We also analyze the approximation/competitive ratio of the greedy algorithm. We observe that for many incremental problems like Knapsack, Maximum Independent Set, and Disjoint Paths, the greedy algorithm has an unbounded competitive ratio. On the other hand, we define a relaxation of submodularity called *α-augmentable* under which the greedy algorithm has a bounded competitive ratio. In particular, this relaxation captures our cardinality constrained versions of Maximum (Weighted) (b-)Matching and Maximum Bridge-Flow, where the incremental set S need not be feasible but only contain a good feasible subset. We get the following result, where the tight lower bound for $\alpha = 2$ is obtained for Maximum Bridge-Flow. Notice that for $\alpha = 1$, we obtain the $\frac{e}{e-1} \approx 1.58$ bound that is known for submodular functions. For $\alpha = 2$, the bound is $\frac{e^2}{e^2-1} \approx 2.313$.

▶ **Theorem 4.** *For every cardinality constrained problem with an α-augmentable objective (defined below), the greedy algorithm has approximation/competitive ratio $\alpha\frac{e^\alpha}{e^\alpha-1}$. This bound is tight for the greedy algorithm on problems with 2-augmentable objectives, which includes* Maximum (Weighted) (b-)Matching *and* Maximum Bridge-Flow.

We emphasize that the families of instances we construct to obtain the lower bounds in Theorems 2 and 4 require the number of elements to tend to infinity, since it takes time for incremental solutions to sufficiently fall behind the optimum solution.

Related Work. Most work on incremental settings has focused on cardinality constrained *minimization* problems. A prominent exception is the robust matching problem, introduced by Hassin and Rubinstein [16]. This problem asks for a weighted matching M with the property that, for every value k, the total weight of the $\min(k, |M|)$ heaviest edges of M comes close to the weight of a maximum weight matching of cardinality k. Note that this differs from our definition of incremental matchings in that the robust matching problem demands that the "incremental" solution consists of a matching, while we allow any edge set that contains a heavy matching as a subset. Since their model is more strict, all of the following competitive ratios carry over to our setting. Note that, in contrast to our setting, the objective function of the robust matching problem is submodular, and hence the greedy algorithm has competitive ratio at most $\frac{e}{e-1} \approx 1.58$ [27]. Hassin and Rubinstein [16] gave an improved, deterministic algorithm that achieves competitive ratio $\sqrt{2} \approx 1.414$. They also give a tight example for the $\sqrt{2}$ ratio, which also works in our incremental setting. Fujita et al. [11] extended this result to matroid intersection, and Kakimura and Makino [18] showed

that every independence system allows for a $\sqrt{\mu}$-competitive solution, with μ being the extendibility of the system. Matuschke at al. [24] describe a randomized algorithm for this problem that, under the assumption that the adversary does not know the outcome of the randomness, has competitive ratio $\ln(4) \approx 1.386$.

A variant of the knapsack problem with a similar notion of robustness was proposed by Kakimura et al. [19]. In this problem a knapsack solution needs to be computed, such that, for every k, the value of the k most valuable items in the knapsack compares well with the optimum solution using k items, for every k. Kakimura et al. [19] restrict themselves to polynomial time algorithms and show that under this restriction a bounded competitive ratio is possible only if the rank quotient of the knapsack system is bounded. In contrast, our results show that if we do not restrict the running time and if we only require our solution to *contain* a good packing with k items for every k, then we can be $(1+\varphi)$-competitive using our generic algorithm, even for generalizations like Multi-Dimensional Knapsack. If we restrict the running time and use the well-known PTAS for the knapsack problem [17, 22], we still get a $(1+\varphi)(1+\varepsilon)$-competitive algorithm. Megow and Mestre [25] and Disser et al. [7] considered another variant of the knapsack problem that asks for an order in which to pack the items that works well for every knapsack capacity. Kobayashi and Takizawa [20] study randomized strategies for cardinality robustness in the knapsack problem.

Hartline and Sharp [15] considered an incremental variant of the maximum flow problem where capacities increase over time. This is in contrast to our framework where the cardinality of the solution increases.

Incremental solutions for cardinality constrained minimization problems have been studied extensively, in particular for clustering [3, 6], k-median [4, 10, 26], minimium spanning tree [1, 12], and facility location [13]. An important result in this domain is the incremental framework given by Lin et al. [23]. This general framework allows to devise algorithms for every incremental minimization problem for which a suitable augmentation subroutine can be formulated. Lin et al. [23] used their framework to match or improve many of the known specialized bounds for the problems above and to derive new bounds for covering problems. In contrast to their result, our incremental framework allows for a general algorithm that works out-of-the-box for a broad class of incremental maximization problems and yields a constant (relatively small) competitive ratio.

Abstractly, incremental problems can be seen as optimization problems under uncertainty. Various approaches to handling uncertain input data have been proposed, ranging from robust and stochastic optimization to streaming and exploration. On this level, incremental problems can be seen as a special case of online optimization problems, i.e., problems where the input data arrives over time (see [2, 9]). Whereas online optimization in general assumes adversarial input, incremental problems restrict the freedom of the adversary to deciding when to stop, i.e., the adversary may choose the cardinality k while all other data is fixed and known to the algorithm. Online problems with such a "non-adaptive" adversary have been studied in other contexts [5, 8, 14]. Note that online problems demand irrevocable decisions in every time step – a requirement that may be overly restrictive in many settings where solutions develop over a long time period. In contrast, our incremental model only requires a growing solution "infrastructure" and allows the actual solution to change arbitrarily over time within this infrastructure.

2 A competitive algorithm for incremental problems

In this section, we show the second part of Theorem 2, i.e., we give an incremental algorithm that is $(1+\varphi \approx 2.618)$-competitive for all incremental problems. For convenience, we define

the *density* δ_S of a set $S \subseteq U$ via $\delta_S := f(S)/|S|$, and we let $\delta_k^\star := \delta_{S_k^\star}$ denote the optimum density for cardinality k. Our algorithm relies on the following two observations that follow from the accountability of the objective function.

▶ **Lemma 5.** *In every incremental problem and for every cardinality k, there is an ordering $\vec{S}_k^\star := \{s_1^\star, s_2^\star, \dots, s_k^\star\} := S_k^\star$, such that $\delta_{\{s_1^\star,\dots,s_i^\star\}} \geq \delta_{\{s_1^\star,\dots,s_{i+1}^\star\}}$ for all $i \in \{1,\dots,k-1\}$. We say that $\vec{S}_k^\star$ is a* greedy order *of $S_k^\star$.*

Proof. By accountability of f, there is an element $s_k^\star \in S_k^\star$ for which

$$\delta_{S_k^\star \setminus \{s_k^\star\}} = \frac{f(S_k^\star \setminus \{s_k^\star\})}{k-1} \geq \frac{f(S_k^\star)}{k} = \delta_{S_k^\star}.$$

We can repeat this argument for $s_{k-1}^\star \in S_k^\star \setminus \{s_k^\star\}$, $s_{k-2}^\star \in S_k^\star \setminus \{s_k^\star, s_{k-1}^\star\}$, etc. to obtain the desired ordering $\vec{S}_k^\star$. ◀

▶ **Lemma 6.** *In every incremental problem and for every $1 \leq k' \leq k$ we have $\delta_{k'}^\star \geq \delta_k^\star$.*

Proof. Fix any cardinality $k > 1$. By accountability of the objective function f, there is an element $s^\star \in S_k^\star$ with

$$\delta_k^\star = \frac{f(S_k^\star)}{k} \leq \frac{f(S_k^\star \setminus \{s^\star\})}{k-1} \leq \frac{S_{k-1}^\star}{k-1} = \delta_{k-1}^\star.$$

It follows that $\delta_k^\star$ is monotonically decreasing in k. ◀

Now, we define $k_0 := 1$ and $k_i := \lceil (1+\varphi) k_{i-1} \rceil$ for all positive integers i. Our algorithm operates in phases $i \in \{0, 1, \dots\}$. In each phase i, we add the elements of the optimum solution $S_{k_i}^\star$ of cardinality k_i to our incremental solution in greedy order (Lemma 5). Note that we allow the algorithm to add elements multiple times (without effect) in order to not complicate the analysis needlessly (of course we would only improve the algorithm by skipping over duplicates). In the following, we denote by t_i the number of steps (possibly without effect) until the end of phase i, i.e., we let $t_0 := k_0$ and $t_i := t_{i-1} + k_i$.

▶ **Lemma 7.** *For every phase $i \in \{0, 1, \dots\}$, we have $t_i \leq \varphi k_i$.*

Proof. We use induction over i, with the case $i = 0$ being trivial, since $t_0 = k_0$. Now assume that $t_{i-1} \leq \varphi k_{i-1}$ for some $i \geq 1$. Using the property $\frac{\varphi}{\varphi+1} = \varphi - 1$ of the golden ratio, we get

$$t_i = t_{i-1} + k_i \leq \varphi k_{i-1} + k_i \leq \frac{\varphi}{\varphi+1} k_i + k_i = \varphi k_i.$$ ◀

Finally, we show the solution $\vec{S}$ computed by our algorithm is $(1+\varphi)$-competitive.

▶ **Theorem 8.** *For every cardinality k, we have $f(\vec{S}_k) \geq f_k^\star/(1+\varphi)$.*

Proof. We use induction over k. The claim is true for $k = t_0 = 1$, since $\vec{S}_1 = S_1^\star$ by definition of the algorithm. For the inductive step, we prove that if the claim is true for $k = t_{i-1}$, then it remains true for all $k \in \{t_{i-1}+1, \dots, t_i\}$. Recall that $k_i = \lceil (1+\varphi) k_{i-1} \rceil$. By Lemma 7, we have

$$t_{i-1} \leq \varphi k_{i-1} < k_i < t_{i-1} + k_i = t_i,$$

and we can therefore distinguish the following cases.

Case 1: $t_{i-1} < k < k_i$. Since $k > t_{i-1}$, our algorithm has already completed phase $i-1$ and added all elements of $S^\star_{k_{i-1}}$, so we have $f(\vec{S}_k) \geq f^\star_{k_{i-1}}$. Because k is an integer and $k < k_i = \lceil (1+\varphi)k_{i-1} \rceil$, we have that $k < (1+\varphi)k_{i-1}$. By Lemma 6, we thus have

$$f^\star_k = \delta^\star_k \cdot k < \delta^\star_{k_{i-1}} \cdot (1+\varphi)k_{i-1} = (1+\varphi) f^\star_{k_{i-1}} \leq (1+\varphi) f(\vec{S}_k).$$

Case 2: $k_i \leq k \leq t_i$. At time k, our algorithm has already completed the first $k - t_{i-1}$ elements of $S^\star_k$. Since the algorithm adds the elements of $S^\star_{k_i}$ in greedy order, we have $f(\vec{S}_k) \geq (k - t_{i-1})\delta^\star_{k_i}$. On the other hand, since $k \geq k_i$, by Lemma 6 we have $f^\star_k = k \cdot \delta^\star_k \leq k \cdot \delta^\star_{k_i}$. In order to complete the proof, it is thus sufficient to show that $k \leq (1+\varphi)(k - t_{i-1})$. To see this, let $k = k_i + k'$ for some non-negative integer k'. Because t_{i-1} is integral, Lemma 7 implies $t_{i-1} \leq \lfloor \varphi k_{i-1} \rfloor$. Since φ is irrational and k_{i-1} is integral, φk_{i-1} cannot be integral, thus

$$k - t_{i-1} = k' + k_i - t_{i-1} \geq k' + \lceil (1+\varphi)k_{i-1} \rceil - \lfloor \varphi k_{i-1} \rfloor = k' + k_{i-1} + 1.$$

This completes the proof, since

$$(1+\varphi)(k - t_{i-1}) \geq (1+\varphi)(k' + k_{i-1} + 1) > k' + (1+\varphi)k_{i-1} + 1 \geq k' + k_i = k. \qquad \blacktriangleleft$$

Corollary 3 follows if we replace $S^\star_{k_i}$ by an α-approximate solution for cardinality k_i.

3 Lower bound on the best-possible competitive ratio

In this section, we show the second part of Theorem 2, i.e., we give a lower bound on the best-possible competitive ratio for the maximization of incremental problems. For this purpose, we define the Region Choosing problem. In this problem, we are given N disjoint sets $R_1, \ldots, R_N$, called *regions*, with region R_i containing i elements with a value of $\delta(i)$ each. We say that $\delta(i)$ is the *density* of region R_i. The total value of all elements in the region R_i is $v(i) := i \cdot \delta(i)$ for all $i \in \{1, \ldots, N\}$.

The objective is to compute an incremental solution $S \subseteq U := \bigcup_{i=1}^N R_i$ such that the maximum value of the items from a single region in S is large. Formally, the objective function is given by $f(S) := \max_{i \in \{1,\ldots,N\}} |R_i \cap S| \cdot v(i)$.

▶ **Observation 9.** Region Choosing *is an incremental problem.*[1]

For our lower bound, we set $\delta(i) := i^{\beta-1}$ for some $\beta \in (0,1)$ that we will choose later. For this choice of β, we have $\delta(i) < \delta(j)$ and $v(i) > v(j)$ for $0 \leq j < i \leq N$. Also, for $N \to \infty$ we have $\lim_{i \to \infty} v(i) = \infty$. We call instances of the Region Choosing problem in this form *β-decreasing*. Observe that in every β-decreasing instance the optimum solution of cardinality $i \leq N$ is to take all i elements from region R_i. This solution has value $f^\star_i = i^\beta$.

In order to impose a lower bound on the best-possible competitive ratio for β-decreasing instances, we need some insights into the structure of incremental solutions with an optimal competitive ratio. First, consider a solution that picks only $i' < i$ elements from region R_i. In this case, we could have picked i' elements from region $R_{i'}$ instead – this would only improve the solution, since densities are decreasing. Secondly, if we take i elements from region R_i, it is always beneficial to take them in an uninterrupted sequence before taking any elements from a region R_j with $j > i$: Our objective depends only on the region with the

[1] This and all other missing proofs are deferred to the full version of this paper.

most value, therefore it never helps to take elements from different regions in an alternating fashion. This leads us the following observation.

▶ **Observation 10.** *For every β-decreasing instance of* Region Choosing *there is an incremental solution with optimal competitive ratio of the following structure: For $k_0 < k_1 < \cdots < k_m \in \mathbb{N}$ with $m \in \mathbb{N}$, it takes k_0 elements from region R_{k_0}, followed by k_1 elements from R_{k_1}, and so on, until finally k_m elements from region R_{k_m} are chosen.*

Thus, we can describe an algorithm for the region-choosing problem by an increasing sequence of region indices $k_0, \dots, k_m$. Note that, in order to have a bounded competitive ratio if $N \to \infty$, we must have $m \to \infty$, since $\lim_{i\to\infty} v(i) \to \infty$. We are interested in a cardinality for which an incremental solution given by $k_0, \dots, k_m$ has a bad competitive ratio. We define

$$\alpha_i := \frac{1}{k_i} \sum_{j=0}^{i} k_j \qquad \text{for all } i \in \{0, \dots, m\}\,.$$

Observe that $\alpha_i > 1$ for all $i \in \{1, \dots, m\}$. We know that the value of the optimum solution for cardinality $\alpha_i k_i$ is $v(\alpha_i k_i) = (\alpha_i k_i)^\beta$, whereas the incremental solution only achieves a value of $v(k_i) = (k_i)^\beta$. This allows us to derive the following necessary condition on the α_i-values of ρ-competitive solutions.

▶ **Observation 11.** *If an incremental solution defined by a sequence $k_0, \dots, k_m$ is ρ-competitive for some $\rho \geq 1$, we must have*

$$\rho \geq \frac{v(\alpha_i k_i)}{v(k_i)} = \left(\frac{\alpha_i k_i}{k_i}\right)^\beta = \alpha_i^\beta \quad \iff \quad \alpha_i \leq \rho^{\frac{1}{\beta}} \qquad \text{for all } i \in \{0, \dots, m\}\,. \tag{2}$$

We will exclude a certain range of values of ρ by showing that we can find a $\beta \in (0, 1)$ such that, for a sufficiently large number of regions N, necessary condition (2) is violated. We do this by showing that, for some $i^\star \in \mathbb{N}$ and some fixed $\varepsilon > 0$, we have $\alpha_{i+1} - \alpha_i > \varepsilon$ for all $i \geq i^\star$, i.e., as i goes to ∞, condition (2) must eventually be violated. The following definition relates a value of $\beta \in (0, 1)$ to a lower bound on the competitive ratio ρ for β-decreasing instances.

▶ **Definition 12.** A pair (ρ, β) with $\rho \geq 1$ and $\beta \in (0, 1)$ is *problematic* if there is $\varepsilon > 0$ such that for all $x \in (1, \rho^{1/\beta}]$ it holds that $h_{\rho,\beta}(x) < 0$, where

$$h_{\rho,\beta}(x) := (\rho^{\frac{1}{\beta}} + \varepsilon - x)^{\frac{1}{1-\beta}} - \frac{x}{x - 1 + \varepsilon}.$$

We show that problematic pairs indeed have the intended property.

▶ **Lemma 13.** *If (ρ, β) is a problematic pair, then ρ is a strict lower bound on the competitive ratio of incremental solutions for β-decreasing instances of* Region Choosing.

All that remains is to specify a problematic pair in order to obtain a lower bound via Lemma 13. It is easy to verify that $(2.18, 0.86)$ is a problematic pair. Note that the resulting bound of 2.18 can slightly be increased to larger values below 2.19.

▶ **Theorem 14.** *There is no* 2.18*-competitive incremental* Region Choosing *algorithm.*

4 The greedy algorithm for a subclass of incremental problems

In this section, we analyze the greedy algorithm that computes an incremental solution $\vec{S}$ with $\vec{S}_k = \vec{S}_{k-1} \cup \{s_k\}$, where $s_k \in \arg\max_{s \in U \setminus \vec{S}_{k-1}} f(\vec{S}_{k-1} \cup \{s_k\})$ and $\vec{S}_0 = \emptyset$. This algorithm is well-known to have competitive ratio $\frac{e}{e-1} \approx 1.58$ if the objective function f is monotone and submodular [27]. Note that every monotone and submodular function is incremental. On the other hand, in general, the greedy algorithm does not have a bounded competitive ratio for incremental problems.

▶ **Observation 15.** *The greedy algorithm has an unbounded competitive ratio for many incremental problems, e.g.,* Knapsack, Weighted Independent Set, *and* Disjoint Paths.

We will now define a subclass of incremental problems where the competitive ratio of greedy can be bounded. Observe that submodularity of a function $f\colon 2^U \to \mathbb{R}_{\geq 0}$ implies that, for every $S \neq T \subseteq U$, there exists an element $t \in T \setminus S$ with $f(S \cup \{t\}) - f(S) \geq (f(S \cup T) - f(S))/|T \setminus S|$. Accordingly, we can define the following relaxation of submodularity.

▶ **Definition 16.** We say that $f\colon 2^U \to \mathbb{R}_{\geq 0}$ is *α-augmentable* for an $\alpha > 0$, if for every $S, T \subseteq U$ with $T \setminus S \neq \emptyset$ there exists an element $t \in T \setminus S$ with

$$f(S \cup \{t\}) - f(S) \geq \frac{f(S \cup T) - \alpha f(S)}{|T|}. \tag{3}$$

Thus, if f is α-augmentable, we can improve a greedy solution if its value is more than a factor of α away from the value of an optimal solution. This definition is meaningful in the sense that it induces an interesting subclass of incremental problems.

▶ **Lemma 17.** *The objective functions of* Maximum (Weighted) (b-)Matching *and* Maximum Bridge-Flow *are 2-augmentable, but not submodular.*

We now show the first part of Theorem 4.

▶ **Theorem 18.** *If the objective function of an incremental problem is α-augmentable, the greedy algorithm is $\alpha\frac{e^\alpha}{e^\alpha-1}$-competitive.*

Proof. Let $\vec{S}_i$ be our greedy incremental solution after i elements have been added. Let us focus on an arbitrary cardinality $k > \alpha$, and say that for this cardinality we have $f_k^\star = \alpha f(\vec{S}_k) + \beta$, for some $\beta > 0$. For cardinalities $k \leq \alpha$, note that $f_1^\star = f(\vec{S}_1)$ and that $f_k^\star \leq k f_1^\star \leq \alpha f_1^\star \leq \alpha f(\vec{S}_k)$ due to sub-additivity. We will show that we must have $\beta \leq \alpha f(\vec{S}_k)/(e^\alpha - 1)$, which proves the theorem for cardinalities $k > \alpha$.

First, let us define $p_k := f(\vec{S}_k) - f(\vec{S}_{k-1})$ to be the additional value obtained by adding the k-th element to our greedy solution $\vec{S}_k$. We claim that

$$p_i \geq \frac{\beta + \alpha \sum_{j=i+1}^{k} p_j}{k - \alpha} \quad \text{for any positive integer } i < k, \text{ and} \quad p_k \geq \frac{\beta}{k - \alpha}\,. \tag{4}$$

To prove (4), we apply (3) for $S = \vec{S}_{i-1}$ and $T = S_k^\star$, which guarantees the existence of a $t \in S_k^\star \setminus \vec{S}_{i-1}$ such that

$$f(\vec{S}_{i-1} \cup \{t\}) - f(\vec{S}_{i-1}) \geq \frac{f(\vec{S}_{i-1} \cup S_k^\star) - \alpha f(\vec{S}_{i-1})}{k} \geq \frac{f_k^\star - \alpha f(\vec{S}_{i-1})}{k} \geq \frac{\beta + \alpha \sum_{j=i}^{k} p_j}{k}.$$

The last inequality holds since we assume $f_k^\star = \alpha f(\vec{S}_k) + \beta$ and for any $i \leq k$ we know that $f(\vec{S}_k) - f(\vec{S}_{i-1}) = \sum_{j=i}^{k} p_j$. Since we construct $\vec{S}_i$ greedily, we have $f(\vec{S}_i) \geq f(\vec{S}_{i-1} \cup \{t\})$

and thus $p_i \geq (\beta + \alpha \sum_{i \leq j \leq k} p_j)/k$. Rearranging to isolate p_i we get the bounds in (4). Next, we claim that

$$p_i \geq \frac{\beta}{k-\alpha} \cdot \left(\frac{k}{k-\alpha}\right)^{k-i} \quad \text{for all } i \leq k. \tag{5}$$

We prove this by induction for decreasing values of i. The induction base for $i = k$ follows directly from (4). For the induction step, we assume that the formula holds for all p_j with $j \in \{i+1, \dots, k\}$. By (4) and the inductive hypothesis, we have

$$\begin{aligned}(k-\alpha) \cdot p_i &\geq \beta + \sum_{j=i+1}^{k} \alpha p_j \geq \beta + \alpha \sum_{j=i+1}^{k} \frac{\beta}{k-\alpha} \cdot \left(\frac{k}{k-\alpha}\right)^{k-j} \\ &= \beta + \frac{\alpha\beta}{k-\alpha} \sum_{j=0}^{k-i-1} \left(\frac{k}{k-\alpha}\right)^{j} = \beta + \frac{\alpha\beta}{k-\alpha} \cdot \frac{(\frac{k}{k-\alpha})^{k-i} - 1}{\frac{k}{k-\alpha} - 1} = \beta \cdot \left(\frac{k}{k-\alpha}\right)^{k-i}, \end{aligned} \tag{6}$$

which shows that the formula also holds for p_i, and thus completes the induction step.

We are now ready to prove the theorem. Recall that we assumed $f_k^\star = \alpha f(\vec{S}_k) + \beta$ and want to show that $\beta < \alpha f(\vec{S}_k)/(e^\alpha - 1)$. We have

$$f(\vec{S}_k) = \sum_{i=1}^{k} p_i \overset{(6)}{\geq} \frac{\beta}{k-\alpha} \sum_{i=1}^{k} \left(\frac{k}{k-\alpha}\right)^{k-i} = \frac{\beta}{k-\alpha} \sum_{i=0}^{k-1} \left(\frac{k}{k-\alpha}\right)^{i} = \frac{\beta}{k-\alpha} \frac{(\frac{k}{k-\alpha})^k - 1}{\frac{k}{k-\alpha} - 1}$$

which can be rearranged to

$$\beta \leq \frac{(k-\alpha)\left(\frac{k}{k-\alpha} - 1\right) f(\vec{S}_k)}{(\frac{k}{k-\alpha})^k - 1} = \frac{\alpha f(\vec{S}_k)}{(\frac{k}{k-\alpha})^k - 1} \leq \frac{\alpha f(\vec{S}_k)}{e^\alpha - 1}$$

The last inequality holds since for any $x > 0$ we have $(1+1/x)^{x+1} \geq e$, and thus for $x = k/\alpha - 1$ it follows that $e \leq \left(1 + \frac{1}{\frac{k}{\alpha} - 1}\right)^{\frac{k}{\alpha}} = \left(1 + \frac{\alpha}{k-\alpha}\right)^{\frac{k}{\alpha}} = \left(\frac{k}{k-\alpha}\right)^{\frac{k}{\alpha}}$ and thus $(\frac{k}{k-\alpha})^k \geq e^\alpha$. ◀

4.1 Lower bound

We now show the second part of Theorem 4, i.e., we show a matching lower bound on the competitive ratio of the greedy algorithm. We show this by constructing the following family of instances for the Maximum Bridge-Flow problem. For $k \in \mathbb{N}$, we define a graph $G_k = (V_k, E_k)$ with designated nodes s and t by

$$\begin{aligned} V_k &:= \{s, t\} \cup \left\{v_i^1, v_i^4 \;\middle|\; i = 1, \dots, 2k\right\} \cup \left\{v_i^2, v_i^3 \;\middle|\; i = 1, \dots, 4k\right\}, \\ E_k &:= E_k^1 \cup E_k^\infty \cup \bigcup_{i=1}^{2k} E_{k,i} \cup \bigcup_{i=1}^{2k} E'_{k,i}, \\ E_k^1 &:= \left\{(s, v_i^2), (v_i^3, t) \;\middle|\; i = 1, \dots, k\right\}, \\ E_k^\infty &:= \left\{(s, v_{3k+i}^2), (v_i^2, v_i^3), (v_{3k+i}^2, v_{3k+i}^3), (v_i^3, t) \;\middle|\; i = 1, \dots, k\right\}, \\ E_{k,i} &:= \left\{(s, v_i^1), (v_i^1, v_{k+i}^2), (v_{k+i}^2, v_{k+i}^3), (v_{k+i}^3, v_i^4), (v_i^4, t)\right\} \quad \text{for all } i = 1, \dots, 2k, \\ E'_{k,i} &:= \left\{(v_i^1, v_j^2), (v_{3k+j}^3, v_i^4) \;\middle|\; j = 1, \dots, k\right\} \quad \text{for all } i = 1, \dots, 2k. \end{aligned}$$

The edge capacities $u_k \colon E_k \to \mathbb{R}_{\geq 0}$ are given by $u_k(e) = (\frac{k}{k-1})^{2k+1-i}$ for $e \in E_{k,i}$, by $u_k(e) = \frac{1}{k}(\frac{k}{k-1})^{2k+1-i}$ for $e \in E'_{k,i}$, by $u_k(e) = 1$ for $e \in E_k^1$, and by $u_k(e) = \infty$ for $e \in E_k^\infty$.

For every G_k, we choose a directed s-t-cut $C_k := \{(v_i^2, v_i^3) \mid i = 1, \ldots, 4k\}$. Without loss of generality, we will assume in the following that we can resolve all ties in the greedy algorithm to our preference. This can be done formally by adding some very small offsets to the edge weights, but we omit this for clarity. Now consider how the greedy algorithm operates on graph G_k.

▶ **Lemma 19.** *In step $j \in \{1, \ldots, 2k\}$, the greedy algorithm picks edge (v_{k+j}^2, v_{k+j}^3).*

With this, we are ready to show the following result, which, together with Lemma 17, implies the second part of Theorem 4.

▶ **Theorem 20.** *The greedy algorithm has competitive ratio at least $\frac{2e^2}{e^2-1} \approx 2.313$ for* Maximum Bridge-Flow.

Proof. By Lemma 19, the greedy algorithm picks the edges $(v_{k+1}^2, v_{k+1}^3), \ldots, (v_{3k}^2, v_{3k}^3)$ in the first $2k$ steps. Thus, after step $2k$, greedy can send an s-t-flow of value

$$\sum_{i=1}^{2k} \left(\frac{k}{k-1}\right)^i = \left(\frac{\left(\frac{k}{k-1}\right)^{2k+1} - 1}{\frac{k}{k-1} - 1} - 1\right) = (k-1)\left(\frac{k}{k-1}\right)^{2k+1} - k\,.$$

On the other hand, the solution of size $2k$ consisting of the edges $(v_1^2, v_1^3), \ldots, (v_k^2, v_k^3)$, and $(v_{3k+1}^2, v_{3k+1}^3), \ldots, (v_{4k}^2, v_{4k}^3)$ results in an (optimal) flow value of

$$2k + 2\sum_{i=1}^{2k} \left(\frac{k}{k-1}\right)^i = 2(k-1)\left(\frac{k}{k-1}\right)^{2k+1}.$$

This corresponds to a competitive ratio of

$$\frac{2(k-1)\left(\frac{k}{k-1}\right)^{2k+1}}{(k-1)\left(\frac{k}{k-1}\right)^{2k+1} - k} = \frac{2\left(\frac{k}{k-1}\right)^{2k}}{\left(\frac{k}{k-1}\right)^{2k} - 1} = \frac{2\left(\frac{k}{k-1}\right)^{2(k-1)+2}}{\left(\frac{k}{k-1}\right)^{2(k-1)+2} - 1}\,.$$

Substituting $x := k - 1$ and using the identity $\lim_{x\to\infty}(1 + 1/x)^x = e$, we get the lower bound on the competitive ratio of the greedy algorithm claimed in Theorem 4 in the limit:

$$\lim_{x\to\infty} \frac{2\left(\frac{x+1}{x}\right)^{2x}\left(\frac{x+1}{x}\right)^2}{2\left(\frac{x+1}{x}\right)^{2x}\left(\frac{x+1}{x}\right)^2 - 1} = \lim_{x\to\infty} \frac{2e^2\left(\frac{x+1}{x}\right)^2}{2e^2\left(\frac{x+1}{x}\right)^2 - 1} = \frac{2e^2}{e^2-1}\,.$$ ◀

5 Conclusion

We have defined a formal framework that captures a large class of incremental problems and allows for incremental solutions with bounded competitive ratio. We also defined a new and meaningful subclass consisting of problems with α-augmentable objective functions for which the greedy algorithm has a bounded competitive ratio. Hopefully our results can inspire future work on incremental problems from a perspective of competitive analysis.

Obvious extensions of our results would be to close the gap between our bounds of 2.618 and 2.18 for the best-possible competitive ratio of incremental algorithms. In particular, it would be interesting whether or not the bound of 2.313 for the greedy algorithm in the 2-augmentable setting can be beaten by some other incremental algorithm already in the general setting. Also, the α-augmentable and strictly submodular settings may allow for

better incremental algorithms than the greedy algorithm. Another question is whether abandoning the accountability condition yields an interesting class of problems. Finally, it may be possible to generalize our framework to problems with a continuously growing budget and a cost associated with each element, instead of a growing cardinality constraint.

Acknowledgements. We wish to thank Andreas Bärtschi and Daniel Graf for initial discussions and the the general idea that lead to the algorithm of Section 2. We are also grateful for the detailed comments provided by an anonymous reviewer.

Deterministic Partially Dynamic Single Source Shortest Paths in Weighted Graphs*

Aaron Bernstein

Technical University of Berlin, Berlin, Germany
bernstei@gmail.com

Abstract

In this paper we consider the decremental single-source shortest paths (SSSP) problem, where given a graph G and a source node s the goal is to maintain shortest distances between s and all other nodes in G under a sequence of online adversarial edge deletions. In their seminal work, Even and Shiloach [JACM 1981] presented an exact solution to the problem in unweighted graphs with only $O(mn)$ total update time over all edge deletions. Their classic algorithm was the state of the art for the decremental SSSP problem for three decades, even when approximate shortest paths are allowed.

The first improvement over the Even-Shiloach algorithm was given by Bernstein and Roditty [SODA 2011], who for the case of an unweighted and undirected graph presented a $(1+\epsilon)$-approximate algorithm with constant query time and a total update time of $O(n^{2+o(1)})$. This work triggered a series of new results, culminating in a recent breakthrough of Henzinger, Krinninger and Nanongkai [FOCS 14], who presented a $(1+\epsilon)$-approximate algorithm for undirected weighted graphs whose total update time is near linear: $O(m^{1+o(1)}\log(W))$, where W is the ratio of the heaviest to the lightest edge weight in the graph. In this paper they posed as a major open problem the question of derandomizing their result.

Until very recently, all known improvements over the Even-Shiloach algorithm were randomized and required the assumption of a non-adaptive adversary. In STOC 2016, Bernstein and Chechik showed the first *deterministic* algorithm to go beyond $O(mn)$ total update time: the algorithm is also $(1+\epsilon)$-approximate, and has total update time $\tilde{O}(n^2)$. In SODA 2017, the same authors presented an algorithm with total update time $\tilde{O}(mn^{3/4})$. However, both algorithms are restricted to undirected, unweighted graphs. We present the *first* deterministic algorithm for *weighted* undirected graphs to go beyond the $O(mn)$ bound. The total update time is $\tilde{O}(n^2\log(W))$.

1 Introduction

The objective of dynamic graph algorithms is to handle an online sequence of update operations while maintaining a desirable functionality on the graph, e.g., the ability to answer shortest path queries. An update operation may involve a deletion or insertion of an edge or a node, or a change in an edge's weight. In case the algorithm can handle only deletions and weight increases it is called decremental, if it can handle only insertions and weight decreases it is called incremental, and if it can handle both it is called fully dynamic.

In this paper we consider the problem of (approximate) single source shortest paths (SSSP) in unweighted undirected graphs, in the decremental setting. Specifically, given an undirected graph G with positive weights and a source node s, our algorithm needs to preform the following operations:

1. Delete(e) – delete the edge e from the graph
2. Increase-Weight(e) – increase the weight of e
3. Distance(v) – return the distance between s and v, i.e., $\mathbf{dist}(s, v)$, in the current graph G.

Fully dynamic shortest paths has a very clear motivation, as computing shortest paths in a graph is one of the fundamental problems of graph algorithms, and many shortest path applications must deal with a graph that is changing over time. The incremental setting is somewhat more restricted, but is applicable to any setting in which the network is only expanding. The decremental setting is often very important from a theoretical perspective, as decremental shortest paths (and decremental *single source* shortest paths especially) are used as a building block in a very large variety of fully dynamic shortest paths algorithms; see e.g. [16, 17, 3, 2, 20, 1] to name just a few. Decremental shortest paths can also have applications to non-dynamic graph problems; see e.g. Madry's paper on efficiently computing multicommodity flows [18].

We say that an algorithm has an approximation guarantee of α if its output to the query Distance(v) is never smaller than the actual shortest distance and is not more than α times the shortest distance. Dynamic algorithms are typically judged by two parameters: the time it takes the algorithm to adapt to an update (the Delete or Increase-Weight operation), and the time to process a query (the Distance operation). Typically one tries to keep the query time small (polylog or constant), while getting the update time as low as possible. All the algorithms discussed in this paper have constant query time, unless noted otherwise. In the decremental setting, which is the focus of this paper, one usually considers the aggregate sum of update times over the *entire* sequence of deletions, which is referred to as the *total update time*.

Related Work

The most naive solution to dynamic SSSP is to simply invoke a static SSSP algorithm after every deletion, which requires $\tilde{O}(m)$ time, using e.g. Dijkstra's algorithm. (The $\tilde{O}$ notation suppresses polylogarithmic factors.) For unweighted graphs, since there can be a total of m deletions, the total update time for the naive implementation is thus $\Omega(m^2)$.

For fully dynamic SSSP, nothing better than the trivial $O(m)$ time per update is known. That is, we do not know how to do better than reconstructing from scratch after every edge update. For this reason, researchers have turned to the decremental (or incremental) case in search of a better solution. The first improvement stems all the way back to 1981, when Even and Shiloach [8] showed how to achieve total update time $O(mn)$ in unweighted undirected graphs. A similar result was independently found by Dinitz [7]. This was later generalized to directed graphs by Henzinger and King [9]. This $O(mn)$ total update time bound is still the state of art, and there are conditional lower bounds [19, 15] showing that it is in fact optimal up to log factors. (The reductions are to boolean matrix multiplication and the online matrix-vector conjecture respectively).

These lower bounds motivated the study of the approximate version of this problem. In 2011, Bernstein and Roditty [6] presented the first algorithm to go beyond the $O(mn)$ bound of Even and Shiloach [8]: they presented a $(1+\epsilon)$-approximate decremental SSSP algorithm for undirected unweighted graphs with $O(n^{2+O(1/\sqrt{\log n})}) = O(n^{2+o(1)})$ total

update time. Henzinger, Krinninger and Nanongkai [13] later improved the total update time to $O(n^{1.8+o(1)} + m^{1+o(1)})$, and soon after the same authors [11] achieved a close to optimal total update time of $O(m^{1+o(1)} \log W)$ in undirected weighted graphs, where W is the largest weight in the graph (assuming the minimum edge weight is 1). The same authors also showed that one can go beyond $O(mn)$ total update time bound in *directed* graphs (with a $(1+\epsilon)$ approximation) [12, 14], although the state of art is still only a small improvement: total update time $O(mn^{0.9+o(1)} \log W)$.

However, every single one of these improvements over the $O(mn)$ bound relies on randomization, and has to make the additional assumption of a *non-adaptive* adversary. In particular, they all assume that the updates of the adversary are completely independent from the shortest paths or distances returned to the user, i.e. that the updates are fixed in advance. This makes these algorithms unsuitable for many settings, and also prevents us from using them as a black box data structure. For this reason, it is highly desirable to have deterministic algorithms for the problem.

Very recently, in STOC 2016, Bernstein and Chechik presented the first *deterministic* algorithm to go beyond $O(mn)$ total update time, again with a $(1+\epsilon)$ approximation. The total update time is $\tilde{O}(n^2)$ [4]. They followed this up with a second deterministic algorithm [5] that has total update time $\tilde{O}(n^{1.5}\sqrt{m}) = \tilde{O}(mn^{3/4})$. Both algorithms rely on the same basic technique, so this is currently the only know technique for deterministically breaking through the $O(mn)$ barrier. However, both results above were limited to undirected, unweighted graphs. In this paper, we show that this core technique can also be applied to weighted graphs.

Our Results

▶ **Theorem 1.** *Let G be an undirected graph with positive edge weights subject to a sequence of edge deletions and weight increases, let s be a fixed source, and let W be the ratio between the largest and smallest edge weights in the graph. there exists a* deterministic *algorithm that maintains $(1+\epsilon)$-approximate distances from s to every vertex in total update time $O(m \log^2(n) \log(nW) + n^2 \log(n) \log(nW)\epsilon^{-2})$. The query time is $O(1)$. (Like most decremental shortest paths algorithms, our result can very easily be extended with the same update time to the incremental case, where the update sequence contains edge insertions and weight increases.)*

(Technical Note: In weighted graphs the number of updates can be very large – i.e. if each update just increases some edge weight by some small ϵ – and so in addition to the total update time above, the algorithm necessarily requires an additional $O(1)$ per update. This $O(1)$ factor is present in all dynamic algorithms, and is typically omitted.)

Our algorithm does not match the randomized state of the art of $\tilde{O}(m^{1+o(1)} \log(W))$ [11], but it is optimal up to log factors for dense graphs, and is the first deterministic algorithm to go beyond the $O(mn)$ barrier in weighted graphs. The algorithm is also much simpler than the randomized algorithm for weighted graphs, and it does not incur the extra $n^{o(1)}$ factor present in the randomized algorithms. Thus, our algorithm is in fact faster than *all* existing randomized algorithms for the problem in dense weighted graphs where $m = \Omega(n^{2-1/\sqrt{\log(n)}})$.

As a final remark, we note that all previous deterministic algorithms to go beyond the $O(mn)$ bound [4, 5] have the strange drawback that there is no obvious way to return an approximate path, only a distance. Our algorithm unfortunately shares this drawback. The reason is that whereas in other dynamic shortest path algorithms the distance returned corresponds to some path in the graph, our distance involves an additive error that is bounded

through a structural claim about the non-existence of certain paths, but does not itself correspond to an actual path (see Lemma 4.4 in [4], Lemma 5.3 in [5], and Lemma 5 in our paper.)

Preliminaries

In our model, an undirected weighted graph is subject to deletions and weight increases. All weights in the original graph are positive. Let $G = (V, E)$ always refer to the *current* versions of the graph. Let m refer to the number of edges in the original graph, and n to the number of vertices. Let $w(u, v)$ refer to the weight of edge (u, v). *Let us assume for simplicity that the minimum weighted in the original graph is at least 1*, and note that since edge weights only increase, this will be true of all version of the graph. Let W be the largest edge weight to ever appear in the graph. For any pair of vertices u, v, let $\pi(u, v)$ be the shortest $u - v$ path in G (ties can be broken arbitrarily), and let $\mathbf{dist}(u, v)$ be the length of $\pi(u, v)$. Let s be the fixed source from which our algorithm must maintain approximate distances, and let ϵ refer to our approximation parameter; when the adversary queries the distance to a vertex v, the algorithm's guarantee is to return a distance $\mathbf{dist}'(v)$ such that $\mathbf{dist}(s, v) \leq \mathbf{dist}'(s, v) \leq (1 + O(\epsilon))\mathbf{dist}(s, v)$. Note that the $(1 + O(\epsilon))$ approximation factor can always be reduced to $(1 + \epsilon)$ without affecting the asymptotic running time by simply starting with a suitably smaller ϵ'.

Given any two sets S, T we define the set difference $S \setminus T$ to contain all elements s such that $s \in S$ but $s \notin T$. We will measure the update time of the dynamic subroutines used by our algorithm in terms of their *total* update time over the entire sequence of edge changes. Note that although edges in the main graph G are only being deleted, there may be edge insertions into the auxiliary graphs used by the algorithm.

2 High Level Overview

Our algorithm extends the techniques in the STOC 2016 paper of Bernstein and Chechik [4] from unweighted to weighted graphs. We now briefly summarize their approach for unweighted graphs, aiming in this overview for total update time $\tilde{O}(n^{2.5})$ instead of $\tilde{O}(n^2)$. We start with the well known fact that the classic Even and Shiloach algorithm has total update time $O(n^{2.5})$ [8] if we only care about distances less than $\sqrt{n}$. So the hard case is long distances in a dense graph. The key observation of [4] is that these two problematic poles cannot coexist. In particular, Bernstein and Chechik showed that any shortest path contains at most $3\sqrt{n}$ vertices of degree more than $\sqrt{n}$. The basic reason is that if we look at every third high-degree vertex on the shortest path, then these vertices must have mutually disjoint neighborhoods, since otherwise there would be a shorter path between them of length 2; the claim then follows because each high-degree vertex has at least $\sqrt{n}$ neighbors, and there are only n vertices in total. Thus, Bernstein and Chechik show that the total contribution of high-degree vertices to the shortest path is small. They then argue that this allows us to effectively "ignore" all vertices of degree $\geq \sqrt{n}$, at the cost of an additive error of only $O(\sqrt{n})$. (we do not go into details of this ignoring here.) This completed their result because for distances less than $O(\sqrt{n}\epsilon^{-1})$ the classic Even and Shiloach has total update time $O(n^{2.5}\epsilon^{-1})$, whereas for longer distances we can afford the $O(\sqrt{n})$ additive error from ignoring high degree vertices (it is subsumed into the $(1 + \epsilon)$ multiplicative error), so the resulting graph only $O(n^{1.5})$ edges.

This technique has no easy extension to weighted graphs via scaling. To see this, say there were two edge weights, 1 and $\sqrt{n}$, and that every vertex had very few incident edges

of weight 1, but $\sqrt{n}$ edges of weight $\sqrt{n}$. Then it is easy to see that distances in the graph could still be as large as n (as opposed to $\sqrt{n}$ in the unweighted case). But we cannot scale weights down, or use some sort of hop-distance technique found elsewhere in the literature, because although the heavy edges are the ones that cause the graph to be dense, the shortest path could still contain many edges of weight 1. There is thus no way in a weighted graph to ignore high-degree vertices.

To overcome this, we switch focus to a notion of degree that considers edge weights. In particular, note that in the example above, although the graph was dense, the total number of edges of weight 1 was small. The first step in our result is to formalize this observation, and show that although we cannot simply ignore vertices of high degree, for any vertex v we *can* ignore its low-weight incident edges if there are many of them. The proof of this is similar to the proof that we can afford to ignore dense vertices in unweighted graphs, but because we have to deal with many edge different weights at once, the analysis is more sophisticated.

The problem is that on its own ignoring large neighborhoods of low-weight edges doesn't help: the result is a graph that is guaranteed to only have a small number of low-weight edges (and a medium number of medium-weight edges), but the graph can still be very dense with high-weight edges. To overcome this, we develop a variation on the standard Even and Shiloach algorithm [8] which is more efficient at dealing with heavy edges but incurs a $(1+\epsilon)$ approximation. The basic intuition is as follows, though the details are somewhat complex. The classic algorithm guarantees that we only touch an edge (u, v) when the distance $\mathbf{dist}(s, u)$ or $\mathbf{dist}(s, v)$ increases. But if (u, v) has high weight, and $\mathbf{dist}(s, u)$ only increases by 1, then the distance increase is insignificant with respect to the total weight on (u, v), and so we can afford to ignore it. The number of times we touch edge (u, v) thus ends up being proportional to $\epsilon^{-1}/w(u, v)$.

All in all, our algorithm is based on the framework of Bernstein and Chechik for unweighted graphs [4], but requires significant modifications both to the high-level orientation (we need a new notion of sparsity that depends on edge weights), as well as to the technical details. The basic approach introduced in [4] of ignoring certain classes of dense vertices has proved quite versatile and powerful (see the two very different applications of it in [4] and [5]), and is currently the *only* known approach for going beyond $O(mn)$ deterministically, so our extension to weighted graphs might be useful in further applications of this approach. Also, our extension of the classic Even and Shiloach algorithm is presented in extreme generality, and might prove useful in other dynamic shortest path problems where one has a graph that has more edges of high weight than of low weight.

3 The Threshold Graph

In our algorithm, each vertex will have a weight cutoff, denoted $\mathbf{cut\text{-}off}(v)$, and will end up "ignoring" the edges below that cutoff. As described in the high-level overview above, the required degree to ignore edges goes up as the edge weights go up.

▶ **Definition 2.** Let the level of edge (u, v) be $\mathbf{level}(u, v) = \lfloor \log(w(u, v)) \rfloor$. For any vertex v, let $I(v)$ contain all edges incident to v (I for incident), and let $I_i(v)$ contain all edges incident to v of level i or less. Now, for any positive threshold τ (not necessarily integral), and any vertex v, we define $\mathbf{cut\text{-}off}_\tau(v)$ to be the *maximum* index i such that $I_i(v)$ contains at least $\tau 2^i$ edges; if no such index exists, $\mathbf{cut\text{-}off}_{\tau(v)}$ is set to 0. We say that an edge (u, v) is τ-heavy if $\mathbf{level}(u, v) \leq \mathbf{cut\text{-}off}_\tau(u)$ OR $\mathbf{level}(u, v) \leq \mathbf{cut\text{-}off}_\tau(v)$; we say that it is τ-light otherwise. Let $\textsc{heavy}(\tau)$ be the set of all τ-heavy edges in G, and let $\textsc{light}(\tau)$ be the set of all τ-light edges in G. Let $G[\textsc{heavy}(\tau)]$ be the graph $(V, \textsc{heavy}(\tau))$. Note that the levels,

cut-offs, heaviness, and lightness are *always* defined with respect to the main graph G, never with respect to auxiliary graphs. Since τ is usually clear from context, we often just write **cut-off**(v), heavy, and light.

▶ **Definition 3.** Given a graph $G = (V, E)$ with $|V| = n$ and $|E| = m$, and a positive threshold τ, define the threshold graph $G_\tau = (V_\tau, E_\tau)$ as follows

- V_τ contains every vertex $v \in V$.
- V_τ also contains an additional vertex c for each connected component C in the graph $G[\text{HEAVY}(\tau)] = (V, \text{HEAVY}(\tau))$
- E_τ contains all edges in $\text{LIGHT}(\tau)$, with their original weights.
- For every vertex $v \in V$, E_τ contains an edge from v to c of weight $1/2$, where c is the component vertex in $V_\tau \setminus V$ that corresponds to the component C in $G[\text{HEAVY}(\tau)]$ that contains v.

For any pair of vertices $s, t \in V$ define $\pi_\tau(s,t)$ to be the shortest path from s to t in G_τ, and define $\mathbf{dist}_\tau(s,t)$ to be the weight of this path.

▶ **Lemma 4.** *For any i, G_τ contains at most n edges of weight $1/2$ that are not in E (one per vertex in V), as well at most $O(n \cdot \tau \cdot 2^i)$ edges at level i.*

Proof. An edge $(u,v) \in E$ of level i is only in E_τ if (u,v) is τ-light, i.e. if **cut-off**$(u) < i$ AND **cut-off**$(v) < i$. But a vertex with **cut-off** less than i has by definition less than $2^i\tau$ incident edges of level i. ◀

The following Lemma is the weighted analogue of Lemma 4.4 in [4], but the most direct extension of that proof to the weighted case would analyze each of the $\log(W)$ edge levels separately, and thus multiply the error by $\log(W)$, eventually leading to a $\log^3(W)$ factor in the total running time of the algorithm. To avoid this extra error, we need a somewhat more sophisticated analysis than in Lemma 4.4 of [4]

▶ **Lemma 5.** *For any graph $G = (V, E)$, any positive integer threshold τ, and any pair of vertices $s, t \in V$:*

$$\mathbf{dist}_\tau(s,t) \leq \mathbf{dist}(s,t) < \mathbf{dist}_\tau(s,t) + \frac{14n}{\tau}.$$

Proof. It is not hard to see that we have $\mathbf{dist}_\tau(s,t) \leq \mathbf{dist}(s,t)$. Simply consider the shortest $s-t$ path $\pi(s,t) \in G$. All the edges in $\pi(s,t) \bigcap \text{LIGHT}(\tau)$ are also in G_τ. Otherwise, for any τ-heavy edge (u,v) on $\pi(s,t)$, recall that the weight $w(u,v)$ in G is always at least 1, and note that because edge (u,v) is τ-heavy, the vertices u and v must be in the same connected component in $G[\text{HEAVY}(\tau)]$, and so there is a path of length 1 from u to v in G_τ: the edge of weight $1/2$ from u to the component vertex c, and then a second edge from c to v.

We now prove that $\mathbf{dist}(s,t) \leq \mathbf{dist}_\tau(s,t) + \frac{14n}{\tau}$. Let $\pi_\tau(s,t)$ be the shortest $s-t$ path in G_τ. Consider the edge set $E^* \subseteq E$ which contains all the τ-light edges of $\pi_\tau(s,t)$ (these edges are also in E), and all τ-heavy edges in E. That is, $E^* = \text{HEAVY}(\tau) \bigcup (\text{LIGHT}(\tau) \bigcap \pi_\tau(s,t))$. Let $G^* = (V, E^*)$. We first observe that there exists an $s-t$ path in G^*. We construct this path by following $\pi_\tau(s,t)$. $\pi_\tau(s,t)$ contains τ-light edges, which are by definition in G^*, as well as subpaths of length 2 of the form $(v,c) \circ (c,w)$, where v and w are in the same connected component C in $G[\text{HEAVY}(\tau)]$. But since v and w are in the same connected component, there is a path of only heavy edges connecting them, and all heavy edges are in G^*.

Now, let $\pi^*(s,t)$ be the *shortest* $s-t$ path in G^*. Let $\mathbf{dist}^*(s,t)$ be the length of $\pi^*(s,t)$. Since G^* is a subgraph of G, we know that $\mathbf{dist}(s,t) \leq \mathbf{dist}^*(s,t)$. We now show that

$$\mathbf{dist}^*(s,t) < \mathbf{dist}_\tau(s,t) + \frac{14n}{\tau} \tag{1}$$

which will complete the proof of the lemma.

We prove Equation 1 by showing that all the heavy edges on $\pi^*(s,t)$ have total weight at most $\frac{14n}{\tau}$: since all the light edges on $\pi^*(s,t)$ are by definition also on $\pi_\tau(s,t)$, this proves the equation.

Let V_H^* be the set of vertices on $\pi^*(s,t)$ that are incident to at least one heavy edge on $\pi^*(s,t)$. Now, for any vertex $v \in V_H^*$, let $\textsc{ball}(v)$ contain v and all vertices $u \in V$, such that there is an edge (u,v) with $\mathbf{level}(u,v) \leq \mathbf{cut\text{-}off}(v)$. Note that by definition of $\mathbf{cut\text{-}off}(v)$, we have $|\textsc{ball}(v)| \geq 2^{\mathbf{cut\text{-}off}(v)}\tau$.

Now, let P be an ordering of the vertices in $\pi^*(s,t)$ in non-increasing order of $\mathbf{cut\text{-}off}$: so if $i < j$ then $\mathbf{cut\text{-}off}(P[i]) \geq \mathbf{cut\text{-}off}(P[j])$. We will now construct a set $\mathcal{IV}$ of *independent* vertices in V_H^* as follows. We start with $\mathcal{IV}$ empty. Now, go through the vertices in V_H^* according to their order in P (so in non-increasing order of cut-off), and for each v do the following: if $\textsc{ball}(v)$ is disjoint from $\textsc{ball}(u)$ for every $u \in \mathcal{IV}$, add v to $\mathcal{IV}$. Clearly if v and w are independent then $\textsc{ball}(v)$ and $\textsc{ball}(w)$ are disjoint. But then recalling that for any v, $|\textsc{ball}(v)| \geq 2^{\mathbf{cut\text{-}off}(v)}\tau$, and that the total number of vertices in the graph is n, we have

$$\sum_{v \in \mathcal{IV}} 2^{\mathbf{cut\text{-}off}(v)} \leq n/\tau \tag{2}$$

We will end up showing that each independent vertex v is "responsible" for at most $14 \cdot 2^{\mathbf{cut\text{-}off}(v)}$ weight from heavy edges on $\pi^*(s,t)$, which will complete our proof. We say that a non-independent vertex u belongs to independent vertex v if $\mathbf{cut\text{-}off}(v) \geq \mathbf{cut\text{-}off}(u)$ and $\textsc{ball}(u)$ and $\textsc{ball}(v)$ are non-disjoint. By our independence construction, every non-independent vertex u belongs to one or more independent vertices.

▶ **Claim 6.** *If v is independent, and u belongs to v, then the distance from v to u along $\pi^*(s,t)$ is at most $4 \cdot 2^{\mathbf{cut\text{-}off}(v)}$.*

Proof. Say, for contradiction, that this was not the case. Then, since u belongs to v, there must be some vertex $z \in \textsc{ball}(v) \bigcap \textsc{ball}(u)$. But by definition of $\textsc{ball}$ we have $\mathbf{level}(v,z) \leq \mathbf{cut\text{-}off}(v)$ and $\mathbf{level}(u,z) \leq \mathbf{cut\text{-}off}(u) \leq \mathbf{cut\text{-}off}(v)$, so by definition of $\mathbf{level}$ there is a path from u to v through z of weight at most $4 \cdot 2^{\mathbf{cut\text{-}off}(v)}$, which contradicts $\pi^*(s,t)$ being the shortest path in G^*. ◀

Now, given any τ-heavy edge (x,y), let the dominant endpoint of (x,y) be the endpoint that comes earlier in P: so in particular, if x is dominant then $\mathbf{cut\text{-}off}(x) \geq \mathbf{cut\text{-}off}(y)$. We say that a τ-heavy edge (x,y) belongs to independent vertex v if the dominant endpoint of (x,y) belongs to v. Note that every τ-heavy edge in $\pi^*(s,t)$ belongs to at least one independent vertex. We now show that if v is independent, then the total weight of τ-heavy edges that belong to v is at most $14 \cdot 2^{\mathbf{cut\text{-}off}(v)}$. Otherwise (for contradiction), at least half that weight would come before or after v, so w.l.o.g, let us say that there is at least $7 \cdot 2^{\mathbf{cut\text{-}off}(v)}$ weight of edges that belong to v and come after v on $\pi^*(s,t)$ – i.e., are closer to t than v is. Let us consider the τ-heavy edge (x,y) that belongs to v and is closest to t, and say that y is closer to t than x. Note that the distance from v to y along $\pi^*(s,t)$ is at least $7 \cdot 2^{\mathbf{cut\text{-}off}(v)}$, so by Claim 6, y cannot belong to v. Thus, since edge (x,y) belongs to

v, x must be the dominant endpoint and belong to v. But if x belongs to v and dominates y then $\textbf{cut-off}(y) \leq \textbf{cut-off}(x) \leq \textbf{cut-off}(v)$, and the only way edge (x, y) could be τ-heavy is if $\textbf{level}(x, y) \leq \textbf{cut-off}(v)$, so $w(x, y) \leq 2 \cdot 2^{\textbf{cut-off}(v)}$, so the distance from v to x along $\pi^*(s, t)$ is still at least $7 \cdot 2^{\textbf{cut-off}(v)} - 2 \cdot 2^{\textbf{cut-off}(v)} = 5 \cdot 2^{\textbf{cut-off}(v)}$, which again contradicts Claim 6. Thus, the total weight of heavy edges on $\pi^*(s, t)$ is at most $14 \sum_{v \in \mathcal{IV}} 2^{\textbf{cut-off}(v)}$, which combined with Equation 2 proves Equation 1, which proves the lemma. ◀

Maintaining the threshold graph G_τ as G changes is easy, because the only hard part is maintaining the connected components C in $G[\text{HEAVY}(\tau)]$, and dynamic connectivity in undirected graphs is a well-studied problem that admits deterministic $O(\log^2(n))$ update time. The details are very similar to those for unweighted graphs (see Lemmas 4.5 and 4.6 in [4]), so we omit the proofs of the following two lemmas.

▶ **Lemma 7.** *Given a graph G subject to a decremental update sequence, and a positive integer threshold τ, we can maintain the graph G_τ in* total *time $O(m \log^2(n))$. Moreover, the total number of edges of weight $1/2$ ever inserted into the graph is $O(n \log(n))$, and the total number of edges (u, v) that have $\textbf{level}(u, v) = i$ when inserted is at most $n\tau 2^i$.*

▶ **Lemma 8.** *Given a graph G subject to a decremental update sequence, a positive integer threshold τ, and a pair of vertices u, v in G, the distance $\textbf{dist}_\tau(u, v)$ in G_τ never decreases as the graph G changes.*

4 An Extension of the Even and Shiloach Algorithm

In the paper of Bernstein and Chechik for unweighted graphs [4], the threshold graph ended up being sparse, and so it was easy to efficiently compute distances within it using the standard Even and Shiloach algorithm with total update time $O(mn)$ [8]. In our paper, however, the threshold graph is only sparse with respect to low-weight edges; that is, because heaviness and lightness is defined in terms of edge weights, the threshold graph can have many edge of high weight. We now present a modification of the Even and Shiloach algorithm that can deal more efficiently with edges of high weight, which makes it perfectly suited to our threshold graph, which has mostly high-weight edges. Like the standard Even and Shiloach algorithm, our extension runs up to a certain depth bound d.

▶ **Definition 9.** Given any number d, the function $\text{BOUND}_d(x)$ is equal to x if $x \leq d$, and to ∞ otherwise.

Note that to apply to the threshold-graph G_τ, the algorithm must be able to handle insertions, as long as they do not change distances. (See Lemmas 7, 8). To this end we need the following definition:

▶ **Definition 10.** Let $G = (V, E)$ be a graph with positive weights ≥ 1, subject a dynamic update sequence of insertions, deletions, and weight-increases. In such a context, let $\mathcal{A}$ contain the set of ALL edges (u, v) to appear in G at any point during the update sequence ($\mathcal{A}$ for all): if an edge (u, v) is deleted and then inserted again, we consider this as two separate edges in $\mathcal{A}$. For every edge $(u, v) \in \mathcal{A}$, let $w_o(u, v)$ (o for original) be the weight of (u, v) when it first appears in $\mathcal{A}$ (this might be in the original graph itself), and let $\textbf{level}_o(u, v) = \lfloor \log(w_o(u, v)) \rfloor$.

▶ **Lemma 11.** *Let $G = (V, E)$ be an undirected graph with positive integer edge weights, s a fixed source, and $d \geq 1$ a depth bound. Say that G is subject to a dynamic sequence of*

edge insertions, deletions, and weight increases, with the property that distances in G never decrease as a result of an update. Then, there exists an algorithm $\mathbf{WSES}(G, s, d)$ *(stands for weight-sensitive Even and Shiloach) that maintains approximate distances* $\mathbf{dist}'(s, v)$ *with* $\mathbf{dist}(s, v) \leq \mathbf{dist}'(s, v) \leq \text{BOUND}_d(\mathbf{dist}(s, v))(1 + \epsilon)$*, and has total update time* $O(nd + \sum_{(u,v)\in\mathcal{A}} \frac{d}{\epsilon w_o(u,v)})$.

Proof. Throughout the proof of this lemma, we will often rely on the following function:

▶ **Definition 12.** Given any positive real numbers β and x, let $\text{ROUND}_\beta(x)$ be the smallest number $y > x$ that is an integer multiple of β.

Our algorithm **WSES** follows the basic procedure of the classic Even and Shiloach algorithm [8] (denoted **ES**), with a few modifications. For this reason we can describe many of the guarantees of **ES** without looking under the hood for exactly how they are implemented, since we keep exactly the same implementation. We only modify the classic algorithm in a few key points. Recall the definition of $\mathcal{A}$ and $w_o(u, v)$ from Definition 10. Since weights only increase, we always have $w(u, v) \geq w_o(u, v)$.

The **ES** algorithm maintains for each vertex v a distance label $\delta(v)$ with the property that $\mathbf{dist}(s, v) = \delta(v)$. In particular, it maintains the invariant that $\delta(s) = 0$, and that if $(u, v) \in E$, then $\delta(v) \leq \delta(u) + w(u, v)$. Our algorithm will also maintain a label $\delta(v)$ for every v, but since we only need an approximation, we guarantee a weaker invariant:

▶ **Invariant 13** (Approximation)**.** *We always have $\delta(s) = 0$. If p is the parent of v in the tree then $\delta(v) \geq \delta(p) + w(p, v)$. Also, for all $(u, v) \in E$, $\delta(v) \leq \delta(u) + w(u, v) + \epsilon w_o(u, v)$.*

Approximation Analysis: We now show that as long as the Approximation Invariant is preserved, we always have $\mathbf{dist}(s, v) \leq \delta(v) \leq (1+\epsilon)\mathbf{dist}(s, v)$. The fact that $\delta(v) \geq \mathbf{dist}(s, v)$ follows trivially for the same reason as in classic **ES**. To prove the other side, consider the shortest path $\pi(s, v)$ in G. Let the vertices in $\pi(s, v)$ be $s_0, s_1, ..., s_q = v$. We show by induction that $\delta(s_i) \leq (1+\epsilon)\mathbf{dist}(s, s_i)$. The claim is trivially true for $i = 0$ because $\delta(s) = 0$ at all times. Now, say the claim is true for s_i, and note that $\mathbf{dist}(s, s_{i+1}) = \mathbf{dist}(s, s_i) + w(s_i, s_{i+1})$. Now, by the Approximation Invariant, we have $\delta(s_{i+1}) \leq \delta(s_i) + w(s_i, s_{i+1}) + \epsilon w_o(s_i, s_{i+1}) \leq \delta(s_i) + (1 + \epsilon)w(s_i, s_{i+1})$ (the last step follows from $w(u, v) \geq w_o(u, v)$). But then by the induction hypothesis we have $\delta(s_{i+1}) \leq (1 + \epsilon)(\mathbf{dist}(s, s_i) + w(s_i, s_{i+1})) = (1 + \epsilon)\mathbf{dist}(s, s_{i+1})$.

We must now show how to efficiently maintain the Approximation Invariant. The classic **ES** algorithm does $O(1)$ time per update for basic setup, and otherwise all the work comes from charging constant time operations to various edges (u, v) and vertices v. The update time invariant in classic **ES** is as follows: we only charge vertex v when $\delta(v)$ increases, and we only charge edge (u, v) when $\delta(u)$ or $\delta(v)$ increases. Since weights are positive integers, every $\delta(u)$ must increase by at least 1, and since we only go up to distance d, each $\delta(v)$ increases at most d times, which yields $O(md)$. To improve upon this, our algorithm maintains a slightly different update time invariant

▶ **Invariant 14** (Update-Time)**.** *A vertex v is only charged when $\delta(v)$ increases. An edge (u, v) is only charged when either* $\text{ROUND}_{\epsilon w_o(u,v)}(\delta(u))$ *or* $\text{ROUND}_{\epsilon w_o(u,v)}(\delta(v))$ *increases.*

Since for any β, $\text{ROUND}_\beta(\delta(v))$ can increase at most d/β before it exceeds d, it is clear that the Update-Time Invariant guarantees the total update bound of the lemma.

Maintaining the Two Invariants: Now, let us recall how the standard **ES** algorithm works. This algorithm only handles deletions, so that is what we focus on first: we later show how to extend our algorithm to handle weight-increases and insertions that do not change distances. We will emphasize the parts of classic **ES** that we will later change in our modified algorithm. First off, each vertex v always maintains label information about its neighbors: *so in particular, for each edge (u, v), vertex v stores a copy $\delta_v(u) = \delta(u)$* (FIRST-DIFFERENCE). The algorithm maintains a shortest path tree T from the root s. We say an edge (u, v) is a tree edge if $(u, v) \in T$, and a non-tree edge if $(u, v) \in E \setminus T$. Whenever a non-tree edge is deleted, shortest distances do not change, so the algorithm does not have to do much. Now, consider the deletion of a tree edge (u, v) where u is the parent of v in T. The algorithm checks in constant time, by cleverly storing local label information $\delta_v(z)$, if v has another edge to a vertex z with $\delta(v) = \delta_v(z) + w(z, v)$. If yes, v can be reconnected without a label increase, the edge (z, v) is added to the tree and all distance labels remain the same so we are done. If not, label $\delta(v)$ must increase, which in turn affects of the children of v, so *The algorithm then examines all the children of v and checks if they can be attached to the tree without increasing their distance in a similar manner.* (SECOND-DIFFERENCE) Some vertices will fail to be reattached with the same label, so the algorithm keeps a list of all vertices that need to be re-attached at a higher label. Each time the algorithm discovers that a label $\delta(v)$ must increase, it increases it by 1 (which is the most optimistic new label it can get) and returns it to the needs-reattachment list in at attempt to reattach v with this higher label. The algorithm examines the vertices in the list in an increasing order of their label. Note that the label of a vertex may be increased many times as a result of an update. *Whenever the label $\delta(v)$ of a vertex v changes, the algorithm must adjust $\delta_u(v)$ for every edge (u, v) in the graph.* (THIRD-DIFFERENCE.)

Note that the algorithm above fails to satisfy the Update-Time Invariant, because although a vertex v is only charged when $\delta(v)$ increases (otherwise the search stops at v and can be charged to the edge that led to v), edge (u, v) is charged whenever $\delta(u)$ or $\delta(v)$ increase even just by 1. In particular, the invariant is not preserved because of the work in SECOND-DIFFERENCE and THIRD-DIFFERENCE. The changes we implement are simple. We start with FIRST-DIFFERENCE: each vertex v will still store local label information $\delta_v(u)$, but now it might be slightly inaccurate. In particular, we always have

▶ **Invariant 15** (Local-Information). $\delta(u) \leq \delta_v(u) \leq \text{ROUND}_{\epsilon w_o(u,v)}(\delta(u))$.

A vertex v will now choose its parent based on the slightly inaccurate local labels $\delta_u(v)$ instead of the true label $\delta(u)$. Let $p(v)$ be the parent of v in the tree.

▶ **Invariant 16** (Parent-Choice). $p(v) = argmax_{u \in \text{NEIGHBORS}(v)}\{\delta_v(u) + w(u, v)\}$ *and* $\delta(v) = \delta_v(p(v)) + w(p(v), v)$.

The Parent-Choice and Local-Information invariants combined clearly guarantee the Approximation Invariant. We must now show how to maintain these efficiently. This leads us to THIRD-DIFFERENCE: when $\delta(v)$ changes, we only update $\delta_u(v)$ for every vertex u when $\text{ROUND}_{\epsilon w_o(u,v)}(\delta(v))$ increases. This ensures that we satisfy the Update-Time Invariant for this step of the algorithm, while still ensuring that all local information adheres to the Local-Information Invariant. We omit the full details, but it very easy to maintain a data structure for each vertex v, that returns in $O(1)$ time per edge all edges (u, v) for which $\text{ROUND}_{\epsilon w_o(u,v)}(\delta(v))$ increased. This is because $w_o(u, v)$ is completely fixed for each edge, while $\delta(v)$ only rises from 1 to d, so we only need d slots per vertex (slot i corresponding to $\delta(v)$ going up from i to $i + 1$), and $O(1)$ time per edge affected in each slot.

The last violation of the Update-Time Invariant was in SECOND-DIFFERENCE. When $\delta(v)$ changes, instead of processing all children u, we only need to process those for which $\delta_u(v)$ changes. But in our modified algorithm this only occurs when $\text{ROUND}_{\epsilon w_o(u,v)}(\delta(v))$ increases, in keeping with the Update-Time Invariant.

We have thus shown how to modify classical **ES** in a way that maintains the Approximation Invariant and the Update-Time Invariant while processing deletions. Increase-Weight(u, v) is processed in the same way: if (u, v) was not a tree edge we do nothing, and otherwise if u was the parent of v, then some invariants will be violated for v, and we fix these in exactly the same way as for a deletion.

We now turn to processing insertions. In classical **ES**, it is trivial to process an insertion of (u, v) that does decrease distances because the distance labels do not change, so we just spend $O(1)$ time fixing update $\delta_v(u)$ and $\delta_u(v)$. In our algorithm, however, a strange difficulty arises: because our labels are approximate, even if the insertion of (u, v) does not decrease distances, it might nonetheless violate the Approximation Invariant: say that $\mathbf{dist}(u) = \mathbf{dist}(v) = 1000$ but $\delta(v) = 1000(1 + \epsilon)$ while $\delta(u) = 1000$ and we insert and edge of weight 1. In this case we cannot afford to decrease $\delta(v)$ because our update time analysis relied on non-decreasing labels. But note that although v now violates the Approximation Invariant, $\delta(v)$ is still a $(1+\epsilon)$ approximation to $\mathbf{dist}(s, v)$, because $\mathbf{dist}(s, v)$ never decreases. We thus rely on the idea used in the "Monotone" **ES** tree of Henzinger et al. [10]: we simply never decrease distance labels. More formally, our distance labels will satisfy the following *relaxed* Approximation Invariant: after every update, for every vertex v, either $\delta(v)$ satisfies the standard Approximation Invariant, or $\delta(v) = \delta^{\text{OLD}}(v)$, where $\delta^{\text{OLD}}(v)$ was the distance label before the update. By an induction on time, it is easy to see that with this relaxed Approximation Invariant, we still always have that $\delta(v) \leq (1 + \epsilon)\mathbf{dist}(s, v)$. If $\delta(v)$ satisfies the approximation invariant, the proof is the same as in the Approximation Analysis above. Otherwise, we have $\delta(v) = \delta^{\text{OLD}}(v)$, in which case by our time induction we have $\delta^{\text{OLD}}(v) \leq (1 + \epsilon)\mathbf{dist}^{\text{OLD}}(s, v)$, and since our updates are guaranteed not to decrease distances, we have $\mathbf{dist}^{\text{OLD}}(s, v) \leq \mathbf{dist}(s, v)$ and we are done. ◀

5 The decremental SSSP algorithm

We now put together all our ingredients to proving the main Theorem 1.

▶ **Lemma 17.** *For any threshold τ, and depth bound $d = n\epsilon^{-1}\tau^{-1}$, we can maintain approximate distances $\mathbf{dist}'_\tau(s, v)$ in total time $O(m \log^2(n) + n^2 \log(n)\epsilon^{-2})$, with the property that $\mathbf{dist}'_\tau(s, v) \leq (1 + \epsilon)\text{BOUND}_d(\mathbf{dist}_\tau(s, v)) + d\epsilon$*

Proof. First we use Lemma 7 to maintain the threshold graph G_τ in $O(m \log^2(n))$ total update time. Then, setting $\beta = \frac{d\epsilon}{2n}$, for each edge $(u, v) \in G_\tau$, we round the edge weight $w(u, v)$ up to the nearest multiple of β. It is easy to see that since every shortest path in the graph contains at most n edges, this weight change incurs an additive error of at most $n\beta = d\epsilon/2$. Since all edge weights are now multiple of β, we can divide all edge weights by factor of β without changing shortest paths, which results in a scaled graph G^s_τ with integral weights for which we have to maintain shortest distances up to depth $d^s = d/\beta = 2n\epsilon^{-1}$. We now run $\mathbf{WSES}(G^s_\tau, s, d^s)$ in the scaled graph, and then scale the resulting distances back up by β. Since **WSES** is a $(1 + \epsilon)$ approximation, we get: $\mathbf{dist}'_\tau(s, v) \leq (1 + \epsilon)\text{BOUND}_d(\mathbf{dist}_\tau(s, v) + d\epsilon/2) \leq (1 + \epsilon)\text{BOUND}_d\mathbf{dist}_\tau(s, v) + d\epsilon$.

Recall that the total update time of $\mathbf{WSES}(G^s_\tau, s, d^s)$ is $O(nd^s + \sum_{(u,v)\in\mathcal{A}} \frac{d^s}{\epsilon w_o(u,v)})$. We know that $O(nd^s) = O(n^2\epsilon^{-1})$. Now, G^s_τ contains two types of edges: edges between a vertex

$v \in V$ and a component vertex $c \in V_\tau \setminus C$, and τ-light edges from the original graph. By Lemma 7, the total number of component edges ever inserted is $O(n \log(n))$, and because of our scaling they all have weight at least 1, so their total contribution to the sum is at most $n \log(n)\epsilon^{-1} \cdot d^s = O(n^2 \log(n)\epsilon^{-2})$. For edges of the original graph, let us look at the contribution of all edges (u, v) with $\textbf{level}_o(u, v) = i$. By Lemmas 4 and 7, the total number of such edges is at most $O(n\tau 2^i)$. Each such edge has $w_o(u, v) \geq 2^i$, which has been scaled down by β in G^s_τ, and so contributes $\frac{d^s \beta}{\epsilon 2^i} = \frac{d}{\epsilon 2^i}$ to the sum. Thus in total we have that each level i contributes a total of $O(n\tau d\epsilon^{-1}) = O(n^2\epsilon^{-2})$.

We complete the proof by arguing that there are only $\log(n)$ contributing levels. For simplicity, let us look at the graph G_τ before scaling. First off, edges of weight more than $d = n\epsilon^{-1}/\tau$ can be ignored, since we do not care about distances greater than d (we are working with BOUND_d). Secondly, from the definition of $\textbf{cut-off}(v)$, an edge (u, v) of weight less than $1/(2\tau)$ will always be heavy and so never appear in G_τ: if $2\tau w(u, v) \leq 2^{\textbf{level}(u,v)}\tau < 1$, then $\textbf{cut-off}(u)$ and $\textbf{cut-off}(v)$ are always at least as large as $\textbf{level}(u, v)$, so (u, v) will remain heavy. Thus, the only edges that appear in our graph have weight between $1/(2\tau)$ and $n/(\epsilon\tau)$, which corresponds to $\log(n/\epsilon) = O(\log(n))$ different levels of edge weights. ◀

▶ **Lemma 18.** *For any distance bound d, with total update time $O(m \log^2(n) + n^2 \log(n)\epsilon^{-2})$ we can maintain approximate distances $\textbf{dist}_d(s, v)$ to all vertices v such that $\textbf{dist}(s, v) \leq \textbf{dist}_d(s, v) \leq \text{BOUND}_d(\textbf{dist}(s, v)) + 15\epsilon d$*

Proof. Set $\tau = n/(\epsilon d)$. By Lemma 17, in total update time $O(m \log^2(n) + n^2 \log(n)\epsilon^{-2})$ we can maintain values $\textbf{dist}'_\tau(s, v)$ with $\textbf{dist}_\tau(s, v) \leq \textbf{dist}'_\tau(s, v) \leq (1+\epsilon)\text{BOUND}_d(\textbf{dist}_\tau(s, v)) + \epsilon d$. Now, By Lemma 5 we have $\textbf{dist}(s, v) - 14n/\tau \leq \textbf{dist}_\tau(s, v) \leq \textbf{dist}(s, v)$. Plugging in our value $\tau = n/(\epsilon d)$ we get $\textbf{dist}(s, v) - 14\epsilon d \leq \textbf{dist}_\tau(s, v) \leq \textbf{dist}(s, v)$. Thus, we have $\textbf{dist}(s, v) - 14\epsilon d \leq \textbf{dist}'_\tau(s, v) \leq \text{BOUND}_d(\textbf{dist}(s, v)) + \epsilon d$. If we return $\textbf{dist}_d(s, v) = \textbf{dist}'_\tau(s, v) + 14\epsilon d$, we get the bound in the lemma. ◀

It is now easy to prove our main Theorem 1. Observe that the maximum distance we could possibly see is nW. Thus, for each $i = 0, 1, 2, 3...\lceil \log(nW) \rceil$, we use Lemma 18 to maintain $\delta_i(v) = \textbf{dist}_{2^i}(s, v)$. By Lemma 18, the total update time is the desired $O(m \log^2(n) \log(nW) + n^2 \log(n) \log(nW)\epsilon^{-2})$. We then output as our final answer: $\textbf{dist}'(v) = \min_i\{\delta_i(v)\}$. Since for each i we have $\delta_i \geq \textbf{dist}(v)$, we have $\textbf{dist}'(v) \geq \textbf{dist}(s, v)$. We now need to show that $\textbf{dist}'(v) \leq (1 + O(\epsilon))\textbf{dist}(s, v)$. It is not hard to see that for $i = \lceil \log(\textbf{dist}(s, v)) \rceil$, we end up with $\delta_i(v) \leq \textbf{dist}(s, v) + 30\epsilon\textbf{dist}(s, v)$, as desired.

