [15], the dimension of $\mathcal{L}(D)$, denoted by $\dim_{\mathbb{F}_q}(D)$, is lower bounded by $\deg(D) - \mathfrak{g} + 1$, i.e., $\dim_{\mathbb{F}_q}(D) \geqslant \deg(D) - \mathfrak{g} + 1$, where $\mathfrak{g}$ is the genus of F. Furthermore, $\dim_{\mathbb{F}_q}(D) = \deg(D) - \mathfrak{g} + 1$ if $\deg(D) \geqslant 2\mathfrak{g} - 1$. In addition, we have the following results [15, Lemma 1.4.8 and Corollary 1.4.12(b)]:

- **(i)** If $\deg(D) < 0$, then $\dim_{\mathbb{F}_q}(D) = 0$;
- **(ii)** For a positive divisor G, we have $\dim_{\mathbb{F}_q}(D) - \dim_{\mathbb{F}_q}(D - G) \leqslant \deg(G)$, i.e., $\dim_{\mathbb{F}_q}(D - G) \geqslant \dim_{\mathbb{F}_q}(D) - \deg(G)$.

Let $\mathrm{Aut}(F/\mathbb{F}_q)$ denote the set of automorphisms of F that fix every element of $\mathbb{F}_q$, i.e.,

$$\mathrm{Aut}(F/\mathbb{F}_q) = \{\tau : \tau \text{ is an automorphism of } F \text{ and } \alpha^\tau = \alpha \text{ for all } \alpha \in \mathbb{F}_q\}.$$

For a place $P \in \mathbb{P}_F$ and an automorphism $\sigma \in \mathrm{Aut}(F/\mathbb{F}_q)$, we denote by P^σ the set $\{f^\sigma : f \in P\}$. Then P^σ is a place and moreover we have $\deg(P^\sigma) = \deg(P)$. The place P^σ is called a conjugate place of P. σ also induces an automorphsim of $\mathrm{Aut}(\mathbb{F}_P/\mathbb{F}_q)$. This

implies that there exists an integer $e \geqslant 0$ such that $\alpha^\sigma = \alpha^{q^e}$ for all $\alpha \in F_P$. σ is called the *Frobenius* of P if $e = 1$, i.e., $\alpha^\sigma = \alpha^q$ for all $\alpha \in F_P$. For a place P and a function $f \in O_P$, we denote by $f(P)$ the residue class of f in F_P. Thus, we have $(f(P))^{q^e} = (f(P))^\sigma = f^\sigma(P^\sigma)$.

Background on cyclotomic function fields. Let x be a transcendental element over $\mathbb{F}_q$ and denote by K the rational function field $\mathbb{F}_q(x)$. Let K^{ac} be an algebraic closure of K. Denote by $\mathbb{F}_q[x]$ the polynomial ring $\mathbb{F}_q[x]$. Let $\mathrm{End}(K^{ac})$ be the ring of homomorphisms from K^{ac} to K^{ac}. We define $\rho_x(z) = z^q + xz$ for all $z \in K^{ac}$. For $i \geqslant 2$, we define $\rho_{x^i}(z) = \rho_x(\rho_{x^{i-1}}(z))$. For a polynomial $p(x) = \sum_{i=0}^n a_i x^i \in \mathbb{F}_q[x]$, we define $\rho_{p(x)}(z) = \sum_{i=0}^n a_i \rho_{x^i}(z)$. For simplicity, we denote $\rho_{p(x)}(z)$ by $z^{p(x)}$. It is easy to see that $z^{p(x)} \in \mathbb{F}_q[x][z]$ is a q-linearized polynomial in z of degree q^d, where $d = \deg(p(x))$.

For a polynomial $p(x) \in \mathbb{F}_q[x]$ of degree d, define the set

$$\Lambda_{p(x)} := \{\alpha \in K^{ac} : \alpha^{p(x)} = 0\}. \tag{3}$$

Then $\Lambda_{p(x)} \simeq \mathbb{F}_q[x]/(p(x))$ is an $\mathbb{F}_q[x]$-module and it has exactly q^d elements. Furthermore, $\Lambda_{p(x)}$ is a cyclic $\mathbb{F}_q[x]$-module. For any generator λ of $\Lambda_{p(x)}$, one has $\Lambda_{p(x)} = \{\lambda^A : A \in \mathbb{F}_q[x]/(p(x))\}$ and λ^A is a generator of $\Lambda_{p(x)}$ if and only if $\gcd(A, p(x)) = 1$. The extension $K(\lambda) = K(\Lambda_{p(x)})$ is a Galois extension over K with $\mathrm{Gal}(K(\Lambda_{p(x)})/K) \simeq (\mathbb{F}_q[x]/p(x))^*$, where $(\mathbb{F}_q[x]/p(x))^*$ is the unit group of the ring $\mathbb{F}_q[x]/(p(x))$. We use σ_A to denote the automorphism of $\mathrm{Aut}(K(\lambda)/K)$ corresponding to A, i.e., $\lambda^{\sigma_A} = \lambda^A$. The size of $(\mathbb{F}_q[x]/p(x))^*$ is denoted by $\Phi(p(x))$. If $p(x)$ is an irreducible polynomial of degree d over $\mathbb{F}_q$, we have $\Phi(p(x)) = q^d - 1$. In this case, the extension $K(\Lambda_{p(x)})/K$ is cyclic and $\mathrm{Gal}(K(\Lambda_{p(x)})/K) \simeq (\mathbb{F}_q[x]/p(x))^* \simeq \mathbb{F}_{q^d}^*$.

3 Construction of subspace design

Let $\sigma \in \mathrm{Aut}(F/\mathbb{F}_q)$ be an automorphism of a finite order. Denote by F^σ the fixed field by $\langle\sigma\rangle$, i.e., $F^\sigma = \{x \in F : x^\sigma = x\}$. By the Galois theory, F/F^σ is a Galois extension and $\mathrm{Gal}(F/F^\sigma) = \langle\sigma\rangle$. Let D be a divisor of F such that $D^\sigma = D$. Assume that Q' is a place of F lying above a rational place Q of F^σ and $Q' \notin \mathrm{supp}(D)$. Furthermore, assume that $\mathcal{V}$ is an $\mathbb{F}_q$-subspace of $\mathcal{L}(D)$ such that $\mathcal{V} \cap \mathcal{L}(D - Q') = \{0\}$.

For each place $P \in \mathbb{P}_F$ such that $P \notin \mathrm{supp}(D)$ and $P, P^{\sigma^{-1}}, \ldots, P^{\sigma^{-(t-1)}}$ are distinct, we define the subspace $\mathcal{H}_P$:

$$\mathcal{H}_P = \{f \in \mathcal{V} : f(P^{\sigma^{-i}}) = 0 \text{ for each } i \in \{0, \ldots, t-1\}\} = \mathcal{V} \cap \mathcal{L}\left(D - \sum_{i=0}^{t-1} P^{\sigma^{-i}}\right). \tag{4}$$

Recall that $f(P)$ is defined to be the residue class of f in the residue field O_P/P. Hence, it is clear that

$$\dim_{\mathbb{F}_q}(\mathcal{H}_P) \geqslant \dim_{\mathbb{F}_q}(\mathcal{V}) + \dim_{\mathbb{F}_q}\left(D - \sum_{i=0}^{t-1} P^{\sigma^{-i}}\right) - \dim_{\mathbb{F}_q}(D) \geqslant \dim_{\mathbb{F}_q}(\mathcal{V}) - t\deg(P).$$

Let $f(P)^\sigma = f(P)^{q^e}$ for some integer $e \geqslant 0$. Thus, we have $f^{\sigma^i}(P^{\sigma^i}) = f(P)^{\sigma^i} = f(P)^{q^{ei}}$ for all integers $i \geqslant 0$.

Define $S_P = \{P^{\sigma^{-i}} : i \in \{0, \ldots, t-1\}\}$, and denote by $\mathcal{F}_r$ a set of places P with degree r such that S_P are disjoint and $|S_P| = t$.

▶ **Theorem 6.** *For any integers s, t with $1 \leqslant s \leqslant t$, the collection $(\mathcal{H}_P)_{P \in \mathcal{F}_r}$ of subspaces of $\mathcal{V}$, each of codimension at most rt, is an $\left(s, \frac{\ell s}{r(t-s+1)}\right)$ strong subspace design, where $\ell = \deg(D)$.*

In the above construction, there is no upper bound on the degree of the divisor D. This makes it possible to compute the dimension of the Riemann-Roch space $\mathcal{L}(D)$. The next construction is for the case when the degree of D is upper bounded by $[F : F^\sigma]$. This construction works for function fields of small genus.

Suppose that there exists a rational place Q in F^σ such that there is only one place Q' of F lying above Q. Let D be a positive divisor of F with $Q' \notin \mathrm{supp}(D)$ and $\deg(D) < n$. For each place $P \in \mathbb{P}_F$ such that $P \notin \mathrm{supp}(D)$ and $P, P^{\sigma^{-1}}, \ldots, P^{\sigma^{-(t-1)}}$ are distinct, we define the subspace $\mathcal{I}_P$:

$$\mathcal{I}_P = \{f \in \mathcal{L}(D) : f(P^{\sigma^{-i}}) = 0 \text{ for each } i \in \{0, \ldots, t-1\}\}. \tag{5}$$

▶ **Theorem 7.** *For any integers s, t with $1 \leqslant s \leqslant t$, the collection $(\mathcal{I}_P)_{P \in \mathcal{F}_r}$ of subspaces of $\mathcal{L}(D)$, each of codimension at most rt, is an $\left(s, \frac{\ell s}{r(t-s+1)}\right)$ strong subspace design, where $\ell = \deg(D)$.*

4 Subspace design from cyclotomic function fields

In this section, we will present subspace design from the construction given in Section 3 by applying cyclotomic function fields. We start with the subspace design in an ambient space of smaller dimension.

The small dimension case. If $\deg(D)$ is smaller than $n = [F : F^\sigma]$ and n is smaller than the genus $\mathfrak{g}(F)$ of F, in general it is hard to compute dimension of the Riemann-Roch space $\mathcal{L}(D)$. Therefore, we cannot use the construction given in Theorem 7. In this subsection, we apply Theorem 7 to the case where we can estimate the dimension of $\mathcal{L}(D)$.

Let F be the rational function field $\mathbb{F}_q(x)$. Let $\sigma \in \mathrm{Aut}(F/\mathbb{F}_q)$ be given by $x \mapsto \gamma x$, where γ is a primitive element of $\mathbb{F}_q^*$. By Theorem 7, one can obtain the subspace design given in [7]. Below we show that the subspace design given in [7] can be realized by using cyclotomic function fields.

Put $K = \mathbb{F}_q(x)$. Let $p_1(x)$ be a monic linear polynomial. For instance, we can simply take $p_1(x) = x$. Then the cyclotomic function field $F_1 := K(\Lambda_{p_1})$ is a cyclic extension over K with $\mathrm{Gal}(F_1/K) \simeq \mathbb{F}_q^*$. In fact, $F_1 = K(\lambda) = \mathbb{F}_q(\lambda)$ with λ satisfying $\lambda^{q-1} + x = 0$. Thus, $K = \mathbb{F}_q(\lambda^{q-1})$. Let γ be a primitive root of $\mathbb{F}_q$ and let $\sigma \in \mathrm{Gal}(F/K)$ be defined by $\lambda^\sigma = \lambda^\gamma = \gamma\lambda$. This gives the exactly the same function fields and automorphism σ as in [7]. Therefore, we conclude that this cyclotomic function field also realizes the subspace design given in [7].

Next we consider a monic *primitive* quadratic polynomial $p_2(x) = x^2 + \alpha x + \beta$ with $\alpha, \beta \in \mathbb{F}_q$. Then the cyclotomic function field $F_2 := K(\Lambda_{p_2})$ is a cyclic extension over K with $\mathrm{Gal}(F_2/K) \simeq (\mathbb{F}_q[x]/(p_2)^*$. In fact, $F_2 = K(\lambda)$ with λ satisfying $\lambda^{q^2-1} + \lambda^{q-1}(x^q + x + \alpha) + x^2 + \alpha x + \beta = 0$. (see [14]). Let σ be a generator of $\mathrm{Gal}(F_2/K)$. Then by the Galois theory, the fixed field F_2^σ is the rational function field $K = \mathbb{F}_q(x)$. The genus of the function field F_2 is $\mathfrak{g}(F_2) = \frac{(q-2)(q+1)}{2}$ [13, 14].

The zero of $p_2(x)$ is the unique ramified place in $\mathbb{F}_q(x)$ and it is totally ramified. Let P' be the unique place of F_2 that lies over the zero of $p_2(x)$. Let ℓ be an even positive integer with $\ell < q^2 - 1$ and let $D = (\ell/2)P'$. Then $\deg(D) = \ell$ and $D^\sigma = D$. Furthermore, we know

that the the zero of $(x-\alpha)$ is fully inert in F_2/K. By Theorem 7, we have the following result.

▶ **Theorem 8.** *For all positive integers s, r, t, m and prime powers q satisfying $s \le t \le m = \zeta q^2$ for some $\zeta \in (0, 1/2]$, the above construction yields a collection of $M = \Omega(\frac{q^r}{rt})$ spaces $\mathcal{I}_1, \ldots, \mathcal{I}_M \subset \mathbb{F}_q^m$, each of codimension rt, which forms an $\left(s', \frac{(1+1/(2\zeta))ms'}{r(t-s'+1)}\right)$ strong subspace design for all $s' \leqslant s$.*

Proof. Choose ℓ such that the dimension of $\mathcal{L}((\ell/2)P')$ is $m = \zeta q^2$. By the Riemman-Roch Theorem, we have $\zeta q^2 \geqslant \deg((\ell/2)P') - \mathfrak{g}(F_2) + 1$, i.e., $\ell \le \zeta q^2 + g - 1 \le (1/2 + \zeta)q^2$. The desired result follows from Theorem 7. ◀

The large dimension case. In this subsection, we will make use of Theorem 6 due to large genus. Let $p(x) \in \mathbb{F}_q[x]$ be a monic primitive polynomial of degree $d \geqslant 2$. Consider the cyclotomic function field $F := K(\Lambda_{p(x)})$, where K is the rational function field $\mathbb{F}_q(x)$. Then F/K is a Galois extension with $\mathrm{Gal}(F/K) \simeq (\mathbb{F}_q[x]/(p(x)))^*$. Thus, $\mathrm{Gal}(F/K)$ is a cyclic group of order $q^d - 1$. Let σ be a generator of this group. Then by the Galois theory, the fixed field F^σ is the rational function field $\mathbb{F}_q(x)$.

The zero of $p(x)$ is the unique ramified place in $\mathbb{F}_q(x)$ and it is totally ramified. Let P' be the unique place of F lying over the zero of $p(x)$. Let Q' be the unique place of F that lies over the zero of x. Since Q' is totally inert, we have $\deg(Q') = [F : F^\sigma] = q^d - 1 := m$.

The genus of the function field F is $\mathfrak{g} = \frac{1}{2}\left(d - 2 + \frac{q-2}{q-1}\right)(q^d - 1) + 1$. Put $D = \left\lceil \frac{2\mathfrak{g}+m-1}{d} \right\rceil P'$. Then $\ell = \deg(D) \geqslant 2\mathfrak{g} + m$ and hence, $\dim_{\mathbb{F}_q}(D - Q') = \deg(D - Q') - \mathfrak{g} + 1$. Choose $\mathcal{V} \subseteq \mathcal{L}(D)$ such that $\mathcal{V}$ and $\mathcal{L}(D - Q')$ are a direct sum of $\mathcal{L}(D)$. Thus, we have $\mathcal{V} \cap \mathcal{L}(D - Q') = \{0\}$ and $\dim_{\mathbb{F}_q}(\mathcal{V}) = \dim_{\mathbb{F}_q}(D) - \dim_{\mathbb{F}_q}(D - Q') = q^d - 1 = m$.

By Theorem 6, we have the following.

▶ **Theorem 9.** *For all positive integers s, r, t, d, m and prime powers q satisfying $\gcd(r, m) = 1$ and $s \le t \le m/r = (q^d - 1)/r$, there is an explicit collection of $M = \Omega(\frac{m \cdot q^r}{rt})$ spaces $\mathcal{H}_1, \ldots, \mathcal{H}_M \subset \mathbb{F}_q^m$, each of codimension at most rt, which forms an $(s', \frac{(d-1/(q-1))ms'}{r(t-s'+1)})$-strong subspace design for all $s' \leqslant s$. Furthermore, the subspace design can be constructed in $\mathrm{poly}(q, m, r)$ time.*

Proof. The subspace design property follows from Theorem 6 since $\ell = \deg(D) \leqslant (d - 1/(q-1))m$. The construction of the subspace design mainly involves finding a basis of $\mathcal{V}$ and evaluations of functions at places of degree r which can be computed in $\mathrm{poly}(q, m, r)$. We can enumerate over all degree r irreducible polynomials $R \in \mathbb{F}_q[x]$ by brute-force in $q^{O(r)}$ time. None of these places are ramified, and each of these places R splits completely into m places of degree r, say $\{P^{\sigma^{i-1}} \mid 1 \leqslant i \leqslant m\}$, in F. So we can pick $b = \lfloor \frac{m}{t} \rfloor$ of these places $P, P^{\sigma^t}, \ldots, P^{\sigma^{(b-1)t}}$, and define a particular subspace of co-dimension rt associated with each of them as in (4). ◀

By setting $t \approx 2s$ and $r \approx \lfloor \frac{\varepsilon m}{2s} \rfloor$ in Theorem 9, we obtain the Main Theorem 4.

Bipartite Perfect Matching in Pseudo-Deterministic NC*

Shafi Goldwasser[1] and Ofer Grossman[2]

Abstract

We present a pseudo-deterministic NC algorithm for finding perfect matchings in bipartite graphs. Specifically, our algorithm is a randomized parallel algorithm which uses poly(n) processors, poly($\log n$) depth, poly($\log n$) random bits, and outputs for each bipartite input graph a **unique** perfect matching with high probability. That is, on the same graph it returns the same matching for almost all choices of randomness. As an immediate consequence we also find a pseudo-deterministic NC algorithm for constructing a depth first search (DFS) tree. We introduce a method for computing the union of all min-weight perfect matchings of a weighted graph in RNC and a novel set of weight assignments which in combination enable isolating a unique matching in a graph.

We then show a way to use pseudo-deterministic algorithms to reduce the number of random bits used by general randomized algorithms. The main idea is that random bits can be *reused* by successive invocations of pseudo-deterministic randomized algorithms. We use the technique to show an RNC algorithm for constructing a depth first search (DFS) tree using only $O(\log^2 n)$ bits whereas the previous best randomized algorithm used $O(\log^7 n)$, and a new sequential randomized algorithm for the set-maxima problem which uses fewer random bits than the previous state of the art.

Furthermore, we prove that resolving the decision question $NC = RNC$, would imply an NC algorithm for finding a bipartite perfect matching and finding a DFS tree in NC. This is not implied by previous randomized NC search algorithms for finding bipartite perfect matching, but is implied by the existence of a pseudo-deterministic NC search algorithm.

1 Introduction

Perfect Matching: Computing a maximum matching in a graph is a paradigm-setting algorithmic problem whose understanding has paved the way to formulating some of the central themes of theoretical computer science. In particular, Edmonds [6] proposed the definition of tractable polynomial-time solvable problems versus intractable non-polynomial time solvable problems following the study of the graph matching problem versus the graph clique problem.

A distinction of importance to our work is between the **decision** version of the perfect matching problem, which asks whether a perfect matching exists, and the **search** version, which asks to return a perfect matching if any exist. Lovász [15] showed that using randomization, determining the decision problem is reducible to testing that certain integer matrices are non-singular[1]. Since the latter can be done in NC, an RNC algorithm for **deciding** if a perfect matching in a graph exists follows. The **search** version was subsequently shown to be in RNC by Karp, Upfal, and Wigderson [14] via a Monte-Carlo algorithm and by Karloff [13] via a Las-Vegas algorithm.

The next breakthrough was the RNC algorithm of Mulmuley, Vazirani, and Vazirani [16]. They assigned random weights to the edges of the graph and proved the elegant *isolation lemma* which states that with high probability such a random assignment induces (isolates) a unique min-weight perfect matching if at least one exists. Subsequently, the unique minimum weight perfect matching can be determined in parallel by assigning each edge to a different processor whose task is to essentially determine if the edge participates in the unique min-weight perfect matching. However, we emphasize that for the same graph and different isolating weight assignments it is highly likely that different perfect matchings will be found.

Quite recently, a significant step forward has been made by Fenner, Gurjar, and Thierauf [7] who showed how to remove randomization but increase the number of processors, for both the decision and the search variants of the perfect matching problem in bipartite graphs. They show a quasi-NC algorithm: that is, a deterministic poly$(\log n)$ time algorithm which uses quasi-polynomially many processors. A main idea of their work was to construct a set of weight assignments and analyze the union of min-weight matchings with respect to these weight assignments. *In their algorithm, the union of min-weight perfect matchings is never explicitly constructed, but is only used in the analysis.* Indeed, it is not known how to deterministically construct the union of min-weight matchings, and our algorithm uses randomness to construct the union of min-weight matchings. Their algorithm to find the matching follows from applying the procedure of Mulmuley et al [16] to the graph with each of the weight functions they construct until an isolating one is found. Furthermore, the weight assignments used by [7] are different from ours. See the discussion in Section 3 after Lemma 8 of its relation to Lemma 2.3 of [7].

Pseudo-determinism: In a different line of work, initiated by Goldwasser and Gat, [8, 5, 11, 12] the class of search problems which can be solved by *pseudo-deterministic* polynomial time algorithms was introduced – these are probabilistic polynomial-time algorithms for search problems that produce a unique output for each given input except with small probability. That is, they return the same output for all but few of the possible random choices. Algorithms that satisfy the aforementioned condition are named pseudo-deterministic (for a formal definition, see Section 2), as they essentially offer the same functionality as deterministic algorithms: from the point of view of a computationally bounded observer, pseudo-deterministic and deterministic algorithms behave the same, since they always output the same answer.

Efficient pseudo-deterministic algorithms have been shown [5, 8, 12, 11] for several search problems for which no efficient deterministic algorithms are known. These problems include number theoretic search problems [12, 8, 5], multi-variate polynomial non-zero findings [8],

[1] The decision problem is equivalent to testing whether the determinant of the Tutte matrix of the graph (or a simplified version of it in the bipartite case) is identically 0.

and several sub-linear algorithms [11]. The latter work of Goldwasser, Goldreich and Ron [11] shows separations between deterministic, randomized and pseudo-deterministic sub-linear algorithms in accordance with the (asymptotic) number of queries they must require.

The larger question of whether the class of pseudo-deterministic polynomial time search problems is strictly contained in the class of probabilistic polynomial time search problems remains open (see the discussion by Goldreich [10] and in [8, 11] and the discussion below). However, the significance of showing a pseudo-deterministic algorithm in lieu of deterministic ones is amply illustrated by the following observation: If $P = BPP$ then any pseudo-deterministic polynomial time algorithm for a search problem implies a polynomial time deterministic algorithm for the problem.[2] In contrast, the randomized versus deterministic complexity of search problems may not be settled by all proofs of $P = BPP$. That is, certain proofs of $P = BPP$ may not generalize to the search setting. A similar situation emerges for the question of randomized versus deterministic parallel complexity of search problems.

We remark that the study of pseudo-deterministic algorithms seems particularly relevant in the parallel and distributed settings: if two parties invoke a pseudo-deterministic algorithm on the same input, they would be guaranteed to obtain the same result with high probability, regardless of the randomness used. In the distributed setting, pseudo-determinism has been used for scheduling algorithms [9].

1.1 Our Results

In this work we initiate the study of pseudo-deterministic algorithms in the context of NC. In particular, in lieu of deterministic NC algorithms for both the decision and search versions of perfect matching in a graph, we ask the following question: Does a pseudo-deterministic NC algorithm exist for the perfect matching search problem? We settle this question affirmatively for bipartite graphs.

We present a pseudo-deterministic NC algorithm for finding perfect matchings in bipartite graphs. Namely, we present a randomized NC algorithm which on input a bipartite graph G outputs a unique (canonical) perfect matching with high probability, if at least one perfect matching exists. All previous RNC algorithms (including [16]) would output different matchings on different executions.

▶ **Theorem 1** (Main Theorem). *There exists a pseudo-deterministic NC algorithm that, given a bipartite graph G, returns a perfect matching of G, or states that none exist. The algorithm uses $O(\log^2(n))$ random bits.*

Aggarwal, Anderson, and Kao [1] present an RNC algorithm for constructing a depth first search tree for directed graphs. Their algorithm's only use of randomization is to solve bipartite min-weight perfect matching as a subroutine. We can adapt our algorithm to find a unique min-weight perfect matching. Hence, our results imply a pseudo-deterministic NC algorithm for computing depth first search (DFS) in general directed graphs.

▶ **Corollary** (DFS). *There exists a pseudo-deterministic NC algorithm that, given a directed graph G, returns a depth first search tree of G.*

In the full version of the paper, we show a general method for using pseudo-determinism to reducing the number of random bits used by general randomized algorithms. The main

[2] This follows from the characterization of Gat and Goldwasser [8] showing that search problems solvable by polynomial time pseudo-deterministic algorithms are exactly the problems solvable by a polynomial time algorithm with access to a BPP oracle for an analogous decision problem.

idea is that random bits used to solve problems pseudo-deterministically can later be reused, thus avoiding the need to sample more random bits. We then show applications of the technique, including the following Theorem:

▶ **Theorem** (DFS With Few Random Bits). *There exists an RNC algorithm that, given a directed graph G, returns a depth first search tree of G using only $O(\log^2(n))$ random bits. Furthermore, the algorithm is pseudo-deterministic.*

Previously, the best known algorithm for computing a DFS in RNC used $O(\log^7(n))$ random bits (and, furthermore, was not pseudo-deterministic).

It is possible to show, as stated below, that the set of problems solvable by NC pseudo-deterministic algorithms are exactly the set of problems solvable by an NC algorithm with an oracle to RNC decision problems. Thus, our main result implies the existence of a deterministic NC algorithm for finding a bipartite perfect matching if $NC = RNC$. Prior works on the perfect matching search problem in bipartite or general graphs do not imply a deterministic NC solution for the perfect matching search problem, even if an NC algorithm were found for the decision version of the problem. More generally, even if $NC = RNC$, it does not generally imply that every *search* problem that is solvable by an RNC algorithm has a deterministic NC solution.

▶ **Lemma** (Pseudo-deterministic NC). *The class of search problems with pseudo-deterministic NC algorithms is the class of search problems solvable by an NC machine given access to an oracle for RNC decision problems.*

Combining the above lemma with Theorem 1, we prove the following:

▶ **Corollary.** *If $NC = RNC$, then there exists a deterministic NC algorithm that given a bipartite graph G, outputs a perfect matching of G (or states that none exists).*

Combining with the reduction of Aggarwal, Anderson, and Kao [1], we also obtain the following:

▶ **Corollary.** *If $NC = RNC$, then given a graph G, there exists an NC algorithm that returns a depth first search tree of G.*

1.2 High Level Ideas of the Algorithm

We now present an overview of the algorithm and proof of Theorem 1.

Let G be the given bipartite graph. At a high level the algorithm will proceed as follows.

1. In deterministic NC we construct a weight assignment w to the edges of G for which the **union graph** of all min-weight perfect matchings with respect to w (i.e., the union of all edges participating in at least one minimum weight matching) is significantly smaller than G.
2. In randomized NC we **construct** the union graph of all min-weight perfect matchings with respect to w.
3. We repeat steps 1 and 2 above, and every so often we contract some edges of the graph, until we arrive at a graph small enough that we can deterministically construct a perfect matching using brute force.
4. We then “uncontract" to arrive at a matching of the original graph.

Note that the only randomized step of the algorithm is step (2): the construction of the union graph of min-weight perfect matchings. Because the union graph of min-weight perfect matchings is unique (i.e., there is only one union of min-weight perfect matchings), this step

of the algorithm is pseudo-deterministic. As all steps in the algorithm are either deterministic or pseudo-deterministic, the resulting algorithm will be in pseudo-deterministic.

Constructing the union of all min-weight perfect matchings of G with respect to w will be an important step in our solution, as it will allow us to prune the graph (removing the edges which participate in no min-weight perfect matching) while maintaining the property that the graph has a perfect matching. We will next show how to use randomization to construct the union.

We remark that it remains an open problem to deterministically compute the union of min-weight perfect matchings in NC. Whereas the *analysis* of the union graph with respect to a particular set of weight assignments plays an important role in the recent quasi-NC result of [7], *they do not explicitly construct it* as part of their decision or search algorithms.

▶ **Lemma** (Union of min-weight perfect matchings). *Let $G(V, E)$ be a bipartite graph with a polynomially bounded weight assignment w to the edges. Let E_1 be the union of all min-weight perfect matchings in G. There exists an RNC algorithm for finding the set E_1.*

The Lemma appears in Section 3 as Lemma 9. We outline the proof below.

We compute the union of min-weight perfect matchings by creating a process, for each edge e_i, whose goal is to determine whether e_i participates in some min-weight perfect matching. To this end, the process creates a new weight assignment w_i which lowers the weight of e_i by a small amount. The new weight assignment is picked so that if e_i is in some w-minimal perfect matching, then e_i must be in all w_i-minimal perfect matchings; whereas if e_i is not in any w-minimal perfect matching, then it must be in none of the w_i-minimal perfect matchings. By finding any (not necessarily unique) w_i-minimal perfect matching (which can be done in RNC using techniques in [16], and is the only randomized step of our algorithm) and checking whether e_i participates in the matching, we can determine whether e_i is in the union of min-weight matchings with respect to w. We can then return the union of all e_i which are in some min-weight matching.

Recall that the goal of constructing the union graph is to reduce the problem to a smaller graph by removing many edges. To apply the above procedure so as to effectively reduce the size of the graph, we deterministically construct a set of weight assignments with the property that constructing the union of all min-weight perfect matchings in G with respect to these assignments (by going through the weight assignments in sequence and removing edges in each iteration) leaves G with many vertices of degree at most 2. We can then contract all vertices of degree at most 2 with their neighbors to get a smaller graph in which we recursively run our algorithm until we remain with only a constant number of vertices. At this point, we can deterministically compute a unique perfect matching in $O(1)$ time. We note that although performing the contraction procedure in NC takes some care, if it is done properly it is easy to extend a perfect matching in the contracted graph to the original graph.

The construction of weight assignments with the above property proceeds as follows. By a theorem in [2], we learn that if the girth (length of the shortest cycle) of G is at least $4 \log n$, then at least $\frac{1}{10}$ of the vertices have degree at most 2. Therefore, if our weight assignments $w_1, \ldots, w_t$ can make all small cycles disappear (when we construct the union of w_1-minimal matchings, then construct the union of w_2-minimal matchings on this new graph, etc., then at the end are left with a graph with no small cycles), we will be able to reduce our problem to a smaller graph by contracting vertices of degree up to 2. It was shown in [7] that for any weight assignment w, every cycle with nonzero circulation (the sum of the weights of the odd edges of a cycle minus the sum of the weights of the even edges of the cycle) disappears

when we look at the union of w-minimal perfect matchings [3]. We thus need to show how to construct a set of weight functions which will ensure that each small (containing fewer than $4 \log n$ vertices) cycle will have nonzero circulation with respect to at least one of the weight functions.

▶ **Lemma** (Non-Zero Circulation for Small Cycles). *Let G be a bipartite graph on n vertices. Then one can construct in NC a set of $O(\log n)$ weight assignments with weights bounded by* $\text{poly}(n)$ *such that every cycle of length up to $4 \log n$ has nonzero circulation for at least one of the weight assignments.*

This Lemma appears in Section 3 as Lemma 8. We remark that the weight assignments used by [7] are different from ours. We point the reader to a discussion following Lemma 8 for its relation to Lemma 2.3 of [7].

To prove this Lemma we first note that if a cycle of length up to $2k = 4 \log n$ has circulation 0, then the sum of the weights of the odd edges equals the sum of the weights of the even edges. That means that there are two subsets of $E(G)$ of size up to k that have the same sum of weights. If we could construct weight functions such that no two sets of size up to k have the same sum of weights with respect to all of the weight functions, we will have proved the Lemma.

The idea of the construction in the Lemma's proof is to have $k + 1$ weight assignments, and let the mth edge have weight

$$w_i(m) = [m^i]_p$$

with respect to the ith weight function, where $[x]_p$ denotes the number between 1 and p which is equal to x modulo p, and where p is an arbitrary prime greater than n^2.

Then, given the sum of the weights (with respect to each of the w_i) of k elements labeled m_1 through m_k, we can retrieve the sums $\sum_{j=1}^{k} m_j^i \pmod p$, for all $1 \leq i \leq k + 1$. Using these sums, we can use Newton's identities to find the minimal polynomial over $\mathbb{F}_p$ with roots $m_1, m_2, \ldots, m_k$, which uniquely determines the set of elements $m_1, m_2, \ldots, m_k$,. Thus, no two distinct subsets of size up to k can have the same sum of weights.

We note that the weights in the Lemma (where $k = 2 \log n$) are of polynomial size.

We now can construct the union of min-weight matchings with respect to w_1 to get a graph G_1. Then, we can construct the union of min-weight matchings in G_1, with respect to w_2, and so on until w_k. When we are done, we have a graph of high girth, so we can contract many vertices of degree up to 2 (recall that a graph of girth greater than $4 \log n$ has at least one tenth of its vertices of degree up to 2). We now have a smaller graph, and we recurse, completing the proof's outline.

1.3 Pseudo-Determinism and Search vs Decision Derandomization

Understanding the role of randomness in computation is one of the main problems in complexity theory. In the context of *decision* problems the separation between P and BPP indeed captures the gap between randomized and deterministic polynomial time algorithms. However, in the context of *search* problems, it does not. Even if we assume $P = BPP$, there may exist search problems solvable by known randomized polynomial time algorithms

[3] We note that in [7] the authors do not construct the union of w-minimal perfect matchings, but only use the union in their analysis of the algorithm. The algorithm in this paper, on the other hand, constructs the union of w-minimal perfect matchings.

which may not succumb to deterministic polynomial time algorithms. In other words, there exist polynomial time search problems whose randomized vs deterministic complexity may not be settled by a proof of $P = BPP$ (it is worth noting that many approaches towards $P = BPP$, such as pseudorandom generators, may generalize to show that search-P = search-BPP, for certain definitions of search-BPP. In particular, any proof of $P = BPP$ strong enough to prove that promise-P = promise-BPP would generalize to the search setting as shown by Goldreich [10]). For example, the problem of generating primes (given 1^n, output a prime with n bits) has an efficient randomized algorithm. However, even under the assumption $P = BPP$, it is not known if there exists a polynomial time deterministic algorithm. A similar situation is the case for the primitive root problem (given a prime p, output a primitive root modulo p). In [8], the authors prove that a problem admits a pseudo-deterministic polynomial time algorithm (i.e., a randomized search algorithm which outputs the same result for all but few random seeds, formally defined in Section 2) if and only if it is polynomial time reducible to a decision problem in BPP. Thus, any pseudo-deterministic algorithm one demonstrates for a search problem would immediately provide a derandomized algorithm for the problem if $P = BPP$. Our understanding of the randomized complexity for search problems in the parallel setting is quite similar to the polynomial time setting. The NC vs RNC question does not capture the full power of randomization in the parallel setting, since resolving the question for decision problems has no direct bearing on the search-NC vs search-RNC question. We remark that the leading derandomization effort in complexity theory, the so called "hardness vs randomness" paradigm, applies to search problems as well. In a nutshell, the tool of the paradigm is to construct pseudo-random generators or hitting-set generators to derandomize. However, other proofs of $NC = RNC$ may have no direct implication about the relationship of NC and RNC in the context of search. The existence of a pseudo-deterministic algorithm for a problem has direct bearing on the derandomization question under the assumption $NC = RNC$. We show in the full version of the paper that if $NC = RNC$, then the set of problems with NC search algorithms equals the set of problems with NC pseudo-deterministic algorithms (i.e., search algorithms in RNC which output the same solution for all but few random seeds). Our argument is similar to the argument shown in [8] regarding the polynomial time setting. Viewed in this light, our main theorem is that if $NC = RNC$, then there exists a deterministic NC algorithm for *finding* a perfect matching in a bipartite graph. While it would be interesting to find general implications about derandomization of search problems under the assumption that decision problems are derandomized, our paper is specifically about the bipartite perfect matching problem.

1.3.1 Organization

In Section 2, we discuss useful definitions and lemmas from prior works. In Section 3, we prove the main lemmas used in the algorithm. In Section 4, we describe the algorithm, and prove its correctness In the full version of the paper, we show a general method for saving random bits using pseudo-determinism, and apply it to save bits in the matching algorithm, as well as in a depth first search algorithm. Furthermore, in the full version we show that if $NC = RNC$, then all pseudo-deterministic NC algorithms can be fully derandomized. In the full version of the paper, we show how to reduce the number of random bits used by our matching algorithm.

2 Background and Preliminaries

We begin with a formal definition of pseudo-deterministic:

▶ **Definition 2** (Pseudo-deterministic)**.** An algorithm A for a relation R is *pseudo-deterministic* if there exists some function s such that A, when executed on input x, outputs $s(x)$ with high probability, and s satisfies $(x, s(x)) \in R$.

To contrast the definition with that of a standard randomized algorithm, we note that a standard randomized algorithm may output a different y on different executions, as long as $(x, y) \in R$.

▶ **Definition 3** (Pseudo-Deterministic NC)**.** We call an algorithm *pseudo-deterministic NC* if it is in RNC, and is pseudo-deterministic.

We now present some lemmas from previous work.

▶ **Lemma 4** (Theorem 2 in [16])**.** *Given a graph G with a weight function $w : E \to \mathbb{Z}$, with polynomially bounded weights, it is possible to construct a w-minimal perfect matching of G in RNC.*

▶ **Definition 5** (Circulation)**.** Let $G(V, E)$ be a graph with weight assignment w. The *circulation* $c_w(C)$ of an even length cycle $C = (v_1, v_2, \ldots, v_k)$ is defined as the alternating sum of the edge weights of C,

$$c_w(C) = |w(v_1, v_2) - w(v_2, v_3) + w(v_3, v_4) - \cdots - w(v_k, v_1)|.$$

Circulation has been used for an NC algorithm for perfect planar bipartite matching [4] and for a quasi-NC algorithm for bipartite matching [7].

▶ **Lemma 6** (Lemma 3.2 in [7])**.** *Let G be a bipartite graph, and let C be a cycle in G. Let w be a weight function such that the cycle C has nonzero circulation. Then the graph G_1 obtained by taking the union of all min-weight perfect matchings on G does not contain the cycle C.*

The proof in [7] relies on the matching polytope. We present a combnatorial proof found by Anup Rao, Amir Shpilka, and Avi Wigderson, based on Hall's Theorem:

Proof. Let G' be the multigraph obtained by taking the disjoint union of all min-weight perfect matchings (i.e., if an edge e appears in k min-weight perfect matchings of G, then G' contains k copies of e).

Suppose that there exists a cycle C of nonzero circulation in G'. Then suppose without loss of generality that the sum of weights of the odd edges of C is larger than the sum of the weights of the even edges. Then we remove a single copy of each odd edge of C from G', and add a single copy of each even edge of C to G'. Call this new graph G''.

We note that G' is a regular graph since it is the disjoint union of matchings, and matchings are regular graphs of degree 1. We also see that every vertex has the same degree in G'' as in G'. Hence, G'' is regular.

We know that every regular bipartite graph is a union of perfect matchings (to prove this, we can induct on the degree. A regular bipartite graph must satisfy Hall's condition. Therefore, it has a perfect matching, which we can remove. We now obtain a new regular graph of lower degree, which by induction must be a union of perfect matchings).

If we let M be the minimal weight of a matching in G, and we suppose G has d min-weight matchings, then the sum of the weights of edges of G' is Md. However, the total weight of all edges in G'' is lower than the total weight of all edges in G'. We know that G'' is regular of degree d, and therefore is a union of d perfect matchings. If we decompose G'' into d perfect

matchings, it is impossible that they all have weight at least M, because G'' had total weight less than Md. Therefore, G'' has a matching of weight less than M, which corresponds to a matching of weight less than M in G. This contradicts the assumption that M is the minimal weight of a matching in G. ◀

The following lemma originates in [2].

▶ **Lemma 7.** *Let H be a graph with girth (length of shortest cycle) $g \geq 4 \log n$. Then H has average degree < 2.5. In particular, at least $\frac{1}{10}$ (a constant fraction) of the vertices have degree at most 2.*

3 Key Lemmas

We present some definitions, as well as key lemmas from previous work, in Section 2.

In [16], a weight assignment is chosen at random such that with high probability there is a unique min-weight perfect matching. Our goal will be to deterministically construct weight assignments with similar properties. Specifically, we will construct weight assignments which give nonzero circulation to small cycles.

▶ **Lemma 8** (Non-Zero Circulation for Small Cycles)**.** *Let G be a bipartite graph on n vertices. Then one can construct in NC a set of $O(\log n)$ weight assignments with weights bounded by $\text{poly}(n)$ such that every cycle of length up to $4 \log n$ has nonzero circulation for at least one of the weight assignments.*

We would like to point out the differences between this Lemma and Lemma 2.3 of [7] (which originates in [3]). At heart, the two Lemmas are quite different, but they seem similar at first glance. Lemma 2.3 of [7] proves that for any number t, one can construct a set of $O(n^2 t)$ weight assignments with weights bounded by $O(n^2 t)$, such that for any set of t cycles, one of the weight assignments gives nonzero circulation to each of the t cycles.

Since the number of length s cycles is at most n^s, their theorem implies a set of $O(n^{s+2})$ weight assignments with weights bounded by $O(n^{s+2})$ (note that this is quasi-polynomial for $s = 4 \log n$, which will be our setting of parameters) such that at least one of the weight assignments gives non-zero circulation to all small cycles.

We can think about the Lemma as an assignment which isolates all small subsets of S. We will later use this Lemma to construct a weight assignment for the graph G.

Proof. Let $S = \{s_1, \ldots, s_m\}$ be the edges of G. Consider the following weight assignments $w_1, w_2, \ldots, w_{2 \log n + 1}$, where we write $w_i(m)$ as shorthand for $w_i(s_m)$:

$$w_i(m) = [m^i]_p,$$

where $[x]_p$ denotes the number between 1 and p which is equal to x modulo p, and where p is an arbitrary prime greater than n^2. We can find such a prime by having n^2 processes each check a different number between n^2 and $2n^2$. Each of these processes initiate $2n^2$ processes which each test divisibility by an integer up to $2n^2$. (Note that this has no implications regarding generating primes in NC since our input is of size n instead of $\log n$).

We will show that there exist no two subsets of size up to $2 \log n$ which have the same sum of weights. Then, in particular, there exists no cycle of length up to $4 \log n$ with circulation 0.

Suppose there exist two distinct subsets of size up to $k = 2 \log n$ with equal sums of weights with respect to each of the w_i. We can add zeroes to both subsets such that the sizes of the

sets are exactly k. Suppose that the sums of the weights of two subsets $A = \{a_1, a_2, \ldots, a_k\}$ and $B = \{b_1, b_2, \ldots, b_k\}$ are the same. This gives us the following equivalences modulo p:

$$\begin{aligned} a_1 + a_2 + \cdots + a_k &\equiv b_1 + b_2 + \cdots + b_k \pmod{p} \\ a_1^2 + a_2^2 + \cdots + a_k^2 &\equiv b_1^2 + b_2^2 + \cdots + b_k^2 \pmod{p} \\ &\cdots \\ a_1^{k+1} + a_2^{k+1} + \cdots + a_k^{k+1} &\equiv b_1^{k+1} + b_2^{k+1} + \cdots + b_k^{k+1} \pmod{p}. \end{aligned}$$

We claim that this implies that $A = B$. We note that if $a_i \equiv b_j$ modulo p, then $a_i = b_j$ because p is larger than n^2 which is larger than the maximal size of a_i or b_j. Therefore, it will suffice to show that the set A and the set B are equivalent in $\mathbb{F}_p$.

Given the sums of the ith powers of the a_j for i between 1 and $k+1$, Newton's identities uniquely determine the values of the fundamental symmetric polynomials in the a_j. Therefore, Newton's identities also uniquely determine the minimal polynomial which has as roots all of the a_j (with multiplicity). We know that this polynomial will be of degree k and therefore since the b_j share this polynomial, the set of the a_i and the set of the b_j must be equal (they are both the set of roots of the same polynomial), completing the proof that the weight assignment has no two distinct subsets of size up to k with the same sum of weights with respect to all of the weight assignments. ◀

The following lemma shows that in RNC we can construct the union of min-weight perfect matchings of a graph G with a weight assignment w.

▶ **Lemma 9** (Union of min-weight perfect matchings). *Let $G(V, E)$ be a bipartite graph with a polynomially bounded weight assignment w to the edges. Let E_1 be the union of all min-weight perfect matchings in G. There exists an RNC algorithm for finding the set E_1.*

The idea behind the proof is that for each edge e_i, we run a process whose goal is to tell whether e_i is part of a min-weight perfect matching. To do so, the process creates a new weight function which lowers the weight of e_i so that if e_i was in a min-weight perfect matching, under the new weight assignment e_i is in *every* min-weight perfect matching (but if e_i was not in any min-weight perfect matching, it should still not be in any min-weight matching). Then, we use Lemma 4 to find a min-weight perfect matching, and we check if e_i is in the matching. e_i will be in the matching if and only if it is part of a min-weight matching with respect to the original weight function w.

Proof. For each edge $e_i \in E$, consider the weight function w_i defined by

$$w_i(e_j) = \begin{cases} 2w(e_j) - 1 & \text{if } i = j, \\ 2w(e_j) & \text{if } i \neq j. \end{cases}$$

Suppose that M is the minimum weight for a matching with respect to w. Then with respect to w_i, the min-weight matching will have weight $2M$ if e_i is in no w-minimal matching. Otherwise, the min-weight matching will have weight $2M - 1$. By finding a w_i-minimal perfect matching (which we can do in RNC by Lemma 4) and checking its weight (or whether e_i participates in the matching), we can determine whether e_i is in a w-minimal matching.

Note that this is highly parallelizable: we can run the above for each edge in parallel. Then, we return the set of all e_i which are part of some w-minimal matching. ◀

4 The Algorithm

We now put everything together to construct an algorithm:

PERFECT-MATCHING(G)

1 Check if G has a matching in RNC using the algorithm of [16].
2 If G does not have a perfect matching, return $\perp$.
3 If $|E(G)| \leq 100$:
4 Find and return a perfect matching of G using brute force.
5 Let $\{w_1, \ldots, w_t\}$ be the weight assignments from Lemma 8 with $t = O(\log n)$.
6 Let $G_0 = G$.
7 For $i = 1, 2, \ldots, t$:
8 Let G_i be the union of w_i-minimal perfect matchings of G_{i-1} (use Lemma 9).
9 Contract vertices of degree up to 2 in G_t to create G' (*see full version of paper for details*).
10 Let $M' =$ PERFECT-MATCHING(G').
11 Extend the matching M' in G' to a matching M in G_t (*see full version of paper for details*).
12 Return M.

We first argue that the algorithm returns a perfect matching with high probability. To do so, we first note that since G_t and G have the same vertices, it is enough to find a perfect matching on G_t. It is therefore enough to show that G' has a perfect matching, and that in step 11 we can extend the perfect matching M' in G' to a perfect matching M in G_t. This requires analyzing the contraction procedure of step 9. The contraction procedure takes some care, but its ideas are non-central to our proof.

The main idea behind the contraction step is that if we contract both edges adjacent to a vertex of degree 2 and find a matching in the new contracted graph, it is easy to turn a perfect matching in the contracted graph to a perfect matching in the original graph. If v is the vertex of degree 2, and its two neighbors are u_1 and u_2, then once we contract the three vertices we can call the new vertex u'. A perfect matching in the contracted graph will have an edge (v', u') adjacent to u'. That edge, in the original graph, must either be of the form (v', u_1) or of the form (v', u_2) (note that it cannot be of the form (u', v), with v being the vertex of degree 2). Suppose without loss of generality that the edge is (v', u_1). Then we can add the edge (v, u_2) to the matching to form a perfect matching M in G_t from the matching M' in G'. Doing this for multiple vertices in parallel leads to some complications which we elaborate on in the full version of the paper.

Note that we can amplify the success probability of step 8 so that the probability of failure is at most $\frac{1}{n}$. Since the step gets executed a total of $O(\log^2 n)$ times ($O(\log n)$ times on each of the $O(\log(n))$ steps of the recursion), by the union bound the probability that step 8 ever fails is at most $\frac{\log^2(n)}{O(n)}$, which can be further amplifies through repetition.

We now argue the algorithm is pseudo-deterministic. We note that randomization is only used in step 8 to construct the union of min-weight matchings. We use the randomization in the following context: given a weight assignment on a graph, construct the union of min-weight perfect matchings of the graph. Since this has a unique correct answer, correctness implies uniqueness. Therefore, our algorithm returns the same output with high probability, and is therefore pseudo-deterministic.

We will now show the algorithm lies in RNC. We note that step 4 takes $O(1)$ time and step 5 is in NC by Lemma 8. The number of iterations of the loop in step 7 is of length $O(\log(n)^2)$, by Lemma 8, and taking the union of min-weight perfect matchings within the loop in step 8 is in RNC by Lemma 9. Note that if G_{i-1} has a perfect matching, then so

does G_i, since G_i is a non-empty union of perfect matchings of G_{i-1}. Therefore, the loop iterations can be performed in RNC.

By Lemma 8 and Lemma 6, we see that after completing the loop, G_t has no cycles of length up to $4 \log n$. By Lemma 7, in step 9 we contract a constant fraction of the vertices, so G' has a constant fraction of the number of vertices of G_t. Therefore, the number of recursive calls of step 10 is $O(\log n)$.

This completes the algorithm's analysis, proving the following theorem:

▶ **Theorem 10.** *There exists a pseudo-deterministic NC algorithm that, given a bipartite graph G on n vertices, returns a perfect matching of G, or states that none exist.*

We note that as a consequence of Theorem 10 and a result appearing in the full version of the paper (the result that if $NC = RNC$, then every pseudo-deterministic NC algorithm can be fully derandomized), if $NC = RNC$ then the bipartite perfect matching search problem can be solved in NC. In the full version, we improve upon Theorem 10 by showing a pseudo-deterministic NC algorithm for bipartite perfect matching which uses only $O(\log^4 n)$ random bits. In the full version of the paper, we further improve upon that by showing a pseudo-deterministic NC algorithm using only $O(\log^2 n)$ random bits.

5 Discussion

We can adapt our algorithm to bipartite maximum matching. Given a bipartite graph G, we add edges such that we have a complete graph, and give weight 1 to each edge of G and weight 0 to each edge not in G. Now, we take the union of max-weight matchings. We know that any matching on this graph will have the same maximal weight (the symmetric difference of two matchings of different weights will contain a cycle of non-zero circulation). We now pseudo-deterministically find a perfect matching in this new graph, and restrict it to G to output a maximum matching.

The above also implies pseudo-deterministic NC algorithms for some network flow problems such as max-flow approximation, which was shown in [17] to be NC-reducible to maximum bipartite matching. In addition, as an immediate corollary we get a pseudo-deterministic algorithm for max flow, where capacities are expressed in unary (this problem was shown to be NC-reducible to bipartite perfect matching in [14])

It remains open to find a pseudo-deterministic NC algorithm for perfect matching in general (non-bipartite) graphs.

In the context of polynomial time pseudo-determinism, there are many fundamental problems with polynomial time randomized algorithms where the existence of pseudo-deterministic polynomial time algorithms remains open. These problems include generating primes (given 1^n, output a prime with n bits); given a prime p and 1^d, finding an irreducible degree d polynomial over $\mathbb{F}_p$; and finding a primitive root modulo p given a prime p and the factorization of $p-1$. We hope for more progress towards finding pseudo-deterministic polynomial time algorithms for these problems.

Acknowledgments. Thanks to Anup Rao for communicating to us his proof with Amir Shpilka and Avi Wigderson of Lemma 6 (also Lemma 3.2 in [7]). We are very grateful to Oded Goldreich for many helpful discussions on this paper and on the connections between the questions of decision versus search derandomization and pseudo-determinism.

A Linear Lower Bound for Incrementing a Space-Optimal Integer Representation in the Bit-Probe Model*

Mikhail Raskin

Department of Computer Science, Aarhus University, Aarhus, Denmark
raskin@mccme.ru

Abstract

We present the first linear lower bound for the number of bits required to be accessed in the worst case to increment an integer in an arbitrary space-optimal binary representation. The best previously known lower bound was logarithmic. It is known that a logarithmic number of read bits in the worst case is enough to increment some of the integer representations that use one bit of redundancy, therefore we show an exponential gap between space-optimal and redundant counters.

Our proof is based on considering the increment procedure for a space optimal counter as a permutation and calculating its parity. For every space optimal counter, the permutation must be odd, and implementing an odd permutation requires reading at least half the bits in the worst case. The combination of these two observations explains why the worst-case space-optimal problem is substantially different from both average-case approach with constant expected number of reads and almost space optimal representations with logarithmic number of reads in the worst case.

1 Introduction

We consider the problem of representing integers in a certain range by binary codes to support efficient increment operations in the bit-probe model. Our main interest is representing integers in the range $0, \ldots, 2^n - 1$ by exactly n bits.

Most computational tasks require storing integers, and in some cases special encodings are better suited to the task. Probably the first encodings used in bit-based memory are the standard positional binary notation and binary coded decimal. We will consider the task of incrementing an integer counter in the bit probe model. Following [5], an increment algorithm is defined as a **decision assignment tree** (DAT), a binary tree where each inner node specifies a bit of the code that has to be read to make a decision, and every leaf node contains a set of changes to the code to perform. In this model the number of bits read by

Table 1 A summary of best known results.

Number of bits read to increment	Space-optimal	Single extra bit
Average	$\Theta(1)$ (binary notation)	
Worst-case	$\geqslant \log_2 n$ [4] $\leqslant n-1$ [2] $\geqslant \frac{n}{2}$ **our contribution**	$\geqslant \log_2 n$ [4] $\leqslant \log_2 n + O(1)$ [8]

an increment is the depth of the corresponding leaf, and the number of bits written is the number of changes in the leaf.

The standard binary notation with n bits reads and writes only 2 bits on average, but has to read and write n bits in the worst case. It is also **space-optimal**, i.e. every combination of bits represents a unique integer. Gray codes [6] allow writing only one bit for each increment operation, but they still require reading all n bits. In the article [5] Fredman introduces the notion of DAT and considers codes that can use more bits than necessary but still require writing only a single bit per update. A logarithmic lower bound is proven for the number of bits read in the worst case for such a code. This bound is sometimes cited in connection with the codes that write a constant number of bits per increment; while the bound is correct, the proof in [5] does use the fact that only one bit is written. Fredman also gave a construction of a code such that the increment procedure needs to read only $O(\log n)$ bits in the worst case, but the code length is worse than for the standard notation by a large multiplicative factor. Frandsen, Miltersen and Skyum consider a more general problem of encoding elements of a generic monoid; their article [4] provides a general lower bound for the number of bits read by an increment procedure for integers in the worst case and a construction of a code with an increment procedure that needs to read $\log_2 n + 1$ bits in the worst case. This code needs $\log_2 n$ extra bits. Constructions developed by Bose et al. in [1] and Rahman and Munro [8] require a single extra bit or less and achieve logarithmic number of bits read by the corresponding increment procedures. Rahman and Munro also prove a lower bound of $\Omega(\sqrt{n})$ bits read in the worst case for the special case when increment reads a different subset of bits for every input or at least each subset of bits is read only for a constant number of inputs (this is a strong condition; for example, the standard binary notation reads only the last bit for half of all the inputs). Elmasry and Katajainen provide a code [3] that uses a logarithmic number of extra bits and requires the increment procedure to read only a logarithmic number of bits in the worst case while ensuring efficient implementation on a word-based RAM machine.

For the space-optimal case there is a code [2] that allows reading $n-1$ bits in the worst case and writes no more than 3 bits for each increment operation. This code has been found by brute force search. The best previously known lower bound on the number of bits to read in the worst case given in [4] is logarithmic in n.

In this paper we close the exponential gap and settle the complexity of the problem up to a multiplicative factor of 2 by proving that every representation of integers from 0 to $2^n - 1$ using n bits require the increment operation to read at least $\frac{n}{2}$ bits in the worst case. The proof uses properties of permutations to explain why the space-optimal codes and the redundant codes are qualitatively different from the point of view of the worst-case complexity of the increment operation.

In the next section we give the standard definitions related to permutations and cite their standard properties. Then we define our model of computation. In the section 3 we give an overview of the core ideas and an outline of the proof.

The Section 4 contains the detailed definitions of the constructions and the proofs of their basic properties. The Section 5 contains the combinatorial details and the final part of the proof. The purpose of the Sections 4 and 5 is to remove any remaining uncertainty after the brief presentation of the proof in the Section 3.

2 Preliminaries

2.1 Algebraic preliminaries

In this subsection we recall algebraic notions and the standard theorems about permutations required by our proof. We follow the definitions from [7], but equivalent definitions can be found in many other abstract algebra books. This subsection can be skipped at the reader's discretion.

▶ **Definition 1.** A **group** is a pair $(G, \circ)$ consisting of a set G and a function $\circ : G \times G \to G$, such that the following conditions hold:

- **Associativity:** $\forall a, b, c \in G : a \circ (b \circ c) = (a \circ b) \circ c$.
- **Neutral element:** $\exists e \in G : \forall a \in G : e \circ a = a \circ e = a$.
  e is called a **neutral element** of a group
- **Inverse element:** $\forall a \in G : \exists b \in G : a \circ b = b \circ a = e$.
  b is called an **inverse element** of a.

▶ **Theorem 2.** *There can be only one neutral element in a group G. Let e denote the unique neutral element in the group. Also, for every $a \in G$ there can be only one inverse element. Let a^{-1} denote the unique inverse element of a. The inverse element of a composition $a \circ b$ is $b^{-1} \circ a^{-1}$.*

▶ **Definition 3.** The **symmetric group** S_n is the group of all bijections (one-to-one correspondences) from the set $\{1, 2, 3, \ldots, n\}$ to itself. The group operation $\circ$ is the composition of functions. Each bijection in the symmetric group is called a **permutation**. The neutral element in the symmetric group is the **identity permutation** $\sigma(x) = x$. The inverse element of a permutation σ is the inverse function σ^{-1}, also called the **inverse permutation** of σ. A permutation $\sigma \in S_n$ can be denoted by $\begin{pmatrix} 1 & 2 & 3 & \cdots & n \\ \sigma(1) & \sigma(2) & \sigma(4) & \cdots & \sigma(n) \end{pmatrix}$. In the present paper $\circ$ will always be written explicitly.

▶ **Definition 4.** Suppose we are given $k \leqslant n$ different elements $x_1, \ldots, x_k \in \{1, \ldots, n\}$. A permutation σ given by

$$\sigma(x_1) = x_2, \quad \sigma(x_2) = x_3, \quad \sigma(x_3) = x_4, \quad \ldots, \quad \sigma(x_{k-1}) = x_k, \quad \sigma(x_k) = x_1$$

and $\sigma(x) = x$ if $x \notin \{x_1, \ldots, x_k\}$ is called a k-**cycle**. It is denoted $\sigma = (x_1\, x_2\, \ldots\, x_k)$. A 2-cycle is also called a **transposition**.

▶ **Definition 5.** Let $\sigma \in S_n$ be a permutation. A pair of indices (i, j) where $1 \leqslant i < j \leqslant n$ is called an **inversion** (of the permutation σ) if $\sigma(i) > \sigma(j)$ (i.e. if the permutation inverts the order in which i and j go).

▶ **Definition 6.** A permutation is called **even** if it has an even number of inversions; otherwise it is called **odd**.

▶ **Theorem 7.** *The composition of two even permutations or two odd permutations is an even permutation. The composition of an even permutation and an odd permutation in any order is an odd permutation. A k-cycle is an odd permutation if k is even and an even permutation if k is odd. The inverse of a permutation has the same parity.*

2.2 The model

▶ **Definition 8.** A **space-optimal code** is an encoding function Enc from $\{0, 1, 2, \ldots, 2^n - 1\}$ to the set of bit sequences of length n. Each code implicitly defines the decoding function $Dec = Enc^{-1}$ and the **increment function** $Inc(x) = Enc(Dec(x) + 1)$. We will also call such codes **counters**.

▶ **Definition 9.** A **decision assignment tree** (DAT) is a binary tree where each inner node specifies a single position in the code and every leaf node contains a set of changes (assignments) in the code. Execution of a DAT on an input bit sequence starts in the root node and then the next node is the left child of the current node if the bit in the specified position of the input code is 0 and the right child of the current node otherwise. When a leaf node is reached, the output is calculated by taking the input and setting the bits in the positions specified for this leaf node to the specified values.

Each DAT defines a function from bit sequences of some length to bit sequences of the same length. We will say that all the nodes visited during execution of DAT on some input (including the root and the leaf node) **handle** this input. The number of bits read is the depth of the corresponding leaf, and the number of bits written to the code is the number of assignments in the leaf.

▶ **Definition 10.** The set $\{0, 1\}^n$ is called an n-dimensional **hypercube**. An element of a hypercube is called a **vertex**. Every vertex has n coordinates. A k-dimensional **face** is a subset of the n-dimensional hypercube defined by specifying the values of some $n - k$ coordinates (we will call these coordinates **fixed**) and allowing all the possible combinations of values of the remaining k coordinates (we will call these coordinates **free**). Each vertex of a hypercube is a bit sequence; we will identify each vertex with the integer it represents in the standard binary notation. The order on the hypercube vertices given by comparing the vertices as integers is called the **lexicographic order**.

3 The bound and the proof outline

The main result of the present paper is: the increment function for every space-optimal code representing integers from 0 to $2^n - 1$ must read at least $\frac{n}{2}$ bits in the worst case. In other words, there is no space optimal code such that the corresponding increment function never reads more than $L(n) := \frac{n}{2} - 1$ bits.

In this section we present an informal outline of the proof. The core idea of the proof is representing the permutation specified by Inc as a composition of two permutations, *Before* and *After*, defined in terms of vertices handled by the same leaf node in the DAT implementing Inc.

Assume that for some n there is a way to encode integers such that the corresponding increment function Inc can be implemented by a DAT that reads at most $L(n)$ bits in the worst case. Without loss of generality we can consider an implementation that always reads exactly $L(n)$ bits. The increment function maps the n-dimensional hypercube into itself and can be considered as a permutation. This permutation is a cycle of length 2^n, and, therefore, an odd permutation.

We will use a representation of the increment function as a composition of two permutations, *Before* and *After*. Each leaf of the DAT implementing Inc handles some $(n - L(n))$-dimensional face of the n-dimensional hypercube. By definition, the restriction of Inc on each of these faces changes some of the bits in the same way for all the vertices in the face.

We also know that Inc is a bijection, therefore only the fixed bits can be changed. This can be interpreted as a parallel translation of the face. The image of each of the faces in F under Inc is again a $(n - L(n))$-dimensional face. Let F denote the set of all the faces handled by any leaf of the DAT. The set of their images, $Inc(F)$, is also a set of faces. Every vertex lies in exactly one face from F and in exactly one face from $Inc(F)$. Let's fix some order of enumeration of F, i.e. $F = \{F_0, F_1, \ldots, F_{2^{n-L(n)}-1}\}$. This also defines an order on $Inc(F)$, namely, $Inc(F) = \{Inc(F_0), \ldots, Inc(F_{2^{n-L(n)}-1})\}$. We can consider three orders on the hypercube: the standard lexicographic ordering; the ordering where we compare two vertices by first compare their corresponding faces in F and fall back to lexicographic order inside each face; and the ordering where we first compare the containing faces from $Inc(F)$. We can enumerate all the vertices of the hypercube according to these three orders. Enumeration in the lexicographic order is the identity permutations. The remaining two orders give non-trivial permutations; we will call them *Before* and *After*. Note that $Inc = After \circ Before^{-1}$, because the i-th vertex in the j-th face of F is by definition of F mapped to the i-th vertex of the j-th face of $Inc(F)$.

We prove that *Before* and *After* are both even. The proof is the same for both permutations. We need to calculate the number of inversions. Every face is enumerated in lexicographic order, so there can be no inversion including two vertices from the same face. When we consider two different faces, they do not intersect and therefore have to have a coordinate which is fixed in both the faces and has a different value. There have to be at least two common free coordinates between the faces if each of them has $L(n) < \frac{n}{2}$ fixed bits and at least one fixed bit position is shared. Faces with two common free coordinates have an even number of inversions using one vertex from each of the faces, because inversions where the less significant common free coordinate doesn't affect the comparison come in multiples of four (two bits in the less significant common position can be flipped at will), and those where the bits in the less significant common position matter come in the multiples of two (the coordinates in the more significant common position must match, and it doesn't matter if both are equal to zero or to one). Therefore the total number of inversions in the permutation *Before* (the same holds for the permutation *After*) is even.

But if *Before* and *After* are both even, $Inc = After \circ Before^{-1}$ has to be even. The contradiction proves that our initial assumption was wrong and the implementation of Inc has to read at least $\frac{n}{2}$ bits in the worst case.

4 Defining the constructions used in the proof

To illustrate some of the notation, we will use the space-optimal integer representation from [2]. This representation was initially found by a brute-force search. Its increment function was presented as a decision assignment tree (Figure 1).

4.1 The cycle defined by the increment function

▶ **Observation 11.** *If the increment function can be described by a decision assignment tree (DAT), it can be represented by a DAT of the same depth with all the leaves having the same depth.*

▶ **Lemma 12.** *For a space-optimal representation of integers in the range $\{0, \ldots, 2^n - 1\}$ the increment function is a bijection of the set of bit strings of length n. By interpreting these strings as integers using standard binary notation, we can represent the increment function as a permutation of $\{0, 1, 2, \ldots, 2^n - 1\}$. This permutation is a cycle of length 2^n. This cycle is an odd permutation.*

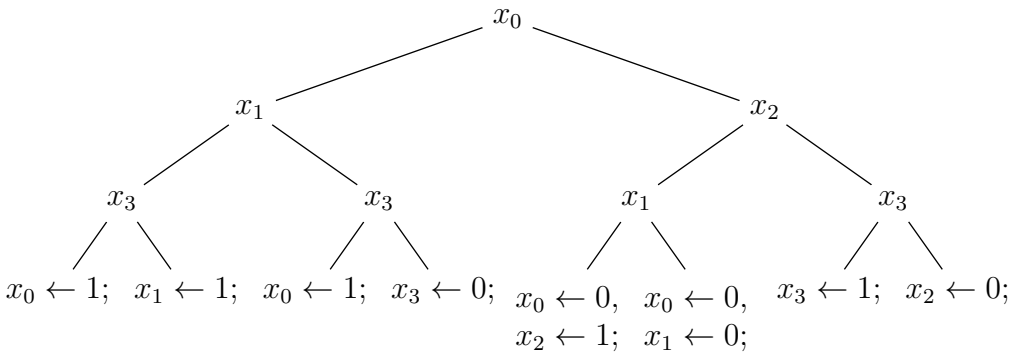

Figure 1 The decision tree from [2].

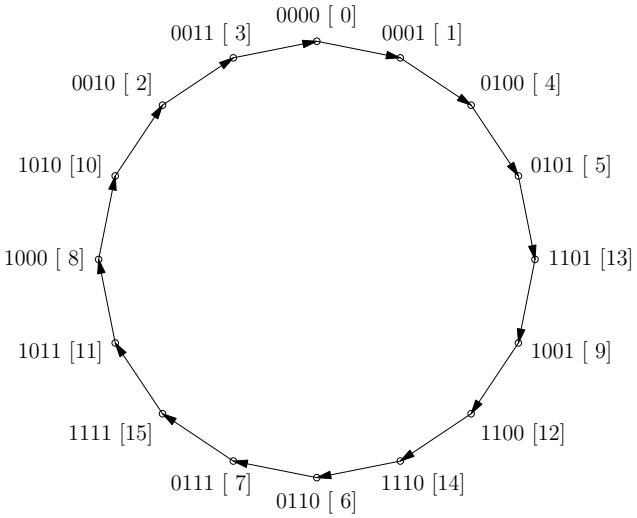

Figure 2 The cycle corresponding to the example from [2].

Proof. The increment function *Inc* maps $Enc(2^n - 1)$ to $Enc(0)$, $Enc(0)$ to $Enc(1)$, $Enc(1)$ to $Enc(2)$, etc. $Enc(0), \ldots, Enc(2^n - 1)$ are all the different binary strings of length n with each string used exactly once, so *Inc* is a bijection. If we interpret the bit strings as integers we get the cycle $(\, Enc(0)\, Enc(1)\, \ldots\, Enc(2^n - 1)\,)$. The cycle is an odd permutation because its length is even.

In the example from [2] the cycle is as shown in the figure. The "first" (x_0) bit from the algorithm's explanation is used as the least significant bit. We can also write this cycle as a table of *Inc* function values:

code	*Inc*(code)	code	*Inc*(code)	code	*Inc*(code)	code	*Inc*(code)
0000 [0]	0001 [1]	0100 [4]	0101 [5]	1000 [8]	1010 [10]	1100 [12]	1110 [14]
0001 [1]	0100 [4]	0101 [5]	1101 [13]	1001 [9]	1100 [12]	1101 [13]	1001 [9]
0010 [2]	0011 [3]	0110 [6]	0111 [7]	1010 [10]	0010 [2]	1110 [14]	0110 [6]
0011 [3]	0000 [0]	0111 [7]	1111 [15]	1011 [11]	1000 [8]	1111 [15]	1011 [11]

The standard notation for this permutation is $\left(\begin{smallmatrix} 0 & 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 & 15 \\ 1 & 4 & 3 & 0 & 5 & 13 & 7 & 15 & 10 & 12 & 2 & 8 & 14 & 9 & 6 & 11 \end{smallmatrix}\right)$, the cycle notation is (0 1 4 5 13 9 12 14 6 7 15 11 8 10 2 3). This permutation has 39 inversions, so it is an odd permutation. ◀

4.2 Decision assignment trees and the corresponding faces

▶ **Lemma 13.** *Given a DAT for a n-bit integer representation and a node of depth k, the set of all inputs handled (in the sense of Definition 9) by the chosen node is an $(n-k)$-dimensional face.*

Proof. The proof goes by induction. The root has depth 0 and handles all the hypercube, which can be considered an n-dimensional face. A child of node of depth k has depth $k+1$; the set of vertices handled by the child node can be obtained from the set of vertices handled by the parent node by fixing the coordinate inspected in the parent node to one of the two possible values. This coordinate was a free coordinate, so we get an $(n-k-1)$-dimensional face out of a $(n-k)$-dimensional one. ◀

▶ **Lemma 14.** *If a DAT implements a bijection, every coordinate in every assignment in the leaf nodes is a fixed coordinate of the face handled by the corresponding node, i.e. this coordinate is inspected in one of the ancestor nodes of the leaf node.*

Proof. All the vertices need to have different images. Assume a leaf node handled two vertices which differ in the assigned coordinate. This leaf node would handle some face containing both vertices, and this face would also contain some two vertices that differ *only* in the assigned coordinate. But these two latter vertices would have the same image, and this is not allowed. ◀

▶ **Lemma 15.** *If a DAT implements a bijection, the image of the face handled by a leaf node is a translation of this face. In particular, the image is also a face of the hypercube.*

Proof. Changing some of the fixed coordinates of a face performs a parallel translation. ◀

We will now illustrate how the faces are moved. The 4-bit counter using 3 reads for every increment corresponds to a 4-dimensional hypercube. It is more convenient to draw it as two 3-dimensional cubes side by side (so the extra coordinate is projected to the vector proportionate to the projection of the first coordinate). In this case the faces corresponding to the decision assignment tree (DAT) leaves are 1-dimensional faces. We will represent the faces corresponding to the DAT leaves by solid lines. Both pictures use the same set of arrows to represent the movement of the faces. The top picture shows the faces before the moves, and the bottom picture shows the faces after the moves.

We can list the vertices by face. Initially they are split in the following way:

face	vertices	vertices (decimal)	face	vertices	vertices (decimal)
a	0000 and 0100	0 and 4	e	0001 and 1001	1 and 9
b	1000 and 1100	8 and 12	f	0011 and 1011	3 and 11
c	0010 and 0110	2 and 6	g	0101 and 0111	5 and 7
d	1010 and 1110	10 and 14	h	1101 and 1111	13 and 15

and after the faces are moved we get a new split:

face	vertices	vertices (decimal)	face	vertices	vertices (decimal)
a	0001 and 0101	1 and 5	e	0100 and 1100	4 and 12
b	1010 and 1110	10 and 14	f	0000 and 1000	0 and 8
c	0011 and 0111	3 and 7	g	1101 and 1111	13 and 15
d	0010 and 0110	2 and 6	h	1001 and 1011	9 and 11

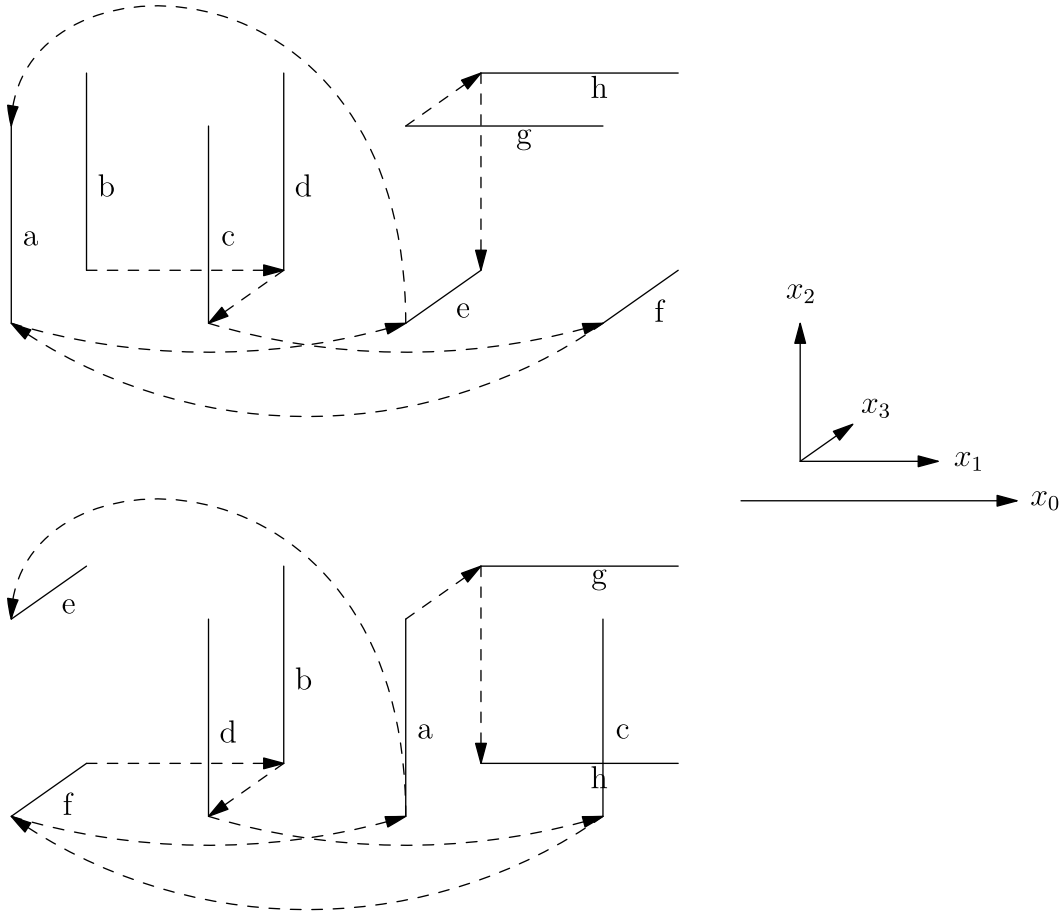

Figure 3 The translations corresponding to the counter from [2]; two pictures show the positions of the 1-dimensional "faces" before and after applying the increment operation.

4.3 Enumerating the faces and the vertices

Assume we have a balanced DAT implementing the increment function *Inc* for a space-optimal integer representation. Each leaf handles the vertices forming a face, these faces are disjoint, have the same dimension and cover the entire hypercube. The *Inc*-images of these faces are again disjoint faces of the same dimension covering the entire hypercube. We need to choose some order on the faces handled by different leaves; it is not important which order we use so we will use the order of leaves in the DAT.

▶ **Definition 16.** Let F_i denote the i-th face in the chosen order.

▶ **Definition 17.** Let *Inc* be a permutation implemented by a balanced DAT of depth l. The *Before* permutation is the enumeration of all the vertices in the hypercube by first enumerating all the vertices in F_0 in the lexicographic order, then all the vertices in F_1, etc. In general, the j-th vertex in the lexicographic order on the face F_i will have the number $i \times 2^l + j$. We could write $Before(i \times 2^l + j) = F_i[j]$. The *After* permutation is defined in a similar way with the j-th vertex in the face $Inc(F_j)$ having the number $i \times 2^l + j$.

▶ **Lemma 18.** *The Inc permutation is the composition of permutations* $Before^{-1}$ *and After, i.e.* $Inc = After \circ Before^{-1}$. *This can also be written as* $\forall k \in \{0, \ldots, 2^n - 1\} : Inc(Before(k)) = After(k)$.

Proof. Let k be represented as $i \times 2^l + j$. We have $Inc(Before(k)) = Inc(Before(i \times 2^l + j)) = Inc(F_i[j]) = Inc(F_i)[j] = After(i \times 2^l + j) = After(k)$ (the j-th element in the i-th face gets translated together with the entire face).

For the example algorithm the $Before(\cdot)$ numbering is:

$$\begin{pmatrix} 0000\ 0001\ 0010\ 0011\ 0100\ 0101\ 0110\ 0111\ 1000\ 1001\ 1010\ 1011\ 1100\ 1101\ 1110\ 1111 \\ 0000\ 0100\ 1000\ 1100\ 0010\ 0110\ 1010\ 1110\ 0001\ 1001\ 0011\ 1011\ 0101\ 0111\ 1101\ 1111 \end{pmatrix}$$

in binary, or $\begin{pmatrix} 0\,1\,2\,3\,4\,5\,6\,7\,8\,9\,10\,11\,12\,13\,14\,15 \\ 0\,4\,8\,12\,2\,6\,10\,14\,1\,9\,3\,11\,5\,7\,13\,15 \end{pmatrix}$ in decimal notation. The $After$ numbering is

$$\begin{pmatrix} 0000\ 0001\ 0010\ 0011\ 0100\ 0101\ 0110\ 0111\ 1000\ 1001\ 1010\ 1011\ 1100\ 1101\ 1110\ 1111 \\ 0001\ 0101\ 1010\ 1110\ 0011\ 0111\ 0010\ 0110\ 0100\ 1100\ 0000\ 1000\ 1101\ 1111\ 1001\ 1011 \end{pmatrix}$$

or $\begin{pmatrix} 0\,1\,2\,3\,4\,5\,6\,7\,8\,9\,10\,11\,12\,13\,14\,15 \\ 1\,5\,10\,14\,3\,7\,2\,6\,4\,12\,0\,8\,13\,15\,9\,11 \end{pmatrix}$. We first enumerate the two vertices in the a face, then the two vertices in the b face, etc. using the positions of the faces before and after the move, respectively. We can see that the $Before$ permutation is odd and the $After$ permutation is even. As the example algorithm reads more than a half of all the bits, getting an odd permutation is possible.

As an illustration, 10 is the first vertex in the d face before the translation of the face by the increment function, $Inc(10) = 2$. The first vertex in the face d (the fourth face) has number 6 in the $Before$ ordering; we see that $Before^{-1}(10) = 6$. After the shift the first vertex in the face d is 2. We see that $After(6) = 2$ and $Inc(10) = After(Before^{-1}(10)) = (After \circ Before^{-1})(10) = 2$. ◀

5 Calculating the parity of the permutations

Both of the permutations $Before$ and $After$ are specified in the same way, by cutting the hypercube into faces and enumerating the faces. It is now sufficient to show that any permutation specified in that way is even if the faces have no more than $L(n) = \frac{n}{2} - 1$ fixed coordinates. We will prove that the $After$ permutation is even; exactly the same proof will work for the $Before$ permutation.

5.1 Faces and the inversions

Recall that an inversion of a permutation σ is a pair of numbers $x < y$ such that $\sigma(x) > \sigma(y)$.

▶ **Lemma 19.** *There are no inversions of the permutation After such that $After(x)$ and $After(y)$ are in the same face.*

Proof. If $After(x)$ and $After(y)$ are in the same face and $x < y$ then x has a lower number inside the face than y. But the face is enumerated in the lexicographic order, so $After(x) < After(y)$. ◀

▶ **Lemma 20.** *Consider two faces, $Inc(F_i)$ and $Inc(F_{i'})$ such that $i < i'$. The number of inversions such that $After(x) \in Inc(F_i)$ and $After(y) \in Inc(F_{i'})$ is even.*

▶ Note 21. If $i > i'$ then there are no inversions because x would always be larger than y.

Proof. Note that the vertices are enumerated face-by-face, so the condition that $After(x) \in Inc(F_i)$ and $After(y) \in Inc(F_{i'})$ guarantees $x < y$. Every vertex in each face has exactly one number, so we can just count the number of pairs (u, v) where $u \in Inc(F_i)$ and $v \in Inc(F_{i'})$ and $u > v$. We will use the assumption that each of the faces has $L(n) = \frac{n}{2} - 1$ fixed coordinates. This means that no more than $n - 2$ coordinates are fixed in any of the two

faces. Therefore there are at least two coordinates that are free for both faces. We can write the faces' coordinates one on top of the other one: $\begin{smallmatrix}0&0&*\\0&*&1\end{smallmatrix}\cdots$ Let us consider the least significant of the common free coordinates and call it p.

We will split all the pairs (u, v) into two groups based on the number of coordinates that have to be checked to perform a lexicographic comparison if we read from the most significant bit. Either it is enough to read only some of the coordinates that are more significant than p, or we need to to read the coordinate p and maybe some more.

(1) The number of pairs of codes where the comparison can be made without considering the bits on the position p (and less significant positions) is even, because half of these codes have 0 in the first face on the position p and the other half have 1.

(2) If we have to consider the bits in the position p, the bits in every more significant common position must be equal. There is an even number of such pairs because changing a pair of bits in the same position from $0, 0$ to $1, 1$ doesn't affect the comparison.

We have split all the pairs with $u > v$ into two even-sized sets, as we have to consider either only bits more significant that the position p or the bits including position p. Therefore the total number of such pairs is even.

This finishes the proof that the number of inversions containing two vertices in the two given faces is even. ◀

5.2 Summarizing the inversion counts

▶ **Lemma 22.** *The After permutation (and the Before permutation) for a Inc function represented by a DAT of depth less than $\frac{n}{2}$ are even.*

Proof. In the previous subsection we have proven that every inversion of the *After* permutation has to include elements from different faces (Lemma 19). We have also proven that for every pair of faces the number of inversions represented by their elements is even (Lemma 20). If we sum the inversions for all the pairs of faces we get all the inversions of the permutation. Therefore the number of inversions of the permutation is even. ◀

Now we can prove the main theorem.

▶ **Theorem 23.** *The increment function for every space-optimal binary code representing integers from 0 to $2^n - 1$ must read at least $\frac{n}{2}$ bits in the worst case. In other words, there is no space optimal binary code such that the corresponding increment function never reads more than $L(n) := \frac{n}{2} - 1$ bits.*

Proof. If there is an increment function for a space-optimal binary integer representation reading at most $L(n)$ bits in the worst case, the corresponding *Before* and *After* permutation would both be even. Then the *Inc* function would be an even permutation. But the increment function for a space-optimal binary integer representation has to be a cycle of length 2^n, i.e. an odd permutation. The contradiction proves that our assumption was impossible. ◀

6 Handling a weaker definition of increment

Our definition of increment assumed that incrementing the largest value always yields zero. This requirement can be removed from the definition.

▶ **Theorem 24.** *Consider an increment procedure for a space-optimal integer representation that correctly handles all the possible values except the maximum and always leaves at least two bits unread. Such a procedure always maps the encoding of the maximum value to the encoding of zero.*

Proof. Let n denote the total amount of bits in the code. Let us assume that the increment procedure applied to the maximum values doesn't yield zero. Let k denote a position where the encoding of zero and the result of incrementing the encoding of the maximum value differ. Without loss of generality we can assume that the encoding of zero has 0 at the position k and the value $a = Inc(Enc(2^n - 1))$ has 1 at the position k.

Let us count the vertices x such that $Inc(x)$ has the value 1 at the position k. Almost all vertices have exactly one preimage, $Enc(0)$ has no preimages and a has 2 preimages, so the answer should be $2^{n-1} + 1$. On the other hand, a face corresponding to a vertex of the DAT can have no, all or half of its vertices in the set, depending on the orientation; in any case this is an even number and the total sum has to be an even number.

The contradiction proves that our assumption is false and incrementing the maximum values has to yield zero as the result. ◀

7 Future directions

Minor tweaks of the presented proof allow to extend the result to cover nondeterministic increment procedures. For $n > 10$ the same bound can be proven even if we allow arbitrary changes of the inspected bits together with an arbitrary reversible linear transformation of the unread bits in every leaf node of a DAT.

Closing the gap between the $\frac{n}{2}$ lower bound and $n - 1$ upper bound remains an open problem. Our conjecture is that the true value is $n - o(n)$.

Acknowledgements. I am grateful to Gerth Brodal for attracting attention to this problem and his help with editing the present paper. I am extremely grateful to Gudmund Frandsen for a lot of useful discussions and the efforts he has spent on reading multiple draft versions of this proof. I am grateful to the anonymous reviewers of this and previous versions of the present paper for their valuable advice regarding presentation. I am grateful to an anonymous reviewer for the suggestion that the existence of common fixed coordinates for disjunct faces improves the bound by one; and for the suggestion that the image of the maximum element can be proven to be zero even if this assumption is not included in the definition.

Abstract

We introduce and investigate *reroutable flows*, a robust version of network flows in which link failures can be mitigated by rerouting the affected flow. Given a capacitated network, a path flow is reroutable if after failure of an arbitrary arc, we can reroute the interrupted flow from the tail of that arc to the sink, without modifying the flow that is not affected by the failure. Similar types of restoration, which are often termed "local", were previously investigated in the context of network design, such as min-cost capacity planning. In this paper, our interest is in computing maximum flows under this robustness assumption. An important new feature of our model, distinguishing it from existing max robust flow models, is that no flow can get lost in the network.

We also study a tightening of reroutable flows, called *strictly reroutable flows*, making more restrictive assumptions on the capacities available for rerouting. For both variants, we devise a reroutable-flow equivalent of an s-t-cut and show that the corresponding max flow/min cut gap is bounded by 2. It turns out that a strictly reroutable flow of maximum value can be found using a compact LP formulation, whereas the problem of finding a maximum reroutable flow is *NP*-hard, even when all capacities are in $\{1, 2\}$. However, the tightening can be used to get a 2-approximation for reroutable flows. This ratio is tight in general networks, but we show that in the case of unit capacities, every reroutable flow can be transformed into a strictly reroutable flow of same value. While it is *NP*-hard to compute a maximal integral flow even for unit capacities, we devise a surprisingly simple combinatorial algorithm that finds a half-integral strictly reroutable flow of value 1, or certifies that no such solutions exits. Finally, we also give a hardness result for the case of multiple arc failures.

sabotage, and in such cases it is desirable to quickly recover the service provided through the network. A crucial frequent requirement of actual network restoration techniques is that restoration is handled locally [13]. As a motivating example, consider a communication network in which data packets are routed along paths. When a link in the network fails, it is desirable to only reroute the traffic that is actually affected by the failure, i.e., those paths that traverse the failing link, without changing or rerouting any part of the flow that is not affected by the failure. Note that arbitrary rearrangement of the flow after a failure is in general more powerful, but it is both undesirable to interrupt customer service and hard to do so reliably and safely [9, 16].

To cope with such a situation, we introduce the concept of reroutable network flows: A flow on s-t-paths is *reroutable* if after failure of any arc $\bar{a} = (\bar{v}, \bar{w})$ in the network, we can reroute all flow that was traversing $\bar{a}$ from $\bar{v}$ to the sink t, while not changing any flow that was not affected by the interruption. Similar concepts were previously discussed in a few other papers [6, 7, 17, 18], but with an emphasis on network design issues, e.g., minimizing the cost of the installed capacity. In contrast, our interest is in computing maximum flows (but we point out that a potential application are feasibility/separation subroutines for capacity reservation). Note that in this setting, we cannot simply send a standard maximum flow, as we need to leave space for rerouting. Before we discuss our findings and better relate them to existing literature, let us formalize the definition of our model.

Network flows. Let $D = (V, A)$ be a digraph with source $s \in V$, a sink $t \in V$ and arc capacities $u \in \mathbb{R}^A_+$. Let $\mathcal{P} \subseteq 2^A$ be the set of simple[1] s-t-paths in D. For arcs $a, \bar{a} \in A$, define

$$\mathcal{P}_a := \{P \in \mathcal{P} : a \in P\} \quad \text{and} \quad \mathcal{P}_{\bar{a} \to a} := \{P \in \mathcal{P} : a, \bar{a} \in P,\, \bar{a} \prec_P a\},$$

where $\bar{a} \prec_P a$ means that P traverses $\bar{a}$ before a. An *s-t-flow* is a vector $x \in \mathbb{R}^{\mathcal{P}}_+$ that assigns a flow value $x(P) \geq 0$ to each $P \in \mathcal{P}$ such that the arc flow values $x(a) := \sum_{P \in \mathcal{P}_a} x(P)$ fulfill the capacity constraint $x(a) \leq u(a)$ for all $a \in A$. The value of a flow x is $\mathrm{val}(x) := \sum_{P \in \mathcal{P}} x(P)$.

Reroutable flows. Let x be an s-t-flow. If an arc $\bar{a} = (\bar{v}, \bar{w}) \in A$ fails, all flow on paths containing the failing arc gets interrupted when it reaches $\bar{v}$. For any $a \in A \setminus \{\bar{a}\}$, we define the *available capacity* of a after failure of $\bar{a}$ by

$$\bar{u}_{x,\bar{a}}(a) := u(a) - \sum_{P \in \mathcal{P}_a \setminus \mathcal{P}_{\bar{a} \to a}} x(P).$$

A *rerouting* of x for the failing arc $\bar{a}$ is a $\bar{v}$-t-flow $x_{\bar{a}}$ of value $x(\bar{a})$ in $(V, A \setminus \{\bar{a}\})$ with capacities $\bar{u}_{x,\bar{a}}$. The flow x is *reroutable* if for every failing arc $\bar{a} \in A$ there is a rerouting $x_{\bar{a}}$ of x.

Strictly reroutable flows. A rerouting $x_{\bar{a}}$ of a flow x for a failing arc $\bar{a}$ is *strict* if $x_{\bar{a}}(a) \leq \bar{u}_x(a) := u(a) - x(a)$ for every $a \in A \setminus \{\bar{a}\}$. We say that x is *strictly reroutable* if for every failing arc $\bar{a} \in A$ there is a strict rerouting of x.

Strictly reroutable flows are both a helpful tool for computing reroutable flows and interesting in their own right, in situations where more conservative assumptions have to be

[1] All our results also work for the case that $\mathcal{P}$ contains non-simple paths, but we restrict to simple paths for ease of notation.

made on the capacities available for rerouting. A natural question is what is the maximum flow value that can be sent by a (strictly) reroutable flow in a given network. We denote the corresponding optimization problem as Max RF and Max SRF, respectively.

1.1 Our results

Complexity of the problems (Sections 2.1 and 2.2). We observe that Max SRF can be solved in polynomial time by formulating it as a linear program. In contrast, Max RF is *NP*-hard, even when $u(a) \in \{1, 2\}$ for all $a \in A$. On the positive side, by showing that the maximum value of a reroutable flow is at most twice as large as the maximum value of a strictly reroutable flow, we obtain a 2-approximation for Max RF for arbitrary capacities. The problem can further be solved exactly in unit capacity networks (see below).

Max flow/min cut gap (Section 2.3). Max flow/min cut results play a central role in network flow theory. We devise a combinatorial upper bound for the maximum reroutable flow value, called *R-cut*, and prove that the corresponding flow/cut gap for both reroutable and strictly reroutable flows is bounded by 2. In fact, our proof is constructive and provides a combinatorial 2-approximation algorithm for the minimum capacity R-cut problem.

Unit capacity networks (Section 3). We consider the case of unit capacities. It turns out that in this case, Max RF and Max SRF are equivalent. Our proof is based on a careful uncrossing argument that allows to transform any reroutable flow into a strictly reroutable flow.

Computing (half-)integral solutions (Section 4). A common property of many flow problems is the existence of an integral optimal solution when capacities are integral. In the case of reroutable flows, this property does not hold. In fact, if we require flow to be integral, the problem becomes *NP*-hard, even for sending a single unit of flow in a unit capacity network. However, for this special case, we devise a simple combinatorial algorithm that computes a half-integral solution or certifies that no flow of value 1 exists. Via our max flow/min cut analysis we also show how to compute 2-approximate half-integral solutions.

Multiple arc failures (Section 5.2). We consider the natural generalization of our problems to multiple simultaneous arc-failures. We show that in this case both variants of the problem are *NP*-hard, even when only two arcs can fail and all arcs have unit capacity. All hardness results in this paper are based on reduction from an intermediary problem, called Forbidden Pairs s-t-Path. They are therefore grouped together in Section 5.

1.2 Related work

As we already pointed out above, "local" rerouting schemes, i.e., schemes that only change flow affected by the failure, have been investigated in network design. A routing scheme in which flow has to be sent along arc-disjoint paths was investigated in [6], see also [18]. The problem of finding a local rerouting from the tail to the head of a failed arc was investigated in [7] and [17]. However, in all these papers the focus was on min-cost capacity planning.

Concepts that deal with the maximization of flow subject to robustness constraints commonly fall under the moniker of *robust flows*. Aggarwal and Orlin [2] studied *k-route flows*. Such a flow is a conic combination of elementary flows, each of which consists of a uniform flow along k disjoint paths. Because of this structure, the failure of any arc can only

destroy a $1/k$ fraction of the flow. A maximum k-route flow can be computed in polynomial time by means of a parametric max flow problem. Another classic model is the *maximum robust flow problem*: Here, the goal is to find a path flow that maximizes the surviving flow after a worst-case failure of k arcs. Aneja et al. [3] showed that for $k = 1$ both an optimal fractional and an optimal integral solution can be found in polynomial time. If k is not bounded by a constant the problem is *NP*-hard [10], but the complexity for any constant value $k \geq 2$ is open. Bertsimas et al. [4] provide an $\Omega(1/k)$-approximation algorithm for the maximum robust flow. Robust flows are closely related to *network flow interdiction*, which takes a dual perspective: The goal is to find a subset of arcs whose removal minimizes the maximum flow value in the remaining network; see the recent article by Chestnut and Zenklusen [8] for an up-to-date overview of this topic.

To the best of our knowledge, the only other flow maximization model that allows for adjustment after the failure are *adaptive flows*, first introduced by Bertsimas et al. [5]: In the first step, an arc flow is specified. After failure of k arcs, a new flow is sent, with the flow value on every arc being bounded by the original flow value. Note that adaptive flows differ from reroutable flows in two important aspects: Adaptive flows allow flow to be 'lost' (the flow value after the failure is lower than the original flow value), whereas in reroutable flows all flow has to reach the sink. Furthermore, adaptive flows can reconfigure the flow in the entire network, whereas in reroutable flows, only the flow affected by the failure can be rerouted.

Another model closely related to reroutable flows is the *online replacement path* problem (ORP) introduced by Adjiashvili et al. [1]. The ORP is a generalization of the shortest path problem: Given a digraph with costs on the arcs, we have to specify an s-t-path. Along the path, we may encounter a failing arc $\bar{a} = \{\bar{v}, \bar{w}\}$, and we have to find a replacement path from $\bar{v}$ to t avoiding $\bar{a}$. The goal is to minimize the total traveled distance, assuming $\bar{a}$ is chosen by an adversary. Adjiashvili et al. [1] show that the ORP can be solved in polynomial time, even when a constant number of arcs fail.

2 LP formulation, approximation, and max flow/min cut

In this section, we discuss the complexity of the two problems and provide bounds on the gap between Max RF and Max SRF. We also introduce an analogue to minimum cuts for reroutable flows and bound the corresponding duality gap. At the end of the section, we show that all our bounds are tight.

2.1 Complexity of Max RF and Max SRF

We now consider an LP formulation for Max SRF. For $\bar{a} \in A$, let $\mathcal{R}(\bar{a})$ be the set of all tail$(\bar{a})$-t-paths in $(V, A \setminus \{\bar{a}\})$, which are exactly the paths that a rerouting for failing arc $\bar{a}$ can use.

$$
\begin{aligned}
[\mathrm{LP}_{\mathrm{strict}}] \qquad \max \quad & \sum_{P \in \mathcal{P}} x(P) & & \\
\text{s.t.} \quad & \sum_{P \in \mathcal{P}_a} x(P) + \sum_{R \in \mathcal{R}(\bar{a}) \,:\, a \in R} x_{\bar{a}}(R) \;\leq\; u(a) & & \forall\, a, \bar{a} \in A \\
& \sum_{P \in \mathcal{P}_{\bar{a}}} x(P) - \sum_{R \in \mathcal{R}(\bar{a})} x_{\bar{a}}(R) \;=\; 0 & & \forall\, \bar{a} \in A \\
& x, x_{\bar{a}} \geq 0 & & \forall\, \bar{a} \in A
\end{aligned}
$$

The first set of constraints bound the capacities for each rerouting; note in particular that for $\bar{a} = a$, the second term becomes 0, ensuring $x(a) \leq u(a)$ for all $a \in A$. The second set of constraints ensures that the rerouting flow $x_{\bar{a}}$ has value $x(\bar{a})$. Although [$\text{LP}_{\text{strict}}$] has an exponential number of variables, it can be solved in polynomial time via dual separation.

▶ **Theorem 1.** Max SRF *can be solved in polynomial time.*

For the special case of unit capacity networks, we show in Section 3 that an optimal solution to [$\text{LP}_{\text{strict}}$] is also optimal for Max RF.

▶ **Theorem 2.** *For $u \equiv 1$,* Max RF *can be solved in polynomial time.*

An LP for Max RF can be obtained by replacing $\sum_{P \in \mathcal{P}_a} x(P)$ by $\sum_{P \in \mathcal{P}_{\bar{a} \to a}} x(P)$ in the capacity constraints of [$\text{LP}_{\text{strict}}$]. Unfortunately, this modification prevents the dual separation approach from working. In fact, it turns out that Max RF is hard as soon as two different capacities occur. The proof of this result is discussed in Section 5.1.

▶ **Theorem 3.** Max RF *is NP-hard, even when $u(a) \in \{1, 2\}$ for all $a \in A$.*

2.2 Reroutable flows vs. strictly reroutable flows

As Max SRF is a tightening of Max RF, the optimal value of the former is at most that of the latter. We show that the gap between the two values cannot be larger than 2. As we can compute maximum strictly reroutable flows, we obatain a 2-approximation for Max RF.

▶ **Lemma 4.** *Let x be an s-t-flow. If x is strictly reroutable, then x is reroutable. If x is reroutable, then $\frac{1}{2}x$ is strictly reroutable.*

▶ **Corollary 5.** *There is a 2-approximation algorithm for* Max RF.

2.3 Max flow/min cut gap for reroutable flows

An *s-t-cut* is a set of arcs that intersects every s-t-path. Its *capacity* is the sum of capacities of its arcs. A fundamental result in network flow theory is that the value of a maximum s-t-flow is equal to the capacity of a minimum s-t-cut. This result has been successfully generalized to many variants of network flows, such as abstract flows [14] or flows over time [11]. However, in other cases, such as multicommodity flows, the equality does not hold and instead, researchers investigate the worst case ratio between maximum flow and minimum cut; see, e.g., [15].

We present a counterpart to an s-t-cut for reroutable flows. It turns out that max flow and min cut are not necessarily equal and we give a tight bound on the corresponding max flow/min cut gap. An *R-cut* is a set of arcs $R \subseteq A$ together with a collection of cuts $(C_a)_{a \in R}$, where each C_a is a tail(a)-t-cut containing a. We denote $(R, (C_a)_{a \in R})$ by (R, C) for short. The capacity of the R-cut (R, C) is

$$\text{cap}(R, C) := \phi(R, C) + \sum_{a \in R} u(C_a \setminus \{a\}),$$

where $\phi(R, C)$ is the capacity of a minimum s-t-cut in $(V, A \setminus \cup_{a \in R} C_a)$.

The intuition behind this definition is the following: For every $a \in R$, all flow that crossed the cut C_a must cross the $C_a \setminus \{a\}$ if a fails. If a flow path does not cross any cut in C_a, then it crosses the minimum s-t-cut in $(V, A \setminus \cup_{a \in R} C_a)$. Therefore the capacity of an R-cut is an upper bound on the value of any reroutable flow.

▶ **Lemma 6.** $\mathrm{val}(x) \leq \mathrm{cap}(R, C)$ *for any reroutable flow* x *and any* R*-cut* (R, C).

It can be shown that R-cuts correspond to integral solutions to the dual of $[\mathrm{LP}_{\mathrm{strict}}]$. We now give a constructive proof bounding the duality gap between maximum strictly reroutable flow and minimum R-cut (or, equivalently, the integrality gap of the dual LP). In Section 2.4 we give an example showing that the bound is tight.

▶ **Theorem 7.** *Let* x *be a strictly reroutable flow of maximum value and let* (R, C) *be an* R*-cut of minimum capacity. Then* $\mathrm{val}(x) \geq \frac{1}{2}\,\mathrm{cap}(R, C)$.

Proof. For $a \in A$, let C_a be minimum $\mathrm{tail}(a)$-t-cut in D containing a and define $u'(a) := \min\{u(a), u(C_a \setminus \{a\})\}$. Let C' be a minimum s-t-cut in D with respect to the capacities u' and let x' be a corresponding maximum flow. Now define $R := \{a \in C' : u'(a) < u(a)\}$. Observe that R and $(C_a)_{a \in R}$ define an R-cut and that $\phi(R, C) \leq u(C' \setminus R)$. We obtain

$$\mathrm{cap}(R, C) \leq \sum_{a \in C' \setminus R} u(a) + \sum_{a \in R} u(C_a \setminus \{a\}) = \sum_{a \in C'} u'(a) = \mathrm{val}(x').$$

Now let $x := x'/2$. It is sufficient to show that x is a strictly reroutable flow. By contradiction assume that there is $\bar{a} \in A$ for which there is no strict rerouting of x. By the max flow/min cut theorem, there must be a $\mathrm{tail}(\bar{a})$-t-cut $\bar{C}$ in $(V, A \setminus \{\bar{a}\})$ with $\sum_{a \in \bar{C}} \bar{u}_x(a) < x(\bar{a})$. Note that $x(a) \leq u'(a)/2 \leq u(a)/2$ for every $a \in A$ by construction of x. Thus

$$\frac{1}{2} \sum_{a \in \bar{C}} u(a) \leq \sum_{a \in \bar{C}} (u(a) - x(a)) < x(\bar{a}) \leq \frac{1}{2} u'(\bar{a}) \leq \frac{1}{2} u(C_{\bar{a}} \setminus \{\bar{a}\}).$$

However, this implies that $\bar{C} \cup \{\bar{a}\}$ is a smaller $\mathrm{tail}(\bar{a})$-t-cut than $C_{\bar{a}}$, a contradiction. ◀

Computing a minimum capacity R-cut. Let us denote the problem of finding an R-cut of minimum capacity by Min R-Cut. The proof of Theorem 7 describes how to compute a 2-approximate solution to this problem.

▶ **Corollary 8.** *There is a* 2*-approximation algorithm for* Min R-Cut.

2.4 Summary of the bounds and tightness

Putting the bounds from Lemma 4 and Theorem 7 together, we obtain the following corollary.

▶ **Corollary 9.** *Let* (R, C) *be a minimum capacity* R*-cut and let* x_{RF} *and* x_{SRF} *be maximal reroutable and strictly reroutable flows, respectively. Then*

$$\mathrm{val}(x_{\mathrm{RF}}) \leq \mathrm{cap}(R, C) \leq 2\,\mathrm{val}(x_{\mathrm{SRF}}) \leq 2\,\mathrm{val}(x_{\mathrm{RF}}).$$

The example given in Figure 1 shows that each of the bounds proven in this section is tight. It also shows that optimal solutions to both Max RF and Max SRF can be fractional, even when capacities are integral. In the depicted network, and in further examples and reductions throughout the paper, we use the following gadget.

Backup links. A *backup link* from v to w is a v-w-path (a', a'') of length 2 in which the intermediate node is incident only to the two arcs of the path and $u(a') := u(a'') := \max_{a \in A} u(a)$. Note that $x(a') = x(a'') = 0$ for any reroutable flow, because when a'' fails, there is no $\mathrm{tail}(a'')$-t-path for rerouting the flow on that arc. A *bidirected* backup link between v and w consists of two distinct backup links, one from v to w and one from w to v.

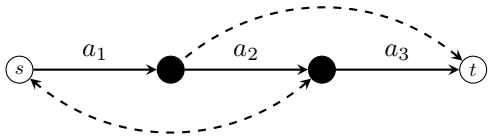

Figure 1 Example showing that the bounds given in Lemma 4 and Theorem 7 are tight. Dashed arcs correspond to (bidirected) backup links, which can only be used for rerouting. When all arcs have unit capacities, the maximum (strictly) reroutable flow has a value of 1/2. When changing the capacity of a_1 to 2, the maximum reroutable flow value increases to 1, whereas the maximum strictly reroutable flow value remains 1/2. The minimum R-cut capacity is 1 in both cases.

▶ Remark. Note that the worst-case for the bounds in Corollary 9 cannot be attained simultaneously, i.e., in any given instance either the max flow/min cut gap or the gap between reroutable and strictly reroutable flow has to be significantly smaller than 2—in fact, at least one of them has to be within $\sqrt{2}$.

3 Unit capacity networks

Throughout this section, we assume $u \equiv 1$. We will show that in this case, any reroutable flow can be transformed into a strictly reroutable flow of the same value. We start by giving an alternative characterization for strictly reroutable flows in unit capacity networks.

Cuts separating t. For $S \subseteq V$, let $\delta^+(S) := \{a \in A : \text{tail}(a) \in S, \text{head}(a) \in V \setminus S\}$ denote the cut induced by S. We define $\mathcal{S} := \{S \subset V \setminus \{t\} : S \neq \emptyset\}$ and let $\mathcal{C} := \{\delta^+(S) : S \in \mathcal{S}\}$ be the set of *t-separating cuts*. W.l.o.g. we assume $\delta^+(S) \neq \emptyset$ for all $S \in \mathcal{S}$, as no vertex in a set S with $\delta^+(S) = \emptyset$ can be on an s-t-path.

▶ **Lemma 10.** *Let x be an s-t-flow for capacities $u \equiv 1$. Then x is strictly reroutable if and only if $\sum_{a \in C}(1 - x(a)) \geq 1$ for all $C \in \mathcal{C}$.*

In the following, we identify those cuts that might violate the condition given in Lemma 10 for a (non-strictly) reroutable flow. We then show that this class of cuts forms a semi-lattice. This allows us to apply an uncrossing of the flow paths that iteratively eliminates the problematic cuts while maintaining reroutability.

Bad cuts. Let x be an s-t-flow and let $C \in \mathcal{C}$ be a t-separating cut. An arc $\bar{a} \in C$ is *(x, C)-bad* if there is an arc $a \in C$ and a path $P \in \mathcal{P}_{\bar{a} \to a}$ with $x(P) > 0$. A cut C is *x-bad* if all arcs $\bar{a} \in C$ are (x, C)-bad.

▶ **Lemma 11.** *Let x be a reroutable flow for capacities $u \equiv 1$. Let $C \in \mathcal{C}$ be a t-separating cut. If $\sum_{a \in C}(1 - x(a)) < 1$ then C is x-bad.*

Proof. By contradiction assume C is not x-bad. Then there must be an arc $\bar{a} \in C$ that is not (x, C)-bad. This implies that $\sum_{P \in \mathcal{P}_{\bar{a} \to a}} x(P) = 0$ for every $a \in C \setminus \{\bar{a}\}$. In particular, $\bar{u}_{x,\bar{a}}(a) = \bar{u}_x(a) = 1 - x(a)$ for all $a \in C \setminus \{\bar{a}\}$. Since all flow in the rerouting of x for failure of $\bar{a}$ needs to cross $C \setminus \{\bar{a}\}$, we obtain $\sum_{a \in C \setminus \{\bar{a}\}} \bar{u}_{x,\bar{a}}(a) \geq x(\bar{a})$. Adding $1 - x(\bar{a})$ to both sides of this inequality yields a contradiction. ◀

▶ **Lemma 12.** *Let x be a flow and let $S, S' \in \mathcal{S}$ be such that $\delta^+(S)$ and $\delta^+(S')$ are both x-bad. Then $\delta^+(S \cup S')$ is an x-bad t-separating cut as well.*

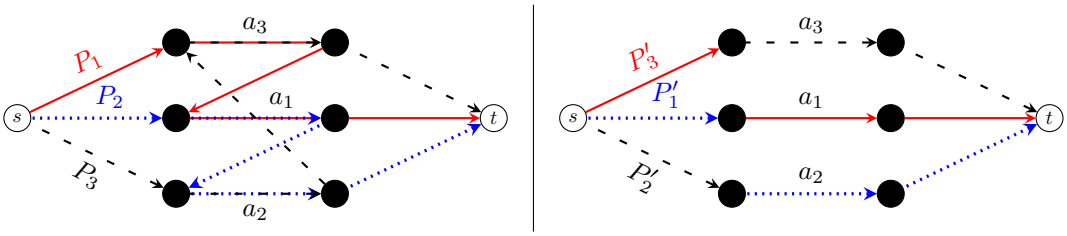

Figure 2 Uncrossing of paths on a bad cut.

Uncrossing paths. Let $P \in \mathcal{P}$. For two nodes $v, w \in V$ visited by P (in that order), we let $P[v, w]$ denote the subpath of path P starting at v and ending at w. Given another path $Q \in \mathcal{P}$ and an arc $a \in P \cap Q$, let $P \times_a Q$ be a simple s-t-path in the concatenation of $P[s, \text{head}(a)]$ and $Q[\text{head}(a), t]$.

▶ **Theorem 13.** *Let x be a reroutable flow for capacities $u \equiv 1$. Then there is a strictly reroutable flow x' with $\text{val}(x') = \text{val}(x)$ and $x'(a) \leq x(a)$ for all $a \in A$.*

Sketch of Proof. If x is not strictly reroutable, then by Lemmas 10 and 11 there must be an x-bad cut. By Lemma 12, there is a "rightmost" x-bad cut $C^* := \delta^+(S^*)$ where S^* is the union of all vertex sets defining x-bad cuts. Because C^* is bad, we obtain flow-carrying paths $P_1, \ldots, P_k$ and arcs $a_1, \ldots, a_k$ such that $a_i \in P_i \cap P_{i+1}$ is the last arc of P_i that crosses C^* for each $i \in [k]$ (with $P_{k+1} := P_1$). See Figure 2 for an illustration.

We uncross these paths by defining $P'_i := P_{i+1} \times_{a_i} P_i$ for $i \in [k]$. We obtain a new flow x' by decreasing the flow on all paths P_i by $\varepsilon := \min_i x(P_i)$ and increasing the flow on paths P'_i by ε for all $i \in [k]$. Observe that $\text{val}(x') = \text{val}(x)$ and $x'(a) \leq x(a)$ for all $a \in A$. We show that x' is also a reroutable flow. To this end, let $\bar{a} \in A$ and let $S \subseteq V \setminus \{t\}$ with $\text{tail}(\bar{a}) \in S$ and define $C := \delta^+(S)$. If $S \not\subseteq S^*$, then C is not x-bad by construction of S^*. In this case, it is easy to show that $\sum_{a \in C \setminus \{\bar{a}\}} \bar{u}_{x',\bar{a}}(a) \geq x'(\bar{a})$. If $S \subseteq S^*$, then a careful analysis shows that $\bar{u}_{x',\bar{a}}(a) \geq \bar{u}_{x,\bar{a}}(a)$ for all $a \in C$. Thus in both cases there is sufficient capacity to reroute flow when $\bar{a}$ fails. We repeat this procedure until we arrive at a strictly reroutable flow. ◀

▶ Remark. The proof of Theorem 13 preserves integrality. More specifically, if $x(P)$ is an integer multiple of α for every $P \in \mathcal{P}$, then x' can be chosen such that also $x'(P)$ is an integer multiple of α for every $P \in \mathcal{P}$.

▶ Remark. The characterization of strictly reroutable flows for unit capacities given in Lemma 10 can be extended to instances with arbitrary capacities. However, in the general case, a non-strictly reroutable flow might not have a bad cut.

4 Computing (half-)integral solutions

In some application contexts, flow cannot be split into arbitrarily small pieces. This is the setting we consider in this section. We say a flow x is *integral*, if $x(P) \in \mathbb{Z}$ for all $P \in \mathcal{P}$. We say that x is *half-integral* if $2x$ is integral.

For many fundamental flow problems, such as Max Flow or Min Cost Flow, integrality comes for free, i.e., as long as capacities are integral, there exists an optimal integral solution. In the case of reroutable flows, this property does not hold, see, e.g., Figure 3. In fact, it turns out to be *NP*-hard to decide whether there is a non-zero integral reroutable flow in a network.

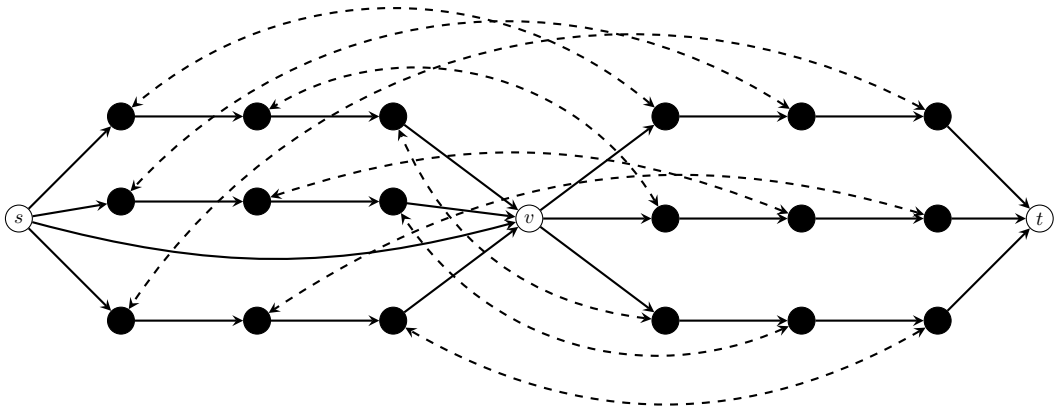

Figure 3 Example network in which no integral or half-integral reroutable flow is optimal. Dashed arcs represent bidirected backup links (see Section 2.4), all arcs have unit capacities. The maximum reroutable flow value is 2. This can only be achieved when $x(s,v) = 1$, the three s-v-paths all carry $1/3$ unit of flow, and the three v-t-paths all carry $2/3$ unit of flow.

▶ **Theorem 14.** *It is NP-hard to decide whether there is an integral (strictly) reroutable flow of value* 1*, even when restricted to instances with* $u \equiv 1$*.*

Note that this problem corresponds to sending a unit of flow along a single s-t-path. The hardness stems from a problem named Forbidden Pairs s-t-Path, which we introduce in Section 5. While it seems that Theorem 14 does not give much space for positive algorithmic results, we can do much better if we relax the integrality requirement slightly.

▶ **Theorem 15.** *Given a network with* $u \equiv 1$*, the algorithm given in Listing1 computes in polynomial time either a half-integral strictly reroutable flow of value* 1*, or correctly determines that no reroutable flow of value* 1 *exists.*

In particular, this implies that if we are interested in sending a single unit of flow, we never need to split our flow in more than two paths. Before we discuss the algorithm from Theorem 15, let us shortly discuss the case of arbitrary capacities. As a consequence of the max flow/min cut result proven in Section 2.3, we obtain the following approximation.

▶ **Theorem 16.** *If* u *is integral, then there is a strictly reroutable half-integral flow* x *with* $\mathrm{val}(x) \geq \mathrm{OPT}/2$*, where* OPT *is the value of a maximum reroutable flow. The flow* x *can be computed in polynomial time.*

Proof. Recall that in the proof of Theorem 7 we computed an s-t-flow x' that was maximal with respect to capacities $u'(a) := \min\{u(a), u(C_a \setminus \{a\})\}$. We then showed that the flow $x := x'/2$ is strictly reroutable and within a factor of 2 of a corresponding R-cut. In particular, $\mathrm{val}(x)$ is within a factor of 2 of the maximum reroutable flow value. Note that if u is integral, also u' is integral, and hence we can choose x' to be integral, ensuring that x is half-integral. ◀

Algorithm for computing a half-integral flow for unit demand

A natural starting point for an algorithm is to identify arcs $a \in A$ such that $\mathrm{tail}(a)$ is disconnected from t in $(V, A \setminus \{a\})$. Obviously, no reroutable flow can send a positive amount

Listing 1 Computing a half-integral reroutable unit demand flow

```
A_0 := ∅, A_1 := ∅
while ∃ a ∈ A \ A_0 : A_1 ∪ {a} is a tail(a)-t-cut in D
  A_0 := A_0 ∪ {a}
  A_1 ← {a' : a' is an s-t-bridge in (V, A \ A_0)}
end while
if A_0 is an s-t-cut in D
  return "No reroutable flow of value 1 exists."
else
  Let P_1, P_2 be two s-t-paths in (V, A \ A_0) such that P_1 ∩ P_2 = A_1.
  Let x be the flow defined by x(P_1) = x(P_2) = 1/2.
  return x
end if
```

of flow along such arcs, as after failure of a, the flow cannot be rerouted to t. Surprisingly, this simple preprocessing step can be generalized to an iterative procedure that solves the problem.

The algorithm, which is formally given in Listing 1, maintains two sets A_0 and A_1. In every iteration, it identifies an arc that cannot carry any flow in any reroutable flow and adds it to A_0. The set A_1 contains the s-t-bridges in the graph $(V, A \setminus A_0)$, i.e., all arcs whose removal disconnects s from t in that graph. Clearly, if $x(a) = 0$ for all $a \in A_0$, then every arc in A_1 must carry 1 unit of flow. If at some point A_0 becomes an s-t-cut, we know that no reroutable flow of value 1 exists. On the other hand, if the algorithm finds no more arcs to add to A_0 while s and t are still connected in $(V, A \setminus A_0)$, it computes two paths P_1, P_2 that only intersect at the bridges, and sends $1/2$ units of flow along each of them.

Proof of Theorem 15. To see that Algorithm 1 terminates in polynomial time, observe that $|A_0|$ is increased in every iteration of the while-loop and the loop thus terminates after at most $|A|$ iterations, each of which can be carried out in polynomial time.

Case 1: No flow exists. We now show that if Algorithm 1 denies the existence of a reroutable flow of value 1, this is indeed correct. By contradiction assume A_0 contains an s-t-cut but there exists a reroutable flow x of value 1. We prove by induction that at any step of algorithm the set A_0 fulfills the property that $x(a) = 0$ for all $a \in A_0$, yielding a contradiction. The claim is clearly true initially, when $A_0 = \emptyset$. Now consider any iteration of the while-loop, considering arc a. By induction hypothesis, every s-t-path P with $x(P) > 0$ must be a path in $(V, A \setminus A_0)$. Note that there is an order $a_1, \ldots, a_\ell$ of the set A_1 of s-t-bridges of $(V, A \setminus A_0)$ such that every such flow-carrying path contains all of these bridges in exactly that order. In particular $x(a_1) = \ldots = x(a_\ell) = 1$. Now consider the next arc a added to A_0 and assume by contradiction that $x(a) > 0$. By choice of a there is a tail(a)-t-cut $C \subseteq A_1 \cup \{a\}$ in D. Note that if $C \cap A_1 = \emptyset$, there is no rerouting of x in case of failure of arc a, as there is no tail(a)-t-path in $(V, A \setminus \{a\})$. Thus, let $a_k \in C \cap A_1$ be the bridge with the highest index k on the cut. We distinguish two cases:

- **(i)** Assume a appears before a_k on every flow-carrying path. Note that C is a tail(a_k)-t-cut because $a_k \in C$ and that $\sum_{a' \in C} \bar{u}_{x,a_k}(a') = 1 - x(a) < 1$. Therefore, the one unit of flow on a_k cannot be rerouted when a_k fails.
- **(ii)** Now assume a occurs after a_k on every flow-carrying path. But then, when a fails, the flow on a cannot be rerouted as all edges in $C \setminus \{a\} \subseteq A_1$ occur before a on every flow-carrying path and thus $\sum_{a' \in C \setminus \{a\}} \bar{u}_{x,a}(a') = 0$.

We thus deduce that $x(a) = 0$, completing the induction.

Case 2: Algorithm returns flow. Finally, we show that if $(V, A \setminus A_0)$ contains an s-t-path after completing the while-loop, then the flow x returned by the algorithm is a strictly reroutable flow. First observe that two s-t-paths P_1, P_2 in $(V, A \setminus A_0)$ with $P_1 \cap P_2 = A_1$ exist by the max flow/min cut theorem, as A_1 contains exactly the bridges of $(V, A \setminus A_0)$. Now consider the failure of any arc $\bar{a} \in A \setminus A_0$. Let C be a tail$(\bar{a})$-t-cut in D minimizing $U(C) := \sum_{a \in C \setminus \{\bar{a}\}} \bar{u}_x(a)$. We show that $U(C) \geq x(\bar{a})$, which by max flow/min cut implies that there is a rerouting of x in case of failure of $\bar{a}$. By termination condition of the while-loop, there is at least one arc $a' \in C \setminus (A_1 \cup \{\bar{a}\})$. Note that $x(a') \in \{0, 1/2\}$ and thus $U(C) \geq 1/2$. If $\bar{a} \notin A_1$, then $x(\bar{a}) \leq 1/2 \leq U(C)$. If $\bar{a} \in A_1$, we distinguish two cases.

(i) If $x(a') = 0$ then $U(C) \geq 1$ and the one unit of flow on $\bar{a}$ can be rerouted.

(ii) If $x(a') = 1/2$, then $a' \notin A_0$. Note that C is a tail(a')-t-cut in D and thus there is $a'' \in C \setminus A_1 \cup \{a'\}$ by termination condition of the while-loop. Note that, because $a'' \notin A_1$, we have $a'' \neq a$ and $x(a'') \leq 1/2$. Thus $U(C) \geq 1$ also in this last case.

We conclude that x is indeed strictly reroutable. ◀

▶ Remark. Note that our proof of Theorem 15 does not make use of Theorem 13. Instead, it gives a simple alternative argument for the equivalence of reroutable and strictly reroutable flows in unit capacity networks, for the special case of unit value flows.

▶ Remark. Theorem 15 implies that, for networks with $u \equiv 1$, if there exists any reroutable flow of value 1, then there exists a half-integral strictly reroutable flow of value 1. The example given in Figure 3, however, reveals that this is no longer true for flows of higher value, as the unique maximum reroutable flow uses paths with flow value 1/3.

5 Hardness results

In this section, we give hardness results for Max RF and some variants of the problem.

Paths avoiding forbidden pairs. Our hardness results are based on reductions from Forbidden Pairs s-t-Path, which is defined as follows: We are given a digraph $D' = (V', A')$, two nodes $s', t' \in V'$, and a set of forbidden arc pairs $\mathcal{F} \subseteq \{\{a, \bar{a}\} : a, \bar{a} \in A\}$. The task is to find an s'-t'-path P that does not contain both arcs of any pair, i.e., $|S \cap P| \leq 1$ for all $S \in \mathcal{F}$. It is not hard to see that Forbidden Pairs s-t-Path is *NP*-hard [12].

5.1 General capacities

▶ **Theorem 3.** Max RF *is NP-hard, even when* $u(a) \in \{1, 2\}$ *for all* $a \in A$.

Sketch of Proof. We construct a gadget that allows us to introduce forbidden pairs for flow paths in the network. Starting with an instance of Forbidden Pairs s-t-Path, we append a sequence of parallel length-2 paths (g_i, h_i) and $(\bar{g}_i, \bar{h}_i)$, one pair of paths for each pair $\{a_i, \bar{a}_i\} \in \mathcal{F}$, leading from t' to the new sink t. For each i, we connect a_i and h_i, and $\bar{a}_i$ and $\bar{h}_i$, respectively, with bidirected backup links. The construction is depicted in Figure 4. In a reroutable s-t-flow of value 2, both h_i and $\bar{h}_i$ are saturated. When a_i fails, the only path for rerouting leads via h_i, hence all flow that traverses a_i must be on paths in $\mathcal{P}_{a_i \to h_i}$. Likewise all flow that traverses $\bar{a}_i$ must be on paths in $\mathcal{P}_{\bar{a}_i \to \bar{h}_i}$. As $\mathcal{P}_{h_i} \cap \mathcal{P}_{\bar{h}_i} = \emptyset$, no flow-carrying path can use both a_i and $\bar{a}_i$ for any i. Thus if a reroutable flow of value 2 exists, there is a path avoiding the forbidden pairs. For the converse of this argument, it is important that $u(a_i) = u(\bar{a}_i) = 2$. This allows for a rerouting when h_i or $\bar{h}_i$ fails. ◀

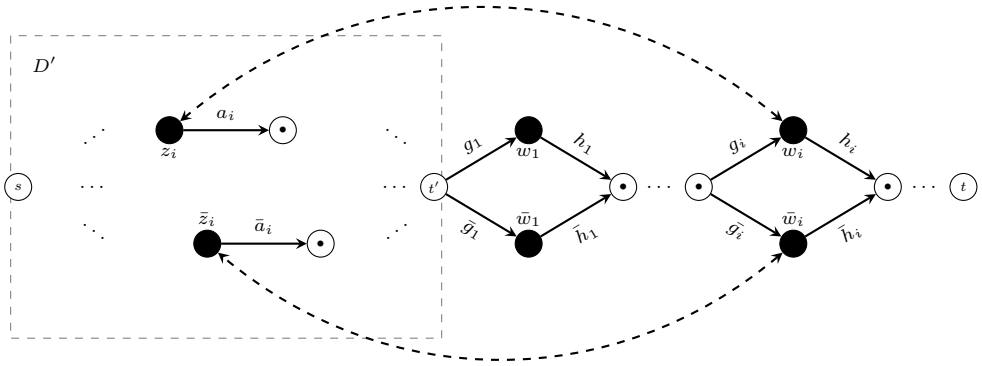

Figure 4 Construction for the proof of Theorem 3. The dashed box contains the graph D' from the Forbidden Pairs s-t-Path instance. The arcs $a_i, \bar{a}_i$ have capacity 2 for all i, all other arcs have unit capacity. In a reroutable flow of value 2, the arcs h_i and $\bar{h}_i$ must be saturated for all i. Any rerouting for a_i has to traverse h_i and any rerouting for $\bar{a}_i$ has to traverse $\bar{h}_i$.

5.2 Multiple arc failures

A natural generalization of Max RF and Max SRF allows multiple simultaneous arc failures. When a set of arcs S fails, flow is interrupted where it first encounters an arc from S and has to be rerouted from that point to the sink. A flow is (strictly) k-reroutable, if there is a rerouting for any failure of a set $S \subseteq A$ with $|S| \leq k$. We denote the corresponding problem of finding a (strictly) k-reroutable flow of maximum value by Max (Strictly) k-Reroutable Flow. It turns out that dealing even with only 2 arc failures in unit capacity networks is *NP*-hard in both cases.

▶ **Theorem 17.** Max (Strictly) k-Reroutable Flow *is NP-hard, even when restricted to instances with* $k = 2$ *and* $u \equiv 1$.

Abstract

We study the parameterized complexity of several positional games. Our main result is that Short Generalized Hex is W[1]-complete parameterized by the number of moves. This solves an open problem from Downey and Fellows' influential list of open problems from 1999. Previously, the problem was thought of as a natural candidate for AW[*]-completeness. Our main tool is a new fragment of first-order logic where universally quantified variables only occur in inequalities. We show that model-checking on arbitrary relational structures for a formula in this fragment is W[1]-complete when parameterized by formula size.

We also consider a general framework where a positional game is represented as a hypergraph and two players alternately pick vertices. In a Maker-Maker game, the first player to have picked all the vertices of some hyperedge wins the game. In a Maker-Breaker game, the first player wins if she picks all the vertices of some hyperedge, and the second player wins otherwise. In an Enforcer-Avoider game, the first player wins if the second player picks all the vertices of some hyperedge, and the second player wins otherwise.

Short Maker-Maker, Short Maker-Breaker, and Short Enforcer-Avoider are respectively AW[*]-, W[1]-, and co-W[1]-complete parameterized by the number of moves. This suggests a rough parameterized complexity categorization into positional games that are complete for the first level of the W-hierarchy when the winning condition only depends on which vertices one player has been able to pick, but AW[*]-complete when it depends on which vertices both players have picked. However, some positional games with highly structured board and winning configurations are fixed-parameter tractable. We give another example of such a game, Short k-Connect, which is fixed-parameter tractable when parameterized by the number of moves.

1 Introduction

In a *positional game* [13], two players alternately claim unoccupied elements of the board of the game. The goal of a player is to claim a set of elements that form a winning set, and/or to prevent the other player from doing so.

Tic-Tac-Toe, its competitive variant played on a 15×15 board, Gomoku, as well as Hex are the most well-known positional games. When the size of the board is not fixed, the decision problem, whether the first player has a winning strategy from a given position in the game is PSPACE-complete for many such games. The first result was established for Generalized Hex, a variant played on an arbitrary graph [8]. Reisch [15] soon followed up with results for gomoku [15] and Hex played on a board [16]. More recently, PSPACE-completeness was obtained for Havannah [4] and several variants of Connect(m, n, k, p, q) [14], a framework that encompasses Tic-Tac-Toe and Gomoku.

In a Maker-Maker game, also known as strong positional game, the winner is the first player to claim all the elements of some winning set. In a Maker-Breaker game, also known as weak positional game, the first player, Maker, wins by claiming all the elements of a winning set, and the second player, Breaker, wins by preventing Maker from doing so. In an Enforcer-Avoider game, the first player, Enforcer, wins if the second player claims all the vertices of a winning set, and the second player, Avoider, wins otherwise.

In this paper, we consider the corresponding short games, of deciding whether the first player has a winning strategy in ℓ moves from a given position in the game, and parameterize them by ℓ. The parameterized complexity of short games is known for games such as generalized chess [19], generalized geography [1, 2], and pursuit-evasion games [20]. For Hex, played on a hexagonal grid, the short game is FPT and for Generalized Hex, played on an arbitrary graph, the short game is W[1]-hard and in AW[*].

When winning sets are given as arbitrary hyperedges in a hypergraph, we refer to the three game variants as Maker-Maker, Maker-Breaker, and Enforcer-Avoider, respectively. Maker-Breaker was first shown PSPACE-complete by Schaefer [17] under the name G_{pos}(POS DNF). A simpler proof was later given by Byskov [5] who also showed PSPACE-completeness of Maker-Maker. To the best of our knowledge, the classical complexity of Enforcer-Avoider has not been established yet.

We will show that the short game for Generalized Hex is W[1]-complete, solving an open problem stated numerous times [4, 7, 6, 10, 18], we establish that the short game for a generalization of Tic-Tac-Toe is FPT, and we determine the parameterized complexity of the short games for Maker-Maker, Maker-Breaker, and Enforcer-Avoider. One of our main tools is a new fragment of first-order logic where universally-quantified variables only occur in inequalities and no other relations. After giving some necessary definitions in the next section, we will state our results precisely, and discuss them. The rest of the paper is devoted to the proofs, with some parts deferred to the long version [3].

2 Preliminaries

Finite structures. A vocabulary τ is a finite set of relation symbols, each having an associated arity. A finite structure $\mathcal{A}$ over τ consists of a finite set A, called the universe, and for each R in τ a relation over A of corresponding arity. An (undirected) graph is a finite structure $G = (V, E)$, where E is a symmetric binary relation. A hypergraph is a finite structure $G = (V \cup E, IN)$, where $IN \subseteq V \times E$ is the incidence relation between vertices and edges. Sometimes it is more convenient to denote a hypergraph instead by a tuple $G = (V, E)$ where E is a set of subsets of V.

First-order logic. We assume a countably infinite set of variables. Atomic formulas over vocabulary τ are of the form $x_1 = x_2$ or $R(x_1, \ldots, x_k)$ where $R \in \tau$ and $x_1, \ldots, x_k$ are variables. The class FO of all first-order formulas over τ consists of formulas that are constructed from atomic formulas over τ using standard Boolean connectives $\neg, \wedge, \vee$ as well as quantifiers $\exists, \forall$ followed by a variable. Let φ be a first-order formula. The size of (a reasonable encoding of) φ is denoted by $|\varphi|$. The variables of φ that are not in the scope of a quantifier are called free variables. We denote by $\varphi(\mathcal{A})$ the set of all assignments of elements of A to the free variables of φ such that φ is satisfied. We call $\mathcal{A}$ a model of φ if $\varphi(\mathcal{A})$ is not empty. The class Σ_1 contains all first-order formulas of the form $\exists x_1, \ldots, \exists x_k \varphi$ where φ is a quantifier free first-order formula.

Parameterized complexity. The class FPT contains all parameterized problems that can be decided by an FPT-algorithm. An FPT-algorithm is an algorithm with running time $f(k) \cdot n^{\mathcal{O}(1)}$, where $f(\cdot)$ is an arbitrary computable function that only depends on the parameter k and n is the size of the problem instance. An FPT-*reduction* of a parameterized problem Π to a parameterized problem Π' is an FPT-algorithm that transforms an instance (I, k) of Π to an instance (I', k') of Π' such that: (i) (I, k) is a yes-instance of Π if and only if (I', k') is a yes-instance of Π', and (ii) $k' = g(k)$, where $g(\cdot)$ is an arbitrary computable function that only depends on k. Hardness and completeness with respect to parameterized complexity classes is defined analogously to the concepts from classical complexity theory, using FPT-reductions. The following parameterized classes will be needed in this paper: FPT $\subseteq$ W[1] $\subseteq$ AW[*]. Many parameterized complexity classes can be defined via a version of the following model checking problem.

MC(Φ)
Instance: Finite structure $\mathcal{A}$ and formula $\varphi \in \Phi$.
Parameter: $\lvert\varphi\rvert$.
Problem: Decide whether $\varphi(\mathcal{A}) \neq \emptyset$.

In particular, the problem MC(Σ_1) is W[1]-complete and the problem MC(FO) is AW[*]-complete (see for example [9]).

Positional games. Positional games are played by two players on a hypergraph $G = (V, E)$. The vertex set V indicates the set of available positions, while the each hyperedge $e \in E$ denotes a winning configuration. For some games, the hyperedges are implicitly defined, instead of being explicitly part of the input. The two players alternatively claim unclaimed vertices of V until either all elements are claimed or one player wins. A *position* in a positional game is an allocation of vertices to the players, who have already claimed these vertices. The *empty position* is the position where no vertex is allocated to a player. The notion of winning depends on the game type. In a *Maker-Maker game*, the first player to claim all vertices of some hyperedge $e \in E$ wins. In a *Maker-Breaker game*, the first player (*Maker*) wins if she claims all vertices of some hyperedge $e \in E$. If the game ends and player 1 has not won, then the second player (*Breaker*) wins. In an *Enforcer-Avoider game*, the first player (*Enforcer*) wins if the second player (*Avoider*) claims all vertices of some hyperedge $e \in E$. If the game ends and player 1 has not won, then the second player wins. A positional game is called an ℓ-move game, if the game ends either after a player wins or both players played ℓ moves. A winning strategy for player 1 is a move for player 1 such that for all moves of player 2 there exists a move of player 1... such that player 1 wins.

3 Results

The first game we consider is a Maker-Maker game that generalizes well-known games Tic-Tac-Toe, Connect6, and Gomoku (also known as Five in a Row). In Connect(m, n, k, p, q), the vertices are cells of an $m \times n$ grid, each set of k aligned cells (horizontally, vertically, or diagonally) is a winning set, the first move by player 1 is to claim q vertices, and then the players alternate claim p unclaimed vertices at each turn. Tic-Tac-Toe corresponds to Connect$(3, 3, 3, 1, 1)$, Connect6 to Connect$(19, 19, 6, 2, 1)$, and Gomoku to Connect$(19, 19, 5, 1, 1)$. Variations with different board sizes are also common. In the Short k-Connect problem, the input is the set of $m \cdot n$ vertices, an assignment of some of these vertices to the two players, the integer p, and the parameter ℓ. The winning sets corresponding to the k aligned cells are implicitly defined. The question is whether player 1 has a winning strategy from this position in at most ℓ moves. We omit q from the problem definition of Short k-Connect since we are modeling games that advanced already past the initial moves. Our first result (proved in Section 4) is that Short k-Connect is fixed-parameter tractable for parameter ℓ. (In all our results, the parameter is the number of moves, ℓ.)

▶ **Theorem 1.** Short k-Connect *is* FPT.

The main reason for this tractability is the rather special structure of the winning sets. It helps reducing the problem to model checking for first-order logic on locally bounded treewidth structures, which is FPT [11].

A similar strategy was recently used to show that Short Hex is FPT [4]. The Hex game is played on a parallelogram board paved by hexagons, each player owns two opposite sides of the parallelogram. Players alternately claim an unclaimed cell, and the first player to connect their sides with a path of connected hexagons wins the game. Note that we may view Hex as a Maker-Breaker game: if the second player manages to disconnect the first players sides, he has created a path connecting his sides. Bonnet et al. [4] also considered a well-known generalization to arbitrary graphs. The Generalized Hex game is played on a graph with two specified vertices s and t. The two players alternately claim an unclaimed vertex of the graph, and player 1 wins if she can connect s and t by vertices claimed by her, and player 2 wins if he can prevent player 1 from doing so. The Short Generalized Hex problem has as input a graph G, two vertices s and t in G, an allocation of some of the vertices to the players, and an integer ℓ. The parameter is ℓ, and the question is whether player 1 has a winning strategy to connect s and t in ℓ moves.

The Short Generalized Hex problem is known to be in AW[*] and was conjectured to be AW[*]-complete [4, 7, 6, 10, 18]. In fact, AW[*] is thought of as the natural home for most short games [7], playing a similar role in parameterized complexity as PSPACE in classical complexity for games with polynomial length. However, Bonnet et al. [4] only managed to show that Short Generalized Hex is W[1]-hard, leaving a complexity gap between W[1] and AW[*]. Our next result is to show that Short Generalized Hex is in W[1]. Thus, Short Generalized Hex is in fact W[1]-complete.

▶ **Theorem 2.** Short Generalized Hex *is* W[1]*-complete.*

Our main tool is a new fragment of first-order logic for which model-checking on arbitrary relational structures is W[1]-complete parameterized by the length of the formula. This fragment, which we call $\forall^{\neq}$-FO, is the fragment of first-order logic where universally-quantified variables appear only in inequalities.

▶ **Theorem 3.** MC($\forall^{\neq}$-FO) *is* W[1]*-complete.*

This result is proved by reducing a formula in $\forall^{\neq}$-FO to a formula in Σ_1. The $\forall^{\neq}$-FO logic makes it convenient to express short games where we can express that player 1 can reach a certain configuration without being blocked by player 2, no matter what configurations player 2 reaches. This is indeed the case for Generalized Hex, where we are merely interested in knowing if player 1 can connect s and t without being blocked by player 2.

More generally, this is the case for Short Maker-Breaker, where the input is a hypergraph $G = (V, E)$, a position, and an integer ℓ, and the question is whether player 1 has a winning strategy to claim all the vertices of some hyperedge in ℓ moves.

▶ **Theorem 4.** Short Maker-Breaker *is* W[1]*-complete.*

The fact that Short Maker-Breaker is PSPACE-complete and W[1]-complete (and *not* AW[*]-complete) may challenge the intuition one has on alternation. Looking at the classical complexity (PSPACE-completeness), it seems that both players have comparable expressivity and impact over the game. As the game length is polynomially bounded, if the outcome could be determined by only guessing a sequence of moves from one player, then the problem would lie in NP. Now from the parameterized complexity standpoint, Short Maker-Breaker is equivalent under FPT reductions to guessing the k vertices of a clique (as in the seminal W[1]-complete k-Clique problem); no alternation there. Those considerations may explain why it was difficult to believe that Generalized Hex is *not* AW[*]-complete as conjectured repeatedly [18, 6, 7].

This is also in contrast to Short Maker-Maker, where the input is a hypergraph $G = (V, E)$, a position, and an integer ℓ, and the question is whether player 1 has a strategy to be the first player claiming all the vertices of some hyperedge in ℓ moves.

▶ **Theorem 5.** Short Maker-Maker *is* AW[*]*-complete.*

For the remaining type of positional games, the Short Enforcer-Avoider problem has as input a hypergraph $G = (V, E)$, a position, and an integer ℓ, and the question is whether player 1 has a strategy to claim ℓ vertices that forces player 2 to complete a hyperedge. Again, player 1 can only block some moves of player 2, and the winning condition for player 1 can be expressed in $\forall^{\neq}$-FO.

▶ **Theorem 6.** Short Enforcer-Avoider *is* co-W[1]*-complete.*

Our results suggest that a structured board may suggest that a positional game is FPT, but otherwise, the complexity depends on how the winning condition for player 1 can be expressed. If it only depends on what positions player 1 has reached, our results suggest that the problem is W[1]-complete, but when the winning condition for player 1 also depends on the position player 2 has reached, the game is probably AW[*]-complete.

4 Short k-Connect is FPT

Graph G represents an $m \times n$ board in the following sense. Every board cell is represented by a vertex. Horizontal, vertical and diagonal neighbouring cells are connected via an edge. Vertex sets V_1 and V_2 represent the vertices already occupied by Player 1 and Player 2. While integer p, the number of stones to be placed during a move, is part of the input, we restrict it to values below constant k as games with $p \geq k$ are trivial.

Short k-Connect
Instance: A graph $G = (V, E)$ representing an $m \times n$ board, occupied vertices $V_1, V_2 \subseteq V$, and integer p and ℓ.
Parameter: ℓ.
Problem: Decide whether Player 1 has a winning strategy with at most ℓ moves.

▶ **Theorem 1.** Short k-Connect *is* FPT.

Proof. We reduce Short k-Connect to first-order model checking MC(FO) on a bounded degree graph. Using a result by Seese [21], it follows that Short k-Connect is FPT. Let (G, V_1, V_2, p, ℓ) be an instance of Short k-Connect, where $G = (V, E)$. We construct instance $(\mathcal{A}, \varphi)$ of MC(FO) as follows. Let *EDGE* be a binary relation symbol and let *V1* and *V2* be unary relation symbols. Then $\mathcal{A}$ is the $\{EDGE, V1, V2\}$-structure $(V, EDGE^{\mathcal{A}}, V1^{\mathcal{A}}, V2^{\mathcal{A}})$ with $EDGE^{\mathcal{A}} \coloneqq E$, $V1^{\mathcal{A}} \coloneqq V_1$, and $V2^{\mathcal{A}} \coloneqq V_2$. FO-formula φ is defined as $\varphi \equiv \exists x_1^1 \exists x_1^2 \dots \exists x_1^p \forall y_1^1 \dots \forall y_1^p \exists x_2^1 \dots \exists x_2^p \forall y_2^1 \dots \exists x_\ell^p \exists u_1 \exists u_2 \dots \exists u_k \forall v_1 \forall v_2 \dots \forall v_k \psi$,

$$\psi \equiv \bigvee_{i=0}^{\ell} \Big[\mathit{legalP1}_i(x_1^1, \dots, x_1^p, y_1^1, \dots, x_\ell^p) \wedge \Big(\neg \mathit{legalP2}_i(x_1^1, \dots, x_1^p, y_1^1, \dots, x_\ell^p) \vee \Big(\mathit{configP1}_i(x_1^1, \dots, x_\ell^p, u_1, \dots, u_k) \wedge \bigwedge_{j=1}^{k-2} \mathit{aligned}(u_j, u_{j+1}, u_{j+2}) \wedge \Big(\neg \mathit{configP2}_i(y_1^1, \dots, y_\ell^p, v_1, \dots, v_k) \vee \neg \bigwedge_{j=1}^{k-2} \mathit{aligned}(v_j, v_{j+1}, v_{j+2}) \Big) \Big) \Big) \Big],$$

$$\begin{aligned}
\mathit{path}(u, v, w) &\equiv \mathit{EDGE}(u, v) \wedge \mathit{EDGE}(v, w), \\
\mathit{hor_vert}(u, v, w) &\equiv \exists x \exists y\, \mathit{path}(u, v, w) \wedge \mathit{path}(u, x, w) \wedge \mathit{path}(u, y, w) \wedge \mathit{path}(x, v, y) \wedge \\
&\qquad \forall z \Big[\big(z \neq v \wedge z \neq x \wedge z \neq y \big) \rightarrow \neg \mathit{path}(u, z, w) \Big], \\
\mathit{diag}(u, v, w) &\equiv \mathit{path}(u, v, w) \wedge \forall x \Big[x \neq v \implies \neg \mathit{path}(u, x, w) \Big], \\
\mathit{aligned}(u, v, w) &\equiv \mathit{hor_vert}(u, v, w) \vee \mathit{diag}(u, v, w).
\end{aligned}$$

Variables x_i^j represent the jth stone in Player 1's ith move and variables y_i^j represent the jth stone in Player 2's ith move. The sequences $u_1 \dots u_k$ and $v_1 \dots v_k$ represent possible winning configurations for Player 1 and Player 2. The structure of ψ is the following. The first disjunction ranging from $i = 0$ to $i = \ell$ represents the number of moves Player 1 needs to win the game. We then ensure that the x variables represent legal moves by Player 1. Further, either variables y do not represent legal moves by Player 2, or Player 1 achieved a winning configuration. For the latter, we assure that variables u represent aligned vertices occupied by Player 1. Finally, we check that Player 2 did not achieve a winning configuration before, that is vertices v do not represent aligned vertices occupied by Player 2. Formula $\mathit{path}(u, v, w)$ expresses that there is a path of length 2 between vertices u and w via v ($\mathit{configP1}_i$ and $\mathit{configP2}_i$ ensure that the arguments are disjoint vertices). Formula $\mathit{hor\_vert}(u, v, w)$ expresses that vertices u, v, and w are aligned horizontally or vertically in this order. A case analysis shows that u, v and w are horizontally or vertically aligned if and only if there are exactly three nodes at distance 1 of u and w, and that v is in the middle of the other two. In case u, v and w are located on one of the border lines of the board, there are exactly two nodes at distance 1. Formula $\mathit{diag}(u, v, w)$ expresses that vertices u, v, and w are diagonally aligned in this order. This is the case if there exists no other length

2 path between u and w. Formula $\mathit{aligned}(u, v, w)$ expresses that vertices u, v, and w are aligned (in that order). Formula $\mathit{legalP1}_i$ (see [3]) ensures that variables x_i^j represent legal moves of Player 1, that is vertices not contained in V_1 or V_2 or previously played vertices. Analogously, $\mathit{legalP2}_i$ ensures that variables y_i^j represent legal moves of Player 2. Formula, $\mathit{configP1}_i$ (see [3]) expresses that variables $u_1, \ldots, u_k$ form a valid configuration of exactly k vertices out of the set of V_1 or vertices played by Player 1. Analogously, $\mathit{configP2}_i$ states that variables $v_1, \ldots, v_k$ form a valid configuration of exactly k vertices out of the set of V_2 or vertices played by Player 2. The size of φ is polynomial in ℓ, k, and p. Since k is a constant and p is bounded by k, we have an FO formula polynomial in our parameter ℓ. Graph G represents a grid with diagonals. Hence, G has maximum degree 8. It follows from Seese [21] that Short Connect is FPT. ◀

5 MC($\forall^{\neq}$-FO) is W[1]-complete

The class $\forall^{\neq}$-FO contains all first-order formulas of the form $Q_1x_1Q_2x_2Q_3x_3 \ldots Q_kx_k\varphi$, with $Q_i \in \{\forall, \exists\}$ and φ being a quantifier free first-order formula such that every $\forall$-quantified variable x_i only occurs in inequalities, that is in relations of the form $x_i \neq x_j$ for some variable x_j. Furthermore, φ does not contain any other variables besides $x_1, \ldots, x_k$.

▶ **Theorem 3.** MC($\forall^{\neq}$-FO) *is* W[1]*-complete.*

Proof. Hardness: Every Σ_1 formula is contained in the class $\forall^{\neq}$-FO. Hence, W[1]-hardness follows from W[1]-completeness of MC(Σ_1).

Membership: By reduction to MC(Σ_1). Let $(\mathcal{A}, \varphi)$ be an instance of MC($\forall^{\neq}$-FO). If φ contains only existential quantifiers then $(\mathcal{A}, \varphi)$ is already an instance of MC(Σ_1). Hence, let $\varphi = Q_1x_1Q_2x_2 \ldots Q_{i-1}x_{i-1}\forall x_i\exists x_{i+1}\exists x_{i+2} \ldots \exists x_k\psi$ with $Q_j \in \{\forall, \exists\}$ for $1 \leq j < i$, ψ is in negation normal form and $|\varphi| = \ell$. That is, x_i is the rightmost of the universal quantified variables. In order to reduce $(\mathcal{A}, \varphi)$ to an instance of MC(Σ_1), we need a way to remove all universal quantifications. We will show how to eliminate the universal quantification of x_i. This technique can then be used to iteratively eliminate all the universal quantifiers. Let $\varphi_1(x_1, \ldots, x_{i-1})$ be the subformula $\varphi_1(x_1, \ldots, x_{i-1}) = \forall x_i\exists x_{i+1} \ldots \exists x_k\psi$. We will show that we can replace $\varphi_1(x_1, \ldots, x_{i-1})$ by

$$\varphi_2(x_1, \ldots, x_{i-1}) = \exists y_i\exists y_{i+1} \ldots \exists y_k\Big(\psi[y_i/x_i, y_{i+1}/x_{i+1}, \ldots, y_k/x_k] \wedge \tag{1}$$

$$\bigwedge_{j=1}^{i-1} \exists y_{i+1}^j\exists y_{i+2}^j \ldots \exists y_k^j\psi[x_j/x_i, y_{i+1}^j/x_{i+1}, y_{i+2}^j/x_{i+2}, \ldots, y_k^j/x_k] \wedge \tag{2}$$

$$\bigwedge_{j=i+1}^{k} \exists y_{i+1}^j\exists y_{i+2}^j \ldots \exists y_k^j\psi[y_j/x_i, y_{i+1}^j/x_{i+1}, y_{i+2}^j/x_{i+2}, \ldots, y_k^j/x_k]\Big). \tag{3}$$

This reduction is an FPT-reduction, since the size of formula φ_2 is a function of the size of formula φ_1. Let $c_1, \ldots, c_{i-1}$ be arbitrary but fixed elements of the universe A of $\mathcal{A}$. We will show that $\varphi_1(x_1, \ldots, x_{i-1}) \equiv \varphi_2(x_1, \ldots, x_{i-1})$ by proving (a) $\varphi_1(c_1, \ldots, c_{i-1}) \to \varphi_2(c_1, \ldots, c_{i-1})$ and (b) $\varphi_2(c_1, \ldots, c_{i-1}) \to \varphi_1(c_1, \ldots, c_{i-1})$. For (a) assume that $\varphi_1(c_1, \ldots, c_{i-1})$ is true. This means, $\varphi_1[c_i/x_i]$ is true for all $c_i \in A$, that is for all $c_i \in A$ there exists an assignment to $x_{i+1}, \ldots, x_k$ such that ψ is true. Part (1) of $\varphi_2(c_1, \ldots, c_{i-1})$ asks for some $c_i \in A$ such that there exists an assignment to $x_{i+1}, \ldots, x_k$ such that ψ is true. Part (2) asks for the existence of an assignment to $x_{i+1}, \ldots, x_k$ such that ψ is true for each of the cases where x_i is one of the elements $c_1, \ldots, c_{i-1}$. Part (3) asks for the existence of an assignment to

$x_{i+1}, \ldots, x_k$ such that ψ is true for each of the cases where x_i is one of the elements that are assigned to $x_{i+1}, \ldots, x_k$ in the model of Part (1). All these are special cases of the universal quantification over x_i, hence $\varphi_2(c_1, \ldots, c_{i-1})$ is true.

For direction (b) assume towards a contradiction that $\varphi_1(c_1, \ldots, c_{i-1})$ is false and that $\varphi_2(c_1, \ldots, c_{i-1})$ is true. Since φ_1 is false, there exists $c_i \in A$ such that $\varphi_1[c_i/x_i]$ is false. We perform a case distinction on the value c_i. First let $c_i = c_j$ for some $j \in \{1, \ldots, i-1\}$. Then let $c_{i+1}, \ldots, c_k$ be the assignments to variables $y^j_{i+1}, \ldots, y^j_k$ in the model of φ_2. The jth conjunct of Part (2) of φ_2 states that ψ holds for $x_i = x_j$ using the assignment $c_{i+1}, \ldots, c_k$. Hence, assigning $c_{i+1}, \ldots, c_k$ to variables $x_{i+1}, \ldots, x_k$ in φ_1 is a model for $\varphi_1[c_i/x_i]$, which contradicts our assumption. As the next case, let $c_{i+1}, \ldots, c_k$ be the assignment to variables $y_{i+1}, \ldots, y_k$ in the model of φ_2 and let $c_i = c_j$ for some $j \in \{i+1, \ldots, k\}$. Let $c'_{i+1}, \ldots, c'_k$ be the assignments to variables $y^j_{i+1}, \ldots, y^j_k$ in the model of φ_2. The conjunct with index j of Part (3) of φ_2 states that ψ holds for $x_i = x_j = c_j$ using the assignment $c'_{i+1}, \ldots, c'_k$. Hence, assigning $c'_{i+1}, \ldots, c'_k$ to variables $x_{i+1}, \ldots, x_k$ in φ_1 is a model for $\varphi_1[c_i/x_i]$, which contradicts our assumption. For the last case, let c_i be one of the remaining values. Let $\ell_1, \ldots, \ell_m$ be all the literals in ψ that contain x_i. All of them are inequalities of the form $x_i \neq x_j$ for $j \neq i$. Let c'_i be the assignment to y_i in the model of φ_2. Let $\ell'_1, \ldots, \ell'_m$ be the literals in $\psi[y_i/x_i, y_{i+1}/x_{i+1}, \ldots, y_k/x_k]$ in Part (1) of φ_2 that correspond to $\ell_1, \ldots, \ell_m$. We have no knowledge about the truth value of these literals ℓ'_j with $1 \leq j \leq m$, but all of the literals ℓ_j in ψ evaluate to true when assigning $c_{i+1}, \ldots, c_k$ to the variables $x_{i+1}, \ldots, x_k$. Since ψ is in negation normal form and the literals $\ell_1, \ldots, \ell_m$ never occur in unnegated form, that is as equalities, changing the truth value of these literal from false to true will never result in changing the truth value of the whole formula from true to false. But since c'_i together with $c_{i+1}, \ldots, c_k$ is a model of Part (1) of φ_2, it holds that for all values of c_i that we consider in this case, that $\varphi_1[c_i/x_i]$ is true, which contradicts our assumption. This completes the case distinction and we have $\varphi_1(x_1, \ldots, x_{i-1}) \equiv \varphi_2(x_1, \ldots, x_2)$. ◀

6 Short Generalized Hex is W[1]-complete

Short Generalized Hex	
Instance:	Graph $G = (V, E)$, vertices $s, t \in V$, vertex sets $V_1, V_2 \subseteq V$ with $V_1 \cap V_2 = \emptyset$, and integer ℓ.
Parameter:	ℓ.
Problem:	Decide whether Player 1 has a winning strategy with at most ℓ moves in the generalized Hex game (G, s, t, V_1, V_2).

A generalized Hex game (G, s, t, V_1, V_2) is a positional game (V', E'), where the positions V' and the winning configurations E' are defined as follows. Set V' contains all vertices of G, that is $V' = V$. Set E' contains a set of vertices $\{v_1, \ldots, v_k\}$ if and only if $\{v_1, \ldots, v_k\} \cup \{s, t\}$ form an $s - t$ path in G. Additionally, vertices in V_1 and V_2 are already claimed by player 1 and player 2, respectively. Since the set of winning configurations of Short Generalized Hex is only defined implicitly, the input size of Short Generalized Hex can be exponential smaller than the number of winning configurations.

▶ **Theorem 2.** Short Generalized Hex *is* W[1]*-complete.*

Proof. Hardness is already known [4]. For membership, we reduce Short Generalized Hex to MC($\forall^{\neq}$-FO). Let $(G, s, t, V_1, V_2, \ell)$ be an instance of Short Generalized Hex, where $G = (V, E)$. Claimed vertices V_1 and V_2 can be preprocessed: (i) every $v \in V_1$ and its incident edges are removed from G and the neighbourhood of v is turned into a clique;

(ii) every $v \in V_2$ and its incident edges are removed from G. Hence, w.l.o.g. we assume that $V_1 = V_2 = \emptyset$. We construct an instance $(\mathcal{A}, \varphi)$ of MC($\forall^{\neq}$-FO) as follows. Let *EDGE* be a binary relation symbol and let S and T be unary relation symbols. Then $\mathcal{A}$ is the $\{EDGE, S, T\}$-structure $(V, EDGE^{\mathcal{A}}, S^{\mathcal{A}}, T^{\mathcal{A}})$ with $EDGE^{\mathcal{A}} := E$, $S^{\mathcal{A}} := \{s\}$, and $T^{\mathcal{A}} := \{t\}$. The $\forall^{\neq}$-FO-formula φ is defined as $\varphi = \exists s \exists t \exists x_1 \forall y_1 \exists x_2 \forall y_2 \dots \forall y_{\ell-1} \exists x_\ell \exists z_1 \exists z_2 \dots \exists z_\ell \psi$, with

$$\psi \equiv S(s) \wedge T(t) \wedge \Big(EDGE(s,t) \vee \bigvee_{i=1}^{\ell} \bigvee_{j=1}^{i} \Big(EDGE(s,z_1) \wedge EDGE(z_j,t) \wedge path_{i,j}(x_1,\dots,x_i,z_1,\dots,z_j) \wedge diff_i(x_1,y_1,\dots,y_{i-1},x_i) \Big) \Big),$$

$$path_{i,j}(x_1,\dots,x_i,z_1,\dots,z_j) \equiv \bigwedge_{h=1}^{j-1} EDGE(z_h,z_{h+1}) \wedge \bigwedge_{h=1}^{j} \bigvee_{k=1}^{i} z_h = x_k,$$

$$diff_i(x_1,y_1,\dots,x_{i-1},y_{i-1},x_i) \equiv \bigwedge_{1 \le j < k \le i} x_j \neq x_k \wedge \bigwedge_{1 \le j < k \le i} y_j \neq x_k.$$

The intuition of φ is the following. The variables x_i, y_i, and z_i represent the moves of Player 1, the moves of Player 2, and the ordered (s,t)-path induced by Player 1's moves, respectively. The variables s and t represent the vertices of the same name. Formula φ expresses that there is either a direct edge between s and t or a s-t path of length j was played. The main disjunctions ($\bigvee$) ensure that we consider wins that take up to ℓ moves, and build s-t path of length up to ℓ. Subformula $path_{i,j}$ will be true if and only if the z variables form a path using only values of the selected values for the x variables. Subformula $diff_i$ ensures that all x variables are pairwise distinct and they are distinct from all y variables with smaller index.

We have $|\varphi| = \mathcal{O}(\ell^4)$, so this is indeed an FPT-reduction and W[1]-membership follows. ◀

7 Short Maker-Breaker is W[1]-complete

Short Maker-Breaker
Instance: Hypergraph $G = (V, E)$, vertex sets $V_1, V_2 \subseteq V$ with $V_1 \cap V_2 = \emptyset$, and integer ℓ.
Parameter: ℓ.
Problem: Decide whether Player 1 has a winning strategy with at most ℓ if vertices V_1 and V_2 are already claimed by Player 1 and Player 2, respectively.

▶ **Theorem 4.** Short Maker-Breaker *is* W[1]*-complete.*

Proof. For showing membership, we reduce Short Maker-Breaker to MC($\forall^{\neq}$-FO). Let (G, V_1, V_2, ℓ) be an instance of Short Maker-Breaker, where $G = (V, E)$ is a hypergraph. Claimed vertices V_1 and V_2 can be preprocessed: (i) every $v \in V_1$ is removed from V and every hyperedge $e \in E$; (ii) every $v \in V_2$ is removed from V and every hyperedge $e \in E$ with $v \in e$ is removed from E. Hence, w.l.o.g. we assume that $V_1 = V_2 = \emptyset$. We construct an instance $(\mathcal{A}, \varphi)$ of MC($\forall^{\neq}$-FO) as follows. Let *IN* and *SIZE* be binary relation symbols. Then $\mathcal{A}$ is the $\{IN, SIZE\}$-structure $(V \cup E \cup \{1,\dots,|V|\}, IN^{\mathcal{A}}, SIZE^{\mathcal{A}})$ with $IN^{\mathcal{A}} := \{(x,e) \mid x \in V, e \in E, x \in e\}$ and $SIZE^{\mathcal{A}} := \{(e,i) \mid e \in E, |e| = i\}$. Hence, the universe of $\mathcal{A}$ consists of the vertices of G, an element for each hyperedge, and an element for some bounded number of integers. The $\forall^{\neq}$-FO-formula φ is defined as $\varphi \equiv \exists x_1 \forall y_1 \dots \forall y_{\ell-1} \exists x_\ell \exists e \exists z_1 \exists z_2 \dots \exists z_\ell \psi$, with

$$\psi \equiv \bigvee_{1 \le j \le i \le \ell} \Big(diff_i(x_1,y_1,\dots,x_i) \wedge SIZE(e,j) \wedge \bigwedge_{k=1}^{j} \bigvee_{h=1}^{i} z_k = x_h \wedge \bigwedge_{1 \le k < h \le j} z_k \neq z_h \wedge \bigwedge_{k=1}^{j} IN(z_k,e) \Big).$$

The subformula $\mathit{diff}_i(x_1, y_1, \ldots, x_i)$ refers to the subformula with same name used in the proof of Theorem 2. That is, it ensures that all x variables are pairwise distinct and that they are distinct from all y variables with smaller index. The intuition of φ is the following. The variables x_i and y_i represent the moves of Maker and the moves of Breaker, respectively. The variables z_i represent the vertices forming the winning configuration of Maker and e represents the hyperedge of this winning configuration. The first disjunction ensures that we consider wins that take up to ℓ moves. The second disjunction ensures that we consider winning configurations that consist of up to i vertices. After checking that e has the correct size ($\mathit{SIZE}(e, j)$), we encode that the values of the z variables are contained in the hyperedge represented by e and that these variables are pairwise disjoint and selected among the moves of Maker (the x variables).

We have $|\varphi| = \mathcal{O}(\ell^4)$, so this is indeed an FPT-reduction and W[1]-membership follows.

For hardness, we reduce k-Multicolored Clique to Short Maker-Breaker. The reduction is essentially the same as the reduction used for showing W[1]-hardness of Generalized Hex [4]. The crucial observation is that the construction of Bonnet et al. [4] contains only a polynomial number of possible $s-t$ paths. Hence, we can encode every such $s-t$-path as a unique hyperedge denoting a winning configuration in Short Maker-Breaker. ◀

8 Short Maker-Maker is AW[*]-complete

Short Maker-Maker
Instance: Hypergraph $G = (V, E)$, vertex sets $V_1, V_2 \subseteq V$ with $V_1 \cap V_2 = \emptyset$, and integer ℓ.
Parameter: ℓ.
Problem: Decide whether Player 1 has a winning strategy with at most ℓ if vertices V_1 and V_2 are already claimed by Player 1 and Player 2.

▶ **Theorem 5.** Short Maker-Maker *is* AW[*]*-complete.*

Proof. For membership, we reduce Short Maker-Maker to MC(FO). Let (G, V_1, V_2, ℓ) be an instance of Short Maker-Maker, where $G = (V, E)$ is a hypergraph. We construct an instance $(\mathcal{A}, \varphi)$ of MC(FO) as follows. Let $\mathit{V1}$, $\mathit{V2}$, and EDGE be unary relation symbols. Let IN be a binary relation symbol. Then $\mathcal{A}$ is the $\{\mathit{V1}, \mathit{V2}, \mathit{EDGE}, \mathit{IN}\}$-structure $(V \cup E, \mathit{V1}^{\mathcal{A}}, \mathit{V2}^{\mathcal{A}}, \mathit{EDGE}^{\mathcal{A}}, \mathit{IN}^{\mathcal{A}})$ with $\mathit{V1}^{\mathcal{A}} := V_1$, $\mathit{V2}^{\mathcal{A}} := V_2$, $\mathit{EDGE}^{\mathcal{A}} := E$, and $\mathit{IN}^{\mathcal{A}} := \{(x, e) \mid x \in V, e \in E, x \in e\}$. Hence, the universe of $\mathcal{A}$ consists of the vertices and the hyperedges of G. The FO-formula φ is defined as $\varphi \equiv \exists x_1 \forall y_1 \ldots \forall y_{\ell-1} \exists x_\ell \psi$, with

$$\psi \equiv \bigvee_{i=0}^{\ell} \mathit{legalP1}_i(x_1, y_1, \ldots, x_\ell) \wedge \Big(\neg \mathit{legalP2}_{i-1}(x_1, y_1, \ldots, x_\ell) \vee \big(\mathit{winP1}_i(x_1, y_1, \ldots, x_\ell) \wedge \neg \mathit{winP2}_{i-1}(x_1, y_1, \ldots, x_\ell)\big)\Big).$$

$$\mathit{winP1}_i(x_1, y_1, \ldots, x_\ell) \equiv \exists e \forall z \mathit{EDGE}(e) \wedge \Big(\neg \mathit{IN}(z, e) \vee \mathit{V1}(z) \vee \bigvee_{j=1}^{i} z = x_j\Big),$$

$$\mathit{winP2}_i(x_1, y_1, \ldots, x_\ell) \equiv \exists e \forall z \mathit{EDGE}(e) \wedge \Big(\neg \mathit{IN}(z, e) \vee \mathit{V2}(z) \vee \bigvee_{j=1}^{i} z = y_j\Big).$$

Variable x_j represent Player 1's jth move and variable y_j represent Player 2's jth move. The first disjunction represents the number of moves i that Player 1 needs to win the game. Formula $\mathit{legalP1}_i$ (see [3]) ensures that variables $(x_j)_{1 \le j \le i}$ represent legal moves of Player 1, that is vertices not contained in V_1 or V_2 or previously played vertices. Analogously, $\mathit{legalP2}_i$ ensures that variables $(y_j)_{1 \le j \le i}$ represent legal moves of Player 2. Formula $\mathit{winP1}_i$ ensures

that Player 1 has won within the i first moves, that is, it has completed a hyperedge with V_1 and variables up to x_i. Analogously, $winP2_i$ ensures that Player 2 has won within the i first moves. We have $|\varphi| = \mathcal{O}(\ell^3)$ and $|\mathcal{A}| = \mathcal{O}(|G|^2)$, so this is indeed an FPT-reduction and AW[*]-membership follows.

For hardness, we reduce from the AW[*]-complete problem Short Generalized Geography on bipartite graphs. The reduction is deferred to the long version [3]. ◀

9 Short Enforcer-Avoider is co-W[1]-complete

Short Enforcer-Avoider
Instance: Hypergraph $G = (V, E)$, vertex sets $V_1, V_2 \subseteq V$ with $V_1 \cap V_2 = \emptyset$, and integer ℓ.
Parameter: ℓ.
Problem: Decide whether Player 1 has a winning strategy with at most ℓ moves if vertices V_1 and V_2 are already claimed by Player 1 and Player 2, respectively.

▶ **Theorem 6.** Short Enforcer-Avoider *is* co-W[1]*-complete.*

Proof. We show that the co-problem of Short Enforcer-Avoider is W[1]-complete. The co-problem of Short Enforcer-Avoider is to decide whether for all strategies of Enforcer, there exists a strategy of Avoider such that during the first ℓ moves, Avoider does not claim a hyperedge. Again, vertices V_1 and V_2 are already claimed by Enforcer and Avoider, respectively. We prove W[1]-hardness by a parameterized reduction from Independent Set and W[1]-membership by reduction to MC($\forall^{\neq}$-FO).

In the W[1]-complete Independent Set problem [6], the input is a graph $G = (V, E)$ and an integer parameter k, and the question is whether G has an independent set of size k, i.e., a set of k pairwise non-adjacent vertices. We construct a positional game $G' = (V', E')$ by replacing each vertex of G by a clique of size $k + 1$. The vertex set V' has vertices $v(1), \ldots, v(k + 1)$ for each vertex $v \in V$, and hyperedges are $E' = \{\{v(i), v(j)\} : v \in V \text{ and } 1 \leq i < j \leq k + 1\} \cup \{\{u(i), v(j)\} : uv \in E \text{ and } 1 \leq i, j \leq k + 1\}$. We claim that G has an independent set of size k if and only if Avoider does not claim a hyperedge in the first k moves in the positional game G' starting from the empty position, that is $V_1 = V_2 = \emptyset$. For the forward direction, suppose $I = \{v_1, \ldots, v_k\}$ is an independent set of G of size k. Then, a winning strategy for Avoider is to claim an unclaimed vertex from $\{v_i(1), \ldots, v_i(k + 1)\}$ at round $i \in \{1, \ldots, k\}$. We note that Enforcer cannot claim all the vertices from $\{v_i(1), \ldots, v_i(k + 1)\}$, since there are not enough moves to do so, and Avoider does not complete a hyperedge with this strategy. On the other hand, suppose Avoider has a winning strategy in k moves. For an arbitrary play by Enforcer, let $\{v_1(i_1), \ldots, v_k(i_k)\}$ denote the vertices claimed by Player 1. Then, $v_i \neq v_j$ and $v_i v_j \notin E$ for any $1 \leq i < j \leq k$, since Player 1 would otherwise claim all the vertices of a hyperedge. Therefore, $\{v_1, \ldots, v_k\}$ is an independent set of G of size k.

For membership, we reduce to MC($\forall^{\neq}$-FO). Let (G, V_1, V_2, ℓ) be an instance of the co-problem of Short Enforcer-Avoider where $G = (V, E)$ is a hypergraph. First we do some preprocessing. We remove all vertices from G that are contained in V_2, that is the vertices already claimed by Avoider. If this results in an empty hyperedge, the instance is a no-instance. Otherwise, we remove all hyperedges that contain a vertex in V_1, that is the vertices already claimed by Enforcer, since Avoider will never lose via these edges anymore. Finally, we remove all vertices from G that are contained in V_1. Let $G = (V, E)$ now refer to the outcome of this preprocessing. By construction all vertices of G are unoccupied and some vertices might not be contained in any hyperedge. If G contains

less than 2ℓ vertices we can solve the problem via brute force in FPT time. Hence, in what follows we assume that there are at least 2ℓ unoccupied vertices in G. We construct an instance $(\mathcal{A}, \varphi)$ of MC($\forall^{\neq}$-FO) as follows. Let $EDGE_i$ be a i-ary relation symbol for $1 \leq i \leq \ell$. Then $\mathcal{A}$ is the $\{EDGE_1, \ldots, EDGE_\ell\}$-structure $(V, {EDGE_1}^{\mathcal{A}}, \ldots, {EDGE_\ell}^{\mathcal{A}})$ with ${EDGE_i}^{\mathcal{A}} := \{(v_1, \ldots, v_i) \mid e \in E, |e| = i, e = \{v_1, \ldots, v_\ell\}\}$, that is ${EDGE_i}^{\mathcal{A}}$ contains every permutation of all hyperedges of cardinality i. The $\forall^{\neq}$-FO-formula φ is defined as

$$\varphi \equiv \forall y_1 \exists x_1 \forall y_2 \exists x_2 \ldots \exists x_\ell \; \mathit{diff}_\ell(y_1, x_1, \ldots, x_\ell) \wedge \bigwedge_{1 \leq i \leq \ell} \bigwedge_{\{z_1, \ldots, z_i\} \subseteq \{x_1, \ldots, x_\ell\}} \neg EDGE_i(z_1, \ldots, z_i),$$

where $\mathit{diff}_i(y_1, x_1, \ldots, x_i) \equiv \bigwedge_{1 \leq j < k \leq i} x_j \neq x_k \wedge \bigwedge_{1 \leq j \leq k \leq i} y_j \neq x_k$.

Subformula $\mathit{diff}_i(y_1, x_1, \ldots, x_i)$ ensures that all x variables are pairwise distinct and they are distinct from all y variables with index less or equal theirs. The intuition of φ is the following. The variables x_i and y_i represent the moves of Avoider and the moves of Enforcer, respectively. Avoider wins if the x variables do not cover a whole hyperedge after ℓ moves. We only have to check hyperedges of size up to ℓ. Hence, for each cardinality $i \leq \ell$, we check for all subsets $z_1, \ldots, z_\ell$ of the x variables that they do not form a hyperedge. Formula φ does not pose any restrictions on the y variables, that is we do not force Enforcer to pick unoccupied vertices. We call a move by Enforcer that picks an already occupied vertex cheating. To prove correctness, we need to show that whenever Enforcer has a winning strategy σ_E that involves cheating, Enforcer also has a winning strategy σ'_E without cheating. We construct σ'_E as follows. We follow strategy σ_E while σ_E does not perform a cheating move. If the next move would be a cheating move, we play a random unoccupied vertex instead and keep track of this vertex in a new set V_r. The next time we need to select a move, we construct a board state s by removing all vertices in V_r from the picks of Enforcer and query strategy σ_E on this state s. If the answer is an unoccupied vertex, we perform this move normally. If instead the answer is a previously played vertex (which might be in V_r), we play a random unoccupied vertex instead and add it to V_r. Since σ_E was a winning strategy, so is σ'_E. Hence, formula φ does not need to check if the y variables correspond to unoccupied vertices. The construction can be done by an FPT algorithm since for each hyperedge $e \in E$ of cardinality i, we create $i! \leq \ell!$ entries in the $EDGE_i$ relation. We have $|\varphi| = \mathcal{O}(\ell^\ell)$, so this is indeed an FPT reduction and W[1]-membership follows. ◀

10 Conclusion

We have seen that the parameterized complexity of short positional games depends crucially on whether both players compete for achieving winning sets, or whether the game can be seen as one player aiming to achieve a winning set and the other player merely blocking the moves of the first player. Naturally, blocking moves correspond to inequalities in first-order logic, and our $\forall^{\neq}$-FO fragment of first-order logic therefore captures that the universal player can only block moves of the existential player. Our W[1]-completeness of MC($\forall^{\neq}$-FO) has been used several times in this paper, but our transformation of $\forall^{\neq}$-FO formulas into Σ_1 formulas may have other uses. As a concrete example related to positional games, Bonnet et al. [4] established that Short Hex is FPT by expressing the problem as a FO formula, and making use of Frick and Grohe's meta-theorem [11], similarly as we did in Section 4. This establishes that the problem is FPT but the running time is non-elementary in ℓ. However, we remark that their FO formula is actually a $\forall^{\neq}$-FO formula of size polynomial in ℓ. Our transformation gives an equivalent Σ_1 formula whose length is single-exponential in ℓ, and the meta-theorem of Grohe and Wöhrle [12] then gives a running time for solving Short Hex that is triply-exponential in ℓ.

Acknowledgments We thank anonymous reviewers for helpful comments and we thank Yijia Chen and Paul Hunter for bringing Grohe and Wöhrle's work [12] to our attention.

Abstract

We are motivated by a tantalizing open question in exact algorithms: can we detect whether an n-vertex directed graph G has a Hamiltonian cycle in time significantly less than 2^n?

We present new randomized algorithms that improve upon several previous works:

1. We show that for any constant $0 < \lambda < 1$ and prime p we can **count** the Hamiltonian cycles modulo $p^{\lfloor (1-\lambda)\frac{n}{3p} \rfloor}$ in expected time less than c^n for a constant $c < 2$ that depends only on p and λ. Such an algorithm was previously known only for the case of counting modulo *two* [Björklund and Husfeldt, FOCS 2013].
2. We show that we can detect a Hamiltonian cycle in $O^*(3^{n-\alpha(G)})$ time and **polynomial space**, where $\alpha(G)$ is the size of the maximum independent set in G. In particular, this yields an $O^*(3^{n/2})$ time algorithm for bipartite directed graphs, which is faster than the exponential-space algorithm in [Cygan *et al.*, STOC 2013].

Our algorithms are based on the algebraic combinatorics of "incidence assignments" that we can capture through evaluation of determinants of Laplacian-like matrices, inspired by the Matrix–Tree Theorem for directed graphs. In addition to the novel algorithms for directed Hamiltonicity, we use the Matrix–Tree Theorem to derive simple algebraic algorithms for detecting out-branchings. Specifically, we give an $O^*(2^k)$-time randomized algorithm for detecting out-branchings with at least k internal vertices, improving upon the algorithms of [Zehavi, ESA 2015] and [Björklund *et al.*, ICALP 2015]. We also present an algebraic algorithm for the directed k-Leaf problem, based on a non-standard monomial detection problem.

1 Introduction

The Hamiltonian cycle problem has played a prominent role in development of techniques for the design of *exact algorithms* for hard problems. The early $O^*(2^n)$ algorithms based on dynamic programming and inclusion-exclusion [1, 20, 19], remained un-challenged for several decades. In 2010, Björklund [3], gave a randomized algorithm running in $O(1.657^n)$ time for the case of undirected graphs. The algorithm taps into the power of algebraic combinatorics, and in particular determinants that enumerate cycle covers.

Despite this progress in the undirected Hamiltonian cycle problem, a substantial improvement in the more general directed version of the problem remains an open problem and a key challenge in the area of exact algorithms. The currently best known general algorithm runs in $O^*(2^{n-\Theta(\sqrt{n/\log n})})$ time [4], and there are no known connections with the theory of SETH-hardness [18] that would – at least partly – dash the hope for a faster algorithm.

A number of recent works have attempted to crack directed Hamiltonicity, revealing that the problem is indeed easier in certain restricted settings. Cygan and Pilipczuk [13] showed that the problem admits an $O^*(2^{(1-\epsilon_d)n})$ time algorithm for graphs with average degree bounded by d, where ϵ_d is a constant with a doubly exponential dependence on d. Cygan *et al.* [12] showed that the problem admits an $O^*(1.888^n)$ time randomized algorithm for bipartite graphs and that the parity of directed Hamiltonian cycles can also be computed within the same time bound. Björklund and Husfeldt [6] showed that the parity of Hamiltonian cycles can be computed in $O^*(1.619^n)$ randomized time in general directed graphs. Finally, Björklund *et al.* [5] showed that the problem can be solved in $O^*((2-\Theta(1))^n)$ time when the graph contains less than 1.038^n Hamiltonian cycles, via a reduction to the parity problem. In this paper we improve or generalize all of these works.

Our results. As one would expect, all recent "below-2^n" algorithm designs for the Hamiltonicity problem rely on algebraic combinatorics and involve formulas that enumerate Hamiltonian cycles. But somewhat surprisingly, none of these approaches employs the directed version of the Matrix–Tree Theorem (see e.g. Gessel and Stanley [17, §11]), one of the most striking and beautiful results in algebraic graph theory. The theorem enables the enumeration of spanning out-branchings, that is, rooted spanning trees with all arcs oriented away from the root, via a determinant polynomial. Our results in this paper derive from a detailed combinatorial understanding and generalization of this classical setup.

The combinatorial protagonist of this paper is the following notion that enables a "two-way" possibility to view each arc in a directed graph:

▶ **Definition 1** (Incidence assignment)**.** Let G be a directed graph with vertex set V and arc set E. For a subset $W \subseteq V$ we say that a mapping $\mu : W \to E$ is an *incidence assignment* if for all $u \in W$ it holds that $\mu(u)$ is incident with u.

In particular, looking at a single arc $uv \in E$, an incidence assignment μ can assign uv in two[1] possible ways: as an out-arc $\mu(u) = uv$ at u, or as an in-arc $\mu(v) = uv$ at v.

From an enumeration perspective the serendipity of this "two-way" possibility to assign an arc becomes apparent when one considers how an incidence assignment μ can realize a

[1] Strictly speaking we are here assuming that both $u \in W$ and $v \in W$. To break symmetry in our applications we do allow also situations where uv has only one possible assignment due to either $u \notin W$ or $v \notin W$.

directed cycle in its image $\mu(W)$. Indeed, let

$$u_1u_2,\ u_2u_3,\ \ldots,\ u_{\ell-1}u_\ell,\ u_\ell u_1 \in E$$

be the arcs of a directed cycle C of length $\ell \geq 2$ in G with $V(C) \subseteq W$. It is immediate that there are now exactly two[2] ways to realize C in the image $\mu(W)$. Namely, we can realize C either (i) using only in-arcs with

$$\mu(u_1) = u_\ell u_1, \quad \mu(u_2) = u_1u_2, \quad \mu(u_3) = u_2u_3, \quad \ldots, \quad \mu(u_\ell) = u_{\ell-1}u_\ell\,, \tag{1}$$

or (ii) using only out-arcs with

$$\mu(u_1) = u_1u_2, \quad \mu(u_2) = u_2u_3, \quad \mu(u_3) = u_3u_4, \quad \ldots, \quad \mu(u_\ell) = u_\ell u_1\,. \tag{2}$$

Incidence assignments thus enable two distinct ways to realize a *directed* cycle. Furthermore, it is possible to *switch* between (1) and (2) so that only the images of $u_1, u_2, \ldots, u_\ell$ under μ are affected. The algebraization of this combinatorial observation is at the heart of the directed Matrix–Tree Theorem (which we will review for convenience of exposition in Sect. 2) and all of our results in this paper.

Our warmup result involves a generalization of the directed Hamiltonian path problem, namely the *k-Internal Out-Branching* problem, where the goal is to detect whether a given directed graph contains a spanning out-branching that has at least k internal vertices. This is a well-studied problem on its own, with several successive improvements the latest of which is an $O^*(3.617^k)$ algorithm by Zehavi [24] and an $O^*(3.455^k)$ algorithm by Björklund *et al.* [9] for the undirected version of the problem.

Using a combination of the directed Matrix–Tree Theorem and a monomial-sieving idea due to Floderus *et al.* [15], in Sect. 3 we show the following:

▶ **Theorem 2** (Detecting a k-Internal Out-Branching)**.** *There exists a randomized algorithm that solves the k-internal out-branching problem in time $O^*(2^k)$ and with negligible probability of reporting a false negative.*

In the full version of the paper [10] we give a further application for the k-Leaf problem, that is, detecting a spanning out-branching with at least k leaves. We note that Gabizon *et al.* [16] have recently given another application of the directed Matrix–Tree Theorem for the problem of detecting out-branchings of bounded degree.

Proceeding to our two main results, in Sect. 4 we observe that the directed Matrix–Tree Theorem leads to a formula for computing the number of Hamiltonian paths in arbitrary characteristic by using a standard inclusion–exclusion approach, which leads to a formula that involves the summation of 2^n determinants. To obtain a below-2^n design, we present a way to randomize the underlying Laplacian matrix so that the number of Hamiltonian paths does not change but in expectation most of the summands vanish modulo a prime power. Furthermore, to efficiently list the non-vanishing terms, we use a variation of an algorithm of Björklund *et al.* [8] that was used for a related problem, computing the permanent modulo a prime power. This leads to our first main result:

▶ **Theorem 3** (Counting directed Hamiltonian cycles modulo a prime power)**.** *For all $0 < \lambda < 1$ there exists a randomized algorithm that, given an n-vertex directed graph and a prime p as input, counts the number of Hamiltonian cycles modulo $p^{\lfloor(1-\lambda)n/(3p)\rfloor}$ in expected time $O^*\big(2^{n(1-\lambda^2/(19p\log_2 p))}\big)$. The algorithm uses exponential space.*

[2] Again strictly speaking it will be serendipitous to break symmetry so that certain cycles will have only one realization instead of two.

A corollary of Theorem 3 is that if G has at most d^n Hamiltonian cycles, we can detect one in time $O(c_d^n)$, where d is any fixed constant and $c_d < 2$ is a constant that only depends on d. As a further corollary we obtain a randomized algorithm for counting Hamiltonian cycles in graphs of bounded average (out-)degree d in $O(2^{(1-\epsilon_d)n})$ time. The constant ϵ_d has a polynomial dependency in d. Previous algorithms had a constant ϵ_d with an exponential dependency on d [7, 13]. (The proofs of these results are relegated to the full version of the paper [10].)

Returning to undirected Hamiltonicity, a key to the algorithm in [3] was the observation that determinants enumerate all non-trivial cycle covers an even number of times. This is due to the fact that each undirected cycle can be traversed in both directions. By picking a special vertex, one can break symmetry and force this to happen only for non-Hamiltonian cycle covers, so that the corresponding monomials cancel in characteristic 2. In Sect. 5 we present a "quasi-Laplacian" matrix whose determinant enables a similar approach for the directed case via algebraic combinatorics of incidence assignments, and furthermore enables one to accommodate a speedup assuming the existence of a good-sized independent set. We specifically prove the following as our second main result:

▶ **Theorem 4** (Detecting a directed Hamiltonian cycle)**.** *There exists a randomized algorithm that solves the directed Hamiltonian cycle problem on a given directed graph G with a maximum independent set of size $\alpha(G)$, in $O^*(3^{n(G)-\alpha(G)})$ time, polynomial space and with negligible probability of reporting a false negative.*

Theorem 4 improves and generalizes the exponential-space algorithm of Cygan *et al.* [12].

Terminology and conventions. All graphs in this paper are directed and without loops and parallel arcs unless indicated otherwise. For an arc e starting from vertex u and ending at vertex v we say that u is the *tail* of e and v is the *head* of e. The vertices u and v are the *ends* of e. A directed graph is *connected* if the undirected graph obtained by removing orientation from the arcs is connected. A subgraph of a graph is *spanning* if the subgraph has the same set of vertices as the graph. A connected directed graph is an *out-branching* if every vertex has in-degree 1 except for the *root* vertex that has in-degree 0. We say that a vertex is *internal* to an out-branching if it has out-degree at least 1; otherwise the vertex is a *leaf* of the out-branching. The (*directed*) *Hamiltonian cycle* problem asks, given a directed graph G as input, whether G has a spanning directed cycle as a subgraph. The notation $O^*(\ )$ suppresses a multiplicative factor polynomial in the input size. We say that an event parameterized by n has *negligible* probability if the probability of the event tends to zero as n grows without bound.

2 The symbolic Laplacian of a directed graph

This section develops the relevant preliminaries on directed graph Laplacians.

Permutations and the determinant. A bijection $\sigma : U \to U$ of a finite set U is called a *permutation* of U. A permutation σ *moves* an element $u \in U$ if $\sigma(u) \neq u$; otherwise σ *fixes* u. The *identity* permutation fixes every element of U. A permutation σ of U is a *cycle* of *length* $k \geq 2$ if there exist distinct $u_1, u_2, \ldots, u_k \in U$ with $\sigma(u_1) = u_2$, $\sigma(u_2) = u_3, \ldots, \sigma(u_{k-1}) = u_k$, $\sigma(u_k) = u_1$ and σ fixes all other elements of U. Two cycles are *disjoint* if every point moved by one is fixed by the other. The set of all permutations of U forms the *symmetric group* $\mathrm{Sym}(U)$ with the composition of mappings as the product operation of the group.

Every nonidentity permutation factors into a unique product of pairwise disjoint cycles. The *sign* of a permutation σ that factors into c disjoint cycles of lengths $k_1, k_2, \ldots, k_c$ is $\operatorname{sgn}(\sigma) = (-1)^{\sum_{j=1}^{c}(k_j-1)}$. The sign of the identity permutation is 1.

The *determinant* of a square matrix A with rows and columns indexed by U is the multivariate polynomial

$$\det A = \sum_{\sigma \in \mathrm{Sym}(U)} \operatorname{sgn}(\sigma) \prod_{u \in U} a_{u,\sigma(u)} \,.$$

The punctured Laplacian determinant via incidence assignments. Let G be a directed graph with n vertices. Associate with each arc $uv \in E = E(G)$ an indeterminate x_{uv}. The *symbolic Laplacian* $L = L(G)$ of G is the $n \times n$ matrix with rows and columns indexed by the vertices $u, v \in V = V(G)$ and the (u, v)-entry defined[3] by

$$\ell_{uv} = \begin{cases} \sum_{w \in V : wu \in E} x_{wu} & \text{if } u = v; \\ -x_{uv} & \text{if } uv \in E; \\ 0 & \text{if } u \neq v \text{ and } uv \notin E. \end{cases} \tag{3}$$

Observe that for each $v \in V$ we have that column v of L sums to zero because the diagonal entries cancel the negative off-diagonal entries. Furthermore, for each $u \in V$ we have that the monomials on row u of L correspond to the arcs incident to u. Indeed, each monomial at the diagonal corresponds to an in-arc to u, and each monomial at an off-diagonal entry corresponds to an out-arc from u. Thus, selecting one monomial from each row corresponds to selecting an incidence assignment.

To break symmetry, select an $r \in V$. The symbolic Laplacian of G *punctured at* r is obtained from L by deleting both row r and column r. We write $L_r = L_r(G)$ for the symbolic Laplacian of G punctured at r. Let us write $\mathcal{B}_r = \mathcal{B}_r(G)$ for the set of all spanning out-branchings of G with root $r \in V$. The following theorem is well-known (see e.g. Gessel and Stanley [17, §11]) and is presented here for purposes of displaying a proof that presents the cancellation argument using incidence assignments.

▶ **Theorem 5** (Directed Matrix–Tree Theorem). $\det L_r = \sum_{H \in \mathcal{B}_r} \prod_{uv \in E(H)} x_{uv}$.

Proof. Let us abbreviate $V_r = V(G) \setminus \{r\}$ and study the determinant

$$\det L_r = \sum_{\sigma \in \mathrm{Sym}(V_r)} \operatorname{sgn}(\sigma) \prod_{u \in V_r} \ell_{u,\sigma(u)} \,. \tag{4}$$

In particular, let us fix an arbitrary permutation $\sigma \in \mathrm{Sym}(V_r)$ and study the monomials of the polynomial $\prod_{u \in V_r} \ell_{u,\sigma(u)}$ with the assumption that this polynomial is nonzero. From (3) it is immediate for each $u \in V_r$ that $\ell_{u,\sigma(u)}$ expands either (i) to the diagonal sum $\sum_{w \in V : wu \in E} x_{wu}$, which happens precisely when σ fixes u with $\sigma(u) = u$, or (ii) to the off-diagonal $-x_{uv}$, which happens precisely when σ moves u with $\sigma(u) = v$.

Let us write $M(\sigma)$ for the set of all incidence assignments $\mu : V_r \to E$ with the properties that (i) each $u \in V_r$ fixed by σ is assigned to an in-arc $\mu(u) = wu \in E$ for some $w \in V$, and (ii) each $u \in V_r$ moved by σ is assigned to the unique out-arc $\mu(u) = uv \in E$ with $\sigma(u) = v$.

[3] Recall that we assume that G is loopless so the entries with $u = v$ are well-defined.

Let us write $f = f(\sigma)$ for the number of elements in V_r fixed by σ. It is immediate by (i) and (ii) that we have

$$\prod_{u \in V_r} \ell_{u,\sigma(u)} = \sum_{\mu \in M(\sigma)} (-1)^{n-1-f(\sigma)} \prod_{u \in V_r} x_{\mu(u)}\,. \tag{5}$$

Next observe that from μ we can reconstruct $\sigma = \sigma(\mu)$ by (i) setting $\sigma(u) = u$ for each u assigned to an in-arc in μ, and (ii) setting $\sigma(u) = v$ for each u assigned to an out-arc uv in μ. Thus the union $M = \bigcup_{\sigma \in Sym(V_r)} M(\sigma)$ is disjoint. Let us call the elements of M *proper* incidence assignments. By (4) and (5) we have

$$\det L_r = \sum_{\mu \in M} (-1)^{n-1-f(\sigma)} \mathrm{sgn}(\sigma(\mu)) \prod_{u \in V_r} x_{\mu(u)}\,. \tag{6}$$

We claim that an incidence assignment μ is proper if and only if for every $u \in V_r$ there is exactly one $u' \in V_r$ such that $\mu(u')$ is an in-arc to u. For the "only if" direction, let σ be the permutation underlying a proper μ, and observe that vertices moved by σ partition to cycles so a σ never moves a vertex to a fixed vertex. Thus, we have $u' = u$ for the points fixed by σ, and $u' = \sigma^{-1}(u)$ is the vertex preceding u along a cycle of σ for points moved by σ. For the "if" direction, define $\sigma(u) = u$ if $u = u'$ and $\sigma(u') = u$ if $u' \neq u$. In the latter case we have $\mu(u') = u'u$, which means that $u'' \neq u'$ and thus $\sigma(u'') = u'$; by uniqueness of u' eventually a cycle must close so σ is a well-defined permutation underlying μ and thus μ is proper.

Let us write $\mathcal{H}_r$ for the set of all spanning subgraphs of G with the property that every vertex in V_r has in-degree 1 and the root r has in-degree 0. From the previous claim it follows that we can view the set $\mu(V_r) = \{\mu(u) : u \in V_r\}$ for a proper μ as an element of $\mathcal{H}_r$. Furthermore, $\mu(V_r)$ is connected (and hence a spanning out-branching with root r) if and only if $\mu(V_r)$ is acyclic.

Consider an arbitrary $H \in \mathcal{H}_r$. If H has a cycle, let C be the least cycle in H according to some fixed but arbitrary ordering of the vertices of G. (Observe that any two cycles in H must be vertex-disjoint and cannot traverse r because r has in-degree 0.) Now consider an arbitrary proper μ that realizes H by $\mu(V_r) = H$. The cycle C is realized in μ by either (1) (in which case $\sigma(\mu)$ fixes all vertices in C), or (2) (in which case $\sigma(\mu)$ traces the cycle C). Furthermore, we may switch between realizations (1) and (2) so that the number of fixed points in the underlying permutation changes by $|V(C)|$ and the sign of the underlying permutation gets multiplied by $(-1)^{|V(C)|-1}$. It follows that the realizations (1) and (2) have different signs and thus cancel each other in (6). If H does not have a cycle, that is, $H \in \mathcal{B}_r$, it follows that there is a unique proper μ that realizes H. Indeed, first observe that H can be realized only by assigning in-arcs since any assignment of an out-arc in μ implies a cycle in $H = \mu(V_r)$, a contradiction. Second, the in-arcs are unique since each $u \in V_r$ has in-degree 1 in H. Finally, since μ assigns only in-arcs the underlying permutation $\sigma(\mu)$ is the identity permutation which has $\mathrm{sgn}(\sigma(\mu)) = 1$ and $(-1)^{n-1-f(\sigma(\mu))} = 1$. Thus, each acyclic H contributes to (6) through a single $\mu \in M$ with coefficient 1. The theorem follows. ◀

3 Corollary for *k*-internal out-branchings

This section proves Theorem 2. We rely on a substitution idea of Floderus *et al.* [15, Theorem 1] to detect monomials with at least k distinct variables.

Let G be an n-vertex directed graph given as input together with a nonnegative integer k. Without loss of generality we may assume that $k \leq n - 1$. Iterate over all choices for a root vertex $r \in V$. Introduce an indeterminate y_u for each vertex $u \in V$ and an

indeterminate z_{uv} for each arc $uv \in E$. Introduce one further indeterminate t. Construct the symbolic Laplacian L of G given by (3) and with the assignment $x_{uv} = (1 + ty_u)z_{uv}$ to the indeterminate x_{uv} for each $uv \in E$. Puncture L at r to obtain L_r. Using, for example, Berkowitz's determinant circuit design [2] for an arbitrary commutative ring with unity, in time $O^*(1)$ build an arithmetic circuit $\mathcal{C}$ of size $O^*(1)$ for $\det L_r$. Viewing $\det L_r$ as a multivariate polynomial over the polynomial ring $R[t, y_u, z_{uv} : u \in V, uv \in E]$ where R is an abstract ring with unity, from Theorem 5 it follows that G has a spanning out-branching rooted at r with at least k internal vertices if and only if the coefficient of t^k in $\det L_r$ (which is a polynomial that is either identically zero or both (i) homogeneous of degree k in the indeterminates y_u and (ii) homogeneous of degree $n-1$ in the indeterminates z_{uv}) has a monomial that is multilinear of degree k in the indeterminates y_u. Indeed, observe that the substitution $x_{uv} = (1 + ty_u)z_{uv}$ tracks in the degree of the indeterminate y_u whether u occurs as an internal vertex or not; the indeterminates z_{uv} make sure that distinct spanning out-branchings will not cancel each other.

To detect a multilinear monomial in $\mathcal{C}$ restricted to the coefficient of t^k we can invoke [11, Lemma 1] or [21, Lemma 2.8]. This results in a randomized algorithm that runs in time $O^*(2^k)$ and has a negligible probability of reporting a false negative. This completes the proof of Theorem 2. ◀

4 Modular counting of Hamiltonian cycles

This section proves Theorem 3. Fix an arbitrary constant $0 < \lambda < 1$. Let $0 < \beta < 1/2$ be a constant whose precise value is fixed later. Let p be a prime and let G be an n-vertex directed graph with vertex set V and arc set E given as input. Without loss of generality (by splitting any vertex u into two vertices, s and t, with s receiving the out-arcs from u, and t receiving the in-arcs to u) we may count the spanning paths starting from s and ending at t instead of spanning cycles. Similarly, without loss of generality we may assume that $2 \leq p < n$. (Indeed, for $p \geq n$ the counting outcome from Theorem 3 is trivial.)

Sieving for Hamiltonian paths among out-branchings. Let $s, t \in V$ be distinct vertices. Let us write $\mathrm{hp}(G, s, t)$ for the set of spanning directed paths that start at s and end at t in G. Recall that we write $V_t = V \setminus \{t\}$ for the t-punctured version of the vertex set V. Let us also write $V_{st} = V \setminus \{s, t\}$. For $O \subseteq V_t$, let L_s^O be the matrix obtained from the Laplacian (3) by first puncturing at s and then substituting $x_{uv} = 0$ for all arcs $uv \in E$ with $u \in V_t \setminus O$. Since a path $P \in \mathrm{hp}(G, s, t)$ is precisely a spanning out-branching rooted at s such that every vertex $u \in V_t$ has out-degree 1, we have, by Theorem 5 and the principle of inclusion and exclusion,

$$\sum_{P \in \mathrm{hp}(G,s,t)} \prod_{uv \in E(P)} x_{uv} = \sum_{O \subseteq V_t} (-1)^{|V_t \setminus O|} \det L_s^O \,. \tag{7}$$

In particular observe that (7) holds in any characteristic.

Cancellation modulo a power of p. With foresight, select $k = \lfloor (1-\lambda)(1/2-\beta)n/p \rfloor$. Our objective is next to show that by carefully injecting entropy into the underlying Laplacian we can, in expectation and working modulo p^k, cancel all but an exponentially negligible fraction of the summands on the right-hand side of (7). Furthermore, we can algorithmically narrow down to the nonzero terms, leading to an exponential improvement to 2^n.

Let us assign $x_{uv} = 1$ for all $uv \in E$ with $u \neq t$. Since no spanning path that ends at t may contain an arc $tu \in E$ for any $u \in V_t$, we may without loss of generality assume that G contains

all such arcs, and assign, independently and uniformly at random $x_{tu} \in \{0, 1, \ldots, p-1\}$. Thus, the summands $\det L_s^O$ for $O \subseteq V_t$ are now integer-valued random variables and (7) evaluates to $|\mathrm{hp}(G, s, t)|$ with probability 1.

Let us next study a fixed $O \subseteq V_t$. Let F_O be the event that L_s^O has no more than k rows where each entry is divisible by p. In particular, $\det L_s^O \not\equiv 0 \pmod{p^k}$ implies F_O. To bound the probability of F_O from above, observe that L_s^O is identically zero at each row $u \in V_{st} \setminus O$ except possibly at the diagonal entries. Furthermore, because of the random assignment to the indeterminates x_{tu}, each diagonal entry at these rows is divisible by p with probability $1/p$. Let us take this intuition and turn it into a listing algorithm for (a superset of the) sets $O \subseteq V_t$ that satisfy F_O.

Bipartitioning. For listing we will employ a meet-in-the-middle approach based on building each set $O \subseteq V_t$ from two parts using the following bipartitioning. Let $V_t^{(1)} \cup V_t^{(2)} = V_t$ be a bipartition with $|V_t^{(1)}| = \lceil n/3 \rceil$ and $|V_t^{(2)}| = n - 1 - \lceil n/3 \rceil$. Associate with each $O_1 \subseteq V_t^{(1)}$ a vector $z^{O_1} \in \{0, 1, \ldots, p-1, \infty\}^{V_{st}}$ with the entry at $u \in V_{st}$ defined by

$$z_u^{O_1} = \begin{cases} \infty & \text{if } u \in O_1; \\ \left(x_{tu} + \sum_{w \in O_1 : wu \in E} x_{wu}\right) \bmod p & \text{otherwise.} \end{cases} \tag{8}$$

Similarly, associate with each $O_2 \subseteq V_t^{(1)}$ a vector $z^{O_2} \in \{0, 1, \ldots, p-1, \infty\}^{V_{st}}$ with the entry at $u \in V_{st}$ defined by

$$z_u^{O_2} = \begin{cases} \infty & \text{if } u \in O_2; \\ \left(-\sum_{w \in O_2 : wu \in E} x_{wu}\right) \bmod p & \text{otherwise.} \end{cases} \tag{9}$$

Suppose now that we have $O_1 \subseteq V_t^{(1)}$ and $O_2 \subseteq V_t^{(2)}$ with $O = O_1 \cup O_2$. We claim that F_O holds only if the vectors z^{O_1} and z^{O_2} agree in at most k entries. Indeed, observe that $z_u^{O_1} = z_u^{O_2}$ holds only if both $u \in V_{st} \setminus O$ and the (u, u)-entry of L_s^O is divisible by p. That is, $z_u^{O_1} = z_u^{O_2}$ implies the entire row u of L_s^O consists only of elements divisible by p. Thus it suffices to list all pairs (O_1, O_2) such that z^{O_1} and z^{O_2} have at most k agreements.

Balanced and unbalanced sets. To set up the listing procedure, let us now partition the index domain V_{st} of our vectors into $b = \lfloor 3 \log_2 p \rfloor$ pairwise disjoint sets $S_1, S_2, \ldots, S_b$ such that we have $\lfloor (n-2)/b \rfloor \leq |S_i| \leq \lceil (n-2)/b \rceil$.

Let us split the sets $O \subseteq V_t$ into two types. Let us say that O is *balanced* if $(1/2 - \beta)n/b \leq |(V_{st} \setminus O) \cap S_i| \leq (1/2 + \beta)n/b$ holds for all $i = 1, 2, \ldots, b$; otherwise O is *unbalanced*. Recalling that $\sum_{j=0}^{\ell} \binom{n}{j} \leq 2^{nH(\ell/n)}$ holds for all integers $1 \leq \ell \leq n/2$, where $H(\rho) = -\rho \log_2 \rho - (1-\rho)\log_2(1-\rho)$ is the binary entropy function, observe that there are in total at most

$$\begin{aligned} 2^{n+1-\min_i |S_i|} b \sum_{j=0}^{\lceil (1/2-\beta)n/b \rceil} \binom{\lfloor n/b+2 \rfloor}{j} &\leq 2^{n-(n-2)/b+3} 2^{(n/b+2)H(1/2-\beta)} b \\ &\leq 2^{n(1-(1-H(1/2-\beta))/b)+7} b \end{aligned} \tag{10}$$

sets O that are unbalanced.

Precomputation and listing. Suppose that $O_1 \subseteq V_t^{(1)}$ and $O_2 \subseteq V_t^{(1)}$ are *compatible* in the sense that z^{O_1} and z^{O_2} agree in at most k entries. For $S \subseteq V_{st}$ and a vector z whose entries

are indexed by V_{st}, let us write z_S for the restriction of z to S. If O_1 and O_2 are compatible, then by an averaging argument there must exist an $i = 1, 2, \ldots, b$ such that $z_{S_i}^{O_1}$ and $z_{S_i}^{O_2}$ agree in at most k/b entries. In particular, this enables us to iterate over O_2 and list all compatible O_1 by focusing only on each restriction to S_i for $i = 1, 2, \ldots, b$. Furthermore, the search inside S_i can be precomputed to look-up tables. Indeed, for each $i = 1, 2, \ldots, b$ and each key $g \in \{0, 1, \ldots, p-1, \infty\}^{S_i}$, let us build a complete list of all subsets $O_1 \subseteq V_t^{(1)}$ such that $z_{S_i}^{O_1}$ and g agree in at most k/b entries. These b look-up tables can be built by processing in total at most

$$\sum_{i=1}^{b} 2^{V_t^{(1)}} (p+1)^{|S_i|} \leq 2^{n/3+7} 2^{(n/(\lfloor 3\log_2 p \rfloor)+2)\log_2(p+1)} \log_2 p = O(2^{0.87n})$$

pairs (O_1, g). This takes time $O^*(2^{0.87n})$ in total.

The main listing procedure now considers each $O_2 \subseteq V_t^{(2)}$ in turn, and for each $i = 1, 2, \ldots, b$ consults the look-up table for direct access to all O_1 such that $z_{S_i}^{O_1}$ and $z_{S_i}^{O_2}$ agree in at most k/b entries. In particular this will list all compatible pairs (O_1, O_2) and hence all sets $O = O_1 \cup O_2$ such that F_O holds.

Expected running time. Let us now analyze the expected running time of the algorithm. We start by deriving an upper bound for the expected number of pairs (O_1, O_2) considered by the main listing procedure. First, observe that the total number of pairs (O_1, O_2) considered by the procedure with $O = O_1 \cup O_2$ unbalanced is bounded from above by our upper bound (10) for the total number of unbalanced O. Indeed, $O_1 = O \cap V_t^{(1)}$ and $O_2 = O \cap V_t^{(2)}$ are uniquely determined by O.

Next, for a pair (O_1, O_2) with balanced $O = O_1 \cup O_2$ and $i = 1, 2, \ldots, b$, let $G_{O_1,O_2,i}$ be the event that $z_{S_i}^{O_1}$ and $z_{S_i}^{O_2}$ agree in at most k/b entries. We seek an upper bound for the probability of $G_{O_1,O_2,i}$ to obtain an upper bound for the expected number of pairs with balanced $O = O_1 \cup O_2$ considered by the main listing procedure. Let $A_{O_1,O_2,i}$ be the number of entries in which $z_{S_i}^{O_1}$ and $z_{S_i}^{O_2}$ agree. We observe that $A_{O_1,O_2,i}$ is binomially distributed with expectation $|(V_t \setminus O) \cap S_i|/p$. Since O is balanced, we have $(1/2 - \beta)n/b \leq |(V_t \setminus O) \cap S_i| \leq (1/2 + \beta)n/b$. We also recall that $k = \lfloor (1-\lambda)(1/2-\beta)n/p \rfloor$. A standard Chernoff bound now gives

$$\begin{aligned}
\Pr(G_{O_1,O_2,i}) &\leq \Pr\big(A_{O_1,O_2,i} \leq k/b\big) \\
&\leq \Pr\big(A_{O_1,O_2,i} \leq (1-\lambda)|(V_t \setminus O) \cap S_i|/p\big) \\
&\leq \exp\big(-\lambda^2 |(V_t \setminus O) \cap S_i|/(2p)\big) \\
&\leq \exp\big(-\lambda^2 (1/2-\beta)n/(2pb)\big)\,.
\end{aligned}$$

Recalling that $b = \lfloor 3\log_2 p \rfloor$, the main listing procedure thus considers in expectation at most $2^n \exp\big(-\lambda^2(1/2-\beta)n/(2p(3\log_2 p))\big)$ pairs (O_1, O_2) with $O = O_1 \cup O_2$ balanced. Recalling our upper bound for the total number of unbalanced sets (10), we thus have that the main listing procedure runs in $O^*\big(2^n \exp\big(-\lambda^2(1/2-\beta)n/(2p(3\log_2 p))\big) + 2^{n(1-(1-H(1/2-\beta))/(3\log_2 p))}\big)$ expected time. Recalling that precomputation runs in $O^*(2^{0.87n})$ time, we thus have for $\beta = 1/6$ that the entire algorithm runs in $O^*(2^{n(1-\lambda^2/(19p\log_2 p))})$ expected time and computes $|\mathrm{hp}(G, s, t)|$ modulo $p^{\lfloor (1-\lambda)n/(3p) \rfloor}$. This completes the proof of Theorem 3. ◀

5 Directed Hamiltonicity via quasi-Laplacian determinants

This section proves Theorem 4. Let G be a directed n-vertex graph given as input.

Finding a maximum independent set. Let $B \cup Y = V(G)$ be a partition of the vertex set into two disjoint sets B ("blue") and Y ("yellow") such that no arc has both of its ends in Y. That is, Y is an independent set.

We can find an Y of the maximum possible size as follows. First, in time polynomial in n compute the maximum-size matching in the undirected graph obtained from G by disregarding the orientation of the arcs. This maximum-size matching must consist of at least $\lfloor n/2 \rfloor$ edges or G does not admit a Hamiltonian cycle. (Indeed, from a Hamiltonian cycle we can obtain a matching with $\lfloor n/2 \rfloor$ edges by taking every other arc in the cycle.) Since for each matching edge it holds that both ends of the edge cannot be in an independent set, we can in time $O^*(3^{n/2})$ find a maximum-size independent set Y of G. Furthermore, $\alpha(G) = |Y| \leq \lfloor n/2 \rfloor + 1$, so we are within our budget of $O^*(3^{n(G)-\alpha(G)})$ in terms of running time. In fact, $|Y| \leq \lfloor n/2 \rfloor$ or otherwise G trivially does not admit a Hamiltonian cycle.

The symbolic quasi-Laplacian. We will first define the quasi-Laplacian and then give intuition for its design. Let us work over a field of characteristic 2. For each $y \in Y$ introduce a copy y_{in} and let Y_{in} be the set of all such copies. Similarly, for each $y \in Y$ introduce a copy y_{out} and let Y_{out} be the set of all such copies. We assume that Y_{in} and Y_{out} are disjoint. For each $j \in Y_{\text{in}} \cup Y_{\text{out}}$ let us write $\underline{j} \in Y$ for the underlying element of Y of which j is a copy. Let B_* be a set of $n - 2|Y|$ elements that is disjoint from both Y_{in} and Y_{out}. For each $uv \in E$ and each $j \in B_* \cup Y_{\text{in}} \cup Y_{\text{out}}$, introduce an indeterminate $x_{uv}^{(j)}$.

Select an arbitrary vertex $s \in B$ for purposes of breaking symmetry and let $I, O \subseteq B$. The *quasi-Laplacian* $Q^{I,O,s} = Q^{I,O,s}(G)$ of G with *skew at* s be the $n \times n$ matrix whose rows are indexed by $u \in B \cup Y$ and whose columns are indexed by $j \in B_* \cup Y_{\text{in}} \cup Y_{\text{out}}$ such that the (u, j)-entry is defined by

$$q_{uj}^{I,O,s} = \begin{cases} \sum_{w \in O : wu \in E, u \in I} x_{wu}^{(j)} & \\ \quad + \sum_{w \in I : uw \in E, u \in O \setminus \{s\}} x_{uw}^{(j)} & \text{(a) if } u \in B \text{ and } j \in B_*; \\ x_{u\underline{j}}^{(j)} & \text{(b) if } u \in O \setminus \{s\} \text{ and } j \in Y_{\text{in}} \text{ with } u\underline{j} \in E; \\ x_{\underline{j}u}^{(j)} & \text{(c) if } u \in I \text{ and } j \in Y_{\text{out}} \text{ with } \underline{j}u \in E; \\ \sum_{w \in O : wu \in E} x_{wu}^{(j)} & \text{(d) if } u \in Y \text{ and } j \in Y_{\text{in}} \text{ with } u = \underline{j}; \\ \sum_{w \in I : uw \in E} x_{uw}^{(j)} & \text{(e) if } u \in Y \text{ and } j \in Y_{\text{out}} \text{ with } u = \underline{j}; \\ 0 & \text{otherwise.} \end{cases} \tag{11}$$

Let us next give some intuition for (11) before proceeding with the proof.

Analogously to the Laplacian (3), the quasi-Laplacian (11) has been designed so that the monomials of each row $u \in B \cup Y$ of $Q^{I,O,s}$ control the assignment of either an in-arc or an out-arc to u in an incidence assignment, and the skew at s is used to break symmetry so that s is always assigned an in-arc to s. In particular, without the skew at row s and with $I = O$, each column of $Q^{I,O,s}$ would sum to zero, in analogy with the (non-punctured) Laplacian.

Let us now give intuition for the columns $j \in Y_{\text{in}}$ and $j \in Y_{\text{out}}$. First, observe by (b) and (d) in (11) that selecting a monomial from column $j \in Y_{\text{in}}$ corresponds to making sure that the in-degree of $\underline{j}$ is 1. Such a selection may be either a "quasi-diagonal" assignment of the in-arc $w\underline{j}$ to $u = \underline{j} \in Y$ via (d) for some $w \in B$; or an "off-diagonal" assignment of the out-arc $u\underline{j}$ to $u \in B$ via (b). Second, observe by (c) and (e) in (11) that selecting a monomial from column $j \in Y_{\text{out}}$ corresponds to making sure that the out-degree of $\underline{j}$ is 1. *Thus, the columns $j \in Y_{\text{in}} \cup Y_{\text{out}}$ enable us to make sure that an incidence assigment has both in-degree* 1 *and out-degree* 1 *at each $u \in Y$ without the use of sieving. This gives us the speed-up from $O^*(3^n)$ to $O^*(3^{n-|Y|})$ running time.* Observe also that the structure for the quasi-Laplacian

$Q^{I,O,s}$ is enabled precisely because Y is an independent set and thus no arc contributes to both in-degree and out-degree in Y.

The quasi-Laplacian determinant sieve. Recalling that we are working over a field of characteristic 2, let us study the sum

$$\sum_{\substack{I,O\subseteq B\\ I\cup O=B\\ s\in I}} \det Q^{I,O,s} = \sum_{I\subseteq B}\sum_{O\subseteq B} \det Q^{I,O,s} = \sum_{\substack{\sigma:B\cup Y\to B_*\cup Y_{\text{in}}\cup Y_{\text{out}}\\ \sigma \text{ bijective}}} \sum_{I\subseteq B}\sum_{O\subseteq B}\prod_{u\in B\cup Y} q^{I,O,s}_{u,\sigma(u)}\,. \quad (12)$$

Observe that the first equality in (12) holds because $Q^{I,O,s}$ has by (11) an identically zero row unless $I\cup O = B$ and $s\in I$; the second equality holds by definition of the determinant in characteristic 2 and changing the order of summation. From (11) and the right-hand side of (12) it is immediate that (12) is either identically zero or a homogeneous polynomial of degree n in the $n|E|$ indeterminates $x^{(j)}_{uv}$ for $j\in B_*\cup Y_{\text{in}}\cup Y_{\text{out}}$ and $uv\in E$. [4] We claim that (12) is not identically zero if and only if G admits at least one spanning cycle. Furthermore, each spanning cycle in G defines precisely $|B_*|!$ distinct monomials in (12).

To establish the claim, fix a bijection $\sigma : B\cup Y\to B_*\cup Y_{\text{in}}\cup Y_{\text{out}}$. Let us write $M(\sigma)$ for the set of all incidence assignments $\mu : B\cup Y\to E$ that are *proper* in the sense that all of the following six requirements hold (cf. (11)):

- (s): $\mu(s)$ is an in-arc to s;
- (a): for all $u\in B$ with $\sigma(u)\in B_*$ it holds that $\mu(u)$ has both of its vertices in B;
- (b): for all $u\in B$ with $\sigma(u)\in Y_{\text{in}}$ it holds that $\mu(u)$ is an in-arc to $\sigma(u)$;
- (c): for all $u\in B$ with $\sigma(u)\in Y_{\text{out}}$ it holds that $\mu(u)$ is an out-arc from $\sigma(u)$;
- (d): for all $u\in Y$ with $\sigma(u)\in Y_{\text{in}}$ it holds that $\mu(u)$ is an in-arc to u and $u=\sigma(u)$; and
- (e): for all $u\in Y$ with $\sigma(u)\in Y_{\text{out}}$ it holds that $\mu(u)$ is an out-arc from u and $u=\sigma(u)$.

Observe that each $\mu\in M(\sigma)$ defines a collection of n arcs $\mu(B\cup Y)=\{\mu(u) : u\in B\cup Y\}$. Let us write Z^μ_{in} (respectively, Z^μ_{out}) for the set of vertices in $B\cup Y$ with zero in-degree (out-degree) with respect to the arcs in $\mu(B\cup Y)$. Since σ is a bijection and thus has a preimage for each $j\in Y_{\text{in}}\cup Y_{\text{out}}$, from (b,c,d,e) above it follows that $Z^\mu_{\text{in}}\subseteq B$ and $Z^\mu_{\text{out}}\subseteq B$. Furthermore, from (a,b,c,d,e) it follows that for the arcs in $\mu(B\cup Y)$ the sum of the in-degrees (and the sum of the out-degrees) of the vertices in B is $|B| = |B_*|+|Y|$. Thus, we have that Z^μ_{in} and Z^μ_{out} are both empty if and only if for the arcs $\mu(B\cup Y)$ both the in-degree and the out-degree of every vertex $u\in B\cup Y$ is 1. (Note that the claim is immediate for $u\in Y$ by (b,c,d,e) and bijectivity of σ.)

Let us now study the right-hand side of (12) for a fixed σ. Using (a,b,c,d,e) and (11) to rearrange in terms of incidence assignments, we have

$$\sum_{I\subseteq V}\sum_{O\subseteq V}\prod_{u\in B\cup Y} q^{I,O,s}_{u,\sigma(u)} = \sum_{\mu\in M(\sigma)}\prod_{u\in B\cup Y} x^{(\sigma(u))}_{\mu(u)} \sum_{I\subseteq Z^\mu_{\text{in}}}\sum_{O\subseteq Z^\mu_{\text{out}}} 1\,. \quad (13)$$

Since we are working in characteristic 2, all other $\mu\in M(\sigma)$ except those for which $\mu(B\cup Y)$ is a cycle cover will cancel in the right-hand side of (13).

Take the sum of (13) over all bijections σ. Consider an arbitrary cycle cover of $B\cup Y$. Let C be a cycle in this cycle cover. Assuming that C does not contain s, we can realize C in an incidence assignment $\mu : B\cup Y\to E$ either using (1) or (2). If C contains s and μ is proper,

[4] Our algorithm for deciding Hamiltonicity will naturally not work with a symbolic representation of (12) but rather in a homomorphic image under a random evaluation homomorphism.

only the realization (1) is possible by (s). To see that realization with a proper $\mu \in M(\sigma)$ for some σ is possible, consider an arbitrary $u \in B \cup Y$ and observe that each image $\mu(u)$ by (b,c,d,e) uniquely determines the image $\sigma(u) \in Y_{\text{in}} \cup Y_{\text{out}}$ when $\mu(u)$ has one vertex in Y; when $\mu(u)$ has both vertices in B, an unused $\sigma(u) \in B_*$ may be chosen arbitrarily so that $\mu \in M(\sigma)$. It follows that any cycle cover with c cycles is realized as exacly $|B_*|!$ distinct monomials $\prod_{u \in B \cup Y} x_{\mu(u)}^{(\sigma(u))}$ in (12), each with coefficient 2^{c-1}. This coefficient is nonzero if and only if $c = 1$.

Completing the algorithm. To detect whether the given n-vertex directed graph G admits a Hamiltonian cycle, first decompose the vertex set into disjoint $V = B \cup Y$ with Y an independent set of size $|Y| = \alpha(G)$ using the algorithm described earlier. Next, in time $O^*(1)$ construct an irreducible polynomial of degree $2\lceil \log_2 n \rceil$ over $\mathbb{F}_2$ (see e.g. von zur Gathen and Gerhard [23, §14.9]) to enable arithmetic in the finite field of order $q = 2^{2\lceil \log_2 n \rceil} \geq n^2$ in time $O^*(1)$ for each arithmetic operation. Next, assign an independent uniform random value from $\mathbb{F}_q$ to each indeterminate $x_{uv}^{(j)}$ with $j \in B_* \cup Y_{\text{in}} \cup Y_{\text{out}}$ and $uv \in E$. Finally, using the assigned values for the indeterminates, compute the left-hand side of (12) using, for example, Gaussian elimination to compute each determinant $\det Q^{I,O,s}$ in $O^*(1)$ operations in $\mathbb{F}_q$. Let us write $r \in \mathbb{F}_q$ for the result of this computation. In particular, we can compute r from a given G in total $O^*(3^{|B|}) = O^*(3^{n(G)-\alpha(G)})$ operations in $\mathbb{F}_q$, and consequently in total $O^*(3^{n(G)-\alpha(G)})$ time. If (12) is identically zero, then clearly $r = 0$ with probability 1. If (12) is not identically zero (and hence a homogeneous polynomial of degree $d = n$ in the indeterminates) then by the DeMillo–Lipton–Schwartz–Zippel lemma [14, 22, 25] we have $r \neq 0$ with probability at least $1 - d/q \geq 1 - n/n^2 \geq 1 - 1/n = 1 - o(1)$. Thus we can decide whether G is Hamiltonian based on whether $r \neq 0$. In particular this gives probability $o(1)$ of reporting a false negative. This completes the proof of Theorem 4. ◀

Improved Hardness for Cut, Interdiction, and Firefighter Problems*†

Euiwoong Lee

Carnegie Mellon University, Pittsburgh, PA, USA
euiwoonl@cs.cmu.edu

Abstract

We study variants of the classic *s-t* cut problem and prove the following improved hardness results assuming the Unique Games Conjecture (UGC).

- For *Length-Bounded Cut* and *Shortest Path Interdiction*, we show that both problems are hard to approximate within any constant factor, even if we allow bicriteria approximation. If we want to cut vertices or the graph is directed, our hardness ratio for Length-Bounded Cut matches the best approximation ratio up to a constant. Previously, the best hardness ratio was 1.1377 for Length-Bounded Cut [4] and 2 for Shortest Path Interdiction [24].
- For any constant $k \geq 2$ and $\epsilon > 0$, we show that *Directed Multicut* with k source-sink pairs is hard to approximate within a factor $k - \epsilon$. This matches the trivial k-approximation algorithm. By a simple reduction, our result for $k = 2$ implies that *Directed Multiway Cut* with two terminals (also known as *s-t Bicut*) is hard to approximate within a factor $2 - \epsilon$, matching the trivial 2-approximation algorithm.
- Assuming a variant of the UGC (implied by another variant of Bansal and Khot [6]), we prove that it is hard to approximate *Resource Minimization Fire Containment* within any constant factor. Previously, the best hardness ratio was 2 [28]. For directed layered graphs with b layers, our hardness ratio $\Omega(\log b)$ matches the best approximation algorithm [3, 9].

Our results are based on a general method of *converting an integrality gap instance to a length-control dictatorship test* for variants of the *s-t* cut problem, which may be useful for other problems.

1 Introduction

One of the most important implications of the Unique Games Conjecture (UGC, [25]) is the results of Khot et al. [26] and Raghavendra [40], which say that for any maximum constraint satisfaction problem (Max-CSP), an integrality gap instance of the standard semidefinite programming (SDP) relaxation can be converted to the NP-hardness result with the same gap. These results initiated the study of beautiful connections between power of convex relaxations and hardness of approximation, from which surprising results for both subjects have been discovered.

While their results hold for problems in Max-CSPs, the framework of *converting an integrality gap instance to hardness* has been successfully applied to covering and graph cut problems. For graph cut problems, Manokaran et al. [34] showed that for *Undirected Multiway Cut* and its generalizations, an integrality gap of the standard linear programming (LP) relaxation implies the hardness result assuming the UGC. Their result is further generalized by Ene et al. [16] by formulating them as *Min-CSPs*. In addition, Kumar et al. [29] studied *Strict CSPs* and showed the same phenomenon for the standard LP relaxation.

One of the limitations of the previous CSP-based transformations from LP gap instances to hard instances is based on the fact that they do not usually preserve the desired structure of the constraint hypergraph.[1] For example, consider the *Length-Bounded Edge Cut* problem where the input consists of a graph $G = (V, E)$, two vertices $s, t \in V$, and a constant $l \in \mathbb{N}$, and the goal is to remove the fewest edges to ensure there is no path from s to t of length less than l. This problem can be viewed as a special case of *Hypergraph Vertex Cover* (HVC) by viewing each edge as a vertex of a hypergraph and creating a hyperedge for every s-t path of length less than l. While HVC is in turn a Strict CSP, its integrality gap instance cannot be converted to hardness using Kumar et al. [29] as a black-box, since the set of hyperedges created in the resulting hard instance is not guaranteed to correspond to the set of short s-t paths of some graph.

For Undirected Multiway Cut, Manokaran et al. [34] bypassed this difficulty by using 2-ary constraints so that the resulting constraint hypergraph becomes a graph again. For *Undirected Node-weighted Multiway Cut*, Ene et al. [16] used the equivalence to *Hypergraph Multiway Cut* [38] so that the resulting hypergraph does not need to satisfy additional structure. These problems are then formulated as a Min-CSP by using many labels which are supposed to represent different connected components. However, these Min-CSP based techniques often require nontrivial problem-specific ideas and do not seem to be easily generalized to many other cut problems.

We study variants of the classical s-t cut problem in both directed and undirected graphs that have been actively studied. We prove the optimal hardness or the first super-constant hardness for them. See Section 1.1 for the definitions of the problems and our results. All our results are based on the general framework of converting an integrality gap instance to a *length-control dictatorship test*. The structure of our length-control dictatorship tests allows us to naturally convert an integrality gap instance for the basic LP for various cut problems to hardness based on the UGC. Section 1.2 provides more detailed intuition of this framework. We believe that our framework is general and will be useful to prove tight inapproximability of other cut problems.

1.1 Problems and Results

Length-Bounded Cut and Shortest Path Interdiction. The *Length-Bounded Cut* problem is a natural variant of s-t cut, where given a graph (directed or undirected), $s, t \in V$, and an integer l, we only want to cut s-t paths of length strictly less than l.[2] Its practical motivation is based on the fact that in most communication / transportation networks, short paths are preferred to be used to long paths [32].

Lovász et al. [31] gave an exact algorithm for Length-Bounded Vertex Cut ($l \leq 5$) in undirected graphs. Mahjoub and McCormick [32] proved that Length-Bounded Edge Cut

[1] One of notable exceptions we are aware is the result of Guruswami et al. [21], using Kumar et al. [29] to show that k-Uniform k-Partite Hypergraph Vertex Cover is hard to approximate within a factor $\frac{k}{2} - \epsilon$ for any $\epsilon > 0$.

[2] It is more conventional to cut s-t paths of length *at most* l. We use this slightly nonconventional way to be more consistent with Shortest Path Interdiction.

admits an exact polynomial time algorithm for $l \leq 4$ in undirected graphs. Baier et al. [4] showed that both Length-Bounded Vertex Cut ($l > 5$) and Length-Bounded Edge Cut ($l > 4$) are NP-hard to approximate within a factor 1.1377. They presented $O(\min(l, \frac{n}{l})) = O(\sqrt{n})$-approximation algorithm for Length-Bounded Vertex Cut and $O(\min(l, \frac{n^2}{l^2}, \sqrt{m})) = O(n^{2/3})$-approximation algorithm for Length-Bounded Edge Cut, with matching LP gaps. Length-Bounded Cut problems have been also actively studied in terms of their fixed parameter tractability [19, 15, 8, 17].

If we exchange the roles of the objective k and the length bound l, the problem becomes *Shortest Path Interdiction*, where we want to maximize the length of the shortest s-t path after removing at most k vertices or edges. It is also one of the central problems in a broader class of *interdiction* problems, where an *attacker* tries to remove some edges or vertices to destroy a desirable property (e.g., short s-t distance, large s-t flow, cheap MST) of a network (see the survey of [42]). The study of Shortest Path Interdiction started in 1980's when the problem was called as the *k-most-vital-arcs* problem [14, 33, 5] and proved to be NP-hard [5]. Khachiyan et al. [24] proved that it is NP-hard to approximate within a factor less than 2. While many heuristic algorithms were proposed [23, 7, 35] and hardness in planar graphs [39] was shown, whether the general version admits a constant factor approximation was still unknown.

Given a graph $G = (V, E)$ and $s, t \in V$, let $\mathsf{dist}(G)$ be the length of the shortest s-t path. For $V' \subseteq V$, let $G \setminus V'$ be the subgraph induced by $V \setminus V'$. For $E' \subseteq E$, we use the same notation $G \setminus E'$ to denote the subgraph $(V, E \setminus E')$. We primarily study undirected graphs. We first present our results for the vertex version of both problems (collectively called as *Short Path Vertex Cut* onwards).

▶ **Theorem 1.** *Assuming the Unique Games Conjecture, for infinitely many values of constant $l \in \mathbb{N}$, the following three tasks are NP-hard: Given an undirected graph $G = (V, E)$ and $s, t \in V$ where there exists $C^* \subseteq V \setminus \{s, t\}$ such that $\mathsf{dist}(G \setminus C^*) \geq l$,*

1. *Find $C \subseteq V \setminus \{s, t\}$ such that $|C| \leq \Omega(l) \cdot |C^*|$ and $\mathsf{dist}(G \setminus C) \geq l$.*
2. *Find $C \subseteq V \setminus \{s, t\}$ such that $|C| \leq |C^*|$ and $\mathsf{dist}(G \setminus C) \geq O(\sqrt{l})$.*
3. *Find $C \subseteq V \setminus \{s, t\}$ such that $|C| \leq \Omega(l^{\frac{\epsilon}{2}}) \cdot |C^*|$ and $\mathsf{dist}(G \setminus C) \geq O(l^{\frac{1+\epsilon}{2}})$ for some $0 < \epsilon < 1$.*

The first result shows that Length Bounded Vertex Cut is hard to approximate within a factor $\Omega(l)$. This matches the best $O(l)$-approximation [4] when l is a constant. The second result shows that Shortest Path Vertex Interdiction is hard to approximate with in a factor $\Omega(\sqrt{\mathsf{OPT}})$, and the third result rules out *bicriteria approximation* – for any constant c, it is hard to approximate both l and $|C^*|$ within a factor of c.

The above results hold for directed graphs by definition. Our hard instances will have a natural *layered* structure, so it can be easily checked that the same results (up to a constant) hold for directed acyclic graphs. Since one vertex can be split as one directed edge, the same results hold for the edge version in directed acyclic graphs.

For Length-Bounded Edge Cut and Shortest Path Edge Interdiction in undirected graphs (collectively called *Short Path Edge Cut* onwards), we prove the following theorems.

▶ **Theorem 2.** *Assuming the Unique Games Conjecture, for infinitely many values of constant $l \in \mathbb{N}$, the following three tasks are NP-hard: Given an undirected graph $G = (V, E)$ and $s, t \in V$ where there exists $C^* \subseteq E$ such that $\mathsf{dist}(V \setminus C^*) \geq l$,*

1. *Find $C \subseteq E$ such that $|C| \leq \Omega(\sqrt{l}) \cdot |C^*|$ and $\mathsf{dist}(G \setminus C) \geq l$.*
2. *Find $C \subseteq E$ such that $|C| \leq |C^*|$ and $\mathsf{dist}(G \setminus C) \geq l^{\frac{2}{3}}$.*
3. *Find $C \subseteq E$ such that $|C| \leq \Omega(l^{\frac{2\epsilon}{3}}) \cdot |C^*|$ and $\mathsf{dist}(G \setminus C) \geq O(l^{\frac{2+2\epsilon}{3}})$ for some $0 < \epsilon < \frac{1}{2}$.*

Our hardness factors for the undirected edge versions, $\Omega(\sqrt{l})$ for Length-Bounded Edge Cut and $\Omega(\sqrt[3]{\mathsf{OPT}})$ for Shortest Path Edge Interdiction, are slightly weaker than those for their vertex counterparts, but we are not aware of any approximation algorithm specialized for the undirected edge versions. It is an interesting open problem whether there exist better approximation algorithms for the undirected edge versions.

Directed Multicut and Directed Multiway Cut. Given a directed graph and two vertices s and t, one of the most natural variants of s-t cut is to remove the fewest edges to ensure that there is no directed path from s to t and no directed path from t to s. This problem is known as *s-t Bicut* and admits the trivial 2-approximation algorithm by computing the minimum s-t cut and t-s cut.

Directed Multiway Cut is a generalization of s-t Bicut that has been actively studied. Given a directed graph with k terminals $s_1, \ldots, s_k$, the goal is to remove the fewest number of edges such that there is no path from s_i to s_j for any $i \neq j$. Directed Multiway Cut also admits 2-approximation [37, 11]. If k is allowed to increase polynomially with n, there is a simple reduction from Vertex Cover that shows $(2-\epsilon)$-approximation is hard under the UGC [18, 27].

Directed Multiway Cut can be further generalized to *Directed Multicut*. Given a directed graph with k source-sink pairs $(s_1, t_1), \ldots, (s_k, t_k)$, the goal is to remove the fewest number of edges such that there is no path from s_i to t_i for any i. Computing the minimum s_i-t_i cut for all i separately gives the trivial k-approximation algorithm. Chuzhoy and Khanna [13] showed Directed Multicut is hard to approximate within a factor $2^{\Omega(\log^{1-\epsilon} n)} = 2^{\Omega(\log^{1-\epsilon} k)}$ when k is polynomially growing with n. Agarwal et al. [2] showed $\tilde{O}(n^{\frac{11}{23}})$-approximation algorithm, which improves the trivial k-approximation when k is large.

Chekuri and Madan [11] showed simple approximation-preserving reductions from Directed Multicut with $k = 2$ to s-t Bicut (the other direction is trivially true), and *(Undirected) Node-weighted Multiway Cut* with $k = 4$ to s-t Bicut. Since Node-weighted Multiway Cut with $k = 4$ is hard to approximate within a factor $1.5 - \epsilon$ under the UGC [16] (matching the algorithm of Garg et al. [18]), the same hardness holds for s-t Bicut, Directed Multiway Cut, and Directed Multicut for constant k. To the best of our knowledge, $1.5 - \epsilon$ is the best hardness factor for constant k even assuming the UGC. In the same paper, Chekuri and Madan [11] asked whether a factor $2 - \epsilon$ hardness holds for s-t Bicut under the UGC.

We prove that for any constant $k \geq 2$, the trivial k-approximation for Directed Multicut might be optimal. Our result for $k = 2$ gives the optimal hardness result for s-t Bicut, answering the question of Chekuri and Madan.

▶ **Theorem 3.** *Assuming the Unique Games Conjecture, for every $k \geq 2$ and $\epsilon > 0$, Directed Multicut with k source-sink pairs is NP-hard to approximate within a factor $k - \epsilon$.*

▶ **Corollary 4.** *Assuming the Unique Games Conjecture, for any $\epsilon > 0$, s-t Bicut is hard to approximate within a factor $2 - \epsilon$.*

▶ Remark. Chekuri and Madan [12] obtained an independent and different proof of Theorem 3.

RMFC. *Resource Minimization for Fire Containment (RMFC)* is a problem closely related to Length-Bounded Cut with the additional notion of time. Given a graph G, a vertex s, and a subset T of vertices, consider the situation where fire starts at s on Day 0. For each Day i ($i \geq 1$), we can *save* at most k vertices, and the fire spreads from currently burning vertices to its unsaved neighbors. Once a vertex is burning or saved, it remains so from then onwards. The process is terminated when the fire cannot spread anymore. RMFC asks to

find a strategy to save k vertices each day with the minimum k so that no vertex in T is burnt. These problems model the spread of epidemics or ideas through a social network, and have been actively studied recently [9, 3, 1, 10].

RMFC, along with other variants, is first introduced by Hartnell [22]. Another well-studied variant is called the *Firefighter* problem, where we are only given $s \in V$ and want to maximize the number of vertices that are not burnt at the end. It is known to be NP-hard to approximate within a factor $n^{1-\epsilon}$ for any $\epsilon > 0$ [3]. King and MacGillivray [28] proved that RMFC is hard to approximate within a factor less than 2. Anshelevich et al. [3] presented an $O(\sqrt{n})$-approximation algorithm for general graphs, and Chalermsook and Chuzhoy [9] showed that RMFC admits $O(\log^* n)$-approximation in trees. Very recently, the approximation ratio in trees has been improved to $O(1)$ [1]. Both Anshelevich et al. [3] and Chalermsook and Chuzhoy [9] independently studied directed layer graphs with b layers, showing $O(\log b)$-approximation.

Our final result on RMFC assumes a variant of the Unique Games Conjecture which is not known to be equivalent to the original UGC. Given a bipartite graph as an instance of Unique Games, it states that in the completeness case, all constraints incident on $(1-\epsilon)$ fraction of vertices in one side are satisfied, and in the soundness case, in addition to having a low value, every $\frac{1}{10}$ fraction of vertices on one side have at least a $\frac{9}{10}$ fraction of vertices on the other side as neighbors. Our conjecture is implied by the conjecture of Bansal and Khot [6] that is used to prove the hardness of *Minimizing Weighted Completion Time with Precedence Constraints* and requires a more strict expansion condition. See [30] for the exact statement.

▶ **Theorem 5.** *Assuming Conjecture 7.5 of [30], it is NP-hard to approximate RMFC in undirected graphs within any constant factor.*

Again, our reduction has a natural layered structure and the result holds for directed layered graphs. With b layers, we prove that it is hard to approximate with in a factor $\Omega(\log b)$, matching the best approximation algorithms [9, 3].

1.2 Techniques

All our results are based on a general method of *converting an integrality gap instance to a dictatorship test*. This method has been successfully applied by Raghavendra [40] for Max-CSPs, Manokaran et al. [34] and Ene et al. [16] for Multiway Cut and Min CSPs, and Kumar et al. [29] for strict CSPs, and by Guruswami et al. [21] for k-uniform k-partite Hypergraph Vertex Cover, and Chekuri and Madan [12] for Directed Multicut. As mentioned in the introduction, the previous CSP-based results do not generally preserve the structure of constraint hypergraphs or use ingenious and specialized tricks to reduce the problem to a CSP.

We bypass this difficulty by constructing a special class of dictatorship tests that we call *length-control dictatorship tests*. Consider a meta-problem where given a directed graph $G = (V, E)$, some terminal vertices, and a set $\mathcal{P}$ of *desired paths* between terminals, we want to remove the fewest number of non-terminal vertices to cut every path in $\mathcal{P}$. The integrality gap instances we use in this work [41, 4, 32, 9] share the common feature that every $p \in \mathcal{P}$ is of length at least r, and the fractional solution cuts $\frac{1}{r}$ fraction of each non-terminal vertex so that each path $p \in \mathcal{P}$ is cut. This gives a good LP value, and additional arguments are required to ensure that there is no efficient integral cut.

Given such an integrality gap instance, we construct our dictatorship test instance as follows. We replace every non-terminal vertex by a *hypercube* $\mathbb{Z}_r^R$ and put edges such that

for two vertices (v, x) and (w, y) where $v, w \in V$ and $x, y \in \mathbb{Z}_r^R$, there is an edge from (v, x) to (w, y) if (1) $(v, w) \in E$ and (2) $y_j = x_j + 1$ for all $j \in [R]$. The set of desired paths $\mathcal{P}'$ is defined to be $\{(s, (v_1, x_1), \ldots, (v_l, x_l), t) : (s, v_1, \ldots, v_l, t) \in \mathcal{P}\}$ (s, t denote some terminals). Note that each path in $\mathcal{P}'$ is also of length at least r. We want to ensure that in the *completeness case* (i.e., every hypercube reveals the same *influential coordinate*), there is a very efficient cut, while in the *soundness case* (i.e., no hypercube reveals an influential coordinate), there is no such efficient cut.

In the completeness case, let $q \in [R]$ be an influential coordinate. For each vertex (v, x) where $v \in V, x \in \mathbb{Z}_r^R$, remove (v, x) if $x_q = 0$. Consider a desired path $p = (s, (v_1, x_1), \ldots, (v_l, x_l), t) \in \mathcal{P}'$ for some terminals s, t and some $v_j \in V, x_j \in \mathbb{Z}_r^R$ $(1 \le j \le l)$, and let $y_j = (x_j)_q$. By our construction, $y_{j+1} = y_j + 1$ for $0 \le j < l$. Since p is desirable, $l \ge r$, so there exists j such that $y_j = (x_j)_q = 0$, but (v_j, x_j) is already removed by our previous definition. Therefore, every desired path is cut by this vertex cut. Note that this cut is integral and cuts exactly $\frac{1}{r}$ fraction of non-terminal vertices. This corresponds to the fractional solution to the gap instance that cuts $\frac{1}{r}$ fraction of every vertex.

For the soundness analysis, our final dictatorship test has additional *noise* vertices and edges to the test defined above. If no hypercube reveals an influential coordinate, the standard application of the invariance principle [36] proves that we can always take an edge between two hypercubes unless we almost completely cut one hypercube. We can then invoke the proof for the integrality gap instance to show that there is no efficient cut.

This idea is implicitly introduced by the work of Svensson [43] for Feedback Vertex Set (FVS) and DAG Vertex Deletion (DVD) by applying the *It ain't over till it's over theorem* to ingeniously constructed dictatorship tests with auxiliary vertices. Guruswami and Lee [20] gave a simpler construction and a new proof using the invariance principle instead of the It ain't over till it's over theorem. Our results are based on the observation that length-control dictatorship tests and LP gap instances *fool* algorithms in a similar way for various cut problems as mentioned above, so that the previous LP gap instances can be plugged into our framework to prove matching hardness results.

This method for the above meta-problem can be almost directly applied to Directed Multicut. For Length-Bounded Cut and RMFC in undirected graphs, we use the fact that the known integrality gap instances have a natural layered structure with s in the first layer and t in the last layer. Every edge is given a natural orientation, and the similar analysis can be applied. For Length-Bounded Cut, another set of edges called *long edges* are added to the dictatorship test. More technical work is required for edge cut versions in undirected graphs (Short Path Edge Cut), and the notion of time (RMFC).

Our framework seems general enough so that they can be applied to integrality gap instances to give strong hardness results. It would be interesting to further abstract this method of converting integrality gap instances to length-bounded dictatorship tests, as well as to apply it to other problems whose approximability is not well-understood.

2 Preliminaries

Graph Terminologies. Depending on whether we cut vertices or edges, we introduce weight $\mathsf{wt}(v)$ for each vertex v, or weight $\mathsf{wt}(e)$ for each edge e. Some weights can be ∞, which means that some vertices or edges cannot be cut. For vertex-weighted graphs, we naturally have $\mathsf{wt}(s) = \mathsf{wt}(t) = \infty$. To reduce the vertex-weighted version to the unweighted version, we duplicate each vertex according to its weight and replace each edge by a complete bipartite graph between corresponding copies. To reduce the edge-weighted version to the unweighted

version, we replace a single edge with parallel edges according to its weight. To reduce to simple graphs, we split each parallel into two edges by introducing a new vertex.

For the Length-Bounded Cut problems, we also introduce length $\mathsf{len}(e)$ for each edge e. It can be also dealt with serially splitting an edge according to its weight. We allow weights to be rational numbers, but as our hardness results are stated in terms of the length, all lengths in this work will be a positive integer.

For a path p, depending on the context, we abuse notation and interpret it as a set of edges or a set of vertices. The length of p is always defined to be the number of edges.

Gaussian Bounds for Correlated Spaces. We introduce the standard tools on correlated spaces from Mossel [36]. Given a probability space (Ω, μ) (we always consider finite probability spaces), let $\mathcal{L}(\Omega)$ be the set of functions $\{f : \Omega \to \mathbb{R}\}$ and for an interval $I \subseteq \mathbb{R}$, $\mathcal{L}_I(\Omega)$ be the set of functions $\{f : \Omega \to I\}$. For a subset $S \subseteq \Omega$, define *measure* of S to be $\mu(S) := \sum_{\omega \in S} \mu(\omega)$. A collection of probability spaces are said to be correlated if there is a joint probability distribution on them. We will denote k correlated spaces $\Omega_1, \dots, \Omega_k$ with a joint distribution μ as $(\Omega_1 \times \cdots \times \Omega_k, \mu)$.

Given two correlated spaces $(\Omega_1 \times \Omega_2, \mu)$, we define the correlation between Ω_1 and Ω_2 by

$$\rho(\Omega_1, \Omega_2; \mu) := \sup \{\mathsf{Cov}[f, g] : f \in \mathcal{L}(\Omega_1), g \in \mathcal{L}(\Omega_2), \mathsf{Var}[f] = \mathsf{Var}[g] = 1\}.$$

Given a probability space (Ω, μ) and a function $f \in \mathcal{L}(\Omega)$ and $p \in \mathbb{R}^+$, let $\|f\|_p := \mathbb{E}_{x \sim \mu}[|f(x)|^p]^{1/p}$.

Consider a product space $(\Omega^R, \mu^{\otimes R})$ and $f \in \mathcal{L}(\Omega^R)$. The *Efron-Stein decomposition* of f is given by

$$f(x_1, \dots, x_R) = \sum_{S \subseteq [R]} f_S(x_S)$$

where (1) f_S depends only on x_S and (2) for all $S \not\subseteq S'$ and all $x_{S'}$, $\mathbb{E}_{x' \sim \mu^{\otimes R}}[f_S(x') | x'_{S'} = x_{S'}] = 0$. The *influence* of the ith coordinate on f is defined by

$$\mathsf{Inf}_i[f] := \mathop{\mathbb{E}}_{x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_R} [\mathop{\mathsf{Var}}_{x_i}[f(x_1, \dots, x_R)].$$

The influence has a convenient expression in terms of the Efron-Stein decomposition.

$$\mathsf{Inf}_i[f] = \| \sum_{S : i \in S} f_S \|_2^2 = \sum_{S : i \in S} \|f_S\|_2^2.$$

We also define the *low-degree influence* of the ith coordinate.

$$\mathsf{Inf}_i^{\le d}[f] := \sum_{S : i \in S, |S| \le d} \|f_S\|_2^2.$$

For $a, b \in [0, 1]$ and $\rho \in (0, 1)$, let

$$\Gamma_\rho(a, b) := \Pr[X \le \Phi^{-1}(a), Y \ge \Phi^{-1}(1 - b)],$$

where X and Y are ρ-correlated standard Gaussian variables and Φ denotes the cumulative distribution function of a standard Gaussian. The following theorem bounds the product of two functions that do not share an influential coordinate in terms of their Gaussian counterparts.

▶ **Theorem 6** (Theorem 6.3 and Lemma 6.6 of [36]). *Let $(\Omega_1 \times \Omega_2, \mu)$ be correlated spaces such that the minimum nonzero probability of any atom in $\Omega_1 \times \Omega_2$ is at least α and such that $\rho(\Omega_1, \Omega_2; \mu) \le \rho$. Then for every $\epsilon > 0$ there exist τ, d depending on ϵ and α such that if $f : \Omega_1^R \to [0, 1], g : \Omega_2^R \to [0, 1]$ satisfy $\min(\mathsf{Inf}_i^{\le d}[f], \mathsf{Inf}_i^{\le d}[g]) \le \tau$ for all i, then $\mathbb{E}_{(x,y) \in \mu^{\otimes R}}[f(x)g(y)] \ge \Gamma_\rho(\mathbb{E}_x[f], \mathbb{E}_y[g]) - \epsilon$.*

Organization. The dictatorship tests for Short Path Edge Cut and Short Path Vertex Cut are presented in Section 3 and 4 respectively. Dictatorship tests for RMFC and Directed Multicut, as well as the reduction from Unique Games based on these tests, will appear in the full version of this paper [30].

3 Short Path Edge Cut

We propose our dictatorship test for Short Path Edge Cut that will be used for proving Unique Games hardness. It is parameterized by positive integers a, b, r, R. It is inspired by the integrality gap instances by Baier et al. [4] Mahjoub and and McCormick [32], and made such that the edge cuts that correspond to *dictators* behave the same as the fractional solution that cuts $\frac{1}{r}$ fraction of every edge. All graphs in this section are undirected.

For positive integers a, b, r, R, we construct $\mathcal{D}^{\mathsf{E}}_{a,b,r,R} = (V, E)$. Let $\Omega = \{0, \dots, r-1\}$, and $\mu : \Omega \mapsto [0,1]$ with $\mu(x) = \frac{1}{r}$ for each $x \in \Omega$. We also define a correlated probability space $(\Omega_1 \times \Omega_2, \nu)$ where both Ω_1, Ω_2 are copies of Ω. It is defined by the following process to sample $(x, y) \in \Omega^2$.

- Sample $x \in \{0, \dots, r-1\}$. Let $y = (x+1) \mod r$.
- With probability $1 - \frac{1}{r}$, output (x, y). Otherwise, resample $x, y \in \Omega$ independently and output (x, y).

Note that the marginal distribution of both x and y is equal to μ. Given $x = (x_1, \dots, x_R) \in \Omega^R$ and $y = (y_1, \dots, y_R) \in \Omega^R$, let $\nu^{\otimes R}(x, y) = \prod_{i=1}^{R} \nu(x_i, y_i)$. We define $\mathcal{D}^{\mathsf{E}}_{a,b,r,R} = (V, E)$ as follows.

- $V = \{s, t\} \cup \{v^i_x\}_{0 \le i \le b, x \in \Omega^R}$. Let v^i denote the set of vertices $\{v^i_x\}_{x \in \Omega^R}$.
- For any $x \in \Omega^R$, there is an edge from s to v^0_x and an edge from v^b_x to t, both with weight ∞ and length 1.
- For $0 \le i < b, x \in \Omega^R$, there is an edge (v^i_x, v^{i+1}_x) of length a and weight ∞. Call it a *long edge*.
- For any $0 \le i < b$ $x, y \in \Omega^R$, there is an edge (v^i_x, v^{i+1}_y) of length 1 and weight $\nu^{\otimes R}(x, y)$. Note that $\nu^{\otimes R}(x, y) > 0$ for any $x, y \in \Omega^R$. Call it a *short edge*. The sum of finite weights is b.

Completeness. We first prove that edge cuts that correspond to *dictators* behave the same as the fractional solution that gives $\frac{1}{r}$ to every short edge. Fix $q \in [R]$ and let E_q be the set of short edges defined by

$$E_q := \{(v^i_x, v^{i+1}_y) : 0 \le i < b, y_q \ne x_q + 1 \mod R \text{ or } (x_q, y_q) = (0, 1)\}.$$

When $(x, y) \in \Omega_1 \times \Omega_2$ is sampled according to ν, the probability that $y_q \ne x_q + 1 \mod R$ or $(x_q, y_q) = (0, 1)$ is at most $\frac{2}{r}$. The total weight of E_q is $\frac{2b}{r}$.

▶ **Lemma 7.** *After removing edges in E_q, the length of the shortest path is at least $a(b-r+1)$.*

Proof. Let $p = (s, v^{i_1}_{x^1}, \dots, v^{i_z}_{x^z}, t)$ be a path from s to t where $i_j \in \{0, \dots, b\}$ and $x^j \in \Omega^R$ for each $1 \le j \le z$. Let $y_j := (x^j)_q \in \{0, \dots, r-1\}$ for each $1 \le j \le z$.

For each $1 \le j < z$, the edge (p_j, p_{j+1}) is either a long edge or a short edge, and either taken forward (i.e., $i_j < i_{j+1}$) or backward (i.e., $i_j > i_{j+1}$). Let $z_{\mathsf{LF}}, z_{\mathsf{SF}}, z_{\mathsf{LB}}, z_{\mathsf{SB}}$ be the number of long edges taken forward, short edges taken forward, long edges taken backward, and shot edges taken backward, respectively ($z_{\mathsf{LF}} + z_{\mathsf{SF}} + z_{\mathsf{LB}} + z_{\mathsf{SB}} = z - 1$). By considering how i_j changes,

$$z_{\mathsf{LF}} + z_{\mathsf{SF}} - z_{\mathsf{LB}} - z_{\mathsf{SB}} = b. \tag{1}$$

Consider how y_j changes. Taking a long edge does not change y_j. Taking a short edge forward increases y_j by 1 mod r, taking a short edge backward decreases y_j by 1 mod r. Since E_q is cut, y_j can never change from 0 to 1. This implies

$$z_{\mathsf{SF}} - z_{\mathsf{SB}} \leq r - 1. \tag{2}$$

(1) − (2) yields $z_{\mathsf{LF}} - z_{\mathsf{LB}} \geq b - r + 1$. The total length of p is at least $a \cdot z_{\mathsf{LF}} \geq a(b - r + 1)$. ◀

Soundness. We first bound the correlation $\rho(\Omega_1, \Omega_2; \nu)$. The following lemma of Wenner [44] gives a convenient way to bound the correlation.

▶ **Lemma 8** (Corollary 2.18 of [44]). *Let $(\Omega_1 \times \Omega_2, \delta\mu + (1-\delta)\mu')$ be two correlated spaces such that the marginal distribution of at least one of Ω_1 and Ω_2 is identical on μ and μ'. Then,*

$$\rho(\Omega_1, \Omega_2; \delta\mu + (1-\delta)\mu') \leq \sqrt{\delta \cdot \rho(\Omega_1, \Omega_2; \mu)^2 + (1-\delta) \cdot \rho(\Omega_1, \Omega_2; \mu')^2}.$$

When (x, y) is sampled from ν, they are completely independent with probability $\frac{1}{r}$. Therefore, we have $\rho := \rho(\Omega_1, \Omega_2; \nu) \leq \sqrt{1 - \frac{1}{r}}$. By Sheppard's Formula,

$$\Gamma_\rho(\frac{1}{2}, \frac{1}{2}) = \frac{1}{4} + \frac{1}{2\pi}\arcsin(-\rho) \geq \frac{1}{4} - \frac{1}{2\pi}\arccos(\frac{1}{\sqrt{r}}) = \sum_{n=0}^{\infty} \frac{(2n)!}{4^n (n!)^2 (2n+1)} (\frac{1}{\sqrt{r}})^{2n+1} \geq \frac{1}{\sqrt{r}}.$$

Apply Theorem 6 ($\rho \leftarrow \rho, \alpha \leftarrow \frac{1}{r^3}, \epsilon \leftarrow \frac{\Gamma_\rho(\frac{1}{2},\frac{1}{2})}{3}$) to get τ and d. We will later apply this theorem with the parameters obtained here.

Fix an arbitrary subset $C \subseteq E$ of short edges. For $0 \leq i < b$, let $C_i = C \cap (v^i \times v^{i+1})$. Call a pair $(i, i+1)$ as the ith layer, and say it is blocked when $\nu^{\otimes R}(C_i) \geq \frac{\Gamma_\rho(\frac{1}{2},\frac{1}{2})}{2}$. Let b' be the number of blocked layers. For $0 \leq i \leq b$, let $S_i \subseteq v^i$ be such that $x \in S_i$ if there exists a path $(s, p_0, \ldots, p_i = v^i_x)$ such that

- For $0 \leq i' \leq i$, $p_{i'} \in v^{i'}$.
- For $0 \leq i' < i$, $(p_{i'}, p_{i'+1})$ is short if and only if the i'th layer is unblocked.

Let $f_i : \Omega^R \mapsto [0, 1]$ be the indicator function of S_i. We prove that if none of f_i reveals any *influential coordinate*, S_b is nonempty, implying that there exists a path using b' long edges and $b - b'$ short edges. Therefore, even after removing edges in C, the length of the shortest path is at most $2 + ab' + (b - b')$.

▶ **Lemma 9.** *Suppose that for any $0 \leq i \leq b$ and $1 \leq j \leq R$, $\mathsf{Inf}_j^{\leq d}[f_i] \leq \tau$. Then $S_b \neq \emptyset$.*

Proof. Assume towards contradiction that $S_b = \emptyset$. Since $S_0 = \Omega^R$ and $S_i = S_{i+1}$ if the ith layer is blocked (and we use long edges), there must exist i such that the ith layer is unblocked and $\mu^{\otimes R}(S_i) \geq \frac{1}{2}, \mu^{\otimes R}(S_{i+1}) < \frac{1}{2}$. All short edges between S_i and $v^{i+1} \setminus S_{i+1}$ are in C_i. Theorem 6 implies that $\nu^{\otimes R}(C_i) > \frac{2}{3}\Gamma_\rho(\frac{1}{2}, \frac{1}{2})$. This contradicts the fact that the ith layer is unblocked. ◀

In summary, in the completeness case, if we cut edges of total weight $k := k(a, b, r) = \frac{2b}{r}$, the length of the shortest path is at least $l := l(a, b, r) = a(b - r + 1)$. In the soundness case, even after cutting edges of total weight k', at most $\frac{2k'}{\Gamma_\rho(\frac{1}{2},\frac{1}{2})} \leq 2k'\sqrt{r}$ layers are blocked, the length of the shortest path is at most $l' = 2 + (b - 2k'\sqrt{r}) + 2ak'\sqrt{r}$.

- Let $a = 4, b = 2r - 1$ so that $k \leq 4, l = 4r$. Requiring $l' \geq l$ results in $k' = \Omega(\sqrt{r})$, giving a gap of $\Omega(\sqrt{r}) = \Omega(\sqrt{l})$ between the completeness case and the soundness case for Length-Bounded Edge Cut.
- Let $a = \sqrt{r}, b = 2r - 1$ so that $k \leq 4, l = r^{1.5}$. Requiring $k' \leq 4$ results in $l' = O(r)$, giving a gap of $\Omega(\sqrt{r}) = \Omega(l^{1/3})$ for Shortest Path Interdiction. Generally, $k' \leq O(r^\epsilon)$ results in $l' \leq O(r^{1+\epsilon})$, giving an $(O(r^\epsilon), O(r^{1/2-\epsilon}))$-bicriteria gap for any $\epsilon \in (0, \frac{1}{2})$.

4 Short Path Vertex Cut

We propose our dictatorship test for Short Path Vertex Cut that will be used for proving Unique Games hardness. It is parameterized by positive integers a, b, r, R and small $\epsilon > 0$. It is inspired by the integrality gap instances by Baier et al. [4] Mahjoub and and McCormick [32], and made such that the vertex cuts that correspond to *dictators* behave the same as the fractional solution that cuts $\frac{1}{r}$ fraction of every vertex. All graphs in this section are undirected.

For positive integers a, b, r, R, and $\epsilon > 0$, define $\mathcal{D}^{\mathsf{V}}_{a,b,r,R,\epsilon} = (V, E)$ be the graph defined as follows. Consider the probability space (Ω, μ) where $\Omega := \{0, \dots, r-1, *\}$, and $\mu : \Omega \mapsto [0, 1]$ with $\mu(*) = \epsilon$ and $\mu(x) = \frac{1-\epsilon}{r}$ for $x \neq *$.

- $V = \{s, t\} \cup \{v^i_x\}_{0 \leq i \leq b, x \in \Omega^R}$. Let v^i denote the set of vertices $\{v^i_x\}_x$.
- For $0 \leq i \leq b$ and $x \in \Omega^R$, $\mathsf{wt}(v^i_x) = \mu^{\otimes R}(x)$. Note that the sum of weights is $b + 1$.
- For any $0 \leq i \leq b$, there are edges from s to each vertex in v_i with length $ai + 1$ and edges from each vertex in v_i to t with length $(b - i)a + 1$.
- For $x, y \in \Omega^R$, we call that x and y are *compatible* if
  - For any $1 \leq j \leq R$: $[y_j = (x_j + 1) \mod r]$ or $[y_j = *]$ or $[x_j = *]$.
- For any $0 \leq i < b$ and compatible $x, y \in \Omega^R$, we have an edge (v^i_x, v^{i+1}_y) of length 1 (called a *short edge*).
- For any i, j such that $0 \leq i < j - 1 < b$ and compatible $x, y \in \Omega^R$, we have an edge (v^i_x, v^j_y) of length $(j - i)a$ (called a *long edge*).

Completeness. We first prove that vertex cuts that correspond to *dictators* behave the same as the fractional solution that gives $\frac{1}{r}$ to every vertex. For any $q \in [R]$, let $V_q := \{v^i_x : 0 \leq i \leq b, x_q = * \text{ or } 0\}$. Note that the total weight of V_q is $(b + 1)(\epsilon + \frac{1-\epsilon}{r})$.

▶ **Lemma 10.** *After removing vertices in V_q, the length of the shortest path is at least $a(b - r + 2)$.*

Proof. Let $p = (s, v^{i_1}_{x^1}, \dots, v^{i_z}_{x^z}, t)$ be a path from s to t where $i_j \in \{0, \dots, b\}$ and $x^j \in \Omega^R$ for each $1 \leq j \leq z$. Let $y_j := (x^j)_q \in \{0, \dots, r-1\}$ for each $1 \leq j \leq z$.

For each $1 \leq j < z$, the edge $(v^{i_j}_{x^j}, v^{i_{j+1}}_{x^{j+1}})$ is either a long edge or a short edge, and either taken forward (i.e., $i_j < i_{j+1}$) or backward (i.e., $i_j > i_{j+1}$). Let $z_{\mathsf{LF}}, z_{\mathsf{SF}}, z_{\mathsf{LB}}, z_{\mathsf{SB}}$ be the number of long edges taken forward, short edges taken forward, long edges taken backward, and shot edges taken backward, respectively ($z_{\mathsf{LF}} + z_{\mathsf{SF}} + z_{\mathsf{LB}} + z_{\mathsf{SB}} = z - 1$). For $1 \leq j \leq z_{\mathsf{LF}}$ (resp. z_{LB}), consider the jth long edge taken forward (resp. backward) – it is $(v^{i_{j'}}_{x^{j'}}, v^{i_{j'+1}}_{x^{j'+1}})$ for some j'. Let s^{F}_j (resp. s^{B}_j) be $|i_{j'} - i_{j'+1}|$. The following equality holds by observing how i_j changes.

$$i_1 + \sum_{j=1}^{z_{\mathsf{LF}}} s^{\mathsf{F}}_j + z_{\mathsf{SF}} - \sum_{j=1}^{z_{\mathsf{LB}}} s^{\mathsf{B}}_j - z_{\mathsf{SB}} = i_z \quad \Rightarrow \quad i_1 + \sum_{j=1}^{z_{\mathsf{LF}}} s^{\mathsf{F}}_j + z_{\mathsf{SF}} - z_{\mathsf{LB}} - z_{\mathsf{SB}} - i_z \geq 0. \tag{3}$$

Consider how y_j changes. Taking any edge forward increases y_j, and taking any edge backward decreases y_j. Since y_j can never be 0 or $*$, we can conclude that

$$z_{\mathsf{LF}} + z_{\mathsf{SF}} - z_{\mathsf{LB}} - z_{\mathsf{SB}} \leq r - 2. \tag{4}$$

(3) − (4) yields

$$i_1 - i_z + \sum_{j=1}^{z_{\mathsf{LF}}} (s_j^{\mathsf{F}} - 1) \geq 2 - r \quad \Rightarrow \quad i_1 - i_z + \sum_{j=1}^{z_{\mathsf{LF}}} s_j^{\mathsf{F}} \geq 2 - r. \tag{5}$$

The total length of p is

$$\begin{aligned} & 2 + a\big(i_1 + b - i_z + \sum_{j=1}^{z_{\mathsf{LF}}} s_j^{\mathsf{F}} + \sum_{j=1}^{z_{\mathsf{LB}}} s_j^{\mathsf{B}}\big) + z_{\mathsf{SF}} + z_{\mathsf{SB}} \\ \geq \; & a\big(i_1 + b - i_z + \sum_{j=1}^{z_{\mathsf{LF}}} s_j^{\mathsf{F}}\big) \\ \geq \; & a(b - r + 2). \end{aligned}$$

◀

Soundness. To analyze soundness, we define a correlated probability space $(\Omega_1 \times \Omega_2, \nu)$ where both Ω_1, Ω_2 are copies of $\Omega = \{0, \ldots, r-1, *\}$. It is defined by the following process to sample $(x, y) \in \Omega^2$.

- Sample $x \in \{0, \ldots, r-1\}$. Let $y = (x+1) \mod r$.
- Change x to $*$ with probability ϵ. Do the same for y independently.

Note that the marginal distribution of both x and y is equal to μ. Assuming $\epsilon < \frac{1}{2r}$, the minimum probability of any atom in $\Omega_1 \times \Omega_2$ is ϵ^2. Furthermore, in our correlated space, $\nu(x, *) > 0$ for all $x \in \Omega_1$ and $\nu(*, x) > 0$ for all $x \in \Omega_2$. We use the following lemma to bound the correlation.

▶ **Lemma 11** (Lemma 2.9 of [36]). *Let $(\Omega_1 \times \Omega_2, \mu)$ be two correlated spaces such that the probability of the smallest atom in $\Omega_1 \times \Omega_2$ is at least $\alpha > 0$. Define a bipartite graph $G = (\Omega_1 \cup \Omega_2, E)$ where $(a, b) \in \Omega_1 \times \Omega_2$ satisfies $(a, b) \in E$ if $\mu(a, b) > 0$. If G is connected, then $\rho(\Omega_1, \Omega_2; \mu) \leq 1 - \frac{\alpha^2}{2}$.*

Therefore, we can conclude that $\rho(\Omega_1, \Omega_2; \nu) \leq \rho := 1 - \frac{\epsilon^4}{2}$. Apply Theorem 6 ($\rho \leftarrow \rho, \alpha \leftarrow \epsilon^2, \epsilon \leftarrow \frac{\Gamma_\rho(\frac{\epsilon}{3}, \frac{\epsilon}{3})}{2}$) to get τ and d. We will later apply this theorem with the parameters obtained here. Fix an arbitrary subset $C \subseteq V$, and $C_i := C \cap v^i$. For $0 \leq i \leq b$, call v^i *blocked* if $\mu^{\otimes R}[C_i(x)] \geq 1 - \epsilon$. At most $\lfloor \frac{\mathsf{wt}(C)}{1-\epsilon} \rfloor$ v^i's can be blocked. Let k' be the number of blocked v^i's, and $z = b + 1 - k'$ be the number of unblocked v^i's. Let $\{v^{i_1}, \ldots, v^{i_z}\}$ be the set of unblocked v^i's with $i_1 < i_2 < \cdots < i_z$.

For $1 \leq j \leq z$, let $S_j \subseteq v^{i_j}$ be such that $x \in S_j$ if there exists a path $(p_0 = s, p_1, \ldots, p_{j-1}, v_x^{i_j})$ such that each $p_{j'} \in v^{i_{j'}} \setminus C$ $(1 \leq j' < j)$. For $1 \leq j \leq z$, let $f_j : \Omega^R \mapsto [0, 1]$ be the indicator function of S_j.

We prove that if none of f_j reveals any *influential coordinate*, $\mu^{\otimes R}(S_z) > 0$. Since any path passing $v^{i_1}, \ldots, v^{i_z}$ (bypassing only blocked v^i's) uses short edges at least $b - 2k'$ times, so the length of the shortest path after removing C is at most $2 + (b - 2k') + 2ak'$.

▶ **Lemma 12.** *Suppose that for any $1 \leq j \leq z$ and $1 \leq i \leq R$, $\mathsf{Inf}_i^{\leq d}[f_j] \leq \tau$. Then $\mu^{\otimes R}(S_z) > 0$.*

Proof. We prove by induction that $\mu^{\otimes R}(S_j) \geq \frac{\epsilon}{3}$. It holds when $j = 1$ since v^{i_1} is unblocked. Assuming $\mu^{\otimes R}(S_j) \geq \frac{\epsilon}{3}$, since S_j does not reveal any influential coordinate, Theorem 6 shows that for any subset $T_{j+1} \subseteq v^{i_{j+1}}$ with $\mu^{\otimes R}(T_{j+1}) \geq \frac{\epsilon}{3}$, there exists an edge between S_j and T_{j+1}. If $S'_{j+1} \subseteq v^{i_{j+1}}$ is the set of neighbors of S_j, we have $\mu^{\otimes R}(S'_{j+1}) \geq 1 - \frac{\epsilon}{3}$. Since $v^{i_{j+1}}$ is unblocked, $\mu^{\otimes R}(S'_{j+1} \setminus C) \geq \frac{2\epsilon}{3}$, completing the induction. ◀

In summary, in the completeness case, if we cut vertices of total weight $k := k(a, b, r, \epsilon) = (b + 1)(\epsilon + \frac{1-\epsilon}{r})$, the length of the shortest path is at least $l := l(a, b, r, \epsilon) = a(b - r + 2)$. In the soundness case, even after cutting vertices of total weight k', the length of the shortest path is at most $2 + (b - \frac{k'}{1-\epsilon}) + 2a(\frac{k'}{1-\epsilon})$.

- Let $a = 4, b = 2r - 2$ and ϵ small enough so that $k \leq 2, l = 4r$. Requiring $l' \geq l$ results in $k' = \Omega(r)$, giving a gap of $\Omega(r) = \Omega(l)$ for Length Bounded Cut.
- Let $a = r, b = 2r - 2$ and ϵ small enough so that $k \leq 2, l = r^2$. Requiring $k' \leq 2$ results in $l' = O(r)$, giving a gap of $\Omega(r) = \Omega(\sqrt{l})$ for Shortest Path Interdiction. Generally, $k' \leq O(r^\epsilon)$ results in $l' \leq O(r^{1+\epsilon})$, giving an $(O(r^\epsilon), O(r^{1-\epsilon}))$-bicriteria gap for any $\epsilon \in (0, 1)$.

Acknowledgments. The author thanks Konstantin Makarychev for useful discussions on Directed Multicut, and Marek Elias for introducing Shortest Path Interdiction.

Subspace-Invariant AC^0 Formulas

Benjamin Rossman*

University of Toronto, Toronto, Canada

Abstract

The n-variable PARITY function is computable (by a well-known recursive construction) by AC^0 formulas of depth $d+1$ and leafsize $n \cdot 2^{dn^{1/d}}$. These formulas are seen to possess a certain symmetry: they are syntactically invariant under the subspace P of even-weight elements in $\{0,1\}^n$, which acts (as a group) on formulas by toggling negations on input literals. In this paper, we prove a $2^{d(n^{1/d}-1)}$ lower bound on the size of syntactically P-invariant depth $d+1$ formulas for PARITY. Quantitatively, this beats the best $2^{\Omega(d(n^{1/d}-1))}$ lower bound in the non-invariant setting [16].

1 Introduction

Let U be a linear subspace of $\{0,1\}^n$. We say that a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is *U-invariant* if $f(x) = f(x \oplus u)$ for all $u \in U$ and $x \in \{0,1\}^n$. (Note that U-invariant Boolean functions are in one-to-one correspondence with functions from the quotient space $\{0,1\}^n/U$ to $\{0,1\}$.) An obvious example is the PARITY function $x \mapsto \bigoplus_{i=1}^n x$, which is P-invariant where P is the linear subspace of even-weight elements in $\{0,1\}^n$.

We may also view U as a group that acts on the set of n-variable Boolean circuits (as well as the set of n-variable Boolean formulas). Here we consider circuits with unbounded fan-in AND and OR gates and inputs labeled by literals in the set $\{X_1, \overline{X}_1, \ldots, X_n, \overline{X}_n\}$, also known as *$AC^0$ circuits* in the setting where depth is bounded. For a circuit C and an element $u \in U$, let C^u be the circuit obtained from C by negating the ith pair of literals (i.e. exchanging X_i and $\overline{X}_i$ as labels on inputs) for all coordinates $i \in [n]$ such that $u_i = 1$. This action of U on circuits is compatible with the action on Boolean functions: for all $u \in U$ and $x \in \{0,1\}^n$, we have $C^u(x) = C(x \oplus u)$.

There are two notions of U-invariance for circuits. We say that C is *syntactically U-invariant* if C is identical to C^u for every $u \in U$ (we define this notion precisely for formulas), while we say that C is *semantically U-invariant* if it computes a U-invariant function. Syntactic U-invariance clearly implies semantic U-invariance. However, the converse is false: a circuit may compute a U-invariant function without being syntactically U-invariant.

For a U-invariant Boolean function f, we define its *U-invariant circuit size* as the minimum number of gates in a syntactically U-invariant circuit that computes it. This quantity may be compared to the usual ("non-invariant") circuit size of f. There are several questions we may ask: What gap, if any, is there between the U-invariant circuit size and non-invariant circuit size of f? Are lower bounds for U-invariant circuit size easier to prove,

and do they suggest new strategies for proving lower bound in the non-invariant setting? The same questions may be asked with respect to U-invariant versions of other complexity measures, such as formula size and bounded-depth versions of both circuit and formula size (noting that the action of U on circuits preserves fan-out and depth).[1]

In this paper, we focus on bounded-depth formula size. Our primary target is the P-invariant PARITY function where P is the linear subspace of even-weight elements in $\{0,1\}^n$. We start from the observation that the best known construction of bounded-depth circuits and formulas for PARITY are syntactically P-invariant. Here we refer to the well-known recursive construction, for all $d \geq 1$, of depth $d+1$ circuits and formulas for PARITY, of size at most $n \cdot 2^{n^{1/d}}$ and $n \cdot 2^{dn^{1/d}}$ respectively. The main result of this paper (Theorem 1) yields a nearly matching lower bound of $2^{d(n^{1/d}-1)}$ on the P-invariant depth $d+1$ formula size of PARITY. This implies a $2^{n^{1/d}-1}$ lower bound on P-invariant depth $d+1$ circuit size.[2] Quantitatively, the lower bounds are stronger than the best known $\Omega(2^{\frac{1}{10}n^{1/d}})$ and $\Omega(2^{\frac{1}{84}d(n^{1/d}-1)})$ lower bounds for non-invariant depth $d+1$ circuits [10] and formulas [16], respectively. Qualitatively, syntactic P-invariance appears to be a severe restriction and unnatural from the standpoint of computation.

The general form of our lower bound is the following theorem.

▶ **Theorem 1.** *Let $U \subset V$ be linear subspaces of $\{0,1\}^n$, and suppose F is a syntactically U-invariant depth $d+1$ formula which is non-constant over V. Then F has size at least $2^{d(m^{1/d}-1)}$ where $m = \min\{|x| : x \in U^\perp \setminus V^\perp\}$ (i.e. m is the minimum Hamming weight of a vector x which is orthogonal to U but non-orthogonal to V).*

Some observations: first, notice that the bound in Theorem 1 does not depend on the parameter n, i.e. the dimension of the ambient hypercube. The lower bound for PARITY described in the previous paragraph is the special case $U = P$ and $V = \{0,1\}^n$. Theorem 1 implies an $m^{1/\log_2(e)}$ lower bound for unbounded-depth formulas, since $\lim_{d\to\infty} d(m^{1/d}-1) = \ln(m)$. It also implies a $2^{m^{1/d}-1}$ lower bound for depth $d+1$ circuits. (However, we get no non-trivial lower bound for unbounded-depth circuits, since $\lim_{d\to\infty} m^{1/d} - 1 = 0$.)

The proof of Theorem 1 uses elementary linear algebra, in particular a small lemma on the existence of linear retractions with small Hamming-weight distortion (Lemma 5). Overall, this is much simpler than the random restriction and polynomial approximation methods typically used to prove AC^0 lower bounds.

1.1 Related Work

Syntactically invariant models of computation have been previously studied from the perspective of Descriptive Complexity, an area that characterizes complexity classes in terms of definability in different logics [11]. In this context, the notion of invariance pertains to the action of S_m on $n = \binom{m}{2}$ binary variables, encoding the edge relation of a simple graph on m vertices. More generally, for a finite relational signature σ, one may consider the action of S_m on $n = \sum_{R\in\sigma} m^{\text{arity}(R)}$ binary variables (encoding the possible σ-structures with universe $\{1,\ldots,m\}$). The action of S_m on the set of variables $\{X_1,\ldots,X_n\}$ induces a

[1] These questions have been asked previously concerning, e.g., the action of the symmetric group S_n on n-invariable circuits. For S_n-invariant Boolean functions (a.k.a. symmetric functions) including PARITY and MAJORITY, there is known to be an exponential gap between U-invariant and non-invariant circuit and formula size. (See the Related Work section, below.)

[2] This follows from the observation that every [syntactically U-invariant] depth $d+1$ circuit of size s is equivalent to a [syntactically U-invariant] depth $d+1$ formula of size at most s^d.

syntactic action of S_m on the set of n-variable Boolean circuits (and many other concrete models of computation, such as branching programs, etc.)

An early result in this area, due to Denenberg et al [8], shows that syntactically S_m-invariant circuits of polynomial size and constant depth (subject to a certain uniformity condition) capture precisely the first-order definable properties of finite σ-structures. A decade later, Otto [13] introduced a certain limit object of finite circuits (also viewed as a form of uniformity) and showed a correspondence between infinitary logic with a bounded number of variables ($L^{\omega}_{\infty\omega}$) and syntactically S_m-invariant circuits of polynomial size and arbitrary depth. Otto also gives characterizations of fixed point and partial fixed point logic in terms of syntactically S_m-invariant networks. More recently, Anderson and Dawar [2] showed a correspondence (under a different uniformity condition) between fixed-point logic (FP) and syntactically S_m-invariant polynomial-size circuits, as well between fixed-point logic with counting (FPC) and syntactically S_m-invariant polynomial-size circuits in the basis that includes majority gates.

So far as I know, this paper is the first to study syntactic invariance under the action of linear subspaces of $\{0,1\}^n$ (i.e. subgroups on $\mathbb{Z}_2^n$) on n-variable Boolean circuits. A different notion of syntactic invariance — with respect to the automorphism group of the input structure — can be found in the literature on Choiceless Polynomial Time [3, 4, 6, 7, 9, 15]. On S_m-invariant tautologies in proof complexity, see [1, 14].

2 Preliminaries

Let $\mathbb{N} = \{0, 1, 2, \dots\}$. Let n and d be arbitrary positive integers. Let $[n] = \{1, \dots, n\}$.

Our lower bound makes use of the following inequality involving the function $n \mapsto dn^{1/d}$:

▶ **Lemma 2.** *For all real numbers $a, b, c > 0$, we have*

$$a + c(b/a)^{1/c} \geq (c+1)b^{1/(c+1)}$$

with equality iff $a = b^{1/(c+1)}$.

Proof. We have $\frac{\partial}{\partial a}\big(a + c(b/a)^{1/c}\big) = 1 - (b/a^{(c+1)})^{1/c}$. Thus, the function $a \mapsto a + c(b/a)^{1/c}$ is seen to have a unique minimum at $a = b^{1/(c+1)}$ where it takes value $(c+1)b^{1/(c+1)}$. ◀

2.1 Linear Algebra

For $x, y \in \{0,1\}^n$, we write $|x| := \sum_{i=1}^n x_i$ for the Hamming weight of x, we write $x \oplus y$ for the bitwise sum of x and y modulo 2 (i.e. the element $z \in \{0,1\}^n$ with $z_i := x_i \oplus y_i$), and we write $\langle x, y\rangle := \bigoplus_{i=1}^n x_i y_i$ for the inner product of x and y.

We write $\mathcal{L}$ for the lattice of linear subspaces of $\{0,1\}^n$. For $U, V \in \mathcal{L}$, we write $\dim(V)$ for the dimension of V, we write $V^{\perp} := \{x \in \{0,1\}^n : \langle x, v\rangle = 0 \text{ for all } v \in V\}$ for the orthogonal complement of V, and we write $U + V$ for the subspace spanned by U and V. We say that U is a *codimension-k subspace* of V if $U \subseteq V$ and $\dim(V) - \dim(U) = k$.

The orthogonal complement has the following properties:

$$\dim(V) + \dim(V^{\perp}) = n, \qquad U \subseteq V \iff V^{\perp} \subseteq U^{\perp},$$
$$V = (V^{\perp})^{\perp}, \qquad (U+V)^{\perp} = U^{\perp} \cap V^{\perp}, \qquad (U \cap V)^{\perp} = U^{\perp} + V^{\perp}.$$

2.2 AC^0 Formulas

We write $\mathcal{F}$ for the set of n-variable AC^0 formulas (with unbounded fan-in AND and OR gates and leaves labeled by literals). Formally, let $\mathcal{F} = \bigcup_{d\in\mathbb{N}} \mathcal{F}_d$ where $\mathcal{F}_d$ is the set of *depth-d formulas*, defined inductively as follows:[3]

- $\mathcal{F}_0$ is the set of literals $\{X_1, \ldots, X_n, \overline{X}_1, \ldots, \overline{X}_n\}$,
- $\mathcal{F}_{d+1}$ is the set of ordered pairs $\{(\gamma, \mathcal{G}) : \gamma \in \{\text{AND}, \text{OR}\}$ and $\mathcal{G}$ is a nonempty subset of $\mathcal{F}_d\}$.

Every $F \in \mathcal{F}$ computes a Boolean function $\{0,1\}^n \to \{0,1\}$, defined in the usual way. For $x \in \{0,1\}^n$, we write $F(x)$ for the value of F on x.

For a nonempty set $S \subseteq \{0,1\}^n$ and $b \in \{0,1\}$, notation $F(S) \equiv b$ is the assertion that $F(x) = b$ for all $x \in S$. We say that F is *non-constant* on S if $F(S) \not\equiv 0$ and $F(S) \not\equiv 1$ (i.e. there exist $x, y \in S$ such that $F(x) = 0$ and $F(y) = 1$).

The *depth* of F is the minimum d such that $F \in \mathcal{F}_d$. The *leafsize* of a formula is the number of depth-0 subformulas. Let *size* of a formula refer to the number of depth-1 subformulas. Inductively,

$$\text{leafsize}(F) = \begin{cases} 0 & \text{if } F \in \mathcal{F}_0, \\ \sum_{G\in\mathcal{G}} \text{size}(G) & \text{if } F = (\gamma, \mathcal{G}) \in \mathcal{F} \setminus \mathcal{F}_0, \end{cases}$$

$$\text{size}(F) = \begin{cases} 0 & \text{if } F \in \mathcal{F}_0, \\ 1 & \text{if } F \in \mathcal{F}_1, \\ \sum_{G\in\mathcal{G}} \text{size}(G) & \text{if } F = (\gamma, \mathcal{G}) \in \mathcal{F} \setminus (\mathcal{F}_0 \cup \mathcal{F}_1). \end{cases}$$

Clearly $\text{size}(F) \le \text{leafsize}(F)$. (Note that size is within a factor 2 of the number of gates in F, which is how one usually measures size of circuits.) We define these two complexity measures since our lower bound naturally applies to size, while the upper bounds are naturally stated in terms of leafsize.

2.3 The Action of $\{0,1\}^n$

We define a group action of $\{0,1\}^n$ on $\mathcal{F}$ as follows. For $u \in \{0,1\}^n$ and $F \in \mathcal{F}$, let F^u be the formula obtained from F by exchanging literals X_i and $\overline{X}_i$ for every $i \in [n]$ with $u_i = 1$. Formally, this action is defined inductively by

$$F^u = \begin{cases} X_i \text{ (resp. } \overline{X}_i) & \text{if } F = X_i \text{ (resp. } \overline{X}_i) \text{ and } u_i = 0, \\ \overline{X}_i \text{ (resp. } X_i) & \text{if } F = X_i \text{ (resp. } \overline{X}_i) \text{ and } u_i = 1, \\ (\gamma, \{G^u : G \in \mathcal{G}\}) & \text{if } F = (\gamma, \mathcal{G}). \end{cases}$$

Clearly F^u has the same depth and size as F. Note that $F^u(x) = F(x \oplus u)$ for all $x \in \{0,1\}^n$.

If U is a linear subspace of $\{0,1\}$ (i.e. subgroup of $\{0,1\}^n$), then we say that an AC^0 formula F is:

- *syntactically U-invariant* if $F^u = F$ for every $u \in U$,
- *semantically U-invariant* if $F(x) = F(x \oplus u)$ for every $u \in U$ and $x \in \{0,1\}^n$.

As remarked in Section 1, syntactic U-invariance implies semantic U-invariance (but not conversely).

---

[3] As a minor convenience, we do not include constants 0 and 1 in $\mathcal{F}_0$, nor do we allow identical sibling subformulas (i.e. multisets $\mathcal{G}$) in the definition of $\mathcal{F}_{d+1}$. This is without loss of generality: the *depth-d formula size* of a Boolean function is unaffected by these restrictions.

2.4 Upper Bound

We briefly review the smallest known construction of bounded-depth formulas for PARITY and observe that these formulas are syntactically P-invariant.

▶ **Proposition 3.** *For all $d, n \geq 1$, the n-variable* PARITY *function is computable by syntactically P-invariant depth $d+1$ formulas of leafsize at most $n \cdot 2^{dn^{1/d}}$ where P is the even-weight subspace of $\{0,1\}^n$. If $n^{1/d}$ is an integer, this bound improves to $n \cdot 2^{d(n^{1/d}-1)}$.*

Proof. For an optimal choice of $k, n_1, \ldots, n_k \geq 1$ with $n_1 + \cdots + n_k = n$, we construct a syntactically P_n-invariant depth $d+1$ formula for PARITY_n — with output gate OR (resp. AND) — by composing the brute-force DNF (resp. CNF) for PARITY_k (in which each variable occurs 2^{k-1} times) with syntactically P_{n_i}-invariant depth d formulas for PARITY_{n_i} (or $1 - \text{PARITY}_{n_i}$) with output gate AND (resp. OR). The minimum leafsize $\beta(d+1, n)$ achievable by this construction is given by the recurrence

$$\beta(1,n) = \begin{cases} 1 & \text{if } n = 1, \\ \infty & \text{if } n > 1, \end{cases} \qquad \beta(d+1,n) = \min_{\substack{k, n_1, \ldots, n_k \geq 1 \\ n_1 + \cdots + n_k = n}} 2^{k-1} \sum_{i=1}^{k} \beta(d, n_i).$$

We now observe:

- If $n^{1/d}$ is an integer, we get $\beta(d+1,n) \leq n \cdot 2^{d(n^{1/d}-1)}$ by setting $k = n^{1/d}$ and $n_1 = \cdots = n_k = n^{(d-1)/d}$.
- For arbitrary $d, n \geq 1$, we get $\beta(d+1,n) \leq n \cdot 2^{dn^{1/d}}$ by setting $k = \lceil n/t \rceil$ and $n_1, \ldots, n_k \in \{t-1, t\}$ where $t = \lfloor n^{(d-1)/d} \rfloor$. ◀

An aside

I suspect that, by analyzing the above recurrence more carefully, the upper bound in Proposition 3 can be improved to $O(n \cdot 2^{d(n^{1/d}-1)})$ for all $d \leq \lceil \log n \rceil$. This is suggested by the observation that PARITY is computable by syntactically P-invariant formulas of depth $\lceil \log n \rceil + 1$ and leafsize $O(n^2)$. Note that the upper bound of Proposition 3 is slack (except when $n^{1/d}$ is an integer), since setting $d = \log n$, we have $n \cdot 2^{d(n^{1/d}-1)} = n^2$ and $n \cdot 2^{dn^{1/d}} = n^3$. Also note that $O(n \cdot 2^{d(n^{1/d}-1)})$ is *not* an upper bound for $d \gg \log n$, since $\Omega(n^2)$ is lower bound even for non-invariant formulas of unbounded depth [12].

3 Linear-Algebraic Lemmas

In this section, we prove a linear-algebraic lemma (Lemma 9) which plays a key role in our lower bound. Recall that S, T, U, V range over the set of linear subspaces of $\{0,1\}^n$, denoted by $\mathcal{L}$.

▶ **Definition 4.** For linear spaces $U \subseteq V$, a *linear retraction* from V to U is a linear function $\rho : V \to U$ such that $\rho(u) = u$ for every $u \in U$.

We next give a small lemma on the existence of linear retractions with small (one-sided) Hamming-weight distortion.

▶ **Lemma 5.** *If U is a codimension-k subspace of V, then there exists a linear retraction $\rho : V \to U$ such that $|\rho(v)|/|v| \leq k+1$ for all $v \in V$.*

Proof. Greedily choose a basis $w_1, \ldots, w_k$ for V over U such that w_i has minimal Hamming weight among elements of $V \setminus \text{Span}(U \cup \{w_1, \ldots, w_{i-1}\})$ for all $i \in [k]$. Each $v \in V$ has a

unique representation $v = u \oplus a_1 w_1 \oplus \cdots \oplus a_k w_k$ where $u \in U$ and $a_1, \ldots, a_k \in \{0,1\}$. Let $\rho : V \to U$ be the map $v \mapsto u$ and observe that this is a linear retraction.

To show that $|\rho(v)| \leq (k+1)|v|$, we first notice that $|a_i w_i| \leq |v|$ for all $i \in [k]$. If $a_i = 0$, this is obvious, as $|a_i w_i| = 0$. If $a_i = 1$, then $v \in V \setminus \mathrm{Span}(U \cup \{w_1, \ldots, w_{i-1}\})$, so by our choice of w_i we have $|a_i w_i| = |w_i| \leq |v|$. Completing the proof, we have

$$\begin{aligned} |\rho(v)| &= |v \oplus a_1 v_1 \oplus \cdots \oplus a_k v_k| \\ &\leq |v| + |a_1 v_1| + \cdots + |a_k v_k| \\ &\leq (k+1)|v|. \end{aligned}$$

◀

▶ **Definition 6.** Define sets $\mathcal{L}_2$ and $\mathcal{L}_4$ as follows:

$$\mathcal{L}_2 = \big\{(U,V) \in \mathcal{L} \times \mathcal{L} : U \text{ is a codimension-1 subspace of } V\big\},$$

$$\mathcal{L}_4 = \big\{((S,T),(U,V)) \in \mathcal{L}_2 \times \mathcal{L}_2 : T \cap U = S \text{ and } T + U = V\big\}.$$

The next lemma shows that $\mathcal{L}_4$ is symmetric under orthogonal complementation.

▶ **Lemma 7.** *For all $((S,T),(U,V)) \in \mathcal{L}_4$, we have $((V^\perp, U^\perp), (T^\perp, S^\perp)) \in \mathcal{L}_4$.*

Proof. This follows from the properties of the orthogonal complement listed in §2.1. Consider any $((S,T),(U,V)) \in \mathcal{L}_4$. First note that $(V^\perp, U^\perp) \in \mathcal{L}_2$ by the fact that $U \subseteq V \implies V^\perp \subseteq U^\perp$ and $\dim(U^\perp) - \dim(V^\perp) = (n - \dim(U)) - (n - \dim(V)) = \dim(V) - \dim(U) = 1$. Similarly, we have $(T^\perp, S^\perp) \in \mathcal{L}_2$. We now have $((V^\perp, U^\perp), (T^\perp, S^\perp)) \in \mathcal{L}_4$ since $U^\perp \cap T^\perp = (T+U)^\perp = V^\perp$ and $U^\perp + T^\perp = (T \cap U)^\perp = S^\perp$. ◀

▶ **Lemma 8.** *For all $S \subset T \subseteq V$ such that $(S,T) \in \mathcal{L}_2$, there exists $U \supseteq S$ such that $((S,T),(U,V)) \in \mathcal{L}_4$ and*

$$\min_{x \in V \setminus U} |x| \geq \frac{1}{\dim(V) - \dim(T) + 1} \min_{y \in T \setminus S} |y|.$$

Proof. By Lemma 5, there exists a linear retraction $\rho : V \to T$ such that $|\rho(v)|/|v| \leq \dim(V) - \dim(T) + 1$ for all $v \in V$. Let $U = \rho^{-1}(S)$ and note that U is a codimension-1 subspace of V. (This follows from applying the Rank-Nullity Theorem to linear functions $\rho : V \to T$ and $\rho|U : U \to S$ and noting that $\ker(\rho) = \ker(\rho|U)$.) We have $S = T \cap U$ and $T + U = V$, hence $((S,T),(U,V)) \in \mathcal{L}_4$. Choosing x with minimum Hamming weight in $V \setminus U$, we observe that $\rho(x) \in T \setminus S$ and $|x| \geq |\rho(v)|/(\dim(V) - \dim(T) + 1)$, which proves the lemma. ◀

▶ **Lemma 9.** *For all $S \subseteq U \subset V$ such that $(U,V) \in \mathcal{L}_2$, there exists $T \subseteq V$ such that $((S,T),(U,V)) \in \mathcal{L}_4$ and*

$$\min_{x \in S^\perp \setminus T^\perp} |x| \geq \frac{1}{\dim(U) - \dim(S) + 1} \min_{y \in U^\perp \setminus V^\perp} |y|.$$

Proof. Follows directly from Lemmas 7 and 8. ◀

4 Proof of Theorem 1

The following lemma gives the base case of Theorem 1 for depth-2 formulas (a.k.a. DNFs and CNFs). In this case, we merely require the hypothesis of semantic rather than syntactic U-invariance. The proof is similar to the standard argument showing that depth-2 formulas for PARITY require 2^{n-1} clauses of width n.

▶ **Lemma 10.** *Suppose F is a depth-2 formula and $(U,V) \in \mathcal{L}_2$ such that $F(U) \equiv b$ and $F(V \setminus U) \equiv 1-b$ for some $b \in \{0,1\}$. Then* $\text{size}(F) \geq 2^{m-1}$ *and* $\text{leafsize}(F) \geq m \cdot 2^{m-1}$ *where* $m = \min\{|x| : x \in U^\perp \setminus V^\perp\}$.

Proof. Without loss of generality, assume that F is a DNF formula (i.e. an OR-of-ANDs formula) and $F(U) \equiv 0$ and $F(V \setminus U) \equiv 1$. (The argument is similar if we replace DNF with CNF, or if we assume that $F(U) \equiv 1$ and $F(V \setminus U) \equiv 0$.) We further assume that F is minimal with respect to the number of clauses and the number of literals in any particular clause.

Consider a clause G of F. This clause G is the AND of some number ℓ of literals. Without loss of generality, suppose these literals involve the first ℓ coordinates. Let π be the projection map $\{0,1\}^n \to \{0,1\}^\ell$. Then there is a point $p \in \{0,1\}^\ell$ such that $G(x) = 1 \iff \pi(x) = p$ for all $x \in \{0,1\}^n$. Observe that $G(U) \equiv 0$ (since $F(U) \equiv 0$) and, therefore, $p \notin \pi(U)$.

We claim that $p \in \pi(V \setminus U)$. To see why, assume for contradiction that $p \notin \pi(V \setminus U)$. Then $G(V) \equiv 0$. But this means that the clause G can be removed from F and the resulting function would still satisfy $F(U) \equiv 0$ and $F(V \setminus U) \equiv 1$. This contradicts the minimality of F with respect to number of clauses.

For each $i \in [\ell]$, let $p^{(i)}$ be the neighbor of p in $\{0,1\}^\ell$ along the ith coordinate. We claim that $p^{(1)}, \ldots, p^{(\ell)} \in \pi(U)$. Without loss of generality, we give the argument showing $p^{(\ell)} \in \pi(U)$. Let G' be the AND of the first $\ell - 1$ literals in G, and let F' be the formula obtained from F by replacing G with G'. For all $x \in \{0,1\}^n$, we have $G(x) \leq G'(x)$ and hence $F(x) \leq F'(x)$. Therefore, $F'(V \setminus U) \equiv 1$. We now note that there exists $u \in U$ such that $F'(u) = 1$ (otherwise, we would have $F'(u) \equiv 0$, contradicting the minimality of F with respect to the width of each clause). Since $F(u) = 0$ and G' is the only clause of F' distinct from the clauses of F, it follows that $G'(u) = 1$. This means that $u_{\{1,\ldots,\ell-1\}} = p_{\{1,\ldots,\ell-1\}}$. We now have $\pi(u) = p^{(\ell)}$ (otherwise, we would have $\pi(u) = p$ and therefore $G(u) = 1$ and $F(u) = 1$, contradicting that fact that $F(U) \equiv 0$).

Since π is a linear function and $\pi(U) \neq \pi(V)$, it follows that $\pi(U)$ is a codimension-1 subspace of $\pi(V)$. The fact that $p \in \pi(V \setminus U)$ and $p^{(1)}, \ldots, p^{(\ell)} \in \pi(U)$ now forces $\pi(V) = \{0,1\}^\ell$ and $\pi(U) = \{q \in \{0,1\}^\ell : |q| \text{ is even}\}$. Therefore, $1^\ell \in \pi(U)^\perp \setminus \pi(V)^\perp$ (writing 1^ℓ for the all-1 vector in $\{0,1\}^\ell$). It follows that $1^\ell 0^{n-\ell} \in U^\perp \setminus V^\perp$ and, therefore, $\ell = |1^\ell 0^{n-\ell}| \geq m$ (by definition of m).

We now observe that

$$\mathop{\mathbb{P}}_{v \in V}[G(v) = 1] = \mathop{\mathbb{P}}_{v \in V}[\pi(v) = p] = \mathop{\mathbb{P}}_{q \in \pi(V)}[q = p] = \mathop{\mathbb{P}}_{q \in \{0,1\}^\ell}[q = p] = 2^{-\ell} \leq 2^{-m}.$$

That is, each clause in F has value 1 over at most 2^{-m} fraction of points in V. Since the set $V \setminus U$ has density $1/2$ in V, we see that 2^{m-1} clauses are required to cover $V \setminus U$.

Subject to the stated minimality assumptions on F (with respect to the number of clauses and, secondarily, to the width of each clause), we conclude that F contains $\geq 2^{m-1}$ clauses, each of width $\geq m$. Therefore, $\text{size}(F) \geq 2^{m-1}$ and $\text{leafsize}(F) \geq m \cdot 2^{m-1}$. ◀

On to our main result:

▶ **Theorem 1 (restated).** *Let $U \subset V$ be linear subspaces of $\{0,1\}^n$, and suppose F is a syntactically U-invariant depth $d+1$ formula which is non-constant over V. Then F has size at least $2^{d(m^{1/d}-1)}$ where $m = \min\{|x| : x \in U^\perp \setminus V^\perp\}$.*

Proof. We first observe that it suffices to prove the theorem in the case where $(U,V) \in \mathcal{L}_2$, that is, U has codimension-1 in V. To see why, note that for any $U \subset V$ where F is

syntactically U-invariant and non-constant over V, there must exist $U \subset W \subseteq V$ such that $(U, W) \in \mathcal{L}_2$ and F is non-constant over W. Assuming the theorem holds with respect to $U \subset W$, it also hold with respect to $U \subset V$, since $U^\perp \setminus V^\perp \subseteq U^\perp \setminus W^\perp$ and hence $\min\{|x| : x \in U^\perp \setminus V^\perp\} \geq \min\{|x| : x \in U^\perp \setminus W^\perp\}$.

Therefore, we assume $(U, V) \in \mathcal{L}_2$ and prove the theorem by induction on d. The base case $d = 1$ is established by Lemma 10.[4] For the induction step, let $d \geq 2$ and assume $F \in \mathcal{F}_{d+1}$ is a syntactically U-invariant and non-constant over V. Without loss of generality, we consider the case where $F = (\mathrm{OR}, \mathcal{G})$ for some nonempty $\mathcal{G} \subseteq \mathcal{F}_d$. (The case where $F = (\mathrm{AND}, \mathcal{G})$ is symmetric, with the roles of 0 and 1 exchanged.)

Since F is syntactically U-invariant, we have $G^u \in \mathcal{G}$ for every $u \in U$ and $G \in \mathcal{G}$. We claim that it suffices to prove the theorem in the case where the action of U on $\mathcal{G}$ is transitive (i.e. $\mathcal{G} = \{G^u : u \in U\}$ for every $G \in \mathcal{G}$). To see why, consider the partition $\mathcal{G} = \mathcal{G}_1 \sqcup \cdots \sqcup \mathcal{G}_t$, $t \geq 1$, into orbits under U. For each $i \in [t]$, let F_i be the formula $(\mathrm{OR}, \mathcal{G}_i)$. Note that F_i is syntactically U-invariant and U acts transitively on $\mathcal{G}_i$. Clearly, we have $F(v) = \bigvee_{i \in [t]} F_i(v)$ for all $v \in V$. Since every U-invariant Boolean function is constant over sets U and $V \setminus U$ (using the fact that U has codimension-1 in V), this means that each F_i satisfies either $F_i(V) \equiv 0$ or $F(v) = F_i(v)$ for all $v \in V$. Because F is non-constant over V, it follows that there exists $i \in [t]$ such that $F(v) = F_i(v)$ for all $v \in V$. In particular, this F_i is non-constant over V. Since $\mathrm{size}(F) \geq \mathrm{size}(F_i)$, we have reduced proving the theorem for F to proving to theorem for F_i.

In light of the preceding paragraph, we proceed under the assumption that U acts transitively on $\mathcal{G}$. Fix an arbitrary choice of $G \in \mathcal{G}$. Let

$$S = \mathrm{Stab}_U(G) \ (= \{u \in U : G^u = G\}),$$
$$a = \dim(U) - \dim(S) + 1.$$

By the Orbit-Stabilizer Theorem,

$$|\mathcal{G}| = |\mathrm{Orbit}_U(G)| = [U : S] = |U|/|S| = 2^{a-1}.$$

Since $\mathrm{size}(G') = \mathrm{size}(G)$ for every $G' \in \mathcal{G}$, we have

$$\mathrm{size}(F) = \sum_{G' \in \mathcal{G}} \mathrm{size}(G') = |\mathcal{G}| \cdot \mathrm{size}(G) = 2^{a-1} \cdot \mathrm{size}(G). \tag{1}$$

We next observe that G^u is syntactically S-invariant for every $u \in U$ (in fact, $S = \mathrm{Stab}_U(G^u)$). This follows from the fact that $(G^u)^s = G^{u \oplus s} = (G^s)^u = G^u$ for every $s \in S$.

By Lemma 9, there exists T such that $((S, T), (U, V)) \in \mathcal{L}_4$ and

$$\min_{x \in S^\perp \setminus T^\perp} |x| \geq \frac{1}{\dim(U) - \dim(S) + 1} \min_{y \in U^\perp \setminus V^\perp} |y| = \frac{m}{a}.$$

We claim that there exists $u \in U$ such that G^u is non-constant on T. There are two cases to consider:

- **Case 1:** *Suppose $F(U) \equiv 0$ and $F(V \setminus U) \equiv 1$.*
  We have $G(U) \equiv 0$ and $G(V) \not\equiv 0$. Fix any $v \in V \setminus U$ such that $G(v) = 1$. In addition, fix any $w \in T \setminus U$ (noting that $T \setminus U$ is nonempty since $U + T = V$ and $U \subset V$). Let $u = v \oplus w$ and note that $u \in U$ (since U is a codimension-1 subspace of V and $v, w \in V \setminus U$). We have $G^u(U) \equiv 0$ and $G^u(w) = G(w \oplus u) = G(v) = 1$. By the S-invariance of G^u, it follows that $G^u(S) \equiv 0$ and $G^u(T \setminus S) \equiv 1$. In particular, G^u is non-constant on T.

[4] Note that Theorem 1 makes sense even when $d = 0$, if we interpret $0 \cdot (m^{1/0} - 1)$ as 0 if $m = 1$ and ∞ if $m > 1$.

- **Case 2:** *Suppose* $F(U) \equiv 1$ *and* $F(V \setminus U) \equiv 0$.
  We have $G(U) \not\equiv 0$ and $G(V \setminus U) \equiv 0$. Fix any $u \in U$ such that $G(u) = 1$. In addition, fix any $w \in T \setminus U$ and let $v = w \oplus u$. We have $G^u(v) = G(v \oplus u) = G(w) = 0$ (since $w \in V \setminus U$ and $G(V \setminus U) \equiv 0$). We also have $G^u(\vec{0}) = G(u) = 1$ where $\vec{0}$ is the origin in $\{0,1\}^n$. By S-invariance of G^u, it follows that $G^u(S) \equiv 1$ and $G^u(T \setminus S) \equiv 0$. In particular, G^u is non-constant on T.

Since G^u is syntactically S-invariant and non-constant on T and $\mathrm{depth}(G^u) = (d-1)+1$, we may apply the induction hypothesis to G^u. Thus, we have

$$\mathrm{size}(G) = \mathrm{size}(G^u) \geq 2^{(d-1)((m/a)^{1/(d-1)}-1)}. \tag{2}$$

Since $d \geq 2$, Lemma 2 tells us

$$a + (d-1)(m/a)^{1/(d-1)} \geq d(m/a)^{1/d}. \tag{3}$$

Putting together (1), (2), (3), we get the desired bound

$$\begin{aligned}\mathrm{size}(F) &\geq 2^{a-1} \cdot 2^{(d-1)((m/a)^{1/(d-1)}-1)} \\ &= 2^{a+(d-1)(m/a)^{1/(d-1)}-d} \\ &\geq 2^{d(m^{1/d}-1)}.\end{aligned}$$

This completes the proof of Theorem 1. ◀

5 Further Remarks and Open Questions

5.1 Another Application of Theorem 1

Theorem 1 applies to interesting subspaces U besides the even-weight subspace P. Here we describe one example. Let G be a simple graph with n edges, so that $\{0,1\}^n$ is identified with the set of spanning subgraphs of G. The *cycle space* of G is the linear subspace $Z \subseteq \{0,1\}^n$ consisting of *even subgraphs* of G (i.e. spanning subgraphs in which every vertex has even degree). Consider the even-weight subspace $Z_0 = \{z \in Z : |z| \text{ is even}\}$. Provided G is non-bipartite, Z_0 is a codimension-1 subspace of Z.

Let $m = \min\{|z| : z \in Z_0^\perp \setminus Z^\perp\}$ as in Theorem 1 with $U = Z_0$ and $V = Z$. It is not hard to show that m is equal to the minimum number of edges whose removal makes G bipartite. (It follows that $m = n - c$ where c is the number edges in a maximum cut in G.) Moreover, if G is a uniform random 3-regular graph on $\frac{2}{3}n$ vertices, then $m = \Omega(n)$ asymptotically almost surely [5]. By these observations, we have:

▶ **Corollary 11.** *Let* $Z \subseteq \{0,1\}^n$ *be the cycle space of a random 3-regular graph with* n *edges, and let* $Z_0 = \{z \in Z : |z| \text{ is even}\}$. *Then a.a.s. every syntactically* Z_0*-invariant depth* $d+1$ *formula that computes* PARITY_n *over* Z *has size* $2^{d(\Omega(n)^{1/d}-1)}$.

5.2 The (U, V)-Search Problem

For linear subspaces $U \subset V$ of $\{0,1\}^n$, consider the following (U,V)-*search problem*: there is a hidden vector $x \in V \setminus U$ and the goal is to learn a nonzero coordinate of x (i.e. any $i \in [n]$ such that $w_i = 1$) by asking queries (i.e. yes/no questions) in the form of linear functions $\{0,1\}^n \to \{0,1\}$. The *d-round query complexity* of this problem is the minimum number of queries required by protocols that solve this problem on all $w \in V \setminus U$ by asking

queries in d consecutive batches (thus, 1-round = non-adaptive). By a slightly simpler version of the argument in the proof of Theorem 1, we can show a $d(m^{1/d}-1)$ lower bound on the d-round query complexity of the (U,V)-search problem for all $U \subset V$ where $m = \min\{|x| : x \in U^\perp \setminus V^\perp\}$.

This (U,V)-search problem is, in some sense, related to the Karchmer-Wigderson game where Alice gets $u \in U$ and Bob gets $v \in V \setminus U$ and their common goal is to learn a nonzero coordinate of $u \oplus v$. For an appropriate definition of "U-invariant protocols" (i.e. whatever comes from syntactically U-invariant formulas), we can translate the pair (u,v) to $(0, u \oplus v)$ without loss of generality and it becomes Alice's task to learn a nonzero coordinate of $u \oplus v$ by asking linear queries.

5.3 Open Questions

We conclude by mentioning some open questions and challenges raised by this work:

1. Does the lower bound of Theorem 1 (or something weaker like $2^{m^{\Omega(1/d)}}$) hold under the weaker assumption of semantic U-invariance, in place of syntactic U-invariance? What about Corollary 11?
2. Considering leafsize (rather than size, i.e. the number of depth-1 subformulas), improve the lower bound of Theorem 1 from $2^{d(m^{1/d}-1)}$ to $m \cdot 2^{d(m^{1/d}-1)}$.
3. Improve the upper bound of Proposition 3 from $n \cdot 2^{dn^{1/d}}$ to $O(n \cdot 2^{d(n^{1/d}-1)})$ for all $d \leq \lceil \log n \rceil$.
4. What is the maximum gap, if any, between U-invariant [depth d] formula size and non-invariant [depth d] formula size?

Acknowledgements. I thank the anonymous referees for their helpful comments.

Abstract

Quantified integer programming is the problem of deciding assertions of the form $\mathrm{Q}_k \boldsymbol{x}_k \ldots \forall \boldsymbol{x}_2 \exists \boldsymbol{x}_1 : A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ where vectors of variables $\boldsymbol{x}_k, \ldots, \boldsymbol{x}_1$ form the vector $\boldsymbol{x}$, all variables are interpreted over $\mathbb{N}$ (alternatively, over $\mathbb{Z}$), and A and $\boldsymbol{c}$ are a matrix and vector over $\mathbb{Z}$ of appropriate sizes. We show in this paper that quantified integer programming with alternation depth k is complete for the kth level of the polynomial hierarchy.

1 Introduction

The problem of integer programming is, given a system of linear inequalities $A \cdot \boldsymbol{x} \geq \boldsymbol{b}$, to decide whether there exists a solution for $\boldsymbol{x}$ in the non-negative integers. This problem has been studied for decades, and its 0–1 version (in which the components of $\boldsymbol{x}$ are constrained to be either 0 or 1) is one of Karp's seminal 21 NP-complete problems [8]. In this paper, we study quantified integer programming (QIP), an extension of integer programming where some of the variables can be quantified universally – so that its instances have the form

$$\mathrm{Q}_k \boldsymbol{x}_k \ \ldots \ \forall \boldsymbol{x}_2 . \ \exists \boldsymbol{x}_1 : A \cdot \boldsymbol{x} \geq \boldsymbol{c} \tag{1}$$

where $\mathrm{Q}_i \in \{\exists, \forall\}$ and $\boldsymbol{x}$ consists of all first-order variables appearing in the vectors $\boldsymbol{x}_i$.

Our main contribution is settling the complexity of QIP with k quantifier blocks (as above): we prove this problem complete for the kth level of the polynomial hierarchy, similarly to the quantified version of SAT.[1] We also show that QIP with an unbounded number of quantifier blocks is PSPACE-hard and decidable in $\mathsf{STA}(*, 2^{n^{O(1)}}, n) \subseteq \mathsf{EXPSPACE}$.[2]

* Supported by the ERC grant AVS-ISS (648701).

1 As in the case of quantified CNF SAT, the innermost block of universal quantifiers, if present, is disregarded; e.g., the $\forall^*\exists^*\forall^*$ fragment is complete for Π_2^{P}. So we find fragments of QIP complete for $\Sigma_1^{\mathsf{P}} = \mathsf{NP}$, Π_2^{P}, Σ_3^{P}, ... , but not for $\mathsf{coNP} = \Pi_1^{\mathsf{P}}$, Σ_2^{P}, ...

2 The complexity class $\mathsf{STA}(s(n), t(n), a(n))$ was introduced by Berman [1] and contains all decision problems that can be decided by an alternating Turing machine in time $t(n)$ using space at most $s(n)$ and alternating at most $a(n)$ times on every computation branch.

Related work and discussion. While the decidability of QIP is immediate – it can be viewed as a syntactic fragment of Presburger arithmetic, the (decidable) first-order theory of the natural numbers with addition and order, in which matrix formulas are constrained to be conjunctions of linear inequalities – its computational complexity has been unknown. It is, of course, not difficult to see that QIP (and in fact Presburger arithmetic) is PSPACE-complete if the interpretation of every first-order variable x_i is restricted to an interval $[l_i, u_i]$ that is given as part of the input: $x_i \in [l_i, u_i]$; see, e.g., [14]. But if $x_i \in \mathbb{N}$, then the best known upper bounds seem to be $\mathsf{STA}(*, 2^{2^{n^{O(1)}}}, O(n)) \subseteq$ 2-EXPSPACE, the generic upper bound for deciding Presburger arithmetic [1], and the $(k-1)$th level of the weak EXP hierarchy for the fragment with k quantifier blocks [6]. The best known lower bound has been Π_2^{P}, established recently by the authors for Π_2-instances of QIP [3, Sec. 4.2].

It may be surprising, and certainly was to the authors, that the complexity of QIP, a natural decision problem, has not yet been established. The main reason is probably that standard quantifier-elimination and automata-based techniques – which are at the core of decision procedures for Presburger arithmetic – fail to yield tight upper bounds for QIP:

- Weispfenning shows that quantifier-elimination procedures for Presburger arithmetic run in time $2^{O(|\Phi|^{(4j)^k})}$ [17, Thm. 2.1], where $|\Phi|$ denotes the size of an input formula Φ with k quantifier blocks and at most j variables in each quantifier block, and that this upper bound is essentially tight [18, Thm. 3.1]. In particular, even the NP upper bound for standard integer programming instances (Σ_1-IP) cannot be obtained by quantifier elimination.
- Automata-based decision procedures for Presburger arithmetic do not suffice either to obtain the bounds for QIP that we establish in this paper. Klaedtke shows [9, Thm. 4.6] that the size of the minimal deterministic finite automaton (DFA) for a formula Φ is upper-bounded by $2^{|\Phi|^{(j+1)^{(k+4)}}}$, which does not give any complexity bounds asymptotically better than those obtained via quantifier elimination.
- Yet another approach to QIP is to construct the semi-linear representation of the set of solutions to the system of linear inequalities of the matrix formula, and then to repeatedly project and complement this set. By an application of [2, Thm. 21], this approach gives a Π_2^{P} upper bound for the Π_2-fragment of QIP; however, as every complementation step increases the number of generators of semi-linear sets by one exponential, this approach would only yield a non-elementary upper bound for general QIP instances and fail to place fragments with bounded alternation depth inside PSPACE.

Our main results are, in short, obtained by means of a new quantifier elimination procedure on *hybrid linear sets*, which are semi-linear sets that represent sets of solutions to systems of linear inequalities. While *existential* projection ($L \mapsto \{x \mid \exists y.\ (x, y) \in L\}$) is a trivial operation on semi-linear sets (in generator representation), in this paper we define a dual operation, which we call *universal projection* ($L \mapsto \{x \mid \forall y.\ (x, y) \in L\}$), and show that its application enables us to eliminate blocks of universal quantifiers without resorting to double complementation ($\forall = \neg\exists\neg$; this would lead to a non-elementary blowup). We spell out (these and other) results of the paper in more detail in Section 3 and outline the techniques in Section 4.

Concurrently with our work and building upon a theorem of Kannan [7], Nguyen and Pak [11] have shown that Presburger arithmetic with fixed number of variables *and* fixed Boolean structure of the matrix formula (and, by necessity, where the total number of occurrences of atomic predicates is fixed) can be solved in polynomial time.

2 Preliminaries

By $\mathbb{Z}$ and $\mathbb{N}$ we denote the sets of integers and non-negative integers, respectively. Given sets X and Y, we denote by $X \Rightarrow Y$ the set of all functions with domain X and co-domain Y. Let $\mathcal{X}$ be a countably infinite set of first-order variables, and with no loss of generality assume some total ordering $\prec$ on $\mathcal{X}$. Given a finite set $X \subseteq \mathcal{X}$, an *X-indexed integer vector* is a function $\boldsymbol{v} \in (X \Rightarrow \mathbb{Z})$, and an *$X$-indexed non-negative integer vector* is a function $\boldsymbol{v} \in (X \Rightarrow \mathbb{N})$. We often call $\boldsymbol{v}$ just an *integer vector* respectively a *(non-negative) vector* when X is clear from the context. Due to the total ordering on $\mathcal{X}$, we can interchangeably write $\boldsymbol{v}$ as a tuple $(v_1, \ldots, v_n) \in \mathbb{Z}^n$ such that $n = |X|$. We denote by $\boldsymbol{e}_i$ the ith unit vector (mapping the ith variable to 1 and all other variables to 0). Addition and multiplication of a vector by a scalar value are defined component-wise. Given a set of non-negative vectors $V \subseteq \mathbb{N}^n$, its *complement* is defined as $\overline{V} := \{\boldsymbol{w} \in \mathbb{N}^n : \boldsymbol{w} \notin V\}$.

A *vector of (first-order) variables over $X \subseteq \mathcal{X}$* is a tuple $\boldsymbol{y} = (y_1, \ldots, y_\ell) \in X^\ell$ such that each $y_i \in X$ and $y_i \prec y_{i+1}$. For $\boldsymbol{v}_i \in (X_i \Rightarrow \mathbb{Z})$, $i \in \{1, 2\}$, with $X_1 \cap X_2 = \emptyset$, by $\boldsymbol{v}_1 \circ \boldsymbol{v}_2$ we denote the vector from $(X_1 \cup X_2) \Rightarrow \mathbb{Z}$ that agrees with $\boldsymbol{v}_i$ on X_i for both $i \in \{1, 2\}$. Given a vector $\boldsymbol{v} \in (X \Rightarrow \mathbb{N})$ and a vector of variables $\boldsymbol{y} = (y_1, \ldots, y_\ell) \in X^\ell$, the *projection of $\boldsymbol{v}$ removing variables $\boldsymbol{y}$* is the vector $\pi_{\boldsymbol{y}}(\boldsymbol{v}) \in ((X \setminus \{y_1, \ldots, y_\ell\}) \Rightarrow \mathbb{N})$ such that $\pi_{\boldsymbol{y}}(\boldsymbol{v})(x) := \boldsymbol{v}(x)$ for all $x \in X \setminus \{y_1, \ldots, y_\ell\}$. This definition of projection naturally extends to sets of vectors:

$$\pi_{\boldsymbol{y}}(V) := \bigcup_{\boldsymbol{v} \in V} \{\pi_{\boldsymbol{y}}(\boldsymbol{v})\} = \{\boldsymbol{v}_1 \mid \text{there is a } \boldsymbol{v}_2 \in (\{y_1, \ldots, y_\ell\} \Rightarrow \mathbb{N}) \text{ such that } \boldsymbol{v}_1 \circ \boldsymbol{v}_2 \in V\}.$$

For sets of vectors $V \subseteq (X \Rightarrow \mathbb{N})$, we additionally define the *universal projection*

$$\pi^*_{\boldsymbol{y}}(V) := \overline{\pi_{\boldsymbol{y}}(\overline{V})} = \{\boldsymbol{v}_1 \mid \text{for all } \boldsymbol{v}_2 \in (\{y_1, \ldots, y_\ell\} \Rightarrow \mathbb{N}) \text{ the vector } \boldsymbol{v}_1 \circ \boldsymbol{v}_2 \text{ is in } V\}.$$

For a vector $\boldsymbol{v} \in \mathbb{Z}^n$, we denote by $\|\boldsymbol{v}\| := \max\{\max_{x \in X} |\boldsymbol{v}(x)|, 2\}$ the *maximum norm* of $\boldsymbol{v}$. For $V \subseteq \mathbb{Z}^n$, we define $\|V\| := \max_{\boldsymbol{v} \in V} \|\boldsymbol{v}\|$. For a matrix A, we define $\|A\|$ to be the norm of its set of column vectors.