6 Conclusions

In this paper we presented the first *deterministic* decremental SSSP algorithm for *weighted* undirected graphs that goes beyond the Even-Shiloach bound of $O(mn)$ total update time. Previously such a result was only known for unweighted undirected graphs. The two main open questions are further improving this total update time, and going beyond $O(mn)$ deterministically for *directed* graphs. Finally, we recall from the introduction that all existing deterministic $o(mn)$ results including ours are only able to return approximate shortest distances, not the paths themselves.

Testing Core Membership in Public Goods Economies*

Greg Bodwin

MIT EECS, Cambridge, MA, USA
greg.bodwin@gmail.com

Abstract

This paper develops a recent line of economic theory seeking to understand public goods economies using methods of topological analysis. Our first main result is a very clean characterization of the economy's core (the standard solution concept in public goods). Specifically, we prove that a point is in the core iff it is Pareto efficient, individually rational, and the set of points it dominates is path connected.

While this structural theorem has a few interesting implications in economic theory, the main focus of the second part of this paper is on a particular algorithmic application that demonstrates its utility. Since the 1960s, economists have looked for an efficient computational process that decides whether or not a given point is in the core. All known algorithms so far run in exponential time (except in some artificially restricted settings). By heavily exploiting our new structure, we propose a new algorithm for testing core membership whose computational bottleneck is the solution of $O(n)$ convex optimization problems on the utility function governing the economy. It is fairly natural to assume that convex optimization should be feasible, as it is needed even for very basic economic computational tasks such as testing Pareto efficiency. Nevertheless, even without this assumption, our work implies for the first time that core membership can be efficiently tested on (e.g.) utility functions that admit "nice" analytic expressions, or that appropriately defined ε-approximate versions of the problem are tractable (by using modern black-box ε-approximate convex optimization algorithms).

1 Introduction

1.1 Background on Public Goods Economics

A basic question in economics is to understand the forces governing the production of public goods. A good is *public* if its use by one person does not reduce its availability to others, and if none are excluded from using the good. Examples include public parks, research information, a clean environment, national defense, radio broadcasts, and so on.

Public goods economies were first explicitly abstracted in a classic paper by Samuelson in 1954 [24], and have since become central objects of study for economists. An important feature of public goods economies is that they are not well modeled by the individualistic "best-response dynamics" which govern familiar economic equilibrium concepts such as the Nash or Walrasian equilibrium. Rather, public goods typically arise as the result of a

communal process – e.g. negotiations, treaties, or taxes – that allow the cost of production to be amortized over all agents that stand to benefit from the good. Accordingly, public goods economics inspired the development of *cooperative game theory*, which seeks to understand these cooperative dynamics and when an agreement to produce public goods is "stable" or when it is doomed to fall apart.

What, exactly, does "stability" mean in this context? The most standard notion is *coalitional stability*, which is given as follows:

▶ **Definition** (Informal)**.** Let $\mathbf{a}$ be an outcome in a public goods economy with agents N (i.e. $\mathbf{a}$ describes the amount of work each agent contributes to produce a public good). We say that $\mathbf{a}'$ is a *deviation* on $\mathbf{a}$ for a nonempty coalition of agents $C \subseteq N$ if no agents in $N \setminus C$ perform work (i.e. $a'_i = 0$ for all $i \notin C$) and all agents in C prefer $\mathbf{a}'$ to $\mathbf{a}$. If there is no deviation on $\mathbf{a}$ for any coalition, then we say $\mathbf{a}$ is *coalitionally stable*. The set of coalitionally stable outcomes is called the *core* of the economy.

Since its inception in the late 1800's [10],[1] the core and cooperative game theory in general have played major roles in many successful economic research programs. More background can be found in most modern game theory textbooks, e.g. [23, 8].

1.2 (Non-)Algorithmic Properties of Public Goods Economies

An inherent conceptual drawback of coalitional stability is its exponential-size definition. In other words, for an outcome $\mathbf{a}$ to be coalitionally stable, *every single one* of the $2^n - 1$ possible coalitions of agents must not have a deviation. Hence, the naive algorithms for testing the coalitional stability of $\mathbf{a}$ must perform computations for all $2^n - 1$ coalitions, and so they suffer exponential runtime. Coalitional stability is not a very convincing solution concept if its implicit notion of "instability" assumes that agents can quickly make exponential time computations in order to find deviations whenever they exist.

This problem has led economists studying public goods to seek more clever methods for solving computational problems related to the core of a public goods economy, which avoid this exponential behavior. Some of the initial work in this vein attacked the closely-related problem of simply outputting any core outcome. The first such solution appeared in the 1960s, when Scarf [25] proved that "balanced" games have nonempty cores, by means of an (exponential time) algorithm that outputs a core point and provably always terminates. Similar results were proved in the setting of public goods economies by Chander and Tulkens [5] and Elliot and Golub [12]. Meanwhile, followup work has suggested that the slow runtime of Scarf's algorithm may be inherent to the problem: Kintali et al. [20] showed that Scarf's algorithm cannot be improved to polynomial runtime (unless P = PPAD), and Deng and Papadimitriou [9] showed that it is NP Complete just to detect whether or not the core is empty (let alone find a point in the core), even in the simple class of graphical games, and even when Scarf's assumption of "balance" is dropped. Other notable hardness results in this vein have come from Conitzer and Sandholm [7] and Greco et al. [18].

There has also been considerable prior work on the "membership testing" problem of determining whether a point taken on input is in the core (this is the question addressed in this paper). Deng and Papadimitriou's work [9] also implies that membership testing is NP hard even in the restricted setting of graphical games, although there are straightforward

[1] Some of the early work on cooperative game theory used the name *contract curve* instead of core. The term *core* was coined in [15].

efficient algorithms in the further restricted setting where the game is superadditive. Conitzer and Sandholm [6] showed that membership testing is co-NP complete in games where coalition values have a "multiple-issue" representation in polynomial space. Faigle et al. [13] showed that the problem is NP complete in a variant of graphical games where payoffs are given by minimum spanning trees of subgraphs. Sung and Dimitrov [26] showed co-NP completeness for membership testing in "hedonic coalition formation games." Goemans and Skutella showed NP completeness for both emptiness and membership testing in "facility location games," and gave formulations of these problems as LP relaxations [16]. There has been work on games defined by *marginal contribution nets* (MC-nets) [19, 11], in which values attainable by coalitions are determined by succinct logical formulae. Li and Conitzer [22] studied emptiness testing and membership testing under various classes of formulae, and obtained various algorithms or NP hardness results depending on the complexity of the formulae allowed.

1.3 Our Results

A recently popular trend in public goods research has been to model economies as networks, and then seek to analyze the economy by studying the topological properties of the underlying "benefits network," describing the ability of agents to transfer utility to each other at any given point (see for example [3, 4, 1, 2, 12]). Much of the initial work focused on Nash equilibria [3, 4, 1, 2] of the economy. A major stride was recently taken by Elliot and Golub [12], who extended the theory to show that the Lindahl equilibria[2] of an economy are precisely the points that are eigenvalues of their own benefits network. They further discuss connections between the Lindahl equilibria and the core – in particular, in any standard model (including theirs) all Lindahl equilibria are also core outcomes [14]. However, they raise an interesting open question to more precisely characterize the core [17] in a similar vein.

Our first main result achieves this goal. We show that the core can be characterized as follows:

▶ **Theorem 1.** *Let* $\mathbf{a}$ *be an outcome in a public goods economy and let* $\mathbf{D_a}$ *be the set of points that no agent prefers to* $\mathbf{a}$*. Then* $\mathbf{a}$ *is in the core if and only if it is Pareto efficient, individually rational, and* $\mathbf{D_a}$ *is path connected.*

(Here, the definition of path connectedness is the standard topological one: for any two points $\mathbf{x}, \mathbf{y} \in \mathbf{D_a}$, there is a continuous function $f : [0, 1] \to \mathbb{R}^n_{\geq \mathbf{0}}$ satisfying $f(0) = \mathbf{x}, f(1) = \mathbf{y}$, and $f(\lambda) \in \mathbf{D_a}$ for all $0 \leq \lambda \leq 1$. The image of $[0, 1]$ under f is called a path.)

An interesting consequence of this theorem is a precise description of the relationship between Lindahl equilibria and core outcomes:

▶ **Theorem 2.** *Assuming that the utility function* $\mathbf{u}$ *is differentiable, the Lindahl equilibria of a public goods economy are precisely the core points whose core membership can be certified using only local information.*

The proof of this corollary is essentially immediate by combining Theorem 1 with a more technical phrasing of Elliot and Golub's result.

While we believe that these two structural theorems hold intrinsic interest, the second half of this paper is intended to demonstrate their power by an application to the algorithmic

[2] The Lindahl equilibria of an economy are the competitive equilibria that would be reached if market externalities were truthfully reported and then bought and sold on an open market. A formal definition is not necessary to read this paper, but can be found in e.g. [23, 8].

problem discussed earlier. We have previously suggested the intuition that the algorithmic core membership testing problem is hard because the naive algorithms must check an exponential number of coalitions for a potential deviation. However, Theorem 1 lets us avoid this brute-force behavior: after checking for Pareto efficiency and individual rationality (which is quite easy), we are left only with the task of checking whether or not $\mathbf{D_a}$ is path-connected. The complexity of this task is non-obvious, but we show that it can be done fairly efficiently, yielding the following result:

▶ **Theorem 3.** *Given an outcome* $\mathbf{a}$ *in an* n*-agent public goods economy, there is an algorithm that decides whether or not* $\mathbf{a}$ *is in the core of a public goods economy. The computational bottleneck in this algorithm is the solution of* $O(n)$ *convex programming problems on the utility function of the economy.*

Hence we essentially have the first polynomial-time tester for coalitional stability in an unrestricted public goods economy, up to the implementation of the necessary convex programming oracle. It is fairly natural in our economic metaphor to assume that convex programming should be tractable: it corresponds to the negotiation process of a group of agents trying to determine how well they can maximize a joint utility function as a group. If even this is impossible, then it is essentially hopeless to efficiently test core membership. One cannot even test the more basic property of Pareto efficiency, a necessary step towards testing core membership, without assuming some computational power along these lines.

Even so, if one does not wish to introduce such assumptions, Theorem 3 implies that several broad special cases of membership testing have efficient algorithms. The most obvious of these is when the utility function and its derivative can be described by a "nice" analytic function on which the standard derivative-based method for exact convex optimization goes through. Less obviously, if convex optimization really is hard for the given utility function (or the utility function of the economy is unknown), one can employ modern ε-approximate convex optimization solvers, which treat the utility function as a black box that can be queried, to solve certain natural ε-approximate relaxations of the core membership testing problem. We discuss this point in the conclusion of the paper, since it is easier to be specific here once the economic model is familiar.

We consider it somewhat surprising that these algorithmic results are possible, given a general dearth of positive results in the area. Moreover, the approach taken by the algorithm is fairly intuitive and seems to plausibly reflect practical behavior. Starting with the grand coalition, we show (via Theorem 1) that we can either determine that the current coalition has a deviation, or we can identify a "least-valuable player" who is formally the least likely agent to participate in a deviation. We then kill this agent and repeat the analysis on the survivors. After n rounds, we have either killed every agent (and thus determined that the given point is coalitionally stable), or we have explicitly found a surviving coalition with a deviation. It is quite reasonable to imagine that a practical search for a deviating coalition might employ a "greedy" method of iteratively killing the agent who seems to be least pulling their weight at the current agreement; an insight of Theorem 3 is that this search heuristic is in fact thorough and will provably produce the right answer.

1.4 Comparison with Prior Work

Elliot and Golub [12] recently studied the Lindahl equilibria in public goods economies, with a focus on characterizing the set of solutions rather than algorithmically computing/testing them. More specifically, they frame the typical model of public goods economies in the language of networks, and use this to equate the eigenvectors of the "benefits network" with

the Lindahl equilibria of the economy. A less general version of this networks interpretation was implicitly used in several other papers concerning Nash equilibria of public goods economies, for example [3, 4, 1, 2]. In this paper, we will adopt the more general networks-based phrasing of public goods economies used by Elliot and Golub, and we will rely on this insight in a critical way to prove our main results.

Per the discussion above, there has been lots of prior work on the algorithmic properties of the core, largely intended to confirm/refute the bounded rationality argument in some economic model. Three questions are commonly studied:

- The *membership testing* problem (discussed above): is a given outcome in the core of the game?
- The *emptiness testing* problem: is the core empty?
- The *member finding* problem: output any solution in the core of the game (if nonempty).

We remark that the latter two problems are already closed in public goods economies: Elliot and Golub [12] show that the core is never empty except in certain degenerate cases, and it can be seen from the model below that the member finding problem is essentially identical to the general problem of convex optimization (which is well beyond the scope of this economically-minded research program). Hence, this work is entirely focused on the membership testing problem.

In order to frame these three questions as proper computational problems, past work has commonly defined a "compressed" cooperative game that allows the payoffs achievable by all 2^n possible coalitions to be expressed on only $\mathsf{poly}(n)$ input bits. For example, in a seminal paper by Deng and Papadimitriou introducing this line of research [9], the authors studied *graphical games* in which weighted edges are placed between agents and the value attainable by a coalition is equal to the total weight contained in its induced subgraph. Upper and lower bounds are often obtained for these problems by exploiting particular features of the compression scheme. By contrast, our goal is to assume as little structure for the problem as possible (since our main results are upper bounds, this is the more general approach). Thus, we allow the economy to be governed by an arbitrarily complex utility function, which does not need to have a succinct representation, or even any algorithmic representation at all. Instead, we allow ourselves black-box constant-time query access to the utility function, which acts as an oracle and thus may have arbitrary complexity. The goal in this substantial generalization is to ensure that our results reveal structure of the core itself, rather than the nature of an assumed compression.

2 The Model and Basic Definitions

2.1 Notation Conventions

Given vectors $\mathbf{a}, \mathbf{a}' \in \mathbb{R}^n$, we will use the following (partial) ordering operations:

- $\mathbf{a} \geq \mathbf{a}'$ means that $a_i \geq a'_i$ for all $1 \leq i \leq n$,
- $\mathbf{a} > \mathbf{a}'$ means that $a_i > a'_i$ for all $i \leq i \leq n$, and
- $\mathbf{a} \gneq \mathbf{a}'$ means that $a_i \geq a'_i$ for all $1 \leq i \leq n$, and $a_j > a'_j$ for some $1 \leq j \leq n$.

Given a subset $C \subseteq \{1, \ldots, n\}$ and a vector $\mathbf{v} \in \mathbb{R}^n$, we write $\mathbf{v}_C$ to denote the restriction of $\mathbf{v}$ to the indices in C; that is, $\mathbf{v}_C$ is the $|C|$ length vector built by deleting the entry v_i from $\mathbf{v}$ for each $i \notin C$.

We use $\mathbf{0}, \mathbf{1}$ as shorthands for the vectors $\langle 0, \ldots, 0 \rangle, \langle 1, \ldots, 1 \rangle$ respectively.

2.2 Economic Model

We adopt the terminology of Elliot and Golub [12] when possible. The salient pieces of our economy are defined as follows:

- The set of agents in the economy is given by $N = [n] = \{1, \ldots, n\}$. A nonempty subset of agents in the economy $C \subseteq N$ is called a *coalition*. The coalition $C = N$ is called the *grand coalition*.
- Each agent i chooses an *action* a_i, which can be any real number in the interval $[0, 1]$. An *outcome* or *point* is a vector $\mathbf{a} \in \mathbb{R}^n$ built by concatenating the actions of all agents.
- There is a continuous *utility function* $\mathbf{u} : [0, 1]^n \to [0, 1]^n$, which maps outcomes to a level of "utility" for each agent. In particular, agent i prefers outcome $\mathbf{a}$ to outcome $\mathbf{a}'$ iff $u_i(\mathbf{a}) > u_i(\mathbf{a}')$. The utility function has the following two properties:
  - *Positive Externalities*: whenever $\mathbf{a} \gneq \mathbf{a}'$ with $a_i = a'_i$, we have $u_i(\mathbf{a}) > u_i(\mathbf{a}')$. This assumption is what places us in the setting of public goods economies; intuitively, it states that an agent gains utility when other agents increase their production of public goods.
  - *Convex Preferences*: we assume that $\mathbf{u}$ is concave.[3] That is, for any outcomes $\mathbf{a}, \mathbf{a}'$ and any $\lambda \in [0, 1]$, we have $\mathbf{u}(\lambda\mathbf{a} + (1 - \lambda)\mathbf{a}') \geq \lambda\mathbf{u}(\mathbf{a}) + (1 - \lambda)\mathbf{u}(\mathbf{a}')$. This standard assumption corresponds to the economic principle of diminishing marginal returns.

2.3 Game Theory Definitions

We recap some well-known definitions from the game theory literature.

▶ **Definition 4** (Pareto Efficiency)**.** An outcome $\mathbf{a}$ is a *Pareto Improvement* on another outcome $\mathbf{a}'$ if $\mathbf{u}(\mathbf{a}) \gneq \mathbf{u}(\mathbf{a}')$. An outcome $\mathbf{a}$ is *Pareto Efficient* if there is no Pareto improvement on $\mathbf{a}$. The set of Pareto efficient outcomes is called the *Pareto Frontier*.

The main solution concept that will be discussed in this paper is *the core*:

▶ **Definition 5** (Deviation)**.** Given an outcome $\mathbf{a}$, an outcome $\mathbf{a}'$ is a *deviation* from $\mathbf{a}$ for a coalition C if $\mathbf{a}'_{N \setminus C} = \mathbf{0}$ and $\mathbf{u}_C(\mathbf{a}') > \mathbf{u}_C(\mathbf{a})$.

▶ **Definition 6** (The Core)**.** An outcome $\mathbf{a}$ is in the *core* of the economy if no coalition has a deviation from $\mathbf{a}$ (equivalently, $\mathbf{a}$ is *coalitionally stable*).

The next definition that will be useful in our proofs is the *projected economy*:

▶ **Definition 7.** Given an economy described by agents N and a utility function $\mathbf{u}$, the *projected economy* for a coalition C is the economy described by agents N and utility function $\mathbf{u}^C(\mathbf{a}_C)$, where

$$\mathbf{u}^C(\mathbf{a}_C) := \mathbf{u}_C(\mathbf{a}_C \cdot \mathbf{0}_{N \setminus C}).$$

In other words, the new $|C|$-dimensional utility function $\mathbf{u}^C$ is obtained by fixing the actions of $N \setminus C$ at 0, allowing any action for C, and then using the old utility function $\mathbf{u}$ to determine the utilities for C in the natural way. We suppress the superscript $\mathbf{u}^C$ when clear from context.

[3] Confusingly, when $\mathbf{u}$ is mathematically concave, one says that preferences are "economically convex" – hence, *convex preferences*.

▶ **Definition 8.** The *dominated set* of $\mathbf{a}$, denoted $\mathbf{D_a}$, is defined as:

$$\mathbf{D_a} := \{\mathbf{a}' \mid \mathbf{u}(\mathbf{a}) \geq \mathbf{u}(\mathbf{a}')\}.$$

In other words, $\mathbf{D_a}$ is the set of points that no agent prefers to $\mathbf{a}$. Note that this is an unusually weak definition of dominance, in the sense that (for example) $\mathbf{D_a}$ contains $\mathbf{a}$ itself.

3 A Topological Characterization of the Core

Our goal in this section is to prove the following structural theorem:

▶ **Theorem 9.** *Let* $\mathbf{a}$ *be an outcome in a public goods economy. Then* $\mathbf{a}$ *is in the core if and only if it is Pareto efficient, individually rational, and* $\mathbf{D_a}$ *is path connected.*

The vast majority of the technical depth of this theorem is tied up in the implication

$$\mathbf{a} \text{ is in the core } \longrightarrow \mathbf{D_a} \text{ is path connected.}$$

The remainder of this forwards implication ($\mathbf{a}$ is in the core $\rightarrow$ neither the grand coalition nor any singleton coalition has a deviation from $\mathbf{a}$) is extremely straightforward: $\mathbf{a}$ is individually rational iff each agent i prefers it to the outcome they can guarantee acting alone, which coincides with the notion that the singleton coalition $\{i\}$ has no deviation from $\mathbf{a}$. In our model, Pareto efficiency coincides with the notion that the grand coalition N has no deviation from $\mathbf{a}$:

▶ **Claim 10.** *Let* $\mathbf{a}$ *be an outcome. If there is an outcome* $\mathbf{a}'$ *satisfying* $\mathbf{a} \gneq \mathbf{a}'$ *(*$\mathbf{a} \lneq \mathbf{a}'$*) and* $\mathbf{u}(\mathbf{a}) \gneq \mathbf{u}(\mathbf{a}')$*, then there is an outcome* $\mathbf{a}''$ *satisfying* $\mathbf{a} > \mathbf{a}''$ *(*$\mathbf{a} < \mathbf{a}'$*) and* $\mathbf{u}(\mathbf{a}) > \mathbf{u}(\mathbf{a}'')$*.*

Proof. We will prove the claim for the case $\mathbf{a} \gneq \mathbf{a}'$; the case $\mathbf{a} \lneq \mathbf{a}'$ follows from a symmetric argument.

Choose an agent i for whom $u_i(a) > u_i(a')$, and then slightly increase a_i. Since $\mathbf{u}$ is continuous, if we increase a_i by a sufficiently small amount then we still have $u_i(a) > u_i(a')$. Additionally, by positive externalities we then have $\mathbf{u}(\mathbf{a}) > \mathbf{u}(\mathbf{a}')$. We can then slightly increase the actions of all agents, such that $\mathbf{a} > \mathbf{a}'$, but with sufficiently small increases we do not destroy the property that $\mathbf{u}(\mathbf{a}) > \mathbf{u}(\mathbf{a}')$. ◀

In this section, we will first give a complete proof of the (easier) backwards implication of Theorem 9, and then we sketch the proof of the forwards implication. Due to space constraints, a full proof of the forwards implication can be found in the full version of this paper.

3.1 Backwards Implication of Theorem 9

First:

▶ **Lemma 11.** *If* $\mathbf{a}$ *is Pareto efficient, then every deviation* $\mathbf{a}'$ *from* $\mathbf{a}$ *satisfies* $\mathbf{a}' \lneq \mathbf{a}$*.*

Proof. Let I be the set of agents i for which $a'_i > a_i$, and suppose towards a contradiction that I is nonempty.

Consider the point $\mathbf{a}''$ defined such that $\mathbf{a}''_{N\setminus I} := \mathbf{a}_{N\setminus I}$ and $\mathbf{a}''_I := \mathbf{a}'_I$. We then have $\mathbf{u}_{N\setminus I}(\mathbf{a}'') > \mathbf{u}_{N\setminus I}(\mathbf{a})$ by positive externalities, since these points differ only in that the (nonempty) coalition I has increased their actions. We also have $\mathbf{u}_I(\mathbf{a}'') \geq \mathbf{u}_I(\mathbf{a}') > \mathbf{u}_I(\mathbf{a})$, where the first inequality follows from positive externalities (since these points differ only in

that the coalition $N \setminus I$ has weakly increased their action), and the second follows from the fact that $\mathbf{a}'$ is a deviation from $\mathbf{a}$ for a coalition C with $I \subseteq C$ (since $\mathbf{a}_I > \mathbf{a}_I$).

We thus have $\mathbf{u}(\mathbf{a}'') > \mathbf{u}(\mathbf{a})$, which contradicts the fact that $\mathbf{a}$ is Pareto efficient. Thus I is empty and the lemma follows. ◀

Second:

▶ **Lemma 12.** *Suppose there is a path $P \subset \mathbb{R}^n_{\geq \mathbf{0}}$ with endpoints $\mathbf{x}, \mathbf{y}$ such that for any $\mathbf{p} \in P$ we have $\mathbf{u}(\mathbf{p}) \leq \mathbf{u}(\mathbf{a})$. If $\mathbf{a}'$ is a deviation from $\mathbf{a}$ for some coalition C satisfying $\mathbf{a}' \lneq \mathbf{x}$, then $\mathbf{a}'$ also must satisfy $\mathbf{a}' \lneq \mathbf{y}$.*

Proof. We walk along P from $\mathbf{x}$ towards $\mathbf{y}$ until we find the first point $\mathbf{p}$ with $p_i = a'_i \neq 0$ for some i. If we reach $\mathbf{y}$ before we find any such point $\mathbf{p}$, it follows that $a'_i = 0$ or $a'_i < x_i$ for all i, and so $\mathbf{a}' \lneq \mathbf{x}$, as claimed. Otherwise, we find such a point $\mathbf{p}$, and we argue towards a contradiction.

We have $\mathbf{p} \neq \mathbf{a}'$, since $\mathbf{u}_C(\mathbf{a}') \gneq \mathbf{u}_C(\mathbf{a})$ but $\mathbf{u}_C(\mathbf{p}) \leq \mathbf{u}_C(\mathbf{a})$. By construction we then have $\mathbf{p} \gneq \mathbf{a}'$. Since $p_i = a'_i$, by positive externalities we then have $u_i(p) > u_i(a')$. Since $a'_i \neq 0$ we have $i \in C$, and since $\mathbf{a}'$ is a deviation for C, this implies $u_i(a') > u_i(a)$. We then have $u_i(p) > u_i(a)$, which contradicts the assumption that $\mathbf{u}(\mathbf{p}) \leq \mathbf{u}(\mathbf{a})$. Therefore no such point $\mathbf{p}$ may be found. ◀

We can now show:

Proof of Theorem 9, Backwards Implication. Assume that $\mathbf{a}$ is robust to deviations by the grand coalition or any singleton coalition, and that $\mathbf{D_a}$ is path connected. Our goal is now to show that $\mathbf{a}$ is in the core.

By Claim 10, the property that the grand coalition has no deviation from $\mathbf{a}$ implies that $\mathbf{a}$ is Pareto efficient. Thus, by Lemma 11 any deviation $\mathbf{a}'$ from $\mathbf{a}$ satisfies $\mathbf{a}' \lneq \mathbf{a}$. Since no singleton coalition has a deviation from $\mathbf{a}$ we have $\mathbf{0} \in \mathbf{D_a}$, and since $\mathbf{D_a}$ is path connected there is a path contained in $\mathbf{D_a}$ with endpoints $\mathbf{a}, \mathbf{a}$. Thus, by Lemma 12, we further have that a deviation $\mathbf{a}'$ must satisfy $\mathbf{a}' \lneq \mathbf{0}$. Since no such point exists, it follows that no deviations from $\mathbf{a}$ exist, and so $\mathbf{a}$ is a core outcome. ◀

3.2 Sketch of Forwards Implication of Theorem 9

We will denote by $\mathbf{d_v u(a)}$ the one-sided directional derivative of $\mathbf{u}$ at $\mathbf{a}$ in the direction $\mathbf{v}$. In other words:

$$\mathbf{d_v u(a)} := \lim_{\lambda \to 0^+} \frac{\mathbf{u}(\mathbf{a} + \lambda \mathbf{v}) - \mathbf{u}(\mathbf{a})}{\lambda}.$$

A nontrivial but standard fact from analysis is that, since $\mathbf{u}$ is concave and well-defined everywhere, this limit is well-defined for all $\mathbf{a}$, except when excluded by a boundary condition (e.g. if $v_i < 0$ but $a_i = 0$ for some agent i) – see [21].

Our key lemma is:

▶ **Lemma 13.** *At any outcome $\mathbf{0} < \mathbf{a} < \mathbf{1}$, exactly one of the following three conditions holds:*

1. *There exist directions $\mathbf{v}_{up} > \mathbf{0}, \mathbf{v}_{down} < \mathbf{0}$ such that $\mathbf{d}_{\mathbf{v}_{up}} \mathbf{u}(\mathbf{a}) > \mathbf{0}$ and $\mathbf{d}_{\mathbf{v}_{down}} \mathbf{u}(\mathbf{a}) < \mathbf{0}$,*
2. *There exist directions $\mathbf{v}_{up} > \mathbf{0}, \mathbf{v}_{down} < \mathbf{0}$ such that $\mathbf{d}_{\mathbf{v}_{up}} \mathbf{u}(\mathbf{a}) \leq \mathbf{0}$ and $\mathbf{d}_{\mathbf{v}_{down}} \mathbf{u}(\mathbf{a}) \leq \mathbf{0}$, or*
3. *There exist directions $\mathbf{v}_{up} > \mathbf{0}, \mathbf{v}_{down} < \mathbf{0}$ such that $\mathbf{d}_{\mathbf{v}_{up}} \mathbf{u}(\mathbf{a}) < \mathbf{0}$ and $\mathbf{d}_{\mathbf{v}_{down}} \mathbf{u}(\mathbf{a}) > \mathbf{0}$.*

The three categories of Lemma 13 carry a useful geometric intuition. Specifically:

▶ **Lemma 14.** *The points in the second category of Lemma 13 are precisely the Pareto Frontier.*

The proofs of these two lemmas are quite technical, and can be found in the full version of this paper. With these in mind, we define

▶ **Definition 15.** We will say that a point in the first category of Lemma 13 is *below the Pareto Frontier*, and a point in the third category of Lemma 13 is *above the Pareto Frontier* (and by Lemma 14, the second category of points in Lemma 13 are on the Pareto Frontier).

The geometric intuition behind this definition is that, starting from a point $\mathbf{x}$ in the first category, one can continuously follow the gradient $\mathbf{v}_{up}$ to eventually obtain a Pareto efficient Pareto improvement $\mathbf{x}' > \mathbf{x}$ (we do not prove this fact formally; it is perhaps useful intuition but not essential to our main results). Similarly, starting from $\mathbf{x}$ in the third category, we can continuously follow the gradient $\mathbf{v}_{down}$ to obtain a Pareto efficient Pareto improvement $\mathbf{x}' < \mathbf{x}$.

We then show:

Proof Sketch of Theorem 9, Forwards Implication (Proof in full version). Suppose $\mathbf{a}$ is a core outcome, and our goal is to show path connectedness of $\mathbf{D_a}$. First, we note that $\mathbf{0} \in \mathbf{D_a}$, since otherwise a singleton coalition can deviate from $\mathbf{a}$ (and $\mathbf{a}$ is in the core, so no such deviation is possible). To show path connectedness of $\mathbf{D_a}$, we consider an arbitrary point $\mathbf{x} \in \mathbf{D_a}$ and construct a path in $\mathbf{D_a}$ from $\mathbf{x}$ to $\mathbf{0}$, thus implying that any two such points $\mathbf{x}, \mathbf{x}' \in \mathbf{D_a}$ have a connecting path in $\mathbf{D_a}$ via $\mathbf{0}$.

We show the existence of the $\mathbf{x} \rightsquigarrow \mathbf{0}$ path with a careful repeated application of Lemma 13. Informally speaking, we progressively slide $\mathbf{x} > \mathbf{0}$ a little bit closer to $\mathbf{0}$ while maintaining the property $\mathbf{x} \in \mathbf{D_a}$. If we ever hit $x_i = 0$ for some agent i, then we restrict our attention to the projected economy discluding agent i and continue. If we eventually exclude all agents in this manner, then we have $\mathbf{x} = \mathbf{0}$ and the process is complete. Otherwise, suppose towards a contradiction that at some $\mathbf{x}$, we cannot slide $\mathbf{x}$ any closer to $\mathbf{0}$ while maintaining $\mathbf{x} \in \mathbf{D_a}$. We make two observations here: (1) $\mathbf{x}$ must be above the Pareto frontier (else we could slide $\mathbf{x}$ in the appropriate direction $\mathbf{v}_{down}$) and so it belongs to the third; and (2) for all agents i still being considered, we have $u_i(x) = u_i(a)$ (else, by the positive externalities assumption, we can unilaterally decrease the action of agent i without destroying $\mathbf{x} \in \mathbf{D_a}$). Hence, by moving $\mathbf{x}$ slightly in the direction $\mathbf{v}_{down}$ (which *improves* the utility of all agents being considered), we have $u_i(x) > u_i(a)$ for all agents being considered, and so the new $\mathbf{x}$ is a deviation from $\mathbf{a}$. Since we have assumed that $\mathbf{a}$ is a core outcome, this is a contradiction, and so the process of sliding $\mathbf{x}$ towards $\mathbf{0}$ can never get stuck in this way. ◀

3.3 Connection to Lindahl Equilibria

Before proceeding towards our algorithm, we take a brief detour in this subsection to observe an interesting implication of Theorem 9 that helps illustrate its broader appeal. Elliot and Golub [12] show the following result:

▶ **Theorem 16** ([12]). *The Lindahl equilibria of a public goods economy with a differentiable utility function are precisely the outcomes* $\mathbf{a}$ *for which* $\mathbf{d_a u(a)} = \mathbf{0}$.

They phrase this theorem in different language related to the "benefits network" of the economy, but this formulation will suit our purposes better. We refer the reader to their paper for a more in-depth discussion of the economic role of the Lindahl equilibria.

Combining Theorem 16 with our machinery for Theorem 9, we obtain:

▶ **Theorem 17.** *In a public goods economy with a differentiable utility function, the Lindahl equilibria are precisely the core outcomes* $\mathbf{a}$ *whose membership can be certified by examining only local information at* $\mathbf{a}$.

The proof of this theorem will use Theorem 16 as a black box, and so we will not actually need to appeal to the formal definition of the Lindahl equilibria in its proof.

Proof. If $\mathbf{a}$ is a Lindahl equilibrium, then by Theorem 16 we have $\mathbf{d_a}\,\mathbf{u}(\mathbf{a}) = \mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) = \mathbf{0}$ (the first equality comes from the assumption that $\mathbf{u}$ is differentiable). We claim that any $\mathbf{a}$ satisfying $\mathbf{d_a}\,\mathbf{u}(\mathbf{a}) = \mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) = \mathbf{0}$ is in the core, and thus its core membership can be verified by examining only these local derivatives. First, note that $\mathbf{a}$ is Pareto efficient by Lemma 14. Therefore, by Lemma 11, any possible deviation $\mathbf{a}'$ from $\mathbf{a}$ satisfies $\mathbf{a}' \lneq \mathbf{a}$. Now let P be the line segment from $\mathbf{0}$ to $\mathbf{a}$. By the assumption of concavity and the fact that $\mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) = \mathbf{0}$, we have $\mathbf{u}(\mathbf{p}) \leq \mathbf{u}(\mathbf{a})$ for all $\mathbf{p} \in P$. Thus, by Lemma 12, we have $\mathbf{a}' \lneq \mathbf{0}$ and so $\mathbf{a}'$ cannot exist and $\mathbf{a}$ is a core outcome.

Now suppose that $\mathbf{a}$ is not a Lindahl equilibrium, and so $\mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) \neq \mathbf{0}$. If we have $\mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) \lneq \mathbf{0}$, then we have $\mathbf{d_a}\,\mathbf{u}(\mathbf{a}) \gneq \mathbf{0}$ (by differentiability) which implies that $\mathbf{a}$ is not Pareto efficient, and hence is not a core outcome. On the other hand, suppose we have $\mathbf{d_{-a}}\,\mathbf{u}(\mathbf{a}) \gneq \mathbf{0}$. In this case, it is impossible to distinguish $\mathbf{u}$ from the utility function $\mathbf{u}'$ that is affine-linear everywhere and agrees with $\mathbf{u}$ at $\mathbf{a}$ using solely local information. Note that $\mathbf{a}$ is *not* in the core of the economy defined by $\mathbf{u}'$, since we have $u_i(\mathbf{0}) > u_i(a)$ for whichever agent i satisfies $d_{-a}\,u_i(\mathbf{a}) > 0$. Thus, if $\mathbf{a}$ is in fact in the core of the economy defined by $\mathbf{u}$, we will need to inspect non-local information about the economy to differentiate $\mathbf{u}$ from $\mathbf{u}'$. ◀

We note that it is possible to prove Theorem 17 as a corollary directly from Theorem 9, but this proof using the underlying machinery is simpler.

4 Algorithm for Testing Core Membership

Our main algorithmic result is:

▶ **Theorem 18.** *Given an outcome* $\mathbf{a}$ *in a public goods economy, there is an algorithm (in the real-RAM model) that decides whether or not* $\mathbf{a}$ *is in the core by solving* $O(n)$ *convex optimization problems and using* $O(n)$ *additional computation time.*

The algorithm is fairly straightforward. We maintain an "active coalition" C_A throughout, as well as a proof that any agent $i \notin C_A$ must play action $a'_i = 0$ in any deviation $\mathbf{a}'$ from $\mathbf{a}$. It is thus safe to assume that any deviating coalition C satisfies $C \subseteq C_A$. Initially $C_A \leftarrow N$, so this invariant is trivially satisfied. After each round, we either find a deviation for C_A from $\mathbf{a}$, or we remove one new agent from C_A. Thus, if we make it n rounds without finding a deviation, then we have $C_A = \emptyset$ and so no deviation from $\mathbf{a}$ is possible.

4.1 Preprocessing: Confirm Pareto Efficiency of a

Before starting the main algorithm, we run the following two programs, with the purpose of testing whether or not $\mathbf{a}$ is Pareto efficient.

▶ **Program 1.** Choose $\mathbf{v}$ to maximize $\min_i d_v\,u_i(a)$
Subj. to $\mathbf{v} \geq \mathbf{0}, \sum_i v_i = 1$

▶ **Program 2.** Choose $\mathbf{v}$ to maximize $\min_i d_v\, u_i(a)$
Subj. to $\mathbf{v} \leq \mathbf{0}, \sum_i v_i = 1$

Note that the concavity of the optimized function $f(v) := \min_i d_v\, u_i(a)$ is immediate from the concavity of $\mathbf{u}$. By Lemma 13, we may immediately conclude that $\mathbf{a}$ is not Pareto efficient (and thus not in the core) iff either of these programs optimizes at a point $\mathbf{v}^*$ satisfying $f(v^*) > 0$. Otherwise, we proceed with the knowledge that $\mathbf{a}$ is Pareto efficient. A key advantage of this is that, by Lemma 11, we may now restrict our search for a deviation $\mathbf{a}'$ to the bounded box $\mathbf{0} \leq \mathbf{a}' \leq \mathbf{a}$. This opens up the ability to use convex programming algorithms, which typically require bounded domains, in the remainder of the algorithm.[4]

4.2 Main Loop: Shrinking C_A

Each of the n rounds of the algorithm consists of three steps. First, we restrict our attention to the projected economy for the coalition C_A. Second, we run the following program:

▶ **Program 3.** Choose $\mathbf{x}$ to maximize $\min_i u_i(x) - u_i(a)$
Subj. to $\mathbf{0} \leq \mathbf{x} \leq \mathbf{a}_{C_A}$

Let $\mathbf{x}^*$ be a maximizing point of Program 3. We have:

▶ **Lemma 19.** *Either* $\mathbf{u}^{C_A}(\mathbf{x}^*) > \mathbf{u}_{C_A}(\mathbf{a})$ *or* $\mathbf{u}^{C_A}(\mathbf{x}^*) \leq \mathbf{u}_{C_A}(\mathbf{a})$*, and* $\mathbf{x}^*$ *is Pareto efficient.*[5]

Proof. First we argue Pareto efficiency. If $\mathbf{x}'$ is a Pareto improvement on $\mathbf{x}^*$, then by Claim 10 there is another point $\mathbf{x}''$ with $\mathbf{u}(\mathbf{x}'') > \mathbf{u}(x^*)$. This $\mathbf{x}''$ would be a superior maximizing point for Program 3, so there can be no Pareto improvement on $\mathbf{x}^*$.

Next, let $i := \arg\max_i u_i(x^*) - u_i(a)$ and $j := \arg\min_j u_j(x^*) - u_j(a)$. If $u_i(x^*) - u_i(a) > u_j(x^*) - u_j(a)$, then (by the same argument used in Claim 10) we can again obtain a superior maximizing point $\mathbf{x}^{**}$ by slightly increasing the action of agent i from $\mathbf{x}^*$. Thus we have $u_i(x^*) - u_i(a) = u_j(x^*) - u_j(a)$, and it follows that either $\mathbf{u}(\mathbf{x}^*) > \mathbf{u}(\mathbf{a})$ or $\mathbf{u}(\mathbf{x}^*) \leq \mathbf{u}(\mathbf{a})$. ◀

In the former case where $\mathbf{u}(\mathbf{x}^*) > \mathbf{u}(\mathbf{a})$, it follows that $\mathbf{x}^*$ is a deviation from $\mathbf{a}$ for the coalition C_A, so we may halt the algorithm. Otherwise, we have $\mathbf{u}(\mathbf{x}^*) \leq \mathbf{u}(\mathbf{a})$. We then observe:

▶ **Lemma 20.** *If* $\mathbf{u}^{C_A}(\mathbf{x}^*) \leq \mathbf{u}_{C_A}(\mathbf{a})$*, then in the full (non-projected) economy, any deviation* $\mathbf{a}'$ *from* $\mathbf{a}$ *for a coalition* $C \subseteq C_A$ *satisfies* $\mathbf{a}'_{C_A} \lneq \mathbf{x}^*$.

Proof. The deviation $\mathbf{a}'$ satisfies $\mathbf{a}'_{N \setminus C} = \mathbf{0}$ and $\mathbf{u}_C(\mathbf{a}') > \mathbf{u}_C(\mathbf{a}) \geq \mathbf{u}_C(\mathbf{x}^*)$. It follows that $\mathbf{a}'_C$ is also a deviation for C from $\mathbf{x}^*$ in the projected economy for C_A. The claim is then immediate from Lemma 11. ◀

One step remains. We run:

▶ **Program 4.** Choose $\mathbf{v}$ to maximize $\min_i d_v\, u_i(x^*)$
Subj. to $\mathbf{v} \leq \mathbf{0}, \sum_i v_i = 1$

[4] This detail is precisely why we use Programs 1 and 2 to check the Pareto efficiency of $\mathbf{a}$, rather than the ostensibly simpler method of searching for $\mathbf{x}^*$ that maximizes $\min_i u_i(x^*) - u_i(a)$: the latter method requires a search for $\mathbf{x}^*$ over an unbounded search space, which rules out many popular methods of convex optimization that we wish to keep available.

[5] Note that these statements hold specifically in the projected economy for C_A.

Algorithm 1: Testing Core Membership of $\mathbf{a}$.

Let $\mathbf{v}_1^* \leftarrow$ output of Program 1;
Let $\mathbf{v}_2^* \leftarrow$ output of Program 2;
if $\mathbf{d}_{\mathbf{v}_1^*}\mathbf{u}(\mathbf{a}) > \mathbf{0}$ *or* $\mathbf{d}_{\mathbf{v}_1^*}\mathbf{u}(\mathbf{a}) > \mathbf{0}$ **then**
  return "$\mathbf{a}$ *is not in the core*";
end
$C_A \leftarrow N$;
while $C_A \neq \emptyset$ **do**
  $\mathbf{x}^* \leftarrow$ output of Program 3;
  if $\mathbf{u}^{C_A}(\mathbf{x}^*) > \mathbf{u}_{C_A}(\mathbf{a})$ **then**
    return "$\mathbf{a}$ *is not in the core*";
  end
  $\mathbf{v}^* \leftarrow$ output of Program 4;
  $C_A \leftarrow C_A \setminus \{\arg\min_{i \in C_A} x_i^*/v_i^*\}$;
end
return "$\mathbf{a}$ *is in the core*";

Let $\mathbf{v}^*$ be a point that maximizes Program 4. We have

▶ **Lemma 21.**

$$\mathbf{d}_{\mathbf{v}^*}\mathbf{u}(\mathbf{x}^*) \leq \mathbf{0}\,.$$

The proof is very similar to the proof of Lemma 19, so we omit it for now. We then finally have:

▶ **Lemma 22.** *Let* $i := \arg\min_i x_i^*/v_i^*$. *Then any deviation* $\mathbf{a}'$ *from* $\mathbf{a}$ *has* $a_i' = 0$.

Proof. By Lemma 20, we have $\mathbf{a}'_{C_A} \lneq \mathbf{x}^*$. Let P be the line segment starting at $\mathbf{x}^*$, extending in the direction $\mathbf{v}^*$ until a point $\mathbf{p}^*$ is reached where $p_i^* = 0$ for some agent i; note that this will specifically be $i = \arg\min_i x_i^*/v_i^*$. By concavity, all $\mathbf{p} \in P$ satisfies $\mathbf{u}(\mathbf{p}) \leq \mathbf{u}(\mathbf{x}^*) \leq \mathbf{u}(\mathbf{a})$. Noting once again that $\mathbf{a}'_{C_A}$ is a deviation for C from $\mathbf{x}^*$ in the projected economy for C_A, it follows from Lemma 12 that $\mathbf{a}'_{C_A} \lneq \mathbf{p}^*$, and so $a_i' = 0$. ◀

With this in mind, the final step in the loop is to delete i from C_A and repeat. After n repetitions, we have $C_A = \emptyset$, so we may halt the algorithm and report that $\mathbf{a}$ is in the core.

4.3 Algorithm Pseudocode

To recap the algorithm, which has been interspersed with proofs of correctness above, we give full pseudocode here.

4.4 Conclusion

Our algorithm implies that core membership testing is efficient under any utility function that admits quick solving of convex programs as described above. However, it may still be desirable to test core membership as best as possible when the underlying utility function is either unknown or badly behaved and so exact convex optimization is impossible. Our algorithm can indeed be adapted to this effect, with a few significant points of caution, by substituting in modern approximate optimization algorithms. Due to space constraints, we defer a discussion of this point to the full version of the paper.

Abstract

In a Stackelberg Pricing Game a distinguished player, the *leader*, chooses prices for a set of items, and the other players, the *followers*, each seeks to buy a minimum cost feasible subset of the items. The goal of the leader is to maximize her revenue, which is determined by the sold items and their prices. Most previously studied cases of such games can be captured by a combinatorial model where we have a base set of items, some with fixed prices, some priceable, and constraints on the subsets that are feasible for each follower. In this combinatorial setting, Briest et al. and Balcan et al. independently showed that the maximum revenue can be approximated to a factor of $H_k \sim \log k$, where k is the number of priceable items.

Our results are twofold. First, we strongly generalize the model by letting the follower minimize any continuous function plus a linear term over any compact subset of $\mathbb{R}^n_{\geq 0}$; the coefficients (or *prices*) in the linear term are chosen by the leader and determine her revenue. In particular, this includes the fundamental case of linear programs. We give a tight lower bound on the revenue of the leader, generalizing the results of Briest et al. and Balcan et al. Besides, we prove that it is strongly NP-hard to decide whether the optimum revenue exceeds the lower bound by an arbitrarily small factor. Second, we study the parameterized complexity of computing the optimal revenue with respect to the number k of priceable items. In the combinatorial setting, given an efficient algorithm for optimal follower solutions, the maximum revenue can be found by enumerating the 2^k subsets of priceable items and computing optimal prices via a result of Briest et al., giving time $O(2^k|I|^c)$ where $|I|$ is the input size. Our main result here is a W[1]-hardness proof for the case where the followers minimize a linear program, ruling out running time $f(k)|I|^c$ unless $\mathsf{FPT} = \mathsf{W}[1]$ and ruling out time $|I|^{o(k)}$ under the Exponential-Time Hypothesis.

1 Introduction

Pricing problems are fundamental in both economics and mathematical optimization. In this paper we study such pricing problems formulated as games, which are usually called *Stackelberg Pricing Games* [18]. In our setting, in order to maximize her revenue one player chooses prices for a number of items and one or several other players are interested in buying these items. Following the standard terminology, the player to choose the prices is called the *leader* while the other players are called *followers*. Depending on the follower's preferences,

computing optimal prices can be a computational non-trivial problem. In a setting where followers have valuations over individual items only, the problem is simple. If, however, valuations become more complex, e.g., over whole subsets of items, pricing problems become much harder–also in a formal sense.

Largely the literature has focused on what we call the *combinatorial setting*: there is a set Y of items and one follower seeks to buy a feasible subset. Some of the items have fixed costs, the others have prices that are chosen by the leader. If the follower buys a feasible subset $S \subseteq Y$ of the items, he has to pay the sum of the fixed costs of the elements of S, plus the leader's prices of the bought elements. The leader's revenue is the sum of the prices of the priceable items in S. This can also be captured by defining a solution space X containing 0/1-vectors corresponding to the feasible subsets S of Y. The goal of the follower is then to minimize a given additive function $f\colon X \to \mathbb{R}$ that depends on both fixed and leader-chosen prices.

So-called Stackelberg Network Pricing Games became popular when Labbé et al. [15] used them to model road toll setting problems. In this game, the leader chooses prices for a subset of *priceable* edges in a network graph while the remaining edges have fixed costs. Each follower has a pair of vertices (s, t) and wants to buy a minimum cost path from s to t, taking into account both the fixed costs and the prices chosen by the leader. The work of Labbé et al. led to a series of studies of the Stackelberg Shortest Path Game. Roche et al. [16] showed that the problem is NP-hard, even if there is only one follower, and it has later been shown to be APX-hard [5, 14]. More recently, other combinatorial optimization problems were studied in their Stackelberg pricing version. For example, Cardinal et al. [9, 10] studied the Stackelberg Minimum Spanning Tree Game, proving APX-hardness and giving some approximation results. Moreover, a special case of the Stackelberg Vertex Cover Game in bipartite graphs has been shown to be polynomially solvable by Briest et al. [7].

To get more familiar with the setting, we briefly discuss an example of the Stackelberg Minimum Spanning Tree Game.

▶ **Example 1.** The left hand side of Figure 1 depicts an instance of the problem. Here the leader can choose the prices p_1, p_2 and p_3 for the dashed edges, while the solid edges have fixed costs as displayed. To motivate the problem, think of the vertices as hubs in a network and of the edges as data connections. In this scenario, the followers are Internet Service Providers and want to connect all the hubs at minimum cost, thus want to compute a minimum spanning tree. The leader owns the dashed connections and wants to set prices, that yield a large revenue. Furthermore, there are competitors who own the solid connections and it is known how much they charge for their usage.

On the right hand side, an optimal pricing ($p_1 = p_2 = 5$ and $p_3 = 4$) and a corresponding minimum spanning tree are depicted. Thus the leader's revenue amounts to 9, which can be verified to be maximum. Observe that we can compute a minimum spanning tree without

any priceable edges; otherwise the leader's revenue is unbounded. In this example, the total cost of such a minimum spanning tree is 17. In contrast, if we set all prices to 0 and let the follower compute a minimum spanning tree, it has a total cost of 8. The difference of these two values, $17 - 8 = 9$, is an upper bound on the revenue of the leader, as explained later. This upper bound, which we denote by R, is sometimes called the optimal *social welfare* and will be important for our approximation result.

An important contribution to the study of Stackelberg Games was the discovery by Briest et al. [7]. They show that the optimal revenue can be approximated surprisingly well using a single-price strategy. For a single-price strategy the leader sets the same price for all of her priceable items. Basically, their result says the following: In any Network Pricing Game with k priceable items, there is some $\lambda \in \mathbb{R}_{\geq 0}$ such that, when assigning the price of λ to all priceable items at once, the obtained revenue is only a factor of H_k away from the optimal revenue. Here, $H_k = \sum_{i=1}^{k} 1/i$ denotes the *k-th harmonic number*. This discovery has been made independently, in a slightly different model, by Balcan et al. [2]. Actually, in both papers [2, 7] a stronger fact is proven: The single-price strategy yields a revenue that is at least R/H_k, where R is a natural upper bound on the optimal revenue. The definition of R was sketched in the example above, and is formally laid out later.

Our results. Our work focuses on pushing the knowledge on Stackelberg Pricing Games beyond the well-studied combinatorial setting, in order to capture more complex problems of the leader. This is motivated by the simple fact that the combinatorial setting is too limited to even model, e.g., a follower that has a minimum cost flow problem—a crucial problem in both, combinatorial optimization and algorithmic game theory. More generally, we might want to be able to give bounds and algorithms in the case when the follower has an arbitrary linear or even convex program. For example, the follower might have a production problem in which he needs to buy certain materials from the leader, but such pricing problems haven't been discussed in the literature so far.

We prove an approximation result that applies even to a setting generalizing linear and convex programs. In our model, the follower minimizes a continuous function f over a compact set of feasible solutions $x \in X \subseteq \mathbb{R}^n_{\geq 0}$. For some of the variables, say x_1 up to x_k, the leader can choose a price vector $p \in \mathbb{R}^k$. Now the follower chooses a vector $x \in X$ that minimizes his objective function $f(x) + \sum_{i=1}^{k} p_i x_i$. We remark that if X is a set containing 0/1-vectors only, then we are back to the classical combinatorial setting. The result of Briest et al. can be transferred to the case when f is non-additive, in view of their original proof. Moreover if X is a polytope and f is additive, the follower minimizes a linear program, which is an important special case.

In Section 2, we formally introduce this more general model and prove the following results.

- **(i)** The maximum revenue obtainable by the leader can be approximated to a logarithmic factor using a single-price strategy. This generalizes the above mentioned result of Briest et al. [7] not only to linear programs but to any kind of follower that is captured by our model.
- **(ii)** The analysis of point (i) is tight. There is a family of instances for which the single-price strategy yields maximum revenue. And this revenue meets the bound of point (i).
- **(iii)** It is strongly NP-hard to decide whether one can achieve a revenue that is only slightly larger than the one guaranteed by the single-price strategy. This holds true even in a very restricted combinatorial setting.

The second part of the paper deals with the parameterized complexity of Stackelberg Pricing Games (Section 3). To the best of our knowledge, the only result in this direction is

an XP-algorithm by Cardinal et al. [10] for the Stackelberg Minimum Spanning Tree Game in graphs of bounded treewidth.

In contrast to structural parameters like the treewidth of the input graph, we consider the complexity of the pricing problem when parameterized by the number of priceable variables (or items in the combinatorial setting). Our main result in this part is a W[1]-hardness proof for the case that the optimization problem of the follower is a linear program, which is arguably one of the most interesting cases that does not fit into the combinatorial setting. This rules out algorithms of running time $f(k)|I|^c$ unless FPT = W[1] for any function f and polynomial $|I|^c$ of the input size; it also rules out running time $|I|^{o(k)}$ under the Exponential-Time Hypothesis of Impagliazzo et al. [13]. This intractability result is complemented by a fairly simple FPT-algorithm with running time $O(2^k|I|^c)$ for any Stackelberg Game that fits into the combinatorial model, when provided with an efficient algorithm for finding optimal follower solutions. The algorithm enumerates all subsets of priceable items and applies a separation argument of Briest et al. [7] to compute optimal leader prices and revenue.

Related work. Most important for our work are the approximation results due to Briest et al. [7] and Balcan et al. [2], which were discussed above.

A larger body of work focuses on specific network problems in their Stackelberg Game version. Briest et al. [7] give a polynomial time algorithm for a special case of the Stackelberg Bipartite Vertex Cover Game. An algorithm with improved running time was later given by Baïou and Barahona [1]. As mentioned, Labbé et al. [15] use the Stackelberg Shortest Path Game to model road toll setting problems. They establish NP-hardness and use LP bilevel formulations to solve small instances. A combinatorial approximation algorithm with the same logarithmic approximation guarantee as the single-price strategy was given by Roch et al. [16]. Moreover, a lower bound on the approximability is due to Briest et al. [5]: they show that the Stackelberg Shortest Path Game is NP-hard to approximate within a factor of less than 2. This is an improvement over previous results by Joret [14] showing APX-hardness. Further research on the Stackelberg Shortest Path Game can be found in a survey by van Hoesel [17]. A similar problem, the Stackelberg Shortest Path Tree Game, is studied by Bilo et al. [4]. They give an NP-hardness proof and develop an efficient algorithm assuming that the number of priceable edges is constant. Later their algorithm was improved by Cabello [8].

Cardinal et al. [9] proved several positive approximation results for the Stackelberg Minimum Spanning Tree Game. In the same paper, they proved that the revenue maximization for this game is APX-hard and strongly NP-hard. We make use of their reduction in the proof of Theorem 7. Furthermore, Cardinal et al. [10] prove that this game remains NP-hard if the instances are planar graphs. However, the problem becomes polynomial-time solvable on graphs of bounded treewidth. Bilo et al. [3] consider the Stackelberg Minimum Spanning Tree Game for complete graphs.

Briest et al. [6] consider Stackelberg Games where the follower's optimization problem cannot be solved to optimality. Instead the follower uses a known approximation algorithm. They show that the Stackelberg Knapsack Game is NP-hard if the follower uses a greedy 2-approximate algorithm, and derive a $2 + \epsilon$ approximation algorithm. Furthermore, the revenue maximization problem can be solved efficiently in the Stackelberg Vertex Cover Game if the follower implements a primal-dual approximation.

2 Approximability of Stackelberg Pricing Games

In this section we first introduce the model in its full generality. Then we give a tight approximation result on the maximum revenue using a single-price strategy. We complement

this with a hardness proof by showing that deciding whether one can achieve a revenue that is only slightly larger than the one guaranteed by the single-price strategy is strongly NP-hard.

Our model. Let k and n be some natural numbers with $k \leq n$. The optimization problem of the follower is the following: He minimizes a continuous function $f : \mathbb{R}^n \to \mathbb{R}$ over his set of feasible solutions $X \subseteq \mathbb{R}^k_{\geq 0} \times \mathbb{R}^{n-k}_{\geq 0}$. The only restriction we put on X is that we require it to be a compact set, i.e., bounded and closed under limits.

The first move of the Stackelberg Pricing Game is made by the *leader*: She chooses a *price vector* $p \in \mathbb{R}^k$. Now the second move is made by the *follower*: He chooses an optimal solution (x^*, y^*) of the program

$$\begin{aligned} \min \quad & p^T x + f(x, y) \\ \text{s.t.} \quad & (x, y) \in X. \end{aligned}$$

The *revenue* of the leader is then given by the value $p^T x^*$. This value is her objective function and it is to be maximized. We remark that this problem has a bilevel structure.

To avoid technicalities, we make the following optimistic assumption: If the follower has several optimal solutions in X, we assume that the solution which is most profitable for the leader is chosen. That is the solution, which maximizes the value $p^T x^*$. Moreover, we assume that there is a point $(x, y) \in X$ with x being the k-dimensional all-zeroes vector. This simply means that the follower has a solution that does not give any revenue to the leader. Otherwise the revenue maximization problem would be unbounded which is obviously not an interesting case.

Before we can state our results for the new model, we need to introduce a number of technical notions. Given a feasible solution $(x, y) \in X$ of the follower, we call the value $\mathbf{1}^T x = \sum_{i=1}^{k} x_i$ the *mass* of (x, y). A *single-price* is a price vector p of the form $p = \lambda \mathbf{1}$ where λ is some real number. Slightly abusing notation, we sometimes call λ the single-price. Note that when the leader uses a single-price the revenue is simply the mass of the follower's solution times the single-price.

Let M be the maximum mass the follower buys if the leader sets all her prices to 0. Formally,

$$\begin{aligned} M := \max \quad & \mathbf{1}^T x \\ \text{s.t.} \quad & \exists y \in \mathbb{R}^{n-k} : \ (x, y) = \arg\min\{f(x', y') : (x', y') \in X\}. \end{aligned}$$

This value M exists since X is a compact set.

Consider, for example, the case where the follower seeks to buy a shortest s-t-path in a network. Then M is the maximum number of priceable edges of a shortest s-t-path in the network, when the priceable edges all have a price of 0 and thus can be bought for free by the follower.

Since X is a compact set, there exists a largest single-price at which the follower buys a non-zero mass from the leader. Let μ be the maximum mass the follower buys at this price. Consider again the case where the follower searches for a shortest s-t-path in a network. Then μ is the maximum number of priceable edges contained in a shortest s-t-path, under the largest single-price for which a shortest path exists that contains a priceable edge.

For all $m \in [0, M]$, let $\Delta(m)$ be the minimum price the follower has to pay if he buys a mass of at most m from the leader. More formally

$$\begin{aligned} \Delta(m) := \min \quad & f(x, y) \\ \text{s.t.} \quad & \mathbf{1}^t x \leq m \\ & (x, y) \in X, \end{aligned}$$

where $\mathbf{1}^t x$ is the mass bought by the follower. This minimum price $\Delta(m)$ exists, because X with the additional constraint of $\mathbf{1}^t x \leq m$ is again a compact set.

As observed by several authors (cf. [2, 5]), an upper bound on the optimum revenue is $R := \Delta(0) - \Delta(M)$. To see this, let r^* be the maximum revenue, and let (x^*, y^*) be the corresponding follower's solution. We have

$$r^* + \Delta(M) \leq r^* + \Delta(\mathbf{1}^T x^*) \leq r^* + f(x^*, y^*) \leq \Delta(0),$$

because $\Delta(0)$ is an upper bound on the objective value of the follower and Δ is non-increasing. We remark that R is indeed a tight upper bound, in the sense that there are examples of games where the maximum revenue equals R, e.g., the minimum spanning tree pricing problem described in the introduction.

As our first result shows, the maximum revenue of the leader is always reasonably close to R, unless the ratio M/μ is large. This is true even if the leader uses a single-price strategy.

▶ **Theorem 2.** *There is a single-price for the Stackelberg Pricing Game over X whose revenue is at least*

$$\frac{R}{1 + \ln\left(\frac{M}{\mu}\right)}.$$

This result extends previous work of Briest et al. [7] and Balcan et al. [2], who proved the above theorem in the combinatorial setting, i.e., for $X \subseteq \{0, 1\}^n$. We give the main idea of the proof of Theorem 2 in the following sketch and defer the full proof to the appendix.

Proof Sketch for Theorem 2. Our proof makes use of the following concept. For each $m \in (0, M]$, let $P(m)$ be the supremum of all single-prices for which the follower has an optimal solution with a mass of at least m from the leader. Using the compactness of X and the continuity of f one can prove that at the single-price of $P(m)$, the follower has an optimal solution of a mass of at least m. Thus, the supremum is indeed a maximum here.

It turns out that there are certain mass values which dictate the value of the function P. Let $T \subseteq (0, M]$ be the set of mass values t for which the follower does not have an optimal solution, at a single-price $P(t)$, with a mass more than t. The set T plays a key role in our proof, as the following claim indicates.

▶ **Claim 3.** *It holds that $\mu \in T$, $M \in T$ and $\mu = \min T$. Moreover, for all $m \in (0, M]$ it holds that $P(m) = \max_{t \in T \cap [m, M]} P(t)$.*

Recall that $\Delta(m)$ is defined as the price the follower has to pay for the non-priceable variables if he buys a mass of at most m from the leader. Similar to the proof of Briest et al. [7] for the combinatorial setting, we next show that the functions P and Δ are closely related. In our case, however, we have to deal with several difficulties that arise because we allow for non-discrete optimization problems of the follower.

Consider the lower convex hull H of the point set $\{(m, \Delta(m)) : 0 \leq m \leq M\}$. Let ∂H be the lower border of H, and let $\hat{\Delta} : [0, M] \to \mathbb{R}$ be the function for which $(m, \hat{\Delta}(m)) \in \partial H$ for all $m \in [0, M]$. We remark that, since $\hat{\Delta}$ is convex and decreasing,

$$D_-\hat{\Delta}(m) = \sup_{\ell<m} \frac{\hat{\Delta}(m) - \hat{\Delta}(\ell)}{m - \ell}, \text{ for each } m \in (0, M].$$

Here, D_- denotes the *lower left Dini derivative* of $\hat{\Delta}$. It is defined, for all $m \in (0, M]$, by

$$D_-\hat{\Delta}(m) = \liminf_{h\to 0^-} \frac{\hat{\Delta}(m) - \hat{\Delta}(m+h)}{h}.$$

As our main claim shows, the values of $P(m)$ and $D_-\hat{\Delta}(m)$ are essentially equal.

▶ **Claim 4.** *Except for a set of measure 0, it holds for all $m \in (0, M)$ that $D_-\hat{\Delta}(m) = -P(m)$.*

To establish Claim 4 is indeed the difficult part of the whole proof. We skip the details due to space constraints.

In the calculation that finishes the proof we make use of the inverse operation of the lower left Dini derivative, the so-called *lower left Dini integral*, denoted $(LD)\underline{\int}$. For more background we refer to the article of Hagood and Thomson [11].

We have

$$R = \Delta(0) - \Delta(M) = \hat{\Delta}(0) - \hat{\Delta}(M) = \lim_{\epsilon\to 0^+} \hat{\Delta}(\epsilon) - \hat{\Delta}(M) = \lim_{\epsilon\to 0^+} (\text{LD}) \underline{\int_\epsilon^M} -D_-\hat{\Delta}(m)\, dm.$$

Due to Claim 4, the integral

$$\lim_{\epsilon\to 0^+} (\text{LD}) \underline{\int_\epsilon^M} P(m)\, dm$$

is well defined and equals

$$\lim_{\epsilon\to 0^+} (\text{LD}) \underline{\int_\epsilon^M} - D_-\hat{\Delta}(m)\, dm.$$

Recall that, by Claim 3, $\mu = \min T$ and so $P(m) = P(\mu)$ for all $m \in (0, \mu]$. Hence,

$$\begin{aligned}\lim_{\epsilon\to 0^+} (\text{LD}) \underline{\int_\epsilon^M} P(m)\, dm &= \lim_{\epsilon\to 0^+} (\text{LD}) \underline{\int_\epsilon^\mu} P(m)\, dm + (\text{LD}) \underline{\int_\mu^M} P(m)\, dm \\ &= \mu \cdot P(\mu) + (\text{LD}) \underline{\int_\mu^M} P(m)\, dm.\end{aligned}$$

Let r be the maximum revenue achieved by the single-price strategy. Note that r is at least the revenue at the single-price $P(m)$, for each $m \in (0, M]$, which is in turn at least $m \cdot P(m)$. We thus have

$$\begin{aligned}\mu \cdot P(\mu) + (\text{LD}) \underline{\int_\mu^M} P(m)\, dm &= \mu \cdot P(\mu) + (\text{LD}) \underline{\int_\mu^M} \frac{m \cdot P(m)}{m}\, dm \\ &\leq r + (\text{LD}) \underline{\int_\mu^M} \frac{r}{m}\, dm \\ &= r + r \cdot (\ln(M) - \ln(\mu)) \\ &= r\left(1 + \ln\left(\frac{M}{\mu}\right)\right).\end{aligned}$$

This shows that $R \leq r(1 + \ln(M/\mu))$, as desired. ◀

Balcan et al. [2] and Briest et al. [7] extend their result to the situation when there are several followers.[1] The same approach works in our generalized model.

Assume there are ℓ followers and each follower has its own optimization problem. Formally, the i-th follower minimizes his objective function $p^T x^i + f_i(x^i, y^i)$ where (x^i, y^i) belongs to the set $X_i \subseteq \mathbb{R}^k_{\geq 0} \times \mathbb{R}^{n-k}_{\geq 0}$ of his feasible solutions, $i = 1, \ldots, \ell$. The pricing vector p appears in the objective function of every follower and is again set by the leader in order to maximize her revenue $\sum_{i=1}^{\ell} p^T x^i$. The difficulty here is that, while each follower has an individual optimization problem, the leader can set only one price vector for all followers at once. There is, however, a canonical way of reducing the pricing game to the case of a single follower. To this end, we consider the pricing game with respect to follower i only, and let μ_i (resp. M_i) be the minimum non-zero mass (resp. the maximum mass) bought by follower i. Moreover, let R_i be the upper bound on the revenue with respect to follower i.

▶ **Corollary 5.** *There is a single-price for the Stackelberg Pricing Game with ℓ followers whose revenue is at least*

$$\frac{\sum_{i=1}^{\ell} R_i}{1 + \ln\left(\frac{\sum_{i=1}^{\ell} M_i}{\min_{i=1}^{\ell} \mu_i}\right)}.$$

To see this, consider a single follower with the feasible subset $X = X_1 \times X_2 \times \ldots \times X_\ell$. It is easy to see that we have $M = \sum_{i=1}^{\ell} M_i$ and $R = \sum_{i=1}^{\ell} R_i$ in this game. Moreover, the smallest non-zero mass μ bought by the newly defined single follower is at least the minimum smallest non-zero mass bought by one of the ℓ followers, that is $\min_{i=1}^{\ell} \mu_i$. Now applying Theorem 2 to the single follower yields Corollary 5.

Theorem 2 is tight in the following sense.

▶ **Proposition 6.** *There are Stackelberg Pricing Games of arbitrarily large R and M in which the optimum revenue equals*

$$(1 + o(1)) \cdot \frac{R}{1 + \ln\left(\frac{M}{\mu}\right)}.$$

This holds true even for games in which the follower minimizes a linear objective function of the form $p^T x + c^T y$ over a uniform matroid.

Note that, in the above statement, every possible pricing is considered and not just single-price strategies. In other words, the lower bound in Theorem 2 is tight not only for single-price strategies, but for arbitrary pricings. So far, it was known that there are combinatorial pricing games where the optimum revenue is in $O(R/\log k)$, where k is the number of priceable elements (cf. [5]). The merit of Proposition 6 is that it shows tightness of Theorem 2 up to a factor of $1 + o(1)$, which is best possible. This fact, and the construction given in the proof of Proposition 6, enable us to prove the following hardness result.

▶ **Theorem 7.** *Fix a sufficiently small rational number $\epsilon > 0$, and consider a Stackelberg Pricing Game where the follower minimizes an objective function of the form $p^T x + c^T y$ over a matroid. It is strongly NP-hard to decide whether there is some pricing of revenue at least*

$$(1 + \epsilon) \cdot \frac{R}{1 + \ln\left(\frac{M}{\mu}\right)}.$$

[1] In this paper we consider the case of *unlimited supply*, meaning that the followers buy their favorite solution independently of each other.

Due to space constraints, the proof of Theorem 7 is deferred to the appendix. In the statement of the above theorem, we assume that the matroid is given by its ground set and a membership oracle. Thus, μ, M, and R can be computed in polynomial time. Moreover, it will be clear from the proof that the natural logarithm can be computed in polynomial time with the precision needed to decide the problem.

Let us remark that the assumption of ϵ being *sufficiently small* is merely technical, and can be dropped by giving a more careful hardness reduction. The message of the above theorem is, however, that there is a sharp contrast between the revenue guaranteed by the simple single-price strategy given in Theorem 2 and anything more than that.

3 Parameterized complexity of Stackelberg Pricing Games with few priceable objects

In this section we study the parameterized complexity of Stackelberg Pricing Games when parameterized by the number of priceable objects. Intuitively, this addresses the question of whether there are improved algorithms for the case that only few objects are priceable. We give a general positive result for the combinatorial model. Our main result in this part, however, is a hardness proof for the linear programming case; we begin with the latter.

In the LP-PRICING problem there is a linear program over which the follower minimizes. The leader may choose the price, i.e. target function coefficient, of k specified variables. Her revenue is determined by the corresponding (weighted) sum over these variables.

LP-PRICING
Input: A linear program with k priceable variables and $\lambda \in \mathbb{Q}$.
Question: Is there a price vector whose revenue is at least λ?

We prove that this problem is at least as hard to solve as the parameterized k-clique problem. The hardness proof creates linear programs with only non-negative variables and non-negative target function over which the follower seeks to minimize. As such it proves hardness also for our more general model parameterized by number of priceable variables.

▶ **Theorem 8.** LP-PRICING *is* W[1]*-hard when parameterized by the number k of priceable variables.*

The theorem is proven by a reduction from the well-known (parameterized) MULTI-COLORED CLIQUE problem. Therein, we are given a k-partite graph G (or, equivalently, a properly k-colored graph) and have to determine whether G contains a clique on k vertices; the problem is W[1]-hard with respect to parameter k. Thus, unless FPT = W[1], there is no algorithm running in time $f(k)n^c$ for instances of size n. Moreover, under the Exponential-Time Hypothesis [13] the reduction implies that there is no $O(n^{o(k)})$ time algorithm for LP-PRICING. In instances created by the reduction the leader can effectively enforce the choice of the k clique vertices by setting appropriate prices for k variables; the remaining variables are used to verify the choice and a certain revenue threshold can only be attained if there is indeed a k-clique. The behavior of these k priceable variables is quite similar to integer variables, as they can be shown to only take specific values from a finite set in solutions meeting the threshold (one value corresponding to each vertex of G). This arguably gives our parameterized LP PRICING problem some similarity to the MIXED ILP FEASIBILITY problem parameterized by the number of integer variables. Interestingly, the latter problem is FPT due to a classic result of Lenstra [12]. Due to space constraints we will restrict ourselves to an informal description of the reduction complemented by some intuition.

Proof Sketch for Theorem 8. We give a parameterized reduction from the W[1]-hard MULTICOLORED CLIQUE(k) problem. Therein, we are given a k-partite graph $G = (V_1, \dots, V_k, E)$ and have to determine whether it contains a clique of size k, i.e., a clique containing exactly one vertex from each partite set. The reduction is polynomial-time computable and creates an instance of LP-PRICING with $k + 1$ priceable variables, proving W[1]-hardness of LP-PRICING.

Much effort in the design of the linear program and the correctness proof goes into setting up constraints on k pairs of variables (x_i, y_i) and forcing each pair to take a value in $\{(p_1, q_1), \dots, (p_n, q_n)\}$; each x_i is priceable and the y_i have fixed prices. We have $p_1 > p_2 > \dots > p_n$ and $q_1 < q_2 < \dots < q_n$ with the high-level idea that changing the price of x_i will make a particular point (p_j, q_j) optimal. Each choice of $(x_i, y_i) = (p_j, q_j)$ corresponds to the selection of one vertex (i, v_i) from the ith partite set V_i of G. Additionally, there are variables $z_{i,j} \geq |y_i - q_j|$ that serve as indicators for whether $y_i = q_j$, and clique-testing constraints on pairs of variables $z_{i,u}, z_{j,v}$ for every non-edge $\{(i, u), (j, v)\}$ of G to prevent choosing both (i, u) and (j, v) for the clique. Notably, there is a single slack variable y_0 present in all clique-testing constraints that is connected to a priceable variable x_0 in such a way that the maximum revenue c_0 for x_0 is only possible if the slack y_0 is not needed, i.e., if all clique-testing constraints are active.

The reader will have noticed that there are no constraints that we could pose in a linear program that would enforce $(x_i, y_i) \in \{(p_1, q_1), \dots, (p_n, q_n)\}$. Instead, the points (p_j, q_j) are the extremal points (when projected to two dimensions) of certain constraints on each pair x_i and y_i; we call these the *core constraints*. There are intended prices $r_1, \dots, r_n$ with the goal of showing that setting the leader price d_i of x_i to r_j leads to $(x_i, y_i) = (p_j, q_j)$ being uniquely optimal. This would probably be easier if we could restrict to $d_i \in \{r_1, \dots, r_n\}$, but we are not allowed to do so. Instead, the strategy is roughly as follows:

1. Consecutive pairs of points (p_j, q_j) and (p_{j+1}, q_{j+1}) are chosen in such a way that for $d_i = r_j$ all choices of (x_i, y_i) on the line segment defined by the two points give the same follower cost including updates to indicator variables $z_{i,j}$. (This is rather helpful for replacement arguments, which we use to disprove solutions not following intended behavior, but does not cover the variable y_0.) The leader payoff in this case is highest for $x_i = p_j$ as $p_j > p_{j+1}$, and we have $r_j := \frac{1}{p_j}$ so that the payoff is exactly 1 in this case.
2. A critical issue is that we must make sure that the leader cannot make a profit larger than 1 with any variable x_i since that may be more beneficial than attempting to gain the revenue for having the clique-testing constraints fulfilled without increasing the slack variable y_0 above 0.
3. A significant part of the proof hence goes towards a technical claim that allows to rule out both profit greater than one for any variable x_i and the case that $p_s > x_i > p_{s+1}$, i.e., that x_i lies between two intended coordinates. To this end, the core constraints on pairs (x_i, y_i) contain varying numbers of slack variables $w_{i,1}, \dots, w_{i,n}$ of fixed prices $r_1, \dots, r_n$. These are placed in such a way that they provide alternative ways of satisfying the core constraints when $d_i \notin \{r_1, \dots, r_n\}$, without keeping the follower from actually paying the full price of x_i in other cases.

We remark that the correctness proof of course also requires the reverse direction of ensuring leader payoff at least $k + c_0$ if G has a clique of size k. Here we are in the easier situation of being able to select leader prices and fixing a suggested solution. We then prove feasibility, which is straightforward, and optimality, which requires combining most of the constraints into a lower bound on the optimal follower cost that matches that of our suggested solution. ◀

Theorem 8 is in sharp contrast to the combinatorial setting, where under mild assumptions one can see the problem to be fixed-parameter tractable. Here we assume that $X \subseteq \{0,1\}^n$ but put no further restriction on the follower's objective function $f : X \to \mathbb{R}$. In particular, this model covers the classical setting where each item has a fixed cost and if the follower buys a set S of items, he has to pay the sum of the fixed costs of the elements of S, plus the leader's price of the bought elements.

▶ **Theorem 9.** *Assume that $X \subseteq \{0,1\}^n$, and that we are given a polynomial-time algorithm to compute an optimal solution of the follower for given leader prices $p \in \mathbb{R}^k$. Then the computation of optimal prices and optimal leader revenue is fixed-parameter tractable, with running time $\mathcal{O}(2^k n^c)$, when parameterized by the number of priceable items.*

In the above statement we make the natural assumption that the input size is at least $n + \text{size}(f)$, where $\text{size}(f)$ denotes the maximum length of the binary encoding of any value f can take.

Proof Sketch for Theorem 9. Due to space constraints the proofs of the claims in this section are deferred to the appendix. We need the following proposition by Briest et al. [7]. It says that if the leader wants to force the follower to pick a certain solution, she can compute suitable prices in polynomial time. We state their result in a slightly more general fashion than in the original paper. Indeed, Briest et al. were only concerned with the case when f is additive but the proof did not make use of the additivity of f at all.

▶ **Proposition 10** (Briest et al. [7])**.** *Given a vector $z \in X$, one can compute an optimal price vector p such that z is an optimal solution of the follower with respect to p, or decide that such a price vector does not exist, in polynomial time.*

Our algorithm works as follows. For each vector $x \in \{0,1\}^k$ we compute a price vector p_x, if exists, such that

(a) there is some $y \in \{0,1\}^{n-k}$ such that the vector (x,y) is an optimal solution of the follower with respect to the price vector p_x,

(b) subject to (a) the revenue $p_x^T x$ is maximum.

When this procedure is finished we choose the vector $\hat{x} \in \{0,1\}^k$ with maximum value of ${p_{\hat{x}}}^T \hat{x}$, and output the price vector $p_{\hat{x}}$. As the next claim shows, this price vector is the optimum solution.

▶ **Claim 11.** *The output $p_{\hat{x}}$ is an optimal price vector for the leader.*

In the remainder of the proof we show how to compute p_x for a fixed candidate vector $x \in \{0,1\}^k$. First we aim to find a vector $y_x \in \{0,1\}^{n-k}$ such that $(x, y_x) \in X$ and, subject to this, $f(x, y_x)$ is minimum. Note that possibly such a vector y_x does not exist. To find a vector y_x, or decide that none exists, we define a price vector p by setting

$$p_i = \begin{cases} -M & \text{if } x_i = 1, \\ M & \text{if } x_i = 0, \end{cases}$$

for all $i \in [k]$. Here, M is a number that is large enough to ensure that

$$\text{for all } (x', y'), (x'', y'') \in X, \text{ it holds that } f(x', y') - f(x'', y'') < M. \tag{1}$$

As both values $|f(x', y')|$ and $|f(x'', y'')|$ are bounded by $2^{\text{size}(f)}$, we may simply put $M = 2^{\text{size}(f)+1} + 1$.

Now we compute an optimal solution of the follower with respect to the price vector p, say (x^*, y^*), using the assumed polynomial-time algorithm.

▶ **Claim 12.** *If for some $y \in \{0,1\}^{n-k}$ it holds that $(x,y) \in X$, then $x^* = x$.*

If $x^* \neq x$, Claim 12 implies that there is no price vector satisfying (a). Thus, we may safely abort the process and go over to the next candidate vector x. Otherwise if $x^* = x$, we put $y_x = y^*$.

▶ **Claim 13.** *$f(x,y_x) \leq f(x,y)$ holds for all $y \in \{0,1\}^{n-k}$ with $(x,y) \in X$.*

Next, we use Proposition 10 to compute a price vector p_x such that the vector (x,y_x) is optimal for the follower and, subject to that, ${p_x}^T x$ is maximum. Note that this price vector does exist since, e.g., the vector p is a feasible price vector. By construction, p_x has the property (a). So far, we only know that ${p_x}^T x$ is maximum subject to the condition that under the price vector p_x the vector (x,y_x) is an optimal solution of the follower.

▶ **Claim 14.** *Subject to (a), the revenue $p_x^T x$ is maximum.*

As the running time of the whole algorithm is $O(2^k \cdot (n + \text{size}(f))^{O(1)})$, the proof is complete. ◀

4 Conclusion and future work

The basis for the first part of this paper were the results of Briest et al. [7] and Balcan et al. [2] who gave a lower bound on the optimal revenue in Stackelberg Network Pricing Games. We proved that this bound carries over to a much more general setting, where, basically, the follower minimizes a continuous function over a compact set of points. This model captures important settings that are not covered by the classical combinatorial model. For example, the case when the follower is minimizing a linear program, e.g., a minimum cost flow problem.

The proven lower bound also holds if a single-price strategy is applied, and it is tight up to a factor of $(1 + o(1))$. Moreover, we used this tightness example to show that it is strongly NP-hard to decide whether the revenue of an optimal pricing exceeds the lower bound by an arbitrarily small linear factor.

In the second part of the paper we studied the parameterized complexity of the revenue maximization problem. It turned out that in the combinatorial setting (i.e., when the follower only has 0/1-valued solutions) there is an elegant FPT algorithm. Once we leave this regime, however, things become more difficult. Indeed, if the follower has an optimization problem in the form of a linear program, the revenue maximization problem becomes W[1]-hard and is thus most likely not FPT.

Several central questions remain. Most importantly, one should consider multiple-follower scenarios. An intriguing model is when the particular resources have a limited supply. In the combinatorial setting, a limited supply means that every item to be sold is available only a limited number of times. Now the followers come one by one, in a certain order, and buy according to their preferences and the prices set by the leader. Balcan et al. [2] prove a tight lower bound on the revenue obtained by the single-price strategy. In the non-combinatorial model, the limited supply might be translated to a constraint of the form $(x,y) \leq s$, where $s \in \mathbb{R}^n_{\geq 0}$ is a fixed vector that is added to the usual constraint $(x,y) \in X$ in the optimization problem of the followers.

Abstract

We study a dynamic market setting where an intermediary interacts with an unknown large sequence of agents that can be either sellers or buyers: their identities, as well as the sequence length n, are decided in an adversarial, online way. Each agent is interested in trading a single item, and all items in the market are identical. The intermediary has some prior, incomplete knowledge of the agents' values for the items: all seller values are independently drawn from the same distribution F_S, and all buyer values from F_B. The two distributions may differ, and we make common regularity assumptions, namely that F_B is MHR and F_S is log-concave.

We focus on online, posted-price mechanisms, and analyse two objectives: that of maximizing the intermediary's profit and that of maximizing the social welfare, under a competitive analysis benchmark. First, on the negative side, for general agent sequences we prove tight competitive ratios of $\Theta(\sqrt{n})$ and $\Theta(\ln n)$, respectively for the two objectives. On the other hand, under the extra assumption that the intermediary knows some bound α on the ratio between the number of sellers and buyers, we design asymptotically optimal online mechanisms with competitive ratios of $1 + o(1)$ and 4, respectively. Additionally, we study the model where the number of items that can be stored in stock throughout the execution is bounded, in which case the competitive ratio for the profit is improved to $O(\ln n)$.

1 Introduction

The design and analysis of electronic markets is of central importance in algorithmic game theory. Of particular interest are trading settings, where multiple parties such as buyers, sellers, and intermediaries exchange goods and money. Typical examples are markets for trading stocks, commodities, and derivatives: sellers and buyers where each one trades a single item and one intermediary for facilitating the transactions. However, the well-understood cases are comparatively quite modest. The very special case of one seller, and one buyer was thoroughly studied by Myerson and Satterthwaite [26] in their seminal paper; they provided a beautiful characterization of many significant properties a mechanism might have, along

with an impossibility theorem showing that it cannot possess them all. The paper also dealt with the case where a broker provides assistance by making two potential trades, one with each agent, while also trying to maximize his profit. This was extended in [15] to multiple sellers and buyers that are all immediately present in an offline manner.

Our work considers a similar setting, but with a key difference: the buyers and sellers appear one-by-one, in a dynamic way. It is natural to study this question in the incomplete information setting in which the intermediary, whose objective is to maximize either profit or welfare, does not know the sequence of buyers and sellers in advance. The framework that we employ to study the question is the standard worst-case analysis of online algorithms whose goal is to do as well as possible in the face of a powerful adversary which tries to embarrass them.

We are not the first to apply techniques from online algorithms to quantify uncertainty in markets: the closest work to ours would be by Blum et al. [8] who consider buyers and sellers trading identical items. In their setting, motivated mostly from a financial standpoint, buyers and sellers arrived in an online manner, with their bids appearing to the trader and expiring after some time. The trader would have to match prospective buyers and sellers to facilitate trade. Among a plethora of interesting results, the trader's profit maximization problem was studied using competitive analysis and techniques from online weighted matchings. The key difference in our setting is that buyers and sellers do not overlap: whenever a seller appears, the intermediary has to decide whether or not to attempt to buy the item, without having a buyer ready to go. Instead, the intermediary stores the item to sell it at a later time. We believe this variation is able to capture "slower" markets, like online marketplaces similar to Amazon or AliExpress (or even regular retail stores), where uncertainty stems from not knowing how large a stock of items to buy, in expectation of the buyers to come.

1.1 Our Results

Our aim is to study this dynamic market setting, where an intermediary faces a sequence of potential buyers and sellers in an online fashion. The goal of the intermediary is to maximize his profit, or society's welfare, by buying from the sellers and selling to buyers. We take a Bayesian approach to their utilities but use competitive analysis for their arrivals: the main difficulty stems from the unknown (and adversarially chosen) sequence of agents. Further particulars and notation is discussed in Section 2. All the online algorithms we design are posted price, which are simple, robust and strongly truthful.

First, in Section 4 we study the case of arbitrary sequences of buyers and sellers and show that the competitive ratio—the ratio of the optimal offline profit over the profit obtained by the online algorithm—is $\Theta(\sqrt{n})$, where n is the total number of buyers and sellers. We also study the social welfare objective, where the goal is to maximize the total utility of all participants, including the sellers, the buyers and the intermediary The competitive ratio here is $\Theta(\log n)$. All these results are achieved via common regularity assumptions on the distributions of the agent values (see Section 3), which we also prove to be necessary, by providing arbitrarily bad competitive ratios in the case they are dropped (Theorem 7).

To overcome the above pessimistic results, we next study in Section 5 the setting where both the online and offline algorithms have a limited stock, i.e. at no point in time can they hold more than K items. In this model, the competitive ratio is improved to $\Theta(K \log n)$, asymptotically matching that of welfare. Finally, we also propose a way to restrict the input sequence, by introducing in Section 6 the notion of α-balanced streams, where at every prefix of the stream the ratio of the number of sellers to buyers has to be at least α. Under this condition we are able to bring down the competitive ratios for both objectives to constants. In

particular, the online posted-price mechanism that we use for profit maximization, and which is derived by a fractional relaxation of the optimal offline profit, achieves an asymptotically optimal ratio of $1 + o(1)$. A similar mechanism is 4-competitive for the welfare objective.

All omitted proofs can be found in the full version of the paper [18].

1.2 Prior Work

Our work is grounded on a string of fruitful research in mechanism design. The main topics that are close to our effort are bilateral trading, trading markets and sequential (online) auctions.

The first step in bilateral trading and mechanism design was made by Myerson and Satterthwaite [26] who proved their famous impossibility result, even for the case of one buyer and one seller. The case for profit maximization was extended to many buyers and sellers, each trading a single identical item, in [15]. Some of the assumptions in our model are based in these two works. The impossibility result in [26], among other difficulties, slowly vanishes for larger markets as was shown by McAffee [25]. There is still active progress being made on this intriguing setting, concentrating on simple mechanisms that provide good approximations either to welfare while staying budget balanced and individually rational [9, 11] or to profit [27]. Other recent developments include a hardness result for computing optimal prices [17] and constant efficiency approximation with strong budget balance [14].

Sequential auctions have also produced a collection of interesting results, either extending the ideas of simple approximate mechanisms instead of more complex, theoretically optimal ones or dealing with entirely new settings. Prominent examples that compare the revenue (or welfare) generated by simple, posted-price sequential auctions to the optimal, proving good approximations in certain cases, are [10] for single-item revenue, [13, 29] for matroid constraints (and some multi-dimensional settings) and [16] for combinatorial auctions. There have been many approaches that apply competitive (worst-case) analysis to mechanism design. The analysis of auctions with unlimited supply is explored in [5, 7] where near optimal algorithms are developed using techniques inspired from no-regret learning. There is also a deep connection between secretary problems and online sequential auctions [21, 20, 3]. Hajiaghayi et al. utilized techniques such as prophet inequalities for unknown market size with distributional assumptions in [22]. A comprehensive exposition of online mechanism design by Parkes can be found in [28].

There are also positive results in online auctions when the valuation distribution is unknown (but usually known to be restricted in some way, having bounded support or being monotone hazard-rate etc). Babaioff et al. explored the case of selling a single item to multiple i.i.d. buyers in [1]. The case of k items in a similar setting was studied in [2], while the case of unlimited items (digital goods auctions) in [23] and [24]. Budget constraints where also introduced in [4], where a procurement auction was the focus.

2 Preliminaries and Notation

The input is a finite string $\sigma \in \{S, B\}^*$ of buyers (B) and sellers (S). The online algorithm has no knowledge of $\sigma(t)$, i.e. whether $\sigma(t) = S$ or $\sigma(t) = B$, before step t. Also, it doesn't know the length $n(\sigma)$ of σ. Denote $n_S(\sigma)$, $n_B(\sigma)$ the number of sellers and buyers, respectively, in σ, and let $N_S(\sigma)$, $N_B(\sigma)$ be the corresponding set of indices, i.e. $N_S(\sigma) = \{t \mid \sigma(t) = S\}$ and $N_B(\sigma) = \{t \mid \sigma(t) = B\}$. Let $N(\sigma) = N_S(\sigma) \cup N_B(\sigma) = \{1, 2, \ldots, n(\sigma)\}$. In the above notation we will often drop the σ if it is clear which input stream we are referring to.

The values of the sellers are drawn i.i.d. from a probability distribution (with cdf) F_S and these of buyers i.i.d. from a distribution F_B, both supported over intervals of nonnegative reals. We denote the random variable of the value of the t-th agent with X_t. We assume that distributions F_S and F_B are continuous, with bounded expectations μ_S and μ_B, and have (well-defined) density functions f_S and f_B, respectively. It will also be useful to denote by X_S a random variable drawn from distribution F_S, and similarly $X_B \sim F_B$, and for any random variable Y and positive integer m use $Y^{(m)}$ to represent the maximum order statistic out of m i.i.d. draws from the same distribution as Y. We will also use the shortcut notation $\mu^{(m)} = \mathbb{E}[Y^{(m)}]$.

We study *posted-price* online algorithms that upon seeing the identity of the t-th agent (whether she is a seller or a buyer), offer a price p_t. We buy one unit of the item from sellers that accept our price (i.e. if $\sigma(t) = S$ and $X_t \leq p_t$) and pay them that price, and we sell to buyers that accept our price (i.e. if $\sigma(t) = B$ and $X_t \geq p_t$), given stock availability (see below), and collect from them that price. So, a price p_{t+1} can only depend on $\sigma(1), \ldots, \sigma(t+1)$ and the result of the comparison $X_i \leq p_i$ in all previous steps $i = 1, 2, \ldots, t$. Let K_t denote the available stock at the beginning of the t-th step, i.e. $K_1 = 0$ and

$$K_{t+1} = \begin{cases} K_t + 1, & \text{if } \sigma(t) = S \ \wedge \ X_t \leq p_t \\ K_t - 1, & \text{if } \sigma(t) = B \ \wedge \ K_t \neq 0 \ \wedge \ X_t \geq p_t \\ K_t, & \text{otherwise.} \end{cases}$$

Then, the set of sellers from whom we bought items during the algorithm's execution is $I_S = \{t \in N_S \mid X_t \leq p_t\}$ and the set of buyers we sold to is $I_B = \{t \in N_B \mid X_t \geq p_t \wedge K_t \neq 0\}$. Notice that these are random variables, depending on the actual realizations of the agent values X_t.

The total *profit* that the intermediary deploying an algorithm A makes throughout the execution on an input stream σ, is the amount he manages to collect from the buyers via successful sales, minus the amount he spent in order to maintain stock availability from the sellers, that is

$$\mathcal{R}(A, \sigma) = \mathbb{E}\left[\sum_{t \in I_B} p_t - \sum_{t \in I_S} p_t\right].$$

The social *welfare* of algorithm A is the sum of valuations that all participants achieve throughout the entire execution. That is, a seller at position t of the stream has a value of X_t if she keeps her item, or a value of p_t if she sold the item to the intermediary; a buyer has a value of $X_t - p_t$ if she managed to buy an item, since the item has a value of X_t and he spent p_t to buy it, or 0 otherwise. And the intermediary, has a value of $\mathcal{R}(A)$ plus the value of the items that he didn't manage to sell in the end and which are now left in his stock. Putting everything together and performing the occurring cancellations, this results in the welfare to be expressed simply as the sum of the values of the sellers that kept their items plus the sum of the values of the buyers that bought an item, i.e.

$$\mathcal{W}(A, \sigma) = \mathbb{E}\left[\sum_{t \in N_S \setminus I_S} X_t + \sum_{t \in I_B} X_t\right]. \tag{1}$$

We use *competitive analysis*, the standard benchmark for online algorithms (see e.g. [12]), in order to quantify the performance of an online algorithm A: we compare it to that of an unrealistic, offline optimal algorithm OPT has access to the entire stream σ in advance.

Then, we say that A is $\rho(n)$-competitive with respect to welfare, if for any feasible input sequence of agents σ with length n and distributions F_S, F_B for the agent values, it is $\mathcal{W}(\text{OPT}, \sigma) \leq \rho(n) \cdot \mathcal{W}(A, \sigma)$. Notice how we allow the competitive ratio $\rho(n)$ to explicitly depend on the input's length, so that we can perform asymptotic analysis as $\mathcal{W}(\text{OPT}, \sigma)$ and n tend to infinity. It is common in competitive analysis to allow for an additional constant in the right hand side of the above expression, that does not depend in the input, and which intuitively can capture some initial configuration disadvantage of the online algorithm. We do that for the case of the profit objective, as this constant will have a very natural interpretation: you can think of it as the maximum amount of deficit on which an online algorithm can run at any point in time, since an adversary can always stop the execution at any time he wishes. Given that interpretation, it makes sense to allow for this constant to depend on seller distribution F_S, since even when we face a single seller at the first step we expect to spend an amount that depends on the realization of her value. Thus, we will say that an online algorithm is $\rho(n)$-competitive with respect to profit, if for any input sequence of agents σ and any probability priors F_S, F_B,

$$\mathcal{R}(\text{OPT}, \sigma) \leq \rho(n) \cdot \mathcal{R}(A, \sigma) + O(\mu_S). \tag{2}$$

3 Distributional Assumptions

Throughout most of the paper we will make some assumptions on the distributions F_B, F_S from which the buyer and seller values are drawn. In particular, we will assume that F_B has *monotone hazard rate (MHR)*, i.e. $\log(1 - F_B(x))$ is concave, and that F_S is *log-concave*, i.e. $\log F_S(x)$ is concave. For convenience, we will collectively refer to both the above constraints as *regularity assumptions*. These conditions are rather standard in the optimal auctions literature, and they encompass a large class of natural of distributions including e.g. exponential, uniform and normal ones. Notice that distributions that satisfy the above conditions also fulfil the regularity requirements introduced in the seminal paper Myerson and Satterthwaite [26] for the single-shot, one buyer and one seller setting of bilateral trade, namely that $x + \frac{F_S(x)}{f_S(x)}$ and $x - \frac{1-F_B(x)}{f_B(x)}$ are both increasing functions. Finally, we must mention that such regularity assumptions are necessary, in the sense that dropping them would result in arbitrarily bad lower bounds for the competitive ratios of our objectives, as it is demonstrated by Theorem 7.

The following two lemmas demonstrate some key properties of distributions satisfying our regularity assumptions and which will be very useful in our subsequent analysis:

▶ **Theorem 1.** *For any random variable Y drawn from an MHR distribution with bounded expectation μ and standard deviation s,*

1. $\Pr[Y \geq y] \geq \frac{1}{e}$ *for any* $y \leq \mu$
2. $\Pr[Y \geq y] < \frac{1}{e}$ *for any* $y > 2\mu$
3. $\mathbb{E}[Y^{(m)}] \leq H_m \cdot \mu$, *where H_m is the m-th harmonic number.*
4. $s \leq \mu$

Proof. A proof of Property 1 can be found in [6, Theorem 3.8], of Property 2 in [6, Corollary 3.10], and of Property 3 in [1, Lemma 13]. For Property 4, from [19, Lemma 2] we know that $\mathbb{E}\left[Y^2\right] \leq 2\mu^2$, so $s^2 = \mathbb{E}\left[Y^2\right] - \mu^2 \leq \mu^2$. ◀

▶ **Lemma 2.** *For any distribution over $[0, \infty)$ with log-concave cdf F and expectation μ,*

$$x \leq e\mu F(x) \qquad \text{for any } x \leq \mu.$$

Finally, we prove the following property bounding the sum of maximum order statistics of a distribution, that holds for general (not necessarily MHR) distributions and might be of independent interest:

▶ **Lemma 3.** *The expected average of the k-th highest out of m independent draws from a probability distribution with expectation μ and standard deviation s can be at most $\mu + 2\sqrt{\frac{m}{k}}s$.*

4 General Setting

We start by studying the general setting where no additional assumptions are enforced on the structure of the input sequence. The adversary is free to arbitrarily choose the identities of the agents.

4.1 Welfare

▶ **Theorem 4.** *Under our regularity assumptions*[1]*, the online auction that posts to any seller and buyer the median of their distribution is $O(\ln n)$-competitive with respect to welfare. This bound is tight.*

Proof. We split the proof of the theorem in two more general lemmas below, corresponding to upper and lower bounds. Then, the upper bound for our case follows easily from Lemma 5 by using constants $c_1 = c_2 = 2$, and taking into consideration that, from Property 3 of Theorem 1, the ratio of the maximum order statistic for the MHR distribution F_B is upper bounded by $r_B(m) \leq H_m \leq O(\ln m)$. For the lower bound, it is enough to observe that this ratio is attained by an exponential distribution, which is MHR.

▶ **Lemma 5.** *For any choice of constants $c_1, c_2 > 1$, the following fixed-price online auction has a competitive ratio of at most $\max\left\{\frac{c_1}{c_1-1}, c_1 c_2 \cdot r_B(n_B)\right\}$ with respect to welfare, where n_B is the number of buyers, and $r_B(m) = \mu_B^{(m)}/\mu_B$ is the ratio between the m-maximum-order statistic and the expectation of the buyer value distribution.*

- *Post to all sellers price $q = F_S^{-1}\left(\frac{1}{c_1}\right)$.*
- *Post to all buyers price $p = F_B^{-1}\left(\frac{c_2-1}{c_2}\right)$.*

Proof. Let A denote our online algorithm and OPT an offline algorithm with optimal expected welfare. Fix an input stream σ. Looking at (1), the maximum welfare that OPT can get from the sellers is at most $\mathbb{E}\left[\sum_{t\in N_S} X_t\right] = n_s\mu_S$, while from the buyers at most $\mathbb{E}\left[|I_B| \cdot X_B^{(n_B)}\right] \leq \kappa\,\mathbb{E}\left[X_B^{(n_B)}\right]$, where κ is the maximum number of sellers that can be matched to *distinct* buyers that arrive after them[2] in σ: clearly, no mechanism can sell more than κ items. Bringing all together we have that

$$\mathcal{W}(\mathrm{OPT}) \leq n_s\mu_S + \kappa\mu_B^{(n_B)} = n_s\mu_S + r_B(n_B)\cdot\kappa\mu_B.$$

[1] As matter of fact, in the proof of Theorem 4 just regularity for the buyer values would suffice, i.e. F_B being MHR.

[2] You can think of that as the maximum size of a matching in the following undirected graph: the nodes are the sellers and the buyers, and there is an edge between any seller and all the buyers that appear after her in σ.

For the online algorithm now, from the sellers we get

$$\sum_{i \in N_S} \Pr[X_i > q] \, \mathbb{E}[X_i | X_i > q] \geq n_s (1 - F_S(q)) \, \mathbb{E}[X_S] = \frac{c_1 - 1}{c_1} \cdot n_S \mu_S$$

and from the buyers at least

$$\kappa \Pr[X_S \leq q] \Pr[X_B \geq p] \, \mathbb{E}[X_i | X_i \geq p] \geq \kappa F_S(q)(1 - F_B(p)) \, \mathbb{E}[X_B] = \frac{1}{c_1} \frac{1}{c_2} \cdot \kappa \mu_B,$$

just by considering one of the κ-size matchings discussed before: if we manage to buy from one of these κ sellers, then we will definitely have stock availability for the matched buyer. ◀

The upper bound in Lemma 5 cannot be improved:

▶ **Lemma 6.** *For* any *probability distribution F, even if the seller and buyer values are i.i.d. from F, the sequence SB^n forces all posted-price online mechanisms to have a competitive ratio of $\Omega(r(n))$, where $r(n) = \mu^{(n)}/\mu$ is the ratio of the n-maximum-order statistic of distribution F to its expectation.* ◀

As the following theorem demonstrates, our regularity assumption on the agent values is necessary if we want to hope for non-trivial bounds. In particular, the lower bound in Lemma 6 can be made arbitrarily high:

▶ **Theorem 7.** *For any constant $\varepsilon \in (0, 1)$, there exists a continuous probability distribution F such that any online posted-price mechanism has a competitive ratio of $\Omega(n^{1-\varepsilon})$ on the input sequence SB^n, even if the values of the sellers and the buyers are i.i.d.*

4.2 Profit

Now we turn our attention to our other objective of interest, that of maximizing the expected profit of the intermediary. As it turns out, this objective has some additional challenges that we need to address. For example, as the following theorem demonstrates, if the distribution of seller values is bounded away from 0, the competitive ratio can be arbitrarily bad, even for i.i.d. values from a uniform distribution. Intuitively, this follows from the impossibility of buying a super-constant number of items within a constant budget.

▶ **Theorem 8.** *For any $a > 0$ and $\varepsilon \in (0, 1)$, if the seller and buyer values are drawn i.i.d. from the uniform distribution over $[a, b]$ where $b > 2a$, then no online posted-price mechanism can have an approximation ratio better than $a \left(1 - \frac{1}{k}\right)^4 n^{1-\varepsilon}$ with respect to profit, where $k = \frac{b}{a} - 1$. In particular, for any uniform distribution over an interval $[1, h]$ with $h \geq 3$ the lower bound is $\frac{1}{2^4} n^{1-\varepsilon} = \Omega\left(n^{1-\varepsilon}\right)$.*

If we consider distributions supported over intervals that include 0, under our regularity assumptions we can do a little better than the trivial lower bound of Theorem 8:

▶ **Theorem 9.** *Under our regularity assumptions, for agent values distributed over intervals that include 0 the following online posted-price mechanism achieves a competitive ratio of $O(n^{\frac{1}{2}+\varepsilon})$ for any $\varepsilon > 0$:*

- *Post to the i-th seller price $q_i = F_S^{-1}\left(\frac{1}{e} \frac{1}{i^{1/2+\varepsilon}}\right)$*
- *Post to all buyers price $p = \mu_B$.*

Proof. Fix an input stream σ of length n. Let μ_B and s_B be the expectation and standard deviation of the buyer value distribution F_B. As in the proof of Lemma 5, let κ denote the maximum number of sellers that can be matched to distinct buyers that arrive after them in σ. If $\mu_B^{(j:m)}$ denotes the expectation of the j-th largest out of m independent draws from F_B, since no algorithm can make more than κ sales over its entire execution, the optimal offline profit is upper bounded by

$$\sum_{j=1}^{\kappa} \mu_B^{(n_B-j+1:n_B)} \leq \sum_{i=n-\kappa+1}^{n} \mu_B^{(i:n)} \leq \kappa\mu_B + 2\sqrt{\kappa n}s_B \leq 3\sqrt{\kappa}\sqrt{n}\mu_B,$$

where for the second inequality we have used Lemma 3 and for the last one we have used Property 4 from Theorem 1 and the obvious fact that $\kappa \leq n$.

For the analysis of the online mechanism now, the expected number of items that it gets from the first κ sellers is $\sum_{i=1}^{\kappa} F_S(q_i) = \frac{1}{e}\sum_{i=1}^{\kappa} \frac{1}{i^{1/2+\varepsilon}} \geq \frac{1}{e}\kappa^{1/2-\varepsilon}$. So, by considering the FIFO matching between these first κ sellers and their corresponding buyers, the expected income of our algorithm is at least $\frac{1}{e}\kappa^{1/2-\varepsilon}(1-F(p)) = \frac{1}{e}\kappa^{1/2-\varepsilon}(1-F(\mu_B)) \geq \frac{1}{e^2}\kappa^{1/2-\varepsilon}$, where in the last step we deployed Property 1 of Theorem 1. So, it only remains to be shown that the online algorithm does not spend more than a constant amount. Indeed, our expected spending is at most

$$\sum_{i=1}^{\infty} q_i F_S(q_i) \leq \sum_{i=1}^{\infty} e\mu_S F_S(q_i)^2 = \frac{1}{e}\mu_S \sum_{i=1}^{\infty} \frac{1}{i^{1+2\varepsilon}} = O(\mu_S),$$

where for the first inequality we have used Lemma 2, taking into consideration that seller prices q_i are decreasing and q_1 is below μ_S. This is true because again from Lemma 2 for $x = \mu_S$ we know that $\mu_S \leq e\mu_S F(\mu_S)$, or equivalently $F(\mu_S) \geq \frac{1}{e} = F(q_1)$. ◀

The algorithm of Theorem 9 is asymptotically optimal:

▶ **Theorem 10.** *If the seller and buyer values are drawn i.i.d. from the uniform distribution over $[0,1]$, then no online posted-price mechanism can have an approximation ratio better than $\Omega(\sqrt{n})$.*

Proof. We use the input sequence $\sigma = S^{n/2}B^{n/2}$ with n even. Let $F(x) = x$ be the cdf of the uniform distribution over $[0,1]$. This time we argue that no online algorithm can buy more than $\Omega(\sqrt{n})$ items from the sellers, in expectation. Indeed, let q_i be the price that the online mechanism posts to the i-th seller. Then, the expected number of items m_σ bought from the sellers is $\sum_{i=1}^{n/2} F(q_i) = \sum_{i=1}^{n/2} q_i$, while the expected expenditure c_σ is $\sum_{i=1}^{n/2} F(q_i)q_i = \sum_{i=1}^{n/2} q_i^2$. By the convexity of the function $t \mapsto t^2$ and Jensen's inequality it must be that

$$m_\sigma = \sum_{i=1}^{n/2} q_i \leq \sqrt{\frac{n}{2}} \left(\sum_{i=1}^{n/2} q_i^2\right)^{\frac{1}{2}} = O\left(\sqrt{c_\sigma}\sqrt{n}\right),$$

so given that our deficit must be $c_\sigma = O(\frac{1}{2})$, we get the desired $m_\sigma = O(\sqrt{n})$. As a result, the online profit can be at most $O(\sqrt{n}) \cdot 1 = O(\sqrt{n})$.

For the offline algorithm we use prices $q = \frac{1}{8}$ and $p = \frac{1}{2}$ for the buyers and sellers, respectively, and by an analogous analysis to that of the proof of Theorem 8, we get that the expected offline profit is at least

$$\frac{n}{2}F(q)(1-F(p))p - \frac{n}{2}F(q)q = \frac{n}{2}\frac{1}{8}\left(1-\frac{1}{2}\right)\frac{1}{2} - \frac{n}{2}\frac{1}{8}\frac{1}{8} = \frac{n}{128} = \Omega(n).$$ ◀

5 Limited Stock

If one looks carefully at the lower bound proof for the profit in Theorem 10, it becomes clear that the source of difficulty for any online algorithm is essentially the fact that without knowledge of the future, you cannot afford to spend a super-constant amount of money into accumulating a large stock of items, without the guarantee that there will be enough demand from future buyers. In particular, it may seem that the offline algorithm has an unrealistic advantage of using a stock of infinite size. The natural way to mitigate this would be to introduce an upper bound K on the number of items that both the online and offline algorithms can store at any point in time. As it turns out, this has a dramatic improvement in the competitive ratio for the profit:

▶ **Theorem 11.** *Assuming stock sizes of at most K items, under our regularity assumptions the following online mechanism is $O\left(Kr \log n\right)$-competitive, where $r = \max\left\{1, \frac{\mu_S}{\mu_B}\right\}$:*

- *If your stock is not currently full, post to sellers price $q = F_S^{-1}\left(\frac{1}{r}\frac{1}{2eK}\right)$*
- *Post to all buyers price $p = \mu_B$.*

Proof. The proof is similar to that of Theorem 9, but certain points need some special care. Let κ again be the maximum number of sellers that can be matched to distinct buyers that follow them, but this time under the added restriction of the K-size stock. This corresponds to the maximum matching with no "temporal" cut of size greater than K. We write "temporal" cut to mean any cut in the graph that separates the vertices (buyers and sellers) $1 \dots i$ from vertices $i+1 \dots n$ — that is, precisely the condition that we cannot match more than K sellers from an initial segment to buyers later in the sequence.

In the full version of our paper we show that such a κ-size matching can be computed not only offline, but also online using a FIFO queue of length K, adding sellers to the queue while it is not full and matching buyers greedily: we post prices to sellers, only if we have free space in our stock, i.e. when the matching queue is not full. We underestimate the online profit by considering only selling an item to the buyer that is matched to the seller from which we bought the item. Mimicking the analysis in the proof of Theorem 9 we can see that the expected number of items bought from the κ matched sellers is $\kappa F_S(q) \geq \kappa \frac{1}{2eK}\frac{1}{r}$.

Now we argue that $q \leq \frac{\mu_B}{2}$. Indeed, since $F_S(q) \leq \frac{1}{e}$ we know for sure that $q \leq \mu_S$, and so from Lemma 2 it is $q \leq e\mu_S F(q) \leq e\mu_S \frac{\mu_B}{\mu_S}\frac{1}{2e} = \frac{\mu_B}{2}$. Next, notice that whenever we make a successful sale, the contribution to profit is $p - q \geq \mu_B - \frac{\mu_B}{2} = \frac{1}{2}\mu_B$.

The rest of the proof can be found in the full version of the paper. ◀

▶ Remark. The above upper bound in Theorem 11, although a substantial improvement from the $\Theta(\sqrt{n})$ one for the general case in Theorem 9, cannot be improved further: the logarithmic lower bound is unavoidable, since a careful inspection of the welfare lower bound in the proof of Lemma 6 reveals that the same analysis carries over to the profit.

6 Balanced Sequences

As we saw in Section 5, introducing a restriction in the size of available stock can improve the performance of our online algorithms with respect to profit. However, the bound is still super-constant. Thus, it is perhaps more reasonable to assume some knowledge of the ratio α between buyers and sellers in sequences the intermediary might face. This allows us finer control over the trade-off between high volume of trades and the hunt for greater order statistics.

In this section we analyse the competitive ratio for profit and welfare obtained by online algorithms on α-*balanced* sequences.

▶ **Definition 12.** Let α be a positive integer. A sequence containing m buyers is called α-balanced if it contains αm sellers and the i-th buyer is preceded by at least αi sellers.

For example, the sequence $SBSSBSBB$ is 1-balanced, but $SBBSSB$ is not. Note that since $n = n_S \frac{\alpha+1}{\alpha} = n_B(\alpha+1)$, we only need to know the number of buyers of a sequence. For convenience, we will denote it by m instead of n_B, as it is used quite often. This constraint eliminates the pathological counterexamples of previous sections (such as SB^m) and introduces a much needed "recurrent" flavour to the market: items are constantly traded and in higher quantities, leading to greater profits for both online and offline algorithms.

6.1 Profit

We first work on profit, deriving bounds for a variety of online and offline mechanisms. Naturally, there are two types of offline mechanisms: adaptive and non-adaptive. The *non-adaptive* posted-price mechanism calculates all prices in advance based on the sequence of buyers and sellers, while the *adaptive* posted-price mechanism can alter the prices on the fly, depending on the outcomes of previous trades.

We show that there is a competitive online mechanism for α-balanced sequences. To do this, we compare the optimal adaptive and non-adaptive profit to the profit of a class of hypothetical mechanisms, called *fractional mechanisms*, which are allowed to buy fractional quantities of items: posting the price p would buy exactly $F_S(p)$ items or sell $1 - F_B(p)$ items. The advantage of using fractional mechanisms is that at any point we know the exact quantity of items in the hands of the intermediary instead of the expectation; an immediate consequence of this is that we know in advance whether there is enough quantity to sell, which implies that *the adaptive and non-adaptive versions of the optimal fractional mechanism are identical.*

We can now give an outline of the results in this section: For α-balanced sequences σ with m buyers and αm sellers, we establish the following relations of optimal profits:

$$\text{adaptive}(\sigma) \leq \text{fractional}(\sigma) \leq \text{fractional}(S^{\alpha m}B^m) \approx \text{non-adaptive}(\sigma), \tag{3}$$

the last of which will be our online algorithm. We begin by the fractional offline mechanism.

▶ **Theorem 13.** *The profit gained by the optimal fractional mechanism for the sequence $S^{\alpha m}B^m$ is*

$$\begin{aligned} \max \quad & m\left(p(1-F_B(p)) - \alpha \cdot qF_S(q)\right) \\ s.t. \quad & 1 - F_B(p) = \alpha F_S(q) \\ & p, q \in [0, \infty). \end{aligned} \tag{4}$$

For other sequences containing αm sellers and m buyers in a different order, we can use the following lemma to establish the middle part of inequality 3.

▶ **Lemma 14.** *For any α-balanced σ with m buyers, fractional$(\sigma) \leq$ fractional$(S^{\alpha m}B^m)$*

▶ **Theorem 15.** *For any sequence σ we have adaptive$(\sigma) \leq$ fractional(σ).*

The intuition behind the proof of the theorem is that the optimal adaptive profit is bounded from above by the optimal fractional adaptive profit (since fractional mechanisms is a more

general class of mechanisms); since in fractional mechanisms optimal adaptive and non-adaptive profits are the same, the theorem follows. For a more rigorous technical treatment, see the full version of our paper.

At this point, we have a clear model of the adversary's power: the fractional mechanism's revenue for sequence $S^{\alpha m}B^m$, setting only two prices p, q for sellers and buyers. Could we do the same online? It seems likely. After all, long sequences of buyers and sellers seem to lead to a similar amount of trading on average by a mechanism setting the same prices.

Based on the previous discussion we propose the following online posted price algorithm:

- Use prices p, q given by the optimal fractional solution for $S^{\alpha m}B^m$(see Theorem 13).

This algorithm works without knowing the length of the sequence chosen by the adversary.

▶ **Lemma 16.** *Let A be the online algorithm defined by the optimal fractional offline prices of (4). Consider two α-balanced sequences σ_1 and σ_2 of equal length. We write $\sigma_1 \succ \sigma_2$ whenever every prefix of σ_1 contains more sellers than the prefix of σ_2 having equal length. Then, $\sigma_1 \succ \sigma_2 \Rightarrow \mathcal{R}(A, \sigma_1) \geq \mathcal{R}(A, \sigma_2)$*

Although not all sequences are comparable (e.g. $SSBBSB$ and $SBSSBB$), the sequence $(S^\alpha B)^m$ is the bottom element among all α-balanced sequences of length $(\alpha+1)m$. This is trivial, as any balanced sequence must have at least $\lceil \frac{i}{(\alpha+1)/(\alpha)} \rceil$ sellers for any prefix of length i and $(S^\alpha B)^m$ is tight for this bound.

To formalize our intuition of making the same number of trades in the long run, we reformulate our algorithm in the more familiar setting of random walks. Instead of considering agents separately, each "timestep" would be one sub-sequence $S^\alpha B$, giving m steps in total. Thus, we are interested in the random variables Z_i, denoting the items in stock at the end of each step, starting with $Z_0 = 0$. Knowing the algorithm buys $\alpha m F_S(q)$ items in expectation, the expected profit can be given by

$$\mathcal{R}((S^\alpha B)^m) = (\alpha m F_S(q) - \mathbb{E}[Z_m])(p-q) - \mathbb{E}[Z_m]\, q, \tag{5}$$

which is the revenue of the expected number of trades minus the cost of the unsold items.

▶ **Lemma 17.** $\mathbb{E}[Z_m] \leq \sqrt{2m\alpha^2 \log m}\left(1 - \frac{2}{m}\right) + 2$

Proof. The process Z_i is almost a martingale but not quite: clearly $\mathbb{E}[Z_i] \leq \alpha m$ for all i and we do have $\mathbb{E}[Z_{i+1}|Z_i \geq 1] = Z_i$ since the expected change in items after that step is $\alpha F_S(q) - (1 - F_B(p)) = 0$ by Theorem 13 . However, $\mathbb{E}[Z_{i+1}|Z_i = 0] > Z_i$, by the no short selling assumption.

We can define Y_i in the same probability space, where $Y_0 = 0$, and

$$Y_{i+1} = Y_i + \begin{cases} Z_{i+1} & \text{if } Y_i > 0 \\ -Z_{i+1} & \text{if } Y_i < 0 \\ \begin{cases} Z_{i+1} & \text{with probability } \frac{1}{2} \\ -Z_{i+1} & \text{with probability } \frac{1}{2} \end{cases} & \text{if } Y_i = 0 \end{cases}. \tag{6}$$

The crucial observation is that Y_i behaves similar to Z_i but has no barrier at 0. Notice, that $|Y_i| \geq Z_i$ for all i and Y_i is a martingale.

Moreover, we have that $|Y_{i+1} - Y_i| \leq \alpha$ thus by the Azuma-Hoeffding inequality we can bound the expected value $\mathbb{E}[Z_m]$:

$$\Pr[Z_m \geq x] \leq \Pr[|Y_m| \geq x] = \Pr[|Y_m - Y_0| \geq x] \leq 2e^{\frac{-x^2}{2m\alpha^2}} \Rightarrow \tag{7}$$

$$\mathbb{E}[Z_m] \leq x\left(1 - 2e^{\frac{-x^2}{2m\alpha^2}}\right) + 2\alpha m e^{\frac{-x^2}{2m\alpha^2}}, \tag{8}$$

where we can set $x = \sqrt{2m\alpha^2 \log m}$ to obtain the simpler form:

$$\mathbb{E}[Z_m] \leq \sqrt{2m\alpha^2 \log m}\left(1 - \frac{2}{m}\right) + 2\alpha. \tag{9}$$

◀

▶ **Lemma 18.** *Let $r = \max\left\{2, \frac{\mu_S}{\mu_B}\right\}$. The optimal value of Programme (4) is at least $m\frac{\mu_B}{2er}$. Furthermore, at any optimal solution the buyer price has to be at most $p \leq 4\ln(4er)\mu_B$.*

▶ **Theorem 19.** *Under our regularity assumptions, the proposed non-adaptive online mechanism is $(1 + o(\alpha^{3/2} r \log r))$-competitive for any balanced sequence, where $r = \max\left\{2, \frac{\mu_S}{\mu_B}\right\}$.*

Proof. Plugging (9) into (5), we get:

$$\begin{aligned}
\mathcal{R}((S^\alpha B)^m) &\geq \alpha m F_S(q)(p-q) - \mathbb{E}[Z_m](p-q) - \mathbb{E}[Z_m] q \\
&\geq \alpha m F_S(q)(p-q) - \left(\sqrt{2m\alpha^2 \log m}\left(1 - \frac{2}{m}\right) + 2\alpha\right) p \\
&\geq \alpha m F_S(q)(p-q) - O(\alpha\sqrt{m \ln mp}).
\end{aligned} \tag{10}$$

Using Lemma 14, Theorem 15 and Theorem 13 we know that for every α-balanced sequence, the profit of our non-adaptive online algorithm is at least $\mathcal{R}((S^\alpha B)^m)$ and the optimal offline is at most that of the fractional on sequence $S^{\alpha m} B^m$, i.e. $\alpha m F_S(q)(p-q)$. Thus, the second term in (10) bounds the additive difference of the online and optimal offline profit, and its ratio with respect to the offline profit is upper bounded by

$$O\left(\frac{\alpha\sqrt{m \ln mp}}{\alpha m F_S(q)(p-q)}\right) = O\left(\frac{\alpha\sqrt{m \ln m}\mu_B \ln(4er)}{m\frac{\mu_B}{2er}}\right) = O\left(\alpha^{3/2}\sqrt{\frac{\ln n}{n}} r \log r\right). \qquad ◀$$

▶ Remark. Among all 1-balanced sequences, the sequence that gives the maximum profit is not $S^m B^m$; intuitively, by moving buyers earlier in the sequence, we obtain more profit by adapting the remaining buying prices to the outcome of these potential trades. For example, the sequence $S^{m/2} B S^{m/2} B^{m-1}$ has better adaptive profit than the sequence $S^m B^m$ for large m. Our work above shows that the difference is asymptotically insignificant, but it remains an intriguing question to determine the balanced sequence with the maximum profit.

6.2 Welfare

Welfare on balanced sequences also improves the competitive ratio of Theorem 4 to a constant. Intuitively, the reason is that the high volume of possible trades dampens the advantage the adversary has in obtaining higher order statistics from buyers.

▶ **Theorem 20.** *The online auction that posts to any seller and buyer the median of their distribution is 4-competitive.*

Notice the above theorem holds without any regularity assumption on the agent value distributions.

Acknowledgements. We want to thank Matthias Gerstgrasser for many helpful discussions and his assistance during the initial development of our paper.

Abstract

We study the fundamental problem of prediction with expert advice and develop regret lower bounds for a large family of algorithms for this problem. We develop simple adversarial primitives, that lend themselves to various combinations leading to sharp lower bounds for many algorithmic families. We use these primitives to show that the classic Multiplicative Weights Algorithm (MWA) has a regret of $\sqrt{\frac{T\ln k}{2}}$ (where T is the time horizon and k is the number of experts), there by completely closing the gap between upper and lower bounds. We further show a regret lower bound of $\frac{2}{3}\sqrt{\frac{T\ln k}{2}}$ for a much more general family of algorithms than MWA, where the learning rate can be arbitrarily varied over time, or even picked from arbitrary distributions over time. We also use our primitives to construct adversaries in the geometric horizon setting for MWA to precisely characterize the regret at $\frac{0.391}{\sqrt{\delta}}$ for the case of 2 experts and a lower bound of $\frac{1}{2}\sqrt{\frac{\ln k}{2\delta}}$ for the case of arbitrary number of experts k (here δ is the probability that the game ends in any given round).

1 Introduction

In this paper we develop tight lower bounds on the regret obtainable by a broad family of algorithms for the fundamental problem of prediction with expert advice. Predicting future events based on past observations, a.k.a. prediction with expert advice, is a classic problem in learning. The experts framework was the first framework proposed for online learning and encompasses several applications as special cases. The underlying problem is an online optimization problem: a *player* has to make a decision at each time step, namely, decide which of the k experts' advice to follow. At every time t, an *adversary* sets gains for each expert: a gain of $g_{i,t}$ for expert i at time t. Simultaneously, the *player*, seeing the gains from all previous steps except t, has to choose an action, i.e., decide on which expert to follow. If the player follows expert $j(t)$ at time t, he gains $g_{j(t),t}$. At the end of each step t, the gains

associated with all experts are revealed to the player, and the player's choice is revealed to the adversary. In the *finite horizon model*, this process is repeated for T steps, and the player's goal is to perform (achieve a cumulative gain) as close as possible to the best single action (best expert) in hindsight, i.e., to minimize his *regret* $R_{T,k}$:

$$R_{T,k} = \max_{1 \le i \le k} \sum_{t=1}^{T} g_{i,t} - \sum_{t=1}^{T} g_{j(t),t}.$$

Apart from assuming that the $g_{i,t}$'s are bounded in $[0,1]$, we don't assume anything else about the gains[1]. Just as natural as the finite horizon model is the model with a *geometric horizon*: the stopping time is a geometric random variable with expectation $\frac{1}{\delta}$. In other words, the process ends at any given step with probability δ, independently of the past. Equivalently, both the player and the adversary discount the future with a $1-\delta$ factor. In this paper, we study both the finite horizon model and the geometric horizon model. We begin with the discussion for finite horizon model below.

Main contribution

In this paper we develop simple adversarial primitives and demonstrate that, when applied in various combinations, they result in remarkably sharp lower bounds for a broad family of algorithms. We first describe the family of algorithms we study, and then discuss our main results.

Multiplicative Weights Algorithm

We begin with the Multiplicative Weights Algorithm, which is a simple, powerful and widely used algorithm for a variety of learning problems. In the experts problem, at each time t, MWA computes the cumulative gain $G_{i,t-1} = \sum_{s=1}^{t-1} g_{i,s}$ of each expert i accumulated over the past $t-1$ steps, and will follow expert i's advice with probability proportional to $e^{\eta G_{i,t-1}}$. Namely, with probability $\frac{e^{\eta G_{i,t-1}}}{\sum_{j=1}^{k} e^{\eta G_{j,t-1}}}$ where η is a parameter that can be tuned. The per-step computation of the algorithm is extremely simple and straightforward. The intuition behind the algorithm is to increase the weight of any expert that performs well by a multiplicative factor. Despite the simplicity and the heuristic origins of the algorithm, it is surprisingly powerful: the pioneering work of Cesa Bianchi et al. [6] showed that MWA obtains a sublinear regret of $\sqrt{\frac{T \ln k}{2}}$, and that this is asymptotically optimal as the number of experts k and the number of time steps T both tend to ∞.

Families of algorithms

The MWA is a single-parameter family of algorithms, i.e., the learning rate parameter η is the only parameter available for the player. In general one could think of η being an arbitrary function of time t, i.e., at step t, algorithm follows expert i with probability $\frac{e^{\eta(t) G_{i,t-1}}}{\sum_{j=1}^{k} e^{\eta(t) G_{j,t-1}}}$. Note that this is a T-parameter family of algorithms and is quite general. The most general family of algorithms we study is when at each time t, the quantity $\eta(t)$ is drawn from an

[1] As one might expect, it turns out that restricting the adversary to set gains in $\{0,1\}$ instead of $[0,1]$ is without loss of generality (see [12] or [20]). Henceforth, we restrict ourselves to the binary adversary, which just sets gains of 0 or 1.

arbitrary distribution F_t over reals. Since F_t could be arbitrary, this is an infinite-parameter family of algorithms. We denote the

1. single parameter MWA family by $\mathcal{A}_{\text{single}}$;
2. family where $\eta(t)$ decreases with t by $\mathcal{A}_{\text{dec}}$;
3. family where $\eta(t)$ is arbitrary function of t by $\mathcal{A}_{\text{arb}}$;
4. family where $\eta(t)$ is drawn from F_t for each t by $\mathcal{A}_{\text{rand}}$.

It is straightforward to see that $\mathcal{A}_{\text{single}} \subseteq \mathcal{A}_{\text{dec}} \subseteq \mathcal{A}_{\text{arb}} \subseteq \mathcal{A}_{\text{rand}}$. The reason we start with $\mathcal{A}_{\text{single}}$ is that it is the classic MWA and precisely characterizing its regret is still open. We study $\mathcal{A}_{\text{dec}}$ because often when MWA algorithms are working with unknown T, they employ a strategy where η decreases with time. We move on to further significantly generalize this by studying $\mathcal{A}_{\text{arb}}, \mathcal{A}_{\text{rand}}$.

Minimax regret, and Notation

We study the standard notion of minimax regret for each of the above family of algorithms. Formally, let $R_{T,k}(A, D)$ denote the expected regret achieved by algorithm A when faced with adversary D in the prediction with expert advice game with T steps and k experts. We use $R_k(A, D)$ to denote the asymptotic[2], in T, value of $R_{T,k}(A, D)$, i.e., $R_k(A, D) = \sqrt{T} \cdot \lim_{T\to\infty} \frac{R_{T,k}(A,D)}{\sqrt{T}}$. The minimax regret of a family $\mathcal{A}_{\mathcal{F}}$ of algorithms against a family $\mathcal{D}_{\mathcal{F}}$ of adversaries is given by $R_{T,k}(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\mathcal{F}}) = \min_{A\in\mathcal{A}_{\mathcal{F}}} \max_{D(A)\in\mathcal{D}_{\mathcal{F}}} R_{T,k}(A, D)$. Let $\mathcal{D}_{\text{univ}}$ denote the universe of all adversaries. We use the shorthand $R_{T,k}(\mathcal{A}_{\mathcal{F}})$ for $R_{T,k}(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}}) = \min_{A\in\mathcal{A}_{\mathcal{F}}} \max_{D(A)\in\mathcal{D}_{\text{univ}}} R_{T,k}(A, D)$. We use $R_k(\mathcal{A}_{\mathcal{F}})$ to denote the asymptotic, in T, value of $R_{T,k}(\mathcal{A}_{\mathcal{F}})$, i.e., $R_k(\mathcal{A}_{\mathcal{F}}) = \sqrt{T} \cdot \lim_{T\to\infty} \frac{R_{T,k}(\mathcal{A}_{\mathcal{F}})}{\sqrt{T}}$.

Goal

One of our goals in this paper is to compute the precise values of $R_k(\mathcal{A}_{\text{single}})$, $R_k(\mathcal{A}_{\text{dec}})$, $R_k(\mathcal{A}_{\text{arb}})$ and $R_k(\mathcal{A}_{\text{rand}})$ for each value of k, and, *describe and compute* the adversarial sequences that realize these regrets. For clarity, we compute the precise values of $R_k(\mathcal{A}_{\mathcal{F}})$ by:

1. computing the best-response adversary in $\mathcal{D}_{\text{univ}}$ for every algorithm in $\mathcal{A}_{\mathcal{F}}$;
2. computing $R_k(\mathcal{A}_{\mathcal{F}})$ the regret of the optimal algorithm in $\mathcal{A}_{\mathcal{F}}$ (i.e., the algorithm that gets the smallest regret w.r.t. its best-response adversary).

In many cases, the first step, namely computing the best-response adversary, is challenging. We find the best-response adversaries for the families $\mathcal{A}_{\text{single}}$ and $\mathcal{A}_{\text{dec}}$. For the families $\mathcal{A}_{\text{arb}}$ and $\mathcal{A}_{\text{rand}}$, we perform the first step approximately, i.e., we compute a nearly best-response adversary, and thus we obtain lower bounds on $R_k(\mathcal{A}_{\text{arb}})$ and $R_k(\mathcal{A}_{\text{rand}})$.

What is known, and what to expect?

It is well known that for $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\text{single}}, \mathcal{A}_{\text{dec}}, \mathcal{A}_{\text{arb}}, \mathcal{A}_{\text{rand}}$: $R_{T,k}(\mathcal{A}_{\mathcal{F}}) \le \sqrt{(T \ln k)/2}$ for all T, k, and in the doubly asymptotic limit, as both T and k go to ∞, the optimal regret of $\mathcal{A}_{\text{single}}$ is $\sqrt{(T \ln k)/2}$, i.e., $\lim_{T\to\infty,k\to\infty} \left(R_{T,k}(\mathcal{A}_{\text{single}})/\sqrt{(T \ln k)/2}\right) = 1$. (see [6, 5]). While there are useful applications for $k \to \infty$, there are also several interesting use-cases of the experts problem with just a few experts (rain-or-shine ($k = 2$), buy-or-sell-or-hold ($k = 3$)). It seems like for small k such as $2, 3, 4$ etc. $R_k(\mathcal{A}_{\text{single}})$ could be a significant constant factor smaller than $\sqrt{(T \ln k)/2}$. And given that families like $\mathcal{A}_{\text{dec}}$ etc. are supersets of $\mathcal{A}_{\text{single}}$,

[2] Although R_k doesn't have a T in the subscript, R_k is still dependent on T. We suppress T merely to indicate asymptotics in T.

it seems even more likely that $R_k(\mathcal{A}_{\text{dec}})$ etc. are constant factor smaller than $\sqrt{(T \ln k)/2}$. Surprisingly, we show that is not the case: the regret of $\sqrt{(T \ln k)/2}$ that is obtained as $k \to \infty$ is *already obtained at* $k = 2$. Thus our work completely closes the gap between upper and lower bounds for all k.

1.1 Main Results

Finite horizon model

1. $R_k(\mathcal{A}_{\text{single}}) = R_k(\mathcal{A}_{\text{dec}}) = \sqrt{\frac{T \ln k}{2}}$ for even k,
   $R_k(\mathcal{A}_{\text{single}}) \geq R_k(\mathcal{A}_{\text{dec}}) \geq \sqrt{\frac{T \ln k}{2}(1 - \frac{1}{k^2})}$ for odd k.
2. $R_k(\mathcal{A}_{\text{arb}}) \geq R_k(\mathcal{A}_{\text{rand}}) \geq \frac{2}{3}\sqrt{\frac{T \ln k}{2}}$ for even k,
   $R_k(\mathcal{A}_{\text{arb}}) \geq R_k(\mathcal{A}_{\text{rand}}) \geq \frac{2}{3}\sqrt{\frac{T \ln k}{2}(1 - \frac{1}{k^2})}$ for odd k.

Geometric horizon model

In the geometric horizon model, the current time t is not relevant, since the expected remaining time for which the game lasts is the same irrespective of how many steps have passed in the past. Thus $\eta(t)$ is without loss of generality, independent of t. Nevertheless, η could still depend on other aspects of the history of the game, like the cumulative gains of all the experts etc. We establish some quick notation before discussing results. Let δ denote the probability that the game stops at any given step, independently of the past (and therefore the expected length of the game is $\frac{1}{\delta}$). Let $R_{\delta,k}(A, D)$ denote the regret achieved by algorithm A when faced with adversary D in the prediction with expert advice game with stopping probability δ and k experts. The minimax regret for a family $\mathcal{A}_{\mathcal{F}}$ of algorithms is given by $R_{\delta,k}(\mathcal{A}_{\mathcal{F}}) = R_{\delta,k}(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}}) = \min_{A \in \mathcal{A}_{\mathcal{F}}} \max_{D \in \mathcal{D}_{\text{univ}}} R_{\delta,k}(A, D)$. Let[3] $R_k(\mathcal{A}_{\mathcal{F}}) = \frac{1}{\sqrt{\delta}} \lim_{\delta \to 0} \sqrt{\delta} \cdot R_{\delta,k}(\mathcal{A}_{\mathcal{F}})$.

We show the following:

1. $R_2(\mathcal{A}_{\text{single}}) = \frac{0.391}{\sqrt{\delta}}$,
2. $R_k(\mathcal{A}_{\text{single}}) \geq \frac{1}{2}\sqrt{\frac{\ln k}{2\delta}}$ for all k.

The regret lower bound of $\frac{1}{2}\sqrt{\frac{\ln k}{2\delta}}$ we obtain is at most a factor 2 away from the regret upper bound of $\sqrt{\frac{\ln k}{2\delta}}$. Further, we show that the adversarial family that we use for the family of algorithms $\mathcal{A}_{\text{single}}$ to obtain the precise regret for 2 experts, also obtains the optimal regret for the universe $\mathcal{A}_{\text{univ}}$ of *all algorithms*. See See the full version [11] for more on this result.

1.2 Simple adversarial primitives and families

While the optimal regret $R_k(\mathcal{A}_{\mathcal{F}})$ is defined by optimizing over the most general family $\mathcal{D}_{\text{univ}}$ of all adversaries, (i.e., $R_k(\mathcal{A}_{\mathcal{F}}) = R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}})$) one of our primary contributions in this work is to develop simple and analytically easy-to-work-with adversarial primitives that we use to construct adversarial families (call a typical such family $\mathcal{D}_{\text{simple}}$) such that:

[3] Note that the notation $R_k(\cdot)$ is overloaded: it could refer to finite or geometric horizon setting depending on the context. But since the setting is clear from the context, we drop the δ vs T.

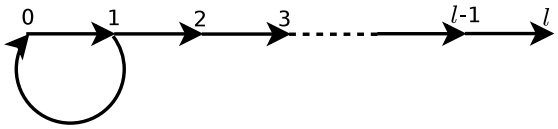

Figure 1 Optimal finite horizon adversary.

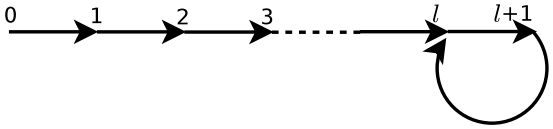

Figure 2 Optimal geometric horizon adversary.

- $\mathcal{D}_{\text{simple}}$ is simple to-describe and to-optimize-over, i.e., computing $\max_{D\in\mathcal{D}_{\text{simple}}} R_{T,k}(A,D)$ is much simpler than computing $\max_{D\in\mathcal{D}_{\text{univ}}} R_{T,k}(A,D)$.
- optimizing over $\mathcal{D}_{\text{simple}}$ is guaranteed to be as good (or approximately as good) as optimizing over $\mathcal{D}_{\text{univ}}$ for many algorithmic families $\mathcal{A}_{\mathcal{F}}$, i.e., $R_k(\mathcal{A}_{\mathcal{F}},\mathcal{D}_{\text{univ}}) = R_k(\mathcal{A}_{\mathcal{F}},\mathcal{D}_{\text{simple}})$ for many $\mathcal{A}_{\mathcal{F}}$. As $R_k(\mathcal{A}_{\mathcal{F}},\mathcal{D}_{\text{univ}}) \geq R_k(\mathcal{A}_{\mathcal{F}},\mathcal{D}_{\text{simple}})$, the non-trivial part is to prove (approximate) equality for $\mathcal{A}_{\mathcal{F}}$.

We demonstrate the versatility of our primitives by using simple combinations of them to develop sharp lower bounds to algorithmic families $\mathcal{A}_{\text{single}}$, $\mathcal{A}_{\text{dec}}$, $\mathcal{A}_{\text{arb}}$, and $\mathcal{A}_{\text{rand}}$. There is a lot of room for further combinations of primitives that might be useful to construct adversarial families tailored to other algorithmic families.

The "looping" and "straight-line" primitives

These primitives are best described by focusing on the case of $k = 2$ experts. In the two experts case, the algorithm makes its decision at step t, by just looking at the difference d of the cumulative gains of the leading and lagging experts' cumulative gains. As such, the adversary has to simply control how the difference d evolves over time. The "looping" primitive simply loops the value of d between 0 and 1 indefinitely (i.e., advances[4] one expert in one step and advances the other in the next step and so on, so that d simply loops between 0 and 1). The "straight-line" adversary simply keeps advancing the value of d by 1 at each step. Interestingly, the worst-case adversary for each of the finite and geometric horizon settings is a composition of looping and straight-line primitives. Strikingly, despite the apparent similarity between two settings, the optimal adversaries in the two models turn out to be "mirror images" of each other. The optimal adversary in finite horizon loops first and then goes in straight-line, while the geometric horizon's optimal does the reverse. The structure of these two families is depicted in Figures 1, 2, that shows the evolution of the difference d between the cumulative gains of the leading and lagging experts. This fundamental difference between the structures of the optimal adversary in these two settings also manifests in the optimal regret values of these two settings.

The generalizations of these primitives for arbitrary k is straightforward. The looping primitive partitions the set of experts into two teams, say A and B, and then it advances all experts in team A in one step and in team B in the other, and so on. The straight-line primitive picks an arbitrary expert and keeps advancing that expert by 1 in each step.

[4] Advances here refers to setting the gain of that expert to 1.

Combining the primitives

Here's how we create effective adversarial families from these primitives. In fact the families are often trivial, i.e., they have only one member and therefore there's nothing to optimize. We ignore the odd and even k distinctions here for ease of description and just focus on the even k case. Please see the technical sections for precise descriptions, which is only slightly different from what is here.

1. Perform $\frac{T-\ell}{2}$ loops and then ℓ straight-line steps, for $\ell = T^{3/4}$. Call this adversary D_{lsdet} (stands for loop-straight-deterministic). Clearly, this adversarial family is simple-to-describe and there is nothing to optimize here as there is only one member in the family. Most importantly, it gives the precisely optimal regret for algorithmic families $\mathcal{A}_{\text{single}}$ and $\mathcal{A}_{\text{dec}}$ as $T \to \infty$. I.e.,

$$\text{For families } \mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\text{single}}, \mathcal{A}_{\text{dec}}: \qquad R_k(\mathcal{A}_{\mathcal{F}}, D_{lsdet}) = \sqrt{\frac{T \ln k}{2}} = R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}}).$$

   The best known regret lower bound for $\mathcal{A}_{\text{single}}$ was $\frac{1}{4}\sqrt{T \log_2 k}$ [13], which leaves a factor 2.35 gap between upper and lower bounds, that our work closes. We are not aware of prior lower bounds for $\mathcal{A}_{\text{dec}}$.
2. Perform $\frac{T-r}{2}$ loops and then r straight-line steps, where r is chosen uniformly at random from $\{0, 1, \ldots, T^{3/4}\}$. This family is simple and there is nothing to optimize here as well. Call this adversary D_{lsrand} (denoting loop, straight, uniformly random). We show that when $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\text{arb}}$ or when $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\text{rand}}$:

$$\text{For families } \mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\text{arb}}, \mathcal{A}_{\text{rand}}: \qquad R_k(\mathcal{A}_{\mathcal{F}}, D_{lsrand}) \geq \frac{2}{3}\sqrt{\frac{T \ln k}{2}} \geq \frac{2}{3} R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}}).$$

   Note that while this lower bound doesn't precisely match the upper bound, the upper bound $R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{\text{univ}}) \leq \sqrt{(T \ln k)/2}$ and is likely even smaller for small k (particularly for a large family of algorithms like $\mathcal{A}_{\text{arb}}$ or $\mathcal{A}_{\text{rand}}$) — *thus our result shows that the ratio between upper and lower bounds is at most* $\frac{3}{2}$ and likely even smaller. To the best of our knowledge our lower bound is the first for the classes $\mathcal{A}_{\text{arb}}$ and $\mathcal{A}_{\text{rand}}$.
3. In geometric horizon, even for the family $\mathcal{A}_{\text{single}}$ and at $k = 2$ experts, instead of a single adversary working for all members of $\mathcal{A}_{\text{single}}$, we have a single-parameter family of adversaries to optimize over. Namely, follow the straight-line primitive for r steps and then the looping primitive for $\frac{T-r}{2}$ steps. Call this single-parameter family (parameterized by r) as $\mathcal{D}_{sl}$. The exact number r is determined by optimizing it as a function of the parameter η used by the algorithm in $\mathcal{A}_{\text{single}}$. Specifically, for the case of 2 experts we show that: $R_2(\mathcal{A}_{\text{single}}, \mathcal{D}_{sl}) = \frac{0.391}{\sqrt{\delta}} = R_2(\mathcal{A}_{\text{single}}, \mathcal{D}_{\text{univ}})$. Note that D_{sl} is again simple-to-describe and straightforward-to-optimize over. Further, it is the precisely optimal adversary family for not just $\mathcal{A}_{\text{single}}$ but also the *universe of all algorithms* $\mathcal{A}_{\text{univ}}$ (see the full version [11] for this result), i.e., $R_2(\mathcal{A}_{\text{univ}}, \mathcal{D}_{\text{univ}}) = R_2(\mathcal{A}_{\text{univ}}, \mathcal{D}_{sl})$.
4. But in the geometric horizon setting, if we don't shoot for the precisely optimal adversary family, and aim for just approximately optimal, then we don't need a single-parameter family: just following one of the two looping/straight-line primitives gives a lower bound of $\frac{1}{2}\sqrt{\frac{\ln k}{2\delta}}$. Let D_ℓ, D_s be the looping and straight line primitives. Then: $R_k(\mathcal{A}_{\text{single}}, \{D_\ell, D_s\}) \geq \frac{1}{2}\sqrt{\frac{\ln k}{2\delta}} \geq \frac{1}{2} R_k(\mathcal{A}_{\text{single}}, \mathcal{D}_{\text{univ}})$. Note that while this lower bound doesn't precisely match the upper bound $R_k(\mathcal{A}_{\text{single}}, \mathcal{D}_{\text{univ}})$, the latter is at most[5] $\sqrt{\frac{\ln k}{2\delta}}$, which is at most a factor 2 larger than lower bound.

[5] This is a simple extension of the standard proof that MWA has a regret upper bound of $\sqrt{(T \ln k)/2}$ in

▶ Remark. To give a sense that the primitives offer enough variety in combination, here is a simple modification over the adversary D_{lsrand}, that we call $D_{lsrand++}$: use D_{lsrand} with probability p, and with probability $1-p$ play the looping primitive D_l for all the T steps. This increases the lower bound from $\frac{2}{3}\sqrt{(T\ln k)/2}$ to $0.68\sqrt{(T\ln k)/2}$ (see the full version [11] for this result). We believe that this can be increased further by picking the stopping time for looping from a non-uniform distribution etc.

1.3 Motivation and discussion

In this work we seek to understand the structure of worst case input sequences for a broad family of algorithms and crisply expose their vulnerabilities. By identifying such structures, we also get the precise regret suffered by them. Our motivation in exploring this question includes the following.

1. After 25 years since MWA was introduced [19, 27], we do not have a sharp regret bound for it. $\mathcal{A}_{\text{single}}$ is known to suffer a regret of at most $\sqrt{\frac{T\ln k}{2}}$, but the best known lower bound on regret is $\frac{1}{4}\sqrt{T\log_2 k}$ [13], with a factor 2.35 gap between these two bounds. For larger families like $\mathcal{A}_{\text{arb}}$, $\mathcal{A}_{\text{rand}}$ no lower bounds were known. For an algorithm as widely used as MWA, it is fruitful to have a sharp regret characterization.
2. The patterns in the worst-case adversarial sequences that we characterize are simple to spot if they exist (or even if anything close exists), and make simple amends to the algorithm that result in significant gains.
3. The problem is theoretically clean and challenging: how powerful are simple input patterns beyond the typically used pure random sequences in inflicting regret?

Related Work

Classic works: The book by Cesa-Bianchi and Lugosi [7] is an excellent source for both applications and references for prediction with expert advice. The prediction with experts advice paradigm was introduced by Littlestone and Warmuth [19] and Vovk [27]. The famous multiplicative weights update algorithm was introduced independently by these two works: as the weighted majority algorithm by [19] and as the aggregating algorithm by [27]. The pioneering work of Cesa-Bianchi et al. [6] considered $\{0,1\}$ outcome space for nature and showed that for the absolute loss function $\ell(x,y)=|x-y|$ (or $g(x,y)=1-|x-y|$), the asymptotically optimal regret is $\sqrt{\frac{T\ln k}{2}}$. This was later extended to $[0,1]$ outcomes for nature by Haussler et al. [15]. The asymptotic optimality of $\sqrt{\frac{T\ln k}{2}}$ for arbitrary loss (gain) functions follows from the analysis of Cesa-Bianchi [5]. When it is known beforehand that the cumulative loss of the optimal expert is going to be small, the optimal regret can be considerably improved, and such results were obtained by Littlestone and Warmuth [19] and Freund and Schapire [9]. With certain assumptions on the loss function, the simplest possible algorithm of following the best expert already guarantees sub-linear regret (see Hannan [14]). Even when the loss functions are unbounded, if the loss functions are exponential concave, sub-linear regret can still be achieved as shown by Blum and Kalai [4]. While our work is focused on the worst-case adversaries for the MWA family of algorithms, Freund and Schapire [10] prove lower bounds for general adaptive game-playing algorithms.

the finite horizon setting with T steps and k experts, and the realization that in the geometric horizon setting, the expected stopping time is $\frac{1}{\delta}$.

Recent works: Gravin et al. [12] give the minimax optimal algorithm, and the regret for the prediction with expert advice problem for the cases of $k = 2$ and $k = 3$ experts. The focus of [12] was providing a regret upper bound for the family of all algorithms, while the focus of this paper is to provide regret lower bounds for large families of algorithms. Luo and Schapire [20] consider a setting where the adversary is restricted to pick gain vectors from the basis vector space $\{\mathbf{e}_1, \ldots, \mathbf{e}_k\}$. Abernethy et al. [3] consider a different variant of experts problem where the game stops when cumulative loss of any expert exceeds given threshold. Abernethy et al. [2] consider general convex games and compute the minimax regret exactly when the input space is a ball, and show that the algorithms of Zinkevich [28] and Hazan et al. [16] are optimal w.r.t. minimax regret. Abernethy et al. [1] provide upper and lower bounds on the regret of an optimal strategy for several online learning problems without providing algorithms, by relating the optimal regret to the behavior of a certain stochastic process. Mukherjee and Schapire [23] consider a continuous experts setting where the algorithm knows beforehand the maximum number of mistakes of the best expert. Rakhlin et al. [25] introduce the notion of sequential Rademacher complexity and use it to analyze the learnability of several problems in online learning w.r.t. minimax regret. Rakhlin et al. [26] use the sequential Rademacher complexity introduced in [25] to analyze learnability w.r.t. general notions of regret (and not just minimax regret). Rakhlin et al. [24] use the notion of conditional sequential Rademacher complexity to find relaxations of problems like prediction with static experts that immediately lead to algorithms and associated regret guarantees. They show that the random playout strategy has a sound basis and propose a general method to design algorithms as a random playout. Koolen [17] studies the regret w.r.t. every expert, rather than just the best expert in hindsight and considers tradeoffs in the Pareto-frontier. McMahan and Abernethy [21] characterize the minimax optimal regret for online linear optimization games as the supremum over the expected value of a function of a martingale difference sequence, and similar characterizations for the minimax optimal algorithm and the adversary. McMahan and Orabona [22] study online linear optimization in Hilbert spaces and characterize minimax optimal algorithms. Chaudhuri et al. [8] describe a parameter-free learning algorithm motivated by the cases of large number of experts k. Koolen and Erven [18] develop a prediction strategy called Squint, and prove bounds that incorporate both quantile and variance guarantees.

2 Finite horizon

We begin our analysis of MWA by focusing on the simple case of $k = 2$ experts. We first identify the structure of the optimal adversary, and through it we obtain the tight regret bound as $T \to \infty$. Before proceeding further, it is useful to recall that when the gains of the leading and lagging experts are given by $g + d$ and g, the MWA algorithm follows these experts with probabilities $\frac{e^{\eta d}}{e^{\eta d}+1}$ and $\frac{1}{e^{\eta d}+1}$ respectively. Thus, when the adversary increases d by 1 i.e., increases the gain of the leading expert by 1, the regret benchmark (namely, the gains of the leading expert) increases by 1, where as MWA is correct only with probability $\frac{e^{\eta d}}{e^{\eta d}+1}$, and this therefore inflicts a regret of $\frac{1}{e^{\eta d}+1}$ on MWA. On the other hand, if the adversary decreases d by 1, then the benchmark doesn't change, where as MWA succeeds with probability $\frac{1}{e^{\eta d}+1}$, and this therefore inflicts a regret of $\frac{-1}{e^{\eta d}+1}$. When the adversary doesn't change d, the regret inflicted is 0.

Structure of the optimal adversary

Let η be the fixed update rate of the optimal MWA (the parameter in the exponent as explained in Section 1)[6]. Against a specific algorithm, an optimal adversary can always be found in the class of deterministic adversaries. The actions of the optimal adversary (against a specific MWA algorithm) depend only on the distance d between leading and lagging experts and time step t.

1. **Loop aggregation:** At each time step, the adversary may either increase or decrease the gap d by 1, or leave d unchanged. We denote these actions of the adversary by $d \xrightarrow{t} d+1$, $d \xrightarrow{t} d-1$, and $d \xrightarrow{t} d$. The respective regret values inflicted on the algorithm are given by $\frac{1}{e^{\eta d}+1}$, $\frac{-1}{e^{\eta d}+1}$, and 0, which are all independent of the time when an action was taken. This means that if the adversary loops between d and $d+1$ at several disconnected points of time, it may as well aggregate all of them and complete all of them in consecutive time steps. I.e., the optimal adversary starts at $d=0$ and then weakly monotonically increases d, stopping at various points $d=s$, looping for an arbitrary length of time between $d=s$ and $d=s-1$ and then proceeding forward.
2. **Staying at same d is dominated:** It is not hard to see that any action $x \to x$ is dominated for the adversary as this wastes a time step and inflicts 0 regret on the algorithm. Thus the "weakly monotonically increases" in the previous paragraph can be replaced by "strictly monotonically increases" (except of course for the stopping points for looping).
3. **Loop(0) domination:** Define $\mathrm{Loop}(d) \stackrel{\mathrm{def}}{=} d \to d+1 \to d$. It is easy to see that the regret inflicted by $\mathrm{Loop}(d)$ is exactly $\frac{1}{e^{\eta d}+1} - \frac{1}{e^{\eta(d+1)}+1}$ and this quantity is maximized at $d=0$. Thus, the optimal adversary should replace all loops by loops at 0. This gives us the structure claimed in Figures 1, 2 for the optimal adversary.

Given the optimal adversary's structure (as described in Figures 1, 2) w.l.o.g. we can assume it to be looping for $\frac{T-\ell}{2}$ steps at 0 and then monotonically increasing d for ℓ steps at which point the game ends. In the following we will analyze the regret inflicted by the optimal adversary (which we showed was optimal for the class of algorithm $\mathcal{A}_{\mathrm{single}}$) against a broader class $\mathcal{A}_{\mathrm{dec}}$ of MWA. The regret of the adversary is:

$$\sum_{t=1}^{\frac{T-\ell}{2}} \left[\frac{1}{2} - \frac{1}{e^{\eta(2t)}+1}\right] + \sum_{d=0}^{\ell-1} \frac{1}{e^{\eta(T-\ell+d+1)d}+1}. \tag{1}$$

Asymptotic regret of the optimal adversary

We first notice that for a fixed adversary with a given ℓ, the regret of MWA with decreasing $\eta(t)$ in (1) is greater than or equal to the regret of MWA with a constant $\eta' = \eta(T-\ell)$, i.e.,

$$\frac{T-\ell}{2}\left[\frac{1}{2} - \frac{1}{e^{\eta'}+1}\right] + \sum_{d=0}^{\ell-1} \frac{1}{e^{d\eta'}+1}. \tag{2}$$

This is true as each individual term in (2) is equal to or smaller than the corresponding term in (1). In the following we are going to use $\ell = T^{3/4}$ for the adversary and for convenience, we write $e^{\eta'(T-\ell)} = \tau = 1 + \frac{\alpha}{\sqrt{T}}$. The two terms in (1) together place strong bounds on what α should be: they imply that $\alpha = \Theta(1)$. We show this in 2 steps: first we show that $\alpha = O(1)$, and then show that $\alpha = \Omega(1)$.

[6] In fact, we can identify the optimal adversary for a much broader family of algorithms (see the full version [11] for more details).

1. The first term in (2) forces α to be $O(1)$. The regret of MWA for $\ell = T^{3/4}$ is at least

$$\frac{T-\ell}{2}\left[\frac{1}{2}-\frac{1}{e^{\eta'}+1}\right] \simeq \frac{T}{2}\left[\frac{1}{2}-\frac{1}{e^{\eta'}+1}\right] = \frac{\alpha\sqrt{T}}{4(1+e^{\eta'})} = \frac{\sqrt{T}}{4(\frac{2}{\alpha}+\frac{1}{\sqrt{T}})}.$$

   Since MWA's regret upper bound in the finite horizon model is $\Theta\left(\sqrt{T}\right)$, α must be $O(1)$.

2. To show that $\alpha = \Theta(1)$ we argue that the regret from the second term of (2) is $\omega(\sqrt{T})$ when $\alpha = o(1)$. For all $d \le \frac{\sqrt{T}}{\alpha}$, we have $\tau^d = (1+\frac{\alpha}{\sqrt{T}})^d \le e$. Thus MWA's regret for $k = \min(\frac{\sqrt{T}}{\alpha}, T^{3/4})$ is at least

$$\sum_{d=0}^{k-1}\frac{1}{\tau^d+1} \ge \sum_{d=0}^{k-1}\frac{1}{e+1} = \Omega(k) = \omega\left(\sqrt{T}\right).$$

   Since MWA's regret upper bound in the finite horizon model is $\Theta\left(\sqrt{T}\right)$, we get $\alpha = \Omega(1)$.