Quantified integer programming (QIP). Let A be an $n \times m$ integer matrix, $\boldsymbol{x} = (x_1, \ldots, x_m) \in X^m$ a vector of first-order variables for some finite $X \subseteq \mathcal{X}$, and $\boldsymbol{c} \in \mathbb{Z}^n$. We call $\mathfrak{S}\colon A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ a *system of linear inequalities*. A *solution* to $\mathfrak{S}$ is a vector $\boldsymbol{v} \in (X \Rightarrow \mathbb{Z})$ such that $A \cdot \boldsymbol{v} \geq \boldsymbol{c}$, where "$\geq$" is interpreted component-wise. We denote by $[\![\mathfrak{S}]\!] \subseteq (X \Rightarrow \mathbb{N})$ the set of *all non-negative solutions* to $\mathfrak{S}$.

Let $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_k$ be vectors of first-order variables over disjoint sets of variables $X_1, \ldots, X_k$, and let $\mathfrak{S}\colon A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ be a system of linear inequalities. A *formula of* QIP is given by

$$\psi = \mathrm{Q}_k \boldsymbol{x}_k.\ \mathrm{Q}_{k-1} \boldsymbol{x}_{k-1}\ \ldots\ \mathrm{Q}_1 \boldsymbol{x}_1 : A \cdot \boldsymbol{x} \geq \boldsymbol{c},$$

where $\mathfrak{S}\colon A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ is a system of linear inequalities as above, $Q_i \in \{\exists, \forall\}$, and $Q_i \neq Q_{i+1}$ for all $1 \leq i < k$, i.e., quantifiers alternate between blocks of variables. The *size* $|\psi|$ of ψ is the number of bits required to write down ψ, where we assume binary encoding of numbers, and also that $|\psi| \geq \max\{2, n + m, \log\|A\|, \log\|\boldsymbol{c}\|\}$. The set $[\![\psi]\!] \subseteq (X \setminus (X_1 \cup \cdots \cup X_k) \Rightarrow \mathbb{N})$ of *non-negative solutions* to ψ is inductively defined as follows:

- for $k = 0$, $[\![\psi]\!] := [\![\mathfrak{S}]\!]$;
- for $k > 0$ and $\psi = \exists \boldsymbol{x}_k.\psi_k$, $[\![\psi]\!] := \pi_{\boldsymbol{x}_k}[\![\psi_k]\!]$; and
- for $k > 0$ and $\psi = \forall \boldsymbol{x}_k.\psi_k$, $[\![\psi]\!] := \pi^*_{\boldsymbol{x}_k}[\![\psi_k]\!]$.

A set $M \subseteq (X \Rightarrow \mathbb{N})$ is QIP-*definable* if there is a QIP-formula ψ such that $M = [\![\psi]\!]$. Whenever $X \subseteq X_1 \cup \cdots \cup X_k$, we say that ψ is a *sentence*. In this case, ψ is *valid* if $[\![\psi]\!] = \{\top\}$ where $\top$ denotes the unique function from $\emptyset$ to $\mathbb{N}$, and *invalid* if $[\![\psi]\!] = \emptyset$. If $X \setminus (X_1 \cup \cdots \cup X_k) = Y = \{y_1, \ldots, y_m\}$, we write $\psi(y_1, \ldots, y_m)$ to indicate that ψ is *open* in Y. Given $a_1, \ldots, a_m \in \mathbb{N}$, we write $\psi[a_1/x_1, \ldots, a_m/x_m]$ to denote the instance of QIP obtained from replacing every occurrence of x_i by a_i in $\mathfrak{S}$. We say that two QIP formulas ψ and ϕ are *equivalent* if $[\![\psi]\!] = [\![\phi]\!]$; note that we may always assume with no loss of generality that ψ and ϕ are open in the same set of variables.

A *(valid) instance* of the QIP problem is a (valid) sentence ψ. We call such a ψ an instance of Σ_k-IP if $Q_k = \exists$, and an instance of Π_k-IP if $Q_k = \forall$. The *alternation depth* of ψ is the number k of quantifier blocks.

Hybrid linear and semi-linear sets. Given finite sets $B, P = \{\boldsymbol{p}_1, \ldots, \boldsymbol{p}_n\} \subseteq \mathbb{N}^m$ called *base* and *period vectors*, the *hybrid linear set generated by B and P* is the set

$$L(B, P) := \{\boldsymbol{b} + \lambda_1 \cdot \boldsymbol{p}_1 + \cdots + \lambda_n \cdot \boldsymbol{p}_n : \boldsymbol{b} \in B, \lambda_i \in \mathbb{N}, 1 \leq i \leq n\}\,.$$

The representation of $L(B, P)$ as the pair B, P (written explicitly) is called the *generator representation*. If B is singleton then $L(B, P)$ is called a *linear set*; a finite union of (hybrid) linear sets is called a *semi-linear set*. For a hybrid linear set in the generator representation $L = L(B, P)$, we denote $\|L\| := \max(\max\|B\|, \max\|P\|)$.

Hybrid linear sets represent sets of solutions to systems of linear inequalities and equalities. The following bounds on the norm in the generator representation follow from [12, Cor. 1] and [2, Prop. 4].

▶ **Proposition 1.** *Let $\mathfrak{S}\colon A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ be a system of linear inequalities such that A is an $n \times m$ integer matrix. Then $[\![\mathfrak{S}]\!] = L(B, P)$ such that $\|B\|, \|P\| \leq (m \cdot \|A\| + \|\boldsymbol{c}\| + 2)^{n+m}$.*

3 Summary

The main result of this paper is the following theorem.

▶ **Theorem 2.** *Σ_k-IP is complete for Σ_k^{P} if k is odd, and Π_k-IP is complete for Π_k^{P} if k is even.*

What happens if the parity of k is different? In this case the innermost quantifiers are universal, and it turns out that they can be eliminated in a trivial way.

▶ **Corollary 3.** *Σ_{k+1}-IP is complete for Σ_k^{P} if k is odd, and Π_{k+1}-IP is complete for Π_k^{P} if k is even.*

The lower bound of Theorem 2 is proved by a reduction from an alternating version of the subset sum problem, which is essentially shown complete for the respective levels of the polynomial-time hierarchy by Travers [15]. Our reduction and more details are given in Section 7.

The upper bound of Theorem 2 is more challenging. Note that in the well-known case of Σ_1-IP, i.e., of the standard integer programming, in order to prove membership of the problem in NP, one needs to obtain polynomial upper bounds on the bit size of minimal solutions to systems of integer linear inequalities. Such bounds were derived by, e.g., von zur Gathen and Sieveking [16]. In our work, we build upon these bounds and generalize them from Σ_1-IP instances to QIP instances.

▶ **Proposition 4** (Small Witness Property). *For a* QIP *instance* ψ *of the form* (1) *with* k *quantifier blocks, the validity of* ψ *does not change if variables of the vector* $\boldsymbol{x}_k$ *(bound by the quantifiers of the outermost block) are interpreted over* $[0, M-1]$ *instead of* $\mathbb{N}$*, where* $\log M = |\psi|^{O(k)}$.

The domains of other variables can then be bounded in turn as follows – which places QIP with fixed alternation depth into PH.

▶ **Proposition 5** (Relativization-Type Theorem). *For a* QIP *instance* ψ *of the form* (1) *with* k *quantifier blocks, the validity of* ψ *does not change if, for each* $i \in [1, k]$*, all variables of the vector* $\boldsymbol{x}_i$ *(bound by the quantifiers of the* i*th innermost block) are interpreted over* $[0, M_i - 1]$ *instead of* $\mathbb{N}$*, where* $\log M_i = |\psi|^{O(2k-i)}$ *and the constant of* $O(\cdot)$ *is independent of* ψ*,* k*, and* i.

Let us point out that in Proposition 5 it is not possible to substitute $[0, M-1]$ for the range of *all* variables; not only using $M = \max M_i$, but in fact using any finite M. For example, the sentence $\forall x.\, \exists y : y = x + 1$ is true if x and y are interpreted in $\mathbb{N}$, but false if they are interpreted in any finite segment $[0, M-1]$.

▶ Remark. The last observation, of course, also holds for Presburger arithmetic in general: any relativization-type theorem (analogous to Proposition 5) must assign different ranges to variables from different quantifier blocks; for instance, this reveals a flaw in the formulation of the relativization-type Theorem 2.2 in [17].

Notice that our small witness property (Proposition 4) is specific to QIP, in the sense that its bound is smaller by one exponential compared to its analogue for general Presburger formulas [17, Thm. 2.2] (the latter is, in fact, tight, as shown implicitly in, e.g., [5, 6]). At the core of our small witness property is a new quantifier elimination procedure for QIP:

▶ **Proposition 6** (Quantifier Elimination). *Given a* QIP *formula* $\phi(\boldsymbol{x})$ *with alternation depth* k*, there exists an equivalent* Σ_1-IP *formula* $\phi'(\boldsymbol{x})$ *with at most* $2^{|\psi|^{O(k)}}$ *existentially quantified variables and numbers of absolute value bounded by* $2^{|\psi|^{O(k)}}$.

The ideas behind Propositions 4 and 6 are outlined in the following Section 4.

Further results. Our results give a uniform upper bound for the general QIP problem, where the number of quantifier blocks can be unbounded. For such a QIP instance, our relativization-type theorem (Proposition 5) suggests doubly exponential ranges for all variables, which places QIP in the complexity class $\mathsf{STA}(*, 2^{n^{O(1)}}, n)$, as $k \le n$. The best lower bound is PSPACE, by the arguments of Section 7.

Another by-product of our techniques is a pseudo-polynomial algorithm for QIP in which the total number of variables is fixed and the matrix formula is $A \cdot \boldsymbol{x} = \boldsymbol{c}$ instead of $A \cdot \boldsymbol{x} \ge \boldsymbol{c}$.

In terms of auxiliary techniques, on the way to our quantifier elimination procedure for QIP we discover (in Sections 5 and 6) some new properties of hybrid linear sets. In particular, these properties enable us to find, as a side result, a polynomial-time algorithm for universality of hybrid linear sets in the generator representation, even if all input numbers are written in binary (Proposition 17 in Section 5).

Finally, our results extend in a natural way to the version of quantified integer programming where all variables are interpreted over $\mathbb{Z}$ instead of over $\mathbb{N}$: the results of Theorem 2 and Corollary 3 still hold.

4 Main ideas

As explained in Section 3, bounding the range of the outermost quantifier is the main technical task in our development. In this section we explain how to do this, thus sketching the ideas behind both the small witness property (Proposition 4) and the quantifier elimination procedure (Proposition 6).

Suppose we start with a QIP instance ψ of the form (1); to find a suitable upper bound M_k for the range of the $\boldsymbol{x}_k$ variables of ψ, we will compute generator representations for the sets of models of formulas

$$\psi_j(\boldsymbol{x}_k, \ldots, \boldsymbol{x}_{j+1}) = \mathrm{Q}_j \boldsymbol{x}_j \ \ldots \ \forall \boldsymbol{x}_2.\ \exists \boldsymbol{x}_1 : A \cdot \boldsymbol{x} \geq \boldsymbol{c}$$

for all $j \in [0, k]$, where, as previously, $\boldsymbol{x}$ is the concatenation of $\boldsymbol{x}_1, \ldots, \boldsymbol{x}_k$. For each value of the parameter j, we will find upper bounds on the integers appearing in these representations, starting with $j = 0$ and culminating with $j = k$. The upper bound for the value of parameter $j = k$ will be a valid choice for M_k.

Let us now describe this computation in more detail. Consider a simple abstract example, a Σ_3-IP instance with 3 variables, $\psi\colon \exists x.\ \forall y.\ \exists z : A \cdot \boldsymbol{x} \geq \boldsymbol{c}$ where $\boldsymbol{x} = (x, y, z)$. Let $L_0 \subseteq \mathbb{N}^3$ be the set of all models of $\psi_0\colon A \cdot \boldsymbol{x} \geq \boldsymbol{c}$; this is a hybrid linear set – denote it $L(C_0, Q_0)$ – with $\|C_0\|$, $\|Q_0\|$ upper-bounded by a polynomial in $\|A\|, \|\boldsymbol{c}\|$ with degree at most the size of ψ (see, e.g., Proposition 1). It follows that $\log\|C_0\|$ and $\log\|Q_0\|$ are polynomial in the size of ψ. It is clear that the the set $L_1 = [\![\psi_1]\!] = \{(x, y) \in \mathbb{N}^2 \mid \text{there exists a } z \in \mathbb{N} \text{ such that } (x, y, z) \in L_0\}$ is simply a projection of $L(C_0, Q_0)$, and in particular $L_1 = L(C, Q)$ where the sets C and Q are obtained by removing z-coordinates from all vectors in C_0 and Q_0, respectively. Hence, $\log\|C\|$ and $\log\|Q\|$ are also polynomial in the size of ψ. (This will, of course, work for all occurrences of the existential quantifier in ψ, including $\exists x$ in our example; but we will need to handle the universal quantifier $\forall y$ before handling $\exists x$.)

The next step is to transform the generator representation $L(C, Q)$ of the set $L_1 = [\![\psi_1]\!]$ into a generator representation of the set

$$L_2 = [\![\psi_2]\!] = \{x \in \mathbb{N} \mid \text{for all } y \in \mathbb{N} \text{ it holds that } (x, y) \in L_1\}.$$

This set L_2 is the *universal projection* of $L(C, Q)$: $L_2 = \pi_y^*(L(C, Q))$; cf. Section 2. As the main technical contribution of the present paper, we show that, in general, (*i*) universal projections of hybrid linear sets are hybrid linear sets themselves and that (*ii*) universal projection as an operation on hybrid linear sets can only lead to a moderate increase in the magnitude of generators. (These results are summarized in Proposition 10 below. For the usual projection, such facts are obvious.)

We now briefly introduce the techniques that we develop for handling the universal projection. Define for each $y \in \mathbb{N}$ the cross section $S(y) = \{x \in \mathbb{N} \mid (x, y) \in L_1\}$, then

$$L_2 = \bigcap_{y \in \mathbb{N}} S(y) \tag{2}$$

by definition. Each set $S(y)$ is a semi-linear set (and, in fact, a hybrid linear set – because it is essentially the intersection of two hybrid linear sets, see Lemma 13, and such intersections are hybrid linear sets themselves, see, e.g., [2, Theorem 6]), but the intersection in (2) is infinite, and, in general, an infinite intersection of semi-linear sets does not have to be semi-linear.[3] However, we prove (in Section 5) the following lemma, which is our first and key insight:

[3] For every $n \geq 1$, consider the hybrid linear set $L_n = \mathbb{N} \setminus \{0, n\} = L([1, n-1] \cup \{2n\}, \{n\})$. Given any $A \subseteq \mathbb{N}$, the intersection $\bigcap_{n \in A} L_n = \mathbb{N} \setminus (\{0\} \cup A)$ is only semi-linear (i.e., ultimately periodic) if so is A.

▶ **Lemma 7.** *Let $L = L(C,Q) \subseteq \mathbb{N}^m$ be a hybrid linear set with $C, Q \subseteq \mathbb{N}^m$. Let the components of vectors be indexed by m variables X, let $U \subseteq X$, $|U| = s$, and suppose $\boldsymbol{u}$ is the corresponding vector of variables. Then the following statements hold:*

- *If, for some variable $u_i \in U$, the set Q contains no multiple of the unit vector $\boldsymbol{e}_i$ associated with u_i, then $\pi^*_{\boldsymbol{u}}(L) = \emptyset$.*
- *Otherwise, denote $a_i = \min\{a \mid a \cdot \boldsymbol{e}_i \in Q\}$ and $H = \{\boldsymbol{b} \in \mathbb{N}^s \mid 0 \le \boldsymbol{b}(u_i) \le a_i - 1 \text{ for all } u_i \in U\}$. Then*

$$\pi^*_{\boldsymbol{u}}(L) = \bigcap_{\boldsymbol{b} \in H} \pi_{\boldsymbol{u}}\big(L(C,Q) \cap \{\boldsymbol{u} = \boldsymbol{b}\}\big)$$

where $\{\boldsymbol{u} = \boldsymbol{b}\}$ denotes the hybrid linear set $\{\boldsymbol{c} \in \mathbb{N}^m \mid \boldsymbol{c}(u_i) = \boldsymbol{b}(u_i) \text{ for all } u_i \in U\}$.

In other words, unless $L_2 = \emptyset$, the intersection in (2) can be made finite without changing its result: $\bigcap_{y \in \mathbb{N}} S(y) = \bigcap_{y < N} S(y)$, where $\log N$ is polynomial in the size of ψ. Since, as we have just mentioned, hybrid linear sets are closed under finite intersections, this shows that the set L_2 is hybrid linear, and, in fact, the following general result follows:

▶ **Proposition 8.** *A set in $\mathbb{N}^m$ is* QIP*-definable iff it is hybrid linear.*

Furthermore, the set L_2 turns out to have a small generator representation as well. Indeed, we first observe that all sets $S(y)$ have representations $L(B_y, P)$ with a common set of periods P and with $\|B_y\|$, $\|P\|$ small if so is $\|y\|$ (Lemma 13 in Section 5). We then prove (in Section 6) the following lemma, which is our second insight:

▶ **Lemma 9.** *Let $L_i = L(C_i, Q)$, $i \in [1,n]$, be hybrid linear sets with $C_i, Q \subseteq \mathbb{N}^m$. The set $S = \bigcap_{i=1}^n L_i$ has a representation $S = L(B,Q)$ where $\|B\| \le \max_{i \in [1,n]} \|L_i\|^{O(m^3)}$ independently of n.*

In other words, long intersections of hybrid linear sets with a common set of periods preserve small representations, regardless of the number of sets in the intersection. Combining Lemmas 7 and 9, we obtain the following statement:

▶ **Proposition 10.** *Let $L = L(C,Q) \subseteq \mathbb{N}^m$ be a hybrid linear set with $C, Q \subseteq \mathbb{N}^m$. Let the components of vectors be indexed by m variables $\boldsymbol{u}, \boldsymbol{v}$, and suppose the vector $\boldsymbol{u}$ has s variables. Then the universal projection $\pi^*_{\boldsymbol{u}}(L)$ has a representation $L(B,P)$ where $P = \pi_{\boldsymbol{u}}(\{\boldsymbol{q} \in Q \mid q_1 = \ldots = q_s = 0\})$ and $\|B\| \le \|L\|^{O(m^5)}$.*

In particular, we conclude that the set $L_2 = \bigcap_{y < N} L(B_y, P)$ has a representation $L(B,P)$ with $\|B\| < M$ where $\log M$ is polynomial in the size of ψ. But note that $\psi = \psi_3$ is true iff $L_2 = [\![\psi_2]\!]$ is non-empty; therefore, the validity of ψ is unchanged if the range of $\exists x$ is changed from $\mathbb{N}$ to $[0, M-1]$. Thus, in our example the bound M_3 can be chosen as M; it can hence be deduced that a Σ_3^{P} algorithm can handle such instances. The argument for the general case follows the same lines.

5 Universal projection and universality

A semi-linear set in $\mathbb{N}^d$ is called *universal* if it is equal to $\mathbb{N}^d$.

▶ **Example 11.** A one-dimensional hybrid linear set $L = L(B,P) \subseteq \mathbb{N}$ with $B, P \subseteq \mathbb{N}$ is universal iff $P \setminus \{0\} \neq \emptyset$ and L contains the integer segment $[0, k-1]$ where $k = \min P \setminus \{0\}$. Indeed, the right-to-left direction is immediate: if L satisfies the conditions above, then $\mathbb{N} = L([0,k-1], \{k\}) \subseteq L$. For the left-to-right direction, suppose $L = \mathbb{N}$. First observe that the set $P \setminus \{0\}$ is non-empty because L is infinite. Therefore, $k > 0$ is well-defined. Second, as $L = \mathbb{N}$, the set L contains all natural numbers, in particular those in $[0, k-1]$.

The following lemma generalizes Example 11; recall that $\boldsymbol{e}_i$ denotes the ith unit vector.

▶ **Lemma 12.** *A hybrid linear set $L = L(B, P) \subseteq \mathbb{N}^m$ with $B, P \subseteq \mathbb{N}^m$ is universal iff P contains vectors $a_i \cdot \boldsymbol{e}_i$ for some $a_i > 0$, for every $i \in [1, m]$, and L contains the box $H = [0, a_1 - 1] \times \ldots \times [0, a_m - 1]$.*

Proof. The right-to-left direction is immediate: if L satisfies the conditions of the lemma, then $\mathbb{N}^m = L(H, \{a_1 \cdot \boldsymbol{e}_1, \ldots, a_m \cdot \boldsymbol{e}_m\}) \subseteq L$. For the left-to-right direction, suppose $L = \mathbb{N}^m$. We first prove that, for each $i \in [1, m]$, the set of periods P contains a vector $a_i \cdot \boldsymbol{e}_i$ with $a_i > 0$. Assume without loss of generality that $i = 1$ and denote $N = \mathbb{N} \times \mathbf{0} \subseteq \mathbb{N}^m$. Since L is universal (and $\mathbb{Q}_{\geq 0} \times \mathbf{0}$ is a face of $\mathbb{Q}^m_{\geq 0}$), $N = L(B, P) \cap N \subseteq L(B \cap N, P \cap N)$. Therefore, the set $P \cap N$ contains at least one vector $a_1 \cdot \boldsymbol{e}_1$ with $a_1 > 0$, otherwise the set N would be finite. Hence, P contains $a_1 \cdot \boldsymbol{e}_1, \ldots, a_m \cdot \boldsymbol{e}_m$ with all $a_i > 0$. It now remains to note that, as $L = \mathbb{N}^m$, the set L contains all nonnegative integer vectors, in particular those in H. This completes the proof. ◀

▶ Remark. If $m = 1$, then in the statement of Lemma 12, the condition $H \subseteq L(B, P)$ is equivalent to the condition $H \subseteq B$, as long as H is defined using the *shortest* vector $a_1 \cdot \boldsymbol{e}_1$ in $P \setminus \{\mathbf{0}\}$. For $m \geq 2$, this is no longer the case.

▶ **Lemma 13.** *Suppose $L = L(C, Q) \subseteq \mathbb{N}^m$ and $M = L(D, E) \subseteq \mathbb{N}^m$ where $E = \{\boldsymbol{e}_1, \ldots, \boldsymbol{e}_s\}$. Then the set $L \cap M$ has a representation $L(B, P)$ where $P = \{\boldsymbol{q} \in Q \mid q_{s+1} = \ldots = q_m = 0\}$ and $\|B\| \leq \|L\|^{O(m^2)} \cdot \|M\|^{O(m)}$.*

We can now restate and prove Lemma 7, which appeared previously in Section 4.

▶ **Lemma 14.** *Let $L = L(C, Q) \subseteq \mathbb{N}^m$ be a hybrid linear set with $C, Q \subseteq \mathbb{N}^m$. Let the components of vectors be indexed by m variables X, let $U \subseteq X$, $|U| = s$, and suppose $\boldsymbol{u}$ is the corresponding vector of variables. Then the following statements hold:*

- *If, for some variable $u_i \in U$, the set Q contains no multiple of the unit vector $\boldsymbol{e}_i$ associated with u_i, then $\pi^*_{\boldsymbol{u}}(L) = \emptyset$.*
- *Otherwise, denote $a_i = \min\{a \mid a \cdot \boldsymbol{e}_i \in Q\}$ and $H = \{\boldsymbol{b} \in \mathbb{N}^s \mid 0 \leq \boldsymbol{b}(u_i) \leq a_i - 1$ for all $u_i \in U\}$. Then*

$$\pi^*_{\boldsymbol{u}}(L) = \bigcap_{\boldsymbol{b} \in H} \pi_{\boldsymbol{u}}\big(L(C, Q) \cap \{\boldsymbol{u} = \boldsymbol{b}\}\big)$$

where $\{\boldsymbol{u} = \boldsymbol{b}\}$ denotes the hybrid linear set $\{\boldsymbol{c} \in \mathbb{N}^m \mid \boldsymbol{c}(u_i) = \boldsymbol{b}(u_i)$ for all $u_i \in U\}$.

Proof. Denote $V = X \setminus U$; we will abuse notation and let symbols $\boldsymbol{u}$ and $\boldsymbol{v}$ refer to U- and V-indexed integer vectors (wherever this creates no confusion). By definition, a vector $\boldsymbol{v}^*$ belongs to $\pi^*_{\boldsymbol{u}}(L)$ if and only if for all $\boldsymbol{u}$ the vector $(\boldsymbol{u}, \boldsymbol{v}^*)$ belongs to L. This condition is equivalent to the requirement that

$$L \cap \{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*\} = \{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*\}. \tag{3}$$

Note that $\{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*\} = L((\mathbf{0}, \boldsymbol{v}^*), E)$ where E is the set of all unit vectors associated with variables $\boldsymbol{u}$. We now apply Lemma 13: $L \cap L((\mathbf{0}, \boldsymbol{v}^*), E) = L(D_{\boldsymbol{v}^*}, R)$ where $R = \{\boldsymbol{q} = (\boldsymbol{u}, \boldsymbol{v}) \in Q \mid \boldsymbol{v} = \mathbf{0}\}$. Now the requirement (3) has the form $L(D_{\boldsymbol{v}^*}, R) = \{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*\}$ and, by Lemma 12, is equivalent to the requirement that, first, the set R contains some multiple of the unit vector, $a_i \cdot \boldsymbol{e}_i$ for some $a_i > 0$, associated with each variable $u_i \in U$, and, second, the set $L(D_{\boldsymbol{v}^*}, R)$ contains the box

$$H(\boldsymbol{v}^*) = \{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*, 0 \leq u_i \leq a_i - 1 \text{ for all variables } u_i \in U\}.$$

Note that in the statement of Lemma 12 we can always choose $a_i \cdot \boldsymbol{e}_i$ to be the shortest vectors of the required form in R; expanding the definition of R then gives

$$a_i = \min\{a \mid a \cdot \boldsymbol{e}_i \in Q\} \qquad \text{for each variable } u_i \in U. \tag{4}$$

We now make the following observations. First, the set R does not depend on the vector $\boldsymbol{v}^*$, but only on Q and on the way the variables are split into $\boldsymbol{u}$ and $\boldsymbol{v}$. Therefore, the condition that R contains $a_i \cdot \boldsymbol{e}_i$ for some $a_i > 0$ is either satisfied or not satisfied for all $\boldsymbol{v}^*$ simultaneously. In the former case, $\pi^*_{\boldsymbol{u}}(L) = \emptyset$; so it suffices to consider the latter case. We have the following equivalence:

$$\boldsymbol{v}^* \in \pi^*_{\boldsymbol{u}}(L) \quad \text{iff} \quad (\boldsymbol{u}, \boldsymbol{v}^*) \in L(D_{\boldsymbol{v}^*}, R) \text{ for all } \boldsymbol{u} \in H$$

where $H = \{\boldsymbol{u} \mid 0 \le u_i \le a_i - 1 \text{ for all variables } u_i \in U\}$ and a_i are as defined in (4). Since $L(D_{\boldsymbol{v}^*}, R)$ was chosen as $L \cap \{(\boldsymbol{u}, \boldsymbol{v}) \in \mathbb{N}^m \mid \boldsymbol{v} = \boldsymbol{v}^*\}$, this is the same as

$$\boldsymbol{v}^* \in \pi^*_{\boldsymbol{u}}(L) \quad \text{iff} \quad (\boldsymbol{u}, \boldsymbol{v}^*) \in L \text{ for all } \boldsymbol{u} \in H,$$

and the equation of the lemma follows. ◀

▶ **Example 15.** Consider any set $L = L(C, \{3\,\boldsymbol{e}_2\}) \subseteq \mathbb{N}^2$ with a finite $C \subseteq \mathbb{N}^2$. Its universal projection $L' = \pi^*_y(L) = \{x \mid (x, y) \in L \text{ for all } y \in \mathbb{N}\}$ can be obtained by taking cross sections $S_b = \{x \mid (x, b) \in L\}$ for $b = 0, 1, 2$, removing the y coordinate, and intersecting the results: $L' = \pi_y(S_0) \cap \pi_y(S_1) \cap \pi_y(S_2)$ where the projection $\pi_y \colon \mathbb{N}^2 \to \mathbb{N}$ removes the y coordinate. So whether or not a specific $a \in \mathbb{N}$ belongs to L' is fully determined by whether the vectors $(a, 0)$, $(a, 1)$, and $(a, 2)$ belong to L. In fact, this conclusion will also hold if instead of L we consider any set $M = L(C, \{3\,\boldsymbol{e}_2\} \cup Q)$ where Q contains no vectors of the form $a \cdot \boldsymbol{e}_2$.

Intermezzo: Deciding universality of hybrid linear sets

The technique developed above, in fact, enables us to show that universality of hybrid linear sets (given in generator representation) can be decided in polynomial time, even if all numbers are written in binary. Consider the following lemma, which is a more general version of Example 11 and Lemma 12.

▶ **Lemma 16.** *Let $L = L(B, P) \subseteq \mathbb{N}^m$ be a hybrid linear set with $B, P \subseteq \mathbb{N}^m$. Define the set of* shallow points*,*

$$W = \big\{\, \boldsymbol{w} \in \mathbb{N}^m \mid \textit{there is no } \boldsymbol{p} \in P \setminus \{\boldsymbol{0}\} \textit{ with } \boldsymbol{w} \ge \boldsymbol{p} \,\big\} = \mathbb{N}^m \setminus \bigcup_{\boldsymbol{p} \in P \setminus \{\boldsymbol{0}\}} (\boldsymbol{p} + \mathbb{N}^m).$$

Then L is universal iff $W \subseteq B$.

Indeed, for Example 11, observe that for $m = 1$ the set W is the integer segment $[0, k-1]$ where $k = \min P \setminus \{0\}$; cf. Remark 5.

For Lemma 12, note that $W \subseteq B$ is only possible if W is finite, which implies that for each $i \in [1, m]$ there is a vector $a_i \cdot \boldsymbol{e}_i \in P$ with $a_i > 0$ (otherwise all such vectors for some given i are in W, and there are infinitely many of them). But then $W \subseteq H = [0, a_1 - 1] \times \ldots \times [0, a_m - 1]$.

▶ **Proposition 17.** *There is a polynomial-time algorithm that takes a hybrid linear set $L(B, P) \subseteq \mathbb{N}^m$, presented as $B, P \subseteq \mathbb{N}^m$ with numbers written in binary, and decides if $L(B, P)$ is universal.*

Proof. By the characterization of Lemma 16, it is sufficient to check if $W \subseteq B$. First check that the necessary condition of Lemma 12 is satisfied: if for some i there is no $a_i \cdot \boldsymbol{e}_i \in P$ with $a_i > 0$, then $L(B, P)$ is not universal. Otherwise consider the Hasse diagram of the partial order $(H, \leq)$, i.e., the directed acyclic graph with vertex set H and all edges $(\boldsymbol{x}, \boldsymbol{y})$ where $\boldsymbol{x} < \boldsymbol{y}$ and there is no $\boldsymbol{z}$ with $\boldsymbol{x} < \boldsymbol{z} < \boldsymbol{y}$. Notice that this graph does not have to be of polynomial size with respect to the input.

Run the depth-first search (DFS) procedure on (a part of) this graph, starting from $\mathbf{0}$ and for each $\boldsymbol{x} \in H$ ordering the outgoing edges $(\boldsymbol{x}, \boldsymbol{y})$ according to the (unique) index $i \in [1, m]$ for which $x_i < y_i$. Whenever the current node is outside W, the algorithm backtracks (observe that the set W is always downward closed, i.e., whenever $\boldsymbol{w} \in W$ and $\boldsymbol{w}' \leq \boldsymbol{w}$, then also $\boldsymbol{w}' \in W$); if it is in W but not in B, the algorithm terminates immediately, reporting that $L(B, P)$ is not universal. If the search finishes, the algorithm concludes that $W \subseteq B$ and reports that $L(B, P)$ is universal. All visited nodes are marked and not re-entered, ensuring that no node is ever visited twice. As all visited notes are checked for inclusion in B, which is given as part of the input, it follows that the running time of the search is proportional to the size of the input, and the entire procedure works in polynomial time. ◀

6 Long intersections

▶ **Lemma 18.** *Let $L_i = L(C_i, Q)$, $i \in [1, n]$, be hybrid linear sets with $C_i, Q \subseteq \mathbb{N}^m$. Suppose the vectors of Q are linearly independent. Then the set $S = \bigcap_{i=1}^{n} L_i$ has a representation $S = L(B, Q)$ where $\|B\| \leq 2^{O(m \log m)} \cdot \max_{i \in [1,n]} \|L_i\| \cdot \|Q\|^m$ independently of n.*

Proof (Sketch). Note that $\bigcap_{i=1}^{n} L(C_i, Q)$ is the union over all $\boldsymbol{c}_1 \in C_1, \ldots, \boldsymbol{c}_n \in C_n$ of $\bigcap_{i=1}^{n} L(\boldsymbol{c}_i, Q)$, so we shall assume with no loss of generality that $C_i = \{\boldsymbol{c}_i\}$ for all i.

Define a point lattice $\mathcal{L} = Q \cdot \mathbb{Z}^r = \{Q \cdot \boldsymbol{u} \mid \boldsymbol{u} \in \mathbb{Z}^r\}$ where $r = |Q|$; see, e.g., [10, Chapter 2]. Vectors $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{Z}^m$ are called *congruent* modulo $\mathcal{L}$, written $\boldsymbol{x} \equiv \boldsymbol{y} \pmod{\mathcal{L}}$, if and only if $\boldsymbol{x} - \boldsymbol{y} \in \mathcal{L}$. This congruence splits $\mathbb{Z}^m$ into a disjoint union of equivalence classes, which have the form $\boldsymbol{x} + \mathcal{L}$ where $\boldsymbol{x} \in \mathbb{Z}^m$. Note that the relation $\equiv$ is compatible with addition and subtraction of elements of Q, in the sense that vectors $\boldsymbol{x} \pm \boldsymbol{q}$, $q \in Q$, belong to the same equivalence class as $\boldsymbol{x}$; therefore, $L_i = \boldsymbol{c}_i + Q \cdot \mathbb{N}^r \equiv \boldsymbol{c}_i \pmod{\mathcal{L}}$. Hence, unless the intersection $\bigcap_{i=1}^{n} L_i$ is empty, it must be the case that $\boldsymbol{c}_i \equiv \boldsymbol{c}_j \pmod{\mathcal{L}}$ for all i, j. We assume in the sequel that this is indeed the case, i.e., all sets L_i are contained in the same equivalence class $\boldsymbol{c}_1 + \mathcal{L}$.

Let us now define the coordinates in $\boldsymbol{c}_1 + \mathcal{L}$ in a natural way. Consider the mapping $\psi \colon \boldsymbol{c}_1 + \mathcal{L} \to \mathbb{Z}^r$ that maps each $\boldsymbol{x}$ into a vector $\boldsymbol{u} = \psi(\boldsymbol{x})$ such that $\boldsymbol{x} = \boldsymbol{c}_1 + Q \cdot \boldsymbol{u}$; note that $\boldsymbol{u}$ exists as long as $\boldsymbol{x} \in \boldsymbol{c}_1 + \mathcal{L}$ and is determined uniquely because the vectors in Q are linearly independent. The mapping ψ is, in fact, a bijection between $\boldsymbol{c}_1 + \mathcal{L}$ and $\mathbb{Z}^r$, so $L_1 \cap \ldots \cap L_n = \psi^{-1}(\psi(L_1) \cap \ldots \psi(L_n))$. Denote $\boldsymbol{f}_i = \psi(\boldsymbol{c}_i)$ and observe that $\psi(L_i) = \psi(\boldsymbol{c}_i) + \mathbb{N}^r$. So a vector $\boldsymbol{v} \in \mathbb{Z}^r$ belongs to the intersection of all $\psi(L_i)$ if and only if $\boldsymbol{v} \geq \boldsymbol{f}_i$ for all $i \in [1, n]$. This condition is satisfied if and only if $\boldsymbol{v} \geq \boldsymbol{f}$ where $\boldsymbol{f}$ is the component-wise maximum of vectors $\boldsymbol{f}_1, \ldots, \boldsymbol{f}_n$; in other words, $\bigcap_{i=1}^{n} \psi(L_i) = \boldsymbol{f} + \mathbb{N}^r$ and $L_1 \cap \ldots \cap L_n = L(\psi^{-1}(\boldsymbol{f}), Q)$.

It remains to find an upper bound on $\|\psi^{-1}(\boldsymbol{f})\|$. Note that $\psi^{-1}(\boldsymbol{f}) = \boldsymbol{c}_1 + Q \cdot \boldsymbol{f}$, so $\|\psi^{-1}(\boldsymbol{f})\| \leq \|\boldsymbol{c}_1\| + \|Q \cdot \boldsymbol{f}\|$. Suppose $\boldsymbol{f} = (f^1, \ldots, f^r)$ and $Q = \{\boldsymbol{q}_1, \ldots, \boldsymbol{q}_r\}$, then $Q \cdot \boldsymbol{f} = f^1 \cdot \boldsymbol{q}_1 + \ldots + f^r \cdot \boldsymbol{q}_r$. Recall that each f^j is, in fact, a component of some $\boldsymbol{f}_i = \psi(\boldsymbol{c}_i)$.

For this $i = i(j)$ it holds that $\boldsymbol{c}_i = \boldsymbol{c}_1 + Q \cdot \boldsymbol{f}_i$, and by [2, Proposition 3] we have

$$|f^j| \leq 2^{O(m \log m)} \cdot \max\left(\|\boldsymbol{c}_i - \boldsymbol{c}_1\|, \|Q\|\right) \cdot \|Q\|^{m-1} \quad \text{and}$$
$$\|\psi^{-1}(\boldsymbol{f})\| \leq \|C_1\| + m \cdot \max_{j \in [1,r]} \|f^j \cdot \boldsymbol{q}_j\| \leq 2^{O(m \log m)} \cdot \max_{i \in [1,n]} \|L_i\| \cdot \|Q\|^m. \quad \blacktriangleleft$$

We can now restate and prove Lemma 9, which appeared previously in Section 4.

▶ **Lemma 19.** *Let $L_i = L(C_i, Q)$, $i \in [1,n]$, be hybrid linear sets with $C_i, Q \subseteq \mathbb{N}^m$. The set $S = \bigcap_{i=1}^n L_i$ has a representation $S = L(B, Q)$ where $\|B\| \leq \max_{i \in [1,n]} \|L_i\|^{O(m^3)}$ independently of n.*

Proof (Sketch). We first apply a discrete version of the Carathéodory theorem [2, Proposition 5] to the set L_1, decomposing it into a union of hybrid linear sets with linearly independent periods:

$$L_1 = \bigcup_j M_j \quad \text{where} \quad M_j = L(D_j, Q_j) \quad \text{and} \quad \|D_j\| \leq \|C_1\| + (\#Q \cdot \|Q\|)^{O(m)},$$

with each $Q_j \subseteq Q$ a set of linear independent vectors (here and below $\#$ denotes the cardinality of a set). The intent is to make it possible to invoke Lemma 18.

Notice that, whereas intersecting two hybrid linear sets L and L' with sets of periods P and $P' \subseteq P$, respectively, will always give a hybrid linear set with the set of periods P' (see, e.g., [2, Theorem 6] and, transitively, Theorem 5.6.1 of [4, p. 180]), this observation would not suffice for our purposes. Indeed, the magnitude of the base vectors in the hybrid linear representation of $L \cap L'$ can still increase compared to the magnitude of the base vectors of L and L'; and so $n-1$ consecutive applications of this operation would lead to a blowup in the representation size if n grows. Instead of using this observation, we will rely on Lemma 18 to defeat the effect of large n, and will use another trick to make its application possible.

Indeed, observe that

$$L_1 \cap L_2 \cap \ldots \cap L_n = \bigcup_j M_j \cap L_2 \cap \ldots \cap L_n = \bigcup_j (M_j \cap L_2) \cap \ldots \cap (M_j \cap L_n).$$

Since the sets of periods of M_j and L_i are Q_j and Q, respectively, it follows by [2, Theorem 6] that each $M_j \cap L_i$ is a hybrid linear set with representation $L(B_{i,j}, Q_j)$, where

$$\|B_{i,j}\| \leq ((\#Q_j + \#Q) \cdot \max(\|M_j\|, \|L_i\|))^{O(m)} \leq \max\left(\|C_1\| + (\#Q \cdot \|Q\|)^{O(m)}, \|L_i\|\right)^{O(m)}.$$

But now, for each j, the intersection of $L(B_{i,j}, Q_j)$, $i \in [2,n]$, satisfies the conditions of Lemma 18, and thus can be written as $L(B_j, Q_j)$ with $\|B_j\|$ small with respect to $\|B_{i,j}\|$ and $\|Q_j\|$ (estimations to follow). Now $S = \bigcup_j L(B_j, Q_j)$, and it remains to note that, as $L_i + L(\mathbf{0}, Q) = L_i$ for all i, it also holds that $S + L(\mathbf{0}, Q) = S$ and hence

$$S = \bigcup_j L(B_j, Q_j) + L(\mathbf{0}, Q) = \bigcup_j L(B_j, Q) = L\left(\bigcup_j B_j,\ Q\right), \quad \text{with}$$
$$\|B_j\| \leq 2^{O(m \log m)} \cdot \max\left(\max_{i \in [2,n]} \|B_{i,j}\|, \|Q_j\|\right) \cdot \|Q_j\|^m \leq \max_{i \in [1,n]} \|L_i\|^{O(m^3)}. \quad \blacktriangleleft$$

7 Lower bounds

We show lower bounds for QIP and Σ_k-IP via a reduction from a generalisation of the classical SubsetSum problem. For odd k, let $\boldsymbol{a}_k \in \mathbb{N}^{m_k}, \ldots, \boldsymbol{a}_1 \in \mathbb{N}^{m_1}$ be vectors of natural

numbers, and let $t \in \mathbb{N}$ be a target. An instance of Σ_k-SubsetSum is a tuple $(\boldsymbol{a}_k, \ldots, \boldsymbol{a}_1, t)$. This instance is a valid instance whenever the following holds:

$$\exists \boldsymbol{x}_k \in \{0,1\}^{m_k}. \, \forall \boldsymbol{x}_{k-1} \in \{0,1\}^{m_{k-1}} \, \ldots \, \exists \boldsymbol{x}_1 \in \{0,1\}^{m_1} : \sum_{i=1}^{k} \boldsymbol{a}_i \cdot \boldsymbol{x}_i = t. \tag{5}$$

Thus, Σ_k-SubsetSum can be viewed as the 0–1 variant of Σ_k-IP, i.e., variables are only interpreted over $\{0,1\}$. For even k, Π_k-SubsetSum is defined analogously. When we take the union of Σ_k-SubsetSum for all $k > 0$, we obtain QSubsetSum.

▶ **Proposition 20.** *For every fixed $k > 0$, for odd k Σ_k-SubsetSum is Σ_k^{P}-complete, and for even k Π_k-SubsetSum is Π_k^{P}-complete.* QSubsetSum *is* PSPACE*-complete.*

Upper bounds for Σ_k-SubsetSum and QSubsetSum can be obtained trivially. The PSPACE lower bound for QSubsetSum was established by Travers in [15, Lem. 4]. Unfortunately, the construction given in [15] does not directly yield Σ_k^{P} hardness for Σ_k-SubsetSum, as the lower bound for QSubsetSum is shown in [15] by a reduction from 3-CNF QBF in which the alternating quantifiers range over *single* variables, and Σ_k^{P} hardness for 3-CNF k-QBF requires an unbounded number of variables in every quantifier block [13]. It is not difficult to show that the construction from [15] can indeed be adapted in order to yield Σ_k^{P} hardness for Σ_k-SubsetSum for odd k, and likewise for even k.

Proof of lower bounds in Theorem 2

We reduce from Σ_k-SubsetSum and show how to transform an instance given as (5) into an equivalent instance of Σ_k-IP. Note that the existentially quantified variables do not present an issue, since, for instance, $\boldsymbol{x}_1 \in \{0,1\}^{m_1}$ iff $\boldsymbol{x}_1 \leq \mathbf{1}$, i.e., (5) is equivalent to

$$\exists \boldsymbol{x}_k \in \{0,1\}^{m_k}. \, \forall \boldsymbol{x}_{k-1} \in \{0,1\}^{m_{k-1}} \, \ldots \, \forall \boldsymbol{x}_2 \in \{0,1\}^{m_2}. \, \exists \boldsymbol{x}_1 : \sum_{i=1}^{k} \boldsymbol{a}_i \cdot \boldsymbol{x}_i = t \wedge \boldsymbol{x}_1 \leq \mathbf{1}. \tag{6}$$

The key insight is that, for universally quantified variables, conjunctions of linear integer constraints can express division with remainder using any fixed divisor. In particular, consider

$$\exists \boldsymbol{x}_k \in \{0,1\}^{m_k}. \, \forall \boldsymbol{x}_{k-1} \in \{0,1\}^{m_{k-1}} \, \ldots \, \forall \boldsymbol{x}_2. \, \exists \boldsymbol{x}_1. \, \exists \boldsymbol{\lambda} : \\ \sum_{i=3}^{k} \boldsymbol{a}_i \cdot \boldsymbol{x}_i + \boldsymbol{a}_2 \cdot (\boldsymbol{x}_2 - 2 \cdot \boldsymbol{\lambda}) + \boldsymbol{a}_1 \cdot \boldsymbol{x}_1 = t \wedge \boldsymbol{x}_1 \leq \mathbf{1} \wedge \mathbf{0} \leq \boldsymbol{x}_2 - 2 \cdot \boldsymbol{\lambda} \leq \mathbf{1}. \tag{7}$$

We claim that the sentences (6) and (7) are equivalent. First, no matter what $\boldsymbol{x}_2$ is, $\boldsymbol{\lambda}$ has to be $\lfloor \boldsymbol{x}_2/2 \rfloor$ in order to satisfy the last constraint of (7). If sentence (6) is true, then (7) is also true. Indeed, if $\boldsymbol{x}_2 \in \{0,1\}^{m_2}$, then we can choose $\boldsymbol{\lambda} = \mathbf{0}$ and the inequalities become the same as before (and thus, for instance, there is an appropriate $\boldsymbol{x}_1$). Analogously, if $\boldsymbol{x}_2$ is outside $\{0,1\}^m$, then it is the vector $\boldsymbol{x}_2 - 2 \cdot \boldsymbol{\lambda}$ that is in $\{0,1\}^{m_2}$, and for this vector we already know the appropriate $\boldsymbol{x}_1$ from the previous formula. Conversely, suppose the sentence (7) is true, then it is in particular true for all choices $\boldsymbol{x}_2 \in \{0,1\}^{m_2}$ in which case $\boldsymbol{\lambda} = \lfloor \boldsymbol{x}_2/2 \rfloor = \mathbf{0}$. Hence, the assignment for $\boldsymbol{x}_1$ chosen in (7) given $\boldsymbol{x}_2$ will also work for (6). This proves the claim.

In fact, the trick above works regardless of how many universal variables we have and at which positions they occur in the quantifier prefix. So we can handle both existential and universal variables and can transform any instance of Σ_k-SubsetSum respectively Π_k-SubsetSum into an equivalent instance of Σ_k-IP respectively Π_k-IP, which yields the desired lower bounds, when variables are interpreted over the natural numbers.

Word Equations in Nondeterministic Linear Space*

Artur Jeż

Institute of Computer Science, University of Wrocław, Wrocław, Poland
aje@cs.uni.wroc.pl

Abstract

Satisfiability of word equations is an important problem in the intersection of formal languages and algebra: Given two sequences consisting of letters and variables we are to decide whether there is a substitution for the variables that turns this equation into true equality of strings. The computational complexity of this problem remains unknown, with the best lower and upper bounds being, respectively, NP and PSPACE. Recently, the novel technique of recompression was applied to this problem, simplifying the known proofs and lowering the space complexity to (nondeterministic) $\mathcal{O}(n \log n)$. In this paper we show that satisfiability of word equations is in nondeterministic linear space, thus the language of satisfiable word equations is context-sensitive. We use the known recompression-based algorithm and additionally employ Huffman coding for letters. The proof, however, uses analysis of how the fragments of the equation depend on each other as well as a new strategy for nondeterministic choices of the algorithm, which uses several new ideas to limit the space occupied by the letters.

1 Introduction

Solving *word equations* was an intriguing problem since the dawn of computer science, motivated first by its ties to Hilbert's 10th problem. Initially it was conjectured that this problem is undecidable, which was disproved in a seminal work of Makanin [10]. At first little attention was given to computational complexity of Makanin's algorithm and the problem itself; these questions were reinvestigated in the '90 [6, 18, 9], culminating in the EXPSPACE implementation of Makanin's algorithm by Gutiérrez [5].

The connection to compression was first observed by Plandowski [16], who showed that a length-minimal solution of size N has a compressed representation of size $\mathsf{poly}(n, \log N)$. Plandowski further explored this approach [14] and proposed a PSPACE algorithm [13], which is the best bound up to date; a simpler PSPACE solution also based on compression was proposed by Jeż [8]. On the other hand, this problem is only known to be NP-hard, and it is conjectured that it is in NP.

The importance of these mentioned algorithms lays with the possibility to extend them (in nontrivial ways) to various scenarios: free groups [11, 1, 3], representation of all solutions [15, 8, 17], traces [12, 2], graph groups [4], terms [7] and others.

* Work supported under National Science Centre, Poland project number 2014/15/B/ST6/00615.

While the computational complexity of word equations remains unknown, its exact space complexity is intriguing as well: Makanin's algorithm uses exponential space [5], Plandowski [13] gave no explicit bound on the space usage of his algorithm, a rough estimation is $\mathsf{NSPACE}(n^5)$, the recent solution of Jeż [8] yields $\mathsf{NSPACE}(n \log n)$. Moreover, for $\mathcal{O}(1)$ variables a linear bound on space complexity was shown [8]; recall that languages recognisable in nondeterministic linear space are exactly the context-sensitive languages.

In this paper we show that satisfiability of word equations can be tested in nondeterministic linear space in terms of the number of bits of the input, thus showing that the language of satisfiable word equations is context-sensitive (and by the famous Immerman–Szelepcsényi theorem: the language of unsatisfiable word equations). The employed algorithm is a (variant of) algorithm of Jeż [8], which additionally uses Huffman coding for letters in the equation. On the other hand, the actual proof uses a different encoding of letters, which extends the ideas used in a (much simpler) proof in case of $\mathcal{O}(1)$ variables [8, Section 5]; the other new ingredient is a different strategy of compression: roughly speaking, previously a strategy that minimised the length of the equation was used. Here, a more refined strategy is used: it simultaneously minimises the size of a particular bit encoding, enforces that changes in the equation (during the algorithm) are local, and limits the amount of new letters that are introduced to the equation.

The bound holds when letters and variables in the input are encoded using an arbitrary encoding, in particular, the Huffman coding (so the most efficient one) is allowed.

2 The (known) algorithm

We first present a slight variation of the algorithm of Jeż [8] and the notions necessary to understand how it works. The proofs are omitted, yet they should be intuitively clear.

Notions. The word equation is a pair (U, V), written as $U = V$, where $U, V \in (\Gamma \cup \mathcal{X})^*$ and Γ and $\mathcal{X}$ are disjoint alphabets of *letters* and *variables*, both are collectively called *symbols*. By n_X we denote the number of occurrences of X in the (current) equation; in the algorithm n_X does not change till X is removed from the equation, in which case n_X becomes 0. A *substitution* is a morphism $S : \mathcal{X} \cup \Gamma \to \Gamma'^*$, where $\Gamma' \supseteq \Gamma$ and $S(a) = a$ for every $a \in \Gamma$, a substitution naturally extends to $(\mathcal{X} \cup \Gamma)^*$. A *solution* of an equation $U = V$ is a substitution S such that $S(U) = S(V)$; given a solution S of an equations $U = V$ we call $S(U)$ the *solution word*. We allow the solution to use letters that are not present in the equation, this does not change the satisfiability: all such letters can be changed to a fixed letter from Γ, and the obtained substitution is still a solution. Yet, the proofs become easier, when we allow the usage of such letters. The alphabet Γ' is usually given implicitly: as the set of letters used by the substitution. A *block* is a string a^ℓ with $\ell \geq 1$ that cannot be extended to the left nor to the right with a.

As we deal with linear-space, the encoding used by the input equation matters. We assume only that the input is given by a fixed (uniquely decodable) coding: each symbol in the input is always given by the same bitstring and given the bitstrings representing the sides of the equation there is only one pair of strings (over $\Gamma \cup \mathcal{X}$) that is encoded in this way. It is folklore that among such codes the Huffman code yields the smallest space consumption (counted in bits) and moreover the Huffman coding can be efficiently computed, also in linear space. As we focus on space counted in bits and use encodings, by $||\alpha||$ we denote the space consumption of the encoding of α, the encoding shall be always clear from the context. Furthermore, whenever we talk about space complexity, it is counted in bits.

Nondeterministic Linear Space. We recall some basic facts about the nondeterministic space-bounded computation. A nondeterministic procedure *is sound*, when given a unsatisfiable word equation $U = V$ it cannot transform it to a satisfiable one, regardless of the nondeterministic choices; a procedure is *complete*, if given a satisfiable equation $U = V$ for some nondeterministic choices it returns a satisfiable equation $U' = V'$. A composition of sound (complete) procedures is sound (complete, respectively). It is enough that we show linear-space bound for one particular computation: as the bound is known, we limit the space available to the algorithm and reject the computations exceeding it.

The algorithm. We use (a variant of) recompression algorithm [8], which conceptually applies the following two operations on $S(U)$ and $S(V)$: given a string w and alphabet Γ

- the Γ block compression of w is a string w' obtained by replacing every block a^ℓ, where $a \in \Gamma$ and $\ell \geq 2$, with a fresh letter a_ℓ;
- the (Γ_ℓ, Γ_r) pair compression of w, where Γ_ℓ, Γ_r is a partition of Γ, is a string w' obtained by replacing every occurrence of a pair $ab \in \Gamma_\ell\Gamma_r$ with a fresh letter c_{ab}.

A *fresh* letter means that it is not currently used in the equation, nor in Γ, yet each occurrence of a fixed ab is replaced with the same letter. The a_ℓ and c_{ab} are just notation conventions, the actual letters in w' do not store the information how they were obtained. For shortness, we call Γ block compression the Γ compression or block compression, when Γ is clear from the context; similar convention applies to (Γ_ℓ, Γ_r) pair compression, called (Γ_ℓ, Γ_r) compression or pair compression, when (Γ_ℓ, Γ_r) is clear from the context. We say that a pair $ab \in \Gamma_\ell\Gamma_r$ is *covered* by a partition Γ_ℓ, Γ_r.

The intuition is that the algorithm aims at performing those compression operations on the solution word and to this end it modifies the equation a bit and then performs the compression operations on U and V (and conceptually also on the solution, i.e. on $S(X)$ for each variable X). Below we describe, how it is performed on the equation.

BlockComp: For the equation $U = V$ and the alphabet Γ of letters in this equation for each variable X we first guess the first and last letter of $S(X)$ as well as the lengths ℓ, r of the longest prefix consisting only of a, called a-prefix, and b-suffix (defined similarly) of $S(X)$. Then we replace X with $a^\ell X b^r$ (or $a^\ell b^r$ or a^ℓ when $S(X) = a^\ell b^r$ or $S(X) = a^\ell$); this operation is called *popping a-prefix and b-suffix*. Then we perform the Γ-block compression on the equation (this is well defined, as we can treat variables as symbols from outside Γ).

PairComp: For the alphabet Γ, which will always be the alphabet of letters in the equation right before the block compression we partition Γ into Γ_ℓ and Γ_r (in a way described in Section 3.2) and then for each variable X guess whether $S(X)$ begins with a letter $b \in \Gamma_r$ and if so, replace X with bX or b, when $S(X) = b$, and then do a symmetric action for the last letter and Γ_ℓ; this operation is later referred to as *popping letters*. Then we perform the (Γ_ℓ, Γ_r) compression on the equation.

LinWordEq works in *phases*, until an equation with both sides of length 1 is obtained: in a single phase it establishes the alphabet Γ of letters in the equation, performs the Γ compression and then repeats: guess the partition of Γ to Γ_ℓ and Γ_r and perform the (Γ_ℓ, Γ_r) compression, until each pair $ab \in \Gamma^2$ was covered by some partition.

Correctness. Given a solution S we say that some nondeterministic choices *correspond to* S, if they are done as if LinWordEq knew S. For instance, it guesses correctly the first letter of $S(X)$ or whether $S(X) = \epsilon$. (The choice of a partition does not fall under this category.)

▶ **Lemma 1** ([8, Lemma 2.8 and Lemma 2.10])**.** BlockComp *is sound and complete; to be more precise, for any solution S of an equation $U = V$ for the nondeterministic choices*

corresponding to S the returned equation $U' = V'$ has a solution S' such that $S'(U')$ is the Γ compression of $S(U)$ and $S'(X)$ is obtained from $S(X)$ by removing the a-prefix and b-suffix, where a is the first letter of $S(X)$ and b the last, and then performing the Γ compression.

When Γ_ℓ and Γ_r are disjoint, the PairComp(Γ_ℓ, Γ_r) *is sound and complete; to be more precise, for any solution S of an equation $U = V$ for the nondeterministic choices corresponding to S the returned equation $U' = V'$ has a solution S' such that $S'(U')$ is the (Γ_ℓ, Γ_r) compression of $S(U)$ and $S'(X)$ is obtained from $S(X)$ by removing the first letter of $S(X)$, if it is in Γ_r, and the last, if it is in Γ_ℓ, and then performing the (Γ_ℓ, Γ_r) compression.*

The solution S' from Lemma 1 is called a *solution corresponding to S* after (Γ_ℓ, Γ_r) compression (Γ compression, respectively); we also talk about a *solution corresponding to S*, when the compression operation is clear from the context and extend this notion to a solution corresponding to S after a phase. What is important later on is how S' is obtained from S: it is modified as if the subprocedures knew first/last letter of $S(X)$ and popped appropriate letters from the variables and then compressed pairs/blocks in substitution for variables.

Lemma 1 yields the soundness and completeness of LinWordEq, for the termination we observe that iterating the compression operations shortens the string by a constant fraction, thus the length of a solution word shortens by a constant fraction in each phase.

▶ **Lemma 2.** *Let w be a string over an alphabet Γ and w' a string obtained from w by a Γ compression followed by a sequence of (Γ_ℓ, Γ_r) compressions (where Γ_ℓ, Γ_r is a partition of Γ) such that each pair $ab \in \Gamma^2$ is covered by some partition. Then $|w'| \leq \frac{2|w|+1}{3}$.*

▶ **Theorem 3.** LinWordEq *is sound, complete and terminates (for appropriate nondeterministic choices) for satisfiable equations. It runs in linear (bit) space.*

In the following, we will also need one more technical property of block compression.

▶ **Lemma 4.** *Consider a solution S during a phase with nondeterministic choices corresponding to S and the corresponding solution S' of $U' = V'$ after the block compression. Then $S'(U')$ has no two consecutive letters $aa \in \Gamma$.*

This is true after block compression and afterwards no letters from Γ are introduced.

Compressing blocks in small space. Storing, even in a concise way, the lengths of popped prefixes and suffixes in Γ compression makes attaining the linear space difficult. This was already observed [8] and a linear-space implementation of BlockComp was given [8]. It performs a different set of operations, yet the effect is the same as for BlockComp. Instead of explicitly naming the lengths of blocks, we treat them as integer parameters; then we declare, which maximal blocks are of the same length (those lengths depend linearly on the parameters); verifying the validity of such a guess is done by writing a system of (linear) Diophantine equations that formalise those equalities and checking its satisfiability. This procedure is described in detail in [8, Section 4]. In the end, it can be implemented in linear bitspace.

▶ **Lemma 5** ([8, Lemma 4.7])**.** BlockComp *can be implemented in space linear in the bit-size of the equation*

Huffman coding. At each step of the algorithm we encode letters (though not variables) in the equation using Huffman coding. This may mean that when going from $U = V$ to $U' = V'$ the encoding of letters changes and in fact using the former encoding in the latter equation

may lead to super-linear space (imagine that we pop from each variable a letter that has a very long code). Using standard methods changing the encoding during a transition from $U = V$ to $U' = V'$ can be done in $\mathcal{O}(||U = V|| + ||U' = V'||)$ bit-space.

▶ **Lemma 6.** *Given a string (encoded using some uniquely decodable code), its Huffman coding can be computed in linear bitspace.*

Each subprocedure of LinWordEq *that transforms an equation $U = V$ to $U' = V'$ can be implemented in bit-space $\mathcal{O}(||U = V||_1 + ||U' = V'||_2)$, where $||\cdot||_1$ and $||\cdot||_2$ are the Huffman codings for letters in $U = V$ and $U' = V'$, respectively.*

3 Space consumption

In order to bound the space consumption, we will use bit-encoding of letters that depends on the current equation. We use the term 'encoding' even though it may assign different codes to different occurrences of the same letter, but two different letters never have the same code. Since we are interested in linear space only, we do not care about the multiplicative $\mathcal{O}(1)$ factors in the space consumption and can assume that our code is prefix-free, say by terminating each encoding with a special symbol \$. We show that such an encoding uses linear space, which also shows that the Huffman encoding of the letters in the equation uses linear space, as Huffman encoding uses the smallest space among the prefix codes.

The idea of our 'encoding' is: for each letter in the current equation we establish an interval I of indices in the original equation (viewed as as string $U_0V_0[1\,..\,|U_0V_0|]$) on which it 'depends' (this has to be formalised) and encode this letter as $U_0V_0[I]\#i$, when it is ith in the sequence of letters assigned I and $U_0V_0[I]$ is the original equation restricted to indices in I The dependency is formalised in Section 3.1, while Section 3.2 first gives the high-level intuition and then upper-bound on the used space.

For technical reasons we insert into the equation ending markers at the beginning and end of U and V, i.e. write them as $@U@, @V@$ for some special symbol @. Those markers are ignored by the algorithm, yet they are needed for the encoding.

3.1 Dependency intervals

First, we need some notation. The input equation is denoted by $U_0 = V_0$, the $U = V$ and $U' = V'$ are used for the current equation and equation after performing some operation. We treat the input equation as a single string U_0V_0 and consider its *indices*, i.e. numbers from 1 to $|U_0V_0|$, denoted by letters i, i', j and intervals of such indices, denoted by letter I, I' or $[i\,..\,j]$. The $U_0V_0[I]$ and $U_0V_0[i\,..\,j]$ denotes the substring of U_0V_0 restricted to indices in $[I]$ or in $[i\,..\,j]$. We use a partial order $\leq$ on intervals: $[i\,..\,j] \leq [i'\,..\,j']$ if $i \leq i'$ and $j \leq j'$.

In the current equation, i.e. the one stored by LinWordEq, we do not consider indices but rather *positions* and denote them by letters p, q. We do not think of them as numbers but rather as pointers: when $U = V$ is transformed by some operation to $U' = V'$ but the letter/variable at position p was not affected by this transformation, we still say that this letter/variable is at position p. On the other hand, the affected letters are on positions that were not present in $U = V$. In the same spirit we denote by p the positions in $U = V$ and the corresponding position in $S(U) = S(V)$. We still use the left-to-right ordering on positions, use $p - 1$ and $p + 1$ to denote the previous and next position; we also consider intervals of positions, yet they are used rarely so that they are not confused with intervals of indices, on which we focus mostly. Given an equation $U = V$ and an interval of positions P by $UV[P]$

we denote the string of letters and variables at positions in P, again, this notation is used rarely. In the input equation the index and position is the same.

With each position p in the (current) equations (including the endmarkers) we associate *dependency interval* $\mathrm{dep}(p)$, called *depint*; if the depint is a single index $\{i\}$, we denote it i. The idea is that the letter at position p is uniquely determined by $U_0V_0[\mathrm{dep}(I)]$ (and the nondeterministic choices of the algorithm), note that it may include both variables and letters. We use the notions of $\subseteq$ and $\supseteq$ for the depints with a usual meaning; we take unions of the them, denoted by $\cup$, but only when the result is an interval. We say that I and I' are similar, denoted as $I \sim I$, if $U_0V_0[I] = U_0V_0[I']$. Given an interval I of indices in U_0V_0 by $\mathrm{Pos}(I)$ we denote positions in the current equation whose depint is I, i.e. $\mathrm{Pos}(I) = \{p \mid \mathrm{dep}(p) = I\}$. In the analysis it is also convenient to look at positions whose depint is a superset of I: $\mathrm{Pos}_{\supseteq}(I) = \{p \mid \mathrm{dep}(p) \supseteq I\}$, this is usually used for $I = \{i\}$

We shall ensure the following properties:

(I1) Given a depint I, the $\mathrm{Pos}(I)$ is an interval of positions, similarly $\mathrm{Pos}_{\supseteq}(I)$.

(I2) Given depints I, I' such that $\mathrm{Pos}(I) \neq \emptyset \neq \mathrm{Pos}(I')$ either $I \leq I'$ or $I \geq I'$.

(I3) For depints $I \sim I'$ it holds that $U_0V_0[I] = U_0V_0[I']$.

Assigning depints to letters. When X at position p pops a letter into position p' then $\mathrm{dep}(p') \leftarrow \mathrm{dep}(p)$ (which is the position of this occurrence of X in the input equation). Whenever we perform the (Γ_ℓ, Γ_r) compression then in parallel for each position p such that $UV[p] \in \Gamma_\ell$ we assign $\mathrm{dep}(p) \leftarrow \mathrm{dep}(p) \cup \mathrm{dep}(p+1)$ ($p+1$ may be a a position variable or an endmarker). Then we perform a symmetric action for positions whose letters are in Γ_r (so for $p-1$).

For Γ compression, we perform in parallel the following operation for each block (perhaps of length 1) of a letter in Γ: given a maximal block a^ℓ at positions $p, p+1, \ldots, p+\ell-1$ we set the depints of those positions to $\bigcup_{i=-1}^{\ell} \mathrm{dep}(p+i)$ (note that $p-1$ and $p+\ell$ are included).

In the following we mostly focus on $\mathrm{Pos}_{\supseteq}(i)$. As this is an interval of positions, we visualize that $\mathrm{Pos}_{\supseteq}(I)$ extends to the neighbouring positions. Thus we will refer to operations of changing the depints before the block compression and pair compression as *extending of* $\mathrm{Pos}_{\supseteq}(I)$ to new positions; those positions *get their depints extended*. Note that this notion does not apply to the case when we pop letters from variables.

Depints defined in this way satisfy the conditions (I1–I3).

▶ **Lemma 7.** *(I1–I3) hold during* LinWordEq.

Proof. We first show (I1) for $\mathrm{Pos}_{\supseteq}(i)$. The proof is by induction; this is true at the beginning. If we make a union of depints, a position adjacent to a position in $\mathrm{Pos}_{\supseteq}(i)$ symbol can become part of $\mathrm{Pos}_{\supseteq}(i)$ (this can be iterated when the depints are changed before the blocks compression), which is fine. During the compression, we compress symbols on positions with the same depints, so this is fine. When we pop a letter from variable at position p to position p' then $\mathrm{dep}(p') = \mathrm{dep}(p) \in \mathrm{Pos}_{\supseteq}(i)$ and by inductive assumption $\mathrm{Pos}_{\supseteq}(i)$ was an interval, which shows the claim.

We now show by induction that $i \leq i'$ implies $\mathrm{Pos}_{\supseteq}(i) \leq \mathrm{Pos}_{\supseteq}(i')$. Clearly this holds at the beginning, as then $\mathrm{Pos}_{\supseteq}(i) = \mathrm{Pos}(i) = \{i\}$ and $\mathrm{Pos}_{\supseteq}(i') = \mathrm{Pos}(i') = \{i'\}$. Consider the moment, in which the condition $\mathrm{Pos}_{\supseteq}(i) \leq \mathrm{Pos}_{\supseteq}(i')$ is first violated, by symmetry it is enough to consider the case in which the first position in $\mathrm{Pos}_{\supseteq}(i')$ is smaller than the first in $\mathrm{Pos}_{\supseteq}(i)$. If this position was just popped then it cannot be popped to the right, as the position of popping variable is in $\mathrm{Pos}_{\supseteq}(i')$. So it was popped to the left. But then the variable that popped it was on position in $\mathrm{Pos}_{\supseteq}(i')$ and by induction assumption $\mathrm{Pos}_{\supseteq}(i') \geq \mathrm{Pos}_{\supseteq}(i)$,

so it had a position from $\mathrm{Pos}_{\supseteq}(i)$ to its left, contradiction. The other option is that this happened when a depint of a position was changed so that it got into $\mathrm{Pos}_{\supseteq}(i')$. But then the position to its right was in $\mathrm{Pos}_{\supseteq}(i')$ and by induction assumption either this position was in $\mathrm{Pos}_{\supseteq}(i)$ or some position to the left of it was; in both cases the position also got into $\mathrm{Pos}_{\supseteq}(i)$.

Now (I1) for $\mathrm{Pos}_{\supseteq}([i\,..\,j])$ for an arbitrary depint $[i\,..\,j]$ follows: $\mathrm{Pos}_{\supseteq}([i\,..\,j]) = \bigcap_{k=i}^{j} \mathrm{Pos}_{\supseteq}(k)$ and as each $\mathrm{Pos}_{\supseteq}(k)$ is an interval, also $\mathrm{Pos}_{\supseteq}([i\,..\,j])$ is.

For the purpose of the proof, define $\mathrm{Pos}_{\subseteq}(I) = \{p \mid \mathrm{dep}(p) \subseteq I\}$ (a dual notion to $\mathrm{Pos}_{\supseteq}(I)$).

▶ **Claim 8.** *$\mathrm{Pos}_{\subseteq}(I)$ consists of consecutive positions. Given two similar depints $I \sim I'$ $UV[\mathrm{Pos}_{\subseteq}(I)]$ and $UV[\mathrm{Pos}_{\subseteq}(I')]$ are equal as sequences of symbols and the corresponding positions in them have similar depints.*

The proof follows by a simple, yet tedious induction and it is omitted.

Claim 8 is stronger than (I3) and so it implies it. Concerning (I1): $\mathrm{Pos}(I) = \mathrm{Pos}_{\supseteq}(I) \cap \mathrm{Pos}_{\subseteq}(I)$; as both are intervals, also $\mathrm{Pos}(I)$ is.

Concerning (I2), we show a stronger statement: given positions $p, p+1$ it holds that $\mathrm{dep}(p) \leq \mathrm{dep}(p{+}1)$. Let i, i' be the leftmost indices in $\mathrm{dep}(p), \mathrm{dep}(p{+}1)$, respectively. Assume for the sake of contradiction that $i > i'$. We already showed that then $\mathrm{Pos}_{\supseteq}(i) \geq \mathrm{Pos}_{\supseteq}(i')$. So if $p+1 \in \mathrm{Pos}_{\supseteq}(i') \leq \mathrm{Pos}_{\supseteq}(i) \ni p$ then also $p \in \mathrm{Pos}_{\supseteq}(i')$, i.e. $i' \in \mathrm{dep}(p)$. As $i' < i$ then the leftmost index in $\mathrm{dep}(p')$ cannot be i. The proof for rightmost index is similar. ◀

Encoding of letters. Letters in $\mathrm{Pos}(I)$ are encoded as $U_0V_0[I]\#1$, $U_0V_0[I]\#2$, etc. Note, that there is no a priori bound on the size of such numbers. Furthermore, if $I' \sim I$ then encoding $I\#i$ and $I'\#i$ is the same (these are the same symbols by (I3).

3.2 Pair compression strategy

We assume that LinWordEq makes the nondeterministic choices according to the solution, thus the space consumption of a run depends only on the choices of the partitions during pair compression, called *a strategy*. We describe a linear-space strategy.

Idea. Imagine we ensured that during one phase each variable popped $\mathcal{O}(1)$ letters and each $\mathrm{Pos}_{\supseteq}(i)$ expanded by $\mathcal{O}(1)$ letters. Then $|\mathrm{Pos}_{\supseteq}(i)| = \mathcal{O}(1)$: we introduced $\mathcal{O}(1)$ positions to $\mathrm{Pos}(i)$, say at most k, and by Lemma 2 among positions in $\mathrm{Pos}_{\supseteq}(i)$ at the beginning of the phase there were at least $2/3$ took part in compression, so their number dropped by $1/3$; thus $|\mathrm{Pos}_{\supseteq}(i)| \leq 3k$. As a result, $|\mathrm{Pos}(I)| \leq 3k$ for each depint I: as $\mathrm{Pos}(I) \subseteq \mathrm{Pos}_{\supseteq}(i)$ for $i \in I$. This would yield that the whole bit-space used for the encoding is linear: each number m used in $U_0V_0[I]\#m$ is at most $3k = \mathcal{O}(1)$, so they increase the size by at most a constant fraction. On the other hand, the depints consume:

$$\sum_{I:\mathrm{depint}} ||U_0V_0[I]|| \cdot |\mathrm{Pos}(I)| = \sum_{i:\mathrm{index}} ||U_0V_0[i]|| \cdot |\mathrm{Pos}_{\supseteq}(i)|$$

(a simple proof is given later) and the right hand side is linear in terms of the input equation: $|\mathrm{Pos}_{\supseteq}(i)| = \mathcal{O}(1)$ and $\sum_{i:\mathrm{index}} ||U_0V_0[i]||$ is the the bit-size of the input equation.

It remains to ensure that $\mathrm{Pos}_{\supseteq}(i)$ do not extend too much and variables do not pop too much letters. Given a phase, we call a letter *new*, if it was introduced during this phase. New letters cannot be popped nor can $\mathrm{Pos}_{\supseteq}(i)$ be extended to positions with new letters. Thus they are used to prevent extending $\mathrm{Pos}_{\supseteq}(i)$ and popping: it is enough to ensure that

the first/last letter of a variable is new and that a letter on the position to the left/right of $\mathrm{Pos}_{\supseteq}(I)$ is new.

Unfortunately, we cannot ensure this for all variables $\mathrm{Pos}_{\supseteq}(i)$. We can make this true *in expectation*: given a random partition there is a $1/4$ probability that a fixed pair is compressed (and the resulting letter is new). This requires formalisation and calculations.

Strategy. Given a solution S of an equation we say that a variable X is *left blocked* if $S(X)$ has at most one letter or the first or second letter in $S(X)$ is new, otherwise a variable is *left unblocked*; define *right blocked* and *right unblocked* variables similarly. An index i is *left blocked* if in $S(U)$ (or $S(V)$, respectively) there is at most position to the left of $\mathrm{Pos}_{\supseteq}(i)$ or one of the letters on the positions one and two to the left of $\mathrm{Pos}_{\supseteq}(i)$ is new, otherwise i is *left unblocked*; define *right blocked* and *right unblocked* indices similarly.

▶ **Lemma 9.** *Consider a solution $S = S_0$ and consecutive solutions $S_1, S_2, \ldots$ corresponding to it during a phase. If a variable X becomes left (right) blocked for some S_k, then it is left (right, respectively) blocked for each S_ℓ for $\ell \geq k$ and it pops to the left (right, respectively) at most 1 letter after it became left (right, respectively) blocked. If an index i becomes left (right) blocked for some S_k then it is left (right, respectively) blocked for each S_ℓ for $\ell \geq k$ and at most one letter to the left (right, respectively) will have its depint extended by i after i became left (right, respectively) blocked.*

The proof follows by a simple case inspection and it is omitted.

The strategy iterates steps 1, 2, 3 and 4. In a step i it chooses a partition so that the corresponding i-th sum below decreases by $1/2$, unless this sum is already 0:

$$\sum_{X\in\mathcal{X} \text{ left unblocked}} n_X \cdot ||X|| + \sum_{X\in\mathcal{X} \text{ right unblocked}} n_X \cdot ||X|| \tag{1}$$

$$\sum_{i\text{: left unblocked index}} ||U_0V_0[i]|| + \sum_{i\text{: right unblocked index}} ||U_0V_0[i]|| \tag{2}$$

$$\sum_{X\in\mathcal{X} \text{ left unblocked}} n_X + \sum_{X\in\mathcal{X} \text{ right unblocked}} n_X \tag{3}$$

$$\sum_{i\text{: left unblocked index}} 1 + \sum_{i\text{: right unblocked index}} 1 \tag{4}$$

The idea of the steps is: (1) upper-bounds the increase of bit-size of depints in the equation after popping letters. So by iteratively halving it we ensure that total encoding increase caused by popping letters is small. Similarly, (2) upper-bounds the increase due to expansion of indices to new depints. The following (3) is connected (in a more complex way) to an increase, after popping, of number of bits used for numbers in the encoding. Similarly (4) to an increase after the extension of depints.

▶ **Lemma 10.** *During the pair compression* LinWordEq *can always choose a partition that at least halves the value of a chosen non-zero sum among* (1)–(4).

Proof. Consider (1) and take a random partition, in the sense that each letter $a \in \Gamma$ goes to the Γ_ℓ with probability $1/2$ and to Γ_r with probability $1/2$. Let us fix a variable X and its side, say left. What happens with $n_X \cdot ||X||$ in (1) in the sum corresponding to left unblocked variables? If X is left blocked then, by Lemma 9, it will stay left blocked and so the contribution is and will be 0. If it is left unblocked, then its two first letters a, b are not new, so they are in Γ. If $S(X)$ has only those two letters, then with probability $1/2$ the a

will be in Γ_r and it will be popped and X will become left blocked (as $S(X)$ has only one letter), the same analysis applies, when the third leftmost letter is new. The remaining case is that the three leftmost letters in $S(X)$ are not new, let them be $a, b, c \in \Gamma$. By Lemma 4 $a \neq b \neq c$. With probability 1/4 $ab \in \Gamma_\ell\Gamma_r$ and with probability 1/4 $bc \in \Gamma_\ell\Gamma_r$. Those events are disjoint (as in one $b \in \Gamma_r$ and in the other $b \in \Gamma_\ell$) and so their union happens with probability 1/2. In both cases X will become left blocked, as a new letter is its first or second in $S(X)$. In all uninvestigated cases the contribution of $n_X \cdot ||X||$ cannot raise, which shows the claim in this case. The case of (3) is shown in the same way.

For (2), the analysis for an index i that is left unblocked is similar, but this time we consider the positions to the left of $\mathrm{Pos}_{\supseteq}(i)$ and $\mathrm{Pos}_{\supseteq}(i)$ can extend to them (instead of letters being popped from variables in case of (1)) and some of them may be compressed to one. Note that if there are no letters to the left/right then this index is blocked from this side. The case of (4) is shown in the same way. ◀

Space consumption. We now give the linear space bound on the size of equation. This formalises the intuition from the beginning of Section 3.2. As a first step, we show an upper-bound on the encoding size of the equation; define

$$H_d(U,V) = \sum_{i:\text{index}} ||U_0V_0[i]|| \cdot |\mathrm{Pos}_{\supseteq}(i)|, \quad H_n(U,V) = \sum_{i:\text{index}} 2|\mathrm{Pos}_{\supseteq}(i)| \cdot \log(|\mathrm{Pos}_{\supseteq}(i)|+1) \ ,$$

and $H(U,V) = H_d(U,V) + H_n(U,V)$. H_d corresponds to the size of $U_0V_0[I]$ in the encoding and H_d: of the numbers in the encoding.

▶ **Lemma 11.** *Given the equation (U,V) it holds that $||(U,V)|| \leq H_d(U,V) + H_n(U,V)$.*

The proof follows by simple symbolic transformation of the definitions.

Instead of showing a linear bound on $||(U,V)||$ we give a linear bound on $H(U,V)$. Recall that (U_0,V_0) denotes the input equation.

▶ **Lemma 12.** *Consider an equation $U = V$, its solution S, a phase of* LinWordEq *which makes the nondeterministic choices according to S and partitions according to the strategy. Let the returned equation be (U',V'). Then $H(U',V') \leq \frac{5}{6}H(U,V) + \alpha||(U_0,V_0)||$ and in a phase H on intermediate equations is at most $\beta H(U,V) + \gamma||(U_0,V_0)||$ for some constants α, β, γ.*

Proof. We separately estimate the H_d and H_n. Concerning H_d, let us first estimate $||U_0V_0[\mathrm{dep}(p)]||$ summed over positions p of letters popped into the equation during a phase (note, this does not include the size of numbers used in the encoding). For each variable we pop perhaps several letters to the left and right before block compression, but those letters are immediately replaced with single letters, so we count each as 1; also, when this side of a variable becomes blocked, it can pop at most one letter. Otherwise, a side of a variable pops at most 1 letter per pair compression, in which it is unblocked from this side. Note that the depint is the same as for variable, so the encoding size is $||X||$. So in total the bit-size of popped letters is at most:

$$\underbrace{\sum_{X\in\mathcal{X}} 2n_X \cdot ||X||}_{\text{block compression}} + \underbrace{\sum_{X\in\mathcal{X}} 2n_X \cdot ||X||}_{\text{after } X \text{ becomes blocked}} + \\ + \sum_{P:\text{ partition}} \left(\sum_{\substack{X\in\mathcal{X} \\ \text{left unblocked in } P}} n_X \cdot ||X|| + \sum_{\substack{X\in\mathcal{X} \\ \text{right unblocked in } P}} n_X \cdot ||X|| \right). \quad (5)$$

Observe that the third sum (the one summed over all partitions) at the beginning of the phase is equal to $\sum_X 2n_X \cdot ||X||$, as no side of the variable is blocked, and by the strategy point (1) its value at least halves every 4th pair compression (and it cannot increase, as by Lemma 9 no side of the variable can cease to be blocked). Thus (5) is at most

$$4\sum_X n_X \cdot ||X|| + 8\sum_X n_X \cdot ||X|| \left(1 + \frac{1}{2} + \frac{1}{4} + \cdots\right) = 20\sum_X n_X \cdot ||X|| \leq 20||(U_0, V_0)|| \ .$$

We now similarly estimate how many positions got into $\mathrm{Pos}_{\supseteq}(i)$ due to expansion of $\mathrm{Pos}_{\supseteq}(i)$: $\mathrm{Pos}_{\supseteq}(i)$ can expand to two letters during the block compression (to be more precise: to positions that are inside a block and to the positions to the let/right ones, but positions in a block are replaced with a single letter and one of them was in $\mathrm{Pos}_{\supseteq}(i)$) to one position at each side after i becomes blocked and by one position for each partition P in which this side of i is not blocked. So the increase in the bit-size is

$$\sum_{i\colon \text{index}} 4||U_0V_0[i]|| + \sum_{P\colon \text{partition}} \Bigg(\sum_{\substack{i\colon \text{index} \\ \text{left unblocked in } P}} ||U_0V_0[i]|| + \sum_{\substack{i\colon \text{index} \\ \text{right unblocked in } P}} ||U_0V_0[i]|| \Bigg) \tag{6}$$

and as in (5) similarly at the beginning of the phase the second sum (so the one summed by partitions) is $\sum_{i\colon \text{index}} 2||U_0V_0[i]|| = 2||(U_0, V_0)||$ and it at least halves every 4th partition, by strategy point (2). Thus similar calculations show that (6) is at most $20||(U_0, V_0)||$.

On the other hand, the number of positions in $\mathrm{Pos}_{\supseteq}(i)$ drops till the end of the phase by at least $\frac{|\mathrm{Pos}_{\supseteq}(i)|}{3} - 1$ due to compression:

1. If $U_0V_0[i]$ is a letter, then $\mathrm{Pos}_{\supseteq}(i)$ are all positions of letters and Lemma 2 yields that $\mathrm{Pos}_{\supseteq}(i)$ looses at least $\frac{|\mathrm{Pos}_{\supseteq}(i)|-1}{3}$ positions.
2. If $U_0V_0[i]$ is an ending marker, then the marker itself is unchanged and the remaining positions in $\mathrm{Pos}_{\supseteq}(i)$ are letter-positions and Lemma 2 applies to them, so $\mathrm{Pos}_{\supseteq}(i)$ looses at least $\frac{|\mathrm{Pos}_{\supseteq}(i)|-2}{3} < \frac{|\mathrm{Pos}_{\supseteq}(i)|}{3} - 1$ positions.
3. If $U_0V_0[i]$ is a variable then $\mathrm{Pos}_{\supseteq}(i)$ includes the position of a variable and Lemma 2 applies to strings of letters to the left and right, say of length ℓ, r, where $\ell + r = |\mathrm{Pos}_{\supseteq}(i)| - 1$.

Then due to compressions $\mathrm{Pos}_{\supseteq}(i)$ looses at least $\frac{\ell-1}{3} + \frac{r-1}{3} = \frac{|\mathrm{Pos}_{\supseteq}(i)|}{3} - 1$ positions.
Thus:

$$\begin{aligned} H_d(U', V') \leq\ & \underbrace{40||(U_0, V_0)||}_{\text{new positions in depints}} + \underbrace{\sum_{i\colon \text{index}} ||U_0V_0[i]|| \cdot \left(\frac{2}{3}|\mathrm{Pos}_{\supseteq}(i)| + 1\right)}_{\text{old positions lost}} \\ &= 40||(U_0, V_0)|| + \sum_{i\colon \text{index}} \frac{2}{3}||U_0V_0[i]|| \cdot |\mathrm{Pos}_{\supseteq}(i)| + \sum_{i\colon \text{index}} ||U_0V_0[i]|| \\ &= 41||(U_0, V_0)|| + \frac{2}{3}H_d(U, V) \ . \end{aligned}$$

We also estimate the maximal value of H_d during the phase, as for intermediate equations we cannot guarantee that the compression reduced the length of all letters. We already showed that in a phase we increase H_d by $40||(U_0, V_0)||$. This yields a bound of $H_d(U, V) + 40||(U_0, V_0)||$, which shows the part of the claim of Lemma for H_d.

Concerning H_n, for an index i let k_i, o_i, e_i denote, respectively: $|\mathrm{Pos}_{\supseteq}(i)|$ at the beginning of the phase, number of positions of letters popped from a variable with depint i and number of positions to whose depint i extended. First we estimate $\sum_{i\colon \text{index}} h(o_i)$ and $\sum_{i\colon \text{index}} h(e_i)$

and then use those estimations to calculate the bound on $H_n(U', V')$. We first inspect the case of o_i; let $P_1, P_2, \ldots$ denote the consecutive partitions in phase. We show that

$$\sum_{i\text{: index}} h(o_i) \leq \sum_{X\in\mathcal{X}} 25n_X + \sum_{m\geq 1} m \cdot \Big(\sum_{\substack{X\in\mathcal{X} \\ \text{left unblocked in } P_m}} n_X + \sum_{\substack{X\in\mathcal{X} \\ \text{right unblocked in } P_m}} n_X \Big). \quad (7)$$

The inequality follows as: if (one occurrence of) X popped o_X letters, then it was not blocked on left/right side for o_1/o_2 partitions, where $o_1 + o_2 \geq o_X - 4$ (note that one sequence can be popped to the left and right during block compression but it is immediately replaced with a single letter, so we treat them as one letter, also one letter can be popped to the left/right after X became blocked). Then in right hand side of (7) the contribution from (one occurrence of) X is at least

$$25 + \frac{o_1(o_1+1) + o_2(o_2+1)}{2} \geq \frac{(o_X-4)^2}{4} + \frac{o_X-4}{2} + 25 \geq o_X \log(o_X+1) \ ,$$

where the first inequality follows as $o_1 + o_2 \geq o_X - 4$ and the second can be checked by simple numerical calculation. Lastly, in (7) each o_i is equal to an appropriate o_X.

The sum in braces on the right hand side of (7) initially is at most $2|U_0V_0| \leq 2||(U_0, V_0)||$ and by strategy choice (3) it is at least halved every 4th step. So this sum is at most:

$$\sum_{i\geq 0} \underbrace{(16i+10)}_{4 \text{ consecutive steps}} \cdot \underbrace{2||(U_0,V_0)||}_{\text{initial size}} \cdot (1/2)^i = 104||(U_0, V_0)||$$

and consequently

$$\sum_{i\text{: index}} h(o_i) \leq 129||(U_0, V_0)|| \ . \quad (8)$$

The analysis for e_i is similar: for a single index i the estimation of the number of position by which $\mathrm{Pos}_{\supseteq}(i)$ extends is the same as the estimation of number of letters popped from an occurrence of a variable, thus

$$\sum_{i\text{: index}} h(e_i) \leq 129||(U_0, V_0)|| \ . \quad (9)$$

We now estimate, how many positions were lost due to compression, recall that k_i is the size of $\mathrm{Pos}_{\supseteq}(i)$ at the beginning of the phase. Using the same analysis as in the case of H_d, from Lemma 2 it follows that at least $\frac{k_i}{3} - 1$ positions were lost in the phase due to compression . Thus

$$H_n(U', V') \leq \sum_{i\text{: index}} h\left(\frac{2}{3}k_i + 1 + o_i + e_i\right). \quad (10)$$

Consider two subcases: if $\frac{2}{3}k_i + 1 + o_i + e_i \leq \frac{5}{6}k_i$, then the summand can be estimated as $h(\frac{5}{6}k_i) \leq \frac{5}{6}h(k_i)$ and we can upper bound the sum over those cases by $\frac{5}{6}\sum_{i\text{: index}} h(k_i)$. If $\frac{2}{3}k_i + 1 + o_i + e_i > \frac{5}{6}k_i$ then $1 + o_i + e_i > \frac{1}{6}k_i$ and so $\frac{2}{3}k_i + 1 + o_i + e_i < 5(1 + o_i + e_i)$. Thus (10) is upper-bounded by:

$$H_n(U', V') \leq \frac{5}{6} \sum_{i\text{: index}} h(k_i) + \sum_{i\text{: index}} h(5(1 + o_i + e_i)) \ .$$

Using simple properties of h as well as (8)–(9) we upper-bound the right hand side by $\frac{5}{6}H_n(U, V) + 15540||(U_0, V_0)||$.

We should estimate the maximal H_n value during the phase, as inside a phase we cannot guarantee that letters get compressed, i.e. estimate $\sum_{i:\text{ index}} h(k_i + o_i + e_i)$. Using similar calculation as in the case of (10) and properties of h we obtain:

$$\sum_{i:\text{ index}} h(k_i + o_i + e_i) \leq 8H_n(U,V) + 2064||(U_0,V_0)|| \ ,$$

which shows the claim of the Lemma in the case of H_n and so also in case of H. ◀

3.3 Proof of Theorem 3

By Lemma 1 all our subprocedures are sound, so we never accept an unsatisfiable equation.

We now give analyse the nondeterministic choices that yield termination, completeness and linear space consumption. Consider an equation $U = V$ at the beginning of the phase, let Γ be the set of letters in this equation. If it has a solution S', then it also has a solution S over Γ such that $|S(X)| = |S'(X)|$ for each variable: we can replace letters outside Γ with a fixed letter from Γ. During the phase we will make nondeterministic choices according to this S.

Let the equation obtained at the end of the phase be $U' = V'$ and S' be the corresponding solution. Then $|S'(U')| \leq \frac{2|S(U)|+1}{3}$ by Lemma 2 and we begin the next phase with S'. Hence we terminate after $\mathcal{O}(\log N)$ phases, where N is the length of some solution of the input equation.

Let the run also choose the partitions according to the strategy. We show by induction that for an equation (U,V) at the beginning of a phase $H(U,V) \leq \delta||(U_0,V_0)||$, where δ is a constant. Initially $H_n(U_0,V_0) = ||(U_0,V_0)||$ and $H_d(U_0,V_0) = 2||(U_0,V_0)||$, as for each index $\text{dep}(i) = \{i\}$; hence the claim holds. By Lemma 12 the inequality at the end of each phase holds for $\delta = 6\alpha$ for α from Lemma 12. For intermediate equations $H(U,V) \leq (6\alpha\gamma + \beta)||(U_0,V_0)||$, by Lemma 12, where β, γ are the constants from Lemma 12.

To upper-bound the space consumption, we also estimate other stored information: we also store the alphabet from the beginning of the phase (this is linear in the size of the equation at the beginning of the phase) and the mapping of this alphabet to the current symbols (linear in the equation at the beginning of the phase plus the size of the current equation). The terminating condition that some pair of letters in Γ^2 was not covered is guessed nondeterministically, we do not store Γ^2. The pair compression and block compression can be performed in linear space, see Lemma 6. Note that this includes the change of Huffman coding.

Abstract

We prove that the full solution set of a twisted word equation with regular constraints is an EDT0L language. It follows that the set of solutions to equations with rational constraints in a context-free group (= finitely generated virtually free group) in reduced normal forms is EDT0L. We can also decide whether or not the solution set is finite, which was an open problem. Moreover, this can all be done in PSPACE. Our results generalize the work by Lohrey and Sénizergues (ICALP 2006) and Dahmani and Guirardel (J. of Topology 2010) with respect to complexity and with respect to expressive power. Both papers show that satisfiability is decidable, but neither gave any concrete complexity bound. Our results concern all solutions, and give, in some sense, the "optimal" formal language characterization.

1 Introduction

In a seminal paper [21] Makanin showed that the problem *WordEquations* is decidable. The first complexity estimation of that problem was a tower of several exponential functions, but this dropped down to PSPACE by Plandowski [24] using compression. The insight that long solutions of word equations can be efficiently compressed is due to [25], which led to the conjecture that WordEquations is NP-complete. In 2013 Jeż applied his *recompression* technique: he presented a new and simple NSPACE($n \log n$) algorithm to solve word equations [16]. (Very recently, he lowered the complexity to NSPACE(n) [17]). Actually his method achieved more: it describes all solutions, copes with rational constraints (which is essential in applications), and it extends to free groups [6]. Building on ideas in [6], Ciobanu and the present authors showed that the full solution set of a given word equation with rational constraints is EDT0L [3]. This was known before only for quadratic word equations by [11]. *EDT0L-languages* are defined by a certain type of Lindenmayer system, see [27]. The motivation for [3] was to prove that the full solution set in reduced words of equations in free groups is an indexed language, an open problem at the time [12, 15]. But EDT0L is better: it is strictly included in the class of indexed languages [9].

The class of finitely generated (f.g. for short) virtually free groups arises in many different ways. A fundamental theorem of Muller and Schupp (relying on [8]) says that a f.g. group is virtually free if and only if it is *context-free* [23]. This means that, given any set of monoid generators A, the set of words $w \in A^*$ which represent $1 \in V$ forms a context-free language. Other characterizations include: (1) fundamental groups of finite graphs of finite groups [18], (2) f.g. groups having a Cayley graph with finite treewidth [19], (3) groups having a finite presentation by some geodesic string rewriting system [13], and (4) f.g. groups having a Cayley graph with decidable monadic second-order theory [19], etc. See [7]. We show that given a f.g. virtually free group V there is a PSPACE-algorithm which produces, for a given equation with rational constraints, an EDT0L grammar which describes the full solution set in reduced words over a natural set of generators. Several remarks are in order here. First, virtually free groups (which are not free) have torsion, and this is serious obstacle to applying the techniques used in [24, 16, 6, 3]. A driving motivation to study virtually free groups is the connection to *word hyperbolic groups* [14]. Solving equations in torsion-free hyperbolic groups reduces to solving equations in free groups [26], but solving equations in word hyperbolic groups with torsion reduces to solving equations in virtually free groups which in turn reduces to solving "twisted" word equations with rational constraints [4]. The question how to solve "twisted" word equations was asked by Makanin ([22, Problem 10.26(b)]) and solved by Lohrey and Sénizergues [20] and Dahmani and Guirardel [4]. Both papers show more general results, and yield independent proofs that satisfiability for equations over a f.g. virtually free group is decidable. The approach in [4] assumes a bound on the so-called "exponent of periodicity", thus it does not handle the full set of solutions. Lohrey and Sénizergues [20] prove a general transfer result which applies to all solutions, but this does not produce any "nice" description. Note that to have "some description" of all solutions is not enough to decide finiteness, in general. Our EDT0L description pays attention that every solution is represented exactly once. The other achievement here is a first known concrete complexity bound: PSPACE, a surprisingly low complexity given the circumstances.

Therefore, the present paper extends [4, 20] in various aspects. As in [4] we are working over twisted word equations with rational constraints, which is the natural approach due to Bass-Serre theory [31], see [18] (and [29, 30] for effective constructions). Our main new contribution is within combinatorics on words. Although we follow the general scheme [16, 6, 3] to define a sound and complete algorithm to produce an NFA describing all solutions, the technical details are quite far from previous methods.

Proofs omitted from the present paper can be found in [5].

1.1 Preliminaries

An *alphabet* is a finite set of *letters*; and Σ^* denotes the free monoid of *words* over Σ. The empty word is denoted by 1. The length $w \in \Sigma^*$ is $|w|$, and $|w|_a$ counts how often a letter a appears in w. Let M be any monoid. Then $u \in M$ is a *factor* of $v \in M$ if we can write $v = xuy$ for some x, y. If $x = 1$ (resp. $y = 1$), then we say that u is a *prefix* (resp. *suffix*) of v. For a prefix, we also write $u \leq v$. An *involution* is a bijection $x \mapsto \overline{x}$ such that $\overline{\overline{x}} = x$ for all x in the set. A *monoid with involution* additionally has to satisfy $\overline{xy} = \overline{y}\,\overline{x}$. If G is a group, then it is a monoid with involution by taking $\overline{g} = g^{-1}$ for all $g \in G$. Thus, we identify $\overline{g}$ and g^{-1} in groups. In the following, every alphabet comes with an involution. This is no restriction since the identity is always an involution for sets. A *morphism* between sets with involution is a mapping respecting the involution. A *morphism* between monoids with involution is a homomorphism $\varphi : M \to N$ such that $\varphi(\overline{x}) = \overline{\varphi(x)}$. For $\Delta \subseteq M \cap N$ we say that it is a Δ-*morphism* if $\varphi(x) = x$ for all $x \in \Delta$. A bijective morphism from a set to itself is called an *automorphism* and the set of automorphisms on a set (or monoid)

M forms the group $\mathrm{Aut}(M)$. Let G be a group. It acts on a set (with involution) X by a mapping $x \mapsto g \cdot x$ if $1 \cdot x = x$, $f \cdot (g \cdot x) = (fg) \cdot x$ (and $f \cdot \overline{x} = \overline{f \cdot x}$). If G acts on a monoid (with involution) M, then we additionally demand that every group element acts as an automorphism: $f \cdot (xy) = (f \cdot x)(f \cdot y)$. Frequently, we write $f(x)$ instead of $f \cdot x$. The specification of regular constraints is given here by assigning to each constant and variable an element in a finite monoid (typically the finite monoid is a monoid of Boolean matrices and arises as the transformation monoid of a finite automaton.) By making the finite monoid larger, we can turn it into a monoid N with involution and where G acts on it. This allows us to represent regular constraints using a morphism $\mu : (A \cup (G \times \mathcal{X}))^* \to N$ which respects the involution and the action of G. In the following we fix the finite monoid N and we assume that all morphisms to N respect the involution and G action. We say that M is an *NG-i-monoid* if M is a monoid with involution and a G action together with a morphism $\mu : M \to N$. (In this abbreviation the i stands for "involution".) If not explicitly stated otherwise all monoids under consideration are NG-i-monoids (including N itself). A morphism between NG-i-monoids M, M' with morphisms μ, μ' is a morphism $\varphi : M \to M'$ such that $\varphi(g \cdot x) = g \cdot (\varphi(x))$ and $\mu'\varphi = \mu$. Henceforth, by default, a morphism means a morphism between NG-i-monoids.

Regular languages in finitely generated free monoids can be defined via nondeterministic finite automata (NFA for short) or via recognizability via homomorphisms to finite monoids, to mention just two possible definitions. This notion extends to every monoid M: an NFA is a directed finite graph $\mathcal{A}$ with initial and final *states*, where the transitions are labeled with elements of the monoid M. A transition labeled by $1 \in M$ is called an *ε-transition*. We say that $m \in M$ is *accepted* by the automaton $\mathcal{A}$ if there exists a path from some initial to some final state such that multiplying the edge labels together yields m. This defines the accepted language $L(\mathcal{A}) = \{m \in M \mid m \text{ is accepted by } \mathcal{A}\}$. According to [10] a subset $L \subseteq M$ is *rational* if and only if L is accepted by some NFA over M. An NFA is called *trim* if every state is on some path from an initial to a final state. Ensuring the NFA that we construct in our proof below is trim, allows us to decide emptiness or finiteness of the solution set.

A subset $L \subseteq A^* \times \cdots \times A^*$ is called *EDT0L* if there some (extended) alphabet C with $c_1, \ldots, c_k \in C$ such that $A \subseteq C$ and a rational set $\mathcal{R} \subseteq \mathrm{End}(C^*)$ of endomorphisms over C^* such that $L = \{(h(c_1), \ldots, h(c_k)) \mid h \in \mathcal{R}\}$. The classical definition for EDT0L refers to $k = 1$. Our definition uses a characterization of EDT0L languages due to Asveld [1, 28].

Let B and $\mathcal{Y}$ be two disjoint NG-i-alphabets. We call B the alphabet of *constants* and $\mathcal{Y}$ the set of *twisted variables*. It is convenient to choose a minimal subset $\mathcal{X} \subseteq \mathcal{Y}$ such that every $Y \in \mathcal{Y}$ has the form $Y = f \cdot X$ for some $X \in \mathcal{X}$ and $f \in G$. Moreover, we assume $X \neq \overline{X}$ for all variables. If G acts without fixed points on $\mathcal{Y}$, then we identify $\mathcal{Y} = G \times \mathcal{X}$ and the action becomes $g \cdot (f, X) = (gf, X)$. By $M(B, \mathcal{X}, \theta, \mu)$ we denote an NG-i-monoid which is generated by $B \cup \{f(X) \mid f \in G, X \in \mathcal{X}\}$ together with a finite set θ of *homogeneous* defining relations, which means every $(x, y) \in \theta$ satisfies $|x| = |y|$. We always assume that $(x, y) \in \theta$ implies $\mu(x) = \mu(y)$, $(\overline{x}, \overline{y}) \in \theta$, and $(f(x), f(y)) \in \theta$ for all $f \in G$, even if these relations are not listed in the specification of θ. For complexity issues we require $|x| \leq 2$ for each $(x, y) \in \theta$ and $|\theta| \in \mathcal{O}(|G| \, \|\mathcal{S}\|^2)$ where $\|\mathcal{S}\|$ is specified in Theorem 1. The homogeneity condition makes it possible to solve the word problem and all other computational issues for the quotient $M(B, \mathcal{X}, \theta, \mu) = M(B, \mathcal{X}, \emptyset, \mu)/\{x = y \mid (x, y) \in \theta\}$ within our space bound.

2 The main results

Let A an alphabet of constants and G be a subgroup of $\mathrm{Aut}(A)$. Initially, the set of twisted variables is $G \times \mathcal{V}$. For a word $w \in A^*$ and $f \in G$ we use the notation $f(w) = (f, w)$;

and we hence identify $(A \cup (G \times \mathcal{V}))^* = ((G \times (A^* \cup \mathcal{V}))^*$. We abbreviate $(1, x)$ as x for $x \in A^* \cup \mathcal{V}$. A system $\mathcal{S}$ of *twisted word equations with rational constraints* is given by a set of pairs $\{(U_i, V_i) \mid 1 \leq i \leq s\}$ where $U_i, V_i \in (A \cup (G \times \mathcal{V}))^*$ are *twisted words* and a morphism $\mu_0 : (A \cup (G \times \mathcal{V}))^* \to N$. It is specified by its restriction to $A \cup \mathcal{V}$; and μ_0 respects the involution and the action of G.

As usual, a twisted equation (U_i, V_i) is also written as $U_i = V_i$. A *solution* of $\mathcal{S}$ is given a morphism $\sigma : \mathcal{V} \to A^*$ which is (uniquely) extended to an A-morphism of NG-i-monoids $\sigma : (A \cup (G \times \mathcal{V}))^* \to A^*$ such that $\sigma(U_i) = \sigma(V_i)$ for all i and $\mu_0\sigma(X) = \mu_0(X)$ for all variables. Hence, $\mu_0\sigma = \mu_0$. The full *solution set* $\mathrm{Sol}(\mathcal{S})$ for $\mathcal{V} = \left\{X_1, \overline{X_1}, \ldots, X_k, \overline{X_k}\right\}$ is $\mathrm{Sol}(\mathcal{S}) = \{(\sigma(X_1), \ldots, \sigma(X_k)) \in A^* \times \cdots \times A^* \mid \sigma \text{ solves } \mathcal{S}\}$. We define the size $\|\mathcal{S}\|$ by $\|\mathcal{S}\| = |G| + |A| + |\mathcal{V}| + s + \sum_{1 \leq i \leq s} |U_i V_i|$.

Convention. For better readability we don't measure N, but we add the general hypotheses that N is given in such a way that the specification and all necessary computations over N (multiplication, computing the involution and the G action) can be done in polynomial space with respect to $\|\mathcal{S}\|$. This is no restriction, as we can add trivial equations to enlarge $\|\mathcal{S}\|$.

▶ **Theorem 1.** *There is a* PSPACE *algorithm which takes as input a system of twisted word equations with rational constraints $\mathcal{S}$ as above with input size $\|\mathcal{S}\|$. The output is an extended alphabet C of size $\mathcal{O}(|G|^2 \|\mathcal{S}\|^2)$, letters $c_X \in C$ for each $X \in \mathcal{V}$, and a trim NFA $\mathcal{A}$ accepting a rational set of A-morphisms $L(\mathcal{A}) \subseteq \mathrm{End}(C^*)$ such that*

$$\mathrm{Sol}(\mathcal{S}) = \left\{(h(c_{X_1}), \ldots, h(c_{X_{|\mathcal{V}|}})) \in C^* \times \cdots \times C^* \;\middle|\; h \in L(\mathcal{A})\right\}. \tag{1}$$

Intermediate equations, which label states of the NFA, have a length bound in $\mathcal{O}(|G| \|\mathcal{S}\|^2)$. Moreover, $\mathrm{Sol}(\mathcal{S}) = \emptyset$ if and only if $L(\mathcal{A}) = \emptyset$, and $|\mathrm{Sol}(\mathcal{S})| < \infty$ if and only if $\mathcal{A}$ doesn't contain any directed cycle.

The result above is far-reaching extension of Makanin's classical result on pure word equations. It combines combinatorics on words, automata theory, formal languages, and group actions on alphabets. It doesn't use band complexes, Makanin-Razborov diagrams or results from algebraic geometry over groups [4, 2]. Here, a virtually free group V is given by a group extension of a free group $F(B)$ with a finite group G with the natural set $A = B \cup B^{-1} \cup G \setminus \{1\}$ as generators. We represent elements of V by *reduced normal forms* in $\widehat{V}$, where $\widehat{V}$ is the set of words in $B^*G \subseteq A^*$ without factors $b\overline{b}$. Thus, we have a natural notion of *solution in reduced normal forms.*

▶ **Corollary 2.** *Let V be a f.g. virtually free group. There is an* NSPACE$(m^2\|\mathcal{S}\|^2 \log(\|\mathcal{S}\|))$ *algorithm such that:*

Input. *A system $\mathcal{S}$ of s equations $U_i = V_i$ over V with rational constraints and in variables $X_1, \ldots, X_k$, where $\|\mathcal{S}\| = k + \sum_{1 \leq i \leq s} |U_i V_i|$ and m denotes the number of states for the NFA's to encode constraints.*

Output. *An extended alphabet C of size $\mathcal{O}(\|\mathcal{S}\|^2)$, letters $c_X \in C$ for each variable, and a trim NFA $\mathcal{A}$ accepting a rational set of A-morphisms over C^* such that*

$$\left\{(h(c_{X_1}), \ldots, h(c_{X_k})) \in (C^*)^k \;\middle|\; h \in L(\mathcal{A})\right\} = \left\{(\sigma(X_1), \ldots, \sigma(X_k)) \in \widehat{V}^k \;\middle|\; \sigma \text{ solves } \mathcal{S}\right\}.$$

Moreover, there is no solution if and only if $L(\mathcal{A}) = \emptyset$, and there are infinitely many solutions if and only if $\mathcal{A}$ contains a directed cycle.

The reduction of Corollary 2 to Theorem 1 follows [4] very closely, see [5] for details:

1. Embed V into a semi-direct product $F(S) \rtimes G$ using Bass-Serre theory. This encodes $\widehat{V}$ as a rational set in S^*G and allows us to view a system of equations over V (with rational constraints) as a system of twisted word equations with rational constraints over S.
2. Handling of rational constraints by transformations on NFA's by standard methods.
3. Projection of EDT0L languages and respecting reduced normal forms using the fact that the embedding satisfies $B \subseteq S$.

3 Outline of the proof of Theorem 1

The actual proof of Theorem 1 is rather technical, so this extended abstract outlines the central ideas only. The focus is on those parts which are original and where the twisting forces us to deviate from what has been done elsewhere. Jeż's recompression technique is based on two procedures: *block-compression* and *pair-compression*; solutions are obtained by iteratively *popping* the first and last letters of variables (performing moves of the form $X \mapsto aX$), which increases the length of the equation, and *compressing* factors by replacing pairs ab and powers a^λ by a single (new) letter. In the "untwisted" setting, when we compress a pair ab we replace every occurrence of the factor that is "visible" in the equation, but in the twisted case, the pair ab appearing on one side of the equation needs to match with $f(ab)$ on the other side, which causes complications. The basic problem is that twisting of a word $(ab)^\lambda$ by some $f \in G$ may result in $f(ab)^\lambda = (ba)^\lambda$. The complications related to this will become clear below. Therefore we introduce two new procedures. First we define a new and more general δ-*periodic-compression* w.r.t. some $\delta \in \Theta(|G|\,\|\mathcal{S}\|)$. In some sense, δ-periodic-compression removes the problem caused by $f(p)^\lambda = q^\lambda$ where p and q are primitive words of length at most δ. (Powers of long primitive words are then handled in later iterations.) Performing one δ-periodic-compression will result in a situation where "equivalent" positions in the solution are far apart. This property is used for our version of pair-compression without the possibility to "uncross" pairs as is the usual strategy. Instead we do the following. First we pop out from every $\sigma(X)$ rather long prefixes and suffixes. After that we find room to compress enough pairs ab into fresh letters c. We cannot compress pairs by their label (twisting prevents that), so we compress only pairs ab where the corresponding two positions have no equivalent position which is located at some border of an occurrence of a variable. This is our leads to a new definition of *twisted-pair-compression*. Of course, we must define precisely when positions are equivalent and everything must take the action of G and rational constraints into account. Last but not least, we must realize the procedure by following arcs in an NFA where the labels are endomorphisms over some extended alphabet C. This yields the EDT0L property of the full solution set, more importantly it transforms questions about solvability of equations into structural properties of a finite graph.

One of the new features presented here is the ambient algebraic structure: in the case of free monoids (resp. free groups) the intermediate monoids were partially commutative. Twisting leads to more complicated defining relations. More concretely, when working with an equation $U = V$ over constants B and variables $\mathcal{X}$ with constraints defined by an NG-i-monoid morphism $\mu : B \cup \mathcal{X} \to N$, we deal with an NG-i-monoid denoted by $M(B, \mathcal{X}, \theta, \mu)$. The algebraic structure is a quotient monoid $(B \cup \mathcal{X})^* / \{xy = zx \mid (xy, zx) \in \theta\}$, where $x \in B \cup \mathcal{X}$ and $y, z \in (B \cup \mathcal{X})^*$ with $|y| = |z|$. The idea is that, reading a word in $w \in (B \cup \mathcal{X})^*$, the position of x is not fixed, it "floats" by conjugating y to z or vice versa, without changing the length of W. This possibility of "floating" is essential in our approach.

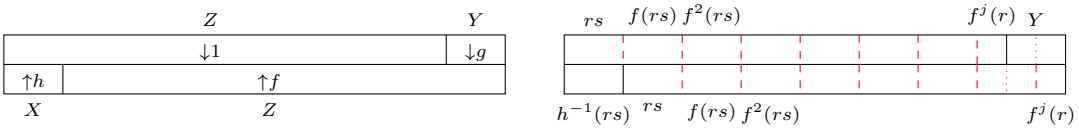

Figure 1 "Graphical" proof of Proposition 3.

3.1 States of the NFA

We start with a system of $\mathcal{S}$ of s equations $U_i = V_i$ over some alphabet A of constants and in variables X_j. We encode $\mathcal{S}$ as a single word using a marker symbol and we obtain the *initial equation* as:

$$W_{\text{init}} = \#X_1\# \cdots \#X_k\#U_1\# \cdots U_s\# \ \overline{\#X_1\# \cdots \#X_k\#V_1\# \cdots V_s\#}. \tag{2}$$

Note that $\sigma(W) = \sigma(\overline{W})$ if and only if $\sigma(U_i) = \sigma(V_i)$ for all i. We fix $n = |W_{\text{init}}|$. Note that this implies $n > |A| + |\mathcal{V}|$ and $\|\mathcal{S}\| \in |G| + \Theta(n)$. States of the transition system are denoted as $(W, B, \mathcal{X}, \theta, \mu)$. We call a state an *extended equation*. Here, B are the current constants and $\mathcal{X}$ are the current variables with $A \subseteq B \subseteq C$ and $\mathcal{X} \subseteq \Omega$ where C and Ω are fixed and of size $\mathcal{O}(|G|^2\|\mathcal{S}\|^2)$ and $W \in M(B, \mathcal{X}, \theta, \mu)$ has length bounded by $\mathcal{O}(|G|\|\mathcal{S}\|^2)$. A solution is a morphism (of NG-i-monoids) $\sigma : M(B, \mathcal{X}, \theta, \mu) \to M(B, \theta, \mu)$ such that $\sigma(W) = \sigma(\overline{W})$. Here, $M(B, \theta, \mu)$ is the submonoid of $M(B, \mathcal{X}, \theta, \mu)$. If θ is empty, then we speak about a *standard state*. We begin at a standard state and the aim is to track for every solution a path from the initial standard state $(W_{\text{init}}, A, G \times \mathcal{V}, \emptyset, \mu_0)$ to some final state $(W, B, \emptyset, \emptyset, \mu)$ without types and variables such that $W = \overline{W}$.

We need to reuse names for constants, so we also need a procedure, called *alphabet-reduction*, to get rid of *invisible* constants. These are letters $b \in B$ where for no $f \in G$ the letter $f(b)$ appears in W. Since a given solution σ might use them, we cannot simply throw them out. This forces us to consider *entire solutions* which are pairs (α, σ) where σ is a solution as above and $\alpha : M(B, \theta, \mu) \to A^*$ is an A-morphism.

3.2 Twisted conjugacy

An important concept in our approach is *twisted conjugacy*. We say that words $x, y \in A^*$ are *twisted conjugate* if there are $f, g, h \in G$ and $z \in A^*$ such that $zg(y) = h(x)f(z)$.

▶ **Proposition 3.** *Let σ be a solution of $Z(g, Y) = (h, X)(f, Z)$ such that $|\sigma(X)|$ satisfies $1 \leq |\sigma(X)| < |\sigma(Z)|$. Then there are words $r \in A^+$, $s \in A^*$ and $e, j \in \mathbb{N}$ with $0 \leq j < |G|$ such that $\sigma(X) = h^{-1}(rs)$ and $\sigma(Z) = ((rs)f(rs) \cdots f^{|G|-1}(rs))^e \, f^0(rs) \cdots f^{j-1}(rs)f^j(r)$.*

3.3 δ-periodic-compression

Recall that $w = a_1 \cdots a_n$ with $a \in A$ has *period* $p \in \mathbb{N}$ if $a_i = a_{i+p}$ for all $1 \leq i \leq n - p$. Let δ be some positive natural number. We say that a word w is *δ-periodic* if it has some period less or equal to than δ. Let u be a prefix (resp. factor, resp. suffix) of some nonempty word w. We say that u is a *maximal δ-periodic prefix (resp. factor, resp. suffix)* in w if we cannot extend the occurrence of the factor u inside w by any letter to the right or left, to get a δ-periodic word. A δ-periodic word w is called *long* if $|w| \geq 3\delta$, and *very long* if $|w| \geq 10\delta$. Standard knowledge in combinatorics on words tells us:

▶ **Lemma 4.** *Let w be a δ-periodic word and $w = p^e r = q^f s$ such that p, q are primitive, $|p| \le |q| \le \delta$, $1 \ne r \le p$, $1 \ne s \le q$, and $|w| \ge 2\delta$. Then $p = q$, $e = f \ge 1$, and $r = s$.*

Let us give a high-level description of our new procedure δ-periodic-compression. For simplicity, we deal just with a single "triangulated" twisted equation $(f, X)w(g, Y) = Z$ where X, Y, Z are variables and $w \in B^*$ is word over the current constants B. We consider a fixed solution σ and we ignore rational constraints by assuming $N = \{1\}$. Moreover, we assume that for every letter $b \in B$ there is some $f \in G$ such that $f(b)$ is a letter in w. Thus, we start with an alphabet-reduction which removes invisible letters for a given solution. Since σ is a solution, we can identify positions in w with positions in $\sigma(Z)$. These identified positions carry the same label and we also say that these positions are *visible*.

Let us consider all very long maximal δ-periodic factors $q^d q'$, written as $up^e rv$, of $\sigma(Z)$ which have an occurrence with a visible position. Note that their total number is bounded by $|w|/\delta$. In the description we assume that $|u| = |v| = 3\delta$, p is primitive of length at most δ and $1 \ne r \le p$. Hence, $up^e rv$ defines the triple (p, r, e) uniquely by Lemma 4.

The idea is that at the end we arrive at a state with a solution where all occurrences of these factors $up^{e_\lambda} rv$ are replaced by $u[r, s, \lambda]v$ where $[r, s, \lambda]$ is the notation for a single fresh letter and $rs = p$. Here λ is a formal symbol taken from some some index set Λ of size at most $|w|/\delta$. In order to avoid many case distinctions we consider the following (in some sense most interesting) special case, only. We assume that $\sigma(X)$ is a very long periodic word, $\sigma(Y)$ has a very long δ-periodic prefix, and $\sigma(Z)$ has a δ-periodic prefix longer than $|\sigma(X)|$, but no long δ-periodic suffix. Moreover, we assume that w has more than two very long δ-periodic factors. Note that $up^{e_\lambda} rv = urq^{e_\lambda} v$ if $1 \ne r \ne p$, $p = rs$, and $q = sr$. Let us resume: let $u_\lambda p_\lambda^{e_\lambda} r_\lambda v_\lambda$ be an occurrence of a very long δ-periodic factor in $\sigma(Z)$ with at least one visible position, $|u_\lambda| = |v_\lambda| = 3\delta$, and p_λ is primitive with $|p_\lambda| \le \delta$. Thus, $\lambda \in \Lambda$. There are three cases which we distinguish by using the names $\lambda, \nu, \rho \in \Lambda$. First, the occurrence of $u_\lambda p_\lambda^{e_\lambda} r_\lambda v_\lambda$ is the δ-periodic prefix of $\sigma(Z)$. As, by our simplification assumption, this prefix is longer than $\sigma(X)$, we deduce that we can write $\sigma(f, X) = u_\lambda p_\lambda^e p'$ with $p' \le p_\lambda$. Second, all "inner" positions $p_\nu^{e_\nu} r_\nu$ of $z = u_\nu p_\nu^{e_\nu} r_\nu v_\nu$ are visible. In this case, since $\sigma(X)$ (resp. $\sigma(Y)$) has a very long prefix (resp. suffix), this corresponds to an occurrence of the factor z in w. Third we can write $\sigma(g, Y) = p'' p_\rho^{e'} r_\rho v_\rho y$ with $e' \ge 6$ and $p'' \le p_\rho$ for some maximal δ-periodic factor $u_\rho p_\rho^{e_\rho} r_\rho v_\rho$ of $\sigma(Z)$ with $\rho \in \Lambda$. Moreover, we are in the case that the maximal δ-periodic prefix of $v_\rho y$ is v_ρ and $y \ne 1$. As we assumed that w has more than two very long δ-periodic factors, we can write $w = w_1 p_\nu^\nu r_\nu w_2$.

The procedure introduces at this point (for each $\lambda \in \Lambda$) new "typed" variables: $[X, p_\lambda]$, $[Y, \overline{p_\lambda}]$, and $[Z, p_\lambda]$. Actually, we need many more variables. Whenever we introduce variable $[V, p]$ we also introduce $[\overline{V}, \overline{p}]$ and $[V, qa]$ for $p = aq$; and we iterate this process. Finally, the action of G is defined by identifying $(f, [V, p])$ with $(1, [V, f(p)]) = [V, f(p)]$. (Note that $(f, [V, p]) = (g, [V, p]) \iff f(p) = g(p)$.)

The maximal number of these typed variables introduced by any equation with at most n variables is at most $2n|G|\delta$. The factor $2n$ is there because we consider for every variable a prefix and a suffix; and the factor δ comes in because $|p| \le \delta$ and with $p = aq$ every conjugate qa is also considered. Let $\mathcal{X}'$ be the enlarged set of untyped variables $X \in \mathcal{X}$ and fresh typed variables $[V, p]$. Together with introducing these variables we switch to the algebraic structure to read the equation in the monoid $M(B, \mathcal{X}', \theta, \mu')$ where the defining relations are given by $\theta = \{(a[V, p], [V, q]a \mid ap = qa \wedge a \in B\}$. We define the *type* of $[V, p]$ to be $\theta([V, p]) = p$ and we observe that the defining relations imply $p[V, p] = [V, p]p$ in $M(B, \mathcal{X}', \theta, \mu')$. We need a stronger notion of *solution* for typed variables in order to prevent that an unsolvable equation is transformed in a solvable one. If $\theta([V, p]) = p$, then we require $\sigma([V, p]) \in p^*$. Since σ is

a morphism, it also satisfies the defining relations. Hence, $a\sigma([V,p]) = \sigma([V,q])a$ implies $|\sigma([V,p])| = |\sigma([V,p])|$, too. The value of $\mu'([V,p])$ is defined implicitly in the following loop.

The loop is over all variables in some order. Of course, whatever happens to a variable V forces a simultaneous change in $\overline{V}$, too. We pop from each variable the maximal δ-periodic suffix of $\sigma(X)$ if this suffix is longer than 3δ. Otherwise we do nothing. As we have no control on the length of this suffix, we introduce a new typed variable. (Clearly, as we consider X and $\overline{X}$ prefixes and suffixes are popped out, and each X may produce two typed variable.) What we do in our concrete situation (where we have $\Lambda = \{\lambda, \nu, \rho\}$) is the following:

1. We substitute (f, X) by $\tau(f, X) = u_\lambda[X, p_\lambda]p_\lambda^\ell p'$. (So, X vanishes.) Moreover, for technical reasons, we require $5\delta < |p_\lambda^\ell p'| \le 6\delta$. We can define $\sigma'([X, p_\lambda]) \in p_\lambda^*$ such that $\sigma(f, X) = u_\lambda\sigma'([X, p_\lambda])p_\lambda^\ell p'$.
2. We substitute (g, Y) by $\tau(g, Y) = p''p_\rho^r[Y, p_\rho](g, Y)$ with the length condition $5\delta < \left|p''p_\rho^r\right| \le 6\delta$. We can define $\sigma'(g, Y) = v_\rho y$ and $\sigma'([Y, p_\rho]) \in p_\rho^*$ such that $\sigma(g, Y) = p''p_\rho^r\sigma'([Y, p_\rho])\sigma'(g, Y)$.
3. We substitute Z by $\tau(Z) = sq^{\ell'}[Z, q]Z$ with the length condition $5\delta < |sq^{\ell'}| \le 6\delta$. Here q is the conjugate of p_λ such that $q = sr_\lambda$, $p_\lambda = r_\lambda s$. We can define $\sigma'(Z) = v_\lambda z$ and $\sigma'([Z, q]) \in q^*$ with $sq^{\ell'}\sigma'([Z, q])\sigma'(Z) = \sigma(Z)$.

This leads to a new solution σ' to the twisted equation $u_\lambda[X, p_\lambda]p_\lambda^\ell p'wp''p_\rho^{r'}[Y, p_\rho](g, Y) = sq^{\ell'}[Z, q]Z$. We rename σ' as σ. Note that u_λ is a prefix of $sq^{\ell'}$. The positions of $[X, p_\lambda]$ and $[Z, q]$ are not adjusted, but our defining relations do not fix these positions. So, we use these defining relations to represent the equation by the following equation between words

$$u_\lambda[X, p_\lambda]p_\lambda^{\ell''}r_\lambda v_\lambda w'u_\rho p_\rho^{r'}r_\rho[Y, p_\rho](g, Y) = u_\lambda[Z, q]p_\lambda^{\ell'''}r_\lambda Z. \tag{3}$$

The morphism σ solves this equation. Moreover, in our concrete situation we have $v_\lambda w'u_\rho = vu_\nu p_\nu^\nu r_\nu u$; and again, we content ourselves to consider the special case where $u_\nu p_\nu^\nu r_\nu$ is the only occurrence of very long δ-periodic factor in $v_\lambda w'u_\rho$. Ignoring u_λ on the left, the remaining task is to compress the equation (where $v_\lambda \le vu_\nu$ and $\overline{u_\rho} \le \overline{u}\,\overline{v_\nu}$)

$$[X, p_\lambda]p_\lambda^{\ell''}r_\lambda vu_\nu p_\nu^\nu r_\nu v_\nu up_\rho^{r'}r_\rho[Y, p_\rho](g, Y) = [Z, q]p_\lambda^{\ell'''}r_\lambda Z \tag{4}$$

with respect to the solution σ. The crucial idea comes next: we use a larger alphabet of constants, we change the type of variables and we introduce more defining relations. For each $\lambda \in \Lambda$ we introduce a new constant, denoted as $[p_\lambda, r_\lambda, \lambda]$, and for each variable $[V, p]$ we introduce a constant $[p]$. Thus, $[p_\lambda, r_\lambda, \lambda]$ and $[p]$ are fresh letters. We also let act G on these letters in the obvious way, so we actually introduce more letters. Let h be the morphism defined by $h([p_\lambda, r_\lambda, \lambda]) = p_\lambda r_\lambda$ and $h([p]) = p$, it means h compresses the words $p_\lambda r_\lambda$ and p into single letters, then Equation (4) is the image under h of the equation

$$[X, p_\lambda][p_\lambda]^{\ell''-1}\,[p_\lambda, r_\lambda, \lambda]\,vu_\nu[p_\nu]^{\nu-1}\,[p_\nu, r_\nu, \nu]\,v_\nu u[p_\rho]^{r'-1}\,[p_\rho, r_\rho, \rho]\,[Y, p_\rho](g, Y) \tag{5}$$

$$= [Z, q][p_\lambda]^{\ell'''-1}\,[p_\lambda, r_\lambda, \lambda]\,Z \tag{6}$$

To have a visual notation we color the letters of the form $[p_\lambda, r_\lambda, \lambda]$ *green*. The procedure continues by redefining the type of a twisted variable $[V, p]$ as the letter $[p]$. We augment θ by more defining relations:

$$\{[V, p][p] = [p][V, p] \mid [V, p] \text{ twisted variable}\} \cup \left\{ [p_\lambda, r_\lambda, \lambda]\,[sr_\lambda] = [p_\lambda]\,[p_\lambda, r_\lambda, \lambda] \;\middle|\; p_\lambda = r_\lambda s \right\}.$$

It is not hard to see that we find a solution σ' of the new equation over the larger alphabet of constants such that $h\sigma' = \sigma h$ which is needed to prove the EDT0L property. The

remaining procedure is essentially the same as in [3]: using transformations either based on substitutions $[V,p] \mapsto [V,p][p]$ and $[V,p] \mapsto 1$ or homomorphisms based on $[p] \mapsto [p][p]$ and $[p_\lambda, r_\lambda, \lambda] \mapsto [p_\lambda, r_\lambda, \lambda]\,[p_\lambda]$ we can compress the above equation and simultaneously the solution such that the equation becomes its final form. We finish δ-periodic compression with

$$[p_\lambda, r_\lambda, \lambda]\, v u_\nu\, [p_\nu, r_\nu, \nu]\, v_\nu u\, [p_\rho, r_\rho, \rho]\, (g, Y) = [Z, q]\, [p_\lambda, r_\lambda, \lambda]\, Z. \tag{7}$$

The typed variables are gone, the letters $[p]$ are not visible anymore, moreover, the new solution doesn't use them. We are back in a free monoid, because none of the defining relations is used anymore. Note that Equation (7) is shorter than the original equation. Indeed, while the initial increase in the length of the equation is in $\mathcal{O}(n\delta)$, each green letter represents the inner part of a very long δ-periodic word of length at least 6δ.

▶ **Proposition 5.** *Let $E_s = (W_s, B_s, \mathcal{X}_s, \emptyset, \mu_s)$ be the state where we started δ-periodic-compression with $|W_s| \geq 8\delta n$; and let $E_t = (W_t, B_t, \mathcal{X}_t, \emptyset, \mu_t)$ the standard state where we finish δ-periodic-compression, and $(W, B, \mathcal{X}, \theta, \mu)$ any state which we have seen on the path from E_s to E_t during the procedure. Then we have $|W_t| \leq |W_s| + 20\delta n$ and $|W| \leq |W_s| + \mathcal{O}(\delta n)$. Moreover, let $n_{\text{new}} = \sum_{b \in B_t \setminus B_s} |W_t|_b$. If $n_{\text{new}} \geq 10n$, then $|W_t| < |W_s|$.*

▶ Remark. Note that n_{new} is the number of green letters we see in W_t. Let σ be the solution after δ-periodic-compression, then for $X \in \mathcal{X}_t$ the length of a δ-periodic prefix (and suffix resp.) is bounded by 3δ. Hence, there is no very long δ-periodic prefix or suffix in $\sigma(X)$.

3.4 Twisted pair-compression

We place ourselves after a sequence of rounds of popping out letters for each variable, alphabet-reduction, and δ-periodic compression. We are at a standard state $E = (W, B, \mathcal{X}, \emptyset, \mu)$ where $\emptyset \neq \mathcal{X} \subseteq \mathcal{V}$. Without restriction, we may assume that $|W| \in \Theta(|G|n^2)$ and that the number of visible green letters is at most $10n$: our construction ensures that $|W| \in \mathcal{O}(|G|n^2)$, and we can always pop out letters to make the equation longer; and if the number of visible green letters exceeds $10n$ then according to Proposition 5 the most recent δ-periodic-compression had decreased the length of the equation, so we can perform another round.

Throughout, it is possible to write $W = U_1 \# u(f,X) w(g,Y) v \# U_2 \overline{U_2'} \,\overline{\#}\, \overline{v} \overline{Z} \overline{u} \,\overline{\#}\, \overline{U_1'}$ with $|U_i'|_\# = |U_i'|_{\overline{\#}}$, $i = 1, 2$. Here $u(f,X)w(g,Y)v = uZv$ is called a *local equation*. For simplicity we may assume that $u, v, w \in B^*$ and that $(f,X), (g,Y), Z = (1,Z)$ are twisted variables. Moreover, we may assume that for each local equation its "dual" equation $\overline{v}(g,\overline{Y})\overline{w}(f,\overline{X})\overline{u} = \overline{v}\overline{Z}\overline{v}$ is also part of the system encoded in W. Since W is long, we can assume that $|uwv|$ is long, too. Since there are at most $\mathcal{O}(n)$ green letters, there are long intervals without green letters. The goal is to compress enough pairs $ab \leq W$ of constants into single letters without causing any conflict or overlap with other pairs or variables that are connected via twisting. We compress pairs according to an equivalence relation between positions. The idea is that whenever we modify a solution at position i, then we must modify $\sigma(W)$ at all equivalent positions $j \equiv i$.

The notion of *equivalent positions* is defined for a given solution σ, it has a reasonably intuitive definition. We write $W = U\overline{V}$ with $\sigma(U) = \sigma(V)$ and $\sigma(U) = a_1 \cdots a_m$ with $a_i \in B$. We associate with U (resp. V) the interval $[1, m] \subseteq \mathbb{N}$ (resp. $[m+1, 2m]$) of positions and we let $i \sim m + i$ for $1 \leq i \leq m$. We say that position i sits directly "above" $m + i$, see Figure 2.

Each occurrence of a twisted variable (f, X) in UV corresponds to some interval of length $|\sigma(X)|$ in $[1, 2m]$ and we identify the i-th positions in each of these intervals for $1 \leq i \leq |\sigma(X)|$. Identified positions are represented by a unique position corresponding to

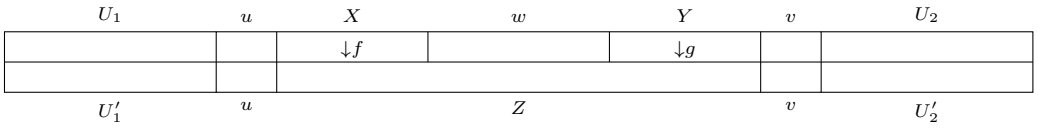

Figure 2 $W = U\overline{V}$ viewed as U on top and V on the bottom and $\sigma(U) = \sigma(V)$ in the middle.

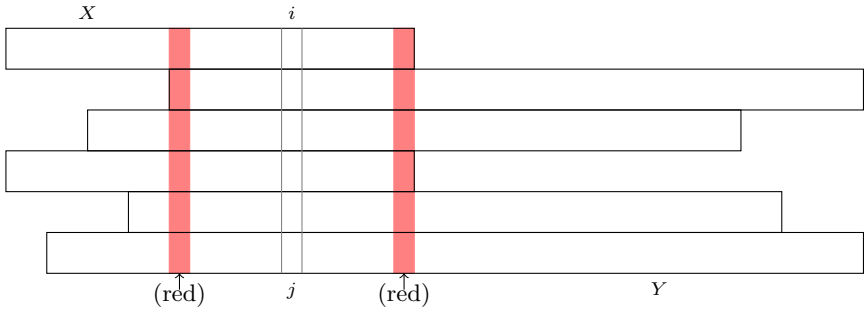

Figure 3 Red positions. We use $\sim$ to put $i \approx j$ into a "domino tower".

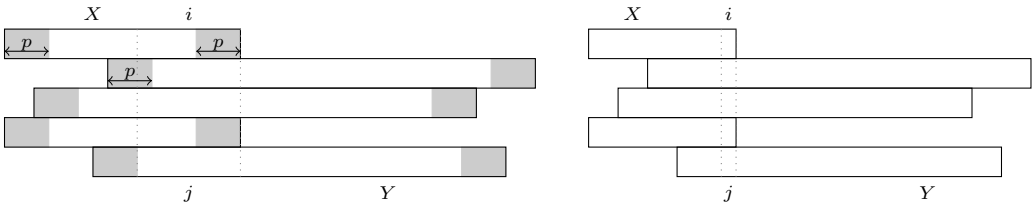
the leftmost occurrence of a twisted variable (f, X) in U. This interval is denoted by $I(X)$. Thus, we identify various positions and we carry over the relation $\sim$: if i and j are identified with i' and j' and if $i' \sim j'$, then we also let $i \sim j$. By $\approx$ we denote the generated equivalence relation of $\sim$. The relation $\approx$ can be visualized in so-called *domino towers* as in Figure 3. Clearly, we may have $i \approx j$ for various $i, j \in I(X)$. For example, an equation $(f, X)a = bX$ forces $i \approx j$ for all $i, j \in I(X)$. There is also a natural notion of duality: $I(X)$ and $I(\overline{X})$ are disjoint, but if we change $\sigma(X)$ at the first position, we must change $\sigma(\overline{X})$ at the last position. Thus, for the i-th position in $I(X)$ we let $\overline{i}$ be the $(|\sigma(X)| - i + 1)$-st position in $I(\overline{X})$; and we write $i \leftrightarrow \overline{i}$. Finally, we let $\equiv \subseteq [1, 2m] \times [1, 2m]$ be the equivalence relation generated by $\approx$ and $\leftrightarrow$. Clearly, if $i \approx j \leftrightarrow \overline{j}$ and the label at position i is $a \in B$, then a labels j and $\overline{a}$ labels $\overline{j}$.

Positions at the borders of some $\sigma(X)$ inside $\sigma(W)$ play a special role because we cannot compress over borders. We color the first and last position in each $I(X)$ *red* (unless it has already the color green) to signal "danger". We color red all positions equivalent to a red position, too. Since the set of green positions is closed under equivalence (they are the fresh letters $[p_\lambda, r_\lambda, \lambda]$), no conflict between red and green is introduced here. It follows that there are at most n pairwise different equivalence classes of red positions.

We extend the notion of equivalence to intervals (without red positions). Let $p \in \mathbb{N}$. We directly link an interval $[i, i + p]$ of positions in $\sigma(X)$ (resp. w, $\sigma(Y)$) to $[j, j + p]$ in $\sigma(Z)$ if there is an equation, for example like $u(f, X)w(g, Y)v = uZv$, such that $\sigma(X)[i, i + p]$ (resp. $w[i, i + p]$, $\sigma(Y)[i, i + p]$) sits directly above the $\sigma(Z)[j, j + p]$; and we write $[i, i + p] \sim [j, j + p]$ in this case. For each interval $[i, i + p]$ of positions in $\sigma(X)$ we also let $[i, i + p] \leftrightarrow [\overline{i + p}, \overline{i}]$. As above, we let $\approx$ and $\equiv$ be the generated equivalence relations of $\sim$ resp. $\sim \cup \leftrightarrow$. Since $i \sim j \iff \overline{i} \sim \overline{j}$ we can deduce

$$[i, i + p] \equiv [j, j + p] \iff [i, i + p] \approx [j, j + p] \vee [i, i + p] \approx [\overline{j + p}, \overline{j}]. \tag{8}$$

▶ **Lemma 6.** *Let $[i - 1, i, i + 1, i + 2]$ be an interval without any red position and where the four positions are pairwise inequivalent. Consider $[i, i + 1] \equiv [j, j + 1] \equiv [k, k + 1]$. Then either $k = j$ and $[j, j + 1] \not\approx [\overline{k} - 1, \overline{k}]$ or $[j, j + 1] \cap [k, k + 1] = \emptyset$.*



(a) $W : [i-p, i+p] \sim [j-p, j+p]$ **(b)** $W_p : i \sim j$

Figure 4 Example illustrating the proof of Lemma 7.

Let $p \in \mathbb{N}$ and σ be a solution for W. For each X we do:

- if $|\sigma(X)| \leq 2p$, then replace X by $\sigma(X)$ and remove X from the set of variables;
- if $|\sigma(X)| > 2p$, then write $\sigma(X) = uwv$ with $|u| = |v| = p$ and replace X by uXv. Change the interval $I(X) = [l, r]$ to $I_p(X) = [l + p, r - p]$. (So, it is smaller.)

Denote the new solution for W_p defined by that procedure by σ_p.

▶ **Lemma 7.** *Let i and j be positions in $\sigma_p(W_p) = \sigma(W)$ which belong to variables in W_p. This means $i, j \in \bigcup\{I_p(X) \mid X \in \mathcal{X}_p\}$. Then we have $i \sim j$ (resp. $i \leftrightarrow j$) for W_p and σ_p if and only if $[i-p, i+p] \sim [j-p, j+p]$ (resp. $[i-p, i+p] \leftrightarrow [j-p, j+p]$) for W and σ.*

We define and fix $\delta = |G|\,\varepsilon$ and $\varepsilon = 30n$. We start at a standard state $E = (W, B, \mathcal{X}, \emptyset, \mu)$ together with a solution σ. For simplicity, we assume that all local equations have the form $u(f, X)w(g, Y)v = uZv$. Moreover, when we start pair-compression (directly after δ-periodic-compression) there are some green letters and corresponding green visible positions.

1. For every X in some order do: either replace X by $\sigma(X)$ (if $|\sigma(X)| \leq 10\delta$) or write $\sigma(X) = ux$ with $|u| = 10\delta$; replace X by $\tau(X) = uX$; rename the new equation and new solution as (E, σ). Define the intervals $I(X)$ as done above color *red* positions in $\sigma(W)$ which are equivalent to a first or last position in $I(X)$ unless they are green.
2. **while** there is an interval $[i-1, i, i+1, i+2]$ such that (1) all four positions are pairwise inequivalent, (2) no position is colored, and (3) all positions are visible **do**

   a. Let ab the label of the middle interval $[i, i+1]$. Choose fresh letter c and define a morphism h by $h(c) = ab$. (Hence, $f(c) = c \iff f(ab) = ab$, too.) Whenever $[i, i+1] \approx [j, j+1]$, then the label of $[j, j+1]$ is $f(ab)$ for some $f \in G$. Replace each of the intervals $[j, j+1]$ and $[\overline{j}-1, \overline{j}]$ by a single new position and label this position with $f(c)$ and $f(\overline{c})$ resp. There is no conflict in this relabeling by Lemma 6. Since there is no red position, there is no "crossing" of the intervals $[j, j+1]$ or $[\overline{j}-1, \overline{j}]$. So, this gives a new but shorter equation W'. We have $h(W') = W$ and new solution σ' such that $h\sigma'(W') = \sigma(W)$ There is a new numbering for the positions, but the colored positions can still be identified.

   b. Define $B' = B \cup \{f(c), f(\overline{c}) \mid f \in G\}$ and $E' = (W', B', \mathcal{X}, \emptyset, \mu')$.

   c. Rename (E', σ') as (E, σ) and transfer the induced coloring.

   end while

If we started the procedure with W and the while loop with W_ℓ, then the loop terminates with an equation W' and we introduced at most $|G|\,(|W_\ell| - |W'|)$ new letters. It is also clear that $|W'| \leq |W| + 20\delta n$ since any increase of length is due to the first steps, where we replaced each variable X either by $\sigma(X)$ or by uXv. The worst case for $|W'|$ is that no compression took place. However, we assume that there at most $10n$ green letters. Hence, we can use the following fact.

▶ **Proposition 8.** *Let (E, σ) with equation W just after a δ-periodic-compression where at most $10n$ green letters are visible. If $|W| \in 20\ell\delta n + \mathcal{O}(\delta n)$, then the pair-compression procedure outputs an equation W' such that $|W'| \leq |W| + 20\delta n$ and $|W'| \leq \frac{59|W|}{60} + \mathcal{O}(\delta n)$.*

Let us highlight that Proposition 8 is the key step in the proof of Theorem 1 and it is here where twisted conjugacy comes into play. Following any given solution at the initial state, it bounds the lengths of all intermediate equations in $\mathcal{O}(\delta n) = \mathcal{O}(|G|n^2)$. Since at a standard state we can perform an alphabet reduction we can bound the size of the extended alphabet C in $\mathcal{O}(|G|^2 n^2)$. Moreover, the number of untyped variables is never increasing. Typed variables disappear and reappear, but their number never grows beyond the size of C.

After δ-periodic compression, no $\sigma(X)$ started or ended in a very long δ-periodic word. In the procedure above either X vanished or we replaced X by uXv where $|u| = |v| = 10\delta$. We carefully colored some position red after that replacement. Consider the new equation with the new solution just after that step; and rename the corresponding pair as (W, σ). Consider positions $i < k$ in $\sigma(W)$ such that no position k with $i \leq k \leq j$ is green. With the help of Proposition 3, Lemma 7 and "domino towers" as depicted in Figure 4, one can show the following fact: if $i \equiv k \equiv j$ for some k, then $|j - i| > \varepsilon$. The fact is not obvious but extremely useful: knowing that equivalent positions are far apart allows one to find enough intervals of length four, such that pair-compression reduces their length to at most three by Lemma 6.

Putting all this together, the overall compression method has the following high-level description. Start at the initial state E_{init} with a given initial entire solution $(\text{id}_{A^*}, \sigma_{\text{init}})$.

begin compression
Rename E_{init} as $E = (W, B, \mathcal{X}, \emptyset, \mu)$; rename $(\text{id}_{A^*}, \sigma_{\text{init}})$ as (α, σ).
Repeat the following loop until $\mathcal{X} = \emptyset$.
begin loop
1. Pop out letters from variables until $|W| \geq 100\delta n$.
2. Define $\kappa > 0$ by $\kappa\delta n = |W|$. Call δ-periodic-compression (starting with an alphabet-reduction), and let W' denote the equation at the end of the procedure.
3. If $|W'| < \kappa\delta n$, then do nothing, else call pair-compression.
end loop
end compression

Proposition 8 implies that $\kappa \in \mathbb{Q}$ is bounded above by some effective constant in $\mathcal{O}(1)$. Defining a weight in $\mathbb{N}^4$ (ordered lexicographically) by

$$\|E, \alpha, \sigma\| = \left(\sum_{X \text{ has no type}} |\alpha\sigma(X)|, \sum_{X \text{ is typed}} |\alpha\sigma(X)|, |W|, |B| \right)$$

finally shows that the compression method terminates for every given solution because every step in the procedures is weight-reducing. This means our algorithm finds all solutions. This finishes the outline of the proof of Theorem 1.

Acknowledgements. We thank the anonymous referees for very helpful feedback.

Abstract

We study a pumping lemma for the word/tree languages generated by higher-order grammars. Pumping lemmas are known up to order-2 word languages (i.e., for regular/context-free/indexed languages), and have been used to show that a given language does not belong to the classes of regular/context-free/indexed languages. We prove a pumping lemma for word/tree languages of arbitrary orders, modulo a conjecture that a higher-order version of Kruskal's tree theorem holds. We also show that the conjecture indeed holds for the order-2 case, which yields a pumping lemma for order-2 tree languages and order-3 word languages.

1 Introduction

We study a pumping lemma for higher-order languages, i.e., the languages generated by higher-order word/tree grammars where non-terminals can take higher-order functions as parameters. The classes of higher-order languages [26, 18, 4, 5, 6] form an infinite hierarchy, where the classes of order-0, order-1, and order-2 languages are those of regular, context-free and indexed languages. Higher-order grammars and languages have been extensively studied by Damm [4] and Engelfriet [5, 6] and recently re-investigated in the context of model checking and program verification [9, 20, 15, 24, 11, 16, 12, 23].

Pumping lemmas [2, 7] are known up to order-2 word languages, and have been used to show that a given language does not belong to the classes of regular/context-free/indexed languages. To our knowledge, however, little is known about languages of order-3 or higher. Pumping lemmas [21, 12] are also known for higher-order *deterministic* grammars (as generators of infinite *trees*, rather than tree languages), but they cannot be applied to non-deterministic grammars.

In the present paper, we state and prove a pumping lemma for unsafe[1] languages of arbitrary orders modulo an assumption that a "higher-order version" of Kruskal's tree theorem [17, 19] holds. Let $\preceq$ be the homeomorphic embedding on finite ranked trees[2], and

[1] See, e.g., [16] for the distinction between safe vs unsafe languages; the class of unsafe languages subsumes that of safe languages.

[2] I.e., $T_1 \preceq T_2$ if there exists an injective map from the nodes of T_1 to those of T_2 that preserves the labels of nodes and the ancestor/descendant-relation of nodes; see Section 2 for the precise definition.

$\prec$ be the strict version of $\preceq$. The statement of our pumping lemma[3] is that for any order-n infinite tree language L, there exist a constant c and a strictly increasing infinite sequence of trees $T_0 \prec T_1 \prec T_2 \prec \cdots$ in L such that $|T_i| \leq \mathbf{exp}_n(ci)$ for every $i \geq 0$, where $\mathbf{exp}_0(x) = x$ and $\mathbf{exp}_{n+1}(x) = 2^{\mathbf{exp}_n(x)}$. Due to the correspondence between word/tree languages [4, 1], it also implies that for any order-n infinite word language L (where $n \geq 1$), there exist a constant c and a strictly increasing infinite sequence of words $w_0 \prec w_1 \prec w_2 \prec \cdots$ in L such that $|w_i| \leq \mathbf{exp}_{n-1}(ci)$ for every $i \geq 0$, where $\prec$ is the subsequence relation. The pumping lemma can be used, for example, to show (modulo the conjecture) that the order-$(n+1)$ language $\{a^{\mathbf{exp}_n(k)} \mid k \geq 0\}$ does not belong to the class of order-n word languages, for $n > 0$. Thus the lemma would also provide an alternative proof of the strictness of the hierarchy of the classes of higher-order languages.[4]

We now informally explain the assumption of "higher-order Kruskal's tree theorem" (see Section 2 for details). Kruskal's tree theorem [17, 19] states that the homeomorphic embedding $\preceq$ is a well-quasi order, i.e., that for any infinite sequence of trees $T_0, T_1, T_2, \ldots$, there exist $i < j$ such that $T_i \preceq T_j$. The homeomorphic embedding $\preceq$ can be naturally lifted (e.g. via the logical relation) to a family of relations $(\preceq_\kappa)_\kappa$ on higher-order tree functions of type κ. Our conjecture of "higher-order Kruskal's theorem" states that, for every simple type κ, $\preceq_\kappa$ is also a well-quasi order on the functions expressed by the simply-typed λ-terms. We prove that the conjecture indeed holds up to order-2 functions, if we take $\preceq_\kappa$ as the logical relation induced from the homeomorphic embedding $\preceq$. Thus, our pumping "lemma" is indeed true for order-2 tree languages and order-3 word languages. To our knowledge, the pumping lemma for those languages is novel. The conjecture remains open for order-3 or higher, which should be of independent interest.

Our proof of the pumping lemma (modulo the conjecture) uses the recent work of Parys [23] on an intersection type system for deciding the infiniteness of the language generated by a given higher-order grammar, and our previous work on the relationship between higher-order word/tree languages [1].

The rest of this paper is organized as follows. Section 2 prepares several definitions and states our pumping lemma and the conjecture more formally. Section 3 derives some corollaries of Parys' result [23]. Section 4 prepares a simplified and specialized version of our previous result [1]. Using the results in Sections 3 and 4, we prove our pumping lemma (modulo the conjecture) in Section 5. Section 6 proves the conjecture on higher-order Kruskal's tree theorem for the order-2 case, by which we obtain the (unconditional) pumping lemma for order-2 tree languages and order-3 word languages. Section 7 discusses related work and Section 8 concludes.

2 Preliminaries

We first give basic definitions needed for explaining our main theorem. We then state the main theorem and provide an overview of its proof.

[3] This should perhaps be called a pumping "conjecture" since it relies on the conjecture of the higher-order Kruskal's tree theorem.

[4] The strictness of the hierarchy of higher-order *safe* languages has been shown by Engelfriet [5] using a complexity argument, and Kartzow [8] observed that essentially the same argument is applicable to obtain the strictness of the hierarchy of unsafe languages as well. Their argument cannot be used for showing that a particular language does not belong to the class of order-n languages.

2.1 λ-terms and Higher-order Grammars

This section gives basic definitions for terms and higher-order grammars.

▶ **Definition 1** (Types and Terms). The set of *simple types*, ranged over by κ, is given by: $\kappa ::= \mathtt{o} \mid \kappa_1 \to \kappa_2$. The order of a simple type κ, written $\mathtt{order}(\kappa)$ is defined by $\mathtt{order}(\mathtt{o}) = 0$ and $\mathtt{order}(\kappa_1 \to \kappa_2) = \max(\mathtt{order}(\kappa_1) + 1, \mathtt{order}(\kappa_2))$. The type $\mathtt{o}$ describes trees, and $\kappa_1 \to \kappa_2$ describes functions from κ_1 to κ_2. The set of $\lambda^{\to,+}$-*terms* (or *terms*), ranged over by s, t, u, v, is defined by:

$$t ::= x \mid a\, t_1 \cdots t_k \mid t_1\, t_2 \mid \lambda x : \kappa.t \mid t_1 + t_2\,.$$

Here, x ranges over variables, and a over constants (which represent tree constructors). Variables are also called *non-terminals*, ranged over by x, y, z, f, g, A, B; and constants are also called *terminals*. A ranked alphabet Σ is a map from a finite set of terminals to natural numbers called *arities*; we implicitly assume a ranked alphabet whose domain contains all terminals discussed, unless explicitly described. $+$ is non-deterministic choice. As seen below, our simple type system forces that a terminal must be fully applied; this does not restrict the expressive power, as $\lambda x_1, \ldots, x_k.a\, x_1 \cdots x_k$ is available. We often omit the type κ of $\lambda x : \kappa.t$. A term is called an *applicative term* if it does not contain λ-abstractions nor $+$, and called a $\lambda^{\to}$-*term* if it does not contain $+$. As usual, we identify terms up to the α-equivalence, and implicitly apply α-conversions.

A (simple) type environment $\mathcal{K}$ is a sequence of type bindings of the form $x : \kappa$ such that if $\mathcal{K}$ contains $x : \kappa$ and $x' : \kappa'$ in different positions then $x \neq x'$. In type environments, non-terminals are also treated as variables. A term t has type κ under $\mathcal{K}$ if $\mathcal{K} \vdash_{\mathtt{ST}} t : \kappa$ is derivable from the following typing rules.

$$\frac{}{\mathcal{K}, x : \kappa, \mathcal{K}' \vdash_{\mathtt{ST}} x : \kappa} \qquad \frac{\Sigma(a) = k \qquad \mathcal{K} \vdash_{\mathtt{ST}} t_i : \mathtt{o} \ \ (\text{for each } i \in \{1, \ldots, k\})}{\mathcal{K} \vdash_{\mathtt{ST}} a\, t_1 \cdots t_k : \mathtt{o}}$$

$$\frac{\mathcal{K} \vdash_{\mathtt{ST}} t_1 : \kappa_2 \to \kappa \qquad \mathcal{K} \vdash_{\mathtt{ST}} t_2 : \kappa_2}{\mathcal{K} \vdash_{\mathtt{ST}} t_1\, t_2 : \kappa} \qquad \frac{\mathcal{K}, x : \kappa_1 \vdash_{\mathtt{ST}} t : \kappa_2}{\mathcal{K} \vdash_{\mathtt{ST}} \lambda x : \kappa_1.t : \kappa_1 \to \kappa_2} \qquad \frac{\mathcal{K} \vdash_{\mathtt{ST}} t_1 : \mathtt{o} \qquad \mathcal{K} \vdash_{\mathtt{ST}} t_2 : \mathtt{o}}{\mathcal{K} \vdash_{\mathtt{ST}} t_1 + t_2 : \mathtt{o}}$$

We consider below only well-typed terms. Note that given $\mathcal{K}$ and t, there exists at most one type κ such that $\mathcal{K} \vdash_{\mathtt{ST}} t : \kappa$. We call κ the type of t (with respect to $\mathcal{K}$). We often omit "with respect to $\mathcal{K}$" if $\mathcal{K}$ is clear from context. The (internal) *order* of t, written $\mathtt{order}_{\mathcal{K}}(t)$, is the largest order of the types of subterms of t, and the *external order* of t, written $\mathtt{eorder}_{\mathcal{K}}(t)$, is the order of the type of t (both with respect to $\mathcal{K}$). We often omit $\mathcal{K}$ when it is clear from context. For example, for $t = (\lambda x : \mathtt{o}.x)\mathtt{e}$, $\mathtt{order}_{\emptyset}(t) = 1$ and $\mathtt{eorder}_{\emptyset}(t) = 0$.

We call a term t *ground* (with respect to $\mathcal{K}$) if $\mathcal{K} \vdash_{\mathtt{ST}} t : \mathtt{o}$. We call t a (finite, Σ-ranked) *tree* if t is a closed ground applicative term consisting of only terminals. We write $\mathbf{Tree}_{\Sigma}$ for the set of Σ-ranked trees, and use the meta-variable π for trees.

The set of *contexts*, ranged over by C, D, G, H, is defined by $C ::= [\,] \mid C\, t \mid t\, C \mid \lambda x.C$. We write $C[t]$ for the term obtained from C by replacing $[\,]$ with t. Note that the replacement may capture variables; e.g., $(\lambda x.[\,])[x]$ is $\lambda x.x$. We call C a $(\mathcal{K}', \kappa')$-$(\mathcal{K}, \kappa)$-*context* if $\mathcal{K} \vdash_{\mathtt{ST}} C : \kappa$ is derived by using axiom $\mathcal{K}' \vdash_{\mathtt{ST}} [\,] : \kappa'$. We also call a $(\emptyset, \kappa')$-$(\emptyset, \kappa)$-context a κ'-κ-*context*. The (internal) *order* of a $(\mathcal{K}', \kappa')$-$(\mathcal{K}, \kappa)$-context, is the largest order of the types occurring in the derivation of $\mathcal{K} \vdash_{\mathtt{ST}} C : \kappa$. A context is called a $\lambda^{\to}$-*context* if it does not contain $+$.

We define the *size* $|t|$ of a term t by: $|x| := 1$, $|a\, t_1 \cdots, t_k| := 1 + |t_1| + \cdots + |t_k|$, $|s\, t| := |s| + |t| + 1$, $|\lambda x.t| := |t| + 1$, and $|s + t| := |s| + |t| + 1$. The size $|C|$ of a context C is defined similarly, with $|[\,]| := 0$.

▶ **Definition 2** (Reduction and Language)**.** The set of *(call-by-name) evaluation contexts* is defined by:

$$E ::= [\,]\,t_1 \cdots t_k \mid a\,\pi_1 \cdots \pi_i\,E\,t_1 \cdots t_k$$

and the *call-by-name reduction* for (possibly open) ground terms is defined by:

$$E[(\lambda x.t)t'] \longrightarrow E[[t'/x]t] \qquad E[t_1 + t_2] \longrightarrow E[t_i] \quad (i = 1, 2)$$

where $[t'/x]t$ is the usual capture-avoiding substitution. We write $\longrightarrow^*$ for the reflexive transitive closure of $\longrightarrow$. A *call-by-name normal form* is a ground term t such that $t \not\longrightarrow t'$ for any t'. For a closed ground term t, we define the *tree language* $\mathcal{L}(t)$ *generated by* t by $\mathcal{L}(t) := \{\pi \mid t \longrightarrow^* \pi\}$. For a closed ground $\lambda^{\to}$-term t, $\mathcal{L}(t)$ is a singleton set $\{\pi\}$; we write $\mathcal{T}(t)$ for such π and call it *the tree of* t.

Note that $t \longrightarrow^* t'$ implies $[s/x]t \longrightarrow^* [s/x]t'$, and that the set of call-by-name normal forms equals the set of trees and ground terms of the form $E[x]$.

For $x : \kappa \vdash_{\mathtt{ST}} t : \mathtt{o}$ where t does not contain the non-deterministic choice, t is called *linear* (with respect to x) if x occurs exactly once in the call-by-name normal form of t. A pair of contexts $[\,] : \kappa \vdash_{\mathtt{ST}} C : \mathtt{o}$ and $[\,] : \kappa \vdash_{\mathtt{ST}} D : \kappa$ is called *linear* if $x : \kappa \vdash_{\mathtt{ST}} C[D^i[x]] : \mathtt{o}$ is linear for any $i \geq 0$ where x is a fresh variable that is not captured by the context applications.

▶ **Definition 3** (Higher-Order Grammar)**.** A *higher-order grammar* (or *grammar* for short) is a quadruple $(\Sigma, \mathcal{N}, \mathcal{R}, S)$, where (i) Σ is a ranked alphabet; (ii) $\mathcal{N}$ is a map from a finite set of non-terminals to their types; (iii) $\mathcal{R}$ is a finite set of *rewriting rules* of the form $A \to \lambda x_1.\cdots\lambda x_\ell.t$, where $\mathcal{N}(A) = \kappa_1 \to \cdots \to \kappa_\ell \to \mathtt{o}$, t is an applicative term, and $\mathcal{N}, x_1 : \kappa_1, \ldots, x_\ell : \kappa_\ell \vdash_{\mathtt{ST}} t : \mathtt{o}$ holds; (iv) S is a non-terminal called the *start symbol*, and $\mathcal{N}(S) = \mathtt{o}$. The *order* of a grammar $\mathcal{G}$ is the largest order of the types of non-terminals. We sometimes write $\Sigma_\mathcal{G}, \mathcal{N}_\mathcal{G}, \mathcal{R}_\mathcal{G}, S_\mathcal{G}$ for the four components of $\mathcal{G}$. We often write $A\,x_1 \cdots x_k \to t$ for the rule $A \to \lambda x_1.\cdots\lambda x_k.t$.

For a grammar $\mathcal{G} = (\Sigma, \mathcal{N}, \mathcal{R}, S)$, the rewriting relation $\longrightarrow_\mathcal{G}$ is defined by:

$$\frac{(A \to \lambda x_1.\cdots\lambda x_k.t) \in \mathcal{R}}{A\,t_1 \cdots t_k \longrightarrow_\mathcal{G} [t_1/x_1, \ldots, t_k/x_k]t} \qquad \frac{t_i \longrightarrow_\mathcal{G} t_i' \qquad i \in \{1, \ldots, k\} \qquad \Sigma(a) = k}{a\,t_1 \cdots t_k \longrightarrow_\mathcal{G} a\,t_1 \cdots t_{i-1}\,t_i'\,t_{i+1} \cdots t_k}$$

We write $\longrightarrow_\mathcal{G}^*$ for the reflexive transitive closure of $\longrightarrow_\mathcal{G}$. The *tree language generated by* $\mathcal{G}$, written $\mathcal{L}(\mathcal{G})$, is the set $\{\pi \mid S \longrightarrow_\mathcal{G}^* \pi\}$.

▶ Remark. An order-n grammar can also be represented as a ground closed order-n $\lambda^{\to,+}$-term extended with the Y-combinator such that $Y_\kappa x.t \longrightarrow [Y_\kappa x.t/x]t$. Conversely, any ground closed order-n $\lambda^{\to,+}$-term (extended with Y) can be represented as an equivalent order-n grammar.

The grammars defined above may also be viewed as generators of word languages.

▶ **Definition 4** (Word Alphabet / br-Alphabet)**.** We call a ranked alphabet Σ a *word alphabet* if it has a special nullary terminal $\mathtt{e}$ and all the other terminals have arity 1; also we call a grammar $\mathcal{G}$ a *word grammar* if its alphabet is a word alphabet. For a tree $\pi = a_1(\cdots(a_n\,\mathtt{e})\cdots)$ of a word grammar, we define $\mathbf{word}(\pi) = a_1 \cdots a_n$. The *word language* generated by a word grammar $\mathcal{G}$, written $\mathcal{L}_\mathtt{w}(\mathcal{G})$, is $\{\mathbf{word}(\pi) \mid \pi \in \mathcal{L}(\mathcal{G})\}$.

The frontier word of a tree π, written $\mathbf{leaves}(\pi)$, is the sequence of symbols in the leaves of π. It is defined inductively by: $\mathbf{leaves}(a) = a$ when $\Sigma(a) = 0$, and $\mathbf{leaves}(a\,\pi_1 \cdots \pi_k) = \mathbf{leaves}(\pi_1) \cdots \mathbf{leaves}(\pi_k)$ when $\Sigma(a) = k > 0$. The *frontier language* generated by $\mathcal{G}$, written

$\mathcal{L}_{\mathtt{leaf}}(\mathcal{G})$, is the set: $\{\mathbf{leaves}(\pi) \mid S \longrightarrow^*_{\mathcal{G}} \pi\}$. A $\mathtt{br}$-*alphabet* is a ranked alphabet such that it has a special binary constant $\mathtt{br}$ and a special nullary constant $\mathtt{e}$ and the other constants are nullary. We consider $\mathtt{e}$ as the empty word ε: for a grammar with a $\mathtt{br}$-alphabet, we also define $\mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}) := (\mathcal{L}_{\mathtt{leaf}}(\mathcal{G}) \setminus \{\mathtt{e}\}) \cup \{\varepsilon \mid \mathtt{e} \in \mathcal{L}_{\mathtt{leaf}}(\mathcal{G})\}$. We call a tree π an $\mathtt{e}$-*free* $\mathtt{br}$-*tree* if it is a tree of some $\mathtt{br}$-alphabet but does not contain $\mathtt{e}$.

We note that the classes of order-0, order-1, and order-2 word languages coincide with those of regular, context-free, and indexed languages, respectively [26].

2.2 Homeomorphic Embedding and Kruskal's Tree Theorem

In our main theorem, we use the notion of homeomorphic embedding for trees.

▶ **Definition 5** (Homeomorphic Embedding). Let Σ be an arbitrary ranked alphabet. The *homeomorphic embedding* order $\preceq$ between Σ-ranked trees[5] is inductively defined by the following rules:

$$\frac{\pi_i \preceq \pi'_i \quad (\text{for all } i \le k)}{a\,\pi_1 \cdots \pi_k \preceq a\,\pi'_1 \cdots \pi'_k}(k = \Sigma(a)) \qquad \frac{\pi \preceq \pi_i}{\pi \preceq a\,\pi_1 \cdots \pi_k}(k = \Sigma(a) > 0,\ i \in \{1, \ldots, k\})$$

For example, $\mathtt{br}\,\mathtt{a}\,\mathtt{b} \preceq \mathtt{br}\,(\mathtt{br}\,\mathtt{a}\,\mathtt{c})\,\mathtt{b}$. We extend $\preceq$ to words: for $w = a_1 \cdots a_n$ and $w' = a'_1 \cdots a'_{n'}$, we define $w \preceq w'$ if $a_1(\cdots(a_n(\mathtt{e}))) \preceq a'_1(\cdots(a'_{n'}(\mathtt{e})))$, where a_i and a'_i are regarded as unary constants and $\mathtt{e}$ is a nullary constant (this order on words is nothing but the (scattered) subsequence relation). We write $\pi \prec \pi'$ if $\pi \preceq \pi'$ and $\pi' \not\preceq \pi$.

Next we explain a basic property on $\preceq$, Kruskal's tree theorem. A *quasi-order* (also called a *pre-order*) is a reflexive and transitive relation. A *well quasi-order* on a set S is a quasi-order $\le$ on S such that for any infinite sequence $(s_i)_i$ of elements in S there exist $j < k$ such that $s_j \le s_k$.

▶ **Proposition 6** (Kruskal's Tree Theorem [17]). *For any (finite) ranked alphabet Σ, the homeomorphic embedding $\preceq$ on Σ-ranked trees is a well quasi-order.*

2.3 Conjecture and Pumping Lemma for Higher-order Grammars

As explained in Section 1, our pumping lemma makes use of a conjecture on "higher-order" Kruskal's tree theorem, which is stated below.

▶ **Conjecture 7.** *There exists a family $(\preceq_\kappa)_\kappa$ of relations indexed by simple types such that*

- *$\preceq_\kappa$ is a well quasi-order on the set of closed $\lambda^{\to}$-terms of type κ modulo $\beta\eta$-equivalence; i.e., for an infinite sequence $t_1, t_2, \ldots$ of closed $\lambda^{\to}$-terms of type κ, there exist $i < j$ such that $t_i \preceq_\kappa t_j$.*
- *$\preceq_{\mathtt{o}}$ is a conservative extension of $\preceq$, i.e., $t \preceq_{\mathtt{o}} t'$ if and only if $\mathcal{T}(t) \preceq \mathcal{T}(t')$.*
- *$(\preceq_\kappa)_\kappa$ is closed under applications, i.e., if $t \preceq_{\kappa_1 \to \kappa_2} t'$ and $s \preceq_{\kappa_1} s'$ then $t\,s \preceq_{\kappa_2} t'\,s'$.*

A candidate of $(\preceq_\kappa)_\kappa$ would be the logical relation induced from $\preceq$. Indeed, if we choose the logical relation as $(\preceq_\kappa)_\kappa$, the above conjecture holds up to order-2 (see Theorem 18 in Section 6).

Actually, for our pumping lemma, the following, slightly weaker property called the *periodicity* is sufficient.

[5] In the usual definition, a quasi order on labels (tree constructors) is assumed. Here we fix the quasi-order on labels to the identity relation.

▶ **Conjecture 8** (Periodicity). *There exists a family $(\preceq_\kappa)_\kappa$ indexed by simple types such that*

- *$\preceq_\kappa$ is a quasi-order on the set of closed $\lambda^{\to}$-terms of type κ modulo $\beta\eta$-equivalence.*
- *for any $\vdash_{\mathtt{ST}} t : \kappa \to \kappa$ and $\vdash_{\mathtt{ST}} s : \kappa$, there exist $i, j > 0$ such that*

$$t^i\ s \preceq_\kappa t^{i+j}\ s \preceq_\kappa t^{i+2j}\ s \preceq_\kappa \cdots .$$

- *$\preceq_{\mathtt{o}}$ is a conservative extension of $\preceq$.*
- *$(\preceq_\kappa)_\kappa$ is closed under applications.*

Note that Conjecture 7 implies Conjecture 8, since if the former holds, for the infinite sequence $(t^i\ s)_i$, there exist $i < i + j$ such that $t^i\ s \preceq_\kappa t^{i+j}\ s$, and then by the monotonicity of $u \mapsto t^j\ u$, we have $t^{i+kj}\ s \preceq_\kappa t^{i+(k+1)j}\ s$ for any $k \geq 0$.

We can now state our pumping lemma.

▶ **Theorem 9** (Pumping Lemma). *Assume that Conjecture 8 holds. Then, for any order-n tree grammar $\mathcal{G}$ such that $\mathcal{L}(\mathcal{G})$ is infinite, there exist an infinite sequence of trees $\pi_0, \pi_1, \pi_2, \ldots \in \mathcal{L}(\mathcal{G})$, and constants c, d such that:* (i) $\pi_0 \prec \pi_1 \prec \pi_2 \prec \cdots$, *and* (ii) $|\pi_i| \leq \mathbf{exp}_n(ci + d)$ *for each $i \geq 0$. Furthermore, we can drop the assumption on Conjecture 8 when $\mathcal{G}$ is of order up to 2.*

By the correspondence between order-n tree grammars and order-$(n+1)$ grammars [4, 1], we also have:

▶ **Corollary 10** (Pumping Lemma for Word Languages). *Assume that Conjecture 8 holds. Then, for any order-n word grammar $\mathcal{G}$ (where $n \geq 1$) such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G})$ is infinite, there exist an infinite sequence of words $w_0, w_1, w_2, \ldots \in \mathcal{L}_{\mathtt{w}}(\mathcal{G})$, and constants c, d such that:* (i) $w_0 \prec w_1 \prec w_2 \prec \cdots$, *and* (ii) $|w_i| \leq \mathbf{exp}_{n-1}(ci + d)$ *for each $i \geq 0$. Furthermore, we can drop the assumption on Conjecture 8 when $\mathcal{G}$ is of order up to 3.*

We sketch the overall structure of the proof of Theorem 9 below. Let $\mathcal{G}$ be an order-n tree grammar. By using the recent type system of Parys [23], if $\mathcal{L}(\mathcal{G})$ is infinite, we can construct order-n linear $\lambda^{\to}$-contexts C, D and an order-n $\lambda^{\to}$-term t such that $\{\mathcal{T}(C[D^i[t]]) \mid i \geq 0\}$ $(\subseteq \mathcal{L}(\mathcal{G}))$ is infinite. It then suffices to show that there exist constants p and q such that $\mathcal{T}(C[D^p[t]]) \prec \mathcal{T}(C[D^{p+q}[t]]) \prec \mathcal{T}(C[D^{p+2q}[t]]) \prec \cdots$. The bound $\mathcal{T}(C[D^{p+iq}]) \leq \mathbf{exp}_n(c + id)$ would then follow immediately from the standard result on an upper-bound on the size of β-normal forms. Actually, assuming Conjecture 8, we can easily deduce $\mathcal{T}(C[D^p[t]]) \preceq \mathcal{T}(C[D^{p+q}[t]]) \preceq \mathcal{T}(C[D^{p+2q}[t]]) \preceq \cdots$. Thus, the main remaining difficulty is to show that the "strict" inequality holds periodically. To this end, we prove it by induction on the order, by making use of three ingredients: an extension of the result of Parys' type system (again) [23], an extension of our previous work on a translation from word languages to tree languages [1], and Conjecture 8. In Sections 3 and 4, we derive corollaries from the results of Parys' and our previous work respectively. We then provide the proof of Theorem 9 (except the statement "Furthermore, ...") in Section 5. We then, in Section 6, discharge the assumption on Conjecture 8 for order up to 2, by proving Conjecture 7 for order up to 2.

3 Corollaries of Parys' Results

Parys [23] developed an intersection type system with judgments of the form $\Gamma \vdash s : \tau \triangleright c$, where s is a term of a simply-typed, infinitary λ-calculus (that corresponds to the λY-calculus) extended with choice, and c is a natural number. He proved that for any order-n closed ground term s, (i) $\emptyset \vdash s : \tau \triangleright c$ implies that s can be reduced to a tree π such that $c \leq |\pi|$, and (ii) if s can be reduced to a tree π, then $\emptyset \vdash s : \tau \triangleright c$ holds for some c such that $|\pi| \leq \mathbf{exp}_n(c)$.

Let $\mathcal{G}$ be an order-n tree grammar and S be its start symbol. By Parys' result,[6] if $\mathcal{L}(\mathcal{G})$ is infinite, there exists a derivation for $\emptyset \vdash S : \mathtt{o} \triangleright c_1 + c_2 + c_3$ in which $\Theta \vdash A : \gamma \triangleright c_1 + c_2$ is derived from $\Theta \vdash A : \gamma \triangleright c_1$ for some non-terminal A. Thus, by "pumping" the derivation of $\Theta \vdash A : \gamma \triangleright c_1 + c_2$ from $\Theta \vdash A : \gamma \triangleright c_1$, we obtain a derivation for $\emptyset \vdash S : \mathtt{o} \triangleright c_1 + kc_2 + c_3$ for any $k \geq 0$. From the derivation, we obtain a $\lambda^{\to}$-term t and $\lambda^{\to}$-contexts C, D of at most order-n, such that $C[D^k[t]]$ generates a tree π_k such that $c_1 + kc_2 + c_3 \leq |\pi_k|$. By further refining the argument above (see the full version for details), we can also ensure that the pair (C, D) is linear. Thus, we obtain the following lemma.

▶ **Lemma 11.** *Given an order-n tree grammar $\mathcal{G}$ such that $\mathcal{L}(\mathcal{G})$ is infinite, there exist order-n linear $\lambda^{\to}$-contexts C, D, and an order-n $\lambda^{\to}$-term t such that:*
1. $\{\mathcal{T}(C[D^k[t]]) \mid k \geq 1\} \subseteq \mathcal{L}(\mathcal{G})$,
2. $\{\mathcal{T}(C[D^{\ell_k}[t]]) \mid k \geq 1\}$ *is infinite for any strictly increasing sequence* $(\ell_k)_k$.

By slightly modifying Parys' type system, we can also reason about the length of a particular path of a tree. Let us annotate each constructor a as $a^{\langle i \rangle}$, where $0 \leq i \leq \Sigma(a)$. We call i a *direction*. We define $|\pi|_{\mathrm{p}}$ by:

$$|a^{\langle 0 \rangle}\, \pi_1 \cdots \pi_k|_{\mathrm{p}} = 1 \qquad |a^{\langle i \rangle}\, \pi_1 \cdots \pi_k|_{\mathrm{p}} = |\pi_i|_{\mathrm{p}} + 1 \quad (1 \leq i \leq k).$$

We define **rmdir** as the function that removes all the direction annotations.

▶ **Lemma 12.** *For any order-n linear $\lambda^{\to}$-contexts C, D and any order-n $\lambda^{\to}$-term t such that $\{\mathcal{T}(C[D^k[t]]) \mid k \geq 1\}$ is infinite, there exist direction-annotated order-n linear $\lambda^{\to}$-contexts G, H, a direction-annotated order-n $\lambda^{\to}$-term u, and $p, q > 0$ such that*
1. $\mathbf{rmdir}(\mathcal{T}(G[H^k[u]])) = \mathcal{T}(C[D^{pk+q}[t]])$ *for any $k \geq 1$,*
2. $\{|\mathcal{T}(G[H^{\ell_k}[u]])|_{\mathrm{p}} \mid k \geq 1\}$ *is infinite for any strictly increasing sequence* $(\ell_k)_k$.

4 Word to Frontier Transformation

We have an "order-decreasing" transformation [1] that transforms an order-$(n+1)$ word grammar $\mathcal{G}$ to an order-n tree grammar $\mathcal{G}'$ (with a $\mathtt{br}$-alphabet) such that $\mathcal{L}_{\mathtt{w}}(\mathcal{G}) = \mathcal{L}^{\varepsilon}_{\mathtt{leaf}}(\mathcal{G}')$. We use this as a method for induction on order; this method was originally suggested by Damm [4] for safe languages.

The transformation in the present paper has been modified from the original one in [1]. On the one hand, the current transformation is a specialized version in that we apply the transformation only to $\lambda^{\to}$-terms instead of terms of (non-deterministic) grammars. On the other hand, the current transformation has been strengthened in that the transformation preserves linearity. Due to the preservation of linearity, a *single*-hole context is transformed to a *single*-hole context, and the uniqueness of an occurrence of $[\,]$ will be utilized for the calculation of the size of "pumped trees" in Lemma 16.

The definition of the current transformation is given just by translating the transformation rules in [1] by following the idea of the embedding of $\lambda^{\to}$-terms into grammars. For the detailed definition, see the full version. By using this transformation, we have:

▶ **Lemma 13.** *Given order-n $\lambda^{\to}$-contexts C, D, and an order-n $\lambda^{\to}$-term t such that the constants in C, D, t are in a word alphabet,*

[6] See Section 6 of [23]. Parys considered a λ-calculus with infinite regular terms, but the result can be easily adapted to terms of grammars.

- $\{\mathcal{T}(C[D^{\ell_i}[t]]) \mid i \geq 0\}$ *is infinite for any strictly increasing sequence* $(\ell_i)_i$*, and*
- C *and* D *are linear,*

there exist order-$(n-1)$ $\lambda^{\to}$*-contexts* G*,* H*, order-*$(n-1)$ $\lambda^{\to}$*-term* u*, and some constant numbers* $c, d \geq 1$ *such that*

- *the constants in* G*,* H*,* u *are in a* `br`*-alphabet*
- *for* $i \geq 0$*,* $\mathcal{T}(G[H^i[u]])$ *is either an* `e`*-free* `br`*-tree or* `e`*, and*

$$\mathbf{word}(\mathcal{T}(C[D^{ci+d}[t]])) = \begin{cases} \varepsilon & (\mathcal{T}(G[H^i[u]]) = \mathtt{e}) \\ \boldsymbol{leaves}(\mathcal{T}(G[H^i[u]])) & (\mathcal{T}(G[H^i[u]]) \neq \mathtt{e}) \end{cases}$$

- G *and* H *are linear.*

Proof. The preservation of meaning (the second condition) follows as a corollary of a theorem in [1]. Also, the preservation of linearity (the third condition) can be proved in a manner similar to the proof of the preservation of meaning in [1], using a kind of subject-reduction. See the full version for the detail. ◀

5 Proof of the Main Theorem

We first prepare some lemmas.

▶ **Lemma 14.** *For* `e`*-free* `br`*-trees* π *and* π'*, if* $\pi \prec \pi'$ *then* $\boldsymbol{leaves}(\pi) \prec \boldsymbol{leaves}(\pi')$*.*

Proof. We can show that $\pi \preceq \pi'$ implies $\mathbf{leaves}(\pi) \preceq \mathbf{leaves}(\pi')$ and then the statement, both by straightforward induction on the derivation of $\pi \preceq \pi'$. ◀

▶ Remark. The above lemma does not necessarily hold for an arbitrary ranked alphabet, especially that with a unary constant; e.g., $\mathtt{a}\,\mathtt{e} \prec \mathtt{a}\,(\mathtt{a}\,\mathtt{e})$ but their leaves are both `e`. Also, it does not hold if a tree contains `e` and if we regard `e` as ε in the leaves word; e.g., for $\mathtt{br}\,\mathtt{a}\,\mathtt{b} \prec \mathtt{br}\,(\mathtt{br}\,\mathtt{a}\,\mathtt{e})\,\mathtt{b}$, their leaves are $\mathtt{ab} \prec \mathtt{aeb}$, but if we regard `e` as ε then $\mathtt{ab} \not\prec \mathtt{ab}$.

▶ **Lemma 15.** *For direction-annotated trees* π *and* π'*, if* $\pi \prec \pi'$ *then* $\mathbf{rmdir}(\pi) \prec \mathbf{rmdir}(\pi')$*.*

Proof. We can show that $\pi \preceq \pi'$ implies $\mathbf{rmdir}(\pi) \preceq \mathbf{rmdir}(\pi')$ and then the statement, both by straightforward induction on the derivation of $\pi \preceq \pi'$. ◀

Now, we prove the following lemma (Lemma 16) by the induction on order. Theorem 9 (except the last statement) will then follow as an immediate corollary of Lemmas 11 and 16.

▶ **Lemma 16.** *Assume that the statement of Conjecture 8 is true. For any order-*n *linear* $\lambda^{\to}$*-contexts* C, D *and any order-*n $\lambda^{\to}$*-term* t *such that* $\{\mathcal{T}(C[D^i[t]]) \mid i \geq 1\}$ *is infinite, there exist* c*,* d*,* j*,* $k \geq 1$ *such that*

- $\mathcal{T}(C[D^j[t]]) \prec \mathcal{T}(C[D^{j+k}[t]]) \prec \mathcal{T}(C[D^{j+2k}[t]]) \prec \cdots$
- $|\mathcal{T}(C[D^{j+ik}[t]])| \leq \mathbf{exp}_n(ci+d) \qquad (i = 0, 1, \dots)$

Proof. The proof proceeds by induction on n. The case $n = 0$ is clear, and we discuss the case $n > 0$ below. By Lemma 12, from C, D, and t, we obtain direction-annotated order-n linear $\lambda^{\to}$-contexts G, H, a direction-annotated order-n $\lambda^{\to}$-term u, and j_0, $k_0 > 0$ such that

$$\mathbf{rmdir}(\mathcal{T}(G[H^i[u]])) = \mathcal{T}(C[D^{j_0+ik_0}[t]]) \text{ for any } i \geq 1 \tag{1}$$

$$\{|\mathcal{T}(G[H^{\ell_i}[u]])|_{\mathrm{p}} \mid i \geq 1\} \text{ is infinite for any strictly increasing sequence } (\ell_i)_i. \tag{2}$$

Next we transform G, H, and u by choosing a path according to directions, i.e., we define G_{p}, H_{p}, and u_{p} as the contexts/term obtained from G, H, and u by replacing each $a^{\langle i\rangle}$ with: (i) $\lambda x_1 \dots x_\ell.a_i x_i$ if $i > 0$ or (ii) $\lambda x_1 \dots x_\ell.\mathtt{e}$ if $i = 0$, where $\ell = \Sigma(a)$ and a_i is a fresh unary constant. For any $i \geq 0$,

$$|\mathcal{T}(G[H^i[u]])|_{\mathrm{p}} = |\mathbf{word}(\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^i[u_{\mathrm{p}}]]))| + 1. \tag{3}$$

We also define a function **path** on trees annotated with directions, by the following induction: $\mathbf{path}(a^{\langle i\rangle}\,\pi_1 \cdots \pi_\ell) = a_i\,\mathbf{path}(\pi_i)$ if $i > 0$ and $\mathbf{path}(a^{\langle 0\rangle}\,\pi_1 \cdots \pi_\ell) = \mathtt{e}$. Then for any $i \geq 0$,

$$\mathbf{path}(\mathcal{T}(G[H^i[u]])) = \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^i[u_{\mathrm{p}}]]). \tag{4}$$

By (2) and (3), $\{\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{\ell_i}[u_{\mathrm{p}}]]) \mid i \geq 0\}$ is infinite for any strictly increasing sequence $(\ell_i)_i$. Also, the transformation from G, H to G_{p}, H_{p} preserves the linearity, because: let N be the normal form of $G[H^i[x]]$ where x is fresh, and N_{p} be the term obtained by applying this transformation to N; then $G_{\mathrm{p}}[{H_{\mathrm{p}}}^i[x]] \longrightarrow^* N_{\mathrm{p}}$, and by the infiniteness of $\{\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^i[u_{\mathrm{p}}]]) \mid i \geq 0\}$, N_{p} must contain x, which implies N_{p} is a linear normal form.

Now we decrease the order by using the transformation in Section 4. By Lemma 13 to G_{p}, H_{p}, and u_{p}, there exist order-$(n-1)$ linear $\lambda^{\to}$-contexts G_l, H_l, an order-$(n-1)$ $\lambda^{\to}$-term u_l, and some constant numbers c', $d' \geq 1$ such that, for any $i \geq 0$, $\mathcal{T}(G_l[{H_l}^i[u_l]])$ is either an $\mathtt{e}$-free $\mathtt{br}$-tree or $\mathtt{e}$, and

$$\mathbf{word}(\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{c'i+d'}[u_{\mathrm{p}}]])) = \begin{cases} \varepsilon & (\mathcal{T}(G_l[{H_l}^i[u_l]]) = \mathtt{e}) \\ \mathbf{leaves}(\mathcal{T}(G_l[{H_l}^i[u_l]])) & (\mathcal{T}(G_l[{H_l}^i[u_l]]) \neq \mathtt{e}). \end{cases} \tag{5}$$

By (2), (3), and (5), $\{\mathcal{T}(G_l[{H_l}^i[u_l]]) \mid i \geq 1\}$ is also infinite.

By the induction hypothesis, there exist j_1 and k_1 such that

$$\mathcal{T}(G_l[{H_l}^{j_1}[u_l]]) \prec \mathcal{T}(G_l[{H_l}^{j_1+k_1}[u_l]]) \prec \mathcal{T}(G_l[{H_l}^{j_1+2k_1}[u_l]]) \prec \cdots.$$

Hence by Lemma 14, we have

$$\mathbf{leaves}(\mathcal{T}(G_l[{H_l}^{j_1}[u_l]])) \prec \mathbf{leaves}(\mathcal{T}(G_l[{H_l}^{j_1+k_1}[u_l]])) \prec \mathbf{leaves}(\mathcal{T}(G_l[{H_l}^{j_1+2k_1}[u_l]])) \prec \cdots.$$

Then by (5), we have

$$\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{c'j_1+d'}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{c'(j_1+k_1)+d'}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{c'(j_1+2k_1)+d'}[u_{\mathrm{p}}]]) \prec \cdots.$$

Let $j_1' = c'j_1 + d'$ and $k_1' = c'k_1$; then

$$\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_1'}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_1'+k_1'}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_1'+2k_1'}[u_{\mathrm{p}}]]) \prec \cdots. \tag{6}$$

Now, by Conjecture 8, there exist $j_2 \geq 0$ and $k_2 > 0$ such that

$$H^{j_2}[u] \preceq_\kappa H^{j_2+k_2}[u] \preceq_\kappa H^{j_2+2k_2}[u] \preceq_\kappa \cdots. \tag{7}$$

Let j_3 be the least j_3 such that $j_3 = j_1' + i_3\,k_1' = j_2 + m_0$ for some i_3 and m_0, and k_3 be the least common multiple of k_1' and k_2, whence $k_3 = m_1 k_1' = m_2 k_2$ for some m_1 and m_2. Then since the mapping $s \mapsto \mathcal{T}(G[H^{m_0}[s]])$ is monotonic, from (7) we have:

$$\mathcal{T}(G[H^{j_3}[u]]) \preceq \mathcal{T}(G[H^{j_3+k_2}[u]]) \preceq \mathcal{T}(G[H^{j_3+2k_2}[u]]) \preceq \cdots.$$

Since $j_3 + ik_3 = j_3 + (im_2)k_2$, we have

$$\mathcal{T}(G[H^{j_3}[u]]) \preceq \mathcal{T}(G[H^{j_3+k_3}[u]]) \preceq \mathcal{T}(G[H^{j_3+2k_3}[u]]) \preceq \cdots. \tag{8}$$

Also, since $j_3 + ik_3 = j'_1 + (i_3 + im_1)k'_1$, from (6) we have

$$\mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_3}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_3+k_3}[u_{\mathrm{p}}]]) \prec \mathcal{T}(G_{\mathrm{p}}[{H_{\mathrm{p}}}^{j_3+2k_3}[u_{\mathrm{p}}]]) \prec \cdots . \tag{9}$$

Thus, from (4), (8), and (9) we obtain

$$\mathcal{T}(G[H^{j_3}[u]]) \prec \mathcal{T}(G[H^{j_3+k_3}[u]]) \prec \mathcal{T}(G[H^{j_3+2k_3}[u]]) \prec \cdots . \tag{10}$$

By applying **rmdir** to this sequence, and by (1) and Lemma 15, we have

$$\mathcal{T}(C[D^{j_0+j_3k_0}[t]]) \prec \mathcal{T}(C[D^{j_0+(j_3+k_3)k_0}[t]]) \prec \mathcal{T}(C[D^{j_0+(j_3+2k_3)k_0}[t]]) \prec \cdots . \tag{11}$$

We define $j = j_0 + k_0 j_3$ and $k = k_0 k_3$; then we obtain

$$\mathcal{T}(C[D^{j}[t]]) \prec \mathcal{T}(C[D^{j+k}[t]]) \prec \mathcal{T}(C[D^{j+2k}[t]]) \prec \cdots .$$

Finally, we show that $|\mathcal{T}(C[D^{j+ik}[t]])| \leq \mathbf{exp}_n(ci + d)$ for some c and d. Since C and D are single-hole contexts, $|C[D^{j+ik}[t]]| = |C| + (j + ik)|D| + |t|$. Let $c = k|D|$ and $d = |C| + j|D| + |t|$; then $|C[D^{j+ik}[t]]| = ci + d$. It is well-known that, for an order-n $\lambda^{\to}$-term s, we have $|\mathcal{T}(s)| \leq \mathbf{exp}_n(|s|)$ (see, e.g., [25, Lemma 3]). Thus, we have $|\mathcal{T}(C[D^{j+ik}[t]])| \leq \mathbf{exp}_n(ci + d)$. ◀

The step obtaining (10) (the steps using Lemma 14 and obtaining (11), resp.) indicates why we need to require $\mathcal{T}(C[D^{j+ik}[t]]) \prec \mathcal{T}(C[D^{j+i'k}[t]])$ for any $i < i'$ rather than $|\mathcal{T}(C[D^{j+ik}[t]])| < |\mathcal{T}(C[D^{j+i'k}[t]])|$ ($\mathcal{T}(C[D^{j+ik}[t]]) \neq \mathcal{T}(C[D^{j+i'k}[t]])$, resp.) to make the induction work.

6 Second-order Kruskal's theorem

In this section, we prove Conjecture 7 (hence also Conjecture 8) up to order-2. First, we extend the homeomorphic embedding $\preceq$ on trees to a family of relations $\preceq_\kappa$ by using logical relation: (i) $t_1 \preceq_{\mathsf{o}} t_2$ if $\emptyset \vdash_{\mathtt{ST}} t_1 : \mathsf{o}$, $\emptyset \vdash_{\mathtt{ST}} t_2 : \mathsf{o}$, and $\mathcal{T}(t_1) \preceq \mathcal{T}(t_2)$. (ii) $t_1 \preceq_{\kappa_1 \to \kappa_2} t_2$ if $\emptyset \vdash_{\mathtt{ST}} t_1 : \kappa_1 \to \kappa_2$, $\emptyset \vdash_{\mathtt{ST}} t_2 : \kappa_1 \to \kappa_2$, and $t_1 s_1 \preceq_{\kappa_2} t_2 s_2$ holds for every s_1, s_2 such that $s_1 \preceq_{\kappa_1} s_2$. We often omit the subscript κ and just write $\preceq$ for $\preceq_\kappa$. We also write $x_1 : \kappa_1, \ldots, x_k : \kappa_k \models t \preceq_\kappa t'$ if $[s_1/x_1, \ldots, s_k/x_k]t \preceq_\kappa [s'_1/x_1, \ldots, s'_k/x_k]t'$ for every $s_1, \ldots, s_k, s'_1, \ldots, s'_k$ such that $s_i \preceq_{\kappa_i} s'_i$.

The relation $\preceq_\kappa$ is well-defined for $\beta\eta$-equivalence classes, and by the abstraction lemma of logical relation, it turns out that the relation $\preceq_\kappa$ is a pre-order for any κ (see the full version for these). Note that the relation is also preserved by applications by the definition of the logical relation. It remains to show that $\preceq_\kappa$ is a well quasi-order for κ of order up to 2.

For ℓ-ary terminal a and $k \geq \ell$, we write $\mathbf{CTerms}_{a,k}$ for the set of terms

$$\{\lambda x_1.\cdots\lambda x_k.a\, x_{i_1}\, \ldots\, x_{i_\ell} \mid i_1 \cdots i_\ell \text{ is a subsequence of } 1 \cdots k\}.$$

We define $\mathsf{o}^0 \to \mathsf{o} := \mathsf{o}$ and $\mathsf{o}^{n+1} \to \mathsf{o} := \mathsf{o} \to (\mathsf{o}^n \to \mathsf{o})$.

The following lemma allows us to reduce $t \preceq_\kappa t'$ on any order-2 type κ to (finitely many instances of) that on order-0 type o.

▶ **Lemma 17.** *Let Σ be a ranked alphabet; κ be $(\mathsf{o}^{k_1} \to \mathsf{o}) \to \cdots \to (\mathsf{o}^{k_m} \to \mathsf{o}) \to \mathsf{o}$; a_i^j be a j-ary terminal not in Σ for $1 \leq i \leq m$ and $0 \leq j \leq k_i$; and t, t' be $\lambda^{\to}$-terms whose type is κ and whose terminals are in Σ. Then $t \preceq_\kappa t'$ if and only if $t\, u_1\, \ldots\, u_m \preceq_{\mathsf{o}} t'\, u_1\, \ldots\, u_m$ for every $u_i \in \cup_{j \leq k_i} \mathbf{CTerms}_{a_i^j, k_i}$.*

Proof. The "only if" direction is trivial by the definition of $\preceq_\kappa$. To show the opposite, assume the latter holds. We need to show that $t\,s_1\,\ldots\,s_m \preceq_{\mathsf{o}} t'\,s_1\,\ldots\,s_m$ holds for every combination of $s_1,\ldots,s_m$ such that $\vdash_{\mathtt{ST}} s_i : \kappa_i$ for each i. Without loss of generality, we can assume that t, t', $s_1,\ldots,s_m$ are $\beta\eta$ long normal forms, and hence that

$$\begin{array}{lll} t = \lambda f_1.\cdots\lambda f_m.t_0 & f_1:\mathsf{o}^{k_1}\to\mathsf{o},\ldots,f_m:\mathsf{o}^{k_m}\to\mathsf{o}\vdash_{\mathtt{ST}} t_0:\mathsf{o} & \\ t' = \lambda f_1.\cdots\lambda f_m.t'_0 & f_1:\mathsf{o}^{k_1}\to\mathsf{o},\ldots,f_m:\mathsf{o}^{k_m}\to\mathsf{o}\vdash_{\mathtt{ST}} t'_0:\mathsf{o} & \\ s_i = \lambda x_1.\ldots\lambda x_{k_i}.s_{i,0} & x_1:\mathsf{o},\ldots,x_{k_i}:\mathsf{o}\vdash_{\mathtt{ST}} s_{i,0}:\mathsf{o} & \text{(for each } i\text{)} \end{array}$$

For each $i \le m$, let $\mathbf{FV}(s_{i,0}) = \{x_{q(i,1)},\ldots,x_{q(i,\ell_i)}\}$, and $u_i \in \mathbf{CTerms}_{a_i^{\ell_i},k_i}$ be the term $\lambda x_1.\cdots\lambda x_{k_i}.a_i^{\ell_i}\,x_{q(i,1)}\,\cdots\,x_{q(i,\ell_i)}$. Let θ and θ' be the substitutions $[u_1/f_1,\ldots,u_m/f_m]$ and $[s_1/f_1,\ldots,s_m/f_m]$ respectively. It suffices to show that $\theta t_0 \preceq_{\mathsf{o}} \theta t'_0$ implies $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_0$, which we prove by induction on $|t'_0|$.

By the condition $f_1:\mathsf{o}^{k_1}\to\mathsf{o},\ldots,f_m:\mathsf{o}^{k_m}\to\mathsf{o}\vdash_{\mathtt{ST}} t_0:\mathsf{o}$, t_0 must be of the form $h\,t_1\,\cdots\,t_\ell$ where h is f_i or a terminal a in Σ, and ℓ may be 0. Then we have

$$\mathcal{T}(\theta t_0) = \begin{cases} a\mathcal{T}(\theta t_1)\cdots\mathcal{T}(\theta t_\ell) & (h=a) \\ a_i^{\ell_i}\mathcal{T}(\theta t_{q(i,1)})\cdots\mathcal{T}(\theta t_{q(i,\ell_i)}) & (h=f_i) \end{cases}$$

Similarly, t'_0 must be of the form $h'\,t'_1\,\cdots\,t'_{\ell'}$ and the corresponding equality on $\mathcal{T}(\theta t'_0)$ holds. By the assumption $\theta t_0 \preceq_{\mathsf{o}} \theta t'_0$, we have $\mathcal{T}(\theta t_0) \preceq \mathcal{T}(\theta t'_0)$. We perform case analysis on the rule used for deriving $\mathcal{T}(\theta t_0) \preceq \mathcal{T}(\theta t'_0)$ (recall Definition 5).

- Case of the first rule: In this case, the roots of $\mathcal{T}(\theta t_0)$ and $\mathcal{T}(\theta t'_0)$ are the same and hence $h = h'$ and $\ell = \ell'$. We further perform case analysis on h.
  - Case $h = a$: For $1 \le j \le \ell$, since $\mathcal{T}(\theta t_j) \preceq \mathcal{T}(\theta t'_j)$, by induction hypothesis, we have $\theta' t_j \preceq_{\mathsf{o}} \theta' t'_j$. Hence $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_0$.
  - Case $h = f_i$: For $1 \le j \le \ell_i$, since $\mathcal{T}(\theta t_{q(i,j)}) \preceq \mathcal{T}(\theta t'_{q(i,j)})$, by induction hypothesis, we have $\theta' t_{q(i,j)} \preceq_{\mathsf{o}} \theta' t'_{q(i,j)}$. Hence, $[\theta' t_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0} \preceq_{\mathsf{o}} [\theta' t'_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$. By the definition of $q(i,j)$, $\theta' t_0 \longrightarrow [\theta' t_j/x_j]_{j\le k_i} s_{i,0} = [\theta' t_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$, and similarly, $\theta' t'_0 \longrightarrow [\theta' t'_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$; hence we have $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_0$.
- Case of the second rule: We further perform case analysis on h'.
  - Case $h' = a$: We have $\mathcal{T}(\theta t_0) \preceq \mathcal{T}(\theta t'_p)$ for some $1 \le p \le \ell'$. Hence by induction hypothesis, we have $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_p$, and then $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_0$.
  - Case $h' = f_i$: We have $\mathcal{T}(\theta t_0) \preceq \mathcal{T}(\theta t'_{q(i,p)})$ for some $1 \le p \le \ell_i$. Hence by induction hypothesis, we have $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_{q(i,p)}$. Also, by the definition of $q(i,p)$, $x_{q(i,p)}$ occurs in $s_{i,0}$. Since $s_{i,0}$ is a $\beta\eta$ long normal form of order-0, the order-0 variable $x_{q(i,p)}$ occurs as a leaf of $s_{i,0}$; hence $\mathcal{T}(\theta' t'_{q(i,p)}) \preceq [\mathcal{T}(\theta' t'_{q(i,j)})/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$. Therefore $\theta' t_0 \preceq_{\mathsf{o}} [\theta' t'_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$. Since $\theta' t'_0 \longrightarrow [\theta' t'_{q(i,j)}/x_{q(i,j)}]_{j\le\ell_i} s_{i,0}$, we have $\theta' t_0 \preceq_{\mathsf{o}} \theta' t'_0$.

◀

As a corollary, we obtain a second-order version of Kruskal's tree theorem.

▶ **Theorem 18.** *Let Σ be a ranked alphabet, κ be an at most order-2 type, and $t_0, t_1, t_2, \ldots$ be an infinite sequence of $\lambda^{\to}$-terms whose type is κ and whose terminals are in Σ. Then, there exist $i < j$ such that $t_i \preceq_\kappa t_j$.*

Proof. Since κ is at most order-2, it must be of the form $(\mathsf{o}^{k_1}\to\mathsf{o})\to\cdots\to(\mathsf{o}^{k_m}\to\mathsf{o})\to\mathsf{o}$. Let a_i^j be a j-ary terminal not in Σ for $1 \le i \le m$ and $0 \le j \le k_i$; $(\cup_{j\le k_1}\mathbf{CTerms}_{a_1^j,k_1})\times\cdots\times(\cup_{j\le k_m}\mathbf{CTerms}_{a_m^j,k_m})$ be $\{(u_{1,1},\ldots,u_{1,m}),\ldots,(u_{p,1},\ldots,u_{p,m})\}$; b be a p-ary terminal not in $\Sigma\cup\{a_i^j \mid 1\le i\le m,\ 0\le j\le k_i\}$; and s_i be the term $b\,(t_i\,u_{1,1}\,\cdots\,u_{1,m})\,\cdots\,(t_i\,u_{p,1}\,\cdots\,u_{p,m})$

for each $i \in \{0, 1, 2, \ldots\}$. Since the set of terminals in $s_0, s_1, s_2, \ldots$ is finite, by Kruskal's tree theorem, there exist i, j such that $s_i \preceq_{\mathsf{o}} s_j$ and $i < j$. Since b occurs just at the root of s_k for each k, $s_i \preceq_{\mathsf{o}} s_j$ implies $t_i\, u_{k,1} \cdots u_{k,m} \preceq_{\mathsf{o}} t_j\, u_{k,1} \cdots u_{k,m}$ for every $k \in \{1, \ldots, p\}$. Thus, by Lemma 17, we have $t_i \preceq_\kappa t_j$ as required. ◀

7 Related Work

As mentioned in Section 1, to our knowledge, pumping lemmas for higher-order word languages have been established only up to order-2 [7], whereas we have proved (unconditionally) a pumping lemma for order-2 tree languages and order-3 word languages. Hayashi's pumping lemma for indexed languages (i.e., order-2 word languages) is already quite complex, and it is unclear how to generalize it to arbitrary orders. In contrast, our proof of a pumping lemma works for arbitrary orders, although it relies on the conjecture on higher-order Kruskal's tree theorem. Parys [21] and Kobayashi [12] studied pumping lemmas for collapsible pushdown automata and higher-order recursion schemes respectively. Unfortunately, they are not applicable to word/tree *languages* generated by (non-deterministic) grammars.

As also mentioned in Section 1, the strictness of hierarchy of higher-order word languages has already been shown by using a complexity argument [5, 8]. We can use our pumping lemma (if the conjecture is discharged) to obtain a simple alternative proof of the strictness, using the language $\{a^{\mathbf{exp}_n(k)} \mid k \geq 0\}$ as a witness of the separation between the classes of order-$(n+1)$ word languages and order-n word languages. In fact, the pumping lemma would imply that there is no order-n grammar that generates $\{a^{\mathbf{exp}_n(k)} \mid k \geq 0\}$, whereas an order-$(n+1)$ grammar that generates the same language can be easily constructed.

We are not aware of studies of the higher-order version of Kruskal's tree theorem (Conjecture 7) or the periodicity of tree functions expressed by the simply-typed λ-calculus (Conjecture 8), which seem to be of independent interest. Zaionc [27, 28] characterized the class of (first-order) word/tree functions definable in the simply-typed λ-calculus. To obtain higher-order Kruskal's tree theorem, we may need some characterization of *higher-order* definable tree functions instead.

We have heavily used the results of Parys' work [23] and our own previous work [1], which both use intersection types for studying properties of higher-order languages. Other uses of intersection types in studying higher-order grammars/languages are found in [10, 15, 22, 12, 3, 14, 13].

8 Conclusion

We have proved a pumping lemma for higher-order languages of arbitrary orders, modulo the assumption that a higher-order version of Kruskal's tree theorem holds. We have also proved the assumption indeed holds for the second-order case, yielding a pumping lemma for order-2 tree languages and order-3 word languages. Proving (or disproving) the higher-order Kruskal's tree theorem is left for future work.

Abstract

A strategy for constructing dynamic programs is introduced that utilises periodic computation of auxiliary data from scratch and the ability to maintain a query for a limited number of change steps. It is established that if some program can maintain a query for $\log n$ change steps after an AC^1-computable initialisation, it can be maintained by a first-order dynamic program as well, i.e., in DynFO. As an application, it is shown that decision and optimisation problems defined by monadic second-order (MSO) and guarded second-order logic (GSO) formulas are in DynFO, if only change sequences that produce graphs of bounded treewidth are allowed. To establish this result, Feferman–Vaught-type composition theorems for MSO and GSO are established that might be useful in their own right.

1 Introduction

Updating the result of a query after a small change to a relational database is an important problem. A theoretical framework for studying when a query can be updated in a declarative fashion was formalised by Patnaik and Immerman [11], and Dong, Su, and Topor [5]. In their formalisation, a dynamic program has a set of logical formulas that update a query after the insertion or deletion of a tuple. The formulas may use additional auxiliary relations that, of course, need to be updated as well. The queries maintainable in this way via first-order formulas constitute the dynamic complexity class DynFO.

Recent work has confirmed that DynFO is quite a powerful class, since it captures, e.g., the reachability query for directed graphs [2], and can even take care of pretty complex change operations [12].

In this paper, we introduce a general strategy for dynamic programs that further underscores the expressive power of DynFO. For a complexity class $\mathcal{C}$ and a function f, we call a query $\mathcal{Q}$ $(\mathcal{C}, f)$-maintainable, if there is a dynamic program (with first-order definable updates) that, starting from some input structure $\mathcal{A}$ and auxiliary relations computed in $\mathcal{C}$ from $\mathcal{A}$, can answer $\mathcal{Q}$ for $f(|\mathcal{A}|)$ many steps, where $|\mathcal{A}|$ denotes the size of the universe of $\mathcal{A}$.

We feel that this notion might be interesting in its own right. However, in this paper we concentrate on the case where $\mathcal{C}$ is (uniform) AC^1 and $f(n) = \log n$. We show that $(\mathrm{AC}^1, \log n)$-maintainable queries are actually in DynFO. We apply this insight to show that all queries and optimisation problems definable in monadic second-order logic (MSO) are in DynFO for (classes of) structures of bounded treewidth, by proving that they are $(\mathrm{AC}^1, \log n)$-maintainable. Likewise for guarded second-order logic (GSO). This implies that decision problems like 3-Colourability or HamiltonCycle as well as optimisation problems like VertexCover and DominatingSet are in DynFO, for such classes of structures.

The proof that MSO-definable queries are $(\mathrm{AC}^1, \log n)$-maintainable on structures of bounded treewidth makes use of a Feferman–Vaught-type composition theorem for MSO which might be useful in its own right.

The result that $(\mathrm{AC}^1, \log n)$-maintainable queries are in DynFO comes with a technical restriction: in a nutshell, it holds for queries that are invariant under insertion of (many) isolated elements. We call such queries *almost domain-independent* and refer to Section 3 for a precise definition.

We emphasise that the main technical challenge in maintaining MSO-queries on graphs of bounded treewidth is that tree decompositions might change drastically after an edge insertion, and can therefore not be maintained incrementally in any obvious way. In particular, the result does not simply follow from the DynFO-maintainability of regular tree languages shown in [8]. We circumvent this problem by periodically recomputing a new tree decomposition (in logarithmic space and thus in AC^1) and by showing that MSO-queries can be maintained for $\mathcal{O}(\log n)$ many change operations, even if they make the tree decomposition invalid.

Contributions

- We introduce the notion of $(\mathcal{C}, f)$-maintainability.
- We show that (almost domain-independent) $(\mathrm{AC}^1, \log n)$-maintainable queries are in DynFO.
- We show that MSO-definable (Boolean) queries are $(\mathrm{AC}^1, \log n)$-maintainable and therefore in DynFO, for structures of bounded treewidth. Likewise for MSO-definable optimisation problems and GSO-definable queries and optimisation problems.
- We state a Feferman–Vaught-type composition theorem for MSO-logic.

Related work. The simulation-based technique for proving that $(\mathrm{AC}^1, \log n)$-maintainable queries are in DynFO is inspired by proof techniques from [2] and [12]. As mentioned above, in [8] it has been shown that tree languages, i.e. MSO on trees, can be maintained in DynFO. In [1], the maintenance of parity games has been studied for graphs of bounded treewidth, though in the restricted setting where the tree decomposition stays the same for all changes.

Organisation. Basic terminology is recalled in Section 2, followed by a short introduction into dynamic complexity in Section 3. In Section 4 we introduce the notion of $(\mathcal{C}, f)$-maintainability and show that $(\mathrm{AC}^1, \log n)$-maintainable queries are in DynFO. A glimpse on the proof techniques for proving that MSO and GSO queries are in DynFO for graphs of bounded treewidth is given in Section 5 via the example 3-Colourability. The proof of the general results is presented in Section 6. An extension to optimisation problems can be found in Section 7. For many proofs, details are deferred to the full version of this paper [4].

2 Preliminaries

We assume familiarity with first-order logic FO and other notions from finite model theory [9, 10]. Some further notation regarding MSO logic and types will be introduced in Section 6.

In this paper we consider finite relational structures over relational signatures $\Sigma = \{R_1, \ldots, R_\ell, c_1, \ldots, c_m\}$, where each R_i is a relation symbol with a corresponding arity $\mathrm{Ar}(R_i)$, and each c_j is a constant symbol. A Σ-structure $\mathcal{A}$ consists of a finite *domain* A, a relation $R_i^{\mathcal{A}} \subseteq A^{\mathrm{Ar}(R_i)}$, and a constant $c_j^{\mathcal{A}} \in A$, for each $i \in \{1, \ldots, \ell\}, j \in \{1, \ldots, m\}$. Sometimes, especially in Section 3, we consider relational structures as relational databases This is basically a different terminology that is common in the context of dynamic complexity, since the original motivation for considering the class DynFO came from relational databases. In particular, the class DynFO will be defined as a class of queries of arbitrary arity.

However, we will mostly consider Boolean queries over structures with a single binary relation symbol E, which can equivalently be viewed as decision problems for graphs $G = (V, E)$. For a set $U \subseteq V$, $G[U]$ denotes the induced subgraph $(U, E \cap (U \times U))$.

We will often use structures that have a linear order $\leq$ and compatible ternary relations encoding arithmetical operations $+$ and $\times$ or a binary BIT relation on the universe. We write $\mathrm{FO}(+, \times)$ or $\mathrm{FO}(\mathrm{BIT})$ to emphasise that we allow first-order formulas to use such additional relations.[1] We also use that $\mathrm{FO}(+, \times) = \mathrm{FO}(\mathrm{BIT})$ [9].

A *tree decomposition* (T, B) of G consists of a (rooted) tree $T = (I, F, r)$ and a function $B \colon I \to 2^V$ such that (1) for all $v \in V$, the set $\{i \in I \mid v \in B(i)\}$ is non-empty, (2) for all $(u, v) \in E$, there is an $i \in I$ with $\{u, v\} \subseteq B(i)$, and (3) the subgraph $T[\{i \in I \mid v \in B(i)\}]$ is connected. We refer to the number of children of a node of T as its *degree*. We denote the parent node of a node i by $p(i)$. The *width* of a tree decomposition is defined as the maximal size of a bag minus 1. The *treewidth* of a graph G is the minimal width among all tree decompositions of G. A tree decomposition is *nice* if (1) T has depth at most $\mathcal{O}(\log n)$, (2) the degree of the nodes is at most 2, and (3) all bags are distinct. We use the following lemma which is an adaption of [7, Lemma 3.1].

▶ **Lemma 1.** *For every graph of treewidth k, a nice tree decomposition of width $4k + 5$ can be computed in logarithmic space.*

In this paper we only consider nice tree decompositions, and due to property (3) of these decompositions we can identify bags with nodes from I.

For two nodes i, i' of I, we write $i' \preceq i$ if i' is in the subtree of T rooted at i and $i' \prec i$ if, in addition, $i' \neq i$. A *triangle* δ of T is a triple (i_0, i_1, i_2) of nodes from I such that $i_1 \preceq i_0$, $i_2 \preceq i_0$, and (1) $i_1 = i_2$ or (2) neither $i_1 \preceq i_2$ nor $i_2 \preceq i_1$. In case of (2) we call the triangle *proper*, in case of (1) *unary*, unless $i_0 = i_1 = i_2$ in which we call it *open*.

[1] The question of $<$-invariance will not be relevant in the context of this paper since the order of insertion of elements to a structure will determine a linear order on the universe.

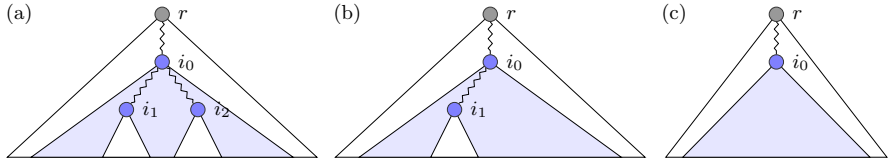

Figure 1 Illustration of (a) a proper triangle (i_0, i_1, i_2), (b) a unary triangle (i_0, i_1, i_1), and (c) an open triangle (i_1, i_1, i_1). The blue shaded area is the part of the tree contained in the triangle.

The subtree $T(\delta)$ *induced* by a triangle consists of all nodes j of T for which the following holds: (i) $j \preceq i_0$, (ii) if $i_1 \prec i_0$ then $j \not\preceq i_1$, and (iii) if $i_2 \prec i_0$ then $j \not\preceq i_2$. That is, for a proper or unary triangle, $T(\delta)$ contains all nodes of the subtree rooted at i_0 which are not below i_1 or i_2. For an open triangle $\delta = (i_0, i_0, i_0)$, $T(\delta)$ is just the subtree rooted at i_0.

Each triangle δ induces a subgraph $G(\delta)$ of G as follows: $V(\delta)$ is the union of all bags of $T(\delta)$. By $B(\delta)$ we denote the set $B(i_0) \cup B(i_1) \cup B(i_2)$ of *interface nodes* of $V(\delta)$. All other nodes are called *inner nodes*. The edge set of $G(\delta)$ consists of all edges of G that involve at least one inner node of $V(\delta)$.

Our main result refers to the complexity class (uniform) AC^1 whose definition can be found, e.g., in [15]. The precise definition of the class is not relevant for this paper. It suffices to know that it contains the classes LOGSPACE and NL and that it can be characterised as the class $\mathrm{IND}[\log n]$ of problems that can be expressed by applying a first-order formula $\mathcal{O}(\log n)$ times [9, Theorem 5.22]. Here, n denotes the size of the universe and the formulas can use built-in relations $+$ and $\times$. Our proofs often assume that $\log n$ is a natural number, but they can be easily adapted to the general case.

3 Dynamic Complexity

We briefly repeat the essentials of dynamic complexity, closely following [13, 3].

The goal of a dynamic program is to answer a given query on an *input database* subjected to changes that insert or delete single tuples. The program may use an auxiliary data structure represented by an *auxiliary database* over the same domain. Initially, both input and auxiliary database are empty; and the domain is fixed during each run of the program.

A dynamic program has a set of update rules that specify how auxiliary relations are updated after a change of the input database. An *update rule* for updating an auxiliary relation T is basically a formula φ. As an example, if $\varphi(\vec{x}, \vec{y})$ is the update rule for auxiliary relation T under insertions into input relation R, then the new version of T after insertion of a tuple $\bar{a}$ to R is $T \stackrel{\text{def}}{=} \{\vec{b} \mid (\mathcal{I}, Aux) \models \varphi(\vec{a}, \vec{b})\}$ where $\mathcal{I}$ and Aux are the current input and auxiliary databases. For a state $\mathcal{S} = (\mathcal{I}, Aux)$ of the dynamic program with input database $\mathcal{I}$ and auxiliary database Aux we denote the state of the program after applying the change sequence α by $\mathcal{P}_\alpha(\mathcal{S})$. The dynamic program *maintains* a k-ary query $\mathcal{Q}$ if, for each non-empty sequence α of changes and each empty input structure $\mathcal{I}_\emptyset$, relation Q in $\mathcal{P}_\alpha(\mathcal{S}_\emptyset)$ and $\mathcal{Q}(\alpha(\mathcal{I}_\emptyset))$ coincide. Here, $\mathcal{S}_\emptyset = (\mathcal{I}_\emptyset, Aux_\emptyset)$, where $Aux_\emptyset$ denotes the empty auxiliary structure over the domain of $\mathcal{I}_\emptyset$, and $\alpha(\mathcal{I}_\emptyset)$ is the input database after applying α.

In this paper, we are particularly interested in maintaining queries for structures of bounded treewidth. There are several ways to adjust the dynamic setting to restricted classes $\mathcal{C}$ of structures. Here, we simply disallow change sequences that construct structures outside $\mathcal{C}$. That is, in the above definition, only change sequences α are considered, for which each prefix transforms an initially empty structure into a structure from $\mathcal{C}$. We say that a program

maintains $\mathcal{Q}$ for a class $\mathcal{C}$ of structures, if Q contains its result after each change sequence α such that the application of each prefix of α to $\mathcal{I}_\emptyset$ yields a structure from $\mathcal{C}$.

The class of queries that can be maintained by a dynamic program is called DynFO. Programs for queries in DynFO$(+,\times)$ have three particular auxiliary relations that are initialised as a linear order and the corresponding addition and multiplication relations.

We say that a query $\mathcal{Q}$ is in DynFO for a class $\mathcal{C}$ of structures, if there is a dynamic program that maintains $\mathcal{Q}$ for $\mathcal{C}$.

The *active domain* $\mathrm{adom}(\mathcal{A})$ of a structure $\mathcal{A}$ contains all elements used in some tuple of $\mathcal{A}$. A query $\mathcal{Q}$ is *almost domain-independent* if there is a $c \in \mathbb{N}$ such that $\mathcal{Q}(\mathcal{A}) \restriction (\mathrm{adom}(\mathcal{A}) \cup B) = \mathcal{Q}(\mathcal{A} \restriction (\mathrm{adom}(\mathcal{A}) \cup B))$ for all structures $\mathcal{A}$ and sets $B \subseteq A \setminus \mathrm{adom}(\mathcal{A})$ with $|B| \geq c$. The following proposition adapts Proposition 7 from [3].

▶ **Proposition 2.** *If a query $\mathcal{Q} \in$ DynFO$(+,\times)$ is almost domain-independent, then also $\mathcal{Q} \in$ DynFO.*

4 Algorithmic Technique

There are alternative definitions of DynFO, where the initial structure is non-empty and the initial auxiliary relations can be computed within some complexity [11, 16]. However, in a practical scenario of dynamic query answering it is conceivable that the quality of the auxiliary relations decreases over time and that they are therefore recomputed from scratch at times. We formalise this notion by a relaxed definition of maintainability in which the initial structure is non-empty, the dynamic program is allowed to apply some preprocessing, and query answers need only be given for a certain number of change steps.

We call a query $\mathcal{Q}$ $(\mathcal{C}, f)$-*maintainable*, for some complexity class[2] $\mathcal{C}$ and some function $f : \mathbb{N} \to \mathbb{R}$, if there is a dynamic program $\mathcal{P}$ and a $\mathcal{C}$-algorithm $\mathcal{A}$ such that for each input database $\mathcal{I}$ over a domain of size n, each linear order $\leq$ on the domain, and each change sequence α of length $|\alpha| \leq f(n)$, the relation Q in $\mathcal{P}_\alpha(\mathcal{S})$ and $\mathcal{Q}(\alpha(\mathcal{I}))$ coincide where $\mathcal{S} = (\mathcal{I}, \mathcal{A}(\mathcal{I}, \leq))$.

Although we feel that $(\mathcal{C}, f)$-maintainability deserves further investigation, in this paper we exclusively use it as a tool to prove that queries are actually maintainable in DynFO. To this end, we show next that every $(\mathrm{AC}^1, \log n)$-maintainable query is actually in DynFO and prove later that the queries in which we are interested are $(\mathrm{AC}^1, \log n)$-maintainable.

▶ **Theorem 3.** *Every $(\mathrm{AC}^1, \log n)$-maintainable, almost domain-independent query is in* DynFO.

Proof Sketch (of Theorem 3. Assume that a dynamic program $\mathcal{P}$ witnesses that an almost domain-independent query $\mathcal{Q}$ is $(\mathrm{AC}^1, \log n)$-maintainable. Thanks to Proposition 2 it suffices to construct a dynamic program $\mathcal{P}'$ that witnesses $\mathcal{Q} \in$ DynFO$(+,\times)$. We restrict ourselves to graphs, for simplicity.

The overall idea is to use a simulation technique similar to the ones used in [2] and [12]. We consider each application of one change as a *time step*. We refer to the graph after time step t as $G_t = (V, E_t)$. After each time step t, $\mathcal{P}'$ starts a thread that uses $\frac{1}{2} \log n$ steps to compute the auxiliary relations for G_t (using $\mathrm{AC}^1 = \mathrm{IND}[\log n]$) and then another $\frac{1}{2} \log n$ steps to apply the $\log n$ changes of time steps $t+1, \ldots, t+\log n$ (two at a time). After these

[2] Strictly speaking $\mathcal{C}$ should be a complexity class of functions. In this paper, the implied class of functions will always be clear from the stated class of decision problems.

$\log n$ steps the thread is ready to answer query $\mathcal{Q}$ about $G_{t+\log n}$ at time step $t+\log n$. Since one such thread starts at every time point, the program can answer query $\mathcal{Q}$, for each time point $\geq \log n$.

We next give details on the two phases and describe how to deal with earlier time points.

For the first phase, we make use of the equality $\mathrm{AC}^1 = \mathrm{IND}[\log n]$. Let ψ be an inductive formula that is applied $d \log n$ times, for some d, to get the auxiliary relations for a given graph G and the given order $\leq$. The program $\mathcal{P}'$ simply applies ψ to G_t for $2d$ times during each time step, and thus the fixpoint of ψ is reached after $\frac{1}{2}\log n$ steps. The change operations that occur during these steps are not applied to G_t directly but rather stored in some additional relation.

During the second phase the $\frac{1}{2}\log n$ stored change operations and the $\frac{1}{2}\log n$ change operations that happen during the next $\frac{1}{2}\log n$ steps are applied to the state after phase 1. To this end, it suffices for $\mathcal{P}'$ to apply two changes during each time step by simulating two update steps of $\mathcal{P}$. Since $\mathcal{P}$ can maintain $\mathcal{Q}$ for $\log n$ changes, at the end of phase 2, at time point $t+\log n$, $\mathcal{P}'$ can give the correct query answer for $\mathcal{Q}$ about $G_{t+\log n}$.

To enable $\mathcal{P}'$ to answer $\mathcal{Q}$ also for time steps $t < \log n$, it proceeds as follows. It starts a new thread at time $\frac{t}{2}$ with a graph with at most $\frac{t}{2}$ edges and applies ψ relative to a domain D_t of size $2t+c$, where c is the constant from (almost) domain-independence. The first phase of this thread lasts from time points $\frac{t}{2}+1$ to $\frac{3t}{4}$, and applies ψ for $4d$ times during each step. As a fixpoint is reached after $\frac{\log(2t+c)}{4} < \frac{t}{4}$ steps, the auxiliary relations are initialised properly (very small t can be handled separately). From time $\frac{3t}{4}+1$ to time t the changes are applied, again two at a time and the thread is ready to answer $\mathcal{Q}$ at time point t. As at time t at most $2t$ elements are used by edges, the almost domain-independence of $\mathcal{Q}$ guarantees that the result computed by the thread relative to D_t coincides with the D_t-restriction of the query result for G_t. The full query result for G_t, possibly including tuples with elements from $V \setminus D_t$, is obtained as follows: a tuple $\bar{t}$ is included in the query result, if it can be generated from a tuple $\bar{t}'$ of the restricted query result by replacing elements from $D_t \setminus \mathrm{adom}(G_t)$ by elements from $V \setminus D_t$ (under consideration of equality constraints among these elements).

The above presentation assumes a separate thread for each time point and each thread uses its own relations. These threads can be combined into one dynamic program as follows. We can safely assume that $n \geq \log n$ and since at each time point at most $\log n$ threads are active, we can number them in a round robin fashion with numbers $1, \ldots, n$. The arity of all auxiliary relations is incremented by one and the additional dimension is used to indicate the number of the thread to which a tuple belongs. ◀

5 Warm-up: 3-Colourability

In this section, we show that the 3-colourability problem 3Col for graphs of bounded treewidth can be maintained in DynFO. Given an undirected graph, 3Col asks whether its vertices can be coloured with three colours such that adjacent vertices have different colours.

▶ **Theorem 4.** *For every k,* 3Col *is in* DynFO *for graphs with treewidth at most k.*

The remainder of this section is dedicated to a proof sketch for this theorem. Thanks to Theorem 3 and the fact that 3Col is almost domain-independent, it suffices to show that 3Col is $(\mathrm{AC}^1, \log n)$-maintainable for graphs with treewidth at most k. In a nutshell, our approach can be summarised as follows.

The AC^1-initialisation computes a nice tree decomposition $T = (I, F, r)$ of width at most $4k+5$ and maximum bag size $\ell \stackrel{\text{def}}{=} 4k+6$, as well as information about the 3-colourability

of induced subgraphs of G. More precisely, it computes, for each triangle δ of T and each 3-colouring C of the nodes of $B(\delta)$, whether there exists a colouring C' of the inner vertices of $G(\delta)$, such that all edges involving at least one inner vertex are consistent with $C \cup C'$.

During the following $\log n$ change operations, the dynamic program does not need to do much. It only maintains a set S of *special* bags: for each *affected* graph node v that participates in any changed (i.e. deleted or inserted) edge, S contains one bag in which v occurs. Also, if two bags are special, their least common ancestor is considered special and is included in S. It will be guaranteed that there are at most $4 \log n$ special bags. With the auxiliary information, a first-order formula φ can test whether G is 3-colourable as follows. By existentially quantifying 8ℓ variables, the formula can choose two bits of information for each of the at most $4\ell \log n$ nodes in special bags. For each such node, these two bits are interpreted as encoding of one of three colours and all that the formula φ needs to do is checking that this colouring of the special bags can be extended to a colouring of G. This can be done with the help of the auxiliary relations computed during the initialisation which provide all necessary information about subgraphs induced by triangles consisting of special bags.

6 MSO and GSO Queries

In this section, we show that for each k and each MSO-sentence φ the model checking problem for φ on structures of treewidth at most k is in DynFO.

After some definitions regarding MSO types, we will state a Feferman–Vaught-type composition theorem for the composition of at most $\mathcal{O}(\log n)$ many structures that meet in a set C of at most $\mathcal{O}(\log n)$ elements. We will show that if the structure is suitably extended by information about the types of the (disjoint) structures outside C, then MSO formulas can be replaced by first-order formulas. This part is formulated for arbitrary relational structures instead of graphs since we think it might be useful in other contexts as well.

Afterwards, we will use the Feferman–Vaught-type composition theorem to show the maintainability of MSO properties on structures of bounded treewidth. Finally, we explain how these results can be lifted to guarded second-order logic.

6.1 MSO-types

MSO-logic is the extension of first-order logic, which allows existential and universal quantification over set variables $X, X_1, \ldots$. The depth of a MSO formula is the maximum nesting depth of (second-order and first-order) quantifiers in the syntax tree of the formula. For a signature Σ and a natural number $d \geq 0$, the *depth-d MSO-type* of a Σ-structure $\mathcal{A}$ is defined as the set of all MSO-sentences φ over Σ of quantifier depth at most d, for which $\mathcal{A} \models \varphi$ holds.

We also need to deal with situations, where we have to take a variable assignment and some additional elements of the structure into account, and therefore the general notion of types is slightly more involved. Let $\mathcal{A}$ be a Σ-structure and $\bar{v} = (v_1, \ldots, v_m)$ a tuple of elements from $\mathcal{A}$. We write $(\mathcal{A}, \bar{v})$ for the structure over $\Sigma \cup \{c_1, \ldots, c_m\}$ which interprets c_i as v_i, for every $i \in \{1, \ldots, m\}$. For a set $\mathcal{Y}$ of first-order and second-order variables and an assignment α for the variables of $\mathcal{Y}$, the depth-d MSO-type of $(\mathcal{A}, \bar{v}, \alpha)$ is the set of MSO-formulas with free variables from $\mathcal{Y}$ of depth d that hold in $(\mathcal{A}, \bar{v}, \alpha)$.

We summarise some basic properties of types in the following. Unless not otherwise stated, *type* always refers to MSO-type. For any $d' < d$ the depth-d' type of a structure results from its depth-d type by simply removing all formulas of depth larger than d'.

For every depth-d type, there is a depth-d MSO formula α_τ that is true in exactly the structures and for those assignments of type τ.

Each depth-d type τ induces a set of depth-$(d-1)$ types over $\mathcal{Y} \cup \{x\}$ (assuming $x \notin \mathcal{Y}$) that can be realised in a structure of type τ, represented by the set of all formulas $\alpha_{\tau'}$ for depth-$(d-1)$ types τ' with free variables set $\mathcal{Y} \cup \{x\}$, for which $\exists x \alpha_{\tau'}$ is in τ. We call a type τ', for which $\exists x\ \alpha_{\tau'}$ is in τ, an x-realisation of τ. Likewise, a depth-$(d-1)$ type τ' is an X-realisation for a depth-d type τ, if $\exists X\ \alpha_{\tau'}$ is in τ. For more background on MSO-logic, types, and the above properties readers might consult, e.g., [10].

6.2 A Feferman–Vaught-type composition theorem

In the following, we give an adaptation of the Feferman–Vaught-type composition theorem from [6] that will be useful for maintaining MSO properties.

Intuitively, the idea is very easy, but the formal presentation will come with some technical complications. For simplicity, we explain the basic idea for graphs first.

In a nutshell, we consider graphs $G = (V, E)$ with a *center* $C \subseteq V$, such that the graph $G[V - C]$ is a disjoint union of components $D_1 - C, \ldots, D_\ell - C$, such that, for some $w > 0$,

- $|D_i \cap C| \leq w$, for every i,
- all edges in E have both end nodes in C or in some D_i, and
- for each i there is some element $v_i \in D_i \cap C$ that is not contained in any D_j, for $j \neq i$.

In this case, we say that $(C, D_1, \ldots, D_\ell, v_1, \ldots, v_\ell)$ is a *weak partition* of G with *center* C, and *connection width* w. We refer to the sets $D_1, \ldots, D_\ell$ as *petals* and the nodes $v_1, \ldots, v_\ell$ as *identifiers* of their respective petals. We emphasise that ℓ is not assumed to be bounded by any constant, only by $|C|$.

Readers who have read the proof sketch for Theorem 4 can think of C as the set of vertices from special bags (plus one inner vertex per clean triangle as identifier).

Our goal is to show that, if a graph G with a weak partition of logarithmic center size is extended by the information about the MSO types of its petals in a suitable way, resulting in a structure G', then MSO formulas over G have equivalent first-order formulas over G'.

In a first step, we show that, if (the center) of G is suitably extended by the information about the MSO types of its petals, then every MSO formula has an equivalent MSO formula whose quantification is restricted to C.[3] In a second step we show that, if in a MSO formula quantification is restricted to some node set C of logarithmic size then there is an equivalent (unrestricted) first-order formula. For the second step we assume that the graph has an additional relation that encodes subsets of C by bounded-size tuples over V.

In the following, we work out the above plan in more detail. We fix some relational signature Σ and assume that it contains a unary relation symbol C.

The definition of weak partitions easily carries over to general Σ-structures. In particular, tuples need to be entirely in C or in some petal D_i. For every i, we call the set $I_i \stackrel{\text{def}}{=} D_i \cap C$ the *interface* of D_i and the nodes of a petal D_i that are *not* in C *inner elements* of D_i.

Let $\mathcal{A}$ be a Σ-structure, $P = (C, D_1, \ldots, D_\ell, v_1, \ldots, v_\ell)$ a weak partition of connection width w, and $d > 0$. For every i, let $\bar{u}^i = (u^i_1, \ldots, u^i_w)$ be a tuple of elements from the interface of D_i such that $u^i_1 = v_i$ and every node from I_i occurs in $\bar{u}^i$. By $\mathcal{A}_i$ we denote the substructure of $\mathcal{A}$ induced by D_i with $u^i_1, \ldots, u^i_w$ as constants but *without* all tuples over C,

[3] As remarked by a reviewer, Proposition 5 below can probably be concluded from Shelah's Composition Theorem for generalised sums [14].

i.e., $\mathcal{A}_i$ only contains tuples with at least one inner element of D_i. The *depth d, width w MSO indicator structure* of $\mathcal{A}$ relative to P and tuples $\bar{u}^i$ is the unique structure $\mathcal{B}$ such that:

- $\mathcal{B}$ is an expansion of $\mathcal{A}$ (with the same universe and the same Σ-relations),
- $\mathcal{B}$ has an additional w-ary relation J that contains all tuples $\bar{u}^i$, and
- $\mathcal{B}$ has additional unary relation symbols R_τ, one for every depth-d MSO-type over $\Sigma \cup \{c_1, \ldots, c_w\}$, and for each such τ, R_τ contains the identifier nodes v_i, for all i, for which the depth-d MSO-type of $(\mathcal{A}_i, \bar{u}^i)$ is τ.

The set of all indicator structures of $\mathcal{A}$ relative to P for varying tuples $\bar{u}^i$ is denoted by $\mathcal{S}(\mathcal{A}, P, w, d)$.

We call a MSO-formula *C-restricted*, if all its quantified subformulas are of one of the following forms.

- $\exists x\ (C(x) \wedge \varphi)$ or $\forall x\ (C(x) \to \varphi)$,
- $\exists X\ (\forall x(X(x) \to C(x)) \wedge \varphi)$ or $\forall X\ (\forall x(X(x) \to C(x)) \to \varphi)$.

▶ **Proposition 5.** *For each $d > 0$, every MSO sentence φ with depth d, and each w, there is a C-restricted MSO sentence ψ such that for every Σ-structure $\mathcal{A}$ with a weak partition P of connection width w and every $\mathcal{B} \in \mathcal{S}(\mathcal{A}, P, w, d)$ it holds $\mathcal{A} \models \varphi$ if and only if $\mathcal{B} \models \psi$.*

Proof. The construction of ψ and the proof of its correctness is by induction on the structure of φ. It can be found in the full version of the paper [4]. ◀

To formalise the second step, we need some further notation. Let $\mathcal{A}$ be a structure with a unary relation C and a $(k+1)$-ary relation Sub, for some k. We say that Sub *encodes subsets of C* if, for each subset $C' \subseteq C$, there is a k-tuple $\bar{t}$ such that, for every element $c \in C$ it holds $c \in C'$ if and only if $(\bar{t}, c) \in \text{Sub}$. Clearly, such an encoding of subsets only exists if $|V|^k \geq 2^{|C|}$ and thus if $|C| \leq k \log |V|$.

▶ **Proposition 6.** *For each C-restricted MSO-sentence ψ over a signature Σ (containing C) and every k there is a first-order sentence χ over $\Sigma \cup \{S\}$ where S is a $(k+1)$-ary relation symbol such that, for every Σ-structure $\mathcal{A}$ and $(k+1)$-ary relation Sub that encodes subsets of C (in $\mathcal{A}$), it holds $\mathcal{A} \models \psi$ if and only if $(\mathcal{A}, \mathit{Sub}) \models \chi$.*

Proof. The proof is straightforward. Formulas $\exists X\ (\forall x(X(x) \to C(x)) \wedge \varphi)$ are translated into formulas $\exists \bar{x}\ \varphi'$, where $\bar{x}$ is a tuple of k variables and φ' results from φ by simply replacing every atomic formula $X(y)$ by $\text{Sub}(\bar{x}, y)$. And likewise for universal set quantification. ◀

By combining Propositions 5 and 6 we immediately get the following result.

▶ **Theorem 7.** *For each $d > 0$, every MSO sentence φ with depth d, and each w, there is a first-order sentence χ such that, for every Σ-structure $\mathcal{A}$ with a weak partition $P = (C, D_1, \ldots, D_\ell, v_1, \ldots, v_\ell)$ of connection width w, every $\mathcal{B} \in \mathcal{S}(\mathcal{A}, P, w, d)$ and a relation Sub that encodes subsets of C, it holds $\mathcal{A} \models \varphi$ if and only if $(\mathcal{B}, \mathit{Sub}) \models \chi$.*

6.3 MSO on structures of bounded treewidth

In this subsection we prove a dynamic version of Courcelle's Theorem: all MSO properties can be maintained in DynFO for graphs with bounded treewidth. More precisely, for a given MSO sentence φ we consider the model checking problem MC_φ that asks whether a given graph G satisfies φ, that is, whether $G \models \varphi$ holds.

▶ **Theorem 8.** *For every* MSO *sentence φ and every k, MC_φ is in* DynFO *for graphs with treewidth at most k.*

Thanks to Theorem 3 it suffices to show that MC_φ is $(\mathrm{AC}^1, \log n)$-maintainable for graphs G with treewidth at most k. We note that it is easy to see MSO-definable queries are almost domain-independent and the respective constant c depends only on the formula φ. The reason is that MSO-formulas can not make use of more than a constant number of isolated nodes.[4] The dynamic program that will be constructed in the proof works very similarly to the one of Theorem 4: during its initialisation it constructs a tree decomposition and appropriate MSO-types for all triangles. During the change sequence, a set C of special nodes is used that contains, for each affected graph node v, at least one bag containing v. The union of all bags represented by the set C induces a weak partition P and the dynamic program basically maintains an MSO indicator structure for G relative to P. Since there are only $\mathcal{O}(\log n)$ many change steps, $|C| = \mathcal{O}(\log n)$ and therefore Theorem 7 yields that from this auxiliary data it can be inferred in a first-order fashion whether $G \models \varphi$.

Proof (of Theorem 8). Thanks to Theorem 3 and the fact that MSO queries are almost domain-independent it suffices to show that MC_φ is $(\mathrm{AC}^1, \log n)$-maintainable in DynFO for graphs with treewidth at most k. Let d be the quantifier depth of φ.

Given a graph $G = (V, E)$, the AC^1 initialisation first computes a nice tree decomposition $T = (I, F, r)$ with bags of size at most $\ell \stackrel{\text{def}}{=} 4k + 6$, together with $\preceq$. With each node i, we associate a tuple $\bar{v}(i) = (v_1, \ldots, v_m, v_1, \ldots, v_1)$ of length ℓ, where $B(i) = \{v_1, \ldots, v_m\}$ and $v_1 < \cdots < v_m$. That is, if the bag size of i is ℓ, this tuple just contains all graph nodes of the bag in increasing order. If the bag size is smaller, the smallest graph node is repeated. The AC^1-initialisation also ensures that arithmetic relations $+$, $\times$ and BIT are available.

The dynamic program further uses additional auxiliary relations S, N, and D_τ, for each depth-d MSO-type τ over the signature that consists of the binary relation symbol E and $3\ell + 1$ constant symbols $c_1, \ldots, c_{3\ell+1}$. From these relations all ingredients needed to apply Theorem 7 can be first-order defined: a weak partition P with center C, an MSO indicator structure, and a relation Sub that encodes subsets of C.

The relation S stores tuples representing special bags, as in the proof of Theorem 4. The relations D_τ provide MSO type information for all triangles. More precisely, for each triangle $\delta = (i_0, i_1, i_2)$ for which the subgraph $G(\delta)$ has at least one inner node, D_τ contains the tuple $(v(\delta), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2))$ if and only if the MSO depth-d type of $(G(\delta), v(\delta), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2))$ is τ, where $v(\delta)$ denotes the smallest inner node of $G(\delta)$ with respect to $\leq$.

The set C always contains all graph nodes that occur in special bags (and thus in S), plus one inner node $v(\delta)$, for each maximal[5] clean triangle with at least one inner node. Relation N maintains a bijection between C and an initial segment of $\leq$. From the auxiliary relations, the relations used for Theorem 7 can be defined as follows.

The relations S and C are used to define a weak partition as follows. Clean triangles with at least two inner nodes become petals of the weak partition. Thus the interface $I(\delta)$ of a petal corresponding to a clean triangle $\delta = (i_0, i_1, i_2)$ contains the nodes from $B(i_0), B(i_1)$, and $B(i_2)$ as well as the node $v(\delta)$. Now, an indicator structure $\mathcal{B} \in \mathcal{S}(\mathcal{A}, P, w, d)$ can be first-order defined as follows. Clearly, clean triangles can be easily first-order defined from the relation S. For each clean triangle $\delta = (i_0, i_1, i_2)$ with at least two inner nodes, the relation J contains a tuple $(\delta(v), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2))$, and the relation R_τ contains $\delta(v)$ if and only if is $(\delta(v), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2)) \in D_\tau$. For defining Sub, we observe that C is of size $b \log n$ for some $b \in \mathbb{N}$. Thus a subset C' of C can be represented by a tuple $(a_1, \ldots, a_b)$ of nodes,

[4] It should be mentioned that structures with a linear order $\leq$ do not have any isolated nodes.
[5] Maximal basically means that all its corner nodes are special.

where an element $c \in C$ is in C' if and only if c is the m-th element of C with respect to the mapping defined by N, $m = (\ell - 1)\log n + j$ and the j-th bit of a_ℓ is one. It is easy to see that the relations can be first-order defined from S, N and D_τ.

How the auxiliary relations are initialised and updated is detailed in the full version. ◀

6.4 Extension to GSO logic

We finally sketch how the results of this section can be extended to guarded second-order logic (GSO). In a nutshell, GSO extends MSO by *guarded second-order quantification*. Thus, it syntactically allows to quantify over non-unary relation variables. However, this quantification is semantically restricted: a tuple $\bar{t} = (a_1, \ldots, a_m)$ can only occur in a quantified relation, if all elements from $\{a_1, \ldots, a_m\}$ occur together in some tuple of the structure, in which the formula is evaluated.

To state the analogue of Proposition 5 for GSO, two definitions need to be modified: GSO indicator structures store information about the respective GSO types instead of MSO types. C-restricted formulas can use GSO-quantifiers only to quantify relations over C, e.g., formulas need to be restricted as in $\exists X\ (\forall \bar{x}(X(x_1, \ldots, x_m) \rightarrow (C(x_1) \wedge \cdots \wedge C(x_m))) \wedge \varphi)$. In the statement of Proposition 5 MSO can simply be replaced by GSO. The proof hardly changes. Of course, there is an additional case for GSO quantification but the types of petals can still be handled by MSO quantification. For Proposition 6, encoding of subsets has to be extended to encoding of subrelations. For the quantification of m-ary relations this encoding has to be done by a $(k+m)$-ary relation, for some k. Such an encoding only exists, if the number of tuples over C in $\mathcal{A}$ is only logarithmic. Analogously, Theorem 7 can be extended.

7 MSO Optimisation Problems

With the techniques presented in the previous section also MSO definable optimisation problems can be maintained in DynFO for graphs with bounded treewidth. An MSO definable optimisation problem OPT_φ is induced by an MSO formula $\varphi(X)$ with a free set variable X. Given a graph G with vertex set V, it asks for a set $A \subseteq V$ of minimal[6] size such that $G \models \varphi(A)$.

From the point of view of dynamic programs, such an optimisation problem is just a unary query, that is, the result is defined by some formula $\psi(x)$ with a free first-order variable x.

▶ **Theorem 9.** *For every* MSO *formula* $\varphi(X)$ *and every* k, OPT_φ *is in* DynFO *for graphs with treewidth at most* k.

A dynamic program for an optimisation problem OPT_φ can be constructed by a modification of a program for the decision problem for the MSO sentence $\exists X\ \varphi$, as constructed in the proof of Theorem 8. Basically, we enrich the type information for each petal by information about the smallest set with which a given (X-realisation) type τ can be obtained.

Proof Sketch (of Theorem 9). We describe how a dynamic program for model checking $\psi \stackrel{\text{def}}{=} \exists X\ \varphi$, where $\varphi(X)$ is an MSO-formula of quantifier depth d, can be adapted to a program for OPT_φ. We reuse the notation from the proof of Theorem 8.

Most auxiliary relations remain as in the program of that proof. However, instead of relations D_τ for depth-$(d+1)$-types τ the program uses relations $\#D_{\tau'}$ and $S_{\tau'}$ for

[6] The adaptation to maximisation problems is straightforward.

X-realisations τ' of such types with the following intention. Let δ be a triangle. If τ' is a depth-d type over $\{E, X, c_1, \ldots, c_{3\ell+1}\}$ that can be realised by some set A, then for the minimal size s of such a set A, $\#D_{\tau'}$ shall contain a tuple $(v(\delta), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2), v_s)$, similarly as in the proof of Theorem 8, but with v_s chosen as the $(s+1)$-th element[7] with respect to $\leq$. Furthermore, for the lexicographically minimal set A of this kind and size s, $S_{\tau'}$ shall contain all tuples $(v(\delta), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2), v)$, where $v \in A$.

The proof of Theorem 8 can be extended to show that the initial versions of these auxiliary relations can be computed in AC^1. For the inductive step of this computation, a type τ of a triangle δ might be achievable by a finite number of combinations of types of its sub-triangles. Here, the overall sizes of the underlying sets for X need to be computed and the minimal solution needs to be picked. This is possible by a $\mathrm{FO}(+,\times)$-formula since the number of possible combinations is bounded by a constant depending only on d and k.

The updates of the auxiliary relations are exactly as in the proof of Theorem 8. Since D_τ needs no updates there, neither $\#D_\tau$ nor S_τ do, here.

It remains to explain how the actual query result can be defined. A close inspection of the proofs of Propositions 5 and 6 reveals that the first-order formula χ equivalent to $\exists X \varphi$, as guaranteed by Theorem 7, is of the form $\exists \bar{x} \exists (\bar{x}_\tau)_\tau \hat{\chi}$, where, in a nutshell, $\bar{x}$ represents all center nodes from C in X and $\bar{x}_\tau$ selects all petals $G(\delta_j)$ that have depth-d MSO type τ. The formula χ can first be adapted such that it defines the set of all nodes v selected in C or occurring in a tuple $(v(\delta), \bar{v}(i_0), \bar{v}(i_1), \bar{v}(i_2), v)$ of $S_{\tau'}$ for the type τ' that was chosen for the petal associated with δ. Next, using the ability of $\mathrm{FO}(+,\times)$ to add up logarithmically many numbers [15, Theorem 1.21], the size of the thus represented set can be determined using $\#D_{\tau'}$. Then, a similar formula can check that there is no (lexicographically) smaller set that makes φ true. We emphasise that the resulting formula so far can become true only for one assignment α for $\bar{x}$ and $\bar{x}_\tau$ and thus a final formula with free variable x can be constructed which becomes true for an assignment α', if and only if $\alpha'(x)$ occurs in the set encoded by this assignment α. ◀

From the proof sketch it is easy to see that a dynamic program can also maintain the *size* s of an optimal solution, either implicitly as $|Q|$ for a distinguished relation Q or as $\{v_s\}$. Also, with the adjustments sketched in subsection 6.4, the result can be extended to GSO definable optimisation problems. We can conclude the following corollary from the results of this and the previous section.

▶ **Corollary 10.** *For every k, the Boolean queries* 3-Colourability *and* HamiltonCycle *and the optimisation problems* VertexCover, DominatingSet *and* ShortestPath *are in* DynFO *for graphs of treewidth at most k.*

8 Conclusion

In this paper, we introduced a strategy for maintaining queries by periodically restarting its computation from scratch and limiting the number of change steps that have to be taken into account. This has been captured in the notion of $(\mathcal{C}, f)$-maintainable queries, and we proved that all $(\mathrm{AC}^1, \log n)$-maintainable, almost domain-independent queries are actually in DynFO. As a consequence, decision and optimisation queries definable in MSO- and

[7] We ignore the case that the size could be as large as $|V|$, which can be handled by some additional encoding.

GSO-logic are in DynFO for graphs of bounded treewidth. For this, we stated a Feferman-Vaught-type composition theorem for these logics, which might be interesting in its own right. Though we phrase our results for MSO and GSO for graphs only, their proofs translate swiftly to general relational structures.

We believe that our strategy will find further applications. For instance, it is conceivable that interesting queries on planar graphs, such as the shortest-path query, can be maintained for a bounded number of changes using auxiliary data computed by an AC^1 algorithm (in particular since many important data structures for planar graphs can be constructed in logarithmic space and therefore in AC^1).

Abstract

We establish an *exact* logical characterization of linear time complexity of cellular automata of dimension d, for any fixed d: a set of pictures of dimension d belongs to this complexity class *iff* it is definable in existential second-order logic restricted to *monotonic* Horn formulas with built-in successor function and $d+1$ first-order variables. This logical characterization is optimal modulo an open problem in parallel complexity. Furthermore, its proof provides a systematic method for transforming an inductive formula defining some problem into a cellular automaton that computes it in linear time.

1 Introduction

Descriptive complexity provides machine-independent views of complexity classes. Typically, Fagin's Theorem [5] characterizes **NP** as the class of problems definable in existential second-order logic (ESO). Similarly, Immerman-Vardi's Theorem [15] and Grädel's Theorem [8, 9] characterize the class **P** by first-order logic plus least fixed-point, and second-order logic restricted to Horn formulas, respectively. The link between *computational* and *descriptive* complexity can be made as *tight* as possible, i.e. linear time or time $O(n^d)$, for a fixed integer d, can be *exactly* characterized [20, 14, 17, 11]. Two of the present authors have proved in [12, 13] that a problem is recognized in linear time on a non-deterministic cellular automaton of dimension d iff it is definable in ESO logic with built-in successor and $d+1$ first-order variables. Is there such a natural characterization in logic for the more interesting deterministic case? This question motivates the present paper.

A number of algorithmic problems (linear context-free language recognizability, product of integers, product of matrices, sorting...) are computable in linear time on cellular automata of appropriate dimension. For each such problem, the literature describes the algorithm of the cellular automaton in an informal way [2, 16]. In parallel computational models,

algorithms are often difficult to design. However, the problems they solve can often be simply defined inductively. For instance, the product of two integers in binary notation is inductively defined by the classical Horner rule.

The first contribution of this paper is the observation that those inductive processes are naturally formalized by Horn formulas [9]. As our second and main contribution, we notice that for every concrete problem defined by a Horn formula with $d+1$ first-order variables ($d \geq 1$), this inductive computation by Horn rules has a precise *geometrical* characterization: It can be modeled as the displacement of a d-dimensional hyperplane H along some fixed line D in a space of dimension $d+1$. Provided we interpret the line D as a temporal axis, the parallel displacement of H with respect to D coincides with a computation of a d-dimensional cellular automaton. The converse is obvious: a d-dimensional cellular automaton computation can be regarded as the parallel displacement of a d-dimensional hyperplane – its set of cells – along the time axis.

In the next section, a logic is designed which captures these inductive behaviors (see Def. 14). Roughly speaking, it is obtained from the logic ESO-HORN taylored by Grädel to characterize **P**, by restricting both the number of first-order variables and the arity of second-order predicate symbols. Besides, it includes an additional restriction – the 'monotonicity condition' – that reflects the geometrical consideration above-mentioned. We denote this logic by mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$.

Now we can quote the main result of the paper (Thm. 15): a set L of d-pictures can be decided in linear time by a deterministic cellular automaton – written $L \in \mathbf{DLIN}^d_{\text{ca}}$ – if, and only if, it can be expressed in mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$. For short:

$$\mathbf{DLIN}^d_{\text{ca}} = \text{mon-ESO-HORN}^d(\forall^{d+1}, \text{arity}^{\,d+1}). \tag{1}$$

A noticeable interest of this result is the constructive method of its proof. In order to design a cellular automaton that computes a problem in linear time, one has to define inductively the problem with a monotonic Horn formula. The normalized form of the formula is automatically obtained: this *is* the program of the cellular automaton[1].

The paper is structured as follows: The next section collects the preliminary definitions and gives a precise statement of our main result. In Sec. 3, we establish the left-to-right inclusion of the identity displayed in (1). The rest of the paper is devoted to the converse inclusion, whose proof is far more involved. In Sec. 4 we build a monotonic Horn formula expressing the language of palindromes (a "toy" example) and deduce from it a cellular automaton that recognizes this language in linear time. Sec. 5 generalizes this construction to any problem defined in mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$, thus completing the proof of (1). In Sec. 6, we conclude by arguing for the optimality of our result.

2 Preliminaries

2.1 Cellular automata, picture languages, linear time

We use the standard terminology of cellular automata as presented in [10].

▶ **Definition 1.** A *cellular automaton of dimension d* (d-CA or CA, for short) is a quadruple $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$, where $d \in \mathbb{N}$ is the *dimension* of the automaton, $\mathcal{Q}$ is a finite set whose elements are called *states*, $\mathcal{N}$ is a finite subset of $\mathbb{Z}^d$ called the *neighborhood* of the automaton, and $\delta : \mathcal{Q}^{\mathcal{N}} \to \mathcal{Q}$ is the *local transition function* of the automaton.

[1] For lack of space, this paper gives only one example of this method on a "toy" problem.

A d-CA acts on a grid of dimension d:

▶ **Definition 2.** A *d-dimensional configuration* $\mathcal{C}$ over the set of states $\mathcal{Q}$ is a mapping from $\mathbb{Z}^d$ to $\mathcal{Q}$. The elements of $\mathbb{Z}^d$ will be referred to as *cells* .

▶ **Definition 3.** Given a cellular automaton $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$, a configuration $\mathcal{C}$ and a cell $c \in \mathbb{Z}^d$, we call *neighborhood of c in $\mathcal{C}$* the mapping $\mathcal{N}_{\mathcal{C}}(c) : \mathcal{N} \to \mathcal{Q}$ defined by $\mathcal{N}_{\mathcal{C}}(c)(v) = \mathcal{C}(c + v)$.

From the local transition function δ of $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$, we can define the *global transition function* of the automaton $\Delta : \mathcal{Q}^{\mathbb{Z}^d} \to \mathcal{Q}^{\mathbb{Z}^d}$ obtained by applying the local rule on each cell, that means $\Delta(\mathcal{C})(c) = \delta(\mathcal{N}_{\mathcal{C}}(c)) = \delta((\mathcal{C}(c + v))_{v \in \mathcal{N}})$, for each cell c.

One identifies the CA $\mathcal{A}$ with its global rule: $\mathcal{A}(\mathcal{C}) = \Delta(\mathcal{C})$ is the image of a configuration $\mathcal{C}$ by the action of $\mathcal{A}$. Moreover, $\mathcal{A}^t(\mathcal{C})$ is the configuration resulting from applying t times the global rule of $\mathcal{A}$ from the initial configuration $\mathcal{C}$.

▶ **Definition 4.** For a given cellular automaton: a state q is *permanent* if a cell in state q remains in this state *regardless* of the states of its neighbors; a state q is *quiescent* if a cell in state q remains in this state if *all* its neighbors are also in state q.

The natural inputs of cellular automata of dimension d are *d-pictures*:

▶ **Definition 5.** Let Σ be a finite alphabet. For integers $d, n \geq 1$, a *picture* of *dimension* d (*d-picture*) and *side* n *over* Σ is a mapping $p : [\![1, n]\!]^d \to \Sigma$. We denote by $\Sigma^{(d)}$ the set of d-pictures over Σ. Any subset of $\Sigma^{(d)}$ is called a *d-picture language* over Σ.

▶ Remark. d-picture languages can capture a wide variety of decision problems if the alphabet Σ is sufficiently expressive. For instance, the product problem of boolean square matrices is a 2-picture problem over the three-part alphabet $\Sigma = \{0, 1\}^3$ that consists of square pictures M such that the projection of M over the last part of the alphabet is equal to the product of its projections over the first two parts.

▶ **Definition 6.** Given a picture $p : [\![1, n]\!]^d \to \Sigma$, we define the *picture configuration* associated with p with *permanent* or *quiescent* state[2] $q_0 \notin \Sigma$ as the function $\mathcal{C}_{p,q_0} : \mathbb{Z}^d \to \Sigma \cup \{q_0\}$ such that $\mathcal{C}_{p,q_0}(\mathbf{x}) = p(\mathbf{x})$ if $\mathbf{x} \in [\![1, n]\!]^d$ and $\mathcal{C}_{p,q_0}(\mathbf{x}) = q_0$ otherwise.

▶ **Definition 7.** Given a d-picture language $L \subseteq \Sigma^d$, we say that a cellular automaton $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}, \delta)$ such that $\Sigma \subseteq \mathcal{Q}$ with permanent states q_a and q_r (accepting and rejecting states) *recognizes* L with permanent state (quiescent state, respectively) $q_0 \in \mathcal{Q} \backslash (\Sigma \cup \{q_a, q_r\})$ *in time* $\tau : \mathbb{N} \to \mathbb{N}$ (for short, $\tau(n)$) if for any picture $p : [\![1, n]\!]^d \to \Sigma$, starting from the configuration $\mathcal{C}_{p,q_0}$ at time 0, the state of cell $\mathbf{n} = (n, \ldots, n)$ of $\mathcal{A}$, called the *reference cell*, is q_a or q_r at time $\tau(n)$ with $\mathcal{A}^{\tau(n)}(\mathcal{C}_{p,q_0})(\mathbf{n}) = q_a$ if $p \in L$ and $\mathcal{A}^{\tau(n)}(\mathcal{C}_{p,q_0})(\mathbf{n}) = q_r$ if $p \notin L$.

▶ **Definition 8.** For $d \geq 1$, we call $\mathbf{DLIN}^d_{ca}$ the class of d-picture problems L for which there exist a d-CA $\mathcal{A}$ with quiescent state q_0 and a function $\tau(n) = O(n)$ such that L can be recognized by $\mathcal{A}$ in time $\tau(n)$. Such a problem is said to be *recognizable in linear time* .

The class $\mathbf{DLIN}^d_{\mathrm{ca}}$ is very robust: it is closed under many changes: neighborhoods, precise time/space bounds, input presentation, etc. The proof of the first part of our main result

[2] The condition that each cell outside the input domain $[\![1, n]\!]^d$ remains in a permanent state (resp. quiescent state) q_0 means that the computation space is exactly the set of input cells (resp. is not bounded).

will use the following restrictive characterization which is a consequence of a general linear acceleration theorem[3] (see *e.g.* [10, 19]).

▶ **Lemma 9** ([10]). $\mathbf{DLIN}^d_{ca}$ *is the class of* d*-picture problems that can be recognized in time* $n-1$ *by a* d*-CA of neighborhood* $\mathcal{N}_2 = \{-2,-1,0,1,2\}^d$ *with* permanent *state* q_0.

2.2 Picture structures and monotonic Horn formulas

The local nature of cellular automata acting on pictures is captured by logical formulas acting on first-order structures, the so-called *picture structures*, that represent these pictures. Before defining picture structures, let us detail their signatures. Given a dimension $d \geq 1$ and k alphabets $\Sigma_1, \ldots, \Sigma_k$, we denote by $\mathsf{sg}(d; \Sigma_1, \ldots, \Sigma_k)$ the signature below:

$$\mathsf{sg}(d; \Sigma_1, \ldots, \Sigma_k) = \{(Q^1_s)_{s\in\Sigma_1}, \ldots, (Q^k_s)_{s\in\Sigma_k}, \mathsf{min}, \mathsf{max}, \mathsf{suc}, \mathsf{pred}\}.$$

Here, each Q^i_s is a d-ary relation symbol, min and max are unary relation symbols, and suc and pred are unary function symbols.

▶ **Definition 10.** Let $p_1, \ldots, p_k$ be pictures of respective alphabets $\Sigma_1, \ldots, \Sigma_k$. We assume that the p_i's have the *same dimension* d and the *same side* n. The *picture structure* of the k-tuple $(p_1, \ldots, p_k)$ is the structure of signature $\mathsf{sg}(d; \Sigma_1, \ldots, \Sigma_k)$ defined as follows:

$$\mathcal{S}(p_1, \ldots, p_k) = \langle [\![1, n]\!], (Q^1_s)_{s\in\Sigma_1}, \ldots, (Q^k_s)_{s\in\Sigma_k}, \mathsf{min}, \mathsf{max}, \mathsf{suc}, \mathsf{pred}\rangle.$$

Symbols of $\mathsf{sg}(d; \Sigma_1, \ldots, \Sigma_k)$ are interpreted on $\mathcal{S}(p_1, \ldots, p_k)$ as follows, where we denote the same way a symbol and its interpretation:

- each Q^i_s is the set of cells of p_i labelled by s. Formally: $Q^i_s = \{a \in [\![1, n]\!]^d : p_i(a) = s\}$;
- min and max are the singleton sets $\{1\}$ and $\{n\}$, respectively;
- suc and pred are the successor and predecessor functions: that is $\mathsf{suc}(n) = n$ and $\mathsf{suc}(a) = a + 1$ for $a \in [\![1, n-1]\!]$; $\mathsf{pred}(1) = 1$ and $\mathsf{pred}(a) = a - 1$ for $a \in [\![2, n]\!]$.

In the following, we will freely use the natural notation $x + i$, for any fixed integer $i \in \mathbb{Z}$. It abbreviates $\mathsf{suc}^i(x)$ if $i > 0$, and $\mathsf{pred}^{-i}(x)$ if $i < 0$. For $i = 0$, it represents x.

We will use the usual definitions and notations in logic (see [4, 18, 9]). All formulas considered hereafter belong to *existential second-order logic*. More precisely, we shall focus on the following logic:

▶ **Definition 11.** $\mathrm{ESO}^d(\forall^{d+1}, \mathrm{arity}^{d+1})$ is the class of formulas of the form $\exists \mathbf{R} \forall \mathbf{x} \psi$, where $\mathbf{R} = (R_1, \ldots, R_r)$ is a tuple of $(d+1)$-ary relation symbols, $\mathbf{x} = (x_0, \ldots, x_d)$ is a $(d+1)$-tuple of first-order variables, and ψ is a quantifier-free first-order formula of signature $\mathsf{sg}(d; \mathbf{\Sigma}) \cup \mathbf{R}$ for some tuple of alphabets $\mathbf{\Sigma} = (\Sigma_1, \ldots, \Sigma_k)$.

Such a formula involves two sorts of predicate symbols: those of $\mathsf{sg}(d; \mathbf{\Sigma})$ are called *input predicates* and those of $\mathbf{R}$ are called *guessed predicates* .

It is proved in [13] that the above logic exactly characterizes $\mathbf{NLIN}^d_{\mathrm{ca}}$, the non-deterministic counterpart of $\mathbf{DLIN}^d_{\mathrm{ca}}$. The 'inclusion' $\mathbf{DLIN}^d_{\mathrm{ca}} \subseteq \mathrm{ESO}^d(\forall^{d+1}, arity^{d+1})$ immediately follows, but the converse inclusion is quite unlikely, since it entails $\mathbf{DLIN}^d_{\mathrm{ca}} = \mathbf{NLIN}^d_{\mathrm{ca}}$, which in turn implies $\mathbf{P} = \mathbf{NP}$. Nevertheless, this engages us in looking for a logic characterizing $\mathbf{DLIN}^d_{\mathrm{ca}}$ *inside* the logic $\mathrm{ESO}^d(\forall^{d+1}, arity^{d+1})$. A first restriction of this logic is naturally suggested by the Grädel's characterization of $\mathbf{P}$ already mentioned in the introduction:

[3] For such a result, we need to increase the set of states of the automaton.

▶ **Definition 12.** ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ brings together formulas $\exists\mathbf{R}\forall\mathbf{x}\psi$ among ESO$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ whose quantifier-free part ψ is a conjunction of Horn clauses of the form[4] $\alpha_1 \wedge \ldots \wedge \alpha_m \to \alpha_0$ such that:

- each premise $\alpha_1, \ldots, \alpha_m$ is
  - either a *guessed atom* $R(x_0 + i_0, \ldots, x_d + i_d)$ with $R \in \mathbf{R}$ and $i_0, \ldots, i_d \in \mathbb{Z}$,
  - or an *input literal* $I(t_1 + i_1, \ldots, t_q + i_q)$ or $\neg I(t_1 + i_1, \ldots, t_q + i_q)$, with $I \in \mathsf{sg}(d; \mathbf{\Sigma})$, $t_1, \ldots, t_q \in \mathbf{x}$, and $i_0, \ldots, i_q \in \mathbb{Z}$;
- the conclusion literal α_0 is either a 'constant' – the boolean $\bot$ or an input literal – or a guessed atom[5] of the restricted form $R(x_0, \ldots, x_d)$ with $R \in \mathbf{R}$.

We will see that this new logic still contains $\mathbf{DLIN}^d_{\text{ca}}$ but that here again the converse inclusion is unlikely, as argued in Sec. 6. Whence the necessity of a further restriction of the logic, detailed in Def. 14. For now, let us give some motivation for this restriction.

The first-order part of an ESO-HORN$^d(\forall^{d+1}, arity^{d+1})$-formula can be viewed as a program whose execution, on a given picture structure taken as input, computes the guessed predicates from the input ones. Consider for instance the Horn clause $R(x-2, y-1) \wedge R'(x+1, y-2) \to R(x, y)$ built on guessed predicates R and R'. It establishes a dependence between the values of the guessed predicates (taken as a whole) at place (x, y) and their values at place $(x-2, y-1)$, on one hand, and at place $(x+1, y-2)$, on the other hand. This notion is formalized by the definition below.

▶ **Definition 13.** Let $\Phi = \exists\mathbf{R}\forall x_0, \ldots, x_d\psi$ be in ESO-HORN$^d(\forall^{d+1}, arity^{d+1})$. A *nonzero* tuple $(i_0, \ldots, i_d) \in \mathbb{Z}^{d+1}$ is an *induction vector* of Φ if there exists a Horn clause C in ψ and two guessed predicates R, R' in $\mathbf{R}$ such that C includes $R(x_0, \ldots, x_d)$ as its conclusion and $R'(x_0 + i_0, \ldots, x_d + i_d)$ among its hypotheses. The set of induction vectors of Φ is called its *induction system* .

The logic involved in the characterization of $\mathbf{DLIN}^d_{\text{ca}}$ that constitutes the core of this paper is defined as follows:

▶ **Definition 14.** A formula $\Phi \in$ ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ with induction system $\mathcal{S}$ is *monotonic* and we write $\Phi \in$ mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ if there exist $a_0, \ldots, a_d \in \mathbb{Z}$ such that each induction vector $(v_0, \ldots, v_d) \in \mathcal{S}$ fulfils $a_0v_0 + \cdots + a_dv_d < 0$. This condition is called the *monotonicity condition* .

In other words, there exists a hyperplane $a_0x_0 + \cdots + a_dx_d = 0$, called a *reference hyperplane* of $\mathcal{S}$, such that each vector $(v_0, \ldots, v_d) \in \mathcal{S}$ belongs to the same strict half-space determined by this hyperplane, that means $a_0v_0 + \cdots + a_dv_d < 0$. One also says that $\mathcal{S} \subset \mathbb{Z}^{d+1}$ *satisfies the monotonicity condition* w.r.t. the reference hyperplane.

We are now in a position to state formally the main result of the paper:

▶ **Theorem 15.** *For* $d \geq 1$, $\mathbf{DLIN}^d_{ca} =$ mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$.

The two 'inclusions' underlying the above characterization are proved in Sec. 3 and 5.

[4] We will always assume that conjunction has priority over implication.

[5] Alternatively, in Horn formulas, 'guessed' predicates and 'guessed' atoms can be called more intuitively 'computed' predicates and 'computed' atoms.

3 $\mathbf{DLIN}_{\mathsf{ca}} \subseteq$ mon-ESO-HORN

▶ **Proposition 16.** *For $d \geq 1$, $\mathbf{DLIN}^d_{ca} \subseteq$ mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$.*

Proof. Let $L \subseteq \Sigma^{(d)}$ be a d-picture language in $\mathbf{DLIN}^d_{\text{ca}}$. By Lemma 9, there exists a CA $\mathcal{A} = (d, \mathcal{Q}, \mathcal{N}_2, \delta)$ of neighborhood $\mathcal{N}_2 = \{-2,-1,0,1,2\}^d$ that recognizes L in time $\tau(n) = n-1$ with *permanent* state q_0. Let $[\![1,n]\!]$ denote the interval of the n instants of the computation of $\mathcal{A}$ on a d-picture of side n; in particular, the initial and final instants are numbered 1 and n, respectively. We are going to construct a formula $\Phi \in$ mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ that defines L, i.e., that expresses that the computation of $\mathcal{A}$ on a d-picture p accepts it. It is of the form $\Phi \equiv \exists (R_s)_{s\in\mathcal{Q}} \forall t \forall \mathbf{c} \psi$ where $\mathbf{c}$ denotes the d-tuple of variables $(c_1, \ldots, c_d)$ and, for $s \in \mathcal{Q}$, the intended meaning of the guessed atom $R_s(t, \mathbf{c})$ is the following: at the instant t, the cell $\mathbf{c}$ is in the state s. For simplicity of notation, let us assume $d = 1$. Also assume $n \geq 5$. The quantifier-free part ψ of Φ is the conjunction of three kinds of Horn clauses:

1. the *initialization clauses*: for each $s \in \Sigma$, the clause $\mathsf{min}(t) \wedge Q_s(c) \to R_s(t,c)$;
2. five kinds of *computation clauses* that compute the state at instant $t > 1$ of any cell c according to its possible neighborhoods for $\mathcal{N}_2 = \{-2,-1,0,1,2\}$:
   (i) $c = 1$; (ii) $c = 2$; (iii) general case $c \in [\![3, n-2]\!]$; (iv) $c = n-1$; (v) $c = n$.
   Let us consider the general case: for any 5-tuple of states $(s_{-2}, s_{-1}, s_0, s_1, s_2) \in (Q - \{q_0, q_a, q_r\})^5$, the clause
   $$\left(\begin{array}{c} R_{s_{-2}}(t-1, c-2) \wedge R_{s_{-1}}(t-1, c-1) \wedge \\ R_{s_0}(t-1, c) \wedge R_{s_1}(t-1, c+1) \wedge R_{s_2}(t-1, c+2) \end{array} \right) \to R_{\delta(s_{-2}, s_{-1}, s_0, s_1, s_2)}(t, c)$$
   computes the state at any instant $t > 1$ of any cell c in the interval $[\![3, n-2]\!]$, which can be tested by the use of $\neg\mathsf{min}()$ and $\neg\mathsf{max}()$ in the premises;
3. the *accepting clause* $R_{q_r}(t,c) \to \bot$, which says that the computation does not reject, and hence accepts, since by hypothesis each computation of $\mathcal{A}$ either accepts or rejects.

By construction, Φ belongs to ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ and the induction system is $\{-1\} \times \{-2,-1,0,1,2\}^d$, which has a reference hyperplane of equation $t = 0$. Hence, $\Phi \in$ mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$, which completes the proof. ◀

4 From the formula to the automaton: the example of palindromes

As the proof of the inclusion mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1}) \subseteq \mathbf{DLIN}^d_{\text{ca}}$ we will give in Sec. 5 is much more elaborate than its converse, we first give in this section its main ideas which are essentially of geometrical nature by now presenting the inductive definition of a "toy" problem by a monotonic Horn formula from which we will derive a cellular automaton that recognizes the problem.

Let PALINDROME(Σ) denote the language of palindromes over a fixed alphabet Σ.

4.1 A monotonic Horn formula defining the language of palindromes

Let us prove that PALINDROME(Σ) is definable in mon-ESO-HORN$^1(\forall^2, \text{arity}^{\,2})$. In addition to the set of input unary predicates $\mathtt{Input} = \{\mathsf{min}, \mathsf{max}, (Q_s)_{s\in\Sigma}\}$ involved in the picture structure that represents a word $w = w_1 w_2 \ldots w_n \in \Sigma^*$, we need to consider three guessed binary predicates symbols $R_=$, $R_<$ and R_{noPal}. The first one is enforced to contain the equality relation. It is used to inductively map the second one on the usual strict linear order over $[\![1,n]\!]$. This is done with the clauses $\theta_1, \ldots, \theta_5$ below:

- $\theta_1 = \mathsf{min}(x) \wedge \mathsf{min}(y) \to R_{=}(x,y)$;
- $\theta_2 = \neg\mathsf{min}(x) \wedge \neg\mathsf{min}(y) \wedge R_{=}(x-1,y-1) \to R_{=}(x,y)$;
- $\theta_3 = \neg\mathsf{max}(x) \wedge R_{=}(x+1,y) \to R_{<}(x,y)$;
- $\theta_4 = \neg\mathsf{max}(x) \wedge R_{<}(x+1,y) \to R_{<}(x,y)$;
- $\theta_5 = R_{<}(x,x) \to \bot$.

The (set of) clauses θ_6 and θ_7 below inductively define R_{noPal} as the set of couples $(x,y) \in [\![1,n]\!]^2$ that fulfill: $x < y$ and the factor $w_x \dots w_y$ of the input word w *is not* a palindrome. Then the clause θ_8 forces w to be a palindrome:

- $\theta_6 = R_{<}(x,y) \wedge Q_s(x) \wedge Q_{s'}(y) \to R_{\mathrm{noPal}}(x,y)$, for all $s \neq s'$ in Σ;
- $\theta_7 = R_{<}(x,y) \wedge R_{\mathrm{noPal}}(x+1,y-1) \to R_{\mathrm{noPal}}(x,y)$;
- $\theta_8 = \mathsf{min}(x) \wedge \mathsf{max}(y) \wedge R_{\mathrm{noPal}}(x,y) \to \bot$.

In conclusion, Palindrome(Σ) is defined by the following formula Φ_{pal}, over the structure $\mathcal{S}(w) = \langle [\![1,n]\!], (Q_s)_{s\in\Sigma}, \mathsf{min}, \mathsf{max}, \mathsf{suc}, \mathsf{pred}\rangle$ associated with an input word $w = w_1 \dots w_n$:

$$\Phi_{\mathrm{pal}} \equiv \exists R_{=}, R_{<}, R_{\mathrm{noPal}} \forall x, y \bigwedge_{i\leq 8} \theta_i.$$

Moreover, Φ_{pal} belongs to ESO-HORN$^1(\forall^2, \mathrm{arity}\,^2)$ and has $\mathcal{S} = \{(-1,-1),(1,0),(1,-1)\}$ as its induction system (see Def. 13) Clearly, the system $\mathcal{S}$ satisfies the monotonicity condition of Def. 14 with the line of equation $-x+2y=0$ as its reference hyperplane. It follows:

▶ **Proposition 17.** Palindrome(Σ) $\in$ mon-ESO-HORN$^1(\forall^2, \mathrm{arity}\,^2)$.

4.2 From Φ_{pal} to $\mathcal{A}_{\mathsf{pal}}$

It remains to transform the formula Φ_{pal} above into a one-dimensional cellular automaton $\mathcal{A}_{pal}$ that recognizes the language Palindrome(Σ). For sake of simplicity, we first ignore the input literals and only take account of guessed atoms in the Horn clauses θ_i. Notice that in each clause whose conclusion is a guessed atom $R(x,y)$, $R \in \{R_{=}, R_{<}, R_{\mathrm{noPal}}\}$, the guessed atoms occurring as premises have one of the following forms:

$$R'(x,y), \quad R'(x+1,y), \quad R'(x+1,y-1), \quad R'(x-1,y-1).$$

Intuitively, if one regards the set $D_t = \{(x,y) \in [\![1,n]\!]^2 \mid -x+2y = t\}$ as the line of cells of a one-dimensional CA at instant t, then the conjunction of the above clauses θ_i can be regarded as the transition function of such a CA (see Fig. 1). More formally, in order to introduce the *time* parameter t, we eliminate one of the variables, x for example, and we regard the other variable, y, as the *space* variable c. That is, one makes the change of variables[6] : $t = -x+2y$; $c = y$.

Let us now explain how the automaton $\mathcal{A}_{\mathrm{pal}}$ to be constructed can take account of the input literals. For each point $(x,y) \in [\![1,n]\!]^2$, we call state(x,y) the tuple of boolean values of all input and output atoms on x and y. That is,

$$\mathrm{state}(x,y) = \begin{pmatrix} \mathsf{min}(x),\ \mathsf{min}(y),\ \mathsf{max}(x),\ \mathsf{max}(y), \\ (Q_s(x))_{s\in\Sigma},\ (Q_s(y))_{s\in\Sigma}, \\ R_{=}(x,y),\ R_{<}(x,y),\ R_{\mathrm{noPal}}(x,y) \end{pmatrix},$$

where the values $R_{=}(x,y)$, $R_{<}(x,y)$, $R_{\mathrm{noPal}}(x,y)$, are deduced by the Horn formula.

[6] There is an analogy between our method and the so-called *loop-skewing* or *polytope/polyhedron* method in compilation and parallel algorithms [6, 1, 7].

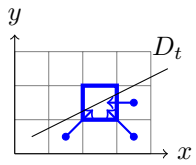

Figure 1 Induction system for guessed atoms before the change of variables.

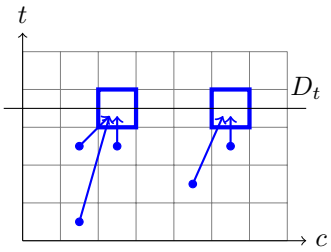

Figure 2 Induction system after the change of variables for guessed atoms (left) and input atoms (right).

We will now discuss the information transit in $\mathcal{A}_{\text{pal}}$; the initialization and termination of the computation will be discussed later. By the change of variables $(x, y) \mapsto (t = -x+2y, c = y)$ whose converse is the function $(t, c) \mapsto (x = -t + 2c, y = c)$, each input atom of the form $I(x)$ becomes $I(-t + 2c)$ and each input atom of the form $I(y)$ becomes $I(c)$. The CA we construct has to memorize in each cell c at instant t the boolean values $I(c)$ and $I(-t + 2c)$, for $I \in \texttt{Input}$. This can be realized as follows:

(a) For each $I(c)$ (former $I(y)$): the CA *conserves* on cell c the boolean value $I(c)$ from an instant $t - 1$ to the next instant t;

(b) For each $I(-t + 2c)$ (former $I(x)$): because of the identity $-t + 2c = -(t - 2) + 2(c - 1)$, whence $I(-t + 2c) \equiv I(-(t - 2) + 2(c - 1))$, the CA only has to *move* to each cell c at instant t the boolean value $I(-(t - 2) + 2(c - 1))$ that is present at instant $t - 2$ on the cell $c - 1$.

All in all, the state of each point $P = (t, c) = (-x + 2y, y)$ is determined by the states of the following points (as shown on Fig. 2):

- $P_1 = (-(x - 1) + 2(y - 1), y - 1) = (t - 1, c - 1)$, $P_2 = (-(x + 1) + 2y, y) = (t - 1, c)$ and $P_3 = (-(x + 1) + 2(y - 1), y - 1) = (t - 3, c - 1)$, because of guessed atoms, and
- $P_2 = (t - 1, c)$ and $P_4 = (t - 2, c - 1)$ because of the above items (a) and (b), respectively, for input atoms.

Hence, the state of a cell c at instant t is determined by the states of: (i) cell $c - 1$ at instant $t - 1$; (ii) cell c at instant $t - 1$; (iii) cell $c - 1$ at instant $t - 3$; (iv) cell $c - 1$ at instant $t - 2$. Figures 1 and 2 below summarize the effects of the change of variables on the induction system.[7]

It seems that we have achieved the design of an automaton of neighborhood $\{-1, 0\}$ that recognizes the language PALINDROME(Σ) in *linear time* since $t = -x + 2y$ and $x, y \in [\![1, n]\!]$ imply $-n + 2 \leq t \leq 2n - 1$. However, it remains to describe both the initialization and the end of the computation.

The result and the initialization of the computation

The result of the computation is `accept` or `reject` according to whether $\mathcal{S}(w)$ does or does not satisfy the formula Φ_{pal}, where $\mathcal{S}(w)$ is the structure $\langle [\![1, n]\!], (Q_s)_{s\in\Sigma}, \mathsf{min}, \mathsf{max}, \mathsf{suc}, \mathsf{pred}\rangle$

[7] At first glance, Conditions (iii) and (iv) seem to contradict the requirement that the state of any cell c of a CA at instant t should be determined by the *only* states of its neighbour cells at the *previous* instant $t - 1$. However, we can overcome the problem by using the ability of a cell to memorize at any instant t its states at instants $t - 1$ and $t - 2$ with a finite number of states.

associated with the input word $w = w_1 \dots w_n$. As this is testified by the clause $\theta_8 = \mathsf{min}(x) \wedge \mathsf{max}(y) \wedge R_{\mathrm{noPal}}(x, y) \to \bot$, on the point of coordinates $(x = 1, y = n)$ which become after the change of variables $(t = -x + 2y = 2n - 1,\ c = y = n)$, the acceptance/rejection can be read on the state of cell $c = n$ at the instant $t = 2n - 1$ so that the final state q_a or q_r is obtained at the following instant $2n$.

The initialization of the computation requires some care in connection with the items (a) and (b) of the previous paragraph, about the input bits:

(1) *Initializing each* $I(c)$ (former $I(y)$): The state of each cell $c \in [\![1, n]\!]$ at the instant just before $-n + 2$, i.e. at instant $-n + 1$, should store the boolean value $I(c)$, for each $I \in \mathtt{Input}$.

(2) *Initializing each* $I(-t + 2c)$ (former $I(x)$): Because of the correspondence $x = -t + 2c$ or, equivalently, $c = (x + t)/2$, for all $x \in [\![1, n]\!]$, the boolean value $I(x)$ should be stored in the state of the cell $c = (x+t)/2$ at the maximal instant $t < -n+2$ such that $(x+t)/2$ is an *integer*; that is the cell $c = (x - n)/2$ at instant $-n$ if $x - n \equiv 0 \pmod 2$ and $c = (x - n + 1)/2$ at instant $-n + 1$ if $x - n \equiv 1 \pmod 2$: see Fig. 3.

The two configurations at the successive instants $-n$ and $-n + 1$ described in items (1) and (2) are called *initialization* configurations. By construction, the space of both configurations – their informative cells, i.e. those in non-quiescent states – is included in the interval $[\![-\lceil n/2 \rceil + 1, n]\!]$.

According to our conventions, the initial configuration of the automaton should be the configuration $\mathcal{C}_{w,q_0}$ associated with the input word w, as defined in Def. 6. However, one can design a routine which, starting from configuration $\mathcal{C}_{w,q_0}$ (with quiescent state q_0), computes the two initialization configurations by using classical techniques of signals in CA's (such as seen in [3]) as shown on Fig. 4. Once each cell contains the right input information, the proper computation can begin. This start will be triggered by a synchronization of all cells of the interval $[\![-\lceil n/2 \rceil + 1, n + 1]\!]$ at time $-n + 1$. The subject of synchronization on cellular automata has been extensively studied (see [21]), here we merely assert that this process can be performed in parallel with no time increase. By a careful examination of this figure, we precisely observe that this precomputation is performed on the interval of cells $[\![-\lceil n/2 \rceil + 1, n + 1]\!]$ during the time interval $[\![-3n, -n + 1]\!]$.[8]

We have now achieved the design of a cellular automaton $\mathcal{A}_{\mathrm{pal}}$ that recognizes in *linear time* the language $\textsc{Palindrome}(\Sigma)$ from the monotonic Horn formula Φ_{pal} that defines it.

5 mon-ESO-HORN $\subseteq$ $\mathbf{DLIN_{ca}}$

The main problem we have to deal with in the general case as in the previous example is the integration of the input to the computation of the CA to be constructed. For that purpose, we will need the following technical lemma whose proof is easy and left to the reader:

▶ **Lemma 18.** *Let* $\mathcal{S} \subset \mathbb{Z}^{d+1}$ *be an induction system satisfying the monotonicity condition w.r.t. some reference hyperplane. Then,* $\mathcal{S}$ *has another reference hyperplane of equation* $a_0x_0 + \dots + a_dx_d = 0$ *where each coefficient* a_i *(*$i \in [\![0, d]\!]$*) is a non-zero integer.*

[8] Notice that our numbering of instants is not canonical. It is only a convenient time scale for describing our algorithm. In particular, the initial instant of the (pre)-computation of the upper part of Fig. 4 is $-2n$ when n is *even* and $-2n - 1$ when n is *odd*, and the initial instant of the two signals of the lower part of Fig. 4 is $-3n$. We let the reader imagine the variants of Fig. 3 and Fig. 4 for the *odd* case.

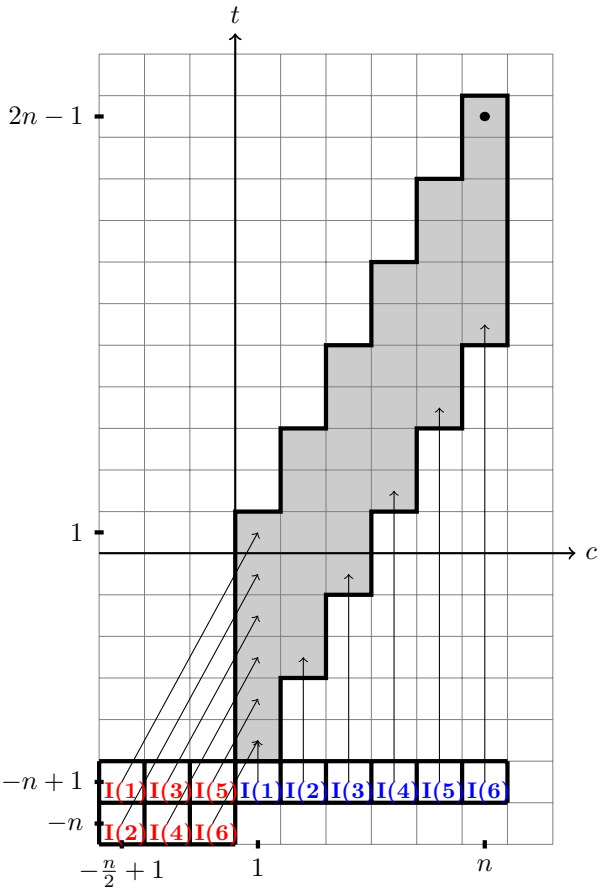

Figure 3 Initial positions and translation vectors for $I(x) = I(-t+2c)$ (in red) and $I(y) = I(c)$ (in blue) when n is *even* (here $n = 6$). The gray parallelogram is where the induction actually happens. The result of the computation lies at the upper right cell.

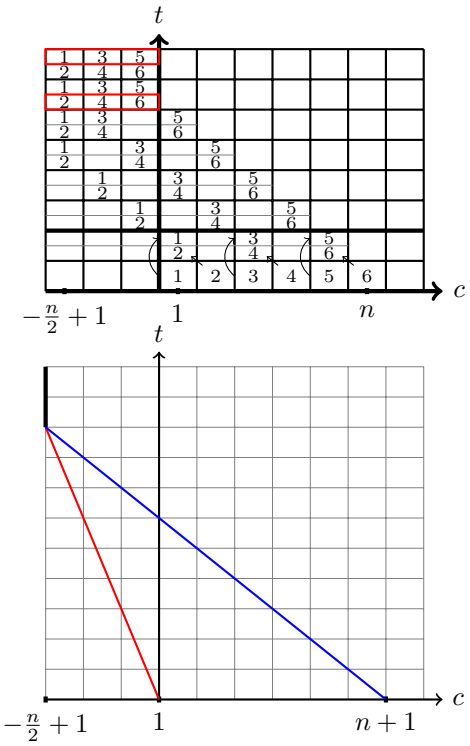

Figure 4 The linear precomputation of $I(x)$ can be done by stacking the information of the cells in the odd columns, then packing it to the left against a "wall" at $c = -\frac{n}{2} + 1$ (n *even*). The bottom figure shows how the wall can be constructed in linear time with two signals of slope $-\frac{1}{3}$ (*resp.* -1) starting in cell 1 (*resp.* $n+1$) at instant $-3n$.

We are now ready to prove the most difficult inclusion of Thm. 15:

▶ **Proposition 19.** *For each* $d \geq 1$, mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{d+1}) \subseteq \mathbf{DLIN}^d_{ca}$.

Proof. Let L be a d-picture language defined by a formula $\Phi \equiv \exists R_1 \dots \exists R_r \forall x_0 \dots \forall x_d\ \psi$ in mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{d+1})$ with an induction system $\mathcal{S}$ and a reference hyperplane $a_0x_0 + a_1x_1 + \dots + a_dx_d = 0$, with coefficients $a_i \in \mathbb{Z}^*$ for all $i \in [\![0, d]\!]$, as justified by Lemma 18. For simplicity of notation, assume all the coefficients a_i are positive.

First, for sake of simplicity, let us ignore the input literals and take account of the only guessed atoms $R_i(x_0 + i_0, \dots, x_d + i_d)$ in the Horn clauses. Intuitively, if one regards the hyperplane $H_t = \{(x_0, x_1, \dots, x_d) \in [\![1, n]\!]^{d+1} \mid a_0x_0 + a_1x_1 + \dots + a_dx_d = t\}$ as the set of cells of a d-dimensional CA at instant t, then the conjunction of Horn clauses ψ can be

regarded as the transition function of such a CA. More formally, in order to introduce the *time* parameter t, we eliminate one of the variables, x_0 for example, and we regard the other variables, $x_1, \dots, x_d$, as the *space* variables, i.e. the respective d coordinates $c_1, \dots, c_d$ of a cell. More precisely, one makes the following change of variables:

$$\left(\begin{array}{l} t = a_0x_0 + \cdots + a_dx_d, \\ c_1 = x_1, \dots, c_d = x_d \end{array} \right), \text{ whose converse is } \left(\begin{array}{l} x_0 = (t - a_1c_1 - \cdots - a_dc_d)/a_0, \\ x_1 = c_1, \dots, x_d = c_d \end{array} \right).$$

As in Section 4.2, we associate with each point $\mathbf{x} = (x_0, \dots, x_d) \in [\![1, n]\!]^{d+1}$, the tuple $\text{state}(\mathbf{x})$ of boolean values of all input and guessed atoms on $\mathbf{x}$. That is,

$$\text{state}(\mathbf{x}) = \left((I(\mathbf{u}))_{\substack{I \in \texttt{Input}, \\ \mathbf{u} \subsetneq \mathbf{x}}}, \ (R(\mathbf{x}))_{R \in \texttt{Guess}} \right).$$

Here, we denote by `Input` (resp. `Guess`) the set of input (resp. guessed) predicates occurring in the formula. Furthermore, $u \in \mathbf{x}$ means that u is any variable among $x_0, \dots, x_d$, while $\mathbf{u} \subsetneq \mathbf{x}$ means that $\mathbf{u}$ is any m-tuple built from those variables, where $m \leq d$ is the arity of I. Besides, the values of the guessed litterals $R(\mathbf{x})$, $R \in \texttt{Guess}$, are deduced by the Horn formula $\forall \mathbf{x} \psi$.

If one ignores the input literals, the state of each point

$$P = (t, c_1, \dots, c_d) = \left(\sum_{j=0}^{d} a_j x_j, \ x_1, \dots, x_d \right)$$

is determined by the states of the points

$$P_v = \left(\sum_{j=0}^{d} a_j (x_j + v_j), \ x_1 + v_1, \dots, x_d + v_d \right) = \left(t + \sum_{j=0}^{d} a_j v_j, \ c_1 + v_1, \dots, c_d + v_d \right)$$

for each vector $v = (v_0, \dots, v_d)$ of the induction system $\mathcal{S}$. In other words the state of the cell $(c_1, \dots, c_d)$ at instant t is determined by the states of the cells $(c_1 + v_1, \dots, c_d + v_d)$ at the respective *previous* instants $t + \sum_{j=0}^{d} a_j v_j$ for the vectors $v = (v_0, \dots, v_d) \in \mathcal{S}$. (Recall that $\sum_{j=0}^{d} a_j v_j < 0$, by hypothesis.)

Let us now explain how the CA we construct can take account of the input atoms, i.e. let us describe how the CA moves the input bits. The crucial point is that at least one of the $d + 1$ variables $x_0, \dots, x_d$ does *not* occur in each input atom because the arity of each input predicate is at most d. This missing variable is used as a 'transport variable' of the values of the concerned input atom. As a *generic* example, let us consider the input atom $I(x_0, x_2, \dots, x_d)$ where I is an input predicate of arity d and where the variable x_1 does not occur[9]. After the above-mentioned change of variables, this atom becomes

$$I(\frac{1}{a_0}(t - a_1c_1 \cdots - a_dc_d), \ c_2, \dots, c_d).$$

Because of the identity $(t - a_1) - a_1(c_1 - 1) - a_2c_2 \cdots - a_dc_d = t - a_1c_1 - a_2c_2 \cdots - a_dc_d$ the automaton only has to *move* to each cell $(c_1, c_2, \dots, c_d)$ at instant t the boolean value

$$I(\frac{1}{a_0}((t - a_1) - a_1(c_1 - 1) - a_2c_2 \cdots - a_dc_d), \ c_2, \dots, c_d)$$

[9] As we have seen in previous examples the case where one variable among $x_2, \dots, x_d$ does not occur in an input atom is similar; the case where x_0 does not occur or the case where the arity of the input predicate is less than d are easier to deal with as we have also seen.

which is stored at instant $t - a_1$ in the state of cell $(c_1 - 1, c_2, \ldots, c_d)$. In terms of cellular automaton, the values of the input atom $I(x_0, x_2, \ldots, x_d)$ are moved/transmitted by linear parallel "signals" which cover all the inductive space $[\![1, n]\!]^{d+1}$.

Time and initialization of the computation: Since the $d+1$ original variables $x_0, \ldots, x_d$ lie in $[\![1, n]\!]$, the domain of the time variable $t = a_0x_0 + \cdots + a_dx_d$ is $[\![A, An]\!]$, where $A = a_0 + \cdots + a_d$. As a consequence, the equation of the cell hyperplane at the *initial* instant (resp. *final* instant) in the space-time diagram is $t = A$ (resp. $t = An$)[10].

The initialization of the input values (input "signals") before the instant $t = A$ is the most delicate/technical part of the computation. It is sufficient to describe the initialization of the values of the input "signals" for our generic example[11] of input atom $\alpha \equiv I(x_0, x_2, \ldots, x_d)$ or, equivalently, $\alpha \equiv I(\frac{1}{a_0}(t - a_1c_1 - \cdots - a_dc_d), c_2, \ldots, c_d)$, for which c_1 (that is the missing variable x_1 of α) is the "transport" variable. To give the reader the geometric intuition of the following construction in the general case we invite her to consult Fig. 3 and 4 of Sec. 4.2 in the particular case of atom $\alpha \equiv I(x) \equiv I(-t + 2c)$ of the formula that defines Palindrome.

Because of the correspondence $t = a_0x_0 + a_1c_1 + a_2x_2 \cdots + a_dx_d$ or, equivalently, $c_1 = (t - a_0x_0 - a_2x_2 \cdots - a_dx_d)/a_1$, with $c_2 = x_2, \ldots, c_d = x_d$, for all $(x_0, x_2, \ldots, x_d) \in [\![1, n]\!]^d$, the boolean value $I(x_0, x_2, \ldots, x_d)$ should be stored – for the initialization of its input "signal" – in the state of the cell $(c_1, x_2, \ldots, x_d)$ such that $c_1 = (t_0 - a_0x_0 - a_2x_2 \cdots - a_dx_d)/a_1$ at the maximal instant $t_0 < A$ (depending on the tuple $(x_0, x_2, \ldots, x_d)$) such that the quotient $(t_0 - a_0x_0 - a_2x_2 \cdots - a_dx_d)/a_1$ is an *integer*. Let i be the integer in $[\![0, a_1 - 1]\!]$ such that $A - a_0x_0 - a_2x_2 \cdots - a_dx_d \equiv -i \pmod{a_1}$. It is easy to verify that $t_0 = A - a_1 + i$. So, the boolean value $I(x_0, x_2, \ldots, x_d)$ should be stored/initialized at the instant $t_0 = A - a_1 + i$ in (the state of) the cell $(c_1, x_2, \ldots, x_d)$ where $c_1 = (A - a_1 + i - a_0x_0 - a_2x_2 \cdots - a_dx_d)/a_1$: see Fig. 3.

Note that for the atom $\alpha \equiv I(x_0, x_2, \ldots, x_d)$, there are a_1 distinct "initialization" configurations in the respective a_1 hyperplanes H_{t_0}, where $t_0 = A - a_1 + i$ with $i \in [\![0, a_1 - 1]\!]$, according to the possible values of the function $f(x_0, x_2, \ldots, x_d) = A - a_0x_0 - a_2x_2 \cdots - a_dx_d$ modulo a_1. Furthermore, one can verify that, by construction, the space of the "initialization" configurations – their informative cells, in non-quiescent states – is included in a hypercube of the form $[\![-bn, bn]\!]^d$, for some constant integer $b > 0$.

Pre-computation and end of computation: The initial configuration of a d-CA that recognizes the d-picture language L should be the *picture configuration* $\mathcal{C}_{p,q_0}$ where p is the input picture. Therefore, there should be a *pre-computation* starting from $\mathcal{C}_{p,q_0}$ that computes the "initialization" configurations of the input atoms of Φ. By the classical technique of signals in CAs (see [3]) we have exemplified above in the case of Palindrome (see Fig. 4), this can be done in linear space and linear time.

Similarly, the result of the computation should be given by the accept/reject state, q_a or q_r, in the *reference* cell $\mathbf{n} = (n, \ldots, n)$. This is realized in linear time by gathering in the reference cell the possible contradictions deduced in cells for Horn clauses.

For lack of space, we have omitted to deal with loops in Horn clauses: the possible presence of guessed atoms of the form $R(t, \mathbf{c})$, i.e. without predecessor/successor functions, *both as conclusions and as hypotheses* of clauses of monotonic Horn formulas seemingly

[10] In the sequel, A always denote the sum $a_0 + \cdots + a_d$. Also, recall that each a_i is positive.
[11] Here again, all the other examples have either exactly the same treatment or a simpler one.

contradicts the "strict monotonicity" of the induction. We leave the reader to cope with this point. This achieves the proof of Prop. 19 and Thm. 15. ◀

6 Optimality of our main result

It is natural to ask whether the monotonicity condition can be removed or weakened in our main result. This is unlikely because it would imply (as the reader can convince herself) the following time-space trade-off which would be a breakthrough in computational complexity:

▶ **Proposition 20.** *If we had* $\mathbf{DLIN}^d_{ca} = \text{ESO-HORN}^d(\forall^{d+1}, \text{arity}^{\,d+1})$ *or the weaker equality* $\mathbf{DLIN}^d_{ca} = \text{weak-mon-ESO-HORN}^d(\forall^{d+1}, \text{arity}^{\,d+1})$ *for a given* $d > 1$*, then any set of words recognizable by a 1-CA in time* n^d *on* n *cells would be recognizable by a* d*-CA in time* $O(n)$ *on* $O(n^d)$ *cells.*

Here, weak-mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ denotes the variant of the class mon-ESO-HORN$^d(\forall^{d+1}, \text{arity}^{\,d+1})$ where the strict inequality $a_0x_0 + \cdots + a_dx_d < 0$ of the monotonicity condition is replaced by the non-strict inequality $a_0x_0 + \cdots + a_dx_d \leq 0$.

Asynchronous Distributed Automata: A Characterization of the Modal Mu-Fragment*

Fabian Reiter

IRIF, Université Paris Diderot, Paris, France
fabian.reiter@gmail.com

Abstract

We establish the equivalence between a class of asynchronous distributed automata and a small fragment of least fixpoint logic, when restricted to finite directed graphs. More specifically, the logic we consider is (a variant of) the fragment of the modal μ-calculus that allows least fixpoints but forbids greatest fixpoints. The corresponding automaton model uses a network of identical finite-state machines that communicate in an asynchronous manner and whose state diagram must be acyclic except for self-loops. Exploiting the connection with logic, we also prove that the expressive power of those machines is independent of whether or not messages can be lost.

1 Introduction

One of the core disciplines of distributed computing is to design and analyze message passing algorithms that solve graph problems in computer networks. Usually, the problem instance considered in that context is precisely the graph defined by the network in which the computations are performed. All nodes of the network run the same algorithm concurrently, and often make no prior assumptions about the size and topology of the graph. Typical problems that can be solved by such distributed algorithms include graph coloring, leader election, and the construction of spanning trees and maximal independent sets. A comprehensive treatment of the subject can be found in [10] and [11].

The present paper follows up on relatively recent results by Hella et al. and Kuusisto, which establish novel connections between modal logic and some restricted classes of distributed algorithms. These weak types of algorithms, referred to in the following as *distributed automata*, can be represented as deterministic finite-state machines that read sets of states instead of the usual alphabetic symbols. Intuitively, to run a distributed automaton on some node-labeled directed graph G, a separate copy of the same machine is placed on every node and initialized to a state that may depend on the node's label. Each node v communicates with its peers by sending its current state q to every outgoing neighbor, while at the same time collecting the states received from its incoming neighbors into a set S. The successor state of q is then computed as a function of q and S. In particular, this means that v cannot distinguish between two incoming neighbors that share the same state. Acting as a semi-decider, the automaton accepts G at position v precisely if v visits an accepting state at some point in time. Either way, all machines of the network run and communicate forever.

In [5, 6], Hella et al. have compared several classes of distributed algorithms, of which the weakest uses the restricted communication model described above. Deviating only in nonessential details from their original definition, we can think of those weakest algorithms as *local synchronous* distributed automata. Here, "synchronous" means that all nodes of the network share a global clock, thereby allowing the computation to proceed in an infinite sequence of rounds. In each round, all the nodes compute their next state simultaneously, based on the information collected in the previous round. By the term "local" we mean that the nodes stop changing their state after a constant number of rounds, a usage in accordance with the established terminology of distributed computing (see, e.g., [12]). Equivalently, the state diagram of a local automaton is acyclic as long as we ignore sink states (i.e., states that cannot be left once reached). The work of Hella et al. reveals an intriguing link between distributed computing and modal logic. In particular, it follows immediately from [5, 6, Thm. 1] that the graph properties recognizable by local synchronous automata are precisely those definable in *backward modal logic*, the variant of (basic) modal logic where the usual modal operators are replaced by their backward-looking variants.

Motivated by the preceding result, the connection with modal logic was further investigated by Kuusisto in [7] and [8]. The former paper lifts the constraint of locality imposed in [5, 6], thereby allowing automata with arbitrary state diagrams. These (nonlocal) synchronous automata are then given a logical characterization in terms of a new recursive logic dubbed *modal substitution calculus*. Furthermore, [7, Prp. 7] shows that on finite graphs, synchronous automata can easily recognize all the properties definable in the least fixpoint fragment of the backward μ-calculus. This logic, which we shall refer to simply as the *backward μ-fragment*, extends backward modal logic with a least fixpoint operator that may not be negated. It thus allows to express statements using least fixpoints, but unlike in the full backward μ-calculus, greatest fixpoints are forbidden. On the other hand, the reverse conversion from synchronous automata to the backward μ-fragment is not possible in general. As explained in [7, Prp. 6], it is easy to come up with a synchronous automaton that makes crucial use of the fact that a node can determine whether it receives the same information from all of its incoming neighbors at exactly the same time. Such a behavior cannot be simulated in the backward μ-fragment. By the same token, even the much more expressive monadic second-order logic (MSO) is incomparable with synchronous automata.

Given that the preceding argument relies solely on synchrony, it seems natural to ask whether removing this feature can lead to a distributed automaton model that has the same expressive power as the backward μ-fragment. The present paper provides a positive answer to this question. We introduce several classes of *asynchronous automata* that transfer the standard notion of asynchronous algorithm to the setting of finite-state machines. Basically, this means that we eliminate the global clock from the network, thus making it possible for nodes to operate at different speeds and for messages to be delayed for arbitrary amounts of time, or even be lost. From the syntactic point of view, an asynchronous automaton is the same as a synchronous one, but it has to satisfy an additional semantic condition: its acceptance behavior must be independent of any timing-related issues. Taking a closer look at the automata obtained by translating formulas of the backward μ-fragment, we can easily see that they are in fact asynchronous. Furthermore, their state diagrams are almost acyclic, except that all the states are allowed to have self-loops (not only the sink states). We call this property *quasi-acyclic*. The paper's main contribution is to show that now we can also go in the other direction: every quasi-acyclic asynchronous automaton can be converted into an equivalent formula of the backward μ-fragment. Incidentally, this remains true even if we consider a seemingly more powerful variant of asynchronous automata, where all messages

are guaranteed to be delivered. To illustrate the basic concepts, an example of an automaton and an equivalent formula will be provided in Figure 1, at the end of the next section.

The remainder of this paper is organized as follows: After giving the necessary formal definitions in Section 2, we state and briefly discuss the main result in Section 3. The proof is then developed in the last two sections. Section 4 presents the rather straightforward translation from logic to automata. The reverse translation is given in Section 5, which is a bit more involved and therefore occupies the largest part of the paper.

2 Preliminaries

We denote the set of Boolean values by $\mathbb{2} = \{0, 1\}$, the set of non-negative integers by $\mathbb{N} = \{0, 1, 2, \dots\}$, and the set of positive integers by $\mathbb{N}_{>0} = \mathbb{N} \setminus \{0\}$. With respect to a given set S, we write 2^S for the power set, S^k for the set of k-tuples ($k \in \mathbb{N}$), and $|S|$ for the cardinality. As a special case of k-tuples, $\mathbb{2}^k$ denotes the set of all binary strings of length k. Furthermore, the length of a string x is written as $|x|$.

For $\ell \in \mathbb{N}$, a (finite) *ℓ-bit labeled directed graph*, abbreviated *digraph*, is a structure $G = (V, E, \lambda)$, where V is a finite nonempty set of nodes, $E \subseteq V \times V$ is a set of directed edges, and $\lambda \colon V \to \mathbb{2}^\ell$ is a labeling that assigns a binary string of length ℓ to each node. Isomorphic digraphs are considered to be equal. If v lies in V, we call the pair (G, v) a *pointed digraph*. Moreover, if uv is an edge in E, then u is called an *incoming neighbor* of v.

▶ **Definition 1** (Distributed Automaton). A (distributed) *automaton* with ℓ-bit input is a tuple $A = (Q, \delta_0, \delta, F)$, where Q is a finite set of states, $\delta_0 \colon \mathbb{2}^\ell \to Q$ is an initialization function, $\delta \colon Q \times \mathbb{2}^Q \to Q$ is a transition function, and $F \subseteq Q$ is a set of accepting states.

To run such an automaton A on a digraph G, we regard the edges of G as FIFO buffers. Each buffer vw will always contain a sequence of states previously traversed by node v. An adversary chooses when v evaluates δ to push a new state to the back of the buffer, and when the current first state gets popped from the front. The details are clarified in the following.

A *trace* of an automaton $A = (Q, \delta_0, \delta, F)$ is a finite nonempty sequence $\sigma = q_1 \dots q_n$ of states in Q such that $q_i \neq q_{i+1}$ and $\delta(q_i, S_i) = q_{i+1}$ for some $S_i \subseteq Q$. We say that A is *quasi-acyclic* if its set of traces $\mathfrak{Q}$ is finite. In other words, its state diagram must not contain any directed cycles, except for self-loops.

For any states $p, q \in Q$ and any (possibly empty) sequence σ of states in Q, we define the unary postfix operators first, last, $\mathsf{pushlast}$ and $\mathsf{popfirst}$ as follows: $p\sigma.\mathsf{first} = \sigma p.\mathsf{last} = p$,

$$\sigma p.\mathsf{pushlast}(q) = \begin{cases} \sigma pq & \text{if } p \neq q, \\ \sigma p & \text{if } p = q, \end{cases} \qquad \text{and} \qquad p\sigma.\mathsf{popfirst} = \begin{cases} \sigma & \text{if } \sigma \text{ is nonempty,} \\ p\sigma & \text{if } \sigma \text{ is empty.} \end{cases}$$

An (asynchronous) *timing* of a digraph $G = (V, E, \lambda)$ is an infinite sequence $\tau = (\tau_1, \tau_2, \tau_3, \dots)$ of maps $\tau_t \colon V \cup E \to \mathbb{2}$, indicating which nodes and edges are active at time t, where 1 is assigned infinitely often to every node and every edge. More formally, for all $t \in \mathbb{N}_{>0}$, $v \in V$ and $e \in E$, there exist $i, j > t$ such that $\tau_i(v) = 1$ and $\tau_j(e) = 1$. We refer to this as the *fairness property* of τ. As a restriction, we say that τ is *lossless-asynchronous* if $\tau_t(uv) = 1$ implies $\tau_t(v) = 1$ for all $t \in \mathbb{N}_{>0}$ and $uv \in E$. Furthermore, τ is called the (unique) *synchronous timing* of G if $\tau_t(v) = \tau_t(e) = 1$ for all $t \in \mathbb{N}_{>0}$, $v \in V$ and $e \in E$.

▶ **Definition 2** (Asynchronous Run). Let $A = (Q, \delta_0, \delta, F)$ be a distributed automaton with ℓ-bit input and $\mathfrak{Q}$ be its set of traces. Furthermore, let $G = (V, E, \lambda)$ be an ℓ-bit labeled

digraph and $\tau = (\tau_1, \tau_2, \tau_3, \dots)$ be a timing of G. The (asynchronous) *run* of A on G timed by τ is the infinite sequence $\rho = (\rho_0, \rho_1, \rho_2, \dots)$ of *configurations* $\rho_t \colon V \cup E \to \mathfrak{Q}$, with $\rho_t(V) \subseteq Q$, which are defined inductively as follows, for $t \in \mathbb{N}$, $v \in V$ and $vw \in E$:

$$\rho_0(v) = \rho_0(vw) = \delta_0(\lambda(v)),$$

$$\rho_{t+1}(v) = \begin{cases} \rho_t(v) & \text{if } \tau_{t+1}(v) = 0, \\ \delta\big(\rho_t(v), \{\rho_t(uv).\mathsf{first} \mid uv \in E\}\big) & \text{if } \tau_{t+1}(v) = 1, \end{cases}$$

$$\rho_{t+1}(vw) = \begin{cases} \rho_t(vw).\mathsf{pushlast}(\rho_{t+1}(v)) & \text{if } \tau_{t+1}(vw) = 0, \\ \rho_t(vw).\mathsf{pushlast}(\rho_{t+1}(v)).\mathsf{popfirst} & \text{if } \tau_{t+1}(vw) = 1. \end{cases}$$

If τ is the synchronous timing of G, we refer to ρ as the *synchronous run* of A on G.

Throughout this paper, we assume that our digraphs, automata and logical formulas agree on the number ℓ of labeling bits. An automaton A *accepts* a pointed digraph (G, v) under timing τ if v visits an accepting state at some point in the run ρ of A on G timed by τ, i.e., if there exists $t \in \mathbb{N}$ such that $\rho_t(v) \in F$. If we simply say that A accepts (G, v), without explicitly specifying a timing τ, then we stipulate that ρ is the synchronous run of A on G.

Given a digraph $G = (V, E, \lambda)$ and a class T of timings of G, the automaton A is called *consistent* for G and T if for all $v \in V$, either A accepts (G, v) under every timing in T, or A does not accept (G, v) under any timing in T. We say that A is *asynchronous* if it is consistent for every possible choice of G and T, and *lossless-asynchronous* if it is consistent for every choice where T contains only lossless-asynchronous timings. By contrast, we call an automaton *synchronous* if we wish to emphasize that no such consistency requirements are imposed. Intuitively, all automata can operate in the synchronous setting, but only some of them also work reliably in environments that provide fewer guarantees.

A *digraph property* is a set L of pointed digraphs. We call L the digraph property *recognized* by an automaton A if it consist precisely of those pointed digraphs that are accepted by A. We denote by AA , LA and SA the classes of digraph properties recognizable by asynchronous, lossless-asynchronous and synchronous automata, respectively. Similarly, QAA , QLA and QSA are the corresponding classes recognizable by quasi-acyclic automata.

Turning to logic, let Var be an infinite supply of propositional variables. We define the formulas of *backward modal logic* with ℓ propositional constants by means of the grammar

$$\varphi ::= \bot \mid \top \mid P_i \mid \neg P_i \mid X \mid (\varphi \vee \varphi) \mid (\varphi \wedge \varphi) \mid \bar{\Diamond}\varphi \mid \bar{\Box}\varphi\,,$$

where $0 \leq i < \ell$ and $X \in \mathrm{Var}$. Note that this syntax ensures that variables cannot be negated. Given such a formula φ, an ℓ-bit labeled digraph $G = (V, E, \lambda)$ and a variable assignment $\alpha \colon \mathrm{Var} \to 2^V$, we write $[\![\varphi]\!]_{G,\alpha}$ to denote the subset of nodes of G at which φ holds with respect to α. For *atomic propositions* P_i and X, the corresponding semantics are defined by $[\![P_i]\!]_{G,\alpha} = \{v \in V \mid \lambda(v)(i) = 1\}$ and $[\![X]\!]_{G,\alpha} = \alpha(X)$, where $\lambda(v)(i)$ is the i-th bit of $\lambda(v)$. The Boolean constants and connectives are interpreted in the usual way, for instance, $[\![\top]\!]_{G,\alpha} = V$ and $[\![(\varphi \vee \psi)]\!]_{G,\alpha} = [\![\varphi]\!]_{G,\alpha} \cup [\![\psi]\!]_{G,\alpha}$. Finally, the *backward diamond* $\bar{\Diamond}$ and the *backward box* $\bar{\Box}$ represent backward-looking modal operators, with the semantics

$$[\![\bar{\Diamond}\varphi]\!]_{G,\alpha} = \big\{v \in V \;\big|\; u \in [\![\varphi]\!]_{G,\alpha} \text{ for some } u \in V \text{ such that } uv \in E\big\} \quad \text{and}$$
$$[\![\bar{\Box}\varphi]\!]_{G,\alpha} = \big\{v \in V \;\big|\; u \in [\![\varphi]\!]_{G,\alpha} \text{ for all } u \in V \text{ such that } uv \in E\big\}.$$

Traditionally, the modal μ-calculus is defined to comprise individual fixpoints which may be nested. However, it is well-known that we can add simultaneous fixpoints to the

μ-calculus without changing its expressive power, and that nested fixpoints of the same type (i.e., least or greatest) can be rewritten as non-nested simultaneous ones (see, e.g., [3, § 3.7] or [9, § 4.3]). The following definition directly takes advantage of this fact. We shall restrict ourselves to the *μ-fragment of the backward μ-calculus*, abbreviated *backward μ-fragment*, where only least fixpoints are allowed, and where the usual modal operators are replaced by their backward-looking variants. Without loss of generality, we stipulate that each formula of the backward μ-fragment with ℓ propositional constants is of the form

$$\varphi = \mu \begin{pmatrix} X_0 \\ \vdots \\ X_k \end{pmatrix} . \begin{pmatrix} \varphi_0(P_0, \dots, P_{\ell-1}, X_0, \dots, X_k) \\ \vdots \\ \varphi_k(P_0, \dots, P_{\ell-1}, X_0, \dots, X_k) \end{pmatrix},$$

where $X_0, \dots, X_k \in \mathrm{Var}$, and $\varphi_0, \dots, \varphi_k$ are formulas of backward modal logic with ℓ propositional constants that may contain no other variables than $X_0, \dots, X_k$.

For every digraph $G = (V, E, \lambda)$, the tuple $(\varphi_0, \dots, \varphi_k)$ gives rise to an operator $f\colon (2^V)^{k+1} \to (2^V)^{k+1}$ that takes some valuation of $\vec{X} = (X_0, \dots, X_k)$ and reassigns to each X_i the resulting valuation of φ_i. More formally, f maps $\vec{W} = (W_0, \dots, W_k)$ to $(W_0', \dots, W_k')$ such that $W_i' = [\![\varphi_i]\!]_{G,[\vec{X} \mapsto \vec{W}]}$. Here, $[\vec{X} \mapsto \vec{W}]$ can be any variable assignment that interprets each X_i as W_i. A (simultaneous) *fixpoint* of the operator f is a tuple $\vec{W} \in (2^V)^{k+1}$ such that $f(\vec{W}) = \vec{W}$. Since, by definition, variables occur only positively in formulas, the operator f is *monotonic*. This means that $\vec{W} \subseteq \vec{W}'$ implies $f(\vec{W}) \subseteq f(\vec{W}')$ for all $\vec{W}, \vec{W}' \in (2^V)^{k+1}$, where set inclusions are to be understood componentwise (i.e., $W_i \subseteq W_i'$ for each i). Therefore, by virtue of a theorem due to Knaster and Tarski, f has a *least fixpoint*, which is defined as the unique fixpoint $\vec{U} = (U_0, \dots, U_k)$ of f such that $\vec{U} \subseteq \vec{W}$ for every other fixpoint $\vec{W}$ of f. As a matter of fact, the Knaster-Tarski theorem even tells us that $\vec{U}$ is equal to $\bigcap \{\vec{W} \in (2^V)^{k+1} \mid f(\vec{W}) \subseteq \vec{W}\}$, where set operations must also be understood componentwise. Another, perhaps more intuitive, way of characterizing $\vec{U}$ is to consider the inductively constructed sequence of approximants $(\vec{U}^0, \vec{U}^1, \vec{U}^2, \dots)$, where $\vec{U}^0 = (\emptyset, \dots, \emptyset)$ and $\vec{U}^{j+1} = f(\vec{U}^j)$. Since this sequence is monotonically increasing and V is finite, there exists $n \in \mathbb{N}$ such that $\vec{U}^n = \vec{U}^{n+1}$. It is easy to check that $\vec{U}^n$ coincides with the least fixpoint $\vec{U}$. For more details and proofs, see, e.g., [4, § 3.3.1].

Having introduced the necessary background, we can finally establish the semantics of φ with respect to G: the set $[\![\varphi]\!]_G$ of nodes at which φ holds is precisely U_0, the first component of $\vec{U}$. A pointed digraph (G, v) satisfies φ, in symbols $(G, v) \models \varphi$, if $v \in [\![\varphi]\!]_G$. Accordingly, the digraph property *defined* by φ is $\{(G, v) \mid (G, v) \models \varphi\}$, and we denote by $\Sigma_1^{\overline{\mu}}$ the class of all digraph properties defined by some formula of the backward μ-fragment.

As usual, two devices (i.e., automata or formulas) are *equivalent* if they specify (i.e., recognize or define) the same property. Figure 1 provides an example of such an equivalence.

3 Main result

Based on the definitions given in Section 2, asynchronous automata are a special case of lossless-asynchronous automata, which in turn are a special case of synchronous automata.[1] Furthermore, quasi-acyclicity constitutes an additional (possibly orthogonal) restriction on these models. We thus immediately obtain the hierarchy of classes depicted in Figure 2a.

[1] This may seem counterintuitive at first sight, but it is actually consistent with the standard terminology of distributed computing: an asynchronous algorithm can always serve as a synchronous algorithm (i.e., it can be executed in a synchronous environment), but the converse is not true.

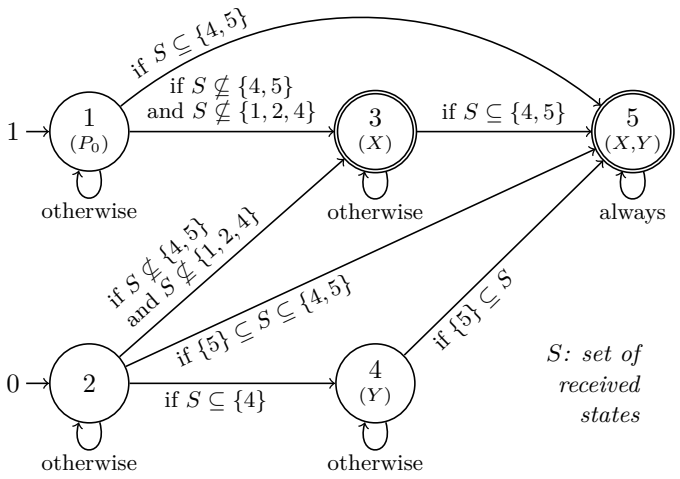

Figure 1 A quasi-acyclic asynchronous distributed automaton equivalent to the formula

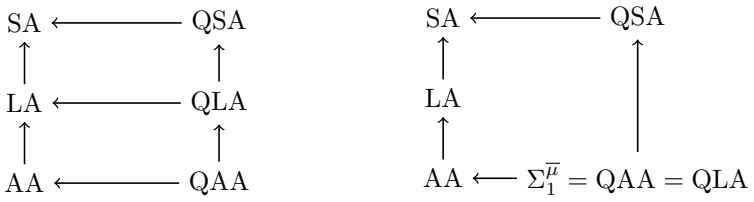
$$\mu \begin{pmatrix} X \\ Y \end{pmatrix} . \begin{pmatrix} (P_0 \wedge Y) \vee \overline{\Diamond} X \\ \overline{\Box} Y \end{pmatrix}$$

of the backward μ-fragment. A given pointed 1-bit labeled digraph (G, v) is accepted by this automaton if and only if, starting at v and following G's edges in the backward direction, it is possible to reach some node u labeled with 1 from which it is impossible to reach any directed cycle.