Now, we obtain the following asymptotic estimate for the second part of (2), where $\eta' \sim e^{\eta'} - 1 = \frac{\alpha}{\sqrt{T}}$.

$$\sum_{d=0}^{\ell-1}\frac{1}{\tau^d+1} \sim \int_0^{\ell}\frac{\mathrm{d}x}{e^{\eta' x}+1} = \frac{1}{\eta'}\ln\left(2\frac{e^{\ell\eta'}}{e^{\ell\eta'}+1}\right) \sim \frac{\sqrt{T}}{\alpha}\left(\ln(2)-\ln(1+e^{-\ell\eta'})\right). \tag{3}$$

The first part of (2) can be estimated as follows

$$\frac{T-\ell}{2}\left[\frac{1}{2}-\frac{1}{e^{\eta'}+1}\right] \sim \frac{T}{2}\left[\frac{e^{\eta'}-1}{2(e^{\eta'}+1)}\right] \sim \frac{T}{2}\cdot\frac{\eta'}{4} = \frac{\alpha\sqrt{T}}{8}. \tag{4}$$

As $e^{-\ell\eta'} = e^{-\alpha T^{1/4}} = o(1)$, (3) simplifies to $\frac{\ln(2)\sqrt{T}}{\alpha}$, while the estimate for (4) is $\frac{\alpha\sqrt{T}}{8}$. Now the estimate $\sqrt{T}\left[\frac{\ln(2)}{\alpha}+\frac{\alpha}{8}\right]$ for the regret in (2) is minimized for the choice of parameter $\alpha = \sqrt{8\ln(2)}$. Then the regret of the optimal MWA is at least $\sqrt{T\cdot\frac{\ln(2)}{2}}(1+o(1))$. It is known that there is MWA for $k=2$ experts with regret at most $\sqrt{T\cdot\frac{\ln(2)}{2}}$ (asymptotic in T). Thus, we obtain the following claim 1 (in the claim below, by "optimal MWA" we mean the MWA with the optimally tuned $\eta(t) = \eta'$).

▶ **Claim 1.** *For $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{single}, \mathcal{A}_{dec}$:* $R_2(\mathcal{A}_{\mathcal{F}}, D_{lsdet}) = \sqrt{\frac{T\ln 2}{2}} = R_2(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{univ})$.

We generalize the adversary for $k=2$ and obtain a tight lower bound for $\mathcal{A}_{\mathrm{dec}}$ matching the known upper bound for arbitrary *even* number k of experts and almost matching bound for *odd* number k of experts. Since $R_k(\mathcal{A}_{\mathrm{single}}) \ge R_k(\mathcal{A}_{\mathrm{dec}})$, the lower bound in Theorem 2 below applies to $\mathcal{A}_{\mathrm{single}}$ as well.

▶ **Theorem 2.** *For $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{single}, \mathcal{A}_{dec}$:*

(i) *For even k:* $R_k(\mathcal{A}_{\mathcal{F}}, D_{lsdet}) = \sqrt{\frac{T\cdot\ln k}{2}} = R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{univ})$.

(ii) *For odd k:* $R_k(\mathcal{A}_{\mathcal{F}}, D_{lsdet}) \ge \sqrt{\frac{T\cdot\ln k}{2}\left(1-\frac{1}{k^2}\right)} \ge \sqrt{1-\frac{1}{k^2}}R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{univ})$.

Proof. Let $\eta(t)$ be the update rate of the optimal MWA, we define $\ell = T^{3/4}$ and $\eta' = \eta(T-\ell)$. We employ the following adversary for the even k number of experts:

1. Divide all experts into two equal parties, numbered A and B. For the first $\frac{T-\ell}{2}$ rounds ($\ell = T^{3/4}$), advance all the experts in party A in even numbered rounds, and all experts in party B in odd numbered rounds.
2. For the remaining ℓ steps, pick an arbitrary expert and keep advancing just that expert.

Similar to (1) this adversary obtains the regret of at least $\sum_{t=1}^{\frac{T-\ell}{2}} \left[\frac{1}{2} - \frac{1}{e^{\eta(2t)}+1}\right] + \sum_{d=0}^{\ell-1} \frac{k-1}{e^{d\cdot\eta(T-\ell+d+1)}+k-1}$. We further notice that similar to (2) the regret of MWA with decreasing $\eta(t)$ in the above expression is greater than or equal to the regret of MWA with a constant $\eta' = \eta(T-\ell)$, i.e., the previous expression is at least

$$\frac{T-\ell}{2}\left[\frac{1}{2} - \frac{1}{e^{\eta'}+1}\right] + \sum_{d=0}^{\ell-1} \frac{k-1}{e^{d\cdot\eta'}+k-1}. \tag{5}$$

We use (4) to estimate the first term of (5). We estimate the second term of (5) similar to (3) as follows.

$$\sum_{d=0}^{\ell-1} \frac{k-1}{e^{d\eta'}+k-1} \sim \int_0^{\ell} \frac{(k-1)\mathrm{d}x}{e^{x\eta'}+k-1} = \frac{1}{\eta'}\ln\left(\frac{k\cdot e^{\ell\eta'}}{e^{\ell\eta'}+k-1}\right) \sim \frac{\sqrt{T}\ln(k)}{\alpha}. \tag{6}$$

Now, combining these two estimates the regret from (5) is at least

$$\frac{\alpha\sqrt{T}}{8} + \frac{\sqrt{T}\ln(k)}{\alpha} \geq 2\cdot\sqrt{\frac{\alpha\sqrt{T}}{8}\cdot\frac{\sqrt{T}\ln(k)}{\alpha}} = \sqrt{\frac{T\ln(k)}{2}},$$

which precisely matches the upper bound on the regret of MWA[6].

For the odd k number of experts we employ almost the same adversary as for even k, although, since k now is odd, we split experts into two parties of *almost* equal sizes (see the full version [11] for more details). ◀

2.1 General variations of MWA

We have seen that the best known MWA with a flat learning rate η achieves optimal (or almost optimal in the case of odd number of experts) regret among all MWAs with monotone decreasing learning rates $\eta(t)$. However, it seems that in the finite horizon model a better strategy for tuning parameters of MWA would be to use higher rates $\eta(t)$ towards the end T. In the following we study a broader family of MW algorithms $\mathcal{A}_{\text{arb}}$ where learning parameter $\eta(t)$ can vary in an arbitrary way. In the following theorem we show that such adaptivity of MWA cannot decrease the regret of the algorithm by more than a factor of 2/3.

▶ Remark. In fact, our analysis extends to the family $\mathcal{A}_{\text{rand}}$ where each $\eta(t)$ can be a random variable drawn from a distribution F_t. Effectively, with a random $\eta(t)$ the algorithm player can get any convex combination $f(G_{i,t-1}, t) = \mathbf{E}_{\eta(t)}[e^{\eta(t)G_{i,t-1}}]$ of $e^{\eta(t)G_{i,t-1}}$ in the vector of probabilities for following each expert i at time t. This constitutes a much richer family of algorithms compared to the standard single parameter MWA family.

▶ **Theorem 3.** *For $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{arb}, \mathcal{A}_{rand}$:*

(i) *For even k: $R_k(\mathcal{A}_{\mathcal{F}}, D_{lsrand}) \geq \frac{2}{3}\sqrt{\frac{T\cdot\ln k}{2}} \geq \frac{2}{3}R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{univ})$.*

(ii) *For odd k: $R_k(\mathcal{A}_{\mathcal{F}}, D_{lsrand}) \geq \frac{2}{3}\sqrt{\frac{T\cdot\ln k}{2}\left(1-\frac{1}{k^2}\right)} \geq \frac{2}{3}\sqrt{1-\frac{1}{k^2}}R_k(\mathcal{A}_{\mathcal{F}}, \mathcal{D}_{univ})$.*

Proof. Define $\ell = T^{3/4}$ and $R = \left[\frac{T-\ell-1}{2}\right]$. We use the following adversary for even number of experts k:

1. Choose $j \in [R]$ uniformly at random. With probability 0.5 don't advance any expert in the first step.
2. Divide all experts into two equal parties, numbered A and B. For the next j rounds, advance all the experts in party A in even numbered rounds, and all experts in party B in odd numbered rounds.
3. For next ℓ steps, pick any expert i and keep advancing just expert i. Do nothing in remaining steps.

The regret of the algorithm is

$$\frac{1}{R}\sum_{j=0}^{R-1}\left[\frac{1}{2}\left(\sum_{t=1}^{j}\left[\frac{1}{2}-\frac{1}{e^{\eta(2t)}+1}\right]+\sum_{d=0}^{\ell-1}\frac{k-1}{e^{d\cdot\eta(2j+d+1)}+k-1}\right)+ \frac{1}{2}\left(\sum_{t=1}^{j}\left[\frac{1}{2}-\frac{1}{e^{\eta(2t+1)}+1}\right]+\sum_{d=0}^{\ell-1}\frac{k-1}{e^{d\cdot\eta(2j+d+2)}+k-1}\right)\right]. \tag{7}$$

Since $\eta(t)$ can be arbitrary nonnegative number, we break (7) into terms with the same $\eta(t)$ (we also drop a few terms to simplify the expression). In the following, we will also assume that $e^{\eta(t)} = 1 + \frac{\alpha(t)}{\sqrt{T}}$, where $\alpha(t) = \Theta(1)$ for every $t \in [T]$. Later we will explain why this assumption is without loss of generality.

$$\begin{aligned}(7) &\geq \frac{1}{2R}\sum_{t=\ell}^{T-\ell-1}\left(\left[R-\lceil t/2\rceil\right]\cdot\left[\frac{1}{2}-\frac{1}{e^{\eta(t)}+1}\right]+\sum_{d=0}^{\ell-1}\frac{k-1}{e^{\eta(t)d}+k-1}\right)\\ &\simeq \sum_{t=\ell}^{T-\ell-1}\left(\left[\frac{R-\lceil t/2\rceil}{R}\right]\frac{\alpha(t)}{8\sqrt{T}}+\frac{\sqrt{T}\ln(k)}{2R\cdot\alpha(t)}\right) \geq \sum_{t=\ell}^{T-\ell-1}2\sqrt{\left[\frac{R-\lceil t/2\rceil}{R}\right]\frac{\alpha(t)}{8\sqrt{T}}\frac{\sqrt{T}\ln(k)}{2R\cdot\alpha(t)}}\\ &= \sqrt{\frac{\ln(k)}{2\cdot 2R}}\sum_{t=\ell}^{T-\ell-1}\sqrt{\left[\frac{R-\lceil t/2\rceil}{R}\right]} \simeq \sqrt{\frac{\ln(k)}{2\cdot T}}\int_0^1\sqrt{1-x}\quad \mathrm{d}x = \sqrt{\frac{\ln(k)}{2T}}\cdot\frac{2}{3}.\end{aligned} \tag{8}$$

In the above derivation we obtain the first approximation $\simeq$ by using approximations from (4) and (6).

We now argue that the assumption $\alpha(t) = \Theta(1)$ is without loss of generality for every $t \in [T]$. We apply a similar argument as in Theorem 1, but now for each individual term with a particular $\eta(t)$. The term $\sum_{d=0}^{\ell-1}\frac{k-1}{e^{\eta(t)d}+k-1}$ in (8) is already large enough for the estimate when $\alpha(t) = o(1)$. The term $\left[R-\lceil t/2\rceil\right]\cdot\left[\frac{1}{2}-\frac{1}{e^{\eta(t)}+1}\right]$ also places a strong bound of $O(1)$ on $\alpha(t)$, when $\left[R-\lceil t/2\rceil\right]$ is constant fraction of T. To argue about t close to the threshold T, we can slightly modify the adversary by playing with a small constant probability ε entirely "looping" strategy (without "straight line" part). This would make the coefficient in front of $\left[\frac{1}{2}-\frac{1}{e^{\eta(t)}+1}\right]$ to be sufficiently large, and at the same time would decrease the lower bound by at most $1-\varepsilon$ factor. Taking ε arbitrary small we obtain the bound in (8). This concludes the proof for the even number of experts

For the odd number of experts k. We slightly modify the adversary analogous to the case of odd number of experts in Theorem 2. This gives us an additional factor of $1-\frac{1}{k^2}$ for each of the looping terms.

Note that since our adversary is independent of how the $\eta(t)$'s are picked in the algorithm, it follows immediately that our lower bound applies for $\mathcal{A}_{\mathcal{F}} = \mathcal{A}_{\mathrm{arb}}, \mathcal{A}_{\mathrm{rand}}$. ◀

▶ Remark. One can slightly improve the lower bound in Theorem 3 and get a better factor than $\frac{2}{3}$. To this end we employ a more complicated adversary by playing with some probability $p > 0$ the same strategy as in Theorem 3 and with the remaining $1 - p$ probability playing purely looping strategy (see the full version [11]).

3 Geometric horizon

We prove two main results in this Section. We derive the structure of the optimal adversary for 2 experts and show that the optimal regret for 2 experts is exactly $\frac{0.391}{\sqrt{\delta}}$ as $\delta \to 0$. For an arbitrary number of experts k, we derive a regret lower bound of $\frac{1}{2}\sqrt{\frac{\ln(k)}{2\delta}}$ (see the full version [11] for proofs of these results).

Abstract

In a recent work (Ghazi et al., SODA 2016), the authors with Komargodski and Kothari initiated the study of *communication with contextual uncertainty*, a setup aiming to understand how efficient communication is possible when the communicating parties imperfectly share a huge context. In this setting, Alice is given a function f and an input string x, and Bob is given a function g and an input string y. The pair (x, y) comes from a known distribution μ and f and g are guaranteed to be close under this distribution. Alice and Bob wish to compute $g(x, y)$ with high probability. The lack of agreement between Alice and Bob on the function that is being computed captures the uncertainty in the context. The previous work showed that any problem with one-way communication complexity k in the standard model (i.e., without uncertainty[1]) has *public-coin* communication at most $O(k(1 + I))$ bits in the uncertain case, where I is the mutual information between x and y. Moreover, a lower bound of $\Omega(\sqrt{I})$ bits on the public-coin uncertain communication was also shown.

However, an important question that was left open is related to the power that public randomness brings to uncertain communication. Can Alice and Bob achieve efficient communication amid uncertainty without using public randomness? And how powerful are public-coin protocols in overcoming uncertainty? Motivated by these two questions:

- We prove the first separation between private-coin uncertain communication and public-coin uncertain communication. Namely, we exhibit a function class for which the communication in the standard model and the public-coin uncertain communication are $O(1)$ while the private-coin uncertain communication is a growing function of n (the length of the inputs). This lower bound (proved with respect to the uniform distribution) is in sharp contrast with the case of public-coin uncertain communication which was shown by the previous work to be within a constant factor from the certain communication. This lower bound also implies the first separation between public-coin uncertain communication and deterministic uncertain communication. Interestingly, we also show that if Alice and Bob *imperfectly share* a sequence of random bits (a setup weaker than public randomness), then achieving a constant blow-up in communication is still possible.
- We improve the lower-bound of the previous work on public-coin uncertain communication. Namely, we exhibit a function class and a distribution (with mutual information $I \approx n$) for which the one-way certain communication is k bits but the one-way public-coin uncertain communication is at least $\Omega(\sqrt{k} \cdot \sqrt{I})$ bits.

Our proofs introduce new problems in the standard communication complexity model and prove lower bounds for these problems. Both the problems and the lower bound techniques may be of general interest.

1 Introduction

In many forms of communication (e.g., human, computer-to-computer), the communicating parties share some context (e.g, knowledge of a language, operating system, communication protocol, encoding/decoding mechanisms.). This context is usually a) *huge* and b) *imperfectly shared* among the parties. Nevertheless, in human communication, very efficient communication is usually possible. Can we come up with a mathematical analogue of this phenomenon of efficient communication based on a huge but imperfectly shared context? Motivated by this general question, the study of "communication amid uncertainty" has been the subject of a series of recent work starting with Goldreich, Juba and Sudan [13, 8] followed by [12, 14, 15, 11, 4]. While early works were very abstract and general, later works (starting with Juba, Kalai, Khanna and Sudan [12]) tried to explore the ramifications of uncertainty in Yao's standard communication complexity model [26]. In particular, the more recent works relax the different pieces of context that were assumed to be *perfectly shared* in Yao's model, such as shared randomness [4], and in a recent work of the authors with Komargodski and Kothari the *function being computed* [6].

Specifically, [6] study the following functional notion of uncertainty in communication. Their setup builds on – and generalizes – Yao's classical model of (distributional) communication complexity, where Alice has an input x and Bob has an input y, with (x, y) being sampled from a distribution μ. Their goal is to communicate minimally so as to compute some function $g(x, y)$ (with high probability over the choice of (x, y)). The understated emphasis of the model is that for many functions g, the communication required is much less than the lengths of x or y, the entropy of x or y or even the conditional entropy of x given y.

The question studied by [6] is: How much of this gain in communication is preserved when the communicating parties do not exactly agree on the function being computed? (We further discuss the importance of this question in Section 1.2.) This variation of the problem is modelled as follows: Alice is given a Boolean function f and an input string x, and Bob is given a Boolean function g and an input string y where (x, y) is sampled from a known distribution μ as before, and (f, g) is chosen (adversarially) from a known class $\mathcal{F}$ of pairs of functions that are close in terms of the Hamming distance Δ_μ (weighted according to μ). Alice and Bob wish to compute $g(x, y)$. Alice's knowledge of the function f (which is close but not necessarily equal to g) captures the uncertainty in the knowledge of the context.

We define the *public-coin uncertain communication complexity* $\mathsf{PubCCU}^{\mu}_{\epsilon}(\mathcal{F})$ as the minimum length of a two-way public-coin protocol whose output is correct with probability at least $1-\epsilon$ over its internal randomness and that of (x, y). We similarly define the *private-coin uncertain communication complexity* $\mathsf{PrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$ by restricting to private-coin protocols. Clearly, $\mathsf{PubCCU}^{\mu}_{\epsilon}(\mathcal{F}) \leq \mathsf{PrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$. The quantities $\mathsf{owPubCCU}^{\mu}_{\epsilon}(\mathcal{F})$ and $\mathsf{owPrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$ are similarly defined by restricting to one-way protocols.[2]

[2] Note that the uncertain model is clearly a generalization of Yao's model which corresponds to the particular case where $\mathcal{F} = \{(f, f)\}$ for some fixed function f. On the other hand, the uncertain model

The previous work ([6]) gave an upper bound on $\mathsf{owPubCCU}^{\mu}_{\epsilon}(\mathcal{F})$ whenever $\mathcal{F}$ consists of functions g whose one-way distributional complexity is small. More precisely, denote by $\mathsf{owCC}^{\mu}_{\epsilon}(g)$ the one-way communication complexity of g in the standard distributional model.[3] Namely, $\mathsf{owCC}^{\mu}_{\epsilon}(g)$ is the minimum length of a one-way deterministic protocol computing g with probability at least $1-\epsilon$ over the randomness of (x,y). Then, [6] showed that if $\mathcal{F}$ consists of pairs (f,g) of functions that are at distance δ, and if $\mathsf{owCC}^{\mu}_{\epsilon}(f), \mathsf{owCC}^{\mu}_{\epsilon}(g) \leq k$, then for every positive θ, $\mathsf{owPubCCU}^{\mu}_{\epsilon+2\delta+\theta}(\mathcal{F}) \leq O_{\theta}(k \cdot (1+I(x;y)))$, where $I(x;y)$ denotes the mutual information between x and y.[4] Note that if μ is a product distribution and if we let the parameter θ be a small constant, then the blow-up in communication is only a constant factor. However, the protocol of [6] crucially uses public randomness, and one of the main motivations behind this work is to understand how large the blow-up would be in the case where Alice and Bob have access to weaker types of randomness (or no randomness at all).

We point out that understanding the type of randomness that is needed in order to cope with uncertainty is a core question in the setup of communication with contextual uncertainty: *If Alice and Bob do not (perfectly) agree on the function being computed, why can we assume that they (perfectly) agree on the shared randomness?*

1.1 Our Contributions

We prove several results about the power of shared randomness in uncertain communication.

Private and Imperfectly Shared Randomness

Our first result (Theorem 1) shows that private-coin protocols are much weaker than public-coin protocols in the setup of communication with contextual uncertainty. Far from obtaining a constant factor blow-up in communication, private-coin protocols incur an increase that is a growing function of n when dealing with uncertainty.

Let $\mathcal{U} \triangleq \mathcal{U}_{2n}$ be the uniform distribution on $\{0,1\}^{2\cdot n}$. For positive integers t and n, we define $\log^{(t)}(n)$ by setting $\log^{(1)}(n) = \log n$, and $\log^{(i)}(n) = \max(\log\log^{(i-1)}(n), 1)$ for all $i \in \{2,\ldots,t\}$.

▶ **Theorem 1** (Lower-bound on private-coin uncertain protocols). *For every sufficiently small $\delta > 0$, there exist a positive integer $\ell \triangleq \ell(\delta)$ and a function class $\mathcal{F} \triangleq \mathcal{F}_{\delta}$ such that*

- **(i)** *For each $(f,g) \in \mathcal{F}$, we have that $\Delta_{\mathcal{U}}(f,g) \leq \delta$.*
- **(ii)** *For each $(f,g) \in \mathcal{F}$, we have that $\mathsf{owCC}^{\mathcal{U}}_{0}(f), \mathsf{owCC}^{\mathcal{U}}_{0}(g) \leq \ell$.*
- **(iii)** *For every $\eta > 0$ and $\epsilon \in (4\delta, 0.5]$, we have that $\mathsf{PrivCCU}^{\mathcal{U}}_{\epsilon/2-2\delta-\eta}(\mathcal{F}) = \Omega(\eta^2 \cdot \log^{(t)}(n))$ for some positive integer $t = \Theta((\epsilon/\delta)^2)$.*

In Theorem 1, the inputs x and y are binary strings of length n and $\mathcal{F}$ is a family of pairs of functions, which each function mapping $\{0,1\}^n \times \{0,1\}^n$ to $\{0,1\}$. Also, the parameter η

can also be viewed as a particular case of Yao's model via an exponential blow-up in the input size. For more on this view (which turns out to be ineffective in our setup), we refer the reader to Note 9 at the end of this section.

[3] By the "easy direction" of Yao's min-max principle, we can without loss of generality consider deterministic (instead of public-coin) protocols when defining $\mathsf{owCC}^{\mu}_{\epsilon}(g)$. We point out that this is not true in the uncertain case.

[4] One interpretation of the dependence of the communication in the uncertain setup on the mutual information $I(x;y)$ is that the players are better able to use the correlation of their inputs in the standard case than in the uncertain case.

can possibly depend on n. We point out that Theorem 1 also implies the first separation between *deterministic* uncertain protocols and public-coin uncertain protocols[5].

▶ Note 2. We point out that the relative power of private-coin and public-coin protocols in the uncertain model is both conceptually and technically different from the standard model. Specifically, the randomness is potentially used in the standard model in order to fool an adversary selecting the input pair (x, y), whereas in the uncertain model, it is used to fool an adversary selecting the pair (f, g) of functions that are promised to be close. This promise makes the task of proving lower bounds against private-coin protocols in the uncertain model (e.g., Theorem 1) significantly more challenging than in the standard model.[6] Moreover, a well-known theorem due to Newman [21] shows that in the standard model, any public-coin protocol can be simulated by a private-coin protocol while increasing the communication by an additive $O(\log n)$ bits. By contrast, there is no known analogue of Newman's theorem in the uncertain case!

▶ Note 3. The construction that we use to prove Theorem 1 cannot give a separation larger than $\Theta(\log \log n)$. Thus, showing a separation of $\omega(\log \log n)$ between private-coin and public-coin protocols in the uncertain case would require a new construction. For more details, see Note 13.

In light of Theorem 1, it is necessary for Alice and Bob to share some form of randomness in order to only incur a constant blow-up in communication for product distributions. Fortunately, it turns out that it is not necessary for Alice and Bob to *perfectly* share a sequence of random coins. If Alice is given a uniform-random string r of bits and Bob is given a string r' obtained by independently flipping each coordinate of r with probability 0.49, then efficient communication is still possible!

More formally, for $\rho \in [0, 1]$, define $\mathsf{owIsrCCU}^{\mu}_{\epsilon,\rho}(\mathcal{F})$ in the same way that we defined $\mathsf{owPubCCU}^{\mu}_{\epsilon}(\mathcal{F})$ except that instead of Alice and Bob having access to public randomness, Alice will have access to a sequence r of independent uniformly-random bits, and Bob will have access to a sequence r' of bits obtained by independently flipping each coordinate of r with probability $(1 - \rho)/2$. Note that this setup of imperfectly shared randomness interpolates between the public randomness and private randomness setups, i.e., $\mathsf{owIsrCCU}^{\mu}_{\epsilon,1}(\mathcal{F}) = \mathsf{owPubCCU}^{\mu}_{\epsilon}(\mathcal{F})$ and $\mathsf{owIsrCCU}^{\mu}_{\epsilon,0}(\mathcal{F}) = \mathsf{owPrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$.

▶ **Theorem 4** (Uncertain protocol using imperfectly shared randomness)**.** *Let $\rho \in (0, 1]$ and μ be a* product *distribution. Let $\mathcal{F}$ consist of pairs (f, g) of functions with $\Delta_\mu(f, g) \leq \delta$, and $\mathsf{owCC}^{\mu}_{\epsilon}(f), \mathsf{owCC}^{\mu}_{\epsilon}(g) \leq k$. Then, for every positive θ, $\mathsf{owIsrCCU}^{\mu}_{\epsilon+2\delta+\theta,\rho}(\mathcal{F}) \leq O_\theta(k/\rho^2)$.*

The *imperfectly shared randomness* model in Theorem 4 was recently independently introduced (in the setup of communication complexity) by Bavarian, Gavinsky and Ito [2] and by Canonne, Guruswami, Meka and Sudan [4] (and it was further studied in [5]). Moreover, our proof of Theorem 4 is based on combining the uncertain protocol of [6] and the locality-sensitive-hashing based protocol of [4].

We point out that Theorem 4 also holds for more general i.i.d. sources of correlated randomness than the one described above. More precisely, for i.i.d. (not necessarily binary)

[5] This uses the fact that private-coin communication complexity is no larger than deterministic communication complexity, both in the certain and uncertain setups.

[6] In particular, the diagonilization-based arguments that imply a separation between the public-coin and the private-coin communication complexities of the Equality function in the standard model completely fail when we impose such a promise.

sources of (imperfectly) shared randomness with *maximal correlation*[7] ρ, the work of Witsenhausen [24] along with the protocols of [4] and [6] imply an uncertain protocol with $O_\theta(k/\rho^2)$ bits of communication.

Public Randomness

We now turn to our next result where we consider the dependence of the upper bound of [6] on the mutual information $I \triangleq I(X;Y)$ in the case of public-coin protocols. The previous work [6] proved a lower bound of $\Omega(\sqrt{I})$ on this dependence, but their lower-bound does not grow with k. We improve this lower bound to $\Omega(\sqrt{k} \cdot \sqrt{I})$.

▶ **Theorem 5** (Improved lower-bound on public-coin uncertain protocols)**.** *For every sufficiently small $\delta > 0$ and every positive integers k, n such that $k = o(\exp(\sqrt{n}))$, there exist an input distribution μ on input pairs $(X, Y) \in \{0,1\}^{k \cdot n} \times \{0,1\}^{k \cdot n}$ with mutual information $I \approx k \cdot n$ and a function class $\mathcal{F} \triangleq \mathcal{F}_{\delta,k,n}$ such that*[8]

- **(i)** *For each $(f, g) \in \mathcal{F}$, we have that $\Delta_\mu(f, g) \leq \delta$.*
- **(ii)** *For each $(f, g) \in \mathcal{F}$, we have that $\mathsf{owCC}_0^\mu(f), \mathsf{owCC}_0^\mu(g) \leq k$.*
- **(iii)** $\mathsf{owPubCCU}_\epsilon^\mu(\mathcal{F}) = \Omega(\sqrt{k} \cdot \sqrt{I})$ *for some absolute constant $\epsilon > 0$ independent of δ.*

As will be explained in detail in Section 2.2, the proof of Theorem 5 is based on an extension of the lower bound construction of [6], which is then analyzed using different techniques.

▶ Note 6. The construction that we use to prove Theorem 5 cannot give a lower bound larger than $\tilde{\Theta}(\sqrt{k} \cdot \sqrt{I})$. Thus, improving on the lower bound in Theorem 5 by more than logarithmic factors in k and I would require a new construction.

New Communication Problems

Our lower bounds in Theorems 1 and 5 are derived by defining new problems in *standard* communication complexity (i.e., without uncertainty) and proving lower bounds for these problems. We describe these problems and our results on these next.

The construction that we use to prove Theorem 1 requires us to understand the following "subset-majority with side information" setup. Alice is given a subset $S \subseteq [n]$ and a string $x \in \{\pm 1\}^n$, and Bob is given a subset $T \subseteq [n]$ and a string $y \in \{\pm 1\}^n$. The subsets S and T are adversarially chosen but are promised to satisfy $S \subseteq T$, $|T| = \ell$ and $|T \setminus S| \leq \delta \cdot \ell$ for some fixed parameters ℓ and δ. The strings x and y are chosen independently and uniformly at random. Alice and Bob wish to compute the function $\mathsf{SubsetMaj}((S,x),(T,y)) \triangleq \mathsf{Sign}(\sum_{i \in T} x_i y_i)$. In words, $\mathsf{SubsetMaj}((S,x),(T,y))$ is equal to 0 if x and y differ on a majority of the coordinates in subset T, and 1 otherwise. Note that S does not directly appear in the definition of the function $\mathsf{SubsetMaj}$ but it can serve as useful side-information for Alice.[9] What is the private-coin communication complexity of computing $\mathsf{SubsetMaj}$ on every (S,T)-pair satisfying the above promise and with high probability over the random choice of (x,y) and over the private randomness? We prove the following (informally stated) lower bound.

---

[7] The *maximal correlation* of a pair (X,Y) of random variables (with support $\mathcal{X} \times \mathcal{Y}$) is defined as $\rho(X,Y) \triangleq \sup \mathbb{E}[F(X)G(Y)]$ where the supremum is over all functions $F : \mathcal{X} \to \mathbb{R}$ and $G : \mathcal{Y} \to \mathbb{R}$ with $\mathbb{E}[F(X)] = \mathbb{E}[G(Y)] = 0$ and $\mathsf{Var}[F(X)] = \mathsf{Var}[G(Y)] = 1$. It is not hard to show that the binary source of imperfectly shared randomness defined in the paragraph preceding Theorem 4 has maximal correlation ρ.

[8] We note that $I \approx k \cdot n$ means that $I/(k \cdot n) \to 0$ as $n \to \infty$.

[9] Note that we could have alternatively defined $\mathsf{SubsetMaj}$ in terms of S, and let T serve as the potentially useful side-information. Our lower bound would also apply to this setup.

▶ **Lemma 7.** *Any private-coin protocol computing* SubsetMaj *on every* (S,T)*-pair satisfying the promise and with high probability over the random choice of* (x,y) *and over the private randomness should communicate at least* $\log^{(t)}(n)$ *bits for some positive integer* t *that depends on* δ *and the error probability.*

The proof of Theorem 5 is based on a construction that leads to the question described next regarding the communication complexity of a particular block-composed function. Namely, consider the following "majority composed with subset-parity with side information" setup. Alice is given a sequence of subsets $S \triangleq (S^{(i)} \subseteq [n])_{i\in[k]}$ and a sequence of strings $x \triangleq (x^{(i)} \in \{0,1\}^n)_{i\in[k]}$, and Bob is given a sequence of subsets $T \triangleq (T^{(i)} \subseteq [n])_{i\in[k]}$ and a sequence of strings $y \triangleq (y^{(i)} \in \{0,1\}^n)_{i\in[k]}$. We consider the following distribution μ on $((S,x),(T,y))$. Independently for each $i \in [k]$, we sample $((S^{(i)},x^{(i)}),(T^{(i)},y^{(i)}))$ as follows: $S^{(i)}$ is a uniform-random subset and $T^{(i)}$ is an ϵ-noisy[10] copy of $S^{(i)}$, and independently $x^{(i)}$ is a uniform-random string and $y^{(i)}$ is an ϵ-noisy copy of x. Here, ϵ is a positive parameter that can depend on n and k. Alice and Bob wish to compute the function $\mathsf{Maj} \circ \mathsf{SubsetParity}((S,x),(T,y)) \triangleq \mathsf{Sign}\big(\sum_{i=1}^{k}(-1)^{\langle T^{(i)},x^{(i)}\oplus y^{(i)}\rangle}\big)$ where $T^{(i)}$ denotes both the subset and its 0/1 indicator vector, the inner product is over $\mathbb{F}_2$, and $x^{(i)} \oplus y^{(i)}$ is the coordinate-wise XOR of $x^{(i)}$ and $y^{(i)}$. What is the communication complexity of computing $\mathsf{Maj} \circ \mathsf{SubsetParity}$ with high probability over the distribution μ? We prove the following lower bound.

▶ **Lemma 8.** *Any* 1*-way protocol computing* $\mathsf{Maj} \circ \mathsf{SubsetParity}$ *with high probability over the distribution* μ *should communicate* $\Omega(k \cdot \epsilon \cdot n)$ *bits.*

In Section 2.1, we outline the proof of Theorem 1 and explain how it leads to the setup of Lemma 7 and how we prove Lemma 7. In Section 2.2, we outline the proof of Theorem 5 and explain how it leads to the setup of Lemma 8 and how we prove Lemma 8.

Before doing so, we discuss some conceptual implications of our results.

1.2 Implications

Functional uncertainty models much of the day-to-day interactions among humans, where a person is somewhat aware of the objectives of the other person she is interacting with, but do not know them precisely. Neither person typically knows exactly what aspects of their own knowledge may be relevant to the interaction, yet they do manage to have a short conversation. This is certainly a striking phenomenon, mostly unexplained in mathematical terms. This line of works aims to explore such phenomena. It is important to understand what mechanisms may come into play here, and what features play a role. Is the ability to make random choices important? Is shared information crucial? Is there a particular measure of distance between functions that makes efficient communication feasible? In order to understand such questions, one first needs to have a ground-level understanding of communication with functional uncertainty. This work tackles several basic questions that remain unexplored.

An ideal model for communication would only assume a constant amount of perfectly shared context between the sender and receiver, such as the knowledge of an encoding/decoding algorithm, one universal Turing machine, etc. Solutions to most interesting communication problems seem to assume a shared information which grows with the length of the inputs.

[10] This means that the indicator vector of $T^{(i)}$ is obtained by independently flipping each coordinate of the indicator vector of $S^{(i)}$ with probability ϵ.

Recent work showed that in many of these scenarios some assumptions about the shared context can be relaxed to an imperfect sharing, but these results are often brittle and break when two or more contextual elements are simultaneously assumed to be imperfectly shared. Our work raises the question of whether *imperfectly shared randomness* would be sufficient to overcome *functional uncertainty*. We show that this is indeed the case for product distributions, but the loss for non-product distributions might be much larger (for this and other open questions, we refer the reader to our conclusion Section 6). Such results highlight the delicate nature of the role of shared context in communication. They beg for a more systematic study of communication which at the very least should be able to mimic the aims, objectives and phenomena encountered in human communication.

▶ Note 9. As mentioned in Footnote 2, the uncertain model is clearly a generalization of Yao's model. Strictly speaking, the uncertain model can also be viewed as a particular case of Yao's model by regarding the function(s) that is being computed as part of the inputs of Alice and Bob, which results in an exponential blow-up in the input-size. This latter view turns out to be fruitless for our purposes. Indeed, from this perspective, all the different well-studied communication functions (such as Equality, Set Disjointness, Pointer Jumping, etc.) are regarded as special cases of one "universal function"! More importantly, this view completely blurs the distinction between the *goal* of the communication (i.e., the function to compute) and the inputs of the parties. On a technical level, it does not simplify the task of proving the lower bounds in Theorems 1 and 5 in any way since it does not capture the promise that the two functions (given to Alice and Bob) are close in Hamming distance. Thus, in the rest of this paper, we stick to the former view and use the expressions "uncertain model" and "standard model" to refer to the setups with and without uncertainty, respectively.

2 Overview of Proofs

2.1 Overview of Proof of Theorem 1

Reduction to Lemma 7

In order to prove Theorem 1, we need to devise a function class for which circumventing the uncertainty is much easier using public randomness than using private randomness. One general setup in which Bob can leverage public randomness to resolve some uncertainty regarding Alice's knowledge is the following "small-set intersection" problem. Assume that Alice is given a subset $S \subseteq [n]$, and Bob is given a subset $T \subseteq [n]$ such that T contains S and $|T| = \ell$, where we think of ℓ as being a large constant. Here, Bob knows that Alice has a subset of his own T but he is uncertain which subset Alice has. Using public randomness, a standard 1-way hashing protocol communicating $\tilde{O}(\ell)$ bits allows Bob to determine S with high probability. On the other hand, using only private randomness, the communication complexity of this task is $\Theta(\log \log n)$ bits.

With the above general setup in mind, we consider functions f_S indexed by small subsets S of coordinates on which they depend. Since we want the functions f_S and f_T to be close in Hamming distance, we enforce $|T \setminus S|$ to be small for every pair (f_S, f_T) of functions in our class, and we let each function f_S be "noise-stable". Since we want our function f_S to genuinely depend on all coordinates in S, the majority function $f_S(x, y) = \mathsf{Sign}(\sum_{i \in S} x_i y_i)$ for $x, y \in \{\pm 1\}^n$ arises as a natural choice. We also let x and y be independent uniform-random strings. In this case, it can be seen that if $|T \setminus S|$ is a small constant fraction of $|T|$, then the quadratic polynomials $\sum_{i \in S} x_i y_i$ and $\sum_{i \in T} x_i y_i$ behave like standard Gaussians with correlation close to 1, and the quadratic threshold functions $f_S(x, y)$ and $f_T(x, y)$ are thus close in Hamming distance.

Note that in the certain case, i.e., when both Alice and Bob agree on S, they can easily compute $f_S(x, y)$ by having Alice send to Bob the ℓ bits $(x_i)_{i \in S}$. Moreover, if Alice and Bob are given access to public randomness in the uncertain case, Bob can figure out S via the hashing protocol mentioned above using $\tilde{O}(\ell)$ bits of communication, which would reduce the problem to the certain case[11]. The bulk of the proof will be to lower-bound the private-coin uncertain communication. Note that by the choice of our function class and distribution, this is equivalent to proving Lemma 7.

Proof of Lemma 7

To prove Lemma 7, the high-level intuition is that a protocol solving the uncertain problem should be essentially revealing to Bob the subset S that Alice holds. Formalizing this intuition turns out to be challenging, especially that a private-coin protocol solving the uncertain problem is only required to output a *single bit* which is supposed to equal the Boolean function $f_T(x, y)$ with high probability over (x, y) and over the private randomness. In fact, this high-level intuition can be shown not to hold in certain regimes[12]. Moreover, the standard proofs that lower bound the communication of small-set intersection do not extend to lower-bound the communication complexity of f_T.

To lower-bound the private-coin communication of solving the uncertain task by a growing function of n, we consider the following *shift communication game*. Bob is given a sorted tuple $\sigma = (\sigma_1, \ldots, \sigma_t)$ of integers with $1 \leq \sigma_1 < \cdots < \sigma_t \leq n$, and Alice is either given the prefix $(\sigma_1, \ldots, \sigma_{t-1})$ of length $t-1$ of σ or the suffix $(\sigma_2, \ldots, \sigma_t)$ of length $t-1$ of σ. Bob needs to determine the input of Alice. We show that a celebrated lower bound of Linial [19] on the *chromatic number* of certain related graphs implies a lower bound of $\log^{(t+1)}(n)$ on the private-coin communication of the shift communication game. We then show that any private-coin protocol solving the uncertain task can be turned into a private-coin protocol solving the shift-communication game with a constant (i.e., independent of n) blow-up in the communication.

2.2 Overview of Proof of Theorem 5

Reduction to Lemma 8

The proof of Theorem 5 builds on the lower-bound construction of [6] which we recall next. Let μ be the distribution over pairs $(x, y) \in \{0,1\}^{2n}$ where x is uniform-random and y is an ϵ-noisy copy of x with $\epsilon = \sqrt{\delta/n}$. Then, the mutual information between x and y satisfies $I \approx n$. For each $S \subseteq [n]$, consider the function $f_S(x, y) \triangleq \langle S, x \oplus y \rangle$ where the inner product is over $\mathbb{F}_2$, $x \oplus y$ denotes the coordinate-wise XOR of x and y, and S is used to denote both the subset and its 0/1 indicator vector. Moreover, consider the class $\mathcal{F}$ of all pairs of functions (f_S, f_T) where $|S \triangle T| \leq \sqrt{\delta n}$. It can be seen that for such S and T, the distance between f_S and f_T under μ is at most δ. If Alice and Bob both know S, then Alice can send the single bit $\langle S, x \rangle$ to Bob who can then output the correct answer $\langle S, x \oplus y \rangle = \langle S, x \rangle \oplus \langle S, y \rangle$. This means that the certain communication is 1 bit. Using the well-known discrepancy method, [6] showed a lower bound of $\Omega(\sqrt{n})$ bits on the communication of the associated uncertain problem. Since in this case $I \approx n$, this in fact lower-bounds the uncertain communication by

[11] Alternatively, Alice and Bob can run the protocol of [6] which would communicate $O(\ell)$ bits.

[12] For example, for constant error probabilities, the 1-way randomized communication complexity of small-set intersection is known to be $\Theta(\ell \cdot \log(\ell))$ bits (see, e.g., [3]) whereas the public-coin protocol of [6] can compute f_T with $O(\ell)$ bits of communication.

$\Omega(\sqrt{I})$ bits. For this construction, this lower bound turns out to be tight up to a logarithmic factor.

To improve the lower-bound from $\sqrt{I}$ to $\sqrt{k} \cdot \sqrt{I}$, we consider the following "block-composed" framework. Let $\{f_{S^{(i)}}(x^{(i)}, y^{(i)}) : i \in [k]\}$ be k independent copies of the above base problem of [6] and consider computing the composed function $g\big(f_{S^{(1)}}(x^{(1)}, y^{(1)}), \ldots, f_{S^{(k)}}(x^{(k)}, y^{(k)})\big)$ for some outer function $g : \{0,1\}^k \to \{0,1\}$. For any choice of g, the certain communication of the composed function would be at most k bits. When choosing the outer function g to use in our lower bound, we thus have two objectives to satisfy. First, g has to be sufficiently *hard* in the sense that its average-case decision tree complexity with respect to the uniform distribution on $\{0,1\}^k$ should be $\Omega(k)$; otherwise, it will not be the case that the uncertain communication of computing g on k copies of the base problem is at least k times the uncertain communication of the base problem. Second, g has to be *noise stable* in order to be able to upper bound the distance between $g\big(f_{S^{(1)}}(\cdot), \ldots, f_{S^{(k)}}(\cdot)\big)$ and $g\big(f_{T^{(1)}}(\cdot), \ldots, f_{T^{(k)}}(\cdot)\big)$.

Note that setting g to be a dictator function would satisfy the noise-stability property, but it clearly would not satisfy the hardness property, as the composed function would be equal to the base function and would thus have uncertain communication $\tilde{O}(\sqrt{n})$ bits. Another potential choice of g is to set it to the parity function on k bits. This function would satisfy the hardness property, but it would strongly violate the noise stability property that is crucial to us. This leads us to setting g to the majority function on k bits, which is well-known to be noise stable, and has average-case decision-tree complexity $\Omega(k)$ with respect to the uniform distribution on $\{0,1\}^k$. In fact, the noise stability of the majority function readily implies an upper bound of $O(\sqrt{\delta})$ on the distance between any pair of composed functions that are specified by tuples of subsets $(S^{(1)}, \ldots, S^{(k)})$ and $(T^{(1)}, \ldots, T^{(k)})$ with $|S^{(i)} \triangle T^{(i)}| \leq \sqrt{\delta n}$ for each $i \in [k]$. The crux of the proof will be to lower-bound the uncertain communication of the majority-composed function by $\Omega(k\sqrt{n})$, which amounts to proving Lemma 8. Since in this block-composed framework the mutual information satisfies $I \approx kn$, this would imply the lower bound of $\Omega(\sqrt{k}\sqrt{I})$ on the uncertain communication in Part (iii) of Theorem 5.

Proof of Lemma 8

We first point out that the average-case *quantum* decision tree complexity of Maj_k with respect to the uniform distribution is $\tilde{O}(\sqrt{k})$ [1]. This implies that any communication complexity lower-bound method that extends to the quantum model cannot prove a lower bound larger than $\tilde{O}(\sqrt{k} \cdot \sqrt{n})$ on our uncertain communication[13]. In particular, we cannot solely rely on the discrepancy bound (as done in [6]), since this bound is known to lower-bound quantum communication. Similarly, the techniques of [22, 23, 18] rely on the generalized discrepancy bound (originally due to [16]) which also lower-bounds quantum communication. Moreover, the recent results of [20] only apply to product distributions (i.e., where Alice's input is independent of Bob's input) in contrast to our case where the inputs of Alice and Bob are very highly-correlated. Finally, the recent works of [9, 10] do not imply lower bounds on the average-case complexity with respect to the distribution that arises in our setup.

To circumvent the above obstacles, we use a new approach that is tailored to our setup and that is outlined next. Let Π be a 1-way protocol solving the uncertain task with high probability. We consider the information that Π reveals about the *inputs to the outer*

[13] Thus, since $I \approx k \cdot n$ in our block-composed framework, such methods cannot be used to improve the lower-bound of $\Omega(\sqrt{I})$ of [6] by more than logarithmic factors.

function, i.e., about the length-k binary string $\left(f_{S^{(1)}}(x^{(1)}, y^{(1)}), \ldots, f_{S^{(k)}}(x^{(k)}, y^{(k)})\right)$. We call this quantity the *intermediate information cost* of Π, and we argue that it is at least $\Omega(k)$ bits. To do so, we recall the Hamming distance function HD_k defined by $\mathsf{HD}_k(u, v) = 1$ if the Hamming distance between u and v is at least $k/2$ and $\mathsf{HD}_k(u, v) = 0$ otherwise. We upper bound the information complexity of computing HD_k over the uniform distribution on $\{0, 1\}^{2k}$ by the intermediate information cost of Π. We do so by giving an information-cost preserving procedure where Alice and Bob are given independent uniformly distributed u and v (respectively) and use their private and public coins in order to simulate the input distribution (X, Y) of our uncertain problem. The known 1-way lower bound of [25] on HD_k under the uniform distribution then implies that Π reveals $\Omega(k)$ bits of information to Bob about the tuple $\left(f_{S^{(1)}}(x^{(1)}, y^{(1)}), \ldots, f_{S^{(k)}}(x^{(k)}, y^{(k)})\right)$. This allows Bob to guess this tuple with probability 0.51^k. We then apply the strong direct product theorem for discrepancy of [17] which, along with the discrepancy-based lower bound on the communication of the base uncertain problem of [6], implies that Π should be communicating at least $\Omega(k\sqrt{n})$ bits.

Organization of the rest of the paper

In Section 3, we give some preliminaries. In Sections 4 and 5, we describe the proofs of Theorems 1 and 5 respectively. All the missing proofs as well as the proof of Theorem 4 appear in the full version. In Section 6, we conclude with some interesting open questions.

3 Preliminaries

For a real number x, we define $\mathsf{Sign}(x)$ to be 1 if $x \geq 0$ and 0 if $x < 0$. For a set S, we write $X \in_R S$ to indicate that X is a random variable that is uniformly distributed on S. For a positive integer n, we let $[n] \triangleq \{1, \ldots, n\}$. For a real number x, we denote $\exp(x)$ a quantity of the form $2^{\Theta(x)}$. For any two subsets $S, T \subseteq [n]$, we let $S \setminus T$ be the set of all elements of S that are not in T. We let $S \triangle T$ be the symmetric difference of S and T, i.e., the union of $S \setminus T$ and $T \setminus S$. For functions $f, g : \mathcal{X} \times \mathcal{Y} \to \{0, 1\}$ and any distribution μ on $\mathcal{X} \times \mathcal{Y}$, we define the distance $\Delta_\mu(f, g) \triangleq \Pr_{(x,y)\sim\mu}[f(x, y) \neq g(x, y)]$ as the Hamming distance between the values of f and g, weighted with respect to μ. If μ is the uniform distribution on $\mathcal{X} \times \mathcal{Y}$, we drop the subscript μ and denote Δ_μ by Δ. We next recall the standard communication complexity model of Yao [26]. For any function $f\colon \mathcal{X} \times \mathcal{Y} \to \{0, 1\}$, we denote by $\mathsf{CC}(f)$, $\mathsf{owCC}(f)$, $\mathsf{PrivCC}_\epsilon(f)$ and $\mathsf{owPrivCC}_\epsilon(f)$ its two-way deterministic, one-way deterministic, two-way private-coin and one-way private-coin communication complexity respectively. For any distribution μ over $\mathcal{X} \times \mathcal{Y}$, we denote by $\mathsf{CC}^\mu_\epsilon(f)$ and $\mathsf{owCC}^\mu_\epsilon(f)$ the two-way distributional and one-way distributional communication complexity of over μ with error ϵ, respectively.

We next recall the model of communication with contextual uncertainty. For more details on this model, we refer the reader to [6]. In this setup, Alice knows a function f and is given an input x, and Bob knows a function g and is given an input y. Let $\mathcal{F} \subseteq \{f\colon \mathcal{X} \times \mathcal{Y} \to \{0, 1\}\}^2$ be a family of pairs of Boolean functions with domain $\mathcal{X} \times \mathcal{Y}$, and μ be a distribution on $\mathcal{X} \times \mathcal{Y}$. We say that a public-coin (resp. private-coin) protocol Π ϵ-computes $\mathcal{F}$ over μ if for every $(f, g) \in \mathcal{F}$, we have that Π outputs the value $g(x, y)$ with probability at least $1 - \epsilon$ over the randomness of $(x, y) \sim \mu$ and over the public (resp. private) randomness of Π.

▶ **Definition 10** (Contextually Uncertain Communication Complexity)**.** Let μ be a distribution on $\mathcal{X} \times \mathcal{Y}$ and $\mathcal{F} \subseteq \{f\colon \mathcal{X} \times \mathcal{Y} \to \{0, 1\}\}^2$. The *two-way (resp. one-way) public-coin communication complexity of $\mathcal{F}$ under contextual uncertainty*, denoted $\mathsf{PubCCU}^\mu_\epsilon(\mathcal{F})$ (resp. $\mathsf{owPubCCU}^\mu_\epsilon(\mathcal{F})$), is the minimum over all two-way (resp. one-way) public-coin protocols Π

that ϵ-compute $\mathcal{F}$ over μ, of the maximum communication complexity of Π over $(f,g) \in \mathcal{F}$, (x,y) from the support of μ and settings of the public coins.

Similarly, the *two-way (resp. one-way) private-coin communication complexity of $\mathcal{F}$ under contextual uncertainty* $\mathsf{PrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$ (resp. $\mathsf{owPrivCCU}^{\mu}_{\epsilon}(\mathcal{F})$) is defined by restricting to two-way (resp. one-way) private-coin protocols.

4 Construction for Private-Coin Uncertain Protocols

We now describe the construction that is used to prove Theorem 1. Each function in our universe is specified by a subset $S \subseteq [n]$ and is of the form $f_S : \{\pm 1\}^n \times \{\pm 1\}^n \to \{0,1\}$ with $f_S(X,Y) \triangleq \mathsf{Sign}(\sum_{i \in S} X_i Y_i)$ for all $X, Y \in \{\pm 1\}^n$. The function class is then defined by

$$\mathcal{F}_\delta \triangleq \{(f_S, f_T) : S \subseteq T,\ |T| = \ell \text{ and } |T \setminus S| \leq \delta' \cdot \ell\},$$

where $\delta' = \alpha \cdot \delta^2$ for some sufficiently small positive absolute constant α, and $\ell = \ell(\delta)$ is a sufficiently large function of δ. The input pair (X,Y) is drawn from the uniform distribution on $\{\pm 1\}^{2n}$. The proof of Part (i) of Theorem 1 follows from the fact that the the polynomials $\sum_{i \in S} X_i Y_i$ and $\sum_{i \in T} X_i Y_i$ behave like zero-mean Gaussians with unit-variance and correlation $\sqrt{1-\delta'}$. The proof of Part (ii) of Theorem 1 is immediate and is given in the full version for completeness. To prove Part (iii) of Theorem 1, the next definition – which is based on the graphs studied by Linial [19]– will be crucial to us.

▶ **Definition 11** (Shift Communication Game $\mathcal{G}_{m,t}$)**.** Let m and t be positive integers with $t \leq m$. In the communication problem $\mathcal{G}_{m,t}$, Bob is given a sorted tuple $\sigma = (\sigma_1, \ldots, \sigma_t)$ of distinct integers with $1 \leq \sigma_1 < \cdots < \sigma_t \leq m$. In the YES case, Alice is given the prefix $(\sigma_1, \ldots, \sigma_{t-1})$ of length $t-1$ of σ. In the NO case, Alice is given the suffix $(\sigma_2, \ldots, \sigma_t)$ of length $t-1$ of σ. Alice and Bob need to determine which of the YES and NO cases occurs.

Lemma 12 lower-bounds the private-coin communication complexity of $\mathcal{G}_{m,t}$. Its proof uses Linial's lower bound on the chromatic number of related graphs.

▶ **Lemma 12.** *There is an absolute constant c such that for every sufficiently small $\epsilon > 0$, we have that* $\mathsf{PrivCC}_{\epsilon}(\mathcal{G}_{m,t}) \geq c \cdot \log^{(t+2)}(m)$.

The proof of Part (iii) of Theorem 1 – which is the main part in the proof of Theorem 1 – is deferred to the full version.

▶ Note 13. As mentioned in Note 3, the above construction cannot give a separation larger than $\Theta(\log \log n)$. This is because using private randomness, Bob can learn the set S using $O(\log \log n)$ bits of communication (see, e.g., [3]). Additionally, Alice can send the coordinates of X indexed by the elements of S to Bob who can then compute $f_S(X,Y)$.

5 Construction for Public-Coin Uncertain Protocols

In this section, we describe the construction that is used to prove Theorem 5. We set

$$\delta' \triangleq c \cdot \delta^2 \quad \text{and} \quad \epsilon \triangleq \sqrt{\delta'/n}, \tag{$\dagger$}$$

where δ is the parameter from the statement of Theorem 5, and $c > 0$ is a small-enough absolute constant. To define our input distribution, we first define a slightly more general distribution μ_η. The support of μ_η is $\{0,1\}^{kn} \times \{0,1\}^{kn}$ and we will view the coordinates of a sample $(x,y) \sim \mu_\eta$ as $x = (x^{(i)})_{i \in [k]}$ and $y = (y^{(i)})_{i \in [k]}$ with $x^{(i)}, y^{(i)} \in \{0,1\}^n$ for all

$i \in [k]$. A sample $(x, y) \sim \mu_\eta$ is generated by letting $x \in_R \{0,1\}^{kn}$ and for all $i \in [k]$ and $j \in [n]$, independently setting $y_j^{(i)}$ to be an η-noisy copy of $x_j^{(i)}$. In other words, we set $y_j^{(i)} = x_j^{(i)}$ w.p. $1-\eta$ and $y_j^{(i)} = 1 - x_j^{(i)}$ w.p. η. Our input distribution is then $\mu_{2\epsilon-2\epsilon^2}$.

We now define our function class $\mathcal{F}_\epsilon$. Each function in our universe is specified by a sequence of subsets $S \triangleq (S^{(i)} \subseteq [n])_{i\in[k]}$ and it is of the form $f_S : \{0,1\}^{2\cdot k\cdot n} \to \{0,1\}$ with[14]

$$f_S(x,y) \triangleq \mathsf{Sign}\Big(\sum_{i\in[k]} (-1)^{\langle S^{(i)}, x^{(i)} \oplus y^{(i)}\rangle}\Big) \tag{1}$$

for all $x, y \in \{0,1\}^{k\cdot n}$, where in Eq. (1) the inner product is over $\mathbb{F}_2$, the sum is over $\mathbb{R}$ and $x^{(i)} \oplus y^{(i)}$ denotes the coordinate-wise XOR of the two length-n binary strings $x^{(i)}$ and $y^{(i)}$. The function class is then defined by $\mathcal{F}_\epsilon \triangleq \{(f_S, f_T) : |S^{(i)} \triangle T^{(i)}| \le \epsilon \cdot n \text{ for all } i \in [k]\}$.

The proof of Part (i) of Theorem 5 follows from known bounds on the noise stability of the majority function. The proof of Part (ii) is immediate. To prove Part (iii), we first define (as in [6]) a communication problem in the standard distributional model that reduces to solving the contextually-uncertain problem specified by the function class $\mathcal{F}_\epsilon$ and the distribution $\mu_{2\epsilon-2\epsilon^2}$. For distributions ϕ and ψ, we denote by $\phi \otimes \psi$ the joint distribution of a sample from ϕ and an independent sample from ψ. The new problem is defined as follows.

- **Inputs:** Alice's input is a pair (S, x) where $S \triangleq (S^{(i)} \subseteq [n])_{i\in[k]}$ and $x \in \{0,1\}^{k\cdot n}$. Bob's input is a pair (T, y) where $T \triangleq (T^{(i)} \subseteq [n])_{i\in[k]}$ and $y \in \{0,1\}^{k\cdot n}$.
- **Distribution:** Let $\mathcal{D}_q$ be the distribution on the pair (S, T) of sequences of k subsets of $[n]$, which is defined by independently setting, for each $i \in [k]$, $S^{(i)}$ to be a uniformly-random subset of $[n]$, and $T^{(i)}$ to be a q-noisy copy of $S^{(i)}$. The distribution on the inputs of Alice and Bob is then given by $\nu_\epsilon \triangleq \mathcal{D}_\epsilon \otimes \mu_{2\epsilon-2\epsilon^2}$ with $\epsilon = \sqrt{\delta'/n}$.
- **Function:** The goal is to compute the function $F : \{0,1\}^{2kn} \times \{0,1\}^{2kn} \to \{0,1\}$ defined by $F((S,x),(T,y)) = f_T(x,y) = \mathsf{Sign}\big(\sum_{i\in[k]} (-1)^{\langle T^{(i)}, x^{(i)} \oplus y^{(i)}\rangle}\big)$.

The next proposition follows from a simple application of the Chernoff bound.

▶ **Proposition 14.** *For any $\theta > 0$, $\mathsf{owPubCCU}_\theta^{\mu_{2\epsilon-2-\epsilon^2}}(\mathcal{F}_\epsilon) \ge \mathsf{owCC}_{\theta+\theta'}^{\nu_\epsilon}(F)$ with $\theta' = 2^{-\Theta(\epsilon\cdot n)}$.*

In the full version, we prove the following lower bound on $\mathsf{owCC}_\theta^{\nu_\epsilon}(F)$, which along with Proposition 14 and the settings of ϵ and δ' in (†), implies Part (iii) of Theorem 5.

▶ **Lemma 15.** *For every sufficiently small positive constant θ, $\mathsf{owCC}_\theta^{\nu_\epsilon}(F) = \Omega(k \cdot \epsilon \cdot n)$.*

6 Open Questions

As mentioned in Notes 3 and 6 in Section 1, significantly improving the bounds from Theorems 1 and 5 seems to require fundamentally new constructions, and is a very important question. Moreover, is there an analogue of the protocol in Theorem 4 for *non-product* distributions?

Another very important and intriguing open question is whether efficient communication under contextual uncertainty is possible in the multi-round setup. Namely, if k is the r-round certain communication, can we upper bound the r-round uncertain communication by some function of k, I and possibly r? Even for $r = 2$ and when the uncertain protocol is allowed

[14] We will use the symbol $S^{(i)}$ to denote both the subset of $[n]$ and its corresponding 0/1 indicator vector.

to use public randomness, no non-trivial protocols are known in this setting. On the other hand, no separations are known for this case (beyond those known for $r = 1$) even if the protocols are restricted to be deterministic.

Abstract

This paper gives the first separation between the power of *formulas* and *circuits* of equal depth in the $\mathrm{AC}^0[\oplus]$ basis (unbounded fan-in AND, OR, NOT and MOD_2 gates). We show, for all $d(n) \leq O(\frac{\log n}{\log\log n})$, that there exist *polynomial-size depth-d circuits* that are not equivalent to *depth-d formulas of size $n^{o(d)}$* (moreover, this is optimal in that $n^{o(d)}$ cannot be improved to $n^{O(d)}$). This result is obtained by a combination of new lower and upper bounds for *Approximate Majorities*, the class of Boolean functions $\{0,1\}^n \to \{0,1\}$ that agree with the Majority function on 3/4 fraction of inputs.

$\mathrm{AC}^0[\oplus]$ formula lower bound. We show that every depth-d $\mathrm{AC}^0[\oplus]$ formula of size s has a 1/8-*error polynomial approximation* over $\mathbb{F}_2$ of degree $O(\frac{1}{d}\log s)^{d-1}$. This strengthens a classic $O(\log s)^{d-1}$ degree approximation for circuits due to Razborov [12]. Since the Majority function has approximate degree $\Theta(\sqrt{n})$, this result implies an $\exp(\Omega(dn^{1/2(d-1)}))$ lower bound on the depth-d $\mathrm{AC}^0[\oplus]$ formula size of all Approximate Majority functions for all $d(n) \leq O(\log n)$.

Monotone AC^0 circuit upper bound. For all $d(n) \leq O(\frac{\log n}{\log\log n})$, we give a randomized construction of depth-d monotone AC^0 circuits (without NOT or MOD_2 gates) of size $\exp(O(n^{1/2(d-1)}))$ that compute an Approximate Majority function. This strengthens a construction of formulas of size $\exp(O(dn^{\frac{1}{2(d-1)}}))$ due to Amano [1].

1 Introduction

The relative power of formulas versus circuits is one of the great mysteries in complexity theory. The central question in this area is whether NC^1 (the class of languages decidable by polynomial-size Boolean formulas) is a proper subclass of P/poly (the class of languages decidable by polynomial-size Boolean circuits). Despite decades of efforts, this question remains wide open.[1] In the meantime, there has been progress on analogues of the NC^1 vs. P/poly question in certain restricted settings. For instance, in the monotone basis (with AND and OR gates only), the power of polynomial-size formulas vs. circuits was separated

[1] In this paper we focus on non-uniform complexity classes. The question of uniform-NC^1 vs. P is wide open as well.

by the classic lower bound of Karchmer and Wigderson [8] (on the monotone formula size of st-Connectivity).

The bounded-depth setting is another natural venue for investigating the question of formula vs. circuits. Consider the elementary fact that every depth-d circuit of size s is equivalent to a depth-d formula of size at most s^{d-1}, where we measure *size* by the number of gates. This observation is valid with respect to any basis (i.e. set of gate types). In particular, we may consider the AC^0 basis (unbounded fan-in AND, OR, NOT gates) and the $\mathrm{AC}^0[\oplus]$ basis (unbounded fan-in MOD_2 gates in addition to AND, OR, NOT gates). With respect to either basis, there is a natural depth-d analogue of the NC^1 vs. P/poly question (where $d = d(n)$ is a parameter that may depend on n), namely whether every language decidable by polynomial-size depth-d circuits is decidable by depth-d formulas of size $n^{o(d)}$ (i.e. better than the trivial $n^{O(d)}$ upper bound).

It is reasonable to expect that this question could be resolved in the sub-logarithmic depth regime ($d(n) \ll \log n$), given the powerful lower bound techniques against AC^0 circuits (Håstad's Switching Lemma [5]) and $\mathrm{AC}^0[\oplus]$ circuits (the Polynomial Method of Razborov [12] and Smolensky [14]). However, because the standard way of applying these techniques does not distinguish between circuits and formulas, it is not clear how to prove quantitatively stronger lower bounds on formula size vis-a-vis circuit size of a given function. Recent work of Rossman [13] developed a new way of applying Håstad's Switching Lemma to AC^0 formulas, in order to prove an $\exp(\Omega(dn^{1/(d-1)}))$ lower bound on the formula size of the Parity function for all $d \leq O(\log n)$. Combined with the well-known $\exp(O(n^{1/(d-1)}))$ upper bound on the circuit size of Parity, this yields an asymptotically optimal separation in the power of depth-d AC^0 formulas vs. circuits for all $d(n) \leq O(\frac{\log n}{\log\log n})$, as well as a super-polynomial separation for all $\omega(1) \leq d(n) \leq o(\log n)$.

In the present paper, we carry out a similar development for formulas vs. circuits in the $\mathrm{AC}^0[\oplus]$ basis, obtaining both an asymptotically optimal separation for all $d(n) \leq O(\frac{\log n}{\log\log n})$ and a super-polynomial separation for all $\omega(1) \leq d(n) \leq o(\log n)$. Our target functions lie in the class of *Approximate Majorities*, here defined as Boolean functions $\{0,1\}^n \to \{0,1\}$ that approximate the Majority function on 3/4 fraction of inputs. First, we show how to apply the Polynomial Method to obtain better parameters in the approximation of $\mathrm{AC}^0[\oplus]$ formulas by low-degree polynomials over $\mathbb{F}_2$. This leads to an $\exp(\Omega(dn^{1/2(d-1)}))$ lower bound on the $\mathrm{AC}^0[\oplus]$ formula size of all Approximate Majority functions. The other half of our formulas vs. circuits separation comes from an $\exp(O(n^{1/2(d-1)}))$ upper bound on the $\mathrm{AC}^0[\oplus]$ circuit size of some Approximate Majority function. In fact, this upper bound is realized by a randomized construction of monotone AC^0 circuits (without NOT or MOD_2 gates). Together these upper and lower bound give our main result:

▶ **Theorem 1.**

(i) *For all* $2 \leq d(n) \leq O(\frac{\log n}{\log\log n})$*, there exist* $\mathrm{AC}^0[\oplus]$ *circuits (in fact, monotone* AC^0 *circuits) of depth* d *and size* $\mathrm{poly}(n)$ *that are not equivalent to any* $\mathrm{AC}^0[\oplus]$ *formulas of depth* d *and size* $n^{o(d)}$*.*

(ii) *For all* $\omega(1) \leq d(n) \leq o(\log n)$*, the class of languages decidable by polynomial-size depth-*d $\mathrm{AC}^0[\oplus]$ *formulas is a proper subclass of the class of languages decidable by polynomial-size depth-*d $\mathrm{AC}^0[\oplus]$ *circuits.*

Separation (i) is asymptotically optimal, in view of the aforementioned simulation of $\mathrm{poly}(n)$-size depth-d circuits by depth-d formulas of size $n^{O(d)}$. Separation (ii) resembles an analogue of $\mathrm{NC}^1 \neq \mathrm{P/poly}$ (or rather $\mathrm{NC}^1 \neq \mathrm{AC}^1$) within the class $\mathrm{AC}^0[\oplus]$. In fact, extending separation (ii) from depth $o(\log n)$ to depth $\log n$ is equivalent the separation of NC^1 and AC^1.

1.1 Proof outline

Improved polynomial approximation

The lower bound for $\mathrm{AC}^0[\oplus]$ formulas follows the general template due to Razborov [12] on proving lower bounds for $\mathrm{AC}^0[\oplus]$ circuits using low-degree polynomials over $\mathbb{F}_2$. Razborov showed that for any Boolean function $f : \{0,1\}^n \to \{0,1\}$ that has an $\mathrm{AC}^0[\oplus]$ circuit of size s and depth d, there is a randomized polynomial $\mathbf{P}$ of degree $O(\log s)^{d-1}$ that computes f correctly on each input with probability $\frac{7}{8}$ (we call such polynomials 1/8-error *probabilistic polynomials*). By showing that some explicit Boolean function f (e.g. the Majority function or the MOD_q function for q odd) on n variables does not have such an approximation of degree less than $\Omega(\sqrt{n})$ [12, 14, 15], we get that any $\mathrm{AC}^0[\oplus]$ circuit of depth d computing f must have size $\exp(\Omega(n^{1/2(d-1)}))$.

In this paper, we improve the parameters of Razborov's polynomial approximation from above for $\mathrm{AC}^0[\oplus]$ *formulas*. More precisely, for $\mathrm{AC}^0[\oplus]$ formulas of size s and depth d, we are able to construct 1/8-error probabilistic polynomials of degree $O(\frac{1}{d}\log s)^{d-1}$. (Since every depth-$d$ circuit of size s is equivalent to a depth-d formula of size at most s^{d-1}, this result implies Razborov's original theorem that $\mathrm{AC}^0[\oplus]$ circuits of size s and depth d have 1/8-error probabilistic polynomials of degree $O(\log s)^{d-1}$.)

We illustrate the idea behind this improved polynomial approximation with the special case of a balanced formula (i.e. all gates have the same fan-in) of fan-in t and depth d. Note that the size of the formula (number of gates) is $\Theta(t^{d-1})$ and hence it suffices in this case to show that it has a 1/8-error probabilistic polynomial of degree $O(\log t)^{d-1}$. We construct the probabilistic polynomial inductively. Given a balanced formula F of depth d and fan-in t, let $F_1, \ldots, F_t$ be its subformulas of depth $d-1$. Inductively, each F_i has a 1/8-error probabilistic polynomial $\mathbf{P}_i$ of degree $O(\log t)^{d-2}$ and by a standard error-reduction [10], it has a $(1/16t)$-error probabilistic polynomial of degree $O(\log t)^{d-1}$ (in particular, at any given input $x \in \{0,1\}^n$, the probability that *there exists* an $i \in [t]$ such that $\mathbf{P}_i(x) \neq F_i(x)$ is at most 1/16). Using Razborov's construction of a 1/16-error probabilistic polynomial of degree $O(1)$ for the output gate of F and composing this with the probabilistic polynomials $\mathbf{P}_i$, we get the result for balanced formulas. This idea can be extended to general (i.e. not necessarily balanced) formulas with a careful choice of the error parameter for each subformula F_i to obtain the stronger polynomial approximation result.

Improved formula lower bounds

Combining the above approximation result with known lower bounds for polynomial approximation [12, 14, 15], we can already obtain stronger lower bounds for $\mathrm{AC}^0[\oplus]$ formulas than are known for $\mathrm{AC}^0[\oplus]$ circuits. For instance, it follows that any $\mathrm{AC}^0[\oplus]$ formula of depth d computing the Majority function on n variables must have size $\exp(\Omega(dn^{1/2(d-1)}))$ for all $d \leq O(\log n)$, which is stronger than the corresponding circuit lower bound. Similarly stronger formula lower bounds also follow for the MOD_q function (q odd).

Separation between formulas and circuits

However, the above improved lower bounds do not directly yield the claimed separation between $\mathrm{AC}^0[\oplus]$ formulas and circuits. This is because we do not have circuits computing (say) the Majority function of the required size. To be able to prove our result, we would need to show that the Majority function has $\mathrm{AC}^0[\oplus]$ circuits of depth d and size $\exp(O(n^{1/2(d-1)}))$ (where the constant in the $O(\cdot)$ is independent of d). However, as far as we know, the strongest

result in this direction [9] only yields $\mathrm{AC}^0[\oplus]$ circuits of size greater than $\exp(\Omega(n^{1/(d-1)}))$,[2] which is superpolynomially larger than the upper bound.

To circumvent this issue, we change the hard functions to the class of *Approximate Majorities*, which is the class of Boolean functions that agree with Majority function on *most* inputs. While this has the downside that we no longer are dealing with an explicitly defined function, the advantage is that the polynomial approximation method of Razborov yields tight lower bounds for some functions from this class.

Indeed, since the method of Razborov is based on polynomial approximations, it immediately follows that the same proof technique also yields the same lower bound for computing Approximate Majorities. Formally, any $\mathrm{AC}^0[\oplus]$ circuit of depth d computing *any* Approximate Majority must have size $\exp(\Omega(n^{1/2(d-1)}))$. On the upper bound side, it is known from the work of O'Donnell and Wimmer [11] and Amano [1] that there *exist* Approximate Majorities that can be computed by monotone AC^0 *formulas* of depth d and size $\exp(O(dn^{1/2(d-1)}))$. (Note that the double exponent $\frac{1}{2(d-1)}$ is now the same in the upper and lower bounds.)

We use the above ideas for our separation between $\mathrm{AC}^0[\oplus]$ formulas and circuits. Plugging in our stronger polynomial approximation for $\mathrm{AC}^0[\oplus]$ formulas, we obtain that any $\mathrm{AC}^0[\oplus]$ formula of depth d computing any Approximate Majority must have size $\exp(\Omega(dn^{1/2(d-1)}))$. In particular, this implies that Amano's construction is tight (up to the universal constant in the exponent) even for $\mathrm{AC}^0[\oplus]$ formulas.

Further, we also modify Amano's construction [1] to obtain better constant-depth *circuits* for Approximate Majorities: we show that there exist Approximate Majorities that are computed by monotone AC^0 circuits of depth d of size $\exp(O(n^{1/2(d-1)}))$ (the constant in the $O(\cdot)$ is a constant independent of d).

Smaller circuits for Approximate Majority

Our construction closely follows Amano's, which in turn is related to Valiant's probabilistic construction [17] of monotone formulas for the Majority function. However, we need to modify the construction in a suitable way that exploits the fact that we are constructing *circuits*. This modification is in a similar spirit to a construction of Hoory, Magen and Pitassi [6] who modify Valiant's construction to obtain smaller monotone circuits (of depth $\Theta(\log n)$) for computing the Majority function exactly.

At a high level, the difference between Amano's construction and ours is as follows. Amano constructs random formulas F_i of each depth $i \leq d$ as follows. The formula F_1 is the AND of a_1 independent and randomly chosen variables. For even (respectively odd) $i > 1$, F_i is the OR (respectively AND) of a_i independent and random copies of F_{i-1}. For suitable values of $a_1, \ldots, a_d \in \mathbb{N}$, the random formula F_d computes an Approximate Majority with high probability. In our construction, we build a depth i circuit C_i for each $i \leq d$ in a similar way, except that each C_i now has M different outputs. Given such a C_{i-1}, we construct C_i by taking M independent randomly chosen subsets $T_1, \ldots, T_M$ of a_i many outputs of C_{i-1} and adding gates that compute either the OR or AND (depending on whether i is even or odd) of the gates in T_i. Any of the M final gates of C_d now serves as the output gate. By an analysis similar to Amano's (see also [6]) we can show that this computes an Approximate Majority with high probability, which finishes the proof.[3]

---

[2] Indeed, this is inevitable with all constructions that we are aware of, since they are actually AC^0 circuits and it is known by a result of Håstad [5] that any AC^0 circuit of depth d for the Majority function must have size $\exp(\Omega(n^{1/(d-1)}))$.

[3] This is a slightly imprecise description of the construction as the final two levels of the circuit are actually defined somewhat differently.

2 Preliminaries

Throughout, n will be a growing parameter. We will consider Boolean functions on n variables, i.e. functions of the form $f : \{0,1\}^n \to \{0,1\}$. We will sometimes identify $\{0,1\}$ with the field $\mathbb{F}_2$ in the natural way and consider functions $f : \mathbb{F}_2^n \to \mathbb{F}_2$ instead.

Given a Boolean vector $y \in \{0,1\}^n$, we use $|y|_0$ and $|y|_1$ to denote the number of 0s and number of 1s respectively in y.

The Majority function on n variables, denoted MAJ_n is the Boolean function that maps inputs $x \in \{0,1\}^n$ to 1 if and only if $|x|_1 > n/2$.

▶ **Definition 2.** An (ε, n)-Approximate Majority is a function $f : \{0,1\}^n \to \{0,1\}$ such that $\Pr_{x \in \{0,1\}^n}[f(x) \neq \mathrm{Maj}_n(x)] \leq \varepsilon$.

As far as we know, the study of this class of functions was initiated by O'Donnell and Wimmer [11]. See also [1, 4].

We refer the reader to [2, 7] for standard definitions of Boolean circuits and formulas. We use AC^0 circuits (respectively formulas) to denote circuits (respectively formulas) of constant depth made up of AND, OR and NOT gates. Similarly, $\mathrm{AC}^0[\oplus]$ circuits (respectively formulas) will be circuits (respectively formulas) of constant depth made up of AND, OR, MOD_2 and NOT gates.

The size of a circuit will denote the number of gates in the circuit and the size of a formula will denote the number of its leaves which is within a constant multiplicative factor of the number of gates in the formula.[4]

3 Lower Bound

In this section, we show that any $\mathrm{AC}^0[\oplus]$ formulas of depth d computing a $(1/4, n)$-Approximate Majority must have size at least $\exp(\Omega(dn^{1/2(d-1)}))$ for all $d \leq O(\log n)$.

We work over the field $\mathbb{F}_2$ and identify it with $\{0,1\}$ in the natural way. The following concepts are standard in circuit complexity (see, e.g., Beigel's survey [3]).

▶ **Definition 3.** Fix any $\varepsilon \in [0,1]$. A polynomial $P \in \mathbb{F}_2[X_1, \ldots, X_n]$ is said to be an *ε-approximating polynomial* for a Boolean function $f : \{0,1\}^n \to \{0,1\}$ if

$$\Pr_{x \in \{0,1\}^n}[f(x) = P(x)] \geq 1 - \varepsilon.$$

We will use the following result of Smolensky [15] (see also Szegedy's PhD thesis [16]).

▶ **Lemma 4** (Smolensky [15])**.** *Let $\varepsilon \in (0, \frac{1}{2})$ be any fixed constant. Any $(\frac{1}{2} - \varepsilon)$-approximating polynomial for the Majority function on n variables must have degree $\Omega(\sqrt{n})$.*

▶ **Corollary 5.** *Let f be any $(1/4, n)$-Approximate Majority and $\varepsilon \in (0, 1/4)$ an arbitrary constant. Then any $(\frac{1}{4} - \varepsilon)$-approximating polynomial for f must have degree $\Omega(\sqrt{n})$.*

Proof. The proof is immediate from Lemma 4 and the triangle inequality. ◀

▶ **Definition 6.** An *ε-error probabilistic polynomial of degree D* for a Boolean function $f : \{0,1\}^n \to \{0,1\}$ is a random variable $\mathbf{P}$ taking values from polynomials in $\mathbb{F}_2[X_1, \ldots, X_n]$ of degree at most D such that for all $x \in \{0,1\}^n$, we have $\Pr[\, f(x) = \mathbf{P}(x) \,] \geq 1 - \varepsilon$.

[4] We assume here without loss of generality that the formula does not contain a gate of fan-in 1 feeding into another.

▶ **Definition 7.** Let $D_\varepsilon(f)$ be the minimum degree of an ε-error probabilistic polynomial for f.

We will make use of the following two lemmas concerning $D_\varepsilon(\cdot)$.

▶ **Lemma 8** (Razborov [12])**.** *Let* OR_n *and* AND_n *be the OR and AND functions on* n *variables respectively. Then* $D_\varepsilon(\mathrm{OR}_n), D_\varepsilon(\mathrm{AND}_n) \leq \lceil \log(1/\varepsilon) \rceil$.

▶ **Lemma 9** (Kopparty and Srinivasan [10] (implicit in proof of Lemma 10))**.** *There is an absolute constant* c_1 *such that for any* $\varepsilon \in (0,1)$*,* $D_\varepsilon(f) \leq c_1 \cdot \lceil \log(1/\varepsilon) \rceil \cdot D_{1/8}(f)$ *for all Boolean functions* f*.*

We now state our main result, which shows that every $\mathrm{AC}^0[\oplus]$ formula of size s and depth $d+1$ admits a 1/8-error approximating polynomial of degree $O(\frac{1}{d}\log s)^d$.

▶ **Theorem 10.** *There is an absolute constant* c_2 *such that, if* f *is computed by an* $\mathrm{AC}^0[\oplus]$ *formula* F *of size* s *and depth* $d+1$*, then* $D_{1/8}(f) \leq 3(c_2(\frac{1}{d}\log(s)+1))^d$.

Proof. The proof is an induction on the depth d of the formula.

The base case $d = 0$ corresponds to the case when the formula is a single AND, OR or MOD_2 gate and we need to show that $D_{1/8}(f) \leq 3$. In the case that the formula is an AND or OR gate, this follows from Lemma 8. If the formula is a MOD_2 gate, this follows from the fact that the MOD_2 function is exactly a polynomial of degree 1.

Let $d \geq 1$. We assume that the formula F is the AND/OR/MOD_2 of sub-formulas $F_1, \ldots, F_m$ computing $f_1, \ldots, f_m$ where F_i has size s_i and depth $d+1$. So F has size $s = s_1 + \cdots + s_m$ and depth $d+2$. Assume that $D_{1/8}(f_i) \leq 3(c_2(\frac{1}{d}\log(s_i)+1))^d$ for all i. We must show that $D_{1/8}(f) \leq 3(c_2(\frac{1}{d+1}\log(s)+1))^{d+1}$.

By Lemma 9, each f_i has an $s_i/(16s)$-error probabilistic polynomial $\mathbf{P}_i$ of degree $c_1 \cdot \lceil \log(16s/s_i) \rceil \cdot D_{1/8}(f_i)$, which is at most

$$3c_1 \cdot 5(\log(s/s_i)+1) \cdot (c_2(\tfrac{1}{d}\log(s_i)+1))^d.$$

Then $(\mathbf{P}_1, \ldots, \mathbf{P}_m)$ jointly computes $(f_1, \ldots, f_m)$ with error 1/16 $(= \sum_{i=1}^m (s_i/(16s)))$.

By a reasoning identical to the base case, it follows that there exists a 1/16-error probabilistic polynomial $\mathbf{Q}$ of degree 4 for the output gate of the formula.

Then $\mathbf{Q}(\mathbf{P}_1, \ldots, \mathbf{P}_m)$ is a 1/8-error probabilistic polynomial for f of degree

$$60c_1 \cdot \max_i (\log(s/s_i)+1) \cdot (c_2(\tfrac{1}{d}\log(s_i)+1))^d.$$

So long as $c_2 \geq 20c_1$, it suffices to show that for all i,

$$(\log(s/s_i)+1) \cdot (\tfrac{1}{d}\log(s_i)+1)^d \leq (\tfrac{1}{d+1}\log(s)+1)^{d+1}.$$

Consider any i and let $a, b \geq 0$ such that $s_i = 2^a$ and $s = 2^{a+b}$. We must show

$$(b+1)\left(\frac{a}{d}+1\right)^d \leq \left(\frac{a+b}{d+1}+1\right)^{d+1}.$$

For fixed $a \geq 0$, as a polynomial in b, the function

$$p_{a,d}(b) := \left(\frac{a+b}{d+1}+1\right)^{d+1} - (b+1)\left(\frac{a}{d}+1\right)^d$$

is nonnegative over $b \geq 0$ with a unique root at $b = a/d$. This follows from

$$\frac{\partial}{\partial b} p_{a,d}(b) = \left(\frac{a+b}{d+1}+1\right)^d - \left(\frac{a}{d}+1\right)^d,$$

which is zero iff $b = a/d$; this value is a minimum of $p_{a,d}$ with $p_{a,d}(a/d) = 0$. ◀

▶ **Corollary 11.** *Fix any constant d and let $n \in \mathbb{N}$ be a growing parameter. Let f be any $(1/4, n)$-Approximate Majority. Then any $\mathrm{AC}^0[\oplus]$ formula of depth d computing f must have size $\exp(\Omega(dn^{1/2(d-1)}))$ for all $d \leq O(\log n)$, where asymptotic notation $O(\cdot)$ and $\Omega(\cdot)$ hide absolute constants (independent of d and n).*

Proof. Say that F is an $\mathrm{AC}^0[\oplus]$ formula of depth d and size s computing f. Then, by Lemma 9, we see that F has a $1/8$-error probabistic polynomial $\mathbf{P}$ of degree $D \leq O(O(\frac{1}{d}\log s + 1)^{d-1})$. In particular, by an averaging argument, there is some fixed polynomial $P \in \mathbb{F}_2[X_1, \ldots, X_n]$ of degree at most D such that P is a $1/8$-error approximating polynomial for f.

Corollary 5 implies that the degree of P must be $\Omega(\sqrt{n})$. Hence, we obtain $O(\frac{1}{d}\log s + 1)^{d-1} \geq \Omega(\sqrt{n})$. It follows that

$$s \geq \exp(\Omega(dn^{1/2(d-1)}) - O(d)).$$

Observe that $\Omega(dn^{1/2(d-1)})$ dominates $O(d)$ so long as $d \leq \varepsilon \log n$ for some absolute constant $\varepsilon > 0$ (depending on the constants in $\Omega(\cdot)$ and $O(\cdot)$). Hence, we get the claimed lower bound $s \geq \exp(\Omega(dn^{1/2(d-1)}))$ for all $d \leq \varepsilon \log n$. ◀

4 Upper Bound

In this section, we show that for any constant ε, there are (ε, n)-Approximate Majorities that can be computed by depth d AC^0 circuits of size $\exp(O(n^{1/2(d-1)}))$.

Let $\varepsilon_0 \in (0, 1)$ be a small enough constant so that the following inequalities hold for any $\beta \leq \varepsilon_0$

- $\exp(-\beta) \leq 1 - \beta\exp(-\beta)$,
- $1 - \beta \geq \exp(-\beta - \beta^2) \geq \exp(-2\beta)$.

(It suffices to take $\varepsilon_0 = 1/2$.)

We need the following technical lemma.

▶ **Lemma 12.** *Let A, s be positive reals, $M, n \in \mathbb{N}$, and $\gamma \in (\frac{1}{n}, \frac{1}{10})$ be such that $e^A \geq n^3$, $n \geq \frac{1}{\varepsilon_0}$, and $s \leq n$. Define $I_0(\gamma) := \{y \in \{0,1\}^M \mid |y|_1 \leq Me^{-A}(1-\gamma)\}$ and $I_1(\gamma) := \{y \in \{0,1\}^M \mid |y|_1 \geq Me^{-A}(1+\gamma)\}$. If we choose $S \subseteq [M]$ of size $t := \lceil e^A \cdot s \rceil$ by picking t random elements from M with replacement, then*

$$x \in I_0(\gamma) \Rightarrow \Pr_S[\bigvee_{j \in S} x_j = 0] \geq \exp(-s) \cdot \exp(s\gamma/2),$$

$$x \in I_1(\gamma) \Rightarrow \Pr_S[\bigvee_{j \in S} x_j = 0] \leq \exp(-s) \cdot \exp(-s\gamma).$$

Further, if $s\gamma \leq \varepsilon_0$, then the above probabilities can be lower bounded and upper bounded by $\exp(-s) \cdot (1 + s\gamma\exp(-s\gamma))$ and $\exp(-s) \cdot (1 - s\gamma\exp(-s\gamma))$ respectively.

A similar statement can be obtained above for the sets $J_1(\gamma) := \{y \in \{0,1\}^M \mid |y|_0 \leq Me^{-A}(1-\gamma)\}$ and $J_0(\gamma) := \{y \in \{0,1\}^M \mid |y|_0 \geq Me^{-A}(1+\gamma)\}$, with the event "$\bigvee_{j\in S} x_j = 0$" being replaced by the event "$\bigwedge_{j\in S} x_j = 1$".

Proof. We give the proof only for $I_0(\gamma)$ and $I_1(\gamma)$. The proof for $J_0(\gamma)$ and $J_1(\gamma)$ is similar.

Consider first the case that $x \in I_1(\gamma)$. In this case, we have the following computation.

$$\begin{aligned}\Pr_S[\bigvee_{j \in S} x_j = 0] &\leq \left(1 - \frac{1+\gamma}{e^A}\right)^{e^A \cdot s} \\ &\leq \exp(-(1+\gamma) \cdot s) \leq \exp(-s) \cdot \exp(-s\gamma). \qquad (1)\end{aligned}$$

The above implies the first upper bound on $\Pr_S[\bigvee_{j\in S} x_j = 0]$ from the lemma statement. When $s\gamma \le \varepsilon_0$, we further have $\exp(-s\gamma) \le 1 - s\gamma\exp(-s\gamma)$, which implies the second upper bound. This proves the lemma when $x \in I_1$.

Now consider the case that $x \in I_0(\gamma)$. We have

$$\begin{aligned}
\Pr_S[\bigvee_{j\in S} x_j = 0] &\ge \left(1 - \frac{1-\gamma}{e^A}\right)^{e^A\cdot s+1} \\
&\ge \exp\left((-\frac{1-\gamma}{e^A} - \frac{1}{e^{2A}})\cdot(e^A\cdot s+1)\right) \\
&= \exp\left(-s + s\gamma - \frac{s}{e^A} - \frac{1-\gamma}{e^A} - \frac{1}{e^{2A}}\right) \\
&\ge \exp\left(-s + s\gamma - \frac{2s}{e^A}\right) \\
&= \exp(-s)\cdot\exp(s\gamma(1 - \frac{2e^{-A}}{\gamma}))) \qquad (2)
\end{aligned}$$

where for the second inequality we have used the fact that since $e^{-A} \le \frac{1}{n^3} \le \varepsilon_0$, we have $1 - \frac{1-\gamma}{e^A} \ge \exp(-\frac{1-\gamma}{e^A} - \frac{1}{e^{2A}})$. Since $e^{-A} \le \frac{1}{n^3} \le \frac{1}{4n} \le \gamma/4$, we can lower bound the right hand side of (2) by $\exp(-s)\cdot\exp(s\gamma/2)$. Also, note that

$$\begin{aligned}
1 - \frac{2e^{-A}}{\gamma} &\ge 1 - \frac{2/n^3}{1/n} = 1 - \frac{2}{n^2} \\
&\ge \exp(-1/n) \ge \exp(-\gamma) \ge \exp(-s\gamma).
\end{aligned}$$

This implies that the RHS of (2) can also be lower bounded by $\exp(-s)\exp(s\gamma\exp(-s\gamma)) \ge \exp(-s)\cdot(1 + s\gamma\exp(-s\gamma))$, which implies the claim about $\Pr_S[\bigvee_{j\in S} x_j = 0]$ assuming that $x \in I_0(\gamma)$. ◀

We now prove the main result of this section.

▶ **Theorem 13.** *For any growing parameter $n \in \mathbb{N}$ and $2 \le d \le O(\frac{\log n}{\log\log n})$ and $\varepsilon > 0$, there is an (ε, n)-Approximate Majority f_n computable by a monotone AC^0 circuit with at most $\exp(O(n^{1/2(d-1)}\log(1/\varepsilon)/\varepsilon))$ many gates, where both $O(\cdot)$'s hide absolute constants (independent of d, ε).*

Proof. We assume throughout that ε is a small enough constant and that n is large enough for various inequalities to hold. We will actually construct a monotone circuit of depth d and size $\exp(O(n^{1/2(d-1)}\log(1/\varepsilon)/\varepsilon))$ computing a $(4\varepsilon, n)$-Approximate Majority, which also implies the theorem.

Fix parameters $A = \lfloor n^{1/2(d-1)} \rfloor$ and $M = \lceil e^{10A} \rceil$. We assume that $A \ge 10\log n$ (which holds as long as $d \le \frac{c\log n}{\log\log n}$ for an absolute constant $c > 0$) and that $\varepsilon \le \varepsilon_0$.

Define a sequence of real numbers $\gamma_0, \gamma_1, \ldots, \gamma_{d-2}$ as follows:

$$\begin{aligned}
\gamma_0 &= \frac{\varepsilon}{\sqrt{n}} \\
\gamma_i &= A\gamma_{i-1}\exp(-2A\gamma_{i-1}), \text{ for each } i \in [d-2].
\end{aligned}$$

It is clear that $\gamma_i \le A^i\gamma_0$ for each $i \in [d-2]$. As a result we also obtain

$$\begin{aligned}
\gamma_i &= A^i\gamma_0\exp(-2A(\gamma_0 + \gamma_1 + \cdots + \gamma_{i-1})) \\
&\ge A^i\gamma_0\exp(-2\gamma_0 A(1 + A + A^2 + \cdots + A^{i-1})) \ge A^i\gamma_0\exp(-3A^i\gamma_0). \qquad (3)
\end{aligned}$$

Let

$$Y_\varepsilon = \left\{ x \in \{0,1\}^n \;\middle|\; |x|_1 \geq \left(\frac{1}{2} + \frac{\varepsilon}{\sqrt{n}}\right) n \right\},$$
$$N_\varepsilon = \left\{ x \in \{0,1\}^n \;\middle|\; |x|_1 \leq \left(\frac{1}{2} - \frac{\varepsilon}{\sqrt{n}}\right) n \right\}.$$

The idea is to define a sequence of circuits $C_1, C_2, \ldots, C_{d-2}$ with n inputs and M outputs such that C_i has depth i and iM many (non-input) gates. Further, for odd i

$$\begin{aligned} x \in N_\varepsilon &\Rightarrow C_i(x) \in I_0(\gamma_i) \\ x \in Y_\varepsilon &\Rightarrow C_i(x) \in I_1(\gamma_i) \end{aligned} \tag{4}$$

and similarly for even i

$$\begin{aligned} x \in N_\varepsilon &\Rightarrow C_i(x) \in J_0(\gamma_i) \\ x \in Y_\varepsilon &\Rightarrow C_i(x) \in J_1(\gamma_i). \end{aligned} \tag{5}$$

After this is done, we will add on top a depth-2 circuit that will reject most inputs from $I_0(\gamma_{d-2})$ or $J_0(\gamma_{d-2})$ – depending on whether $d-2$ is odd or even respectively – and accept most inputs from $I_1(\gamma_{d-2})$ or $J_1(\gamma_{d-2})$.

We begin with the construction of $C_1, \ldots, C_{d-2}$ which is done by induction.

Construction of C_1. The base case of the induction is the construction of C_1, which is done as follows. We choose M i.i.d. random subsets $T_1, \ldots, T_M \subseteq [n]$ in the following way: for each $i \in [M]$, we sample A random elements of $[n]$ with replacement. Let $b_i^x = \bigwedge_{j \in T_i} x_j$.

If $x \in N_\varepsilon$, then the probability that $b_i^x = 1$ is given by

$$\Pr[b_i^x = 1] \leq \left(\frac{1}{2} - \gamma_0\right)^A \leq \frac{1}{2^A}(1 - 2\gamma_0)^A \leq \frac{1}{e^A}(1 - \gamma_0 A)$$

where the last inequality follows from the fact that $(1-z)^A \leq (1 - zA + \frac{A^2 z^2}{2})$.

Let $\delta = 1/n^3$. Note in particular that $2\delta/\gamma_0 A \leq \varepsilon_0$ for large enough n.

By a Chernoff bound, the probability that $\frac{1}{M}\sum_i b_i^x \geq \frac{1}{e^A}(1 - \gamma_0 A)(1+\delta)$ is bounded by $\exp(-\Omega(\delta^2 M/e^A)) \leq \exp(-\Omega(e^{9A}/n^6)) \leq \exp(-n)$, since $e^A \geq n^{10}$. Thus, with probability at least $1 - \exp(-n)$, we have

$$\begin{aligned} \frac{\sum_i b_i^x}{M} &\leq \frac{1}{e^A}(1 - \gamma_0 A)(1+\delta) \\ &\leq \frac{1}{e^A}(1 - \gamma_0 A + \delta) = \frac{1}{e^A}(1 - \gamma_0 A(1 - \frac{\delta}{\gamma_0 A})) \\ &\leq \frac{1}{e^A}(1 - \gamma_0 A \exp(-\frac{2\delta}{\gamma_0 A})) \leq \frac{1}{e^A}(1 - \gamma_0 A \exp(-\gamma_0 A)) \\ &\leq \frac{1}{e^A}(1 - \gamma_1). \end{aligned} \tag{6}$$

Above, we have used the fact that $(1 - \frac{\delta}{\gamma_0 A}) \geq \exp(\frac{-2\delta}{\gamma_0 A})$ since $\delta/\gamma_0 A \leq \varepsilon_0$ for large enough n, as noted above.

If $x \in Y_\varepsilon$, then the probability that $b_i^x = 1$ is given by

$$\begin{aligned}\Pr[b_i^x = 1] &\geq \left(\frac{1}{2} + \gamma_0\right)^A \\ &\geq \frac{1}{2^A}(1 + 2\gamma_0)^A \geq \frac{1}{e^A}(1 + \gamma_0 A) \\ &\geq \frac{1}{e^A}(1 + \gamma_0 A).\end{aligned}$$

As above, we can argue that the probability that $\frac{1}{M}\sum_i b_i^x \leq \frac{1}{e^A}(1 + \gamma_0 A)(1 - \delta)$ is at most $\exp(-n)$. Thus, with probability $1 - \exp(-n)$

$$\begin{aligned}\frac{\sum_i b_i^x}{M} &\geq \frac{1}{e^A}(1 + \gamma_0 A)(1 - \delta) \\ &\geq \frac{1}{e^A}(1 + \gamma_0 A - 2\delta) = \frac{1}{e^A}(1 + \gamma_0 A(1 - \frac{2\delta}{\gamma_0 A})) \\ &\geq \frac{1}{e^A}(1 + \gamma_0 A \exp(-\frac{4\delta}{\gamma_0 A})) \geq \frac{1}{e^A}(1 + \gamma_0 A \exp(-\gamma_0 A)) \\ &\geq \frac{1}{e^A}(1 + \gamma_1). \qquad (7)\end{aligned}$$

Thus, by a union bound over x, we can fix a choice of $T_1, \ldots, T_M$ so that (6) holds for all $x \in N_\varepsilon$ and (7) holds for all $x \in Y_\varepsilon$. Hence, (4) holds for $i = 1$ as required. This concludes the construction of C_1, which just outputs the values of $\bigwedge_{j \in T_i} x_j$ for each i.

Construction of C_{i+1}. For the inductive case, we proceed as follows. We assume that i is odd (the case that i is even is similar). So by the inductive hypothesis, we know that (4) holds and hence that $C_i(x) \in I_0(\gamma_i)$ or $I_1(\gamma_i)$ depending on whether $x \in N_\varepsilon$ or Y_ε. Let $\gamma := \gamma_i$. Let the output gates of C_i be $g_1, \ldots, g_M$.

We choose $T_1, \ldots, T_M \subseteq [M]$ randomly as in the statement of Lemma 12 with $s = A$. Note that the chosen parameters satisfy all the hypotheses of Lemma 12. Further we also have $s\gamma \leq A \cdot A^i\gamma_0 \leq A^{d-1} \cdot \frac{\varepsilon}{\sqrt{n}} \leq \varepsilon_0$.

The random circuit C' is defined to be the circuit obtained by adding M OR gates to C_i such that the jth OR gate computes $\bigvee_{k \in T_j} g_k$. Let b_j^x be the output of the jth OR gate on $C_i(x)$.

By Lemma 12, we have

$$\begin{aligned}x \in N_\varepsilon &\Rightarrow \Pr_S[b_j^x = 0] \geq \exp(-A) \cdot (1 + A\gamma\exp(-A\gamma)) \\ x \in Y_\varepsilon &\Rightarrow \Pr_S[b_j^x = 0] \leq \exp(-A) \cdot (1 - A\gamma\exp(-A\gamma)) \qquad (8)\end{aligned}$$

Let $\delta = \frac{1}{n^3}$. Note that $A\gamma \in [\frac{1}{\sqrt{n}}, \frac{1}{n^{1/2(d-1)}}]$ and hence for large enough n, $\frac{2\delta}{A\gamma\exp(-A\gamma)} \leq \varepsilon_0$.

Assume $x \in N_\varepsilon$. In this case, the Chernoff bound implies that the probability that $\sum_{j \in [M]} b_j^x \leq M\exp(-A) \cdot (1 + A\gamma\exp(-A\gamma))(1 - \delta)$ is at most $\exp(-\Omega(\delta^2 M/e^A)) \leq \exp(-n)$.

When this event does not occur, we have

$$\begin{aligned}\frac{\sum_i b_i^x}{M} &\geq \frac{1}{e^A}(1 + A\gamma\exp(-A\gamma))(1-\delta)\\ &\geq \frac{1}{e^A}(1 + A\gamma\exp(-A\gamma) - 2\delta) = \frac{1}{e^A}(1 + A\gamma\exp(-A\gamma)(1 - \frac{2\delta}{A\gamma\exp(-A\gamma)}))\\ &\geq \frac{1}{e^A}(1 + A\gamma\exp(-A\gamma)\cdot\exp(-\frac{4\delta}{A\gamma\exp(-A\gamma)}))\\ &\geq \frac{1}{e^A}(1 + A\gamma\exp(-A\gamma)\cdot\exp(-A\gamma))\\ &\geq \frac{1}{e^A}(1 + A\gamma\exp(-2A\gamma)) \geq \frac{1}{e^A}(1+\gamma_{i+1}). \qquad (9)\end{aligned}$$

We have used above that for large enough n, $\frac{2\delta}{A\gamma\exp(-A\gamma)} \leq \varepsilon_0$ and hence $1 - \frac{2\delta}{A\gamma\exp(-A\gamma)} \geq \exp(\frac{-4\delta}{A\gamma\exp(-A\gamma)})$.

Similarly when $x \in Y_\varepsilon$, the Chernoff bound tells us that the probability that $\sum_{j\in[M]} b_j^x \geq M\exp(-A)\cdot(1 - A\gamma\exp(-A\gamma))(1+\delta)$ is at most $\exp(-n)$. In this case, we get

$$\begin{aligned}\frac{\sum_i b_i^x}{M} &\leq \frac{1}{e^A}(1 - A\gamma\exp(-A\gamma))(1+\delta)\\ &\leq \frac{1}{e^A}(1 - A\gamma\exp(-A\gamma) + \delta) = \frac{1}{e^A}(1 - A\gamma\exp(-A\gamma)(1 - \frac{\delta}{A\gamma\exp(-A\gamma)}))\\ &\leq \frac{1}{e^A}(1 - A\gamma\exp(-A\gamma)\cdot\exp(-\frac{2\delta}{A\gamma\exp(-A\gamma)}))\\ &\leq \frac{1}{e^A}(1 - A\gamma\exp(-A\gamma)\cdot\exp(-A\gamma))\\ &= \frac{1}{e^A}(1 - A\gamma\exp(-2A\gamma)) \geq \frac{1}{e^A}(1-\gamma_{i+1}). \qquad (10)\end{aligned}$$

By a union bound, we can fix $T_1, \ldots, T_M$ so that (9) and (10) are true for all $x \in N_\varepsilon$ and $x \in Y_\varepsilon$ respectively. This gives us the circuit C_{i+1} which satisfies all the required properties.

The top two levels of the circuit. At the end of the above procedure we have a circuit C_{d-2} of depth $d-2$ and at most $(d-2)M$ gates that satisfies one of (4) or (5) depending on whether $d-2$ is odd or even respectively. We assume that $d-2$ is even (the other case is similar).

Define $\gamma := \gamma_{d-2}$. Recall from (3) that $\gamma \geq A^{d-2}\gamma_0\exp(-3A^{d-2}\gamma_0) \geq A^{d-2}\gamma_0/2$.

Let $M' = \lceil\exp(\frac{10A\log(1/\varepsilon)}{\varepsilon} + 10A)\rceil$. We choose M' many subsets $T_1, \ldots, T_{M'} \subseteq [M]$ i.i.d. so that each T_j is picked as in Lemma 12 with $s = 10A\log(1/\varepsilon)/\varepsilon$. Note that

$$s\gamma \geq s\frac{A^{d-2}\gamma_0}{2} = \frac{10A\log(1/\varepsilon)}{\varepsilon}\cdot\frac{A^{d-2}}{2}\cdot\frac{\varepsilon}{\sqrt{n}} \geq 5\log(1/\varepsilon).$$

Say $g_1, \ldots, g_M$ are the output gates of C_{d-2}. We define the random circuit C' (with n inputs and M' outputs) to be the circuit obtained by adding M' AND gates such that the jth AND gate computes $\bigwedge_{k\in T_j} g_k$. Let b_j^x be the output of the jth AND gate on $C_{d-2}(x)$.

By Lemma 12, we have

$$\begin{aligned}x \in N_\varepsilon &\Rightarrow \Pr_S[b_j^x = 1] \leq \exp(-s)\cdot\exp(-s\gamma) \leq \varepsilon^2\cdot\exp(-s)\\ x \in Y_\varepsilon &\Rightarrow \Pr_S[b_j^x = 1] \geq \exp(-s)\cdot\exp(s\gamma/2) \geq \frac{\exp(-s)}{\varepsilon^2}. \qquad (11)\end{aligned}$$

Say $x \in N_\varepsilon$. By a Chernoff bound, the probability that $\sum_j b_j^x \geq 2\varepsilon^2 M' \exp(-s)$ is at most $\exp(-\Omega(\varepsilon^2 M' \exp(-s))) \leq \exp(-\Omega(\varepsilon^2 e^{10A})) \leq \exp(-n)$. Similarly, when $x \in Y_\varepsilon$, the probability that $\sum_j b_j^x \leq \frac{M' \exp(-s)}{2\varepsilon^2}$ is also bounded by $\exp(-n)$. By a union bound, we can fix a $T_1, \ldots, T_{M'}$ to get a circuit C_{d-1} such that

$$x \in N_\varepsilon \Rightarrow |C_{d-1}(x)|_1 \leq 2\varepsilon^2 \exp(-s) M'$$
$$x \in Y_\varepsilon \Rightarrow |C_{d-1}(x)|_1 \geq \frac{1}{2\varepsilon^2} \exp(-s) M'. \tag{12}$$

This gives us the depth $d-1$ circuit C_{d-1}. Note that C_{d-1} has $M' + O(dM) = O(M')$ gates.

To get the depth d circuit, we choose a random subset $T \subseteq [M']$ by sampling exactly $\lceil \exp(s) \rceil$ many elements of $[M']$ with replacement. We construct a random depth-d circuit C'_d by taking the OR of the the output gates of C_{d-1} indexed by the subset T.

From (12) it follows that

$$x \in N_\varepsilon \Rightarrow \Pr_T[C'_d(x) = 1] \leq |T| \cdot 2\varepsilon^2 \exp(-s) \leq 4\varepsilon^2 < \varepsilon$$
$$x \in Y_\varepsilon \Rightarrow \Pr_T[C'_d(x) = 0] \leq \left(1 - \frac{\exp(-s)}{2\varepsilon^2}\right)^{\exp(s)} \leq \exp(-1/2\varepsilon^2) < \varepsilon.$$

The final inequalities in each case above hold as long as ε is a small enough constant.

It follows from the above that there is a choice for T such that C'_d makes an error – i.e. $C'_d(x) = 1$ for $x \in N_\varepsilon$ or $C'_d(x) = 0$ for $x \in Y_\varepsilon$ – on at most a 2ε fraction of inputs from $N_\varepsilon \cup Y_\varepsilon$. We fix such a choice for T and the corresponding circuit C.

We have

$$\begin{aligned}\Pr_{x \in \{0,1\}^n}[C(x) \neq \mathrm{Maj}_n(x)] &\leq \Pr_{x \in Y_\varepsilon \cup N_\varepsilon}[C(x) \neq \mathrm{Maj}_n(x)] + \Pr_{x \in \{0,1\}^n}[x \notin Y_\varepsilon \cup N_\varepsilon] \\ &\leq 2\varepsilon + \Pr_{x \in \{0,1\}^n}[x \notin Y_\varepsilon \cup N_\varepsilon].\end{aligned}$$

Finally by Stirling's approximation we get

$$\Pr_{x \in \{0,1\}^n}[x \notin Y_\varepsilon \cup N_\varepsilon] = \frac{1}{2^n} \sum_{m \in [\frac{n}{2} - \varepsilon\sqrt{n}, \frac{n}{2} + \varepsilon\sqrt{n}]} \binom{n}{m} \leq \frac{1}{2^n} \sum_{m \in [\frac{n}{2} - \varepsilon\sqrt{n}, \frac{n}{2} + \varepsilon\sqrt{n}]} \binom{n}{n/2} \leq 2\varepsilon.$$

Hence we see that the circuit C computes a $(4\varepsilon, n)$-Approximate Majority, which proves Theorem 13.

The circuit has depth d and size $O(M') = \exp(O(n^{1/2(d-1)} \log(1/\varepsilon)/\varepsilon))$. ◀

5 Conclusion

Our main results extend straightforwardly to $\mathrm{AC}^0[\mathrm{MOD}_p]$ for any fixed prime p. The proofs are exactly the same except for the fact that the approximating polynomials of degree $O(\frac{1}{d} \log s)^{d-1}$ from Section 3 are constructed over $\mathbb{F}_p$.

Using the fact [14] that any (1/4)-approximating polynomial over $\mathbb{F}_p$ (p odd) for the Parity function on n variables must have degree $\Omega(\sqrt{n})$, we see that any polynomial-sized $\mathrm{AC}^0[\mathrm{MOD}_p]$ formula computing the Parity function on n variables must have depth $\Omega(\log n)$. This strengthens a result of Rossman [13] which gives this statement for AC^0 formulas.

Abstract

The Sensitivity Conjecture and the Log-rank Conjecture are among the most important and challenging problems in concrete complexity. Incidentally, the Sensitivity Conjecture is known to hold for monotone functions, and so is the Log-rank Conjecture for $f(x \wedge y)$ and $f(x \oplus y)$ with monotone functions f, where $\wedge$ and $\oplus$ are bit-wise AND and XOR, respectively. In this paper, we extend these results to functions f which alternate values for a relatively small number of times on any monotone path from 0^n to 1^n. These deepen our understandings of the two conjectures, and contribute to the recent line of research on functions with small alternating numbers.

1 Introduction

A central topic in Boolean function complexity theory is relations among different combinatorial and computational measures [29]. For Boolean functions, there is a large family of complexity measures such as block sensitivity, certificate complexity, decision tree complexity (including its randomized and quantum versions), degree (including its approximate version), etc, that are all polynomially related [13]. One outlier[1] is sensitivity, which a priori could be exponentially smaller than the ones in that family. The famous Sensitivity Conjecture raised by Nisan and Szegedy [48] says that sensitivity is also polynomially related to the block sensitivity and others in the family. Despite a lot of efforts, the best upper bound we know is still exponential: $\mathsf{bs}(f) \le \mathsf{C}(f) \le \left(\frac{8}{9} + o(1)\right) \mathsf{s}(f) 2^{\mathsf{s}(f)-1}$ from [25], improving upon previous work [54, 2, 3]. See a recent survey [24] about this conjecture and how it has resisted many serious attacks.

Communication complexity quantifies the minimum amount of communication required for computing functions whose inputs are distributed among two or more parties [31]. In

† Most of this work was done when Chengyu Lin was in Chinese University of Hong Kong.

1 There are complexity measures, such as $\mathbb{F}_2$-degree, polynomial threshold degree, total influence, Boolean circuit depth, CNF/DNF size, that are *known* not to belong to the polynomially equivalent class. But the position of sensitivity is elusive.

the standard bipartite setting, the function F has two inputs x and y, with x given to Alice and y to Bob. The minimum number of bits needed to be exchanged to compute $F(x,y)$ for all inputs (x,y) is the communication complexity $\mathsf{CC}(F)$. It has long been known [41] that the logarithm of the rank of communication matrix $M_F \stackrel{\text{def}}{=} [F(x,y)]_{x,y}$ is a lower bound of $\mathsf{CC}(F)$. Perhaps the most prominent and long-standing open question about communication complexity is the Log-rank Conjecture proposed by Lovász and Saks [37], which asserts that $\mathsf{CC}(F)$ of any Boolean function F is also upper bounded by a polynomial of $\log \mathsf{rank}(M_F)$. The conjecture has equivalent forms related to chromatic number conjecture in graph theory [37], nonnegative rank [36], Boolean roots of polynomials over real numbers [61], quantum sampling complexities [4, 65], etc. Despite a lot of efforts devoted to the conjecture in the past decades, the best upper bound is $\mathsf{CC}(F) = O\big(\sqrt{\mathsf{rank}(M_F)}\log\left(\mathsf{rank}(M_F)\right)\big)$ by Lovett [39], which is still exponentially far from the target.

While these two conjectures are notoriously challenging in their full generality, special classes of functions have been investigated. In particular, the Sensitivity Conjecture is confirmed to hold for monotone functions, as the sensitivity coincides with block sensitivity and certificate complexity for those functions [47]. The Log-rank Conjecture is not known to be true for monotone functions, but it holds for monotone functions on two bit-wise compositions between x and y. More specifically, two classes of bit-wise composed functions have drawn substantial attention. The first class contains AND functions $F = f \circ \wedge$, defined by $F(x,y) = f(x \wedge y)$, where $\wedge$ is the bit-wise AND of $x, y \in \{0,1\}^n$. Taking the outer function f to be the n-bit OR, we get Disjointness, the function that has had a significant impact on both communication complexity theory itself [53] and applications to many other areas such as streaming, data structures, circuit complexity, proof complexity, game theory and quantum computation [15]. The AND functions also contain other well known functions such as Inner Product, AND-OR trees [28, 33, 27, 19], and functions exhibiting gaps between communication complexity and log-rank [49]. The second class is XOR functions $F = f \circ \oplus$, defined by $F(x,y) = f(x \oplus y)$, where $\oplus$ is the bit-wise XOR function. This class includes Equality [62, 46, 1, 7, 11] and Hamming Distance [63, 16, 26, 34, 35] as special cases.

Both AND and XOR functions have recently drawn much attention [38, 12, 67, 32, 42, 55, 35, 59, 66, 50, 64], partly because their communication matrix rank has intimate connections to the polynomial representations of the outer function f. Specifically, the rank of $M_{f\circ\wedge}$ is exactly the Möbius sparsity[2] $\mathtt{mono}(f)$, the number of nonzero coefficients $\alpha(S)$ in the multilinear polynomial representation $f(x) = \sum_{S\subseteq[n]} \alpha(S) \prod_{i\in S} x_i$ for $f : \{0,1\}^n \to \{0,1\}$ [12]. And the rank of $M_{f\circ\oplus}$ is exactly the Fourier sparsity $\|\hat{f}\|_0$, the number of nonzero Fourier coefficients $\hat{f}(S)$ in the multilinear polynomial representation $f(x) = \sum_{S\subseteq[n]} \hat{f}(S) \prod_{i\in S} x_i$ for $f : \{+1,-1\}^n \to \{0,1\}$.

It is known that the Log-rank Conjecture holds for these two classes of functions when the outer function f is monotone [38, 42], and this work aims to extend these as well as the sensitivity result on monotone functions, to functions that are *close to* being monotone. One needs to be careful about the distance measure here, since the widely-used (e.g. in property testing and computational learning) normalized Hamming distance $\mathsf{dist}(f,g) = \Pr_{x\in\{0,1\}^n}[f(x) \neq g(x)]$ does not meet our requirement. Indeed, if we flip the value $f(x)$ at just one input x, then this changes f by an exponentially small amount measured by dist, but the sensitivity would change from a small $\mathsf{s}(f)$ to a large $n - \mathsf{s}(f)$. Similarly, the Fourier sparsity is also very sensitive to local changes ($\|\hat{f}\|_0$ to $2^n - \|\hat{f}\|_0$), and so is Möbius sparsity

[2] Named after the Möbius transform from f to α.

if we flip the value at 0^n.

One robust distance measure to monotone functions, which has recently drawn an increasingly amount of attention, is the alternating number, defined as follows. View the Boolean hypercube $\{0,1\}^n$ as a lattice with the partial order $x \preceq y$ if $x_i \leq y_i$ for all i. A path $x^{(1)} \to \cdots \to x^{(k)}$ on $\{0,1\}^n$ is monotone if $x^{(i)} \prec x^{(i+1)}$ for all i. The alternating number of a function f on $\{0,1\}^n$ is the maximum number of i's with $f(x^{(i)}) \neq f(x^{(i+1)})$, on any monotone path $x^{(0)} \to \cdots \to x^{(n)}$ from 0^n to 1^n. It is clear that constant functions have alternating number 0, and monotone functions have alternating number 1. For general functions f, we have $\mathsf{alt}(f) \leq n$, thus $\mathsf{alt}(f)$ is a sub-linear complexity measure. The smaller $\mathsf{alt}(f)$ is, the closer it is to monotone functions. Studies of the alternating number dated back to [40], in which Markov showed that the inversion complexity, the minimum number of negation gates needed in any Boolean circuit computing f, is exactly $\lceil \log_2(\mathsf{alt}(f)+1) \rceil$. Late work investigated the inversion complexity/alternating number over computational models such as constant-depth circuit [52], bounded-depth circuit [56], Boolean formula [43], and non-deterministic circuit [44]. It has been recently shown that small alternating number can be exploited in learning Boolean circuits [10]. Also there are some studies in cryptography considering the effect of negation gates [23].

In this paper, we study the Sensitivity and Log-rank Conjectures for functions whose alternating numbers are small, compared to sensitivity, Möbius sparsity and Fourier sparsity. First, the following theorem shows that the Sensitivity Conjecture holds for f with $\mathsf{alt}(f) = \mathrm{poly}(\mathsf{s}(f))$.

▶ **Theorem 1.** *For any function $f : \{0,1\}^n \to \{0,1\}$, it holds that*

$$\mathsf{bs}(f) = O(\mathsf{alt}(f)^2 \cdot \mathsf{s}(f)).$$

Note that if a function is non-degenerate in the sense that it depends on all n variables, then the sensitivity is at least $\Omega(\log n)$ [54], therefore the above theorem also confirms the Sensitivity Conjecture for non-degenerate functions f with $\mathsf{alt}(f) = \mathrm{poly}\log n$.

The next two theorems confirmed the Log-rank Conjecture for $f \circ \oplus$ with $\mathsf{alt}(f) = \mathrm{poly}\log(\|\hat{f}\|_0)$, and for $f \circ \wedge$ with $\mathsf{alt}(f) = O(1)$.

▶ **Theorem 2.** *For any function $f : \{0,1\}^n \to \{0,1\}$, it holds that*

$$\mathsf{CC}(f \circ \oplus) \leq 2 \cdot \mathsf{alt}(f) \cdot \log^2 \mathsf{rank}(M_{f\circ\oplus}).$$

▶ **Theorem 3.** *For any function $f : \{0,1\}^n \to \{0,1\}$, it holds that*

$$\mathsf{CC}(f \circ \wedge) \leq O(\log^{\mathsf{alt}(f)+1} \mathsf{rank}(M_{f\circ\wedge})).$$

In the last theorem, the dependence on $\mathsf{alt}(f)$ can be slightly improved (by a factor of 2) if a factor of $\log n$ is tolerated in the communication cost.

Related work

The Sensitivity Conjecture has many equivalent forms, summarized in the survey [24]. Also see the recent paper [18] which tries to solve this conjecture using a communication game approach. At the other end of the spectrum, [51, 5] seek the largest possible separation between sensitivity and block sensitivity, and [9] got a super-quadratic separation between sensitivity and query complexity. Apart from monotone functions [47], the Sensitivity Conjecture has also been confirmed on graph properties [60], cyclically-invariant function [14],

read-once functions [45], functions admitting the Normalized Block property [57] and several cases of read-k formulas [8]. Other than the conjecture itself, some recent work [6, 21, 22] discussed combinatorial and computational structures of low-sensitivity functions.

For the Log-rank Conjecture, apart from the equivalent forms mentioned earlier, some seemingly weaker formulations in terms of the largest monochromatic rectangle size [49], randomized communication complexity and information cost [17] are actually equivalent to the original conjecture. For lower bounds, the best one had been $\mathsf{CC}(F) = \Omega\left((\log \mathsf{rank}(M_F))^{\log_3 6}\right)$ (attributed to Kushilevitz in [49]), achieved by an AND function, until the recent result of $\mathsf{CC}(F) = \tilde{\Omega}\left(\log^2 \mathsf{rank}(M_F)\right)$ [20]. For XOR functions $f \circ \oplus$, the Log-rank Conjecture is confirmed when f is symmetric [67], monotone [42], linear threshold functions (LTFs) [42], AC^0 functions [30], has low $\mathbb{F}_2$-degree [59] or small spectral norm [59]. For AND functions $f \circ \wedge$, it seems that the conjecture is only confirmed on monotone functions [38].

2 Preliminaries

2.1 n-bit (Boolean) functions

We use $[n]$ to denote the set $\{1, 2, \ldots, n\}$. The all-0 n-bit string is denoted by 0^n and the all-1 n-bit string is denoted by 1^n.

For a Boolean function $f : \{0,1\}^n \to \{0,1\}$, its $\mathbb{F}_2$-degree is the degree of f viewed as a polynomial over $\mathbb{F}_2$. Such functions f can be also viewed as polynomials over $\mathbb{R}$: $f(x) = \sum_{S\subseteq[n]} \alpha(S)x^S$, where $x^S = \prod_{i\in S} x_i$. If we represent the domain by $\{+1,-1\}^n$, then the polynomial (still over $\mathbb{R}$) changes to $f(x) = \sum_{S\subseteq[n]} \hat{f}(S)x^S$, usually called Fourier expansion of f. The coefficients $\alpha(S)$ and $\hat{f}(S)$ in the two $\mathbb{R}$-polynomial representations capture many important combinatorial properties of f. We denote by $\mathtt{mono}(f)$ the Möbius sparsity, the number of non-zero coefficients $\alpha(S)$, and by $\|\hat{f}\|_0$ the Fourier sparsity, the number of non-zero coefficients $\hat{f}(S)$. Some basic facts used in this paper are listed as follows.

▶ **Fact 4.** *For any $f : \{0,1\}^n \to \{0,1\}$, $\deg_2(f) = n$ if and only if $|f^{-1}(1)|$ is odd.*

▶ **Fact 5.** *For any $f : \{0,1\}^n \to \{0,1\}$, $\deg_2(f) \le \log \|\hat{f}\|_0$.*

For any input $x \in \{0,1\}^n$ and $i \in [n]$, let x^i be the input obtained from x by flipping the value of x_i. For a Boolean function $f : \{0,1\}^n \to \{0,1\}$ and an input x, if $f(x) \neq f(x^i)$, then we say that x is *sensitive to coordinate* i, and i is a *sensitive coordinate* of x. We can also define these for blocks. For a set $B \subseteq [n]$, let x^B be the input obtained from x by flipping x_i for all $i \in B$. Similarly, if $f(x) \neq f(x^B)$, then we say that x is *sensitive to block* B, and B is a *sensitive block* of x. The *sensitivity* $\mathsf{s}(f,x)$ *of function* f *on input* x is the number of sensitive coordinates i of x: $\mathsf{s}(f,x) = |\{i \in [n] : f(x) \neq f(x^i)\}|$, and the *sensitivity of function* f is $\mathsf{s}(f) = \max_x \mathsf{s}(f,x)$. It is easily seen that the n-bit AND and OR functions both have sensitivity n. The *block sensitivity* $\mathsf{bs}(f,x)$ *of function* f *on input* x is the maximal number of disjoint sensitive blocks of x, and the *block sensitivity of function* f is $\mathsf{bs}(f) = \max_x \mathsf{bs}(f,x)$. Note that there are always $\mathsf{bs}(f,x)$ many disjoint *minimal* sensitive blocks, in the sense that any $B \subsetneq B_i$ is not a sensitive block of x.

For a Boolean function $f : \{0,1\}^n \to \{0,1\}$ and an input $x \in \{0,1\}^n$, the *certificate complexity* $\mathsf{C}(f,x)$ *of function* f *on input* x is the minimal number of variables restricting the value of which fixes the function to a constant. The *certificate complexity* of f is $\mathsf{C}(f) = \max_x \mathsf{C}(f,x)$, and the *minimal certificate complexity* of f is $\mathsf{C}_{\min}(f) = \min_x \mathsf{C}(f,x)$. The *decision tree complexity* $\mathsf{DT}(f)$ of function f is the minimum depth of any decision tree that computes f.

A *subfunction* or a *restriction* of a function f on $\{0,1\}^n$ is obtained from f by restricting the values of some variables. Sometimes we say to restrict f to *above* an input d, or to take the subfunction f' over $\{x : x \succeq d\}$, then we mean to restrict variables x_i to be 1 whenever $d_i = 1$. Similarly, we say to restrict f to *under* an input u, or take the subfunction f' over $\{x : x \preceq u\}$, meaning to restrict x_i to be 0 whenever $u_i = 0$.

Let $\mathcal{F}_n$ be the set of all the real-valued functions on $\{0,1\}^n$. A complexity measure $M : \cup_{n=1}^{\infty}\mathcal{F}_n \to \mathbb{R}$ is *downward non-increasing* if $M(f') \leq M(f)$ for all subfunction f' of f. That is, restricting variables does not increase the measure M. It is easily seen that the $\mathbb{F}_2$-degree, the alternating number, the decision tree complexity, the sensitivity, the block sensitivity, the certificate complexity, the Fourier sparsity, are all downward non-increasing. When M is not downward non-increasing, it makes sense to define the *closure* by $M^{\text{clo}}(f) = \max_{f'} M(f')$ where the maximum is taken over all subfunctions f' of f. In particular, $\mathsf{C}^{\text{clo}}_{\min}(f) = \max_{f'} \mathsf{C}_{\min}(f')$. The next theorem relates decision tree complexity to $\mathsf{C}^{\text{clo}}_{\min}$.

▶ **Theorem 6** ([59]). *For any $f : \{0,1\}^n \to \{0,1\}$, it holds that $\mathsf{DT}(f) \leq \mathsf{C}^{\text{clo}}_{\min}(f) \deg_2(f)$.*

(The original theorem proved was actually $\mathsf{PDT}(f) \leq \mathsf{C}^{\text{clo}}_{\oplus,\min}(f) \deg_2(f)$, where $\mathsf{PDT}(f)$ is the parity decision tree complexity and $\mathsf{C}^{\text{clo}}_{\oplus,\min}(f)$ is the parity minimum certificate complexity. But as observed by [58], the same argument applies to standard decision tree as well.)

For general Boolean functions f, we have $\mathsf{s}(f) \leq \mathsf{bs}(f) \leq \mathsf{C}(f)$. But when f is monotone, equalities are achieved.

▶ **Fact 7.** *If $f : \{0,1\}^n \to \{0,1\}$ is monotone, then $\mathsf{s}(f) = \mathsf{bs}(f) = \mathsf{C}(f)$.*

▶ **Fact 8** ([42]). *If $f : \{0,1\}^n \to \{0,1\}$ is monotone, then $\mathsf{s}(f) \leq \deg_2(f)$.*

One can associate a partial order $\preceq$ to the Boolean hypercube $\{0,1\}^n$: $x \preceq y$ if $x_i \leq y_i$ for all i. We also write $y \succeq x$ when $x \preceq y$. If $x \preceq y$ but $x \neq y$, then we write $x \prec y$ and $y \succ x$. A path $x^{(1)} \to \cdots \to x^{(k)}$ on $\{0,1\}^n$ is *monotone* if $x^{(i)} \prec x^{(i+1)}$ for all i.

▶ **Definition 9.** For any function on $\{0,1\}^n$, the *alternating number of a path* $x^{(1)} \to \cdots \to x^{(k)}$ is the number of $i \in \{1,2,...,k-1\}$ with $f(x^{(i)}) \neq f(x^{(i+1)})$. The alternating number $\mathsf{alt}(f,x)$ of input $x \in \{0,1\}^n$ is the maximum alternating number of any monotone path from 0^n to x, and the *alternating number of a function* f is $\mathsf{alt}(f) = \mathsf{alt}(f, 1^n)$. Equivalently, one can also define $\mathsf{alt}(f)$ to be the largest k such that there exists a list $\{x^{(1)}, x^{(2)}, \ldots, x^{(k+1)}\}$ with $x^{(i)} \preceq x^{(i+1)}$ and $f(x^{(i)}) \neq f(x^{(i+1)})$, for all $i \in [k]$.

A function $f : \{0,1\}^n \to \mathbb{R}$ is *monotone* if $f(x) \leq f(y)$, $\forall x \preceq y$. A function $f : \{0,1\}^n \to \mathbb{R}$ is *anti-monotone* if $f(x) \leq f(y)$, $\forall x \succeq y$. It is not hard to see that $\mathsf{alt}(f) = 0$ iff f is constant, and $\mathsf{alt}(f) = 1$ iff f is monotone or anti-monotone.

▶ **Definition 10.** For a function f on $\{0,1\}^n$, an input $u \in \{0,1\}^n - \{1^n\}$ is called a *max term* if $f(u) \neq f(1^n)$, and $f(x) = f(1^n)$ for all $x \succ u$. An input $d \in \{0,1\}^n - \{0^n\}$ is called a *min term* if $f(d) \neq f(0^n)$, and $f(x) = f(0^n)$ for all $x \prec d$.

2.2 Communication complexity

Suppose that for a bivariate function $F(x,y)$, the input x is given to Alice and y to Bob. The (deterministic) *communication complexity* $\mathsf{CC}(F)$ is the minimum number of bits needed to be exchanged by the best (deterministic) protocol that computes F (on the worst-case input).

The rank (over $\mathbb{R}$) of the communication matrix for bit-wise composed functions coincides with some natural parameters of the outer function f. For XOR functions $f \circ \oplus$, it holds that $\mathsf{rank}(M_{f\circ\oplus}) = \|\hat{f}\|_0$, and for AND functions $f \circ \wedge$, it holds that $\mathsf{rank}(M_{f\circ\wedge}) = \mathtt{mono}(f)$. When f is OR function of n variables, we have $\mathsf{rank}(M_{f\circ\wedge}) = \mathtt{mono}(\mathsf{OR}_n) = 2^n - 1$.

It is well known that communication can simulate queries. More specifically, for XOR functions and AND functions, we have that

$$\mathsf{CC}(f \circ \wedge) \le 2\mathsf{DT}(f) \text{ and } \mathsf{CC}(f \circ \oplus) \le 2\mathsf{DT}(f). \tag{1}$$

In a {0,1}-communication matrix M, for $b \in \{0,1\}$, a *b-rectangle* is a submatrix of all entries equal to b. The *b-covering number* $\mathsf{Cover}_b(M)$ of matrix M is the minimum number of b-rectangles that can cover all b entries in M. (These b-rectangles need not be disjoint.) For notational convenience, we sometimes write $\mathsf{Cover}_1(F)$ for $\mathsf{Cover}_1(M_F)$. Lovász [36] showed the following bounds.

▶ **Theorem 11** ([36]). *For any Boolean funcion $F(x, y)$, it holds that*

$$\log \mathsf{Cover}_b(M_F) \le \mathsf{CC}(F) \le \log \mathsf{Cover}_b(M_F) \cdot \log \mathsf{rank}(M_F).$$

3 The Sensitivity Conjecture

This section is devoted to the proof of Theorem 1. We will first show the following lemma, in which the first statement is used in this section and the second statement will be used in Section 4 for proving the Log-rank Conjecture of XOR functions.

▶ **Lemma 12.** *For any $f : \{0,1\}^n \to \{0,1\}$, it holds that*
1. $\max\{\mathsf{C}(f, 0^n), \mathsf{C}(f, 1^n)\} \le \mathsf{alt}(f) \cdot \mathsf{s}(f)$
2. $\max\{\mathsf{C}(f, 0^n), \mathsf{C}(f, 1^n)\} \le \mathsf{alt}(f) \cdot \deg_2(f)$.

Proof. First note that it suffices to prove the two upper bounds for $\mathsf{C}(f, 0^n)$, because then we can take $g(x) = f(\bar{x})$ to get that $\mathsf{C}(f, 1^n) = \mathsf{C}(g, 0^n) \le \mathsf{alt}(g) \cdot \mathsf{s}(g) = \mathsf{alt}(f) \cdot \mathsf{s}(f)$.

We prove upper bounds on $\mathsf{C}(f, 0^n)$ by induction on $\mathsf{alt}(f)$. When $\mathsf{alt}(f) = 1$, the function is either monotone or anti-monotone, thus

$$\mathsf{C}(f, 0^n) \le \mathsf{C}(f) = \mathsf{s}(f) \le \deg_2(f),$$

where the first inequality is by definition of $\mathsf{C}(f, 0^n)$, the middle equality is by Fact 7 and the last inequality is because $\mathsf{s}(f) \le \deg_2(f)$ for monotone f (Fact 8). Now we assume that the inequalities in the lemma hold for $\mathsf{alt}(f) < a$ and we will show that they hold for f with $\mathsf{alt}(f) = a$ as well. Let u be a max term of f. Define $S_0(u) \stackrel{\text{def}}{=} \{i \in [n] : u_i = 0\}$, and consider the subcube above u: $\{x : x \succeq u\}$. Let f' be the subfunction obtained by restricting f on this subcube. By the definition of max term $f(u) \ne f(u^i)$ for all $i \in S_0(u)$. Therefore,

$$|S_0(u)| \le \mathsf{s}(f, u) \le \mathsf{s}(f). \tag{2}$$

We know that any point $z \succ u$ has $f(z) = f(1^n) \ne f(u)$. So the number of 1-inputs of f' is odd, implying that $\deg_2(f') = |S_0(u)|$ (Fact 4). Thus we have

$$|S_0(u)| = \deg_2(f') \le \deg_2(f). \tag{3}$$

Now consider another restriction of f, this time to the subcube *under* u, *i.e.* $\{x : x \preceq u\}$. This is implemented by restricting all variables in $S_0(u)$ to 0, yielding a subfunction f'' with

$\mathsf{alt}(f'') \le \mathsf{alt}(f) - 1$. Using induction hypothesis, we have that

$$\begin{aligned}\mathsf{C}(f'', 0^{[n]-S_0(u)}) &\le \mathsf{alt}(f'') \cdot \min\{\mathsf{s}(f''), \deg_2(f'')\} \\ &\le (\mathsf{alt}(f) - 1) \cdot \min\{\mathsf{s}(f), \deg_2(f)\} \end{aligned} \tag{4}$$

Recall that f'' is obtained from f by restricting $|S_0(u)|$ variables, thus

$$\mathsf{C}(f, 0^n) \le |S_0(u)| + \mathsf{C}(f'', 0^{[n]-S_0(u)}).$$

Plugging Eq.(2) and Eq.(4) into the above inequality gives

$$\mathsf{C}(f, 0^n) \le \mathsf{alt}(f) \cdot \min\{\mathsf{s}(f), \deg_2(f)\},$$

completing the induction. ◀

Now we are ready to prove the following theorem, which gives an explicit constant for Theorem 1.

▶ **Theorem 13.** *For any boolean function f,*

$$\mathsf{bs}(f) \le \begin{cases} C_t \cdot \mathsf{s}(f) & \text{if } \mathsf{alt}(f) = 2t, \\ (C_t + 1) \cdot \mathsf{s}(f) & \text{if } \mathsf{alt}(f) = 2t + 1, \end{cases} \tag{5}$$

where $C_t = \sum_{i=1}^{t}(i+2) = \frac{1}{2}t(t+5)$.

Proof. We prove Eq.(5) by induction on $t = \lfloor \mathsf{alt}(f)/2 \rfloor$. Clearly it holds when $t = 0$: If $\mathsf{alt}(f) = 0$ then f is a constant function and $\mathsf{bs}(f) = \mathsf{s}(f) = 0$. When $\mathsf{alt}(f) = 1$, f is monotone or anti-monotone, thus $\mathsf{bs}(f) = \mathsf{s}(f)$.

Now for any Boolean function f with $\mathsf{alt}(f) > 1$, we first consider the case when $\mathsf{alt}(f) = 2t \ge 2$. We will bound the block sensitivity for each input x. Consider the following possible properties for x:

1. there exists a max term u of f such that $x \preceq u$;
2. there exists a min term d of f such that $x \succeq d$.

Case 1: x satisfies at least one of the above conditions. Without loss of generality assume it satisfies the first one; the other case can be similarly argued. Fix such a max term $u \succeq x$. By definition of max term, we know that $\mathsf{alt}(f, u) \le \mathsf{alt}(f) - 1$, and that u is sensitive to all $i \in S_0(u) \stackrel{\text{def}}{=} \{i : u_i = 0\}$. Therefore, $|S_0(u)| \le \mathsf{s}(f, u) \le \mathsf{s}(f)$.

Let f' be the subfunction of f restricted on the subcube $\{t : t \preceq u\}$, then $\mathsf{alt}(f') = \mathsf{alt}(f, u) \le \mathsf{alt}(f) - 1 = 2t - 1 = 2(t-1) + 1$.

By induction hypothesis and the fact that sensitivity is downward non-increasing, we have

$$\mathsf{bs}(f', x) \le \mathsf{bs}(f') \le (C_{t-1} + 1) \cdot \mathsf{s}(f') \le (C_{t-1} + 1) \cdot \mathsf{s}(f). \tag{6}$$

Next it is not hard to see that

$$\mathsf{bs}(f, x) \le \mathsf{bs}(f', x) + |S_0(u)|. \tag{7}$$

Indeed, take any disjoint minimal sensitive blocks $B_1, \ldots, B_\ell \subseteq [n]$ of x (with respect to f), where $\ell = \mathsf{bs}(f, x)$. If $B_i \subseteq [n] - S_0(u)$, then x is still sensitive to B_i in f'. As the B_i's are disjoint, at most $|S_0(u)|$ many B_i's are not contained in $[n] - S_0(u)$, thus at least

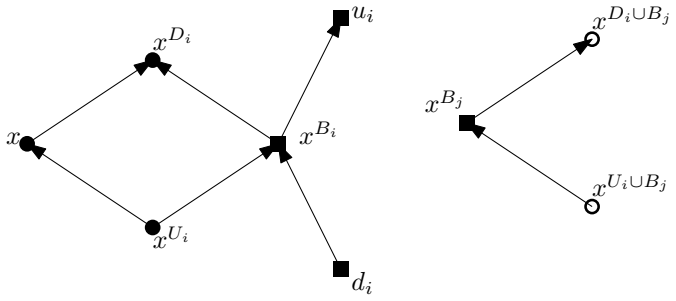

Figure 1 Order among different inputs used in the proof. Arrows indicate the partial order in $\{0,1\}^n$. Solid round circles stand for one Boolean value, and squares stand for the other. The value for hollow circles are not fully determined, but we will show that most of them share the same value with the squares.

$\mathsf{bs}(f,x) - |S_0(u)|$ blocks B_i are still sensitive blocks of x in f'. Therefore, $\mathsf{bs}(f,x) - |S_0(u)| \leq \mathsf{bs}(f',x)$, as Eq.(7) claimed.

Combining Eq.(6), Eq.(7), and the fact that $|S_0(u)| \leq \mathsf{s}(f)$, we conclude that

$$\mathsf{bs}(f,x) \leq \mathsf{bs}(f',x) + |S_0(u)| \leq (C_{t-1}+1)\cdot \mathsf{s}(f') + \mathsf{s}(f) \leq (C_{t-1}+2)\cdot \mathsf{s}(f), \tag{8}$$

which is at most $C_t \cdot \mathsf{s}(f)$ by our setting of parameter $C_t = \sum_{i=1}^{t}(i+2) = C_{t-1} + t + 2$.

Case 2: x satisfies neither of the conditions 1 and 2. So $f(x)$ needs to be the same with both $f(0^n)$ and $f(1^n)$, and f is constant on both subcubes $\{t : t \succeq x\}$ and $\{t : t \preceq x\}$. Otherwise we can take a minimal d where $d \preceq x$ and $f(d) = f(x) \neq f(0^n)$ and by definition d is a min term, or take the maximal u where $u \succeq x$ and $f(u) = f(x) \neq f(1^n)$ and by definition u is a max term.

Fix $\ell = \mathsf{bs}(f,x)$ disjoint minimal sensitive blocks $\{B_1, B_2, \ldots, B_\ell\}$ of x. For each block B_i, decompose it into $B_i = U_i \cup D_i$ where $U_i = \{i \in B_i : x_i = 1\}$ and $D_i = \{i \in B_i : x_i = 0\}$, as depicted below.

$$x = (\overbrace{\underbrace{0\ldots0}_{D_1}\underbrace{1\ldots1}_{U_1}}^{B_1})(\overbrace{\underbrace{0\ldots0}_{D_2}\underbrace{1\ldots1}_{U_2}}^{B_2})\cdots(\overbrace{\underbrace{0\ldots0}_{D_l}\underbrace{1\ldots1}_{U_l}}^{B_l})0\ldots01\ldots1$$

First we will show that for each i, x^{U_i} satisfies condition 1 and x^{D_i} satisfies condition 2, *i.e.* there exist some max term $u \succeq x^{U_i}$ and some min term $d \preceq x^{D_i}$. (See Figure 1 for an illustration.) Indeed, for any sensitive block B_i of x, $f(x^{B_i}) \neq f(x) = f(0^n) = f(1^n)$. Take a *maximal* u_i such that $u_i \succeq x^{B_i}$ and $f(u_i) = f(x^{B_i})$. By definition u_i is a max term. Similarly we can take a min term d_i where $d_i \preceq x^{B_i}$. Then from the definition of U_i and D_i we can conclude that $x^{U_i} \preceq x^{B_i} \preceq u_i$ and $x^{D_i} \succeq x^{B_i} \succeq d_i$. Moreover, both U_i and D_i cannot be empty, since otherwise either $x \preceq x^{D_i} = x^{B_i} \preceq u_i$ or $x \succeq x^{U_i} = x^{B_i} \succeq d_i$, contradicting our assumption of **case 2**. This further indicates that $f(x) = f(x^{U_i}) = f(x^{D_i})$ as we have taken each B_i to be a *minimal* sensitive block.

Next we are going to find some U_i or D_i such that x^{U_i} or x^{D_i} is sensitive to most B_i's. In this case if there are many sensitive blocks of input x, x^{U_i} or x^{D_i} must have high block sensitivity. But we have eliminate this possibility in case 1. To achieve this, we count the following two quantities:

- $\#U$: the number of pairs (i,j) such that $i \neq j$ and $f(x^{U_i}) \neq f(x^{U_i \cup B_j})$,
- $\#D$: the number of pairs (i,j) such that $i \neq j$ and $f(x^{D_i}) \neq f(x^{D_i \cup B_j})$.

Recall that $f(x) = f(x^{U_i}) = f(x^{D_i})$ and $f(x) \neq f(x^{B_j})$, thus it is equivalent to counting

- $\#U$: the number of pairs (i, j) such that $i \neq j$ and $f(x^{B_j}) = f(x^{U_i \cup B_j})$,
- $\#D$: the number of pairs (i, j) such that $i \neq j$ and $f(x^{B_j}) = f(x^{D_i \cup B_j})$.

Now we bound the number of such i's for each j. Fix a block B_j, and consider the subfunction f^u on the subcube $\{z : z \succeq x^{B_j}\}$ and the subfunction f^d on the subcube $\{z : z \preceq x^{B_j}\}$. Let us look at f^u first. Because $D_i \cap B_j = \varnothing$ whenever $i \neq j$, $x^{D_i \cup B_j} \succeq x^{B_j}$ which lies in the domain of f^u. By the definition of certificate complexity of f^u on input x^{B_j}, there is a subcube C of co-dimension $\mathsf{C}(f^u, x^{B_j})$ (with respect to $\{z : z \succeq x^{B_j}\}$) containing x^{B_j}, s.t. f takes a constant 0/1 value on C. Denote by S the set of coordinates in this certificate. Then $S \subseteq \{k \in [n] : (x^{B_j})_k = 0\}$ and $|S| = \mathsf{C}(f^u, x^{B_j})$. Now for each D_i, if $D_i \cap S = \varnothing$, then $f(x^{B_j}) = f(x^{D_i \cup B_j})$ as the values of the certificate variables S are not flipped. As all $\{D_i\}_{i \neq j}$ are disjoint, at most $\mathsf{C}(f^u, x^{B_j})$ many of D_i's may intersect S. Thus $f(x^{B_j}) = f(x^{D_i \cup B_j})$ for all but at most $\mathsf{C}(f^u, x^{B_j})$ many of D_i. Similarly we can say that all but at most $\mathsf{C}(f^d, x^{B_j})$ many of U_i's $(i \neq j)$ satisfy that $f(x^{B_j}) = f(x^{U_i \cup B_j})$. Applying Lemma 12 (statement 1), we have

$$\mathsf{C}(f^u, x^{B_j}) \leq \mathsf{alt}(f^u) \cdot \mathsf{s}(f^u) \leq \mathsf{alt}(f^u) \cdot \mathsf{s}(f),$$

$$\mathsf{C}(f^d, x^{B_j}) \leq \mathsf{alt}(f^d) \cdot \mathsf{s}(f^d) \leq \mathsf{alt}(f^d) \cdot \mathsf{s}(f).$$

Because $\mathsf{alt}(f^u) + \mathsf{alt}(f^d) \leq \mathsf{alt}(f) = 2t$, and there are ℓ sensitive blocks B_i, thus from the second definition of $\#U$ and $\#D$ we can see that

$$\begin{aligned} \#U + \#D &\geq \ell \cdot \big((\ell - 1 - \mathsf{alt}(f^u) \cdot \mathsf{s}(f)) + (\ell - 1 - \mathsf{alt}(f^d) \cdot \mathsf{s}(f))\big) \\ &\geq \ell \cdot 2\,(\ell - 1 - t \cdot \mathsf{s}(f))\,. \end{aligned} \tag{9}$$

Since there are 2ℓ of U_i's and D_i's in total, by pigeonhole principle there must be a T_i (being U_i or D_i) that contributes to at least $(\#U + \#D)/2\ell \geq \ell - 1 - t \cdot \mathsf{s}(f)$ to $(\#U + \#D)$. Fix this T_i. By definition of $\#U$ and $\#D$, there exist at least $\ell - 1 - t \cdot \mathsf{s}(f)$ blocks B_j with $i \neq j$ and $f(x^{T_i}) \neq f(x^{T_i \cup B_j})$. That is, x^{T_i} is sensitive to at least $\ell - 1 - t \cdot \mathsf{s}(f)$ blocks B_j where $j \neq i$. Considering that x^{T_i} is also sensitive to $B_i \backslash T_i$, we conclude that

$$\mathsf{bs}(f, x^{T_i}) \geq 1 + (\ell - 1 - t \cdot \mathsf{s}(f)) = \mathsf{bs}(f, x) - t \cdot \mathsf{s}(f).$$

Finally, recall that we have showed that x^{T_i} satisfies one of the condition 1 and 2. Therefore x^{T_i} is an input falling into **case 1**. By Eq.(8), we have $\mathsf{bs}(f, x^{T_i}) \leq (C_{t-1} + 2) \cdot \mathsf{s}(f)$. Putting everything together, we have

$$\mathsf{bs}(f, x) \leq \mathsf{bs}(f, x^{T_i}) + t \cdot \mathsf{s}(f) \leq (C_{t-1} + 2 + t) \cdot \mathsf{s}(f) = C_t \cdot \mathsf{s}(f).$$

This finishes the proof for $\mathsf{alt}(f) = 2t$.

When $\mathsf{alt}(f) = 2t + 1$, for any input x, $f(x)$ must differ from either $f(0^n)$ or $f(1^n)$ since $f(0^n) \neq f(1^n)$. Without loss of generality, assume that $f(x) \neq f(0^n)$. Take the minimal d such that $d \preceq x$ and $f(d) = f(x) \neq f(0^n)$. By definition d is a min term and x satisfies condition 2. Then using the same analysis above as in **case 1**, we can show $\mathsf{bs}(f, x) \leq (C_t + 1) \cdot \mathsf{s}(f)$ and this finishes the proof. ◀

4 The Log-Rank Conjecture

We prove Theorem 2 and 3 in this section. We start with Theorem 2, which is now easy given Lemma 12. Recall that the second statement of Lemma 12 says that $\max\{\mathsf{C}(f, 0^n), \mathsf{C}(f, 1^n)\} \leq$

$\mathsf{alt}(f) \cdot \deg_2(f)$, therefore

$$\mathsf{C}_{\min}(f) \le \mathsf{alt}(f) \cdot \deg_2(f). \tag{10}$$

As both $\mathsf{alt}(f)$ and $\deg_2(f)$ are downward non-increasing, applying Eq.(10) to all subfunctions of f yields $\mathsf{C}^{\mathrm{clo}}_{\min}(f) \le \mathsf{alt}(f) \cdot \deg_2(f)$. Since $\mathsf{DT}(f) \le \mathsf{C}^{\mathrm{clo}}_{\min}(f) \cdot \deg_2(f)$ (Theorem 6) we get the following.

▶ **Theorem 14.** *For any $f : \{0,1\}^n \to \{0,1\}$, it holds that $\mathsf{DT}(f) \le \mathsf{alt}(f) \cdot \deg_2(f)^2$.*

Theorem 2 follows from this together with the fact that $\mathsf{CC}(f \circ \oplus) \le 2\mathsf{DT}(f)$ (Eq.(1)) and that $\deg_2(f) \le \log \|\hat{f}\|_0 = \log \mathsf{rank}(M_{f\circ\oplus})$ (Fact 5).

Note that if we use the first statement of Lemma 12, we will get the following corollary, which gives better dependence on $\mathsf{alt}(f)$ for low $\mathbb{F}_2$-degree functions.

▶ **Corollary 15.** $\mathsf{DT}(f) \le \mathsf{alt}(f)\mathsf{s}(f) \cdot \deg_2(f)$.

Next we prove Theorem 3 for AND functions. Different than the above approach for XOR functions of going through $\mathsf{DT}(f)$, we directly argue communication complexity of AND functions. Recall that Theorem 3 says that

$$\mathsf{CC}(f \circ \wedge) \le \min\{O(\log^{a+1} \mathsf{rank}(M_{f\circ\wedge})), O(\log^{\frac{a+3}{2}} \mathsf{rank}(M_{f\circ\wedge}) \log n)\}.$$

Proof of Theorem 3. Without loss of generality, we can assume that $f(0^n) = 0$ since otherwise we can compute $\neg f$ first and negate the answer (note that $\mathsf{rank}(M_{\neg f\circ\wedge})$ differs from $\mathsf{rank}(M_{f\circ\wedge})$ by at most 1). For notational convenience let us define $r = \mathtt{mono}(f) = \mathsf{rank}(M_{f\circ\wedge})$ and $\ell = \log r$. For $b \in \{0,1\}$, further define $C_b^{(a)}$ to be the maximum $\mathsf{Cover}_b(f \circ \wedge)$ over all functions $f : \{0,1\}^n \to \{0,1\}$ with alternating number a and $f(0^n) = 0$. We will give three bounds for $C_b^{(a)}$ in terms of $C_b^{(a-1)}$, and combining them gives the claimed result in Theorem 3.

Bound 1, from max terms. We apply this bound for $C_b^{(a)}$ when a and b have different parities, that is, when a is even and $b = 1$, and when a is odd and $b = 0$. Consider the first case and the second is similar. Take any Boolean function f with $f(0^n) = 0$ and $\mathsf{alt}(f) = a$ is even, we have $f(1^n) = 0$. Any 1-input is under some max term, so it is enough to cover inputs under max terms when bounding the $\mathsf{Cover}_1(f)$. Take an arbitrary max term $u \in \{0,1\}^n$. Suppose its Hamming weight is s. Considering the subfunction f' on $\{t : t \succeq u\}$, which is an OR function of $n - s$ variables. In the communication setting, this is the Disjointness function of $n - s$ variables. Thus $\ell = \log \mathsf{rank}(M_{f\circ\wedge}) \ge n - s$. This implies that all max terms u of f are ℓ-close to 1^n in Hamming distance. Considering that different max terms are incomparable by definition, we know that the number of max terms is at most $\binom{n}{\ell}$.

Next we upper bound the 1-rectangles by giving a partition of set of 1-inputs into 1-rectangles. For each max term $u \in \{0,1\}^n$, let $U = \{i \in [n] : u_i = 1\}$, and $k = n - |U|$, then $k \le \ell$. The submatrix $\{(x,y) : x, y \in \{0,1\}^n, x \wedge y \preceq u\}$ is partitioned into 3^k submatrices as follows. Suppose that the set of 0-coordinates in u is $\{i_1, \ldots, i_k\}$, then for each i_j, we can choose (x_{i_j}, y_{i_j}) from the set $\{(0,0),(0,1),(1,0)\}$ to enforce $x_{i_j} \wedge y_{i_j} = 0$. Thus there are 3^k ways of restricting these k variables in $\bar{U}$, giving 3^k submatrices. Let $f_u : \{0,1\}^U \to \{0,1\}$ be the subfunction of f restricted on the subcube $\{t : t \preceq u\}$ where $f_u(z_U) = f(z_U, 0_{\bar{U}})$. (Here the input to f is $x' \wedge y'$ at U and 0 at $\bar{U}$.) Note that each of the 3^k submatrices is still the communication matrix of $f_u \circ \wedge$ for some max term u. Also note that this f_u has $f_u(0_U) = 0$,

but $f_u(1_U) = 1$ and $\mathsf{alt}(f_u) \leq \mathsf{alt}(f) - 1$. Since all the 1-inputs of f are under some max term u, the 1-covering number $\mathsf{Cover}^1(f \circ \wedge)$ can be upper bounded by the following:

$$\mathsf{Cover}_1(f \circ \wedge) \leq \sum_{u:\text{max term}} 3^\ell \cdot \mathsf{Cover}_1(f_u \circ \wedge) \leq \binom{n}{\ell} \cdot 3^\ell \cdot \max_{u:\text{max term}} \mathsf{Cover}_1(f_u \circ \wedge).$$

Using the fact $\mathsf{alt}(f_u) \leq \mathsf{alt}(f) - 1$, and that the above inequality holds for any f, we have the following bound on $C_1^{(a)}$:

$$\log C_1^{(a)} \leq 3\ell \cdot \log n + \log C_1^{(a-1)}, \text{ when } a \text{ is even.} \tag{11}$$

Similarly, when a is odd, $f(1^n) = 1$, and thus any 0-input is under some max term. A similar argument shows the following bound on $C_0^{(a)}$:

$$\log C_0^{(a)} \leq 3\ell \cdot \log n + \log C_0^{(a-1)}, \text{ when } a \text{ is odd.} \tag{12}$$

Bound 2, from min terms. Take any Boolean function f with $f(0^n) = 0$. Then any 1-input must be above some min term. Take any min term d. Let $D = \{i : d_i = 1\}$. If we restrict variables x_i and y_i to 1 for all $i \in D$, then we go to a rectangle $\{(x, y) : x_i = y_i = 1, \forall i \in D\}$. The union of these rectangles for all min terms d contains all 1-inputs. Restrict f on the subcube $\{z : z \succeq d\}$ to get a subfunction f_d, which has $f_d(0^{\bar{D}}) = 1$, and $\mathsf{alt}(f_d) \leq \mathsf{alt}(f) - 1$. Note that for each min term d, we have $\alpha(d) = \sum_{x \preceq d} (-1)^{|d \oplus x|} f(x) = 1 \neq 0$ [3], which contributes 1 to $\mathtt{mono}(f)$, thus the number of min terms is at most $\mathtt{mono}(f) = r$. Since each 1-input of f is above some min term d, the 1-covering number $\mathsf{Cover}_1(f)$ has

$$\mathsf{Cover}_1(f \circ \wedge) \leq \sum_{d:\text{min term}} \mathsf{Cover}_1(f_d \circ \wedge) \leq r \cdot \max_{d:\text{min term}} \mathsf{Cover}_1(f_d \circ \wedge).$$

Note that $\mathsf{alt}(f_d) \leq \mathsf{alt}(f) - 1$, and f_d takes value 1 on its all-0 input, thus $\mathsf{Cover}_1(f_d \circ \wedge) = \mathsf{Cover}_0(\neg f_d \circ \wedge) \leq C_0^{(a-1)}$ (note that the maximum in the definition of C_0 is over all f with $f(0^n) = 0$). This implies

$$\log C_1^{(a)} \leq \ell + \log C_0^{(a-1)}. \tag{13}$$

Note that this inequality holds as long as $f(0^n) = 0$, regardless of the parity of a.

Bound 3, from CC. When a is odd, we have a bound for $C_0^{(a)}$ by Eq.(12) and a bound for $C_1^{(a)}$ by Eq.(13). When a is even, we have two bounds for $C_1^{(a)}$, Eq.(11) and Eq.(13), but no bound for $C_0^{(a)}$. Note that we can always use CC to bound $C_0^{(a)}$:

$$\begin{aligned}\log \mathsf{Cover}_0(f \circ \wedge) &\leq \mathsf{CC}(f \circ \wedge) \\ &\leq \log \mathsf{rank}(M_{f \circ \wedge}) \cdot \log \mathsf{Cover}_1(f \circ \wedge) \\ &= \ell \cdot \log \mathsf{Cover}_1(f \circ \wedge),\end{aligned}$$

This implies that

$$\log C_0^{(a)} \leq \ell \cdot \log C_1^{(a)}. \tag{14}$$

[3] If $f(0^n) = 1$, then for each min term d, we have $\alpha(d) = \sum_{x \preceq d} (-1)^{|d \oplus x|} f(x) = -1$, which is still non-zero.

Similarly it also holds that $\log C_1^{(a)} \le \ell \cdot \log \mathsf{C}_0^{(a)}$.

Now we combine the three bounds and prove the theorem by induction on a. In the base case of $a = 0$, the function is constant 0 and thus $C_0^{(0)} = 1$ and $C_1^{(0)} = 0$. For general a, we can repeatedly apply Eq.(13) and Eq.(14) to get

$$\log C_1^{(a)} \le \sum_{i=1}^{a} \ell^i = (1 + o(1))\ell^a.$$

Thus $\mathsf{CC}(f \circ \wedge) \le \ell \cdot \log C_1^{(a)} \le (1 + o(1))\ell^{a+1}$.