(a) immediate by the definitions **(b)** collapse shown in this paper

Figure 2 Hierarchy of the classes of digraph properties recognizable by distributed automata, depending on whether the automata are synchronous (S), lossless-asynchronous (L), asynchronous (A), or quasi-acyclic (Q). The arrows denote inclusion (e.g., LA ⊆ SA).

Our main result provides a simplification of this hierarchy: the classes QAA and QLA are actually equal to the class of digraph properties definable in the backward μ-fragment. This yields the revised diagram shown in Figure 2b.

▶ **Theorem 3** ($\Sigma_1^{\overline{\mu}}$ = QAA = QLA)**.** *When restricted to finite digraphs, the backward μ-fragment is effectively equivalent to the classes of quasi-acyclic asynchronous automata and quasi-acyclic lossless-asynchronous automata.*

Proof. The forward direction is given by Proposition 4 (in Section 4), which asserts that $\Sigma_1^{\overline{\mu}} \subseteq$ QAA, and the trivial observation that QAA ⊆ QLA. For the backward direction, we use Proposition 7 (in Section 5), which asserts that QLA ⊆ $\Sigma_1^{\overline{\mu}}$. ◀

As stated before, synchronous automata are more powerful than the backward μ-fragment (and incomparable with monadic second-order logic). This holds even if we consider only quasi-acyclic automata, i.e., the inclusion $\Sigma_1^{\overline{\mu}} \subset$ QSA is known to be strict (see [7, Prp. 6]). Moreover, an upcoming paper will show that the inclusion QSA ⊂ SA is also strict.

In contrast, it remains open whether quasi-acyclicity is in fact necessary for characterizing $\Sigma_1^{\overline{\mu}}$. On the one hand, this notion is crucial for our proof (see Proposition 7), but on the other hand, no digraph property separating AA or LA from $\Sigma_1^{\overline{\mu}}$ has been found so far.

4 Computing least fixpoints using asynchronous automata

In this section, we prove the easy direction of the main result. Given a formula φ of the backward μ-fragment, it is straightforward to construct a (synchronous) distributed automaton A that computes on any digraph the least fixpoint $\vec{U}$ of the operator associated with φ. As long as it operates in the synchronous setting, A simply follows the sequence of approximants $(\vec{U}^0, \vec{U}^1, \dots)$ described in Section 2. It is important to stress that the very same observation has previously been made in [7, Prp. 7] (formulated from a different point of view). In the following proposition, we refine this observation by giving a more precise characterization of the obtained automaton: it is always quasi-acyclic and capable of operating in a (possibly lossy) asynchronous environment.

▶ **Proposition 4** ($\Sigma_1^{\overline{\mu}} \subseteq$ QAA). *For every formula of the backward μ-fragment, we can effectively construct an equivalent quasi-acyclic asynchronous automaton.*

Proof. Let $\varphi = \mu(X_0, \dots, X_k).(\varphi_0, \dots, \varphi_k)$ be a formula of the backward μ-fragment with ℓ propositional constants. Without loss of generality, we may assume that the subformulas $\varphi_0, \dots, \varphi_k$ do not contain any nested modal operators. To see this, suppose that $\varphi_i = \overline{\Diamond}\psi$. Then φ is equivalent to $\varphi' = \mu(X_0, \dots, X_i, \dots, X_k, Y).(\varphi_0, \dots, \varphi_i', \dots, \varphi_k, \psi)$, where Y is a fresh propositional variable and $\varphi_i' = \overline{\Diamond}Y$. The operator $\overline{\Box}$ and Boolean combinations of $\overline{\Diamond}$ and $\overline{\Box}$ are handled analogously.

We now convert φ into an equivalent automaton $A = (Q, \delta_0, \delta, F)$ with state set $Q = 2^{\{P_0, \dots, P_{\ell-1}, X_0, \dots, X_k\}}$. The idea is that each node v of the input digraph has to remember which of the atomic propositions $P_0, \dots, P_{\ell-1}, X_0, \dots, X_k$ have, so far, been verified to hold at v. Therefore, we define the initialization function such that $\delta_0(x) = \{P_i \mid x(i) = 1\}$ for all $x \in 2^\ell$. Let us write $(q, S) \models \varphi_i$ to indicate that a pair $(q, S) \in Q \times 2^Q$ satisfies a subformula φ_i of φ. This is the case precisely when φ_i holds at any node v that satisfies exactly the atomic propositions in q and whose incoming neighbors satisfy exactly the propositions specified by S. Note that this satisfaction relation is well-defined in our context because the nesting depth of modal operators in φ_i is at most 1. With that, the transition function of A can be succinctly described by $\delta(q, S) = q \cup \{X_i \mid (q, S) \models \varphi_i\}$. Since $q \subseteq \delta(q, S)$, we are guaranteed that the automaton is quasi-acyclic. Finally, the accepting set is given by $F = \{q \mid X_0 \in q\}$.

It remains to prove that A is asynchronous and equivalent to φ. Let $G = (V, E, \lambda)$ be an ℓ-bit labeled digraph and $\vec{U} = (U_0, \dots, U_k) \in (2^V)^{k+1}$ be the least fixpoint of the operator f associated with $(\varphi_0, \dots, \varphi_k)$. Due to the asynchrony condition, we must consider an arbitrary timing $\tau = (\tau_1, \tau_2, \dots)$ of G. The corresponding run $\rho = (\rho_0, \rho_1, \dots)$ of A on G timed by τ engenders an infinite sequence $(\vec{W}^0, \vec{W}^1, \dots)$, where each tuple $\vec{W}^t = (W_0^t, \dots, W_k^t) \in (2^V)^{k+1}$ specifies the valuation of every variable X_i at time t, i.e., $W_i^t = \{v \in V \mid X_i \in \rho_t(v)\}$. Since A is quasi-acyclic and V is finite, this sequence must eventually stabilize at some value $\vec{W}^\infty$, and each node accepts if and only if it belongs to W_0^∞. Reformulated this way, our task is to demonstrate that $\vec{W}^\infty$ equals $\vec{U}$, regardless of the timing τ.

"$\vec{W}^\infty \subseteq \vec{U}$": We show by induction that $\vec{W}^t \subseteq \vec{U}$ for all $t \in \mathbb{N}$. This obviously holds for $t = 0$, since $\vec{W}^0 = (\emptyset, \dots, \emptyset)$. Now, consider any node $v \in V$ at an arbitrary time t. Let q be the current state of v and S be the set of current states of its incoming neighbors. Depending

on τ, it might be the case that v actually receives some outdated information S' instead of S. However, given that the neighbors' previous states cannot contain more variables than their current ones (by construction), and that variables can only occur positively in each φ_i, we know that $(q, S') \models \varphi_i$ implies $(q, S) \models \varphi_i$. Hence, if v performs a local transition at time t, then the only new variables that can be added to its state must lie in $\{X_i \mid (q, S) \models \varphi_i\}$. On a global scale, this means that $\vec{W}^{t+1} \setminus \vec{W}^t \subseteq f(\vec{W}^t)$. Furthermore, by the induction hypothesis, the monotonicity of f, and the fact that $\vec{U}$ is a fixpoint, we have $f(\vec{W}^t) \subseteq f(\vec{U}) = \vec{U}$. Putting both together, and again relying on the induction hypothesis, we obtain $\vec{W}^{t+1} \subseteq \vec{U}$.

"$\vec{W}^\infty \supseteq \vec{U}$": For the converse direction, we make use of the Knaster-Tarski theorem, which gives us the equality $\vec{U} = \bigcap\{\vec{W} \in (2^V)^{k+1} \mid f(\vec{W}) \subseteq \vec{W}\}$. With this, it suffices to show that $f(\vec{W}^\infty) \subseteq \vec{W}^\infty$. Consider some time $t \in \mathbb{N}$ such that $\vec{W}^{t'} = \vec{W}^\infty$ for all $t' \geq t$. Although we know that every node has reached its final state at time t, the FIFO buffers of some edges might still contain obsolete states from previous times. However, the fairness property of τ guarantees that our customized popfirst operation is executed infinitely often at every edge, while the pushlast operation has no effect because all the states remain unchanged. Therefore, there must be a time $t' \geq t$ from which on each buffer contains only the current state of its incoming node, i.e., $\rho_{t''}(uv) = \rho_{t''}(u)$ for all $t'' \geq t'$ and $uv \in E$. Moreover, the fairness property of τ also ensures that every node v reevaluates the local transition function δ infinitely often, based on its own current state q and the set S of states in the buffers associated with its incoming neighbors. As this has no influence on v's state, we can deduce that $\{X_i \mid (q, S) \models \varphi_i\} \subseteq q$. Consequently, we have $f(\vec{W}^{t'}) \subseteq \vec{W}^{t'}$, which is equivalent to $f(\vec{W}^\infty) \subseteq \vec{W}^\infty$. ◀

5 Capturing asynchronous runs using least fixpoints

This section is dedicated to proving the converse direction of the main result, which will allow us to translate any quasi-acyclic lossless-asynchronous automaton into an equivalent formula of the backward μ-fragment (see Proposition 7). Our proof builds on two concepts: the invariance of distributed automata under backward bisimulation (stated in Proposition 5) and an ad-hoc relation "$\triangleright$" that captures the possible behaviors of a fixed lossless-asynchronous automaton A (in a specific sense described in Lemma 6).

We start with the notion of backward bisimulation, which is defined like the standard notion of bisimulation (see, e.g., [1, Def. 2.16] or [2, Def. 5]), except that edges are followed in the backward direction. Formally, a *backward bisimulation* between two ℓ-bit labeled digraphs $G = (V, E, \lambda)$ and $G' = (V', E', \lambda')$ is a binary relation $R \subseteq V \times V'$ that fulfills the following conditions for all $vv' \in R$:

1. $\lambda(v) = \lambda'(v')$,
2. if $uv \in E$, then there exists $u' \in V'$ such that $u'v' \in E'$ and $uu' \in R$, and, conversely,
3. if $u'v' \in E'$, then there exists $u \in V$ such that $uv \in E$ and $uu' \in R$.

We say that the pointed digraphs (G, v) and (G', v') are *backward bisimilar* if there exists such a backward bisimulation R relating v and v'. It is easy to see that distributed automata cannot distinguish between backward bisimilar structures:

▶ **Proposition 5.** *Distributed automata are invariant under backward bisimulation. That is, for every automaton A, if two pointed digraphs (G, v) and (G', v') are backward bisimilar, then A accepts (G, v) if and only if it accepts (G', v').*

Proof. Let R be a backward bisimulation between G and G' such that $vv' \in R$. Since acceptance is defined with respect to the synchronous behavior of the automaton, we need

only consider the synchronous runs $\rho = (\rho_0, \rho_1, \dots)$ and $\rho' = (\rho'_0, \rho'_1, \dots)$ of A on G and G', respectively. Now, given that the FIFO buffers on the edges of the digraphs merely contain the current state of their incoming node, it is straightforward to prove by induction on t that every pair of nodes $uu' \in R$ satisfies $\rho_t(u) = \rho'_t(u')$ for all $t \in \mathbb{N}$. ◀

We now turn to the mentioned relation "$\triangleright$", which is defined with respect to a fixed automaton. For the remainder of this section, let A denote an automaton (Q, δ_0, δ, F), and let $\mathfrak{Q}$ denote its set of traces. The relation $\triangleright \subseteq (2^{\mathfrak{Q}} \times \mathfrak{Q})$ specifies whether, in a lossless-asynchronous environment, a given trace σ can be traversed by a node whose incoming neighbors traverse the traces of a given set $\mathfrak{S}$. Loosely speaking, the intended meaning of $\mathfrak{S} \triangleright \sigma$ ("$\mathfrak{S}$ enables σ") is the following: Take an appropriately chosen digraph under some lossless-asynchronous timing τ, and observe the corresponding run of A up to a specific time t; if node v was initially in state $\sigma.\mathsf{first}$ and at time t it has *seen* its incoming neighbors traversing precisely the traces in $\mathfrak{S}$, then it is possible for τ to be such that at time t, node v has traversed exactly the trace σ. This relation can be defined inductively: As the base case, we specify that for every $q \in Q$ and $S \subseteq Q$, we have $S \triangleright q.\mathsf{pushlast}(\delta(q, S))$. For the inductive clause, consider a trace $\sigma \in \mathfrak{Q}$ and two finite (possibly equal) sets of traces $\mathfrak{S}, \mathfrak{S}' \subseteq \mathfrak{Q}$ such that the traces in $\mathfrak{S}'$ can be obtained by appending at most one state to the traces in $\mathfrak{S}$. More precisely, if $\pi \in \mathfrak{S}$, then $\pi.\mathsf{pushlast}(p) \in \mathfrak{S}'$ for some $p \in Q$, and conversely, if $\pi' \in \mathfrak{S}'$, then $\pi' = \pi.\mathsf{pushlast}(\pi'.\mathsf{last})$ for some $\pi \in \mathfrak{S}$. We shall denote this auxiliary relation by $\mathfrak{S} \rightrightarrows \mathfrak{S}'$. If it holds, then $\mathfrak{S} \triangleright \sigma$ implies $\mathfrak{S}' \triangleright \sigma.\mathsf{pushlast}(q)$, where $q = \delta(\sigma.\mathsf{last}, \{\pi'.\mathsf{last} \mid \pi' \in \mathfrak{S}'\})$.

The next step is to show (in Lemma 6) that our definition of "$\triangleright$" does indeed capture the intuition given above. To formalize this, we first introduce two further pieces of terminology.

First, the notions of configuration and run can be enriched to facilitate discussions about the past. Let $\rho = (\rho_0, \rho_1, \dots)$ be a run of A on a digraph $G = (V, E, \lambda)$ (timed by some timing τ). The corresponding *enriched run* is the sequence $\hat{\rho} = (\hat{\rho}_0, \hat{\rho}_1, \dots)$ of *enriched configurations* that we obtain from ρ by requiring each node to remember the entire trace it has traversed so far. Formally, for $t \in \mathbb{N}$, $v \in V$ and $e \in E$,

$$\hat{\rho}_0(v) = \rho_0(v), \qquad \hat{\rho}_{t+1}(v) = \hat{\rho}_t(v).\mathsf{pushlast}(\rho_{t+1}(v)) \qquad \text{and} \qquad \hat{\rho}_t(e) = \rho_t(e).$$

Second, we will need to consider finite segments of timings and enriched runs. A *lossless-asynchronous timing segment* of a digraph G is a finite sequence $\tau = (\tau_1, \dots, \tau_r)$ that could be extended to a whole lossless-asynchronous timing $(\tau_1, \dots, \tau_r, \tau_{r+1}, \dots)$. Likewise, for an initial enriched configuration $\hat{\rho}_0$ of G, the corresponding *enriched run segment* timed by τ is the sequence $(\hat{\rho}_0, \dots, \hat{\rho}_r)$, where each $\hat{\rho}_{t+1}$ is computed from $\hat{\rho}_t$ and τ_{t+1} in the same way as for an entire enriched run.

Equipped with the necessary terminology, we can now state and prove a (slightly technical) lemma that will allow us to derive benefit from the relation "$\triangleright$". This lemma essentially states that if $\mathfrak{S} \triangleright \sigma$ holds and we are given enough nodes that traverse the traces in $\mathfrak{S}$, then we can take those nodes as the incoming neighbors of a new node v and delay the messages received by v in such a way that v traverses σ, without losing any messages.

▶ **Lemma 6.** *For every trace $\sigma \in \mathfrak{Q}$ and every finite (possibly empty) set of traces $\mathfrak{S} = \{\pi_1, \dots, \pi_\ell\} \subseteq \mathfrak{Q}$ that satisfy the relation $\mathfrak{S} \triangleright \sigma$, there exist lower bounds $m_1, \dots, m_\ell \in \mathbb{N}_{>0}$ such that the following statement holds true:*

For any $n_1, \dots, n_\ell \in \mathbb{N}_{>0}$ satisfying $n_i \geq m_i$, let G be a digraph consisting of the nodes $(u_i^j)_{i,j}$ and v, and the edges $(u_i^j v)_{i,j}$, with index ranges $1 \leq i \leq \ell$ and $1 \leq j \leq n_i$. If we start from the enriched configuration $\hat{\rho}_0$ of G, where

$$\hat{\rho}_0(u_i^j) = \pi_i, \qquad \hat{\rho}_0(u_i^j v) = \pi_i \qquad \text{and} \qquad \hat{\rho}_0(v) = \sigma.\mathsf{first},$$

then we can construct a (nonempty) lossless-asynchronous timing segment $\tau = (\tau_1, \dots, \tau_r)$ *of* G*, where* $\tau_t(u_i^j) = 0$ *and* $\tau_t(v) = 1$ *for* $1 \le t \le r$*, such that the corresponding enriched run segment* $\hat{\rho} = (\hat{\rho}_0, \dots, \hat{\rho}_r)$ *timed by* τ *satisfies*

$$\hat{\rho}_{r-1}(u_i^j v) = \pi_i.\mathsf{last} \qquad \textit{and} \qquad \hat{\rho}_r(v) = \sigma.$$

Proof. We proceed by induction on the definition of "$\triangleright$". In the base case, where $\mathfrak{S} = \{p_1, \dots, p_\ell\} \subseteq Q$ and $\sigma = q.\mathsf{pushlast}(\delta(q, \mathfrak{S}))$ for some $q \in Q$, the statement holds with $m_1 = \cdots = m_\ell = 1$. This is witnessed by a timing segment $\tau = (\tau_1)$, where $\tau_1(u_i^j) = 0$, $\tau_1(v) = 1$, and $\tau_1(u_i^j v)$ can be chosen as desired.

For the inductive step, we assume that the statement holds for σ and $\mathfrak{S} = \{\pi_1, \dots, \pi_\ell\}$ with some values $m_1, \dots, m_\ell$. Now consider any other set of traces $\mathfrak{S}' = \{\pi'_1, \dots, \pi'_{\ell'}\}$ such that $\mathfrak{S} \rightrightarrows \mathfrak{S}'$, and let $\sigma' = \sigma.\mathsf{pushlast}(q)$, where $q = \delta(\sigma.\mathsf{last}, \{\pi'_k.\mathsf{last} \mid \pi'_k \in \mathfrak{S}'\})$. Since $\mathfrak{S} \triangleright \sigma$, we have $\mathfrak{S}' \triangleright \sigma'$. The remainder of the proof consists in showing that the statement also holds for σ' and $\mathfrak{S}'$ with some large enough integers $m'_1, \dots, m'_{\ell'}$. Let us fix $m'_k = \sum \{m_i \mid \pi_i.\mathsf{pushlast}(\pi'_k.\mathsf{last}) = \pi'_k\}$. (As there is no need to find minimal values, we opt for easy expressibility.)

Given any numbers $n'_1, \dots, n'_{\ell'}$ with $n'_k \ge m'_k$, we choose suitable values $n_1, \dots, n_\ell$ with $n_i \ge m_i$, and consider the corresponding digraph G described in the lemma. Because we have $\mathfrak{S} \rightrightarrows \mathfrak{S}'$, we can assign to each node u_i^j a state p_i^j such that $\pi_i.\mathsf{pushlast}(p_i^j) \in \mathfrak{S}'$. Moreover, provided our choice of $n_1, \dots, n_\ell$ was adequate, we can also ensure that for each $\pi'_k \in \mathfrak{S}'$, there are exactly n'_k nodes u_i^j such that $\pi_i.\mathsf{pushlast}(p_i^j) = \pi'_k$. (Note that nodes with distinct traces $\pi_i, \pi_{i'} \in \mathfrak{S}$ might be mapped to the same trace $\pi'_k \in \mathfrak{S}'$, in case $\pi_{i'} = \pi_i p_i^j$.) It is straightforward to verify that such a choice of numbers and such an assignment of states are always possible, given the lower bounds $m'_1, \dots, m'_{\ell'}$ specified above.

Let us now consider the lossless-asynchronous timing segment $\tau = (\tau_1, \dots, \tau_r)$ and the corresponding enriched run segment $\hat{\rho} = (\hat{\rho}_0, \dots, \hat{\rho}_r)$ provided by the induction hypothesis. Since the $\mathsf{popfirst}$ operation has no effect on a trace of length 1, we may assume without loss of generality that $\tau_t(u_i^j v) = 0$ if $\hat{\rho}_{t-1}(u_i^j v)$ has length 1, for $t < r$. Consequently, if we start from the alternative enriched configuration $\hat{\rho}'_0$, where

$$\hat{\rho}'_0(u_i^j) = \pi_i.\mathsf{pushlast}(p_i^j), \qquad \hat{\rho}'_0(u_i^j v) = \pi_i.\mathsf{pushlast}(p_i^j) \qquad \text{and} \qquad \hat{\rho}'_0(v) = \sigma.\mathsf{first},$$

then the corresponding enriched run segment $(\hat{\rho}'_0, \dots, \hat{\rho}'_r)$ timed by τ can be derived from $\hat{\rho}$ by simply applying "$\mathsf{pushlast}(p_i^j)$" to $\hat{\rho}_t(u_i^j)$ and $\hat{\rho}_t(u_i^j v)$, for $t < r$. We thus get

$$\hat{\rho}'_{r-1}(u_i^j v) = \pi_i.\mathsf{last}.\mathsf{pushlast}(p_i^j) \qquad \text{and} \qquad \hat{\rho}'_r(v) = \sigma.$$

We may also assume without loss of generality that $\tau_r(u_i^j v) = 1$ if $\hat{\rho}'_{r-1}(u_i^j v)$ has length 2, since this does not affect $\hat{\rho}$ and lossless-asynchrony is ensured by $\tau_r(v) = 1$. Hence, it suffices to extend τ by an additional map τ_{r+1}, where $\tau_{r+1}(u_i^j) = 0$, $\tau_{r+1}(v) = 1$, and $\tau_{r+1}(u_i^j v)$ can be chosen as desired. The resulting enriched run segment $(\hat{\rho}'_0, \dots, \hat{\rho}'_{r+1})$ satisfies

$$\hat{\rho}'_r(u_i^j v) = p_i^j = \pi'_k.\mathsf{last} \ \text{ (for some } \pi'_k \in \mathfrak{S}') \qquad \text{and} \qquad \hat{\rho}'_{r+1}(v) = \sigma.\mathsf{pushlast}(q) = \sigma'. \quad \blacktriangleleft$$

Finally, we can put the pieces together and prove the converse direction of Theorem 3:

▶ **Proposition 7** ($\mathrm{QLA} \subseteq \Sigma_1^{\overline{\mu}}$)**.** *For every quasi-acyclic lossless-asynchronous automaton, we can effectively construct an equivalent formula of the backward* μ*-fragment.*

Proof. Assume that $A = (Q, \delta_0, \delta, F)$ is a quasi-acyclic lossless-asynchronous automaton with ℓ-bit input. Since it is quasi-acyclic, its set of traces $\mathfrak{Q}$ is finite, and thus we can afford

to introduce a separate propositional variable X_σ for each trace $\sigma \in \mathfrak{Q}$. Making use of the relation "$\triangleright$", we convert A into an equivalent formula $\varphi = \mu\big[X_0, (X_\sigma)_{\sigma\in\mathfrak{Q}}\big].\big[\varphi_0, (\varphi_\sigma)_{\sigma\in\mathfrak{Q}}\big]$ of the backward μ-fragment, where

$$\varphi_0 = \bigvee_{\substack{\sigma\in\mathfrak{Q}\\ \sigma.\mathsf{last}\in F}} X_\sigma, \tag{a}$$

$$\varphi_q = \bigvee_{\substack{x\in\mathfrak{D}^\ell\\ \delta_0(x)=q}} \Big(\bigwedge_{x(i)=1} P_i \wedge \bigwedge_{x(i)=0} \neg P_i \Big) \qquad \text{for each } q \in Q, \quad \text{and} \tag{b}$$

$$\varphi_\sigma = X_{\sigma.\mathsf{first}} \wedge \bigvee_{\substack{\mathfrak{S}\subseteq\mathfrak{Q}\\ \mathfrak{S}\triangleright\sigma}} \Big(\big(\bigwedge_{\pi\in\mathfrak{S}} \bar{\Diamond} X_\pi\big) \wedge \big(\bar{\Box} \bigvee_{\pi\in\mathfrak{S}} X_\pi\big) \Big) \qquad \text{for each } \sigma \in \mathfrak{Q} \text{ with } |\sigma| \geq 2. \tag{c}$$

Note that this formula can be constructed effectively because an inductive computation of "$\triangleright$" must terminate after at most $|\mathfrak{Q}| \cdot 2^{|\mathfrak{Q}|}$ iterations.

To prove that φ is indeed equivalent to A, let us consider an arbitrary ℓ-bit labeled digraph $G = (V, E, \lambda)$ and the corresponding least fixpoint $\vec{U} = (U_0, (U_\sigma)_{\sigma\in\mathfrak{Q}}) \in (\mathfrak{D}^V)^{|\mathfrak{Q}|+1}$ of the operator f associated with $(\varphi_0, (\varphi_\sigma)_{\sigma\in\mathfrak{Q}})$.

The easy direction is to show that for all nodes $v \in V$, if A accepts (G, v), then (G, v) satisfies φ. For that, it suffices to consider the synchronous enriched run $\hat{\rho} = (\hat{\rho}_0, \hat{\rho}_1, \dots)$ of A on G. (Any other run timed by a lossless-asynchronous timing would exhibit the same acceptance behavior.) As in the proof of Proposition 5, we can simply ignore the FIFO buffers on the edges of G because $\hat{\rho}_t(uv) = \hat{\rho}_t(u).\mathsf{last}$. Using this, a straightforward induction on t shows that every node $v \in V$ satisfies $\{\hat{\rho}_t(u) \mid uv \in E\} \triangleright \hat{\rho}_{t+1}(v)$ for all $t \in \mathbb{N}$. (For $t = 0$, the claim follows from the base case of the definition of "$\triangleright$""; for the step from t to $t+1$, we can immediately apply the inductive clause of the definition.) This in turn allows us to prove that each node v is contained in all the components of $\vec{U}$ that correspond to a trace traversed by v in $\hat{\rho}$, i.e., $v \in U_{\hat{\rho}_t(v)}$ for all $t \in \mathbb{N}$. Naturally, we proceed again by induction: For $t = 0$, we have $\hat{\rho}_0(v) = \delta_0(\lambda(v)) \in Q$, hence the subformula $\varphi_{\hat{\rho}_0(v)}$ defined in equation (b) holds at v, and thus $v \in U_{\hat{\rho}_0(v)}$. For the step from t to $t+1$, we need to distinguish two cases. If $\hat{\rho}_{t+1}(v)$ is of length 1, then it is equal to $\hat{\rho}_t(v)$, and there is nothing new to prove. Otherwise, we must consider the appropriate subformula $\varphi_{\hat{\rho}_{t+1}(v)}$ given by equation (c). We already know from the base case that the conjunct $X_{\hat{\rho}_{t+1}(v).\mathsf{first}} = X_{\hat{\rho}_0(v)}$ holds at v, with respect to any variable assignment that interprets each X_σ as U_σ. Furthermore, by the induction hypothesis, $X_{\hat{\rho}_t(u)}$ holds at every incoming neighbor u of v. Since $\{\hat{\rho}_t(u) \mid uv \in E\} \triangleright \hat{\rho}_{t+1}(v)$, we conclude that the second conjunct of $\varphi_{\hat{\rho}_{t+1}(v)}$ must also hold at v, and thus $v \in U_{\hat{\rho}_{t+1}(v)}$. Finally, assuming A accepts (G, v), we know by definition that $\hat{\rho}_t(v).\mathsf{last} \in F$ for some $t \in \mathbb{N}$. Since $v \in U_{\hat{\rho}_t(v)}$, this implies that the subformula φ_0 defined in equation (a) holds at v, and therefore that (G, v) satisfies φ.

For the converse direction of the equivalence, we have to overcome the difficulty that φ is more permissive than A, in the sense that a node v might lie in U_σ, and yet not be able to follow the trace σ under any timing of G. Intuitively, the reason why we still obtain an equivalence is that A cannot take advantage of all the information provided by any particular run, because it must ensure that for *all* digraphs, its acceptance behavior is independent of the timing. It turns out that even if v cannot traverse σ, some other node v' in an indistinguishable digraph will be able to do so. More precisely, we will show that

> if $v \in U_\sigma$, then there exists a pointed digraph (G', v'), backward bisimilar to (G, v), and a lossless-asynchronous timing τ' of G', such that $\hat{\rho}'_t(v') = \sigma$ for some $t \in \mathbb{N}$, (∗)

where $\hat{\rho}'$ is the enriched run of A on G' timed by τ'. Now suppose that (G, v) satisfies φ. By

equation (a), this means that $v \in U_\sigma$ for some trace σ such that $\sigma.\mathsf{last} \in F$. Consequently, A accepts the pointed digraph (G', v') postulated in $(*)$, based on the claim that v' traverses σ under timing τ' and the fact that A is lossless-asynchronous. Since (G, v) and (G', v') are backward bisimilar, it follows from Proposition 5 that A also accepts (G, v).

It remains to verify $(*)$. We achieve this by computing the least fixpoint $\vec{U}$ inductively and proving the statement by induction on the sequence of approximants $(\vec{U}^0, \vec{U}^1, \dots)$. Note that we do not need to consider the limit case, since $\vec{U} = \vec{U}^n$ for some $n \in \mathbb{N}$.

The base case is trivially true because all the components of $\vec{U}^0$ are empty. Furthermore, if σ consists of a single state q, then we do not even need to argue by induction, as it is evident from equation (b) that for all $j \geq 1$, node v lies in U_q^j precisely when $\delta_0(\lambda(v)) = q$. It thus suffices to set $(G', v') = (G, v)$ and choose the timing τ' arbitrarily. Clearly, we have $\hat{\rho}'_0(v') = \delta_0(\lambda(v)) = q$ if $v \in U_q^j$.

On the other hand, if σ is of length at least 2, we must assume that statement $(*)$ holds for the components of $\vec{U}^j$ in order to prove it for U_σ^{j+1}. To this end, consider an arbitrary node $v \in U_\sigma^{j+1}$. By the first conjunct in (c) and the preceding remarks regarding the trivial cases, we know that $\delta_0(\lambda(v)) = \sigma.\mathsf{first}$ (and incidentally that $j \geq 1$). Moreover, the second conjunct ensures the existence of a (possibly empty) set of traces $\mathfrak{S}$ that satisfies $\mathfrak{S} \triangleright \sigma$ and that represents a "projection" of v's incoming neighborhood at stage j. By the latter we mean that for all $\pi \in \mathfrak{S}$, there exists $u \in V$ such that $uv \in E$ and $u \in U_\pi^j$, and conversely, for all $u \in V$ with $uv \in E$, there exists $\pi \in \mathfrak{S}$ such that $u \in U_\pi^j$.

Now, for each trace $\pi \in \mathfrak{S}$ and each incoming neighbor u of v that is contained in U_π^j, the induction hypothesis provides us with a pointed digraph $(G'_{u:\pi}, u'_\pi)$ and a corresponding timing $\tau'_{u:\pi}$, as described in $(*)$. We make $n_{u:\pi} \in \mathbb{N}$ distinct copies of each such digraph $G'_{u:\pi}$. From this, we construct $G' = (V', E', \lambda')$ by taking the disjoint union of all the $\sum n_{u:\pi}$ digraphs, and adding a single new node v' with $\lambda'(v') = \lambda(v)$, together with all the edges of the form $u'_\pi v'$ (i.e., one such edge for each copy of every u'_π). Given that every $(G'_{u:\pi}, u'_\pi)$ is backward bisimilar to (G, u), we can guarantee that the same holds for (G', v') and (G, v) by choosing the numbers of digraph copies in G' such that each incoming neighbor u of v is represented by at least one incoming neighbor of v'. That is, for every u, we require that $n_{u:\pi} \geq 1$ for some π.

Finally, we construct a suitable lossless-asynchronous timing τ' of G', which proceeds in two phases to make v' traverse σ in the corresponding enriched run $\hat{\rho}'$. In the first phase, where $0 < t \leq t_1$, node v' remains inactive, which means that every τ_t assigns 0 to v' and its incoming edges. The state of v' at time t_1 is thus still $\sigma.\mathsf{first}$. Meanwhile, in every copy of each digraph $G'_{u:\pi}$, the nodes and edges behave according to timing $\tau'_{u:\pi}$ until the respective copy of u'_π has completely traversed π, whereupon the entire subgraph becomes inactive. By choosing t_1 large enough, we make sure that the FIFO buffer on each edge of the form $u'_\pi v'$ contains precisely π at time t_1. In the second phase, which lasts from $t_1 + 1$ to t_2, the only active parts of G' are v' and its incoming edges. Since the number $n_{u:\pi}$ of copies of each digraph $G'_{u:\pi}$ can be chosen as large as required, we stipulate that for every trace $\pi \in \mathfrak{S}$, the sum of $n_{u:\pi}$ over all u exceeds the lower bound m_π that is associated with π when invoking Lemma 6 for σ and $\mathfrak{S}$. Applying that lemma, we obtain a lossless-asynchronous timing segment of the subgraph induced by v' and its incoming neighbors. This segment determines our timing τ' between $t_1 + 1$ and t_2 (the other parts of G' being inactive), and gives us $\hat{\rho}'_{t_2}(v') = \sigma$, as desired. Naturally, the remainder of τ', starting at $t_2 + 1$, can be chosen arbitrarily, so long as it satisfies the properties of a lossless-asynchronous timing.

As a closing remark, note that the pointed digraph (G', v') constructed above is very similar to the standard unraveling of (G, v) into a (possibly infinite) tree. (The set of nodes

of that tree-unraveling is precisely the set of all directed paths in G that start at v; see, e.g., [1, Def. 4.51] or [2, § 3.2]). However, there are a few differences: First, we do the unraveling backwards, because we want to generate a backward bisimilar structure, where all the edges point toward the root. Second, we may duplicate the incoming neighbors (i.e., children) of each node in the tree, in order to satisfy the lower bounds imposed by Lemma 6. Third, we stop the unraveling process at a finite depth (not necessarily the same for each subtree), and place a copy of the original digraph G at every leaf. ◀

Acknowledgments. I would like to thank Olivier Carton, my PhD supervisor, for many pleasant discussions and constructive comments.

Abstract

We provide a counterexample to a conjecture by Thiagarajan (1996 and 2002) that regular prime event structures correspond exactly to those obtained as unfoldings of finite 1-safe Petri nets. The same counterexample is used to disprove a closely related conjecture by Badouel, Darondeau, and Raoult (1999) that domains of regular event structures with bounded $\natural$-cliques are recognizable by finite trace automata. Event structures, trace automata, and Petri nets are fundamental models in concurrency theory. There exist nice interpretations of these structures as combinatorial and geometric objects and both conjectures can be reformulated in this framework. Namely, the domains of prime event structures correspond exactly to pointed median graphs; from a geometric point of view, these domains are in bijection with pointed CAT(0) cube complexes.

A necessary condition for both conjectures to be true is that domains of respective regular event structures admit a regular nice labeling. To disprove these conjectures, we describe a regular event domain (with bounded $\natural$-cliques) that does not admit a regular nice labeling. Our counterexample is derived from an example by Wise (1996 and 2007) of a nonpositively curved square complex $\mathbf{X}$ whose universal cover $\widetilde{\mathbf{X}}$ is a CAT(0) square complex containing a particular plane with an aperiodic tiling.

1 Introduction

Event structures, introduced by Nielsen, Plotkin, and Winskel [18, 29, 30], are a widely recognized abstract model of concurrent computation. An event structure is a partially ordered set of events together with a conflict relation. The partial order captures the causal dependency of events. The conflict relation models incompatibility of events so that two events that are in conflict cannot simultaneously occur in any state of the computation. Consequently, two events that are neither ordered nor in conflict may occur concurrently. The domain of an event structure consists of all computation states, called configurations. Each computation state is a subset of events subject to the constraints that no two conflicting events can occur together in the same computation and if an event occurred in a computation then all events on which it causally depends have occurred too. Therefore, the domain of an event structure $\mathcal{E}$ is the set $\mathcal{D}(\mathcal{E})$ of all finite configurations ordered by inclusion. An event e

is said to be enabled by a configuration c if $e \notin c$ and $c \cup \{e\}$ is a configuration. The degree of an event structure $\mathcal{E}$ is the maximum number of events enabled by a configuration of $\mathcal{E}$. The future of a configuration c is the set of all finite configurations c' containing c.

Among other things, the importance of event structures stems from the fact that several fundamental models of concurrent computation lead to event structures. Nielsen, Plotkin, and Winskel [18] proved that every 1-safe Petri net N unfolds into an event structure $\mathcal{E}_N$. Later results of [19] and [30] show in fact that 1-safe Petri nets and event structures represent each other in a strong sense. In the same vein, Stark [25] established that the domains of configurations of trace automata are exactly the conflict event domains; a presentation of domains of event structures as trace monoids (Mazurkiewicz traces) or as asynchronous transition systems was given in [22] and [6], respectively. In both cases, the events of the resulting event structure are labeled in a such a way that any two events enabled by the same configuration are labeled differently (such a labeling is usually called a nice labeling). To deal with *finite* 1-safe Petri nets, Thiagarajan [26, 27] introduced the notions of regular event structure and regular trace event structure. A regular event structure $\mathcal{E}$ is an event structure with a finite number of isomorphism types of futures of configurations and finite degree. A regular trace event structure is an event structure $\mathcal{E}$ whose events can be nicely labeled by the letters of a finite trace alphabet $M = (\Sigma, I)$ in a such a way that any two concurrent events define a pair of I and there exists only a finite number of isomorphism types of labeled futures of configurations. These definitions were motivated by the fact that the event structures $\mathcal{E}_N$ arising from *finite* 1-safe Petri nets N are regular: Thiagarajan [26] proved that event structures of *finite* 1-safe Petri nets correspond to regular trace event structures. This lead Thiagarajan to formulate the following conjecture:

▶ **Conjecture 1** ([26, 27]). *An event structure $\mathcal{E}$ is isomorphic to the event structure $\mathcal{E}_N$ arising from a finite 1-safe Petri net N if and only if $\mathcal{E}$ is regular.*

Badouel, Darondeau, and Raoult [2] formulated two similar conjectures about conflict event domain that are recognizable by finite trace automata. The first one is equivalent to Conjecture 1, while the second one is formulated in a more general setting with an extra condition. We formulate their second conjecture in the particular case of event structures:

▶ **Conjecture 2** ([2]). *The domain of an event structure $\mathcal{E}$ is recognizable if and only if $\mathcal{E}$ is regular and has bounded $\natural$-cliques.*

In view of previous results, to establish Conjecture 1, it is necessary for a regular event structure $\mathcal{E}$ to define a regular nice labeling with letters from some trace alphabet (Σ, I). Nielsen and Thiagarajan [20] proved in a technically involved but very nice combinatorial way that all regular conflict-free event structures satisfy Conjecture 1. In a equally difficult and technical proof, Badouel et al. [2] proved that their conjectures hold for context-free event domains, i.e., for domains whose underlying graph is a context-free graph sensu Müller and Schupp [17]. In this paper, we present a counterexample to Thiagarajan's Conjecture based on a more geometric and combinatorial view on event structures. We show that our example also provides a counterexample to Conjecture 2 of Badouel et al.

We use the striking bijections between the domains of event structures, median graphs, and CAT(0) cube complexes. Median graphs have many nice properties and admit numerous characterizations. They have been investigated in several contexts for more than half a century, and play a central role in metric graph theory; for more detailed information, the interested reader can consult the surveys [3, 4]. On the other hand, CAT(0) cube complexes are central objects in geometric group theory [23, 24, 33]. They have been characterized in a

nice combinatorial way by Gromov [12] as simply connected cube complexes in which the links of 0-cubes are simplicial flag complexes. It was proven in [9, 21] that 1-skeleta of CAT(0) cube complexes are exactly the median graphs. Barthélemy and Constantin [5] proved that the Hasse diagrams of domains of event structures are median graphs and every pointed median graph is the domain of an event structure. The bijection between pointed median graphs and event domains established in [5] can be viewed as the classical characterization of prime event domains as prime algebraic coherent partial orders provided by Nielsen, Plotkin, and Winskel [18]. Via these bijections, the events of an event structure $\mathcal{E}$ correspond to the parallelism classes of edges of the domain $D(\mathcal{E})$ viewed as a median graph.

Our counter-example is based on Wise's [31, 32] nonpositively curved square complex $\mathbf{X}$ with one vertex and six squares, whose edges are colored in five colors, and whose colored universal cover $\widetilde{\mathbf{X}}$ contains a particular plane with an aperiodic tiling. As a result, $\widetilde{\mathbf{X}}$ is a CAT(0) square complex whose edges are colored by the colors of their images in $\mathbf{X}$ and are directed in such a way that all edges in the same parallelism class are oriented in the same way. With respect to this orientation, all vertices of $\widetilde{\mathbf{X}}$ are equivalent up to automorphism. We modify the complex $\mathbf{X}$ by taking its barycentric subdivision and by adding to the middles of the edges of $\mathbf{X}$ directed paths of five different lengths in order to encode the colors of the edges of $\mathbf{X}$ (and $\widetilde{\mathbf{X}}$) and to obtain a nonpositively curved square complex W. The universal cover $\widetilde{W}$ of W is a directed (but no longer colored) CAT(0) square complex. Since $\widetilde{W}$ is the universal cover of a finite complex W, $\widetilde{W}$ has a finite number of equivalence classes of vertices up to automorphism. From $\widetilde{W}$ we derive a domain of a regular event structure $\widetilde{W}_{\tilde{v}}$ by considering the future of an arbitrary vertex $\tilde{v}$ of $\widetilde{\mathbf{X}}$. Using the fact that $\widetilde{\mathbf{X}}$ contains a particular plane with an aperiodic tiling, we prove that $\widetilde{W}_{\tilde{v}}$ does not admit a regular nice labeling, thus $\widetilde{W}_{\tilde{v}}$ does not have a regular trace labeling.

Due to space limitations, some proofs are omitted; a full version of the paper is available on arXiv [8].

2 Event structures

2.1 Event structures and domains

An *event structure* is a triple $\mathcal{E} = (E, \leq, \#)$, where

- E is a set of *events*,
- $\leq \subseteq E \times E$ is a partial order of *causal dependency*,
- $\# \subseteq E \times E$ is a binary, irreflexive, symmetric relation of *conflict*,
- $\downarrow e := \{e' \in E : e' \leq e\}$ is finite for any $e \in E$,
- $e\#e'$ and $e' \leq e''$ imply $e\#e''$.

What we call here an event structure is usually called a *prime event structure*. Two events e', e'' are *concurrent* (notation $e' \| e''$) if they are order-incomparable and they are not in conflict. The conflict $e'\#e''$ between two elements e' and e'' is said to be *minimal* (notation, $e'\#_\mu e''$) if there is no event $e \neq e', e''$ such that either $e \leq e'$ and $e\#e''$ or $e \leq e''$ and $e\#e'$. Also define the binary relation $\lessdot \subseteq E \times E$ as follows: set $e \lessdot e'$ if and only if $e \leq e', e \neq e'$, and for every e'' if $e \leq e'' \leq e'$, then $e'' = e$ or $e'' = e'$. Given two event structures $\mathcal{E}_1 = (E_1, \leq_1, \#_1)$ and $\mathcal{E}_2 = (E_2, \leq_2, \#_2)$, a map $f : E_1 \to E_2$ is an isomorphism if f is a bijection such that $e \leq_1 e'$ iff $f(e) \leq_2 f(e')$ and $e\#_1 e'$ iff $f(e)\#_2 f(e')$ for every $e, e' \in E_1$. If such an isomorphism exists, then $\mathcal{E}_1$ and $\mathcal{E}_2$ are said to be isomorphic; notation $\mathcal{E}_1 \equiv \mathcal{E}_2$.

A *labeled event structure* $\mathcal{E}^\lambda = (\mathcal{E}, \lambda)$ is defined by an *underlying event structure* $\mathcal{E} = (E, \leq, \#)$ and a *labeling* λ that is a map from E to some alphabet Σ. Two labeled event structures $\mathcal{E}_1^{\lambda_1} = (\mathcal{E}_1, \lambda_1)$ and $\mathcal{E}_2^{\lambda_1} = (\mathcal{E}_2, \lambda_2)$ are isomorphic (notation $\mathcal{E}_1^{\lambda_1} \equiv \mathcal{E}_2^{\lambda_2}$) if there

exists an isomorphism f between the underlying event structures $\mathcal{E}_1$ and $\mathcal{E}_2$ such that $\lambda_2(f(e_1)) = \lambda_1(e_1)$ for every $e_1 \in E_1$.

A *configuration* of an event structure $\mathcal{E} = (E, \leq, \#)$ is any finite subset $c \subset E$ of events which is *conflict-free* ($e, e' \in c$ implies that e, e' are not in conflict) and *downward-closed* ($e \in c$ and $e' \leq e$ implies that $e' \in c$) [30]. Notice that $\varnothing$ is always a configuration and that $\downarrow e$ and $\downarrow e \setminus \{e\}$ are configurations for any $e \in E$. The *domain* of an event structure is the set $\mathcal{D} := \mathcal{D}(\mathcal{E})$ of all configurations of $\mathcal{E}$ ordered by inclusion; (c', c) is a (directed) edge of the Hasse diagram of the poset $(\mathcal{D}(\mathcal{E}), \subseteq)$ if and only if $c = c' \cup \{e\}$ for an event $e \in E \setminus c$. An event e is said to be *enabled* by a configuration c if $e \notin c$ and $c \cup \{e\}$ is a configuration. Denote by $en(c)$ the set of all events enabled at the configuration c. Two events are called *co-initial* if they are both enabled at some configuration c. Note that if e and e' are co-initial, then either $e \#_\mu e'$ or $e \| e'$. It is easy to see that two events e and e' are in minimal conflict $e \#_\mu e'$ if and only if $e \# e'$ and e and e' are co-initial. The *degree* $\deg(\mathcal{E})$ of an event structure $\mathcal{E}$ is the least positive integer d such that $|en(c)| \leq d$ for any configuration c of $\mathcal{E}$. We say that $\mathcal{E}$ has *finite degree* if $\deg(\mathcal{E})$ is finite. The *future* (or the *filter*) $\mathcal{F}(c)$ of a configuration c is the set of all configurations c' containing c: $\mathcal{F}(c) = \uparrow c := \{c' \in \mathcal{D}(\mathcal{E}) : c \subseteq c'\}$, i.e., $\mathcal{F}(c)$ is the principal filter of c in the ordered set $(\mathcal{D}(\mathcal{E}), \subseteq)$.

For an event structure $\mathcal{E} = (E, \leq, \natural)$, let $\natural$ be the least irreflexive and symmetric relation on the set of events E such that $e_1 \natural e_2$ if (1) $e_1 \| e_2$, or (2) $e_1 \#_\mu e_2$, or (3) there exists an event e_3 that is co-initial with e_1 and e_2 at two different configurations such that $e_1 \| e_3$ and $e_2 \#_\mu e_3$. If $e_1 \natural e_2$ and this comes from condition (3), then we write $e_1 \natural_{(3)} e_2$. A $\natural$-*clique* is a subset S of events such that $e_1 \natural e_2$ for any $e_1, e_2 \in S$.

A labeling $\lambda : E \to \Sigma$ of an event structure $\mathcal{E}$ (or of its domain $\mathcal{D}(\mathcal{E})$) is called a *nice labeling* if any two events that are co-initial have different labels [22]. A nice labeling of $\mathcal{E}$ can be reformulated as a coloring of the directed edges of the Hasse diagram of its domain $\mathcal{D}(\mathcal{E})$ subject to the following local conditions:

- **Determinism:** The edges outgoing from the same vertex of $\mathcal{D}(\mathcal{E})$ have different colors.
- **Concurrency:** the opposite edges of each square of $\mathcal{D}(\mathcal{E})$ are colored with the same color.

2.2 Regular event structures

In this subsection, we recall the definitions of regular event structures, regular trace event structures, and regular nice labelings of event structures. We closely follow the definitions and notations of [26, 27, 20]. Let $\mathcal{E} = (E, \leq, \#)$ be an event structure. Let c be a configuration of $\mathcal{E}$. Set $\#(c) = \{e' : \exists e \in c, e \# e'\}$. The *event structure rooted at* c is defined to be the triple $\mathcal{E}\backslash c = (E', \leq', \#')$, where $E' = E \setminus (c \cup \#(c))$, $\leq'$ is $\leq$ restricted to $E' \times E'$, and $\#'$ is $\#$ restricted to $E' \times E'$. It can be easily seen that the domain $\mathcal{D}(\mathcal{E}\backslash c)$ of the event structure $\mathcal{E}\backslash c$ is isomorphic to the filter $\mathcal{F}(c)$ of c in $\mathcal{D}(\mathcal{E})$ such that any configuration c' of $\mathcal{D}(\mathcal{E})$ corresponds to the configuration $c' \setminus c$ of $\mathcal{D}(\mathcal{E}\backslash c)$.

For an event structure $\mathcal{E} = (E, \leq, \#)$, define the equivalence relation $R_\mathcal{E}$ on its configurations in the following way: for two configurations c and c' set $c R_\mathcal{E} c'$ if and only if $\mathcal{E}\backslash c \equiv \mathcal{E}\backslash c'$. The *index* of an event structure $\mathcal{E}$ is the number of equivalence classes of $R_\mathcal{E}$, i.e., the number of isomorphism types of futures of configurations of $\mathcal{E}$. The event structure $\mathcal{E}$ is *regular* [26, 27, 20] if $\mathcal{E}$ has finite index and finite degree.

Now, let $\mathcal{E}^\lambda = (\mathcal{E}, \lambda)$ be a labeled event structure. For any configuration c of $\mathcal{E}$, if we restrict λ to $\mathcal{E}\backslash c$, then we obtain a labeled event structure $(\mathcal{E}\backslash c, \lambda)$ denoted by $\mathcal{E}^\lambda\backslash c$. Analogously, define the equivalence relation $R_{\mathcal{E}^\lambda}$ on its configurations by setting $c R_{\mathcal{E}^\lambda} c'$ if and only if $\mathcal{E}^\lambda\backslash c \equiv \mathcal{E}^\lambda\backslash c'$. The index of $\mathcal{E}^\lambda$ is the number of equivalence classes of $R_{\mathcal{E}^\lambda}$. We

say that an event structure $\mathcal{E}$ admits a *regular nice labeling* if there exists a nice labeling λ of $\mathcal{E}$ with a finite alphabet Σ such that $\mathcal{E}^\lambda$ has finite index.

We continue by recalling the definition of regular trace event structures from [26, 27]. A *(Mazurkiewicz) trace alphabet* is a pair $M = (\Sigma, I)$, where Σ is a finite non-empty alphabet set and $I \subset \Sigma \times \Sigma$ is an irreflexive and symmetric relation called the *independence relation*. As usual, Σ^* is the set of finite words with letters in Σ. The independence relation I induces the equivalence relation $\sim_I$, which is the reflexive and transitive closure of the binary relation $\leftrightarrow_I$: *if* $\sigma, \sigma' \in \Sigma^*$ *and* $(a, b) \in I$, *then* $\sigma ab\sigma' \leftrightarrow_I \sigma ba\sigma'$. The relation $D := (\Sigma \times \Sigma) \setminus I$ is called the *dependence relation*. An *M-labeled event structure* is a labeled event structure $\mathcal{E}^\lambda = (\mathcal{E}, \lambda)$, where $\mathcal{E} = (E, \leq, \#)$ is an event structure and $\lambda : E \to \Sigma$ is a labeling function which satisfies the following conditions:

- (LES1) $e \#_\mu e'$ implies $\lambda(e) \neq \lambda(e')$,
- (LES2) $e \lessdot e'$ or $e \#_\mu e'$, then $(\lambda(e), \lambda(e')) \in D$,
- (LES3) if $(\lambda(e), \lambda(e')) \in D$, then $e \leq e'$ or $e' \leq e$ or $e \# e'$.

We call λ a *trace labeling* of $\mathcal{E}$. The conditions (LES2) and (LES3) on the labeling function ensures that the concurrency relation $\|$ of $\mathcal{E}$ respects the independence relation I of M. In particular, since I is irreflexive, from (LES3) it follows that any two concurrent events are labeled differently. Since by (LES1) two events in minimal conflict are also labeled differently, this implies that λ is a finite nice labeling of $\mathcal{E}$.

An M-labeled event structure $\mathcal{E}^\lambda = (\mathcal{E}, \lambda)$ is *regular* if $\mathcal{E}^\lambda$ has finite index. Finally, an event structure $\mathcal{E}$ is called a *regular trace event structure* [26, 27] iff there exists a trace alphabet $M = (\Sigma, I)$ and a regular M-labeled event structure $\mathcal{E}^\lambda$ such that $\mathcal{E}$ is isomorphic to the underlying event structure of $\mathcal{E}^\lambda$. From the definition immediately follows that every regular trace event structure is also a regular event structure. It turns out that the converse is equivalent to Conjecture 1. Namely, [27] establishes the following equivalence (this result dispenses us from giving a formal definition of 1-safe Petri nets; the interested readers can find it in the papers [27, 20]):

▶ **Theorem 3** ([27, Theorem 1]). *$\mathcal{E}$ is a regular trace event structure if and only if there exists a finite 1-safe Petri net N such that $\mathcal{E}$ and $\mathcal{E}_N$ are isomorphic.*

In view of this theorem, Conjecture 1 is equivalent to the following conjecture:

▶ **Conjecture 4.** *$\mathcal{E}$ is a regular event structure iff $\mathcal{E}$ is a regular trace event structure.*

Badouel et al. [2] considered recognizable conflict event domains that are more general than the domains of event structures we consider in this paper. Since the domain of an event structure $\mathcal{E}$ is recognizable if and only if $\mathcal{E}$ is a regular trace event structure (see [16, Section 5]), Conjecture 2 can be reformulated as follows:

▶ **Conjecture 5.** *$\mathcal{E}$ is a regular event structure iff $\mathcal{E}$ is a regular trace event structure and $\mathcal{E}$ has bounded $\natural$-cliques.*

Since any regular trace labeling is a regular nice labeling, any regular event structure $\mathcal{E}$ not admitting a regular nice labeling is a counter-example to Conjecture 4 (and thus to Conjecture 1). If, additionally, $\mathcal{E}$ has bounded $\natural$-cliques, $\mathcal{E}$ is also a counter-example to Conjecture 5 (and thus to Conjecture 2).

3 Domains, median graphs, and CAT(0) cube complexes

In this section, we recall the bijections between domains of event structures and median graphs/CAT(0) cube complexes established in [1] and [5], and between median graphs and 1-skeleta of CAT(0) cube complexes established in [9] and [21].

Let $G = (V, E)$ be a simple, connected, not necessarily finite graph. The *distance* $d_G(u, v)$ between two vertices u and v is the length of a shortest (u, v)-path, and the *interval* $I(u, v)$ between u and v consists of all vertices on shortest (u, v)–paths. A graph G is *median* if for any three vertices x, y, z of G, there exists a unique vertex $m = m(x, y, z)$, called the *median* of x, y, z, simultaneously lying on the intervals $I(x, y), I(x, z)$, and $I(y, z)$. Basic examples of median graphs are trees, hypercubes, rectangular grids, and Hasse diagrams of distributive lattices and of median semilattices [3]. With any vertex v of a median graph $G = (V, E)$ is associated a *canonical partial order* $\leq_v$ defined by setting $x \leq_v y$ if and only if $x \in I(v, y)$; v is called the *basepoint* of $\leq_v$. Since G is bipartite, the Hasse diagram G_v of the partial order $(V, \leq_v)$ is the graph G in which any edge xy is directed from x to y if and only if the inequality $d_G(x, v) < d_G(y, v)$ holds. We call G_v a *pointed median graph*.

Median graphs can be obtained from hypercubes by amalgams and median graphs are themselves isometric subgraphs of hypercubes. The canonical isometric embedding of a median graph G into a (smallest) hypercube can be determined by the so called *Djoković-Winkler ("parallelism")* relation Θ on the edges of G [11, 28]. For median graphs, the equivalence relation Θ can be defined as follows. First say that two edges uv and xy are in relation Θ_0 if they are either equal or opposite edges of a 4-cycle $uvxy$ in G. Then let Θ be the transitive closure of Θ_0. We denote by $\{\Theta_i : i \in I\}$ the equivalence classes of the relation Θ (in [5], they were called parallelism classes). Each equivalence class $\Theta_i, i \in I$, is a cutset of G: namely, it splits $V(G)$ in two convex subgraphs A_i, B_i of G (A subgraph H of G is *convex* if for all $u, v \in V(H)$, $I(u, v) \subseteq V(H)$). The equivalence relation Θ is fundamental in the bijection between event structures and median graphs:

▶ **Theorem 6** ([5]). *The Hasse diagram of the domain $(\mathcal{D}(\mathcal{E}), \subseteq)$ of any event structure $\mathcal{E} = (E, \leq, \#)$ is a median graph. Conversely, for any median graph G and any basepoint v of G, the pointed median graph G_v is isomorphic to the Hasse diagram of the domain of an event structure.*

In the construction of an event structure $\mathcal{E}_v$ from a median graph G pointed at a vertex v, the events $e_i, i \in I$ of $\mathcal{E}_v$ correspond to the equivalence classes $\Theta_i, i \in I$ of Θ. Two classes Θ_i and Θ_j define concurrent events if and only if they cross, i.e., there exists a square $uvxy$ where $uv, xy \in \Theta_i$ and $uy, vx \in \Theta_j$. For two events e_i, e_j, we have $e_i \prec e_j$ if and only if the cutset Θ_i separates v from the edges of Θ_j. Finally, two events e_i, e_j are in conflict if and only if Θ_i and Θ_j do not cross and neither separates the other from v.

A *cube complex* is a cell complex X whose cells are unit Euclidean cubes of various dimensions such that any two intersecting cubes of X intersect in a common face. The 0-cubes and the 1-cubes of X are called *vertices* and *edges* of X and define the graph $X^{(1)}$, the 1-*skeleton* of X. The *star* $\mathrm{St}(v, X)$ of a vertex v of X is the subcomplex spanned by all cubes containing v. A cube complex X is *simply connected* if every cycle C of its 1-skeleton is null-homotopic, i.e., it can be contracted to a single point by elementary homotopies. Given two cube complexes X and Y, a *covering (map)* is a surjection $p\colon Y \to X$ mapping cubes to cubes and such that $p|_{\mathrm{St}(v,Y)}\colon \mathrm{St}(v, Y) \to \mathrm{St}(p(v), X)$ is an isomorphism for every vertex v in Y. The space Y is then called a *covering space* of X. A *universal cover* of X is a simply connected covering space; it always exists and it is unique up to isomorphism [13, Sections 1.3 and 4.1]. The universal cover of a complex X will be denoted by $\widetilde{X}$. In particular, if X is simply connected, then its universal cover $\widetilde{X}$ is X itself.

An important class of cube complexes studied in geometric group theory and combinatorics is the class of CAT(0) cube complexes. In this case, being CAT(0) is equivalent to the unicity of geodesics in the ℓ_2 metric; see [7] for this and other properties of CAT(0) spaces. Gromov [12] gave a beautiful combinatorial characterization of CAT(0) cube complexes as

simply connected cube complexes satisfying the following condition: *if three $(k+2)$-cubes pairwise intersect in a $(k+1)$-cube and all three intersect in a k-cube, then they are included in a $(k+3)$-cube.* A cube complex X satisfying this combinatorial condition is called a *nonpositively curved (NPC)* complex. As a corollary of Gromov's result, for any NPC complex X, its universal cover $\widetilde{X}$ is CAT(0).

There is a well-known bijection between median graphs and CAT(0) cube complexes [9, 21]. Each median graph G gives rise to a cube complex $X(G)$ obtained by replacing all hypercubes of G by Euclidean unit cubes. Endowed with the intrisic ℓ_2-metric, $X(G)$ is a CAT(0) space. Conversely, the 1-skeleton of any CAT(0) cube complex is a median graph. In fact, a graph G is median if and only if its cube complex is simply connected and G satisfies the 3-cube condition [9]: *if three squares of G pairwise intersect in an edge and all three intersect in a vertex, then they belong to a 3-cube.*

This link between event domains, median graphs, and CAT(0) cube complexes allows a more geometric and combinatorial approach to several questions on event structures (and to work only with CAT(0) cube complexes viewed as event domains). For example, this allowed [10] to disprove the so-called *nice labeling conjecture* of Rozoy and Thiagarajan [22] asserting that any event structure of finite degree admits a finite nice labeling.

4 Directed NPC Complexes

Since we can define event structures from their domains, universal covers of NPC complexes represent a rich source of event structures. To obtain regular event structures, it is natural to consider universal covers of finite NPC complexes. Moreover, since domains of event structures are directed, it is natural to consider universal covers of NPC complexes whose edges are directed. However, the resulting directed universal covers are not in general domains of event structures. In particular, the domains corresponding to pointed median graphs given by Theorem 6 cannot be obtained in this way. In order to overcome this difficulty, we introduce directed median graphs and directed NPC complexes. Using these notions, one can naturally define regular event structures starting from finite directed NPC complexes.

A *directed median graph* is a pair (G, o), where G is a median graph and o is an orientation of the edges of G in a such a way that opposite edges of squares of G have the same direction. By transitivity of Θ, all edges from the same parallelism class Θ_i of G have the same direction. Since each Θ_i partitions G into two parts, o defines a partial order $\prec_o$ on the vertex-set of G. For a vertex v of G, let $\mathcal{F}_o(v, G) = \{x \in V : v \prec_o x\}$ be the principal filter of v in the partial order $(V(G), \prec_o)$.

The following lemma shows that choosing an arbitrary vertex in a directed median graph as a basepoint, one can define the domain of an event structure.

▶ **Lemma 7.** *For any vertex v of a directed median graph (G, o), the following holds:*

1. *$\mathcal{F}_o(v, G)$ induces a convex subgraph of G;*
2. *the restriction of the partial order $\prec_o$ on $\mathcal{F}_o(v, G)$ coincides with the restriction of the canonical basepoint order $\leq_v$ on $\mathcal{F}_o(v, G)$;*
3. *$\mathcal{F}_o(v, G)$ with $\prec_o$ is the domain of an event structure;*
4. *for any vertex $u \in \mathcal{F}_o(v, G)$, the principal filter $\mathcal{F}_o(u, G)$ is included in $\mathcal{F}_o(v, G)$ and $\mathcal{F}_o(u, G)$ coincides with the principal filter of u with respect to the canonical basepoint order $\leq_v$ on $\mathcal{F}_o(v, G)$.*

A *directed NPC complex* is a pair (Y, o), where Y is a NPC complex and o is an orientation of the edges of Y in a such a way that the opposite edges of the same square of Y have the

same direction. The orientation o of the edges of Y induces in a natural way an orientation $\tilde{o}$ of the edges of its universal cover $\widetilde{Y}$, so that $(\widetilde{Y}, \tilde{o})$ is a directed NPC complex and $(\widetilde{Y}^{(1)}, \tilde{o})$ is a directed median graph. We now formulate the crucial regularity property of directed median graphs $(\widetilde{Y}^{(1)}, \tilde{o})$ when (Y, o) is finite.

▶ **Lemma 8.** *If (Y, o) is a finite directed NPC complex, then $(\widetilde{Y}^{(1)}, \tilde{o})$ is a directed median graph with at most $|V(Y)|$ isomorphism types of principal filters.*

Combining Lemmas 7 and 8, we obtain the following result.

▶ **Proposition 9.** *Let (Y, o) be a finite directed NPC complex. Then for any vertex $\tilde{v}$ of the universal cover $\widetilde{Y}$ of Y, the principal filter $\mathcal{F}_{\tilde{o}}(\tilde{v}, \widetilde{Y}^{(1)})$ with the partial order $\prec_{\tilde{o}}$ is the domain of a regular event structure with at most $|V(Y)|$ different isomorphism types of futures.*

A *square complex* X is a combinatorial 2-complex whose 2-cells are attached by closed combinatorial paths of length 4. Thus, one can consider each 2-cell as a square attached to the 1-skeleton $X^{(1)}$ of X. A square complex X is a VH*-complex* (*vertical-horizontal complex*) if the 1-cells (edges) of X are partitioned into two sets V and H called *vertical* and *horizontal* edges respectively, and the edges in each square alternate between edges in V and H. Notice that if X is a VH-complex, then X satisfies the Gromov's nonpositive curvature condition since no three squares may pairwise intersect on three edges with a common vertex. A VH-complex X is a *complete square complex* (CSC) [32] if any vertical edge and any horizontal edge incident to a common vertex belong to a common square of X. By [32, Theorem 3.8], if X is a complete square complex, then the universal cover $\widetilde{X}$ of X is isomorphic to the Cartesian product of two trees. By a *plane* Π in $\widetilde{X}$ we will mean a convex subcomplex of $\widetilde{X}$ isometric to $\mathbb{R}^2$ tiled by the grid $\mathbb{Z}^2$ into unit squares.

5 Wise's event domain $\widetilde{W_{\tilde{v}}}$

In this section, we construct the domain $\widetilde{W_{\tilde{v}}}$ of a regular event structure (with bounded $\natural$-cliques) that does not admit a regular nice labelling. To do so, we start with a directed colored CSC $\mathbf{X}$ introduced by Wise [32]. In the following, we consider directed colored VH-complexes, in which each edge has an orientation and a color. Such complexes will be denoted by bold letters, like $\mathbf{X}$. Sometimes, we need to forget the colors and the orientations of the edges of these complexes. For a complex $\mathbf{X}$, we denote by X the complex obtained by forgetting the colors and the orientations of the edges of $\mathbf{X}$ (X is called the *support* of $\mathbf{X}$), and we denote by (X, o) the directed complex obtained by forgetting the colors of $\mathbf{X}$.

5.1 Wise's square complex $\mathbf{X}$ and its universal cover $\widetilde{\mathbf{X}}$

The complex $\mathbf{X}$ consists of six squares as indicated in Figure 1 (reproducing Figure 3 of [32]). Each square has two vertical and two horizontal edges. The horizontal edges are oriented from left to right and vertical edges from bottom to top. Denote this orientation of edges by o. The vertical edges of squares are colored white, grey, and black and denoted a, b, and c, respectively. The horizontal edges of squares are colored by single or double arrow, and denoted x and y, respectively. The six squares are glued together by identifying edges of the same color and respecting the directions to obtain the square complex $\mathbf{X}$. Note that $\mathbf{X}$ has a unique vertex, five edges, and six squares. It can be directly checked that $\mathbf{X}$ is a complete square complex, and consequently (X, o) is a directed NPC complex. Let H_X denote the subcomplex of X consisting of the 2 horizontal edges and let V_X denote the subcomplex of X consisting of the 3 vertical edges.

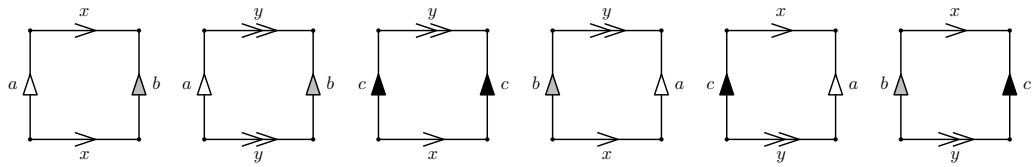

Figure 1 The 6 squares defining the complex $\mathbf{X}$.

The universal cover $\widetilde{H_X}$ of H_X is the 4-regular infinite tree F_4. Its edges inherit the orientations from their images in H_X: each vertex of $\widetilde{H_X}$ has two incoming and two outgoing arcs. Analogously, the universal cover $\widetilde{H_V}$ of H_V is the 6-regular infinite tree F_6 where each vertex has three incoming and three outgoing arcs. Let $\tilde{v}_1$ be any vertex of $\widetilde{H_X}$. Then the principal filter of $\tilde{v}_1$ is the infinite binary tree T_2 rooted at $\tilde{v}_1$: all its vertices except $\tilde{v}_1$ have one incoming and two outgoing arcs, while $\tilde{v}_1$ has two outgoing arcs and no incoming arc. Analogously, the principal filter of any vertex $\tilde{v}_2$ in the ordered set $\widetilde{H_V}$ is the infinite ternary tree T_3 rooted at $\tilde{v}_2$.

Let $\widetilde{\mathbf{X}}$ be the universal cover of $\mathbf{X}$ and let $p : \widetilde{\mathbf{X}} \to \mathbf{X}$ be a covering map. Let $\widetilde{X}$ denote the support of $\widetilde{\mathbf{X}}$. Since $\mathbf{X}$ is a CSC, by [32, Theorem 3.8], $\widetilde{X}$ is the Cartesian product $F_4 \times F_6$ of the trees F_4 and F_6. The edges of $\widetilde{\mathbf{X}}$ are colored and oriented as their images in $\mathbf{X}$, and are also classified as horizontal or vertical edges. The squares of $\widetilde{\mathbf{X}}$ are oriented as their images in $\mathbf{X}$, thus two opposite edges of the same square of $\widetilde{\mathbf{X}}$ have the same direction. This implies that all classes of parallel edges of $\widetilde{\mathbf{X}}$ are oriented in the same direction. Denote this orientation of the edges of $\widetilde{\mathbf{X}}$ by $\tilde{o}$. The 1-skeleton $\widetilde{X}^{(1)}$ of $\widetilde{X}$ together with $\tilde{o}$ is a directed median graph. Let $\tilde{v} = (\tilde{v}_1, \tilde{v}_2)$ be any vertex of $\widetilde{X}$, where $\tilde{v}_1$ and $\tilde{v}_2$ are the coordinates of $\tilde{v}$ in the trees F_4 and F_6. Then the principal filter $\mathcal{F}_{\tilde{o}}(\tilde{v}, \widetilde{X}^{(1)})$ of $\tilde{v}$ is the Cartesian product of the principal filters of $\tilde{v}_1$ in F_4 and of $\tilde{v}_2$ in F_6, i.e., is isomorphic to $T_2 \times T_3$.

By Lemma 7, the orientation of the edges of $\mathcal{F}_{\tilde{o}}(\tilde{v}, \widetilde{X}^{(1)})$ corresponds to the canonical basepoint orientation of $\mathcal{F}_{\tilde{o}}(\tilde{v}, \widetilde{X}^{(1)})$ with $\tilde{v}$ as the basepoint. Moreover, by Proposition 9, $\mathcal{F}_{\tilde{o}}(\tilde{v}, \widetilde{X}^{(1)})$ is the domain of a regular event structure with one isomorphism type of futures.

5.2 Aperiodicity of $\widetilde{\mathbf{X}}$

We recall here the main properties of $\widetilde{\mathbf{X}}$ established in [32, Section 5]. Let $\tilde{v} = (\tilde{v}_1, \tilde{v}_2)$ be an arbitrary vertex of $\widetilde{\mathbf{X}}$, where $\tilde{v}_1$ and $\tilde{v}_2$ are defined as before. From the definition of the covering map, the loop of $\mathbf{X}$ colored y gives rise to a bi-infinite horizontal path P_y of $\widetilde{\mathbf{X}}^{(1)}$ passing via $\tilde{v}$ and whose all edges are colored y and are directed from left to right. Analogously, there exists a bi-infinite vertical path P_c of $\widetilde{\mathbf{X}}^{(1)}$ passing via $\tilde{v}$ and whose all edges are colored c and are directed from bottom to top.

The projection of P_y on the horizontal factor F_4 is a bi-infinite path P^h of F_4 passing via $\tilde{v}_1$. Analogously, the projection of P_c on the vertical factor F_6 is a bi-infinite path P^v of F_6 passing via $\tilde{v}_2$. Consequently, the convex hull $\mathrm{conv}(P_y \cup P_c)$ of $P_y \cup P_c$ in the graph $\widetilde{\mathbf{X}}^{(1)}$ is isomorphic to the Cartesian product of $P^h \times P^v$ of the paths P^h and P^v. Therefore the subcomplex of $\widetilde{\mathbf{X}}$ spanned by $\mathrm{conv}(P_y \cup P_c)$ is a plane Π_{yc} tiled into squares (recall that each square is of one of 6 types and its sides are colored by the letters a, b, c, x, y), see Figure 2.

In our counterexample we will use the following result of [32] that was used to show that the plane Π_{yc} is not tiled periodically by the preimages of the squares of $\mathbf{X}$. Denote by P_y^+ the (directed) subpath of P_y having $\tilde{v}$ as the origin (this is a one-infinite horizontal path). Analogously, let P_c^+ be the (vertical) subpath of P_c having $\tilde{v}$ as the origin. The convex hull of $P_y^+ \cup P_c^+$ is a quarter of the plane Π_{yc}, which we denote by Π_{yc}^{++}. Any shortest path in

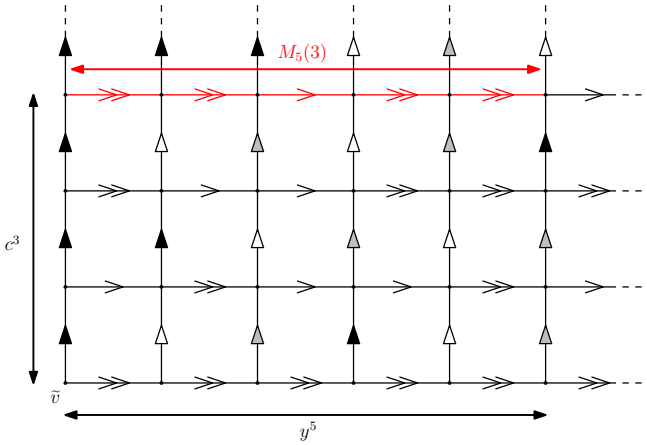

Figure 2 Part of the plane Π_{yc}^{++} appearing in $\widetilde{\mathbf{X}}$.

$\widetilde{\mathbf{X}}^{(1)}$ from $\tilde{v}$ to a vertex $\tilde{u} \in \Pi_{yc}^{++}$ can be viewed as a word in the alphabet $A = \{a, b, c, x, y\}$. For an integer $n \geq 0$, denote by y^n the horizontal subpath of P_y^+ beginning at $\tilde{v}$ and having length n. Analogously, for an integer $m \geq 0$, denote by c^m the vertical subpath of P_c^+ beginning at $\tilde{v}$ and having length m. Let $M_n(m)$ denote the horizontal path of Π_{yc}^{++} of length n beginning at the endpoint of the vertical path c^m. $M_n(m)$ determines a word which is the label of the side opposite to y^n in the rectangle which is the convex hull of y^n and c^m (see Figure 2). Let $M_n(m)$ also denote this corresponding word.

▶ **Proposition 10** ([32, Proposition 5.9]). *For each n, the words $\{M_n(m) : 0 \leq m \leq 2^n - 1\}$ are all distinct, and thus, every positive word in x and y of length n is $M_n(m)$ for some m.*

5.3 The square complex W and its universal cover $\widetilde{W}$

Let $\beta\mathbf{X}$ denote the first barycentric subdivision of $\mathbf{X}$: each square C of $\mathbf{X}$ is subdivided into four squares C_1, C_2, C_3, C_4 by adding a middle vertex to each edge of C and connecting it to the center of C by an edge. This way each edge e of C is subdivided into two edges e_1, e_2, which inherit the orientation and the color of e. The four edges connecting the middle vertices of the edges of C to the center of C are oriented from left to right and from bottom to top (see the middle figure of Figure 3). Denote the resulting orientation by o'. This way, $(\beta\mathbf{X}, o')$ is a directed and colored square complex. Again, denote by βX the support of $\beta\mathbf{X}$. The universal cover $\widetilde{\beta X}$ of βX is the Cartesian product $\beta F_4 \times \beta F_6$ of the trees βF_4 and βF_6, where βF_4 is the first barycentric subdivision of F_4 and βF_6 is the first barycentric subdivision of F_6. Additionally, $(\widetilde{\beta X}, \tilde{o}')$ is a directed CAT(0) square complex. We assign a *type* to each vertex of $\widetilde{\beta\mathbf{X}}$: the preimage of the unique vertex of $\mathbf{X}$ is of type 0 and is called a 0-*vertex*, the preimages of the middles of edges of $\mathbf{X}$ are of type 1 and are called 1-*vertices*, and the preimages of centers of squares of $\mathbf{X}$ are of type 2 and are called 2-*vertices*.

To encode the colors of the edges of $\mathbf{X}$, we introduce our central object, the square complex W (whose edges are no longer colored). Let $A = \{a, b, c, x, y\}$ and let $r : A \to \{1, 2, 3, 4, 5\}$ be a bijective map. The complex W is obtained from βX by adding to each 1-vertex z of βX a path R_z of length $r(\alpha)$ if z is the middle of an edge colored $\alpha \in A$ in $\mathbf{X}$. The path R_z has one end at z (called the *root* of R_z) and z is the unique common vertex of R_z and βX (we call such added paths R_z *tips*). Denote by o^* the orientation of the edges of W defined as follows: the edges of βX are oriented as in $(\beta X, o)$ and the edges of tips are oriented away

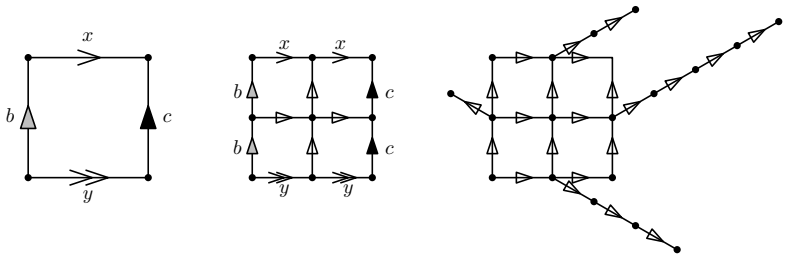

Figure 3 A square of $\mathbf{X}$ and the corresponding subcomplexes in $(\beta\mathbf{X}, o')$ and (W, o^*).

from their roots (see the rightmost figure of Figure 3 for the encoding of the last square of Figure 1). As a result, we obtain a finite directed NPC square complex (W, o^*).

Consider the universal cover $\widetilde{W}$ of W. It can be viewed as the complex $\widetilde{\beta X}$ with a path of length $r(\alpha)$ added to each 1-vertex which encodes an edge of $\widetilde{\mathbf{X}}$ of color $\alpha \in A$. We say that the vertices of $\widetilde{W}$ lying only on tips are of type 3 and they are called 3-*vertices*. Let $\tilde{o}^*$ denote the orientation of the edges of $\widetilde{W}$ induced by the orientation o^* of W. Then $(\widetilde{W}, \tilde{o}^*)$ is a directed CAT(0) square complex. Since W is finite, the directed median graph $(\widetilde{W}^{(1)}, \tilde{o}^*)$ has a finite number of isomorphisms types of principal filters $\mathcal{F}_{\tilde{o}^*}(\tilde{z}, \widetilde{W}^{(1)})$.

Let $\tilde{v}$ be any 0-vertex of $\widetilde{W}$. Denote by $\widetilde{W}_{\tilde{v}}$ the principal filter $\mathcal{F}_{\tilde{o}^*}(\tilde{v}, \widetilde{W}^{(1)})$ of vertex $\tilde{v}$ in $(\widetilde{W}^{(1)}, \prec_{\tilde{o}^*})$. By Proposition 9, $\widetilde{W}_{\tilde{v}}$ together with the partial order $\prec_{\tilde{o}^*}$ is the domain of a regular event structure, which we call *Wise's event domain*. Since vertices of different types of $\widetilde{W}$ are incident to a different number of outgoing squares, any isomorphism between two filters of $(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ preserves the types of vertices. We summarize all this in the following:

▶ **Proposition 11.** *$(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ is the domain of a regular event structure. Any isomorphism between any two filters of $(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ preserves the types of vertices.*

5.4 $(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ does not have a regular nice labeling

In this subsection we prove that the event structure associated to Wise's event domain is a counterexample to Thiagarajan's conjecture (Theorem 12) and to the conjecture of Badouel et al. [2] (Theorem 12 and Proposition 13).

▶ **Theorem 12.** *$(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ does not admit a regular nice labeling.*

Proof. Since $\widetilde{W}_{\tilde{v}}$ is the principal filter of a 0-vertex $\tilde{v}$, $\widetilde{W}_{\tilde{v}}$ contains all vertices of $\widetilde{\mathbf{X}}$ located in the quarter of plane Π^{++}_{yc} of $\widetilde{\mathbf{X}}$, in particular it contains the vertices of the paths P^+_c and P^+_y. Notice also that $\widetilde{W}_{\tilde{v}}$ contains the barycenters and the tips corresponding to the edges of Π^{++}_{yc}. Suppose by way of contradiction that $\widetilde{W}_{\tilde{v}}$ has a regular nice labeling λ. Since $\widetilde{W}_{\tilde{v}}$ has only a finite number of isomorphism types of labeled filters, the vertical path P^+_c contains two 0-vertices, $\tilde{z}'$ and $\tilde{z}''$, which have isomorphic labeled principal filters. Let $\tilde{z}'$ be the end of the vertical subpath c^k of P^+_c and $\tilde{z}''$ be the end of the vertical subpath c^m of P^+_c, and suppose without loss of generality that $k < m$. Let $n > 0$ be a positive integer such that $m \leq 2^n - 1$. Consider the horizontal convex paths $M_n(k)$ and $M_n(m)$ of Π^{++}_{yc} of length n beginning at the vertices $\tilde{z}'$ and $\tilde{z}''$, respectively. For any $0 \leq i \leq n$, denote by $\tilde{z}_{k,i}$ the ith vertex of $M_n(k)$ (in particular, $\tilde{z}_{k,0} = \tilde{z}'$). Analogously, denote by $\tilde{z}_{m,i}$ the ith vertex of $M_n(m)$ (in particular, $\tilde{z}_{m,0} = \tilde{z}''$). In $\widetilde{W}_{\tilde{v}}$, the paths $M_n(k)$ and $M_n(m)$ give rise to two convex horizontal paths $M^*_n(k)$ and $M^*_n(m)$ obtained from $M_n(k)$ and $M_n(m)$ by subdividing their edges. Denote by $\tilde{u}_{k,i}$ the unique common neighbor of $\tilde{z}_{k,i}$ and $\tilde{z}_{k,i+1}$, $0 \leq i < n$, in

$M_n^*(k)$ (and in $\widetilde{W}^{(1)}$). Analogously, denote by $\tilde{u}_{m,i}$ the unique common neighbor of $\tilde{z}_{m,i}$ and $\tilde{z}_{m,i+1}$, $0 \leq i < n$. The paths $M_n^*(k)$ and $M_n^*(m)$ belong to the principal filters $\mathcal{F}_{\tilde{o}^*}(\tilde{z}', \widetilde{W}^{(1)})$ and $\mathcal{F}_{\tilde{o}^*}(\tilde{z}'', \widetilde{W}^{(1)})$, respectively.

By Proposition 10, the words $M_n(k)$ and $M_n(m)$ are different. Let f be an isomorphism between the filters $\mathcal{F}_{\tilde{o}^*}(\tilde{z}_{k,0}, \widetilde{W}^{(1)})$ and $\mathcal{F}_{\tilde{o}^*}(\tilde{z}_{m,0}, \widetilde{W}^{(1)})$. Since the words $M_n(k)$ and $M_n(m)$ are different, from the choice of the lengths of tips in the complexes W and $\widetilde{W}$ it follows that f cannot map the path $M_n^*(k)$ to the path $M_n^*(m)$ by a vertical translation, i.e., there exists an index $0 \leq j < n$ such that $f(\tilde{z}_{k,j+1}) \neq \tilde{z}_{m,j+1}$; let i be the smallest such index. Set $\tilde{z} := f(\tilde{z}_{k,i+1})$ and $\tilde{u} := f(\tilde{u}_{k,i})$. Since f preserves the types of vertices, $\tilde{z}$ is a 0-vertex and $\tilde{u}$ is a 1-vertex. Since f maps a convex path $M_n^*(k)$ to a convex path, $\tilde{u}$ is the unique common neighbor of $\tilde{z}_{m,i}$ and $\tilde{z}$. Since each 1-vertex is the barycenter of a unique edge of $\widetilde{\mathbf{X}}$ and $\tilde{z} \neq \tilde{z}_{m,i+1}$, we deduce that $\tilde{u} \neq \tilde{u}_{m,i}$. The edge $\tilde{z}_{k,i}\tilde{u}_{k,i}$ is directed from $\tilde{z}_{k,i}$ to $\tilde{u}_{k,i}$. Analogously the edges $\tilde{z}_{m,i}\tilde{u}_{m,i}$ and $\tilde{z}_{m,i}\tilde{u}$ are directed from $\tilde{z}_{m,i}$ to $\tilde{u}_{m,i}$ and $\tilde{u}$, respectively. Since $\tilde{z}_{k,i}\tilde{u}_{k,i}$ and $\tilde{z}_{m,i}\tilde{u}_{m,i}$ are parallel edges, they define the same event and therefore $\lambda(\tilde{z}_{k,i}\tilde{u}_{k,i}) = \lambda(\tilde{z}_{m,i}\tilde{u}_{m,i})$. On the other hand, since f maps the edge $\tilde{z}_{k,i}\tilde{u}_{k,i}$ to the edge $\tilde{z}_{m,i}\tilde{u}$ and the map f preserves the labels, we have $\lambda(\tilde{z}_{k,i}\tilde{u}_{k,i}) = \lambda(\tilde{z}_{m,i}\tilde{u})$. As a result, $\tilde{z}_{m,i}$ has two outgoing edges, $\tilde{z}_{m,i}\tilde{u}_{m,i}$ and $\tilde{z}_{m,i}\tilde{u}$, having the same label, contrary to the assumption that λ is a nice labeling. This contradiction shows that $(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ does not admit a regular nice labeling. This concludes the proof of the theorem. ◀

▶ **Proposition 13.** *Wise's event domain $(\widetilde{W}_{\tilde{v}}, \prec_{\tilde{o}^*})$ has bounded $\natural$-cliques.*

6 Conclusions and open questions

In this paper, we presented an example of a regular event domain $\widetilde{W}_{\tilde{v}}$ with bounded degree and bounded $\natural$-cliques which does not admit a regular nice labeling. Consequently, the domain $\widetilde{W}_{\tilde{v}}$ is not recognizable and the prime event structure whose domain is $\widetilde{W}_{\tilde{v}}$ is not a regular trace event structure. This provides a counterexample to Conjecture 1 of Thiagarajan and Conjecture 2 of Badouel, Darondeau, and Raoult.

The event domain $\widetilde{W}_{\tilde{v}}$ is a 2-dimensional CAT(0) cube complex. The proof that our example $\widetilde{W}_{\tilde{v}}$ does not admit a regular nice labeling strongly uses the fact that the universal cover $\widetilde{\mathbf{X}}$ of Wise's complex $\mathbf{X}$ [32] contains a particular aperiodic tiled plane (that is called *antitorus* by Wise). We think that the relationship between the existence of aperiodic planes and nonexistence of regular labelings is more general. As observed by Kari and Papasoglu [14], any *4-way deterministic* tile-set gives rise to a CAT(0) VH-complex that is the universal cover of a finite NPC complex. In [14], they presented a 4-way deterministic aperiodic tile-set T_{KP}, i.e., all tilings of $\mathbb{R}^2$ using tiles from T_{KP} are aperiodic. Based on this result, Lukkarila [15] proved that for 4-way deterministic tile-sets the tiling problem is undecidable. We conjecture that one can use this result to show that *deciding if a regular event domain admits a regular nice labeling is undecidable*. As a first step in this direction, our proof can be adapted to show that any 4-way deterministic aperiodic tile-set T (in particular, T_{KP}) also provides a counterexample to Conjectures 1 and 2.

Even if Conjecture 1 does not hold in general, it would be interesting to exhibit classes of event structures for which this conjecture is true. Badouel et al. [2] showed that both conjectures hold for context-free domains. Context-free graphs are particular Gromov-hyperbolic graphs. An interesting challenge would be to *establish Conjecture 1 for Gromov-hyperbolic domains*. A positive answer would settle the previous undecidability question. As we noticed already, Conjecture 1 was positively solved by Nielsen and Thiagarajan [20] for conflict-free event structures. A possible way to extend their result is to *consider this*

conjecture for confusion-free domains introduced by Nielsen et al. [18]. From geometric and combinatorial points of view, context-free and conflict-free domains have quite different structural properties and give rise to different kinds of CAT(0) cube complexes. For instance, in context-free domains (and more generally, hyperbolic domains), isometric square-grids are bounded while conflict-free domains can contain arbitrarily large square-grids.

Abstract

Recent developments in formal verification have identified *approximate liftings* (also known as *approximate couplings*) as a clean, compositional abstraction for proving differential privacy. There are two styles of definitions for this construction. Earlier definitions require the existence of one or more witness distributions, while a recent definition by Sato uses universal quantification over all sets of samples. These notions have different strengths and weaknesses: the universal version is more general than the existential ones, but the existential versions enjoy more precise composition principles.

We propose a novel, existential version of approximate lifting, called ⋆-*lifting*, and show that it is equivalent to Sato's construction for discrete probability measures. Our work unifies all known notions of approximate lifting, giving cleaner properties, more general constructions, and more precise composition theorems for both styles of lifting, enabling richer proofs of differential privacy. We also clarify the relation between existing definitions of approximate lifting, and generalize our constructions to approximate liftings based on f-divergences.

1 Introduction

Differential privacy [7] is a rigorous notion of statistical privacy that delivers strong individual guarantees for privacy-preserving computations. Informally, differential privacy guarantees to every individual that their (non)-participation in a database will have a small (in a rigorous, quantitative sense) effect on the results obtained by third parties when querying the database. The formal definition of differential privacy is parametrized by two non-negative real numbers, (ϵ, δ). These parameters quantify the effect of individuals on the output of the private query;

smaller values give stronger privacy guarantees. The main strengths of differential privacy lie in its theoretical elegance, minimal assumptions, and flexibility for many applications.

Motivated by the importance of differential privacy, programming language researchers have developed approaches based on dynamic analysis, type systems, and program logics for formally proving differential privacy for programs. (We refer the interested reader to a recent survey [4] for an overview of this growing field.) In this paper, we consider approaches based on relational program logics [5, 6, 10, 2, 3, 11]. To capture the quantitative nature of differential privacy, these systems rely on a quantitative generalization of probabilistic couplings (see, e.g., [9, 13, 14]), called *approximate liftings* or (ϵ, δ)-liftings. Existing works have considered several potential definitions. While all definitions support compositional reasoning and enable program logics that can verify complex examples from the privacy literature, the various notions of approximate liftings have different strengths and weaknesses.

Broadly speaking, one class of definitions require the existence of one or two *witness distributions* that "couple' the two executions of programs. The earliest definition [5] supports accuracy-based reasoning for the Laplace mechanism, while subsequent definitions [6, 10] support more precise composition principles from differential privacy and can be generalized to other notions of distance on distributions. These definitions, and their associated program logics, were designed for discrete distributions.

In the course of extending these ideas to continuous distributions, Sato [11] proposes a radically different notion of approximate lifting, which does not rely on witness distributions. Instead, it uses a universal quantification over all sets of samples. Sato shows that this definition is strictly more general than the existential versions, but it is unclear (a) whether the gap can be closed and (b) whether his construction satisfies the same composition principles enjoyed by some existential definitions.

As a consequence, there is currently no single approximate lifting with the properties needed to support all existing formalized proofs of differential privacy. Furthermore, some of the most involved privacy proofs cannot be formalized at all, as their proofs require a combination of tools from several kinds of approximate liftings.

Outline of the paper

After reviewing the necessary mathematical preliminaries in Section 2, we introduce our main technical contribution: a new, existential definition of approximate lifting. This construction, which we call ⋆-*lifting*, is a generalization of an existing definition by Barthe and Olmedo [6, 10]. The key idea is to allow the witness distributions to have a larger domain, broadening the class of approximate liftings. By a maximum flow/minimum cut argument, we show that ⋆-liftings are equivalent to Sato's lifting over discrete distributions. This equivalence can be viewed as an approximate version of Strassen's theorem [12], a classical result in probability theory describing the existence of probabilistic couplings. We present the definition of ⋆-lifting and the proof of equivalence in Section 3.

Then, we show that ⋆-liftings satisfy desirable theoretical properties. We are able to leverage the equivalence of liftings in two ways. In one direction, Sato's definition gives simpler proofs of more general properties of ⋆-liftings. In the other direction, ⋆-liftings – like other existential definitions – can smoothly incorporate composition principles from the theory of differential privacy. Our connection shows that Sato's definition can use these principles in the discrete case. We describe the key theoretical properties of ⋆-liftings in Section 4.

Finally, we provide a thorough comparison of ⋆-lifting with existing definitions of approximate lifting in Section 5, and describe how to construct ⋆-liftings for more general version of approximate liftings based on f-divergences in Section 6.

Overall, the equivalence of $\star$-liftings and Sato's lifting, along with the natural theoretical properties satisfied by the common notion, suggest that these definitions are two views on the same concept: an approximate version of probabilistic coupling.

2 Background

To model probabilistic behavior, we work with *discrete sub-distributions*.

▶ **Definition 1.** A *sub-distribution* over a set A is defined by its mass function $\mu : A \to \mathbb{R}^+$, which gives the probability of the singleton events $a \in A$. This mass function must be s.t. $|\mu| \triangleq \sum_{a \in A} \mu(a)$ is well-defined and at most 1. In particular, the *support* $\mathrm{supp}(\mu) \triangleq \{a \in A \mid \mu(a) \neq 0\}$ must be discrete (i.e. finite or countably infinite). When the *weight* $|\mu|$ is equal to 1, we call μ a *(proper) distribution*. We let $\mathbb{D}(A)$ denote the set of sub-distributions over A. The probability of an event $E(x)$ w.r.t. μ, written $\mathbb{P}_{x\sim\mu}[E(x)]$ or $\mathbb{P}_{\mu}[E]$, is defined as $\sum_{x \in A \mid E(x)} \mu(x)$.

Simple examples of sub-distributions include the *null sub-distribution* $\mathbb{0}^A \in \mathbb{D}(A)$, which maps each element of A to 0, and the *Dirac distribution centered on* x, written $\mathbb{1}_x$, which maps x to 1 and all other elements to 0. One can equip distributions with a monadic structure using the Dirac distributions $\mathbb{1}_x$ for the unit and *distribution expectation* $\mathbb{E}_{x\sim\mu}[f(x)]$ for the bind; if μ is a distribution over A and f has type $A \to \mathbb{D}(B)$, then the bind defines a sub-distribution over B: $\mathbb{E}_{a\sim\mu}[f(a)] : b \mapsto \sum_a \mu(a) \cdot f(a)(b)$.

If $f : A \to B$, we can lift f to a function $f^\sharp : \mathbb{D}(A) \to \mathbb{D}(B)$ as follows: $f^\sharp(\mu) \triangleq \mathbb{E}_{a\sim\mu}[\mathbb{1}_{f(a)}]$ – or, equivalently, $f^\sharp(\mu) : b \mapsto \mathbb{P}_{a\sim\mu}[a \in f^{-1}(b)]$. For instance, when working with sub-distributions over pairs, this allows to obtain the probabilistic versions $\pi_1^\sharp$ and $\pi_2^\sharp$ (called *marginals*) of the usual projections π_1 and π_2. One can check that the *first* and *second marginals* $\pi_1^\sharp(\mu)$ and $\pi_2^\sharp(\mu)$ of a distribution μ over $A \times B$ are also given by the following equations: $\pi_1^\sharp(\mu)(a) = \sum_{b \in B} \mu(a, b)$ and $\pi_2^\sharp(\mu)(b) = \sum_{a \in A} \mu(a, b)$. When $f : A \to \mathbb{D}(B)$, we will abuse notation and write the lifting $f^\sharp : \mathbb{D}(A) \to \mathbb{D}(B)$ to mean $f^\sharp(\mu) \triangleq \mathbb{E}_{x\sim\mu}[f(x)]$.

Finally, if $\alpha : A \to \mathbb{R}^+$, we write $\alpha[X] \in \mathbb{R}^+ \cup \{\infty\}$ for $\sum_{x \in X} \alpha(x)$. Moreover, if $\alpha : A \times B \to \mathbb{R}^+$, we write $\alpha[X, Y]$ (resp. $\alpha[x, Y]$, $\alpha[X, y]$) for $\alpha[X \times Y]$ (resp. $\alpha[\{x\} \times Y$, $\alpha[X \times \{y\}]$). Note that for a sub-distribution $\mu \in \mathbb{D}(A)$ and an event $E \subseteq A$, $\mathbb{P}_\mu[E] = \mu[E]$.

We now review the definition of differential privacy.

▶ **Definition 2** (Dwork et al. [7])**.** A probabilistic computation $M : A \to \mathbb{D}(B)$ satisfies (ϵ, δ)-*differential privacy* w.r.t. an adjacency relation $\phi \subseteq A \times A$ iff for every pair of inputs $a, a' \in A$ such that $a \; \phi \; a'$ and every subset of outputs $E \subseteq B$,

$$\mathbb{P}_{M(a)}[E] \leq e^\epsilon \cdot \mathbb{P}_{M(a')}[E] + \delta.$$

It is useful to define a notion of distance on distributions, reflecting differential privacy.

▶ **Definition 3** (Barthe and Olmedo [5], Barthe et al. [6], Olmedo [10])**.** Let $\epsilon \geq 0$. The ϵ-*DP divergence* $\Delta_\epsilon(\mu_1, \mu_2)$ between two sub-distributions $\mu_1, \mu_2 \in \mathbb{D}(B)$ is defined as

$$\sup_{E \subseteq B} \left(\mathbb{P}_{\mu_1}[E] - e^\epsilon \cdot \mathbb{P}_{\mu_2}[E]\right).$$

Then, differential privacy admits an alternative characterization based on DP divergence.

▶ **Lemma 4.** *A probabilistic computation $M : A \to \mathbb{D}(B)$ satisfies* (ϵ, δ)-differential privacy *w.r.t. an adjacency relation $\phi \subseteq A \times A$ iff $\Delta_\epsilon(M(a), M(a')) \leq \delta$ for every pair of inputs $a, a' \in A$ such that $a \; \phi \; a'$.*

Our new definition of approximate lifting is inspired by a version of approximate liftings involving two witness distributions, proposed by Barthe and Olmedo [6], Olmedo [10].

▶ **Definition 5** (Barthe and Olmedo [6], Olmedo [10]). Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be sub-distributions, $\epsilon, \delta \in \mathbb{R}^+$ and $\mathcal{R}$ be a binary relation over A & B. An (ϵ, δ)-*approximate* 2-*lifting* of μ_1 & μ_2 for $\mathcal{R}$ is a pair $(\mu_\triangleleft, \mu_\triangleright)$ of sub-distributions over $A \times B$ s.t.

1. $\pi_1^\sharp(\mu_\triangleleft) = \mu_1$ and $\pi_2^\sharp(\mu_\triangleright) = \mu_2$;
2. $\Delta_\epsilon(\mu_\triangleleft, \mu_\triangleright) \leq \delta$; and
3. $\mathrm{supp}(\mu) \subseteq \mathcal{R}$.

We write $\mu_1 \; \mathcal{R}^{(2)}_{\epsilon,\delta} \; \mu_2$ if there exists an (ϵ, δ)-approximate (2-)lifting of μ_1 & μ_2 for $\mathcal{R}$; the (2) indicates that there are two witnesses in this definition of lifting.

Combined with Lemma 4, a probabilistic computation $M : A \to \mathbb{D}(B)$ is (ϵ, δ)-differentially private if and only if for every two adjacent inputs $a \; \phi \; a'$, there is an approximate lifting of the equality relation: $M(a) =^{(2)}_{\epsilon,\delta} M(a')$.

2-liftings can be generalized by varying the notion of distance given by Δ_ϵ; we will return to this point in Section 6. These liftings also satisfy useful theoretical properties, but some of the properties are not as general as we would like. For example, it is known that 2-liftings satisfy the following mapping property.

▶ **Theorem 6** (Barthe et al. [2]). *Let $\mu_1 \in \mathbb{D}(A_1)$, $\mu_2 \in \mathbb{D}(A_2)$, $f_1 : A_1 \to B_1$, $f_2 : A_2 \to B_2$* surjective *maps and $\mathcal{R}$ a binary relation on B_1 & B_2. Then*

$$f_1^\sharp(\mu_1) \; \mathcal{R}^{(2)}_{\epsilon,\delta} \; f_2^\sharp(\mu_2) \iff \mu_1 \; \mathcal{S}^{(2)}_{\epsilon,\delta} \; \mu_2$$

where $a_1 \; \mathcal{S} \; a_2 \overset{\triangle}{\iff} f_1(a_1) \; \mathcal{R} \; f_2(a_2)$.

This property can be used to pull back an approximate lifting on two distributions over B_1, B_2 to an approximate lifting on two distributions over A_1, A_2. For applications in program logics, B_1, B_2 could be the domain of a program variable, A_1, A_2 could be the set of memories, and f_1, f_2 could project a memory to a program variable. While the mapping theorem is quite useful, it is puzzling why it only applies to surjective maps. For instance, this theorem cannot be used when the maps f_1, f_2 embed a smaller space into a larger space.

For another example, there exist 2-liftings of the following form, sometimes called the *optimal subset coupling*.

▶ **Theorem 7** (Barthe et al. [2]). *Let $\mu \in \mathbb{D}(A)$ and consider two subsets $P_1 \subseteq P_2 \subseteq A$. Suppose that P_2 is a* strict subset *of A. Then, we have the following equivalence:*

$$\mathbb{P}_\mu[P_2] \leq e^\epsilon \cdot \mathbb{P}_\mu[P_1] \iff \mu \; \mathcal{R}^{(2)}_{\epsilon,0} \; \mu,$$

where $a_1 \; \mathcal{R} \; a_2 \overset{\triangle}{\iff} a_1 \in P_1 \iff a_2 \in P_2$.

In this construction, it is puzzling why the larger subset P_2 must be a *strict* subset of the domain A. For example, this theorem does not apply for $P_2 = A$, but we may be able to construct the approximate lifting if we simply embed A into a larger space B – even though μ has support over A! Furthermore, it is not clear why the subsets must be nested, nor is it clear why we can only relate μ to itself.

These shortcomings suggest that the definition of 2-liftings may be problematic. While the distance condition appears to be the most constraining requirement, the marginal and support conditions are responsible for the main issues.

Witnesses can only use pairs in the relation

For some relations $\mathcal{R}$, there may be elements a such that $a\ \mathcal{R}\ b$ does not hold for any b, or vice versa. It can be impossible find witnesses with the correct marginals on these elements, even if the distance condition can be easily satisfied. For instance, we can sometimes construct a pair $\mu_\triangleleft$ and $\mu_\triangleright$ satisfying the distance requirement, but where $\mu_\triangleright$ needs additional mass to achieve the marginal requirement for an element b. Adding this mass anywhere preserves the distance bound, but there may not be an element a such that $a\ \mathcal{R}\ b$.

No canonical choice of witnesses

A related problem is that the marginal requirement only constrains one marginal of each witness distribution. Along the other component, the witnesses may place the mass anywhere on any pair in the relation. As a result, witnesses to an approximate lifting $\mu_1\ \mathcal{R}^{(2)}_{\epsilon,\delta}\ \mu_2$ may have mass outside of $\mathrm{supp}(\mu_1) \times \mathrm{supp}(\mu_2)$, even though it seems that only elements in the support should be relevant to the lifting.

3 $\star$-Liftings and Strassen's Theorem

To improve the theoretical properties of 2-liftings, we propose a simple extension: allow witnesses to be distributions over a larger set.

▶ **Notation 8.** Let A be a set. We write $A^\star$ for $A \uplus \{\star\}$.

▶ **Definition 9** ($\star$-lifting)**.** Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be sub-distributions, $\epsilon, \delta \in \mathbb{R}^+$ and $\mathcal{R}$ be a binary relation over A & B. An (ϵ,δ)-*approximate* $\star$-*lifting* of μ_1 & μ_2 for $\mathcal{R}$ is a pair of sub-distributions $\eta_\triangleleft \in \mathbb{D}(A \times B^\star)$ and $\eta_\triangleright \in \mathbb{D}(A^\star \times B)$ s.t.

1. $\pi_1^\sharp(\eta_\triangleleft) = \mu_1$ and $\pi_2^\sharp(\eta_\triangleright) = \mu_2$;
2. $\mathrm{supp}(\eta_{\triangleleft|A\times B}), \mathrm{supp}(\eta_{\triangleright|A\times B}) \subseteq \mathcal{R}$; and
3. $\Delta_\epsilon(\overline{\eta_\triangleleft}, \overline{\eta_\triangleright}) \leq \delta$, where $\overline{\eta_\bullet}$ is the canonical lifting of $\eta_\bullet$ to $A^\star \times B^\star$.

We write $\mu_1\ R^{(\star)}_{\epsilon,\delta}\ \mu_2$ if there exists an (ϵ,δ)-approximate lifting of μ_1 & μ_2 for $\mathcal{R}$.

By adding an element $\star$, we address both problems discussed at the end of the previous section. First, for every $a \in A$, witnesses may place mass at $(a,\star)$; for every $b \in B$, witnesses may place mass at $(\star,b)$. Second, $\star$ can serve as a generic element where all mass that lies outside the supports $\mathrm{supp}(\mu_1) \times \mathrm{supp}(\mu_2)$ may be placed, while preserving the marginal and distance requirements, giving more control over the form of the witnesses.

▶ **Lemma 10.** *Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be distributions such that $\mu_1\ \mathcal{R}^{(\star)}_{\epsilon,\delta}\ \mu_2$. Then, there are witnesses with support contained in $\mathrm{supp}(\mu_1)^\star \times \mathrm{supp}(\mu_2)^\star$.*

3.1 Basic Properties

$\star$-liftings satisfy all basic properties satisfied by other notions of lifting. We start by proving that this new definition of lifting still characterizes differential privacy.

▶ **Lemma 11.** *A randomized algorithm $P : A \to \mathbb{D}(B)$ is (ϵ,δ)-differentially private for ϕ iff for all $a_1, a_2 \in A$, $a_1\ \phi\ a_2$ implies $P(a_1) =^{(\star)}_{\epsilon,\delta} P(a_2)$.*

The next lemma establishes several other basic properties of $\star$-liftings: monotonicity, and closure under relational and sequential composition.

▶ **Lemma 12.**

- *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$, and $\mathcal{R}$ be a binary relation over A & B. If $\mu_1 \ \mathcal{R}^{(\star)}_{\epsilon,\delta} \ \mu_2$, then for any $\epsilon' \geq \epsilon$, $\delta' \geq \delta$ and $\mathcal{S} \supseteq \mathcal{R}$, we have $\mu_1 \ \mathcal{S}^{(\star)}_{\epsilon',\delta'} \ \mu_2$.*
- *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$, $\mu_2 \in \mathbb{D}(C)$ and $\mathcal{R}$ (resp. $\mathcal{S}$) be a binary relation over A & B (resp. over B & C). If $\mu_1 \ \mathcal{R}^{(\star)}_{\epsilon,\delta} \ \mu_2$ and $\mu_2 \ \mathcal{S}^{(\star)}_{\epsilon',\delta'} \ \mu_3$, then $\mu_1 \ (\mathcal{S} \circ \mathcal{R})^{(\star)}_{\epsilon+\epsilon',\delta+e^{\epsilon}\cdot\delta'} \ \mu_3$.*
- *For $i \in \{1,2\}$, let $\mu_i \in \mathbb{D}(A_i)$ and $\eta_i : A_i \to \mathbb{D}(B_i)$. Let $\mathcal{R}$ (resp. $\mathcal{S}$) be a binary relation over A_1 & A_2 (resp. over B_1 & B_2). If $\mu_1 \ \mathcal{R}^{(\star)}_{\epsilon,\delta} \ \mu_2$ for some $\epsilon, \delta \geq 0$ and for any $(a_1, a_2) \in \mathcal{R}$, $\eta_1(a_1) \ \mathcal{S}^{(\star)}_{\epsilon',\delta'} \ \eta_2(a_2)$ for some $\epsilon', \delta' \geq 0$, then*

  $$\mathbb{E}_{\mu_1}[\eta_1] \ \mathcal{S}^{(\star)}_{\epsilon+\epsilon',\delta+\delta'} \ \mathbb{E}_{\mu_2}[\eta_2].$$

3.2 Equivalence with Sato's Definition

In recent work on verifying differential privacy over general, continuous distributions, Sato [11] proposes an alternative definition of approximate lifting. In the special case of discrete distributions, where measurability of events can be forgotten, his definition can be stated as follows.

▶ **Definition 13** (Sato [11])**.** Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$, $\mathcal{R}$ be a binary relation over A & B and $\epsilon, \delta \geq 0$. Then, there is an (ϵ, δ)-approximate lifting of μ_1 & μ_2 for $\mathcal{R}$ if

$$\forall X \subseteq A.\, \mu_1[X] \leq e^{\epsilon} \cdot \mu_2[\mathcal{R}(X)] + \delta.$$

Notice that this definition has no witness distributions at all; instead, it uses a universal quantifier over all subsets. We can show that ⋆-liftings are equivalent to Sato's definition in the case of discrete distributions. This equivalence is reminiscent of Strassen's theorem from probability theory, which characterizes the existence of probabilistic couplings.

▶ **Theorem 14** (Strassen [12])**.** *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$ be two proper distributions, and $\mathcal{R}$ let be a binary relation over A & B. Then there exists a joint distribution $\mu \in \mathbb{D}(A \times B)$ with support in $\mathcal{R}$ such that $\pi_1^{\sharp}(\mu) = \mu_1$ and $\pi_2^{\sharp}(\mu) = \mu_2$ if and only if*

$$\forall X \subseteq A.\, \mu_1[X] \leq \mu_2[\mathcal{R}(X)].$$

Our result (Theorem 19) can be viewed as a generalization of Strassen's theorem to approximate couplings. The key ingredient in our proof is the *max-flow min-cut* theorem for *countable* networks; we begin by reviewing the basic setting.

▶ **Definition 15** (Flow network)**.** A *flow network* is a structure $((V, E), \top, \bot, c)$ s.t. $\mathcal{N} = (V, E)$ is a loop-free directed graph without infinite simple path (or rays), $\top$ and $\bot$ are two distinct distinguished vertices of $\mathcal{N}$ s.t. no edge starts from $\bot$ and ends at $\top$, and $c : E \to \mathbb{R}^+ \cup \{+\infty\}$ is a function assigning to each edge of $\mathcal{N}$ a capacity. The capacity c is extended to V^2 by assigning capacity 0 to any pair (u, v) s.t. $(u, v) \notin E$.

▶ **Definition 16** (Flow)**.** Given a flow network $\mathcal{N} \triangleq ((V, E), \top, \bot, c)$, a function $f : V^2 \to \mathbb{R}$ is a *flow* for $\mathcal{N}$ iff

1. $\forall u, v \in V.\, f(u, v) \leq c(u, v)$,
2. $\forall u, v \in V.\, f(u, v) = -f(v, u)$, and
3. $\forall u \in V.\, u \notin \{\top, \bot\} \implies \sum_{v \in V} f(u, v) = 0$ (Kirchhoff's Law).

The *mass* $|f|$ of a flow f is defined as $|f| \triangleq \sum_{v \in V} f(\top, v) \in \mathbb{R}\{\cup + \infty\}$.

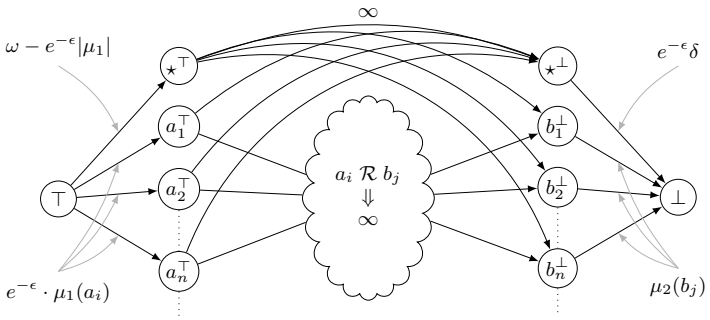

Figure 1 Flow Network in Theorem 19.

▶ **Definition 17** (Cut). Given a flow network $\mathcal{N} \triangleq ((V, E), \top, \perp, c)$, a *cut* for $\mathcal{N}$ is any set $C \subseteq V$ that partition V s.t. $\top \in V$ but $\perp \notin V$. The *cut-set* $\mathcal{E}(C)$ of a cut C is defined as: $\{(u, v) \in E \mid u \in S, v \notin S\}$. The *capacity* $|C| \in \mathbb{R}^+ \cup \{\infty\}$ of a cut is defined as $|C| \triangleq \sum_{(u,v)\in\mathcal{E}(C)} c(u, v)$.

For flow networks with finitely many vertices an edges, the maximum flow is equal to the minimum cut. Aharoni et al. [1] consider when this is the case for a countable network. For the flow networks that we consider in this paper – where there are no infinite directed paths – equality holds.

▶ **Theorem 18** (Weak Countable Max-Flow Min-Cut). *Let $\mathcal{N}$ be a network flow. Then,*

$$\sup\{|f| \mid f \text{ is a flow for } \mathcal{N}\} = \inf\{|C| \mid C \text{ is a cut for } \mathcal{N}\}$$

and both the supremum and infimum are reached.

We are now ready to prove an approximate version of Strassen's theorem, thereby showing equivalence between $\star$-liftings and Sato's liftings.

▶ **Theorem 19.** *Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$, $\mathcal{R}$ be a binary relation over A & B and $\epsilon, \delta \in \mathbb{R}^+$. Then, $\mu_1 \, R^{(\star)}_{\epsilon,\delta} \, \mu_2$ iff $\forall X \subseteq A. \, \mu_1(X) \leq e^\epsilon \cdot \mu_2(\mathcal{R}(X)) + \delta$.*

Proof. We only detail the reverse direction. We can assume that A and B are countable; in the case where A and B are not both countable, we first consider the restriction of μ_1 and μ_2 to their respective supports – which are countable sets – and construct witnesses to the $\star$-lifting. The witnesses can then be extended to a coupling of μ_1 and μ_2 by adding a null mass to the extra points.

Let $\omega \triangleq |\mu_2| + e^{-\epsilon} \cdot \delta$ and let $\top$ and $\perp$ be fresh symbols. For any set X, define $X^\top$ and $X^\perp$ resp. as $\{x^\top \mid x \in X\}$ and $\{x^\perp \mid x \in X\}$. Let $\mathcal{N}$ be the flow network of Figure 1 whose resp. source and sink are $\top$ and $\perp$, whose set of vertices V is $\{\top, \perp\} \uplus (A^\star)^\top \uplus (B^\star)^\perp$, and whose set of edges E is $E_\top \uplus E_\perp \uplus E_\mathcal{R} \uplus E_\star$ with

$$E_\top \triangleq \{\top \mapsto_{\mu_1(a)} a^\top \mid a \in A\} \qquad E_\perp \triangleq \{b^\perp \mapsto_{e^{-\epsilon}\mu_2(b)} \perp \mid b \in B\}$$
$$E_\mathcal{R} \triangleq \{a^\top \mapsto_\infty b^\perp \mid a \, \mathcal{R} \, b \vee a = \star \vee b = \star\} \qquad E_\star \triangleq \{\top \mapsto_{(\omega - e^{-\epsilon}|\mu_1|)} \star^\top, \; \star^\perp \mapsto_{e^{-\epsilon}\delta} \perp\}.$$

Let C be a cut of $\mathcal{N}$ – in the following, we use C independently for the cut C and its cut-set $\mathcal{E}(C)$. We check $|C| \geq \omega$. If $C \cap E_\mathcal{R} \neq \emptyset$ then $|C| = \infty$. Note that $C \cap E_\star = \emptyset$ implies $C \cap E_\mathcal{R} \neq \emptyset$. If $(\top, \star^\top) \in C$ and $(\perp, \star^\perp) \notin C$ then we must have $E_\top \subseteq C$. This implies that $|C| \geq \omega$ since $E_\top \uplus \{(\top, \star^\top)\}$ is a cut with capacity ω. If $(\top, \star^\top) \notin C$ and $(\perp, \star^\perp) \in C$ then

we have $|C| \geq \omega$ in the similar way as above. Otherwise (i.e. $C \cap E_{\mathcal{R}} = \emptyset$ and $E_\star \subseteq C$), for C to be a cut, we must have $\mathcal{R}(A - A^\dagger) \subseteq B^\dagger$ where $A^\dagger \triangleq \{x \in A \mid (\top, x^\top) \in C\}$ and $B^\dagger \triangleq \{y \in B \mid (y^\perp, \perp) \in C\}$. Thus,

$$\begin{aligned}|C| &= e^{-\epsilon} \cdot \mu_1[A^\dagger] + \mu_2[B^\dagger] + |E_\star| \\ &\geq e^{-\epsilon} \cdot \mu_1[A^\dagger] + \mu_2[\mathcal{R}(A - A^\dagger)] + e^{-\epsilon} \cdot \delta + (\omega - e^{-\epsilon} \cdot |\mu_1|) \\ &\geq e^{-\epsilon} \cdot (\mu_1[A^\dagger] + \mu_1[A - A^\dagger]) + \omega - e^{-\epsilon} \cdot |\mu_1| = \omega.\end{aligned}$$

Hence, $E_\top \uplus \{(\star^\perp, \perp)\}$ is a minimum cut with capacity ω. By Theorem 18, we obtain a maximum flow f with mass ω. Note that the flow f saturates the capacity of all edges in $E_\top$, $E_\perp$, and $E_\star$. Let $\hat{f} : (a, b) \in A^\star \times B^\star \mapsto f(a^\top, b^\perp)$. We now define the following distributions:

$$\begin{aligned}\eta_\triangleleft : A \times B^\star &\to \mathbb{R}^+ & \eta_\triangleright : A^\star \times B &\to \mathbb{R}^+ \\ (a, b) &\mapsto e^\epsilon \cdot \hat{f}(a, b) & (a, b) &\mapsto \hat{f}(a, b).\end{aligned}$$

We clearly have $\pi_1^\sharp(\eta_\triangleleft) = \mu_1$ and $\pi_2^\sharp(\eta_\triangleright) = \mu_2$. Moreover, by construction of the flow network $\mathcal{N}$, $\mathrm{supp}(\hat{f}_{|A \times B}) \subseteq \mathcal{R}$. Hence, $\mathrm{supp}(\eta_{\triangleleft|A \times B}), \mathrm{supp}(\eta_{\triangleright|A \times B}) \subseteq \mathcal{R}$. It remains to show that $\Delta_\epsilon(\overline{\eta_\triangleleft}, \overline{\eta_\triangleright}) \leq \delta$. Let X be a subset of $A^\star \times B^\star$. Let $\overline{X_a} \triangleq \{a \in A \mid (a, \star) \in X\}$, $\overline{X_b} \triangleq \{b \in B \mid (\star, b) \in X\}$ and $\overline{X} \triangleq X \cap (A \times B)$. Then,

$$\begin{aligned}\overline{\eta_\triangleleft}[X] - e^\epsilon \cdot \overline{\eta_\triangleright}[X] &= e^\epsilon \left(\hat{f}[\overline{X}] + \hat{f}[\overline{X_a} \times \{\star\}]\right) - e^\epsilon \left(\hat{f}[\overline{X}] + \hat{f}[\{\star\} \times \overline{X_b}]\right) \\ &\leq e^\epsilon \cdot \hat{f}[\overline{X_a} \times \{\star\}] \leq e^\epsilon \cdot \hat{f}[A \times \{\star\}] = \delta.\end{aligned}$$

The last equality holds by Kirchhoff's law: $\hat{f}[A \times \{\star\}] = \sum_{a \in A} f(a^\top, \star^\perp) = f(\star^\perp, \perp) = e^{-\epsilon} \cdot \delta$. ◀

4 Properties of ⋆-Liftings

Our main theorem can be used to show a variety of natural properties of ⋆-liftings. To begin, we can generalize the mapping property from Theorem 6, lifting the requirement that the maps must be surjective.

▶ **Lemma 20.** *Let $\mu_1 \in \mathbb{D}(A_1)$, $\mu_2 \in \mathbb{D}(A_2)$, $f_1 : A_1 \to B_1$, $f_2 : A_2 \to B_2$ and $\mathcal{R}$ a binary relation on B_1 & B_2. Let $\mathcal{S}$ such that $a_1 \mathrel{\mathcal{S}} a_2 \iff f_1(a_1) \mathrel{\mathcal{R}} f_2(a_2)$. Then*

$$f_1^\sharp(\mu_1) \mathrel{\mathcal{R}_{\epsilon,\delta}^{(\star)}} f_2^\sharp(\mu_2) \iff \mu_1 \mathrel{\mathcal{S}_{\epsilon,\delta}^{(\star)}} \mu_2.$$

Similarly, we can generalize the existing rules for up-to-bad reasoning (cf. Barthe et al. [2, Theorem 13]), which restrict the post-condition to be equality. There are two versions: the conditional event is either on the left side, or the right side. Note that the resulting index $\overline{\delta}$ are different in the two cases.

▶ **Lemma 21.** *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$, $\theta \subseteq A$ and $\mathcal{R} \subseteq A \times B$. Assume that $\mu_1 \, (\theta_\triangleleft \implies \mathcal{R})_{\epsilon,\delta}^{(\star)} \, \mu_2$ for some parameters $\epsilon, \delta \geq 0$. Then, $\mu_1 \, \mathcal{R}_{\epsilon,\overline{\delta}}^{(\star)} \, \mu_2$, where $\overline{\delta} \triangleq \delta + \mu_1[\overline{\theta}]$.*

▶ **Lemma 22.** *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$, $\theta \subseteq B$ and $\mathcal{R} \subseteq A \times B$. Assume that $\mu_1 \, (\theta_\triangleright \implies \mathcal{R})_{\epsilon,\delta}^{(\star)} \, \mu_2$ for some parameters $\epsilon, \delta \geq 0$. Then, $\mu_1 \, \mathcal{R}_{\epsilon,\overline{\delta}}^{(\star)} \, \mu_2$, where $\overline{\delta} \triangleq \delta + e^\epsilon \cdot \mu_2[\overline{\theta}]$.*

As a consequence, an approximately lifted relation can be conjuncted with a one-sided predicate if the δ parameter is increased. This principle is useful for constructing approximate liftings that express *accuracy* bounds: when $\theta_{a,\triangleleft}$ is an event that happens with high probability, we can assume that $\theta_{a,\triangleleft}$ holds if we increase the δ parameter of the approximate lifting.

▶ **Lemma 23.** *Let $\mu_1 \in \mathbb{D}(A)$, $\mu_2 \in \mathbb{D}(B)$, $\theta_a \subseteq A$, $\theta_b \subseteq B$ and $\mathcal{R} \subseteq A \times B$. Assume that $\mu_1 \ \mathcal{R}^{(\star)}_{\epsilon,\delta} \ \mu_2$. Then, $\mu_1 \ (\theta_{a,\triangleleft} \wedge \mathcal{R})^{(\star)}_{\epsilon,\delta_a} \ \mu_2$ and $\mu_1 \ (\theta_{b,\triangleright} \wedge \mathcal{R})^{(\star)}_{\epsilon,\delta_b} \ \mu_2$ where $\delta_a \triangleq \delta + \mu_1[\overline{\theta_a}]$ and $\delta_b \triangleq \delta + e^{\epsilon} \cdot \mu_2[\overline{\theta_b}]$.*

$\star$-liftings also support a significant generalization of optimal subset coupling. Unlike the known construction for 2-liftings (Theorem 7), the two subsets need not be nested, and either subset may be the entire domain. Furthermore, the distributions μ_1, μ_2 need not be the same, or even have the same domain. Finally, the equivalence is valid for any parameters (ϵ, δ), not just $\delta = 0$.

▶ **Theorem 24** (Barthe et al. [2])**.** *Let $\mu_1 \in \mathbb{D}(A_1)$, $\mu_2 \in \mathbb{D}(A_2)$ and consider two subsets $P_1 \subseteq A_1, P_2 \subseteq A_2$. Then, we have the following equivalence:*

$$\mathbb{P}_{\mu_1}[P_1] \leq e^{\epsilon} \cdot \mathbb{P}_{\mu_2}[P_2] + \delta \wedge \mathbb{P}_{\mu_1}[A_1 - P_1] \leq e^{\epsilon} \cdot \mathbb{P}_{\mu_2}[A_2 - P_2] + \delta \iff \mu_1 \ \mathcal{R}^{(\star)}_{\epsilon,\delta} \ \mu_2,$$

where $a_1 \ \mathcal{R} \ a_2 \overset{\triangle}{\iff} a_1 \in P_1 \iff a_2 \in P_2$.

Proof. Immediate by Theorem 19. ◀

Finally, we can directly extend known composition theorems from differential privacy to $\star$-liftings. This connection is quite useful for lifting existing results from the privacy literature–which can be quite sophisticated – to approximate liftings.

▶ **Lemma 25.** *Pose $\mathbb{R}_2^+ \triangleq \mathbb{R}^+ \times \mathbb{R}^+$ and let $(\mathbb{R}_2^+)^*$ be the set of finite sequences over $\mathbb{R}_2^+$. Let $r : (\mathbb{R}_2^+)^* \to \mathbb{R}_2^+$ be a* DP-composition operator*, i.e. r is an operator such that for any sets A, D and family $\{f_i : D \times A \to \mathbb{D}(A)\}_{i<n}$ of functions, if for every $a \in A$ and $i < n$, $f_i(-, a) : D \to \mathbb{D}(A)$ is (ϵ_i, δ_i)-differentially private for some parameters $\epsilon_i, \delta_i \geq 0$ and fixed adjacency relation ϕ, then, for any $a \in A$, $F(-, a)$ is (ϵ^*, δ^*)-differentially private for ϕ, where $F : (d, a) \mapsto (\bigcirc_{i<n} \ (f_i(d, -))^{\sharp})(\mathbb{1}_a)$ is the the n-fold composition of the $[f_i]_{i<n}$ and $(\epsilon^*, \delta^*) \triangleq r([(\epsilon_i, \delta_i)]_{i<n})$.*

Let $n \in \mathbb{N}$ and assume given two families of sets $\{A_i\}_{i\leq n}$ and $\{B_i\}_{i\leq n}$, together with a family of binary relations $\{\mathcal{R}(i) \subseteq A_i \times B_i\}_{i\leq n}$. Fix two families of functions $\{g_i : A_i \to \mathbb{D}(A_{i+1})\}_{i<n}$ and $\{h_i : B_i \to \mathbb{D}(B_{i+1})\}_{i<n}$ s.t. for any $i < n$ and $(a, b) \in \mathcal{R}(i)$ we have:
1. *$g_i(a) \ \mathcal{R}(i+1)^{(\star)}_{\epsilon_i,\delta_i} \ h_i(b)$ for some parameters $\epsilon_i, \delta_i \geq 0$, and*
2. *$g_i(a)$ and $h_i(b)$ are proper distributions.*
Then, for $(a_0, b_0) \in \mathcal{R}_0$, there exists a $\star$-lifting

$$G(a_0) \ \mathcal{R}(n)^{(\star)}_{\epsilon^*,\delta^*} \ H(b_0)$$

where $(\epsilon^*, \delta^*) \triangleq r([(\epsilon_i, \delta_i)]_{i<n})$, and $G : A_0 \to \mathbb{D}(A_n)$ and $H : B_0 \to \mathbb{D}(B_n)$ are the n-fold compositions of $[g_i]_{i\leq n}$ and $[h_i]_{i\leq n}$ respectively – i.e. $G(a) \triangleq (\bigcirc_{i<n} \ g_i^{\sharp})(\mathbb{1}_a)$ and $H(b) \triangleq (\bigcirc_{i<n} \ h_i^{\sharp})(\mathbb{1}_b)$.

For some of the more sophisticated composition results (notably, the advanced composition theorem by Dwork et al. [8]), Lemma 25 is not quite strong enough and requires a slight adaptation of the notion of $\star$-lifting. We refer to the full version of the paper for more details.

5 Comparison with Existing Approximate Liftings

Now that we have seen ⋆-liftings, we briefly consider other definitions of approximate liftings. We have already seen 2-liftings, which involve two witnesses (Definition 5). Evidently, ⋆-liftings strictly generalize 2-liftings.

▶ **Theorem 26.** *For all binary relations $\mathcal{R}$ over A & B and parameters $\epsilon, \delta \geq 0$, we have $\mathcal{R}^{(2)}_{\epsilon,\delta} \subseteq \mathcal{R}^{(\star)}_{\epsilon,\delta}$. There exist relations and parameters where the inclusion is strict.*

Proof. The inclusion $\mathcal{R}^{(2)}_{\epsilon,\delta} \subseteq \mathcal{R}^{(\star)}_{\epsilon,\delta}$ is immediate. We have a strict inclusion $\mathcal{R}^{(2)}_{\epsilon,\delta} \subsetneq \mathcal{R}^{(\star)}_{\epsilon,\delta}$ even for $\delta = 0$ by considering the optimal subset coupling from Theorem 7. Consider a distribution μ over set A, and let $P_1 \subseteq P_2 = A$. There is an $(\epsilon, 0)$-approximate ⋆-lifting (by Theorem 24), but a $(\epsilon, 0)$-approximate 2-lifting does not exist if μ has non-zero mass outside of P_1: the first witness $\mu_\triangleleft$ must place non-zero mass at (a_1, a_2) with $a_1 \notin P_1$ in order to have $\pi_1^\sharp(\mu_\triangleleft) = \mu$, but we must have $a_2 \notin P_2$ for the support requirement, and there is no such a_2. ◀

It is more interesting to compare ⋆-liftings with the original definitions of (ϵ, δ)-approximate lifting, by Barthe et al. [5]. They introduce two notions, a symmetric lifting and an asymmetric lifting, each using a single witness distribution. We will focus on the asymmetric version.

▶ **Definition 27** (Barthe et al. [5])**.** Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be sub-distributions, $\epsilon, \delta \in \mathbb{R}^+$ and $\mathcal{R}$ be a binary relation over A & B. An (ϵ, δ)-*approximate* 1-*lifting* of μ_1 & μ_2 for $\mathcal{R}$ is a sub-distribution $\mu \in \mathbb{D}(A \times B)$ s.t.

1. $\pi_1^\sharp(\mu) \leq \mu_1$ and $\pi_2^\sharp(\mu) \leq \mu_2$;
2. $\Delta_\epsilon(\mu_1, \pi_1^\sharp(\mu)) \leq \delta$; and
3. $\mathrm{supp}(\mu) \subseteq \mathcal{R}$.

In the first point we take the point-wise order on sub-distributions: if μ and μ' are sub-distributions over X, then $\mu \leq \mu'$ when $\mu(x) \leq \mu'(x)$ for all $x \in X$. We will write $\mu_1 \; \mathcal{R}^{(1)}_{\epsilon,\delta} \; \mu_2$ if there exists an (ϵ, δ)-approximate 1-lifting of μ_1 & μ_2 for $\mathcal{R}$; the (1) indicates that there is one witness for this lifting.

1-liftings bear a close resemblance to *probabilistic couplings* from probability theory, which also have a single witness. However, 1-liftings are less well-understood theoretically than 2-liftings – basic properties such as mapping (Theorem 20) are not known to hold; the subset coupling (Theorem 7) is not known to exist.

Somewhat surprisingly, 1-liftings are equivalent to ⋆-liftings (and hence by Theorem 19, also to Sato's approximate lifting).

▶ **Theorem 28.** *For all binary relations $\mathcal{R}$ over A & B and parameters $\epsilon, \delta \geq 0$, we have $\mathcal{R}^{(1)}_{\epsilon,\delta} = \mathcal{R}^{(\star)}_{\epsilon,\delta}$.*

6 ⋆-Lifting for f-Divergences

The definition of ⋆-lifting can be extended to lifting constructions based on general f-divergences, as previously proposed by Barthe and Olmedo [6], Olmedo [10]. Roughly, a f-divergence a function $\Delta_f(\mu_1, \mu_2)$ that measures the difference between two probability distributions μ_1 and μ_2. Much like we generalized their definition for (ϵ, δ)-liftings, we can define ⋆-lifting with f-divergences. Before going any further, let us first define formally f-divergences. We denote by $\mathcal{F}$ the set of non-negative convex functions vanishing at 1: $\mathcal{F} = \{f : \mathbb{R}^+ \to \mathbb{R}^+ \mid f(1) = 0\}$. We also adopt the following notational conventions: $0 \cdot f(0/0) \triangleq 0$, and $0 \cdot f(x/0) \triangleq x \cdot \lim_{t \to 0^+} t \cdot f(1/t)$; we write L_f for the limit.

▶ **Definition 29.** Given $f \in \mathcal{F}$, the *f-divergence* $\Delta_f(\mu_1, \mu_2)$ between two distributions μ_1 and μ_2 in $\mathbb{D}(A)$ is defined as:

$$\Delta_f(\mu_1, \mu_1) = \sum_{a \in A} \nu(a) f\left(\frac{\mu_1(a)}{\mu_2(a)}\right).$$

Examples of f-divergences include statistical distance ($f(t) = \frac{1}{2}|t-1|$), Kullback-Leibler divergence ($f(t) = \ln(t) - t + 1$), and Hellinger distance ($f(t) = \frac{1}{2}(\sqrt{t}-1)^2$).

▶ **Definition 30** ($\star$-lifting for f-divergences)**.** Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be distributions, $\mathcal{R}$ be a binary relation over A & B, and $f \in \mathcal{F}$. An $(f;\delta)$-*approximate lifting* of μ_1 & μ_2 for $\mathcal{R}$ is a pair of distributions $\eta_\triangleleft \in \mathbb{D}(A \times B^\star)$ and $\eta_\triangleright \in \mathbb{D}(A^\star \times B)$ s.t.

- $\pi_1^\sharp(\eta_\triangleleft) = \mu_1$ and $\pi_2^\sharp(\eta_\triangleright) = \mu_2$;
- $\mathrm{supp}(\eta_{\triangleleft|A\times B}), \mathrm{supp}(\eta_{\triangleright|A\times B}) \subseteq \mathcal{R}$; and
- $\Delta_f(\overline{\eta_\triangleleft}, \overline{\eta_\triangleright}) \leq \delta$,

where $\overline{\eta_\bullet}$ is the canonical lifting of $\eta_\bullet$ to $A^\star \times B^\star$. We will write: $\mu_1 \; R_{f;\delta}^{(\star)} \; \mu_2$ if there exists an $(f;\delta)$-approximate lifting of μ_1 & μ_2 for $\mathcal{R}$.

$\star$-liftings for f-divergences compose sequentially.

▶ **Lemma 31.** *Suppose f has divergence statistical distance, Kullback-Leibler, or Hellinger distance. For $i \in \{1,2\}$, let $\mu_i \in \mathbb{D}(A_i)$ and $\eta_i : A_i \to \mathbb{D}(B_i)$. Let $\mathcal{R}$ (resp. $\mathcal{S}$) be a binary relation over A_1 & A_2 (resp. over B_1 & B_2). If $\mu_1 \; \mathcal{R}_{f;\delta}^{(\star)} \; \mu_2$ for some $\delta \geq 0$ and for any $(a_1, a_2) \in \mathcal{R}$ we have $\eta_1(a_1) \; \mathcal{S}_{f;\delta'}^{(\star)} \; \eta_2(a_2)$ for some $\delta' \geq 0$, then*

$$\mathbb{E}_{\mu_1}[\eta_1] \; \mathcal{S}_{f;\delta+\delta'}^{(\star)} \; \mathbb{E}_{\mu_2}[\eta_2].$$

Much like the $\star$-liftings we saw before, $\star$-liftings for f-divergences have witness distributions with support determined by the support of μ_1 and μ_2 (cf. Lemma 10).

▶ **Lemma 32.** *Let $\mu_1 \in \mathbb{D}(A)$ and $\mu_2 \in \mathbb{D}(B)$ be distributions such that $\mu_1 \; R_{f;\delta}^{(\star)} \; \mu_2$. Then, there are witnesses with support contained in* $\mathrm{supp}(\mu_1)^\star \times \mathrm{supp}(\mu_2)^\star$.

Finally, the mapping property from Lemma 20 holds also for these $\star$-liftings. While the proof of Lemma 20 relies on the equivalence for Sato's definition, there is no such equivalence (or definition) for general f-divergences. Therefore, we must work directly with the witnesses of the approximate lifting.

▶ **Lemma 33.** *Let $\mu_1 \in \mathbb{D}(A_1)$, $\mu_2 \in \mathbb{D}(A_2)$, $g_1 : A_1 \to B_1$, $g_2 : A_2 \to B_2$ and $\mathcal{R}$ a binary relation on B_1 & B_2. Let $\mathcal{S}$ such that $a_1 \; \mathcal{S} \; a_2 \overset{\triangle}{\iff} g_1(a_1) \; \mathcal{R} \; g_2(a_2)$. Then*

$$g_1^\sharp(\mu_1) \; \mathcal{R}_{f;\delta}^{(\star)} \; g_2^\sharp(\mu_2) \iff \mu_1 \; \mathcal{S}_{f;\delta}^{(\star)} \; \mu_2.$$

7 Conclusion

We have proposed a new definition of approximate lifting that unifies existing constructions and satisfies an approximate variant of Strassen's theorem. Our notion is useful both to simplify the soundness proof of existing program logics and to strengthen some of their proof rules. We see at least two important directions for future work. First, adapting existing program logics (for instance, apRHL [5]) to use $\star$-liftings, and formalizing examples that were out of reach of previous systems. Second, our notion of $\star$-liftings only applies when distributions have discrete support. It would be interesting to see if $\star$-liftings – and the approximate Strassen's theorem – can be generalized to the continuous setting.

Acknowledgments. We thank the anonymous reviewers for their helpful suggestions.

Abstract

We develop a new bisimulation (pseudo)metric for weighted finite automata (WFA) that generalizes Boreale's linear bisimulation relation. Our metrics are induced by seminorms on the state space of WFA. Our development is based on spectral properties of sets of linear operators. In particular, the joint spectral radius of the transition matrices of WFA plays a central role. We also study continuity properties of the bisimulation pseudometric, establish an undecidability result for computing the metric, and give a preliminary account of applications to spectral learning of weighted automata.

1 Introduction

Weighted finite automata (WFA) form a fundamental computational model that subsumes probabilistic automata and various other types of quantitative automata. They are much used in machine learning and natural language processing, and are certainly relevant to quantitative verification and to the theory of control systems [16]. The theory of minimization of weighted finite automata goes back to Schützenberger [30] which implicitly exploits duality as made explicit in [9]. In [6] we began studying *approximate* minimization of WFA by using spectral methods. The idea there was to obtain automata for a given weighted language, smaller than the minimal possible which, of course, means that the automaton constructed does not *exactly* recognize the given weighted language but comes "close enough."

In [6] the notion of proximity to the desired language was captured by an ℓ_2 distance. However, a powerful technique for understanding approximate behavioural equivalence is by using more general *behavioural metrics*. In particular, with a behavioural pseudometric we recover bisimulation as the kernel. Such behavioural metrics for Markov processes were proposed by Giacalone et al. [20] and the first successful pseudometric that has bisimulation as its kernel is due to Desharnais et al. [14, 15]; see [28] for an expository account. The subject was greatly developed by van Breugel and Worrell [32] among others. For WFA, a beautiful treatment of linear bisimulation relations was given by Boreale [10]. We were

motivated to develop a metric analogue of Boreale's linear bisimulation with the eventual goal of using it to analyze approximate minimization. In the present paper we develop the general theory of bisimulation (pseudo)metrics for WFA (and for weighted languages) deferring the application to approximate minimization to future work.

It turns out that in the linear algebraic setting appropriate to WFA it is a (semi)norm rather than a (pseudo)metric that is the fundamental quantity of interest. Indeed, as one might expect, in a vector space setting norms and seminorms are the natural objects from which metrics and pseudometrics can be derived. The bisimulation metric that we construct actually comes from a bisimulation seminorm which is obtained, as usual, using the Banach fixed-point theorem. Interestingly, we also provide a closed-form expression for the fixed point bisimulation seminorm and use it to study several of its properties.

Our main contributions are:

1. The construction of bisimulation seminorms and the associated pseudometric on WFA (Section 3). The existence of the fixed point depends on some delicate applications of spectral theory, specifically the joint spectral radius of a set of matrices.
2. We obtain metrics on the space of weighted languages from the metrics on WFA (Section 3).
3. We show two continuity properties of the metric; one using definitions due to Jaeger et al. [24] and the other developed here (Section 4).
4. We show undecidability results for computing our metrics (Section 5).
5. Nevertheless, we show that one can successfully exploit these metrics for applications in machine learning (Section 6).

The metric of the present paper led naturally to some sophisticated topological and spectral theory arguments which one would not have anticipated from the treatment of linear bisimulation in [10].

2 Background

In this section we recall preliminary definitions and results that will be used throughout the rest of the paper. We assume the reader is familiar with norms and vector spaces; these topics are reviewed in the appendix [4]. Here we discuss Boreale's linear bisimulation relations for weighted automata and provide a short primer on the joint spectral radius of a set of linear operators.

2.1 Strings and Weighted Automata

Given a finite alphabet Σ we let $\Sigma^\star$ denote the set of all finite strings with symbols in Σ and let Σ^∞ denote the set of all infinite strings with symbols in Σ and we write $\Sigma^\omega = \Sigma^\star \cup \Sigma^\infty$. The length of a string $x \in \Sigma^\omega$ is denoted by $|x|$; $|x| = \infty$ whenever $x \in \Sigma^\infty$. Given a string $x \in \Sigma^\omega$ and an integer $0 \leq t \leq |x|$ we write $x_{\leq t}$ to denote the prefix containing the first t symbols from x, with $x_{\leq 0} = \epsilon$. Given an integer $t \geq 0$ we will write Σ^t (resp. $\Sigma^{\leq t}$) for the set of all strings with length equal to (resp. at most) t. The reverse of a finite string $x = x_1 x_2 \cdots x_t$ is given by $\bar{x} = x_t x_{t-1} \cdots x_1$.

We only consider automata with weights in the real field $\mathbb{R}$. We will mostly be concerned with properties of weighted automata that are invariant under change of basis. Accordingly, our presentation uses weighted automata whose state space is an abstract real vector space.

A weighted finite automaton (WFA) is a tuple $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma \in \Sigma} \rangle$ where Σ is a finite alphabet, V is a finite-dimensional vector space, $\alpha \in V$ is a vector representing the initial weights, $\beta \in V^*$ is a linear form representing the final weights, and $\tau_\sigma : V \to V$ is a

linear map representing the transition indexed by $\sigma \in \Sigma$. The vectors in V are called states of A. We shall denote by $n = \dim(A) = \dim(V)$ the dimension of A. The transition maps τ_σ can be extended to arbitrary finite strings in the obvious way.

A weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ computes the function $f_A : \Sigma^\star \to \mathbb{R}$ (sometimes also referred to as the weighted language in $\mathbb{R}^{\Sigma^\star}$ recognized by A) given by $f_A(x) = \beta(\tau_x(\alpha))$. Given a WFA $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ and a state $v \in V$ we define the weighted automaton $A_v = \langle \Sigma, V, v, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ obtained from A by taking v as the initial state. We call f_{A_v} the function realized by state v. Similarly, give a linear form $w \in V^*$ we define the weighted automaton $A^w = \langle \Sigma, V, \alpha, w, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ where the final weights are replaced by w. The reverse of a weighted automaton A is $\bar{A} = \langle \Sigma, V^*, \beta, \alpha, \{\tau_\sigma^\top\}_{\sigma\in\Sigma}\rangle$, where $\tau_\sigma^\top : V^* \to V^*$ is the transpose of τ_σ. It is easy to check that the function computed by $\bar{A}$ satisfies $f_{\bar{A}}(x) = f_A(\bar{x})$ for all $x \in \Sigma^\star$.

2.2 Linear Bisimulations

Linear bisimulations for weighted automata were introduced by Boreale in [10]. Here we recall the key definition and several important facts.

▶ **Definition 1.** A *linear bisimulation* for a weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ on a vector space V is a linear subspace $W \subseteq V$ satisfying the following two conditions:

1. $\beta(v) = 0$ for all $v \in W$; that is, $W \subseteq \ker(\beta)$, and
2. W is invariant by each τ_σ; that is, $\tau_\sigma(W) \subseteq W$ for all $\sigma \in \Sigma$.

Furthermore, two states $u, v \in V$ are called W-*bisimilar* if $u - v \in W$.

In particular, the trivial subspace $W = \{0\}$ is always a linear bisimulation. The notion of W-bisimilarity induces an equivalence relation on V which we will denote by $\sim_W$. The kernel of an equivalence relation $\sim$ on a vector space V is the set of vectors in the equivalence class of the null vector: $\ker(\sim) = \{v \in V : v \sim 0\}$. It is immediate from the definition that for any bisimulation relation $\sim_W$ we have $\ker(\sim_W) = W$.

Given a weighted automaton A we say that $u, v \in V$ are A-bisimilar if there exists a bisimulation W for A such that $u \sim_W v$. The corresponding equivalence relation is denoted by $\sim_A$. Boreale showed in [10] that for every WFA A there exists a bisimulation W_A such that $\sim_{W_A}$ exactly coincides with $\sim_A$, and the bisimulation can be obtained as $W_A = \ker(\sim_A)$. He also showed that W_A is in fact the largest linear bisimulation for A in the sense that any other linear bisimulation W for A must be a subspace of W_A. Accordingly, we shall refer to the relation $\sim_A$ and the subspace W_A as A-bisimulation.

Note that the subspaces considered in Definition 1 are independent of the initial state α of A. In fact, A-bisimilarity can be understood as a relation between possible initial states for A. Indeed, using the definition of $\sim_A$ it is immediate to check that for any states $u, v \in V$ we have $u \sim_A v$ if and only if $f_{A_u} = f_{A_v}$. This implies that in a WFA where the bisimulation W_A corresponding to $\sim_A$ satisfies $W_A = \{0\}$ every state realizes a different function. Such an automaton is called observable. A weighted automaton is called reachable if the reverse $\bar{A}$ is observable.

A weighted automaton A is minimal if for any other weighted automaton A' over the same alphabet such that $f_A = f_{A'}$ we have $\dim(A) \leq \dim(A')$. It is also shown in [10] that linear bisimulations can be used to characterize minimality, in the sense that A is minimal if and only if it is observable and reachable.

2.3 Joint Spectral Radius

The joint spectral radius of a set of linear operators is a natural generalization of the spectral radius of a single linear operator. The joint spectral radius and several equivalent notions have been thoroughly studied since the 1960's. These radiuses arise in many fundamental problems in operator theory, control theory, and computational complexity. See [25] for an introduction to their properties and applications. Here we recall the basic definitions and some important facts related to quasi-extremal norms.

▶ **Definition 2.** The *joint spectral radius* of a collection $M = \{\tau_i\}_{i\in I}$ of linear maps $\tau_i : V \to V$ on a normed vector space $(V, \|\cdot\|)$ is defined as

$$\rho(M) = \limsup_{t\to\infty} \left(\sup_{T\in I^t} \left\| \prod_{i\in T} \tau_i \right\| \right)^{1/t} = \lim_{t\to\infty} \left(\sup_{T\in I^t} \left\| \prod_{i\in T} \tau_i \right\| \right)^{1/t} .$$

The second equality above is a generalization of Gelfand's formula for the spectral radius of a single operator due to Daubechies and Lagarias [11, 12]. An important fact about the joint spectral radius is that $\rho(M)$ is independent of the norm $\|\cdot\|$, i.e. one obtains the same radius regardless of the norm given to the vector space V. The joint spectral radius behaves nicely with respect to direct sums, in the sense that given two sets of operators $M = \{\tau_i\}_{i\in I}$ and $M' = \{\tau'_i\}_{i\in I}$, then $\rho(\{\tau_i \oplus \tau'_i\}_{i\in I}) = \max\{\rho(M), \rho(M')\}$.

The notion of joint spectral radius can be readily extended to weighted automata. Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ be a weighted automaton with states on a normed vector space $(V, \|\cdot\|)$. Then the spectral radius of A is defined as $\rho(A) = \rho(M)$ where $M = \{\tau_\sigma\}_{\sigma\in\Sigma}$. In this case the definition above can be rewritten as

$$\rho(A) = \lim_{t\to\infty} \left(\sup_{x\in\Sigma^t} \|\tau_x\| \right)^{1/t} .$$

Now we discuss several fundamental properties of the joint spectral radius that will play a role in the rest of the paper. Like in the case of the classic spectral radius, the joint spectral radius is upper bounded by the norms of the operators in M: $\rho(M) \leq \sup_{i\in I} \|\tau_i\|$. Obtaining lower bounds for $\rho(M)$ is a major problem directly related to the hardness of computing approximations to $\rho(M)$. An approach often considered in the literature is to search for extremal norms. A norm $\|\cdot\|$ on V is extremal for M if the corresponding induced norm satisfies $\|\tau_i\| \leq \rho(M)$ for all $i \in I$. This immediately implies that given an extremal norm for M we have $\rho(M) = \sup_{i\in I} \|\tau_i\|$. Conditions on M guaranteeing the existence of an extremal norm have been derived by Barabanov and others; see [33] and references therein. However, most of these conditions are quite technical and algorithmically hard to verify. On the other hand, if one only insists on approximate extremality, the following result, due to Rota and Strang, guarantees the existence of such norms for any set of matrices M that is compact with respect to the topology generated by the operator norm in V.

▶ **Theorem 3** ([29])**.** *Let $M = \{\tau_i\}_{i\in I}$ be a compact set of linear maps on V. For any $\eta > 0$ there exists a norm $\|\cdot\|$ on V that satisfies $\|\tau_i(v)\| \leq (\rho(M) + \eta)\|v\|$ for every $i \in I$ and every $v \in V$.*

The statement above is in fact a special case of Proposition 1 in [29]; a proof for finite sets M can be found in [8]. An important result due to Barabanov [7] states that the function $M \mapsto \rho(M)$ defined on compact sets of operators is continuous (see also [22]). Another result that we will need was again proved by Barbanov in [7] and it states that if M is a bounded

set of linear operators and $\bar{M}$ denotes its closure then $\rho(M) = \rho(\bar{M})$. Note that if M is bounded then its closure $\bar{M}$ is compact by the Heine–Borel theorem.

A special case which makes the joint spectral radius easier to work with is when the set of matrices M is irreducible. A set of linear maps M is called *irreducible* if the only subspaces $W \subseteq V$ such that $\tau_i(W) \subseteq W$ for all $i \in I$ are $W = \{0\}$ and $W = V$. If there exists a non-trivial subspace $W \subset V$ invariant by all τ_i we say that M is reducible. In fact, almost all sets of matrices are irreducible in following sense. The Hausdorff distance between two sets of linear maps M and M' on the same normed vector space $(V, \|\cdot\|)$ is given by

$$d_H(M, M') = \max\left\{ \sup_{\tau \in M} \inf_{\tau' \in M'} \|\tau - \tau'\|, \sup_{\tau' \in M'} \inf_{\tau \in M} \|\tau - \tau'\| \right\} .$$

It is possible to show that irreducible sets of matrices are dense among compact sets of matrices with respect to the topology induced by the Haussdorff distance. Furthermore, Wirth showed in [33] that the joint spectral radius is locally Lipschitz continuous around irreducible sets of matrices with respect to the Hausdorff topology (see also [26] for explicit expressions for the Lipschitz constants). This can be seen as an extension of Barabanov's continuity result providing extra information about the behaviour of the function $M \mapsto \rho(M)$.

Again, the concept of irreducibility can be readily extended to WFA. We say that the weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma \in \Sigma} \rangle$ is irreducible if $M = \{\tau_\sigma\}_{\sigma \in \Sigma}$ is irreducible. This concept will play a role in Section 6. The following result provides a characterization of irreducibility for weighted automata in terms of minimality. In particular, the result shows that irreducibility is a stronger condition than minimality. A proof is provided in the appendix [4].

▶ **Theorem 4.** *A weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma \in \Sigma} \rangle$ is irreducible if and only if A_v^w is minimal for all $v \in V$ and $w \in V^*$ with $v \neq 0$ and $w \neq 0$.*

3 Bisimulation Seminorms and Pseudometrics for WFA

In the same way that the largest bisimulation relation in many settings can be obtained as a fixed point of a certain operator on equivalence relations, a possible way to define bisimulation (pseudo)metrics is via a similar fixed-point construction. See [17] for an example in the case of Markov decision processes. In this section, the fixed-point construction is used to obtain a bisimulation seminorm on states of a given WFA. Given two WFA we can build their difference automaton A and compute the corresponding seminorm of the initial state of A. This construction yields a bisimulation pseudometric between weighted automata.

Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma \in \Sigma} \rangle$ be a weighted automaton over the vector space V. Let $\mathcal{S}$ denote the set of all seminorms on V. Given $\gamma > 0$ we define the map $F_{A,\gamma} : \mathcal{S} \to \mathcal{S}$ between seminorms given by

$$F_{A,\gamma}(s)(v) = |\beta(v)| + \gamma \max_{\sigma \in \Sigma} s(\tau_\sigma(v)) \ . \tag{1}$$

Note that this definition is independent of the initial state α, as is the linear bisimulation for A described in Section 2.2. In the sequel we shall write F instead of $F_{A,\gamma}$ whenever A and γ are clear from the context.

To verify that $F : \mathcal{S} \to \mathcal{S}$ is well defined we must check that the image $F(s)$ of any seminorm s is also a seminorm. Absolute homogeneity is immediate by the linearity of β

and τ_σ and the absolute homogeneity of s. For the subadditivity we have

$$\begin{aligned} F(s)(u+v) &= |\beta(u+v)| + \gamma \max_{\sigma\in\Sigma} s(\tau_\sigma(u+v)) \\ &= |\beta(u)+\beta(v)| + \gamma \max_{\sigma\in\Sigma} s(\tau_\sigma(u)+\tau_\sigma(v)) \\ &\leq |\beta(u)| + |\beta(v)| + \gamma \max_{\sigma\in\Sigma} (s(\tau_\sigma(u)) + s(\tau_\sigma(v))) \\ &\leq F(s)(u) + F(s)(v) \ , \end{aligned}$$

where the last inequality uses subadditivity of the maximum.

To construct bisimulation seminorms for the states of a weighted automaton A we shall study the fixed points of $F_{A,\gamma}$. We start by showing that $F_{A,\gamma}$ has a unique fixed point whenever γ is small enough.

▶ **Theorem 5.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$. If $\gamma < 1/\rho(A)$, then $F_{A,\gamma}$ has a unique fixed point.*

Proof. For simplicity, let $F = F_{A,\gamma}$. By the assumption on γ there exists some $\delta > 0$ such that $\gamma \leq 1/(\rho(A)+\delta)$. Now take $M = \{\tau_\sigma\}_{\sigma\in\Sigma}$ and $\eta = \delta/2$ and let $\|\cdot\|$ be the corresponding quasi-extremal norm on V obtained from Theorem 3. Using this norm we can endow $\mathcal{S}$ with the metric given by $d(s,s') = \sup_{\|v\|\leq 1} |s(v) - s'(v)|$ to obtain a complete metric space $(\mathcal{S}, d)$. To see this, note that for a fixed v with $\|v\| \leq 1$ the sequence $(s_n(v))$ is Cauchy, hence convergent. Call this limit $s(v)$; it is straightforward to see that this defines a seminorm. Thus, if we show that F is a contraction on $\mathcal{S}$ with respect to this metric, then by Banach's fixed point theorem F has a unique fixed point. To see that F is indeed a contraction we start by observing that:

$$d(F(s),F(s')) = \sup_{\|v\|\leq 1} |F(s)(v) - F(s')(v)| = \gamma \sup_{\|v\|\leq 1} \left| \max_\sigma s(\tau_\sigma(v)) - \max_{\sigma'} s'(\tau_{\sigma'}(v)) \right| \ . \quad (2)$$

Fix any $v \in V$ with $\|v\| \leq 1$ and suppose without loss of generality (otherwise we exchange s and s') that $\max_\sigma s(\tau_\sigma(v)) \geq \max_{\sigma'} s'(\tau_{\sigma'}(v))$. Then, letting $\sigma_* = \arg\max_\sigma s(\tau_\sigma(v))$ and using the absolute homogeneity of s and s', it can be shown that:

$$\left| \max_\sigma s(\tau_\sigma(v)) - \max_{\sigma'} s'(\tau_{\sigma'}(v)) \right| \leq \|\tau_{\sigma_*}(v)\| d(s,s') \ . \quad (3)$$

We refer the reader to the appendix [4], for a full derivation. Finally, we use the definition of $\|\cdot\|$ and the choices of δ and η to see that

$$\gamma \|\tau_{\sigma_*}(v)\| \leq \gamma(\rho(A)+\eta)\|v\| \leq \frac{\rho(A)+\delta/2}{\rho(A)+\delta} < 1 \ ,$$

from which we conclude by combining (2) with (3) that $d(F(s),F(s')) < d(s,s')$. ◀

We now exhibit the fixed point of $F_{A,\gamma}$ in closed form. This provides a useful formula for studying properties of the resulting seminorm.

▶ **Theorem 6.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$. Suppose $\gamma < 1/\rho(A)$ and let $s_{A,\gamma} \in \mathcal{S}$ be the fixed point of $F_{A,\gamma}$. Then for any $v \in V$ we have*

$$s_{A,\gamma}(v) = \sup_{x\in\Sigma^\infty} \sum_{t=0}^{\infty} \gamma^t |\beta(\tau_{x_{\leq t}}(v))| = \sup_{x\in\Sigma^\infty} \sum_{t=0}^{\infty} \gamma^t |f_{A_v}(x_{\leq t})| \ . \quad (4)$$

The proof can be found in the appendix [4]. The next theorem is the main result of this section. It shows that any seminorm arising as a fixed point of $F_{A,\gamma}$ captures the notion of A-bisimulation through its kernel for any γ. Namely, two states $u, v \in V$ are A-bisimilar if and only if $s_{A,\gamma}(u - v) = 0$. Note that this result is independent of the choice of γ, as long as the fixed point of $F_{A,\gamma}$ is guaranteed to exist.

▶ **Definition 7.** Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ be a weighted automaton with A-bisimulation $\sim_A$. We say that a seminorm s over V is a *bisimulation seminorm* for A if $\ker(s) = \ker(\sim_A)$.

▶ **Theorem 8.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$. For any $0 < \gamma < 1/\rho(A)$ the fixed point $s_{A,\gamma} \in \mathcal{S}$ of $F_{A,\gamma}$ is a bisimulation seminorm for A.*

Proof. For simplicity, let $F = F_{A,\gamma}$ and $s = s_{A,\gamma}$. Since $W_A = \ker(\sim_A)$ is the largest bisimulation for A, it suffices to show that $\ker(s)$ is a bisimulation for A with $W_A \subseteq \ker(s)$. For the first property we recall that $\ker(s)$ is a linear subspace of V and note that for any $v \in \ker(s)$ we have, using Theorem 6,

$$0 = s(v) = |\beta(v)| + \sup_{x\in\Sigma^\infty} \sum_{t=1}^{\infty} \gamma^t |\beta(\tau_{x_{\leq t}}(v))| \geq |\beta(v)| \geq 0 \ .$$

Therefore $\ker(s) \subseteq \ker(\beta)$. Using the fact that $\beta(v) = 0$, we can also verify the invariance of $\ker(s)$ under all τ_σ, namely $s(\tau_\sigma(v)) = 0$ for all $v \in \ker(s)$ and $\sigma \in \Sigma$ (the full derivation is shown in the appendix [4]). Therefore $\ker(s)$ is a bisimulation for A.

Now let $v \in W_A$. Since W_A is contained in the kernel of β and is invariant for all τ_σ, we see that $\beta(\tau_x(v)) = 0$ for all $x \in \Sigma^\star$. Therefore, using the expression for s given in Theorem 6 we obtain $s(v) = 0$. This concludes the proof. ◀

Because every fixed point of $F_{A,\gamma}$ is a seminorm whose kernel agrees with that of Boreale's bisimulation relation $\sim_A$, we shall call them *γ-bisimulation seminorms* for A. Interestingly, we can show that when A is observable then every γ-bisimulation seminorm is in fact a norm.

▶ **Corollary 9.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ and $\gamma < 1/\rho(A)$. If A is observable then the γ-bisimulation seminorm $s_{A,\gamma}$ is a norm.*

Proof. By Theorem 8 and the observability of A we have $\ker(s_{A,\gamma}) = \ker(\sim_A) = \{0\}$. Thus, $s_{A,\gamma}$ is a norm. ◀

Given an automaton A, and state vectors $v, w \in V$, the pseudometric between states of A induced by $s_{A,\gamma}$ is $d_{A,\gamma}(v, w) = s_{A,\gamma}(v - w)$. Pseudometrics of this form will be called *γ-bisimulation pseudometrics*. By Corollary 9, if A is observable then $d_{A,\gamma}$ is in fact a metric.

To conclude this section we show how to use our γ-bisimulation pseudometrics to define a pseudometric between weighted automata. In order to capture the idea of distance between two WFA let us build the automaton computing the difference between their functions. Given weighted automata $A_i = \langle \Sigma, V_i, \alpha_i, \beta_i, \{\tau_{i,\sigma}\}_{\sigma\in\Sigma}\rangle$ for $i = 1, 2$, we define their *difference automaton* as $A = A_1 - A_2 = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ where $V = V_1 \oplus V_2$, $\alpha = \alpha_1 \oplus (-\alpha_2)$, $\beta = \beta_1 \oplus \beta_2$, and $\tau_\sigma = \tau_{1,\sigma} \oplus \tau_{2,\sigma}$ for all $\sigma \in \Sigma$. Note that A satisfies $f_A(x) = f_{A_1}(x) - f_{A_2}(x)$ for all $x \in \Sigma^\star$ and that $\rho(A) = \max\{\rho(A_1), \rho(A_2)\}$. Then, letting $s_{A,\gamma}$ be the bisimulation seminorm for A we are ready to define our bisimulation distance between weighted automata.

▶ **Definition 10.** Let A_1 and A_2 be two weighted automata and let A be their difference automaton. For any $\gamma < 1/\rho(A)$ we define the *γ-bisimulation distance* between A_1 and A_2 as $d_\gamma(A_1, A_2) = s_{A,\gamma}(\alpha)$.

By exploiting the closed form expression for $s_{A,\gamma}$ given in Theorem 6 we can provide a closed form expression for d_γ.

▶ **Corollary 11.** *Let A_1 and A_2 two weighted automata and $\gamma < 1/\max\{\rho(A_1), \rho(A_2)\}$. Then the γ-bisimulation distance between A_1 and A_2 is given by*

$$d_\gamma(A_1, A_2) = \sup_{x \in \Sigma^\infty} \sum_{t=0}^{\infty} \gamma^t \left| f_{A_1}(x_{\leq t}) - f_{A_2}(x_{\leq t}) \right| \quad . \tag{5}$$

Using the properties of our bisimulation seminorms one can immediately see that d_γ is indeed a pseudometric between all pairs of WFA such that $\gamma < 1/\rho(A_1 - A_2)$. It is also easy to see that d_γ captures the notion of equivalence between weighted automata, in the sense that $d_\gamma(A_1, A_2) = 0$ if and only if $f_{A_1} = f_{A_2}$. Therefore, since minimal weighted automata are unique up to a change of basis, the only way to have $d_\gamma(A_1, A_2) = 0$ when A_1 is minimal is to have either $A_1 = A_2$ or A_2 is a non-minimal WFA recognizing the same weighted language as A_1. In particular, this implies that d_γ is a metric on the set of all minimal WFA A with $\gamma < 1/\rho(A)$.

4 Continuity Properties

In this section we study several continuity properties of our bisimulation pseudometrics between weighted automata. The continuity notions we consider are adapted from those presented by Jaeger et al. in [24], which are developed for labelled Markov chains. Here we extend their definitions of parameter continuity and property continuity to the case of weighted automata. Such notions can be motivated by applications of metrics between transition systems to problems in machine learning [15, 19, 18]; see Section 6 for a discussion on how to use our bisimulation pseudometrics in the analysis of learning algorithms.

4.1 Parameter Continuity

Given a sequence of weighted automata A_i converging to a weighted automaton A, parameter continuity captures the notion that, as the weights in A_i converge to the weights in A, the behavioural distance between A_i and A tends to zero. To make this formal we first define convergence for a sequence of automata and then parameter continuity.

▶ **Definition 12.** Let $(A_i)_{i\in\mathbb{N}}$ be a sequence of WFA $A_i = \langle \Sigma, V, \alpha_i, \beta_i, \{\tau_{i,\sigma}\}_{\sigma\in\Sigma}\rangle$ over the same alphabet Σ and normed vector space $(V, \|\cdot\|)$. We say that the sequence (A_i) *converges* to $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ if $\lim_{i\to\infty} \|\alpha_i - \alpha\| = 0$, $\lim_{i\to\infty} \|\beta_i - \beta\|_* = 0$, and $\lim_{i\to\infty} \|\tau_{i,\sigma} - \tau_\sigma\| = 0$ for all $\sigma \in \Sigma$.

▶ **Definition 13.** A pseudometric d between weighted automata is *parameter continuous* if for any sequence $(A_i)_{i\in\mathbb{N}}$ converging to some weighted automaton A we have $\lim_{i\to\infty} d(A, A_i) = 0$.

The main result of this section is the following theorem stating that our bisimulation pseudometric d_γ is parameter continuous.

▶ **Theorem 14.** *The γ-bisimulation distance between weighted automata is parameter continuous for any sequence of weighted automata $(A_i)_{i\in\mathbb{N}}$ converging to a weighted automaton A with $\gamma < 1/\rho(A)$.*

The proof of this result is quite technical and combines the following two tools:

1. A technical estimate of $d_\gamma(A, A_i)$ in terms of the distance between the weights of A and A_i with respect to a certain norm (Lemma 25 in the appendix [4]). This result also plays a prominent result in Section 6.
2. Several topological properties of the joint spectral radius discussed in Section 2.3.

These proofs are given in the appendix [4].

4.2 Input Continuity

Inspired by the notion of property continuity presented in [24], input g-continuity encapsulates the idea that an upper bound on the behavioural distance between two systems should entail an upper bound on the difference between their outputs on any input $x \in \Sigma^\star$.

▶ **Definition 15.** Let $g : \mathbb{N} \to \mathbb{R}$ be such that $g(l) > 0$ for all $l \in \mathbb{N}$. A distance function d between weighted automata is *input g-continuous* when the following holds: if $(A_i)_{i\in\mathbb{N}}$ is a sequence of weighted automata such that $\lim_{i\to\infty} d(A, A_i) = 0$ for some weighted automaton A, then one has

$$\lim_{i\to\infty} \sup_{x\in\Sigma^\star} \frac{|f_A(x) - f_{A_i}(x)|}{g(|x|)} = 0 \ . \tag{6}$$

Note the special case $g(l) = 1$ is tightly related to the notion of property continuity presented in [24]. The authors of that paper consider differences between the probabilities of the same event under different labelled Markov chains, and therefore always have numbers between 0 and 1. However, for general weighted automata the quantity $|f_A(x) - f_{A'}(x)|$ can grow unboundedly with $|x|$. Thus, in some cases we will need to have a $g(|x|)$ growing with $|x|$ in order to guarantee that (6) stays bounded. The next two results, whose proofs are deferred to the appendix [4], show that essentially $g(|x|) = \gamma^{-|x|}$ is the threshold between input continuity and input non-continuity in our γ-bisimulation pseudometrics.

▶ **Theorem 16.** *The pseudometric d_γ from Definition 10 is input g-continuous for any $g(l) = \Omega(\gamma^{-l})$.*

Note that when $\gamma > 1$ (i.e. when dealing with weighted automata with $\rho(A) \leq 1$) we have $g(l) = 1 \in \Omega(\gamma^{-l})$. This shows that in the case of weighted automata A where every transition operator τ_σ can be represented by a stochastic matrix – a fact that implies $\rho(A) = 1$ – our γ-bisimulation pseudometric is property continuous with respect to the definition in [24].

Further, if g does not grow fast enough as a function of the size of $x \in \Sigma^\star$, then our bisimulation pseudometric is not input g-continuous. In particular, the proof of Theorem 17 provides simple examples of cases where d_γ is not input g-continuous.

▶ **Theorem 17.** *Let $0 < \gamma < 1$. The pseudometric d_γ from Definition 10 is not input g-continuous for any $g(l) = c^{o(l)}$ with $c > 1$.*

5 An Undecidability Result

In this section we will prove that given a weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$, a discount factor $\gamma < 1/\rho(A)$, and a threshold $\nu > 0$, it is undecidable to check whether $s_{A,\gamma}(\alpha) > \nu$. This implies that in general the seminorms and pseudometrics studied in the previous sections are not computable.

The proof of our undecidability result involves a reduction from an undecidable planning problem. Partially observable Markov decision processes (POMDPs) are a generalization of

Markov Decision Processes (MDPs) where we have a set of observations Ω and conditional observation probabilities O. Each state emits some observation $o \in \Omega$ with a certain probability, and so we have a belief over which state we are in after taking an action and observing o. An MDP is a special case of a POMDP where each state has a unique observation, and an unobservable Markov decision process (UMDP) is a special case of a POMDP where all the states emit the same observation. While planning for infinite-horizon UMDPs is undecidable [27], planning for finite-horizon POMDPs is decidable.

Formally, a UMDP is a tuple $U = \langle \Sigma, Q, \alpha, \{\beta_\sigma\}_{\sigma\in\Sigma}, \{T_\sigma\}_{\sigma\in\Sigma}, \gamma\rangle$ where Σ is a finite set of actions, Q is a finite set of states, $\alpha : Q \to [0,1]$ is a probability distribution over initial states in Q, $\beta_\sigma : Q \to \mathbb{R}$ represents the rewards obtained by taking action σ from every state in Q, $T_\sigma : Q \times Q \to [0,1]$ is the transition kernel between states for action σ (i.e. $T_\sigma(q,q')$ is the probability of transitioning to q' given that action σ is taken in q), and $0 < \gamma < 1$ is a discount factor. The value $V_U(x)$ of an infinite sequence of actions $x \in \Sigma^\infty$ in U is the expected discounted cumulative reward collected by executing the actions in x in U starting from a state drawn from α. This can be obtained as follows:

$$V_U(x) = \sum_{t=1}^{\infty} \gamma^{t-1} \alpha^\top T_{x_{\leq t-1}} \beta_{x_t} \ , \tag{7}$$

where $T_y = T_{y_1} \cdots T_{y_t}$ for any finite string $y = y_1 \cdots y_t$ and $T_\epsilon = I$. The following undecidability result was proved by Madani et al. in [27].

▶ **Theorem 18** (Theorem 4.4 in [27]). *The following problem is undecidable: given a UMDP U and a threshold ν decide whether there exists a sequence of actions $x \in \Sigma^\infty$ such that $V_U(x) > \nu$.*

Given a UMDP $U = \langle \Sigma, Q, \alpha, \{\beta_\sigma\}_{\sigma\in\Sigma}, \{T_\sigma\}_{\sigma\in\Sigma}, \gamma\rangle$, we say that U has action-independent rewards if $\beta_\sigma = \beta$ for all $\sigma \in \Sigma$. We say that U has non-negative rewards if $\beta_\sigma(q) \geq 0$ for all $q \in Q$ and $\sigma \in \Sigma$. A careful inspection of the proof in [27] reveals that in fact the reduction provided in the paper always produces as output a UMDP with non-negative action-independent rewards. Thus, we have the following corollary, which forms the basis of our reduction showing that s_γ is not computable.

▶ **Corollary 19.** *The problem in Theorem 18 remains undecidable when restricted to UMDP with non-negative action-independent rewards.*

▶ **Theorem 20.** *The following problem is undecidable: given a weighted automaton $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$, a discount factor $\gamma < 1/\rho(A)$, and a threshold $\nu > 0$, decide whether $s_{A,\gamma}(\alpha) > \nu$.*

Proof. Let $U = \langle \Sigma, Q, \alpha, \beta, \{T_\sigma\}_{\sigma\in\Sigma}, \gamma\rangle$ be a UMDP with non-negative action-independent rewards. With each UMDP of this form we associate the weighted automaton $A = \langle \Sigma, \mathbb{R}^Q, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$. Here we assume that the linear form $\beta : \mathbb{R}^Q \to \mathbb{R}$ is given by $\beta(v) = v^\top \beta$, and that the linear operators $\tau_\sigma : \mathbb{R}^Q \to \mathbb{R}^Q$ are given by $\tau_\sigma(v) = v^\top T_\sigma$.

Note that the matrices T_σ are row-stochastic and therefore we have $\rho(A) \leq \max_\sigma \|\tau_\sigma\|_\infty = 1$. Thus, the discount factor in U satisfies $\gamma < 1 \leq 1/\rho(A)$ and the bisimulation seminorm $s_{A,\gamma}$ associate with A is defined. Using that U has non-negative action-independent rewards we can write for any $x \in \Sigma^\infty$:

$$V_U(x) = \sum_{t=1}^{\infty} \gamma^{t-1} \alpha^\top T_{x_{\leq t-1}} \beta = \sum_{t=0}^{\infty} \gamma^t \alpha^\top T_{x_{\leq t}} \beta = \sum_{t=0}^{\infty} \gamma^t |\alpha^\top T_{x_{\leq t}} \beta| = \sum_{t=0}^{\infty} \gamma^t |\beta(\tau_{x\leq t}(\alpha))| \ .$$

Therefore we have the relation $s_{A,\gamma}(\alpha) = \sup_{x \in \Sigma^\infty} V_U(x)$ between the bisimulation seminorm of A and the value of U. Since deciding whether $V_U(x) > \nu$ for some $x \in \Sigma^\infty$ is undecidable, the theorem follows. ◀

6 Application: Spectral Learning for WFA

An important problem in machine learning is that of finding a weighted automaton $\hat{A}$ approximating an unknown automaton A given only access to data generated by A. A variety of algorithms in different learning frameworks have been considered in the literature; see [5] for an introductory survey. In most learning scenarios it is impossible to exactly recover the target automaton A from a finite amount of data. In that case one aims for algorithms with formal guarantees of the form "the output $\hat{A}$ automaton gets closer to A as the amount of training data grows". To prove such a result one obviously needs a way to measure the distance between two WFA. In this section we show how our γ-bisimulation pseudometric can be used to provide formal learning guarantees for a family of learning algorithms widely referred to as spectral learning. We also briefly discuss the case for behavioural metrics in automata learning problems and compare our metric to other metrics used in the spectral learning literature.

Generally speaking, spectral learning algorithms for WFA work in two phases: the first phase uses the data obtained from the target automaton A to estimate a finite sub-block of the Hankel matrix of f_A; the second phase computes the singular value decomposition of this Hankel matrix and uses the corresponding singular vectors to solve a set of systems of linear equations yielding the weights of the output WFA $\hat{A}$. The Hankel matrix of a function $f : \Sigma^\star \to \mathbb{R}$ is an infinite matrix $H_f \in \mathbb{R}^{\Sigma^\star \times \Sigma^\star}$ with entries given by $H_f(x, y) = f(xy)$, where xy denotes the string obtained by concatenating the prefix x with the suffix y. Spectral learning algorithms work with a finite sub-block $H \in \mathbb{R}^{P \times S}$ of this Hankel matrix indexed by a set of prefixes $P \subset \Sigma^\star$ and a set of suffixes $S \subset \Sigma^\star$. The pair $B = (P, S)$ is usually an input to the algorithm, in which case formal learning guarantees can be provided under the assumption that B is complete for H_{f_A}. This assumption essentially states that the sub-block of H_{f_A} indexed by B contains enough information to recover a WFA equivalent to A, and is composed of a syntactic condition ensuring B contains a set of prefixes and their extensions by any symbol in Σ, and an algebraic condition ensuring the rank of the Hankel sub-matrix indexed by B has the same rank as the full Hankel matrix H_{f_A}. We refer the reader to [5, 3] for further details about the spectral learning algorithm and a discussion of the completeness property for B. In the sequel we focus on the analysis of the error in the output of the spectral learning algorithm, and show how to provide learning guarantees in terms of our distance d_γ.

The following lemma encapsulates the first step of the analysis of spectral learning algorithms. It shows how the error between the operators of A and $\hat{A}$ depends on the error between the true and the approximated Hankel matrix as measured by the standard operator ℓ_2-norm.

▶ **Lemma 21.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma \in \Sigma} \rangle$ be a WFA and let H be a finite sub-block of the Hankel matrix H_{f_A} indexed by $B = (P, S)$. Suppose $\hat{A} = \langle \Sigma, V, \hat{\alpha}, \hat{\beta}, \{\hat{\tau}_\sigma\}_{\sigma \in \Sigma} \rangle$ is the WFA returned by the spectral learning algorithm using an estimation $\hat{H}$ of H. Let $\|\cdot\|$ be any norm on V. If B is complete, then we have $\|\alpha - \hat{\alpha}\|, \|\beta - \hat{\beta}\|_*, \max_{\sigma \in \Sigma} \|\tau_\sigma - \hat{\tau}_\sigma\| \leq O(\|H - \hat{H}\|_2)$ as $\|H - \hat{H}\|_2 \to 0$. Furthermore, the constants hidden in the big-O notation only depend on the norm $\|\cdot\|$, the Hankel sub-block indices $B = (P, S)$, and the size of the alphabet $|\Sigma|$.*

Proof. Combine Lemma 9.3.5 and Lemma 6.3.2 from [2]. ◀

The results from [2] also provide explicit expressions for the constants hidden in the big-O notation. Concentration of measure for random matrices can be used to show that as the amount of training data increases then the distance between H and $\hat{H}$ converges to zero with high probability (see e.g. [13]). Thus, Lemma 21 implies that as more training data becomes available, spectral learning will output a WFA $\hat{A}$ converging to A.

The last step in the analysis involves showing that as the weights of $\hat{A}$ get closer to the weights of A, the behaviour of the two automata also gets closer. Invoking the parameter continuity of d_γ (Theorem 14) one readily sees that $d_\gamma(A, \hat{A}) \to 0$ as $\|H - \hat{H}\|_2 \to 0$. This provides a proof of consistency of spectral learning with respect to the γ-bisimulation pseudometric. However, machine learning applications often require more precise information about the convergence rate of $d_\gamma(A, \hat{A})$ in order to, for example, compute the amount of data required to achieve a certain error. The following result provides such rate of convergence in the case where the target automaton is irreducible.

▶ **Theorem 22.** *Let $A = \langle \Sigma, V, \alpha, \beta, \{\tau_\sigma\}_{\sigma\in\Sigma}\rangle$ be an irreducible WFA and let H be a finite sub-block of the Hankel matrix H_{f_A} indexed by $B = (P, S)$. Suppose $\hat{A} = \langle \Sigma, V, \hat{\alpha}, \hat{\beta}, \{\hat{\tau}_\sigma\}_{\sigma\in\Sigma}\rangle$ is the WFA returned by the spectral learning algorithm using an estimation $\hat{H}$ of H. Suppose B is complete. Then for any $\gamma < 1/\rho(A)$ we have $d_\gamma(A, \hat{A}) \leq O(\|H - \hat{H}\|_2)$ as $\|H - \hat{H}\|_2 \to 0$. Furthermore, the hidden constants in the big-O notation only depend on A, γ, the Hankel block indices $B = (P, S)$, and the size of the alphabet $|\Sigma|$.*

The local Lipschitz continuity of ρ around irreducible sets of matrices plays an important role in the proof of this result (see the appendix [4]). Nonetheless, the irreducibility constraint is not a stringent one since the sets of irreducible matrices are known to be dense among compact sets of matrices with respect to the Hausdorff metric.

We conclude this section by comparing Theorem 22 with analyses of spectral learning based on other error measures. We start by noting that all finite-sample analyses of spectral learning for WFA we are aware of in the literature provide error bounds in terms of some finite variant of the ℓ_1 distance. In particular, the analyses in [23, 31] bound $\sum_{x\in\Sigma^t} |f_A(x) - f_{\hat{A}}(x)|$ for a fixed $t \geq 0$, while the analyses in [1, 2, 21] extend the bounds to $\sum_{x\in\Sigma^{\leq t}} |f_A(x) - f_{\hat{A}}(x)|$ for a fixed $t \geq 0$. This approach poses several drawbacks, including:

1. Finite ℓ_1-norms provide a pseudo-metric between WFA whose kernel includes pairs of non-equivalent WFA.
2. The number of samples required to achieve a certain error increase with the horizon t, meaning that more data is required to get the same error on longer strings, and that existing bounds become vacuous in the case $t \to \infty$.

In contrast, our result in terms of d_γ establishes a bound on the discrepancy between A and $\hat{A}$ on strings of arbitrary length and will never assign zero distance to a pair of automata realizing different functions. Furthermore, our bisimulation metric still makes sense outside the setting of spectral learning of probabilistic automata where most of the techniques mentioned above have been developed.

7 Conclusion

The metric developed in this paper was very much motivated and informed by spectral ideas. Not surprisingly it was well suited for analyzing spectral learning algorithms for weighted automata. Two obvious directions for future work are:

1. Approximation algorithms for the bisimulation metric.
2. Exploring the relation to approximate minimization.

Both of these are well underway. It seems that some recent ideas from non-linear optimization are very useful in developing approximation algorithms and we hope to be able to report our results soon. Exploring the relation to approximate minimization is less further along, but the spectral ideas at the heart of the approximate minimization algorithm in [6] should be well adapted to the techniques of the present paper.

Acknowledgements. We would like to thank Doina Precup who was actively involved in the approximate minimization work.

Abstract

We address the behavioral metric-based approximate minimization problem of Markov Chains (MCs), i.e., given a finite MC and a positive integer k, we are interested in finding a k-state MC of *minimal* distance to the original. By considering as metric the bisimilarity distance of Desharnais at al., we show that optimal approximations always exist; show that the problem can be solved as a bilinear program; and prove that its threshold problem is in PSPACE and NP-hard. Finally, we present an approach inspired by expectation maximization techniques that provides suboptimal solutions. Experiments suggest that our method gives a practical approach that outperforms the bilinear program implementation run on state-of-the-art bilinear solvers.

1 Introduction

Minimization of finite automata, i.e., the process of transforming a given finite automaton into an equivalent one with minimum number of states, has been a major subject since the 1950s due to its fundamental importance for any implementation of finite automata tools.

The first algorithm for the minimization of deterministic finite automata (DFAs) is due to Moore [27], with time complexity $O(n^2 s)$, later improved by the now classical Hopcroft's algorithm [17] to $O(ns \log n)$, where n is the number of states and s the size of the alphabet. Their algorithms are based on a partition refinement of the states into equivalence classes of the *Myhill-Nerode equivalence relation*. Partition refinement has been employed in the definition of efficient minimization procedures for a wide variety of automata: by Kanellakis and Smolka [19, 20] for the minimization of labelled transition systems (LTSs) w.r.t. Milner's

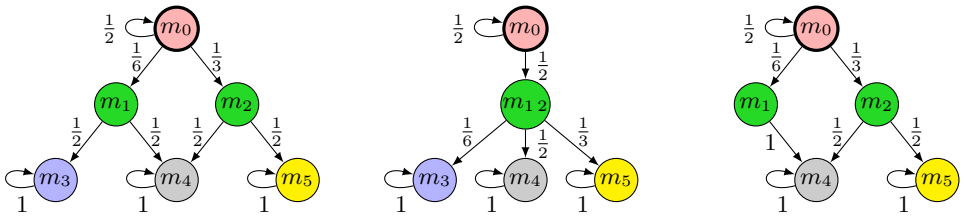
strong bisimulation [26]; by Baier [4] for the reduction of Markov Chains (MCs) w.r.t. Larsen and Skou's probabilistic bisimulation [23]; by Alur et al. [2] and by Yannakakis and Lee [30], respectively, for the minimization of timed transition systems and timed-automata. This technique was used also in parallel and distributed implementations of the above algorithms [31, 8], and in the online reachability analysis of transition systems [24].

In [18], Jou and Smolka observed that for reasoning about the behavior of probabilistic systems (and more in general, all type of quantitative systems), rather than equivalences, a notion of distance is more reasonable in practice, since it permits "*a shift in attention from equivalent processes to probabilistically similar processes*". This observation motivated the development of metric-based semantics for quantitative systems, that consists in proposing 1-bounded pseudometrics capturing the similarities of the behaviors in the presence of small variations of the quantitative data. These pseudometrics generalize behavioral equivalences in the sense that, two processes are at distance 0 iff they are equivalent, and at distance 1 if no significant similarities can be observed between them.

The first proposal of a behavioral pseudometric is due to Desharnais et al. [12] on labelled MCs, a.k.a. *probabilistic bisimilarity distance*, with the property that two MCs are at distance 0 iff they are probabilistic bisimilar. Its definition is parametric on a discount factor $\lambda \in (0, 1]$ that controls the significance of the future steps in the measurement. This pseudometric has been greatly studied by van Breugel and Worrell [28, 29, 10] who noticed, among other notable results, its relation with the Kantorovich distance on probability distributions and provided a polynomial-time algorithm for its computation.

The introduction of metric-based semantics motivated the interest in the approximate minimization of quantitative systems. The goal of approximate minimization is to start from a minimal automaton and produce a smaller automaton that is close to the given one in a certain sense. The desired size of the approximating automaton is given as input. Inspired by the aggregation of equivalent states typical of partition refinement techniques, in [15], the approximate minimization problem has been approached by aggregating states having relative smaller distance. An example of this approach on MCs using the λ-bisimilarity distance of Desharnais et al. is shown below.



Let $\mathcal{M}$ be the MC on the left and assume we want to approximate it by an MC with at most 5 states. Since m_1, m_2 are the only two states at distance less than 1, the most natural choice for an aggregation shall collapse (via convex combination) m_1 and m_2, obtaining the MC in the middle, which has distance $\frac{4}{9}(\frac{\lambda^2}{2-\lambda})$ from $\mathcal{M}$. However, the approximate aggregation of states does not necessarily yield the closest optimal solution. Indeed, the MC on the right is a closer approximant of $\mathcal{M}$, at distance $\frac{1}{6}(\frac{\lambda^2}{2-\lambda})$ from it.

In this paper we address the issue of finding *optimal* solutions to the approximate minimization problem. Specifically we aim to answer to the following problem, left open in [15]: "*given a finite MC and a positive integer k, what is its 'best' k-state approximant? Here by 'best' we mean a k-state MC at minimal distance to the original*". We refer to this

problem as *Closest Bounded Approximant* (CBA) and we present the following results related to it.

1. We characterize CBA as a bilinear optimization problem, proving the existence of *optimal* solutions. As a consequence of this result, approximations of optimal solutions can be obtained by checking the feasibility of bilinear matrix inequalities (BMIs) [22, 21].
2. We provide upper- and lower-bound complexity results for the threshold problem of CBA, called *Bounded Approximant* problem (BA), that asks whether there exists a k-state approximant with distance from the original MC bounded by a given rational threshold. We show that BA is in PSPACE and NP-hard. As a corollary we obtain NP-hardness for CBA.
3. We introduce the *Minimum Significant Approximant Bound* (MSAB) problem, that asks what is the minimum size k for an approximant to have some significant similarity to the original MC (i.e., at distance strictly less than 1). We show that this problem is NP-complete when one considers the undiscounted bisimilarity distance.
4. Finally, we present an algorithm for finding suboptimal solutions of CBA that is inspired by Expectation Maximization (EM) techniques [25, 7]. Experiments suggest that our method gives a practical approach that outperforms the bilinear program implementation – state-of-the-art bilinear solvers [21] fails to handle MCs with more than 5 states!

Related Work. In [16], the approximate minimization of MCs is addressed via the notion of *quasi-lumpability*. An MC is quasi-lumpable if the given aggregations of the states can be turned into actual bisimulation-classes by a small perturbation of the transition probabilities. This approach differs from ours since there is no relation to a proper notion of behavioral distance (the approximation is w.r.t. the supremum norm of the difference of the stochastic matrices) and we do not consider any approximate aggregation of states. In [6], Balle et al. consider the approximate minimization of weighted finite automata (WFAs). Their method is via a truncation of a canonical normal form for WFAs that they introduced for the SVD decomposition of infinite Hankel matrices. Both [16] and [6] do not consider the issue of finding the *closest* approximant, which is the main focus of this paper, instead they give upper bounds on the distance from the given model.

2 Markov Chains and Bisimilarity Pseudometric

In this section we introduce the notation and recall the definitions of (discrete-time) *Markov chains* (MCs), *probabilistic bisimilarity* of Larsen and Skou [23], and the *probabilistic bisimilarity pseudometric* of Desharnais et al. [13].

For $R \subseteq X \times X$ an equivalence relation, $X/_R$ denotes its quotient set and $[x]_R$ denotes the R-equivalence class of $x \in X$. $\mathcal{D}(X)$ denotes the set of discrete probability distributions on X, i.e., functions $\mu\colon X \to [0,1]$, s.t. $\mu(X) = 1$, where $\mu(E) = \sum_{x\in E} \mu(x)$ for $E \subseteq X$.

In what follows we fix a countable set L of labels.

▶ **Definition 1** (Markov Chain). A *Markov chain* is a tuple $\mathcal{M} = (M, \tau, \ell)$ consisting of a finite nonempty *set of states* M, a *transition distribution function* $\tau\colon M \to \mathcal{D}(M)$, and a *labelling function* $\ell\colon M \to L$.

Intuitively, if $\mathcal{M}$ is in state m it moves to state m' with probability $\tau(m)(m')$. Labels represent atomic properties that hold in certain states. The set of labels of $\mathcal{M}$ is denoted by $L(\mathcal{M}) = \{\ell(m) \mid m \in M\}$. Hereafter, we use $\mathcal{M} = (M, \tau, \ell)$ and $\mathcal{N} = (N, \theta, \alpha)$ to range over MCs and we refer to their constituents implicitly.

▶ **Definition 2** (Probabilistic Bisimulation [23]). An equivalence relation $R \subseteq M \times M$ is a *probabilistic bisimulation* on $\mathcal{M}$ if whenever $m\ R\ n$, then
1. $\ell(m) = \ell(n)$, and
2. for all $C \in M/_R$, $\tau(m)(C) = \tau(n)(C)$.

Two states $m, n \in M$ are *probabilistic bisimilar w.r.t.* $\mathcal{M}$, written $m \sim_{\mathcal{M}} n$ if they are related by some probabilistic bisimulation on $\mathcal{M}$. In fact, probabilistic bisimilarity is the greatest probabilistic bisimulation.

Any bisimulation R on $\mathcal{M}$ induces a quotient construction, the *R-quotient of $\mathcal{M}$*, denoted $\mathcal{M}/_R = (M/_R, \tau/_R, \ell/_R)$, having R-equivalence classes as states, transition function $\tau/_R([m]_R)([n]_R) = \sum_{u \in [n]_R} \tau(m)(u)$, and labelling function $\ell/_R([m]_R) = \ell(m)$. An MC $\mathcal{M}$ is said *minimal* if it is isomorphic to its quotient w.r.t. probabilistic bisimilarity.

A 1-bounded *pseudometric* on X is a function $d\colon X \times X \to [0,1]$ such that, for any $x, y, z \in X$, $d(x,x) = 0$, $d(x,y) = d(y,x)$, and $d(x,y) + d(y,z) \geq d(x,z)$. 1-bounded pseudometrics on X forms a complete lattice under the point-wise partial order $d \sqsubseteq d'$ iff, for all $x, y \in X$, $d(x,y) \leq d'(x,y)$.

A pseudometric is said to lift an equivalence relation if it enjoys the property that two points are at distance zero iff they are related by the equivalence. A lifting for the probabilistic bisimilarity is provided by the *bisimilarity distance* of Desharnais et al. [13]. Its definition is based on the *Kantorovich (pseudo)metric* on probability distributions over a finite set X, defined as $\mathcal{K}(d)(\mu,\nu) = \min\left\{\int d\,\mathrm{d}\omega \mid \omega \in \Omega(\mu,\nu)\right\}$, where d is a (pseudo)metric on X and $\Omega(\mu,\nu)$ denotes the set of *couplings* for (μ,ν), i.e., distributions $\omega \in \mathcal{D}(X \times X)$ such that, for all $E \subseteq X$, $\omega(E \times X) = \mu(E)$ and $\omega(X \times E) = \nu(E)$.

▶ **Definition 3** (Bisimilarity Distance). Let $\lambda \in (0,1]$. The λ-discounted *bisimilarity pseudometric* on $\mathcal{M}$, denoted by δ_λ, is the least fixed-point of the following functional operator on 1-bounded pseudometrics over M (ordered point-wise)

$$\Psi_\lambda(d)(m,n) = \begin{cases} 1 & \text{if } \ell(m) \neq \ell(n) \\ \lambda \cdot \mathcal{K}(d)(\tau(m),\tau(n)) & \text{otherwise}. \end{cases}$$

The operator Ψ_λ is monotonic, hence, by Tarski fixed-point theorem, δ_λ is well defined.

Intuitively, if two states have different labels δ_λ considers them as "incomparable" (i.e., at distance 1), otherwise their distance is given by the Kantorovich distance w.r.t. δ_λ between their transition distributions. The *discount factor* $\lambda \in (0,1]$ controls the significance of the future steps in the measurement of the distance; if $\lambda = 1$, the distance is said *undiscounted*.

The distance δ_λ has also a characterization based on the notion of coupling structure.

▶ **Definition 4** (Coupling Structure). A function $\mathcal{C}\colon M \times M \to \mathcal{D}(M \times M)$ is a *coupling structure* for $\mathcal{M}$ if for all $m, n \in M$, $\mathcal{C}(m,n) \in \Omega(\tau(m),\tau(n))$.

Intuitively, a coupling structure can be thought of as an MC on the cartesian product $M \times M$, obtained as the probabilistic combination of two copies of $\mathcal{M}$.

Given a coupling structure $\mathcal{C}$ for $\mathcal{M}$ and $\lambda \in (0,1]$, let $\gamma^{\mathcal{C}}_\lambda$ be the least fixed-point of the following operator on $[0,1]$-valued functions $d\colon M \times M \to [0,1]$ (ordered point-wise)

$$\Gamma^{\mathcal{C}}_\lambda(d)(m,n) = \begin{cases} 1 & \text{if } \ell(m) \neq \ell(n) \\ \lambda \int d\,\mathrm{d}\mathcal{C}(m,n) & \text{otherwise}. \end{cases}$$

The function $\gamma^{\mathcal{C}}_\lambda$ is called *λ-discounted discrepancy* of $\mathcal{C}$, and the value $\gamma^{\mathcal{C}}_\lambda(m,n)$ is the λ-discounted probability of hitting from (m,n) a pair of states with different labels in $\mathcal{C}$.

▶ **Theorem 5** (Minimal coupling criterion [10]). *For arbitrary MCs $\mathcal{M}$ and discount factors $\lambda \in (0,1]$, $\delta_\lambda = \min\{\gamma^{\mathcal{C}}_\lambda \mid \mathcal{C}$ coupling structure for $\mathcal{M}\}$.*

Usually, MCs are associated with an initial state to be thought of as their initial configurations. In the rest of the paper when we talk about the distance between two MCs, written $\delta_\lambda(\mathcal{M},\mathcal{N})$, we implicitly refer to the distance between their initial states computed over the disjoint union of their MCs.

3 The Closest Bounded Approximant Problem

In this section we introduce the *Closest Bounded Approximant* problem w.r.t. δ_λ (CBA-λ), and give a characterization of it as a bilinear optimization problem.

▶ **Definition 6** (Closest Bounded Approximant). Let $k \in \mathbb{N}$ and $\lambda \in (0,1]$. The *closest bounded approximant problem* w.r.t. δ_λ for an MC $\mathcal{M}$ is the problem of finding an MC $\mathcal{N}$ with at most k states minimizing $\delta_\lambda(\mathcal{M},\mathcal{N})$.

Clearly, when k is greater than or equal to the number of bisimilarity classes of $\mathcal{M}$, an optimal solution of CBA-λ is the bisimilarity quotient. Therefore, without loss of generality, we will assume $1 \leq k < |M|$ and $\mathcal{M}$ to be minimal. Note that, under these assumptions $\mathcal{M}$ must have at least two nodes with different labels.

Let $\mathrm{MC}(k)$ denote the set of MCs with at most k states and $\mathrm{MC}_A(k)$ its restriction to those using only labels in $A \subseteq L$. Using this notation, the optimization problem CBA-λ on the instance $\langle \mathcal{M}, k\rangle$ can be reformulated as finding an MC $\mathcal{N}^*$ such that

$$\delta_\lambda(\mathcal{M},\mathcal{N}^*) = \min\{\delta_\lambda(\mathcal{M},\mathcal{N}) \mid \mathcal{N} \in \mathrm{MC}(k)\}\ , \tag{1}$$

In general, it is not obvious that for arbitrary instances $\langle \mathcal{M}, k\rangle$ a minimum in (1) exists. At the end of the section, we will show that such a minimum always exists (Corollary 9).

A useful property of CBA-λ is that an optimal solution can be found among the MCs using labels from the given MC.

▶ **Lemma 7** (Meaningful labels). *Let $\mathcal{M}$ be an MC. Then, for any $\mathcal{N}' \in \mathrm{MC}(k)$ there exists $\mathcal{N} \in \mathrm{MC}_{L(\mathcal{M})}(k)$ such that $\delta_\lambda(\mathcal{M},\mathcal{N}) \leq \delta_\lambda(\mathcal{M},\mathcal{N}')$.*

In the following, fix $\langle \mathcal{M}, k\rangle$ as instance of CBA-λ, let $m_0 \in M$ be the initial state of $\mathcal{M}$. By Lemma 7, Theorem 5 and Tarski fixed-point theorem

$$\begin{aligned}
&\inf\{\delta_\lambda(\mathcal{M},\mathcal{N}) \mid \mathcal{N} \in \mathrm{MC}(k)\} = && (2)\\
&\quad = \inf\{\gamma^{\mathcal{C}}_\lambda(\mathcal{M},\mathcal{N}) \mid \mathcal{N} \in \mathrm{MC}_{L(\mathcal{M})}(k) \text{ and } \mathcal{C} \in \Omega(\mathcal{M},\mathcal{N})\} && (3)\\
&\quad = \inf\{d(\mathcal{M},\mathcal{N}) \mid \mathcal{N} \in \mathrm{MC}_{L(\mathcal{M})}(k), \mathcal{C} \in \Omega(\mathcal{M},\mathcal{N}), \text{ and } \Gamma^{\mathcal{C}}_\lambda(d) \sqsubseteq d\}\ , && (4)
\end{aligned}$$

where $\Omega(\mathcal{M},\mathcal{N})$ denotes the set of all coupling structures for the disjoint union of $\mathcal{M}$ and $\mathcal{N}$. This simple change in perspective yields a translation of the problem of computing the optimal value of CBA-λ to the bilinear program in Figure 1.

In our encoding, $N = \{n_0, \ldots, n_{k-1}\}$ are the states of an arbitrary $\mathcal{N} = (N, \theta, \alpha) \in \mathrm{MC}(k)$ and n_0 is the initial one. The variable $\theta_{n,v}$ is used to encode the transition probability $\theta(n)(v)$. Hence, a feasible solution satisfying (9–11) will have the variable $c^{m,n}_{u,v}$ representing the value $\mathcal{C}(m,n)(u,v)$ for a coupling structure $\mathcal{C} \in \Omega(\mathcal{M},\mathcal{N})$. An assignment for the variables $\alpha_{n,l}$ satisfying (7–8) encodes (uniquely) a labeling function $\alpha\colon N \to L(\mathcal{M})$ satisfying the following property:

$$\text{for all } n \in N, l \in L(\mathcal{M}) \qquad \alpha_{n,l} = 1 \quad \text{iff} \quad \alpha(n) = l\,. \tag{12}$$

$$
\begin{aligned}
&\text{mimimize} && d_{m_0,n_0} && && \\
&\text{such that} && \lambda \textstyle\sum_{(u,v)\in M\times N} c_{u,v}^{m,n} \cdot d_{u,v} \le d_{m,n} && m\in M,\, n\in N && (5)\\
& && 1-\alpha_{n,l} \le d_{m,n} \le 1 && n\in N,\, l\in L(\mathcal{M}),\, \ell(m)\neq l && (6)\\
& && \alpha_{n,l}\cdot\alpha_{n,l'} = 0 && n\in N,\, l,l'\in L(\mathcal{M}),\, l\neq l' && (7)\\
& && \textstyle\sum_{l\in L(\mathcal{M})} \alpha_{n,l} = 1 && n\in N && (8)\\
& && \textstyle\sum_{v\in N} c_{u,v}^{m,n} = \tau(m)(u) && m,u\in M,\, n\in N && (9)\\
& && \textstyle\sum_{u\in M} c_{u,v}^{m,n} = \theta_{n,v} && m\in M,\, n,v\in N && (10)\\
& && c_{u,v}^{m,n} \ge 0 && m,u\in M,\, n,v\in N && (11)
\end{aligned}
$$

Figure 1 Characterization of CBA-λ as a bilinear optimization problem.

The constraint (7) models the fact that each node $n \in N$ is assigned to at most one label $l \in L(\mathcal{M})$, and the constraint (8) ensures that each node is assigned to at least one label. Conversely, any labeling $\alpha\colon N \to L(\mathcal{M})$ admits an assignment of the variables $\alpha_{n,l}$ that satisfy (7–8) and (12). Finally, an assignment for the variables $d_{m,n}$ satisfying the constraints (5–6) represents a prefix point of $\Gamma_\lambda^{\mathcal{C}}$. Note that (6) guarantees that $d_{m,n} = 1$ whenever $\alpha(n) \neq \ell(m)$ – indeed, by (7), $\alpha_{n,l} = 0$ iff $\alpha(n) \neq \ell(m)$.

Let $F_\lambda\langle\mathcal{M}, k\rangle$ denote the bilinear optimization problem in Figure 1. Directly from the arguments stated above we obtain the following result.

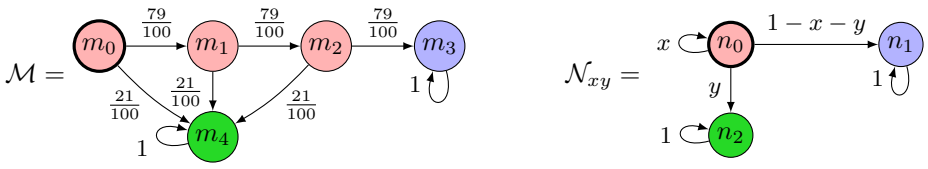
▶ **Theorem 8.** $\inf\{\delta_\lambda(\mathcal{M},\mathcal{N}) \mid \mathcal{N}\in \mathrm{MC}(k)\}$ *is the optimal value of* $F_\lambda\langle\mathcal{M},k\rangle$.

▶ **Corollary 9.** *Any instance of CBA-*λ *admits an optimal solution.*

Proof. Let h be the number of variables in $F_\lambda\langle\mathcal{M},k\rangle$. The constraints (6–11) describe a compact subset of $\mathbb{R}^h$ – it is an intersection of closed sets bounded by $[0,1]^h$. The objective function of $F_\lambda\langle\mathcal{M},k\rangle$ is linear, hence the infimum is attained by a feasible solution. The thesis follows by Theorem 8. ◀

The following example shows that even by starting with a MC with rational transition probabilities, optimal solutions for CBA-λ may have irrational transition probabilities.

▶ **Example 10.** Consider the MC $\mathcal{M}$ depicted below, with initial state m_0 and labeling represented by colors. An optimal solution of CBA-1 on $\langle\mathcal{M},3\rangle$ is the MC $\mathcal{N}_{xy}$ depicted below, with initial state n_0 and parameters $x = \frac{1}{30}\left(10+\sqrt{163}\right)$, $y = \frac{21}{100}$.



Since the distance $\delta_1(\mathcal{M},\mathcal{N}_{xy}) = \frac{436}{675} - \frac{163\sqrt{163}}{13500} \approx 0.49$ is irrational, by [10, Proposition 13], any optimal solution must have some irrational transition probability.

Next we show that the above is indeed an optimal solution. Assume by contradiction that $\mathcal{N}^* \not\sim \mathcal{N}_{xy}$ is an optimal solution. By Lemma 7, we can assume $L(\mathcal{N}^*) \subseteq L(\mathcal{M})$. If

$L(\mathcal{N}^*) = L(\mathcal{M})$, then $\delta_1(\mathcal{M},\mathcal{N}^*) = \min\{\delta_1(\mathcal{M},\mathcal{N}_{zy}) \mid z \in [0,1-y]\}$ since one can show that for any $y' \neq y$ and z', there exists $z \in [0,1-y]$, such that $\delta_1(\mathcal{M},\mathcal{N}_{zy}) \leq \delta_1(\mathcal{M},\mathcal{N}_{z'y'})$. $\delta_1(\mathcal{M},\mathcal{N}_{zy})$ is analytically solved by $z^3 - z^2 - \frac{21}{100}z - \frac{79}{100}$ and its minimum value is achieved at $z = \frac{1}{30}\left(10 + \sqrt{163}\right)$. This contradicts $\mathcal{N}^* \not\sim \mathcal{N}_{xy}$. Assume $L(\mathcal{N}^*) \subsetneq L(\mathcal{M})$. By [10, Corollary 11], for any measurable set $A \subseteq L^\omega$, $\delta_1(\mathcal{M},\mathcal{N}^*) \geq |\mathbb{P}_{\mathcal{M}}(A) - \mathbb{P}_{\mathcal{N}^*}(A)|$, where $\mathbb{P}_{\mathcal{N}}(A)$ denotes the probability that a run of $\mathcal{N}$ is in A. If $\ell(m_0) \notin L(\mathcal{N}^*)$, we have that $\delta_1(\mathcal{M},\mathcal{N}^*) \geq |\mathbb{P}_{\mathcal{M}}(\ell(m_0)L^\omega) - \mathbb{P}_{\mathcal{N}^*}(\ell(m_0)L^\omega)| = \mathbb{P}_{\mathcal{M}}(\ell(m_0)L^\omega) = 1 > \delta_1(\mathcal{M},\mathcal{N}_{xy})$. Analogously, if $\ell(m_3) \notin L(\mathcal{N}^*)$ we have $\delta_1(\mathcal{M},\mathcal{N}^*) \geq \mathbb{P}_{\mathcal{M}}(L^*\ell(m_3)L^\omega) = \left(\frac{79}{100}\right)^3 > \delta_1(\mathcal{M},\mathcal{N}_{xy})$. Finally, if $\ell(m_4) \notin L(\mathcal{N}^*)$, $\delta_1(\mathcal{M},\mathcal{N}^*) \geq \mathbb{P}_{\mathcal{M}}(L^*\ell(m_4)L^\omega) = \frac{21}{100}\sum_{i=0}^{2}\left(\frac{79}{100}\right)^i > \delta_1(\mathcal{M},\mathcal{N}_{xy})$. ◀

4 The Bounded Approximant Threshold Problem

The *Bounded Approximant problem* w.r.t. δ_λ (BA-λ) is the threshold decision problem of CBA-λ, that, given MC $\mathcal{M}$, integer $k \geq 1$, and rational $\epsilon \geq 0$, asks whether there exists $\mathcal{N} \in \mathrm{MC}(k)$ such that $\delta_\lambda(\mathcal{M},\mathcal{N}) \leq \epsilon$.

From the characterization of CBA-λ as a bilinear optimization problem (Theorem 8) we immediately get the following complexity upper-bound for BA-λ.

▶ **Theorem 11.** *For any $\lambda \in (0,1]$, BA-λ is in PSPACE.*

Proof. By Theorem 8, deciding an instance $\langle \mathcal{M}, k, \epsilon\rangle$ of BA-λ can be encoded as a decision problem for the existential theory of the reals, namely, checking the feasibility of the constraints (6–11) in conjunction with $d_{m_0,n_0} \leq \epsilon$. The encoding is polynomial in the size of $\langle \mathcal{M}, k, \epsilon\rangle$, thus it can be solved in PSPACE (*cf.* Canny [9]). ◀

In the rest of the section we provide a complexity lower-bound for BA-λ, by showing that BA-λ is NP-hard via a reduction from Vertex Cover. Recall that, a vertex cover of an undirected graph G is a subset C of vertices such that every edge in G has at least one endpoint in C. Given a graph G and a positive integer h, the Vertex Cover problem asks if G has a cover of size at most h.

Before presenting the reduction we establish structural properties for an optimal solution of CBA-λ in the case the given MC has injective labeling (i.e., no two distinct states with the same label). Specifically, we show that an optimal solution for an instance $\langle \mathcal{M}, k\rangle$ of CBA-λ can be found among MCs with injective labeling into $L(\mathcal{M})$.

▶ **Lemma 12.** *If $\mathcal{M}$ has injective labeling, there exists $\mathcal{N} \in \mathrm{MC}_{L(\mathcal{M})}(k)$ with injective labeling that minimizes the distance $\delta_\lambda(\mathcal{M},\mathcal{N})$.*

▶ **Lemma 13.** *For all $m \in M$ and $n \in N$, $\delta_\lambda(m,n) \geq \lambda \cdot \tau(m)(\{u \in M \mid \ell(u) \notin L(\mathcal{N})\})$.*

Note that Lemma 13 provides a lower-bound on the optimal distance between $\mathcal{M}$ and any $\mathcal{N} \in \mathrm{MC}(k)$. This lower-bound will be useful in the proof of the following result.

▶ **Theorem 14.** *For any $\lambda \in (0,1]$, BA-λ is NP-hard.*

Proof. We provide a polynomial-time many-one reduction from Vertex Cover.

Let $\langle G = (V,E), h\rangle$ be an instance of Vertex Cover and let $e = |E|$. Without loss of generality we assume $e \geq 2$ and $k < n$. From G we construct the MC $\mathcal{M}_G = (M, \tau, \ell)$ as follows. The set of states M is given as the union of V and E to which we add two extra states: a root r (thought of as the initial state) and a sink s. Each node of $\mathcal{M}_G$ is associated with a unique label (i.e., ℓ is injective). The sink state s and all $v \in V$ loop to themselves

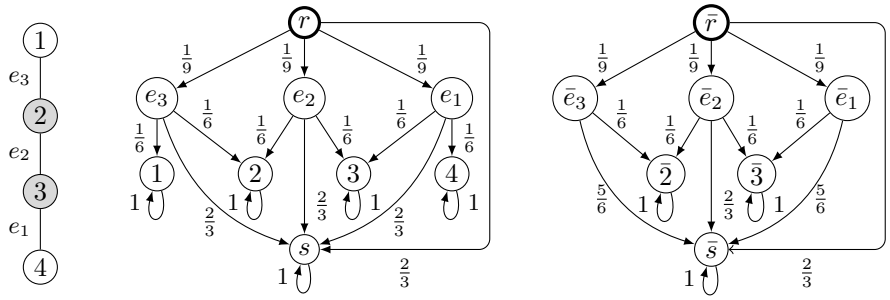


Figure 2 (Left) An undirected graph G; (Center) The MC $\mathcal{M}_G$ associated to the graph G; (Right) The MC $\mathcal{M}_C$ associated to the vertex cover $C = \{2, 3\}$ of G. (see Thm. 14).

with probability 1. All the other states go with probability $1 - \frac{1}{e}$ to the sink state s. The rest of their transition probability mass is assigned as follows. The root r goes with probability $\frac{1}{e^2}$ to each $a \in E$, and all $(u, v) \in E$ go with probability $\frac{1}{2e}$ to their endpoints u, v. An example of construction for $\mathcal{M}_G$ is given in Figure 2. Next we show that

$$\langle G, h\rangle \in \textsc{Vertex Cover} \qquad \text{iff} \qquad \langle \mathcal{M}_G, e + h + 2, \tfrac{\lambda^2}{2e^2}\rangle \in \text{BA-}\lambda\,.$$

($\Rightarrow$) Let C be a h-vertex cover of G. Construct $\mathcal{M}_C \in \mathrm{MC}(e + h + 2)$ by taking a copy of $\mathcal{M}_G$, removing all states in $V \setminus C$, and redirecting the exceeding transition probability to the sink state s (an example is shown in Figure 2). Next we show that $\delta_\lambda(\mathcal{M}_G, \mathcal{M}_C) \leq \frac{\lambda^2}{2e^2}$. For convenience, the states in $\mathcal{M}_C$ will be marked with a bar. By construction of $\mathcal{M}_G, \mathcal{M}_C$, for each $a \in E$, $\delta_\lambda(a, \overline{a}) \leq \frac{\lambda}{2e}$. Thus, $\delta_\lambda(\mathcal{M}_G, \mathcal{M}_C) = \delta_\lambda(r, \bar{r}) = \frac{\lambda}{e^2}\sum_{a\in E}\delta_\lambda(a, \overline{a}) \leq \frac{\lambda^2}{2e^2}$.

($\Leftarrow$) By contradiction, assume there exists $\mathcal{N} = (N, \theta, \alpha) \in \mathrm{MC}(e + h + 2)$ such that $\delta_\lambda(\mathcal{M}_G, \mathcal{N}) \leq \frac{\lambda^2}{2e^2}$ but no vertex cover of G of size h. Since ℓ is injective, by Lemma 12 we can assume α to be injective and $L(\mathcal{N}) \subseteq L(\mathcal{M}_G)$. We consider three cases separately:

Case: $\ell(s) \notin L(\mathcal{N})$. By Lemma 13 and the fact that $e > 1$ and $\lambda \in (0, 1]$, we get the following contradiction: $\delta_\lambda(\mathcal{M}_G, \mathcal{N}) = \delta_\lambda(r, n_0) \geq \lambda \cdot \tau(r)(s) = \frac{\lambda(e-1)}{e} > \frac{\lambda^2}{2e^2}$.

Case: $\ell((u, v)) \notin L(\mathcal{N})$, for some $(u, v) \in E$. By Lemma 13 and the fact that $\lambda \in (0, 1]$ and $e > 1$, leading to the contradiction $\delta_\lambda(\mathcal{M}_G, \mathcal{N}) = \delta_\lambda(r, n_0) \geq \lambda \cdot \tau(r)((u, v)) = \frac{\lambda}{e^2} > \frac{\lambda^2}{2e^2}$.

Case: $\ell(s) \in L(\mathcal{N})$ and $\{\ell((u, v)) \mid (u, v) \in E\} \subseteq L(\mathcal{N})$. Let $N' \subseteq N$ be the states with labels in $\{\ell(u) \mid u \in V\}$. By the structural hypothesis assumed on $\mathcal{N}$, we have $|N'| \leq h$. For each $(u, v) \in E$, two possible cases apply: if $\alpha(n) \in \{\ell(u), \ell(v)\}$, for some $n \in N'$, then $\delta_\lambda((u, v), \overline{(u, v)}) \geq \frac{\lambda}{2e}$; otherwise $\delta_\lambda((u, v), \overline{(u, v)}) \geq \frac{\lambda}{e} > \frac{\lambda}{2e}$. By hypothesis, there is no vertex cover of size h, hence there is at least one edge $(u, v) \in E$ for which the second case applies. Therefore, $\delta_\lambda(\mathcal{M}_G, \mathcal{N}) = \delta_\lambda(r, n_0) = \frac{\lambda}{e^2}\sum_{(u,v)\in E}\delta_\lambda((u, v), \overline{(u, v)}) > \frac{\lambda}{e^2} \cdot e \cdot \frac{\lambda}{2e} = \frac{\lambda^2}{2e^2}$.

The instance $\langle \mathcal{M}_G, e + h + 2, \frac{\lambda^2}{2e^2}\rangle$ of BA-λ can be constructed in polynomial time in the size of $\langle G, h\rangle$. Thus, since Vertex Cover is NP-hard, so is BA-λ. ◀

5 Minimum Significant Approximant Bound

Recall that, two MCs are at distance 1 from each other when there is no significant similarity between their behaviors. Thus an MC $\mathcal{N}$ is said to be a *significant approximant* for the MC $\mathcal{M}$ w.r.t. δ_λ if $\delta_\lambda(\mathcal{M}, \mathcal{N}) < 1$.

Given an MC $\mathcal{M}$, the *Minimum Significant Approximant Bound* problem w.r.t. δ_λ (MSAB-λ) looks for the smallest k such that $\delta_\lambda(\mathcal{M}, \mathcal{N}) < 1$, for some $\mathcal{N} \in \mathrm{MC}(k)$. The decision version of this problem is called *Significant Bounded Approximant problem* w.r.t. δ_λ

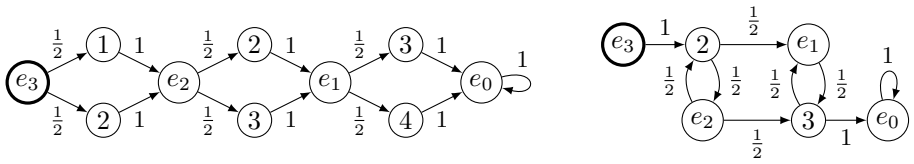

Figure 3 (Left) The MC $\mathcal{M}_G$ associated to the graph G in Figure 2 and (right) an MC $\mathcal{N}$ associated to the vertex cover $C = \{1, 2\}$ of G such that $\delta_1(\mathcal{M}_G, \mathcal{N}) < 1$ (cf. Theorem 16).

(SBA-λ), and asks whether, for a given positive integer k, there exists $\mathcal{N} \in \mathrm{MC}(k)$ such that $\delta_\lambda(\mathcal{M}, \mathcal{N}) < 1$.

When the discount factor $\lambda < 1$, the two problems above turn out to be trivial. Indeed, $\delta_\lambda(\mathcal{M}, \mathcal{N}) \leq \lambda$ when the initial states of $\mathcal{M}$ and $\mathcal{N}$ have the same label. On the contrary, in the case the distance is undiscounted ($\lambda = 1$), these problems are NP-complete. Before presenting the result, we provide the following technical lemma.

▶ **Lemma 15.** *Let $\mathcal{M}$ be a MC (assumed to be minimal) with initial state m_0 and $G(\mathcal{M})$ its underlying directed graph. Then, $\langle \mathcal{M}, k \rangle \in$ SBA-1 iff there exists a bottom strongly connected component (SCC) $G' = (V, E)$ in $G(\mathcal{M})$ and a path $m_0 \dots m_h$ in $G(\mathcal{M})$ such that $m_h \in V$ and $|\{\ell(m_i) \mid i < h, \nexists \text{ a path } v_i \dots v_{h-1} m_h \text{ in } G' \text{ s.t. } \forall i \leq j < h. \ell(m_j) = \ell(v_j)\}| + |V| \leq k$.*

▶ **Theorem 16.** *SBA-1 is NP-complete.*

Proof. The membership in NP is easily proved by using the characterization in Lemma 15 and exploiting Tarjan's algorithm for generating bottom SCCs. As for the NP-hardness, we provide a polynomial-time many-one reduction from Vertex Cover. Let $G = (V, E)$ be a graph with $E = \{e_1, \dots, e_n\}$. We construct the MC $\mathcal{M}_G$ as follows. The set of states is given by the set of edges E along with two states e_i^1 and e_i^2, for each edge $e_i \in E$, representing the two endpoints of e_i and an extra sink state e_0. The initial state is e_n. The transition probabilities are given as follows. The sink state e_0 loops with probability 1 to itself. Each edge $e_i \in E$ goes with probability $\frac{1}{2}$ to e_i^1 and e_i^2, respectively. For $1 \leq i \leq n$, the states e_i^1 and e_i^2 go with probability 1 to the state e_{i-1}. The edge states and the sink state are labelled by pairwise distinct labels, while the endpoints states e_i^1 and e_i^2 are labelled by the node in V they represent. An example of construction for $\mathcal{M}_G$ is shown in Figure 3.

Next we show the following equivalence:

$$\langle G, h \rangle \in \text{Vertex Cover} \qquad \text{iff} \qquad \langle \mathcal{M}_G, h + n + 1 \rangle \in \text{SBA-1} \tag{13}$$

By construction, $\mathcal{M}_G$ is minimal and its underlying graph H has a unique bottom strongly connected component, namely the self-loop in e_0. Each path $p = e_n \rightsquigarrow e_0$ in H passes through all edge states, and the set of labels of the endpoint states in p is a vertex cover of G. Since $e_0, \dots, e_n$ have pairwise distinct labels, we have that G has a vertex cover of size at most h iff there exists a path in H from e_n to e_0 that has at most $n + 1 + h$ different labels. Thus, (13) follows by Lemma 15. ◀

6 An Expectation Maximization-like Heuristic

In this section we describe an approximation algorithm for determining suboptimal solutions of CBA-λ for an arbitrary instance $\langle \mathcal{M}, k \rangle$.

Algorithm 1 Approximate Minimization – Expectation Maximization-like heuristic

Input: $\mathcal{M} = (M, \tau, \ell)$, $\mathcal{N}_0 = (N, \theta_0, \alpha)$, and $h \in \mathbb{N}$.

1. $i \leftarrow 0$
2. **repeat**
3. $\quad i \leftarrow i + 1$
4. $\quad$ compute $\mathcal{C} \in \Omega(\mathcal{M}, \mathcal{N}_{i-1})$ such that $\delta_\lambda(\mathcal{M}, \mathcal{N}_{i-1}) = \gamma^{\mathcal{C}}_\lambda(\mathcal{M}, \mathcal{N}_{i-1})$
5. $\quad \theta_i \leftarrow \textsc{UpdateTransition}(\theta_{i-1}, \mathcal{C})$
6. $\quad \mathcal{N}_i \leftarrow (N, \theta_i, \alpha)$
7. **until** $\delta_\lambda(\mathcal{M}, \mathcal{N}_i) > \delta_\lambda(\mathcal{M}, \mathcal{N}_{i-1})$ or $i \geq h$
8. **return** $\mathcal{N}_{i-1}$

Given an initial approximant $\mathcal{N}_0 \in \mathrm{MC}(k)$, the algorithm produces a sequence of MCs $\mathcal{N}_0, \mathcal{N}_1, \ldots$ in $\mathrm{MC}(k)$ having successively decreased distance from $\mathcal{M}$. We defer until later a discussion of how the initial MC $\mathcal{N}_0$ is chosen. The procedure is described in Algorithm 1.

The intuitive idea of the algorithm is to iteratively update the initial MC by assigning relatively greater probability to transitions that are most representative of the behavior of the MC $\mathcal{M}$ w.r.t. δ_λ. The procedure stops when the last iteration has not yield an improved approximant w.r.t. the preceding one. The input also includes a parameter $h \in \mathbb{N}$ that bounds the number of iterations.

The rest of the section explains two heuristics for implementing the UpdateTransition function invoked at line 5. This function shall return the transition probabilities for the successive approximant (see line 6).

Define $\beta^{\mathcal{C}}_\lambda$ to be the least fixed-point of the following functional operator on 1-bounded real-valued functions $d\colon M \times N \to [0,1]$ (ordered point-wise):

$$B^{\mathcal{C}}_\lambda(d)(m,n) = \begin{cases} 1 & \text{if } \gamma^{\mathcal{C}}_\lambda(m,n) = 0 \\ 0 & \text{if } \ell(m) \neq \alpha(n) \\ (1-\lambda) + \lambda \int_{M\times N} d \, \mathrm{d}\mathcal{C}(m,n) & \text{otherwise}\,. \end{cases}$$

By Theorem 5, the relation $R_{\mathcal{C}} = \big\{(m,n) \mid \gamma^{\mathcal{C}}_\lambda(m,n) = 0\big\}$ is easily shown to be a bisimulation, specifically, the greatest bisimulation induced by $\mathcal{C}$.

Define $\mathcal{C}_\lambda$ as the MC obtained by augmenting $\mathcal{C}$ with an 'sink' state $\perp$ to which any other state moves with probability $(1-\lambda)$. Intuitively, the value $\beta^{\mathcal{C}}_\lambda(m,n)$ can be interpreted as the reachability probability in $\mathcal{C}_\lambda$ of either hitting the sink state or a pair of bisimilar states in $R_{\mathcal{C}}$ along a path formed only by pairs of states with identical labels starting from (m,n).

▶ **Lemma 17.** *For all $m \in M$ and $n \in N$, $\beta^{\mathcal{C}}_\lambda(m,n) = 1 - \gamma^{\mathcal{C}}_\lambda(m,n)$.*

From equation (3) and Lemma 17, we can turn the problem CBA-λ as

$$\operatorname{argmax} \big\{\beta^{\mathcal{C}}_\lambda(\mathcal{M},\mathcal{N}) \mid \mathcal{N} \in \mathrm{MC}_{L(\mathcal{M})}(k),\, \mathcal{C} \in \Omega(\mathcal{M},\mathcal{N})\big\}\,. \tag{14}$$

Equation (14) says that a solution of CBA-λ is the right marginal of a coupling structure $\mathcal{C}$ such that $\mathcal{C}_\lambda$ maximizes the probability of generating paths with prefix in $\cong^*(R_{\mathcal{C}} \cup \perp)$ starting from the pair (m_0, n_0) of initial states[1], where $\cong = \{(m,n) \notin R_{\mathcal{C}} \mid \ell(m) = \alpha(n)\}$.

In the rest of the section we assume $\mathcal{N}_{i-1} \in \mathrm{MC}(k)$ to be the current approximant with associated coupling structure $\mathcal{C} \in \Omega(\mathcal{M}, \mathcal{N}_{i-1})$ as in line 4 in Algorithm 1.

[1] We borrowed notation from regular expressions, such as union, concatenation, and Kleene star, to express the set of finite paths $\cong^* R_{\mathcal{C}}$ as a language over the alphabet $M \times N$.

The "Averaged Marginal" Heuristic. The first heuristic is inspired by the Expectation Maximization (EM) algorithm described in [7]. The idea is to count the expected number of occurrences of the transitions in $\mathcal{C}$ in the set of paths $\cong^* R_{\mathcal{C}}$ and, in accordance with (14), updating $\mathcal{C}$ by increasing the probability of the transitions that were contributing the most.

For each $m, u \in M$ and $n, v \in N$ let $Z^{m,n}_{u,v} \colon (M \times N)^\omega \to \mathbb{N}$ be the random variable that counts the number of occurrences of the edge $((m,n)(u,v))$ in a prefix in $\cong^*(R_{\mathcal{C}} \cup \bot)$ of the given path. We denote by $\mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}]$ the expected value of $Z^{m,n}_{u,v}$ w.r.t. the probability distribution induced by $\mathcal{C}_\lambda$. Using these values we define the optimization problem EM$\langle \mathcal{N}, \mathcal{C} \rangle$:

$$\begin{aligned}
&\text{maximize} && \textstyle\sum_{m,u \in M} \sum_{n,v \in N} \mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}] \cdot \ln(c^{m,n}_{u,v}) && \\
&\text{such that} && \textstyle\sum_{v \in N} c^{m,n}_{u,v} = \tau(m)(u) && m,u \in M,\ n \in N && (15)\\
& && \textstyle\sum_{u \in M} c^{m,n}_{u,v} = \theta_{n,v} && m \in M,\ n,v \in N && (16)\\
& && c^{m,n}_{u,v} \geq 0 && m,u \in M,\ n,v \in N &&
\end{aligned}$$

A solution of EM$\langle \mathcal{N}, \mathcal{C} \rangle$ can be used to improve a pair $\langle \mathcal{N}, \mathcal{C} \rangle$ in the sense of (14).

▶ **Theorem 18.** *If $\beta^{\mathcal{C}}_\lambda(\mathcal{M}, \mathcal{N}) > 0$, then an optimal solution for EM$\langle \mathcal{N}, \mathcal{C} \rangle$ describes an MC $\mathcal{N}' \in \mathrm{MC}(k)$ and a coupling structure $\mathcal{C}' \in \Omega(\mathcal{M}, \mathcal{N}')$ such that $\beta^{\mathcal{C}'}_\lambda(\mathcal{M}, \mathcal{N}') \geq \beta^{\mathcal{C}}_\lambda(\mathcal{M}, \mathcal{N})$.*

Unfortunately, EM$\langle \mathcal{N}, \mathcal{C} \rangle$ does not have an easy analytic solution and turns out to be inefficiently solved by nonlinear optimization methods. On the contrary, the relaxed optimization problem obtained by dropping the constraints (16) has a simple analytic solution, and the first heuristic at line 5, updates θ_i as follows[2]

$$c^{m,n}_{u,v} = \frac{\tau(m)(n) \cdot \mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}]}{\sum_{x \in N} \mathbf{E}[Z^{m,n}_{u,x} | \mathcal{C}]}, \quad \theta_i(n)(v) = \begin{cases} \theta_{i-1}(n)(v) & \text{if } \exists m \in M.\, n\ R_{\mathcal{C}}\ m \\ \dfrac{\sum_{m,u \in M} c^{m,n}_{u,v}}{\sum_{x \in N} \sum_{m,u \in M} c^{m,n}_{u,x}} & \text{otherwise} \end{cases}$$

Note that, the $c^{m,n}_{u,v}$ above may not describe a coupling structure. Nevertheless we recover the transition probability θ_i, from it by averaging the right marginals.

The "Averaged Expectations" Heuristic. In contrast to the previous case, the second heuristic will update θ_i by directly averaging the expected values of $Z^{m,n}_{u,v}$ as follows

$$\theta_i(n)(v) = \begin{cases} \theta_{i-1}(n)(v) & \text{if } \exists m \in M.\, n\ R_{\mathcal{C}}\ m \\ \dfrac{\sum_{m,u \in M} \mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}]}{\sum_{x \in N} \sum_{m,u \in M} \mathbf{E}[Z^{m,n}_{u,x} | \mathcal{C}]} & \text{otherwise}\,. \end{cases}$$

Computing the Expected Values. We compute $\mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}]$ using a variant of the *forward-backward* algorithm for hidden Markov models. Let $Z^{m,n} \colon (M \times N)^\omega \to \mathbb{N}$ be the random variable that counts the number of occurrences of the pair (m,n) in a prefix in $\cong^*(R_{\mathcal{C}} \cup \bot)$ of the path. We compute the expected value of $Z^{m,n}$ w.r.t. the probability induced by $\mathcal{C}_\lambda$ as the solution $z_{m,n}$ of the following system of equations

$$z_{m,n} = \begin{cases} 0 & \text{if } m \ncong n \\ \iota(m,n) + \lambda \sum_{u,v} (z_{u,v} + 1) \cdot \mathcal{C}(u,v)(m,n) & \text{otherwise}\,, \end{cases}$$

where ι denotes the characteristic function for $\{(m_0, n_0)\}$. Then, the expected value of $Z^{m,n}_{u,v}$ w.r.t. the probability induced by $\mathcal{C}_\lambda$ is given by $\mathbf{E}[Z^{m,n}_{u,v} | \mathcal{C}] = \lambda \cdot z_{m,n} \cdot \mathcal{C}(m,n)(u,v) \cdot \beta^{\mathcal{C}}_\lambda(u,v)$.

[2] By abusing the notation, whenever the nominator is 0, we consider entire expression equal to 0, regardless of any division by 0. The same convention is used implicitly in the rest of the section.

Table 1 Comparison of the performance of Algorithm 1 on the IPv4 zeroconf protocol and the classic Drunkard's Walk w.r.t. the heuristics AM and AE.

Choosing the initial approximant. Similarly to EM algorithms, the choice of the initial approximant $\mathcal{N}_0$ may have a significant effect on the quality of the solution. For the labeling of the states, one should follow Lemma 7. As for the choice of the underlying structure one shall be guided by Lemma 15. However, due to Theorem 14, it seems unlikely to have generic good strategies for a starting approximant candidate. Nevertheless, good selections for the transition probabilities may be suggested by looking at the problem instance.

Experimental Results Table 1 shows the results of some tests[3] on Algorithm 1. run on a number of instances $\langle \mathcal{M}, k \rangle$ of increasing size, where $\mathcal{M}$ is the bisimilarity quotient of either the IPv4 protocol [5, Ex.10.5] or the drunkard's walk, parametric on the number of states $|M|$. As initial approximant we use a suitably small instance of the same model. Each row reports the distance to the original model respectively from $\mathcal{N}_0$ and $\mathcal{N}_h$, where h is the total number of iterations; and execution time (in seconds). We compare the two heuristics, averaged marginals (AM) and averaged expectation (AE), on the same initial approximant.

The results obtained on the IPv4 protocol show significant improvements between the initial and the returned approximant. Notably, these are obtained in very few iterations. On this model, AM gives approximants of better quality compared with those obtained using AE; however AE seems to be slightly faster than AM. On the drunkard's walk model, the two heuristics exhibit opposite results w.r.t. the previous experiment: AE provides the best solutions with fewer iterations and significantly lower execution times.

7 Conclusions and Future Work

To the best of our knowledge, this is the first paper addressing the complexity of the *optimal* approximate minimization of MCs w.r.t. a behavioral metric semantics. Even though for a good evaluation of our heuristics more tests are needed, the current results seem promising. Moreover, in the light of [10, 3], relating the probabilistic bisimilarity distance to the LTL-model checking problem as $\delta_1(\mathcal{M}, \mathcal{N}) \geq |\mathbb{P}_{\mathcal{M}}(\varphi) - \mathbb{P}_{\mathcal{N}}(\varphi)|$, for all $\varphi \in$ LTL, our results might be used to lead saving in the overall model checking time. A deeper study of this topic

[3] The tests are done on a prototype implementation coded in Mathematica® (`http://people.cs.aau.dk/giovbacci/tools.html`) running on an Intel Core-i5 2.5GHz with 8GB of DDR3 RAM 1600MHz.

will be the focus of future work. We close with an interesting open problem. Membership of BA-λ in NP is left open. However, by arguments analogous to [11, 14] and leveraging on the ideas that made us produce the MC in Example 10, we suspect that BA-λ is hard for the square-root-sum problem. The latter is known to be NP-hard and in PSPACE, but membership in NP has been open since 1976. Allender et al. [1] showed that it can be decided in the 4th level of the counting hierarchy, thus it is unlikely its PSPACE-completeness.

Abstract

Labelled Markov processes are probabilistic versions of labelled transition systems. In general, the state space of a labelled Markov process may be a continuum. Logical characterizations of probabilistic bisimulation and simulation were given by Desharnais et al. These results hold for systems defined on *analytic* state spaces and assume that there are countably many labels in the case of bisimulation and finitely many labels in the case of simulation.

In this paper, we first revisit these results by giving simpler and more streamlined proofs. In particular, our proof for simulation has the same structure as the one for bisimulation, relying on a new result of a topological nature. This departs from the known proof for this result, which uses domain theory techniques and falls out of a theory of approximation of Labelled Markov processes.

Both our proofs assume the presence of countably many labels. We investigate the necessity of this assumption, and show that the logical characterization of bisimulation may fail when there are uncountably many labels. However, with a stronger assumption on the transition functions (continuity instead of just measurability), we can regain the logical characterization result, for arbitrarily many labels. These new results arose from a new game-theoretic way of understanding probabilistic simulation and bisimulation.

1 Introduction

It is now 40 years since the logical characterization of bisimulation was established by van Benthem [14] and by Hennessy and Milner [10] for nondeterministic transition systems. It was shown that two states (or processes) are bisimilar if and only if they satisfied the same formulas of a modal logic that has come to be called Hennessy-Milner logic. The probabilistic version was studied by Larsen and Skou [12] who defined probabilistic bisimulation for discrete probabilistic transition systems and established a logical characterization theorem for discrete systems with a strong finite-branching assumption.

The analysis of bisimulation was extended to continuous state spaces by Blute et al. [4] and a logical characterization was shown by Desharnais et al. [6, 7] who proved the result without using any negative constructs in the logic nor any kind of finite branching assumptions. Their proofs marked a departure from the usual combinatorial arguments and used some non-trivial results from measure theory, specifically using remarkable properties of analytic spaces; see [13] for an expository account.

The fact that the logical characterization result can be established with a purely positive logic was a surprise at the time. It opened the door to the possibility that there could be a logical characterization of *simulation*; we define this precisely below but the idea should be intuitively clear. A clever example, due to Josée Desharnais [8], showed that this cannot be done with the same logic as the one used for bisimulation; one needs to have disjunction in the logic. A logical characterization of simulation was proved [8] for transition systems with *finitely many* labels. The main contribution of [8] was approximation theory which included a domain-theoretic treatment; the logical characterization result fell out of the domain theory results. Desharnais [5] in her thesis gave a proof not using domain theory in the discrete case. What remained unknown until now is a proof that works for countably many labels, continuous state spaces and, if possible, not using domain theory. We provide such a result, extending the characterization for simulation to countably many labels with a proof very much analogous to the one given for bisimulation.

1.1 Results

1. We give a characterization of bisimulation and simulation in terms of Spoiler/Duplicator games. This is elementary but interesting: it was the main driver of the intuitions that led to the proofs of the present paper though, in the end, one does not actually need the games to establish the results.
2. The logical characterization of bisimulation has a proof which has a structure which can be boiled down to two main ingredients: Dynkin's π-λ theorem and the Unique Structure Theorem for analytic spaces. For simulation, it turns out that a completely analogous proof exists. It is enough to replace the two main ingredients by new positive versions: a positive analogue of the monotone class theorem and a positive UST, both of which we prove. This simplifies the previous domain-theoretic proof and clarifies the picture. The small price to pay is to move from analytic spaces to Polish ones; moving back to analytic is future work.
3. Both proofs rely on the countability of the set of formulas. This is necessary, as an explicit counterexample shows. But if the transition structure is continuous, logical characterization results are regained for arbitrary sized sets of labels. As far as we know, this is the first result of this type for uncountable label spaces.

Both logical characterization proofs, for bisimulation and simulation, have a similar structure and can even be said to follow the same *top-level* strategy as the original Hennessy-Milner proof.

2 Probabilistic systems and logics

We review some definitions and concepts from measure theory and topology. We assume that the reader is familiar with concepts like: σ-algebra, measurable functions, measures, topology and continuity.

Given a topological space X the σ-algebra induced by its open sets (or its closed sets) is called the *Borel algebra*; we will always work with Borel algebras of topological spaces. We call them Borel spaces.

A topological space is said to be *separable* if it has a countable dense subset. For metric spaces this is equivalent to having a countable base of open sets. A Polish space is the topological space underlying a complete separable metric space. Note that a space like $(0,1)$ which is not complete in its usual metric is nevertheless Polish, since it can be given a complete metric that produces the same topology. If X, Y are Polish spaces and $f : X \to Y$ is a continuous function then the image $f(X) \subset Y$ is an *analytic* space. The class of analytic spaces is not altered if we allow f to be measurable instead of continuous or if we take the image of a Borel set instead of all of X.

▶ **Definition 1.** A **Markov kernel** on a Borel space (X, Σ) is a function $\tau : X \times \Sigma \to [0,1]$ such that for each fixed $x \in X$, the set function $\tau(x, \cdot)$ is a sub-probability measure, and for each fixed $C \in \Sigma$ the function $\tau(\cdot, C)$ is a measurable function.

One interprets $\tau(x, C)$ as the probability of the process starting in state x making a transition into one of the states in C.

▶ **Definition 2.** A **labelled Markov process** (LMP) $\mathcal{S}$ with label set $\mathcal{A}$ is a structure $(X, \Sigma, \{\tau_a \mid a \in \mathcal{A}\})$, where (X, Σ) is a Borel space and

$$\tau_a : X \times \Sigma \longrightarrow [0,1]$$

is a Markov kernel for each $a \in \mathcal{A}$.

A key concept is bisimulation. The following definition is adapted from Larsen and Skou [12] to deal with measurability issues.

▶ **Definition 3** (Bisimulation)**.** Let $\mathcal{S} = (X, \Sigma, \tau)$ be a labelled Markov process. An equivalence relation R on X is a **bisimulation** if whenever xRy, with $x, y \in X$, we have that for all $a \in \mathcal{A}$ and every R-closed measurable set $C \in \Sigma$, $\tau_a(x, C) = \tau_a(y, C)$. We say that x and y are bisimilar, denoted $x \approx y$, if there exists a bisimulation R such that xRy.

The modal logic $\mathcal{L}_\wedge$ used in the logical characterization theorem of [7] is generated by the grammar:

$$\phi ::= \top \mid \phi \wedge \phi \mid \langle a \rangle_p \phi$$

where p ranges over rational numbers between 0 and 1. A state x satisfies the modal formula $\langle a \rangle_p \phi$ if there exists a measurable subset C with every state in C satisfying ϕ and $\tau_a(x, C) > p$. It is easy to show that the sets defined by formulas $[\![\phi]\!] := \{x \mid x \models \phi\}$ are all measurable. We write $x \equiv_\wedge y$ to say that x and y satisfy the same formulas in $\mathcal{L}_\wedge$.

The logical characterization theorem for probabilistic bisimulation is:

▶ **Theorem 4** ([7])**.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is analytic and $\mathcal{A}$ is countable, and for any $x, y \in X$, we have that $x \equiv_\wedge y$ if and only if $x \approx y$.* ◀

For a preorder R on a set X, we say that $C \subseteq X$ is *R-closed* if $x \in C$ and xRy implies $y \in C$, for all $x, y \in X$.

▶ **Definition 5** (Simulation)**.** Let $\mathcal{S} = (X, \Sigma, \tau)$ be a labelled Markov process. An preorder relation R on X is a **simulation** if whenever xRy, with $x, y \in X$, we have that for all $a \in \mathcal{A}$ and every R-closed measurable set $C \in \Sigma$, $\tau_a(x, C) \leq \tau_a(y, C)$. We say that x is simulated by y, denoted $x \lesssim y$, if there exists a simulation R such that xRy.

The logic $\mathcal{L}_{\vee\wedge}$ extends $\mathcal{L}_{\wedge}$ with disjunction:

$$\phi \;=\; \top \;\mid\; \phi \wedge \phi \;\mid\; \phi \vee \phi \;\mid\; \langle a \rangle_p \phi.$$

We write $x \leq_{\vee\wedge} y$ to say that every formula in $\mathcal{L}_{\vee\wedge}$ satisfied by x is also satisfied by y.

The previous logical characterization theorem for probabilistic simulation is:

▶ **Theorem 6** ([8]). *For any labelled Markov process (X, Σ, τ) where (X, Σ) is analytic and $\mathcal{A}$ is finite, and for any $x, y \in X$, we have that $x \leq_{\vee\wedge} y$ if and only if $x \lesssim y$.*

Existing proofs of Theorems 4 and 6 span several pages each, and are markedly dissimilar. In particular, the latter relies on the machinery of domain theory. One of our main contributions is to provide new, short proofs of both results.

3 Probabilistic (bi)simulation games

The classical notion of bisimulation and simulation for nondeterministic processes has a simple and elegant characterization in terms of games. These games, played between two players named Spoiler (who tries to prove that some two states in a process are not bisimilar) and Duplicator (who claims the opposite), provide convenient intuitions about the essence of bisimilarity.

To the best of our knowledge, probabilistic bisimulation and simulations have not been characterized by games before. In this section we fill this gap; as we shall see, the relevant games have a pleasantly simple structure, even in the setting of continuous space processes.

We begin with the case of **bisimulation game**. As in the classical case, we consider a spoiler/duplicator game with two players. Duplicator's plays are pairs of states that she claims are bisimilar. Spoiler tries to show that a given pair of states proffered by Duplicator are not bisimilar. Let $\mathcal{S} = (X, \Sigma, \tau)$ be a labelled Markov process, and $x, y \in X$. The bisimulation game starting from the position (x, y) alternates between moves of the following kinds:

- Spoiler chooses $a \in A$ and $C \in \Sigma$ such that $\tau_a(x, C) \neq \tau_a(y, C)$,
- Duplicator answers by choosing $x' \in C$ and $y' \notin C$ and the game continues from (x', y').

A player who cannot make a move at any point loses. Duplicator wins if the game goes on forever.

Note that the only way for Spoiler to win is to choose $C = X$ at some point; otherwise Duplicator can always choose some x' and y' as prescribed. (The only other situation where Duplicator cannot proceed would be $C = \emptyset$, but that is not a legal move for Spoiler since always $\tau_a(x, \emptyset) = \tau_a(y, \emptyset) = 0$.) On the other hand, Duplicator can win either by forcing an infinite play or by reaching a position (x, y) where $\tau_a(x, C) = \tau_a(y, C)$ for every $C \in \Sigma$.

The intuition behind the game should be clear. Spoiler tries to prove that states x and y are not bisimilar by showing a label a and a set C, purportedly closed under bisimilarity, such that the probabilities of a-labelled transitions to C are different for x and y. This difference of probabilities is checked but not disputed by Duplicator, who instead claims that C, in fact, is not closed under bisimilarity. She does that by choosing $x' \in C$ and $y' \notin C$ and claiming that these two are bisimilar; the game then proceeds in the same fashion.

Before we formally prove the correctness of this game, let us spend a moment to consider what makes a game-theoretic characterization "elegant". In our opinion, the classical bisimulation game for nondeterministic processes is elegant because it allows one to characterize a global property of behaviours (bisimilarity) in terms of a game whose rules only depend on local considerations. Indeed, whether a move in the game is legal or not does not depend on

bisimilarity or other long-range properties, but merely on local observations about transition capabilities that cannot be disputed by either player.

We argue that this criterion of elegance is satisfied by our probabilistic game. One can imagine the players engaging in a brief experiment with the given Markov process after each move by Spoiler, to determine that the two transition probabilities involved are indeed different. By performing random a-transitions from x and y sufficiently many times, Spoiler can demonstrate to Duplicator, with an arbitrarily high confidence level, that the probabilities of getting to C are different and so that the move to C is legal for Spoiler. It is important to note, comparing the game to the definition of probabilistic bisimulation itself, that the legality of a Spoiler's move does not depend on the set C being actually closed under bisimilarity; a game with such a condition would not be "elegant".

The question of *how many* random transitions are enough to convince Duplicator that a Spoiler's move is legal, and hence how much time it takes for Spoiler to win the game if x and y are not bisimilar, suggests a potentially interesting connection of the bisimulation game to the quantitative framework of metrics on labelled Markov processes [9]. We leave this for future work.

Back to formal development. Since all infinite plays are won by the same player (Duplicator), standard game-theoretic arguments prove that:

▶ **Fact 7.** *The bisimulation game is determined, i.e., from every position (x, y) either Spoiler has a winning strategy or Duplicator does.* ◀

From this we infer:

▶ **Theorem 8.** *The states x and y are bisimilar if and only if Duplicator has a winning strategy from (x, y).*

Proof. For the left-to-right implication, for bisimilar x and y, we construct a winning strategy from (x, y) for Duplicator. In this strategy, for any move a and C by Spoiler, Duplicator chooses some arbitrary $x' \in C$ and $y' \notin C$ such that x' and y' are bisimilar. This is always possible: since Spoiler's move was legal, and it originated from a pair of bisimilar states, C cannot be closed under bisimilarity. This strategy is winning for Duplicator since it allows her response to any move by Spoiler, and Duplicator wins all infinite plays.

For the right-to-left implication, we shall show that the set R of all pairs (x, y) whence Duplicator has a winning strategy, is a bisimulation. To this end, first we need to show that R is an equivalence relation. Reflexivity is immediate, since from a position (x, x) Spoiler has no legal moves. For symmetry, given a winning strategy from (x, y) Duplicator builds a strategy from (y, x) trivially: she simply replies to any first move by Spoiler as if she would reply to a move from (x, y), and then she follows the given strategy. For transitivity, assume winning strategies for Duplicator from (x, y) and (y, z). A winning strategy for (x, z) works as follows: for a legal move a and C from Spoiler, it must be that $\tau_a(x, C) \neq \tau_a(y, C)$ or $\tau_a(y, C) \neq \tau_a(z, C)$. Depending on which of these inequalities holds, reply according to the strategy from (x, y) or from (y, z), and then follow that winning strategy.

Now assume towards contradiction that R is not a bisimulation. This means that for some x, y such that xRy, there exists a letter a in A and an R-closed subset C of X such that $\tau_a(x, C) \neq \tau_a(y, C)$. Consider a and C as a Spoiler's move from (x, y). No matter what Duplicator chooses as $x' \in C$ and $y' \notin C$, since C is R-closed we have that not $(x'Ry')$ and, by Fact 7, Spoiler has a winning strategy from (x', y'). This forms a winning strategy for Spoiler from (x, y), contradicting the assumption that xRy. ◀

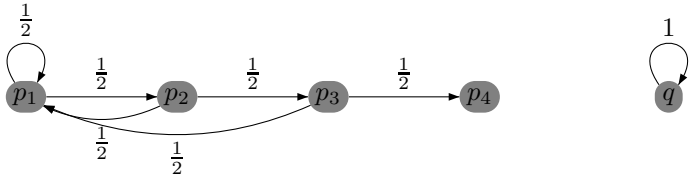

Figure 1 It takes four steps for Spoiler to convince Duplicator that the state p_1 does not simulate q.

Simulation game is defined in a very similar fashion, alternating the following moves:

- Spoiler chooses $a \in A$ and $C \in \Sigma$ such that $\tau_a(x, C) > \tau_a(y, C)$,
- Duplicator answers by choosing $x' \in C$ and $y' \notin C$ and the game continues from (x', y').

Again, a player who cannot make a move at any point loses, and Duplicator wins all infinite plays.

The intuition behind the game is as before, except now Spoiler maintains that his chosen sets C are $\lesssim$-closed, and Duplicator contradicts that by choosing $x' \in C$ and $y' \notin C$ and maintaining that $x' \lesssim y'$. All other considerations remain virtually the same, up to and including:

▶ **Theorem 9.** *$x \lesssim y$ if and only if Duplicator has a winning strategy from (x, y).*

▶ **Example 10.** We illustrate the simulation game on an example (see Fig. 1). In this Markov process there is only one label. From the state q, the process loops forever. On the other hand, from the state p_1, one can reach the deadlock state p_4 through the path to p_2 and p_3.

We examine the simulation game and how Spoiler can successfully prove to Duplicator that the state p_1 does not simulate q. We start the simulation game from (q, p_1). A possible first move is $C = \{q, p_2\}$ since $\tau(q, C) = 1 > \tau(p_1, C) = \frac{1}{2}$, but it allows Duplicator to play (q, p_1), back to the original position. A smarter move is $C = \{q, p_1\}$, to which Duplicator has several possible answers, all losing. For instance, if Duplicator plays (q, p_4), Spoiler wins immediately by choosing $C = X$. Duplicator may survive more steps by playing (q, p_2), then (q, p_3), before the fatal (q, p_4).

4 Logical characterization of bisimulation, revisited

In this section, we give a short proof for the logical characterization of bisimulation, which relies on two ingredients: the π-λ theorem and the Unique Structure Theorem.

4.1 The π-λ Theorem and the Unique Structure Theorem

A *π-system* is a family of subsets of a set X closed under finite intersections. A *λ-system* is a family that contains X and is closed under complement and countable disjoint unions. A *σ-algebra* is a family closed under complement, countable unions and countable intersections. For a family $\mathcal{E}$, let $\sigma(\mathcal{E})$ denote the least σ-algebra that contains $\mathcal{E}$.

▶ **Theorem 11** (Dynkin's π-λ theorem, [3]). *For any π-system Π and a λ-system Λ on the same set X, if $\Pi \subseteq \Lambda$ then $\sigma(\Pi) \subseteq \Lambda$.*

Below, $\equiv_{\mathcal{E}}$ is the relation of equivalence up to $\mathcal{E}$, i.e., $x \equiv_{\mathcal{E}} y$ if and only if, for every $Y \in \mathcal{E}$, $x \in Y$ iff $y \in Y$.

▶ **Theorem 12** (Unique Structure Theorem, [1]). *In any analytic space (X, Σ), for every countable family $\mathcal{E} \subseteq \Sigma$ such that $X \in \mathcal{E}$, every measurable, $\equiv_{\mathcal{E}}$-closed subset of X is an element of $\sigma(\mathcal{E})$.*

4.2 Logical Characterization

▶ **Theorem 13.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is analytic and $\mathcal{A}$ is countable, $\equiv_\wedge$ is a bisimulation.*

Proof. Take some $x, y \in X$ and assume that there exists some $a \in \mathcal{A}$ such that $\tau_a(x, C) \neq \tau_a(y, C)$ for some $\equiv_\wedge$-closed set $C \in \Sigma$. We need to prove that $x \not\equiv_\wedge y$.

Denote $\delta = \tau_a(x, -)$ and $\gamma = \tau_a(y, -)$. If $\delta(X) > \gamma(X)$, then pick a rational number p such that $\delta(X) > p > \gamma(X)$; it is easy so see that $x \models \langle a \rangle_p \top$ and $y \not\models \langle a \rangle_p \top$, therefore $x \not\equiv_\wedge y$. The same formula distinguishes x and y if $\delta(X) < \gamma(X)$.

If $\delta(X) = \gamma(X)$ then pick any $\equiv_\wedge$-closed $C \in \Sigma$ such that $\delta(C) \neq \gamma(C)$. Define

$$\Pi = \{[\![\phi]\!] \mid \phi \in \mathcal{L}_\wedge\} \qquad \text{and} \qquad \Lambda = \{Y \in \Sigma \mid \delta(Y) = \gamma(Y)\}.$$

It is easy to see that Π is a π-system and Λ is a λ-system (in particular, Λ is closed under complement since $\delta(X) = \gamma(X)$). Clearly, $\equiv_\Pi = \equiv_\wedge$. Moreover, since there are only countably many formulas, Π is countable and, by Theorem 12, $C \in \sigma(\Pi)$. Since by assumption $C \notin \Lambda$, we have $\sigma(\Pi) \not\subseteq \Lambda$, hence (by Theorem 11) $\Pi \not\subseteq \Lambda$. In other words, there exists an $\mathcal{L}_\wedge$ formula ϕ such that $\delta([\![\phi]\!]) \neq \gamma([\![\phi]\!])$.

Without loss of generality, assume $\delta([\![\phi]\!]) > \gamma([\![\phi]\!])$ and pick $p \in \mathbb{Q}$ such that $\delta([\![\phi]\!]) > p > \gamma([\![\phi]\!])$. We readily obtain $x \models \langle a \rangle_p \phi$ and $y \not\models \langle a \rangle_p \phi$, hence $x \not\equiv_\wedge y$ as requested. ◀

This easily implies Theorem 4, repeated here:

▶ **Corollary 14.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is analytic and $\mathcal{A}$ is countable, and for any $x, y \in X$, we have that $x \equiv_\wedge y$ if and only if $x \approx y$.*

Proof. The right-to-left implication is an easy induction on the structure of formulas. The left-to-right implication is immediate by Theorem 13. ◀

5 Logical characterization of simulation, revisited

Our proof of the logical characterization of simulation is completely analogous to the one for bisimulation. It is enough to replace the two main ingredients (Theorems 11 and 12) by new ones.

5.1 The Positive Monotone Class Theorem and the Positive Unique Structure Theorem

A *lattice of sets* is a family of subsets of a set X closed under finite unions and intersections.[1] A *monotone class* is a family closed under unions of increasing chains and under intersections of decreasing chains. A *σ-lattice of sets* is a family of sets closed under countable unions and countable intersections. For a family $\mathcal{E}$, let $L(\mathcal{E})$ denote the least σ-lattice of sets that contains $\mathcal{E}$.

[1] A lattice of sets is sometimes called *ring of sets*. However, in measure theory ring of sets means something else (a family closed under union and set difference), so we choose a different name.

▶ **Theorem 15** (Positive Monotone Class Theorem). *For any lattice of sets $\mathcal{E}$ and any monotone class $\mathcal{M}$ on the same set X, if $\mathcal{E} \subseteq \mathcal{M}$ then $L(\mathcal{E}) \subseteq \mathcal{M}$.*

This result is similar and easier to prove than Theorem 11, and it should be treated as folklore.

Below, $\sqsubseteq_{\mathcal{E}}$ is the preorder determined by $\mathcal{E}$, i.e., $x \sqsubseteq_{\mathcal{E}} y$ if and only if, for every $Y \in \mathcal{E}$, $x \in Y$ implies $y \in Y$.

▶ **Theorem 16** (Positive Unique Structure Theorem). *In any Polish space (X, Σ), for every countable family $\mathcal{E} \subseteq \Sigma$, every nonempty, different from X, measurable and $\sqsubseteq_{\mathcal{E}}$-closed subset of X is an element of $L(\mathcal{E})$.*

This result strengthens Theorem 12, albeit on the restricted domain of Polish spaces. (Extending it to analytic spaces is future work.) Its proof is also more involved, using ideas similar to the proof of Lusin's Separation Theorem for analytic sets (see [11]). The proof was pointed out to us by Roman Pol.

5.2 The logical characterization

▶ **Theorem 17.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is Polish and $\mathcal{A}$ is countable, $\leq_{\wedge}$ is a simulation.*

Proof. Take some $x, y \in X$ and assume that there exists some $a \in A$ such that $\tau_a(x, C) > \tau_a(y, C)$ for some $\leq_{\wedge}$-closed set $C \in \Sigma$. We need to prove that $x \not\leq_{\wedge} y$.

Denote $\delta = \tau_a(x, -)$ and $\gamma = \tau_a(y, -)$. Pick any $\leq_{\wedge}$-closed $C \in \Sigma$ such that $\delta(C) > \gamma(C)$. Then C cannot be empty, since $\delta(\emptyset) = \gamma(\emptyset) = 0$. If $C = X$, pick a rational number p such that $\delta(X) > p > \gamma(X)$; it is easy so see that $x \models \langle a \rangle_p \top$ and $y \not\models \langle a \rangle_p \top$, therefore $x \not\leq_{\wedge} y$.

If $C \neq X$, define

$$\mathcal{E} = \{[\![\phi]\!] \mid \phi \in \mathcal{L}_{\wedge}\} \qquad \text{and} \qquad \mathcal{M} = \{Y \in \Sigma \mid \delta(Y) \leq \gamma(Y)\}.$$

It is easy to see that $\mathcal{E}$ is a lattice of sets and (by continuity of measure) $\mathcal{M}$ is a monotone class. Clearly, $\sqsubseteq_{\mathcal{E}} = \leq_{\wedge}$. Moreover, since there are only countably many formulas, $\mathcal{E}$ is countable hence, by Theorem 16, $C \in L(\mathcal{E})$. Since by assumption $C \notin \mathcal{M}$, we have $L(\mathcal{E}) \not\subseteq \mathcal{M}$, hence (by Theorem 15) $\mathcal{E} \not\subseteq \mathcal{M}$. In other words, there exists a formula ϕ such that $\delta([\![\phi]\!]) > \gamma([\![\phi]\!])$. Pick $p \in \mathbb{Q}$ such that $\delta([\![\phi]\!]) > p > \gamma([\![\phi]\!])$. We readily obtain $x \models \langle a \rangle_p \phi$ and $y \not\models \langle a \rangle_p \phi$, hence $x \not\leq_{\wedge} y$ as requested. ◀

Compared to Theorem 6, the following easy consequence is restricted to Polish spaces but generalized to countable sets of labels.

▶ **Corollary 18.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is Polish and $\mathcal{A}$ is countable, and for any $x, y \in X$, we have that $x \leq_{\wedge} y$ if and only if $x \lesssim y$.*

Proof. The right-to-left implication is an easy induction on the structure of formulas. The left-to-right implication is immediate by Theorem 17. ◀

6 The case of uncountably many labels

Our proofs of the logical characterizations for simulation and bisimulation rely on the assumption that the set of formulas (and, equivalently, the set of transition labels) is countable. In this section we investigate the necessity of this assumption. We first observe that indeed if there are uncountably many labels, then the logical characterization fails in general. However, we show that if the transition structure is continuous, then the logical characterization holds again, without any assumption on the set of labels.

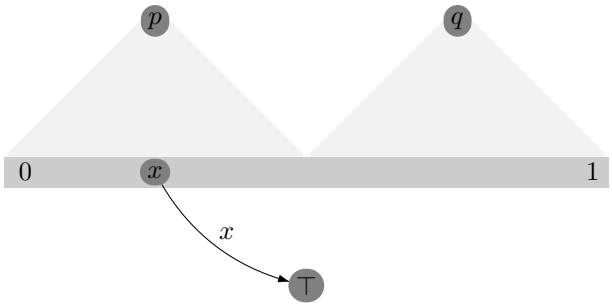

Figure 2 The two states p and q do not simulate each other, but they satisfy the same formulas of $\mathcal{L}_{\curlywedge}$.

6.1 A counterexample

In the classical logical characterization of (bi)similarity for nondeterministic labelled transition systems [10], one can restrict to a logic with finite conjunction and disjunction only if the systems in question satisfy a finite branching property called image finiteness: each state can have only finitely many successors for any given transition label. Since [6, 7] it has been known that this restriction does not apply to probabilistic systems, where a finitary logic is enough to characterize bisimilarity on systems with arbitrary (probabilistic) branching.

On the other hand, in the classical nondeterministic setting, once image finiteness is ensured, the size of the set of transition labels matters very little. Even if infinitely many, or even uncountably many labels are permitted, a finitary logic (with a correspondingly large set of modal operators) is enough to characterize (bi)similarity for nondeterministic transition systems labelled with them.

We now show that this is not the case for labelled Markov processes with continuous state spaces. Specifically, we show an example where the set of labels is uncountable and the logical characterization fails, even though the space of states is a particularly simple, compact Polish space.

Denote $X = \{p, q, \top\} \cup [0, 1]$. We equip X with the smallest σ-algebra that makes all Borel sets of $[0, 1]$ as well as the singletons $\{p\}, \{q\}$ and $\{\top\}$ measurable. Denote by μ the Lebesgue[2] probability measure on $[0, 1]$.

Consider a set of actions $\mathcal{A} = [0, 1]$. Define functions $\tau_a : X \times \Sigma \to [0, 1]$ for each $a \in \mathcal{A}$ as follows:

$$\begin{array}{rcl} \tau_a(p, C) & = & \mu(C \cap [0, \frac{1}{2}]) \\ \tau_a(q, C) & = & \mu(C \cap [\frac{1}{2}, 1]) \\ \tau_a(x, \top) & = & \begin{cases} 1 & \text{if } x = a \\ 0 & \text{otherwise} \end{cases} \end{array}$$

The following proposition easily implies that logical characterizations both for bisimulation and for simulation fail for this labelled Markov process.

▶ **Proposition 19.** *Neither p nor q simulates the other, but they satisfy the same formulas of $\mathcal{L}_{\curlywedge}$.*

[2] We mean the usual measure on $[0, 1]$ which assigns to intervals their length. However this is usually extended to the Lebesgue σ-algebra, i.e., the one obtained by completing the Borel σ-algebra with respect to this measure. We are just using this measure on the Borel sets.

Proof. We prove that neither p nor q simulates the other. First, for any x, y in $[0,1]$, if $x \neq y$ then neither of these simulates the other. Indeed, from x, the action $a = x$ leads to $\top$ with probability 1 and leads nowhere from y. It follows that every subset of $[0,1]$ is $\lesssim$-closed; in particular this applies to $[0, \frac{1}{2}]$ and $[\frac{1}{2}, 1]$. This implies that neither p nor q simulates the other, because $\tau_a(p, [0, \frac{1}{2}]) = 1$ and $\tau_a(q, [0, \frac{1}{2}]) = 0$, and vice-versa $\tau_a(p, [\frac{1}{2}, 1]) = 0$ and $\tau_a(q, [\frac{1}{2}, 1]) = 1$.

To see that p and q satisfy the same formulas, we observe that for every finite subset $\mathcal{B} \subseteq \mathcal{A}$, p and q do simulate each other (indeed, they are even bisimilar) in the system restricted to labels from $\mathcal{B}$. The claim easily follows from this, since every formula of $\mathcal{L}_{\vee\wedge}$ uses finitely many labels.

So for a finite $\mathcal{B} \subseteq \mathcal{A}$, define a relation R on X to be the least equivalence relation such that pRq and xRy for each $x, y \in [0,1] \setminus \mathcal{B}$. We claim that R is a bisimulation on the system restricted to labels with $\mathcal{B}$. The only nontrivial case is the pair pRq: every R-closed set $C \subseteq [0,1]$ is either finite or co-finite, from which it easily follows that $\tau_a(p, C) = \tau_a(q, C)$. ◀

Intuitively, the core of the problem here is the highly non-continuous nature of transitions from $[0,1]$, allowing one to observe specific states from that uncountable space. Indeed, as we show in the following section, the problem disappears and the logical characterizations hold if we assume that the transition function $\tau_a(\cdot, C)$ is continuous for each a and C.

6.2 Logical characterizations for continuous transition functions

Given a labelled Markov process (X, Σ, τ) with labels from a set $\mathcal{A}$, we denote by $(X, \Sigma, \tau_{|\mathcal{B}})$ the same system restricted to labels from $\mathcal{B} \subseteq \mathcal{A}$.

▶ **Theorem 20.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is Polish and such that for all $a \in \mathcal{A}, C \in \Sigma$, the function $\tau_a(\cdot, C)$ is continuous, there exists a countable set $\mathcal{B}$ such that the bisimilarity relation $\approx$ on $(X, \Sigma, \tau_{|\mathcal{B}})$ coincides with that on (X, Σ, τ).*

Proof. We will use the fact that, under the above assumptions, X^2 is also a Polish space for the product topology, hence it satisfies the *hereditary Lindelöf property*: any open cover of a subset of X^2 has a countable subcover.

By definition, the bisimilarity relation $\approx$ on (X, Σ, τ) is the largest bisimulation. It is standard to define it as the greatest fixpoint of a certain operator on binary relations on X. For us it will be convenient to speak in terms of complements, and we consider the *complement* of $\approx$ as the *least* fixpoint of the operator:

$$\Phi(R) = \left\{ (x,y) \in X^2 \;\middle|\; \exists a \in \mathcal{A}, \exists C \in \Sigma \ (X^2 \setminus R)\text{-closed, s.t. } \tau_a(x, C) \neq \tau_a(y, C) \right\}$$

Thanks to Tarski's fixed point theorem, this is obtained by defining a sequence $(W_\alpha)_\alpha$ of subsets of X^2 indexed by ordinals α: for $\alpha + 1$ a successor ordinal and β a limit ordinal, define:

$$\begin{array}{lcl} W_0 & = & \emptyset \\ W_{\alpha+1} & = & \left\{ (x,y) \in X^2 \;\middle|\; \exists a \in \mathcal{A}, \exists C \in \Sigma \ (X^2 \setminus W_\alpha)\text{-closed, s.t. } \tau_a(x, C) \neq \tau_a(y, C) \right\} \\ W_\beta & = & \bigcup_{\alpha < \beta} W_\alpha. \end{array}$$

The complement of $\approx$ on (X, Σ, τ) is the union of all W_α for all ordinals α. More specifically, $(W_\alpha)_\alpha$ form an increasing sequence that reaches a fixpoint at some ordinal γ not larger than the cardinality of $\mathcal{P}(X^2)$.

Note that all W_α are open sets in X^2. This is proved by ordinal induction: for a successor ordinal, $W_{\alpha+1}$ is a union of sets of the form

$$\{(x,y) \in X^2 \mid \tau_a(x,C) \neq \tau_a(y,C)\}$$

for some a and C. Such a set is open, since it is the inverse image of the (open) inequality relation on $[0,1]$ along the continuous function $\tau_a(\cdot, C)$.

For each ordinal α we construct a countable subset $\mathcal{B}_\alpha \subseteq \mathcal{A}$ such that W_α calculated on $(X, \Sigma, \tau_{|\mathcal{B}_\alpha})$ coincides with W_α calculated on (X, Σ, τ).

For sucessor ordinals, rewrite the definition of $W_{\alpha+1}$ as:

$$W_{\alpha+1} = \bigcup_{a \in \mathcal{A}} \{(x,y) \in X^2 \mid \exists C \in \Sigma\ (X^2 \setminus W_\alpha)\text{-closed, s.t. } \tau_a(x,C) \neq \tau_a(y,C)\}.$$

This is a union of open sets. Since X^2 is hereditary Lindelöf, one can extract a countable subcover of this union, indexed by some set $\mathcal{B} \subseteq \mathcal{A}$. It is then enough to take $\mathcal{B}_{\alpha+1} = \mathcal{B}_\alpha \cup \mathcal{B}$.

For limit ordinals, extract a countable subcover of the union $W_\beta = \bigcup_{\alpha<\beta} W_\alpha$ and take $\mathcal{B}_\beta$ to be the union of the $\mathcal{B}_\alpha$'s defined for α's from that subcover.

Now the countable set $\mathcal{B}_\gamma$, where γ is the ordinal for which W_γ reaches the least fixpoint of Φ, satisfies the desired property. ◀

The same result holds for simulation:

▶ **Theorem 21.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is Polish and such that for all $a \in \mathcal{A}, C \in \Sigma$, the function $\tau_a(\cdot, C)$ is continuous, there exists a countable set $\mathcal{B}$ such that the similarity preorder $\lesssim$ on $(X, \Sigma, \tau_{|\mathcal{B}})$ coincides with that on (X, Σ, τ).*

Proof. Completely analogous to the proof of Theorem 20, but with the operator

$$\Phi(R) = \{(x,y) \in X^2 \mid \exists a \in \mathcal{A}, \exists C \in \Sigma\ (X^2 \setminus R)\text{-closed, s.t. } \tau_a(x,C) > \tau_a(y,C)\}$$

instead. In particular the fact that each W_α is open, still holds. ◀

The following immediately follows from Theorems 20 and 21 in the light of Corollaries 14 and 18.

▶ **Corollary 22.** *For any labelled Markov process (X, Σ, τ) where (X, Σ) is Polish and such that for all $a \in \mathcal{A}, C \in \Sigma$, the function $\tau_a(\cdot, C)$ is continuous, for any $x, y \in X$,*

- *$x \equiv_\wedge y$ if and only if $x \approx y$,*
- *$x \leq_\curlywedge y$ if and only if $x \lesssim y$.*

7 Conclusions

The results of this paper suggest that we have arrived at a deeper understanding of the interplay of modal logic and probabilistic transition structure. Variations of the logic can also be used for logical characterization of bisimulation, for example, with the modal construct and just disjunction instead of just conjunction, as studied in [2]. The arguments are minor variations of the proofs given in Section 3sec:bisim. The earlier proof of logical characterization of simulation [8] emerged as a by-product of the theory of approximation; the proof of the present paper is direct. It is particularly pleasing that the two logical characterization proofs have the same general shape and also resemble the overall strategy of the Hennessy-Milner proof.

The game characterization, though elementary, is both pleasing and intriguing. As suggested earlier, there might be interesting links to metrics and the number of moves it takes for Spoiler to win a game. The connection between metrics and bisimulation is well understood but it is possible that via the game one might gain a more quantitative understanding of the numerical significance of the metric.

Acknowledgments. We are very much indebted to Roman Pol, who showed us the proof of Theorem 16 which had eluded us for a long time.

We would like to thank the Simons Institute for hosting the program *Logical Structures in Computation* during the Fall of 2016 where we were able to work together in a congenial atmosphere. We are grateful to Martin Otto and Thomas Colcombet for stimulating conversations in Berkeley.

Abstract

Zero automata are a probabilistic extension of parity automata on infinite trees. The satisfiability of a certain probabilistic variant of MSO, called TMSO + ZERO, reduces to the emptiness problem for zero automata. We introduce a variant of zero automata called nonzero automata. We prove that for every zero automaton there is an equivalent nonzero automaton of quadratic size and the emptiness problem of nonzero automata is decidable, with complexity co-NP. These results imply that TMSO + ZERO has decidable satisfiability.

1 Introduction

In this paper, we prove that emptiness is decidable for two classes of automata, namely *zero* and *nonzero* automata. Zero automata were introduced as a tool for recognizing models of a probabilistic extension of MSO on infinite trees [1]. Nonzero automata, introduced in this paper, are equivalent to zero automata, but have simpler semantics.

Both zero and nonzero automata are probabilistic extensions of parity automata on infinite trees. Here we focus on the case of binary trees. The automaton performs a random walk on the infinite binary input tree: when the automaton is in a state q on a node labelled with a, it selects non-deterministically a transition (q, a, r_0, r_1) and moves with equal probability $\frac{1}{2}$ either to the left node in state r_0 or to the right node in state r_1.

The set of branches of the infinite binary tree is equipped with the uniform probability measure, which is used to define the acceptance condition. There are two variants of the acceptance condition, one for zero automata and one for nonzero automata

A *nonzero* automaton is equipped with a total order $\leq$ on its set of states Q and three accepting subsets of states $F_\forall, F_1$ and $F_{>0}$. A run is accepting if:

(a) on every branch the limsup state (i.e. the maximal state seen infinitely often) is in $F_\forall$;
(b) and with probability 1 the limsup state is in F_1;
(c) and every time the run visits a state in $F_{>0}$ there is a nonzero probability that all subsequent states are in $F_{>0}$.

* Full version with proof is [2], `http://arxiv.org/abs/1702.06858`.

Condition (a) is the classical parity condition for tree automata and condition (b) is equivalent to the qualitative condition from [5]. Condition (c) seems to be new. Conditions (a) and (b) are used to define the acceptance condition of zero automata as well, the difference between zero and nonzero automata lies in condition (c).

The paper [1] introduced a variant of MSO on infinite trees with a probabilistic quantifier, called TMSO+zero, inspired by probabilistic MSO from [9]. In the case where zero is the unary predicate which checks whether a set of branches has probability 0, the contribution of [1] was a proof that for every formula of this logic one can compute a zero automaton which accepts the same trees. The logic is powerful enough to formulate properties like "every node in the tree has a descendant node labelled with b and the set of branches with infinitely many b has probability 0". As argued in [1], the motivation for this logic is twofold. First, it extends various probabilistic logics known in the literature, e.g. qualitative probabilistic CTL* [8], or qualitative probabilistic CTL* extended with ω-regular path properties [3]. Second, the logic, although less general than MSO, represents a robust class of languages of infinite trees that goes beyond classical MSO, and thus falls under the scope of the programme of searching for decidable extensions of MSO.

The emptiness problem for zero automata was not solved in [1], thus leaving open the logic's decidability. A step toward an emptiness algorithm was made in [10], where it was shown that for subzero automata – the special case of zero automata where only conditions (a) and (b) are used – one can decide if the recognized language contains a regular tree. In this paper we prove that zero and nonzero automata have decidable emptiness, and therefore also the logic from [1] has decidable satisfiability.

The main results of this paper are:

(i) For every zero automaton there is an equivalent nonzero automaton of quadratic size.
(ii) A nonzero automaton with $F_\forall = Q$ is nonempty if and only if its language contains a regular tree of size $|Q|$. This is decidable in NP.
(iii) The emptiness problem of nonzero automata is in co-NP.

To prove (iii) we provide a reduction of the emptiness problem to the computation of the winner of a parity game called the *jumping game*. For that we rely on (ii): the states of the jumping game are regular runs of a nonzero automaton where $F_\forall = Q$. According to (i) the emptiness problem for zero automata is in co-NP as well.

These results were recently improved: the emptiness problem is actually in NP$\cap$co-NP, and even in PTIME if $F_\forall = Q$, see [2].

The plan of the paper is as follows. In Section 2 we introduce zero and nonzero automata and state our main result (iii) (Theorem 3). In Section 3 we show (i) (Lemma 5). In Section 4 we focus on the special case where $Q = F_\forall$ and show (ii) (Theorem 10). In Section 5 we introduce jumping games and combine the previous results to provide a proof of (iii).

2 Zero and nonzero automata

This section introduces trees and nonzero and zero automata.

Trees, branches and subtrees. The automata of this paper describe properties of infinite binary labelled trees. A node in a tree is a sequence in $\{0,1\}^*$. A *tree* over an alphabet Σ is a function $t : \{0,1\}^* \to \Sigma$. We use standard terminology for trees: node, root, left child, right child, leaf, ancestor and descendant. A *branch* is a sequence in $\{0,1\}^\omega$, viewed as an infinite sequence of left or right turns. A branch *visits* a node if the node is a prefix of the branch.

A *subtree* is a non-empty and ancestor-closed set of nodes. A subtree is *leaf-free* if each of its nodes has at least one child in the subtree. A branch of a subtree is a branch which visits only nodes of the subtree.

Probability measure over branches. We use the *coin-flipping* measure on $\{0,1\}^\omega$: each bit is chosen independently at random, with 0 and 1 having equal probability, and every Borel subset of $\{0,1\}^\omega$ is measurable. The probability of a subtree is the probability of the set of branches of the subtree. The inner regularity of the coin-flipping measure (see e.g. [7, Theorem 17.10]) implies:

▶ **Lemma 1.** *The probability of a measurable set E is the supremum of the probabilities of the subtrees whose every branch belongs to E.*

Nonzero automata. Intuitively, a nonzero automaton is a nondeterministic parity tree automaton which has the extra ability to check whether the set of branches satisfying the parity condition has zero or nonzero probability.

▶ **Definition 2.** The syntax of a nonzero automaton is a tuple

$$\underbrace{Q}_{\text{states}} \qquad \underbrace{\Sigma}_{\text{input alphabet}} \qquad \underbrace{\Delta \subseteq Q \times \Sigma \times Q^2}_{\text{transitions}},$$

with all components finite, together with a total order $\leq$ on Q and three subsets

$$F_\forall, F_1, F_{>0} \subseteq Q \ .$$

A *run* of the automaton on an input tree $t : \{0,1\}^* \to \Sigma$ is an infinite binary tree $r : \{0,1\}^* \to Q$ whose root is labelled by the maximal state of Q, also called the *initial* state and which is consistent with the transition relation in the usual sense, i.e. $\forall v \in \{0,1\}^*, (r(v), t(v), r(v0), r(v1)) \in \Delta$. Define the *limsup* of a branch of the run to be the maximal state that appears infinitely often on the branch.

The run is *accepting* if it is surely, almost-surely and nonzero accepting:

- **surely accepting:** every branch has limsup in $F_\forall$; and
- **almost-surely accepting:** the set of branches with limsup in F_1 has probability 1; and
- **nonzero accepting:** for every node v with state in $F_{>0}$, the set of branches which visit v and visit only $F_{>0}$-labelled nodes below v has nonzero probability.

The emptiness problem. The emptiness problem asks whether an automaton has an accepting run. Our main result:

▶ **Theorem 3.** *Emptiness of a nonzero automaton is decidable in co-*NP.

Proof. This is a corollary of a series of intermediary results. In section 4 we focus on the special case where $F_\forall = Q$ (Theorem 10). In section 5 we reduce the emptiness problem for nonzero automata to the computation of the winner in a parity game called the *jumping game* (Lemma 17) and give an NP algorithm to compute the winner of the jumping game (Lemma 18). ◀

Zero automata. Nonzero automata are a variant of *zero automata* introduced in [1]. A zero automaton differs slightly from a nonzero automaton in that it uses a notion of "seed state" for the nonzero acceptance condition. On top of $F_\forall, F_1$ and $F_{>0}$ there is a subset $Q_{\text{seed}} \subseteq Q$. A run is accepting if it is surely, almost-surely and *zero* accepting:

- **zero accepting:** for every node v with state $q \in Q_{\text{seed}}$, with nonzero probability the run visits node v, then below v visits only states $\leq q$ and moreover has limsup in $F_{>0}$.

In the next section, we show that every zero automaton can be transformed in an equivalent nonzero automaton of quadratic size (Lemma 5). Combined with Theorem 3,

▶ **Corollary 4.** *The emptiness problem of zero automata is decidable in co-*NP*.*

According to [1], this implies that TMSO + zero has decidable satisfiability when zero is the unary predicate checking that a set of branches has probability 0.

An example: the dense but not very dense language. A tree over alphabet $\{a, b\}$ is *dense but not very dense* if:

1. every node has a descendant with label a; and
2. there is zero probability that a branch visit infinitely many nodes with letter a.

This language is non-empty, contains no regular tree and is recognized by a nonzero automaton. This automaton has three states, totally ordered as follows:

$$\underbrace{s}_{\text{searching for } a} < \underbrace{n}_{\text{not searching for } a} < \underbrace{f}_{\text{just found } a} .$$

The automaton begins in state f in the root. When the automaton reads a node with label b, then it sends s to some child and n to the other child, regardless of its current state. Choosing which child gets s and which child gets n is the only source of nondeterminism in this automaton. When the automaton sees letter a, it sends f to both children regardless of its current state. The acceptance condition is:

$$F_\forall = \{n, f\} \qquad F_1 = \{n\} \qquad F_{>0} = \emptyset \ .$$

3 From zero to nonzero automata

In this section we show that nonzero automata are as expressive as zero automata.

▶ **Lemma 5.** *For every zero automaton one can compute a nonzero automaton of quadratic size which accepts the same trees.*

The rest of the section is dedicated to the proof of Lemma 5, which is a direct corollary of Lemma 7 and Lemma 8 below.

Without loss of generality, we assume that in every *zero* automaton $F_{>0} \subseteq F_1 \subseteq F_\forall$. Changing F_1 for $F_1 \cap F_\forall$ and $F_{>0}$ for $F_{>0} \cap F_1$ does not modify the set of accepting runs of a zero automaton, since all branches should have limsup in $F_\forall$ and if the limsup is equal with nonzero probability to some $q \in F_{>0}$ then necessarily $q \in F_1$. By contrast, for *nonzero* automata there is no obvious reason for the same remark to hold.

We make use of an intermediary acceptance condition. Let r be a run. We say that a path from a node v to a node w is *seed-consistent* if whenever the path visits a seed state s, subsequent states are $\leq s$.

- **Strong zero acceptance condition:** for every node v labelled by a seed state, there is a seed-consistent path from v to a strict descendant w of v such that the state $r(w)$ of w is in $F_{>0}$ and there is a nonzero probability that the run
  - visits node w and visits only states $\leq r(w)$ below w,
  - has limsup $r(w)$,
  - in case $r(w) \notin Q_{\text{seed}}$, visits no seed state below w,
  - in case $r(w) \in Q_{\text{seed}}$, visits no seed state other than $r(w)$ below w.

Actually, the strong zero and zero acceptance conditions coincide (proof in appendix):

▶ **Lemma 6.** *A run is zero accepting if and only if it is strongly zero accepting.*

Construction of the nonzero automaton. Intuitively, every *zero* automaton can be simulated by a *nonzero* automaton which guesses on the fly a run of the zero automaton and checks simultaneously that the guessed run is strongly zero accepting. Whenever the automaton visits a node v with a seed state then it enters in the next step a *path-finding state* and guesses a seed-consistent path to a node w which is a witness of the strong zero condition. Once on the node w the automaton enters a *subtree-guessing* state and starts guessing a leaf-free subtree of the run, whose nodes are labelled by states $\leq r(w)$, whose branches have limsup $r(w)$ and which has nonzero probability.

There are some verifications to do in order to certify that the guessed run is strongly zero accepting. The surely accepting condition is used to prevent the automaton from staying forever in the path-finding mode and also to check that every branch of the subtree has limsup $r(w)$. The nonzero condition is used to check that the subtree has nonzero probability. To perform these verifications, the nonzero automaton stores some data in its control state. In path-finding mode the automaton records the smallest seed state seen so far in order to check on-the-fly that the path from v to w is seed-consistent. In subtree-guessing mode the automaton keeps track of the state $r(w)$.

The set of states of this automaton is denoted R, every state in R has as a first component a control state Q of the zero automaton. Precisely, R is the union of three sets:

- **normal states:** Q,
- **path-finding states:** $\{(q, s) \mid q \in Q, s \in Q_{\text{seed}}, q \leq s\}$,
- **subtree-guessing states:** $\{(q, f, *) \mid q \in Q, f \in F_{>0}, q \leq f, (q \notin Q_{\text{seed}} \vee q = f)\}$.

We equip R with any order $\prec$ such that

- the projection on the first component $\Pi_1 : (R, \prec) \to (Q, <)$ is monotonic,
- $(q, s) \prec q$ for every $q \in Q$ and $s \in Q_{\text{seed}}$ with $q \leq s$.

The zero, almost-surely and surely accepting conditions are defined respectively as:

$$G_{>0} = \text{ the set of subtree-guessing states,}$$
$$G_1 = F_1 \cup \{(f, f, *) \mid f \in F_{>0}\},$$
$$G_\forall = F_\forall \cup \{(f, f, *) \mid f \in F_{>0}\} \ .$$

The transitions of the automaton can be informally described as follows. The nonzero automaton guesses on the fly a run $\rho : \{0, 1\}^* \to Q$ of the zero automaton by storing the value of $\rho(v)$ as the first component of its own control state on the node v. The nonzero automaton stays in the set of normal states as long as the run does not enter a seed state. On a node v labelled by $s \in Q_{\text{seed}}$, the nonzero automaton starts looking for a path to a descendant node w that satisfies the strong zero condition. For that in the next step the automaton enters either a path-finding or a subtree-guessing state. While in a path-finding state, the

automaton guesses on the fly a seed-consistent path. Whenever the run is in a nonzero state $f \in F_{>0}$ the nonzero automaton can enter the subtree-guessing state $(f, f, *)$, or not. While in subtree-guessing mode the second component is constant, and the automaton control state is of type $(q, f, *)$ with $q \leq f$ and $q \notin Q_{\text{seed}}$ unless $q = f \in Q_{\text{seed}}$. From a subtree-guessing state the automaton may switch back any time to a normal state.

Formally, for every transition $q \to r_0, r_1$ of the zero automaton, there is a transition

$$q' \to r'_0, r'_1$$

in the nonzero automaton if the first component of q' is q and

$$r'_0 = \begin{cases} r_0 & \text{whenever } q' \text{ is not path-finding} \\ (r_0, r_0, *) & \text{whenever } \begin{cases} q \in Q_{\text{seed}}, q' = q \text{ and } r_0 \in F_{>0} \text{ and } r_0 \leq q \\ \text{or } q' = (q, s) \text{ and } r_0 \in F_{>0} \text{ and } r_0 \leq s, \end{cases} \\ (r_0, f, *) & \text{whenever } q' = (q, f, *) \text{ and } r_0 \leq f \text{ and } (r_0 \notin Q_{\text{seed}} \vee r_0 = f). \end{cases}$$

The possible values of r'_1 are symmetric. There are also *left path-finding transitions*: for every seed states $s, s' \in Q_{\text{seed}}$ such that $q \leq s$ and $r_0 \leq s$ there are transitions

$$q' \to (r_0, s'), r_1 \text{ where } q' = \begin{cases} q \text{ or } (q, q) \text{ if } q = s \\ (q, s) \text{ otherwise} \end{cases} \quad \text{and } s' = \begin{cases} s & \text{if } r_0 \notin Q_{\text{seed}} \\ r_0 & \text{if } r_0 \in Q_{\text{seed}}. \end{cases}$$

There may also be a symmetric *right path-finding transition* $(q, s) \to r_0, (r_1, s')$ when the symmetric conditions hold.

The next two lemmas relate the accepting runs of the zero and the nonzero automata, their proofs can be found in the appendix.

▶ **Lemma 7.** *Let $d : \{0,1\}^* \to R$ be an accepting run of the nonzero automaton. Then its projection $r = \Pi_1(d)$ on the first component is an accepting run of the zero automaton.*

▶ **Lemma 8.** *If the zero automaton has an accepting run $r : \{0,1\}^* \to Q$ then the nonzero automaton has an accepting run $d : \{0,1\}^* \to R$ such that $r = \Pi_1(d)$.*

4 Emptiness of $F_\forall$-trivial automata is in NP

A run of a nonzero automaton needs to satisfy simultaneously three conditions, which correspond to the accepting sets $F_\forall, F_1, F_{>0}$. For a subset

$$I \subseteq \{F_\forall, F_1, F_{>0}\}$$

define I-automata to be the special case of nonzero automata where only the acceptance conditions corresponding to I need to be satisfied. These are indeed special cases: ignoring $F_{>0}$ can be achieved by making it empty, ignoring F_1 can be achieved by making it equal to $F_\forall$, and ignoring $F_\forall$ can be achieved by making it equal to all states Q.

Generalizing parity automata, with standard and qualitative semantics. A $\{F_\forall\}$-automaton is a parity automaton. Thus solving emptiness for nonzero automata is at least as hard as emptiness for parity automata on trees, which is polynomial time equivalent to solving parity games, in NP ∩co-NP [12] or in quasi-polynomial time [4].

A $\{F_1\}$-automaton is the same as a parity automaton with qualitative semantics as introduced in [5]. Emptiness for such automata can be solved in polynomial time using standard linear programming algorithms for Markov decision processes.

Subzero automata. A $\{F_1, F_\forall\}$-automaton is the same as a *subzero* automaton as considered in [10]. In [10], it was shown how to decide if a subzero automaton accepts some regular tree. Since some subzero automata are nonempty but accept no regular trees, see e.g. the example in [1], the result from [10] does not solve non-emptiness for subzero automata.

$F_\forall$-trivial automata. In a $\{F_1, F_{>0}\}$-automaton, the surely accepting condition is trivial, i.e. $F_\forall = Q$. We call such automata $F_\forall$-trivial. The acceptance of a run of a $F_\forall$-trivial automaton depends only on the probability measure on Q^ω induced by the run, individual branches do not matter.

▶ **Definition 9** (Positional run)**.** A run is *positional* if whenever the states of two nodes coincide then the states of their left children coincide and the states of their right children coincide.

▶ **Theorem 10.** *If a $F_\forall$-trivial automaton has an accepting run, then it has a positional accepting run. Emptiness of $F_\forall$-trivial automata is in co-*NP*.*

This result was recently improved in [2]: the complexity is actually PTIME. The proof of this theorem relies on the notion of acceptance witnesses.

▶ **Definition 11** (Transition graph and acceptance witness)**.** Let D be a set of transitions.

The transition graph of D, denoted G_D, is the directed graph whose vertices are all states appearing in one of the transitions in D, denoted Q_D, and whose edges are induced by the transitions in D: for every $(q, a, l, r) \in D$ both (q, l) and (q, r) are edges of G_D.

The set D is an *acceptance witness* if it satisfies the four following conditions:

(i) Q_D contains the initial state of the automaton and G_D has no dead-end,
(ii) the maximum of every bottom strongly connected component (BSCC) of G_D is in F_1,
(iii) every BSCC of G_D is either contained in $F_{>0}$ or does not intersect $F_{>0}$,
(iv) from every state in $F_{>0} \cap Q_D$ there is a path in $F_{>0} \cap Q_D$ to a BSCC contained in $F_{>0}$.

▶ **Lemma 12.** *If a $F_\forall$-trivial automaton has an acceptance witness, it has a positional accepting run.*

Proof. The proof is by induction on $N_D = |D| - |Q_D|$. Since G_D has no dead-end, every state in Q_D is the source of a transition in D thus $N_D \geq 0$.

If $N_D = 0$ then for every state $q \in Q_D$ there is a unique transition $\delta_q = (q, a_q, l_q, r_q)$. Let ρ be the positional run whose root has the initial state and every node with vertex $q \in Q_D$ has children l_q and r_q, which is well-defined according to property (i). We show that ρ is an accepting run. The graph G_D can be seen as a Markov chain, with probability either 1 or $\frac{1}{2}$ on every edge, depending on the out-degree. The probability measure on Q_D^ω produced by the random walk on ρ coincide with the probability measure on Q_D^ω produced by this finite Markov chain: indeed both measures coincide on finite cylinders $q_0 \cdots q_n Q_D^\omega$. Basic theory of finite homogenous Markov chain implies that almost-surely every branch of the run ends up in one of the BSCCs of G_D and visits all its states infinitely often. Thus property (ii) ensures that the run ρ is almost-surely accepting. Properties (iii) and (iv) guarantee that the run is moreover nonzero-accepting.

Assume now that $N_D > 0$. We show that there is a strictly smaller acceptance witness $D' \subsetneq D$. Let $q \in Q_D$ which is the source of several transitions in D, then D' is obtained by removing from D all these transitions except one. To choose which transition δ to keep, pick some shortest path $q = q_0 \dots q_n$ in G_D of length ≥ 1 which leads to a maximal state of one of the BSCCs of G_D. Moreover if $q \in F_{>0}$ we require the whole path to stay in $F_{>0}$. By

definition of G_D there is at least one transition in D whose origin is q and one of the two successors is q_1. To get D' we delete all other transitions with source q from D.

Clearly property (i) is preserved by this operation. To address properties (ii)–(iv), we show that every BSCC B' of $G_{D'}$ is either a BSCC of G_D or contained in the BSCC B of G_D whose maximum is q_n, in which case $\max B = \max B' = q_n$. There are two cases. If B' does not contain q_n then it does not contain q either (because $q = q_0 \dots q_n$ is still a path in $G_{D'}$). Since the only difference between G_D and $G_{D'}$ are the outgoing transitions from q then B' is actually a BSCC of G_D. If B' contains q_n then $B' \subseteq B$ (because there are less edges in $G_{D'}$ than in G_D) and since $q_n = \max B$ then $\max B = \max B'$.

As a consequence property (ii) and (iii) are preserved. And property (iv) is preserved as well: in case $q \notin F_{>0}$ then there is nothing to prove and in case $q \in F_{>0}$ then $q = q_0 \dots q_n$ is still a path in $G_{D'}$, with all vertices in $F_{>0}$. Moreover the set of vertices from which q_n is accessible is the same in G_D and $G_{D'}$ thus q_n is in a BSCC of $G_{D'}$. ◀

A strong version of the converse implication of Lemma 12 holds:

▶ **Lemma 13.** *If a $F_\forall$-trivial automaton has an accepting run, it has an acceptance witness.*

Proof. We fix an accepting run ρ on some input tree t. To extract an acceptance witness from ρ, we make use of the notion of end-component introduced in [6].

▶ **Definition 14** (End-component)**.** The *transition of a node v* is $d(v) = (\rho(v), t(v), \rho(v0), \rho(v1))$. For every branch b, we denote $\Delta^\infty(b)$ the set of transitions labelling infinitely many nodes of the branch. For every subset $D \subseteq \Delta$ we denote B_D the set of branches b such that $\Delta^\infty(b) = D$. A set of transitions $D \subseteq \Delta$ is an *end-component* of the run if B_D has nonzero probability.

Call a branch b *even* if for every transition $\delta = (q, a, l, r) \in \Delta^\infty(b)$, not only the state q but also the states l and ρ appear infinitely often on the branch in the run ρ. Almost-surely every branch is even, because each time a branch visits a node with transition δ it proceeds left or right with equal probability $\frac{1}{2}$. As a consequence,

▶ **Lemma 15.** *Let D be an end-component of the run. Then the transition graph of D has no dead-end, is strongly connected and its maximal state is in F_1.*

Proof. Denote G_D the transition graph of D, with states Q_D. Since D is an end-component then B_D has non-zero probability, and since almost every branch is even then B_D contains at least one even branch b. The set of states appearing infinitely often on b is exactly Q_D. By removing a prefix long enough of b so that only states in Q_D occur on the remaining suffix then one obtains a path in G_D which visits every state in Q_D infinitely often. Thus G_D has no dead-end and is strongly connected. Moreover every even branch in B_D has limsup $\max Q_D$ and since the run is almost-surely accepting then $\max Q_D \in F_1$. ◀

Let $\mathcal{D}$ be the collection of all end-components of the run ρ. We define two subsets of $\mathcal{D}$, denoted respectively $\mathcal{D}_0$ and $\mathcal{D}_1$, which collect the end-components whose states are respectively included in $F_{>0}$ and disjoint from $F_{>0}$. Let $D_0 \subseteq \Delta$ (resp. $D_1 \subseteq \Delta$) be the union of all end-components in $\mathcal{D}_0$ (resp. in $\mathcal{D}_1$). These transitions are easy to reach:

▶ **Lemma 16.** *Every node v has a descendant w whose transition $d(w)$ belongs to $D_0 \cup D_1$. Moreover if the state of v is in $F_{>0}$ then w can be chosen such that the path v to w is labelled by $F_{>0}$ and the transition $d(w)$ is in D_0.*

Proof. Let v be a node and S_v the set of branches which visit v and, in case v is labelled by $F_{>0}$, visit only $F_{>0}$-labelled nodes below v. Since the run is accepting then S_v has positive probability. By definition of end-components, almost-every branch is in $\bigcup_{D\in\mathcal{D}} B_D$. Thus there exists an end-component D such that $B_D \cap S_v$ has positive probability. As a consequence, v has a descendant w whose transition is in D. Since almost-every branch is even and $B_D \cap S_v$ has positive probability then there is at least one branch in $B_D \cap S_v$ which visits infinitely often all states appearing in Q_D. In case v is labelled by $F_{>0}$, this implies that $Q_D \subseteq F_{>0}$ thus $D \in \mathcal{D}_0$, and the proof of the second statement is complete. In case v has no descendant labelled by $F_{>0}$ this implies that $Q_D \cap F_{>0} = \emptyset$ thus $D \in \mathcal{D}_1$, and the first statement holds in this case. In the remaining case, v has a descendant v' labelled with $F_{>0}$, which itself has a descendant w whose transition belongs to some $D \in \mathcal{D}_0$, thus the first statement holds for v. ◀

We terminate the proof of Lemma 13. Let G_0 (resp. G_1) the transition graph of D_0 (resp. D_1) and denote Q_0 (resp. Q_1) the set of states of G_0 (resp. G_1).

Let D be the set of all transitions appearing in the run. According to Lemma 16, in the transition graph G_D, $Q_0 \cup Q_1$ is accessible from every state $q \in Q_D$ and moreover Q_0 is accessible from every state $q \in Q_D \cap F_{>0}$ following a path in $Q_D \cap F_{>0}$.

We say that an edge (q, r) of G_D is *progressive* if $q \notin Q_0 \cup Q_1$ and either ($q \in F_{>0}$ and $r \in F_{>0}$ and (q, r) decrements the distance to Q_0 in G_D) or ($q \notin F_{>0}$ and (q, r) decrements the distance to $Q_0 \cup Q_1$ in G_D). Every state in $Q_D \setminus (Q_0 \cup Q_1)$ is the source of at least one progressive edge.

We denote D_+ the union of D_0 and D_1 plus all the transitions $\delta = (q, a, r_0, r_1) \in D$ such that either (q, r_0) or (q, r_1) is progressive. Then D_+ has all four properties of Lemma 12. Denote G_+ the transition graph associated to D_+. Property (i) holds because every state in Q_D, including the initial state, is either in $Q_0 \cup Q_1$ or is the source of a progressive edge.

Remark that the BSCCs of G_+ are exactly the BSCCs of G_0 and G_1. Since both G_0 and G_1 are unions of strongly connected graphs, they are equal to the union of their BSCCs. The BSCCs of G_0 and G_1 are still BSCCs in G_+ because no edges are added inside them (progressive edges have their source outside G_0 and G_1). Following the progressive edges leads to G_0 or G_1 from every state in G_+, thus there are no other BSCCs in G_+.

This implies property (ii) because, according to Lemma 15, both graphs G_0 and G_1 are the union of strongly connected graphs whose maximal states are in F_1. This also implies property (iii) since $Q_0 \subseteq F_{>0}$ and $Q_1 \cap F_{>0} = \emptyset$. Property (iv) is obvious for states in Q_0 because Q_0 is a union of BSCCs included in $F_{>0}$. Property (iv) holds as well for states in $(Q_D \cap F_{>0}) \setminus Q_0$, the path to Q_0 is obtained following the progressive edges in $F_{>0} \times F_{>0}$. ◀

Proof of Theorem 10. According to Lemma 13, the existence of an accepting run implies the existence of an acceptance witness and according to Lemma 12 this implies the existence of a positional accepting run. Guessing a subset of transitions and checking it is an acceptance witness can be done in non-deterministic polynomial time. ◀

5 Emptiness of nonzero automata is in co-NP

In this section we show how to decide the emptiness of nonzero automata. The main ingredient are jumping games.

Call a run $\{F_1, F_{>0}\}$-*accepting* if it satisfies the almost-surely and the nonzero acceptance condition, but it does not necessarily satisfy the surely accepting condition, and the condition on the initial state is dropped as well.

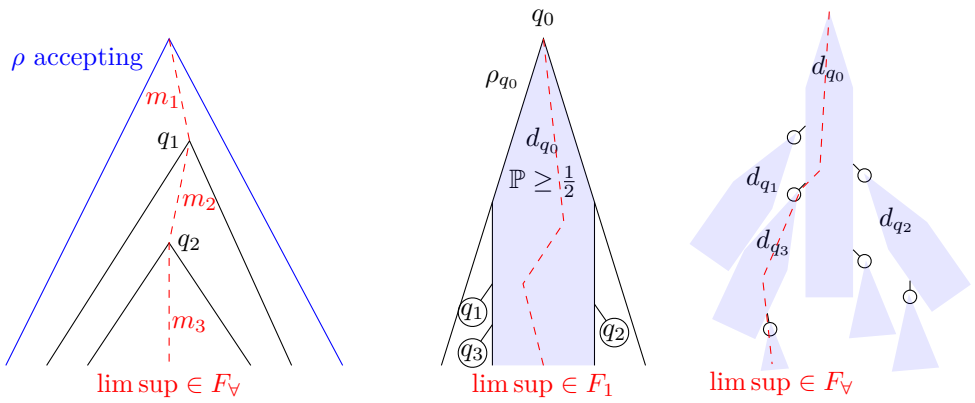

Figure 1 The left picture illustrates how an accepting run is turned into a winning strategy for Automaton in the jumping game, the two other pictures illustrate the converse transformation.

The jumping game. For a run ρ, define its *profile* to be the set of state pairs (q, m) such that some non-root node in ρ has state q and m is the maximal state of its strict ancestors.

The *jumping game* is a parity game played by two players, *Automaton* and *Pathfinder*. Positions of Automaton are states of the automaton and positions of Pathfinder are profiles of $\{F_1, F_{>0}\}$-accepting runs, not necessarily positional. The game is an edge-labelled parity game, i.e. the priorities are written on the edges. The edges originating in Automaton positions are of the form

$$q \xrightarrow{q} \Pi \qquad \text{such that } \Pi \text{ is the profile of some } \{F_1, F_{>0}\}\text{-accepting run with root state } q.$$

The edges originating in Pathfinder positions are of the form

$$\Pi \xrightarrow{m} q \qquad \text{such that } (q, m) \in \Pi.$$

We say that Automaton wins the jumping game if he has a winning strategy from the position which is the initial state of the automaton. If the play ever reaches a dead-end, i.e. a state which is not the root of any $\{F_1, F_{>0}\}$-accepting run, then the game is over and Automaton loses. Otherwise Automaton wins iff the limsup of the priorities is in $F_\forall$.

Lemmas 17 and 18 below establish that non-emptiness of a nonzero automaton is equivalent to Automaton winning the jumping game, and this can be decided in NP.

▶ **Lemma 17.** *The automaton is nonempty if and only if Automaton wins the jumping game.*

Sketch of Proof. The proof transforms an accepting run ρ of the nonzero automaton into a winning strategy σ of Automaton, and back, this is illustrated by Fig. 1.

When the nonzero automaton has an accepting run ρ, Automaton can win the jumping game as follows. For a start, Automaton plays the profile Π_0 of ρ. Then Pathfinder chooses some pair $(q_1, m_1) \in \Pi_0$, by definition of profiles this corresponds to some non-root node v_1 of ρ labelled by q_1 and m_1 is the maximal state of the ancestors of v_1. At each step $n > 0$, Pathfinder chooses some pair $(q_n, m_n) \in \Pi_n$ corresponding to some node v_{n+1} whose v_n is a strict ancestor, and Automaton plays the profile Π_n of the subtree ρ_n of ρ rooted in v_n. Since the run ρ is accepting then *a fortiori* the run ρ_n is $\{F_1, F_{>0}\}$-accepting. Quite clearly, this is a winning strategy for Automaton.

Conversely, we use a positional winning strategy of Automaton (whose existence is well-known [12]) to build an accepting run of the nonzero automaton. Denote W the set of states

winning for Automaton. With every state q in W we associate the profile Π_q chosen by the positional winning strategy of Automaton and a $\{F_1, F_{>0}\}$-accepting run ρ_q with profile Π_q.

We show the existence of a leaf-free subtree d_q of ρ_q such that:

(a) the set of branches of d_q has probability $\geq \frac{1}{2}$,

(b) *every* branch of d_q has limsup in F_1,

(c) for every node v of d_q with state in $F_{>0}$, the set of branches of d_q which visit v and visit only $F_{>0}$-labelled nodes below v has nonzero probability.

Since ρ_q is almost-surely accepting, then according to Lemma 1, there is a subtree d_q of ρ_q whose set of branches has probability $\geq \frac{1}{2}$ and *all of them* have limsup in F_1 (while in the run ρ_q there may be a non-empty set of branches with limsup in $F_\forall \setminus F_1$, with probability zero). Since we are only interested in branches of d_q, we can assume that d_q is leaf-free. This guarantees properties a) and b) but not c), however using Lemma 1 again, we can extend d_q to d'_q such that property c) holds as well.

These partial runs $(d'_q)_{q\in W}$ can be combined in order to get a graph whose unravelling, starting from the initial state, is an accepting run of the automaton. Each time a branch enters a subtree d'_q, there is probability $\geq \frac{1}{2}$ to stay in d_q forever. Thus almost every branch of the unravelling eventually stays in one of the subtrees $(d'_q)_{q\in W}$, thus has limsup in $F_1 \subseteq F_\forall$ according to property b). As a consequence the unravelling is almost-surely accepting. Still, with probability 0, some branches switch infinitely often from a subtree to another. These branches correspond to an infinite play consistent with σ and are $F_\forall$-accepting. ◀

▶ **Lemma 18.** *Given a nonzero automaton, whether Automaton wins the jumping game is decidable in* NP .

The game is not constructed explicitly, which would require exponential time, but strategies of Automaton can be represented in a compact way, which is enough to get the NP upper bound. This result was recently improved: the winner can be decided in NP∩co-NP, see [2].

Sketch of Proof. By positional determinacy of parity games, it suffices to find a positional strategy of player Automaton, which maps states to profiles of $\{F_1, F_{>0}\}$-accepting runs. It is equivalent and easier to find an *acceptance witness*. This is a pair (W, σ) where W is a subset of Q containing the initial state of the automaton, and $\sigma : W \to 2^{W\times W}$ satisfies:

α) For every sequence $(q_0, m_0)(q_1, m_1)\dots$ in $(W \times W)^\omega$, if q_0 is the initial state of the automaton and $\forall n, (q_{n+1}, m_{n+1}) \in \sigma(q_n)$ then $\limsup_n m_n \in F_\forall$.

β) $\forall q \in W$, $\sigma(q)$ *contains* the profile of a $\{F_1, F_{>0}\}$-accepting run with initial state q.

Finding a witness can be done in NP. Condition α) is checked in linear time. Given $\Pi \subseteq Q\times Q$, one can use Theorem 10 to check condition Condition β) in NP, by storing in the state space of the automaton the maximal state of the ancestors of the curent node. ◀

Example: the everywhere positive language. A tree t on the alphabet $\{a, b\}$ is *everywhere positive* if for every node v,

1. there is positive probability to see only the letter $t(v)$ below v,
2. there is positive probability to see finitely many times the letter $t(v)$ below v.

This language is non-empty and contains no regular tree. The language of everywhere positive trees with root state a is recognized by a nonzero automaton with six states

$$\{s_b < s_a < n_b < n_a < f_b < f_a\} \quad .$$

On a node labelled by letter a, the automaton can perform a transition from any of the three states $\{s_b, n_b, f_a\}$, meaning intuitively "searching for b", "not searching for b" and "just

found a". From these states the automaton can choose any pair of successor states which intersects $\{s_b, f_b\}$. Transitions on letter b are symmetrical. The acceptance condition is:

$$F_\forall = \{n_a, n_b, f_a, f_b\} \qquad F_1 = F_\forall \qquad F_{>0} = \{n_a, s_a, n_b, s_b\} \ .$$

Among the simplest moves of Automaton in the jumping game are the two moves $n_b \to \{(n_b, n_b)(s_b, n_b)\}$ and $s_b \to \{(n_b, n_b)(s_b, n_b)\}$, which correspond to the profiles of some $\{F_1, F_{>0}\}$-accepting runs on the tree whose all nodes have letter a, and everywhere in the tree the automaton applies the same two transitions $n_b \to_b (n_b, s_b)$ and $s_b \to_b (n_b, s_b)$. In those runs, the automaton always looks for a letter b in the right direction (state s_b), and does not look for b in the left direction (state n_b). Since the tree has no b at all then the quest for a letter b is hopeless, and on all branches of the run that ultimately always turn right (i.e. branches in $\{0,1\}^*1^\omega$), the automaton ultimately stays in state s_b and the branch has limsup s_b, which is neither in $F_\forall$ nor in F_1. But such branches happen with probability zero: almost-every branch performs infinitely many turns left and right, thus has limsup n_b. As a consequence such a run is almost-surely accepting: Such a run is nonzero-accepting as well because every node labelled by $F_{>0}$ has all its descendants labelled by $F_{>0}$.

Yet legal, these two moves are not good options for Automaton in the jumping game because then Pathfinder can generate the play

$$s_b \xrightarrow{s_b} \{(n_b, n_b)(s_b, n_b)\} \xrightarrow{n_b} s_b \xrightarrow{s_b} \{(n_b, n_b)(s_b, n_b)\} \xrightarrow{s_b} s_b \xrightarrow{s_b} \dots$$

which has limsup $n_b = \max\{s_b, n_b\}$ and is losing for Automaton since $n_b \notin F_\forall$.

Actually, Automaton can win with the moves

$$s_a/n_a \to \{(f_a, f_a), (n_b, f_a), (s_b, f_a), (n_a, n_a), (s_a, n_a)\}$$
$$f_a \to \{(n_b, f_a), (s_b, f_a)\}$$

and their symmetric counterparts from states $\{s_b, n_b, f_b\}$. In the jumping game, this forces Pathfinder to take only edges labelled by one of the states $\{f_a, n_a, f_b, n_b\}$. These states dominate the states $\{s_a, s_b\}$ thus the limsup of the corresponding plays is in $F_\forall$ and Automaton wins.

6 Conclusion

We have shown that the emptiness problem for zero and nonzero automata is decidable and belongs to co-NP. As a consequence, the satisfiability for the logic MSO+zero from [1] is decidable (in non-elementary time), when zero is the unary predicate that checks a set of branches has probability 0.

As shown by Stockmeyer, the satisfiability problem for first-order logic on finite words cannot be solved in elementary time [11]. Therefore any translation from a logic stronger than first-order logic on finite words (such as TMSO+zero on infinite trees) to an automaton model with elementary emptiness (such as nonzero automata) is necessarily non-elementary. This does not make the relatively low NP complexity of nonzero automata any less interesting. One can imagine other logics than TMSO+zero, either less expressive or maybe even equally expressive but less succinct, which will have a relatively low complexity by virtue of a translation into nonzero automata. One natural direction is the study of temporal logics.

Our results were recently improved [2]: the emptiness of nonzero automata actually belongs to NP∩co-NP, and is even in PTIME for $F_\forall$-trivial automata.

Acknowledgments. We thank Henryk Michalewski and Matteo Mio for helpful discussions.

Abstract

We look at characterizing which formulas are expressible in rich decidable logics such as guarded fixpoint logic, unary negation fixpoint logic, and guarded negation fixpoint logic. We consider semantic characterizations of definability, as well as effective characterizations. Our algorithms revolve around a finer analysis of the tree-model property and a refinement of the method of moving back-and-forth between relational logics and logics over trees.

1 Introduction

A major line of research in computational logic has focused on obtaining extremely expressive decidable logics. The guarded fragment (GF) [1], the unary negation fragment (UNF) [23], and the guarded negation fragment (GNF) [3] are rich decidable fragments of first-order logic. Each of these has extensions with a fixpoint operator that retain decidability: GFP [18], UNFP [23], and GNFP [3] respectively. In each case the argument relies on "moving to trees". This involves showing that the logic possesses the tree-like model property: whenever there is a satisfying model for a formula, it can be taken to be of tree-width that can be effectively computed from the formula. Such models can be coded by trees, thus reducing satisfiability of the logic to satisfiability of a corresponding formula over trees, which can be decided using automata-theoretic techniques. This method has been applied for decades (e.g. [25, 16]).

A question is how to recognize formulas in these logics, and more generally how to distinguish the properties of the formulas in one logic from another. Clearly if we start with a formula in an undecidable logic, such as first-order logic or least fixed point logic (LFP), we have no possibility for effectively recognizing any non-trivial property. But we could still hope for an insightful semantic characterization of the subset that falls within the decidable logic. One well-known example of this is van Benthem's theorem [24] characterizing modal logic within first-order logic – a first-order sentence is equivalent to a modal logic sentence exactly when it is bisimulation-invariant. For fixpoint logics, an analogous characterization is the Janin-Walukiewicz theorem [20], stating that the modal mu-calculus (L_μ) captures the bisimulation-invariant fragment of monadic second-order logic (MSO). If we start in one decidable logic and look to characterize another decidable logic, we could hope for a

characterization that is effective. For example, Otto [22] showed that if we start with a formula of L_μ, we can determine whether it can be expressed in modal logic.

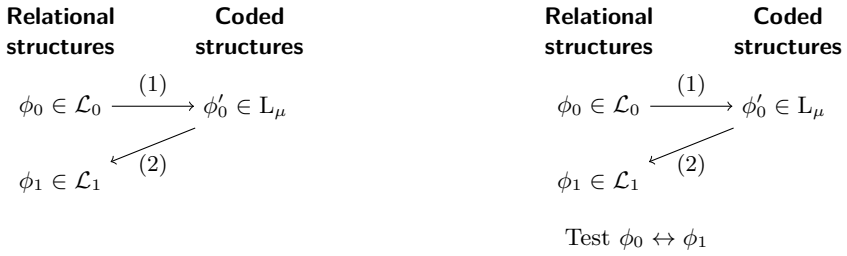
In this work we will investigate both semantic and effective characterizations. We will begin with GFP. Grädel, Hirsch, and Otto [16] have already provided a characterization of GFP-definability within a very rich logic extending MSO called guarded second-order logic (GSO). The characterization is exactly analogous to the van Benthem and Janin-Walukiewicz results mentioned above: GFP captures the "guarded bisimulation-invariant" fragment of GSO. The characterization makes use of a refinement of the method used for decidability of these logics, which moves *back-and-forth between relational structures and trees*: (1) define a *forward mapping* taking a formula ϕ_0 in the larger logic (e.g. GSO invariant under guarded bisimulation) over relational structures to a formula ϕ'_0 over trees that describes codes of structures satisfying ϕ_0; (2) define a *backward mapping* based on the invariance going back to some ϕ_1 in the restricted logic (e.g. GFP). The method is shown in Figure 1a.

Our first main theorem is an effective version of the above result: if we start with a formula in certain richer decidable fixpoint logics, such as GNFP, we can decide whether the formula is in GFP. At the same time we provide a refinement of [16] which accounts for two signatures, the one allowed for arbitrary relations and the one allowed for "guard relations" that play a key role in the syntax of all guarded logics. We extend this result to deciding membership in the "k-width fragment", GNFP^k; roughly speaking this consists of formulas built up from guarded components and positive existential formulas with at most k variables. We provide a semantic characterization of this fragment within GSO, as the fragment closed under the corresponding notion of bisimulation (essentially, the GN^k-bisimulation of [3]). As with GFP, we show that the characterization can be made effective, provided that one starts with a formula in certain larger decidable logics. The proof also gives an effective characterization for the k-width fragment of UNFP.

As in the method for invariance and decidability above, we apply a forward mapping to move from a formula ϕ_0 in a larger logic $\mathcal{L}_0$ on relational structures to a formula ϕ'_0 on tree encodings. But then we can apply a *different backward mapping*, tuned towards the smaller logic $\mathcal{L}_1$ and the special properties of its tree-like models. The backward mapping of a tree property ϕ'_0 is always a formula ϕ_1 in the smaller logic $\mathcal{L}_1$ (e.g. GFP). But it is no longer guaranteed to be "correct" unconditionally – i.e. to always characterize structures whose codes satisfy ϕ'_0. Still, we show that *if* the original formula ϕ_0 is definable in the smaller logic $\mathcal{L}_1$, then the backward mapping applied to the forward mapping gives such a definition. Since we can check equivalence of two sentences in these logics effectively, this property suffices to get decidability of definability. The revised method is shown schematically in Figure 1b.

The technique above has a few inefficiencies; first, the general forward mapping passes through MSO and has non-elementary complexity. Secondly, the technique implicitly moves between relational structures and trees *twice*: once to construct ϕ_0, and a second time to check that ϕ_0 is equivalent to ϕ_1, which in turn requires first forming a formula ϕ'_1 over trees via a forward mapping and then checking its equivalence with ϕ'_0. We show that in some cases we can optimize this, allowing us to get tight bounds on the equivalence problem.

We show that our results "restrict" to fragments of these guarded logics, including their first-order fragments. In particular, our results give effective characterizations of GF definability when the input is in FO. They can be thus seen as a generalization of well-known effective characterizations of the conjunctive existential formulas in GF, the *acyclic queries*. We show that we can apply our techniques to the problem of transforming conjunctive formulas to a well-known efficiently-evaluable form (acyclic formulas) relative to GF theories. These results complement previous results on query evaluation with constraints from [6, 13].



(a) Back-and-forth for Semantic Characterization.

(b) Back-and-forth for Effective Characterization.

Figure 1

This refined back-and-forth method can be tuned in a number of ways, allowing us to control the signature as well as the sublogic. We show this can be adapted to give an approximation of the formula ϕ_0 within the logic $\mathcal{L}_1$, which is a kind of *uniform interpolant*.

2 Preliminaries

We work with finite relational signatures σ. We use $\boldsymbol{x}, \boldsymbol{y}, \dots$ (respectively, $\boldsymbol{X}, \boldsymbol{Y}, \dots$) to denote vectors of first-order (respectively, second-order) variables. For a formula ϕ, we write $\phi(\boldsymbol{x})$ to indicate that the free first-order variables in ϕ are among $\boldsymbol{x}$. If we want to emphasize that there are also free second-order variables $\boldsymbol{X}$, we write $\phi(\boldsymbol{x}, \boldsymbol{X})$. We often use α to denote atomic formulas, and if we write $\alpha(\boldsymbol{x})$ then we assume that the free variables in α are precisely $\boldsymbol{x}$. The *width* of ϕ, denoted $\mathrm{width}(\phi)$, is the maximum number of free variables in any subformula of ϕ, and the width of a signature σ is the maximum arity of its relations.

The *Guarded Negation Fragment* of FO [3] (denoted GNF) is built up inductively according to the grammar $\phi ::= R\,\boldsymbol{x} \mid \exists x.\phi \mid \phi \vee \phi \mid \phi \wedge \phi \mid \alpha(\boldsymbol{x}) \wedge \neg\phi(\boldsymbol{x})$ where R is either a relation symbol or the equality relation, and α is an atomic formula or equality such that $\mathrm{free}(\alpha) \supseteq \mathrm{free}(\phi)$. Such an α is a *guard*. If we restrict α to be an equality, then each negated formula can be rewritten to use at most one free variable; this is the *Unary Negation Fragment*, UNF [23]. GNF is also related to the *Guarded Fragment* [1] (GF), typically defined via the grammar $\phi ::= R\,\boldsymbol{x} \mid \exists \boldsymbol{x}.\alpha(\boldsymbol{xy}) \wedge \phi(\boldsymbol{xy}) \mid \phi \vee \phi \mid \phi \wedge \phi \mid \neg\phi(\boldsymbol{x})$ where R is either a relation symbol or the equality relation, and α is an atomic formula or equality that uses all of the free variables of ϕ. Here it is the quantification that is guarded, rather than negation. GNF subsumes GF sentences and UNF formulas.