If we can tolerate a $\log n$ factor, then the dependence on a can be made slightly better. Assume that a is even, we have

$$\begin{aligned}
\log C_1^{(a)} &\le \ell + \log C_0^{(a-1)} && \text{(by Eq.(13))} \\
&\le \ell + 3\ell \log n + \log C_0^{(a-2)} && \text{(by Eq.(12))} \\
&\le \ell + 3\ell \log n + \ell \log C_1^{(a-2)}. && \text{(by Eq.(14))}
\end{aligned}$$

Solving this recursion gives $\log C_1^{(a)} \le O(\ell^{\frac{a}{2}} \log n)$, and thus $\mathsf{CC} = O(\ell^{\frac{a}{2}+1} \log n)$. When a is odd, we can use Eq.(13) and Eq.(14) to reduce it to the "even a" case, resulting a bound $\mathsf{CC} \le O(\ell^{\frac{a+3}{2}} \log n)$. Putting these two cases together, we get the claimed bound. ◀

Abstract

We show that *randomized* communication complexity can be superlogarithmic in the partition number of the associated communication matrix, and we obtain near-optimal *randomized* lower bounds for the Clique vs. Independent Set problem. These results strengthen the deterministic lower bounds obtained in prior work (Göös, Pitassi, and Watson, FOCS 2015). One of our main technical contributions states that information complexity when the cost is measured with respect to only 1-inputs (or only 0-inputs) is essentially equivalent to information complexity with respect to all inputs.

1 Introduction

A prior work [16] exhibited a boolean function $F\colon \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ whose deterministic communication complexity is superlogarithmic in the *partition number*

$$\chi(F) \;\coloneqq\; \chi_0(F) + \chi_1(F)$$

where $\chi_i(F)$ is the least number of rectangles (sets of the form $A \times B$ where $A \subseteq \mathcal{X}$, $B \subseteq \mathcal{Y}$) needed to partition the set $F^{-1}(i)$. In this follow-up work, we upgrade the lower-bound results from [16] to hold against randomized protocols – here the notation $\tilde{\Omega}(m)$ hides factors polylogarithmic in m.

▶ **Theorem 1.** *There is an F with randomized communication complexity $\tilde{\Omega}(\log^{1.5} \chi(F))$.*

▶ **Theorem 2.** *There is an F with randomized communication complexity $\tilde{\Omega}(\log^{2} \chi_1(F))$.*

A main technical contribution of our paper – which is key to both the proofs of Theorem 1 as well as the subsequent strengthening by [5] – informally states that the information complexity of a function (as defined by [9]) remains essentially unchanged if the cost is

measured with respect to only 1-inputs (or only 0-inputs) rather than all inputs. We say a protocol Π is ϵ-correct if it succeeds with probability at least $1-\epsilon$ on each input, and define $\mathrm{IC}(\Pi)$ as the maximum over all input distributions of the information cost (defined later), and define $\mathrm{IC}^b(\Pi)$ similarly but with the maximum over all distributions over b-inputs (for some $b \in \{0,1\}$).

▶ **Theorem 3.** *Fix any F and $b \in \{0,1\}$. For every 1/3-correct protocol Π there is a 1/3-correct protocol Π' such that $\mathrm{IC}(\Pi') \leq O\big(\mathrm{IC}^b(\Pi) + \log(\mathrm{CC}(\Pi)+2)\big)$. Moreover, $\mathrm{CC}(\Pi') \leq O\big(\mathrm{CC}(\Pi)\cdot\log(\mathrm{CC}(\Pi)+2)\big)$.*

In the theorem statement above, the additional lower order term involving the communication cost appears due to technical reasons. This makes the statement slightly weaker but this is mitigated in the aforementioned applications due to the additional fact that we can also bound the communication cost of the new protocol.

1.1 Applications and discussion

Theorem 1

Prior to this work, no examples of F were known with randomized communication complexity larger than $\log\chi(F)$. In fact, such a separation cannot be obtained using the usual rectangle-based lower-bound methods, as catalogued by Jain and Klauck [17]. In particular, Theorem 1 shows that randomized complexity can be polynomially larger than the *partition bound* [17, 19], which is one of the most powerful general lower bound methods for randomized communication. (Consequently, our proof of Theorem 1 has to exploit another powerful lower-bound method, namely *information complexity*.) Note also that every F has deterministic communication complexity at least $\log\chi(F)$ and at most $O(\log^2\chi(F))$, where the latter upper bound is a classical result of [2]. Theorem 1 shows that the upper bound cannot be improved much even if we allow randomization.

Theorem 2

The relationship between $\chi_1(F)$ and the communication complexity of F can be equivalently formulated in the language of the *Clique vs. Independent Set* game, played on a graph derived from F (Alice holds a clique, Bob holds an independent set: do they intersect?). See [34, §4] or [21, §4.4] for the equivalence. Yannakakis [34] (extending [2]) proved that every F has deterministic communication complexity at most $O(\log^2\chi_1(F))$. Our Theorem 2 shows that this upper bound is essentially tight even if we allow randomized protocols, and it implies that there is a graph on n nodes for which Clique vs. Independent Set requires $\tilde{\Omega}(\log^2 n)$ randomized communication. (The deterministic upper bound $O(\log^2 n)$ holds for all graphs.)

Extension complexity. In fact, we prove Theorem 2 by showing that (the negation of) the function F has high *approximate nonnegative rank* (a.k.a. smooth rectangle bound; see Section 2 for definitions). One consequence in the field of *extended formulations* (see [34, 11] for definitions) is that we obtain a graph G such that the polytope generated by the so-called "clique inequalities" of G has extension complexity $n^{\tilde{\Omega}(\log n)}$. (The slack matrix associated with the clique inequalities is simply (the negation of) the Clique vs. Independent Set game. These inequalities capture the independent set polytope of G when G is perfect – our graph G however is not.) The previous bound in this direction was $n^{\Omega(\log^{0.128} n)}$ from a related work [13]. Technically speaking, the lower bound from [13] was proved for *nondeterministic* communication complexity, so the full result remains incomparable with Theorem 2.

Log-rank conjecture. The famous log-rank conjecture of Lovász and Saks [30] postulates that the deterministic communication complexity of F is polynomially related to $\log \operatorname{rank}(F)$. Gavinsky and Lovett [12] have shown that the conjecture is equivalent to asking whether the randomized communication complexity of F is polynomially bounded in $\log \operatorname{rank}(F)$. Here our Theorem 2 gives at least a near-quadratic separation between the randomized communication complexity of F and $\log \operatorname{rank}(F) \leq \log \chi_1(F)$; the previous best lower bound was $\Omega(\log^{1.63} \operatorname{rank}(F))$ due to Kushilevitz [26]. Furthermore, Troy Lee has pointed out to us that our construction underlying Theorem 2 exhibits nearly a 4-th power separation between the logarithms of *approximate nonnegative rank* and *approximate rank*. This gives lower bounds for the so-called *log-approximate-rank conjecture* [28, Conjecture 42], which is the randomized analogue of the log-rank conjecture. The previous best separation was quadratic (as witnessed by the set-disjointness problem).

Theorem 3

One-sided information complexity satisfies a famous direct sum property ([6, 9]): for any protocol Π computing $\mathrm{AND}_k \circ F^k$ (i.e., the AND of k copies of F) there exists a protocol Π' computing F with $\mathrm{IC}^1(\Pi') \leq O(\mathrm{IC}^1(\Pi)/k)$ (see, e.g., [5, Claim 37]). One can also formulate a dual lemma for $\mathrm{OR}_k \circ F^k$ in terms of IC^0. This is the context where our Theorem 3 relating IC and IC^1 (and IC^0) is useful: it implies that analogous direct sum lemmas hold for *two-sided* information complexity, up to low order terms. Iterating such a two-sided lemma some constantly many times, one obtains an alternative proof for the result that every n-bit constant-depth balanced read-once AND–OR tree with binary bottom fan-in (defining an Alice–Bob bipartition of input bits) has randomized communication complexity $\Omega(n)$; this result was first proved in [20, 29] even for *unbalanced* trees.

Another application of Theorem 3 appears in the recent work [5]. They improved our 1.5-th power separation in Theorem 1 to near-quadratic (which is optimal) by iteratively applying Theorem 3 to analyze a communication analogue of a query-complexity construction due to Ambainis, Kokainis, and Kothari [4] (which is a variation of usual AND–OR trees).

1.2 Our techniques

The basic strategy in [16] for obtaining the deterministic versions of Theorems 1–2 was to first obtain analogous gaps in the easier-to-understand world of query complexity, then "lift" the results to communication complexity using a so-called *simulation lemma*. For getting randomized lower bounds, two obstacles immediately present themselves: (i) The functions studied in [16] are too easy for randomized protocols (as shown by [31]). (ii) There is no known simulation lemma for the bounded-error randomized setting.

To handle obstacle (i), we modify the functions from [16] in a way that preserves their low partition numbers while eliminating the structure that was exploitable by randomized protocols. (Similar constructions have been given by [3, 1].) To handle obstacle (ii) for Theorem 2, we actually prove a lower bound for a model that is stronger than the standard randomized model, but for which there *is* a known simulation lemma [15]. This idea alone does not handle obstacle (ii) for Theorem 1, though. For that, we start by giving a proof of the query complexity analogue of Theorem 1, then develop a way to *mimic* that argument using communication complexity, by going through information complexity (exploiting machinery from [23] and [10]). In the process, this yields our Theorem 3 (one-sided is equivalent to two-sided information complexity), which is of independent interest.

2 Complexity Measures

We study the following communication complexity models/measures; see Figure 1. For any complexity measure $\mathcal{C}$ we write $\mathsf{co}\mathcal{C}(F) \coloneqq \mathcal{C}(\neg F)$ and $2\mathcal{C}(F) \coloneqq \max\{\mathcal{C}(F), \mathsf{co}\mathcal{C}(F)\}$ for short.

- **P^{cc}:** The deterministic communication complexity of F is denoted $\mathsf{P}^{\mathsf{cc}}(F)$.
- **$\mathsf{BPP}^{\mathsf{cc}}$:** The randomized communication complexity of F is denoted $\mathsf{BPP}^{\mathsf{cc}}(F)$.
- **$\mathsf{UP}^{\mathsf{cc}}$:** Recall (e.g., [27, 21]) that a cost-c nondeterministic protocol for F corresponds to a covering (allowing overlaps) of $F^{-1}(1)$ with 2^c rectangles. A nondeterministic protocol is *unambiguous* if on every 1-input there is a unique accepting computation; combinatorially, this means we have a disjoint covering (partition) of $F^{-1}(1)$. We define $\mathsf{UP}^{\mathsf{cc}}(F) \coloneqq \lceil \log \chi_1(F) \rceil$. Thus $\mathsf{coUP}^{\mathsf{cc}}(F) = \lceil \log \chi_0(F) \rceil$, and $2\mathsf{UP}^{\mathsf{cc}}(F) \in \lceil \log \chi(F) \rceil \pm 1$.
- **$\mathsf{WAPP}^{\mathsf{cc}}$:** Abstractly speaking, a WAPP computation (*Weak Almost-Wide* PP; introduced in [8]) is a randomized computation that accepts 1-inputs with probability in $[(1-\epsilon)\alpha, \alpha]$, and 0-inputs with probability in $[0, \epsilon\alpha]$, where $\epsilon < 1/2$ is an error parameter and $\alpha = \alpha(n) > 0$ is arbitrary.
  Instantiating this for protocols, we define $\mathsf{WAPP}^{\mathsf{cc}}_{\epsilon}(F)$ as the least "cost" of a randomized (public-coin) protocol Π that computes F in the above sense; the "cost" of a protocol Π with parameter α is defined as the usual communication cost (number of bits communicated) plus $\log(1/\alpha)$. In this definition, we may assume w.l.o.g. that Π is *zero-communication* [23]: Π is simply a probability distribution over rectangles R, and Π accepts an input (x, y) iff $(x, y) \in R$ for the randomly chosen R. Such a protocol Π exchanges only 2 bits to check the condition $(x, y) \in R$, and the rest of the cost is coming from having a tiny α.
  We note that $\mathsf{WAPP}^{\mathsf{cc}}$ corresponds to the (one-sided) *smooth rectangle bound* of [17], which is known to be equivalent to *approximate nonnegative rank* [24]. A consequence of this equivalence is that $\mathsf{WAPP}^{\mathsf{cc}}$ could alternatively be defined without charging anything for $\alpha > 0$, as long as we restrict our protocols to be *private-coin*; see also [15, Theorem 9]. Also, $2\mathsf{WAPP}^{\mathsf{cc}}$ is equivalent to the *relaxed partition bound* of [23] (we elaborate on this in Section 4.2). We remark that $\mathsf{WAPP}^{\mathsf{cc}}$ is not amenable to efficient amplification of the error parameter; there can be an exponential gap between $\mathsf{WAPP}^{\mathsf{cc}}_{\epsilon}$ and $\mathsf{WAPP}^{\mathsf{cc}}_{\delta}$ for different constants ϵ and δ, at least for partial functions [15, Theorem 6].

Define the following decision tree models/measures for a boolean function $f\colon \{0,1\}^n \to \{0,1\}$:

- **P^{dt}:** The deterministic decision tree complexity of f is denoted $\mathsf{P}^{\mathsf{dt}}(f)$.
- **$\mathsf{BPP}^{\mathsf{dt}}$:** The randomized decision tree complexity of f is denoted $\mathsf{BPP}^{\mathsf{dt}}(f)$.
- **$\mathsf{UP}^{\mathsf{dt}}$:** A nondeterministic decision tree is a DNF formula. We think of the conjunctions in the DNF formula as *certificates* – partial assignments to inputs that force the function to be 1. The cost is the maximum number of input bits read by a certificate. A nondeterministic decision tree is *unambiguous* if on every 1-input there is a unique accepting certificate. We define $\mathsf{UP}^{\mathsf{dt}}(f)$ as the least cost of an unambiguous decision tree for f. Other works that have studied unambiguous decision trees include [33, 7, 13, 16, 25].
- **$\mathsf{WAPP}^{\mathsf{dt}}$:** We define $\mathsf{WAPP}^{\mathsf{dt}}_{\epsilon}(f)$ as the least height of a randomized decision tree that accepts 1-inputs with probability in $[(1-\epsilon)\alpha, \alpha]$, and 0-inputs with probability in $[0, \epsilon\alpha]$, where $\alpha = \alpha(n) > 0$ is arbitrary. (Note that only the number of queries matters; we do not charge for α being small.) Like the communication version, this measure is not amenable to efficient amplification of the error parameter [15].
  The analogue of a $\mathsf{WAPP}^{\mathsf{cc}}$ protocol being w.l.o.g. a distribution over rectangles is that a $\mathsf{WAPP}^{\mathsf{dt}}$ decision tree is w.l.o.g. a distribution over conjunctions. This implies that we may characterize $\mathsf{WAPP}^{\mathsf{dt}}_{\epsilon}(f)$ using *conical juntas*: A *conical junta* h is a nonnegative

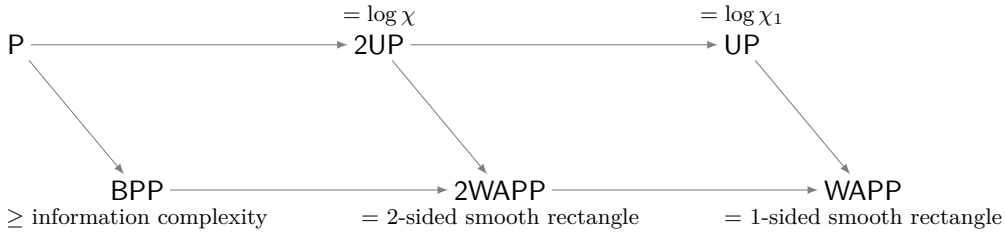

Figure 1 Models of computation that can be instantiated for both communication and query complexity. Here A ⟶ B means that model B can simulate model A without any overhead.

linear combination of conjunctions. That is, $h = \sum w_C C$ where the sum ranges over conjunctions $C\colon \{0,1\}^n \to \{0,1\}$ and $w_C \geq 0$ for all C. Then $\mathsf{WAPP}^{\mathsf{dt}}_{\epsilon}(f)$ is the least *degree* (maximum width of a conjunction with positive weight in h) of a conical junta h that ϵ-approximates f in the sense that $h(z) \in [1-\epsilon, 1]$ for all $z \in f^{-1}(1)$, and $h(z) \in [0, \epsilon]$ for all $z \in f^{-1}(0)$. Other works have studied conical juntas under such names as the (one-sided) *partition bound for query complexity* [17] and *query complexity in expectation* [22].

3 Overview

In this section we give an outline for obtaining our main results, Theorems 1–2. For complexity models/measures $\mathcal{C}$ and $\mathcal{C}'$, we informally say "$\mathcal{C}$-vs-$\mathcal{C}'$ gap" to mean the existence of a function whose $\mathcal{C}$ complexity is significantly higher than its $\mathcal{C}'$ complexity. Using the notation defined in Section 2, we can rephrase our main results as follows.

▶ **Theorem 1 ($\mathsf{BPP}^{\mathsf{cc}}$-vs-$\mathsf{2UP}^{\mathsf{cc}}$).** *There is an F such that* $\mathsf{BPP}^{\mathsf{cc}}(F) \geq \tilde{\Omega}(\mathsf{2UP}^{\mathsf{cc}}(F)^{1.5})$.

▶ **Theorem 2 ($\mathsf{BPP}^{\mathsf{cc}}$-vs-$\mathsf{UP}^{\mathsf{cc}}$).** *There is an F such that* $\mathsf{BPP}^{\mathsf{cc}}(F) \geq \tilde{\Omega}(\mathsf{UP}^{\mathsf{cc}}(F)^{2})$.

1. **Tribes-List (Section 3.1):** Our starting point is to define *Tribes-List*, a variant of a function introduced in [16]. Its purpose is to witness a BPP-vs-UP gap for query complexity.
2. **Composition (Section 3.2):** Next, we modify Tribes-List using two types of function composition, which we call *lifting* and AND-*composition*, to obtain candidate functions for BPP-vs-2UP gaps in both query and communication complexity.
3. **Overview of proofs (Section 3.3):** With the candidate functions defined, we outline our strategy to prove the desired communication lower bounds.

3.1 Tribes-List

The *Tribes-List* function $\mathrm{TL}\colon \{0,1\}^n \to \{0,1\}$ is defined on $n \coloneqq \Theta(k^3 \log k)$ bits where k is a parameter. We think of the input as a $k \times k$ matrix M with entries M_{ij} taking values from the alphabet $\Sigma \coloneqq \{0,1\} \times ([k]^{k-1} \cup \{\perp\})$. Here each entry is encoded with $\Theta(k \log k)$ bits, and we assume that the encoding of $M_{ij} = (m_{ij}, p_{ij}) \in \Sigma$ is such that a single bit is used to encode the value $m_{ij} \in \{0,1\}$ and another bit is used to encode whether or not $p_{ij} = \perp$. If $p_{ij} \neq \perp$, then we can learn its exact value in $[k]^{k-1}$ by querying all the $\Theta(k \log k)$ bits.

Informally, we have $\mathrm{TL}(M) = 1$ iff M has a unique all-$(1,*)$ column (here $*$ is a wildcard) that also contains an entry with $k-1$ pointers to entries of the form $(0,*)$ in all other

Unambiguous decision tree for TL:

Nondeterministically guess a column index $j \in [k]$. Consider the entries $M_{ij} = (m_{ij}, p_{ij})$ for $i \in [k]$: check that $m_{ij} = 1$ for all i and that $p_{ij} \neq \bot$ for at least one i (this is $\leq 2k$ queries). Let i be the first row index for which $p_{ij} \neq \bot$ and read the full value of p_{ij} (this is $\Theta(k \log k)$ queries). Interpret $p_{ij} \in [k]^{[k] \setminus \{j\}}$ as a *list of pointers*, describing a row index for all columns other than j. For each of these $k-1$ pointed-to entries $M_{i'j'}$, check that $m_{i'j'} = 0$ (this is $k-1$ queries).

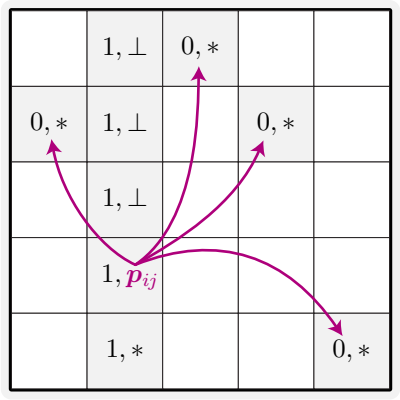

Figure 2 The unambiguous decision tree that defines the Tribes-List function.

columns. More formally, we define TL in Figure 2 by describing an unambiguous decision tree of cost $\Theta(k \log k)$ computing it.

3.2 Composition

Given a base function witnessing some complexity gap, we will establish a different but related complexity gap by transforming the function into a more complex one via one (or both) of the following operations involving function composition: *lifting* and AND-*composition*. Lifting is used to go from a query complexity gap to an analogous communication complexity gap. AND-composition is used to go from a gap with a UP upper bound to a gap with a 2UP upper bound. To show that an operation indeed converts one gap to another gap, we need two types of results: an observation showing how the relevant upper bounds behave under the operation, and a more difficult lemma showing how the relevant lower bounds behave under the operation.

Lifting

Let $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ be a fixed two-party function (called the *gadget*). We can *lift* $f\colon \{0,1\}^n \to \{0,1\}$ via the gadget g to obtain a two-party composed function $f \circ g^n\colon (\{0,1\}^b)^n \times (\{0,1\}^b)^n \to \{0,1\}$ where Alice is given $x = (x_1, \ldots, x_n)$ and Bob is given $y = (y_1, \ldots, y_n)$ (with each $x_i, y_i \in \{0,1\}^b$) and the goal is to compute $(f \circ g^n)(x,y) \coloneqq f(g(x_1,y_1), \ldots, g(x_n,y_n))$.

A decision tree for f generally yields a corresponding type of communication protocol for $f \circ g^n$: whenever the decision tree queries the i-th bit, Alice and Bob communicate $b+1$ bits to evaluate the corresponding bit $g(x_i, y_i)$. By counting conjunctions, it can be verified that such a connection holds for the 2UP and UP models as well:

▶ **Observation 4.** *For all* $f\colon \{0,1\}^n \to \{0,1\}$, $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$, *and* $\mathcal{C} \in \{\mathsf{2UP}, \mathsf{UP}\}$, *we have* $\mathcal{C}^{\mathsf{cc}}(f \circ g^n) \leq \mathcal{C}^{\mathsf{dt}}(f) \cdot O(b + \log n)$.

For any model $\mathcal{C}$, a result in the converse direction (giving a black-box method of converting a communication protocol for $f \circ g^n$ into a comparably efficient decision tree for

f) is highly nontrivial and is called a *simulation lemma*. In this work, we use a simulation lemma for $\mathcal{C} = \mathsf{WAPP}$:

▶ **Lemma 5** (Simulation for **WAPP** [15]). *For all* $f\colon \{0,1\}^n \to \{0,1\}$ *and constants* $0 < \epsilon < \delta < 1/2$, *we have* $\mathsf{WAPP}^{\mathsf{dt}}_{\delta}(f) \leq O\big(\mathsf{WAPP}^{\mathsf{cc}}_{\epsilon}(f \circ g^n)/\log n\big)$ *where* $g\colon \{0,1\}^b \times \{0,1\}^b \to \{0,1\}$ *is the inner-product gadget defined as follows:* $b = b(n) := 100 \log n$, *and* $g(x_i, y_i) := \langle x_i, y_i \rangle \bmod 2$.

AND-composition

Given $f\colon \{0,1\}^n \to \{0,1\}$ we can compose it with the k-bit AND function to obtain $\mathrm{AND} \circ f^k\colon (\{0,1\}^n)^k \to \{0,1\}$ defined by $(\mathrm{AND} \circ f^k)(z_1, \ldots, z_k) = 1$ iff $f(z_i) = 1$ for all i. Similarly, given $F\colon \mathcal{X} \times \mathcal{Y} \to \{0,1\}$ we can obtain $\mathrm{AND} \circ F^k\colon \mathcal{X}^k \times \mathcal{Y}^k \to \{0,1\}$ defined by $(\mathrm{AND} \circ F^k)(x, y) = 1$ iff $F(x_i, y_i) = 1$ for all i.

AND-composition converts a UP upper bound into a $\mathsf{2UP}$ upper bound [16]:

▶ **Observation 6.** *For all* f *and* k, *we have* $\mathsf{2UP}^{\mathsf{dt}}(\mathrm{AND} \circ f^k) \leq k \cdot \mathsf{UP}^{\mathsf{dt}}(f) + O(\mathsf{UP}^{\mathsf{dt}}(f)^2)$. *Similarly, for all* F *and* k, *we have* $\mathsf{2UP}^{\mathsf{cc}}(\mathrm{AND} \circ F^k) \leq k \cdot \mathsf{UP}^{\mathsf{cc}}(F) + O(\mathsf{UP}^{\mathsf{cc}}(F)^2 + \log k)$.

The two parts of Observation 6 are analogous, so we describe the idea only in terms of the query complexity part. Since $\mathsf{coUP}^{\mathsf{dt}}(f) \leq \mathsf{P}^{\mathsf{dt}}(f) \leq O(\mathsf{UP}^{\mathsf{dt}}(f)^2)$, it suffices to have $\mathsf{coUP}^{\mathsf{dt}}(f)$ as the second term on the right side. The idea is to let a 1-certificate for $\mathrm{AND} \circ f^k$ be comprised of 1-certificates for each of the k copies of f, and a 0-certificate for $\mathrm{AND} \circ f^k$ be comprised of a 0-certificate for the first copy of f that evaluates to 0, together with 1-certificates for each of the preceding copies of f.

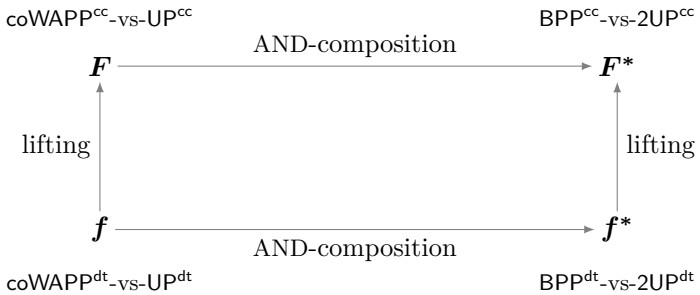
On the other hand, the following lemma (proven in Section 4.1) shows that randomized query complexity goes up by a factor of k under AND-composition.

▶ **Lemma 7.** *For all* f *and* k, *we have* $\mathsf{BPP}^{\mathsf{dt}}(f) \leq O\big(\mathsf{BPP}^{\mathsf{dt}}(\mathrm{AND} \circ f^k)/k\big)$.

We note that Lemma 7 qualitatively strengthens the tight direct sum result for randomized query complexity in [18] since computing the outputs of all k copies of f is at least as hard as computing the AND of the outputs. Similarly, if we could prove an analogue of Lemma 7 for communication complexity, it would qualitatively strengthen the notoriously-open tight direct sum conjecture for randomized communication complexity.

3.3 Overview of proofs

The following diagram shows how we construct the functions used to witness our gaps. Starting with some f, we can lift it to obtain F, or we can apply AND-composition to obtain f^*. We can obtain F^* by either lifting f^* or equivalently applying AND-composition to F.



Proof of Theorem 2

We start by discussing the proof of Theorem 2 as it will be used in the proof of Theorem 1. We actually prove the following stronger version of Theorem 2 that gives a lower bound even against $\mathsf{coWAPP}^{\mathsf{cc}}_{\epsilon}(F) \leq O(\mathsf{BPP}^{\mathsf{cc}}(F))$:

▶ **Theorem 2⋆ (coWAPP$^{\mathsf{cc}}$-vs-UP$^{\mathsf{cc}}$).** *There is an F s.t.* $\mathsf{coWAPP}^{\mathsf{cc}}_{0.04}(F) \geq \tilde{\Omega}(\mathsf{UP}^{\mathsf{cc}}(F)^2)$.

Our proof follows the same outline as in [16] and only requires us to lift the following analogous result for query complexity (proved in the full version [14]):

▶ **Lemma 8 (coWAPP$^{\mathsf{dt}}$-vs-UP$^{\mathsf{dt}}$).** $\mathsf{coWAPP}^{\mathsf{dt}}_{0.05}(\mathrm{TL}) \geq \tilde{\Omega}(\mathsf{UP}^{\mathsf{dt}}(\mathrm{TL})^2)$.

To derive Theorem 2⋆, set $f \coloneqq \mathrm{TL}$ and $F \coloneqq f \circ g^n$, where g is the gadget from Lemma 5 and n is the input length of f. Recall that $\mathsf{UP}^{\mathsf{dt}}(f) \geq n^{\Omega(1)}$. Thus by Observation 4, $\mathsf{UP}^{\mathsf{cc}}(F) \leq \mathsf{UP}^{\mathsf{dt}}(f) \cdot O(\log n) \leq \tilde{O}(\mathsf{UP}^{\mathsf{dt}}(f))$, and by Lemma 5, $\mathsf{coWAPP}^{\mathsf{cc}}_{0.04}(F) \geq \Omega(\mathsf{coWAPP}^{\mathsf{dt}}_{0.05}(f) \cdot \log n) \geq \Omega(\mathsf{coWAPP}^{\mathsf{dt}}_{0.05}(f))$. Thus $\mathsf{coWAPP}^{\mathsf{cc}}_{0.04}(F) \geq \tilde{\Omega}(\mathsf{UP}^{\mathsf{cc}}(F)^2)$.

Proof of Theorem 1

An "obvious" strategy for Theorem 1 would be again to first prove the analogous query complexity result and then lift it to communication complexity. (This is the outline used for the analogous result in [16].) In other words, we would follow the lower-right path in the above diagram:

Obvious strategy

(a) Start with f witnessing a $\mathsf{BPP}^{\mathsf{dt}}$-vs-$\mathsf{UP}^{\mathsf{dt}}$ gap.
(b) Obtain f^* witnessing a $\mathsf{BPP}^{\mathsf{dt}}$-vs-$2\mathsf{UP}^{\mathsf{dt}}$ gap by applying AND-composition to f.
(c) Obtain F^* witnessing a $\mathsf{BPP}^{\mathsf{cc}}$-vs-$2\mathsf{UP}^{\mathsf{cc}}$ gap by lifting f^*.

We have the tools to complete steps (a) and (b):

▶ **Lemma 9 (BPP$^{\mathsf{dt}}$-vs-2UP$^{\mathsf{dt}}$).** *There is an f such that* $\mathsf{BPP}^{\mathsf{dt}}(f) \geq \tilde{\Omega}(2\mathsf{UP}^{\mathsf{dt}}(f)^{1.5})$.

Proof. This is witnessed by $f^* \coloneqq \mathrm{AND} \circ \mathrm{TL}^k$ where $k \coloneqq \mathsf{UP}^{\mathsf{dt}}(\mathrm{TL})$. By Observation 6, $2\mathsf{UP}^{\mathsf{dt}}(f^*) \leq O(k^2)$, and by Lemmas 7–8,

$$\mathsf{BPP}^{\mathsf{dt}}(f^*) \geq \Omega(k \cdot \mathsf{BPP}^{\mathsf{dt}}(\mathrm{TL})) \geq \Omega(k \cdot \mathsf{coWAPP}^{\mathsf{dt}}_{0.05}(\mathrm{TL})) \geq \tilde{\Omega}(k^3)\,. \qquad \blacktriangleleft$$

Unfortunately, we do not know how to carry out step (c), because we currently lack a simulation lemma for BPP. (We believe that such a lemma is true, and it is an interesting open problem to prove this!) We get around this obstacle by reversing the order of steps (b) and (c), that is, we instead follow the upper-left path in the diagram:

Modified strategy

(a′) Start with f witnessing a $\mathsf{coWAPP}^{\mathsf{dt}}$-vs-$\mathsf{UP}^{\mathsf{dt}}$ gap.
(b′) Obtain F witnessing a $\mathsf{coWAPP}^{\mathsf{cc}}$-vs-$\mathsf{UP}^{\mathsf{cc}}$ gap by lifting f.
(c′) Obtain F^* witnessing a $\mathsf{BPP}^{\mathsf{cc}}$-vs-$2\mathsf{UP}^{\mathsf{cc}}$ gap by applying AND-composition to F.

Steps (a′) and (b′) are just Theorem 2⋆. For step (c′) it would suffice to have an analogue of Lemma 7 for communication complexity. This is open, but fortunately we have some wiggle room since it suffices to have coWAPP_ϵ instead of BPP on the left side of Lemma 7. For this, we *can* prove a communication analogue (indeed, with $\mathsf{2WAPP}_\epsilon$ instead of coWAPP_ϵ):

▶ **Lemma 10.** *For all F, k, and constants $0 < \epsilon < 1/2$, we have*

$$\mathsf{2WAPP}^{\mathsf{cc}}_\epsilon(F) \;\leq\; O\big(\mathsf{BPP}^{\mathsf{cc}}(\mathrm{AND} \circ F^k)/k + \log \mathsf{BPP}^{\mathsf{cc}}(\mathrm{AND} \circ F^k)\big).$$

To derive Theorem 1, let F be the function in Theorem 2⋆, and let $F^* := \mathrm{AND} \circ F^k$ where $k := \mathsf{UP}^{\mathsf{cc}}(F)$. Then F^* witnesses Theorem 1: By Observation 6, $\mathsf{2UP}^{\mathsf{cc}}(F^*) \leq O(k^2)$, and by Lemma 10, $\mathsf{BPP}^{\mathsf{cc}}(F^*) \geq \Omega\big(k \cdot (\mathsf{2WAPP}^{\mathsf{cc}}_{0.04}(F) - O(\log k))\big) \geq \Omega\big(k \cdot (\mathsf{coWAPP}^{\mathsf{cc}}_{0.04}(F) - O(\log k))\big) \geq \tilde{\Omega}(k^3)$.

Proof of Lemma 10

We start with the intuition for the proof of Lemma 7, which is a warmup for Lemma 10. For brevity let $f^* := \mathrm{AND} \circ f^k$. Given an input z for f, the basic idea is to plant z into a random coordinate of $f^*(z_1, \ldots, z_k)$, and plant random 1-inputs into the other coordinates, and then run the randomized decision tree for f^*. If q is the query complexity of f^*, the expected number of bits of z that are queried (over a random 1-input) will be at most q/k. Our new randomized decision tree will simulate this but abort after $8q/k$ queries to z have been made. If an answer is returned, we output the same value for $f(z)$, and if no answer is returned within this many queries, then we output 0. A simple analysis shows that we succeed with high probability in the average-case (which is equivalent to worst-case by the minimax theorem).

To prove Lemma 10, we would like to mimic this argument in the communication world, using the fact that internal information complexity is sandwiched between $\mathsf{BPP}^{\mathsf{cc}}$ and $\mathsf{2WAPP}^{\mathsf{cc}}$ [23] and satisfies a sort of AND-composition analogous to Lemma 7 using well-known properties (by planting the input into a random coordinate, and planting random 1-inputs into the other coordinates). However there is a significant barrier to this idea "just working": the AND-composition property (direct sum lemma) requires a distribution over 1-inputs of F (one-sided), while the relation to $\mathsf{2WAPP}^{\mathsf{cc}}$ requires an arbitrary distribution over inputs to F (two-sided). To bridge this divide, we prove a new property of information complexity: the one-sided version is essentially equivalent to the two-sided version. A key ingredient in showing the latter is the "information odometer" of [10], which allows us to keep track of the amount of information that has been revealed, and abort the protocol once we have reached our limit, and argue that we can carry this out without revealing too much extra information. We note that this one-vs-two sided information complexity lemma is the only component of the proof of Theorem 1 that distinguishes between arbitrary rectangle partitions ($\mathsf{2UP}^{\mathsf{cc}}$) and rectangle partitions induced by protocols (P^{cc}).

Organization

The only ingredients that remain to be proved are Lemma 8 (which we prove in the full version [14] and Lemma 7 and Lemma 10 (both of which we prove in Section 4).

4 AND-Composition Lemmas

In this section we prove Lemma 7 and Lemma 10, restated here for convenience.

▶ **Lemma 11.** *For all f and k, we have* $\mathsf{BPP}^{\mathsf{dt}}(f) \le O\big(\mathsf{BPP}^{\mathsf{dt}}(\mathrm{AND} \circ f^k)/k\big)$.

▶ **Lemma 12.** *For all F, k, and constants $0 < \epsilon < 1/2$, we have*

$$\mathsf{2WAPP}^{\mathsf{cc}}_{\epsilon}(F) \;\le\; O\big(\mathsf{BPP}^{\mathsf{cc}}(\mathrm{AND} \circ F^k)/k + \log \mathsf{BPP}^{\mathsf{cc}}(\mathrm{AND} \circ F^k)\big).$$

4.1 AND-composition for query complexity

We now prove Lemma 7. For brevity let $f^* \coloneqq \mathrm{AND} \circ f^k$. Let T^* be a height-q randomized decision tree for f^* with error $1/8$. We design a height-$8q/k$ randomized decision tree for f with error $1/4$.

Let D be an arbitrary distribution over $f^{-1}(1)$. Consider the following randomized decision tree T that takes $z \in \{0,1\}^n$ as input:

1. Pick $i \in [k]$ uniformly at random and let $z_i \coloneqq z$.
2. For $j \in [k] \setminus \{i\}$ sample $z_j \sim D$ independently.
3. Run $T^*(z_1, \ldots, z_k)$ until it has made $8q/k$ queries in the i-th component.
4. If T^* already produced an output in Step 3, output the same bit; else output 0.

Note that with probability 1 we have $f^*(z_1, \ldots, z_k) = f(z)$. Let R_T denote T's randomness and R_{T^*} denote T^*'s randomness. If $f(z) = 0$ then

$$\mathbb{P}_{R_T}[T(z) = 1] \;\le\; \max_{(z_1,\ldots,z_k) \in (f^*)^{-1}(0)} \mathbb{P}_{R_{T^*}}[T^*(z_1, \ldots, z_k) = 1] \;\le\; 1/8 \;\le\; 1/4.$$

Furthermore,

$$\begin{aligned}
\mathbb{P}_{z\sim D,\, R_T}[T(z) = 0] \;&=\; \mathbb{P}_{z_1,\ldots,z_k \sim D,\, i\in[k],\, R_{T^*}}\begin{bmatrix} T^*(z_1,\ldots,z_k) \text{ outputs 0 or makes more} \\ \text{than } 8q/k \text{ queries in the } i\text{-th component} \end{bmatrix} \\
&\le\; \max_{(z_1,\ldots,z_k)\in(f^*)^{-1}(1)} \left(\begin{array}{l} \mathbb{P}_{R_{T^*}}[T^*(z_1,\ldots,z_k) = 0] + \\ \max_{R_{T^*}} \mathbb{P}_{i\in[k]}\begin{bmatrix} T^*(z_1,\ldots,z_k) \text{ makes more than} \\ 8q/k \text{ queries in the } i\text{-th component} \end{bmatrix} \end{array} \right) \\
&\le\; 1/8 + 1/8 \;=\; 1/4.
\end{aligned}$$

Now let D be an arbitrary distribution over $\{0,1\}^n$ and define T w.r.t. $(D \,|\, f^{-1}(1))$. We have

$$\begin{aligned}
\mathbb{P}_{z\sim D,\, R_T}[T(z) \neq f(z)] \;&=\; \textstyle\sum_{b\in\{0,1\}} \mathbb{P}_{z\sim(D\,|\,f^{-1}(b)),\, R_T}[T(z) \neq b] \cdot \mathbb{P}_{z\sim D}[f(z) = b] \\
&\le\; \textstyle\sum_{b\in\{0,1\}} (1/4) \cdot \mathbb{P}_{z\sim D}[f(z) = b] \;=\; 1/4.
\end{aligned}$$

By the minimax theorem, there is a height-$8q/k$ randomized decision tree (a mixture of the T's) that on any input produces the wrong output with probability $\le 1/4$.

4.2 Definitions

We adopt the following conventions throughout the proof of Lemma 10. We denote random variables with upper-case letters, and we denote particular outcomes of the random variables with the corresponding lower-case letters. All communication protocols are randomized and mixed-coin, and we use (R, R_A, R_B) to denote the public randomness, Alice's private randomness, and Bob's private randomness, respectively. We say a protocol Π is ϵ-correct for F if for all (x, y), $\mathbb{P}_{R,R_A,R_B}[\Pi(x, y) = F(x, y)] \ge 1 - \epsilon$. For a distribution D over

inputs, we say Π is (ϵ, D)-correct for F if $\mathbb{P}_{(X,Y)\sim D,\, R,R_A,R_B}[\Pi(X,Y) = F(X,Y)] \geq 1-\epsilon$. The internal information cost of a protocol Π with respect to $(X,Y) \sim D$ is defined as $\mathrm{IC}_D(\Pi) := \mathbb{I}(R,M\,;X\,|\,Y) + \mathbb{I}(R,M\,;Y\,|\,X) = \mathbb{I}(M\,;X\,|\,Y,R) + \mathbb{I}(M\,;Y\,|\,X,R)$ where the random variable M is the concatenation of all messages. We also let $\mathrm{CC}(\Pi)$ denote the worst-case communication cost of Π.

It is convenient for us to work with a measure $\mathsf{2WAPP}^{\mathsf{cc}*}$ that is defined slightly differently from $\mathsf{2WAPP}^{\mathsf{cc}}$ but is equivalent in the sense that for all F and $0 < \epsilon < 1/2$, $\mathsf{2WAPP}^{\mathsf{cc}}_{\epsilon}(F) \leq \mathsf{2WAPP}^{\mathsf{cc}*}_{\epsilon}(F) \leq O(\mathsf{2WAPP}^{\mathsf{cc}}_{\epsilon/2}(F))$. We note that $\mathsf{2WAPP}^{\mathsf{cc}}$ directly expresses the two-sided smooth rectangle bound of [17], while $\mathsf{2WAPP}^{\mathsf{cc}*}$ directly expresses the relaxed partition bound of [23] and was the definition used in [15].

▶ **Definition 13.** We define $\mathsf{2WAPP}^{\mathsf{cc}*}_{\epsilon}(F)$ as the minimum of $\mathrm{CC}(\Pi)+\log(1/\alpha)$ over all $\alpha > 0$ and all protocols Π with output values $\{0,1,\perp\}$ such that for all (x,y), $\mathbb{P}[\Pi(x,y) \neq \perp] \leq \alpha$ and $\mathbb{P}[\Pi(x,y) = F(x,y)] \geq (1-\epsilon)\alpha$ (i.e., Π is $(1-(1-\epsilon)\alpha)$-correct).

We also need the distributional version of $\mathsf{2WAPP}^{\mathsf{cc}*}$.

▶ **Definition 14.** For an input distribution D, we define $\mathsf{2WAPP}^{\mathsf{cc}*}_{\epsilon,D}(F)$ as the minimum of $\mathrm{CC}(\Pi) + \log(1/\alpha)$ over all $\alpha > 0$ and all protocols Π with output values $\{0,1,\perp\}$ such that $\mathbb{P}[\Pi(x,y) \neq \perp] \leq \alpha$ for all (x,y), and $\mathbb{P}[\Pi(X,Y) = F(X,Y)] \geq (1-\epsilon)\alpha$ for $(X,Y) \sim D$ (i.e., Π is $(1-(1-\epsilon)\alpha, D)$-correct).

4.3 AND-composition for communication complexity

We now outline the proof of Lemma 10. Recall that the proof of Lemma 7 involved these steps:

- **(i)** embedding the input into a random coordinate of a k-tuple and filling the other coordinates with random 1-inputs (to cut the cost on 1-inputs by a factor k),
- **(ii)** aborting the execution if the cost became too high (to ensure low cost also on 0-inputs while maintaining average-case correctness on 1-inputs),
- **(iii)** using the minimax theorem to go from average-case to worst-case correctness.

We start by noting that an analogue of (i) holds for information complexity (which lower bounds $\mathsf{BPP}^{\mathsf{cc}}$). Then as one of our main technical contributions we prove an analogue of (ii) for information complexity. Then inbetween (ii) and (iii) we insert a step applying the known result that information complexity upper bounds $\mathsf{2WAPP}^{\mathsf{cc}*}$ in the distributional setting. Finally we use the analogue of (iii) for $\mathsf{2WAPP}^{\mathsf{cc}*}$. Formally, Lemma 10 follows by stringing together the following lemmas.

▶ **Lemma 15.** *Fix any F, k, $0 < \epsilon < 1/2$, and distribution D over $F^{-1}(1)$. For every ϵ-correct protocol Π for $\mathrm{AND} \circ F^k$ there is an ϵ-correct protocol Π' for F with $\mathrm{IC}_D(\Pi') \leq \mathrm{CC}(\Pi)/k$ and $\mathrm{CC}(\Pi') \leq \mathrm{CC}(\Pi)$.*

▶ **Lemma 16.** *Fix any F, constants $0 < \epsilon < \delta < 1/2$, and input distribution D, and let $D^1 := (D\,|\,F^{-1}(1))$. For every (ϵ, D)-correct protocol Π there is a (δ, D)-correct protocol Π' with $\mathrm{IC}_D(\Pi') \leq O\big(\mathrm{IC}_{D^1}(\Pi) + \log(\mathrm{CC}(\Pi)+2)\big)$.*

▶ **Lemma 17.** *Fix any F, constants $0 < \epsilon < \delta < 1/2$, and input distribution D. For every (ϵ, D)-correct protocol Π we have $\mathsf{2WAPP}^{\mathsf{cc}*}_{\delta,D}(F) \leq O(\mathrm{IC}_D(\Pi) + 1)$.*

▶ **Lemma 18.** *Fix any F and $0 < \epsilon < 1/2$. Then $\mathsf{2WAPP}^{\mathsf{cc}*}_{\epsilon}(F) \leq 2 + \max_D \mathsf{2WAPP}^{\mathsf{cc}*}_{\epsilon,D}(F)$.*

Lemma 15 is a standard application of the "direct sum" property of information cost. Lemma 16 is proved in Section 4.4 and relies on [10]. Lemma 17 is due to [23, Theorem 1.1 of the ECCC version]. Lemma 18 follows from an argument in [23, Appendix A of the ECCC version] that uses LP duality.

The moral conclusion of Lemma 16 is that "one-sided information complexity" is essentially equivalent to "two-sided information complexity" for average-case protocols. Combining Lemma 16 with [9, Theorem 3.5 of the ECCC version] shows that a similar equivalence holds for worst-case protocols. More specifically, a distribution-independent definition of information complexity for bounded-error protocols can be obtained by maximizing over all input distributions; our corollary shows that this measure is essentially unchanged if we maximize only over distributions over 1-inputs (or symmetrically, 0-inputs).

▶ **Corollary 19.** *Fix any F, constants $0 < \epsilon < \delta < 1/2$, and $b \in \{0,1\}$. Then*

$$\inf_{\substack{\delta\text{-correct} \\ \text{protocols } \Pi}} \max_{\substack{D \text{ over} \\ \text{all inputs}}} \mathrm{IC}_D(\Pi) \;\leq\; \max_{\substack{D \text{ over} \\ b\text{-inputs}}} \inf_{\substack{\epsilon\text{-correct} \\ \text{protocols } \Pi}} O\big(\mathrm{IC}_D(\Pi) + \log(\mathrm{CC}(\Pi) + 2)\big).$$

Theorem 3 follows by swapping the quantifiers on the right side of the inequality in Corollary 19 (which only weakens the statement), and by straightforwardly accounting for the communication cost in the proof. We can also assume the protocol Π' has error $\leq 1/3$ by a standard error reduction technique (take a majority vote of several runs of the protocol), which does not affect information complexity except by constant factors. We do not directly employ this worst-case version of Lemma 16, but it is used in the follow-up work [5].

4.4 One-sided information vs. two-sided information

Intuition for Lemma 16

Recall the following idea, which was implicit in the proof of Lemma 7. Suppose we have a randomized decision tree computing some function, and we have a bound b on the expected number of queries made over a random 1-input. Then to obtain a randomized decision tree with a worst-case query bound, we can keep track of the number of queries made during the execution and halt and output 0 if it exceeds, say, $8b$. Correctness on 0-inputs is maintained since we either run the original decision tree to completion and thus output 0 with high probability, or we abort and output 0 anyway. We get average-case correctness on 1-inputs since by Markov's inequality, with probability at least $7/8$ the original decision tree uses at most $8b$ queries, in which case we run it to completion and output 1 with high probability.

The high-level intuition is to mimic this idea for information complexity. We have a protocol with a bound on the information cost w.r.t. the distribution D^1 over 1-inputs. The "information odometer" of [10] allows us to "keep track of" information cost, so we can halt and output 0 if it becomes too large. This will guarantee that the information cost is low w.r.t. the input distribution D, and correctness on 0-inputs is maintained. However, there is a complication with showing the average-case correctness on 1-inputs.

For each computation path specified by an input (x, y), an outcome of public randomness r, and a full sequence of messages m, there is a contribution $c_{x,y,r,m}$ such that the information cost w.r.t. D is the expectation of $c_{x,y,r,m}$ over a random computation path with $(x, y) \sim D$. Similarly, there is a contribution $c^1_{x,y,r,m}$ such that the information cost w.r.t. D^1 is the expectation of $c^1_{x,y,r,m}$ over a random computation path with $(x, y) \sim D^1$. These contributions play the role of "number of queries" along a computation path in the decision tree setting, but a crucial difference is that $c_{x,y,r,m} \neq c^1_{x,y,r,m}$ in general; i.e., the contribution to information cost depends on the input distribution (whereas number of queries did not). To show the

average-case correctness on 1-inputs, we need a bound on the typical value of $c_{x,y,r,m}$, whereas the assumption that information cost w.r.t. D^1 is low gives us a bound on the typical value of $c^1_{x,y,r,m}$.

Thus the heart of the argument is to show that typically, $c_{x,y,r,m}$ is not much larger than $c^1_{x,y,r,m}$. Intuitively, one might expect the difference to be at most 1, since the only additional information that can be revealed (beyond what is revealed under D^1) should be the fact that (x, y) is a 1-input (which is 1 bit of information). More precisely, we show that for given (x, y), the expected difference depends on how balanced F is on the x row and the y column. Then we just need to note that F is typically reasonably balanced for both the x row and the y column.

The formal proof of Lemma 16 is deferred to the full version [14] due to space constraints.

Acknowledgments. We thank Mark Braverman, Troy Lee, and Omri Weinstein for discussions. Work done by M.G. while at IBM Research Almaden.

Abstract

Two distributions over n-bit strings are (k, δ)-wise indistinguishable if no statistical test that observes k of the n bits can tell the two distributions apart with advantage better than δ. Motivated by secret sharing and cryptographic leakage resilience, we study the existence of pairs of distributions that are (k, δ)-wise indistinguishable, but can be distinguished by some function f of suitably low complexity. We prove bounds tight up to constants when f is the OR function, and tight up to logarithmic factors when f is a read-once uniform AND $\circ$ OR formula, extending previous works that address the perfect indistinguishability case $\delta = 0$.

We also give an elementary proof of the following result in approximation theory: If p is a univariate degree-k polynomial such that $|p(x)| \leq 1$ for all $|x| \leq 1$ and $p(1) = 1$, then $\hat{\ell}_1(p) \geq 2^{\Omega(p'(1)/k)}$, where $\hat{\ell}_1(p)$ is the sum of the absolute values of p's coefficients. A more general statement was proved by Servedio, Tan, and Thaler (2012) using complex-analytic methods.

As a secondary contribution, we derive new threshold weight lower bounds for bounded depth AND-OR formulas.

1 Introduction

Two random variables X and Y over $\{0,1\}^n$ are (locally) (k, δ)-*wise indistinguishable* if for all subsets $S \subseteq \{1, \ldots, n\}$ of size k, the induced marginal distributions $(X_i : i \in S)$ and $(Y_i : i \in S)$ are within statistical distance δ. We say function $f : \{0,1\}^n \to \{0,1\}$ *reconstructs from* the pair (X, Y) with error at most ε if $\mathbb{E}[f(X)] - \mathbb{E}[f(Y)] \geq 1 - \varepsilon$. In this work we investigate conditions under which a suitable f can reconstruct from some pair of locally indistinguishable distributions.

The parity function on n bits provides an extreme example of this phenomenon: The uniform distributions over $\{0,1\}^n$ conditioned on the parity of all the bits taking value zero and one, respectively, are $(n-1, 0)$-wise indistinguishable, but parity reconstructs from them perfectly. Our focus will be on reconstruction functions that have representations of constant depth and size polynomial in n (i.e., in the class AC^0). Functions in this class exclude large parities [6, 18, 7], and are in fact strongly uncorrelated with them under the uniform distribution [8].

The OR function

The OR function on n inputs is arguably the most elementary example of this type. We prove matching upper and lower bounds reconstruction by the OR function with respect to (k, δ)-wise indistinguishable distributions. In the range where the reconstruction error is constant, we obtain the following results.

▶ **Theorem 1.** *For every n and $k \geq 5\sqrt{n}$ and every pair of $(k, 2^{-O(n/k)})$-wise indistinguishable distributions X, Y over $\{0,1\}^n$, $\Pr[\mathrm{OR}(X) = 1] - \Pr[\mathrm{OR}(Y) = 1] \leq 1/3$.*

▶ **Theorem 2.** *For every n and $k \leq n/2$ there exists a pair of $(k, 2^{-\Omega(n/k)})$-wise indistinguishable distributions X, Y over $\{0,1\}^n$ such that $\Pr[\mathrm{OR}(X) = 1] - \Pr[\mathrm{OR}(Y) = 1] \geq 2/3$.*

The distributions X and Y in Theorem 2 are uniformly sampleable by circuit families of constant depth and size polynomial in n.

These results extend our previous work with Ishai and Viola [3], which only considered perfect bounded indistinguishability, i.e., the case $\delta = 0$. It is shown there that $(2\sqrt{n}, 0)$-wise and $(\sqrt{n}/2, 0)$-wise indistinguishability yield the conclusions of Theorems 1 and 2, respectively. Those proofs make use of results about the approximability of the OR function by real-valued polynomials of Linial and Nisan [10] and Nisan and Szegedy [13].

Our work with Ishai and Viola also explains the relevance of bounded indistinguishability to the computational complexity of secret sharing and cryptographic leakage resilience. In the context of secret sharing, (k, δ)-wise indistinguishability postulates that the joint view of any k parties can predict the secret with advantage at most δ. In a *visual secret sharing* scheme [12], the secret to be shared is a pixel, each of n parties receives a transparency and the pixel is recovered by superimposing the transparencies. The procedure can be applied independently to every pixel in an image. The *contrast* of the scheme is the fraction of pixels that are reconstructed correctly.

Theorems 1 and 2 describe the best possible tradeoff between the size and the reconstruction advantage of the adversarial coalition for visual secret sharing schemes [12] with constant contrast. Theorem 2' in Section 3 is a refinement of Theorem 2 that specifies the dependence of the indistinguishability parameters on the contrast.

Linial and Nisan [10] studied an incomparable notion of δ-indistinguishability in which the family of statistical tests consists of ANDs over arbitrary subsets of the input bits. They proved analogues of Theorems 1 and 2 for $\delta \geq 2^{-c\sqrt{n}}$ and $\delta \leq 2^{-c\sqrt{n}\log n}$, respectively (for suitable constants c and C).

A consequence in approximation theory

A. A. Markov showed that among all real-valued univariate degree k polynomials p such that $|p(x)| \leq 1$ for all $|x| \leq 1$, the derivative $p'(1)$ is maximized by the Chebyshev polynomial T_k of degree k with $T_k'(1) = k^2$. The weight $\hat{\ell}_1(T_k)$ of the Chebyshev polynomial, defined as the sum of the absolute values of its coefficients, is exponential in k. At the other end of the spectrum, the polynomial x^k has weight 1 and derivative k at 1. Interpolating between the two, the degree-k polynomial $T_r(x^{k/r})$ has weight exponential in r and derivative rk at 1 whenever r divides k. With one small additional hypothesis, we prove that this is the best possible up to the constant in the exponent:

▶ **Theorem 3.** *There exists a constant $C > 0$ such that if $p\colon \mathbb{R} \to \mathbb{R}$ is a degree-k polynomial with $|p(x)| \leq 1$ for all $|x| \leq 1$ and $p(1) = 1$ then $p'(1) \leq Ck \log \hat{\ell}_1(p)$.*

The polynomials $p(x) = T_r(x^{\lfloor k/r \rfloor})$ certify that the bound is tight up to the constant factor.

Servedio, Tan, and Thaler [14] proved a more general form of Theorem 3: Under the same assumptions, they showed that $\max_{x\in[-1,1]}|p'(x)| \leq Ck \log \hat{\ell}_1(p)$. (Their bound is stated in a slightly weaker form.) Our proof is based on elementary counting, a large deviation bound, and some basic calculus, while Servedio et al.'s makes use of Hadamard's Three Circle Theorem from complex analysis.

Perfect and almost-perfect reconstruction

In the setting of secret sharing, reconstruction errors are undesirable as they entail possible loss of information in the sharing phase. There, perfect reconstruction is a desirable feature. The OR function is not up to the task (for non-trivial parameter settings): It is easily observed that perfect reconstruction by OR requires $(1, 1/n)$-wise indistinguishability of the underlying distributions X and Y. We show, however, that read-once CNFs and higher depth AND-OR trees can perfectly reconstruct from distributions of approximate bounded indistinguishability:

▶ **Theorem 4.** *For any fixed d, and for all n and k, there exists a pair of $(k, 2^{-\Omega((n/k)^{1-1/d})})$-wise indistinguishable distributions that can be perfectly reconstructed by the depth-d AND-OR tree with top fan-in $(n/k)^{1/d}$, middle fan-ins $(n/k)^{2/d}$, and bottom fan-in $\frac{k^{(2d-3)/d}}{n^{(d-3)/d}}$.*

Setting $d = 2$ results in the following corollary:

▶ **Corollary 5.** *For all n and k there exists a pair of $(k, 2^{-\Omega((n/k)^{1/2})})$-wise indistinguishable distributions that can be perfectly reconstructed by the function $\mathrm{AND}_{(n/k)^{1/2}} \circ \mathrm{OR}_{(nk)^{1/2}}$.*

Here, $\mathrm{AND}_{n/m} \circ \mathrm{OR}_m$ is a read-once monotone CNF with fan-in m at the bottom OR gates and fan-in n/m at the top AND gate. We prove that Corollary 5 is essentially tight for read-once CNFs. In Proposition 13, however, we show that *almost* perfect reconstruction by functions of this type is possible with substantially better parameters.

Threshold weight

The degree-k threshold weight of a function $f\colon \{0,1\}^n \to \{0,1\}$ is the minimum weight of a nonzero degree-k polynomial p with integer coefficients such that $p(x)f(x) \geq 0$ for all x. Beigel [1] and Servedio et al. [14] construct a length-n decision list that requires degree-k threshold weight $2^{\Omega(\sqrt{n/k})}$. Bun and Thaler [5] give a read-once DNF over n variables that requires the same degree-k threshold weight, and construct a polynomial size AND-OR circuit of depth 3 that requires degree-k threshold weight $2^{\Omega(n/k^{3/2})}$. Sherstov [16] constructed a depth 4 circuit of polynomial size that requires threshold weight $2^{\Omega(\sqrt{n})}$ for all k. Our methods yield the following incomparable bound:

▶ **Corollary 6.** *The depth-d AND-OR tree given in the statement of Theorem 4 requires degree-k threshold weight $2^{\Omega((n/k)^{1-1/d})}$.*

In Section 6 we show that this result implies the degree-independent threshold weight lower bound for formulas of Sherstov [15].

Our proofs

Impossibility of reconstruction by OR from $(2\sqrt{n}, 0)$-wise indistinguishable distributions follows easily from the existence of a degree $2\sqrt{n}$ polynomial p that approximates the OR

function pointwise: The distinguishing advantage of the OR function can be at most the pointwise approximation error. The relaxed assumption of approximate local indistinguishability introduces an additional error term proportional to the weight of the approximating polynomial. Lemma 7 recasts the problem in the univariate setting, following previous works. To prove Theorem 1 we instantiate Lemma 7 with a polynomial of the form $T_r(x^{k/r})$ for a suitable choice of r. The relevant properties of this polynomial are that it is bounded on $[-1, 1]$, has weight $2^{O(r)}$ and has value $\Omega(kr/n)$ at $x = 1 + 1/2n$.

In the setting of perfect bounded indistinguishability, the maximum distinguishing advantage of OR with respect to $(k, 0)$-wise indistinguishable distributions *equals* the minimum error that a k-approximating polynomial for OR must have by linear programming duality. Thus, high approximate degree readily implies the existence of locally indistinguishable distributions that can be told apart by the OR function. In the approximate setting this duality is not preserved: While existence of low-degree, low-weight approximate polynomials implies hardness of reconstruction, it is not at all clear that the converse should hold. To prove a converse to Theorem 1 we instead resort to combinatorial means.

We prove Theorem 2 by a reduction to the case of perfect bounded indistinguishability. Previous works give the existence of $(\Omega(\sqrt{\varepsilon n}), 0)$-wise indistinguishable distributions X and Y such that $\Pr[\mathrm{OR}(X) = 1] - \Pr[\mathrm{OR}(Y) = 1] \geq 1 - \varepsilon$. (As observed in [3], the dual polynomials of Špalek [17] and Bun and Thaler [4] show that such distributions can be sampled by uniform constant-depth, polynomial-size circuit families.) We consider the following distributions X' and Y' over $\{0, 1\}^N$, where $N \geq n$: Sample n coordinates of $\{1, \ldots, N\}$ uniformly at random, embed a sample of X and Y, respectively, in these coordinates, and set all the other entries of X and Y to zero. The distinguishing advantage of OR is not affected by this transformation. On the other hand, any "local view" of size K in $\{1, \ldots, N\}$ expects to observe $K \cdot n/N$ of the embedded samples. Provided this number is sufficiently smaller than the indistinguishability parameter k, by a large deviation bound this local view can reconstruct from the distributions X and Y only with small probability.

Since Theorem 2 proves the optimality of Theorem 1, it follows that no choice of univariate polynomial p that is bounded on $[-1, 1]$ can have significantly larger value at $x = 1 + 1/2n$ than the polynomial $T_r(x^{k/r})$ among all those of weight $2^{O(r)}$. By the mean value theorem, there must exist some x in $[1, 1 + 1/2n]$ such that $p'(x)$ is at most $O(kr)$. Proving Theorem 3 requires showing that $p'(1) = O(kr)$. Our proof of Theorem 3 in Section 4 bounds the rate of change of $p'(x)$ around $x = 1$ as a function of the weight of p. Since this norm is small, for a suitable choice of n we can conclude from a somewhat delicate calculation that $p'(1) = O(kr)$ and prove Theorem 3.

The proof of Theorem 4 extends the reduction to perfect bounded indistinguishability to the setting of higher depth trees. This was studied in [3] and is a consequence of the seminal lower bound of Minsky and Papert [11]. Optimality is proved by an explicit construction of low-weight approximating polynomials as in Theorem 1. In the near-perfect setting, the requisite lower bound on approximate degree was obtained by Bun and Thaler [5] (extending Beigel [2]).

2 Optimality of distributions: Proof of Theorem 1

We first present a limitation of the OR function's ability to reconstruct from distributions that are almost k-wise indistinguishable. This is completed in two steps. First, we reduce the question to one of polynomials. Specifically, we demonstrate that the existence of certain polynomials that approximate OR allow us to upper bound the ability of OR to reconstruct

from these distributions, where the degree and size of coefficients of the polynomial relate to the indistinguishability parameters. The second step is to construct these polynomials and calculate the indistinguishability parameters as a function of their degree and $\hat{\ell}_1$ norm.

2.1 Indistinguishability from approximating polynomials

▶ **Lemma 7.** *Assume $p\colon \mathbb{R} \to \mathbb{R}$ is a degree-k polynomial such that $|p(x)| \le 1$ for all x such that $|x| \le 1$ and $j(p,n) = p(1+2/n) - 1 \ge 0$. For all pairs of (k,δ)-wise indistinguishable distributions X and Y over $\{-1,1\}^n$,*

$$\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] \le \frac{2}{2 + j(p,n)} + e^2 \cdot \delta \cdot \hat{\ell}_1(p).$$

Here, we assume a representation in which OR evaluates to zero if any of its inputs are -1 and to 1 otherwise.

In the case of perfect indistinguishability (i.e., $\delta = 0$), such approximations of the OR function by polynomials already appear in the work of Linial and Nisan. Lemma 7 shows that the presence of local error δ introduces an additional term proportional to the weight of the approximation polynomial. The term $j(p,n)$ can be improved slightly to $p(1+2/(n-1)) - 1$.

In the proof of Lemma 7 we will use the following facts, which themselves are proven after the lemma.

▶ **Fact 8.** *Let p be a degree-k univariate polynomial and $p^*(x) = p(ax+b)$, where $|a|+|b| \ge 1$. Then $\hat{\ell}_1(p^*) \le (|a| + |b|)^k \hat{\ell}_1(p)$.*

▶ **Fact 9.** *If p is a univariate polynomial and $\mathbf{p}(x_1, \ldots, x_n) = p((x_1 + \cdots + x_n)/n)$ then $\hat{\ell}_1(\mathbf{p}) \le \hat{\ell}_1(p)$.*

Proof of Lemma 7. Let

$$p^*(x) = \gamma \cdot p\Big(x + \frac{2}{n}\Big) \quad \text{where} \quad \gamma = \frac{1}{2 + j(p,n)}.$$

Then $|p^*(x)| \le \gamma$ for $x \in [-1, 1 - \frac{2}{n}]$ and $p^*(1) = 1 - \gamma$. The multivariate polynomial

$$\mathbf{p}^*(x_1, \ldots, x_n) = p^*\Big(\frac{x_1 + \cdots + x_n}{n}\Big)$$

satisfies $|\mathbf{p}^*(\mathbf{x}) - \mathrm{OR}(\mathbf{x})| \le \gamma$ for all $\mathbf{x} \in \{-1,1\}^n$. Expanding $\mathbf{p}^*$ in the Fourier basis, we can write $\mathbf{p}^*(\mathbf{x}) = \sum_{|S| \le k} \hat{\mathbf{p}}^*_S \chi_S(\mathbf{x})$, where $\chi_S(\mathbf{x}) = \prod_{i \in S} x_i$. Then

$$\begin{aligned}
\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] &\le \mathbb{E}[\mathbf{p}^*(X) + \gamma] - \mathbb{E}[\mathbf{p}^*(Y) - \gamma] \\
&\le 2\gamma + \mathbb{E}[\mathbf{p}^*(X)] - \mathbb{E}[\mathbf{p}^*(Y)] \\
&= 2\gamma + \sum\nolimits_{|S| \le k} \hat{\mathbf{p}}^*_S \cdot \big(\mathbb{E}[\chi_S(X)] - \mathbb{E}[\chi_S(Y)]\big) \\
&\le 2\gamma + \sum\nolimits_{S} |\hat{\mathbf{p}}^*_S| \cdot 2\delta \\
&= 2\gamma + 2\delta \cdot \hat{\ell}_1(\mathbf{p}^*).
\end{aligned}$$

The second to last step holds because χ_S is a k-local distinguisher with range $\{-1,1\}$, so its distinguishing advantage is at most 2δ. From Facts 8 and 9 it follows that

$$\hat{\ell}_1(\mathbf{p}^*) \le \frac{1}{2 + j(p,n)} \cdot \Big(1 + \frac{2}{n}\Big)^k \cdot \hat{\ell}_1(p) \le \frac{1}{2} \cdot \Big(\frac{n+2}{n}\Big)^k \cdot \hat{\ell}_1(p) \le \frac{e^2}{2} \cdot \hat{\ell}_1(p).$$

for $k < n$ as desired. ◀

Proof of Fact 8. If all the coefficients of a polynomial q are positive then $\hat{\ell}_1(q) = q(1)$. For $p(x) = \sum_{i=0}^{k} c_i x^i$ let $\tilde{p}(x) = \sum_{i=0}^{k} |c_i| x^i$. Then

$$\hat{\ell}_1(\tilde{p}(|a|x + |b|)) = \tilde{p}(|a| + |b|) \leq (|a| + |b|)^k \tilde{p}(1) = (|a| + |b|)^k \hat{\ell}_1(p).$$

The coefficients of $\tilde{p}(|a|x + |b|)$ dominate those of $p(ax + b)$, so we can conclude that $\hat{\ell}_1(p(ax + b)) \leq \hat{\ell}_1(\tilde{p}(|a|x + |b|)) \leq (|a| + |b|)^k \hat{\ell}_1(p)$. ◀

Proof of Fact 9. If $p(x) = \sum_{i=0}^{k} c_i x^i$ then

$$\hat{\ell}_1(\mathbf{p}) \leq \sum_{i=0}^{d} \frac{|c_i|}{n^i} \hat{\ell}_1\big((x_1 + ... + x_n)^i\big) \leq \sum_{i=0}^{d} \frac{|c_i|}{n^i} \cdot n^i = \hat{\ell}_1(p),$$

where the second to last step holds because all of the coefficients in $(x_1 + \cdots + x_n)^i$ are nonnegative, so the weight is $(1 + \cdots + 1)^i = n^i$. ◀

2.2 Construction of approximating polynomials

Our approximating polynomials will take the form of a Chebyshev polynomial evaluated at an appropriately chosen monomial. We note that Servedio, Tan, and Thaler in [14] also use polynomials of this form to give a degree-weight tradeoff of polynomials approximating the OR function.

For the proof of Theorem 1, we set $p(x) = T_r(x^d)$, where $d = \lfloor k^2/20n \rfloor \geq 1$, $r = \lfloor k/d \rfloor$, and T_r is the Chebyshev polynomial of degree r.

The Chebyshev polynomials satisfy (1) $|T_r(x)| \leq 1$ for all $x \in [-1, 1]$, (2) $T_r(1) = 1$, (3) $T_r'(1) = r^2$, (4) $T_r''(x) \geq 0$ for all $x \geq 1$, and (5) $\hat{\ell}_1(T_r) \leq 2^{2r}$. The first four properties are well-known; we provide a short proof of the fifth.

Proof of Property 5. We use an alternate definition of the Chebyshev polynomial: $T_r(x) = \frac{r}{2} \sum_{i=0}^{r/2} \frac{(-1)^i}{r-i} \binom{r-i}{i} 2^{r-2i} x^{r-2i}$. Thus, we have:

$$\hat{\ell}_1(T_r) = \frac{r}{2} \sum_{i=0}^{r/2} \frac{1}{r-i} \binom{r-i}{i} 2^{r-2i} \leq \sum_{i=0}^{r/2} \binom{r-i}{i} 2^{r-2i} \leq 2^r \sum_{i=0}^{r/2} \binom{r}{i} \leq 2^{2r}.$$ ◀

From properties (2), (3), and (4) it follows that

$$j(p, n) = p(1 + 2/n) - 1 \geq p'(1) \cdot \frac{2}{n} = \frac{2dr^2}{n} \geq \frac{k^2}{2dn} \geq 10.$$

The second to last inequality holds since for our choice of parameters $d \leq k$, so $r \geq 1$, and therefore $r \geq k/2d$.

By property (5), $\hat{\ell}_1(p) = 2^{2r} \leq 2^{2k/d}$. We now show this is at most $2^{80n/k}$. When $k^2 \geq 20n$, $d \geq k^2/40n$ and so $\hat{\ell}_1(p) \leq 2^{80n/k}$. Otherwise, $d = 1$, and $\hat{\ell}_1(p)$ is at most $2^{2k} \leq 2^{40n/k}$.

Finally, by property (1) $|p(x)| \leq 1$ for $|x| \leq 1$. By Lemma 7,

$$\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] \leq \frac{2}{2 + 10} + e^2 \delta \cdot 2^{80n/k} \leq \frac{1}{3}$$

as long as $\delta \leq 2^{-80n/k}/6e^2$, proving Theorem 1.

3 Construction of distributions: Proof of Theorem 2

We reduce the existence of (k, ϵ)-indistinguishable distributions that can be reconstructed by the OR function to the analogous question for distributions of perfect bounded indistinguishability:

▶ **Lemma 10.** *For every $\varepsilon, N, K \leq N/2$ and $n \leq \epsilon N^2/121K^2$ the following holds. Assume there exist $(\sqrt{\epsilon n}, 0)$-wise indistinguishable distributions X, Y over $\{0,1\}^n$. Then there exist distributions X', Y' over $\{0,1\}^N$ such that $\mathbb{E}[\mathrm{OR}(X')] = \mathbb{E}[\mathrm{OR}(X)]$, $\mathbb{E}[\mathrm{OR}(Y')] = \mathbb{E}[\mathrm{OR}(Y)]$, and X', Y' are $(K, 2^{-\Omega(\epsilon N/K)})$-wise indistinguishable.*

Proof. To sample from X' (resp. Y'), first select a random set of n "active" indices among the N choices. Then, sample a string from X (resp. Y) and fill in the n indices with the sampled bits. Fill in the remaining $N - n$ places with 0s. This process does not change the chance that OR accepts a string, so the reconstruction error remains the same.

We now need to check that X', Y' are $(K, 2^{-\Omega(\epsilon N/K)})$-wise indistinguishable. Let S be any subset of $\{1, \ldots, N\}$ of size K and E be the event that at most k of the active indices fall in S. Conditioned on E, the projections of X' and Y' on S contain at most k bits from X and Y, respectively, and are therefore perfectly indistinguishable. Therefore the distinguishing advantage of any test $T\colon \{0,1\}^S \to \{0,1\}$ can be at most the probability that E does not occur.

To upper bound this probability, we take a union bound over all possible $\binom{K}{k}$ subsets of k active indices in S. For each such set, there is a probability of n/N that the first index is active, a probability of $(n-1)/(N-1)$ that the second index is active conditioned on the first one, and so on, obtaining:

$$\begin{aligned}\Pr[\text{there are at least } k \text{ active indices in } S] &\leq \binom{K}{k} \cdot \frac{n}{N} \cdot \frac{n-1}{N-1} \cdot \ldots \cdot \frac{n-k+1}{N-k+1} \\ &\leq \left(\frac{eK}{k} \cdot \frac{n}{N-k+1}\right)^k.\end{aligned}$$

Since $K \leq N/2$, we have that $k \leq N/2$ and $1/(N-k+1) \leq 2/N$. Plugging these estimates in, we conclude that the distinguishing advantage is at most $(2eKn/kN)^k$. We now set our parameters so that $\sqrt{\epsilon n} = k = 11nK/N$, implying that $(2eKn/kN)^k$ is upper bounded by $2^{-k} = 2^{-\Omega(nK/N)} = 2^{-\Omega(\epsilon N/K)}$. ◀

Now that we have reduced the problem of finding $(K, 2^{-\Omega(\epsilon N/K)})$-wise indistinguishable distributions to the one of finding $(\sqrt{\epsilon n}, 0)$-wise indistinguishable ones, for some specific n, we are ready to prove the following refinement of Theorem 2, which will be needed for the proof of Theorem 3.

▶ **Theorem 2'.** *For every ε, N, and $K \leq N/2$ there exists a pair of $(K, 2^{-\Omega(\epsilon N/K)})$-wise indistinguishable distributions X', Y' over $\{0,1\}^N$ such that $\mathbb{E}[\mathrm{OR}(X')] - \mathbb{E}[\mathrm{OR}(Y')] \geq 1 - \epsilon$.*

Proof. Corollary 2.2 in [3] shows the existence of $(\sqrt{\epsilon n}, 0)$-wise indistinguishable distributions X, Y over $\{0,1\}^n$ such that $\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] = 1 - O(\epsilon)$. If $K \leq \sqrt{\epsilon N}/11$ the theorem follows directly from this Corollary. Otherwise, we apply Lemma 10 with $n = \lfloor \epsilon N^2/121K^2 \rfloor$ to X, Y and obtain the desired conclusion. ◀

4 Proof of Theorem 3

To prove Theorem 3 we reason as follows. Suppose there is a polynomial p of degree k such that $|p(x)| \leq 1$ for $|x| \leq 1$ and $p(1) = 1$. For $\varepsilon = p(1 + 2/n) - 1$, Theorem 2' and Lemma 7 together imply that

$$1 - \frac{\varepsilon}{6} \leq \mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] \leq \frac{2}{2+\varepsilon} + 2^{-\Omega(\varepsilon n/k)} \cdot \hat{\ell}_1(p),$$

from where we can conclude that $\hat{\ell}_1(p) \geq \Omega(\varepsilon) \cdot 2^{\Omega(\varepsilon n/k)}$, provided $\varepsilon \leq 1$. If the leading $\Omega(\varepsilon)$ term could be ignored, we would obtain Theorem 3 by taking the limit of the right-hand side as n goes to infinity and $\varepsilon n/2$ approaches $p'(1)$.

To account for the $\Omega(\varepsilon)$ term, we work with a carefully chosen, finite value of n. Our choice of n is sufficiently large so that the term $2^{\Omega(\varepsilon n/k)}$ dominates the term $\Omega(\varepsilon)$ in the expression lower bounding $\hat{\ell}_1(p)$, but sufficiently small so that $\varepsilon n/2$ is still lower bounded by $\Omega(p'(1))$. If n was a function of k only, this would be impossible as the value $\varepsilon = p(1+2/n)-1$ could even be negative. Our choice of n depends on the polynomial p itself via the parameters $\hat{\ell}_1(p)$ and $p'(1)$.

This description assumed that ε was at most one (or bounded by some fixed constant). The case of large ε can be handled along the same lines and is in fact technically easier.