The fixpoint extensions of these logics (denoted GNFP, UNFP, and GFP) extend the base logic with formulas $[\mathbf{lfp}_{X,\boldsymbol{x}}.\alpha(\boldsymbol{x}) \wedge \phi(\boldsymbol{x}, X, \boldsymbol{Y})](\boldsymbol{x})$ where (i) $\alpha(\boldsymbol{x})$ is an atomic formula or equality guarding $\boldsymbol{x}$, (ii) X only appears positively in ϕ, (iii) second-order variables like X cannot be used as guards. Some alternative (but equi-expressive) ways to define the fixpoint extension are discussed in [3]; in all of the definitions, the important feature is that tuples in the fixpoint are guarded by an atom in the original signature. In UNFP, there is an additional requirement that only unary or 0-ary predicates can be defined using the fixpoint operators. GNFP subsumes both GFP sentences and UNFP formulas. These logics are all contained in LFP, the fixpoint extension of FO, so the semantics are inherited from there.

It is often helpful to consider the formulas in a normal form. *Strict normal form* GNFP

formulas can be generated using the following grammar:

$$\phi ::= \bigvee_i \exists \boldsymbol{x}_i . \bigwedge_j \psi_{ij}$$
$$\psi ::= R\,\boldsymbol{x} \mid X\,\boldsymbol{x} \mid \alpha(\boldsymbol{x}) \wedge \phi(\boldsymbol{x}) \mid \alpha(\boldsymbol{x}) \wedge \neg\phi(\boldsymbol{x}) \mid [\mathbf{lfp}_{X,\boldsymbol{x}} .\alpha(\boldsymbol{x}) \wedge \phi(\boldsymbol{x}, X, \boldsymbol{Y})](\boldsymbol{x})$$

where α is an atomic formula or equality statement such that $\text{free}(\alpha) = \text{free}(\phi)$; we call such an α a *strict guard*. Every GNFP-formula can be converted into this form in a canonical way with an exponential blow-up in size. We denote by GNFP^k the set of GNFP-formulas that are of width k when they are brought into this normal form. For convenience in proofs, we are using a slightly different normal form than previous papers on these logics.

These guarded fixpoint logics are expressive: the μ-calculus is contained in each of these fixpoint logics, and every positive existential formula is expressible in UNFP and GNFP (and even UNF and GNF). Nevertheless, these logics are decidable and have nice model theoretic properties. In particular satisfiability and finite satisfiability is 2-ExpTime-complete for GNF and GNFP [5]. The same holds for UNFP and GFP [23, 18]. GNFP (and hence UNFP and GFP) has the tree-like model property [5]: if ϕ is satisfiable, then ϕ is satisfiable over structures of bounded tree-width. In fact satisfiable GNFP^k formulas have satisfying structures of tree-width $k-1$. GNF (and hence UNF and GF) has the finite-model property [5]: if ϕ is satisfiable, then ϕ is satisfiable in a finite structure. This does not hold for the fixpoint extensions. In this paper we will be concerned with equivalence over all structures.

In this work we will be interested in varying the signatures considered, and in distinguishing more finely which relations can be used in guards. If we want to emphasize the relational signature σ being used, then we will write, e.g., $\text{GNFP}[\sigma]$. For $\sigma_g \subseteq \sigma$, we let $\text{GNFP}[\sigma, \sigma_g]$ denote the logic built up as in GNFP but allowing only relations $R \in \sigma$ at the atomic step and only guards α using equality or relations $R \in \sigma_g$. We define $\text{GFP}[\sigma, \sigma_g]$ similarly. Note that $\text{UNFP}[\sigma]$ is equivalent to $\text{GNFP}[\sigma, \emptyset]$, since if the only guards are equality guards, then the formula can be rewritten to use only unary negation and monadic fixpoints.

Guarded second-order logic over a signature σ (denoted $\text{GSO}[\sigma]$) is a fragment of second-order logic in which second-order quantification is interpreted only over guarded relations, i.e. over relations where every tuple in the relation is guarded by some predicate from σ. We refer the interested reader to [16] for more background and some equivalent definitions of this logic. The logics UNFP, GNFP, and GFP can all be translated into GSO.

A special kind of signature is a *transition system signature* Σ consisting of a finite set of unary predicates (corresponding to a set of propositions) and binary predicates (corresponding to a set of actions). A structure for such a signature is a *transition system*. Trees allowing both edge-labels and node-labels have a natural interpretation as transition systems. We will be interested in two logics over transition system signatures. One is *monadic second-order logic* (denoted MSO) – where second-order quantification is only over unary relations. MSO is contained in GSO, because unary relations are trivially guarded. While MSO and GSO can be interpreted over arbitrary signatures, there are logics like *modal logic* that have syntax specific to transition system signatures. Another is the *modal μ-calculus* (denoted L_μ), an extension of modal logic with fixpoints. Given a transition system signature Σ, formulas $\phi \in \text{L}_\mu[\Sigma]$ can be generated using the grammar $\phi ::= P \mid X \mid \phi \wedge \phi \mid \neg\phi \mid \langle\rho\rangle\phi \mid \mu X.\phi$ where P is a unary relation in Σ and ρ is a binary relation in Σ. The formulas $\mu X.\phi$ are required to use the variable X only positively in ϕ, and the semantics define a least-fixpoint operation based on ϕ. It is easy to see that L_μ can be translated into MSO.

It is well-known that σ-structures of tree-width $k-1$ can be encoded by labelled trees over an alphabet that depends only on the signature of the structure and k, which we denote $\Sigma^{\text{code}}_{\sigma,k}$. Our encoding scheme will make use of trees with both node and edge labels, i.e. trees over a

transition system signature $\Sigma^{\text{code}}_{\sigma,k}$. Roughly speaking, a node label is a set of unary relations (like $R_{i_1,\ldots,i_n}$) from $\Sigma^{\text{code}}_{\sigma,k}$ that encodes the set of atomic formulas (like $R(a_{i_1},\ldots,a_{i_n})$) that hold of the elements represented at that node, and an edge label ρ is a binary relation from $\Sigma^{\text{code}}_{\sigma,k}$ that indicates the relationship between the names of encoded elements in neighboring nodes. This scheme differs slightly from the one used in [16]. The exact coding conventions are not important for understanding the ideas in the rest of the paper. Given some $\Sigma^{\text{code}}_{\sigma,k}$-tree $\mathcal{T}$, we say $\mathcal{T}$ is *consistent* if it satisfies certain natural conditions that ensure that the tree actually corresponds to a code of some tree decomposition of a σ-structure. A consistent $\Sigma^{\text{code}}_{\sigma,k}$-tree $\mathcal{T}$ can be decoded to an actual σ-structure, denoted $\mathfrak{D}(\mathcal{T})$.

Bisimulation games and unravellings. The logic L_μ over transition system signatures lies within MSO. Similarly the guarded logics GFP, UNFP, and GNFP all lie within GSO and apply to arbitrary-arity signatures. It is easy to see that these containments are proper. In each case, what distinguishes the smaller logic from the larger is *invariance* under certain equivalences called *bisimulations*, each of which is defined by a certain player having a winning strategy in a two-player infinite game played between players Spoiler and Duplicator.

For L_μ, the appropriate game is the classical *bisimulation game* between transition systems $\mathfrak{A}$ and $\mathfrak{B}$. It is straightforward to check that $\mathrm{L}_\mu[\Sigma]$-formulas are Σ-bisimulation invariant, i.e. they cannot distinguish between Σ-bisimilar transition systems. We will make use of a stronger result of Janin and Walukiewicz [20] that the μ-calculus is the bisimulation-invariant fragment of MSO (we state it here for trees because of how we use this later): A class of trees is definable in $\mathrm{L}_\mu[\Sigma]$ iff it is definable in MSO$[\Sigma]$ and closed under Σ-bisimulation within the class of all Σ-trees. Moreover, the translation between these logics is effective.

We now describe a generalization of these games between structures $\mathfrak{A}$ and $\mathfrak{B}$ over a signature σ with arbitrary arity relations, parameterized by some subsignature σ' of the structures. Each position in the game is a partial σ' homomorphism h from $\mathfrak{A}$ to $\mathfrak{B}$, or vice versa. The *active structure* in position h is the structure containing the domain of h. The game starts from the empty partial map from $\mathfrak{A}$ to $\mathfrak{B}$. In each round of the game, Spoiler chooses between one of the following moves:

- *Extend:* Spoiler chooses some set X of elements in the active structure such that $X \supseteq \mathrm{dom}(h)$, and Duplicator must then choose h' extending h (i.e. such that $h(c) = h'(c)$ for all $c \in \mathrm{dom}(h)$) such that h' is a partial σ' homomorphism; Duplicator loses if this is not possible. Otherwise, the game proceeds from the position h'.
- *Switch:* Spoiler chooses to switch active structure. If h is not a partial σ' isomorphism, then Duplicator loses. Otherwise, the game proceeds from the position h^{-1}.
- *Collapse:* Spoiler selects some $X \subseteq \mathrm{dom}(h)$ and the game continues from position $h \restriction_X$.

Duplicator wins if she can continue to play indefinitely.

We will consider several variants of this game. These were essentially known already in the literature (see, e.g., [16, 17, 3]), sometimes with different names or minor technical differences in the definitions. For $k \in \mathbb{N}$ and $\sigma_g \subseteq \sigma'$:

1. **k-width guarded negation bisimulation game**: The $\mathrm{GN}^k[\sigma', \sigma_g]$-game is the version of the game where the domain of every position h is of size at most k, and Spoiler can only make a switch move at h if $\mathrm{dom}(h)$ is strictly σ_g-guarded in the active structure.
2. **block k-width guarded negation bisimulation game**: The $\mathrm{BGN}^k[\sigma', \sigma_g]$-game is like the $\mathrm{GN}^k[\sigma', \sigma_g]$-game, but additionally Spoiler is required to alternate between extend/switch moves and moves where he collapses to a strictly σ_g-guarded set. We call it the "block" game since Spoiler must select all of the new extension elements in a single block, rather than as a series of small extensions. The key property is that the game alternates

between positions with a strictly σ_g-guarded domain, and positions of size at most k. The restriction mimics the alternation between formulas of width at most k and strictly σ_g-guarded formulas within normalized GNFP^k formulas.

3. **guarded bisimulation game**: The $\mathrm{G}[\sigma', \sigma_g]$-game is the version of the game where the domain of every position must be strictly σ_g-guarded in the active structure. Note that in such a game, every position h satisfies $|\mathrm{dom}(h)| \leq \mathrm{width}(\sigma_g)$.

We say $\mathfrak{A}$ and $\mathfrak{B}$ are $\mathrm{GN}^k[\sigma', \sigma_g]$-*bisimilar* if Duplicator has a winning strategy in the $\mathrm{GN}^k[\sigma', \sigma_g]$-game starting from the empty position. We say a sentence ϕ is $\mathrm{GN}^k[\sigma', \sigma_g]$-*invariant* if for any pair of $\mathrm{GN}^k[\sigma', \sigma_g]$-bisimilar σ'-structures, $\mathfrak{A} \models \phi$ iff $\mathfrak{B} \models \phi$. A logic $\mathcal{L}$ is $\mathrm{GN}^k[\sigma', \sigma_g]$-invariant if every sentence in $\mathcal{L}$ is $\mathrm{GN}^k[\sigma', \sigma_g]$-invariant. When the guard signature is the entire signature, we will write, e.g., $\mathrm{GN}^k[\sigma']$ instead of $\mathrm{GN}^k[\sigma', \sigma']$.

It is known that the bisimulation games characterize certain fragments of FO: $\mathrm{GF}[\sigma']$ is the $\mathrm{G}[\sigma']$-invariant fragment of $\mathrm{FO}[\sigma']$ [1] and $\mathrm{GNF}^k[\sigma']$ can be characterized as either the $\mathrm{BGN}^k[\sigma']$-invariant or the $\mathrm{GN}^k[\sigma']$-invariant fragment of $\mathrm{FO}[\sigma']$ (this follows from work in [3] and [7]). Likewise, for fixpoint logics and fragments of GSO, $\mathrm{GFP}[\sigma']$ is the $\mathrm{G}[\sigma']$-invariant fragment of $\mathrm{GSO}[\sigma']$ [16], while $\mathrm{UNFP}^k[\sigma']$ is the $\mathrm{BGN}^k[\sigma', \emptyset]$-invariant fragment of $\mathrm{GSO}[\sigma']$ (this follows from [9]). The survey in [17] also describes some of these invariance results.

In this paper, we will prove a corresponding characterization for $\mathrm{GNFP}^k[\sigma']$ in terms of $\mathrm{BGN}^k[\sigma']$-invariance: $\mathrm{GNFP}^k[\sigma']$ is the $\mathrm{BGN}^k[\sigma']$-invariant fragment of $\mathrm{GSO}[\sigma']$ (see Theorem 16). Note that for fixpoint logics, $\mathrm{GN}^k[\sigma']$-invariance is strictly weaker than $\mathrm{BGN}^k[\sigma']$-invariance, and applies to other decidable logics (e.g. [7]).

Unravellings. Given a σ-structure $\mathfrak{A}$ and $k \in \mathbb{N}$ and $\sigma_g \subseteq \sigma' \subseteq \sigma$, we would like to construct a structure that is $\mathrm{GN}^k[\sigma', \sigma_g]$-bisimilar to $\mathfrak{A}$ but has a tree-decomposition of bounded tree-width. A standard construction achieves this, called the $\mathrm{GN}^k[\sigma', \sigma_g]$-unravelling of $\mathfrak{A}$. Let Π_k be the set of finite sequences of the form $Y_0 Y_1 \dots Y_m$ such that $Y_0 = \emptyset$ and each Y_i is a set of elements from $\mathfrak{A}$ of size at most k. Each such sequence can be seen as the projection to $\mathfrak{A}$ of a play in the $\mathrm{GN}^k[\sigma', \sigma_g]$-bisimulation game between $\mathfrak{A}$ and some other structure. For Y a set of elements from $\mathfrak{A}$, let $\mathrm{AT}_{\mathfrak{A},\sigma'}(Y)$ be the set of atoms that hold of the elements in Y: $\{R(a_1, \dots, a_l) : R \in \sigma', \{a_1, \dots, a_l\} \subseteq Y, \mathfrak{A} \models R(a_1, \dots, a_l)\}$. Now define a $\Sigma^{\mathrm{code}}_{\sigma',k}$-tree $\mathcal{U}_{\mathrm{GN}^k[\sigma',\sigma_g]}(\mathfrak{A})$ where each node corresponds to a sequence in Π_k, and the sequences are arranged in prefix order. Roughly speaking, the node label of every $v = Y_0 \dots Y_{m-1} Y_m$ is an encoding of $\mathrm{AT}_{\mathfrak{A},\sigma'}(Y_m)$, and the edge label between its parent u and v indicates the relationship between the shared elements $Y_{m-1} \cap Y_m$ encoded in u and v. We define $\mathfrak{D}(\mathcal{U}_{\mathrm{GN}^k[\sigma',\sigma_g]}(\mathfrak{A}))$ to be the $\mathrm{GN}^k[\sigma', \sigma_g]$-unravelling of $\mathfrak{A}$. By restricting the set Π_k to reflect the possible moves in the games, we can define unravellings based on the other bisimulation games in a similar fashion. We summarize the two unravellings that will be most relevant:

1. **block k-width guarded negation unravelling**: The $\mathrm{BGN}^k[\sigma', \sigma_g]$-unravelling is denoted $\mathfrak{D}(\mathcal{U}_{\mathrm{BGN}^k[\sigma',\sigma_g]}(\mathfrak{A}))$. Its encoding $\mathcal{U}_{\mathrm{BGN}^k[\sigma',\sigma_g]}(\mathfrak{A})$ is obtained by considering only sequences $Y_0 \dots Y_m \in \Pi_k$ such that for all *even* i, $Y_{i-1} \supseteq Y_i$ and $Y_i \subseteq Y_{i+1}$ and Y_i is strictly σ_g-guarded in $\mathfrak{A}$. The tree $\mathcal{U}_{\mathrm{BGN}^k[\sigma',\sigma_g]}(\mathfrak{A})$ is consistent and is called a *σ_g-guarded-interface tree* since it alternates between *interface nodes* with strictly σ_g-guarded domains – corresponding to collapse moves in the game – and *bag nodes* with domain of size at most k that are not necessarily σ_g-guarded.
2. **guarded unravelling**: The $\mathrm{G}[\sigma', \sigma_g]$-unravelling is denoted $\mathfrak{D}(\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{A}))$ and its encoding $\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{A})$ is obtained by considering only sequences $Y_0 \dots Y_m \in \Pi_k$ such that for all i, Y_i is strictly σ_g-guarded in $\mathfrak{A}$. The tree $\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{A})$ is consistent and is called a *σ_g-guarded* tree since the domain of every node in the tree is strictly σ_g-guarded.

All of these unravellings are bisimilar to $\mathfrak{A}$, with respect to the appropriate notion of bisimilarity. Because these unravellings have tree decompositions of some bounded tree-width, this proposition implies that these guarded logics have tree-like models. The structural differences in the tree decompositions will be exploited for our definability decision procedures.

3 Decidability via back-and-forth and equivalence

We now give the main components of our approach, and explain how they fit together.

The first component is a *forward mapping*, translating an input GSO formula ϕ_0 to an MSO formula ϕ_0' over tree-codes, holding on the codes that correspond to tree-like models of ϕ_0. We will be interested only in formulas that are invariant under a form of guarded bisimulation or guarded negation bisimulation, so we assume the input is a GN^l-invariant formula, for some $l \geq \mathrm{width}(\sigma)$. For such formulas, we can actually define a forward mapping that produces a μ-calculus formula.

▶ **Lemma 1** (Fwd, adapted from [16]). *Given a $\mathrm{GN}^l[\sigma]$-invariant sentence $\phi \in \mathrm{GSO}[\sigma]$ and given some $k \geq \mathrm{width}(\sigma)$, we can construct $\phi^\mu \in \mathrm{L}_\mu[\Sigma^{code}_{\sigma,\max\{k,l\}}]$ such that for all consistent $\Sigma^{code}_{\sigma,\max\{k,l\}}$-trees $\mathcal{T}$, $\mathcal{T} \models \phi^\mu$ iff $\mathfrak{D}(\mathcal{T}) \models \phi$.*

The second component will depend on our target sublogic $\mathcal{L}_1$. It requires a mapping (not necessarily effective) taking a σ-structure $\mathfrak{B}$ to a tree structure $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})$ such that $\mathfrak{D}(\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B}))$ agrees with $\mathfrak{B}$ on all $\mathcal{L}_1$ sentences. Informally, $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})$ will be the encoding of some unravelling of $\mathfrak{B}$ appropriate for $\mathcal{L}_1$, perhaps with additional properties. A *backward mapping for* $\mathcal{L}_1$ takes sentences ϕ_0' over tree codes (with some given k and σ) to a sentence $\phi_1 \in \mathcal{L}_1$ such that: for all σ-structures $\mathfrak{B}$, $\mathfrak{B} \models \phi_1$ iff $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B}) \models \phi_0'$.

The formula ϕ_1 will depend on simplifying the formula ϕ_0' based on the fact that one is working on an unravelling. For $\mathcal{L}_1 = \mathrm{GFP}[\sigma', \sigma_g]$ over subsignatures σ', σ_g of the original signature σ, $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})$ will be a guarded unravelling; the results of [16] can easily be refined to give the formula component in $\mathrm{GFP}[\sigma', \sigma_g]$. For GNFP^k, providing both the appropriate unravelling and the formula in the backward mappings will require more work.

The $\mathcal{L}_1$ *definability problem for logic* $\mathcal{L}$ asks: given some input sentence $\phi \in \mathcal{L}$, is there some $\psi \in \mathcal{L}_1$ such that ϕ and ψ are logically equivalent? The forward and backward method of Figure 1b gives us a generic approach to this problem. The algorithm consists of applying the forward mapping to get ϕ_0', applying the backward mapping to ϕ_0' based on $\mathcal{L}_1$ to get ϕ_1, and then checking if ϕ_1 is equivalent to ϕ_0. We claim ϕ_0 is $\mathcal{L}_1$ definable iff ϕ_0 and ϕ_1 are equivalent. If ϕ_0 and ϕ_1 are logically equivalent then ϕ_0 is clearly $\mathcal{L}_1$ definable using ϕ_1. In the other direction, suppose that ϕ_0 is $\mathcal{L}_1$-definable. Fix $\mathfrak{B}$, and let $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})$ be given by the backward mapping. Then

$$\begin{aligned}\mathfrak{B} \models \phi_0 &\Leftrightarrow \mathfrak{D}(\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})) \models \phi_0 \text{ since } \mathfrak{D}(\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})) \text{ agrees with } \mathfrak{B} \text{ on } \mathcal{L}_1 \text{ sentences} \\ &\Leftrightarrow \mathcal{U}_{\mathcal{L}_1}(\mathfrak{B}) \models \phi_0' \text{ by Lemma Fwd} \Leftrightarrow \mathfrak{B} \models \phi_1 \text{ by Backward Mapping for } \mathcal{L}_1.\end{aligned}$$

Hence, ϕ_0 and ϕ_1 are logically equivalent, as required. Thus, we get the following general decidability result:

▶ **Proposition 2.** *Let $\mathcal{L}_1$ be a subset of $\mathrm{GN}^l[\sigma]$-invariant $\mathrm{GSO}[\sigma]$ such that we have an effective backward mapping for $\mathcal{L}_1$. Then the $\mathcal{L}_1$ definability problem is decidable for $\mathrm{GN}^l[\sigma]$-invariant $\mathrm{GSO}[\sigma]$.*

Above, we mean that there is an algorithm that decides $\mathcal{L}_1$ definability for any input $\mathrm{GSO}[\sigma]$ sentence that is $\mathrm{GN}^l[\sigma]$-invariant, with the output being arbitrary otherwise. The

approach above gives a definability test in the usual sense for inputs in GNFP[σ], since these are all GN^l[σ]-invariant for some l. In particular we will see that we can test whether a GNFP^l[σ] sentence is in GFP[σ'] or in GNFP^k[σ']. But there are larger GN^l-invariant logics (e.g. [7]), and the algorithm immediately applies to these as well.

4 Identifying GFP definable sentences

For GFP, we can instantiate the high-level algorithm by giving a backward mapping.

▶ **Lemma 3** (GFP-Bwd, adapted from [16]). *Given $\phi^\mu \in \mathrm{L}_\mu[\Sigma^{code}_{\sigma,m}]$ and $\sigma_g \subseteq \sigma' \subseteq \sigma$, ϕ^μ can be translated into $\psi \in \mathrm{GFP}[\sigma', \sigma_g]$ such that for all σ-structures $\mathfrak{B}$, $\mathfrak{B} \models \psi$ iff $\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{B}) \models \phi^\mu$.*

Plugging this into our high-level algorithm, with $\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{B})$ as $\mathcal{U}_{\mathcal{L}_1}(\mathfrak{B})$, we get decidability of the GFP-definability problem:

▶ **Theorem 4.** *The* GFP[σ', σ_g] *definability problem is decidable for* GN^k[σ]*-invariant* GSO[σ] *where $k \geq \mathrm{width}(\sigma)$ and $\sigma_g \subseteq \sigma' \subseteq \sigma$.*

There are two sources of inefficiency in the high-level algorithm. First, the forward mapping is non-elementary since we pass through MSO on the way to a μ-calculus formula. Second, testing equivalence of the original sentence with the sentence produced by the forward and backward mappings implicitly requires a second forward mapping in order to reduce the problem to regular language equivalence on trees.

For the special case of input in GNFP, we can use an optimized procedure that avoids these inefficiencies and allows us to obtain an optimal complexity bound.

▶ **Theorem 5.** *The* GFP[σ', σ_g] *definability problem is* 2-ExpTime*-complete for input in* GNFP[σ].

The main idea behind our optimized procedure is to directly use automata throughout the process. First, for input ϕ in GNFP it is known from [9] how to give a forward mapping that directly produces a tree automaton $\mathcal{A}_\phi$ (with exponentially-many states) that accepts a consistent tree $\mathcal{T}$ iff $\mathfrak{D}(\mathcal{T}) \models \phi$ – exactly the consistent trees that satisfy ϕ^μ. This direct construction avoids passing through MSO, and can be done in 2-ExpTime. We can then construct an automaton $\mathcal{A}'_\phi$ from $\mathcal{A}_\phi$ that accepts a tree $\mathcal{T}$ iff $\mathcal{U}_{\mathrm{G}[\sigma',\sigma_g]}(\mathfrak{D}(\mathcal{T}))$; we call this the G[$\sigma', \sigma_g$]*-view automaton*, since it mimics the view of $\mathcal{T}$ running on the guarded unravelling of $\mathfrak{D}(\mathcal{T})$. This can be seen as an automaton that represents the composition of the backward mapping with the forward mapping. With these constructions in place, we have the following improved algorithm to test definability of ϕ in GFP: construct $\mathcal{A}_\phi$ from ϕ, construct $\mathcal{A}'_\phi$ from $\mathcal{A}_\phi$, and test equivalence of $\mathcal{A}_\phi$ and $\mathcal{A}'_\phi$ over consistent trees. Note that with this improved procedure it is not necessary to actually construct the backward mapping, or to pass forward to trees for a second time in order to test equivalence. Overall, the procedure can be shown to run in 2-ExpTime. A reduction from GFP-satisfiability testing, which is known to be 2-ExpTime-hard, yields the lower bound.

Our results give us a corollary on definability in fragments of FO when the input is in FO:

▶ **Corollary 6.** *The* GF[σ', σ_g] *definability problem is decidable for* GN^l[σ]*-invariant* FO[σ] *where $k, l \geq \mathrm{width}(\sigma)$ and $\sigma_g \subseteq \sigma' \subseteq \sigma$.*

Note that in this work we are characterizing sublogics within fragments of fixpoint logics and within fragments of first-order logic. We do not deal with identifying first-order definable formulas within a fixpoint logic, as in [10, 8].

We also can get a version of the definability result for a restriction of fixpoint logic. One well-studied restriction is called alternation-freeness (see, e.g., [14, 2]). We say a sentence ϕ in GFP is *alternation-free* if it does not contain subformulas $\psi_1 := [\mathbf{lfp}_{Y,\boldsymbol{y}} . \chi_1](\boldsymbol{y})$ and $\psi_2 := [\mathbf{gfp}_{Z,\boldsymbol{z}} . \chi_2](\boldsymbol{z})$ such that Y occurs in χ_2 and ψ_2 is a subformula of ψ_1, or Z occurs in χ_1 and ψ_1 is a subformula of ψ_2 (recall that a greatest fixpoint can be defined in terms of least fixpoints and negations as $[\mathbf{gfp}_{Z,\boldsymbol{z}} . \chi_2](\boldsymbol{z}) \equiv \neg[\mathbf{lfp}_{Z,\boldsymbol{z}} . \neg\chi_2[\neg Z/Z]](\boldsymbol{z})$). Alternation-free fragments of GNFP and L_μ are defined by restricting the nesting of fixpoints in a similar way. It is desirable to know if a sentence is in this alternation-free fragment of GFP since this fragment has better computational properties: for instance, model checking for this alternation-free fragment can be done in linear time. This was shown in [14]. A language called DATALOG-LITE – a variant of DATALOG that has some restricted forms of negation and universal quantification – was also introduced, and shown to exactly characterize this alternation-free GFP [14]. A corollary of the definability result in this section, is that it is possible to decide definability in alternation-free GFP when the input is in alternation-free GNFP, using the same decision procedure as before. Roughly speaking, this comes from observing that if the input is in alternation-free GNFP, then the forward mapping produces alternation-free L_μ, and the backward mapping produces alternation-free GFP.

▶ **Corollary 7.** *The alternation-free* GFP$[\sigma']$ *(equivalently,* DATALOG-LITE$[\sigma']$*) definability problem is decidable in* 2-ExpTime *for input in alternation-free* GNFP$[\sigma]$.

We can also apply our theorem to answer some questions about *conjunctive queries (CQs)*: formulas built up from relational atoms via $\wedge$ and $\exists$. When the input ϕ to our definability algorithm is a CQ, ϕ can be written as a GF sentence exactly when it is *acyclic*: roughly speaking, this means it can be built up from guarded existential quantification (see [15]). Transforming a query to an acyclic one could be quite relevant in practice, since acyclic queries can be evaluated in linear time [26]. There are well-known methods for deciding whether a CQ ϕ is acyclic, and recently these have been extended to the problem of determining whether ϕ is acyclic for all structures satisfying a set of constraints (e.g., Guarded TGDs [6] or Functional Dependencies [13]). Using Corollary 6 above along with an equivalence between guardedness and acyclicity that follows from [4], we can get an analogous result for arbitrary constraints in the guarded fragment:

▶ **Corollary 8.** *Given a set of* GF *sentences* Σ *and a CQ sentence* Q*, we can decide whether there is a union of acyclic CQs* Q' *equivalent to* Q *for all structures satisfying* Σ*. The problem is* 2-ExpTime*-complete.*

Note that if Σ consists of universal Horn constraints ("TGDs"), then a CQ Q is equivalent to union of CQs Q' relative to Σ implies that it is equivalent to one of the disjuncts of Q'. Thus the result above implies decidability of acyclicity relative to universal horn GF sentences, one of the main results of [6].

5 Identifying GNFP^k and UNFP^k sentences

We now turn to extending the prior results to GNFP and UNFP. In order to make use of the back-and-forth approach described in the previous section, we must be able to restrict to structures of some bounded tree-width. For GFP this tree-width depends only on the signature σ', so this width-restriction was implicit in the GFP$[\sigma', \sigma_g]$-definability problems. However, for GNFP and UNFP this bound on the tree-width depends on the width of the formula, so for definability questions, we must state this width explicitly. Hence, in this section, we consider definability questions related to GNFP^k and UNFP^k.

We apply the high-level algorithm of Proposition 2, using the forward mapping of Lemma 1. The unravelling and backward mapping for GNFP^k is more technically challenging than the corresponding construction for GFP.

We first need an appropriate notion of unravelling. We use a variant of the block k-width guarded negation unravelling discussed in Section 2, but we will need to assume we have a certain repetition of facts. This idea of modifying a classical unravelling to include extra copies of certain pieces of the structure has been used before (e.g. the ω-expansions in [21], and "shrewd" unravellings for UNFP^k in [9]). We will need a new, subtler property for GNFP^k, which we call "plumpness".

In order to define the property that this special unravelling has, we need to define how we can modify copies of certain parts of the structure in a way that still leads to a GN^k-bisimilar structure. Let τ and τ' be sets of σ'-facts over some elements A. Let $I, J \subseteq A$. We say τ and τ' agree on J if for all σ'-atoms $R(a_1, \ldots, a_l)$ with $\{a_1, \ldots, a_l\} \subseteq J$, $R(a_1, \ldots, a_l) \in \tau$ iff $R(a_1, \ldots, a_l) \in \tau'$. We say τ' is an (σ_g, I)-*safe restriction* of τ if (i) $\tau' \subseteq \tau$; (ii) τ' agrees with τ on I; (iii) τ' agrees with τ on every $J \subseteq A$ that is σ_g-guarded in τ'. Note that τ itself is considered a trivial (σ_g, I)-safe restriction of τ. Here is another example:

▶ **Example 9.** Consider signatures $\sigma' = \{U, R, T\}$ and $\sigma_g = \{R\}$, where U is a unary relation, R is a binary relation, and T is a ternary relation. Consider $I = \{1, 2\}$ and $\tau = \{U(1),\, U(3),\, R(1,2),\, R(2,3),\, R(3,1),\, T(3,2,2)\}$. Then the possible (σ_g, I)-safe restrictions of τ are τ itself and

$$\tau'_1 = \left\{ \begin{array}{c} U(1),\, U(3) \\ R(1,2),\, R(2,3) \\ T(3,2,2) \end{array} \right\} \qquad \tau'_2 = \left\{ \begin{array}{c} U(1),\, U(3) \\ R(1,2),\, R(3,1) \\ T(3,2,2) \end{array} \right\} \qquad \tau'_4 = \left\{ \begin{array}{c} U(1),\, U(3) \\ R(1,2) \\ T(3,2,2) \end{array} \right\}$$

$$\tau'_3 = \left\{ \begin{array}{c} U(1),\, U(3) \\ R(1,2),\, R(3,1) \end{array} \right\} \qquad \tau'_5 = \left\{ \begin{array}{c} U(1),\, U(3) \\ R(1,2) \end{array} \right\}.$$

Note that we cannot drop facts over unary relations (since these are always trivially guarded), and we can never drop facts over I. Further, the σ_g-facts that we keep restrict what other facts we can drop, since for any σ_g-guarded set that remains we must preserve facts over that set. By a (σ_g, I)-safe restriction of a node in a tree decomposition, we mean a (σ_g, I)-safe restriction of the atoms represented by the node. We will be interested in trees with the property that for every bag node w, all safe restrictions of w are realized by siblings of w. Formally a $\Sigma^{\mathrm{code}}_{\sigma',k}$-tree has the σ_g-*plumpness property* if for all interface nodes v: if w is a ρ_0-child of v over names J with $I = \mathrm{rng}(\rho_0)$ and τ is the encoded set of σ'-atoms that hold at w, then for any (σ_g, I)-safe restriction τ' of τ, there is a ρ_0-child w' of v such that (i) τ' is the encoded set of σ'-atoms that hold at w'; (ii) for each ρ-child u' of w', there is a ρ-child u of w such that the subtrees rooted at u and u' are bisimilar; and (iii) for each ρ-child u of w such that $\mathrm{dom}(\rho)$ is strictly σ_g-guarded in τ', there is a ρ-child u' of w' such that the subtrees rooted at u' and u are bisimilar.

▶ **Example 10.** Let $\mathcal{T}$ be a plump tree. Suppose there is an interface node v in $\mathcal{T}$ with label encoding $\tau_0 = \{U(1), R(1,2)\}$, and there is a ρ_0-child w of v such that the label of w is the encoding of $\tau = \{U(1), U(3), R(1,2), R(2,3), R(3,1), T(3,2,2)\}$ from Example 9, and ρ_0 is the identity function with domain $\{1, 2\}$. Then by plumpness there must also be ρ_0-children $w_1, \ldots, w_5$ of v with labels encoding $\tau'_1, \ldots, \tau'_5$ from Example 9.

The following proposition shows that one can obtain unravellings that are plump:

▶ **Proposition 11.** *Let $\mathfrak{B}$ be a σ-structure, $k \in \mathbb{N}$, and $\sigma_g \subseteq \sigma' \subseteq \sigma$. There is a consistent, plump, σ_g-guarded-interface tree $\mathcal{U}^{\text{plump}}_{\text{BGN}^k[\sigma',\sigma_g]}(\mathfrak{B})$ such that $\mathfrak{B}$ is $\text{BGN}^k[\sigma',\sigma_g]$-bisimilar to $\mathfrak{D}(\mathcal{U}^{\text{plump}}_{\text{BGN}^k[\sigma',\sigma_g]}(\mathfrak{B}))$. We call $\mathfrak{D}(\mathcal{U}^{\text{plump}}_{\text{BGN}^k[\sigma',\sigma_g]}(\mathfrak{B}))$ the* plump unravelling *of $\mathfrak{B}$.*

Returning to the components required for the application of Proposition 2, we see that Proposition 11 says that $\mathfrak{B}$ is $\text{BGN}^k[\sigma',\sigma_g]$-bisimilar to $\mathfrak{D}(\mathcal{U}^{\text{plump}}_{\text{BGN}^k[\sigma',\sigma_g]}(\mathfrak{B}))$ as required for an application of Proposition 2. Plumpness will come into play in the backward mapping:

▶ **Lemma 12** (GNFP^k-Bwd). *Given $\phi^\mu \in \text{L}_\mu[\Sigma^{code}_{\sigma,m}]$, relational signatures σ_g and σ' with $\sigma_g \subseteq \sigma' \subseteq \sigma$, and $k \leq m$, we can construct $\psi \in \text{GNFP}^k[\sigma',\sigma_g]$ such that for all σ-structures $\mathfrak{B}$, $\mathfrak{B} \models \psi$ iff $\mathcal{U}^{\text{plump}}_{\text{BGN}^k[\sigma',\sigma_g]}(\mathfrak{B}) \models \phi^\mu$.*

There is a naïve backward mapping of the μ-calculus into LFP, by structural induction. The problem is that the formula produced by the translation fails to be in GNFP^k for two reasons. First, the inductive step for negation in the naïve algorithm simply applies negation to the recursively-produced formula. Clearly this can produce unguarded negation. Similarly, the recursive step for fixpoints may use unguarded fixpoints.

For example, the original μ-calculus formula can include subformulas of the form $\langle\rho\rangle\text{ExactLabel}(\tau)$ where τ is a set of unary relations from $\Sigma^{\text{code}}_{\sigma',k}$, and $\text{ExactLabel}(\tau)$ asserts P for all $P \in \tau$ and $\neg P$ for all unary relations P not in τ. This would be problematic for a straightforward backward mapping, since the backward translation of some $\neg R_{i_1,\ldots,i_n}$ would be converted into an unguarded negation $\neg R(x_{i_1},\ldots,x_{i_n})$. On the other hand the formula $\langle\rho\rangle\text{GNLabel}(\tau)$ where $\text{GNLabel}(\tau)$ asserts P for all $P \in \tau$ but only asserts $\neg P$ for unary relations P that are not in τ but whose indices are σ_g-guarded by some $P' \in \tau$ would be unproblematic, since this could be translated to a formula with σ_g-guarded negation. The key observation is that from an interface node in a plump tree, these two formulas are equivalent: if $\mathcal{T}, v \models \langle\rho\rangle\text{GNLabel}(\tau)$ at any interface node v, then plumpness ensures that if there is some ρ-child w' of v with label τ' satisfying $\text{GNLabel}(\tau)$, then there is a ρ-child w of v with label τ satisfying $\text{ExactLabel}(\tau)$ – it can be checked that τ is a $(\sigma_g, \text{rng}(\rho))$-safe restriction of τ'. Thus the proof of Lemma GNFP^k-Bwd relies on first simplifying L_μ-formulas so that problematic subformulas like $\text{ExactLabel}(\tau)$ are eliminated, with the correctness of this simplification holding only over plump trees. After this simplification, an inductive backward mapping can be applied.

Using the above lemma and Proposition 2, we obtain the following analog of Theorem 4.

▶ **Theorem 13.** *The $\text{GNFP}^k[\sigma',\sigma_g]$ definability problem is decidable for $\text{GN}^l[\sigma]$-invariant $\text{GSO}[\sigma]$ and $k, l \geq \text{width}(\sigma)$.*

Since $\text{UNFP}^k[\sigma']$ is just $\text{GNFP}^k[\sigma',\emptyset]$, we obtain the following corollary:

▶ **Corollary 14.** *The $\text{UNFP}^k[\sigma']$ definability problem is decidable for $\text{GN}^l[\sigma]$-invariant $\text{GSO}[\sigma]$ and $k, l \geq \text{width}(\sigma)$.*

We get corollaries for fragments of FO, analogous to Corollary 6:

▶ **Corollary 15.** *The $\text{GNF}^k[\sigma',\sigma_g]$ and $\text{UNF}^k[\sigma']$ definability problems are decidable for $\text{GN}^l[\sigma]$-invariant $\text{FO}[\sigma]$ and $k, l \geq \text{width}(\sigma)$.*

We can also apply the backward and forward mappings to get a semantic characterization for GNFP^k, analogous to the Janin-Walukiewicz theorem. The following extends a result of [3] characterizing GNF^k formulas as the BGN^k-invariant fragment of FO.

▶ **Theorem 16.** *$\text{GNFP}^k[\sigma',\sigma_g]$ is the $\text{BGN}^k[\sigma',\sigma_g]$-invariant fragment of $\text{GSO}[\sigma']$.*

The proof is similar to the characterizations of Janin-Walukiewicz and [16], and can also be seen as a variant of Proposition 2, where we use $\mathrm{BGN}^k[\sigma', \sigma_g]$-invariance rather than equivalence to a $\mathrm{GNFP}^k[\sigma', \sigma_g]$ sentence in justifying that the input formula is equivalent to the result of the composition of backward and forward mappings.

Interpolation. The forward and backward mappings utilized for the definability questions can also be used to prove that GFP and GNFP^k have a form of interpolation.

Let ϕ_{L} and ϕ_{R} be sentences over signatures σ_{L} and σ_{R} such that $\phi_{\mathrm{L}} \models \phi_{\mathrm{R}}$ (ϕ_{L} entails ϕ_{R}). An *interpolant* for such a validity is a formula θ for which $\phi_{\mathrm{L}} \models \theta$ and $\theta \models \phi_{\mathrm{R}}$, and θ mentions only relations appearing in both ϕ_{L} and ϕ_{R}. We say a logic $\mathcal{L}$ has *Craig interpolation* if for all $\phi_{\mathrm{L}}, \phi_{\mathrm{R}} \in \mathcal{L}$ with $\phi_{\mathrm{L}} \models \phi_{\mathrm{R}}$, there is an interpolant $\theta \in \mathcal{L}$ for it. We say a logic $\mathcal{L}$ has the stronger *uniform interpolation* property if one can obtain θ from ϕ_{L} and a signature σ', and θ can serve as an interpolant for any ϕ_{R} entailed by ϕ_{L} and such that the common signature of ϕ_{R} and ϕ_{L} is contained in σ'. A uniform interpolant can be thought of as the best over-approximation of ϕ_{L} over σ'.

Uniform interpolation holds for L_μ [11] and UNFP^k [9]. Unfortunately, $\mathrm{GFP}[\sigma]$ and $\mathrm{GNFP}^k[\sigma]$ both fail to have uniform interpolation and Craig interpolation (this follows from [19, 9]). However, if we disallow subsignature restrictions that change the guard signature, then we regain interpolation. This "preservation of guard" variant was investigated first by Hoogland, Marx, and Otto in the context of Craig interpolation [19]. The uniform variant was introduced by D'Agostino and Lenzi [12], who called it *uniform modal interpolation*. Formally, we say a guarded logic $\mathcal{L}[\sigma, \sigma_g]$ with guard signature $\sigma_g \subseteq \sigma$ has *uniform modal interpolation* if for any $\phi_{\mathrm{L}} \in \mathcal{L}[\sigma, \sigma_g]$ and any subsignature $\sigma' \subseteq \sigma$ containing σ_g, there exists a formula $\theta \in \mathcal{L}[\sigma', \sigma_g]$ such that ϕ_{L} entails θ and for any σ'' containing σ_g with $\sigma'' \cap \sigma \subseteq \sigma'$ and any $\phi_{\mathrm{R}} \in \mathcal{L}[\sigma'', \sigma_g]$ entailed by ϕ_{L}, θ entails ϕ_{R}. It was shown in [12] that GF has uniform modal interpolation. We strengthen this to GFP and GNFP^k.

▶ **Theorem 17.** *For σ a relational signature, $\sigma_g \subseteq \sigma$, $k \in \mathbb{N}$: $\mathrm{GFP}[\sigma, \sigma_g]$ and $\mathrm{GNFP}^k[\sigma, \sigma_g]$ sentences have uniform modal interpolation, and the interpolants can be found effectively.*

We sketch the argument for $\mathrm{GFP}[\sigma, \sigma_g]$. Consider $\phi_{\mathrm{L}} \in \mathrm{GFP}[\sigma, \sigma_g]$ of width k and subsignature $\sigma' \subseteq \sigma$ containing σ_g. We apply Lemma Fwd to get a formula $\phi_{\mathrm{L}}^\mu \in \mathrm{L}_\mu[\Sigma^{\mathrm{code}}_{\sigma,k}]$ that captures codes of tree-like models of ϕ_{L}. We want to go backward now, to get a formula over the subsignature σ'. We saw that the backward mapping for $\mathrm{GFP}[\sigma', \sigma_g]$ (Lemma 3) can do this: it can start with a μ-calculus formula over $\Sigma^{\mathrm{code}}_{\sigma,k}$, and produce a formula in $\mathrm{GFP}[\sigma', \sigma_g]$. As discussed earlier, the formula produced by this backward mapping has a nice property related to definability: it is equivalent to ϕ_{L} exactly when ϕ_{L} is definable in $\mathrm{GFP}[\sigma', \sigma_g]$. In general, however, we do not expect ϕ_{L} to be equivalent to a formula over the subsignature – for uniform interpolation we just want to *approximate* the formula over this subsignature. The backward mapping of ϕ_{L}^μ does not always do this. Hence, it is necessary to add one additional step before taking the backward mapping: we apply uniform interpolation for the μ-calculus [11], obtaining $\theta^\mu \in \Sigma^{\mathrm{code}}_{\sigma',k}$ which is entailed by ϕ_{L}^μ and entails each $\mathrm{L}_\mu[\Sigma^{\mathrm{code}}_{\sigma',k}]$-formula implied by ϕ_{L}^μ. Finally, we apply Lemma $\mathrm{GFP}[\sigma', \sigma_g]$-Bwd to θ^μ to get $\theta \in \mathrm{GFP}[\sigma', \sigma_g]$. We can check that $\theta \in \mathrm{GNFP}^k[\sigma', \sigma_g]$ is the required uniform modal interpolant for ϕ_{L} over subsignature σ'.

Theorem 17 also implies that UNFP^k has the traditional uniform interpolation property: since the guard signature is empty for UNFP^k, uniform modal interpolation and uniform interpolation coincide. This was shown already in [9].

6 Conclusions

In this paper we have taken a first look at effective characterizations of definability in expressive logics. We did not allow constants in the formulas in this paper, but we believe that similar effective characterization results hold for guarded fixpoint logics with constants. We leave open the question of definability in GNFP without any width restriction. For this the natural way to proceed is to bound the width of a defining sentence based in terms of the input. We also note that our results on fixpoint logics hold only when equivalence is considered over all structures, leaving open the corresponding questions over finite structures.

Abstract

We investigate the decidability and computational complexity of (deductive) conservative extensions in fragments of first-order logic (FO), with a focus on the two-variable fragment FO^2 and the guarded fragment GF. We prove that conservative extensions are undecidable in any FO fragment that contains FO^2 or GF (even the three-variable fragment thereof), and that they are decidable and 2ExpTime-complete in the intersection GF^2 of FO^2 and GF.

1 Introduction

Conservative extensions are a fundamental notion in logic. In mathematical logic, they provide an important tool for relating logical theories, such as theories of arithmetic and theories that emerge in set theory [35, 31]. In computer science, they come up in diverse areas such as software specification [12], higher order theorem proving [15], and ontologies [24]. In these applications, it would be very useful to decide, given two sentences φ_1 and φ_2, whether $\varphi_1 \wedge \varphi_2$ is a conservative extension of φ_1. As expected, this problem is undecidable in first-order logic (FO). In contrast, it has been observed in recent years that conservative extensions are decidable in many modal and description logics [13, 26, 27, 7]. This observation is particularly interesting from the viewpoint of ontologies, where conservative extensions have many natural applications including modularity and reuse, refinement, versioning, and forgetting [9, 24].

Regarding decidability, conservative extensions thus seem to behave similarly to the classical satisfiability problem, which is also undecidable in FO while it is decidable for modal

and description logics. In the case of satisfiability, the aim to understand the deeper reasons for this discrepancy and to push the limits of decidability to more expressive fragments of FO has sparked a long line of research that identified prominent decidable FO fragments such as the two-variable fragment FO^2 [34, 29], its extension with counting quantifiers C^2 [19], the guarded fragment GF [1], and the guarded negation fragment GNF [4], see also [6, 16, 33, 23] and references therein. These fragments have sometimes been used as a replacement for the modal and description logics that they generalize, and in particular the guarded fragment has been proposed as an ontology language [3]. Motivated by this situation, the aim of the current paper is to study the following two questions:

1. Are conservative extensions decidable in relevant fragments of FO such as FO^2, C^2, GF, and GNF?
2. What are the deeper reasons for decidability of conservative extensions in modal and description logics and how far can the limits of decidability be pushed?

To be more precise, we concentrate on *deductive* conservative extensions, that is, $\varphi_1 \wedge \varphi_2$ is a conservative extension of φ_1 if for every sentence ψ formulated in the signature of φ_1, $\varphi_1 \wedge \varphi_2 \models \psi$ implies $\varphi_1 \models \psi$. There is also a *model-theoretic* notion of conservative extension which says that $\varphi_1 \wedge \varphi_2$ is a conservative extension of φ_1 if every model of φ_1 can be extended to a model of φ_2 by interpreting the additional symbols in φ_2. Model-theoretic conservative extensions imply deductive conservative extensions, but the converse fails unless one works with a very expressive logic such as second-order logic [24]. In fact, model-theoretic conservative extensions are undecidable even for some very inexpressive description logics that include neither negation nor disjunction [25]. Deductive conservative extensions, as studied in this paper, are closely related to other important notions in logic, such as uniform interpolation [30, 36, 5]. For example, in logics that enjoy Craig interpolation, a decision procedure for conservative extensions can also be used to decide whether a given sentence φ_2 is a uniform interpolant of a given sentence φ_1 regarding the symbols used in φ_2.

Instead of concentrating only on conservative extensions, we also consider two related reasoning problems that we call Σ-entailment and Σ-inseparability, where Σ denotes a signature. The definitions are as follows: a sentence φ_1 Σ-entails a sentence φ_2 if for every sentence ψ formulated in Σ, $\varphi_2 \models \psi$ implies $\varphi_1 \models \psi$. This can be viewed as a more relaxed notion of conservative extension where it is not required that one sentence actually extends the other as in the conjunction $\varphi_1 \wedge \varphi_2$ used in the definition of conservative extensions. Two sentences φ_1, φ_2 are Σ-inseparable if they Σ-entail each other. We generally prove lower bounds for conservative extensions and upper bounds for Σ-entailment, in this way obtaining the same decidability and complexity results for all three problems.

Our first main result is that conservative extensions are undecidable in FO^2 and (the three-variable fragment of) GF, and in fact in all fragments of FO that contain at least one of the two; note that the latter is not immediate because the separating sentence ψ in the definition of conservative extensions ranges over all sentences from the considered fragment, giving greater separating power when we move to a larger fragment. The proofs are by reductions from the halting problem for two-register machines and a tiling problem, respectively. We note that undecidability of conservative extensions also implies that there is no extension of the logic in question in which consequence is decidable and that has effective uniform interpolation (in the sense that uniform interpolants exist and are computable). We then show as our second main result that, in the two-variable guarded fragment GF^2, Σ-entailment is decidable in 2ExpTime. Regarding the satisfiability problem, GF^2 behaves fairly similarly to modal and description logics. It is thus suprising that deciding Σ-entailment (and conservative extensions) in GF^2 turns out to be much more challenging than in most modal

and description logics. There, the main approach to proving decidability of Σ-entailment is to first establish a suitable model-theoretic characterization based on bisimulations which is then used as a foundation for a decision procedure based on tree automata [27, 7]. In GF^2, an analogous characterization in terms of appropriate guarded bisimulation fails. Instead, one has to demand the existence of *k-bounded* (guarded) bisimulations, *for all* k, and while tree automata can easily handle bisimulations, it is not clear how they can deal with such an infinite family of bounded bisimulations. We solve this problem by a very careful analysis of the situation and by providing another characterization that can be viewed as being 'half way' between a model-theoretic characterization and an automata-encoding of Σ-entailment.

We also observe that a 2ExpTime lower bound from [13] for conservative extensions in description logics can be adapted to GF^2, and consequently our upper bound is tight. It is known that GF^2 enjoys Craig interpolation and thus our results are also relevant to deciding uniform interpolants and to a stronger version of conservative extensions in which the separating sentence ψ can also use 'helper symbols' that occur neither in φ_1 nor in φ_2.

2 Preliminaries

We introduce the fragments of classical first-order logic (FO) that are relevant for this paper. We generally admit equality and disallow function symbols and constants. With FO^2, we denote the *two-variable fragment of FO*, obtained by fixing two variables x and y and disallowing the use of other variables [34, 29]. In FO^2 and fragments thereof, we generally admit only predicates of arity one and two, which is without loss of generality [17]. In the *guarded fragment of FO*, denoted *GF*, quantification is restricted to the pattern

$$\forall \mathbf{y}(\alpha(\mathbf{x},\mathbf{y}) \to \varphi(\mathbf{x},\mathbf{y})) \quad \exists \mathbf{y}(\alpha(\mathbf{x},\mathbf{y}) \wedge \varphi(\mathbf{x},\mathbf{y}))$$

where $\varphi(\mathbf{x},\mathbf{y})$ is a GF formula with free variables among $\mathbf{x},\mathbf{y}$ and $\alpha(\mathbf{x},\mathbf{y})$ is an atomic formula $R\mathbf{xy}$ or an equality $x = y$ that in either case contains all variables in $\mathbf{x},\mathbf{y}$ [1, 16]. The formula α is called the *guard* of the quantifier. The k-variable fragment of GF, defined in the expected way, is denoted GF^k. Apart from the logics introduced so far, in informal contexts we shall also mention several related description logics. Exact definitions are omitted, we refer the reader to [2].

A *signature* Σ is a finite set of predicates. We use $\mathrm{GF}(\Sigma)$ to denote the set of all GF-sentences that use only predicates from Σ (and possibly equality), and likewise for $\mathrm{GF}^2(\Sigma)$ and other fragments. We use $\mathsf{sig}(\varphi)$ to denote the set of predicates that occur in the FO formula φ. Note that we consider equality to be a logical symbol, rather than a predicate, and it is thus never part of a signature. We write $\varphi_1 \models \varphi_2$ if φ_2 is a logical consequence of φ_1. The next definition introduces the central notions studied in this paper.

▶ **Definition 1.** Let F be a fragment of FO, φ_1, φ_2 F-sentences and Σ a signature. Then

1. φ_1 Σ-*entails* φ_2, written $\varphi_1 \models_\Sigma \varphi_2$, if for all $F(\Sigma)$-sentences ψ, $\varphi_2 \models \psi$ implies $\varphi_1 \models \psi$;
2. φ_1 and φ_2 are Σ-*inseparable* if φ_1 Σ-entails φ_2 and vice versa;
3. $\varphi_1 \wedge \varphi_2$ is a *conservative extension* of φ_1 if φ_1 $\mathsf{sig}(\varphi_1)$-entails $\varphi_1 \wedge \varphi_2$.

Note that Σ-entailment could equivalently be defined as follows when F is closed under negation: φ_1 Σ-*entails* φ_2 if for all $F(\Sigma)$-sentences ψ, satisfiability of $\varphi_1 \wedge \psi$ implies satisfiability of $\varphi_2 \wedge \psi$. If φ_1 does not Σ-entail φ_2, there is thus an $F(\Sigma)$-sentence ψ such that $\varphi_1 \wedge \psi$ is satisfiable while $\varphi_2 \wedge \psi$ is not. We refer to such ψ as a *witness sentence* for non-Σ-entailment.

▶ **Example 2.** (1) Σ-entailment is a weakening of logical consequence, that is, $\varphi_1 \models \varphi_2$ implies $\varphi_1 \models_\Sigma \varphi_2$ for any Σ. The converse is true when $\mathsf{sig}(\varphi_2) \subseteq \Sigma$.

(2) Consider the GF^2 sentences $\varphi_1 = \forall x \exists y Rxy$ and $\varphi_2 = \forall x(\exists y(Rxy \wedge Ay) \wedge \exists y(Rxy \wedge \neg Ay))$ and let $\Sigma = \{R\}$. Then $\psi = \forall xy(Rxy \to x = y)$ is a witness for $\varphi_1 \not\models_\Sigma \varphi_2$. If φ_1 is replaced by $\varphi_1' = \forall x \exists y(Rxy \wedge x \neq y)$ we obtain $\varphi_1' \models_\Sigma \varphi_2$ since GF^2 cannot count the number of R-successors.

It is important to note that different fragments F of FO give rise to different notions of Σ-entailment, Σ-inseparability and conservative extensions. For example, if φ_1 and φ_2 belong to GF^2, then they also belong to GF and to FO^2, but it might make a difference whether witness sentences range over all GF^2-sentences, over all GF-sentences, or over all FO^2-sentences. If we want to emphasize the fragment F in which witness sentences are formulated, we speak of $F(\Sigma)$-entailment instead of Σ-entailment and write $\varphi_1 \models_{F(\Sigma)} \varphi_2$, and likewise for $F(\Sigma)$-inseparability and F-conservative extensions.

▶ **Example 3.** Let φ_1', φ_2, and $\Sigma = \{R\}$ be from Example 2 (2). Then φ_1' $\mathrm{GF}^2(\Sigma)$-entails φ_2 but φ_1' does not $\mathrm{FO}(\Sigma)$-entail φ_2; a witness is given by $\forall xy_1y_2((Rxy_1 \wedge Rxy_2) \to y_1 = y_2)$.

Note that conservative extensions and Σ-inseparability reduce in polynomial time to Σ-entailment (with two calls to Σ-entailment required in the case of Σ-inseparability). Moreover, conservative extensions reduce in polynomial time to Σ-inseparability. We thus state our upper bounds in terms of Σ-entailment and lower bounds in terms of conservative extensions.

There is a natural variation of each of the three notions in Definition 1 obtained by allowing to use additional 'helper predicates' in witness sentences. For a fragment F of FO, F-sentences φ_1, φ_2, and a signature Σ, we say that φ_1 *strongly* Σ*-entails* φ_2 if φ_1 Σ'-entails φ_2 for any Σ' with $\Sigma' \cap \mathsf{sig}(\varphi_2) \subseteq \Sigma$. Strong Σ-inseparability and strong conservative extensions are defined accordingly. Strong Σ-entailment implies Σ-entailment, but the converse may fail.

▶ **Example 4.** $\mathrm{GF}(\Sigma)$-entailment does not imply strong $\mathrm{GF}(\Sigma)$-entailment. Let φ_1 state that the binary predicate R is irreflexive and symmetric and let φ_2 be the conjunction of φ_1 and $\forall x(Ax \to \forall y(Rxy \to \neg Ay)) \wedge \forall x(\neg Ax \to \forall y(Rxy \to Ay))$. Thus, an $\{R\}$-structure satisfying φ_1 can be extended to a model of φ_2 if it contains no R-cycles of odd length. Now observe that any satisfiable $\mathrm{GF}(\{R\})$ sentence is satisfiable in a forest $\{R\}$-structure (see Section 4 for a precise definition). Hence, if a $\mathrm{GF}(\{R\})$-sentence is satisfiable in an irreflexive and symmetric structure then it is satisfiable in a structure without odd cycles and so φ_1 $\mathrm{GF}(\{R\})$-entails φ_2. In contrast, for the fresh ternary predicate Q and $\psi = \exists x_1x_2x_3(Qx_1x_2x_3 \wedge Rx_1x_2 \wedge Rx_2x_3 \wedge Rx_3x_1)$ we have $\varphi_2 \models \neg\psi$ but $\varphi_1 \not\models \neg\psi$ and so ψ witnesses that φ_1 does not $\mathrm{GF}(\{R, Q\})$-entail φ_2.

The example above is inspired by proofs that GF does not enjoy Craig interpolation [21, 11]. This is not accidental, as we explain next. Recall that a fragment F of FO *has Craig interpolation* if for all F-sentences ψ_1, ψ_2 with $\psi_1 \models \psi_2$ there exists an F-sentence ψ (called an F*-interpolant for* ψ_1, ψ_2) such that $\psi_1 \models \psi \models \psi_2$ and $\mathsf{sig}(\psi) \subseteq \mathsf{sig}(\psi_1) \cap \mathsf{sig}(\psi_2)$. F *has uniform interpolation* if one can always choose an F-interpolant that does not depend on ψ_2, but only on ψ_1 and $\mathsf{sig}(\psi_1) \cap \mathsf{sig}(\psi_2)$. Thus, given ψ_1, ψ and Σ with $\psi_1 \models \psi$ and $\mathsf{sig}(\psi) \subseteq \Sigma$, then ψ is a *uniform* $F(\Sigma)$*-interpolant of* ψ_1 iff ψ strongly $F(\Sigma)$-entails ψ_1. Both Craig interpolation and uniform interpolation have been investigated extensively, for example for intuitionistic logic [30], modal logics [36, 10, 28], guarded fragments [11], and description logics [27]. The following observation summarizes the connection between (strong) Σ-entailment and interpolation.

▶ **Theorem 5.** *Let F be a fragment of FO that enjoys Craig interpolation. Then $F(\Sigma)$-entailment implies strong $F(\Sigma)$-entailment. In particular, if $\varphi_2 \models \varphi_1$ and $\mathsf{sig}(\varphi_1) \subseteq \Sigma$, then φ_1 is a uniform $F(\Sigma)$-interpolant of φ_2 iff φ_1 $F(\Sigma)$-entails φ_2.*

Proof. Assume φ_1 does not strongly $F(\Sigma)$-entail φ_2. Then there is an F-sentence ψ with $\mathsf{sig}(\psi) \cap \mathsf{sig}(\varphi_2) \subseteq \Sigma$ such that $\varphi_2 \models \psi$ and $\varphi_1 \wedge \neg\psi$ is satisfiable. Let χ be an interpolant for φ_2 and ψ in F. Then $\neg\chi$ witnesses that φ_1 does not $F(\Sigma)$-entail φ_2. ◀

The *uniform interpolant recognition problem for* F is the problem to decide whether a sentence ψ is a uniform $F(\Sigma)$-interpolant of a sentence ψ'. It follows from Theorem 5 that in any fragment F of FO that enjoys Craig interpolation, this problem reduces in polynomial time to Σ-inseparability in F and that, conversely, conservative extension in F reduces in polynomial time to the uniform interpolant recognition problem in F. Neither GF nor FO^2 nor description logics with role inclusions enjoy Craig interpolation [21, 8, 24], but GF^2 does [21]. Thus, our decidability and complexity results for Σ-entailment in GF^2 also apply to strong Σ-entailment and the uniform interpolant recognition problem.

3 Undecidability

We prove that conservative extensions are undecidable in GF^3 and in FO^2, and consequently so are Σ-entailment and Σ-inseparability (as well as strong Σ-entailment and the uniform interpolant recognition problem). These results hold already without equality and in fact apply to all fragments of FO that contain at least one of GF^3 and FO^2 such as the guarded negation fragment [4] and the two-variable fragment with counting quantifiers [19].

We start with the case of GF^3, using a reduction from the halting problem of two-register machines. A (deterministic) *two-register machine (2RM)* is a pair $M = (Q, P)$ with $Q = q_0, \dots, q_\ell$ a set of *states* and $P = I_0, \dots, I_{\ell-1}$ a sequence of *instructions*. By definition, q_0 is the *initial state*, and q_ℓ the *halting state*. For all $i < \ell$,

- either $I_i = +(p, q_j)$ is an *incrementation instruction* with $p \in \{0, 1\}$ a register and q_j the subsequent state;
- or $I_i = -(p, q_j, q_k)$ is a *decrementation instruction* with $p \in \{0, 1\}$ a register, q_j the subsequent state if register p contains 0, and q_k the subsequent state otherwise.

A *configuration* of M is a triple (q, m, n), with q the current state and $m, n \in \mathbb{N}$ the register contents. We write $(q_i, n_1, n_2) \Rightarrow_M (q_j, m_1, m_2)$ if one of the following holds:

- $I_i = +(p, q_j)$, $m_p = n_p + 1$, and $m_{1-p} = n_{1-p}$;
- $I_i = -(p, q_j, q_k)$, $n_p = m_p = 0$, and $m_{1-p} = n_{1-p}$;
- $I_i = -(p, q_k, q_j)$, $n_p > 0$, $m_p = n_p - 1$, and $m_{1-p} = n_{1-p}$.

The *computation* of M on input $(n, m) \in \mathbb{N}^2$ is the unique longest configuration sequence $(p_0, n_0, m_0) \Rightarrow_M (p_1, n_1, m_1) \Rightarrow_M \cdots$ such that $p_0 = q_0$, $n_0 = n$, and $m_0 = m$. The halting problem for 2RMs is to decide, given a 2RM M, whether its computation on input $(0, 0)$ is finite (which implies that its last state is q_ℓ).

We show how to convert a given 2RM M into GF^3-sentences φ_1 and φ_2 such that M halts on input $(0, 0)$ iff $\varphi_1 \wedge \varphi_2$ is not a conservative extension of φ_1. Let $M = (Q, P)$ with $Q = q_0, \dots, q_\ell$ and $P = I_0, \dots, I_{\ell-1}$. We assume w.l.o.g. that $\ell \geq 1$ and that if $I_i = -(p, q_j, q_k)$, then $q_j \neq q_k$. In φ_1, we use the following set Σ of predicates:

- a binary predicate N connecting a configuration to its successor configuration;
- binary predicates R_1 and R_2 that represent the register contents via the length of paths;
- unary predicates $q_0, \dots, q_\ell$ representing the states of M;
- a unary predicate S denoting points where a computation starts.

We define φ_1 to be the conjunction of several GF^2-sentences. First, we say that there is a point where the computation starts:[1]

$$\exists x Sx \wedge \forall x(Sx \to (q_0 x \wedge \neg\exists y\, R_0 xy \wedge \neg\exists y\, R_1 xy))$$

And second, we add that whenever M is not in the final state, there is a next configuration. For $0 \leq i < \ell$:

$$\begin{aligned}
\forall x(q_i x \to \exists y(Nxy \wedge q_j y)) \quad & \text{if } I_i = +(p, q_j) \\
\forall x((q_i x \wedge \neg\exists y R_p xy) \to \exists y(Nxy \wedge q_j y)) \quad & \text{if } I_i = -(p, q_j, q_k) \\
\forall x((q_i x \wedge \exists y R_p xy) \to \exists y(Nxy \wedge q_k y)) \quad & \text{if } I_i = -(p, q_j, q_k)
\end{aligned}$$

The second sentence φ_2 is constructed so as to express that either M does not halt or the representation of the computation of M contains a defect, using the following additional predicates:

- a unary predicate P used to represent that M does not halt;
- binary predicates $D_p^+, D_p^-, D_p^=$ used to describe defects in incrementing, decrementing, and keeping register $p \in \{0, 1\}$;
- ternary predicates $H_1^+, H_2^+, H_1^-, H_2^-, H_1^=, H_2^=$ used as guards for existential quantifiers.

In fact, φ_2 is the disjunction of two sentences. The first sentence says that the computation does not terminate:

$$\exists x\,(Sx \wedge Px) \wedge \forall x\,(Px \to \exists y\,(Nxy \wedge Py))$$

while the second says that registers are not updated properly:

$$\begin{aligned}
\exists x \exists y\,\big(Nxy \wedge \big(& \bigvee_{I_i = +(p,q_j)} (q_i x \wedge q_j y \wedge (D_p^+ xy \vee D_{1-p}^= xy)) \\
& \vee \bigvee_{I_i = -(p,q_j,q_k)} (q_i x \wedge q_k y \wedge (D_p^- xy \vee D_{1-p}^= xy)) \\
& \vee \bigvee_{I_i = -(p,q_j,q_k)} (q_i x \wedge q_j y \wedge (D_p^= xy \vee D_{1-p}^= xy))\big)\big) \\
\wedge \forall x \forall y\,(D_p^+ xy \to & (\neg\exists z\, R_p yz \vee (\neg\exists z\, R_p xz \wedge \exists z\,(R_p yz \wedge \exists x R_p zx)) \\
& \vee \exists z(H_1^+ xyz \wedge R_p xz \wedge \exists x(H_2^+ xzy \wedge R_p yx \wedge D_p^+ zx)).
\end{aligned}$$

In this second sentence, additional conjuncts that implement the desired behaviour of $D_p^=$ and D_p^- are also needed; they are constructed analogously to the last three lines above (but using guards H_j^- and $H_j^=$), details are omitted. The following is proved in the appendix of the full version of this paper.

▶ **Lemma 6.**

1. *If M halts, then $\varphi_1 \wedge \varphi_2$ is not a GF^2-conservative extension of φ_1.*
2. *If there exists a Σ-structure that satisfies φ_1 and cannot be extended to a model of φ_2 (by interpreting the predicates in $\mathsf{sig}(\varphi_2) \setminus \mathsf{sig}(\varphi_1)$), then M halts.*

In the proof of Point 1, the sentence that witnesses non-conservativity describes a halting computation of M, up to global $\mathrm{GF}^2(\Sigma)$-bisimulations. This can be done using only two variables. The following result is an immediate consequence of Lemma 6.

[1] The formulas that are not syntactically guarded can easily be rewritten into such formulas.

▶ **Theorem 7.** *In any fragment of FO that extends the three-variable guarded fragment GF^3, the following problems are undecidable: conservative extensions, Σ-inseparability, Σ-entailment, and strong Σ-entailment.*

Since Point 1 of Lemma 6 ensures GF^2-witnesses, Theorem 7 can actually be strengthened to say that GF^2-conservative extensions of GF^3-sentences are undecidable.

Our result for FO^2 is proved by a reduction of a tiling problem that asks for the tiling of a rectangle (of any size) such that the borders are tiled with certain distinguished tiles. Because of space limitations, we defer details to the appendix of the full version and state only the obtained result.

▶ **Theorem 8.** *In any fragment of FO that extends FO^2, the following problems are undecidable: conservative extensions, Σ-inseparability, Σ-entailment, and strong Σ-entailment.*

It is interesting to note that the proof of Theorem 8 also shows that FO^2-conservative extensions of $\mathcal{ALC}$-TBoxes are undecidable while it follows from our results below that GF^2-conservative extensions of $\mathcal{ALC}$-TBoxes are decidable.

4 Characterizations

The undecidability results established in the previous section show that neither the restriction to two variables nor guardedness alone are sufficient for decidability of conservative extensions and related problems. In the remainder of the paper, we show that adopting both restrictions simultaneously results in decidability of Σ-entailment (and thus also of conservative extensions and of inseparability). We proceed by first establishing a suitable model-theoretic characterization and then use it as the foundation for a decision procedure based on tree automata. We in fact establish two versions of the characterization, the second one building on the first one.

We start with some preliminaries. An *atomic 1-type for* Σ is a maximal satisfiable set τ of atomic $\mathrm{GF}^2(\Sigma)$-formulas and their negations that use the variable x, only. We use $\mathrm{at}^\Sigma_{\mathfrak{A}}(a)$ to denote the atomic 1-type for Σ realized by the element a in the structure $\mathfrak{A}$. An *atomic 2-type for* Σ is a maximal satisfiable set τ of atomic $\mathrm{GF}^2(\Sigma)$-formulas and their negations that use the variables x and y, only, and contains $\neg(x = y)$. We say that τ is *guarded* if it contains an atom of the form Rxy or Ryx, R a predicate symbol. We use $\mathrm{at}^\Sigma_{\mathfrak{A}}(a, b)$ to denote the atomic 2-type for Σ realized by the elements a, b in the structure $\mathfrak{A}$. A relation $\sim \subseteq A \times B$ is a *$GF^2(\Sigma)$-bisimulation between $\mathfrak{A}$ and $\mathfrak{B}$* if the following conditions hold whenever $a \sim b$:

1. $\mathrm{at}^\Sigma_{\mathfrak{A}}(a) = \mathrm{at}^\Sigma_{\mathfrak{B}}(b)$;
2. for every $a' \neq a$ such that $\mathrm{at}^\Sigma_{\mathfrak{A}}(a, a')$ is guarded, there is a $b' \neq b$ such that $\mathrm{at}^\Sigma_{\mathfrak{A}}(a, a') = \mathrm{at}^\Sigma_{\mathfrak{B}}(b, b')$ and $a' \sim b'$ (forth condition);
3. for every $b' \neq b$ such that $\mathrm{at}^\Sigma_{\mathfrak{B}}(b, b')$ is guarded, there is an $a' \neq a$ such that $\mathrm{at}^\Sigma_{\mathfrak{A}}(a, a') = \mathrm{at}^\Sigma_{\mathfrak{B}}(b, b')$ and $a' \sim b'$ (back condition).

We write $(\mathfrak{A}, a) \sim_\Sigma (\mathfrak{B}, b)$ and say that $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$ are *$GF^2(\Sigma)$-bisimilar* if there is a $\mathrm{GF}^2(\Sigma)$-bisimulation $\sim$ between $\mathfrak{A}$ and $\mathfrak{B}$ with $a \sim b$. If the domain and range of $\sim$ coincide with A and B, respectively, then $\sim$ is called a *global $GF^2(\Sigma)$-bisimulation*.

We next introduce a bounded version of bisimulations. For $k \geq 0$, we write $(\mathfrak{A}, a) \sim^k_\Sigma (\mathfrak{B}, b)$ and say that $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$ are *k-$GF^2(\Sigma)$-bisimilar* if there is a $\sim \subseteq A \times B$ such that the first condition for bisimulations holds and the back and forth conditions can be iterated up to k times starting from a and b; a formal definition is in the appendix of the full version. It is straightforward to show the following link between k-GF^2-bisimilarity and GF^2-sentences of guarded quantifier depth k (defined in the obvious way).

▶ **Lemma 9.** *Let $\mathfrak{A}$ and $\mathfrak{B}$ be structures, Σ a signature, and $k \geq 0$. Then the following conditions are equivalent:*

1. *for all $a \in A$ there exists $b \in B$ with $(\mathfrak{A}, a) \sim^k_\Sigma (\mathfrak{B}, b)$ and vice versa;*
2. *$\mathfrak{A}$ and $\mathfrak{B}$ satisfy the same $GF^2(\Sigma)$-sentences of guarded quantifier depth at most k.*

The corresponding lemma for $\mathrm{GF}^2(\Sigma)$-sentences of unbounded guarded quantifier depth and $\mathrm{GF}^2(\Sigma)$-bisimulations holds if $\mathfrak{A}$ and $\mathfrak{B}$ satisfy certain saturation conditions (for example, if $\mathfrak{A}$ and $\mathfrak{B}$ are ω-saturated). It can then be proved that an FO-sentence φ is equivalent to a GF^2 sentence iff its models are preserved under global $\mathrm{GF}^2(\mathsf{sig}(\varphi))$-bisimulations [18, 14]. In modal and description logic, global Σ-bisimulations can often be used to characterize Σ-entailment in the following natural way [27]: φ_1 Σ-entails φ_2 iff every for every (tree) model $\mathfrak{A}$ of φ_1, there exists a (tree) model $\mathfrak{B}$ of φ_2 that is globally Σ-bisimilar to $\mathfrak{A}$. Such a characterization enables decision procedures based on tree automata, but does not hold for GF^2.

▶ **Example 10.** Let $\varphi_1 = \forall x \exists y Rxy$ and let $\varphi_2 = \varphi_1 \wedge \exists x Bx \wedge \forall x(Bx \to \exists y(Ryx \wedge By))$. Let $\mathfrak{A}$ be the model of φ_1 that consists of an infinite R-path with an initial element. Then there is no model of φ_2 that is globally $\mathrm{GF}^2(\{R\})$-bisimilar to $\mathfrak{A}$ since any such model has to contain an infinite R-path with no initial element. Yet, φ_2 is a conservative extension of φ_1 which can be proved using Theorem 11 below.

We give our first characterization theorem that uses unbounded bisimulations in one direction and bounded bisimulations in the other.

▶ **Theorem 11.** *Let φ_1, φ_2 be GF_2-sentences and Σ a signature. Then $\varphi_1 \models_\Sigma \varphi_2$ iff for every model $\mathfrak{A}$ of φ_1 of finite outdegree, there is a model $\mathfrak{B}$ of φ_2 such that*

1. *for every $a \in A$ there is a $b \in B$ such that $(\mathfrak{A}, a) \sim_\Sigma (\mathfrak{B}, b)$*
2. *for every $b \in B$ and every $k \geq 0$, there is an $a \in A$ such that $(\mathfrak{A}, a) \sim^k_\Sigma (\mathfrak{B}, b)$.*

The direction ($\Leftarrow$) follows from Lemma 9 and ($\Rightarrow$) can be proved using compactness and ω-saturated structures. Because of the use of k-bounded bisimulations (for unbounded k), it is not clear how to use Theorem 11 to find a decision procedure based on tree automata. In the following, we formulate a more 'operational' but also more technical characterization that no longer mentions bounded bisimulations. It additionally refers to forest models $\mathfrak{A}$ of φ_1 (of finite outdegree) instead of unrestricted models, but we remark that Theorem 11 also remains true under this modification.

A structure $\mathfrak{A}$ is a *forest* if its Gaifman graph is a forest. Thus, a forest admits cycles of length one and two, but not of any higher length. A (Σ-)*tree* in a forest structure $\mathfrak{A}$ is a maximal (Σ)-connected substructure of $\mathfrak{A}$. When working with forest structures $\mathfrak{A}$, we will typically view them as directed forests rather than as undirected ones. This can be done by choosing a root for each tree in the Gaifman graph of $\mathfrak{A}$, thus giving rise to notions such as successor, descendant, etc. Which node is chosen as the root will always be irrelevant. Note that the direction of binary relations does not need to reflect the successor relation. When speaking of a *path* in a forest structure $\mathfrak{A}$, we mean a path in the directed sense; when speaking of a *subtree*, we mean a tree that is obtained by choosing a root a and restricting the structure to a and its descendants. We say that $\mathfrak{A}$ is *regular* if it has only finitely many subtrees, up to isomorphism.

To see how we can get rid of bounded bisimulations, reconsider Theorem 11. The characterization is still correct if we pull out the quantification over k in Point 2 so that the theorem reads '...iff for every model $\mathfrak{A}$ of φ_1 of finite outdegree and every $k \geq 0$, there is...'. In fact, this modified version of Theorem 11 is even closer to the definition of Σ-entailment. It

also suggests that we add a marking $A_\perp \subseteq A$ of elements in $\mathfrak{A}$, representing 'break-off points' for bisimulations, and then replace k-bisimulations with bisimulations that stop whenever they have encountered the *second* marked element on the same path—in this way, the distance between marked elements (roughly) corresponds to the bound k in k-bisimulations. However, we would need a marking $A_\perp$, for any $k \geq 0$, such that there are infinitely many markers on any infinite path and the distance between any two markers in a tree is at least k. It is easy to see that such a marking may not exist, for example when $k = 3$ and $\mathfrak{A}$ is the infinite full binary tree. We solve this problem as follows. First, we only demand that the distance between any two markers *on the same path* is at least k. And second, we use the markers only when following bisimulations upwards in a tree while downwards, we use unbounded bisimulations. This does not compromise correctness of the characterization.

We next introduce a version of bisimulations that implement the ideas just explained. Let $\mathfrak{A}$ and $\mathfrak{B}$ be forest models, Σ a signature, and $A_\perp \subseteq A$. Two relations $\sim_\Sigma^{A_\perp,0}, \sim_\Sigma^{A_\perp,1} \subseteq A \times B$ form an $A_\perp$*-delimited* $GF^2(\Sigma)$*-bisimulation* between $\mathfrak{A}$ and $\mathfrak{B}$ if the following conditions are satisfied:

1. if $(\mathfrak{A}, a) \sim_\Sigma^{A_\perp,0} (\mathfrak{B}, b)$, then $\mathrm{at}_\mathfrak{A}^\Sigma(a) = \mathrm{at}_\mathfrak{B}^\Sigma(b)$ and
   a. for every $a' \neq a$ with $\mathrm{at}_\mathfrak{A}^\Sigma(a, a')$ guarded, there is a $b' \neq b$ such that $(\mathfrak{A}, a') \sim_\Sigma^{A_\perp,i} (\mathfrak{B}, b')$ where $i = 1$ if a' is the predecessor of a and $a' \in A_\perp$, and $i = 0$ otherwise;
   b. for every $b' \neq b$ with $\mathrm{at}_\mathfrak{B}^\Sigma(b, b')$ guarded, there is an $a' \neq a$ such that $(\mathfrak{A}, a') \sim_\Sigma^{A_\perp,i} (\mathfrak{B}, b')$ where $i = 1$ if a' is the predecessor of a and $a' \in A_\perp$, and $i = 0$ otherwise;
2. if $(\mathfrak{A}, a) \sim_\Sigma^{A_\perp,1} (\mathfrak{B}, b)$ and the predecessor of a in $\mathfrak{A}$ is not in $A_\perp$, then $\mathrm{at}_\mathfrak{A}^\Sigma(a) = \mathrm{at}_\mathfrak{B}^\Sigma(b)$ and
   a. for every $a' \neq a$ with $\mathrm{at}_\mathfrak{A}^\Sigma(a, a')$ guarded, there is a $b' \neq b$ such that $(\mathfrak{A}, a') \sim_\Sigma^{A_\perp,i} (\mathfrak{B}, b')$ where $i = 0$ if a is the predecessor of a' and $a \in A_\perp$, and $i = 1$ otherwise;
   b. for every $b' \neq b$ with $\mathrm{at}_\mathfrak{B}^\Sigma(b, b')$ guarded, there is an $a' \neq a$ such that $(\mathfrak{A}, a') \sim_\Sigma^{A_\perp,i} (\mathfrak{B}, b')$ where $i = 0$ if a is the predecessor of a' and $a \in A_\perp$, and $i = 1$ otherwise.

Then $(\mathfrak{A}, a)$ and $(\mathfrak{B}, b)$ are $A_\perp$*-delimited* $GF^2(\Sigma)$*-bisimilar*, in symbols $(\mathfrak{A}, a) \sim_\Sigma^{A_\perp} (\mathfrak{B}, b)$, if there exists an $A_\perp$-delimited $\mathrm{GF}^2(\Sigma)$-bisimulation $\sim_\Sigma^{A_\perp,0}, \sim_\Sigma^{A_\perp,1}$ between $\mathfrak{A}$ and $\mathfrak{B}$ such that $(\mathfrak{A}, a) \sim_\Sigma^{A_\perp,0} (\mathfrak{B}, b)$.

Let φ be a GF^2-sentence. We use $\mathsf{cl}(\varphi)$ to denote the set of all subformulas of φ closed under single negation and renaming of free variables (using only the available variables x and y). A 1*-type for* φ is a subset $t \subseteq \mathsf{cl}(\varphi)$ that contains only formulas of the form $\psi(x)$ and such that $\varphi \wedge \exists x \bigwedge t(x)$ is satisfiable. For a model $\mathfrak{A}$ of φ and $a \in A$, we use $\mathsf{tp}_\mathfrak{A}(a)$ to denote the 1-type $\{\psi(x) \in \mathsf{cl}(\varphi) \mid \mathfrak{A} \models \psi(a)\}$, assuming that φ is understood from the context. We say that the 1-type t is *realized* in $\mathfrak{A}$ if there is an $a \in A$ with $\mathsf{tp}_\mathfrak{A}(a) = t$. We are now ready to formulate our final characterizations.

▶ **Theorem 12.** *Let φ_1, φ_2 be GF^2-sentences and Σ a signature. Then $\varphi_1 \models_\Sigma \varphi_2$ iff for every regular forest model $\mathfrak{A}$ of φ_1 that has finite outdegree and for every set $A_\perp \subseteq A$ with $A_\perp \cap \rho$ infinite for any infinite Σ-path ρ in $\mathfrak{A}$, there is a model $\mathfrak{B}$ of φ_2 such that*

1. *for every $a \in A$, there is a $b \in B$ such that $(\mathfrak{A}, a) \sim_\Sigma (\mathfrak{B}, b)$;*
2. *for every 1-type t for φ_2 that is realized in $\mathfrak{B}$, there are $a \in A$ and $b \in B$ such that $\mathsf{tp}_\mathfrak{B}(b) = t$ and $(\mathfrak{A}, a) \sim_\Sigma^{A_\perp} (\mathfrak{B}, b)$.*

Regularity and finite outdegree are used in the proof of Theorem 12 given in the appendix of the full version, but it follows from the automata constructions below that the theorem is still correct when these qualifications are dropped.

5 Decidability and Complexity

We show that Σ-entailment in GF^2 is decidable and 2ExpTime-complete, and thus so are conservative extensions and Σ-inseparability. The upper bound is based on Theorem 12 and uses alternating parity automata on infinite trees. Since Theorem 12 does not provide us with an obvious upper bound on the outdegree of the involved tree models, we use alternating tree automata which can deal with trees of any finite outdegree, similar to the ones introduced by Wilke [37], but with the capability to move both downwards and upwards in the tree.

A *tree* is a non-empty (and potentially infinite) set of words $T \subseteq (\mathbb{N} \setminus 0)^*$ closed under prefixes. We generally assume that trees are finitely branching, that is, for every $w \in T$, the set $\{i \mid w \cdot i \in T\}$ is finite. For any $w \in (\mathbb{N} \setminus 0)^*$, as a convention we set $w \cdot 0 := w$. If $w = n_0 n_1 \cdots n_k$, we additionally set $w \cdot -1 := n_0 \cdots n_{k-1}$. For an alphabet Θ, a Θ-*labeled tree* is a pair (T, L) with T a tree and $L : T \to \Theta$ a node labeling function.

A *two-way alternating tree automata (2ATA)* is a tuple $\mathcal{A} = (Q, \Theta, q_0, \delta, \Omega)$ where Q is a finite set of *states*, Θ is the *input alphabet*, $q_0 \in Q$ is the *initial state*, δ is a *transition function* as specified below, and $\Omega : Q \to \mathbb{N}$ is a *priority function*, which assigns a priority to each state. The transition function maps a state q and some input letter $\theta \in \Theta$ to a *transition condition* $\delta(q, \theta)$ which is a positive Boolean formula over the truth constants true and false and transitions of the form q, $\langle - \rangle q$, $[-]q$, $\Diamond q$, $\Box q$ where $q \in Q$. The automaton runs on Θ-labeled trees. Informally, the transition q expresses that a copy of the automaton is sent to the current node in state q, $\langle - \rangle q$ means that a copy is sent in state q to the predecessor node, which is then required to exist, $[-]q$ means the same except that the predecessor node is not required to exist, $\Diamond q$ means that a copy is sent in state q to some successor, and $\Box q$ that a copy is sent in state q to all successors. The semantics is defined in terms of runs in the usual way, we refer to the appendix of the full version for details. We use $L(\mathcal{A})$ to denote the set of all Θ-labeled trees accepted by $\mathcal{A}$. It is standard to verify that 2ATAs are closed under complementation and intersection. We show in the appendix that the emptiness problem for 2ATAs can be solved in time exponential in the number of states.

We aim to show that given two GF^2-sentences φ_1 and φ_2 and a signature Σ, one can construct a 2ATA $\mathcal{A}$ such that $L(\mathcal{A}) = \emptyset$ iff $\varphi_1 \models_{\mathrm{GF}^2(\Sigma)} \varphi_2$. The number of states of the 2ATA $\mathcal{A}$ is polynomial in the size of φ_1 and exponential in the size of φ_2, which yields the desired 2ExpTime upper bounds.

Let φ_1, φ_2, and Σ be given. Since the logics we are concerned with have Craig interpolation, we can assume w.l.o.g. that $\Sigma \subseteq \mathsf{sig}(\varphi_1)$. With Θ, we denote the set of all pairs (τ, M) where τ is an atomic 2-type for $\mathsf{sig}(\varphi_1)$ and $M \in \{0, 1\}$. For $p = (\tau, M) \in \Theta$, we use p^1 to denote τ and p^2 to denote M. A Θ-labeled tree (T, L) represents a forest structure $\mathfrak{A}_{(T,L)}$ with universe $A_{(T,L)} = T$ and where $w \in A^{\mathfrak{A}_{(T,L)}}$ if $A(y) \in L(w)$ and $(w, w') \in R^{\mathfrak{A}_{(T,L)}}$ if one of the following conditions is satisfied: (1) $w = w'$ and $Ryy \in L(w)^1$; (2) w' is a successor of w and $Rxy \in L(w')^1$; (3) w is a successor of w' and $Ryx \in L(w)^1$. Thus, the atoms in a node label that involve only the variable y describe the current node, the atoms that involve both variables x and y describe the connection between the predecessor and the current node, and the atoms that involve only the variable x are ignored. The M-components of node labels are used to represent a set of markers $A_\perp = \{w \in A_{(T,L)} \mid L(w)^2 = 1\}$. It is easy to see that, conversely, for every tree structure $\mathfrak{A}$ over Σ, there is a Θ-labeled tree (T, L) such that $\mathfrak{A}_{(T,L)} = \mathfrak{A}$.

To obtain the desired 2ATA $\mathcal{A}$, we construct three 2ATAs $\mathcal{A}_1, \mathcal{A}_2, \mathcal{A}_3$ and then define $\mathcal{A}$ so that it accepts $L(\mathcal{A}_1) \cap \overline{L(\mathcal{A}_2)} \cap L(\mathcal{A}_3)$. The 2ATA $\mathcal{A}_3$ only makes sure that the set $A_\perp \subseteq A_{(T,L)}$ is such that for any infinite Σ-path ρ, $A_\perp \cap \rho$ is infinite (as required by

Theorem 12), we omit details. We construct $\mathcal{A}_1$ so that it accepts a Θ-labeled tree (T, L) iff $\mathfrak{A}_{(T,L)}$ is a model of φ_1. The details of the construction, which is fairly standard, can be found in the appendix. The number of states of $\mathcal{A}_1$ is polynomial in the size of φ_1 and independent of φ_2. The most interesting automaton is $\mathcal{A}_2$.

▶ **Lemma 13.** *There is a 2ATA $\mathcal{A}_2$ that accepts a Θ-labeled tree (T, L) iff there is a model $\mathfrak{B}$ of φ_2 s.t. Conditions 1 and 2 from Theorem 12 are satisfied when $\mathfrak{A}$ is replaced with $\mathfrak{A}_{(T,L)}$.*

The general idea of the construction of $\mathcal{A}_2$ is to check the existence of the desired model $\mathfrak{B}$ of φ_2 by verifying that there is a set of 1-types for φ_2 from which $\mathfrak{B}$ can be assembled, represented via the states that occur in a successful run. Before we can give details, we introduce some preliminaries.

A 0-*type* s *for* φ_2 is a maximal set of sentences $\psi() \in \mathsf{cl}(\varphi_2)$ such that $\varphi_2 \wedge s$ is satisfiable. A 2-*type* λ *for* φ_2 is a maximal set of formulas $\psi(x, y) \in \mathsf{cl}(\varphi_2)$ that contains $\neg(x = y)$ and such that $\varphi_2 \wedge \exists xy\, \lambda(x, y)$ is satisfiable. If a 2-type λ contains the atom Rxy or Ryx for at least one binary predicate R, then it is *guarded*. If additionally $R \in \Sigma$, then it is Σ-*guarded*. Note that each 1-type contains a (unique) 0-type and each 2-type contains two (unique) 1-types. Formally, we use λ_x to denote the 1-type obtained by restricting the 2-type λ to the formulas that do not use the variable y, and likewise for λ_y and the variable x. We use TP_n to denote the set of n-types for φ_2, $n \in \{0, 1, 2\}$. For $t \in \mathsf{TP}_1$ and a $\lambda \in \mathsf{TP}_2$, we say that λ is *compatible with* t and write $t \approx \lambda$ if the sentence $\varphi_2 \wedge \exists xy(t(x) \wedge \lambda(x, y))$ is satisfiable; for $t \in \mathsf{TP}_1$ and $T \subseteq \mathsf{TP}_2$ a set of guarded 2-types, we say that T is a *neighborhood for* t and write $t \approx T$ if the sentence

$$\varphi_2 \wedge \exists x\big(t(x) \wedge \bigwedge_{\lambda \in T} \exists y\, \lambda(x, y) \wedge \forall y \bigvee_{R \in \mathsf{sig}(\varphi_2)} ((Rxy \vee Ryx) \to \bigvee_{\lambda \in T} \lambda(x, y))\big)$$

is satisfiable. Note that each of the mentioned sentences is formulated in GF^2 and at most single exponential in size (in the size of φ_1 and φ_2), thus satisfiability can be decided in 2ExpTime.

To build the automaton $\mathcal{A}_2$ from Lemma 13, set $\mathcal{A}_2 = (Q_2, \Theta, q_0, \delta_2, \Omega_2)$ where Q_2 is

$$\{q_0, q_\bot\} \cup \mathsf{TP}_0 \cup \{t, t^?, t_\uparrow, t_\downarrow, t_\&, t^i, t^i_\uparrow, t^i_\downarrow \mid t \in \mathsf{TP}_1,\ i \in \{0, 1\}\} \cup$$
$$\{\lambda, \lambda_\uparrow, \lambda^i, \lambda^i_\uparrow \mid \lambda \in \mathsf{TP}_2,\ i \in \{0, 1\}\},$$

Ω_2 assigns two to all states except for those of the form $t^?$, to which it assigns one.

The automaton begins by choosing the 0-type s realized in the forest model $\mathfrak{B}$ of φ_2 whose existence it aims to verify. For every $\exists x\varphi(x) \in s$, it then chooses a 1-type t in which $\varphi(x)$ is realized in $\mathfrak{B}$ and sends off a copy of itself to find a node where t is realized. To satisfy Condition 1 of Theorem 12, at each node it further chooses a 1-type that is compatible with s, to be realized at that node. This is implemented by the following transitions:

$$\begin{aligned}
\delta_2(q_0, \sigma) &= \bigvee_{s \in \mathsf{TP}_0} \big(s \wedge \bigwedge_{\exists x\, \varphi(x) \in s} \bigvee_{\substack{t \in \mathsf{TP}_1 \mid \\ s \cup \{\varphi(x)\} \subseteq t}} t^?\big) \\
\delta_2(s, \sigma) &= \Box s \wedge \bigvee_{t \in \mathsf{TP}_1, s \subseteq t} t \\
\delta_2(t^?, \sigma) &= \langle -1 \rangle t^? \vee \Diamond t^? \vee t^0
\end{aligned}$$

where s ranges over TP_0. When a state of the form t is assigned to a node w, this is an obligation to prove that there is a $\mathrm{GF}^2(\Sigma)$-bisimulation between the element w in $\mathfrak{A}_{(T,L)}$ and

an element b of type t in $\mathfrak{B}$. A state of the form t^0 represents the obligation to verify that there is an $A_\bot$-delimited $\mathrm{GF}^2(\Sigma)$-bisimulation between w and an element of type t in $\mathfrak{B}$. We first verify that the former obligations are satisfied. This requires to follow all successors of w and to guess types of successors of b to be mapped there, satisfying the back condition of bisimulations. We also need to guess successors of b in $\mathfrak{B}$ (represented as a neighborhood for t) to satisfy the existential demands of t and then select successors of a to which they are mapped, satisfying the "back" condition of bisimulations. Whenever we decide to realize a 1-type t in $\mathfrak{B}$ that does not participate in the bisimulation currently being verified, we also send another copy of the automaton in state $t^?$ to guess an $a \in A_{(T,L)}$ that we can use to satisfy Condition 2 from Theorem 12:

$$\delta_2(t,(\tau,M)) \;=\; t_\uparrow \wedge \Box t_\downarrow \wedge \bigvee_{T \mid t \approx T} \bigwedge_{\lambda \in T} (\Diamond\lambda \vee \lambda_\uparrow) \quad \text{if } \tau_y =_\Sigma t$$

$$\begin{array}{rcll}
\delta_2(t,(\tau,M)) &=& \mathsf{false} & \text{if } \tau_y \neq_\Sigma t \\
\delta_2(t_\downarrow,(\tau,M)) &=& \mathsf{true} & \text{if } \tau \text{ is not } \Sigma\text{-guarded} \\
\delta_2(t_\downarrow,(\tau,M)) &=& \displaystyle\bigvee_{\lambda \mid t \approx \lambda \wedge \tau =_\Sigma \lambda} \lambda_y & \text{if } \tau \text{ is } \Sigma\text{-guarded} \\
\delta_2(t_\uparrow,(\tau,M)) &=& \mathsf{true} & \text{if } \tau \text{ is not } \Sigma\text{-guarded} \\
\delta_2(t_\uparrow,(\tau,M)) &=& \displaystyle\bigvee_{\lambda \mid t \approx \lambda \wedge \tau =_\Sigma \lambda^-} [-1]\lambda_y & \text{if } \tau \text{ is } \Sigma\text{-guarded} \\
\delta_2(\lambda,(\tau,M)) &=& \lambda_y & \text{if } \lambda \text{ is } \Sigma\text{-guarded and } \tau =_\Sigma \lambda \\
\delta_2(\lambda,(\tau,M)) &=& \mathsf{false} & \text{if } \lambda \text{ is } \Sigma\text{-guarded and } \tau \neq_\Sigma \lambda \\
\delta_2(\lambda,(\tau,M)) &=& \lambda^?_y & \text{if } \lambda \text{ is not } \Sigma\text{-guarded} \\
\delta_2(\lambda_\uparrow,(\tau,M)) &=& \langle -1\rangle \lambda_y & \text{if } \lambda \text{ is } \Sigma\text{-guarded and } \tau =_\Sigma \lambda^- \\
\delta_2(\lambda_\uparrow,(\tau,M)) &=& \mathsf{false} & \text{if } \lambda \text{ is } \Sigma\text{-guarded and } \tau \neq_\Sigma \lambda^- \\
\delta_2(\lambda_\uparrow,(\tau,M)) &=& \lambda^?_y & \text{if } \lambda \text{ is not } \Sigma\text{-guarded}
\end{array}$$

where $\tau_y =_\Sigma t$ means that the atoms in τ that mention only y are identical to the Σ-relational atoms in t (up to renaming x to y), $\tau =_\Sigma \lambda$ means that the restriction of λ to Σ-atoms is exactly τ, and λ^- is obtained from λ by swapping x and y. We need further transitions to satisfy the obligations represented by states of the form t^0, which involves checking $A_\bot$-delimited bisimulations. Details are given in the appendix where also the correctness of the construction is proved.

▶ **Theorem 14.** *In GF^2, Σ-entailment and conservative extensions can be decided in time $2^{2^{p(|\varphi_2| \cdot \log |\varphi_1|)}}$, for some polynomial p. Moreover, Σ-inseparability is in* 2ExpTime.

Note that the time bound for conservative extensions given in Theorem 14 is double exponential only in the size of φ_2 (that is, the extension). In ontology engineering applications, φ_2 will often be small compared with φ_1.

A matching lower bound is proved using a reduction of the word problem of exponentially space-bounded alternating Turing machines, see the appendix for details. The construction is inspired by the proof from [13] that conservative extensions in the description logic $\mathcal{ALC}$ are 2ExpTime-hard, but the lower bound does not transfer directly since we are interested here in witness sentences that are formulated in GF^2 rather than in $\mathcal{ALC}$.

▶ **Theorem 15.** *In any fragment of FO that contains GF^2, the problems Σ-entailment, Σ-inseparability, conservative extensions, and strong Σ-entailment are* 2ExpTime*-hard.*

6 Conclusion

We have shown that conservative extensions are undecidable in (extensions of) GF and FO^2, and that they are decidable and 2ExpTime-complete in GF^2. It thus appears that decidability of conservative extensions is linked even more closely to the tree model property than decidability of the satisfiability problem: apart from cycles of length at most two, GF^2 enjoys a 'true' tree model property while GF only enjoys a bounded treewidth model property and FO^2 has a rather complex regular model property that is typically not even made explicit. As future work, it would be interesting to investigate whether conservative extensions remain decidable when guarded counting quantifiers, transitive relations, equivalence relations, or fixed points are added, see e.g. [32, 22, 20]. It would also be interesting to investigate a finite model version of conservative extensions.

Models and Termination of Proof Reduction in the $\lambda\Pi$-Calculus Modulo Theory

Gilles Dowek

Inria and École normale supérieure de Paris-Saclay, Cachan Cedex, France
gilles.dowek@ens-paris-saclay.fr

Abstract

We define a notion of model for the $\lambda\Pi$-calculus modulo theory and prove a soundness theorem. We then define a notion of super-consistency and prove that proof reduction terminates in the $\lambda\Pi$-calculus modulo any super-consistent theory. We prove this way the termination of proof reduction in several theories including Simple type theory and the Calculus of constructions.

1 Introduction

1.1 Models and termination

In Predicate logic, a model is defined by a domain $\mathcal{M}$, a set $\mathcal{B}$ of truth values, and an interpretation function, parametrized by a valuation ϕ, mapping each term t to an element $[\![t]\!]_\phi$ of $\mathcal{M}$, and each proposition A to an element $[\![A]\!]_\phi$ of $\mathcal{B}$.

Predicate logic can be extended to Deduction modulo theory [11, 12], where a congruence on propositions defining a computational equality, also known as definitional equality in Constructive type theory [17], is added. Proofs of a proposition A are then considered to also be proofs of any proposition congruent to A. In Deduction modulo theory, like in Predicate logic, a model is defined by a domain $\mathcal{M}$, a set $\mathcal{B}$ of truth values, and an interpretation function.

Usually, the set $\mathcal{B}$ is the two-element set $\{0, 1\}$, but the notion of model can be extended to a notion of many-valued model, where $\mathcal{B}$ is an arbitrary Boolean algebra, a Heyting algebra, a pre-Boolean algebra [5], or a pre-Heyting algebra [9]. Boolean algebras permit to introduce intermediate truth values for propositions that are neither provable nor disprovable, Heyting algebras to construct models of constructive logic, and pre-Boolean and pre-Heyting algebras, where the order relation $\leq$ is replaced by a pre-order relation, to distinguish a notion of weak equivalence: $[\![A]\!]_\phi \leq [\![B]\!]_\phi$ and $[\![B]\!]_\phi \leq [\![A]\!]_\phi$, for all ϕ, from a notion of strong equivalence: $[\![A]\!]_\phi = [\![B]\!]_\phi$, for all ϕ. In Deduction modulo theory, the first corresponds to the provability of $A \Leftrightarrow B$ and the second to the congruence.

In a model valued in a Boolean algebra, a Heyting algebra, a pre-Boolean algebra, or a pre-Heyting algebra, a proposition A is said to be valid when it is weakly equivalent to the proposition $\top$, that is when, for all ϕ, $[\![A]\!]_\phi \geq \tilde{\top}$, and this condition can be rephrased as $[\![A]\!]_\phi = \tilde{\top}$ in Boolean and Heyting algebras. A congruence $\equiv$ defined on propositions is said to be valid when, for all A and B such that $A \equiv B$, A and B are strongly equivalent, that is, for all ϕ, $[\![A]\!]_\phi = [\![B]\!]_\phi$. Note that the relation $\leq$ is used in the definition of the validity of a proposition, but not in the definition of the validity of a congruence.

Proof reduction terminates in Deduction modulo a theory defined by a set of axioms $\mathcal{T}$ and a congruence $\equiv$, when this theory has a model valued in the pre-Heyting algebra of reducibility candidates [12]. As a consequence, proof reduction terminates if the theory is super-consistent, that is if, for all pre-Heyting algebras $\mathcal{B}$, it has a model valued in $\mathcal{B}$ [9]. This theorem permits to completely separate the semantic and the syntactic aspects that are often mixed in the usual proofs of termination of proof reduction. The semantic aspect is in the proof of super-consistency of the considered theory and the syntactic in the universal proof that super-consistency implies termination of proof reduction.

For the termination of proof reduction, the congruence matters, but the axioms do not. Thus, the pre-order relation $\leq$ does not matter in the algebra of reducibility candidates and it is possible to define it as the trivial pre-order relation such that $C \leq C'$, for all C and C'. Such a pre-Heyting algebra is said to be trivial. As the pre-order is trivial, all the conditions defining pre-Heyting algebras, such as $a \tilde{\wedge} b \leq a$, $a \tilde{\wedge} b \leq b$... are always satisfied in a trivial pre-Heyting algebra, and a trivial pre-Heyting algebra is just a set equipped with arbitrary operations $\tilde{\wedge}$, $\tilde{\Rightarrow}$... Thus, in order to prove that proof reduction terminates in Deduction modulo a theory defined by a set of axioms $\mathcal{T}$ and a congruence $\equiv$, it is sufficient to prove that for all trivial pre-Heyting algebras $\mathcal{B}$, the theory has a model valued in $\mathcal{B}$.

1.2 The λΠ-calculus modulo theory

In Predicate logic and in Deduction modulo theory, terms, propositions, and proofs belong to three distinct languages. But, it is more thrifty to consider a single language, such as the λΠ-calculus modulo theory [8], which is implemented in the Dedukti system [1], or Martin-Löf's Logical Framework [21], and express terms, propositions, and proofs, in this language. For instance, in Predicate logic, 0 is a term, $P(0) \Rightarrow P(0)$ is a proposition and $\lambda\alpha : P(0)\ \alpha$ is a proof of this proposition. In the λΠ-calculus modulo theory, all these expressions are terms of the calculus. Only their types differ: 0 has type nat, $P(0) \Rightarrow P(0)$ has type $Type$ and $\lambda\alpha : P(0)\ \alpha$ has type $P(0) \Rightarrow P(0)$.

Like the λΠ-calculus, the λΠ-calculus modulo theory is a λ-calculus with dependent types, but, like in Deduction modulo theory, its conversion rule is extended to an arbitrary congruence, typically defined with a confluent and terminating rewrite system. This idea of extending the conversion rule beyond β-reduction is already present in Martin-Löf type theory. It is used, in various ways, in different systems [20, 6, 13, 3].

1.3 From pre-Heyting algebras to Π-algebras

The first goal of this paper is to extend the notion of pre-Heyting algebra to a notion of Π-algebra, adapted to the λΠ-calculus modulo theory.

In Predicate logic and in Deduction modulo theory, the propositions are built from atomic propositions with the connectors and quantifiers $\top$, $\bot$, $\wedge$, $\vee$, $\Rightarrow$, $\forall$, and $\exists$. Accordingly, the operations of a pre-Heyting algebra are $\tilde{\top}$, $\tilde{\bot}$, $\tilde{\wedge}$, $\tilde{\vee}$, $\tilde{\Rightarrow}$, $\tilde{\forall}$, and $\tilde{\exists}$. In the λΠ-calculus and in the λΠ-calculus modulo theory, the only connector is Π. Thus, a Π-algebra mainly has an operation $\tilde{\Pi}$. As expected, its properties are a mixture of the properties of the implication and of the universal quantifier of the pre-Heyting algebras.

1.4 Layered models

The second goal of this paper is to extend the usual notion of model to the λΠ-calculus modulo theory.

Extending the notion of model to many-sorted predicate logic requires to consider not just one domain $\mathcal{M}$, but a family of domains $\mathcal{M}_s$ indexed by the sorts. For instance, in a model of Simple type theory, the family of domains is indexed by simple types. In the $\lambda\Pi$-calculus modulo theory, the sorts also are just terms of the calculus. Thus, we shall define a model of the $\lambda\Pi$-calculus modulo theory by a family of domains $(\mathcal{M}_t)_t$ indexed by the terms of the calculus and a function $[\![.]\!]$ mapping each term t of type A and valuation ϕ to an element $[\![t]\!]_\phi$ of $\mathcal{M}_A$.

The functions $\mathcal{M}$ and $[\![.]\!]$ are similar, in the sense that both their domains is the set of terms of the calculus. The goal of the model construction is to define the function $[\![.]\!]$ and the function $\mathcal{M}$ can be seen as a tool helping to define this function. For instance, if f is a constant of type $A \to A$, where A is a term of type $Type$, and we have the rule $f(x) \longrightarrow x$, we want to define the interpretation $[\![f]\!]$ as the identity function over some set, but to state which, we must first define the function $\mathcal{M}$ that maps the term A to a set $\mathcal{M}_A$, and then define $[\![f]\!]$ as the identity function over the set $\mathcal{M}_A$.

In Predicate logic and in Deduction modulo theory, terms may be typed with sorts, but the sorts themselves have no type. In the $\lambda\Pi$-calculus modulo theory, in contrast, terms have types that have types... This explains that, in some cases, constructing the function $\mathcal{M}$ itself requires to define first another function $\mathcal{N}$, that is used as a tool helping to define this function. This can be iterated to a several layer model, where the function $[\![.]\!]$ is defined with the help of a function $\mathcal{M}$, that is defined with the help of a function $\mathcal{N}$, that is defined with the help... The number of layers depends on the model. Such layered constructions are common in proofs of termination of proof reduction [14, 18, 4], for instance for Pure Type Systems where sorts are stacked: $Type_0 : Type_1 : Type_2 : Type_3$.

Note that, in this definition of the notion of model, when a term t has type A, we do not require $[\![t]\!]_\phi$ to be an element of $[\![A]\!]_\phi$, but of $\mathcal{M}_A$. This is consistent with the notion of model of many-sorted predicate logic, where we require $[\![t]\!]_\phi$ to be an element of $\mathcal{M}_s$ and where $[\![s]\!]_\phi$ is often not even defined.

Valuations must be handled with care in such layered models. In a three layer model, for instance, the definition of $\mathcal{N}_t$ is absolute, the definition of $\mathcal{M}_t$ is relative to a valuation ψ, mapping each variable of type A to an element of $\mathcal{N}_A$, and the definition of $[\![t]\!]$ is relative to a valuation ψ and to a valuation ϕ mapping each variable of type A to an element of $\mathcal{M}_{A,\psi}$.

1.5 Super-consistency and proof reduction

The third goal of this paper is to use this notion of Π-algebra to define a notion of super-consistency and to prove that proof reduction, that is β-reduction, terminates in the $\lambda\Pi$-calculus modulo any super-consistent theory.

We prove this way the termination of proof reduction in several theories expressed in the $\lambda\Pi$-calculus modulo theory, including Simple type theory [11] and the Calculus of constructions [8]. Together with confluence, this termination of proof reduction is a property required to define these theories in the system Dedukti [1].

In Section 2, we recall the definition of the $\lambda\Pi$-calculus modulo theory and give three examples of theories expressed in this framework. In Section 3, we introduce the notion of Π-algebra and that of model for the $\lambda\Pi$-calculus modulo theory and we prove a soundness theorem. In Section 4, we define the notion of super-consistency and prove that the three theories introduced in Section 2 are super-consistent. In Section 5, we prove that proof reduction terminates in the $\lambda\Pi$-calculus modulo any super-consistent theory.

Figure 1 The λΠ-calculus.

2 The λΠ-calculus modulo theory

2.1 The λΠ-calculus

The syntax of the λΠ-calculus is

$$t = x \mid Type \mid Kind \mid \Pi x : t\ t \mid \lambda x : t\ t \mid t\ t$$

and the typing rules are given in Figure 1.

As usual, we write $A \to B$ for $\Pi x : A\ B$ when x does not occur in B. The α-equivalence relation is defined as usual and terms are identified modulo α-equivalence. The relation β – one step β-reduction at the root – is defined as usual. If r is a relation on terms, we write $\longrightarrow_r^1$ for the congruence closure of r, $\longrightarrow_r^+$ for the transitive closure of $\longrightarrow_r^1$, $\longrightarrow_r^*$ for its reflexive-transitive closure, and $\equiv_r$ for its reflexive-symmetric-transitive closure.

If Σ, Γ, and Δ are contexts, a substitution θ, binding the variables of Γ, is said to *have type* $\Gamma \rightsquigarrow \Delta$ *in* Σ if for all $x : A$ in Γ, we have $\Sigma, \Delta \vdash \theta x : \theta A$. In this case, if $\Sigma, \Gamma \vdash t : B$, then $\Sigma, \Delta \vdash \theta t : \theta B$.

Types are preserved by β-reduction. The β-reduction relation is confluent and strongly terminating. And each term has a unique type modulo β-equivalence [16].

A term t, well-typed in some context Γ, is a *kind* if its type in this context is $Kind$. For instance, $Type$ and $nat \to Type$ are kinds. It is a *type family* if its type is a kind. In particular, it is a *type* if its type is $Type$. For instance, nat, $array$, and $(array\ 0)$ are type families, among which nat and $(array\ 0)$ are types. It is an *object* if its type is a type. For instance, 0 and [0] are objects.

\end{array}
$$

with a finite number of quantifiers $\forall_A$

Figure 2 Simple type theory.

2.2 The λΠ-calculus modulo theory

▶ **Definition 1** (Rewrite rule). A *rewrite rule* is a triple $l \longrightarrow^{\Gamma} r$ where Γ is a context and l and r are β-normal terms. Such a rule is *well-typed* in the context Σ if, in the $\lambda\Pi$-calculus, the context Σ, Γ is well-formed and there exists a term A such that the terms l and r both have type A in this context.

If Σ is a context, $l \longrightarrow^{\Gamma} r$ is a rewrite rule well-typed in Σ and θ is a substitution of type $\Gamma \rightsquigarrow \Delta$ in Σ, then the terms θl and θr both have type θA in the context Σ, Δ. The relation $\mathcal{R}$ – one step $\mathcal{R}$-reduction at the root – is defined by: $t\ \mathcal{R}\ u$ is there exists a rewrite rule $l \longrightarrow^{\Gamma} r$ and a substitution θ such that $t = \theta l$ and $u = \theta r$. The relation $\beta\mathcal{R}$ – one step $\beta\mathcal{R}$-reduction at the root – is the union of β and $\mathcal{R}$.

▶ **Definition 2** (Theory). A *theory* is a pair formed with a context Σ, well-formed in the $\lambda\Pi$-calculus, and a set of rewrite rules $\mathcal{R}$, well-typed in Σ in the $\lambda\Pi$-calculus.

The variables declared in Σ are called *constants*. They replace the sorts, the function symbols, the predicate symbols, and the axioms of a theory in Predicate logic.

▶ **Definition 3** (The λΠ-calculus modulo theory). The $\lambda\Pi$-*calculus modulo* $\Sigma, \mathcal{R}$ is the extension of the $\lambda\Pi$-calculus obtained modifying the **Declaration** rules to replace the condition $x \notin \Gamma$ with $x \notin \Sigma, \Gamma$, the **Variable** rules to replace the condition $x : A \in \Gamma$ by $x : A \in \Sigma, \Gamma$, and the **Conversion** rules to replace the condition $A \equiv_{\beta} B$ with $A \equiv_{\beta\mathcal{R}} B$.

In this paper, we assume that the relation $\longrightarrow^{1}_{\beta\mathcal{R}}$ is confluent and has the subject reduction property. Confluence and subject reduction are indeed needed to build models and prove termination of proof reduction. This is consistent with the methodology proposed in [2]: first prove confluence and subject reduction, then termination.

2.3 Examples of theories

Simple type theory can be expressed in Deduction modulo theory [10]. The main idea in this presentation is to distinguish terms of type o from propositions. If t is a term of type o, the corresponding proposition is written $\varepsilon(t)$. The term t is a *propositional content* or a *code* of the proposition $\varepsilon(t)$. This way, it is not possible to quantify over propositions, but it is possible to quantify over codes of propositions: there is no proposition $\forall X\ (X \Rightarrow X)$, but there is a proposition $\forall x\ (\varepsilon(x) \Rightarrow \varepsilon(x))$, respecting the syntax of Predicate logic, where the predicate symbol ε is applied to the variable x to form a proposition. In this presentation,

$$
\begin{array}{rcl}
type & : & Type \\
\iota & : & type \\
o & : & type \\
arrow & : & type \to type \to type \\
\eta & : & type \to Type \\
\Rightarrow & : & (\eta\ o) \to (\eta\ o) \to (\eta\ o) \\
\forall & : & \Pi a : type\ (((\eta\ a) \to (\eta\ o)) \to (\eta\ o)) \\
\varepsilon & : & (\eta\ o) \to Type \\
 & & \\
(\eta\ (arrow\ x\ y)) & \longrightarrow & (\eta\ x) \to (\eta\ y) \\
(\varepsilon\ (\Rightarrow\ x\ y)) & \longrightarrow & (\varepsilon\ x) \to (\varepsilon\ y) \\
(\varepsilon\ (\forall\ x\ y)) & \longrightarrow & \Pi z : (\eta\ x)\ (\varepsilon\ (y\ z))
\end{array}
$$

Figure 3 Simple type theory with a parametric quantifier.

each simple type is a sort and, for each simple type A, there is a quantifier $\forall_A$. Thus, the language contains an infinite number of sorts and an infinite number of constants.

This presentation can be adapted to the λΠ-calculus modulo theory. To avoid declaring an infinite number of constants for simple types, we can just declare two constants ι and o of type $Type$ and use the product of the λΠ-calculus modulo theory to represent the simple types $\iota \to \iota$, $\iota \to \iota \to \iota$, $\iota \to o$... We should declare an infinite number of quantifiers $\forall_A$, indexed by simple types, but this can be avoided as, in each specific proof, only a finite number of such quantifiers occur. This leads to the theory presented in Figure 2.

Another possibility is to add the type A as an extra argument of the quantifier $\forall$. To do so, we need to introduce a type $type$ for codes of simple types, two constants ι and o, of type $type$, and not $Type$, a constant $arrow$ of type $type \to type \to type$, and a decoding function η of type $type \to Type$. This way, the quantifier $\forall$ can be given the type $\Pi a : type\ (((\eta\ a) \to (\eta\ o)) \to (\eta\ o))$. This leads to the theory presented in Figure 3.

The Calculus of constructions [7] can also be expressed in the λΠ-calculus modulo theory [8] as the theory presented in Figure 4.

3 Algebras and Models

3.1 Π-algebras

The notion of Π-algebra is an adaptation of that of pre-Heyting algebra to the λΠ-calculus.

▶ **Definition 4** (Π-algebra)**.** A Π-algebra is formed with

- a set $\mathcal{B}$,
- a pre-order relation $\leq$ on $\mathcal{B}$,
- an element $\tilde{\top}$ of $\mathcal{B}$,
- a function $\tilde{\wedge}$ from $\mathcal{B} \times \mathcal{B}$ to $\mathcal{B}$,
- a subset $\mathcal{A}$ of $\mathcal{P}^+(\mathcal{B})$, the set of non-empty subsets of $\mathcal{B}$,
- a function $\tilde{\Pi}$ from $\mathcal{B} \times \mathcal{A}$ to $\mathcal{B}$,

such that

- $\tilde{\top}$ is a maximal element for $\leq$, that is for all a in $\mathcal{B}$, $a \leq \tilde{\top}$,
- $a\ \tilde{\wedge}\ b$ is a greatest lower bound of $\{a, b\}$ for $\leq$, that is $a\ \tilde{\wedge}\ b \leq a$, $a\ \tilde{\wedge}\ b \leq b$, and for all c, if $c \leq a$ and $c \leq b$, then $c \leq a\ \tilde{\wedge}\ b$,
- $a \leq \tilde{\Pi}(b, S)$ if and only if for all c in S, $a\ \tilde{\wedge}\ b \leq c$.

A Π-algebra is *full* if $\mathcal{A} = \mathcal{P}^+(\mathcal{B})$, that is if $\tilde{\Pi}$ is total on $\mathcal{B} \times \mathcal{P}^+(\mathcal{B})$.

$$
\begin{array}{rcl}
type & : & Type \\
o & : & type \\
\eta & : & type \to Type \\
\varepsilon & : & (\eta\ o) \to Type \\
\dot{\Pi}_{KK} & : & \Pi x : type\ (((\eta\ x) \to type) \to type) \\
\dot{\Pi}_{TT} & : & \Pi x : (\eta\ o)\ (((\varepsilon\ x) \to (\eta\ o)) \to (\eta\ o)) \\
\dot{\Pi}_{KT} & : & \Pi x : type\ (((\eta\ x) \to (\eta\ o)) \to (\eta\ o)) \\
\dot{\Pi}_{TK} & : & \Pi x : (\eta\ o)\ (((\varepsilon\ x) \to type) \to type)
\end{array}
$$

$$
\begin{array}{rcl}
(\eta\ (\dot{\Pi}_{KK}\ x\ y)) & \longrightarrow & \Pi z : (\eta\ x)\ (\eta\ (y\ z)) \\
(\varepsilon\ (\dot{\Pi}_{TT}\ x\ y)) & \longrightarrow & \Pi z : (\varepsilon\ x)\ (\varepsilon\ (y\ z)) \\
(\varepsilon\ (\dot{\Pi}_{KT}\ x\ y)) & \longrightarrow & \Pi z : (\eta\ x)\ (\varepsilon\ (y\ z)) \\
(\eta\ (\dot{\Pi}_{TK}\ x\ y)) & \longrightarrow & \Pi z : (\varepsilon\ x)\ (\eta\ (y\ z))
\end{array}
$$

Figure 4 The Calculus of constructions.

Note that is the relation $\leq$ is a pre-order, and not necessarily an order, greatest lower bounds are not necessarily unique, when they exist.

Note also that, from the operation $\tilde{\Pi}$, we can define an exponentiation operation $b \tilde{\to} c = \tilde{\Pi}(b, \{c\})$ that verifies the usual properties of exponentiation: $a \leq b \tilde{\to} c$ if and only if $a\ \tilde{\wedge}\ b \leq c$. When the set S has a greatest lower bound $\tilde{\bigwedge} S$, the operation mapping b and S to $b \tilde{\to} \tilde{\bigwedge} S$ verifies the same properties as $\tilde{\Pi}$: $a \leq b \tilde{\to} \tilde{\bigwedge} S$ if and only if $a\ \tilde{\wedge}\ b \leq \tilde{\bigwedge} S$ if and only if for all c in S, $a\ \tilde{\wedge}\ b \leq c$. But this decomposition is possible only when all sets of $\mathcal{A}$ have greatest lower bounds.

▶ **Example 5.** The algebra $\langle \{0,1\}, 1, \tilde{\wedge}, \mathcal{P}^+(\{0,1\}), \tilde{\Pi} \rangle$, where $\tilde{\wedge}$ and $\tilde{\Pi}$ are defined by the tables below, is a Π-algebra. Note that, dropping the middle column of the table of $\tilde{\Pi}$, we get the table of implication and, dropping the first line, that of the universal quantifier.

$\tilde{\wedge}$	0	1
0	0	0
1	0	1

$\tilde{\Pi}$	$\{0\}$	$\{0,1\}$	$\{1\}$
0	1	1	1
1	0	0	1

3.2 Models valued in a Π-algebra $\mathcal{B}$

▶ **Definition 6** (Model). A *model* is a family of interpretation functions $\mathcal{D}^1, ..., \mathcal{D}^n$ such that for all i, $\mathcal{D}^i$ is a function mapping each term t of type B in some context Γ, function ϕ_1 mapping each variable $x : A$ of Γ to an element of $\mathcal{D}^1_A$, ..., and function ϕ_{i-1} mapping each variable $x : A$ of Γ to an element of $\mathcal{D}^{i-1}_{A,\phi_1,...,\phi_{n-2}}$, to some $\mathcal{D}^i_{t,\phi_1,...,\phi_{i-1}}$ in $\mathcal{D}^{i-1}_{B,\phi_1,...,\phi_{i-2}}$, and for all t, u, ϕ_1, ..., ϕ_{n-1}

$$\mathcal{D}^n_{(u/x)t,\phi_1,...,\phi_{n-1}} = \mathcal{D}^n_{t,(\phi_1,x=\mathcal{D}^1_u),...,(\phi_{n-1},x=\mathcal{D}^{n-1}_{u,\phi_1,...,\phi_{n-2}})}$$

For the last function $\mathcal{D}^n$, we write $[\![t]\!]_{\phi_1,...,\phi_{n-1}}$ instead of $\mathcal{D}^n_{t,\phi_1,...,\phi_{n-1}}$.

In the examples presented in this paper, we use the cases $n = 2$ and $n = 3$ only. The general definition then specializes as follows.

▶ **Example 7.** When $n = 2$, a model is given by two functions $\mathcal{M}$ and $[\![.]\!]$ such that
- $\mathcal{M}$ is a function mapping each term t of type B in Γ to some $\mathcal{M}_t$,
- $[\![.]\!]$ is a function mapping each term t of type B in Γ and function ϕ mapping each variable $x : A$ of Γ to an element of $\mathcal{M}_A$, to some $[\![t]\!]_\phi$ in $\mathcal{M}_B$, such that for all t, u and ϕ

$$[\![(u/x)t]\!]_\phi = [\![t]\!]_{\phi, x=[\![u]\!]_\phi}.$$

This generalizes of the usual definition of *model* for many-sorted predicate logic.

Note that if f is a constant of type $A \to A \to A$, we can define the function $\hat{f}$ mapping a and b in $\mathcal{M}_A$ to $[\![(f\ x\ y)]\!]_{x=a,y=b}$. Using the property $[\![(u/x)t]\!]_\phi = [\![t]\!]_{\phi,x=[\![u]\!]_\phi}$, we then get $[\![(f\ t\ u)]\!]_\phi = \hat{f}([\![t]\!]_\phi, [\![u]\!]_\phi)$, which is the usual definition of an interpretation.

Note also that the first interpretation function $\mathcal{M}$ does not depend on any valuation, so it must be very rudimentary. For instance in Definition 15 below, for all objects and most types, we have $\mathcal{M}_t = \{e\}$. Only the types o, $o \to o$... are interpreted in a non trivial way. Nevertheless, it is sufficient to support the definition of the function $[\![.]\!]$.

▶ **Example 8.** When $n = 3$, a model is given by three functions $\mathcal{N}$, $\mathcal{M}$, and $[\![.]\!]$ such that
- $\mathcal{N}$ is a function mapping each term t of type B in Γ to some $\mathcal{N}_t$,
- $\mathcal{M}$ is a function mapping each term t of type B in Γ and function ψ mapping each variable $x : A$ of Γ to an element of $\mathcal{N}_A$, to some $\mathcal{M}_{t,\psi}$ in $\mathcal{N}_B$,
- $[\![.]\!]$ is a function mapping each term t of type B in Γ, function ψ mapping each variable $x : A$ of Γ to an element of $\mathcal{N}_A$, and function ϕ mapping each variable $x : A$ of Γ to an element of $\mathcal{M}_{A,\psi}$, to some $[\![t]\!]_{\psi,\phi}$ in $\mathcal{M}_{B,\psi}$, such that for all t, u, ψ, and ϕ

$$[\![(u/x)t]\!]_{\psi,\phi} = [\![t]\!]_{(\psi, x=\mathcal{M}_{u,\psi}),(\phi, x=[\![u]\!]_{\psi,\phi})}.$$

▶ **Definition 9** (Model valued in a Π-algebra $\mathcal{B}$)**.** Let $\mathcal{B} = \langle \mathcal{B}, \tilde{\top}, \tilde{\wedge}, \mathcal{A}, \tilde{\Pi} \rangle$ be a Π-algebra. A model is *valued in* $\mathcal{B}$ if
- $\mathcal{D}^{n-1}_{Kind,\phi_1,...,\phi_{n-2}} = \mathcal{D}^{n-1}_{Type,\phi_1,...,\phi_{n-2}} = \mathcal{B}$,
- $[\![Kind]\!]_{\phi_1,...,\phi_{n-1}} = [\![Type]\!]_{\phi_1,...,\phi_{n-1}} = \tilde{\top}$,
- $[\![\Pi x : C\ D]\!]_{\phi_1,...,\phi_{n-1}} = \tilde{\Pi}([\![C]\!]_{\phi_1,...,\phi_{n-1}}, \{[\![D]\!]_{(\phi_1,x=c_1),...,(\phi_{n-1},x=c_{n-1})} \mid c_1 \in \mathcal{D}^1_C, ..., c_{n-1} \in \mathcal{D}^{n-1}_{C,\phi_1,...,\phi_{n-2}}\})$.

We often write $\overline{\phi}$ for a sequence $\phi_1, ..., \phi_n$ and, if $\overline{c} = c_1, ..., c_n$, we write $\overline{\phi}, x = \overline{c}$ for the sequence $(\phi_1, x = c_1), ..., (\phi_n, x = c_n)$.

▶ **Definition 10** (Validity)**.** A model $\mathcal{M}$ valued in some Π-algebra $\mathcal{B}$ is *model* of a theory $\Sigma, \mathcal{R}$, or the theory is *valid* in the model, if
- for all constants $c : A$ in Σ, we have $[\![A]\!] \geq \tilde{\top}$,
- and for all A and B well-typed in a context Γ, such that $A \equiv_{\beta\mathcal{R}} B$, we have for all i, for all $\overline{\phi}$, $\mathcal{D}^i_{A,\overline{\phi}} = \mathcal{D}^i_{B,\overline{\phi}}$.

▶ **Theorem 11** (Soundness)**.** *Let $\mathcal{M}$ be a model, valued in some Π-algebra $\mathcal{B}$, of a theory $\Sigma, \mathcal{R}$. Then, for all judgments $x_1 : A_1, ..., x_p : A_p \vdash t : B$ derivable in $\Sigma, \mathcal{R}$, and for all $\overline{\phi}$, we have*

$$[\![A_1]\!]_{\overline{\phi}} \tilde{\wedge} ... \tilde{\wedge} [\![A_p]\!]_{\overline{\phi}} \leq [\![B]\!]_{\overline{\phi}}.$$

▶ **Corollary 12** (Consistency)**.**
- *Let $\mathcal{M}$ be a model, valued in some Π-algebra $\mathcal{B}$, of a theory $\Sigma, \mathcal{R}$. Then, for all judgments $\vdash t : B$ derivable in $\Sigma, \mathcal{R}$, we have $[\![B]\!]_{\overline{\phi}} \geq \tilde{\top}$.*

- *Let $\mathcal{M}$ be a model, valued in the two-element* Π*-algebra of Example 5, of a theory* $\Sigma, \mathcal{R}$*. Then, for all judgments* $\vdash t : B$*, derivable in this theory, we have* $[\![B]\!]_{\overline{\phi}} = 1$*.*
- *Let* $\Sigma, \mathcal{R}$ *be a theory that has a model, valued in the two-element* Π*-algebra of Example 5. Then, there is no term* t *such that the judgment* $P : Type \vdash t : P$ *is derivable in* Σ, Γ*.*

4 Super-consistency

4.1 Super-consistency

We now want to define a notion of notion of *super-consistency*: a theory is super-consistent if for every Π-algebra, there exists a model of this theory valued in this algebra.

Unfortunately, this constraint is sometimes too strong, as it does not allow to define interpretations as fixed points, for instance if we have a rule $P \longrightarrow ((P \Rightarrow Q) \Rightarrow Q)$, we want to define the interpretation of P as the fixed point of the function mapping b to $(b \mathrel{\tilde{\Rightarrow}} a) \mathrel{\tilde{\Rightarrow}} a$, where a is the interpretation of Q, but this function does not have a fixed point in all Π-algebras. Thus, we weaken this constraint, requiring the existence of model for *complete* Π-algebras only. Defining this notion of completeness requires to introduce an order relation $\sqsubseteq$, that need not be related to the pre-order $\leq$.

▶ **Definition 13** (Ordered, complete Π-algebra)**.** A Π-algebra is *ordered* if it is equipped with an order relation $\sqsubseteq$ such that the operation $\tilde{\Pi}$ is left anti-monotonic and right monotonic with respect to $\sqsubseteq$, that is

- if $a \sqsubseteq b$, then for all S, $\tilde{\Pi}(b, S) \sqsubseteq \tilde{\Pi}(a, S)$,
- if $S \sqsubseteq T$, then for all a, $\tilde{\Pi}(a, S) \sqsubseteq \tilde{\Pi}(a, T)$,

where the relation $\sqsubseteq$ is extended to sets of elements of $\mathcal{B}$ in a trivial way: $S \sqsubseteq T$ if for all a in S, there exists a b in T such that $a \sqsubseteq b$.

It is *complete* if every subset of $\mathcal{B}$ has a least upper bound for the relation $\sqsubseteq$.

▶ **Definition 14** (Super-consistency)**.** A theory $\Sigma, \mathcal{R}$, is *super-consistent* if, for every full, ordered and complete Π-algebra $\mathcal{B}$, there exists a model $\mathcal{M}$, valued in $\mathcal{B}$, of $\Sigma, \mathcal{R}$.

We now prove that the three theories presented in Section 2.3 are super-consistent.

4.2 Simple type theory

Let $\mathcal{B} = \langle \mathcal{B}, \tilde{\top}, \tilde{\wedge}, \mathcal{P}^+(\mathcal{B}), \tilde{\Pi} \rangle$ be a full Π-algebra. We construct a model of Simple type theory, valued in $\mathcal{B}$, in two steps. The first is the construction of the interpretation function $\mathcal{M}$ and the second the construction of the interpretation function $[\![.]\!]$. The key idea in this construction is to take $\mathcal{M}_o = \mathcal{B}$, to interpret ε as the identity over $\mathcal{B}$, and $\Rightarrow$ like $\rightarrow$ in order to validate the rewrite rule

$$\varepsilon\ (\Rightarrow\ \ x\ y) \longrightarrow (\varepsilon\ x) \rightarrow (\varepsilon\ y)\,.$$

Let S and T be two sets, we write $\mathcal{F}(S, T)$ for the set of functions from S to T. Let $\{e\}$ be an arbitrary one-element set such that e is not in $\mathcal{B}$.

▶ **Definition 15** (A model of Simple type theory)**.**

- $\mathcal{M}_{Kind} = \mathcal{M}_{Type} = \mathcal{B}$,
- $\mathcal{M}_{\Pi x:C\ D} = \mathcal{F}(\mathcal{M}_C, \mathcal{M}_D)$, except if $\mathcal{M}_D = \{e\}$, in which case $\mathcal{M}_{\Pi x:C\ D} = \{e\}$,
- $\mathcal{M}_\iota = \mathcal{M}_\Rightarrow = \mathcal{M}_{\forall_A} = \mathcal{M}_\varepsilon = \{e\}$,
- $\mathcal{M}_o = \mathcal{B}$,

- $\mathcal{M}_x = \{e\}$,
- $\mathcal{M}_{\lambda x:C\ t} = \mathcal{M}_t$,
- $\mathcal{M}_{(t\ u)} = \mathcal{M}_t$.

- $[\![Kind]\!]_\phi = [\![Type]\!]_\phi = \tilde{\top}$,
- $[\![\Pi x : C\ D]\!]_\phi = \tilde{\Pi}([\![C]\!]_\phi, \{[\![D]\!]_{\phi,x=c} \mid c \in \mathcal{M}_C\})$,
- $[\![\iota]\!]_\phi = \tilde{\top}$,
- $[\![o]\!]_\phi = \tilde{\top}$,
- $[\![\Rightarrow]\!]_\phi$ is the function mapping a and b in $\mathcal{B}$ to $\tilde{\Pi}(a, \{b\})$,
- $[\![\forall_C]\!]_\phi$ is the function mapping f in $\mathcal{F}(\mathcal{M}_C, \mathcal{B})$ to $\tilde{\Pi}([\![C]\!]_\phi, \{(f\ c) \mid c \in \mathcal{M}_C\})$,
- $[\![\varepsilon]\!]_\phi$ is the identity on $\mathcal{B}$,
- $[\![x]\!]_\phi = \phi x$,
- $[\![\lambda x : C\ t]\!]_\phi$ is the function mapping c in $\mathcal{M}_C$ to $[\![t]\!]_{\phi,x=c}$, except if for all c in $\mathcal{M}_C$, $[\![t]\!]_{\phi,x=c} = e$ in which case $[\![\lambda x : C\ t]\!]_\phi = e$,
- $[\![(t\ u)]\!]_\phi = [\![t]\!]_\phi\ [\![u]\!]_\phi$, except if $[\![t]\!]_\phi = e$, in which case $[\![(t\ u)]\!]_\phi = e$.

We prove that if $\Gamma \vdash t : B$, and ϕ is a function mapping variables $x : A$ of Γ to elements of $\mathcal{M}_A$, then $[\![t]\!]_\phi \in \mathcal{M}_B$. That for all t, u and ϕ, $[\![(u/x)t]\!]_\phi = [\![t]\!]_{\phi,x=[\![u]\!]_\phi}$. And that if $t \equiv_{\beta\mathcal{R}} u$ then $\mathcal{M}_t = \mathcal{M}_u$ and $[\![t]\!]_\phi = [\![u]\!]_\phi$. We thus get the following theorem.

▶ **Theorem 16.** *Simple type theory is super-consistent.*

4.3 Simple type theory with a parametric quantifier

In a model of Simple type theory with a parametric quantifier, like in the previous section, we want to take $\mathcal{M}_o = \mathcal{B}$. But, unlike in the previous section, we do not have $o : Type$, but $o : type : Type$. So o is now an object.

In the previous section, we took $\mathcal{M}_t = \{e\}$ for all objects. This permitted to define $\mathcal{M}_{(t\ u)}$ and $\mathcal{M}_{\lambda x:C\ t}$ as $\mathcal{M}_t$ and validate β-reduction trivially. But this is not possible anymore in Simple type theory with a parametric quantifier, where $\mathcal{M}_o$ is $\mathcal{B}$ and $\mathcal{M}_{arrow(o,o)}$ is $\mathcal{F}(\mathcal{B}, \mathcal{B})$. So, we cannot define $\mathcal{M}_{\lambda x:type\ x}$ to be $\mathcal{M}_x$, but we need to define it as a function. To help to construct this function, we need to construct first another interpretation function $(\mathcal{N}_t)_t$ and parametrize the definition of $\mathcal{M}_t$ itself by a function ψ mapping variables of type A to elements of $\mathcal{N}_A$. Thus the model is a three layer model.

Like in the previous section, we want to define $\mathcal{M}_{\Pi x:C\ D,\psi}$, as the set of functions from $\mathcal{M}_{C,\psi}$ to $\mathcal{M}_{D,\psi'}$. But to define this set $\mathcal{M}_{D,\psi'}$, we need to extend the function ψ, mapping x to an element of $\mathcal{N}_C$. To have such an element of $\mathcal{N}_C$, we need to define $\mathcal{M}_{\Pi x:C\ D,\psi}$ as the set of functions mapping $\langle c', c\rangle$ in $\mathcal{N}_C \times \mathcal{M}_{C,\psi}$ to an element of $\mathcal{M}_{D,(\psi,x=c')}$. As a consequence, if ϕ is a function mapping x of type A to some element of $\mathcal{M}_A$, we need to define $[\![(t\ u)]\!]_\phi$ not as $[\![t]\!]_\phi\ [\![u]\!]_\phi$ but as $[\![t]\!]_\phi\ \langle \mathcal{M}_{u,\psi}, [\![u]\!]_\phi\rangle$. As a consequence $[\![.]\!]$ must be parametrized by both ψ and ϕ.

Let $\mathcal{B} = \langle \mathcal{B}, \tilde{\top}, \tilde{\wedge}, \mathcal{P}^+(\mathcal{B}), \tilde{\Pi}\rangle$ be a full Π-algebra.

Let $\{e\}$ be an arbitrary one-element set. Let $\mathcal{U}$ be a set containing $\mathcal{B}$ and $\{e\}$, and closed by function space and Cartesian product, that is such that if S and T are in $\mathcal{U}$ then so are $S \times T$ and $\mathcal{F}(S, T)$. Such a set can be constructed, with the replacement scheme, as follows

$$\begin{aligned} \mathcal{U}_0 &= \{\mathcal{B}, \{e\}\}, \\ \mathcal{U}_{n+1} &= \mathcal{U}_n \cup \{S \times T \mid S, T \in \mathcal{U}_n\} \cup \{\mathcal{F}(S, T) \mid S, T \in \mathcal{U}_n\}, \\ \mathcal{U} &= \bigcup_n \mathcal{U}_n. \end{aligned}$$

Then, let $\mathcal{V}$ be the smallest set containing $\{e\}$, $\mathcal{B}$, and $\mathcal{U}$, and closed by Cartesian product and dependent function space, that is, if S is in $\mathcal{V}$ and T is a family of elements of $\mathcal{V}$ indexed by S, then the set of functions mapping an element s of S to an element of T_s is an element of $\mathcal{V}$. As noted in [19], the construction of the set $\mathcal{V}$, unlike that of $\mathcal{U}$, requires an inaccessible cardinal. Note that $\mathcal{U}$ is both an element and a subset of $\mathcal{V}$.

▶ **Definition 17** (A model of Simple type theory with a parametric quantifier)**.**

- $\mathcal{N}_{Type} = \mathcal{N}_{Kind} = \mathcal{V}$,
- $\mathcal{N}_{\Pi x:C\ D}$ is the set $\mathcal{F}(\mathcal{N}_C, \mathcal{N}_D)$, except if $\mathcal{N}_D = \{e\}$, in which case $\mathcal{N}_{\Pi x:C\ D} = \{e\}$,
- $\mathcal{N}_{type} = \mathcal{U}$,
- $\mathcal{N}_\iota = \mathcal{N}_o = \mathcal{N}_{arrow} = \mathcal{N}_\Rightarrow = \mathcal{N}_\forall = \mathcal{N}_\eta = \mathcal{N}_\varepsilon = \{e\}$,
- $\mathcal{N}_x = \{e\}$,
- $\mathcal{N}_{\lambda x:C\ t} = \mathcal{N}_t$,
- $\mathcal{N}_{(t\ u)} = \mathcal{N}_t$.

- $\mathcal{M}_{Kind,\psi} = \mathcal{M}_{Type,\psi} = \mathcal{B}$,
- $\mathcal{M}_{\Pi x:C\ D,\psi,\phi}$ is the set of functions f mapping $\langle c', c\rangle$ in $\mathcal{N}_C \times \mathcal{M}_{C,\psi}$ to an element of $\mathcal{M}_{D,(\psi,x=c')}$, except if for all c' in $\mathcal{N}_C$, $\mathcal{M}_{D,(\psi,x=c')} = \{e\}$, in which case $\mathcal{M}_{\Pi x:C\ D,\psi} = \{e\}$,
- $\mathcal{M}_{type,\psi} = \mathcal{B}$,
- $\mathcal{M}_{\eta,\psi}$ is the function of $\mathcal{F}(\mathcal{U}, \mathcal{V})$ mapping S to S,
- $\mathcal{M}_{\varepsilon,\psi}$ is the function of $\mathcal{F}(\{e\}, \mathcal{V})$, mapping e to $\{e\}$,
- $\mathcal{M}_{\iota,\psi} = \{e\}$,
- $\mathcal{M}_{o,\psi} = \mathcal{B}$,
- $\mathcal{M}_{arrow,\psi}$ is the function mapping S and T in $\mathcal{U}$ to the set $\mathcal{F}(\{e\} \times S, T)$, except if $T = \{e\}$ in which case it maps S and T to $\{e\}$,
- $\mathcal{M}_{\Rightarrow,\psi} = \mathcal{M}_{\forall,\psi} = e$,
- $\mathcal{M}_{x,\psi} = \psi x$,
- $\mathcal{M}_{\lambda x:C\ t,\psi}$ is the function mapping c in $\mathcal{N}_C$ to $\mathcal{M}_{t,(\psi,x=c)}$, except if for all c in $\mathcal{N}_C$, $\mathcal{M}_{t,(\psi,x=c)} = e$, in which case $\mathcal{M}_{\lambda x:C\ t,\psi} = e$,
- $\mathcal{M}_{(t\ u),\psi} = \mathcal{M}_{t,\psi}\ \mathcal{M}_{u,\psi}$, except if $\mathcal{M}_{t,\psi} = e$ in which case $\mathcal{M}_{(t\ u),\psi} = e$.

- $[\![Kind]\!]_{\psi,\phi} = [\![Type]\!]_{\psi,\phi} = \tilde{\top}$,
- $[\![\Pi x : C\ D]\!]_{\psi,\phi} = \tilde{\Pi}([\![C]\!]_{\psi,\phi}, \{[\![D]\!]_{(\psi,x=c'),(\phi,x=c)} \mid c' \in \mathcal{N}_C, c \in \mathcal{M}_{C,\psi}\})$,
- $[\![type]\!]_{\psi,\phi} = \tilde{\top}$,
- $[\![\iota]\!]_{\psi,\phi} = \tilde{\top}$,
- $[\![o]\!]_{\psi,\phi} = \tilde{\top}$,
- $[\![arrow]\!]_{\psi,\phi}$ is the function from $\mathcal{U} \times \mathcal{B}$ and $\mathcal{U} \times \mathcal{B}$ to $\mathcal{B}$ mapping $\langle S, a\rangle$ and $\langle T, b\rangle$ to $\tilde{\Pi}(a, \{b\})$,
- $[\![\Rightarrow]\!]_{\psi,\phi}$ is the function $\{e\} \times \mathcal{B}$ and $\{e\} \times \mathcal{B}$ to $\mathcal{B}$ mapping $\langle e, a\rangle$ and $\langle e, b\rangle$ to $\tilde{\Pi}(a, \{b\})$,
- $[\![\forall]\!]_{\psi,\phi}$ is the function mapping $\langle S, a\rangle$ in $\mathcal{U} \times \mathcal{B}$, and $\langle e, g\rangle$ in $\{e\} \times \mathcal{F}(\{e\} \times S, \mathcal{B})$ to $\tilde{\Pi}(a, \{(g\ \langle e, s\rangle) \mid s \in S\})$,
- $[\![\eta]\!]_{\psi,\phi}$ is the function from $\mathcal{U} \times \mathcal{B}$ to $\mathcal{B}$, mapping $\langle S, a\rangle$ to a,
- $[\![\varepsilon]\!]_{\psi,\phi}$ is the function from $\{e\} \times \mathcal{B}$ to $\mathcal{B}$, mapping $\langle e, a\rangle$ to a,
- $[\![x]\!]_{\psi,\phi} = \phi x$,
- $[\![\lambda x : C\ t]\!]_{\psi,\phi}$ is the function mapping $\langle c', c\rangle$ in $\mathcal{N}_C \times \mathcal{M}_{C,\psi}$ to $[\![t]\!]_{(\psi,x=c'),(\phi,x=c)}$, except if for all $\langle c', c\rangle$ in $\mathcal{N}_C \times \mathcal{M}_{C,\psi}$, $[\![t]\!]_{(\psi,x=c'),(\phi,x=c)} = e$, in which case $[\![\lambda x : C\ t]\!]_{\psi,\phi} = e$,
- $[\![(t\ u)]\!]_{\psi,\phi} = [\![t]\!]_{\psi,\phi}\ \langle \mathcal{M}_{u,\psi}, [\![u]\!]_{\psi,\phi}\rangle$, except if $[\![t]\!]_{\psi,\phi} = e$, in which case $[\![(t\ u)]\!]_{\psi,\phi} = e$.

We prove that if $\Gamma \vdash t : B$ and ψ is a function mapping the variables $x : A$ of Γ to elements of $\mathcal{N}_A$, then $\mathcal{M}_{t,\psi} \in \mathcal{N}_B$. That if $\Gamma \vdash t : B$, ψ is a function mapping variables $x : A$ of Γ to elements of $\mathcal{N}_A$, and ϕ is a function mapping variables $x : A$ of Γ to elements of $\mathcal{M}_{A,\psi}$, then $[\![t]\!]_{\psi,\phi} \in \mathcal{M}_{B,\psi}$ and $[\![(u/x)t]\!]_{\psi,\phi} = [\![t]\!]_{\psi,x=\mathcal{M}_{u,\psi}\phi,x=[\![u]\!]_{\psi,\phi}}$. And that if $t \equiv_{\beta\mathcal{R}} u$ then $\mathcal{N}_t = \mathcal{N}_u$, $\mathcal{M}_{t,\psi} = \mathcal{M}_{u,\psi}$, and $[\![t]\!]_{\psi,\phi} = [\![u]\!]_{\psi,\phi}$. We thus get the following theorem.

▶ **Theorem 18.** *Simple type theory with a parametric quantifier is super-consistent.*

Note that the set $\mathcal{V}$, thus an inaccessible cardinal, are not really needed to prove the super-consistency of Simple type theory with a parametric quantifier if we can adapt the notion of model in such a way that the family $\mathcal{N}$ is defined for type families only. The systematic development of this notion of partial interpretation is left for future work.

A similar proof for the Calculus of constructions is given in the long version of the paper.

5 Termination of proof reduction

We finally prove that proof reduction terminates in the λΠ-calculus modulo any super-consistent theory.

In Deduction modulo theory, we can define a congruence with non terminating rewrite rules, without affecting the termination of proof reduction. For instance, the rewrite rule $c \longrightarrow c$ does not terminate, but the congruence it defines is the identity and proofs modulo this congruence are just proofs in pure Predicate logic. Thus, proof reduction in Deduction modulo this congruence terminates. So, in the λΠ-calculus modulo this congruence, the β-reduction terminates, but the $\beta\mathcal{R}$-reduction does not, as the $\mathcal{R}$-reduction alone does not terminate. Here, we restrict to prove the termination of β-reduction, not $\beta\mathcal{R}$-reduction. In some cases, like for the three theories presented above, the termination of the $\beta\mathcal{R}$-reduction is a simple corollary of the termination of the β-reduction. In some others, it is not.

The main notion used in this proof is that of *reducibility candidate* introduced by Girard [15]. Our inductive definition, however, follows that of Parigot [22].

▶ **Definition 19** (Candidates). The set $\tilde{\top}$ is defined as the set of strongly terminating terms.

Let C be a set of terms and S be a set of sets of terms. The set $\tilde{\Pi}(C, S)$ is defined as the set of strongly terminating terms t such that if $t \longrightarrow^*_\beta \lambda x : A\ t'$ then for all t'' in C, and for all D in S, $(t''/x)t' \in D$.

Candidates are inductively defined by the three rules

- the set $\tilde{\top}$ of all strongly terminating terms is a candidate,
- if C is a candidate and S is a set of candidates, then $\tilde{\Pi}(C, S)$ is a candidate,
- if S is a non empty set of candidates, then $\bigcap S$ is a candidate.

We write $\mathcal{C}$ for the set of candidates. The algebra $\langle \mathcal{C}, \leq, \tilde{\top}, \tilde{\wedge}, \mathcal{P}^+(\mathcal{C}), \tilde{\Pi}\rangle$, where $\leq$ is the trivial relation such that $C \leq C'$ always, and $\tilde{\wedge}$ is any function from $\mathcal{C} \times \mathcal{C}$ to $\mathcal{C}$, for instance the constant function equal to $\tilde{\top}$, is a full Π-algebra. It is ordered by the subset relation and complete for this order. If C is a candidate, then all the elements of C strongly terminate.

Consider a super-consistent theory $\Sigma, \mathcal{R}$. We want to prove that β-reduction terminates in the λΠ-calculus modulo this theory.

As usual, we want to associate a candidate $[\![A]\!]$ to each term A in such a way that if t is a term of type A, then $t \in [\![A]\!]$. In the λΠ-calculus modulo theory, the main difficulty is to assign a candidates to terms in such a way that if $A \equiv B$ then $[\![A]\!] = [\![B]\!]$. For instance, if we have the rule $P \longrightarrow P \Rightarrow P$ that permits to type all lambda-terms, including non terminating ones, we should associate, to the term P, a candidate C such that $C = C \tilde{\Rightarrow} C$,

but there is no such candidate. For super-consistent theories, in contrast, such an assignment exists, as the theory has a model $\mathcal{M}$ valued in the Π-algebra $\langle \mathcal{C}, \leq, \tilde{\top}, \tilde{\wedge}, \mathcal{P}^+(\mathcal{C}), \tilde{\Pi} \rangle$. In this model, if t is a term of type B in some context Γ, then $[\![B]\!]_{\overline{\phi}}$ is a candidate.

We then prove that if Γ is a context, $\overline{\phi} = \phi_1, ..., \phi_n$ is be a sequence of valuations, σ is a substitution mapping every $x : A$ of Γ to an element of $[\![A]\!]_{\overline{\phi}}$ and t is a term of type B in Γ, then $\sigma t \in [\![B]\!]_{\overline{\phi}}$. We thus get the following theorem.

▶ **Theorem 20.** *In a super-consistent theory $\Sigma, \equiv$, all well-typed terms strongly terminate.*

Abstract

We analyse how the standard reductions between constraint satisfaction problems affect their proof complexity. We show that, for the most studied propositional and semi-algebraic proof systems, the classical constructions of pp-interpretability, homomorphic equivalence and addition of constants to a core preserve the proof complexity of the CSP. As a result, for those proof systems, the classes of constraint languages for which small unsatisfiability certificates exist can be characterised algebraically. We illustrate our results by a gap theorem saying that a constraint language either has resolution refutations of bounded width, or does not have bounded-depth Frege refutations of subexponential size. The former holds exactly for the widely studied class of constraint languages of bounded width. This class is also known to coincide with the class of languages with Sums-of-Squares refutations of sublinear degree, a fact for which we provide an alternative proof. We hence ask for the existence of a natural proof system with good behaviour with respect to reductions and simultaneously small size refutations beyond bounded width. We give an example of such a proof system by showing that bounded-degree Lovász-Schrijver satisfies both requirements.

1 Introduction

The notion of efficient reduction is at the heart of all subareas of computational complexity. However, in some subareas such as proof complexity, even though the concept exists, it is much less developed. The study of the lengths of proofs has developed mostly by studying combinatorial statements, each somewhat in isolation. There is little theory, for instance, explaining why the best studied families of propositional tautologies are encodings of the pigeonhole principle or those derived from systems of linear equations over the 2-element field. Whether there is any connection between the two is an even less explored mystery.

Luckily this fact is subject to revision, especially if proof complexity exports its methods to the study of problems beyond universal combinatorial statements. Consider the NP-hard optimization problem called MAX-CUT. The objective is to find a partition of the vertices

of a given graph which maximizes the number of edges that cross the partition. The best efficient approximation algorithm known for this problem relies on certifying a bound on the optimum of its semidefinite programming relaxation. Once the certificate for the relaxation is in place, a rounding procedure gives an approximate integral solution: at worst 87% of the optimum in this case [12].

In the example of the previous paragraph, the problem that is subject to proof complexity analysis is that of certifying a bound on the optimum of an arbitrary MAX-CUT instance. The celebrated Unique Games Conjecture (UGC) can be understood as a successful approach to explaining why current algorithms and proof complexity analyses stop being successful where they do, and reductions play an important role there [26]. One of the interesting open problems in this area is whether the analysis of the Sums-of-Squares semidefinite programming hierarchy of proof systems (SOS) could be used to improve over the 87% approximation ratio for MAX-CUT. Any improvement on this would improve the approximation status of all problems that reduce to it, and refute the UGC [16]. For the constraint satisfaction problem, in which all constraints must be satisfied, the analogue question was resolved very recently also by exploiting the theory of reducibility: in that arena, low-degree SOS unsatisfiability proofs exist only for problems of *bounded width* [11, 25].

The goal of this paper is to develop the standard theory of reductions between constraint satisfaction problems in a way that it applies to many of the proof systems from the literature, including but not limited to SOS. Doing this requires a good amount of tedious work, but at the same time has some surprises to offer that we discuss next.

Consider a constraint language B given by a finite domain of values, and relations over that domain. The instances of the constraint satisfaction problem (CSP) over B are given by a set of variables and a set of constraints, each of which binds some tuple of the variables to take values in one of the relations of B. The literature on CSPs has focussed on three different types of conditions that, if met by two constraint languages, give a reduction from the CSP of one language to the CSP of the other. These conditions are a) *pp-interpretability*, b) *homomorphic equivalence*, and c) *addition of constants to the core* (see [9, 5]). What makes these three types of reductions important is that they correspond to classical algebraic constructions at the level of the *algebras of polymorphisms* of the constraint languages. Indeed, pp-interpretations correspond to taking homomorphic images, subalgebras and powers. The other two types of reductions put together ensure that the algebra of the constraint language is idempotent. Thus, for any fixed algorithm, heuristic, or method $\mathcal{M}$ for deciding the satisfiability of CSPs, if the class of constraint languages that are solvable by $\mathcal{M}$ is closed under these notions of reducibility, then this class admits a purely algebraic characterization in terms of identities.

Our first result is that, for most proof systems P in the literature, each of these methods of reduction preserves the proof complexity of the problem with respect to proofs in P. Technically, what this means is that if B is obtained from B' by a finite number of constructions a), b) and c), then, for an appropriate fixed encoding scheme of the statement that an instance is unsatisfiable, efficient proofs of unsatisfiability in P for instances of B' translate into efficient proofs of unsatisfiability in P for instances of B. The propositional proof systems for which we prove this include DNF-resolution with terms of bounded size, bounded-depth Frege, and Frege. The semi-algebraic proof systems for which we prove it include Sherali-Adams, Lasserre/SOS, and Lovász-Schrijver of bounded and unbounded degree.

Our second main result is an application: we obtain unconditional gap theorems for the proof complexity of CSPs. Building on the bounded-width theorem for CSPs [4, 8], the

known correspondance between local consistency algorithms, existential pebble games and bounded width resolution [17, 2], the lower bounds for propositional and semi-algebraic proof systems [1, 19, 6, 7, 13, 10], and a modest amount of additional work to fill in the gaps, we prove the following strong gap theorem:

▶ **Theorem 1.** *Let B be a finite constraint language. Then exactly one of the following holds:*

1. *B has resolution refutations of bounded width and hence polynomial size,*
2. *B has neither Frege refutations of bounded depth and subexponential size, nor Lasserre/SOS refutations of sublinear degree.*

Moreover, case *1.* in Theorem 1 happens precisely if B has bounded width. As noted earlier, the collapse of Lasserre/SOS to bounded width was already known; here we give a different proof. As an immediate corollary we get that resolution is also captured by algebra, despite the fact that our methods fall short to prove that it is closed under reductions.

▶ **Corollary 2.** *Let B be a finite constraint language. Then B has resolution refutations of subexponential size if and only if B has resolution refutations of polynomial size, if and only if B has resolution refutations of bounded width.*

Our third main result is about proof systems that operate with polynomial inequalities beyond Lasserre/SOS. Theorem 1 raises a question of identifying a proof system that can surpass bounded width. In other words: is there a natural proof system for which the class of languages that have efficient unsatisfiability proofs is closed under the standard reducibility methods for CSPs, and that at the same time has efficient unsatisfiability proofs beyond bounded width? By the bounded-width theorem for CSPs, one way, and indeed the only way, of surpassing bounded width is by having efficient proofs of unsatisfiability for systems of linear equations over some finite Abelian group. In view of the limitations of certain semi-algebraic proof systems that are imposed by Theorem 1, it is perhaps a surprise that, as we show, bounded degree Lovász-Schrijver (LS) is such a proof system.

▶ **Theorem 3.** *Unsatisfiable systems of linear equations over the 2-element group have LS refutations of bounded degree and polynomial size.*

Proving this amounts to showing that Gaussian elimination over $\mathbb{Z}_2$ can be simulated by reasoning with low-degree polynomial inequalities over $\mathbb{R}$. The proof of this counter-intuitive fact relies on earlier work in proof complexity for reasoning about gaps of the type $(-\infty, c] \cup [c+1, +\infty)$, for $c \in \mathbb{Z}$, through quadratic polynomial inequalities [15].

We want to close by pointing out that another proof system that can efficiently solve CSPs of bounded width, and that at the same time goes beyond bounded width, is the proof system that operates with ordered binary decision diagrams from [3]. Although it looks unlikely that our methods could be used for this proof system, whether it is closed under the standard CSP reducibilities is something that was not checked, neither in [3], nor here.

2 Preliminaries

2.1 Propositional logic and proofs

A literal is a variable X or the negation of a variable $\overline{X}$. We think of $\wedge$ and $\vee$ as commutative, associative and idempotent. Negation is allowed only on literals, so formulas are in negation normal form. If A is a formula, we define its complement $\overline{A}$ by exchanging $\vee$ and $\wedge$ and negating literals. The size of a formula A is the number of symbols in it.

We work with a Tait-style proof system for propositional logic that we call *Frege*. Its rules are *axiom*, *cut*, *introduction of conjunction*, and *weakening*:

$$\frac{}{A \vee \overline{A}} \qquad \frac{C \vee A \quad D \vee \overline{A}}{C \vee D} \qquad \frac{C \vee A \quad D \vee B}{C \vee D \vee (A \wedge B)} \qquad \frac{C}{C \vee A}. \tag{1}$$

In these rules, C and D could be the empty formula 0 or its complement 1, and A is a formula. A *Frege proof* of A from a set of formulas H is a sequence of formulas ending with A each of which is either in H, or follows from previous formulas in the sequence by one of the inference rules. The proof is called a *refutation* of H if the last formula is the empty formula 0. As a proof system, Frege is sound and implicationally complete. If $\mathcal{C}$ is a class of formulas, a $\mathcal{C}$-Frege proof is one that has all its formulas in the class $\mathcal{C}$. The size of a proof is the sum of the sizes of the formulas in it.

A k-term is a conjunction of at most k literals and a k-clause is a disjunction of at most k literals. A k-DNF is a disjunction of k-terms and a k-CNF is a conjunction of k-clauses. We define the classes of $\Sigma_{t,k}$- and $\Pi_{t,k}$-formulas inductively. For $t = 1$, these are just the classes of k-DNF and k-CNF formulas, respectively. For $t \geq 2$, a formula is $\Sigma_{t,k}$ if it is a disjunction of $\Pi_{t-1,k}$-formulas, and it is $\Pi_{t,k}$ if it is a conjunction of $\Sigma_{t-1,k}$-formulas. We write Σ_t and Π_t for $\Sigma_{t,1}$ and $\Pi_{t,1}$, respectively. The t and the k in $\Sigma_{t,k}$ and $\Pi_{t,k}$ are called the *depth* and the *bottom fan-in*, respectively.

Observe that Σ_1-Frege is essentially resolution, and $\Sigma_{1,k}$-Frege is the system R(k) introduced by Krajicek [18], also known as Res(k), k-DNF resolution, and k-DNF Frege. This proof system is important for us because it is the weakest for which we can prove closure under reductions. It is a sound and implicationally complete proof system for proving k-DNFs from k-DNFs. A resolution proof has *width* k if all clauses in it are k-clauses.

In this paper, we use the expression *Frege proof of depth d and bottom fan-in k* to mean a $\Sigma_{d,k}$-Frege proof. *Bounded-depth Frege* means Σ_d-Frege for some d. This coincides with other definitions in the literature. Again, Frege of depth d and bottom fan-in k, as a proof system, is sound and implicationally complete for proving $\Sigma_{d,k}$-formulas from $\Sigma_{d,k}$-formulas.

2.2 Polynomials and algebraic proofs

Let $X_1, \ldots, X_n$ be n algebraic commuting variables ranging over $\mathbb{R}$. We define proof systems for inequalities $P \geq 0$, where P is a polynomial in $\mathbb{R}[X_1, \ldots, X_n]$. We think of equations $P = 0$ as two inequalities $P \geq 0$ and $-P \geq 0$. For our purposes it will suffice to have the variables range over $\{0, 1\}$. Accordingly, we introduce *twin* variables $\bar{X}_1, \ldots, \bar{X}_n$ with the meaning that $\bar{X}_i = 1 - X_i$ for $i = 1, \ldots, n$.

In all proof systems, the following axioms will be imposed on these variables:

$$X_i^2 - X_i = 0 \qquad \bar{X}_i^2 - \bar{X}_i = 0 \qquad X_i + \bar{X}_i - 1 = 0, \tag{2}$$

$$X_i \geq 0 \qquad \bar{X}_i \geq 0 \qquad 1 - X_i \geq 0 \qquad 1 - \bar{X}_i \geq 0 \qquad 1 \geq 0. \tag{3}$$

Observe that $X_i\bar{X}_i = 0$ follows from these axioms: multiply $X_i + \bar{X}_i - 1 = 0$ by X_i and use $X_i^2 - X_i = 0$. This sort of reasoning is captured by the proof systems we are about to define.

Let P and Q denote polynomials. In addition to the axioms in (2), we consider rules of inference for deriving polynomial inequalities: from $P \geq 0$ and $Q \geq 0$, derive $P + Q \geq 0$, and from $P \geq 0$ and $Q \geq 0$ derive $PQ \geq 0$. Also we allow square inequalities for free: $P^2 \geq 0$. These are called *addition*, *multiplication* and *positivity of squares*.

If H denotes a system of polynomial inequalities $P_1 \geq 0, \ldots, P_r \geq 0$, a *semi-algebraic proof* of $P \geq 0$ from H is a sequence of polynomial inequalities ending with $P \geq 0$ each of

which is either in H, or is an axiom inequality from (2) and (3), or follows from previous inequalities in the sequence by one of the inference rules. The semi-algebraic proof is called a *refutation* of H if the last inequality is $-1 \geq 0$. As a proof system for inequalities evaluated over $\{0,1\}$, this is sound and implicationally complete (we note, however, that without some restrictions on the domain of evaluation, completeness is not true).

The main complexity measures for semi-algebraic proofs are size and degree. Polynomials are typically represented as explicit sums of monomials, or as algebraic formulas or circuits. Using formulas or circuits as representations requires some additional technicalities that we want to avoid (see [22, 14]). For all our examples below, we use the representation of an explicit sum of monomials; its size includes the sizes of the coefficients.

The proofs in the *Lovász-Schrijver* (LS) proof system are semi-algebraic proofs for which the following restrictions apply: 1) the polynomial Q in the multiplication rule is either a positive real or a variable, and 2) the positivity-of-squares is not allowed. When it is allowed, the system is called *Positive Semidefinite Lovász-Schrijver* and is denoted LS$^+$. Originally the Lovász-Schrijver proof system was defined to manipulate quadratic polynomials only (see [21, 23]). We follow [15] and consider the extension to arbitrary degree. For LS- and LS$^+$-proofs, an important complexity measure originally studied by Lovász and Schrijver is its *rank*, which is the maximum nesting depth of multiplication by a variable in the proof. Note that, due to possible cancellations, the degree of an LS-proof could in principle be much smaller than its rank.

We define two additional proof systems called *Sherali-Adams* (SA) and *Lasserre/Sums-of-Squares* (SOS). One way to do that is by thinking of them as subsystems LS and LS$^+$ proof systems, respectively, with the additional restriction that all applications of the multiplication rule must *precede* all applications of the addition rule. Due to the structural restriction in which multiplications precede additions, we can think of a proof of $P \geq 0$ from H as a polynomial identity of the form

$$\sum_{i=1}^{r} c_i \cdot P_i \cdot \prod_{j \in J_i} X_j \prod_{k \in K_i} \bar{X}_k = P, \tag{4}$$

where $c_1, \ldots, c_r$ are non-negative real numbers, and $P_1, \ldots, P_r$ are polynomials such that either the inequality $P_i \geq 0$ is in the set of hypothesis H, or they are axiom polynomials from (2) and (3), or they are squares of polynomials, when these are allowed. Note that the size of an SA or SOS proof thought of as a semi-algebraic proof is polynomially related to the sum of the sizes of the non-zero c_i's in (4).

We close this section by noting the relationships between LS and SA proofs on one hand, and LS$^+$ and SOS proofs on the other. Clearly, each SA proof of degree d is also an LS proof of degree d. The converse is certainly not true, but what is true is that every LS proof of degree d and rank k can be converted into an SA proof of degree $d + k$, where the rank is the complexity measure for LS proofs that we defined earlier. The same relationships hold between LS$^+$ and SOS: every SOS-proof of degree d is an LS$^+$ of degree d, and every LS$^+$ proof of degree d and rank k can be converted into an SOS-proof of degree $d + k$. The conversions go by swapping the order in which the addition and the multiplication rules are applied in LS proofs, when they appear in the *wrong* order. See [20] for a related discussion.

2.3 Constraint satisfaction problem

There are many equivalent definitions of the constraint satisfaction problem. Here we use the definition in terms of homomorphisms. Below we introduce the necessary terminology.

A *relational vocabulary* L is a set of symbols, each symbol has an associated arity. A *structure* $\mathbb{B}$ over L is a set B, called a *domain* together with a set of relations over B. For each $R \in L$ or arity r, there is a relation $R(\mathbb{B}) \subseteq B^r$ sometimes called an *interpretation* of R in $\mathbb{B}$. We say that a relational structure is finite if its domain is finite and it has finitely many non-empty relations. For two structures $\mathbb{B}$ and $\mathbb{B}'$ over the same vocabulary L, a *homomorphism* from $\mathbb{B}$ to $\mathbb{B}'$ is a function $h\colon B \to B'$, which preserves all the relations, that is, if $(b_1, \ldots, b_r) \in R(\mathbb{B})$, then $(h(b_1), \ldots, h(b_r)) \in R(\mathbb{B}')$, for each $R \in L$.

For a fixed L-structure $\mathbb{B}$ over a relational vocabulary L, the constraint satisfaction problem of $\mathbb{B}$, denoted CSP($\mathbb{B}$), is the following computational problem: given a finite L-structure $\mathbb{A}$, decide whether there exists a homomorphism from $\mathbb{A}$ to $\mathbb{B}$. In the context of CSP the structure $\mathbb{B}$ is often called a *constraint language*. We usually assume that the constraint language $\mathbb{B}$ is finite.

To reason about propositional proof systems for CSP we use the following fixed encoding. By CNF($\mathbb{A}, \mathbb{B}$) we denote the CNF formula which has clauses

1. $\bigvee_{b \in B} X(a, b)$ for each $a \in A$,
2. $\overline{X(a, b_0)} \vee \overline{X(a, b_1)}$ for each $a \in A$ and $(b_0, b_1) \in B^2$ with $b_0 \neq b_1$,
3. $\overline{X(a_1, b_1)} \vee \cdots \vee \overline{X(a_r, b_r)}$ for each natural number r, each $R \in L$ of arity r, each $(a_1, \ldots, a_r) \in R(\mathbb{A})$, and each $(b_1, \ldots, b_r) \in B^r \setminus R(\mathbb{B})$.

It is not difficult to see that the formula CNF($\mathbb{A}, \mathbb{B}$) is satisfiable if and only if there is a homomorphism from $\mathbb{A}$ to $\mathbb{B}$.

To reason about semi-algebraic proof systems in the context of CSP we use the following fixed encoding. By INEQ($\mathbb{A}, \mathbb{B}$) we denote the system of linear inequalities defined as follows:

1. $\sum_{b \in B} X(a, b) - 1 \geq 0$ for each $a \in A$,
2. $\bar{X}(a, b_0) + \bar{X}(a, b_1) - 1 \geq 0$ for each $a \in A$ and $(b_0, b_1) \in B^2$ with $b_0 \neq b_1$,
3. $\sum_{i=1}^{r} \bar{X}(a, b_i) - 1 \geq 0$ for each natural number r, each $R \in L$ of arity r, each $(a_1, \ldots, a_r) \in R(\mathbb{A})$, and each $(b_1, \ldots, b_r) \in B^r \setminus R(\mathbb{B})$.

It is easy to see that the above system of linear inequalities has a solution satisfying the axioms from (2) and (3) if and only if there is a homomorphism from $\mathbb{A}$ to $\mathbb{B}$.

The existential k-pebble game is played on two relational structures $\mathbb{A}$ and $\mathbb{B}$ over the same vocabulary by two players called Spoiler and Duplicator. The players are given two corresponding sets of pebbles $\{a_1, \ldots, a_k\}$ and $\{b_1, \ldots, b_k\}$. In each round Spoiler picks one of the k pebbles $a_1, \ldots, a_k$, say a_i, and puts it on an element of the structure $\mathbb{A}$. Duplicator responds by picking the corresponding pebble b_i and placing it on some element of the structure $\mathbb{B}$. For simplicity, in any given configuration of the game let us identify a pebble with the element of the structure that it is placed on. Spoiler wins if at any point during the game the partial function $f : A \to B$ defined by $f(a_i) = b_i$, for each pebbled element a_i of $\mathbb{A}$, is either not well defined or is not a partial homomorphism. Otherwise, the Duplicator wins.

A finite relational structure $\mathbb{B}$ has *width* k if, for every finite structure $\mathbb{A}$ of the same vocabulary as $\mathbb{B}$, if there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$, then Spoiler wins the existential k-pebble game on $\mathbb{A}$ and $\mathbb{B}$. The structure $\mathbb{B}$ has *bounded width* if it has width k for some k. Structures of bounded width are exactly those structures for which CSP($\mathbb{B}$) can be solved by a local consistency algorithm [17].

3 Closure under reductions

There are three types of reductions often considered in the context of CSPs: a) pp-interpretability b) homomorphic equivalence c) addition of constants to a core.

Let $\mathbb{B}$ and $\mathbb{B}'$ be finite relational structures over finite vocabularies L and L'. The structure $\mathbb{B}'$ is *pp-definable* in $\mathbb{B}$ if is has the same domain and for every relation symbol $T \in L'$ the relation $T(\mathbb{B}')$ is definable in $\mathbb{B}$ by a *pp-formula*, i.e., a first order formula using only symbols from L, conjunction, equality, and existential quantification. Formally, for every relation symbol $T \in L'$ there exists a pp-formula $\phi_T(x_1, \ldots, x_r)$, where r is the arity of T, such that $T(\mathbb{B}') = \{(b_1, \ldots, b_r) \in B^r : \mathbb{B} \models \phi_T(x_1/b_1, \ldots, x_r/b_r)\}$.

Pp-interpretability is a generalization of pp-definability which allows for changing the domain of a CSP language. Given two relational structures $\mathbb{B}$ and $\mathbb{B}'$, we say that $\mathbb{B}'$ is *pp-interpretable* in $\mathbb{B}$ if there exist a positive integer n and a surjective partial function $f\colon B^n \to B'$ such that the preimages of all relations in $\mathbb{B}'$ (including the equality relation) and the domain of f are pp-definable in $\mathbb{B}$. One of the fundamental results of the *algebraic approach* to the constraint satisfaction problem is that, whenever $\mathbb{B}'$ is pp-interpretable in $\mathbb{B}$, the CSP of the language $\mathbb{B}'$ is not harder than the CSP of the language $\mathbb{B}$ [9].

Structures $\mathbb{B}$ and $\mathbb{B}'$ over a vocabulary L are *homomorphically equivalent* if there exist homomorphisms from $\mathbb{B}$ to $\mathbb{B}'$ and from $\mathbb{B}'$ to $\mathbb{B}$. Obviously, if L-structures $\mathbb{B}$ and $\mathbb{B}'$ are homomorphically equivalent, then any L-structure $\mathbb{A}$ maps homomorphically to $\mathbb{B}$ if and only if it maps homomorphically to $\mathbb{B}'$. So the CSP problems over both languages are the same.

Homomorphic equivalence allows us to focus on studying constraint satisfaction problems of well-behaved structures which in this context turn out to be those exhibiting little symmetry. A finite relational structure is called a *core* if all its endomorphisms are surjective. It is known that every relational structure has a homomorphically equivalent substructure that is a core. Core structures can be extended by one-element unary relations which we refer to as *constants*, without increasing the complexity of the language [9].

It has been shown recently [5] that any class of constraint languages that is closed under the constructions a), b) and c) has an algebraic characterization in terms of identities of height 1. Here we show that DNF Frege, bounded-depth Frege, Frege, Sherali-Adams, Sums-of-Squares and Lovász-Schrijver proof systems behave well with respect to those three types of reductions.

Let us fix relational structures $\mathbb{B}$ and $\mathbb{B}'$ such that $\mathbb{B}'$ is obtained from $\mathbb{B}$ by a finite sequence of constructions a), b) and c). There is a known polynomial-time computable transformation that maps instances $\mathbb{A}'$ of CSP($\mathbb{B}'$) to instances $\mathbb{A}$ of CSP($\mathbb{B}$) such that $\mathbb{A}$ is satisfiable if and only if $\mathbb{A}'$ is satisfiable, and the size of $\mathbb{A}$ is linear in the size of $\mathbb{A}'$. We prove that this transformation satisfies the following:

▶ **Theorem 4.** *For any positive integers t, k and s, and any instance $\mathbb{A}'$, if there is a Frege refutation of* CNF($\mathbb{A}, \mathbb{B}$) *of depth t, bottom fan-in k, and size s, then there is a Frege refutation of* CNF($\mathbb{A}', \mathbb{B}'$) *of depth t, bottom fan-in polynomial in k, and size polynomial in the size of $\mathbb{A}'$ and s.*

▶ **Theorem 5.** *For any positive integers k and s, and any instance $\mathbb{A}'$, if there is a Sherali-Adams, Sums-of-Squares or Lovász-Schrijver refutation of* INEQ($\mathbb{A}, \mathbb{B}$) *of degree k and size s, then there is, respectively, a Sherali-Adams, Sums-of-Squares or Lovász-Schrijver refutation of* INEQ($\mathbb{A}', \mathbb{B}'$) *of degree linear in k and size polynomial in the size of $\mathbb{A}'$ and s.*

We point out that Theorem 5 in the case of the Sherali-Adams and Sums-of-Squares proof systems can be extracted from [24] and [25]. We include it here to illustrate the broad applicability of the systematic proof-complexity approach.

The main idea in proving the above theorems for all the proof systems under consideration is the same. The refutation for an instance $\mathbb{A}$ of CSP($\mathbb{B}$) is transformed into a refutation for an instance $\mathbb{A}'$ of CSP($\mathbb{B}'$) by substituting the variables of CNF($\mathbb{A}, \mathbb{B}$) or INEQ($\mathbb{A}, \mathbb{B}$) by

DNFs with bounded terms and a bounded number of terms or by polynomials with bounded degree, a bounded number of monomials and coefficients from a fixed, finite set, respectively. The additional condition we need to ensure in order to control the growth of the size and depth/degree of the refutations is that each formula from $\mathrm{CNF}(\mathbb{A},\mathbb{B})$ and every polynomial inequality from $\mathrm{INEQ}(\mathbb{A},\mathbb{B})$ after applying the substitution is a logical consequence of a bounded number of formulas/inequalities from $\mathrm{CNF}(\mathbb{A}',\mathbb{B}')$ or $\mathrm{INEQ}(\mathbb{A}',\mathbb{B}')$, respectively.

4 Upper bound

We say that a finite relational structure $\mathbb{B}$ has *resolution refutations of bounded width* if there is a positive integer k such that, for every finite structure $\mathbb{A}$ over the same vocabulary, if there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$, then $\mathrm{CNF}(\mathbb{A},\mathbb{B})$ has a resolution refutation of width k. The goal of this section is to prove the following:

▶ **Theorem 6.** *Let $\mathbb{B}$ be a finite relational structure. The following are equivalent:*
1. *$\mathbb{B}$ has bounded width,*
2. *$\mathbb{B}$ has resolution refutations of bounded width.*

In preparation for the proof we revisit the characterization of resolution width in terms of existential pebble games from [2].

Let $L = \{R_0, \ldots, R_q\}$ be a finite relational vocabulary consisting of $q+1$ symbols of arity q. Let $\mathbb{S}_q$ be an L-structure with two-element domain $\{0,1\}$, where each relation $R_i(\mathbb{S}_q)$ encodes the set of valuations that satisfy a q-clause with i negated variables. More precisely, for $0 \leq i \leq q$, let $R_i(\mathbb{S}_q) = \{0,1\}^q \setminus \{(x_1,\ldots,x_q)\}$ where $(x_1,\ldots,x_q) \in \{0,1\}^q$ is the vector defined by $x_j = 0$ for $j > i$ and $x_j = 1$, otherwise. Now for every q-CNF F, we define an L-structure $\mathbb{A}_F$. Its domain is the set of variables in F, and $R_i(\mathbb{A}_F)$ is the set of all tuples $(X_1,\ldots,X_q)$ such that the clause $\overline{X_1} \vee \ldots \vee \overline{X_i} \vee X_{i+1} \vee \ldots \vee X_q$ belongs to F. We allow the variables in the clauses to repeat, so the definition covers clauses with less than q literals. Observe that partial homomorphisms from $\mathbb{A}_F$ to $\mathbb{S}_q$ correspond to partial truth assignments to the variables of F that do not falsify any clause from F. Hence, for every q-CNF F, it holds that F is satisfiable if and only if there is a homomorphism from $\mathbb{A}_F$ to $\mathbb{S}_q$.

▶ **Theorem 7** ([2])**.** *Let k and q be positive integers such that $k \geq q$ and let F be q-CNF. Then F has a resolution refutation of width k if and only if Spoiler wins the existential $(k+1)$-pebble game on $\mathbb{A}_F$ and $\mathbb{S}_q$.*

We use the above theorem to establish a similar correspondence between existential pebble games on structures $\mathbb{A}$ and $\mathbb{B}$ and bounded width resolution refutations of $\mathrm{CNF}(\mathbb{A},\mathbb{B})$.

▶ **Lemma 8.** *Let $\mathbb{A}$ and $\mathbb{B}$ be relational structures over the same vocabulary of maximum arity r, let $q = |B|$, and let k be an integer such that $k \geq q$ and $k \geq r$. Then:*
1. *if Spoiler wins the existential $(k+2)$-pebble game on $\mathbb{A}$ and $\mathbb{B}$, then $\mathrm{CNF}(\mathbb{A},\mathbb{B})$ has a resolution refutation of width $k+q$,*
2. *if Duplicator wins the existential $(k+2)$-pebble game on $\mathbb{A}$ and $\mathbb{B}$, then $\mathrm{CNF}(\mathbb{A},\mathbb{B})$ does not have a resolution refutation of width $k+1$.*

Proof of Theorem 6. For the implication 1 to 2, assume that $\mathbb{B}$ has bounded width, say l. Let $k = \max\{q, r, l\}$, where $q = |B|$ and r is the maximum arity of the vocabulary of $\mathbb{B}$. Let $\mathbb{A}$ be a structure over the same vocabulary and assume that there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$. Then Spoiler wins the existential l-pebble game on $\mathbb{A}$ and $\mathbb{B}$, and hence also the existential $(k+2)$-pebble game on $\mathbb{A}$ and $\mathbb{B}$, since $k+2 \geq l$. The hypotheses of Lemma 8

hold, so by part *1* CNF$(\mathbb{A},\mathbb{B})$ has a resolution refutation of width $k+q$. This shows that $\mathbb{B}$ has resolution refutations of width $k+q$, and hence resolution refutations of bounded width.

For the implication 2 to 1, assume that $\mathbb{B}$ has resolution refutations of width l. Again let $k=\max\{q,r,l\}$. Let $\mathbb{A}$ be a structure over the same vocabulary as $\mathbb{B}$ and assume that there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$. Then CNF$(\mathbb{A},\mathbb{B})$ has a resolution refutation of width l, and hence of width $k+1$ since $k+1\geq l$. The hypotheses of Lemma 8 hold, so by part *2* in that lemma, Spoiler wins the existential $(k+2)$-pebble game on $\mathbb{A}$ and $\mathbb{B}$. This shows that $\mathbb{B}$ has width $k+2$, and hence bounded width. ◀

5 Lower bounds

Let $d(n)$ and $s(n)$ be functions. We say that a finite relational structure $\mathbb{B}$ has Frege refutations of depth $d(n)$ and size $s(n)$ if, for every finite structure $\mathbb{A}$ over the same vocabulary, if there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$, then CNF$(\mathbb{A},\mathbb{B})$ has a Frege refutation of depth $d(|A|)$ and size $s(|A|)$. We say that $\mathbb{B}$ has Frege refutations of bounded depth and subexponential size if there exist $d(n)=O(1)$ and $s(n)=2^{n^{o(1)}}$ such that $\mathbb{B}$ has Frege refutations of depth $d(n)$ and size $s(n)$.

Similarly, we say that a finite relational structure $\mathbb{B}$ has Sums-of-Squares refutations of degree $d(n)$ if, for every finite structure $\mathbb{A}$ over the same vocabulary, if there is no homomorphism from $\mathbb{A}$ to $\mathbb{B}$, then INEQ$(\mathbb{A},\mathbb{B})$ has a Sums-of-Squares refutation of degree $d(|A|)$. We say that $\mathbb{B}$ has Sums-of-Squares refutations of sublinear degree if there exists $d(n)=o(n)$ such that $\mathbb{B}$ has Sums-of-Squares refutations of degree $d(n)$. We prove:

▶ **Theorem 9.** *Let $\mathbb{B}$ be a finite relational structure. The following are equivalent:*
1. *$\mathbb{B}$ has bounded width,*
2. *$\mathbb{B}$ has Frege refutations of bounded depth and subexponential size,*
3. *$\mathbb{B}$ has Sums-of-Squares refutations of sublinear degree.*

The equivalence of *1* and *3* is known [11, 25]. Here we provide an alternative proof. The implication *1* to *2* follows from Theorem 6: every resolution refutation is a Frege refutation of depth one, and if the refutation has bounded width, then it has polynomial size and hence subexponential size. The implication *1* to *3* follows from Theorem 6 via the fact that bounded-degree SA simulates bounded-width resolution: bounded-width resolution is simulated by bounded-degree SA, which implies Sums-of-Squares refutations of a constant, and hence sublinear, degree.

For both implications *2* to *1* and *3* to *1* we use an algebraic characterization of unbounded width. We begin with some definitions.

Let $G=(G,+,0)$ be a finite Abelian group. For each $g\in G$ and every $(z_1,\ldots,z_k)\in\mathbb{Z}^k$, we define a relation $R_{(g,z_1,\ldots,z_k)}=\{(g_1,\ldots,g_k)\in G^k : z_1g_1+\ldots+z_kg_k=g\}$, where z_ig_i is a shortcut for the sum of $|z_i|$ copies of $\mathrm{sign}(z_i)g_i$. Let $\sim$ be the equivalence relation on the set $G\times\mathbb{Z}^k$ that identifies tuples defining the same relation. Since there are only finitely many k-ary relations on the finite set G, the equivalence relation $\sim$ has finitely many equivalence classes. Let $L(G,k)$ be the relational vocabulary that for every equivalence class $[(g,z_1,\ldots,z_k)]$ has one k-ary relation symbol $E_{[(g,z_1,\ldots,z_k)]}$, and let $\mathbb{B}(G,k)$ be the $L(G,k)$-structure that has domain G and where each relation symbol $E_{[(g,z_1,\ldots,z_k)]}$ is interpreted as $R_{(g,z_1,\ldots,z_k)}$. The CSP of $\mathbb{B}(G,k)$ is called kLIN(G). Instances of kLIN(G) are systems of linear equations over the group G with k variables per equation.

▶ **Theorem 10** ([4, 8])**.** *Let $\mathbb{B}$ be a finite relational structure. The following are equivalent:*

1. $\mathbb{B}$ *does not have bounded width,*
2. *there exists a non-trivial finite Abelian group* G *such that* $\mathbb{B}(G,3)$ *is pp-interpretable in* $\mathbb{B}^+$*, where* $\mathbb{B}^+$ *is the expansion of the core of* $\mathbb{B}$ *with all constants.*

Thus, in view of Theorems 4 and 5, in order to prove that *2* implies *1*, and that *3* implies *1* in Theorem 9, it suffices to prove lower bounds for $3\mathrm{LIN}(G)$, for every non-trivial finite Abelian group G.

For bounded-depth Frege we appeal to the lower bound for the pigeonhole principle [1, 6, 19]. To use that we need to be able to encode the pigeonhole principle as an unsatisfiable system of equations over an arbitrary Abelian group G. In [7], such a reduction was obtained for the so-called *Tseitin formulas*, that encode a certain system of linear equations over $\mathbb{Z}_2$ that is derived from an expander graph. Here we adapt the formulas to encode systems of linear equations over arbitrary finite Abelian groups and then show that the reduction in [7] can be adapted to our formulas. For Sums-of-Squares, unlike for bounded-depth Frege, we do not need to adapt an existing lower bound proof from the literature for $\mathbb{Z}_2$ to all finite Abelian groups because this was already done. The lower bound that we need to complete the proof of Theorem 9 is the following.

▶ **Theorem 11** ([10]). *For every non-trivial finite Abelian group* G *there exists a positive* δ *such that for every sufficiently large integer* n *there is an* n*-variable unsatisfiable instance* $\mathbb{A}$ *of* $3\mathrm{LIN}(G)$ *such that every SOS refutation of* $\mathrm{INEQ}(\mathbb{A}, \mathbb{B}(G,3))$ *has degree at least* δn*.*

The exact statement from [10] is Theorem G.8 from Appendix G, which differs from the version above. However, the original one implies the variant that we need.

6 Upper bounds in Lovász-Schrijver

In this section we show that all unsatisfiable instances of $3\mathrm{LIN}(\mathbb{Z}_2)$ have LS refutation of degree 6 and size polynomial in the number of variables. Indeed, the argument to get polynomial-size upper bound in constant degree works equally well for $3\mathrm{LIN}(\mathbb{Z}_p)$, when p is prime, with some inessential complications. We focus on $\mathbb{Z}_2$ for simplicity.

6.1 Initial remarks on the encoding

We identify the elements of the two-element field $\mathbb{Z}_2$ with $\{0,1\}$. Let $\mathbb{E}$ be an instance of $k\mathrm{LIN}(\mathbb{Z}_2)$ with n variables. In the encoding $\mathrm{INEQ}(\mathbb{E}, \mathbb{B}(\mathbb{Z}_2,k))$ of $\mathbb{E}$ as a system of linear inequalities, there are four variables $X(a,0), X(a,1), \bar{X}(a,0), \bar{X}(a,1)$ for each variable a in $\mathbb{E}$. Note, however, that they are restricted to satisfy $X(a,0) = \bar{X}(a,1)$ and $\bar{X}(a,0) = X(a,1)$ by the inequality $X(a,0) + X(a,1) - 1 \geq 0$ from INEQ and the default equations in (2), which in this case read $X(a,0)^2 - X(a,0) = X(a,1)^2 - X(a,1) = 0$ and $X(a,0) + \bar{X}(a,0) - 1 = X(a,1) + \bar{X}(a,1) - 1 = 0$. Consequently, in the following we will ignore the variables of the type $X(a,0)$ and their twins and keep only the variables $X(a,1)$ and $\bar{X}(a,1)$. In order to simplify the notation even further, we will assume that the variables of $\mathbb{E}$ are called $X_1, \ldots, X_n$, and that those of INEQ are called $X_1, \ldots, X_n$ and $\bar{X}_1, \ldots, \bar{X}_n$.

We interpret the variables $X_1, \ldots, X_n$ as ranging over $\mathbb{Z}_2$ or $\mathbb{Q}$ depending on the context. Let E be an equation of $\mathbb{E}$, say $E : a_1X_1 + \cdots + a_nX_n = b$, where $a_1, \ldots, a_n \in \mathbb{Z}_2$ and $b \in \mathbb{Z}_2$. Without loss of generality we can assume that there are exactly k many a_i's that are 1. In INEQ, the encoding of this equation is given by the following inequalities:

$$\sum_{i \in T} \bar{X}_i + \sum_{i \in I \setminus T} X_i - 1 \geq 0 \qquad \text{for all } T \subseteq I \text{ such that } |T| \equiv 1 - b \mod 2,$$

where $I = \{i \in [n] : a_i \neq 0\}$. Note that $|I| = k$. We write $\mathcal{S}(E)$ to denote this set of inequalities; it has exactly 2^{k-1} many inequalities, and all of them are satisfied in $\mathbb{Q}$ by a $\{0,1\}$-assignment if and only if the equation E is satisfied in $\mathbb{Z}_2$ by the same assignment. Let $\mathcal{S}(\mathbb{E})$ be the union of all $\mathcal{S}(E)$ as E ranges over the equations in $\mathbb{E}$. Observe that, except for the small detail that only half of the variables are used, INEQ is basically the same as $\mathcal{S}(\mathbb{E})$.

6.2 Some technical lemmas

For every linear form $L(X_1, \ldots, X_n) = \sum_{i=1}^n a_i X_i$ with rational coefficients $a_1, \ldots, a_n$ and every integer c, let $D_c(L) = (L - c)(L - c + 1)$, which is a quadratic polynomial. In words, the inequality $D_c(L) \geq 0$ states that L does not fall in the open interval $(c - 1, c)$. Such statements have short proofs of low degree:

▶ **Lemma 12** ([15]). *For every integer c and for every linear form $L(X_1, \ldots, X_n) = \sum_{i=1}^n a_i X_i$ with integer coefficients $a_1, \ldots, a_n$, there is a LS proof of the inequality $D_c(L) \geq 0$ (from nothing) of degree 3 and size polynomial in $\max\{|a_i| : i = 1, \ldots, n\}$, $|c|$ and n.*

In the following, for $I \subseteq [n]$ and $T \subseteq I$, let $M_T^I(X_1, \ldots, X_n) := \prod_{i \in T} X_i \prod_{i \in I \setminus T} \bar{X}$. As usual, $M_\emptyset^I(X_1, \ldots, X_n) = 1$. Such polynomials are called *extended monomials*.

▶ **Lemma 13.** *For every $I \subseteq [n]$, there is an LS proof of $\sum_{T \subseteq I} M_T^I - 1 = 0$ (from nothing) of degree $|I|$ and size polynomial in $2^{|I|}$, and for every $T \subseteq I \subseteq [n]$, there is an LS proof of $\left(\sum_{i \in I} X_i - |T|\right) M_T^I = 0$ (from nothing) of degree $|I| + 1$ and size polynomial in $|I|$.*

6.3 Simulating Gaussian elimination

Now we prove the main result of this section.

▶ **Theorem 14.** *Let $\mathbb{E}$ be an instance of $3\mathrm{LIN}(\mathbb{Z}_2)$ with n variables and m equations. If $\mathbb{E}$ is unsatisfiable, then $\mathcal{S}(\mathbb{E})$ has an LS refutation of degree 6 and size polynomial in n and m.*

Proof. Write $\mathbb{E}$ in matrix form $AX = b$, where X is a column vector of n variables, A is a matrix in $\mathbb{Z}_2^{m \times n}$, and b is a vector in $\mathbb{Z}_2^m$. Let $a_{j,1}, \ldots, a_{j,n}$ be the j-th row of A, so the j-th equation of $\mathbb{E}$ is $E_j : a_{j,1}X_1 + \cdots + a_{j,n}X_n = b_j$. Assume $\mathbb{E}$ is unsatisfiable over $\mathbb{Z}_2$. Then b cannot be expressed as a $\mathbb{Z}_2$-linear combination of the columns of A, so the $\mathbb{Z}_2$-rank of the matrix $[\, A \mid b \,]$ exceeds the $\mathbb{Z}_2$-rank of A. Since the rank of A is at most n, this means that there exists a subset of at most n rows J such that, with arithmetic in $\mathbb{Z}_2$, we have $\sum_{j \in J} a_{j,i} = 0$ for every $i \in [n]$, and at the same time $\sum_{j \in J} b_j = 1$. In order to simplify the notation, we assume without loss of generality that $J = \{1, \ldots, |J|\}$.

For every $k \in \{0, \ldots, |J|\}$, define the linear form

$$L_k(X_1, \ldots, X_n) := \frac{1}{2}\left(\sum_{j=1}^{k}\sum_{i=1}^{n} a_{j,i}X_i + \sum_{j=k+1}^{|J|} b_j\right).$$

In this definition of L_k, the coefficients $a_{j,i}$ and b_j are interpreted as rationals. We provide proofs of $D_c(L_k) \geq 0$ for every $c \in R_k := \{0, \ldots, (k+1)n\}$ by reverse induction on $k \in \{0, \ldots, |J|\}$.

The base case $k = |J|$ is a special case of Lemma 12. To see why note that the condition $\sum_{j \in J} a_{j,i} = 0$ over $\mathbb{Z}_2$ means that, if arithmetic were done in $\mathbb{Q}$, then $\sum_{j \in J} a_{j,i}$ is an even natural number. But then all the coefficients of

$$L_{|J|}(X_1, \ldots, X_n) = \frac{1}{2}\sum_{j=1}^{|J|}\sum_{i=1}^{n} a_{j,i}X_i = \sum_{i=1}^{n}\left(\frac{1}{2}\sum_{j=1}^{|J|} a_{j,i}\right)X_i$$

are integers. Hence Lemma 12 applies.

Suppose now that $0 \leq k \leq |J| - 1$ and that we have a proof of $D_d(L_{k+1}) \geq 0$ available for every $d \in R_{k+1}$. Fix $c \in R_k$; our immediate goal is to give a proof of $D_c(L_k) \geq 0$. As k is fixed, write L in place of L_{k+1}, and let the $(k+1)$-st equation E_{k+1} be written as $\sum_{i \in I} X_i = b$, where $I = \{i \in [n] : a_{k+1,i} = 1\}$. Note that $L = L_k + \ell/2$ where $\ell := -b + \sum_{i \in I} X_i$. Fix $T \subseteq I$ such that $|T| \equiv b \bmod 2$, and let $d = c + (t - b)/2$ where $t = |T|$. Note that $d \in R_{k+1}$ as $c \in R_k$ and $0 \leq t \leq n$ and $0 \leq b \leq 1$ are such that $t - b$ is even. Multiplying $D_d(L) \geq 0$ by the extended monomial M_T^I we get $(L - d)(L - d + 1)M_T^I \geq 0$. Replacing $L = L_k + \ell/2$ in the factor $(L - d)$ and recalling $d = c + (t - b)/2$, this inequality can be written as

$$(L_k - c)(L - d + 1)M_T^I + (L - d + 1)\tfrac{1}{2}A \geq 0, \tag{5}$$

where $A := (\ell + b - t)M_T^I$. By the second part of Lemma 13 we have a proof of $A = 0$, and hence of $(L - d + 1)A/2 = 0$. Composing with (5) we get a proof of $(L_k - c)(L - d + 1)M_T^I \geq 0$. The same argument applied to the factor $(L - d + 1)$ of this inequality gives $(L_k - c)(L_k - c + 1)M_T^I \geq 0$. This is precisely $D_c(L_k)M_T^I \geq 0$. Adding up over all $T \subseteq I$ with $|T| \equiv b \bmod 2$ we get

$$D_c(L_k) \sum_{\substack{T \subseteq I \\ |T| \equiv b}} M_T^I \geq 0. \tag{6}$$

Now note that for each $T \subseteq I$ such that $|T| \equiv 1 - b \mod 2$, the inequality $-M_T^I \geq 0$ is the multiplicative encoding of one of the inequalities in $\mathcal{S}(E)$. Thus, it is not difficult to show that it has an SA derivation from this inequality of size polynomial in $|I|$ and degree $|I| + 1$. Therefore, we get proofs of $-M_T^I \geq 0$, and hence of $M_T^I = 0$, for every $T \subseteq I$ such that $|T| \equiv 1 - b \bmod 2$. But then also of $D_c(L_k)M_T^I = 0$ for every such T. Adding up and composing with (6) we get

$$D_c(L_k) \sum_{T \subseteq I} M_T^I \geq 0. \tag{7}$$

From Lemma 13 we get $1 - \sum_{T \subseteq I} M_T^I = 0$, and hence $D_c(L_k) - D_c(L_k) \sum_{T \subseteq I} M_T^I \geq 0$, from which $D_c(L_k) \geq 0$ follows from addition with (7).

At this point we proved $D_c(L_0) \geq 0$ for every $c \in R_0 = \{0, \ldots, n\}$. Recall now that $\sum_{j=1}^{|J|} b_j$ is odd, say $2q + 1$, and at most n. In particular $q + 1$ belongs to R_0 and $L_0 = q + 1/2$. Thus we have a proof of $D_{q+1}(L_0) \geq 0$ where $D_{q+1}(L_0) = -(1/2)(1/2) = -1/4$. Multiplying by 4 we get the contradiction $-1 \geq 0$. ◀

7 Conclusions and Open Questions

Theorems 4 and 5 imply that for the proof systems under consideration the class of constraint languages admitting efficient refutations can be characterised algebraically. For most of those proof systems such a characterisation follows from the fact that efficient proofs of unsatisfiability exist exactly for languages of bounded width. However, by Theorem 14 the class of constraint languages admitting efficient refutations in Lovász-Schrijver, and consequently also the class of constraint languages admitting efficient Frege refutations, exceed bounded width. At the same time both of those classes are shown to admit algebraic characterisations. Providing such characterisations is a natural open problem that arises from our work.

A related direction that is also suggested by our work is whether the proof complexity of approximating MAX CSPs is also preserved by reductions. On the one hand, it is known that pp-definability preserves *almost satisfiability*; i.e., if $\mathbb{B}'$ is pp-definable in $\mathbb{B}$, then if $\mathbb{A}'$ is

an instance of MAX CSP($\mathbb{B}'$) that is almost satisfiable, then its standard transformation into an instance $\mathbb{A}$ of MAX CSP($\mathbb{B}$) is also almost satisfiable. The question we raise is the following: For which proof systems is it also the case that if there are efficient proofs that $\mathbb{A}$ is far from satisfiable then there also are efficient proofs that $\mathbb{A}'$ is far from satisfiable? Depending on how the terms "almost satisfiable" and "far from satisfiable" are quantified, a positive answer for such questions could lead to an algebraic approach to the theory of approximability of MAX CSPs and the UGC.

Abstract

We study the problem of enumerating the satisfying valuations of a circuit while bounding the *delay*, i.e., the time needed to compute each successive valuation. We focus on the class of *structured d-DNNF circuits* originally introduced in knowledge compilation, a sub-area of artificial intelligence. We propose an algorithm for these circuits that enumerates valuations with linear preprocessing and delay linear in the Hamming weight of each valuation. Moreover, valuations of constant Hamming weight can be enumerated with linear preprocessing and constant delay.

Our results yield a framework for efficient enumeration that applies to all problems whose solutions can be compiled to structured d-DNNFs. In particular, we use it to recapture classical results in database theory, for factorized database representations and for MSO evaluation. This gives an independent proof of constant-delay enumeration for MSO formulae with first-order free variables on bounded-treewidth structures.

1 Introduction

When a computational problem has many solutions, computing all of them at once can take too much time. *Enumeration algorithms* are an answer to this challenge, and have been studied in many contexts (see overview in [36]). They generally consist of two phases. First, in a *preprocessing phase*, the input is read and indexed. Second, in an *enumeration phase* that uses the preprocessing result, the solutions are computed one after the other. The goal is to limit the amount of time between each pair of successive solutions, which is called *delay*.

We focus on a well-studied class of efficient enumeration algorithms with very strict requirements: the preprocessing must be *linear* in the input size, and the delay between

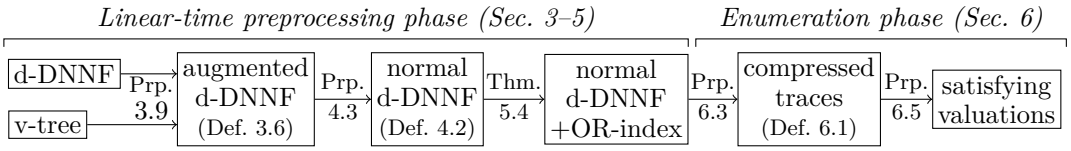

Figure 1 Overview of the proof of Theorem 2.1.

successive solutions must be *constant*. Such algorithms have been studied in particular for database applications, to enumerate query answers (see [19, 6, 20, 7, 8, 25, 24] and the recent survey [33]), or to enumerate the tuples of factorized database representations [29].

One shortcoming of these existing enumeration algorithms is that they are typically shown by building a custom index structure tailored to the problem, and designing ad hoc preprocessing and enumeration algorithms. This makes it hard to generalize them to other problems, or to implement them efficiently. In our opinion, it would be far better if enumeration for multiple problems could be done via one generic representation of the results to enumerate, reusing general algorithms for the preprocessing and enumeration phases.

This paper accordingly proposes a new framework for constant-delay enumeration algorithms, inspired by the field of *knowledge compilation* in artificial intelligence. Knowledge compilation studies how the solutions to computational problems can be *compiled* to generic representations, in particular classes of *Boolean circuits*, on which reasoning tasks can then be solved using general-purpose algorithms. In this paper, we show how this knowledge compilation approach can be implemented for constant-delay enumeration, by compiling to a prominent class of circuits from knowledge compilation called *deterministic decomposable negation normal form* (in short, d-DNNF) [17]. These circuits generalize several forms of branching programs such as OBDDs [18] and were recently shown to be more expressive than Boolean circuits of bounded treewidth [13]. Further, there are many efficient algorithms to compute d-DNNF representations of small width CNF formulae for a wide range of width notions [12], and even software implementations to compute such representations for given Boolean functions [30, 14]. d-DNNFs are also intimately related to state-of-the-art propositional model counters based on exhaustive DPLL [21], to syntactically multi-linear arithmetic circuits [32], and to probabilistic query evaluation in database theory [22].

Our main technical contribution is an efficient algorithm to enumerate the satisfying valuations of a d-DNNF under a standard structuredness assumption, namely, assuming that a so-called *v-tree* is given [31]: this assumption holds in all works cited above. Our first main result (Theorem 2.1) shows that we can enumerate the satisfying valuations of such a circuit with linear preprocessing and delay linear in the Hamming weight of each valuation. Further, our second main result (Theorem 2.2) shows that, if we impose a constant bound on the Hamming weight, we can enumerate the valuations with constant delay. In these results we express valuations succinctly as the set of the variables that they set to true.

To show our results, we consider d-DNNFs under a semantics with implicit negation: variables that are not tested must be set to zero. We call this semantics *zero-suppressed*, like zero-suppressed OBDDs [37]. Our preprocessing rewrites such d-DNNFs to a normal form (Section 4) and pre-computes a multitree reachability index on them (Section 5), allowing us to enumerate efficiently the *traces* of the circuit and the desired valuations (Section 6). To enumerate for d-DNNFs in standard semantics, we show how to rewrite them to zero-suppressed semantics, using the structuredness assumption and a new notion of *range gates* to make the process efficient (Section 3). The overall proof (see Figure 1) is very modular.

Our second contribution is to illustrate how our circuit-based framework and enumeration results can be useful in database theory. As a proof of concept, we present two known results

that we can extend, or recapture with an independent proof. First, we re-prove with our framework that the answers to MSO queries on trees and bounded-treewidth structures can be enumerated with linear preprocessing and delay linear in each assignment, i.e., constant-delay if the free variables are first-order. This was previously shown by Bagan [6] with a custom construction, by Kazana and Segoufin [25] using a powerful result of Colcombet [15], and by Courcelle [16] in a more general setting (but with $O(n \log n)$ preprocessing) using AND/OR-DAGs (that share some similarities with DNNFs). Our proof follows our proposed approach: we compute a circuit representation of the output following the provenance constructions in [4], and simply apply our enumeration result to this circuit. Second, we show how d-DNNFs generalize the deterministic factorized representations of relational instances studied in database theory [29]. We can thus enumerate with linear preprocessing and constant delay for arbitrary deterministic d-representations, which extends the result of [29].

The paper is structured as follows. Section 2 gives the main definitions and results. We then describe the preprocessing phase of our algorithm: we reduce the input circuit to zero-suppressed semantics in Section 3, rewrite it to a normal form in Section 4, and compute the multitree index in Section 5. We then describe the enumeration algorithm in Section 6. We present our two applications in Section 7 and conclude in Section 8. Due to space restrictions, many details and the proofs are found in the complete version [3].

2 Preliminaries and Problem Statement

Circuits. A circuit $C = (G, W, g_0, \mu)$ is a directed acyclic graph (G, W) whose vertices G are called *gates*, whose edges W are called *wires*, which has an *output gate* $g_0 \in G$, and where each gate $g \in G$ has a *type* $\mu(g)$ among $\wedge$ (AND-gate), $\vee$ (OR-gate), $\neg$ (NOT-gate), or var (variable). We represent the circuit with adjacency lists that indicate, for each gate $g \in G$, the gates having a wire to g (called the *inputs* of g), and the gates of which g is an input; the number of such gates is called respectively the *fan-in* and *fan-out* of g. The size $|C|$ of this representation is then $|G| + |W|$. We require that variables have fan-in zero, that NOT-gates have fan-in one, and we will always work on *negation normal form* (NNF) circuits where the input of NOT-gates is always a variable. A circuit without NOT-gates is called *monotone*.

We write C_{var} for the set of variables of C. A *valuation* of C_{var} is a function $\nu : C_{\text{var}} \to \{0, 1\}$. A circuit defines a *Boolean function* on C_{var}, i.e., a function ϕ that maps each valuation ν of C_{var} to $\{0, 1\}$. The image of ν by ϕ is defined by substituting each gate in C_{var} by its value in ν, evaluating the circuit using the standard semantics of Boolean operations, and returning the value of the output gate g_0. Note that AND-gates (resp., OR-gates) with no inputs always evaluate to 1 (resp., to 0) in this process. We call a gate *unsatisfiable* if it evaluates to 0 under all valuations (and *satisfiable* otherwise); we call it *0-valid* if it evaluates to 1 under the valuation which sets all variable gates to 0. We say that ν *satisfies* C if ϕ maps ν to 1 (i.e., g_0 evaluates to 1 under ν), and call ν a *satisfying valuation*.

For enumeration, we represent a valuation ν of C as the set S_ν of variables of C_{var} that it sets to 1, i.e., $\{g \in C_{\text{var}} \mid \nu(g) = 1\}$. We call S_ν an *assignment*, and a *satisfying assignment* if ν is a satisfying valuation. The *Hamming weight* $|\nu|$ of ν is the cardinality of S_ν. Unlike valuations, assignments of constant Hamming weight are of constant size, no matter the size of C_{var}. We write $\{\}$ for the empty assignment, and write $\emptyset$ for an empty set of assignments.

The main class of circuits that we will study are *d-DNNFs* [17], of which we now recall the definition. We say that an AND-gate g of a circuit C is *decomposable* if there is no pair $g_1 \neq g_2$ of input gates to g such that some variable $g' \in C_{\text{var}}$ has a directed path both to g_1 and to g_2: intuitively, a decomposable AND-gate is a conjunction of inputs on disjoint sets of

variables. We say that an OR-gate g of C is *deterministic* if there is no pair $g_1 \neq g_2$ of input gates of g and valuation ν of C such that g_1 and g_2 both evaluate to 1 under ν: intuitively, a deterministic OR-gate is a disjunction of mutually exclusive inputs. A circuit C is a *d-DNNF* if all its AND-gates are decomposable, and all its OR-gates are deterministic.

We further study the subclass of d-DNNFs called *structured d-DNNFs*, i.e., those having a *v-tree* [31]. A *v-tree* on a set S of variables is a rooted unranked ordered tree T whose set of leaves is exactly S. We write $<_T$ for the order on T in which the nodes are visited in a pre-order traversal. For a circuit C, we say that a v-tree T on the set C_{var} is a *v-tree* of C if there is a mapping λ from the gates of C to the nodes of T such that: (i) λ maps the variables of C to themselves; (ii) for each wire (g, g') of C, the node $\lambda(g)$ is a descendant of $\lambda(g')$ in T; and (iii) for each AND-gate g of C with inputs $g_1, \ldots, g_n$ (in this order), the nodes $\lambda(g_1), \ldots, \lambda(g_n)$ are descendants of $\lambda(g)$, none of them is a descendant of another, and we have $\lambda(g_1) <_T \cdots <_T \lambda(g_n)$. Note that having a v-tree implies (by iii) that all AND-gates are decomposable. A *structured d-DNNF* is a d-DNNF C given with a v-tree T of C.

Enumeration. As usual for efficient enumeration algorithms [33], we work in the RAM model with uniform cost measure (see, e.g., [2]), where pointers, numbers, labels for vertices and edges, etc., have constant size; thus an assignment has size linear in its Hamming weight.

An *enumeration algorithm with linear-time preprocessing* computes a set of results $\mathcal{S}(\mathcal{I})$ from an input instance $\mathcal{I}$. It consists of two parts. First, the *preprocessing phase* takes as input an instance $\mathcal{I}$ and produces in *linear time* an indexed instance $\mathcal{I}'$ and an initial *state*. Second, the *enumeration phase* repeatedly calls an algorithm $\mathcal{A}$. Each call to $\mathcal{A}$ takes as input the indexed instance $\mathcal{I}'$ and the current state, and returns a result and a new state: a special state value indicates that the enumeration is over so $\mathcal{A}$ should not be called again. The results produced by the calls to $\mathcal{A}$ must be exactly the elements of $\mathcal{S}(\mathcal{I})$, with no duplicates.

We say that the enumeration algorithm has *linear delay* if the time to produce each new output element $\mathcal{E}$ is linear in the size of $\mathcal{E}$ (and independent of the input instance $\mathcal{I}$). In particular, when the output elements have constant size, each element must be produced with constant delay, which we call *constant-delay enumeration*. The *memory usage* of an enumeration algorithm is the maximum number of memory cells used during the enumeration phase (not counting the indexed instance $\mathcal{I}'$, which resides in read-only memory), expressed as a function of the input instance size $|\mathcal{I}|$ and of the size $|\mathcal{O}|$ of the largest output (as in [6]). Note that constant delay does not imply a bound on memory usage, because the state can become large even if we only add a constant quantity of information at each step.

Main results. Our main theorem on circuit enumeration is the following:

▶ **Theorem 2.1.** *Given a structured d-DNNF C with a v-tree T, we can enumerate its satisfying assignments with linear-time preprocessing, linear delay, and memory usage $O(|\mathcal{O}| \cdot \log |C|)$, where $|\mathcal{O}|$ is the Hamming weight of the largest assignment.*

If we fix a maximal Hamming weight $k \in \mathbb{N}$, we can show constant-delay enumeration:

▶ **Theorem 2.2.** *For any $k \in \mathbb{N}$, given a structured d-DNNF C with a v-tree T, we can enumerate its satisfying assignments of Hamming weight $\leq k$ with preprocessing in time $O(|T| + k^2 \cdot |C|)$, delay in $O(k)$, and memory in $O(k \cdot \log |C|)$, i.e., linear-time preprocessing and constant delay for fixed k.*

In both results, remember that $|C|$ is the number of gates *and wires* of C. We prove our two results in Sections 3–6: the first three sections present the three steps of the linear-time

preprocessing algorithm, and the last one presents the enumeration algorithm. We then use the results for database applications in Section 7, in particular re-proving constant-delay enumeration for MSO queries with free first-order variables on bounded-treewidth structures.

The memory bound in our results is not constant and depends logarithmically on the input. While we think that this is reasonable, we also show constant-memory enumeration for some restricted circuit classes: the details are deferred to [3] for lack of space.

3 Reducing to Zero-Suppressed Semantics

We start our linear preprocessing by rewriting the input circuit to an alternative *zero-suppressed* semantics where negation is coded implicitly. For this rewriting, we will use the structuredness assumption on the circuit, in a weaker form called having a *compatible order*: this is the first thing that we present. We will also extend slightly our circuit formalism, to concisely represent sets of inputs with *range gates* that use this order: we present this second. Last, we present the alternative semantics, and give our translation result (Proposition 3.9).

Compatible orders. Our structuredness requirement is to have a *compatible order*:

▶ **Definition 3.1.** An *order* for a circuit C is a total order $<$ on C_{var}. For two variables $g_1, g_2 \in C_{\mathrm{var}}$, the *interval* $[g_1, g_2]$ consists of the variables g which are between g_1 and g_2 for $<$, i.e., $g_1 \leq g \leq g_2$ or $g_2 \leq g \leq g_1$. The *interval* of a gate g is then $[\min(g), \max(g)]$, where $\min(g)$ denotes the smallest gate according to $<$ that has a directed path to g, and $\max(g)$ is defined analogously. In particular, the interval of any $g \in C_{\mathrm{var}}$ is $[g, g] = \{g\}$.

We say that the order $<$ is *compatible* with C if, for every AND-gate g with inputs $g_1, \ldots, g_n$ (in this order), for all $1 \leq i < j \leq n$, we have $\max(g_i) < \min(g_j)$; in particular, the intervals of $g_1, \ldots, g_n$ are pairwise disjoint.

Note that, if a circuit C has compatible order $<$, every AND-gate g is decomposable: if some $g' \in C_{\mathrm{var}}$ had a directed path to two inputs of g then their intervals would intersect.

Observe further that, given a structured d-DNNF C with a v-tree T, we can easily compute a compatible order $<$ for C in linear time in T. Indeed, let $<$ be the restriction to C_{var} of the order $<_T$ on T given by pre-order traversal. Considering any suitable mapping λ from C to T, for any gate g, we know that $\min(g)$ is no less than the first leaf of T in $<$ reachable from $\lambda(g)$, and that $\max(g)$ is no greater than the last leaf reachable from $\lambda(g)$. The intervals of the inputs $g_1, \ldots, g_n$ to an AND-gate are then pairwise disjoint, because they are included in the sets of reachable leaves from the nodes $\lambda(g_1), \ldots, \lambda(g_n)$ in the v-tree, and none of these nodes is a descendant of another, so they cannot share any descendant leaf. Hence, if we know a v-tree T for C then we know an order $<$ for C.

Augmented circuits. We use compatible orders to define circuits with a new type of gates:

▶ **Definition 3.2.** For $k \in \mathbb{N}$, we define a *k-augmented circuit* C as a circuit with a compatible order $<$ and with k additional types of gates, called *range gates*: there are the *$=i$-range gates* for $0 \leq i < k$, and the *$\geq k$-range gates*. These gates must have exactly two inputs, which must be variables of C (they are not necessarily different, so we allow multi-edges in circuits for this purpose). We talk of *augmented circuits* when the value of k does not matter.

When evaluating a k-augmented circuit under a valuation ν, each $=i$-range gate g (resp., $\geq k$-range gate g) with inputs g_1 and g_2 evaluates to 1 if there are exactly i gates (resp., at least k gates) in $[g_1, g_2]$ set to 1 by ν; note that g may be unsatisfiable if $|[g_1, g_2]|$ is too small.

Range gates are related to the threshold gates studied in circuit complexity (see e.g. [11]), but we only apply them directly to variables. We can of course emulate range gates with standard gates, e.g., ≥ 0-gates always evaluate to 1, and a ≥ 1-range gate on g_1 and g_2 can be expressed as an OR-gate g having the interval $[g_1, g_2]$ as its set of inputs. However, the point of range gates is that we can now write this in constant space, thanks to $<$. This will be important to rewrite circuits in linear time to our alternative semantics.

Zero-suppressed semantics. We are now ready to introduce our alternative semantics for augmented circuits. We will do so only on *monotone* augmented circuits, i.e., without NOT-gates, because negation will be coded implicitly. We use the notion of *traces*:

▶ **Definition 3.3.** An *upward tree* T of a monotone augmented circuit $C = (G, W, \mu, g_0)$ is a subgraph (G', W') of C, with $G' \subseteq G$ and $W' \subseteq W$, which is a rooted tree up to reversing the direction of the wires. For all $(g', g) \in W'$, we call $g' \in G'$ a *child* of $g \in G'$ in T, and call g the *parent* of g' in T; note that g' is an input of g in C. A gate $g \in G'$ in T is an *internal gate* of T if it has a child in T, and a *leaf* otherwise. T is a *partial trace* if its internal gates are AND-gates and OR-gates and if its gates satisfy the following:

- for every AND-gate g in T, *all* its inputs in C are children of g in T;
- for every OR-gate g in T, *exactly one* of its inputs in C is a child of g in T.

Note that T cannot contain OR-gates with no inputs, and that its leaves consist of range gates, variable gates, and AND-gates with no inputs. We call T a *trace* of C if its root is g_0.

We define traces as trees, not general DAGs, because we cannot reach the same gate in a trace by two different paths (remember that AND-gates in augmented circuits are decomposable). We can see each trace (G', W') of $C = (G, W, \mu, g_0)$ as an augmented circuit (G', W', μ, g_0), up to adding to range gates in the trace their inputs in C, and we then have:

▶ **Observation 3.4.** *A valuation ν of a monotone augmented circuit C satisfies C if and only if ν satisfies a trace of C.*

Observe that we can check if a valuation ν of C satisfies a trace T simply by looking at the value of ν on the leaves of T; the definition of ν outside the intervals of the leaves does not matter. We will change this point to define zero-suppressed semantics, where ν can only satisfy T if it maps to 0 all the other variables. We then call ν a *minimal valuation* of T:

▶ **Definition 3.5.** Let C be a monotone augmented circuit, ν be a valuation of C, and T be a trace or partial trace of C. We call ν a *minimal valuation* of T if:

- For every variable g in T, we have $\nu(g) = 1$;
- For every $\bowtie i$-range gate g in T with inputs g_1 and g_2 in C (where $\bowtie \in \{=, \geq\}$ and $i \in \mathbb{N}$), the number n of variables in $[g_1, g_2]$ that are set to 1 by ν satisfies the constraint $n \bowtie i$;
- All other variables of C_{var} are set to 0 by ν.

Note that this implies that ν satisfies T. We call ν a *minimal valuation* for a gate g of C (resp., for C) if it is a minimal valuation of a partial trace rooted at g (resp., at the output g_0).

Note that C may have two minimal valuations ν_1 and ν_2 whose assignments S_1 and S_2 are such that $S_1 \subsetneq S_2$ (see, e.g., Example 3.7 below). Minimality only imposes that, relatively to a trace T, the valuation sets to 0 all variables that are not tested in T. Minimal valuations allow us to define the *zero-suppressed semantics* of a monotone augmented circuit C: the satisfying valuations of C in this semantics are those that are minimal for some trace.

▶ **Definition 3.6.** A monotone augmented circuit C in *zero-suppressed semantics* captures the (generally non-monotone) Boolean function Φ mapping a valuation ν to 1 iff ν is a minimal valuation for C. We call $S(C)$ the set of satisfying assignments of C in this semantics.

We call C a *d-DNNF in zero-suppressed semantics* if it satisfies the analogue of determinism: there is no OR-gate g with two inputs $g_1 \neq g_2$ and valuation ν of C that is a minimal valuation for both g_1 and g_2. (Decomposability again follows from the compatible order.)

▶ **Example 3.7.** Consider the monotone circuit C whose output gate is an OR-gate with three inputs: x, y, and an AND-gate of y and z. The circuit C captures $x \vee y$ in standard semantics, and it is not a d-DNNF. C has three traces, having one minimal valuation each. In the zero-suppressed semantics, we have $S(C) = \{\{x\}, \{y\}, \{y, z\}\}$, and C captures the Boolean function $(x \wedge \neg y \wedge \neg z) \vee (\neg x \wedge y)$. Further, C is a d-DNNF in that semantics.

Zero-suppressed semantics makes enumeration easier, because it expresses negation implicitly in a very concise way. The name is inspired by zero-suppressed OBDDs [37, Chapter 8]: variables that are not tested when following a trace are implicitly set to 0. We can equivalently define the assignments $S(C)$ of C inductively as follows:

▶ **Lemma 3.8.** *Let C be a monotone augmented circuit. Let us define inductively a set of assignments $S(g)$ for each gate g in the following way:*

- *for all $g \in C_{\mathrm{var}}$, we set $S(g) := \{g\}$;*
- *for all $\bowtie i$-range gates g with inputs g_1 and g_2, we set $S(g) := \{t \subseteq [g_1, g_2] \mid |t| \bowtie i\}$;*
- *for all OR-gates g with inputs $g_1, \ldots, g_n$, we set $S(g) := \bigcup_{1 \leq i \leq n} S(g_i)$ (with $S(g) = \emptyset$ if g has no inputs);*
- *for all AND-gates g with inputs $g_1, \ldots, g_n$, we set $S(g) := \{S_1 \cup \cdots \cup S_n \mid (S_1, \ldots, S_n) \in \prod_{1 \leq i \leq n} S(g_i)\}$ (with $S(g) = \{\{\}\}$ if g has no inputs); observe that the unions are always disjoint because C has a compatible order.*

Then, for any gate g, the set $S(g)$ contains exactly the assignments that describe a minimal valuation for g. In particular, for g_0 the output gate of C, the set $S(g_0)$ is exactly $S(C)$.

We can now state our main reduction result for this section: we can rewrite any d-DNNF to an equivalent d-DNNF in zero-suppressed semantics, by introducing ≥ 0-range gates to write explicitly that the variables not tested in a trace are unconstrained:

▶ **Proposition 3.9.** *Given a d-DNNF circuit C and a compatible order $<$, we can compute in linear time a monotone 0-augmented circuit C^* having $<$ as a compatible order, such that C^* is a d-DNNF in zero-suppressed semantics and such that $S(C^*)$ is exactly the set of satisfying assignments of C.*

4 Reducing to Normal Form Circuits

In this section, given Proposition 3.9, we work on a monotone 0-augmented d-DNNF circuit C in zero-suppressed semantics, with a compatible order $<$ to define the semantics of range gates. We present our next two preprocessing steps for the enumeration of the assignments $S(C)$ of C: restricting our attention to valuations of the right Hamming weight (for Theorem 2.2 only), and bringing C to a normal form that makes enumeration easier.

Homogenization. Our input augmented circuit C in zero-suppressed semantics may have satisfying assignments of arbitrary Hamming weight. When proving Theorem 2.1, this is intended, and the construction that we are about to describe is not necessary. However, when proving Theorem 2.2 about enumerating valuations of constant weight, we need to restrict

our attention to such valuations, to ensure constant delay. We do so using the following homogenization result, adapted from the technique of Strassen [34]:

▶ **Proposition 4.1.** *Given $k \in \mathbb{N}$ and a monotone augmented d-DNNF circuit C in zero-suppressed semantics with compatible order $<$, we can construct in time $O(k^2 \cdot |C|)$ a monotone augmented d-DNNF circuit C' in zero-suppressed semantics with compatible order $<$ such that $S(C') = \{t \in S(C) \mid |t| \leq k\}$.*

Proof Sketch. We create $k+2$ copies of each gate g, with each copy capturing the assignments of a specific weight from 0 to k inclusive (or, for the $k+2$-th copy, the assignments with weight $> k$). In particular, for $\geq$0-gates g, for $0 \leq i \leq k$, we use an $=i$-gate for the copy of g capturing weight i. We then re-wire the circuit so that weights are correctly preserved. ◀

Note that this is the only place where our preprocessing depends on k: in particular, for constant k, the construction is linear-time. This result allows us to assume in the sequel that the set of assignments of the circuit in zero-suppressed semantics contains precisely the valuations that we are interested in, i.e., those that have suitable Hamming weight.

Normal form. Now that we have focused on the interesting valuations of our circuit C, we can bring it to our desired normal form:

▶ **Definition 4.2.** A *normal* circuit C is a monotone augmented circuit such that:

- C is *arity-two*, i.e., each gate has fan-in at most two.
- C is $\emptyset$-*pruned*, i.e., no gate g is unsatisfiable (i.e., each gate has some minimal valuation).
- C is $\{\}$-*pruned*, i.e., no gate g is 0-valid (i.e., the valuation that sets all variables to 0 is not a minimal valuation for any gate).
- C is *collapsed*, i.e., it has no AND-gate with fan-in 1.
- C is *discriminative*, i.e., for every OR-gate g with an input that is not an OR-gate (we call g an *exit*), g has fan-in 1, fan-out 1, and the one gate with g as input is an OR-gate.

C is a *normal d-DNNF* if it is additionally a d-DNNF in the zero-suppressed semantics.

The pruned requirements slightly weaken the expressiveness of normal circuits C, because they forbid that $S(C) = \emptyset$ or $\{\} \in S(C)$, which are easy to handle separately. We then have:

▶ **Proposition 4.3.** *Given a monotone augmented d-DNNF circuit C in zero-suppressed semantics with compatible order $<$ and with $S(C) \neq \emptyset$ and $S(C) \neq \{\{\}\}$, we can build in $O(|C|)$ a normal d-DNNF C', with $<$ as a compatible order, such that $S(C') = S(C) \backslash \{\{\}\}$.*

Proof Sketch. We reuse the construction of Proposition 4.1 with $k = 1$ to split the gates so that they are not 0-valid, eliminate bottom-up the unsatisfiable gates, make C arity-two in a straightforward way, collapse all AND-gates with fan-in 1, and make C discriminative by inserting new OR-gates (i.e., the exits) on all wires from non-OR-gates to OR-gates. ◀

This result allows us to assume in the sequel that we are working with normal d-DNNFs.

5 Indexing OR-Components

This section presents the last step of our preprocessing. Remember that we now work with a normal d-DNNF, and we want to enumerate its set of assignments. Intuitively, this last preprocessing will help us to enumerate the choices that can be made at OR-gates. Formally, we will work on the *OR-components* of our circuit:

▶ **Definition 5.1.** The *OR-component* K of an OR-gate g in a normal circuit C is the set of OR-gates that can be reached from g by going only through OR-gates, following wires in either direction. We abuse notation and also see K as a DAG, whose vertices are the gates of K, and whose edges are the wires between them.

Recall from Definition 4.2 that, as C is discriminative, all gates of an OR-component K with no inputs in K must be exits; we call them the *exits* of K. For a gate g in K, the *exits* of g are the gates of K that have a directed path to g in K; intuitively, they are the "possible choices" for a partial trace rooted at g. Our goal is to preprocess each OR-component of C to be able to enumerate efficiently the exits of all OR-gates of C. This enumeration task is tricky, however: exploring K naively when enumerating would take time dependent of C, but materializing a reachability index would take quadratic preprocessing time. Thus, we design an efficient indexing scheme, using the fact that OR-components are *multitrees*:

▶ **Definition 5.2.** A DAG G is a *multitree* if it has no pair $n \neq n'$ of vertices such that there are two different directed paths from n to n'. In particular, forests are multitrees, and so are polytrees (DAGs with no undirected cycles).

▶ **Lemma 5.3.** *For any normal d-DNNF C, each OR-component of C is a multitree.*

We can then prepare the enumeration of exits of gates in OR-components, by designing an efficient and generic indexing scheme on *multitrees* (see [3]). We deduce:

▶ **Theorem 5.4.** *Given a normal d-DNNF C, we can compute in $O(|C|)$ a structure called* OR-index *allowing us to do the following: given an OR-gate g of C, enumerate the exits of g in its OR-component K, with constant delay and memory usage $O(\log |K|)$.*

6 Enumerating Assignments

We have described in the previous sections our linear-time preprocessing on the input circuit: this produces a normal d-DNNF C together with an OR-index, and we wish to enumerate its assignments $S(C)$ in zero-suppressed semantics. In this section, we show that we can enumerate the elements of $S(C)$, producing each assignment t with delay $O(|t|)$.

To prove this, we will go back to our definition of zero-suppressed semantics in Section 3, namely, the minimal valuations of the traces of C (recall Definition 3.3). We will proceed in two steps. First, we use our preprocessing and the OR-index to show an efficient enumeration scheme for the traces of C, in a compact representation called *compressed traces*. Second, we show how to enumerate efficiently the minimal valuations of a compressed trace.

Compressed traces. We cannot enumerate traces directly because they can be arbitrarily large (e.g., contain long paths of OR-gates) even for assignments of small weight. We accordingly define *compressed traces* as a variant of traces that collapse such paths:

▶ **Definition 6.1.** An *OR-path* of a monotone augmented circuit $C = (G, W, \mu, g_0)$ is a path from $g \in G$ to $g' \in G$ where all intermediate gates are OR-gates; in particular if $(g, g') \in W$ then there is an OR-path from g to g'. A *compressed upward tree* of C is a pair (G', W') where $G' \subseteq G$ and where $W' \subseteq G' \times G'$ is such that for each $(g, g') \in W'$ there is an OR-path from g to g': we require that T is a rooted tree up to reversing the direction of the edges. T is a *compressed partial trace* if its internal gates are AND-gates and OR-gates such that:

- for every AND-gate g in T, *all* its inputs in C are children of g in T;
- for every exit g in T (it is an OR-gate), its one input in C is a child of g in T;
- for every non-exit OR-gate g in T, *exactly one* of its *exits* g' in C is a child of g in T.

We write $|T| := |G'|$. We call T a *compressed trace* of C if its root is g_0. The *minimal valuations* of a compressed trace are defined like for non-compressed traces (Definition 3.5).

The use of compressed traces is that their size is linear in that of their minimal valuations:

▶ **Lemma 6.2.** *For any compressed trace T of a normal circuit C and minimal valuation ν for T and C, we have $|T| \leq 6 \cdot |\nu|$.*

From a trace T in a normal d-DNNF C, we can clearly define a compressed trace T' with the same leaves, as follows. Whenever T contains an OR-gate g whose parent gate g' in T is not an OR-gate (or when g is the root of T), as g cannot be an exit, we know that there is a OR-path in T from g to an exit g'' of g in its OR-component. We "compress" this OR-path in T' as an edge from g to g''. Conversely, given a compressed trace T', we can fill it to a trace T with the same leaves, by replacing each edge from g to g' by a witnessing OR-path; there is only one way to do so because OR-components are multitrees (Lemma 5.3). Hence, there is a bijection between traces and compressed traces that preserves the set of leaves. As the minimal valuations of traces and compressed traces are defined in the same way from this set, we can simply enumerate compressed traces instead of traces. We can then show:

▶ **Proposition 6.3.** *Given a normal d-DNNF C with its OR-index, we can enumerate its compressed traces, with the delay to produce each compressed trace T being in $O(|T|)$.*

In particular, if all compressed traces have constant size, then the delay is constant.

Proof Sketch. At each AND-gate, we enumerate the lexicographic product of the partial traces of its two children; at each OR-gate, we enumerate its exits using the OR-index. ◀

Enumerating valuations of a compressed trace. We now show how, given a compressed trace T, we can enumerate its minimal valuations (recall Definition 3.5). Restricting our attention to the leaves of T, we can rephrase our problem in the following way:

▶ **Definition 6.4.** The *assignment enumeration problem* for a total order $<$ on gates C_{var} is as follows: given pairwise disjoint intervals $[g_1^-, g_1^+], \ldots, [g_n^-, g_n^+]$, and cardinality constraints $\bowtie_1 i_i, \ldots, \bowtie_n i_n$, where $0 < i_j \leq \left|[g_j^-, g_j^+]\right|$ and $\bowtie_j \in \{=, \geq\}$, enumerate the values of the products $t_1 \times \cdots \times t_n$ for all the assignments of the $t_j \subseteq [g_j^-, g_j^+]$ such that $|t_j| \bowtie_j i_j$ for all j.

Indeed, remember that, as C is $\{\}$-pruned, the leaves of T consist of variables and range gates, and their intervals are pairwise disjoint thanks to decomposability. A $\bowtie i$-gate with inputs g^-, g^+ codes the interval $[g^-, g^+]$ with cardinality constraint $\bowtie i$, and a variable g simply codes $[g, g]$ with constraint $= 1$. Further, thanks to $\{\}$-pruning, we know that no range gate is labeled with $= 0$ or ≥ 0, and thanks to $\emptyset$-pruning, we know that no range gate is labeled with an infeasible cardinality constraint. We claim:

▶ **Proposition 6.5.** *We can enumerate the solutions to the assignment enumeration problem for $<$ on C_{var}, with each solution t being produced with delay linear in its size $|t|$.*

Again, this is constant-delay when all solutions have size bounded by a constant.

Proof Sketch. We enumerate the possible assignments of weights to intervals with constant-delay, to reduce to the case where all cardinality constraints are equalities. We then enumerate the assignments in lexicographic order, using an existing scheme [26, Section 7.2.1.3]. ◀

We have concluded the proof of Theorem 2.1 (see Figure 1) and 2.2. Given our input d-DNNF C and v-tree T rewritten to a compatible order, we rewrite C to an equivalent normal d-DNNF and compute the OR-index. We then enumerate compressed traces, and the valuations for each trace. The proof of Theorem 2.2 is the same except that we additionally use Proposition 4.1 before Proposition 4.3 to restrict to valuations of Hamming weight $\leq k$.

7 Applications

We now present two applications of our main results. Our first application recaptures the well-known enumeration results for MSO queries on trees [6, 23]. The second application describes links to factorized databases and strengthens the enumeration result of [29].

MSO enumeration. Recall that the class of *monadic second-order* formulae (MSO) consists of first-order logical formulae extended with quantification over sets, see e.g. [27]. The *enumeration problem* for a fixed MSO formula $\phi(X_1, \ldots, X_k)$ with free second-order variables, given a structure I, is to enumerate the *answers* of ϕ on I, i.e., the k-tuples $(B_1, \ldots, B_k)$ of subsets of the domain of I such that I satisfies $\phi(B_1, \ldots, B_k)$. We measure the *data complexity* of this task, i.e., its complexity in the input structure, with the query being fixed.

It was shown by Bagan [6] that MSO query enumeration on *trees* and *bounded treewidth structures* can be performed with linear-time preprocessing and delay linear in each MSO assignment; in particular, if the free variables of the formula are first-order, then the delay is constant. This latter result was later re-proven by Kazana and Segoufin [25]. We show how to recapture this theorem from our main results. From the results of Courcelle and standard techniques (see, e.g., [23], Theorem 6.3.1 and Section 6.3.2), we restrict to binary trees.

▶ **Definition 7.1.** Let Γ be a finite alphabet. A Γ-*tree* T is a rooted unordered binary tree where each node $n \in T$ carries a label in Γ. We abuse notation and identify T to its node set. *MSO formulae on* Γ-*trees* are written on the signature consisting of one binary predicate for the edge relation and unary predicates for each label of Γ.

Let $\phi(X_1, \ldots, X_k)$ be an MSO formula on Γ-trees, and let T be a Γ-tree. We will show our enumeration result by building a structured circuit capturing the *assignments* of ϕ on T:

▶ **Definition 7.2.** A *singleton* on $X_1, \ldots, X_k$ and T is an expression of the form $\langle X_i : n \rangle$ with $n \in T$. An *assignment* on $X_1, \ldots, X_k$ and T is a set S of singletons: it defines a k-tuple $(B_1^S, \ldots, B_k^S)$ of subsets of T by setting $B_i^S := \{n \in T \mid \langle X_i : n \rangle \in S\}$ for each i. The *assignments* of ϕ on T are the assignments S such that T satisfies $\phi(B_1^S, \ldots, B_k^S)$.

We will enumerate assignments instead of answers: this makes no difference because we can always rewrite each assignment in linear time to the corresponding answer. We now state the key result: we can efficiently build circuits (with singletons as variable gates) that capture the assignments to MSO queries. (While these circuits are not augmented circuits, they are decomposable, so the definition of zero-suppressed semantics clearly extends.)

▶ **Theorem 7.3.** *For any fixed MSO formula $\phi(X_1, \ldots, X_k)$ on Γ-trees, given a Γ-tree T, we can build in time $O(|T|)$ a monotone d-DNNF circuit C in zero-suppressed semantics whose set $S(C)$ of assignments (as in Definition 3.6) is exactly the set of assignments of ϕ on T.*

Proof Sketch. We simplify ϕ to have a single free variable and limit to assignments on leaves as in [6], and rewrite ϕ to a deterministic tree automaton A using the result of Thatcher and Wright [35], in time independent of T (though the runtime is generally nonelementary in ϕ).

We then compute our circuit as a variant of the *provenance circuits* in our earlier work [4], observing that it is a d-DNNF thanks to the determinism of the automaton as in [5]. This second step is in $O(|A| \cdot |T|)$, so linear in T. A self-contained proof is given in [3]. ◀

Note that the resulting circuit is already in zero-suppressed semantics, and has no range gates. By continuing as in the proof of Theorem 2.1 (for free second-order variables) or of Theorem 2.2 (for free first-order variables), we deduce the MSO enumeration results of [6, 25]. Note that, once we have computed the tree automaton for the query and the circuit representation, our proof of the enumeration result is completely query-agnostic: we simply apply our enumeration construction on the circuit. Our proof also does not depend on the factorization forest decomposition theorem of [15] used by [25]; it consists only of the simple circuit manipulation and indexing that we presented in Sections 4–6. Note that the delay is in $O(k \cdot |T|)$, with no large hidden constants, and $O(k)$ for first-order variables.

A limitation of our approach is that our memory usage bound includes a logarithmic factor in T, whereas [6, 25] show constant-memory enumeration. However, we can show that the circuit computed in Theorem 7.3 satisfies an *upwards-determinism* condition that allow us to replace the indexing scheme of Theorem 5.4 (our memory bottleneck) by a more efficient index. We can thus reprove the constant-memory enumeration of [6, 25]: see [3].

Factorized representations. Our second application is the *factorized representations* of [29], a concise way to represent database relations [1] by "factoring out" common parts. The atomic factorized relations are the empty relation $\emptyset$, the relation $\langle\rangle$ containing only the empty tuple, and singletons $\langle A : a\rangle$ where A is an attribute and a is an element. Larger relations are built using the relational union and Cartesian product operators on sub-relations with compatible schemas. For example, $\langle A_1 : a_1\rangle \times (\langle A_2 : a_2\rangle \cup \langle A_2 : a_2'\rangle)$ is a factorized representation of the relation on attributes A_1, A_2 containing the tuples (a_1, a_2) and (a_1, a_2'). A *d-representation* is a factorized representation given as a DAG, to reuse common sub-expressions. We show that d-representations can be seen as circuits in zero-suppressed semantics:

▶ **Lemma 7.4.** *For any d-representation D, let C be the monotone circuit obtained by replacing $\times$ and $\cup$ by AND and OR, replacing $\emptyset$ and $\langle\rangle$ by AND-gates and OR-gates with no inputs, and keeping singletons as variables. Then all AND-gates of C are decomposable, and $S(C)$ (defined as in Section 3) is exactly the database relation represented by D.*

Hence, our results in Theorem 2.2 can be rephrased in terms of factorized representations:

▶ **Theorem 7.5.** *The tuples of a deterministic d-representation D over a schema $\mathcal{S}$ can be enumerated with linear-time preprocessing, delay $O(|\mathcal{S}|)$, and memory $O(|\mathcal{S}| \log |D|)$.*

Note that the existing enumeration result on factorized representations (Theorem 4.11 of [29]) achieves a constant memory bound, unlike ours, but it applies only to deterministic d-representations that are *normal* (Definition 4.6 of [29]), which we do not assume. Normal d-representations are intuitively pruned and collapsed circuits where *no OR-gate is an input to an OR-gate*: this assumption avoids the need, e.g., for the constructions of Section 5.

8 Conclusion

We have shown how to enumerate satisfying valuations for the structured d-DNNF circuits used in AI, with linear preprocessing and delay linear in each valuation (so constant delay for constant Hamming weight). We applied this to factorized databases, and to MSO query

enumeration [6, 23]. Beyond this, however, our method implies efficient enumeration for all knowledge compilation problems that compile to structured d-DNNFs (see Introduction).

A natural question is to extend our constructions for other tasks, e.g., computing the i-th valuation [6, 9]; managing updates [28]; or enumerating in order of weight, or in lexicographic order: this latter problem is open for MSO [33, Section 6.1] but results are known for factorized representations following an f-tree [10]. Another direction is to strengthen our results to constant-memory enumeration on all d-DNNFs, or generalize them to other classes. We also plan to study practical implementations, because our construction only performs simple and modular transformations on input circuits, with no hidden large constants.

Abstract

We propose an automata-theoretic framework for modularly expressing computations on streams of data. With weighted automata as a starting point, we identify three key features that are useful for an automaton model for stream processing: expressing the regular decomposition of streams whose data items are elements of a complex type (e.g., tuple of values), allowing the hierarchical nesting of several different kinds of aggregations, and specifying modularly the parallel execution and combination of various subcomputations. The combination of these features leads to subtle efficiency considerations that concern the interaction between nondeterminism, hierarchical nesting, and parallelism. We identify a syntactic restriction where the nondeterminism is unambiguous and parallel subcomputations synchronize their outputs. For automata satisfying these restrictions, we show that there is a space- and time-efficient streaming evaluation algorithm. We also prove that when these restrictions are relaxed, the evaluation problem becomes inherently computationally expensive.

1 Introduction

Finite-state automata have been used very successfully to solve the problem of pattern matching in strings [1]. For simple patterns that are given as regular expressions, there have been proposed several pattern-matching algorithms based on Nondeterministic Finite Automata (NFAs) [31] or Deterministic Finite Automata (DFAs) [7] with strong efficiency guarantees. A particularly desirable feature of such automata-based algorithms is that they process the input text in one pass, i.e. by reading each letter of the input text consecutively from left to right, thus adhering to the so-called *streaming model* of computation [28].

Pattern-matching is one basic computational problem that arises in the context of data stream processing [14], i.e. the processing of data that arrives in real time at a high rate (e.g., for analyzing stock market data and web click-streams, or for monitoring sensor measurements and network traffic). To process data streams, the core computational problem that typically needs to be solved is the aggregation of parts of the stream into numerical values. For example, calculating the average price of a stock, monitoring the amount of network traffic an IP address has generated so far, or maintaining for a sensor the minimum and maximum

measurements it has recorded over the last 10 minutes. Given the usefulness of automata for finding patterns in streams of symbols, the question arises whether similar automata-based techniques can be employed for computing quantitative summaries of data streams.

We are thus led to consider weighted automata [19], which extend classical nondeterministic automata by annotating transitions with *weights* and can be used for the computation of simple quantitative properties on finite or infinite strings of symbols [10]. Weighted automata have found applications in speech and language processing [26], and they are also used for modeling systems and verifying quantitative properties of these systems [12]. However, the computational problems that are relevant for quantitative verification are analysis questions such as universality and equivalence. These questions are decidable only when the weights and the operations used on them are very simple [24, 2], so the studied models are usually equipped with a very limited set of primitive operations that are insufficient for expressing realistic streaming computations.

Since weighted automata are not expressive enough for typical streaming computations, our goal is to extend them for this purpose while maintaining the efficiency of their evaluation. First, we notice that the elements of data streams are typically not symbols from a finite alphabet but rather structured objects such as tuples of values. It is therefore necessary to work in the *symbolic* setting [33, 34]: the input elements belong to a potentially infinite alphabet D, and we consider a collection of primitive predicates on D for describing subclasses of elements using Boolean formulas over the primitive predicates. Additionally, realistic computations often involve the parsing of an input stream and aggregation of subcomputations; for example, we may want to subsample a sequence of sensor measurements by averaging them in groups of three consecutive measurements, and then compute the maximum measurement of every minute. Naturally describing such calculations requires that we allow *hierarchical nesting* of operations. In general, the required subcomputations may be disjoint from one another, and need to be executed in parallel. For example, suppose the automaton $\mathcal{A}_1$ describes a long-term average (e.g., over the last month) of a sensor measurement, $\mathcal{A}_2$ calculates a short-term average (e.g., over the last minute), and op is the "absolute difference" binary operation. Then, the construct $\mathrm{op}(\mathcal{A}_1, \mathcal{A}_2)$ describes the *parallel execution* of $\mathcal{A}_1$ and $\mathcal{A}_2$ and the *combination* of their results using the op operation. Thus, the overall computation outputs the distance between the short-term and long-term average. This construct for parallelism facilitates the modular description of computations.

Our contribution. Putting these desired features together in a model that supports nondeterministic parsing, hierarchical nesting of quantitative operations and modular parallelism is challenging. The core computational problem is the incremental evaluation of automata on unbounded data streams, and the goal is to provide an algorithm with strong space- and time-efficiency guarantees. We will establish formally that the naive combination of the desired features makes efficient evaluation impossible. Moreover, we will show that by restricting to unambiguous nondeterminism [9] and by constraining the parallel execution of $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_k)$ so that the automata $\mathcal{A}_i$ synchronize their outputs, we can achieve very efficient evaluation. More specifically, our main results are the following:

1. The evaluation problem for automata that allow ambiguous nondeterminism and nesting of quantitative operations requires space that is linear in the size of the input stream.
2. The evaluation problem for automata with unambiguous nondeterminism and unsynchronized parallel execution requires space that is exponential in the size of the automaton.
3. For automata that are unambiguous and allow only synchronized parallel execution, the evaluation problem requires space and time-per-element that is quadratic in the size of the automaton and independent of the size of the stream.

Related work. The features of our Streaming Automata (SAs) were inspired by the Quantitative Regular Expressions (QREs) of [5], which have constructs for parallelism and nesting of sequential aggregators. QREs were extended in [25] with streaming relational operations [22], and an efficient implementation was given for processing realistic workloads (Yahoo streaming benchmark [13] and NEXMark benchmark [32]). However, the evaluation algorithm of [5] and the implementation of [25] were not based on automata-theoretic techniques. A simplified version of the QREs of [5] without parameters allows a straightforward translation into our SAs that is very similar to the translation of unambiguous regexes into unambiguous NFAs. This translation is desirable not only because it gives rise to a cleaner evaluation algorithm, but also because it opens the door for systematic query optimization using automata-theoretic techniques, which could be explored in future research.

The model of Cost Register Automata (CRAs) was proposed in [4] and was shown in [5] to be expressively equivalent to QREs. However, CRAs cannot be used for the efficient evaluation of QREs, because the translation of QREs into CRAs incurs a doubly exponential blowup. The model of Streaming Automata that is proposed here is an appropriate setting for the efficient evaluation of QREs.

A two-level variant of weighted automata for infinite strings has recently been proposed [11] that can express long-run quantitative properties of a stream, for example, the average response time of a system. By restricting both the nesting depth (to 1) and the allowed aggregation operations, the model of [11] is shown to have decidable emptiness and universality problems. With the goal of modeling realistic streaming computations, we focus on arbitrary nesting and a general set of operations. We are therefore concerned primarily with evaluation complexity rather than decidability of these problems.

Symbolic automata and transducers [33, 34, 15, 16] have been introduced for matching and transforming strings over large or infinite alphabets. Our work builds on symbolic automata but instead addresses the problem of quantitative aggregation.

There is also related work on data words and data/register automata and their associated logics [23, 29, 18, 8]. These models operate on words over an infinite alphabet, which is typically of the form $\Sigma \times \mathbb{N}$, where Σ is a finite set of tags. They allow the comparison of infinite values using only the equality predicate. In contrast, our SAs do not allow binary predicates on stream elements, but instead allow a rich set of operations on the values.

More broadly, there is a vast line of research on efficient algorithms for the streaming model of computation. See the survey [28] and some illustrative works [27, 20, 3, 17, 6] that have been influential. The algorithms studied in this line of research are designed for specific problems (for example, finding the number of distinct elements in a stream) and typically use approximation and randomization. Our considerations here are orthogonal, and complementary, to the literature on streaming algorithms. We study the hierarchical nesting of several different kinds of aggregations, and we study the computational resources that are needed for parsing the stream and combining all intermediate results.

2 Streaming Automata

Symbolic input. Figure 1 shows two symbolic weighted automata over different inputs. $\mathcal{M}_1$ implements MaxBlockSum: on an input stream of natural numbers separated into (possibly empty) blocks by the separator 0, it returns the maximum sum of a block. As we may view $\mathcal{M}_1$ as a weighted automaton over the semiring $(\mathbb{N} \cup \{-\infty\}, \max, +)$, it does not yet introduce anything new to our model except the symbolic input. All transitions use the formal variable x to denote the current input data item, a natural number; the syntax

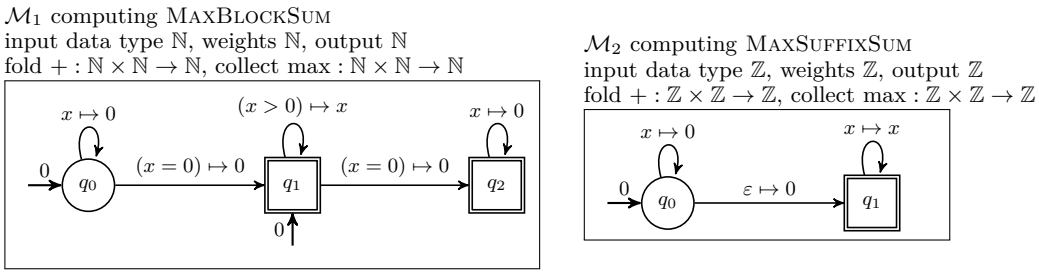

Figure 1 Weighted automata with symbolic input.

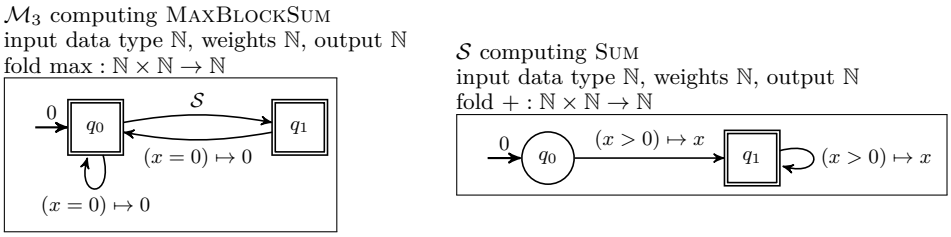

Figure 2 A streaming automaton employing hierarchy.

$\varphi(x) \mapsto \alpha(x)$ means that if x matches predicate φ, then the transition can be taken, and has weight $\alpha(x)$. We write simply $x \mapsto \alpha(x)$ if φ is True, i.e. if any x is allowed. A transition labeled with $\varepsilon \mapsto r$ matches the empty string and has weight r.

$\mathcal{M}_1$ starts at q_0 for some time, mapping each input x to weight 0 (effectively ignoring it). Then, it nondeterministically picks a block by transitioning to q_1 on input the separator $x = 0$. (q_1 is also a start state, which corresponds to the first block, before any 0 has occurred.) At q_1, all inputs matching the predicate $x > 0$ are assigned weight x. Finally, on input $x = 0$, the end of the block, it transitions to q_2, where future x are again assigned weight 0. $\mathcal{M}_1$ adds up (*folds*) all the assigned weights to obtain the total weight of the path, which is by construction the sum of the particular block chosen. The output of the automaton is the maximum weight (*collect*) over all paths.

$\mathcal{M}_2$ implements MaxSuffixSum: on an input stream of integers, it returns the maximum sum of a suffix of those integers. The input data type is now $\mathbb{Z}$ rather than $\mathbb{N}$. $\mathcal{M}_2$ (like $\mathcal{M}_1$) starts at q_0 and assigns inputs x to weight 0 for some time. Then, it nondeterministically guesses the start of the suffix by switching to q_1, where each future input x is assigned weight x. The fold operation is again $+$, so that the weight of the path is the sum of that particular suffix. The collect operation returns the max over all paths, i.e. over all suffixes.

Hierarchy. The nondeterminism of $\mathcal{M}_2$ is very natural: exactly where the best suffix starts cannot be known ahead of time, so we choose it nondeterministically. In contrast, since the input to $\mathcal{M}_1$ is *parsable* into a sequence of blocks, using nondeterminism to choose a block seems artificial. Instead, we would like to deterministically parse the stream into blocks, then call a subroutine (sum) on each block. Figure 2 shows how to do this in our model. First, the weighted automaton $\mathcal{S}$ is built to compute the sum of a nonempty input stream by straightforwardly folding with $+$. $\mathcal{M}_3$ parses the stream into blocks separated by 0 and calls $\mathcal{S}$ as a *subautomaton* on each block, where the weight of that transition is the return value of $\mathcal{S}$. All the block sums returned by $\mathcal{S}$ are now weights along a single path, and they are folded with the operation max.

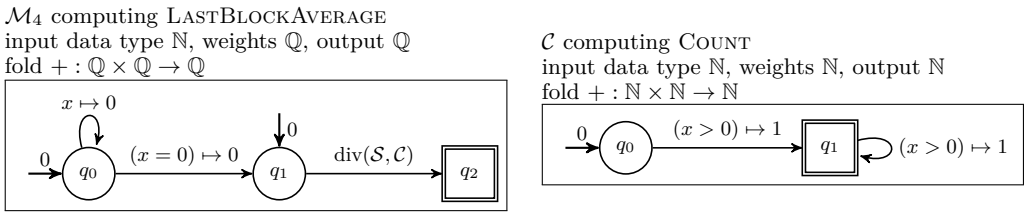

Figure 3 A streaming automaton employing parallelism.

The example of MaxBlockSum is a typical case where the two operations of a nondeterministic weighted automaton (fold $\otimes$ and collect $\oplus$) can be replaced by a hierarchy of two streaming automata, each of which is *unambiguous*: there is at most one accepting path on any given input string. The fold operation of $\mathcal{M}_1$ $(+)$ becomes the fold operation of $\mathcal{S}$, and the collect operation of $\mathcal{M}_1$ (max) becomes the fold operation of $\mathcal{M}_3$. Unambiguity implies that the collect operations in $\mathcal{M}_3$ and $\mathcal{S}$ are never used, and need not be specified.

Parallelism. After parsing a stream into blocks, multiple computations may be required on each block. For this purpose, in our model a transition may be labeled not just with a single subautomaton (as in $\mathcal{M}_3$), but with a call $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_m)$ where each $\mathcal{A}_i$ is a subautomaton. In a simple example, the stream is separated by 0 into blocks, and we want to report the average of the last block. Figure 3 gives an automaton $\mathcal{M}_4$ implementing this. On every 0 character $\mathcal{M}_4$ may nondeterministically guess that we are now going to the last block, and move from q_0 to q_1. It subsequently makes an invocation $\mathrm{div}(\mathcal{S}, \mathcal{C})$ to two subautomata. $\mathcal{S}$ (from Figure 2) returns the sum of the elements in the block if there is at least one, and $\mathcal{C}$ returns the count if there is at least one. $\mathrm{div} : \mathbb{N} \times \mathbb{N} \to \mathbb{Q}$ then divides the two results to get average. The *parallelism* arises because the stream is read into both $\mathcal{S}$ and $\mathcal{C}$ in parallel.

Like $\mathcal{M}_3$, $\mathcal{M}_4$ is unambiguous, with at most one accepting path on each input. $\mathcal{M}_4$ also satisfies *parallel-consistency*: in the call to $\mathrm{div}(\mathcal{S}, \mathcal{C})$, $\mathcal{S}$ and $\mathcal{C}$ were defined on the same input strings. Our definition of a *streaming automaton* requires both unambiguity and parallel-consistency; the necessity of these restrictions is justified by Section 4.

Formal definition

The general definition is parameterized by a *signature* $(\mathcal{D}, \mathcal{O}, D, \mathcal{P})$, where $\mathcal{D}$ is a collection of (possibly infinite) types, and $\mathcal{O}$ is a collection of operations $D_1 \times D_2 \times \cdots \times D_k \to D_{k+1}$ with each D_i a type in $\mathcal{D}$. We write $\mathcal{O}[D_1 \times D_2 \times \cdots \times D_k \to D_{k+1}]$ for the set of operations in $\mathcal{O}$ which are functions of the specific indicated function type. $D \in \mathcal{D}$ is a specific set for the input stream, and $\mathcal{P}$ is a set of predicates, which are identified with subsets of D. We require that $\mathcal{P}$ is closed under Boolean operations, and that satisfiability for $\varphi \in \mathcal{P}$ is decidable as in [34]. From this point, we assume the fixed signature $(\mathcal{D}, \mathcal{O}, D, \mathcal{P})$.

The class of *nondeterministic streaming automata* is defined hierarchically as $\mathrm{NSA} := \bigcup_{k=0}^{\infty} \mathrm{NSA}_k$. For $k \geq 0$, an element of NSA_k is a tuple $(Q, X, Y, \Delta, I, F, \otimes, \oplus)$, semantically representing a partial function from D^* to Y. Q is a finite set of *states*, $X \in \mathcal{D}$ is the *weight type*, $Y \in \mathcal{D}$ is the *output type*, and Δ is a set of *transitions*. Each transition goes from a state $q \in Q$ to a state $q' \in Q$, and has a *label*, which is one of three *kinds*: (i) A satisfiable predicate $\varphi \in \mathcal{P}$ and a *weight assignment* $\alpha \in \mathcal{O}[D \to X]$. (ii) An epsilon (ε) and a *weight* $x \in X$. (iii) A call to $\mathrm{op}(\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_m)$, where $\mathrm{op} \in \mathcal{O}[Y_1 \times Y_2 \times \cdots \times Y_m \to X]$ and each $\mathcal{A}_i \in \mathrm{NSA}_{k-1}$, such that the output type of $\mathcal{A}_i$ is Y_i. The weight of the transition in this case will be op applied to the outputs of the $\mathcal{A}_i$.

$I : Q \rightharpoonup Y$ is the *initialization function*, a partial function assigning an initial value to the computation. Its domain is the set of *initial states*, denoted $Q_I \subseteq Q$. Conversely, $F : Q \rightharpoonup X$ is the *final function*; it allows for slightly more flexibility than in our examples by appending a final weight to accepting paths. Its domain is the set of *final states* or *accepting states*, denoted $Q_F \subseteq Q$. The *fold operation* $\otimes \in \mathcal{O}[Y \times X \to Y]$ folds together the weights along a path, and the *collect operation* $\oplus \in \mathcal{O}[Y \times Y \to Y]$ combines the results of all accepting paths to arrive at a final output value. The operation $\oplus$ must be commutative and associative, and $\otimes$ must be left-distributive over $\oplus$.

The class NSA_0, in which there are no transitions of kind (iii), consists of symbolic weighted automata. A *subautomaton* of $\mathcal{A}$ is an automaton $\mathcal{A}_i \in \mathrm{NSA}_{k-1}$ appearing in a transition of kind (iii) in A. The *size* of A is the sum of the number of states $|Q|$, the number of transitions $|\Delta|$, and the sizes of all the subautomata, counted with multiplicity. Effectively, an automaton must be written down once for every time it is used.

As in the examples, the automaton $\mathcal{A}$ is semantically interpreted as a function $[\![\mathcal{A}]\!] : L(\mathcal{A}) \to Y$, where $L(\mathcal{A}) \subseteq D^*$ is the regular *language* of $\mathcal{A}$. $L(\mathcal{A})$ and $[\![\mathcal{A}]\!]$ are defined recursively by also defining $L(\tau)$ and $[\![\tau]\!]$ for each transition τ of the automaton. (i) For a transition τ labeled with predicate $\varphi \subseteq D$ and weight assignment $\alpha : D \to X$, $L(\tau) = \{d \in D \mid \varphi(d)\}$, and $[\![\tau]\!](d) = \alpha(d)$. (ii) For an epsilon transition τ with weight $x \in X$, $L(\tau) = \{\varepsilon\}$ and $[\![\tau]\!](\varepsilon) = x$. (iii) Finally, for a transition τ labeled with $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_m)$, the language $L(\tau) = L(\mathcal{A}_1) \cap \cdots \cap L(\mathcal{A}_m)$, and for any string $s \in L(\tau)$, $[\![\tau]\!](s) = \mathrm{op}([\![\mathcal{A}_1]\!](s), \ldots, [\![\mathcal{A}_m]\!](s))$.

For an automaton $\mathcal{A} \in \mathrm{NSA}_k$, a *path* on input $s \in D^*$ consists of a sequence of states $q_0, q_1, q_2, \ldots, q_n \in Q$, a sequence of strings $s_1, s_2, \ldots, s_n \in D^*$, and a sequence of transitions $\tau_1, \tau_2, \ldots, \tau_n \in \Delta$, such that $q_0 \in Q_I$, $s = s_1 s_2 \ldots s_n$, and for each i, τ_i is a transition from q_{i-1} to q_i such that $s_i \in L(\tau_i)$. A path is *accepting* if $q_n \in Q_F$. The *language* $L(\mathcal{A})$ is the set of strings s for which there exists an accepting path on input s. The *weight* of an accepting path is, with left-to-right evaluation order, $I(q_0) \otimes [\![\tau_1]\!](s_1) \otimes [\![\tau_2]\!](s_2) \otimes \cdots \otimes [\![\tau_n]\!](s_n) \otimes F(q_n) \in Y$.

An *implicit ε-transition* is a transition τ with $\varepsilon \in L(\tau)$. $\mathcal{A}$ is *well-formed* if it has no implicit ε-transition cycles, and all of its subautomata are well-formed. Finally, the evaluation of $\mathcal{A}$ on input $s \in L(\mathcal{A})$ is given by $[\![\mathcal{A}]\!](s) := y_1 \oplus \cdots \oplus y_N \in Y$, where $y_1, \ldots, y_N$ are the weights of *all* (finitely many) distinct accepting paths on input s. As $\oplus$ is commutative and associative, this is well-defined.

Streaming automata. We recursively say that an NSA $\mathcal{A}$ is *unambiguous* if there is at most one accepting path on every input string, and each subautomaton of $\mathcal{A}$ is unambiguous. An NSA $\mathcal{A}$ is called *parallel-consistent* if, at every transition of kind (iii) labeled with $\mathrm{op}(\mathcal{A}_1, \mathcal{A}_2, \ldots, \mathcal{A}_m)$, $L(\mathcal{A}_1) = L(\mathcal{A}_2) = \cdots = L(\mathcal{A}_m)$, and every subautomaton is parallel-consistent. A *streaming automaton (SA)* is an NSA $\mathcal{A}$ that is unambiguous and parallel-consistent. The collect operation $\oplus$ of an SA may be left off, as it is never invoked. We additionally assume that every SA is *trim*: every state has an accepting path which goes through it, and all subautomata are trim.

Checking if an NSA is an SA. Both of the two restrictions (unambiguity and parallel-consistency) can be checked efficiently. The main idea is to assign to each subautomaton $\mathcal{A}$ an *underlying NFA* $\mathrm{NFA}(\mathcal{A})$, such that $L(\mathcal{A}) = L(\mathrm{NFA}(\mathcal{A}))$, from the bottom up. Given an NSA $\mathcal{A}$, the algorithm recursively verifies that $\mathcal{A}$ is unambiguous and parallel-consistent, and also returns the NFA $\mathrm{NFA}(\mathcal{A})$ such that $L(\mathcal{A}) = L(\mathrm{NFA}(\mathcal{A}))$. Assume this has been done for all subautomata of $\mathcal{A}$. Checking parallel-consistency of a transition labeled $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_m)$ is then the equivalence problem for the unambiguous NFAs $\mathrm{NFA}(\mathcal{A}_1), \ldots, \mathrm{NFA}(\mathcal{A}_m)$; ex-

actly this problem is solved in polynomial time by a nontrivial algorithm of [30]. Once parallel-consistency is established, we form NFA($\mathcal{A}$) by replacing each transition labeled with op($\mathcal{A}_1, \ldots, \mathcal{A}_m$) with ε-transitions to and from a copy of NFA($\mathcal{A}_1$). Crucially, we assume parallel-consistency in only using $\mathcal{A}_1$. This guarantees that the NFA is linear in the size of $\mathcal{A}$, and avoids the alternative of constructing an NFA for $L(\mathcal{A}_1) \cap \cdots \cap L(\mathcal{A}_m)$. The construction preserves accepting paths, so $L(\mathcal{A}) = L(\text{NFA}(\mathcal{A}))$, and if one is unambiguous, both are. Finally, checking that NFA($\mathcal{A}$) is unambiguous is a reachability check in NFA($\mathcal{A}$) $\times$ NFA($\mathcal{A}$).

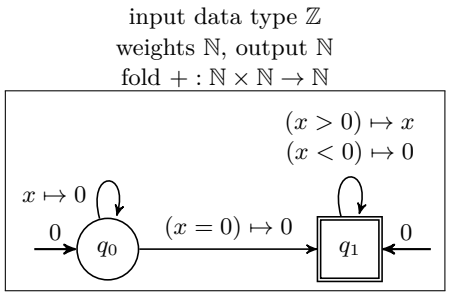
The necessary operations for the algorithm to work lift to the symbolic setting given the decidability restrictions on the predicates. See e.g. Corollary 1 of [34].

3 Evaluation Algorithm

In this section we present a space- and time-efficient evaluation algorithm for streaming automata, i.e. NSAs that are unambiguous and parallel-consistent. We will show that for such automata the space footprint of the evaluation algorithm and the time required to process each element are independent of the size of the stream and quadratic in the size of the automaton. As we will see in Section 4, both these syntactic restrictions on automata are necessary for the efficiency guarantees that we present.

Given an SA $\mathcal{A}$ and a sequence w of data items, the computation of $[\![\mathcal{A}]\!](w)$ amounts to discovering a global hierarchical path for w that may span several levels of subautomata and performing incrementally the aggregations that are prescribed by the top level and all subautomata. The crucial challenge is that the unambiguous nondeterminism of $\mathcal{A}$ requires the exploration of all possible paths *in parallel*. It is not obvious how this can be accomplished using a small amount of space, and indeed Theorem 5 in the next section shows that this is impossible in the presence of ambiguous nondeterminism. For plain NFAs or weighted automata, ambiguous nondeterminism is not an issue, because when two tokens end up at the same state during evaluation they can be merged. For streaming automata, however, such merging is not possible. The main insight is that unambiguity guarantees that no two tokens will ever end up at the same state, even at the lowest level of the automaton. As the evaluation algorithm explores each tentative path, it maintains a *stack of values* for that path, which holds the partial aggregates for the subpaths that have been discovered so far. We can think of these stacks as "execution tokens" that are updated whenever a simple transition occurs (upon consumption of a data item), and which are passed to subautomata as a way to implement the recursive definition of global accepting paths.

Before presenting the technical details, let us give a very high-level description of the evaluation algorithm and its correctness proof. First, we will introduce the notion of a *configuration*, which describes the assignment of stack tokens to the active states of the automaton. This is a generalization of configurations for NFAs, which only indicate the active states. We will define a semantics for configurations, which summarizes the accepting paths from active states as well as the computations that are performed along these paths. Then, the correctness proof of the algorithm can be reduced to establishing a simple semantic property for configurations: if C is the current configuration and C' is the configuration that the evaluation algorithm computes from C after consuming the data item d, then $[\![C']\!](w) = [\![C]\!](dw)$ for every possible suffix w. The presence of several nested levels of subautomata presents a major challenge for proving this property, since a subautomaton potentially has to compute simultaneously on several subsequences of the stream seen so far (we call these subsequences "parallel input threads").



start/next	configuration	input threads
[9]	$q_0 : [9, 0]$ $q_1 : [9, 0]$	{[9] ε}
2	$q_0 : [9, 0]$ $q_1 : [9, 2]$	{[9] 2}

3	$q_0 : [9, 0]$ $q_1 : [9, 5]$	{[9] 2 -1 3}
0	$q_0 : [9, 0]$ $q_1 : [9, 0]$	{[9] 2 -1 3 0}
6	$q_0 : [9, 0]$ $q_1 : [9, 6]$	{[9] 2 -1 3 0 6}

Figure 4 Example evaluation of an SA on one input thread.

▶ **Example 1.** The automaton of Figure 4 computes on a stream of integers and outputs the sum of all strictly positive numbers that have occurred after the last occurrence of a 0 (or from the start if no 0 has occurred yet). We start the execution by supplying a *context stack*, which holds the partial aggregations of upper levels (if there are any), and then we supply the sequence of data items. The context stack [9] of this example is initialized by pushing the aggregate 0 onto it, and then every time an element is consumed the aggregate at the top of the stack is appropriately updated.

▶ **Example 2.** The automaton of Figure 5 computes on a stream of integers and outputs the sum of all strictly positive numbers that have occurred as long as there are exactly two occurrences of a 0. We can compute on several parallel input threads by supplying a new context stack every time we want to spawn a new thread of execution. Figure 5 shows an example execution with three different input threads. By starting a new input thread after the occurrence of a 0 we guarantee that there is at most one stack token on each state.

Epsilon transitions can be eliminated in a bottom-up fashion with a variant of the standard ε-elimination construction for weighted automata [19]. We consider in this section automata that are free of both explicit and implicit ε-transitions, and we assume w.l.o.g. that every invocation $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_k)$ has its own call state p, from which no other transition emanates.

Suppose that V is the type of all *values*. Let St be the type of all finite stacks of values, and [] be the empty stack. We consider the total operation $\mathsf{push} : \mathsf{St} \times V \to \mathsf{St}$, and the partial operations $\mathsf{pop} : \mathsf{St} \rightharpoonup \mathsf{St}$ and $\mathsf{top} : \mathsf{St} \rightharpoonup V$. The operations pop and top are undefined on the empty stack. We write $s.\mathsf{push}(x)$ to denote the application of push on the stack s and the value x. Similarly, we write $s.\mathsf{pop}$ and $s.\mathsf{top}$ for the other operations. For example, we have $[].\mathsf{push}(x).\mathsf{push}(y) = [x].\mathsf{push}(y) = [x, y]$ and $[x, y].\mathsf{pop}.\mathsf{top} = [x].\mathsf{top} = x$. We write $\mathsf{St}[X_1, \ldots, X_{n-1}, X_n]$ for the type of stacks of size n whose top element is of type X_n, the next-to-top element is of type X_{n-1} and so on. We call all types of this form *bounded stack types*. If $T = \mathsf{St}[X_1, \ldots, X_n]$ then we write $T@[X_{n+1}, \ldots, X_{n+m}]$ to denote the type $\mathsf{St}[X_1, \ldots, X_n, X_{n+1}, \ldots, X_{n+m}]$. We also abbreviate $T@[X_{n+1}]$ by $T@X_{n+1}$.

The *rank* of an SA $\mathcal{A}$ is the smallest k such that $\mathcal{A} \in \mathrm{NSA}_k$, or in other words the nesting depth of the automaton. We define the notion of a configuration for an automaton by induction on its rank. For an automaton $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ of rank 0 and a bounded stack type T, an $(\mathcal{A}, T)$-*configuration* is a partial map $C : Q \rightharpoonup T@Y$; we denote the domain $\mathrm{dom}(C)$. Intuitively, the configuration describes the placement of stack tokens on some of the states of $\mathcal{A}$. For an automaton $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ of rank strictly greater than 0, an $(\mathcal{A}, T)$-configuration C is a vector consisting of a partial function $C_0 : Q \rightharpoonup T@Y$ and a

Figure 5 Example evaluation of an SA on several input threads.

subconfiguration for every subautomaton occurrence. More specifically, for every transition $(p, \mathrm{op}_i(\mathcal{A}_{i1}, \mathcal{A}_{i2}, \ldots, \mathcal{A}_{in}), q)$ of $\mathcal{A}$, the configuration C specifies an $(\mathcal{A}_{i1}, T@Y)$-configuration C_{i1} and a $(\mathcal{A}_{ij}, \mathsf{St}[])$-configuration C_{ij} for $j = 2, \ldots, n$. That is, the configuration describes the placement of stack tokens on the top-level states and specifies subconfigurations for the subautomata occurrences. We write $\mathrm{Cfg}\langle \mathcal{A}, T\rangle$ for the set of all $(\mathcal{A}, T)$-configurations.

For an automaton $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ and an $(\mathcal{A}, T)$-configuration C, we will define simultaneously C-paths, unambiguity of C, and the denotation $[\![C]\!] : D^* \rightharpoonup T@Y$ by induction on the rank of $\mathcal{A}$. A C-path is a path starting from the configuration C.

- ***Automaton $\mathcal{A}$ of rank 0***: A *C-path* (labeled with $d_1 d_2 \ldots d_n \in D^*$) is a sequence of the following form: $q_0 \to^{\phi_1/\sigma_1}_{d_1/x_1} q_1 \to^{\phi_2/\sigma_2}_{d_2/x_2} \cdots \to^{\phi_n/\sigma_n}_{d_n/x_n} q_n$, such that $q_0 \in \mathrm{dom}(C)$ and $(q_{i-1}, \phi_i, \sigma_i, q_i) \in \Delta$ with $\phi_i(d_i) = \mathit{true}$ and $x_i = \sigma_i(d_i)$ for every $i = 1, \ldots, n$. A C-path is said to be *accepting* if it ends with an accepting state. The *weight* of an accepting C-path is defined to be the value $\mathrm{fold}(y, \otimes, x_1 x_2 \ldots x_n x_{n+1})$ where $y = C(q_0).\mathsf{top}$ and $x_{n+1} = F(q_n)$. The configuration C is *unambiguous* if for every label $w \in D^*$ there is at most one accepting C-path labeled with w. For an unambiguous configuration C, the denotation $[\![C]\!] : D^* \rightharpoonup T@Y$ is defined as follows: if there is an accepting C-path π labeled with w starting with the state q, then $[\![C]\!]\ w = s.\mathsf{pop}.\mathsf{push}(y)$ where $s = C(q)$ is the initial stack and y is the weight of π.
- ***Automaton $\mathcal{A}$ of rank greater than 0***: A *top-level C-path* is a sequence of top-level transitions that can be of the following two forms:

$$p \to^{\phi/\sigma}_{d/x} q \qquad \text{where } (p, \phi, \sigma, q) \in \Delta \text{ with } \phi(d) = \mathit{true} \text{ and } x = \sigma(d)$$

$$p \to^{\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_n)}_{w/x} q \qquad \text{where } w \neq \varepsilon \text{ and } (p, \mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_n), q) \in \Delta \text{ with } x = \mathrm{op}([\![\mathcal{A}_1]\!]\ w, \ldots, [\![\mathcal{A}_n]\!]\ w)$$

that starts with a state in the domain of C_0. Now, a *cross-level C-path* is a sequence of

top-level transitions with an additional prefix called a cross-level transition:

$$\rightarrow_{w/t}^{\mathrm{op}(\mathcal{A}_{i1},\ldots,\mathcal{A}_{in})} q \quad \text{where } w \neq \varepsilon \text{ and } (p, \mathrm{op}(\mathcal{A}_{i1},\ldots,\mathcal{A}_{in}), q) \in \Delta \text{ for some state } p$$
$$s_1 = [\![C_{i1}]\!](w) : T@[Y, Z_1] \text{ and } s_j = [\![C_{ij}]\!](w) : [Z_j] \text{ for } j = 2,\ldots,n$$
$$t = s_1.\mathsf{pop}.\mathsf{pop}.\mathsf{push}(s_1.\mathsf{pop}.\mathsf{top} \otimes \mathrm{op}(z_1,\ldots,z_n)) \text{ where } z_j = s_j.\mathsf{top}$$

Such a prefix summarizes a path in the lower levels, and its annotation w/t specifies both a label $w \neq \varepsilon$ and a stack $t : T@Y$ for continuing at the top level. The label of a path is the concatenation from left to right of the strings over D that annotate the transitions. The *weight* of a top-level C-path is defined as in the 0-rank case, and the *weight* of a cross-level C-path is similar but the initial stack is specified by the first (cross-level) transition. The configuration C is *unambiguous* if it satisfies the following two conditions:

1. For every label $w \in D^*$ there is at most one accepting C-path (top-level or cross-level) labeled with w.
2. For every transition $(p, \mathrm{op}(\mathcal{A}_{i1},\ldots,\mathcal{A}_{in}), q)$, the denotations $[\![C_{i1}]\!]$, …, $[\![C_{in}]\!]$ have equal domains.

For an unambiguous configuration C, the denotation $[\![C]\!] : D^* \rightharpoonup T@Y$ is defined as follows: if there is an accepting C-path π (top-level or cross-level) labeled with w, then $[\![C]\!]\ w = s.\mathsf{pop}.\mathsf{push}(y)$ where s is the initial stack (specified by C_0 for top-level C-paths, and by the initial transition for the cross-level C-paths) and y is the weight of π.

For an SA $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ and a bounded stack type T, we define the denotation $\langle\!\langle \mathcal{A} \rangle\!\rangle_T : T \to (D^* \rightharpoonup T@Y)$ as $\langle\!\langle \mathcal{A} \rangle\!\rangle_T\ s\ w = s.\mathsf{push}([\![\mathcal{A}]\!]\ w)$.

Figure 6 describes the evaluation algorithm for the base case of a streaming automaton of rank 0. Observe that the algorithm specifies a procedure $\mathbf{next}(d)$ for consuming the element d, and a procedure $\mathbf{start}(s)$ for starting a new input thread given the context stack s. This generalization of being able to start several parallel input threads is necessary when the automaton is nested beneath other upper-level automata.

Figure 7 describes the evaluation algorithm for the case of a streaming automaton of rank strictly greater than 0. The interface is the same as for the base case: there are procedures $\mathbf{start}(s)$ and $\mathbf{next}(d)$. The main difference is that the algorithm in this case has to deal with the invocation transitions: every time a token is at a call state the corresponding subautomata are restarted, and every time the subautomata have output the corresponding return state is updated with the output stack.

▶ **Lemma 3.** Let $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ be an SA and T be a bounded stack type. Then:

1. Let C be an unambiguous $(\mathcal{A}, T)$-configuration and s a stack of type T so that $[\![C]\!]$ and $\langle\!\langle \mathcal{A} \rangle\!\rangle_T(s)$ are disjoint. Then, the configuration $\mathbf{start}(C, s)$, as described operationally in Figure 6 and Figure 7, is unambiguous and satisfies $[\![\mathbf{start}(C, s)]\!] = [\![C]\!] \sqcup \langle\!\langle \mathcal{A} \rangle\!\rangle_T(s)$.
   Notation: If f and g are partial functions with disjoint domains, the partial function $f \sqcup g$ has domain $\mathrm{dom}(f) \cup \mathrm{dom}(g)$ and agrees with both f and g.
2. Let C be an unambiguous $(\mathcal{A}, T)$-configuration and $d \in D$. Then, the configuration $\mathbf{next}(C, d)$, as described operationally in Figure 6 and Figure 7, is unambiguous and satisfies $[\![\mathbf{next}(C, d)]\!]\ w = [\![C]\!]\ dw$ for all sequences $w \in D^*$.

Lemma 3 establishes the main semantic property for configurations that is needed for proving the correctness of the evaluation algorithm.

▶ **Theorem 4.** *The streaming algorithm of Figure 6 and Figure 7 solves the evaluation problem for streaming automata. The space footprint of the algorithm and the processing time per element are independent of the length of the stream and quadratic in the size of the automaton (assuming that the data types require unit space and the operations unit time).*

Streaming automaton $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ of rank 0 & bounded stack type T.
state: unambiguous $(\mathcal{A}, T)$-configuration $C : \mathrm{Cfg}\langle\mathcal{A}, T\rangle$, that is, $C : Q \rightharpoonup T@Y$

    if ($\mathit{this}.C(q)$ is defined) then return $\mathit{this}.C(q)$
  return nil

start($\mathrm{Cfg}\langle\mathcal{A}, T\rangle$ *this*, $T\ s$) : // precondition: $[\![\mathit{this}.C]\!]$ and $\langle\!\langle\mathcal{A}\rangle\!\rangle_T(s)$ are disjoint
  foreach $q \in Q_I$ do // place token on each initial state
    // $\mathit{this}.C(q)$ must be undefined
    $\mathit{this}.C(q) := s.\mathsf{push}(I(q))$

next($\mathrm{Cfg}\langle\mathcal{A}, T\rangle$ *this*, $D\ d$) :
  $\mathrm{Map}\langle Q, T@Y\rangle\ C_{\mathrm{next}} := \bot$
  foreach transition (p, ϕ, σ, q) in Δ do
    if $\phi(d) = \mathit{true}$ then
      $T@Y\ s := \mathit{this}.C(p)$ // current stack
      $Y\ y := s.\mathsf{top} \otimes \sigma(d)$ // new value
      $C_{\mathrm{next}}(q) := s.\mathsf{pop}.\mathsf{push}(y)$ // new stack
  $\mathit{this}.C := C_{\mathrm{next}}$

Figure 6 General evaluation algorithm for an SA of rank 0.

The guarantees of Theorem 4 apply unconditionally to the case of constant-size types and operations (e.g., integers and floating-point numbers specified by machine architectures). In the case of infinite data types, one may need to account for the additional complexity of computing on their unbounded values to obtain a more precise analysis. In any case, however, Theorem 4 can be understood as saying that the computational overhead of parsing the input stream and combining the intermediate results is not significant.

4 Lower Bounds

The efficient evaluation algorithm of the previous section depends crucially on the unambiguity and parallel-consistency of the automata. In fact, both these syntactic restrictions are essential for efficient evaluation. More specifically, ambiguous nondeterminism can make the streaming space complexity of evaluation linear in the size of stream. Moreover, the absence of parallel-consistency allows the encoding of unambiguous regular expressions with intersection. The streaming matching problem for such expressions requires space that is exponential in the size of the expression. These lower bounds highlight the difficulty of efficiently evaluating quantitative automata that allow for the interaction between nondeterminism and parallelism.

Consider a stream of natural numbers and the problem MinAvgSuffix for the streaming computation of the function $f(x_1x_2\ldots x_n) = \min_{i=1}^{n} \mathrm{average}(x_i, x_{i+1}, \ldots, x_n)$, where $x_1x_2\ldots x_n$ is the stream seen so far. An NSA similar to M_2 of Figure 1 may be constructed which computes from each suffix a pair $(\mathrm{sum}, \mathrm{count})$, and that is nested inside an automaton dividing the components of the pair to obtain the average. Since this automaton computes MinAvgSuffix, the following theorem asserts a lower bound for the evaluation problem of NSAs with two-level nesting but without parallelism.

Streaming automaton $\mathcal{A} = (Q, X, Y, \Delta, I, F, \otimes)$ **of rank** > 0 **& bounded stack type** T**.**
state: unambiguous $(\mathcal{A}, T)$-configuration $C : \mathrm{Cfg}\langle \mathcal{A}, T\rangle$

      $z_j :=$ **output**($\mathit{this}.C_{ij}$).top for all $j = 2, \ldots, n$
      $C_0^{\mathrm{next}}(q) := s_1'.\mathsf{pop}.\mathsf{push}(y \otimes \mathrm{op}(z_1, z_2, \ldots, z_n))$
  foreach transition $(p, \mathrm{op}(\mathcal{A}_{i1}, \ldots, \mathcal{A}_{in}), q)$ in Δ do // restart subautomata
    if ($C_0^{\mathrm{next}}(p) \neq \mathsf{nil}$) then // check if there is token on invocation state
      start($\mathit{this}.C_{i1}, C_0^{\mathrm{next}}(p)$); **start**($\mathit{this}.C_{ij}, []$) for $j = 2, \ldots, n$
      $C_0^{\mathrm{next}}(p) := \mathsf{nil}$
  $\mathit{this}.C_0 := C_0^{\mathrm{next}}$

Figure 7 General evaluation algorithm for an SA of rank strictly greater than 0.

▶ **Theorem 5.** *Any streaming algorithm for* MinAvgSuffix *requires* $\Omega(n)$ *bits of memory, where* n *is the size of the stream seen so far.*

The following theorem states that the parallel-consistency requirement is essential for evaluation that is quadratic in the size of the automaton. The idea is based on [21].

▶ **Theorem 6.** *The evaluation problem for unambiguous streaming automata without the parallel-consistency restriction requires space exponential in the size of the automaton.*

5 Conclusion

We have considered symbolic weighted automata extended with two crucial features for expressing streaming computations: hierarchical nesting of several aggregators, and parallel execution. The following table summarizes the space complexity of the evaluation problem, where m is the size of the automaton and n the length of the data stream:

	no nesting	nesting without parallelism	consistent parallelism	general parallelism
unambiguous nondeterminism	$O(m)$	$O(m^2)$	$O(m^2)$ [Thm 4]	$O(\exp(m))$ [Thm 6]
general nondeterminism	$O(m)$	$\Omega(n)$ [Thm 5]	$\Omega(n)$	$\Omega(n)$

In *nesting without parallelism*, a transition may call a single subautomaton. *General parallelism* allows transitions with the construct $\mathrm{op}(\mathcal{A}_1, \ldots, \mathcal{A}_m)$, which matches only those strings accepted by every $\mathcal{A}_i$. *Consistent parallelism* restricts this to require $L(\mathcal{A}_1) = \cdots = L(\mathcal{A}_m)$. These complexities assume that the types of the signature require unit space, and that the operations and predicates require unit time.

Abstract

Deterministic two-way transducers define the robust class of regular functions which is, among other good properties, closed under composition. However, the best known algorithms for composing two-way transducers cause a double exponential blow-up in the size of the inputs. In this paper, we introduce a class of transducers for which the composition has polynomial complexity. It is the class of reversible transducers, for which the computation steps can be reversed deterministically. While in the one-way setting this class is not very expressive, we prove that any two-way transducer can be made reversible through a single exponential blow-up. As a consequence, we prove that the composition of two-way transducers can be done with a single exponential blow-up in the number of states.

A uniformization of a relation is a function with the same domain and which is included in the original relation. Our main result actually states that we can uniformize any non-deterministic two-way transducer by a reversible transducer with a single exponential blow-up, improving the known result by de Souza which has a quadruple exponential complexity. As a side result, our construction also gives a quadratic transformation from copyless streaming string transducers to two-way transducers, improving the exponential previous bound.

1 Introduction

Automata and transducers. Automata theory is a prominent domain of theoretical computer science, initiated in the 60s [4] and still very active nowadays. Many extensions of finite automata have been studied such as automata over more complex structures (infinite words, trees, *etc*) or transducers which can be seen as automata with an additional write-only output tape and which will be the focus of our study in the remainder of this article.

Transducers have been studied for almost as long as automata [1] and important results have been obtained, however the theory of transducers is not as advanced as automata theory.

* The full version of this article can be found at [5], http://arxiv.org/abs/1702.07157.

Figure 1 The language A^*aA^* can be recognized by a deterministic (left) or codeterministic (right) automaton, but not by a reversible one.

One of the reasons for this is that many descriptions which are equivalent for automata become different in expressiveness in the case of transducers. For instance, deterministic and non-deterministic automata recognize the same class of languages, the *regular languages*. However this is not the case for transducers since in particular a deterministic transducer must realize a function while a non-deterministic one may realize a relation. Similarly, by allowing the reading head to move left and right, one gets a two-way model of automata and it is known that two-way automata are as expressive as one-way automata [12]. However two-way transducers can model relations and functions that are unobtainable in the one-way case, such as the function mirror which reverses its input. Recently, two-way transducers were also proven to be equivalent to the one-way deterministic model of *streaming string transducers* [2], which can be thought of as transducers with write-only registers.

Reversible transducers. A transition system is called *reversible* when for every input, the directed graph of configurations is composed of nodes of in-degree and out-degree at most one. This property is stronger than the more studied notion of determinism since it allows to navigate back and forth between the steps of a computation. In this article, we study the class of transducers that are simultaneously deterministic and codeterministic, *i.e.* reversible. The main motivation for the definition of this class is its good properties with respect to composition. When we consider one-way transducers, runs only go forward and thus determinism gives good properties for composition: the next step of a run is computed in constant time. However, when considering composition of two-way transducers, the second machine can move to the left, which corresponds to rewinding the run of the first machine. Then the stronger property of reversibility allows for this back and forth navigation over runs of transducers, and we recover the property of reaching the next (or previous here) step of a computation in a constant time. This leads to the recovery of the polynomial state complexity of composition which exists for deterministic one-way transducers.

Let us now discuss the expressiveness of reversible transducers. Regarding automata in the one-way case, it is well-known that any regular language can be recognized by a deterministic one-way automaton and symmetrically by a codeterministic one-way automaton, since the mirror of a regular language is still regular. However, the class of one-way reversible automata is very restrictive (see Figure 1 for an example or [11] for a study of its expressive power, where they are called bideterministic). It turns out however, that if we allow bidirectionality then any regular language can be recognized by a reversible automaton. In fact, a two-way reversible automaton can be constructed from either a one-way or two-way automaton using only a linear number of states (see [9] and [10], respectively). We prove, as a consequence of our main theorem, that reversible transducers are as expressive as functional two-way transducers, and exactly capture the class of regular functions. As stated earlier, regular functions are also characterized by streaming string transducers (SST). As a byproduct, we also give a quadratic construction from copyless SST to reversible transducers, improving results from [3, 6].

Synthesis problem and uniformization of transducers. In the bigger picture of verification, two-way transducers can be used to model transformations of programs or non-reactive systems. If we consider the synthesis problem, where the specification is given as a relation of admissible input-output pairs, an implementation is then given as a function, with the same domain, relating a unique output to a given input. The uniformization problem asks if given a relation, we can extract a function that has the same domain, and is included in the relation. We argue that the synthesis problem can be instantiated in the setting of transformations as the problem of uniformization of a non-deterministic two-way transducer by a functional transducer. Our main result states that we can uniformize any non-deterministic two-way transducer by a reversible transducer with a single exponential blow-up.

Related work. As stated earlier, reversible one-way automata were already considered in [11]. Two-way reversible automata were shown to capture the regular languages in [9] by a construction from a one-way deterministic automaton to a two-way reversible automaton with a linear blow-up. This construction was extended to two-way automata in [10], still with a linear complexity. However, these constructions for automata cannot be simply extended to transducers because more information is needed in order to produce the outputs at the right moment. To the best of our knowledge, reversible transducers have not been studied yet, however, since we introduce reversible transducers as a tool for the composition of transducers, our work can be linked with the construction of Hopcroft and Ullman that gives the composition of a one-way transducer and a two-way transducer, while preserving determinism. Our construction strictly improves theirs, since ours produces, with a polynomial complexity instead of an exponential one, a reversible transducer that can in turn be easily composed.

A procedure for the uniformization of a two-way non-deterministic transducer by a deterministic one has been known since [7]. The complexity of this procedure is quadruply exponential, while our construction is done in a single one, and produces a reversible transducer.

Organization of the paper. Preliminary definitions are given in the next Section. In Section 3, we present our main results on composability and expressiveness of reversible transducers. Section 4 is devoted to the main technical construction of the paper. Connections with streaming string transducers are discussed in Section 5 while further works are considered in Section 6.

2 Automata and transducers

Given a finite alphabet A, we denote by A^* the set of finite words over A, and by ε the empty word. We will denote by $A_{\vdash\dashv}$ the alphabet $A \uplus \{\vdash, \dashv\}$, where the new symbols $\vdash$ and $\dashv$ are called the *left* and *right endmarkers*. A *language* over A is a subset $\mathcal{L}$ of A^*. Given two finite alphabets A and B, a *transduction* from A to B is a relation $\mathcal{R} \subseteq A^* \times B^*$.

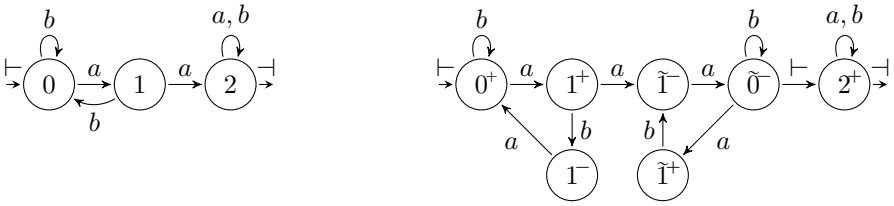
Automata. A *two-way finite state automaton* (2FA) is a tuple $\mathcal{A} = (A, Q, q_I, q_F, \Delta)$, where A is a finite alphabet; Q is a finite set of states partitioned into the set of forward states Q^+ and the set of backward states Q^-; $q_I \in Q^+$ is the initial state; $q_F \in Q^+$ is the final state; $\Delta \subseteq Q \times A_{\vdash\dashv} \times Q$ is the state transition relation. By convention, q_I and q_F are the only forward states verifying $(q_I, \vdash, q) \in \Delta$ and $(q, \dashv, q_F) \in \Delta$ for some $q \in Q$. However, for any backward state $p^- \in Q^-$, Δ might contain transitions $(p^-, \vdash, q)$ and $(q, \dashv, p^-)$, for some

$q \in Q$. Note that, in our figures, we do not represent explicitly the initial and final states, and rather use arrows labeled with the endmarkers to indicate the corresponding transitions. A configuration $u.p.u'$ of $\mathcal{A}$ is composed of two words $u, u' \in A^*_{\vdash\dashv}$ and a state $p \in Q$. The configuration $u.p.u'$ admits a set of successor configurations, defined as follows. If $p \in Q^+$, the input head currently reads the first letter of the suffix $u' = a'v'$. The successor of $u.p.u'$ after a transition $(p, a', q) \in \Delta$ is either $ua'.q.v'$ if $q \in Q^+$, or $u.q.u'$ if $q \in Q^-$. Conversely, if $p \in Q^-$, the input head currently reads the last letter of the prefix $u = va$. The successor of $u.p.u'$ after $(p, a', q) \in \Delta$ is $u.q.u'$ if $q \in Q^+$, or $v.q.au'$ if $q \in Q^-$. For every word $u \in A^*_{\vdash\dashv}$, a *run* of $\mathcal{A}$ on u is a sequence of successive configurations $\varrho = u_0.q_0.u'_0, \dots, u_m.q_m.u'_m$ such that for every $0 \leqslant i \leqslant m$, $u_i u'_i = u$. The run ϱ is called *initial* if it starts in configuration $q_I.u$, *final* if it ends in configuration $u.q_F$, *accepting* if it is both initial and final, and *end-to-end* if it starts and ends on the boundaries of u. More precisely, it is called *left-to-right* if $q_0, q_m \in Q^+$ and $u_0 = u'_m = \varepsilon$; *right-to-left* if $q_0, q_m \in Q^-$ and $u'_0 = u_m = \varepsilon$; *left-to-left* if $q_0 \in Q^+$, $q_m \in Q^-$ and $u_0 = u_m = \varepsilon$; *right-to-right* if $q_0 \in Q^-$, $q_m \in Q^+$ and $u'_0 = u'_m = \varepsilon$. Abusing notations, we also denote by Δ the extension of the state transition relation to a subset of $Q \times A^*_{\vdash\dashv} \times Q$ composed of the triples (p, u, q) such that there exists an end-to-end run on u between p and q. For every triple $(p, u, q) \in \Delta$, we say that q is a *u-successor* of p and that p is a *u-predecessor* of q. The language $\mathcal{L}_\mathcal{A}$ *recognized* by $\mathcal{A}$ is the set of words $u \in A^*$ such that $\vdash u \dashv$ admits an accepting run, i.e., $(q_I, \vdash u \dashv, q_F) \in \Delta$. The automaton $\mathcal{A}$ is called

- a *one-way finite state automaton* (1FA) if the set Q^- is empty;
- *deterministic* if for all $(p, a) \in Q \times A_{\vdash\dashv}$, there is at most one $q \in Q$ verifying $(p, a, q) \in \Delta$;
- *codeterministic* if for all $(q, a) \in Q \times A_{\vdash\dashv}$, there is at most one $p \in Q$ verifying $(p, a, q) \in \Delta$;
- *reversible* if it is both deterministic and codeterministic.
- *weakly branching* if for all $a \in A$ there is at most one state $p \in Q$ and one pair of distinct states $q_1, q_2 \in Q$ such that $(p, a, q_1) \in \Delta$ and $(p, a, q_2) \in \Delta$.

An automaton with several initial and final states can be simulated by using non-determinism while reading the endmarker $\vdash$ and non-codeterminism while reading the endmarker $\dashv$, hence requiring a single initial state and a single final state does not restrict the expressiveness of our model. Let us remark that unlike in the case of most two-way machines, a reversible two-way automaton always halts on any input. Indeed, codeterminism insures that it is never the case that two transitions head to the same configuration. Hence, the unique run (due to determinism) cannot loop since no configuration can be visited twice, and the first configuration starts from the left of the initial endmarker, which is a configuration that cannot be reached later on in the run.

Transducers. A *two-way finite state transducer* (2FT) is a tuple $\mathcal{T} = (A, B, Q, q_I, q_F, \Delta, \mu)$, where B is a finite alphabet; $\mathcal{A}_\mathcal{T} = (A, Q, q_I, q_F, \Delta)$ is a 2FA, called the *underlying automaton* of $\mathcal{T}$; and $\mu : \Delta \to B^*$ is the output function. A run of $\mathcal{T}$ is a run of its underlying automaton, and the language $\mathcal{L}_\mathcal{T}$ recognized by $\mathcal{T}$ is the language $\mathcal{L}_{\mathcal{A}_\mathcal{T}} \in A^*$ recognized by its underlying automaton. Given a run ϱ of $\mathcal{T}$, we set $\mu(\varrho) \in B^*$ as the concatenation of the images by μ of the transitions of $\mathcal{T}$ occurring along ϱ. Note that in the deterministic (or codeterministic) case we are able to extend μ to end-to-end runs since in this case we can unambiguously associate an end-to-end run to a unique sequence of transitions (p, u, q). The transduction $\mathcal{R}_\mathcal{T} \subseteq A^* \times B^*$ defined by $\mathcal{T}$ is the set of pairs (u, v) such that $u \in \mathcal{L}_\mathcal{T}$ and $\mu(\varrho) = v$ for an accepting run ϱ of $\mathcal{A}_\mathcal{T}$ on $\vdash u \dashv$. Two transducers are called *equivalent* if they define the same transduction. A transducer $\mathcal{T}$ is respectively called one-way (1FT), deterministic, weakly branching, codeterministic or reversible, if its underlying automaton has the corresponding property.



(a) A deterministic 1FA $\mathcal{A}_1$ **(b)** A reversible 2FA $\mathcal{A}_2$

Figure 2 Two automata recognizing the language $\mathcal{L}_{aa} = A^*aaA^*$.

Examples. Let us consider the language $\mathcal{L}_{aa} \subseteq \{a, b\}^*$ composed of the words that contain two a symbols in a row. This language is recognized by the deterministic one-way automaton $\mathcal{A}_1$, represented in Figure 2a, and by the reversible two-way automaton $\mathcal{A}_2$, represented in Figure 2b. However, it is not recognizable by a one-way reversible automaton. Let us analyze the behavior of $\mathcal{A}_2$ to see how moving back and forth through the input allows it to recognize $\mathcal{L}_{aa}$ in a reversible manner. First, $\mathcal{A}_2$ uses an intermediate step to go from 1^+ back to 0^+ when reading a b, to avoid creating non-codeterminism. Second, once $\mathcal{A}_2$ reads two consecutive a symbols, it does not go directly in the final state looping on every input, since this would generate non-codeterminism. Instead, $\mathcal{A}_2$ goes in an inverse copy of the first three states, where it rewind its run until the left endmarker. It is then free to go in the looping accepting state.

3 Results on reversible transducers

In this section, we present the main results of our paper. In Subsection 3.1, we show the polynomial composition of reversible transducers. In the following, we give expressiveness results of the class of reversible transducers, relying on this composition procedure as well as the construction presented in Section 4.

3.1 Composition of reversible transducers

The nicest feature of reversible transducers has to be the low complexity (and simplicity) of their composition. Indeed the composition of two such transducers is polynomial in the number of states of the inputs, and the construction is itself quite simple. This is due to the fact that the difficult part in the composition of transducers is to be able to navigate the run easily. In the one-way case, the composition is easy since runs can only move forward. In the two-way case, one needs to advance in the run, but also rewind it. Since the former is made easy by the determinism, and the latter is symmetrically handled by the codeterministim, composition of reversible transducers is straightforward. Let us also remark that only the first transducer has to be reversible in order to obtain a polynomial complexity. However the reversible nature of the obtained transducer depends on the input transducers being both reversible.

▶ **Theorem 1.** *Let $\mathcal{T}_1$ be a reversible two-way transducers and $\mathcal{T}_2$ be two-way transducer with n_1 and n_2 states respectively, such that $\mathcal{T}_1$ can be composed with $\mathcal{T}_2$. Then one can construct a two-way transducer $\mathcal{T}_3$ with $n_1 \cdot n_2$ states realizing $\mathcal{R}_{\mathcal{T}_2} \circ \mathcal{R}_{\mathcal{T}_1}$.*
Furthermore, if $\mathcal{T}_2$ is reversible, deterministic or codeterministic, then so is $\mathcal{T}_3$.

Proof. Let $\mathcal{T}_1 = (A, B, Q, q_I, q_F, \Delta, \mu)$ and $\mathcal{T}_2 = (B, C, P, p_I, p_F, \Gamma, \nu)$. We define $\mathcal{T}_3 = (A, C, Q \times P, (q_I, p_I), (q_F, p_F), \Theta, \xi)$. The idea is that at each step, $\mathcal{T}_3$ simulates a transition

$\delta \in \Delta$, plus the behavior of $\mathcal{T}_2$ over the production $\mu(\delta) \in B^*$ of this transition. To be precise, the transducer $\mathcal{T}_3$ also detects when it simulates an initial or final configuration of $\mathcal{T}_1$ (i.e. upon reading an endmarker in the initial or final state), and accordingly adds the corresponding endmarker to the production before simulating $\mathcal{T}_2$. The partition of the set of states of $\mathcal{T}_3$ depends on the combination of the signs of both components. If $\mathcal{T}_2$ is moving to the right, we use the determinism of $\mathcal{T}_1$, we update the first component of the current state according to the unique transition δ originating from it, and we simulate $\mathcal{T}_2$ entering $\mu(\delta)$ from the left. To do so, $\mathcal{T}_3$ needs to have access to the same letter of the input tape as $\mathcal{T}_1$. Thus, we have $(Q^+ \times P^+) \subseteq (Q \times P)^+$ and $(Q^- \times P^+) \subseteq (Q \times P)^-$. If $\mathcal{T}_2$ is moving to the left, then we use the codeterminism of $\mathcal{T}_1$ to rewind the corresponding run, we update the first component of the current state according to the unique transition δ arriving in it, and we simulate $\mathcal{T}_2$ entering $\mu(\delta)$ from the right. To do so, $\mathcal{T}_3$ needs to have access to the letter on the other side of the input head (with respect to $\mathcal{T}_1$). Thus, we have $(Q^- \times P^-) \subseteq (Q \times P)^+$ and $(Q^+ \times P^-) \subseteq (Q \times P)^-$.

We now define the transition function Θ and the production function ξ. Let $(q, a, q') \in \Delta$ be a transition of $\mathcal{T}_1$ such that $\varrho = (p, v, p')$ is an end-to-end run of $\mathcal{T}_2$, where v denotes the word $\mu(q, a, q') \in B^*$.

- If ϱ is a left-to-right run of $\mathcal{T}_2$, then $((q, p), a, (q', p'))$ belongs to Θ and produces $\nu(p, v, p')$.
- If ϱ is a left-to-left run of $\mathcal{T}_2$, then $((q, p), a, (q, p'))$ belongs to Θ and produces $\nu(p, v, p')$.
- If ϱ is a right-to-right run of $\mathcal{T}_2$, then $((q', p), a, (q', p'))$ belongs to Θ and produces $\nu(p, v, p')$.
- If ϱ is a right-to-left run of $\mathcal{T}_2$, then $((q', p), a, (q, p'))$ belongs to Θ and produces $\nu(p, v, p')$.

The behavior of the transducer $\mathcal{T}_3$ is completely determined by the combined behaviors of transducers $\mathcal{T}_1$ and $\mathcal{T}_2$. When $\mathcal{T}_3$ simulates a transition of $\mathcal{T}_1$, it also simulates the corresponding end-to-end run of $\mathcal{T}_2$ over the production of this transition. If the direction of both simulations is the same, then $\mathcal{T}_3$ moves forward. Otherwise, it moves backward. The transducer stops when it reaches a final state in both $\mathcal{T}_1$ over the input, and $\mathcal{T}_2$ over the simulated run over partial productions of the run of $\mathcal{T}_1$ over the input. Then the final output of $\mathcal{T}_3$ is the concatenation of the outputs of the partial runs of $\mathcal{T}_2$ it simulates, which corresponds to the output of $\mathcal{T}_1$. Hence, the transducer $\mathcal{T}_3$ realizes the composition $\mathcal{T}_2 \circ \mathcal{T}_1$. The possible determinism (resp. codeterminism) of $\mathcal{T}_3$ is a direct consequence of the one of $\mathcal{T}_1$ and $\mathcal{T}_2$. Indeed, a witness of non-determinism (resp. non codeterminism) of $\mathcal{T}_3$ can be traced back to a witness run of either $\mathcal{T}_1$ or $\mathcal{T}_2$ that is not deterministic (resp.codeterministic). ◀

3.2 One-way transducers

In the next subsections, we give some procedures to construct a reversible transducer from either a one-way or a two-way transducer. The main ingredient of the proofs is the technical construction from Lemma 6 (presented in Section 4) which constructs a reversible transducer from a *weakly branching* codeterministic one-way transducer. The proofs of this section share the same structure: in order to build a reversible transducer that defines a function $\mathcal{F}$, we express $\mathcal{F}$ as a composition of transductions definable by reversible transducers, and we conclude by using Theorem 1. The detailed constructions are presented in the full version of this article. Building on Lemma 6, we show that codeterministic one-way transducers can be expressed as the composition of weakly branching codeterministic ones.

▶ **Theorem 2.** *Given a codeterministic 1FT with n states, one can effectively construct an equivalent reversible 2FT with $4n^2$ states.*

Proof. Let $\mathcal{T}$ be a codeterministic 1FT with n states. The function $\mathcal{R}_\mathcal{T}$ can be expressed as the composition $\mathcal{R}_{\mathcal{T}'} \circ \mathcal{R}_\mathcal{M}$, where $\mathcal{M}$ and $\mathcal{T}'$ are defined as follows.

- Transducer $\mathcal{M}$ is a reversible 1FT with a single state that multiplies all the letters of the input word by n while marking them with a state of $\mathcal{T}$;
- Transducer $\mathcal{T}'$ is a weakly branching and codeterministic one-way transducer that has the same set of states as $\mathcal{T}$. On input $\mathcal{R}_\mathcal{M}(u)$, $\mathcal{T}'$ mimics the behavior of $\mathcal{T}$ on u, while using the fact that the input word is larger to desynchronize the non-deterministic branchings that were occurring simultaneously in $\mathcal{T}$. Intuitively, a transition of $\mathcal{T}$ can only be taken by $\mathcal{T}'$ at the copy of the letter corresponding to the target state of the transition.

By Lemma 6, $\mathcal{T}'$ can be made into a reversible 2FT $\mathcal{T}''$ with $4n^2$ states. Therefore, since both $\mathcal{T}''$ and $\mathcal{M}$ are reversible, we can conclude using Theorem 1, finally obtaining a reversible 2FT with $4n^2$ states equivalent to $\mathcal{T}$. ◀

Using composition again, the statement can be extended to deterministic one-way transducers.

▶ **Theorem 3.** *Given a deterministic 1FT with n states, one can effectively construct an equivalent reversible 2FT with $36n^2$ states.*

Proof. Let $\mathcal{T}$ be a deterministic 1FT with n states. Then $\overline{\mathcal{T}}$, the transducer obtained by reversing all transitions of $\mathcal{T}$, is codeterministic. The function $\mathcal{R}_\mathcal{T}$ can be expressed as the composition $\mathcal{R}_{M_B} \circ \mathcal{R}_{\overline{\mathcal{T}}} \circ \mathcal{R}_{M_A}$, where M_A and M_B realize the mirror functions over the input and output alphabet of $\mathcal{T}$ respectively. Both of them are realized by a 3 states reversible transducer. Then by Theorem 2, we can construct $\overline{\mathcal{T}}'$ which has $4n^2$ states, is reversible and realizes the same function as $\overline{\mathcal{T}}$. By Theorem 1, we can compose the three transducers, finally obtaining a reversible transducer equivalent to $\mathcal{T}$ with $9 \cdot 4n^2$ states. ◀

3.3 Two-way transducers

We now prove our main result, which states that any two-way transducer can be uniformized by a reversible two-way transducer. Let us recall that uniformization by a deterministic transducer was done in [7]. We use similar ideas for the uniformization. The key difference is that we rely on the construction of Section 4 while in [7], the main construction is the tree-trimming construction of Hopcroft-Ullman from [8].

▶ **Theorem 4.** *Given a 2FT $\mathcal{T}$ with n states, one can effectively construct a reversible 2FT $\mathcal{T}'$ whose number of states is exponential in n, and verifying $\mathcal{L}_{\mathcal{A}_{\mathcal{T}'}} = \mathcal{L}_{\mathcal{A}_\mathcal{T}}$ and $\mathcal{R}_{\mathcal{T}'} \subseteq \mathcal{R}_\mathcal{T}$.*

Proof. Let $\mathcal{T} = (A, B, Q, q_I, q_F, \Delta, \mu)$ be a 2FT with n states. We define a function uniformizing $\mathcal{R}_\mathcal{T}$ as the composition $\mathcal{R}_{\mathcal{T}'} \circ \mathcal{R}_\mathcal{U} \circ \mathcal{R}_{\mathcal{D}_r}$, where $\mathcal{D}_r$, $\mathcal{U}$ and $\mathcal{T}$ are defined as follows.

- The right-oracle $\mathcal{D}_r$ is a codeterministic one-way transducer with 2^{n^2+n} states that enriches each letter of the input word $u \in A^*_{\vdash\dashv}$ with information concerning the behavior of $\mathcal{T}$ on the corresponding suffix, represented by the set of pairs that admit a left-to-left run, and the set of states from which $\mathcal{T}$ can reach the final state.
- The uniformizer $\mathcal{U}$ is a deterministic one-way transducer with $n!$ states. On input $u' = \mathcal{R}_{\mathcal{D}_r}(u)$, $\mathcal{U}$ uses the information provided by $\mathcal{D}_r$ to pick a run ϱ_u of $\mathcal{T}$ on input u, and enriches each letter a_i of the input word with the sequence of transitions occurring in the run ϱ_u that correspond to the letter a_i.
- Finally, the reversible transducer $\mathcal{T}'$ has the same set of states as $\mathcal{T}$, and follows the instructions left by $\mathcal{U}$ to solve the non-determinism and the non-codeterminism.

As a consequence of Theorem 2 and Theorem 3, there exist two reversible 2FT $\mathcal{D}_r{}'$ and $\mathcal{U}'$ whose number of states are exponential in n, and that verify $\mathcal{R}_{\mathcal{D}_r'} = \mathcal{R}_{\mathcal{D}_r}$ and $\mathcal{R}_{\mathcal{U}'} = \mathcal{R}_{\mathcal{U}}$. Therefore, since $\mathcal{D}_r{}', \mathcal{U}'$ and $\mathcal{T}'$ are reversible, by Theorem 1 there exists a reversible transducer $\mathcal{T}''$ whose number of states is exponential in n, and that satisfies $\mathcal{R}_{\mathcal{T}''} = \mathcal{R}_{\mathcal{T}'} \circ \mathcal{R}_{\mathcal{U}'} \circ \mathcal{R}_{\mathcal{D}_r{}'} = \mathcal{R}_{\mathcal{T}}$. ◀

The following result is a direct corollary of Theorem 4, applied to deterministic two-way transducers.

▶ **Corollary 5.** *Reversible two-way transducers are as expressive as deterministic two-way transducers.*

4 The tree-outline construction

In this section lies the heart of our result. We show that any *weakly branching* and codeterministic transducer can be made reversible. These hypotheses allow us to simplify our proof, and still obtain a more general result, as a corollary.

▶ **Lemma 6.** *Let $\mathcal{T}$ be a codeterministic and weakly branching 1FT with m states. Then one can effectively construct a reversible 2FT $\mathcal{T}'$ with $4m^2$ states that is equivalent to $\mathcal{T}$.*

Proof. The construction presented in this proof is illustrated on an example in Figure 3. Let $\mathcal{T} = (A, Q, q_I, q_F, \Delta, \mu)$ be a codeterministic 1FT, and let $\prec$ be a total order over Q. As an example, take the codeterministic 1FT T presented in figure 3a.

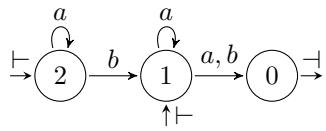
Let $\mathcal{T}' = (A, \mathcal{F}, f_I, f_F, \Delta', \mu')$ be a 2FT defined as follows:

On input $u \in \mathcal{L}_{\mathcal{T}}$, $\mathcal{T}'$ explores depth first the run-tree T_u composed of the initial runs of $\mathcal{T}$ on the word $\vdash u \dashv$ (illustrated in Figure 3b). More precisely it explores the "sheath" of the run-tree (see Figure 3c for a graphical representation). To do this, the states of $\mathcal{T}'$ are composed of two states of $\mathcal{T}$ with a marker. The first state represents the upper part of the sheath, while the second state represents the lower part. Moreover the marker is used to denote whether we are above the branch ($\underline{q}$) or below the branch ($\overline{q}$).

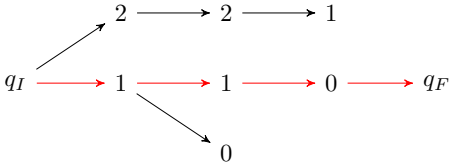
Initially we start with the state $(\underline{q_I}, \overline{q_I})$ and go forward according to the transitions of $\mathcal{T}$. While moving forward whenever a branching state q is reached, if the state is marked $\underline{q}$ it moves to the maximal successor of q (in order to stay above the branch) and symmetrically if the state is marked $\overline{q}$ it moves to the minimal successor of q (in order to stay below the branch). Whenever one of the branches reaches a dead end we continue the sheath exploration by switching the marker (*i.e.* changing from above the branch to below or vice-versa) and start moving backward accordingly to the transitions of $\mathcal{T}$. While moving backward, if the successor of a branching state q is reached, while we were inside the fork, *e.g.* in state $\overline{q_{\max}}$ (where $q_{\max}$ is the maximal successor of q), we continue the exploration of the sheath by going in the state $\underline{q_{\min}}$ and we start moving forward again. Whenever the upper and lower explorations of the sheath coincide, *i.e.* in states of the form $(\underline{q}, \overline{q})$ (represented in red in Figure 3d), it means we are on a prefix of the accepting run, we can thus produce the corresponding output.

Formally $\mathcal{T}' = (A, \mathcal{F}, f_I, f_F, \Delta', \mu')$ is defined as follows:

- $\mathcal{F} = \mathcal{F}^+ \cup \mathcal{F}^-$ where $\mathcal{F}^+ = \underline{Q} \times \overline{Q} \cup \overline{Q} \times \underline{Q}$ and $\mathcal{F}^- = (\overline{Q} \times \overline{Q} \cup \underline{Q} \times \underline{Q}) \backslash \{(\overline{p}, \overline{p}), (\underline{p}, \underline{p}) \mid p \in Q\}$
- $f_I = (\underline{q_I}, \overline{q_I})$
- $f_F = (\underline{q_F}, \overline{q_F})$
- We define the transition relation Δ' by differentiating several types of behavior, depending on whether we are going **f**orward, or **b**ackward, whether the **u**pper component or the



(a) A codeterministic transducer $\mathcal{T}$



(b) The run-tree of $\mathcal{T}$ on $\vdash ab \dashv$

(d) The run of $\mathcal{T}'$

Figure 3 Illustrations of the proof concepts of Lemma 6. For the sake of clarity, the outputs of $\mathcal{T}$ are omitted.

lower component is involved, and whether it is above or below its branch. Let p and q be two states in Q, and $a \in A$ be a letter.

If p has no a-successor, then:

(fua) $\big((\underline{p}, \overline{q}), a, (\overline{p}, \overline{q})\big) \in \Delta'$, and

(fuw) $\big((\overline{p}, \underline{q}), a, (\underline{p}, \underline{q})\big) \in \Delta'$.

If p has an a-successor, but not q, then:

(flw) $\big((\underline{p}, \overline{q}), a, (\underline{p}, \underline{q})\big) \in \Delta'$, and

(fla) $\big((\overline{p}, \underline{q}), a, (\overline{p}, \overline{q})\big) \in \Delta'$.

Otherwise, p and q admit an a-successor. We denote $p_{\max}$ (resp. $p_{\min}$) the maximal (resp. minimal) a-successor of p (resp. q) with respect to $\prec$. Then:

If $p_{\min} \neq p_{\max}$, then:

(buw) $\big((\overline{p_{\max}}, \overline{q}), a, (\underline{p_{\min}}, \overline{q})\big) \in \Delta'$, and

(bua) $\big((\underline{p_{\min}}, \underline{q}), a, (\overline{p_{\max}}, \underline{q})\big) \in \Delta'$.

If $q_{\min} \neq q_{\max}$, then:

(bla) $\big((\underline{p}, \underline{q_{\min}}), a, (\underline{p}, \overline{q_{\max}})\big) \in \Delta'$

(blw) $\big((\overline{p}, \overline{q_{\max}}), a, (\overline{p}, \underline{q_{\min}})\big) \in \Delta'$

(fualw) $\big((\underline{p}, \overline{q}), a, (\underline{p_{\max}}, \overline{q_{\min}})\big) \in \Delta'$,

(fuwla) $\big((\overline{p}, \underline{q}), a, (\overline{p_{\min}}, \underline{q_{\max}})\big) \in \Delta'$,

(bulw) $\big((\overline{p_{\min}}, \overline{q_{\min}}), a, (\overline{p}, \overline{q})\big) \in \Delta'$, and

(bula) $\big((\underline{p_{\max}}, \underline{q_{\max}}), a, (\underline{p}, \underline{q})\big) \in \Delta'$.

- We define μ' as the function such that for every $(p, a, q) \in \Delta$:
  - if $q = p_{\min} = p_{\max}$ then $\mu'\big((\underline{p}, \overline{p}), a, (\underline{q}, \overline{q})\big) = \mu(p, a, q)$
  - if $q = p_{\min} \neq p_{\max}$ then $\mu'\big((\overline{p_{\max}}, \overline{q}), a, (\underline{q}, \overline{q})\big) = \mu(p, a, q)$
  - if $q = p_{\max} \neq p_{\min}$ then $\mu'\big((\underline{q}, \underline{p_{\min}}), a, (\underline{q}, \overline{q})\big) = \mu(p, a, q)$

  and $\mu'(t) = \varepsilon$ for every $t \in \Delta'$ which is not of one of theses forms.

One can see, by a case study that $\mathcal{T}'$ is deterministic. Indeed, the fact that $\mathcal{T}$ is weakly branching implies that the rules **(buw)** and **(bua)** are mutually exclusive with the rules **(bla)** and **(blw)**. Moreover these four rules are mutually exclusive with the rules **(bulw)** and **(bula)** by construction. And since $\mathcal{T}$ is codeterministic, the predecessor is unique. Finally, the rules **(fua)**, **(fuw)**, **(flw)**, **(fla)**, **(fualw)**, and **(fuwla)** are mutually exclusive by construction, since the conditions on the number of a-successors are incompatible.

A similar case study gives that $\mathcal{T}'$ is codeterministic. Hence $\mathcal{T}'$ is reversible.

A detailed proof of the equivalence between $\mathcal{T}$ and $\mathcal{T}'$ can be found in the full version of the article, and we give a quick intuition of the proof. It relies on two main arguments. The first one is that at any point if the transducer $\mathcal{T}'$ follows two different runs, then it will come back to the same position, where the state that leads to the shortest run has been switched. Following this, we then prove that upon any branching, $\mathcal{T}'$ comes back to the same position but since the shortest run has been switched, it is able to solve the non-determinism, take the transition of the accepting run and produce the correct output. ◀

5 Streaming string transducers

Streaming string transducers, which were introduced in [2], are one-way deterministic automata with additional write-only registers. Partial outputs are stored in the registers via register updates, and at the end of a run an output is produced using these registers. Thus an SST realizes a function over words, and it is known that they are as expressive as 2FT [2]. Direct transformations from SST to 2FT were already considered in [3, 6]. However, these constructions were exponential in the number of states (and linear in the number of registers). Using Theorem 3, we are able to get a construction which is quadratic in the number of states (and also linear in the number of registers). Before explaining the construction, let us formally define the SST.

Substitutions. Given a finite alphabet A and a finite set $\mathcal{X}$ of variables. Let $\mathcal{S}_{\mathcal{X},A}$ denote the set of functions $\sigma : \mathcal{X} \to (\mathcal{X} \cup A)^*$. The elements of $\mathcal{S}_{\mathcal{X},A}$ are called *substitutions*. Any substitution σ can be extended to range over both variables and letters of the output alphabet $\hat{\sigma} : (\mathcal{X} \cup A)^* \to (\mathcal{X} \cup A)^*$ by setting $\hat{\sigma}(a) = a$ for every $a \in A^*$ and $\hat{\sigma}(uv) = \hat{\sigma}(u)\hat{\sigma}(v)$ for $u, v \in (\mathcal{X} \cup A)^*$. This allows us to easily compose substitutions from $\mathcal{S}_{\mathcal{X},A}$ by defining $\sigma_2 \circ \sigma_1$ as the usual function composition $\hat{\sigma_2} \circ \sigma_1$. We denote by $\mathsf{Id}_{\mathcal{X}}$ the identity element of $\mathcal{S}_{\mathcal{X},A}$, which maps every variable to itself, and by σ_ε the substitution mapping every variable to ε.

A substitution σ is called *copyless* if for every $X \in \mathcal{X}$, each variable $Y \in \mathcal{X}$ appears at most once in $\sigma(X)$, and for every $Y \in \mathcal{X}$ there exists at most one $X \in \mathcal{X}$ such that Y appears in $\sigma(X)$.

Streaming string transducers. A *streaming string transducer* (SSTfor short) is a tuple $\mathcal{Z} = (A, B, Q, q_I, q_F, \Delta, \mathcal{X}, O, \tau)$, where B is the output alphabet, $\mathcal{A}_\mathcal{Z} = (A, Q, q_I, q_F, \Delta)$ is a one-way deterministic automaton, called the underlying automaton of $\mathcal{Z}$; $\mathcal{X}$ is a finite set of variables; $O \in \mathcal{X}$ is the final variable; $\tau : \Delta \to \mathcal{S}_{\mathcal{X},B}$ is the output function. A run of $\mathcal{Z}$ is a run of its underlying automaton, and the language $\mathcal{L}_\mathcal{Z}$ recognized by $\mathcal{Z}$ is the language $\mathcal{L}_{\mathcal{A}_\mathcal{Z}} \in A^*$ recognized by its underlying automaton. Given a run ϱ of $\mathcal{Z}$ on u, we set $\tau(\varrho) \in \mathcal{S}_{\mathcal{X},B}$ as the composition of the images by τ of the transitions of $\mathcal{Z}$ occuring along ϱ. The transduction $\mathcal{R}_\mathcal{Z} \subseteq A^* \times B^*$ defined by $\mathcal{Z}$ is the function mapping any word u of $\mathcal{L}_{\mathcal{A}_\mathcal{Z}}$ to $(\sigma_\varepsilon \circ \tau(\varrho))(O)$, where ϱ is the single accepting run of $\mathcal{A}_\mathcal{Z}$ on $\vdash u \dashv$. The SST $\mathcal{Z}$ is called copyless, if for every run ϱ of $\mathcal{Z}$ the substitution $\tau(\varrho)$ is copyless.

▶ **Theorem 7.** *Given a copyless SST with n states and m variables, one can effectively construct an equivalent reversible 2FT with $8m \cdot n^2$ states.*

Proof. We write $\mathcal{Z}$ as the composition of a one-way deterministic transducer $\mathcal{D}_1$ and a reversible one $\mathcal{T}$. The first transducer has the same underlying automaton as $\mathcal{Z}$, the difference being that it outputs the substitution of $\mathcal{Z}$ instead of applying it. Then $\mathcal{T}$ is a transducer that navigates the substitutions to produce the output word of $\mathcal{Z}$. This can be done in a reversible fashion thanks to the property of copylessness of $\mathcal{Z}$. Note that the transducer $\mathcal{T}$ was already defined in [6], Section 4. Formally, let $\mathcal{Z} = (A, B, Q, q_I, q_F, \Delta, \mathcal{X}, O, \tau)$ be a copyless SST with n states and m variables, and let $S_{\mathcal{Z}} \subset \mathcal{S}_{A,\mathcal{X}}$ be the range of τ. We express $\mathcal{R}_{\mathcal{Z}}$ as the composition of $\mathcal{R}_{\mathcal{D}_1} : \mathcal{L}_{\mathcal{A}_{\mathcal{Z}}} \to S_{\mathcal{Z}}^*$ and $\mathcal{R}_{\mathcal{T}_2} : S_{\mathcal{Z}}^* \to B^*$, defined as follows.

- $\mathcal{D}_1$ is a deterministic 1FT obtained by stripping $\mathcal{Z}$ of its SST structure, i.e., $\mathcal{D}_1 = (A, S_{\mathcal{Z}}, Q, q_I, q_F, \Delta, \tau)$. It maps each word of $\mathcal{L}_{\mathcal{A}_{\mathcal{Z}}}$ to the corresponding sequence of substitutions.
- $\mathcal{T} = (S_{\mathcal{Z}}, B, P, init, fin, \Gamma, \nu)$ where $P^+ = \mathcal{X}^o \uplus \{init, fin\}$, $P^- = \mathcal{X}^i$. States labeled by i (resp. o) are *in* (resp. *out*) states and appear when we start (resp. finish) producing a variable. We define Γ and ν as follows:
  - $(init, \sigma, init) \in \Gamma$;
  - $(init, \vdash, O^i) \in \Gamma$;
  - $(O^o, \dashv, fin) \in \Gamma$;
  - $(X^i, \sigma, Y^i) \in \Gamma$ and $\nu((X^i, \sigma, Y^i)) = v$ if $\sigma(X) = vY...$ with $v \in B^*$;
  - $(X^i, \sigma, X^o) \in \Gamma$ and $\nu((X^i, \sigma, X^o)) = v$ if $\sigma(X) = v$;
  - $(X^o, \sigma, Y^i) \in \Gamma$ and $\nu((X^o, \sigma, Y^i)) = v$ if there exists a variable Z where $\sigma(Z) = ...XvY..$;
  - $(X^o, \sigma, Y^o) \in \Gamma$ and $\nu((X^o, \sigma, Y^o)) = v$ if $\sigma(Y) = ...Xv$.

  Due to copylessness, for any σ and any variable X, there is at most one variable Y such that X appears in $\sigma(Y)$. Plus, as the variables are ordered by their appearance in $\sigma(Y)$, the transducer $\mathcal{T}$ is reversible. It starts by reaching the end of the word, then starts producing the variable O. By following the substitution tree of O, it then produces exactly the image of the input by $\mathcal{Z}$.

By Theorem 3, there exists a reversible 2FT $\mathcal{D}_1'$ with $4n^2$ states satisfying $\mathcal{R}_{\mathcal{D}_1'} = \mathcal{R}_{\mathcal{D}_1}$. Finally, since both $\mathcal{D}_1'$ and $\mathcal{T}$ are reversible, by Theorem 1 there exists a reversible transducer $\mathcal{T}'$ with $8m \cdot n^2$ states such that $\mathcal{R}_{\mathcal{T}'} = \mathcal{R}_{\mathcal{T}} \circ \mathcal{R}_{\mathcal{D}_1'} = \mathcal{R}_{\mathcal{Z}}$. ◀

6 Conclusion

We argue that reversible transducers can be seen as a canonical representation of regular transductions. We believe that the polynomial complexity of composition of reversible transducers is a good tool for the verification of cascades of transformations of non-reactive systems. While preserving the expressive power of functional transducers, reversible transducers allow for easier manipulations, the best example being their polynomial composition. Thanks to the tree-outline construction that we presented, one can uniformize a non-determinsitic two-way transducer by a reversible one with a single exponential blow-up. This improves the known constructions that were used up to now, however it is still open whether this blow-up can be avoided. In [10] the authors extended the result of [9] and showed that deterministic two-way automata can be made reversible with a linear blow-up. We conjecture that our approach can also be extended to the two-way case and that deterministic two-way transducers can be made reversible using only a polynomial number of states.

We have shown that applying this construction allows for a quadratic transformation from copyless streaming string transducers to reversible two-way transducers. The converse does not hold, since even on languages deterministic two-way automata are known to be exponentially more succint than deterministic one-way automata. Beyond this, we do not reject the possibility that if one were to embed some recognition power into the variables of a SST, it may be possible to have a polynomial transformation from reversible automata to copyless SST.

Abstract

We study various models of transducers equipped with origin information. We consider the semantics of these models as particular graphs, called origin graphs, and we characterise the families of such graphs recognised by streaming string transducers.

1 Introduction

This paper is about string-to-string transductions with origin semantics. A string-to-string transduction is a binary relation between strings over fixed input and output alphabets. Examples include the *squaring* transduction $w \mapsto ww$ or the *subword* transduction, which is the set of pairs (u, v) such that v is a subword of u. Note that squaring is a function, while subword is a relation; both types will be studied. The origin semantics of a transduction (technically speaking, of a device computing it) consists not only of pairs (u, v) of input and output words, but also gives an *origin mapping* that specifies which positions of the input word were used to produce which positions of the output word. For example, suppose that we model the squaring transduction by a two-way automaton which does two consecutive left-to-right passes over the input word and copies the input word in each one. In this case, the origin semantics over a particular input word can be visualised as follows:

An object as in the above picture is called an *origin graph*, and we define an *origin string-to-string transduction* to be a set of origin graphs. Origin semantics is more fine-grained semantics than the usual semantics of transductions in the sense that even if two devices compute the same transduction, they might not have the same origin semantics. Origin semantics were introduced in [5], where it was shown that existing models of transducers, such as two-way transducers (also called two-way automata with outputs, e.g. [11]), MSO string-to-string transductions [9], or streaming string transducers [1, 3] can be equipped with origin semantics so that they generate not sets of pairs of words, but sets of origin graphs (the name origin graph is new in this paper). Furthermore, existing results on equivalence between models remain true when the origin semantics are used [5]. We aim to study sets of origin graphs that are origin semantics of transducers. There are two parts.

In the first part, we study decision problems that involve MSO properties of origin graphs. The main result (not very hard) is that when given an MSO formula on origin graphs, and an origin string-to-string transduction realised by a nondeterministic streaming string transducer, one can decide if the formula is true in some origin graph from the transduction. This result gives a generic framework for deciding questions like: is the origin mapping order preserving? The result is proved by using techniques from the theory of MSO transductions [9].

In the second part, we study the structural properties of those classes of origin graphs that can be obtained by taking the origin semantics of some streaming string transducer (or any of the other equivalent models). Our goal is to describe them in a machine independent way. The principal result, Theorem 10, gives the following characterisation: a set of origin graphs is the origin semantics of some nondeterministic streaming string transducer if and only if it has three properties: (1) it is MSO-definable as a set of coloured graphs; (2) it has bounded degree; and (3) it has bounded crossing, which means intuitively that the origin mapping does not oscillate too much. The idea to give a machine independent characterisation of origin semantics was already present in Theorem 1 from [5]. We believe however that origin graphs are a more intuitive and visual notion than the factorised words used in [5]. Furthemore, modelling the origin as a relational structure (the input word, the output word, and the origin information) makes it possible to use MSO logic, or to make the connection with structural notions such as clique width or tree width. Hence, this paper can be seen as a natural complement to the results form [5], or possibly a clearer picture. Furthermore, we study more general models than [5], in particular we allow nondeterminism and ε-transitions.

Important related work is the paper [10], which proposes to use logic to describe properties of origin graphs (they use the name *productions*). In [10], the authors ask about the decidability of checking if a transducer, seen as a set of origin graphs, satisfies a specification given in some logic. This is the direct inspiration for our results in Section 3, in particular our Theorem 6 which says that it is decidable if a given MSO formula is true in some origin graph generated by a given transducer. In [10], the logic used to express properties of origin graphs is a strict fragment of MSO, called $\mathcal{L}_T$, a type of two-variable logic. Therefore, our Theorem 6 is stronger than the model-checking result mentioned in [10, Section VI]. The reason why [10] uses a logic weaker than MSO is that they want to answer different questions than model-checking a given transducer; in particular the logic $\mathcal{L}_T$ is shown to have decidable satisfiability when evaluated on the class of all origin graphs, contrary to MSO.

2 Origin semantics

Define a *string-to-string transduction with input alphabet* Σ *and output alphabet* Γ to be a relation $R \subseteq \Sigma^* \times \Gamma^*$. A transduction is *functional* when it is a partial function.

▶ **Example 1** (Running example). Define the *squaring* functional transduction to be the function $\{a,b\}^* \to \{a,b\}^*$ defined by $w \mapsto ww$.

2.1 Transductions recognised by streaming string transducers

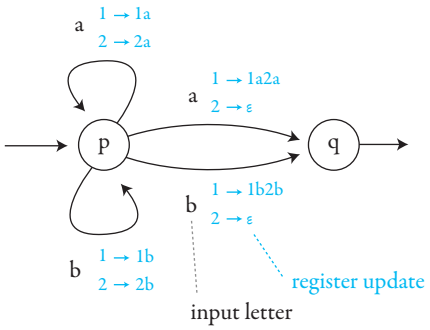
The main topic of this paper is the class of string-to-string transductions recognised by streaming string transducers [1]. Another equivalent presentation of this class is MSO string-to-string transductions, or a suitably defined nondeterministic version of two-way automata with output. We will mainly use the definition in terms of streaming string transducers, so we begin by defining that model.

Streaming string transducers. A streaming string transducer is a device which is used to transform (possibly non-deterministically) a word over an input alphabet into a word over an output alphabet. Because of nondeterminism, one input might produce several outputs, possibly zero. The output is prepared by using registers. Before describing the device itself, let us explain how registers are used. Let Γ be an output alphabet and let $\mathcal{R}$ be a set of *register names*. Define a *register valuation* to be a function $\mathcal{R} \to \Gamma^*$ and a *register update* to be a function $\mathcal{R} \to (\Gamma \cup \mathcal{R})^*$. A register update is viewed as a function from register valuations to register valuations in the following sense: if v is a register valuation and u is a register update, then applying u to v yields a register valuation which stores in register r the value $u(r)$ with each register name replaced by its contents under v. For example if $\mathcal{R}$ has only one register, and u is a register update defined by $r \mapsto ara$, then applying u to a register valuation simply adds the letter a to both the beginning and end of the word stored in the unique register r. A register update u is called *copyless* if for every register name r there is at most one register name s such that r appears in $u(s)$, and furthermore r appears at most once in $u(s)$.

▶ **Definition 2** (Streaming string transducer). The syntax[1] of a streaming string transducer with input alphabet Σ and output alphabet Γ consists of:

- a nondeterministic automaton $\mathcal{B}$ with input alphabet Σ, called the *underlying automaton*;
- a finite set of *register names* $\mathcal{R}$ with a distinguished *output register* $r_o \in \mathcal{R}$;
- a labelling of transitions in $\mathcal{B}$ by copyless register updates.

▶ **Example 3** (Running example). The squaring function is recognised by a functional streaming string transducer which has two registers 1,2, with the output register being 1. The following picture shows this underlying automaton and its labelling by register updates.

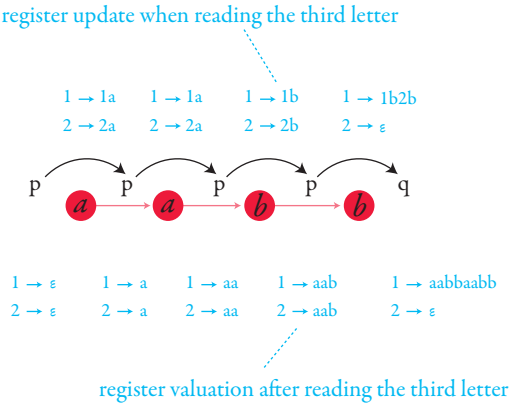


[1] Our syntax for streaming string transducers is different than the one used in [1], but it is routine to show that the expressive power is the same, as long as we allow nondeterminism.

The automaton uses nondeterminism to guess the last position so that the two registers are concatenated, however every nonempty input word admits exactly one run.

The semantics of a streaming string transducer is defined as follows. Suppose that ρ is a run of the underlying automaton $\mathcal{B}$, i.e., a sequence of transitions. Consider the empty register valuation which maps all registers to the empty word, and then apply all the register updates that label the transitions in ρ, beginning with the first transition and ending with the last transition. The output of ρ is defined to be the word over the output alphabet contained in the output register in the valuation described this way. Finally, the semantics of a streaming string transducer is defined to be the string-to-string transduction which consists of pairs (v, w) such that v is a word over the input alphabet and w is the output of some accepting run over the input word.

▶ **Example 4** (Running example)**.** Here is a picture of a run of the transducer from Example 3:



A streaming string transducer is called *unambiguous* if the automaton $\mathcal{B}$ admits at most one accepting run on every input word[2]. For an unambiguous streaming string transducer, its semantics is a partial function $\Sigma^* \to \Gamma^*$. The transducer in Example 3 is unambiguous.

2.2 Origin semantics and origin graphs

We now turn to the origin semantics of transducers. The idea is to give not just the output word, but also say which input positions were used to produce which output positions. The formalisation we use in this paper is *origin graphs*. Let fix an input alphabet Σ and an output alphabet Γ. For $w \in \Sigma^*$ and $v \in \Gamma^*$, an *origin graph* with input w and output v is defined to be a relational structure of the following form:

- the universe is the disjoint union of positions in w and positions in v;
- there are two binary predicates for the successor relations in w and v;
- there is a binary predicate, called the *origin mapping*, which is a total function from output positions to input positions;
- for each $a \in \Sigma \cup \Gamma$ there is a unary predicate which identifies positions with label a.

[2] One could also consider a streaming string transducer where the underlying automaton is deterministic. In this case, we would need to slightly modify the semantics, by adding a final function which performs a register update after reading the last input letter (e.g. concatenating the two registers as in the running example). After adding such final function, the deterministic model would have the same expressive power as the unambiguous variant used in this paper, see [1].

Note that the vocabulary of the relational structure depends on the choice of input and output alphabets; therefore a more formal definition would require talking about origin graphs over (Σ, Γ) where Σ is the input alphabet and Γ is the output alphabet. An origin graph can also be viewed as a directed graph, with vertices coloured by letters of the input and output alphabets, and edges coloured by three possible colours: successor edge in the input word, successor edge in the output word, and origin edge. Not every directed graph coloured this way is an origin graph; in an origin graph the input successors form a path, the output successors form a path on the remaining vertices, and the origin edges give a total function from the second path to the first one.

▶ **Definition 5.** An *origin string-to-string transduction* (origin transduction for short) consists of an input alphabet, an output alphabet, and a set of origin graphs over these alphabets.

Note that an origin transduction might contain origin graphs which differ only on the origin mapping. Here is an example picture, for the (not necessarily connected) subword relation equipped with the natural origin semantics:

An origin transduction is called *functional* if every input word appears in at most one origin graph. An example of a functional origin transduction is the squaring in our running example, when equipped with the natural origin information. A non-example is the subword relation.

Let us define the origin semantics of a streaming string transducer. When reading an input position x, the transducer executes a register update. Such a register update creates some new letters which are added to registers, and also moves the contents between registers. We assume that the origin of these created letters is the input position x, and remains this way even if the position is moved to different registers in subsequent transitions. Using this description, we can associate an origin graph to each run of the transducer. We say that an origin transduction is the *origin semantics of* (or to use an alternative name, *recognised by*) a streaming string transducer if it is the set of origin graphs corresponding to its successful runs. Note that, when the automaton is nondeterministic, different successful runs over the same input word and producing the same output word might generate different origin graphs.

3 MSO on origin graphs

In this section, we discuss properties of origin graphs that can be defined in monadic second-order logic MSO. This is the logic which extends first-order logic by allowing quantification over sets of elements in the universe (but not sets of pairs, nor sets of sets, etc.). For a definition of the syntax and semantics of MSO, see [9].

MSO on origin graphs. An origin graph is a special case of a relational structure. If the input and output alphabets are Σ and Γ, then the vocabulary of the relational structure consists of three binary relations (input edge, output edge, origin edge) as well as one unary predicate for each letter in $\Sigma \cup \Gamma$. We use the name *origin vocabulary of* (Σ, Γ) for this vocabulary. An MSO formula over this vocabulary defines a set of origin graphs, namely those

origin graphs where it is true. Note that the structures over the origin vocabulary which are origin graphs are a set definable in MSO, essentially because one can axiomatise in MSO (but not, e.g. in first-order logic) that a directed graph is a single finite directed path. Therefore when talking about MSO-definable sets of origin graphs, it makes no difference whether or not we require the MSO formula to check if a structure is actually an origin graph.

The following result shows that satisfiability of MSO over origin graphs produced by a given streaming string transducer is decidable.

▶ **Theorem 6.** *The following problem is decidable:*
Input: *A nondeterministic streaming string transducer $\mathcal{A}$ and an* MSO *formula φ over the origin vocabulary corresponding to $\mathcal{A}$;*
Question: *Is φ true in some origin graph in the origin semantics of $\mathcal{A}$?*

Proof Sketch. To prove this result it is convenient to use MSO transductions in the sense of Courcelle and Engelfriet, see [9]. We first convert $\mathcal{A}$ into a nondeterministic MSO transduction, which can be done while preserving origin semantics [5][3]. Given an MSO representation of $\mathcal{A}$, we can easily get an MSO transduction which inputs a word over the input alphabet, and outputs (non-deterministically) an origin graph that corresponds to some possible output of $\mathcal{A}$. Consider the following language

$$L = \{w \in \Sigma^* : \varphi \text{ is true in an origin graph produced by } \mathcal{A} \text{ on } w\}$$

By the Backward Translation Theorem (e.g. [9], p.66) the language L is definable in MSO, as the inverse image of an MSO-definable property under an MSO transduction. Therefore, L is regular, since MSO defines only regular word languages. ◀

▶ **Example 7.** An origin graph is called *order preserving* if the origin mapping gives a non-decreasing function from output positions to input positions. The set of order preserving origin graphs is clearly definable in MSO. Theorem 3 in [5] says that if an origin transduction has only order preserving origin graphs and is recognised by a streaming string transducer, then it is already recognised by a nondeterministic one-way transducer. Therefore Theorem 6 gives an algorithm for deciding if a streaming string transducer is equivalent, in terms of origin semantics, to a one-way nondeterministic transducer (such decidability, and even a polynomial time algorithm, although with inputs represented in a different way, was already given in [5]).

▶ **Example 8** (Running example)**.** Consider the squaring transduction. Every origin graph in this transduction satisfies the following property, which can be formalised in MSO: the output positions can be partitioned into two connected blocks, such that the origin mapping is order preserving when restricted to each of the blocks. For functional origin transductions, this property corresponds to being recognised by a deterministic two-way transducer which does two left-to-right passes on the input.

A corollary of the proof of Theorem 6 is that when the transducer $\mathcal{A}$ is fixed, then there is a linear time algorithm (which simply runs a finite automaton) for checking if a given input word can produce an origin graph satisfying φ.

▶ **Proposition 9.** *If an origin transduction is recognised by a streaming string transducer, then it is definable in* MSO *as a set of origin graphs.*

[3] In [5] the conversion is done in the deterministic case, but it can be easily extended to the nondeterministic case.

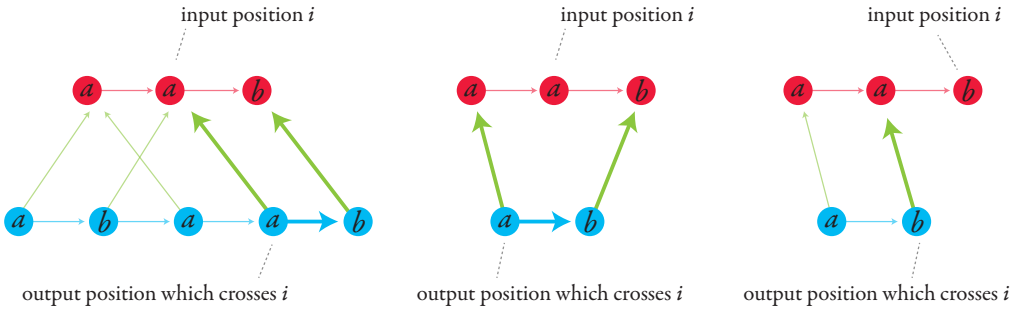
Note that the converse of the above proposition is false, even assuming that there is a bound on the number output positions which can originate in the same input position, see Examples 13 and 15. The issue is that it is more difficult to produce an origin graph (using the origin semantics of an MSO transduction) than it is to check if a given origin graph is correct.

4 Which sets of origin graphs are recognised by SSTs?

Which sets of origin graphs are recognised by streaming string transducers (equivalently, MSO transductions)?

What about functional streaming string transducers? The main goal of this paper is to give machine independent characterisations of such sets. This is Theorem 10 below, which says that a set of origin graphs is recognised by a streaming string transducer if and only if it is MSO-definable, has bounded origin (i.e., each input position is the origin of a bounded number of output positions), and it has bounded crossing, as explained below.

An output position j in the graph is said to *cross* an input position i if the position j has origin at most i and the successor of j either does not exist (i.e. j is the last output position) or has origin greater than i. Intuitively, to go from the origin of position j to the origin position $j+1$ on the input word, a reading head needs to cross position i. Here is a picture:



▶ **Theorem 10.** *Let $\mathcal{G}$ be an origin transduction, i.e., an input alphabet, an output alphabet, and a set of origin graphs over these alphabets. Then $\mathcal{G}$ is recognised by a streaming string transducer with k registers if and only if it satisfies all of the following conditions:*

bounded origin: *there is some $m \in \mathbb{N}$ such that in every origin graph from $\mathcal{G}$, every input position is the origin of at most m output positions;*

k-crossing: *in every origin graph from $\mathcal{G}$, every input position is crossed by at most k output positions;*

mso-definable: *there is an MSO formula which is true in exactly the origin graphs from $\mathcal{G}$.*

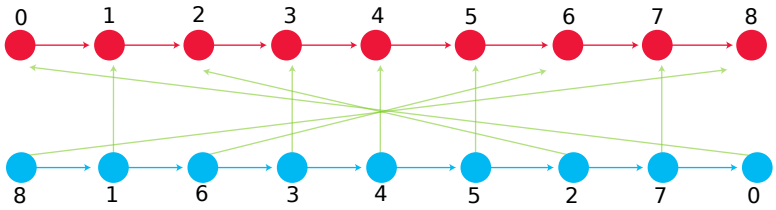
The theorem allows one to decide if a given SST can be implemented with fewer registers preserving origin semantics. This does not help with the resource minimisation problem from [4], because in [4] origin information can be be changed in the minimisation process.

The proof of the theorem is sketched in the next section. A corollary of the theorem is that an origin transduction is recognised by a streaming string transducer if and only if it has bounded origin, is MSO definable, and has bounded crossing (i.e., k-crossing for some k). The following three examples show how the three conditions in Theorem 10 are minimal, i.e., none of the conditions is implied by the remaining ones.

▶ **Example 11** (MSO definable)**.** Consider the identity origin transduction with its domain restricted to some non-regular subset of inputs, e.g. words of prime length. This origin transduction satisfies all conditions in Theorem 10 except for MSO definability.

▶ **Example 12** (Bounded origin)**.** Consider an origin transduction (with one letter in both the input and output alphabets) which is only defined on inputs with one letter and then copies the unique output letter an arbitrary number of times (therefore every output position originates in the unique input position). This origin transduction satisfies all conditions in Theorem 10 except for bounded origin. Streaming string transducers with ε-transitions, as discussed in Section 5, will be able to recognise this example.

▶ **Example 13** (Bounded crossing)**.** Consider the following origin transduction, which is functional. The input and output alphabets have only one letter each. The domain is words of odd length. A word of length $2n+1$ is mapped to a word of same length, but the origins are shuffled so that the origins of odd numbered positions are the same position, while the origins for even numbered positions are reversed. More precisely, if the positions are $0, \ldots, 2n$ then the origin of an odd numbered position $2i+1$ is $2i+1$, while the origin of an even numbered position $2i$ is $2n-2i$. Here is the picture of an origin graph in this origin transduction:



We claim that this origin transduction has unbounded crossing, but satisfies the remaining conditions in Theorem 10. To show unbounded crossing, observe that if the length of the input word is $2n+1$, then the middle input position n is crossed by all even numbered output positions greater than n. Clearly every origin graph in the transduction has bounded origin, because each input position is the origin of exactly one output position. For MSO definability, we observe that an origin graph belongs to the transduction if and only if it satisfies all the following conditions which are definable in MSO (in fact, first-order logic):

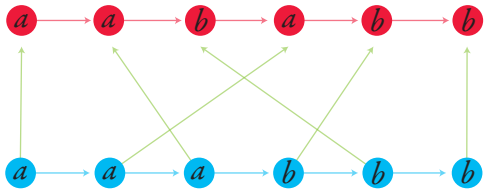
1. the origin of the first output position is the last input position;
2. the origin of the second output position is the second input position;
3. if $j > 1$ is an odd output position with origin i, then the origin of $j-2$ is $i-2$;
4. if $j > 1$ is an even output position with origin i, then the origin of $j-2$ is $i+2$.

Tree width. In Theorem 10, we use bounded crossing as one of the conditions. Another candidate for a structural property on origin graphs is that they have bounded tree width (see e.g. [9] for a definition). The following result shows that bounded tree width (and even bounded path width, which corresponds to the width of path decompositions, i.e., the special case of tree decompositions where the tree is a path) is a necessary condition for being recognised by a streaming string transducer. Indeed, we show that any origin transduction which is bounded crossing has bounded path width. Moreover, we can express the crossing boundedness property in terms of a particular path decomposition of bounded width.

▶ **Proposition 14.** *Every bounded crossing origin transduction has bounded path width.*

We now show that bounded path width is not a sufficient condition, in the sense that the bottom-up implication of Theorem 10 would fail if we would replace bounded crossing by bounded path width. One example is the origin transduction from Example 13, which can be shown to have bounded path width. Here is another example, which also shows that bounded crossing and recognisability by streaming string transducers are both notions that are not closed under reversing origin edges.

▶ **Example 15.** Consider a variant of the squaring function, which is defined only on words of even length, and maps a word w to uv where u (resp. v) is the subword consisting of the odd-numbered (resp. even-numbered) positions of w. This transduction is easily seen to be recognised by a (deterministic) streaming string transducer, and hence the underlying set $\mathcal{G}$ of origin graphs has bounded tree width by Proposition 14. Define $\mathcal{G}'$ to be the set of origin graphs which are obtained from $\mathcal{G}$ by reversing the origin edges. Here is a picture of an origin graph in $\mathcal{G}'$:



Since the origin mapping is bijective, $\mathcal{G}'$ is also a set of origin graphs. It has bounded origin (bounded by 1). By Theorem 10 and Proposition 14, $\mathcal{G}$ is MSO definable and has bounded path width. Path width and MSO definability are not changed by reversing arrows, and therefore $\mathcal{G}'$ has bounded origin, bounded path width and is also MSO-definable. Nevertheless, $\mathcal{G}'$ is not the origin semantics of any streaming string transducer. Indeed, if $\mathcal{A}$ would be a streaming string transducer recognising $\mathcal{G}'$, then the pre-image under $\mathcal{A}$ of the regular set $(aa + bb)^*$ would be the non-regular set of words of the form ww over the alphabet $\{a, b\}$, contradicting the fact that regular word languages are preserved under taking pre-images of streaming string transducers (essentially the Backwards Translation Theorem from [9]).

Recognisability. In Theorem 10, the conditions used are bounded origin, bounded crossing and MSO definability. While bounded origin and bounded crossing are purely combinatorial properties of graphs, MSO definability has a more syntactic character. A less syntactic alternative to MSO definability would be to use *recognisability* in the sense of Definition 4.29 in [8]. Intuitively speaking, a class of relational structures is called recognisable if it has finite index for a certain naturally defined equivalence relation à la Myhill Nerode. In [6] it is shown that if a class of relational structures has bounded tree width, then recognisability is the same as thing as definability in MSO. Therefore, in the statement of Theorem 10 we could replace MSO definability by recognisability, and the theorem would still be true.

The functional case. Theorem 10 gives a characterisation of origin transductions recognised by streaming string transducers. Recall that a streaming string transducer was called unambiguous if its underlying automaton had at most one successful run for each input word. Such transducers are equivalent to the deterministic model in [3], also when using origin semantics [5]. They can only recognise functional origin transductions. As it turns out, this is the only restriction, i.e., if an origin transduction is functional and recognised by a (possibly ambiguous) streaming string transducer, then it is recognised by an unambiguous one. Furthermore, in the functional case the condition on bounded origin becomes superfluous.

▶ **Theorem 16.** *Let $\mathcal{G}$ be an origin transduction. Then $\mathcal{G}$ is recognised by an unambiguous streaming string transducer with k registers if and only if it is functional, k-crossing and* MSO*-definable.*

Unambiguous streaming string transducers can moreover be simulated by deterministic ones (in the sense of Alur and Černý [1]) but at the cost of adding registers [2].

5 Sketch of the proof

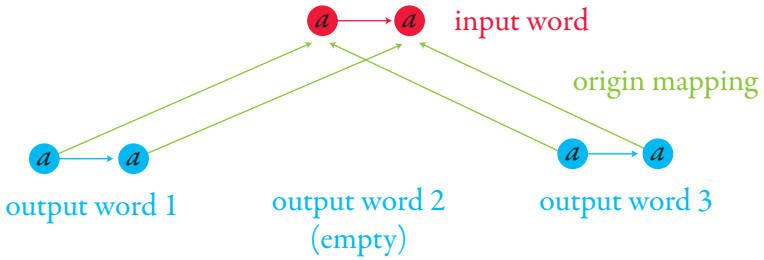
To prove Theorems 10 and 16, we first characterise the origin graphs which can be generated by streaming string transducers with ε-transitions. A streaming string transducer with ε-transitions is the generalisation of the model described in Definition 2, where ε-transitions are allowed in the underlying automaton. The origin mapping is defined so that if an output position is created (i.e., added to some register) by an ε-transition, then its origin is the most recently read input letter. To make this well defined, we make the syntactic restriction that no ε-transitions can be used when in an initial state, and therefore the first transition in each run must consume an input letter.

▶ **Example 17.** Consider the set of origin graphs where the input word has only one letter, and hence this letter is the origin of all output positions, and the output word is $a^n b^n$ for some $n \in \mathbb{N}$. To recognise this string transduction, we use two registers. After reading the unique input position, the automaton enters a loop of ε-transitions. Each one appends a to one register, and b to the other. At the end, the transducer does an ε-transition to the accepting state which concatenates both registers.

The above example shows that when ε-transitions are allowed, the origin semantics of a streaming string transducer needs no longer to be MSO-definable. Theorem 18 below shows that if we additionally assume that a set of origin graphs is MSO-definable, then being the semantics of a streaming string transducer with ε-transitions is equivalent to having bounded crossing. The theorem is the main step in our proof of Theorems 10 and 16.

▶ **Theorem 18.** *Let $\mathcal{G}$ be an origin transduction which is* MSO*-definable. Then, $\mathcal{G}$ is recognised by a k-register streaming string transducer with ε-transitions if and only if $\mathcal{G}$ is k-crossing.*

We sketch the proof here. The left-to-right implication is straightforward, and does not need the assumption on MSO definability. Below we discuss the converse implication. The idea is that if an origin graph has bounded crossing, then it can be constructed by applying a sequence of elementary operations to the empty graph. Intermediate objects produced by these elementary operations are going to be like origin graphs, except that the output word might be in several pieces, corresponding intuitively to the register contents. Define a *k-block origin graph* to be the extension of origin graphs where there are exactly k output words, which are called *blocks*, some of which may be empty, as in the following picture for $k = 3$:



To transform k-block origin graphs, we use the following toolkit of operations, which corresponds intuitively to the registers in a streaming string transducer.

Input. This operation takes one parameter, a letter a of the input alphabet. The result of the operation is that a new position with letter a is added to the end of the input word;

Output. This operation takes three parameters: a *target block* $i \in \{1, \ldots, k\}$, a *content* c which is either a letter of the output alphabet or a number $j \in \{1, \ldots, k\}$ different than i,

and a *side* $s \in \{\text{left,right}\}$. The result of the operation is that the content (i.e., either an output letter of or the contents of register c, depending on the type of c) is concatenated to the left/right (depending on the side s) of the target block i. If the content is a letter, then its origin is set to be the last input position (if there is no input position and the content is a letter, then the operation fails).

We write Ω_k for the above set of operations (assuming that the alphabets are implicit from the context), which is finite. Define *k-folding* to be the function from $(\Omega_k)^*$ to k-block origin graphs which maps a sequence of operations to the k-block origin graph obtained by successively applying the sequence of operations starting from the empty k-block origin graph. Note that k-folding is partial, because the output operation can fail.

▶ **Lemma 19.** *The k-folding operation is (a) surjective; and (b) an* MSO *interpretation.*

Proof of Theorem 18. We only show the right-to-left implication. Suppose then that $\mathcal{G}$ is an origin transduction which is MSO definable and is k-crossing. Define $\mathcal{G}'$ to be the set of k-block origin graphs such that: (i) the i-th output word is empty for $i \neq 1$; and (ii) if only the input and 1-st output word are kept, the resulting origin graph belongs to $\mathcal{G}$. If $\mathcal{G}$ is MSO definable, then so is $\mathcal{G}'$. Let $L \subseteq (\Omega_k)^*$ be those sequences of operations whose k-folding is in $\mathcal{G}'$. By Lemma 19 (b) and the Backwards Translation Theorem [9], L is definable in MSO. By Lemma 19 (a), $\mathcal{G}'$ is equal to the image of L under k-folding. By Büchi-Elgot-Trakhtenbrot's Theorem [7], L is recognised by a finite automaton. We transform this finite automaton into a k-register nondeterministic streaming string transducer with ε-transitions by translating any letter σ of Ω_k into:

- a transition reading an input symbol without updating the registers, if σ is of type input;
- an ε-transition with an appropriate register operation if σ is of type output. ◀

To complete the proof of Theorem 10, we finally show that if the origin semantics of an εNSST has bounded origin then ε-transitions can be eliminated.

6 Classes of origin transductions and perspectives

Our main contribution is a characterisation of the origin semantics of streaming string transducers (deterministic; nondeterministic; with ε-transitions providing MSO-definability), using properties of the origin graphs such as functionality, origin boundedness, crossing boundedness and MSO-definability. The origin transductions recognised by these transducers form a hierarchy depicted in red in the figure below, where DSST (resp. NSST, εNSST) denotes the family of origin transductions recognised by a deterministic (resp. nondeterministic, nondeterministic with ε-transitions) streaming string transducer.

The figure also includes two-way transducers, which define an orthogonal hierarchy, depicted in blue. We consider deterministic and nondeterministic variants as well as those with *common guess*. A two-way transducer (deterministic or not) is equipped with a common guess if, before starting the computation, a finite colouring of the input positions is performed, and this colouring is the same each time the head revisits a position. This strictly increases the expressivity, e.g. the relation $\{(u, vv) \mid v \text{ is a subword of } u\}$ is recognised by a two-way transducer with common guess but not without. The origin semantics of a two-way transducer is defined in a natural way, i.e., an output letter originates in the input position which was scanned by the input head when the letter has been produced. In the figure, the classes of origin transductions recognised by two-way automata are denoted respectively by 2DT, 2NT, and 2NT with common guess.

The class of functions recognised by deterministic two-way transducers (resp. with common guess) is known to be the same as the one recognised by deterministic streaming string transducers [11, 1] (resp. nondeterministic streaming string transducers [3]), even when considering the origin semantics [5].

Finally, we denote by MSOT the family of origin transductions recognised by a nondeterministic MSO-transduction. It is equal to NSST [3, 11]. The transductions recognised by deterministic MSO-transductions are the same as for DSST [1], this remains true with origin semantics [5].

We can prove that all the MSO-definable (resp. bounded origin) origin transductions in εNSST are recognised by a nondeterministic two-way transducer with common guess (resp., are in NSST). Moreover, all the transductions that have bounded origin and which are recognised by a nondeterministic two-way transducer with common-guess, are recognised by a streaming string tranducer (and have therefore bounded crossing). All the other intersections are nonempty and can be populated with some origin transductions (with their natural origin information) as depicted in the figure.

Abstract

A word-to-word function is continuous for a class of languages $\mathcal{V}$ if its inverse maps $\mathcal{V}$_languages to $\mathcal{V}$. This notion provides a basis for an algebraic study of transducers, and was integral to the characterization of the sequential transducers computable in some circuit complexity classes.

Here, we report on the decidability of continuity for functional transducers and some standard classes of regular languages. Previous algebraic studies of transducers have focused on the structure of the underlying input automaton, disregarding the output. We propose a comparison of the two algebraic approaches through two questions: When are the automaton structure and the continuity properties related, and when does continuity propagate to superclasses?

1 Introduction

The algebraic theory of regular languages is tightly interwoven with fundamental questions about the computing power of Boolean circuits and logics. The most famous of these braids revolves around $\mathcal{A}$, the class of *aperiodic* or *counter-free* languages. Not only is it expressed using the logic FO[<], but it can be seen as the basic building block of AC^0, the class of languages recognized by circuit families of polynomial size and constant depth, this class being in turn expressed by the logic FO[arb] (see [18] for a lovely account). This pervasive interaction naturally prompts to lift this study to the functional level, hence to *rational functions*. This was started in [4], where it was shown that a subsequential (i.e., input-deterministic) transducer computes an AC^0 function iff it preserves the regular languages of AC^0 by inverse image. Buoyed by this clean, semantic characterization, we wish to further investigate this latter property for different classes: say that a function $f\colon A^* \to B^*$ is $\mathcal{V}$_continuous, for a class of languages $\mathcal{V}$, if for every language $L \subseteq B^*$ of $\mathcal{V}$, the language $f^{-1}(L)$ is also a language of $\mathcal{V}$. Our main focus will be on deciding $\mathcal{V}$_continuity for rational functions; before listing our main results, we emphasize two additional motivations.

First, there has been some historical progression towards this goal. Noting, in [9], that inverse rational functions provide a uniform and compelling view of a wealth of natural operations on regular languages, Pin and Sakarovitch initiated in [10] a study of regular-continuous functions. It was already known at the time, by a result of Choffrut (see [3,

Theorem 2.7]), that regular-continuity together with some uniform continuity property *characterize* functions computed by subsequential transducers. This characterization was instrumental in the study of Reutenauer and Schützenberger [15], who already noticed the peculiar link between uniform continuity for some distances on words and continuity for certain classes of languages. This link was tightened by Pin and Silva [11] who formalized this topological approach and generalized it to rational relations. More recently [12], the same authors made precise the link unveiled by Reutenauer and Schützenberger, and developed a fascinating and robust framework in which language continuity has a topological interpretation (see the beginning of Section 3, as we build upon this theory). Pin and Silva [13] notably proposed thereafter a study of functions that propagate continuity for a class to subclasses.

Second, the interweaving between languages, circuits, and logic that was alluded to previously can in fact be formally stated (see again [18, 19]). As a central property towards this formalization is the correspondence between "cascade products" of automata, stacking of circuits, and nesting of formulas, respectively. Strikingly, these operations can all be seen as inverse rational functions [19]. These operations being intrinsic in the construction of complex objects, decompositions are often naturally used to specify languages, circuits, and formulas (see, e.g., [17, Section 5.5]). We remark that a sufficient condition for the result of the composition to be in some given class (of languages, circuits, or logic formulas), is that each rational function be continuous for that class. Hence deciding continuity allows to give a sufficient condition for this membership question *without* computing the result of the composition, which is subject to combinatorial blowup.

Here, we report on three questions, the first two relating continuity to the main other algebraic approach to transducers, while allowing a more gentle introduction to the evaluation of *profinite words* by transducers:

- When is the transducer *structure* (i.e., its so-called *transition monoid*) impacting its continuity? The results of Reutenauer and Schützenberger [15] can indeed be seen as the starting point of two distinct algebraic theories for rational functions; on the one hand, the study of continuity, and on the other the study of the transition monoid of the transducer (by disregarding the output). This latter endeavor was carried by [5].
- What is the impact of *variety inclusion* on the inclusion of the related classes of continuous rational functions? When the focus is solely on the structure of the transducer, there is a natural propagation to superclasses; when is it the case for continuity?
- When is $\mathcal{V}$_continuity decidable for rational functions? We show decidability for the varieties $\mathcal{J}, \mathcal{R}, \mathcal{L}, \mathcal{DA}, \mathcal{A}, \mathcal{C}om, \mathcal{A}b, \mathcal{G}_{\mathrm{sol}}$, and $\mathcal{G}$; these constitute our main results.

2 Preliminaries

We assume some familiarity with the theory of automata and transducers, and concepts related to metric spaces (see, e.g., [3, 8] for presentations pertaining to our topic). Apart from these prerequisites, for which the notation is first settled, the presentation is self-contained.

We will use A and B for alphabets, and A^* for words over A, with 1 the empty word. For each word u, there is a smallest v, called the *primitive root* of u, such that $u = v^c$ for some c; if $c = 1$, then u is itself *primitive*. We write $|u|$ for the length of a word $u \in A^*$ and $\mathsf{alph}(u)$ for the set of letters that appear in u. For a word $u \in A^*$ and a language $L \subseteq A^*$, we write $u^{-1}L$ for $\{v \mid u \cdot v \in L\}$, and symmetrically for Lu^{-1}, these two operations being called the left and right quotients of L by u, respectively. We naturally extend concatenation and quotients to relations, in a component-wise fashion, e.g., for $R \subseteq A^* \times A^*$ and a pair $\rho \in A^* \times A^*$, we may use $\rho^{-1}R$ and $R\rho^{-1}$. We write L^{c} for the complement of L. A *variety* is

a mapping $\mathcal{V}$ which associates with each alphabet A a set $\mathcal{V}(A^*)$ of regular languages closed under the Boolean operations and quotient, and such that for any morphism $h\colon A^* \to B^*$ and any $L \in \mathcal{V}(B^*)$, it holds that $h^{-1}(L) \in \mathcal{V}(A^*)$. Reg is the variety that maps every alphabet A to the set $\mathrm{Reg}(A^*)$ of regular languages over A. Given two languages $K, L \subseteq A^*$, we say that they are $\mathcal{V}$_separable if there is a $S \in \mathcal{V}(A^*)$ such that $K \subseteq S$ and $L \cap S = \emptyset$.

Transducers. A transducer τ is a 9-tuple $(Q, A, B, \delta, I, F, \lambda, \mu, \rho)$ where (Q, A, δ, I, F) forms an automaton (i.e., Q is a state set, A an input alphabet, $\delta \subseteq Q \times A \times Q$ a transition set, $I \subseteq Q$ a set of initial states, and $F \subseteq Q$ a set of final states), and additionally, B is an output alphabet and $\lambda\colon I \to B^*, \mu\colon \delta \to B^*, \rho\colon F \to B^*$ are the output functions. We write $\tau_{q,q'}$ for τ with $I := \{q\}$ and $F := \{q'\}$, adjusting λ and ρ to output 1 if they were undefined on these states. Similarly, $\tau_{q,\bullet}$ is τ with $I := \{q\}$ and F unchanged, and symmetrically for $\tau_{\bullet,q}$. For $q \in Q$ and $u \in A^*$, we write $q.u$ for the set of states reached from q by reading u. We assume that all the transducers and automata under study have no useless state, that is, that all states appear in some accepting path.

With $w \in A^*$, let $t\_1 t\_2 \cdots t\_|w| \in \delta^*$ be an accepting path for w, starting in a state $q \in I$ and ending in some $q' \in F$. The output of this path is $\lambda(q)\mu(t\_1)\mu(t\_2)\cdots\mu(t\_n)\rho(q')$, and we write $\tau(w)$ for the set of outputs of such paths. We use τ for both the transducer and its associated partial function from A^* to subsets of B^*. Relations of the form $\{(u, v) \mid v \in \tau(u)\}$ are called *rational relations*.

The transducer τ is *unambiguous* if there is at most one accepting path for each word. In that case $\tau_{q,q'}$ is also an unambiguous transducer for any states q, q'. When τ is unambiguous, it realizes a word-to-word function: the set of functions computed by unambiguous transducers is the set of *rational functions*. Further restricting, if the underlying automaton is deterministic, we say that τ is *subsequential*. If τ is a finite union of subsequential rational functions of disjoint domains, we say that τ is *plurisubsequential*.

Word distances, profinite words. For a variety $\mathcal{V}$ of regular languages, we define a distance between words for which, intuitively, two words are close if it is hard to separate them with $\mathcal{V}$ languages. Define $d\_\mathcal{V}(u, v)$, for words $u, v \in A^*$, to be 2^{-r} where r is the size of the smallest automaton that recognizes a language of $\mathcal{V}(A^*)$ that separates $\{u\}$ from $\{v\}$; if no such language exists, then $d\_\mathcal{V}(u, v) = 0$. It can be shown that this distance is a *pseudo-ultrametric* [8, Section VII.2]; we make only implicit and innocuous use of this fact.

We simply write d for d_Reg. The complete metric space that is the completion of (A^*, d) is denoted $\widehat{A^*}$ and is called the *free profinite monoid*, its elements being the *profinite words*, and the concatenation being naturally extended. By definition, if $(u\_n)\_n > 0$ is a Cauchy sequence, it should hold that for any regular language L, there is a N such that either all u_n with $n > N$ belong to L, or none does. For any $x \in A^*$, define the profinite word $x^\omega = \lim x^{n!}$, and more generally, $x^{\omega - c} = \lim x^{n! - c}$. That $(x^{n!})\_n > 0$ is a Cauchy sequence is a starting point of the profinite theory [8, Proposition VI.2.10]; it is also easily checked that $x^{c \times \omega} = \lim x^{c \times n!}$ is equal to x^ω for any integer $c \geq 1$. Given a language $L \subseteq A^*$, we write $\overline{L} \subseteq \widehat{A^*}$ for its closure, and we note that if L is regular, $\overline{L}^{\mathrm{c}} = \overline{L^{\mathrm{c}}}$ and for L' regular, $\overline{L \cup L'} = \overline{L} \cup \overline{L'}$, and similarly for intersection (see [8, Theorem VI.3.15]).

Equations. For $u, v \in \widehat{A^*}$, a language $L \subseteq A^*$ *satisfies the (profinite) equation* $u = v$ if for any words $s, t \in A^*$, $[s \cdot u \cdot t \in \overline{L} \Leftrightarrow s \cdot v \cdot t \in \overline{L}]$. Similarly, a class of languages satisfies an equation if all the languages of the class satisfy it. For a variety $\mathcal{V}$, we write $u = \_\mathcal{V} v$, and

say that u is equal to v in $\mathcal{V}$, if $\mathcal{V}(A^*)$ satisfies $u = v$. For a partial function f, $f(u) = \_\mathcal{V} f(v)$ means that either both $f(u)$ and $f(v)$ are undefined, or they are both defined and equal in $\mathcal{V}$.

Given a set E of equations over $\widehat{A^*}$, the class of languages *defined* by E is the class of languages over A^* that satisfy all the equations of E. Reiterman's theorem shows in particular that for any variety $\mathcal{V}$ and any alphabet A, $\mathcal{V}(A^*)$ is defined by a set of equations (the precise form of which being studied in [6]).

More on varieties. Borrowing from Almeida and Costa [2], we say that a variety $\mathcal{V}$ is *supercancellative* when for any alphabet A, any $u, v \in \widehat{A^*}$ and $x, y \in A$, if $u \cdot x = \_\mathcal{V} v \cdot y$ or $x \cdot u = \_\mathcal{V} y \cdot v$, then $u = \_\mathcal{V} v$ and $x = y$. This implies in particular that for any word $w \in A^*$, both $w \cdot A^*$ and $A^* \cdot w$ are in $\mathcal{V}(A^*)$. We further say that a variety $\mathcal{V}$ *separates words* if for any $s, t \in A^*$, $\{s\}$ and $\{t\}$ are $\mathcal{V}$_separable.

Our main applications revolve around some classical varieties, that we define over any possible alphabet A as follows, where x, y range over all of A^*, and a, b over A:

- $\mathcal{J}$, def. by $(xy)^\omega \cdot x = y \cdot (xy)^\omega = (xy)^\omega$
- $\mathcal{R}$, def. by $(xy)^\omega \cdot x = (xy)^\omega$
- $\mathcal{L}$, def. by $y \cdot (xy)^\omega = (xy)^\omega$
- $\mathcal{DA}$, def. by $x^\omega \cdot z \cdot x^\omega = x^\omega$ for all $z \in \mathsf{alph}(x)^*$
- $\mathcal{A}$, def. by $x^{\omega+1} = x^\omega$
- $\mathcal{Com}$, def. by $ab = ba$
- $\mathcal{A}_\mathcal{B}$, def. by $ab = ba$ and $a^\omega = 1$
- $\mathcal{G}_{\text{nil}}$, the languages rec. by nilpotent groups
- $\mathcal{G}_{\text{sol}}$, the languages rec. by solvable groups
- $\mathcal{G}$, the languages rec. by groups

The varieties included in $\mathcal{A}$ are called *aperiodic varieties* and those in $\mathcal{G}$ are called *group varieties*. Precise definitions, in particular for the group varieties, can be found in [18, 14]; we simply note that in group varieties, x^ω equals 1 for all $x \in A^*$. All these varieties except for $\mathcal{A}_\mathcal{B}$ and $\mathcal{Com}$ separate words, and only $\mathcal{DA}$ and $\mathcal{A}$ are supercancellative. They verify:

$$\begin{array}{ccc} & \subsetneq\ \mathcal{R}\ \supsetneq & \\ \mathcal{J} = \mathcal{R} \cap \mathcal{L} & \mathcal{DA} \subsetneq \mathcal{A} & \\ & \supsetneq\ \mathcal{L}\ \subsetneq & \end{array} \qquad \begin{array}{c} \subsetneq\ \mathcal{Com} \\ \mathcal{A}_\mathcal{B} = \mathcal{G} \cap \mathcal{Com} \subsetneq \mathcal{G}_{\text{nil}} \subsetneq \mathcal{G}_{\text{sol}} \subsetneq \mathcal{G} \end{array}$$

On transducers and profinite words. For a profinite word u and a state q of an unambiguous transducer τ, the set $q.u$ is well-defined; indeed, with $u = \lim u\_n$, the set $q.u\_n$ is eventually constant, as otherwise for some state q', the domain of $\tau_{q,q'}$ would be a regular language that separates infinitely many u_n's.

A transducer $\tau\colon A^* \to B^*$ is a *$\mathcal{V}$_transducer*,[1] for a variety $\mathcal{V}$, if for some set of equations E defining $\mathcal{V}(A^*)$, for all $(u = v) \in E$ and all states q of τ, it holds that $q.u = q.v$. A rational function is *$\mathcal{V}$_realizable* if it is realizable by a $\mathcal{V}$_transducer.

Continuity. For a variety $\mathcal{V}$, a function $f\colon A^* \to B^*$ is $\mathcal{V}$_continuous[2] iff for any $L \in \mathcal{V}(B^*)$, $f^{-1}(L) \in \mathcal{V}(A^*)$. We mostly restrict our attention to rational functions, and their being

[1] The usual definition of $\mathcal{V}$_transducer is based on the so-called transition monoid of τ, see, e.g., [15]; the definition here is easily seen to be equivalent by [1, Lemma 3.2] and [4, Lemma 1].

[2] A note on terminology: There has been some fluctuation on the use of the term "continuous" in the literature, mostly when a possible incompatibility arises with topology. In [13], the authors use the term "preserving" in the more general context of functions from monoids to monoids. In our study, we focus on word to word functions, in which the natural topological context provides a solid basis for the use of "continuous," as used in [11, 4].

computed by transducers implies that they are countably many. We note that much more Reg_continuous functions exist, in particular uncomputable ones:

▶ **Proposition 1.** *There are uncountably many Reg_continuous functions.*

3 Continuity: The profinite approach

We build upon the work of Pin and Silva [11] and develop tools specialized to rational functions. In Section 3.1, we present a lemma asserting the equivalence between $\mathcal{V}$_continuity and the "preservation" of the defining equations for $\mathcal{V}$. In the sections thereafter, we specialize this approach to rational functions. As noted in [11], it often occurs that results about rational functions can be readily applied to the larger class of Reg_continuous functions; here, this is in particular the case for the Preservation Lemma of Section 3.1.

Our main appeal to a classical notion of continuity is given by the:

▶ **Theorem 2** ([12, Theorem 4.1])**.** *Let $f\colon A^* \to B^*$. It holds that f is $\mathcal{V}$_continuous iff f is uniformly continuous for the distance $d\_\mathcal{V}$.*

Consequently, if f is Reg_continuous then it has a unique extension to the free profinite monoids, written $\widehat{f}\colon \widehat{A^*} \to \widehat{B^*}$. The salient property of this mapping is that it is continuous in the *topological sense* (see, e.g., [8]). For our specific needs, we simply mention that it implies that for any regular language L, we have that $\widehat{f}^{-1}(\overline{L})$ is closed (that is, it is the closure of some set).

3.1 The Preservation Lemma: Continuity is preserving equations

The Preservation Lemma gives us a key characterization in our study: it ties together continuity and some notion of preservation of equations. This can be seen as a generalization to functions of equation satisfaction for languages. We will need the following technical lemma that extends [8, Proposition VI.3.17] from morphisms to arbitrary Reg_continuous functions; interestingly, this relies on a quite different proof.

▶ **Lemma 3.** *Let $f\colon A^* \to B^*$ be a Reg_continuous function and L a regular language. It holds that $\widehat{f}^{-1}(\overline{L}) = \overline{f^{-1}(L)}$.*

▶ **Lemma 4** (Preservation Lemma)**.** *Let $f\colon A^* \to B^*$ be a Reg_continuous function and E a set of equations that defines $\mathcal{V}(A^*)$. The function f is $\mathcal{V}$_continuous iff for all $(u = v) \in E$ and words $s, t \in A^*$, $\widehat{f}(s \cdot u \cdot t) = \_\mathcal{V}\widehat{f}(s \cdot v \cdot t)$.*

Proof. *(Only if)* Suppose f is $\mathcal{V}$_continuous. Let $u, v \in \widehat{A^*}$ such that $u = \_\mathcal{V}v$, and $s, t \in A^*$. Since by $\mathcal{V}$_continuity $f^{-1}(B^*) \in \mathcal{V}(A^*)$, either both $s \cdot u \cdot t$ and $s \cdot v \cdot t$ belong to the closure of this language, or they both do not. The latter case readily yields the result, hence suppose we are in the former case.

By definition, $u = \lim u\_n$ and $v = \lim v\_n$ for some Cauchy sequences of words $(u\_n)\_n > 0$ and $(v\_n)\_n > 0$. Since $s \cdot u \cdot t = \_\mathcal{V}s \cdot v \cdot t$, the hypothesis yields that $d\_\mathcal{V}(s \cdot u\_n \cdot t, s \cdot v\_n \cdot t)$ tends to 0. By Theorem 2, f is uniformly continuous for $d\_\mathcal{V}$, hence $d\_\mathcal{V}(f(s \cdot u\_n \cdot t), f(s \cdot v\_n \cdot t))$ also tends to 0 (note that both $f(s \cdot u\_n \cdot t)$ and $f(s \cdot v\_n \cdot t)$ are defined for all n big enough). This shows that $\widehat{f}(s \cdot u \cdot t) = \_\mathcal{V}\widehat{f}(s \cdot v \cdot t)$.

(If) Suppose that f preserves the equations of E as in the statement. Let $L \in \mathcal{V}(B^*)$, we wish to verify that $L' = f^{-1}(L) \in \mathcal{V}(A^*)$, or equivalently by definition, that L' satisfies all the equations of E. Let $(u = v) \in E$ be one such equation, and $s, t \in A^*$; we must show that $s \cdot u \cdot t \in \overline{L'} \Leftrightarrow s \cdot v \cdot t \in \overline{L'}$.

Suppose $s \cdot u \cdot t \in \overline{L'}$. Since f is Reg_continuous, it holds that $\widehat{f}(s \cdot u \cdot t) \in \overline{L}$ (observe that $\widehat{f}(s \cdot u \cdot t)$ is indeed defined). By hypothesis, $\widehat{f}(s \cdot u \cdot t) = \_\mathcal{V}\widehat{f}(s \cdot v \cdot t)$; now since $L \in \mathcal{V}(B^*)$, it must hold that $\widehat{f}(s \cdot v \cdot t) \in \overline{L}$. Taking the inverse image of $\widehat{f}$ on both sides, it thus holds that $s \cdot v \cdot t \in \widehat{f}^{-1}(\overline{L})$, and Lemma 3 then shows that $s \cdot v \cdot t \in \overline{L'}$. As the argument works both ways, this shows that $s \cdot u \cdot t \in \overline{L'} \Leftrightarrow s \cdot v \cdot t \in \overline{L'}$, concluding the proof. ◀

Continuity can be seen as preserving *membership* to $\mathcal{V}$ (by inverse image); this is where the nomenclature "$\mathcal{V}$_preserving function" of [13] stems from. Strikingly, this could also be worded as preserving *nonmembership* to $\mathcal{V}$:

▶ **Proposition 5.** *A Reg_continuous total*[3] *function $f\colon A^* \to B^*$ is $\mathcal{V}$_continuous iff for all $L \subseteq A^*$ that do* not *belong to $\mathcal{V}(A^*)$, $f(L)$ and $f(L^c)$ are not $\mathcal{V}$_separable.*

3.2 The profinite extension of rational functions

The Preservation Lemma already hints at our intention to see transducers as computing functions from and to the free profinite monoids. Naturally, if τ is a rational function, its being Reg_continuous allows us to do so (by Theorem 2). For $u = \lim u\_n$ a profinite word, we will write $\tau(u)$ for $\widehat{\tau}(u)$, i.e., the limit $\lim \tau(u\_n)$, which exists by continuity. In this section, we develop a slightly more combinatorial approach to this evaluation, and address two classes of profinite words: those expressed as $s \cdot u \cdot t$ for s, t words and u a profinite word, and those expressed as x^ω for x a word.

Recall that for a transducer state q and a profinite word u, $q.u$ is well-defined. As a consequence, if s and t are words and τ is unambiguous, then there is at most one initial state q_0, one $q \in q\_0.s$ and one $q' \in q.u$ such that $q'.t$ is final, and these states exist iff $\tau(s \cdot u \cdot f)$ is defined. Thus:

▶ **Lemma 6.** *Let τ be an unambiguous transducer from A^* to B^*, $s, t \in A^*$ and $u \in \widehat{A^*}$. Suppose $\tau(s \cdot u \cdot f)$ is defined, and let q_0, q, q' be the unique states such that q_0 is initial, $q \in q\_0.s$, $q' \in q.u$, and $q'.t$ is final. The following holds: $\tau(s \cdot u \cdot t) = \tau_{\bullet,q}(s) \cdot \tau_{q,q'}(u) \cdot \tau_{q',\bullet}(t)$.*

▶ **Lemma 7.** *Let τ be an unambiguous transducer from A^* to B^* and $x \in A^*$. If $\tau(x^\omega)$ is defined, then there are words $s, y, t \in B^*$ such that: $\tau(x^\omega) = s \cdot y^{\omega-1} \cdot t$.*

These constitute our main ways to effectively evaluate the image of profinite words through transducers. Their use being quite ubiquitous in our study, we will rarely refer to these lemmata nominally.

3.3 The Syncing Lemma: Preservation Lemma applied to transducers

We apply the Preservation Lemma on transducers and deduce a slightly more combinatorial characterization of transducers describing continuous functions. This does not provide an immediate decidable criterion, but our decidability results will often rely on it. The goal of the forthcoming lemma is to decouple, when evaluating $s \cdot u \cdot t$ (with the notations of the Preservation Lemma), the behavior of the u part and that of the s, t part. This latter part will be tested against an *equalizer* set:

[3] In all the varieties we are interested in, one can easily modify any partial function into a total function while preserving its continuity properties.

▶ **Definition 8** (Equalizer set). Let $u, v \in \widehat{A^*}$. The *equalizer set* of u and v in $\mathcal{V}$ is:

$$\mathsf{Equ}\_\mathcal{V}(u,v) = \{(s,s',t,t') \in (A^*)^4 \mid s \cdot u \cdot t = \_\mathcal{V} s' \cdot v \cdot t'\} \ .$$

▶ Remark. The complexity of equalizer sets can be surprisingly high. For instance, letting $\mathcal{V}$ be the class of languages defined by $\{x^2 = x^3 \mid x \in A^*\}$, there is a profinite word u for which $\mathsf{Equ}\_\mathcal{V}(u,u)$ is undecidable. On the other hand, equalizer sets quickly become less complex for common varieties; for instance, Lemma 12 will provide a simple form for the equalizer sets of aperiodic supercancellative varieties.

▶ **Definition 9** (Input synchronization). Let $R, S \subseteq A^* \times B^*$. The *input synchronization* of R and S is defined as the relation over $B^* \times B^*$ obtained by synchronizing the first component of R and S: $R \bowtie S = \{(u,v) \mid (\exists s)[(s,u) \in R \wedge (s,v) \in S]\}$ $\big(= S \circ R^{-1}\big)$.

Naturally, the input synchronization of two rational functions is a rational relation.

▶ **Lemma 10** (Syncing Lemma). *Let τ be an unambiguous transducer from A^* to B^* and E a set of equations that defines $\mathcal{V}(A^*)$. The function τ is $\mathcal{V}$_continuous iff:*

1. *$\tau^{-1}(B^*) \in \mathcal{V}(A^*)$, and*
2. *For any $(u = v) \in E$, any states p, q, any $p' \in p.u$, and any $q' \in q.v$, and letting $u' = \tau_{p,p'}(u)$ and $v' = \tau_{q,q'}(v)$: $(\tau_{\bullet,p} \bowtie \tau_{\bullet,q}) \times (\tau_{p',\bullet} \bowtie \tau_{q',\bullet}) \subseteq \mathsf{Equ}\_\mathcal{V}(u',v')$.*

3.4 A profinite toolbox for the aperiodic setting

In this section, we provide a few lemmata pertaining to our study of aperiodic continuity. We show that the equalizer sets of aperiodic supercancellative varieties are well-behaved. Intuitively, the larger the varieties are, the more their nonempty equalizer sets will be similar to the identity. For instance, if $s \cdot x^\omega = \_\mathcal{A} x^\omega$, for words s and x, it should hold that s and x have the same primitive root. We first note the following easy fact that will only be used in this section; it is reminiscent of the notion of *equidivisibility*, studied in the profinite context by Almeida and Costa [2].

▶ **Lemma 11.** *Let u, v be profinite words over an alphabet A and $\mathcal{V}$ be a supercancellative variety. Suppose that there are $s, t \in A^*$ such that $u \cdot t = \_\mathcal{V} s \cdot v$, then there is a $w \in \widehat{A^*}$ such that $u = \_\mathcal{V} s \cdot w$ and $v = \_\mathcal{V} w \cdot t$. If moreover $u = v$ and $\mathcal{V}$ is aperiodic, then $u = \_\mathcal{V} s \cdot u \cdot t$.*

▶ **Lemma 12.** *Let u, v be profinite words over an alphabet A and $\mathcal{V}$ be an aperiodic supercancellative variety. Suppose $\mathsf{Equ}\_\mathcal{V}(u,v)$ is nonempty. There are words $x, y \in A^*$ and two pairs $\rho\_1, \rho\_2 \in (A^*)^2$ such that: $\mathsf{Equ}\_\mathcal{V}(u,v) = \Big(Id \cdot \big((x^*, x^*)\rho\_1^{-1}\big)\Big) \times \Big(\big(\rho\_2^{-1}(y^*, y^*)\big) \cdot Id\Big)$.*

▶ **Lemma 13.** *Let x, y be words. For every aperiodic supercancellative variety $\mathcal{V}$, it holds that $\mathsf{Equ}\_\mathcal{V}(x^\omega, y^\omega) = \mathsf{Equ}\_\mathcal{A}(x^\omega, y^\omega)$.*

▶ Remark. For two aperiodic supercancellative varieties $\mathcal{V}$ and $\mathcal{W}$, we could further show that if both $\mathsf{Equ}\_\mathcal{V}(u,v)$ and $\mathsf{Equ}\_\mathcal{W}(u,v)$ are nonempty, then they are equal, for any profinite words u, v. It may however happen that one equalizer set is empty while the other is not; for instance, with $u = (ab)^\omega$ and $v = (ab)^\omega \cdot a \cdot (ab)^\omega$, the equalizer set of u and v in $\mathcal{DA}$ is nonempty, while it is empty in $\mathcal{A}$.

4 Intermezzos

We present a few facts of independent interest on continuous rational functions. Through this, we develop a few examples, showing in particular how the Preservation and Syncing

Lemmata can be used to show (non)continuity. In a first part, we study when the structure of the transducer is relevant to continuity, and in a second, when the (non)inclusion of variety relates to (non)inclusion of the class of continuous rational functions.

4.1 Transducer structure and continuity

As noted by Reutenauer and Schützenberger [15, p. 231], there exist numerous natural varieties $\mathcal{V}$ for which any $\mathcal{V}$_realizable rational function is $\mathcal{V}$_continuous. Indeed:

▶ **Proposition 14.** *Let $\mathcal{V}$ be a variety of languages closed under inverse $\mathcal{V}$_realizable rational function. Any $\mathcal{V}$_realizable rational function is $\mathcal{V}$_continuous. This holds in particular for the varieties $\mathcal{A}, \mathcal{G}_{\text{sol}}$, and $\mathcal{G}$.*

▶ **Proposition 15.** *For $\mathcal{V} \in \{\mathcal{J}, \mathcal{L}, \mathcal{R}, \mathcal{DA}, \mathcal{A}_B, \mathcal{G}_{\text{nil}}, \mathcal{C}_{OM}\}$, there are $\mathcal{V}$_realizable rational functions that are not $\mathcal{V}$_continuous.*

The converse concern, that is, whether all $\mathcal{V}$_continuous rational functions are $\mathcal{V}$_realizable, was mentioned by Reutenauer and Schützenberger [15] for $\mathcal{V} = \mathcal{A}$.

▶ **Proposition 16.** *For $\mathcal{V} \in \{\mathcal{J}, \mathcal{L}, \mathcal{R}, \mathcal{DA}, \mathcal{A}, \mathcal{A}_B, \mathcal{C}_{OM}\}$, there are $\mathcal{V}$_continuous rational functions that are not $\mathcal{V}$_realizable.*

Proof. *(The aperiodic cases)* Let $A = \{a\}$, a unary alphabet. Consider the transducer τ that removes every second a: its minimal transducer not being a $\mathcal{A}$_transducer, it is not $\mathcal{A}$_realizable (this is a property of subsequential transducers [15]). However, all the unary languages of $\mathcal{V}$ are either finite or co-finite, and hence for any $L \in \mathcal{V}(A^*)$, $\tau^{-1}(L)$ is either finite or co-finite, hence belongs to $\mathcal{V}(A^*)$.

(The $\mathcal{A}_B$ and $\mathcal{C}_{OM}$ cases) Over $A = \{a, b\}$, define τ to map words w in aA^* to $(ab)^{|w|}$, and words w in bA^* to $(ba)^{|w|}$. Clearly, a and b cannot act commutatively on the transducer. Now $\tau(ab) = \_\mathcal{C}_{OM}\tau(ba)$, and moreover $\tau(x^\omega) = \_\mathcal{A}_B(ab)^\omega = \_\mathcal{A}_B1 = \tau(1)$, hence τ is continuous for both $\mathcal{A}_B$ and $\mathcal{C}_{OM}$ by the Preservation Lemma. ◀

We delay the positive answers to that question, namely for $\mathcal{G}_{\text{nil}}, \mathcal{G}_{\text{sol}}, \mathcal{G}$, to Corollary 27 as they constitute our main lever towards the decidability of continuity for these classes.

4.2 Variety inclusion and inclusion of classes of continuous functions

In this section, we study the consequence of variety (non)inclusion on the inclusion of the related classes of continuous rational functions. This is reminiscent of the notion of *heredity* studied by [12], where a function is $\mathcal{V}$_hereditarily continuous if it is $\mathcal{W}$_continuous for each subvariety $\mathcal{W}$ of $\mathcal{V}$. Variety noninclusion provides the simplest study case here:

▶ **Proposition 17.** *Let $\mathcal{V}$ and $\mathcal{W}$ be two varieties. If $\mathcal{V} \not\subseteq \mathcal{W}$ then there are $\mathcal{V}$_continuous rational functions that are not $\mathcal{W}$_continuous.*

The remainder of this section focuses on a dual statement:

If $\mathcal{V} \subsetneq \mathcal{W}$, are all $\mathcal{V}$_continuous rational functions $\mathcal{W}$_continuous?

We first focus on group varieties. Naturally, if 1. $\mathcal{V}$_continuous rational functions are $\mathcal{V}$_realizable and 2. $\mathcal{W}$_realizable rational functions are $\mathcal{W}$_continuous, this holds. Appealing to the forthcoming Corollary 27 for point 1 and Proposition 14 for point 2, we then get:

▶ **Proposition 18.** *For $\mathcal{V}, \mathcal{W} \in \{\mathcal{G}_{\text{nil}}, \mathcal{G}_{\text{sol}}, \mathcal{G}\}$ with $\mathcal{V} \subsetneq \mathcal{W}$, all $\mathcal{V}$_continuous rational functions are $\mathcal{W}$_continuous. This however fails for $\mathcal{V} = \mathcal{A}_B$ and for any $\mathcal{W} \in \{\mathcal{G}_{\text{nil}}, \mathcal{G}_{\text{sol}}, \mathcal{G}\}$.*

Proof. It remains to show the case $\mathcal{V} = \mathcal{A}_B$. This is in fact the same example as in the proof of Proposition 16, to wit, over $A = \{a, b\}$, the rational function τ that maps $w \in aA^*$ to $(ab)^{|w|}$, and words $w \in bA^*$ to $(ba)^{|w|}$. Indeed, we saw that this function is continuous for $\mathcal{A}_B$, but it holds that $\tau(a) = ab$ on the one hand, and $\tau(b^\omega a) = (ba)^\omega ba = \_\mathcal{W}ba$, but $ab \neq \_\mathcal{W}ba$. The Preservation Lemma then shows that τ is not continuous for $\mathcal{W}$. ◀

▶ **Proposition 19.** *All $\mathcal{A}_B$_continuous rational functions are $\mathcal{C}_{OM}$_continuous.*

We now turn to aperiodic varieties. For lesser expressive varieties, the property fails:

▶ **Proposition 20.** *For $\mathcal{V} \in \{\mathcal{J}, \mathcal{L}, \mathcal{R}\}$ and $\mathcal{W} \in \{\mathcal{L}, \mathcal{R}, \mathcal{DA}, \mathcal{A}\}$ with $\mathcal{V} \subsetneq \mathcal{W}$, there are $\mathcal{V}$_continuous rational functions that are not $\mathcal{W}$_continuous.*

▶ **Proposition 21.** *Any $\mathcal{DA}$_continuous rational function is $\mathcal{A}$_continuous.*

Proof. First note that both $\mathcal{DA}$ and $\mathcal{A}$ satisfy the hypotheses of Lemma 12. Consider a $\mathcal{DA}$_continuous rational function $\tau\colon A^* \to B^*$. By the Syncing Lemma, to show that it is $\mathcal{A}$_continuous, it is enough to show that 1. $\tau^{-1}(B^*) \in \mathcal{A}(A^*)$, and 2. That some input synchronizations of τ, based on equations of the form $x^\omega = \_\mathcal{A}x^{\omega+1}$, belong to an equalizer set of the form (by Lemma 7):

$$\mathsf{Equ}\_\mathcal{A}(\alpha \cdot y^\omega \cdot \beta,\ \alpha' \cdot z^\omega \cdot \beta') = \{(s, s', t, t') \mid (s \cdot \alpha,\ s' \cdot \alpha',\ \beta \cdot t,\ \beta' \cdot t') \in \mathsf{Equ}\_\mathcal{A}(y^\omega,\ z^\omega)\}\ .$$

Applying the Syncing Lemma on τ for the variety $\mathcal{DA}$, we get that point 1 is true, since $\tau^{-1}(B^*) \in \mathcal{DA}(A^*)$. Similarly, point 2 is true since $x^\omega = x^{\omega+1}$ is an equation of $\mathcal{DA}$, and Lemma 13 implies that the equalizer set of the equation above is the same in $\mathcal{DA}$ and $\mathcal{A}$. ◀

▶ **Proposition 22.** *There are nonrational functions that are continuous for both $\mathcal{DA}$ and Reg but are not $\mathcal{A}$_continuous.*

5 Deciding continuity for transducers

5.1 Deciding continuity for group varieties

Reutenauer and Schützenberger showed in [15] that a rational function is $\mathcal{G}$_continuous iff it is $\mathcal{G}$_realizable. Since this is proven effectively, it leads to the decidability of $\mathcal{G}$_continuity. In Proposition 14, we saw that the right-to-left statement also holds for $\mathcal{G}_{\text{sol}}$; we now show that the left-to-right statement holds for all group varieties $\mathcal{V}$ that contain $\mathcal{G}_{\text{nil}}$. As in [15], but with sensibly different techniques, we show that $\mathcal{V}$_continuous transducers are plurisubsequential. The Syncing Lemma will then imply that such transducers are $\mathcal{V}$_transducers. Both properties rely on the following normal form:

▶ **Lemma 23.** *Let τ be a transducer. An equivalent transducer τ' can be constructed by adjoining some codeterministic automaton to τ so that for any states p, q of τ':*

$$\Big[(\exists x, y)\big[\emptyset \neq (\tau'_{p,\bullet} \bowtie \tau'_{q,\bullet}) \subseteq (x, y) \cdot Id\big]\Big] \Rightarrow p = q\ .$$

Alternatively, the "dual" property can be ensured, adjoining a deterministic automaton to τ, so that for any states p, q of τ':

$$\Big[(\exists x, y)\big[\emptyset \neq (\tau'_{\bullet,p} \bowtie \tau'_{\bullet,q}) \subseteq Id \cdot (x, y)\big]\Big] \Rightarrow p = q\ .$$

▶ **Lemma 24.** *Let $\mathcal{V}$ be a variety of group languages that contains $\mathcal{G}_{\mathrm{nil}}$. For any $\mathcal{V}_$continuous unambiguous transducer τ, the transducer obtained by applying the dual of Lemma 23, then applying its first part, is a plurisubsequential $\mathcal{V}_$transducer.*

Proof. Write τ' for the result of the dual part of Lemma 23 on τ, and τ'' for the result of the first part of Lemma 23 on τ'. For these transducers, call a triple a states (p, q, q') a *fork* on a if from p, the transducer can go to q and q' reading one a, and there is a path from q to p reading only a's. Dually, a triple (q, q', p) is a *reverse fork* on a if the transducer can go from q and q' to p reading one a, and there is a path from p to q that reads only a. In both cases, the fork is *proper* if $q \neq q'$. We rely on two facts:

▶ **Fact 25.** *There are no proper forks or reverse forks in τ''.*

▶ **Fact 26.** *For any state p of τ'' and any letter a, it holds that $p \in p.a^\omega$.*

Consider a state p in τ'' and a letter a. As $p \in p.a^\omega$ by Fact 26, there is a cycle of a's on p. Call q the first state of that cycle. Next, let q' be such that (p, a, q') is a transition of τ''. Clearly, (p, q, q') forms a fork, hence by Fact 25, $q = q'$. Thus τ'' is plurisubsequential.

It remains to show that τ'' is a $\mathcal{V}_$transducer. To do so, consider an equation $u = \_\mathcal{V}v$, a state q of τ'', and let $p = q.u$ and $p' = q.v$. We show that $p = p'$, concluding the proof. We rely on the Syncing Lemma, since τ'' is $\mathcal{V}_$continuous; it ensures in particular that:

$$(\tau''_{\bullet,q} \bowtie \tau''_{\bullet,q}) \times (\tau''_{p,\bullet} \bowtie \tau''_{p',\bullet}) \subseteq \mathsf{Equ}\_\mathcal{V}(u', v') \quad \text{with } u' = \tau''_{q,p}(u), v' = \tau''_{q,p'}(v) \ . \tag{1}$$

Let (s, s, t_1, t_2) be in the left-hand side. It holds that $s \cdot u' \cdot t\_1 = \_\mathcal{V}s \cdot v' \cdot t\_2$, thus $u' \cdot t\_1 = \_\mathcal{V}v' \cdot t\_2$ (here and in the following, we derive equivalent equations by appealing to the fact that the *free group* is embedded, in a precise sense, in $\mathcal{V}$ [16, § 6.1.9]). Now consider another tuple (s', s', t_1', t_2') again in the left-hand side of Equation (1). It also holds that $u' \cdot t\_1' = \_\mathcal{V}v' \cdot t\_2'$, hence we obtain that $t\_1 \cdot t\_2^{-1} = \_\mathcal{V}t\_1' \cdot t\_2'^{-1}$. This is in turn equal in $\mathcal{V}$ to some $\alpha \cdot \beta^{-1}$ such that α and β are words that do not share the same last letter. This shows that $t\_1 = \alpha \cdot t$ and $t\_2 = \beta \cdot t$ for some word t, and similarly for t_1' and t_2'. More generally: $(\tau''_{p,\bullet} \bowtie \tau''_{p',\bullet}) \subseteq (\alpha, \beta) \cdot Id$, and the normal form of Lemma 23 thus shows that $p = p'$. ◀

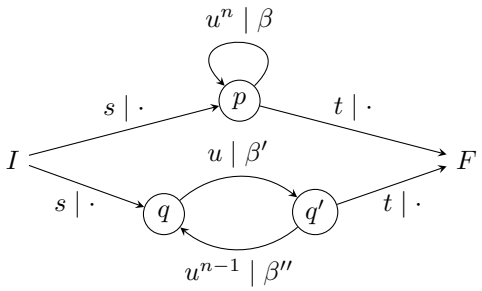
▶ **Corollary 27.** *For $\mathcal{V} \in \{\mathcal{G}_{\mathrm{nil}}, \mathcal{G}_{\mathrm{sol}}, \mathcal{G}\}$, any $\mathcal{V}_$continuous rational function is $\mathcal{V}_$realizable.*

▶ **Theorem 28.** *Let $\mathcal{V}$ be a variety of group languages that includes $\mathcal{G}_{\mathrm{nil}}$ and that is closed under inverse $\mathcal{V}_$realizable rational functions. It is decidable, given an unambiguous transducer, whether it realizes a $\mathcal{V}_$continuous function. This holds in particular for $\mathcal{G}_{\mathrm{sol}}$ and $\mathcal{G}$.*

5.2 Deciding continuity for aperiodic varieties

We saw in Section 4.1 that the approach of the previous section cannot work: there is no correspondence between continuity and realizability for aperiodic varieties. Herein, we use the Syncing Lemma to decide continuity in two main steps. First, note that all of our aperiodic varieties are defined by an infinite number of equations for each alphabet. The Syncing Lemma would thus have us check an infinite number of conditions; our first step is to reduce this to a finite number, which we stress through the forthcoming notion of "pertaining triplet" of states. Second, we have to show that the inclusion of the second point of the Syncing Lemma can effectively be checked. This will be done by simplifying this condition, and showing a decidability property on rational relations.

▶ **Definition 29.** A triplet of states (p, q, q') is *pertaining* if there are words s, u, t and an integer n such that:



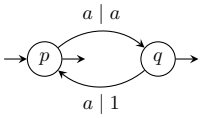
where $\cdot$ means "any word." Further, a pertaining triplet is *empty* if, in the above picture, $\beta = \beta'\beta'' = 1$ and *full* if both words are nonempty; it is *degenerate* if only one of β or $\beta'\beta''$ is empty.

It is called "pertaining" as the second point of the Syncing Lemma elaborates on properties of such a triplet, in particular, since $u^\omega = u^{\omega+1}$ is an equation of $\mathcal{A}$. The following characterization of $\mathcal{A}$_continuity is then made *without appeal* to equations or profinite words:

▶ **Lemma 30.** *A transducer $\tau\colon A^* \to B^*$ is $\mathcal{A}$_continuous iff all of the following hold:*

1. $\tau^{-1}(B^*) \in \mathcal{A}(A^*)$;
2. *For all full pertaining triplets (p, q, q'), there exist $x, y \in B^*$ and $\rho\_1, \rho\_2 \in (B^*)^2$ such that $\tau_{\bullet,p} \bowtie \tau_{\bullet,q} \subseteq Id \cdot \big((x^*, x^*)\rho\_1^{-1}\big)$ and $\tau_{p,\bullet} \bowtie \tau_{q',\bullet} \subseteq \big(\rho\_2^{-1}(y^*, y^*)\big) \cdot Id$;*
3. *For all empty pertaining triplets (p, q, q') it holds that $(\tau_{\bullet,p} \bowtie \tau_{\bullet,q}) \cdot (\tau_{p,\bullet} \bowtie \tau_{q',\bullet}) \subseteq Id$;*
4. *No pertaining triplet is degenerate.*

▶ **Example 31.** We show that the transducer of Proposition 16 is $\mathcal{A}$_continuous. Let τ be:



First, the function is total, hence the first point of Lemma 30 is verified. Second, there are no empty nor degenerate pertaining triplets, hence the third and fourth points are verified. Now the full pertaining triplets are $(p, p, p), (p, p, q), (q, q, q)$, and (q, q, p). We check that the pertaining triplet (p, p, q) verifies the second condition of Lemma 30, the other cases being similar or clear. The first half of the condition is immediate. Now $\tau_{p,\bullet} \bowtie \tau_{q,\bullet} = \{(a^{\lfloor n+1/2 \rfloor}, a^{\lfloor n/2 \rfloor}) \mid n \geq 0\}$ which verifies the condition.

We now show that the property of Lemma 30 is indeed decidable:

▶ **Proposition 32.** *It is decidable, given a rational relation $R \subseteq A^* \times A^*$, whether there is a word $x \in A^*$ and a pair $\rho \in (A^*)^2$, such that $R \subseteq Id \cdot \big((x^*, x^*)\rho^{-1}\big)$.*

▶ Remark. In general, the problem of deciding, given a rational relation R and a *recognizable* relation K, whether $R \subseteq Id \cdot K$, is undecidable. Indeed, testing $R \cap Id = \emptyset$ is undecidable [3], and equivalent to testing:

$$R \subseteq Id \cdot \big((A^+ \times \{1\}) \cup (\{1\} \times A^+) \cup \bigcup\nolimits\_{a \neq b \in A} (a \cdot A^* \times b \cdot A^*)\big) \ ,$$

the right-hand side being of the form $Id \cdot K$.

▶ **Theorem 33.** *It is decidable, given an unambiguous transducer, whether it realizes an $\mathcal{A}$_continuous function.*

The same approach, with carefully tweaked conditions, yields:

▶ **Theorem 34.** *For $\mathcal{V} = \mathcal{J}, \mathcal{R}, \mathcal{L}, \mathcal{DA}$, it is decidable, given an unambiguous transducer, whether it realizes a $\mathcal{V}$_continuous function.*

5.3 Deciding $\mathcal{C}om$- and $\mathcal{A}b$-continuity

The case of $\mathcal{C}om$ and $\mathcal{A}b$ is comparatively much simpler, in particular because these varieties are defined using a finite number of equations for each alphabet. However, the argument relies on different ideas:

▶ **Theorem 35.** *For $\mathcal{V} = \mathcal{C}om, \mathcal{A}b$, it is decidable, given an unambiguous transducer, whether it realizes a $\mathcal{V}$_continuous function.*

Proof. We apply the Syncing Lemma. Its first point is clearly decidable. We reduce its second point to decidable properties about semilinear sets (see, e.g., [7]). We also rely on the notion of Parikh image, that is, the mapping $\mathsf{Pkh}\colon A^* \to \mathbb{N}^A$ such that $\mathsf{Pkh}(w)$ maps $a \in A$ to the number of a's in the word w.

Since every $\mathcal{A}b$_continuous function is $\mathcal{C}om$_continuous (Proposition 19), the conditions to test for $\mathcal{A}b$_continuity are included in those for $\mathcal{C}om$_continuity—this can also be seen as a consequence of the fact that if u, v are words, $\mathsf{Equ}\_\mathcal{A}b(u, v) = \mathsf{Equ}\_\mathcal{C}om(u, v)$.

Let $\tau\colon A^* \to B^*$ be a given transducer. Consider an equation $ab = ba$ and four states p, p', q, q' of τ. Write $u = \tau_{p,p'}(ab)$ and $v = \tau_{q,q'}(ba)$. We ought to check, by the Syncing Lemma, the inclusion in $\mathsf{Equ}\_\mathcal{C}om(u, v) = \{(s, s', t, t') \mid s \cdot u \cdot t = \_\mathcal{C}om s' \cdot v \cdot t'\}$ of some input synchronization. Now this set is the set of (s, s', t, t') such that $\mathsf{Pkh}(s \cdot u \cdot t) = \mathsf{Pkh}(s' \cdot v \cdot t')$, and is thus defined by a simple semilinear property. The input synchronizations themselves, e.g., $\tau_{\bullet,p} \bowtie \tau_{\bullet,q}$, are rational relations, and their component-wise Parikh image is thus a semilinear set. Since the inclusion of semilinear sets is decidable, the inclusion of the second point of the Syncing Lemma is also decidable.

For $\mathcal{A}b$, we should additionally check the equations $a^\omega = 1$. The reasoning is similar. Consider three states (p, p', q), and write $x \cdot u^{\omega-1} \cdot y$ for $\tau_{p,p'}(a^\omega)$. By commutativity and the fact that $u^{\omega-1}$ acts as an inverse of u in the equations holding in $\mathcal{A}b$, we have that $(s, s', t, t') \in \mathsf{Equ}\_\mathcal{A}b(x \cdot u^{\omega-1} \cdot y, 1)$ iff $s \cdot t = \_\mathcal{A}b s' \cdot u \cdot t'$. This again reduces the inclusion of the second point of the Syncing Lemma to a decidable semilinear property. ◀

6 Discussion

We presented a study of continuity in functional transducers, on the one hand focused on general statements (Section 3), on the other hand on continuity for classical varieties. The heart of this contribution resides in decidability properties (Section 5), although we also addressed natural and related questions in a systematic way (Section 4). We single out two main research directions.

First, there is a sharp contrast between the genericity of the Preservation and Syncing Lemma and the technicality of the actual proofs of decidability of continuity. To which extent can these be unified and generalized? We know of two immediate extensions: 1. the generic results of Section 3 readily apply to Boolean algebras of languages closed under quotient, a relaxation of the conditions imposed on varieties, and 2. the varieties $\mathcal{G}\_p$ of languages recognized by p-groups can also be shown to verify Proposition 14 and Lemma 24, hence

$\mathcal{G}_p$_continuity is decidable for transducers. Beyond these two points, we do not know how to show decidability for $\mathcal{G}_{\text{nil}}$ (which is the *join* of the $\mathcal{G}_p$), and the surprising complexity of the equalizer sets for some Burnside varieties (e.g., the one defined by $x^2 = x^3$, see the Remark on page 7) leads us to conjecture that continuity may be undecidable in that case, hence that no unified way to show the decidability of continuity exists.

Second, the notion of continuity may be extended to more general settings. For instance, departing from regular languages, it can be noted that every recursive function is continuous for the class of recursive languages. Another natural generalization consists in studying $(\mathcal{V}, \mathcal{W})$_continuity, that is, the property for a function to map $\mathcal{W}$_languages to $\mathcal{V}$_languages by inverse image. This would provide more flexibility for a sufficient condition for cascades of languages (or stackings of circuits, or nestings of formulas) to be in a given variety.

Acknowledgment. We are deeply indebted to Jorge Almeida (in particular for the Remark on page 7), Luc Dartois, Bruno Guillon (in particular for the Remark on page 11), Ismaël Jecker, and Jean-Éric Pin for their insightful comments and kind help.

Abstract

An astonishing fact was established by Lee A. Rubel (1981): there exists a fixed non-trivial fourth-order polynomial differential algebraic equation (DAE) such that for any positive continuous function φ on the reals, and for any positive continuous function $\epsilon(t)$, it has a $\mathcal{C}^\infty$ solution with $|y(t) - \varphi(t)| < \epsilon(t)$ for all t. Lee A. Rubel provided an explicit example of such a polynomial DAE. Other examples of universal DAE have later been proposed by other authors.

However, while these results may seem very surprising, their proofs are quite simple and are frustrating for a computability theorist, or for people interested in modeling systems in experimental sciences. First, the involved notions of universality is far from usual notions of universality in computability theory because the proofs heavily rely on the fact that constructed DAE does not have unique solutions for a given initial data. Indeed, in general a DAE may not have a unique solution, given some initials conditions. But Rubel's DAE *never* has a unique solution, even with a countable number of conditions of the form $y^{(k_i)}(a_i) = b_i$. This is very different from usual notions of universality where one would expect that there is clear unambiguous notion of evolution for a given initial data, for example as in computability theory. Second, the proofs usually rely on solutions that are piecewise defined. Hence they cannot be analytic, while analycity is often a key expected property in experimental sciences. Third, the proofs of these results can be interpreted more as the fact that (fourth-order) polynomial algebraic differential equations is a too loose a model compared to classical ordinary differential equations. In particular, one may challenge whether the result is really a universality result.

The question whether one can require the solution that approximates φ to be the unique solution for a given initial data is a well known open problem [Rubel 1981, page 2], [Boshernitzan 1986, Conjecture 6.2]. In this article, we solve it and show that Rubel's statement holds for polynomial ordinary differential equations (ODEs), and since polynomial ODEs have a unique solution given an initial data, this positively answers Rubel's open problem. More precisely, we show that there exists a **fixed** polynomial ODE such that for any φ and $\epsilon(t)$ there exists some initial condition that yields a solution that is ϵ-close to φ at all times.

The proof uses ordinary differential equation programming. We believe it sheds some light on computability theory for continuous-time models of computations. It also demonstrates that ordinary differential equations are indeed universal in the sense of Rubel and hence suffer from the same problem as DAEs for modelization: a single equation is capable of modelling any phenomenon with arbitrary precision, meaning that trying to fit a model based on polynomial DAEs or ODEs is too general (if it has a sufficient dimension).

1 Introduction

A very astonishing result was established by Lee A. Rubel in 1981 [19]. There exists a universal fourth-order algebraic differential equation in the following sense.

▶ **Theorem 1** ([19]). *There exists a non-trivial fourth-order implicit differential algebraic equation*

$$P(y', y'', y''', y'''') = 0 \tag{1}$$

where P is a polynomial in four variables with integer coefficients, such that for any continuous function φ on $(-\infty, \infty)$ and for any positive continuous function $\epsilon(t)$ on $(-\infty, \infty)$, there exists a $\mathcal{C}^\infty$ solution y such that

$$|y(t) - \varphi(t)| < \epsilon(t)$$

for all $t \in (-\infty, \infty)$.

Even more surprising is the fact that Rubel provided an explicit example of such a polynomial P that is particularly simple:

$$\begin{aligned} 3y'^4y''y''''^2 \quad & -4y'^4y'''^2y'''' + 6y'^3y''^2y'''y'''' + 24y'^2y''^4y'''' \\ & -12y'^3y''y'''^3 - 29y'^2y''^3y'''^2 + 12y''^7 \qquad = 0 \end{aligned} \tag{2}$$

While this result looks very surprising at first sight, Rubel's proofs turns out to use basic arguments, and can be explained as follows. It uses the following classical trick to build $\mathcal{C}^\infty$ piecewise functions: let $g(t) = e^{-1/(1-t^2)}$ for $-1 < t < 1$, and $g(t) = 0$ otherwise. It is not hard to see that function g is C^∞ and Figure 1 shows that g looks like a "bump". Since it satisfies $\frac{g'(t)}{g(t)} = -\frac{2t}{(1-t^2)^2}$, then $g'(t)(1-t^2)^2 + g(t)2t = 0$ and $f(t) = \int_0^t g(u)du$ satisfies the polynomial differential algebraic equation $f''(1-t^2)^2 + f'(t)2t = 0$. Since this equation is homogeneous, it also holds for $af + b$ for any a and b. The idea is then to obtain a fourth order DAE that is satisfied by every function $y(t) = \gamma f(\alpha t + \beta) + \delta$, for all $\alpha, \beta, \gamma, \delta$. After some computations, Rubel obtained the universal differential equation (2).

Functions of the type $y(t) = \gamma f(\alpha t + \beta) + \delta$ generate what Rubel calls S-modules: a function that values A at a, B at b, is constant on $[a, a + \delta]$, monotone on $[a + \delta, b - \delta]$,

constant on $[b-\delta, b]$, by an appropriate choice of $\alpha, \beta, \gamma, \delta$. Summing S-modules corresponds to gluing then together, as is depicted in Figure 1. Note that finite, as well as infinite sums[1] of S-modules still satisfy the equation (2) and thus any piecewise affine function (and hence any continuous function) can be approximated by an appropriate sum of S-modules. This concludes Rubel's proof of universality.

As one can see, the proof turns out to be frustrating because the equation essentially allows any behavior. This may be interpreted as merely stating that differential algebraic equations is simply too lose a model. Clearly, a key point is that this differential equation does not have a unique solution for any given initial condition: this is the core principle used to glue a finite or infinite number of S-modules and to approximate any continuous function. Rubel was aware of this issue and left open the following question in [19, page 2].

> "It is open whether we can require in our theorem that the solution that approximates φ to be the unique solution for its initial data."

Similarly, the following is conjectured in [4, Conjecture 6.2].

> "Conjecture. There exists a non-trivial differential algebraic equation such that any real continuous function on $\mathbb{R}$ can be uniformly approximated on all of $\mathbb{R}$ by its real-analytic solutions"

The purpose of this paper is to provide a positive answer to both questions. We prove that a fixed polynomial ordinary differential equations (ODE) is universal in above Rubel's sense. At a high level, our proofs are based on ordinary differential equation programming. This programming is inspired by constructions from our previous paper [7]. Here, we mostly use this programming technology to achieve a very different goal and to provide positive answers to these above open problems.

We also believe they open some lights on computability theory for continuous-time models of computations. In particular, it follows that concepts similar to Kolmogorov complexity can probably be expressed naturally by measuring the complexity of the initial data of a (universal-) polynomial ordinary differential equations for a given function. We leave this direction for future work.

1.1 Related work and discussions

First, let us mention that Rubel's universal differential equation has been extended in several papers. In particular, Duffin proved in [12] that implicit universal differential equations with simpler expressions exists, such as $n^2 y''''y'^2 + 3n(1-n)y'''y''y' + (2n^2-3n+1)y''^3 = 0$ for any $n > 3$. The idea of [12] is basically to replace the $\mathcal{C}^\infty$ function g of [19] by some piecewise polynomial of fixed degree, that is to say by splines. Duffin also proves that considering trigonometric polynomials for function $g(x)$ leads to the universal differential equation $ny''''y'^2 + (2-3n)y'''y''y' + 2(n-1)y''^3 = 0$. This is done at the price of approximating function φ respectively by splines or trigonometric splines solutions which are $\mathcal{C}^n$ (and n can be taken arbitrary big) but not $\mathcal{C}^\infty$ as in [19]. Article [8] proposes another universal differential equation whose construction is based on Jacobian elliptic functions. Notice that [8] is also correcting some statements of [12].

[1] With some convergence or disjoint domain conditions.

All the results mentioned so far are concerned with approximations of continuous functions over the whole real line. Approximating functions over a compact domain seems to be a different (and somewhat easier for our concerns) problem, since basically by compactness, one just needs to approximate the function locally on a finite number of intervals. A 1986 reference survey discussing both approximation over the real line and over compacts is [4]. Recently, over compact domains, the existence of universal ordinary differential equation $\mathcal{C}^\infty$ of order 3 has been established in [11]: it is shown that for any $a < b$, there exists a third order $\mathcal{C}^\infty$ differential equation $y''' = F(y, y', y'')$ whose solutions are dense in $\mathcal{C}^0([a, b])$. Notice that this is not obtained by explicitly stating such an order 3 universal ordinary differential, and that this is a weaker notion of universality as solutions are only assumed to be arbitrary close over a compact domain and not all the real line. Order 3 is argued to be a lower bound for Lipschitzian universal ODEs [11].

Rubel's result has sometimes been considered to be related to be the equivalent, for analog computers, of the universal Turing machines. This includes Rubel's paper motivation given in [19, page 1]. We now discuss and challenge this statement.

Indeed, differential algebraic equations are known to be related to the General Purpose Analog Computer (GPAC) of Claude Shannon [20], proposed as a model of the Differential Analysers [9], a mechanical programmable machine, on which he worked as an operator. Notice that the original relations stated by Shannon in [20] between differential algebraic equations and GPACs have some flaws, that have been corrected later by [18] and [13]. Using the better defined model of GPAC of [13], it can be shown that functions generated by GPAC exactly correspond to polynomial ordinary differential equations. Some recent results have established that this model, and hence polynomial ordinary differential equations can be related to classical computability [5] and complexity theory [7].

However, we do not really follow the statement that Rubel's result is the equivalent, for analog computers, of the universal Turing machines. In particular, Rubel's notion of universality is completely different from the ones in computability theory. For a given initial data, a (deterministic) Turing machine has only one possible evolution. On the other hand, Rubel's equation does not dictate any evolution but rather some conditions that any evolution has to satisfy. In other words, Rubel's equation can be interpreted as the equivalent of an invariant of the dynamics of (Turing) machines, rather than a universal machine in the sense of classical computability.

Notice that while several results have established that (polynomial) ODEs are able to simulate the evolution of Turing machines (see e.g. [5, 15, 7]), the existence of a universal ordinary differential equation does not follow from them. To understand the difference, let us restate the main result of [15], of which [7] is a more advanced version for polynomial-time computable functions.

▶ **Theorem 2.** *A function $f : [a, b] \to \mathbb{R}$ is computable (in the framework of Computable Analysis) if and only if there exists some polynomials $p : \mathbb{R}^{n+1} \to \mathbb{R}^n$, $p_0 : \mathbb{R} \to \mathbb{R}$ with computable coefficients and $\alpha_1, \ldots, \alpha_{n-1}$ computable reals such that for all $x \in [a, b]$, the solution $y : [a, b] \to \mathbb{R}^n$ to the Cauchy problem*

$$y(0) = (\alpha_1, \ldots, \alpha_{n-1}, p_0(x)), \qquad y' = p(y)$$

satisfies that for all $t \geqslant 0$ that

$$|f(x) - y_1(t)| \leqslant y_2(t) \quad \text{and} \quad \lim_{t\to\infty} y_2(t) = 0.$$

Since there exists a universal Turing machine, there exists a "universal" polynomial ODE for computable functions. But there are major differences between Theorem 2 and the result

of this paper (Theorem 3). Even if we have a strong link between the Turing machines's configuration and the evolution of the differential equation, this is not enough to guarantee what the trajectory of the system will be at all times. Indeed, Theorem 2 only guarantees that $y_1(t) \to f(x)$ asymptotically. On the other hand, Theorem 3 guarantees the value of $y_1(t)$ at all times. Notice that our universality result also applies to functions that are not computable (in which case the initial condition is computable from the function but still not computable).

We would like to mention some implications for experimental sciences that are related to the classical use of ODEs in such contexts. Of course, we know that this part is less formal from a mathematical point of view, but we believe this discussion has some importance: A key property in experimental sciences, in particular physics is analyticity. Recall that a function is analytic if its is equal to its Taylor expansion in any point. It has sometimes been observed that "natural" functions coming from Nature are analytic, even if this cannot be a formal statement, but more an observation. We obtain a fixed universal polynomial ODEs, so in particular all its solution must be analytic[2], and it follows that universality holds even with analytic functions. All previous constructions mostly worked by gluing together $\mathcal{C}^\infty$ or $\mathcal{C}^n$ functions, and as it is well known "gluing" of analytic functions is impossible. We believe this is an important difference with previous works.

As we said, Rubel's proof can be seen as an indication that (fourth-order) polynomial implicit DAE is too loose model compared to classical ODEs, allowing in particular to glue solutions together to get new solutions. As observed in many articles citing Rubel's paper, this class appears so general that from an experimental point of view, it makes littles sense to try to fit a differential model because a single equation can model everything with arbitrary precision. Our result implies the same for polynomial ODEs since, for the same reason, a single equation of sufficient dimension can model everything.

Notice that our constructions have at the end some similarities with Voronin's theorem. This theorem states that Riemann's ζ function is such that for any analytic function $f(z)$ that is non-vanishing on a domain U homeomorphic to a closed disk, and any $\epsilon > 0$, one can find some real value t such that for all $z \in U$, $|\zeta(z + it) - f(z)| < \epsilon$. Notice that ζ function is a well-known function known not to be solution of any polynomial DAE (and consequently polynomial ODE), and hence there is no clear connexion to our constructions based on ODEs. We invite to read the post [17] in "Gödel's Lost Letter and P=NP" blog for discussions about potential implications of this surprising result to computability theory.

1.2 Formal statements

▶ **Theorem 3** (Universal PIVP). *There exists a* ***fixed*** *polynomial vector p in d variables such that for any functions $f \in C^0(\mathbb{R})$ and $\varepsilon \in C^0(\mathbb{R}, \mathbb{R}_{>0})$, there exists $\alpha \in \mathbb{R}^d$ such that there exists a unique solution $y : \mathbb{R} \to \mathbb{R}^d$ to $y(0) = \alpha$, $y' = p(y)$. Furthermore, this solution satisfies that $|y_1(t) - f(t)| \leqslant \varepsilon(t)$ for all $t \in \mathbb{R}$, and it is analytic.*

It is well-known that polynomial ODEs can be transformed into DAEs that have the same analytic solutions, see [10] for example. The following then follows for DAEs.

▶ **Theorem 4** (Universal DAE). *There exists a* ***fixed*** *polynomial p in $d+1$ variables such that for any functions $f \in C^0(\mathbb{R})$ and $\varepsilon \in C^0(\mathbb{R}, \mathbb{R}_{>0})$, there exists $\alpha_0, \ldots, \alpha_{d-1} \in \mathbb{R}$ such that*

[2] Which is not the case for polynomial DAEs.

there exists a unique ***analytic*** *solution* $y : \mathbb{R} \to \mathbb{R}$ *to* $y(0) = \alpha_0, y'(0) = \alpha_1, \ldots, y^{(d-1)}(0) = \alpha_{d-1}$, $p(y, y', \ldots, y^d) = 0$. *Furthermore, this solution satisfies that* $|y(t) - f(t)| \leqslant \varepsilon(t)$ *for all* $t \in \mathbb{R}$.

▶ Remark. Notice that both theorems apply even when f is not computable. In this case, the initial condition(s) α exist but are not computable. We believe that α is always *computable from* f and ε, that is the mapping $(f, \varepsilon) \mapsto \alpha$ is computable in the framework of Computable Analysis, with an adequate representation of f, ε and α.

▶ Remark. Notice that we do not provide explicitly in this paper the considered polynomial ODE, nor its dimension d. But it can be derived by following the constructions. We currently estimate d to be more than three hundred following the precise constructions of this paper (but also to be very far from the optimal). We did not try to minimize d in the current paper, as we think our results are sufficiently hard to be followed in this paper for not beeing complicated by considerations about optimizations of dimensions.

▶ Remark. Both theorems are stated for *total functions* f and ε over $\mathbb{R}$. It trivially applies to any continuous partial function that can be extended to a continuous function over $\mathbb{R}$. In particular, it applies to any functions over $[a, b]$. It is not hard to see that it also applies to functions over (a, b) by rescaling $\mathbb{R}$ into (a, b) using the cotangent:

$$z(t) = y\left(-\cot\left(\tfrac{t-a}{b-a}\pi\right)\right) \quad \text{satisfies} \quad z'(t) = \phi'(t)p(z(t)), \quad \phi'(t) = \tfrac{\pi}{b-a}(1 + \phi(t)^2).$$

More complex domains such as $[a, b)$ and $(a, b]$ (with a possibly infinite) can also be obtain in a similar fashion.

2 Overview of the proof

A first a priori difficulty is that if one considers a fixed polynomial ODE $y' = p(y)$, one could think that the growth of its solutions is constrained by p and thus cannot be arbitrary. This would then prevent us from building a universal ODE simply because it could not grow fast enough. This fact is related to Emil Borel's conjecture in [3] (see also [16]) that a solution, *defined over* $\mathbb{R}$, to a system with n variables has growth bounded by roughly $e_n(x)$, the $n-$th iterate of exp. The conjecture is proved for $n = 1$ [3], but has been proven to be false for $n = 2$ in [21] and [2]. Bank [1] then adapted the previous counter-examples to provide a DAE whose non-unique increasing real-analytic solutions at infinity do not have any majorant. See the discussions (and Conjecture 6.1) in [4] for discussions about the growth of solutions of DAEs, and their relations to functions $e_n(x)$.

Thus, the first important part of this paper is to refine Bank's counter-example to build `fastgen`, a fast-growing function that satisfies even stronger properties. The second major ingredient is to be able to approximate a function with arbitrary precision everywhere. Since this is a difficult task, we use `fastgen` to our advantage to show that it is enough to approximate functions that are bounded and change slowly (think 1-Lipschitz, although the exact condition is more involved). That is to say, to deal with the case where there is no problem about the growth and rate of change of functions in some way. This is the purpose of the function `pwcgen` which can build arbitrary almost piecewise constant functions as long as they are bounded and change slowly.

It should be noted that the entire paper, we construct *generable functions* (in several variables) (see Section 3.1). For most of the constructions, we only use basic facts like the fact that generable functions are stable under arithmetic, composition and ODE solving. We know that generable functions satisfy polynomial partial equations and use this fact only at

the very end to show that the generable approximation that we have built, in fact, translates to a polynomial ordinary differential equation.

The rest of the paper is organized as follows. In Section 3, we recall some concepts and results from other articles. The main purpose of this section is to present Theorem 10. This theorem is the analog equivalent of doing an assignment in a periodic manner. Section 4 is devoted to `fastgen`, the fast-growing function. In Section 5, we show how to generate a sequence of dyadic rationals. In Section 6, we show how to generate a sequence of bits. In Section 7, we show how to leverage the two previous sections to generate arbitrary almost piecewise constant functions. Section 8 is then devoted to the proof of our main theorem.

3 Concepts and results from other articles

3.1 Generable functions

The following concept can be attributed to [20]: a function $f : \mathbb{R} \to \mathbb{R}$ is said to be a PIVP (Polynomial Initial Value Problem) function if there exists a system of the form $y' = p(y)$, where p is a (vector of) polynomial, with $f(t) = y_1(t)$ for all t, where y_1 denotes first component of the vector y defined in $\mathbb{R}^d$. We need in our proof to extend this concept to talk about multivariable functions. In [6], we introduced the following class, which can be seen as extensions of [14].

▶ **Definition 5** (Generable function)**.** Let $d, e \in \mathbb{N}$, I be an open and connected subset of $\mathbb{R}^d$ and $f : I \to \mathbb{R}^e$. We say that f is generable if and only if there exists an integer $n \geqslant e$, a $n \times d$ matrix p consisting of polynomials with coefficients in $\mathbb{R}$, $x_0 \in \mathbb{R}^d$, $y_0 \in \mathbb{R}^n$ and $y : I \to \mathbb{R}^n$ satisfying for all $x \in I$:

- $y(x_0) = y_0$ and $J_y(x) = p(y(x))$
- $f(x) = (y_1(x), \ldots, y_e(x))$

▶ y satisfies a polynomial differential equation[3],

▶ the components of f are components of y.

This class strictly generalizes functions generated by polynomial ODEs. Indeed, in the special case of $d = 1$ (the domain of the function has dimension 1), the above definition is equivalent to saying that $y' = p(y)$ for some polynomial p. The interested reader can read more about this in [6].

For the purpose of this paper, the reader only needs to know that the class of generable functions enjoys many stability properties that make it easy to create new functions from basic operations. Informally, one can add, subtract, multiply, divide and compose them at will, the only requirement is that the domain of definition must always be connected. In particular, the class of generable functions contains some common mathematical functions:

- (multivariate) polynomials,
- trigonometric functions: sin, cos, tan, etc,
- exponential and logarithm: exp, ln,
- hyperbolic trigonometric functions: sinh, cosh, tanh.

Two famous examples of functions that are *not* in this class are the ζ and Γ, we refer the reader to [6] and [14] for more information.

A nontrivial fact is that generable functions are always analytic. This property is well-known in the one-dimensional case but is less obvious in higher dimensions, see [6] for more details. Moreover, generable functions satisfy the following crucial properties.

[3] J_y denotes the Jacobian matrix of y.

▶ **Lemma 6** (Closure properties of generable functions). *Let $f :\subseteq \mathbb{R}^d \to \mathbb{R}^n$ and $g :\subseteq \mathbb{R}^e \to \mathbb{R}^m$ be generable functions. Then $f + g$, $f - g$, fg, $\frac{f}{g}$ and $f \circ g$ are generable*[4].

▶ **Lemma 7** (Generable functions are closed under ODE). *Let $d \in \mathbb{N}$, $J \subseteq \mathbb{R}$ an interval, $f :\subseteq \mathbb{R}^d \to \mathbb{R}^d$ generable, $t_0 \in J$ and $y_0 \in \operatorname{dom} f$. Assume there exists $y : J \to \operatorname{dom} f$ satisfying*

$$y(t_0) = y_0 \qquad y'(t) = f(y(t))$$

for all $t \in J$, then y is generable (and unique).

In fact, generable functions satisfy the stronger (albeit more obscure) theorem

▶ **Theorem 8** (Generable functions are closed under ODE). *Let $d, n \in \mathbb{N}$, $\Omega \subseteq \mathbb{R}^d$, $t_0 \in \mathbb{R}$, $(J_\alpha)_{\alpha\in\Omega}$ a family of open intervals containing t_0 and $G : \Omega \to \mathbb{R}^n$, $F :\subseteq \mathbb{R}^d \to \mathbb{R}^d$ generable. Assume that $X = \{(\alpha, t) : \alpha \in \Omega, t \in J_\alpha\}$ is an open connected set and that there exists $f : X \to \operatorname{dom} F$ satisfying*

$$f(\alpha, t_0) = G(\alpha) \qquad \frac{\partial f}{\partial t}(\alpha, t) = F(f(\alpha, t))$$

for all $\alpha \in \Omega$ and $t \in J_\alpha$. Then f is generable (and unique).

3.2 Helper functions and constructions

We mentioned earlier that a number of common mathematical functions are generable. However, for our purpose, we will need less common functions that one can consider to be programming gadgets. One such operation is rounding (computing the nearest integer). Note that, by construction, generable functions are analytic and in particular must be continuous. It is thus clear that we cannot build a perfect rounding function and in particular we have to compromise on two aspects:

- we cannot round numbers arbitrarily close to $n + \frac{1}{2}$ for $n \in \mathbb{Z}$: thus the function takes a parameter λ to control the size of the "zone" around $n + \frac{1}{2}$ where the function does not round properly,
- we cannot round without error: thus the function takes a parameters μ that controls how good the approximation must be.

▶ **Lemma 9** (Round, [6]). *There exists a generable function* round *such that for any $n \in \mathbb{Z}$, $x \in \mathbb{R}$, $\lambda > 2$ and $\mu \geqslant 0$:*

- *if $x \in \left[n - \frac{1}{2}, n + \frac{1}{2}\right]$ then $|\operatorname{round}(x, \mu, \lambda) - n| \leqslant \frac{1}{2}$,*
- *if $x \in \left[n - \frac{1}{2} + \frac{1}{\lambda}, n + \frac{1}{2} - \frac{1}{\lambda}\right]$ then $|\operatorname{round}(x, \mu, \lambda) - n| \leqslant e^{-\mu}$.*

The other very useful operation is the analog equivalent of a discrete assignment, done in a periodic manner. More precisely, we consider a particular class of ODEs

$$y'(t) = \operatorname{pereach}(t, \phi(t), y(t), g(t))$$

adapted from the constructions of [7].

This equation alternates between two behaviors, for all $n \in \mathbb{N}$.

- During $J_n = [n, n + \frac{1}{2}]$, it performs $y(t) \to \overline{g}$ where $\min_{t\in J_n} g(t) \leqslant \overline{g} \leqslant \max_{t\in J_n} g(t)$. So in particular, if $g(t)$ is almost constant over this time interval, then it is essentially $y(t) \to g$. Then ϕ controls how good the convergence is: the error is of the order of $e^{-\phi}$.

[4] With the obvious dimensional condition associated with each operation.

- During $J'_n = [n+\frac{1}{2}, n+1]$, the systems tries to keep y constant, ie $y' \approx 0$. More precisely, the system enforces that $|y'(t)| \leqslant e^{-\phi(t)}$.

▶ **Theorem 10** (Periodic reach). *There exists a generable function* $\mathrm{pereach} : \mathbb{R}^2_{\geqslant 0} \times \mathbb{R}^2 \to \mathbb{R}$ *such that for any* $I = [n, n+1]$ *with* $n \in \mathbb{N}$, $y_0 \in \mathbb{R}$, $\phi, \psi \in C^0(I, \mathbb{R}_{\geqslant 0})$ *and* $g \in C^0(I, \mathbb{R})$, *the unique solution to*

$$y(n) = y_0, \qquad y'(t) = \psi(t)\,\mathrm{pereach}(t, \phi(t), y(t), g(t))$$

exists over I.

- *If there exists* $\bar{g} \in \mathbb{R}$ *and* $\eta \in \mathbb{R}_{\geqslant 0}$ *such that* $|g(t) - \bar{g}| \leqslant \eta$ *for all* $t \in [n, n+\frac{1}{2}]$, *then* $|y(t) - \bar{g}| \leqslant \eta + \exp\left(-\int_n^t \psi(u)\phi(u)du\right)$ *whenever* $\int_n^t \psi(u)\phi(u)du \geqslant 1$ *for all* $t \in [n, n+\frac{1}{2}]$, *and* $|y(t) - \bar{g}| \leqslant \max(\eta, |y(n) - \bar{g}|)$ *for all* $t \in [n, n+\frac{1}{2}]$ *without condition.*
- *For all* $t \in [n+\frac{1}{2}, n]$, $|y(t) - y(n+\frac{1}{2})| \leqslant \int_{n+\frac{1}{2}}^t \psi(u)\exp(-\phi(u))\,du$.

In particular, the first item implies that $y(t) \geqslant \min_{u\in[n,t]} g(t) - \exp\left(-\int_n^t \phi(u)du\right)$ *whenever* $\int_n^t \phi(u)du \geqslant 1$ *for all* $t \in [n, n+\frac{1}{2}]$, *and* $y(t) \geqslant \min\left(y(n), \min_{u\in[n,t]} g(t)\right)$.

4 Generating fast growing functions

Our construction crucially relies on our ability to build functions of arbitrary growth. At the end of this section, we obtain a function `fastgen` with a straightforward specification: for any infinite sequence $a_0, a_1, \ldots$ of positive numbers, we can find a suitable $\alpha \in \mathbb{R}$ such that $\mathrm{fastgen}(\alpha, n) \geqslant a_n$ for all $n \in \mathbb{N}$. Furthermore, we can ensure that $\mathrm{fastgen}(\alpha, \cdot)$ is increasing. Notice, and this is the key point, that the definition of `fastgen` is independent of the sequence a: a single generable function (and thus differential system) can have arbitrary growth by simply tweaking its initial value.

Our construction builds on the following lemma proved by [1], based on an example of [2]. The proof essentially relies on the function $\frac{1}{2-\cos(x)-\cos(\alpha x)}$ which is generable and well-defined for all positive x if α is irrational. By carefully chosing α, we can make $\cos(x)$ and $\cos(\alpha x)$ simultaneously arbitrary close to 1.

▶ **Lemma 11** ([1]). *There exists a positive nondecreasing generable function* g *and an absolute constant* $c > 0$ *such that for any increasing sequence* $a \in \mathbb{N}^{\mathbb{N}}$ *with* $a_n \geqslant 2$ *for all* n, *there exists* $\alpha \in \mathbb{R}$ *such that* $g(\alpha, \cdot)$ *is defined over* $[1, \infty)$ *and for any* $n \in \mathbb{N}$ *and* $t \geqslant 2\pi b_n$, $g(\alpha, t) \geqslant c a_n$ *where* $b_n = \prod_{k=0}^{n-1} a_k$.

Essentially, this lemma proves that there exists a function g such that for any $n \in \mathbb{N}$, $g(\alpha, a_0 a_1 \cdots a_{n-1}) \geqslant a_n$. Note that this is not quite what we are aiming for: the function g is indeed $\geqslant a_n$ but at times $a_0 a_1 \cdots a_{n-1}$ instead of n. Since $a_0 a_1 \cdots a_{n-1}$ is a very big number, we need to "accelerate" g so that it reaches this values faster. This is a chicken-and-egg problem because to accelerate g, we need to build a fast growing function. We now try to explain how to solve this problem. Consider the following sequence:

$$x_0 = a_0, \qquad x_{n+1} = x_n g(x_n).$$

Then observe that

$$x_1 = x_0 g(x_0) = a_0 g(a_0) \geqslant a_0 a_1, \qquad x_2 = x_1 g(x_1) \geqslant a_0 a_1 g(a_0 a_1) \geqslant a_0 a_1 a_2, \quad \ldots$$

It is not hard to see that $x_n \geqslant a_0 a_1 \cdots a_n \geqslant a_n$. We then use our generable gadget of Section 3.2 to simulate this discrete sequence with a differential equation. Intuitively, we

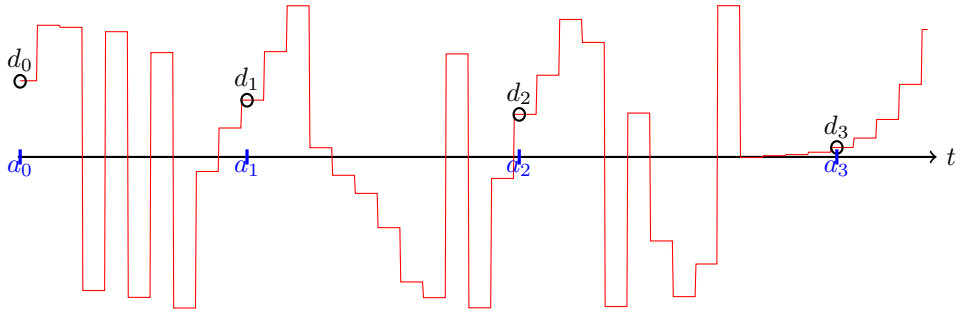

Figure 2 Graph of dygen for $d_0 = 2^{-1}$, $d_1 = 2^{-3} + 2^{-1}$, $d_2 = 2^{-5} + 2^{-2}$ and $d_3 = 2^{-4}$ (other values ignored) assuming that $\delta = 9$. We get that $a_0 = 0$, $a_1 = 10$, $a_2 = 22$, $a_3 = 36$.

build a differential equation such that the solution y satisfies $y(n) \approx x_n$. More precisely, we use two variables y and z such that over $[n, n + 1/2]$, $z' \approx 0$ and $y(t) \to zg(z)$ and over $[n+1/2, n+1]$, $y' \approx 0$ and $z(t) \to y$. Then if $y(n) \approx z(n) \approx x_n$ then $y(n+1) \approx z(n+1) \approx x_{n+1}$.

▶ **Theorem 12.** *There exists* $\Gamma \subseteq \mathbb{R}$ *and a positive generable function* $\mathrm{fastgen} : \Gamma \times \mathbb{R}_{\geqslant 0} \to \mathbb{R}$ *such that for any* $x \in \mathbb{R}^{\mathbb{N}}_{\geqslant 0}$*, there exists* $\alpha \in \Gamma$ *such that for any* $n \in \mathbb{N}$ *and* $t \in \mathbb{R}_{\geqslant 0}$*,*

$$\mathrm{fastgen}(\alpha, t) \geqslant x_n \qquad \text{if } t \geqslant n.$$

Furthermore, $\mathrm{fastgen}(\alpha, \cdot)$ *is nondecreasing.*

5 Generating a sequence of dyadic rationals

A major part of the proof requires to build a function to approximate arbitrary numbers over intervals $[n, n + 1]$. Ideally we would like to build a function that gives x_0 over $[0, 1]$, x_1 over $[1, 2]$, etc. Before we get there, we solve a somewhat simpler problem by making a few assumptions:

- we only try to approximate dyadic numbers, *i.e.* numbers of the form $m2^{-p}$, and furthermore we only approximate with error 2^{-p-3},
- if a dyadic number has size p, meaning that it can be written as $m2^{-p}$ but not $m'2^{-p+1}$ then it will take a time interval of p units to approximate: $[k, k + p]$ instead of $[k, k + 1]$,
- the function will only approximate the dyadics over intervals $[k, k + \frac{1}{2}]$ and not $[k, k + 1]$.

This processus is illustrated in Figure 2: given a sequence $d_0, d_1, \ldots$ of dyadics, there is a corresponding sequence $a_0, a_1, \ldots$ of times such that the function approximate d_k over $[a_k, a_k + \frac{1}{2}]$ within error 2^{-p_k} where p_k is the size of d_k. The theorem contains an explicit formula for a_k that depends on some absolute constant δ.

Let $\mathbb{D}_p = \{m2^{-p} : m \in \{0, 1, \ldots, 2^p - 1\}\}$ and $\mathbb{D} = \bigcup_{n\in\mathbb{N}} \mathbb{D}_p$ denote the set of dyadic rationals in $[0, 1)$. For any $q \in \mathbb{D}$, we define its *size* by $\mathfrak{L}(q) = \min\{p \in \mathbb{N} : q \in \mathbb{D}_p\}$.

▶ **Theorem 13.** *There exists* $\delta \in \mathbb{N}_{>0}$*,* $\Gamma \subseteq \mathbb{R}^2$ *and a generable function* $\mathrm{dygen} : \Gamma \times \mathbb{R}_{\geqslant 0} \to \mathbb{R}$ *such that for any dyadic sequence* $q \in \mathbb{D}^{\mathbb{N}}$*, there exists* $(\alpha, \beta) \in \Gamma$ *such that for any* $n \in \mathbb{N}$*,*

$$|\mathrm{dygen}(\alpha, \beta, t) - q_n| \leqslant 2^{-\mathfrak{L}(q_n)-3} \qquad \text{for any } t \in [a_n, a_n + \tfrac{1}{2}]$$

where $a_n = \sum_{k=0}^{n-1} (\mathfrak{L}(q_k) + \delta)$*. Furthermore,* $|\mathrm{dygen}(\alpha, \beta, t)| \leqslant 1$ *for all* α, β *and* t*.*

6 Generating a sequences of bits

We saw in the previous section how to generate a dyadic generator. Unfortunately, we saw that it generates dyadic d_n at times a_n, whereas we would like to get d_n at time n for our approximation. Our approach is to build a signal generator that will be high exactly at times a_n. Each the signal will be high, the system will copy the value of the dyadic generator to a variable and wait until the next signal. Since the signal is binary, we only need to generate a sequence of bits. Note that this theorem has a different flavour from the dyadic generator: it generates a more restrictive set of values (bits) but does so much better because we have better control of the timing and we can approximate the bits with arbitrary precision.

▶ Remark. Although it is possible to define `bitgen` using `dygen`, it does not, in fact, gives a shorter proof but definitely gives a more complicated function.

▶ **Theorem 14.** *There exists* $\Gamma \subseteq \mathbb{R}$ *and a generable function* $\operatorname{bitgen} : \Gamma \times \mathbb{R}^2_{\geqslant 0} \to \mathbb{R}$ *such that for any bit sequence* $b \in \{0,1\}^{\mathbb{N}}$*, there exists* $\alpha_b \in \Gamma$ *such that for any* $\mu \in \mathbb{R}_{\geqslant 0}$*,* $n \in \mathbb{N}$ *and* $t \in [n, n + \frac{1}{2}]$*,*

$$|\operatorname{bitgen}(\alpha_b, \mu, t) - b_n| \leqslant e^{-\mu}.$$

Furthermore, $|\operatorname{bitgen}(\alpha, \mu, t)| \leqslant 1$ *for all* α, μ *and* t*.*

7 Generating an almost piecewise constant function

We have already explained the main intuition of this section in previous sections. Using the dyadic generator and the bit generator as a signal, we can construct a system that "samples" the dyadic at the right time and then holds this value still until the next dyadic. In essence, we just described an almost piecewise constant function. This function still has a limitation: its rate of change is small so it can only approximate slowly changing functions.

▶ **Theorem 15.** *There exists an absolute constant* $\delta \in \mathbb{N}$*,* $p \in \mathbb{N}$*,* $\Gamma \subseteq \mathbb{R}^p$ *and a generable function* $\operatorname{pwcgen} : \Gamma \times \mathbb{R}_{\geqslant 0} \to \mathbb{R}$ *such that for any dyadic sequence* $q \in \mathbb{D}^{\mathbb{N}}$ *then there exists* $\alpha \in \Gamma$ *such that for any* $n \in \mathbb{N}$*,*

$$|\operatorname{pwcgen}(\alpha, t) - q_n| \leqslant 2^{-\mathfrak{L}(q_n)} \qquad \text{for any } t \in [a_n + \tfrac{1}{2}, a_{n+1}]$$

and[5]

$$\operatorname{pwcgen}(\alpha, t) \in \left[\operatorname{pwcgen}(\alpha, a_n), \operatorname{pwcgen}(\alpha, a_n + \tfrac{1}{2})\right] \qquad \text{for any } t \in [a_n, a_n + \tfrac{1}{2}]$$

where $a_n = \sum_{k=0}^{n-1} (\delta + \mathfrak{L}(q_k))$*.*

8 Proof of the main theorem

The proof works in several steps. First we show that using an almost constant function, we can approximate functions that are bounded and change very slowly. We then relax all these constraints until we get to the general case. In the following, we only consider total functions over $\mathbb{R}$. See Remark on page 6 for more details.

[5] With the convention that $[a, b] = [\min(a, b), \max(a, b)]$.

▶ **Definition 16** (Universality)**.** Let $I \subseteq \mathbb{R}$ and $\mathcal{C} \subseteq C^0(I) \times C^0(I, \mathbb{R}_{>0})$. We say that the universality property holds for $\mathcal{C}$ if there exists $d \in \mathbb{N}$ and a generable function $\mathfrak{u}$ such that for any $(f, \varepsilon) \in \mathcal{C}$, there exists $\alpha \in \mathbb{R}^d$ such that

$$|\mathfrak{u}(\alpha, t) - f(t)| \leqslant \varepsilon(t) \qquad \text{for any } t \in \mathrm{dom}(f).$$

▶ **Lemma 17.** *There exists a constant $c > 0$ such that the universality property holds for all (f, ε) on $\mathbb{R}_{\geqslant 0}$ such that for all $t \in \mathbb{R}_{\geqslant 0}$:*

- *ε is decreasing and $-\log_2 \varepsilon(t) \leqslant c' + t$ for some constant c',*
- *$f(t) \in [0, 1]$,*
- *$|f(t) - f(t')| \leqslant c\varepsilon(t+1)$ for all $t' \in [t, t+1]$.*

Proof Sketch. This is essentially a application of `pwcgen` with a small twist. Indeed the bound on f guarantees that dyadic rationals are enough. The bound on the rate of change of f guarantees that a single dyadic can provide an approximation for a long enough time. And the bound on ε guarantees that we do not need too many digits for the approximations. ◀

▶ **Lemma 18.** *The universality property holds for all (f, ε) on $\mathbb{R}_{\geqslant 0}$ such that f and ε are differentiable, ε is decreasing and $f(t) \in [0, 1]$ for all $t \in \mathbb{R}_{\geqslant 0}$.*

Proof Sketch. Consider $F = f \circ h^{-1}$ and $E = \varepsilon \circ h^{-1}$ where h is a fast-growing function like `fastgen`. Then the faster h grows, the slower E and F change and thus we can apply Lemma 17 to (F, E). We recover an approximation of f from the approximation of F. ◀

▶ **Lemma 19.** *The universality property holds for all (f, ε) on $\mathbb{R}_{\geqslant 0}$ such that f is differentiable and ε is decreasing.*

Proof Sketch. Consider $F = \frac{1}{2} + \frac{f}{h}$ and $\varepsilon = \frac{f}{h}$ where h is a fast-growing function like `fastgen`. By taking h big enough, we can ensure that $F(t) \in [0, 1]$ and apply Lemma 18 to (F, E). We then recover an approximation of f from the approximation of F. ◀

▶ **Lemma 20.** *The universality property holds for all continuous (f, ε) on $\mathbb{R}_{\geqslant 0}$.*

Proof Sketch. Observe that the set of differential functions is dense in the set of continuous functions and apply Lemma 19. ◀

▶ **Lemma 21.** *The universality property holds for all continuous (f, ε) on $\mathbb{R}$.*

Proof Sketch. Let f^+ be the approximating of f over $\mathbb{R}_{\geqslant 0}$, using Lemma 20. Then we extend and modify f^+ to $\mathbb{R}$ in such a way that the approximation is still good over $\mathbb{R}_{\geqslant 0}$ but the function almost vanishes over $(-\infty, 0]$. We then do the same to $t \mapsto f(-t) - f^+(-t)$ and sum the two functions. ◀

We can now show the main theorem.

Proof of Theorem 3. Lemma 21 gives a generable function $\mathfrak{u}$. There exists α such that

$$|\mathfrak{u}(\alpha, t) - f(t)| \leqslant \varepsilon(t).$$

And since $\mathfrak{u}$ is generable, $t \mapsto \mathfrak{u}(\alpha, t)$ satisfies a PIVP. ◀

Abstract

We investigate a subclass of languages recognized by vector addition systems, namely languages of nondeterministic Parikh automata. While the regularity problem (is the language of a given automaton regular?) is undecidable for this model, we surprisingly show decidability of the regular separability problem: given two Parikh automata, is there a regular language that contains one of them and is disjoint from the other? We supplement this result by proving undecidability of the same problem already for languages of visibly one counter automata.

1 Introduction

We investigate separability problems for languages of finite words. We say that a language U is *separated from* a language V *by* S if $U \subseteq S$ and $V \cap S = \emptyset$. In the sequel we also often say that U *and* V are *separated by* S. For two families of languages $\mathcal{F}$ and $\mathcal{G}$, the $\mathcal{F}$ *separability problem for* $\mathcal{G}$ asks for two given languages $U, V \in \mathcal{G}$ whether U is separated from V by some language from $\mathcal{F}$. The same notion of separability makes clearly sense if $\mathcal{F}$ and $\mathcal{G}$ are classes of sets of vectors instead of classes of languages. In this paper, we consider the case where $\mathcal{F}$ are regular languages and $\mathcal{G}$ languages recognized by Parikh automata, and the case where $\mathcal{F}$ are the unary sets and $\mathcal{G}$ the semilinear sets.

Motivation. Separability is a classical problem in theoretical computer science. It was investigated most extensively in the area of formal languages, for $\mathcal{G}$ being the family of all regular word languages. Since regular languages are effectively closed under complement, the

$\mathcal{F}$ separability problem is a generalization of the $\mathcal{F}$ characterization problem, which asks whether a given language belongs to $\mathcal{F}$. Indeed, $L \in \mathcal{F}$ if and only if L is separated from its complement by some language from $\mathcal{F}$. Separability problems for regular languages attracted recently a lot of attention, which resulted in establishing the decidability of $\mathcal{F}$ separability for various families $\mathcal{F}$ such as the piecewise testable languages [7, 15] (recently generalized to finite ranked trees [9]), the locally and locally threshold testable languages [14], the languages definable in first order logic [17], and the languages of certain higher levels of the first order hierarchy [16], among others.

Separability of nonregular languages attracted little attention till now. The reasons for this may be twofold. First, for regular languages one can use standard algebraic tools, like syntactic monoids, and indeed most of the results have been obtained with the help of such techniques. Second, some strong intractability results have been known already since 70's, when Szymanski and Williams proved that regular separability of context-free languages is undecidable [18]. Later Hunt [10] generalized this result for every class $\mathcal{F}$ closed under finite boolean combinations and containing all languages of the form $w\Sigma^*$ for $w \in \Sigma^*$. This is a very weak condition, so it seemed that nothing nontrivial can be done outside regular languages with respect to separability problems. Furthermore, Szymanski and Williams's negative result has recently been strengthened by considering two incomparable subclasses of pushdown automata. First, Kopczyński has shown that regular separability is undecidable for languages of visibly pushdown automata [13], and then Czerwiński and Lasota have shown that the same problem is undecidable for one counter automata [6].

On the positive side, piecewise testable separability has been shown decidable for context-free languages, languages of vector addition systems (VAS languages), and some other classes of languages [8]. Another surprising result has been recently obtained by Czerwiński and Lasota [6] who show that regular separability is decidable (and PSPACE-complete) for languages recognized by one counter nets (i.e., one counter automata without zero test). Notice that in all these examples regularity (resp. piecewise testability) is undecidable, but regular (resp. piecewise testable) separability *is* decidable, and until recently there were not many results of this kind.

Finally, in [5] we have shown decidability of *unary separability* of reachability sets of vector addition systems (VASes). By *unary sets* we mean Parikh images of commutative regular languages, and thus the latter problem is equivalent to commutative regular separability of (commutative closures of) VAS languages. The decidability status of the regular separability problem for the whole class of VAS languages remains open.

Our contribution. This paper is a continuation of the line of research trying to understand the regular separability problem for language classes beyond regular languages. We report a further progress towards solving the open problem mentioned above by providing a positive decidability result and a new negative undecidability result: As our first (positive) result, we show decidability of the regular separability problem for the subclass of VAS languages where we allow negative counter values during a run. This class of languages is also known as languages of *integer VASSes*, and it admits many different characterizations; for instance, it coincides with languages of *one-way reversal-bounded counter machines* [11], *Parikh automata* [12] (cf. also [2, Proposition 11]), which in turn are equivalent to the very similar model of *constrained automata* [3]. In this paper, we present our results in terms of constrained automata, but given the similarity with Parikh automata (and in light of their equivalence), we overload the name Parikh automata for both models.

Notice that PA languages are not closed under complement, and thus our decidability result about regular separability does not imply decidability of the regularity problem (is

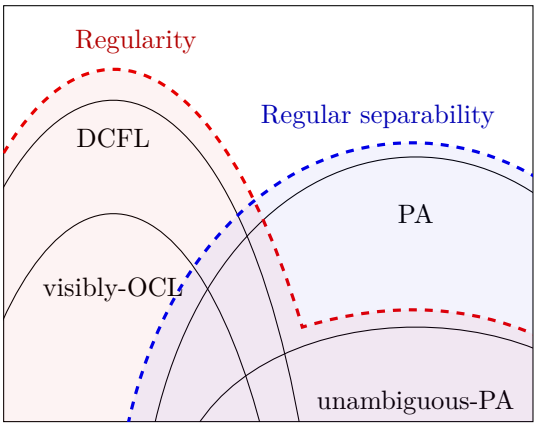

Figure 1 The regularity and the regular separability problems.

the language of a given Parikh automaton regular?). Moreover, the regularity problem for PA languages is actually *undecidable* [2][1], which makes our decidability result one of few instances where regularity is undecidable but regular separability is decidable; cf. Fig 1.

Parikh automata are finite nondeterministic automata where accepting runs are further restricted to satisfy a semilinear condition on the multiset of transitions appearing in the run. Our decidability result is actually stated in the more general setting of $\mathcal{C}$-*Parikh automata*, where $\mathcal{C} \subseteq \bigcup_{d\in\mathbb{N}} \mathcal{P}(\mathbb{N}^d)$ is a class of sets of vectors used as an acceptance condition. We prove that the regular separability problem for languages of $\mathcal{C}$-Parikh automata effectively reduces to the *unary* separability problem for the class $\mathcal{C}$ itself, provided that $\mathcal{C}$ is effectively closed under inverse images of affine functions. Two prototypical classes $\mathcal{C}$ satisfying the latter closure condition are semilinear sets and VAS reachability sets. Moreover, unary separability of semilinear sets is known to be decidable [4], and as recalled before the same result has recently been extended to VAS reachability sets [5]. As a consequence of our reduction, we deduce decidability of regular separability of $\mathcal{C}$-Parikh automata languages where the acceptance condition $\mathcal{C}$ can be instantiated to either the semilinear sets, or the VAS reachability sets.

We complement our decidability result by a new negative undecidability result subsuming simultaneously Kopczyński's undecidability for visibly pushdown languages [13] and Czerwiński and Lasota's undecidability of one counter languages [6]: We show that regular separability is undecidable for (deterministic[2]) visibly one counter languages. Inside the proof we use the result from [6], but actually in order to only reprove [13] it would be sufficient to use the old work by Szymanski and Williams [18].

2 Preliminaries

Vectors. A set $S \subseteq \mathbb{N}^d$ is *linear* if there exist a *base* $b \in \mathbb{N}^d$ and *periods* $p_1, \ldots, p_k \in \mathbb{N}^d$ s.t. $S = \{b + n_1p_1 + \ldots + n_kp_k \mid n_1, \ldots, n_k \in \mathbb{N}\}$, and it is *semilinear* if it is a finite union of linear sets. For a vector $v \in \mathbb{N}^d$ and $i \in \{1, \ldots, d\}$, let $v[i]$ denote its i-th coordinate. For $n \in \mathbb{N}$, we say that two vectors $x, y \in \mathbb{N}^d$ are n-*unary equivalent*, written $x \equiv_n y$, if for every coordinate $i \in \{1, \ldots, d\}$ it holds $x[i] \equiv y[i] \mod n$ and moreover $x[i] \leq n \iff y[i] \leq n$. A

[1] Later shown decidable for unambiguous PA [3].
[2] Determinism here is irrelevant because this class can be determinized.

set $S \subseteq \mathbb{N}^d$ is *unary* if for some n, S is a union of equivalence classes of $\equiv_n$. Intuitively, to decide membership in a unary set S it is enough to count on every coordinate exactly up to some threshold n, and modulo n for values larger than n. Unary sets are semilinear.

Let $\Sigma = \{a_1, \ldots, a_k\}$ be a totally ordered alphabet. For a word $w \in \Sigma^*$ and a letter $a_i \in \Sigma$, by $\#_{a_i}(w)$ we denote the number of letters a_i in w. The *Parikh image* of a word $w \in \Sigma^*$ is the vector $\Pi(w) = (\#_{a_1}(w), \ldots, \#_{a_k}(w)) \in \mathbb{N}^k$. The *Parikh image* of a language $L \subseteq \Sigma^*$ is $\Pi(L) = \{\Pi(w) \mid w \in L\}$, the set of Parikh images of all words belonging to L.

Parikh automata. A *nondeterministic finite automaton with ε-transitions* (ε-NFA) $\mathcal{A} = (Q, I, F, T)$ over a finite alphabet Σ consists of a finite set of states Q, two distinguished subsets of initial and final states $I, F \subseteq Q$, and a set of transitions $T \subseteq Q \times \Sigma_\varepsilon \times Q$, where $\Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$. A *nondeterministic Parikh automaton*[3] is a pair $(\mathcal{A}, S)$ consisting of an ε-NFA $\mathcal{A}$ and a semilinear set $S \subseteq \mathbb{N}^d$, where $d = |T|$ is the number of transitions of $\mathcal{A}$. Notice that we allow ε-transitions in the definition of Parikh automata. A *run* of a Parikh automaton over a word $w = a_1 \ldots a_n \in \Sigma^*$ is a sequence of transitions $\rho = t_1 \ldots t_n \in T^*$, where $t_i = (q_{i-1}, a_i, q_i)$, starting in an initial state q_0. A run ρ is *accepting* if its ending state q_n is final and $\Pi(\rho) \in S$ (we assume here that the set of transitions T is totally ordered). The language of a Parikh automaton, denoted $L(\mathcal{A}, S)$, contains all words w admitting an accepting run; it is thus a subset of the language $L(\mathcal{A})$ of the underlying ε-NFA.

One can generalize Parikh automata by using some other family of vector sets in the place of semilinear sets. For a class $\mathcal{C} \subseteq \bigcup_{d \in \mathbb{N}} \mathcal{P}(\mathbb{N}^d)$ of vector sets, a *$\mathcal{C}$-Parikh automaton* is a pair $(\mathcal{A}, S)$, where $\mathcal{A}$ is an ε-NFA and $S \in \mathcal{C}$. The language $L(\mathcal{A}, S)$ is defined as above.

A $\mathcal{C}$-Parikh automaton $(\mathcal{A}, S)$ is *deterministic* if the underlying automaton $\mathcal{A}$ is so; here, we assume that a deterministic automaton does not have ε-transitions. The languages of (non)deterministic $\mathcal{C}$-Parikh automata are shortly called (non)deterministic $\mathcal{C}$-Parikh languages below.

3 Main results

We call a function $f : \mathbb{N}^k \to \mathbb{N}^\ell$ *affine* if it is of the form $f(v) = Mv + u$ for an integer non-negative matrix M of dimension $\ell \times k$ and a vector $u \in \mathbb{N}^\ell$. In a special case when $u = 0$ we call the function f *linear*. A class of vector sets $\mathcal{C} \subseteq \bigcup_{d \in \mathbb{N}} \mathcal{P}(\mathbb{N}^d)$ is called *robust* if it fulfills the following two conditions:

- $\mathcal{C}$ is effectively closed under inverse images of affine functions,
- the unary separability problem is decidable for $\mathcal{C}$.

Our first main result is decidability of the regular separability problem for $\mathcal{C}$-Parikh automata.

▶ **Theorem 1.** *The regular separability problem is decidable for $\mathcal{C}$-Parikh automata, for every robust class $\mathcal{C}$ of vector sets.*

The proof of Theorem 1 is split into two parts. In Section 4 we provide a reduction of the regular separability problem for *nondeterministic* $\mathcal{C}$-Parikh automata to the same problem for *deterministic* ones; this step is crucial for understanding how the regular separability problem differs from the regularity problem, which does not admit a similar reduction. Then in Section 5 we reduce the regular separability problem for deterministic $\mathcal{C}$-Parikh automata to the unary separability problem for vector sets in $\mathcal{C}$.

[3] This is the same as *constrained automata* from [3].

In Section 6 we consider two instantiations of the class $\mathcal{C}$. First, taking $\mathcal{C}$ to be the semilinear sets we derive decidability for (ordinary) Parikh automata. Second, we consider the class $\mathcal{C}_{\text{SEC-VAS}}$ of *sections of* reachability sets of VASes (detailed definitions are deferred to Section 6), which allows us to obtain decidability for $\mathcal{C}_{\text{SEC-VAS}}$-Parikh automata. Note that the latter model properly extends Parikh automata.

Before proceeding with the rest of the proof for our decidability result, we present a generic reduction of the regular separability problem from which we can immediately derive a new undecidability result, which is our second main contribution.

3.1 A generic reduction

We observe that regular separability of homomorphic images of a class of languages $\mathcal{G}$ reduces to regular separability for $\mathcal{G}$ itself (cf. Lemma 2 below). Since nondeterministic Parikh automata are the homomorphic image of deterministic ones, we reduce regular separability for the nondeterministic class to the deterministic one (shown in Sec. 4); together with the decidability result for the deterministic class presented in Sec. 5, this proves Theorem 1.

Our reduction can also be used to derive undecidability results. Since context-free languages are the homomorphic image of (deterministic) visibly pushdown languages (cf. [1, Theorem 5.2]), and since regular separability is undecidable for the former class [18], we concisely reprove the recent LICS'16 result by Kopczyński [13] about undecidability of regular separability of visibly pushdown languages. Moreover, this result can be further strengthened to (deterministic) visibly one counter languages using the same observation and the recent result by Czerwiński and Lasota [6] about undecidability of regular separability for one counter automata (cf. Sec. 3.2).

We now present our generic reduction. Given two alphabets Σ and Γ, a *homomorphism* is a function $h : \Sigma \to \Gamma^*$ which extends homomorphically to a function from Σ^* to Γ^*, and thus to languages. For $\mathcal{G}$ a class of languages and $\mathcal{H}$ a class of homomorphisms, let $\mathcal{H}(\mathcal{G})$ be the class of languages obtained by applying some homomorphism from $\mathcal{H}$ to some language in $\mathcal{G}$.

▶ **Lemma 2.** *If $\mathcal{G}$ and $\mathcal{H}(\mathcal{G})$ are effectively closed under inverse images of homomorphisms from $\mathcal{H}$, then the regular separability problem in $\mathcal{H}(\mathcal{G})$ reduces to the same problem in $\mathcal{G}$.*

In statements of this form, "effective" means that for given finite computational model representing $L \in \mathcal{G}$ and $h \in \mathcal{H}$, one can effectively find a representation with a finite computational model for $h^{-1}(L) \in \mathcal{G}$, and similarly for $\mathcal{H}(\mathcal{G})$. The reduction above is a consequence of the following fundamental relationship between separators and (inverse) images of functions. (We do not exploit the further structure of homomorphisms here.)

▶ **Lemma 3.** *Let $L \subseteq \Sigma^*, K \subseteq \Gamma^*$ be two languages, and let $h : \Sigma^* \to \Gamma^*$ be a function.*
1. *If R separates $h(L)$ and K, then $h^{-1}(R)$ separates L and $h^{-1}(K)$.*
2. *If R separates L and $h^{-1}(K)$, then $h(R)$ separates $h(L)$ and K.*

Proof. The proof is elementary and it is given for completeness. For the first point, $L \subseteq h^{-1}(R)$ follows from the inclusion $h(L) \subseteq R$ since $L \subseteq h^{-1}(h(L))$, and the disjointness of $h^{-1}(R)$ and $h^{-1}(K)$ follows from disjointness of R and K. For the second point, the inclusion $h(L) \subseteq h(R)$ follows by the inclusion $L \subseteq R$, and the disjointness of $h(R)$ and K follows from the disjointness of R and $h^{-1}(K)$. ◀

Since regular languages are closed under images and inverse images of homomorphisms, we immediately obtain the following corollary.

▶ **Corollary 4.** *Let h be a homomorphism. Languages $h(L), K$ are regular separable if, and only if, $L, h^{-1}(K)$ are so.*

Since regular languages are closed under complement, the regular separability problem is in fact symmetric. Combining this observation with the corollary above, we can now prove correctness of our generic reduction.

Proof of Lemma 2. Let $h(L), K$ be two languages in $\mathcal{H}(\mathcal{G})$. By Corollary 4, regular separability for $h(L), K$ is the same as for $L, h^{-1}(K)$. Since $\mathcal{H}(\mathcal{G})$ is closed under inverse images by assumption, $h^{-1}(K)$ equals the image $g(K_1)$ of language K_1 in $\mathcal{G}$ for some g from $\mathcal{H}$. We have thus reduced to regular separability for $L, g(K_1)$, where now both L and K_1 are in $\mathcal{G}$. Since regular languages are closed under complement, regular separability for $L, g(K_1)$ is the same for $g(K_1), L$. Applying once more Corollary 4, the latter statement is equivalent to regular separability for $K_1, g^{-1}(L)$. Since $\mathcal{G}$ closed under inverse images by assumption, $g^{-1}(L)$ is itself in $\mathcal{G}$. Since every step was effective, this concludes the proof. ◀

3.2 A new undecidability result

A *one counter automaton* is a finite-state device manipulating a single natural counter, which can be incremented, decremented, and tested for zero; it is *visible* if the input symbol uniquely determines which counter operation will be performed. Therefore, languages recognized by visible one counter automata are a strict subclass of visibly pushdown languages [1]. It was recently proved that regular separability for one counter automata is undecidable [6], which is incomparable with undecidability for visibly pushdown languages [13].

As a consequence of Lemma 2 we obtain undecidability of regular separability for visible one counter automata, which is our second main result, strengthening both [6] and [13].

▶ **Theorem 5.** *Regular separability of languages recognised by (deterministic) visible one counter automata is undecidable.*

Let $\mathcal{G}$ be the class of languages recognized by visible one counter automata, and let $\mathcal{H}$ be the class of letter-to-letter (non-erasing) homomorphisms, i.e., functions of the form $h : \Sigma \to \Gamma$. In order to apply Lemma 2, it suffices to show that languages recognized by one counter automata are the effective homomorphic image of those recognized by the visible subclass, and that both classes are effectively closed under inverse images of letter-to-letter homomorphisms. We begin with the second result.

▶ **Lemma 6.** *One counter languages and visibly one counter languages are effectively closed under inverse images of letter-to-letter homomorphisms.*

Proof. Given one counter automaton $\mathcal{A}$ over Σ and a letter-to-letter homomorphism $h : \Gamma \to \Sigma$, one computes an automaton $\mathcal{B}$ over Γ of the same kind s.t. $L(\mathcal{B}) = h^{-1}(L(\mathcal{A}))$ as follows. The automaton $\mathcal{B}$ is obtained by replacing a transition reading $a \in \Sigma$ in $\mathcal{A}$ by corresponding transitions reading $b \in \Gamma$ *performing the same counter operation*, for every $b \in h^{-1}(a)$. Is it easy to check that $L(\mathcal{B}) = h^{-1}(L(\mathcal{A}))$, as required. Moreover, if $\mathcal{A}$ was visible, since the counter operation is preserved, $\mathcal{B}$ will be visible too. ◀

Proof of Theorem 5. It remains to show that one counter languages are the effective homomorphic image of visible one counter languages. This is easy to show. Let $L \subseteq \Sigma^*$ be a one counter language. Each symbol $a \in \Sigma$ is split into three symbols $a_{\mathsf{inc}}, a_{\mathsf{dec}}, a_{=0?}$. The corresponding homomorphism h just forgets the new annotation, i.e., $h(a_{\mathsf{inc}}) = h(a_{\mathsf{dec}}) = h(a_{=0?}) = a$; notice that h is letter-to-letter and non-erasing. Counter operations for the

new automaton are made visible by replacing an increment operation over a by the same operation over a_{inc}, and similarly for decrements and tests. Clearly, we obtain a visible one counter automaton recognizing a language M s.t. $L = h(M)$. Thus, by Lemma 2, Lemma 6, and the undecidability of regular separability of one counter languages [6, Theorem 2], we obtain that regular separability for visibly one counter languages is undecidable. ◀

4 From nondeterministic to deterministic PA

The aim of this section is to prove the following lemma:

▶ **Lemma 7.** *If $\mathcal{C}$ is effectively closed under inverse images of linear mappings, then the regular separability problem of nondeterministic $\mathcal{C}$-Parikh automata effectively reduces to the same problem for deterministic ones.*

As a consequence of Lemma 7, we can focus on separability of deterministic PA languages in the rest of the paper. Let $\mathcal{G}$ be the class of deterministic $\mathcal{C}$-Parikh automata languages, and let $\mathcal{H}$ be the class of *letter-to-letter erasing homomorphism*, i.e., functions of the form $h : \Sigma \to (\Gamma \cup \{\varepsilon\})$ extended homomorphically to $\Sigma^* \to \Gamma^*$. The proof of the lemma follows immediately from Lemma 2 once we prove that nondeterministic languages are the effective images of deterministic ones (cf. Lemma 8), and that both classes are closed under inverse images (cf. Lemma 9). In the rest of the section, we assume that the class $\mathcal{C}$ is closed under inverse images of linear mappings, which is the case for a robust class $\mathcal{C}$ (cf. Sec. 3).

▶ **Lemma 8.** *Every nondeterministic $\mathcal{C}$-Parikh language is the effective image of a letter-to-letter erasing homomorphism of a deterministic $\mathcal{C}$-Parikh language.*

Proof. Fix a nondeterministic $\mathcal{C}$-Parikh automaton $(\mathcal{A}, S)$ over the alphabet Σ, and let T be the set of transitions of $\mathcal{A}$. Consider the letter-to-letter erasing homomorphism $h : T \to (\Sigma \cup \{\varepsilon\})$ that maps a transition (p, a, q) to a. Let $(\mathcal{B}, S)$ be the deterministic $\mathcal{C}$-Parikh automaton over the alphabet T which is obtained from $\mathcal{A}$ by relabelling every transition of $t = (p, a, q) \in T$ of $\mathcal{A}$ as a (unique) transition (p, t, q) of $\mathcal{B}$. Notice that the acceptance condition of $\mathcal{B}$ is the same as that for $\mathcal{A}$, since we only relabelled transitions. One easily verifies that $L(\mathcal{A}, S) = h(L(\mathcal{B}, S))$, as required. ◀

▶ **Lemma 9.** *Deterministic and nondeterministic $\mathcal{C}$-Parikh languages are effectively closed under inverse images of letter-to-letter erasing homomorphisms.*

Proof. Given a deterministic $\mathcal{C}$-Parikh automaton $(\mathcal{A}, S)$ over Σ and a letter-to-letter erasing homomorphism $h : \Gamma \to (\Sigma \cup \{\varepsilon\})$, one computes a deterministic $\mathcal{C}$-Parikh automaton $(\mathcal{B}, T)$ s.t. $L(\mathcal{B}, T) = h^{-1}(L(\mathcal{A}, S))$ as follows. The automaton $\mathcal{B}$ is obtained by replacing every transition (p, a, q) in $\mathcal{A}$ by transitions (p, b, q), one for every $b \in h^{-1}(a)$. Moreover, each state p in the automaton $\mathcal{B}$ has a self-loop (p, b, p) for every $b \in h^{-1}(\varepsilon)$. The constraint $T \in \mathcal{C}$ is the inverse image of S under the linear function obtained by counting a transition (p, b, q) as a transition $(p, h(b), q)$ if $h(b) \neq \varepsilon$, and by counting (p, b, q) as zero (i.e., ignoring it) otherwise. Finally, the constraint T, and hence also the automaton $(\mathcal{B}, T)$ can be computed. Is it easy to check that $L(\mathcal{B}, T) = h^{-1}(L(\mathcal{A}, S))$, as required. Moreover, if $\mathcal{A}$ is deterministic, and h is a function, then the resulting automaton $\mathcal{B}$ is also deterministic. ◀

5 Regular separability reduces to unary separability

In this section we reduce regular separability of deterministic $\mathcal{C}$-Parikh languages to unary separability of vector sets in $\mathcal{C}$.

▶ **Lemma 10.** *Let $\mathcal{C}$ be a class of vectors effectively closed under inverse images of affine mappings. The regular separability problem for deterministic $\mathcal{C}$-Parikh automata reduces to the unary separability problem for vector sets in $\mathcal{C}$.*

The rest of this section is devoted to the proof of the lemma. Let $L_1, L_2 \subseteq \Sigma^*$ be languages of deterministic $\mathcal{C}$-Parikh automata $(\mathcal{A}_1, S_1)$ and $(\mathcal{A}_2, S_2)$, respectively. There are three steps:

1. As the first step, we show that w.l.o.g. we may assume $\mathcal{A}_1 = \mathcal{A}_2$.
2. In the second step, we partition Σ^* into finitely many regular languages $K_1, \ldots, K_m$ and we reduce regular separability of L_1 and L_2 to regular separability of $L_1 \cap K_i$ and $L_2 \cap K_i$ for every $i \in \{1, \ldots, m\}$. These subproblems turn out to be easier than the general one, due to the additional structural information encoded in the languages K_i's.
3. In the last step, we reduce regular separability of $L_1 \cap K_i$ and $L_2 \cap K_i$ to unary separability of vector sets in $\mathcal{C}$.

Step 1: Unifying the underlying automaton. As the input languages are subsets of regular languages recognised by their underlying finite automata, $L_1 = L(\mathcal{A}_1, S_1) \subseteq L(\mathcal{A}_1)$ and $L_2 = L(\mathcal{A}_2, S_2) \subseteq L(\mathcal{A}_2)$, it is enough to consider separability of L_1 and L_2 *inside* the intersection of $L(\mathcal{A}_1)$ and $L(\mathcal{A}_2)$:

▶ **Proposition 1.** *The languages L_1 and L_2 are regular separable if, and only if, the languages $L_1 \cap L(\mathcal{A}_2)$ and $L_2 \cap L(\mathcal{A}_1)$ are so.*

Proof. The "only if" direction is trivial as every language separating L_1 and L_2 separates $L_1 \cap L(\mathcal{A}_2)$ and $L_2 \cap L(\mathcal{A}_1)$ as well. For the opposite direction, we observe that if a regular language S separates $L_1 \cap L(\mathcal{A}_2)$ and $L_2 \cap L(\mathcal{A}_1)$, then $S' = (S \cap L(\mathcal{A}_1)) \cup \overline{L(\mathcal{A}_2)}$ is a regular language separating L_1 and L_2. ◀

Let $\mathcal{A}$ be the product automaton of $\mathcal{A}_1$ and $\mathcal{A}_2$, and thus $L(\mathcal{A}) = L(\mathcal{A}_1) \cap L(\mathcal{A}_2)$. It is deterministic since both $\mathcal{A}_1$ and $\mathcal{A}_2$ are so. We claim that one can compute sets $U_1, U_2 \in \mathcal{C}$ such that $L_1 \cap L(\mathcal{A}_2) = L(\mathcal{A}, U_1)$ and $L_2 \cap L(\mathcal{A}_1) = L(\mathcal{A}, U_2)$. The set T of transitions of $\mathcal{A}$ is a subset of the product $T_1 \times T_2$ of transitions of $\mathcal{A}_1$ and $\mathcal{A}_2$, and thus there are obvious projections functions $\pi_1 : T \to T_1$ and $\pi_2 : T \to T_2$. If we enumerate the transition sets, say $T_1 = \{t_1^1, \ldots, t_1^m\}$, $T_2 = \{t_2^1, \ldots, t_2^n\}$, and $T = \{t_1, \ldots, t_\ell\}$ with $\ell \leq m \cdot n$, we obtain $\pi_1 : \{1, \ldots, \ell\} \to \{1, \ldots, m\}$ and $\pi_2 : \{1, \ldots, \ell\} \to \{1, \ldots, n\}$. We use these projections to define two linear (and in particular, affine) functions $\psi_1 : \mathbb{N}^\ell \to \mathbb{N}^m$ and $\psi_2 : \mathbb{N}^\ell \to \mathbb{N}^n$ which instead of counting transitions in T, count the corresponding transitions in T_1 or in T_2, respectively; formally,

$$\psi_1(v)[j] = \sum_{i:\pi_1(i)=j} v[i] \qquad \psi_2(v)[j] = \sum_{i:\pi_2(i)=j} v[i].$$

Finally, we set $U_1 := \psi_1^{-1}(S_1)$ and $U_2 := \psi_2^{-1}(S_2)$. Intuitively, U_1 and U_2 are as S_1 and S_2, except that instead of single transitions of $\mathcal{A}_1$ or $\mathcal{A}_2$ they are seeing pairs of transitions, and simply ignore one of them. Since $\mathcal{C}$ is closed under inverse images of affine mappings by assumption, $U_1, U_2 \in \mathcal{C}$. For the rest of the proof we may thus assume that the input automata are $(\mathcal{A}, U_1)$ and $(\mathcal{A}, U_2)$.

Step 2: Regular partitioning using skeletons. We finitely partition Σ^* s.t. words belonging to the same partition behave similarly with respect to automaton $\mathcal{A}$. We use the notion of *skeleton* of a run, defined already in [3], where it was used to solve the regularity problem

of *unambiguous* Parikh automata. The idea is to traverse a run from left to right while removing (and counting) simple cycles visiting states that have already appeared.

A *simple cycle* is a sequence of transitions $c = t_1 \dots t_n \in T^*$, where $t_i = (q_{i-1}, a_i, q_i)$, starting and ending in the same state $q_0 = q_n$ where $q_1, \dots, q_n$ are pairwise distinct. Two simple cycles c, d are *equivalent* if one is a cyclic permutation of the other. Let $[c]$ denote the equivalence class of c, and let $[c_1], \dots, [c_m]$ be a fixed enumeration of all such equivalence classes. (Since a simple cycle cannot visit the same state twice, except the initial state, it has length at most n, and thus the number of simple cycles, and also of equivalence classes thereof, is $m \leq d^n$, where d is the number of transitions of the automaton.) The skeleton is an inductively defined function from runs to pairs consisting of a run and a vector $v \in \mathbb{N}^m$. In the base case, $\textsc{skel}(\varepsilon) = (\varepsilon, 0)$. For the induction step, suppose that $\textsc{skel}(t_1 \dots t_{k-1}) = (u_1 \dots u_\ell, v)$ is already defined, and let q be the ending state of the new transition t_k. If q does not appear in the run $u_1 \dots u_\ell$, then we put $\textsc{skel}(t_1 \dots t_k) = (u_1 \dots u_\ell t_k, v)$. Otherwise, let u_h, for $h < \ell$, be the last transition that ends in state q, and consider the cycle $c = u_{h+1} \dots u_\ell t_k \in [c_j]$ (for some $1 \leq j \leq m$). We have two cases to consider. If all states visited by this cycle appeared before in $u_1 \dots u_h$, then we call this cycle *absorbed* and we remove it by putting $\textsc{skel}(t_1 \dots t_k) = (u_1 \dots u_h, v + e_j)$, where e_j is the vector which is 1 in coordinate j, and 0 everywhere else. Otherwise, we just put $\textsc{skel}(t_1 \dots t_k) = (u_1 \dots u_\ell t_k, v)$.

We remove only simple cycles visiting states that have already appeared before in order to have the following useful property.

▶ **Proposition 2.** *If* $\textsc{skel}(\rho) = (\hat{\rho}, v)$*, then* ρ *and* $\hat{\rho}$ *visit the same set of states.*

By abusing nomenclature, we call a run ρ a *skeleton* if $\textsc{skel}(\rho) = (\rho, v)$, for some $v \in \mathbb{N}^m$. It is easy to see that the length of a skeleton is at most n^2, where n is the number of states in the automaton $\mathcal{A}$. (Assume towards a contradiction that the length of the skeleton is longer than n^2. By the pigeonhole principle, some state is thus visited more than n times, so there are at least n cycles in between two consecutive occurrences of this state in the skeleton. Therefore it is impossible that each loop contains some new state not present in all the previous loops, and thus one of these loops should be removed during the process of creating the skeleton, a contradiction.) Consequently, if d is the total number of transitions of $\mathcal{A}$, then there are at most d^{n^2} skeletons. Let $\rho_1, \dots, \rho_h$ be all the skeletons, with $h \leq d^{n^2}$. We define K_i to be the set of all words w having an accepting run ρ in automaton $\mathcal{A}$ with $\textsc{skel}(\rho) = \rho_i$. Since $\mathcal{A}$ is deterministic we know that $K_i \cap K_j = \emptyset$ for $i \neq j$. Therefore $K_1, \dots, K_h$ and $K_{h+1} = \Sigma^* \setminus (\bigcup_{1 \leq i \leq h} K_i)$ form a partition of Σ^*. All languages K_i are necessarily regular, since the skeleton can be computed by a finite automaton. The following lemma can be seen as a generalization of Proposition 1 and it is immediate to prove.

▶ **Lemma 11.** *Let* Σ^* *be partitioned into regular languages* $K_1, \dots, K_k$*. Two languages* $L_1, L_2 \subseteq \Sigma^*$ *are regular separable if, and only if,* $L_1 \cap K_i$ *and* $L_2 \cap K_i$ *are regular separable for every* $i \in \{1, \dots, k\}$*.*

It remains to decide regular separability for the languages $L(\mathcal{A}, U_1) \cap K_i$ and $L(\mathcal{A}, U_2) \cap K_i$. In the following, fix a skeleton ρ and the set of words K with skeleton ρ. Since we have fixed a skeleton, we assume w.l.o.g. that the acceptance conditions U_1, U_2 are included in $\Pi(K)$.

Step 3: Reduction to unary separability for $\mathcal{C}$. Let the set of transitions of the automaton be $T = \{t_1, \dots, t_d\}$ (thus $\rho \in T^*$), and let $\mu : \mathbb{N}^m \to \mathbb{N}^d$ be the following affine function that

transforms counting cycles into counting transitions:

$$\mu(x_1, \ldots, x_m) = \Pi(\rho) + \sum_{1 \leq j \leq m} \Pi([c_j]) \cdot x_j.$$

Since $\Pi(c) = \Pi(d)$ for $c, d \in [c_j]$, $\Pi([c_j])$ is well-defined. Notice that μ is affine, and not linear, since we must take into account the initial cost of the skeleton $\Pi(\rho)$. Let $V_1 = \mu^{-1}(U_1)$ and $V_2 = \mu^{-1}(U_2)$ be the corresponding sets counting cycles instead of transitions. Since we assumed $U_1, U_2 \subseteq \Pi(K)$, every vector $v \in V_1$ is realizable by an accepting run $\hat{\rho}$ s.t. $\textsc{skel}(\hat{\rho}) = (\rho, v)$. Since $\mathcal{C}$ is closed under the inverse image of affine mappings, $V_1, V_2 \in \mathcal{C}$.

▶ **Lemma 12.** *The following two conditions are equivalent:*
1. *The two languages $L(\mathcal{A}, U_1) \cap K, L(\mathcal{A}, U_2) \cap K \subseteq \Sigma^*$ are regular separable.*
2. *The two sets of vectors $V_1, V_2 \subseteq \mathbb{N}^m$ are unary separable.*

Proof. For the implication 1) $\Rightarrow$ 2), suppose R is a regular language separating $L(\mathcal{A}, U_1) \cap K$ and $L(\mathcal{A}, U_2) \cap K$. For two words $x, y \in \Sigma^*$, define $x \equiv_R y$ if $x \in R \iff y \in R$. Fix $\omega \in \mathbb{N}$ such that for all words $x, y, z \in \Sigma^*$,

$$xy^{\omega}z \;\equiv_R\; xy^{2\omega}z. \tag{1}$$

It is easy to see that for every regular language R such ω exists. The simplest way of showing this is to consider the syntactic monoid M of R and to let ω be its idempotent power, i.e., a number such that $m^{\omega} = (m^{\omega})^2$ for every $m \in M$.

Recall n-unary equivalence: $u \equiv_n v$ if $u[i] \equiv v[i] \mod n$ and moreover $u[i] \leq n \iff v[i] \leq n$ for every coordinate $1 \leq i \leq m$. It is enough to show that for all $v_1 \in V_1, v_2 \in V_2$ it holds $v_1 \not\equiv_{\omega} v_2$. Indeed, if this is the case, the unary set $S = \{v \in \mathbb{N}^m \mid \exists_{v_1 \in V_1} v \equiv_{\omega} v_1\}$ separates V_1 and V_2.

Suppose, towards a contradiction, that there are some $v_1 \in V_1, v_2 \in V_2$ such that $v_1 \equiv_{\omega} v_2$. There are runs ρ_1, ρ_2 s.t. $\textsc{skel}(\rho_1) = (\rho, v_1)$ and $\textsc{skel}(\rho_2) = (\rho, v_2)$. We extend the equivalence $\equiv_R$ on runs by saying that $\rho_1 \equiv_R \rho_2$ if their two labellings are $\equiv_R$-equivalent. Since the labelling of ρ_1 is in $L(\mathcal{A}, U_1) \cap K$, and similarly for ρ_2, if $\rho_1 \equiv_R \rho_2$, then we derive a contradiction since R was supposed to separate $L(\mathcal{A}, U_1) \cap K$ and $L(\mathcal{A}, U_2) \cap K$. While in general $\rho_1 \equiv_R \rho_2$ does not hold, we can construct two *canonical runs* $\hat{\rho}_1$ and $\hat{\rho}_2$ s.t. (1) $\textsc{skel}(\hat{\rho}_1) = (\rho, v_1)$ (thus the labelling of $\hat{\rho}_1$ is also in $L(\mathcal{A}, U_1) \cap K$), (2) $\textsc{skel}(\hat{\rho}_2) = (\rho, v_2)$ (similarly), and (3) $\hat{\rho}_1 \equiv_R \hat{\rho}_2$ (thus bringing the contradiction). We show the construction for $\hat{\rho}_1$; the one for $\hat{\rho}_2$ is similar. By Proposition 2, states visited by the run ρ_1 are among those visited by the skeleton ρ, and in particular every absorbed cycle (i.e., $v_1[j] \neq 0$) also has this property. While in general a simple cycle $d \in [c_j]$ starting (and ending) at some state q cannot be reintroduced in the skeleton ρ at any position labelled by q (because not all states in d need to have appeared before this position), there always is a position i_j in the skeleton labelled by some state q_j and a simple cycle $\hat{c}_j \in [c_j]$ *starting (and ending) at* q_j s.t. all states in $\hat{c}_j$ have appeared already before position i_j in the skeleton. Assume w.l.o.g. that $i_1 \leq \cdots \leq i_m$. It is possible to split the skeleton ρ as $\alpha_0 \cdots \alpha_m$ s.t., for every $0 \leq j \leq m$, $\alpha_j \in T^*$ is a sequence of transitions, and the prefix $\alpha_0 \cdots \alpha_{j-1}$ has length i_j (thus ends in q_j). Then, define $\hat{\rho}_1$ and similarly $\hat{\rho}_2$ as

$$\hat{\rho}_1 := \alpha_0 \hat{c}_1^{v_1[1]} \alpha_1 \cdots \alpha_{m-1} \hat{c}_m^{v_1[m]} \alpha_m \quad \text{and} \quad \hat{\rho}_2 := \alpha_0 \hat{c}_1^{v_2[1]} \alpha_1 \cdots \alpha_{m-1} \hat{c}_m^{v_2[m]} \alpha_m.$$

(This is well-defined since $v_1 \equiv_{\omega} v_2$ implies $v_1[j] \neq 0$ iff $v_2[j] \neq 0$.) Properties (1) and (2) above are guaranteed by construction. For Property (3), since $v_1 \equiv_{\omega} v_2$, by repetitive use of Equation (1) we have $\hat{\rho}_1 \equiv_R \hat{\rho}_2$. This concludes the proof of the first implication.

For proving the implication (2) ⇒ (1), suppose that a unary set S separates V_1 and V_2. We claim that the language $R = L(\mathcal{A}, \mu(S)) \cap K$ is regular and separates $L(\mathcal{A}, U_1) \cap K$ and $L(\mathcal{A}, U_2) \cap K$. We first verify that R separates these two languages. Clearly, $U_1 \subseteq \mu(V_1) \subseteq \mu(S)$, so $L(\mathcal{A}, U_1) \cap K \subseteq L(\mathcal{A}, \mu(S)) \cap K = R$. The disjointness of $L(\mathcal{A}, U_2) \cap K$ and R is shown by contradiction. Suppose that there is a word $w \in K$ belonging both to $L(\mathcal{A}, \mu(S))$ and to $L(\mathcal{A}, U_2)$, let ρ be the run of $\mathcal{A}$ over w and let $v = \Pi(\rho)$. We have $v \in \mu(S) \cap U_2$, which implies $v = \mu(s)$ for some $s \in S \cap \mu^{-1}(U_2) = S \cap V_2$. In consequence $S \cap V_2$ is nonempty, thus contradicting the assumption that S separates V_1 and V_2.

In order to prove that R is regular it suffices to prove that $L(\mathcal{A}, \mu(S))$ is regular. The finite nondeterministic automaton recognizing this language simulates a run $\rho = t_{i_1} \dots t_{i_\ell}$ of $\mathcal{A}$, and accepts when $\Pi(\rho) \in \mu(S)$. Since S is unary, the automaton can evaluate this condition using finite memory. For every cycle c_j, the automaton stores a vector $x_j < \Pi(c_j)$, and a number n_j up to the unary equivalence $\equiv_n$, with the following meaning: the vector $\Pi(c_i)$ has been already executed n_j times, and x_i is the current "remainder". Additionally, the automaton stores a vector $x \leq \Pi(\rho)$ which is counting those transitions on the skeleton which have not been counted as cycles. At every input letter the automaton guesses nondeterministically one of cycles c_i or the skeleton and updates x_j, n_j and x accordingly. The automaton accepts when $x = \Pi(\rho_i)$, $x_j = 0$ for all j, and $(n_1, \dots, n_m) \in S$. ◀

6 Applications

We derive two corollaries of Theorem 1. By a *projection* we mean a function $\pi_{k,I} : \mathbb{N}^k \to \mathbb{N}^{|I|}$, for $I \subseteq \{1 \dots k\}$, that drops coordinates not in I. We start with a simple but useful lemma:

▶ **Lemma 13.** *If a class $\mathcal{C} \subseteq \bigcup_{d \in \mathbb{N}} \mathcal{P}(\mathbb{N}^d)$ contains all semilinear sets and is effectively closed under intersections, projections, and inverse images of projections, then it is effectively closed under inverse images of affine maps.*

Proof. Let S be a set in $\mathcal{C}$ and $f : \mathbb{N}^k \to \mathbb{N}^\ell$ be an affine map defined by $f(u) = Mu + v$ for $M = (m_{i,j})$ a matrix of dimension $\ell \times k$ and v a vector of dimension ℓ. Let $e_j \in \mathbb{N}^k$ be the vector s.t. $e_j[j] = 1$ and 0 otherwise, and let $m_j = (m_{1,j}, m_{2,j}, \dots, m_{\ell,j})$ be the (transpose of) the j-th column of M. First remark that the set $E_1 = \{(x, f(x)) \mid x \in \mathbb{N}^k\} \subseteq \mathbb{N}^{k+\ell}$ is linear with base $(0^k, v)$ and periods $\{p_1, \dots, p_k\}$, where $p_j = (e_j, m_j) \in \mathbb{N}^{k+\ell}$. Thus, $E_1 \in \mathcal{C}$. Therefore the set $E_2 = E_1 \cap \pi^{-1}_{k+\ell,I}(S)$ is also in $\mathcal{C}$, for $I = \{k+1, \dots, k+\ell\}$. Finally, we conclude since $\pi_{k+\ell,J}(E_2) = f^{-1}(S)$ with $J = \{1, \dots, k\}$. ◀

▶ **Corollary 14.** *Regular separability is decidable for nondeterministic Parikh automata.*

Proof. In order to apply Theorem 1 for $\mathcal{C}$ being semilinear sets, we need to know that the class of semilinear sets is robust. First, Lemma 13 yields effective closure under inverse images of affine maps, as semilinear sets are effectively closed under boolean combinations, images, and inverse images of projections. Second, decidability of the unary separability problem for semilinear sets is a corollary of the main result in [4]. This theorem states that separability of rational relations in $\Sigma^* \times \mathbb{N}^m$ by recognizable relations is decidable. If we ignore the Σ^* component we get the same result for rational and recognizable relations in $\mathbb{N}^m$, which are exactly semilinear sets and unary sets, respectively. ◀

For the second corollary we have to introduce vector addition systems and sections thereof. A d-dimensional *vector addition system* (VAS) is a pair $V = (s, T)$, where $s \in \mathbb{N}^d$ is a *source* configuration and $T \subseteq_{\text{FIN}} \mathbb{Z}^d$ is a finite set of *transitions*. A *run* is a sequence

$$(v_0, t_0, v_1), (v_1, t_1, v_2), \dots, (v_{n-1}, t_{n-1}, v_n) \in \mathbb{N}^d \times T \times \mathbb{N}^d$$

such that for all $i \in \{0, \ldots, n-1\}$ we have $v_i + t_i = v_{i+1}$ and $v_0 = s$. The *target* of this run is the configuration v_n. The *reachability set* of a VAS V is the set of targets of all its runs.

In order to ensure robustness, we slightly enlarge the family of VAS reachability sets to *sections* thereof. The intuition about a section is that we fix values on a subset of coordinates in vectors, and collect all the values that can occur on the other coordinates. For a subset $I \subseteq \{1, \ldots, d\}$, the projection $\pi_{d,I}$ extends element-wise to sets of vectors $S \subseteq \mathbb{N}^d$, denoted $\pi_{d,I}(S)$. For a vector $u \in \mathbb{N}^{d-|I|}$, the *section* of S w.r.t. I and u is the set

$$\pi_{d,I}(\{v \in S \mid \pi_{d,\{1,\ldots,d\}\setminus I}(v) = u\}) \subseteq \mathbb{N}^{|I|} \ .$$

We denote by $\mathcal{C}_{\text{SEC-VAS}}$ the family of all sections of VAS reachability sets.

▶ **Corollary 15.** *$\mathcal{C}_{\text{SEC-VAS}}$-Parikh automata.*

Proof. We apply Theorem 1 for $\mathcal{C} = \mathcal{C}_{\text{SEC-VAS}}$; we thus need to show that class $\mathcal{C}_{\text{SEC-VAS}}$ is robust. Decidability of unary separability of sets from $\mathcal{C}_{\text{SEC-VAS}}$ is shown in Theorem 9 in [5]. Effective closure of $\mathcal{C}$ under inverse images of affine functions will follow by Lemma 13 once we prove all its assumptions. First, $\mathcal{C}_{\text{SEC-VAS}}$ contains all semilinear sets. Effective closure under intersections is shown in Proposition 7 in [5]. Effective closure under inverse images of projections is easy: extend the VAS with additional coordinates, and allow it to arbitrarily increase these coordinates. Finally, to see that $\mathcal{C}_{\text{SEC-VAS}}$ is effectively closed under projections consider a section $S \subseteq \mathbb{N}^d$ of the reachability set of a VAS V, and a subset of coordinates $I \subseteq \{1, \ldots, d\}$. We construct a VAS V' which is like V, but additionally allows to decrease every coordinate from $\{1, \ldots, d\} \setminus I$. The projection $\pi_{d,I}(S)$ of S onto I is a section of the reachability set of V' defined similarly as S, but with an additional requirement that all coordinates from $\{1, \ldots, d\} \setminus I$ have value 0. ◀

7 Conclusions

We have shown that the regular separability problem for $\mathcal{C}$-Parikh automata is decidable, for every class $\mathcal{C}$ of acceptance conditions satisfying mild assumptions. In particular, we have shown decidability for $\mathcal{C}$ being either the semilinear sets or sections of VAS reachability sets. We have complemented our positive result by proving undecidability for visibly one counter languages, which sharpens two existing undecidability results.

The complexity of our algorithm depends on two factors: the complexity of unary separability for $\mathcal{C}$, and the complexity of computing inverse images of sets in $\mathcal{C}$ under affine mappings. The first factor is the dominant one here, since computing inverse images can be shown to be in PTIME for both semilinear sets and sections of VAS reachability sets (cf. [5]). Under this assumption, it can be seen that our reduction from nondeterministic to deterministic automata in Sec. 4 is also PTIME. Moreover, when reducing to unary separability in Sec. 5, since there are at most exponentially many skeletons and simple cycles, we obtain exponentially many unary separability instances, each of exponential size. Therefore, all together our reduction can be performed in exponential space.

On the other hand, the complexity of unary separability for semilinear sets and VAS sections is much higher. For semilinear sets, no upper bounds have been published for this problem, but an analysis of the algorithm of [4] yields an elementary bound[4]. For VAS sections, one can easily see that unary separability is at least as hard as the VAS reachability problem [5], which is hard for exponential space and not known to be primitive recursive.

[4] The problem becomes PTIME for the subclass of *diagonal* linear sets, in which case unary separability becomes the same as *modular separability*, and the latter problem is PTIME [4].

Abstract

Given an integer base $b > 1$, a set of integers is represented in base b by a language over $\{0, 1, ..., b-1\}$. The set is said to be b-recognisable if its representation is a regular language. It is known that eventually periodic sets are b-recognisable in every base b, and Cobham's theorem implies the converse: no other set is b-recognisable in every base b.

We are interested in deciding whether a b-recognisable set of integers (given as a finite automaton) is eventually periodic. Honkala showed that this problem is decidable in 1986 and recent developments give efficient decision algorithms. However, they only work when the integers are written with the least significant digit first.

In this work, we consider the natural order of digits (Most Significant Digit First) and give a quasi-linear algorithm to solve the problem in this case.

1 Introduction

Let $b > 1$ be an integer base. We let $[\![b]\!] = \{0, 1, \ldots, b-1\}$ denote the canonical alphabet of base-b digits. If $u = u_\ell \cdots u_0$ belongs to $[\![b]\!]^*$, we let $\overline{u}$ denote the *value* of u in base b, *i.e.*, $\overline{u} = \sum_{i=0}^{\ell} u_i\, b^i$. Note that the leftmost digit is the most significant one. We let $\langle n \rangle$ denote the (shortest) *base-b representation* of n. We set $\langle 0 \rangle$ to be the empty word ε. If reference to the base b is needed, we write $\langle n \rangle_b$. Thus $\langle n \rangle$ is the unique word u over $[\![b]\!]$ not starting with

0 and such that $\overline{u} = n$. Moreover, for every $u \in [\![b]\!]^*$ such that $\overline{u} = n$, there exists $i \geq 0$ such that $u = 0^i\langle n\rangle$.

1.1 Our contribution

In this paper, we develop an algorithm to decide whether a given deterministic automaton $\mathcal{A}$ over the alphabet $[\![b]\!]$ accepts, by value, an (eventually) periodic set of integers. More precisely, the question is to decide whether there exist integers $p \geq 1$ and $N \geq 0$ such that, for all words $u \in [\![b]\!]^*$, if $\overline{u} \geq N$, then u is accepted by $\mathcal{A}$ if and only if $\langle \overline{u} + p\rangle$ is accepted as well. *Acceptance by value* means that words sharing the same value are either all accepted or all rejected. Stated otherwise, a word u is accepted by $\mathcal{A}$ if and if only if $0u$ is accepted. In the literature, one also finds the term "saturated language". The main result of this paper is the following.

▶ **Theorem 1.** *Given an integer base $b > 1$ and a n-state deterministic automaton $\mathcal{A}$ over the alphabet $[\![b]\!]$, it is decidable in $O(bn \log n)$ time whether or not $\mathcal{A}$ accepts, by value, some eventually periodic set of integers.*

Due to space constraints, this paper deals with the purely periodic case only. The general case is treated similarly [8].

Theorem 1 relies on a characterisation of the minimal automata accepting by value purely periodic sets. This characterisation is given Section 4. It relies on the notion of ultimately-equivalent states which is previously introduced in Section 2.2. In Section 3, we study the structure of the naive automaton accepting an arbitrary purely periodic sets, and its minimisation.

We stress the fact that the input automaton $\mathcal{A}$ reads words most significant digit first (MSDF). This is an important difference with other results discussed in the literature. For instance, an efficient algorithm to solve this decision problem is provided for automata reading least significant digit first (LSDF) [15, 16]. One can therefore think that it is enough to take the reversal of $\mathcal{A}$ and thus consider entries LSDF. Nevertheless, the reversal of $\mathcal{A}$ has first to be determinised. This potentially leads to an exponential blow-up in the number of states and thus to an inefficient procedure. For instance, this event occurs for the language $L_n = 0^*\,1\,(0+1)^n\,1\,(0+1+\varepsilon)^n$ and its mirror K_n: the number of states in the minimal automaton accepting L_n (resp. K_n) grows linearly (resp. exponentially) with n. Evaluating L_n as MSDF encodings or K_n as LSDF encodings yields the same finite (thus eventually periodic) set of integers.

1.2 Motivations and related results

We say that a set $X \subseteq \mathbb{N}$ is *b-recognisable* if $\langle X\rangle_b$ is accepted by some finite automaton. One reason why eventually periodic sets of integers play a special role comes from the celebrated theorem of Cobham about the dependence to the base of b-recognisability.

▶ **Theorem** (Cobham, [12]). *Let $b, c > 1$ be two multiplicatively independent integers. A set X of integers is such that the languages $\langle X\rangle_b$ and $\langle X\rangle_c$ are both accepted by finite automata if and only if X is eventually periodic.*

In combinatorics on words, when studying morphic words (for details and definitions, for instance, see [2, 5]), Cobham's theorem can be reformulated as follows. Let $b, c > 1$ be two multiplicatively independent integers. An infinite word $\mathbf{x}$ is both b-automatic and c-automatic if and only if $\mathbf{x}$ is of the form uv^ω where u, v are finite words. Indeed, a set

of integers is b-recognisable if and only if its characteristic sequence is b-automatic. The decision problem considered in our Theorem 1 is well known to be decidable.

▶ **Theorem** (Honkala, [14]). *It is decidable whether or not a given b-automatic word is eventually periodic.*

Complexity issues are however not considered at all in Honkala's paper. The decidability of our problem of interest can also be obtained using a first-order logic characterisation of b-recognisable sets given by Büchi's theorem, and the fact that Presburger arithmetic is decidable [10, 1]. These independent approaches all lead to decision procedures with exponential complexity.

Using LSDF convention, efficient decision procedures are known. First, Leroux obtained a quadratic decision procedure [15] for eventually-periodic b-recognisable sets of integers, that relies on intricate geometrical constructions. (Leroux's result is indeed stated in a multi-dimensional setting, *i.e.*, the problem is to decide whether or not a b-recognisable subset of $\mathbb{N}^d$ is semi-linear.) Still using LSDF convention, the third author and Sakarovitch designed a quasilinear algorithm [16]. The general idea is similar to the one we use here: finding characteristic properties that are preserved by minimisation. However, the criterion used in the present work is mostly unrelated to [16] and yields a very different decision algorithm.

1.3 Generalisation to real numbers

Real numbers can be encoded in a base $b > 1$ by extending positional encoding to infinite words: A word encoding a real is composed of a finite prefix corresponding to an integer part, followed by a single occurrence of a distinguished symbol acting as a separator, and an infinite suffix representing a fractional part. Infinite-word automata are then able to recognise sets of reals. It has been established that *weak deterministic automata*, a restricted class of infinite-word automata, are sufficiently expressive for recognising all sets definable in mixed integer and real first-order additive arithmetic [7].

The properties of sets of real numbers that can be recognised by weak deterministic automata in all bases $b > 1$ have been investigated [6]. Such sets generalise to the real domain the notion of eventual periodicity; they precisely correspond to finite combinations of eventually periodic sets of integers, and intervals of $[0, 1]$. Checking whether an automaton recognises such a set can be done by first splitting this automaton into finite-state machines operating on the integer and fractional parts of encodings. The former are then checked in the same way as for MSDF integer encodings, and the latter by verifying that they obey the structure documented in [6].

1.4 Generalisation to other numeration systems

Automatic words form a particular class of morphic words. Similarly, integer-base systems are special cases of more general numeration systems such as those built on a linear recurrent sequence. One can define a *numeration system* as a one-to-one map s from $\mathbb{N}$ to a language L over a finite alphabet. The integer n is mapped to its representation $s(n)$ within the considered system. Hence, it is natural to ask, for given a numeration system s and a subset M of L accepted by a finite automaton $\mathcal{A}$, whether or not the s-recognisable set $s^{-1}(M) \subseteq \mathbb{N}$ is eventually periodic.

On the one hand, Honkala's result is extended as follows. It is decidable whether or not a given morphic word is eventually periodic [13, 17]. On the other hand, Büchi's theorem can

be extended to linear numeration systems whose characteristic polynomial is the minimal polynomial of a Pisot number. See, for details, [9]. In that setting, several decision problems in combinatorics on words, including the ultimate periodicity problem, are decidable [11]. Using Honkala's techniques, the decision problem considered in our Theorem 1 is generalised to a large class of numeration systems in [4]. In particular, there are systems in this class for which the logical setting may not be applied. For all these decidability results presented in a wider context, no efficient procedure is known.

2 Preliminaries

In this paper, we only consider deterministic accessible finite automata with an input alphabet of the form $[\![b]\!]$. We use the acceptance-by-value convention. Thus, we may assume that the initial state bears a loop with label 0. In particular, this will always be the case after minimisation. Let $\mathcal{A}$ be an automaton. Its set of states (resp. its initial state, its set of final states) is denoted by $Q_{\mathcal{A}}$ (resp. $i_{\mathcal{A}}$, $F_{\mathcal{A}}$). If the considered automaton is clear from the context, $(s \cdot u)$ is the state s' such that $s \xrightarrow{u} s'$. The language accepted by $\mathcal{A}$ is denoted by $L(\mathcal{A})$. In this section, we recap basic results about automata.

2.1 Automaton morphisms and pseudo-morphisms

▶ **Definition 2.** Given two (accessible) automata $\mathcal{A}$ and $\mathcal{M}$ over $[\![b]\!]$, an *automaton morphism* $\mathcal{A} \to \mathcal{M}$ is a function $\phi : Q_{\mathcal{A}} \to Q_{\mathcal{M}}$ that satisfies:

$$\phi(i_{\mathcal{A}}) = i_{\mathcal{M}} \tag{1}$$

$$\forall s \in Q_{\mathcal{A}},\ \forall a \in [\![b]\!] \quad (s \cdot a) \text{ exists in } \mathcal{A} \iff (\phi(s) \cdot a) \text{ exists in } \mathcal{M} \tag{2}$$

$$\forall s, s' \in Q_{\mathcal{A}},\ \forall a \in [\![b]\!] \quad s \xrightarrow{a} s' \text{ in } \mathcal{A} \implies \phi(s) \xrightarrow{a} \phi(s') \text{ in } \mathcal{M} \tag{3}$$

$$F_{\mathcal{A}} = \phi^{-1}(F_{\mathcal{M}}) \tag{4}$$

▶ **Definition 3.** If a function ϕ satisfies (1), (2) and (3) but not necessarily (4), then we say that we have an *automaton pseudo-morphism*.

▶ **Definition 4.** Two states s, s' of an automaton $\mathcal{A}$ are *Nerode-equivalent* if, for every word u, $(s \cdot u)$ exists and is final if and only if $(s' \cdot u)$ exists and is final.

We recall the following classical result. See, for instance, [18].

▶ **Theorem 5** (Myhill–Nerode)**.** *Let $\mathcal{A}$ be a complete automaton. Among all the complete automata accepting $L(\mathcal{A})$, up to isomorphism, there exists a unique one with a minimal number of states, called the* minimisation of $\mathcal{A}$*. Moreover, if $\mathcal{M}$ denotes the minimisation of $\mathcal{A}$, then there exists an automaton morphism $\phi : \mathcal{A} \to \mathcal{M}$ (called the* minimisation morphism*) such that*

$$\forall s, s' \in \mathcal{A} \quad \phi(s) = \phi(s') \iff s \text{ and } s' \text{ are Nerode-equivalent.} \tag{5}$$

If $\mathcal{A}$ is an automaton and u is a word, we write $(\mathcal{A} \cdot u)$ as a shorthand for $(i_{\mathcal{A}} \cdot u)$, i.e., the state reached by the run of u in $\mathcal{A}$.

▶ **Lemma 6.** *Let $\mathcal{A}$ and $\mathcal{M}$ be two complete (and accessible) automata. There exists a pseudo-morphism $\mathcal{A} \to \mathcal{M}$ if and only if every pair of words u, u' such that $(\mathcal{M} \cdot u) \neq (\mathcal{M} \cdot u')$ also satisfies $(\mathcal{A} \cdot u) \neq (\mathcal{A} \cdot u')$.*

Proof. Forward direction. Since a pseudo-morphism ϕ respects transitions and the initial state, it follows that, for every word u, $(\mathcal{M}\cdot u) = \phi(\mathcal{A}\cdot u)$. The statement follows immediately.

Backward direction. For every state s, we choose a word u_s such that $(\mathcal{A}\cdot u_s) = s$ (such a word exists because $\mathcal{A}$ is accessible). We define a function $\phi : Q_{\mathcal{A}} \to Q_{\mathcal{M}}$ as follows. For every state $s \in Q_{\mathcal{A}}$, $\phi(s) = (\mathcal{M}\cdot u_s)$. Let us show that ϕ is an automaton pseudo-morphism.

Let s be a state of $\mathcal{A}$ and let u be a word such that $(\mathcal{A}\cdot u) = s$. Since $(\mathcal{A}\cdot u) = (\mathcal{A}\cdot u_s)$, the hypothesis implies $(\mathcal{M}\cdot u) = (\mathcal{M}\cdot u_s)$. The definition of ϕ is therefore independent of the choice of the words u_s.

In particular, $\phi(i_{\mathcal{A}}) = (\mathcal{M}\cdot u_{i_{\mathcal{A}}}) = (\mathcal{M}\cdot\varepsilon) = i_{\mathcal{M}}$ hence ϕ satisfies (1). Moreover, since both $\mathcal{A}$ and $\mathcal{M}$ are complete, and since ϕ is a total function, ϕ also satisfies (2). Let $t \xrightarrow{a} t'$ be a transition of $\mathcal{A}$. By definition $\phi(t) = (\mathcal{M}\cdot u_t)$ and since the definition of ϕ does not depend on the choice of the words u_s, we may assume that $u_{t'} = u_t a$. It then follows that

$$\phi(t') = (\mathcal{M}\cdot(u_t a)) = ((\mathcal{M}\cdot u_t)\cdot a) = \phi(t)\cdot a\ .$$

In other words, $\phi(t) \xrightarrow{a} \phi(t')$ is a transition of $\mathcal{M}$. ◀

2.2 Ultimately-equivalent states

Our decision procedure involves the determination of ultimately-equivalent states defined as follows.

▶ **Definition 7.** Let $\mathcal{A}$ be an automaton over $[\![b]\!]$. Let $m \geq 1$ be an integer. Two states s, s' of $\mathcal{A}$ are *m-ultimately-equivalent* if

$$\forall u \in [\![b]\!]^* \quad |u| \geq m \implies (s\cdot u) = (s'\cdot u)\ .$$

Two states are *ultimately-equivalent* if they are m-ultimately-equivalent for some $m \geq 1$.

▶ Remark. Note that ultimate-equivalence is indeed an equivalence relation: if s and s' are m-ultimately-equivalent while s' and s'' are m'-ultimately-equivalent, then s and s'' are $\max(m, m')$-ultimately-equivalent.

Given an automaton $\mathcal{A}$ over $[\![b]\!]$, the computation of this relation is easy. Let us build a directed graph $\mathcal{G} = (V, E)$ as follows. The vertex-set is $V = Q_{\mathcal{A}} \times Q_{\mathcal{A}}$ and the edge set is:

$$\forall (s,t),(s',t') \in V,\ s \neq t$$
$$(s,t) \to (s',t') \text{ in } \mathcal{G} \iff \exists a \in [\![b]\!] \text{ such that } \mathcal{A} \text{ features } \begin{cases} s \xrightarrow{a} s' \\ t \xrightarrow{a} t' \end{cases}\ . \quad (6)$$

In particular, vertices of the form (s, s) never qualify for the above condition and thus have no outgoing edges. Observe that two distinct states s, t of $\mathcal{A}$ are ultimately-equivalent if and only if (s, t) may not reach in $\mathcal{G}$ a strongly connected component.

Computing the strongly connected components of a graph is done in linear time (e.g., with Tarjan's algorithm [19]). Hence, the set of the pairs of states of $\mathcal{A}$ that are ultimately-equivalent may be computed in time $O(bn^2)$. This complexity can be improved as follows.

▶ **Proposition 8** (Béal, Crochemore, [3]). *Let $\mathcal{A}$ be an automaton over $[\![b]\!]$ and n the number of states in $\mathcal{A}$. The ultimate-equivalence classes of $\mathcal{A}$ may be computed in time $O(bn\log n)$.*

Proof Sketch. We take verbatim the algorithm in [3]. One starts from the trivial partition and iteratively merges states. Each step of the algorithm consists in merging two states that are 1-ultimately-equivalent. The purpose of Béal and Crochemore was to show that starting with a so-called AFT automaton $\mathcal{A}$, the result is the minimisation of $\mathcal{A}$. Starting with any automaton $\mathcal{A}$, the resulting automaton is not necessarily minimal. However, one can observe that its states are precisely the ultimate-equivalence classes of $\mathcal{A}$. ◀

As a direct consequence of the definition of an automaton morphism, ultimate-equivalence commutes with automaton morphisms.

▶ **Lemma 9.** *Let $\mathcal{A}$ and $\mathcal{M}$ be two automata such that there is an automaton morphism $\phi : \mathcal{A} \to \mathcal{M}$. Let s and s' be two states of $\mathcal{A}$ that are ultimately-equivalent (w.r.t. $\mathcal{A}$), then $\phi(s)$ and $\phi(s')$ are also ultimately-equivalent (w.r.t. $\mathcal{M}$).*

3 Purely periodic b-recognisable sets

The content of this section is the following. Section 3.1 gives the definition and main properties of the "naive" automaton $\mathcal{A}_{(p,R)}$ accepting the purely periodic set $R + p\mathbb{N}$. Then, in Section 3.2 we study the relationship between ultimate equivalence and Nerode equivalence in $\mathcal{A}_{(p,R)}$. In Section 3.3, we show how to extract relevant information on the period p from the minimisation of $\mathcal{A}_{(p,R)}$.

▶ **Notation 10.** *Let $p > 0$ and $b > 1$ be two integers. Throughout this section, the quantities k, d, j, ψ are fixed as follows.*

- *Let k, d be the unique integers such that $p = k\,d$ where k is the greatest divisor of p coprime with b. In particular, the prime factors occurring in the prime decomposition of d all appear in the prime decomposition of b. Moreover, $(k, d) = 1$.*
- *Since $(k, b) = 1$, the order of b in $\mathbb{Z}/k\mathbb{Z}$ is well defined and denoted by ψ, i.e., $b^\psi \equiv 1\ [k]$.*
- *Let j be the least integer such that d is a divisor of b^j.*

Let $s < k$ and $t < d$ be two integers. Let $\langle s, t\rangle$ denote the integer of $\mathbb{Z}/p\mathbb{Z}$ congruent to s modulo k and t modulo d. This integer is unique by the Chinese remainder theorem. Note that if n is an integer less than p, then $n = \langle n\%k, n\%d\rangle$ where $n\%k$ denote the remainder of the division of n by k.

3.1 The automaton $\mathcal{A}_{(p,R)}$ and its minimisation

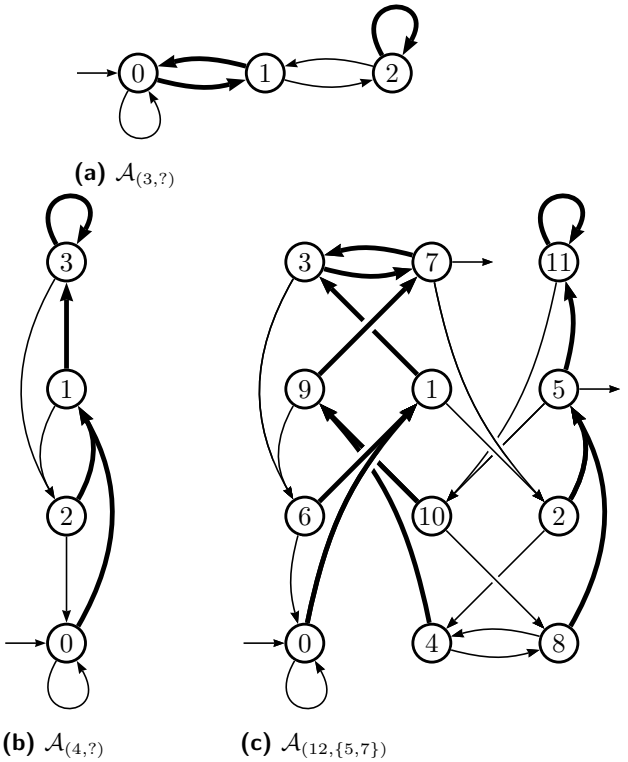
▶ **Definition 11.** A subset P of integers is *purely periodic*, if there exist $p \geq 1$ and a subset $R \subseteq \{0, \dots, p-1\}$ such that $P = R + p\mathbb{N}$.

For instance, $\{0, 1\} + 4\mathbb{N}$ is purely periodic but $\{4, 5\} + 4\mathbb{N}$ is not. Let $p \geq 1$ be an integer and R be a subset of $\{0, \dots, p-1\}$. We say that the parameter (p, R) is *proper*, if p is the smallest period of the purely periodic set $R + p\mathbb{N}$. For instance, $(4, \{0, 1\})$ is proper but $(4, \{0, 2\})$ is not because $\{0, 2\} + 4\mathbb{N} = \{0\} + 2\mathbb{N}$.

The following definition is ubiquitous when dealing with periodic sets of integers. It is an easy exercise to show that this automaton accepts base-b representations of integers whose remainder modulo p belongs to R.

▶ **Definition 12.** We let $\mathcal{A}_{(p,R)}$ denote the automaton $\mathcal{A}_{(p,R)} = \langle [\![b]\!], \mathbb{Z}/p\mathbb{Z}, \delta, 0, R\rangle$ where δ is defined as

$$\forall n \in \mathbb{Z}/p\mathbb{Z},\ \forall a \in [\![b]\!] \quad n \xrightarrow{a} nb + a\ .$$



(a) $\mathcal{A}_{(3,?)}$ **(b)** $\mathcal{A}_{(4,?)}$ **(c)** $\mathcal{A}_{(12,\{5,7\})}$

Figure 1 The automaton $\mathcal{A}_{(12,\{5,7\})}$, as the product automaton of $\mathcal{A}_{(4,?)}$ by $\mathcal{A}_{(3,?)}$.

When we are only interested in the transitions of the automaton $\mathcal{A}_{(p,R)}$, it is sometimes convenient to leave the set of final states unspecified. In that case, we write $\mathcal{A}_{(p,?)}$ for the automaton where the final/non-final status of the states is not set.

▶ **Example 13.** Figure 1c shows $\mathcal{A}_{(12,\{5,7\})}$ in base 2. Transitions with label 1 (resp. 0) are represented with bold (resp. thin) edges.

As can be seen, for instance, in Figure 2, the automaton $\mathcal{A}_{(p,R)}$ is not necessarily minimal.

▶ **Lemma 14.** *For every word* $u \in [\![b]\!]^*$, $(\mathcal{A}_{(p,R)} \cdot u) = (\overline{u}\%p) = \langle \overline{u}\%k, \overline{u}\%d \rangle$.

Proof. This follows directly from the definition of the transition function of $\mathcal{A}_{(p,?)}$. ◀

▶ **Property 15.** *The automaton* $\mathcal{A}_{(p,R)}$ *is strongly connected.*

Proof. Let n, m be two states. The state n is of the form $\langle i, i' \rangle$. Let u be a word satisfying

$$\overline{u} \equiv \langle k - i, 0 \rangle [p] \ , \quad |u| \geq j \quad \text{and} \quad |u| \equiv 0 [\psi] \ .$$

The last two conditions are easily satisfied by adding a suitable number of leading zeroes. Reading u from n leads to the initial state 0. Obviously, reading $\langle m \rangle$ from 0 leads to m. ◀

The next lemma states that the automaton $\mathcal{A}_{(p,?)}$ is the product automaton $\mathcal{A}_{(k,?)} \times \mathcal{A}_{(d,?)}$. This easily follows from the Chinese remainder theorem and Lemma 14.

▶ **Lemma 16.** *For all integers* $s, s' \in \mathbb{Z}/k\mathbb{Z}$, $t, t' \in \mathbb{Z}/d\mathbb{Z}$ *and every word* $u \in [\![b]\!]^*$,

$$\langle s, t \rangle \xrightarrow{u} \langle s', t' \rangle \text{ in } \mathcal{A}_{(p,?)} \iff \begin{cases} s \xrightarrow{u} s' \text{ in } \mathcal{A}_{(k,?)} \\ t \xrightarrow{u} t' \text{ in } \mathcal{A}_{(d,?)} \end{cases}$$

The fact that k is coprime with b implies the following result.

▶ **Lemma 17.** *With the definition introduced in Notation 10, the automaton $\mathcal{A}_{(k,?)}$ is a group automaton: each letter induces a permutation on the set of states.*

Proof. Since k is coprime with b, the function $f_0 : \mathbb{Z}/k\mathbb{Z} \to \mathbb{Z}/k\mathbb{Z}$ defined by $s \mapsto sb$ is a permutation of $\mathbb{Z}/k\mathbb{Z}$. Hence, so is the function f_a defined by $s \mapsto (sb + a)$, for every letter $a \in [\![b]\!]$. The action of a in $\mathcal{A}_{(k,?)}$ is exactly f_a, a permutation of the states. ◀

3.2 Nerode-equivalence and ultimate-equivalence in $\mathcal{A}_{(p,R)}$

Within the setting of Example 13 where rows (resp. columns) of the product automaton $\mathcal{A}_{(p,R)} \approx \mathcal{A}_{(d,?)} \times \mathcal{A}_{(k,?)}$ correspond to the equivalence classes modulo d (resp. modulo k), the forthcoming Proposition 19 shows that Nerode-equivalent states in $\mathcal{A}_{(p,R)}$ must belong to the same column. See, for instance, Figure 2. Then, we show that all states belonging to the same column are ultimately-equivalent.

▶ **Lemma 18.** *If (p, R) is proper, then for all distinct integers i and i', $0 \leq i, i' < k$, the states id and $i'd$ are not Nerode-equivalent.*

Proof. Since (p, R) is proper and $id \neq i'd$, there exists an integer m such that $(id + m) \in R + p\mathbb{N}$ and $(i'd + m) \notin R + p\mathbb{N}$.

We let u denote a word such that $\overline{u} = m$ and $|u| \equiv 0[\psi]$ (in other words, u is the word $\langle m \rangle$ padded with an appropriate number of 0's); it thus holds that $b^{|u|} \equiv 1\ [k]$. Reading the word u respectively from the states id and $i'd$ leads to the states:

$$id \cdot u = idb^{|u|} + m \quad \text{and} \quad i'd \cdot u = i'db^{|u|} + m\ .$$

The integer $(idb^{|u|} + m)$ is congruent to $(id + m)$ modulo k (since $b^{|u|} \equiv 1\ [k]$) as well as modulo d (since both are obviously congruent to m) hence modulo p. The same reasoning also applies to the second state, finally yielding:

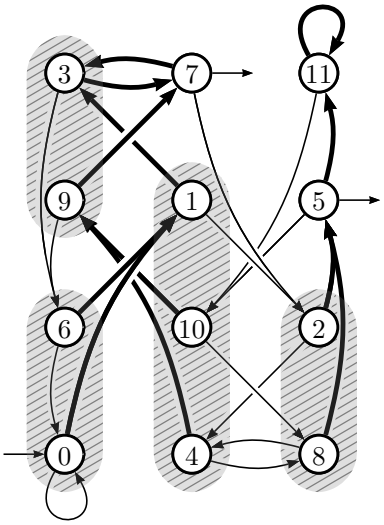
$$id \cdot u = id + m \quad \text{and} \quad i'd \cdot u = i'd + m\ .$$

The first state belongs to R and is thus final while the second does not belong to R and thus is not final. The word u is then a witness of the fact that id and $i'd$ are not Nerode-equivalent. ◀

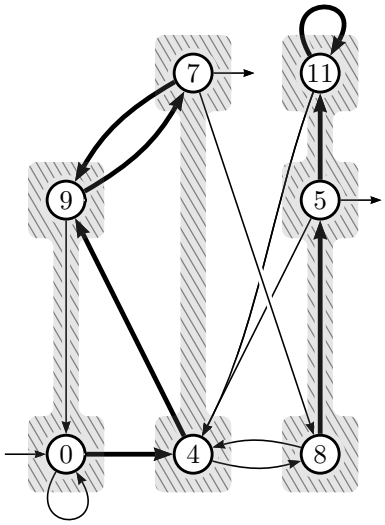
▶ **Proposition 19.** *Let (p, R) be proper. If i and i' are Nerode-equivalent states, then they are congruent modulo k.*

Proof. Proof by contrapositive. Let i and i' be two states that are not congruent modulo k. By definition of j, see Notation 10, the states $(i \cdot 0^j)$ and $(i' \cdot 0^j)$ are both congruent to 0 modulo d. However the operation $i \mapsto ib$ is a permutation of $\mathbb{Z}/k\mathbb{Z}$, hence $(i \cdot 0^j)$ and $(i' \cdot 0^j)$ are not congruent modulo k. It follows that $(i \cdot 0^j) = ld$ and $(i' \cdot 0^j) = l'd$ for some distinct $l, l' \in \mathbb{Z}/k\mathbb{Z}$. Lemma 18 then yields that these states are not Nerode-equivalent, hence that i and i' are not either. ◀

▶ **Lemma 20.** *Let s and s' be two states of $\mathcal{A}_{(p,R)}$. With the definition introduced in Notation 10, if $s \equiv s'[k]$, then s and s' are j-ultimately-equivalent.*



(a) Nerode-equivalence classes of $\mathcal{A}_{(12,\{5,7\})}$



(b) Pseudo-morphism equivalence classes in the minimisation of $\mathcal{A}_{(12,\{5,7\})}$

Figure 2 Minimisation morphism of $\mathcal{A}_{(12,\{5,7\})}$ and pseudo-morphism of its minimisation.

Proof. Let u be any word of length j. Since s and s' are congruent modulo k, there exists $i \in \mathbb{Z}/k\mathbb{Z}$ and $l, l' \in \mathbb{Z}/d\mathbb{Z}$ such that $s = \langle i, l\rangle$ and $s' = \langle i, l'\rangle$. Then, from Lemma 16 and using the fact that $lb^j \equiv 0\ [d]$, we get

$$(s \cdot u) = \langle ib^j + \overline{u},\ lb^j + \overline{u}\rangle = \langle ib^j + \overline{u},\ \overline{u}\rangle\ .$$

Similarly $(s' \cdot u) = \langle ib^j + \overline{u},\ \overline{u}\rangle = (s \cdot u)$. ◀

3.3 Circuits labelled by the digit 0

A circuit in which every arc is labelled by the digit 0 is called for short a *0-circuit*. For instance, the automaton $\mathcal{A}_{(12,\{5,7\})}$ depicted in Figure 1 has two such circuits: $0 \xrightarrow{0} 0$ and $4 \xrightarrow{0} 8 \xrightarrow{0} 4$. We will see that the number of states belonging to 0-circuits has a special meaning.

▶ **Lemma 21.** *A state of $\mathcal{A}_{(p,R)}$ is a multiple of d if and only if it belongs to a 0-circuit.*

Proof. Forward direction. It is enough to show that every state of the form id, for $i \in \mathbb{Z}/k\mathbb{Z}$, has a predecessor by 0 of the form $i'd$, $i' \in \mathbb{Z}/k\mathbb{Z}$. Simple arithmetic yields that $(b^{-1}i)d$ is suitable, where b^{-1} is the inverse of b in $\mathbb{Z}/k\mathbb{Z}$.

Backward direction. Proof by contrapositive. Let s be a state which is not a multiple of d. The state $(s \cdot 0^j)$ is a multiple of d. Therefore, for every integer $i \geq j$, the state $(s \cdot 0^i)$ is a multiple of d, hence is not equal to s. Since $\mathcal{A}_{(p,R)}$ is deterministic, $(s \cdot 0^i)$ cannot be equal to s for $i < j$ either. ◀

The next proposition follows from Lemmas 21 and 18. Recall that k is the largest integer coprime with b such that $p = k\,d$ and $d \geq 1$ (see Notation 10).

▶ **Proposition 22.** *If (p, R) is proper, the minimisation of $\mathcal{A}_{(p,R)}$ possesses exactly k states that belong to 0-circuits.*

4 Characterisation of automata accepting purely periodic sets

The next result will allow us to decide whether a deterministic automaton $\mathcal{A}$ over $[\![b]\!]$, given as input, is such that $\overline{L(\mathcal{A})}$ is a purely periodic set of integers, i.e., whether or not it is of the form $R + p\mathbb{N}$ for some R and p. We say that an equivalence relation $\sim_1$ is a *refinement* of another equivalence relation $\sim_2$ if for every x and y, $x \sim_1 y \implies x \sim_2 y$.

▶ **Theorem 23.** *Let $b > 1$ be a base and $\mathcal{A}$ a minimal automaton over $[\![b]\!]$. Let ℓ be the number of states in $\mathcal{A}$ that belong to 0-circuits. The automaton $\mathcal{A}$ accepts by value a purely periodic set of integers if and only if the following conditions are fulfilled.*

(a) *There exists a pseudo-morphism $\phi : \mathcal{A} \to \mathcal{A}_{(\ell,?)}$.*

(b) *The equivalence relation induced by ϕ is a refinement of the ultimate-equivalence relation.*

(c) *The initial state of $\mathcal{A}$ bears a self-loop labelled by the digit 0*

Proof of forward direction. Since the automaton $\mathcal{A}$ is minimal and accepts by value, the initial state of $\mathcal{A}$ necessarily bears a loop labelled by the digit 0; in other words, item (3) holds.

More precisely, since $\mathcal{A}$ accepts by value a purely periodic set of integers, there exists a smallest period p and a remainder-set $R \subseteq \{0, \dots, p-1\}$ such that $L(\mathcal{A}) = 0^*\langle R + p\mathbb{N}\rangle$. Note that (p, R) is proper by choice of p. We make use of Notation 10. In particular, k is the greatest divisor of p that is coprime with b.

Since $\mathcal{A}$ is minimal, it is isomorphic to the minimisation of any automaton accepting $L(\mathcal{A})$, in particular, to the minimisation of $\mathcal{A}_{(p,R)}$. It then follows from Proposition 22 that $\ell = k$.

To prove that there exists a pseudo-morphism $\phi : \mathcal{A} \to \mathcal{A}_{(k,?)}$, we will apply Lemma 6. Let u,u' be two words such that $(\mathcal{A}_{(k,?)} \cdot u) \neq (\mathcal{A}_{(k,?)} \cdot u')$. Let us show that $(\mathcal{A} \cdot u) \neq (\mathcal{A} \cdot u')$. Since $(\mathcal{A}_{(k,?)} \cdot u) \neq (\mathcal{A}_{(k,?)} \cdot u')$, we have that $\overline{u} \not\equiv \overline{u'}$ $[k]$. Due to Lemma 14, $(\mathcal{A}_{(p,R)} \cdot u)$ and $(\mathcal{A}_{(p,R)} \cdot u')$ are not congruent modulo k. It then follows from Proposition 19 that the states $(\mathcal{A}_{(p,R)} \cdot u)$ and $(\mathcal{A}_{(p,R)} \cdot u')$ are not Nerode-equivalent, which implies that $(\mathcal{A} \cdot u) \neq (\mathcal{A} \cdot u')$ because $\mathcal{A}$ is the minimisation of $\mathcal{A}_{(p,R)}$.

Let s and s' be two states of $\mathcal{A}$ such that $\phi(s) = \phi(s')$. We have to show that s and s' are ultimately-equivalent. Let u and u' be two words such $(\mathcal{A} \cdot u) = s$ and $(\mathcal{A} \cdot u') = s'$. Since ϕ is a pseudo-morphism, we get that

$$(\mathcal{A}_{(k,?)} \cdot u) = \phi(s) = \phi(s') = (\mathcal{A}_{(k,?)} \cdot u')$$

and so $\overline{u} \equiv \overline{u'}$ $[k]$. Applying Lemma 14 yields that the states $(\mathcal{A}_{(p,R)} \cdot u)$ and $(\mathcal{A}_{(p,R)} \cdot u')$ are congruent modulo k, and by Lemma 20, these states are ultimately-equivalent. Since $\mathcal{A}$ is the minimisation of $\mathcal{A}_{(p,R)}$, we have an automaton morphism $\mathcal{A}_{(p,R)} \to \mathcal{A}$. Finally, since ultimate-equivalence commutes with automaton morphism (Lemma 9), $(\mathcal{A} \cdot u) = s$ and $(\mathcal{A} \cdot u') = s'$ are ultimately-equivalent. ◀

Proof of backward direction. By assumption, for all $i \in \mathbb{Z}/\ell\mathbb{Z}$, the states in $\phi^{-1}(i)$ are ultimately-equivalent. For every integer $i \in \mathbb{Z}/\ell\mathbb{Z}$, we let m_i denote the least integer such that, for all s, s' in $\phi^{-1}(i)$, $(s \cdot u) = (s' \cdot u)$ whenever $|u| \geq m_i$. Let $m = \max\{m_i \mid i \in \mathbb{Z}/\ell\mathbb{Z}\}$.

Let u, u' be two words with respective values that are congruent modulo ℓb^m. Note that, in particular, $\overline{u}$ and $\overline{u'}$ are thus congruent modulo b^m. Let us show that u and u' reach the same state in $\mathcal{A}$.

Since $\mathcal{A}$ bears a self-loop labelled by 0 on the initial state, the word $0^m u$ is such that $\overline{0^m u} = \overline{u}$ and $\mathcal{A} \cdot 0^m u = \mathcal{A} \cdot u$. We may thus assume that u and u' are longer than m.

There exist factorisations $u = vw$ and $u' = v'w'$ such that the lengths of w and w' are both equal to m. Since $\overline{u}$ and $\overline{u'}$ are congruent modulo b^m, w and w' are equal: $u = vw$, $u' = v'w$.

Assume without loss of generality that $\overline{u} \geq \overline{u'}$. Hence $\overline{u} - \overline{u'} = (\overline{v} - \overline{v'})b^m$ is congruent to 0 modulo ℓb^m. We deduce that $\overline{v}$ and $\overline{v'}$ are congruent modulo ℓ. By Lemma 14, the respective runs of v and v' in $\mathcal{A}_{(\ell,?)}$ reach the same state: $(\mathcal{A}_{(\ell,?)} \cdot v) = (\mathcal{A}_{(\ell,?)} \cdot v')$. From assumption (1), we get $\phi(\mathcal{A} \cdot v) = \phi(\mathcal{A} \cdot v')$. In other words, the states $(\mathcal{A} \cdot v)$ and $(\mathcal{A} \cdot v')$ are ϕ-equivalent. Hence, by assumption (2), they are m_i-ultimately-equivalent. Since $|w| = m \geq m_i$ (by choice of m), we get that $(\mathcal{A} \cdot v \cdot w) = (\mathcal{A} \cdot v' \cdot w)$: the run in $\mathcal{A}$ of the words $u = vw$ and $u' = v'w$ indeed reach the same state.

We have just shown that words whose values are congruent modulo ℓb^m have runs in $\mathcal{A}$ reaching the same states, hence either all are accepted by $\mathcal{A}$ or none of them are. The run of a word u is then accepted by $\mathcal{A}$ if and only if $\langle \overline{u} \% (\ell b^m) \rangle$ is. Finally, a word u is accepted by $\mathcal{A}$ if and only if $\overline{u} \% (\ell b^m)$ belongs to the set $R \subseteq \{0, \ldots, \ell b^m - 1\}$, defined by

$$R = \{\ i \in \mathbb{Z}/\ell b^m \mathbb{Z} \mid (\mathcal{A} \cdot \langle i \rangle) \text{ is final } \}\ . \qquad \blacktriangleleft$$

▶ **Remark 24.** *In the proof of the forward direction, it was stated that $\ell = k$ (where k is the greatest divisor of the period which is coprime with the base). It is also the case in the backward direction. Indeed, the automaton $\mathcal{A}$ is shown to accept a purely periodic set of integers. Let (p, R) denotes the* ***proper*** *parameter of this set (it is not necessarily the one given in the proof). Since $\mathcal{A}$ is minimal, it is a quotient of $\mathcal{A}_{(p,R)}$. It then follows from Proposition 22 that, ℓ, the number of states belonging to 0-circuits, is equal to k, the greatest divisor of the period which is coprime with the base.*

4.1 Complexity and algorithmic issues

Theorem 23 yields an algorithm to decide whether a given deterministic automaton $\mathcal{A}$ accepts by value a purely periodic set of integers:

0. if necessary, minimise $\mathcal{A}$ and make it complete;
1. count the number ℓ of states of $\mathcal{A}$ that belong to 0-circuits;
2. build the automaton $\mathcal{A}_{(\ell,?)}$;
3. construct, if it exists, the pseudo morphism $\phi : \mathcal{A} \to \mathcal{A}_{(\ell,?)}$;
4. check whether, for all $x \in \mathbb{Z}/\ell\mathbb{Z}$, the states of $\phi^{-1}(x)$ are ultimately-equivalent.

Let us denote by n the number of states of $\mathcal{A}$. Step (0) can be carried out in $O(bn \log n)$ time. Steps (1) and (2) can obviously be performed in $O(bn)$ time. A morphism between deterministic automata, if it exists, can be computed by a single traversal of the bigger automaton; the same algorithm also works for pseudo-morphisms: Step (3) also runs in $O(bn)$ time. The ultimate-equivalence classes of $\mathcal{A}$ can be computed in time $O(bn \log n)$ from Proposition 8, hence so is the execution of Step (4).

▶ **Corollary 25.** *Let $b > 1$ be a base and $\mathcal{A}$ be a n-state deterministic automaton over $[\![b]\!]$. It is decidable in $O(bn \log n)$ time whether $\mathcal{A}$ accepts by value a purely periodic set of integers.*

▶ **Remark 26.** *Remark 24 gives a very fast rejection test. Indeed, before Step (2) we may check whether the integer ℓ (computed by Step (1)) is coprime with b. If it is not the case, $\mathcal{A}$ may be rejected already.*

▶ **Example 27.** We start with the minimal automaton $\mathcal{A}$ depicted in Figure 3. Step (1) is shown in Figure 4: $\mathcal{A}$ has five states belonging 0-circuits and thus, $\ell = 5$. Step (2) then consists in constructing $\mathcal{A}_{(5,?)}$, shown in 5. There is a pseudo-morphism $\mathcal{A} \to \mathcal{A}_{(5,?)}$, whose

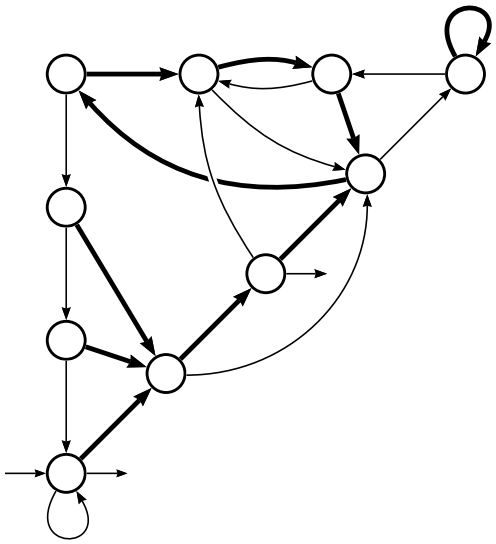


Figure 3 An automaton $\mathcal{A}$.

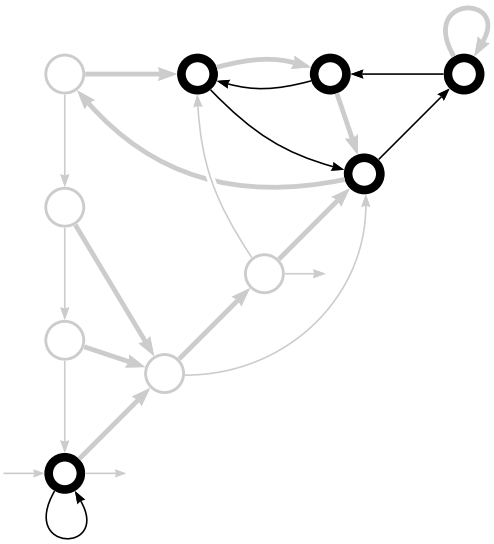

Figure 4 The 0-circuits have 5 states in total.

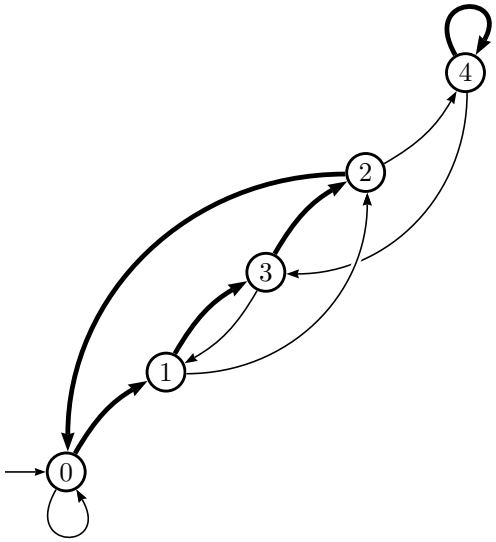

Figure 5 The automaton $\mathcal{A}_{(5,?)}$.

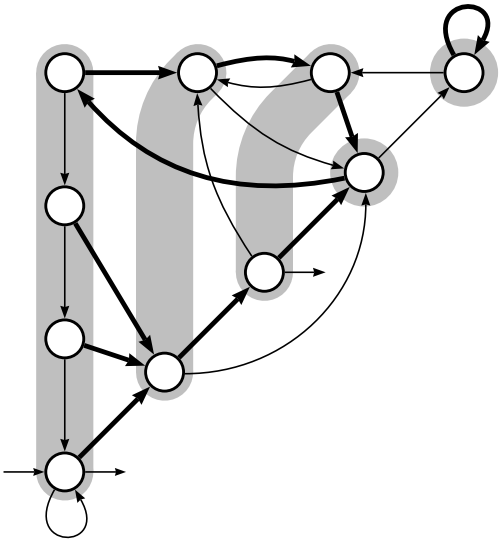

Figure 6 Equivalence classes of the relation induced by the pseudo-morphism $\mathcal{A} \to \mathcal{A}_{(5,?)}$.

equivalence classes are represented in Figure 6. Finally, one could check that Step (4) holds: all states belonging to the same class are 3-ultimately-equivalent. Hence $\mathcal{A}$ accepts an eventually periodic set of period $2^3 \times 5$. It is indeed the minimisation of $\mathcal{A}_{(40,\{0,3\})}$.

5 Generalisation to eventually periodic sets

Let us now consider the eventually periodic sets of integers that are not purely periodic (see Definition 11). We say that such sets are *impurely periodic* and Theorem 28 below gives a characterisation of the minimal automata that accept them.

▶ **Theorem 28.** *Let $b > 1$ be a base and let $\mathcal{A}$ be a minimal automaton over $[\![b]\!]$. We write $(\ell + 1)$ for the number of states in $\mathcal{A}$ that belong to 0-circuits. The automaton $\mathcal{A}$ accepts by value an **im**purely periodic set of integers if and only if the following conditions are met.*

(a) *There exists a pseudo-morphism $\phi : \mathcal{A} \to \mathcal{A}_{(\ell,?)}$.*

(b) *The initial state excluded, the equivalence relation induced by ϕ is a refinement of the ultimate-equivalence relation.*

(c) *The initial state bears a self-loop labelled by the digit 0 and features no other incoming transitions.*

Due to space constraints we do not detail the proof of Theorem 28. Although it is not immediate, it is much similar to the proof of Theorem 23 and may be found in arXiv [8].

As stated by the next corollary, Theorem 28 gives an algorithm to decide whether an automaton accepts an impurely periodic set of integers. It is the same as the one from Section 4.1 with the following modification and addition:

0 to **3.** same tests as in Section 4.1.

4. check whether, for every $x \in \mathbb{Z}/\ell\mathbb{Z}$, the **non-initial** states of $\phi^{-1}(x)$ are ultimately-equivalent;

5. check whether the initial state has no incoming transition.

▶ **Corollary 29.** *Let b be a base and $\mathcal{A}$ be a n-state deterministic automaton over $[\![b]\!]$. It is decidable in $O(bn \log n)$ time whether $\mathcal{A}$ accepts by value an impurely periodic set of integers.*

Since an eventually periodic set is either purely or impurely periodic, Theorem 1 is a direct consequence of Corollaries 25 and 29.

Abstract

Whether the reachability problem for branching vector addition systems, or equivalently the provability problem for multiplicative exponential linear logic, is decidable has been a long-standing open question. The one-dimensional case is a generalisation of the extensively studied one-counter nets, and it was recently established polynomial-time complete provided counter updates are given in unary. Our main contribution is to determine the complexity when the encoding is binary: polynomial-space complete.

1 Introduction

Background. Vector addition systems, also known as Petri nets (cf., e.g., Reisig's book [21]), are one of the longest established, most extensively studied, and most widely applied models of concurrent computing systems. Their branching generalisation has attracted considerable attention in recent years from the research community on logic in computer science. In addition to the simplicity and elegance of the model, this popularity is due to remarkably close connections with computational linguistics [20, 22], cryptographic protocols [25], linear logic [8, 16], semi-structured databases [13, 1], recursively parallel programs [5], game semantics [7], and timed pushdown systems [6].

A central decision problem for branching vector addition systems is reachability: whether a computation tree exists that has the given root and leaves. Similarly to the simpler setting of Petri nets, this problem has turned out to be very challenging. However, in contrast to Petri nets where the challenge is determining the complexity of reachability below a currently best cubic-Ackermann bound [17], even decidability is still open for the branching vector addition systems reachability problem. For reasons indicated above, the latter question was

Table 1 Complexity of reachability for one-dimensional vector addition systems with states, depending on the presence of branching and the encoding of counter updates.

	unary	binary
1VASS	NL-complete [24, 15]	NP-complete [11]
1BVASS	P-complete [10]	PSPACE-complete

recently highlighted by Bojańczyk as one of a handful of most interesting open problems in computer science logic [4].[1]

The decidability of the branching reachability problem is in fact open already in two dimensions. However, in one dimension, i.e. when there is only one counter, Göller et al. [10] established decidability, and more precisely polynomial-time completeness provided the numbers that specify the counter updates in the system are given in unary. The precise complexity with the encoding in binary remained undetermined.

From another point of view, our investigation builds on the voluminous literature on decision problems for one-counter automata, a ubiquitous class obtained by either dropping one counter from Minsky (two-counter) machines or restricting pushdown automata to one stack symbol. In particular, the complexity of the reachability problem for one-counter systems is known: NL-completeness with the updates given in unary is a classical result [24, 15], and NP-completeness for succinct systems is due to Haase et al. [11] (cf. the latter paper for further references on the subject).

Contributions. Our main result is the closure of the complexity gap for the reachability problem on succinct one-dimensional branching vector addition systems with states (1BVASS), which was between NP hardness inherited from 1VASS [11] and EXPTIME membership that follows from the P membership for unary 1BVASS [10].[2] We show that the problem is in fact PSPACE-complete, which fills the little Table 1.

The fact that the complexities for 1BVASS correspond exactly to 'adding alternation' to the complexities for 1VASS makes them easy to remember. However, it is quite misleading in terms of proofs, at least as far as we can see. The branchings in computations of BVASS are not alternations: counter valuations at child nodes are summed, not compared for equality.[3] Already in the unary case, the proof of P-completeness for 1BVASS [10] is considerably more involved than of NL-completeness for 1VASS [24, 15]. In our proof of PSPACE-completeness for binary 1BVASS, there are several substantial new insights in comparison to both unary 1BVASS and binary 1VASS [11]:

- we introduce a novel notion of implicit reachability witnesses, show that such a witness of at most an exponential size always exists, and hence argue that it can be guessed and checked in polynomial space;
- for the exponential bound on the size of witnesses, a polynomial bound on their counter valuations as for unary 1BVASS [10] is not sufficient because trees with exponentially long branches may be doubly exponentially large;

[1] Although decidability has been stated in a published journal article [2], we believe that claim has not been accepted by the community due to lack of proof, cf. [23, Footnote 4].

[2] We remark that we write 'with states' because stateless (B)VAS are sometimes considered in higher dimensions since states can be encoded at the expense of three additional counters; and that 1VASS, i.e. one-counter nets, are as hard as one-counter systems in this context since the ability to zero-test the counter does not make reachability significantly more complex.

[3] Reachability for alternating VASS is actually undecidable, for relatively trivial reasons [19].

- one of the techniques we employ for establishing the exponential bound involves a novel rewriting strategy, which may be of wider interest since it transforms fragments of computation trees to a normal form that features principal branches, whereas the lack of such a structure has hitherto been an obstacle to generalising Kosaraju's approach [14, 17] to BVASS;
- in contrast to the other three hardness results summarised in Table 1, our lower bound proof is highly intricate, resting on a system of encodings and checks through which alternation can be simulated by additive branching up to a linear depth.

Organisation. After the next section in which we define the systems we consider and observe some of their basic properties, the two sections that follow contain the PSPACE-membership proof. In the penultimate section, we present the PSPACE-hardness construction, and then finish with some concluding remarks.

2 Preliminaries

1BVASS. A *one-dimensional branching vector addition system with states* (*1BVASS* for short) is a triple $B = (Q, \Delta, I)$ where Q is a non-empty finite set of *states*, Δ is a non-empty finite subset of $Q \times Q \times \mathbb{Z} \times Q$, and $I \subseteq Q$ is a finite set of *initial states*. An element $\delta = (q_L, q_R, z, q)$ in Δ is called a *transition*, and the integer z is called the *displacement* of the transition. In the sequel, the maximal absolute displacement is denoted by M. A *configuration* is a pair in $Q \times \mathbb{N}$, and a configuration in $I \times \{0\}$ is called an *initial configuration*. Since the displacements are given in binary, we define the size of B as $|B| = |Q| + |\Delta| \log_2(M+1)$.

Trees. We write $u \preceq v$ if u is a prefix of v and $u \prec v$ if u is a strict prefix. A *tree* is a non-empty finite prefix-closed subset T of $\{L, R\}^*$ satisfying the property that $tL \in T$ if, and only if, $tR \in T$ for every $t \in T$. Elements of T are called *nodes*. Its *root* is the empty word ε. An *ancestor* s of a node t is a prefix of t. In that case t is called a *descendant* of s. By writing *strict* descendants and ancestors we exclude $s = t$. A *child* of a node t is a node tL or tR in T. A node is called a *leaf* if it has no child, and it is said *internal* otherwise. The *sibling* of a node $t \neq \varepsilon$ in the tree T is the node obtained by swapping the last letter. The *height* of a node t is $|t|$. The size of a tree T is its cardinality $|T|$. The *height* of T is the maximal height of any of its nodes. The *subtree* of T rooted at a node t in T is the tree $t^{-1}T = \{t' \in \{L, R\}^* \mid tt' \in T\}$. The *truncation* of T at a node t is the tree $T \backslash t\{L, R\}^+$. Notice that t becomes a leaf of that truncated tree.

Runs and Reachability. We consider labeled trees T where each node t is labeled by a state $q_t \in Q$ and a value $n_t \in \mathbb{N}$ defining a configuration (q_t, n_t). A *run* ρ is a labeled tree such that for every internal node t, there exists an integer z such that (q_{tL}, q_{tR}, z, q_t) is a transition in Δ and such that $n_t = n_{tL} + n_{tR} + z$. The notions of height, size, subtree (called subrun in that context), and truncation are extended from trees to runs as one would expect. Notice that the labels are ignored in the size of a run.

A run is said to be *complete* if every leaf is labeled by an initial configuration. We write *partial run*, instead of run, when we want to emphasize that the run could be not complete. A configuration is said to be *reachable* if it is the root configuration of a complete run. We are mostly interested in the *reachability problem*: given a 1BVASS B and a configuration (q, n) decide whether (q, n) is reachable. The size of the input is $|B| + \log_2(n+1)$.

▶ **Example 1.** Fix numbers n, b such that $0 \leq b \leq 2^n$. We define the 1BVASS $B = (Q, \Delta, I)$, where $Q = \{q_1 \dots q_n\} \cup \{q_I, q_F\}$ and $I = \{q_I\}$. There are three types of transitions:

$$(q_I, q_I, 0, q_1), (q_I, q_I, 1, q_1); \quad (q_i, q_i, 0, q_{i+1}) \text{ for all } i < n; \quad (q_n, q_n, -b, q_F).$$

The first two transitions initialize q_1 with 0 or 1; the next n transitions build a full binary tree below each state q_i; and the last transition decreases the value of the counter by b. Consider the reachability problem of $(q_F, 0)$. The complete runs with $(q_F, 0)$ in the root are full binary trees of height $n+1$ such that the number of nodes with state q_1 is 2^n and exactly b of them have value 1.

Contexts and Concatenation. A *context* $\pi = (\rho, t)$ is a run ρ equipped with a distinguished leaf t called the *source* of π. The label of t is called the *source configuration* of π. Such a context is also called a context from the source configuration up to the root configuration of ρ. Given a node t in a run ρ and an ancestor s of t, i.e. such that $t = su$ for some word u, we define the context between (s, t) as the subrun rooted at s of the truncation at t of ρ, equipped with u as the source node. An ancestor of the source t is called a *main node* of π. The set of main nodes of π is called the *main branch*. A *dangling node* in π is a node that is a sibling of a main node. A *dangling configuration* is a configuration of such a node.

The concatenation $\pi\rho$ of a context π with a run ρ is defined if the source configuration (p, m) of π and the root configuration (q, n) of ρ satisfy $p = q$ and if the natural numbers labeling the main nodes of π are larger than or equal to $m - n$. Then $\pi\rho$ is defined by adding to the main nodes of π the integer $n - m$, and replacing the leaf node t of that context with ρ. Notice that $\pi\rho$ is a run. Contexts can be *concatenated* a similar way. The concatenation $\pi\pi'$ of a context $\pi = (\rho, t)$ with a context $\pi' = (\rho', t')$ is defined if $\pi\rho'$ is defined. In that case $\pi\pi'$ is the context $(\pi\rho', tt')$.

Cycles and Minimal Nodes. A context from (p, m) up to (q, n) is called a *cycle* if the source is distinct from the root node and $p = q$. The cycle is said to be simple if on the main branch only the source and the root have the same states. A main node v is said to be *minimal* in a cycle if its value is minimal on the main branch, i.e., $n_v \leq n_{v'}$ for any other main node v'. We write *d-cycle* do emphasize the growth of the cycle, where $d = n - m$. The cycle is said to be *increasing* if $d > 0$, *zero* if $d = 0$, and *decreasing* if $d < 0$.

Let π be a d-cycle, and let p be the state of its source node. Let $\rho = \rho_1\pi\rho_2$ be a context or a run. By *removing* π from ρ we obtain $\rho' = \rho_1\rho_2$ (provided there is no drop below 0). Similarly, let $\rho = \rho_1\rho_2$ be a context or a run such that the source of ρ_1 has state label p. By *inserting* π into v we obtain $\rho_1\pi\rho_2$ (provided that there is no drop below 0). Notice that it is always safe to remove decreasing cycles and to add increasing cycles.

3 d-Coverability

A key role in our polynomial-space algorithm for the reachability problem is played by a more relaxed notion of 'coverability modulo d': instead of reaching a value x exactly, it is allowed to reach any value which is at least x, provided the difference with x is a multiple of d. More formally, a configuration (q, n) is said to be *d-coverable* where $d > 0$ is a natural number if there exists a reachable configuration (q, x) with $x \in n + \mathbb{N}.d$. A *d-coverability run* of a configuration (q, n) is a complete run rooted by a configuration (q, x) with $x \in n + \mathbb{N}.d$. Note that a similar notion of d-reachability was used to show P-completeness for reachability of unary 1BVASS [10].

This section culminates by establishing that every d-coverable configuration (q, n) admits a 'small' d-coverability run, namely of size bounded by $(n+5).(d2^{|B|})^6$. We present most of the proof, which is an orchestration of pigeonhole arguments and safe collapses, as a sequence of lemmas. Let us start with a simple observation about divisibility of subset sums.

▶ **Lemma 2.** *Let $z_1, \ldots, z_d$ be a non-empty sequence of integers. There exists a non-empty finite set $J \subseteq \{1, \ldots, d\}$ such that d divides $\sum_{j \in J} z_j$.*

▶ **Lemma 3.** *Let (q, n) be a configuration and let ρ be a d-coverability run of (q, n) of minimal size. If the size of ρ is larger than $|Q|.2^{|Q|}.d^2$ then ρ contains an increasing cycle.*

Proof. Let ρ be a d-coverability run of (q, n). Suppose: (1) the height of ρ is smaller than $|Q|.d$; and (2) for every height $\ell \geq 1$ the number of nodes in ρ of height ℓ is smaller than $2^{|Q|}.d$. Then it follows that the number of nodes of ρ is bounded by 1 (the root) plus $|Q|.d$ times $2^{|Q|}.d - 1$ (the remaining nodes). Hence the size is bounded by $|Q|.2^{|Q|}.d^2$. It remains to show that if (1) or (2) does not hold then ρ is not minimal or contains an increasing cycle.

In the first case (1) assume that the height of ρ is at least $|Q|.d$. In that case, there exists a node t such that $|t| = |Q|.d$. The nodes on the branch from the root to t are the prefixes of t. It follows that the number of nodes on that branch is equal to $|Q|.d+1$. Notice that if every state of Q occurs at most d times on that branch, then the number of nodes of that branch is bounded by $|Q|.d$ and we get a contradiction. It follows that some state q occurs at least $d+1$ times as a label of a node in that branch. If ρ does not contain any increasing cycle, then all repetitions induce zero or decreasing cycles. Lemma 2 shows that by removing at most d such cycles in that branch we get another d-coverability run of (q, n), smaller than ρ.

In the second case (2) assume that there exists a level $\ell \geq 1$ such that the number of nodes in ρ of height ℓ is at least $2^{|Q|}.d$. It follows that $\ell \geq |Q|$. Notice that these nodes have ancestors in level $\ell - |Q|$. Since the number of elements in level ℓ that have the same ancestors in level $\ell - |Q|$ is bounded by $2^{|Q|}$, it follows that the level $\ell - |Q|$ contains at least d distinct nodes $t_1, \ldots, t_d$ such that, for some words $u_1, \ldots, u_d$ of length $|Q|$, we have $t_i u_i \in \rho$ for every $1 \leq i \leq d$. The pigeon-hole principle shows that we can extract a cycle in the context between $(t_i, t_i u_i)$ for every i. If ρ contains no increasing cycles, then these cycles are zero or decreasing. Lemma 2 shows that by removing at most d such cycles we get another d-coverability run of (q, n), smaller than ρ. ◀

Small d-coverability runs are obtained thanks to the class of *witnesses of d-coverability* defined as follows. A *witness of d-coverability* of a configuration (q, n) is a partial run ψ with the root labeled (q, x), where $x \in n + \mathbb{N}.d$. Every leaf labeled by a configuration (p, m) that is not initial is equipped with a complete run with root label (p, y) with $y \equiv m \mod d$ and containing an increasing cycle. A node of ψ is said to be *modular* when it is an ancestor of such a leaf. We show in the sequel that the existence of d-coverability runs implies the existence of small witnesses of d-coverability. Moreover we provide a way to forge small d-coverability runs from small witnesses of d-coverability.

▶ **Lemma 4.** *Every d-coverable configuration (q, n) has a witness ψ such that:*

- *the subruns of ψ rooted at non-modular nodes have size at most $|Q|.2^{|Q|}.d^2$, and*
- *the complete runs attached to modular leaves have size at most $2|Q|.2^{|Q|}.d^2 + 1$.*

Proof Sketch. We truncate a minimal d-coverability run, bottom-up, at the first increasing cycles. The bounds follow from Lemma 3. ◀

To reduce the number of modular nodes, we introduce an operation on d-coverability witnesses that collapses cycles between modular nodes, as follows. Given a modular leaf ℓ and two ancestors u, v satisfying $u \prec v \preceq \ell$ such that $q_u = q_v$, we transform the witness as follows. First, we introduce the minimal $k \geq 0$ such that $r = kd - n_u + n_v$ is non-negative. Second, we relabel the branch from the root to the leaf ℓ by adding r on nodes s such that $\varepsilon \preceq s \preceq u$ and by adding kd on nodes s such that $v \preceq s \preceq \ell$. It is readily seen that the new labels of u and v are equal. Third, we remove the cycle between u and v by collapsing[4] the nodes $u \prec v$. Notice that after this transformation we get a witness of d-coverability for $(q, n + r)$ where (q, n) was the root label of the original witness of d-coverability. We obtain the following lemma whose proof is along the same lines as that of Lemma 3.

▶ **Lemma 5.** *Let (q, n) be a configuration. By iteratively collapsing cycles, every witness of d-coverability of (q, n) can be simplified into a witness with at most $|Q|.2^{|Q|}.d^2$ modular nodes and where the height of each modular node is smaller than $|Q|.d$.*

▶ **Lemma 6.** *We may relabel modular nodes of any witness of d-coverability of (q, n) in such a way that $n_\ell < n + d + |Q|.d.M$ for every modular leaf ℓ.*

▶ **Theorem 7.** *Every d-coverable configuration (q, n) admits a d-coverability run of size at most $(n + 5).(d2^{|B|})^6$.*

Proof. By applying Lemmas 4, 5, and 6 in succession, we get a witness of d-coverability for (q, n) satisfying the bounds in these lemmas. Assume first that the root node of that witness is not a modular node. In that case the witness of d-coverability of (q, n) is in fact a d-coverability run of (q, n) and by Lemma 4 the size of this run is bounded by $|Q|.2^{|Q|}.d^2$.

Now, suppose that the root node of the witness is a modular node. Let μ be the number of all modular nodes, and ζ the number of all non-modular nodes. By Lemma 5 we get $\mu \leq |Q|.2^{|Q|}.d^2$. We bound ζ as follows. A non-modular node t is called a side node if it is the sibling of a modular node. Observe that non-modular nodes are descendant of side nodes and by Lemma 4 subruns rooted in side nodes have sizes bounded by $|Q|.2^{|Q|}.d^2$. Since the number of side nodes is bounded by μ, we derive that $\zeta \leq \mu.|Q|.2^{|Q|}.d^2$.

To build a d-coverability run from the witness we iterate the following process for each modular leaf ℓ in the witness. As a first step, we transform the attached complete run ρ_ℓ of ℓ in such a way its root label (q_ℓ, x) satisfies $x \in n_\ell + \mathbb{N}d$. Recall that ρ_ℓ contains an increasing cycle π. The above-mentioned transformation simply amounts to iterating this cycle $d.n_\ell$ times. By Lemma 4 the size of ρ_ℓ is bounded by $2.|Q|.2^{|Q|}.d^2 + 1$, which also bounds the size of π. The size of the resulting complete run ρ'_ℓ is bounded by $2.|Q|.2^{|Q|}.d^2 + 1$ (the size of ρ_ℓ) plus $d.n_\ell.2.|Q|.2^{|Q|}.d^2$ (the result of iterating the increasing cycle). It follows that the size of $\rho_{\ell'}$ is bounded by $2.(d.n_\ell + 1).|Q|.2^{|Q|}.d^2 + 1$. By Lemma 6 we have $n_\ell < n + d + |Q|.d.M$, so we get that the size of $\rho_{\ell'}$ is bounded by $2(n + 3).M.|Q|^2.2^{|Q|}.d^4 + 1$.

Let (q_ℓ, m_ℓ) be the configuration of the root of ρ'_ℓ. Observe that $m_\ell \in n_\ell + \mathbb{N}d$. In the second step we add $m_\ell - n_\ell$ to each node on the branch from ℓ to the root of the witness. After this step, the new label of ℓ is equal to the root label of ρ'_ℓ. As a third step, we simply replace the leaf ℓ by the complete run ρ'_ℓ.

We obtain a d-coverability run ρ for (q, n) of size $\mu + \zeta$, plus the sum of the sizes of the complete runs ρ'_ℓ for each modular leaf ℓ. This is bounded by

$$\mu + \mu.|Q|.2^{|Q|}.d^2 + \mu.(2(n + 3).M.|Q|^2.2^{|Q|}.d^4 + 1) \leq (2n + 9).M.|Q|^3.4^{|Q|}.d^6.$$

Since $M.2^{|Q|} \leq 2^{|B|}$, we get that the size of ρ is at most $(n + 5).(d2^{|B|})^6$. ◀

[4] Collapsing two nodes $u \prec v$ consists in replacing the labeled subtree rooted in u by the labeled subtree rooted in v.

4 Reachability

This section is devoted to the proof of the following theorem.

▶ **Theorem 8.** *The reachability problem for 1BVASS is in* PSPACE.

The complexity is w.r.t. the sizes of the input 1BVASS and root configuration, both encoded in binary. Our proof relies on the following small witness property.

▶ **Lemma 9.** *If c is a reachable configuration with a value bounded by $2^{|B|}$ in a given 1BVASS B then there exists a complete run of size at most $2^{60|B|^3}$ with root configuration c.*

Indeed, Lemma 9 implies Theorem 8. First, notice that for configurations with value bigger than $2^{|B|}$ it suffices to solve the problem for value 0 with an auxiliary step in the given BVASS. More precisely, if we ask for reachability of (q, n) we can add two states r, r' such that r is initial, a new transition $(q, r, -n, r')$, and change the question to reachability of $(r', 0)$. To verify if a configuration c with a value bounded by $2^{|B|}$ is reachable, we guess a complete run for c in nondeterministic polynomial space. Since it is impossible to maintain, in polynomial space, all nodes of the run in the memory, we only maintain the ancestors of the currently processed node whose other child was not processed yet. For every processed node v if it is an initial configuration then we go back to the closest ancestor a whose other child was not verified and proceed with that child. In this case we remove the ancestor a from the memory. Otherwise, we guess nondeterministically two children of v such that their triple satisfies some transition in Δ and continue with one of the children. The procedure nondeterministically guesses to proceed with the child whose subtree contains at most half of the leaves in the complete run. It remains to observe that the procedure does not need to remember more than $60|B|^3$ ancestors, otherwise the complete run would require more than $2^{60|B|^3}$ nodes. Notice that it is possible that a node has an exponential number of ancestors, but the procedure does not need to remember them all. The rest of this section is devoted to prove Lemma 9.

Small complete runs are forged from the so-called witnesses of reachability. Formally, the class of *witnesses of reachability* is defined inductively as follows. A witness of reachability w of a configuration c is a partial run with root labeled by c and such that every leaf labeled by (p, m) that is not an initial configuration is a reachable configuration equipped with an *implicit* decreasing simple cycle up to the configuration $(p, 0)$. Implicit means that only the main branch and the dangling nodes of the decreasing cycle are given explicitly. Each dangling configuration is equipped with a witness of reachability. Notice that every configuration admitting a witness is reachable since the leaves of the top most partial run of that witness are labeled by reachable configurations. The *depth* of a witness of reachability is defined as follows. The depth of a complete run is zero, and the depth of a witness of reachability that is not a complete run is one plus the maximal depth of the witnesses of reachability defining the dangling configurations of the decreasing cycles. The depth of a witness of reachability w is denoted by $\mathrm{depth}(w)$. Figure 1 shows an example witness of reachability, suggesting how we turn it into a complete run. To bound the sizes of complete runs obtained from reachability witnesses we introduce the value $\mathrm{maxsize}(w)$ denoting the size of the biggest partial runs occurring in a witness of reachability w. The following lemma shows that $\mathrm{maxsize}(w)$ provides a simple way to bound values occurring in w.

▶ **Lemma 10.** *For every witness of reachability w of a configuration with a value bounded by $2^{|B|}$, the root values of the partial runs used by w are bounded by $2^{|B|}$. Moreover, any value occuring in w is bounded by $2^{2|B|} \cdot \mathrm{maxsize}(w)$.*

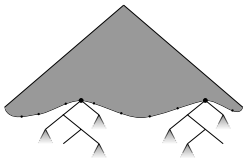

Figure 1 A witness whose topmost partial run has two leaves that are not initial. Decreasing cycles are attached, and the dangling configurations are provided with their subwitnesses.

Proof. The maximal root values can be bounded by observing that, except for the top most partial run of w, partial runs provide root configurations that are dangling configurations of simple decreasing cycles. It follows that these values cannot exceed $|Q|.M \leq 2^{|B|}$. We bound the other values as follows. Observe that the total sum of displacements plus the leave values of a partial run is equal to its root value. It follows that every value of w is bounded by $2^{|B|} + \text{maxsize}(w).M \leq 2^{2|B|}.\,\text{maxsize}(w)$. ◀

▶ **Lemma 11.** *Let w be a witness of reachability of a configuration (q,n) satisfying $n \leq 2^{|B|}$ in a 1BVASS B. There exists a complete run ρ_w with root label (q,n) and size bounded by $(2^{10|B|}.\,\text{maxsize}(w))^{2(\text{depth}(w)+1)}$.*

Proof. We associate to $s, \ell \in \mathbb{N}$ the set $C_{s,\ell}$ of configurations (q,n) such that $n \leq 2^{|B|}$ and such that there exists a witness of reachability w of (q,n) such that $\text{maxsize}(w) \leq s$ and $\text{depth}(w) \leq \ell$. We also define $f(s,\ell) = \max_{c \in C_{s,\ell}}(|\rho_c|)$, where $|\rho_c|$ is the minimal size of a complete run rooted at c. Such a run always exist since c is reachable. Notice that $f(s,0) \leq s$ since a witness of reachability of depth 0 is a complete run.

We provide a bound for $f(s,\ell+1)$ using $f(s,\ell)$. Consider a configuration $c \in C_{s,\ell+1}$. There exists a witness of reachability of c with depth bounded by $\ell+1$ such that $\text{maxsize}(w) \leq s$. Let ρ be the top most partial run of w. Suppose there is a leaf labeled by a non-initial configuration (p,m) that is provided with an implicit simple decreasing cycle up to $(p,0)$. Let us denote by $-d$ the effect of that cycle. As the cycle is simple, it follows that $d \leq |Q|.M \leq 2^{|B|}$. The dangling configurations $c_1, \ldots, c_k$ of that cycle are given by witnesses of reachability $w_1, \ldots, w_k$ such that $\text{depth}(w_j) \leq \ell$ and $\text{maxsize}(w_j) \leq s$. It follows that $c_1, \ldots, c_k \in C_{\ell,s}$. By induction, the dangling configurations $c_1, \ldots, c_k$ can be replaced by complete runs of size bounded by $f(s,\ell)$. Since the cycle is simple, $k \leq |Q|$. After these replacements we obtain an (explicit) simple cycle π of size at most $|Q| + |Q|.f(s,\ell)$. Moreover, since (p,m) is reachable, it is d-coverable. Theorem 7 shows that there exists a d-coverability run for (p,m) of size at most $(m+5).(d.2^{|B|})^6$. Lemma 10 shows that $m \leq 2^{2|B|}.\,\text{maxsize}(w)$. Since $5 \leq 2^{3|B|}.\,\text{maxsize}(w)$ we get $m + 5 \leq 2^{4|B|}.\,\text{maxsize}(w)$. We derive that there is a d-coverability run ρ of (p,m) of size bounded by $\lambda = 2^{16|B|}.\,\text{maxsize}(w) \leq 2^{16|B|}.s$.

There exists $k \in \mathbb{N}$ such that $(p, m + k.d)$ is the root configuration of ρ. In order to obtain a complete run with root configuration (p,m), we just have to consider $\pi^k\rho$. Notice that we can never reach a value below zero since π is a decreasing cycle up to $(p,0)$. As $m + k.d \leq \lambda.M$, it follows that $k \leq \lambda.M$. We have proved that there exists a complete run with root configuration (p,m) and of size bounded by $\lambda.M.(|Q| + |Q|f(s,\ell)) + \lambda \leq 2^{19|B|}.s.f(s,\ell)$. Finally, by replacing every non-terminal leaf by a complete run as performed previously, we get a complete run with root configuration c and size bounded by $2^{19|B|}.s^2.f(s,\ell)$. We have proved that $f(s,\ell+1)$ is bounded by that value. An immediate induction shows that

$$f(s,\ell) \leq (2^{19|B|}.s^2)^\ell.f(s,0) \leq (2^{19|B|}.s^2)^\ell.s \leq (2^{10|B|}.s)^{2(\ell+1)}.$$ ◀

By Lemma 11, to prove Lemma 9 it suffices to find a witness w such that maxsize(w) is bounded exponentially and depth(w) is bounded polynomially in the size of the given 1BVASS. Before we prove that we introduce some notation and two auxiliary lemmas.

Before the next lemma we introduce an operation that intuitively moves increasing cycles from left branches to right branches. By applying that operation as many times as possible, we obtain a so-called *saturated* partial run. Formally, a partial run ρ is said to be *reducible* in a node s if there exists an increasing cycle π between (sL, t) for some node $t \succeq sL$, and a minimal node v in π such that q_v is the state of some descendant of sR. A partial run that is not reducible is said to be *saturated*.

▶ **Lemma 12.** *For every partial run ρ there exists a saturated partial run ρ' with the same root configuration, the same number of nodes, and the same mutiset of leaf configurations.*

Proof. Assume that a partial run ρ is reducible on a node s. Let us denote by π an increasing d-cycle between (sL, t) in ρ for some node $t \succeq sL$ and a minimal node v in π such that $q_v = q_{v'}$ for some v', a descendant of sR. Let $\pi = \pi_1\pi_2$ be such that π_1 is the fragment of π with the source node v. We define $\pi' = \pi_2\pi'_1$, where π'_1 is obtained from π_1 by decreasing all values on the main branch by n_v. Since v is minimal, notice that π' is an increasing d-cycle from $(q_v, 0)$ up to (q_v, d) such that the multiset of configurations of nodes not on the main branch in π and π' are equal. By removing from ρ the increasing cycle π, and inserting the increasing cycle π' into v', we get a partial run ρ' such that the root configuration, the number of nodes, and the mutiset of leaf configurations remain the same as in ρ. Notice that by removing π we decrease the value of s by d, but by inserting π' its value is increased by d, therefore, these operations do not cause a drop below 0. Since this transformation can be performed only a finite number of times, at some point, we get a saturated run satisfying the lemma. ◀

▶ **Lemma 13.** *The number of nodes of a saturated run with root labeled (q, n) with $n \leq 2^{|B|}$ that does not contain any decreasing or zero cycles is bounded by $2^{5|B|^2}$.*

To prove Lemma 9 we will decompose partial runs that contain a decreasing cycle. Since such cycles are not necessarily simple, we provide the following lemma.

▶ **Lemma 14.** *For every decreasing cycle π there exists a state p that labels a main node of π and a simple decreasing cycle π' up to $(p, 0)$ such that the set of dangling configurations of π' is included in the set of dangling configurations of π.*

Proof of Lemma 9. We consider a reachable configuration c with a value bounded by $2^{|B|}$. Obviously c admits a witness of reachability because every complete run is a witness. By Lemma 11 we need to find a witness w of c such that maxsize(w), depth(w) have proper bounds. To do so, we associate to every witness w the sequence of natural numbers $s(w) = (s_j)_{j\geq 1}$, where s_j is the number of partial runs of size j in w, called the *rank* of w. These sequences are ordered colexicographically by the total order $\sqsubseteq$ defined by $(s_j)_{j\geq 1} \sqsubseteq (s'_j)_{j\geq 1}$ if the two sequences are equal or there exists $j \geq 1$ such that $s_j < s'_j$ and $s_i = s'_i$ for every $i > j$. Notice that sequences $s(w)$ have finite support, i.e., $\{j \mid s_j \neq 0\}$ is finite. When restricted to sequences with finite support the order $\sqsubseteq$ is well-founded, i.e., there are no infinite decreasing sequences. We consider for the remainder of the proof a reachability witness w with a minimal rank (for $\sqsubseteq$).

Suppose w has depth $\ell > |Q|$. Then there exists a sequence $\pi_1 \dots \pi_\ell$ of implicit decreasing simple cycles such that π_{i+1} is a cycle equipped to the partial run of a dangling node in π_i. Then there exist $i < j$ such that π_i and π_j have the same state in the root. We replace π_i with

π_j. In particular we remove all cycles $\pi_i \dots \pi_{j-1}$ and all partial runs that were associated to them. The resulting witness has a smaller rank which contradicts our minimality assumption on w.

Now, suppose that w contains partial runs of size bigger than $2^{5|B|^2}$. Let σ be a partial run having the maximal size and such that its depth is maximal (with respect to others of the same size). Notice that all partial runs of larger depth are smaller than σ. Using Lemma 12 we turn σ into a saturated run without changing the multiset of configurations of the leaves. Lemma 10 shows that the run σ has root value at most $2^{|B|}$ and thus by Lemma 13 there exists a decreasing or a zero cycle π in σ. If π is a zero cycle then we just remove it obtaining a smaller rank which contradicts our minimality assumption on w. Otherwise, π is a decreasing cycle. By Lemma 14 there exists a state p that labels a main node u of π and a simple decreasing cycle π' up to $(p, 0)$ such that the set of dangling configurations of π' is included in the set of dangling configurations of π. Since π is a cycle, we can assume w.l.o.g. that u is distinct from the source of π. Let v be the original node of u in σ. By assuption on u, notice that v is an internal node of σ. We define σ' as the partial run truncated at v and equip it with the simple decreasing cycle π'. Since v is an internal node, σ' is smaller from σ. The configurations of dangling nodes in π' are also configurations of dangling nodes in π, which come from σ. We use the partial subruns of σ as partial runs for dangling nodes in π'. These subruns come with implicit simple decreasing cycles and additional partial runs of smaller depth. Notice that, possibly, we have introduced double copies of partial runs of smaller depth. Let us show that the resulting witness w' has a smaller rank which will contradict our minimality assumption on w. Recall that all partial runs of bigger depth are smaller than σ. Since we have decreased the size of σ, and all introduced partial runs are of smaller size than σ it follows that $s(w') \sqsubset s(w)$.

We have proved that $\mathrm{depth}(w) \leq |Q|$ and $\mathrm{maxsize}(w) \leq 2^{5|B|^2}$. From Lemma 11, we get a complete run rooted by (q, n) with size bounded by $2^{60|B|^3}$. ◀

5 Hardness

We prove that the reachability problem for 1BVASS is PSpace-hard. Intuitively, one would like to encode runs of an alternating PTime Turing machine: the tape configuration is maintained as the binary representation of the counter value, and alternation is represented by the branching structure of the run. At first sight, binary rules of BVASS are not compatible with any sort of alternation: the value ℓ of a node may come from two arbitrary values ℓ_1, ℓ_2 from children with the sole restriction that $\ell = \ell_1 + \ell_2$. It thus seems pointless to pretend to replicate information encoded in ℓ into both ℓ_1 and ℓ_2. However, we show that one can enforce —in a highly restricted setting— that transitions behave in a regular way, where $\ell = 2 \cdot \ell_1 = 2 \cdot \ell_2$. Using this, child nodes can recover information from the parent node: the i-th bit of the child has a 1 iff the $i+1$-th bit of the parent has a 1. In this way information can be 'copied' into different branches, and we can benefit from some form of alternation.

▶ **Theorem 15.** *The reachability problem for 1BVASS is* PSpace*-hard.*

Proof Idea. The proof goes by reduction from the PSpace-complete problem of validity for Quantified Boolean Formulas. Given a QBF sentence, such as

$$\varphi = \forall P_1\ \exists P_2\ \forall P_3\ (P_1 \vee \neg P_2 \vee P_3) \wedge (\neg P_1 \vee P_2),$$

we define a polynomial size 1BVASS $\mathcal{B}$, in such a way that the configuration $(q_1, 0)$ is reachable if, and only if, φ is valid. Transitions in $\mathcal{B}$ enforce that any complete run for $(q_1, 0)$ encodes a 'certificate' of the validity of φ. In particular, this certificate contains

- nondeterministic choices for the valuation of existentially quantified variables such as P_2;
- one branch for each of the exponentially-many valuations for universally quantified variables, such as P_1 and P_3;
- for each branch encoding a valuation, a sub-branch for each disjunctive clause, certifying that the clause is true under that valuation.

Levels. For this reduction, it is natural to think of runs as proceeding top-down instead of bottom-up as done hitherto. That is, we start with a configuration $(q_1, 0)$ at the root, and we build valuations going downward until eventually finding an initial configuration on every branch. From this perspective, transitions of $\mathcal{B}$ 'increment' a value $c > 0$ before 'splitting' the value into children with states q', q'' with a transition of the form $(q', q'', -c, q)$. The behaviour of $\mathcal{B}$ ensure that any complete run for $(q_1, 0)$ can be divided into 'levels', so that the i-th level of the tree contains encodings for the choices of valuations for the first i variables of φ. For the purpose of this sketch, the level i is the set of all nodes of height $2 \cdot i$ in the run (*e.g.*, in the run of Figure 2, nodes at level i are those labelled q_{i+1}).

Valuation encoding. Variable valuations are encoded in the counter value by exploiting its compact binary representation, which throughout the run remains always a bitstring of quadratic length in the size of the sentence φ. The counter value bitstring can be split into equal length *segments*, one for each variable, so that the i-th segment is a $2m$ substring encoding the valuation of the i-th variable of φ, where m is the number of universally quantified variables plus the $\log_2$ of the number of conjuncts of φ —in our running example, $m = 3$. The encoding of a valuation for a variable will evolve along the run, for example the encoding for P_1 being true at nodes at different levels may differ. This is because branchings change the counter value and thus its binary representation. For a node at level j, the encoding for a *true* ($\top$) valuation of a variable P_i with $i \leq j$ is through a bitstring $0^{u(j)-1}10^{2m-u(j)}$ at the i-th segment, where $u(j)$ is the number of universally quantified variables P_i with $i \leq j$ in the input sentence —in our example, $u = \{(1,1),(2,1),(3,2)\}$. Similarly, the way to encode a *false* ($\bot$) valuation is through the bitstring $0^{m+u(j)-1}10^{m-u(j)}$. For φ as above, where $m = 3$, the valuation $\{(P_1, \top), (P_2, \bot), (P_3, \bot)\}$ at level 3 (*i.e.*, $j = 3$, $u(j) = 2$) is represented by the bitstring $z = (010|000)(000|010)(000|010)$ (parentheses and pipes are only to improve readability). Let us call the '(i, j)-bit' the j-th most significant bit of the i-th most significant segment in the bitstring, and let $c_{i,j} \in \mathbb{N}$ be the number whose sole (i, j)-bit is 1 in its binary representation (*e.g.*, for z as above, $z = c_{1,2} + c_{2,5} + c_{3,5}$).

As discussed before, for this reduction to work we need that already defined valuation are somehow 'replicated' in all the subtrees, that is, when a configuration branches, information on the valuations is preserved in both children configurations and remains uncorrupted. For this, we enforce that, for every internal node t inside a complete run for $(q_1, 0)$ of $\mathcal{B}$, either:

1. t has a right child with the initial configuration $(q_I, 0)$, or, otherwise,
2. both children of t have the same value, that is, $n_t = 2 \cdot n_{tL} = 2 \cdot n_{tR}$.

Assuming such a property (as verified by the run of Fig. 2), information can be 'spread' along branches of a run: at any node t of type (2) the i-th least significant bit of n_t is 1 iff the $(i-1)$-th least significant bit of n_{tL} and n_{tR} are 1. We use transitions of type (1) to generate a new valuation for the i-th variable, and transitions of type (2) to split the current valuation into two branches. For example, a configuration containing a *true* segment with bitstring $0^{i-1}10^{2m-i}$ is split into two children whose segment value is now 0^i10^{2m-i-1}, which still codes a *true* value for the next level $i + 1$. The choice of m is such that it corresponds

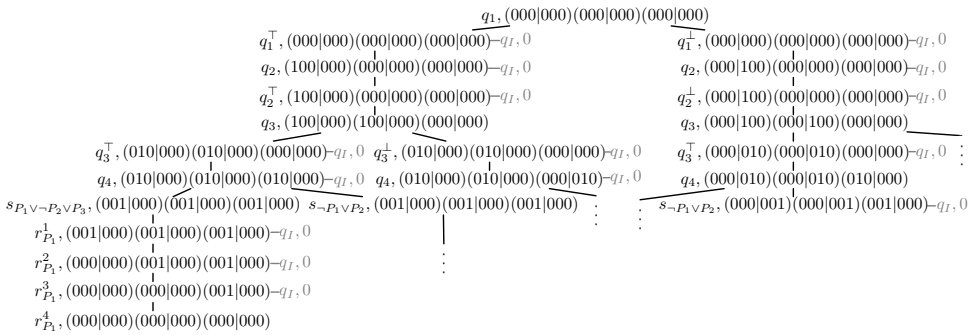

Figure 2 Clipping of a complete run for $(q_1, 0)$. Values are represented by 3 segments of 6 bits.

to the maximum number of transitions of type (2) in any root-to-leaf branch of the run. In other words, m is the maximum distance that a 1-bit can 'travel' along the run.

Here we only show how to build $\mathcal{B}$ for our running example φ. We use the state space $Q = \{q_j, q_i^\top, q_i^\bot, s_\psi, r_A^j, q_I \mid 1 \leq i \leq 3, 1 \leq j \leq 4, \psi : \text{clause}, A : \text{atom}\}$. For each universally quantified variable P_i (*i.e.*, for $i = 1, 3$) we include a transition $(q_i^\top, q_i^\bot, 0, q_i)$, which splits the run into a subtree where P_i is true ($q_i^\top$) and another where it is false ($q_i^\bot$). On the other hand, for each existentially quantified variable P_i (*i.e.*, for $i = 2$), we include non-deterministic transitions $(q_i^\top, q_I, 0, q_i)$ and $(q_i^\bot, q_I, 0, q_i)$, which choose one valuation for P_i. Each state $q_i^\top$ and $q_i^\bot$ has a transition incrementing the corresponding bit in the encoding: $(q_{i+1}, q_I, -c, q_i^\top)$ for c having its $(i, u(i))$-bit in 1, and 0's elsewhere; and $(q_{i+1}, q_I, -\bar{c}, q_i^\bot)$ for $\bar{c}$ having its $(i, m + u(i))$-bit in 1, and 0's elsewhere. Finally, $\mathcal{B}$ checks for the satisfaction of both clauses by splitting the computation through the transition $(s_{P_1 \vee \neg P_2 \vee P_3}, s_{\neg P_1 \vee P_2}, 0, q_4)$. For each clause, $\mathcal{B}$ chooses the atom which will witness its satisfaction, with transitions $(r_A^1, q_I, 0, s_\psi)$ for every disjunctive clause ψ of φ and atom A of ψ (*e.g.*, for $\psi = \neg P_1 \vee P_2$ and $A = \neg P_1$). Finally, the job of r_A^1 is to decrement the (i, m)-bit for verifying that P_i holds true, or the $(i, 2m)$-bit otherwise. However, this choice between the (i, m)- and the $(i, 2m)$-bit must be consistent with the choice of the atom A (*e.g.*, if $A = \neg P_2$ then we must verify that P_2 is false and thus we shouldn't allow the decrement of the (i, m)-bit). Concretely, we include a transition $(r_A^{i+1}, q_I, c_{i,m}, r_A^i)$ if and only if A is not $\neg P_i$; and we include $(r_A^{i+1}, q_I, c_{i,2m}, r_A^i)$ iff A is not P_i. Finally, the initial states I is defined as all states r_A^4 for an atom A, as well as q_I.

Figure 2 contains a depiction of a complete run witnessing the validity of φ. ◀

6 Conclusion

An interesting next question is the complexity of the reachability problem for two-dimensional BVASS, which we conjecture decidable. One approach to establishing decidability could be by generalising the classical algorithm of Hopcroft and Pansiot for two-dimensional VASS [12]. To determine the precise complexity, investigating branching extensions of the flatness notion (cf. [18, 3]) and the cutting technique (cf. [9]) seem like promising directions.

Abstract

In this paper, we investigate the finite satisfiability and model checking problems for the logic D of the sub-interval relation under the homogeneity assumption, that constrains a proposition letter to hold over an interval if and only if it holds over all its points. First, we prove that the satisfiability problem for D, over finite linear orders, is **PSPACE**-complete; then, we show that its model checking problem, over finite Kripke structures, is **PSPACE**-complete as well.

1 Introduction

For a long time, interval temporal logic (ITL) was considered as an attractive, but impractical, alternative to standard point-based ones. On the one hand, as pointed out, among others, by Kamp and Reyle [9], "truth, as it pertains to language in the way we use it, relates sentences not to instants but to temporal intervals", and thus ITL is a natural choice for a specification/representation language; on the other hand, the high undecidability of the satisfiability problem for the most well-known ITLs, such as Halpern and Shoham's HS [7] and Venema's CDT [18], prevented an extensive use of them (in fact, some very restricted variants of them have been successfully applied in formal verification and AI over the years).

† The work by Alberto Molinari, Angelo Montanari, and Pietro Sala has been supported by the GNCS project *Logic and Automata for Interval Model Checking*.

The recent discovery of a significant number of expressive enough and computationally well-behaved ITLs changed the landscape a lot [6, 13]. Among them, the logic A$\overline{\text{A}}$ of temporal neighborhood [5] and the logic D of (temporal) sub-intervals [4] have a central position. In this paper, we focus on the latter one. D features one modality only, which corresponds to the Allen relation *during* [1]. Since any sub-interval can be defined as an initial sub-interval of an ending one, or, equivalently, as an ending sub-interval of an initial one, it is a (proper) fragment of the logic BE of Allen's relations *started-by* and *finished-by*. From a computational point of view, D is a real character: its satisfiability problem is **PSPACE**-complete over the class of dense linear orders [4, 16] (the problem is undecidable for BE [10]), it becomes undecidable when the logic is interpreted over the classes of finite and discrete linear orders [11], and it is still unknown over the class of all linear orders. As for its expressiveness, unlike A$\overline{\text{A}}$– which is expressively complete with respect to the two-variable fragment of first-order logic for binary relational structures over various linearly-ordered domains [5, 15] – three variables are needed to encode D in first-order logic (the two-variable property is a sufficient condition for decidability, but it is not a necessary one).

In this paper, we show that the decidability of the satisfiability problem for D over the class of finite linear orders can be recovered under the homogeneity assumption (such an assumption constrains a proposition letter to hold over an interval if and only if it holds over all its points). We first prove that the problem belongs to **PSPACE** by exploiting a suitable contraction method. In addition, we prove that the proposed satisfiability checking algorithm can be turned into a **PSPACE** model checking procedure for D formulas over finite Kripke structures (under the homogeneity assumption); **PSPACE**-hardness of both problems follows via a reduction from the language universality problem of nondeterministic finite-state automata. **PSPACE**-completeness of D model checking strongly contrasts with the case of BE, for which only a nonelementary model checking procedure is known [12] and an **EXPSPACE**-hardness result has been given [2].

The rest of the paper is organized as follows. In Section 2, we provide some background knowledge. Then, in Section 3, we prove the **PSPACE** membership of the satisfiability problem for D over finite linear orders (under the homogeneity assumption). Finally, in Section 4, we show that the model checking problem for D over finite Kripke structures (again, under the homogeneity assumption) is in **PSPACE** as well.

All the proofs – here omitted because of lack of space – can be found in [3].

2 The logic D of the sub-interval relation

Let $\mathbb{S} = \langle S, < \rangle$ be a linear order. An *interval* over $\mathbb{S}$ is an ordered pair $[x, y]$, where $x \leq y$. We denote the set of all intervals over $\mathbb{S}$ by $\mathbb{I}(\mathbb{S})$. We consider three possible *sub-interval relations*: (i) the *reflexive* sub-interval relation (denoted as $\sqsubseteq$), defined by $[x, y] \sqsubseteq [x', y']$ iff $x' \leq x$ and $y \leq y'$, (ii) the *proper (or irreflexive)* sub-interval relation (denoted as $\sqsubset$), defined by $[x, y] \sqsubset [x', y']$ iff $[x, y] \sqsubseteq [x', y']$ and $[x, y] \neq [x', y']$, and (iii) the *strict* sub-interval relation (denoted as $\Subset$), defined by $[x, y] \Subset [x', y']$ iff $x' < x$ and $y < y'$.

The three modal logics $\text{D}_{\sqsubseteq}$, $\text{D}_{\sqsubset}$, and $\text{D}_{\Subset}$ feature the same language, consisting of a set $\mathcal{AP}$ of proposition letters/variables, the logical connectives $\neg$ and $\vee$, and the modal operator $\langle D \rangle$. Formally, formulae are defined by the grammar: $\varphi ::= p \mid \neg\varphi \mid \varphi \vee \varphi \mid \langle D \rangle \varphi$, with $p \in \mathcal{AP}$. The other connectives, as well as the logical constants $\top$ (true) and $\bot$ (false), are defined as usual; moreover, the dual universal modal operator $[D]\varphi$ is defined as $\neg\langle D \rangle \neg\varphi$. The length of a formula φ, denoted as $|\varphi|$, is the number of sub-formulas of φ.

The semantics of $\text{D}_{\Subset}$, $\text{D}_{\sqsubset}$, and $\text{D}_{\sqsubseteq}$ only differ in the interpretation of the $\langle D \rangle$ operator.

For the sake of brevity, we use $\circ \in \{\sqsubset, \sqsubset, \sqsubseteq\}$ as a shorthand for any of the three sub-interval relations. The semantics of a sub-interval logic $\mathrm{D}_\circ$ is defined in terms of *interval models* $\mathbf{M} = \langle \mathbb{I}(\mathbb{S}), \circ, \mathcal{V} \rangle$. The *valuation function* $\mathcal{V} : \mathcal{AP} \mapsto 2^{\mathbb{I}(\mathbb{S})}$ assigns to every proposition variable p the set of intervals $\mathcal{V}(p)$ over which p holds. The *satisfiability relation* $\models$ is defined as:

- for every proposition letter $p \in \mathcal{AP}$, $\mathbf{M}, [x,y] \models p$ iff $[x,y] \in \mathcal{V}(p)$;
- $\mathbf{M}, [x,y] \models \neg\psi$ iff $\mathbf{M}, [x,y] \not\models \psi$ (i.e., it is not true that $\mathbf{M}, [x,y] \models \psi$);
- $\mathbf{M}, [x,y] \models \psi_1 \vee \psi_2$ iff $\mathbf{M}, [x,y] \models \psi_1$ or $\mathbf{M}, [x,y] \models \psi_2$;
- $\mathbf{M}, [x,y] \models \langle D \rangle \psi$ iff there is an interval $[x',y'] \in \mathbb{I}(\mathbb{S})$ s.t. $[x',y'] \circ [x,y]$ and $\mathbf{M}, [x',y'] \models \psi$.

A $\mathrm{D}_\circ$-formula is $\mathrm{D}_\circ$-*satisfiable* if it holds over some interval of an interval model and it is $\mathrm{D}_\circ$-*valid* if it holds over every interval of every interval model.

In this paper, we restrict our attention to the finite satisfiability problem, that is, satisfiability over the class of finite linear orders. The problem has been shown to be *undecidable* for $\mathrm{D}_\sqsubset$ and $\mathrm{D}_\sqsubset$ [11] and *decidable* for $\mathrm{D}_\sqsubseteq$ [14]. In the following, we show that decidability can be recovered for $\mathrm{D}_\sqsubset$ and $\mathrm{D}_\sqsubset$ by restricting to the class of *homogeneous* interval models. We fully work out the case of $\mathrm{D}_\sqsubset$ (for the sake of simplicity, we will write D for $\mathrm{D}_\sqsubset$), and then we briefly explain how to adapt the proofs to $\mathrm{D}_\sqsubset$.

▶ **Definition 1.** A model $\mathbf{M} = \langle \mathbb{I}(\mathbb{S}), \circ, \mathcal{V} \rangle$ is homogeneous if, for every interval $[x,y] \in \mathbb{I}(\mathbb{S})$ and every $p \in \mathcal{AP}$, it holds that $[x,y] \in \mathcal{V}(p)$ iff $[x',x'] \in \mathcal{V}(p)$ for every $x \leq x' \leq y$.

Hereafter, we will refer to the logic D interpreted over homogeneous models as $\mathrm{D}|_{\mathcal{H}om}$.

2.1 A spatial representation of interval models

We now introduce some basic definitions and notation which will be extensively used in the following. Given a D-formula φ, we define the *closure of* φ, denoted by $\mathrm{CL}(\varphi)$, as the set of all sub-formulas ψ of φ and of their negations $\neg\psi$ (we identify $\neg\neg\psi$ with ψ).

▶ **Definition 2.** Given a D-formula φ, a φ-atom A is a subset of $\mathrm{CL}(\varphi)$ such that: (i) for every $\psi \in \mathrm{CL}(\varphi)$, $\psi \in A$ iff $\neg\psi \notin A$, and (ii) for every $\psi_1 \vee \psi_2 \in \mathrm{CL}(\varphi)$, $\psi_1 \vee \psi_2 \in A$ iff $\psi_1 \in A$ or $\psi_2 \in A$.

The idea underlying atoms is to enforce a "local" (or Boolean) form of consistency among the formulas it contains, that is, a φ-atom A is a *maximal, locally consistent subset* of $\mathrm{CL}(\varphi)$. As an example, $\neg(\psi_1 \vee \psi_2) \in A$ iff $\neg\psi_1 \in A$ and $\neg\psi_2 \in A$. However, note that the definition does not set any constraint on $\langle D \rangle \psi$ formulas, hence the word "local". We denote the set of all φ-atoms as $\mathcal{A}_\varphi$; its cardinality is clearly bounded by $2^{|\varphi|}$ (by point (i) of Definition 2). Atoms are connected by the following binary relation D_φ.

▶ **Definition 3.** Let D_φ be a binary relation over $\mathcal{A}_\varphi$ such that, for each pair of atoms $A, A' \in \mathcal{A}_\varphi$, $A \; D_\varphi \; A'$ holds iff both $\psi \in A'$ and $[D]\psi \in A'$ for each formula $[D]\psi \in A$.

Let A be a φ-atom. We denote by $\mathcal{R}eq_D(A)$ the set $\{\psi \in \mathrm{CL}(\varphi) : \langle D \rangle \psi \in A\}$ of "temporal requests" of A. In particular, if $\psi \notin \mathcal{R}eq_D(A)$, then $[D]\neg\psi \in A$ (by the definition of φ-atom). Moreover, we denote by REQ_φ the set of all arguments of $\langle D \rangle$-formulas in $\mathrm{CL}(\varphi)$, namely, $\mathrm{REQ}_\varphi = \{\psi : \langle D \rangle \psi \in \mathrm{CL}(\varphi)\}$. Finally, we denote by $\mathcal{O}bs_D(A)$ the set $\{\psi \in A : \psi \in \mathrm{REQ}_\varphi\}$ of observables of A. It is easy to prove by induction the next proposition, stating that, once the proposition letters of A and its temporal requests have been fixed, A gets unambiguously determined.

▶ **Proposition 4.** *For any* D*-formula* φ*, given a set* $R \subseteq \mathrm{REQ}_\varphi$ *and a set* $P \subseteq \mathrm{CL}(\varphi) \cap \mathcal{AP}$*, there exists a unique* φ*-atom* A *that satisfies* $\mathcal{R}eq_D(A) = R$ *and* $A \cap \mathcal{AP} = P$*.*

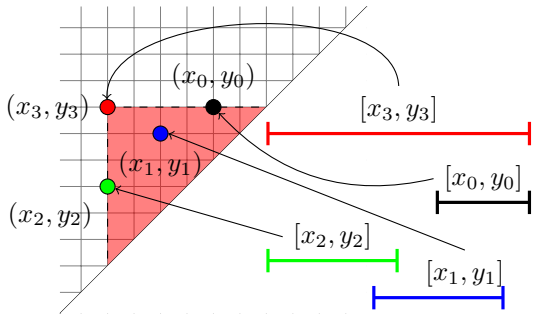

Figure 1 Correspondence between intervals and points of the compass structure.

We now provide a natural interpretation of D over grid-like structures, called *compass structures*, by exploiting the existence of a natural bijection between intervals $[x, y]$ and points (x, y), with $x \leq y$, of an $S \times S$ grid, where $\mathbb{S} = \langle S, < \rangle$ is a finite linear order. Such an interpretation was originally proposed by Venema in [17], and it can also be given for HS and all its (other) fragments.

As an example, Figure 1 shows four intervals $[x_0, y_0], \ldots, [x_3, y_3]$, respectively represented by the points in the grid $(x_0, y_0), \ldots, (x_3, y_3)$, such that: (i) $[x_0, y_0], [x_1, y_1], [x_2, y_2] \sqsubset [x_3, y_3]$, (ii) $[x_1, y_1] \sqsubset\!\!\!\cdot\, [x_3, y_3]$, and (iii) $[x_0, y_0], [x_2, y_2] \not\sqsubset [x_3, y_3]$. The red region highlighted in Figure 1 contains all and only the points (x, y) such that $[x, y] \sqsubset [x_3, y_3]$. Allen interval relation *contains* can thus be represented as a spatial relation between pairs of points. In the following, we make use of $\sqsubset$ also for relating points, i.e., given two points $(x, y), (x', y')$ of the grid, $(x', y') \sqsubset (x, y)$ iff $(x', y') \neq (x, y)$ and $x \leq x' \leq y' \leq y$. Compass structures, repeatedly exploited to establish the following complexity results, can be formally defined as follows.

▶ **Definition 5.** Given a finite linear order $\mathbb{S} = \langle S, < \rangle$ and a D-formula φ, a *compass φ-structure* is a pair $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, where $\mathbb{P}_\mathbb{S}$ is the set of points of the form (x, y), with $x, y \in S$ and $x \leq y$, and $\mathcal{L}$ is a function that maps any point $(x, y) \in \mathbb{P}_\mathbb{S}$ to a φ-atom $\mathcal{L}(x, y)$ in such a way that for all pairs of points $(x, y) \neq (x', y') \in \mathbb{P}_\mathbb{S}$, if $x \leq x' \leq y' \leq y$, then $\mathcal{L}(x, y)\ D_\varphi\ \mathcal{L}(x', y')$ (*temporal consistency*).

Due to temporal consistency, the following important property holds in compass structures.

▶ **Lemma 6.** *Given a compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, for all pairs of points $(x', y'), (x, y) \in \mathbb{P}_\mathbb{S}$, if $(x', y') \sqsubset (x, y)$, then $\mathcal{R}eq_D(\mathcal{L}(x', y')) \subseteq \mathcal{R}eq_D(\mathcal{L}(x, y))$ and $\mathcal{O}bs_D(\mathcal{L}(x', y')) \subseteq \mathcal{R}eq_D(\mathcal{L}(x, y))$.*

Fulfilling compass structures are defined as follows.

▶ **Definition 7.** A compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ is said to be *fulfilling* if, for every point $(x, y) \in \mathbb{P}_\mathbb{S}$ and each formula $\psi \in \mathcal{R}eq_D(\mathcal{L}(x, y))$, there exists a point $(x', y') \sqsubset (x, y)$ in $\mathbb{P}_\mathbb{S}$ such that $\psi \in \mathcal{L}(x', y')$.

Note that if $\mathcal{G}$ is fulfilling, then $\mathcal{R}eq_D(\mathcal{L}(x, x)) = \emptyset$ for all points "on the diagonal" $(x, x) \in \mathbb{P}_\mathbb{S}$.

We say that a compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ *features* a formula ψ if there exists a point $(x, y) \in \mathbb{P}_\mathbb{S}$ such that $\psi \in \mathcal{L}(x, y)$. The following result holds.

▶ **Proposition 8.** *A* D*-formula φ is satisfiable iff there is a fulfilling compass φ-structure that features it.*

In a fulfilling compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, where $S = \{0, \ldots, t\}$, w.l.o.g., we will sometimes assume φ to be satisfied by the maximal interval $[0, t]$, that is, $\varphi \in \mathcal{L}(0, t)$.

The notion of homogeneous models directly transfers to compass structures.

▶ **Definition 9.** A compass φ-structure $\mathcal{G} = (\mathbb{P}_{\mathbb{S}}, \mathcal{L})$ is *homogeneous* if, for every point $(x, y) \in \mathbb{P}_{\mathbb{S}}$ and each $p \in \mathcal{AP}$, we have that $p \in \mathcal{L}(x, y)$ iff $p \in \mathcal{L}(x', x')$ for all $x \leq x' \leq y$.

Proposition 8 can be tailored to homogeneous compass structures as follows.

▶ **Proposition 10.** *A* $\mathrm{D}|_{\mathcal{H}om}$*-formula* φ *is satisfiable iff there is a fulfilling homogeneous compass* φ*-structure that features it.*

3 Satisfiability of $\mathrm{D}|_{\mathcal{H}om}$ over finite linear orders

In this section, we devise a satisfiability checking procedure for $\mathrm{D}|_{\mathcal{H}om}$-formulas over finite linear orders, which will also allow us to easily derive a model checking algorithm for $\mathrm{D}|_{\mathcal{H}om}$ over finite Kripke structures. To start with, we show that there is a ternary relation between φ-atoms, that we denote by $\mathrel{=}^{D_\varphi}\!\!\rightarrow$, such that if it holds among all atoms in consecutive positions of a compass φ-structure, then the structure is fulfilling. Hence, we may say that $\mathrel{=}^{D_\varphi}\!\!\rightarrow$ is the rule for labeling fulfilling compasses. Next, we introduce an equivalence relation $\sim$ between *rows* of a compass φ-structure. Since it has finite index – exponentially bounded by $|\varphi|$ – and it preserves fulfillment of compasses, it is intuitively possible to "contract" the structures when we can find two related rows. Moreover, any contraction done according to $\sim$ keeps the same atoms (only the number of their occurrences may vary), and thus if a compass features φ before the contraction, then φ is still featured after it. This fact is exploited to build a satisfiability algorithm for $\mathrm{D}|_{\mathcal{H}om}$-formulas which makes use of *polynomial working space* only, because (i) it only needs to keep track of two rows of a compass at a time, (ii) all rows satisfy some nice properties that make it possible to succinctly encode them, and (iii) compass contractions are implicitly performed by means of a reachability check in a suitable graph, whose nodes are the equivalence classes of $\sim$.

Let us now introduce the aforementioned ternary relation $\mathrel{=}^{D_\varphi}\!\!\rightarrow$ among atoms.

▶ **Definition 11.** Given three φ-atoms A_1, A_2 and A_3, we say that A_3 is D_φ-generated by A_1, A_2 (written $A_1 A_2 \mathrel{=}^{D_\varphi}\!\!\rightarrow A_3$) if: (i) $A_3 \cap \mathcal{AP} = A_1 \cap A_2 \cap \mathcal{AP}$ and (ii) $\mathcal{R}eq_D(A_3) = \mathcal{R}eq_D(A_1) \cup \mathcal{R}eq_D(A_2) \cup \mathcal{O}bs_D(A_1) \cup \mathcal{O}bs_D(A_2)$.

It is immediate to check that $A_1 A_2 \mathrel{=}^{D_\varphi}\!\!\rightarrow A_3$ iff $A_2 A_1 \mathrel{=}^{D_\varphi}\!\!\rightarrow A_3$, that is, the order of the first two components in the ternary relation is irrelevant. The next result, following from Proposition 4, proves that $\mathrel{=}^{D_\varphi}\!\!\rightarrow$ expresses a *functional dependency* on φ-atoms.

▶ **Lemma 12.** *Given two* φ*-atoms* $A_1, A_2 \in \mathcal{A}_\varphi$*, there exists* exactly one φ*-atom* $A_3 \in \mathcal{A}_\varphi$ *such that* $A_1 A_2 \mathrel{=}^{D_\varphi}\!\!\rightarrow A_3$*.*

Definition 11 and Lemma 12 can be exploited to label a homogeneous compass φ-structure $\mathcal{G}$, namely, to determine the φ-atoms labeling all the points (x, y) of $\mathcal{G}$, starting from the ones on the diagonal. The idea is the following: if two φ-atoms A_1 and A_2 label respectively the greatest proper prefix $[x, y-1]$, that is, the point $(x, y-1)$, and the greatest proper suffix $[x+1, y]$, that is, $(x+1, y)$, of the same interval $[x, y]$, then the atom A_3 labeling $[x, y]$ is unique, and it is precisely the one satisfying $A_1 A_2 \mathrel{=}^{D_\varphi}\!\!\rightarrow A_3$ (see Figure 2). The next lemma proves that this is the general rule for labeling fulfilling homogeneous compasses.

▶ **Lemma 13.** *Let* $\mathcal{G} = (\mathbb{P}_{\mathbb{S}}, \mathcal{L})$*.* $\mathcal{G}$ *is a fulfilling homogeneous compass* φ*-structure iff, for every pair* $x, y \in S$*, we have: (i)* $\mathcal{L}(x, y-1)\mathcal{L}(x+1, y) \mathrel{=}^{D_\varphi}\!\!\rightarrow \mathcal{L}(x, y)$ *if* $x < y$*, and (ii)* $\mathcal{R}eq_D(\mathcal{L}(x, y)) = \emptyset$ *if* $x = y$*.*

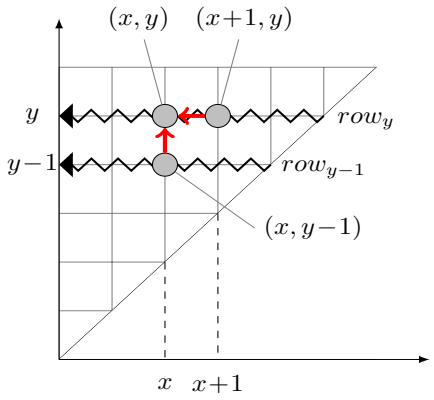

Figure 2 Rule for labeling homogeneous fulfilling compass φ-structures.

Now we introduce the concept of φ-row, which can be viewed as the ordered sequence of (the occurrences of) atoms labelling a row of a compass φ-structure. Given an atom $A \in \mathcal{A}_\varphi$, we call it *reflexive* if $A\ D_\varphi\ A$, *irreflexive* otherwise.

▶ **Definition 14.** A φ-row is a finite sequence of φ-atoms $row = A_0^{m_0} \cdots A_n^{m_n}$, where A^m stands for m repetitions of A, such that for each $0 \leq i \leq n$, we have that $m_i > 0$ – if $m_i > 1$, then A_i is reflexive – and for each $0 \leq j < i$, it holds that $A_i\ D_\varphi\ A_j$, $A_i \neq A_j$, and $(A_j \cap \mathcal{AP}) \supseteq (A_i \cap \mathcal{AP})$. Moreover, $\mathcal{R}eq_D(A_0) = \emptyset$.

The length of a φ-row $row = A_0^{m_0} \cdots A_n^{m_n}$ is defined as $|row| = \sum_{0 \leq i \leq n} m_i$, and for each $0 \leq j < |row|$, the j-th element, denoted by $row[j]$, is the j-th symbol in the word $A_0^{m_0} \cdots A_n^{m_n}$, e.g., $row[0] = A_0$, $row[m_0] = A_1$, ... We denote by $\mathcal{R}ows_\varphi$ the set of all possible φ-rows. This set may be infinite.

The number of distinct atoms in any φ-row is bounded. Since for each $0 \leq i \leq n$ and each $0 \leq j < i$, $A_i\ D_\varphi\ A_j$, it holds that $\mathcal{R}eq_D(A_j) \subseteq \mathcal{R}eq_D(A_i)$. Therefore, two monotonic sequences for every φ-row can be considered, one increasing, i.e., $\emptyset = \mathcal{R}eq_D(A_0) \subseteq \mathcal{R}eq_D(A_1) \subseteq \ldots \subseteq \mathcal{R}eq_D(A_n)$, and one decreasing, i.e., $(A_0 \cap \mathcal{AP}) \supseteq (A_1 \cap \mathcal{AP}) \supseteq \ldots \supseteq (A_n \cap \mathcal{AP})$. The number of distinct elements is bounded by $|\varphi|$ in the former sequence and by $|\varphi| + 1$ in the latter (as $|\,\mathrm{REQ}_\varphi\,| \leq |\varphi| - 1$ and $|\mathcal{AP}| \leq |\varphi|$–w.l.o.g., we can consider only the letters actually occurring in φ). Since, as already shown (Proposition 4), a set of requests and a set of proposition letters uniquely determine a φ-atom, any φ-row may feature at most $2|\varphi|$ distinct atoms, i.e., $n < 2|\varphi|$.

Given a homogeneous compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, for every $y \in S$, we define row_y as the word of φ-atoms $row_y = \mathcal{L}(y, y) \cdots \mathcal{L}(0, y)$, i.e., the sequence of atoms labeling points of $\mathcal{G}$ with the same y-coordinate, starting from the one on the diagonal inwards (see Figure 2).

▶ **Lemma 15.** *Let $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ be a fulfilling homogeneous compass φ-structure. For every $y \in S$, row_y is a φ-row.*

We now define the *successor* relation between pairs of φ-rows, denoted as $=^{row_\varphi}\!\!\rightarrow$, which is basically a component-wise application of $=^{D_\varphi}\!\!\rightarrow$ over the elements of two φ-rows (remember that atoms on rows are collected from right to left).

▶ **Definition 16.** Given two φ-rows row and row', we say that row' is a *successor* of row, or $row =^{row_\varphi}\!\!\rightarrow row'$, if $|row'| = |row| + 1$, and for all $0 \leq i < |row|$, $row[i] row'[i] =^{D_\varphi}\!\!\rightarrow row'[i+1]$.

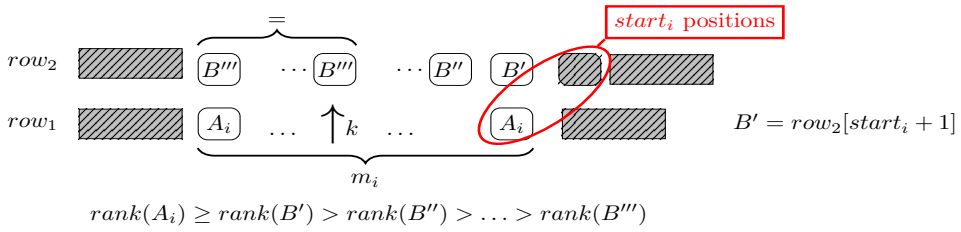

Figure 3 A graphical account of the proof of Lemma 18.

The next lemma states that consecutive rows in homogeneous fulfilling compass φ-structures respect the successor relation.

▶ **Lemma 17.** *Let $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, with $\mathcal{R}eq_D(\mathcal{L}(x,x)) = \emptyset$ for all $(x,x) \in \mathbb{P}_\mathbb{S}$. $\mathcal{G}$ is a fulfilling homogeneous compass φ-structure iff, for each $0 \leq y < |S| - 1$, $row_y =^{row_\varphi}\!\!\Rightarrow row_{y+1}$.*

Given an atom $A \in \mathcal{A}_\varphi$, we define the *rank of A*, written $rank(A)$, as $|\,\mathrm{REQ}_\varphi\,| - |\mathcal{R}eq_D(A)|$. Clearly, $rank(A) < |\varphi|$. Whenever $A\ D_\varphi\ A'$, for some $A' \in \mathcal{A}_\varphi$, $\mathcal{R}eq_D(A') \subseteq \mathcal{R}eq_D(A)$, and hence $rank(A) \leq rank(A')$ and $|\mathcal{R}eq_D(A) \setminus \mathcal{R}eq_D(A')| \leq rank(A')$. We can see the *rank* of an atom as the "number of degrees of freedom" that it gives to the atoms that stay "above it". In particular, by definition, for every φ-row $row = A_0^{m_0} \cdots A_n^{m_n}$, we have $rank(A_0) \geq \ldots \geq rank(A_n)$. The next result uses the notion of rank to provide an insight on how consecutive φ-rows are connected (see Figure 3).

▶ **Lemma 18.** *Let row_1, row_2 be two φ-rows, with $row_1 = A_0^{m_0} \cdots A_n^{m_n}$ and $row_1 =^{row_\varphi}\!\!\Rightarrow row_2$. For each $0 \leq i \leq n$, let $start_i = \sum_{0 \leq j < i} m_j$. If $m_i > rank(A_i)$, then there exists $start_i < k \leq start_i + m_i$ such that: (i) $row_2[k]$ is reflexive; (ii) $rank(row_2[j]) > rank(row_2[j+1])$ for each $start_i < j < k$; (iii) $row_2[j] = row_2[j+1]$ for each $k \leq j < start_i + m_i$; (iv) if m' is the exponent of the atom $row_2[k]$, then $m' > rank(row_2[k])$.*

Proof. If $m_i = 1$, by hypothesis we have $rank(A_i) = 0$. Hence, $rank(row_2[start_i + 1]) = 0$, because $row_1 =^{row_\varphi}\!\!\Rightarrow row_2$, and thus $row_2[start_i + 1]$ is (trivially) reflexive. All claims hold by choosing $k = start_i + 1$.

Let us then assume $m_i > 1$. First, we prove that for each $start_i < j \leq start_i + m_i$, if $row_2[j]$ is reflexive, then for each $j \leq j' \leq start_i + m_i$, $row_2[j'] = row_2[j]$. If $j = start_i + m_i$ there is nothing to prove. Thus, let us consider $j < start_i + m_i$. Since we are assuming that $row_2[j]$ is reflexive, then $\mathcal{O}bs_D(row_2[j]) \subseteq \mathcal{R}eq_D(row_2[j])$. Since $row_1 =^{row_\varphi}\!\!\Rightarrow row_2$, we have that $\mathcal{R}eq_D(A_i), \mathcal{O}bs_D(A_i) \subseteq \mathcal{R}eq_D(row_2[j])$, and $\mathcal{R}eq_D(row_2[j+1]) = \mathcal{R}eq_D(row_2[j]) \cup \mathcal{O}bs_D(row_2[j]) \cup \mathcal{R}eq_D(A_i) \cup \mathcal{O}bs_D(A_i) = \mathcal{R}eq_D(row_2[j])$. Moreover, again from $row_1 =^{row_\varphi}\!\!\Rightarrow row_2$, we have that $row_2[j] \cap \mathcal{AP} = row_2[j-1] \cap A_i \cap \mathcal{AP}$ and $row_2[j+1] \cap \mathcal{AP} = row_2[j] \cap A_i \cap \mathcal{AP} = row_2[j-1] \cap A_i \cap \mathcal{AP}$. Thus, $row_2[j+1] = row_2[j]$, because the two atoms feature exactly the same requests and proposition letters (Proposition 4). Then, since $A_i\ row_2[j] =^{D_\varphi}\!\!\Rightarrow row_2[j+1]$, by iterating the reasoning and exploiting Lemma 12 we can conclude that $row_2[j] = row_2[j']$ for each $j \leq j' \leq start_i + m_i$.

Now, it can be easily shown that if we have two atoms A and A' such that $A\ D_\varphi\ A'$ and A' is irreflexive, then $rank(A) < rank(A')$, and we have just proved that we cannot interleave reflexive atoms with irreflexive ones "above" the A_i's (all irreflexive atoms must "come before" reflexive ones in the part of row_2 "above" the A_i's). Thus, in the worst possible case, the atoms $row_2[start_i + 1], \ldots, row_2[start_i + rank(A_i)]$ may be irreflexive (as $rank(row_2[start_i + 1]) > \ldots > rank(row_2[start_i + rank(A_i)])$ and $rank(A_i) \geq rank(row_2[start_i + 1])$). Note that these irreflexive atoms may be the "first" $rank(A_i)$ atoms above the A_i's only, and not the

"first" $rank(A_i)+1$, since any atom with rank equal to 0 is reflexive. We conclude that $row_2[start_i+rank(A_i)+1]$ must be reflexive. Thus, we can choose $k = start_i+rank(A_i)+1$. Since by hypothesis $m_i \geq rank(A_i)+1$, we get that $start_i < k \leq start_i + m_i$.

As for the last claim, we have that $rank(row_2[k]) \leq rank(row_2[start_i+1]) - (k - start_i - 1) \leq rank(A_i) - (k - start_i - 1)$. Then, the exponent m' of $row_2[k]$ is such that $m' \geq m_i - (rank(A_i) - rank(row_2[k]))$, that is, at least $m_i - (rank(A_i) - rank(row_2[k]))$ atoms labelled by $row_2[k]$ occur in the block $start_i+1, \ldots, start_i+m_i$ of row_2 (see Figure 3). Since by hypothesis $m_i > rank(A_i)$, then $m_i - rank(A_i) > 0$ and $rank(row_2[k]) < m'$. ◀

Now we introduce an equivalence relation $\sim$ over $\mathcal{R}ows_\varphi$ which is the key ingredient of the proofs showing that both satisfiability and MC for D$|_{\mathcal{H}om}$-formulas are decidable.

▶ **Definition 19.** Given two φ-rows $row_1 = A_0^{m_0} \cdots A_n^{m_n}$ and $row_2 = \hat{A}_0^{\hat{m}_0} \cdots \hat{A}_{\hat{n}}^{\hat{m}_{\hat{n}}}$, we say that they are *equivalent*, written $row_1 \sim row_2$, if (i) $n = \hat{n}$, and (ii) for each $0 \leq i \leq n$, $A_i = \hat{A}_i$, and $m_i = \hat{m}_i$ or both m_i and $\hat{m}_i$ are (strictly) greater than $rank(A_i)$.

Note that if two rows feature the same set of atoms, the lower the rank of an atom A_i, the lower the number of occurrences of A_i both the rows have to feature in order to belong to the same equivalence class. As an example, let row_1 and row_2 be two rows with $row_1 = A_0^{m_0}A_1^{m_1}$, $row_2 = A_0^{\overline{m}_0}A_1^{\overline{m}_1}$, $rank(A_0) = 4$, and $rank(A_1) = 3$. If $m_1 = 4$ and $\overline{m}_1 = 5$ they are both greater than $rank(A_1)$, and hence they do not violate the condition for $row_1 \sim row_2$. On the other hand, if $m_0 = 4$ and $\overline{m}_0 = 5$, we have that m_0 is less than or equal to $rank(A_0)$. Thus, in this case, $row_1 \not\sim row_2$ due to the indexes of A_0. This happens because $rank(A_0)$ is greater than $rank(A_1)$. Two cases in which $row_1 \sim row_2$ are $m_0 = \overline{m}_0$ and $m_0, \overline{m}_0 \geq 5$.

The relation $\sim$ has finite index, which is roughly bounded by the number of all the possible φ-rows $row = A_0^{m_0} \cdots A_n^{m_n}$, with exponents m_i ranging from 1 to $|\varphi|$. Since (i) the number of possible atoms is $2^{|\varphi|}$, (ii) the number of *distinct* atoms in any φ-row is at most $2|\varphi|$, and (iii) the number of possible functions $f : \{1, \ldots, \ell\} \to \{1, \ldots, |\varphi|\}$ is $|\varphi|^\ell$, we have that the number of distinct equivalence classes of $\sim$ is bounded by

$$\sum_{j=1}^{2|\varphi|} (2^{|\varphi|})^j \cdot |\varphi|^j \leq 2^{3|\varphi|^2},$$

which is exponential in the length of the input formula φ. We denote the set of the equivalence classes of $\sim$ over all the possible φ-rows by $\mathcal{R}ows_\varphi^\sim$.

Now we extend the relation $=^{row_\varphi}\!\!\Rightarrow$ to equivalence classes of $\sim$ in the following way.

▶ **Definition 20.** Given two φ-row classes $[row_1]_\sim$ and $[row_2]_\sim$, we say that $[row_2]_\sim$ is a successor of $[row_1]_\sim$, written $[row_1]_\sim =^{row_\varphi}\!\!\Rightarrow [row_2]_\sim$, if there exist $row_1' \in [row_1]_\sim$ and $row_2' \in [row_2]_\sim$ such that $row_1' =^{row_\varphi}\!\!\Rightarrow row_2'$.

The following result proves that if some $row_1' \in [row_1]_\sim$ has a successor in $[row_2]_\sim$, then *every* φ*-row* of $[row_1]_\sim$ has a successor in $[row_2]_\sim$.

▶ **Lemma 21.** *Given two* φ*-row classes* $[row_1]_\sim$ *and* $[row_2]_\sim$ *such that* $[row_1]_\sim =^{row_\varphi}\!\!\Rightarrow [row_2]_\sim$, for every $row \in [row_1]_\sim$ *there exists* $row' \in [row_2]_\sim$ *such that* $row =^{row_\varphi}\!\!\Rightarrow row'$.

The proof, omitted for space reasons, begins by considering two φ-rows, row and $\overline{row}$, such that $row \in [row_1]_\sim$, $\overline{row} \in [row_2]_\sim$, and $row =^{row_\varphi}\!\!\Rightarrow \overline{row}$ (such a pair always exists by Definition 20). Then, we consider another φ-row, $row' \neq row$ in $[row_1]_\sim$, and we show (constructively) how to build $\overline{row}' \in [row_2]_\sim$ such that $row' =^{row_\varphi}\!\!\Rightarrow \overline{row}'$. This is sufficient to

Input: a D$|_{\mathcal{H}om}$-formula φ

1. Put $M \leftarrow 2^{3|\varphi|^2}$, $step \leftarrow 0$ and $row \leftarrow A$ for some atom $A \in \mathcal{A}_\varphi$ with $\mathcal{R}eq_D(A) = \emptyset$.
2. If there exists $0 \leq i < |row|$ such that $\varphi \in row[i]$, return **satisfiable**.
3. If $step = M - 1$, return **unsatisfiable**.
4. Non-deterministically generate a φ-row row' and check that $row =^{row_\varphi}\!\!\Rightarrow row'$.
5. Put $step \leftarrow step + 1$ and $row \leftarrow row'$.
6. Go back to 2.

Figure 4 Non-deterministic procedure deciding the satisfiability of a D$|_{\mathcal{H}om}$-formula φ.

prove the claim: $\overline{row}'$ is built by making use of the facts that $row' \sim row$ and $row =^{row_\varphi}\!\!\Rightarrow \overline{row}$, and of the properties stated by Lemma 18.

The following result arranges the equivalence classes $\mathcal{R}ows_\varphi^\sim$ in a graph $G_{\varphi\sim}$.

▶ **Definition 22.** Let φ be a D$|_{\mathcal{H}om}$-formula. The $\varphi\sim$*graph* of φ is the graph $G_{\varphi\sim} = (\mathcal{R}ows_\varphi^\sim, =^{row_\varphi}\!\!\Rightarrow)$.

The next theorem reduces the problem of satisfiability checking for a D$|_{\mathcal{H}om}$-formula φ over finite linear orders (equivalent, by Proposition 10, to deciding if there is a homogeneous fulfilling compass φ-structure that features φ) to a reachability problem in the $\varphi\sim$graph, allowing us to determine the computational complexity of the former problem.

▶ **Theorem 23.** *Given a* D$|_{\mathcal{H}om}$*-formula φ, there exists a homogeneous fulfilling compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ that features φ iff there exists a path in $G_{\varphi\sim} = (\mathcal{R}ows_\varphi^\sim, =^{row_\varphi}\!\!\Rightarrow)$ from some class $[row]_\sim \in \mathcal{R}ows_\varphi^\sim$ to some class $[row']_\sim \in \mathcal{R}ows_\varphi^\sim$ such that* (1) *there exists $row_1 \in [row]_\sim$ with $|row_1| = 1$, and* (2) *there exist $row_2 \in [row']_\sim$ and $0 \leq i < |row_2|$ such that $\varphi \in row_2[i]$.*

Proof. Preliminarily we observe that, in (1), if $|row_1| = 1$, then $\{row_1\} = [row]_\sim$; moreover, in (2), if for $row_2 \in [row']_\sim$ and $0 \leq i < |row_2|$ we have that $\varphi \in row_2[i]$, then for any $row_2' \in [row']_\sim$, there is $0 \leq i' < |row_2'|$ such that $\varphi \in row_2'[i']$.

($\Rightarrow$) Let us consider a homogeneous fulfilling compass φ-structure $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ that features φ. By Lemmata 15 and 17, $\mathcal{L}(0,0) =^{row_\varphi}\!\!\Rightarrow row_1 =^{row_\varphi}\!\!\Rightarrow \cdots =^{row_\varphi}\!\!\Rightarrow row_{\max(S)}$. Thus there exist two indexes $0 \leq j \leq \max(S)$ and $0 \leq i < |row_j|$ for which $\varphi \in row_j[i]$. By Definition 20, we get that $[\mathcal{L}(0,0)]_\sim =^{row_\varphi}\!\!\Rightarrow [row_1]_\sim =^{row_\varphi}\!\!\Rightarrow \cdots =^{row_\varphi}\!\!\Rightarrow [row_j]_\sim$ is a path in $G_{\varphi\sim}$; it is immediate to check that it fulfils requirements (1) and (2).

($\Leftarrow$) Let us assume there exists a path $[row_0]_\sim =^{row_\varphi}\!\!\Rightarrow \cdots =^{row_\varphi}\!\!\Rightarrow [row_m]_\sim$ in $G_{\varphi\sim} = (\mathcal{R}ows_\varphi^\sim, =^{row_\varphi}\!\!\Rightarrow)$ for which $|row_0| = 1$ and there exists i such that $\varphi \in row_m[i]$. By applying repeatedly Lemma 21 we get that there exists a sequence $row_0' =^{row_\varphi}\!\!\Rightarrow \cdots =^{row_\varphi}\!\!\Rightarrow row_m'$ of φ-rows where $row_0' = row_0$, for every $0 \leq j \leq m$, $row_j' \in [row_j]_\sim$, and there exists i' such that $\varphi \in row_m'[i']$. We observe that, by Definition 16, $|row_j'| = |row_{j-1}'| + 1$ for $1 \leq j \leq m$ and, since $|row_0'| = 1$, we have $|row_j'| = j + 1$. Let us now define $\mathcal{G} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$ where $S = \{0, \ldots, m\}$ and $\mathcal{L}(x,y) = row_y'[y - x]$ for every $0 \leq x \leq y \leq m$. By Lemma 17, $\mathcal{G}$ is a fulfilling homogeneous compass φ-structure. Finally, since $\varphi \in row_m'[i']$, $\mathcal{G}$ features φ. ◀

The size of $G_{\varphi\sim} = (\mathcal{R}ows_\varphi^\sim, =^{row_\varphi}\!\!\Rightarrow)$ is bounded by $|\mathcal{R}ows_\varphi^\sim|^2$, which is exponential in $|\varphi|$. However, it is possible to (non-deterministically) perform a reachability in $G_{\varphi\sim}$ by using space *logarithmic* in $|\mathcal{R}ows_\varphi^\sim|^2$. The *non-deterministic* procedure of Figure 4 exploits this fact in order to decide the satisfiability of a D$|_{\mathcal{H}om}$-formula φ, by using only a working space

polynomial in $|\varphi|$: it searches for a suitable path in $G_{\varphi\sim}$, $[row_0]_\sim \Rightarrow^{row_\varphi} \cdots \Rightarrow^{row_\varphi} [row_m]_\sim$, where $row_0 = A$ for $A \in \mathcal{A}_\varphi$ with $\mathcal{R}eq_D(A) = \emptyset$, $m < M$, and $\varphi \in row_m[i]$ for $0 \leq i < |row_m|$. At the j-th iteration of line 4., row_j is non-deterministically generated, and it is checked whether $row_{j-1} \Rightarrow^{row_\varphi} row_j$. The procedure terminates after at most M iterations, where M is the maximum possible length of a simple path in $G_{\varphi\sim}$.