Proof of Theorem 3. Let $p\colon \mathbb{R} \to \mathbb{R}$ be a degree-k polynomial such that $|p(x)| \leq 1$ for all $|x| \leq 1$ and $p(1) = 1$. Let $\varepsilon = p(1 + 2/n) - 1$ for $n = 4k^2\hat{\ell}_1(p)/p'(1)$. Expanding $p(1 + 2/n)$ around 1 we obtain

$$p(1 + 2/n) = p(1) + \frac{p'(1)}{n/2} + \sum_{i \geq 2} \frac{1}{(n/2)^i} \cdot \frac{p^{(i)}(1)}{i!}$$

where $p^{(i)}(1)$ is the i-th derivative of p at 1. Since $p(1) = 1$ it follows that

$$\varepsilon = p(1 + 2/n) - p(1) \geq \frac{p'(1)}{n/2} - \sum_{i \geq 2} \frac{1}{(n/2)^i} \cdot \frac{|p^{(i)}(1)|}{i!}.$$

A calculation of the derivatives shows that $|p^{(i)}|/i! \leq \binom{k}{i} \cdot \hat{\ell}_1(p)$ and so

$$\varepsilon \geq \frac{p'(1)}{n/2} - \sum_{i \geq 2} \frac{\binom{k}{i}}{(n/2)^i} \cdot \hat{\ell}_1(p) = \frac{p'(1)}{n/2} - \hat{\ell}_1(p) \cdot \sum_{i \geq 2} \left(\frac{k}{n/2}\right)^i \cdot \frac{1}{i!}. \tag{1}$$

Since $p'(1) \leq \hat{\ell}_1(p') \leq k\hat{\ell}_1(p)$, n is at least $4k$ and

$$\sum_{i \geq 2} \left(\frac{k}{n/2}\right)^i \cdot \frac{1}{i!} \leq \left(\frac{k}{n/2}\right)^2 \cdot \sum_{i \geq 2} \frac{1}{i!} \leq \left(\frac{k}{n/2}\right)^2.$$

From (1) we obtain that

$$\varepsilon \geq \frac{p'(1)}{n/2} - \hat{\ell}_1(p) \cdot \frac{k^2}{(n/2)^2} \geq \frac{p'(1)}{n}. \tag{2}$$

where the second inequality follows from our choice of n.

By Lemma 7 for every pair of (k, δ)-wise indistinguishable distributions X and Y over $\{0,1\}^n$,

$$\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] \leq \frac{2}{2+\varepsilon} + e^2\delta\hat{\ell}_1(p).$$

If $\varepsilon \leq 1$, by Theorem 2' there exist $(k, 2^{-c\varepsilon n/k})$-wise indistinguishable distributions X and Y such that $\mathbb{E}[OR(X)] - \mathbb{E}[OR(Y)] \geq 1 - \varepsilon/6$. Setting $\delta = 2^{-c\varepsilon n/k}$ we obtain

$$e^2\delta\hat{\ell}_1(p) \geq 1 - \frac{\varepsilon}{6} - \frac{2}{2+\varepsilon} \geq \left(1 - \frac{\varepsilon}{6}\right) - \left(1 - \frac{\varepsilon}{3}\right) = \frac{\varepsilon}{6}.$$

Using inequality (2) and the definition of n we have

$$6e^2\hat{\ell}_1(p) \geq \varepsilon \cdot 2^{c\varepsilon n/k} \geq \frac{p'(1)}{n} \cdot 2^{cp'(1)/2k} = \frac{1}{\hat{\ell}_1(p)} \cdot \left(\frac{p'(1)}{2k}\right)^2 \cdot 2^{cp'(1)/2k}.$$

After rearranging terms we obtain

$$\hat{\ell}_1(p) \geq \frac{1}{\sqrt{6}e} \cdot \frac{p'(1)}{2k} \cdot 2^{cp'(1)/4k}.$$

Since $\hat{\ell}_1(p)$ is also at least $p(1) = 1$, it follows that $2^{\Omega(p'(1)/4k)}$, proving the theorem when $\varepsilon \leq 1$.

If $\varepsilon > 1$, by Theorem 2 there exist $(k, 2^{-cn/k})$-wise indistinguishable distributions X and Y such that $\mathbb{E}[\mathrm{OR}(X)] - \mathbb{E}[\mathrm{OR}(Y)] \geq 5/6$ and $e^2\delta\hat{\ell}_1(p) \geq 5/6 - 2/3 \geq 1/6$. Setting $\delta = 2^{-cn/k}$,

$$\hat{\ell}_1(p) \geq \frac{1}{6e^2} \cdot 2^{cn/k} \geq 2^{cp'(1)/2k}$$

using (2) and the assumption $\varepsilon > 1$. ◀

5 AND-OR formulas and perfect reconstruction

In this section we prove Theorem 4, give a variant with better parameters that provides almost-perfect reconstruction, and show that Theorem 4 is tight in the depth-2 case with respect to all uniform read-once AND ∘ OR formulas.

We first extend Lemma 10 to AND ∘ OR formulas of depth d:

▶ **Lemma 11.** *Assume there exist $(k, 0)$-wise indistinguishable distributions X and Y over $\{0,1\}^n$ for a regular depth-d AND ∘ OR tree f over n variables and with lowest-level fan-in m. Then there exist $(K, 2^{-\Omega(k)})$-wise indistinguishable distributions X' and Y' over $\{0,1\}^N$, $N = nM/m$, such that $\mathbb{E}[f'(X')] = \mathbb{E}[f(X)]$ and $\mathbb{E}[f'(Y')] = \mathbb{E}[f(Y)]$, where f' is a function taking the same form as f, except for that the lowest-level fan-in is M, provided $m \leq M/2$, $k/K \geq 4m/M$ and $n \leq m \cdot 2^{m-1}$.*

Proof. To sample from X' (resp. Y'), first sample a string from X (resp. Y), then extend each of the blocks with $M - m$ zeros positioned uniformly at random. Call the indices i in which X'_i inherits some bit of X *active*.

The distribution on active indices of X' can be described in the following alternative manner: First, choose each index i to be potentially active independently at random with probability $p = 2m/M$. If any block of X' has fewer than m potentially active indices, declare failure (F). Conditioned on not failing ($\overline{F}$), choose the active indices in each block uniformly at random among the potentially active ones.

Now let S be any set consisting of at most K inputs of f'. Let B be the event that S contains more than $2pK$ active indices. By Chernoff and union bounds,

$$\Pr[B|\overline{F}] \leq \frac{\Pr[B]}{1 - \Pr[F]} \leq \frac{2^{-pK}}{1 - (n/m)2^{-m}} \leq 2^{-k+1}$$

by our choice of parameters. As in the proof of Lemma 10 we conclude that X' and Y' must satisfy the conclusion. ◀

Proof of Theorem 4. We will use N and K to denote the quantities n and k from the statement of the theorem. By [15] and [3] there exist X and Y that are $(k, 0)$-wise indistinguishable but perfectly reconstructible by $\mathrm{AND}_{n^{1/2d-1}} \circ \mathrm{OR}_{n^{2/2d-1}} \circ \ldots \circ \mathrm{OR}_m$ for $m = n^{2/2d-1}$ and $k = \Omega(n^{\frac{d-1}{2d-1}})$. We will assume $K \geq N^{\frac{d-1}{2d-1}}$, for otherwise there is nothing left to prove. Set $k = (N/CK)^{1-1/d}$ for a sufficiently large constant C and $M = 4Km/k$. If $m > M/2$ then the conclusion follows directly from [15, 3] (as K will be at most a constant in terms of d times $N^{\frac{d-1}{2d-1}}$). If $n > m \cdot 2^{m-1}$, $(N/K)^{1-1/d}$ is upper bounded by a constant so the conclusion holds trivially. Otherwise, the statement of the theorem follows from Lemma 11. ◀

In the case $d = 2$, the parameters in Theorem 4 are the best possible, up to logarithmic terms, for all read-once CNFs. (The regime $k < n^{1/3}$ is resolved in [11, 3].)

▶ **Theorem 12.** *There exists a constant c such that for any n and $k \geq n^{1/3}$, no read-once CNF over n variables can perfectly reconstruct from any pair of $(k, 2^{-\Omega((n/k)^{1/2}\log^2 n)})$-wise indistinguishable distributions.*

The proof is omitted from this version owing to space limitations. If an exponentially small reconstruction error is acceptable, much better parameters for the underlying distributions are achievable:

▶ **Proposition 13.** *For all n, m, and k, the function $\mathrm{AND}_{n/m} \circ \mathrm{OR}_m$ can reconstruct from some pair of $(k, 2^{-\Omega(m/k)})$-wise indistinguishable distributions with error at most $2^{-\Omega(n/m)}$.*

Proof. Bun and Thaler [5] (improving work of Beigel) showed, via the connection in [3], that $\mathrm{AND}_{n/m} \circ \mathrm{OR}_m$ can reconstruct from some pair of $(\sqrt{m}, 0)$-wise indistinguishable distributions with error at most $2^{-\Omega(n/m)}$. We apply Lemma 11 with $k = \sqrt{m}$ and $M = mK/k$. ◀

6 A threshold weight lower bound

Proof of Corollary 6. Let X and Y be $(k, 2^{-\Omega((n/k)^{1-1/d})})$-wise indistinguishable distributions that the function f from Theorem 4 can perfectly reconstruct from. If p is a degree-k polynomial such that $|f(x) - p(x)| \leq 1/2 - 2^{-t}$ then by Lemma 7,

$$1 = \mathbb{E}[f(X)] - \mathbb{E}[f(Y)] \leq (1 - 2^{1-t}) + 2^{1-\Omega((n/k)^{1-1/d})} \cdot \hat{\ell}_1(p),$$

from where $\hat{\ell}_1(p) \geq 2^{\Omega((n/k)^{1-1/d})-t}$. Setting $t = c \cdot (n/k)^{1-1/d}$ gives the desired lower bound on $\hat{\ell}_1(p)$. ◀

The *threshold weight* of a function is its minimum degree-k threshold weight over all k. A result of Krause [9] (see also Lemma 27 in [5]) can be used to convert lower bounds on degree-k threshold weight into ones independent of degree.

▶ **Fact 14** (Krause, 2005). *For $f\colon \{0,1\}^n \to \{0,1\}$, let $F\colon \{0,1\}^{3n} \to \{0,1\}$ be given by $F(x_1, \ldots, x_n, y_1, \ldots, y_n, z_1, \ldots, z_n) = f(\ldots, (\overline{z_i} \text{ AND } x_i) \text{ OR } (z_i \text{ AND } y_i), \ldots)$. For any k, if f requires degree-k threshold weight w then F requires threshold weight $\sqrt{\min\{w/2n, 2^k\}}$.*

Applying Fact 14 to Corollary 6, we obtain a linear-size depth-d family of formulas that requires threshold weight $2^{\Omega(n^{1/2-1/(4d-6)})}$ on inputs of length n, matching Sherstov's bound for formulas [15].

Acknowledgments. We thank Mark Bun for telling us about the work of Servedio, Tan, and Thaler and for his advice on polynomial approximations, and the ICALP 2017 reviewers for several helpful suggestions.

Abstract

We consider the following natural "above guarantee" parameterization of the classical Longest Path problem: For given vertices s and t of a graph G, and an integer k, the problem Longest Detour asks for an (s,t)-path in G that is at least k longer than a shortest (s,t)-path. Using insights into structural graph theory, we prove that Longest Detour is fixed-parameter tractable (FPT) on undirected graphs and actually even admits a single-exponential algorithm, that is, one of running time $\exp(O(k)) \cdot \mathrm{poly}(n)$. This matches (up to the base of the exponential) the best algorithms for finding a path of length at least k.

Furthermore, we study the related problem Exact Detour that asks whether a graph G contains an (s,t)-path that is exactly k longer than a shortest (s,t)-path. For this problem, we obtain a randomized algorithm with running time about $2.746^k \cdot \mathrm{poly}(n)$, and a deterministic algorithm with running time about $6.745^k \cdot \mathrm{poly}(n)$, showing that this problem is FPT as well. Our algorithms for Exact Detour apply to both undirected and directed graphs.

1 Introduction

The Longest Path problem asks, given an undirected n-vertex graph G and an integer k, to decide whether G contains a path of length at least k, that is, a self-avoiding walk with at least k edges. This problem is a natural generalization of the classical NP-complete Hamiltonian Path problem, and the parameterized complexity community has paid exceptional attention to it. For instance, Monien [28] and Bodlaender [4] showed *avant*

la lettre that Longest Path is fixed-parameter tractable with parameter k and admits algorithms with running time $2^{O(k \log k)} n^{O(1)}$. This led Papadimitriou and Yannakakis [29] to conjecture that Longest Path is solvable in polynomial time for $k = \log n$, and indeed, this conjecture was resolved in a seminal paper of Alon, Yuster, and Zwick [2], who introduced the method of color coding and derived from it the first algorithm with running time $2^{O(k)} n$. Since this breakthrough of Alon et al. [2], the problem Longest Path occupied a central place in parameterized algorithmics, and several novel approaches were developed in order to reduce the base of the exponent in the running time [19, 22, 9, 8, 23, 33, 15, 15, 3]. We refer to two review articles in Communications of ACM [14, 24] as well as to the textbook [12, Chapter 10] for an extensive overview of parameterized algorithms for Longest Path. Let us however note that the fastest known randomized algorithm for Longest Path is due to Björklund et al. [3] and runs in time $1.657^k \cdot n^{O(1)}$, whereas the fastest known deterministic algorithm is due to Zehavi [34] and runs in time $2.597^k \cdot n^{O(1)}$.

In the present paper, we study the problem Longest Path from the perspective of an "above guarantee" parameterization that can attain small values even for long paths: For a pair of vertices $s, t \in V(G)$, we use $d_G(s,t)$ to denote the distance, that is, the length of a shortest path from s to t. We then ask for an (s,t)-path of length at least $d_G(s,t) + k$, and we parameterize by this offset k rather than the actual length of the path to obtain the problem Longest Detour. In other words, the first $d_G(s,t)$ steps on a path sought by Longest Detour are complimentary and will not be counted towards the parameter value. This reflects the fact that shortest paths can be found in polynomial time and could (somewhat embarrassingly) be much better solutions for Longest Path than the paths of logarithmic length found by algorithms that parameterize by the path length.

We study two variants of the detour problem, one asking for a detour of length at least k, and another asking for a detour of length exactly k.

Longest Detour	**Parameter:** k
Input: Graph G, vertices $s, t \in V(G)$, and integer k.	
Task: Decide whether there is an (s,t)-path in G of length at least $d_G(s,t) + k$.	

Exact Detour	**Parameter:** k
Input: Graph G, vertices $s, t \in V(G)$, and integer k.	
Task: Decide whether there is an (s,t)-path in G of length exactly $d_G(s,t) + k$.	

Our parameterization above the length of a shortest path is a new example in the general paradigm of "above guarantee" parameterizations, which was introduced by Mahajan and Raman [26]. Their approach was successfully applied to various problems, such as finding independent sets in planar graphs (where an independent set of size at least $\frac{n}{4}$ is guaranteed to exist by the Four Color Theorem), or the maximum cut problem, see e.g. [1, 11, 17, 16, 27].

Our results

We show the following tractability results for Longest Detour and Exact Detour:

- Longest Detour is fixed-parameter tractable (FPT) on undirected graphs. The running time of our algorithm is single-exponential, i.e., it is of the type $2^{O(k)} \cdot n^{O(1)}$ and thus asymptotically matches the running time of algorithms for Longest Path. Our approach requires a non-trivial argument in graph structure theory to obtain the single-exponential algorithm; a mere FPT-algorithm could be achieved with somewhat less effort. It should also be noted that a straightforward reduction rules out a running time of $2^{o(k)} \cdot n^{O(1)}$ unless the exponential-time hypothesis of Impagliazzo and Paturi [20] fails.

- Exact Detour is FPT on directed and undirected graphs. Actually, we give a polynomial-time Turing reduction from Exact Detour to the standard parameterization of Longest Path, in which we ask on input u, v and $k \in \mathbf{N}$ whether there is a (u, v)-path of length k. This reduction only makes queries to instances with parameter at most $2k + 1$. Pipelined with the fastest known algorithms for Longest Path mentioned above, this implies that Exact Detour admits a bounded-error randomized algorithm with running time $2.746^k n^{O(1)}$, and a deterministic algorithm with running time $6.745^k n^{O(1)}$.

By a self-reducibility argument, we also show how to construct the required paths rather than just detect their existence. This reduction incurs only polynomial overhead.

Techniques

The main idea behind the algorithm for Longest Detour is the following combinatorial theorem, which shows the existence of specific large planar minors in large-treewidth graphs while circumventing the full machinery used in the Excluded Grid Theorem [31]. Although the Excluded Grid Theorem already shows that graphs of sufficiently large treewidth contain arbitrary fixed planar graphs, resorting to more basic techniques allows us to show that linear treewidth suffices for our specific cases. More specifically, we show that there exists a global constant $c \in \mathbf{N}$ such that every graph of treewidth at least $c \cdot k$ contains as a subgraph a copy of a graph $K_4^{\geq k}$, which is any graph obtained from the complete graph K_4 by replacing every edge by a path with at least k edges. The proof of this result is based on the structural theorems of Leaf and Seymour [25] and Raymond and Thilikos [30].

With the combinatorial theorem at hand, we implement the following win/win approach: If the treewidth of the input graph is less than $c \cdot k$, we use known algorithms [5, 15] to solve the problem in single-exponential time. Otherwise the treewidth of the input graph is at least $c \cdot k$ and there must be a $K_4^{\geq k}$, which we use to argue that any path visiting the same two-connected component as $K_4^{\geq k}$ can be prolonged by rerouting it through $K_4^{\geq k}$. To this end, we set up a fixed system of linear inequalities corresponding to the possible paths in $K_4^{\geq k}$ such that rerouting is possible if and only if the system is unsatisfiable. We then verify the unsatisfiability of this fixed system by means of a computer-aided proof (more specifically, a linear programming solver). From LP duality, we also obtain a short certificate for the unsatisfiability, which we include in the full version of this extended abstract.

The algorithm for Exact Detour is based on the following idea. We run breadth-first search (BFS) from vertex v to vertex u. Then, for every (u, v)-path P of length $d_G(u, v) + k$, all but at most k levels of the BFS-tree contain exactly one vertex of P. Using this property, we are able to devise a dynamic programming algorithm for Exact Detour, provided it is given access to an oracle for Longest Path.

The remaining part of the paper is organized as follows. Section 2 contains definitions and preliminary results used in the technical part of the paper. In Section 3, we give an algorithm for Longest Detour while Section 4 is devoted to Exact Detour. Due to space constraints, we defer some proofs, some figures, a search-to-decision reduction for Longest Detour and Exact Detour to the full version of this extended abstract. Statements whose proofs are omitted here are marked with $\star$.

2 Preliminaries

We consider graphs G to be undirected, and we denote by uv an undirected edge joining vertices $u, v \in V(G)$. A *path* is a self-avoiding walk in G; the *length* of the path is its number of edges. An (s, t)-path for $s, t \in V(G)$ is a path that starts at s and ends at t. We allow

paths to have length 0, in which case $s = t$ holds. For a vertex set $X \subseteq V(G)$, denote by $G[X]$ the subgraph induced by X.

Tree decompositions. A *tree decomposition* $\mathcal{T}$ of a graph G is a pair $(T, \{X_t\}_{t \in V(T)})$, where T is a tree in which every node t is assigned a vertex subset $X_t \subseteq V(G)$, called a bag, such that the following three conditions hold:

(T1) Every vertex of G is in at least one bag, that is, $V(G) = \bigcup_{t \in V(T)} X_t$.

(T2) For every $uv \in E(G)$, there exists a node $t \in V(T)$ such that X_t contains both u and v.

(T3) For every $u \in V(G)$, the set T_u of all nodes of T whose corresponding bags contain u, induces a connected subtree of T.

The *width* of the tree decomposition $\mathcal{T}$ is the integer $\max_{t \in V(T)} |X_t| - 1$, that is, the size of its largest bag minus 1. The *treewidth* of a graph G, denoted by $\mathrm{tw}(G)$, is the smallest possible width that a tree decomposition of G can have.

We will need the following algorithmic results about treewidth.

▶ **Proposition 1** ([6]). *There is a $2^{O(k)} \cdot n$ time algorithm that, given a graph G and an integer k, either outputs a tree decomposition of width at most $5k + 4$, or correctly decides that $\mathrm{tw}(G) > k$.*

▶ **Proposition 2** ([5, 15]). *There is an algorithm with running time $2^{O(\mathrm{tw}(G))} \cdot n^{O(1)}$ that computes a longest path between two given vertices of a given graph.*

Let us note that the running time of Proposition 2 can be improved to $2^{O(\mathrm{tw}(G))} \cdot n$ by making use of the matroid-based approach from [15].

Our main theorem is based on graph minors, and we introduce some notation here.

▶ **Definition 3.** A *topological minor model* of H in G is a pair of functions (f, p) with $f : V(H) \to V(G)$ and $p : E(H) \to 2^{E(G)}$ such that

1. f is injective, and
2. for every edge $uv \in E(H)$, the graph $G[p(uv)]$ is a path from $f(u)$ to $f(v)$ in G, and
3. for edges $e, g \in E(H)$ with $e \neq g$, the paths $G[p(e)]$ and $G[p(g)]$ intersect only in endpoints or not at all.

The graph T *induced by* the topological minor model (f, p) is the subgraph of G that consists of the union of all paths $G[p(uv)]$ over all $uv \in E(H)$. The vertices in $f(V(H))$ are the *branch vertices* of T, and $G[p(e)]$ *realizes* the edge e in T.

3 Win/Win algorithm for Longest Detour

Throughout this section, let G be an undirected graph with n vertices and m edges, let $s, t \in V(G)$ and $k \in \mathbb{N}$. We wish to decide in time $2^{O(k)} \cdot n^{O(1)}$ whether G contains an (s, t)-path of length at least $d_G(s, t) + k$. To avoid trivialities, we assume without loss of generality that G is connected and $s \neq t$ holds. Moreover, we can safely remove vertices v that are not part of any (s, t)-path.

▶ **Definition 4.** Let G be a graph and let $s, t \in V(G)$. The *(s, t)-relevant part of G* is the graph induced by all vertices contained in some (s, t)-path. We denote it by $G_{s,t}$.

The graph $G_{s,t}$ can be computed efficiently from the block-cut tree of G. Recall that the *block-cut tree* of a connected graph G is a tree where each vertex corresponds to a *block*, that is, a maximal biconnected component $B \subseteq V(G)$, or to a *cut vertex*, that is, a vertex whose removal disconnects the graph. A block B and a cut vertex v are adjacent in the block-cut tree if and only if there is a block B' such that $B \cap B' = \{v\}$.

▶ **Lemma 5** (⋆). *Let B_s and B_t denote the blocks of G that contain s and t, respectively. Furthermore, let P be the unique (B_s, B_t)-path in the block-cut tree of G. Then $G_{s,t}$ is the graph induced by the union of all blocks visited by P.*

We formulate an immediate implication of Lemma 5 that will be useful later.

▶ **Corollary 6.** *The block-cut tree of $G_{s,t}$ is a (B_s, B_t)-path.*

Hopcroft and Tarjan [18] proved that the block-cut tree of a graph can be computed in linear time using DFS. Hence we obtain an algorithm for computing $G_{s,t}$ from G.

▶ **Corollary 7.** *There is a linear-time algorithm that computes $G_{s,t}$ from G.*

3.1 The algorithm

By definition, the graph $G_{s,t}$ contains the same set of (s,t)-paths as G. Our algorithm for Longest Detour establishes a "win/win" situation as follows: We prove that, if the treewidth of $G_{s,t}$ is "sufficiently large", then (G, s, t, k) is a YES-instance of Longest Detour. Otherwise the treewidth is small, and we use a known treewidth-based dynamic programming algorithm for computing the longest (s,t)-path. Hence the algorithm builds upon the following subroutines:

1. The algorithm from Corollary 7, computing the relevant part $G_{s,t}$ of G in time $O(n+m)$.
2. Compute Treewidth(G, w) from Proposition 1, which is given G and $w \in \mathbb{N}$ as input, and either constructs a tree-decomposition T of G whose width is bounded by $5w+4$, or outputs LARGE. If the algorithm outputs LARGE, then $\mathrm{tw}(G) > w$ holds. The running time is $2^{O(w)} \cdot n$.
3. Longest Path(G, T, s, t) from Proposition 2, which is given G, s, t and additionally a tree-decomposition T of G, and outputs a longest (s,t)-path in G. The running time is $2^{O(w)} \cdot n^{O(1)}$, where w denotes the width of T.

We now formalize what we mean by "sufficiently large" treewidth.

▶ **Definition 8.** A function $f : \mathbb{N} \to \mathbb{N}$ is *detour-enforcing* if, for all $k \in \mathbb{N}$ and all graphs G with vertices s and t, the following implication holds: If $\mathrm{tw}(G_{s,t}) > f(k)$, then G contains an (s,t)-path of length at least $d_G(s,t) + k$.

▶ **Theorem 9.** *The function $f : k \mapsto 32k + 2$ is detour-enforcing.*

We defer the proof of this theorem to the next section, and instead state Algorithm D, which uses f to solve Longest Detour. Algorithm D turns out to be an FPT-algorithm already when any detour-enforcing function f is known (as long as it is polynomial-time computable), and it becomes faster when detour-enforcing f of slower growth are used.

Algorithm D (Longest Detour) *Given (G, s, t, k), this algorithm decides whether the graph G contains an (s,t)-path of length at least $d_G(s,t) + k$.*

D1 (Restrict to relevant part) Compute $G_{s,t}$ using Corollary 7.
D2 (Compute shortest path) Compute the distance d between s and t in $G_{s,t}$.
D3 (Compute tree-decomposition) Call Compute Treewidth$(G_{s,t}, f(k))$.
  D3a (Small treewidth) If the subroutine found a tree-decomposition T of width at most $f(k)$, call Longest Path$(G_{s,t}, T, s, t)$. Output YES if there is an (s,t)-path of length at least $d + k$, otherwise output NO.
  D3b (Large treewidth) If the subroutine returned LARGE, output YES.

We prove the running time and correctness of Algorithm D.

▶ **Lemma 10 (⋆).** *For every polynomial-time computable detour-enforcing function $f : \mathbb{N} \to \mathbb{N}$, Algorithm D solves* Longest Detour *in time $2^{O(f(k))} \cdot n^{O(1)}$.*

Theorem 9 and Lemma 10 imply a $2^{O(k)} \cdot n^{O(1)}$ time algorithm for Longest Detour.

3.2 Overview of the proof of Theorem 9

In our proof of Theorem 9, large subdivisions of K_4 play an important role. Intuitively speaking, a sufficiently large subdivision of K_4 in $G_{s,t}$ allows us to route some (s,t)-path through it and then exhibit a long detour within that subdivision.

▶ **Definition 11.** For $k \in \mathbb{N}$, a graph F is a $K_4^{\geq k}$ if it can be obtained by subdividing each edge of K_4 at least k times. Please note that the numbers of subdivisions do not need to agree for different edges.

We show in Section 3.3 that graphs G containing $K_4^{\geq k}$ subgraphs in $G_{s,t}$ have k-detours.

▶ **Lemma 12.** *Let G be a graph and $k \in \mathbb{N}$. If $G_{s,t}$ contains a $K_4^{\geq k}$ subgraph, then G contains an (s,t)-path of length at least $d_G(s,t) + k$.*

Since the graph obtained by subdividing each edge of K_4 exactly k times is a planar graph on $O(k)$ vertices, the Excluded Grid Theorem yields a function $f : \mathbb{N} \to \mathbb{N}$ such that every graph of treewidth at least $f(k)$ contains some $K_4^{\geq k}$ minor. Furthermore, since every $K_4^{\geq k}$ has maximum degree 3, this actually shows that G contains some $K_4^{\geq k}$ as a *subgraph*. Thus, Lemma 12 implies that f is detour-enforcing, and a proof of this lemma immediately implies a weak version of Theorem 9.

By recent improvements on the Excluded Grid Theorem [7, 10], the function f above is at most a polynomial. However, even equipped with this deep result we cannot obtain a single-exponential algorithm for Longest Detour using the approach of Lemma 10: It would require f to be linear. In fact, excluding grids is too strong a requirement for us, since every function f obtained as a corollary of the full Excluded Grid Theorem must be super-linear [32]. We circumvent the use of the Excluded Grid Theorem and prove the following lemma from more basic principles.

▶ **Lemma 13.** *For graphs G and $k \in \mathbb{N}$, if $\mathrm{tw}(G) \geq 32k+2$, then G contains a $K_4^{\geq k}$ subgraph.*

Together, Lemmas 13 and 12 imply Theorem 9.

Proof of Theorem 9. Let G and $s,t \in V(G)$ and $k \in \mathbb{N}$ be such that $\mathrm{tw}(G_{s,t}) > f(k)$. By Lemma 13, the graph $G_{s,t}$ contains a $K_4^{\geq k}$ subgraph, so Lemma 12 implies that G contains an (s,t)-path of length $d_G(s,t) + k$. This shows that f is indeed detour-enforcing. ◀

3.3 Proof of Lemma 12: Rerouting in subdivided tetrahedra

Let (G,s,t,k) be an instance for Longest Detour such that $G_{s,t}$ contains a $K_4^{\geq k}$ subgraph M. We want to prove that $G_{s,t}$ has a path of length at least $d_G(s,t) + k$; in fact, we construct the desired detour entirely in the subgraph M, for which reason we first need to route some (s,t)-path through M.

▶ **Lemma 14 (⋆).** *There are two distinct vertices $u,v \in V(M)$ and two vertex-disjoint paths P_s and P_t in G such that P_s is an (s,u)-path, P_t is a (v,t)-path, and they only intersect with $V(M)$ at u and v.*

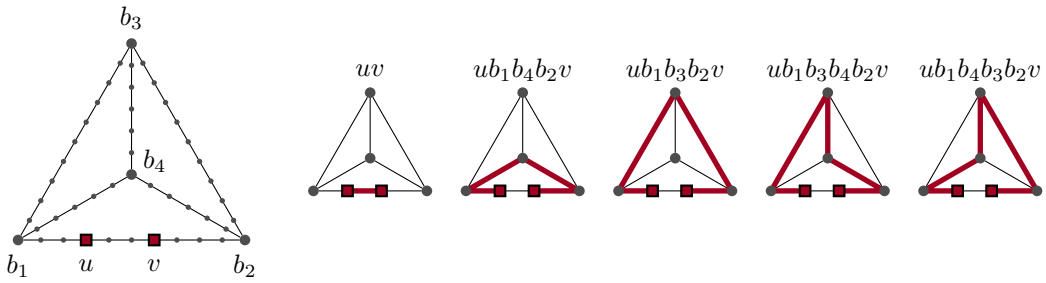

Figure 1 *Left:* One of the three possible cases for the relative positions of vertices u and v (*red squares*) in a subdivided tetrahedron $K_4^{\geq k}$ with degree-3 vertices $b_1, \ldots, b_4$ (*gray dots*) and at least $k = 5$ subdivision vertices (*small gray dots*). Here, u and v lie in the same subdivided edge. See the full version of the paper for the remaining cases. *Right:* An exhaustive list of all (u, v)-paths (*thick red*); Lemma 15 implies that the longest among them is at least k longer than the shortest one.

The proof of this lemma uses the fact that every block in the block-cut tree is biconnected. Next we show that every $K_4^{\geq k}$-graph M contains long detours.

▶ **Lemma 15.** *Let M be a $K_4^{\geq k}$-graph. For every two distinct vertices $u, v \in V(M)$, there is a (u, v)-path of length at least $d_M(u, v) + k$ in M.*

The proof idea is to distinguish cases depending on where u, v lie in M relative to each other. For each case, we can exhaustively list all (u, v)-paths (see Figure 1). We do not quite know the lengths of these paths, but we do know that each has length at least $d_M(u, v)$; moreover, each (b_i, b_j)-path in M for two distinct degree-3 vertices b_i and b_j has length at least k, since we subdivided K_4 at least k times. The claim of Lemma 15 is that one of the (u, v)-paths must have length at least $d_M(u, v)$. To prove this, we set up a linear program where the variables are $d_M(u, v)$, k, and the various path segment lengths; its infeasibility informs us that indeed a path that is longer by k must exist.

Proof Sketch for Lemma 15. Let M be a $K_4^{\geq k}$-graph, let $u, v \in V(M)$, and let $b_1, \ldots, b_4$ denote the four degree-3 vertices of M. Let P_u be a path in M that realizes an edge of K_4 and satisfies $u \in V(P_u)$, and let P_v be such a path with $v \in V(P_v)$. We distinguish three cases, one of which is depicted in Figure 1:

1. The two paths are the same, that is, $P_u = P_v$.
2. The two paths share a degree-3 vertex, that is, $|V(P_u) \cap V(P_v)| = 1$.
3. The two paths are disjoint, that is, $V(P_u) \cap V(P_v) = \emptyset$.

By the symmetries of K_4, this case distinction is exhaustive. Since K_4 has automorphisms that map any edge to any other edge, we can further assume that P_u is the path implementing the edge b_1b_2 such that P_u visits the vertices b_1, u, v, and b_2 in this order, see Figure 1.

We exhaustively list the set $\mathcal{P}$ of (u, v)-paths of M in Figure 1. Each path is uniquely specified by the sequence of the degree-3 vertices it visits. For example, consider the path $ub_1b_4b_2v$: This path consists of the four edge-disjoint segments ub_1, b_1b_4, b_4b_2, and b_2v; in the example figure, these segments have length 3, 6, 6, and 4, respectively. Given a path $P \in \mathcal{P}$, let $S(P)$ be the set of its segments between u, v, and the degree-3 vertices. For a path or a path segment s, we denote its length by $\ell(s)$.

Since M is a $K_4^{\geq k}$, every edge of K_4 is realized by a path of length at least k in M. Hence, $\ell(b_ib_j) \geq k$ holds for all i, j with $i \neq j$. Moreover, we have $\ell(b_1b_2) = \ell(b_1u) + \ell(uv) + \ell(vb_2)$ in case 1. Let $d = d_M(u, v)$; clearly $\ell(P) \geq d$ holds for all $P \in \mathcal{P}$. Our goal is to show that M has a (u, v)-path P with $\ell(P) \geq d + k$. To this end, we treat d, k, and all path

segment lengths $\ell(b_ib_j)$ for $i \neq j$ and $\ell(b_1u), \ell(uv), \ell(vb_2)$ as variables in a system of linear inequalities and establish that the claim holds if this system is unsatisfiable:

$$\ell(b_ib_j) \geq k\,, \qquad \text{for all } i,j \text{ with } i \neq j\,, \tag{1}$$

$$\ell(b_1u) + \ell(uv) + \ell(vb_2) = \ell(b_1b_2)\,, \tag{2}$$

$$\sum_{s \in S(P)} \ell(s) \geq d\,, \qquad \text{for all } P \in \mathcal{P}\,, \tag{3}$$

$$\sum_{s \in S(P)} \ell(s) \leq d + k - 1\,, \qquad \text{for all } P \in \mathcal{P}\,. \tag{4}$$

This system has eleven variables. Please note that d and k are also considered as variables in our formulation. The constraints in (1) express that M realizes each edge of K_4 by a path of length at least k. The constraints in (2) express that u and v lie on the path b_1b_2 and break it up into segments. The constraints in (3) express that no (u,v)-path is shorter than d in length, and the constraints in (4) express that every (u,v)-path has length strictly less than $d+k$. In the full version of this extended abstract, we prove that the linear program is infeasible, and so every setting for the variables that satisfies (1)–(3) must violate an inequality from (4); this means that M must contain a (u,v)-path of length at least $d+k$ in case 1. The proof is analogous when u and v are on different subdivided edges of the subdivided tetrahedron. We conclude that, no matter how u and v lie relative to each other in M, there is always a (u,v)-path that is at least k longer than a shortest one. ◀

This allows us to conclude Lemma 12 rather easily.

Proof of Lemma 12. Let $d = d_G(s,t)$ be the length of a shortest (s,t)-path in G. Let M be a $K_4^{\geq k}$ in $G_{s,t}$, and let P_s, P_t, u, and v be the objects guaranteed by Lemma 14. Let P_{uv} be a shortest (u,v)-path that only uses edges of M; its length is $d_M(u,v)$. Since the combined path P_s, P_{uv}, P_t is an (s,t)-path, its length is at least d.

Finally, Lemma 15 guarantees that there is a (u,v)-path Q_{uv} in M whose length is at least $d_M(u,v)+k$. Therefore, the length of the (s,t)-path P_s, Q_{uv}, P_t satisfies

$$\begin{aligned}\ell(P_s) + \ell(Q_{uv}) + \ell(P_t) &\geq \ell(P_s) + (d_M(u,v)+k) + \ell(P_t)\\ &= \ell(P_s) + \ell(P_{uv}) + \ell(P_t) + k \geq d + k\,.\end{aligned}$$

We constructed a path of at least length $d+k$ as required. ◀

3.4 Proof of Lemma 13: Large treewidth entails subdivided tetrahedra

To prove Lemma 13, we require some preliminaries from graph minors theory, among them a term for vertex sets that enjoy very favorable connectivity properties.

▶ **Definition 16** ([13])**.** Let G be a graph and $A, B \subseteq V(G)$. The pair (A,B) is a *separation* in G if the sets $A \setminus B$ and $B \setminus A$ are non-empty and no edge runs between them. The *order* of (A,B) is the cardinality of $A \cap B$.

For $S \subseteq V(G)$, we say that S is *linked* in G if, for every $X, Y \subseteq S$ with $|X| = |Y|$, there are $|X|$ vertex-disjoint paths between X and Y that intersect S exactly at its endpoints.

With these definitions at hand, we can adapt a result by Leaf and Seymour [25] to prove the following lemma on topological minor containment in graphs of sufficiently large treewidth. For any forest F on k vertices, with maximum degree 3, it asserts that graphs G of treewidth $\Omega(k)$ admit a separation such that one side contains F as a topological minor,

with the branch vertices of this topological minor being contained in $A \cap B$ and linked in G. We will use this lemma to complete the topological F-minor in $G[A]$ to a larger graph by using disjoint paths between vertices in $A \cap B$.

▶ **Lemma 17** ($\star$). *Let F be a forest on $k > 0$ vertices with maximum degree 3 and let G be a graph. If $\mathrm{tw}(G) \geq \frac{3}{2}k - 1$, then G has a separation (A, B) of order $|V(F)|$ such that:*

1. *There is a topological minor model (f, p) of F in $G[A]$.*
2. *For every vertex $v \in V(F)$ of degree ≤ 2, we have $f(v) \in A \cap B$.*
3. *$A \cap B$ is linked in $G[B]$.*

Building upon Lemma 17, we then prove Lemma 13 by adapting work of Raymond and Thilikos [30], who used a variant of Lemma 17 to prove the existence of k-wheel minors in graphs of treewidth $\Omega(k)$. To this end, let T and P be obtained by k-subdividing the full binary tree with 8 leaves, and the path with 8 vertices, respectively. We invoke Lemma 17 with F instantiated to the disjoint union $T \cup P$. Since F has $21k + 2$ vertices, we obtain from Lemma 17 that any graph G with $\mathrm{tw}(G) \geq 32k + 2 \geq \frac{3}{2} \cdot (21k + 2)$ has a separation (A, B) of order $|V(F)|$ that contains F in $G[A]$ and has $A \cap B$ linked in $G[B]$.

Let X_F denote the eight leaves of T, and let Y_F denote the eight non-subdivision vertices of P. Furthermore, let $X_G, Y_G \subseteq A \cap B$ denote the images of X_F and Y_F in $G[A]$ under a topological minor model guaranteed by Lemma 17. Since $A \cap B$ is linked, we can find eight disjoint paths connecting X_G and Y_G in $G[B]$. We then prove that, regardless of how these paths connect X_G and Y_G, they always complete the topological minor model of F to one of $K_4^{\geq k}$ in G. (The full version illustrates this in a figure.) Lemma 13 then follows.

Proof of Lemma 13. Let $k \in \mathbb{N}$ and let G be a graph with $\mathrm{tw}(G) \geq 32k + 2$. As before, let T denote the full binary tree with 8 leaves, with root r, after each edge was subdivided k times. Let P denote the path on 8 vertices after subdividing each edge k times.

We write $X_F = \{x_1, \ldots, x_8\}$ for the leaves of T, and we write $Y_F = \{y_1, \ldots, y_8\}$ for the vertices in P that were not obtained as subdivision vertices. Finally, we write F for the disjoint union $T \cup P$ and consider $X_F, Y_F \subseteq V(F)$. Note that $|V(F)| = 21k + 2$ and that the degree of all vertices in $X_F \cup Y_F$ is bounded by 2.

By Lemma 17, there is a separation (A, B) in G of order $|V(F)|$ such that $A \cap B$ is linked, and there is a topological minor model (f, p) of F in $G[A]$ with $f(X_F \cup Y_F) \subseteq A \cap B$. We write $X_G = \{f(v) \mid v \in X_F\}$ and $Y_G = \{f(v) \mid v \in Y_F\}$. In the following, we aim at completing the subgraph induced by (f, p) in G to a $K_4^{\geq k}$ subgraph.

Since $A \cap B$ is linked in $G[B]$, there are vertex-disjoint paths $L_1, \ldots, L_8$ between X_G and Y_G in $G[B]$ that avoid $A \cap B$ except at their endpoints. For $i \in [8]$, denote the endpoints of L_i in X_G and Y_G by s_i and t_i, respectively. Assume without limitation of generality (by reordering paths) that $t_i = f(y_i)$ holds for all $i \in [8]$. Furthermore, for $x \in X_G$, write $\sigma(x)$ for the vertex of Y_G that x is connected to via its path among $L_1, \ldots, L_8$.

Let S denote the image of T under (f, p), which is a tree; let $\mathit{root}(S) = f(r)$. Write S_1, S_2 for the two subtrees of S rooted at the children of $\mathit{root}(S)$. Let $\mathit{lca}(s_1, s_8)$ denote the lowest common ancestor of s_1 and s_8 in S. We distinguish two cases:

Case 1: We have $\mathit{lca}(s_1, s_8) \neq \mathit{root}(S)$. That is, s_1 and s_8 are both in S_1 or both in S_2. Assume without limitation of generality that $s_1, s_8 \in V(S_1)$, as the argument proceeds symmetrically otherwise. Let x and x' be two distinct leaves of S_2. Then we find a $K_4^{\geq k}$ in G by defining branch vertices $w = \mathit{lca}(s_1, s_8)$, $p = \mathit{lca}(x, x')$, $a = \sigma(x)$, and $b = \sigma(x')$. Note that $p \notin \{x, x'\}$ and that the four vertices are distinct.

We realize the edge pw along the (p, w)-path present in S, and ab along the (a, b)-path present in P. We realize pa by concatenating the (p, x)-path in S and the (x, a)-path in

$G[B]$, and we realize pb likewise. To realize wa, we proceed as follows: If a precedes b in the order on P, then concatenate the (w, s_1)-path in S with L_1 and the (y_1, a)-path in P. If b precedes a, then concatenate the (w, s_8)-path in S with L_8 and the (y_8, a)-path in P. Realize wb symmetrically. Then every edge between pairs in $\{w, p, a, b\}$ is realized, and it is so by a path of length at least k. This gives a topological minor model of $K_4^{\geq k}$ in G.

Case 2: We have $lca(s_1, s_8) = root(S)$. That is, s_1 and s_8 are in different subtrees S_1 and S_2. Let R be a subtree of height 2 in S that is disjoint from the (s_1, s_8)-path in S. It is easy to verify that such a subtree indeed exists; denote its root by p, its leaves by x, x', and its parent in S by w. Furthermore, define $a = \sigma(x)$ and $b = \sigma(x')$. We declare $\{w, p, a, b\}$ as branch vertices and connect them as in the previous case.

In both cases, the constructed topological minor model shows that G contains a $K_4^{\geq k}$ subgraph. This proves the lemma. ◀

4 Dynamic programming algorithm for exact detour

We devise an algorithm for Exact Detour using a reduction to Exact Path, the problem that is given (G, s, t, k) to determine whether there is an (s, t)-path of length exactly k.

▶ **Theorem 18 (⋆).** Exact Detour *is fixed-parameter tractable. In particular, it has a bounded-error randomized algorithm with running time* $2.746^k \operatorname{poly}(n)$*, and a deterministic algorithm with running time* $6.745^k \operatorname{poly}(n)$*.*

Before we state the algorithm, let us introduce some notation. Let $s, t \in V(G)$. For any $x \in V(G)$, we abbreviate $d_G(s, x)$, that is, the distance from s to x in G, with $d(x)$, and we let the i-th layer of G be the set of vertices x with $d(x) = i$. For $u, v \in V(G)$ with $d(u) < d(v)$, we write $G_{[u,v]}$ for the graph $G[X]$ induced by the vertex set X that contains u, v, and all vertices x with $d(u) < d(x) < d(v)$. We also write $G_{[u,\infty)}$ for the graph $G[X]$ induced by the vertex set X that contains u and all vertices x with $d(u) < d(x)$. These graphs can be computed in linear time using breadth-first search starting at s. We now describe an algorithm for Exact Detour that makes queries to an oracle for Exact Path.

The general idea is as follows. Let G be an undirected graph, and consider an (s, t)-path P of length $d + k$ where $d = d_G(s, t)$, and let x be a token that travels along this path from s to t. As the token advances one step in the path, the number $d(x)$ can be incremented, decremented, or stay the same. When x moves from s to t, we must increment $d(x)$ at least d times, can decrement it at most $k/2$ times, and keep it unchanged at most k times; the reason is that the path must reach t but must use exactly k edges more than a shortest path. The crucial observation is that there are at most k different layers whose intersection with the path P contains more than one vertex. The idea for the algorithm is to guess the layers with more than one vertex and run an algorithm for Exact Path on them.

Algorithm A (Exact Detour) *Given (G, s, t, k), this algorithm decides whether the graph G contains an (s, t)-path of length exactly $d_G(s, t) + k$.*

A1 (Initialize table) For each $x \in V(G)$ with $d(x) \leq d(t)$, set $T[x] = \emptyset$.
When the algorithm halts, every entry $T[x]$ of the table is meant to satisfy the following property Q_x: For each integer ℓ with $d(t) - d(x) \leq \ell \leq d(t) - d(x) + k$, the set $T[x]$ contains ℓ if and only if $G_{[x,\infty)}$ contains an (x, t)-path of length ℓ.

A2 (Compute entries for the last $k+1$ layers) For each $x \in V(G)$ with $d(t) - k \leq d(x) \leq d(t)$, let $T[x]$ be the set of all integers ℓ with $\ell \in \{0, \ldots, 2k\}$ such that there is an (x, t)-path of length ℓ in $G_{[x,\infty)}$ (that is, call Exact Path $(G_{[x,\infty)}, x, t, \ell)$).
When this step finishes, all vertices x in the last $k + 1$ layers satisfy property Q_x.

A3 (Inductively fill in earlier layers) For each d from $d(t)-k-1$ down to 0, for each x with $d(x)=d$, and for each y with $d(x)<d(y)\leq d(x)+k+1$, we do the following:

A3a Compute the set L of all $\ell' \in \{0,\ldots,2k+1\}$ such that there is an (x,y)-path of length ℓ' in $G_{[x,y]}$ (that is, call Exact Path $(G_{[x,y]},x,y,\ell')$).

A3b Set $T[x] := T[x] \cup (L + T[y])$.

We will show that, when all vertices of a layer d have been considered, all vertices x in the layers d and higher satisfy property Q_x.

A4 Accept if and only if $(d_G(s,t)+k) \in T[s]$ holds.

▶ **Lemma 19.** *Algorithm A is a polynomial-time Turing reduction from* Exact Detour *to* Exact Path*; on instances with parameter k, all queries have parameter at most $2k+1$.*

Proof. The running time of A is polynomially bounded since breadth-first search can be used to discover all partial graphs $G_{[x,y]}$ and $G_{[x,\infty)}$, and we loop at most over every pair of vertices in A2 and A3. For the parameter bound, note that the queries in A2 and A3 are for paths of length at most $2k$ and $2k+1$, respectively. It remains to prove the correctness.

We execute algorithm A on an instance (G,s,t,k). For the correctness, it suffices to prove that property Q_s holds at the end of the execution: Note that ℓ with $\ell = d_G(s,t)+k$ lies in the interval $[d(t)-d(s), d(t)-d(s)+k]$ since $d(s)=0$ and $d(t)=d_G(s,t)$ holds. Moreover, we have $G_{[s,\infty)}=G$. Thus Q_s guarantees that $\ell \in T[s]$ holds if and only if G contains an (s,t)-path of length ℓ, which by step A4 implies that A accepts if and only if (G,s,t,k) is a yes-instance of Exact Detour. Therefore it remains to prove that Q_s holds at the end of the execution of A. We do so using the following claim.

Claim: For all x with $0 \leq d(x) \leq d(t)$, property Q_x holds forever after the entry $T[x]$ is written to for the last time.

We prove this claim by induction on $d(x)$. For the base case, let x be a vertex with $d(x) \geq d(t)-k$. The entry $T[x]$ is only written to in step A2. To prove that Q_x holds after A2, let ℓ be an integer with $d(t)-d(x) \leq \ell \leq d(t)-d(x)+k$. Note that $d(t)-d(x) \geq 0$ and $d(t)-d(x)+k \leq d(t)-(d(t)-k)+k \leq 2k$ holds, and so step A2 adds ℓ to $T[x]$ if and only if the graph $G_{[x,\infty)}$ contains an (x,t)-path of length ℓ. Therefore, Q_x holds forever after A2 has been executed.

For the induction step, let x be a vertex with $d(x) < d(t)-k$. By the induction hypothesis, Q_y holds for all y with $d(y) > d(x)$. The entry $T[x]$ is only written to in step A3b, and when it is first written to, the outer d-loop in A3 has fully processed all layers larger than $d(x)$. Thus already when $T[x]$ is written to for the first time, Q_y holds for all y with $d(y) > d(x)$. Let T be the table right after A3b writes to $T[x]$ for the last time. It remains to prove that $T[x]$ satisfies Q_x. Let ℓ be an integer with $d(t)-d(x) \leq \ell \leq d(t)-d(x)+k$.

Claim: There is an (x,t)-path of length ℓ if and only if $T[x]$ contains ℓ.

For the forward direction, let P be an (x,t)-path in $G_{[x,\infty)}$ of length exactly ℓ. There are exactly ℓ vertices $u \in V(P) \setminus \{x\}$. Moreover, since every edge $uv \in E(P)$ satisfies $|d(u)-d(v)| \leq 1$, every $d \in \{d(x)+1,\ldots,d(t)\}$ must have some vertex $u \in V(P)$ with $d(u)=d$. Since $\ell \leq d(t)-d(x)+k$, there are at most k distinct d where more than one vertex $u \in V(P)$ satisfies $d(u)=d$. By the pigeon hole principle, there exists an integer d in the $(k+1)$-element set $\{d(x)+1,\ldots,d(x)+k+1\}$ such that there is exactly one vertex $y \in V(P)$ with $d(y)=d$.

Let $P_{[x,y]}$ be the subpath of P between x and y, and let ℓ' be its length. By construction, $P_{[x,y]}$ is an (x,y)-path in $G_{[x,y]}$. Moreover, we have $\ell' \leq \ell - (d(t)-d(y))$ since $V(P)\setminus\{x\}$ contains ℓ vertices u, at least $d(t)-d(y)$ of which satisfy $d(u) > d(y)$. By choice of ℓ and y, we obtain $\ell' \leq d(y)-d(x)+k \leq 2k+1$. For this setting of y and ℓ', step A3a detects the

path $P_{[x,y]}$ and ℓ' is added to the set L. The second piece $P_{[y,\infty]}$ of the path P is a (y,t)-path in $G_{[y,\infty]}$ of some length ℓ'' between $d(t)-d(y)$ and $d(t)-d(y)+k$; since Q_y holds when A3b is executed for x and y, the set $T[y]$ contains ℓ'', and so $\ell = \ell' + \ell''$ gets added to $T[x]$. Since elements never get removed from $T[x]$, the forward direction of the claim holds.

For the backward direction of the claim, assume that $T[x]$ contains ℓ. This means that ℓ is added in step A3b during the execution of the algorithm; in particular, consider the variables $y \in V(G)$, $\ell' \in L$, and $\ell'' \in T[y]$ when $\ell = \ell' + \ell''$ is added to $T[x]$. By the induction hypothesis, $\ell'' \in T[y]$ implies that there is a (y,t)-path in $G_{[y,\infty)}$ of length ℓ''. Moreover, ℓ' was set in A3a in such a way that there is an (x,y)-path of length ℓ' in the graph $G_{[x,y]}$. Combined, these two paths yield a single (x,t)-path in $G_{[x,\infty)}$ of length ℓ. The backward direction of the claim follows. ◀

The randomized algorithm of Björklund et al. [3] is for a variant of Exact Path where the terminal vertices s and t are not given, that is, any path of length exactly k yields a YES-instance. Their algorithm applies to our problem as well, with the same running time. We sketch an argument for this observation here. Recall that the idea is to reduce the problem to checking whether a certain polynomial is identically zero – this polynomial is defined by summing over all possible labelled walks of length k (see [12, Sec. 10.4.3]). We modify the polynomial by adding two leaf-edges, one incident to s and one to t, and restricting our attention only to $(k+2)$-walks that contain these two edges. The required information for such walks can still be computed efficiently as before. The crux of the proof is that walks that are not paths cancel out over a field of characteristic two; this argument works by a local re-orientation of segments of the walk – an operation that does not change the vertices of the walk and must therefore keep s and t fixed. The graph G contains a k-path if and only if the polynomial is not identically zero; this property remains true in our case. The rest of the argument goes through as before, so the algorithm of Björklund et al. applies to Exact Path with no significant loss in the running time.

The deterministic algorithm of Zehavi [34] also does not expect the terminal vertices to be given, but this algorithm works for the weighted version of the problem. In the weighted k-path problem, we are given a graph G, weights w_e on each edge, a number k, and a number W, and the question is whether there is a path of length exactly k such that the sum of all edge weights along the path is at most W. We observe the following simple reduction from Exact Path (with terminal vertices s and t) to the weighted k-path problem (without terminal vertices): Every edge gets assigned the same edge weight 2, except for the new leaf-edges at s and t, which get edge weight 1. Now every path with exactly $k+2$ edges has weight at most $W = 2k+2$ if and only if the first and the last edges of the path are the leaf-edges we added. Due to this reduction, Zehavi's algorithm applies to Exact Path with no significant loss in the running time.

Theorem 18 follows from Algorithm A by using either the algorithm of Björklund et al. [3] or Zehavi [34] as the oracle. We remark that Theorem 18 and Algorithm A apply to directed graphs as well, in which case an algorithm for Exact Path in directed graphs needs to be used (color coding yields the fastest randomized algorithm [2], while Zehavi's deterministic algorithm also applies to directed graphs).

Open problem. We conclude with an open problem: what is the complexity of Longest Detour in directed graphs? Neither directed treewidth nor cylindrical grid minors [21] seem to help. Can one even find an (s,t)-path of length $\geq d_G(s,t)+1$ in polynomial time?

Acknowledgments. We thank Daniel Lokshtanov, Meirav Zehavi, Petr Golovach, Saket Saurabh, Stephan Kreutzer, and Tobias Mömke for helpful discussions and answers.

Abstract

We pursue a study of the Generalized Demand Matching problem, a common generalization of the b-Matching and Knapsack problems. Here, we are given a graph with vertex capacities, edge profits, and asymmetric demands on the edges. The goal is to find a maximum-profit subset of edges so the demands of chosen edges do not violate the vertex capacities. This problem is **APX**-hard and constant-factor approximations are already known.

Our main results fall into two categories. First, using iterated relaxation and various filtering strategies, we show with an efficient rounding algorithm that if an additional matroid structure $\mathcal{M}$ is given and we further only allow sets $F \subseteq E$ that are independent in $\mathcal{M}$, the natural LP relaxation has an integrality gap of at most $\frac{25}{3} \approx 8.333$. This can be further improved in various special cases, for example we improve over the 15-approximation for the previously-studied Coupled Placement problem [Korupolu et al. 2014] by giving a 7-approximation.

Using similar techniques, we show the problem of computing a minimum-cost base in $\mathcal{M}$ satisfying vertex capacities admits a $(1, 3)$-bicriteria approximation: the cost is at most the optimum and the capacities are violated by a factor of at most 3. This improves over the previous $(1, 4)$-approximation in the special case that $\mathcal{M}$ is the graphic matroid over the given graph [Fukanaga and Nagamochi, 2009].

Second, we show Demand Matching admits a polynomial-time approximation scheme in graphs that exclude a fixed minor. If all demands are polynomially-bounded integers, this is somewhat easy using dynamic programming in bounded-treewidth graphs. Our main technical contribution is a sparsification lemma that allows us to scale the demands of some items to be used in a more intricate dynamic programming algorithm, followed by some randomized rounding to filter our scaled-demand solution to one whose original demands satisfy all constraints.

1 Introduction

Many difficult combinatorial optimization problems involve resource allocation. Typically, we have a collection of resources, each with finite supply or **capacity**. Additionally there are tasks to be accomplished, each with certain requirements or **demands** for various resources. Frequently the goal is to select a maximum value set of tasks and allocate the required amount of resources to each task while ensuring we have enough resources to accomplish the chosen tasks. This is a very well-studied paradigm: classic problems include Knapsack, Maximum Matching, and Maximum Independent Set, and more recently-studied problems include Unsplittable Flow [1] and Coupled Placement [9]. In general, we cannot hope to get non-trivial approximation algorithms for these problems. Even the simple setting of Maximum Independent Set is inapproximable [8, 18], so research frequently focuses on well-structured special cases.

Our primary focus is when each task requires at most two different resources. Formally, in Generalized Demand Matching (GDM) we are given a graph $G = (V, E)$ with, perhaps, parallel edges. The vertices should be thought of as resources and the tasks as edges. Each $v \in V$ has a capacity $b_v \geq 0$ and each $uv \in E$ has demands $d_{u,e}, d_{v,e} \geq 0$ and a value $p_{uv} \geq 0$. A subset $M \subseteq E$ is *feasible* if $d_v(\delta(v) \cap M) \leq b_v$ for each $v \in V$ (we use $d_v(S)$ as shorthand for $\sum_{e \in S} d_{v,e}$ when $S \subseteq \delta(v)$). We note that the simpler term Demand Matching (DM) is used when $d_{u,e} = d_{v,e}$ for each edge $e = uv$ (e.g. [15, 17]).

DM is well-studied from the perspective of approximation algorithms. It is fairly easy to get constant-factor approximations and some work has been done refining these constants. Moreover the integrality gap of a natural LP relaxation is also known to be no worse than a constant (see the related work section). On the other hand, DM is **APX**-hard [15].

Our main results come in two flavours. First, we look to a generalization we call Matroidal Demand Matching ($\mathsf{GDM_M}$). Here, we are given the same input as in GDM but there is also a matroid $\mathcal{M} = (E, \mathcal{I})$ over the edges E with independence system $\mathcal{I} \subseteq 2^E$ that further restricts feasibility of a solution. A set $F \subseteq E$ is feasible if it is feasible as a solution to the underlying GDM problem and also $F \in \mathcal{I}$. We assume $\mathcal{M}$ is given by an efficient independence oracle. Our algorithms will run in time that is polynomial in the size of G and the maximum running time of the independence oracle.

As a special case, $\mathsf{GDM_M}$ includes the previously-studied Coupled Placement problem. In Coupled Placement, we are given a bipartite graph $G = (V, E)$ with vertex capacities. The tasks are not individual edges, rather for each task j and each $e = uv \in E$ we have demands $d^j_{u,e}, d^j_{v,e}$ placed on the respective endpoints u, v for placing j on edge e. Finally, each task j has a profit p_j and the goal is to select a maximum-profit subset of tasks j and, for each chosen task j, assign j to an edge of G so vertex capacities are not violated. We note that an edge may receive many different tasks. This can be viewed as an instance of $\mathsf{GDM_M}$ by creating parallel copies of each edge $e \in E$, one for each task j with corresponding demand values and profit for j and letting $\mathcal{M}$ be the partition matroid ensuring we take at most one edge corresponding to any task.

For another interesting case, consider an instance where, in addition to tasks requiring resources from a shared pool, each also needs to be connected to a nearby power outlet. We can model such an instance by letting $\mathcal{M}$ be a transversal matroid over a bipartite graph where tasks form one side, outlets form the other side, and an edge indicates the edge can reach the outlet.

In fact $\mathsf{GDM_M}$ can be viewed as a packing problem with a particular submodular objective function. These are studied in [2] so the problem is not new; our results are improved

approximations. Our techniques also apply to give bicriteria approximations for the variant of GDM_M where we must pack a cheap base of the matroid while obeying congestion bounds. In the special case where $\mathcal{M}$ is the graphic matroid over G itself (i.e. the Minimum Bounded-Congestion Spanning Tree problem), we get an improved bicriteria approximation.

Second, we study GDM in special graph classes. In particular, we demonstrate a PTAS in families of graphs that exclude a fixed minor. This is complemented by showing that even DM is strongly NP-hard in simple planar graphs, thereby ruling out a fully-polynomial time approximation scheme (FPTAS) in simple planar graphs unless $\mathbf{P} = \mathbf{NP}$.

1.1 Statements of Results and Techniques

We first establish some notation. For a matroid $\mathcal{M} = (E, \mathcal{I})$, we let $r_\mathcal{M} : 2^E \to \mathbb{Z}_{\geq 0}$ be the rank function for $\mathcal{M}$. We omit the subscript $\mathcal{M}$ if the matroid is clear from the context. For $v \in V$ we let $\delta(v)$ be all edges having v as one endpoint; for $F \subseteq E$ we let $\delta_F(v)$ denote $\delta(v) \cap F$. For a vector of values x indexed by a set S, we let $x(A) = \sum_{i \in A} x_i$ for any $A \subseteq S$. A **polynomial-time approximation scheme** (PTAS) is an approximation algorithm that accepts an additional parameter $\epsilon > 0$. It finds a $(1+\epsilon)$-approximation in time $O(n^{f(\epsilon)})$ for some function f (where n is the size of the input apart from ϵ), so the running time is polynomial for any constant $\epsilon > 0$. An FPTAS is a PTAS with running time being polynomial in $\frac{1}{\epsilon}$ and n.

We say an instance of GDM has a **consistent ordering of edges** if E can be ordered such that the restriction of this ordering to each set $\delta(v)$ has these edges $e \in E$ appear in nondecreasing order of demands $d_{v,e}$. For example, DM itself has a consistent ordering of demands, just sort edges by their demand values. This more general case was studied in [13]. We say the instance is **conflict-free** if for any $e, f \in E$ we have that $\{e, f\}$ does not violate the capacity of any vertex.

In the first half of our paper, we mostly study the following linear-programming relaxation of GDM_M. Here, $r : 2^E \to \mathbb{Z}$ is the rank function for $\mathcal{M}$.

$$\max : \left\{ \sum_{e \in E} p_e x_e : \sum_{e \in \delta(v)} d_{v,e} x_e \leq b_v \ \forall v \in V, \quad x(A) \leq r(A) \ \ \forall A \subseteq E, \quad x \geq 0 \right\} \quad \textbf{(LP-M)}$$

Note $x(\{e\}) \leq 1$ is enforced for each $e \in E$ as $r(\{e\}) \leq 1$. It is well-known that the constraints can be separated in polynomial time when given an efficient independence oracle for $\mathcal{M}$, so we can find an extreme point optimum solution to (**LP-M**) in polynomial time.

Throughout, we assume each edge is feasible by itself. This is without loss of generality: an edge that is infeasible by itself can be discarded[1]. We first prove the following.

▶ **Theorem 1.** *Let* $\mathrm{OPT}(\textbf{LP-M})$ *denote the optimum solution value of* (**LP-M**). *If* $d_{v,e} \leq b_v$ *for each* $v \in V, e \in \delta(v)$ *then we can find, in polynomial time, a feasible solution* $\mathsf{M} \subseteq E$ *such that* $\mathrm{OPT}(\textbf{LP-M})/p(\mathsf{M})$ *(and, thus, the integrality gap) is at most:*

- $\frac{25}{3}$ *in general graphs*
- 7 *in bipartite graphs*
- 5 *if the instance has a consistent ordering of edges*
- 4 *if the instance is conflict-free*
- $1 + O(\epsilon^{1/3})$ *if* $d_{v,e} \leq \epsilon \cdot b_v$ *for each* $v \in V, e \in \delta(v)$ *(i.e. edges are* ϵ***-small)***

[1] This is a standard step when studying packing LPs, even the natural Knapsack LP relaxation has an unbounded integrality gap if we consider items that do not fit by themselves.

These bounds also apply to graphs with parallel edges, so we get a 7-approximation for Coupled Placement, which beats the previously-stated 15-approximation in [9].

We prove all bounds in Theorem 1 using the same framework: iterated relaxation to find some $\mathsf{M}' \in \mathcal{I}$ with $p(\mathsf{M}') \geq OPT_{LP}$ that may violate some capacities by a controlled amount, followed by various strategies to pare the solution down to a feasible solution. We note constant-factor approximations for GDM_M were already implicit in [2], the bounds in Theorem 1 improve over their bounds and are relative to (**LP-M**) whereas [2] involves multilinear extensions of submodular functions.

Our techniques can also be used to address a variant of GDM_M. The input is the same, except we are required to select a base of $\mathcal{M}$. The goal is to find a minimum-value base satisfying the vertex capacities. More formally, let Minimum Bounded-Congestion Matroid Basis be given the same way as in GDM_M, except the goal is to find a minimum-cost base B of $\mathcal{M}$ satisfying the vertex capacities (i.e. the cheapest base that is a solution to the GDM_M problem).

When all demands are 1, this is the Minimum Bounded-Degree Matroid Basis problem which, itself, contains the famous Minimum Bounded-Degree Spanning Tree problem. As an important special case, we let Minimum Bounded-Congestion Spanning Tree denote the problem when $k = 2$ with arbitrary demands where $\mathcal{M}$ is the graphic matroid over G. Even determining if there is a feasible solution is **NP**-hard, so we settle with approximations that may violate the capacities a bit. Consider the following LP relaxation, which we write when G can even be a hypergraph.

$$\min : \left\{ \sum_{e \in E} p_e x_e : \sum_{e \in \delta(v)} d_{v,e} x_e \leq b_v \ \forall v \in V, \quad x(A) \leq r(A) \ \forall A \subseteq E, \quad x(E) = r(E), \quad x \geq 0 \right\} \tag{\textbf{LP-B}}$$

As a side effect of how we prove Theorem 1, we also prove the following.

▶ **Corollary 2.** *If G is a hypergraph where each edge has size at most k, then in polynomial time we can either determine there is no integral point in* (**LP-B**) *or we can find a base* B *of* $\mathcal{M}$ *such that* $p(\mathsf{B}) \leq \mathrm{OPT}(\textbf{LP-B})$ *and* $d_v(\delta_\mathsf{B}(v)) \leq b_u + k \cdot \max_{e \in \delta(v)} d_{v,e}$ *for each* $v \in V$.

▶ **Theorem 3.** *There is a* $(1, 1 + k)$*-bicriteria approximation for* Minimum Bounded-Congestion Matroid Basis.

In particular, there is a $(1, 3)$-bicriteria approximation for Minimum Bounded-Congestion Spanning Tree, beating the previous best $(1, 4)$-bicriteria approximation [5]. Theorem 3 matches the bound in [9] for the special case of Coupled Placement in k-partite hypergraphs, but in a more general setting.

One could also ask if we can generalize Theorem 1 to hypergraphs. An $O(k)$-approximation is already known [2] and the integrality gap of (**LP-M**) is $\Omega(k)$ even without matroid constraints, so we could not hope for an asymptotically better approximation. We remind the reader that our focus in GDM_M is improved constants in the case of graphs ($k = 2$).

Our second class of results are quite easy to state. We study GDM in families of graphs that exclude a fixed minor. It is easy to see GDM is strongly **NP**-hard in planar graphs if one allows parallel edges as it is even strongly **NP**-hard with just two vertices, *e.g.* see [6, 11]. We show the presence of parallel edges is not the only obstacle to getting an FPTAS for GDM (or even DM) in planar graphs.

▶ **Theorem 4.** DM *is NP-hard in simple, bipartite planar graphs even if all demands, capacities, values, and vertex degrees are integers bounded by a constant.*

We then present our main result in this vein, which gives a PTAS for GDM in planar graphs among other graph classes.

▶ **Theorem 5.** GDM *admits a PTAS in families of graphs that exclude a fixed minor.*

This is obtained through the usual reduction to bounded-treewidth graphs [4]. We would like to scale demands to be polynomially-bounded integers, as then it is easy to solve the problem using dynamic programming over the tree decomposition. But packing problems are too fragile for scaling demands naively: an infeasible solution may be regarded as feasible in the scaled instance.

We circumvent this issue with a sparsification lemma showing there is a near-optimal solution M' where, for each vertex v, after packing a constant number of edges across v the remaining edges in $\delta_{\mathsf{M}'}(v)$ have very small demand compared with even the residual capacity. Our dynamic programming algorithm then guesses these large edges in each bag of the tree decomposition and packs the remaining edges according to scaled values. The resulting solution may be slightly infeasible, but the blame rests on our scaling of *small* edges and certain pruning techniques can be used to whittle this solution down to a feasible solution with little loss in the profit.

1.2 Related Work

DM (the case with symmetric demands) is well-studied. Shepherd and Vetta initially give a 3.264-approximation in general graphs and a 2.764-approximation in bipartite graphs [15]. These are all with respect to the natural LP relaxation, namely (**LP-M**) with matroid constraints replaced by $x_e \leq 1, \forall e \in E$. They also prove that DM is **APX**-hard even in bipartite graphs and give an FPTAS in the case G is a tree.

Parekh [13] improved the integrality gap bound for general graphs to 3 in cases of GDM that have a consistent ordering of edges. Singh and Wu improve the gap in bipartite graphs to 2.709 [17]. The lower bound on the integrality gap for general graphs is 3 [15], so the bound in [13] is tight. In bipartite graphs, the gap is at least 2.699 [17].

Bansal, Korula, Nagarajan, and Srinivasan study the generalization of GDM to hypergraphs [2]. They show if each edge has at most k endpoints, the integrality gap of the natural LP relaxation is $\Theta(k)$. They also prove that a slight strengthening of this LP has a gap of at most $(e + o(1)) \cdot k$. Even more relevant to our results is that they prove if the value function over the edges is submodular, then rounding a relaxation based on the multilinear extension of submodular functions yields a $\left(\frac{e^2}{e-1} + o(1)\right) \cdot k$-approximation. For $k = 2$, this immediately gives a constant-factor approximation for GDM_M by considering the submodular objective function $f : 2^E \to \mathbb{R}$ given by $f(S) = \max\{p(S') : S' \subseteq S, S' \in \mathcal{I}\}$.

They briefly comment on the case $k = 2$ in their work and say that even optimizations to their analysis for this special case yields only a 11.6-approximation for DM (i.e. without a matroid constraint). So our $\frac{25}{3}$-approximation for GDM_M is an improvement over their work. They also study the case where $d_{v,e} \leq \epsilon \cdot b_v$ for each $v \in V$ and each hyperedge $e \in \delta(v)$ and present an algorithm for GDM with submodular objective functions whose approximation guarantee tends to $\frac{4e^2}{e-1}$ as $\epsilon \to 0$ (with k fixed).

As noted earlier, our results yield improvements for two specific problems. First, our 7-approximation for GDM_M in bipartite graphs improves over the 15-approximation for Coupled Placement [9]. The generalization of Coupled Placement to k-partite hypergraphs is also studied in [9] where they obtain an $O(k^3)$-approximation, but this was already inferior to the $O(k)$-approximation in [2] when viewing it as a submodular optimization problem with packing constraints.

Second, our work also applies to the Minimum-Congestion Spanning Tree problem, defined earlier. Determining if there is even a feasible solution is **NP**-hard as this models the Hamiltonian Path problem. A famous result of Singh and Lau shows if all demands are 1 (so we want to bound the degrees of the vertices) then we can find a spanning tree with cost at most the optimum cost (if there is any solution) that violates the degree bounds additively by $+1$ [16]. In the case of arbitrary demands, the best approximation so far is a $(1, 4)$-approximation [5]: it finds a spanning tree whose cost is at most the optimal cost and violates the capacities by a factor of at most 4. It is known that obtaining a $(1, c)$-approximation is **NP**-hard for any $c < 2$ [7].

2 Approximation Algorithm for Demand Matching Problem

Here we present approximation algorithms for GDM_M and prove Theorem 1 and Corollary 2. Our algorithm consists of two phases: the iterative relaxation phase and the pruning phase. The first finds a set $\mathsf{M}' \in \mathcal{I}$ with $p(\mathsf{M}') \geq \mathrm{OPT}(\textbf{LP-M})$ that places demand at most $b_v + 2 \cdot \max_{e \in \delta_{\mathsf{M}'}(v)} d_{v,e}$ on each $v \in V$. The second prunes M' to a feasible solution, different pruning strategies are employed to prove the various bounds in Theorem 1.

2.1 Iterative Relaxation Phase

This part is presented for the more general case of hypergraphs where each edge has at most k endpoints. Our GDM_M results in Theorem 1 pertain to $k = 2$, but we will use properties of this phase in our proof of Corollary 2. The algorithm starts with (**LP-M**) and iteratively removes edge variables and vertex capacities.

We use the following notation. For some $W \subseteq V, F \subseteq E$, a matroid $\mathcal{M}'$ with ground set F, and values $b'_v, v \in W$ we let $\textbf{LP-M}[W, F, \mathcal{M}', b']$ denote the LP relaxation we get from (**LP-M**) over the graph (V, F) with matroid $\mathcal{M}'$ where we drop capacity constraints for $v \in V - W$ and use capacities b'_v for $v \in W$.

Note that the relevant graph for $\textbf{LP-M}[W, F, \mathcal{M}', b']$ still has all vertices V, it is just that some of the capacity constraints are dropped. Also, for a matroid $\mathcal{M}'$ and an edge $e \in F$ we let $\mathcal{M}' - e$ be the matroid obtained by deleting e and, if $\{e\}$ is independent in $\mathcal{M}'$, we let $\mathcal{M}'/e$ be the matroid obtained by contracting e (i.e. a set A is independent in $\mathcal{M}'/e$ if and only if $A \cup \{e\}$ is independent in $\mathcal{M}'$).

Algorithm 1 describes the steps in the iterated relaxation phase. Correct execution and termination are consequences of the following two lemmas. Their proofs are standard for iterated techniques and are deferred to the full version.

▶ **Lemma 6.** *Throughout the execution of the algorithm, whenever $\mathcal{M}'$ is contracted by e we have $\{e\}$ is independent (i.e. e is not a loop) in $\mathcal{M}'$.*

▶ **Lemma 7.** *The algorithm terminates in polynomial time and the returned set M' is an independent set in $\mathcal{M}$ with $p(\mathsf{M}') \geq \mathrm{OPT}(\textbf{LP-M})$. Furthermore, if at any point $W' = \emptyset$ then the corresponding extreme point solution x^* is integral.*

The last statement in the lemma emphasizes the last case in the body of the loop cannot be encountered if $W' = \emptyset$.

Next, we prove M' is a feasible demand matching with respect to capacities $b_v + k \cdot \max_{e \in \delta(v)} d_{e,v}$ for each $v \in V$ by utilizing the following claim.

▶ **Claim 8.** *In any iteration, if $0 < x^*_e < 1$ for each $e \in F$ then $|\delta_F(v)| \leq x^*(\delta_F(v)) + k$ for some $v \in W$.*

Algorithm 1 Iterated Relaxation Procedure for $\mathsf{GDM}_{\mathsf{M}}$.

$W \leftarrow V, F \leftarrow E, \mathcal{M}' \leftarrow \mathcal{M}$
$b'_v \leftarrow b_v$ for each $v \in V$
$\mathsf{M}' \leftarrow \emptyset$
while $F \neq \emptyset$ **do**
  solve **LP-M**$[W, F, \mathcal{M}', b']$ to get an optimum extreme point x^*
  if $x^*_e = 0$ for some $e \in F$ **then**
    $F \leftarrow F - \{e\}$
    $\mathcal{M}' \leftarrow \mathcal{M}' - e$ ▷ fix x^*_e to 0 from now on
  else if $x^*_e = 1$ for some $e \in F$ **then**
    $F \leftarrow F - \{e\}$
    $\mathcal{M}' \leftarrow \mathcal{M}'/e$
    $\mathsf{M}' \leftarrow \mathsf{M}' \cup \{e\}$ ▷ fix x^*_e to 1 from now on
    $b'_v \leftarrow b'_v - d_{v,e}$ for each endpoint v of e ▷ permanently allocate space for e
  else
    let v be any vertex in W with minimum value $|\delta_F(v)| - x^*(\delta_F(v))$
    $W \leftarrow W - \{v\}$ ▷ drop the capacity constraint for v
return M'

Proof. Let $A_1 \subsetneq A_2 \subsetneq \ldots \subsetneq A_t \subseteq F$ be any *maximal-length chain of tight sets*. That is, $x^*(A_i) = r_{\mathcal{M}'}(A_i)$ for each A_i in the chain. Then the indicator vectors $\chi_{A_i} \in \{0,1\}^F$ of the sets A_i are linearly independent and every other $A \subseteq F$ with $x^*(A_i) = r_{\mathcal{M}'}(A)$ has $\chi_A \in \text{span}\{\chi_{A_i} : 1 \leq i \leq t\}$. This can be proven by using uncrossing techniques that exploit submodularity of $r_{\mathcal{M}'}$, see Chapter 5 of [10].

Now, as $A_{i-1} \subsetneq A_i$ for $1 < i \leq t$ and $x^*_e > 0$ for each $e \in F$, we see $r_{\mathcal{M}'}(A_i) = x^*(A_i) > x^*(A_{i-1}) = r_{\mathcal{M}'}(A_{i-1})$. Since the ranks are integral and $r_{\mathcal{M}'}(A_1) \neq 0$ (as $A_1 \neq \emptyset$), then $r_{\mathcal{M}}(A_i) \geq i$ for all $1 \leq i \leq t$.

Note that $|F| \leq t + |W|$ because of the number of non-zero (fractional) variables is at most the size of a basis for the tight constraints. We have

$$\begin{aligned}\sum_{v \in W} |\delta_F(v)| - x^*(\delta_F(v)) &\leq \sum_{v \in V} |\delta_F(v)| - x^*(\delta_F(v)) \leq k \cdot (|F| - x^*(F)) \\ &\leq k \cdot (|F| - r_{\mathcal{M}'}(A_t)) \leq k \cdot (|F| - t) \leq k \cdot |W|.\end{aligned}$$

The second bound holds because each edge has at most k endpoints, so it can contribute $1 - x^*_e \geq 0$ at most k times throughout the sum. Thus, some $v \in W$ satisfies the claim. ◀

▶ **Lemma 9.** *Algorithm 1 returns a set $\mathsf{M}' \in \mathcal{I}$ such that $d_v(\delta_{\mathsf{M}'}(v) - L(v)) \leq b_v$ where $L(v)$ denotes the $\min\{k, |\delta_{\mathsf{M}'}(v)|\}$ edges $e \in \delta_{\mathsf{M}'}(v)$ with greatest demand $d_{v,e}$ across v.*

Proof. We know $\mathsf{M}' \in \mathcal{I}$ by Lemma 7. Consider an iteration where a vertex $v \in W$ is removed from W. Claim 8 shows $|\delta_F(v)| \leq x^*(\delta_F(v)) + k$.