The working space used by the procedure is polynomial: M and *step* (which ranges in $[0, M-1]$) can be encoded in binary with $\lceil \log_2 M \rceil + 1 = O(|\varphi|^2)$ bits. At each step, we need to keep track of two φ-rows at a time, the current one, *row*, and its successor, *row*$'$: each φ-row can be represented as a sequence of at most $2|\varphi|$ (distinct) atoms, each one with an exponent that, by construction, cannot exceed M. Moreover, each φ-atom A can be represented using exactly $|\varphi|$ bits (for each $\psi \in \mathrm{CL}(\varphi)$, we set a bit to 1 if $\psi \in A$, and to 0 if $\neg\psi \in A$). Hence a φ-row can be encoded using $2|\varphi| \cdot (|\varphi| + \lceil \log_2 M \rceil + 1) = O(|\varphi|^3)$ bits. Finally, the condition $row \Rightarrow^{row_\varphi} row'$ can be checked by $O(|\varphi|^2)$ bits of space once we have guessed *row*$'$. This analysis entails the following result (we recall that **NPSPACE** = **PSPACE**).

▶ **Theorem 24.** *The satisfiability problem for* $\mathrm{D}|_{\mathcal{H}om}$*-formulas over finite linear orders is in* ***PSPACE****.*

We now outline which are the modifications to the previous concepts needed for proving the decidability of satisfiability for $\mathrm{D}|_{\mathcal{H}om}$ with the strict relation $\boxdot$, in place of $\sqsubset$. It is sufficient to replace the definitions of $\Rightarrow^{D_\varphi}$, φ-*row* and $\Rightarrow^{row_\varphi}$ with the following ones. For the sake of simplicity, we introduce a dummy atom $\boxdot$, for which we assume $\mathcal{R}eq_D(\boxdot) = \mathcal{O}bs_D(\boxdot) = \emptyset$.

▶ **Definition 25.** Given $A_1, A_3, A_4 \in \mathcal{A}_\varphi$ and $A_2 \in \mathcal{A}_\varphi \cup \{\boxdot\}$, we say that A_4 is $D_\varphi\, \boxdot$-generated by A_1, A_2, A_3, written $A_1, A_2, A_3 \Rightarrow^{D_\varphi \boxdot} A_4$ iff (i) $A_4 \cap \mathcal{AP} = A_1 \cap A_3 \cap \mathcal{AP}$ and (ii) $\mathcal{R}eq_D(A_4) = \mathcal{R}eq_D(A_1) \cup \mathcal{R}eq_D(A_3) \cup \mathcal{O}bs_D(A_2)$.

The idea of this definition is that, if an interval $[x, y]$, with $x < y$, is labeled by A_4, and the three subintervals $[x, y-1]$, $[x+1, y-1]$, and $[x+1, y]$ by A_1, A_2, A_3, resp., we want $A_1, A_2, A_3 \Rightarrow^{D_\varphi \boxdot} A_4$. In particular, if $x = y - 1$, then $A_2 = \boxdot$ (because $[x+1, y-1]$ is not a valid interval). Note that only $[x+1, y-1] \boxdot [x, y]$, hence we want $\mathcal{O}bs_D(A_2) \subseteq \mathcal{R}eq_D(A_4)$; moreover, since the requests of A_1 and A_3 are fulfilled by a strict subinterval of $[x, y]$, it must be $\mathcal{R}eq_D(A_1) \subseteq \mathcal{R}eq_D(A_4)$ and $\mathcal{R}eq_D(A_3) \subseteq \mathcal{R}eq_D(A_4)$.

▶ **Definition 26.** A φ-$\boxdot$-row is a finite sequence of φ-atoms $row = A_0^{m_0} \cdots A_n^{m_n}$ such that for every $0 \leq i \leq n$ we have $m_i > 0$, and for every $0 \leq j < i$, $\mathcal{R}eq_D(A_j) \subseteq \mathcal{R}eq_D(A_i)$, $A_i \neq A_j$, and $(A_j \cap \mathcal{AP}) \supseteq (A_i \cap \mathcal{AP})$. Moreover $\mathcal{R}eq_D(A_0) = \emptyset$.

▶ **Definition 27.** Given two φ-rows *row* and *row*$'$, we say that *row*$'$ is a successor of *row*, denoted as $row \Rightarrow^{row_\varphi \boxdot} row'$, if $|row'| = |row| + 1$, and for every $0 \leq i < |row|$, $row[i]row[i-1]row'[i] \Rightarrow^{D_\varphi \boxdot} row'[i+1]$, where we assume $row[i-1] = \boxdot$ if $i = 0$.

We conclude the section by stating the **PSPACE**-completeness of satisfiability for $\mathrm{D}|_{\mathcal{H}om}$ over finite linear orders (under both the *strict* and the *proper* semantic variants). The hardness proof can be found in [3].

▶ **Theorem 28.** *The satisfiability problem for* $\mathrm{D}|_{\mathcal{H}om}$*-formulas over finite linear orders is* ***PSPACE****-complete.*

4 Model checking for $\mathrm{D}|_{\mathcal{H}om}$ over Kripke structures

In this section we focus our attention on the *model checking (MC)* problem for $\mathrm{D}|_{\mathcal{H}om}$, namely, the problem of checking whether some behavioural properties, expressed as $\mathrm{D}|_{\mathcal{H}om}$-formulas,

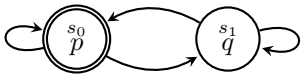

Figure 5 Kripke structure $\mathcal{K}_2$.

are satisfied by a model of a given system. The typical models are *Kripke structures*, which will now be introduced along with the semantic definition of $\mathrm{D}|_{\mathcal{H}om}$ over them.

▶ **Definition 29.** A *finite Kripke structure* is a tuple $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$, where $\mathcal{AP}$ is a finite set of proposition letters, W is a finite set of states, $E \subseteq W \times W$ is a left-total relation between states, $\mu : W \to 2^{\mathcal{AP}}$ is a total labelling function, and $s_0 \in W$ is the initial state.

For all $s \in W$, $\mu(s)$ is the set of proposition letters that hold on s, while E is the transition relation that describes the evolution of the system over time.

Figure 5 depicts the finite Kripke structure $\mathcal{K}_2 = (\{p, q\}, \{s_0, s_1\}, E, \mu, s_0)$, with $E = \{(s_0,s_0),(s_0,s_1),(s_1,s_0),(s_1,s_1)\}$, $\mu(s_0) = \{p\}$, and $\mu(s_1) = \{q\}$. The initial state s_0 is identified by a double circle.

▶ **Definition 30.** A *trace* ρ of a finite Kripke structure $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$ is a finite sequence of states $s_1 \cdots s_n$, with $n \geq 1$, such that $(s_i, s_{i+1}) \in E$ for $i = 1, \ldots, n-1$.

For any trace $\rho = s_1 \cdots s_n$, we define: (i) $|\rho| = n$, and for $0 \leq i \leq |\rho| - 1$, $\rho(i) = s_{i+1}$; (ii) $\rho(i, j) = s_{i+1} \cdots s_{j+1}$, for $0 \leq i \leq j \leq |\rho| - 1$, is the subtrace of ρ bounded by i and j. Finally, if the first state of ρ is s_0 (the initial state of $\mathcal{K}$), ρ is called an *initial trace*.

▶ **Definition 31.** The interval model $\mathbf{M}_\rho = \langle \mathbb{I}(\mathbb{S}), \circ, \mathcal{V} \rangle$ *induced by a trace* ρ of a finite Kripke structure $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$ is the homogeneous interval model such that:
(i) $S = \{0, \ldots, |\rho| - 1\}$, and (ii) for all $x \in S$ and $p \in \mathcal{AP}$: $[x, x] \in \mathcal{V}(p)$ iff $p \in \mu(\rho(x))$.

▶ **Definition 32.** Let $\mathcal{K}$ be a finite Kripke structure and ψ be a $\mathrm{D}|_{\mathcal{H}om}$-formula. We say that a trace $\rho(i, j)$ of $\mathcal{K}$ satisfies ψ, denoted as $\mathcal{K}, \rho(i, j) \models \psi$, iff $\mathbf{M}_\rho, [i, j] \models \psi$. Moreover, we say that $\mathcal{K}$ models ψ, written $\mathcal{K} \models \psi$, iff for all *initial* traces ρ' of $\mathcal{K}$, it holds that $\mathcal{K}, \rho' \models \psi$. The *MC problem* for $\mathrm{D}|_{\mathcal{H}om}$ over finite Kripke structures is the problem of deciding if $\mathcal{K} \models \psi$.

Note that $p \in \mathcal{AP}$ holds over $\rho = s_1 \cdots s_n$ iff it holds over all the states $s_1, \ldots, s_n$ of ρ (*homogeneity assumption*). Since the number of initial traces of $\mathcal{K}$ is infinite, MC for $\mathrm{D}|_{\mathcal{H}om}$ over Kripke structures is not trivially decidable. We now describe how, with a slight modification of the previous satisfiability procedure, it is possible to derive a MC algorithm for $\mathrm{D}|_{\mathcal{H}om}$-formulas φ over finite Kripke structures $\mathcal{K}$. The idea is to consider some finite linear orders – not all the possible ones, unlike the case of satisfiability – precisely those corresponding to (some) initial traces of $\mathcal{K}$, checking whether $\neg\varphi$ holds over them: in such a case we have found a counterexample, and we can conclude that $\mathcal{K} \not\models \varphi$. To ensure this kind of "satisfiability driven by the traces of $\mathcal{K}$", we make a product between $\mathcal{K}$ and the previous graph $G_{\varphi\sim}$, getting what we call a "$(\varphi \sim \mathcal{K})$-*graph*". In the following, we will also exploit the notion of "compass structure *induced by a trace* ρ of $\mathcal{K}$", which is a fulfilling homogeneous compass φ-structure built from ρ and completely determined by it.

Given a finite Kripke structure $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$ and a $\mathrm{D}|_{\mathcal{H}om}$-formula φ, we consider the $(\varphi \sim \mathcal{K})$-graph $G_{\varphi\sim\mathcal{K}}$, which is basically the product of $\mathcal{K}$ and $G_{\varphi\sim} = (\mathcal{R}ows^{\sim}_{\varphi}, {}^{=row_\varphi}\!\!\rightarrow)$, formally defined as: $G_{\varphi\sim\mathcal{K}} = (\Gamma, \Xi)$, where:

- Γ is the maximal subset of $W \times \mathcal{R}ows^{\sim}_{\varphi}$ s.t.: if $(s, [row]_\sim) \in \Gamma$ then $\mu(s) = row[0] \cap \mathcal{AP}$;
- $\big((s_1, [row_1]_\sim), (s_2, [row_2]_\sim)\big) \in \Xi$ iff (i) $\big((s_1, [row_1]_\sim), (s_2, [row_2]_\sim)\big) \in \Gamma^2$, (ii) $(s_1, s_2) \in E$, and (iii) $[row_1]_\sim \, {}^{=row_\varphi}\!\!\rightarrow [row_2]_\sim$.

Input: a Kripke structure $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$, a D$|_{\mathcal{H}om}$-formula φ

1. Put $M \leftarrow |W| \cdot 2^{3|\varphi|^2}$, $step \leftarrow 0$ and $(s, row) \leftarrow (s_0, A)$ for some atom $A \in \mathcal{A}_\varphi$ with $\mathcal{R}eq_D(A) = \emptyset$ and $A \cap \mathcal{AP} = \mu(s_0)$.
2. If $\varphi \notin row[|row| - 1]$, return **yes**.
3. If $step = M - 1$, return **no**.
4. Non-deterministically choose s' such that $(s, s') \in E$.
5. Non-det. generate a φ-row row' and check that $row'[0] \cap \mathcal{AP} = \mu(s')$ and $row \,{}^{=row_\varphi}\!\!\rightarrow row'$.
6. Put $step \leftarrow step + 1$ and $(s, row) \leftarrow (s', row')$.
7. Go back to 2.

Figure 6 Non-deterministic procedure deciding the existence of initial traces ρ such that $\mathcal{K}, \rho \not\models \varphi$.

Note that the definition of Γ is well-given, since for all $row' \in [row]_\sim$, $row'[0] = row[0]$. The size of $G_{\varphi\sim\mathcal{K}}$ is bounded by $(|W| \cdot |\mathcal{R}ows^{\sim}_{\varphi}|)^2$.

Given a generic trace ρ of $\mathcal{K}$, we define the compass φ-structure *induced by* ρ as the fulfilling homogeneous compass φ-structure $\mathcal{G}_{(\mathcal{K},\rho)} = (\mathbb{P}_\mathbb{S}, \mathcal{L})$, where $S = \{0, \ldots, |\rho| - 1\}$, and for $0 \le x < |\rho|$, $\mathcal{L}(x, x) \cap \mathcal{AP} = \mu(\rho(x))$ and $\mathcal{R}eq_D(\mathcal{L}(x, x)) = \emptyset$. Note that, given ρ, $\mathcal{G}_{(\mathcal{K},\rho)}$ always exists and is unique: all φ-atoms $\mathcal{L}(x, x)$ "on the diagonal" are determined by the labeling of $\rho(x)$ (and by the absence of requests). Moreover, by Lemma 17, all the other atoms $\mathcal{L}(x, y)$, for $0 \le x < y < |\rho|$, are determined by the ${}^{=row_\varphi}\!\!\rightarrow$ relation between φ-rows.

The following property can easily be proved by induction.

▶ **Proposition 33.** *Given a Kripke structure $\mathcal{K}$, a trace ρ of $\mathcal{K}$, and a* D$|_{\mathcal{H}om}$*-formula φ, for all $0 \le x \le y < |\rho|$ and for all subformulas ψ of φ: $\mathcal{K}, \rho(x, y) \models \psi$ iff $\psi \in \mathcal{L}(x, y)$ in $\mathcal{G}_{(\mathcal{K},\rho)}$.*

We can now introduce Theorem 34, that can be regarded as a version of Theorem 23 for MC.

▶ **Theorem 34.** *Given a Kripke structure $\mathcal{K} = (\mathcal{AP}, W, E, \mu, s_0)$ and a* D$|_{\mathcal{H}om}$*-formula φ, there exists an initial trace ρ of $\mathcal{K}$ such that $\mathcal{K}, \rho \models \varphi$ iff there exists a path in $G_{\varphi\sim\mathcal{K}} = (\Gamma, \Xi)$ from some node $(s_0, [row]_\sim) \in \Gamma$ to some node $(s, [row']_\sim) \in \Gamma$ such that: (1) there is $row_1 \in [row]_\sim$ with $|row_1| = 1$, and (2) there is $row_2 \in [row']_\sim$ with $\varphi \in row_2[|row_2| - 1]$.*

Now, analogously to the case of satisfiability, we can perform a reachability in $G_{\varphi\sim\mathcal{K}}$, exploiting the previous theorem to decide whether there is an initial trace ρ of $\mathcal{K}$ such that $\mathcal{K}, \rho \models \neg\varphi$, for a D$|_{\mathcal{H}om}$-formula φ (i.e., the complementary problem of MC $\mathcal{K} \models \varphi$). The *non-deterministic* procedure of Figure 6 searches for a suitable path in $G_{\varphi\sim\mathcal{K}}$, $(s_0, [row_0]_\sim) \stackrel{\Xi}{\rightarrow} \cdots \stackrel{\Xi}{\rightarrow} (s_m, [row_m]_\sim)$, where $row_0 = A \in \mathcal{A}_\varphi$ with $\mathcal{R}eq_D(A) = \emptyset$, $A \cap \mathcal{AP} = \mu(s_0)$, $m < M$, and $\neg\varphi \in row_m[|row_m| - 1]$ (i.e., $\varphi \notin row_m[|row_m| - 1]$). At the j-th iteration of lines 4./5., $(s_{j-1}, s_j) \in E$ is selected, and row_j is non-deterministically generated checking that $row_j[0] \cap \mathcal{AP} = \mu(s_j)$ and $row_{j-1} \,{}^{=row_\varphi}\!\!\rightarrow row_j$.

Basically, the same observations about the working space of the procedure in Figure 4 can be done also for this algorithm, except for the space used to encode in binary $M \le |W| \cdot 2^{3|\varphi|^2}$ and *step*, ranging in $[0, M - 1]$, which is $O(\log |W| + |\varphi|^2)$ bits. Moreover we need to store two states, s and s' of $\mathcal{K}$, that need $O(\log |W|)$ bits to be represented.

▶ **Theorem 35.** *The MC problem for* D$|_{\mathcal{H}om}$*-formulas over finite Kripke structures is **PSPACE**-complete. Moreover, for constant-length formulas, it is **NLOGSPACE**-complete.*

Proof. Membership is immediate by the previous space analysis, and the fact that the complexity classes **NPSPACE** = **PSPACE** and **NLOGSPACE** are closed under complement.

As for the **PSPACE**-hardness, we make a reduction from the **PSPACE**-complete *problem of universality* of the language of an NFA [8]. The full proof can be found in [3]. For the **NLOGSPACE**-hardness, there exists a trivial reduction from the *problem of (non-)reachability* of two nodes in a directed graph. ◀

Finally, it is possible to adapt the procedure also for *strict* $\mathrm{D}|_{\mathcal{H}om}$ (by exploiting Definitions 25–27).

5 Conclusions

In this paper, we have shown that both satisfiability and model checking for the logic D of sub-intervals – over finite linear orders and finite Kripke structures, respectively – are **PSPACE**-complete, under the homogeneity assumption. We are investigating the possibility of generalizing the given procedures to cope with the logic BE: nothing is known about its satisfiability, while a large gap separates known upper and lower bounds for model checking.

Acknowledgements. We sincerely thank an anonymous reviewer for his/her thorough review and valuable comments, which significantly contributed to improving the quality of the publication – in particular for spotting a problem with the hardness proof of satisfiability in the submitted paper, and suggesting a possible solution.

Abstract

The *beyond worst-case synthesis problem* was introduced recently by Bruyère et al. [10]: it aims at building system controllers that provide strict worst-case performance guarantees against an antagonistic environment while ensuring higher expected performance against a stochastic model of the environment. Our work extends the framework of [10] and follow-up papers, which focused on quantitative objectives, by addressing the case of ω-regular conditions encoded as parity objectives, a natural way to represent functional requirements of systems.

We build strategies that satisfy a main parity objective on all plays, while ensuring a secondary one with sufficient probability. This setting raises new challenges in comparison to quantitative objectives, as one cannot easily mix different strategies without endangering the functional properties of the system. We establish that, for all variants of this problem, deciding the existence of a strategy lies in $\mathsf{NP} \cap \mathsf{coNP}$, the same complexity class as classical parity games. Hence, our framework provides additional modeling power while staying in the same complexity class.

1 Introduction

Beyond worst-case synthesis. *Two-player zero-sum games* [18, 21] and *Markov decision processes* (MDPs) [17, 4] are popular frameworks for decision making in adversarial and uncertain environments respectively. In the former, a system controller (player 1) and its environment (player 2) compete antagonistically, and synthesis aims at strategies that ensure a specified behavior *against all possible strategies of the environment*. In the latter, the system is faced with a given stochastic model of its environment, and the focus is on satisfying a given level of expected performance, or a *specified behavior with a sufficient probability*.

The *beyond worst-case synthesis* framework [10] unites both views: we look for strategies that provide both *strict worst-case guarantees* and a *good level of performance against the*

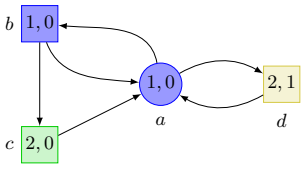

Figure 1 An MDP where player 1 can ensure p_1 surely and p_2 almost-surely.

stochastic model. Such requirements are natural in practical situations (e.g., see [9, 23] for applications to the shortest path problem). The original paper [10] dealt with mean-payoff and shortest path objectives. Follow-up work include, e.g., multi-dimensional extensions [14], optimization of the expected mean-payoff under hard Boolean constraints [1] or under energy constraints [7], or integration of beyond worst-case concepts in the tool Uppaal [15].

Parity objectives. We study the beyond worst-case problem for ω-regular conditions encoded as *parity objectives*. Parity games have been under close scrutiny for a long time due to their importance (e.g., they subsume modal μ-calculus model checking [16]) and their intriguing complexity: they belong to the class of problems in $\mathsf{NP} \cap \mathsf{coNP}$ [19] and despite many efforts (see [11] for pointers), whether they belong to P is still an open question.

In the aforementioned papers dealing with beyond worst-case problems, the focus was on *quantitative* objectives (e.g., mean-payoff). While it is usually the case that *qualitative* objectives, such as parity, are easier to deal with than quantitative ones, this is not true in the setting considered in this paper. Indeed, in the context of quantitative objectives, it is conceivable to alternate between two strategies along a play, such that one – efficient – strategy balances the performance loss due to playing the other – less efficient – strategy for a limited stretch of play infinitely often. In the context of qualitative objectives, this is no more possible in general, as one strategy may induce behaviors (such as invalidating the parity condition infinitely often) that can never be counteracted by the other one. Hence, in comparison, we need to define more elaborate analysis techniques to detect when satisfying *both* the worst-case and the probabilistic constraints with a single strategy is actually possible.

Example. Consider the MDP of Figure 1. Circle states are owned by player 1 (system) and square states are owned by player 2 (environment). In the stochastic model of the environment, square states are probabilistic, and, when not specified, we consider the uniform distribution over their successors. Each state is labelled with a name and two integers x, y representing priorities defined by two functions, p_1 and p_2. An infinite path in the graph is winning for player 1 and parity objective p_i, $i \in \{1, 2\}$, if the *maximal* priority seen infinitely often along the path for function p_i is *even*. We claim that player 1 has a strategy λ to ensure that (i) all plays consistent with λ satisfy p_1 (i.e., p_1 is surely satisfied) and (ii) the probability measure induced by λ on this MDP ensures that p_2 is satisfied with probability one (i.e., almost-surely).

One such λ is as follows. It plays an infinite sequence of rounds of n_i steps, $i \in \mathbb{N}$. In round i, in state a, the strategy chooses b for n_i steps, such that the probability to reach c during round i is larger than $1 - 2^{-i}$ (this is possible as at each step c is reached from b with probability $\frac{1}{2}$). If during round i, c is not reached (which can happen with a small probability) then λ goes to d once. Then the next round $i+1$ is started. This infinite-memory strategy ensures both (i) and (ii). Indeed, it can be shown that the probability that λ plays d infinitely often is zero. Also, during each round, the maximal priority for p_1 is guaranteed to be even because if c is not visited, d is systematically played.

Finally, we can prove that player 1 needs infinite memory to ensure p_1 surely and p_2 almost-surely, and also, that this is the best that player 1 can do here: he has no strategy to enforce surely both p_1 and p_2 at the same time.

Outline and contributions. We consider MDPs with two parity objectives (i.e., using different priority functions). We study the problem of deciding the existence of a strategy that ensures the first parity objective *surely* (i.e., on all plays) while yielding a *probability at least equal to (resp. greater than) a given rational threshold* to satisfy the second parity objective. In Section 2, we formally define the framework and recall important results from the literature. In Section 3, as an intermediate step, we solve the problem of ensuring the first parity objective surely while visiting a target set of states with sufficient probability: this tool will help us several times later. We prove that the corresponding decision problem is in $\mathsf{NP} \cap \mathsf{coNP}$ and at least as hard as parity games, and that finite-memory strategies are sufficient. In Section 4, we solve the problem for the two parity objectives, where the second one must hold *almost-surely* (i.e., with probability one). Our main tools are the novel notion of *ultra-good end-components*, as well as the reachability problem solved in Section 3. We generalize our approach to arbitrary probability thresholds in Section 5, in which we introduce the notion of *very-good end-components*. In both the almost-sure and the arbitrary threshold cases, we prove that the decision problem belongs to $\mathsf{NP} \cap \mathsf{coNP}$ and is at least as hard as parity games. In contrast to the reachability case, we prove that infinite memory is in general necessary. Full proofs are presented in the extended version of this paper [5].

Additional related work. The beyond worst-case synthesis framework illustrates the usefulness of non-zero-sum games for reactive synthesis [8, 22]. Other types of multi-objective specifications in stochastic models have been considered: e.g., percentile queries generalize the classical threshold probability problem to several dimensions [24]. In [3], Baier et al. study the quantitative analysis of MDPs under weak and strong fairness constraints. They provide algorithms for computing the probability for ω-regular properties in worst and best-case scenarios, when considering strategies that in addition satisfy weak or strong fairness constraints almost-surely. In contrast, we are able to consider similar objectives but for strategies that satisfy weak or strong fairness constraints surely, i.e., with certainty and not only with probability one. In [1], Almagor et al. consider the optimization of the expected mean-payoff under hard Boolean constraints in weighted MDPs. Our concept of ultra-good end-component builds upon their notion of super-good one. A reduction to mean-payoff parity games [12] is part of the identification process of both types of end-components.

2 Preliminaries

Directed graphs. A *directed graph* is a pair $G = (S, E)$ with S a set of vertices, called *states*, and $E \subseteq S \times S$ a set of directed edges. We focus here on *finite* graphs (i.e., $|S| < \infty$). Given a state $s \in S$, we denote by $\mathtt{Succ}(s) = \{s' \in S \mid (s, s') \in E\}$ the set of successors of s by edges in E. We assume that graphs are non-blocking, i.e., for all $s \in S$, $\mathtt{Succ}(s) \neq \emptyset$.

A *play* in G from an initial state $s \in S$ is an infinite sequence of states $\pi = s_0 s_1 s_2 \dots$ such that $s_0 = s$ and $(s_i, s_{i+1}) \in E$ for all $i \geq 0$. The *prefix* up to the $(n+1)$-th state of π is the finite sequence $\pi(0, n) = s_0 s_1 \dots s_n$. We resp. denote the first and last states of a prefix $\rho = s_0 s_1 \dots s_n$ by $\mathtt{First}(\rho) = s_0$ and $\mathtt{Last}(\rho) = s_n$. For a play π, we naturally extend the notation to $\mathtt{First}(\pi)$. Finally, for $i \in \mathbb{N}$, $\pi(i) = s_i$, and for $j > i$, $\pi(i, j) = s_i \dots s_j$. The set of plays of G is $\mathtt{Plays}(G)$ and the set of prefixes is $\mathtt{Pref}(G)$. For a set of plays Π, we

denote by $\texttt{Pref}(\Pi)$ the set of prefixes of these plays. Given two prefixes $\rho = s_0 \dots s_m$ and $\rho' = s'_0 \dots s'_n$ in $\texttt{Pref}(G)$, we denote their *concatenation* as $\rho \cdot \rho' = s_0 \dots s_m s'_0 \dots s'_n$. This is not necessarily a valid prefix of G. The same holds for a prefix concatenated with a play.

Probability distributions. Given a countable set A, a (rational) *probability distribution* on A is a function $p\colon A \to [0,1] \cap \mathbb{Q}$ such that $\sum_{a \in A} p(a) = 1$. We write $\mathcal{D}(A)$ the set of probability distributions on A. The *support* of $p \in \mathcal{D}(A)$ is $\texttt{Supp}(p) = \{a \in A \mid p(a) > 0\}$.

Markov decision processes. An *MDP* is a tuple $\mathcal{M} = (G, S_1, S_2, \delta)$ where (i) $G = (S, E)$ is a directed graph; (ii) (S_1, S_2) is a partition of S into states of player 1 (denoted by $\mathcal{P}_1$ and representing the system) and states of player 2 (denoted by $\mathcal{P}_2$ and representing the *stochastic* environment); (iii) $\delta\colon S_2 \to \mathcal{D}(S)$ is the transition function that, given a stochastic state $s \in S_2$, defines the probability distribution $\delta(s)$ over the successors of s, such that for all $s \in S_2$, $\texttt{Supp}(\delta(s)) = \texttt{Succ}(s)$. An MDP where for all $s \in S_1$, $|\texttt{Succ}(s)| = 1$ is a fully-stochastic process called a *Markov chain* (MC). A prefix $\rho \in \texttt{Pref}(\mathcal{M})$ belongs to $\mathcal{P}_i$, $i \in \{1,2\}$, if $\texttt{Last}(\rho) \in S_i$. The set of prefixes that belong to $\mathcal{P}_i$ is denoted by $\texttt{Pref}_i(\mathcal{M})$.

Strategies. A *strategy* for $\mathcal{P}_1$ is a function $\lambda\colon \texttt{Pref}_1(\mathcal{M}) \to \mathcal{D}(S)$, such that for all $\rho \in \texttt{Pref}_1(\mathcal{M})$, we have $\texttt{Supp}(\lambda(\rho)) \subseteq \texttt{Succ}(\texttt{Last}(\rho))$. The set of all strategies in $\mathcal{M}$ is denoted by Λ. *Pure* strategies have their support equal to a singleton for all prefixes. We mention that a strategy is *randomized* to stress on the need for randomness in general.

A strategy λ for $\mathcal{P}_1$ can be encoded by a stochastic state machine with outputs, called *stochastic Moore machine*, $\texttt{M}$. A strategy λ is *finite-memory* if $\texttt{M}$ is finite, and *memoryless* if it has only one state. That is, it does not depend on the history but only on the current state of the MDP: in this case, we have that $\lambda\colon S_1 \to \mathcal{D}(S)$. Finally, if the same strategy can be used regardless of the initial state, we say that a *uniform* strategy exists.

A play π is *consistent* with a strategy λ if for all $n \geq 0$ such that $\pi(n) \in S_1$, we have that $\pi(n+1) \in \texttt{Supp}(\lambda(\pi(0,n))$. It is defined similarly for prefixes. We write $\texttt{Out}^{\mathcal{M}}(\lambda) \subseteq \texttt{Plays}(G)$ the set of plays consistent with λ. We use $\texttt{Out}^{\mathcal{M}}_s(\lambda)$ when fixing an initial state s.

Markov chain induced by a strategy. An MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$ and a strategy λ for $\mathcal{P}_1$ determine an MC $\mathcal{C} = (G', \delta')$. Given $s \in S$ an initial state and $\mathcal{A} \subseteq \texttt{Plays}(G)$ a measurable set, we denote by $\mathbb{P}^{\lambda}_{\mathcal{M},s}[\mathcal{A}]$ the *probability* of event $\mathcal{A}$ when $\mathcal{M}$ is executed with initial state s and strategy λ.

Objectives. Given an MDP $\mathcal{M} = (G, S_1, S_1, \delta)$, an *objective* is a set of plays $\mathcal{A} \subseteq \texttt{Plays}(G)$. We consider two classical objectives from the literature. Both define measurable events. To define them, we introduce the following notation: given a play $\pi \in \texttt{Plays}(G)$, let $\inf(\pi) = \{s \in S \mid \forall\, i \geq 0, \exists\, j \geq i, \pi(j) = s\}$ be the set of states seen infinitely often along π.

Reachability. Given a target $T \subseteq S$, this objective asks for plays that visit T: $\texttt{Reach}(T) = \{\pi \in \texttt{Plays}(G) \mid \exists\, n \geq 0, \pi(n) \in T\}$. We later use the LTL notation $\Diamond T$ for event $\texttt{Reach}(T)$.

Parity. Let $p\colon S \to \{1, 2, \dots, d\}$ be a *priority function* that maps each state to an integer priority, where $d \leq |S| + 1$ (w.l.o.g.). The parity objective asks that, among the priorities seen infinitely often, the *maximal* one be even: $\texttt{Parity}(p) = \{\pi \in \texttt{Plays}(G) \mid \max_{s \in \inf(\pi)} p(s) \text{ is even}\}$. We later simply use p to denote the event $\texttt{Parity}(p)$.

End-components and sub-MDPs. Let $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$ be an MDP. An *end-component* (EC) of $\mathcal{M}$ is a set $C \subseteq S$ such that (i) $\forall\, s \in C \cap S_2$, $\texttt{Succ}(s) \subseteq C$ and $\forall\, s \in C \cap S_1$,

$\mathtt{Succ}(s) \cap C \neq \emptyset$; and (ii) C is *strongly connected*, i.e., for any two states $s, s' \in C$, there exists a path from s to s' that stays in C. It is well-known that inside an EC C, $\mathcal{P}_1$ can force the visit of any state $s \in C$ with probability 1 (that is, when $\mathcal{P}_2$ is seen as stochastic and obeys the strategy δ), see e.g., [4]. The union of two ECs with non-empty intersection is an EC. An EC C is thus *maximal* if, for every EC C', $C' \subseteq C \vee C' \cap C = \emptyset$.

Given an EC $C \subseteq S$ of $\mathcal{M}$, we write $\mathcal{M}_{\restriction C}$ the *sub-MDP* defined by $\mathcal{M}_{\restriction C} = (G' = (C, E \cap C \times C), S'_1 = S_1 \cap C, S'_2 = S_2 \cap C, \delta')$, where $\delta' \colon S'_2 \to \mathcal{D}(C)$ is the restriction of δ to the domain C. Note that $\mathcal{M}_{\restriction C}$ is a well-defined MDP: it has no deadlock since C is strongly connected and in all stochastic states s, $\mathtt{Supp}(\delta'(s)) \subseteq C$ (as C was an EC in $\mathcal{M}$).

Technical lemma. We recall a classical result about MDPs that will be useful later on.

▶ **Lemma 1** (Optimal reachability [4]). *Given an MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$ and a target set $T \subseteq S$, we can compute for each state $s \in S$ the maximal probability $v^*_s = \sup_{\lambda \in \Lambda} \mathbb{P}^\lambda_{\mathcal{M},s}[\Diamond T]$ to reach T, in polynomial time. There is an optimal uniform pure memoryless strategy λ^* that enforces v^*_s from all $s \in S$. Now, fix $s \in S$ and $c \in \mathbb{Q}$ such that $c < v^*_s$. Then there exists $k \in \mathbb{N}$ such that by playing λ^* from s for k steps, we reach T with probability larger than c.*

Events and probabilistic operators. Consider an MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$. Recall that we have defined two types of measurable events (specific subsets of $\mathtt{Plays}(G)$) with respective notations $\Diamond T$ for $T \subseteq S$ (reachability), and p for $p \colon S \to \{1, \dots, d\}$ a priority function (parity). We define three operators to reason about the probabilities of these events: $\mathtt{S}$, $\mathtt{P}_{\sim c}$, and $\mathtt{AS}$. Given an event $\mathcal{A}$ and a state s, they are used as follows:

- $\mathcal{A}$ is *sure* from s, denoted $s \models \mathtt{S}(\mathcal{A})$, if there exists a strategy λ of $\mathcal{P}_1$ such that $\mathtt{Out}^{\mathcal{M}}_s(\lambda) \subseteq \mathcal{A}$. Here probabilities are ignored and we consider $\mathcal{P}_2$ as antagonistic.
- $\mathcal{A}$ *holds with probability at least equal to (resp. greater than)* $c \in \mathbb{Q}$ from s, denoted $s \models \mathtt{P}_{\geq c}(\mathcal{A})$ (resp. $s \models \mathtt{P}_{>c}(\mathcal{A})$) if there exists λ such that $\mathbb{P}^\lambda_{\mathcal{M},s}[\mathcal{A}] \geq c$ (resp. $> c$).
- $\mathcal{A}$ is *almost-sure* from s, denoted $s \models \mathtt{AS}(\mathcal{A})$, if there exists λ such that $\mathbb{P}^\lambda_{\mathcal{M},s}[\mathcal{A}] = 1$.

For any operator $\mathtt{O}$, we say that such a λ is a *witness strategy* for $s \models \mathtt{O}(\mathcal{A})$ and we write $s, \lambda \models \mathtt{O}(\mathcal{A})$ to denote it. We will also consider *combinations* of the type $s \models \mathtt{O}_1(\mathcal{A}_1) \wedge \mathtt{O}_2(\mathcal{A}_2)$ for two operators and events: in this case, we require that the same strategy be a witness for both conjuncts, i.e., that there exists λ such that $s, \lambda \models \mathtt{O}_1(\mathcal{A}_1)$ and $s, \lambda \models \mathtt{O}_2(\mathcal{A}_2)$. Finally, we will sometimes use different MDPs, in which case we add the considered MDP $\mathcal{M}$ as a subscript on $\models$, e.g., $s \models_{\mathcal{M}} \mathtt{O}(\mathcal{A})$. We drop this subscript when the context is clear.

Beyond worst-case problems. Let $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$ be an MDP, $s \in S$ be an initial state, and p_1, p_2 be two priority functions. We provide algorithms to decide the existence of a witness strategy — and synthesize it — for the following formulae: (i) $s \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$, and (ii) $s \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\sim c}(p_2)$ for $\sim \in \{>, \geq\}$ and $c \in \mathbb{Q} \cap [0, 1)$.

3 Reachability under parity constraints

We study two variants, given $s \in S$, $T \subseteq S$, and $p \colon S \to \{1, \dots d\}$: (i) $s \models \mathtt{S}(p) \wedge \mathtt{AS}(\Diamond T)$, and (ii) $s \models \mathtt{S}(p) \wedge \mathtt{P}_{\sim c}(\Diamond T)$ for $\sim \in \{>, \geq\}$ and $c \in \mathbb{Q} \cap [0, 1)$.

Almost-sure reachability. This case can be solved by reduction to a slight variant studied in [2, Lemma 3] (extended version of [1]). The approach of [2, Lemma 3] relies on a reduction

to a Büchi-parity game: sufficiency of finite memory follows from this reduction. The lower complexity bound is trivial: it suffices to fix $T = S$ to obtain a classical parity game [19].

▶ **Theorem 2.** *Given an MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$, a state $s_0 \in S$, a priority function $p\colon S \to \{1, \dots, d\}$, and a target set of states $T \subseteq S$, it can be decided in $\mathsf{NP} \cap \mathsf{coNP}$ if $s_0 \models \mathtt{S}(p) \wedge \mathtt{AS}(\Diamond T)$. If the answer is* Yes*, then there exists a finite-memory witness strategy. This decision problem is at least as hard as solving parity games.*

Reachability with threshold probability. We first study strategies that maximize the probability of reaching a target $T \subseteq S$ in an MDP $\mathcal{M}$. By Lemma 1, we have an optimal uniform pure memoryless strategy λ^* that enforces v^*_s from all $s \in S$. We define the set $E^{\neg\mathrm{opt}} = \{(s, s') \in E \mid s \in S_1 \wedge v^*_s > v^*_{s'}\}$ that contains all edges that are *non-optimal choices* for $\mathcal{P}_1$ in the sense that they result in a strict decrease of the probability to reach T. We show that playing, for a finite number of steps, edges that are optimal (i.e., in $E^{\mathrm{opt}} = E \setminus E^{\neg\mathrm{opt}}$), and then switching to an optimal strategy, like λ^*, produces an optimal strategy too.

▶ **Lemma 3.** *Let λ^* be an optimal uniform pure memoryless strategy in $\mathcal{M}$ to reach T, from all states in S. If λ is a strategy that plays only edges in E^{opt} for m steps, for $m \in \mathbb{N}$, and then switches to λ^*, then λ is also optimal to reach T from all states in S.*

We now turn to the problem $s_0 \models \mathtt{S}(p) \wedge \mathtt{P}_{\sim c}(\Diamond T)$ and establish the following result.

▶ **Theorem 4.** *Given an MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$, a state $s_0 \in S$, a priority function $p\colon S \to \{1, \dots, d\}$, a target set of states $T \subseteq S$, and a probability threshold $c \in [0, 1) \cap \mathbb{Q}$, it can be decided in $\mathsf{NP} \cap \mathsf{coNP}$ if $s_0 \models \mathtt{S}(p) \wedge \mathtt{P}_{\sim c}(\Diamond T)$ for $\sim \in \{>, \geq\}$. If the answer is* Yes*, then there exists a finite-memory witness strategy. This decision problem is at least as hard as solving parity games.*

Proof Sketch. First, we restrict $\mathcal{M}$ to the $\subseteq$-maximal sub-MDP $\mathcal{M}^{\mathrm{w}}$ in which $\mathcal{P}_1$ can ensure $\mathtt{S}(p_1)$ from all states, by solving a classical parity game, which is in $\mathsf{NP} \cap \mathsf{coNP}$ [19]. Indeed, if $s_0 \not\models \mathtt{S}(p)$, the answer is No. In $\mathcal{M}^{\mathrm{w}}$, $\mathcal{P}_1$ has a uniform pure memoryless strategy λ^p that ensures $\mathtt{S}(p)$ from every state.

The case $> c$ is the easier. First, we compute the maximal probability $v^*_{s_0}$ to reach T and an optimal strategy λ^*, in polynomial time (Lemma 1). If $v^*_{s_0} \leq c$, then the answer is clearly No. Otherwise, we claim it is Yes. We construct a witness strategy λ for $s_0 \models \mathtt{S}(p) \wedge \mathtt{P}_{>c}(\Diamond T)$ from λ^* and λ^p as follows. Starting in s_0, the strategy λ plays as λ^* for k steps where k is taken as in Lemma 1: the probability to reach T after k steps is strictly greater than c, which implies that $s_0, \lambda \models \mathtt{P}_{>c}(\Diamond T)$. Then, λ switches to λ^p. Since parity is prefix-independent, we have that $s_0, \lambda \models \mathtt{S}(p)$, and we are done. Our procedure lies in $\mathsf{P}^{\mathsf{NP} \cap \mathsf{coNP}} = \mathsf{NP} \cap \mathsf{coNP}$ [6], and λ is finite-memory since λ^* and λ^p are memoryless and k is finite.

We now turn to case $\geq c$. We compute $v^*_{s_0}$ in polynomial time. If $v^*_{s_0} > c$, then we answer Yes as we apply the same reasoning as in the previous case. If $v^*_{s_0} < c$, then we trivially answer No. The more involved case is $v^*_{s_0} = c$. We must verify that probability c is still achievable if, in addition, it is required to enforce $\mathtt{S}(p)$. To answer this, we modify $\mathcal{M}^{\mathrm{w}}$ and we reduce our problem to the almost-sure case of Theorem 2. Intuitively, we construct the MDP $\mathcal{M}'$ as follows. (i) We enrich states with one bit that records if T has been visited. (ii) While T has not been visited, we suppress all edges controlled by $\mathcal{P}_1$ that are not optimal for reachability, i.e., all edges in $E^{\neg\mathrm{opt}}$. (iii) While T has not been visited, we delete all states that cannot reach T and normalize the probability of the edges that survive this deletion.

We prove that $s'_0 \models_{\mathcal{M}'} \mathtt{S}(p) \wedge \mathtt{AS}(\Diamond T') \iff s_0 \models_{\mathcal{M}^{\mathrm{w}}} \mathtt{S}(p) \wedge \mathtt{P}_{\geq c}(\Diamond T)$ holds, where s'_0 is the initial state in $\mathcal{M}'$ and T' the translation of T. The crux is the restriction to E^{opt}

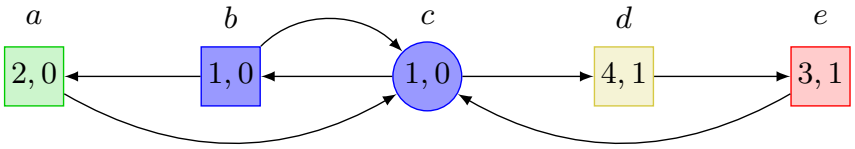

Figure 2 This MDP is a UGEC: going to d satisfies $(\mathbf{1_U})$, whereas going to b satisfies $(\mathbf{2_U})$.

before visiting T: $\mathcal{P}_1$ must be able to ensure $\mathtt{S}(p_1)$ while using only edges that are optimal for reachability if T cannot be forced surely. As the almost-sure problem is in $\mathsf{NP} \cap \mathsf{coNP}$ by Theorem 2, and $\mathcal{M}'$ is polynomially larger than $\mathcal{M}^{\mathrm{w}}$ (and thus $\mathcal{M}$), we obtain the claimed complexity using $\mathsf{P}^{\mathsf{NP}\cap\mathsf{coNP}} = \mathsf{NP} \cap \mathsf{coNP}$ [6]. Our reduction implies that the witness strategy can be finite-memory. Again, this problem generalizes parity games by taking $T = S$. ◀

4 Almost-sure parity under parity constraints

Overview and key lemma. We consider an MDP $\mathcal{M} = (G = (S, E), S_1, S_1, \delta)$ with two priority functions p_1 and p_2. We look at the problem $s \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$. The cornerstone of our approach is the notion of *ultra-good end-component*.

▶ **Definition 5.** An end-component C of $\mathcal{M}$ is *ultra-good* (UGEC) if in the sub-MDP $\mathcal{M}_{\restriction C}$, the following two properties hold:

- $(\mathbf{1_U})$ $\forall\, s \in C$, $s \models_{\mathcal{M}_{\restriction C}} \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond C^{\max}_{\mathrm{even}}(p_1))$, where

$$C^{\max}_{\mathrm{even}}(p_i) = \left\{ s \in C \mid (p_i(s) \text{ is even}) \wedge (\forall\, s' \in C,\ p_i(s') \text{ is odd} \implies p_i(s') < p_i(s)) \right\}$$

  contains the states with even priorities that are larger than any odd priority in C (this set can be empty for arbitrary ECs but needs to be non-empty for UGECs);
- $(\mathbf{2_U})$ $\forall\, s \in C$, $s \models_{\mathcal{M}_{\restriction C}} \mathtt{AS}(p_1) \wedge \mathtt{AS}(p_2)$, or equivalently, $s \models_{\mathcal{M}_{\restriction C}} \mathtt{AS}(p_1 \cap p_2)$.

We introduce the following notations: $\mathrm{UGEC}(\mathcal{M})$ is the set of all UGECs of $\mathcal{M}$, and $\mathcal{U} = \cup_{U \in \mathrm{UGEC}(\mathcal{M})} U$ is the set of states that belong to a UGEC in $\mathcal{M}$.

Intuitively, within a UGEC, $\mathcal{P}_1$ has a strategy to almost-surely visit $C^{\max}_{\mathrm{even}}(p_1)$ while guaranteeing $\mathtt{S}(p_1)$, and he also has a (generally different) strategy that almost-surely ensures both parity objectives. Figure 2 gives an example of UGEC. This notion strengthens the concept of *super-good* EC from [1]: essentially, the super-good ECs are exactly the ECs satisfying $(\mathbf{1_U})$. Thus, every UGEC is a super-good EC, but the converse is false.

The central lemma underpinning our approach is the following.

▶ **Lemma 6.** *The following equivalence holds:*

$$s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond \mathcal{U}) \iff s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2).$$

Essentially, this lemma permits to reduce the problem under study to the one treated in Theorem 2, provided that we are able to compute $\mathcal{U}$, the set of states appearing in a UGEC. The rest of this section is dedicated to the proof of this lemma and its consequences.

Left-to-right implication (sufficient condition). We first study witness strategies for conditions $(\mathbf{1_U})$ and $(\mathbf{2_U})$ of Definition 5. For $(\mathbf{1_U})$, it was shown in the proof of [2, Lemma 3] (extended version of [1]) that deciding if the condition holds is in $\mathsf{NP} \cap \mathsf{coNP}$ and that uniform finite-memory witness strategies exist. For $(\mathbf{2_U})$, we establish the following lemma.

▶ **Lemma 7.** *Let C be an EC of $\mathcal{M}$. The following assertions hold.*

1. *It can be decided in polynomial time if condition $(\mathbf{2_U})$ holds.*
2. *If it holds, then there exists a (uniform randomized) memoryless witness strategy $\lambda_{2,C}$ and a sub-EC $D \subseteq C$ such that $D^{\max}_{\text{even}}(p_1) \neq \emptyset$, $D^{\max}_{\text{even}}(p_2) \neq \emptyset$, and for all $s \in C$, we have that $\mathbb{P}^{\lambda_{2,C}}_{\mathcal{M}_{\restriction C},s}\left[\{\pi \in \mathtt{Out}^{\mathcal{M}_{\restriction C}}(\lambda_{2,C}) \mid \inf(\pi) = D\}\right] = 1$.*
3. *Furthermore, $\lambda_{2,C}$ satisfies the following property: $\forall\, s \in C$, $\forall\, \varepsilon > 0$, $\exists\, n \in \mathbb{N}$ such that $\mathbb{P}^{\lambda_{2,C}}_{\mathcal{M}_{\restriction C},s}\left[\{\pi \in \mathtt{Out}^{\mathcal{M}_{\restriction C}}(\lambda_{2,C}) \mid \exists\, i,\, 0 \leq i \leq n,\, \pi(i) \in D^{\max}_{\text{even}}(p_1)\}\right] \geq 1 - \varepsilon$.*

Proof Sketch. For Point **2**, we resort on a classical result on almost-sure reachability of ECs and almost-sure satisfaction of both parity objectives. For Point **3**, we use Lemma 1 and Point **2**. For Point **1**, we show that (i) the existence of a sub-EC D such that $D^{\max}_{\text{even}}(p_1) \neq \emptyset$ and $D^{\max}_{\text{even}}(p_2) \neq \emptyset$ is not only necessary but also sufficient to satisfy condition $(\mathbf{2_U})$, and (ii) the existence of such a set can be decided in polynomial time. For (i), it suffices to build a uniform randomized memoryless strategy λ that reaches the sub-EC D almost-surely and then plays uniformly at random in it forever: λ will be a witness for $s \models_{\mathcal{M}_{\restriction C}} \mathtt{AS}(p_1) \wedge \mathtt{AS}(p_2)$, so condition $(\mathbf{2_U})$ holds in C. For (ii), we first check if $C^{\max}_{\text{even}}(p_1) \neq \emptyset$ and $C^{\max}_{\text{even}}(p_2) \neq \emptyset$. If this holds, then $D = C$ and the answer is Yes (it takes linear time obviously). If it does not hold, then we compute the sets $C^{\max}_{\text{odd}}(p_i) = \big\{s \in C \mid (p_i(s) \text{ is odd}) \wedge (\forall\, s' \in C,\, p_i(s') \text{ is even} \implies p_i(s') < p_i(s))\big\}$ and we iterate this procedure in the sub-EC $C' \subset C$ defined as $C' = C \setminus \mathtt{Attr}_2\big(C^{\max}_{\text{odd}}(p_1) \cup C^{\max}_{\text{odd}}(p_2)\big)$, where $\mathtt{Attr}_2$ is the classical attractor for $\mathcal{P}_2$. A suitable D exists if and only if this procedure stops before $C' = \emptyset$. In addition, this procedure takes at most $|C|$ iterations (as we remove at least one state at each step) and each iteration takes linear time. ◀

We will now prove that inside any UGEC, there is a strategy for $\mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$. From now on, let C be a UGEC of $\mathcal{M}$, $\lambda_{1,C}$ be a uniform finite-memory witness strategy for $(\mathbf{1_U})$ in Definition 5, and $\lambda_{2,C}$ be a uniform randomized memoryless one for $(\mathbf{2_U})$, additionally satisfying the properties of Lemma 7. We build a strategy λ_C based on $\lambda_{1,C}$ and $\lambda_{2,C}$.

▶ **Definition 8.** Let $C \in \mathrm{UGEC}(\mathcal{M})$. Let $(n_i)_{i\in\mathbb{N}}$ be a sequence of naturals n_i such that $\mathbb{P}^{\lambda_{2,C}}_{\mathcal{M}_{\restriction C},s}\left[\{\pi \in \mathtt{Out}^{\mathcal{M}_{\restriction C}}(\lambda_{2,C}) \mid \exists\, i,\, 0 \leq i \leq n_i,\, \pi(i) \in D^{\max}_{\text{even}}(p_1)\}\right] \geq 1 - 2^{-i}$, whose existence is guaranteed by Lemma 7. We build strategy λ_C as follows, starting with $i = 0$.

(a) Play $\lambda_{2,C}$ for n_i steps. Then $i = i + 1$ and go to **(b)**.

(b) If $D^{\max}_{\text{even}}(p_1)$ was visited in phase **a)**, then go to **(a)**.
Else, play $\lambda_{1,C}$ until $C^{\max}_{\text{even}}(p_1)$ is reached and then go to **(a)**.

Observe that λ_C requires infinite memory. In the next lemma, we prove that λ_C is a proper witness for $\mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$ in the UGEC C.

▶ **Lemma 9.** *Let $C \in \mathrm{UGEC}(\mathcal{M})$. For all $s \in C$, it holds that $s, \lambda_C \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$.*

Proof Sketch. First consider $s, \lambda_C \models \mathtt{S}(p_1)$. Fix any $\pi \in \mathtt{Out}^{\mathcal{M}_{\restriction C}}_s(\lambda_C)$: we will show that $\max_{s' \in \inf(\pi)} p_1(s')$ is even. Three cases are possible: (i) λ_C switches infinitely often between $\lambda_{1,C}$ and $\lambda_{2,C}$, (ii) it eventually plays $\lambda_{1,C}$ forever, and (iii) it eventually plays $\lambda_{2,C}$ forever. In case (i), $C^{\max}_{\text{even}}(p_1)$ is visited infinitely often. Since any state in this set has an even priority higher than any odd priority in C, we are good. In case (ii), we know that $s, \lambda_{1,C} \models \mathtt{S}(p_1)$. By prefix-independence, we are also good. In case (iii), $D^{\max}_{\text{even}}(p_1)$ is visited infinitely often, and, eventually, play π never leaves the sub-EC D. Hence, we are good here too and we conclude that $s, \lambda_C \models \mathtt{S}(p_1)$.

To show that $s, \lambda_C \models \mathtt{AS}(p_2)$, we prove that λ_C almost-surely ends up in playing only $\lambda_{2,C}$ (which ensures $\mathtt{AS}(p_2)$). The crux here is the choice of durations n_i for the strategy: we

can show that the probability to never play $\lambda_{1,C}$ again after round i tends to one when i tends to infinity. This entails the needed result. ◀

We can now prove the left-to-right implication of Lemma 6. For this, assume that for $s_0 \in S$, we have that $\lambda_{\mathcal{U}}$ is a witness for $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond \mathcal{U})$, where we recall that $\mathcal{U}$ represents the union of all UGECs of the MDP $\mathcal{M}$. Note that such a strategy can be finite-memory w.l.o.g. as proved in Theorem 2. We build a global strategy λ as follows.

▶ **Definition 10.** Based on strategies $\lambda_{\mathcal{U}}$ and λ_C for all $C \in \mathrm{UGEC}(\mathcal{M})$, we build the global strategy λ as follows.
(a) Play $\lambda_{\mathcal{U}}$ until a UGEC C is reached, then go to **(b)**.
(b) Play λ_C forever.

This strategy requires infinite memory because of the strategies λ_C. We prove that λ is a witness for $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$.

▶ **Lemma 11.** *It holds that* $s_0, \lambda \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$.

Right-to-left implication (necessary condition). We now turn to the converse implication of Lemma 6, i.e., that $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$ implies $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond \mathcal{U})$. We start by an intermediate lemma regarding witness strategies: it establishes that all states reachable via such a strategy also satisfy the property.

▶ **Lemma 12.** *For every state* $s \in S$*, every strategy* λ *such that* $s, \lambda \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$*, and every prefix* $\rho \in \mathtt{Pref}(\mathtt{Out}_s^{\mathcal{M}}(\lambda))$*, we have that* $\mathtt{Last}(\rho) \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$.

The next lemma establishes that at least one UGEC must exist in $\mathcal{M}$.

▶ **Lemma 13.** *The following holds:* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2) \implies \mathrm{UGEC}(\mathcal{M}) \neq \emptyset$.

Proof Sketch. Given $\Pi \subseteq \mathtt{Plays}(G)$, we define $\mathtt{States}(\Pi) = \{s \in S \mid \exists \pi \in \Pi, \exists n \in \mathbb{N}, \pi(n) = s\}$. We then study the set

$$\mathcal{S} = \left\{ R \subseteq S \mid \exists\, s \in S, \exists \lambda \in \Lambda, (s, \lambda \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)) \wedge (R = \mathtt{States}(\mathtt{Out}_s^{\mathcal{M}}(\lambda))) \right\}.$$

Intuitively, it contains any subset of S that captures all states reachable by some witness strategy λ, from some state $s \in S$. First note that $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$ implies that $\mathcal{S}$ is non-empty, as for a witness strategy λ, $R = \mathtt{States}(\mathtt{Out}_{s_0}^{\mathcal{M}}(\lambda)) \in \mathcal{S}$, by definition.

We then show that all minimal elements of $\mathcal{S}$ for set inclusion $\subseteq$ are UGECs, which suffices to establish our lemma. The most important ingredients to prove that any $R \in \min_{\subseteq}(\mathcal{S})$ is a UGEC are the following. First the existence, for any $s \in R$, of a strategy λ_R such that $s, \lambda_R \models_{\mathcal{M}_{\restriction R}} \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$ (i.e., λ_R satisfies the property without leaving R), which follows from Lemma 12 and the minimality of R in $\mathcal{S}$. Second, proving that $R_{\mathrm{even}}^{\max}(p_1)$ is dense in the subtree induced by $\mathtt{Out}_s^{\mathcal{M}}(\lambda_R)$, that is, that for every prefix ρ, the subtree defined by λ_R from ρ reaches a state of $R_{\mathrm{even}}^{\max}(p_1)$, and that this holds in all subsequent subtrees. From this density argument, we can derive a witness strategy for condition $(\mathbf{1_U})$ in Definition 5. ◀

Collecting in $\mathcal{U}_{\min} = \cup_{R \in \min_{\subseteq}(\mathcal{S})} R$ all states that belong to minimal sets R of $\mathcal{S}$, we finally prove the implication.

▶ **Lemma 14.** *The following holds:* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2) \implies s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond \mathcal{U}_{\min})$.

Algorithm. Lemma 11 and Lemma 14 prove the correctness of the reduction presented in Lemma 6. It is the cornerstone of our algorithm.

▶ **Theorem 15.** *Given an MDP $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$, a state $s_0 \in S$, and two priority functions $p_i \colon S \to \{1, \dots, d\}$, $i \in \{1, 2\}$, it can be decided in* NP∩coNP *if $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$. If the answer is* Yes*, then there exists an infinite-memory witness strategy, and infinite memory is in general necessary. This decision problem is at least as hard as solving parity games.*

Proof. The algorithm can be sketched as follows:

1. Compute the set $\max_{\subseteq}(\mathrm{SGEC}(\mathcal{M}))$ of maximal super-good ECs, using [1]. Those are the maximal ECs satisfying condition $(\mathbf{1_U})$ in Definition 5. There are only polynomially many of them, and their computation is in NP ∩ coNP.
2. For each of them, check if $(\mathbf{2_U})$ holds using Lemma 7, in polynomial time. If an EC does not satisfy $(\mathbf{2_U})$, then it is also the case of all its sub-ECs (as seen in the proof of Lemma 7). Hence, we have that $\mathcal{U} = \{C \in \max_{\subseteq}(\mathrm{SGEC}(\mathcal{M})) \mid C \text{ satisfies } (\mathbf{2_U})\}$.
3. Decide if $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond\mathcal{U})$ using Theorem 2. This is in NP ∩ coNP. If it holds, then answer Yes, otherwise answer No.

Its correctness was established in Lemma 6. It belongs to $\mathsf{P}^{\mathsf{NP}\cap\mathsf{coNP}} = \mathsf{NP} \cap \mathsf{coNP}$ [6], and it trivially generalizes classical parity games (e.g., by taking $p_2 \colon s \mapsto 0$ for all $s \in S$).

Finally, let us discuss strategies. A witness strategy λ plays as follows: (i) it plays as the finite-memory strategy witness for $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(\Diamond\mathcal{U})$ given by Theorem 2 until a UGEC C is reached, (ii) then it switches to the infinite-memory strategy λ_C described in Definition 8. It is clear that such a strategy is a witness for $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{AS}(p_2)$, as expected.

Infinite memory is required in general, as shown in the UGEC C in Figure 2: there exists no finite-memory witness strategy in C. Indeed, assume $\mathcal{P}_1$ is restricted to a finite-memory strategy λ. To be able to ensure p_1 on the play in which $\mathcal{P}_2$ always goes to c from b, $\mathcal{P}_1$ must visit d infinitely often, and because of the finite memory of λ, he must do it after a bounded number of steps along which a is not visited: say n steps. Hence, the probability to do it will be bounded from below by a strictly positive constant, here $2^{-\frac{n}{2}}$ (the probability that $\mathcal{P}_2$ chooses c for $\frac{n}{2}$ times in a row), all along a consistent play. Therefore, $\mathcal{P}_1$ will almost-surely visit d infinitely often, and p_2 will actually be satisfied with probability zero. ◀

5 Parity with threshold probability under parity constraints

We now turn to the problem $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\sim c}(p_2)$ for $\sim \in \{>, \geq\}$ and $c \in \mathbb{Q} \cap [0, 1)$.

Very-good end-components. In addition to UGECs, we need the new notion of *very-good end-component*.

▶ **Definition 16.** An end-component C of $\mathcal{M}$ is *very-good* (VGEC) if the following two properties hold:

- $(\mathbf{1_V})$ $\forall\, s \in C$, $s \models_{\mathcal{M}} \mathtt{S}(p_1)$;
- $(\mathbf{2_V})$ $\forall\, s \in C$, $s \models_{\mathcal{M}_{\restriction C}} \mathtt{AS}(p_1) \wedge \mathtt{AS}(p_2)$, or equivalently, $s \models_{\mathcal{M}_{\restriction C}} \mathtt{AS}(p_1 \cap p_2)$.

We introduce the following notations: $\mathrm{VGEC}(\mathcal{M})$ is the set of all VGECs of $\mathcal{M}$, and $\mathcal{V} = \cup_{V \in \mathrm{VGEC}(\mathcal{M})} V$ is the set of states that belong to a VGEC in $\mathcal{M}$.

Note that in condition $(\mathbf{1_V})$, $\mathcal{P}_1$ is allowed to leave C to ensure $\mathtt{S}(p_1)$: this is in contrast to condition $(\mathbf{1_U})$ for UGECs, in Definition 5. On the contrary, condition $(\mathbf{2_V})$ is exactly the same as $(\mathbf{2_U})$. From these definitions, it is trivial to see that any UGEC is also a VGEC,

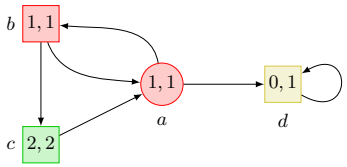

Figure 3 The EC $\{a, b, c\}$ is very-good but not ultra-good, as $\mathcal{P}_1$ has to leave it to ensure $\mathtt{S}(p_1)$.

but the converse is false. Consider Figure 3: $\{a, b, c\}$ is a VGEC. The strategy ensuring $(\mathbf{2_V})$ from a is to go to b, and the strategy ensuring $(\mathbf{1_V})$ from a is to go to d. As we will prove in Lemma 18 and as in all VGECs, $\mathcal{P}_1$ can ensure $a \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>1-\varepsilon}(p_2)$ for any $\varepsilon > 0$. Still, $\{a, b, c\}$ is not a UGEC: no strategy ensures $\mathtt{S}(p_1)$ on $\mathcal{M}_{\downarrow\{a,b,c\}}$, as $\mathcal{P}_2$ can enforce the play $(ab)^\omega$ that has odd maximal priority. This illustrates why the notion of UGEC is too strong when reasoning about threshold probability, hence why we need to introduce VGECs.

Available strategies in VGECs. As for UGECs, we will use witness strategies for $(\mathbf{1_V})$ and $(\mathbf{2_V})$. Deciding if $(\mathbf{1_V})$ holds is solving a classical parity game, in $\mathsf{NP} \cap \mathsf{coNP}$ [19]. Uniform pure memoryless witness strategies exist: let λ_1 be such a witness. For simplicity of presentation, *we assume in the following that all states of* $\mathcal{M}$ *satisfy* $(\mathbf{1_V})$, as otherwise they will trivially not satisfy the properties we consider (as $\mathtt{S}(p_1)$ will not be ensured). For $(\mathbf{2_V})$, we established in Lemma 7 that deciding if it holds is in polynomial time and that uniform randomized memoryless witness strategies exist: let $\lambda_{2,C}$ be one of them.

Reaching VGECs. We prove a strong relationship between the measure of paths that satisfy p_1 and p_2, and the measure of paths that reach VGECs, under any strategy.

▶ **Lemma 17.** *For all $s \in S$, and all $\lambda \in \Lambda$, the following holds:* $\mathbb{P}^{\lambda}_{\mathcal{M},s}[\Diamond \mathcal{V}] \geq \mathbb{P}^{\lambda}_{\mathcal{M},s}[p_1 \cap p_2]$.

Limit-sure satisfaction in VGECs. For each state in a VGEC, we claim that the parity objective p_2 can be satisfied with probability arbitrarily close to one, while ensuring p_1 surely.

▶ **Lemma 18.** *Let $C \in \mathrm{VGEC}(\mathcal{M})$. For all $s \in C$ and $\varepsilon \in (0, 1]$, the following property holds:* $s \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>1-\varepsilon}(p_2)$.

Proof Sketch. As for UGECs, we build a witness strategy based on two simpler ones: λ_1 and $\lambda_{2,C}$. However, our strategy here depends on ε. The rough idea is as follows: the witness strategy λ_ε will play $\lambda_{2,C}$ for longer and longer rounds, and switch to λ_1 forever if $D^{\max}_{\mathrm{even}}(p_1)$ is not visited along one of those rounds. Using Lemma 7 cleverly, we can define the sequence of round lengths in such a way that the probability to play as $\lambda_{2,C}$ forever exceeds $1 - \varepsilon$, yielding the result. ◀

The strict threshold case. We reduce the problem to a reachability problem toward $\mathcal{V}$. The first lemma gives a sufficient condition under which the property is satisfied. Its proof tells us how to construct witness strategies.

▶ **Lemma 19.** *The following holds:* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(\Diamond \mathcal{V}) \implies s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(p_2)$.

Proof Sketch. We build a witness strategy λ based on (i) $\lambda_{\Diamond \mathcal{V}}$, a strategy that ensures to reach $\mathcal{V}$ with probability $q > c$ from s_0, (ii) λ_1, and (iii) $\lambda_{\varepsilon,C}$ from Lemma 18 for a well-chosen $\varepsilon > 0$ and every VGEC C. The idea is to first play $\lambda_{\Diamond \mathcal{V}}$ long enough so that a VGEC C is reached with probability close to q and, if such a C is reached, to switch to $\lambda_{\varepsilon,C}$ for ε

sufficiently small so that the total probability to satisfy p_2 is higher than c. If no VGEC is reached, λ switches to λ_1, hence ensuring $\mathtt{S}(p_1)$. ◀

This second lemma gives a necessary condition. Its proof uses Lemma 17.

▶ **Lemma 20.** *The following holds:* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(p_2) \implies s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(\Diamond \mathcal{V})$.

The non-strict threshold case. As we solved the strict case, the only interesting remaining case is when $\mathcal{P}_1$, while surely forcing p_1, can force p_2 with probability c, but no more. The main tool here is UGECs. The first lemma gives a sufficient condition. Its proof is constructive. Recall that $\mathcal{U} = \cup_{U \in \mathrm{UGEC}(\mathcal{M})} U$.

▶ **Lemma 21.** *The following holds:* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(\Diamond \mathcal{U}) \implies s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(p_2)$.

Proof Sketch. We define a witness strategy based on (i) $\lambda_{\Diamond \mathcal{U}}$, a witness for $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(\Diamond \mathcal{U})$, and (ii) strategies λ_C for every UGEC C: it suffices to play $\lambda_{\Diamond \mathcal{U}}$ as long as no UGEC C is reached and to switch to λ_C when reached, if ever. ◀

The next lemma gives a necessary condition, keeping in mind that we consider the case where $\mathcal{P}_1$ cannot ensure probability strictly larger than c.

▶ **Lemma 22.** *The following holds:* $(s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(p_2)) \wedge (s_0 \not\models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(p_2)) \implies s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(\Diamond \mathcal{U})$.

Algorithm. Based on the reductions shown above, we can now establish an algorithm and complexity results for the threshold problem.

▶ **Theorem 23.** *Given an MDP* $\mathcal{M} = (G = (S, E), S_1, S_2, \delta)$*, a state* $s_0 \in S$*, and two priority functions* $p_i \colon S \to \{1, \dots, d\}$*,* $i \in \{1, 2\}$*, it can be decided in* $\mathsf{NP} \cap \mathsf{coNP}$ *if* $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\sim c}(p_2)$ *for* $\sim \in \{>, \geq\}$ *and* $c \in \mathbb{Q} \cap [0, 1)$*. If the answer is* Yes*, then there exists an infinite-memory witness strategy, and infinite memory is in general necessary. This decision problem is at least as hard as solving parity games.*

Proof. The algorithm can be sketched as follows:

1. Remove from $\mathcal{M}$ all states where $\mathtt{S}(p_1)$ does not hold, as well as their attractor for $\mathcal{P}_2$: if s_0 is removed, then answer No. Let $\mathcal{M}'$ be the remaining MDP. This operation is in $\mathsf{NP} \cap \mathsf{coNP}$ as it consists in solving a classical parity game [19].
2. Compute the set $\mathcal{V}$ representing the union of VGECs in $\mathcal{M}'$. This can be done in polynomial time by computing the maximal ECs of $\mathcal{M}'$ and applying Lemma 7 to check condition $(\mathbf{2_V})$ for each of them (condition $(\mathbf{1_V})$ holds thanks to the previous step).
3. Decide if $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>c}(\Diamond \mathcal{V})$ using Theorem 4. This is in $\mathsf{NP} \cap \mathsf{coNP}$. If it holds, then answer Yes. If it does not hold and $\sim$ is $>$, then answer No, otherwise, i.e., if $\sim$ is $\geq$, continue with the next step.
4. Use the sub-algorithm described in Theorem 15 to compute the set $\mathcal{U}$ representing the union of UGECs in $\mathcal{M}'$. This is in $\mathsf{NP} \cap \mathsf{coNP}$.
5. Decide if $s_0 \models \mathtt{S}(p_1) \wedge \mathtt{P}_{\geq c}(\Diamond \mathcal{U})$ using Theorem 4. This is in $\mathsf{NP} \cap \mathsf{coNP}$. If it holds, answer Yes, otherwise answer No.

The correctness of this algorithm follows from Lemma 19, Lemma 20, Lemma 21, and Lemma 22. It belongs to $\mathsf{P}^{\mathsf{NP} \cap \mathsf{coNP}} = \mathsf{NP} \cap \mathsf{coNP}$ [6], and it trivially generalizes classical parity games (e.g., by taking $p_2 \colon s \mapsto 0$ for all $s \in S$).

Finally, let us discuss strategies. Witness strategies for the case $>$ (resp. $\geq$) were described in Lemma 19 (resp. Lemma 21). In both cases, infinite memory is in general required, because it is in general necessary to play optimally in both VGECs and UGECs. For UGECs, see Theorem 15 for an example. For VGECs, consider the VGEC $\{a, b, c\}$ in the MDP of Figure 3. We claim that for every finite-memory strategy λ ensuring $\mathtt{S}(p_1)$, the probability to ensure p_2 is zero, hence there is no finite-memory witness for $a \models \mathtt{S}(p_1) \wedge \mathtt{P}_{>1-\varepsilon}(p_2)$. As argued for the UGEC case, in order to ensure p_1 on the play in which $\mathcal{P}_2$ always goes to a from b, $\mathcal{P}_1$ must go to d at some point, and because of the finite memory of λ, he must do it after a bounded number of steps along which c is not visited: say n steps. Again, the probability to do it will be bounded from below by a strictly positive constant, here $2^{-\frac{n}{2}}$ (the probability that $\mathcal{P}_2$ chooses a for $\frac{n}{2}$ times in a row), all along a consistent play. Therefore, $\mathcal{P}_1$ will almost-surely go to d, and p_2 will actually be satisfied with probability zero. ◀

6 Conclusion

We further extended the beyond worst-case synthesis framework by studying the case of two parity objectives and proved $\mathsf{NP} \cap \mathsf{coNP}$ membership for all considered variants.

Our algorithms can easily be generalized to more than two parity objectives as long as we consider only the $\mathtt{S}$ and $\mathtt{AS}$ operators. Indeed, we have that for any MDP $\mathcal{M}$, any state s in $\mathcal{M}$, and any number of priority functions $p_1, \dots p_n$, it holds that $s \models \bigwedge_i \mathtt{S}(p_i) \bigwedge_j \mathtt{AS}(p_j) \iff s \models \mathtt{S}\big(\bigwedge_i p_i\big) \wedge \mathtt{AS}\big(\bigwedge_j p_j\big)$, and it is easy to reduce the latter problem to $s' \models \mathtt{S}(p') \wedge \mathtt{AS}(p'')$ on a (larger) MDP $\mathcal{M}'$, using classical techniques (e.g., any conjunction of parity objectives can be expressed as a Muller condition [13], that in turn can be transformed into a single parity condition on a larger graph [20]). Extending this generalization to the operator $\mathtt{P}_{\sim c}$ is more challenging and would require to mix our techniques to methods for percentile queries [24]: an interesting direction for future work.

Another question is the limits of finite-memory strategies. We saw that in general, infinite memory is needed. We would like to investigate under which additional conditions finite-memory strategies suffice, and to develop corresponding algorithms.

Synchronizability of Communicating Finite State Machines is not Decidable*

Abstract

A system of communicating finite state machines is *synchronizable* [1, 4] if its send trace semantics, i.e. the set of sequences of sendings it can perform, is the same when its communications are FIFO asynchronous and when they are just rendez-vous synchronizations. This property was claimed to be decidable in several conference and journal papers [1, 4, 3, 2] for either mailboxes ($*$-1) or peer-to-peer (1-1) communications, thanks to a form of small model property. In this paper, we show that this small model property does not hold neither for mailbox communications, nor for peer-to-peer communications, therefore the decidability of synchronizability becomes an open question. We close this question for peer-to-peer communications, and we show that synchronizability is actually undecidable. We show that synchronizability is decidable if the topology of communications is an oriented ring. We also show that, in this case, synchronizability implies the absence of unspecified receptions and orphan messages, and the channel-recognizability of the reachability set.

1 Introduction

Asynchronous distributed systems are error prone not only because they are difficult to program, but also because they are difficult to execute in a reproducible way. The slack of communications, measured by the number of messages that can be buffered in a same communication channel, is not always under the control of the programmer, and even when it is, it may be delicate to choose the right size of the communication buffers.

Slack elasticity of a distributed system with asynchronous communications is the property that the "observable behaviour" of the system is the same whatever the slack of communications is. There are actually as many notions of slack elasticity as there are notions of observable behaviours (and of distributed systems). Slack elasticity has been studied in various contexts: for hardware design [16], with the goal of ensuring that some code transformations are semantic-preserving, for parallel programming in MPI [18, 19], for ensuring the absence of deadlocks and other bugs, or more recently for web services and choreographies [1, 4, 2], for verifying various properties, among which choreography realizability [3].

This paper focuses on *synchronizability* [1], a special form of slack elasticity that was defined by Basu and Bultan for analyzing choreographies. Synchronizability is the slack elasticity of the send trace semantics of the system: a system of communicating finite state machines is synchronizable if any asynchronous trace can be mimicked by a synchronous one that contains the same send actions in the same order. Synchronizability was claimed decidable first for mailbox communications [4], where each peer stores all incoming messages in a unique mailbox in a FIFO fashion. Later, the decidability claim was extended to peer-to-peer communications [2], where there is a FIFO queue for every pair of peers. Synchronizability seemed to contrast with many other properties of systems of communicating finite state machines (including deadlock-freedom, absence of orphan messages, boundedness, etc) that are undecidable for systems of just two machines [6]. The proof relied on the claim that synchronizability would be the same as 1-synchronizability, which states that any 1-bounded trace can be mimicked by a synchronous trace.

In this paper, we show that the two claims are actually false: 1-synchronizability does not imply synchronizability, and at least for peer-to-peer communications, synchronizability is undecidable. We also show that the two claims hold, however, if we restrict to systems where the communication topology is an oriented, unidirectional ring, in particular the topology of a system with two peers only. While proving that 1-synchronizability implies synchronizability for ring topologies we also show that 1-synchronizability implies the absence of unspecified receptions and orphan messages, and that the reachability set is channel-recognizable.

Outline. The paper focuses on the peer-to-peer communication model. Section 2 introduces all notions of communicating finite state machines and synchronizability. In Section 3, we show that synchronizability is undecidable. Section 4 shows the decidability of synchronizability on ring topologies. Section 5 concludes with discussions and open problems about other communication models, in particular the mailbox communication model that was the first and the most studied model in previous works on synchronizability. Due to space constraints, several proofs are omitted and can be found in a companion long version [11].

Related Work. The analysis of systems of communicating finite state machines has always been a very active topic of research. Systems with channel-recognizable (aka QDD [5] representable) reachability sets are known to enjoy a decidable reachability problem [17]. Heussner *et al* developed a CEGAR approach based on regular model-checking [13]. Classifications of communication topologies according to the decidability of the reachability problems are known for FIFO, FIFO+lossy, and FIFO+bag communications [8, 9]. In [15, 14], the bounded context-switch reachability problem for communicating machines extended with local stacks modeling recursive function calls is shown decidable under various assumptions. Session types dialects have been introduced for systems of communicating finite state machines [10], and were shown to enforce various desirable properties. Existentially-bounded systems are systems of communicating finite state machines that were studied in a language-theoretic perspective: in [12], in particular, correspondences have been established among message sequence charts languages defined on the one hand by (universally/existentially bounded) systems of communicating machines and on the other hand by monadic second order logic over partial orders and automata Whether a system of communicating machines is existentially bounded, respectively existentially k-bounded for a fixed k, is undecidable in the general case, but it is unknown whether it remains undecidable for systems that are non-blocking.

2 Preliminaries

Messages and topologies. A *message set* M is a tuple $\langle \Sigma_M, p, \mathsf{src}, \mathsf{dst}\rangle$ where Σ_M is a finite set of letters (more often called messages), $p \geq 1$ and $\mathsf{src}, \mathsf{dst}$ are functions that associate to every letter $a \in \Sigma$ naturals $\mathsf{src}(a) \neq \mathsf{dst}(a) \in \{1, \ldots, p\}$. We often write $a^{i\to j}$ for a message a such that $\mathsf{src}(a) = i$ and $\mathsf{dst}(a) = j$; we often identify M and Σ_M and write for instance $M = \{a_1^{i_1\to j_1}, a_2^{i_2\to j_2}, \ldots\}$ instead of $\Sigma_M = \ldots$, or $w \in M^*$ instead of $w \in \Sigma_M^*$. The communication topology associated to M is the graph G_M with vertices $\{1, \ldots, p\}$ and with an edge from i to j if there is a message $a \in \Sigma_M$ such that $\mathsf{src}(a) = i$ and $\mathsf{dst}(a) = j$. G_M is an *oriented ring* if the set of edges of G_M is $\{(i, j) \mid i + 1 = j \bmod p\}$.

Traces. An *action* λ over M is either a send action $!a$ or a receive action $?a$, with $a \in \Sigma_M$. The peer $\mathsf{peer}(\lambda)$ of action λ is defined as $\mathsf{peer}(!a) = \mathsf{src}(a)$ and $\mathsf{peer}(?a) = \mathsf{dst}(a)$. We write $\mathsf{Act}_{i,M}$ for the set of actions of peer i and Act_M for the set of all actions over M. A *M-trace* τ is a finite (possibly empty) sequence of actions. We write Act_M^* for the set of M-traces, ϵ for the empty M-trace, and $\tau_1 \cdot \tau_2$ for the concatenation of two M-traces. We sometimes write $!?a$ for $!a \cdot ?a$. A M-trace τ is a prefix of υ, $\tau \leq_{\mathsf{pref}} \upsilon$ if there is θ such that $\upsilon = \tau \cdot \theta$. The prefix closure $\downarrow S$ of a set of M-traces S is the set $\{\tau \in \mathsf{Act}_M^* \mid \text{there is } \upsilon \in S \text{ such that } \tau \leq_{\mathsf{pref}} \upsilon\}$. For a M-trace τ and peer ids $i, j \in \{1, \ldots, p\}$ we write

- $\mathsf{send}(\tau)$ (resp. $\mathsf{recv}(\tau)$) for the sequence of messages sent (resp. received) during τ, *i.e.* $\mathsf{send}(!a) = a$, $\mathsf{send}(?a) = \epsilon$, and $\mathsf{send}(\tau_1 \cdot \tau_2) = \mathsf{send}(\tau_1) \cdot \mathsf{send}(\tau_2)$ (resp. $\mathsf{recv}(!a) = \epsilon$, $\mathsf{recv}(?a) = a$, and $\mathsf{recv}(\tau_1 \cdot \tau_2) = \mathsf{recv}(\tau_1) \cdot \mathsf{recv}(\tau_2)$).
- $\mathsf{onPeer}_i(\tau)$ for the M-trace of actions λ in τ such that $\mathsf{peer}(\lambda) = i$.
- $\mathsf{onChannel}_{i\to j}(\tau)$ for the M-trace of actions λ in τ such that $\lambda \in \{!a, ?a\}$ for some $a \in M$ with $\mathsf{src}(a) = i$ and $\mathsf{dst}(a) = j$.
- $\mathsf{buffer}_{i\to j}(\tau)$ for the word $w \in M^*$, if it exists, such that $\mathsf{send}(\mathsf{onChannel}_{i\to j}(\tau)) = \mathsf{recv}(\mathsf{onChannel}_{i\to j}(\tau)) \cdot w$.

A M-trace τ is *FIFO* (resp. a *k-bounded FIFO*, for $k \geq 1$) if for all $i, j \in \{1, \ldots, p\}$, for all prefixes τ' of τ, $\mathsf{buffer}_{i\to j}(\tau')$ is defined (resp. defined and of length at most k). A M-trace is *synchronous* if it is of the form $!?a_1 \cdot !?a_2 \cdots !?a_k$ for some $k \geq 0$ and $a_1, \ldots, a_k \in M$. In particular, a synchronous M-trace is a 1-bounded FIFO M-trace (but the converse is false). A M-trace τ is *stable* if $\mathsf{buffer}_{i\to j}(\tau) = \epsilon$ for all $i \neq j \in \{1, \ldots, p\}$.

Two M-traces τ, υ are *causal-equivalent* $\tau \overset{\text{causal}}{\sim} \upsilon$ if

1. τ, υ are FIFO, and
2. for all $i \in \{1, \ldots, p\}$, $\mathsf{onPeer}_i(\tau) = \mathsf{onPeer}_i(\upsilon)$.

The relation $\overset{\text{causal}}{\sim}$ is a congruence with respect to concatenation. Intuitively, $\tau \overset{\text{causal}}{\sim} \upsilon$ if τ is obtained from υ by iteratively commuting adjacent actions that are not from the same peer and do not form a "matching send/receive pair".

Peers, systems, configurations. A system (of communicating machines) over a message set M is a tuple $\mathcal{S} = \langle \mathcal{P}_1, \ldots, \mathcal{P}_p\rangle$ where for all $i \in \{1, \ldots, p\}$, the peer $\mathcal{P}_i$ is a finite state automaton $\langle Q_i, q_{0,i}, \Delta_i\rangle$ over the alphabet $\mathsf{Act}_{i,M}$ and with (implicitly) Q_i as the set of accepting states. We write $L(\mathcal{P}_i)$ for the set of M-traces that label a path in $\mathcal{P}_i$ starting at the initial state $q_{0,i}$.

Let the system $\mathcal{S}$ be fixed. A *configuration* γ of $\mathcal{S}$ is a tuple $(q_1, \ldots, q_p, w_{1,2}, \ldots, w_{p-1,p})$ where q_i is a state of $\mathcal{P}_i$ and for all $i \neq j$, $w_{i,j} \in M^*$ is the content of channel $i \to j$. A configuration is *stable* if $w_{i,j} = \epsilon$ for all $i, j \in \{1, \ldots, p\}$ with $i \neq j$.

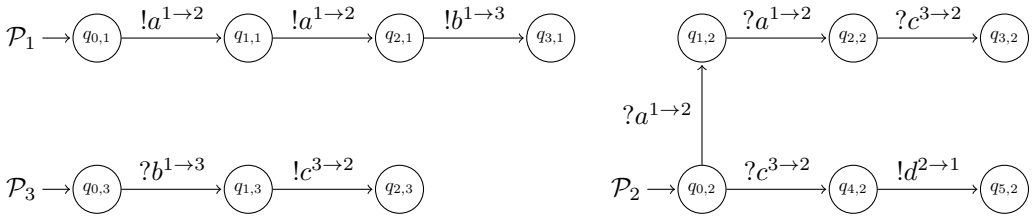

Figure 1 System of Example 1 and Theorem 3.

Let $\gamma = (q_1, \dots, q_p, w_{1,2}, \dots, w_{p-1,p})$, $\gamma' = (q'_1, \dots, q'_p, w'_{1,2}, \dots, w'_{p-1,p})$ and $m \in M$ with $\mathsf{src}(m) = i$ and $\mathsf{dst}(m) = j$. We write $\gamma \xrightarrow{!m}_{\mathcal{S}} \gamma'$ (resp. $\gamma \xrightarrow{?m}_{\mathcal{S}} \gamma'$) if $(q_i, !m, q'_i) \in \Delta_i$ (resp. $(q_j, ?m, q'_j) \in \Delta_j$), $w'_{i,j} = w_{i,j} \cdot m$ (resp. $w_{i,j} = m \cdot w'_{i,j}$) and for all k, ℓ with $k \neq i$ (resp. with $k \neq j$), $q_k = q'_k$ and $w'_{k,\ell} = w_{k,\ell}$ (resp. $w'_{\ell,k} = w_{\ell,k}$). If $\tau = \lambda_1 \cdot \lambda_2 \cdots \lambda_n$, we write $\xrightarrow{\tau}_{\mathcal{S}}$ for $\xrightarrow{\lambda_1}_{\mathcal{S}} \xrightarrow{\lambda_2}_{\mathcal{S}} \dots \xrightarrow{\lambda_n}_{\mathcal{S}}$. We often write $\xrightarrow{\tau}$ instead of $\xrightarrow{\tau}_{\mathcal{S}}$ when $\mathcal{S}$ is clear from the context. The *initial configuration* of $\mathcal{S}$ is the stable configuration $\gamma_0 = (q_{0,1}, \dots, q_{0,p}, \epsilon, \dots, \epsilon)$. A M-trace τ is a trace of system $\mathcal{S}$ if there is γ such that $\gamma_0 \xrightarrow{\tau} \gamma$. Equivalently, τ is a trace of $\mathcal{S}$ if

1. it is a FIFO trace, and
2. for all $i \in \{1, \dots, p\}$, $\mathsf{onPeer}_i(\tau) \in L(\mathcal{P}_i)$.

For $k \geq 1$, we write $\mathsf{Traces}_k(\mathcal{S})$ for the set of k-bounded traces of $\mathcal{S}$, $\mathsf{Traces}_0(\mathcal{S})$ for the set of synchronous traces of $\mathcal{S}$, and $\mathsf{Traces}_\omega(\mathcal{S})$ for $\bigcup_{k\geq 0} \mathsf{Traces}_k(\mathcal{S})$.

▶ **Example 1.** Consider the message set $M = \{a^{1\to2}, b^{1\to3}, c^{3\to2}, d^{2\to1}\}$ and the system $\mathcal{S} = \langle \mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3 \rangle$ where $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$ are as depicted in Fig. 1. Then

$$\begin{aligned} L(\mathcal{P}_1) &= \downarrow\{!a^{1\to2} \cdot !a^{1\to2} \cdot !b^{1\to3}\} \\ L(\mathcal{P}_2) &= \downarrow\{?a^{1\to2} \cdot ?a^{1\to2} \cdot ?c^{3\to2} \ , \ ?c^{3\to2} \cdot !d^{2\to1}\} \\ L(\mathcal{P}_3) &= \downarrow\{?b^{1\to3} \cdot !c^{3\to2}\}. \end{aligned}$$

An example of a stable trace is $!a^{1\to2} \cdot !a^{1\to2} \cdot !?b^{1\to3} \cdot !c^{3\to2} \cdot ?a^{1\to2} \cdot ?a^{1\to2} \cdot ?c^{3\to2}$. Let $\tau = !a^{1\to2} \cdot !a^{1\to2} \cdot !?b^{1\to3} \cdot !?c^{3\to2} \cdot !d^{2\to1}$. Then $\tau \in \mathsf{Traces}_2(\mathcal{S})$ is a 2-bounded trace of the system $\mathcal{S}$, and $\gamma_0 \xrightarrow{\tau} (q_{3,1}, q_{5,2}, q_{2,3}, a^{1\to2}a^{1\to2}, \epsilon, d^{2\to1}, \epsilon, \epsilon, \epsilon)$.

Two traces τ_1, τ_2 are $\mathcal{S}$-*equivalent*, $\tau_1 \overset{\mathcal{S}}{\sim} \tau_2$, if $\tau_1, \tau_2 \in \mathsf{Traces}_\omega(\mathcal{S})$ and there is γ such that $\gamma_0 \xrightarrow{\tau_i} \gamma$ for both $i = 1, 2$. It follows from the definition of $\overset{\text{causal}}{\sim}$ that if $\tau_1 \overset{\text{causal}}{\sim} \tau_2$ and $\tau_1, \tau_2 \in \mathsf{Traces}_\omega(\mathcal{S})$, then $\tau_1 \overset{\mathcal{S}}{\sim} \tau_2$.

Synchronizability. Following [4], we define the observable behaviour of a system as its set of send traces enriched with their final configurations when they are stable. Formally, for any $k \geq 0$, we write $\mathcal{J}_k(\mathcal{S})$ and $\mathcal{I}_k(\mathcal{S})$ for the sets

$$\begin{aligned} \mathcal{J}_k(\mathcal{S}) &= \{\mathsf{send}(\tau) \mid \tau \in \mathsf{Traces}_k(\mathcal{S})\} \\ \mathcal{I}_k(\mathcal{S}) &= \mathcal{J}_k(\mathcal{S}) \cup \{(\mathsf{send}(\tau), \gamma) \mid \gamma_0 \xrightarrow{\tau} \gamma, \gamma \text{ stable}, \tau \in \mathsf{Traces}_k(\mathcal{S})\}. \end{aligned}$$

Synchronizability is then defined as the slack elasticity of these observable behaviours.

▶ **Definition 2** (Synchronizability [1, 4])**.** A system $\mathcal{S}$ is *synchronizable* if $\mathcal{I}_0(\mathcal{S}) = \mathcal{I}_\omega(\mathcal{S})$. $\mathcal{S}$ is called *language synchronizable* if $\mathcal{J}_0(\mathcal{S}) = \mathcal{J}_\omega(\mathcal{S})$.

For convenience, we also introduce a notion of k-synchronizability: for $k \geq 1$, a system $\mathcal{S}$ is k-*synchronizable* if $\mathcal{I}_0(\mathcal{S}) = \mathcal{I}_k(\mathcal{S})$, and *language* k-synchronizable if $\mathcal{J}_0(\mathcal{S}) = \mathcal{J}_k(\mathcal{S})$. A system is therefore (language) synchronizable if and only if it is (language) k-synchronizable for all $k \geq 1$.

▶ **Theorem 3.** *There is a system $\mathcal{S}$ that is 1-synchronizable, but not synchronizable.*

Proof. Consider again the system $\mathcal{S}$ of Example 1. Let $\gamma_{ijk} := (q_{i,1}, q_{j,2}, q_{k,3}, \epsilon, \ldots, \epsilon)$. Then

$$\begin{array}{lcl} \mathcal{J}_0(\mathcal{S}) & = & \downarrow \{a^{1\to 2} \cdot a^{1\to 2} \cdot b^{1\to 3} \cdot c^{3\to 2}\} \\ \mathcal{J}_1(\mathcal{S}) & = & \mathcal{J}_0(\mathcal{S}) \\ \mathcal{J}_2(\mathcal{S}) & = & \downarrow \{a^{1\to 2} \cdot a^{1\to 2} \cdot b^{1\to 3} \cdot c^{3\to 2} \cdot d^{2\to 1}\} \\ \mathcal{I}_k(\mathcal{S}) & = & \mathcal{J}_k(\mathcal{S}) \cup \mathsf{Stab} \qquad \text{for all } k \geq 0 \end{array}$$

where $\mathsf{Stab} = \{(\epsilon, \gamma_0), (a^{1\to 2}, \gamma_{101}), (a^{1\to 2} \cdot a^{1\to 2}, \gamma_{202}), (a^{1\to 2} \cdot a^{1\to 2} \cdot b^{1\to 3}, \gamma_{312}), (a^{1\to 2} \cdot a^{1\to 2} \cdot b^{1\to 3} \cdot c^{3\to 2}, \gamma_{323})\}$. ◀

This example contradicts Theorem 4 in [2], which stated that $\mathcal{J}_0(\mathcal{S}) = \mathcal{J}_1(\mathcal{S})$ implies $\mathcal{J}_0(\mathcal{S}) = \mathcal{J}_\omega(\mathcal{S})$. This also shows that the decidability of synchronizability for peer-to-peer communications is open despite the claim in [2]. The next section closes this question.

▶ Remark. In Section 5, we give a counter-example that addresses communications with mailboxes, *i.e.* the first communication model considered in all works about synchronizability, and we list several other published theorems that our counter-example contradicts.

3 Undecidability of Synchronizability

In this section, we show the undecidability of synchronizability for systems with at least three peers. The key idea is to reduce a decision problem on a FIFO automaton $\mathcal{A}$, i.e. an automaton that can both enqueue and dequeue messages in a unique channel, to the synchronizability of a system $\mathcal{S}_\mathcal{A}$. The reduction is quite delicate, because synchronizability constrains a lot the way $\mathcal{S}_\mathcal{A}$ can be defined (a hint for that being that $\mathcal{S}_\mathcal{A}$ *must* involve three peers). It is also delicate to reduce from a classical decision problem on FIFO automata like *e.g.* the reachability of a control state, and we first establish the undecidability of a well-suited decision problem on FIFO automata, roughly the reception of a message m with some extra constraints. We can then construct a system $\mathcal{S}''_{\mathcal{A},m}$ such that the synchronizability of $\mathcal{S}''_{\mathcal{A},m}$ is equivalent to the non-reception of the special message m in $\mathcal{A}$.

A *FIFO automaton* is a finite state automaton $\mathcal{A} = \langle Q, \mathsf{Act}_\Sigma, \Delta, q_0 \rangle$ over an alphabet of the form Act_Σ for some finite set of letters Σ with all states being accepting states. A FIFO automaton can be thought as a system with only one peer, with the difference that, according to our definition of systems, a peer can only send messages to peers different from itself, whereas a FIFO automaton enqueues and dequeues letters in a unique FIFO queue, and thus, in a sense, "communicates with itself". All notions we introduced for systems are obviously extended to FIFO automata. In particular, a configuration of $\mathcal{A}$ is a tuple $\gamma = (q, w) \in Q \times \Sigma^*$, it is stable if $w = \epsilon$, and the transition relation $\gamma \xrightarrow{\tau} \gamma'$ is defined exactly the same way as for systems. For technical reasons, we consider two mild restrictions on FIFO automata:

(***R1***) for all $\gamma_0 \xrightarrow{\tau} (q, w)$, either $\tau = \epsilon$ or $w \neq \epsilon$ (in other words, all reachable configurations are unstable, except the initial one);

(***R2***) for all $(q_0, \lambda, q) \in \Delta$, $\lambda = !a$ for some $a \in \Sigma$ (in other words, there is no receive action labeling a transition from the initial state).

▶ **Lemma 4.** *The following decision problem is undecidable.*
Input *A FIFO automaton $\mathcal{A}$ that satisfies (R1) and (R2), and a message m.*
Question *Is there a M-trace τ such that $\tau \cdot ?m \in \mathsf{Traces}_\omega(\mathcal{A})$?*

Proof. This kind of result is often considered folklore, but it seems it could be informative to detail a possible construction. We reduce from the existence of a finite tiling given a set of tiles and a pair of initial and final tiles. Intuitively, we construct a FIFO automaton that outputs the first row of the tiling, storing it into the queue, and then for all next row $i+1$, the automaton outputs the row tile after tile, popping a tile of row i in the queue in between so as to check that each tile of row $i+1$ vertically coincides with the corresponding tile of row i. Consider a tuple $\mathcal{T} = \langle T, t_0, t_F, H, V\rangle$ where T is a finite set of tiles $t_0, t_F \in T$ are initial and final tiles, and $H, V \subseteq T \times T$ are horizontal and vertical compatibility relations. Without loss of generality, we assume that there is a "padding tile" $\square$ such that $(t, \square) \in H \cap V$ for all $t \in T$. For a natural $n \geq 1$, a n-tiling is a function $f : \mathbb{N} \times \{1, \ldots, n\} \to T$ such that

1. $f(0,0) = t_0$,
2. there are $(i_F, j_F) \in \mathbb{N} \times \{1, \ldots, n\}$ such that $f(i_F, j_F) = t_F$,
3. $(f(i,j), f(i,j+1)) \in H$ for all $(i,j) \in \mathbb{N} \times \{1, \ldots, n-1\}$, and
4. $(f(i,j), f(i+1,j)) \in V$ for all $(i,j) \in \mathbb{N} \times \{1, \ldots, n\}$.

The problem of deciding, given a tuple $\mathcal{T} = \langle T, t_0, t_F, H, V\rangle$, whether there is some $n \geq 1$ for which there exists a n-tiling, is undecidable.[1] Let $\mathcal{T} = \langle T, t_0, t_F, H, V\rangle$ be fixed. We define the FIFO automaton $\mathcal{A}_\mathcal{T} = \langle Q, \Sigma, \Delta, q_0\rangle$ with $Q = \{q_{t,0}, q_{\downarrow=t}, q_{\leftarrow=t}, q_{\leftarrow=t,\downarrow=t'} \mid t \in T, t' \in T \cup \{\$\}\} \cup \{q_0, q_1\}$, $\Sigma = T \cup \{\$\}$, and $\Delta \subseteq Q \times \mathsf{Act}_\Sigma \times Q$, with

$$\begin{array}{rcl}
\Delta & = & \{(q_0, !t_0, q_{t_0,0})\} \cup \{(q_{t,0}, !t', q_{t',0}) \mid (t,t') \in H\} \cup \{(q_{t,0}, !\$, q_1) \mid t \in T\} \\
& \cup & \{(q_1, ?t, q_{\downarrow=t}) \mid t \in T)\} \cup \{(q_{\downarrow=t}, !t', q_{\leftarrow=t'}) \mid (t,t') \in V\} \\
& \cup & \{(q_{\leftarrow=t}, ?t', q_{\leftarrow=t,\downarrow=t'}) \mid t \in T, t' \in T \cup \{\$\}\} \\
& \cup & \{(q_{\leftarrow=t,\downarrow=t'}, !t'', q_{\leftarrow=t''}) \mid (t,t'') \in H \text{ and } (t',t'') \in V\} \\
& \cup & \{(q_{\leftarrow=t,\downarrow=\$}, !\$, q_1) \mid t \in T\}
\end{array}$$

Therefore, any execution of $\mathcal{A}_\mathcal{T}$ is of the form

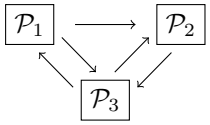
$$!t_{1,1} \cdot !t_{1,2} \cdots !t_{1,n} \cdot !\$ \cdot ?t_{1,1} \cdot !t_{2,1} \cdot ?t_{1,2} \cdot !t_{2,2} \cdots !t_{2,n} \cdot ?\$ \cdot !\$ \cdot ?t_{2,1} \cdot !t_{3,1} \cdots$$

where $t_{1,1} = t_0$, $(t_{i,j}, t_{i+1,j}) \in V$ and $(t_{i,j}, t_{i,j+1}) \in H$. The following two are thus equivalent:

1. there is $n \geq 1$ such that $\mathcal{T}$ admits a n-tiling
2. there is a trace $\tau \in \mathsf{Traces}_\omega(\mathcal{A})$ that contains $?t_F$. ◀

Let us now fix a FIFO automaton $\mathcal{A} = \langle Q_\mathcal{A}, \mathsf{Act}_\Sigma, \Delta_\mathcal{A}, q_0\rangle$ that satisfies $(R1)$ and $(R2)$. Let $M = M_1 \cup M_2 \cup M_3$ be such that all messages of Σ can be exchanged among all peers in all directions but $2 \to 1$, *i.e.*

$$\begin{array}{rcl}
M_1 & = & \{a^{1\to2}, a^{1\to3}, a^{3\to1} \mid a \in \Sigma\} \\
M_2 & = & \{a^{3\to2}, a^{1\to2}, a^{2\to3} \mid a \in \Sigma\} \\
M_3 & = & \{a^{1\to3}, a^{3\to1}, a^{3\to2}, a^{2\to3} \mid a \in \Sigma\}
\end{array}$$



Intuitively, we want $\mathcal{P}_1$ to mimick $\mathcal{A}$'s decisions and the channel $1 \to 2$ to mimick $\mathcal{A}$'s queue as follows. When $\mathcal{A}$ would enqueue a letter a , peer 1 sends $a^{1\to2}$ to peer 2, and when $\mathcal{A}$ would dequeue a letter a, peer 1 sends to peer 2 via peer 3 the order to dequeue a, and waits for the acknowledgement that the order has been correcly executed. Formally, let $\mathcal{P}_1 = \langle Q_1, q_{0,1}, \Delta_1\rangle$ be defined by $Q_1 = Q_\mathcal{A} \uplus \{q_\delta \mid \delta \in \Delta_\mathcal{A}\}$ and $\Delta_1 = \{(q, !a^{1\to2}, q') \mid$

[1] Note that, due to the presence of the padding tile, this problem is equivalent to the problem of the existence of a finite rectangular tiling that contains t_0 at the beginning of the first row and t_F anywhere in the rectangle, which in turn is equivalent to the termination of a Turing machine.

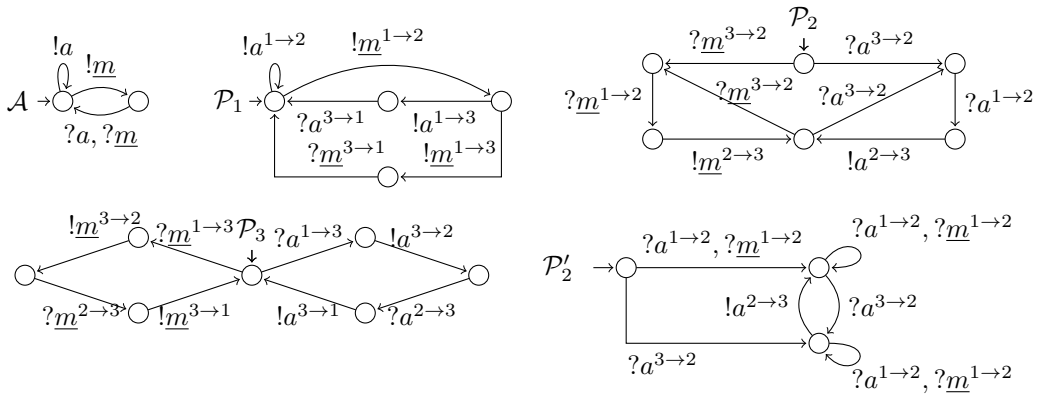


Figure 2 The FIFO automaton $\mathcal{A}$ of Example 5 and its associated systems $\mathcal{S}_\mathcal{A} = \langle \mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3 \rangle$ and $\mathcal{S}'_{\mathcal{A},\underline{m}} = \langle \mathcal{P}_1, \mathcal{P}'_2, \mathcal{P}_3 \rangle$. The sink state $q_\perp$ and the transitions $q \xrightarrow{?\underline{m}^{3\to2}} q_\perp$ are omitted in the representation of $\mathcal{P}'_2$.

$(q, !a, q') \in \Delta_\mathcal{A}\} \cup \{(q, !a^{1\to3}, q_\delta), (q_\delta, ?a^{3\to1}, q') \mid \delta = (q, ?a, q') \in \Delta_\mathcal{A}\}$. The roles of peers 2 and 3 is then rather simple: peer 3 propagates all messages it receives, and peer 2 executes all orders it receives and sends back an acknowledgement when this is done. Let $\mathcal{P}_2 = \langle Q_2, q_{0,2}, \Delta_2 \rangle$ and $\mathcal{P}_3 = \langle Q_3, q_{0,3}, \Delta_3 \rangle$ be defined as we just informally described, with a slight complication about the initial state of $\mathcal{P}_2$ (this is motivated by technical reasons that will become clear soon).

$$
\begin{aligned}
Q_2 &= \{q_{0,2}, q_{1,2}\} \cup \{q_{a,1}, q_{a,2} \mid a \in \Sigma\} \qquad Q_3 = \{q_{0,3}\} \cup \{q_{a,1}, q_{a,2}, q_{a,3} \mid a \in \Sigma\} \\
\Delta_2 &= \{(q_{0,2}, ?a^{3\to2}, q_{a,1}), (q_{1,2}, ?a^{3\to2}, q_{a,1}), (q_{a,1}, ?a^{1\to2}, q_{a,2}), (q_{a,2}, !a^{2\to3}, q_{1,2}) \mid a \in \Sigma\} \\
\Delta_3 &= \{(q_{0,3}, ?a^{1\to3}, q_{a,1}), (q_{a,1}, !a^{3\to2}, q_{a,2}), (q_{a,2}, ?a^{2\to3}, q_{a,3}), (q_{a,3}, !a^{3\to1}, q_{0,3}) \mid a \in \Sigma\}
\end{aligned}
$$

▶ **Example 5.** Consider $\Sigma = \{a, \underline{m}\}$ and the FIFO automaton $\mathcal{A} = \langle \{q_0, q_1\}, \mathsf{Act}_\Sigma, \Delta, q_0 \rangle$ with transition relation $\Delta_\mathcal{A} = \{(q_0, !a, q_0), (q_0, !\underline{m}, q_1), (q_1, ?a, q_0), (q_1, ?\underline{m}, q_0)\}$. Then $\mathcal{A}$ and the peers $\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3$ are depicted in Fig. 2.

Let $\mathcal{S}_\mathcal{A} = \langle \mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3 \rangle$. There is a tight correspondence between the k-bounded traces of $\mathcal{A}$, for $k \geq 1$, and the k-bounded traces of $\mathcal{S}_\mathcal{A}$: every trace $\tau \in \mathsf{Traces}_k(\mathcal{A})$ induces the trace $h(\tau) \in \mathsf{Traces}_k(\mathcal{S}_\mathcal{A})$ where $h : \mathsf{Act}_\Sigma^* \to \mathsf{Act}_M$ is the homomorphism from the traces of $\mathcal{A}$ to the traces of $\mathcal{S}_\mathcal{A}$ defined by $h(!a) = !a^{1\to2}$ and $h(?a) = !?a^{1\to3} \cdot !?a^{3\to2} \cdot ?a^{1\to2} \cdot !?a^{2\to3} \cdot !?a^{3\to1}$. The converse is not true: there are traces of $\mathcal{S}_\mathcal{A}$ that are not prefixes of a trace $h(\tau)$ for some $\tau \in \mathsf{Traces}_k(\mathcal{A})$. This happens when $\mathcal{P}_1$ sends an order to dequeue $a^{1\to3}$ that correspond to a transition $?a$ that $\mathcal{A}$ cannot execute. In that case, the system blocks when $\mathcal{P}_2$ has to execute the order.

▶ **Lemma 6.** *For all $k \geq 0$,* $\mathsf{Traces}_k(\mathcal{S}_\mathcal{A}) = \downarrow \{h(\tau) \mid \tau \in \mathsf{Traces}_k(\mathcal{A})\} \cup \downarrow \{h(\tau) \cdot !?a^{1\to3} \cdot !?a^{3\to2} \mid \tau \in \mathsf{Traces}_k(\mathcal{A}), (q_0, \epsilon) \xrightarrow{\tau} (q, w), (q, ?a, q') \in \Delta\}$.

Since $\mathcal{A}$ satisfies $(R1)$, all stable configurations that are reachable in $\mathcal{S}_\mathcal{A}$ are reachable by a synchronous trace, and since it satisfies $(R2)$, the only reachable stable configuration is the initial configuration. Moreover, $\mathcal{J}_0(\mathcal{S}_A) = \{\epsilon\}$ and $\mathcal{J}_k(\mathcal{S}_\mathcal{A}) \neq \{\epsilon\}$ for $k \geq 1$ (provided $\mathcal{A}$ sends at least one message). As a consequence, $\mathcal{S}_\mathcal{A}$ is not synchronizable.

Let us fix now a special message $\underline{m} \in \Sigma$. We would like to turn $\mathcal{S}_\mathcal{A}$ into a system that is synchronizable, except for the send traces that contain $\underline{m}^{2\to3}$. Note that, by Lemma 6, $\mathcal{S}_\mathcal{A}$

has a send trace that contains $\underline{m}^{2\to3}$ if and only if there are traces of $\mathcal{A}$ that contain $?\underline{m}$. Roughly, we need to introduce new behaviours for the peer 2 that will "flood" the system with many synchronous traces. Let $\mathcal{S}'_{\mathcal{A},\underline{m}} = \langle \mathcal{P}_1, \mathcal{P}'_2, \mathcal{P}_3\rangle$ be the system $\mathcal{S}_\mathcal{A}$ in which the peer $\mathcal{P}_2$ is replaced with the peer $\mathcal{P}'_2 = \langle Q'_2, q_{0,2}, \Delta'_2\rangle$ defined as follows.

$$\begin{array}{rcl} Q'_2 & = & \{q_{0,2}, q'_{0,2}\} \cup \{q'_{a,1} \mid a \in \Sigma, a \neq \underline{m},\} \cup \{q_\perp\} \\ \Delta'_2 & = & \{(q_{0,2}, ?a^{1\to2}, q'_{0,2}), (q, ?a^{1\to2}, q) \mid a \in \Sigma, q \neq q_{0,2}\} \\ & \cup & \{(q_{0,2}, ?a^{3\to2}, q'_{a,1}), (q'_{0,2}, ?a^{3\to2}, q'_{a,1}), (q'_{a,1}, !a^{2\to3}, q'_{0,2}), \mid a \in \Sigma, a \neq \underline{m}\} \\ & \cup & \{(q, ?\underline{m}^{3\to2}, q_\perp) \mid q \in Q'_2\} \end{array}$$

▶ **Example 7.** For $\Sigma = \{a, \underline{m}\}$, and $\mathcal{A}$ as in Example 5, $\mathcal{P}'_2$ is depicted in Fig. 2 (omitting the transitions to the sink state $q_\perp$).

Intuitively, $\mathcal{P}'_2$ can always receive any message from peer $\mathcal{P}_1$. Like $\mathcal{P}_2$, it can also receive orders to dequeue from peer $\mathcal{P}_3$, but instead of executing the order before sending an acknowledgement, it ignores the order as follows. If $\mathcal{P}'_2$ receives the order to dequeue a message $a^{1\to2} \neq \underline{m}^{1\to2}$, $\mathcal{P}'_2$ acknowledges $\mathcal{P}_3$ but does not dequeue in the $1 \to 2$ queue. If the order was to dequeue $\underline{m}$, $\mathcal{P}'_2$ blocks in the sink state $q_\perp$. The system $\mathcal{S}'_\mathcal{A} = \langle \mathcal{P}_1, \mathcal{P}'_2, \mathcal{P}_3\rangle$ contains many synchronous traces: any M-trace $\tau \in L(\mathcal{P}_1)$ labeling a path in automaton $\mathcal{P}_1$ can be lifted to a synchronous trace $\tau' \in \mathsf{Traces}_0(\mathcal{S}_{\mathcal{A},\underline{m}})$ provided $!\underline{m}^{1\to3}$ does not occur in τ. However, if $\mathcal{P}_1$ takes a $!\underline{m}^{1\to3}$ transition, it gets blocked for ever waiting for $\underline{m}^{3\to1}$. Therefore, if $!a^{1\to3}$ occurs in a synchronous trace τ of $\mathcal{S}'_{\mathcal{A},\underline{m}}$, it must be in the last four actions, and this trace leads to a deadlock configuration in which both 1 and 3 wait for an acknowledgement and 2 is in the sink state.

Let $L^{\underline{m}}(\mathcal{A})$ be the set of traces τ recognized by $\mathcal{A}$ as a finite state automaton (over the alphabet Act_Σ) such that either $?\underline{m}$ does not occur in τ, or it occurs only once and it is the last action of τ. For instance, with $\mathcal{A}$ as in Example 5, $L^{\underline{m}}(\mathcal{A}) =\downarrow \left(!a^* \cdot !\underline{m} \cdot ?a\right)^* \cdot !a^* \cdot !\underline{m} \cdot ?\underline{m}$. Let $h' : \mathsf{Act}^*_\Sigma \to \mathsf{Act}^*_M$ be the morphism defined by $h'(!a) =!?a^{1\to2}$ for all $a \in \Sigma$, $h'(?a) = !?a^{1\to3} \cdot !?a^{3\to2} \cdot !?a^{2\to3} \cdot !?a^{3\to1}$ for all $a \neq \underline{m}$, and $h'(?\underline{m}) =!?\underline{m}^{1\to3} \cdot !?\underline{m}^{3\to2}$.

▶ **Lemma 8.** $\mathsf{Traces}_0(\mathcal{S}'_{\mathcal{A},\underline{m}}) =\downarrow \{h'(\tau) \mid \tau \in L^{\underline{m}}(\mathcal{A})\}$.

Let us now consider an arbitrary trace $\tau \in \mathsf{Traces}_\omega(\mathcal{S}'_{\mathcal{A},\underline{m}})$. Let $h'' : \mathsf{Act}^*_M \to \mathsf{Act}^*_M$ be such that $h''(!a^{1\to2}) =!?a^{1\to2}$, $h''(?a^{1\to2}) = \epsilon$, and $h''(\lambda) = \lambda$ otherwise. Then $h''(\tau) \in \mathsf{Traces}_0(\mathcal{S}'_{\mathcal{A},\underline{m}})$ and $\tau \overset{\mathcal{S}}{\sim} h''(\tau)$ for $\mathcal{S} = \mathcal{S}'_{\mathcal{A},\underline{m}}$. Indeed, τ and $h''(\tau)$ are the same up to insertions and deletions of receive actions $?a^{1\to2}$, and every state of $\mathcal{P}'_2$ (except the initial one) has a self loop $?a^{1\to2}$. Therefore,

▶ **Lemma 9.** *$\mathcal{S}'_{\mathcal{A},\underline{m}}$ is synchronizable.*

Let us now consider the system $\mathcal{S}''_{\mathcal{A},\underline{m}} = \langle \mathcal{P}_1, \mathcal{P}_2 \cup \mathcal{P}'_2, \mathcal{P}_3\rangle$, where $\mathcal{P}_2 \cup \mathcal{P}'_2 = \langle Q_2 \cup Q'_2, q_{02}, \Delta_2 \cup \Delta''_2\rangle$ is obtained by merging the initial state $q_{0,2}$ of $\mathcal{P}_2$ and $\mathcal{P}'_2$. Note that $\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) = \mathcal{I}_k(\mathcal{S}_\mathcal{A}) \cup \mathcal{I}_k(\mathcal{S}'_{\mathcal{A},\underline{m}})$, because $q_{0,2}$ has no incoming edge in $\mathcal{P}_2 \cup \mathcal{P}'_2$.

▶ **Lemma 10.** *Let $k \geq 1$. The following two are equivalent:*
1. *there is τ such that $\tau \cdot ?\underline{m} \in \mathsf{Traces}_k(\mathcal{A})$;*
2. *$\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) \neq \mathcal{I}_0(\mathcal{S}''_{\mathcal{A},\underline{m}})$.*

Proof. Let $k \geq 1$ be fixed.

(1) $\Longrightarrow$ (2) Let τ be such that $\tau \cdot ?\underline{m} \in \mathsf{Traces}_k(\mathcal{A})$. By Lemma 6, there is $\upsilon \in \mathcal{I}_k(\mathcal{S}_\mathcal{A})$ such that $\underline{m}^{2\to3}$ occurs in υ (take $\upsilon = \mathsf{send}(h(\tau \cdot ?\underline{m}))$). By Lemma 6, $\upsilon \notin \mathcal{I}_0(\mathcal{S}_\mathcal{A}) = \emptyset$, and by Lemma 8, $\upsilon \notin \mathcal{I}_0(\mathcal{S}'_{\mathcal{A},\underline{m}})$. Therefore $\upsilon \in \mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) \setminus \mathcal{I}_0(\mathcal{S}''_{\mathcal{A},\underline{m}})$.

(2) $\Longrightarrow$ (1) By contraposite. Let $\mathsf{Traces}_k(\mathcal{A}\backslash ?\underline{m}) = \{\tau \in \mathsf{Traces}_k(\mathcal{A}) \mid ?\underline{m} \text{ does not occur in } \tau\}$, and let us assume $\neg(1)$, *i.e.* $\mathsf{Traces}_k(\mathcal{A}\backslash ?\underline{m}) = \mathsf{Traces}_k(\mathcal{A})$. Let us show that $\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) = \mathcal{I}_0(\mathcal{S}''_{\mathcal{A},\underline{m}})$. From the assumption $\neg(1)$ and Lemma 6, it holds that $\mathsf{Traces}_k(\mathcal{S}_{\mathcal{A}}) =$

$$\begin{array}{rl} & \downarrow\{h(\tau) \mid \tau \in \mathsf{Traces}_k(\mathcal{A}\backslash ?\underline{m})\} \\ \cup & \downarrow\{h(\tau)\cdot !?a^{1\to 3}\cdot !?a^{3\to 2} \mid \tau \in \mathsf{Traces}_k(\mathcal{A}\backslash ?\underline{m}), (q_0,\epsilon) \xrightarrow{\tau} (q,w), (q,?a,q') \in \Delta\}. \end{array}$$

By $\mathsf{send}(h(\tau)) = \mathsf{send}(h'(\tau))$ and $\mathsf{Traces}_k(\mathcal{A}\backslash ?\underline{m}) \subseteq L^{\underline{m}}(\mathcal{A})$, we get that

$$\mathcal{I}_k(\mathcal{S}_{\mathcal{A}}) \quad \subseteq \quad \downarrow\{\mathsf{send}(h'(\tau)) \mid \tau \in L^{\underline{m}}(\mathcal{A})\}$$

and therefore, by Lemma 8, $\mathcal{I}_k(\mathcal{S}_{\mathcal{A}}) \subseteq \mathcal{I}_0(\mathcal{S}'_{\mathcal{A},\underline{m}})$. Since $\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) = \mathcal{I}_k(\mathcal{S}_{\mathcal{A}}) \cup \mathcal{I}_k(\mathcal{S}'_{\mathcal{A},\underline{m}})$ and since by Lemma 9 $\mathcal{I}_k(\mathcal{S}'_{\mathcal{A},\underline{m}}) = \mathcal{I}_0(\mathcal{S}'_{\mathcal{A},\underline{m}})$, we get that $\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) \subseteq \mathcal{I}_0(\mathcal{S}''_{\mathcal{A}\underline{m}})$, and thus $\mathcal{I}_k(\mathcal{S}''_{\mathcal{A},\underline{m}}) = \mathcal{I}_0(\mathcal{S}''_{\mathcal{A}\underline{m}})$. ◀

▶ **Theorem 11.** *Synchronizability (resp. language synchronizability) is undecidable.*

Proof. Let a FIFO automaton $\mathcal{A}$ satisfying $(R1)$ and $(R2)$ and a message $\underline{m}$ be fixed. By Lemma 10, $\mathcal{S}''_{\mathcal{A},\underline{m}}$ is non synchronizable iff there is a trace τ such that $\tau \cdot ?\underline{m} \in \mathsf{Traces}_\omega(\mathcal{A})$. By Lemma 4, this is an undecidable problem. ◀

4 The case of oriented rings

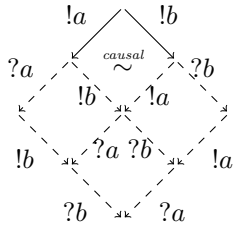
In the previous section we established the undecidability of synchronizability for systems with (at least) three peers. In this section, we show that this result is tight, in the sense that synchronizability is decidable if G_M is an oriented ring, in particular if the system involves two peers only. This relies on the fact that 1-synchronizability implies synchronizability for such systems. This property is highly non-trivial, and below we only sketch the main steps of the proof, identifying when the hypothesis on the ring topology becomes necessary.

The starting point is a confluence property on arbitrary 1-synchronizable systems.

▶ **Lemma 12.** *Let $\mathcal{S}$ be a 1-synchronizable system. Let $\tau \in \mathsf{Traces}_0(\mathcal{S})$ and $a, b \in M$ be such that*

1. $\tau \cdot !a \in \mathsf{Traces}_1(\mathcal{S})$,
2. $\tau \cdot !b \in \mathsf{Traces}_1(\mathcal{S})$, *and*
3. $\mathsf{src}(a) \neq \mathsf{src}(b)$.

If υ_1, υ_2 are any two of the six different shuffles of $!a \cdot ?a$ with $!b \cdot ?b$, then $\tau \cdot \upsilon_1 \in \mathsf{Traces}_\omega(\mathcal{S})$, $\tau \cdot \upsilon_2 \in \mathsf{Traces}_\omega(\mathcal{S})$ and $\tau \cdot \upsilon_1 \overset{\mathcal{S}}{\sim} \tau \cdot \upsilon_2$.



▶ Remark. This lemma should not be misunderstood as a consequence of causal equivalence. Observe indeed that the square on top of the diagram is the only square that commutes for causal equivalence. The three other squares only commute with respect to $\overset{\mathcal{S}}{\sim}$, and they commute for $\overset{\text{causal}}{\sim}$ only if some extra assumptions on a and b are made. For instance, the left square does commute for $\overset{\text{causal}}{\sim}$ if and only if $\mathsf{dst}(a) \neq \mathsf{src}(b)$.

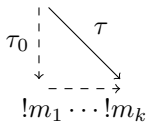
Lemma 12 then generalizes to arbitrary sequences of send actions with rather technical arguments.

▶ **Lemma 13.** *Let $\mathcal{S}$ be a 1-synchronizable system. Let $a_1, \ldots, a_n, b_1, \ldots b_m \in M$ and $\tau \in \mathsf{Traces}_0(\mathcal{S})$ be such that*
1. $\tau \cdot !a_1 \cdots !a_n \in \mathsf{Traces}_n(\mathcal{S})$,
2. $\tau \cdot !b_1 \cdots !b_m \in \mathsf{Traces}_m(\mathcal{S})$, *and*
3. $\mathsf{src}(a_i) \neq \mathsf{src}(b_j)$ *for all* $i \in \{1, \ldots, n\}$ *and* $j \in \{1, \ldots, m\}$.
Then for any two different shuffles υ_1, υ_2 of $!?a_1 \cdot !?a_2 \cdots !?a_n$ with $!?b_1 \cdot !?b_2 \cdots !?b_m$, it holds that $\tau \cdot \upsilon_1 \in \mathsf{Traces}_\omega(\mathcal{S})$, $\tau \cdot \upsilon_2 \in \mathsf{Traces}_\omega(\mathcal{S})$ and $\tau \cdot \upsilon_1 \overset{\mathcal{S}}{\sim} \tau \cdot \upsilon_2$.

For the rest of the proof, the hypothesis on the communication topology being an oriented ring becomes necessary. We follow the rough idea in [4], also used for half-duplex systems [7], and show a trace normalization property.

▶ **Definition 14** (Normalized trace)**.** A M-trace τ is *normalized* if there is a synchronous M-trace τ_0, $n \geq 0$, and messages $a_1, \ldots, a_n$ such that $\tau = \tau_0 \cdot !a_1 \cdots !a_n$.

▶ **Lemma 15** (Trace Normalization)**.** *Assume M is such that the communication topology G_M is an oriented ring. Let $\mathcal{S} = \langle \mathcal{P}_1, \ldots, \mathcal{P}_p \rangle$ be a 1-synchronizable M-system. For all $\tau \in \mathsf{Traces}_\omega(\mathcal{S})$, there is a normalized trace $\mathsf{norm}(\tau) \in \mathsf{Traces}_\omega(\mathcal{S})$ such that $\tau \overset{\mathcal{S}}{\sim} \mathsf{norm}(\tau)$.*



Proof. By induction on τ. Let $\tau = \tau' \cdot \lambda$, be fixed. Let us assume by induction hypothesis that there is a normalized trace $\mathsf{norm}(\tau') \in \mathsf{Traces}_\omega(\mathcal{S})$ such that $\tau' \overset{\mathcal{S}}{\sim} \mathsf{norm}(\tau')$. Let us reason by case analysis on the last action λ of τ. The easy case is when λ is a send action: then, $\mathsf{norm}(\tau') \cdot \lambda$ is a normalized trace, and $\mathsf{norm}(\tau') \cdot \lambda \overset{\mathcal{S}}{\sim} \tau' \cdot \lambda$ by right congruence of $\overset{\mathcal{S}}{\sim}$. The difficult case is when λ is $?a$ for some $a \in M$. Let $i = \mathsf{src}(a)$, $j = \mathsf{dst}(a)$, *i.e.* $i + 1 = j \bmod p$. By the definitions of a normal trace and $\overset{\text{causal}}{\sim}$, there are $\tau'_0 \in \mathsf{Traces}_0(\mathcal{S})$, $a_1, \ldots, a_n, b_1, \ldots, b_m \in M$ such that

$$\mathsf{norm}(\tau') \overset{\text{causal}}{\sim} \tau'_0 \cdot !a_1 \cdots !a_n \cdot !b_1 \cdots !b_m$$

with $\mathsf{src}(a_k) = i$ for all $k \in \{1, \ldots, n\}$ and $\mathsf{src}(b_k) \neq i$ for all $k \in \{1, \ldots, m\}$. Since G_M is an oriented ring, $\mathsf{dst}(a_1) = j$, therefore $a_1 = a$ (because by hypothesis j may receive a in the configuration that $\mathsf{norm}(\tau')$ leads to). Let $\mathsf{norm}(\tau) = \tau'_0 \cdot !a \cdot ?a \cdot !b_1 \cdots !b_m \cdot !a_2 \cdots !a_n$ and let us show that $\mathsf{norm}(\tau) \in \mathsf{Traces}_\omega(\mathcal{S})$ and $\tau \overset{\mathcal{S}}{\sim} \mathsf{norm}(\tau)$.

Since $\mathsf{norm}(\tau') \in \mathsf{Traces}_\omega(\mathcal{S})$, we have in particular that $\tau'_0 \cdot !a \in \mathsf{Traces}_1(\mathcal{S})$ and $\tau'_0 \cdot !b_1 \cdots !b_n \in \mathsf{Traces}_\omega(\mathcal{S})$. Consider the two traces

$$\begin{aligned} \upsilon_1 = &\quad \tau'_0 \cdot !a \cdot ?a \cdot !b_1 \cdots !b_n \cdot ?b_1 \cdots ?b_n \\ \upsilon_2 = &\quad \tau'_0 \cdot !a \cdot !b_1 \cdots !b_n \cdot ?a \cdot ?b_1 \cdots ?b_n. \end{aligned}$$

By Lemma 13, $\upsilon_1, \upsilon_2 \in \mathsf{Traces}_\omega(\mathcal{S})$ and both lead to the same configuration, and in particular to the same control state q for peer j. The actions $?b_1$, $?b_2, \ldots ?b_n$ are not executed by peer j (because $\mathsf{src}(m) \neq i$ implies $\mathsf{dst}(m) \neq j$ on an oriented ring), so the two traces

$$\begin{aligned} \upsilon'_1 = &\quad \tau'_0 \cdot !a \cdot ?a \cdot !b_1 \cdots !b_n \\ \upsilon'_2 = &\quad \tau'_0 \cdot !a \cdot !b_1 \cdots !b_n \cdot ?a \end{aligned}$$

lead to two configurations γ'_1, γ'_2 with the same control state q for peer j as in the configuration reached after υ_1 or υ_2. On the other hand, for all $k \neq j$, $\mathsf{onPeer}_k(\upsilon'_1) = \mathsf{onPeer}_k(\upsilon'_2)$, therefore $\upsilon'_1 \overset{\mathcal{S}}{\sim} \upsilon'_2$. Since $\tau'_0 \cdot !a \cdot !a_2 \cdots !a_n \in \mathsf{Traces}_n(\mathcal{S})$, and $\mathsf{onPeer}_i(\tau'_0 \cdot !a) = \mathsf{onPeer}_i(\upsilon'_1) = \mathsf{onPeer}_i(\upsilon'_2)$, the two traces

$$\begin{aligned} \upsilon''_1 = &\quad \tau'_0 \cdot !a \cdot ?a \cdot !b_1 \cdots !b_n \cdot !a_2 \cdots !a_n \\ \upsilon''_2 = &\quad \tau'_0 \cdot !a \cdot !b_1 \cdots !b_n \cdot ?a \cdot !a_2 \cdots !a_n \end{aligned}$$

belong to $\mathsf{Traces}_\omega(\mathcal{S})$ and $\upsilon''_1 \overset{\mathcal{S}}{\sim} \upsilon''_2$. Consider first υ''_1: this is $\mathsf{norm}(\tau)$ as defined above, therefore $\mathsf{norm}(\tau) \in \mathsf{Traces}_\omega(\mathcal{S})$, and $\mathsf{norm}(\tau) \overset{\mathcal{S}}{\sim} \upsilon''_2$. Consider now υ''_2. By definition, $\upsilon''_2 \overset{\text{causal}}{\sim} \mathsf{norm}(\tau') \cdot ?a$. By hypothesis, $\mathsf{norm}(\tau') \overset{\mathcal{S}}{\sim} \tau'$, therefore $\mathsf{norm}(\tau') \cdot ?a \overset{\text{causal}}{\sim} \tau$. To sum up, $\mathsf{norm}(\tau) \overset{\mathcal{S}}{\sim} \upsilon''_2 \overset{\text{causal}}{\sim} \mathsf{norm}(\tau') \cdot ?a \overset{\mathcal{S}}{\sim} \tau$, therefore $\mathsf{norm}(\tau) \overset{\mathcal{S}}{\sim} \tau$. ◀

As a consequence of Lemma 15, 1-synchronizability implies several interesting properties on the reachability set.

▶ **Definition 16** (Channel-recognizable reachability set [17, 7])**.** Let $\mathcal{S} = \langle \mathcal{P}_1, \ldots, \mathcal{P}_p \rangle$ with $\mathcal{P}_i = \langle Q_i, \Delta_i, q_{0,i} \rangle$. The (coding of the) *reachability set* of $\mathcal{S}$ is the language $\mathsf{Reach}(\mathcal{S})$ over the alphabet $(M \cup \bigcup_{i=1}^{p} Q_i)^*$ defined as $\{q_1 \cdots q_p \cdot w_1 \cdots w_p \mid \gamma_0 \xrightarrow{\tau} (q_1, \ldots, q_p, w_1, \ldots, w_p), \tau \in \mathsf{Traces}_\omega(\mathcal{S})\}$. $\mathsf{Reach}(\mathcal{S})$ is *channel-recognizable* (or QDD representable [5]) if it is a recognizable (and rational) language.

▶ **Theorem 17.** *Let M be a message set such that G_M is an oriented ring, and let $\mathcal{S}$ be a M-system that is 1-synchronizable. Then*

1. *the reachability set of $\mathcal{S}$ is channel recognizable,*
2. *for all $\tau \in \mathsf{Traces}_\omega(\mathcal{S})$, for all $\gamma_0 \xrightarrow{\tau} \gamma$, there is a stable configuration γ', $n \geq 0$ and $m_1, \ldots m_n \in M$ such that $\gamma \xrightarrow{?m_1 \cdots ?m_n} \gamma'$.*

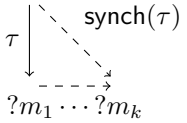
In particular, $\mathcal{S}$ neither has orphan messages nor unspecified receptions [7].

Proof. 1. Let S be the set of stable configurations γ such that $\gamma_0 \xrightarrow{\tau} \gamma$ for some $\tau \in \mathsf{Traces}_0(\mathcal{S})$; S is finite and effective. By Lemma 15, $\mathsf{Reach}(\mathcal{S}) = \bigcup\{\mathsf{Reach}^!(\gamma) \mid \gamma \in S\}$, where $\mathsf{Reach}^!(\gamma) = \{q_1 \cdots q_p \cdot w_1 \cdots w_p \mid \gamma \xrightarrow{!a_1 \cdots !a_n} (q_1, \ldots, q_p, w_1, \ldots, w_p), n \geq 0, a_1, \ldots a_n \in M\}$ is an effective rational language.

2. Assume $\gamma_0 \xrightarrow{\tau} \gamma$. By Lemma 15, $\gamma_0 \xrightarrow{\tau_0 \cdot !m_1 \cdots !m_r} \gamma$ for some $\tau_0 \in \mathsf{Traces}_0(\mathcal{S})$. Then $\tau_0 \cdot !m_1 \cdots !m_r \overset{\text{causal}}{\sim} \tau_0 \cdot \tau_1$ where $\tau_1 := !a_1 \cdots !a_n \cdot b_1 \cdots b_m$ for some $a_1, \ldots, a_n, b_1, b_m$ such that $\mathsf{src}(a_i) \neq \mathsf{src}(b_j)$ for all $i \in \{1, \ldots, n\}$ and $j \in \{1, \ldots, m\}$. By Lemma 13, $\tau_0 \cdot \tau_1 \cdot \overline{\tau_1} \in \mathsf{Traces}_\omega(\mathcal{S})$ (where $\overline{\tau_1} = ?a_1 \cdots ?a_n \cdot ?b_1 \cdots ?b_m$), and therefore $\gamma_0 \xrightarrow{\tau_0 \cdot \tau_1} \gamma \xrightarrow{\overline{\tau_1}} \gamma'$ for some stable configuration γ'.

◀

▶ **Theorem 18.** *Let M be a message set such that G_M is an oriented ring. For any M-system $\mathcal{S}$, $\mathcal{S}$ is 1- synchronizable if and only if it is synchronizable.*



In order to prove Theorem 18, we prove by induction on the length of τ that $\tau \cdot ?m_1 \cdots ?m_k \overset{\mathcal{S}}{\sim} \mathsf{synch}(\tau)$ for some messages $m_1, \ldots, m_k$, where $\mathsf{synch}(\tau)$ denotes the unique synchronous M-trace such that $\mathsf{send}(\mathsf{synch}(\tau)) = \mathsf{send}(\tau)$.

▶ **Theorem 19.** *Let M be a message set such that G_M is an oriented ring. The problem of deciding whether a given M-system is synchronizable is decidable.*

5 Extensions

We considered the notions of synchronizability and language synchronizability introduced by Basu and Bultan [2] and we showed that both are not decidable for systems with peer-to-peer FIFO communications, called (1-1) type systems in [2]. In the same work, Basu and Bultan considered the question of the decidability of language synchronizability for other communication models. All the results we presented so far do not have any immediate consequences on their claims for these communication models. Therefore, we briefly discuss now what we can say about the decidability of language synchronizability for the other communication models that have been considered.

Non FIFO communications. In [2], language synchronizability is studied for systems where peers communicate through bags instead of queues, thus allowing to reorder messages. Language synchronizability is decidable for bag communications: $\mathsf{Traces}_\omega^{bag}(\mathcal{S})$ is the trace language of a Petri net, $T_0(\mathcal{S}) = \{\tau \in \mathsf{Act}_M^* \mid \mathsf{send}(\tau) \in \mathcal{J}_0^{bag}(\mathcal{S})\}$ is an effective regular language, $\mathcal{S}$ is language synchronizable iff $\mathsf{Traces}_\omega^{bag}(\mathcal{S}) \subseteq T_0(\mathcal{S})$, and whether the trace language of a Petri is included in a given regular language reduces to the coverability problem. Lossy communications where not considered in [2], but the same kind of argument would also hold for lossy communications. However, our Example 1 is a counter-example for Lemma 3 in [2], *i.e.* the notion of language 1-synchronizability for bag communications defined in [2] does not imply language synchronizability. The question whether (language) synchronizability can be decided more efficiently than by reduction to the coverability problem for Petri nets is open.

Non peer-to-peer communications. The other communication models considered in [2] keep the FIFO queue model, but differ in the way queues are distributed among peers. The $*$-1 (mailbox) model assumes a queue per receiver. This model is the first model that was considered for (language) synchronizability [1, 4]. Our Example 1 is not easy to adapt for this communication model. We therefore design a completely different counter-example.

▶ **Example 20.** Consider the system of communicating machines depicted in Fig. 3. Assume that the machines communicate via mailboxes, like in [1, 4], i.e. all messages that are sent to peer i wait in a same FIFO queue Q_i, and let $\mathcal{J}_k^{*-1}(\mathcal{S})$ denote the k-bounded send traces of $\mathcal{S}$ within this model of communications. Then $\mathcal{J}_0^{*-1}(\mathcal{S}) = \mathcal{J}_1^{*-1}(\mathcal{S}) \neq \mathcal{J}_2^{*-1}(\mathcal{S})$, as depicted in Figure 3. Therefore $\mathcal{S}$ is language 1-synchronizable but not language synchronizable, which contradicts Theorem 1 in [1], Theorem 2 in [3], and Theorem 2 in [2]. It can be noticed that it does not contradict Theorem 1 in [4], but it contradicts the Lemma 1 of the same paper, which is used to prove Theorem 1.

Many problems are therefore left for future work: the (un)decidability of synchronizability for the mailbox semantics, the largest class of communication topologies for which 1-synchronizability implies synchronizability (either for the peer-to-peer semantics or for the mailbox one), the study of language synchronizability, etc. Our intention in this work was limited to the identification of some of these problems, and maybe to explain why the errors in [1, 4, 2] were missed by so many reviewers.

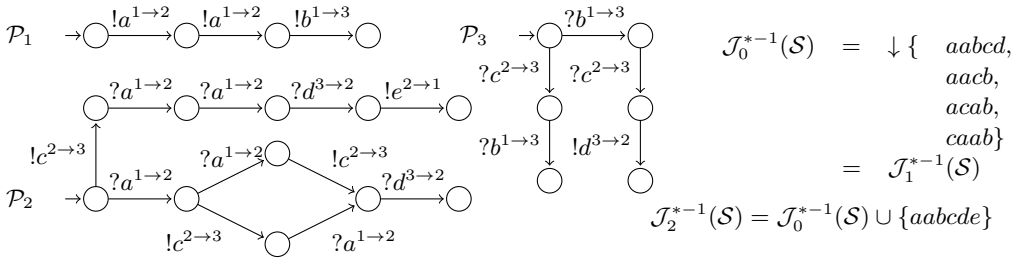


Figure 3 Language 1-synchronizability does not imply language synchronizability for 1-$*$ (mailbox) communications *à la* [1, 4].

Acknowledgement. We would like to thank the anonymous reviewers of our paper for relevant suggestions of improvements, and for an accurate reading of our proofs.

Abstract

In this paper, we study the notion of *admissibility* for randomised strategies in *concurrent games*. Intuitively, an admissible strategy is one where the player plays 'as well as possible', because there is no other strategy that *dominates* it, i.e., that wins (almost surely) against a superset of adversarial strategies. We prove that admissible strategies always exist in concurrent games, and we characterise them precisely. Then, when the objectives of the players are ω-regular, we show how to perform *assume-admissible synthesis*, i.e., how to compute admissible strategies that win (almost surely) under the hypothesis that the other players play admissible strategies only.

1 Introduction

In a concurrent n-player game played on a graph, all n players *independently* and *simultaneously* choose moves at each round of the game, and those n choices determine the next state of the game [14]. Concurrent games generalise turn-based games and it is well-known that, while deterministic strategies are sufficient in the turn-based case, randomised strategies are necessary for winning with probability one even for reachability objectives. Intuitively, randomisation is necessary because, in concurrent games, in each round, players choose their moves simultaneously. Randomisation makes it possible to choose a good move with some probability without the knowledge of the moves that the other players are simultaneously choosing. As a consequence, there are two classical semantics that are considered to analyse these games *qualitatively*: winning with certainty (sure semantics in the terminology of [14]), and winning with probability one (almost sure semantics in the terminology of [14]). We consider both semantics here.

Figure 2 The relationships between the classes of Admissible, LA, and SCO strategies for three families of games. All the inclusions are strict.

Previous papers on concurrent games are mostly concerned with two-player zero-sum games, i.e. two players that have fully antagonistic objectives. In this paper, we consider the *more general setting* of n-player non zero-sum concurrent games in which each player has its own objective. The notion of winning strategy is not sufficient to study non zero-sum games and other solution concepts have been proposed. One such concept is the notion of *admissible strategy* [1].

For a player with objective Φ, a strategy σ is said to be *dominated* by a strategy σ' if σ' does as well as σ with respect to Φ against all the strategies of the other players and strictly better for some of them. A strategy σ is *admissible* for a player if it is not dominated by any other of his strategies. Clearly, playing a strategy which is not admissible is sub-optimal and a rational player should only play admissible strategies. While recent works have studied the notion of admissibility for n-player non zero-sum game graphs [5, 15, 10, 8, 7], they are all concerned with the special case of turn-based games and this work is the first to consider the more general concurrent games.

Throughout the paper, we consider the running example in Figure 1. This is a concurrent game played by two players. Player 1's objective is to reach Trg, while Player 2 wants to reach s_2. Edges are labelled by pairs of moves of both players which activate that transition (where $-$ means 'any move'). It is easy to see that no player can enforce its objective with or without randomisation, so, there is no winning strategy in this game for either player. This is because moving from s_0 to s_1 and from s_1 to s_2 requires the cooperation of both players. Moreover, the transitions from s_2 behave as in the classical 'matching pennies' game: player 1 must chose between f and g; player 2 between f' and g'; and the target is reached only when the choices 'match'. So, randomisation is needed to make sure Trg is reached with probability one, from s_2. In the paper, we will describe the dominated and admissible strategies of this game.

Technical contributions. First, we study the notion of admissible strategies for both the *sure* and *almost sure* semantics of concurrent games. We show in Theorem 8 that in both semantics admissible strategies always exist. The situation is thus similar to the turn-based case [5, 10]. Nevertheless, the techniques used in this simpler case do not generalise easily to the concurrent case and we need substantially more involved technical tools here. To obtain

our universal existence result, we introduce two weaker solution concepts: *locally admissible moves* and *strongly cooperative optimal* strategies. While cooperative optimal strategies were already introduced in [7] and shown equivalent to admissible strategies in the turn based setting, they are strictly weaker than admissible strategies in the concurrent setting (both for the sure and the almost sure semantics), and they need to be combined with the notion of locally admissible moves to fully characterise admissible strategies. In the special case of safety objectives, we can show that admissible strategies are exactly those that always play locally admissible moves. This situation is depicted in Figure 2.

Second, we build on our characterisation of admissible strategies based on the notions of locally admissible moves and strongly cooperative optimal strategies to obtain algorithms to solve the *assume admissible synthesis* problem for concurrent games. In the assume admissible synthesis problem, we ask whether a given player has an *admissible* strategy that is *winning* against *all admissible* strategies of the other players. So this rule relaxes the classical synthesis rule by asking for a strategy that is winning against the admissible strategies of the other players only and not against all of them. This is reasonable as in a multi-player game, each player has his own objective which is generally not the complement of the objectives of the other players. The assume-admissible rule makes the hypothesis that players are rational, hence they play admissible strategies and it is sufficient to win against those strategies. Our algorithm is applicable to all ω-regular objectives and it is based on a reduction to a zero-sum two-player game in the sure semantics. While this reduction shares intuitions with the reduction that we proposed in [8] to solve the same problem in the turn-based case, our reduction here is based on games with imperfect information [18]. In contrast, in the turn-based case, games of perfect information are sufficient. The correctness and completeness of our reduction are proved in Theorem 11.

Related works. Concurrent *two player zero-sum* games are studied in [14] and [11]. We rely on the algorithms defined in [11] to compute states from which players have almost surely winning strategies. States where players have (deterministic) winning strategies can be computed by a reduction to more classical turn-based game graphs [2]. Nash equilibria have been studied in concurrent games [6], but without randomised strategies. None of those papers consider the notion of admissibility.

We use the notion of admissibility to obtain synthesis algorithms for systems composed of several sub-systems starting from non zero-sum specifications. Other approaches have been proposed based the notion of Nash equilibria (which suffer from the well-known limitation of non-credible threats): assume-guarantee synthesis [12] and rational synthesis [16, 17]. Those works assume the simpler setting of turn-based games and so they do not deal with randomised strategies.

Finally, in [13], Damm and Finkbeiner use the notion of *dominant strategy* to provide a compositional semi-algorithm for the (undecidable) distributed synthesis problem. However, the notion of dominant strategy is strictly stronger than the notion of admissible strategies, and dominant strategies are not guaranteed to exist, unlike admissible ones.

2 Preliminaries

Concurrent games played on graphs. Let $P = \{1, 2, \dots n\}$ be a set of players. A *concurrent game* played on a finite graph by the players in P is a tuple $\mathcal{G} = (S, \Sigma, s_{\mathsf{init}}, (\Sigma_p)_{p \in P}, \delta)$ where,

(i) S is a finite set of *states*; and $s_{\mathsf{init}} \in S$ the *initial state*;

(ii) Σ is a finite set of *actions*;

(iii) For all $p \in P$, $\Sigma_p : S \to 2^\Sigma \setminus \{\emptyset\}$ is an *action assignment* that assigns, to all states $s \in S$, the set of actions available to player p from state s.

(iv) $\delta : S \times \Sigma \times \ldots \times \Sigma \to S$ is the *transition function.*

We write $\Sigma(s) = \Sigma_1(s) \times \ldots \times \Sigma_n(s)$ for all $s \in S$. It is often convenient to consider a player p separately and see the set of all other players $P \setminus \{p\}$ as a single player denoted $-p$. Hence, the set of actions of $-p$ in state s is: $\Sigma_{-p}(s) =_{\text{def}} \prod_{q \in P \setminus \{p\}} \Sigma_q(s)$. We assume that $\Sigma_i(s) \cap \Sigma_j(s) = \emptyset$ for all $s \in S$ and $i \neq j$. We denote by $\text{Succ}(s, a) = \{\delta(s, a, b) \mid b \in \Sigma_{-p}(s)\}$ the set of possible *successors* of the state $s \in S$ when player p performs action $a \in \Sigma_p(s)$. A particular case of concurrent games are the *turn-based games*. A game $\mathcal{G} = (S, \Sigma, s_{\mathsf{init}}, (\Sigma_p)_{p \in P}, \delta)$ is turn-based iff for all states $s \in S$, there is a unique player p s.t. the successors of s depend only on p's choice of action, i.e., $\text{Succ}(s, a)$ contains exactly one state for all $a \in \Sigma_p(s)$.

A *history* is a finite path $h = s_1 s_2 \ldots s_k \in S^*$ s.t.

(i) $k \in \mathbb{N}$;

(ii) $s_1 = s_{\mathsf{init}}$; and

(iii) for every $2 \leq i \leq k$, there exists $(a_1, \ldots, a_n) \in \Sigma^{|P|}$ with $s_i = \delta(s_{i-1}, a_1, \ldots, a_n)$.

The *length* $|h|$ of a history $h = s_1 s_2 \ldots s_k$ is its number of states k; for every $1 \leq i \leq k$, we denote by h_i the state s_i and by $h_{\leq i}$ the history $s_1 s_2 \ldots s_i$. We denote by $\text{last}(h)$ the last state of h, that is, $\text{last}(h) = h_{|h|}$. A *run* is defined similarly as a history except that its length is infinite. For a run $\rho = s_1 s_2 \ldots \in S^\omega$ and $i \in \mathbb{N}$, we also write $\rho_{\leq i} = s_1 s_2 \ldots s_i$ and $\rho_i = s_i$. Let $\texttt{Hist}(\mathcal{G})$ (resp. $\texttt{Runs}(\mathcal{G})$) denote the set of histories (resp. runs) of $\mathcal{G}$. The game is played from the initial state s_{init} for an infinite number of rounds, producing a run. At each round $i \geq 0$, with current state s_i, all players p select simultaneously an action $a_p^i \in \Sigma_p(s_i)$, and the state $\delta(s_i, a_1^i, \ldots, a_n^i)$ is appended to the current history. The selection of the action by a player is done according to strategies defined below.

Randomised moves and strategies. Given a finite set A, a probability distribution on A is a function $\alpha : A \to [0, 1]$ such that $\sum_{a \in A} \alpha(a) = 1$; and we let $\text{Supp}(\alpha) = \{a \mid \alpha(a) > 0\}$ be the support of α. We denote by $\alpha(B) = \sum_{a \in B} \alpha(a)$ the probability of a given set B according to α. The set of probability distributions on A is denoted by $\mathcal{D}(A)$. A *randomised move* of player p in state s is a probability distribution on $\Sigma_p(s)$, that is, an element of $\mathcal{D}(\Sigma_p(s))$. A randomised move that assigns probability 1 to an action and 0 to the others is called a *Dirac move*. We will henceforth denote randomised moves as sums of actions weighted by their respective probabilities. For instance $0.5f + 0.5g$ denotes the randomised move that assigns probability 0.5 to f and g (and 0 to all other actions). In particular, we denote by b a Dirac move that assigns probability 1 to action b.

Given a state s and a tuple $\boldsymbol{\beta} = (\beta_p)_{p \in P} \in \prod_{p \in P} \mathcal{D}(\Sigma_p(s))$ of randomised moves from s, one per player, we let $\delta_r(s, \boldsymbol{\beta}) \in \mathcal{D}(S)$ be the probability distribution on states s.t. for all $s' \in S$: $\delta_r(s, \boldsymbol{\beta})(s') = \sum_{\boldsymbol{a} \mid \delta(s, \boldsymbol{a}) = s'} \boldsymbol{\beta}(\boldsymbol{a})$, where $\boldsymbol{\beta}(a_1, \ldots, a_n) = \prod_{i=1}^n \beta_i(a_i)$. Intuitively, $\delta_r(s, \boldsymbol{\beta})(s')$ is the probability to reach s' from s when the players play according to $\boldsymbol{\beta}$.

A *strategy* for player p is a function σ from histories to randomised moves (of player p) such that, for all $h \in \texttt{Hist}(\mathcal{G})$: $\sigma(h) \in \mathcal{D}(\Sigma_p(\text{last}(h)))$. A strategy is called Dirac at history h, if $\sigma(h)$ is a Dirac move; it is called Dirac if it is Dirac at all histories. We denote by $\Gamma_p(\mathcal{G})$ the set of player-p strategies in the game, and by $\Gamma_p^{det}(\mathcal{G})$ the set of player-p strategies that only use Dirac moves (those strategies are also called *deterministic*); we might omit $\mathcal{G}$ if it is clear from context. A *strategy profile* $\boldsymbol{\sigma}$ for a subset $A \subseteq P$ of players is a tuple $(\boldsymbol{\sigma}_p)_{p \in A}$ with $\boldsymbol{\sigma}_p \in \Gamma_p$ for all $p \in A$. When the set of players A is omitted, we assume $A = P$. Let $\boldsymbol{\sigma} = (\boldsymbol{\sigma}_p)_{p \in P}$ be a strategy profile. Then, for all players p, we let $\boldsymbol{\sigma}_{-p}$ denote the restriction

of $\boldsymbol{\sigma}$ to $P \setminus \{p\}$ (hence, $\boldsymbol{\sigma}_{-p}$ can be regarded as a strategy of player $-p$ that returns, for all histories h, a randomised move from $\prod_{p \in P \setminus \{p\}} \mathcal{D}(\Sigma_p(s)) \subseteq \mathcal{D}(\Sigma_{-p}(\text{last}(h)))$). We sometimes denote $\boldsymbol{\sigma}$ by the pair $(\boldsymbol{\sigma}_p, \boldsymbol{\sigma}_{-p})$. Given a history h, we let $(\boldsymbol{\sigma}_p)_{p \in A}(h) = (\boldsymbol{\sigma}_p(h))_{p \in A}$.

Let h be a history and let ρ be a history or a run. Then, we write $h \subseteq_{\mathsf{pref}} \rho$ iff h is a prefix of ρ, i.e., $\rho_{\leq |h|} = h$. Given two strategies $\sigma, \sigma' \in \Gamma_p$, and a history h, we let $\sigma\langle h \leftarrow \sigma' \rangle$ be the strategy that follows σ and *shifts* to σ' as soon as h has been played (i.e. $\sigma\langle h \leftarrow \sigma' \rangle$ is s.t. for all histories h': $\sigma\langle h \leftarrow \sigma' \rangle(h') = \sigma'(h')$ if $h \subseteq_{\mathsf{pref}} h'$; and $\sigma\langle h \leftarrow \sigma' \rangle(h') = \sigma(h')$ otherwise).

Probability measure and outcome of a profile. Given a history h, we let $\text{Cyl}(h) = \{\rho \mid h \subseteq_{\mathsf{pref}} \rho\}$ be the *cylinder* of h. To each strategy profile $\boldsymbol{\sigma}$, we associate a probability measure $\mathbb{P}_{\boldsymbol{\sigma}}$ on certain sets of runs. First, for a history h, we define $\mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(h))$ inductively on the length of h: $\mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(s_{\mathsf{init}})) = 1$, and $\mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(h's')) = \mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(h')) \cdot \delta_r(\text{last}(h'), \boldsymbol{\sigma}(h'))(s')$when $|h| > 1$ and $h = h's'$. Based on this definition, we can extend the definition of $\mathbb{P}_{\boldsymbol{\sigma}}$ to any Borel set of runs on cylinders. In particular, the function $\mathbb{P}_{\boldsymbol{\sigma}}$ is well-defined for all ω-regular sets of runs, that we will consider in this paper [19]. We extend the $\texttt{Hist}$ notation and let $\texttt{Hist}(\boldsymbol{\sigma})$ be the set of histories h such that $\mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(h)) > 0$. Given a profile $\boldsymbol{\sigma}$ we denote by $\texttt{Outcome}(\boldsymbol{\sigma})$ the set of runs ρ s.t. all prefixes h of ρ belong to $\texttt{Hist}(\boldsymbol{\sigma})$. In particular, $\mathbb{P}_{\boldsymbol{\sigma}}(\texttt{Outcome}(\boldsymbol{\sigma})) = 1$. Note that when $\boldsymbol{\sigma}$ is composed of Dirac strategies then $\texttt{Outcome}(\boldsymbol{\sigma})$ is a singleton. The outcome (set of histories) of a strategy $\sigma \in \Gamma_p$, denoted by $\texttt{Outcome}(\sigma)$ ($\texttt{Hist}(\sigma)$), is the union of outcomes (set of histories, respectively) of profile $\boldsymbol{\sigma}$ s.t. $\boldsymbol{\sigma}_p = \sigma$.

Winning conditions. To determine the gain of all players in the game $\mathcal{G}$, we define *winning conditions* that can be interpreted with two kinds of semantics denoted by the symbols $\texttt{S}$ for the *sure semantics* or and $\texttt{A}$ for the *almost sure semantics*. A winning condition Φ is a subset of $\texttt{Runs}(\mathcal{G})$ called *winning runs*. From now on, we assume that concurrent games are equipped with a function Φ, called the winning condition, and mapping all players $p \in P$ to a winning condition $\Phi(p)$. A profile $\boldsymbol{\sigma}$ is $\texttt{A}$-winning for $\Phi(p)$ if $\mathbb{P}_{\boldsymbol{\sigma}}(\Phi) = 1$ which we write $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{A}} \Phi(p)$. A profile $\boldsymbol{\sigma}$ is $\texttt{S}$-winning for $\Phi(p)$ if $\texttt{Outcome}(\mathcal{G}, \boldsymbol{\sigma}) \subseteq \Phi(p)$ which we write $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{S}} \Phi(p)$. Note that when $\boldsymbol{\sigma}$ is Dirac, the two semantics coincide: $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{S}} \Phi(p)$ iff $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{A}} \Phi(p)$. The profile $\boldsymbol{\sigma}$ is $\texttt{A}$-winning from h if $h \in \texttt{Hist}(\mathcal{G}, \boldsymbol{\sigma})$ and $\mathbb{P}_{\boldsymbol{\sigma}}(\Phi(p) \mid \text{Cyl}(h)) = \mathbb{P}_{\boldsymbol{\sigma}}(\Phi(p) \cap \text{Cyl}(h))/\mathbb{P}_{\boldsymbol{\sigma}}(\text{Cyl}(h)) = 1$ which we denote $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{A}}_h \Phi(p)$. The profile $\boldsymbol{\sigma}$ is $\texttt{S}$-winning from h if $\{\rho \in \texttt{Outcome}(\mathcal{G}, \boldsymbol{\sigma}) \mid h \subseteq_{\mathsf{pref}} \rho\} \subseteq \Phi(p)$, which we denote $\mathcal{G}, \boldsymbol{\sigma} \models^{\texttt{S}}_h \Phi(p)$. We often omit $\mathcal{G}$ in notations when clear from the context. Most of our definitions and results hold for both semantics and we often state them using the symbol $\star \in \{\texttt{S}, \texttt{A}\}$ as in the following definition. Given a semantics $\star \in \{\texttt{S}, \texttt{A}\}$, a strategy σ for player p (from a history h) is called $\star$-winning for player p if for every $\tau \in \Gamma_{-p}$, the profile (σ, τ) is $\star$-winning for player p (from h). Note that a strategy σ for player p is $\texttt{S}$-winning iff $\texttt{Outcome}(\sigma) \subseteq \Phi(p)$. We often describe winning conditions using standard linear temporal operators $\Box$ and $\Diamond$; *e.g.* $\Box\Diamond S$ means the set of runs that visit infinitely often S. See [3] for a formal definition.

A winning condition $\Phi(p)$ is *prefix-independent* if for all $s_1 s_2 \ldots \in \Phi(p)$, and all $i \geq 1$: $s_i s_{i+1} \ldots \in \Phi(p)$. When $\Phi(p)$ contains all runs that do not visit some designated set $\mathsf{Bad}_p \subseteq S$ of states, we say that $\Phi(p)$ is a *safety condition*. A safety game is a game whose winning condition Φ is such that $\Phi(p)$ is a safety condition for all players p. Without loss of generality, we assume that safety games are so-called *simple* safety games: a safety game $(S, \Sigma, s_{\mathsf{init}}, (\Sigma_p)_{p \in P}, \delta)$ is *simple* iff for all players p, for all $s \in S$: $s \in \mathsf{Bad}_p$ implies that no $s' \notin \mathsf{Bad}_p$ is reachable from s. That is, once the safety condition is violated, then it remains violated forever at all future histories.

▶ **Example 1.** Let us consider three player-1 strategies in Figure 1.
(i) σ_1 is any strategy that plays a in s_0;
(ii) σ_2 is any strategy that plays b in s_0, d in s_1 and f in s_2; and
(iii) σ_3 is any strategy that plays b in s_0, d in s_1, and $0.5f + 0.5g$ in s_2.
Clearly, σ_1 never allows one to reach Trg while some runs respecting σ_2 and σ_3 do (remember that there is no $\star$-winning strategy in this game). We will see later that the best choice of player 1 (among σ_2, σ_3) depends on the semantics we consider. In the almost-sure semantics, σ_3 is 'better' for player 1, because σ_3 is an $\mathtt{A}$-winning strategy from all histories ending in s_2, while σ_2 is not. On the other hand, in the sure semantics, playing σ_2 is 'better' for player 1 than σ_3. Indeed, for all player-2 strategies τ, either $\mathtt{Outcome}(\sigma_3, \tau)$ contains only runs that do not reach s_2 (hence, do not reach Trg either), or $\mathtt{Outcome}(\sigma_3, \tau)$ contains at least a run that reaches s_2, but, in this case, it also contains a run of the form hs_2^ω that does not reach Trg (because, intuitively, player 1 plays *both* f and g from s_2). So, σ_3 is not $\mathtt{S}$-winning against any τ, while σ_2 wins at least against a player 2 strategy that plays b' in s_0, d' in s_1 and f' in s_2. We formalise these intuitions in the next section.

3 Admissibility

In this section, we define the central notion of the paper: admissibility [5, 9]. Intuitively, a strategy is admissible when it plays 'as well as possible'. Hence the definition of admissible strategies is based on a notion of domination between strategies: a strategy σ' dominates another strategy σ when σ' wins every time σ does. Obviously, players have no interest in playing dominated strategies, hence admissible strategies are those that are not dominated. Apart from these (classical) definitions, we characterise admissible strategies as those that satisfy two weaker notions: they must be both *strongly cooperative optimal* and play only *locally-admissible moves*. Finally, we discuss important characteristics of admissible strategies that will enable us to perform assume-admissible synthesis (see Section 4).

In this section, we fix a game $\mathcal{G}$, a player p, and, following our previous conventions, we denote by Γ_{-p} the set $\{\boldsymbol{\sigma}_{-p} \mid \boldsymbol{\sigma} \in \Gamma\}$.

Admissible strategies. We first recall the classical notion of *admissible strategy* [5, 1]. Given two strategies $\sigma, \sigma' \in \Gamma_p$, we say that σ is $\star$-*weakly dominated* by σ', denoted $\sigma \preccurlyeq^\star \sigma'$, if for all $\tau \in \Gamma_{-p}$: $(\sigma, \tau) \models^\star \Phi(p)$ *implies* $(\sigma', \tau) \models^\star \Phi(p)$. This indeed captures the idea than σ' is *not worse* that σ, because it wins (for p) every time σ does. Note that $\preccurlyeq^\star$ is not anti-symmetric, hence we write $\sigma \approx^\star \sigma'$ when σ and σ' are equivalent, i.e. $\sigma \preccurlyeq^\star \sigma'$ and $\sigma' \preccurlyeq^\star \sigma$. In other words $\sigma \approx^\star \sigma'$ iff for every $\tau \in \Gamma_{-p}$, $(\sigma, \tau) \models^\star \Phi(p) \Leftrightarrow (\sigma', \tau) \models^\star \Phi(p)$. When $\sigma \preccurlyeq^\star \sigma'$ but $\sigma' \not\preccurlyeq^\star \sigma$ we say that σ is $\star$-*dominated* by σ', and we write $\sigma \prec^\star \sigma'$. Observe that $\sigma \prec^\star \sigma'$ holds if and only if $\sigma \preccurlyeq^\star \sigma'$ and there exists at least one $\tau \in \Gamma_{-p}$, such that $(\sigma, \tau) \not\models^\star \Phi(p)$ and $(\sigma', \tau) \models^\star \Phi(p)$. That is, σ' is now *strictly better* than σ. Then, *a strategy σ is* ***$\star$-admissible*** *iff there is no strategy σ' s.t. $\sigma \prec^\star \sigma'$*, i.e., σ is $\star$-admissible iff it is not $\star$-dominated.

▶ **Example 2.** Let us continue our running example, by formalising the intuitions we have sketched in Example 1. Since σ_1 does not allow to reach the target, while some runs respecting σ_2 and σ_3 do, we have: $\sigma_1 \prec^\star \sigma_2$ and $\sigma_1 \prec^\star \sigma_3$. Moreover, $\sigma_2 \prec^{\mathtt{A}} \sigma_3$ because σ_3 is $\mathtt{A}$-winning from any history that ends in s_2 while σ_2 is not because it does not $\mathtt{A}$-win against a player 2 strategy that would always play g' in s_2 (and both strategies behave the same way in s_0 and s_1). On the other hand, $\sigma_3 \prec^{\mathtt{S}} \sigma_2$ since we saw in Example 1 that every profile containing σ_3 is not $\mathtt{S}$-winning while some profiles containing σ_2 are. We will see later that σ_3 is $\mathtt{A}$-admissible and σ_2 is $\mathtt{S}$-admissible.

Values of histories. Before we discuss strongly cooperative optimal and locally admissible strategies, we associate *values* to histories. Let h be a history, and σ be a strategy of player p. Then, the *value of h w.r.t. σ for semantics $\star \in \{\mathtt{S}, \mathtt{A}\}$* is defined as follows. $\chi^\star_\sigma(h) = 1$ if σ is $\star$-winning from h; $\chi^\star_\sigma(h) = 0$ if there are $\tau \in \Gamma_{-p}$ and $\tau' \in \Gamma_{-p}$ s.t. $(\sigma, \tau) \models^\star_h \Phi(p)$, and $(\sigma, \tau') \not\models^\star_h \Phi(p)$; and -1 otherwise.

Value $\chi^\star_\sigma(h) = 1$ corresponds to the case where σ is $\star$-winning for player p from h (thus, against all possible strategies in Γ_{-p}). When $\chi^\star_\sigma(h) = 0$, σ is *not* $\star$-winning from h (because of τ' in the definition), but the other players can still help p to reach his objective (by playing some τ s.t. $(\sigma, \tau) \models^\star_h \Phi(p)$, which exists by definition). Last, $\chi^\star_\sigma(h) = -1$ when there is no hope for p to $\star$-win, even with the collaboration of the other players. In this case, there is no τ s.t. $(\sigma, \tau) \models^\star_h \Phi(p)$. Hence, having $\chi^\star_\sigma(h) = -1$ is stronger than saying that σ is not winning—when σ is not winning, we could have $\chi^\star_\sigma(h) = 0$ as well.

We define the value of a history h for player p as the best value he can achieve with his different strategies: $\chi^\star_p(h) = \max_{\sigma \in \Gamma_p} \chi^\star_\sigma(h)$. Last, for $v \in \{-1, 0, 1\}$, let $\mathtt{Val}^\star_{p,v}$ be the set of histories h s.t. $\chi^\star_p(h) = v$.

Strongly cooperative optimal strategies. We are now ready to define *strongly cooperative optimal* (SCO) strategies. Recall that, in the classical setting of turn-based games, admissible strategies are exactly the SCO strategies [9]. We will see that this condition is still necessary but not sufficient in the concurrent setting.

A strategy σ of Player p is $\star$-SCO at h iff $\chi^\star_\sigma(h) = \chi^\star_p(h)$; and σ is $\star$-SCO iff it is $\star$-SCO at all $h \in \mathtt{Hist}(\sigma)$. Intuitively, when σ is a $\star$-SCO strategy of Player p, the following should hold:

- **(i)** if p has a $\star$-winning strategy from h (i.e. $\chi^\star_p(h) = 1$), then, σ should be $\star$-winning (i.e. $\chi^\star_\sigma(h) = 1$); and
- **(ii)** otherwise if p has no $\star$-winning strategy from h but still has the opportunity to $\star$-win with the help of other players (hence $\chi^\star_p(h) = 0$), then, σ should enable the other players to help p fulfil his objective (i.e. $\chi^\star_\sigma(h) = 0$).

Observe that when $\chi^\star_p(h) = -1$, no continuation of h is $\star$-winning for p, so $\chi^\star_\sigma(h) = -1$ for all strategies σ.

▶ **Example 3.** Consider again the example in Figure 1. For the almost-sure semantics, we have $\mathtt{Val}^{\mathtt{A}}_{p,1} = \{h \mid \mathrm{last}(h) \in \{s_2, \mathsf{Trg}\}\}$, and $\mathtt{Val}^{\mathtt{A}}_{p,0} = \{h \mid \mathrm{last}(h) \in \{s_0, s_1\}\}$. For the sure semantics, we have: $\mathtt{Val}^{\mathtt{S}}_{1,1} = \{h \mid \mathrm{last}(h) = \mathsf{Trg}\}$, and $\mathtt{Val}^{\mathtt{S}}_{1,0} = \{h \mid \mathrm{last}(h) \neq \mathsf{Trg}\}$. Consider again the three strategies σ_1, σ_2 and σ_3 from Example 1. We see that σ_2 is $\mathtt{S}$-SCO but it is not $\mathtt{A}$-SCO because, for all profiles h ending in s_2: $\chi^{\mathtt{A}}_{\sigma_2}(h) = 0$ while $h \in \mathtt{Val}^{\mathtt{A}}_{1,1}$. On the other hand, σ_3 is $\mathtt{A}$-SCO; but it is not $\mathtt{S}$-SCO. Indeed, one can check that, for all strategies $\tau \in \Gamma_2$: if $\mathtt{Outcome}(\sigma_3, \tau)$ contains a run reaching Trg, then it also contains a run that cycles in s_2. So, for all such strategies τ, $\mathtt{Outcome}(\sigma_3, \tau) \not\models^{\mathtt{S}} \Phi(1)$, hence $\chi^{\mathtt{S}}_{\sigma_3}(h) = -1$ for all histories that end in s_2; while $\chi^{\mathtt{S}}_p(h) = 0$ since $\chi^{\mathtt{S}}_{\sigma'}(h) = 0$ for all Dirac strategies σ'.

Next, let us build a strategy σ'_3 that is $\mathtt{A}$-dominated by σ_3 (hence, not $\mathtt{A}$-admissible), but $\mathtt{A}$-SCO. We let σ'_3 play as σ_3 except that σ'_3 plays c the first time s_1 is visited (hence ensuring that the self-loop on s_1 will be taken after the first visit to s_1). Now, σ'_3 is $\mathtt{A}$-dominated by σ_3, because

- **(i)** σ_3 $\mathtt{A}$-wins every time σ'_3 does; but
- **(ii)** σ'_3 does not $\mathtt{A}$-win against the player 2 strategy τ that plays d' only when s_1 is visited for the first time, while σ_3 $\mathtt{A}$-wins against τ.

However, σ'_3 is SCO because playing c keeps the value of the history equal to $0 = \chi^{\mathtt{A}}_1(h)$ (intuitively, playing c once does not prevent the other players from helping in the future).

As similar example can be built in the S semantics. Thus, **there are $\star$-SCO strategies which are not admissible**, so, being $\star$-SCO is not a sufficient criterion for admissibility.

Locally admissible moves and strategies. Let us now discuss another criterion for admissibility, which is more *local* in the sense that it is based on a domination between *moves* available to each player after a given history. Let h be a history, and let α and α' be two randomised moves in $\mathcal{D}(\Sigma_p)$. We say that α is *$\star$-weakly dominated* at h by α' (denoted $\alpha \leqslant^\star_h \alpha'$) iff for all $\sigma \in \Gamma_p$ such that $h \in \mathtt{Hist}(\sigma)$ and $\sigma(h) = \alpha$, there exists $\sigma' \in \Gamma_p$ s.t. $h \in \mathtt{Hist}(\sigma')$, $\sigma'(h) = \alpha'$ and $\sigma \preccurlyeq^\star \sigma'$. Observe that the relation $\leqslant^\star_h$ is not anti-symmetric. We let $\simeq^\star_h$ be the equivalence relation s.t. $\alpha \simeq^\star_h \beta$ iff $\alpha \leqslant^\star_h \beta$ and $\beta \leqslant^\star_h \alpha$. When $\alpha \leqslant^\star_h \alpha'$ but $\alpha' \not\leqslant^\star_h \alpha$ we say that α is *$\star$-dominated* at h by α' and denote this by $\alpha <^\star_h \alpha'$. When a randomised move α is not $\star$-dominated at h, we say that α is *$\star$-locally-admissible* ($\star$-LA) at h. This allows us to define a more local notion of dominated strategy: *a strategy σ of player p is **$\star$-locally-admissible** ($\star$-LA) if $\sigma(h)$ is a $\star$-LA move at h, for all histories h.*

▶ **Example 4.** Consider the Dirac move f and the non-Dirac move $0.5f + 0.5g$ played from s_2 in the example in Figure 1. One can check that $0.5f + 0.5g <^{\mathtt{S}}_{s_2} f$. Indeed, consider a strategy σ s.t. $\sigma(h) = 0.5f + 0.5g$ for some h with $\mathrm{last}(h) = s_2$. Then, playing $\sigma(h)$ from h will never allow Player 1 to reach Trg *surely* at the next step, whatever Player 2 plays; while playing, for instance, f (Dirac move) ensures player 1 to reach Trg surely at the next step, against a Player-2 strategy that plays f'. Thus, σ_2 is S-LA but σ_3 is not.

On the other hand, after every randomised move played in state s_2, the updated state is s_2 or s_3 from which A-winning strategies exist, thus $f \simeq^{\mathtt{A}}_h g \simeq^{\mathtt{A}}_h \lambda f + (1-\lambda)g$ for all $\lambda \in [0,1]$ and all histories h s.t. $\mathrm{last}(h) = s_2$ (so, in particular, $\lambda f + (1-\lambda)g \leqslant^{\mathtt{A}}_h f$ and $\lambda f + (1-\lambda)g \leqslant^{\mathtt{A}}_h g$). It follows that both σ_2 and σ_3 are A-LA. However, in the long run, player 1 needs to play $\lambda f + (1-\lambda)g$, with $\lambda \in (0,1)$, infinitely often in order to A-win. In fact, σ_3 is A-winning from s_2 while σ_2 is not. Thus, **there are $\star$-LA strategies which are not admissible**, so being $\star$-LA is not a sufficient criterion for $\star$-admissibility.

We close this section by several lemmata that allow us to better characterise the notion of LA strategies. First, we observe that, while randomisation might be necessary for winning in certain concurrent games (for example, in Figure 1, no Dirac move allows player 1 to reach Trg *surely* from s_2, while playing repeatedly f and g with equal probability ensures to reach Trg with probability 1) randomisation is useless when a player wants to play only locally admissible moves. This is shown by the next Lemma (point (1)), saying that, *if a randomised move α plays some action a with some positive probability, then α is weakly dominated by the Dirac move a.* However, this does not immediately allow us to characterise admissible moves: some Dirac moves could be dominated (hence non-admissible), and some non-Dirac moves could be admissible too. Points (2) and (3) elucidate this: *among Dirac moves, the non-dominated ones are admissible*, and *a non-Dirac move is admissible iff all the Dirac moves that occur in its support are admissible and equivalent to each other.*

▶ **Lemma 5.** *For all histories h and all randomised moves α:*

(i) *For all $a \in Supp(\alpha)$: $\alpha \leqslant^\star_h a$;*

(ii) *Dirac moves that are not $\star$-dominated at h by another Dirac move are $\star$-LA;*

(iii) *A move α is $\star$-LA at h iff, for all $a \in Supp(\alpha)$:*

1. *a is $\star$-LA at h; and*

2. *$a \simeq^\star_h b$ for all $b \in Supp(\alpha)$.*

▶ **Example 6.** As we have seen in Example 4, $0.5f + 0.5g <^{\mathtt{S}}_{s_2} f$. Note that a strategy σ' s.t. $\sigma'(h) = 0.5f + 0.5g$ for all h with $\mathrm{last}(h) = s_2$ has value $\chi^{\mathtt{S}}_{\sigma'}(h) = -1$, while $\chi^{\mathtt{S}}_1(h) = 0$.

This example seems to suggest that the local dominance of two moves coincide with the natural order on the values of histories that are obtained when playing those moves (in other words $x <_h^\star y$ would hold iff the value of the history obtained by playing x is smaller than or equal to the value obtained by playing y). This is not true for histories of value 0: we have seen that a and b are $\leqslant_h^\star$-incomparable, yet playing a or b from s_0 yields a history with value 0 in all cases (even when s_1 is reached). The next Lemma gives a precise characterisation of the dominance relation between Dirac moves in terms of values:

▶ **Lemma 7.** *For all players p, histories h with $\mathrm{last}(h) = s$ and Dirac moves $a, b \in \Sigma_p(s)$: $a \leqslant_h^\star b$ if, and only if the following conditions hold for every $c \in \Sigma_{-p}(s)$ where we write $s_{(a,c)} = \delta(s,(a,c))$ and $s_{(b,c)} = \delta(s,(b,c))$:*

(i) $\chi_p^\star(hs_{(a,c)}) \leq \chi_p^\star(hs_{(b,c)})$;

(ii) *if* $\chi_p^\star(hs_{(a,c)}) = \chi_p^\star(hs_{(b,c)}) = 0$ *then* $s_{(a,c)} = s_{(b,c)}$.

Characterisation and existence of admissible strategies. Equipped with our previous results, we can now establish the main results of this section. First, we show that *$\star$-admissible strategies are exactly those that are both $\star$-LA and $\star$-SCO* (Theorem 8(i)). Then, we show that *admissible strategies always exist* in concurrent games (Theorem 8(ii)).

▶ **Theorem 8** (Characterisation and existence of admissible strategies)**.** *The following holds for all strategies σ in a concurrent game with semantics $\star \in \{\mathtt{S}, \mathtt{A}\}$:*

(i) *σ is $\star$-admissible iff σ is $\star$-LA and $\star$-SCO; in the special case of simple safety objectives, if σ is $\star$-LA then σ is $\star$-admissible.*

(ii) *there is a $\star$-admissible strategy σ' such that $\sigma \preccurlyeq^\star \sigma'$.*

In particular, point (2) implies that admissible strategies always exist in concurrent games.

▶ **Example 9.** We consider again the example in Figure 1, and consider strategies σ_2 and σ_3 as defined in Example 1. Remember that these two strategies do their best to reach s_2, and that, from s_2, σ_2 plays deterministically f, while σ_3 plays f and g with equal probabilities. From Example 3, we know that σ_2 is S-SCO but not A-SCO; while σ_3 is A-SCO but not S-SCO. Indeed, we have already argued in Example 2 that σ_2 is not A-admissible, and that σ_3 is not S-admissible. However, from Example 4, we know that σ_2 is S-LA and that σ_3 is A-LA. So, by Theorem 8, σ_2 is S-admissible and σ_3 is A-admissible as expected.

Finally, we close the section by a finer characterisation of $\star$-admissible strategies. We show that:

(i) in the sure semantics, there is always an S-admissible strategy that plays Dirac moves only; and

(ii) in the almost-sure semantics, there is always an A-admissible strategy that plays Dirac moves only in histories of values 0 or -1.

The difference between the two semantics should not be surprising, as we know already that randomisation is sometimes needed to win (i.e., from histories of value 1) in the almost sure semantics:

▶ **Proposition 10.** *For all player-p strategies σ in a concurrent game:*

(i) *If σ is S-admissible then there exists a Dirac strategy σ' such that $\sigma \simeq^S \sigma'$.*

(ii) *If σ is A-admissible then there exists a strategy σ' that plays only Dirac moves in histories of value ≤ 0 such that $\sigma \simeq^A \sigma'$.*

4 Assume admissible synthesis

In this section we discuss an *assume-admissible synthesis* framework for concurrent games. With classical synthesis, one tries to compute *winning* strategies for all players, i.e., strategies that *always win* against *all possible strategies* of the other players. Unfortunately, it might be the case that such *unconditionally* winning strategies do not exist, as in our example. As explained in the introduction, the assume-admissible synthesis rule relaxes the classical synthesis rule: instead of searching for strategies that win unconditionally, the new rule requires winning against the *admissible strategies* of the other players. So, a strategy may satisfy the new rule while not winning unconditionally. We claim that winning against admissible strategies is well enough assuming that the players are *rational*; if we assume that players only play strategies that are good for achieving their objectives, *i.e.* admissible ones.

The general idea of the assume-admissible synthesis algorithm is to reduce the problem (in a concurrent n-player game) to the synthesis of a winning strategy *in a 2-player zero-sum concurrent game of imperfect information, in the $\mathcal{S}$-semantics* (even when the original assume-admissible problem is in the $\mathtt{A}$-semantics), where the objective of player 1 is given by an LTL formula. Such games are solvable using techniques presented in [11].

More precisely, from a concurrent game $\mathcal{G}$ in the semantics $\star \in \{\mathtt{S}, \mathtt{A}\}$ and player p, we build a game $\mathcal{G}_p^\star$ with the above characteristics, which is used to decide the assume-admissible synthesis rule. If such a solution exists, our algorithm constructs a witness strategy. For example, the game $\mathcal{G}_1^\star$ corresponding to the game in Figure 1 is given in Figure 3. The main ingredients for this construction are the following.

(i) In $\mathcal{G}_p^\star$, the protagonist is player p, and the second player is $-p$.

(ii) Although randomisation is needed to win in such games in general, we interpret $\mathcal{G}_p^\star$ in the $\mathtt{S}$-semantics only. In fact, we have seen that for the protagonist, Dirac moves suffice in states of value 0; so the only states where he might need randomisation are those of value 1 (randomisation does not matter if the value is -1 since the objective is lost anyway). Hence we define winning condition to be $\Phi(p) \vee \Diamond \mathtt{Val}^\star_{p,1}$ enabling us to consider only histories of values 0 in $\mathcal{G}_p^\star$; and thus hiding the parts of the game where randomisation might be needed. We also prove that we can restrict to Dirac strategies for $-p$ when it comes to admissible strategies.

(iii) In order to restrict the strategies to admissible ones, we only allow $\star$-LA moves in $\mathcal{G}_p^\star$. These moves can be computed by solving classical 2-player games ([2]) using Lemma 7. For example, in Figure 3, moves c and c' are removed since they are not $\mathtt{A}$-LA.

(iv) Last, since $\star$-admissible strategies are those that are both $\star$-LA and $\star$-SCO (see Theorem 8), we also need to ensure that the players play $\star$-SCO. This is more involved than $\star$-LA, as the $\star$-SCO criterion is not *local*, and requires information about the *sequence of actual moves* that have been played, which cannot be deduced, in a concurrent game, from the sequence of visited states. So, we store, in the states of $\mathcal{G}_p^\star$, the moves that have been played by all the players to reach the state. For example, in Figure 3, the state labelled by $s_1, (b, b')$ means that $\mathcal{G}$ has reached s_1, and that the last actions played by the players were b and b' respectively. However, players' strategies must not depend on this extra information since they do not have access to this information in $\mathcal{G}$ either. We thus interpret $\mathcal{G}_p^\star$ as a game of *imperfect information* where all the states labelled by the same state of $\mathcal{G}$ are in the same observation class. We can then encode that the players must play $\star$-SCO strategies in the new objective of the games, which will be given as an LTL formula, as we describe below.

To ensure we can effectively solve subproblems mentioned above, we consider ω-regular objectives. We also restrict ourselves to prefix-independent winning conditions to simplify the presentation. In the case of ω-regular objectives, prefix-independence is not a restrictive hypothesis (we can always compute the product of the game graph with a deterministic parity automaton that accepts the ω-regular objective and consider a parity winning condition). The values of the histories depend thus only on their last states, i.e. for all pairs of histories h_1 and h_2: $\mathrm{last}(h_1) = \mathrm{last}(h_2)$ implies that $\chi^\star_p(h_1) = \chi^\star_p(h_2)$. We denote by $\chi^\star_p(s)$ the value $\chi^\star_p(h)$ of all histories h s.t. $\mathrm{last}(h) = s$. Last, we assume that a player cannot play the same action from two different states, i.e. $\forall s_1 \neq s_2$, $\Sigma_{s_1}(p) \cap \Sigma_{s_2}(p) = \emptyset$. Thus, we say that *move a is $\star$-LA* when a is $\star$-LA from all histories ending in the unique state where a is available.

The game $\mathcal{G}^\star_p$. Let us now describe precisely the construction of $\mathcal{G}^\star_p$. Given an n-player concurrent game $\mathcal{G} = (S, \Sigma, s_{\mathsf{init}}, (\Sigma_p)_{p\in P}, \delta)$ with winning condition Φ considered under semantics $\star \in \{\mathtt{S}, \mathtt{A}\}$, and given a player p, we define the two-player zero-sum concurrent game $\mathcal{G}^\star_p = (\overline{S}, \overline{\Sigma}, \overline{s_{\mathsf{init}}}, (\overline{\Sigma}_p, \overline{\Sigma}_{-p}), \overline{\delta})$ where:

- **(i)** $\overline{S} = S \times \overline{\Sigma}^n \cup \{\overline{s_{\mathsf{init}}}\}$;
- **(ii)** $\overline{\Sigma}$ is the set of Dirac $\star$-LA moves in Σ;
- **(iii)** $\overline{s_{\mathsf{init}}} = s_{\mathsf{init}}$ is the initial state;
- **(iv)** $\overline{\Sigma}_p$ is such that $\overline{\Sigma}_p(s)$ is the set of Dirac $\star$-LA moves of p in s, for all $s \in S$;
- **(v)** $\overline{\Sigma}_{-p}$ is s.t. for all $s \in S$: $\overline{\Sigma}_{-p}(s)$ is the set of moves $\boldsymbol{a}$ of $-p$ in s s.t. for all $q \neq p$, a_q is a Dirac $\star$-LA move;
- **(vi)** $\overline{\delta}$ updates the state according to δ, remembering the last actions played: $\overline{\delta}(\overline{s_{\mathsf{init}}}, \boldsymbol{b}) = (\delta(s_{\mathsf{init}}, \boldsymbol{b}), \boldsymbol{b})$ and $\overline{\delta}((s, \boldsymbol{a}), \boldsymbol{b}) = (\delta(s, \boldsymbol{b}), \boldsymbol{b})$ for all $s \in S$.

Note that the game $\mathcal{G}^\star_p$ depends on whether $\star = \mathtt{A}$ or $\star = \mathtt{S}$ because the two semantics yield different sets of LA-moves. However, we interpret $\mathcal{G}^\star_p$ in the sure semantics, so both players can play Dirac strategies only in $\mathcal{G}^\star_p$.

Let us now explain how we obtain an imperfect information game by defining an *observation function* $\mathfrak{o}$. Note that histories in $\mathcal{G}^\star_p$ are of the form: $\overline{h} = \overline{s_{\mathsf{init}}}(s_1, \boldsymbol{a}_1)(s_2, \boldsymbol{a}_2)\cdots(s_n, \boldsymbol{a}_n)$. Then, let $\mathfrak{o} : \overline{S} \to S$ be the mapping that, intuitively, projects moves away from states. For example, in Figure 3, states with observation s_0 are in the dashed rectangle. That is: $\mathfrak{o}(s, \boldsymbol{a}) = s$ for all states s, and $\mathfrak{o}(\overline{s_{\mathsf{init}}}) = s_{\mathsf{init}}$. We extend $\mathfrak{o}$ to histories recursively: $\mathfrak{o}(\overline{s_{\mathsf{init}}}) = s_{\mathsf{init}}$ and $\mathfrak{o}(h(s_n, \boldsymbol{a}_n)) = \mathfrak{o}(h)s_n$. To make $\mathcal{G}^\star_p$ a game of imperfect information, we request that, in $\mathcal{G}^\star_p$, players play only strategies σ s.t. $\sigma(h_1) = \sigma(h_2)$ whenever $\mathfrak{o}(h_1) = \mathfrak{o}(h_2)$.

We relate the strategies in the original game $\mathcal{G}$ with the strategies in $\mathcal{G}^\star_p$, which we need to extract admissible strategies in $\mathcal{G}$ from the winning strategies in $\mathcal{G}^\star_p$ and thus perform assume-admissible synthesis. First, given a player-p strategy σ in $\mathcal{G}$ (i.e., $\sigma \in \Gamma_p(\mathcal{G})$), we say that a strategy $\overline{\sigma} \in \Gamma^{\mathrm{det}}_p(\mathcal{G}^\star_p)$ is a *realisation* of σ iff:

- **(i)** $\overline{\sigma}$ is Dirac; and
- **(ii)** $\overline{\sigma}(h) \in \mathrm{Supp}(\sigma(h)))$ for all h.

Note that every $\star$-LA strategy $\sigma \in \Gamma_i(\mathcal{G})$ admits realisations σ in $\Gamma_i(\mathcal{G}^\star_p)$. Second, given a player-p Dirac strategy σ in $\mathcal{G}^\star_p$ (i.e., $\sigma \in \Gamma^{\mathrm{det}}_p(\mathcal{G}^\star_p)$) we say that $\hat{\sigma} \in \Gamma_p(\mathcal{G})$ is an *extension* of σ iff, for all $h \in \mathtt{Hist}(\mathcal{G}^\star_p, \sigma)$: $\hat{\sigma}(\mathfrak{o}(h)) = \sigma(h)$.

The assume-admissible synthesis technique. As explained above, the assume-admissible rule boils down to computing a winning strategy $\overline{\sigma}$ for player-p in $\mathcal{G}^\star_p$ w.r.t. the winning condition $\Phi_{\mathcal{G}^\star_p}$, and extracting, from $\overline{\sigma}$, the required admissible strategy in $\mathcal{G}$.

We will now formally define $\Phi_{\mathcal{G}_p^\star}$. Let p be a player (in $\mathcal{G}$); and let us denote by $\mathsf{st}(a)$ the (unique) state from which a is available, for all actions a. We define $\texttt{AfterHelpMove}_p^\star$ as

$$\texttt{AfterHelpMove}_p^\star = \{(s, \boldsymbol{a}) \in \overline{S} \mid \exists s' \in \mathrm{Succ}(\mathsf{st}(a_p), a_p) : \chi_p^\star(s') \geq 0 \wedge s' \neq s \wedge \chi_p^\star(s) = 0\}.$$

That is, when $(s, \boldsymbol{a}) \in \texttt{AfterHelpMove}_p^\star$, in $\mathcal{G}$, player p has played a_p from $\mathsf{st}(a_p)$ and, due to player $-p$'s choice, $\mathcal{G}$ has reached s. However, with another choice of player $-p$, the game could have moved to a different state s' from which $-p$ can help p to win as $\chi_p^\star(s') \geq 0$. Intuitively, in runs that visit states of value 0 infinitely often, states from $\texttt{AfterHelpMove}_p^\star$ should be visited infinitely often for player p to play SCO, i.e. such runs might not be winning, but this cannot be blamed on player p who has sought repeatedly the collaboration of the other players to enforce his objective. Observe further that the definition of this predicate requires the labelling of the states (by actions) we have introduced in $\mathcal{G}_p^\star$. For example, in Figure 3, $\texttt{AfterHelpMove}_2^{\mathtt{A}} = \big\{\big(s_0, (a, b')\big), \big(s_1, (b, b')\big)\big\}$. We let $\Phi_0^\star(p) = \Diamond\neg\texttt{Val}_{p,0}^\star \vee \Phi(p) \vee \Box\Diamond\texttt{AfterHelpMove}_p^\star$ and $\Phi_1^\star(p) = \big(\Diamond\texttt{Val}_{p,1}^\star\big) \to \Phi(p)$. Let us define $\Phi_{\mathcal{G}_p^\star} = \big(\bigwedge_{q\neq p} \Phi_0^\star(q) \wedge \Phi_1^\star(q)\big) \to \big(\Phi(p) \vee \Diamond\texttt{Val}_{p,1}^\star\big)$.

▶ **Theorem 11** (Assume-admissible synthesis)**.** *Player p has a $\star$-admissible strategy σ that is $\star$-winning against all player $-p$ $\star$-admissible strategies in $\mathcal{G}$ iff Player p has an $\mathcal{S}$-winning strategy in $\mathcal{G}_p^\star$ for the objective $\Phi_{\mathcal{G}_p^\star}$. Such a $\star$-admissible strategy σ can be effectively computed (from any player p $\mathcal{S}$-winning strategy in $\mathcal{G}_p^\star$).*

Let us explain how we build a strategy in $\mathcal{G}$ with the desired properties, from any player p strategy enforcing $\Phi_{\mathcal{G}_p^\star}$ in $\mathcal{G}_p^\star$. Remember that $\mathcal{G}_p^\star$ ensures that the players play $\star$-LA moves only. We will use $\Phi_{\mathcal{G}_p^\star}$ to make sure that, when SCO strategies are played by $-p$ (relying on the extra information we have encoded in the states), then p reaches a state of value 1. First, consider $\Phi_0^\star(q)$ for $q \neq p$. Runs that satisfy this formula are either those that visit states of value 0 only finitely often ($\Diamond\neg\texttt{Val}_{q,0}^\star$); or those that stay in states of value 0, in which case they must be either winning ($\Phi(q)$) or visit infinitely often states where Player q could have been helped by the other players ($\Box\Diamond\texttt{AfterHelpMove}_q^\star$). This is a necessary condition on runs visiting only value 0 states for the strategy to be SCO. Next, observe that $\Phi_1^\star(q)$ states that *if* a history of value 1 is entered *then* Player q must win. This allows us to understand the left part of the implication in $\Phi_{\mathcal{G}_p^\star}$: the implication can be read as 'if all other players play a $\star$-admissible strategy, then either p should win ($\Phi(p)$) or a state of value 1 for player p should eventually be visited ($\Diamond\texttt{Val}_{p,1}^\star$)'. Then a strategy $\hat{\sigma}$ (in $\mathcal{G}$) that wins against admissible strategies can be extracted from a winning strategy $\overline{\sigma}$ (in $\mathcal{G}_p^\star$) in a straightforward way, *except* when $\overline{\sigma}$ enforces to reach a state of value 1 ($\Diamond\texttt{Val}_{p,1}^\star$ in $\Phi_{\mathcal{G}_p^\star}$). In this case, σ cannot follow $\overline{\sigma}$, but must rather switch to a *winning* strategy, which:

(i) is guaranteed to exist since the state that has been reached has value 1; and

(ii) can be computed using classical techniques [11].

The strategy $\hat{\sigma}$ is not necessarily admissible but by Theorem 8 (1), there is an admissible strategy σ with $\hat{\sigma} \preccurlyeq^\star \sigma$. By weak domination, σ wins against more profiles than $\hat{\sigma}$, in particular, against the profiles of admissible strategies of the other players.

▶ **Example 12.** In our running example, observe that $\neg\texttt{Val}_{2,0}^{\mathtt{A}} = \texttt{Val}_{2,1}^{\mathtt{A}} = \{Win\}$ since there is no state of value -1 in $\mathcal{G}$. Hence, $\Phi(2) = \Diamond Win = \Diamond\texttt{Val}_{2,1}^{\mathtt{A}} = \Diamond\neg\texttt{Val}_{2,0}^{\mathtt{A}}$. Finally, $\texttt{AfterHelpMove}_2^{\mathtt{A}} = \big\{\big(s_0, (a, b')\big), \big(s_1, (b, b')\big)\big\}$, so, after simplification: $\Phi_{\mathcal{G}_1^{\mathtt{A}}} = \big[\Diamond Win \vee \Box\Diamond\big((s_0, (a, b')) \vee (s_1, (b, b'))\big)\big] \to \Diamond Win$. Thus, to win in $\mathcal{G}_1^{\mathtt{A}}$ (under the *sure* semantics), player 1 must ensure to reach Win as long as player 2 visits the set of *bold* states in Figure 3 infinitely often. A winning strategy $\overline{\sigma}$ in $\mathcal{G}_1^{\mathtt{A}}$ consists in (eventually) always playing b from

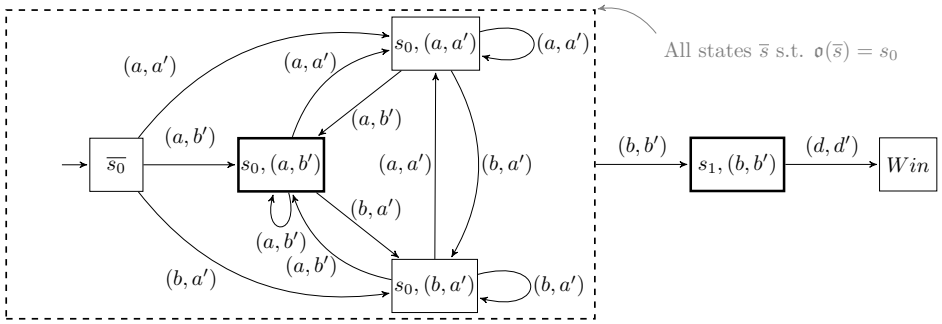

Figure 3 The game $\mathcal{G}_1^{\mathtt{A}}$ obtained from the game in Figure 1. Bold states $\big(s_0, (a, b')\big)$ and $\big(s_1, (b, b')\big)$ are the states of $\mathtt{AfterHelpMove}_2^{\mathtt{A}}$. There is a (b, b')-labelled transition from all states in the dashed rectangle to $\big(s_1, (b, b')\big)$.

all states in the dashed rectangle; and d from $\big(s_1, (b, b')\big)$. Observe that this strategy is compatible with $\mathfrak{o}$. From $\overline{\sigma}$, we can extract an admissible player 1 strategy in $\mathcal{G}$: always play b in s_0; always play d in s_1; and play a winning strategy from s_2 (which is of value 1), for instance: always play $0.5f + 0.5g$ from s_2 like σ_3 does.

We conclude by two remarks on simple safety games and on the choice of our semantics. First, note that assume-admissible synthesis is simpler in simple safety games, since the admissible strategies are exactly the $\star$-LA strategies in this case (see Theorem 8). So, one can build $\mathcal{G}_p$ from $\mathcal{G}$ by pruning the actions which are not $\star$-LA (the labelling by actions is not necessary anymore), and look for a player p winning strategy. Second, in the semantics of concurrent games considered in this paper, players see, at each step, the transition taken but not the actual moves of the other player even once they are played. An alternative semantics could be that the players discover simultaneously the moves of other players after each step, as in the Rock-Paper-Scissors game. The former semantics is more general than the latter since moves played at the preceding round can always be encoded in the current state (as we did in the construction of $\mathcal{G}_p^\star$). Our results remain meaningful in this simpler case (in particular the characterisation of admissible strategies), but assume-admissible synthesis can be performed by reducing to games with *perfect* information.

Abstract

We study the problem of finding the cycle of minimum cost-to-time ratio in a directed graph with n nodes and m edges. This problem has a long history in combinatorial optimization and has recently seen interesting applications in the context of quantitative verification. We focus on strongly polynomial algorithms to cover the use-case where the weights are relatively large compared to the size of the graph. Our main result is an algorithm with running time $\tilde{O}(m^{3/4}n^{3/2})$, which gives the first improvement over Megiddo's $\tilde{O}(n^3)$ algorithm [JACM'83] for sparse graphs.[1] We further demonstrate how to obtain both an algorithm with running time $n^3/2^{\Omega(\sqrt{\log n})}$ on general graphs and an algorithm with running time $\tilde{O}(n)$ on constant treewidth graphs. To obtain our main result, we develop a parallel algorithm for negative cycle detection and single-source shortest paths that might be of independent interest.

1 Introduction

We revisit the problem of computing the cycle of minimum cost-to-time ratio (short: minimum ratio cycle) of a directed graph in which every edge has a cost and a transit time. The problem has a long history in combinatorial optimization and has recently become relevant to the computer-aided verification community in the context of quantitative verification and synthesis of reactive systems [11, 13, 24, 7, 10, 6, 14]. The shift from quantitative to qualitative properties is motivated by the necessity of taking into account the resource

consumption of systems (such as embedded systems) and not just their correctness. For algorithmic purposes, these systems are usually modeled as directed graphs where vertices correspond to states of the system and edges correspond to transitions between states. Weights on the edges model the resource consumption of transitions. In our case, we allow two types of resources (called cost and transit time) and are interested in optimizing the ratio between the two quantities. By giving improved algorithms for finding the minimum ratio cycle we contribute to the algorithmic progress that is needed to make the ideas of quantitative verification and synthesis applicable.

From a purely theoretic point of view, the minimum ratio problem is an interesting generalization of the minimum mean cycle problem.[2] A natural question is whether the running time for the more general problem can match the running time of computing the minimum cycle mean (modulo lower order terms). In terms of weakly polynomial algorithms, the answer to this question is yes, since a binary search over all possible values reduces the problem to negative cycle detection. In terms of strongly polynomial algorithms, with running time independent of the encoding size of the edge weights, the fastest algorithm for the minimum ratio cycle problem is due to Megiddo [42] and runs in time $\tilde{O}(n^3)$, whereas the minimum mean cycle can be computed in $O(mn)$ time with Karp's algorithm [38]. This has left an undesirable gap in the case of sparse graphs for more than three decades.

Our results. We improve upon this situation by giving a strongly polynomial time algorithm for computing the minimum ratio cycle in time $O(m^{3/4}n^{3/2}\log^2 n)$ (Theorem 21 in Section 4). We obtain this result by designing a suitable parallel negative cycle detection algorithm and combining it with Megiddo's parametric search technique [42]. We first present a slightly simpler randomized version of our algorithm with one-sided error and the same running time (Theorem 18 in Section 3).

As a side result, we develop a new parallel algorithm for negative cycle detection and single-source shortest paths (SSSP) that we use as a subroutine in the minimum ratio cycle algorithm. This new algorithm has work $\tilde{O}(mn + n^3h^{-3})$ and depth $O(h)$ for any $\log n \leq h \leq n$. Our algorithm uses techniques from the parallel transitive closure algorithm of Ullman and Yannakakis [52] (in particular as reviewed in [39]) and our contribution lies in extending these techniques to directed graphs with positive *and negative* edge weights. In particular, we partially answer an open question by Shi and Spencer [50] who previously gave similar trade-offs for single-source shortest paths in *undirected* graphs with positive edge weights. We further demonstrate how the parametric search technique can be applied to obtain minimum ratio cycle algorithms with running time $\tilde{O}(n)$ on constant treewidth graphs (Corollary 24 in Section 5). Our algorithms do not use fast matrix multiplication. We finally show that if fast matrix multiplication is allowed then slight further improvements are possible, specifically we present an $n^3/2^{\Omega(\sqrt{\log n})}$ time algorithm on general graphs (see full version of this paper).

Prior Work. The minimum ratio problem was introduced to combinatorial optimization in the 1960s by Dantzig, Blattner, and Rao [22] and Lawler [40]. The existing algorithms can be classified according to their running time bounds as follows: strongly polynomial algorithms, weakly polynomial algorithms, and pseudopolynomial algorithms. In terms of strongly polynomial algorithms for finding the minimum ratio cycle we are aware of the following two results:

[2] In the minimum cycle mean problem we assume the transit time of each edge is 1.

- $O(n^3 \log n + mn \log^2 n)$ time using Megiddo's second algorithm [42] together with Cole's technique to reduce a factor of $\log \log n$ [21],
- $O(mn^2)$ time using Burn's primal-dual algorithm [9].

For the class of weakly polynomial algorithms, the best algorithm is to follow Lawler's binary search approach [40, 41], which solves the problem by performing $O(\log(nW))$ calls to a negative cycle detection algorithm. Here $W = O(CT)$ if the costs are given as integers from 1 to C and the transit times are given as integers from 1 to T. Using an idea for efficient search of rationals [47], a somewhat more refined analysis by Chatterjee et al. [14] reveals that it suffices to call the negative cycle detection algorithm $O(\log(|a \cdot b|))$ times when the value of the minimum ratio cycle is $\frac{a}{b}$. Since the initial publication of Lawler's idea, the state of the art in negative cycle detection algorithms has become more diverse. Each of the following five algorithms gives the best known running time for some range of parameters (and the running times have to be multiplied by the factor $\log(nW)$ or $\log(|a \cdot b|)$ to obtain an algorithm for the minimum ratio problem):

- $O(mn)$ time using a variant of the Bellman-Ford algorithm [26, 3, 45],
- $n^3/2^{\Omega(\sqrt{\log n})}$ time using a recent all-pairs shortest paths (APSP) algorithm by Williams [53, 12],
- $\tilde{O}(n^\omega W)$ time using fast matrix multiplication [48, 54], where $2 \leq \omega < 2.3728639$ is the matrix multiplication coefficient [29],
- $O(m\sqrt{n} \log W)$ time using Goldberg's scaling algorithm [31],
- $\tilde{O}(m^{10/7} \log W)$ time using the interior point method based algorithm of Cohen et al. [20]

The third group of minimum ratio cycle algorithms has a pseudopolynomial running time bound. After some initial progress [34, 30, 35], the state of the art is an algorithm by Hartmann and Orlin [33] that has a running time of $O(mnT)$.[3] Other algorithmic approaches, without claiming any running time bounds superior to those reported above, were given by Fox [27], v. Golitschek [32], and Dasdan, Irani, and Gupta [23].

Recently, the minimum ratio problem has been studied specifically for the special case of constant treewidth graphs by Chatterjee, Ibsen-Jensen, and Pavlogiannis [14]. The state of the art for negative cycle detection on constant treewidth graphs is an algorithm by Chaudhuri and Zaroliagis with running time $O(n)$ [17], which by Lawler's binary search approach implies an algorithm for the minimum ratio problem with running time $O(n \log(nW))$. Chatterjee et al. [14] report a running time of $O(n \log(|a \cdot b|))$ based on the more refined binary search mentioned above and additionally give an algorithm that uses $O(\log n)$ space (and hence polynomial time).

As a subroutine in our minimum ratio cycle algorithm, we use a new parallel algorithm for negative cycle detection and single-source shortest paths. The parallel SSSP problem has received considerable attention in the literature [50, 39, 18, 8, 49, 19, 43, 44, 5], but we are not aware of any parallel SSSP algorithm that works in the presence of negative edge weights (and thus solves the negative cycle detection problem). To the best of our knowledge, the only strongly polynomial bounds reported in the literature are as follows: For weighted, directed graphs with non-negative edge weights, Broda, Träff, and Zaroliagis [8] give an implementation of Dijkstra's algorithm with $O(m \log n)$ work and $O(n)$ depth. For weighted, undirected graphs with positive edge weights, Shi and Spencer [49] gave (1) an algorithm with $O(n^3 t^{-2} \log n \log(nt^{-1}) + m \log n)$ work and $O(t \log n)$ depth and (2) an algorithm with $O((n^3 t^{-3} + mnt^{-1}) \log n)$ work and $O(t \log n)$ depth, for any $\log n \leq t \leq n$.

[3] Note that the more fine-grained analysis of Hartmann and Orlin actually gives a running time of $O(m(\sum_{u \in V} \max_{e=(u,v)} t(e)))$.

2 Preliminaries

In the following, we review some of the tools that we use in designing our algorithm.

2.1 Parametric Search

We first explain the parametric search technique as outlined in [1]. Assume we are given a property $\mathcal{P}$ of real numbers that is *monotone* in the following way: if $\mathcal{P}(\lambda)$ holds, then also $\mathcal{P}(\lambda')$ holds for all $\lambda' < \lambda$. Our goal is to find λ^*, the *maximum* λ such that $\mathcal{P}(\lambda)$ holds. In this paper for example, we will associate with each λ a weighted graph G_λ and $\mathcal{P}$ is the property that G_λ has no negative cycle. Assume further that we are given an algorithm $\mathcal{A}$ for deciding, for a given λ, whether $\mathcal{P}(\lambda)$ holds. If λ were known to only assume integer or rational values, we could solve this problem by performing binary search with $O(\log W)$ calls to the decision algorithm, where W is the number of possible values for λ. However, this solution has the drawback of not yielding a strongly polynomial algorithm.

In parametric search we run the decision algorithm 'generically' at the maximum λ^*. As the algorithm does not know λ^*, we need to take care of its control flow ourselves and any time the algorithm performs a comparison we have to 'manually' evaluate the comparison on behalf of the algorithm. If each comparison takes the form of testing the sign of an associated low-degree polynomial $p(\lambda)$, this can be done as follows. We first determine all roots of $p(\lambda)$ and check if $\mathcal{P}(\lambda')$ holds for each such root λ' using another instance of the decision algorithm $\mathcal{A}$. This gives us an interval between successive roots containing λ^* and we can thus resolve the comparison. With every comparison we make, the interval containing λ^* shrinks and at the end of this process we can output a single candidate. If the decision algorithm $\mathcal{A}$ has a running time of T, then the overall algorithm for computing λ^* has a running time of $O(T^2)$.

A more sophisticated use of the technique is possible, if in addition to a sequential decision algorithm $\mathcal{A}_\mathrm{s}$ we have an efficient parallel decision algorithm $\mathcal{A}_\mathrm{p}$. The parallel algorithm performs its computations simultaneously on P_p processors. The number of parallel computation steps until the last processor is finished is called the *depth* D_p of the algorithm, and the number of operations performed by all processors in total is called the *work* W_p of the algorithm.[4] For parametric search, we actually only need parallelism w.r.t. comparisons involving the input values. We denote by the *comparison depth* of $\mathcal{A}_\mathrm{p}$ the number of parallel comparisons (involving input values) until the last processor is finished.

We proceed similar to before: We run $\mathcal{A}_\mathrm{p}$ 'generically' at the maximum λ^* and (conceptually) distribute the work among P_p processors. Now in each parallel step, we might have to resolve up to P_p comparisons. We first determine all roots of the polynomials associated to these comparisons. We then perform a binary search among these roots to determine the interval of successive roots containing λ^* and repeat this process of resolving comparisons at every parallel step to eventually find out the value of λ^*. If the sequential decision algorithm $\mathcal{A}_\mathrm{s}$ has a running time of T_s and the parallel decision algorithm runs on P_p processors in D_p parallel steps, then the overall algorithm for computing λ^* has a running time of $O(P_\mathrm{p}D_\mathrm{p} + D_\mathrm{p}T_\mathrm{s}\log P_\mathrm{p})$. Formally, the guarantees of the technique we just described can be summarized as follows.

[4] To be precise, we use an abstract model of parallel computation as formalized in [28] to avoid distraction by details such as read or write collisions typical to PRAM models.

▶ **Theorem 1** ([1, 42]). *Let $\mathcal{P}$ be a property of real numbers such that if $\mathcal{P}(\lambda)$ holds, then also $\mathcal{P}(\lambda')$ holds for all $\lambda' < \lambda$ and let $\mathcal{A}_p$ and $\mathcal{A}_s$ be algorithms deciding for a given λ whether $\mathcal{P}(\lambda)$ holds such that*

- *the control flow of $\mathcal{A}_p$ is only governed by comparisons that test the sign of an associated polynomial in λ of constant degree,*
- *$\mathcal{A}_p$ is a parallel algorithm with work W_p and comparison depth D_p, and*
- *$\mathcal{A}_s$ is a sequential algorithm with running time T_s.*

Then there is a (sequential) algorithm for finding the maximum value λ such that $\mathcal{P}(\lambda)$ holds with running time $O(W_p + D_p T_s \log W_p)$.

Note that $\mathcal{A}_\mathrm{p}$ and $\mathcal{A}_\mathrm{s}$ need not necessarily be different algorithms. In most cases however, the fastest sequential algorithm might be the better choice for minimizing running time.

2.2 Characterization of Minimum Ratio Cycle

We consider a directed graph $G = (V, E, c, t)$, in which every edge $e = (u, v)$ has a cost $c(e)$ and a transit time $t(e)$. We want to find the cycle C that minimizes the cost-to-time ratio $\sum_{e \in C} c(e) / \sum_{e \in C} t(e)$.

For any real λ define the graph $G_\lambda = (V, E, w_\lambda)$ as the modification of G with weight $w_\lambda(e) = c(e) - \lambda t(e)$ for every edge $e \in E$. The following structural lemma is the foundation of many algorithmic approaches towards the problem.

▶ **Lemma 2** ([22, 41]). *Let λ^* be the value of the minimum ratio cycle of G.*

- *For $\lambda > \lambda^*$, the value of the minimum weight cycle in G_λ is < 0.*
- *The value of the the minimum weight cycle in G_{λ^*} is 0. Each minimum weight cycle in G_{λ^*} is a minimum ratio cycle in G and vice versa.*
- *For $\lambda < \lambda^*$, the value of the minimum weight cycle in G_λ is > 0.*

The obvious algorithmic idea now is to find the right value of λ with a suitable search strategy and reduce the problem to a series of negative cycle detection instances.

2.3 Characterization of Negative Cycle

▶ **Definition 3.** A *potential function* $p\colon V \to \mathbb{R}$ assigns a value to each vertex of a weighted directed graph $G = (V, E, w)$. We call a potential function p *valid* if for every edge $e = (u, v) \in E$, the condition $p(u) + w(e) \geq p(v)$ holds.

The following two lemmas outline an approach for negative cycle detection.

▶ **Lemma 4** ([25]). *A weighted directed graph contains a negative cycle if and only if it has no valid potential function.*

▶ **Lemma 5** ([37]). *Let $G = (V, E, w)$ be a weighted directed graph and let $G' = (V', E', w')$ be the supergraph of G consisting of the vertices $V' = V \cup \{s'\}$ (i.e. with an additional super-source s'), the edges $E' = E \cup \{s'\} \times V$ and the weight function w' given by $w'(s', v) = 0$ for every vertex $v \in V$ and $w'(u, v) = w(u, v)$ for all pairs of vertices $u, v \in V$. If G does not contain a negative cycle, then the potential function p defined by $p(v) = d_{G'}(s', v)$ for every vertex $v \in V$ is valid for G.*

Thus, an obvious strategy for negative cycle detection is to design a single-source shortest paths algorithm that is correct whenever the graph contains no negative cycle. If the graph contains no negative cycle, then the distances computed by the algorithm can be verified to

be a valid potential. If the graph does contain a negative cycle, then the distances computed by the algorithm will not be a valid potential (because a valid potential does not exist) and we can verify that the potential is not valid.

2.4 Computing Shortest Paths in Parallel

In our algorithm we use two building blocks for computing shortest paths in the presence of negative edge weights in parallel. The first such building block was also used by Megiddo [42].

▶ **Observation 6.** *By repeated squaring of the min-plus matrix product, all-pairs shortest paths in a directed graph with real edge weights can be computed using work $O(n^3 \log n)$ and depth $O(\log n)$.*

The second building block is a subroutine for computing the following restricted version of shortest paths.

▶ **Definition 7.** The *shortest h-hop path* from a vertex s to a vertex t is the path of minimum weight among all paths from s to t with at most h edges.

Note that a shortest h-hop path from s to t does not exist, if all paths from s to t use more than h edges. Furthermore, if there is a shortest path from s to t with at most h edges, then the h-hop shortest path from s to t is a shortest path as well. Shortest h-hop paths can be computed by running h iterations of the Bellman-Ford algorithm [26, 3, 45].[5] Similar to shortest paths, shortest h-hop paths need not be unique. We can enforce uniqueness by putting some arbitrary but fixed order on the vertices of the graph and sorting paths according to the induced lexicographic order on the sequence of vertices of the paths. Note that the Bellman-Ford algorithm can easily be adapted to optimizing lexicographically as its second objective.

▶ **Observation 8.** *By performing h iterations of the Bellman-Ford algorithm, the lexicographically smallest shortest h-hop path from a designated source vertex s to each other vertex in a directed graph with real edge weights can be computed using work $O(mh)$ and depth $O(h)$.*

We denote by $\pi(s,t)$ the lexicographically smallest shortest path from s to t and by $\pi^h(s,t)$ the lexicographically smallest shortest h-hop path from s to t. We denote by $V(\pi^h(s,t))$ and $E(\pi^h(s,t))$ the set of nodes and edges of $\pi^h(s,t)$, respectively.

2.5 Approximate Hitting Sets

▶ **Definition 9.** Given a collection of sets $\mathcal{S} \subseteq 2^U$ over a universe U, a hitting set is a set $T \subseteq H$ that has non-empty intersection with every set of $\mathcal{S}$ (i.e., $S \cap T \neq \emptyset$ for every $S \in \mathcal{S}$).

Computing a hitting set of minimum size is an NP-hard problem. For our purpose however, rough approximations are good enough. The first method to get a sufficiently small hitting set uses a simple randomized sampling idea and was introduced to the design of graph algorithms by Ullman and Yannakakis [52]. We use the following formulation.

▶ **Lemma 10.** *Let $c \geq 1$, let U be a set of size s and let $\mathcal{S} = \{S_1, S_2, \ldots, S_k\}$ be a collection of sets over the universe U of size at least q. Let T be a subset of U that was obtained by choosing*

[5] The first explicit use of the Bellman-Ford algorithm to compute shortest h-hop paths that we are aware of is in Thorup's dynamic APSP algorithm [51].

each element of U independently with probability $p = \min(x/q, 1)$ where $x = c \ln(ks) + 1$. Then, with high probability (whp), i.e., probability at least $1 - 1/s^c$, the following two properties hold:

1. *For every $1 \leq i \leq k$, the set S_i contains an element of T, i.e., $S_i \cap T \neq \emptyset$.*
2. *$|T| \leq 3xs/q = O(cs \log(ks)/q)$.*

The second method is to use a heuristic to compute an approximately minimum hitting set. In the sequential model, a simple greedy algorithm computes an $O(\log n)$-approximation [36, 2]. We use the following formulation.

▶ **Lemma 11.** *Let U be a set of size s and let $\mathcal{S} = \{S_1, S_2, \ldots, S_k\}$ be a collection of sets over the universe U of size at least q. Consider the simple greedy algorithm that picks an element u in U that is contained in the largest number of sets in $\mathcal{S}$ and then removes all sets containing u from $\mathcal{S}$, repeating this step until $\mathcal{S} = \emptyset$. Then the set T of elements picked by this algorithm satisfies:*

1. *For every $1 \leq i \leq k$, the set S_i contains an element of T, i.e., $S_i \cap T \neq \emptyset$.*
2. *$|T| \leq O(s \log(k)/q)$.*

Proof. We follow the standard proof of the approximation ratio $O(\log n)$ for the greedy set cover heuristic. The first statement is immediate, since we only remove sets when they are hit by the picked element. Since each of the k sets contains at least q elements, on average each element in U is contained in at least kq/s sets. Thus, the element u picked by the greedy algorithm is contained in at least kq/s sets. The remaining number of sets is thus at most $k - kq/s = k(1 - q/s)$. Note that the remaining sets still have size at least q, since they do not contain the picked element u. Inductively, we thus obtain that after i iterations the number of remaining sets is at most $k(1 - q/s)^i$, so after $O(\log(k) \cdot s/q)$ iterations the number of remaining sets is less than 1 and the process stops. ◀

The above greedy algorithm is however inherently sequential and thus researchers have studied more sophisticated algorithms for the parallel model. The state of the art in terms of deterministic algorithms is an algorithm by Berger et al. [4][6].

▶ **Theorem 12** ([4]). *Let $\mathcal{S} = \{S_1, S_2, \ldots, S_k\}$ be a collection of sets over the universe U, let $n = |U|$ and $m = \sum_{1 \leq i \leq k} |S_i|$. For $0 < \epsilon < 1$, there is an algorithm with work $O((m+n)\epsilon^{-6} \log^4 n \log m \log^6(nm))$ and depth $O(\epsilon^{-6} \log^4 n \log m \log^6(nm))$ that produces a hitting set of $\mathcal{S}$ of size at most $(1+\epsilon)(1+\ln \Delta) \cdot OPT$, where Δ is the maximum number of occurrences of any element of U in $\mathcal{S}$ and OPT is the size of a minimum hitting set.*

3 Randomized Algorithm for General Graphs

3.1 A Parallel SSSP Algorithm

In the following we design a parallel SSSP algorithm that can be used to check for negative cycles. Formally, we will in this subsection prove the following statement.

[6] Berger et al. actually give an approximation algorithm for the following slightly more general problem: Given a hypergraph $H = (V, E)$ and a cost function $c\colon V \to \mathbb{R}$ on the vertices, find a minimum cost subset $R \subseteq V$ that covers H, i.e., an R that minimizes $c(R) = \sum_{v \in R} c(v)$ subject to the constraint $e \cap R \neq \emptyset$ for all $e \in E$.

▶ **Theorem 13.** *There is an algorithm that, given a weighted directed graph $G = (V, E, w)$ containing no negative cycles, computes the shortest paths from a designated source vertex s to all other vertices spending $O(mn \log n + n^3 h^{-3} \log^4 n)$ work with $O(h + \log n)$ depth for any $1 \leq h \leq n$. The algorithm is correct with high probability and all its comparisons are performed on sums of edge weights on both sides.*

The algorithm proceeds in the following steps:

1. Let $C \subseteq V$ be a set containing each vertex v independently with probability $p = \min(3ch^{-1} \ln n, 1)$ for a sufficiently large constant c.
2. If $|C| > 9cnh^{-1} \ln n$, then terminate.
3. For every vertex $x \in C \cup \{s\}$ and every vertex $v \in V$, compute the shortest h-hop path from x to v in G and its weight $d^h_G(x, v)$.
4. Construct the graph $H = (C \cup \{s\}, (C \cup \{s\})^2, w_H)$ whose set of vertices is $C \cup \{s\}$, whose set of edges is $(C \cup \{s\})^2$ and for every pair of vertices $x, y \in C \cup \{s\}$ the weight of the edge (x, y) is $w_H(x, y) = d^h_G(x, y)$.
5. For every vertex $x \in C$, compute the shortest path from s to x in H and its weight $d_H(s, x)$.
6. For every vertex $t \in V$, set $\delta(t) = \min_{x \in C \cup \{s\}}(d_H(s, x) + d^h_G(x, t))$.

3.1.1 Correctness

In order to prove the correctness of the algorithm, we first observe that as a direct consequence of Lemma 10 the randomly selected vertices in C with high probability hit all lexicographically smallest shortest $\lfloor h/2 \rfloor$-hop paths of the graph.

▶ **Observation 14.** *Consider the collection of sets*

$$\mathcal{S} = \{V(\pi^{\lfloor h/2 \rfloor}(u, v)) \mid u, v \in V \text{ with } d^{\lfloor h/2 \rfloor}_G(u, v) < \infty \text{ and } |E(\pi^{\lfloor h/2 \rfloor}(u, v))| = \lfloor h/2 \rfloor\}$$

containing the vertices of the lexicographically smallest shortest $\lfloor h/2 \rfloor$-hop paths with exactly $\lfloor h/2 \rfloor$ edges between all pairs of vertices. Then, with high probability, C is a hitting set of $\mathcal{S}$ of size at most $9cnh^{-1} \ln n$.

▶ **Lemma 15.** *If G contains no negative cycle, then $\delta(t) = d_G(s, t)$ for every vertex $t \in V$ with high probability.*

Proof. First note that the algorithm incorrectly terminates in Step 2 only with small probability. We now need to show that, for every vertex $t \in V$, $\delta(t) := \min_{x \in C \cup \{s\}}(d_H(s, x) + d^h_G(x, t)) = d_G(s, t)$. First observe that every edge in H corresponds to a path in G (of the same weight). Thus, the value $\delta(t)$ corresponds to some path in G from s to t (of the same weight) which implies that $d_G(s, t) \leq \delta(t)$ (as no path can have weight less than the distance).

Now let $\pi(s, t)$ be the lexicographically smallest shortest path from s to t in G. Subdivide π into consecutive subpaths $\pi_1, \ldots, \pi_k$ such that π_i for $1 \leq i \leq k-1$ has exactly $\lfloor h/2 \rfloor$ edges, and π_k has at most $\lfloor h/2 \rfloor$ edges. Note that if π itself has at most $\lfloor h/2 \rfloor$ edges, then $k = 1$. Since every subpath of a lexicographically smallest shortest path is also a lexicographically smallest shortest path, the paths $\pi_1, \ldots, \pi_k$ are lexicographically smallest shortest paths as well. As the subpaths $\pi_1, \ldots, \pi_{k-1}$ consist of exactly $\lfloor h/2 \rfloor$ edges, each of them is contained in the collection of sets $\mathcal{S}$ of Observation 14. Therefore, each subpath π_i, for $1 \leq i \leq k-1$, contains a vertex $x_i \in C$ with high probability.

Set $x_0 = s$ and $x_k = t$, and observe that for every $0 \leq i \leq k-1$, the subpath of $\pi(s,t)$ from x_i to x_{i+1} is a shortest path from x_i to x_{i+1} with at most h edges and thus $d^h_G(x_i, x_{i+1}) = d_G(x_i, x_{i+1})$. We now get the following chain of inequalities:

$$\begin{aligned} d_G(s,t) = \sum_{0\leq i\leq k-1} d_G(x_i,x_{i+1}) &= \sum_{0\leq i\leq k-1} d^h_G(x_i,x_{i+1}) \\ &= \Big(\sum_{0\leq i\leq k-2} w_H(x_i,x_{i+1})\Big) + d^h_G(x_{k-1},t) \\ &\geq d_H(x_0,x_{k-1}) + d^h_G(x_{k-1},t) \\ &= d_H(s,x_{k-1}) + d^h_G(x_{k-1},t) \\ &\geq \min_{x\in C\cup\{s\}} (d_H(s,x) + d^h_G(x,t)) = \delta(t)\,. \end{aligned}$$

◀

Note that we have formally argued only that the algorithm correctly computes the *distances* from s. It can easily be checked that the shortest paths can be obtained by replacing the edges of H with their corresponding paths in G.

3.1.2 Running Time

▶ **Lemma 16.** *The algorithm above can be implemented with $O(mn\log n + n^3h^{-3}\log^4 n)$ and $O(h+\log n)$ depth such that all its comparisons are performed on sums of edge weights on both sides.*

Proof. Clearly, in Steps 1–2, the algorithm spends $O(m+n)$ work with $O(1)$ depth. Step 3 can be carried out by running h iterations of Bellman-Ford for every vertex $x \in C$ in parallel (see Lemma 8), thus spending $O(|C|\cdot mh)$ work with $O(h)$ depth. Step 4 can be carried out by spending $O(|C|^2)$ work with $O(1)$ depth. Step 5 can be carried out by running the min-plus matrix multiplication based APSP algorithm (see Lemma 6), thus spending $O(|C|^3\log n)$ work with $O(\log n)$ depth. The naive implementation of Step 6 spends $O(n|C|)$ work with $O(|C|)$ depth. Using a bottom-up 'tournament' approach where in each round we pair up all values and let the maximum value of each pair proceed to the next round, this can be improved to work $O(n|C|)$ and depth $O(\log n)$.

It follows that by carrying out the steps of the algorithm sequentially as explained above, the overall work is $O(|C|\cdot mh + |C|^3\log n)$ and the depth is $O(h+\log n)$. As the algorithm ensures that $|C| \leq 9cnh^{-1}\ln n$ for some constant c, the work is $O(mn\log n + n^3h^{-3}\log^4 n)$ and the depth is $O(h+\log n)$. ◀

3.1.3 Extension to Negative Cycle Detection

To check whether a weighted graph $G = (V,E,w)$ contains a negative cycle, we first construct the graph G' (with an additional super-source s') as defined in Lemma 5. We then run the SSSP algorithm of Theorem 13 from s' in G' and set $p(v) = d_{G'}(s',t)$ for every vertex $t \in V$. We then check whether the function p defined in this way is a valid potential function for G testing for every edge $e = (u,v)$ (in parallel) whether $p(u) + w(u,v) \geq p(v)$. If this is the case, then we output that G contains no negative cycle, otherwise we output that G contains a negative cycle.

▶ **Corollary 17.** *There is a randomized algorithm that checks whether a given weighted directed graph contains a negative cycle with $O(mn\log n + n^3h^{-3}\log^4 n)$ work and $O(h+\log n)$ depth for any $1 \leq h \leq n$. The algorithm is correct with high probability and all its comparisons are performed on sums of edge weights on both sides.*

Proof. Constructing the graph G' and checking whether p is a valid potential can both be carried out with $O(m+n)$ work and $O(1)$ depth. Thus, the overall work and depth bounds are asymptotically equal to the SSSP algorithm of Theorem 13.

If G contains no negative cycle, then the SSSP algorithm correctly computes the distances from s' in G'. Thus, the potential p is valid by Lemma 5 and our algorithm correctly outputs that there is no negative cycle. If G contains a negative cycle, then it does not have any valid potential by Lemma 4. Thus, the potential p defined by the algorithm cannot be valid and the algorithm outputs correctly that G contains a negative cycle. ◀

3.2 Finding the Minimum Ratio Cycle

Using the negative cycle detection algorithm as a subroutine, we obtain an algorithm for computing a minimum ratio cycle in time $\tilde{O}(n^{3/2}m^{3/4})$.

▶ **Theorem 18.** *There is a randomized one-sided-error Monte Carlo algorithm for computing a minimum ratio cycle with running time* $O(n^{3/2}m^{3/4}\log^2 n)$.

Proof. By Lemma 2 we can compute the value of the minimum ratio cycle by finding the largest value of λ such that G_λ contains no negative-weight cycle. We want to apply Theorem 1 to find this maximum λ^* by parametric search. As the sequential negative cycle detection algorithm A_s we use Orlin's minimum weight cycle algorithm [46] with running time $T(n,m) = O(mn)$. The parallel negative cycle detection algorithm A_p of Corollary 17 has work $W(n,m) = O(mn\log n + n^3h^{-3}\log^4 n)$ and depth $D(n,m) = O(h+\log n)$, for any choice of $1 \le h \le n$. Any comparison the latter algorithm performs is comparing sums of edge weights of the graph. Since in G_λ edge weights are linear functions in λ, the control flow only depends on testing the sign of degree-1 polynomials in λ. Thus, Theorem 1 is applicable[7] and we arrive at a sequential algorithm for finding the value of the minimum ratio cycle with running time $O(mn\log n(h+\log n) + n^3h^{-3}\log^4 n)$. Finally, to output the minimum ratio cycle and not just its value, we run Orlin's algorithm for finding the minimum weight cycle in G_{λ^*}, which takes time $O(mn)$. By setting $h = n^{1/2}m^{-1/4}\log n$ the overall running time becomes $O(n^{3/2}m^{3/4}\log^2 n)$. ◀

4 Deterministic Algorithm for General Graphs

We now present a deterministic variant of our minimum ratio cycle algorithm, with the same running time as the randomized algorithm up to logarithmic factors.

4.1 Deterministic SSSP and Negative Cycle Detection

We can derandomize our SSSP algorithm by combining a preprocessing step with the parallel hitting set approximation algorithm of [4]. Formally, we will prove the following statement.

▶ **Theorem 19.** *There is a deterministic algorithm that, given a weighted directed graph containing no negative cycles, computes the shortest paths from a designated source vertex s to all other vertices spending* $O(mn\log^2 n + n^3h^{-3}\log^7 n + n^2h\log^{11} n)$ *work with* $O(h+\log^{11} n)$ *depth for any* $1 \le h \le n$.

[7] Formally, Theorem 1 only applies to deterministic algorithms. However, only step 1 of our parallel algorithm is randomized, but this step does not depend on λ. All remaining steps are deterministic. We can thus first perform steps 1 and 2, and invoke Theorem 1 only on the remaining algorithm. The output guarantee then holds with high probability.

From this, using Lemmas 4 and 5 analogously to the proof of Corollary 17, we get the following corollary for negative cycle detection.

▶ **Corollary 20.** *There is a deterministic algorithm that checks whether a given weighted directed graph contains a negative cycle with* $O(mn\log^2 n + n^3h^{-3}\log^7 n + n^2h\log^{11} n)$ *work and* $O(h+\log^{11} n)$ *depth for any* $1 \leq h \leq n$.

Our deterministic SSSP algorithm does the following:

1. For all pairs of vertices $u, v \in V$, compute the shortest $\lfloor h/2 \rfloor$-hop path $\pi^{\lfloor h/2 \rfloor}(u,v)$ from u to v in G.[8]
2. Compute an $O(\log n)$-approximate set cover C of the system of sets $\mathcal{S} = \{V(\pi^{\lfloor h/2 \rfloor}(u,v)) \mid u, v \in V \text{ with } d_G^{\lfloor h/2 \rfloor}(u,v) < \infty \text{ and } |E(\pi^{\lfloor h/2 \rfloor}(u,v))| = \lfloor h/2 \rfloor\}$.
3. Proceed with steps 3 to 6 of the algorithm in Section 3.1.

4.1.1 Correctness

Correctness is immediate: In the previous proof of Lemma 15 we relied on the fact that C is a hitting set of $\mathcal{S}$. In the above algorithm, this property is guaranteed directly.

4.1.2 Running Time

Step 1 can be carried out by running h iterations of the Bellman-Ford algorithm for every vertex $v \in V$. By Lemma 8 this uses $O(mnh)$ work and $O(h)$ depth. We carry out Step 2 by running the algorithm of Theorem 12 to compute an $O(\log n)$-approximate hitting set of $\mathcal{S}$ with work $O(n^2h\log^{11} n)$ and depth $O(\log^{11} n)$. Lemma 10 gives a randomized process that computes a hitting set of $\mathcal{S}$ of expected size $O(nh^{-1}\log n)$. By the probabilistic method, this implies that there exists a hitting set of size $O(nh^{-1}\log n)$. We can therefore use the algorithm of Theorem 12 to compute a hitting set $\mathcal{S}$ of size $O(nh^{-1}\log^2 n)$. The work is $O(n^2h\log^{11} n)$ and the depth is $O(\log^{11} n)$. Carrying out the remaining steps with a hitting set C of size $O(nh^{-1}\log^2 n)$ uses work $O(mh|C| + |C|^3\log n) = O(mn\log^2 n + n^3h^{-3}\log^7 n)$ and depth $O(h+\log n)$. Thus, our overall SSSP algorithm has work $O(mn\log^2 n + n^3h^{-3}\log^7 n + n^2h\log^{11} n)$ and depth $O(h+\log^{11} n)$.

4.2 Minimum Ratio Cycle

We again obtain a minimum ratio cycle algorithm by applying parametric search (Theorem 1). We obtain the same running time bound as for the randomized algorithm.

▶ **Theorem 21.** *There is a deterministic algorithm for computing a minimum ratio cycle with running time* $O(n^{3/2}m^{3/4}\log^2 n)$.

Proof sketch. The proof is analogous to the proof of Theorem 18, with the only exception that we use the deterministic parallel negative cycle detection algorithm of Corollary 20. However, we do not necessarily need to run the algorithm of Theorem 12 to compute an approximate hitting set. Instead we can also run the greedy set cover heuristic (Lemma 11) for this purpose. The reason is that at this stage, the greedy heuristic does not need to perform any comparisons involving the edge weights of the input graph, which are the only operations that are costly in the parametric search technique. This means that finding an approximate hitting

[8] Note that in case there are multiple shortest $\lfloor h/2 \rfloor$-hop paths from u to v, any tie-breaking is fine for the algorithm and its analysis.

set C of size $O(nh^{-1}\log n)$ can be implemented with $O(\sum_{S\in\mathcal{S}}|S|) = O(n^2h)$ work and $O(1)$ comparison depth. Thus, we use a parallel negative cycle detection algorithm A_{p} which has work $W(n,m) = O(mh|C| + |C|^3\log n + n^2h) = O(mn\log n + n^3h^{-3}\log^4 n + n^2h)$ and depth $D(n,m) = O(h+\log n)$, for any choice of $1 \le h \le n$. We thus obtain a sequential minimum ratio cycle algorithm with running time $O(mn\log n + n^3h^{-3}\log^4 n + n^2h + mn\log n(h+\log n))$, for any choice of $1 \le h \le n$. Note that the summands $mn\log n$ and n^2h are both dominated by the last summand $mn\log n(h+\log n)$. Setting $h = n^{1/2}m^{-1/4}\log n$ to optimize the remaining summands, the running time becomes $O(n^{3/2}m^{3/4}\log^2 n)$. ◀

5 Near-Linear Time Algorithm for Constant Treewidth Graphs

In the following we demonstrate how to obtain a nearly-linear time algorithm (in the strongly polynomial sense) for graphs of constant treewidth. We can use the following results of Chaudhuri and Zaroliagis [17] who studied the shortest paths problem in graphs of constant treewidth.[9]

▶ **Theorem 22** ([17]). *There is a deterministic algorithm that, given a weighted directed graph containing no negative cycles, computes a data structure that after $O(n)$ preprocessing time can answer, for any pair of vertices, distance queries in time $O(\alpha(n))$, where $\alpha(\cdot)$ is the inverse Ackermann function. It can also report a corresponding shortest path in time $O(\ell\alpha(n))$, where ℓ is the number of edges of the reported path.*

▶ **Theorem 23** ([16]). *There is a deterministic negative cycle algorithm for weighted directed graphs of constant treewidth with $O(n)$ work and $O(\log^2 n)$ depth.*

We now apply the reduction of Theorem 1 to the algorithm of Theorem 23 to find λ^*, the value of the minimum ratio cycle, in time $O(n\log^3 n)$ (using $T_{\mathrm{s}}(n) = W_{\mathrm{p}}(n) = O(n)$, and $D_{\mathrm{p}}(n) = O(\log^2 n)$). We then use the algorithm of Theorem 22 to find a minimum weight cycle in G_{λ^*} in time $O(n\alpha(n))$: Each edge $e = (u,v)$ together with the shortest path from v to u (if it exists) defines a cycle and we need to find the one of minimum weight by asking the corresponding distance queries. For the edge $e = (u,v)$ defining the minimum weight cycle we query for the corresponding shortest path from v to u. This takes time $O(n)$ as a graph of constant treewidth has $O(n)$ edges. We thus arrive at the following guarantees of the overall algorithm.

▶ **Corollary 24.** *There is a deterministic algorithm that computes the minimum ratio cycle in a directed graph of constant treewidth in time $O(n\log^3 n)$.*

6 Conclusion

We have presented a faster strongly polynomial algorithm for finding a cycle of minimum cost-to-time ratio, a problem which has a long history in combinatorial optimization and recently became relevant in the context of quantitative verification. Our approach combines parametric search with new parallelizable single-source shortest path algorithms and also yields small improvements for graphs of constant treewidth and in the dense regime. The main open problem is to push the running time down to $\tilde{O}(mn)$, nearly matching the strongly polynomial upper bound for the less general problem of finding a minimum mean cycle.

[9] The first result of Chaudhuri and Zaroliagis [17] has recently been complemented with a space-time trade-off by Chatterjee, Ibsen-Jensen, and Pavlogiannis [15] at the cost of polynomial preprocessing time that is too large for our purposes.

Abstract

We revisit fundamental problems in undirected and directed graphs, such as the problems of computing spanning trees, shortest paths, steiner trees, and spanning arborescences of minimum cost. We assume that there are d different cost functions associated with the edges of the input graph and seek for solutions to the resulting multidimensional graph problems so that the p-norm of the different costs of the solution is minimized. We present combinatorial algorithms that achieve very good approximations for this objective. The main advantage of our algorithms is their simplicity: they are as simple as classical combinatorial graph algorithms of Dijkstra and Kruskal, or the greedy algorithm for matroids.

1 Introduction

We study generalizations of some very well-known combinatorial optimization problems, such as the problem of computing a minimum spanning tree in a graph. In its classical version, we are given an undirected graph with edge costs and the objective is to compute a spanning tree of minimum cost on the graph. We revisit fundamental problems of this kind by assuming that there are d different cost functions associated with the edges of the input graph. Then, a spanning tree has d different cost values, one for each cost function. Our objective is to compute a spanning tree that minimizes a specific aggregate value of these costs.

At first glance, this is the type of multi-objective (or multi-criteria) optimization problems that arise in many diverse disciplines, including engineering, economics and business, healthcare, and more. Here, our motivation stems from the recently emerging trend of *participatory budgeting* [1]. According to it, optimization problems related to the use of budget for building public facilities are solved taking into account the view the citizens have for the input. In the example above, each of the d different cost functions can be thought of as provided by a single individual. Consistent to this, we will assume that the parameter d is large.

We use the general term *minimum multidimensional resource selection* (MMRS) to refer to the class of problems that we study. In addition to parameter d, an instance of such a problem consists of a set R of resources, a d-dimensional cost vector $\boldsymbol{c}_r$ for each resource $r \in R$, the set of feasible solutions $\mathcal{F}$ (subsets of resources) and an additional parameter $p \geq 1$. The objective of MMRS is to select a feasible solution S so that the quantity $\| \sum_{r \in S} \boldsymbol{c}_r \|_p$ is minimized. Note that the sum inside the norm is d-dimensional and its entries represent the cost of S with respect to the d cost functions. Then, the p-norm is used for aggregating these entries into a single value.

Even though the problem has not been considered before in the general version we just defined it, efficient solutions to some of its variants follow by recent advances on randomized rounding of fractional solutions for linear program relaxations. In contrast to such sophisticated techniques, we insist on deterministic algorithms that are extremely simple. More concretely, we consider the following problems:

- We warm up with MMRS in *matroids*, in which the feasible solutions that form set $\mathcal{F}$ are the bases of a matroid defined over the resources. A typical subproblem is when the resources are the edges of a graph and the feasible solutions correspond to spanning trees of the graph. For MMRS on matroids, we present a variation of the greedy algorithm on matroids (e.g., see [18]) and show that it yields $\mathcal{O}(\min\{p, \log d\})$-approximate solutions.
- *Shortest multidimensional path* (SMP). Again, the resources correspond to edges of a graph and the feasible solutions are subsets of edges that connect two designated nodes. An approximation guarantee of $\mathcal{O}(\min\{p, \log d\})$ is obtained by a Dijkstra-like algorithm.
- *Minimum multidimensional steiner tree* (MMST). Unlike the spanning tree version mentioned above, in MMST the feasible solutions are not matroid bases. Furthermore, the classical trick in the single dimensional case (see, e.g., [19]) of approximating the minimum steiner tree by a minimum spanning tree does not carry over when we have different costs (the cost functions do not necessarily form a metric). Still, we have a Kruskal-like algorithm that uses our shortest multidimensional path algorithm as subroutine and achieves (asymptotically) the same approximation guarantee.
- *Minimum multidimensional arborescence* (MMA). Here, the resources are the edges of a directed graph and the feasible solutions are spanning trees, directed away from a designated root node. We present another simple algorithm that uses our shortest multidimensional path algorithm as a subroutine and prove it to be $\mathcal{O}(\min\{p, \log d\} \cdot \log n)$-approximate, where n is the graph size.

We complement these results with an inapproximability statement. For $p = \infty$, none of the above problems admit a polynomial-time constant approximation algorithm, under standard complexity assumptions. Here we exploit a gap-preserving reduction from the vector scheduling problem which has been proved to be inpproximable in [7].

Our analysis is inspired by the literature on online scheduling and in particular from [2, 5] where the objective is to minimize the p-norm of machine loads. En route, we exploit a nice structural property that is satisfied by feasible solutions of the problems that we study, and implies that greedy solutions for them are efficient.

Related work. The field of multi-objective optimization has traditionally considered similar problems to ours, with approximation algorithms playing a major role. It seems though that the questions considered there are mostly related to approximating the Pareto-curve (i.e., the set of solutions which are not dominated by any other). For instance, Diakonikolas et al. [11] (see also the references therein) study the problem of computing a minimum set of solutions that approximates within a specified accuracy, $\epsilon > 0$, the Pareto curve of bi-objective optimization problems, containing many important widely studied problems such as shortest paths, spanning tree, matching, etc. We notice that these questions are fundamentally different than the ones we study here. Also, they turn out to be computationally meaningful only on instances in which d is a small constant (since otherwise the problem becomes notoriously hard due to fact that the Pareto-curve becomes huge [16]). Instead, we are interested in many different cost functions.

Chekuri et al. [8] (see also [9]) study the problem of solving (or, better, approximating the optimal solution of) *minimax integer programs* subject to a matroid constraint; this is essentially what we call MMRS on matroids with a value of infinity for parameter p. Chekuri et al. [8] present a $\mathcal{O}(\log d/\log\log d)$-approximation algorithm for this problem that exploits sophisticated randomized rounding techniques. We remark that our bound is slightly higher than theirs but the advantage of our result is in the simplicity of the algorithm. A special case is covered in [4], where the computation of a spanning tree minimizing the maximum number of times its edges cross a given set of cuts is considered.

Other investigations related to our setting are the multi-budgeted optimization problems. There are d different cost functions defined over the set of resources. In addition, there are d budget values that constrain each of the d costs of a solution. The objective is to compute a feasible solution whose budget violation factor is as small as possible across all cost dimensions. These problems have been tackled using sophisticated approaches such as Lagrangian relaxations combined with various technical properties of the underlying combinatorial structure, and linear programming together with iterative rounding techniques. Such approaches were used to develop PTASes for spanning trees [14, 17], shortest paths [13, 15], and matchings and matroid intersection [3] with $d = 2$. Grandoni et al. [12] consider d-budgeted versions of classical problems. They show PTASes for spanning trees, matroid bases, and bipartite matchings. Moreover they get a deterministic approximation scheme for d-budgeted matchings in general graphs. We emphasize that the authors of [12] use linear programming formulations and iterative rounding techniques that work for constant values of d only. Finally, Chekuri et al. [10] give a randomized PTAS for matroid intersection and matchings with any fixed number of budget constraints.

Roadmap. We begin with some necessary mathematical background in Section 2. Our main lemma is presented in Section 3. Then, Sections 4-7 are devoted to the each of the four problems mentioned above. We conclude with our inapproximability result in Section 8.

2 Mathematical Background

We summarize definitions and simple properties of p-norms and matroids. For an integer $d \geq 1$, define $[d] = \{1, 2, \ldots, d\}$ and $\mathbf{0}^d$ as the vector $(0, \ldots, 0)^T \in \mathbb{R}^d$. We denote by $\overline{\mathbb{R}} = \mathbb{R}_{\geq 1} \cup \{\infty\}$ the set of reals that are higher than 1, extended with the value ∞.

We later exploit the following two properties of the function $f(x) = x^t$ for every $t \geq 1$.

▶ **Lemma 1.** *For every $x, y, h \geq 0$ with $y \geq x$ and $t \geq 1$, $(x + h)^t - x^t \leq (y + h)^t - y^t$.*

▶ **Lemma 2.** *Given $x \geq 0$, $t \geq 1$, and n non-negative real values $h_1, \ldots, h_n$,*

$$\sum_{i\in[n]} \left((x+h_i)^t - x^t\right) \leq \left(x + \sum_{i\in[n]} h_i\right)^t - x^t.$$

The first property comes by observing that $(x+h)^t - x^t$ has non-negative derivative with respect to x when $t \geq 1$, while the second one is due to convexity of the monomial x^t (see [6] for a proof).

For a vector $\boldsymbol{x} = (x_1, \ldots, x_d) \in \mathbb{R}^d$ and $p \in \overline{\mathbb{R}}$, the value $\|\boldsymbol{x}\|_p = \left(\sum_{i\in[d]} x_i^p\right)^{1/p}$ is called the *p-norm* of $\boldsymbol{x}$. We recall two fundamental properties possessed by p-norms.

▶ Property 3. For every $\boldsymbol{x} \in \mathbb{R}^d$ and $p, p' \in \overline{\mathbb{R}}$ such that $p' \leq p$, $\|\boldsymbol{x}\|_p \leq \|\boldsymbol{x}\|_{p'}$.

▶ Property 4 (Minkowsi's Inequality). For every $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^d$ and $p \in \overline{\mathbb{R}}$, $\|\boldsymbol{x}+\boldsymbol{y}\|_p \leq \|\boldsymbol{x}\|_p + \|\boldsymbol{y}\|_p$.

The next lemma shows how to use the logarithmic norm to approximate all other p-norms; its proof follows easily by the definitions.

▶ **Lemma 5.** *For every $\boldsymbol{x} \in \mathbb{R}^d$ and $p \in \overline{\mathbb{R}}$, $\|\boldsymbol{x}\|_{\ln d} \leq e\|\boldsymbol{x}\|_p$.*

A *matroid* is a pair $M = (R, \mathcal{X})$ such that R is a finite set, called the *ground set*, and $\mathcal{X}$ is a family of subsets of R with the following properties:

1. $\emptyset \in \mathcal{X}$,
2. if $X \in \mathcal{X}$ and $Y \subset X$, then $Y \in \mathcal{X}$ (*hereditary property*),
3. if $X, Y \in \mathcal{X}$ and $|X| > |Y|$, then there exists $x \in X \setminus Y$ such that $Y \cup \{x\} \in \mathcal{X}$ (*independent set exchange property*).

A *basis* for matroid M is a set $B \in \mathcal{X}$ such that $B \cup \{x\} \notin \mathcal{X}$ for every $x \in R \setminus B$. The independent set exchange property implies that all bases of M have the same cardinality which is called the *rank* of M and is denoted by $r(M)$.

For every two bases $B_1, B_2 \in \mathcal{X}$, denote by $G(B_1 \Delta B_2)$ the bipartite graph (V, E) such that $V = (B_1 \setminus B_2) \cup (B_2 \setminus B_1)$ and $E = \{\{e_1, e_2\} : e_1 \in B_1 \setminus B_2, e_2 \in B_2 \setminus B_1, B_1 \setminus \{e_1\} \cup \{e_2\} \in \mathcal{X}\}$. We shall make extensive use of the following fundamental result (see [18]).

▶ Proposition 6. There exists a perfect matching in the graph $G(B_1 \Delta B_2)$.

Given an undirected graph $G = (V, E)$, let $\mathcal{X}$ be the family of all subsets of E which do not contain cycles. The pair $M = (E, \mathcal{X})$ is a matroid and is called the *graphic matroid* defined over G. The set of bases for M is the set of all spanning trees for G, so that $r(M) = |V| - 1$.

3 Problem Statement and the PAID Property

The minimum multidimensional resource selection (MMRS) problem is a collection of instances of the form $I = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}, p)$, where R is a set of resources such that each resource $r \in R$ has an associated d-dimensional cost vector $\boldsymbol{c}_r \in \mathbb{R}^d_+$, $\mathcal{F} \subseteq 2^R \setminus \emptyset$ is a set of feasible solutions, and $p \in \overline{\mathbb{R}}$. For a subset of resources $S \subseteq R$, define its multidimensional load as $\boldsymbol{\ell}(S) = \sum_{r\in S} \boldsymbol{c}_r$ and denote by $\ell_i(S)$ its ith element. An optimal solution for I is any solution belonging to $\operatorname{argmin}_{S\in\mathcal{F}} \left\{\|\boldsymbol{\ell}(S)\|_p\right\}$, that is, any feasible solution minimizing the p-norm of its multidimensional load. Denote by $\mathsf{OPT}(I) = \|\boldsymbol{\ell}(S^*)\|_p$, where $S^* \in \operatorname{argmin}_{S\in\mathcal{F}} \left\{\|\boldsymbol{\ell}(S)\|_p\right\}$, the p-norm of the multidimensional load of an optimal solution for I.

We shall denote by $\mathsf{MMRS}(p)$ the natural restriction of the MMRS obtained by fixing the value of p. When referring to an instance $I \in \mathsf{MMRS}(p)$, we remove the value of p from the description of I and simply write $I = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F})$.

Given a set X and an integer $k \geq 1$, a *partial k-decomposition* of X is an ordered family of k sets $(X_1, \ldots, X_k)$ such that $\bigcup_{i\in[k]} X_i \subseteq X$. A *$\beta$-intersecting partial k-decomposition* of X is a partial k-decomposition of X $(X_1, \ldots, X_k)$ such that $|\{i \in [k] : x \in X_i\}| \leq \beta$ for every $x \in X$, that is, no element of X occurs in more than β components of the decomposition. A k-decomposition of X is a partial *k-decomposition* of X $(X_1, \ldots, X_k)$ such that $\bigcup_{i\in[k]} X_i = X$. A *$k$-partition* of X is a 1-intersecting k-decomposition of X.

▶ **Definition 7.** Fix an instance $I \in \mathsf{MMRS}(p)$. A feasible solution S for I has the *pairwise β-intersecting decomposition* property (henceforth, β-PAID property) if there exist a k-decomposition of S $(S_1, \ldots, S_k)$ and a β-intersecting partial k-decomposition of an optimal solution S^* for I $(S_1^*, \ldots, S_k^*)$ such that, for every $i \in [k]$,

$$\|\boldsymbol{\ell}(S_{\leq i})\|_p \leq \|\boldsymbol{\ell}(S_{\leq i-1}) + \boldsymbol{\ell}(S_i^*)\|_p\,, \tag{1}$$

where $S_{\leq i} = \bigcup_{j\in[i]} S_j$ and $S_{\leq 0} = \emptyset$.

The importance of the PAID property is captured by the following result.

▶ **Lemma 8.** *Fix an instance $I \in \mathsf{MMRS}(p)$. If a feasible solution S for I possesses the β-PAID property, then $\|\boldsymbol{\ell}(S)\|_p \leq \frac{\beta p}{\ln 2}\mathsf{OPT}(I)$.*

Proof. We get

$$\begin{aligned}
\left(\|\boldsymbol{\ell}(S)\|_p\right)^p &= \sum_{j\in[d]} \ell_j(S)^p = \sum_{i\in[k]} \left(\sum_{j\in[d]} \ell_j(S_{\leq i})^p - \sum_{j\in[d]} \ell_j(S_{\leq i-1})^p\right)\\
&\leq \sum_{i\in[k]} \left(\sum_{j\in[d]} \left(\ell_j(S_{\leq i-1}) + \ell_j(S_i^*)\right)^p - \sum_{j\in[d]} \ell_j(S_{\leq i-1})^p\right)\\
&= \sum_{j\in[d]}\sum_{i\in[k]} \left(\left(\ell_j(S_{\leq i-1}) + \ell_j(S_i^*)\right)^p - \ell_j(S_{\leq i-1})^p\right)\\
&\leq \sum_{j\in[d]}\sum_{i\in[k]} \left(\left(\ell_j(S) + \ell_j(S_i^*)\right)^p - \ell_j(S)^p\right)\\
&\leq \sum_{j\in[d]} \left(\left(\ell_j(S) + \sum_{i\in[k]} \ell_j(S_i^*)\right)^p - \ell_j(S)^p\right)\\
&\leq \sum_{j\in[d]} \left(\left(\ell_j(S) + \beta\ell_j(S^*)\right)^p - \ell_j(S)^p\right)\\
&= \sum_{j\in[d]} \left(\ell_j(S) + \beta\ell_j(S^*)\right)^p - \sum_{j\in[d]} \ell_j(S)^p\\
&\leq \left(\|\boldsymbol{\ell}(S)\|_p + \beta\|\boldsymbol{\ell}(S^*)\|_p\right)^p - \left(\|\boldsymbol{\ell}(S)\|_p\right)^p.
\end{aligned}$$

The first inequality follows by raising both sides of inequality (1) to p. The second and third inequalities follow from Lemmas 1 and 2, respectively. The fourth inequality holds since $(S_1^*, \ldots, S_k^*)$ is a β-intersecting partial k-decomposition of S^*. The fifth inequality follows by Minkowski's inequality (by raising both of its sides to p).

By rearranging, we obtain $\left(2^{1/p} - 1\right)\|\boldsymbol{\ell}(S)\|_p \leq \beta\|\boldsymbol{\ell}(S^*)\|_p$, which implies

$$\|\boldsymbol{\ell}(S)\|_p \leq \frac{\beta\|\boldsymbol{\ell}(S^*)\|_p}{2^{1/p} - 1} = \frac{\beta\|\boldsymbol{\ell}(S^*)\|_p}{e^{\ln 2/p} - 1} \leq \frac{\beta p}{\ln 2}\|\boldsymbol{\ell}(S^*)\|_p,$$

Algorithm 1 $(M, d, (\boldsymbol{c}_r)_{r\in R}, p)$

$S_0 \leftarrow \emptyset$
$i \leftarrow 0$
while $S_{\leq i}$ is not a basis for M **do**
  $i \leftarrow i + 1$
  $C_i \leftarrow \{x \in R : S_{\leq i-1} \cup \{x\} \in \mathcal{X}\}$
  $S_i \leftarrow \operatorname{argmin}_{x\in C_i} \|\boldsymbol{\ell}(S_{\leq i-1} \cup \{x\})\|_p$
end while
$S \leftarrow S_{\leq i}$
return S

where the last inequality comes from the fact that $e^x \geq x + 1$ for every $x \geq 0$. Since S^* is an optimal solution for I, the claim follows. ◀

By exploiting Lemma 5, we get the following approximability result; the proof is omitted due to lack of space.

▶ **Lemma 9.** *Let S be an α-approximate solution to an instance $I = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}) \in$ MMRS$(\ln d)$. Then, S is an $O(\alpha)$-approximate solution to the instance $\overline{I} = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}) \in$ MMRS(p) with $p \geq \ln d$.*

By putting all together, we get the following general approximation theorem.

▶ **Theorem 10.** *Let A be an algorithm which, for every instance $I \in$ MMRS, computes a feasible solution for I possessing the β-PAID property. Then, A approximates* MMRS *within a factor of $O(\beta \cdot \min\{p, \log d\})$.*

Proof. Fix an instance $I = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}, p) \in$ MMRS. We can use algorithm A to obtain a feasible solution S for I possessing the β-PAID property. By Lemma 8, S is an $O(p\beta)$-approximate solution for I. Moreover, we can use algorithm A to obtain a feasible solution S for the instance $I' = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}, \ln d)$ possessing the β-PAID property. By Lemma 8, S is an $O(\beta \log d)$-approximate solution for I' so that, by Lemma 9, S is also an $O(\beta \log d)$-approximate solution for I. ◀

4 MMRS on Matroids

As a warmup application of our technique, we first consider instances $(R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}, p) \in$ MMRS such that $\mathcal{F}$ is the set of bases of a matroid $M = (R, \mathcal{X})$. We propose a simple greedy algorithm (Algorithm 1) to approximate MMRS in this case.

The following lemma characterizes the approximation guarantee achieved by Algorithm 1.

▶ **Lemma 11.** *Fix an instance $I = (R, d, (\boldsymbol{c}_r)_{r\in R}, \mathcal{F}, p) \in$ MMRS such that $\mathcal{F}$ is the set of bases of a matroid $M = (R, \mathcal{X})$. Algorithm 1 returns a feasible solution for I possessing the* 1-PAID *property.*

Proof. The fact that Algorithm 1 terminates by returning a feasible solution $S \in \mathcal{F}$ (i.e., a basis for M) follows from the classical analysis of the greedy algorithm for matroids. Set $k = r(M)$ and let S^* be an optimal solution to I. Define $R(S, S^*) = S \cap S^*$ and consider graph $G(S \Delta S^*)$. By Proposition 6, there exists a bijective function $f : S \setminus R(S, S^*) \to S^* \setminus R(S, S^*)$.

Note that Algorithm 1 implicitly defines a k-partition $(S_1, \ldots, S_k)$ of S. Now define the k-partition $(S_1^*, \ldots, S_k^*)$ of S^* such that, for every $i \in [k]$,

$$S_i^* = \begin{cases} S_i & \text{if } S_i \in R(S, S^*), \\ f(S_i) & \text{if } S_i \notin R(S, S^*). \end{cases}$$

Fix an index $i \in [k]$. We claim that, at the ith iteration of the while-loop of Algorithm 1, $S_{\leq i-1} \cup \{S_i^*\} \in C_i$. In fact, if this is not the case, it must be $S_{\leq i-1} \cup \{S_i^*\} \notin \mathcal{X}$. However, by the definition of f, we have that $S \setminus \{S_i\} \cup \{S_i^*\} \in \mathcal{X}$ which, by the hereditary property of matroids, implies that $S_{\leq i-1} \cup \{S_i^*\} \in \mathcal{X}$: a contradiction. Now, given that $S_i^* \in C_i$, the greedy choice performed at line 6 of Algorithm 1 implies that $\|\boldsymbol{\ell}(S_{\leq i})\|_p \leq \|\boldsymbol{\ell}(S_{\leq i-1} \cup S_i^*)\|_p \leq \|\boldsymbol{\ell}(S_{\leq i-1}) + \boldsymbol{\ell}(S_i^*)\|_p$. ◀

By combining the above lemma with Theorem 10, we obtain the following result.

▶ **Theorem 12.** *Algorithm 1 approximates* MMRS *on matroids within a factor of* $O(\min\{p, \log d\})$.

5 Shortest Multidimensional Path

Given a directed graph $G = (V, E)$, in which every edge $e \in E$ is associated with a d-dimensional weight $\boldsymbol{c}_e \in \mathbb{R}_+^d$, a pair $(s, t) \in V^2$ of source-destination nodes, and value $p \in \overline{\mathbb{R}}$, the shortest multidimensional path (SMP) problem is the restriction of MMRS to instances with $R = E$ and $\mathcal{F} = \{S \subseteq E : S \text{ is an } (s,t)\text{-path in } G\}$.

For our purposes, we shall need to solve instances of the SMP when dealing with other MMRSs on graphs. For such a reason, we shall define an approximation algorithm for the SMP which requires more general input parameters than the ones needed to solve the SMP.

Towards this end, consider the multidimensional generalization of Dijkstra's algorithm, denoted as Algorithm 2, defined in the following. It takes as input the graph G, the integer d, the pair of nodes (s, t), the value p, and a set of edges E' which may contain either edges in E and edges not in E, and makes use of the data structures PATH and DISTANCE. Given a node $v \in V$, PATH is an array such that PATH$[v]$ contains a path connecting s to v, and DISTANCE is an array such that DISTANCE$[v]$ contains the value $\|\boldsymbol{\ell}(\text{PATH}[v] \cup E')\|_p$.

The following lemma characterizes the approximation guarantee achieved by Algorithm 2.

▶ **Lemma 13.** *Fix an instance $I = (G, d, s, t, p) \in$ SMP. Then, Algorithm 2, executed with parameters G, d, s, t, p and $\emptyset$, returns a feasible solution for I possessing the* 1-PAID *property.*

Proof. The fact that, when executed with parameters G, d, s, t, p and $\emptyset$, Algorithm 2 terminates by returning a set of edges $S = \text{PATH}[t]$ inducing an (s,t)-path in G follows from the classical analysis of Dijkstra's algorithm. Hence, we only need to show that S possesses the 1-PAID property.

Let S^* be an optimal solution to I. For a node v and a path P, let $pred_P(v)$ be the predecessor of node v along P. A node v is a *merging node* for S and S^* if (i) $v \in \{s, t\}$ or (ii) v occurs along both S and S^* and $pred_S(v) \neq pred_{S^*}(v)$. Denote by $M(S, S^*) = (s = v_0, v_1, \ldots, v_j = t)$ the sequence of merging nodes for S and S^* numbered according to the order in which they occur along S. A node $v_i \in M(S, S^*)$ is *redundant* if v_i occurs along S^* before some other merging node v_j with $j < i$. Denote by $\overline{M}(S, S^*) = (s = \overline{v}_0, \overline{v}_1, \ldots, \overline{v}_k = t)$ the sequence of nodes obtained from $M(S, S^*)$ by removing all the redundant ones (see Figure 1 for an illustrating example).

Algorithm 2 (G, d, s, t, p, E')

```
1: for each v ∈ V do
2:     PATH[v] ← ∅
3:     DISTANCE[v] ← +∞
4: end for
5: DISTANCE[s] ← ‖ℓ(E′)‖_p
6: Q ← V
7: while Q is not empty do
8:     v ← argmin_{u∈Q}{DISTANCE[u]}
9:     for each (v, u) ∈ E do
10:        if DISTANCE[u] > ‖ℓ(PATH[v] ∪ (v, u) ∪ E′)‖_p then
11:            PATH[u] ← PATH[v] ∪ (v, u)
12:            DISTANCE[u] ← ‖ℓ(PATH[v] ∪ (v, u) ∪ E′)‖_p
13:        end if
14:    end for
15:    Q ← Q \ {v}
16: end while
17: return PATH[t]
```

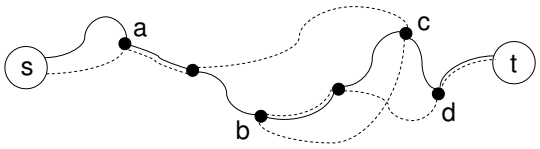

Figure 1 The definition of non-redundant merging nodes used in the proof of Lemma 13. The solid lines represent the (s,t)-path S returned by Algorithm 2, while the dashed ones represent the optimal solution S^* (solid and dashed lines are drawn adjacently when some set of edges are shared by S and S^*). We have $M(S,S^*) = \{s,a,b,c,d,t\}$ and $\overline{M}(S,S^*) = \{s,a,b,d,t\}$ since node c is redundant.

Let $(S_1,\ldots,S_k)$ and $(S_1^*,\ldots,S_k^*)$ be the k-partitions of S and $\overline{S}^*$, respectively, such that, for every $i \in [k]$, S_i (resp., S_i^*) is the set of edges connecting $\overline{v}_{i-1}$ to $\overline{v}_i$ in S (resp., S^*).

The well-known semantics of Dijkstra's algorithm guarantees that, for every $i \in [k]$, the set of edges S_i satisfies the inequality

$$\mathsf{DISTANCE}[\overline{v}_i] \leq \|\boldsymbol{\ell}(\mathsf{PATH}[\overline{v}_{i-1}] \cup S_i^*)\|_p,$$

where, by construction, $\mathsf{DISTANCE}[\overline{v}_i] = \|\boldsymbol{\ell}(S_{\leq i})\|_p$ and

$$\|\boldsymbol{\ell}(\mathsf{PATH}[\overline{v}_{i-1}] \cup S_i^*)\|_p = \|\boldsymbol{\ell}(S_{\leq i-1} \cup S_i^*)\|_p \leq \|\boldsymbol{\ell}(S_{\leq i-1}) + \boldsymbol{\ell}(S_i^*)\|_p .$$

Hence, the claim follows. ◀

By combining Lemma 13 with Theorem 10, we obtain the following result.

▶ **Theorem 14.** *Algorithm 2 approximates* SMP *within a factor of* $O(\min\{p, \log d\})$.

We conclude this section by showing a fundamental lemma that will allow us to use Algorithm 2 as a subroutine of approximation algorithms for other MMRSs defined on graphs.

▶ **Lemma 15.** *Given an instance $I \in$ MMRS, let $(S_1, \ldots, S_k)$ be a k-decomposition of a feasible solution S for I and $(S_1^*, \ldots, S_k^*)$ be a β-intersecting partial k-decomposition of an optimal solution S^* for I. If, for every $i \in [k]$, there exists an instance $I_i = (G_i, d, s_i, t_i, p) \in$ SMP such that S_i is an (s_i, t_i)-path in G_i computed by using Algorithm 2 executed with parameters G_i, d, s_i, t_i, p and $S_{\leq i-1}$, and S_i^* is an (s_i, t_i)-path in G_i, then S possesses the β-PAID property.*

Proof. The proof is a direct extension of the proof of Lemma 13. In fact, it suffices to exploit the decomposition technique used therein within the decompositions $(S_1, \ldots, S_k)$ and $(S_1^*, \ldots, S_k^*)$. Toward this end, denoting by $(S_{i,1}, \ldots, S_{i,h_i})$ and $(S_{i,1}^*, \ldots, S_{i,h_i}^*)$ the h_i-partitions of S_i and S_i^*, respectively, that are obtained as in the proof of Lemma 13 and setting $m = \sum_{\in[k]} h_i$, we have that

$$(S_{1,1}, \ldots, S_{1,h_1}, \ldots, S_{k,1}, \ldots, S_{k,h_k}) = (T_1, \ldots, T_m)$$

is an m-decomposition of S and that

$$(S_{1,1}^*, \ldots, S_{1,h_1}^*, \ldots, S_{k,1}^*, \ldots, S_{k,h_k}^*) = (T_1^*, \ldots, T_m^*)$$

is a β-intersecting partial m-decomposition of S^*. By the same arguments used in the proof of Lemma 13, we obtain that $\|\boldsymbol{\ell}(T_{\leq i})\|_p \leq \|\boldsymbol{\ell}(T_{\leq i-1} \cup T_i^*)\|_p \leq \|\boldsymbol{\ell}(T_{\leq i-1}) + \boldsymbol{\ell}(T_i^*)\|_p$ for each $i \in [m]$, thus proving the claim. ◀

6 Minimum Multidimensional Steiner Tree

Given an undirected graph $G = (V, E)$, in which every edge $e \in E$ is associated with a d-dimensional weight $\boldsymbol{c}_e \in \mathbb{R}_+^d$, a set of $r+1$ required nodes $N = \{v_1, \ldots, v_{r+1}\} \subseteq V$, and a value $p \in \overline{\mathbb{R}}$, the minimum multidimensional Steiner tree (MMST) problem is the restriction of MMRS to instances with $R = E$ and such that $\mathcal{F}$ is the set of all trees in G whose set of nodes contains N.

We propose Algorithm 3, a Kruskal-like algorithm which takes as input the graph G, the integer d, the set of required nodes N and the value p, and uses Algorithm 2 and the functions *set*, *merge* and *prune* as subroutines. Given a required node v and an h-partition $P = \{P_1, P_2, \ldots, P_h\}$ of N, function *set* returns the set $P_i \in P$ such that $v \in P_i$; given a partition $P = \{P_1, P_2, \ldots, P_h\}$ of N and two sets $P_i, P_j \in P$, function *merge* returns the partition of N obtained from P by merging P_i and P_j; finally, given a set of edges S, function *prune* returns a maximal set of edges $S' \subseteq S$ not inducing cycles in G.

The following lemma characterizes the approximation guarantee achieved by Algorithm 3.

▶ **Lemma 16.** *Fix an instance $I = (G, d, N, p) \in$ MMST. Then, Algorithm 3 returns a feasible solution for I possessing the* 2-PAID *property.*

Proof. By the well-known semantics of Kruskal's algorithm, we have that the while-loop at lines 4-12 of Algorithm 3 is executed exactly r times so that $S = (S_1, \ldots, S_r)$ induces a subgraph of G spanning N and $\overline{S} = prune(S)$ is a Steiner tree spanning N. This implies that the set of edges $\overline{S}$ returned by Algorithm 3 is a feasible solution for I. We shall prove that S possesses the 2-PAID property which, given that $\overline{S} \subset S$, implies the claim.

Let S^* be an optimal solution to I. Our proof is based on the following idea: for every $i \in [r]$, we associate a path $g(i) \in S^*$ to path $\pi(s_i, t_i) = S_i$ such that every edge in S^* appears at most twice along all sets of paths $\{g(1), \ldots, g(r)\}$. We shall prove that, using this function, we obtain an r-decomposition of S and a 2-intersecting r-decomposition of

Algorithm 3 (G, d, N, p)

1: $S_0 \leftarrow \emptyset$
2: $i \leftarrow 1$
3: $P_i \leftarrow \{\{v_1\}, \ldots, \{v_{r+1}\}\}$
4: **while** $P_i \neq N$ **do**
5: **for** each $(s,t) \in N^2 : set(s, P_i) \neq set(t, P_i)$ **do**
6: $\pi(s,t) \leftarrow$ Algorithm 2$(G, d, s, t, p, S_{\leq i-1})$
7: **end for**
8: $(s_i, t_i) \leftarrow \text{argmin}_{(s,t) \in N^2 : set(s,P_i) \neq set(t,P_i)} \{\|\boldsymbol{\ell}(S_{\leq i-1} \cup \pi(s,t))\|_p\}$
9: $S_i \leftarrow \pi(s_i, t_i)$
10: $P_{i+1} \leftarrow merge(P_i, set(P_i, s_i), set(P_i, t_i))$
11: $i \leftarrow i + 1$
12: **end while**
13: **return** $prune(S_{\leq i-1})$

S^*, meeting the conditions required in order to apply Lemma 15; the claim will then follow directly.

Towards this end, given two required nodes $u, v \in N$, let $\Sigma_{uv} = \{\pi^1_{uv}, \ldots, \pi^{p_{uv}}_{uv}\}$ denote the set of all (u,v)-paths in G. Define $\widetilde{G} = (N, \widetilde{E})$ as the multi-graph such that there are p_{uv} edges $\{\widetilde{e}^1_{uv}, \ldots, \widetilde{e}^{p_{uv}}_{uv}\}$ between every pair of nodes $u, v \in N$, with $\boldsymbol{c}_{\widetilde{e}^i_{uv}} = \boldsymbol{\ell}(\pi^i_{uv})$ for every $i \in [p_{uv}]$; so, there is a cost-preserving bijection between edges in $\widetilde{G}$ and paths in G. Given a path π in G, denote by $\widetilde{e}(\pi)$ its correspondent edge in $\widetilde{G}$ and, vice-versa, given an edge $\widetilde{e}$ of $\widetilde{G}$, denote by $\rho(\widetilde{e})$ its correspondent path in G.

We observe the following facts:

1. S induces a spanning tree $T(S)$ for $\widetilde{G}$ defined as $T(S) = \{\widetilde{e}(\pi(s_i, t_i)) \in \widetilde{E} : i \in [r]\}$.
2. S^* induces a spanning tree $T(S^*)$ for $\widetilde{G}$ defined as follows: let $(v_1, \ldots, v_{r+1})$ be the ordered sequence of the $r+1$ nodes in N listed according to the order in which appear along a Depth First Search of S^* starting from an arbitrary required node $v_1 \in N$, then $T(S^*) = \{\widetilde{e}(\pi^*_i) : i \in [r]\}$, where π^*_i is the (v_i, v_{i+1})-path in S^*. It is well-known that every edge in S^* occurs at most twice in the set of paths $\{\widetilde{e}(\pi^*_1), \ldots, \widetilde{e}(\pi^*_r)\}$.
3. Since both $T(S)$ and $T(S^*)$ are bases of the graphic matroid defined over $\widetilde{G}$, by applying Proposition 6, there exists a bijection $f : T(S) \setminus T(S^*) \to T(S^*) \setminus T(S)$.

Let us define a function $g : [r] \to S^*$ such that, for every $i \in [r]$,

$$g(i) = \begin{cases} \pi(s_i, t_i) & \text{if } \widetilde{e}(\pi(s_i, t_i)) \in T(S^*), \\ \rho(f(\widetilde{e}(\pi(s_i, t_i)))) & \text{if } \widetilde{e}(\pi(s_i, t_i)) \notin T(S^*). \end{cases}$$

For every $i \in [r]$, set $S^*_i = g(i)$. We have that $(S_1, \ldots, S_r)$ is an r-decomposition of S and $(S^*_1, \ldots, S^*_r)$ is a 2-intersecting r-decomposition of S^*. Our aim now is to apply Lemma 15.

Towards this end, fix an index $i \in [r]$ and denote by s^*_i and t^*_i the two endpoints of path $g(i)$. We observe that it must be $set(s^*_i, P_i) \neq set(t^*_i, P_i)$. Indeed, if this is not the case, then $(T(S) \setminus \widetilde{e}(\pi(s_i, t_i)) \cup \widetilde{e}(g(i))$ cannot be a basis of the graphic matroid defined over $\widetilde{G}$.

At the ith iteration of the while-loop at lines 4-12 of Algorithm 3, P_i represents the set of connected components of G induced by the set of edges $S_{\leq i-1}$. Define $\overline{G}_i$ as the multi-graph obtained from G by contracting the connected components containing $set(s_i, P_i)$ and $set(s^*_i, P_i)$ into a super-node $\overline{s}_i$ and the connected components containing $set(t_i, P_i)$ and $set(t^*_i, P_i)$ into a super node $\overline{t}_i$. Let G_i be the graph obtained from $\overline{G}_i$ by splitting every

multi-edge $e = \{u_i, u_j\}$ of weight $\boldsymbol{c}_e$ into two edges $\{u_i, u_{ij}\}$ and $\{u_{ij}, u_j\}$ of weights $\boldsymbol{c}_e$ and $\mathbf{0}^d$, respectively.

If $set(s_i, P_i) = set(s_i^*, P_i)$ and $set(t_i, P_i) = set(t_i^*, P_i)$, we have that $(G_i, \overline{s}_i, \overline{t}_i, p)$ is an instance of the SMP meeting the conditions of Lemma 15, by which, we obtain the claim. If $set(s_i, P_i) = set(s_i^*, P_i)$ and $set(t_i, P_i) = set(t_i^*, P_i)$ does not hold, since G is an undirected graph, we may assume without loss of generality that $set(s_i^*, P_i) \neq set(t_i, P_i)$ and $set(s_i, P_i) \neq set(t_i^*, P_i)$ (in fact, if one of the two inequalities does not hold, we can exchange the role of s_i^* and t_i^* and have both of them satisfied).

Now observe that there is a cost-preserving bijection b between the set of paths connecting any node in $set(s_i, P_i) \cup set(s_i^*, P_i)$ to any node in $set(t_i, P_i) \cup set(t_i^*, P_i)$ in G and the set of $(\overline{s}_i, \overline{t}_i)$-paths in G_i. Moreover, by the assumption $set(s_i, P_i) \neq set(t_i^*, P_i)$, it follows that path $b(S_i)$ is an $(\overline{s}_i, \overline{t}_i)$-path in G_i; similarly, by the assumption $set(s_i^*, P_i) \neq set(t_i, P_i)$, it follows that path $b(g_i)$ is an $(\overline{s}_i, \overline{t}_i)$-path in G_i.

Thus, in order to apply Lemma 15 and obtain the claim, we need to prove that there are suitable tie breaking rules for which $b(S_i)$ is the output of Algorithm 2 when executed with parameters G_i, d, $\overline{s}_i$, $\overline{t}_i$, p and $S_{\leq i-1}$ on the instance $(G_i, d, \overline{s}_i, \overline{t}_i, p) \in$ SMP. Assume, by way of contradiction, that for any possible tie breaking rule, Algorithm 2 never returns an $(\overline{s}_i, \overline{t}_i)$-path π_i such that $\pi_i = b(S_i)$. This implies that there exists an $(\overline{s}_i, \overline{t}_i)$-path π_i^* such that $\|\boldsymbol{\ell}(S_{\leq i-1} \cup \pi_i^*)\|_p < \|\boldsymbol{\ell}(S_{\leq i-1} \cup \pi_i)\|_p$ by which we obtain $\|\boldsymbol{\ell}(S_{\leq i-1} \cup b^{-1}(\pi_i^*))\|_p < \|\boldsymbol{\ell}(S_{\leq i-1} \cup b^{-1}(\pi_i))\|_p$, where $b^{-1}(\pi_i^*)$ is some (s,t)-path in G with $set(s, P_i) \neq set(t, P_i)$. This contradicts $S_i = \text{argmin}_{(s,t) \in N^2 : set(s,P_i) \neq set(t,P_i)} \{\|\boldsymbol{\ell}(S_{\leq i-1} \cup \pi(s,t))\|_p\}$. ◀

By combining Lemma 16 with Theorem 10, we obtain the following result.

▶ **Theorem 17.** *Algorithm 3 approximates* MMST *within a factor of* $O(\min\{p, \log d\})$.

7 Minimum Multidimensional Arborescence

Given a directed connected graph $G = (V, E)$, with $|V| = n$, in which every edge $e \in E$ is associated with a d-dimensional weight $\boldsymbol{c}_e \in \mathbb{R}_+^d$, a node $s \in V$ and a value $p \in \overline{\mathbb{R}}$, the minimum multidimensional arborescence (MMA) problem is the restriction of MMRS to instances with $R = E$ and such that $\mathcal{F}$ is the set of all the directed trees in G rooted at s. Recall that a directed tree $T \subset E$ rooted at s is a set of $n-1$ edges such that, for every $t \in V$, there exists a directed (s,t)-path in T.

A *rooted weakly connected component* of G is a subgraph $H = (V', E')$ of G possessing at least one root, that is, a node from which it is possible to reach any other node in V' by following a direct path in E'. Call the *representative node* of a rooted weakly connected component any of its roots. When the set of roots of a rooted weakly connected component H contains s, the representative node of H is always assumed to be s.

We propose Algorithm 4 which, starting from the set of rooted weakly connected components of G obtained by considering all nodes in V as singletons, repeatedly merges rooted weakly connected components of G until an arborescence rooted at s is obtained. Given a set of edges S, function *repr* first computes the set C of weakly connected components of G induced by S, and then computes a representative for every element of C. Observe that, by our assumption, $s \in repr(C)$ for every set of rooted weakly connected components C. Given a set of edges S and a node u, function *nodes* computes the set of nodes belonging to the weakly connected component containing u. Finally, given a set of edges S, function *prune* returns a maximal subset of S not inducing cycles in G.

The following lemma characterizes the approximation guarantee achieved by Algorithm 4. Its proof is omitted due to lack of space.

Algorithm 4 (G, d, s, p)

$S_0 \leftarrow \emptyset$
$C_1 \leftarrow V$
$i \leftarrow 1$
while $C_i \neq \{s\}$ **do**
  $S_i \leftarrow S_{i-1}$
  for each $u \in C_i \setminus \{s\}$ **do**
    for each $v \in V \setminus nodes(u, S_{i-1})$ **do**
      $\pi(v, u) \leftarrow Algorithm\ 2(G, d, v, u, p, S_i)$
    end for
    $\delta(u) \leftarrow \text{argmin}_{v \in V \setminus nodes(u, S_{i-1})}\{\|\boldsymbol{\ell}(S_i \cup \pi(v, u))\|_p\}$
    $S_i \leftarrow S_i \cup \pi(\delta(u), u)$
  end for
  $C_{i+1} \leftarrow repr(S_i)$
  $i \leftarrow i + 1$
end while
return $prune(S_{i-1})$

▶ **Lemma 18.** *Fix an instance $I = (G, d, s, p) \in$ MMA. Then, Algorithm 4 returns a feasible solution for I possessing the $O(\log n)$-PAID property.*

By combining Lemma 18 with Theorem 10, we obtain the following result.

▶ **Theorem 19.** *Algorithm 4 approximates* MMA *within a factor of $O(\log n \cdot \min\{p, \log d\})$.*

8 An Inapproximability Result

We conclude by complementing our positive algorithmic results with the following hardness statement.

▶ **Theorem 20.** *For every constant $\kappa \geq 1$, the problems* MMRS(∞) *on matroids,* SMP(∞), MMST(∞), *and* MMA(∞) *cannot be approximated up to a factor κ unless* NP=ZPP.

Proof. Our proof defines a simple approximation-preserving reduction from the Vector Scheduling Problem VSP. An instance of the VSP is defined by n tasks to be scheduled on m identical machines. Every task i has a d-dimensional load vector $\boldsymbol{c}_i \in \mathbb{R}^d_+$ and the objective is to minimize the load over all machines and all dimensions. Chekuri and Kanna [7] showed that, for every constant $\kappa \in \mathbb{R}$, this problem cannot be approximated up to a factor κ unless NP=ZPP.

Given an instance of the VSP, we define an undirected multi-graph $G = (V, E)$ with $n+1$ nodes and mn edges defined as follows: $V = \{v_0, v_1, \ldots, v_n\}$, and for every $i \in [n-1]$ there are m edges $e_i^1, \ldots, e_i^m \in E$ connecting nodes v_{i-1} and v_i such that, for every $j \in [m]$, edge e_i^j has a (dm)-dimensional cost

$$\boldsymbol{c}(e_i^j) = (\underbrace{\mathbf{0}^d, \ldots, \mathbf{0}^d}_{j-1 \text{ times}}, \boldsymbol{c}_i, \underbrace{\mathbf{0}^d, \ldots, \mathbf{0}^d}_{m-j \text{ times}}).$$

Observe that every schedule of the n tasks to the m machines corresponds to a (v_0, v_n)-path in G and viceversa. Moreover, the objective value of the two solutions is exactly the same. Since G can be easily translated into a graph G' by splitting every multi-edge into two edges of the same total cost, we have that the hardness result for the VSP extends also

to $\mathsf{SMP}(\infty)$. Given that every spanning tree for G' is a (v_0, v_n)-path in G', the hardness result extends to $\mathsf{MMRS}(\infty)$ on matroids and to $\mathsf{MMST}(\infty)$ when the set of required nodes contains both v_0 and v_n. Finally, by directing every edge in E from v_{i-1} to v_i, we obtain the same hardness result for $\mathsf{MMA}(\infty)$. ◀

Abstract

In this paper we study a stochastic variant of the celebrated k-server problem. In the k-server problem, we are required to minimize the total movement of k servers that are serving an online sequence of t requests in a metric. In the stochastic setting we are given t independent distributions $\langle P_1, P_2, \ldots, P_t \rangle$ in advance, and at every time step i a request is drawn from P_i.

Designing the optimal online algorithm in such setting is NP-hard, therefore the emphasis of our work is on designing an approximately optimal online algorithm. We first show a structural characterization for a certain class of *non-adaptive* online algorithms. We prove that in general metrics, the best of such algorithms has a cost of no worse than three times that of the optimal online algorithm. Next, we present an integer program that finds the optimal algorithm of this class for any arbitrary metric. Finally by rounding the solution of the linear relaxation of this program, we present an online algorithm for the stochastic k-server problem with an approximation factor of 3 in the line and circle metrics and factor of $O(\log n)$ in a general metric of size n. In this way, we achieve an approximation factor that is independent of k, the number of servers.

Moreover, we define the *Uber* problem, motivated by extraordinary growth of online network transportation services. In the Uber problem, each demand consists of two points -a source and a destination- in the metric. Serving a demand is to move a server to its source and then to its destination. The objective is again minimizing the total movement of the k given servers. We show that given an α-approximation algorithm for the k-server problem, we can obtain an $(\alpha + 2)$-approximation algorithm for the Uber problem. Motivated by the fact that demands are usually highly correlated with the time (e.g. what day of the week or what time of the day the demand has arrived), we study the *stochastic Uber* problem. Using our results for stochastic k-server we can obtain a 5-approximation algorithm for the stochastic Uber problem in line and circle metrics, and a $O(\log n)$-approximation algorithm for general metrics.

Furthermore, we extend our results to the correlated setting where the probability of a request arriving at a certain point depends not only on the time step but also on the previously arrived requests.

1 Introduction

The k-server problem is one of the most fundamental problems in online computation that has been extensively studied in the past decades. In the k-server problem we have k mobile servers on a metric space $\mathcal{M}$. We receive an online sequence of t requests where the i^{th} request is a point $r_i \in \mathcal{M}$. Upon the arrival of r_i, we need to move a server to r_i, at a cost equal to the distance from the current position of the server to r_i. The goal is to minimize the total cost of serving all requests.

Manasse, McGeoch, and Sleator [31] introduced the k-server problem as a natural generalization of several online problems, and a building block for other problems such as the metrical task systems. They considered the adversarial model, in which the online algorithm has no knowledge of the future requests. Following the proposition of Sleator and Tarjan [34], they evaluate the performance of an online algorithm using competitive analysis. In this model, an online algorithm ALG is compared to an *offline* optimum algorithm OPT which is aware of the entire input in advance. For a sequence of requests ρ, let $|\mathrm{ALG}(\rho)|$ and $|\mathrm{OPT}(\rho)|$ denote the total cost of ALG and OPT for serving ρ. An algorithm is *c-competitive* if for every ρ, $|\mathrm{ALG}(\rho)| \leq c\,|\mathrm{OPT}(\rho)| + c_0$ where c_0 is independent of ρ.

Manasse *et al.* [31] showed a lower bound of k for the competitive ratio of any deterministic algorithm in any metric space with at least $k+1$ points. The celebrated *k-server conjecture* states that this bound is tight for general metrics. For several years the known upper bounds were all exponential in k, until a major breakthrough was achieved by Koutsoupias and Papadimitriou [29], who showed that the so-called *work function algorithm* is $(2k-1)$-competitive. Proving the tight competitive ratio has been the "holy grail" of the field in the past two decades. This challenge has led to the study of the problem in special spaces such as the uniform metric (also known as the paging problem), line, circle, and trees metrics (see [15, 16] and references therein). We also refer the reader to Section 1.3 for a short survey of randomized algorithms, particularly the recent result of Bansal, Buchbinder, Madry, and Naor [7] which achieves the competitive ratio of $O(\log^3 n \log^2 k)$ for discrete metrics that comprise n points.

The line metric (or Euclidean 1-dimensional metric space) is of particular interest for developing new ideas. Chrobak, Karloof, Payne, and Vishwnathan [15] were the first to settle the conjecture in the line by designing an elegant k-competitive algorithm. Chrobak and Larmore [16] generalized this approach to tree metrics. Later, Bartal and Koutsoupias [10] proved that the work function algorithm is also k-competitive in line. Focusing on the special case of $k = 2$ in line, Bartal *et al.* [9] show that, using randomized algorithms, one can break the barrier of lower bound k by giving a 1.98-competitive algorithm for the case where we only have two servers.

Despite the strong lower bounds for the k-server problem, there are heuristics algorithms that are *constant* competitive in practice. For example, for the paging problem- the special case of uniform metric- the least recently used (LRU) strategy is shown to be experimentally constant competitive (see Section 1.3). In this paper we present an algorithm an run it on real world data to measure its empirical performance. In particular we use the distribution of car accidents obtained from road safety data. Our experiments illustrate our algorithm is performing even better in practice. See the full version of the paper for more details.

The idea of comparing the performance of an online algorithm (with zero-knowledge of the future) to the request-aware offline optimum has led to crisp and clean solutions. However, that is not without its downsides. The results in the online model are often very pessimistic leading to theoretical guarantees that are hardly comparable to experimental results. Indeed, one way to tighten this gap is to use stochastic information about the input data as we describe in this paper.

We should also point out that the competitive analysis is not the only possible or necessarily the most suitable approach for this problem. Since the distributions from which the input is generated are known, one can use dynamic programming (or enumeration of future events) to derive the optimal movement of servers. Unfortunately, finding such an optimal online solution using the distributions is an NP-hard problem [1], thus the dynamic programming or any other approach takes exponential time. This raises the question that how well one can perform in comparison to the best online solution. In the rest of the paper we formally define the model and address this question.

A natural and well-motivated generalization of k-server is to assume the demands are two points instead of just one, consisting of a source and a destination. To serve a demand we need to move a server to the source and then move it to the destination. We call this problem the *Uber* problem. One can see, the Uber problem is the same as k-server when the sources and the destinations are the same. We also show that, given an α-approximation algorithm for the k-server problem, we can obtain a $(\alpha + 2)$-approximation algorithm for the Uber problem. Thus our results for k-server also apply to the Uber problem.

1.1 The Stochastic Model

In this paper, we study the *stochastic k-server problem* where the input is not chosen adversarially, but consists of draws from given probability distributions. This problem has lots of applications such as network transportations and equipment replacement in data centers. The current mega data centers contain hundreds of thousands of servers and switches with limited life-span. For example servers usually retire after at most three years. The only efficient way to scale up the maintenance in data centers is by automation, and robots are designed to handle maintenance tasks such as repairs or manual operations on servers. The replacement process can be modeled as requests that should be satisfied by robots, and robots can be modeled as servers. This problem also has applications in physical networks. As an example, suppose we model a shopping service (e.g. Google Express) as a k-server problem in which we receive an online sequence of shopping requests for different stores. We have k shopping cars (i.e., servers) that can serve the requests by traveling to the stores. It is quiet natural to assume that on a certain time of the week/day, the requests arrive from a distribution that can be discovered by analyzing the history. For example, an Uber request is more likely to be from suburb to midtown in the morning, and from midtown to suburb at night. We formalize this stochastic information as follows.

For every $i \in [1 \cdots t]$, a discrete probability distribution P_i is given in advance from which request r_i will be drawn at time step i. The distributions are chosen by the adversary and are assumed to be independent but not necessarily identical. This model is inspired by the

[1] Reduction from k-median to Stochastic k-server: to find the k median of set S of vertices, one can construct an instance of stochastic k-server with $t = 1$ and $P_1(v) = 1/|S|$ for every $v \in S$. The best initialization of the servers gives the optimum solution to k-median of S.

well-studied model of *prophet inequalities* [2] [30, 25]. As mentioned before, the case of line metric has proven to be a very interesting restricted case for studying the k-server problem. In this paper, we focus mainly on the class of line metric though our results carry over to circle metric and general metrics as well.

In the adversarial model, the competitive ratio seems to be the only well-defined notion for analyzing the performance of online algorithms. However, in the presence of stochastic information, one can derive a much better benchmark that allows us to make fine-grained distinctions between the online algorithms. We recall that in the offline setting, for a class of algorithms $\mathcal{C}$, the natural notion to measure the performance of an algorithm $\text{ALG} \in \mathcal{C}$ is the *approximation ratio* defined as the worse case ratio of $|\text{ALG}|$ to $|\text{OPT}(\mathcal{C})|$ where $\text{OPT}(\mathcal{C})$ is the optimal algorithm in the class. In this paper, we also measure the performance of an online algorithm by its approximation ratio– compared to the *optimal online solution*. We note that given distributions $P_1, \ldots, P_t$, one can iteratively compute the optimal online solution by solving the following exponential-size dynamic program: for every $i \in [0 \cdots t]$ and every possible placement A of k servers (called a *configuration*) on the metric, let $\tau(i, A)$ denote the minimum expected cost of an online algorithm for serving the first i requests and then moving the servers to configuration A. Note that $\tau(i, A)$ can inductively be computed via the following recursive formula

$$\tau(i, A) = \min_B \tau(i-1, B) + \mathrm{E}_{r_i \sim P_i} [\text{min. distance from } B \text{ to } A \text{ subject to serving } r_i] \ ,$$

where $\tau(0, A)$ is initially zero for every A.

1.2 Our Results [3]

Our first main result is designing a constant approximation algorithm in the line metric when the distributions for different time steps are not necessarily identical.

▶ **Theorem 1.** *There exists a 3-approximation online algorithm for the stochastic k-server problem in the line metric. The running time is polynomial in k and the sum of the sizes of the supports of input distributions. The same guarantee holds for the circle metric.*

For the general metric, we present an algorithm with a logarithmic approximation guarantee.

▶ **Theorem 2.** *There exists a $O(\log n)$-approximation online algorithm for the stochastic k-server problem in a general metric of size n.*

We prove the theorems using two important structural results. The first key ingredient is a general reduction from class of online algorithms to a restricted class of *non-adaptive algorithms* while losing only a constant factor in the approximation ratio. Recall that a configuration is a placement of k-servers on the metric. We say an algorithm ALG is *non-adaptive* if it follows the following procedure: ALG pre-computes a sequence of configurations $A_0, A_1, \ldots, A_t$. We start by placing the k-servers on A_0. Upon the arrival of r_i, (i) we move the servers to configuration A_i; next (ii) we move the closest server s to r_i; and finally (iii) we return s to its original position in A_i. We first prove the following structural result.

---

[2] In the prophet inequality setting, given (not necessarily identical) distributions $P_1, \ldots, P_t$, an online sequence of values $x_1, \ldots, x_n$ where x_i is drawn from P_i, an onlooker has to choose one item from the succession of the values, where x_i is revealed at step i. The onlooker can choose a value only at the time of arrival. The goal is to maximize the chosen value.

[3] In the interest of space, we have omitted some of the proofs. We refer the reader to the full version of the paper in order to see all of the proofs.

▶ **Theorem 3.** *For the stochastic k-server problem in the general metric, the optimal non-adaptive online algorithm is within 3-approximation of the optimal online algorithm.*

Using the aforementioned reduction, we focus on designing the optimal non-adaptive algorithm. We begin by formulating the problem as an integer program. The second ingredient is to use the relaxation of this program to formalize a natural *fractional variant* of the problem. In this variant, a configuration is a fractional assignment of *server mass* to the points of the metric such that the total mass is k. To serve a request at point r_i, we need to move some of the mass to have at least one amount of server mass on r_i. The cost of moving the server mass is naturally defined as the integral of the movement of infinitesimal pieces of the server mass. By solving the linear relaxation of the integer program, we achieve the optimal fractional non-adaptive algorithm. We finally prove Theorems 1 and 2 by leveraging the following rounding techniques. The rounding method in line has been also observed by Türkoglu [35]. We provide the proof for the case of line in Section 5 for the sake of completeness. The rounding method for general metrics is via the well-known embedding of a metric into a distribution of well-separated trees while losing a logarithmic factor in the distortion. Bansal *et al.* [7] use a natural rounding method similar to that of Blum, Burch, and Kalai [12] to show that any fractional k-server movement on well-separated trees can be rounded to an integral counterpart by losing only a constant factor.

▶ **Theorem 4** (first proven in [35]). *Let* ALG_f *denote a fractional k-server algorithm in the line, or circle. One can use* ALG_f *to derive a randomized integral algorithm* ALG *such that for every request sequence σ,* $\mathrm{E}\left[|\mathrm{ALG}(\sigma)|\right] = |\mathrm{ALG}_f(\sigma)|$. *The expectation is over the internal randomness of* ALG. *Furthermore, in the stochastic model* ALG *can be derandomized.*

▶ **Theorem 5** (proven in [7]). *Let* ALG_f *denote a fractional k-server algorithm in any metric. One can use* ALG_f *to derive a randomized integral algorithm* ALG *such that for every request sequence σ,* $\mathrm{E}\left[|\mathrm{ALG}(\sigma)|\right] \leq O(\log n)\,|\mathrm{ALG}_f(\sigma)|$.

We also show that having an α-approximation algorithm for k-server, we can obtain a $(\alpha+2)$-approximation for the Uber problem, using a simple reduction.

▶ **Theorem 6.** *Let* ALG *denote an α-approximation algorithm for k-server. One can use* ALG *to derive a $(\alpha+2)$-approximation algorithm for the Uber problem.*

Proof. Consider an instance of the Uber problem I_U. Let s_i and t_i denote the i-th source and destination, respectively. We generate an instance of the k-server problem I_k by removing every t_i from I_U. In other words the demands are s_i's. We use ALG to provide a solution for I_U as follows. For satisfying the i-th demand, we use ALG to move a server to s_i. Then using the shortest path from s_i to t_i, we move that server to t_i and then return it back to s_i. Let OPT_U and OPT_k denote the cost of the optimal solutions for I_U and I_k, respectively. Let $d(s_i, t_i)$ denote the distance of t_i from s_i in the metric. Let C denote the total movement of the servers. We have,

$$\mathrm{OPT}_U \geq \mathrm{OPT}_k\,.$$

$$\mathrm{OPT}_U \geq \sum_i d(s_i, t_i).$$

$$C \leq \alpha\,\mathrm{OPT}_k + 2\sum_i d(s_i, t_i) \leq (\alpha+2)\,\mathrm{OPT}_U\,.$$ ◀

1.3 Further Related Work

The randomized algorithms often perform much better in the online paradigm. For the k-server problem, a lower bound of $\Omega(\log k)$ is shown by [28] for the competitive ratio of randomized algorithms in most common metrics. Despite the exponential gap, compared to the lower bound of deterministic algorithms, very little is known about the competitiveness of randomized algorithms. In fact, the only known algorithms with competitive ratios below k, work either in the uniform metric (also known as the paging problem [21, 32, 2, 8]), a metric comprising $k+1$ points [23], and two servers on the line [9]. Two decades after the introduction of the k-server problem, a major breakthrough was achieved by Bansal *et al.* [7] in discrete metrics with sub-exponential size. If $\mathcal{M}$ comprise n points, their randomized algorithm achieves a competitive ratio of $O(\log^3 n \log^2 k)$.

The case of uniform metric has been extensively studied under various stochastic models motivated by the applications in computer caching. Koutsoupias and Papadimitriou [29] consider two refinements of the competitive analysis for server problems. First, they consider the *diffuse adversary* model. In this model, at every step i the adversary chooses a distribution D_i over the uniform metric of the paging problem. Then the i^{th} request is drawn from D_i which needs to be served. The distribution D_i is not known to the online algorithm and it may depend on the previous requests. However, in their paper, they consider the case wherein it is guaranteed that for every point p, $D_i(p) \leq \epsilon$ for a small enough ϵ; i.e., the next request is not predictable with absolute certainty for the adversary. The results of Koutsoupias and Papadimitriou and later Young [36] shows that the optimum competitive ratio in this setting is close to $1 + \Theta(k\epsilon)$.

The second refinement introduced in [29] restricts the optimal solution to having lookahead at most ℓ. Hence, one can define a *comparative ratio* which indicates the worst-case ratio of the cost of the best online solution to the best solution with lookahead ℓ. They show that for the k-server problem, and more generally the metrical task system problem, there are online algorithms that admit a comparative ratio of $2\ell + 1$; for some instances this ratio is tight.

Various other models of restricting the adversary (access graph model [14, 26, 22], fault rate model [27, 6, 19], etc) have also been considered for the paging problem (see [33, 11] and references therein for a further survey of these results). Unfortunately, many of the stochastic settings considered for the paging problem do not seem to have a natural generalization beyond the uniform metric setting. For example, in the diffuse adversary model, most of the studied distributions do not weaken the adversary in the general metric. In this paper, we look for polynomial-time *approximation* algorithms in the class of online algorithms that have access to the distributions.

We would like to mention that various online problems have been previously considered under prophet inequality model or i.i.d. model (where all distributions are identical). The maximum matching problem, scheduling, and online network design has been extensively studied in these models(see e.g. [4, 3, 5, 17, 1, 18]). In the graph connectivity problems, Garg, Gupta, Leonardi,and Sankowski [24] consider the online variants of Steiner tree and several related problems under the i.i.d. stochastic model. In the adversarial model, there exists an $\Omega(\log n)$ lower bound on the competitive ratio of any online algorithm, where n is the number of demands. However, Garg *et al.* show that under the i.i.d. assumption, these problems admit online algorithms with constant or $O(\log \log n)$ competitive ratios. We refer the reader to the excellent book by Borodin and El-Yaniv [13] for further study of online problems.

2 Preliminaries

In this section we formally define the stochastic k-server problem. The classical k-server problem is defined on a metric $\mathcal{M}$ which consists of points that could be infinitely many. For every two points x and y in metric $\mathcal{M}$, let $d(x, y)$ denote the distance of x from y which is a symmetric function and satisfies the triangle inequality. More precisely for every three points x, y, and z we have

$$d(x, x) = 0 \tag{1}$$
$$d(x, y) = d(y, x) \tag{2}$$
$$d(x, y) + d(y, z) \geq d(x, z). \tag{3}$$

In the k-server problem the goal is to place k servers on k points of the metric, and move these servers to satisfy the requests. We refer to every placement of the servers on the metric points by a *configuration*. Let $\rho = \langle r_1, r_2, \ldots, r_t \rangle$ be a sequence of requests, the goal of the k-server problem is to find configurations $\langle A_0, A_1, A_2, \ldots, A_t \rangle$ such that for every i there exists a server on point r_i in configuration A_i. We say such a list of configurations is *valid* for the given list of requests. A valid sequence of configurations is optimal if $\sum d(A_{i-1}, A_i)$ is minimized where $d(X, Y)$ stands for the minimum cost of moving servers from configuration X to configuration Y. An optimal sequence $\langle A_0, A_1, \ldots, A_t \rangle$ of configurations is called an optimal offline solution of $\mathrm{OFKS}(\mathcal{M}, \rho)$ when ρ is known in advance. We refer to the optimal cost of such movements with $|\mathrm{OFKS}(\mathcal{M}, \rho)| = \sum d(A_{i-1}, A_i)$.

We also define the notion of *fractional configuration* as an assignment of the metric points to non-negative real numbers. More precisely, each number specifies a mass of fractional server on a point. Every fractional solution adheres to the following condition: The total sum of the values assigned to all points is exactly equal to k. Analogously, a fractional configuration serves a request r_i if there is a mass of size at least 1 of server assigned to point r_i. An offline fractional solution of the k-server problem for a given sequence of requests ρ is defined as a sequence of fractional configurations $\langle A_0, A_1, \ldots, A_t \rangle$ such that A_i serves r_i.

In the online k-server problem, however, we are not given the whole sequence of requests in the beginning, but we will be informed of every request once its realization is drawn. An algorithm $\mathcal{A}$ is an online algorithm for the k-server problem if it reports a configuration A_0 as an initial configuration and upon realization of every request r_i it returns a configuration A_i such that $\langle A_0, A_1, \ldots, A_i \rangle$ is valid for $\langle r_1, r_2, \ldots, r_i \rangle$. If $\mathcal{A}$ is deterministic, it generates a unique sequence of configurations for every sequence of requests. Let $\mathcal{A}(\mathcal{M}, \rho)$ be the sequence that $\mathcal{A}$ generates for requests in ρ and $|\mathcal{A}(\mathcal{M}, \rho)|$ denote its cost.

In the online stochastic k-server problem, in addition to metric $\mathcal{M}$, we are also given t independent probability distributions $\langle P_1, P_2, \ldots, P_t \rangle$ which show the probability that every request r_i is realized on a point of the metric at each time. An algorithm $\mathcal{A}$ is an online algorithm for such a setting, if it generates a configuration for every request r_i not solely based on $\langle r_1, r_2, \ldots, r_i \rangle$ and $\langle A_0, A_1, \ldots, A_{i-1} \rangle$ but also with respect to the probability distributions. Similarly, we define the cost of an online algorithm $\mathcal{A}$ for a given sequence of requests ρ with $|\mathcal{A}(\mathcal{M}, \rho, \langle P_1, P_2, \ldots, P_t \rangle)|$. We define the expected cost of an algorithm $\mathcal{A}$ on metric $\mathcal{M}$ and with probability distributions $\langle P_1, P_2, \ldots, P_t \rangle$ by

$$|\mathcal{A}(\mathcal{M}, \langle P_1, P_2, \ldots, P_t \rangle)| = \mathbb{E}_{\forall i, r_i \sim P_i} |\mathcal{A}(\mathcal{M}, \rho, \langle P_1, P_2, \ldots, P_t \rangle)|.$$

For every metric $\mathcal{M}$ and probability distributions $\langle P_1, P_2, \ldots, P_t \rangle$ we refer to the online algorithm with the minimum expected cost by $\mathrm{OPT}_{\mathcal{M}, \langle P_1, P_2, \ldots, P_t \rangle}$.

An alternative way to represent a solution of the k-server problem is as a vector of configurations $\langle B_0, B_1, \ldots, B_t\rangle$ such that B_i does not necessarily serve request r_i. The cost of such solution is equal to $\sum d(B_{i-1}, B_i) + \sum 2d(B_i, r_i)$ where $d(B_i, r_i)$ is the minimum distance of a server in configuration B_i to request r_i. The additional cost of $2d(B_i, r_i)$ can be thought of as moving a server from B_i to serve r_i and returning it back to its original position. Thus, every such representation of a solution can be transformed to the other representation. Similarly, $d(B_i, r_i)$ for a fractional configuration B_i is the minimum cost which is incurred by placing a mass 1 of server at point r_i. We use letter B for the configurations of such solutions throughout the paper.

In this paper the emphasis is on the stochastic k-server problem on the line metric. We define the line metric $\mathcal{L}$ as a metric of points from $-\infty$ to $+\infty$ such that the distance of two points x and y is always equal to $|x-y|$. Moreover, we show that deterministic algorithms are as powerful as randomized algorithms in this setting, therefore we only focus on deterministic algorithms in this paper. Thus, from here on, we omit the term deterministic and every time we use the word algorithm we mean a deterministic algorithm unless otherwise is explicitly mentioned.

3 Structural Characterization

Recall that an online algorithm $\mathcal{A}$ has to fulfill the task of reporting a configuration A_i upon arrival of request r_i based on $\langle A_0, A_1, \ldots, A_{i-1}\rangle$, $\langle r_1, r_2, \ldots, r_i\rangle$, and $\langle P_1, P_2, \ldots, P_t\rangle$. We say an algorithm $\mathcal{B}$ is *request oblivious*, if it reports configuration B_i regardless of request r_i. As such, $\mathcal{B}$ generates configurations $\langle B_0, B_1, \ldots, B_t\rangle$ for a sequence of requests $\langle r_1, r_2, \ldots, r_t\rangle$ and the cost of such configuration is $\sum d(B_{i-1}, B_i) + \sum 2d(B_i, r_i)$. More precisely, no matter what request r_i is, $\mathcal{B}$ will generate the same configuration for a given list of past configurations $\langle B_0, B_1, \ldots, B_{i-1}\rangle$, a given sequence of past requests $\langle r_1, r_2, \ldots, r_{i-1}\rangle$, and the sequence of probability distributions $\langle P_1, P_2, \ldots, P_t\rangle$. In the following we show that every online algorithm $\mathcal{A}$ can turn into a request oblivious algorithm $\mathcal{B}_\mathcal{A}$ that has a cost of at most $|3\mathcal{A}(\mathcal{M}, \rho, \langle P_1, P_2, \ldots, P_t\rangle)|$ for a given sequence of requests ρ.

▶ **Lemma 7.** *Let $\mathcal{A}$ be an online algorithm for the stochastic k-server problem. For any metric $\mathcal{M}$, there exists a request oblivious algorithm $\mathcal{B}_\mathcal{A}$ such that*

$$|\mathcal{B}_\mathcal{A}(\mathcal{M}, \langle P_1, P_2, \ldots, P_t\rangle)| \leq 3|\mathcal{A}(\mathcal{M}, \langle P_1, P_2, \ldots, P_t\rangle)|.$$

An immediate corollary of Lemma 7 is that the optimal request oblivious algorithm has a cost of at most $|3\,\mathrm{OPT}_{\mathcal{M},\langle P_1,P_2,\ldots,P_t\rangle}(\mathcal{M}, \langle P_1, P_2, \ldots, P_t\rangle)|$. Therefore, if we only focus on the request oblivious algorithms, we only lose a factor of 3 in comparison to the optimal online algorithm. The following lemma states a key structural lemma for an optimal request oblivious algorithm.

▶ **Lemma 8.** *For every request oblivious algorithm $\mathcal{B}$, there exists a randomized request oblivious algorithm $\mathcal{B}'$ with the same expected cost which is not only oblivious to the last request, but also oblivious to all requests that have come prior to this.*

Proof. For any given request oblivious online algorithm $\mathcal{B}$, we construct an online algorithm $\mathcal{B}'$ which is oblivious to all of the requests as follows: For an input $\langle B_1, B_2, \ldots, B_{i-1}\rangle$ of configurations and probability distributions $\langle P_1, P_2, \ldots, P_t\rangle$, draw a sequence of requests $\langle r_1, r_2, \ldots, r_i\rangle$ from $\langle P_1, P_2, \ldots, P_t\rangle$ conditioned on the constraint that $\mathcal{B}$ would generate configurations $\langle B_1, B_2, \ldots, B_{i-1}\rangle$ for requests $\langle r_1, r_2, \ldots, r_{i-1}\rangle$. Now, report the output of $\mathcal{B}$ for inputs $\langle B_1, B_2, \ldots, B_{i-1}\rangle$, $\langle r_1, r_2, \ldots, r_i\rangle$, and $\langle P_1, P_2, \ldots, P_t\rangle$.

We define the cost of step i of algorithm B' as $d(B_{i-1}, B_i) + 2d(B_i, r_i)$. Due to the construction of algorithm $\mathcal{B}'$, the expected cost of this algorithm at every step i for a random sequence of requests is equal to the expected cost of algorithm $\mathcal{B}$ for a random sequence of requests drawn from $\langle P_1, P_2, \ldots, P_t \rangle$. Therefore, the expected cost of both algorithms for a random sequence of requests are equal and thus $|\mathcal{B}(\mathcal{M}, \langle P_1, P_2, \ldots, P_t \rangle)| = |\mathcal{B}'(\mathcal{M}, \langle P_1, P_2, \ldots, P_t \rangle)|$. ◀

Lemma 8 states that there always exists an optimal randomized request oblivious online algorithm that returns the configurations regardless of the requests. We call such an algorithm *non-adaptive*. Since a non-adaptive algorithm is indifferent to the sequence of the requests, we can assume it always generates a sequence of configurations just based on the distributions. For an optimal of such algorithms, all such sequence of configurations should be optimal as well. Therefore, there always exists an optimal non-adaptive online algorithm which is deterministic. By Lemma 7 not only do we know the optimal request oblivious algorithm is at most 3-approximation, but also the same holds for the optimal non-adaptive algorithm.

▶ **Theorem 9.** *There exists a sequence of configurations $\langle B_0, B_1, \ldots, B_t \rangle$ such that an online algorithm which starts with B_0 and always returns configuration B_i upon arrival of request r_i has an opproximation factor of at most 3.*

4 Fractional Solutions

In this section we provide a fractional online algorithm for the k-server problem that can be implemented in polynomial time. Note that by Theorem 9 we know that there exist configurations $\langle \mathcal{B}_1, \mathcal{B}_2, \ldots, \mathcal{B}_t \rangle$ such that the expected cost of a non-adaptive algorithm that always returns these configurations is at most 3 times the cost of an optimal online algorithm. Therefore, we write an integer program to find such configurations with the least expected cost. Next, we provide a relaxed LP of the integer program and show that every feasible solution of such LP corresponds to a fractional online algorithm for the stochastic k-server problem. Hence, solving such a linear program, that can be done in polynomial time, gives us a fractional online algorithm for the problem.

4.1 Linear Program

Recall that given t independent distributions $\langle P_1, \ldots, P_t \rangle$ for online stochastic k-server, an adaptive algorithm can be represented by $t+1$ configurations $\langle B_0, \ldots, B_t \rangle$. Upon the arrival of each request r_i, we move the servers from configuration B_{i-1} to B_i and then one server serves r_i and goes back to its position in B_i. The objective is to find the configurations such that the cost of moving to new configurations in addition to the expected cost of serving the requests is minimized. Therefore the problem can formulated in an offline manner. First we provide an integer program in order to find a vector of configurations with the least cost.

The decision variables of the program represent the configurations, the movement of servers from one configuration to another, and the way that each possible request is served. In particular, at each time step τ:

- For each node v there is a variable $b_{\tau,v} \in N$ denoting the number of servers on node v.
- For each pair of nodes u and v, there is a movement variable $f_{\tau,u,v} \in N$ denoting the number of servers going from u to v for the next round.
- For each node v and possible request node r, there is a variable $x_{\tau,v,r} \in \{0, 1\}$ denoting whether r is served by v or not.

In the following integer program, the first set of constraints ensures the number of servers on nodes at each time is updated correctly according to the movement variables. The second set of constraints ensures that each possible request is served by at least one server. The third set of constraints ensures that no possible request is served by an empty node. By the definition, the cost of a sequence of configurations $\langle B_0, \ldots, B_t \rangle$ is $\sum_{i=1}^{t} d(B_{i-1}, B_i) + 2\sum_{i=1}^{t} d(B_i, r_i)$. Thus the objective is to minimize the expression

$$\sum_{\tau} \sum_{u,v} f_{\tau,u,v} d(u,v) + 2 \sum_{\tau} \sum_{v} \sum_{r} x_{\tau,v,r} \Pr(z \sim P_\tau = r) d(v,r),$$

where $\Pr(z \sim P_\tau = r)$ denotes the probability that r is requested at time τ.

$$\begin{aligned}
&\text{min.} && \sum_{\tau} \sum_{u,v} f_{\tau,u,v} d(u,v) + 2 \sum_{\tau} \sum_{v} \sum_{r} x_{\tau,v,r} \Pr(z \sim P_\tau = r) d(v,r) \\
&\forall \tau, v && b_{\tau+1,v} = b_{\tau,v} + \sum_{u} f_{\tau,u,v} - \sum_{u} f_{\tau,v,u}. \\
&\forall \tau, u, v && \sum_{v} x_{\tau,v,r} \geq 1. \\
&\forall \tau, v, r && x_{\tau,v,r} \leq b_{\tau,v}. \\
&\forall \tau && \sum_{v} b_{\tau,v} \leq k. \\
&\forall \tau, v, r && x_{\tau,v,r} \in \{0,1\}. \\
&\forall \tau, u, v && f_{\tau,u,v} \in N. \\
&\forall \tau, v && b_{\tau,v} \in N.
\end{aligned}$$

Now we consider the following relaxation of the above integer program.

$$\begin{aligned}
&\text{min.} && \sum_{\tau} \sum_{u,v} f_{\tau,u,v} d(u,v) + 2 \sum_{\tau} \sum_{v} \sum_{r} x_{\tau,v,r} \Pr(z \sim P_\tau = r) d(v,r) \\
&\forall \tau, v && b_{\tau+1,v} = b_{\tau,v} + \sum_{u} f_{\tau,u,v} - \sum_{u} f_{\tau,v,u}. \\
&\forall \tau, u, v && \sum_{v} x_{\tau,v,r} \geq 1. \\
&\forall \tau, v, r && x_{\tau,v,r} \leq b_{\tau,v}. \\
&\forall \tau && \sum_{v} b_{\tau,v} \leq k.
\end{aligned}$$

5 Reduction from Integral k-server to Fractional k-server

In this section we show how we can obtain an integral algorithm for the stochastic k-server problem from a fractional algorithm. We first show that every fractional algorithm for the line metric can be modified to an integral algorithm with the same cost. Next, we study the problem on HST metrics; we give a rounding method that produces an integral algorithm from a fractional algorithm while losing a constant factor. Finally, we leverage the previously known embedding techniques to show every metric can be embedded into HST's with a distortion of at most $O(\log n)$. This will lead to a rounding method for obtaining an integral algorithm from every fractional algorithm on general metrics while losing a factor of at most $O(\log n)$. Combining this with the 3 approximation fractional algorithm that we provide

in Section 4, we achieve an $O(\log n)$ approximation algorithm for the stochastic k-server problem on general graphs.

5.1 Integrals Are as Strong as Fractionals On the Line

In this section we show every fractional algorithm on the line metric can be derandomized to an integral solution with the same expected cost. The rounding method is as follows: For every fractional configuration A, we provide an integral configuration $\mathrm{I}(A)$ such that (i) the distance of two configurations A_1 and A_2 is equal to the expected distance of two configurations $\mathrm{I}(A_1)$ and $\mathrm{I}(A_2)$. (ii) for every point x in the metric that A has a server mass of size at least 1 on x, there exists a server on point x in $\mathrm{I}(A)$.

Let for every point x in the metric, $A(v)$ denote the amount of server mass on node v of the line. For every fractional configuration B, we define a mass function $f_A : (0, k] \to V$ as follows. $f_A(x) = v_j$ if and only if j is the minimum integer such that $\sum_{i=1}^{j-1} A(i) < x$ and $\sum_{i=1}^{j} A(i) \geq x$. Intuitively, if one gathers the server mass by sweeping the line from left to right, $f_A(x)$ is the first position on which we have gathered x amount of server mass. The rounding algorithm is as follows:

- Pick a random real number r in the interval $[0, 1)$.
- $\mathrm{I}(A)$ contains k servers on positions $f_A(r)$, $f_A(r+1)$, $f_A(r+2)$, $\ldots$, $f_A(r+k-1)$.

Note that the rounding method uses the same r for all of the configurations. More precisely, we draw r from $[0, 1)$ at first and use this number to construct the integral configurations from fractional configurations. The following two lemmas show that both of the properties hold for the rounding algorithm we proposed.

▶ **Lemma 10.** *Let A be a fractional configuration and x be a point such that $A(x) \geq 1$. Then $\mathrm{I}(A)$ has a server on x.*

Proof. Due to the construction of our rounding method, for every two consecutive servers a and b in $\mathrm{I}(\mathcal{A})$, the total mass of servers after a and before b in the fractional solution is less than 1. Therefore, $\mathrm{I}(A)$ should put a server on point x, otherwise the total mass of servers in the fractional solution between the first server before x and the first server after x would be at least 1. ◀

The next lemma shows that the rounding preserves the distances between the configurations in expectation.

▶ **Lemma 11.** *Let A_1 and A_2 be two fractional configurations and $|A_1 - A_2|$ be their distance. The following holds for the distances of the configurations*

$$\mathbb{E}|\,\mathrm{I}(A_1) - \mathrm{I}(A_2)| = |A_1 - A_2|.$$

Proof. The key point behind the proof of this lemma is that the distance of two fractional configurations A_1 and A_2 can be formulated as follows

$$|A_1 - A_2| = \int_0^1 |\,\mathrm{I}_\omega(A_1) - \mathrm{I}_\omega(A_2)| d_\omega$$

where $\mathrm{I}_\omega(A)$ stands for an integral configurations which places the servers on points $f_A(\omega)$, $f_A(\omega+1)$, $f_A(\omega+2)$, $\ldots$, $f_A(\omega+k-1)$. Since at the beginning of the rounding method we draw r uniformly at random, the expected distance of the two rounded configurations is exactly equal to

$$\int_0^1 |\,\mathrm{I}_\omega(A_1) - \mathrm{I}_\omega(A_2)| d_\omega$$

which is equal to the distance of A_1 from A_2. ◀

▶ **Theorem 12.** *For any given fractional online algorithm $\mathcal{A}$ for the k-server problem on the line metric, there exists an online integral solution for the same problem with the same expected cost.*

5.2 Reduction for General Graphs

An HST is a undirected rooted tree in which every leaf represents a point in the metric and the distance of a pair of points in the metric is equal to the distance of the corresponding leaves in the tree. In an HST, weights of the edges are uniquely determined by the depth of the vertices they connect. More precisely, in a σ-HST the weight of an edges between a vertex v and its children is equal to σ^{h-d_v} where h stands for the height of the tree and d_v denotes the depth of vertex v.

Since HSTs are very well structured, designing algorithms on HSTs is relatively easier in comparison to a more complex metric. Therefore, a classic method for alleviating the complexity of the problems is to first embed the metrics into HSTs with a low distortion and then solve the problems on these trees.

Perhaps the most important property of the HSTs is the following:

▶ Observation 1. For every pair of leaves $u, v \in T$ of an HST, the distance of u and v is uniquely determined by the depth of their deepest common ancestor.

Note that, the higher the depth of the common ancestor is, the lower the distance of the leaves will be. Therefore, the closest leaves to a leaf v are the ones that share the most common ancestors with v. Bansal *et al.* propose a method for rounding every fractional solution of the k-server problem to an integral solution losing at most a constant factor [7].

▶ **Theorem 13** ([7])**.** *Let T be a σ-HST with n leaves, $\sigma > 5$, and let $A = \langle A_0, A_1, A_2, \ldots, A_t \rangle$ be a sequence of fractional configurations. There is an online procedure that maintains a sequence of randomized k-server configurations $S = \langle S_0, S_1, S_2, \ldots, S_t \rangle$ satisfying the following two properties:*

- *At any time i, the state S_i is consistent with the fractional state A_i.*
- *If the fractional state changes from x_{i-1} to x_i at time i, incurring a movement cost of c_i, then the state S_{i-1} can be modified to a state S_i while incurring a cost of $O(c_i)$ in expectation.*

Embedding general metrics into trees and in particular HSTs has been the subject of many studies. The seminal work of Fakcharoenphol *et al.* [20] has shown that any metric can be randomly embedded to σ-HSTs with distortion $O(\frac{\sigma \log n}{\log \sigma})$.

▶ **Theorem 14** ([20])**.** *There exists a probabilistic method to embed an arbitrary metric $\mathcal{M}$ into σ-HSTs with distortion $\frac{\sigma \log n}{\log \sigma}$.*

Therefore, to round a fractional solution on a general metric, we first embed it into 6-HSTs with a distortion of at most $O(\log n)$ and then round the solution while losing only a constant factor. This will give us an integral algorithm that has an expected cost of at most $O(\log n)$ times the optimal.

▶ **Theorem 15.** *For any given fractional online algorithm $\mathcal{A}$ for the k-server problem on an arbitrary metric, there exists an online integral solution for the same problem having a cost of no worse that $O(\log n)$ times the cost of $\mathcal{A}$ in expectation.*

Acknowledgment. We would like to thank Shi Li for having helpful discussions.

Multiple Source Dual Fault Tolerant BFS Trees*

Manoj Gupta[1] and Shahbaz Khan†[2]

Abstract

Let $G = (V, E)$ be a graph with n vertices and m edges, with a designated set of σ sources $S \subseteq V$. The *fault tolerant subgraph* for any graph problem maintains a sparse subgraph $H = (V, E')$ of G with $E' \subseteq E$, such that for any set F of k failures, the solution for the graph problem on $G \setminus F$ is maintained in its subgraph $H \setminus F$. We address the problem of maintaining a fault tolerant subgraph for computing *Breath First Search tree* (BFS) of the graph from a single source $s \in V$ (referred as k FT-BFS) or multiple sources $S \subseteq V$ (referred as k FT-MBFS). We simply refer to them as FT-BFS (or FT-MBFS) for $k = 1$, and dual FT-BFS (or dual FT-MBFS) for $k = 2$.

The problem of k FT-BFS was first studied by Parter and Peleg [ESA13]. They designed an algorithm to compute FT-BFS subgraph of size $O(n^{3/2})$. Further, they showed how their algorithm can be easily extended to FT-MBFS requiring $O(\sigma^{1/2}n^{3/2})$ space. They also presented matching lower bounds for these results. The result was later extended to solve dual FT-BFS by Parter [PODC15] requiring $O(n^{5/3})$ space, again with matching lower bounds. However, their result was limited to only edge failures in undirected graphs and involved very complex analysis. Moreover, their solution doesn't seems to be directly extendible for dual FT-MBFS problem.

We present a similar algorithm to solve dual FT-BFS problem with a much simpler analysis. Moreover, our algorithm also works for vertex failures and directed graphs, and can be easily extended to handle dual FT-MBFS problem, matching the lower bound of $O(\sigma^{1/3}n^{5/3})$ space described by Parter [PODC15]. The key difference in our approach is a much simpler classification of path interactions which formed the basis of the analysis by Parter [PODC15].

1 Introduction

Graph networks are extensively used to study real world applications ranging from communication networks as internet and telephony, to supply chain networks, road networks etc. Every now and then, these networks are susceptible to failures of links and nodes, which drastically affects the performance of these applications. Hence, most algorithms developed for these applications are also studied in the *fault tolerant model*, which aims to provide solutions to the corresponding problem that are resilient to such failures. Since such failures of nodes or links in the network though unpredictable are rare and are often readily repaired, the applications generally address the scenarios expecting the number of simultaneous faults to

be much smaller than the size of the network. This aspect is often modeled by bounding such failures using some parameter k (typically $k << n$), and studying fault tolerant structures resilient to upto k failures.

Among the different approaches to develop fault tolerance in a structure, we use the approach of computing a *fault tolerant subgraph* described as follows. For a given graph $G = (V, E)$, the fault tolerant subgraph for any graph problem maintains a sparse subgraph $H = (V, E')$ of G having $E' \subseteq E$, such that for any set of edge (or vertex) failures $F \subseteq E$ (or $F \subseteq V$), the solution for the graph problem on $G' = (V, E \setminus F)$ (or $G' = (V \setminus F, E)$) is maintained in its subgraph $H' = (V, E \setminus F)$ (or $H' = (V \setminus F, E)$). We shall henceforth abuse the notation to denote the graphs after such a set of failures F as $G \setminus F$ and $H \setminus F$ respectively. A standard motivation for this approach is a communication network where each link corresponds to a communication channel [16], where the system designer is required to purchase or lease the channels to be used by the application. Hence, the aim is to acquire a minimal set of these channels (the subgraph H of G) for successfully performing the application with resilience of upto k faults. Fault tolerant subgraphs are also developed for other graph problems maintaining reachability [13, 2, 3], strong-connectivity [3] and approximate shortest paths from a single source [12, 17, 5] and all sources [7, 9, 6, 14, 4].

Breadth First Search (BFS) is a fundamental technique for graph traversal. From any given source $s \in V$, BFS produces a rooted spanning tree in $O(m + n)$ time. For an unweighted graph, the BFS tree from a source s is also the shortest path tree from s because it preserves the shortest path from s to every vertex $v \in V$ that is reachable from s. We are thus interested to maintain fault tolerant subgraphs for computing BFS trees from a single source (referred as k FT-BFS) and multiple sources k FT-MBFS described as follows.

▶ **Definition 1** (k FT-BFS)**.** Given a graph $G = (V, E)$ with a designated source $s \in V$, build a subgraph $H = (V, E')$ with $E' \subseteq E$, such that after any set F of k failures in G, the BFS tree from s in $H \setminus F$ is a valid BFS tree from s in $G \setminus F$.

▶ **Definition 2** (k FT-MBFS)**.** Given a graph $G = (V, E)$ with a designated set of sources $S \subseteq V$, build a subgraph $H = (V, E')$ with $E' \subseteq E$, such that after any set F of k failures in G, for each $s \in S$ the BFS tree from s in $H \setminus F$ is a valid BFS tree from s in $G \setminus F$.

For convenience of notation, for $k = 1$ and $k = 2$ we refer to these problems as FT-BFS (or FT-MBFS) and dual FT-BFS (or dual FT-MBFS). The problems of k FT-BFS (and k FT-MBFS) were first studied by Parter and Peleg [16] for a single failure. They designed an algorithm to compute FT-BFS requiring $O(n^{3/2})$ space. Further, they showed their result can be easily extended to FT-MBFS requiring $O(\sigma^{1/2}n^{3/2})$ space. Moreover, their upper bounds were complemented by matching lower bounds for both their results. This result was later extended to address dual FT-BFS by Parter [15] requiring $O(n^{5/3})$ space. However, the application of this result was limited to only edge failures in undirected graphs. Though the analysis of their result was significantly complex, it paved a way for developing the theory studying the interaction of replacement paths after a single edge failure, their classification and corresponding properties. Further, they also generalized the lower bound for k FT-MBFS to $\Omega(\sigma^{\frac{1}{k+1}}n^{2-\frac{1}{k+1}})$ which matches their solution for dual FT-BFS. They also stated extensions of their result to dual FT-MBFS (or k FT-BFS) as an open problem.

The difference in complexity of dual FT-BFS over FT-BFS also reinforces the idea that extending such results from one failure to two failures (and beyond) requires a significantly more advanced analysis. As described by Parter [15], for the problem of maintaining shortest paths *"a sharp qualitative and quantitative difference"* has been widely noted while handling a single failure and multiple failures. For the problem of maintaining fault tolerant distance

oracles, despite a simple and elegant algorithm for a single edge failure [8], the solution for two edge failures [10] is significantly complex. In fact, the authors [10] themselves mention that extending their approach beyond 2 edge failure would be infeasible due to numerous case analysis involved, requiring a fundamentally different approach. This key difference is also visible when we compare other problems, as bi-connectivity with tri-connectivity, single fault tolerant reachability [13, 2] with dual fault tolerant reachability [3], etc. Hence, simplifying the analysis of dual FT-BFS (and hence dual FT-MBFS) structures seem to be an essential building block for further developments of the problem for multiple failures.

1.1 Our Contributions

We design optimal algorithms for constructing dual FT-BFS and dual FT-MBFS structures. In principle, the core algorithm of our construction for dual FT-BFS is same as the one given by Parter [15], with a much simpler and more powerful analysis. As a result, our algorithm also works for vertex failures and directed graphs. Also, our dual FT-BFS structure can also be easily extended to handle dual FT-MBFS (as in case of FT-BFS [16]), which matches the lower bound described by Parter [15]. Thus, we optimally solve two open problems (dual FT-BFS for directed graphs and dual FT-MBFS for any graphs) as follows.

▶ **Theorem 3** (Optimal dual FT-BFS). *Given any graph $G = (V, E)$ having n vertices and m edges, with a designated source $s \in V$, there is a polynomial time constructable dual FT-BFS subgraph H having $O(n^{5/3})$ edges.*

▶ **Theorem 4** (Optimal dual FT-MBFS). *Given any graph $G = (V, E)$ having n vertices and m edges, with a designated set of σ sources $S \subseteq V$, there is a polynomial time constructable dual FT-MBFS subgraph H having $O(\sigma^{1/3} n^{5/3})$ edges.*

Our analysis is performed using simple techniques based on *counting arguments*. We classify a set of shortest paths as *standard* paths and prove the properties of *disjointness* and *convergence* for a designated suffix of such paths. The extension to directed graphs additionally uses the notion of *segmentable* paths (similar notion of *regions* was used in [15]) for every set of *converging* shortest paths, and establishes several interesting properties for them. These properties and analysis techniques might be of independent interest in the theory of shortest paths.

1.2 Related Work

As described earlier BFS is strongly related to shortest paths. Demetrescu et al. [8] showed that there exist weighted directed graphs, for which a fault tolerant subgraph requires $\Theta(m)$ edges for maintaining shortest paths even from a single source after a vertex failure. Hence, they designed a data-structure of size $\tilde{O}(n^2)$ [1] that reports all pairs shortest distances after a vertex failure in $O(1)$ time. Duan and Pettie [10] extended this result to two failures requiring nearly same (upto $poly \log n$ factors) size and reporting time.

Other related problems include fault tolerant DFS and fault tolerant reachability. Baswana et al. [1] presented a $\tilde{O}(m)$ sized fault tolerant data structure that reports the DFS tree of an undirected graph after k faults in $\tilde{O}(nk)$ time. For single source reachability, Baswana et al. [3] presented an algorithm for computing fault tolerant reachability subgraphs for k faults using $O(2^k n)$ edges. This result was also shown to be optimal upto constant factors.

[1] $\tilde{O}(\cdot)$ notation hides poly-log(n) factors

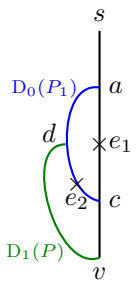

Figure 1 Showing P_0 (in black), $\mathrm{D}_0(P_1)$ (in blue) and $\mathrm{D}_1(P)$ (in green). Here $P_1 = P_0[s,a] \cup \mathrm{D}_0(P_1) \cup P_0[c,v]$ and $P = P_0[s,a] \cup \mathrm{D}_0(P_1)[a,d] \cup \mathrm{D}_1(P)$.

1.3 Outline of the paper

We now present a brief outline of our paper. In Section 2, we present the basic notations that shall be used throughout the paper, which shall be followed by a brief overview of our approach and analysis in Section 3. In Section 4, we shall first begin with the description of our algorithm for dual FT-BFS and the properties of the shortest paths found using it, which shall be followed by the formal analysis. We then present our algorithm for dual FT-MBFS and its analysis, drawing similarities with solution of dual FT-BFS. Finally, we present the concluding remarks for our paper in Section 6. Due to page constraints some proofs have been omitted and deferred to the full paper [11]. For the sake of simplicity, we only describe our algorithm and analysis for edge failures. However, the same analysis can also be used to handle vertex failures.

2 Preliminaries

Given a graph $G = (V, E)$ with n vertices and m edges with a set of designated source $s \in S$. The following notations shall be used throughout the paper.

- $P, \mathcal{P}$: A path is denoted by P, where $Source(P)$ and $Dest(P)$ represents the source and destination of path P. In most parts of the paper, $Source(P) = s$ and $Dest(P) = v$. A set of paths is denoted by $\mathcal{P}$. Generally, we assume a path from s to v starts from the top (s) and ends at bottom (v). For two paths P', P'', we say P' leaves *earlier/higher* (or *later/lower*) than P'' from P, if P' leaves P closer to s (or closer to v) than P''.
- $\mathrm{F}(P)$: For the shortest path P from $Source(P)$ to $Dest(P)$ after a set of edge failures, this set of failed edges is denoted by $\mathrm{F}(P) = \{e_1, e_2, \ldots, e_k\}$ (say), where e_i denotes the i^{th} edge in the sequence. Similarly for some path P', e'_i denotes the i^{th} edge in the sequence.
- P_i: If $\mathrm{F}(P) = \{e_1, e_2, \ldots, e_k\}$, then P_i is the shortest path avoiding the first i edge of $\mathrm{F}(P)$, i.e., $\mathrm{F}(P_i) = \{e_1, e_2, \ldots, e_i\}$, where $0 \leq i < k$. Again, for most parts of the paper, P_0 denotes the shortest path from s to v in G.
- $\mathrm{D}_i(P)$: If $|\mathrm{F}(P)| = k$, the detour path of P from P_i, $\mathrm{D}_i(P) = P \setminus \{\cup_{j=0}^{i} P_j\}$ [2], where $1 \leq i < k-1$. For dual case, $D_0(P)$ is the detour of P from P_0, $\mathrm{D}_1(P)$ is the detour of P from P_1, and $\mathrm{D}_0(P_1)$ is the detour of P_1 from P_0 (See Figure 1).
- $LastE(P)$: The last edge of a path P.
- $P[x, y]$: The sub-path of P starting from x to y, where $x, y \in P$.

[2] This construction may give a set of disjoint subpaths of P instead of a single subpath. However, in most cases this path will be a single subpath, else we assume $\mathrm{D}_i(P)$ to be the last such subpath on P.

We define the property of *convergence* of a set of paths $\mathcal{P}$ as follows. The paths in $\mathcal{P}$ are said to be *converging* if on intersection of any two paths $P, P' \in \mathcal{P}$, both P and P' merge and do not diverge till the end of the paths.

3 Overview

For analyzing the size of dual FT-BFS subgraph, i.e., the number of edges in shortest paths from the source s to each vertex $v \in V$ after any two failures, it suffices to count only the last edge of every such path P, for each $v \in V$ [16, 15]. The novelty of our approach is the classification of such paths based on interaction of corresponding P_1 and P_0, whereas Parter [15] studied the different interactions of P_1 and P'_1, for two such paths P and P'.

We primarily use the disjointness of a designated suffix of such a path P (referred as $LastLeg(P)$) with *counting* arguments to bound the number of such paths. To achieve this, we classify some of these paths as *standard paths* based on the interactions of corresponding P_1 and P_0. The number of *non-standard* paths can be easily bound using simple *counting* arguments. The set of *standard* paths exhibit several interesting properties including convergence of corresponding paths $\mathrm{D}_0(P_1)$. We further classify the *standard* paths into *long standard* paths and *short standard* paths, each bounded separately using relatively harder techniques. For sake of easier presentation we first bound the number of *short standard* paths only for undirected graphs, with extension to directed graphs requiring an additional notion of *segmentable* paths. The only difference in the analysis of dual FT-MBFS is the definition of *standard* paths and dealing with interaction of P_1 with P'_0 corresponding to other sources.

4 Dual FT-BFS

We shall now describe our algorithm to compute sparse dual FT-BFS subgraph H from a source $s \in V$. For every vertex $v \in V$, our algorithm computes the shortest paths from s to v avoiding upto two failures and adds the last edge of each such path to the adjacency list of vertex v. Note that repeating the procedure for each vertex on such a path adds the entire path to H [16, 15].

Our algorithm starts by adding the shortest path between s and v, i.e., P_0. It then processes single edge failures on P_0. We then find the replacement path P for all two edge failures $\{e_1, e_2\}$ such that $e_1 \in P_0$ and $e_2 \in P_1$. Further, in case $e_2 \in P_0 \cap P_1$ then e_1 is higher than e_2 on P_0.

However, we want to process all the failures in some particular order. This ordering plays a crucial role in the analysis. To this end, we define this ordering π as follows. The first failure in π is $F = \emptyset$, which adds P_0. The ordering π then contains single edge failures of type $F = \{e\}$ (where $e \in P_0$), ordered by their decreasing distance from s on P_0. Finally, we order the remaining failures as follows: for any two failures $F = \{e_1, e_2\}$ and $F' = \{e'_1, e'_2\}$ (with corresponding replacement paths P and P'), $F \prec_\pi F'$ if either (1) e_1 is farther than e'_1 from s on P_0, or (2) $e_1 = e'_1$ and e_2 is farther than e'_2 from s on P_1 (note that $P_1 = P'_1$ in this case). If $F \prec_\pi F'$, F is said to be *lower* than F' in π.

For any failure of $F = \{e_1, \cdots, e_k\}$, we define the *preferred* shortest path avoiding F. Our preferred shortest path will be a path of shortest length avoiding F. However, there can be multiple such paths of same length. We use following rules to choose a unique preferred path.

Procedure Dual-FT-BFS(s, v, π): Augments the dual FT-BFS subgraph H, such that for BFS tree of G rooted at s after any two edge failures in G, the incoming edges to v are preserved in H.

```
1 foreach Failure F, where 0 ≤ |F| ≤ 2, ordered from lower to higher in π do
2     P ← Preferred path from s to v in G avoiding F;
3     if LastE(P) ∉ H then
4         Assign P for failure of F;
5         Add LastE(P) to H;
6     end
7 end
```

▶ **Definition 5.** Path P is **preferred** for failure of $\{e_1, \cdots, e_k\}$ where each $e_i \in P_{i-1}$, if

1. For each i, P leaves P_{i-1} before e_i exactly once.
2. For any other P' also avoiding $\{e_1, \cdots, e_i\}$, we have either (i) $|P| < |P'|$, (ii) $|P| = |P'|$, and for some $0 \leq i \leq k$, both P and P' leaves each of $P_0, ..., P_{i-1}$ at the same vertex, but P leaves P_i earlier than P', (iii) P is lexicographically smaller [3] than P'.

Intuitively, out of all the shortest paths avoiding F (say for $|F| = 2$), the preferred path leaves the path P_0 and/or P_1 as early as possible. In order to avoid the preferred path leaving P_0 (or P_1) multiple times just to achieve an earlier point of divergence from P_0 (or P_1), the first condition is imposed. The last condition in (2) is just to break ties between two paths that are of same length and leave P_0 and P_1 at the same vertex.

Finally, in order to add the preferred shortest path P avoiding a failure F, our algorithm simply adds $LastE(P)$ to H, which suffices to add the entire path as described earlier. Moreover, we also assign the corresponding P to the failure F if it was the first failure to add this edge in H. As a result, if P and P' are two preferred paths avoiding F and F' respectively where $LastE(P) = LastE(P')$, then if $F \prec_\pi F'$, only the path P shall be assigned to F. Refer to Procedure Dual-FT-BFS for the pseudocode of our algorithm.

In order to calculate the size of H, it is sufficient to analyze the number of different last edges added on each $v \in V$ in H. Let the set of all paths from s to v avoiding failures $F \subseteq E$ (where $|F| \leq 2$) be $\mathcal{P}_v$. We thus define the paths that will be counted for establishing the space bound as follows.

▶ **Definition 6.** The path $P \in \mathcal{P}_v$ is called *contributing* if while processing $\mathrm{F}(P)$, $LastE(P) \notin H$, i.e., P adds a new edge adjacent to v in H.

In order to count the number of contributing paths to a vertex v, we only need to consider its interactions with other contributing paths in $\mathcal{P}_v$. This is because, if any other path $P \in \mathcal{P}_x$ passes through v using some new edge, so does the corresponding $P' \in \mathcal{P}_v$ with $\mathrm{F}(P) = \mathrm{F}(P')$. Thus, to analyze the size of H, it suffices to look at last edges of the contributing paths in $\mathcal{P}_v$ for each vertex v separately.

[3] Let P and P' first diverge from each other to $x \in P$ and $x' \in P'$ respectively, i.e., $P[s, x] \setminus \{x\} = P'[s, x'] \setminus \{x'\}$. If the index of x is lower than that of x' then P is said to be *lexicographically smaller* than P'.

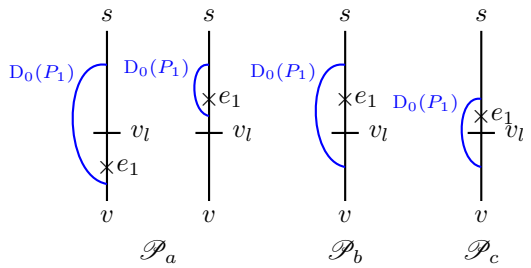

Figure 2 Classification of contributing paths: $\mathscr{P}_a$: Non-Standard Paths, $\mathscr{P}_b$: Long Standard Paths and $\mathscr{P}_c$: Short Standard Paths.

4.1 Properties of contributing paths

Parter [15] presented a simple proof bounding the number of contributing paths avoiding multiple failures on P_0 to $O(\sqrt{n})$ for each vertex v (an alternate proof using *counting arguments* is presented in the full paper [11]). Hence, excluding these paths, every contributing path satisfies the following properties (see full paper [11] for proofs).

▶ **Lemma 7.** *Excluding $O(\sqrt{n})$ paths, each contributing path P from s to v avoiding $\{e_1, e_2\}$ satisfies following properties*

$\mathbb{P}_1$: *$e_1 \in P_0$ and $e_2 \in \mathrm{D}_0(P_1)$.*

$\mathbb{P}_2$: *Except at v, $\mathrm{D}_0(P)$ does not intersect with P_0 and $\mathrm{D}_1(P)$ does not intersect with P_1, after diverging from P_0 and P_1 respectively.*

$\mathbb{P}_3$: *For any path P' which avoids $\{e_1, e_2\}$, P is the preferred path over P'.*

$\mathbb{P}_4$: *If P also avoids some failure F' where $F' \prec_\pi F$, then there exist another path P' which is the preferred path for F' over P, where P' does not avoid F.*

4.2 Space Analysis

As described earlier, in order to bound the size of dual FT-BFS subgraph to $O(n^{5/3})$, it suffices to bound the number of *contributing* paths from s to each vertex $v \in V$ avoiding two edge failures to $O(n^{2/3})$. Further, using $\mathbb{P}_1$ we are only concerned with a contributing path P if $e_1 \in P_0$ and $e_2 \in \mathrm{D}_0(P_1)$.

We first divide the path P_0 into two parts as follows. Let $v_l \in P_0$ be the vertex such that $|P_0[v_l, v]| = n^{1/3}$. We define $P_{high} = P_0[s, v_l]$ and $P_{low} = P_0[v_l, v]$. If $|P_0| < n^{1/3}$, we assume $v_l = s$ where $P_{high} = \phi$. We shall now define the *standard paths* as follows.

▶ **Definition 8** (Standard Paths)**.** A contributing path P is called a *standard path* if (a) $e_1 \in P_{high}$, and (b) $\mathrm{D}_0(P_1)$ merges with P_0 on P_{low}, i.e., $Dest(\mathrm{D}_0(P_1)) \in P_{low}$.

We can thus classify the contributing paths into following three types (see Figure 2):

$\mathscr{P}_a$: Non-standard paths.

$\mathscr{P}_b$: Long standard paths, i.e., standard paths with $|\mathrm{D}_0(P_1)| \geq n^{2/3}$.

$\mathscr{P}_c$: Short standard paths, i.e., standard paths with $|\mathrm{D}_0(P_1)| < n^{2/3}$.

Clearly, the sets $\mathscr{P}_a$, $\mathscr{P}_b$ and $\mathscr{P}_c$ are mutually disjoint and collectively exhaustive. Further, we define a set $\mathscr{P}_{1x}$ (for $x = a, b$ and c), where for each $P \in \mathscr{P}_x$, we add the corresponding P_1 to $\mathscr{P}_{1x}$. In addition, we identify the disjoint suffix of a path P as follows (see Figure 3).

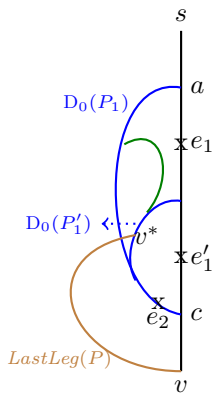

Figure 3 P avoids $\{e_1, e_2\}$. Its detour $D_1(P)$ (shown in blue) last intersects $LastPath(P) = P_1'$. P diverges from P_1' at v^*, i.e., $LastLeg(P) = P[v^*, v]$ (shown in brown).

▶ **Definition 9.** For each $P \in \mathscr{P}_x$, for $x = a, b$ or c, we define the following

1. $LastPath(P)$: The path in $\mathscr{P}_{1x}$ that intersects last with P. If P diverges from P_0 and does not intersect any path in $\mathscr{P}_{1x}$, we set $LastPath(P) = P_0$.
2. $LastLeg(P)$: The part of P after diverging from $LastPath(P)$, i.e., $P[v^*, v]$, where v^* is the last vertex of P on $P \cap LastPath(P)$.

The suffix $LastLeg(P)$ of a contributing path P satisfies the following properties (see full paper [11] for proofs).

▶ **Lemma 10.** *For every set $\mathscr{P}_x$ (for $x = a, b$ or c), we have the following.*

(a) *For any $P, P' \in \mathscr{P}_x$, $LastLeg(P)$ and $LastLeg(P')$ are disjoint (except at v), i.e., $LastLeg(P) \cap LastLeg(P') = \{v\}$. Further, each P, P' starts from a distinct vertex on $\mathscr{P}_{1x}$.*

(b) *Number of paths $P \in \mathscr{P}_x$ with $|LastLeg(P)| > n^{1/3}$ or $LastPath(P) = P_0$, is $O(n^{2/3})$.*

Remark: Lemma 102 claims that $LastLeg(P)$ is disjoint from other $LastLeg(P')$, where $P \in \mathscr{P}_x$ and $P' \in \mathscr{P}_{x'}$ only when $x = x'$. However, in case $x \neq x'$ they can intersect and our proof does not require their disjointness.

Equipped with these properties we can easily analyze the number of *non-standard paths* ($\mathscr{P}_a$) and *standard paths* ($\mathscr{P}_b$ and $\mathscr{P}_c$) in the following sections.

4.2.1 Analyzing non-standard paths $\mathscr{P}_a$

Using Lemma 102, we know that the number of $P \in \mathscr{P}_a$ with $|LastLeg(P)| > n^{1/3}$ or $LastPath(P) = P_0$ is $O(n^{2/3})$. We now focus on the case when $|LastLeg(P)| \leq n^{1/3}$ and $LastPath(P) \in \mathscr{P}_{1a}$. For any path P, let $v^* = Source(LastLeg(P))$. Since $LastLeg(P)$ is a detour from $LastPath(P)[v^*, v]$ avoiding the entire P_0 (using $\mathbb{P}_2$), we have $|LastPath(P)[v^*, v]| \leq |LastLeg(P)| \leq n^{1/3}$. By definition, a contributing path P is *non-standard* if either (a) $e_1 \in P_{low}$, or (b) $D_0(P_1)$ merges with P_0 on P_{high}, i.e., $Dest(D_0(P_1)) \in P_{high}$. Hence, for every P, $LastPath(P)$ would correspond to one of the two cases (a) or (b). Case (b) is clearly not be applicable here because $|LastPath(P)[v^*, v]| \geq |P_{low}| = n^{1/3}$ (since $Dest(LastPath(P)) \in P_{high}$). For case (a), on each $LastPath(P) \in \mathscr{P}_{1a}$, v^* can be one of $n^{1/3}$ vertices of $LastPath(P)$ closest to v. Further, since $e_1 \in P_{low}$, there are only $n^{1/3}$ such paths in $\mathscr{P}_{1a}$ because each such path corresponds to failure of unique edge in P_{low}. Thus,

there are only $n^{1/3} \times n^{1/3} = n^{2/3}$ different vertices v^* limiting the number of $P \in \mathscr{P}_a$ with $|LastLeg(P)| \leq n^{1/3}$ to $O(n^{2/3})$ (using Lemma 101).

Properties of standard paths ($\mathscr{P}_b$ or $\mathscr{P}_c$)

We shall now prove two important properties of standard paths (see full paper [11] for proofs). The first result states that if $\mathrm{D}_0(P_1)$ and $\mathrm{D}_0(P_1')$ intersect, where $P, P' \in \mathscr{P}_{1b} \cup \mathscr{P}_{1c}$, then they cannot diverge. The second result states that the length of paths in $\mathscr{P}_b \cup \mathscr{P}_c$ are different. A similar result was proved by Parter[15].

▶ **Lemma 11.** *For the set of contributing* standard *paths, we have the following properties.*

(a) *The set of paths* $\{\mathrm{D}_0(P_1) | P_1 \in \mathscr{P}_{1b} \cup \mathscr{P}_{1c}\}$*, is converging.*

(b) *(Parter [15]) For any two paths* $P, P' \in \mathscr{P}_b \cup \mathscr{P}_c$*,* $|P| \neq |P'|$*.*

4.2.2 Analyzing long standard paths $\mathscr{P}_b$

We first prove a generic technique to bound the number of contributing paths P if the set of corresponding paths P_1 is converging and each P_1 sufficiently long.

▶ **Theorem 12.** *Given a set* $\mathcal{P}$ *of converging paths satisfying Lemma 101, where for each* $P_1 \in \mathcal{P}$ *we have* $|P_1| \geq \alpha^2$ *(where* $\alpha \geq 1$*), the number of contributing paths* P *having* $P_1 \in \mathcal{P}$ *is* $O(n/\alpha)$*.*

Proof. Recall the definition of $LastPath(P)$, here we shall define $LastPath(P)$ (and hence $LastLeg(P)$) corresponding to paths in $\mathcal{P}$ (rather than $\mathscr{P}_{1x}$ in Definition 9). Using Lemma 101, if $|LastLeg(P)| \geq \alpha$, then P can be associated with α unique vertices of $LastLeg(P)$. This limits the total number of such paths to $O(n/\alpha)$. Hence, we assume that $LastLeg(P)) \leq \alpha$.

For each path $P_1 \in \mathcal{P}$, let $v_l = Dest(P_1)$. Similarly, for each such P, let the last intersection vertex of $LastLeg(P)$ and $LastPath(P)$ be v^*. Using Lemma 101, we know that for each such contributing path P, its corresponding $LastLeg(P)$ starts from a distinct vertex of $\mathcal{P}$. Since $LastLeg(P)$ is a detour from $LastPath(P)[v^*, v_l]$ avoiding the entire P_1 (using $\mathbb{P}_2$), we have $|LastLeg(P)| \geq |LastPath(P)[v^*, v_l]|$. Since $|LastLeg(P)| \leq \alpha$, v^* can be one of α vertices of $LastPath(P)$ closest to v_l.

We shall associate each such vertex v^* on $LastPath(P) \in \mathcal{P}$ uniquely with α vertices of $LastPath(P)$, for all $LastPath(P) \in \mathcal{P}$, as follows. Let the vertices of some $LastPath(P)$ be $v_1, ..., v_k$ where v_1 is the closest vertex to v_l. For each v_i, $i = 1, ..., \alpha$, we associate the vertices $v_{(i-1)\alpha}, ..., v_{i\alpha}$. Since $|LastPath(P)| \geq \alpha^2$ (by definition of $\mathcal{P}$) and $i \in [1, \alpha]$ such an association can be made. Now, in order to prove that such an association is unique, i.e., a vertex x is not associated with two different vertices v_1^*, v_2^* of $\mathcal{P}$, we exploit the convergence of $\mathcal{P}$ as follows. Clearly if $x \in P_1$ for a unique path $P_1 \in \mathcal{P}$, there is a unique $v_1^* \in \mathcal{P}$ to which it is associated. However, if $x \in P_1$ and $x \in P_1'$ for any two paths $P_1, P_1' \in \mathcal{P}$, then P_1 and P_1' will not diverge after intersection (by convergence of $\mathcal{P}$). This implies $P_1[x, v_l] = P_1'[x, v_l']$. Thus, the corresponding $v_1^* \in P_1$ and $v_2^* \in P_1'$ would also be same as by definition $v_1^* \in P_1[x, v_l]$. Hence, for every P emerging from v^* with $|LastPath(P)[v^*, v_l]| \leq \alpha$, the corresponding v^* can be uniquely associated with at least α vertices of $\mathcal{P}$. This limits the total number of such paths to $O(n/\alpha)$ proving the theorem. ◀

Using Lemma 111 and by definition of long standard paths $\mathscr{P}_b$, Theorem 12 is applicable for the set $\mathrm{D}_0(P_1)$ for $P_1 \in \mathscr{P}_{1b}$ and $\alpha = n^{1/3}$ limiting the number of paths in $\mathscr{P}_b$ to $O(n^{2/3})$.

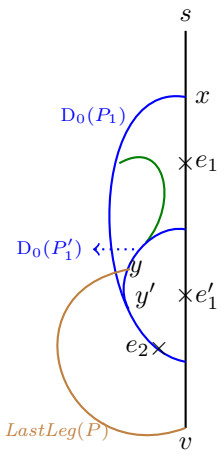

Figure 4 Let P_1' be $LastPath(P)$. Then the path $P_0[s,x] \cup P_1[x,y'] \cup P_1'[y',y] \cup LastLeg(P)$ is a valid path avoiding $\{e_1, e_2\}$.

4.2.3 Analyzing short standard paths $\mathscr{P}_c$

To highlight the simplicity of our approach, we only analyze the paths in $\mathscr{P}_c$ for undirected graphs here. For extension of this proof to handle directed graphs we use the theory of *segmentable paths* (refer to full paper [11] for details).

Using Lemma 102, we know that the number of $P \in \mathscr{P}_c$ with $|LastLeg(P)| > n^{1/3}$ or $LastPath(P) = P_0$ is $O(n^{2/3})$. We now focus on the case when $|LastLeg(P)| \leq n^{1/3}$ and $LastPath(P) \in \mathscr{P}_{1c}$. Any such contributing path P can be divided into two parts (see Figure 4), (a) $P[s,y]$, where $y = Source(LastLeg(P))$, and (b) $P[y,v] = LastLeg(P)$. We will now find an alternate path for $P[s,y]$, which will help us in bounding its length. Since P is a contributing path, it diverges from $LastPath(P)$ which requires either e_1 or e_2 to be on $LastPath(P)[y,v]$. By definition of *standard paths*, we have $D_0(LastPath(P))$ terminates on P_0 only on P_{low}, whereas $e_1 \notin P_{low}$ ensuring that $e_1 \notin LastPath(P)$. Thus, $e_2 \in LastPath(P)[y,v]$ and hence it intersects with P_1 as $e_2 \in P_1$. Using Lemma 111, we can thus say that $LastPath(P)$ and P_1 merge at some vertex say y', where $e_2 \in LastPath(P)[y',v] = P_1[y',v]$ (see Figure 4). We have an alternate path for $P[s,y]$ avoiding $F(P)$ formed by $P_1[s,y'] \cup LastPath(P)[y',y]$. Let $x = Source(D_0(P_1))$. Since $P[s,v]$ is the shortest path avoiding $F(P)$ we have

$$\begin{aligned}
|P| &= |P[s,y]| + |P[y,v]| \\
&= |P_1[s,y]| + |P[y,v]| \\
&\leq |P_1[s,y']| + |LastPath(P)[y',y]|) + |LastLeg(P)[y,v]| \\
&= (|P_1[s,x]| + |P_1[x,y']|) + |LastPath(P)[y',y]| + |LastLeg(P)[y,v]| \\
&\leq |P_0| + |D_0(P_1)| + |D_0(LastPath(P))| + |LastLeg(P)| \\
&\leq |P_0| + n^{2/3} + n^{2/3} + n^{1/3} \qquad \text{(by definition of } \mathscr{P}_c\text{)}
\end{aligned}$$

Now, using Lemma 112, we know that for any $P, P' \in \mathscr{P}_c$ we have $|P| \neq |P'|$. We thus arrange the paths in $\mathscr{P}_c$ (except the ones in Lemma 102) in the increasing order of sizes, where i^{th} such path has the length $\geq |P_0| + i$ (as all paths at least as long as P_0). Since for any such $P \in \mathscr{P}_c$ we also have $|P| \leq |P_0| + 3n^{2/3}$ (described above), clearly the number of paths in $\mathscr{P}_c$ are $O(n^{2/3})$ (for i upto $3n^{2/3}$).

Procedure Dual-FT-MBFS(S,v,π): Augments the dual FT-MBFS subgraph H, such that for BFS tree of G rooted at each $s \in S$ after any two edge failures in G, the incoming edges to v are preserved in H.

1 **foreach** $s \in S$ **do** Dual-FT-BFS(s,v,$\pi_s(0)$) ;
2 **foreach** $s \in S$ **do** Dual-FT-BFS(s,v,$\pi_s(1)$) ;
3 **foreach** $s \in S$ **do** Dual-FT-BFS(s,v,$\pi_s(2)$) ;

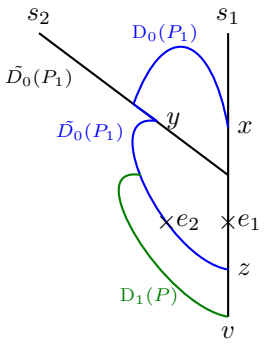

Figure 5 Shortest path avoiding $\{e_1, e_2\}$ is P. $D_1(P)$ last intersects $\tilde{P}_0(P_1) = P_0(s_2, v)$. P_1 diverges from $\tilde{P}_0(P_1)$ at y, i.e., $\tilde{D}_0(P_1) = P_1[y, z]$ (shown in blue). P also diverges from $\tilde{P}_0(P)$ at y, i.e., $\tilde{D}_0(P) = P[y, v]$.

This completes the proof of our dual FT-BFS result in Theorem 3.

5 Extension to dual FT-MBFS

In this section we shall extend our analysis of the previous section to handle σ sources using total $O(\sigma^{1/3}n^{5/3})$ space. We follow the approach similar to the case for single source. Let S be the set of sources, where $|S| = \sigma$. Given a source s, let $\pi_s \subseteq \pi$ denote the ordering of edge failure of size upto 2. Let $\pi_s(0), \pi_s(1)$ and $\pi_s(2)$ be the subset of π_s of size 0, 1 and 2 respectively. Our algorithm for finding dual FT-MBFS mimics the single source case.

The first for loop in the above procedure finds shortest path from each source to v. We shall refer to the set of the shortest paths from each source to v for different $s \in S$ as $\mathscr{P}_0$. We then move on to find the shortest path from each source to v avoiding one edge failure and two failures respectively.

In the previous section, for each contributing path P (that avoids ≥ 1 failure), we saw that it necessarily diverges from P_0. Since we have multiple paths in $\mathscr{P}_0$, we define some new notations (see Figure 5).

▶ **Definition 13** (Modified P_0 and $D_0(P)$).

1. For any path P (or its corresponding P_1), we define $\tilde{P}_0(P)$ (or $\tilde{P}_0(P_1)$) to be the last path from $\mathscr{P}_0$ which intersects with P (or P_1), say at vertex y, such that at least one of e_1 or e_2 is present in $\tilde{P}_0(P)[y, v]$ (or $e_1 \in \tilde{P}_0(P_1)[y, v]$).
2. For any path P (or P_1), we define $\tilde{D}_0(P) = P[v^*, v]$ (or $\tilde{D}_0(P_1) = P_1[v_0^*, v]$), where v^* is the last vertex of P (or P_1) on $P \cap \tilde{P}_0(P)$ (or $P_1 \cap \tilde{P}_0(P_1)$).

Note that in the single source case, both P and P_1 diverge from the same path P_0. However, in multiple source that path $\tilde{P}_0(P)$ and $\tilde{P}_0(P_1)$ may differ. This is one of the

major changes from the single source case. In fact, the reader will see that all our lemmas in Section 4 extend here with P_0 changed to $\tilde{P}_0(P)$ and $\mathrm{D}_0(P)$ changed to $\tilde{D}_0(P)$. However, for completeness we have re-proven all lemmas.

5.1 Properties of Contributing paths

We now describe important properties of paths in $\mathscr{P}_0$ and contributing paths as follows (see full paper [11] for proofs).

▶ **Lemma 14.** *The set of paths $\mathscr{P}_0$ is converging.*

The number of contributing paths avoiding failures in $\mathscr{P}_0$ can easily bounded to $O(\sqrt{\sigma n})$ for each v (see full paper [11] for details). Excluding these paths, every contributing path satisfies the following properties.

▶ **Lemma 15.** *Excluding $O(\sqrt{\sigma n})$ paths, for any contributing path P from s to v avoiding $\{e_1, e_2\}$, the following properties holds true*
$\mathbb{P}_1$ **:** *$e_1 \in P_0$ and $e_2 \in \mathrm{D}_0(P_1)$.*
$\mathbb{P}_2$ **:** *$\tilde{D}_0(P)$ does not intersect with any path in $\mathscr{P}_0$. Also, if $\tilde{D}_0(P)$ diverges from P_1 it does not intersect it again.*

5.2 Space Analysis

As described earlier, in order to bound the size of dual FT-MBFS subgraph to $O(\sigma^{1/3}n^{5/3})$, it suffices to bound the number of *contributing* paths from $s \in S$ to each vertex $v \in V$ avoiding two edge failures to $O(\sigma^{1/3}n^{2/3})$. Further, using $\mathbb{P}_1$ we are only concerned with a contributing path P if $e_1 \in P_0$ and $e_2 \in \mathrm{D}_0(P_1)$. For the sake of highlighting similarity with single source case, we shall use $n_\sigma = n/\sigma$ throughout the section.

We first divide the paths in $\mathscr{P}_0$ into two parts as follows. For each $s \in S$, let $P_0(s, v)$ be the shortest path from s to v. Let v_{ls} be the vertex such that $|P_0(s, v)[v_{ls}, v]| = n_\sigma^{1/3}$. We define $\mathcal{P}_{low} = \{P_0(s, v)[v_{ls}, v] \mid s \in S\}$ and $\mathcal{P}_{high} = \{P_0(s, v)[s, v_{ls}] \mid s \in S\}$. This definition naturally extends the P_{low} and P_{high} defined in the single source case.

With this modified $\mathcal{P}_{low}$ and $\mathcal{P}_{high}$, we use the same definition of *standard paths* and hence $\mathscr{P}_a$ and $\mathscr{P}_{1a}$. However, the distinction of *long standard paths* ($\mathscr{P}_b$) from *short standard paths* ($\mathscr{P}_c$) would now be done by using $\tilde{D}_0(P_1)$ instead of $D_0(P_1)$. Hence, the *long standard paths* would be the standard paths with $|\tilde{D}_0(P_1)| \geq n_\sigma^{2/3}$. Finally, the definition of $LastPath(P)$ and $LastLeg(P)$ does not change, except in case $LastPath(P) = \phi$, we use $LastPath(P) = \tilde{P}_0(P)$ instead of $LastPath(P) = P_0$ (recall Definition 9). Moreover, the properties of $LastLeg(P)$ also remain same except for Lemma 102 which is modified as follows.

▶ Lemma 10. For every set $\mathscr{P}_x$ (for $x = a, b$ or c), we have the following.
b^***.** Number of paths $P \in \mathscr{P}_x$ with $|LastLeg(P)| > n_\sigma^{\frac{1}{3}}$ or $LastPath(P) = \tilde{P}_0(P)$, is $O(\sigma^{\frac{1}{3}} n^{\frac{2}{3}})$.

Now, using the properties described in Lemma 10 (see full paper [11] for proof), we can analyze the number of *non-standard paths* ($\mathscr{P}_a$) using the same *counting arguments* as in case of single source, bounding the number of such paths to $O(\sigma^{1/3}n^{2/3})$ (see full paper [11] for details). Hence, we only focus on analyzing the *standard paths* ($\mathscr{P}_b$ and $\mathscr{P}_c$) as follows.

Properties of standard paths ($\mathscr{P}_b$ and $\mathscr{P}_c$)

Recall the properties of *standard paths* described in Lemma 11. For multiple sources, Lemma 111 does not hold, because for two paths P and P', their corresponding paths $\mathrm{D}_0(P_1)$

and $\mathrm{D}_0(P_1')$ can diverge after intersection, if they start from different sources say s_1, s_2 (for $s_1 = s_2$, Lemma 111 applies). For example (see Figure 5), P_1 avoids e_1 on $P_0[s_1, v]$. Also, $\mathrm{D}_0(P_1)$ passes through $P_0[s_2, v]$. Let P_1' be a path avoiding e_1' on $P_0[s_2, v] \cap P_1$, such that $\mathrm{D}_0(P_1')$ intersect $\mathrm{D}_0(P_1)$ before $\mathrm{D}_0(P_1)$ enters $P_0[s_2, v]$. Hence, $\mathrm{D}_0(P_1')$ has to diverge from $\mathrm{D}_0(P_1)$ as $\mathrm{D}_0(P_1)$ passes through e_1' after the intersection.

This is the primary reason for defining *modified detour* $\tilde{D}_0(P_1)$, for which a lemma equivalent to Lemma 111 holds. Thus, the analysis of *standard paths* for multiple sources, uses $\tilde{D}_0(P_1)$ instead of $D_0(P_1)$ satisfying the following properties.

▶ **Lemma 16.** *For the set of contributing* standard *paths, we have the following properties.*

(a) *The set of paths* $\{\tilde{D}_0(P_1) | P_1 \in \mathscr{P}_{1b} \cup \mathscr{P}_{1c}\}$*, is converging.*

(b) *The number of paths* $P \in \mathscr{P}_b \cup \mathscr{P}_c$*, which* $Source(LastLeg(P)) \notin \tilde{D}_0(P_1')$ *for some* $P_1' \in \mathscr{P}_{1b} \cup \mathscr{P}_{1c}$ *are* $O(\sigma^{1/3} n^{2/3})$*.*

Using Lemma 162, we only have to bound the number of *standard paths* whose $LastLeg(P)$ originates from some $\tilde{D}_0(P_1')$. Using Lemma 10$b^*$and by definition of long standard paths $\mathscr{P}_b$, Theorem 12 is applicable for the set $\tilde{D}_0(P_1)$ for $P_1 \in \mathscr{P}_{1b}$ and $\alpha = n_\sigma^{1/3}$, bounding number of such paths in $\mathscr{P}_b$ to $O(\sigma^{1/3} n^{2/3})$. This leaves only the number of *short standard paths* that originate from some $\tilde{D}_0(P_1')$ described in the following section.

5.2.1 Analyzing short standard paths $\mathscr{P}_c$

Again, we only analyze the paths in $\mathscr{P}_c$ for undirected graphs here (see full paper [11] for directed graphs). Using Lemma 10$b^*$and Lemma 162, we know that the number of $P \in \mathscr{P}_c$ with $|LastLeg(P)| > n_\sigma^{1/3}$ or $LastPath(P) = \tilde{P}_0(P)$ or $Source(LastLeg(P)) \notin \tilde{D}_0(P_1')$ (for some $P_1' \in \mathscr{P}_{1c}$) is $O(\sigma^{1/3} n^{2/3})$. We thus focus on the case when $|LastLeg(P)| \leq n_\sigma^{1/3}$ and $LastPath(P) \in \mathscr{P}_{1c}$ with $Source(LastLeg(P)) \in \tilde{D}_0(LastPath(P))$. Any such path can be divided into three parts (not necessarily non-empty) including (a) $P[s, x] = P_1[s, x]$, where $x = Source(\tilde{D}_0(P_1))$, (b) $P[x, y]$ where $y = Source(LastLeg(P))$ and (c) $P[y, v] = LastLeg(P)$.

We find alternate paths for $P[s, x]$ and $P[x, y]$, which will help us in bounding their respective lengths (see Figure 6). By definition $\tilde{P}_0(P_1)$ intersects with P_0 and passes through e_1. Further, using Lemma 14 we know that P_0 and $\tilde{P}_0(P_1)$ will merge after the intersection at some point, say x', where $e_1 \in \tilde{P}_0(P_1)[x', v] = P_0[x', v]$. Hence, we have an alternate path for $P_1[s, x]$ avoiding e_1 and e_2 (since $e_2 \notin \mathscr{P}_0$ by $\mathbb{P}_2$) formed by $P_0[s, x'] \cup \tilde{P}_0(P_1)[x', x]$. Now, bounding $P[x, y]$ is exactly same as in the case of single source, using $\tilde{D}_0(P_1)$ instead of $\mathrm{D}_0(P_1)$, bounding $P[x, y]$ to $2n_\sigma^{2/3}$ as shown in Figure 6 (see full paper [11] for an exhaustive proof). Since $P[s, v]$ is the shortest path avoiding $\mathrm{F}(P)$ we have

$$
\begin{aligned}
|P| &= |P_0[s, x]| + |P_1[x, y]| + |P[y, v]| && \text{(by definition of } x \text{ and } y\text{)} \\
&\leq (|P_0[s, x']| + |\tilde{P}_0(P_1)[x', x]|) + 2n_\sigma^{2/3} + n_\sigma^{1/3} && \text{(Similar to dual FT-BFS)} \\
&\leq |P_0[s, v]| + |\tilde{P}_0(P_1)[x, v]| + 2n_\sigma^{2/3} + n_\sigma^{1/3} \\
&\leq |P_0[s, v]| + |\tilde{D}_0(P_1)[x, v]| + 2n_\sigma^{2/3} + n_\sigma^{1/3} \\
&\qquad (\tilde{D}_0(P_1) \text{ is a detour from } \tilde{P}_0(P_1), \text{ hence } |\tilde{D}_0(P_1)[x, v]| > |\tilde{P}_0(P_1)[x, v]|) \\
&\leq |P_0[s, v]| + n_\sigma^{2/3} + 2n_\sigma^{2/3} + n_\sigma^{1/3} && \text{(by definition of } \mathscr{P}_c\text{)}
\end{aligned}
$$

Now, for any $s \in S$, let $\mathscr{P}_c(s)$ be the set of all contributing paths in $\mathscr{P}_c$ that start from s. Using Lemma 112 (that holds for $P \in \mathscr{P}_c(s)$), we know that for any $P, P' \in \mathscr{P}_c(s)$ we have $|P| \neq |P'|$. We thus arrange the paths in $\mathscr{P}_c(s)$ (except the ones in Lemma 10$b^*$and

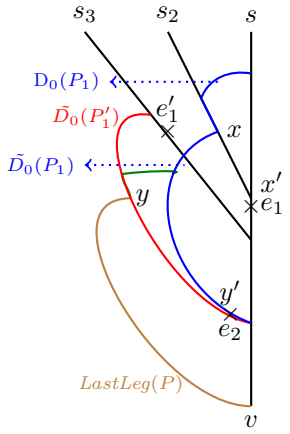

Figure 6 Let $\tilde{P}_0(P_1) = P_0(s_2, v)$, $LastPath(P) = P_1'$ and $\tilde{P}_0(P_1') = P_0(s_3, v)$. Then the path $P_0[s, x'] \cup \tilde{P}_0(P_1)[x', x] \cup \tilde{D}_0(P_1)[x, y'] \cup \tilde{D}_0(P_1')[y', y] \cup LastLeg(P)$ is a valid path avoiding $\{e_1, e_2\}$.

Lemma 162) in the increasing order of sizes, where i^{th} such path has the length $\geq |P_0(s, v)| + i$ (as all paths at least as long as $P_0(s, v)$). Since for any such $P \in \mathscr{P}_c(s)$ we also have $|P| \leq |P_0[s, v]| + 4n^{2/3}$ (described above), clearly the number of paths in $\mathscr{P}_c(s)$ are $O(n_\sigma^{2/3})$ (for i upto $4n^{2/3}$). Hence, overall the number of paths in $\mathscr{P}_c$ considering all sources $s \in S$ are $O(\sigma * n_\sigma^{2/3}) = O(\sigma^{1/3} n^{2/3})$.

This completes the proof of Theorem 4.

6 Conclusion

In this paper, we simplified the analysis in [15] for dual FT-BFS problem and extended it to dual FT-MBFS problem. Unfortunately, extending our result to k FT-MBFS (or even k FT-BFS) problem requires a lot of case analysis. Ideally, one would wish to design a simple data structure to handle multiple failures using some new insight with little or no case analysis. A natural step would be to completely understand these simple cases and derive significant inferences from them to develop new techniques. The simplicity of FT-BFS structure [16] enables a clear understanding of the basic technique used for its construction and analysis. Our work aims to be a significant step to achieve the same for dual FT-BFS by simplifying the result of [15] and generalizing it similar to [16].

Abstract

A graph U is an induced universal graph for a family $\mathcal{F}$ of graphs if every graph in $\mathcal{F}$ is a vertex-induced subgraph of U.

We give upper and lower bounds for the size of induced universal graphs for the family of graphs with n vertices of maximum degree D. Our new bounds improve several previous results except for the special cases where D is either near-constant or almost $n/2$. For constant even D Butler [Graphs and Combinatorics 2009] has shown $O\big(n^{D/2}\big)$ and recently Alon and Nenadov [SODA 2017] showed the same bound for constant odd D. For constant D Butler also gave a matching lower bound. For generals graphs, which corresponds to $D = n$, Alon [Geometric and Functional Analysis, to appear] proved the existence of an induced universal graph with $(1 + o(1)) \cdot 2^{(n-1)/2}$ vertices, leading to a smaller constant than in the previously best known bound of $16 \cdot 2^{n/2}$ by Alstrup, Kaplan, Thorup, and Zwick [STOC 2015].

In this paper we give the following lower and upper bound of

$$\binom{\lfloor n/2 \rfloor}{\lfloor D/2 \rfloor} \cdot n^{-O(1)} \text{ and } \binom{\lfloor n/2 \rfloor}{\lfloor D/2 \rfloor} \cdot 2^{O\left(\sqrt{D \log D} \cdot \log(n/D)\right)},$$

respectively, where the upper bound is the main contribution. The proof that it is an induced universal graph relies on a randomized argument. We also give a deterministic upper bound of $O\Big(\frac{n^k}{(k-1)!}\Big)$. These upper bounds are the best known when $D \leq n/2 - \tilde{\Omega}(n^{3/4})$ and either D is even and $D = \omega(1)$ or D is odd and $D = \omega\left(\frac{\log n}{\log \log n}\right)$. In this range we improve asymptotically on the previous best known results by Butler [Graphs and Combinatorics 2009], Esperet, Arnaud and Ochem [IPL 2008], Adjiashvili and Rotbart [ICALP 2014], Alon and Nenadov [SODA 2017], and Alon [Geometric and Functional Analysis, to appear].

1 Introduction

A graph $G = (V, E)$ is said to be an *induced universal graph* for a family $\mathcal{F}$ of graphs if it contains each graph in $\mathcal{F}$ as a vertex-induced subgraph. A graph $H = (V', E')$ is contained in G as a *vertex-induced subgraph* if $V' \subseteq V$ and $E' = \{vw \mid v, w \in V' \wedge vw \in E\}$. Induced universal graphs have been studied since the 1960s [45, 49], and bounds on the sizes of induced universal graphs have been given for many families of graphs, including general, bipartite [11], and bounded arboricity graphs [10]. In Table 2 in Section 2.3 we give an overview of the state of the art for various graph families along with the results in this paper.

1.1 Adjacency labeling schemes and induced universal graphs

An *adjacency labeling scheme* for a given family $\mathcal{F}$ of graphs assigns *labels* to the vertices of each graph in $\mathcal{F}$ such that a *decoder* given the labels of two vertices from a graph, and no other information, can determine whether or not the vertices are adjacent in the graph. The labels are assumed to be bit strings, and the goal is to minimize the maximum label size. A b-bit labeling scheme uses at most b bits per label. Information theoretical studies of adjacency labeling schemes go back to the 1960s [16, 17], and efficient labeling schemes were introduced in [35, 47]. The first labeling schemes for bounded degree graphs were given in [17]. Let $g_v(\mathcal{F})$ be the smallest number of vertices in any induced universal graph for a family of graphs $\mathcal{F}$. In the families of graphs we study in this paper, a graph always has n vertices, unless explicitly stated otherwise.

A labelling scheme for $\mathcal{F}$ is said to have *unique labels* if no two vertices in the same graph from $\mathcal{F}$ are given the same label. We have the following connection between induced universal graph sizes and label sizes.

▶ **Theorem 1** ([35]). *A family $\mathcal{F}$ of graphs has a b-bit adjacency labeling scheme with unique labels iff $g_v(\mathcal{F}) \leq 2^b$.*

1.2 Our results

The contribution of this paper are stronger bounds on the size of induced universal graphs for bounded degree graphs. Our new bounds are the best known for a significant part of the parameter space, specifically we improve on previous results unless D is either near-constant or almost $n/2$. The best known results for the entire parameter range of induced universal graphs for bounded degree D graphs are shown in Table 1. When the bounded degree D is constant then Butler [18] along with Alon and Nenadov [8] gave optimal bounds. When D is even and of size $\omega(1)$ and when D is odd and of size $\omega(\log n / \log\log n)$ our first new upper bound is the best known as long as $D = O((\log n)\log\log n)$. Let $\mathcal{G}_D$ be the family of graphs with n vertices and maximum degree D. We show the following.

▶ **Theorem 2.** *For the family $\mathcal{G}_D$ of graphs with bounded degree D on n nodes*

$$g_v(\mathcal{G}_D) \leq 8 \cdot \frac{n^k}{(k-1)!}, \quad \text{where } k = \lceil D/2 \rceil .$$

Table 1 The state-of-the-art landscape for induced universal graph sizes. The first column denotes in which range the corresponding bound is the best known.

Range of D	Bound	Reference
D even and $D = O(1)$	$O(n)^{D/2}$	[18]
D odd and $D \in \left[3, O\left(\frac{\log n}{\log\log n}\right)\right]$	$O(D)^D\, n^{D/2}$	[8]
D even and $D \in \left[\omega(1), O\left((\log n)^2 \log\log n\right)\right]$	$O\left(\frac{n^{D/2}}{(D/2-1)!}\right)$	Theorem 2
D odd and $D \in \left[\omega\left(\frac{\log n}{\log\log n}\right), O\left((\log n)^2 \log\log n\right)\right]$	$O\left(\frac{n^{(D+1)/2}}{((D-1)/2)!}\right)$	Theorem 2
$D \in \left[\omega\left((\log n)^2 \log\log n\right), \frac{n}{2} - \Omega\left(n^{3/4}\log^{3/4} n\right)\right]$	$\binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} 2^{O\left(\sqrt{D\log D}\log(n/D)\right)}$	Theorem 3
$D \geq \frac{n}{2} - O\left(n^{3/4}\log^{3/4} n\right)$	$(1+o(1))2^{(n-1)/2}$	[5]

Our second new upper bound is the smallest induced universal graph for the interval starting where Theorem 2 ends and as long as $D \leq \frac{n}{2} - O\left(n^{3/4}\log^{3/4} n\right)$. The previous best upper bound for such large D was $\binom{n}{\lceil D/2\rceil} n^{O(1)}$ due to Adjiashvili and Rotbart [3]. The bound presented in Theorem 3 is a randomized construction, which works for any D, and which improves asymptotically on Adjiashvili and Rotbart [3] for $D = \omega(1)$. We show the following.

▶ **Theorem 3.** *For the family $\mathcal{G}_D$ of graphs with bounded degree D on $n \geq 2D$ nodes*

$$g_v(\mathcal{G}_D) \leq \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} \cdot 2^{O\left(\sqrt{D\log D}\cdot\log(n/D)\right)}.$$

We note that our bound together with the lower bound from Corollary 8 shows that for $D = \omega(1)$, $g_v(\mathcal{G}_D) = \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor}^{1\pm o(1)}$. In contrast when $D \leq n/2(1-\Omega(1))$ and $D = \Omega(n)$ the bound $\binom{n}{\lceil D/2\rceil} n^{O(1)}$ due to Adjiashvili and Rotbart [3] is $\binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor}^{1+\Omega(1)}$, so we give the first near-optimal induced universal graph when D is superconstant.

From a labeling scheme perspective, the combination of Theorems 2 and 3 shows the existence of an adjacency labeling scheme for $\mathcal{G}_D$ of size

$$\log\binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} + O\left(\min\left\{D + \log n, \sqrt{D\log D}\log(n/D)\right\}\right).$$

This new labeling scheme improves upon previous in the same ranges as the improvements for the induced universal graphs as shown in Table 1.

In Corollary 8 we show that the any adjacency labeling scheme for $\mathcal{G}_D$ must have labels of size at least $\log\binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} - O(\log n)$. Our new lower bounds differ from our upper bounds by $O\left(\min\left\{D + \log n, \sqrt{D\log D}\log(n/D)\right\}\right)$, which is at most $O(\sqrt{n\log n})$.

2 Related results

2.1 Maximum degree D

Let $k = \lceil D/2\rceil$. To give an upper bound for any value of D Butler [18] showed the following corollary, which follows from the classic decomposition theorem by Petersen (see [41]):

▶ **Corollary 4** ([18]). *Let $G \in \mathcal{G}_D$ be a graph on n vertices with maximum degree D. Then G can be decomposed into k edge disjoint subgraphs where the maximum degree of each subgraph is at most 2.*

To achieve an upper bound for $g_v(\mathcal{G}_D)$ this can be combined with:

▶ **Theorem 5** ([20]). *Let $\mathcal{F}$ and $\mathcal{Q}$ be two families of graphs and let G be an induced universal graph for $\mathcal{F}$. Suppose that every graph in the family $\mathcal{Q}$ can be edge-partitioned into ℓ parts, each of which forms a graph in $\mathcal{F}$. Then $g_v(\mathcal{Q}) \leq |V[G]|^\ell$.*

Using Theorem 5, Butler [18] concluded that $g_v(\mathcal{G}_D) \leq (6.5n)^k$. Similarly Esperet *et al.* [29] achieved $g_v(\mathcal{G}_D) \leq (2.5n + O(1))^k$, and most recently it was shown by Abrahamsen *et al.* [2] that $g_v(\mathcal{G}_D) \leq (2n-1)^k < 2^k n^k$ due to an induced universal graph for $\mathcal{G}_2$ of size $2n-1$.

For constant maximum degree D, Butler [18] also showed $g_v(\mathcal{G}_D) = \Omega(n^{D/2})$, hence when D is even and constant, $g_v(\mathcal{G}_D) = \Theta(n^{D/2})$ is the right answer up to constant factors due to the above bounds.

2.2 Constant odd degree

A *universal* graph for a family of graphs $\mathcal{F}$ is a graph that contains each graph from $\mathcal{F}$ as a subgraph (not necessarily vertex induced). It is a natural question how to construct universal graphs with as few edges as possible.

A graph has *arboricity* k if the edges of the graph can be partitioned into at most k forests. Graphs with maximum degree D have arboricity bounded by $\lfloor \frac{D}{2} \rfloor + 1$ [19, 40].

When D is odd and constant, some improvement has been achieved on the above bounds on $g_v(\mathcal{G}_D)$ by arguments involving universal graphs and graphs with bounded arboricity [7, 29]. Let $\mathcal{A}_k$ denote a family of graphs with arboricity at most k.

▶ **Theorem 6** ([20]). *Let G be a universal graph for $\mathcal{A}_k$ and d_i the degree of vertex i in G. Then $g_v(\mathcal{A}_k) \leq \sum_i (d_i + 1)^k$.*

Alon and Capalbo [6] described a universal graph with n vertices of maximum degree $c(D)n^{1-2/D}\log^{4/D} n$ for the family $\mathcal{G}_D$, where $D \geq 3$ and $c(D)$ is a constant. Using this bound in Theorem 6, Esperet *et al.* [29] noted that for odd D (and hence arboricity $k = \lceil \frac{D}{2} \rceil$), we get $g_v(\mathcal{G}_D) \leq c_1(D)n^{k-\frac{1}{D}}\log^{2+\frac{2}{D}} n$, for a constant $c_1(D)$.[1] Using the slightly better universal graphs from [7] the maximum degree is reduced to $c(D)n^{1-2/D}$ [4], giving $g_v(\mathcal{G}_D) \leq c_2(D)n^{k-\frac{1}{D}}$, for a constant $c_2(D)$. Note that applying Theorem 6 along with universal graph [7] as above, then for even values of D this would give $g_v(\mathcal{G}_D) \leq c_3(D)n^{\frac{D}{2}+1-\frac{2}{D}}$, for a constant $c_3(D)$. Recently, Alon and Nenadov [8] showed an upper bound $g_v(\mathcal{G}_D) = O(n^{D/2})$, coinciding with Butler's lower bound up to constant factors for any constant D.

2.3 Other graph families

For the family of general, undirected graphs on n vertices, Alstrup *et al.* [11] gave an induced universal graph with $O(2^{n/2})$ vertices, which matches a lower bound by Moon [45]. More recently Alon [5] showed a construction that is tight up to an additive lower order term. We note that whereas the construction of [11] is presented as a labeling scheme, with efficient encoding and constant decoding time. However, it is not obvious if the the induced universal graph from [5] can be transformed into a labeling scheme without requiring that either the encoder or decoder use exponential space or time.

[1] In [29] a typo states that the maximum degree for the universal graph in [6] is $c(D)n^{2-2/D}\log^{4/D} n$. The theorem in [6] only states the total number of edges being $c(D)n^{2-2/D}\log^{4/D} n$, however the maximum degree is $c(D)n^{1-2/D}\log^{4/D} n$ [4].

Table 2 Induced-universal graphs for various families of graphs. "P" is results in this paper. For the max degree results $k = \lceil D/2 \rceil$. In the result for families of graphs with an excluded minor, the $O(1)$ term in the exponent depends on the fixed minor excluded.
* The upper bounds from [11] are labeling schemes with efficient encoding and constant decoding time, but the upper bounds are larger by a constant factor. It is not obvious if the induced universal graph from [5] can be transformed into a labeling scheme without requiring that either the encoder or decoder use exponential space or time.

Graph family	Lower bound	Upper bound	Lower/Upper
General *	$2^{\frac{n-1}{2}}$	$(1+o(1)) \cdot 2^{\frac{n-1}{2}}$	[45]/[5, 11]
Tournaments *	$2^{\frac{n-1}{2}}$	$(1+o(1)) \cdot 2^{\frac{n-1}{2}}$	[46]/[5, 11]
Bipartite *	$(1-o(1)) \cdot 2^{\frac{n}{4}}$	$(1+o(1)) \cdot 2^{\frac{n}{4}}$	[42]/[5, 11]
A: Max degree D	$\binom{\lfloor n/2 \rfloor}{\lfloor D/2 \rfloor} \cdot n^{-O(1)}$	$O\left(\frac{n^k}{(k-1)!}\right)$	P([39, 43, 44])/P
B: Max degree D	$\binom{\lfloor n/2 \rfloor}{\lfloor D/2 \rfloor} \cdot n^{-O(1)}$	$\binom{\lfloor n/2 \rfloor}{\lfloor D/2 \rfloor} \cdot 2^{O(\sqrt{D \log D} \cdot \log(n/D))}$	P([39, 43, 44])/P
C: Constant max degree D	$\Omega(n^{D/2})$	$O(n^{D/2})$	[18]/[8]
Max degree 2	$11 \lfloor n/6 \rfloor$	$2n-1$	[29]/[2]
Acyclic, max degree 2	$\lfloor 3/2n \rfloor$	$\lfloor 3/2n \rfloor$	[2]/[2]
Excluding a fixed minor	$\Omega(n)$	$n^2(\log n)^{O(1)}$	[33]
Planar	$\Omega(n)$	$n^2(\log n)^{O(1)}$	[33]
Planar, constant degree	$\Omega(n)$	$O(n^2)$	[20]
Outerplanar	$\Omega(n)$	$n(\log n)^{O(1)}$	[33]
Outerplanar, constant degree	$\Omega(n)$	$O(n)$	[20]
Treewidth l	$n2^{\Omega(l)}$	$n(\log \frac{n}{l})^{O(l)}$	[33]
Constant arboricity l	$\Omega(n^l)$	$O(n^l)$	[12]/[10]

It follows from [10, 12] that $g_v(\mathcal{A}_k) = \Theta(n^k)$ for the family $\mathcal{A}_k$ of graphs with constant arboricity k and n vertices. Using universal graphs constructed by Babai *et al.* [13], Bhatt *et al.* [14], and Chung *et al.* [21, 22, 23, 24], Chung [20] obtained the best currently known bounds for e.g. induced universal graphs for planar and outerplanar bounded degree graphs.

Labeling schemes are being widely used and well-studied in the theory community: Chung [20] gave labels of size $\log n + O(\log \log n)$ for adjacency labeling in trees, which was improved to $\log n + O(\log^* n)$ [12] and in [15, 20, 31, 32, 36] to $\log n + \Theta(1)$ for various special cases of trees. Finally it was improved to $\log n + \Theta(1)$ for general trees [10].

Using labeling schemes, it is possible to avoid costly access to large global tables and instead only perform local and distributed computations. Such properties are used in applications such as XML search engines [1], network routing and distributed algorithms [26, 27, 30, 51], dynamic and parallel settings [25, 38], and various other applications [37, 48, 50].

A survey on induced universal graphs and adjacency labeling can be found in [11]. See [34] for a survey on labeling schemes for various queries. We give an overview in Table 2 of dominating existing and new results. In the table, "P" refer to a result in this paper and we define $k = \lceil D/2 \rceil$. The "A" and "B" case below represent two different constructions. The upper bound in "B" is a randomized construction.

3 Preliminaries

Let $[n] = \{0, \ldots, n-1\}$, $\mathbb{N}_0 = \{0, 1, 2, \ldots\}$, $\mathbb{N} = \mathbb{N}_1 = \{1, 2, \ldots\}$, and let $\log n$ refer to $\log_2 n$. For a graph G, let $V[G]$ be the set of vertices and $E[G]$ be the set of edges of G, and let $|G| = |V[G]|$ be the number of vertices. We denote the maximum degree of graph G as $\Delta(G)$. For $i \in \mathbb{N}$, let P_i denote a path with i vertices, and for $i > 2$, let C_i denote a simple cycle with i vertices. We let G^2 denote the square of the unweighted graph G, i.e., there is an edge between two nodes in G^2 if they have at most distance two in G. For a boolean statement B we will denote by $[B]$ the value 1 if B is true and 0 otherwise.

Let G and U be two graphs and let $\lambda\colon V[G] \to V[U]$ be an injective function. If λ has the property that $uv \in E[G]$ if and only if $\lambda(u)\lambda(v) \in E[U]$, we say that λ is an *embedding function* of G into U. G is an *induced subgraph* of U if there exists an embedding function of G into U, and in that case, we say that G is *embedded* in U and that U *embeds* G. Let $\mathcal{F}$ be a family of graphs. U is an *induced universal graph* for $\mathcal{F}$ if G is an induced subgraph of U for each $G \in \mathcal{F}$.

4 General D

In this section we present two upper bounds on $g_v(\mathcal{G}_D)$, the number of nodes in the smallest induced universal graph for graphs on n nodes with bounded degree D. In Theorem 2 we give a deterministic construction of an induced universal graph for $\mathcal{G}_D$ that relies on the fact that P_n^2 is a sparse universal graph for $\mathcal{G}_2$.

In Theorem 3 we give a randomized labeling scheme for $\mathcal{G}_D$. For every graph in the family $\mathcal{G}_D$ we give a randomized assignment of labels to the nodes of the graph and show that the labels are short with non-zero probability, thereby showing that there exist short labels for every graph in $\mathcal{G}_D$. This in turn implies an upper bound on $g_v(\mathcal{G}_D)$. Combining the two results shows the existence of an adjacency labeling scheme for $\mathcal{G}_D$ of size $\log \binom{\lfloor n/2 \rfloor \lfloor}{\lfloor D/2 \rfloor} + O\big(\min\big\{D + \log n, \sqrt{D \log D} \log(n/D)\big\}\big)$.

In Section 4.2 we show to use the results by Liebenau and Wormald [39] to give lower bounds on $g_v(\mathcal{G}_D)$. These lower bounds imply that any adjacency labeling scheme for $\mathcal{G}_D$ must have labels of size at least $\log \binom{\lfloor n/2 \rfloor \lfloor}{\lfloor D/2 \rfloor} - O(\log n)$, which means that the upper bounds are tight up to an additive term of size $O\big(\min\big\{D + \log n, \sqrt{D \log D} \log(n/D)\big\}\big)$, which is at most $O(\sqrt{n \log n})$.

4.1 Upper bounds on $g_v(\mathcal{G}_D)$

We present the proof of our first upper bound stated in Theorem 2.

Proof. For a set S we let $S^{\leq \ell}$ denote the set of all subsets of S of size $\leq \ell$. We note that $\big|S^{\leq \ell}\big| \leq 2\frac{|S|^\ell}{\ell!}$ whenever S is finite.

Fix n, D, let $k = \lceil D/2 \rceil$ and let $H_n = P_n^2$ be the square of the path of length n. Identify the vertices of H_n with $[n]$ in the obvious way. Then two nodes i, j in H_n are adjacent if and only if they are different and $|i - j| \leq 2$. We define the graph G to have vertex set $V[G] = [n] \times [2]^2 \times [n]^{\leq k-1}$. For a node $u = (i, x, y, S)$ in G, we define $id(u) = i$. We also

define $N'(u)$ in the following way:

$$N'(u) = \begin{cases} S & x = y = 0 \\ S \cup \{i+1\} & x = 1, y = 0 \\ S \cup \{i+2\} & x = 0, y = 1 \\ S \cup \{i+1, i+2\} & x = y = 1 \end{cases} .$$

There is an edge between u and v in G if $id(u) \in N'(v)$ or $id(v) \in N'(u)$. We proceed to show that G is an induced universal graph for $\mathcal{G}_D$. Let H be a graph in $\mathcal{G}_D$. We will show that H is an induced subgraph of G. By Corollary 4 we know that we can decompose the edges of H into k edge disjoint subgraphs, $H_0, H_1, \ldots, H_{k-1}$, such that each H_i has vertex set $V[H_i] = V[H]$ and maximum degree at most 2. First we order the nodes of H as $u_0, u_1, \ldots, u_{n-1}$ such that all edges (u_i, u_j) in H_0 satisfy $|i - j| \leq 2$. This is possible since H_0 has maximum degree at most 2, and therefore consists of only paths and cycles. We let x_i (resp. y_i) be 1 if there is an edge from u_i to u_{i+1} (resp. u_{i+2}) in H_0. That is:

$$x_i = [(u_i, u_{i+1}) \in E[H_0]] , \; y_i = [(u_i, u_{i+2}) \in E[H_0]] .$$

We now orient the edges of each of the graphs $H_1, \ldots, H_{k-1}$ such that the out degree of each node is at most 1. This is possible since each of H_i has maximum degree at most 2. We let S_i be the set of all u_i's outgoing neighbours in the graphs $H_1, \ldots, H_{k-1}$, and note that S_i contains at most $k - 1$ elements. We let $\lambda : H \to G$ be defined by $\lambda(i) = (i, x_i, y_i, S_i)$. It is now straightforward to check that λ is an embedding function and therefore that H is an induced subgraph of G. Since H was arbitrarily chosen this shows that G is an induced universal graph of $\mathcal{G}_D$. The number of nodes in G is exactly $4n \cdot \left|[n]^{\leq k-1}\right|$ which yields the desired result. ◀

The intuition behind the randomized bound below is the following. Consider placing all n vertices on a circle in a randomly chosen order and rename the vertices with indices $[n]$ following the order on the circle. Now, a vertex $v \in [n]$ remembers its neighbours in the next half of the circle, i.e., v stores all the adjacent vertices among $\{v + 1, \ldots, v + \lceil n/2 \rceil\}$ (where indices are taken modulu n). If two vertices u, v are adjacent, then clearly either u stores the index of v or conversely, hence an adjacency query can be answered. See Figure 1. A standard application of Chernoff bounds implies that vertex v with high probability stores at most $D/2 + O(\sqrt{D \log n})$ indices. However, this can be tightened by a Lovász Local Lemma argument, since each random variable that denote which indices should be stored depend on at most D^2 other such random variables. This allows us to tigthen the number of stored indices to $D/2 + O(\sqrt{D \log D})$, and it follows that there exists an ordering of the points on the circle where every vertex stores that many neighbours and the theorem follows.
We are ready to show Theorem 3.

Proof. Fix n, D and wlog assume that n is odd. For $D \leq \log n$ the result follows from Theorem 2 so assume that $D \geq \log n$. We assume that n and D are bounded from below by a sufficiently large constant. Let G be a graph in $\mathcal{G}_D$, and wlog assume that $V[G] = [n]$. Let $t_0, t_1, \ldots, t_{n-1} \in [n]$ be chosen independently and uniformly at random, and let $\mathrm{id} : [n] \to [n]$ be a bijection that assigns an identifier to each node of G such that

$$(t_i, i) \prec (t_j, j) \Rightarrow \mathrm{id}(i) < \mathrm{id}(j),$$

for all values of $i, j \in [n]$, where $\prec$ is the lexicographical ordering. We construct the function id by sorting the values t_i, and then choosing id to be a bijection such that

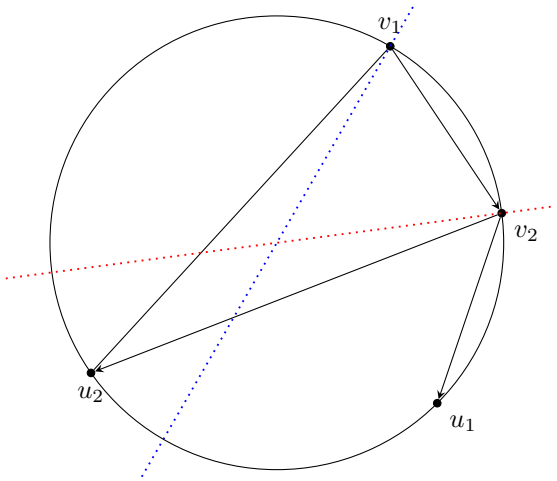

Figure 1 The intuition of the randomized upper bound. Pictured are adjacency relations stored by v_1 and v_2 – an edge denotes adjecency and a directed edge (v, u) denotes v stores its relation to u. Here v_1 stores v_2 but not u_2 as u_2 is on the wrong side of v_1's bisection, and v_2 stores u_1 and u_2, but not v_1 as it is on the wrong side of v_2's bisection.

$(t_{\mathrm{id}(0)}, \mathrm{id}(0)), \ldots, (t_{\mathrm{id}(n-1)}, \mathrm{id}(n-1))$ is a non-decreasing sequence. We note that the values t_i determine id uniquely.

For each $i \in [n]$ we let $S_i \subseteq [n]$ be the set that contains all neighbours j of i for which it holds that:

$$(t_j - t_i) \bmod n \in \left\{0, 1, 2, \ldots, \frac{n-1}{2}\right\}$$

That is, we define S_i by:

$$S_i = \left\{j \in [n] \mid \{i, j\} \in E[G],\ (t_j - t_i) \bmod n \in \left\{0, 1, 2, \ldots, \frac{n-1}{2}\right\}\right\} \tag{1}$$

We say that the values t_i are *good* if the following properties hold for all $i \in [n]$:

$$|S_i| \leq \frac{D}{2} + C\sqrt{D \log D} \tag{2}$$

$$\max_{j \in S_i} \{(\mathrm{id}(j) - \mathrm{id}(i)) \bmod n\} \leq \frac{n}{2} + \max\left\{\frac{n}{D}, C\sqrt{n \log n}\right\} \tag{3}$$

where $C > 0$ is a (sufficiently large) constant to be chosen later. Firstly, we will show that, when choosing the t_i's randomly, they are good with non-zero probability. For $i \in [n]$ let A_i be the event that (2) does not hold for S_i. Let $\mathcal{A} = \{A_i \mid i \in [n]\}$ and for each $A_i \in \mathcal{A}$ let $\Gamma(A_i)$ denote the set of all events A_j where $j \neq i$ has distance at most two to i in G. We note that since G has maximum degree at most D we have that $|\Gamma(A_i)| \leq D^2$. For each $i \in [n]$ the event A_i is independent of all events $\mathcal{A} \setminus (\{A_i\} \cup \Gamma(A_i))$ for the following reason. The event A_i is determined exclusively by the values t_j where $j = i$ or j is a neighbour of i in G. For each A_j such that $A_j \in \mathcal{A} \setminus (\{A_i\} \cup \Gamma(A_i))$ we have that j has distance at least three to i, and A_j is determined by the values $t_{j'}$ where $j' = j$ or j' is a neighbour of j. No such j' can also be a neighbour of i since j has distance three to i and we conclude that A_i is independent of the events $\mathcal{A} \setminus (\{A_i\} \cup \Gamma(A_i))$ for each $i \in [n]$. By a Chernoff bound we have that A_i happens, i.e. (2) is false for S_i, with probability at most $e^{-\Theta(C^2 \log D)}$. Choosing C

sufficiently large this is smaller than $\frac{1}{2}D^{-10}$. Let $x(A_i) = D^{-10}$ for each $i \in [n]$. Then for each $i \in [n]$ we have:

$$x(A_i) \prod_{A_j \in \Gamma(A_i)} (1 - x(A_j)) \geq D^{-10} \left(1 - D^{-10}\right)^{D^2} = D^{-10} e^{-\Theta\left(D^{-10}\right) \cdot D^2}$$
$$> \frac{1}{2} D^{-10} \geq P(A_i)$$

By the Lovász Local Lemma [28, 9] we conclude that the probability that none of $A_i, i \in [n]$ happen is bounded below by

$$\prod_{i \in [n]} (1 - x(A_i)) = \left(1 - D^{-10}\right)^n = e^{-\Theta\left(nD^{-10}\right)}.$$

That is, (2) holds for all S_i with probability at least $e^{-\Theta\left(nD^{-10}\right)}$. For a any value of $i \in [n]$ the probability that (3) is false is at most $\min\left\{e^{-\Theta\left(nD^{-2}\right)}, n^{-\Omega(C^2)}\right\}$ by a standard Chernoff bound. And by a union bound over all choices of $i \in [n]$ (3) holds for all values of i with probability a least $1 - n \min\left\{e^{-\Theta\left(nD^{-2}\right)}, n^{-\Omega(C^2)}\right\}$. Therefore, the probability that the chosen t_is are good is at least

$$e^{-\Theta\left(nD^{-10}\right)} + \left(1 - n \min\left\{e^{-\Theta\left(nD^{-2}\right)}, n^{-\Omega(C^2)}\right\}\right) - 1. \tag{4}$$

We note that (4) is positive if and only if

$$e^{-\Theta\left(nD^{-10}\right)} > n \min\left\{e^{-\Theta\left(nD^{-2}\right)}, n^{-\Omega(C^2)}\right\}, \tag{5}$$

and this can be verified, e.g. by considering the cases $D \leq n^{1/3}$ and $D > n^{1/3}$. That is, the values t_i are good with non-zero probability.

Now fix a good choice of t_i and the corresponding identifier function, id, and the sets S_i. We can now encode the values $\mathrm{id}(i)$ and the set S_i using at most $O(\log n) + \lg \binom{n'}{D'}$ bits where n' and D' are defined by:

$$n' = \left\lfloor \frac{n}{2} + \max\left\{\frac{n}{D}, C\sqrt{n \log n}\right\} \right\rfloor, \quad D' = \left\lfloor \frac{D}{2} + C\sqrt{D \log D} \right\rfloor$$

Let $D'' = \min\left\{\left\lfloor \frac{n'}{2} \right\rfloor, D'\right\}$. Then for any node i we can encode $\mathrm{id}(i)$ and the set $\{(\mathrm{id}(j) - \mathrm{id}(i)) \bmod n \mid j \in S_i\}$ using at most $O(\log n) + \log \binom{n'}{D''}$ bits for the following reason: Firstly, $\mathrm{id}(i)$ can clearly be stored using $O(\log n)$ bits. Secondly, the set of differences $\{(\mathrm{id}(j) - \mathrm{id}(i)) \bmod n \mid j \in S_i\}$ contains at most D' elements which are all contained in $\{1, 2, \ldots, n'\}$, and hence it can be stored using at most $\log\left(n\binom{n'}{D''}\right)$ bits. Given the labels of two nodes i, j we can compute their ids, $\mathrm{id}(i)$ and $\mathrm{id}(j)$, and infer whether $\mathrm{id}(i) \in S_j$ or $\mathrm{id}(j) \in S_i$, i.e. whether i and j are adjacent. Hence we have described a labeling scheme for $\mathcal{G}_D$ using at most $O(\log n) + \log \binom{n'}{D''}$ bits, and therefore

$$g_v(\mathcal{G}_D) \leq \binom{n'}{D''} n^{O(1)}. \tag{6}$$

We first note that:

$$\binom{n'}{D''} \leq \binom{n'}{\lfloor D/2 \rfloor} \cdot \left(\frac{n'}{\lfloor D/2 \rfloor}\right)^{D'' - \lfloor D/2 \rfloor} \leq \binom{n'}{\lfloor D/2 \rfloor} \cdot 2^{O\left(\sqrt{D \log D} \cdot \log(n/D)\right)}. \tag{7}$$

Furthermore we also have:

$$\binom{n'}{\lfloor D/2\rfloor} \leq \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} \cdot \left(\frac{n'-\lfloor D/2\rfloor}{\lfloor n/2\rfloor-\lfloor D/2\rfloor}\right)^{\lfloor D/2\rfloor} = \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor} \cdot \left(1+\frac{n'-\lfloor n/2\rfloor}{\lfloor n/2\rfloor-\lfloor D/2\rfloor}\right)^{\lfloor D/2\rfloor}. \tag{8}$$

We have that $\lfloor n/2\rfloor - \lfloor D/2\rfloor = \Omega(n)$ since $D \leq \frac{n}{2}$ and therefore we get:

$$\left(1+\frac{n'-\lfloor n/2\rfloor}{\lfloor n/2\rfloor-\lfloor D/2\rfloor}\right)^{\lfloor D/2\rfloor} = \left(1+O\left(\frac{n'-\lfloor n/2\rfloor}{n}\right)\right)^{\lfloor D/2\rfloor} \leq e^{O\left(\frac{n'-\lfloor n/2\rfloor}{n}\cdot\lfloor D/2\rfloor\right)}. \tag{9}$$

By the definition of n' we have that

$$\frac{n'-\lfloor n/2\rfloor}{n}\lfloor D/2\rfloor = \max\left\{\frac{1}{D}, C\sqrt{\frac{\log n}{n}}\right\}\cdot\lfloor D/2\rfloor = O\left(\sqrt{D\log D}\right). \tag{10}$$

Combining (8), (9) and (10) we get that

$$\binom{n'}{\lfloor D/2\rfloor} \leq 2^{O\left(\sqrt{D\log D}\right)}\binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor}. \tag{11}$$

Combining (6) with (7) and (11) gives us the desired upper bound on $g_v(\mathcal{G}_D)$

$$g_v(\mathcal{G}_D) \leq \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor}\cdot 2^{O\left(\sqrt{D\log D}\cdot\log(n/D)\right)}.$$

4.2 Lower bounds on $g_v(\mathcal{G}_D)$

In this section we show how to apply the bounds from [39] on the number of graphs of a given degree sequence. For a graph G with nodes $(u_1, u_2, \ldots, u_n)$ the *degree sequence* of G is $(d_1, d_2, \ldots, d_n)$ where d_i is the degree of u_i. Applying [39, Conjecture 1.1] on a degree sequence $(d, d, \ldots, d)$ we obtain

▶ **Corollary 7** ([39]). *Let n, d be integers such that nd is even and $1 \leq d \leq n-1$. Let $\mu = \frac{d}{n-1}$. The number of d-regular graphs on n nodes is*

$$(1+o(1))\sqrt{2}e^{1/4}\left(\mu^{\mu}(1-\mu)^{1-\mu}\right)^{n(n-1)/2}\binom{n-1}{d}^{n}.$$

We now show that the bound from Corollary 7 implies a lower bound on the size of the induced universal graph for bounded degree graphs:

▶ **Corollary 8.** *For the family $\mathcal{G}_D$ of graphs with bounded degree D on n nodes*

$$g_v(\mathcal{G}_D) = \Omega\left(\sqrt{\frac{1}{\sqrt{D}}\binom{n}{D}}\right). \tag{12}$$

We remark that together with Stirling's approximation, Corollary 8 implies that $g_v(\mathcal{G}_D) \geq \binom{\lfloor n/2\rfloor}{\lfloor D/2\rfloor}n^{-O(1)}$.

Proof. It is clearly enough to prove (12) when $D \leq \left\lfloor \frac{n}{2} \right\rfloor$, since the right hand side is non-increasing for $D \geq \left\lfloor \frac{n}{2} \right\rfloor$. Let $N = 2\left\lfloor \frac{n}{2} \right\rfloor$ be the largest even integer not greater than n. So we assume that $2D \leq N$.

Let X be the number of D-regular graphs on N nodes. By Corollary 7 we have that

$$X = \Theta\left(\left(\mu^\mu (1-\mu)^{1-\mu}\right)^{N(N-1)/2} \binom{N-1}{D}^N \right), \tag{13}$$

where $\mu = \frac{D}{N-1}$. By Stirling's approximation we have that:

$$\begin{aligned}
\binom{N-1}{D} &= \Theta\left(\frac{\sqrt{N-1}\left(\frac{N-1}{e}\right)^{N-1}}{\sqrt{D}\left(\frac{D}{e}\right)^{D}\sqrt{N-1-D}\left(\frac{D}{e}\right)^{D}} \right) \\
&= \Theta\left(\sqrt{\frac{N-1}{D(N-1-D)}} \left(\mu^\mu (1-\mu)^{1-\mu}\right)^{-(N-1)} \right) \\
&= \Theta\left(\sqrt{\frac{1}{D}} \left(\mu^\mu (1-\mu)^{1-\mu}\right)^{-(N-1)} \right).
\end{aligned}$$

Rearranging gives that:

$$\left(\mu^\mu (1-\mu)^{1-\mu}\right)^{(N-1)N/2} = \Theta\left(\sqrt{\frac{1}{D}} \binom{N-1}{D}^{-1} \right)^{N/2}$$

If we insert this into (13) we get that:

$$X = \Theta\left(\sqrt{\frac{1}{D}} \binom{N-1}{D}^{-1} \right)^{N/2} \binom{N-1}{D}^N = \Theta\left(\sqrt{\frac{1}{\sqrt{D}} \binom{N-1}{D}} \right)^N.$$

Since $2D \leq N$ we have that $\binom{N-1}{D} = \Theta\left(\binom{n}{D}\right)$. Clearly X is smaller than $\mathcal{G}_D$, and therefore:

$$|\mathcal{G}_D|^{1/n} = \Omega\left(\sqrt{\frac{1}{\sqrt{D}} \binom{n}{D}} \right) \tag{14}$$

Let G be the induced universal graph for the family $\mathcal{G}_D$. Let $V = [n]$. Any graph H from $\mathcal{G}_D$ on the vertex set V is uniquely defined by the embedding function f of H in G. Since there are no more than $|V[G]|^n$ ways to choose f we get that $|V[G]|^n \geq |\mathcal{G}_D|$. Inserting (14) this shows (12) the following way,

$$g_v(\mathcal{G}_D) = |V[G]| \geq |\mathcal{G}_D|^{1/n} = \Omega\left(\sqrt{\frac{1}{\sqrt{D}} \binom{n}{D}} \right).$$

Abstract

An overarching issue in resource management of wireless networks is assessing their *capacity*: *How much communication can be achieved in a network, utilizing all the tools available: power control, scheduling, routing, channel assignment and rate adjustment?* We propose the first framework for approximation algorithms in the physical model that addresses these questions in full, including rate control. The approximations obtained are doubly logarithmic in the link length and rate diversity. Where previous bounds are known, this gives an exponential improvement.

A key contribution is showing that the complex interference relationship of the physical model can be simplified into a novel type of amenable conflict graphs, at a small cost. We also show that the approximation obtained is provably the best possible for any conflict graph formulation.

1 Introduction

The effective use of wireless networks revolves around utilizing fully all available diversity. This can include power control, scheduling, routing, channel assignment and *transmission rate control* on the links, the latter being an issue of key interest for us. The long-studied topic of *network capacity* deals with how much communication can be achieved in a network when its resources are utilized to the fullest. This can be formalized in different ways, involving a range of problems. The communication ability of packet networks is characterized by the capacity region, i.e. the set of traffic rates that can be supported by any scheduling policy. In order to achieve *low delays and optimal throughput*, the classic result of Tassiulas and Ephremides [28] and followup work in the area (e.g. [25]) point out a core optimization problem that lies at the heart of such questions – the *maximum weight independent set of links (*Mwisl*)* problem: from a given set of communication links with associated weights/utilities, find an *independent (conflict-free, subject to the interference model) subset of maximum total weight.*

This reduction applies to very general settings involving single-hop and multi-hop, as well as fixed and controlled transmission rate networks. Moreover, approximating MWISL within any factor implies achieving the corresponding fraction of the capacity region. This makes MWISL a central problem in the area. Unfortunately, solving this problem in its full generality is notoriously hard, since it is well known that MWISL is effectively inapproximable (under standard complexity theory) e.g. in models described by general conflict relations or general graphs. Moreover, in general, even approximating the capacity region in polynomial time within a non-trivial bound, while keeping the delays in reasonable bounds, is hard under standard assumptions [27].

We tackle this question in the *physical model* of communication. Towards this end, we develop a general approximation framework that not only helps us to approximate MWISL, but can also be used for tackling various other scheduling problems, such as TDMA scheduling, joint routing and scheduling and others. The problems handled can additionally involve path or flow selection, multiple channels and radios, and packet scheduling. We obtain *double-logarithmic* (in link and rate diversity) approximation for these problems, exponentially improving the previously known logarithmic approximations, and, importantly, extending them to incorporate *different fixed rates and rate control*. The crucial feature of the approach (which makes it so general) is that it involves transforming the complex physical model into an unweighted/undirected conflict graph and solving the problems simply on these graphs. Perhaps surprisingly, we find that our schema attains the best possible performance of *any* conflict graph representation. Numerical simulations show that the conflict graph framework is a good approximation for the physical model on randomly placed network instances as well. Our approach also finesses the task of selecting optimum power settings by using *oblivious* power assignment, one that depends only on the properties of the link itself and not on other links. The performance bounds are however in comparison with the optimum solution that can use arbitrary power settings.

Technically, our approach generalizes our earlier framework [14]. Our extensions required substantial changes throughout the whole body of arguments. That formulation works only for uniform constant rates, and the generalization requires substantial new ideas. One indicator of the challenges overcome is that we could prove that our doubly-logarithmic approximation is best possible in the presence of different rates, while better approximations are known to hold in the case of uniform rates [14].

We make some undemanding assumptions about the settings. We assume that the networks are *interference-constrained*, in that interference rather than the ambient noise is the determining factor of proper reception. This assumption is common and is particularly natural in settings with rate control, since the impact of noise can always be made negligible by avoiding the highest rates, losing only a small factor in performance. We also assume that nodes are (arbitrarily) located in a doubling metric, which generalizes Euclidean space, allowing the modeling of some of non-geometric effects seen in practice.

Our Results. Our results can be summarized as follows:

- We establish a general framework for tackling wireless scheduling and related problems,
- Our approximations hold for nearly all such problems, including variable rates settings,
- We obtain exponential improvement over previously known approximations,
- The approximations are obtained via simple conflict graphs, as opposed to the complicated physical model, and by using *oblivious* power assignments,
- We establish tight bounds indicating the limitations of our method.

Related work. Gupta and Kumar introduced the physical model of interference/communication with log-path fading in their influential paper [10], and it has remained the default in

analytic studies. Moscibroda and Wattenhofer [26] initiated worst-case analysis of scheduling problems in networks of arbitrary topology, which is also the setting of interest in this paper. There has been significant progress in understanding scheduling problems with fixed uniform rates. NP-completeness results have been given for different variants [8, 21, 24]. Early work on approximation algorithms involve (directly or indirectly) partitioning links into length groups, which results in performance guarantees that are at least logarithmic in Δ, the link length diversity: TDMA scheduling and uniform weights MWISL [8, 5, 11], non-preemptive scheduling [7], joint power control, scheduling and routing [4], and joint power control, routing and throughput scheduling in multiple channels [2], to name a few. Constant-factor approximations are known for uniform weight MWISL (in restricted power regimes [12] and (general) power control [22]). Standard approaches translate the constant-factor approximations for the uniform weight MWISL into $O(\log n)$ approximations for TDMA scheduling and general MWISL. Many problems become easier, including MWISL and TDMA scheduling, in the regime of linear power assignments [6, 33, 13, 29]. Recently, a $O(\log^* \Delta)$-approximation algorithm was given for TDMA scheduling and MWISL [14], by transforming the physical model into a conflict graph. We build on this approach, and extend it into a general framework that covers other problems and incorporates support for rate control.

Very few results are known for problems involving rate control. The constant-factor approximation for MWISL with uniform weights and arbitrary but fixed rates proposed by Kesselheim [23] can be used to obtain $O(\log n)$-approximations for TDMA scheduling and MWISL with rate control, where n is the number of links. Another recent work [9] handles the TDMA scheduling problem (with fixed but different rates), obtaining an approximation independent of the number of links n, but the ratio is polynomial in Δ. There have been numerous algorithms that try to approximate or replace MWISL in the context of packet scheduling. Several examples include Longest-Queue-First Scheduling (LQF) [20], Maximal Scheduling [34], Carrier Sense Multiple Access (CSMA) [19]. The approximations obtained usually depend on some parameter of the conflict graph, such as the *interference degree*. In the case of CSMA (and other similar protocols), it is known that the algorithms are throughput-optimal, but in general they take exponential time to stabilize, or otherwise require constant degree conflict graphs [18]. It is also well known that many scheduling problems such as vertex coloring and MWISL are easy to approximate in bounded *inductive independence* graphs, such as geometric intersection graphs or protocol model. However, fidelity to the cumulative nature of interference and the question of modeling rate control are among the significant issues faced by such graph models.

Paper Organization. The fundamental ideas of our approximation framework are described in Section 2. After introducing the model and definition in Section 3, we derive the core technical part, the approximation of the physical model by the conflict graphs, in Section 4, and the optimality of approximation. The framework is applied to obtain approximations for fixed rate scheduling problems in Section 5 and for problems with rate control in Section 6 (the latter two can be read separately from Section 4). Due to space constraints, several technical proofs are deferred to the full version of this paper.

2 Approximation Method

Before defining the details, let us describe the main idea behind the approximation technique. In essence, we define a notion of approximation of an independence system[1] $\mathcal{I}_{\mathcal{P}} = (L, \mathcal{E}_{\mathcal{P}})$ by

[1] An independence system $\mathcal{I}$ over a set of vertices V is a pair $\mathcal{I} = (V, \mathcal{E})$, where $\mathcal{E} \subseteq 2^V$ is a collection of subsets of vertices that is closed under subsetting: if $S \in \mathcal{E}$ and $S' \subset S$, then $S' \in \mathcal{E}$.

a graph $\mathcal{G} = (L, E)$ over the set L of links. The system $\mathcal{I}_\mathcal{P}$ corresponds to the cumulative interference in the physical model, while $\mathcal{G}$ is a conflict graph describing pairwise conflicts between links. We will refer to independent sets in $\mathcal{I}_\mathcal{P}$ as *feasible sets*, and to independent sets in $\mathcal{G}$ as *independent sets*, to avoid confusion.

The approximation is described by several key properties.

Refinement (Feasibility of Independent Sets). Every independent set S in $\mathcal{G}$ must be feasible, i.e. $S \in \mathcal{E}_\mathcal{P}$. Thus, finding an independent set in $\mathcal{G}$ gives also a feasible set in $\mathcal{I}_\mathcal{P}$.

Tightness (of refinement). There is a small number k such that every feasible set $S \in \mathcal{I}_\mathcal{P}$ is a union of at most k independent sets in $\mathcal{G}$. The smallest such k is called the *tightness* of refinement. This property guarantees that even an optimal (for a problem in question) feasible set can be covered with a few independent sets.

The two properties above establish a tight connection between the two models. That allows us to take nearly *every* scheduling problem in the physical model and reduce it to the corresponding problem in conflict graphs (in a way formalized in Section 5), by paying only an approximation factor depending on the tightness k. However, in order for this scheme to work, it should be easier to solve such problems in $\mathcal{G}$, which leads to the third key property.

Computability. There are efficient (approximation) algorithms for scheduling-related problems such as *vertex coloring* and *maximum weight independent set* in $\mathcal{G}$.

A graph $\mathcal{G}$ satisfying the properties above is said to be a *refinement* of $\mathcal{I}_\mathcal{P}$. The main effort in the following two sections is to define an appropriate conflict graph refinement for the physical model and prove these key properties. We find such a family that approximates the physical model with nearly constant tightness, i.e. double-logarithmic in length and rate diversity and show that this is best possible for any conflict graph, up to constant factors. This approximation allows us to bring to bear the large body of theory of graph algorithms, greatly simplifying both the exposition and the analysis.

3 Model

In scheduling problems, the basic object of consideration is a set L of n communication links, numbered from 1 to n, where each link $i \in L$ represents a single-hop communication request between two wireless nodes located in a metric space – a sender node s_i and receiver node r_i.

We assume the nodes are located in a metric space with distance function d. We denote $d_{ij} = d(s_i, r_j)$ and $l_i = d(s_i, r_i)$. The latter is called the *length* of link i. Let $d(i, j)$ denote the minimum distance between the nodes of links i and j.

The nodes have adjustable transmission power levels. A *power assignment* for the set L is a function $P : L \to \mathbb{R}_+$. For each link i, $P(i)$ defines the power level used by the sender node s_i. In the physical model of communication, when using a power assignment P, a transmission of a link i is successful if and only if

$$SIR(S, i) = \frac{P(i)/l_i^\alpha}{\sum_{j \in S \setminus \{i\}} P(j)/d_{ji}^\alpha} \geq \beta_i, \tag{1}$$

where $\beta_i > 1$ denotes the minimum signal to noise ratio required for link i, $\alpha \in (2, 6)$ is the path loss exponent and S is the set of links transmitting concurrently with link i. Note that we omit the noise term in the formula above, since we focus on interference limited networks. This can be justified by the fact that one can simply slightly decrease the transmission rates

to make the effect of the noise negligible, then restore the rates by paying only constant factors in approximation.

A set S of links is called *P-feasible* if the condition (1) holds for each link $i \in S$ when using power assignment P. We say S is *feasible* if there exists a power assignment P for which S is P-feasible.

Effective Length. Let us denote $\mathfrak{l}_i = \beta_i^{1/\alpha} l_i$ and call it the *effective length* of link i. Let $\Delta(L) = \max_{i,j \in L}\{\mathfrak{l}_i/\mathfrak{l}_j\}$ denote the *(effective) length diversity* of instance L. We call a set S of links *equilength* if for every two links $i, j \in S$, $\mathfrak{l}_i \leq 2\mathfrak{l}_j$, i.e., $\Delta(S) \leq 2$. Note that with the introduction of effective length, the feasibility constraint (1) becomes: $\frac{P(i)}{\mathfrak{l}_i^\alpha} \geq \sum_{j \in S\setminus\{i\}} \frac{P(j)}{d_{ji}^\alpha}$. This looks like the same formula but with uniform rates $\beta_i' = 1$. However, there is an essential difference between the two: the quantities $\mathfrak{l}_i$ are not related to the metric space in the same way as lengths l_i, as $\mathfrak{l}_i$ can be arbitrarily larger than l_i.

Metrics. The *doubling dimension* of a metric space is the infimum of all numbers $\delta > 0$ such that for every ϵ, $0 < \epsilon \leq 1$, every ball of radius $r > 0$ has at most $C\epsilon^{-\delta}$ points of mutual distance at least ϵr where $C \geq 1$ is an absolute constant. For example, the m-dimensional Euclidean space has doubling dimension m [16]. We let m denote the doubling dimension of the space containing the links. We will assume $\alpha > m$, which is the standard assumption $\alpha > 2$ in the Euclidean plane.

4 Conflict Graph Approximation of Physical Model

In this section we present the $O(\log\log\Delta)$-tight refinement of the physical model by conflict graphs. The first part introduces our conflict graph $\mathcal{G}_f$ that generalizes the conflict graph definition of [14] and extends it to general thresholds/rates. The three subsequent parts give the proofs of the three key properties: refinement, tightness and computability. The last part argues the asymptotic optimality of $O(\log\log\Delta)$-tightness for any conflict graph, which contrasts the $O(\log^*\Delta)$ bound known in the uniform thresholds setting.

▶ **Theorem 1.** *There is an $O(\log\log\Delta)$-tight refinement of the physical model by a conflict graph family $\mathcal{G}(L)$.*

Conflict Graphs. We define the conflict graph family as follows.

▶ **Definition 2.** Let $f : \mathbb{R}_+ \to \mathbb{R}_+$ be a positive non-decreasing function. Links i, j are said to be *f-independent* if $d_{ij}d_{ji} > \mathfrak{l}_i\mathfrak{l}_j f\left(\mathfrak{l}_{max}/\mathfrak{l}_{min}\right)$, where $\mathfrak{l}_{min} = \min\{\mathfrak{l}_i, \mathfrak{l}_j\}, \mathfrak{l}_{max} = \max\{\mathfrak{l}_i, \mathfrak{l}_j\}$, and otherwise *$f$-adjacent*. A set of links is f-independent (f-adjacent) if they are pairwise f-independent (f-adjacent).

The conflict graph $\mathcal{G}_f(L)$ of a set L of links is the graph with vertex set L, where two vertices are adjacent if and only if they are f-adjacent.

This definition extends the conflict graphs introduced in [14], where the independence criterion was $d(i,j)/l_{min} > f(l_{max}/l_{min})$ (l_{max}, l_{min} are the length of the longer and shorter links, resp.). When all threshold values β_i are constant, the latter essentially follows from the definition above by "canceling" l_{max} with the larger value of d_{ij}, d_{ji} (modulo constant factors). In general, however, the effective lengths can be very different from the actual link lengths, and feasibility requires more separation than given by graphs involving distances only. A technical difficulty introduced by the new definition is that we have to keep track of two distances d_{ij} and d_{ji} instead of the single distance $d(i,j)$, but this appears to be necessary.

We will be particularly interested in *sub-linear* functions $f(x) = O(x)$. A function f is *strongly sub-linear* if for each constant $c \geq 1$, there is a constant c' such that $cf(x)/x \leq f(y)/y$ for all $x, y \geq 1$ with $x \geq c'y$. Note that if f is strongly sub-linear then $f(x) = o(x)$. For example, the functions $f(x) = x^\delta$ $(\delta < 1)$ and $f(x) = \log x$ are strongly sub-linear.

Refinement: Feasibility of Independent Sets. Our goal now is to find a function f such that each independent set in $\mathcal{G}_f$ is feasible. It is clear that this can be achieved by letting f grow sufficiently fast. But we should not let it grow too fast, so as to not affect tightness. We also need to indicate which power assignment makes the independent sets in $\mathcal{G}_f$ feasible. Our approach is to preselect a family of *oblivious power assignments*, that are local to each link and do not depend on others, and then find an appropriate function f. Consider the family of power assignments P_τ parameterized by $\tau \in (0, 1)$, where $P_\tau(i) \sim \ell_i^{\tau\alpha}$ for each link i. In order to obtain P_τ-feasibility, we take conflict graphs $\mathcal{G}_f$ with $f(x) = \gamma x^\delta$ for $\delta \in (0, 1)$ and $\gamma \geq 1$. Such graphs are denoted as $\mathcal{G}_\gamma^\delta$. We show that every independent set in $\mathcal{G}_\gamma^\delta$ for appropriate γ and δ is P_τ-feasible for some τ.

▶ **Theorem 3.** *Let $\delta_0 = \frac{\alpha-m+1}{2(\alpha-m)+1}$. If $\delta \in (\delta_0, 1)$ and the constant $\gamma > 1$ is large enough, there is a value $\tau \in (0, 1)$ such that each independent set in $\mathcal{G}_\gamma^\delta$ is P_τ-feasible.*

The proof is an adaptation of the ideas used in the proof of [15, Cor. 6] to our definition of conflict graphs and effective lengths. Given an independent set S in $\mathcal{G}_\gamma^\delta$ and a link i, we bound the interference of S on i by first splitting S into equilength subsets, bounding the contribution of each subset separately, then combining the bounds into one. The core of the proof is a careful application of a common packing argument in doubling metric spaces.

Tightness of Refinement. Now, let us bound the number of f-independent sets that are necessary to cover a feasible set. We show that this number is $O(f^*(\Delta(S)))$ for any feasible set S, where f^* is defined for every strongly sub-linear function, as follows. For each integer $c \geq 1$, the function $f^{(c)}(x)$ is defined inductively by: $f^{(1)}(x) = f(x)$ and $f^{(c)}(x) = f(f^{(c-1)}(x))$. Let $x_0 = \inf\{x \geq 1, f(x) < x\} + 1$; such a point exists for every $f(x) = o(x)$. The function $f^*(x)$, is defined by: $f^*(x) = \arg\min_c\{f^{(c)}(x) \leq x_0\}$ for arguments $x > x_0$, and $f^*(x) = 1$ for the rest. Note that for a function $f(x) = \gamma x^\delta$ with constants $\gamma > 0$ and $\delta \in (0, 1)$, $f^*(\Delta) = \Theta(\log\log\Delta)$, which is the tightness bound we are aiming for.

▶ **Theorem 4.** *Consider a non-decreasing strongly sub-linear function f. Every feasible set S can be split into $O(f^*(\Delta(S)))$ subsets, each independent in $\mathcal{G}_f(S)$.*

Let us fix a function f with properties as in the theorem. We establish the partition in Thm. 4 in two steps. The first step is to show that feasible set S can be partitioned into a constant number of independent sets in $\mathcal{G}_\rho^0(S)$ for any constant ρ, i.e., subsets S' such that for every pair of links $i, j \in S'$, $d_{ij}d_{ji} > \rho\ell_i\ell_j$. Such subsets are called ρ-independent for short. The second step is to show that for an appropriate constant ρ, each ρ-independent set can be partitioned into at most $O(f^*(\Delta))$ of f-independent subsets.

The first step is easy. Each feasible set can be partitioned into at most $2\rho^{\alpha/2}$ subsets, each of them feasible with updated thresholds $\{\rho^{\alpha/2}\beta_i\}$. This is a direct application of Corollary 2 of [3]. Let S' be such a subset and let $i, j \in S'$. The feasibility constraint for i and j implies:

$$P(i)/l_i^\alpha \geq \rho^{\alpha/2}\beta_i P(j)/d_{ji}^\alpha \text{ and } P(j)/l_j^\alpha \geq \rho^{\alpha/2}\beta_j P(i)/d_{ij}^\alpha.$$

By multiplying together the inequalities above, canceling $P(i)$ and $P(j)$ and raising to the power of $1/\alpha$, we obtain: $d_{ij}d_{ji} \geq \rho\ell_i\ell_j$, as required.

The proof of the second step requires the following lemmas, which constitute the most significant technical difference from the proof of the corresponding theorem in [14], as they encapsulate the technicalities of dealing with our definition of conflict graphs: It is not sufficient to bound only one of the distances between links (such as $d(i,j)$ in [14]); we need a bound on the product of two distances.

▶ **Lemma 5.** *Let i,j,k be such that $\ell_i \le \ell_j \le \ell_k$ and i is f-adjacent with both j and k, where f is a non-decreasing sublinear function. Then*

$$d_{jk}d_{kj} < 18\ell_i\ell_k f(\ell_k/\ell_i) + 13\ell_j\ell_k + 2\ell_j\sqrt{\ell_i\ell_k f(\ell_k/\ell_i)} + \ell_k\sqrt{\ell_i\ell_j f(\ell_j/\ell_i)}.$$

▶ **Lemma 6.** *Let i be a link and $\rho > 1$. If E is a ρ-independent set of links where each $j \in E$ is f-adjacent with i and satisfies $\ell_i \le \ell_j \le c\ell_i$ for a constant c, then $|E| = O(1)$.*

Proof of Theorem 4. By the discussion above, it is sufficient to show that each ρ-independent set S, for appropriate constant $\rho > 1$, can be partitioned into a small number of f-independent sets. We choose $\rho = 3c_f + 31$, where c_f is such that $f(x) \le c_f x$ for all $x \ge 1$ (recall that f is sub-linear). Partitioning is done by the following *inductive* coloring procedure: 1. Consider the links in a non-increasing order by effective length, 2. Assign each link the first natural number that has not been assigned to an f-adjacent link yet. Clearly, such a procedure defines a partitioning of S into f-independent subsets.

Fix a link $i \in S$. Let T denote the set of links in $j \in S$ that have greater effective length than i and are f-adjacent with i. In order to complete the proof, it is enough to show that $|T| = O(f^*(\Delta))$, as $|T|$ is an upper bound on the number assigned to link i.

Since $f(x)$ is strongly sub-linear, there exists $x_0 = \inf\{x \ge 1, f(x) < x\} + 1$. Let us split T into two subsets A and B, where A contains the links $j \in T$ such that $\ell_j \le x_0\ell_i$ and $B = T \setminus A$. By Lemma 6, we have that $|A| = O(1)$, so we concentrate on B.

Let j,k be arbitrary links in B such that $\ell_j \le \ell_k$. By applying Lemma 5 and using the definition of c_f, we obtain: $d_{jk}d_{kj} < 18\ell_i\ell_k f(\ell_k/\ell_i) + (3c_f + 13)\ell_j\ell_k$. Recall that j and k are $(\rho = 3c_f + 31)$-independent, so $d_{jk}d_{kj} > (3c_f + 31)\ell_j\ell_k$, which gives us $\ell_j/\ell_i < f(\ell_k/\ell_i)$. Let $1,2,\ldots,t = |B|$ be an arrangement of the links in B in a non-decreasing order by effective length and let $\lambda_j = \ell_j/\ell_i$ for $j = 1,2,\ldots,t$. We have just shown that

$$x_0 \le \lambda_1 < f(\lambda_2) \le f(f(\lambda_3)) \le \cdots \le f^{(t-1)}(\lambda_t),$$

namely, $t - 1 \le f^*(\lambda_t) = O(f^*(\Delta))$. Thus, $|T| = |A| + |B| = O(1) + O(f^*(\Delta))$. ◀

Computability. Computability of our conflict graph construction is demonstrated through the notion of *inductive independence*. An n-vertex graph G is *k-inductive independent* if there is an ordering $v_1, v_2, \ldots, v_n$ of vertices such that for each v_i, the subgraph of G induced by the set $N_G(v_i) \cap \{v_i, v_{i+1}, \ldots, v_n\}$ has no independent set larger than k, where $N_G(v)$ denotes the neighborhood of vertex v. It is well known, e.g. [1, 35], that vertex coloring and MWISL problems are k-approximable in k-inductive independent graphs.

▶ **Theorem 7.** *Let f be a non-decreasing strongly sub-linear function with $f(x) \ge 40$ for all $x \ge 1$. For every set L, the graph $\mathcal{G}_f(L)$ is constant inductive independent.*

The proof is somewhat similar to that of Thm. 4. The inductive independence ordering non-decreasing order of links by length. With this in mind, the proof of Thm. 4 can be applied, with the following core difference: while in Thm. 4 the goal was, for a link i, to bound the number of *ρ-independent* links that have greater effective length and are f-adjacent with i, here we need to bound the number of *f-independent* links that have greater effective length and are f-adjacent with i.

Optimality of $O(\log\log\Delta)$-tightness. Here we show that the obtained tightness is essentially best possible, by demonstrating that every reasonable conflict graph formulation must incur an $O(\log\log\Delta)$ factor. We depart from some basic assumptions on conflict graphs. First, since the feasibility of a set of links is precisely determined by the values $\mathfrak{l}_i$ and d_{ij}, we assume that in a conflict graph, the adjacency of two links i, j is a predicate of variables $\mathfrak{l}_i, \mathfrak{l}_j, d_{ij}, d_{ji}$. Another basic observation is that the feasibility formula is scale-free w.r.t. those values; hence, we assume that so is a conflict graph formulation. This allows us to reduce the number of variables in the adjacency predicate: $\frac{\mathfrak{l}_{max}}{\mathfrak{l}_{min}}, \frac{d_{ij}}{\mathfrak{l}_{min}}, \frac{d_{ji}}{\mathfrak{l}_{min}}$, where $\mathfrak{l}_{min}$ and $\mathfrak{l}_{max}$ are the smaller and larger values of $\mathfrak{l}_i, \mathfrak{l}_j$, respectively. Our construction will consist of only *unit-length* links (i.e. $l_i = 1$) of mutual distance at least 3. In this case, we can further reduce the number of variables by noticing that in such instances, $d_{ij} = \Theta(d_{ji}) = \Theta(d(i,j))$. Thus, the conflict relation is essentially determined by two variables: $\frac{d(i,j)}{\mathfrak{l}_{min}}$ and $\frac{\mathfrak{l}_{max}}{\mathfrak{l}_{min}}$. By separating the variables, the conflict predicate boils down to a relation $\frac{d(i,j)}{\mathfrak{l}_{min}} > f(\frac{\mathfrak{l}_{max}}{\mathfrak{l}_{min}})$ for a function f. Note that this is similar to the conflict graph definition of [14], except that the lengths are replaced with effective lengths.

Let us show that the refinement property requires that $f(x) = \Omega(\sqrt{x})$ in such a graph. Let us fix a function $f : [1,\infty) \to [1,\infty)$. Let i, j be unit-length links with $\beta_j = 1$ and $\beta_i = X^\alpha > 1$, where X is a parameter. Assume further that the links i, j are placed on the plane so that $d(i,j) = 3f(X) = 3f(\mathfrak{l}_i/\mathfrak{l}_j)$, which means the links are f-independent. Thus, i, j must form a feasible set: $\frac{P(i)}{\mathfrak{l}_i^\alpha} > \frac{P(j)}{d_{ji}^\alpha}$ and $\frac{P(j)}{\mathfrak{l}_j^\alpha} > \frac{P(i)}{d_{ij}^\alpha}$. Multiplying these inequalities together and canceling $P(i)$ and $P(j)$ out, gives: $d_{ij}d_{ji} > \mathfrak{l}_i\mathfrak{l}_j = X$. This implies that we must have $d(i,j) = \Theta(\sqrt{d_{ij}d_{ji}}) = \Omega(\sqrt{X})$, which in turn implies that $f(X) = d(i,j)/3 = \Omega(\sqrt{X})$.

Now, a simple modification of the construction in [14, Thm. 9] gives a set S of unit-length links arranged on the line and with appropriately chosen thresholds β_i and distances $d(i,j)$, such that every two links are f-adjacent, but the whole set S is feasible. Such a construction can be done with the number of links $n = \Omega(f^*(\Delta))$, i.e. there is a *feasible* set of links that cannot be split in less than $\Omega(f^*(\Delta))$ f-independent subsets. Since $f(x) = \Omega(\sqrt{x})$, we have $f^*(x) = \Omega(\log\log x)$, which proves that the tightness must be at least $\Omega(\log\log\Delta)$.

5 Approximating Fixed-Rate Scheduling

We detail now the more classical problems that can be handled with our framework, starting with those involving fixed datarates. Intuitively, our framework can handle a problem if there is a correspondence between solutions in the physical model instance and solutions in the refinement graph. The refinement property ensures that the graph solutions map directly to feasible solutions in the physical model — we need to ensure a (approximate) correspondence in the other direction. We will argue that an optimal solution in the physical model has a counterpart in the graph instance, whose quality decreases only by the tightness factor k.

General Approximation Framework. Common scheduling-related optimization problems can be classified as *covering* or *packing*.

In covering problems, a feasible solution σ contains a (ordered) covering of the set L of links with feasible sets $\pi = \langle S_1, S_2, \ldots, S_t\rangle$ (i.e., $\cup_t S_t = L$), which we call *time slots*, and the objective is to minimize a function $f_\sigma(\pi)$ of the covering, which may also depend on other problem constraints.

In packing problems, a feasible solution σ contains a *fixed* number c of feasible sets (packing), $\eta = \langle S_1, S_2, \ldots, S_c\rangle$, not necessarily covering L, which we call *channels*, and the objective is to maximize a function $g_\sigma(\eta)$ of the packing.

Given a refinement $\mathcal{G}$ and a cover $\pi = \langle S_1, S_2, \ldots, S_t \rangle$ of L by feasible sets, we call another cover $\pi' = \langle S_1^1, \ldots S_1^{h_1}, S_2^1, \ldots, S_t^1, \ldots, S_t^{h_t} \rangle$, a refinement of π if $\langle S_i^1, \ldots S_i^{h_i} \rangle$ is a cover of S_i by *independent* sets in $\mathcal{G}$. Similarly, given a packing $\eta = \langle S_1, S_2, \ldots, S_c \rangle$, a refinement of η is another packing $\eta' = \langle S_1', S_2', \ldots, S_c' \rangle$, where $S_i' \subseteq S_i$ is an independent set in $\mathcal{G}$.

Formally, a covering problem is *refinable* if for every k-tight refinement $\mathcal{G}$ and a solution σ with cover π, there is a feasible solution σ' containing a refinement π' of π, and such that $f_\sigma(\pi) \geq \frac{f_{\sigma'}(\pi')}{k}$. A packing problem is *refinable* if for every k-tight refinement $\mathcal{G}$ and a solution σ with a packing $\eta = \langle S_1, S_2, \ldots, S_c \rangle$, there is a feasible solution σ' containing a refinement η' of η, and such that $g_\sigma(\eta) \leq k \cdot g_{\sigma'}(\eta')$.

▶ **Theorem 8.** *Let $\mathcal{G}$ be a k-tight refinement of the physical model. For every refinable problem, a ρ-approximation algorithm in $\mathcal{G}$ gives $k \cdot \rho$-approximation in the physical model.*

Thus, in order to obtain an approximation for a specific problem, it is sufficient to show that the problem is refinable: then the solution in a k-tight refinement gives a solution with an additional approximation factor k. Refinability requires the objective function of the problem to have certain linearity property. Examples of refinable covering problems include the ones where the objective function is the number of time slots or the sum of completion times (i.e. indices of time slots). Perhaps the simplest example of a refinable packing problem is the *maximal independent set of links* problem, where the objective is the size of the feasible set (i.e., there is only a single channel). Below, we apply the refinement framework to some important scheduling problems, which leads to $O(\log \log \Delta)$-approximation for all of them.

MWISL with Fixed Weights. Consider the MWISL problem, where the weights ω_i of links are fixed positive numbers. It is easy to see that this is a refinable packing problem, as the objective function – the sum of weights – is linear with respect to partition. Thus, since there is a constant factor approximation to MWISL in $\mathcal{G}(L)$ (by computability), it gives an $O(\log \log \Delta)$-approximation in the physical model (by Thm. 8).

Multi-Channel Selection. Given a natural number c – the number of channels – the goal is to select a maximum number of links that can be partitioned into c feasible subsets (a subset for each channel). Again, this is easily seen to be a refinable packing problem, as the objective function – the total number of links across all channels, is linear w.r.t. partitioning. A simple greedy algorithm gives constant factor approximation to multi-channel selection in constant-inductive independent graphs, which translates to an $O(\log \log \Delta)$-approximation in the physical model.

TDMA Scheduling. The goal is to partition the set L of links into the minimum number of feasible subsets. This is a covering problem, and the objective function is the number of slots, which is linear w.r.t. partitioning. A simple *first-fit* style greedy algorithm gives constant factor approximation to vertex coloring in constant inductive independent graphs, which gives an $O(\log \log \Delta)$-approximation to TDMA scheduling in the physical model.

Fractional Scheduling. This is a fractional variant of TDMA scheduling with an additional constraint of link demands. A *fractional schedule* for a set L of links is a collection of feasible sets with rational values $\mathcal{S} = \{(I_k, t_k) : k = 1, 2 \ldots, q\} \subseteq \mathcal{E}_\mathcal{P} \times \mathbb{R}_+$, where $\mathcal{E}_\mathcal{P}$ is the set of all feasible subsets of L. The sum $\sum_{k=1}^{q} t_k$ is the *length* of the schedule $\mathcal{S}$. The *link capacity vector* $c_\mathcal{S} : L \to \mathbb{R}_+$ associated with the schedule $\mathcal{S}$ is given by $c_\mathcal{S}(i) = \sum_{(I,t) \in \mathcal{S} : I \ni i} t$.

Essentially, the link capacity shows how much scheduling time each link gets. Finally, a *link demand vector* $d : L \to \mathbb{R}_+$ indicates how much scheduling time each link needs.

The *fractional scheduling problem* is a covering type problem, where given a demand vector d, the goal is to compute a minimum length schedule that serves the demands d, namely, for each link $i \in L$, $c_{\mathcal{S}}(i) \geq d(i)$. Since the cost function $\sum_{k=1}^{q} t_k$ is again linear w.r.t. partitioning of a schedule, it is readily checked that the fractional scheduling problem is also refinable. A simple greedy algorithm presented in [31] achieves constant factor approximation for fractional scheduling in constant inductive independent graphs. This gives an $O(\log\log\Delta)$-approximation in the physical model.

Joint Routing and Scheduling. Consider an ordered set of p source-destination node pairs (multihop communication requests) (u_i, v_i), $i = 1, 2, \ldots, p$, with associated weights/utilities $\omega_i > 0$, in a multihop network given by a directed graph G, where the *edges* of the graph are the transmission links. Let $\mathcal{P}_i$ denote the set of directed (u_i, v_i) paths in G and let $\mathcal{P} = \cup_i \mathcal{P}_i$. Then a *path flow* for the given set of requests is a set $\mathcal{F} = \{(P_k, \delta_k) : k = 1, 2, \ldots\} \subseteq \mathcal{P} \times \mathbb{R}_+$. The *link flow vector* $f_{\mathcal{F}}$ corresponding to path flow $\mathcal{F}$, with $f_{\mathcal{F}}(i) = \sum_{(P,\delta)\in\mathcal{F}:P\ni i} \delta$ for each link i, shows the flow along each link.

The *multiflow routing and scheduling problem* is a covering problem, where given source-destination pairs with associated utilities, the goal is to find a path flow $\mathcal{F}$ together with a fractional link schedule $\mathcal{S}$ of length 1, such that[2] for each link i, the link flow is at most the link capacity provided by the schedule, $f_{\mathcal{F}}(i) \leq c_{\mathcal{S}}(i)$, and the *flow value*

$$W = \sum_{i=1}^{p} \omega_i \cdot \sum_{(P_k,\delta_k)\in\mathcal{F}, P_k\in\mathcal{P}_i} \delta_k$$

is maximized. Let us verify that this problem is also refinable. Consider a feasible solution in (the physical model) that consists of a path flow $\mathcal{F} = \{(P_k, \delta_k) : k = 1, 2, \ldots\}$ and a schedule $\mathcal{S} = \{(I_k, t_k) : k = 1, 2, \ldots\}$ of length $\sum_{k\geq 1} t_k = 1$, such that $f_{\mathcal{F}}(i) \leq c_{\mathcal{S}}(i)$. As observed in the previous section, the schedule $\mathcal{S}$ can be refined into a schedule $\mathcal{S}' = \{(I_k^s, t_k)\}_{k,s}$ in $\mathcal{G}(L)$, where $\mathcal{S}'$ serves the same demand vector as $\mathcal{S}$ does, and $\mathcal{S}'$ has length at most $K = O(\log\log\Delta)$ times more than the length of $\mathcal{S}$. Now we normalize the refined schedule to have length 1. Then, the following modified path flow $\mathcal{F}' = \{(P_k, \delta_k/K) : k = 1, 2, \ldots\}$ together with the new schedule will be feasible in $\mathcal{G}(L)$, as all link demands will be served. Moreover, the value of $\mathcal{F}'$ is at most K times that of $\mathcal{F}$. Hence, the problem is refinable.

Thus, applying the constant factor approximation algorithm of [32] for constant inductive independent conflict graphs (the result holds with unit utilities) gives an $O(\log\log\Delta)$-approximation for multiflow routing and scheduling problem in the physical model. It should also be noted that the fractional scheduling and routing and scheduling problems can be reduced to the Mwisl problem using linear programming techniques (described e.g. in [17]), as it was shown in [30]. We will further discuss this in Section 6.

Extensions to Multi-Channel Multi-Antenna Settings. All problems above may be naturally generalized to the case when there are several channels (e.g. frequency bands) available and moreover, wireless nodes are equipped with multiple antennas and can work in different channels simultaneously. We denote the setting with multiple antennas/channels as *MC-MA*.

[2] Essentially, the schedule here gives a probability distribution over the feasible sets of links.

It is easy to show that our refinement framework can be extended to MC-MA with very little change. Assume that each node u is equipped with $a(u)$ antennas numbered from 1 to $a(u)$ and can use a set $\mathcal{C}(u)$ of channels. Consider a link i that corresponds to the pair of nodes s_i and r_i. There are $a(s_i)a(r_i)|\mathcal{C}(s_i) \cap \mathcal{C}(r_i)|$ *virtual* links corresponding to each selection of an antenna of the sender node s_i, an antenna of receiver node r_i and a channel $c \in \mathcal{C}(s_i) \cap \mathcal{C}(r_i)$ available to both nodes. Thus a virtual link is described by the tuple (i, a_s, a_r, c), where a_s (a_r) denotes the antenna index at s_i (r_i, respectively), and c denotes the channel. We call link i *the original* of its virtual links. Note that the formulation above can easily be generalized to the case where certain antennas don't work in certain channels, e.g., due to multi-path fading.

A set of (virtual) links S is feasible in MC-MA if and only if no two links in S share an antenna (i.e., they do not use the same antenna of the same node), and for each channel c, the set of originals of links in S using channel c is feasible in the physical model. Then, an $O(\log\log\Delta)$-tight refinement for the MC-MA physical model by a conflict graph can be found by a simple extension of the existing refinement for the single channel case to the virtual links. This implies, in particular, that all scheduling problems considered in the previous sections can also be approximated in the MC-MA setting within an approximation factor $O(\log\log\Delta)$, as the corresponding approximations for the conflict graph hold with MC-MA [32].

6 Rate Control and Scheduling

The most important application of efficient approximation algorithms for scheduling problems with different thresholds is the application to scheduling with rate control. This is achieved first by obtaining a double-logarithmic approximation to Mwisl with rate control. This will then lead to similar approximations for fractional scheduling and joint routing and scheduling problems.

MWISL with Rate Control. By Shannon's theorem, given a set S of links simultaneously transmitting in the same channel, the transmission rate $r(S, i)$ of a link i is a function of $SIR(S, i)$. Thus, we consider the Mwisl problem where each link i has an associated *utility function* $u^i : \mathbb{R}_+ \to \mathbb{R}_+$, and the weight of link i is the value of u^i at $SIR(S, i)$ if link i is selected in the set, and 0 otherwise. As before, the goal is, given the links with utility functions, to find a subset S that maximizes the total weight $\sum_{i\in S} u^i(r(S, i))$. We assume that $u^i(SIR(S, i)) = 0$ if $SIR(S, i) < 1$.

An $O(\log n)$-approximation for this variant of Mwisl has been obtained in [23]. We show that this can be replaced with $O(\log\log\Delta')$, where $\Delta'(L) = \max_{i,j\in L} \frac{u^i_{max} l_i}{u^j_{min} l_j}$ and u^i_{min}, u^i_{max} are the minimum and maximum possible utility values for the given instance and link. This is achieved by reducing the problem to Mwisl in an extended instance.

Let us fix a utility function u. First, assume that the possible set of weights for each link is a discrete set $u_{min} = u_1 < u_2 < \cdots < u_t = u_{max}$. Then, we can replace each link i with t copies $i_1, i_2, \cdots, i_t$ with different thresholds and fixed weights, where $\omega_{i_k} = u_k$ and $\beta_{i_k} = \min\{x : u^{i_k}(x) \geq u_k\}$ if $\beta_{i_k} \geq 1$ and $\omega_{i_k} = 0$ otherwise. Now, the problem becomes a Mwisl problem for the modified instance L' with link replicas and fixed weights. Observe that no feasible set in L' contains more than a single copy of the same link, as the copies occupy the same geometric place, implying that each feasible set of the extended instance corresponds to a feasible set of the original instance, with an obvious transformation. The effective length diversity of the extended instance is $\Delta(L') = \Delta'(L)$. Thus, using the approximation

algorithm for the fixed rate MWISL problem, we obtain an $O(\log\log\Delta'(L))$-approximation for MWISL with rate control.

For the case when the number of possible utility values is too large or the set is continuous, a standard trick can be applied. Let u^i_{max}, u^i_{min} be as before. The extended instance L' is constructed by replacing each link i with $O(\log u^i_{max}/u^i_{min})$ copies $i_1, i_2, \ldots$ of itself and assigning each replica i_k weight $\omega_k = 2^{k-1}$ and threshold $\beta_k = \min\{x : 2^{k-1} \le u^i(x) \le 2^k\}$ if $\beta_k \ge 1$ and let $\omega_k = 0$ otherwise. It is easy to see that the optimum value of MWISL with fixed rates in L' is again an $O(\log\log\Delta'(L))$-approximation to MWISL with rate control.

If the value $\log u^i_{max}/u^i_{min}$ is still too large, it may be inefficient to have $O(\log u^i_{max}/u^i_{min})$ copies for each link. It is another standard observation that only the last $O(\log n)$ copies of each link really matter, as restricting to only those links degrades approximation by a factor of at most 2.

Fractional Scheduling with Rate Control. In this formulation, we redefine a fractional schedule to be a set $\mathcal{S} = \{(I_k, t_k) : k = 1, 2 \ldots, q\} \subseteq 2^L \times \mathbb{R}_+$, namely, I_k are arbitrary subsets, rather than independent ones. We redefine the link capacity vector $\hat{c}_\mathcal{S}$ to incorporate the rates as follows:

$$\hat{c}_\mathcal{S}(i) = \sum_{(I,t)\in\mathcal{S}: I\ni i} t \cdot r(i, I). \tag{2}$$

The *fractional scheduling with rate control* problem is to find a minimum length schedule $\mathcal{S}$ that serves a given demand vector d, namely, such that for each link $i \in L$, $\hat{c}_\mathcal{S}(i) \ge d(i)$.

The problem can be formulated as an exponential size linear program LP_1, as follows.

$$\min \sum_{I\subseteq L} t_I \text{ subject to } \sum_{I\subseteq L: I\ni i} t_I \cdot r(i, I) \ge d(i) \qquad \forall i \in L$$
$$t_I \ge 0 \qquad \forall I \subseteq L$$

The dual program LP_2 looks as follows:

$$\max \sum_{i\in L} d(i) y_i \text{ subject to } \sum_{i\in I} y_i \cdot r(i, I) \ge 1 \qquad \forall I \subseteq L$$
$$y_i \ge 0 \qquad \forall i \in L$$

As [17, Thm. 5.1] states, if there is an approximation algorithm that finds a set $\hat{I}$ such that $\sum_{i\in\hat{I}} y_i r(i, \hat{I}) \ge \frac{1}{a} \max_{I\subseteq L} \sum_{i\in I} y_i r(i, I)$, then there is an a-approximation algorithm for LP_1, where the former algorithm acts as an approximate separation oracle for LP_1. But this auxiliary problem is simply a special case of the MWISL with rate control, which we can approximate within a double-logarithmic factor. Thus, there is an approximation preserving reduction from the fractional scheduling with rate control to MWISL with rate control. By the obtained approximation for MWISL, we obtain an $O(\log\log\Delta')$-approximation for fractional scheduling with rate control.

Routing, Scheduling and Rate Control. The rate-control variant of the routing and scheduling problem is formulated in the same way as for the fixed rate setting, with the only modified constraint being the capacity constraints, which, instead of the link capacity vector $c_\mathcal{S}$, now use the modified variant $\hat{c}_\mathcal{S}$ that incorporates the link rates (see the definition in (2)).

This problem can also be reduced to MWISL with rate control, using similar methods as for the fractional scheduling problem. The reduction is nearly identical to the reduction of fixed rate versions of these problems to MWISL, presented in [30, Thm. 4.1].

Thus, we can conclude that there is an $O(\log \log \Delta')$-approximation algorithm for joint routing, scheduling and rate control that uses MWISL with rate control as a subroutine.

Abstract

We define the Streaming Communication model that combines the main aspects of communication complexity and streaming. Input arrives as a stream, spread between several agents across a network. Each agent has a bounded memory, which can be updated upon receiving a new bit, or a message from another agent. We provide tight tradeoffs between the necessary resources, i.e. communication between agents and memory, for some of the canonical problems from communication complexity by proving a strong general lower bound technique. Second, we analyze the Approximate Matching problem and show that the complexity of this problem (i.e. the achievable approximation ratio) in the one-way variant of our model is strictly different both from the streaming complexity and the one-way communication complexity thereof.

1 Introduction

In the last decade we have witnessed a big shift in the way data is produced and computation is performed. First, we now have to deal with enormous amounts of data that we cannot even store in memory (internet traffic, CERN experiments, space expeditions). Second, computations do not happen in a single processor or machine, but with multi-core processors and multiple machines in cloud architectures. All these real-world changes necessitate that we revisit and extend our models and tools for studying the efficiency and hardness of computational problems.

Imagine the following situation: some input is spread across a network. The agents want to compute some function f which depends on everybody's input.This is an archetypal problem of Communication Complexity (CC) [29], which offers a way to estimate the number of bits that need to be exchanged, under various settings, in order to achieve that goal. There are many different CC models, depending whether the agents can speak directly between them or through a referee, and whether they can use multiple rounds of communication or just a single one. Communication complexity has found a variety of applications both in networks and distributed computing but also in other areas of theoretical computer science, including, circuit lower bounds, fomulae size, VLSI design, etc. All these communication

models however have a feature in common. They assume the agents are computationally unbounded and that the input is delivered all at once.

In a distributed context as that of sensor networks, not only are there several computing agents, the input might not even be given all at once. The *streaming model* [1] has been defined precisely to capture the fact that the input of an agent is so big it cannot be stored or read several times. Instead it comes bit by bit. Some function of the stream needs to be computed, but the available space is not big enough to store the entire input. The streaming model has been extensively studied in recent years with a plethora of interesting upper and lower bounds on the necessary memory to solve specific streaming problems [27]. More recently, the turnstile model has received a lot of attention. In this model, streams are made of both insertions and deletions, and the function to be computed depends on the remaining elements (and eventually their respective frequencies). Indeed, any streaming algorithm in this model can be turned into an algorithm based solely on the updates of linear sketches [25].

1.1 The Streaming Communication model.

We would like to combine the two above mentioned models to include both that inputs are distributed among different agents and also are coming as streams at each agent. Each agent is given a bounded memory to store what she sees. We refer to this extension as the *Streaming Communication (SC) model*. Even though communication arguments have often been invoked in proving lower bounds for regular streaming models, as in the seminal work of [1, 3], this model has not been rigorously defined previously, in spite of its theoretical appeal and relevance for actual communication networks. More formally, in the SC model consider two agents, Alice and Bob, want to compute some function f that depends on inputs (x, y) that are respectively distributed to each agent, x to Alice and y to Bob. Both inputs arrive as data streams and each agent has a bounded memory of a given size S. Agents may or may not speak every time they receive a bit. They can also update their memory based on the previous bit they read, the previous message they received and of course the actual content of their memory.

Additionally to the memory size S of Alice and Bob, the other relevant parameters we consider are the number R of communication rounds and the number T of bits in the full transcript (the concatenation of all messages). In the *one-way* SC model, there is only a single message from Alice to Bob at the end of the streams. Observe that we do not bound the size of each message, since we show that those can always be assumed to be of at most $S + 1$ bits (**Proposition 5**).

1.2 Related models

Before we present our results in the streaming communication model, we review some related works in the communication and streaming models. As explained previously, our goal is to provide rigorous tradeoffs between the two resources: memory storage and communication between the players, in a model where inputs are coming as streams.

The most relevant work is [15, 16]. There, two parties receive two streams and at the end of the streams each party sends their workspace to a referee which uses both workspaces to compute some function of the union of the two streams. In this model, we can also see elements both from streaming algorithms and communication complexity, albeit of the restricted form of simultaneous message passing. Here we provide a more general framework for communication and we look at a much wider variety of problems and protocols.

One of the powerful and often used techniques in streaming algorithms is linear sketches, which naturally provide very simple SC protocols even in the one-way setting, by just combining the linear sketches at the end of the protocol. In fact, in the turnstile model, when streams are made of sequences of insertions and deletions and the function to be computed is a function of the remaining elements (and eventually their respective frequencies), any streaming algorithm can be turned into an algorithm based solely on the updates of linear sketches [25]. Hence, here we focus on other stream models, such as the one of insertion only, which are more challenging in the context of SC protocols.

In the distributed streaming functional monitoring setup initially proposed by [11], k servers receiving a stream have to allow a coordinator to continuously monitor a given quantity (see also [10, 9, 13] for earlier works in the database community on the monitoring topic). Several follow-up works studied this model (see e.g. [8, 26, 18, 12, 28]). These all focus on communication and do not consider *both* resources, memory storage and communication simultaneously. They can be viewed as extending [15, 16] with greater number of players. The communication model however is still restricted to simultaneous messages to a referee.

Another line of work studies bounded-memory versions of communication [24, 5, 7]. Several models have been proposed that share the same structure. The input is given all at once, but the players only have bounded space to store the conversation while further restrictions can be placed on the algorithms used by the players, for example to be straight line programs [24], or branching programs [5].

Last, [14] studies another model that deals with distributed parallel streaming platforms, where now, the stream arrives in parallel and arbitrarily partitioned to a set of different agents that communicate in order to solve the task.

1.3 Our results

As a first step, we restrict ourselves in this work to the 2-player case. Our first results, detailed in Section 2.4, show connections between our new model and its two parent models, Communication Complexity and Streaming. We show that the total transcript size T and the product RS (number of rounds times memory size) are both lower bounded by the communication complexity $C(f)$ of the f we wish to compute, up to logarithmic factors (**Proposition 6**). Those factors come from an inherent notion of clock in our SC model.

The comparison with streaming algorithms is more subtle. Since the i-th bit of Alice's input arrives at the same time as the i-th bit of Bob's input, the correct comparison is with a single streaming model where the stream is the one we get by interleaving Alice's and Bob's stream. We denote by $\mathcal{S}^{\mathbf{int}}(f)$ the memory required by a streaming algorithm for computing a function f, when the two streams are interleaved in a single stream. We first observe than interleaving streams instead of concatenating them can lead to an exponential blow up (**Theorem 8**). Then we show that $\mathcal{S}^{\mathbf{int}}(f)$ is a lower bound on twice the memory size S of players (**Proposition 9**).

Then it is natural to ask if there is always a polynomial relation between, on one hand, the parameters of a protocol in the SC model (S, R and T), and on the other hand, the communication complexity $C(f)$ (randomized or deterministic) of the function when the input is all given in the beginning and the memory $\mathcal{S}^{\mathbf{int}}(f)$ necessary in the single stream model. We show that this is not true in general by providing an example for which $\mathcal{S}^{\mathbf{int}}(f) = C(f) = O(\log n)$ but $R \cdot S = \Omega(n)$, when $S = \Omega(\log n)$ (**Theorem 10**). This implies that the SC complexity of a function f may not be immediately derived neither by its communication complexity nor by its streaming complexity. This is one of the main reasons why our model is interesting and necessitates novel techniques for its study.

The first of our two main results is a general technique for proving tradeoffs between memory and communication in our model. The smaller the memory, the more frequent communication has to be. For instance, one expects that for functions whose communication complexity is n, i.e. where all bits are necessary, players with a memory of size S *have to* speak at least every S rounds (either deterministic or randomized), since if they remain silent for more than S rounds, they start to lose information about their input. More precisely, any function f that can be written as $f(x,y) = G(g_1(x^1,y^1), g_2(x^2,y^2), \ldots, g_L(x^L,y^L))$, where G is a function satisfying some assumptions. Then, any randomized protocol computing f must have $R \cdot S = \Omega(\sum_{\ell \in L} C(g_\ell))$ (**Theorem 13**). We can apply our theorem to many canonical communication functions, including $IP_n, DISJ_n$ or $TRIBES_n$, and show that any protocol satisfies $R \cdot S = \Omega(n)$ (**Theorem 14**).

In Section 4, we study problems arising in the context of graph streaming. We work in the insert only model, meaning that the graph is presented as a stream of its edges in an arbitrary order. Indeed, as opposed to the turnstile model, where any algorithm can be turned into a linear sketches based on [25], the situation is much more intriguing for problems where linear sketches are not used. In particular, in the context of streaming algorithms for graph problems, *Approximate Matching* has been extensively studied, and its streaming complexity is still unknown. Given a stream of edges (in an arbitrary order) of an n-vertex graph G and some space restriction, the goal is to output a collection of edges from G forming a matching, as big as possible in G. The matching size estimation is a different and somehow easier problem [21].

It is known that any streaming algorithm for Approximate Matching using $\widetilde{O}(n)$ memory cannot achieve a ratio better than $\frac{e}{e-1}$ [20], whereas the best known algorithm is a simple greedy algorithm which provides a 2-approximation. In the one-way CC model, without memory constraints, it has been also showed that a $\frac{3}{2}$-approximation is the tight bound when Alice's message is restricted to $\widetilde{O}(n)$ bits [17]. Both these works use in a clever way the so-called Ruzsa-Szemerédi graphs.

We study both the general SC model and its one-way variant. Our main bounds are for the one-way variant, the weaker model combining the restrictions of both CC and streaming models: we show a lower bound of $\frac{e+1}{e-1} \approx 2.16$ for the approximation factor unless $S = n^{1+\Omega(\frac{1}{\log \log n})}$ (**Corollary 17**), which is strictly higher than both the single stream lower bound of $\frac{e}{e-1} \approx 1.58$ with same space constraints and the one-way communication lower bound of 1.5. We also provide a one-way SC protocol achieving an approximation ratio of 3 with the same space constraints (**Theorem 16**), thus leaving as an open question the optimal approximation ratio. Moreover, we show that how often the players communicate makes a big difference, namely we show how to implement the simple greedy algorithm when Alice and Bob can communicate during the protocol that provides a ratio of 2, strictly better than our lower bound for the one-way SC model.

Let us emphasize that all previous lower bounds, including the ones in the turnstile models [2, 22], do not readily apply to the one-way SC model for the Approximate Matching problem. However, our main lower bound in the one-way SC model uses as a black-box the hard distributions of graph streams of [17, 20]. Therefore, further improvements in the streaming context may lead to improvements in our model. Given a hard distribution μ of graphs for the approximate matching for streaming algorithms, we show how to extend this distribution to produce a hard distribution μ_2 in our one-way SC model (**Theorem 21**).

2 The streaming communication model

We provide some background on communication complexity and streaming and then, we define our model and describe some initial results.

2.1 Communication Complexity

We start by reviewing some results in the usual models of communication complexity (CC), defined by Yao [29]. For more details about the communication complexity model, please refer to [23]. In the communication complexity models, generically denoted by CC, players aim at computing some function which depends on their disjoint inputs, by communicating. Each player determines her message based on previous messages and her input. The goal is to minimize the total length of the protocol transcript.

In the randomized case, we will allow the players to share public randomness. Allowing for public randomness makes our lower bounds stronger, while the protocols we provide will be deterministic. We will also consider the expected, rather than maximal, length of transcripts and define the average randomized communication complexity of a function.

▶ **Definition 1.** For a given protocol Π, we denote by $\Pi(x, y, r)$ the transcript with inputs x, y and public randomness r. The worst case (resp. expected) communication complexity of a function f with error ε is defined as $C_\varepsilon(f) = \min_\Pi \max_{x,y} \max_r |\Pi(x, y, r)|$ and $C_\varepsilon^{avg}(f) = \min_\Pi \max_{x,y} \mathbb{E}_r(|\Pi(x, y, r)|)$, where the minimum is taken over protocols computing f with error ε, and the expectation on the second line is with respect to the randomness r used in Π.

The following proposition relates the average and worst case randomized communication complexities.

▶ **Proposition 2** ([23]). *For any $\varepsilon, \delta > 0$, it holds that, $\delta \cdot C_{\varepsilon+\delta}(f) \leq C_\varepsilon^{avg}(f) \leq C_\varepsilon(f)$.*

Some of the canonical functions studied in communication complexity are the equality problem, denoted EQ_n where the players output 1 iff their inputs $x, y \in \{0, 1\}^n$ are equal, the disjointness problem, denoted $DISJ_n$ where the goal is to check whether the n-bit strings interpreted as sets intersect or not, and the inner product problem IP_n where the players need to output the inner product of their inputs modulo 2.

The functions $DISJ_n$ and IP_n are "hard" functions for CC, in the sense that almost all the input must be sent even when we allow for randomization, error and expected length. The following two bounds, which we will need later, can be derived for example from [4], where the notion of information cost is used.

▶ **Theorem 3.** *Any protocol for $DISJ_n$ or IP_n with error $1/2 - \varepsilon$ has communication complexity $\Omega(\varepsilon^2 n)$.*

2.2 Streaming algorithms

In the streaming model, the input comes as a stream to an algorithm whose task is to compute some function of the stream while using only a limited amount of memory and making a single or a few passes through the input stream. See [27] for a general introduction to the topic. If possible, the updates should also be fast. It was defined in the seminal work of [1] where the authors provided upper and lower bounds for computing some stream statistics. Since then, a plethora of results have appeared for computing statistics of the stream, as well as for graph theoretic problems. For the graph problems, we will assume

that the graph is revealed to the algorithm as a stream, one edge at a time. In the more recent turnstile model, streams are made of both insertions and deletions, and the goal is to compute some function that depends only the remaining elements (and eventually their respective frequencies). As we have said, any problem in the turnstile model can be solved via linear sketches [25].

2.3 The new model of Streaming Communication protocols

We show how to extend the original model of communication complexity to account for streaming inputs. In the Streaming Communication SC model we consider that the inputs x, y are not given all at once to the two players Alice and Bob but rather come as a stream. Moreover each player only has limited storage, S bits of memory. In the randomized case, the players also have access to a shared random bit string r which may be infinite. They may use as many coins as they like from these strings.

A *protocol* Π in the streaming communication model is specified by four functions $\Phi^A, \Phi^B, \Psi^A, \Psi^B$. Each time slot i is divided in two phases:

1. Each party receives a message from the other party (m_i^B and m_i^A resp.) and updates their memory (that was in state σ_i^A and σ_i^B resp.) according to the function Φ^A and Φ^B resp. This function also depends and the shared random string r, which is not restricted in size.
2. Messages m_{i+1}^A and m_{i+1}^B are produced using the functions Ψ^A and Ψ^B resp., that depend on the current memory states σ_{i+1}^A and σ_{i+1}^B resp., the newly read input bit, and the randomness r. The messages might be empty and they could also be arbitrarily big in principle, though we will see in Proposition 5 that their size can be assumed to be $S+1$ without loss of generality.

$\sigma_{i+1}^{A/B} := \Phi^{A/B}(m_i^{B/A}, \sigma_i^{A/B}, r)$ and $m_{i+1}^{A/B} := \Psi^{A/B}(\sigma_{i+1}^{A/B}, x_{i+1}, r)$. Moreover, we assume that the streams end with a special EOF symbol and that once the streams are finished, the players only get one last round of communication, and then they have to output something.

▶ **Definition 4** (SC protocols)**.** An SC protocol Π uses S bits of memory, R rounds, and T bits when

1. The memory size of each player is at most S bits;
2. The (expected) number of time slots where either $m_i^A \neq \emptyset$ or $m_i^B \neq \emptyset$ is at most R;
3. The (expected) size of all exchanged messages is at most T bits.

The expectation is over the randomness of the protocol and worst-case over the inputs. An SC protocol is said to be *one-way* if there is a single message from Alice to Bob after the streams have been received, and only Bob computes the function.

Note, that our model carries an implicit notion of time due to the players reading their streams synchronously, and hence, the ability to send empty messages can be used to reduce communication [19]. However the gain is only logarithmic in the number of available time slots (see Section 2.4). We could have avoided such extra power, by defining a model where agents know when they should speak or read a bit, based on the previous messages they received and their memory content. Nevertheless, we opted for our model, as it is simpler to state and the necessary resources do not change by more than a factor logarithmic in the input size.

When we prove lower bounds or communication-memory tradeoffs, we do not consider the complexity of $\Phi^{A/B}$. These functions could be of arbitrarily high complexity. To make things simple, we assume they are the same functions for every round $i \in [n]$, but they can

depend on n. This framework captures the streaming model as a special case, when the output depends on the stream of Alice only.

2.4 Properties of the SC model

Several times in our proofs, we will consider an SC protocol and use it to solve problems in the standard models of CC. It is convenient to have a bound on how big the messages $m^{A/B}$ can be.

The length of the messages $m^{A/B}$ could be very big in the SC protocol, but we now show that the SC protocol can be simulated replacing them by length $S+1$ messages.

▶ **Proposition 5.** *In the SC model, we may always assume that the size of the messages is at most $S+1$ bits, up to redefining the transition functions $\Phi^{A/B}$.*

Proof. Consider a protocol Π with associated functions $\Phi^{A/B}, \Psi^{A/B}$.

The players can exchange their S size memory and the last input symbol instead of the actual messages. Hence, it is possible to redefine functions $\Phi^{A/B}, \Psi^{A/B}$ and directly assume messages have length $\leq S+1$. The new equations with $S+1$ bit messages would read $\sigma_{i+1}^{A/B} := \Phi^{A/B}(\Psi^{B/A}(\sigma_i^{B/A}, y_i, r), \sigma_i^{A/B}, r)$ and $m_{i+1}^{A/B} := \Psi^{A/B}(\sigma_{i+1}^{A/B}, x_{i+1}, r)$. ◀

Any protocol in the SC model can be simulated with another protocol in the usual CC model with a small overhead. Note that due to the implicit time in the SC model, we cannot immediately conclude that the SC model is harder than the usual communication model. Nevertheless, this time issue induces only an extra logarithmic factor.

▶ **Proposition 6.** *We can simulate any protocol Π in the SC model with parameters S, R, T with another protocol Π' in the normal communication model such that its communication cost $C(\Pi')$ is bounded as $C(\Pi') \leq T(1+2\log n)$ and $C(\Pi') \leq R(S+2\log n+1)$.*

We now compare the SC model to streaming algorithms, that is when there is a single player and a single stream. There are various ways to combine streams x and y in a single stream. Since x_i is presented to Alice at the same time as y_i to Bob, in a single player model x_i should be presented just before y_i to the player. This explains why we consider the interleaved streaming model.

▶ **Definition 7.** Let $\mathcal{S}^{\mathbf{int}}(f)$ be the amount of memory required for a streaming algorithm to compute f where the input stream is x, y interleaved, that is to say, $x_1, y_1, x_2, y_2, \ldots, x_n, y_n$.

It turns out that interleaving streams instead of concatenating streams may affect the memory requirement of the function for a standard streaming algorithm by an exponential factor. A proof of the following result is provided in the full version of this paper.

▶ **Theorem 8.** *There is a function f such that $\mathcal{S}^{\mathbf{int}}(f) = \Omega(n)$, whereas there is a streaming algorithm to compute f with memory $O(\log n)$ when streams are concatenated.*

First let us observe that $S^{\mathbf{int}}(f)$ provides a lower bound in the SC model.

▶ **Proposition 9.** *Let f be a function. Then, any protocol in the SC model for the function f, where Alice and Bob use memories of size S, must have $2S \geq S^{\mathbf{int}}(f)$.*

It is natural to ask if there is a polynomial relation bounding the parameters S, R, T of a protocol in the SC model in terms of the streaming complexity $\mathcal{S}^{\mathbf{int}}(f)$ and the communication complexity $C(f)$, at least when $S = O(\mathcal{S}^{\mathbf{int}}(f))$. This appears to not hold in general. The following result is shown in the full version of the paper.

▶ **Theorem 10.** *There exists a function f such that $\mathcal{S}^{\mathbf{int}}(f) = C(f) = O(\log n)$ but any protocol computing f in the SC model must have $R \cdot S = \Omega(n)$. This holds for $S = \Omega(\log n)$.*

3 Communication primitives

We provide a general theorem that provides tight tradeoffs both in the deterministic and randomized case for a variety of functions, including $DISJ_n, IP_n, TRIBES_n$.

3.1 A general lower bound

In this section we show a general result that gives a lower bound for a large class of functions. We will obtain the lower bounds for the usual primitives $DISJ, IP, TRIBES$ as a corollary. We treat ε as a constant. The assumption we make is of a structural kind. Namely, as explained in Definition 12 we assume the function to be computed can be written in a depth-2 fashion, as a composition of an outer function G with inner gadgets g_ℓ.

▶ **Definition 11.** We call a function G on L variables *non trivial* if the following holds. There exists a word $a \in \{0,1\}^L$ such that for all ℓ there exists a postfix $b_\ell \in \{0,1\}^{L-\ell-1}$ such that $G(a_{\leq \ell} u b_\ell)$ depends on the bit u. More formally $G(a_{\leq \ell} 0 b_\ell) \neq G(a_{\leq \ell} 1 b_\ell)$.

This may look as a restrictive condition. In fact, most natural functions that depend on every bit are "non trivial" in this sense. For the function $\bigoplus$, a, b can be chosen arbitrarily. The functions OR and AND are also non trivial. For instance for AND, $a = b = 1^L$ will do.

We borrow the next definition from [4] (extending it slightly).

▶ **Definition 12** (Block-decomposable functions)**.** Let $I_1, \ldots, I_L$ be an interval partition of $[n]$, which we refer to as *blocks*. For $\ell \in [L]$, let $t_\ell = |I_\ell|$ be the length of I_ℓ. Given strings $x, y \in \{0,1\}^n$, write x^ℓ (resp. y^ℓ) for the restriction of x (resp. y) to indices in block I_ℓ. We say $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ is *G-decomposable* with primitives (g_ℓ), where $G : \{0,1\}^L \to \{0,1\}$ and $g_\ell : \{0,1\}^{t_\ell} \times \{0,1\}^{t_\ell} \to \{0,1\}$, if for all inputs x, y we have $f(x,y) = G(g_1(x^1, y^1), g_2(x^2, y^2), \ldots, g_L(x^L, y^L))$.

Assuming f is G-decomposable, our goal is to show lower bound the communication needed to compute f in the SC model in terms of the communication complexity of each g_ℓ and the available memory.

▶ **Theorem 13.** *Assume the function $f : \{0,1\}^n \times \{0,1\}^n \to \{0,1\}$ is G-decomposable with primitives $(g_\ell)_{\ell \in L}$, and that G is non-trivial. Let $C_{\varepsilon+\delta}(g_\ell)$ be the worst-case randomized communication complexity of g_ℓ in the usual communication model. Then, any randomized protocol computing f with error ε in the SC model with S bits of memory, R expected communication rounds and T expected bits of total communication, must have*

$$R \geq \sum_{\ell \leq L} \frac{\delta C_{\varepsilon+\delta}(g_\ell) - S}{S + 2\log t_\ell + 1}, \quad T \geq \sum_{\ell \leq L} \frac{\delta C_{\varepsilon+\delta}(g_\ell) - S}{1 + 2\log t_\ell}.$$

We can get a similar bound in the deterministic case, where we use the deterministic communication complexity of the g_ℓ's. Last, if G is $\bigoplus$ we may remove δ from the above bounds, changing the complexities $C_{\varepsilon+\delta}(g_\ell)$ to $C^{avg}_{\varepsilon}(g_\ell)$.

3.2 Applications

Before proving Theorem 13, we give a few corollaries. Note that the upper bounds are trivial. Remind the function $TRIBES$, which is an AND of Set Intersections is defined by $TRIBES_n(x,y) := AND_{i \leq \sqrt{n}} \circ OR_{j \leq \sqrt{n}} (x_{ij} \bigwedge y_{ij})$.

▶ **Theorem 14.** *Any randomized protocol in the SC model that computes the function IP_n, $DISJ_n$, or $TRIBES_n$ and uses S memory and R communication rounds must have $R \cdot S = \Omega(n)$.*

Proof. We start with $DISJ_n$. We write $DISJ_n(x,y) = AND_{\ell=1}^{n/k}\left(DISJ_\ell(x^\ell, y^\ell)\right)$, and use the previous result with $G = AND$ and $g_\ell = DISJ_k$. It follows from Theorem 3 that $R_{\varepsilon+\delta}(DISJ_k) = \Omega(k)$. We omit the dependency on ε and δ in the term $\Omega()$, treating these parameters as fixed constants. The number of rounds for any randomized protocol in the SC model is at least $\sum_{\ell=1}^{\frac{n}{k}} \frac{\Omega(k)-S}{S+2\log k}$. We get the result choosing $k = \Omega(S)$.

In the case of IP_n, the function $f = IP_n$ is the composition of $G = \bigoplus$ over $\frac{n}{k}$ coordinates with $g_\ell = IP$ (for each $\ell \leq \frac{n}{k}$), over k coordinates. Theorem 3 gives $C_\varepsilon^{avg}(g_\ell) \geq \Omega(k)$. Theorem 13 yields the bound, taking $k = 10S$. We omit the case of $TRIBES_n$ as it follows from a similar argument. ◀

4 Approximate Matching in the Streaming Communication model

The main problem we consider is that of computing an approximate matching. The stream corresponds to edges (in an arbitrary order) of a bipartite graph $G = (P, Q, E)$ over vertex set P, Q, and the algorithm has to output a collection of edges which forms a matching. All edges in the output have to be in the original graph. In the vertex arrival setting, each vertex from Q arrives together with all the edges it belongs to. Our goal is to understand what is the best approximation ratio we can hope for, for a given memory (and message size).

We start by some notations. In a graph $G = (P, Q, E)$, if $U \subseteq P \cup Q$ and $V \subseteq P \cup Q$ are subsets of the vertices, we denote by $E(U, V) \subseteq E$ the edges with endpoints in U and V. We also denote by $OPT(G)$ the maximum size of a matching in G.

Observe now that when communication can occur at any step, the greedy algorithm, which is currently the best algorithm in the standard streaming model, can be implemented easily by having Alice communicate to Bob every time she adds an edge to her matching.

▶ **Proposition 15.** *The greedy algorithm, which achieves a 2-approximation, can be implemented using $n \log n$ bits of communication and n rounds in the SC model.*

Thus, we now focus on the one-way SC model, where the communication is restricted to happen once the streams have been fully read. In this setting, we will get different lower and upper bounds than in the streaming model. We start by a positive result.

▶ **Theorem 16** (Greedy matchings)**.** *If Alice sends Bob a maximal matching of her graph, then Bob can compute a 3-approximation. In particular a 3-approximation can be computed in a deterministic one-way SC protocol using $O(n \log n)$ memory and message size.*

Proof. Let G_1, G_2 be the respective graphs that Alice and Bob get, and let M_1, M_2 be their respective computed maximal matchings. We show that there is a matching in $M_1 \cup M_2$ of size at least $|OPT(G)|/3$.

The proof goes in two steps. Let ℓ be the size of $V(M_1 \cup M_2)$. We prove first that there is a matching of size $\geq \frac{\ell}{3}$ in the graph $M_1 \cup M_2$, and then that the number of edges in $OPT(G)$ is at most ℓ.

The first part is easy. Observe that $M_1 \cup M_2$ has maximal degree 2. Then there must be a matching of size at least $\ell/3$ from Theorem 7 in [6].

For the second part, we construct an injection $OPT(G) \hookrightarrow V(M_1 \cup M_2)$. Let $e = (u_1, u_2) \in OPT(G)$. Assume w.l.o.g. $e \in G_1$. Then either u_1 or u_2 is matched in M_1 (or both), by maximality of M_1. Map e to (one of) its matched endpoints in M_1. ◀

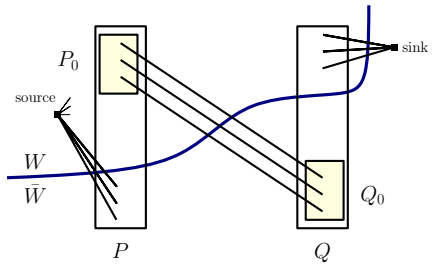

Figure 1 The figure shows how the maxflow mincut theorem is used to argue about the size of a matching in a bipartite graph G over vertex set $P \times Q$ drawn from a distribution μ. Only edges from the cut are drawn. The source and sink are added for the sake of the argument, they are not part of G.

Our lower bound is obtained using a black box reduction that we develop in the following sections. It is a direct consequence of the combination of Theorem 21 and Theorem 19.

▶ **Corollary 17** (A $(e+1)/(e-1)$ lower bound)**.** *Any protocol achieving a ratio of* $\frac{e+1}{e-1} - \eta \approx 2.16 - \eta$*, for some constant* η*, in the vertex arrival setting needs communication* $n^{1+\Omega(1/\log\log n)}$ *where the hidden constant in the* $\Omega(.)$ *depends on* η*.*

4.1 Hard distributions for streaming algorithms

Our notion of hard distribution is tailored to capture the distributions appearing in [17, 20]. They are distributions over streams of graphs, that is over graphs and edge orderings.

We will use the following definition for constructing families of hard distributions when $n \to \infty$ and α, η are fixed. Therefore $O()$ and $o()$ notations have to be understood in that context.

▶ **Definition 18** (Hard distribution)**.** A distribution μ over streams of bipartite graphs $G = (P, Q, E)$ is an $(\alpha, n, m(n), \eta)$-*hard distribution* when P and Q are sets of size n and the following holds

1. There is a cut $W, \overline{W}$ of vertices such that $|W \cap Q| + |\overline{W} \cap P| \leq (1 - \alpha + \eta)n$.
2. There is a matching M of size $(1-\eta)n$ in G that can be decomposed into $M_0 \cup M'$ such that
   - **(i)** $P_0 := V(M_0) \cap P$ and $Q_0 := V(M_0) \cap Q$ are of fixed size (in the support of μ) larger than $(\alpha - \eta)n$ and smaller than αn; and
   - **(ii)** $P_0 \subseteq W$ and $Q_0 \subseteq \overline{W}$.
3. Every streaming algorithm **Alg** with $o(m)$ bits of memory that outputs E^* with $E^* \subseteq E$ must satisfy $|E^* \cap E((W \cap P) \times (\overline{W} \cap Q))| = o(n)$ with probability $1 - o(1)$.

In particular, a streaming algorithm with small memory can only maintain on hard distributions a small fraction of edges $E((W \cap P) \times (\overline{W} \cap Q))$ and therefore of M_0. In addition, observe that for every matching E^* and cut $(W, \overline{W})$ (see Figure 1) it holds that $|M| \leq |W \cap Q| + |\overline{W} \cap P| + E((W \cap P) \times (\overline{W} \cap Q))$. Thus edges from $E(W \cap P \times \overline{W} \cap Q)$ are also crucial for obtaining a good matching.

The existence of hard distributions is ensured by [17, 20]. The hard distributions families are not exactly presented as we present them here. The following Theorem follows from results in [20] involving more parameters, for the purpose of the construction itself. We disregard those since we use the existence of hard distribution families as a black box.

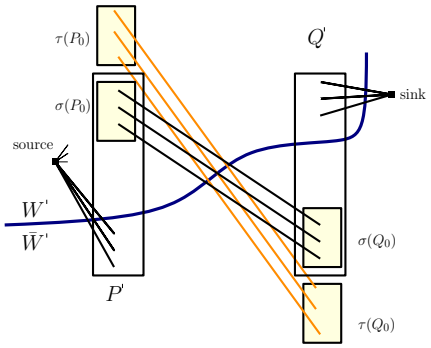

Figure 2 The construction of μ_2.

▶ **Theorem 19** ([20]). *For all $\eta > 0$ and n, there is a $(1/e, n, m(n), \eta)$-hard distribution μ over graphs of n vertices with $m(n) = n^{1+\Omega(\frac{1}{\log\log n})}$, where the notation $\Omega(.)$ hides a dependency on η.*

Sketch of Proof. Specifically, point (1) of our definition follows from [20, Lemma 13], point (2) follows from [20, Claim 12], and point (3) follows from [20, Lemma 14]. ◀

4.2 Lifting hard distributions to streaming communication protocols

Let μ be an (α, n, m, η)-hard distribution for streaming algorithms. We will show how to extend it to a distribution μ_2 for the two party version of the approximate matching problem. At a high level, we give the players two copies of the same graph G randomly chosen according to μ, but embedded into two different but overlapping subsets of vertices (see Figure 2). The non-overlapping parts correspond to edges from $E(W \cap P \times \overline{W} \cap Q)$ (see Definition 18), and are therefore hard to maintain, but necessary to setup a large matching.

From now on, identify P with the set $[n]$. Set $\beta := 1 + \alpha$. Our labelings are defined over vertex set $P' \times Q' := [\beta n] \times [\beta n]$, and are encoded by injections from $[n]$ to $[\beta n]$ (where for simplicity βn is understood as an integer).

Given a hard distribution μ, we define a distribution μ_2 as follows.

▶ **Definition 20** (The distribution μ_2). Let μ be a hard distribution, where P and Q are identified with $[n]$. Then sampling a bipartite graph over vertex set $P' \times Q' = [\beta n] \times [\beta n]$ from μ_2 is defined as follows

- Sample $G \sim \mu$. Let $(W, \overline{W})$ and P_0, Q_0 be the corresponding cut and sets from Definition 18.
- Sample σ, τ uniformly at random such that $\sigma(P_0) \cup \tau(P_0) = \emptyset = \sigma(Q_0) \cup \tau(Q_0)$ are disjoint, and σ, τ are equal on $P \setminus P_0$. Such injections σ, τ are called *G-compatible*.

In addition, define $G_\sigma := (\sigma(P), \sigma(Q), E_\sigma)$, where $E_\sigma = \{(\sigma(u), \sigma(v)) \mid (u, v) \in E\}$, and G_τ similarly. Alice is given G_σ and Bob is given G_τ with the same order as under μ.

In this construction, observe that edges sent to Alice and Bob may overlap. In fact the distribution can be tweaked to make edges disjoint using a simple gadget, while preserving the same lower bound (see the full version of this paper). We can now state our main result for the reduction.

▶ **Theorem 21** (Generic reduction). *If there exists an (α, n, m, η)-hard distribution for approximate matching, then any protocol in the one-way SC model whose approximation ratio is $\frac{1-\alpha}{1+\alpha} - O(\eta)$ has to use $\Omega(m)$ memory.*

Proof. Define a cut for the two player instance as $W' := \sigma(W) \cup \tau(P_0)$, $\overline{W}' := \sigma(\overline{W}) \cup \tau(Q_0)$. It follows from the max-flow min-cut argument that any matching E^* has size at most $|E^*| \leq |\overline{W}' \cap Q'| + |W' \cap P'| + |E^* \cap E(W' \cap P' \times \overline{W}' \cap Q')|$.

Moreover note that by construction $|\overline{W}' \cap Q'| = |\sigma(\overline{W}) \cap Q'|$. Indeed $\tau(P_0) \cap Q' = \emptyset$. Then we can write $|\sigma(\overline{W}) \cap Q'| = |W \cap Q|$ and similarly for $|W' \cap P'|$ (see also Figure 2). It follows that

$$|\overline{W}' \cap Q'| + |\overline{W}' \cap P'| = |\overline{W} \cap Q| + |\overline{W} \cap P| \leq (1 - \alpha + \eta)\, n.$$

The set of edges the protocol outputs is included in $E^*_A \cup E^*_B$ by definition. Under the high probability event that these sets only have an overlap of $o(n)$ with the "important edges" $E(W' \cap P \times \overline{W}' \cap Q)$ (see Lemma 22 below) then, if E^* is the output matching by a protocol using $o(m)$ memory, then using Lemma 22 the matching $E^* \subseteq E^*_A \cup E^*_B$ is of size at most $(1 - \alpha + \eta)\, n + o(n) \leq (1 - \alpha + 2\eta)\, n$ (for large enough n).

On the other hand, there is a matching between $\sigma(P)$ and $\sigma(Q)$ of size $(1 - \eta)n$ and a matching of size $(\alpha - \eta)n$ between $\tau(P_0)$ and $\tau(Q_0)$ (using Point (2) in the definition of a hard distribution for approximate matching, Definition 18). We identified $\sigma(P) \sqcup \tau(P_0)$ with $[\beta n]$ and hence under μ_2 there is a matching of size $(\alpha - \eta)n + (1 - \eta)n = \beta n - 2\eta n$. This shows that the approximation ratio of a protocol using $o(m)$ memory is smaller than $\frac{\beta n - 2\eta n}{(1 - \alpha + 2\eta)} = \frac{1+\alpha}{1-\alpha} - O(\eta)$. ◀

▶ **Lemma 22.** *Let* $\boldsymbol{Alg}$ *be a protocol for the two party case, i.e. a pair of algorithms for Alice and Bob* $\boldsymbol{Alg} = (\boldsymbol{Alg}_A, \boldsymbol{Alg}_B)$*. Let* E^*_A *(resp.* E^*_B*) denote the edges* $\boldsymbol{Alg}_A$ *(resp.* $\boldsymbol{Alg}_B$*) outputs, assuming only* $o(m)$ *memory is used. With probability* $1 - o(1)$ *over the choice of* σ, τ, G*, or alternatively with probability* $1 - o(1)$ *under* μ_2*, it holds that*

$$|E^*_A \cap E(W' \cap P' \times \overline{W}' \cap Q')| = o(n), \quad \textit{and similarly} \quad |E^*_B \cap E(W' \cap P' \times \overline{W}' \cap Q')| = o(n).$$

Proof. The proof consists in building from $\mathbf{Alg}_A$, and similarly $\mathbf{Alg}_B$, a streaming algorithm for μ. Indeed, for inputs over vertices $[n]$ distributed according to μ, simply pick a random σ apply it to the input, and run $\mathbf{Alg}_A$ on the graph G_σ. Then output $E^*_0 := \sigma^{-1}(E^*_A)$.

First observe that the distribution of σ and the distribution of G are independent. Therefore, conditioned on G, the injection σ is uniform. It follows that μ_2's first marginal is also the distribution of G_σ, where $G \sim \mu$ and σ is uniform and independent.

Then, using Definition 18, with probability $1 - o(1)$ over the choice of σ and $G \sim \mu$, we obtain that $|E^*_A \cap E(W' \cap P' \times \overline{W}' \cap Q')| = |E^*_0 \cap E(W \cap P \times \overline{W} \cap Q)| = o(n)$, which concludes the proof. ◀

Abstract

We study which property testing and sublinear time algorithms can be transformed into graph streaming algorithms for random order streams. Our main result is that for bounded degree graphs, any property that is constant-query testable in the adjacency list model can be tested with *constant space* in a single-pass in random order streams. Our result is obtained by estimating the distribution of local neighborhoods of the vertices on a random order graph stream using constant space.

We then show that our approach can also be applied to constant time approximation algorithms for bounded degree graphs in the adjacency list model: As an example, we obtain a constant-space single-pass random order streaming algorithms for approximating the size of a maximum matching with additive error ϵn (n is the number of nodes).

Our result establishes for the first time that a large class of sublinear algorithms can be simulated in random order streams, while $\Omega(n)$ space is needed for many graph streaming problems for adversarial orders.

1 Introduction

Very large and complex networks abound. Some of the prominent examples are gene regulatory networks, health/disease networks, and online social networks like Facebook, Google+, Linkedin and Twitter. The interconnectivity of neurons in human brain, relations in database systems, and chip designs are some further examples. Some of these networks can be quite large and it may be hard to store them completely in the main memory and some

may be too large to be stored at all. However, these networks contain valuable information that we want to reveal. For example, social networks can provide insights into the structure of our society, and the structure in gene regulatory networks might yield insights into diseases. Thus, we need algorithms that can analyze the structure of these networks quickly.

One way to approach this problem is to design graph streaming algorithms [16, 1]. A graph streaming algorithm gets access to a stream of edges in some order and exactly or approximately solves problems on the graph defined by the stream. The challenge is that a graph streaming algorithm should use space sublinear in the size of the graph. We focus on algorithms that make only *one pass* over the graph stream. It has been shown that many natural graph problems require $\Omega(n)$ space in the *adversarial order* model where n is the number of nodes in the graph and the edges can arrive in arbitrary order (see eg.,[8, 9]), and thus most of previous work has focused on the *semi-streaming* model, in which the algorithms are allowed to use $O(n \cdot \operatorname{poly}\log n)$ space. However, in many interesting applications, the graphs are sparse and so they can be fully stored in the semi-streaming model making this model useless in this setting. This raises the question *whether there are at least some natural conditions under which one can solve graph problems with space $o(n)$, possibly even $\log^{O(1)} n$ or constant.*

One such condition that recently received increasing attention is that the edges arrive in *random order*, i.e. in the order of a uniformly random permutation of the edges (e.g., [5, 22, 19]). Uniformly random or near-uniformly random ordering is a natural assumption and can arise in many contexts. Indeed, previous work has shown that some problems that are hard for adversarial streams can be solved in the random order model. Konrad et al. [22] gave single-pass semi-streaming algorithms for maximum matching for bipartite and general graphs with approximation ratio strictly larger than $1/2$ in the random order semi-streaming model, while no such approximation algorithm is known in the adversary order model. Kapralov et al. [19] gave a polylogarithmic approximation algorithm in polylogarithmic space for estimating the size of maximum matching of an unweighted graph in one pass over a random order stream. Assadi et al. [2] recently showed that in the adversarial order and *dynamic* model where edges can be both inserted and deleted, any polylogarithmic approximation algorithm of maximum matching size requires $\tilde{\Omega}(n)$ space. On the other hand, Chakrabarti et al. [5] presented an $\Omega(n)$ space lower bound for any single pass algorithm for graph connectivity in the random order streaming model, which is very close to the optimal $\Omega(n \log n)$ space lower bound in the adversarial order model [30]. In general, it is unclear which graph problems can be solved in random order streams using much smaller space than what is required for adversarially ordered streams.

An independent area of research is *property testing*, where with certain *query* access to an object (eg., random vertices or neighbors of a vertex for graphs), there are algorithms that can determine if the object satisfies a certain property, or is far from having such a property [29, 11, 12]. The area of property testing has seen fundamental results, including testing various general graph properties. For example, it has been shown that many interesting properties (including connectivity, planarity, minor-freeness, hyperfiniteness) of bounded degree graphs can be tested with a constant number of queries [12, 3, 25]. Another very related area of research is called *constant-time* (or in general, *sublinear-time*) *approximation* algorithms, where we are given query access to an object (for example a graph) and the goal is to approximate the objective value of an optimal solution. For example, in bounded degree graphs, one can approximate the cost of the optimal solution with constant query complexity for some fundamental optimization problems (e.g., minimum spanning tree weight [6], maximal matching size [26]; see also Section 1.3).

A fundamental question is if such results from property testing and constant-time approximation algorithms will lead to better graph streaming algorithms. Huang and Peng [17] recently considered the problem of estimating the minimum spanning tree weight and property testing for general graphs in dynamic and adversarial order model. They showed that a number of properties (e.g., connectivity, cycle-freeness) of general n-vertex graphs can be tested with space complexity $O(n^{1-\varepsilon})$ and one can $(1+\varepsilon)$-approximate the weight of minimum spanning tree with similar space guarantee. Furthermore, there exist $\Omega(n^{1-O(\varepsilon)})$ space lower bounds for these problems that hold even in the insertion-only model [17].

1.1 Overview of Results

In this paper we provide a general framework that transforms bounded-degree graph property testing to very space-efficient random order streaming algorithms.

To formally state our main result, we first review some basic definitions of graph property testing. A *graph property* is a property that is invariant under graph isomorphism. Let $G = (V, E)$ be a graph with maximum degree upper bounded by a constant d, and we also call G a *d-bounded* graph. In the *adjacency list model* for (bounded-degree) graph property testing, we are given query access to the adjacency list of the input d-bounded graph $G = (V, E)$. That is, for any vertex $v \in V$ and index $i \leq d$, one can query the ith neighbor (if exists) of vertex v in constant time. Given a property Π, we are interested in testing if a graph G satisfies Π or is *ε-far* from satisfying Π while making as few queries as possible, where G is said to be ε-far from satisfying Π if one has to insert/delete more than εdn edges to make it satisfy Π. We call a property *constant-query testable* if there exists a testing algorithm (also called *tester*) for this property such that the number of performed queries depends only on parameters ε, d and is independent of the size of the input graph.

Given a graph property Π, we are interested in *approximately* testing it in a single-pass stream with a goal similar to the above. That is, the algorithm uses little space and with high constant probability, it accepts the input graph G if it satisfies P and rejects G if it is ε-far from satisfying P (see Section 4 for formal definitions). Our main result is as follows.

▶ **Theorem 1.** *Any d-bounded graph property that is constant-query testable in the adjacency list model can be tested in the uniformly random order streaming model with constant space.*

To the best of our knowledge, this is the first non-trivial graph streaming algorithm with constant space complexity (measured in the number of *words*, where a word is a space unit large enough to encode an ID of any vertex in the graph.) By the constructions in [17], there exist graph properties (e.g., connectivity and cycle-freeness) of d-bounded graphs such that any single-pass streaming algorithm in the insertion-only and *adversary order* model must use $\Omega(n^{1-O(\varepsilon)})$ space. In contrast to this lower bound, our main result implies that d-bounded connectivity and cycle-freeness can be tested in constant space in the random order stream model, since they are constant-query testable in the adjacency list model [12].

Our approach also works for simulating *constant-time approximation* algorithms as graph streaming algorithms with constant space. For a minimization (resp., maximization) optimization problem P and an instance I, we let $\mathrm{OPT}(I)$ denote the value of some optimal solution of I. We call a value x an (α, β)-approximation for the problem P, if for any instance I, it holds that $\mathrm{OPT}(I) \leq x \leq \alpha \cdot \mathrm{OPT}(I) + \beta$ (resp., $\frac{\mathrm{OPT}(I)}{\alpha} - \beta \leq x \leq \mathrm{OPT}(I)$). For example, it is known that there exists a constant-query algorithm for $(1, \varepsilon n)$-approximating the maximal matching size of any n-vertex d-bounded graph [26]. That is, the number of queries made by the algorithm is independent of n and only depends on ε, d. As an application, we show:

▶ **Theorem 2.** *Let $0 < \varepsilon < 1$ and d be constants. Then there exists an algorithm that uses constant space in the random order model, and with probability $2/3$, $(1, \varepsilon n)$-approximates the size of some maximal matching in d-bounded graphs.*

We also remark that in a similar way, many other sublinear time algorithms for bounded degree graphs can be simulated in random order streams. Finally, our results can actually be extended to a model which requires weaker assumptions on the randomness of the order of edges in the stream, but we describe our results for the uniformly random order model, and leave the remaining details for later.

1.2 Technical Overview

The local neighborhood of depth k of a vertex v is the subgraph rooted at v and induced by all vertices of distance at most k from v. We call such a rooted subgraph a *k-disc*. Suppose that we are given a sufficiently large graph G whose maximum degree d is constant. This means that for any constant k, a k-disc centered at an arbitrary vertex v in G has constant size. Now assume that there exists an algorithm $\mathcal{A}$ that, independent of the labeling of the vertices of G, accesses G by querying random vertices and exploring their k-discs. We observe that any constant-query property tester (see for example [13, 7]) falls within the framework of such an algorithm. If instead of the graph G we are given the distribution of k-discs of the vertices of G, we can use this distribution to simulate the algorithm $\mathcal{A}$ and output with high probability the same result as executing the algorithm $\mathcal{A}$ on G itself. Thus, the problem of developing constant-query property testers in random order streams can be reduced to the problem of designing streaming algorithms that approximate the distribution of k-discs in G.

The main technical contribution of this paper is an algorithm that given a random order stream S of edges of an underlying d-bounded degree graph G, approximates the distribution of k-discs of G up to an additive error of δ. We would like to mention that if the edges arrive in adversarial order, any algorithm that approximates the distribution of k-discs of G requires almost linear space [32, 17], hence the assumption of random order streams (or something similar) is necessary to obtain our result.

Now in order to approximate the distribution of k-discs of the graph G we do the following. We proceed by sampling vertices uniformly at random and then perform a BFS for each sampled vertex using the arrival of edges along the stream S. Note that the new edges of the stream S that do not connect to the currently explored vertices are discarded. Let us call the k-disc that is observed by doing such a BFS from some vertex v to be Δ_1. Due to possibility of missing edges during the BFS, this subgraph may be different from the true k-disc Δ_2 rooted at v.

Fortunately, since the edges arrive in a uniformly random order, we can infer the conditional probability $\Pr[\Delta_1|\Delta_2]$. That is, given the true rooted subgraph Δ_2, we can compute the conditional probability of seeing a rooted subgraph Δ_1 in a random order stream when the true k-disc is Δ_2.

We define the partial order on the set of k-discs given by $\Delta_1 \preccurlyeq \Delta_2$ whenever Δ_1 is a root-preserving isomorphic subgraph of Δ_2. For every two k-discs Δ_1 and Δ_2 with $\Delta_1 \preccurlyeq \Delta_2$ we compute the conditional probability $\Pr[\Delta_1|\Delta_2]$. Using the set of all conditional probabilities $\Pr[\Delta_1|\Delta_2]$ we can estimate or approximate the distribution of k-discs of the graph G whose edges are revealed according to the stream S. In order to simplify the analysis of our algorithm, we require a natural independence condition for non-intersecting k-discs. Finally, we use the approximated distribution of k-discs to simulate the algorithm $\mathcal{A}$ by the machinary that we explained above.

We remark that the idea of using a partial order to compute a distribution of k-discs in bounded degree graphs has first been used in [7]. However, the setting in [7] was quite different as it dealt with directed graphs where an edge can only be seen from one side (and the sample sizes required in that paper were only slightly sublinear in n).

1.3 Other Related Work

Feigenbaum et al. [10] initiated the study of property testing in streaming model, and they gave efficient testers for some properties of a sequence of data items (rather than graphs as we consider here). Bury and Schwiegelshohn [4] gave a lower bound of $n^{1-O(\varepsilon)}$ on the space complexity of any algorithm that $(1-\varepsilon)$-approximates the size of maximum matching in adversarial streams. Kapralov et al. [20] showed that in random streams, $\tilde{\Omega}(\sqrt{n})$ space is necessary to distinguish if a graph is bipartite or 1/2-far from being bipartite. Previous work has extensively studied streaming graph algorithms in both the insertion-only and dynamic models, see the recent survey [24].

In the framework of d-bounded graph property testing, it is now known that many interesting properties are constant-query testable in the adjacency list model, including k-edge connectivity, cycle-freeness, subgraph-freeness [12], k-vertex connectivity [33], minor-freeness [15, 3], matroids related properties [18, 31], hyperfinite properties [25], subdivision-freeness [21]. Constant-time approximation algorithms in d-bounded graphs are known to exist for a number of fundamental optimization problems, including $(1+\varepsilon)$-approximating the weight of minimum spanning tree [6], $(1,\varepsilon n)$-approximating the size of maximal/maximum matching [26, 34], $(2,\varepsilon n)$-approximating the minimum vertex cover size [28, 23, 27], $(O(\log d),\varepsilon n)$-approximating the minimum dominating set size [28, 26]. For d-bounded minor-free graphs, there are constant-time $(1,\varepsilon n)$-approximation algorithms for the size of minimum vertex cover, minimum dominating set and maximum independent set [15].

2 Preliminaries

Let $G=(V,E)$ be an n-vertex graph with maximum degree upper bounded by some constant d, where we often identify V as $[n] := \{1,\cdots,n\}$. We also call such a graph d-bounded graph. In this paper, we will assume the algorithms have the knowledge of n, d. We assume that G is represented as a sequence of edges, which we denote as $\textsc{Stream}(G)$.

Graph k-discs. Let $k \geq 1$. The k-disc around a vertex v is the subgraph rooted at vertex v and induced by the vertices within distance at most k from v. Note that for an n-vertex graph, there are exactly n k-discs. Let $\mathcal{H}_{d,k} = \{\Delta_1,\cdots,\Delta_N\}$ be the set of all k-disc isomorphism types, where $N = N_{d,k}$ is the number of all such types (and is thus a constant). In the following, we will refer to a k-disc of some vertex v in the graph G as $\mathrm{disc}_{k,G}(v)$ and a k-disc type as Δ. Note that for every vertex v, there exists a unique k-disc type $\Delta \in \mathcal{H}_{d,k}$ such that $\mathrm{disc}_{k,G}(v)$ is isomorphic to Δ, denoted as $\mathrm{disc}_{k,G}(v) \cong \Delta$. (Throughout the paper, we call two rooted graphs H_1, H_2 isomorphic to each other if there is a root-preserving mapping from the vertex set of H_1 to the vertex set of H_2.)

We further assume that all the elements in $\mathcal{H}_{d,k}$ are ordered according to the natural partial order among k-disc types. More specifically, for any two k-disc types Δ_i, Δ_j, we let $\Delta_i \succcurlyeq \Delta_j$ (or equivalently, $\Delta_j \preccurlyeq \Delta_i$) denote that Δ_j is root-preserving isomorphic to some subgraph of Δ_i. Then we order all the k-disc types $\Delta_1,\cdots,\Delta_N$ such that if $\Delta_i \succcurlyeq \Delta_j$, then $i \leq j$. Let $\mathcal{G}(j)$ denote all the indices i, except j itself, such that $\Delta_i \succcurlyeq \Delta_j$.

Locally random order streams. Let Σ_E denote the set of all permutations (or orderings) over the edge set E. Note that each $\sigma \in \Sigma_E$ determines the order of edges arriving from the stream. Let $\mathcal{D} = \mathcal{D}(\Sigma_E)$ denote a probability distribution over Σ_E. In particular, we let $\mathcal{U} = \mathcal{U}(\Sigma_E)$ denote the uniform distribution over Σ_E. Given a stream σ of edges, we define the *observed k-disc of v from the stream*, denoted as $\mathrm{disc}_k(v, \sigma)$, to be the subgraph rooted at v and induced by all edges that are sequentially collected from the stream and the endpoints of which are within distance at most k to v. This is formally defined in the following algorithm STREAM_k-DISC.

Algorithm 1 The observed k-disc of v from the stream

```

8:                     ℓ_x ← the distance between x and v in the graph G' = (U, F)
9:                 end for
10:            end if
11:        else if both u, v are contained in U then
12:            F ← F ∪ {(u, w)}
13:            for x ∈ U do
14:                ℓ_x ← the distance between x and v in the graph G' = (U, F)
15:            end for
16:        end if
17:    end for
18:    return disc_k(v, σ) ← the subgraph rooted at v and induced by all edges in F
19: end procedure
```

Now we formally define a locally random distribution on the order of edges.

▶ **Definition 3.** Let $d, k > 0$. Let $G = (V, E)$ be a d-bounded graph. Let $\mathcal{D}$ be a distribution over all the orderings of edges in E. Let $\Lambda_k = \{\lambda(\Delta_i|\Delta_j) : 0 \le \lambda(\Delta_i|\Delta_j) \le 1, \Delta_j \succcurlyeq \Delta_i, 1 \le i, j \le N\}$ be a set of real numbers in $[0, 1]$. We call $\mathcal{D}$ a *locally random Λ_k-distribution* over G with respect to k-disc types, if for σ sampled from $\mathcal{D}$, the following conditions are satisfied:

1. (*Conditional probabilities*) For any vertex v with k-disc isomorphic to Δ_j, the probability that its observed k-disc $\mathrm{disc}_k(v, \sigma) \cong \Delta_i$ is $\lambda(\Delta_i|\Delta_j)$, for any i such that $\Delta_j \succcurlyeq \Delta_i$.
2. (*Independence of disjoint k-discs*) For any two disjoint k-discs $\mathrm{disc}_{k,G}(v)$ and $\mathrm{disc}_{k,G}(u)$, their observed k-discs $\mathrm{disc}_k(v, \sigma)$ and $\mathrm{disc}_k(u, \sigma)$ are independent.

Note that the set Λ_k cannot be an arbitrary set, as there might be no distribution satisfying the above condition. On the other hand, if there indeed exists a distribution satisfying the condition with numbers in Λ_k, then we call the set Λ_k *realizable*. In the following, we call a stream a *locally random order stream* if there exists a family of realizable sets $\Lambda = \{\Lambda_k\}_{k\ge1}$, such that the edge order is sampled from some locally random Λ_k-distribution with respect to k-disc types, for any integer $k \ge 1$. We have the following lemma.

▶ **Lemma 4.** *Let $d \geq 1$. For any $k \geq 1$, there exists $n_0 = n_0(k,d)$, such that for $n \geq n_0$, any d-bounded n-vertex graph $G = (V,E)$, the uniform permutation $\mathcal{U}$ over E is a locally random Λ_k-distribution over G with respect to k-disc types, for some realizable $\Lambda_k := \{\lambda(\Delta_i|\Delta_j) : 0 \leq \lambda(\Delta_i|\Delta_j) \leq 1, \Delta_j \succcurlyeq \Delta_i, 1 \leq i,j \leq N\}$. Furthermore, if we let $\kappa := \max_{i,j:\Delta_j \succcurlyeq \Delta_i} \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)}$, $\lambda_{\min} := \min_{i \leq N} \lambda(\Delta_i|\Delta_i)$, then $\kappa \leq 2^{2d^{k+1}}$, $\lambda_{\min} \geq \frac{1}{(2d^{k+1})!}$.*

Proof. Note that for any vertex v with $\mathrm{disc}_{k,G}(v) \cong \Delta_j$, the probability that the observed k-disc of v is isomorphic to Δ_i is exactly the fraction of orderings σ such that $\mathrm{disc}_k(v,\sigma) \cong \Delta_i$, where $\Delta_j \succcurlyeq \Delta_i$. We use such a fraction, which is a fixed real number, to define $\lambda(\Delta_i|\Delta_j)$. Observe that for an ordering σ sampled from $\mathcal{U}$, it directly satisfies the second condition Item 2 in Definition 3. Since there are at most $2d^{k+1}$ edges in any k-disc, the probability of observing a full k-disc is at least $\frac{1}{(2d^{k+1})!}$, that is, $\lambda_{\min} \geq \frac{1}{(2d^{k+1})!}$. Furthermore, since the k-disc type Δ_j might contain at most $\binom{|E(\Delta_j)|}{|E(\Delta_i)|} \leq 2^{2d^{k+1}}$ different subgraphs that are isomorphic to Δ_i, it holds that $\lambda(\Delta_i|\Delta_j) \leq \sum_{F:F \text{ subgraph of } \Delta_j, F \cong \Delta_i} \lambda(\Delta_i|\Delta_i) \leq 2^{2d^{k+1}} \lambda(\Delta_i|\Delta_i)$ for any i,j such that $\Delta_j \succcurlyeq \Delta_i$. This completes the proof of the lemma. ◀

The above lemma shows that the uniformly random order stream is a special case of a locally random order stream. Another natural class of locally random order stream is ℓ-wise independent permutation of edges for any $\ell = \omega_n(1)$ (i.e., any function that tends to infinity as n goes to infinity) for n-vertex bounded degree graphs, but for our qualitative purposes here, it suffices to consider uniformly random order streams.

3 Approximating the k-Disc Type Distribution

In this section, we show how to approximate the distribution of k-disc types of any d-bounded graph in locally random order streams.

Recall that for any k,d, we let $N = N_{d,k}$ be the constant denoting the number of all possible k-disc isomorphism types. For any $i \leq N$, let V_i be the set of vertices from V with k-disc isomorphic to Δ_i in the input graph G, that is, $V_i := \{v | v \in V, \mathrm{disc}_{k,G}(v) \cong \Delta_i\}$. Note that $f_i = \frac{|V_i|}{n}$ is the fraction of vertices with k-disc isomorphic to Δ_i.

▶ **Lemma 5.** *Let $G = (V,E)$ be a d-bounded graph presented in a locally random order stream defined by a Λ_k-distribution $\mathcal{D}$ over G with respect to k-disc types, for some integer k. Let $\kappa := \max_{i,j:\Delta_j \succcurlyeq \Delta_i} \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)}$, $\lambda_{\min} := \min_{i \leq N} \lambda(\Delta_i|\Delta_i)$. Then for any constant $\delta > 0$, there exists an algorithm that uses $O(\frac{\kappa^{2N} \cdot d^{3k+2} \cdot 3^{3N+1}}{\delta^2 \lambda_{\min}})$ space, and with probability $\frac{2}{3}$, for any $i \leq N$, approximates the fraction f_i of vertices with k-disc isomorphic to Δ_i in G with additive error δ.*

Proof. Our algorithm is as follows. We first sample a constant number of vertices, which are called centers. Then for each center v, we collect the observed k-disc of v from the stream. Then we postprocess all the collected edges and use the corresponding empirical distribution of k-disc types of all centers to estimate the distribution of k-disc types of the input graph. The formal description is given in Algorithm 2.

Note that since there are $s = \frac{8\kappa^{2N} \cdot d^{2k+1} \cdot 3^{3N+1}}{\delta^2 \lambda_{\min}}$ vertices in A and only edges that belong to the k-discs of these vertices will be collected by our algorithm, the space complexity of the algorithm is $O(sd^{k+1}) = O(\frac{\kappa^{2N} \cdot d^{3k+2} \cdot 3^{3N+1}}{\delta^2 \lambda_{\min}})$, which is constant.

Now we show the correctness of the algorithm.

Algorithm 2 Approximating the distribution of k-disc types

procedure k-DISC_DISTRIBUTION(STREAM(G),Λ_k,n, d, k, δ)
  sample a set A of $s := \frac{8\kappa^{2N} \cdot d^{2k+1} \cdot 3^{3N+1}}{\delta^2 \lambda_{\min}}$ vertices uniformly at random
  for each $v \in A$ **do**
    $H_v \leftarrow$ STREAM_k-DISC(STREAM(G),v,k) ▷ to collect observed k-disc of v
  end for
end procedure

procedure POSTPROCESSING
  $H \leftarrow$ the graph spanned by $\cup_{v \in A} H_v$
  for $i = 1$ to N **do**
    $Y_i \leftarrow |\{v : v \in A, \mathrm{disc}_{k,H}(v) \cong \Delta_i\}|/s$
    $X_i \leftarrow (Y_i - \sum_{j \in \mathcal{G}(i)} X_j \cdot \lambda(\Delta_i|\Delta_j)) \cdot \lambda^{-1}(\Delta_i|\Delta_i)$.
  end for
  return $X_1, \cdots, X_N$
end procedure

We let $A \sim \mathcal{U}_V$ denote that A is the set of s vertices sampled uniformly at random from V. For any $i \leq N$, let A_i be the set of vertices from A with k-disc isomorphic to Δ_i in the input graph G, that is, $A_i := \{v | v \in A, \mathrm{disc}_{k,G}(v) \cong \Delta_i\}$. Note that $\mathrm{E}_{A \sim \mathcal{U}_V}[|A_i|] = s \cdot \frac{|V_i|}{n}$.

Let $\beta_i = 3^{i-N-2}, \theta_i = (3\kappa)^{i-N-1}$. By Chernoff bound and our setting of s which satisfy that $s \geq \Omega(\frac{1}{(\delta\theta_i)^2 \beta_i})$, we have the following claim.

▶ **Claim 6.** *For any $i \leq N$, $\Pr_{A \sim \mathcal{U}_V}[|\frac{|A_i|}{s} - \frac{|V_i|}{n}| \leq \delta\theta_i] \geq 1 - \beta_i$.*

We assume for now that A is a fixed set with s vertices. We let $\sigma \sim \mathcal{D}$ denote that the edge ordering σ is sampled from $\mathcal{D}$. For any $v \in A$, let $Z_{v,i}$ be the indicator random variable of the event that the observed k-disc $\mathrm{disc}_k(v, \sigma)$ of v is isomorphic to Δ_i for $\sigma \sim \mathcal{D}$. Note that $\Pr_{\sigma \sim \mathcal{D}}[Z_{v,i} = 1] = \lambda(\Delta_i|\Delta_j)$ if $\mathrm{disc}_{k,G}(v) \cong \Delta_j$. Let $Y_i^{(\sigma)} := \frac{|\{v : v \in A, \mathrm{disc}_k(v,\sigma) \cong \Delta_i\}|}{s}$ denote the fraction of vertices in A with observed k-disc isomorphic to Δ_i. By definition, it holds that $Y_i^{(\sigma)} = \frac{1}{s} \sum_{\substack{v \in A_j \\ j \in \mathcal{G}(i) \cup \{i\}}} Z_{v,i}$, and furthermore, $\mathrm{E}_{\sigma \sim \mathcal{D}}[Y_i^{(\sigma)}] = \frac{1}{s} \sum_{j \in \mathcal{G}(i) \cup \{i\}} |A_j| \cdot \lambda(\Delta_i|\Delta_j)$.
Let $X_i^{(\sigma)} = (Y_i^{(\sigma)} - \sum_{j \in \mathcal{G}(i)} X_j^{(\sigma)} \cdot \lambda(\Delta_i|\Delta_j)) \cdot \lambda^{-1}(\Delta_i|\Delta_i)$.

We have the following claim.

▶ **Claim 7.** *For any $i \leq N$, it holds that $E_{\sigma \sim \mathcal{D}}[X_i^{(\sigma)}] = \frac{|A_i|}{s}$.*

Proof. We prove the claim by induction. For $i = 1$, it holds that $\mathrm{E}_{\sigma \sim \mathcal{D}}[X_1^{(\sigma)}] = \mathrm{E}_{\sigma \sim \mathcal{D}}[Y_1^{(\sigma)}] \cdot \lambda^{-1}(\Delta_1|\Delta_1) = \frac{|A_1|}{s} \cdot \lambda(\Delta_1|\Delta_1) \cdot \lambda^{-1}(\Delta_1|\Delta_1) = \frac{|A_1|}{s}$. Assuming that the claim holds for $i-1$, and we prove it holds for i as well. By definition, we have that

$$\begin{aligned}
&\mathrm{E}_{\sigma \sim \mathcal{D}}[X_i^{(\sigma)}] = \mathrm{E}_{\sigma \sim \mathcal{D}}[(Y_i^{(\sigma)} - \sum_{j \in \mathcal{G}(i)} X_j^{(\sigma)} \cdot \lambda(\Delta_i|\Delta_j)) \cdot \lambda^{-1}(\Delta_i|\Delta_i)] \\
= &\Big(\sum_{j \in \mathcal{G}(i) \cup \{i\}} \frac{|A_j|}{s} \cdot \lambda(\Delta_i|\Delta_j) - \sum_{j \in \mathcal{G}(i)} \mathrm{E}_{\sigma \sim \mathcal{D}}[X_j^{(\sigma)}] \cdot \lambda(\Delta_i|\Delta_j) \Big) \cdot \lambda^{-1}(\Delta_i|\Delta_i) \\
= &\Big(\sum_{j \in \mathcal{G}(i) \cup \{i\}} \frac{|A_j|}{s} \cdot \lambda(\Delta_i|\Delta_j) - \sum_{j \in \mathcal{G}(i)} \frac{|A_j|}{s} \cdot \lambda(\Delta_i|\Delta_j) \Big) \cdot \lambda^{-1}(\Delta_i|\Delta_i) = \frac{|A_i|}{s},
\end{aligned}$$

where the second to last equation follows from the induction. ◀

We can now bound the variance of $Y_i^{(\sigma)}$ as shown in the following claim.

▶ **Claim 8.** *For any $i \leq N$, it holds that $Var_{\sigma\sim\mathcal{D}}[Y_i^{(\sigma)}] \leq \frac{1}{s^2} \cdot d^{2k+1} \sum_{j\in\mathcal{G}(i)\cup\{i\}} |A_j| \cdot \lambda(\Delta_i|\Delta_j)$.*

Proof. Recall that $Y_i^{(\sigma)} = \frac{1}{s} \sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}$. Note that for each $v \in A$, by the independence assumption on $\mathcal{D}$, the random variable $Z_{v,i}$ can only correlate with the corresponding variables for vertices that are within distance at most $2k$ from v. The number of such vertices is at most $1 + d + d^2 + \cdots + d^{2k} < d^{2k+1}$. Let $\mathrm{dt}(u, v)$ denote the distance between u, v in the graph G. Then we have that

$$\begin{aligned}
&\mathrm{E}_{\sigma\sim\mathcal{D}}[(\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i})^2] = \mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} \sum_{\substack{u\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i} \cdot Z_{u,i}] \\
= \;& \mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} (\sum_{\substack{u\in A_j \\ j\in\mathcal{G}(i)\cup\{i\} \\ \mathrm{dt}_G(u,v)\leq 2k}} Z_{v,i} \cdot Z_{u,i} + \sum_{\substack{u\in A_j \\ j\in\mathcal{G}(i)\cup\{i\} \\ \mathrm{dt}_G(u,v)>2k}} Z_{v,i} \cdot Z_{u,i})] \\
\leq \;& \mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} \sum_{\substack{u\in A_j \\ j\in\mathcal{G}(i)\cup\{i\} \\ \mathrm{dt}_G(u,v)\leq 2k}} Z_{v,i}] + \left(\sum_{j\in\mathcal{G}(i)\cup\{i\}} [|A_j|] \cdot \lambda(\Delta_i|\Delta_j)\right)^2 \\
\leq \;& d^{2k+1}\mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}] + (\mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}])^2 \\
= \;& d^{2k+1} \cdot \sum_{j\in\mathcal{G}(i)\cup\{i\}} |A_j| \cdot \lambda(\Delta_i|\Delta_j) + (\mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}])^2,
\end{aligned}$$

where the first inequality follows from the fact that $Z_{u,i} \leq 1$, and that for any two vertices u, v with $\mathrm{dt}(u, v) > 2k$, $Z_{u,i}, Z_{v,i}$ are independent.

Then we have that

$$\begin{aligned}
\mathrm{Var}_{\sigma\sim\mathcal{D}}[Y_i^{(\sigma)}] &= \frac{1}{s^2} \cdot \mathrm{Var}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}] \\
&= \frac{1}{s^2}\left(\mathrm{E}_{\sigma\sim\mathcal{D}}[(\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i})^2] - (\mathrm{E}_{\sigma\sim\mathcal{D}}[\sum_{\substack{v\in A_j \\ j\in\mathcal{G}(i)\cup\{i\}}} Z_{v,i}])^2\right) \\
&\leq \frac{1}{s^2} \cdot d^{2k+1} \sum_{j\in\mathcal{G}(i)\cup\{i\}} |A_j| \cdot \lambda(\Delta_i|\Delta_j).
\end{aligned}$$

◀

We next prove that each $X_i^{(\sigma)}$ is concentrated around its expectation with high probability.

▶ **Claim 9.** *For any $i \leq N$, it holds that $\Pr_{\sigma\sim\mathcal{D}}[|X_i^{(\sigma)} - E_{\sigma\sim\mathcal{D}}[X_i^{(\sigma)}]| \leq \theta_i\delta] \geq 1 - \beta_i$.*

Proof. We prove the claim by induction. For $i = 1$, it holds that

$$\begin{aligned}
&\Pr_{\sigma\sim\mathcal{D}}[|X_1^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_1^{(\sigma)}]| \leq \theta_1\delta] \leq \Pr_{\sigma\sim\mathcal{D}}[|Y_1^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[Y_1^{(\sigma)}]| \cdot \lambda^{-1}(\Delta_1|\Delta_1) \geq \delta\theta_1] \\
\leq \;& \frac{\mathrm{Var}_{\sigma\sim\mathcal{D}}[Y_1^{(\sigma)}]}{(\delta\theta_1)^2 \cdot \lambda^2(\Delta_1|\Delta_1)} \leq \frac{d^{2k+1}|A_1| \cdot \lambda(\Delta_1|\Delta_1)}{s^2 \cdot (\delta\theta_1)^2 \cdot \lambda^2(\Delta_1|\Delta_1)} \leq \frac{d^{2k+1}}{s(\delta\theta_1)^2 \cdot \lambda(\Delta_1|\Delta_1)} \leq \beta_1,
\end{aligned}$$

where the last inequality follows from our choice of β_1, θ_1 and s which satisfy that $s \geq \frac{d^{2k+1}}{(\delta\theta_1)^2\beta_1 \cdot \lambda(\Delta_1|\Delta_1)}$. Now let us consider arbitrary $i \geq 2$, assuming that the claim holds for any $j \leq i-1$. First, with probability (over the randomness that $\sigma \sim \mathcal{D}$) at least $1 - \sum_{j=1}^{i-1} \beta_j = 1 - \sum_{j=1}^{i-1} 3^{j-N-2} \geq 1 - \frac{\beta_i}{2}$, it holds that for all $j \leq i-1$, $|X_j^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_j^{(\sigma)}]| \leq \theta_j\delta$. This further implies that with probability at least $1 - \frac{\beta_i}{2}$,

$$\begin{aligned}
&|\sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[(\sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)})]| \\
\leq &\sum_{j\in\mathcal{G}(i)} |X_j^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_j^{(\sigma)}]| \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)} \\
\leq &\sum_{j\in\mathcal{G}(i)} \delta\theta_j \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)} \leq \kappa \cdot \sum_{j\in\mathcal{G}(i)} \delta\theta_j \leq \kappa \cdot \sum_{j=1}^{i-1} \delta(3\kappa)^{j-N} \leq \frac{\theta_i\delta}{2}.
\end{aligned}$$

Now note that

$$\begin{aligned}
&\Pr_{\sigma\sim\mathcal{U}}[|Y_i^{(\sigma)} - \mathrm{E}[Y_i^{(\sigma)}]| \cdot \lambda(\Delta_i|\Delta_i)^{-1} \geq \frac{\theta_i\delta}{2}] \leq \frac{4 \cdot \mathrm{Var}_{\sigma\sim\mathcal{D}}[Y_i^{(\sigma)}]}{(\delta\theta_i)^2 \cdot \lambda(\Delta_i|\Delta_i)^2} \\
\leq &\frac{4 \cdot d^{2k+1} \sum_{j\in\mathcal{G}(i)\cup\{i\}} |A_j| \cdot \lambda(\Delta_i|\Delta_j)}{s^2 \cdot (\delta\theta_i)^2 \cdot \lambda(\Delta_i|\Delta_i)^2} \leq \frac{4 \cdot d^{2k+1} \cdot \kappa}{s \cdot (\delta\theta_i)^2 \cdot \lambda(\Delta_i|\Delta_i)} \leq \frac{\beta_i}{2},
\end{aligned}$$

where the last inequality follows from our choice of β_i, θ_i and s which satisfy that $s \geq \frac{8\kappa \cdot d^{2k+1}}{(\delta\theta_i)^2\beta_i \cdot \lambda(\Delta_i|\Delta_i))}$.

Therefore, with probability (over $\sigma \sim \mathcal{D}$) at least $1 - \frac{\beta_i}{2} - \frac{\beta_i}{2} = 1 - \beta_i$, it holds that

$$\begin{aligned}
&|X_i^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_i^{(\sigma)}]| \\
= &\left|\frac{Y_i^{(\sigma)} - \sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)} - \mathrm{E}_{\sigma\sim\mathcal{D}}\left[\frac{Y_i^{(\sigma)} - \sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)}\right]\right| \\
= &\left|\frac{(Y_i^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[Y_i^{(\sigma)}])}{\lambda(\Delta_i|\Delta_i)} - \left(\sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[(\sum_{j\in\mathcal{G}(i)} X_j^{(\sigma)} \cdot \frac{\lambda(\Delta_i|\Delta_j)}{\lambda(\Delta_i|\Delta_i)})]\right)\right| \\
\leq &\frac{\delta\theta_i}{2} + \frac{\delta\theta_i}{2} = \delta\theta_i.
\end{aligned}$$

◀

Now with probability (over both $A \sim \mathcal{U}_V$ and $\sigma \sim \mathcal{D}$) at least $1 - \beta_i - \beta_i$, it holds that

$$\begin{aligned}
&\left|X_i^{(\sigma)} - \frac{|V_i|}{n}\right| \leq \left|X_i^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_i^{(\sigma)}]\right| + \left|\mathrm{E}_{\sigma\sim\mathcal{D}}[X_i^{(\sigma)}] - \frac{|V_i|}{n}\right| \\
= &\left|X_i^{(\sigma)} - \mathrm{E}_{\sigma\sim\mathcal{D}}[X_i^{(\sigma)}]\right| + \left|\frac{|A_i|}{s} - \frac{|V_i|}{n}\right| \leq \delta\theta_i + \delta\theta_i = 2\delta\theta_i.
\end{aligned}$$

Finally, with probability at least $1 - 2\sum_{j=1}^{N} \beta_j = 1 - 2\sum_{j=1}^{N} 3^{j-N-2} \geq 1 - \frac{1}{3}$, it holds that for all $i \leq N$, $|X_i - \frac{|V_i|}{n}| \leq 2\theta_i\delta \leq \delta$. This completes the proof of the lemma. ◀

4 Constant-Query Property Testing

In this section, we show how to transform constant-query property testers in the adjacency list model to constant-space property testers in the random order stream model in a single pass and prove our main result Theorem 1. (Our transformation also works in the locally

random order model as defined in Definition 3, but for simplicity, we only state our result in the uniformly random order model.)

▶ **Definition 10.** Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a property of d-bounded graphs, where Π_n is a property of graphs with n vertices. We say that Π is testable with query complexity q, if for every ε, d and n, there exists an algorithm that performs $q = q(n, \varepsilon, d)$ queries to the adjacency list of the graph, and with probability at least $2/3$, accepts any n-vertex d-bounded graph G satisfying Π, and rejects any n-vertex d-bounded graph that is ε-far from satisfying Π. If $q = q(\varepsilon, d)$ is a function independent of n, then we call Π constant-query testable.

Similarly, we can define constant-space testable properties in graph streams.

▶ **Definition 11.** Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be a property of d-bounded graphs, where Π_n is a property of graphs with n vertices. We say that Π is testable with space complexity q, if for every ε, d and n, there exists an algorithm that performs a single pass over an edge stream of an n-vertex d-bounded graph G, uses $q = q(n, \varepsilon, d)$ space, and with probability at least $2/3$, accepts G if it satisfies Π, and rejects G if it is ε-far from satisfying Π. If $q = q(\varepsilon, d)$ is a function independent of n, then we call Π constant-space testable.

The proof of Theorem 1 is based on the following known fact: every constant-query property tester can be simulated by some canonical tester which only samples a constant number of vertices, and explores the k-discs of these vertices, and then makes deterministic decisions based on the explored subgraph. This implies that it suffices to approximate the distribution of k-disc types of the input graph to test the corresponding property. Formally, we will use the following lemma relating the constant-time testable properties and their k-disc distributions. For any graph G, let $S_{G,k}$ denote the subgraph spanned by the union of k-discs rooted at k uniformly sampled vertices from G. The following lemma is implied by Lemma 3.2 in [7] (which was built on [14] and [13]). (The result in [7] is stated for d-bounded directed graphs, while it also holds in the undirected case.)

▶ **Lemma 12.** *Let $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ be any d-bounded graph property that is testable with $q = q(\varepsilon, d)$ query complexity in the adjacency list model. Then there exist integer n_0, $k = c \cdot q$ for some large universal constant c, and an infinite sequence of $\mathcal{F} = \{\mathcal{F}_n\}_{n\geq n_0}$ such that for any $n \geq n_0$, $\mathcal{F}_n$ is a set of digraphs, each being a union of k disjoint k-discs, and for any n-vertex graph G,*

- *if G satisfies Π_n, then with probability* at most $\frac{5}{12}$, *$S_{G,k}$ is isomorphic to one of the members in $\mathcal{F}_n$.*
- *if G is ε-far from satisfying Π_n, then with probability* at least $\frac{7}{12}$, *$S_{G,k}$ is isomorphic to one of the members in $\mathcal{F}_n$.*

Now we are ready to prove Theorem 1.

Proof Sketch of Theorem 1. The proof follows almost directly from the proof of Theorem 1.1 in [7]. We sketch the algorithm and its analysis, and refer to [7] for further details.

The algorithm is as follows. For any property $\Pi = (\Pi_n)_{n\in\mathbb{N}}$ that is testable with query complexity $q = q(\varepsilon, d)$ in the adjacency list model, we set $k = c \cdot q$ as guaranteed in Lemma 12, and set $N = N(d, k)$, $\delta = \frac{1}{48(2kN)^k}$. Let G be any n-vertex graph with $n \geq n_1 := n_1(d, k)$ that is represented by a uniformly random order edge stream, where n_1 is some sufficiently large constant. (For graphs with $n < n_1$ vertices, one can trivally test Π_n with constant space.) Let Λ_k be the set of probabilities as guaranteed in Lemma 4. We first invoke the algorithm k-Disc_Distribution(Stream(G), $\Lambda_k, n, d, k, \delta$) to get estimators $X_1, \cdots, X_N$ for the

fraction $f_1, \cdots, f_N$ of vertices whose k-discs are isomorphic to $\Delta_1, \cdots, \Delta_N$, respectively. As guaranteed by Lemma 5, with probability at least $2/3$, it holds that for any $i \leq N$, $|X_i - f_i| \leq \delta$. Conditioned on this event, we approximate the frequency of each subgraph F in $\mathcal{F}_n$ as guaranteed in Lemma 12, where $F = (\Gamma_1, \cdots, \Gamma_k)$ is a multiset of k-discs. That is, for each $F = (\Gamma_1, \cdots, \Gamma_k)$, we calculate its empirical frequency as $\text{estim}(F) = \frac{\prod_{i=1}^{N} \binom{X_i \cdot n}{x_i}}{\binom{n}{k}}$, where x_i is the number of copies among $\Gamma_1, \cdots, \Gamma_k$ that are of the same type as Δ_i, for $1 \leq i \leq N$. Finally, we accept the graph if and only if $\sum_{F \in \mathcal{F}_n} \text{estim}(F) < \frac{1}{2}$.

By Lemma 5 and our setting of δ, the space used by the algorithm is $O(\frac{\kappa^{2N} \cdot d^{3k+2} \cdot 3^{3N+1}}{\delta^2 \lambda_{\min}}) = O(\frac{\kappa^{2N} \cdot d^{3k+2} \cdot 3^{3N+1} \cdot (2kN)^{2k}}{\lambda_{\min}})$.

For the correctness of the algorithm, note that if X_i's are good estimators for f_i's, then the empirical probability $\text{estim}(F)$ is close to the probability that $S_{G,k}$, the subgraph spanned by the union of k-discs rooted at k uniformly sampled vertices from G, spans a subgraph that is isomorphic to F. This implies that the quantity $\sum_{F \in \mathcal{F}_n} \text{estim}(F)$ is a good estimator for the probability that $S_{G,k}$ is isomorphic to one of the members in $\mathcal{F}$. Combining this with Lemma 12, we can show that if G satisfies Π_n, then $\sum_{F \in \mathcal{F}_n} \text{estim}(F) < \frac{1}{2}$ and if G is ε-far from satisfying the property Π_n, then $\sum_{F \in \mathcal{F}_n} \text{estim}(F) \geq \frac{1}{2}$. We omit details here. ◀

5 Constant-Time Approximation Algorithms

As we mentioned in the introduction, to simulate any constant-time algorithm that is independent of the labeling of the vertices, and accesses the graph by sampling random vertices and exploring neighborhoods (or k-discs for some k) of these vertices, it suffices to have the distribution of k-disc types. Now we explain slightly more about this simulation and sketch the proof of Theorem 2. In order to approximate the size of the solution of an optimization problem (e.g., maximum matching, minimum vertex cover), it has been observed by Parnas and Ron [28] that it suffices to have efficient oracle $\mathcal{O}_S$ access to a solution S. This is true since one can attain a good estimator for the size of S by sampling a constant number of vertices, performing corresponding queries to the oracle $\mathcal{O}_S$ and then returning the fraction of vertices that belong to S based on the returned answers from $\mathcal{O}_S$. Nguyen and Onak [26] implemented such an oracle via an elegant approach of locally simulating the classical greedy algorithm. In particular, they showed the following result.

▶ **Lemma 13** ([26]). *There exist $q = q(\varepsilon, d)$, an oracle $\mathcal{O}_M$ to a maximal matching M, and an algorithm that queries $\mathcal{O}_M$ about all the edges incident to a set of $s = O(1/\varepsilon^2)$ randomly sampled vertices and with probability at least $2/3$, returns an estimator that is $(1, \varepsilon n)$-approximation of the size of M, and each query to $\mathcal{O}_M$ performs at most q queries to the adjacency list of the graph.*

A key observation is that the algorithm in Lemma 13 can be viewed as first sampling s q-discs from the graph and then perform $\mathcal{O}_M$ queries on each of these q-discs. It is easy to see that with high probability 0.99, all these q-discs are disjoint. Furthermore, the answer of the above oracle only depends on the structure of the corresponding neighborhood of the starting vertex v and the random ordering of the edges belonging to this neighborhood. Now we can approximate the size of a maximal matching in the random order streaming model as follows: we first invoke Algorithm 2 to get an estimator for the distribution of q-discs. Then we can simulate the oracle on this distribution.

Acknowledgments. We would like to thank G. Cormode, H. Jowhari for helpful discussions.

Abstract

We consider the task of graph exploration. An n-node graph has unlabeled nodes, and all ports at any node of degree d are arbitrarily numbered $0, \ldots, d-1$. A mobile agent has to visit all nodes and stop. The exploration time is the number of edge traversals. We consider the problem of how much knowledge the agent has to have a priori, in order to explore the graph in a given time, using a deterministic algorithm. This a priori information (advice) is provided to the agent by an oracle, in the form of a binary string, whose length is called the size of advice. We consider two types of oracles. The instance oracle knows the entire instance of the exploration problem, i.e., the port-numbered map of the graph and the starting node of the agent in this map. The map oracle knows the port-numbered map of the graph but does not know the starting node of the agent. What is the minimum size of advice that must be given to the agent by each of these oracles, so that the agent explores the graph in a given time?

We first consider exploration in polynomial time, and determine the exact minimum size of advice to achieve it. This size is $\log\log\log n - \Theta(1)$, for both types of oracles.

When advice is large, there are two natural time thresholds: $\Theta(n^2)$ for a map oracle, and $\Theta(n)$ for an instance oracle, that can be achieved with sufficiently large advice. We show that, with a map oracle, time $\Theta(n^2)$ cannot be improved in general, regardless of the size of advice. We also show that the smallest size of advice to achieve this time is larger than n^δ, for any $\delta < 1/3$.

For an instance oracle, advice of size $O(n \log n)$ is enough to achieve time $O(n)$. We show that, with any advice of size $o(n \log n)$, the time of exploration must be at least n^ϵ, for any $\epsilon < 2$, and with any advice of size $O(n)$, the time must be $\Omega(n^2)$.

We also investigate minimum advice sufficient for fast exploration of Hamiltonian graphs.

1 Introduction

Exploration of networks by visiting all of their nodes is one of the basic tasks performed by a mobile agent in networks. In applications, a software agent may need to collect data placed at nodes of a network, or a mobile robot may need to collect samples of air or ground in a contaminated mine whose corridors form links of a network, with corridor crossings represented by nodes.

The network is modeled as a simple connected undirected graph $G = (V, E)$ with n nodes, called *graph* in the sequel. Nodes are unlabeled, and all ports at any node of degree d are arbitrarily numbered $0, \ldots, d-1$. The agent is initially situated at a starting node v of the graph. When the agent located at a current node u gets to a neighbor w of u by taking port i, it learns the port j by which it enters node w and it learns the degree of w. The agent has to visit all nodes of the graph and stop. The agent is computationally unbounded and cannot mark the visited nodes.

The *time* of the exploration is the number of edge traversals. We consider the problem of how much knowledge the agent has to have a priori, in order to explore the graph in a given time, using a deterministic algorithm. It is well-known that some information is necessary, as witnessed even by the class of rings in which ports at all nodes are numbered 0,1 in clockwise order. Navigating in such a ring, the agent cannot learn its size. If there existed an exploration algorithm not using any a priori knowledge, then it would have to stop after some t steps in every ring, and hence would fail to explore a $(t+2)$-node ring.

Following the paradigm of *algorithms with advice* [1, 13, 17, 18, 21, 20, 22, 23, 24, 25, 26, 27, 29], this a priori information (advice), needed for exploration, is provided to the agent by an *oracle*, in the form of a binary string, whose length is called the *size of advice*. We consider two types of oracles. An *instance oracle* knows the entire instance of the exploration problem, i.e., the port-numbered map of the graph and the starting node of the agent in this map. A *map oracle* knows the port-numbered map of the graph but does not know the starting node of the agent. Formally, a map oracle is a function $f : \mathcal{G} \longrightarrow S$, where $\mathcal{G}$ is the set of graphs and S is the set of finite binary strings. An instance oracle is a function $f : \mathcal{I} \longrightarrow S$, where $\mathcal{I}$ is the set of pairs (G, v), with $G \in \mathcal{G}$ and v being the starting node of the agent in graph G. The advice s is an input to an exploration algorithm. We say that exploration in time t with advice of size x given by an instance oracle is possible, if there exists advice of length x depending on the instance (G, v), and an exploration algorithm using this advice, which explores every graph in time t, starting from node v. Likewise, we say that exploration in time t with advice of size x given by a map oracle is possible, if there exists advice of length x depending on the graph G, and an exploration algorithm using this advice, which explores every graph in time t, starting from any node. (Integers x and t depend on the size of the graph.) Proving that such an exploration is possible consists in showing an oracle of the appropriate type giving advice of size x, and an exploration algorithm using this advice and working in time t, for any graph and any starting node. Proving that such an exploration is impossible consists in showing that, for any oracle of the appropriate type giving advice of size x, and for any exploration algorithm using it, there exists a graph and a starting node for which this algorithm will exceed time t.

The central question studied in this paper is:

What is the minimum size of advice that has to be given to the agent by an instance oracle (resp. by a map oracle) to permit the agent to explore any graph in a given time?

Our main contributions are negative results of two types:

- impossibility results showing that the less powerful map oracle cannot help to achieve the same exploration time as the more powerful instance oracle, regardless of the size of advice;
- lower bounds showing that the size of some natural advice leading to a simple exploration in a given time cannot be improved significantly.

While in most cases our bounds on the size of advice are asymptotically tight, in one case the remaining gap is cubic.

1.1 Our results

We first consider exploration in polynomial time, and determine the exact minimum size of advice to achieve it. Indeed, we prove that some advice of size $\log\log\log n - c$, for any constant c, is sufficient to permit polynomial exploration of all n-node graphs, and that no advice of size $\log\log\log n - \phi(n)$, where ϕ is any function diverging to infinity, can help to do this. Both these results hold both for the instance and for the map oracles.

On the other side of the spectrum, when advice is large, there are two natural time thresholds: $\Theta(n^2)$ for a map oracle, and $\Theta(n)$ for an instance oracle. This is because, in both cases, these time benchmarks can be achieved with sufficiently large advice (advice of size $O(n\log n)$ suffices). We show that, with a map oracle, time $\Theta(n^2)$ cannot be improved in general, regardless of the size of advice. What is then the smallest advice to achieve time $\Theta(n^2)$ with a map oracle? We show that this smallest size of advice is larger than n^δ, for any $\delta < 1/3$.

For large advice, the situation changes significantly when we allow an instance oracle instead of a map oracle. In this case, advice of size $O(n\log n)$ is enough to achieve time $O(n)$. Is such a large advice needed to achieve linear time? We answer this question affirmatively. Indeed, we show more: with any advice of size $o(n\log n)$, the time of exploration must be at least n^ϵ, for any $\epsilon < 2$, and with any advice of size $O(n)$, the time must be $\Omega(n^2)$.

We finally look at Hamiltonian graphs, as for them it is possible to achieve the absolutely optimal exploration time $n-1$, when sufficiently large advice (of size $O(n\log n)$) is given by an instance oracle. We show that a map oracle cannot achieve this: regardless of the size of advice, the time of exploration must be $\Omega(n^2)$, for some Hamiltonian graphs. On the other hand, even for an instance oracle, with advice of size $o(n\log n)$, optimal time $n-1$ cannot be achieved: indeed, we show that the time of exploration with such advice must sometimes exceed the optimal time $n-1$ by a summand n^ϵ, for any $\epsilon < 1$.

Our results permit us to compare advice of different size and of different quality. The size is defined formally, and for quality we may say that advice given by an instance oracle is superior to advice given by a map oracle, because an instance oracle, seeing not only the graph but also the starting node of the agent, can use the allowed bits of advice in a better way. Looking from this perspective it turns out that both size and quality of advice provably matter. The fact that quality of advice matters is proved by the following pair of results: for a map oracle, time $\Theta(n^2)$ cannot be beaten, regardless of the size of advice, while for an instance oracle time $O(n)$ can be achieved with $O(n\log n)$ bits of advice. The fact that the size of advice matters (with the same quality) is proved by the following pair of results: for an instance oracle, time $O(n)$ can be achieved with $O(n\log n)$ bits of advice, but with $o(n\log n)$ bits of advice time must be at least n^ϵ, for any $\epsilon < 2$.

1.2 Related work

The problem of exploration and navigation of mobile agents in an unknown environment has been extensively studied in the literature for many decades (cf. the survey [33]). The explored environment has been modeled in two distinct ways: either as a geometric terrain in the plane, e.g., an unknown terrain with convex obstacles [9], or a room with polygonal [12] or rectangular [5] obstacles, or as we do in this paper, i.e., as a graph, assuming that the agent may only move along its edges. The graph model can be further specified in two different ways: either the graph is directed, in which case the agent can move only from tail to head of a directed edge [2, 6, 7, 13], or the graph is undirected (as we assume) and the agent can traverse edges in both directions [4, 8, 16, 30, 31]. The efficiency measure

adopted in most papers dealing with exploration of graphs is the time (or cost) of completing this task, measured by the number of edge traversals by the agent. Some authors [4, 8, 16] impose further restrictions on the moves of the agent.

Another direction of research concerns exploration of anonymous graphs. In this case it is impossible to explore arbitrary graphs and stop after exploration, if no marking of nodes is allowed, and if nothing is known about the graph. Hence some authors [6, 7] allow *pebbles* which the agent can drop on nodes to recognize already visited ones, and then remove them and drop them in other places. A more restrictive scenario assumes a stationary token that is fixed at the starting node of the agent [11, 32]. Exploring anonymous graphs without the possibility of marking nodes (and thus possibly without stopping) is investigated, e.g., in [14, 19]. The authors concentrate attention not on the cost of exploration but on the minimum amount of memory sufficient to carry out this task. In the absence of marking nodes, in order to guarantee stopping after exploration, some knowledge about the graph is required, e.g., an upper bound on its size [11, 34].

Providing nodes or agents with arbitrary kinds of information that can be used to perform network tasks more efficiently has been previously proposed in [1, 13, 17, 18, 21, 20, 22, 23, 24, 25, 26, 27, 29] in contexts ranging from graph coloring to broadcasting and leader election. This approach was referred to as *algorithms with advice*. The advice is given either to nodes of the network or to mobile agents performing some network task. In the first case, instead of advice, the term *informative labeling schemes* is sometimes used, if different nodes can get different information.

Several authors studied the minimum size of advice required to solve network problems in an efficient way. In [27], given a distributed representation of a solution for a problem, the authors investigated the number of bits of communication needed to verify the legality of the represented solution. In [21], the authors compared the minimum size of advice required to solve two information dissemination problems using a linear number of messages. In [22], it was shown that advice of constant size given to the nodes enables the distributed construction of a minimum spanning tree in logarithmic time. In [15, 17], the advice paradigm was used for online problems. In particular, in [15] the authors studied online graph exploration with advice in labeled weighted graphs. In the case of [29], the issue was not efficiency but feasibility: it was shown that $\Theta(n \log n)$ is the minimum size of advice required to perform monotone connected graph clearing. In [26], the authors studied radio networks for which it is possible to perform centralized broadcasting in constant time. In [24], the authors studied the problem of topology recognition with advice given to nodes. The topic of [28] and [35] was the size of advice needed for fast leader election, resp. in anonymous trees and in arbitrary anonymous graphs. Exploration with advice was previously studied only for trees [20], and algorithm performance was measured using the competitive approach. In the present paper, the performance measure of an algorithm is the order of magnitude of exploration time, and hence the case of trees is trivial, as they can be explored in linear time without any advice.

2 Exploration in polynomial time

As a warm-up, we first consider the following question: What is the minimum size of advice permitting the agent to explore any graph in time polynomial in the size of the graph? In this section we give the exact answer to this question, both for the instance oracle and for the map oracle.

It is well-known that, if the agent knows an upper bound n' on the number n of nodes of the graph, then exploration in time polynomial in n' is possible, starting from any node of the

graph. The first result implying this fact was proved in [3]. The exploration proposed there works in time $O(n'^5 \log n')$, and is based on Universal Traversal Sequences (UTS). Later on, an exploration algorithm working in time polynomial in n' based on Universal Exploration Sequences (UXS) was established in [34]. While the polynomial in the latter paper has much higher degree, the solution from [34] can be carried out in logarithmic memory. Both UTS and UXS permit to find a sequence of port numbers to be followed by the agent, regardless of the topology of the graph and of its starting node. In the case of UTS, the sequence of port numbers to be followed is the UTS itself, and in the case of UXS it is constructed term by term, on the basis of the UXS and of the port number by which the agent entered the current node. Regardless of which solution is used, we have the following proposition:

▶ **Proposition 1** ([3, 34]). *If the agent knows an upper bound n' on the number n of nodes of the graph, there exists an algorithm with input n' that permits the agent starting at any node of the graph to explore the graph and stop after $P(n')$ steps, where P is some polynomial.*

The positive part of our result on minimum advice is formulated in the following lemma. Its proof is based on Proposition 1. The advice given to the agent is some prefix of the binary representation of the number $\lfloor \log \log n \rfloor$, on the basis of which the agent computes a rough but sufficiently precise upper bound on the size of the graph which permits it to explore the graph, in time polynomial in its size.

▶ **Lemma 2.** *For any positive constant c, there exists an exploration algorithm using advice of size $\lfloor \log \log \log n - c \rfloor$, that works in time polynomial in n, for any n-node graph.*

The next result shows that the upper bound from the previous lemma is tight. Indeed, the following lower bound holds even for oriented rings, i.e., rings in which ports 0 and 1 are in clockwise order at every node.

▶ **Lemma 3.** *For any function $\phi : \mathbb{N} \to \mathbb{N}$ such that $\phi(n) \to \infty$ as $n \to \infty$, it is not possible to explore an n-node oriented ring in polynomial time, using advice of size at most $\log \log \log n - \phi(n)$.*

Notice that Lemmas 2 and 3 hold both for the instance oracle and for the map oracle. The positive result from Lemma 2 holds even for the map oracle, as the advice concerns the size of the graph and does not require knowing the starting node of the agent. The negative result from Lemma 3 holds even for the instance oracle, as it is true even in oriented rings, where knowledge of the starting node does not provide any insight, since all nodes look the same. Hence Lemmas 2 and 3 imply the following theorem that gives a precise answer to the question stated at the beginning of this section.

▶ **Theorem 4.** *The minimum size of advice permitting the agent to explore any graph in time polynomial in the size n of the graph is $\log \log \log n - \Theta(1)$, both for the instance oracle and for the map oracle.*

3 Fast exploration

When advice given to the agent can be large, there are two natural time thresholds: $\Theta(n^2)$ for a map oracle, and $\Theta(n)$ for an instance oracle. This is because, in both cases, these time benchmarks can be achieved with sufficiently large advice. Indeed, we have the following proposition.

▶ **Proposition 5.**

1. *There exists an exploration algorithm, working in time $O(n^2)$ and using advice of size $O(n \log n)$, provided by a map oracle, for n-node graphs.*
2. *There exists an exploration algorithm, working in time $O(n)$ and using advice of size $O(n \log n)$, provided by an instance oracle, for n-node graphs.*

In the rest of this section we prove negative results indicating the quality of the natural solution given in Proposition 5. For the map oracle, we show that quadratic exploration time cannot be beaten, and we give a lower bound on the size of advice sufficient to guarantee this time. For the instance oracle, we show that Proposition 5 gives optimal advice for linear exploration time.

3.1 Map oracle

Our first result for the map oracle shows that, regardless of the size of advice, exploration time $\Theta(n^2)$ cannot be beaten, for some n-node graphs.

We will use the following construction from [10] of a family $\mathcal{H}_X$ of graphs.

Let H be an $\frac{m}{2}$-regular graph with m nodes, where m is even, e.g., the complete bipartite graph. Let T be the set of edges of any spanning tree of H. Let S be the set of edges of H outside T. Let $s = |S| = \frac{m^2}{4} - m + 1$ and $S = \{e_1, e_2, \cdots, e_s\}$.

For $x \in \{0,1\}^s \setminus \{0^s\}$, the $(2m)$-node graph H_x is constructed from H by taking two disjoint copies H' and H'' of H, and crossing some pairs of edges from one copy to the other. For $i = 1, \cdots, s$, if the $i-$th bit of x is 1, then the edge $e_i = (u_i, v_i)$ is deleted from both copies of H and two copies of e_i are crossed between the two copies of H. More precisely, let $\{v_1, \cdots, v_m\}$ be the set of nodes of H and let v'_i and v''_i be the nodes corresponding to v_i, in H' and H'', respectively. Let V' and V'' be the sets of nodes of H' and H'', respectively. Define $H_x = (V' \cup V'', E_x)$, where $E_x = \{(v'_i, v'_j), (v''_i, v''_j) : (v_i, v_j) \in T\} \cup \{(v'_i, v''_j), (v''_i, v'_j) : e_k = (v_i, v_j) \in S \text{ and } x_k = 1\}$. Let $\mathcal{H}_X = \{H_x : x \in \{0,1\}^s \setminus \{0^s\}\}$.

According to the result from [10], for every node $v \in H$, there exists some sequence $x(v) \in \{0,1\}^s \setminus \{0^s\}$ such that if an exploration of H performed according to some sequence W of port numbers, starting from node v_1, visits node v at most s times, then in one of the copies H' or H'' in $H_{x(v)}$ the node v' or v'' is not visited at all, if the same sequence W is used to explore the graph $H_{x(v)}$ starting from v'_1. Intuitively, the result from [10] shows a class of graphs with the property that if some node in one of these graphs is not visited many times, then the exploration algorithm fails *in some other graph* of this class. There is no control in which graph of the class this will happen. We use the graphs from [10] as building blocks to prove a different kind of lower bound. Indeed, we construct a *single graph* having the property that if some of its nodes are not visited many times, then exploration must fail in this graph. This will prove a lower bound on exploration time for some graph, even if the agent knows the entire graph.

Using the graphs $H_x \in \mathcal{H}_X$ from [10] we construct the graph $\widehat{G}$ as follows. For any $1 \leq i \leq m$, let $v'_1(i)$ be the node corresponding to node v'_1 from H' in the graph $H_{x(v_i)}$. Connect the graphs $H_{x(v_i)}$, for $1 \leq i \leq m$, and an oriented cycle C with nodes $\{y_1, \cdots, y_m\}$ (port numbers 0,1 are in clockwise order at each node of the cycle), by adding edges $(y_i, v'_1(i))$, for $1 \leq i \leq m$. The port numbers corresponding to these edges are: 2 at y_i and $\frac{m}{2}$ at $v'_1(i)$. The cycle C is called the *main cycle* of $\widehat{G}$. See Fig. 1.

Let $n = 2m^2 + m$ be the number of nodes in $\widehat{G}$.

By the construction of $\widehat{G}$, any exploration algorithm with the agent starting from any node of the main cycle, has the following *obliviousness property*. For any step i of the

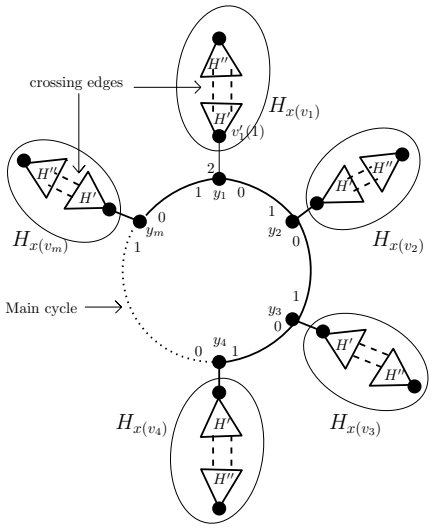

Figure 1 Construction of $\widehat{G}$.

algorithm, if the agent is at some node v in this step, and the algorithm prescribes taking some port p at this node, then the port q through which the agent enters the adjacent node w in the $(i+1)$-th step, and the degree of the node w are predetermined (i.e., they are independent of the starting node in the main cycle). Intuitively, the agent does not learn anything during the algorithm execution. Therefore, every exploration algorithm with the agent starting from any node of the main cycle can be uniquely coded by a sequence of port numbers which the agent takes in consecutive steps of its exploration.

Let $\mathcal{A}$ be any exploration algorithm for $\widehat{G}$, and suppose that the agent starts from some node of the main cycle. We use $\cdot$ for concatenation of sequences.

▶ **Lemma 6.** *Let U be the sequence of port numbers corresponding to the movement of the agent according to algorithm $\mathcal{A}$, starting at some node of the main cycle C of $\widehat{G}$. Then $U = B'_1 \cdot (2) \cdot B_1 \cdot (\frac{m}{2}) \cdot B'_2 \cdot (2) \cdot B_2 \cdot (\frac{m}{2}) \cdots B'_p \cdot (2) \cdot B_p \cdot (\frac{m}{2}) \cdot B'_{p+1}$, where each B'_j is a sequence of port numbers corresponding to the movement of the agent along C and each B_j is a sequence of port numbers corresponding to the movement of the agent inside some $H_{x(v_i)}$.*

Call an exploration algorithm of $\widehat{G}$ *non-repetitive*, if the agent, starting from the main cycle, enters each $H_{x(v_i)}$, for $1 \leq i \leq m$, exactly once. By definition, the sequence of port numbers corresponding to a non-repetitive algorithm can be written as $D'_1 \cdot (2) \cdot D_1 \cdot (\frac{m}{2}) \cdot D'_2 \cdot (2) \cdot D_2 \cdot (\frac{m}{2}) \cdots D'_m \cdot (2) \cdot D_m \cdot (\frac{m}{2}) \cdot D'_{m+1}$, where each D'_j is a sequence of port numbers corresponding to the movement of the agent along C and each D_j is a sequence of port numbers corresponding to the movement of the agent inside some $H_{x(v_i)}$. Notice that since the algorithm is non-repetitive, the number of blocks D_j is exactly m.

The following lemma proves that in order to show a lower bound on the exploration time in $\widehat{G}$, it is enough to consider only the class of non-repetitive algorithms.

▶ **Lemma 7.** *If the agent starts from some node of the main cycle of $\widehat{G}$ and executes any exploration algorithm $\mathcal{A}$ of $\widehat{G}$, then there exists a non-repetitive algorithm $\mathcal{A}'$ for this agent, such that the exploration time of $\mathcal{A}'$ is at most the exploration time of $\mathcal{A}$.*

The next lemma implies that the sequence U corresponding to a correct non-repetitive exploration algorithm must be long.

▶ **Lemma 8.** *Let $U = D'_1 \cdot (2) \cdot D_1 \cdot (\frac{m}{2}) \cdot D'_2 \cdot (2) \cdot D_2 \cdot (\frac{m}{2}) \cdots D'_m \cdot (2) \cdot D_m \cdot (\frac{m}{2}) \cdot D'_{m+1}$ be the sequence of port numbers corresponding to a non-repetitive algorithm. If there exists some D_i such that the agent following D_i in H starting from node v_1 visits some node v_j of H at most s times, then there exists a starting node in the main cycle of $\widehat{G}$, such that the agent starting at this node and following U does not visit all the nodes of $\widehat{G}$.*

▶ **Theorem 9.** *Any exploration algorithm using any advice given by a map oracle must take time $\Omega(n^2)$ on graph $\widehat{G}$, for some starting node in the main cycle, for arbitrarily large n.*

Proof. By Lemma 7, it is enough to consider only non-repetitive algorithms. Let $U = D'_1 \cdot (2) \cdot D_1 \cdot (\frac{m}{2}) \cdot D'_2 \cdot (2) \cdot D_2 \cdot (\frac{m}{2}) \cdots D'_m \cdot (2) \cdot D_m \cdot (\frac{m}{2}) \cdot D'_{m+1}$ be the sequence of port numbers corresponding to such an algorithm. Then by Lemma 8, for each i, $1 \leq i \leq m$, the agent following D_i in H starting from node v_1 visits each node v_j of H, for $1 \leq j \leq m$, at least $s+1$ times. Therefore the length of D_i is at least $(s+1)m$. Hence, the length of U is at least $\sum_{i=1}^{m}(s+1)m = (s+1)m^2 = m^2(\frac{m^2}{4} - m + 1)$. Since $n = 2m^2 + m$, the length of U is in $\Omega(n^2)$. ◀

Theorem 9 shows that, for some n-node graph, no advice given by a map oracle can help to explore this graph in time better than $\Theta(n^2)$. It is then natural to ask what is the minimum size of advice to achieve time $\Theta(n^2)$ with a map oracle, for every n-node graph. Our next result shows that any exploration algorithm using advice of size n^δ for $\delta < \frac{1}{3}$, must take time $\omega(n^2)$, on some n-node graph.

Fix a constant $\epsilon < \frac{1}{2}$. Let H be an $\frac{m}{2}$-regular graph with m nodes, where m is even. Let $\{v_1, \cdots, v_m\}$ be the set of nodes of H. Consider a subset $Z \subset \{1, 2, \cdots, m\}$ of size m^ϵ. Let $p = m^\epsilon$ and $n = 2mp + p$. We construct an n-node graph $\widehat{G_Z}$ from H. The construction of $\widehat{G_Z}$ is similar to the construction of $\widehat{G}$ at the beginning of this section. Let $Z = \{z_1, z_2, \cdots, z_p\}$. To construct $\widehat{G_Z}$, connect the (previously described) graphs $H_{x(v_{z_i})}$, for $1 \leq i \leq p$, and an oriented cycle C' (called the main cycle) with nodes $\{y_1, \cdots, y_p\}$, by adding edges $(y_i, v'_1(z_i))$, for $1 \leq i \leq p$. The port numbers corresponding to these edges are: 2 at y_i and $\frac{m}{2}$ at $v'_1(z_i)$. Note that the same obliviousness property applies to exploration algorithms in graphs $\widehat{G_Z}$, when the agent starts from a node of the main cycle.

Let $\widehat{\mathcal{G}_Z}$ be the set of all possible graphs $\widehat{G_Z}$ constructed from H. We have $|\widehat{\mathcal{G}_Z}| = \binom{m}{p}$.

▶ **Theorem 10.** *For any $\epsilon < \frac{1}{2}$, any exploration algorithm using advice of size $o(n^{\frac{\epsilon}{1+\epsilon}} \log n)$ must take time $\omega(n^2)$ on some graph of the class $\widehat{\mathcal{G}_Z}$ and for some starting node in the main cycle of this graph, for arbitrarily large n.*

Proof. Since $\epsilon < \frac{1}{2}$, there exists an integer c such that $\epsilon < \frac{c-1}{2c-1}$. We show that if the size of the advice is at most $\frac{1}{2c} m^\epsilon \log(m^{1-\epsilon}) \leq \frac{1-\epsilon}{2c(1+\epsilon)} (\frac{n}{2})^{\frac{\epsilon}{1+\epsilon}} \log \frac{n}{2}$, then there exists a graph in $\widehat{\mathcal{G}_Z}$ for which the time required for exploration is $\omega(n^2)$. We have $|\widehat{\mathcal{G}_Z}| = \binom{m}{m^\epsilon} \geq (m^{1-\epsilon})^{m^\epsilon}$. There are fewer than $(m^{1-\epsilon})^{\frac{m^\epsilon}{c}}$ different binary strings of length at most $\frac{1}{2c} m^\epsilon \log(m^{1-\epsilon})$. By the pigeonhole principle, there exists a family of graphs $\widehat{\mathcal{G}} \subset \widehat{\mathcal{G}_Z}$ of size at least $(m^{1-\epsilon})^{(c-1)\frac{m^\epsilon}{c}}$ such that all the graphs in $\widehat{\mathcal{G}}$ get the same advice.

Define $F(\widehat{\mathcal{G}}) = \bigcup \Big\{ \{v_{z_1}, v_{z_2}, \cdots, v_{z_p}\} : Z = \{z_1, z_2, \cdots, z_p\} \text{ and } \widehat{G_Z} \in \widehat{\mathcal{G}} \Big\}$. Intuitively, $F(\widehat{\mathcal{G}})$ is the subset of nodes of H, such that for each $v \in F(\widehat{\mathcal{G}})$, there exists some graph in $\widehat{\mathcal{G}}$ that contains $H_{x(v)}$ as a subgraph.

Claim: $|F(\widehat{\mathcal{G}})| \geq |\widehat{\mathcal{G}}|^{\frac{1}{p}}$.

Proof. We prove the claim by contradiction. Suppose that $|F(\widehat{\mathcal{G}})| < |\widehat{\mathcal{G}}|^{\frac{1}{p}}$. Each graph in $\widehat{\mathcal{G}}$ has p different subgraphs $H_{x(v)}$, where $v \in |F(\widehat{\mathcal{G}})|$. There are $\binom{|F(\widehat{\mathcal{G}})|}{p}$ different graphs in $\widehat{\mathcal{G}}$ which is at most $|F(\widehat{\mathcal{G}})|^p < |\widehat{\mathcal{G}}|$. This contradiction proves the claim. ◀

Consider the exploration of some graph $\widehat{G_Z} \in \widehat{\mathcal{G}}$ starting from the main cycle. Let $U = D'_1 \cdot (2) \cdot D_1 \cdot (\frac{m}{2}) \cdot D'_2 \cdot (2) \cdot D_2 \cdot (\frac{m}{2}) \cdots D'_p \cdot (2) \cdot D_m \cdot (\frac{m}{2}) \cdot D'_{p+1}$ be the sequence of port numbers corresponding to a non-repetitive algorithm exploring $\widehat{G_Z}$. Then for each i, $1 \leq i \leq p$, the agent following D_i in H starting from node v_1 must visit each node $v \in F(\widehat{\mathcal{G}})$ at least $s+1$ times. (Otherwise, there would exist a graph in $\widehat{\mathcal{G}}$ and a starting node in the main cycle, for which one node would not be explored by U). Hence, for sufficiently large m, the length of D_i is at least $(s+1)|F(\widehat{\mathcal{G}})| \geq \frac{m^2}{5} m^{\frac{(c-1)(1-\epsilon)}{c}}$, because $s \geq \frac{m^2}{5}$. Therefore, the length of U is at least $p\frac{m^2}{5} m^{\frac{(c-1)(1-\epsilon)}{c}} = \frac{1}{5} m^{\epsilon} m^2 m^{\frac{(c-1)(1-\epsilon)}{c}} = \frac{1}{5} m^{2+\epsilon+\frac{(c-1)(1-\epsilon)}{c}} = \frac{1}{5} m^{2+2\epsilon+(\frac{c-1}{c}+\frac{1-2c}{c}\epsilon)}$. Since $\epsilon < \frac{c-1}{2c-1}$, we have $(\frac{c-1}{c} + \frac{1-2c}{c}\epsilon) > 0$. Therefore, the length of U is in $\omega((2m^{1+\epsilon} + m^{\epsilon})^2) = \omega(n^2)$, and hence exploration time is in $\omega(n^2)$. ◀

Since $\epsilon < \frac{1}{2}$ implies $\frac{\epsilon}{1+\epsilon} < \frac{1}{3}$, Theorem 10 yields the following corollary.

▶ **Corollary 11.** *For any $\delta < \frac{1}{3}$, any exploration algorithm using advice of size $o(n^{\delta})$ must take time $\omega(n^2)$ on some n-node graph, for arbitrarily large n.*

3.2 Instance oracle

For the instance oracle we show a general lower bound on the size of advice needed to achieve a given exploration time. The main corollaries of this lower bound are:

- the size of advice $\Theta(n \log n)$ from Proposition 5, sufficient to achieve linear exploration time, cannot be beaten;
- for advice of linear size, exploration time must be quadratic.

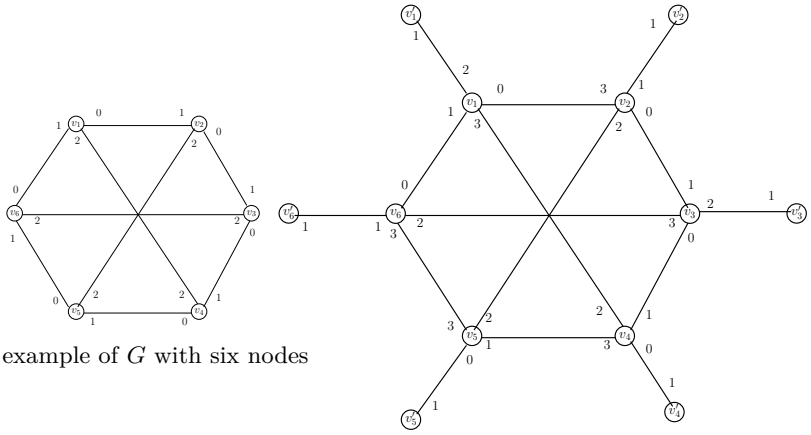
To prove our lower bound we will use the following construction.

Let G be an $\frac{n}{4}$-regular $\frac{n}{2}$-node graph, where n is divisible by 4. We can use, for example the complete bipartite graph with $\frac{n}{2}$ nodes. Let $m = \frac{n}{2}$. Let v_1, v_2, $\cdots$, v_m be the nodes of G. Let $x = (x_1, x_2, \cdots, x_m)$ be a sequence of m integers where $0 \leq x_i \leq \frac{m}{2} - 1$, for $i = 1, \cdots, m$. Let X be the set of all such sequences.

We construct an n-node graph G_x as follows. For each $i = 1, \cdots, m$, add a new node v'_i of degree 1 to G. Replace the port number x_i at v_i by port number $\frac{m}{2}$. Add the edge (v_i, v'_i) with the port number x_i at v_i. An example of the construction of G_x from G is shown in Fig. 2. Let $\mathcal{G}_X$ be the set of all possible graphs G_x constructed from G.

▶ **Theorem 12.** *For any function $\phi : \mathbb{N} \longrightarrow \mathbb{N}$, and for any exploration algorithm using advice of size $o(n\phi(n))$, this algorithm must take time $\Omega(\frac{n^2}{2^{\phi(n)}})$ on some n-node graph from the family $\mathcal{G}_X$, for arbitrarily large integers n.*

Proof. Let n be divisible by 4. We show that if the size of the advice is at most $\frac{n\phi(n)}{4} - 1$, then there exists an n-node graph in the family $\mathcal{G}_X$, for which the time required for exploration is $\Omega(\frac{n^2}{2^{\phi(n)}})$. We have $|\mathcal{G}_X| = |X| = (\frac{m}{2})^m$. There are fewer than $2^{\frac{m\phi(2m)}{2}} = (2^{\phi(2m)})^{\frac{m}{2}}$ different binary strings of length at most $\frac{2m\phi(2m)}{4} - 1 = \frac{n\phi(n)}{4} - 1$. By the pigeonhole principle, there exists a family of graphs $\mathcal{G} \subset \mathcal{G}_X$, of size at least $\frac{(\frac{m}{2})^m}{(2^{\phi(2m)})^{\frac{m}{2}}}$, such that all the graphs in $\mathcal{G}$ get the same advice. Let $Y = \{x \in X : G_x \in \mathcal{G}\}$. Let $z = \frac{m}{2^{\phi(2m)+2}}$ and let



(a) An example of G with six nodes

(b) G_x for the sequence $x = (2, 1, 2, 0, 0, 1)$

Figure 2 The construction of G_x from G.

$J = \{j : |\{x_j : x \in Y\}| \geq z\}$. Intuitively, J is the set of indices, for which the set of terms of sequences x that produce graphs from $\mathcal{G}$ is large. Let $p = |J|$.

Claim: $p > \frac{m}{2}$.

Proof. We prove the claim by contradiction. Suppose that $p \leq \frac{m}{2}$. Since $p \leq \frac{m}{2}$ and $z < \frac{m}{2}$, we have $(\frac{m}{2})^p \cdot z^{m-p} \leq (\frac{m}{2})^{\frac{m}{2}} \cdot z^{\frac{m}{2}}$. Note that for all $i \in \{1, 2, \cdots, m\} \setminus J$, we have $|\{x_i : x \in Y\}| < z$, and for $j \in J$, we have $|\{x_j : x \in Y\}| \leq \frac{m}{2}$. Therefore, $|\mathcal{G}| < (\frac{m}{2})^p \cdot z^{m-p}$. Hence, $|\mathcal{G}| < (\frac{m}{2})^{\frac{m}{2}} (\frac{m}{2^{\phi(2m)+2}})^{\frac{m}{2}} = \frac{m^m}{2^{\frac{m}{2}} (2^{\phi(2m)+2})^{\frac{m}{2}}} < |\mathcal{G}|$, which is a contradiction. This proves the claim. ◀

Consider any exploration algorithm for the class $\mathcal{G}$. There exists a graph $G_x \in \mathcal{G}$, such that, at each node v_j of G_x, for $j \in J$, the agent must take all the ports in $\{x_j : x \in Y\}$. Indeed, suppose that the agent does not take some port x_j, where $j \in J$ and $x \in Y$. Consider the exploration of any graph $G_{x'} \in \mathcal{G}$, where $x'_j = x_j$. Since the agent can visit v'_j only coming from v_j, using port x'_j in $G_{x'}$, the node v'_j remains unexplored, as the port x'_j at v_j is never used, which is a contradiction. Hence, the agent must visit at least $\frac{m}{2^{\phi(2m)+2}}$ ports at each node v_j for $j \in J$. Since $|J| > \frac{m}{2}$, the time required for exploration is at least $\frac{m^2}{2^{\phi(2m)+3}}$, i.e., it is at least $\frac{n^2}{2^{\phi(n)+5}}$. ◀

If $\phi(n) = c$ where c is a constant, then Theorem 12 implies that any exploration algorithm using advice of size at most $\frac{cn}{2}$, must take time at least $\frac{n^2}{2^{c+3}}$. This implies that, if the size of advice is at most $c'n$, for any constant c', then exploration time is $\Omega(n^2)$. Hence we have the following corollary.

▶ **Corollary 13.** *Any exploration algorithm using advice of size $O(n)$ must take time $\Omega(n^2)$ on some n-node graph, for arbitrarily large n.*

For $\phi(n) \in o(\log n)$, Theorem 12 implies an exploration time $\omega(n)$ which shows that the upper bound on the size of advice from Proposition 5 is asymptotically tight for exploration in linear time. The following corollary improves this statement significantly, showing that exploration time is very sensitive to the size of advice at the threshold $\Theta(n \log n)$ of the latter.

▶ **Corollary 14.** *Consider any constant $\epsilon < 2$. Any exploration algorithm using advice of size $o(n \log n)$ must take time $\Omega(n^\epsilon)$, on some n-node graph, for arbitrarily large n.*

Proof. If the size of advice is $o(n \log n)$, then it is $n\phi(n)$, where $\phi(n) = \frac{\log n}{f(n)}$, with $f(n) \to \infty$ as $n \to \infty$. Theorem 12 implies that exploration time must be $\Omega\left(\frac{n^2}{2^{\frac{\log n}{f(n)}}}\right) = \Omega\left(\frac{n^2}{n^{\frac{1}{f(n)}}}\right)$. Since, for any constant $\delta > 0$, we have $n^{\frac{1}{f(n)}} \in O(n^\delta)$, the corollary holds. ◀

4 Exploration of Hamiltonian graphs

In this section we turn attention to Hamiltonian graphs. These graphs have a special feature from the point of view of exploration: with sufficiently large advice of appropriate type, the agent can explore a Hamiltonian graph without any loss of time, visiting each node exactly once, i.e., in time $n-1$, for n-node graphs. Indeed, an instance oracle can give as advice the sequence of port numbers along a Hamiltonian cycle, from the starting node of the agent, and then the agent takes the prescribed ports in $n-1$ consecutive steps. Since it is enough to give $n-1$ port numbers, and the binary representation of each port number uses $O(\log n)$ bits, advice of size $O(n \log n)$, given by an instance oracle, suffices.

We show that neither the quality nor the size of advice can be decreased to achieve the goal of optimal exploration of Hamiltonian graphs. To prove the first statement, we show a graph which is impossible to explore in time $n-1$ when advice of any size is given by a map oracle. Indeed, we construct an n-node Hamiltonian graph for which even knowing the entire map of the graph (but not knowing its starting node) an agent must use time $\Omega(n^2)$ to explore it. To prove the second statement, we construct a class of n-node Hamiltonian graphs for which advice of size $o(n \log n)$, even given by an instance oracle, is not enough to permit exploration of graphs in this class in time $n-1$. Indeed, we show more: any exploration algorithm using such advice must exceed the optimal time $n-1$ by a summand n^ϵ, for any $\epsilon < 1$, on some graph of this class.

In order to prove the first result, we construct a $(3n)$-node Hamiltonian graph $\tilde{G}$ from the n-node graph $\widehat{G}$ described in Section 3.1. First, we consider an $\frac{m}{2}$-regular m-node Hamiltonian graph H (for example, the complete bipartite graph). Let $v_1, v_2, \cdots, v_m$ be the nodes of H along a Hamiltonian cycle. The graph $\widehat{G}$ is constructed from H as described in Section 3.1, where the Hamiltonian path $(v_1, v_2, \cdots, v_m)$ is taken as the spanning tree T. We construct the Hamiltonian graph $\tilde{G}$ from the graph $\widehat{G}$ as follows. Denote by $d(v)$ the degree of node v in $\widehat{G}$. For each node v in $\widehat{G}$, consider a cycle of three nodes $v(1)$, $v(2)$, and $v(3)$, in $\tilde{G}$, with port numbers $3d(v), 3d(v)+1$ in clockwise order at each of these three nodes. For each edge (u, v) in $\widehat{G}$, such that the port numbers corresponding to this edge are p at u and q at v, add, in $\tilde{G}$, the edges $(u(i), v(j))$, for $1 \leq i, j \leq 3$, with the following port numbers. The port numbers corresponding to edge $(u(i), v(j))$ are: $p + (j-1)d(u)$ at $u(i)$ and $q + (i-1)d(v)$ at $v(j)$, see Fig. 3.

▶ **Lemma 15.** *The graph $\tilde{G}$ is Hamiltonian.*

Let $\mathcal{A}$ be an exploration algorithm for $\tilde{G}$ starting from node $y_i(1)$, for some $i \leq m$. We describe the following algorithm $\mathcal{A}^*$ on $\widehat{G}$, starting from node y_i. Ignore all moves of $\mathcal{A}$ taking port $3d(v)$ or $3d(v)+1$ at a node $v(j)$, for $1 \leq j \leq 3$, of $\tilde{G}$. Replace every move of $\mathcal{A}$ taking port $r = p + (i-1)d(v)$, at node $v(j)$, for $1 \leq j \leq 3$, in $\tilde{G}$, where $0 \leq p \leq d(v)-1$, by a move taking port p in $\widehat{G}$.

Then the agent executing $\mathcal{A}^*$ in $\widehat{G}$, starting from the main cycle, explores all the nodes. The time used by $\mathcal{A}^*$ in $\widehat{G}$ does not exceed the time used by $\mathcal{A}$ in $\tilde{G}$. Since, by Theorem 9, any

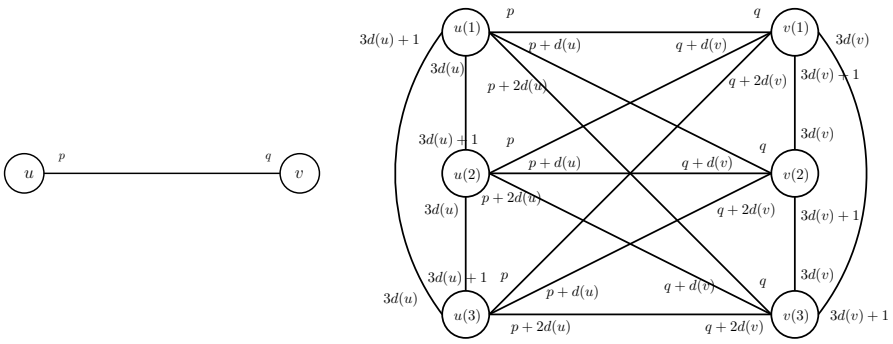


Figure 3 The construction of $\tilde{G}$ from $\widehat{G}$.

exploration algorithm for $\widehat{G}$, starting from the main cycle, must take time $\Omega(n^2)$, algorithm $\mathcal{A}$ must take time $\Omega(n^2)$ to explore $\tilde{G}$. Replacing $3n$ by n we have the following theorem.

▶ **Theorem 16.** *Any exploration algorithm using any advice given by a map oracle must take time $\Omega(n^2)$ on some n-node Hamiltonian graph, for arbitrarily large n.*

Our last result shows that advice of size $o(n \log n)$ causes significant increase of exploration time for some Hamiltonian graphs, as compared to optimal time $n-1$ achievable with advice of size $O(n \log n)$, given by an instance oracle.

▶ **Theorem 17.** *For any constant $\epsilon < 1$, and for any exploration algorithm using advice of size $o(n \log n)$, this algorithm must take time $n + n^{\epsilon}$, on some n-node Hamiltonian graph, for arbitrarily large n.*

5 Conclusion

Most of our lower bounds on the size of advice are either exactly or asymptotically tight. The lower bound $\log \log \log n - \Theta(1)$ on the size of advice sufficient to explore all n-node graphs in polynomial time is exactly tight: with advice of any such size, polynomial exploration is possible, and with advice of any smaller size it is not. For an instance oracle, the lower bound $\Omega(n \log n)$ on the size of advice sufficient to explore n-node graphs in $O(n)$ time is asymptotically tight, as we gave a linear time exploration algorithm using advice of size $O(n \log n)$. An exception to this tightness is the lower bound on the size of advice given by a map oracle, permitting exploration in time $O(n^2)$. While the natural upper bound is $O(n \log n)$, our lower bound is only n^{δ} for any $\delta < \frac{1}{3}$. Hence the main remaining question is:

What is the smallest advice, given by a map oracle, permitting exploration of n-node graphs in time $O(n^2)$?

Acknowledgements. We are grateful to Adrian Kosowski for early discussions on the subject of this paper and for drawing our attention to [10].

Abstract

The secretary problem is a classic model for online decision making. Recently, combinatorial extensions such as matroid or matching secretary problems have become an important tool to study algorithmic problems in dynamic markets. Here the decision maker must know the numerical value of each arriving element, which can be a demanding informational assumption. In this paper, we initiate the study of combinatorial secretary problems with *ordinal information*, in which the decision maker only needs to be aware of a preference order consistent with the values of arrived elements. The goal is to design online algorithms with small competitive ratios.

For a variety of combinatorial problems, such as bipartite matching, general packing LPs, and independent set with bounded local independence number, we design new algorithms that obtain constant competitive ratios.

For the matroid secretary problem, we observe that many existing algorithms for special matroid structures maintain their competitive ratios even in the ordinal model. In these cases, the restriction to ordinal information does not represent any additional obstacle. Moreover, we show that ordinal variants of the submodular matroid secretary problems can be solved using algorithms for the linear versions by extending [18]. In contrast, we provide a lower bound of $\Omega(\sqrt{n}/(\log n))$ for algorithms that are oblivious to the matroid structure, where n is the total number of elements. This contrasts an upper bound of $O(\log n)$ in the cardinal model, and it shows that the technique of thresholding is not sufficient for good algorithms in the ordinal model.

1 Introduction

The secretary problem is a classic approach to model online decision making under uncertain input. The interpretation is that a firm needs to hire a secretary. There are n candidates and they arrive sequentially in random order for an interview. Following an interview, the firm learns the value of the candidate, and it has to make an immediate decision about hiring him

before seeing the next candidate(s). If the candidate is hired, the process is over. Otherwise, a rejected candidate cannot be hired at a later point in time. The optimal algorithm is a simple greedy rule that rejects all candidates in an initial learning phase. In the following acceptance phase, it hires the first candidate that is the best among all the ones seen so far. It manages to hire the best candidate with optimal probability $1/e$. Notably, it only needs to know if a candidate is the best seen so far, but no exact numerical values.

Since its introduction [15], the secretary problem has attracted a huge amount of research interest. Recently, a variety of combinatorial extensions have been studied in the literature [7] capturing a variety of fundamental online allocation problems in networks and markets, such as network design [28], resource allocation [25], medium access in networks [22], or competitive admission processes [12]. Prominently, in the matroid secretary problem [8], the elements of a weighted matroid arrive in uniform random order (e.g., weighted edges of an undirected graph G). The goal is to select a max-weight independent set of the matroid (e.g., a max-weight forest of G). The popular *matroid secretary conjecture* claims that for all matroids, there exists an algorithm with a constant *competitive ratio*, i.e., the expected total weight of the solution computed by the algorithm is at least a constant fraction of the total weight of the optimum solution. Despite much progress on special cases, the conjecture remains open. Beyond matroids, online algorithms for a variety of combinatorial secretary problems with downward-closed structure have recently been studied (e.g., matching [28, 25], independent set [22], linear packing problems [26] or submodular versions [18]).

The best known algorithms for matroid or matching secretary problems rely heavily on knowing the exact weight structure of elements. They either compute max-weight solutions to guide the admission process or rely on advanced bucketing techniques to group elements based on their weight. For a decision maker, in many applications it can be quite difficult to determine an exact cardinal preference for each of the incoming candidates. In contrast, in the original problem, the optimal algorithm only needs *ordinal information* about the candidates. This property provides a much more robust guarantee, since the numerical values can be arbitrary, as long as they are consistent with the preference order.

In this paper, we study algorithms for combinatorial secretary problems that rely only on ordinal information. We assume that there is an unknown value for each element, but our algorithms only have access to the *total order* of the elements arrived so far, which is consistent with their values. We term this the *ordinal model*; as opposed to the *cardinal model*, in which the algorithm learns the exact values. We show bounds on the competitive ratio, i.e., we compare the quality of the computed solutions to the optima in terms of the exact underlying but unknown numerical values. Consequently, competitive ratios for our algorithms are robust guarantees against uncertainty in the input. Our approach follows a recent line of research by studying the potential of algorithms with ordinal information to approximate optima based on numerical values [4, 3, 1, 10].

1.1 Our Contribution

We first point out that many algorithms proposed in the literature continue to work in the ordinal model. In particular, a wide variety of algorithms for variants of the matroid secretary problem with constant competitive ratios continue to obtain their guarantees in the ordinal model (see Table 1 for an overview). This shows that many results in the literature are much stronger, since the algorithms require significantly less information. Notably, the algorithm of [9] extends to the ordinal model and gives a ratio of $O(\log^2 r)$ for general matroids, where r is the rank of the matroid. In contrast, the improved algorithms with ratios of $O(\log r)$ and $O(\log \log r)$ [8, 30, 16] are not applicable in the ordinal model.

For several combinatorial secretary problems we obtain new algorithms for the ordinal model. For online bipartite matching we give an algorithm that is $2e$-competitive. More generally, it obtains a ratio of $3e$ when the value of the matching is a submodular set function of the chosen edges. We also extend this result to online packing LPs with at most d non-zero entries per variable. Here we obtain an $O(d^{(B+1)/B})$-competitive algorithm, where B is a tightness parameter of the constraints. Another extension is matching in general graphs, for which we give a 8.78-competitive algorithm.

We give an $O(\alpha_1^2)$-competitive algorithm for the online weighted independent set problem in graphs, where α_1 is the local independence number of the graph. For example, for the prominent case of unit-disk graphs, $\alpha_1 = 5$ and we obtain a constant-competitive algorithm.

For matroids, we extend a result of [18] to the ordinal model: The reduction from submodular to linear matroid secretary can be done with ordinal information for marginal weights of the elements. More specifically, we show that whenever there is an algorithm that solves the matroid secretary problem in the ordinal model on some matroid class and has a competitive ratio of α, there is also an algorithm for the submodular matroid secretary problem in the ordinal model on the same matroid class with a competitive ratio of $O(\alpha^2)$. The ratio can be shown to be better if the linear algorithm satisfies some further properties.

Lastly, we consider the importance of knowing the weights, ordering, and structure of the domain. For algorithms that have complete ordinal information but cannot learn the specific matroid structure, we show a lower bound of $\Omega(\sqrt{n}/(\log n))$, even for partition matroids, where n is the number of elements in the ground set. This bound contrasts the $O(\log^2 r)$-competitive algorithm and indicates that learning the matroid structure is crucial in the ordinal model. Moreover, it contrasts the cardinal model, where thresholding algorithms yield $O(\log r)$-competitive algorithms without learning the matroid structure.

For structural reasons, we present our results in a slightly different order. We first discuss the matroid results in Section 3. Then we proceed with matching and packing in Section 4 and independent set in Section 5. Due to spatial constraints, all missing proofs are deferred to the full version [23].

2 Preliminaries and Related Work

In the typical problem we study, there is a set E of elements arriving sequentially in random order. The algorithm knows $n = |E|$ in advance. It must accept or reject an element before seeing the next element(s). There is a set $\mathcal{S} \subseteq 2^E$ of *feasible solutions*. $\mathcal{S}$ is downward-closed, i.e., if $S \in \mathcal{S}$, then $S' \in \mathcal{S}$ for every $S' \subseteq S$. The goal is to accept a feasible solution that maximizes an objective function f. In the *linear version*, each element has a *value* or *weight* w_e, and $f(S) = \sum_{e \in S} w_e$. In the *submodular version*, f is submodular and $f(\emptyset) = 0$.

In the linear ordinal model, the algorithm only sees a strict total order over the elements seen so far that is consistent with their weights (ties are broken arbitrarily). For the submodular version, we interpret the value of an element as its marginal contribution to a set of elements. In this case, our algorithm has access to an *ordinal oracle* $\mathcal{O}(S)$. For every subset S of arrived elements, $\mathcal{O}(S)$ returns a total order of arrived elements consistent with their marginal values $f(e|S) = f(S \cup \{e\}) - f(S)$. We chose this particular model because it elegantly aligns with the online setting. Both stronger and weaker definitions are possible and these are interesting avenues for future work.

Given this information, we strive to design algorithms with small competitive ratio $f(S^*)/\mathbb{E}[f(S_{alg})]$. Here S^* is an optimal feasible solution and S_{alg} the solution returned by the algorithm. Note that S_{alg} is a random variable due to random-order arrival and possible internal randomization of the algorithm.

Table 1 Existing algorithms for matroid secretary problems that provide the same guarantee in the ordinal model.

Matroid	general	k-uniform	graphic	cographic	transversal	laminar	regular
Ratio	$O(\log^2 r)$	$1 + O(\sqrt{1/k})$, e	$2e$	$3e$	16	$3\sqrt{3}e$	$9e$
Reference	[9]	[15, 27, 6]	[28]	[31]	[13]	[24]	[14]

In the matroid secretary problem, the pair $\mathcal{M} = (E, \mathcal{S})$ is a matroid. We summarize in Table 1 some of the existing results for classes of the (linear) problem that transfer to the ordinal model. The algorithms for all restricted matroid classes other than the graphic matroid assume a-priori complete knowledge of the matroid – only weights are revealed online. The algorithms do not use cardinal information, their decisions are based only on ordinal information. As such, they translate directly to the ordinal model. Notably, the algorithm from [9] solves even the general submodular matroid secretary problem in the ordinal model.

2.1 Related Work

Our work is partly inspired by [4, 5], who study ordinal approximation algorithms for classical optimization problems. They design constant-factor approximation algorithms for matching and clustering problems with ordinal information and extend the results to truthful mechanisms. Our approach here differs due to online arrival. Anshelevich et al. [3] examine the quality of randomized social choice mechanisms when agents have metric preferences but only ordinal information is available to the mechanism. Previously, [1, 10] studied ordinal measures of efficiency in matchings, for instance the average rank of an agent's partner.

The literature on the secretary problem is too broad to survey here. We only discuss directly related work on online algorithms for combinatorial variants. In[29, 21], the authors study hiring a single secretary when only a partial ordering of the candidates is available. For multiple-choice secretary, where we can select any k candidates, there are algorithms with ratios that are constant and asymptotically decreasing in k [27, 6]. More generally, the matroid secretary problem has attracted a large amount of research interest [8, 11, 30, 16], and the best-known algorithm in the cardinal model has ratio $O(\log \log r)$. For results on specific matroid classes, see the overview in Table 1. Extensions to the submodular version are treated in [9, 18].

Another prominent domain is online bipartite matching, in which one side of the graph is known in advance and the other arrives online in random order, each vertex revealing all incident weighted edges when it arrives [28]. In this case, there is an optimal algorithm with ratio e [25]. Moreover, our paper is related to Göbel et al. [22] who study secretary versions of maximum independent set in graphs with bounded inductive independence number ρ. They derive an $O(\rho^2)$-competitive algorithm for unweighted and an $O(\rho^2 \log n)$-competitive algorithm for weighted independent set.

In addition, algorithms have been proposed for further variants of the secretary problem, e.g., the temp secretary problem (candidates hired for a fixed duration) [19], parallel secretary (candidates interviewed in parallel) [17], or local secretary (several firms and limited feedback) [12]. For these variants, some existing algorithms (e.g., for the temp secretary problem in [19]) directly extend to the ordinal model. In general, however, the restriction to ordinal information poses an interesting challenge for future work in these domains.

Algorithm 1: Greedy [18]

Input : ground set E
Output : independent set I

Let $I \leftarrow \emptyset$ and $E' \leftarrow E$.
while $E' \neq \emptyset$ **do**
  Let $u \leftarrow \max_{u'} f(u'|I)$ and $E' \leftarrow E' \setminus \{u\}$;
  if $(I \cup \{u\}$ independent in $\mathcal{M}) \wedge (f(u|I) \geq 0)$ **then** add u to I;

Algorithm 2: Online(p) algorithm [18]

Input : $n = |E|$, size of the ground set
Output : independent set $Q \cap N$

Choose X from the binomial distribution $B(n, 1/2)$.
Reject the first X elements of the input. Let L be the set of these elements.
Let M be the output of Greedy on the set L.
Let $N \leftarrow \emptyset$.
for *each element* $u \in E \setminus L$ **do**
  Let $w(u) \leftarrow 0$.
  if u *accepted by Greedy applied to* $M \cup \{u\}$ **then**
    With probability p do the following:
    Add u to N.
    Let $M_u \subseteq M$ be the solution of Greedy immediately before it adds u to it.
    $w(u) \leftarrow f(u|M_u)$.
  Pass u to Linear with weight $w(u)$.
return $Q \cap N$, where Q is the output of Linear.

3 Matroids

3.1 Submodular Matroids

We start our analysis by showing that – in addition to algorithms for special cases mentioned above – a powerful technique for submodular matroid secretary problems [18] can be adjusted to work even in the ordinal model. More formally, in this section we show that there is a reduction from submodular matroid secretary problems with ordinal information (SMSPO) to linear matroid secretary problems with ordinal information (MSPO). The reduction uses Greedy (Algorithm 1) as a subroutine and interprets the marginal value when added to the greedy solution as the value of an element. These values are then forwarded to whichever algorithm (termed Linear) that solves the linear version of the problem. In the ordinal model, we are unable to see the exact marginal values. Nevertheless, we manage to construct a suitable ordering for the forwarded elements. Consequently, we can apply algorithm Linear as a subroutine to obtain a good solution for the ordinal submodular problem.

Let $\mathcal{M} = (E, \mathcal{S})$ be the matroid, f the submodular function, and E the ground set of elements. The marginal contribution of element u to set M is denoted by $f(u|M) = f(M \cup \{u\}) - f(M)$. Since f can be non-monotone, Greedy in the cardinal model also checks if the marginal value of the currently best element is positive. While we cannot explicitly make this check in the ordinal model, note that $f(u|M) \geq 0 \iff f(M \cup \{u\}) \geq f(M) = f(M \cup \{u'\})$

for every $u' \in M$. Since the ordinal oracle includes the elements of M in the ordering of marginal values, there is a way to check positivity even in the ordinal model. Therefore, our results also apply to non-monotone functions f.

A potential problem with Algorithm 2 is that we must compare marginal contributions of different elements w.r.t. different sets. We can resolve this issue by following the steps of the Greedy subroutine that tries to add new elements to the greedy solution computed on the sample. We use this information to construct a correct ordering over the marginal contributions of elements that we forward to Linear.

▶ **Lemma 1.** *Let us denote by s_u the step of Greedy in which the element u is accepted when applied to $M + u$. Then $s_{u_1} < s_{u_2}$ implies $f(u_1|M_{u_1}) \geq f(u_2|M_{u_2})$.*

Proof. First, note that $M_{u_1} \subset M_{u_2}$ when $s_1 < s_2$. We denote by m_{u_1} the element of M that would be taken in step s_{u_1} if u_1 would not be available. Then we know that $f(u_1|M_{u_1}) \geq f(m_{u_1}|M_{u_1})$. Furthermore, since $s_1 < s_2$, $f(m_{u_1}|M_{u_1}) \geq f(u_2|M_{u_1})$. Lastly, by using submodularity, we know that $f(u_2|M_{u_1}) \geq f(u_2|M_{u_2})$. ◀

When $s_{u_1} = s_{u_2}$, then $M_{u_1} = M_{u_2}$ so the oracle provides the order of marginal values. Otherwise, the lemma yields the ordinal information. Thus, we can construct an ordering for the elements that are forwarded to Linear that is consistent with their marginal values in the cardinal model. Hence, the reduction can be applied in the ordinal model, since the algorithm executes exactly the same as in the cardinal model, and all results from [18] continue to hold. We mention only the main theorem. It implies constant ratios for all problems in Table 1 in the submodular version.

▶ **Theorem 2.** *Given an arbitrary algorithm Linear for MSPO that is α-competitive on a matroid class, there is an algorithm for SMSPO with competitive ratio is at most $24\alpha(3\alpha+1) = O(\alpha^2)$ on the same matroid class. For SMSPO with monotone f, it can be improved to $8\alpha(\alpha+1)$.*

3.2 A Lower Bound

Another powerful technique in the cardinal model is thresholding, where we first sample a constant fraction of the elements to learn their weights. Based on the largest weight observed, we pick a threshold and accept subsequent elements greedily if they exceed the threshold. This approach generalizes the classic algorithm [15] and provides logarithmic ratios for many combinatorial domains [8, 28, 22, 12]. Intuitively, these algorithms *learn the weights but not the structure.*

We show that this technique does not easily generalize to the ordinal model. The algorithms with small ratios in the ordinal model rely heavily on the matroid structure. Indeed, in the ordinal model we show a polynomial lower bound for algorithms in the matroid secretary problem that learn the ordering but not the structure. Formally, we slightly simplify the setting as follows. The algorithm receives the global ordering of all elements in advance. It determines (possibly at random) a threshold position in the ordering. Then elements arrive and are accepted greedily if ranked above the threshold. Note that the algorithm does not use sampling, since in this case the only meaningful purpose of sampling is learning the structure. We call this a *structure-oblivious* algorithm.

▶ **Theorem 3.** *Every structure-oblivious randomized algorithm has a competitive ratio of at least $\Omega(\sqrt{n}/(\log n))$.*

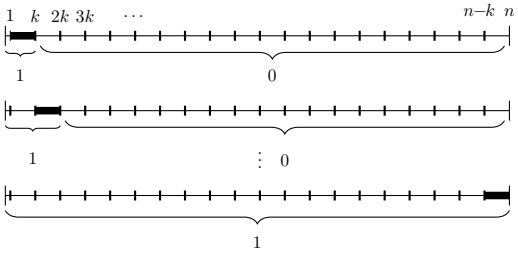

Figure 1 Values for the family of instances described in the proof of Theorem 11, where the position of the "valuable" ones is denoted by the thick segment.

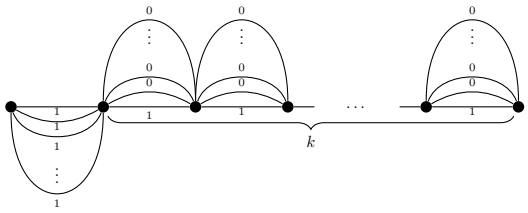

Figure 2 One instance from the family described in the proof of Theorem 11.

Proof. In the proof, we restrict our attention to instances with weights in $\{0, 1\}$ (for a formal justification, see the full version [23]). We give a distribution of such instances on which every deterministic algorithm has a competitive ratio of $\Omega(\sqrt{n}/(\log n))$. Using Yao's principle, this shows the claimed result for randomized algorithms.

All instances in the distribution are based on a graphic matroid (in fact, a partition matroid) of the following form. There is a simple path of $1 + k$ segments. The edges in each segment have weight of 0 or 1. We call the edges with value 1 in the last k segments the "valuable edges". The total number of edges is the same in each instance and equals $n + 1$. All edges in the first segment have value 1 and there is exactly one edge of value 1 in all other segments (that being the aforementioned valuable edges). In the first instance there are in total $k + 1$ edges of value 1 (meaning that there is only one edge in the first segment). In each of the following instances this number is increased by k (in the i-th instance there are $(i - 1) \cdot k + 1$ edges in the first segment) such that the last instance has only edges with value 1 (there are $n - k + 1$ edges in the first segment). The zero edges are always equally distributed on the last k path segments. The valuable edges are lower in the ordering than any non-valuable edge with value 1 (see Figure 1). Each of the instances appears with equal probability of $\frac{k}{n}$ (see Figure 2 for one example instance).

A deterministic algorithm picks a threshold at position i. The expected value of the solution is

$$\mathbb{E}[w(S_{alg})] \leq 1 + \frac{k}{n} \sum_{\ell=1}^{\frac{i}{k}} \frac{k}{\ell} \leq 1 + \frac{k^2}{n} \log \frac{i}{k} \leq \frac{k^2}{n} \log \frac{n}{k} + 1 \ ,$$

where log denotes the natural logarithm and the expression results from observing that the algorithm cannot obtain more than a value of 1 if its threshold i falls above the valuable 1's. Otherwise it gets an additional fraction of k, depending on how close the threshold is positioned to the valuable 1's. For instance, if the threshold is set between 1 and k positions

below the valuable 1's, the algorithm will in expectation select edges of total value of at least $1 + k/2$. This follows from the random arrival order of the edges and the fact that the ratio of valuable to non-valuable edges that the algorithm is ready to accept is at least $1 : 2$. Furthermore, we see that for this distribution of instances the optimal way to set a deterministic threshold is at the lowest position. Using $k = \sqrt{n}$, a lower bound on the competitive ratio is

$$\frac{k}{\frac{k^2}{n}\log\frac{n}{k} + 1} = \frac{n}{k\log\frac{n}{k} + \frac{n}{k}} = \Omega\left(\frac{\sqrt{n}}{\log n}\right) \quad . \qquad \blacktriangleleft$$

4 Matching and Packing

4.1 Bipartite Matching

In this section, we study online bipartite matching. The vertices on the right side of the graph (denoted by R) are static and given in advance. The vertices on the left side (denoted by L) arrive sequentially in a random order. Every edge $e = (r, l) \in R \times L$ has a non-negative weight $w(e) \geq 0$. In the cardinal model, each vertex of L reveals upon arrival the weights of all incident edges. In the ordinal model, we are given a total and strict order of all edges that have arrived so far, consistent with their weights[1]. Before seeing the next vertex of L, the algorithm has to decide to which vertex $r \in R$ (if any) it wants to match the current vertex l. A match that is formed cannot be revoked. The goal is to maximize the total weight of the matching.

The algorithm for the cardinal model in [25] achieves an optimal competitive ratio of e. However, this algorithm heavily exploits cardinal information by repeatedly computing max-weight matchings for the edges seen so far. For the ordinal model, our Algorithm 3 below obtains a competitive ratio of $2e$. While similar in spirit, the main difference is that we rely on a greedy matching algorithm, which is based solely on ordinal information. It deteriorates the ratio only by a factor of 2.

Here we assume to have access to ordinal preferences over all the edges in the graph. Note that the same approach works if the vertices provide correlated (ordinal) preference lists consistent with the edge weights, for every vertex from R and every arrived vertex from L. In this case, the greedy algorithm can still be implemented by iteratively matching and removing a pair that mutually prefers each other the most, and it provides an approximation guarantee of 2 for the max-weight matching (see, e.g., [2]). In contrast, if we receive only preference lists for vertices on one side, there are simple examples that establish super-constant lower bounds on the competitive ratio[2].

▶ **Lemma 4.** *Let the random variable A_v denote the contribution of the vertex $v \in L$ to the output, i.e. weight assigned to v in M. Let $w(M^*)$ denote the value of the maximum-weight matching in G. For $l \in \{\lceil \frac{n}{e} \rceil, \ldots, n\}$,*

$$\mathbb{E}[A_l] \geq \frac{\lceil \frac{n}{e} \rceil}{l-1} \cdot \frac{w(M^*)}{2n} \quad .$$

[1] Ties are broken arbitrarily, but consistently over the arrival process.

[2] Consider a bipartite graph with two nodes on each side (named A,B and 1,2). If we only know that both A and B prefer 1 to 2, the ratio becomes at least 2 even in the offline case. Similar examples imply that the (offline) ratio must grow in the size of the graph.

Algorithm 3: Bipartite Matching

Input : vertex set R and cardinality $n = |L|$
Output : matching M

Let L' be the first $\lfloor \frac{n}{e} \rfloor$ vertices of L, and $M \leftarrow \emptyset$;
for *each* $\ell \in L \setminus L'$ **do**
  $L' \leftarrow L' \cup \{\ell\}$;
  $M^{(\ell)} \leftarrow$ greedy matching on $G[L' \cup R]$;
  Let $e^{(\ell)} \leftarrow (\ell, r)$ be the edge assigned to ℓ in $M^{(\ell)}$;
  if $M \cup \{e^{(\ell)}\}$ is a matching **then** add $e^{(\ell)}$ to M;

Proof. We first show that $e^{(\ell)}$ has a significant expected weight. Then we bound the probability of adding $e^{(\ell)}$ to M.

In step ℓ, $|L'| = \ell$ and the algorithm computes a greedy matching $M^{(\ell)}$ on $G[L' \cup R]$. The current vertex ℓ can be seen as selected uniformly at random from L', and L' can be seen as selected uniformly at random from L. Therefore, $\mathbb{E}[w(M^{(\ell)})] \geq \frac{\ell}{n} \cdot \frac{w(M^*)}{2}$ and $\mathbb{E}[w(e^{(\ell)})] \geq \frac{w(M^*)}{2n}$. Here we use that a greedy matching approximates the optimum by at most a factor of 2 [2].

Edge $e^{(\ell)}$ can be added to M if r has not been matched already. The vertex r can be matched only when it is in $M^{(k)}$ where $\lceil n/e \rceil \leq k \leq l-1$. The probability of r being matched in step k is at most $\frac{1}{k}$ and the order of the vertices in steps $1, \ldots, k-1$ is irrelevant for this event.

$$\Pr[r \text{ unmatched in step } \ell] = \Pr\left[\bigwedge_{k=\lceil n/e \rceil}^{\ell-1} r \notin e^{(k)}\right] \geq \prod_{k=\lceil n/e \rceil}^{\ell-1} \frac{k-1}{k} = \frac{\lceil \frac{n}{e} \rceil - 1}{\ell - 1}$$

We now know that $\Pr[M \cup e^{(\ell)} \text{ is a matching}] \geq \frac{\lfloor n/e \rfloor}{\ell - 1}$. Using this and $\mathbb{E}[w(e^{(\ell)})] \geq \frac{w(M^*)}{2n}$, the lemma follows. ◀

▶ **Theorem 5.** *Algorithm 3 for bipartite matching is* $2e$*-competitive.*

Proof. The weight of matching M can be obtained by summing over random variables A_ℓ.

$$\mathbb{E}[w(M)] = \mathbb{E}\left[\sum_{\ell=1}^{n} A_\ell\right] \geq \sum_{\ell=\lceil n/e \rceil}^{n} \frac{\lfloor n/e \rfloor}{\ell - 1} \cdot \frac{w(M^*)}{2n} = \frac{\lfloor n/e \rfloor}{2n} \sum_{\ell=\lfloor n/e \rfloor}^{n-1} \frac{1}{\ell} \cdot w(M^*)$$

Since $\frac{\lfloor n/e \rfloor}{n} \geq \frac{1}{e} - \frac{1}{n}$ and $\sum_{\ell=\lfloor n/e \rfloor}^{n-1} \frac{1}{l} \geq \ln \frac{n}{\lfloor n/e \rfloor} \geq 1$, it follows that

$$\mathbb{E}[w(M)] \geq \left(\frac{1}{e} - \frac{1}{n}\right) \cdot \frac{w(M^*)}{2} \quad . \qquad \blacktriangleleft$$

We can use the same algorithm and the same analysis in the submodular version, where greedy gives a 3-approximation [20]. It builds the matching by greedily adding an edge that maximizes the marginal improvement of f, which is the information delivered by the ordinal oracle. Hence, our algorithm is $3e$-competitive for the submodular version.

Algorithm 4: Packing LP

Input : capacities $\mathbf{b}$, total number of requests n, probability $p = \frac{e(2d)^{1/B}}{1+e(2d)^{1/B}}$
Output : assignment vector $\mathbf{y}$

Let L' be the first $p \cdot n$ requests, and $\mathbf{y} \leftarrow \mathbf{0}$;
for *each* $j \notin L'$ **do**
  $L' \leftarrow L' \cup \{j\}$;
  $\mathbf{x}^{(L')} \leftarrow$ greedy assignment on the LP for L';
  $\mathbf{y}_j \leftarrow \mathbf{x}_j^{(L')}$;
  if $\neg(\mathbf{A}(\mathbf{y}) \leq \mathbf{b})$ **then** $\mathbf{y}_j \leftarrow \mathbf{0}$;

4.2 Packing

Our results for bipartite matching can be extended to online packing LPs of the form $\max \mathbf{c}^\tau \mathbf{x}$ s.t. $\mathbf{Ax} \leq \mathbf{b}$ and $\mathbf{0} \leq \mathbf{x} \leq \mathbf{1}$, which model problems with m resources and n online requests coming in random order. Each resource $i \in [m]$ has a capacity b_i that is known in advance, together with the number of requests. Every online request comes with a set of options, where each option has its profit and resource consumption. Once a request arrives, the coefficients of its variables are revealed and the assignment to the variables has to be determined.

Formally, request $j \in [n]$ corresponds to variables $x_{j,1}, \ldots, x_{j,K}$ that represent K options. Each option $k \in [K]$ contributes with profit $c_{j,k} \geq 0$ and has resource consumption $a_{i,j,k} \geq 0$ for resource i. Overall, at most one option can be selected, i.e., there is a constraint $\sum_{k\in[K]} x_{j,k} \leq 1, \forall j \in [n]$. The objective is to maximize total profit while respecting the resource capacities. The offline problem is captured by the following linear program:

$$\max \sum_{j\in[n]} \sum_{k\in[K]} c_{j,k} x_{j,k} \quad \text{s.t.} \quad \sum_{j\in[n]} \sum_{k\in[K]} a_{i,j,k} x_{j,k} \leq b_i \qquad i \in [m]$$
$$\sum_{k\in[K]} x_{j,k} \leq 1 \qquad j \in [n]$$

As a parameter, we denote by d the maximum number of non-zero entries in any column of the constraint matrix $\mathbf{A}$, for which by definition $d \leq m$. We compare the solution to the fractional optimum, which we denote by $\mathbf{x}^*$. The competitive ratio will be expressed in terms of d and the capacity ratio $B = \min_{i\in[m]} \left\lfloor \frac{b_i}{\max_{j\in[n],k\in[K]} a_{i,j,k}} \right\rfloor$.

Kesselheim et al. [25] propose an algorithm that heavily exploits cardinal information – it repeatedly solves an LP-relaxation and uses the solution as a probability distribution over the options. Instead, our Algorithm 4 for the ordinal model is based on greedy assignments in terms of profits $c_{j,k}$. More specifically, the greedy assignment considers variables $x_{j,k}$ in non-increasing order of $c_{j,k}$. It sets a variable to 1 if this does not violate the capacity constraints, and to 0 otherwise.

▶ **Theorem 6.** *Algorithm 4 for online packing LPs is $O(d^{(B+1)/B})$-competitive.*

4.3 Matching in General Graphs

Here we study the case when vertices of a general undirected graph arrive in random order. In the beginning, we only know the number n of vertices. Each edge in the graph has a non-negative weight $w(e) \geq 0$. Each vertex reveals the incident edges to previously arrived

Algorithm 5: General Matching

Input : vertex set V and cardinality $n = |V|$
Output : matching M

Let R be the first $\lfloor \frac{n}{2} \rfloor$ vertices of V;
Let L' be the further $\lfloor \frac{n}{2e} \rfloor$ vertices of V, and $M \leftarrow \emptyset$;
for *each* $\ell \in V \setminus L'$ **do**
  $L' \leftarrow L' \cup \{\ell\}$;
  $M^{(\ell)} \leftarrow$ greedy matching on $G[L' \cup R]$;
  Let $e^{(\ell)} \leftarrow (\ell, r)$ be the edge assigned to ℓ in $M^{(\ell)}$;
  if $M \cup \{e^{(\ell)}\}$ is a matching **then** add $e^{(\ell)}$ to M;

vertices and their weights (cardinal model), or we receive a total order over all edges among arrived vertices that is consistent with the weights (ordinal model). An edge can be added to the matching only in the round in which it is revealed. The goal is to construct a matching with maximum weight.

We can tackle this problem by prolonging the sampling phase and dividing the vertices into "left" and "right" vertices. Algorithm 5 first samples $n/2$ vertices. These are assigned to be the set R, corresponding to the static side of the graph in bipartite matching. The remaining vertices are assigned to be the set L. The algorithm then proceeds by sampling a fraction of the vertices of L, forming a set L'. The remaining steps are exactly the same as in Algorithm 3.

▶ **Theorem 7.** *Algorithm 5 for matching in general graphs is* $12e/(e+1)$*-competitive, where* $12e/(e+1) < 8.78$.

5 Independent Set and Local Independence

In this section, we study maximum independent set in graphs with bounded local independence number. The set of elements are the vertices V of an underlying undirected graph G. Each vertex has a weight $w_v \geq 0$. We denote by $N(v)$ the set of direct neighbors of vertex v. Vertices arrive sequentially in random order and reveal their position in the order of weights of vertices seen so far. The goal is to construct an independent set of G with maximum weight. The exact structure of G is unknown, but we know that G has a bounded local independence number α_1.

▶ **Definition 8.** An undirected graph G has local independence number α_1 if for each node v, the cardinality of every independent set in the neighborhood $N(v)$ is at most α_1.

We propose Algorithm 6, which is inspired by the Sample-and-Price algorithm for matching in [28]. Note that Göbel et al. [22] construct a more general approach for graphs with bounded *inductive* independence number ρ. However, they only obtain a ratio of $O(\rho^2 \log n)$ for the weighted version, where a competitive ratio of $\Omega(\log n / \log^2 \log n)$ cannot be avoided, even in instances with constant ρ. These algorithms rely on ρ-approximation algorithms for the offline problem that crucially exploit cardinal information.

Similar to [28], we reformulate Algorithm 6 into an equivalent approach (Algorithm 7) for the sake of analysis. Given the same arrival order, the same vertices are in the sample. Algorithm 7 drops all vertices from S that have neighbors in S while Algorithm 6 keeps one of them. Hence, $\mathbb{E}[w(S_{Alg_6})] \geq \mathbb{E}[w(S_{Sim})]$. In what follows, we analyze the performance

Algorithm 6: Independent Set in Graphs with Bounded Local Independence Number

Input : $n = |G|$, $p = \sqrt{\alpha_1/(\alpha_1+1)}$
Output : independent set of vertices S

Set $k \leftarrow \text{Binom}(n,p)$, $S \leftarrow \emptyset$;
Reject first k vertices of G, denote this set by G';
Build a maximal independent set of vertices from G' greedily, denote this set by M_1;
for *each* $v \in G \setminus G'$ **do**
    $w^* \leftarrow \max\{w \mid \mathcal{N}(v) \cap M_1\}$;
    if $(v > w^*) \wedge (S \cup \{v\}$ independent set$)$ **then** add v to S;

Algorithm 7: Simulate

Input : $n = |G|$, $p = \sqrt{\alpha_1/(\alpha_1+1)}$
Output : independent set of vertices S

Sort all vertices in G in non-increasing order of value;
Initialize $M_1, M_2 \leftarrow \emptyset$;
for *each* $v \in G$ *in sorted order* **do**
    if $M_1 \cup \{v\}$ *independent set* **then**
        flip a coin with probability p of heads;
        if heads **then** $M_1 \leftarrow M_1 \cup \{v\}$; **else** $M_2 \leftarrow M_2 \cup \{v\}$;
$S \leftarrow M_2$;
for *each* $w \in S$ **do**
    if w has neighbors in S **then** remove w and all his neighbors from S;

of Simulate. The first lemma follows directly from the definition of the local independence number.

▶ **Lemma 9.** $\mathbb{E}[w(M_1)] \geq p \cdot \frac{w(S^*)}{\alpha_1}$, *where* $\alpha_1 \geq 1$ *is the local independence number of* G.

▶ **Lemma 10.** $\mathbb{E}\big[|\mathcal{N}(v) \cap M_2| \;\big|\; v \in M_2\big] \leq \frac{\alpha_1(1-p)}{p}$.

Proof. Let us denote by X_u^1 and X_u^2 the indicator variables for the events $u \in M_1$ and $u \in M_2$ respectively. Then,

$$\begin{aligned}\mathbb{E}\big[|\mathcal{N}(v) \cap M_2| \;\big|\; v \in M_2\big] &= \mathbb{E}\left[\sum_{u \in \mathcal{N}(v)} X_u^2 \;\middle|\; v \in M_2\right] = \sum_{u \in \mathcal{N}(v)} \mathbb{E}\big[X_u^2 \;\big|\; v \in M_2\big] \\ &= \frac{1-p}{p} \sum_{u \in \mathcal{N}(v)} \mathbb{E}\big[X_u^1 \;\big|\; v \in M_2\big] \leq \frac{1-p}{p} \cdot \alpha_1 \ . \end{aligned}$$

◀

▶ **Theorem 11.** *Algorithm 7 for weighted independent set is* $O(\alpha_1^2)$*-competitive, where* α_1 *is the local independence number of the graph.*

Proof. By using Markov's inequality and Lemma 10,

$$\begin{aligned} \Pr[|\mathcal{N}(v) \cap M_2| \geq 1 \;\big|\; v \in M_2] &\leq \alpha_1 \cdot (1-p)/p \\ \text{and} \quad \Pr[|\mathcal{N}(v) \cap M_2| < 1 \;\big|\; v \in M_2] &> 1 - (\alpha_1(1-p)/p) \ . \end{aligned}$$

Thus, we can conclude that

$$\mathbb{E}[w(S)] \geq \left(1 - \alpha_1 \cdot \frac{1-p}{p}\right) \cdot \mathbb{E}[w(M_2)] \geq \left(1 - \alpha_1 \cdot \frac{1-p}{p}\right) \cdot \frac{1-p}{\alpha_1} \cdot w(S^*) \ .$$

The ratio is optimized for $p = \sqrt{\frac{\alpha_1}{\alpha_1+1}}$, which proves the theorem. ◀

As a prominent example, $\alpha_1 = 5$ in the popular class of unit-disk graphs. In such graphs, our algorithm yields a constant competitive ratio for online independent set in the ordinal model.

Abstract

We consider a price competition between two sellers of perfect-complement goods. Each seller posts a price for the good it sells, but the demand is determined according to the sum of prices. This is a classic model by Cournot (1838), who showed that in this setting a monopoly that sells both goods is better for the society than two competing sellers.

We show that non-trivial pure Nash equilibria always exist in this game. We also quantify Cournot's observation with respect to both the optimal welfare and the monopoly revenue. We then prove a series of mostly negative results regarding the convergence of best response dynamics to equilibria in such games.

1 Introduction

In this paper we study a model of a pricing game between two firms that sell goods that are perfect complements to each other. These goods are only demanded in bundles, at equal quantities, and there is no demand for each good by itself. The two sellers simultaneously choose prices p_1, p_2 and the demand at these prices is given by $\mathcal{D}(p_1 + p_2)$ where $\mathcal{D}$ is the demand for the bundle of these two complementary goods. The revenue of seller i is thus $p_i \cdot \mathcal{D}(p_1 + p_2)$, and as we assume zero production costs, this is taken as his utility.

This model was first studied in Cournot's famous work [9]. In [9], Cournot studied two seminal oligopoly models. The first, and the more famous, model is the well known Cournot oligopoly model about sellers who compete through quantities. We study a second model that was proposed by Cournot in the same work, regarding price competition between sellers of perfect complements.[1] Cournot considered a model of a duopoly selling perfect complements, and he suggested zinc and copper as an example. In Cournot's example, a manufacturer of zinc may observe that some of her major customers produce brass (made of zinc and copper);

* The full version of this paper can be found in an arXiv paper under the same title, see https://arxiv.org/abs/1706.00219.

[1] [25] showed that these two different models by Cournot actually share the same formal structure.

Therefore, zinc manufacturers indirectly compete with manufacturers of copper, as both target the money of brass producers. Another classic example of a duopoly selling perfect complements is by [12], who studied how owners of two consecutive segments of a canal determine the tolls for shippers; Clearly, every shipper must purchase a permit from both owners for being granted the right to cross the canal. Another, more contemporary, example for perfect complements might be high-tech or pharmaceutical firms that must buy the rights to use two registered patents to manufacture its product; The owners of the two patents quote prices for the usage rights, and these patents can be viewed as perfect complements.

Cournot, in his 1838 book, proved a counterintuitive result saying that competition among multiple sellers of complement goods lead to a *worse* social outcome than the result reached by a monopoly that controls the two sellers. Moreover, both the profits of the firms and the consumer surplus increase in the monopoly outcome. In the legal literature, this phenomenon was termed "the tragedy of the anticommons" (see, [6, 17, 21]). In our work, we will quantify the severity of this phenomenon.

Clearly, if the demand at a sufficiently high price is zero, then there are *trivial* equilibria in which both sellers price prohibitively high, and nothing is sold. This raises the following question: *Do non-trivial equilibria, in which some pairs of items are sold, always exist?* We study this question as well as some natural follow-ups: *What are the revenue and welfare properties of such equilibria? What are the properties of equilibria that might arise as a result of best-response dynamics?*

For the sake of quantification, we study a *discretized version* of this game in which the demand changes only finitely many times. The number of discrete steps in the demand function, also viewed as the number of possible types of buyers, is denoted by n and is called the number of *demand levels*.

Our first result proves the existence of non-trivial pure Nash equilibria.

▶ **Theorem 1.** *For any demand function with n demand levels there exists at least one non-trivial pure Nash equilibrium.*

We prove the theorem using an artificial dynamics which starts from zero prices and continues in steps. In each step, one seller best responds to the other seller's price, and after each seller best responds, the total price of both is symmetrized: both prices are replaced by their average. We show that the total price is monotonically non-decreasing, and thus it terminates after at most n steps in the non-trivial equilibrium of highest revenue and welfare.

In our model, it is easy to observe that there are multiple equilibria for some demand functions. How different can the welfare and revenue of these equilibria be? A useful parameter for bounding the difference, as well as bounding the inefficiency of equilibria, turns out to be D, the ratio between the demand at price 0 and the demand at the highest price v_{max} for which there is non-zero demand.

Consider the following example with two ($n = 2$) types of buyers: a single buyer that is willing to pay "a lot", 2, for the bundle of the two goods, and many, $D - 1 >> 2$, buyers that are willing to pay "a little", 1, each, for the bundle. A monopolist (that controls both sellers) would have sold the bundle at the low price 1. At this price, all the D buyers decide to buy, leading to revenue D and optimal social welfare of $D + 1$. Equilibria here belong to two types: the "bad" equilibria[2] have high prices, $p_1 + p_2 = 2$, (which certainly is an equilibrium when, say, $p_1 = p_2 = 1$) and achieve low revenue and low social welfare of 2. The "good" equilibria

[2] It turns out that in our model there is no conflict between welfare and revenue in equilibria - the lower the total price, the higher the welfare and the revenue in equilibria (see Proposition 6).

have low prices, $p_1 + p_2 = 1$ (which is an equilibrium as long as $p_1, p_2 \geq 1/D$), and achieve optimal social welfare as well as the monopolist revenue, both values are at least D. Thus, we see that the ratio of welfare (and revenue) between the "good" and "bad" equilibria can be very high, as high as $\Omega(D)$. This can be viewed as a negative "Price of Anarchy" result.

We next focus on the best equilibria and present bounds on the "Price of Stability" of this game; We show that the ratio between the optimal social welfare and the best equilibrium revenue[3] is bounded by $O(\sqrt{D})$, and that this is tight when $D = n$. When n is very small, the ratio can only grow as 2^n and not more. In particular, for constant n the ratio is a constant, in contrast to the lower bound of $\Omega(D)$ on "Price of Anarchy" for $n = 2$, presented above.

▶ **Theorem 2.** *For any instance, the optimal welfare and the monopolist revenue are at most* $O(\min\{2^n, \sqrt{D}\})$ *times the revenue of the best equilibrium. These bounds are tight.*

We now turn to discuss how such markets converge to equilibria, and in case of multiple equilibria, which of them will be reached? We consider best response dynamics in which players start with some initial prices and repeatedly best-reply to each other. We study the quality of equilibria reached by the dynamics, compared to the best equilibria.

Clearly, if the dynamics happen to start at an equilibrium, best replying will leave the prices there, whether the equilibrium is good or bad. But what happens in general: which equilibrium will they "converge" to when starting from "natural" starting points, if any, and how long can that take? Zero prices (or other, very low prices) are probably the most natural starting point. However, as can be seen by the example above, starting from zero prices may result in the worst equilibrium.[4] Another natural starting point is a situation where the two sellers form a cartel and decide to post prices that sum to the monopoly price. Indeed, in our example above, if the two sellers equally split the monopoly price, this will be the best equilibrium. However, we know that cartel solutions are typically unstable, and the participants will have incentives to deviate to other prices and thus start a price updating process. We prove a negative result in this context, showing that starting from any split of the monopoly price might result in bad equilibria. We also check what would be the result of dynamics that start at random prices. Again, we prove a negative result showing situations where dynamics starting from random prices almost surely converge to bad equilibria. Finally, we show that convergence might take a long time, even with only two demand levels. Following is a more formal description of these results about the best-response dynamics:

▶ **Theorem 3.** *The following statements hold:*

- *There are instances with* 3 *demand levels for which a best-response dynamics starting from any split of a monopoly price reaches the worst equilibrium that is factor* $\Omega(\sqrt{D})$ *worse than the best equilibrium in terms of both revenue and welfare.*
- *For any* $\epsilon > 0$ *and* $D > 2/\epsilon$ *there are instances with* 2 *demand levels for which a best-response dynamics starting from uniform random prices in* $[0, v_{max}]^2$ *reaches the worst equilibrium with probability* $1 - \epsilon$*, while the best equilibrium has welfare and revenue that is factor* $\epsilon \cdot D$ *larger.*

[3] Note that this also shows the same bounds on the ratio between the optimal welfare and the welfare in the best equilibrium, as well as the ratio between the monopolist revenue and the revenue in the best equilibrium.

[4] In this example, the best response to price of 0 is price of 1. Next, the first seller will move from price of 0 to price of 1 as well, resulting in the worst equilibrium.

- *For any $n \geq 2$ and $\epsilon > 0$ there are instances with n demand levels for which a best-response dynamics starting from uniform random prices in $[0, v_{max}]^2$ almost surely (with probability 1) reaches the worst equilibrium, while the best equilibrium has welfare and revenue that is factor $\Omega(2^n)$ larger.*
- *(Slow convergence.) For any $K > 0$ there is an instance with only 2 demand levels ($n = 2$) and $D < 2$ for which a best-response dynamics continues for at least K steps before converging to an equilibrium.*

Thus, best-reply dynamics may take a very long time to converge, and then typically end up at a very bad equilibrium. While for very simple ($n = 2$) markets we know that convergence will always occur, we do not know whether convergence is assured for every market.

Open Problem. *Do best reply dynamics always converge to an equilibrium or may they loop infinitely?* We do not know the answer even for $n = 3$.

More related work. While this paper studies price competition between sellers of perfect complements, the classic Bertrand competition [5] studied a similar situation between sellers of perfect substitutes. Bertrand competition leads to an efficient outcome with zero profits for the sellers. [4] studied Bertrand-like competition over a network of sellers. In another paper [3], we studied a network of sellers of perfect complements, where we showed how equilibrium properties depend on the graph structure, and we proved price-of-stability results for lines, cycles, trees etc. Chawla and Roughgarden [8] studied the price of anarchy in two-sided markets with consumers interested in buying flows in a graph from multiple sellers, each selling limited bandwidth on a single edge. Their model is fundamentally different than ours (e.g., they consider combinatorial demand by buyers, and sellers with limited capacities) and their PoA results are with respect to unrestricted Nash Equilibrium, while we focus on non-trivial ones (in our model the analysis of PoA is straightforward for unrestricted NE). A similar model was also studied in [7].

[11] extended the complements model of Cournot to accommodate multiple brands of compatible goods. [10] studied pricing strategies for complementary software products. The paper by [14] directly studied the Cournot/Ellet model, but when buyers approach the sellers (or the tollbooths on the canal) sequentially.

[15] discussed best-response dynamics in a Cournot Oligopoly model with linear demand functions, and proved that they converge to equilibria. Another recent paper [19] studied how no-regret strategies converge to Nash equilibria in Cournot and Bertrand oligopoly settings; The main results in [19] are positive, showing how such strategies lead to a positive-payoff outcomes in Bertrand competition, but they do not consider such a model with complement items.

Best-response dynamics is a natural description of how decentralized markets converge to equilibria, see, e.g., [13, 20], or to approximate equilibria, e.g., [2, 24]. The inefficiency of equilibria in various settings has been extensively studied, see, [18, 22, 23, 1, 16].

We continue as follows: Section 2 defines our model and some basic equilibrium properties. In Section 3 we prove the existence of non trivial equilibria. In Section 4 we study the results of best-response dynamics. Finally, Section 5 compares the quality of the best equilibria to the optimal outcomes.

2 Model and Preliminaries

We consider two sellers, each selling a single, homogeneous, divisible good. The sellers have zero manufacturing cost for the good they sell, and an unlimited supply is available from each good. All the buyers in the economy are interested in bundles of these two goods, and the goods are perfect complements for the buyers. That is, each buyer only demands a bundle consists of two goods, in equal quantities[5], and there is no demand for each good separately. The demand for the bundle of the two goods is given by a demand function $\mathcal{D}(\cdot)$, where $\mathcal{D}(p) \in \mathbb{R}_+$ is the quantity of each of the two goods which is demanded when the price for one unit of the bundle of the two goods is $p \in \mathbb{R}_+$.

The sellers simultaneously offer prices for the goods they sell. Each seller offers a single price, and cannot discriminate between buyers. If the two prices offered by the sellers are p and q then $p+q$ is the *total price* and the demand in this market is $\mathcal{D}(p+q)$. The revenue of the seller that posts a price p is thus $p \cdot \mathcal{D}(p+q)$, the revenue of the second seller is $q \cdot \mathcal{D}(p+q)$ and the total revenue of the two selling firms is denoted by $R(p+q) = (p+q) \cdot \mathcal{D}(p+q)$. The maximal revenue that a monopoly that owns the two sellers can achieve is $\sup_x x \cdot \mathcal{D}(x)$ and we use p^* to denote a monopolist price.[6]

Discrete Demand Levels. In this paper we consider discrete demand curves, where potential buyers only have $n \geq 2$ different values denoted by $\vec{v}$, such that $v_1 > v_2 > \cdots > v_n > 0$. The demand at each price v_i is denoted by $d_i = \mathcal{D}(v_i)$, and assuming a downward sloping demand curve we get that $\vec{d}$ is increasing, that is, $0 < d_1 < d_2 < \cdots < d_n$. For convenience, we define $v_0 = \infty$ and $d_0 = 0$. The parameter n is central in our analysis and it denotes the number of *demand levels* in the economy. Another parameter that we frequently use is the *total demand* D, which is the ratio between the highest and lowest demand at non-zero prices, that is $D = d_n/d_1$. In other words, D is the maximal demand d_n measured in units of the minimal non-zero demand d_1 (Note that $D > 1$). The *social welfare* in the economy is the total value generated for the consumers. The social welfare, given a total price x, is $SW(x) = \sum_{i|x<v_i} v_i(d_i - d_{i-1})$, and the optimal welfare is $SW(0) = \sum_{i=1}^{n} v_i(d_i - d_{i-1})$.

Strategies and Equilibria. The sellers engage in a price competition. We say that p is a *best response* to a price q of the other seller if $p \in argmax_{p'}\ p' \cdot \mathcal{D}(p'+q)$, and let the set of all best responses to q be $BR(q)$. We consider the pure Nash equilibria (NE) of this full-information pricing game. A pure Nash equilibrium is a pair of prices such that each price is a best response to the other price, that is, (p, q) such that $p \in BR(q)$ and $q \in BR(p)$.

It is easy to see that NE always exist in this game, but unfortunately some of them are trivial and no item is sold, and thus their welfare is zero; For example, (∞, ∞) is always an equilibrium with zero welfare and revenue. We will therefore focus on a subset of NE that are *non-trivial*, i.e., where some quantity is sold. It is not immediate to see that non-trivial equilibria exist, and we will begin by proving (in Section 3) that such equilibria indeed always exist. On the other hand, we will show that multiplicity of equilibria is a problem even for

[5] This actually assumes that the ratio of demand of the two goods is fixed, as we can normalized the units to assume that it is 1 for both.

[6] Our paper considers demand functions for which the monopoly revenue is attained and a monopolist price exists. When there is more than one price that maximizes the monopoly profit, our claims regarding p^* will hold for each one of these prices. When necessary, we will treat the different prices separately.

this restricted set of equilibria, as there might be an extreme variance in their revenue and efficiency.

2.1 Basic Equilibrium Properties

We now describe some basic structural properties of equilibria in the pricing game between sellers of complement goods. We use these properties throughout the paper.

We start with a simple observation claiming that all best response dynamics lead to a total price which is exactly one of the demand values. This holds as otherwise any seller can slightly increase his price, selling the same quantity and increasing his revenue.

▶ **Observation 4.** *Let $x \leq v_1$ be some price offered by one seller, and $BR(x)$ be a best response of the other seller to the price x. Then, it holds that $x + BR(x) = v_i$ for some $i \in \{1, ..., n\}$. In particular, for every pure non-trivial NE (p, q), it holds that $p + q = v_i$ for some i.*

Next, we prove a useful lemma claiming that the set of equilibria with a particular total price is convex. Intuitively, the idea in the proof is that a seller with a higher offer cares more about changes in the demand than a seller with a lower offer. Therefore, if the seller with the higher offer decided not to deviate to an increased price, clearly the other seller would not deviate as well. The proof of the lemma appears in the full version of the paper.

▶ **Lemma 5.** *If (p, q) is a pure NE then $(x, p + q - x)$ is also a pure NE for every $x \in [\min\{p, q\}, \max\{p, q\}]$. In particular, $((p + q)/2, (p + q)/2)$ is also a pure NE.*

We next observe that there is no conflict between welfare and revenue in equilibrium: an equilibrium with the highest welfare also has the highest equilibrium revenue. This holds since equilibria with lower total price obtain higher revenue and welfare. We can thus say that any equilibrium with minimal total price is the "best" as it is as good as possible on both dimensions: welfare and revenue. Similarly, any equilibrium with maximal total price is the "worst".

▶ **Proposition 6.** *Both welfare and revenue of equilibria are monotonically non-increasing in the total price. Therefore, an equilibrium with the minimal total price has both the highest welfare and the highest revenue, among all equilibria. Similarly, an equilibrium with the maximal total price has both the lowest welfare as well as the lowest revenue, among all equilibria.*

Proof. Consider two equilibria, one with total price v and the other with total price $w > v$. The claim that the welfare is non-increasing in the total price follows immediately from the definition. We will show that for $w > v$ it holds that $R(v) \geq R(w)$.

Lemma 5 shows that if there is an equilibrium with total price p then $(p/2, p/2)$ is also an equilibrium. As $(v/2, v/2)$ is an equilibrium, it holds that deviating to $w - v/2$ is not beneficial for a seller, and thus $R(v)/2 \geq (w - v/2)\mathcal{D}(w) \geq (w/2)\mathcal{D}(w) = R(w)/2$ and thus $R(v) \geq R(w)$ as claimed. ◀

Finally, we give a variant of a classic result by Cournot [9], which shows, somewhat counterintuitively, that a single monopolist that sells two complementary goods is better for the society than two competing sellers for each selling one of the good.

▶ **Proposition 7.** *The total price in any equilibrium is at least as high as the minimal monopolist price p^*. Thus, the welfare and revenue achieved by the monopolist price p^* are at least as high as the welfare and revenue (resp.) of the best equilibria.*

Proof. Assume that there is an equilibrium with total price $p < p^*$. As p^* is the minimal monopolist price it holds that $R(p) < R(p^*)$. Additionally, as there is an equilibrium with total price p then by Lemma 5 the pair $(p/2, p/2)$ is an equilibrium, where each seller has revenue $R(p)/2$. As $p < p^*$ a seller might deviate to $p^* - p/2 > p^*/2 > 0$, and since such deviation is not beneficial, it holds that $R(p)/2 \geq (p^* - p/2)\mathcal{D}(p^*) > (p^*/2)\mathcal{D}(p^*) = R(p^*)/2$ and thus $R(p) > R(p^*)$, a contradiction.

By Proposition 6, it follows that the welfare and revenue achieved by the minimal monopolist price p^* are no less than those in the best equilibrium. ◀

3 Existence of Non-Trivial Equilibria

In this section we show that non-trivial equilibria always exist. We first note that the structural lemmas from the previous sections seem to get us almost there: We know from Obs. 4 that the total price in equilibrium must equal one of the v_i's; We also know that if p, q is an equilibrium, then $(\frac{p+q}{2}, \frac{p+q}{2})$ is also an equilibrium. Therefore, if an equilibrium exists, then $(\frac{v_i}{2}, \frac{v_i}{2})$ must be an equilibrium for some i. However, these observations give a simple way of finding an equilibrium *if an equilibrium indeed exists*, but they do not prove existence on their own.

We give a constructive existence proof, by showing an algorithm based on an artificial dynamics that always terminates in a non-trivial equilibrium. The algorithm is essentially a sequence of best responses by the sellers, but with a twist: after every best-response step the prices are averaged. We show that this dynamics always stops at a non-trivial equilibrium and thus in particular, such equilibria exist. Moreover, when starting from prices of zero, the dynamics terminates at the best equilibrium. We formalize these claims in Proposition 10 below, from which we can clearly derive the existence of non-trivial equilibrium claimed in the next theorem as an immediate corollary.

▶ **Theorem 8.** *For any instance $(\vec{v}, \vec{d})$ there exists at least one non-trivial pure Nash equilibrium.*

Before we formally define the dynamics, we prove a simple lemma showing that the total price weakly increases as one seller best-responds to a higher price.

▶ **Lemma 9** (Monotonicity Lemma)**.** *Let $br_x \in BR(x)$ be a best reply of a seller to a price x and let $br_y \in BR(y)$ be a best reply of a seller to a price y. If $x < y \leq v_1$ then $y + br_y \geq x + br_x$.*

Proof. As $x < y \leq v_1$ by Observation 4, we know that there exists i such that $x + br_x = v_i$ and j such that $y + br_y = v_j$. As the second seller is best responding at each price level, $\mathcal{D}(v_i)(v_i - x) \geq \mathcal{D}(v_j)(v_j - x)$ and $\mathcal{D}(v_i)(v_i - y) \leq \mathcal{D}(v_j)(v_j - y)$. Together, we get that $(v_j - x)/(v_i - x) \leq \mathcal{D}(v_i)/\mathcal{D}(v_j) \leq (v_j - y)/(v_i - y)$. Now notice that the function $(a-x)/(b-x)$ is non-decreasing in x iff $a \geq b$ thus, since $y > x$, it follows that $v_j \geq v_i$. ◀

We next formally define the price-updating dynamics that we call *symmetrized best response dynamics*. It works similarly to the best response dynamics with one small difference: at each step, before a seller acts, the price of both sellers is replaced by their average price.

More formally, we start from some profile of prices (x_0, y_0). We then symmetrize the prices to $(\frac{x_0+y_0}{2}, \frac{x_0+y_0}{2})$, and then we let the first seller best reply to get prices (x_1, y_1), where $x_1 \in BR(\frac{x_0+y_0}{2})$ and $y_1 = \frac{x_0+y_0}{2}$. In one case, when the utility of the seller is 0, we need to break ties carefully: if $0 \in BR(\frac{x_0+y_0}{2})$ then we assume that $x_1 = 0$, that is, a seller with zero utility prices at 0. We then symmetrize again to $(\frac{x_1+y_1}{2}, \frac{x_1+y_1}{2})$, and then we let the second

seller best respond, symmetrize again, and continue similarly in an alternating order. The dynamic stops if the price remains unchanged in some step.

It turns out that symmetrized best response dynamics quickly converges to a non-trivial equilibrium. Moreover, we show that this dynamics is guaranteed to end up in the best equilibria. Theorem 8 follows from the following proposition.

▶ **Proposition 10.** *For any instance with n demand levels, the symmetrized best response dynamics starting with prices $(0, 0)$ reaches a non-trivial equilibrium in at most n steps, in each of them the total price increases. Moreover, this equilibrium achieves the highest social welfare and the highest revenue among all equilibria.*

Proof. We first argue that for any starting point, the sum of players' prices in the symmetrized dynamics is either monotonically increasing or monotonically decreasing. To see that, let us look at the symmetric price profiles of two consecutive steps: (x, x) and then (y, y) where $y = (x + br_x)/2$ for some $br_x \in BR(x)$ and then (z, z) where $z = (y + br_y)/2$ for some $br_y \in BR(y)$. If $x = y$, then (x, x) is an equilibrium and we are done. We first observe that if $y > x$ then $z \geq y$. Indeed, our monotonicity lemma (Lemma 9) shows exactly that: if $y > x$ then for any $br_x \in BR(x)$ and $br_y \in BR(y)$ it holds that $y + br_y \geq x + br_x$ and therefore $z \geq y$. Similarly, if $y < x$ then $z \leq y$.

To prove convergence, note that until the step where the process terminates, the total price must be either strictly increasing or strictly decreasing. Due to Observation 4, the total price at each step must be equal to v_i for some i. Since there are exactly n distinct values, the process converges after at most n steps. Note that if we reach a price level of v_n or v_1 the process must stop (no seller will have a best response that crosses these values), and a non-trivial equilibrium is reached.

Finally, we will show that a symmetrized dynamics starting at zero prices reaches an equilibrium with maximal revenue and welfare over all equilibria. Using Proposition 6, it is sufficient to show that such process reaches an equilibrium with minimum total price over all possible equilibria. This follows from the following claim:

▶ **Claim 11.** *The total price reached by a symmetrized best-response dynamics starting from a total price level x is bounded from above by the total price reached by the same dynamics starting from a total price of $y > x$,*

Proof. It is enough to show that the prices reached after a single step from x are at most those reached by a single step from y, since we can then repeat and show that this holds after all future steps. For a single step this holds due to the monotonicity lemma (Lemma 9): given some total price z, the new total price after a single step of symmetrizing the price and best responding is $f(z) = z/2 + br_{z/2}$ for some $br_{z/2} \in BR(z/2)$, and since $y > x$ it holds that $f(y) \geq f(x)$ by Lemma 9. ◀

We complete the proof by showing how the proposition follows from the last claim. Let p be the total price of the highest welfare equilibrium (lowest equilibrium price). We use the claim on total price 0 and total price $p > 0$. The symmetrized best-response dynamics starting at p stays fixed and the total price never changes, while the dynamics starting at 0 must strictly increase the total price at each step, and never go over p, and thus must end at p after at most n steps. This concludes the proof of the proposition. ◀

4 Best Response Dynamics

In the previous section we saw that non-trivial NE always exist in our price competition model, and that the best equilibrium can be easily computed. We now turn to discuss whether we can expect agents in these markets to reach such equilibria via natural adaptive heuristics. We consider the process of repeated best responses. Such a process starts from some profile of prices (p, q), then the first seller chooses a price which is a best response to q, the second seller best responds to the price chosen by the first seller, and they continue in alternating order. The process stops if no seller can improve his utility by changing his price. As we aim for non-trivial equilibria, a seller that cannot gain a positive profit chooses the best response of zero. A sequential best response process has simple and intuitive rules. The main difference between different possible dynamics of this form is in their starting prices. We will study the importance of the choice of starting prices.

Our results for best-response dynamics are negative: we show that starting from cartel prices might result in bad equilibria. We then consider starting from random prices and show that this might not help. Finally, we show that convergence time of the dynamics may be very long, even with only two demand levels.

4.1 Quality of the Dynamics' Outcomes

Probably the most natural starting prices to consider in best responses dynamics are $(0, 0)$. We start with a simple example that shows that such dynamics might result in an equilibrium with very low welfare, even when another equilibrium with high welfare exists. The gap between the quality of these equilibria is in the order of D (in the full version of the paper (see Appendix B) we show that this is the largest possible gap between equilibria).

▶ **Example 12.** Consider a market with 2 demand levels, $v_1 = 2$, $v_2 = 1$, $d_1 = 1$ and $d_2 = D$. Here, a best response dynamics starting from prices $(0, 0)$ moves to $(1, 0)$ and then ends in equilibrium prices $(1, 1)$. This NE has welfare of 2, while $(1/2, 1/2)$ is an equilibrium with welfare of $D + 1$ and revenue of D.

It follows that even with 2 demand levels, the total revenue in the highest revenue equilibrium can be factor $D/2$ larger than both the welfare and revenue of the equilibrium reached by best-response dynamics starting from prices $(0, 0)$.

One might hope that starting the dynamics from a different set of prices will guarantee convergence to a good equilibrium. Clearly, if the dynamics somehow starts from the prices of the best equilibrium it will immediately stop, but our goal is exactly to study whether the agents can adaptively reach such equilibria. One can consider two reasonable approaches for studying the starting points of the dynamics: the first approach assumes that the sellers initially agree to act as a cartel and price the bundle at the monopolist price, dividing the monopoly profit among themselves. It is well known that such a cartel is not stable, and sellers may have incentives to deviate to a different price; We would like to understand where such dynamics will stop. The second approach considers starting from a random pair of prices, and hoping that there will be a sufficient mass of starting points for which the dynamics converges to a good equilibrium. We move to study the two approaches below.

4.1.1 Dynamics Starting at a Split of the Monopolist Price

We now study best-response dynamics that start from a cartelistic solution: the total price at the starting stage is equal to the price a monopoly would have set had it owned the two

selling firms. In Example 12 we saw that splitting the monopolist price between the two sellers results in the best equilibrium. One may hope that this will generalize and such starting points ensure converging to good outcomes. In the full version we show that this is indeed the case for two demand levels. However, we next show that even with three demand levels, the welfare and revenue of the equilibrium reached by such best-response dynamics can be much lower than the revenue of the best equilibria. This holds not only when the two seller split the monopolist price evenly, but for any cartelistic split of this price. Proof can be found in the full version of this paper.

▶ **Proposition 13.** *For any large enough total demand D there is an instance with 3 demand levels and monopolist price p^* for which best response dynamics starting from any pair $(p^* - q, q)$ for $q \in [0, p^*]$, ends in an equilibrium of welfare and revenue of only 1, while there exist another equilibrium of welfare and revenue at least $\sqrt{D}/4$.*

We conclude that starting from both sellers (arbitrarily) splitting the monopolist price does not ensure that the dynamics ends in a good equilibrium, even with only 3 demand levels.

4.1.2 Dynamics Starting at Random Prices

We now consider a second approach for studying the role of starting prices in best-response dynamics. We assume that the starting prices are determined at random, and ask what are the chances that a sequence of best responses will reach a good equilibrium. Unfortunately this approach fails as well. We next show that for any $\epsilon > 0$, there is an instance with only two demand levels for which the dynamics starting from a uniform random price vector in $[0, v_1]^2$ has probability of at most ϵ of ending in an equilibrium with high welfare and revenue (although such equilibrium exists).

▶ **Proposition 14** (High probability of convergence to bad equilibria, $n = 2$)**.** *For any small enough $\epsilon > 0$ and total demand D such that $\epsilon D > 2$, there is an instance with two demand levels ($n = 2$) that has an equilibrium of welfare and revenue of at least ϵD, but best-response dynamics starting with uniform random pair of prices in $[0, v_1]^2$ ends in an equilibrium of welfare and revenue of only 1 with probability at least $1 - \epsilon$.*

Proof. Consider the input with $n = 2$ demand levels satisfying $v_1 = 1 > v_2 = \epsilon$ and $d_1 = 1 < d_2 = D$. A pair of prices (p, q) with $p + q = v_2$ results in welfare and total revenue of ϵD, and if $\epsilon D > 2$, the pair $(v_2/2, v_2/2)$ is indeed an equilibrium. On the other hand, for small enough ϵ the pair of prices $(1/2, 1/2)$ is also an equilibrium, and its welfare and revenue are only 1. Finally, observe that unless the price that the first best response in dynamics refers to is at most $v_2 = \epsilon$, the first best response results in an equilibrium with total price of 1, and welfare and revenue of 1. The probability that the process stops after a single step is therefore at least $1 - \epsilon$, and the claim follows. ◀

We show that Proposition 14 is essentially tight.

▶ **Proposition 15.** *For any instance with two demand levels for which the ratio of welfare of the best and worst equilibrium is ϵD for some $1 > \epsilon > 2/D$, it holds that the probability of the dynamics ending at the best equilibrium when starting from a uniform random pair of prices in $[0, v_1]^2$ is at least $\epsilon - 2/D$.*

Proof. Normalize the welfare of the worse equilibrium to 1 (and thus the value is 1) and the demand to 1. The best equilibrium is for demand D and value $\epsilon < 1$, since the equilibria

welfare ratio is ϵD. For any pair of prices (p, q) such that $1/D < q < \epsilon - 1/D$, the best response to q is $\epsilon - q$ as it gives revenue larger than $D \cdot (1/D) = 1$, while the maximal revenue for a seller in the other equilibrium is 1. Given price $\epsilon - q < \epsilon - 1/D$, the best response is q as it gives revenue larger than 1, while deviation will give revenue of at most 1. We conclude that with probability at least $\epsilon - 2/D$ the dynamics stops after a single best response, at the best equilibrium, as claimed. ◀

Proposition 14 only gives high probability of convergence to a low welfare equilibrium, but this will not occur with certainty. We next show that one can construct instances in which except of a measure zero set of starting prices, every dynamics will end up in an equilibrium with very low welfare, although equilibrium with high welfare exists. Moreover, we show that the welfare gap between the good and bad equilibria increases exponentially in the number of demand levels n.

▶ **Theorem 16** (Almost sure convergence to bad equilibria, large n)**.** *For any number of demand levels $n \geq 2$ and $\epsilon > 0$ that is small enough, there exists an instance that has an equilibrium with welfare $2 \cdot (2-\epsilon)^{n-1} - 1$ and revenue of $(2-\epsilon)^{n-1}$, but best response dynamics starting with pair of prices chosen uniformly at random over $[0, v_1]^2$ almost surely ends in an equilibrium of welfare and revenue of only 1.*

To prove the theorem, we build an instance where the pair of prices $(v_i/2, v_i/2)$ forms an equilibrium for any i. In this instance, the total revenue from a total price v_i is $(2-\epsilon)^{i-1}$. In particular, $(v_n/2, v_n/2)$ is an equilibrium that attains the monopolist revenue and the optimal welfare of $O((2-\epsilon)^n)$. However, best response dynamics starting by best responding to any price which is not *exactly* $v_i/2$ (for some i) terminates in an equilibrium with total price of $v_1 = 1$ and welfare of 1. Thus, the set of pairs from which the dynamics does not end at welfare of 1 is finite and has measure 0, so the dynamics almost surely converges to the worst equilibrium. The full proof is in the full version of the paper.

4.2 Time to Convergence

Up to this point we considered the quality of equilibria reached by best response dynamics. In this section, we will show that not only that best response dynamics reach equilibria of poor quality, it may also take them arbitrary long time to converge. Moreover, the long convergence time is possible even with only 2 demand levels and total demand that is close to 1.

Specifically, we will show that as the difference between the demand of adjacent values becomes smaller, the convergence time can increase. More formally, we let $W = \frac{d_n}{min_{i=2}^{n}\{d_i - d_{i-1}\}}$ be the ratio between the maximal demand and the minimal change in demand. Note that if $d_1 = 1$ and every d_i is an integer, then $d_1 = min_{i=2}^{n}\{d_i - d_{i-1}\}$ and thus $W = D$; if demands are not restricted to be integers, W might be much larger than D even in the case that $d_1 = 1$, for example if $d_1 = 1$ and $d_2 = 1 + \epsilon = D$ then $W = 1/\epsilon$ is large while $D = 1 + \epsilon \approx 1$. We show a simple setting with only two demand levels and with D close to 1 in which the dynamics takes time linear in W.

▶ **Theorem 17** (Slow convergence)**.** *For any W, best response dynamics starting from zero prices may require each seller to update his price $W - 1$ times to converge to an equilibrium. Moreover, this holds even with 2 demand levels ($n = 2$) and with $D = \frac{W}{W-1}$ which is close to 1 when W is large.*

Proof. We consider the following setting given some $\epsilon > 0$ that is small enough: $v_1 = 1$ and $d_1 = 1$, $v_2 = 1 - \epsilon$ and $d_2 = \frac{1}{1-2\epsilon}$. In this case, $W = d_2/(d_2 - d_1) = \frac{1}{2\epsilon}$. We will show that for this instance best response dynamics starting at $(0, 0)$ takes at least $W - 1 = \frac{1}{2\epsilon} - 1$ steps to converge to an equilibrium.

Let p_m, q_m denote the price offered by the two sellers after m best-response steps for each seller (p_m is the offer of the seller who plays first). We will prove by induction that $p_m = 1 - m\epsilon$ and $q_m = m\epsilon$ whenever $m + 1 < \frac{1}{2\epsilon}$.

We first handle the base case. With zero prices, the first seller can price at $v_1 = 1$ and get profit 1, or price at $v_2 = 1 - \epsilon$ and get profit $(1 - \epsilon) \cdot \frac{1}{1-2\epsilon} > 1$. Thus, $p_1 = 1 - \epsilon$. Now, the best response of the other seller is clearly $q_1 = \epsilon$ as pricing at total price of $1 - \epsilon$ gains her 0 profit.

We next move to the induction step. Assume that the claim is true for some m, i.e., $(p_m, q_m) = (1 - m\epsilon, m\epsilon)$, and we prove it for $m + 1$ (as long as $m + 1 < \frac{1}{2\epsilon}$). If the second seller prices at $m\epsilon$, the first seller will maximize profit by pricing either at $1 - (m + 1)\epsilon$ or at $1 - m\epsilon$ (recall that by Observation 4 after a seller is best responding, the price will be equal to either v_1 or v_2).

The gain from the first price is $(1 - (m + 1)\epsilon) \cdot \frac{1}{1-2\epsilon}$ and the gain from the latter price is $1 - m\epsilon$. Simple algebra shows that $(1 - (m + 1)\epsilon) \cdot \frac{1}{1-2\epsilon} > 1 - m\epsilon$ iff $m < \frac{1}{2\epsilon}$.

Now, assume that the first seller prices at $1 - (m + 1)\epsilon$, the second seller maximizes profit by pricing either at $(m + 1)\epsilon$ or at $1 - \epsilon - (1 - (m + 1)\epsilon) = m\epsilon$. The second seller chooses a price of $(m + 1)\epsilon$ if $(m + 1)\epsilon > \frac{1}{1-2\epsilon} m\epsilon$. Simple algebra shows that this holds iff $m + 1 < \frac{1}{2\epsilon}$. This concludes the induction step and completes the proof. ◀

We observe that with two demand levels, convergence to equilibrium is guaranteed, and the above linear bound is actually tight. Proof appears in the full version of the paper.

▶ **Proposition 18.** *For any instance with 2 demand levels ($n = 2$), best response dynamics starting from any price profile will stop in an equilibrium after each seller updates his price at most W times.*

5 The Quality of the Best Equilibrium

In this section, we study the price of stability in our game, that is, the ratio between the quality of the best equilibrium and the optimal outcome (both for revenue and welfare). The following theorem gives two upper bounds for the price of stability. One bound shows that for every total demand D, the best equilibrium and the optimal outcome are at most factor $O(\sqrt{D})$ away, for both welfare and revenue. The second bound is exponential in n, but it is independent of D. This implies, in particular, that the price of stability in markets with a small number of demand levels is small even for a very large D.

▶ **Theorem 19.** *For any instance, the optimal welfare and the monopolist revenue are at most $O(\min\{2^n, \sqrt{D}\})$ times the revenue of the best equilibrium.*

As the bound holds for the revenue of the best equilibrium, it clearly also holds for the welfare of that equilibrium. The proof of the theorem is in the full version of this paper.

The next theorem shows that the above price-of-stability bounds are tight. It describes instances where the gap between the best equilibrium and the optimal outcome is asymptotically at least 2^n and $\sqrt{D}$, for both welfare and revenue. We prove the theorem in the full version of the paper.

▶ **Theorem 20.** *For any number of demand levels n, there exists an instance for which the optimal welfare and the monopolist revenue are at least factor $\Omega(2^n)$ larger than the best equilibrium welfare and revenue, respectively.*

In addition, there exists an instance with integer demands for which the optimal welfare and the monopolist revenue are at least factor $\Omega(\sqrt{D})$ larger than the best equilibrium welfare and revenue, respectively.

Abstract

We consider the problem of firefighting to save a critical subset of nodes. The firefighting game is a turn-based game played on a graph, where the fire spreads to vertices in a breadth-first manner from a source, and firefighters can be placed on yet unburnt vertices on alternate rounds to block the fire. In this work, we consider the problem of saving a critical subset of nodes from catching fire, given a total budget on the number of firefighters.

We show that the problem is para-NP-hard when parameterized by the size of the critical set. We also show that it is fixed-parameter tractable on general graphs when parameterized by the number of firefighters. We also demonstrate improved running times on trees and establish that the problem is unlikely to admit a polynomial kernelization (even when restricted to trees). Our work is the first to exploit the connection between the firefighting problem and the notions of important separators and tight separator sequences.

Finally, we consider the spreading model of the firefighting game, a closely related problem, and show that the problem of saving a critical set parameterized by the number of firefighters is W[2]-hard, which contrasts our FPT result for the non-spreading model.

1 Introduction

The problem of Firefighting [17] formalizes the question of designing inoculation strategies against a contagion that is spreading through a given network. The goal is to come up with a strategy for placing firefighters on nodes in order to intercept the spread of fire. More precisely, firefighting can be thought of as a turn-based game between two players, traditionally the fire and the firefighter, played on a graph G with a source vertex s. The game proceeds as follows.

- At time step 0, fire breaks out at the vertex s. A vertex on fire is said to be *burned*.
- At every odd time step $i \in \{1, 3, 5, \ldots\}$, when it is the turn of the firefighter, a firefighter is placed at a vertex v that is not already on fire. Such a vertex is permanently *protected*.
- At every even time step $j \in \{2, 4, 6, \ldots\}$, the fire spreads in the natural way: every vertex adjacent to a vertex on fire is burned (unless it was protected).

* A full version of the paper is available at https://arxiv.org/abs/1705.10923.

The game stops when the fire cannot spread any more. A vertex is said to be *saved* if there is a protected vertex on every path from s to v. The natural algorithmic question associated with this game is to find a strategy that optimizes some desirable criteria, for instance, maximizing the number of saved vertices [4], minimizing the number of rounds, the number of firefighters per round [6], or the number of burned vertices [13, 4], and so on. These questions are well-studied in the literature, and while most variants are NP-hard, approximation and parameterized algorithms have been proposed for various scenarios. See the excellent survey [14] as well as references within for more details.

In this work, we consider the question of finding a strategy that saves a designated subset of vertices, which we shall refer to as the *critical set*. We refer to this problem as Saving A Critical Set (SACS) (we refer the reader to Section 2 for the formal definitions). This is a natural objective in situations where the goal is to save specific locations as opposed to saving some number of them. This version of the problem has been studied by [6, 18, 7] and is known to be NP-hard even when restricted to trees.

Our aim of designing firefighting solutions in order to save a critical set is well-motivated. In the context of studying networked systems for instance, it is often desirable to protect a specific set of critical infrastructure against any vulnerabilities that are cascading through the network (see [15] and [12] for an overview of *survivable network analysis* which aim to design networked systems that survive in the face of failures by providing critical services). Similarly, in the context of handling widely different risk factors that a contagion might have for different sections of the population (e.g. risk-factors that the epidemic of avian flu have for different subpopulations [5]), it is natural to ask for inoculation strategies to protect the identified at-risk groups.

Our Contributions and Methodology. We initiate the study of Saving A Critical Set from a parameterized perspective. We first show that the problem is para-NP-hard when parameterized by the size of the critical set, by showing that Saving A Critical Set is NP-complete even on instances where the size of the critical set is one. It is already clear from known results that Saving A Critical Set is para-NP-hard also when parameterized by treewidth. A third natural parameter is the number of firefighters deployed to save the critical set. Our main result is that Saving A Critical Set is FPT when parameterized by the number of firefighters, although it is not likely to have a polynomial kernel.

Our FPT algorithm is a recursive algorithm that uses the structure of tight separator sequences. The notion of tight separator sequences was introduced in [19] and has several applications [16, 20, 21] (some of which invoke modified definitions). A tight separator sequence is, informally speaking, a sequence of minimal separators such that the reachability set of S_i is contained in the reachability set of S_{i+1}. Note that any firefighting solution is a $s - C$ separator, where s is the source of the fire, and C is the critical subset of vertices. We also obtain faster algorithms on trees by using important separators.

As is common with such approaches, we do not directly solve SACS, but an appropriately generalized form, which encodes information about the behavior of some solution on the "border" vertices, which in this case is the union of all the separators in the tight separator sequence.

Related Work. The Firefighting problem has received much attention in recent years. It has been studied in the parameterized complexity setting [4, 7, 10, 2] but mostly by using the number of vertices burnt or saved as parameters. King et.al. [18] showed that for a tree of degree at most 3, it is NP-hard to save a critical set with budget of one firefighter per round,

but is polynomial time when the fire starts from a vertex of degree at most 2. Chopin [7] extended the hardness result of [18] to a per-round budget $b \geq 1$ and to trees with maximum degree $b + 2$. Chalermsook et.al.[6] gave an approximation to the number of firefighters per round when trying to protect a critical set.

Anshelevich et.al. [1] initiated the study of the spreading model, where the vaccination also spreads through the network. In Section 4 we study this problem in the parameterized setting.

2 Preliminaries

In this section, we introduce the notation and the terminology that we will need to describe our algorithms. Most of our notation is standard. We use $[k]$ to denote the set $\{1, 2, \ldots, k\}$, and we use $[k]_{\mathcal{O}}$ and $[k]_{\mathcal{E}}$, respectively, to denote the odd and even numbers in the set $[k]$.

Graphs, Important Separators and Tight Separator Sequences. We introduce here the most relevant definitions, and use standard notation pertaining to graph theory based on [9, 11]. All our graphs will be simple and undirected unless mentioned otherwise. For a graph $G = (V, E)$ and a vertex v, we use $N(v)$ and $N[v]$ to refer to the open and closed neighborhoods of v, respectively. The *distance* between vertices u, v of G is the length of a shortest path from u to v in G; if no such path exists, the distance is defined to be ∞. A graph G is said to be *connected* if there is a path in G from every vertex of G to every other vertex of G. If $U \subseteq V$ and $G[U]$ is connected, then U itself is said to be connected in G. For a subset $S \subseteq V$, we use the notation $G \setminus S$ to refer to the graph induced by the vertex set $V \setminus S$.

The following definitions about important separators and tight separator sequences will be relevant to our main FPT algorithm. We first define the notion of the reachability set of a subset X with respect to a subset S.

▶ **Definition 1** (Reachable Sets)**.** Let $G = (V, E)$ be an undirected graph, let $X \subseteq V$ and $S \subseteq V \setminus X$. We denote by $R_G(X, S)$ the set of vertices of G *reachable* from X in $G \setminus S$ and by $NR_G(X, S)$ the set of vertices of G not reachable from X in $G \setminus S$. We drop the subscript G if it is clear from the context.

We now turn to the notion of an X-Y separator and what it means for one separator to cover another.

▶ **Definition 2** (Covering by Separators)**.** Let $G = (V, E)$ be an undirected graph and let $X, Y \subset V$ be two disjoint vertex sets. A subset $S \subseteq V \setminus (X \cup Y)$ is called an $X - Y$ separator in G if $R_G(X, S) \cap Y = \emptyset$, or in other words, there is no path from X to Y in the graph $G \setminus S$. We denote by $\lambda_G(X, Y)$ the size of the smallest $X - Y$ separator in G. An $X - Y$ separator S_1 is said to *cover* an $X - Y$ separator S with respect to X if $R(X, S_1) \supset R(X, S)$. If the set X is clear from the context, we just say that S_1 covers S. An $X - Y$ separator is said to be inclusionwise minimal if none of its proper subsets is an $X - Y$ separator.

If $X = \{x\}$ is a singleton, then we abuse notation and refer to a $x - Y$ separator rather than a $\{x\} - Y$ separator. A separator S_1 dominates S if it covers S and is not larger than S in size:

▶ **Definition 3** (Dominating Separators [8])**.** Let $G = (V, E)$ be an undirected graph and let $X, Y \subset V$ be two disjoint vertex sets. An $X - Y$ separator S_1 is said to *dominate* an $X - Y$ separator S with respect to X if $|S_1| \leq |S|$ and S_1 covers S with respect to X. If the set X is clear from the context, we just say that S_1 dominates S.

We finally arrive at the notion of important separators, which are those that are not dominated by any other separator.

▶ **Definition 4** (Important Separators [8]). Let $G = (V, E)$ be an undirected graph, $X, Y \subset V$ be disjoint vertex sets and $S \subseteq V \setminus (X \cup Y)$ be an $X - Y$ separator in G. We say that S is an *important* $X - Y$ separator if it is inclusionwise minimal and there does not exist another $X - Y$ separator S_1 such that S_1 dominates S with respect to X.

It is useful to know that the number of important separators is bounded as an FPT function of the size of the important separators.

▶ **Lemma 5** ([8]). *Let $G = (V, E)$ be an undirected graph, $X, Y \subset V$ be disjoint vertex sets of G. For every $k \geq 0$ there are at most 4^k important $X - Y$ separators of size at most k. Furthermore, there is an algorithm that runs in time $O(4^k k(m + n))$ which enumerates all such important X-Y separators, where $n = |V|$ and $m = |E|$.*

We are now ready to recall the notion of tight separator sequences introduced in [19]. However, the definition and structural lemmas regarding tight separator sequences used in this paper are closer to that from [21]. Since there are minor modifications in the definition as compared to the one in [21], we give the requisite proofs for the sake of completeness.

▶ **Definition 6.** Let X and Y be two subsets of $V(G)$ and let $k \in \mathbb{N}$. A *tight (X,Y)-reachability sequence* of order k is an ordered collection $\mathcal{H} = \{H_0, H_1, \ldots, H_q\}$ of sets in $V(G)$ satisfying the following properties:

- $X \subseteq H_i \subseteq V(G) \setminus N[Y]$ for any $0 \leq i \leq q$;
- $X = H_0 \subset H_1 \subset H_2 \subset \cdots \subset H_q$;
- for every $0 \leq i \leq q$, H_i is reachable from X in $G[H_i]$ and every vertex in $N(H_i)$ can reach Y in $G - H_i$
  (implying that $N(H_i)$ is a minimal (X,Y)-separator in G);
- $|N(H_i)| \leq k$ for every $1 \leq i \leq q$;
- $N(H_i) \cap N(H_j) = \emptyset$ for all $1 \leq i, j \leq q$ and $i \neq j$;
- For any $0 \leq i \leq q - 1$, there is no (X,Y)-separator S of size at most k where $S \subseteq H_{i+1} \setminus N[H_i]$ or $S \cap N[H_q] = \emptyset$ or $S \subseteq H_1$.

We let $S_i = N(H_i)$, for $1 \leq i \leq q$, $S_{q+1} = Y$, and $\mathcal{S} = \{S_0, S_1, \ldots, S_q, S_{q+1}\}$. We call $\mathcal{S}$ a *tight (X,Y)-separator sequence* of order k.

▶ **Lemma 7** (see for example [21]). *There is an algorithm that, given an n-vertex m-edge graph G, subsets $X, Y \in V(G)$ and an integer k, runs in time $O(kmn^2)$ and either correctly concludes that there is no (X,Y)-separator of size at most k in G or returns the sets $H_0, H_1, H_2 \setminus H_1, \ldots, H_q \setminus H_{q-1}$ corresponding to a tight (X,Y)-reachability sequence $\mathcal{H} = \{H_0, H_1, \ldots, H_q\}$ of order k.*

Proof. The algorithm begins by checking whether there is an X-Y separator of size at most k. If there is no such separator, then it simply outputs the same. Otherwise, it uses the algorithm of Lemma 5 to compute an arbitrary important X-Y separator S of size at most k such that there is no X-Y separator of size at most k that covers S.

Although the algorithm of Lemma 5 requires time $O(4^k k(m + n))$ to enumerate *all* important X-Y separators of size at most k, *one* important separator of the kind described in the previous paragraph can in fact be computed in time $O(kmn)$ by the same algorithm.

If there is no X-S separator of size at most k, we stop and return the set $R(X, S)$ as the only set in a tight (X, Y)-reachability sequence. Otherwise, we recursively compute a tight (X, S)-reachability sequence $\mathcal{P} = \{P_0, \ldots, P_r\}$ of order k and define $\mathcal{Q} = \{P_0, \ldots, P_r, R(X, S)\}$

as a tight (X, Y)-reachability sequence of order k. It is straightforward to see that all the properties required of a tight (X, Y)-reachability sequence are satisfied. Finally, since the time required in each step of the recursion is $O(kmn)$ and the number of recursions is bounded by n, the number of vertices, the claimed running time follows. ◀

Saving a Critical Set. We now turn to the definition of the firefighting problem. The game proceeds as described earlier: we are given a graph G with a vertex $s \in V(G)$. To begin with, the fire breaks out at s and vertex s is burning. At each step $t \geq 1$, first the firefighter protects one vertex not yet on fire - this vertex remains permanently protected - and the fire then spreads from burning vertices to all unprotected neighbors of these vertices. The process stops when the fire cannot spread anymore. In the definitions that follow, we formally define the notion of a firefighting strategy.

▶ **Definition 8** (Firefighting Strategy)**.** A k-step firefighting strategy is defined as a function $\mathfrak{h} : [2k]_{\mathcal{O}} \to V(G)$. Such a strategy is said to be *valid in G with respect to s* if, for all $i \in [2k]_{\mathcal{O}}$, when the fire breaks out in s and firefighters are placed according to $\mathfrak{h}$ for all time steps up to $i-2$, the vertex $\mathfrak{h}(i)$ is not burning at time step i, and the fire cannot spread anymore after timestep $2k$. If G and s are clear from the context, we simply say that $\mathfrak{h}$ is a valid strategy.

▶ **Definition 9** (Saving C)**.** For a vertex s and a subset $C \subseteq V(G) \setminus \{s\}$, a firefighting strategy $\mathfrak{h}$ is said to save C if $\mathfrak{h}$ is a valid strategy and $\{\mathfrak{h}(i) \mid i \in [2k]_{\mathcal{O}}\}$ is a $\{s\}$-C separator in G, in other words, there is no path from s to any vertex in C if firefighters are placed according to $\mathfrak{h}$.

We are now ready to define the parameterized problem that is the focus of this work.

Saving A Critical Set (SACS)	Parameter: k
Input:	An undirected n-vertex graph G, a vertex s, a subset $C \subseteq V(G) \setminus \{s\}$, and an integer k.
Question:	Is there a valid k-step strategy that saves C when a fire breaks out at s?

Parameterized Complexity. We follow standard terminology pertaining to parameterized algorithms based on the monograph [9]. Here we define a known technique to prove kernel lower bounds, called cross composition. Towards this, we first define polynomial equivalence relations.

▶ **Definition 10** (polynomial equivalence relation [3])**.** An equivalence relation $\mathcal{R}$ on Σ^*, where Σ is a finite alphabet, is called a *polynomial equivalence relation* if the following holds: (1) equivalence of any $x, y \in \Sigma^*$ can be checked in time polynomial in $|x| + |y|$, and (2) any finite set $S \subseteq \Sigma^*$ has at most $(\max_{x \in S} |x|)^{O(1)}$ equivalence classes.

▶ **Definition 11** (cross-composition [3])**.** Let $L \subseteq \Sigma^*$ and let $Q \subseteq \Sigma^* \times \mathbb{N}$ be a parameterized problem. We say that L *cross-composes* into Q if there is a polynomial equivalence relation $\mathcal{R}$ and an algorithm which, given t strings $x_1, x_2, \ldots, x_t$ belonging to the same equivalence class of $\mathcal{R}$, computes an instance $(x^*, k^*) \in \Sigma^* \times \mathbb{N}$ in time polynomial in $\sum_{i=1}^{t} |x_i|$ such that: (i) $(x^*, k^*) \in Q \Leftrightarrow x_i \in L$ for some $1 \leq i \leq t$ and (ii) k^* is bounded by a polynomial in $(\max_{1 \leq i \leq t} |x_i| + \log t)$.

The following theorem allows us to rule out the existence of a polynomial kernel for a parameterized problem.

▶ **Theorem 12** ([3]). *If an* NP-hard *problem $L \subseteq \Sigma^*$ has a cross-composition into the parameterized problem Q and Q has a polynomial kernel then NP $\subseteq$ coNP/poly.*

3 The Parameterized Complexity of Saving a Critical Set

In this section, we describe the FPT algorithm for Saving A Critical Set and our cross-composition construction for trees. The starting point for our FPT algorithm is the fact that every solution to an instance (G, s, C, k) of SACS is in fact a s-C separator of size at most k. Although the number of such separators may be exponential in the size of the graph, it is a well-known fact that the number of *important* separators is bounded by $4^k n^{O(1)}$ [8]. For several problems, one is able to prove that there exists a solution that is in fact an important separator. In such a situation, an FPT algorithm is immediate by guessing the important separator.

In the SACS problem, unfortunately, there are instances where none of the solutions are important separators. However, this approach turns out to be feasible if we restrict our attention to trees, leading to improved running times. This is described in greater detail in Section 3.2. Further, in Section 3.3, we also show that we do not expect SACS to admit a polynomial kernel under standard complexity-theoretic assumptions. We establish this by a cross-composition from SACS itself, using the standard binary tree approach, similar to [2].

We describe our FPT algorithm for general graphs in Section 3.1. This is an elegant recursive procedure that operates over tight separator sequences, exploiting the fact that a solution can never be contained entirely in the region "between two consecutive separators". Although the natural choice of measure is the solution size, it turns out that the solution size by itself cannot be guaranteed to drop in the recursive instances that we generate. Therefore, we need to define an appropriate generalized instance, and work with a more delicate measure. We now turn to a detailed description of our approach.

We note that the SACS problem is para-NP-complete when parameterized by the size of the critical set, by showing that the problem is already NP-complete when the critical set has only one vertex.

▶ **Theorem 13** ($\star$). SACS *is* NP-complete *even when the critical set has one vertex.*

3.1 The FPT Algorithm

Towards the FPT algorithm for SACS, we first define a generalized firefighting problem as follows. In this problem, in addition to (G, s, C, k), we are also given the following:

- $P \uplus Q \subseteq [2k]_{\mathcal{O}}$, a set of *available time steps*,
- $Y \subset V(G)$, a subset of *predetermined firefighter locations*, and
- a bijection $\gamma : Q \to Y$, a *partial strategy* for Q.

The goal here is to find a valid partial k-step firefighting strategy over $(P \cup Q)$ that is consistent with γ on Q and saves C when the fire breaks out at s. We assume that no firefighters are placed during the time steps $[2k]_{\mathcal{O}} \setminus (P \cup Q)$. For completeness, we formally define the notion of a valid partial firefighting strategy over a set.

▶ **Definition 14** (Partial Firefighting Strategy). A *partial* k-step firefighting strategy on $X \subseteq [2k]_{\mathcal{O}}$ is defined as a function $\mathfrak{h} : X \to V(G)$. Such a strategy is said to be *valid in* G *with respect to* s if, for all $i \in X$, when the fire breaks out in s and firefighters are placed

according to $\mathfrak{h}$ for all time steps upto $[i-1]_{\mathcal{O}} \cap X$, the vertex $\mathfrak{h}(i)$ is not burning at time step i. If G and s are clear from the context, we simply say that $\mathfrak{h}$ is a valid strategy over X.

What it means for partial strategy to save C is also analogous to what it means for a strategy to save C. The only difference here is that we save C despite not placing any firefighters during the time steps j for $j \in [2k]_{\mathcal{O}} \setminus X$.

▶ **Definition 15** (Saving C with a Partial Strategy)**.** For a vertex s and a subset $C \subseteq V(G) \setminus \{s\}$, a partial firefighting strategy $\mathfrak{h}$ over X is said to save C if $\mathfrak{h}$ is a valid strategy and $\cup_{i \in X} \mathfrak{h}(i)$ is a $s-C$ separator in G, in other words, there is no path involving only burning vertices from s to any vertex in C if the fire starts at s and firefighters are placed according to $\mathfrak{h}$.

The intuition for considering this generalized problem is the following: when we recurse, we break the instance G into two parts, say subgraphs G' and H. An optimal strategy for G employs some firefighters in H at some time steps X, and the remaining firefighters in G' at time steps $[2k]_{\mathcal{O}} \setminus X$. When we recurse, we would therefore like to achieve two things:

- Capture the interactions between G' and H when we recursively solve H, so that a partial solution that we obtain from the recursion aligns with the larger graph, and
- Constrain the solution for the instance H to only use time steps in X, "allowing" firefighters to work in G' for the remaining time steps.

The constrained time steps in our generalized problem cater to the second objective, and the predetermined firefighter locations partially cater to the first. We now formally define the generalized problem.

Saving A Critical Set With Restrictions (SACS-R)	Parameter: k
Input:	An undirected n-vertex graph G, vertices s and g, a subset $C \subseteq V(G) \setminus \{s\}$, a subset $P \uplus Q \subseteq [2k]_{\mathcal{O}}$, $Y \subset V(G)$ (such that $\lvert Y\rvert = \lvert Q\rvert$, $2k-1 \in Q$ and $g \in Y$), a bijeciton $\gamma : Q \to Y$ such that $\gamma(2k-1) = g$, and an integer k.
Question:	Is there a valid partial k-step strategy over $P \cup Q$ that is consistent with γ on Q and that saves C when a fire breaks out at s?

We use p and q to denote $|P|$ and $|Q|$, respectively. Note that we can solve an SACS instance (G, s, C, k) by adding an isolated vertex g and solving the SACS-R instance $(G, s, C, 2k+2, g, P, Q, Y, \gamma)$, where $P = [2k]_{\mathcal{O}}$, $Q = \{2k+1\}$, $Y = \{g\}$ and $\gamma(2k+1) = g$. Therefore, it suffices to describe an algorithm that solves SACS-R. The role of the vertex g is mostly technical, and will be clear in due course.

We now describe our algorithm for solving an instance $\mathcal{I} := (G, s, C, k, g, P, Q, Y, \gamma)$ of SACS-R. Throughout this discussion, for the convenience of analysis of Yes instances, let $\mathfrak{h}$ be an arbitrary but fixed valid partial firefighting strategy in G over $P \cup Q$, consistent with γ on Q, that saves C. Our algorithm is recursive and works with pieces of the graph based on a tight $s-C$-separator sequence of separators of size at most $|P|$ in $G \setminus Y$. We describe the algorithm in three parts: the pre-processing phase, the generation of the recursive instances, and the merging of the recursively obtained solutions.

Phase 0 – Preprocessing. Observe that we have the following easy base cases:

- If $G \setminus Y$ has no $s-C$ separators of size at most p, then the algorithm returns No.
- If $p = 0$, then we have a Yes-instance if, and only if, s is separated from C in $G \setminus Y$ and $\mathfrak{h} := \gamma$ is a valid partial firefighting strategy over Q. In this case, the algorithm outputs Yes or No as appropriate.

- If $p > 0$ and s is already separated from C in $G \setminus Y$, then we return YES, since any arbitrary partial strategy over $P \cup Q$ that is consistent with γ on Q is a witness solution.

If we have a non-trivial instance, then our algorithm proceeds as follows. To begin with, we compute a tight $s - C$ separator sequence of order p in $G \setminus Y$. Recalling the notation of Definition 6 , we use $S_0, \ldots, S_{q+1}$ to denote the separators in this sequence, with S_0 being the set $\{s\}$ and $S_{q+1} = C$. We also use $W_0, W_1, \ldots, W_q, W_{q+1}$ to denote the reachability regions between consecutive separators. More precisely, if $\mathcal{H}$ is the tight $s - C$ reachability sequence associated with $\mathcal{S}$, then we have:

$$W_i := H_i \setminus N[H_{i-1}] \text{ for } 1 \leq i \leq q,$$

while W_{q+1} is defined as $G \setminus (N[H_q] \cup C)$. We will also frequently employ the following notation:

$$\mathcal{S} = \bigcup_{i=1}^{q} S_i \text{ and } \mathcal{W} = \bigcup_{i=1}^{q+1} W_i.$$

This is a slight abuse of notation since $\mathcal{S}$ is also used to denote the sequence $S_0, \ldots, S_{q+1}$, but the meaning of $\mathcal{S}$ will typically be clear from the context.

We first observe that if $q > k$, the separator S_q can be used to define a valid partial firefighting strategy. The intuition for this is the following: since every vertex in S_q is at a distance of at least k from s, we may place firefighters on vertices in S_q in any order during the available time steps. Since $|S_q| \leq p$ and S_q is a $s - C$ separator, this is a valid solution. Thus, we have shown the following:

▶ **Lemma 16.** *If G admits a tight $s - C$ separator sequence of order q in $G \setminus Y$ where $q > k$, then $\mathcal{I}$ is a* YES*-instance.*

Therefore, we return YES if $q > k$ and assume that $q \leq k$ whenever the algorithm proceeds to the next phase.

This concludes the pre-processing stage.

Phase 1 – Recursion. Our first step here is to guess a partition of the set of available time steps, P, into $2q + 1$ parts, denoted by $A_0, \ldots, A_q, A_{q+1}$ and $B_1, \ldots, B_{q+1}$. The partition of the time steps represents how a solution might distribute the timings of its firefighting strategy among the sets in $\mathcal{S}$ and $\mathcal{W}$. The set A_i denotes our guess of $\cup_{v \in S_i} \mathfrak{h}^{-1}(v)$ and B_j denotes our guess of $\cup_{v \in W_j} \mathfrak{h}^{-1}(v)$. Note that the number of such partitions is $(2q + 1)^p \leq (2k + 1)^k$. We define $g_0(k) := (2k + 1)^k$. We also use $\mathcal{T}_1(P)$ to denote the partition $A_0, \ldots, A_q$ and $\mathcal{T}_2(P)$ to denote $B_0, \ldots, B_{q+1}$.

We say that the partition $(\mathcal{T}_1(P), \mathcal{T}_2(P))$ is non-trivial if none of the B_i's are such that $B_i = P$. Our algorithm only considers non-trivial partitions – the reason this is sufficient follows from the way tight separator sequences are designed, and this will be made more explicit in due course.

Next, we would like to guess the behavior of a partial strategy over P restricted to $\mathcal{S}$. Informally, we do this by associating a signature with the strategy $\mathfrak{h}$, which is is a labeling of the vertex set with labels corresponding to the status of a vertex in the firefighting game when it is played out according to $\mathfrak{h}$. Every vertex is labeled as either a vertex that had a firefighter placed on it, a burned vertex, or a saved vertex. The labels also carry information about the earliest times at which the vertices attained these statuses. More formally, we have the following definition.

▶ **Definition 17.** Let $\mathfrak{h}$ be a valid k-step firefighting strategy (or a partial strategy over X). The signature of $\mathfrak{h}$ is defined as a labeling $\mathfrak{L}_\mathfrak{h}$ of the vertex set with labels from the set:

$$\mathcal{L} = (\{\mathfrak{f}\} \times X) \cup (\{\mathfrak{b}\} \times [2k]_\mathcal{E}) \cup \{\mathfrak{p}\},$$

where:

$$\mathfrak{L}_\mathfrak{h}(v) = \begin{cases} (\mathfrak{f}, t) & \text{if } \mathfrak{h}(t) = v, \\ (\mathfrak{b}, t) & \text{if } t \text{ is the earliest time step at which } v \text{ burns}, \\ \mathfrak{p} & \text{if } v \text{ is not reachable from } s \text{ in } G \setminus (\{\mathfrak{h}(i) \mid i \in [2k]_\mathcal{O}\}) \end{cases}$$

We use array-style notation to refer to the components of $\mathfrak{L}(v)$, for instance, if $\mathfrak{L}(v) = (\mathfrak{b}, t)$, then $\mathfrak{L}(v)[0] = \mathfrak{b}$ and $\mathfrak{L}(v)[1] = t$. The algorithm begins by guessing the restriction of $\mathfrak{L}_\mathfrak{h}$ on $\mathcal{S}$, that is, it loops over all possible labellings:

$$\mathfrak{T} : \mathcal{S} \to (\{\mathfrak{f}\} \times P) \cup (\{\mathfrak{b}\} \times [2k]_\mathcal{E}) \cup \{\mathfrak{p}\}.$$

The labeling $\mathfrak{T}$ is called legitimate if, for any $u \neq v$, whenever $\mathfrak{T}(u)[0] = \mathfrak{T}(v)[0] = \mathfrak{f}$, we have $\mathfrak{T}(u)[1] \neq \mathfrak{T}(v)[1]$. We say that a labeling $\mathfrak{T}$ over $\mathcal{S}$ is compatible with $\mathcal{T}_1(P) = (A_0, \ldots, A_q)$ if we have:

- for all $0 \leq i \leq r$, if $v \in S_i$ and $\mathfrak{h}(v)[0] = \mathfrak{f}$, then $\mathfrak{h}(v)[1] \in A_i$.
- for all $0 \leq i \leq r$, if $t \in A_i$, there exists a vertex $v \in S_i$ such that $\mathfrak{h}^{-1}(\mathfrak{f}, t) = v$.

The algorithm considers only legitimate labelings compatible with the current choice of $\mathcal{T}_1(P)$. By Lemma 16, we know that any tight $s - C$ separator sequence considered by the algorithm at this stage has at most k separators of size at most p each. Therefore, we have that the number of labelings considered by the algorithm is bounded by $g_1(k) := (p + k + 1)^{(kp)} \leq (3k)^{O(k^2)} \leq k^{O(k^2)}$.

We are now ready to split the graph into $q + 1$ recursive instances. For $1 \leq i \leq q + 1$, let us define $G_i = G[S_{i-1} \cup W_i \cup S_i \cup Y]$. Also, let $\mathfrak{T}_i := \mathfrak{T} \mid_{V(G_i) \cap \mathcal{S}}$. Notice that when using G_i's in recursion, we need to ensure that the independently obtained solutions are compatible with each other on the non-overlapping regions, and consistent on the common parts. We force consistency by carrying forward the information in the signature of $\mathfrak{h}$ using appropriate gadgets, and the compatibility among the W_i's is a result of the partitioning of the time steps.

Fix a partition of the available time steps P into $\mathcal{T}_1(P)$ and $\mathcal{T}_2(P)$, a compatible labeling $\mathfrak{T}$ and $1 \leq i \leq q + 1$. We will now define the SACS-R instance $\mathcal{I}\langle i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}_i\rangle$. Recall that $\mathcal{I} = (G, s, C, k, g, P, Q, Y, \gamma)$. To begin with, we have the following:

- Let $X_i = A_{i-1} \cup A_i$ and let $P_i = B_i$.
- Let $Q_i := X_i \cup Q$ and $Y_i := Y \cup X_i$. We define γ_i as follows:

$$\gamma_i(t) = \begin{cases} \gamma(t) & \text{if } t \in Q, \\ v & \text{if } t \in X_i \text{ and } \mathfrak{T}_i(v) = (\mathfrak{f}, t) \end{cases}$$

Note that γ_i is well-defined because the labeling was legitimate and compatible with $\mathcal{T}_1(P)$. We define H_i to be the graph $\chi(G_i, \mathfrak{T}_i)$, which is described below.

- To begin with, $V(H_i) = V(G_i) \cup \{s^\star, t^\star\}$
- Let $v \in V(G_i)$ be such that $\mathfrak{T}_i(v)[0] = \mathfrak{b}$. Use ℓ to denote $\mathfrak{T}_i(v)[1]/2$. Now, we do the following:
  - Add $k + 1$ internally vertex disjoint paths from $s^\star$ to v of length $\ell + 1$, in other words, these paths have $\ell - 1$ internal vertices.
  - Add $k + 1$ internally vertex disjoint paths from v to g of length $k - \ell - 1$.

Algorithm 1: Solve-SACS-R($\mathcal{I}$)

Input: An instance $(G, s, C, k, g, P, Q, Y, \gamma)$, $p := |P|$
Result: YES if $\mathcal{I}$ is a YES-instance of SACS-R, and NO otherwise.

```
1  if p = 0 and s and C are in different components of G \ Y then return YES;
2  else return NO;
3  if p > 0 and s and C are in different components of G \ Y then return YES;
4  if there is no s − C separator of size at most p then return NO;
5  Compute a tight s − C separator sequence S of order p.
6  if the number of separators in S is greater than k then return YES;
7  else
8      for a non-trivial partition T_1(P), T_2(P) of P into 2q + 1 parts do
9          for a labeling 𝔗 compatible with T_1(P) do
10             if ⋀_{i=1}^{q+1} (Solve-SACS-R(I⟨i, T_1(P), T_2(P), 𝔗_i⟩)) then return YES;
11     return NO
```

- Let $v \in V(G_i)$ be such that $\mathfrak{T}_i(v) = \mathfrak{p}$. Add an edge from v to $t^\star$.
- We also make $k+1$ copies of the vertices $t^\star$ and all vertices that are labeled either burned or saved. This ensures that no firefighters are placed on these vertices.

For $1 \leq i \leq q+1$, the instance $\mathcal{I}\langle i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}_i\rangle$ is now defined as $(\chi(G_i, \mathfrak{T}_i), s^\star, C = \{t^\star\}, k, g, P_i, Q_i, Y_i, \gamma_i)$.

Phase 2 – Merging. Our final output is quite straightforward to describe once we have the $\mathfrak{h}[\mathfrak{T}_i, i]$'s. Consider a fixed partition of the available time steps P into $\mathcal{T}_1(P)$ and $\mathcal{T}_2(P)$, and a labeling $\mathfrak{T}$ of $\mathcal{S}$ compatible with $\mathcal{T}_1(P)$. If all of the $(q+1)$ instances $\mathcal{I}\langle i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}_i\rangle$, $1 \leq i \leq q+1$ return YES, then we also return YES, and we return NO otherwise. Indeed, in the former case, let $\mathfrak{h}[i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}]$ denote a valid partial firefighting strategy for the instance $\mathcal{I}\langle i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}_i\rangle$. We will show that $\mathfrak{h}^\star$, described as follows, is a valid partial firefighting strategy that saves C.

- For the time steps in Q, we employ firefighters according to γ.
- For the time steps in $\mathcal{T}_1(P)$, we employ firefighters according to $\mathfrak{T}$. This is a well-defined strategy since $\mathfrak{T}$ is a compatible labeling.
- For all remaining time steps, i.e, those in $\mathcal{T}_2(P) = \{B_1, \ldots, B_{q+1}\}$, we follow the strategy given by $\mathfrak{h}[i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}]$.

It is easily checked that the strategy described above agrees with $\mathfrak{h}[i, \mathcal{T}_1(P), \mathcal{T}_2(P), \mathfrak{T}]$ for all i. Also, the strategy is well-defined, since $\mathcal{T}_1(P)$ and $\mathcal{T}_2(P)$ form a partition of the available time steps. Next, we will demonstrate that $\mathfrak{h}^\star$ is indeed a valid strategy that saves C, and also analyze the running time of the algorithm.

Due to lack of space, we refer the reader to the full version of this work for the analysis of the algorithm.

3.2 A Faster Algorithm For Trees

In this section we consider the setting when the input graph G is a tree. WLOG, we consider the vertex s to be the root of the tree. We first state an easy claim that shows that WLOG, we can consider the critical set to be the leaves. The proof of the following lemma follows from the fact that the firefighting solution has to be a $s - C$ separator.

▶ **Lemma 18.** *When the input graph G is a tree, if there exists a solution to* SACS*, there exists a solution such that all firefighter locations are on nodes that are on some path from s to C.*

Given the above claim, our algorithm to construct a firefighting solution is the following– exhaustively search all the important $s - C$ separators that are of size k. For each vertex v in a separator Y, we place firefighters on Y in the increasing order of distance from s and check whether this is a valid solution. The following lemma claims that if there exists a firefighting solution, the above algorithm will return one.

▶ **Lemma 19** (⋆). *Solving the* SACS *problem for input graphs that are trees takes time $O^*(4^k)$.*

3.3 No Polynomial Kernel, Even on Trees

Given that there is a FPT algorithm for SACS when restricted to trees, in this section we show that SACS on trees has no polynomial kernel. As mentioned before, the proof technique used here is on the similar lines of the proof showing no polynomial kernel for SAVING ALL BUT k-VERTICES by Bazgan et. al.[2].

▶ **Theorem 20** (⋆). SACS *when restricted to trees does not admit polynomial kernel, unless NP $\subseteq$ coNP/poly.*

4 The Spreading Model

The spreading model for firefighters was defined by Anshelevich et al. [1] as "Spreading Vaccination Model". In contrast to the firefighting game described in Section 1, in the spreading model, the firefighters (vaccination) also spread at even time steps as similar to that of the fire. That is, at any even time step if there is a firefighter at node v_i, then the firefighter extends (vaccination spreads) to all the neighbors of v_i which are not already on fire or are not already protected by a firefighter. Consider a node v_i which is not already protected or burning at time step $2j$. If u_i and w_i are neighbors of v_i, such that, u_i was already burning at time step $2j - 1$ and w_i was protected at time step $2j - 1$, then at time step $2j$, v_i is protected. That is, in the spreading model the firefighters dominate or win over fire. For the spreading model, the firefighting game can be defined formally as follows:

- At time step 0, fire breaks out at the vertex s. A vertex on fire is said to be *burned*.
- At every odd time step $i \in \{1, 3, 5, \ldots\}$, when it is the turn of the firefighter, a firefighter is placed at a vertex v that is not already on fire. Such a vertex is permanently *protected*.
- At every even time step $j \in \{2, 4, 6, \ldots\}$, first the firefighter extends to every adjacent vertex to a vertex protected by a firefighter (unless it was already protected or burned), then the fire spreads to every vertex adjacent to a vertex on fire (unless it was already protected or burned). Needless to say, the vertices protected at even time steps are also permanently *protected*.

In the following theorem, we show that in spite of the spreading power that the firefighters have, SACS is hard.

▶ **Theorem 21** (⋆). *In the spreading model,* SACS *is as hard as k-*Dominating Set.

5 Summary and Conclusions

In this work, we presented the first FPT algorithm, parameterized by the number of firefighters, for a variant of the Firefighter problem where we are interested in protecting a critical set. We also presented a faster algorithms on trees. In contrast, we also show that in the spreading model protecting a critical set is W[2]-hard. Our algorithms exploit the machinery of important separators and tight separator sequences. We believe that this opens up an interesting approach for studying other variants of the Firefighter problem.

Abstract

In this work, we study theoretical models of *programmable matter* systems. The systems under consideration consist of spherical modules, kept together by magnetic forces and able to perform two minimal mechanical operations (or movements): *rotate* around a neighbor and *slide* over a line. In terms of modeling, there are n nodes arranged in a 2-dimensional grid and forming some initial *shape*. The goal is for the initial shape A to *transform* to some target shape B by a sequence of movements. Most of the paper focuses on *transformability* questions, meaning whether it is in principle feasible to transform a given shape to another. We first consider the case in which only rotation is available to the nodes. Our main result is that deciding whether two given shapes A and B can be transformed to each other is in **P**. We then insist on rotation only and impose the restriction that the nodes must maintain global connectivity throughout the transformation. We prove that the corresponding transformability question is in **PSPACE** and study the problem of determining the minimum *seeds* that can make feasible otherwise infeasible transformations. Next we allow both rotations and slidings and prove universality: any two connected shapes A, B of the same number of nodes, can be transformed to each other without breaking connectivity. The worst-case number of movements of the generic strategy is $\Theta(n^2)$. We improve this to $O(n)$ parallel time, by a pipelining strategy, and prove optimality of both by matching lower bounds. We next turn our attention to distributed transformations. The nodes are now distributed processes able to perform communicate-compute-move rounds. We provide distributed algorithms for a general type of transformation.

1 Introduction

Programmable matter refers to any type of matter that can *algorithmically* change its physical properties. For a concrete example, imagine a material formed by a collection of spherical nanomodules kept together by magnetic forces. Each module is capable of storing (in some internal representation) and executing a simple program that handles communication with nearby modules and that controls the module's electromagnets, in a way that allows the module to *rotate* or *slide* over neighboring modules. Such a material would be able to adjust its *shape* in a programmable way. Other examples of physical properties of interest for real applications would be connectivity, color [25, 5], and strength of the material.

There are already some first impressive outcomes towards the development of programmable materials (even though it is evident that there is much more work to be done in the direction of real systems), such as programmed DNA molecules that self-assemble into desired structures [28, 14] and large collectives of tiny identical robots that orchestrate resembling a single multi-robot organism (e.g., the Kilobot system [30]). Other systems for programmable matter include [21, 23]. Ambitious long-term applications of programmable materials include molecular computers, collectives of nanorobots injected into the human circulatory system for monitoring and treating diseases, or even self-reproducing and self-healing machines (see also [27]).

Apart from the fact that systems work is still in its infancy, there is also an apparent lack of unifying formalism and theoretical treatment. Still there are some first theoretical efforts aiming at understanding the fundamental possibilities and limitations of this prospective. The area of *algorithmic self-assembly* tries to understand how to program molecules (mainly DNA strands) to manipulate themselves, grow into machines and at the same time control their own growth [14]. The theoretical model guiding the study in algorithmic self-assembly is the Abstract Tile Assembly Model (aTAM) [33, 29] and variations. Recently, a model, called the *nubot* model, was proposed for studying the complexity of self-assembled structures with active molecular components [34]. Another very recent model, called the *Network Constructors* model, studied what stable networks can be constructed by a population of finite-automata that interact randomly like molecules in a well-mixed solution and can establish bonds with each other according to the rules of a common small protocol [26]. The development of Network Constructors was based on the *Population Protocol* model of Angluin *et al.* [2], that does not include the capability of creating bonds and focuses more on the computation of functions on inputs. A very interesting fact about population protocols is that they are formally equivalent to *chemical reaction networks* (CRNs), "which model chemistry in a *well-mixed solution* and are widely used to describe information processing occurring in natural cellular regulatory networks" [15]. Also the recently proposed *Amoebot* model, "offers a versatile framework to model self-organizing particles and facilitates rigorous algorithmic research in the area of programmable matter" [10, 12, 11, 13]. Other related work includes mobile and reconfigurable robotics [6, 24, 31, 20, 32, 8, 7, 4, 36, 1, 35], puzzles [9, 22], and passive systems [2, 3, 26, 19, 33, 29].

It seems that the right way for theory to boost the development of more refined real systems is to reveal the *transformation capabilities of mechanisms and technologies that are available now*, rather than by exploring the unlimited variety of theoretical models that are not expected to correspond to a real implementation in the near future. In this paper, we follow such an approach, by studying the transformation capabilities of models for programmable matter, which are based on minimal mechanical capabilities, easily implementable by existing technology.

1.1 Our Approach

We study a minimal programmable matter system consisting of n cycle-shaped modules, with each module (or *node*) occupying at any given time a cell of the 2-dimensional (abbreviated "2D" throughout) grid (no two nodes can occupy the same cell at the same time). Therefore, the composition of the programmable matter systems under consideration is discrete. Our main question throughout is whether an initial arrangement of the material can *transform* (either in principle, e.g., by an external authority, or by itself) to some other target arrangement. In more technical terms, we are provided with an *initial shape* A and a *target shape* B and we are asked whether A *can be transformed to* B via a sequence of *valid* transformation steps. Usually, a step consists either of a *valid movement* of a single node (in the *sequential case*) or of more than one nodes at the same time (in the *parallel case*). We consider two quite primitive types of movement. The first one, called *rotation*, allows a node to rotate 90° around one of its neighbors either clockwise or counterclockwise and the second one, called *sliding*, allows a node to slide by one position "over" two neighboring nodes. Both movements succeed only if the whole direction of movement is free of obstacles (i.e., other nodes blocking the way). More formal definitions are provided in Section 2. One part of the paper focuses on the case in which only rotation is available to the nodes and the other part studies the case in which both rotation and sliding are available. The latter case has been studied to some extent in the past in the, so called, *metamorphic systems* [17, 18, 16], which makes those studies the closest to our approach.

For rotation only, we introduce the notion of *color-consistency* and prove that if two shapes are not color-consistent then they cannot be transformed to each other. On the other hand, color-consistency does not guarantee transformability, as there is an infinite set of pairs (A, B) such that A and B are color consistent but still they cannot be transformed to each other. At this point, observe that if A can be transformed to B then the inverse is also true, as all movements considered in this paper are *reversible*. We distinguish two main types of transformations: those that are allowed to break the connectivity of the shape during the transformation and those that are not; we call the corresponding problems Rot-Transformability and RotC-Transformability, respectively. Our main result regarding Rot-Transformability is that Rot-Transformability $\in \mathbf{P}$. To prove polynomial-time decidability, we prove that two connected shapes A and B of the same order (i.e., having the same number of nodes) are transformable to each other iff both have at least one movement available. Therefore, transformability reduces to checking the availability of a movement in the initial and target shapes.

We next study RotC-Transformability, in which again the only available movement is rotation, but now connectivity of the material has to be preserved throughout the transformation. The property of preserving the connectivity is expected to be a crucial property for programmable matter systems, as it allows the material to maintain coherence and strength, to eliminate the need for wireless communication, and, finally, enables the development of more effective power supply schemes, in which the modules can share resources or in which the modules have no batteries but are instead constantly supplied with energy by a centralized source (or by a supernode that is part of the material itself). Such benefits can lead to simplified designs and potentially to reduced size of individual modules. We first prove that RotC-Transformability $\in$ **PSPACE**. The rest of our results here are strongly based on the notion of a *seed*. This stems from the observation that a large set of infeasible transformations become feasible by introducing to the initial shape an additional, and usually quite small, seed; i.e., a small shape that is being attached to some point of the initial shape. We investigate seeds that could serve as components capable of traveling the

perimeter of an arbitrary connected shape A. Such seed-shapes are very convenient as they are capable of "simulating" the *universal transformation* techniques that are possible if we have both rotation and sliding movements available (discussed in the sequel). To this end, we prove that all seeds of size ≤ 4 cannot serve for this purpose, by proving that they cannot even walk the perimeter of a simple line shape. On the other hand, we manage to show that a *6-seed* succeeds, and this provides a first indication, that there might be a large family of shapes that can be transformed to each other with rotation only and without breaking connectivity.

Next, we consider the case in which both rotation and sliding are available and insist on connectivity preservation. We first provide a proof that this combination of simple movements is *universal* w.r.t. transformations, as any pair of connected shapes A and B of the same order can be transformed to each other without ever breaking the connectivity throughout the transformation (a first proof of this fact had already appeared in [16]). This generic transformation requires $\Theta(n^2)$ sequential movements in the worst case. By a potential-function argument we show that no transformation can improve on this worst-case complexity for some specific pairs of shapes and this lower bound is independent of connectivity preservation; it only depends on the inherent *transformation-distance* between the shapes. To improve on this, either some sort of parallelism must be employed or more powerful movement mechanisms, e.g., movements of whole sub-shapes in one step. We investigate the former approach, and prove that there is a *pipelining* general transformation strategy that improves the time to $O(n)$ (parallel time). We also give a matching $\Omega(n)$ lower bound. On the way, we also show that this parallel complexity is feasible even if the nodes are labeled, meaning that individual nodes must end up in specific positions of the target-shape.

Finally, we assume that the nodes are distributed processes able to perform communicate-compute-move rounds (where, again, both rotation and sliding movements are available) and provide distributed algorithms for a general type of transformation.

Section 2 brings together all definitions and basic facts that are used throughout the paper. In Section 3, we study programmable matter systems equipped only with rotation movement. In Section 4, we insist on rotation only, but additionally require that the material maintains connectivity throughout the transformation. In Section 5, we investigate the combined effect of rotation and sliding movements. Finally, in Section 6 we conclude and give further research directions that are opened by our work.

2 Preliminaries

The programmable matter systems considered in this paper operate on a 2D square grid, with each position (or *cell*) being uniquely referred to by its $y \geq 0$ and $x \geq 0$ coordinates. Such a system consists of a set V of n *modules*, called *nodes* throughout. Each node may be viewed as a spherical module fitting inside a cell of the grid. At any given time, each node $u \in V$ occupies a cell $o(u) = (o_y(u), o_x(u)) = (i, j)$ (where i corresponds to a row and j to a column of the grid) and no two nodes may occupy the same cell. At any given time t, the positioning of nodes on the grid defines an undirected *neighboring relation* $E(t) \subset V \times V$, where $\{u, v\} \in E$ iff $o_y(u) = o_y(v)$ and $|o_x(u) - o_x(v)| = 1$ or $o_x(u) = o_x(v)$ and $|o_y(u) - o_y(v)| = 1$, that is, if u and v are either *horizontal* or *vertical* neighbors on the grid, respectively. A more informative way to define the system at a given time t, and thus often more convenient, is as a mapping $P_t \colon \mathbb{N}_{\geq 0} \times \mathbb{N}_{\geq 0} \to \{0, 1\}$ where $P_t(i, j) = 1$ iff cell (i, j) is occupied by a node.

At any given time t, $P_t^{-1}(1)$ defines a *shape*. Such a shape is called *connected* if $E(t)$ defines a connected graph. A connected shape is called *convex* if for any two occupied cells,

the line that connects their centers does not pass through an empty cell. We call a shape *discrete-convex* if for any two occupied cells, belonging either to the same row or the same column, the line that connects their centers does not pass through an empty cell; i.e., in the latter we exclude diagonal lines. We call a shape *compact* if it has no holes.

In general, shapes can *transform* to other shapes via a sequence of one or more *movements* of individual nodes. Time consists of discrete *steps* (or *rounds*) and in every step, zero or more movements may occur. In the *sequential* case, at most one movement may occur per step, and in the *parallel* case any number of "valid" movements may occur in parallel. [1] We consider two types of movements: (i) *rotation* and (ii) *sliding*. In both movements, a single node moves relative to one or more neighboring nodes as we just explain.

A single *rotation* movement of a node u is a 90° *rotation* of u around one of its neighbors. Let (i, j) be the current position of u and let its neighbor be v occupying the cell $(i-1, j)$ (i.e., lying below u). Then u can *rotate* 90° clockwise (counterclockwise) around v iff the cells $(i, j+1)$ and $(i-1, j+1)$ ($(i, j-1)$ and $(i-1, j-1)$, respectively) are both empty. By rotating the whole system 90°, 180°, and 270°, all possible rotation movements are defined analogously. A single *sliding* movement of a node u is a one-step horizontal or vertical movement "over" a horizontal or vertical line of (neighboring) nodes of length 2. In particular, if (i, j) is the current position of u, then u can *slide* rightwards to position $(i, j+1)$ iff $(i, j+1)$ is not occupied and there exist nodes at positions $(i-1, j)$ and $(i-1, j+1)$ or at positions $(i+1, j)$ and $(i+1, j+1)$, or both. Precisely the same definition holds for up, left, and down sliding movements by rotating the whole system 90°, 180°, and 270° counterclockwise, respectively.

Let A and B be two shapes. We say that A *transforms to* B *via a movement* m (which can be either a rotation or a sliding), denoted $A \xrightarrow{m} B$, if there is a node u in A such that if u applies m, then the shape resulting after the movement is B (possibly after rotations and translations of the resulting shape, depending on the application). We say that A *transforms in one step to* B (or that B *is reachable in one step from* A), denoted $A \to B$, if $A \xrightarrow{m} B$ for some movement m. We say that A *transforms* to B (or that B is *reachable* from A) and write $A \rightsquigarrow B$, if there is a sequence of shapes $A = C_0, C_1, \ldots, C_t = B$, such that $C_i \to C_{i+1}$ for all i, $0 \leq i < t$. We should mention that we do not always allow m to be any of the two possible movements. In particular, in Sections 3 and 4 we only allow m to be a rotation, as we there restrict attention to systems in which only rotation is available. We shall clearly explain what movements are permitted in each part of the paper. Observe now that both rotation and sliding are *reversible* movements, a fact that we extensively use in our results. Based on this, it can be proved that the relation '$\rightsquigarrow$' is a partial equivalence relation. When the only available movement is rotation, there are shapes in which no rotation can be performed. If we introduce a *null* rotation, then every shape may transform to itself by applying the *null* rotation, and '$\rightsquigarrow$' becomes an equivalence relation.

The following are the main transformation problems that are considered in this work:

Rot-Transformability. Given an initial shape A and a target shape B (usually both connected), decide whether A can be transformed to B (usually, under translations and rotations of the shapes) using only a sequence of rotation movements.

RotC-Transformability. Special case of Rot-Transformability, where A and B are connected shapes and connectivity must be preserved throughout the transformation.

RS-Transformability. Variant of Rot-Transformability in which both rotation and sliding movements are available.

[1] By "valid", we mean here subject to the constraint that their whole movement paths correspond to pairwise disjoint sub-areas of the grid.

Minimum-Seed-Determination. Given an initial shape A and a target shape B determine a minimum-size seed and an initial positioning of that seed relative to A that makes the transformation from A to B feasible.

3 Rotation

In this section, the only permitted movement is 90° *rotation* around a neighbor. Our main result in this section is that Rot-Transformability $\in \mathbf{P}$.

Consider a black and red checkered coloring of the 2D grid. Any shape S may be viewed as a colored shape consisting of $b(S)$ blacks and $r(S)$ reds. Call two shapes A and B *color-consistent* if $b(A) = b(B)$ and $r(A) = r(B)$ and call them *color-inconsistent* otherwise. Call a transformation from a shape A to a shape C *color-preserving* if A and C are color consistent.

▶ **Observation 1.** *The rotation movement is color-preserving. Formally, $A \rightsquigarrow C$ (restricted to rotation only) implies that A and C are color-consistent. In particular, every node beginning from a black (red) position of the grid, will always be on black (red, respectively) positions throughout a transformation.*

Based on this property of the rotation movement, we may call each node *black* or *red* throughout a transformation, based only on its initial coloring. Observation 1 gives a partial way to determine that two shapes A and B cannot be transformed to each other by rotations.

▶ **Proposition 2.** *If two shapes A and B are color-inconsistent, then it is impossible to transform one to the other by rotations only.*

▶ **Proposition 3.** *There is a generic connected shape, called* line-with-leaves*, that has a color-consistent version for any connected shape A.*

Proof. Let red be the majority color of A and k be the number of black nodes of A. Consider a bi-color line starting with a black node and ending to a black node, such that all k blacks are exhausted. To do this, $k-1$ reds are needed in order to alternate blacks and reds on the line. Since A is connected, it can have at most $3k+1$ reds. By adding red leaf-nodes around the blacks of the line, we can achieve the whole range of possible number of reds, from k to $3k+1$. ◀

Based on this, we now show that the inverse of Proposition 2 is not true, that is, it does not hold that any two color-consistent shapes can be transformed to each other by rotations.

▶ **Proposition 4.** *There is an infinite set of pairs (A, B) of connected shapes, such that A and B are color-consistent but cannot be transformed to each other by rotations only.*

Proof. For shape A, take a rhombus in which no node is able to rotate. By Proposition 3, any such A has a color-consistent shape B from the family of line-with-leaves shapes, such that $B \neq A$. We conclude that A and B are distinct color-consistent shapes which cannot be transformed to each other, and there is an infinite number of such pairs, as the number of black nodes of A can be made arbitrarily large. ◀

Propositions 2 and 4 give a partial characterization of pairs of shapes that cannot be transformed to each other. Observe that the impossibilities proved so far, hold for all possible transformations based on rotation only, including those that are allowed to break connectivity.

The next theorem states that the inclusion between RotC-Transformability and Rot-Transformability is strict, that is, there are strictly more feasible transformations if we allow connectivity to break. We prove this by showing that there is a feasible

transformation, namely folding a spanning line in half, in Rot-Transformability\RotC-Transformability.

▶ **Theorem 5.** RotC-Transformability ⊂ Rot-Transformability.

Aiming at a general transformation, we ask whether there is some minimal addition to a shape that would allow it to transform. The solution turns out to be as small as a *2-line seed* (a bi-color pair, usually referred to as "2-line" or "2-seed") lying initially somewhere "outside" the boundaries of the shape. Based on the above assumptions, we prove that any pair of color-consistent connected shapes A and B can be transformed to each other. The idea is to exploit the fact that the 2-line can move freely in any direction and to use it in order to extract from A another 2-line. In this way, a 4-line seed is formed, which can also move freely in all directions. Then we use the 4-line as a transportation medium for carrying the nodes of A, one at a time. We exploit these mobility mechanisms to transform A into a uniquely defined shape from the line-with-leaves family of Proposition 3. But if any connected shape A with an extra 2-line can be transformed to its color-consistent line-with-leaves version with an extra 2-line, then this also holds inversely due to reversibility, and it follows that any A can be transformed to any B by transforming A to its line-with-leaves version L_A and then inverting the transformation from B to $L_B = L_A$.

▶ **Theorem 6.** *If connectivity can break and there is a 2-line seed provided "outside" the initial shape, then any pair of color-consistent connected shapes A and B can be transformed to each other by rotations only.*

Proof. Without loss of generality (due to symmetry and the 2-line's unrestricted mobility), it suffices to assume that the seed is provided somewhere below the lowest row l occupied by the shape A. We show how A can be transformed to L_A with the help of the seed. We define L_A as follows: Let k be the cardinality of the minority color, let it be the black color. As there are at least k reds, we can create a horizontal line of length $2k$, i.e., $u_1, u_2, \ldots, u_{2k}$, starting with a black (i.e., u_1 is black), and alternating blacks and reds. In this way, the blacks are exhausted. The remaining $\leq (3k+1) - k = 2k+1$ reds are then added as leaves of the black nodes, starting from the position to the left of u_1 and continuing counterclockwise, i.e., below u_1, below u_3, ..., below u_{2k-1}, above u_{2k-1}, above u_{2k-3}, and so on. This gives the same shape from the line-with-leaves family, for all color-consistent shapes (observe that the leaf to the right of the line is always placed). L_A shall be constructed on rows $l-5$ to $l-3$ (not necessarily inclusive), with u_1 on row $l-4$ and a column j preferably between those that contain A.

First, extract a 2-line from A, from row l, so that the 2-line seed becomes a 4-line seed. To see that this is possible for every shape A of order at least 2, distinguish the following two cases: (i) If the lowest row has a horizontal 2-line, then the 2-line can leave the shape without any help and approach the 2-seed. (ii) If not, then take any node u of row l. As A is connected and has at least two nodes, u must have a neighbor v above it. The only possibility that the 2-line u,v is not free to leave A is when v has both a left and a right neighbor, but this can be resolved with the help of the 2-line.

To transform A to L_A, given the 4-line seed, do the following:

- While blacks is still present in A:
  - If on the current lowest row occupied by A, there is a 2-line that can be extracted alone and moved towards L_A, then perform the shortest such movement that attaches the 2-line to the right endpoint of L_A's line $u_1, u_2, \ldots$.
  - If not, then do the following. Maintain a *repository* of nodes at the empty space below row $l-7$, initially empty. If, either in the lowest row of A or in the repository, there

is a node of opposite color than the current color of the right endpoint of L_A's line, use the 4-line to transfer such a node and make it the new right endpoint of L_A's line. Otherwise, use the 4-line to transfer a node of the lowest row of A to the repository.

- Once black has been exhausted from A and the repository (i.e., when u_{2k-3} has been placed; u_{2k-1} and u_{2k} will only be placed in the end as they are part of the 4-line), transfer a red to position u_{2k-2}. If there are no more nodes left, run the termination phase, otherwise transfer the remaining nodes (all red) with the 4-line, one after the other, and attach them as leaves around the blacks of L_A's line, beginning from the position to the left of u_1 counterclockwise, as described above (skipping position u_{2k}).
- Termination phase: the line-with-leaves is ready, apart from positions u_{2k-1}, u_{2k} which require a 2-line from the 4-line. If the position above u_{2k-1} is empty, then extract a 2-line from the 4-line and transfer it to the positions u_{2k-1}, u_{2k}. This completes the transformation. If the position above u_{2k-1} is occupied by a node u_{2k+1}, then place the whole 4-line vertically with its lowest endpoint on u_{2k}. Then rotate the top endpoint counterclockwise, to move above u_{2k+1}, then rotate u_{2k+1} clockwise around it to move to its left, then rotate the node above u_{2k} counterclockwise to move to u_{2k-1}, and finally restore u_{2k+1} to its original position. This completes the construction (the 2-line that always remains can be transferred in the end to a predefined position).

◀

The natural next question is to what extent the 2-line seed assumption can be dropped. Clearly, by Proposition 4, this cannot be always possible. The following lemma gives a sufficient and necessary condition for dropping the 2-line seed assumption.

▶ **Lemma 7.** *A 2-seed can be extracted from a shape iff a single rotation move is available on the shape.*

▶ **Theorem 8.** Rot-Transformability $\in \mathbf{P}$.

Proof. If the two connected input shapes of the same order are not already equal, then, by Lemma 7 and Theorem 6, it suffices to check if both shapes have an available movement. If yes, *accept*, otherwise, *reject*. These checks can be easily performed in polynomial time. ◀

4 Rotation and Connectivity Preservation

In this section, we restrict our attention to transformations that transform a connected shape A to one of its color-consistent connected shapes B, without ever breaking the connectivity of the shape on the way. As already mentioned in the introduction, connectivity preservation is a very desirable property for programmable matter, as, among other positive implications, it guarantees that communication between all nodes is maintained, it minimizes transformation failures, requires less sophisticated actuation mechanisms, and increases the external forces required to break the system apart.

We begin by proving that RotC-Transformability can be decided in deterministic polynomial space.

▶ **Theorem 9.** RotC-Transformability $\in$ **PSPACE**.

As already shown in Theorem 5, the connectivity-preservation constraint increases the class of infeasible transformations. A convenient turnaround in such cases, is to introduce a suitable seed that can assist the transformation. For example, we can circumvent the impossibility of folding a line $u_1, u_2, \ldots, u_n$ in half, by adding a 3-line seed v_1, v_2, v_3, horizontally aligned

over nodes u_3, u_4, u_5 of the line. Interestingly, adding the seed over nodes u_4, u_5, u_6 does not work. Therefore, the problem that we face in such cases, is to find a minimum seed (could be any connected small shape, not necessarily a line) and a placement of that seed, that enables the otherwise infeasible transformation (*Minimum-Seed-Determination* problem). In the rest of this section, we try to identify a minimum seed that can walk the perimeter of any shape, hoping that it will be able to move nodes gradually to a predetermined position, in order to transform the initial shape into a line-with-leaves (as in Theorem 6, but without ever breaking connectivity this time). [2]

▶ **Theorem 10.** *If connectivity must be preserved:* (i) *Any* (≤ 4)*-seed cannot traverse the perimeter of a line,* (ii) *a 6-seed can traverse the perimeter of any discrete-convex shape.*

5 Rotation and Sliding

In this section, we study the combined effect of rotation and sliding movements. We begin by proving that rotation and sliding together are *transformation-universal*, meaning that they can transform any given shape to any other shape of the same size without ever breaking the connectivity during the transformation.

▶ **Theorem 11.** *Let A and B be any connected shapes, such that $|A| = |B| = n$. Then A and B can be transformed to each other by rotations and slidings, without breaking the connectivity during the transformation.*

Proof. It suffices to show that any connected shape A can be transformed to a spanning line L using only rotations and slidings and without breaking connectivity during the transformation. If we show this, then A can be transformed to L and B can be transformed to L (as A and B have the same order, therefore corresponding to the same spanning line L), and by reversibility of these movements, A and B can be transformed to each other via L.

Pick the rightmost column of the grid containing at least one node of A, and consider the lowest node of A in that column. Call that node u. Observe that all cells to the right of u are empty. Let the cell of u be (i, j). The final constructed line will start at (i, j) and end at $(i, j + n - 1)$.

The transformation is partitioned into $n - 1$ phases. In each phase k, we pick a node from the original shape and move it to position $(i, j + k)$, that is, to the right of the right endpoint of the line formed so far. In phase 1, position $(i, j + 1)$ is a cell of the perimeter of A. So, even if it happens that u is a node of degree 1, it can be proved that there must be another such node $v \in A$ that can walk the whole perimeter of $A' = A - \{v\}$. As $u \neq v$, $(i, j + 1)$ is also part of the perimeter of A', therefore, v can move to $(i, j + 1)$ by rotations and slidings. But A' is connected, $A' \cup \{(i, j + 1)\}$ is also connected, and also all intermediate shapes were connected, because v moved on the perimeter and, therefore, it never disconnected from the rest of the shape during its movement.

In general, the transformation preserves the following invariant. At the beginning of phase k, $1 \leq k \leq n - 1$, there is a connected shape $S(k)$ (where $S(1) = A$) to the left of of column j (j inclusive) and a line of length $k - 1$ starting from position $(i, j + 1)$ and growing to the right. Restricting attention to $S(k)$, there is always a $v \neq u$ that could (hypothetically) move to position $(i, j + 1)$ if it were not occupied. This implies that before the final movement that

[2] Another way to view this, is as an attempt to simulate the universal transformations based on combined rotation and sliding (presented in Section 5), in which single nodes are able to walk the perimeter of the shape.

would place v on $(i, j+1)$, v must have been in $(i+1, j)$ or $(i+1, j+1)$, if we assume that v always walks in the clockwise direction. Observe now that from each of these positions v can perform zero or more right slidings above the line in order to reach the position above the right endpoint $(i, j+k-1)$ of the line. When this occurs, a final clockwise rotation makes v the new right endpoint of the line. The only exception is when v is on $(i+1, j+1)$ and there is no line to the right of (i, j) (this implies the existence of a node on $(i+1, j)$, otherwise connectivity of $S(k)$ would have been violated). In this case, v just performs a single downward sliding to become the right endpoint of the line. ◀

▶ **Theorem 12.** *The transformation of Theorem 11 requires $\Theta(n^2)$ movements in the worst case.*

Theorem 12 shows that the above generic strategy is slow in some cases, as is the case of transforming a staircase shape into a spanning line. A *staircase* is defined as a shape of the form $(i, j), (i-1, j), (i-1, j+1), (i-2, j+1), (i-2, j+2), (i-3, j+2), \ldots$. We shall now show that there are pairs of shapes for which any strategy and not only this particular one, may require a quadratic number of steps to transform one shape to the other.

▶ **Definition 13.** Define the *potential of a shape A* as its minimum "distance" from the line L, where $|A| = |L|$. The *distance* is defined as follows: Consider any placement of L relative to A and any pairing of the nodes of A to the nodes of the line. Then sum up the Manhattan distances [3] between the nodes of each pair. The minimum sum between all possible relative placements and all possible pairings is the distance between A and L and also A's potential.

Observe that the potential of the line is 0 as it can be totally aligned on itself and the sum of the distances is 0.

▶ **Lemma 14.** *The potential of a staircase is $\Theta(n^2)$.*

Proof. We prove it for horizontal placement of the line, as the vertical case is symmetric. Any such placement leaves either above or below it at least half of the nodes of the staircase (maybe minus 1). W.l.o.g. let it be above it. Every two nodes, the height increases by 1, therefore there are 2 nodes at distance 1, 2 at distance 2,..., 2 at distance n/4. Any matching between these nodes and the nodes of the line gives for every pair a distance at least as large as the vertical distance between the staircase's node and the line, thus, the total distance is at least $2 \cdot 1 + 2 \cdot 2 + ... + 2 \cdot (n/4) = 2 \cdot (1 + 2 + ... + n/4) = (n/4) \cdot (n/4 + 1) = \Theta(n^2)$. We conclude that the potential of the staircase is $\Theta(n^2)$. ◀

▶ **Theorem 15.** *Any transformation strategy based on rotations and slidings which performs a single movement per step requires $\Theta(n^2)$ steps to transform a staircase into a line.*

Proof. To show that $\Omega(n^2)$ movements are needed to transform the staircase into a line, it suffices to observe that the difference in their potentials is that much and that one rotation or one sliding can decrease the potential by at most 1. ◀

▶ Remark. The above lower bound is independent of connectivity preservation. It is just a matter of the total distance based on single distance-one movements.

Finally, it is interesting to observe that such lower bounds can be computed in polynomial time, because there is a polynomial-time algorithm for computing the distance between two shapes.

---

[3] The Manhattan distance between two points (i, j) and (i', j') is given by $|i - i'| + |j - j'|$.

▶ **Proposition 16.** *Let A and B be connected shapes. Then their distance $d(A, B)$ can be computed in polynomial time.*

To give a faster transformation either pipelining must be used (allowing for more than one movement in parallel) or more complex mechanisms that move sub-shapes consisting of many nodes, in a single step. We follow the former approach, by allowing an unbounded number of rotation and/or sliding movements to occur simultaneously in a single step (though, in pairwise disjoint areas).

▶ **Proposition 17.** *There is a pipelining strategy that transforms a staircase into a line in $O(n)$ parallel time.*

Proof. Number the nodes of the staircase 1 through n starting from the top and following the staircase's connectivity until the bottom-right node is reached. These gives an odd-numbered upper diagonal and an even-numbered lower diagonal. Node 1 moves as in Theorem 11. Any even node w starts moving as long as its upper odd neighbor has reached the same level as w (e.g., node 2 first moves after node 1 has arrived to the right of node 3). Any odd node $z > 1$ starts moving as long as its even left neighbor has moved one level down (e.g., node 3 first moves after node 2 has arrived to the right of 5). After a node starts moving, it moves in every step as in Theorem 11 (but now many nodes can move in parallel, implementing a pipelining strategy). It can be immediately observed that any node i starts after at most 3 movements of node $i - 1$ (actually, only 2 movements for even i), so after, roughly, at most $3n$ steps, node $n - 2$ starts. Moreover, a node that starts, arrives at the right endpoint of the line after at most n steps, which means that after at most $4n = O(n)$ steps, all nodes have taken their final position in the line. ◀

Proposition 17 gives a hint that pipelining could be a general strategy to speed-up transformations. We next show how to generalize this technique to any possible pair of shapes.

▶ **Theorem 18.** *Let A and B be any connected shapes, such that $|A| = |B| = n$. Then there is a pipelining strategy that can transform A to B (and inversely) by rotations and slidings, without breaking the connectivity during the transformation, in $O(n)$ parallel time.*

Proof. The transformation is a pipelined version of the sequential transformation of Theorem 11. Now, instead of picking an arbitrary next candidate node of $S(k)$ to walk the perimeter of $S(k)$ clockwise, we always pick the rightmost clockwise node $v_k \in S(k)$, that is, the node that has to walk the shortest clockwise distance to arrive at the line being formed. This implies that the subsequent candidate node v_{k+1} to walk is always "behind" v_k in the clockwise direction and is either already free to move or is enabled after v_k's departure. Observe that after at most 3 clockwise movements, v_k can no longer be blocking v_{k+1} on the (possibly updated) perimeter. Moreover, the clockwise move of v_{k+1} only introduces a gap in its original position, therefore it only affects the structure of the perimeter "behind" it. The strategy is to start the walk of node v_{k+1} as soon as v_k is no longer blocking its way. As in Proposition 17, once a node starts, it moves in every step, and again any node arrives at the end of the forming line after at most n movements. It follows that if the pipelined movement of nodes cannot be blocked in any way, after $4n = O(n)$ steps all nodes must have arrived at their final positions. Observe now that the only case in which pipelining could be blocked is when a node is sliding through a (necessarily dead-end) "tunnel" of height 1. To avoid this, the nodes shortcut the tunnel, by visiting only its first position (i, j) and then simply skipping the whole walk inside it (that walk would just return them to position (i, j) after a number of steps). ◀

We next show that even if A and B are labeled shapes, that is, their nodes are assigned the indices $1, \ldots, n$ (uniquely, i.e., without repetitions), we can still transform the labeled A to the labeled B with only a linear increase in parallel time. We only consider transformations in which the nodes never change indices in any way (e.g., cannot transfer them, or swap them), so that each particular node of A must eventually occupy (physically) a particular position of B (the one corresponding to its index).

▶ **Corollary 19.** *The labeled version of the transformation of Theorem 18 can be performed in $O(n)$ parallel time.*

An immediate observation is that a linear-time transformation does not seem satisfactory for all pairs of shapes. To this end, take a square S and rotate its top-left corner u, one position clockwise, to obtain an almost-square S'. Even though, a single counter-clockwise rotation of u suffices to transform S' to S, the transformation of Theorem 18 may go all the way around and first transform S' to a line and then transform the line to S. In this particular example, the distance between S and S', according to Definition 13, is 2, while the generic transformation requires $\Theta(n)$ parallel time. So, it is plausible to ask if any transformation between two shapes A and B can be performed in time that grows as a function of their distance $d(A, B)$. We show that this cannot always be the case, by presenting two shapes A and B with $d(A, B) = 2$, such that A and B require $\Omega(n)$ parallel time to be transformed to each other.

▶ **Proposition 20.** *There are two shapes A and B with $d(A, B) = 2$, such that A and B require $\Omega(n)$ parallel time to be transformed to each other.*

In the full version, we also study the RS-Transformability problem in distributed systems and give an algorithm that transforms a large family of shapes into a spanning line:

▶ **Theorem 21.** *We provide an algorithm, called* Compact Line*, that can transform any compact shape into a spanning line.*

6 Conclusions and Further Research

There are many open problems related to the findings of the present work. First, a compromise could be to allow some restricted degree of connectivity breaking. There are other meaningful "good" properties that we would like to maintain throughout a transformation, like the *strength* of the shape.

Transformation seems in general harder if we restrict the maximum area or dimensions during its course. Also, restricting the boundaries gives models equivalent to several interesting puzzles, like the famous 15-puzzle. Techniques developed in the context of puzzles could prove valuable for analyzing and characterizing discrete programmable matter systems.

We intentionally restricted attention to very minimal actuation mechanisms. More sophisticated mechanical operations would enable a larger set of transformations and possibly also reduce the time complexity. Such an example is the ability of a node to become inserted between two neighboring nodes.

There are also some promising specific technical questions: What is the exact complexity of RotC-Transformability? What is the complexity of computing the optimum transformation? Can it be satisfactorily approximated? Finally, regarding the distributed transformations, there are various interesting variations of the model considered here, that would make sense. One of them is to assume nodes that are oblivious w.r.t. their orientation.

Abstract

We initiate the study of network monitoring algorithms in a class of hybrid networks in which the nodes are connected by an *external network* and an *internal network* (as a short form for externally and internally controlled network). While the external network lies outside of the control of the nodes (or in our case, the monitoring protocol running in them) and might be exposed to continuous changes, the internal network is fully under the control of the nodes. As an example, consider a group of users with mobile devices having access to the cell phone infrastructure. While the network formed by the WiFi connections of the devices is an external network (as its structure is not necessarily under the control of the monitoring protocol), the connections between the devices via the cell phone infrastructure represent an internal network (as it can be controlled by the monitoring protocol). Our goal is to continuously monitor properties of the external network with the help of the internal network. We present scalable distributed algorithms that efficiently monitor the number of edges, the average node degree, the clustering coefficient, the bipartiteness, and the weight of a minimum spanning tree. Their performance bounds demonstrate that monitoring the external network state with the help of an internal network can be done much more efficiently than just using the external network, as is usually done in the literature.

1 Introduction

In this paper we propose a new model for the study of distributed algorithms for communication networks that is based on a class of hybrid networks that is becoming more and more important. In this class of hybrid networks, the nodes are connected by an *external*

network and an *internal network*. While the external network is not under the control of the nodes, the internal network is fully under their control. Such hybrid networks can be found at a physical as well as logical level. Consider, for instance, the case that we have a set of wireless devices with access to the cell phone infrastructure that are dispersed over a limited area like a city center so that they can form a connected network using their WiFi connections. The advantage of this type of network is that the devices would in principle be able to exchange information without the use of the cell phone infrastructure, which would save costs. However, this may come at the price of having large message delays and even being unable to handle certain tasks as there might be network partitions from time to time. Therefore, if it is possible to design protocols that only require a small amount of message exchanges via the cell phone infrastructure in order to solve certain tasks much faster and more reliably than via the WiFi network, users may find it acceptable to make use of the cell phone infrastructure. Another example is an expedition or a rescue team that is connected via satellite telephones, which nowadays can support both satellite as well as wireless communication. In the logical world, one can envision a peer-to-peer network formed by friendship links in a social network. Just communicating via these friendship links has the advantage that all interactions are trusted. However, due to the irregular structure of the social network it has the disadvantage that it might be hard to perform certain tasks like network monitoring or finding anyone efficiently. Therefore, it might also be useful to have a network of untrusted links on top of the social network in order to be able to quickly approximate certain properties of it or to find shortest paths. A common theme in all of these examples is having two communication modes that significantly differ concerning their control and in which control comes with costs like financial cost, acceptance, reliability, or integrity. There is already a large body of literature on network algorithms for the case of static or dynamic networks whose topology is not under the control of the nodes. On the other side, there also exists an abundance of network algorithms in which the topology is fully under the control of the nodes, like in peer-to-peer systems. However, to the best of our knowledge, nothing rigorous in the context of network monitoring has been shown yet for *combinations* of these networks, so this paper initiates the rigorous study of this direction.

1.1 Model and Problem Statement

We consider networks with a *static* node set and a *dynamic* edge set. Time proceeds in *synchronous rounds* and for each round i we are given a set of undirected edges E_i. The *external network* in round i is represented by the undirected graph $G_i = (V, E_i)$. We assume that the degree of G_i is polylogarithmic for all i. An algorithm has no control over the edges in E_i, however it can establish additional *overlay edges* to form an *internal network* or *overlay network*: Each node u has a unique *identifier* $\mathrm{id}(u)$ which is a bit string of length $O(\log n)$ where $n = |V|$. Let $D_i(u)$ be the set of identifiers stored by a node u in round i. We define the set of overlay edges in round i as $D_i = \{(u, v) \mid u \in V \text{ and } v \in D_i(u)\}$. A node has immediate access to the identifiers of its neighbors in G_i and can store such an identifier for future reference. In round i, a node u can send a distinct message to each node v such that $\{u, v\} \in E_i$ or $(u, v) \in D_i$. A message sent in round i arrives at the beginning of round $i + 1$. The local memory and computation of the nodes is unbounded. However, a node can send and receive at most polylogarithmically many bits in each round.

We investigate *monitoring problems*. In these problems, a designated node s that we call the *monitor node* or simply *monitor* has to continuously observe a property of the external network like the number of edges or the weight of a minimum spanning tree. Formally, a property p is a function from the set of undirected graphs into some set of property values.

Since the external network G_i is dynamic, the property value $p(G_i)$ can change from round to round. We say an algorithm *monitors a property* p with *setup time* i_0 and *delay* δ if for all rounds $i \geq i_0$ the monitor node outputs the property value $p(G_i)$ by round $i + \delta$. We refer to the first i_0 rounds of the execution of a monitoring algorithm as the *setup phase* and refer to the remaining rounds as the *monitoring phase*. Initially, the set of overlay edges D_0 is empty. An algorithm can use the setup phase to construct an initial internal network that supports the computation of the property value. It can continue to adapt the internal network during the monitoring phase. We assume the graph G_0 to be connected. Beyond this, we make no assumptions about the evolution of the edge set.

1.2 Related Work

In the networking community, the name "hybrid network" has been used in the context of networks containing equipment from multiple vendors, consisting of different physical networks or communication modes, or networks incorporating both peer-to-peer and client-server approaches. These topics are not related to our work, so we do not consider them.

There is a large body of literature on overlay networks, especially in the context of peer-to-peer systems. Whereas most of the proposed overlay networks do not worry about the underlying network, there is also a number of proposals for so-called locality-aware overlays, with prominent examples like Tapestry [37] and Pastry [34]. However, these constructions are only concerned about adapting or optimizing the overlay to the underlying network and do not aim at monitoring properties of the underlying network with the help of the overlay.

The dynamic external network assumed by our model is related to the *dynamic graph model* introduced by Kuhn et al. [24], in which an adversary changes the edge set of a graph in every round. Kuhn et al. [24] focus on solving the counting and the token dissemination problem in that model, which has been further considered, for example, in [12, 15] (see [5] for an overview). Abshoff and Meyer auf der Heide study how to perform continuous aggregation in these networks [1]. However, like the other works in this area, they do not consider establishing additional overlay edges. Another approach related to ours is the work by Michail and Spirakis [28], which extends the population protocol model to a model in which nodes can decide whether to keep connections proposed to them or not, but there is no underlying network to monitor.

Some of our algorithms make use of techniques particularly known from the field of parallel computation. For example, it is well-known how to use *pointer jumping* [18] in order to perform rapid tree traversals in PRAMs (see e.g. [3, 19, 35]). Furthermore, there exists an abundance of parallel algorithms computing MSTs in such models, the best of which achieve a runtime of $O(\log n)$ (see [16] for an overview). The algorithm presented in Section 2 has some similarities with [19]. However, we are not aware of any distributed implementation of such an algorithm with runtime $o(\log^2 n)$ that does not cause high node congestion. This is also the problem with the various algorithms proposed for the congested clique model, which has recently received a considerable amount of attention (e.g., [7, 11, 17, 25, 27]).

Our algorithms make extensive use of a subroutine for the construction of overlay networks that we present in Section 2. This subroutine transforms a given graph into a rooted tree of constant degree and depth $O(\log n)$. Angluin et al. [2] proposed a similar subroutine that achieves the same result and that even works in an asynchronous setting. However, the subroutine of Angluin et al. is randomized while our subroutine is deterministic. As a consequence, all monitoring algorithms presented in this work are also fully deterministic. Furthermore, our subroutine can be used for the efficient construction of a spanning tree of a given graph, which cannot directly be achieved using the approach by Angluin et al.

Table 1 This table summarizes the results of this work. W is the maximum weight of an edge in the graph. The algorithm for monitoring the exact weight of a minimum spanning tree requires integral edge weights while the approximation algorithm has no such requirement. The latter algorithm approximates the weight M up to an additive factor of $\pm\varepsilon M$.

Monitoring Problem	Setup Time	Delay	Section
Number of Edges	$O(\log^2 n)$	$O(\log n/\log\log n)$	3
Average Node Degree	$O(\log^2 n)$	$O(\log n/\log\log n)$	3
Clustering Coefficient	$O(\log^2 n)$	$O(\log n/\log\log n)$	3
Bipartiteness	0	$O(\log^2 n)$	4
Exact MST Weight	0	$O(W+\log^2 n)$	5.1
Approximate MST Weight	$O(\log^2 n)$	$O(\log(W)/\varepsilon\cdot\log^2(W/\varepsilon)+\log n/\log\log n)$	5.2

In the algorithms presented in Section 3 the monitor continuously collects data from the nodes of the network by performing *aggregation*. There is a huge amount of work on aggregation in the context of sensor networks, but research in this area has focused on monitoring environmental properties, the state of systems (like bridges or airplanes) or facilities (like warehouses). Distributed aggregation has also been studied extensively for conventional, static networks (see, e.g., [4, 22, 23] or [26] for a comprehensive overview), but not for hybrid forms as considered in this paper.

One of the network properties considered in this work is the weight of a minimum spanning tree (or MST), see Section 5. The problem of computing an MST in a distributed manner is well studied, see for example [13, 14, 32, 33]. The problem of computing only the *weight* of an MST instead of the MST itself has been studied in the area of sequential sublinear algorithms. This line of research was initiated by Chazelle et al. [8] and continued in [6, 9, 10]. Our algorithms for monitoring the weight of an MST apply the ideas of Chazelle et al. [8] in a distributed context and also incorporate some ideas from [10].

1.3 Our Contribution

We initiate the study of hybrid networks consisting of externally and internally controlled edges and present *deterministic* algorithms for *monitoring network properties* in such networks. Our results are summarized in Table 1. As a byproduct of the algorithms for monitoring the weight of a minimum spanning tree, we also present algorithms for the distributed computation of minimum spanning trees in hybrid networks. Since the delays trivially increase to $\Omega(n)$ in the worst case when just using an external network, our results demonstrate that with the help of hybrid networks monitoring can be done exponentially faster compared to just having an external network.

2 Setup Phase

All monitoring algorithms presented in this work that rely on a dedicated setup phase use a common algorithm for the construction of the initial overlay network. This algorithm organizes the nodes into a tree T of polylogarithmic degree and depth $O(\log n/\log\log n)$ that is rooted at the monitor. In this section, we first present a more general algorithm that we refer to as the *Overlay Construction Algorithm*. This algorithm shares some similarities with an algorithm of Angluin et al. [2]. The algorithm is also frequently used as a subroutine throughout the remainder of this work. Based on this algorithm, we describe how the desired

tree T can be constructed at the end of the section. For simplicity, we assume that every node knows the total number of nodes n. The algorithms can be modified to remove this assumption.

For a given bidirected connected graph G of polylogarithmic degree, the Overlay Construction Algorithm arranges the nodes of G into a tree of constant degree and depth $O(\log n)$. On a high level, the algorithm works as follows. It operates on *supernodes* which are groups of nodes that act in coordination. Let the identifier of a supernode be the highest identifier of the nodes it contains. Define two supernodes u, v to be adjacent if there are nodes x, y that are adjacent in G such that x is in u and y is in v. Initially, each node forms a supernode on its own. The algorithm alternatingly executes a *grouping step* and a *merging step*. In the grouping step, each supernode u determines the neighboring supernode v with the highest identifier. If $\mathrm{id}(v) > \mathrm{id}(u)$ then u sends a *merge request* to v. Consider the graph whose node set is the set of all supernodes and that contains a directed edge (u, v) if u sent a merge request to v. Since each supernode sends at most one merge request to a supernode of higher identifier, this graph is a forest. During the merging step, each tree of this forest is merged into a new supernode. Before we describe how this high-level algorithm can be implemented by the nodes, we analyze the number of iterations of consecutive grouping and merging steps until only a single supernode remains. The following lemma can be shown by observing that each supernode merges with another supernode within at most 2 iterations.

▶ **Lemma 1.** *After $O(\log n)$ iterations only a single supernode remains.*

At the beginning of every *grouping step*, the following *invariant* holds: Each supernode is internally organized in an overlay forming a tree of constant degree and depth $O(\log n)$ that is rooted at the node with the highest identifier and each node knows the identifier of its supernode. The nodes cooperatively simulate the behavior of their respective supernodes during the grouping step as follows. Consider a supernode u and the corresponding internal tree T_u. First, every node of u sends $\mathrm{id}(u)$ along every incident edge in the original graph G. Thereby, every node learns the identifiers of its neighboring supernodes. Then, the nodes of u use a convergecast along T_u to determine the identifier of the supernode v with the highest identifier among the neighbors of u. This convergecast also collects the identifier of the node x with the highest identifier in u that is adjacent to a node in v. Once this convergecast is complete, the root of T_u knows both $\mathrm{id}(v)$ and $\mathrm{id}(x)$. If $\mathrm{id}(v) > \mathrm{id}(u)$ then the root of u sends a message to x. Upon receiving this message, x sends a merge request to a neighboring node in v and sends a broadcast through T_u to establish itself as the new root of T_u. The nodes in G wait with starting the merging step until $O(\log n)$ rounds have passed to guarantee that the above operations are completed in all supernodes and all nodes start the merging step at the same time.

At the beginning of every *merging step*, we have the following situation. Consider the graph consisting of the internal trees of all supernodes together with all edges along which a merge request has been sent. This graph is a forest and the trees of this forest form the new supernodes resulting from the merging step. Therefore, the nodes of each new supernode v are already arranged into a tree T_v. Furthermore, v contains exactly one former root node that did not instruct a node to send a merge request. It is not hard to see that this node has the highest identifier in v and therefore becomes the root of T_v. In its current state, T_v can have up to polylogarithmic degree and linear depth. To restore the invariants required at the beginning of a grouping step, we have to transform T_v into a tree of constant degree and depth $O(\log n)$. Furthermore, we have to make sure that all nodes in v know the identifier $\mathrm{id}(v)$ of the root of T_v.

First, we reorganize T_v into a *child-sibling tree*. For this, each inner node y arranges its children into a path sorted by increasing identifier and only keeps the child with the lowest identifier. Each former child of y changes its parent to be its predecessor on the path and stores its successor as a *sibling*. In the resulting child-sibling tree, each node stores at most three identifiers: a parent, a sibling, and a child. By interpreting the sibling of a node as a second child, we get a binary tree. This transformation of T_v into a binary tree takes $O(1)$ rounds.

Based on this binary tree, we construct a *ring* of *virtual nodes* as follows. Consider the depth-first traversal of the tree that visits the children of each node in order of increasing identifier. A node occurs at most three times in this traversal. Let each node act as a distinct virtual node for each such occurrence and let $k \leq 3n$ be the number of virtual nodes. A node can locally determine the predecessor and successor of its virtual nodes according to the traversal. Therefore, the nodes can connect their virtual nodes into a ring in $O(1)$ rounds.

Next, we use pointer jumping to quickly add *chords* (i.e., shortcut edges) to the ring. The virtual nodes execute the following protocol for $\lfloor \log n \rfloor + 1 \geq \lfloor \log k \rfloor - 1$ rounds. Each virtual node y learns two identifiers ℓ_t and r_t in each round t of this protocol. Let ℓ_0 and r_0 be the predecessor and successor of y in the ring. In round t, y sends ℓ_t to r_t and vice versa. At the beginning of round $t+1$, y receives one identifier from ℓ_t and r_t, respectively. It sets ℓ_{t+1} to the identifier received from ℓ_t and r_{t+1} to the identifier received from r_t. It then proceeds to the next round of the protocol. In every round of this protocol each virtual node adds a new chord to the ring by introducing its latest neighbors to each other. The distance between these neighbors w.r.t the ring doubles from round to round up to the point where the distance exceeds the number of virtual nodes k. Based on this observation, it is not hard to show that after the specified number of rounds, the diameter of the graph has reduced to $O(\log n)$ while the degree has grown to $O(\log n)$. Once the protocol finished, the root of v initiates a broadcast from one of its virtual nodes followed by a convergecast to determine the number of virtual nodes k.

Finally, we use the chords to construct a binary tree of depth $O(\log n)$. For this, the root of v initiates a broadcast by sending a message to its neighbors $\ell_{t'}$ and $r_{t'}$ where $t' = \lfloor \log k \rfloor - 1$. A node that receives the broadcast after t steps forwards it to $\ell_{t'}$ and $r_{t'}$ where $t' = \max\{\lfloor \log k \rfloor - t - 1, 0\}$. It is not hard to see that the binary tree constructed by this broadcast has depth $O(\log n)$ and contains all nodes of the ring. At this point, the nodes discard all overlay edges constructed so far and only keep the edges of the binary tree. We then merge the virtual nodes back together such that each node adopts the edges of its virtual nodes. This results in a graph of degree at most 6 and diameter $O(\log n)$. Note that this graph is not necessarily a tree. To construct a tree that satisfies the invariants for the grouping step, the root of v sends another broadcast through the resulting graph to construct a breadth-first search tree that has constant degree and diameter $O(\log n)$. This broadcast also informs all nodes in v about $\mathrm{id}(v)$. The operations described above take $O(\log n)$ rounds overall. As before, all nodes in G wait for $O(\log n)$ rounds to pass so that they enter the next grouping step at the same time.

Once only a single supernode u remains, which is the case if during a grouping step no node reports the identifier of a neighboring supernode, T_u covers all nodes of G and has the desired properties. Since the algorithm runs for $O(\log n)$ iterations and each iteration takes $O(\log n)$ rounds, we have the following theorem.

▶ **Theorem 2.** *Given any bidirected connected graph G of n nodes and polylogarithmic degree, the Overlay Construction Algorithm constructs a constant degree tree of depth $O(\log n)$ that contains all nodes of G and that is rooted at the node with the highest identifier. The algorithm takes $O(\log^2 n)$ rounds.*

Theorem 2 directly implies the following corollary.

▶ **Corollary 3.** *Consider a bidirected graph G of n nodes and polylogarithmic degree. For each connected component C of G, the Overlay Construction Algorithm constructs a constant degree tree of depth $O(\log |C|)$ that contains all nodes of C and that is rooted at the node with the highest identifier in C. The algorithm takes $O(\log^2 |C|)$ rounds in each component and $O(\log^2 n)$ rounds overall.*

Finally, note that the algorithm only sends merge requests along edges of G. This gives rise to the following observation.

▶ **Observation 4.** *For a bidirected connected graph G, the edges along which the Overlay Construction Algorithm sends the merge requests form a spanning tree of G.*

So by letting the nodes locally mark the edges that carry a merge request, the algorithm can be used for the distributed construction of a spanning tree of G in $O(\log^2 n)$ time. While this observation is not immediately relevant for the setup phase, it will be useful in later sections.

Based on the Overlay Construction Algorithm, it is easy to achieve the goal for the setup phase of organizing the nodes into a tree T of polylogarithmic degree and depth $O(\log n / \log\log n)$ that is rooted at the monitor s. At the beginning of the setup phase, each node stores the identifiers of its neighbors in the given graph G_0 that represents the external network. This effectively creates a bidirected overlay network that directly corresponds to the undirected graph G_0. Note that G_0 is connected by assumption. Therefore, we can use the Overlay Construction Algorithm to construct a tree of constant degree and depth $O(\log n)$ that contains all nodes in the network. Once the algorithm terminates, s broadcasts a message through the resulting tree to establish itself as the new root. This does not increase the asymptotic depth of the tree. We then decrease the depth to $O(\log n / \log\log n)$ as follows. Each node x broadcasts its identifier down the tree up to a distance of $\lceil \log\log n \rceil$. Every node that receives the broadcast of x establishes an edge to x. It is not hard to see that this creates a graph of at most polylogarithmic degree and diameter $O(\log n / \log\log n)$. Finally, s sends a broadcast through this graph to create a breadth-first search tree that has the desired properties. We have the following theorem.

▶ **Theorem 5.** *A setup time of $O(\log^2 n)$ rounds is sufficient to organize the nodes of the network into a tree T of polylogarithmic degree and depth $O(\log n / \log\log n)$.*

Unless otherwise stated, we assume in the following sections that the setup phase is executed as described above.

3 Three Simple Monitoring Problems

In order to introduce some basic concepts that underlie all monitoring algorithms presented in this work, we first consider three simple monitoring problems. Specifically, we show how to monitor the number of edges, the average node degree, and the clustering coefficient of the network by performing *aggregation* on the tree T constructed during the setup phase.

Consider the problem of monitoring the number of edges. We first present an algorithm that efficiently determines the number of edges in a graph G and then show how this algorithm can be used to continuously monitor the number of edges. It is well known that the number of edges in a graph is $|E| = 1/2 \cdot \sum_{u \in V} \deg(u)$ where $\deg(u)$ is the degree of a node u. Therefore, we can compute $|E|$ by aggregating the sum of all node degrees in the following way. In the first round, each leaf node u in T sends $\deg(u)$ to its parent. Once an inner node

u has received a value x_j from each of its children, it sends $\deg(u) + \sum_j x_j$ to its parent. After $O(\log n / \log\log n)$ rounds, the monitor s has received a value from each of its children and can use these values together with its own degree to compute $|E|$ as described above.

To continuously monitor $|E_i|$ for every $i \geq i_0$, the above algorithm is executed in a *pipelined fashion*: In each round $i \geq i_0$ a new instance of the algorithm is started. The instances run in parallel and do not interact with each other. At the beginning of a round i, each node stores the identifiers of its neighbors in the graph G_i that represents the external network to create a copy of the graph in form of an overlay network that the algorithm can operate on. This copy is discarded once the corresponding instance of the algorithm terminates. The messages sent by an instance of the algorithm are labeled with the round number in which the instance was started so that received messages can be correctly assigned. Note that the number of bits a node sends and receives per round in the given algorithm is polylogarithmic. Since the delay of the algorithm is also polylogarithmic, the number of bits a node sends and receives in the pipelined execution is polylogarithmic as well. We have the following theorem.

▶ **Theorem 6.** *The number of edges can be monitored with setup time $O(\log^2 n)$ and delay $O(\log n / \log\log n)$.*

In the remainder of this work, we only present algorithms that compute the value of a network property for a single graph G and implicitly assume that the respective algorithm is executed in a pipelined fashion to solve the monitoring problem under consideration.

Based on the ideas of the algorithm above, it is easy to solve a number of monitoring problems that can be reduced to aggregation. For example, one can monitor the average node degree by letting s multiply the result of the given algorithm with $2/n$ before outputting it. This gives us the following corollary.

▶ **Corollary 7.** *The average node degree can be monitored with setup time $O(\log^2 n)$ and delay $O(\log n / \log\log n)$.*

As a final example, we consider the *clustering coefficient* of a network [36]. Intuitively, the clustering coefficient reflects the relative number of triangles in a graph G. It is particularly relevant in the context of biological and social networks [29, 30, 31, 36]. Formally, the clustering coefficient of a node u is defined as

$$C(u) = \frac{2 \cdot |\{v, w \in N(u) \mid \{v, w\} \in E\}|}{\deg(u) \cdot (\deg(u) - 1)},$$

where $N(u)$ is the set of neighbors of u. The clustering coefficient of a graph G is defined as $C(G) = 1/n \cdot \sum_{u \in V} C(u)$. Each node u can compute $C(u)$ in constant time by communicating with its neighbors. Therefore, $C(G)$ can be computed by aggregating the sum of all $C(u)$ along T and dividing the result by n at the monitor. We have the following theorem.

▶ **Theorem 8.** *The clustering coefficient can be monitored with setup time $O(\log^2 n)$ and delay $O(\log n / \log\log n)$.*

4 Bipartiteness

In this section, we consider the problem of monitoring whether the network forms a *bipartite* graph. Our algorithm is based on the following commonly known approach (see e.g. [20]). Given a connected graph G, compute a rooted spanning tree of G and assign a color from $\{0, 1\}$ to each node that corresponds to the parity of its depth in the spanning tree. We say

an edge is *valid* if it connects nodes of different colors and *invalid* otherwise. G is bipartite if and only if all edges are valid. It remains to show how this approach can be implemented efficiently in our framework.

According to Observation 4, we can use the Overlay Construction Algorithm to mark the edges of a spanning tree S in G. Define the monitor s to be the root of S. Each node has to determine the parity of its depth in S to set its color. Since S might have linear depth, a simple broadcast from s does not constitute an efficient solution to this problem. Instead, we use pointer jumping along a depth-first traversal of S to determine the colors of the nodes. We define the traversal of S as follows. The traversal starts at s and moves to the neighbor of s in S with the lowest identifier. For a node u, let $u_0, \ldots, u_{\deg(u)-1}$ be the neighbors of u in S arranged by increasing identifier. When the traversal reaches u from a node u_i, it continues on to node $u_{(i+1) \bmod \deg(u)}$. The traversal finishes when it reaches s from the neighbor of s in S with the highest identifier. Define the *traversal distance* $d(u)$ to be the number of steps required to reach u for the first time in this traversal. As we will show in Lemma 9, the parity of $d(u)$ equals the parity of the depth of u in S. For now, we focus on computing $d(u)$ efficiently for all nodes.

Each node u simulates one virtual node for each occurrence of u in the traversal, and the nodes connect these virtual nodes into a ring. More specifically, each node u simulates virtual nodes $v_0, \ldots, v_{\deg(u)-1}$ such that v_i is the successor of a virtual node of u_i and the predecessor of a virtual node of $u_{(i+1) \bmod \deg(u)}$ in the ring. Note that the resulting ring consists of $2(n-1)$ virtual nodes. We use pointer jumping to add chords to the ring following the same protocol we used during the merging step of the Overlay Construction Algorithm. We define ℓ_0 to be the successor of a virtual node and r_0 to be the predecessor of a virtual node. We execute the protocol for $t = \lfloor \log(2(n-1)) \rfloor$ rounds so that each node constructs chords ℓ_i and r_i for each $1 \leq i \leq t$. Each chord ℓ_i (resp. r_i) bridges a distance of exactly 2^i along the ring. The chords allow us to efficiently compute the values $d(u)$ in the following way. Let v^* be the virtual node simulated by s that precedes a virtual node of the neighbor of s with the lowest identifier. v^* stores the value 0 and initiates a broadcast by sending a message with value 2^i along each chord ℓ_i for $0 \leq i \leq t$. Consider a virtual node that receives a broadcast message and that has not yet stored a value. Let x be the value associated with the received message. The virtual node stores x and sends a message containing the value $x + 2^i$ along each chord ℓ_i for $0 \leq i \leq t$. It is not hard to see that this broadcast reaches all virtual nodes within $O(\log n)$ rounds and the value stored at a virtual node v after the broadcast finishes corresponds to the length of the path from v^* to v along the ring. Therefore, each node u can determine the value $d(u)$ by taking the minimum of the values stored at its virtual nodes. Once all nodes computed their traversal distance in this way, each node u determines whether it is incident to an invalid edge by checking for each neighbor w in G whether $d(u) \equiv d(w) \mod 2$. Then, the nodes use a convergecast to inform s whether there is an invalid edge. If so, s outputs that G is not bipartite. Otherwise, s outputs that G is bipartite.

To establish the correctness of the algorithm, we show the following lemma.

▶ **Lemma 9.** *For each node u, the parity of the depth of u equals the parity of $d(u)$.*

Proof. Note that the tree is traversed in a depth-first order. Therefore, the traversal takes an even number of steps between any two visits of the same node. Let P be the shortest path from s to u in S. The length of P equals the depth of u. The traversal follows P but takes a detour whenever it explores a branch outside of P. By the argument above, each such detour has even length. Therefore, the parity of the depth of u equals the parity of $d(u)$. ◀

We can monitor bipartiteness for a disconnected graph by performing the above algorithm on its connected components and aggregating the results on the tree T built in the setup phase. Furthermore, we can reduce the setup time to 0 by delaying the first monitoring phase until T is constructed, which does not asymptotically increase the total delay. This implies the following theorem.

▶ **Theorem 10.** *The bipartiteness of a graph can be monitored with setup time* 0 *and delay* $O(\log^2 n)$.

5 Minimum Spanning Tree

We now turn to the problem of monitoring the *weight* of a *minimum spanning tree* (or *MST*). We assume that the edge set changes from round to round but the external network always stays connected. Additionally, we assume that each edge has a weight that can also change every round. We present an algorithm that monitors the exact MST weight in Section 5.1 and an algorithm that monitors an approximation of the MST weight with a shorter delay in Section 5.2. Both algorithms are based on a sequential approximation algorithm by Chazelle et al. [8]. As a byproduct, we describe in Section 5.3 how the algorithms for computing the MST weight can be adapted for the distributed computation of an actual MST.

5.1 Exact MST Weight

The main idea behind the algorithm is to reduce the computation of the weight of an MST in a graph G to counting the number of connected components in certain subgraphs of G. This idea was first introduced by Chazelle et al. [8]. We assume that the edge weights are taken from the set $\{1, 2, \dots, W\}$ for some given $W \in \mathbb{N}$. Define the *threshold graph* $G^{(\ell)}$ to be the subgraph of G consisting of all edges with weight at most ℓ, and define $c^{(\ell)}$ to be the number of connected components in $G^{(\ell)}$. The MST weight M can be computed from the values $c^{(\ell)}$ as shown in the following lemma.

▶ **Lemma 11** (Chazelle et al. [8])**.** *In a graph with edge weights from* $\{1, 2, \dots, W\}$*, the MST weight is* $M = n - W + \sum_{i=1}^{W-1} c^{(i)}$.

Based on Lemma 11, the monitor can compute the MST weight as follows. Consider the threshold graph $G^{(\ell)}$ for some $\ell \in \{1, 2, \dots W-1\}$. According to Corollary 3, executing the Overlay Construction Algorithm on $G^{(\ell)}$ creates an overlay network in which each connected component of $G^{(\ell)}$ is spanned by a rooted tree of overlay edges. Each node knows whether it is a root of one of these trees. Therefore, we can determine $c^{(\ell)}$ by counting the number of roots, which can easily be achieved using aggregation along the tree T that results from the setup phase. By iterating this process, the monitor learns the value $c^{(\ell)}$ for each $\ell \in \{1, 2, \dots W-1\}$. It can then use the equation given in Lemma 11 to compute the MST weight. Since T is only used after the algorithm already ran for $O(\log^2 n)$ rounds, we can construct T during the monitoring phase and therefore skip the setup phase. Furthermore, we can reduce the delay by computing up to $\log^2 n$ different $c^{(i)}$'s in parallel. This implies the following theorem.

▶ **Theorem 12.** *For edge weights from* $\{1, 2, \dots, W\}$*, the MST weight can be monitored with setup time* 0 *and delay* $O(W + \log^2 n)$.

5.2 Approximate MST Weight

Next, we present an algorithm that monitors the MST weight with a significantly shorter delay at the cost of a small approximation error. The algorithm is less restrictive in that it allows the edge weights to be real numbers from the interval $[1, W]$ for a given $W \in \mathbb{R}$. It is based on the same general idea as the algorithm from the previous section but additionally incorporates ideas from the work of Czumaj and Sohler [10].

First, each node rounds up the edge weight of each incident edge to a power of $(1+\varepsilon)$ for a fixed ε with $0 < \varepsilon \leq 1$. In the resulting graph G', each edge weight is of the form $(1+\varepsilon)^i$ where $0 \leq i \leq \log_{1+\varepsilon} W$. Let M' be the MST weight in G'. We have the following lemma, which is analogous to Lemma 11 from the previous section.

▶ **Lemma 13** (Czumaj and Sohler [10]). *In a graph with edge weights of the form $(1+\varepsilon)^i$ for $0 \leq i \leq \log_{1+\varepsilon} W$, the MST weight is $M' = n - W + \varepsilon \cdot \sum_{i=0}^{\log_{1+\varepsilon} W - 1} (1+\varepsilon)^i \cdot c^{((1+\varepsilon)^i)}$.*

Based on Lemma 13, we can compute M' by determining the number of connected components $c^{((1+\varepsilon)^i)}$ in $\log_{1+\varepsilon} W$ many threshold graphs. While this already implies an improvement over the algorithm from the previous section, we can further reduce the delay by ignoring large components in the threshold graphs.

Consider some threshold graph $G^{((1+\varepsilon)^i)}$. We execute the Overlay Construction Algorithm as in the previous section but we stop its execution after $O(\log^2(2W/\varepsilon))$ rounds. By Corollary 3, the algorithm is guaranteed to finish its computation in each connected component of size at most $2W/\varepsilon$. In larger connected components, the algorithm may finish but is not guaranteed to do so. It is easy to modify the algorithm such that all nodes of a connected component know whether the algorithm finished its computation for that connected component. This allows us to ignore root nodes in connected components for which the algorithm did not finish. Thereby, the algorithm establishes a unique root node for each connected component of size at most $2W/\varepsilon$ while in each larger connected component either a unique root node is established or no root is established. Let $\hat{c}^{((1+\varepsilon)^i)}$ be the number of root nodes established in this way. The nodes determine the value of $\hat{c}^{((1+\varepsilon)^i)}$ using aggregation along the tree T constructed in the setup phase.

As in the previous section, the nodes iteratively execute this process for each i such that $0 \leq i \leq \log_{1+\varepsilon} W$. After the Overlay Construction Algorithm finishes for an iteration, the nodes start the aggregation for counting the number of roots. The nodes do not wait for this aggregation to finish but rather execute it in parallel to the next iteration. Thereby, we slightly interleave consecutive iterations which reduces the overall delay. After the monitor has learned the values $\hat{c}^{((1+\varepsilon)^i)}$, it computes and outputs $\hat{M} = n - W + \varepsilon \cdot \sum_{i=0}^{\log_{1+\varepsilon} W - 1} (1+\varepsilon)^i \cdot \hat{c}^{((1+\varepsilon)^i)}$. We have the following theorem.

▶ **Theorem 14.** *For edge weights from $[1, W]$, the MST weight M can be monitored up to an additive term of $\pm\varepsilon M$ for any $0 < \varepsilon \leq 1$ with setup time $O(\log^2 n)$ and delay $O\left(\frac{\log W}{\varepsilon} \cdot \log^2\left(\frac{W}{\varepsilon}\right) + \frac{\log n}{\log\log n}\right)$.*

Proof. We first show the approximation factor. Rounding up the edge weights to a power of $(1+\varepsilon)$ increases the MST weight by a factor of at most $(1+\varepsilon)$. Therefore, we have $M \leq M' \leq (1+\varepsilon) \cdot M$. When computing the values $\hat{c}^{((1+\varepsilon)^i)}$ the algorithm potentially ignores all connected components of size larger than $2W/\varepsilon$. In each threshold graph there are at most $\varepsilon n/(2W)$ such connected components. The algorithm cannot overestimate the number of connected components. Therefore, we have $c^{((1+\varepsilon)^i)} - \varepsilon n/(2W) \leq \hat{c}^{((1+\varepsilon)^i)} \leq c^{((1+\varepsilon)^i)}$. For the upper bound on the output $\hat{M}$ of the algorithm, the equations above together with the definitions of M' and $\hat{M}$ directly imply $\hat{M} \leq M' \leq (1+\varepsilon) \cdot M$. For the lower bound on $\hat{M}$, we

have $\hat{M} \geq n - W + \varepsilon \cdot \sum_{i=0}^{\log_{1+\varepsilon} W - 1} (1+\varepsilon)^i \cdot \left(c^{((1+\varepsilon)^i)} - \frac{\varepsilon n}{2W} \right) = M' - \frac{\varepsilon^2 n}{2W} \cdot \sum_{i=0}^{\log_{1+\varepsilon} W - 1} (1+\varepsilon)^i \geq M' - \frac{\varepsilon}{2} \cdot n \geq (1-\varepsilon) \cdot M$, where we assume $n \geq 2$ so that $n \leq M + 1 \leq 2M$ for the last inequality.

We now turn to the delay of the algorithm. The algorithm iteratively computes the values $\hat{c}^{((1+\varepsilon)^i)}$ for $\log_{1+\varepsilon} W = O(\log(W)/\varepsilon)$ threshold graphs. In each of these iterations the modified Overlay Construction Algorithm is executed for $O(\log^2(W/\varepsilon))$ rounds. After the Overlay Construction Algorithm finishes in the last iteration, the nodes have to wait for the final aggregation to complete. This takes an additional $O(\log / \log \log n)$ rounds. ◀

Finally, if $W = n^{O(1)}$ we can execute $\log W$ iterations of the algorithm in parallel which gives us the following corollary.

▶ **Corollary 15.** *For edge weights from $[1, W]$ where $W = n^{O(1)}$, the MST weight M can be monitored up to an additive term of $\pm\varepsilon M$ for any $0 < \varepsilon \leq 1$ with setup time $O(\log^2 n)$ and delay $O\left(\frac{1}{\varepsilon} \cdot \log^2\left(\frac{W}{\varepsilon}\right) + \frac{\log n}{\log \log n}\right)$.*

5.3 Distributed Computation of MSTs

Based on the ideas of the previous two sections, we can devise algorithms that mark the edges of an MST instead of just computing the MST weight. While these algorithms do not fit into the monitoring context, they represent natural extensions of the given algorithms and demonstrate that the underlying ideas might be useful outside of network monitoring.

First, we run the Overlay Construction Algorithm on the graph $G^{(1)}$ and mark all edges along which a merge request is sent. We then add the edges of weight 2 and run the Overlay Construction Algorithm again to further merge the supernodes while still marking edges as before. We keep adding edges of increasing weight in this way until we reach the threshold graph $G^{(W)}$ in which only a single supernode remains. By Observation 4, the marked edges form a spanning tree of G. Furthermore, at any given time the algorithm only adds edges of minimal weight to the spanning tree. Therefore, the algorithm is essentially a distributed implementation of Kruskal's Algorithm [21] so that the spanning tree computed by the algorithm is in fact an MST. We have the following theorem.

▶ **Theorem 16.** *Consider a network that initially forms a bidirected connected graph G with edge weights from $\{1, 2, \ldots, W\}$ for some $W \in \mathbb{N}$. There is an algorithm that marks the edges of an MST in G in $O(W \log^2 n)$ rounds.*

Combining this approach with the ideas from Section 5.2 gives us the following theorem.

▶ **Theorem 17.** *Consider a network that initially forms a bidirected connected graph G with edge weights from $[1, W]$ for some $W \in \mathbb{R}$. Let M be the weight of an MST in G. There is an algorithm that marks the edges of a spanning tree in G with weight M' such that $M \leq M' \leq (1+\varepsilon) \cdot M$ in $O(1/\varepsilon \cdot \log W \cdot \log^2 n)$ rounds.*

6 Future Work

We were only able to present a small number of monitoring problems in hybrid networks in this work. However, there is an abundance of classical problems in the literature that can be newly investigated under this model. As we tried to demonstrate in Section 5.3, the idea of using the ability to establish new edges to speed up computation can also be applied outside of network monitoring. We would be very interested in seeing further applications of this idea in other contexts.

Abstract

We develop a simple and generic method to analyze randomized rumor spreading processes in fully connected networks. In contrast to all previous works, which heavily exploit the precise definition of the process under investigation, we only need to understand the probability and the covariance of the events that uninformed nodes become informed. This universality allows us to easily analyze the classic push, pull, and push-pull protocols both in their pure version and in several variations such as messages failing with constant probability or nodes calling a random number of others each round. Some dynamic models can be analyzed as well, e.g., when the network is a $G(n,p)$ random graph sampled independently each round [Clementi et al. (ESA 2013)].

Despite this generality, our method determines the expected rumor spreading time precisely apart from additive constants, which is more precise than almost all previous works. We also prove tail bounds showing that a deviation from the expectation by more than an additive number of r rounds occurs with probability at most $\exp(-\Omega(r))$.

We further use our method to discuss the common assumption that nodes can answer any number of incoming calls. We observe that the restriction that only one call can be answered leads to a significant increase of the runtime of the push-pull protocol. In particular, the double logarithmic end phase of the process now takes logarithmic time. This also increases the message complexity from the asymptotically optimal $\Theta(n \log\log n)$ [Karp, Shenker, Schindelhauer, Vöcking (FOCS 2000)] to $\Theta(n \log n)$. We propose a simple variation of the push-pull protocol that reverts back to the double logarithmic end phase and thus to the $\Theta(n \log\log n)$ message complexity.

1 Introduction

Randomized rumor spreading is one of the core primitives to disseminate information in distributed networks. It builds on the paradigm that nodes call random neighbors and exchange information with these contacts. This gives highly robust dissemination algorithms belonging to the broader class of gossip-based algorithms that, due to their epidemic nature, are surprisingly efficient and scalable. Randomized rumor spreading has found numerous applications, among others, maintaining the consistency of replicated databases [9], disseminating large amounts of data in a scalable manner [25], and organizing any kind of communication in highly dynamic and unreliable networks like wireless sensor networks and mobile ad-hoc networks [21]. Randomized rumor spreading processes are also

used to model epidemic processes like viruses spreading over the internet [1], news spreading in social networks [10], or opinions forming in social networks [24].

The importance of these processes not only has led to a huge body of experimental results, but, starting with the influential works of Frieze and Grimmett [16] and Karp, Shenker, Schindelhauer, and Vöcking [22] also to a large number of mathematical analyses of rumor spreading algorithms giving runtime or robustness guarantees for existing algorithms and, based on such findings, proposing new algorithms.

Roughly speaking, two types of results can be found in the literature, general bounds trying to give a performance guarantee based only on certain graph parameters and analyses for specific graphs or graph classes. In the domain of general bounds, there is the classic maximum-degree-diameter bound of [13] and more recently, a number of works bounding the rumor spreading time in terms of conductance or other expansion properties [26, 6, 18, 19], which not only greatly helped our understanding of existing processes, but could also be exploited to design new dissemination algorithms [2, 3, 4, 20]. The natural downside of such general results is that they often do not give sharp bounds. It seems that among the known graph parameters, none captures very well how suitable this network structure is for randomized rumor spreading. Also, it has to be mentioned that these results mostly apply to the push-pull protocol.

The other research direction followed in the past is to try to prove sharper bounds for specific graph classes. This led, among others, to the results that the push-protocol spreads a rumor in a complete graph in time $\log_2 n + \ln n \pm \omega(1)$ with high probability $1 - o(1)$ (whp.) [28] (and in time $\log_{2-p} n + \frac{1}{p} \ln n \pm o(\log n)$ when messages fail independently with probability p), whereas the push-pull protocol does so in time $\log_3 n + O(\log \log n)$ [22]. The push protocol spreads rumors in hypercubes in time $O(\log n)$ whp. [13], determining the leading constant is a major open problem. For Erdős-Rény random graphs with edge probability asymptotically larger than the connectivity threshold, again a runtime of $\log_{2-p} n + \frac{1}{p} \ln n \pm o(\log n)$ was shown for the push protocol allowing transmission errors with rate p [14]. For preferential attachment graphs, which are often used as model for real-world networks, it was proven that the push-protocol needs $\Omega(n^\alpha)$ rounds, $\alpha > 0$ some constant, whereas the push-pull protocol takes time $\Theta(\log n)$ and $\Theta((\log n)/\log \log n)$ when nodes avoid to call the same neighbor twice in a row [5, 10]. Even faster rumor spreading times were shown on Chung-Lu power-law random graphs [15].

One weakness of all these results on specific graphs is that they very much rely on the particular properties of the protocol under investigation. Even in fully connected networks (complete graphs), the existing analyses for the basic push protocol [16, 28, 12], the push protocol in the presence of transmission failures [11], the push protocol with multiple calls [27], and the push-pull protocol [22] all uses highly specific arguments that cannot be used immediately for the other processes. This is despite the fact that the global behavior of these processes is often very similar. For example, all processes mentioned have an exponential expansion phase in which the number of informed node roughly grows by a constant factor until a constant fraction of the nodes is informed. Clearly, this hinders a faster development of the field. Note that the typical analysis of a rumor spreading protocol in the papers cited above needs between six and eight pages of proofs.

1.1 Our Results

In this work, we make a big step forward towards overcoming this weakness. We propose a *general analysis method* for all symmetric and memoryless rumor spreading processes in complete networks. It allows to easily analyze all rumor spreading processes mentioned above

and many new ones. The key to this generality is showing that the rumor spreading times for these protocols are determined by the probabilities p_k of a new node becoming informed in a round starting with k informed nodes together with a mild bound on the covariance on the indicator random variables of the events that new nodes become informed. Consequently, all other particularities of the protocol can safely be ignored.

Despite this generality, our method gives bounds for the expected rumor spreading time that are *tight apart from an additive constant number of rounds*. Such tight bounds so far have only been obtained once, namely for the basic push protocol [12].

Our method also gives *tail bounds* stating that deviations from the expectation by an additive number of at least r of rounds occur with probability at most $A' \exp(-\alpha' r)$, where $A', \alpha' > 0$ are absolute constants. Such a precise tail bound was previously given only for the push protocol in [12]. Note that our tail bounds imply the usual whp-statements, e.g., that overshooting the expectation by any $\omega(1)$ term happens with probability $o(1)$ only, and that a rumor spreading time of $O(\log n)$ can be obtained with probability $1 - n^{-c}$, c any constant, by making the implicit constant in the time bound large enough.

We use our method to obtain the following particular results. We only state the expected runtimes. In all cases, the above tail bounds are valid as well.

Classic protocols, robustness: We start by analyzing the three basic push, pull, and push-pull protocols. In the *push protocol*, in each round each informed node calls a random node and sends a copy of the rumor to it. In the *pull protocol*, in each round each uninformed node calls a random node and tries to obtain the rumor from it. In the *push-pull protocol*, all nodes contact a random node and in each such contact the informed nodes send rumor to the communication partner.

For these three protocols, both in the fault-free setting and when assuming that calls fail independently with probability $1 - p$, our method easily yields the expected rumor spreading times given in Table 1. Note that all previous works apart from [12] did not state explicitly a bound for the expected runtime. Note further that for half of the settings regarded in Table 1 no previous result existed. In particular, we are the first to find that the double logarithmic shrinking phase observed by Karp et al. [22] for the push-pull protocol disappears when messages fail with constant probability p, and is instead replaced by an ordinary shrinking regime with the number of uninformed nodes reducing by roughly a factor of $(1-p)e^{-p}$ each round. This observation is not overly deep, but has the important consequence that the message complexity of the push-pull protocol raises from the theoretically optimal $\Theta(n \log \log n)$ value proven in [22] to an order of magnitude of $\Theta(n \log n)$ in the presence of a constant rate of transmission errors. Hence the significant superiority of the push-pull protocol over the push protocol in the fault-free setting reduces to a constant-factor advantage in the faulty setting.

Multiple calls: Panagiotou, Pourmiri, and Sauerwald [27] proposed a variation of the classic protocols in which the number of calls (always to different nodes) each node performs when active is a positive random variable R. They mostly assume that for each node, this random number is sampled once at the beginning of the process. For the case that R has constant expectation and variance, they show that the rumor spreading time of the push protocol is $\log_{1+\mathbb{E}[R]} n + \frac{1}{\mathbb{E}[R]} \ln n \pm o(\log n)$ with high probability and that the rumor spreading time of the push-pull protocol is $\Omega(\log n)$ with probability $1 - \varepsilon$, $\varepsilon > 0$. When R follows a power law with exponent $\beta = 3$, the push-pull protocol takes $\Theta(\frac{\log n}{\log \log n})$ rounds, and when $2 < \beta < 3$, it takes $\Theta(\log \log n)$ rounds.

Table 1 New and previous-best results for rumor spreading time T of the classic rumor spreading protocols in complete graphs on n vertices. The first line of each table entry contains the result that follows from the method proposed in this work, the second line states the best previous result (if any). For all new bounds on the expected rumor spreading time, a tail bound of type $\mathbb{P}[|T \geq \mathbb{E}[T]| \geq r] \leq A' \exp(-\alpha' r)$ with $A', \alpha' > 0$ suitable constants follows as well from this work. In [12], such a bound was given for the rumor spreading time of the push protocol without transmission failures.

	no transmission failures	calls fail indep. with prob. $1-p \in (0,1)$
push protocol	$\mathbb{E}[T] = \log_2 n + \ln n \pm O(1)$ $\lfloor \log_2 n \rfloor + \ln n - 1.116 \leq \mathbb{E}[T] \leq \lceil \log_2 n \rceil + \ln n + 2.765 + o(1)$ [12]	$\mathbb{E}[T] = \log_{1+p} n + \frac{1}{p} \ln n \pm O(1)$ $T = \log_{1+p} n + \frac{1}{p} \ln n \pm o(\log n)$ whp. [11]
pull protocol	$\mathbb{E}[T] = \log_2 n + \log_2 \ln n \pm O(1)$	$\mathbb{E}[T] = \log_{1+p} n + \frac{1}{\ln \frac{1}{1-p}} \ln n \pm O(1)$
push-pull protocol	$\mathbb{E}[T] = \log_3 n + \log_2 \ln n \pm O(1)$ $T = \log_3 n \pm O(\log \log n)$ whp. [22]	$\mathbb{E}[T] = \log_{1+2p} n + \frac{1}{p + \ln \frac{1}{1-p}} \ln n \pm O(1)$

The model of [27] makes sense when assuming that nodes have generally different communication capacities. To model momentarily different capacities, e.g., caused by being occupied with other communication tasks, we assume that the random variable is resampled for each node in each round. We also allow R to take the value 0. Again for the case $\mathbb{E}[R] = \Theta(1)$ and $\mathrm{Var}[R] = O(1)$, we show that the expected rumor spreading time of the push protocol is $\log_{1+\mathbb{E}[R]} n + \frac{1}{\mathbb{E}[R]} \ln n \pm O(1)$. The rumor spreading time of the push-pull protocol depends critically on the smallest value ℓ which R takes with positive probability. If $\ell = 0$, that is, with constant probability nodes contact no other node, then there is no double exponential shrinking and the expected rumor spreading time is $\log_{1+2\mathbb{E}[R]} n + \frac{1}{\mathbb{E}[R] - \ln \mathbb{P}[R=0]} \ln n \pm O(1)$. If nodes surely perform at least one call, then we have a double exponential shrinking regime and an expected rumor spreading time of $\log_{1+2\mathbb{E}[R]} n + \log_{1+\ell} \ln n \pm O(1)$.

Dynamic networks: We also show that our method is capable of analyzing dynamic networks when the dynamic is memory-less. Clementi et al. [7] have shown that when the network in each round is a newly sampled $G(n,p)$ random graph, then for any constant c the rumor spreading time of the push protocol is $\Theta(\log(n)/\min\{p, 1/n\})$ with probability $1 - n^{-c}$. We sharpen this result for the most interesting regime that $p = a/n$, a a positive constant. For this case, we show that the expected rumor spreading time is $\log_{2-e^{-a}} n + \frac{1}{1-e^{-a}} \ln(n) + O(1)$. Our tail bound $\mathbb{P}[|T - \mathbb{E}[T]| \geq r] \leq A' \exp(-\alpha' r)$ for suitable constants $A', \alpha > 0$ implies also the large deviation statement of [7] (where for $\Theta(\log n)$ deviations in the lower tail the trivial $\log_2(n)$ lower bound holding with probability 1 should be used).

Answering single calls only: We finally use our method to discuss an aspect mostly ignored by previous research. While in all protocols above (apart from the one of [27]) it is assumed that each node can call at most one other node per round, it is tacitly assumed in the pull and push-pull protocols that nodes can answer all incoming calls. For complete graphs on n vertices, the classic balls-into-bins theory immediately gives that in a typical round there is at least one node that receives $\Theta(\frac{\log n}{\log \log n})$ calls. So unlike for the outgoing traffic, nodes are implicitly assumed to be able to handle very different amounts of incoming traffic in one round.

The first to discuss this issue are Daum, Kuhn, and Maus [8] (also the SIROCCO 2016 best paper). Among other results, they show that if only one incoming call can be answered and if this choice is taken adversarially, then there are networks where a previously polylogarithmic

rumor spreading time of the pull protocol becomes $\tilde{\Omega}(\sqrt{n})$. If the choice which incoming call is answered is taken randomly, then things improve and the authors show that for any network, the rumor spreading times of the pull and push-pull protocol increase by at most a factor of $O(\frac{\Delta(G)}{\delta(G)} \log n)$ compared to the variant in which all incoming calls are answered. Subsequently, Ghaffari and Newport [17] showed that with the restriction to accept only one incoming call, the general performance guarantees for the push-pull protocol in terms of vertex expansion or conductance [18, 19] do not hold. Kiwi and Caro [23] showed that solving the problem of multiple incoming calls via a FIFO queue can lead to extremely long rumor spreading times.

With our generic method, we can easily analyze this aspect of rumor spreading on complete graphs. While for the pull protocol only the growth phase mildly slows down, giving a total expected rumor spreading time of $\mathbb{E}[T] = \log_{2-1/e} n + \log_2 \ln n \pm O(1)$, for the push-pull protocol also the double logarithmic shrinking phase breaks down and we observe a total runtime of $\mathbb{E}[T] = \log_{3-2/e} n + \frac{1}{2} \ln n \pm O(1)$ and, similarly as for the push-pull protocol with transmission failures, an increase of the message complexity to $\Theta(n \log n)$. The reason, as our proof reveals, is that when a large number of nodes are informed, then their push calls have little positive effect (as in the classic push-pull protocol), but they now also block other nodes' pull calls from being accepted. This problem can be overcome by changing the protocol so that informed nodes stop calling others when the rumor is $\log_{3-2/e} n$ rounds old. The rumor spreading time of this modified push-pull protocol is $\mathbb{E}[T] = \log_{3-2/e} n + \log_2 \ln n \pm O(1)$ and, when halted at the right moment, this process takes $\Theta(n \log \log n)$ messages.

2 Outline of the Analysis Method

As just discussed, the main advantages of our approach are its universality and the very tight bounds it proves. We now briefly sketch the main new ideas that lead to this progress. Interestingly, they are rather simpler than the ones used in previous works.

2.1 Tight Bounds via a Target-Failure Calculus

We first describe how we obtain estimates for the rumor spreading time that are *tight apart from additive constants*. Let us take as example the classic push protocol. It is easy to compute that in a round starting with k informed nodes, the expected number of newly informed nodes is $E(k) = k - \Theta(k^2/n)$. Hence roughly speaking the number of informed nodes doubles each round (which explains the $\log_2 n$ part of the $\log_2 n + \ln n \pm O(1)$ rumor spreading time), but there is a growing gap to truly doubling caused by (i) calls reaching already informed nodes and (ii) several calls reaching the same target. This weakening of the doubling process was a main difficulty in all previous works.

The usual way to analyze this weakening doubling process is to partition the rumor spreading process in phases and within each phase to uniformly estimate the progress. For example, Pittel [28] considers 7 phases. He argues first that with high probability the number if informed nodes doubles until $n_1 = o(\sqrt{n})$ nodes are informed. Then, until $n_2 = n/\log^2(n)$ nodes are informed, with high probability in each round the number of informed nodes increases by at least a factor of $2(1 - \frac{1}{\log^2(n)})$. Consequently, this second phase lasts at most $\log_{2(1-\frac{1}{\log^2(n)})}(n_2/n_1)$ rounds. While this type of argument gives good bounds for phases bounded away from the middle regime with both $\Theta(n)$ nodes informed and uninformed, we do not see how this "estimating a phase uniformly" argument can cross the middle regime without losing a number $\omega(1)$ of rounds.

For this reason, we proceed differently. To prove upper bounds on rumor spreading times, for each number k of informed nodes, we formulate a pessimistic round target $E_0(k)$ that is sufficiently below the expected number $E(k)$ of newly informed nodes. Here "sufficiently below" means that the probability $q(k)$ to fail reaching this target number of informed nodes is small, but not necessarily $o(1)$ as in all previous analyses. Using a restart argument, we observe that the random time needed to go from k informed nodes to at least $E_0(k)$ informed nodes is stochastically dominated by 1 plus a geometric random variable with parameter $1 - q(k)$, where all our geometric random variables count the number of failures until success (this is one of the two definitions of geometric distributions that are in use). In particular, the expected time to go from k to at least $E_0(k)$ informed nodes is at most $1 + \frac{q(k)}{1-q(k)}$.

The second, again elementary, key argument is that when we define a sequence of round targets by $k_0 := 1$, $k_1 := E_0(k_0)$, $k_2 := E_0(k_1), \dots$ with suitably defined $E_0(\cdot)$, then the k_i grow almost like 2^i (in the example of the classic push protocol). More precisely, there is a $T = \log_2 n \pm O(1)$ such that $k_T = \Theta(n)$. Hence together with the previous paragraph we obtain that the number of rounds to reach k_T informed nodes is dominated by T plus a sum of independent geometric random variables. This sum has expectation $\sum_{i=0}^{T-1} \frac{q(k_i)}{1-q(k_i)} = O(\sum_{i=0}^{T-1} q(k_i))$, so it suffices that the sum of the failure probabilities $q(k_i)$ is a constant (unlike in previous works, where it needed to be $o(1)$). A closer look at this sum also gives the desired tail bounds.

Similarly, to prove matching lower bounds, we define optimistic round targets $E_0(k)$ such that a round starting with k informed nodes finds it unlikely to reach $E_0(k)$ informed nodes. Since again we want to allow failure probabilities that are constant, we now have to be more careful and also quantify the probability to overshoot $E_0(k)$ by larger quantities. This will then allow to argue that when defining a sequence of round targets recursively as above, then the expected number of targets overjumped (and thus the expected number of rounds saved compared to the "one target per round" calculus), is only constant.

We remark that a target-failure argument similar to ours was used already in [12], there however only to give an upper bound for the runtime of the push protocol in the regime from n^s, s a small constant, to $\Theta(n)$ informed nodes, that is, the later part of the exponential growth regime of the push process, in which via Chernoff bounds very strong concentration results could be exploited. Hence the novelty of this work with respect to the target-failure argument is that this analysis method can be used (i) also from the very beginning of the process on, where we have no strong concentration, (ii) also for the exponential and double exponential shrinking regimes of rumor spreading processes, and (iii) also for lower bounds.

2.2 Uniform Treatment of Many Rumor Spreading Processes

As discussed earlier, the previous works regarding different rumor spreading processes on complete graphs all had to use different arguments. The reason is that the processes, even when looking similar from the outside, are intrinsically different when looking at the details. As an example, let us consider the first few rounds of the push and the pull protocol. In the push protocol, we just saw that while there are at most $o(\sqrt{n})$ nodes informed, then a birthday paradox type argument gives that with high probability we have perfect doubling in each round. For the pull process, in which each uninformed node calls a random node and becomes informed when the latter was informed, we also easily compute that a round starting with k informed nodes creates an expected number of $(n-k)\frac{k}{n} = k - \frac{k^2}{n}$ newly informed nodes. However, since these are binomially distributed, there is no hope for perfect doubling. In fact, for the first constant number of rounds, we even have a constant probability that not a single node becomes informed.

The only way to uniformly treat such different processes is by making the analysis depend only on general parameters of the process as opposed to the precise definition. Our second main contribution is distilling a few simple conditions that (i) subsume essentially all symmetric and time-invariant rumor spreading processes on complete graphs and (ii) suffice to prove rumor spreading times via the above described target-failure method. All this is made possible by the observation that the target-failure method needs much less in terms of failure probabilities than previous approaches, in particular, it can tolerate constant failure probabilities. Consequently, instead of using Chernoff and Azuma bounds for independent or negatively correlated random variables (which rely on the precise definition of the process), it suffices to use Chebyshev's inequality as concentration result.

Consequently, to apply our method we only need to (i) understand (with a certain precision) the probability p_k that an uninformed node becomes informed in a round starting with k informed nodes; recall that we assumed symmetry, that is, this probability is the same for all uninformed nodes, and (ii) we need to have a mild upper bound on the covariance of the indicator random variables of the events that two nodes become informed.

The probabilities p_k usually are easy to compute from the protocol definition. Also, we do not know them precisely. For example, for the growth phase of the push protocol discussed above, it suffices to know that there are constants $a < 2$ and a' such that for all $k < n/2$ we have $\frac{k}{n}(1 - a\frac{k}{n}) \leq p_k \leq \frac{k}{n}(1 + a'\frac{k}{n})$. This (together with the covariance condition) is enough to show that the rumor spreading process takes $\log_2 n \pm O(1)$ rounds to inform $n/2$ nodes or more. The constants a, a' have no influence on the final result apart from the additive constant number of rounds hidden in the $O(1)$ term. The covariances are also often easy to bound with sufficient precision, among others, because many in processes the events that two uniformed nodes become informed are independent or negatively correlated.

In our general analysis method, we profit from the fact that seemingly all reasonable rumor spreading processes in complete networks can be described via three regimes:

Exponential growth: Up to a constant fraction fn of informed nodes, $p_k = \gamma_n \frac{k}{n}(1 \pm O(\frac{k}{n}))$. The number of informed nodes thus increases roughly by a factor of $(1 + \gamma_n)$ in each round, hence the expected time to reach fn informed nodes or more is $\log_{1+\gamma_n} n \pm O(1)$.

Exponential shrinking: From a certain constant fraction $u = n - k = gn$ of uninformed nodes on, the probability of remaining uninformed satisfies $1 - p_{n-k} = e^{-\rho_n} \pm O(\frac{u}{n})$. This leads to a shrinking of the number of uninformed nodes by essentially a factor of $e^{-\rho_n}$ per round. Hence when starting with gn informed nodes, it takes another $\frac{1}{\rho_n} \ln n \pm O(1)$ rounds in expectation until all are informed.

Double exponential shrinking: From a certain constant fraction $u = n - k = gn$ of uninformed nodes on, the probability of remaining uninformed satisfies $1 - p_{n-k} = \Theta((\frac{u}{n})^{\ell-1})$. Now the expected time to go from gn uninformed nodes to no uninformed node is $\log_\ell \ln n \pm O(1)$.

Due to their different nature, we cannot help treating these three regimes separately, however all with the target-failure method. Hence the main differences between these regimes lie in defining the pessimistic estimates for the targets, computing the failure probabilities, and computing the number of intermediate targets until the goal is reached. All this only needs computing expectations, using Chebyshev's inequality, and a couple of elementary estimates.

3 Precise Statement of the Technical Results

In this work, we consider only *homogeneous rumor spreading processes* characterized as follows. We always assume that we have n nodes. Each node can be either *informed* or *uninformed*. We assume that the process starts with exactly one node being informed. Uninformed nodes may become informed, but an informed node never becomes uninformed. We consider a discrete time process, so the process can be partitioned into *rounds*. In each round each uninformed node can become informed. Whenever a round starts with k nodes being informed, then the probability for each uninformed node to become informed is some number p_k, which only depends on the number k of informed nodes at the beginning of the round.

The main insight of this work is that for such homogeneous rumor spreading processes we can mostly ignore the particular structure of the process and only work with the *success probabilities* p_k defined above and the *covariance numbers* c_k defined as follows.

▶ **Definition 1** (Covariance numbers)**.** For a given homogeneous rumor spreading process and $k \in [1..n-1]$ let c_k be the smallest number such that whenever a round starts with k informed nodes and for any two uninformed nodes x_1, x_2, the indicator random variables X_1, X_2 for the events that these nodes become informed in this round satisfy

$$\mathrm{Cov}[X_1, X_2] \leq c_k.$$

Upper bound for these covariances imply upper bounds on the variance of the number of nodes newly informed in a round. If the latter is small, Chebyshev's inequality yields that the actual number of newly informed nodes deviates not a lot from its expectation (which is determined by p_k).

Our main interest is studying after how many round all nodes are informed.

▶ **Definition 2** (Rumor spreading times)**.** Consider a homogeneous rumor spreading process. For all $t = 0, 1, \dots$ denote by I_t the number of informed nodes at the end of the t-th round ($I_0 := 1$). Let $k \leq m \leq n$. By $T(k, m)$ we denote the time it takes to increase the number of informed nodes from k to m or more, that is,

$$T(k, m) = \min\{t - s | I_s = k \text{ and } I_t \geq m\}.$$

We call $T(1, n)$ the rumor spreading time of the process.

As it turns out, almost all homogeneous rumor spreading processes can be analyzed via three regimes.

3.1 Exponential Growth Regime

When not too many nodes are informed, in most rumor spreading processes we observe roughly a constant-factor increase of the number of informed nodes in one round, however, this increase becomes weaker with increasing number of informed nodes.

▶ **Definition 3** (Exponential growth conditions)**.** Let γ_n be bounded between two positive constants. Let $a, b, c \geq 0$ and $0 < f < 1$. We say that a homogeneous rumor spreading process satisfies the *upper (respectively lower) exponential growth conditions* in $[1, fn[$ if for any $n \in \mathbb{N}$ big enough the following properties are satisfied for any $k < fn$.

(i) $p_k \geq \gamma_n \frac{k}{n} \cdot \left(1 - a\frac{k}{n} - \frac{b}{\ln n}\right)$ (respectively $p_k \leq \gamma_n \frac{k}{n} \cdot \left(1 + a\frac{k}{n} + \frac{b}{\ln n}\right)$).

(ii) $c_k \leq c\frac{k}{n^2}$.

In the case of the upper exponential growth condition, we also require $af < 1$.

These growth conditions suffice to prove that in an expected time of at most (respectively at least) $\log_{1+\gamma_n} n \pm O(1)$ rounds a linear number of nodes becomes informed. Consequently, the decrease of the dissemination speed when more nodes are informed (quantified by the term $-a\frac{k}{n}$ in the upper exponential growth condition), which was a main difficulty in previous analyses, has only an $O(1)$ influence on the rumor spreading time.

▶ **Theorem 4.** *If a homogeneous rumor spreading process satisfies the upper (lower) exponential growth conditions in* $[1, fn[$*, then there are constants* $A', \alpha' > 0$ *such that*

$$\mathbb{E}[T(1, fn)] \underset{(\geq)}{\leq} \log_{1+\gamma_n} n \underset{(-)}{+} O(1),$$

$$\mathbb{P}[T(1, fn) \underset{(\leq)}{\geq} \log_{1+\gamma_n} n \underset{(-)}{+} r] \leq A' \exp(-\alpha' r) \text{ for all } r \in \mathbb{N}.$$

When the lower exponential growth conditions are satisfied, then also there is an $f' \in]f, 1[$ *such that with probability* $1 - O\left(\frac{1}{n}\right)$ *at most* $f'n$ *nodes are informed at the end of round* $T(1, fn)$*.*

We note that the upper tail bound is tight apart from the implicit constants. This is witnessed, for example, by the pull protocol, where rounds starting with only a constant number of informed nodes have a constant probability of not informing any new node.

3.2 Exponential Shrinking Regime

In a sense dual to the previous regime, in many rumor spreading processes we observe that the number of uninformed nodes shrinks by a constant factor once sufficiently many nodes are informed. Again, the weaker shrinking at the beginning of this regime has only an $O(1)$ influence on the resulting rumor spreading times.

▶ **Definition 5** (Exponential shrinking conditions)**.** Let ρ_n be bounded between two positive constants. Let $0 < g < 1$, and $a, c \in \mathbb{R}_{\geq 0}$. We say that a homogeneous rumor spreading process satisfies the *upper (respectively lower) exponential shrinking conditions* if for any $n \in \mathbb{N}$ big enough, the following properties are satisfied for all $u = n - k \leq gn$.

(i) $1 - p_k = 1 - p_{n-u} \leq e^{-\rho_n} + a\frac{u}{n}$ (respectively $1 - p_k = 1 - p_{n-u} \geq e^{-\rho_n} - a\frac{u}{n}$).

(ii) $c_k = c_{n-u} \leq \frac{c}{u}$.

For the upper exponential shrinking conditions, we also assume that $e^{-\rho_n} + ag < 1$.

▶ **Theorem 6.** *If a homogeneous rumor spreading process satisfies the upper (lower) exponential shrinking conditions, then there are* $A'\alpha' > 0$ *such that*

$$\mathbb{E}[T(n - \lfloor gn \rfloor, n)] \underset{(\geq)}{\leq} \frac{1}{\rho_n} \ln n \underset{(-)}{+} O(1),$$

$$\mathbb{P}[T(n - \lfloor gn \rfloor, n) \underset{(\leq)}{\geq} \frac{1}{\rho_n} \ln n \underset{(-)}{+} r] \leq A' \exp(-\alpha' r) \text{ for all } r \in \mathbb{N}.$$

Again, the upper tail bound is tight apart from the constants as shown by the last rounds of the push protocol.

3.3 Double Exponential Shrinking Regime

Protocols using pull operations in the absence of transmission failures display a faster reduction of the number if uninformed nodes.

▶ **Definition 7** (Double exponential shrinking conditions). Let $g \in]0,1]$, $\ell > 1$, and $a, c \in \mathbb{R}_{\geq 0}$ such that $ag^{\ell-1} < 1$. We say that a homogeneous rumor spreading process satisfies the *upper (respectively lower) double exponential shrinking conditions* if for any n big enough the following properties are satisfied for all $u = n - k \in [1, gn]$.

(i) $1 - p_{n-u} \leq a\left(\frac{u}{n}\right)^{\ell-1}$ (respectively $1 - p_{n-u} \geq a\left(\frac{u}{n}\right)^{\ell-1}$).

(ii) $c_{n-u} \leq c\frac{n}{u^2}$.

▶ **Theorem 8.** *If a homogeneous rumor spreading process satisfies the upper (lower) double exponential shrinking conditions, then there are $A', \alpha' > 0$ and R (depending on α) such that*

$$\mathbb{E}[T(n - \lfloor gn \rfloor, n)] \underset{(\geq)}{\leq} \log_\ell \ln n \underset{(-)}{+} O(1),$$

$$\mathbb{P}[T(n - \lfloor gn \rfloor, n) \geq \log_\ell \ln n + r] \leq O(n^{-\alpha' r + A'}) \text{ for all } r \in \mathbb{N},$$

$$(\mathbb{P}[T(n - \lfloor gn \rfloor, n) \leq \log_\ell \ln n - R] \leq O(n^{-1+2\ell\alpha})).$$

The last rounds of the push-pull protocol show that the upper tail bound is tight apart from the constants. The lower tail bound is clearly not best possible, but most likely good enough for most purposes.

3.4 Connecting Regimes

While often these above described three regimes suffice to fully analyze a rumor spreading process, occasionally it is necessary or convenient to separately regard a constant number of rounds between the growth and the shrinking regime. This is achieved by the following two lemmas.

▶ **Lemma 9.** *Consider a homogeneous rumor spreading process. Let $0 < \ell < m < n$ and $0 < p < 1$. Suppose for any number $\ell \leq k < m$, we have $p_k \geq p$. Then*

$$\mathbb{E}[T(\ell, m)] \leq \tfrac{n-\ell}{n-m} \cdot \tfrac{1}{p},$$

$$\mathbb{P}[T(\ell, m) > r] \leq \tfrac{n-\ell}{n-m} \cdot (1-p)^r \text{ for all } r \in \mathbb{N}.$$

▶ **Lemma 10.** *Let $f, p \in]0,1[$ and $c > 0$. Suppose that for any $k < fn$ we have $p_k \leq p$ and $c_k \leq \frac{c}{n}$. Then there exists $f' \in]f, 1[$ such that with probability $1 - O\left(\frac{1}{n}\right)$ at the end of some round the number of informed nodes will be between fn and $f'n$.*

4 Applying the Above Technical Results

In this section, we sketch how to use the above tools to obtain some of the results described in Section 1.1. To ease the notation we always assume that nodes call random nodes, that is, including themselves. The main observation is that computing the p_k is usually very elementary. For the covariance conditions, often we easily observe a negative or zero covariance, but when this is not true, then things can become technical.

For the *basic push, pull, and push-pull protocols*, we easily observe that all covariances to be regarded are negative or zero: Knowing that one uninformed node x_1 becomes informed in the current round has no influence on the pull call of another uninformed node x_2. When the protocol has push calls and x_1 was informed via a push call, then this event makes it slightly less likely that x_2 becomes informed via a push call, simply because at least one informed node is occupied with calling x_1.

The success probabilities p_k are easy to compute right from the protocol definition. When k nodes are informed, then the probabilities that an uninformed node becomes informed are

$$p_k = \begin{cases} 1-(1-1/n)^k & \text{for the push protocol,} \\ k/n & \text{for the pull protocol,} \\ p_k = 1-(1-1/n)^k \frac{n-k}{n} & \text{for the push-pull protocol.} \end{cases}$$

Using elementary estimates like $1-k/n \leq (1-1/n)^k \leq 1-k/n+k^2/2n^2$, we see that the push and pull protocols satisfy the exponential growth conditions with $\gamma_n = 1$, whereas the push-pull protocol does the same with $\gamma_n = 2$. The push protocol satisfies the exponential shrinking conditions with $\rho_n = 1$. The pull and push-pull protocols satisfy the double exponential shrinking conditions with $\ell = 2$. All growth conditions are satisfied at least up to $k = n/2$ informed nodes and all shrinking conditions are satisfied at least for $u \leq n/2$ uninformed nodes, so we do not need the intermediate lemmas. This proves our results given in Table 1 for the fault-free case.

Faulty communication: The same arguments (with different constants γ_n and ρ_n) suffice to analyze these protocols when messages get lost independently with probability $1-p$. The only structural difference is that now for the pull and push-pull protocols uninformed nodes remain uninformed with at least constant probability. For this reason, now all three protocols have an exponential shrinking phase.

The push-pull protocol with the restriction that nodes *answer only a single incoming call* randomly chosen among the incoming calls is an example where the exponential growth and shrinking conditions are harder to prove. To compute the p_k we assume that all n calls have a random unique priority in $[1..n]$ and that the call with lowest priority number is accepted. For fixed priority, the probability of being accepted is easy to compute, and this leads to the success probability of a pull call. For the probability to become informed via a push call, the simple argument that the first incoming call is from an informed node with probability k/n solves the problem. When showing the covariance conditions, we face the problem that it is indeed not clear if we have negative or zero covariance. The event that some node becomes informed increases the chance that this node received a push call. This push call cannot interfere with another node's pull call to an informed node. So it does have some positive influence on the probability of another uninformed node to become informed. Fortunately, for our covariance conditions allow some positive correlation. Because of this, very generally speaking, we can ignore certain difficulties to handle situations when they occur rare enough.

Dynamic communication graphs: Being maybe the result where it is most surprising that bounds sharp apart from additive constants can be obtained, we now regard in more detail a problem regarded in [7]. There, the performance of push rumor spreading in a group of n agents was investigated when the actual communication network is changing in each round. As one such dynamic models, it was assumed that the communication graph in each round is a newly sampled $G(n,p)$ random graph, that is, there is an edge independently with probability p between any two vertices. For the ease of presentation, we assume that the edge probability equals $p = a/n$ for some constant $a > 0$. This is clearly the most interesting case. For such (and larger) p, a rumor spreading time of $\Theta(\log n)$ was shown to hold with inverse-polynomial failure probability. Recalling that for $p = a/n$ the graph $G(n,p)$ is not connected and has vertex degrees ranging from 0 to $\Theta(\log(n)/\log\log(n))$, this result is not obvious. Also, observe that the actions of all nodes in one round take place in the same random graph, so there are dependencies that have to be taken into account.

▶ **Theorem 11.** *Let T be the time the push protocol needs to inform n nodes when in each round a newly sampled $G(n,p)$, $p = a/n$, random graph represents the communication network. Then*

$$\mathbb{E}[T] = \log_{2-e^{-a}} n + \tfrac{1}{1-e^{-a}} \ln(n) \pm O(1)$$

and there are constants $A', \alpha' > 0$ such that $\mathbb{P}[|T - \mathbb{E}[T]| \geq r] \leq A' \exp(\alpha' r)$ holds for all $r \in \mathbb{N}$.

Recall that a vertex is isolated with probability $e^{-a} + O(1/n)$. Clearly, an informed vertex when isolated necessarily fails to inform another vertex in this round. The rumor spreading time proven above is the same as the one for the case that the communication network is always a complete graph, but calls fail independently with probability e^{-a}. Hence in a sense the changing topology (with low vertex degrees) is not harmful apart from the effect that it creates isolated vertices with constant rate. We did not expect this.

To prove Theorem 11, we first observe that the covariance properties are fulfilled. By symmetry, we can assume that in a round starting with k informed nodes, we first sample the random graph and decide for each node which neighbor it potentially calls in this round, and only then decide randomly which k nodes are informed and have these call the random neighbor determined before. Conditioning on the outcome of random graph, neighbor choice, and on that nodes x and y are not informed, in the remaining random experiment the events "x becomes informed" and "y becomes informed" clearly are negatively correlated.

Estimating the probability p_k for an uninformed node to become informed in a round starting with k informed nodes, is slightly technical. Since it is unlikely that two neighbors of an uninformed node x are connected by an edge, the main contribution to p_k stems from the case that the informed neighbors of x form an independent set. Conditioning on this outcome of the edges in $\{x\} \cup N(x)$, each informed neighbor of x has an independent probability of roughly $(1-e^{-a})/a$ of calling x, giving (again taking care of the dependencies) a probability of roughly $1 - p_k \approx (1 - \frac{a}{n}\frac{1-e^{-a}}{a})^k$ for the event that no informed node calls x. From this, we estimate $\frac{k}{n}(1-e^{-a})(1 - \frac{k+O(1)}{2n}(1-e^{-a})) \leq p_k \leq \frac{k}{n}(1 - e^{-a} + O(1/n))$, showing that the exponential growth conditions are satisfied with $\gamma_n = 1 - e^{-a}$. Similar arguments, again taking some care for the dependencies that the random graph imposes on the actions of informed neighbors, show that the upper exponential shrinking conditions are satisfied for $\rho_n = 1 - e^{-a}$, whereas the lower exponential shrinking conditions are satisfied with $\rho_n = 1 - e^{-a} + O(\log(n)^2/n)$.

5 Summary, Outlook

In this work, we presented a general, easy-to-use method to analyze homogeneous rumor spreading processes on complete networks (including memoryless dynamic settings). Such processes are important in many applications, among others, due to the use of random peer sampling services in many distributed systems. Such processes also correspond to the fully mixed population model in mathematical epidemiology.

The two main strengths of our method are (i) that it builds only on estimates for the probability and the covariance of the events that new nodes become informed—consequently, many processes can be analyzed with identical arguments (as opposed to all previous works), and (ii) that it determines the expected rumor spreading time precise apart from additive constants (with tail bounds giving in most cases that deviations by an additive number r of rounds occur with probability $\exp(-\Omega(r))$ only). The key to our results is distilling

growth and shrinking conditions which cover essentially all previously regarded homogeneous processes and which imply the desired runtime bounds.

From a broader perspective, this work shows that the traditional approach to randomized processes of splitting the analysis in several phases and then trying to understand each phase with uniform arguments might not be the ideal way to capture the nature of processes with a behavior changing continuously over time. While we demonstrated that the more careful round-target approach is better suited for homogeneous rumor spreading processes, one can speculate if similar ideas are profitable for other randomized algorithms or processes regarded in computer science.

Abstract

Iterative load balancing algorithms for indivisible tokens have been studied intensively in the past, e.g., [21, 18, 24]. Complementing previous worst-case analyses, we study an average-case scenario where the load inputs are drawn from a fixed probability distribution. For cycles, tori, hypercubes and expanders, we obtain almost matching upper and lower bounds on the discrepancy, the difference between the maximum and the minimum load. Our bounds hold for a variety of probability distributions including the uniform and binomial distribution but also distributions with unbounded range such as the Poisson and geometric distribution. For graphs with slow convergence like cycles and tori, our results demonstrate a substantial difference between the convergence in the worst- and average-case. An important ingredient in our analysis is a new upper bound on the t-step transition probability of a general Markov chain, which is derived by invoking the evolving set process.

1 Introduction

In the last decade, large parallel networks became widely available for industrial and academic users. An important prerequisite for their efficient usage is to balance their work efficiently. Load balancing is known to have applications to scheduling [27], routing [9], numerical computation such as solving partial differential equations [29, 28, 26], and finite element computations [13]. In the standard abstract formulation of load balancing, processors are represented by nodes of a graph, while links are represented by edges. The objective is to balance the load by allowing nodes to exchange loads with their neighbors via the incident edges. In this work we will study a decentralized and iterative load balancing protocol where a processor knows only its current load and that of the neighboring processors. Based on this, decides how much load should be sent (or received).

Load Balancing Models. A widely used approach is diffusion, e.g., the first-order-diffusion scheme [9, 18], where the amount of load sent along each edge in each round is proportional to the load difference between the incident nodes. In this work, we consider the alternative, the so-called matching model, where in each round only the edges of a matching are used

to average the load locally. In comparison to diffusion, the matching model reduces the communication in the network and moreover tends to behave in a more "monotone" fashion than diffusion, since it avoids concurrent load exchanges which may increase the maximum load or decrease the minimum load in certain cases.

We measure the smoothness of the load distribution by the so-called *discrepancy*, which is the difference between the maximum and minimum load among all nodes. In view of more complex scenarios where jobs are eventually removed or new jobs are generated, the discrepancy seems to be a more appropriate measure than the *makespan*, which only considers the maximum load.

Many studies in load balancing assume that load is arbitrarily divisible. In this so-called *continuous case*, load balancing corresponds to a Markov chain on the graph and one can resort to a wide range of established techniques to analyze the convergence speed [6, 11, 18]. In particular, the *spectral gap* captures the time to reach a small discrepancy fairly accurately, e.g., see [25, 21] for the diffusion and see [7, 17] for the matching model.

However, in many applications a processor's load may consist of tasks which are not further divisible. That is why the continuous case has been also referred to as "idealized case" [21]. A natural way to model indivisible tasks is the *unit-size token model* where one assumes a smallest load entity, the unit-size token, and load is always represented by a multiple of this smallest entity. In the following, we will refer to the unit-size token model as the *discrete case*.

Initiated by the work of [21], there has been a number of studies on load balancing in the discrete case. Unlike the deterministic rounding in [21], [24] analyzed a randomized rounding based strategy, meaning that an excess token will be distributed uniformly at random among the two communicating nodes. The authors of [24] proved that with this strategy the time to reach constant discrepancy in the discrete case is essentially the same as the corresponding time in the continuous case. Their results hold both for the *random matching model*, where in each round a new random matching is generated by a simple distributed protocol, and the *balancing circuit model* (a.k.a. dimension exchange), where a fixed sequence of matching is applied periodically. In this work, we will focus on the *balancing circuit model*, which is particularly well suited for highly structured graphs such as cycles, tori or hypercubes.

Worst-Case vs. Average-Case Inputs. Previous work has almost always adopted the usual worst-case framework for deriving bounds on the load discrepancy [21]. That means any upper bound on the discrepancy holds for an arbitrary input, i.e., an arbitrary initial load vector. While it is of course very natural and desirable to have such general bounds, the downside is that for graphs with poor expansion like cycles or 2D-tori, the convergence is rather slow, i.e., quadratic or linear in the number of nodes n. This serves as a *motivation* to explore an average-case input. Specifically, we assume that the number of load items at each node is sampled independently from a fixed distribution. Our main results demonstrate that the convergence of the load vector is considerably quicker (measured by the load discrepancy), especially on networks with slow convergence in the worst-case such as cycles and 2D-tori.

We point out that many related problems including scheduling on parallel machines or load balancing in a dynamic setting (meaning that jobs are continuously added and processed) have been studied under random inputs, e.g., [3, 12, 2]. To the best of our knowledge, only very few works have studied this question in iterative load balancing. One exception is [22], which investigated the performance of continuous load balancing on tori in the diffusion model. In contrast to this work, however, only upper bounds are given and they hold for the multiplicative ratio between maximum and minimum load, rather than the discrepancy.

Another related work is [4], which presents a distributed algorithm for community detection that is based on averaging a random $\{-1, 1\}$ initial load vector.

1.1 Notation and Background

We assume that $G = (V, E)$ is an undirected, connected graph with n nodes labeled in $[0, n-1]$. Unless stated otherwise, all logarithms are to the base e. The notations $\mathbb{P}[\mathcal{E}]$ and $\mathbb{E}[X]$ denote the probability of an event $\mathcal{E}$ and the expectation of a random variable X, respectively. For any n-dimensional vector x, $\mathrm{disc}(x) = \max_i x_i - \min_i x_i$ denotes the *discrepancy*. By $\frac{\mathbf{1}}{\mathbf{n}}$ we denote the vector with all values being $\frac{1}{n}$.

Matching Model. In the *matching model* (sometimes also called *dimension exchange model*), every two matched nodes in round t balance their load as evenly as possible. This can be expressed by a symmetric n by n matching matrix $\mathbf{M}^{(t)}$, where with slight abuse of notation we use the same symbol for the matching and the corresponding matching matrix. Formally, matrix $\mathbf{M}^{(t)}$ is defined by $\mathbf{M}^{(t)}_{u,u} = 1/2$, $\mathbf{M}^{(t)}_{v,v} = 1/2$ and $\mathbf{M}^{(t)}_{u,v} = \mathbf{M}^{(t)}_{v,u} = 1/2$ if $\{u, v\} \in \mathbf{M}^{(t)} \subseteq E$, and $\mathbf{M}^{(t)}_{u,u} = \mathbf{M}^{(t)}_{v,v} = 1$, $\mathbf{M}^{(t)}_{u,v} = 0$ $(u \neq v)$ if u, v are not matched.

Balancing Circuit. In the *balancing circuit model*, a specific sequence of matchings is applied periodically. More precisely, let $\mathbf{M}^{(1)}, \ldots, \mathbf{M}^{(d)}$ be a sequence of d matching matrices, also called *period* [1]. Then in step $t \geq 1$, we apply the matching matrix $\mathbf{M}^{(t)} := \mathbf{M}^{(((t-1) \mod d)+1)}$. We define the *round matrix* by $\mathbf{M} := \prod_{s=1}^{d} \mathbf{M}^{(s)}$. If $\mathbf{M}$ is symmetric, we define $\lambda(\mathbf{M})$ to be its second largest eigenvalue (in absolute value). Following [21], if $\mathbf{M}$ is not symmetric (which is usually the case), we define $\lambda(\mathbf{M})$ as the second largest eigenvalue of the symmetric matrix $\mathbf{M} \cdot \mathbf{M}^T$, where $\mathbf{M}^T$ is the transpose of $\mathbf{M}$. We always assume that $\lambda(\mathbf{M}) < 1$, which is guaranteed to hold if the matrix $\mathbf{M}$ is irreducible. Since $\mathbf{M}$ is doubly stochastic, all powers of $\mathbf{M}$ are doubly stochastic. A natural choice for the d matching matrices is given by an edge coloring of G. There are various efficient distributed edge coloring algorithms, e.g. [20, 19].

Balancing Circuit on Specific Topologies. For *cycles*, we will consider the natural "Odd-Even" scheme meaning that for $\mathbf{M}^{(1)}$, the matching consists of all edges $\{j, (j+1) \pmod n\}$ for any odd j, while for $\mathbf{M}^{(2)}$, the matching consists of all edges $\{j, (j+1) \pmod n\}$ for any even j. More generally, for r-dimensional tori with vertex set $[0, n^{1/r} - 1]^r$, we will have $2 \cdot r$ matchings in total, meaning that for every dimension $1 \leq i \leq r$ we have two matchings along dimension i, similar to the definition of matchings for the cycle. For *hypercubes*, the canonical choice is dimension exchange consisting of $d = \log_2 n$ matching matrices $\mathbf{M}^{(i)}$ by $\mathbf{M}^{(i)}_{u,v} = 1/2$ if and only if the bit representation of u and v differ only in bit i.

Continuous Case vs. Discrete Case. In the continuous case, load is arbitrarily divisible. Let $\xi^{(0)} \in \mathbb{R}^n$ be the initial load represented as a row vector, and in every round two matched nodes average their load perfectly. We consider the load vector $\xi^{(t)}$ after t rounds in the balancing circuit model (that means, after the executions of $t \cdot d$ matchings in total). This process corresponds to a linear system $\xi^{(t)} = \xi^{(t-1)} \mathbf{M}$, which results in $\xi^{(t)} = \xi^{(0)} \mathbf{M}^t$.

Let us now turn to the discrete case with indivisible, unit-size tokens. Let $x^{(0)} \in \mathbb{N}^n$ be the initial load vector with average load $\overline{x} := \sum_{w \in V} x^{(0)}_w / n$, and $x^{(t)}$ be the load vector at the end of round t. In case the sum of tokens of the two paired nodes is odd, we employ the

[1] Note that d may be different from the maximal degree (or degree) of the underlying graph.

random orientation (or *randomized rounding*) [21, 24]. More precisely, if there are two nodes u and v with load a and b being paired by matching $\mathbf{M}^{(t)}$, then node u gets either $\lceil \frac{a+b}{2} \rceil$ or $\lfloor \frac{a+b}{2} \rfloor$ tokens, with probability $1/2$ each. The remaining tokens are assigned to node v.

The Average-Case Setting. We consider a setting where each entry of the initial load vector $x^{(0)}$ is chosen from an exponentially concentrated probability distribution D with expectation μ and variance σ^2 (see Definition 1.1). Our main results in this paper hold for all distributions satisfying the following definition.

▶ **Definition 1.1.** A distribution D over $\mathbb{N} \cup \{0\}$ with expectation μ and variance σ^2 is *exponentially concentrated* if there is a constant $\kappa > 0$ so that for any $X \sim D$, $\delta > 0$,

$$\mathbb{P}\left[|X - \mu| \geq \delta \cdot \sigma\right] \leq \exp\left(-\kappa\delta\right).$$

In the following, we refer to **average-case** when the initial number of load items on each vertex is drawn independently from a fixed exponentially concentrated distribution.

▶ **Lemma 1.2.** *The uniform distribution, binomial distribution, geometric distribution and Poisson distribution are all exponentially concentrated.*

▶ **Lemma 1.3.** *Let D be an exponentially concentrated distribution and let $X \sim D$. Then,*

$$\mathbb{P}\left[|X - \mu| \leq 8/\kappa \cdot \sigma \log n\right] \geq 1 - n^{-3}.$$

In particular, the initial discrepancy satisfies $\operatorname{disc}(x^{(0)}) = O(\sigma \cdot \log n)$ *with probability* $1 - n^{-2}$.

The advantage of Lemma 1.3 is that we can use a simple conditioning trick to work with distributions that have a finite range and can therefore be analyzed by Hoeffding's inequality. Therefore in the analysis we may simply work with a bounded-range distribution $\widetilde{D}$, which is D under the condition that only values in the interval $[\mu - 8/\kappa \cdot \sigma \log n, \mu + 8/\kappa \cdot \sigma \log n]$ occur.

1.2 Our results

Our first contribution is a general formula that allows us to express the load difference between an arbitrary pair of nodes in round t.

▶ **Theorem 1.4.** *Consider the balancing circuit model with an arbitrary round matrix $\mathbf{M}$ in the average case. Then for any pair of nodes u, v and round t, it holds for any $\delta > 0$ that*

$$\mathbb{P}\left[\left|x_u^{(t)} - x_v^{(t)}\right| \geq \delta \cdot 16\sqrt{2}/\kappa \cdot \sigma \cdot \log n \cdot \left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2 + \sqrt{64 \log n}\right] \leq 2 \cdot e^{-\delta^2} + 2n^{-3}.$$

Furthermore, for any pair of vertices u, v, we have the following lower bound:

$$\mathbb{P}\left[\left|x_u^{(t)} - x_v^{(t)}\right| \geq \sigma/(2\sqrt{2 \log_2 \sigma}) \cdot \left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2 - \sqrt{64 \log n}\right] \geq \frac{1}{16}.$$

▶ Remark. The lower bound above is useless if σ is small, say, at most a constant. However for sufficiently large σ, the lower bound gives a useful result (see also Section 4 & 5).

The proof of the upper bound Theorem 1.4 is the easier direction, and it relies on a previous result relating continuous and discrete load balancing from [24]. The lower bound is technically more challenging and applies a generalized version of the central limit theorem.

Together, the upper and lower bound in the above result establish that the load deviation between any two nodes u and v is essentially captured by $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2$. However, in

some instances it might be desirable to have a more tangible estimate at the expense of generality. To this end, we first observe that $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2^2 \leq 4 \cdot \max_{k\in V} \left\|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\right\|_2^2$ (see Lemma 3.1). Hence we are left with the problem of bounding the t-step probability vector $\mathbf{M}^t_{\cdot,k}$.

For reversible Markov chains, the last expression has been analyzed in several works. For example, [15, Lemma 3.6] implies that for random walks on graphs, $\mathbf{P}^t_{u,v} = O(\deg(v)/\sqrt{t})$. However, the Markov chain associated to $\mathbf{M}$ is not reversible in general. For irreversible Markov chains, [14] used the so-called evolving set process to derive a similar bound. Specifically, they proved in [14, Theorem 17.17] that if $\mathbf{P}$ denotes the transition matrix of a lazy random walk (i.e., a random walk with loop probability at least 1/2) on a graph with maximal degree Δ, π the stationary distribution of $\mathbf{P}$, then for any vertex $x \in V$:

$$\left|\mathbf{P}^t_{x,x} - \pi_x\right| \leq \frac{\sqrt{2}\Delta^{5/2}}{\sqrt{t}}.$$

Such estimates have been used in applications besides load balancing, including distributed random walks and spanning tree enumeration [23, 15]. Here we generalize this result to Markov chains with an arbitrary loop probability and to arbitrary t-step transition probabilities:

▶ **Theorem 1.5.** *Let $\mathbf{P}$ be the transition matrix of an irreducible Markov chain and π its stationary distribution. Then we have for all states x, y and step t,*

$$\left|\mathbf{P}^t_{x,y} - \pi_y\right| \leq \frac{\pi_{\max}^{3/2}}{\pi_{\min}^{3/2}} \cdot \frac{2}{\beta^{1/2}\alpha}\sqrt{\frac{1-\beta+\alpha}{\alpha t}},$$

where $\alpha := \min_{u\neq v} \mathbf{P}_{u,v} > 0$ and $\beta := \min_u \mathbf{P}_{u,u} > 0$.

Applying this bound to a round matrix $\mathbf{M}$ formed of $d = O(1)$ matchings we obtain $\left|\mathbf{M}^t_{u,v} - 1/n\right| = O(t^{-1/2})$. It should be noted that [24, Lemma 2.5] proved a weaker version where the upper bound is only $O(t^{-1/8})$ instead of $O(t^{-1/2})$. As proven in Lemma 4.2, the bound $O(t^{-1/2})$ is asymptotically tight if we consider the balancing circuit model on *cycles*.

Combining the bound in Theorem 1.5 with the upper bound in Theorem 1.4 yields:

▶ **Theorem 1.6.** *Consider the balancing circuit model with an arbitrary round matrix $\mathbf{M}$ consisting of $d = O(1)$ matchings in the average case. The discrepancy after t rounds is $O(t^{-1/4} \cdot \sigma \cdot (\log n)^{3/2} + \sqrt{\log n})$ with probability $1 - O(n^{-1})$.*

Since the initial discrepancy in the average case is $O(\sigma \cdot \log n)$ (see Lemma 1.3), Theorem 1.6 implies that in the average case, there is a significant decrease (roughly of order $t^{-1/4}$) in the discrepancy, regardless of the underlying topology. For round matrices $\mathbf{M}$ with small second largest eigenvalue, the next result provides a significant improvement:

▶ **Theorem 1.7.** *Consider the balancing circuit model with an arbitrary round matrix $\mathbf{M}$ consisting of d matchings in the average case. We can derive that the discrepancy after t rounds is $O(\lambda(\mathbf{M})^{t/4} \cdot \sigma \cdot (\log n)^{3/2} + \sqrt{\log n})$ with probability $1 - O(n^{-1})$.*

In Section 4, we derive bounds on the discrepancy for concrete topologies (see Table 1).

Finally, we discuss our results and compare them with the convergence of the discrepancy in the worst-case in Section 5. On a high level, these results demonstrate that on all the considered topologies, we have much faster convergence in the average-case than in the worst-case. However, if we are only interested in the time to achieve a very small, say, constant or poly-logarithmic discrepancy, then we reveal an interesting dichotomy: we have a quicker convergence than in the worst-case iff the standard deviation σ is smaller than some threshold depending on the topology. We observe the same phenomena in our experiments.

Table 1 Discrepancy bounds (without logarithmic factors) for different topologies.

2 Proof of the General Bound (Theorem 1.4)

2.1 Proof of Theorem 1.4 (Upper Bound)

We will use the following result from [24] that bounds the deviation between the continuous and discrete load, assuming that we have $\xi^{(0)} = x^{(0)}$.

▶ **Theorem 2.1** ([24, Theorem 3.6(i)]). *Consider the balancing circuit model with an arbitrary round matrix* $\mathbf{M}$*. Then for any round* $t \geq 1$ *it holds that*

$$\mathbb{P}\left[\max_{w \in V} \left|x_w^{(t)} - \xi_w^{(t)}\right| \leq \sqrt{16 \cdot \log n}\right] \geq 1 - 2n^{-3}.$$

The basic proof idea is as follows. Since $\xi_u^{(t)} - \xi_v^{(t)} = \sum_{w \in V} \xi_w^{(0)} \cdot (\mathbf{M}_{w,u}^t - \mathbf{M}_{w,v}^t)$, it is a weighted sum of n i.i.d. random variables and its expectation is 0. We then can apply Hoeffding's inequality to obtain the theorem.

2.2 Proof of Theorem 1.4 (Lower Bound)

The proof of the lower bound will use the following quantitative version of a central limit type theorem for independent but non-identical random variables.

▶ **Theorem 2.2** (Berry-Esseen [5, 10] for non-identical r.v.). *Let* $X_1, X_2, ..., X_n$ *be independently distributed with* $\mathbb{E}[X_i] = 0$, $\mathbb{E}\left[X_i^2\right] = \mathrm{Var}(X_i) = \sigma_i^2$, *and* $\mathbb{E}\left[|X_i|^3\right] = \rho_i < \infty$. *If* $F_n(x)$ *is the distribution of* $\frac{X_1 + ... + X_n}{\sqrt{\sigma_1^2 + \sigma_2^2 + ... + \sigma_n^2}}$ *and* $\Phi(x)$ *is the standard normal distribution, then*

$$|F_n(x) - \Phi(x)| \leq C_0 \psi_0,$$

where $\psi_0 = \left(\sum_{i=1}^n \sigma_i^2\right)^{-3/2} \cdot \sum_{i=1}^n \rho_i$ *and* $C_0 > 0$ *is a constant.*

With this concentration tool at hand, we are able to prove the lower bound in Theorem 1.4. Unfortunately, it appears quite difficult to apply Theorem 2.2 directly to $\xi_u^{(t)} - \xi_v^{(t)}$, since we need a good bound on the error term ψ_0. To this end, we will first partition the vertex set V into buckets with equal contribution to $\xi_u^{(t)} - \xi_v^{(t)}$. Then we will apply Theorem 2.2 to the bucket with the largest variance.

Proof of Theorem 1.4 (Lower Bound). We first consider $\xi_u^{(t)} - \xi_v^{(t)}$:

$$dev := \xi_u^{(t)} - \xi_v^{(t)} = \sum_{w \in V} \xi_w^{(0)} \cdot \left(\mathbf{M}_{w,u}^t - \mathbf{M}_{w,v}^t\right),$$

which is a weighted sum of i.i.d. random variables with expectation μ and variance σ^2. As mentioned earlier, we have $\mathbb{E}[dev] = \sum_{w \in V} \mathbb{E}\left[\xi_w^{(0)}\right] \cdot \left(\mathbf{M}_{w,u}^t - \mathbf{M}_{w,v}^t\right) = 0$ since $\mathbf{M}$ is a doubly stochastic matrix. Of course, we could apply Theorem 2.2 directly to dev, but it

appears difficult to control the error term ψ_0. Therefore we will first partition the above sum into buckets where the weights of the random variables are roughly the same.

More precisely, we will partition V into $2\log_2\sigma$ buckets, where for each i we have $V_i := \left\{w \in V : |\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}| \in (2^{-i-1}, 2^{-i}]\right\}$ for $1 \le i \le 2\log_2\sigma - 1$, and $V_{2\log_2\sigma} := \left\{w \in V : \left|\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right| \le \frac{1}{\sigma^2}\right\}$.

Further, let us consider the variance of dev, since $\mathrm{Var}(aX) = a^2\mathrm{Var}(X)$ and the inputs are independent random variables:

$$\sigma^2_{dev} = \sum_{w\in V} \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2 \sigma^2.$$

Then by the pigeonhole principle there exists an index $1 \le i \le 2\log_2\sigma$ such that

$$\sum_{w\in V_i} \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2 \sigma^2 \ge \frac{1}{2\log_2\sigma} \cdot \sigma^2_{dev}.$$

This is equivalent to

$$\sum_{w\in V_i} \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2 \ge \frac{1}{2\log_2\sigma} \cdot \sum_{w\in V} \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2.$$

Firstly, if such index i is just $2\log_2\sigma$, we can prove the lower bound easily. Now we can derive that, for all w in V_i,

$$\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2^2 \le \left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_\infty \cdot \left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_1 \le \frac{1}{\sigma^2} \cdot 2 = O(\sigma^{-2}).$$

Then in Theorem 1.4 $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2$ is $O(\sigma^{-1})$ and the lower bound holds trivially. Therefore, we will assume in the remainder of the proof that $i < 2\log_2\sigma$.

We now decompose dev into $dev = S + S^c$, where

$$S := \sum_{w\in V_i} \xi^{(0)}_w \cdot \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right) \text{ and } S^c := \sum_{w\notin V_i} \xi^{(0)}_w \cdot \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right).$$

Let us first analyze S. We need to apply Theorem 2.2 to S. Before applying Theorem 2.2, we scale the original distribution to $\xi^{'(0)}_w = \xi^{(0)}_w - \mu$ to make the expectation be 0. In preparation for this, let us first upper bound ψ_0. Using the definition of exponentially concentrated distributions, it follows that for any constant k, the first k moments of $\xi^{'(0)}_w$ are all bounded from above by $O(\sigma^k)$. Hence,

$$\psi_0 = \frac{\sum_{w\in V_i} \mathbb{E}\left[\left|\xi^{'(0)}_w \cdot \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)\right|^3\right]}{\left(\sum_{w\in V_i} \mathbb{E}\left[\left(\xi^{'(0)}_w \cdot \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)\right)^2\right]\right)^{3/2}} \le \frac{O(\sigma^3) \cdot \sum_{w\in V_i} \left|\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right|^3}{\sigma^3 \left(\sum_{w\in V_i} \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2\right)^{3/2}}.$$

Recalling that for any $w \in V_i$, $\left|\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right| \in (2^{-i-1}, 2^{-i}]$, we can simplify the above expression as follows:

$$\psi_0 = O\left(\frac{|V_i| \cdot 2^{-3i}}{|V_i|^{3/2} \cdot 2^{-3i}}\right) = O(|V_i|^{-1/2}).$$

In the following, we will assume that $|V_i| \geq C_1$, where $C_1 > 0$ is a sufficiently large constant to be specified later. Since $\mathrm{Var}(aX) = a^2\mathrm{Var}(X)$, we have

$$F_n(x) = \mathbb{P}\left[\frac{\sum_{w\in V_i} \xi_w^{'(0)} \cdot \left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)}{\sigma\sqrt{\sum_{w\in V_i}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}} \leq x\right]$$
$$= \mathbb{P}\left[S - \mathbb{E}\left[S\right] \leq x\sigma\sqrt{\sum_{w\in V_i}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}\right].$$

Since $|V_i| \geq C_1$, there is a constant $C_2 = C_2(C_1, C_0) > 0$ such that $C_0 \cdot \psi_0 \leq C_2$ and

$$\mathbb{P}\left[S - \mathbb{E}\left[S\right] \geq x\sigma\sqrt{\sum_{w\in V_i}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}\right] \geq \Phi(-x) - C_0\psi_0 \geq \Phi(-x) - C_2.$$

Now let $\Phi^c(x)$ denote the complement of the standard normal distribution. By using [1, Formula 7.1.13] and substitution we get:

$$\frac{1}{\sqrt{\pi}(x + \sqrt{x^2+2})e^{x^2}} < \Phi^c(x) \leqslant \frac{1}{\sqrt{\pi}(x + \sqrt{x^2+4/\pi})e^{x^2}}.$$

Hence by $\Phi(-x) = \Phi^c(x)$, choosing $x = 1$ and C_1 sufficiently large,

$$\mathbb{P}\left[S - \mathbb{E}\left[S\right] \geq \sigma\sqrt{\sum_{w\in V_i}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}\right] \geq \frac{1}{16}.$$

Similarly, we can derive that

$$\mathbb{P}\left[\mathbb{E}\left[S\right] - S \geq \sigma\sqrt{\sum_{w\in V_i}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}\right] \geq \frac{1}{16}.$$

Hence, independent of what the value S^c is, there is still a probability of at least $1/16$ so that $|S + S^c| \geq \sigma/2 \cdot \sqrt{1/(2\log_2\sigma)} \cdot \sqrt{\sum_{w\in V}\left(\mathbf{M}^t_{w,u} - \mathbf{M}^t_{w,v}\right)^2}$, which completes the proof for the case $|V_i| \geq C_1$. The case $|V_i| < C_1$ is similar and omitted here. The basic idea is not to apply Berry-Esseen but simply use the fact that any exponentially distributed random variable deviates from the expectation by $\Omega(\sigma)$ with constant probability. ◀

3 Proof of the Universal Bounds (Theorem 1.6, Theorem 1.7)

In the previous section we proved that the deviation between the loads of two nodes u and v is essentially captured by $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2$. However, in some cases it might be hard to compute or estimate this quantity for arbitrary vertices u and v. Therefore we will establish Theorem 1.6 which gives a more concrete estimate.

3.1 Proof of Theorem 1.6

The proof of Theorem 1.6 is fairly involved and we sketch the high level ideas. We first show that $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2^2$ can be upper bounded in terms of the ℓ_2-distance to the stationary distribution.

▶ **Lemma 3.1.** *Consider the balancing circuit model with an arbitrary round matrix* $\mathbf{M}$*. Then for all* $u, v \in V$*, we have* $\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\|_2^2 \leq 4 \cdot \max_{k\in V} \|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2$*. Further, for any* $u \in V$ *we have* $\max_{v\in V} \|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\|_2^2 \geq \|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2$*.*

The next step and main ingredient of the proof of Theorem 1.6 is to establish that $\|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\|_\infty = O(1/\sqrt{t})$. This result will be a direct application of a general bound on the t-step probabilities of an arbitrary, possibly non-reversible Markov chain, as given in Theorem 1.5 from page 5:

In this subsection we prove Theorem 1.6, assuming the correctness of Theorem 1.5 whose proof is deferred to Section 3.2.

Proof of Theorem 1.6. By Theorem 1.4 and Lemma 3.1, we obtain

$$\mathbb{P}\left[\left|x_u^{(t)} - x_v^{(t)}\right| \geq \delta \cdot 16\sqrt{2}/\kappa \cdot \sigma \cdot \log n \cdot \max_{k\in V}\left\|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\right\|_2 + \sqrt{64 \log n}\right] \leq 2e^{-\delta^2} + 2n^{-3}.$$

Hence we can find a $\delta = \sqrt{3 \log n}$ so that the latter probability gets smaller than $4n^{-3}$. Further, by applying Theorem 1.5 with $\alpha = \beta = 2^{-d}$ to $\mathbf{P} = \mathbf{M}$ we conclude that $\|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\|_\infty = O(t^{-1/2})$, since $d = O(1)$. Using $\|.\|_2^2 \leq \|.\|_\infty \cdot \|.\|_1$, $\|\mathbf{M}^t_{\cdot,k} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2 = O(t^{-1/2})$ and the union bound, $\mathrm{disc}(x^{(t)}) = O(t^{-1/4} \cdot \sigma \cdot (\log n)^{3/2} + \sqrt{\log n})$ with probability at least $1 - 4n^{-1}$. ◀

3.2 Proof of Theorem 1.5

This section is devoted to the proof of Theorem 1.5. Our proof is based on the evolving-set process, which is a Markov chain based on any given irreducible, not necessarily reversible Markov chain on Ω. For the definition of the evolving set process, we closely follow the exposition in [14, Chapter 17].

Let $\mathbf{P}$ denote the transition matrix of an irreducible Markov chain and π its stationary distribution. $\mathbf{P}^t$ is the t-step transition probability matrix. The *edge measure* Q is defined by $Q_{x,y} := \pi_x \mathbf{P}_{x,y}$ and $Q(A, B) = \sum_{x\in A, y\in B} Q_{x,y}$.

▶ **Definition 3.2.** Given a transition matrix $\mathbf{P}$, the **evolving-set process** is a Markov chain on subsets of Ω defined as follows. Suppose the current state is $S \subset \Omega$. Let U be a random variable which is uniform on $[0, 1]$. The next state of the chain is the set

$$\tilde{S} = \left\{y \in \Omega : \frac{Q(S, y)}{\pi_y} \geq U\right\}.$$

This chain is *not irreducible* because $\varnothing$ and Ω are absorbing states. It follows that

$$\mathbb{P}\left[y \in S_{t+1} \,|\, S_t\right] = \frac{Q(S_t, y)}{\pi_y}$$

since the probability that $y \in S_{t+1}$ is equal to the probability of the event that the chosen value of U is less than $\frac{Q(S_t,y)}{\pi_y}$.

▶ **Proposition 3.3** ([14, Proposition 17.19])**.** *Let* (M_t) *be a non-negative martingale with respect to* (Y_t)*, and define* $T_h := \min\{t \geq 0 : M_t = 0 \text{ or } M_t \geq h\}$*. Assume that for any* $h \geq 0$

- *For* $t < T_h$*,* $\mathrm{Var}(M_{t+1} \,|\, Y_0, \ldots, Y_t) \geq \sigma^2$*, and*
- $M_{T_h} \leq Dh$*.*

Let $T := T_1$*. If* M_0 *is a constant, then* $\mathbb{P}\left[T > t\right] \leq \frac{2M_0}{\sigma}\sqrt{\frac{D}{t}}$*.*

We now generalize [14, Lemma 17.14] to cover arbitrarily small loop probabilities.

▶ **Lemma 3.4.** *Let (U_t) be a sequence of independent random variables, each uniform on $[0,1]$, such that S_{t+1} is generated from S_t using U_{t+1}. Then with $\beta := \min_u \mathbf{P}_{u,u} > 0$,*

$$\mathbb{E}\left[\pi(S_{t+1}) \,|\, U_{t+1} \le \beta, S_t = S\right] \ge \pi(S) + Q(S, S^c),$$
$$\mathbb{E}\left[\pi(S_{t+1}) \,|\, U_{t+1} > \beta, S_t = S\right] \le \pi(S) - \frac{\beta Q(S, S^c)}{1-\beta}.$$

The derivation of the next lemma closely follows the analysis in [14, Chapter 17].

▶ **Lemma 3.5.** *For any two states x, y, $\left|\mathbf{P}^t_{x,y} - \pi_y\right| \le \frac{\pi_y}{\pi_x} \cdot \mathbb{P}_{\{x\}}\left[\tau > t\right]$.*

Now we want to use Proposition 3.3 to bound $\mathbb{P}_{\{x\}}[\tau > t]$. To apply it, we substitute the following parameters: M_0 is be $\pi(\{x\})$, Y_t is S_t, and $T = T_1 := \min\{t \ge 0 : \pi(S_t) = 0 \text{ or } \pi(S_t) \ge 1\}$. Hence in our case, τ is the same as T (or T_1) in the proposition. The following two lemmas elaborate on the two preconditions (i) and (ii) of Proposition 3.3.

▶ **Lemma 3.6.** *For any time t and $S_0 = \{x\}$, $\mathrm{Var}_{S_t}(\pi(S_{t+1})) \ge \beta \pi_{\min}^2 \alpha^2$.*

Finally, we derive an upper bound on the amount by which S_t can increase in one iteration.

▶ **Lemma 3.7.** *For any time t and $S_0 = \{x\}$, $\pi(S_{t+1}) \le \left(\frac{1-\beta}{\alpha} + 1\right) \frac{\pi_{\max}}{\pi_{\min}} \cdot \pi(S_t)$.*

The proof of Theorem 1.5 follows then by combining Proposition 3.3, Lemma 3.4, Lemma 3.5, Lemma 3.6 and Lemma 3.7.

3.3 Proof of Theorem 1.7

We now prove the following discrepancy bound that depends on the $\lambda(\mathbf{M})$, as defined in Section 1.1.

Proof of Theorem 1.7. By [24, Lemma 2.4], for any pair of vertices $u, v \in V$, $\left|\mathbf{M}^t_{u,v} - \frac{1}{n}\right| \le \lambda(\mathbf{M})^{t/2}$. Hence by Lemma 3.1, $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2 = O(\lambda(\mathbf{M})^{t/4})$. The bound on the discrepancy follows from Theorem 1.4 and the union bound over all vertices. ◀

4 Applications to Different Graph Topologies

Cycles. Recall that for the cycle, $V = \{0, \ldots, n-1\}$ is the set of vertices, and the distance between two vertices is $\mathrm{dist}(x,y) = \min\{y - x, x + n - y\}$ for any pair of vertices $x < y$.

The upper bound on the discrepancy follows directly from Theorem 1.6, and it only remains to prove the lower bound. To this end, we will apply the lower bound in Theorem 1.4 and need to derive a lower bound on $\|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2$. Intuitively, if we had a simple random walk, we could immediately infer that this quantity is $\Omega(1/\sqrt{t})$. Since after t steps, the random walk is with probability $\approx 1/\sqrt{t}$ at any vertex with distance at most $O(\sqrt{t})$. To prove that this also holds for the load balancing process, we first derive a concentration inequality that upper bounds the probability for the random walk to reach a distant state:

▶ **Lemma 4.1.** *Consider the standard balancing circuit model on the cycle with round matrix $\mathbf{M}$. Then for any $u \in V$ and $\delta \in (0, n/2 - 1)$, we have*

$$\sum_{v \in V:\ \mathrm{dist}(u,v) \ge \delta} \mathbf{M}^t_{u,v} \le 2 \cdot \exp\left(-\frac{(\delta-2)^2}{8t}\right).$$

With the help of Lemma 4.1, we can indeed verify our intuition:

▶ **Lemma 4.2.** *Consider the standard balancing circuit model on the cycle with round matrix* $\mathbf{M}$*. Then for any vertex* $u \in V$*,* $\|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2 = \Omega(1/\sqrt{t})$.

Lemma 4.2 also proves that the factor $\sqrt{1/t}$ in the upper bound in Theorem 1.5 is the best possible. The lower bound on the discrepancy now follows by combining Lemma 4.2 with Theorem 1.4 and Lemma 3.1 stating that for any vertex $u \in V$, there exists another vertex $v \in V$ such that $\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\|_2^2 \geq \|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2 = \Omega(1/\sqrt{t})$.

Tori. In this section we consider r-dimensional tori, where $r \geq 1$ is any constant. For the upper bound, note that the computation of $\mathbf{M}^t_{\cdot,\cdot}$ can be decomposed to independent computations in the r dimensions, and each dimension has the same distribution as the cycle on $n^{1/r}$ vertices. Specifically, if we denote by $\widetilde{\mathbf{M}}$ the round matrix of the standard balancing circuit scheme on the cycle with $n^{1/r}$ vertices and $\mathbf{M}$ is the round matrix of the r-dimensional torus with n vertices, then for any pair of vertices $x = (x_1, \ldots, x_r), v = (y_1, \ldots, y_r)$ on the torus we have $\mathbf{M}^t_{x,y} = \prod_{i=1}^r \widetilde{\mathbf{M}}^t_{x_i,y_i}$. From Theorem 1.5, $|\widetilde{\mathbf{M}}^t_{x_i,y_i} - \frac{1}{n^{1/r}}| = O(t^{-1/2})$, and therefore, since r is a constant,

$$\mathbf{M}^t_{x,y} \leq \prod_{i=1}^{r} \left(\frac{1}{n^{1/r}} + O(t^{-1/2}) \right) = O(t^{-r/2} + n^{-1}),$$

and thus $\left\|\mathbf{M}^t_{x,y} - \frac{\mathbf{1}}{\mathbf{n}}\right\|_2^2 = O(t^{-r/2})$ for any pair of vertices x, y. Hence by Lemma 3.1, $\left\|\mathbf{M}^t_{\cdot,u} - \mathbf{M}^t_{\cdot,v}\right\|_2^2 = O(t^{-r/2})$. Plugging this bound into Theorem 1.4 yields that the load difference between any pair of the nodes u and v at round t is at most $O(t^{-r/4} \cdot \sigma \cdot \log^{3/2} n + \sqrt{\log n})$ with probability at least $1 - 4n^{-1}$. The bound on the discrepancy now simply follows by the union bound.

We now turn to the lower bound on the discrepancy. With the same derivation as in Lemma 4.2 we obtain the following result:

▶ **Lemma 4.3.** *Consider the standard balancing circuit model on the* r*-dimensional torus with round matrix* $\mathbf{M}$*. Then for any vertex* $u \in V$*,* $\|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\|_2^2 = \Omega(t^{-r/2})$.

The lower bound on the torus follows by combining Lemma 4.3 and Theorem 1.4.

Expanders. The upper bound $O(\lambda(\mathbf{M})^{t/4} \cdot \sigma \cdot (\log n)^{3/2} + \sqrt{\log n})$ for expanders follows immediately from Theorem 1.7. For the lower bound, since the round matrix consists of d matchings, it is easy to verify that whenever $\mathbf{M}^t_{u,v} > 0$, we have $\mathbf{M}^t_{u,v} \geq 2^{-d \cdot t}$. Consequently, for any vertex $u \in V$, $\left\|\mathbf{M}^t_{\cdot,u} - \frac{\mathbf{1}}{\mathbf{n}}\right\|_2^2 = \Omega(2^{-d \cdot t})$. Plugging this into Theorem 1.4 yields a lower bound on the discrepancy which is $\Omega(2^{-d \cdot t/2} \cdot \sigma / \sqrt{\log \sigma})$.

Hypercubes. For the hypercube, there is a worst-case bound of $\log_2 \log_2 n + O(1)$ [16, Theorem 5.1 & 5.3] for any input after $\log_2 n$ iterations of the dimension-exchange, i.e., after one execution of the round matrix. Hence, we will only analyze the discrepancy after s matchings, where $1 \leq s < \log_2 n$. By applying the same analysis as in Theorem 1.7, but now with $|\prod_{s=1}^t \mathbf{M}^{(s)}_{u,v} - \frac{1}{n}| \leq 2^{-t}$, we obtain that the discrepancy is $O(2^{-t/2} \cdot \sigma \cdot (\log n)^{3/2} + \sqrt{\log n})$. Applying Theorem 1.4, we obtain the lower bound $\Omega(2^{-t/2} \cdot \sigma / \sqrt{\log \sigma})$.

5 Discussion and Empirical Results

We will now compare our average-case to a worst-case scenario on cycles, 2D-tori and hypercubes. For the sake of concreteness, we always assume that the input is drawn from a

uniform distribution $\mathsf{Uni}[0, 2K]$. Our choice for the worst-case load vector will have (roughly) the same number of tokens and initial discrepancy. However, the exact definition of the vector will depend on the underlying topology.

Cycles and 2D-Tori For the worst-case setting on cycles, fix an arbitrary node $u \in V$ and let all nodes with distance at most $n/4$ initially have a load of $2K$ while all the other nodes have load 0. This gives rise to a load vector with nK tokens and initial discrepancy $2K$. For 2D-tori, fix an arbitrary node $u \in V$ and assign a load of $2K$ to the $n/2$ nearest neighbors and load 0 otherwise. This defines a load vector with nK tokens and initial discrepancy $2K$.

The next result provides a lower bound on the discrepancy for cycles and 2D-tori in the aforementioned worst-case setting. It essentially shows that for worst-case inputs, $\Omega(n^2)$ rounds and $\Omega(n)$ rounds are necessary for the cycle, 2D-tori, respectively, in order to reduce the discrepancy by more than a constant factor. This stands in sharp contrast to Theorem 1.6, proving a decay of the discrepancy by $\approx t^{-1/4}$, starting from the first round.

▶ **Proposition 5.1.** *For the aforementioned worst-case setting on the cycle, it holds for any round $t > 0$ that* $\operatorname{disc}(x^{(t)}) \geq \frac{1}{8} \cdot K \cdot \left(1 - \exp\left(-\frac{n^2}{2048t}\right)\right) - \sqrt{64 \log n}$, *with probability at least $1 - n^{-1}$. Further, for 2D-tori, it holds for any round $t > 0$ that* $\operatorname{disc}(x^{(t)}) \geq \frac{1}{8} \cdot K \cdot \left(1 - \exp\left(-\frac{n}{2048t}\right)\right) - \sqrt{64 \log n}$, *with probability at least $1 - n^{-1}$.*

Hypercube. We will consider only $\log_2 n$ rounds, since the discrepancy is $\log_2 \log_2 n + O(1)$ after $\log_2 n$ rounds and $O(1)$ after $2 \log_2 n$ rounds [16]. A natural corresponding worst-case distribution is to have load $2K$ on all nodes whose $\log_2 n$-th bit is equal to 1 and 0 otherwise. This way the discrepancy is only reduced in the final round $\log_2 n$.

Experiments. For each of the cycle, 2D-torus and hypercube, we consider two comparative experiments with an average-case initial load vector and a worst-case initial load vector.

The first experiment considers a "lightly loaded case", where the theoretical results suggest that a small (i.e., constant or logarithmic) discrepancy is reached before the expected worst-case load balancing time, which are $\approx n^2$ for cycles and $\approx n$ for 2D-tori. The second experiment considers a "heavily loaded case", where the theoretical results suggest that a small discrepancy is not reached faster than in the worst-case.

For cycles and 2D-tori we choose for the lightly loaded case $K = \sqrt{n}$ and for the heavily loaded case $K = n^2$. The experiments confirm the theoretical results in the sense that for both choices of K, we have a much quicker convergence of the discrepancy than in the worst case. However, the experiments also demonstrate that only in the lightly loaded case we reach a small discrepancy quickly, whereas in the heavily loaded case there is no big difference between worst-case and average-case if it comes to the time to reach a small discrepancy.

On the hypercube, our bounds on the discrepancy suggest a smaller K in comparison to the experiments on cycles and 2D-tori. That is why we choose $K = n^{1/4}$ in the lightly loaded case and $K = n$ in the heavily loaded case. With these adjustments of K in both cases, the experimental results of the hypercube are inline with the ones for the cycle and 2D-tori. More details including the plots can be found in the full version [8].

Abstract

Inspired by the work of Kempe et al. [Kempe, Kleinberg, Oren, Slivkins, EC 2013], we introduce and analyze a model on opinion formation; the update rule of our dynamics is a simplified version of that of [Kempe, Kleinberg, Oren, Slivkins, EC 2013]. We assume that the population is partitioned into types whose interaction pattern is specified by a graph. Interaction leads to population mass moving from types of smaller mass to those of bigger mass. We show that starting uniformly at random over all population vectors on the simplex, our dynamics converges point-wise with probability one to an independent set. This settles an open problem of [Kempe, Kleinberg, Oren, Slivkins, EC 2013], as applicable to our dynamics. We believe that our techniques can be used to settle the open problem for the Kempe et al. dynamics as well.

Next, we extend the model of Kempe et al. by introducing the notion of birth and death of types, with the interaction graph evolving appropriately. Birth of types is determined by a Bernoulli process and types die when their population mass is less than ϵ (a parameter). We show that if the births are infrequent, then there are long periods of "stability" in which there is no population mass that moves. Finally we show that even if births are frequent and "stability" is not attained, the total number of types does not explode: it remains logarithmic in $1/\epsilon$.

1 Introduction

The birth, growth and death of political parties, organizations, social communities and product adoption groups (e.g., whether to use Windows, Mac OS or Linux) often follows common patterns, leading to the belief that the dynamics underlying these processes has much in common. Understanding this commonality is important for the purposes of predictability and hence has been the subject of study in mathematical social science for many years [4, 7, 8, 14, 26]. In recent years, the growth of social communities on the Internet, and their increasing economic and social value, has provided fresh impetus to this study [1, 2, 5, 17].

In this paper, we continue along these lines by building on a natural model proposed by Kempe et al. [15]. Their model consists of an influence graph G on n vertices (types, parties) into which the entire population mass is partitioned. Their main tenet is that individuals in smaller parties tend to get influenced by those in bigger parties [1]. Individuals in the two vertices connected by an edge can interact with each other. These interactions result in individuals moving from smaller to bigger in population vertices. Kempe et al. characterize stable equilibria of this dynamics via the notion of Lyapunov stability, and they show that under any stable equilibrium, the entire mass lies in an independent set, i.e., the population breaks into non-interacting islands. The message of this result is clear: a population is (Lyapunov) stable, in the sense that the system does not change by much under small perturbations, only if people of different opinions do not interact. They also showed convergence to a fixed point, not necessarily an independent set, starting from any initial population vector and influence graph. One of their main open problems was to determine whether starting uniformly at random over all population vectors on the unit simplex, their dynamics converge with probability one to an independent set.

We first settle this open problem in the affirmative for a modification of the dynamics, which however is similar to that of Kempe et al. in spirit in that it moves mass from smaller to bigger parties (the dynamics is defined below along with a justification). We believe that the ideas behind our analysis can be used to settle the open problem for the dynamics of Kempe et al. as well, via a more complicated spectral analysis of the Jacobian of the update rule of the dynamics (see Section 3.2).

Whereas the model of Kempe et al. captures and studies the effects of migration of individuals across types in a very satisfactory manner, it is quite limited in that it does not include the birth and death of types. In this paper, we model birth and death of types. In order to arrive at realistic definitions of these notions, we first conducted case studies of political parties in several countries. We present below a case study on Greek politics, but similar phenomena arise in India, Spain, Italy and Holland (see Wikipedia pages).

The Siriza party in Greece provides an excellent example of birth of a party (this information is readily available in Wikipedia pages). This party was essentially in a dormant state until the first 2012 elections in which it got 16.8% of the vote, mostly taken away from the Pasok party, which dropped from 43.9% to 13.2% in the process (Wikipedia). In the second election in 2012, Siriza increased its vote to 26.9% and Pasok dropped to 12.3%. Finally, in 2015, Siriza increased to 36.3% and Pasok dropped further to 4.7%. Another party, Potami, was formed in 2015 and got 6.1% of the vote, again mainly from Pasok. However, in a major 2016 poll, it seems to have collapsed and is likely be absorbed by other parties. In contrast, the KKE party in Greece, which had almost no interactions with the rest of the parties (and was like a disconnected component), has remained between 4.5-8.5% of the vote over the last 26 years.

Motivated by these examples, we have modeled birth and death of types in the following manner. We model population as a continuum, as is standard in population dynamics, and time is discrete. This is the same as arXiv Version 1 of [15], which is what we will refer to

[1] Changes in the sizes of political parties and other organizations can occur for a multitude of possible reasons, such as changes in economic conditions, immigration flows, wars and terrorism, and drastic changes in technology (such as the introduction of the Internet, smart phones and social media). Studying changes due to these multitude of reasons in a systematic quantitative manner is unrealistic. For this reason, many authors in computer science and the social sciences have limited their work to studying the effects of relative sizes of the groups, in itself a key factor, e.g. see [15] and references therein. Following these works, our paper also takes a similar approach.

throughout this paper; the later versions study the continuous time analog. The birth of a new type in our model is determined by a Bernoulli process, with parameter p. The newly born type absorbs mass from all other types via a randomized process given by an arbitrary distribution with finite support (see Section 2.2). After birth, the new type is connected to an arbitrary, though non-empty, set of other types. Our model has a parameter ϵ, and when the size of a type drops below ϵ, it simply dies, moving its mass equally among its neighbors.

Our rule for migration of mass, which is somewhat different from that of Kempe et al. is motivated by the following considerations. For a type u, $\boldsymbol{x}_u$ will denote the fraction of population that is of type u. Assume that types u and v have an edge, i.e., their populations interact. If so, we will assume that some individuals of the smaller type get influenced by the larger one and move to the larger one. The question is what is a reasonable assumption on the population mass that moves.

For arriving at the rule proposed in this paper, consider three situations. If $\boldsymbol{x}_u = .02$ and $\boldsymbol{x}_v = .25$, i.e., the smaller type is very small, then clearly not many people will move. If $\boldsymbol{x}_u = .22$ and $\boldsymbol{x}_v = .25$, i.e., the types are approximately of the same population size, then again we expect not many people to move. Finally, if $\boldsymbol{x}_u = .15$ and $\boldsymbol{x}_v = .25$, i.e., both types are reasonably big and their difference is also reasonably big, then we expect several people to move from the smaller to the bigger type. From these considerations, we propose that the amount of population mass moving from v to u, assuming $\boldsymbol{x}_v < \boldsymbol{x}_u$, is given by the rule

$$f_{v\to u}^{(t)} = \boldsymbol{x}_u^{(t)}\boldsymbol{x}_v^{(t)} \cdot F_{uv}(\boldsymbol{x}_u^{(t)} - \boldsymbol{x}_v^{(t)}),$$

where $F_{uv}(z) = F_{vu}(z)$ is a function that captures the level of influence between u, v. We assume that $F_{uv} : [-1, 1] \to [-1, 1]$ is continuously differentiable, $F_{uv}(0) = 0$ (there is no population flow between two neighboring types if they have the same fraction of population), is increasing and finally it is odd, i.e., $F_{uv}(-z) = -F_{uv}(z)$ (so that $f_{v\to u}^{(t)} = -f_{u\to v}^{(t)}$).

In this simplified setting we have made the assumption that the system is closed, i.e., that it does not get influence from outside factors (e.g., economical crisis, immigrations flows, terrorism etc).

1.1 Our results and techniques

We first study our migration dynamics without birth and death and settle the open problem of Kempe et al., as it applies to our dynamics.

We show that the dynamics converges set-wise to a fixed point, i.e., there is a set S containing only fixed points such that the distance between the trajectory of the dynamics and S goes to zero for all starting population vectors. To show this convergence result, we use a simple potential function of the population mass namely, the ℓ_2^2 norm of the population vector, and we show that this potential is strictly increasing at each time step (unless the dynamics is at a fixed point). Moreover, the potential is bounded, hence the result follows.

Next, we strengthen this result by showing point-wise convergence as well. The latter result is technically deeper and more difficult, since it means that every trajectory converges to a specific fixed point $\boldsymbol{p}$. We show point-wise convergence by constructing a *local* potential function that is decreasing in a small neighborhood of the limit point $\boldsymbol{p}$. The potential function is always non-zero in that small neighborhood and is zero only at $\boldsymbol{p}$.

Using the latter result and one of the most important theorems in dynamical systems, the Center Stable Manifold Theorem, we prove that with probability one, under an initial population vector picked uniformly at random from the unit simplex, our dynamics converges point-wise to a fixed point $\boldsymbol{p}$, where the *active* types w in $\boldsymbol{p}$, i.e., $w \in V(G)$ so that $\boldsymbol{p}_w > 0$, form an independent set of G. This involves characterization of the linearly stable (see

Section 2.3 for definition) fixed points and proving that the update rule of the dynamics is a local diffeomorphism[2]. This settles the open problem of Kempe et al., mentioned in the Introduction, for our dynamics. This result is important because it allows us to perform a long-term average case analysis of the behavior of our dynamics and make predictions.

Next, we introduce birth and death in our model. Clearly there will be no convergence in this case since new parties are created all the time. Instead we define and study a notion of "stability" which is different from the classical notions that appear in dynamical systems (see Section 2.3 for the definition of the classical notion and Definition 12 for our notion). A dynamics is (T, d)-stable if and only if $\forall t: \ T \leq t \leq T + d$, no population mass moves at step t. We show that despite birth and death, there are arbitrarily long periods of "stability" with high probability, for a sufficiently small p. Finally, we show that in the long run, with high probability, for a sufficiently large p, the number of types in the population will be $O(\log(1/\epsilon))$. This may seem counter-intuitive, since with a large p new types will be created often; however, since new types absorb mass from old types, the old types die frequently. In contrast, in the short term (from the definition of ϵ) we can have up to $\Theta(1/\epsilon)$ types.

Let us give an interpretation of the results of the previous paragraph in terms of political parties of certain countries (information obtained from Wikipedia). Countries do have periods of political stability, e.g., during 1981-85, 2004-07, no new major (with more than 1% of the vote) parties were formed in Greece, moreover there was no substantial change in the percentage of votes won by parties in successive elections. The parameter ϵ can be interpreted as the fraction of people that can form a party that participates in elections. The minimum size of a party arises for organizational and legal reasons, and is $\Theta(1/Q)$, where Q is the population of the country and therefore ϵ is inversely related to population. The message of the latter theorem is that the number of political parties grows at most as the logarithm of the population of the country, i.e. $O(\log Q)$ [3]. The following data supports this fact. The population of Greece, Spain and India in 2015 was $1.1e7, 4.6e7$ and $1.2e9$, respectively, and the number of parties that participated in the general elections was 20, 32 and 50, respectively.

1.2 Related work

As stated above, we build on the work of Kempe et al. [15]. They model their dynamics in a similar way, i.e., there is a flow of population for every interacting pair of types u, v. The flow goes from smaller to bigger types; in our case the mass is just the population of a type. One very interesting common trait between the two dynamics is that the fixed points have similar description: all types with positive mass belonging to the same connected component C have the same mass. Stable fixed points also have the same properties in both dynamics, namely they are independent sets. The update rules of the two dynamics are somewhat different; our simpler dynamics helps us in proving stronger results.

One of the most studied models is the following: there is a graph G in which each vertex denotes an individual having two possible opinions. At each time step, an individual is chosen at random who next chooses his opinion according to the majority (best response) opinion among his neighbors. This has been introduced by Galam[10] and appeared in [22, 9], where they address the question: in which classes of graphs do individuals reach consensus. The same dynamics, but with each agent choosing his opinion according to noisy

[2] Continuously differentiable, the inverse exists and is also continuously differentiable (in some small neighborhood of each point).

[3] This is just an upper bound, countries like UK, US satisfy this rule too.

best response (the dynamics is a Markov chain) has been studied in [21, 16] and many other papers referenced therein. They give bounds for the hitting time and expected time of the consensus state (risk dominant) respectively.

Another well-known model for the dynamics of opinion formation in multi-agent systems is Hegselmann-Krause [11]. Individuals are discrete entities and are modeled as points in some opinion space (e.g., real line). At every time step, each individual moves to the mass center of all the individuals within unit distance. Typical questions are related to the rate of convergence (see [6] and references therein). Finally, another classic model is the voter model, where there is a fixed graph G among the individuals, and at every time step, a random individual selects a random neighbor and adopts his opinion [12]. For more information on opinion formation dynamics of an individual using information learned from his neighbors, see [13] for a survey (also see [29] for more information on opinion formation models).

Other works, including dynamical systems that show convergence to fixed points, are [23, 19, 18, 24, 20, 27]. [27] focuses on quadratic dynamics and they show convergence in the limit. On the other hand [3] shows that sampling from the distribution this dynamics induces at a given time step is PSPACE-complete. In [23, 19], it is shown that replicator dynamics in linear congestion and 2-player coordination games converges to pure Nash equilibria, and in [18, 24] it is shown that gradient descent converges to local minima, avoiding saddle points even in the case where the fixed points are uncountably many.

Organization: In Section 2 we describe our dynamics formally and give the necessary definitions about dynamical systems. In Section 3 we show that our dynamics without births/deaths converges with probability one to fixed points $\boldsymbol{p}$ so that the set of types with positive population, i.e., active types, form an independent set of G. Finally, in Section 4 we first show that there is no explosion in the number of types (i.e., the order never becomes $\Theta(1/\epsilon)$) and also we perform stability analysis using our notion.

2 Preliminaries

Notation: We denote the probability simplex on a set of size n as Δ_n. Vectors in $\mathbb{R}^n$ are denoted in boldface and $\boldsymbol{z}_j$ denotes the jth coordinate of a given vector $\boldsymbol{z}$. Time indices are denoted by superscripts. Thus, a time indexed vector $\boldsymbol{z}$ at time t is denoted as $\boldsymbol{z}^{(t)}$. We use the letters $J, \mathbb{J}$ to denote the Jacobian of a function and finally we use f^t to denote the composition of f by itself t times.

2.1 Migration dynamics

Let $G = (V, E)$ be an undirected graph on n vertices (which we also call types), and let N_v denote the set of neighbors of v in G. During the whole dynamical process, each vertex v has a non-negative population mass representing the fraction of the population of type v. We consider a discrete-time process and let $\boldsymbol{x}_v^{(t)}$ denote the mass of v at time step t. It follows that the condition

$$\sum_{v \in V(G)} \boldsymbol{x}_v^{(t)} = 1,$$

must be maintained for all t, i.e., $\boldsymbol{x}^{(t)} \in \Delta_n$[4] for all $t \in \mathbb{N}$.

[4] Recall that Δ_n denotes the unit simplex of dimension $n+1$, where $|V(G)| = n$.

Additionally, we consider a dynamical migration rule where the population can move along edges of G at each step. The movement at step t is determined by $\boldsymbol{x}^{(t)}$. Specifically, for $uv \in E(G)$, the amount of mass moving from v to u at step t is given by

$$f_{v\to u}^{(t)} = \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} F_{uv}(\boldsymbol{x}_u^{(t)} - \boldsymbol{x}_v^{(t)}).$$

For all $uv \in E(G)$ we assume that $F_{uv} : [-1,1] \to [-1,1]$ is a continuously differentiable function such that:

1. $F_{uv}(0) = 0$ (there is no population flow between two neighboring types if they have the same fraction of population),
2. F_{uv} is increasing (the larger $\boldsymbol{x}_u - \boldsymbol{x}_v$, the more population moving from v to u),
3. F_{uv} is odd i.e., $F_{uv}(-z) = -F_{uv}(z)$ (so that $f_{v\to u}^{(t)} = -f_{u\to v}^{(t)}$).

It can be easily derived from the assumptions that $F_{uv}(z) \geq F_{uv}(0) = 0$ for $z \geq 0$ and $F'_{uv}(-z) = F'_{uv}(z)$ for $z \in [-1,1]$, where F'_{uv} denotes the derivative of F_{uv}. Note that $f_{v\to u}^{(t)} > 0$ implies that population is moving from v to u, and $f_{v\to u}^{(t)} < 0$ implies that population is moving in the other direction. The update rule for the population of type u can be written as

$$\begin{aligned} \boldsymbol{x}_u^{(t+1)} &= \boldsymbol{x}_u^{(t)} + \sum_{v\in N_u} f_{v\to u}^{(t)} && (1)\\ &= \boldsymbol{x}_u^{(t)} + \sum_{v\in N_u} \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} F_{uv}(\boldsymbol{x}_u^{(t)} - \boldsymbol{x}_v^{(t)}). && (2) \end{aligned}$$

We denote the update rule of the dynamics as $g : \Delta_n \to \Delta_n$, i.e., we have that

$$\boldsymbol{x}^{(t+1)} = g(\boldsymbol{x}^{(t)}).$$

Therefore it holds that $\boldsymbol{x}^{(t)} = g^t(\boldsymbol{x}^{(0)})$, where g^t denotes the composition of g by itself t times. It is easy to see g is well-defined for $\sup_{z\in[-1,1]} |F_{uv}(z)| \leq 1$ for all $uv \in E(G)$, in the sense that if $\boldsymbol{x}^{(t)} \in \Delta_n$ then $\boldsymbol{x}^{(t+1)} \in \Delta_n$. This is true since for all u we get (using induction, i.e., $\boldsymbol{x}^{(t)} \in \Delta_n$)

$$\begin{aligned} \boldsymbol{x}_u^{(t+1)} &= \boldsymbol{x}_u^{(t)} + \sum_{v\in N_u} \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} F_{uv}(\boldsymbol{x}_u^{(t)} - \boldsymbol{x}_v^{(t)})\\ &\geq \boldsymbol{x}_u^{(t)} - \sum_{v\in N_u} \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} \geq \boldsymbol{x}_u^{(t)} - \boldsymbol{x}_u^{(t)}(1 - \boldsymbol{x}_u^{(t)}) \geq 0, \end{aligned}$$

moreover it holds

$$\begin{aligned} \boldsymbol{x}_u^{(t+1)} &= \boldsymbol{x}_u^{(t)} + \sum_{v\in N_u} \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} F_{uv}(\boldsymbol{x}_u^{(t)} - \boldsymbol{x}_v^{(t)})\\ &\leq \boldsymbol{x}_u^{(t)} + \sum_{v\in N_u} \boldsymbol{x}_u^{(t)} \boldsymbol{x}_v^{(t)} \leq \boldsymbol{x}_u^{(t)} + \boldsymbol{x}_u^{(t)}(1 - \boldsymbol{x}_u^{(t)}) \leq \boldsymbol{x}_u^{(t)} + 1 - \boldsymbol{x}_u^{(t)} = 1, \end{aligned}$$

and also $\sum_u \boldsymbol{x}_u^{(t+1)} = \sum_u \boldsymbol{x}_u^{(t)} = 1$ (the other terms cancel out).

2.2 Birth and death of types

Political parties or social communities don't tend to survive once their size becomes "small" and hence there is a need to incorporate death of parties in our model. We will define a global parameter ϵ in our model. When the population mass of a type v becomes smaller than some fixed value ϵ, we consider it to be dead and move its mass arbitrarily to existing

types. Formally, if $\boldsymbol{x}_v^{(t)} \leq \epsilon$ then $\boldsymbol{x}_v^{(t)} \leftarrow 0$ and $\boldsymbol{x}_u^{(t)} \leftarrow \boldsymbol{x}_u^{(t)} + \boldsymbol{x}_v^{(t)} / |N_v|$ for all $u \in N_v$. Also, vertex v is removed and edges are added arbitrarily on its neighbors to ensure connectivity of the resulting graph.

▶ Remark. It is not hard to see that the maximum number of types is $1/\epsilon$ (by definition). We say that we have explosion in the number of types if they are of $\Theta(1/\epsilon)$. In Theorem 16 we show that in the long run, the number of types is much smaller – it is $O(\log(1/\epsilon))$ with high probability.

Every so often, new political opinions emerge and like-minded people move from the existing parties to create a new party, which then follows the normal dynamics to either survive or die out. To model birth of new types, at each time step, with probability p, we create a new type v such that v takes a portion of mass from each existing type independently. The amount of mass going to v from each u follows an arbitrary distribution in the range $[\beta_{\min}, \beta_{\max}]$. Specifically, let $\boldsymbol{Z}_u \sim \mathcal{D}$ where $\mathcal{D}$ is a distribution with support $[\beta_{\min}, \beta_{\max}]$, the amount of mass going from u to v is $\boldsymbol{Z}_u \boldsymbol{x}_u$. We connect v to the existing graph arbitrarily such that it remains connected.

Additionally, we make a small change to the migration dynamics defined in Section 2.1 to make it more realistic. Our tenet is that population mass migrates from smaller to bigger types because of influence. However, if the two types are of approximately the same size, the difference is size is not discernible and hence migration should not happen. To incorporate this, we introduce a new parameter $\delta > 0$ and if $|\boldsymbol{x}_u - \boldsymbol{x}_v| \leq \delta$, we assume that no population moves from u to v.

Finally, each step of the dynamics consists of there phases in the following order:

1. Migration: the dynamics follows the update rule from Section 2.1.
2. Birth: with probability p, a new type v is created and takes mass from the existing types.
3. Death: a type with mass smaller than ϵ dies out and move its mass to the existing types.

▶ Remark. For any different order of phases, all proofs in the paper still go through with minimal changes.

2.3 Definitions and basics

A recurrence relation of the form $\boldsymbol{z}^{(t+1)} = f(\boldsymbol{z}^{(t)})$ is a discrete time dynamical system, with update rule $f : \mathcal{S} \to \mathcal{S}$ (for our purposes, the set $\mathcal{S}$ is Δ_n). The point $\boldsymbol{p}$ is called a *fixed point* or *equilibrium* of f if $f(\boldsymbol{p}) = \boldsymbol{p}$. A fixed point $\boldsymbol{p}$ is called *Lyapunov stable* (or just stable) if for every $\varepsilon > 0$, there exists a $\zeta = \zeta(\varepsilon) > 0$ such that for all $\boldsymbol{z}$ with $\|\boldsymbol{z} - \boldsymbol{p}\| < \zeta$ we have that $\left\|f^k(\boldsymbol{z}) - \boldsymbol{p}\right\| < \varepsilon$ for every $k \geq 0$. We call a fixed point $\boldsymbol{p}$ *linearly stable* if, for the Jacobian $J(\boldsymbol{p})$ of f, it holds that its spectral radius is at most one. It is true that if a fixed point $\boldsymbol{p}$ is stable then it is linearly stable but the converse does not hold in general [25]. A sequence $(f^t(\boldsymbol{z}^{(0)}))_{t\in\mathbb{N}}$ is called a *trajectory* of the dynamics with $\boldsymbol{z}^{(0)}$ as starting point. A common technique to show that a dynamical system converges to a fixed point is to construct a function $P : \Delta_m \to \mathbb{R}$ such that $P(f(\boldsymbol{z})) > P(\boldsymbol{z})$ unless $\boldsymbol{z}$ is a fixed point. We call P a *potential* or *Lyapunov* function.

3 Convergence to independent sets almost surely

In this section we prove that the deterministic dynamics (assuming no death/birth of types, namely the graph G remains fixed) converges point-wise to fixed points $\boldsymbol{p}$ where $\{v : \boldsymbol{p}_v > 0\}$ (set of active types) is an independent set of the graph G, with probability one assuming that the starting point $\boldsymbol{x}^{(0)}$ follows an atomless distribution with support in Δ_n. To do that,

we show that for all starting points $\boldsymbol{x}^{(0)}$, the dynamics converges point-wise to fixed points. Moreover we prove that the update rule of the dynamics is a diffeomorphism and that the linearly stable fixed points $\boldsymbol{p}$ of the dynamics satisfy the fact that the set of active types in $\boldsymbol{p}$ is an independent set of G. Finally, our main claim of the section follows by using Center-Stable Manifold theorem.

Structure of fixed points. The fixed points of the dynamics (1) are vectors $\boldsymbol{p}$ such that for each $uv \in E(G)$, at least one of the following conditions must hold:

1. $\boldsymbol{p}_v = \boldsymbol{p}_u$, 2. $\boldsymbol{p}_v = 0$, 3. $\boldsymbol{p}_u = 0$.

Therefore, for each fixed point $\boldsymbol{p}$, the set of active types (types with non-zero population mass) with respect to $\boldsymbol{p}$ must form a set of connected components such that all types in each component have the same population mass. We first prove that the dynamics converges point-wise to fixed points.

3.1 Point-wise convergence

Initially, we consider the function $\Phi(\boldsymbol{x}) = \sum_v \boldsymbol{x}_v^2$ and state the following lemma on Φ.

▶ **Lemma 1 (Lyapunov (potential) function).** *Let $\boldsymbol{x}$ be a point with $\boldsymbol{x}_u > \boldsymbol{x}_v$. Let $\boldsymbol{y}$ be another point such that $\boldsymbol{y}_v = \boldsymbol{x}_v - d$, $\boldsymbol{y}_u = \boldsymbol{x}_u + d$ for some $0 < d \leq \boldsymbol{x}_v$ and $\boldsymbol{y}_z = \boldsymbol{x}_z$ for all $z \neq u, v$. Then $\Phi(\boldsymbol{x}) < \Phi(\boldsymbol{y})$.*

If we think of $\boldsymbol{x}$ as a population vector, Lemma 1 implies that $\Phi(\boldsymbol{x})$ increases if population is moving from a smaller type to a bigger type.

▶ **Theorem 2 (Set-wise convergence).** *$\Phi(\boldsymbol{x}^{(t)})$ is strictly increasing along every nontrivial trajectory, i.e., $\Phi(\boldsymbol{x}^{t+1}) = \Phi(g(\boldsymbol{x}^{(t)})) \geq \Phi(\boldsymbol{x}^{(t)})$ with equality only when $\boldsymbol{x}^{(t)}$ is a fixed point. As a corollary, the dynamics converges to fixed points (set-wise convergence).*

Using the above theorem (Theorem 2) along with the construction of a local Lyapunov function, we can show the following theorem:

▶ **Theorem 3 (Point-wise convergence).** *The dynamics converges point-wise to fixed points.*

Proof Sketch of Theorems 2 and 3. We show Theorem 2 by first breaking the migration step from $\boldsymbol{x}^{(t)}$ to $\boldsymbol{x}^{(t+1)}$ into multiple steps which involve migration between two types only and using Lemma 1. Moreover, given a limit point $\boldsymbol{p}$ of a trajectory with initial population vector $\boldsymbol{x}^{(0)}$, we create a local Lyapunov function Ψ that depends on $\boldsymbol{p}$, i.e., $\Psi(\boldsymbol{x}, \boldsymbol{p}) = \sum_{v:\boldsymbol{p}_v>0}(\boldsymbol{p}_v - \boldsymbol{x}_v)$. Ψ is decreasing and nonnegative in a neighborhood of $\boldsymbol{p}$, and zero only at $\boldsymbol{p}$. Since $\boldsymbol{p}$ is a limit point, there is a subsequence of times $t_k \to \infty$ so that the dynamics for these times converges to $\boldsymbol{p}$, therefore the dynamics converges to $\boldsymbol{p}$ as $t \to \infty$, with initial condition $\boldsymbol{x}^{(0)}$. ◀

3.2 Diffeomorphism and stability analysis via Jacobian

In this section we compute the Jacobian J of g and then perform spectral analysis on J. The Jacobian of g is the following:

$$\frac{\partial g_u}{\partial \boldsymbol{x}_u} = J_{u,u} = 1 + \sum_{v \in N_u} \boldsymbol{x}_v \left[F_{uv}(\boldsymbol{x}_u - \boldsymbol{x}_v) + \boldsymbol{x}_u F'_{uv}(\boldsymbol{x}_u - \boldsymbol{x}_v)\right],$$

$$\frac{\partial g_u}{\partial \boldsymbol{x}_v} = J_{u,v} = \boldsymbol{x}_u \left[F_{uv}(\boldsymbol{x}_u - \boldsymbol{x}_v) - \boldsymbol{x}_v F'_{uv}(\boldsymbol{x}_u - \boldsymbol{x}_v)\right] \text{ if } uv \in E(G) \text{ else } 0.$$

▶ **Lemma 4** (Local Diffeomorphism). *The Jacobian is invertible on the subspace* $\sum_v \boldsymbol{x}_v = 1$, *for* $\sup_{z\in[-1,1]} |F_{uv}(z)| < \frac{1}{2}$ *for each* $uv \in E(G)$. *Moreover,* g *is a local diffeomorphism in a neighborhood of* Δ_n.

▶ **Lemma 5** (Linearly stable fixed point ⇒ independent set). *Let* $\boldsymbol{p}$ *be a fixed point such that there exists a connected component* C *of size greater than 1, and all types* $v \in C$ *have the same positive mass* $\boldsymbol{p}_v > 0$. *Then the Jacobian at* $\boldsymbol{p}$ *has an eigenvalue with absolute value greater than one.*

Proof Sketch of Lemmas 4 and 5. To prove Lemma 4, it suffices to show that the Jacobian $J(\boldsymbol{x})$ is invertible and then use the Inverse Function theorem. Invertibility comes from the fact that $J(\boldsymbol{x})$ is shown to be strictly diagonally dominant for $|F_{uv}(z)| < \frac{1}{2}$ for each $uv \in E(G)$ and $z \in [-1, 1]$. Moreover, to show Lemma 5, we can show that if a fixed point $\boldsymbol{p}$ does not induce an independent set, then the trace of the Jacobian of size $l \times l$ (after removing columns and rows of non-active types) at $\boldsymbol{p}$ is greater than l. Since the trace of a matrix is equal to the sum of its eigenvalues, the maximum eigenvalue in absolute value is greater than one and the claim follows. ◀

▶ Remark. Lemmas 4 and 5 are the key Lemmas for the next subsection in which we prove our first main result (Theorem 6 and Corollary 10). If one wants to prove such a result for the model of Kempe et al., these are the two lemmas that need to be adapted to their setting. Analyzing the Jacobian of the update rule of that model is very challenging since the update rule is a rational function, compared to our model which is generic but the derivatives are simpler to compute and analyze.

3.3 Center-stable manifold and average case analysis

In this section we prove our first main result, Corollary 10, which is a consequence of the following theorem:

▶ **Theorem 6.** *Assume that* $\max_{z\in[-1,1]} |F_{uv}(z)| < 1/2$ *for all* $uv \in E(G)$. *The set of points* $\boldsymbol{x} \in \Delta_n$ *such that dynamics 1 starting at* $\boldsymbol{x}$ *converges to a fixed point* $\boldsymbol{p}$ *whose active types do not form an independent set of* G *has measure zero.*

To prove Theorem 6, we are going to use arguably one of the most important theorems in dynamical systems, called *Center Stable Manifold Theorem*:

▶ **Theorem 7** (Center-stable Manifold Theorem [28]). *Let* $\boldsymbol{p}$ *be a fixed point for the* C^r *local diffeomorphism* $f : U \to \mathbb{R}^m$ *where* $U \subset \mathbb{R}^m$ *is an open neighborhood of* $\boldsymbol{p}$ *in* $\mathbb{R}^m$ *and* $r \geq 1$. *Let* $E^s \oplus E^c \oplus E^u$ *be the invariant splitting of* $\mathbb{R}^m$ *into generalized eigenspaces of the Jacobian* $J(\boldsymbol{p})$ *that correspond to eigenvalues of absolute value less than one, equal to one, and greater than one. To the* $J(\boldsymbol{p})$ *invariant subspace* $E^s \oplus E^c$ *there is an associated local* f *invariant* C^r *embedded disc* W^{sc}_{loc} *tangent to the linear subspace at* $\boldsymbol{p}$ *and a ball* B *around* $\boldsymbol{p}$ *such that:*

$$f(W^{sc}_{loc}) \cap B \subset W^{sc}_{loc}. \text{ If } f^m(\boldsymbol{x}) \in B \text{ for all } m \geq 0, \text{ then } \boldsymbol{x} \in W^{sc}_{loc}. \tag{3}$$

Since an n-dimensional simplex Δ_n in $\mathbb{R}^n$ has dimension $n-1$, we need to take a projection of the domain space ($\sum_v \boldsymbol{x}_v = 1$) and accordingly redefine the map g. Let $\boldsymbol{x}$ be a point mass in Δ_n. Let u be a fixed type and define $h : \mathbb{R}^n \to \mathbb{R}^{n-1}$ so that we exclude the variable $\boldsymbol{x}_u$ from $\boldsymbol{x}$, i.e., $h(\boldsymbol{x}) = \boldsymbol{x}_{-u}$. We substitute the variable $\boldsymbol{x}_u$ with $1 - \sum_{v\neq u} \boldsymbol{x}_v$ and let g' be the resulting update rule of the dynamics $g'(\boldsymbol{x}_{-u}) = g(\boldsymbol{x})$. The following lemma gives a relation between the eigenvalues of the Jacobians of functions g and g'.

▶ **Lemma 8.** *Let J, J' be the Jacobian of g, g' respectively. Let λ be an eigenvalue of J such that λ does not correspond to left eigenvector $(1, \ldots, 1)$ (with eigenvalue 1). Then J' has also λ as an eigenvalue.*

Before we proceed with the proof sketch of Theorem 6 and Corollary 10, we state the following which is a corollary of Lemmas 4, 5 and 8 and also uses classic properties for determinants of matrices.

▶ **Corollary 9.** *Let $\boldsymbol{p}$ be a fixed point whose active types do not form an independent set in G. Then J' at $h(\boldsymbol{p})$ has an eigenvalue with absolute value greater than one. Additionally, the Jacobian J' of g' is invertible in $h(\Delta_n)$ and as a result g' is a local diffeomorphism in a neighborhood of $h(\Delta_n)$.*

▶ **Corollary 10** (Convergence to independent sets)**.** *Suppose that $\max_{z\in[-1,1]} |F_{uv}(z)| < 1/2$ for all $uv \in E(G)$. If the initial mass vector $\boldsymbol{x}^{(0)} \in \Delta_n$ is chosen from an atomless distribution, then the dynamics converges point-wise with probability 1 to a point $\boldsymbol{p}$ whose active types form an independent set in G.*

Proof Sketch of Theorem 6 and Corollary 10. The proof of Corollary 10 comes from Theorem 3 and Theorem 6.

The main steps for the proof of Theorem 6 are as follows: Due to Center-Stable Manifold theorem (we can use it since the update rule of the dynamics is a local diffeomorphism, by Lemma 4 and Lemma 9) we have that the set of initial population vectors that stay trapped in a small enough neighborhood of an unstable fixed point is a lower dimensional manifold, hence a zero measure set. Any initial condition that converges point-wise to this unstable fixed point must at some time t reach points in this set. All of these initial conditions can thus be covered by a countable union of pre-images of the zero measure neighborhood implied by the Center-Stable Manifold theorem. Because the update rule is a local diffeomorphism, these pre-images must also be of zero measure and the countable union of zero measure sets imply a zero measure region of attraction for each unstable equilibrium. The only remaining hurdle is to cover the set of linearly unstable fixed points with a countable cover of the small neighborhoods. Finally, by Lemma 5 any fixed point $\boldsymbol{p}$ whose active types do not form an independent set of G is linearly unstable and the claim follows. ◀

Corollary 10 is illustrated in Figure 1 for the case of a 3-path and a triangle. As shown in the figure, if the initial condition is chosen uniformly at random from a point in the simplex, the dynamics converges to an independent set with probability one.

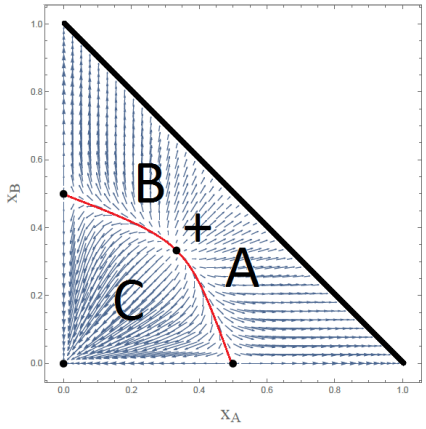
4 Stability and bound on the number of types

In this section we consider dynamical systems with migration, death and birth and prove two probabilistic statements on stability and number of types. The following direct application of Chernoff's bound is used intensively to attain probabilistic guarantees.

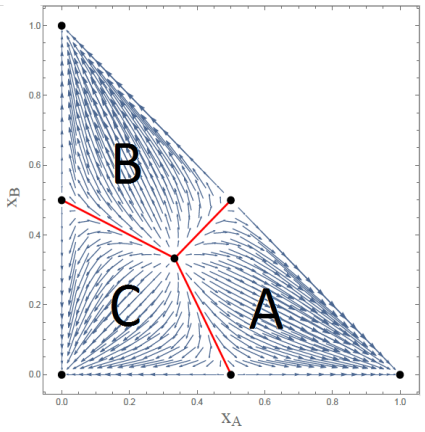
▶ **Lemma 11.** *In a period of t steps, there are at least $tp/2$ births with probability at least $1 - e^{-tp/8}$ and there are at most $3tp/2$ births with probability at least $1 - e^{-tp/6}$.*

4.1 Stability

We define the notion of stability and give a stability result for a dynamical system involving migration, death and birth. For the rest of the paper, we denote by $\alpha_{\min} =$



(a) The region with "C" corresponds to the initial population vectors so that the dynamics converges to the fixed point where all the population is of type C. The region "A+B" corresponds to the initial population masses so that the dynamics converges to a fixed point where part of the population is of type A and the rest of type B.



(b) Each region "A", "B", "C" corresponds to the initial population vectors so that the dynamics converges to all the population being of type A, B, C respectively. It is easy to see that an initial vector $(\boldsymbol{x}_A, \boldsymbol{x}_B, \boldsymbol{x}_C)$ converges to the fixed point where all population is of type $\arg\max_{i\in\{A,B,C\}} \boldsymbol{x}_i$. In case of ties, the limit population is split equally among the tied types (symmetry).

Figure 1 Migration dynamics phase portrait for path and triangle of 3 types A, B, C respectively and for $F_{uv}(z) = 0.25z$ for all $uv \in E(G)$. The black points and the line correspond to the fixed points. $\boldsymbol{x}_A, \boldsymbol{x}_B$ correspond to the fractions of people that are of type A, B. We omit $\boldsymbol{x}_C$ since $\boldsymbol{x}_C = 1 - \boldsymbol{x}_A - \boldsymbol{x}_B$.

$\min_{uv\in E(G), z\in[-1,1]} F'_{uv}(z)$ and $\alpha_{\max} = \max_{uv\in E(G), z\in[-1,1]} F'_{uv}(z)$. $\alpha_{\min}, \alpha_{\max}$ are non-negative and finite since F_{uv} is continuously differentiable, increasing and $[-1, 1]$ is a compact set. It can be seen easily that for each $uv \in E(G)$ and $z \in [-1, 1]$,

$$\alpha_{\min}(z - 0) \le F_{uv}(z) - F_{uv}(0) \le \alpha_{\max}(z - 0).$$

Since $F_{uv}(0) = 0$, $\alpha_{\min} z \le F_{uv}(z) \le \alpha_{\max} z$.

▶ **Definition 12** ((T, d)-Stable dynamics). A dynamics is (T, d)-stable if and only if $\forall T \le t \le T + d$, no population mass moves in the migration phase at step t.

We state the following two lemmas whose proofs come from the definition of Φ.

▶ **Lemma 13.** *If the dynamics is not $(t, 0)$-stable, the migration phase at time t increases Φ by at least $2\alpha_{\min}\epsilon\delta^3$.*

▶ **Lemma 14.** *Each birth can decrease Φ by at most $2\beta_{\max}$.*

With the two above lemmas, we can give a theorem on the "stability" of the dynamics:

▶ **Theorem 15** ("Stable" for long enough). *Assume $\alpha_{\min} > 0$. Let $p < \min\left(\frac{\epsilon\delta^3\alpha_{\min}}{3\beta_{\max}}, \frac{2}{3}\right)$ and $t > \frac{1}{\epsilon\delta^3\alpha_{\min} - 3p\beta_{\max}}$. With probability at least $1 - e^{-tp/6}$, the dynamics is $\left(T, \frac{1}{3p}\right)$-stable for some $T \le t$.*

Proof Sketch. Consider a period of t steps. Lemma 11 guarantees that there are at most $3tp/2$ births in the period with the desired probability. In the migration phases of the period, Φ can either increase if there is a migration or remain unchanged otherwise.

Assume that Φ increases in more than $t/2$ migration phases. Using Lemma 13 and Lemma 14, we can bound the net increase of Φ in the period. Specifically, the net increase is least $t(\alpha_{\min}\epsilon\delta^3 - 3p\beta_{\max})$, which is greater than 1. Therefore, we have reached a contradiction.

It follows that Φ cannot increase in more than $t/2$ migration phases, and must remain unchanged in at least $t/2$ migration phases. Since there are at most $3tp/2$ births, there must be no migration in a period of $1/(3p)$ consecutive steps. ◀

4.2 Bound on the number of types

In this section we investigate a behavior of the dynamics following a long period of time. Specifically, we show that after a large number of steps, the number of types can not be too high. Our goal is to prove the following theorem:

▶ **Theorem 16** (Lack of explosion). *Let $\alpha_{\max} \leq p/512$ and $t \geq (16/p)\log^2(1/\epsilon)$. The dynamics at step t has at most $72\log(1/\epsilon)$ types with probability at least $1 - 3\epsilon$.*

First we give the following lemma, which says that if the number of types is large enough, then after a fixed period of time, it will decrease by a factor of roughly 2.

▶ **Lemma 17.** *Let $\alpha_{\max} \leq p/512$ and k be the number of types at step t_0. If $k \geq 48\log(1/\epsilon)$, with probability at least $1 - 2\epsilon^2$, the number of types at step $t_0 + (16/p)\log(1/\epsilon)$ is at most $k/2 + 24\log(1/\epsilon)$.*

Proof Sketch of Theorem 16. Consider the last $(16/p)\log^2(1/\epsilon)$ steps of the dynamics. We call a period of $(16/p)\log(1/\epsilon)$ steps a *decreasing period* if it satisfies the condition in Lemma 17, i.e, if the number of types k at the beginning of the period is at least $48\log(1/\epsilon)$, and the number of types at the end of the period is at most $k/2 + 24\log(1/\epsilon)$.

Construct a set P of periods of length $(16/p)\log(1/\epsilon)$ as follows. Start with $t' = 0$ and repeat the following step until $t' = t$. If $t' + (16/p)\log(1/\epsilon) \leq t$ and the number of types at t' is at least $48\log(1/\epsilon)$, let i be the period from t' to $t' + (16/p)\log(1/\epsilon)$, and add i to P. Update $t' \leftarrow t' + (16/p)\log(1/\epsilon)$. Else update $t' \leftarrow t' + 1$.

Assume that all periods in P are decreasing periods. By Lemma 17, the probability of such an outcome occurring is at least $1 - 2\epsilon$. With that assumption, if the number of types ever becomes smaller than $48\log(1/\epsilon)$ and reaches $48\log(1/\epsilon)$ again, it will be at least $48\log(1/\epsilon)$ after a period of $(16/p)\log(1/\epsilon)$ steps unless there are less than $(16/p)\log(1/\epsilon)$ subsequent steps. In that case, by Lemma 11, the probability that in the remaining steps, there are at most $24\log(1/\epsilon)$ births is at least $1 - \epsilon$. By union bound, the probability of both outcomes occurring is at least $1 - 3\epsilon$.

Moreover, since the number of types at the beginning is at most $1/\epsilon$, with the assumption, it must become smaller than $48\log(1/\epsilon)$ at some step of the dynamics. The theorem then follows. ◀

Abstract

Population protocols are a distributed computing model appropriate for describing massive numbers of agents with very limited computational power (finite automata in this paper), such as sensor networks or programmable chemical reaction networks in synthetic biology. A population protocol is said to require a leader if every valid initial configuration contains a single agent in a special "leader" state that helps to coordinate the computation. Although the class of predicates and functions computable with probability 1 (stable computation) is the same whether a leader is required or not (semilinear functions and predicates), it is not known whether a leader is necessary for fast computation. Due to the large number of agents n (synthetic molecular systems routinely have trillions of molecules), efficient population protocols are generally defined as those computing in polylogarithmic in n (parallel) time. We consider population protocols that start in leaderless initial configurations, and the computation is regarded finished when the population protocol reaches a configuration from which a different output is no longer reachable.

In this setting we show that a wide class of functions and predicates computable by population protocols are not *efficiently* computable (they require at least linear time), nor are some linear functions even efficiently *approximable*. It requires at least linear time for a population protocol even to approximate division by a constant or subtraction (or any linear function with a coefficient outside of $\mathbb{N}$), in the sense that for sufficiently small $\gamma > 0$, the output of a sublinear time protocol can stabilize outside the interval $f(m)(1 \pm \gamma)$ on infinitely many inputs m. In a complementary positive result, we show that with a sufficiently large value of γ, a population protocol *can* approximate any linear f with nonnegative rational coefficients, within approximation factor γ, in $O(\log n)$ time. We also show that it requires linear time to exactly compute a wide range of semilinear functions (e.g., $f(m) = m$ if m is even and $2m$ if m is odd) and predicates (e.g., parity, equality).

1 Introduction

Population protocols were introduced by Angluin, Aspnes, Diamadi, Fischer, and Peralta[3] as a model of distributed computing in which the agents have very little computational power and no control over their schedule of interaction with other agents. They can be thought of as a special case of a model of concurrent processing introduced in the 1960s, known alternately as vector addition systems[16], Petri nets[19], or commutative semi-Thue systems (or, when all transitions are reversible, "commutative semigroups")[9, 17]. As well as being an appropriate model for electronic computing scenarios such as sensor networks, they are a useful abstraction of "fast-mixing" physical systems such as animal populations[22], gene regulatory networks[8], and chemical reactions.

The latter application is especially germane: several recent wet-lab experiments demonstrate the systematic engineering of custom-designed chemical reactions [23, 12, 7, 20], unfortunately in all cases having a cost that scales linearly with the number of unique chemical species (states). (The cost can even be quadratic if certain error-tolerance mechanisms are employed [21].) Thus, it is imperative in implementing a molecular computational system to keep the number of distinct chemical species at a minimum. On the other hand, it is common (and relatively cheap) for the total number of such molecules (agents) to number in the trillions in a single test tube. It is thus important to understand the computational power enabled by a large number of agents n, where each agent has only a constant number of states (each agent is a finite state machine).

A population protocol is said to require a leader if every valid initial configuration contains a single agent in a special "leader" state that helps to coordinate the computation. Studying computation without a leader is important for understanding essentially distributed systems where symmetry breaking is difficult. Further, in the chemical setting obtaining single-molecule precision in the initial configuration is difficult. Thus, it would be highly desirable if the population protocol did not require an exquisitely tuned initial configuration.

1.1 Introduction to the model

A population protocol is defined by a finite set Λ of *states* that each agent may have, together with a *transition function*[1] $\delta : \Lambda^2 \to \Lambda^2$. A *configuration* is a nonzero vector $\mathbf{c} \in \mathbb{N}^\Lambda$ describing, for each $\overline{s} \in \Lambda$, the *count* $\mathbf{c}(\overline{s})$ of how many agents are in state $\overline{s}$. By convention we denote the number of agents by $n = \|\mathbf{c}\| = \sum_{\overline{s}\in\Lambda} \mathbf{c}(\overline{s})$. Given states $\overline{r}_1, \overline{r}_2, \overline{p}_1, \overline{p}_2 \in \Lambda$, if $\delta(\overline{r}_1, \overline{r}_2) = (\overline{p}_1, \overline{p}_2)$ (denoted $\overline{r}_1, \overline{r}_2 \to \overline{p}_1, \overline{p}_2$), and if a pair of agents in respective states $\overline{r}_1$ and $\overline{r}_2$ interact, then their states become $\overline{p}_1$ and $\overline{p}_2$.[2] The next pair of agents to interact is chosen uniformly at random. The expected (parallel) time for any event to occur is the expected number of interactions, divided by the number of agents n. This measure of time is based on the natural parallel model where each agent participates in a constant number of interactions in one unit of time; hence $\Theta(n)$ total interactions are expected per unit time [5].

The most well-studied population protocol task is computing Boolean-valued *predicates*. It is known that a protocol *stably decides* a predicate $\phi : \mathbb{N}^k \to \{0, 1\}$ (meaning computes

[1] Some work allows nondeterministic transitions, in which the transition function maps to subsets of $\Lambda \times \Lambda$. Our results are independent of whether transitions are nondeterministic, and we choose a deterministic, symmetric transition function, rather than a more general relation $\delta \subseteq \Lambda^4$, merely for notational convenience.

[2] In the most generic model, there is no restriction on which agents are permitted to interact. If one prefers to think of the agents as existing on nodes of a graph, then it is the complete graph K_n for a population of n agents.

the correct answer with probability 1; see Section 6 for a formal definition) if [3] and only if [4] ϕ is semilinear.

Population protocols can also compute integer-valued *functions* $f : \mathbb{N}^k \to \mathbb{N}$. Suppose we start with $m \leq n/2$ agents in "input" state $\overline{x}$ and the remaining agents in a "quiescent" state $\overline{q}$. Consider the protocol with a single transition rule $\overline{x}, \overline{q} \to \overline{y}, \overline{y}$. Eventually exactly $2m$ agents are in the "output" state $\overline{y}$, so this protocol computes the function $f(m) = 2m$. Furthermore (letting $\#\overline{s}$ = count of state $\overline{s}$), if $\#\overline{q} - 2m = \Omega(n)$ initially (e.g., $\#\overline{q} = 3m$), then it takes $\Theta(\log n)$ expected time until $\#\overline{y} = 2m$. Similarly, the transition rule $\overline{x}, \overline{x} \to \overline{y}, \overline{q}$ computes the function $f(m) = \lfloor m/2 \rfloor$, but exponentially slower, in expected time $\Theta(n)$. The transitions $\overline{x}_1, \overline{q} \to \overline{y}, \overline{q}$ and $\overline{x}_2, \overline{y} \to \overline{q}, \overline{q}$ compute $f(m_1, m_2) = m_1 - m_2$ (assuming $m_1 \geq m_2$), also in time $\Theta(n)$ if $m_1 = m_2 + O(1)$.

Formally, we say a population protocol *stably computes* a function $f : \mathbb{N}^k \to \mathbb{N}$ if, for every "valid" initial configuration $\mathbf{i} \in \mathbb{N}^\Lambda$ representing input $\mathbf{m} \in \mathbb{N}^k$ (via counts $\mathbf{i}(\overline{x}_1), \ldots, \mathbf{i}(\overline{x}_k)$ of "input" states $\Sigma = \{\overline{x}_1, \ldots, \overline{x}_k\} \subseteq \Lambda$) with probability 1 the system reaches from $\mathbf{i}$ to $\mathbf{o}$ such that $\mathbf{o}(\overline{y}) = f(\mathbf{m})$ ($\overline{y} \in \Lambda$ is the "output" state) and $\mathbf{o}'(\overline{y}) = \mathbf{o}(\overline{y})$ for every $\mathbf{o}'$ reachable from $\mathbf{o}$ (i.e., $\mathbf{o}$ is *stable*). Defining what constitutes a "valid" initial configuration (i.e., what non-input states can be present initially, and how many) is nontrivial. In this paper we focus on population protocols without a *leader*—a state present in count 1, or small count—in the initial configuration. Here, we equate "leaderless" with initial configurations in which no positive state count is sublinear in the population size n.

It is known that a function $f : \mathbb{N}^k \to \mathbb{N}$ is stably computable by a population protocol if and only if its *graph* $\{(\mathbf{m}, f(\mathbf{m})) \mid \mathbf{m} \in \mathbb{N}^k\} \subset \mathbb{N}^{k+1}$ is a semilinear set [4, 11]. This means intuitively that it is piecewise affine, with each affine piece having rational slopes.

Despite the exact characterization of predicates and functions stably computable by population protocols, we still lack a full understanding of which of the stably computable (i.e., semilinear) predicates and functions are computable *quickly* (say, in time polylogarithmic in n) and which are only computable slowly (linear in n). For positive results, significantly more is known about time to *convergence* [5] with a leader (time to reach a configuration with the correct answer). In this paper we shed new light on time to *stabilization* without a leader (time to reach a configuration from which the answer is *guaranteed to remain correct*).

1.2 Contributions

Definition of function computation and approximation. We formally define computation and approximation of functions $f : \mathbb{N}^k \to \mathbb{N}$ for population protocols. This mode of computation was discussed briefly in the first population protocols paper[3, Section 3.4], which focused more on Boolean predicate computation, and it was defined formally in the more general model of chemical reaction networks[11, 13]. Some subtle issues arise that are unique to population protocols. We also formally define a notion of function *approximation* with population protocols, which has its own issues.

Inapproximability of most linear functions with sublinear time and sublinear error. Recall that the transition rule $\overline{x}, \overline{x} \to \overline{y}, \overline{q}$ computes $f(m) = \lfloor m/2 \rfloor$ in linear time. Consider the transitions $\overline{a}, \overline{x} \to \overline{b}, \overline{y}$ and $\overline{b}, \overline{x} \to \overline{a}, \overline{q}$, starting with $\#\overline{x} = m$, $\#\overline{a} = \gamma m$ for some $0 < \gamma < 1$, and $\#\overline{y} = \#\overline{q} = 0$ (so $n = m + \gamma m$ total agents). Then eventually $\#\overline{y} \in \{m/2, \ldots, m/2 + \gamma m\}$ and $\#\overline{x} = 0$ (stabilizing $\#\overline{y}$), after $O(\frac{1}{\gamma} \log n)$ expected time. (This is analyzed in more detail in Section 5.) Thus, if we tolerate an error linear in n, then f can be approximated in logarithmic time. However, Theorem 4.1 shows this error bound to be tight: *any* leaderless population protocol that approximates $f(m) = \lfloor m/2 \rfloor$, or any other linear function with a

coefficient outside of $\mathbb{N}$ (such as $\lfloor 4m/3 \rfloor$ or $m_1 - m_2$), requires at least linear time to achieve sublinear error.

As a corollary, such functions cannot be stably computed in sublinear time (since computing exactly is the same as approximating with zero error). Conversely, it is simple to show that any linear function with all coefficients in $\mathbb{N}$ is stably computable in logarithmic time (Observation 5.1). Thus we have a dichotomy theorem for the efficiency (with regard to stabilization) of computing linear functions f by leaderless population protocols: if all of f's coefficients are in $\mathbb{N}$, then it is computable in logarithmic time, and otherwise it requires linear time.

Approximability of nonnegative rational-coefficient linear functions with logarithmic time and linear error. Theorem 4.1 says that no linear function with a coefficient outside of $\mathbb{N}$ can be stably computed with sublinear time and sublinear error. In a complementary positive result, Theorem 5.2, by relaxing the error to linear, and restricting the coefficients to be *nonnegative* rationals (but not necessarily integers), we show how to approximate any such linear function in logarithmic time. (It is open if $m_1 - m_2$ can be approximated with linear error in logarithmic time.)

Uncomputability of many nonlinear functions in sublinear time. What about non-linear functions? Theorem 3.1 states that sublinear time computation cannot go much beyond linear functions with coefficients in $\mathbb{N}$. We show any function computable in sublinear time is *eventually*-$\mathbb{N}$-*linear*, which we define to be linear with nonnegative integer coefficients on all sufficiently large inputs. Examples of non-eventually-$\mathbb{N}$-linear functions, that provably cannot be computed in sublinear time, include $f(m_1, m_2) = \min(m_1, m_2)$ (computable slowly via $\overline{x}_1, \overline{x}_2 \to \overline{y}, \overline{q}$), and $f(m) = m - 1$ (computable slowly via $\overline{x}, \overline{x} \to \overline{x}, \overline{y}$).

The only remaining semilinear functions whose asymptotic time complexity remains unknown are those "piecewise linear" functions that switch between pieces only near the boundary of $\mathbb{N}^k$; for example, $f(m) = 0$ if $m \leq 3$ and $f(m) = m$ otherwise.

Undecidability of many predicates in sublinear time. Every semilinear predicate $\phi : \mathbb{N}^k \to \{0, 1\}$ is stably decidable in $O(n)$ time [5]. Some, such as $\phi(m) = 1$ iff $m \geq 1$, are stably decidable in $O(\log n)$ time by a leaderless protocol, in this case by the transition $\overline{x}, \overline{q} \to \overline{x}, \overline{x}$, where $\overline{x}$ "votes" for output 1 and $\overline{q}$ votes 0. A predicate is *eventually constant* if $\phi(\mathbf{m}_0) = \phi(\mathbf{m}_1)$ for all sufficiently large $\mathbf{m}_0, \mathbf{m}_1$. We show that if a leaderless population protocol stably decides a predicate ϕ in sublinear time, then ϕ is eventually constant. Examples of non-eventually constant predicates include parity ($\phi(m) = 1$ iff m is odd), majority ($\phi(m_1, m_2) = 1$ iff $m_1 \geq m_2$), and equality ($\phi(m_1, m_2) = 1$ iff $m_1 = m_2$). It does *not* include certain semilinear predicates, such as $\phi(m) = 1$ iff $m \geq 1$ (decidable in $O(\log n)$ time) or $\phi(m) = 1$ iff $m \geq 2$ (decidable in $O(n)$ time, and no faster protocol is known).

Note that there is a fundamental difficulty in extending the last two stated negative results to functions and predicates that "do something different only near the boundary of $\mathbb{N}^k$". This is because for inputs where one state is present in small count, the population protocol could in principle use that input as a "leader state"—and no longer be leaderless.

It is possible that the non-eventually constant predicates and non-eventually-$\mathbb{N}$-linear functions, which cannot be computed in sublinear time in our setting, *could* be efficiently computed in the following ways: (1) *With an initial leader* stabilizing to the correct answer in sublinear time, (2) Without initial leaders but *converging* to the correct output in sublinear time. (3) (With or without a leader) stabilizing to an output in sublinear time but *allowing a small probability of incorrect output.*

1.3 Related work

Positive results. Angluin, Aspnes, Diamadi, Fischer, and Peralta [3] showed that any semilinear predicate can be decided in expected parallel time $O(n \log n)$, later improved to $O(n)$ by Angluin, Aspnes, and Eisenstat [5]. More strikingly, the latter paper showed that if an initial leader is present (a state assigned to only a single agent in every valid initial configuration), then there is a protocol for ϕ that *converges* to the correct answer in expected time $O(\log^5 n)$. However, this protocol's expected time to *stabilize* is still provably $\Omega(n)$. Chen, Doty, and Soloveichik [11] showed in the related model of chemical reaction networks (borrowing techniques from the related predicate results [3, 4]) that any semilinear *function* (integer-output $f : \mathbb{N}^k \to \mathbb{N}$) can similarly be computed with expected convergence time $O(\log^5 n)$ if an initial leader is present, but again with much slower stabilization time $O(n \log n)$. Doty and Hajiaghayi [13] showed that any semilinear function can be computed by a chemical reaction network without a leader with expected convergence and stabilization time $O(n)$. Although the chemical reaction network model is more general, these results hold for population protocols.

Since efficient computation seems to be helped by a leader, the computational task of leader election has received significant recent attention. In particular, Alistarh and Gelashvili [2] showed that in a variant of the model allowing the number of states λ_n to grow with the population size n, a protocol with $\lambda_n = O(\log^3 n)$ states can elect a leader with high probability in $O(\log^3 n)$ expected time. Alistarh, Aspnes, Eisenstat, Gelashvili, and Rivest [1] later showed how to reduce the number of states to $\lambda_n = O(\log^2 n)$, at the cost of increasing the expected time to $O(\log^{5.3} n \log \log n)$.

Negative results. The first attempt to show the limitations of sublinear time population protocols, using the more general model of chemical reaction networks, was made by Chen, Cummings, Doty, and Soloveichik [10]. They studied a variant of the problem in which negative results are easier to prove, an "adversarial worst-case" notion of sublinear time: the protocol is required to be sublinear time not only from the initial configuration, but also from any reachable configuration. They showed that the predicates computable in this manner are precisely those whose output depends only on the presence or absence of states (and not on their exact positive counts). Doty and Soloveichik [14] showed the first $\Omega(n)$ lower bound on expected time from valid initial configurations, proving that any protocol electing a leader with probability 1 takes $\Omega(n)$ time.

These techniques were recently improved by Alistarh, Aspnes, Eisenstat, Gelashvili, and Rivest [1], who showed that even with up to $\lambda_n = O(\log \log n)$ states, any protocol electing a leader with probability 1 requires nearly linear time: $\Omega(n/\text{polylog } n)$. They used these tools to prove time lower bounds for another important computational task: majority (detecting whether state $\overline{x}_1$ or $\overline{x}_2$ is more numerous in the initial population, by stabilizing on a configuration in which the state with the larger initial count occupies the whole population).

In contrast to these previous results on the specific tasks of leader election and majority, we obtain time lower bounds for a broad class of functions and predicates, showing "most" of those computable at all by population protocols, cannot be computed in sublinear time. Since they all *can* be computed in linear time, this settles their asymptotic population protocol time complexity.

Informally, one explanation for our result could be that some computation requires electing "leaders" as part of the computation, and other computation does not. Since leader election itself requires linear time as shown in [14], the computation that requires it is necessarily inefficient. It is not clear, however, how to define the notion of a predicate or function

computation requiring electing a leader somewhere in the computation, but recent work by Michail and Spirakis helps to clarify the picture [18].

2 Preliminaries

If Λ is a finite set (in this paper, of *states*, which will be denoted as lowercase Roman letters with an overbar such as $\overline{s}$), we write $\mathbb{N}^\Lambda$ to denote the set of functions $\mathbf{c} : \Lambda \to \mathbb{N}$. Equivalently, we view an element $\mathbf{c} \in \mathbb{N}^\Lambda$ as a vector of $|\Lambda|$ nonnegative integers, with each coordinate "labeled" by an element of Λ. (By assuming some canonical ordering $\overline{s}_1, \ldots, \overline{s}_k$ of Λ, we also interpret $\mathbf{c} \in \mathbb{N}^\Lambda$ as a vector $\mathbf{c} \in \mathbb{N}^k$.) Given $\overline{s} \in \Lambda$ and $\mathbf{c} \in \mathbb{N}^\Lambda$, we refer to $\mathbf{c}(\overline{s})$ as the *count of* $\overline{s}$ *in* $\mathbf{c}$. Let $\|\mathbf{c}\| = \|\mathbf{c}\|_1 = \sum_{\overline{s}\in\Lambda} \mathbf{c}(\overline{s})$. We write $\mathbf{c} \leq \mathbf{c}'$ to denote that $\mathbf{c}(\overline{s}) \leq \mathbf{c}'(\overline{s})$ for all $\overline{s} \in \Lambda$. Since we view vectors $\mathbf{c} \in \mathbb{N}^\Lambda$ equivalently as multisets of elements from Λ, if $\mathbf{c} \leq \mathbf{c}'$ we say $\mathbf{c}$ is a *subset* of $\mathbf{c}'$. For $\alpha > 0$, we say that $\mathbf{c} \in \mathbb{N}^k$ is α-*dense* if, for all $i \in \{1, \ldots, k\}$, if $\mathbf{c}(i) > 0$, then $\mathbf{c}(i) \geq \alpha\|\mathbf{c}\|$.

It is sometimes convenient to use multiset notation to denote vectors, e.g., $\{\overline{x}, \overline{x}, \overline{y}\}$ and $\{2\overline{x}, \overline{y}\}$ both denote the vector $\mathbf{c}$ defined by $\mathbf{c}(\overline{x}) = 2$, $\mathbf{c}(\overline{y}) = 1$, and $\mathbf{c}(\overline{s}) = 0$ for all $\overline{s} \notin \{\overline{x}, \overline{y}\}$. Given $\mathbf{c}, \mathbf{c}' \in \mathbb{N}^\Lambda$, we define the vector component-wise operations of addition $\mathbf{c} + \mathbf{c}'$, subtraction $\mathbf{c} - \mathbf{c}'$, and scalar multiplication $m\mathbf{c}$ for $m \in \mathbb{N}$. For a set $\Delta \subset \Lambda$, we view a vector $\mathbf{c} \in \mathbb{N}^\Delta$ equivalently as a vector $\mathbf{c} \in \mathbb{N}^\Lambda$ by assuming $\mathbf{c}(\overline{s}) = 0$ for all $\overline{s} \in \Lambda \setminus \Delta$. Write $\mathbf{c} \restriction \Delta$ to denote the vector $\mathbf{d} \in \mathbb{N}^\Delta$ such that $\mathbf{c}(\overline{s}) = \mathbf{d}(\overline{s})$ for all $\overline{s} \in \Delta$. In this paper, the floor function $\lfloor\cdot\rfloor : \mathbb{R} \to \mathbb{Z}$ is defined to be the integer *closest to 0* that is distance < 1 from the input, e.g., $\lfloor -3.4 \rfloor = -3$ and $\lfloor 3.4 \rfloor = 3$.

We say a function $f : \mathbb{N}^k \to \mathbb{N}$ is *eventually-*$\mathbb{N}$*-affine* if there are $b, c_1, \ldots, c_k \in \mathbb{N}$ and $m_0 \in \mathbb{N}$ such that for all $\mathbf{m} \in \mathbb{N}^k_{\geq m_0}$, $f(\mathbf{m}) = b + \sum_{i=1}^k c_i \mathbf{m}(i)$. We say a function $f : \mathbb{N}^k \to \mathbb{N}$ is *eventually-*$\mathbb{N}$*-linear* if it is eventually-$\mathbb{N}$-affine with offset $b = 0$, i.e., if $f(\mathbf{0}) = 0$. We say the function is $\mathbb{N}$*-linear* if it is eventually-$\mathbb{N}$-linear with $m_0 = 0$. Similarly, a function is $\mathbb{Q}_{\geq 0}$*-linear* if there are $c_1, \ldots, c_k \in \mathbb{Q}_{\geq 0}$ such that for all $\mathbf{m} \in \mathbb{N}^k$, $f(\mathbf{m}) = \sum_{i=1}^k \lfloor c_i \mathbf{m}(i) \rfloor$.

2.1 Population Protocols

A *population protocol* is a pair $\mathcal{P} = (\Lambda, \delta)$, where Λ is a finite set of *states* and $\delta : \Lambda^2 \to \Lambda^2$ is the (symmetric) *transition function*. A *configuration* of a population protocol is a vector $\mathbf{c} \in \mathbb{N}^\Lambda$, with the interpretation that $\mathbf{c}(\overline{s})$ agents are in state $\overline{s} \in \Lambda$. If there is some "current" configuration $\mathbf{c}$ understood from context, we write $\#\overline{s}$ to denote $\mathbf{c}(\overline{s})$. By convention, the value $n \in \mathbb{Z}_{\geq 1}$ represents the total number of agents $\|\mathbf{c}\|$. A *transition* is a 4-tuple $\tau = (\overline{r}_1, \overline{r}_2, \overline{p}_1, \overline{p}_2) \in \Lambda^4$, written $\tau : \overline{r}_1, \overline{r}_2 \to \overline{p}_1, \overline{p}_2$, such that $\delta(\overline{r}_1, \overline{r}_2) = (\overline{p}_1, \overline{p}_2)$. If an agent in state $\overline{r}_1$ interacts with an agent in state $\overline{r}_2$, then they change states to $\overline{p}_1$ and $\overline{p}_2$. This paper typically defines a protocol by a list of transitions, with δ implicit. There is a *null* transition $\delta(\overline{r}_1, \overline{r}_2) = (\overline{r}_1, \overline{r}_2)$ if a different output for $\delta(\overline{r}_1, \overline{r}_2)$ is not specified.

Given $\mathbf{c} \in \mathbb{N}^\Lambda$ and transition $\tau : \overline{r}_1, \overline{r}_2 \to \overline{p}_1, \overline{p}_2$, we say that τ is *applicable* to $\mathbf{c}$ if $\mathbf{c} \geq \{\overline{r}_1, \overline{r}_2\}$, i.e., $\mathbf{c}$ contains 2 agents, one in state $\overline{r}_1$ and one in state $\overline{r}_2$. If τ is applicable to $\mathbf{c}$, then write $\tau(\mathbf{c})$ to denote the configuration $\mathbf{c} - \{\overline{r}_1, \overline{r}_2\} + \{\overline{p}_1, \overline{p}_2\}$ (i.e., that results from applying τ to $\mathbf{c}$); otherwise $\tau(\mathbf{c})$ is undefined. A finite or infinite sequence of transitions (τ_i) is a *transition sequence*. Given a $\mathbf{c}_0 \in \mathbb{N}^\Lambda$ and a transition sequence (τ_i), the induced *execution sequence* (or *path*) is a finite or infinite sequence of configurations $(\mathbf{c}_0, \mathbf{c}_1, \ldots)$ such that, for all $i \geq 1$, $\mathbf{c}_i = \tau_{i-1}(\mathbf{c}_{i-1})$. If a finite execution sequence, with associated transition sequence $\overline{q}$, starts with $\mathbf{c}$ and ends with $\mathbf{c}'$, we write $\mathbf{c} \Longrightarrow_q \mathbf{c}'$. We write $\mathbf{c} \Longrightarrow_\mathcal{P} \mathbf{c}'$ (or $\mathbf{c} \Longrightarrow \mathbf{c}'$ when $\mathcal{P}$ is clear from context) if such a path exists (i.e., it is possible to reach from $\mathbf{c}$ to $\mathbf{c}'$) and we say that $\mathbf{c}'$ is *reachable* from $\mathbf{c}$. Let $\mathsf{post}_\mathcal{P}(\mathbf{c}) = \{\mathbf{c}' \mid \mathbf{c} \Longrightarrow_\mathcal{P} \mathbf{c}'\}$ to denote the set of

all configurations reachable from $\mathbf{c}$, writing $\mathsf{post}(\mathbf{c})$ when $\mathcal{P}$ is clear from context. If it is understood from context what is the initial configuration $\mathbf{i}$, then say $\mathbf{c}$ is simply *reachable* if $\mathbf{i} \Longrightarrow \mathbf{c}$. If a transition $\tau : \overline{r}_1, \overline{r}_2 \to \overline{p}_1, \overline{p}_2$ has the property that for $i \in \{1, 2\}$, $\overline{r}_i \notin \{\overline{p}_1, \overline{p}_2\}$, or if ($\overline{r}_1 = \overline{r}_2$ and ($\overline{r}_i \neq \overline{p}_1$ or $\overline{r}_i \neq \overline{p}_2$)), then we say that τ *consumes* $\overline{r}_i$; i.e., applying τ reduces the count of $\overline{r}_i$. We say τ *produces* $\overline{p}_i$ if it increases the count of $\overline{p}_i$.

2.2 Time Complexity

The model used to analyze time complexity is a discrete-time Markov process, whose states correspond to configurations of the population protocol. In any configuration the next interaction is chosen by selecting a pair of agents uniformly at random and applying transition function δ to determine the next configuration. Since a transition may be null, self-loops are allowed. To measure time we count the expected total number of interactions (including null), and divide by the number of agents n. (In the population protocols literature, this is often called "parallel time"; i.e. n interactions among a population of n agents corresponds to one unit of time). Let $\mathbf{c} \in \mathbb{N}^\Lambda$ and $C \subseteq \mathbb{N}^\Lambda$. Denote the probability that the protocol reaches from $\mathbf{c}$ to some configuration $\mathbf{c}' \in C$ by $\mathsf{Pr}[\mathbf{c} \Longrightarrow C]$. If $\mathsf{Pr}[\mathbf{c} \Longrightarrow C] = 1$, define the *expected time to reach from* $\mathbf{c}$ *to* C, denoted $\mathsf{T}[\mathbf{c} \Longrightarrow C]$, to be the expected number of interactions to reach from $\mathbf{c}$ to some $\mathbf{c}' \in C$, divided by the number of agents $n = \|\mathbf{c}\|$. If $\mathsf{Pr}[\mathbf{c} \Longrightarrow C] < 1$ then $\mathsf{T}[\mathbf{c} \Longrightarrow C] = \infty$.

3 Exact computation of nonlinear functions

In Section 4, we obtained a precise characterization of the linear functions stably computable in sublinear time by population protocols and furthermore show that those not exactly computable in sublinear time are not even approximable with sublinear error in sublinear time. However, the class of functions stably computable (in any amount of time) by population protocols is known to contain non-linear functions such as $f(m_1, m_2) = \max(m_1, m_2)$, or $f(m) = m$ if m is even and $f(m) = 2m$ if m is odd. In fact a function is stably computable by a population protocol if and only if its *graph* $\{(\mathbf{m}, f(\mathbf{m})) \mid \mathbf{m} \in \mathbb{N}^k\}$ is a semilinear set [4, 11]. A set $A \subseteq \mathbb{N}^k$ is *semilinear* if and only if [15] it is expressible as a finite number of unions, intersections, and complements of sets of one of the following two forms: *threshold sets* of the form $\{\mathbf{x} \mid \sum_{i=1}^k a_i \cdot \mathbf{x}(i) < b\}$ for some constants $a_1, \ldots, a_k, b \in \mathbb{Z}$ or *mod sets* of the form $\{\mathbf{x} \mid \sum_{i=1}^k a_i \cdot \mathbf{x}(i) \equiv b \mod c\}$ for some constants $a_1, \ldots, a_k, b, c \in \mathbb{N}$. Say that a set $P \subseteq \mathbb{N}^k$ is a *periodic coset* if there exist $\mathbf{b}, \mathbf{p}_1, \ldots, \mathbf{p}_l \in \mathbb{N}^k$ such that $P = \{\mathbf{b} + n_1\mathbf{p}_1 + \ldots + n_l\mathbf{p}_l \mid n_1, \ldots, n_l \in \mathbb{N}\}$. (These are typically called "linear" sets, but we wish to avoid confusion with linear functions.) Equivalently, a set is semilinear if and only if it is a finite union of periodic cosets. We say a function $f : \mathbb{N}^k \to \mathbb{N}$ is *semilinear* if its *graph* $\{(\mathbf{m}, f(\mathbf{m})) \mid \mathbf{m} \in \mathbb{N}^k\} \subset \mathbb{N}^{k+1}$ is a semilinear set. A function f is stably computable by a population protocol (given unbounded time) if and only if f is semilinear [11, 4].

Although our technique fails to completely characterize the efficient computability of all semilinear functions, we show that a wide class of semilinear functions cannot be stably computed in sublinear time: functions that are not eventually $\mathbb{N}$-linear. The only exceptions, for which we cannot prove linear time is required, yet neither is there known a counterexample protocol stably computing the function in sublinear time, are functions whose "non-integral-linearities are near the boundary of $\mathbb{N}^k$". For example, the function $f(m) = 0$ if $m \leq 3$ and $f(m) = m$ otherwise is non-linear (although it is semilinear, so stably computable), but restricted to the domain of inputs > 3, it is linear with positive integer coefficients. Thus it is an example of a function whose "population protocol time complexity" is unknown.

Corollary 4.2 and Observation 5.1 imply that a linear function is stably computable in sublinear time by a population protocol if and only if it is $\mathbb{N}$-linear. Theorem 3.1 generalizes the forward direction (restricted to nonlinear functions) to eventually-$\mathbb{N}$-linear functions.

We first give a formal definition of function computation by population protocols. A *function-computing population protocol* is a tuple $\mathcal{C} = (\Lambda, \delta, \Sigma, \overline{y}, \overline{q})$, where (Λ, δ) is a population protocol, $\Sigma = \{\overline{x}_1, \ldots, \overline{x}_k\} \subset \Lambda$ is the set of *input states*, $\overline{y} \in \Lambda$ is the *output state*, and $\overline{q} \in \Lambda \setminus \Sigma$ is the *quiescent state*. We say that a configuration $\mathbf{o} \in \mathbb{N}^\Lambda$ is *stable* if, for all $\mathbf{o}' \in \mathsf{post}(\mathbf{o})$, $\mathbf{o}(\overline{y}) = \mathbf{o}'(\overline{y})$, i.e., the count of $\overline{y}$ cannot change once $\mathbf{o}$ is reached.

Let $f : \mathbb{N}^k \to \mathbb{N}$, $\mathbf{i} \in \mathbb{N}^\Lambda$, and let $\mathbf{m} = \mathbf{i} \restriction \Sigma$. We say that $\mathcal{C}$ *stably computes* f *from* $\mathbf{i}$ if, for all $\mathbf{c} \in \mathsf{post}(\mathbf{i})$, there exists a stable $\mathbf{o} \in \mathsf{post}(\mathbf{c})$ such that $\mathbf{o}(\overline{y}) = f(\mathbf{m})$, i.e., $\mathcal{C}$ stabilizes to the correct output from the initial configuration $\mathbf{i}$. However, for any input $\mathbf{m} \in \mathbb{N}^k$, there are many initial configurations $\mathbf{i} \in \mathbb{N}^\Lambda$ representing it (i.e., such that $\mathbf{i} \restriction \Sigma = \mathbf{m}$). We now formalize what sort of initial configurations $\mathcal{C}$ is required to handle.

We say a function $q_0 : \mathbb{N}^k \to \mathbb{N}$ is *linearly bounded* if there is a constant $c \in \mathbb{N}$ such that, for all $\mathbf{m} \in \mathbb{N}^k$, $q_0(\mathbf{m}) \leq c\|\mathbf{m}\|$. We say that $\mathcal{C}$ *stably computes* f if there is a linearly bounded function $q_0 : \mathbb{N}^k \to \mathbb{N}$ such that, for any $\mathbf{i} \in \mathbb{N}^\Lambda$, defining $\mathbf{m} = \mathbf{i} \restriction \Sigma$, if $\mathbf{i}(\overline{q}) \geq q_0(\mathbf{m})$ and $\mathbf{i}(\overline{s}) = 0$ for all $\overline{s} \in \Lambda \setminus (\Sigma \cup \{\overline{q}\})$, then $\mathcal{C}$ stably computes f from $\mathbf{i}$. It is well-known[6] that this is equivalent to requiring, under the randomized model in which the next interaction is between a pair of agents picked uniformly at random, that the protocol stabilizes on the correct output with probability 1. More formally, given $f : \mathbb{N}^k \to \mathbb{N}$ and $\mathbf{m} \in \mathbb{N}^k$, defining $S^{\mathcal{C}}_{f,\mathbf{m}} = \{\mathbf{o} \in \mathbb{N}^\Lambda \mid \mathbf{o} \text{ is stable and } \mathbf{o}(\overline{y}) = f(\mathbf{m})\}$, $\mathcal{C}$ stably computes f if and only if, for all $\mathbf{m}$, defining $\mathbf{i}$ with $\mathbf{i} \restriction \Sigma = \mathbf{m}$ as above with $\mathbf{i}(\overline{q})$ sufficiently large, $\mathsf{Pr}\left[\mathbf{i} \Longrightarrow S^{\mathcal{C}}_{f,\mathbf{m}}\right] = 1$. It is also equivalent to requiring that every fair infinite execution leads to a correct stable configuration, where an execution is *fair* if every configuration infinitely often reachable appears infinitely often in the execution. We say that an initial configuration $\mathbf{i}$ so defined is *valid*. Since all semilinear functions are linearly bounded [11], a linearly bounded q_0 suffices to ensure there are enough agents to represent the output of a semilinear function, even if we choose $\mathbf{i}(\overline{q}) = q_0(\mathbf{i} \restriction \Sigma)$. If q_0 were *not* linearly bounded, and thus a super-linear count of state $\overline{q}$ is required, we would essentially need to do non-semilinear computation just to initialize the population protocol.

Let $f : \mathbb{N}^k \to \mathbb{N}$ and $t : \mathbb{N} \to \mathbb{N}$. Given a function-computing population protocol $\mathcal{C}$ that stably computes f, we say $\mathcal{C}$ *stably computes* f *in expected time* t if, for all valid initial configurations $\mathbf{i}$ of $\mathcal{C}$, letting $\mathbf{m} = \mathbf{i} \restriction \Sigma$, $\mathsf{T}\left[\mathbf{i} \Longrightarrow S^{\mathcal{C}}_{f,\mathbf{m}}\right] \leq t(n)$.

▶ **Theorem 3.1.** *Let $f : \mathbb{N}^k \to \mathbb{N}$, and let $\mathcal{C}$ be a function-computing population protocol that stably computes f. If f is not eventually-$\mathbb{N}$-linear then $\mathcal{C}$ takes expected time $\Omega(n)$.*

Techniques developed in previous work for proving time lower bounds [14, 1] can certainly generalize beyond leader election and majority, although it was not clear what precise category of computation they cover. However, to extend the impossibility results to all not eventually-$\mathbb{N}$-linear functions, we needed to develop new tools.

Both in prior and current work, the high level intuition of the proof technique is as follows. The overall argument is a proof by contradiction: if sublinear time computation is possible then we find a nefarious execution sequence which stabilizes to an incorrect output. In more detail, sublinear time computation requires avoiding "bottlenecks"—having to go through a transition in which both states are present in small count (constant independent of the number of agents n). Traversing even a single such transition requires linear time. Technical lemmas show that bottleneck-free execution sequences from α-dense initial configurations (i.e., initial configurations where every state that is present is present in at least αn count)

are amenable to predictable "surgery" [14, 1]. At the high level, the surgery lemmas show how states that are present in "low" count when the population protocol stabilizes, can be manipulated (added or removed) such that only "high" count other states are affected. Since it can also be shown that changing high count states in a stable configuration does not affect its stability, this means that the population protocol cannot "notice" the surgery, and remains stabilized to the previous output. For leader election, the surgery allows one to remove an additional leader state (leaving us with no leaders). For majority computation [1], the input in the minority must be present in low count (or absent) at the end. This allows one to add enough of the minority input to turn it into the majority, while the protocol continues to output the wrong answer.

However, applying the previously developed surgery lemmas to fool a more general function computing population protocol is more difficult. The surgery to consume additional input states affects the count of the output state, which could be present in "large count" at the end. How do we know that the effect of the surgery on the output is not consistent with the desired output of the function? In order to arrive at a contradiction we develop two new techniques, both of which are necessary to cover all cases. The first involves showing that the slope of the change in the count of the output state as a function of the input states is inconsistent. The second involves exposing the semilinear structure of the graph of the function being computed, and forcing it to enter the "wrong piece" (i.e., periodic coset).

4 Sublinear-time, sublinear-error approximation of linear functions with negative or non-integer coefficients is impossible

A *function-approximating population protocol* is a tuple $\mathcal{A} = (\Lambda, \delta, \Sigma, \overline{y}, \overline{q}, \overline{a})$, where $(\Lambda, \delta, \Sigma, \overline{y}, \overline{q})$ is a function-computing population protocol and $\overline{a} \in \Lambda \setminus (\Sigma \cup \{\overline{y}, \overline{q}\})$ is the *approximation state*. Let $\epsilon, \tau \in \mathbb{N}$; intuitively τ represents the "target" (or "true") function output, and ϵ represents the allowed approximation error. We say that a configuration $\mathbf{o} \in \mathbb{N}^\Lambda$ is ϵ-τ-*correct* if $|\mathbf{o}(\overline{y}) - \tau| \leq \epsilon$.

Let $f : \mathbb{N}^k \to \mathbb{N}$, $\epsilon \in \mathbb{N}$, $\mathbf{i} \in \mathbb{N}^\Lambda$, and let $\mathbf{m} = \mathbf{i} \upharpoonright \Sigma$. We say that $\mathcal{A}$ *stably* ϵ-*approximates* f *from* $\mathbf{i}$ if, for all $\mathbf{c} \in \mathsf{post}(\mathbf{i})$, there exists a $\mathbf{o} \in \mathsf{post}(\mathbf{c})$ that is stable and ϵ-$f(\mathbf{m})$-correct, i.e., from the initial configuration $\mathbf{i}$, $\mathcal{A}$ gets the output to stabilize to a value at most ϵ from the correct output. Let $S^{\mathcal{A}}_{f,\mathbf{m},\epsilon} = \{\mathbf{o} \in \mathbb{N}^\Lambda \mid \mathbf{o}$ is stable and ϵ-$f(\mathbf{m})$-correct $\}$. Note that $\mathcal{A}$ stably ϵ-approximates f from $\mathbf{i}$ if and only if $\mathsf{Pr}\left[\mathbf{i} \Longrightarrow S^{\mathcal{A}}_{f,\mathbf{m},\epsilon}\right] = 1$.

Let $\mathcal{E} : \mathbb{N} \to \mathbb{N}$; the choice of $\mathcal{E}$ as a function instead of a constant reflects the idea that the approximation error is allowed to depend on the initial count $\mathbf{i}(\overline{a})$ of the approximation state $\overline{a}$, i.e., $\mathcal{E}(\mathbf{i}(\overline{a}))$ is the desired approximation error. We say that $\mathcal{A}$ *stably* $\mathcal{E}$-*approximates* f if there are $a_0 \in \mathbb{N}$ and linearly bounded $q_0 : \mathbb{N}^{k+1} \to \mathbb{N}$ such that, for any $\mathbf{i} \in \mathbb{N}^\Lambda$, defining $\mathbf{m} = \mathbf{i} \upharpoonright \Sigma$, if $\mathbf{i}(\overline{a}) \geq a_0$, $\mathbf{i}(\overline{q}) \geq q_0(\mathbf{m}, \mathbf{i}(\overline{a}))$, and $\mathbf{i}(\overline{s}) = 0$ for all $\overline{s} \in \Lambda \setminus (\Sigma \cup \{\overline{q}, \overline{a}\})$, then $\mathcal{A}$ stably $\mathcal{E}(\mathbf{i}(\overline{a}))$-approximates f from $\mathbf{i}$.[3] An initial configuration $\mathbf{i}$ so defined is *valid*.

As we consider leaderless population protocols, we need to make sure that $\overline{a}$ does not act as a small count "leader". Consistent with the rest of this paper, we reason about initial configurations with $\mathbf{i}(\overline{a}) \geq \alpha n$ for some $\alpha > 0$ to ensure α-density.

Let $f : \mathbb{N}^k \to \mathbb{N}$. In defining running time for function-approximating population protocols, we express the expected time as a function of *both* the total number of agents

[3] I.e., the initial count $\mathbf{i}(\overline{a})$ can influence the initial required count $\mathbf{i}(\overline{q})$, since adding more initial $\overline{a}$ may imply that more quiescent agents are required as "fuel". However, a_0 is constant, not a function of $\mathbf{m}$.

$n = \|\mathbf{i}\|$ *and* the initial count $\mathbf{i}(\overline{a})$ of approximation states. Let $\mathcal{E} : \mathbb{N} \to \mathbb{N}$ and $t : \mathbb{N}^2 \to \mathbb{N}$. Given a function-approximating population protocol $\mathcal{A}$ that $\mathcal{E}$-approximates f, we say $\mathcal{A}$ $\mathcal{E}$-approximates f *in expected time* t if, for all valid initial configurations $\mathbf{i}$ of $\mathcal{A}$, letting $\mathbf{m} = \mathbf{i} \upharpoonright \Sigma$, $\mathsf{T}\left[\mathbf{i} \Longrightarrow S^{\mathcal{A}}_{f,\mathbf{m},\mathcal{E}(\mathbf{i}(\overline{a}))}\right] \leq t(n, \mathbf{i}(\overline{a}))$.

The following theorem states that given any linear function f and any population protocol $\mathcal{P}$, if f has a non-integer or negative coefficient, then $\mathcal{P}$ requires at least linear time to approximate f with sublinear error. It states this by contrapositive: if the protocol takes sublinear time, then the error $\mathcal{E} : \mathbb{N} \to \mathbb{N}$ must grow at least linearly with the initial count of approximation state $\overline{a}$. In particular, the initial configurations $\mathbf{i}$ (letting $n = \|\mathbf{i}\|$) on which our argument maximizes the error have $\mathbf{i}(\overline{a}) = \Omega(n)$. Thus, the fact that $\mathcal{E}(a) \geq \gamma a$ implies that on these $\mathbf{i}$, the error is $\Omega(n)$.

▶ **Theorem 4.1.** *Let $f : \mathbb{N}^k \to \mathbb{N}$ be a linear function that is not $\mathbb{N}$-linear. Let $\mathcal{E} : \mathbb{N} \to \mathbb{N}$. Let $\mathcal{A}$ be a function-approximating population protocol that stably $\mathcal{E}$-approximates f in expected time t, where for some $\alpha > 0$, $t(n, \alpha n) = o(n)$. Then there is a constant $\gamma > 0$ such that, for infinitely many $a \in \mathbb{N}$, $\mathcal{E}(a) \geq \gamma a$.*

A protocol stably computing f also stably $\mathcal{E}$-approximates f for $\mathcal{E}(a) = 0$, so we have:

▶ **Corollary 4.2.** *Let $f : \mathbb{N}^k \to \mathbb{N}$ be a linear function $f(\mathbf{m}) = \sum_{i=1}^{k} \lfloor c_i \mathbf{m}(i) \rfloor$, where $c_i \notin \mathbb{N}$ for some $i \in \{1, \ldots, k\}$. Let $\mathcal{C}$ be a function-computing population protocol that stably computes f. Then $\mathcal{C}$ takes expected time $\Omega(n)$.*

This gives a complete classification of the asymptotic efficiency of computing linear functions $f(\mathbf{m}) = \sum_{i=1}^{k} \lfloor c_i \mathbf{m}(i) \rfloor$ with population protocols. If $c_i \in \mathbb{N}$ for all $i \in \{1, \ldots, k\}$, then f is stably computable in logarithmic time by Observation 5.1. Otherwise, f requires linear time to stably compute by Corollary 4.2.

5 Logarithmic-time, linear-error approximation of linear functions with nonnegative rational coefficients is possible

It is easy to see that any $\mathbb{N}$-linear function f can be stably computed in logarithmic time. Recall that $\overline{x}, \overline{q} \to \overline{y}, \overline{y}$ stably computes $f(m) = 2m$ in expected time $O(\log n)$. The extension to larger coefficients and multiple inputs is routine:

▶ **Observation 5.1.** *Let $f : \mathbb{N}^k \to \mathbb{N}$ be an $\mathbb{N}$-linear function. There is a function-computing population protocol that stably computes f in expected time $O(\log n)$.*

We now describe how to stably approximate linear functions with nonnegative *rational* coefficients, i.e., $\mathbb{Q}_{\geq 0}$-linear functions, with a linear approximation error, in logarithmic time. (It is open to do this for negative coefficients, e.g., $f(m_1, m_2) = m_1 - m_2$). Recall the following simple example of a population protocol that approximately divides by 2 (that is, with probability 1 it outputs a value guaranteed to be a certain distance to the correct output), with a linear approximation error, and is fast ($O(\log n)$ time) with initial counts $\#\overline{x} = m$, $\#\overline{a} = \gamma m$, and $\#\overline{q} = \#\overline{y} = 0$:

$$\overline{a}, \overline{x} \to \overline{b}, \overline{y}$$
$$\overline{b}, \overline{x} \to \overline{a}, \overline{q}$$

which stabilizes $\#\overline{y}$ to somewhere in the interval $\{m/2, m/2 + 1, \ldots, m/2 + \gamma m\}$.

To see that the protocol is correct, note that the transition sequence can make $\#\overline{y}$ closer to one endpoint of the interval or the other depending on which transitions are chosen to consume the *last* γm of $\overline{x}$, but no matter what, the first transition executes at least as many times as the second, but not more than γm times more.

If $\#\overline{a} = 1$ initially, the above protocol stably computes $\lfloor m/2 \rfloor$ (taking linear time just for the last transition; and in total takes $\Theta(n \log n)$ time, by a coupon collector argument).

To see that the protocol takes $O(\log n)$ time if $\#\overline{a} = \gamma m$ initially, note $n = m + \gamma m \leq 2m$. Observe that $\#\overline{a} + \#\overline{b} = \gamma m$ in any reachable configuration. Thus the probability any given interaction is one of the above two transitions is $\approx \frac{\gamma m \#\overline{x}}{n^2}$, so the expected number of interactions until such a transition occurs is $\frac{n^2}{\gamma m \#\overline{x}}$. After m such transitions occur, all the input $\overline{x}$ is gone and the protocol stabilizes, which by linearity of expectation takes expected number of interactions

$$\sum_{\#\overline{x}=1}^{m} \frac{n^2}{\gamma m \#\overline{x}} = \frac{n^2}{\gamma m} \sum_{\#\overline{x}=1}^{m} \frac{1}{\#\overline{x}} \approx \frac{n^2}{\gamma m} \ln m \leq \frac{n^2}{\gamma n/2} \ln n = \frac{2n}{\gamma} \ln n,$$

i.e., expected parallel time $\frac{2}{\gamma} \ln n$. Thus this shows a tradeoff between accuracy and speed in a single protocol, adjustable by the initial count of $\overline{a}$. In this case, the approximation error increases, and the expected time to stabilization decreases, with increasing initial $\#\overline{a}$.

More generally, we can prove the following. In particular, if $a = \Omega(n)$, then $t(n, a) = O(\log n)$. Also, if $a = o(n)$, then the approximation error is $o(n)$, and if $a = \omega(\log n)$, then the expected time is $o(n)$ also. This does not contradict Theorem 4.1 since setting $a = o(n)$ implies the initial configurations are not all α-dense for a fixed $\alpha > 0$.

▶ **Theorem 5.2.** *Let $f : \mathbb{N}^k \to \mathbb{N}$ be a $\mathbb{Q}_{\geq 0}$-linear function. Let $\mathcal{E} : \mathbb{N} \to \mathbb{N}$ be the identity function. Define $t : \mathbb{N}^2 \to \mathbb{N}$ by $t(n, a) = \frac{n}{a} \log n$. Then there is a function-approximating population protocol $\mathcal{A}$ that $\mathcal{E}$-approximates f in expected time $O(t)$.*

The basic analysis is similar to the example protocol above, and the extension to rational coefficients other than $\frac{1}{2}$ follows techniques used in similar papers on function computation with chemical reaction networks [11, 13].

6 Predicate computation

In this section we show that a wide class of Boolean predicates cannot be stably computed in sublinear time by population protocols (without a leader). Intuitively, this is the class of predicates $\phi : \mathbb{N}^k \to \{0, 1\}$ such that for all $m \in \mathbb{N}$, there are two inputs $\mathbf{m}_0, \mathbf{m}_1 \in \mathbb{N}^k_{\geq m}$ such that $\phi(\mathbf{m}_0) \neq \phi(\mathbf{m}_1)$. (See the definition of *eventually constant* below.)

Formally, a *predicate-deciding population protocol* is a tuple $\mathcal{D} = (\Lambda, \delta, \Sigma, \Upsilon_1)$, where (Λ, δ) is a population protocol, $\Sigma \subseteq \Lambda$ is the set of *input states*, and $\Upsilon_1 \subseteq \Lambda$ is the set of *1-voters*. By convention, we define $\Upsilon_0 = \Lambda \setminus \Upsilon_1$ to be the set of *0-voters*. The *output* $\Phi(\mathbf{c})$ of a configuration $\mathbf{c} \in \mathbb{N}^\Lambda$ is $b \in \{0, 1\}$ if $\mathbf{c}(\overline{s}) = 0$ for all $\overline{s} \in \Upsilon_{1-b}$ (i.e., if the vote is unanimously b); the output is undefined if voters of both types are present. We say $\mathbf{o} \in \mathbb{N}^\Lambda$ is *stable* if $\Phi(\mathbf{o})$ is defined and for all $\mathbf{o}' \in \mathsf{post}(\mathbf{o})$, $\Phi(\mathbf{o}') = \Phi(\mathbf{o})$. For all $\mathbf{m} \in \mathbb{N}^k$, define initial configuration $\mathbf{i}_\mathbf{m} \in \mathbb{N}^\Lambda$ by $\mathbf{i}_\mathbf{m} \upharpoonright \Sigma = \mathbf{m}$ and $\mathbf{i}_\mathbf{m} \upharpoonright (\Lambda \setminus \Sigma) = \mathbf{0}$. Call such an initial configuration *valid*. For any valid initial configuration $\mathbf{i}_\mathbf{m} \in \mathbb{N}^\Lambda$ and predicate $\phi : \mathbb{N}^k \to \{0, 1\}$, let $S_{\mathbf{i}_\mathbf{m}, \phi} = \{\mathbf{o} \in \mathbb{N}^\Lambda \mid \mathbf{i}_\mathbf{m} \Longrightarrow \mathbf{o}, \mathbf{o} \text{ is stable, and } \Phi(\mathbf{o}) = \phi(\mathbf{m})\}$. A population protocol *stably decides* a predicate $\phi : \mathbb{N}^k \to \{0, 1\}$ if, for any valid initial configuration $\mathbf{i}_\mathbf{m} \in \mathbb{N}^\Lambda$, $\mathsf{Pr}[\mathbf{i}_\mathbf{m} \Longrightarrow S_{\mathbf{i}_\mathbf{m}, \phi}] = 1$. This is equivalent to requiring that for all $\mathbf{c} \in \mathsf{post}(\mathbf{i}_\mathbf{m})$, there is $\mathbf{o} \in \mathsf{post}(\mathbf{c})$ such that $\mathbf{o}$ is stable and $\Phi(\mathbf{o}) = \phi(\mathbf{m})$.

For example, the protocol defined by transitions

$$\overline{x}_1, \overline{x}_2 \to \overline{q}_1, \overline{q}_2$$
$$\overline{x}_1, \overline{q}_2 \to \overline{x}_1, \overline{q}_1$$
$$\overline{x}_2, \overline{q}_1 \to \overline{x}_2, \overline{q}_2$$
$$\overline{q}_1, \overline{q}_2 \to \overline{q}_1, \overline{q}_1$$

if $\Upsilon_1 = \{\overline{x}_1, \overline{q}_1\}$ and $\Upsilon_0 = \{\overline{x}_2, \overline{q}_2\}$, decides whether $m_1 = \mathbf{i}(\overline{x}_1) \geq m_2 = \mathbf{i}(\overline{x}_2)$. The first transition stops once the less numerous input state is gone. If $\overline{x}_1$ (resp. $\overline{x}_2$) is left over, then the second (resp. third) transition converts $\overline{q}_i$ states to its vote. If neither is left over (i.e., if $m_1 = m_2$, requiring output 1), the fourth transition converts all $\overline{q}_2$ states to $\overline{q}_1$.

Let $\phi : \mathbb{N}^k \to \{0,1\}$, and for $b \in \{0,1\}$, define $\phi^{-1}(b) = \{\mathbf{m} \in \mathbb{N}^k \mid \phi(\mathbf{m}) = b\}$ to be the set of inputs on which ϕ outputs b. We say ϕ is *eventually constant* if there is $m_0 \in \mathbb{N}$ such that ϕ is constant on $\mathbb{N}^k_{\geq m_0} = \{\mathbf{m} \in \mathbb{N}^k \mid (\forall i \in \{1, \ldots, k\})\ \mathbf{m}(i) \geq m_0\}$, i.e., either $\phi^{-1}(0) \cap \mathbb{N}^k_{\geq m_0} = \emptyset$ or $\phi^{-1}(1) \cap \mathbb{N}^k_{\geq m_0} = \emptyset$. In other words, although ϕ may have an infinite number of each output, "sufficiently far from the boundary" (where all coordinates exceed m_0), only one output appears.

The following theorem shows that any predicate that is not eventually constant cannot be stably decided in sublinear time by a population protocol.

▶ **Theorem 6.1.** *Let $\phi : \mathbb{N}^k \to \{0,1\}$ and $\mathcal{D}$ be a predicate-deciding population protocol that stably decides ϕ. If ϕ is not eventually constant, then $\mathcal{D}$ takes expected time $\Omega(n)$.*

Alistarh, Aspnes, Eisenstat, Gelashvili, and Rivest [1] showed a linear-time lower bound on any leaderless population protocol deciding the majority predicate. Recall that their technique is based on showing that after adding enough of the input in the minority to change it to the majority, the effect of this addition can be effectively nullified by surgery of the transition sequence, yielding a stable configuration with the original (now incorrect) answer. The technique can be extended easily to show various other specific predicates, such as equality and parity, also require linear time. We use the same technique of finding pairs of inputs with opposite correct answers and apply a similar transition sequence surgery. The main difficulty in showing Theorem 6.1, which covers the class of *all* predicates that are semilinear but not eventually constant, is to identify a common characteristic that can be exploited to find pairs of inputs that are α-dense for some $\alpha > 0$. Here, we rely on the semilinear structure of the predicate computed. Indeed, note that we cannot find such α-dense pairs for the predicate $\phi : \mathbb{N}^2 \to \{0,1\}$ with support $\{(k, 2^k) \mid k \in \mathbb{N}\}$, which is not eventually constant (but also not semilinear).

7 Open Questions

Time complexity of other functions. What is the optimal time complexity of computing semilinear functions and predicates not satisfying the hypotheses of Theorems 3.1 and 6.1; namely the *eventually-$\mathbb{N}$-linear* functions, (e.g., $f(m) = 0$ if $m < 3$ and $f(m) = m$ otherwise) and *eventually-constant* predicates (e.g., $\phi(m) = 1$ iff $m \geq 2$)?

Stabilization vs convergence. Measuring time to stabilization in the randomized model, as we do here, measures the expected time until the probability of changing the output becomes 0. Our proof shows only that stabilization must take expected $\Omega(n)$ time. However, convergence could occur much earlier in a transition sequence than stabilization (we can say

a particular transition sequence *converged* at the point when the output count is the same in every subsequently reached configuration). We conjecture that similar negative results hold for convergence for leaderless population protocols. It is also open whether stabilization can occur in sublinear time, *even with an initial leader*. The known stably computing protocols converging in $O(\log^5 n)$ time [5, 11] provably require expected time $\Omega(n)$ to stabilize.

Acknowledgements. We are grateful to Sungjin Im for the proof of an important technical lemma, and we thank anonymous reviewers for very helpful comments.