Let $F^k_v = \{e_1, \ldots, e_k\}$ be the k edges of this iteration in $\delta_F(v)$ having largest demand (if $|\delta_F(v)| < k$ then let $F^k_v = \delta_F(v)$). Then

$$\sum_{e \in \delta_F(v) - F^k_v} d_{v,e} \leq \sum_{e \in \delta_F(v)} d_{v,e} \cdot x^*_{e,v} \leq b'_v.$$

The first bound follows because if we shift x^*-values from larger- to smaller-demand edges the value $\sum_{e \in \delta_F(v)} d_{v,e} x^*_{e,v}$ does not increase. We can continue to do this until each $e \in \delta_F(v) - F^k_v$ has one unit of x^*-mass because $|\delta_F(v)| - k \leq x^*(\delta_F(v))$.

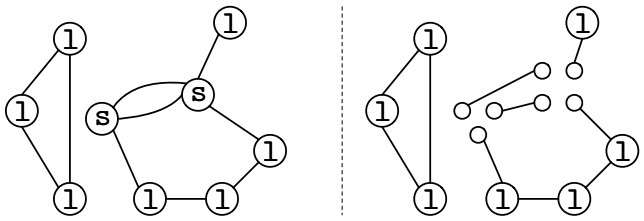

Figure 1 Left: The graph with vertex labels `s` and `l` and edges A. **Right**: The graph $\overline{G}$ obtained by "shattering" the `s` vertices. Notice the maximum degree is 2, the `ss` edges are isolated, and the `sl` edges lie on paths.

At this point of the algorithm, we have $d_v(\delta_{\mathsf{M}}(v)) = b_v - b'_v$ (letting M denote the set M' from the current iteration). So $d_v(\delta_F(v) - F_v^k) + d_v(\delta_{\mathsf{M}}(v)) \leq b_v$. We conclude by noting the edges returned by the algorithm contains only edges in $\mathsf{M} \cup F$ so $d_v(\mathsf{M}' - L(v)) \leq b_v$. ◀

Proof of Corollary 2. If there is no feasible solution to (**LP-M**), then there can be no integral solution. Otherwise, we use the same iterated relaxation technique as in Algorithm 1, except on (**LP-B**), whose polytope is the restriction of the polytope from (**LP-M**) to the base polytope of $\mathcal{M}$ (which is also integral, Corollary 40.2d of [14]).

All arguments are proven in essentially the same way. So we can find, in polynomial time, a base B with $p(\mathsf{B}) \leq \mathrm{OPT}(\textbf{LP-B})$ where $d_v(\delta_{\mathsf{B}}(v)) \leq b_v + k \cdot \max_{e \in \delta_{\mathsf{B}}(v)} d_{v,e}$. ◀

2.2 Pruning phase

We focus on $\mathsf{GDM}_{\mathsf{M}}$ ($k = 2$) in this section and show how to prune a set $\mathsf{M}' \subseteq E$ satisfying the properties of Lemma 9 to a feasible solution $\mathsf{M} \subseteq \mathsf{M}'$ while controlling the loss in its value. Each part of Theorem 1 is proved through the following lemmas. In each, for a vertex $v \in V$ we let $L(v)$ be the two edges with highest d_v-value in $\delta_{\mathsf{M}'}(v)$ (or $L(v) = \delta_{\mathsf{M}'}(v)$ if $|\delta_{\mathsf{M}'}(v)| \leq 1$). We also let $S(v) = \delta_{\mathsf{M}'}(v) - L(v)$ be the remaining edges. Note $d_v(\delta_{S(v)}(v)) \leq b_v$.

▶ **Lemma 10.** *For arbitrary graph G and arbitrary demands, we can find a feasible demand matching $\mathsf{M} \subseteq \mathsf{M}'$ with $p(\mathsf{M}) \geq p(\mathsf{M}') \cdot \frac{3}{25}$.*

Proof. For each vertex v, label v randomly with `s` with probability α or with `l` with probability $1 - \alpha$ (for α to be chosen later). Say $e \in \mathsf{M}'$ *agrees* with the labelling for an endpoint v if either $e \in S(v)$ and v is labelled `s`, or $v \in L(v)$ and v is labelled `l`. Let $\mathsf{A} \subseteq \mathsf{M}'$ be the edges agreeing with the labelling on both endpoints.

Modify the graph (V, A) by replacing each $v \in V$ labelled `s` with $|\delta_{\mathsf{A}}(v)|$ vertices and reassigning the endpoint v of each $e \in \delta_{\mathsf{A}}(v)$ to one of these vertices in a one-to-one fashion. See Figure 1 for an illustration. Call this new graph $\overline{G}$.

Each vertex in $\overline{G}$ has degree at most 2 so $\overline{G}$ decomposes naturally into paths and cycles. Each path with ≥ 2 edges can be decomposed into 2 matchings and each cycle can be decomposed into 3 matchings. Randomly choose one such matching for each path and cycle to keep and discarding the remaining edges on these paths and cycles. Note edges uv of $\overline{G}$ where u and v both had degree 1 are not discarded.

Let M be the resulting set of edges, viewed in the original graph G. Note that M is feasible: any vertex labelled `s` already had its capacity satisfied by A because $\delta_{\mathsf{A}}(v) \subseteq S(v)$. Any vertex labelled `l` has at most one of its incident edges in A chosen to stay in M.

Let $e = uv \in \mathsf{M}'$, we place a lower bound on $\mathbf{Pr}[e \in \mathsf{M}]$ by analyzing a few cases.

- If $e \in S(u) \cap S(v)$, then $\mathbf{Pr}[e \in \mathsf{M}] = \mathbf{Pr}[e \in \mathsf{A}] = \alpha^2$.

- If $e \in S(u) \cap L(v)$ or vice-versa then $\mathbf{Pr}[e \in \mathsf{M}] = \alpha \cdot (1-\alpha)/2$ (note e does not lie on a cycle in $\overline{G}$ since one endpoint is labelled $\mathtt{s}$).
- If $e \in L(u) \cap L(v)$ then $\mathbf{Pr}[e \in \mathsf{M}] = (1-\alpha)^2/3$.

Choosing $\alpha = 2/5$, we have $\mathbf{E}[p(\mathsf{M})] \geq p(\mathsf{M}') \cdot \frac{3}{25}$. ◀

We can efficiently derandomize this technique as follows. First, we use a pairwise independent family of random values to generate a probability space over labelings of V with $O(|V|)$ events such that the distribution of labels over pairs $u, v \in V$ is the same as with independently labelling the vertices. See Chapter 11 of [12] for details of this technique. For each such labelling, we decompose the paths and cycles of $\overline{G}$ into matchings and keep the most profitable matching from each path and cycle instead of randomly picking one.

▶ **Lemma 11.** *For a conflict-free instance of* $\mathsf{GDM}_{\mathsf{M}}$*, we can find a feasible solution* $\mathsf{M} \subseteq \mathsf{M}'$ *with* $p(\mathsf{M}) \geq \frac{p(\mathsf{M}')}{4}$.

Proof. The set A from the proof of Lemma 10 is already feasible so it does not need to be pruned further. In this case, choose $\alpha = 1/2$. ◀

▶ **Lemma 12.** *If the given graph* G *is bipartite, then we can find a feasible solution* $\mathsf{M} \subseteq \mathsf{M}'$ *with* $p(\mathsf{M}) \geq \frac{p(\mathsf{M}')}{7}$.

Proof. Say V_L, V_R are the two sides of V. We first partition M' into 4 groups:

$$\{uv \in \mathsf{M}' : uv \in S(u) \cap S(v)\},$$
$$\{uv \in \mathsf{M}' : uv \in L(u) \cap L(v)\},$$
$$\{uv \in \mathsf{M}' : uv \in S(u) \cap L(v)\},$$
$$\{uv \in \mathsf{M}' : uv \in L(u) \cap S(v)\}.$$

The first set is feasible. The latter three sets can each be partitioned into two feasible sets as follows. For one of these sets, form $\overline{G}$ as in the proof of Lemma 10. Each cycle can also be decomposed into two matchings because G, thus $\overline{G}$, is bipartite. Between all sets listed above, we have partitioned M' into 7 feasible sets. Let M be one with maximum profit. ◀

▶ **Lemma 13.** *For an arbitrary graph* $G = (V, E)$ *with a consistent ordering on edges, we can find a feasible demand matching* $\mathsf{M} \subseteq \mathsf{M}'$ *with* $p(\mathsf{M}) \geq \frac{p(\mathsf{M}')}{5}$.

Proof. We partition M' into five groups in this case. Consider the edges in decreasing order of the consistent ordering. When edge $e = uv$ is considered, assign it to a group that does not include edges in $L(u) \cup L(v)$ that come before e in the ordering. As $|L(u) \cup L(v)| \leq 4$, the edges can be partitioned into five groups this way. Each group A is a feasible demand matching since $\delta_{\mathsf{A}}(v) \subseteq S(v)$ or $|\delta_{\mathsf{A}}(v)| = 1$ for each vertex v. Now let M be the group with maximum profit, so $p(\mathsf{M}) \geq \frac{p(\mathsf{M}')}{5}$. ◀

▶ **Lemma 14.** *If* $d_{v,e} \leq \epsilon \cdot b_v$ *for each* $v \in V, e \in \delta(v)$*, we can find a feasible demand matching* $\mathsf{M} \subseteq \mathsf{M}'$ *with* $p(\mathsf{M}) \geq (1 - O(\epsilon^{1/3})) \cdot p(\mathsf{M}')$.

This is proven using a common randomized pruning procedure so the proof is skipped in this extended abstract. See, for example, [3] for a similar treatment in another packing problem.

3 Demand Matching in Excluded-Minor Families

In this section we prove GDM admits a PTAS in graphs that exclude a fixed graph as a minor. Our proof of Theorem 4 (the **NP**-hardness) appears in the full version. Throughout we let OPT denote the optimum solution value to the given GDM instance.

Let H be a graph and let $\mathcal{G}_H$ be all graphs that exclude H as a minor. Our PTAS uses the following decomposition.

▶ **Theorem 15** (Demaine, Hajiaghayi, and Kawarabayashi [4]). *There is a constant c_H depending only on H such that for any k and any $G \in \mathcal{G}_H$, the vertices V of G can be partitioned into $k+1$ disjoint sets so that the union of any k of these sets induce a graph with treewidth bounded by $c_H \cdot k$. Such a partition can be found in time that is polynomial in $|V|$.*

Using this decomposition, we have a PTAS for GDM when $G \in \mathcal{G}_H$ if we have a PTAS for GDM in bounded-treewidth graphs.

Intuition for our approach is given at the end of Section 1.1. We assume, for simplicity, that all $d_{v,e}$-values are distinct so we can naturally speak of *the* largest demands in a set. This is without loss of generality, we could scale demands and capacities by a common value so they are integers and then subtract $\frac{2i+j}{3|E|^2}$ from the j'th endpoint of the i'th edge according to some arbitrary ordering. Such a perturbation does not change feasibility of solutions as the total amount subtracted from all edges is < 1.

3.1 A Sparsification Lemma

We present our sparsification lemma, which even holds for general instances of $\mathsf{GDM}_{\mathsf{M}}$.

▶ **Lemma 16** (Sparsification Lemma). *For each $\epsilon > 0$ there is a feasible solution $\mathsf{M} \subseteq E$ with the following properties.*

- $p(\mathsf{M}) \geq (1-2\epsilon) \cdot \mathrm{OPT}$
- *for each $v \in V$, there is some $M_v \subseteq \mathsf{M}$ with $|M_v| \leq 1/\epsilon^2$ such that $d_{v,e} \leq \epsilon \cdot (b_v - d_v(\delta_{M_v}(v)))$ for all $e \in \delta_{\mathsf{M}-M_v}(v)$*

Think of M_v as the "large" edges in $\delta_{\mathsf{M}}(v)$ and $\delta_{\mathsf{M}-M_v}(v)$ as the "small" edges in $\delta_{\mathsf{M}}(v)$. Note that some $e \in \mathsf{M}$ may be designated large on one endpoint and small on the other.

Proof. Let M^* be an optimum solution. For each $v \in V$, if $|\delta_{\mathsf{M}^*}(v)| \geq 1/\epsilon^2$ then let L_v be the $1/\epsilon^2$ edges in $\delta_{\mathsf{M}^*}(v)$ with greatest d_v-demand and R_v be a random subset of L_v of size $1/\epsilon$. If $|\delta_{\mathsf{M}^*}(v)| < 1/\epsilon^2$, simply let $L_v = \delta_{\mathsf{M}^*}(v)$ and $R_v = \emptyset$.

Set $\mathsf{M} = \mathsf{M}^* - \cup_{v \in V} R_v$ and for each $v \in V$ set $M_v = \mathsf{M} \cap L_v$. Clearly M is feasible as it is a subset of the optimum solution. For each $e = uv \in \mathsf{M}^*$, e lies in R_u or R_v with probability at most ϵ each, so $\mathbf{Pr}[e \notin \mathsf{M}] \leq 2\epsilon$. Thus, $\mathbf{E}[p(\mathsf{M})] \geq (1-2\epsilon) \cdot \mathrm{OPT}$.

Now we focus on proving the second property for M. Let v be an arbitrary vertex in V. By construction $|M_v| \leq |L_v| \leq 1/\epsilon^2$. If $|R_v| = 0$ then $\delta_{\mathsf{M}-M_v}(v) = \emptyset$, otherwise, $|R_v| = 1/\epsilon$ and for each remaining $e \in \delta_{\mathsf{M}-M_v}(v)$, we note that $d_{v,e} + d_v(\delta_{M_v}(v)) + \sum_{e' \in R_v} d_{v,e'} \leq b_v$ because the terms represent a subset of edges of M^* incident to v. Rearranging and using the fact that $d_{v,e'} \geq d_{v,e}$ for any $e' \in R_v$ shows $\frac{1}{\epsilon} \cdot d_{v,e} \leq b_v - d_v(\delta_{M_v}(v))$. ◀

This motivates the following notion of a relaxed solution.

▶ **Definition 17.** An ϵ-relaxed solution is a subset $\mathsf{M} \subseteq E$ along with sets $M_v \subseteq \delta_{\mathsf{M}}(v)$ with $|M_v| \leq 1/\epsilon^2$ for each $v \in V$ such that the following hold. First, let $\overline{b}_v = b_v - d_v(\delta_{M_v}(v))$ for each $v \in V$. Next, for each $e \in \delta_{\mathsf{M}-M_v}(v)$, let $d'_{v,e}$ be the value of $d_{v,e}$ rounded down to the nearest integer multiple of $\frac{\epsilon}{|E|}\overline{b}_v$. Then the following must hold:

- **Large Edge Feasibility**: $d_v(\delta_{M_v}(v)) \leq b_v$ for each $v \in V$.
- **Small Edges**: $d_{v,e} \leq \epsilon \bar{b}_v$ for each $v \in V$ and each $e \in \delta_{\mathsf{M}-M_v}(v)$.
- **Discretized Small Edge Feasibility**: $d'_v(\delta_{\mathsf{M}-M_v}(v)) \leq \overline{b_v}$ for each $v \in V$.

The set M in an ϵ-relaxed solution is not necessarily a feasible GDM solution under the original demands d. As we will see shortly, it can be pruned to get a feasible solution without losing much value. Note the scaling from d to d' for some of the edges e in the definition is done independently for each endpoint of e: the demand at different endpoints may be shifted down by different amounts.

Sometimes we informally say just a set $\mathsf{M} \subseteq E$ itself is an ϵ-relaxed solution even if we do not explicitly mention the corresponding M_v sets.

▶ **Lemma 18.** *Let* M *be an* ϵ*-relaxed solution with maximum possible value* $p(\mathsf{M})$*. Then* $p(\mathsf{M}) \geq (1 - 2\epsilon) \cdot OPT$*.*

Proof. The set M and its corresponding M_v subsets from Lemma 16 suffices. ◀

▶ **Lemma 19.** *Given any* ϵ*-relaxed solution* $\mathsf{M} \subseteq E$*, we can efficiently find some* $\mathsf{M}' \subseteq \mathsf{M}$ *that is a feasible* GDM *solution with* $p(\mathsf{M}') \geq (1 - O(\epsilon^{1/3})) \cdot p(\mathsf{M})$*.*

The idea is that the $\{0, 1\}$ indicator vector of M is almost a feasible solution to (**LP-M**) with the trivial matroid $\mathcal{I} = 2^E$ in the residual instance after all "large" edges are packed so it can be pruned to a feasible solution while losing very little value by appealing to the last bound in Theorem 1. There is a minor subtlety in how to deal with edges that are both "small" and "large". The proof is deferred to the full version.

3.2 A Dynamic Programming Algorithm

Suppose $G = (V, E)$ has treewidth at most τ and that we are given a tree decomposition $\mathcal{T} = (\mathcal{B}, E_{\mathcal{T}})$ of G where each $B \in \mathcal{B}$ has $|B| \leq \tau + 1$. Recall this means the following:

1. For each $v \in V$, the set of bags $\mathcal{B}_v = \{B \in \mathcal{B} : v \in B\}$ form a connected subtree of $\mathcal{T}$.
2. For each $uv \in E$, there is at least one bag $B \in \mathcal{B}$ with $u, v \in B$.

Let $B^r \in \mathcal{B}$ be some arbitrarily chosen *root* bag. View $\mathcal{T}$ as being rooted at B^r. We may assume that each $B \in \mathcal{B}$ has at most two children. In fact, it simplifies our recurrence a bit to assume each $B \in \mathcal{B}$ is either a leaf in $\mathcal{T}$ or has precisely two children. This is without loss of generality. Arbitrarily order the children of a non-leaf vertex so one is the *left* child and one is the *right* child. For a bag B, let $\mathcal{T}_B$ be the subtree of $\mathcal{T}$ rooted at B (so $\mathcal{T}_{B^r} = \mathcal{T}$).

For each $v \in V$, say $\overline{B}_v$ is the bag containing v that is closest to the root B^r. Note for $uv \in E$ with $\overline{B}_u \neq \overline{B}_v$ that one of $\overline{B}_u$ or $\overline{B}_v$ lies on the path between the other and B^r (by the properties of tree decompositions). For each $B \in \mathcal{B}$ and each $v \in B$, we partition a subset of the edges of $\delta(v)$ into four groups:

- $\delta^{\texttt{here}}(v : B) = \{uv \in \delta(v) : \overline{B}_u = B\}$.
- $\delta^{\texttt{left}}(v : B) = \{uv \in \delta(v) : \overline{B}_u$ lies in the left subtree of $B\}$.
- $\delta^{\texttt{right}}(v : B) = \{uv \in \delta(v) : \overline{B}_u$ lies in the right subtree of $B\}$.
- $\delta^{\texttt{up}}(v : B) = \{uv \in \delta(v) : \overline{B}_u$ lies between B and $B^r\}$.

The only other edges $uv \in \delta(v)$ not accounted for here do not have $\overline{B}_u$ in either $\mathcal{T}_B$ or between B and B^r. We note if $B = \overline{B}_v$, then every edge in $\delta(v)$ lies in one of the four groups and for any $uv \in \delta^{\texttt{up}}(v : B)$ we must have $u \in B$ (otherwise no bag contains u and v, which is impossible since $uv \in E$) and, consequently, $\overline{B}_u$ lies between B and B^r. This will be helpful to remember when we describe the recurrence.

Dynamic Programming States

Let $\Delta := \{\texttt{here}, \texttt{left}, \texttt{right}, \texttt{up}\}$ be the set of "directions" used above. The DP states are given by tuples Φ with the following components.

- A bag $B \in \mathcal{B}$.
- For each $v \in B$, a subset $M_v \subseteq \delta(v)$ with $|M_v| \leq 1/\epsilon^2$.
- For each $v \in B$ and $\kappa \in \Delta$, an integer $a_{v,\kappa} \in \{0, \ldots, |E|/\epsilon\}$ such that $\sum_{\kappa \in \Delta} a_{v,\kappa} \leq \frac{|E|}{\epsilon}$.

The number of such tuples is at most $|\mathcal{B}| \cdot |E|^{O(\tau/\epsilon^2)} \cdot (|E|/\epsilon)^{O(\tau)}$, which is polynomial in G when τ and ϵ are regarded as constants. The idea behind $a_{v,\kappa}$ is that it describes how to reserve the discretized d'_v-demand for edges $uv \in \delta^\kappa(v : B) - M_v$. Of course, other edges in $\delta(v)$ not in the partitions $\delta^\kappa(v : B)$ may be in an optimal ϵ-relaxed solution. They will either be explicitly guessed in M_v or will be considered in a state higher up the tree by the time the bag $\overline{B}_v$ is processed.

Dynamic Programming Values

For each such tuple $\Phi = (B; \langle M_v \rangle_{v \in B}; \langle a_{v,\kappa} \rangle_{v \in B, \kappa \in \Delta})$, we let $f(\Phi)$ denote the maximum total value of an ϵ-relaxed solution $\mathsf{M}' \subseteq E$ (with corresponding large sets M'_v for $v \in V$) satisfying the following properties. We slightly abuse notation and say $v \in \mathcal{T}_B$ for some $v \in V$ if v lies in some bag of the subtree $\mathcal{T}_B$.

- Each $uv \in \mathsf{M}'$ has at least one endpoint in $\mathcal{T}_B$.
- $M'_v = M_v$ for each $v \in B$.
- Each $uv \in \mathsf{M}'$ with both $\overline{B}_u, \overline{B}_v \notin \mathcal{T}_B$ lies in $M'_u \cup M'_v$.
- For $v \in B$ let $\overline{b_v} = b_v - d_v(\delta_{M'_v}(v))$. For $\kappa \in \Delta$ and $v \in B$, it must be that $d'_v(\delta^\kappa(v : B) \cap \mathsf{M}' - M'_v) \leq a_{v,\kappa} \cdot \frac{\epsilon}{|E|} \cdot \overline{b_v}$ where $d'_{v,e}$ is the largest integer multiple of $\frac{\epsilon}{|E|} \cdot \overline{b_v}$ that is at most $d_{v,e}$ for $e \in \delta_{\mathsf{M}' - M'_v}(v)$.

The last point is a bit technical. Intuitively, it says the scaled demand of small edges incident to v coming from some direction $\kappa \in \Delta$ fit in the capacity of v reserved for that direction.

If there is no such F, we say $f(\Phi) = -\infty$. Note the maximum of $f(\Phi)$ over all configurations Φ for the root bag B_r is the maximum value over all ϵ-relaxed solutions.

3.2.1 The Recurrence

For the sake of space, details behind the recurrence are deferred to the full version. We just outline the main ideas. A tuple Φ is a base case if the bag B is a leaf of $\mathcal{T}$. In this case, only edges in some $\delta^\kappa(v : B)$ set for $\kappa \in \{\texttt{here}, \texttt{up}\}$ are considered (there are none in the directions `left`, `right`). We find the optimal way to pack such edges that are not part of a "large" set M_v while ensuring the d'_v-demands do not violate the residual capacities $\overline{b_v}$ and, in particular, for each direction κ we ensure this packing does not violate the part of the residual capacity for that direction allocated by the $a_{v,\kappa}$ values. This subproblem is just the Multi-Dimensional Knapsack problem with $2|B|$ knapsacks. A standard pseudopolynomial-time algorithm can be used to solve it as the scaled demands are from a polynomial-size discrete range.

For the recursive step, we try all pairs of configurations $\Phi^{\texttt{left}}, \Phi^{\texttt{right}}$ that are "consistent" with Φ. Really this just means they agree on the sets M_v for shared vertices v and they agree on how much demand $a_{v,\kappa}$ should be allocated for each direction. For each such consistent pair, we pack small edges in $\delta^{\texttt{here}}(v : B)$ and $\delta^{\texttt{up}}(v : B)$ optimally such that their scaled demands do not violate the $a_{v,\kappa}$-capacities, again using Multi-Dimensional Knapsack.

Abstract

We consider 5the problem of covering a set of vectors of a given finite dimensional linear space (vector space) by a subspace generated by a set of vectors of minimum size. Specifically, we study the Space Cover problem, where we are given a matrix M and a subset of its columns T; the task is to find a minimum set F of columns of M disjoint with T such that that the linear span of F contains all vectors of T. This is a fundamental problem arising in different domains, such as coding theory, machine learning, and graph algorithms.

We give a parameterized algorithm with running time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$ solving this problem in the case when M is a totally unimodular matrix over rationals, where k is the size of F. In other words, we show that the problem is fixed-parameter tractable parameterized by the rank of the covering subspace. The algorithm is "asymptotically optimal" for the following reasons.

Choice of matrices: Vector matroids corresponding to totally unimodular matrices over rationals are exactly the regular matroids. It is known that for matrices corresponding to a more general class of matroids, namely, binary matroids, the problem becomes W[1]-hard being parameterized by k.

Choice of the parameter: The problem is NP-hard even if $|T| = 3$ on matrix-representations of a subclass of regular matroids, namely cographic matroids. Thus for a stronger parameterization, like by the size of T, the problem becomes intractable.

Running Time: The exponential dependence in the running time of our algorithm cannot be asymptotically improved unless Exponential Time Hypothesis (ETH) fails.

Our algorithm exploits the classical decomposition theorem of Seymour for regular matroids.

1 Introduction

We consider the fundamental problem of covering a subspace of a given finite dimensional linear space (vector space) by a set of vectors of minimum size. The input of the problem is a matrix M given together with a function w assigning a nonnegative weight to each column of M and a set T of terminal column-vectors T of M. The task is to find a minimum set of column-vectors F of M (if such a set exists) which is disjoint with T and generates a subspace containing the linear space generated by T. In other words, $T \subseteq \mathrm{span}(F)$, where $\mathrm{span}(F)$ is the linear span of F. We refer to this problem as the Space Cover problem.

The Space Cover problem encompasses various problems arising in different domains. The Minimum Distance problem in coding theory asks for a minimum dependent set of columns in a matrix over GF(2). This problem can be reduced to Space Cover by finding for each column t in matrix M a minimum set of columns in the remaining part of the matrix that cover $T = \{t\}$. The complexity of this problem was asked by Berlekamp et al. [2] and remained open for almost 30 years. It was resolved only in 1997, when Vardy showed it to be NP-complete [38]. The parameterized version of the Minimum Distance problem, namely Even Set, asks whether there is a dependent set $F \subseteq X$ of size at most k. The parameterized complexity of Even Set is a long-standing open question in the area, see e.g. [8]. In the language of matroid theory, the problem of finding a minimum dependent set is known as Matroid Girth, i.e. the problem of finding a circuit in matroid of minimum length [39]. In machine learning this problem is known as the Subspace Recovery problem [20]. This problem also generalizes the problem of computing the rank of a tensor.

For our purposes, it is convenient to rephrase the definition of the Space Cover problem in the language of matroids. Given a matrix N, let $M = (E, \mathcal{I})$ denote the matroid where the ground set E corresponds to the columns of N and $\mathcal{I}$ denote the family of subsets of linearly independent columns. This matroid is called the vector matroid corresponding to matrix N. Then for matroids, finding a subspace covering T corresponds to finding $F \subseteq E \setminus T$, $F \in \mathcal{I}$, such that $|F| \leq k$ and T is spanned by F. Let us remind that in a matroid set F spans T, denoted by $T \subseteq \mathrm{span}(F)$, if $r(F) = r(T \cup F)$. Here $r\colon 2^E \to \mathbb{N}_0$ is the rank function of M. (We use $\mathbb{N}_0$ to denote the set of nonnegative integers.)

Then Space Cover is defined as follows.

Space Cover **Parameter:** k
Input: A binary matroid $M = (E, \mathcal{I})$ given together with its matrix representation over GF(2), a weight function $w\colon E \to \mathbb{N}_0$, a set of *terminals* $T \subseteq E$, and a nonnegative integer k.
Question: Is there a set $F \subseteq E \setminus T$ with $w(F) \leq k$ such that $T \subseteq \mathrm{span}(F)$?

Since a representation of a binary matroid is given as a part of the input, we always assume that the *size* of M is $||M|| = |E|$. For regular matroids, testing matroid regularity can be done efficiently, see e.g. [37], and when the input binary matroid is regular, the requirement that the matroid is given together with its representation can be omitted.

It is known (see, e.g., [26]) that Space Cover on special classes of binary matroids, namely graphic and cographic matroids, generalizes two well-studied optimization problems on graphs, namely Steiner Tree and Multiway Cut. Both problems play fundamental roles in parameterized algorithms.

Recall that in the Steiner Forest problem we are given a (multi) graph G, a weight function $w\colon E \to \mathbb{N}$, a collection of pairs of distinct vertices $\{x_1, y_1\}, \ldots, \{x_r, y_r\}$ of G, and a nonnegative integer k. The task is to decide whether there is a set $F \subseteq E(G)$ with $w(F) \leq k$

such that for each $i \in \{1, \ldots, r\}$, graph $G[F]$ contains an (x_i, y_i)-path. To see that Steiner Forest is a special case of Space Cover, for instance $(G, w, \{x_1, y_1\}, \ldots, \{x_r, y_r\}, k)$ of Steiner Forest, we construct the following graph. For each $i \in \{1, \ldots, r\}$, we add a new edge $x_i y_i$ to G and assign an arbitrary weight to it; notice that we can create multiple edges this way. Denote by G' the obtained mulitigraph and let T be the set of added edges and let $M(G')$ be the graphic matroid associated with G'. Then a set of edges $F \subseteq E(G)$ forms a graph containing all (x_i, y_i)-paths if an only if $T \subseteq \mathrm{span}(F)$ in $M(G')$.

The special case of Steiner Forest when $x_1 = x_2 = \cdots = x_r$, i.e. when set F should form a connected subgraph spanning all demand vertices, is the Steiner Tree problem, the fundamental problem in network optimization. By the classical result of Dreyfus and Wagner [10], Steiner Tree is fixed-parameter tractable (FPT) parameterized by the number of terminals. The study of parameterized algorithms for Steiner Tree has led to the design of important techniques, such as Fast Subset Convolution [3] and the use of branching walks [29]. Research on the parameterized complexity of Steiner Tree is still on-going, with recent significant advances for the planar version of the problem [33]. Algorithms for Steiner Tree are frequently used as a subroutine in FPT algorithms for other problems; examples include vertex cover problems [19], near-perfect phylogenetic tree reconstruction [4], and connectivity augmentation problems [1].

The dual of Space Cover, i.e., the variant of Space Cover asking whether there is a set $F \subseteq E \setminus T$ with $w(F) \leq k$ such that $T \subseteq \mathrm{span}(F)$ in the dual matroid M^*, is equivalent to the Restricted Subset Feedback Set problem. In this problem the task is for a given matroid M, a weight function $w\colon E \to \mathbb{N}_0$, and a nonnegative integer k, to decide whether there is a set $F \subseteq E \setminus T$ with $w(F) \leq k$ such that matroid M' obtained from M by deleting the elements of F has no circuit containing an element of T. Hence, Space Cover for cographic matroids is equivalent to Restricted Subset Feedback Set for graphic matroids. Restricted Subset Feedback Set for graphs was introduced by Xiao and Nagamochi [40], who showed that this problem is FPT parameterized by $|F|$. Let us note that in order to obtain an algorithm for Space Cover with a single-exponential dependence in k, we also need to design a new algorithm for Space Cover on cographic matroids which improves significantly the running time achieved by Xiao and Nagamochi [40].

Multiway Cut, another fundamental graph problem, is the special case of Restricted Subset Feedback Set, and therefore of Space Cover. In the Multiway Cut problem we are given a (multi) graph G, a weight function $w\colon E \to \mathbb{N}$, a set $S \subseteq V(G)$, and a nonnegative integer k. The task is to decide whether there is a set $F \subseteq E(G)$ with $w(F) \leq k$ such that the vertices of S are in distinct connected components of the graph obtained from G by deleting edges of F. Indeed, let (G, w, S, k) be an instance of Multiway Cut. We construct graph G' by adding a new vertex u and connecting it to the vertices of S. Denote by T the set of added edges and assign weights to them arbitrarily. Then (G, w, S, k) is equivalent to the instance $(M(G'), w, T, k)$ of Restricted Subset Feedback Set. If $|S| = 2$, Multiway Cut is exactly the classical min-cut problem which is solvable in polynomial time. However, as it was proved by Dahlhaus et al. [6] already for three terminals the problem becomes NP-hard. Marx, in his celebrated work on important separators [28], has shown that Multiway Cut is FPT when parameterized by the size of the cut $|F|$.

While Steiner Tree is FPT parameterized by the number of terminal vertices, the hardness results for Multiway Cut with three terminals yields that Space Cover parameterized by the size of the terminal set T is Para-NP-complete even if restricted to cographic matroids. This explains why we parameterize Space Cover by the rank of the span and not the size of the terminal set.

There is also a strong argument that Space Cover is not tractable in its full generality on binary matroids for the following reason. It follows from the result of Downey et al. [9] on the hardness of the Maximum-Likelihood Decoding problem, that Space Cover is W[1]-hard for binary matroids when parameterized by k even if restricted to the inputs with one terminal and unit-weight elements. However, it is still possible to establish the tractability of the problem on a large class of binary matroids. Sandwiched between graphic and cographic (where the problem is FPT) and binary matroids (where the problem is intractable) is the class of regular matroids. Our main theorem establishes the tractability of Space Cover on regular matroids.

▶ **Theorem 1.** Space Cover *on regular matroids is solvable in time* $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

We believe that due to the generality of Space Cover, Theorem 1 will be useful in the study of various optimization problems on regular matroids. As an example, we consider the Rank h-Reduction problem, see e.g. [24]. Here we are given a binary matroid M and positive integers h and k, the task is to decide whether it is possible to decrease the rank of M by at least h by deleting k elements. For graphic matroids, this is the h-Way Cut problem, which is for a connected graph G and positive integers h and k, to decide whether it is possible to separate G into at least h connected components by deleting at most k edges. By the celebrated result of Kawarabayashi and Thorup [25], h-Way Cut is FPT parameterized by k even if h is a part of the input. The result of Kawarabayashi and Thorup cannot be extended to cographic matroids; we show that for cographic matroids the problem is W[1]-hard when parameterized by $h + k$. On the other hand, by making use of Theorem 1, we solve Rank h-Reduction in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(h)}$ on regular matroids.

Let us also remark that the running time of our algorithm is asymptotically optimal: unless Exponential Time Hypothesis fails, there is no algorithm of running time $2^{o(k)} \cdot ||M||^{\mathcal{O}(1)}$ solving Space Cover on graphic (Steiner Tree) or cographic (Multiway Cut) matroids, see e.g. [5].

Related work. The main building block of our algorithm is the fundamental theorem of Seymour [34] on a decomposition of regular matroids. Roughly speaking (we define it properly in Section 2), the Seymour's decomposition provides a way to decompose a regular matroid into much simpler *base* matroids that are graphic, cographic or have a constant size in such way that all "communication" between base matroids is limited to "cuts" of small rank (we refer to the monograph of Truemper [37] and the survey of Seymour [35] for the introduction to matroid decompositions). This theorem has a number of important combinatorial and algorithmic applications. Among the classic algorithmic applications of Seymour's decomposition are the polynomial time algorithms of Truemper [36] (see also [37]) for finding maximum flows and shortest routes and the polynomial algorithm of Golynski and Horton [18] for constructing a minimum cycle basis. More recent applications of Seymour's decomposition can be found in approximation, on-line and parameterized algorithms. Godberg and Jerrum [17] used Seymour's decomposition theorem for obtaining a fully polynomial randomized approximation scheme (FPRAS) for the partition function of the ferromagnetic Ising model on regular matroids. Dinitz and Kortsarz in [7] applied the decomposition theorem for the Matroid Secretary problem. In [12], Gavenciak, Král and Oum initiated the study of the Minimum Spanning Circuit problem for matroids that generalizes the classical Cycle Through Elements problem for graphs. The problem asks for a matroid M, a set $T \subseteq E$ and a nonnegative integer ℓ, whether there is a circuit C of M with $T \subseteq C$ of size at most ℓ. Gavenciak, Král and Oum [12] proved that the problem is

FPT when parameterized by ℓ if $|T| \leq 2$. Very recently, in [11], we extended this result by showing that Minimum Spanning Circuit is FPT when parameterized by $k = \ell - |T|$.

On a very superficial level, all the algorithmic approaches based on the Seymour's decomposition theorem utilize the same idea: solve the problem on base matroids and then "glue" solutions into a global solution. However, such a view is a strong oversimplification. First of all, the original decomposition of Seymour in [34] was not meant for algorithmic purposes and almost every time to use it algorithmically one has to apply nontrivial adjustments to the original decomposition. For example, in order to solve Matroid Secretary on regular matroids, Dinitz and Kortsarz in [7] had to give a refined decomposition theorem suitable for their algorithmic needs. Similarly, in order to use the decomposition theorem for approximation algorithms, Goldberg and Jerrum in [17] had to add several new ingredients to the original Seymour's construction. We face exactly the same nature of difficulties in using Seymour's decomposition theorem. Our starting point is the variant of the decomposition theorem proved by Dinitz and Kortsarz in [7]. However, this theorem as it is can also not be used "statically" for our purposes. Our algorithm, while recursively constructing a solution has to "dynamically" transform the decomposition. This occurs when the algorithm processes cographic matroids "glued" with other matroids and for that part of the algorithm the transformation of the decomposition is essential.

2 Algorithm roadmap

In this section we give a high level overview of our algorithm for Space Cover. Due to space restrictions, all details and proofs are postponed for a journal version of our paper. We assume that the reader is acquainted with the basics of Matroid theory and refer to the book of Oxley [32] for the introduction.

We denote the ground set of matroid $M = (E, \mathcal{I})$ by $E(M)$ or simply by E if it does not create confusion. Recall that a set $X \subseteq E$ *spans* $e \in E$ if $r(X \cup \{e\}) = r(X)$, and $\mathrm{span}(X) = \{e \in E \mid X \text{ spans } e\}$, where r is the rank function of M. Respectively, X *spans a set* $T \subseteq E$ if $T \subseteq \mathrm{span}(X)$. An (inclusion) minimal dependent set is called a *circuit* of M. An one-element circuit is called *loop*, and if $\{e_1, e_2\}$ is a two-element circuit, then it is said that e_1 and e_2 are *parallel*. A set $X \subseteq E$ is a *cycle* of M if X is either empty or X is a disjoint union of circuits. Let G be a (multi) graph. The *cycle* matroid $M(G)$ has the ground set $E(G)$ and a set $X \subseteq E(G)$ is independent if $X = \emptyset$ or $G[X]$ has no cycles. Notice that C is a circuit of $M(G)$ if and only if C induces a cycle of G. The *bond* matroid $M^*(G)$ with the ground set $E(G)$ is dual to $M(G)$, and X is a circuit of $M^*(G)$ if and only if X is a minimal cut-set of G. It is said that M is a *graphic* matroid if M is isomorphic to $M(G)$ for some graph G and M is *cographic* if M is isomorphic to $M^*(G)$.

Our algorithm uses the following observation.

▶ **Observation 2.** *Let $e \in E$ and $X \subseteq E \setminus \{e\}$ for a matroid M. Then $e \in \mathrm{span}(X)$ if and only if there is a circuit C such that $e \in C \subseteq X \cup \{e\}$.*

By Observation 2, to solve Space Cover we have to find $F \subseteq E \setminus T$ with $w(F) \leq k$ such that for every $t \in T$, there is circuit C of M such that $t \in C \subseteq F \cup \{t\}$.

2.1 Regular matroid decompositions

In this section we describe matroid decomposition theorems that are pivotal for the algorithm for Space Cover. Roughly speaking, the classical theorem of Seymour [34] says that every regular matroid can be decomposed via "small sums" into basic matroids which are graphic,

cographic and very special matroid of constant size called R_{10}. To describe the decomposition of matroids, we need the notion of "ℓ-sums" of matroids; we refer to [32, 37] for a formal introduction to matroid sums. However, for our purpose, it is sufficient that we restrict ourselves to binary matroids and up to 3-sums [34]. Recall that, for two sets X and Y, $X \triangle Y = (X \setminus Y) \cup (Y \setminus X)$ denotes the symmetric difference of X and Y. For two binary matroids M_1 and M_2, the *sum* of M_1 and M_2, denoted by $M_1 \triangle M_2$, is the matroid M with the ground set $E(M_1) \triangle E(M_2)$ whose cycles are all subsets $C \subseteq E(M_1) \triangle E(M_2)$ of the form $C = C_1 \triangle C_2$, where C_1 is a cycle of M_1 and C_2 is a cycle of M_2.

▶ **Definition 3** ($\{1,2,3\}$-sum)**.** For matroids M_1, M_2 and their sum M,

(S1) If $E(M_1) \cap E(M_2) = \emptyset$ and $E(M_1), E(M_2) \neq \emptyset$, then M is the 1-*sum* of M_1 and M_2 and we write $M = M_1 \oplus_1 M_2$.

(S2) If $|E(M_1) \cap E(M_2)| = 1$, then M is the 2-*sum* of M_1 and M_2 and we write $M = M_1 \oplus_2 M_2$.

(S3) If $|E(M_1) \cap E(M_2)| = 3$, the 3-element set $Z = E(M_1) \cap E(M_2)$ is a circuit of M_1 and M_2, then M is the 3-*sum* of M_1 and M_2 and we write $M = M_1 \oplus_3 M_2$.

If $M = M_1 \oplus_k M_2$ for some $k \in \{1,2,3\}$, then we write $M = M_1 \oplus M_2$.

Note that the definitions of (S2) and (S3) in [34] include some additional restrictions for $E(M_1) \cap E(M_2)$ but, as it was pointed by Dinitz and Kortsarz in [7], they are used only to ensure the nontriviality and can be omitted for algorithmic applications.

▶ **Definition 4** ($\{1,2,3\}$-decomposition)**.** A $\{1,2,3\}$-*decomposition* of a matroid M is a collection of matroids $\mathcal{M}$, called the *basic matroids*, and a rooted binary tree T in which M is the root and the elements of $\mathcal{M}$ are the leaves such that any internal node is either 1-, 2- or 3-sum of its children.

We also need the special binary matroid R_{10} which is represented over GF(2) by the 5×10-matrix whose columns are formed by vectors that have exactly three non-zero entries (or rather three ones) and no two columns are identical. Seymour's theorem [34] states that every regular matroid has a $\{1,2,3\}$-decomposition in which every basic matroid is graphic, cographic or isomorphic to R_{10}.

Dinitz and Kortsarz in [7] obtained a variant of matroid decomposition which is more handy for our purposes. This variant is based on the notion conflict graph.

▶ **Definition 5** ([7])**.** Let $(T, \mathcal{M})$ be a $\{1,2,3\}$-decomposition of a matroid M. The *conflict* (or *intersection*) graph of $(T, \mathcal{M})$ is the graph G_T with the vertex set $\mathcal{M}$ such that distinct $M_1, M_2 \in \mathcal{M}$ are adjacent in G_T if and only if $E(M_1) \cap E(M_2) \neq \emptyset$.

▶ **Theorem 6** ([7])**.** *For a given regular matroid M, there is a (conflict) tree $\mathcal{T}$, whose set of nodes is a set of matroids $\mathcal{M}$, where each element of $\mathcal{M}$ is a graphic or cographic matroid, or a matroid obtained from R_{10} by (possibly) adding parallel elements, that has the following properties: (i) if two distinct matroids $M_1, M_2 \in \mathcal{M}$ have nonempty intersection, then M_1 and M_2 are adjacent in $\mathcal{T}$, (ii) for any distinct $M_1, M_2 \in \mathcal{M}$, the intersection $E(M_1) \cap E(M_2)$ satisfies one of the properties (S1)–(S3) of 1, 2 or 3-sums, (iii) M is obtained by the consecutive performing 1, 2 or 3-sums for adjacent matroids in any order. Moreover, $\mathcal{T}$ can be constructed in a polynomial time.*

If $\mathcal{T}$ is a conflict tree for matroid M, we say that M is defined by $\mathcal{T}$.

2.2 Elementary reductions for Space Cover

In this section we give some elementary reduction rules that we apply on the instances of Space Cover to make it more structured. This structure will be exploited by our FPT algorithm. In particular, our algorithm crucially utilizes the fact that the solution F we are seeking is of size at most k. However, the way our algorithm is designed, in certain cases the weights of elements can be changed and it can occur that some elements could have been assigned weight zero by w. In this case a solution F of weight at most k does not imply that it is a solution of size at most k. These reduction rules allow us to take care of such situations.

▶ **Reduction Rule 1** (Zero-element). *If there is an element $e \in E \setminus T$ with $w(e) = 0$, then contract e.*

▶ **Reduction Rule 2** (Terminal circuit). *If there is a circuit $C \subseteq T$, then delete an arbitrary element $e \in C$ from M.*

Let us note that Reduction Rules 1 and 2 can be applied in time polynomial in $||M||$.

2.3 Solving Space Cover for basic matroids

We start by solving Space Cover on basic matroids that are building blocks of regular matroid: R_{10}, graphic and cographic matroids. For R_{10} the solution is trivial and for graphic matroids it is an easy extension of the classic Dreyfus-Wagner algorithm [10] for Steiner Tree. However, a single-exponential algorithm for cographic matroids requires new ideas.

Thus we obtain the following lemmata.

▶ **Lemma 7.** Space Cover *can be solved in polynomial time for matroids that can be obtained from R_{10} by adding parallel elements, element deletions and contractions.*

▶ **Lemma 8.** Space Cover *on graphic matroids is solvable in time $4^k \cdot ||M||^{\mathcal{O}(1)}$.*

▶ **Lemma 9.** Space Cover *can be solved in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$ on cographic matroids.*

By the results of Xiao and Nagamochi [40], Restricted Subset Feedback Set can be solved in time $2^{\mathcal{O}(k \log k)} \cdot ||M||^{\mathcal{O}(1)}$ on graphic matroids. It immediately implies that Space Cover can be solved in the same time on cographic matroids by the duality of these problems. To improve this running time and get a single-exponential dependence in k, we construct a new algorithm based on the idea of enumeration of *important cuts* proposed by Marx in [28], see also [5]. Let G be a graph such that M is isomorphic to the bond matroid $M^*(G)$ of G. By the duality of Space Cover and Restricted Subset Feedback Set, a set $F \subseteq E(G) \setminus T$ spans T if and only if the edges of T are the bridges of $G - F$. The set of circuits of M is the set of inclusion-minimal edge cut-sets of G. Hence we restate Space Cover as a cut problem in G: for a given set $T \subseteq E(G)$, we need to find a minimum set $F \subseteq E(G) \setminus T$ such that the edges of T are bridges of $G - F$. For our purpose, we need to modify the definition of an important cut given by Marx [28, 5]. Let $s \in V(G)$ be a vertex of G, $T \subseteq V(G) \setminus \{s\}$ be a set of terminals, and k be a nonnegative integer. We say that a set $W \subseteq V(G)$ is *interesting* if $G[W]$ is connected, $s \in W$, and $|T \cap W| \leq 1$. For $W \subseteq V(G)$, by $\Delta(W)$ we denote the set of edges of G with exactly one end-vertex in W. Given two interesting sets W_1 and W_2 we say that W_1 is *better than* W_2 and denote by $W_2 \preceq W_1$ if $W_2 \subseteq W_1$, $|\Delta(W_1)| \leq |\Delta(W_2)|$, and $T \cap W_1 \subseteq T \cap W_2$. For set of terminals $T \subseteq V(G) \setminus \{s\}$, an interesting set W is (s, T, k)-*semi-important* if $|\Delta(W)| \leq k$ and there is

no set W' such that $W \preceq W'$. The set of edges $\Delta(W)$ of a (s,T,k)-semi-important set W is called a (s,T,k)-*semi-important cut*. We show that the number of (s,T,k)-semi-important cuts is in $16^k \cdot n^{\mathcal{O}(1)}$. Moreover, such cuts can be enumerated within the same time. The crux in the proof of Lemma 9 is the recursive algorithm computing the solution. The running time of the algorithm can be estimated by a polynomial of the number of (s,T,k)-semi-important cuts.

2.4 Solving Space Cover for regular matroids

Now we conjure all that have developed so far and design an algorithm for Space Cover on regular matroids, running in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$. We first give some generic steps, followed by steps when matroid in consideration is either graphic and cographic and ending with a result that ties them all.

Let (M,w,T,k) be a given instance of Space Cover. First, we exhaustively apply Reduction Rules 1-2. To simplify notations, we also denote the reduced instance by (M,w,T,k). We say that a matroid M is *basic* if it is graphic, cographic or can be obtained from R_{10} by adding parallel elements. By Lemmata 7, 8, and 9, we have the following lemma.

▶ **Lemma 10.** *Let (M,w,T,k) be an instance of* Space Cover*. If M is a basic matroid, then* Space Cover *can be solved in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.*

From now onwards we assume that matroid M in the instance (M,w,T,k) is not basic. Now using Theorem 6, we find a conflict tree $\mathcal{T}$. Recall that the set of nodes of $\mathcal{T}$ is the collection of basic matroids $\mathcal{M}$, its the edges correspond to 1-, 2− and 3-sums and that M can be constructed from $\mathcal{M}$ by performing the sums corresponding to the edges of $\mathcal{T}$ in an arbitrary order. Our algorithm is based on performing *bottom-up* traversal of the tree $\mathcal{T}$. We select an arbitrarily *node r as the root* of $\mathcal{T}$. This defines the natural parent-child relationship for the nodes of $\mathcal{T}$. We say that node M_s is a *sub-leaf* if all its children are leaves of $\mathcal{T}$. Observe that there always exists a sub-leaf in a tree on at least two nodes and that this node can be found in polynomial time.

We first modify the decomposition by an exhaustive application of the following rule.

▶ **Reduction Rule 3** (Terminal flipping)**.** *If there is a child M_ℓ of a sub-leaf M_s such that there is $e \in E(M_s) \cap E(M_\ell)$ that is parallel to a terminal $t \in E(M_\ell) \cap T$ in M_ℓ, then delete t from M_ℓ and add t to M_s as an element parallel to e.*

It is easy to show that Reduction Rule 3 is safe and can be applied in polynomial time. From now we assume that there is no child M_ℓ of M_s such that there exists an element $e \in E(M_s) \cap E(M_\ell)$ that is parallel to a terminal $t \in E(M_\ell) \cap T$ in M_ℓ. This is important because it allows us to reduce the parameter while branching. In what follows, we do a bottom-up traversal of $\mathcal{T}$ and at each step we delete one of the children of M_s. A child of M_s is deleted either because of an application of a reduction rule, or because of recursively solving the problem on a smaller sized tree. It is possible that, while recursively solving the problem, we could possibly modify (or replace) M_s to encode some auxiliary information that we have already computed while solving the problem. If at some moment we arrive at the case $T = \emptyset$, then algorithm returns yes and stops. If at some moment the situation with $E \setminus T = \emptyset$ or $|T| > k$ occurs, then we return no and stop.

2.4.1 Processing leaves

For a sub-leaf node M_s, we say that a child M_ℓ of M_s is a 1, 2 or 3-*leaf* if the edge between M_s and M_ℓ corresponds to 1, 2 or 3-sum respectively. While the cases with 1- and 2-leaves

are relatively easy to settle, the case when M_ℓ is a 3-leaf is difficult. We start from generic steps which do not depend on the types of M_s and its child.

If M_ℓ is an 1-leaf such that $E(M_\ell)$ does not contain terminals, we simply delete M_ℓ from $\mathcal{T}$ and consider the problem for the matroid defined by the obtained tree. If M_ℓ is an 1-leaf such that $T_\ell = E(M_\ell) \cap T \neq \emptyset$, then we can solve Space Cover for M_ℓ with the set of terminals T_ℓ independently. More formally, we find minimum $k' \leq k$ such that $(M_\ell, w_\ell, T_\ell, k')$ is a yes-instance of Space Cover using Lemma 10. Then if such k' exist, we consider the matroid M' defined by $\mathcal{T}'$ obtained from $\mathcal{T}$ by the deletion of M_s and then solve the problem for $(M', w, T \cap E(M'), k - k')$. Safeness of this reduction immediately follows from the definition of 1-sum, and the reduction can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

For 2-leaves, we either reduce a leaf or apply a recursive procedure based on whether the leaf contains a terminal or not. Let M_ℓ be 2-leaf that is adjacent to M_s is $\mathcal{T}$ and $E(M_s) \cap E(M_\ell) = \{e\}$. Let also M' be the matroid defined by $\mathcal{T}'$ obtained from $\mathcal{T}$ by the deletion of M_ℓ.

If M_ℓ does not contain terminals, we find a circuit of M_ℓ of minimum weight w_ℓ containing e assuming that the weight of e is 0. Notice, that this can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$ by solving Space Cover on M_ℓ for the unique terminal e. Then we delete M_ℓ from $\mathcal{T}$, assign the weight w_ℓ to the element e of M_s and then solve the problem for M'.

Suppose that M_ℓ is a 2-leaf with terminals. Let $T_\ell = E(M_\ell) \cap T$ and $T' = T \setminus T_\ell$. Notice that due to Reduction Rule 3, M_ℓ has no terminal parallel to e. In particular, it can be shown that this implies that the total weight of the elements of M_ℓ in any solution is positive and this makes the branching possible, because the selection of elements of a solution in M_ℓ reduces the parameter. Notice here that we allow zero weights but all such nonterminal elements are contracted by Reduction Rule 1. We have three branching cases corresponding to the behavior of a (potential) solution F. Recall that by Observation 2, for each $t \in T$, there is a circuit C such that $t \in C \subseteq F \cup \{t\}$.

Case 1. There is $t \in T'$ and a circuit C of M such that $t \in C \subseteq F \cup \{t\}$ and C contains an element of M_ℓ. To handle this case, we consider Space Cover on M_ℓ with the terminals $T_e \cup \{e\}$, that is, we declare e to be a terminal. We find the minimum $0 < k' \leq k$ such that $(M_\ell, w, T_\ell \cup \{e\}, k')$ is a yes-instance of Space Cover using Lemma 10. Then we assign the weight 0 to e in M_s and solve the problem for $(M', w, T', k - k')$.

Case 2. There is $t \in T_\ell$ and a circuit C of M such that $t \in C \subseteq F \cup \{t\}$ and C contains an element of M'. This case is handled symmetrically to Case 1 and, respectively, we find the minimum $0 < k' \leq k$ such that (M_ℓ, w, T_ℓ, k') is a yes-instance of Space Cover where e is assumed to have the weight 0. Then we solve the problem for $(M', w, T' \cup \{e\}, k - k')$.

Case 3. None of the above cases occur, i.e., every terminal from M_ℓ is spanned by elements of M_ℓ in F and every terminal from M' is spanned by elements of M'. Then we can solve the problem independently for M_ℓ and M' assuming that the weight of e is $k + 1$ which forbids using e in a solution. We find minimum $0 < k' \leq k$ such that $(M_\ell, w_\ell, T_\ell, k')$ is a yes-instance of Space Cover and then solve the problem for $(M', w, T', k - k')$.

It is possible to show this branching is exhaustive. We show also that one call of the step (without recursive calls) can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

Suppose now that M_ℓ is a 3-leaf adjacent to M_s in $\mathcal{T}$. We again differentiate between cases when it has terminals or not. Assume that M_ℓ contains $T_\ell = E(M_\ell) \cap T \neq \emptyset$. Denote

by $Z = E(M_s) \cap E(M_\ell)$. As for 2-leaves, we observe that there are no terminals of T_ℓ that are parallel to the elements of Z in M_ℓ and we can branch according to the possible variants of the behavior of a (potential) solution F. The case analysis is technically complicated, because we have more variants of the behavior of F comparing to the case analysis for 2-leaves. Still, the majority of the cases are handled by similar arguments and we omit them here, but there is one case that makes our algorithm complicated and we briefly discuss it here.

Denote by M' the matroid defined by $\mathcal{T}'$ obtained from $\mathcal{T}$ by the deletion of M_ℓ. Suppose that there is $t \in T'$ and a circuit C of M such that $t \in C \subseteq F \cup \{t\}$ and C contains an element of M_ℓ, and there is $t' \in T_\ell$ and a circuit C' of M such that $t' \in C' \subseteq F \cup \{t'\}$ and C' contains an element of M'. Then it can be shown that there are distinct $e_i, e_j \in Z$ such that $C = C_1 \triangle C_2$, $C' = C'_1 \triangle C'_2$ where C_1, C'_1 are circuits of M_ℓ, C_2, C'_2 are circuits of M', $C_1 \cap C_2 = \{e_i\}$ and $C'_1 \cap C'_2 = \{e_j\}$. We declare $w(e_i) = w(e_j) = 0$ and let the weight of the third element of Z to be $k+1$. Then we find the minimum $0 < k' \leq k$ such that $(M_\ell, w, T_\ell \cup \{e_i\}, k')$ is a yes-instance of Space Cover and afterwards solve the problem for $(M', w, T' \cup \{e_j\}, k - k')$.

However, it can lead to the following situation. We have solutions F_ℓ and F' for $(M_\ell, w, T_\ell \cup \{e_i\}, k')$ and $(M', w, T' \cup \{e_j\}, k - k')$. Then there are circuits C_ℓ of M_ℓ and C' of M' such that $e_i \in C_\ell \subseteq F_\ell \cup \{e_i\}$ and $e_j \in C' \subseteq F' \cup \{e_j\}$. If $e_j \in C_\ell$ and $e_i \in C'$, then $(F_\ell \triangle F') \setminus Z$ is not a solution for M. To avoid this situation, we have to solve a special variant of Space Cover for $(M_\ell, w, T_\ell \cup \{e_i\}, k')$ where we put on the solution F_ℓ the additional condition that $e_i \in \mathrm{span}(F_\ell \setminus e_j)$. Due to this technicality, we also have to provide algorithms solving this version of Space Cover on basic matroids. This is done by constructing variants of the algorithm from Lemmata 8 and 9.

For this branching, we show that it is exhaustive and one call of this branching step (without recursive calls) can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

We approach the most challenging part concerning processing of 3-leaves without terminals. At this stage we can assume that $\mathcal{T}$ has only 3-leaves. The way to handle this case depends on the type of the sub-leaf M_s adjacent to a 3-leaf M_ℓ. Since M_ℓ is a 3-leaf, we have that M_s is either graphic or cographic, because R_{10} has no circuit of odd size.

Suppose that M_s is a graphic matroid. Let G be a graph such that its cycle matroid $M(G)$ is isomorphic to M_s. The algorithm that constructs a good $\{1,2,3\}$-decomposition also could be used to output the graph G. We assume that $M(G) = M_s$. The idea is to replace M_ℓ by attaching a gadget to G. Recall that the circuits of $M(G)$ are exactly the cycles of G. Since Z is a circuit of $M(G)$, the elements of Z form a cycle of G. Denote by v_1, v_2, v_3 its vertices. We modify G by adding a new vertex u and making it adjacent to v_1, v_2, v_3. Denote by G' the obtained graph. We assign weights to the edges of Z and the new edges according to the possible structure of a solution F in M_ℓ by solving auxiliary instances of Space Cover on M_ℓ. It can happen that to span T in M, we only need the property that $F \cap E(M_\ell)$ spans in M_ℓ a unique edge v_iv_j of Z. Then we find a spanning set F_ℓ of minimum weight $w_{ij} \leq k$ in M_ℓ for the terminal v_iv_j such that $v_hv_i, v_hv_j \notin F_\ell$ for $h \neq i, j$. Then we define $w(v_iv_j) = w_{ij}$ if F_ℓ exists and set $w(v_iv_j) = k+1$ otherwise. The other important possibility is that $F \cap E(M_\ell)$ spans in M_ℓ all v_iv_j for distinct $i, j \in \{1,2,3\}$. We find a spanning set F_ℓ of minimum weight $w' \leq k$ in M_ℓ for the terminal set Z. We show that it is possible to assign the weights to the edges uv_i for $i \in \{1,2,3\}$ in such a way that $w(uv_1) + w(uv_2) + w(uv_3) = w'$ and $w(uv_i) + w(uv_j) \geq w(v_iv_j)$ for $i, j \in \{1,2,3\}$ if such a solution F_ℓ exist. Otherwise, we simply set $w(uv_i) = k+1$ for $i \in \{1,2,3\}$. To complete the reduction, we consider the matroid M' defined by $\mathcal{T}'$ obtained from $\mathcal{T}$ by the deletion of M_ℓ where M_s is replaced by $M(G')$. Then we solve Space Cover for (M', w, T, k). We show that the reduction can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

The case when M_s is a cographic matroid is most challenging. Let G be a graph such that the bond matroid of G is isomorphic to M_s. Without loss of generality, we can assume that G is connected. Recall also that the circuits of the bond matroid $M^*(G)$ are exactly minimal cut-sets of G.

Isomorphism between M_s and $M^*(G)$ is not necessarily unique. We choose an isomorphism between M_s and $M^*(G)$ that is beneficial for our algorithmic purposes. Let $M_\ell^{(1)}, \ldots, M_\ell^{(s)}$ denote those leaves of the conflict tree $\mathcal{T}$ that are also the children of M_s. Let $Z_i = E(M_s) \cap E(M_\ell^{(i)})$, $i \in \{1, \ldots, s\}$. If M_s has a parent M^* in $\mathcal{T}$ and $E(M_s) \cap E(M^*) \neq \emptyset$, then let $Z^* = E(M_s) \cap E(M^*)$; we *emphasize* that Z^* may not exist. Next we define the notion of a *clean cut*.

▶ **Definition 11.** We say that $\alpha(Z_i) \subseteq E(G)$ is a *clean cut* with respect to an isomorphism $\alpha\colon M_s \to M^*(G)$, if there is a component H of $G - \alpha(Z_i)$ such that (i) H has no bridge, (ii) $E(H) \cap \alpha(Z_j) = \emptyset$ for $j \in \{1, \ldots, s\}$, and (iii) $E(H) \cap \alpha(Z^*) = \emptyset$ if Z^* exists. We call H a *clean component* of $G - \alpha(Z_i)$.

Next we show that given any isomorphism between M_s and $M^*(G)$, we can obtain another isomorphism between M_s and $M^*(G)$ with respect to which we have at least one clean component.

▶ **Lemma 12.** *There is an isomorphism $\alpha\colon M_s \to M^*(G)$ and a child $M_\ell^{(i)}$ of M_s such that $\alpha(Z_i)$ is a clean cut with respect to α. Moreover, given any arbitrary isomorphism from M_s to $M^*(G)$, one can obtain such an isomorphism and a clean cut together with a clean component in polynomial time.*

Using Lemma 12, we can always assume that we have an isomorphism of M_s to $M^*(G)$ such that for a child M_ℓ of M_s in $\mathcal{T}$, $Z = E(M_s) \cap E(M_\ell)$ is mapped to a clean cut. To simplify notations, we assume that $M_s = M^*(G)$ and Z is a clean cut with respect to this isomorphism. Denote by H the clean component. Let $Z = \{e_1, e_2, e_3\}$ and let $e_i = x_i y_i$ for $i \in \{1, 2, 3\}$, where $y_1, y_2, y_3 \in V(H)$. Notice that some y_1, y_2, y_3 can be the same.

We first handle the case when $E(H) \cap T = \emptyset$. Similarly to the case of a graphic subleaf, we replace M_ℓ by a gadget. The difference is that the gadget replaces M_s *and* H. We modify G as follows. First, we delete H. Then we construct three new pairwise adjacent vertices z_1, z_2, z_3 and make z_i adjacent to x_i for $i \in \{1, 2, 3\}$. Let G' be the obtained graph. We analyze the possible structure of a solution in H and M_ℓ, and use this information to assign weight to the edges $x_i z_i$ for $i \in \{1, 2, 3\}$ and $z_i z_j$ for $i, j \in \{1, 2, 3\}$ similarly to the case of a graphic subleaf. Finally, we consider the matroid M' defined by $\mathcal{T}'$ obtained from $\mathcal{T}$ by the deletion of M_s where M_s is replaced by $M(G')$. Then we solve Space Cover for (M', w, T, k). We prove that the reduction can be done in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

It remains to consider the case $E(H) \cap T \neq \emptyset$. In this case, we either reduce H or recursively solve the problem on smaller H. Rather than describing these steps, we observe that we can decompose M_s further using the decomposition theorem given in [37, Chapter 8] using the cut $\{x_1y_1, x_2y_2, x_3y_3\}$. This way, we obtain a new leaf with terminals and can apply the already described rules.

Concerning the total running time, observe that we apply reduction rules either in polynomial time or in $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$ time. After each reduction rule we obtain a conflict tree with a smaller number of vertices, hence we use reductions a polynomial number of times. For each of the branching rule, in the recursive call we reduce the parameter, hence the number of nodes in the corresponding search tree is in $2^{\mathcal{O}(k)}$. Therefore the running time of the algorithm is $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(1)}$.

3 Reducing rank

In the well-known h-Way Cut problem, we are given a connected graph G and positive integers h and k, the task is to find at most k edges whose removal increases the number of connected components by at least h. The problem has a simple formulation in terms of matroids: Given a graph G and an integers k, h, find k elements of the graphical matroid of G whose removal reduces its rank by at least h. This motivated Joret and Vetta [24] to introduce the Rank h-Reduction problem on matroids. Here we define Rank h-Reduction on binary matroids.

Rank h-Reduction	**Parameter:** k
Input: A binary matroid $M = (E, \mathcal{I})$ given together with its matrix representation over GF(2) and two positive integers h and k.	
Question: Is there a set $X \subseteq E$ with $\|X\| \leq k$ such that $r(M) - r(M - X) \geq h$?	

As a corollary of Theorem 1, we show that on regular matroids Rank h-Reduction is FPT for any fixed h.

We use the following lemma.

▶ **Lemma 13.** *Let M be a binary matroid and let $k \geq h$ be positive integers. Then M has a set $X \subseteq E$ with $|X| \leq k$ such that $r(M) - r(M - X) \geq h$ if and only if there are disjoint sets $F, T \subseteq E$ such that $|T| = h$, $|F| \leq k - h$, and $T \subseteq \mathrm{span}(F)$ in M^*.*

For graphic matroids, when Rank h-Reduction is equivalent to h-Way Cut, the problem is FPT parameterized by k even if h is a part of the input [25]. Unfortunately, similar result does not hold for cographic matroids.

▶ **Proposition 14.** Rank h-Reduction *is* W[1]*-hard for cographic matroids parameterized by $h + k$.*

However, by Theorem 1, for fixed h, Rank h-Reduction is FPT parameterized by k on regular matroids.

▶ **Theorem 15.** Rank h-Reduction *can be solved in time $2^{\mathcal{O}(k)} \cdot ||M||^{\mathcal{O}(h)}$ on regular matroids.*

4 Conclusion

In this paper, we used the structural theorem of Seymour for designing parameterized algorithm for Space Cover. While structural graph theory and graph decompositions serve as the most usable tools in the design of parameterized algorithms, the applications of structural matroid theory in parameterized algorithms are limited. There is a series of papers about width-measures and decompositions of matroids (see, in articular, [21, 22, 23, 27, 30, 31] and the bibliography therein) but, apart of this specific area, we are not aware of other applications except the works Gavenciak et al. [12] and our recent work [11]. In spite of the tremendous progress in understanding the structure of matroids representable over finite fields [13, 14, 15, 16], this rich research area still remains to be explored from the perspective of parameterized complexity.

As a concrete open problem, what about the parameterized complexity of Space Cover on any proper minor-closed class of binary matroids?

Abstract

Suppose $\mathcal{F}$ is a finite family of graphs. We consider the following meta-problem, called $\mathcal{F}$-Immersion Deletion: given a graph G and an integer k, decide whether the deletion of at most k edges of G can result in a graph that does not contain any graph from $\mathcal{F}$ as an immersion. This problem is a close relative of the $\mathcal{F}$-Minor Deletion problem studied by Fomin et al. [FOCS 2012], where one deletes vertices in order to remove all minor models of graphs from $\mathcal{F}$. We prove that whenever all graphs from $\mathcal{F}$ are connected and at least one graph of $\mathcal{F}$ is planar and subcubic, then the $\mathcal{F}$-Immersion Deletion problem admits:

- a constant-factor approximation algorithm running in time $\mathcal{O}(m^3 \cdot n^3 \cdot \log m)$;
- a linear kernel that can be computed in time $\mathcal{O}(m^4 \cdot n^3 \cdot \log m)$; and
- a $\mathcal{O}(2^{\mathcal{O}(k)} + m^4 \cdot n^3 \cdot \log m)$-time fixed-parameter algorithm,

where n, m count the vertices and edges of the input graph. Our findings mirror those of Fomin et al. [FOCS 2012], who obtained similar results for $\mathcal{F}$-Minor Deletion, under the assumption that at least one graph from $\mathcal{F}$ is planar. An important difference is that we are able to obtain a *linear* kernel for $\mathcal{F}$-Immersion Deletion, while the exponent of the kernel of Fomin et al. depends heavily on the family $\mathcal{F}$. In fact, this dependence is unavoidable under plausible complexity assumptions, as proven by Giannopoulou et al. [ICALP 2015]. This reveals that the kernelization complexity of $\mathcal{F}$-Immersion Deletion is quite different than that of $\mathcal{F}$-Minor Deletion.

1 Introduction

On the $\mathcal{F}$-Minor Deletion problem. Let us fix a finite family of graphs $\mathcal{F}$. A graph is called *$\mathcal{F}$-minor-free* if it does not contain any graph from $\mathcal{F}$ as a minor. Given a class of graphs $\mathcal{G}$, we denote by $\mathbf{obs}_{\mathrm{mn}}(\mathcal{G})$ the set of minor-minimal graphs not in $\mathcal{G}$. The celebrated Graph Minors Theorem [32] states that for $\mathcal{G}$ closed under taking minors, the set $\mathbf{obs}_{\mathrm{mn}}(\mathcal{G})$ is finite. In other words, $\mathcal{G}$ is characterized by a finite set of minor-obstructions, as $\mathcal{G}$ is exactly the class of $\mathcal{F}$-minor-free graphs, for $\mathcal{F} = \mathbf{obs}_{\mathrm{mn}}(\mathcal{G})$. Hence, studying classes of $\mathcal{F}$-minor-free graphs for finite families $\mathcal{F}$ is the same as studying general minor-closed properties of graphs.

Fomin et al. [14] performed an in-depth study of the following parameterized[1] problem, named $\mathcal{F}$-Minor Deletion[2]: *Given a graph G and an integer parameter k, decide whether one can remove at most k vertices from G to obtain an $\mathcal{F}$-minor-free graph.* By considering different families $\mathcal{F}$, the $\mathcal{F}$-Minor Deletion problem generalizes a number of concrete problems of prime importance in parameterized complexity, such as Vertex Cover, Feedback Vertex Set, or Planarization. It is easy to see that, for every fixed k, the graph class $\mathcal{G}^{\mathrm{mn}}_{k,\mathcal{F}}$ consisting of the graphs in the YES-instances (G,k) of $\mathcal{F}$-Minor Deletion, is closed under taking of minors. By the meta-algorithmic consequences of the Graph Minors series of Robertson and Seymour [32, 30], it follows (non-constructively) that $\mathcal{F}$-Minor Deletion admits an FPT-algorithm. The optimization of the running time of such FPT-algorithms for several instantiations of $\mathcal{F}$ has been a stimulating project in parameterized algorithm design. So far, it has been focused on problems generated by minor-closed graph classes.

The goal of Fomin et al. [14] was to obtain results of general nature for $\mathcal{F}$-Minor Deletion, which would explain why many concrete problems captured as its subcases are efficiently solvable using parameterized algorithms and kernelization. This has been achieved under the assumption that $\mathcal{F}$ contains at least one planar graph. More precisely, for any class $\mathcal{F}$ that contains at least one planar graph, the work of Fomin et al. [14] gives the following:

- a randomized constant-factor approximation running in time $\mathcal{O}(nm)$;
- a polynomial kernel for the problem; that is, a polynomial-time algorithm that, given an instance (G,k) of $\mathcal{F}$-Minor Deletion, outputs an equivalent instance (G',k') with $k' \leq k$ and $|G'| \leq \mathcal{O}(k^c)$, for some constant c that depends on $\mathcal{F}$;
- an FPT-algorithm for $\mathcal{F}$-Minor Deletion in time $2^{\mathcal{O}(k)} \cdot n$ (note this originally required that all graphs from $\mathcal{F}$ be connected; Kim et al. [24] showed how to lift this assumption);
- a proof that every graph in $\mathbf{obs}_{\mathrm{mn}}(\mathcal{G}^{\mathrm{mn}}_{k,\mathcal{F}})$ has at most $k^{c_{\mathcal{F}}}$ vertices, for some constant $c_{\mathcal{F}}$ that depends (non-constructively) on $\mathcal{F}$.

The assumption that $\mathcal{F}$ contains at least one planar graph is crucial for the approach of Fomin et al. [14]. Namely, from the Excluded Grid Minor Theorem of Robertson and Seymour [31] it follows that for such families $\mathcal{F}$, $\mathcal{F}$-minor-free graphs have treewidth bounded by a constant depending only of $\mathcal{F}$. Therefore, a YES-instance of $\mathcal{F}$-Minor Deletion

[1] A *parameterized* problem can be seen as a subset of $\Sigma^* \times \mathbb{N}$. For graph problems, the string x in an instance $(x,k) \in \Sigma^* \times \mathbb{N}$ usually encodes a graph G. An FPT-algorithm for the problem is then an algorithm working in $f(k) \cdot |x|^{O(1)}$ time. See [12, 8, 29] for more on parameterized algorithms and complexity.

[2] Fomin et al. used the name $\mathcal{F}$-Deletion. We write $\mathcal{F}$-Minor Deletion instead for clarity.

roughly has to look like a constant-treewidth graph plus k additional vertices that can have arbitrary connections. Having exposed this structure, Fomin et al. [14] apply protrusion-based techniques that originate in the work on *meta-kernelization* [3, 15]. Roughly speaking, the idea is to identify large parts of the graphs that have constant treewidth and a small interface towards the rest of the graph (so-called *protrusions*), which can then be replaced by smaller gadgets with the same combinatorial behaviour. Such preprocessing based on *protrusion replacement* is the base of all three aforementioned results for $\mathcal{F}$-Minor Deletion. In the absence of a constant bound on the treewidth of an $\mathcal{F}$-minor-free graph, the technique breaks completely. In fact, the kernelization complexity of Planarization, that is, $\mathcal{F}$-Minor Deletion for $\mathcal{F} = \{K_5, K_{3,3}\}$, is a notorious open problem.

An interesting aspect of the work of Fomin et al. [14] is that the exponent of the polynomial bound on the size of the kernel for $\mathcal{F}$-Minor Deletion grows quite rapidly with the family $\mathcal{F}$. Recently, it has been shown by Giannopoulou et al. [17] that in general this growth is unavoidable: unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$, for every constant η, the Treewidth-η Deletion problem (delete k vertices to get a graph of treewidth at most η) has no kernel with $\mathcal{O}(k^{\eta/4-\epsilon})$ vertices for any $\epsilon > 0$. Since graphs of treewidth η can be characterized by a finite set of forbidden minors $\mathcal{F}_\eta$, at least one of which is planar, this refutes the hypothesis that all $\mathcal{F}$-Minor Deletion problems admit polynomial kernels with a uniform bound on the degree of the polynomial. However, as shown by Giannopoulou et al. [17], such bounds can be achieved for some specific problems, like vertex deletion to graphs of constant tree-depth.

Immersion problems. Recall that a graph H can be *immersed* into a graph G (or that H is an *immersion* of G) if there is a mapping from vertices of H to pairwise different vertices of G and from edges of H to pairwise *edge-disjoint paths* connecting the images of its endpoints[3]. Such a mapping is called an *immersion model*. Just like the minor relation, the immersion relation imposes a partial order on the class of graphs. Alongside with the minor order, Robertson and Seymour [33] proved that graphs are well-quasi-ordered under the immersion order as well. This implies that for every graph class $\mathcal{G}$ that is closed under taking immersions, the set $\mathbf{obs}_{\mathrm{im}}(\mathcal{G})$ containing immersion minimal graphs that do not belong in $\mathcal{G}$, is finite (we call $\mathbf{obs}_{\mathrm{im}}(\mathcal{G})$ the *immersion obstruction set* of $\mathcal{G}$). Therefore $\mathcal{G}$ can be characterized by a finite set of forbidden immersions. The general intuition is that immersion is a containment relation that corresponds to *edge* cuts, whereas the minor relation corresponds to *vertex* cuts. Also, the natural setting for immersions is the setting of *multigraphs*. Hence, all the graphs considered in this paper may have parallel edges connecting the same pair of endpoints.

Recently, there has been a growing interest in immersion-related problems [28, 10, 16, 25, 18, 20, 36, 4, 9, 1, 21, 11] both from the combinatorial and the algorithmic point of view. Most importantly for us, Wollan proved in [36] an analogue of the Excluded Grid Minor Theorem, which relates the size of the largest wall graph that is contained in a graph as an immersion with a new graph parameter called *tree-cut width*. By a *subcubic graph* we mean a graph of maximum degree at most 3. The following theorem follows from the work of Wollan [36].

▶ **Theorem 1** ([18]). *For every planar subcubic graph H, there exists a constant a_H such that every graph not containing H as an immersion has tree-cut width bounded by a_H.*

In other words, for any family $\mathcal{F}$ of graphs that contains some planar subcubic graph, the tree-cut width of $\mathcal{F}$-immersion-free graphs is bounded by a universal constant depending

[3] In this paper we consider *weak immersions* only, as opposed to *strong immersions* where the paths are forbidden to traverse images of vertices other than the endpoints of the corresponding edge.

on $\mathcal{F}$ only. In Section 2 we discuss the precise definition of tree-cut width and how exactly Theorem 1 follows from the work of Wollan [36]. Also, note that if a family of graphs $\mathcal{F}$ does not contain any planar subcubic graph, then there is no uniform bound on the tree-cut width of $\mathcal{F}$-immersion-free graphs. Indeed, wall graphs are then $\mathcal{F}$-immersion-free, because all their immersions are planar and subcubic, and they have unbounded tree-cut width.

After the introduction of tree-cut width by Wollan [36], the new parameter gathered substantial interest from the algorithmic and combinatorial community [16, 28, 18, 25]. It seems that tree-cut width serves the same role for immersion-related problems as treewidth serves for minor-related problems and, in a sense, it can be seen as an "edge-analogue" of treewidth. In particular, given the tree-cut width bound of Theorem 1 and the general approach of Fomin et al. [14] to $\mathcal{F}$-Minor Deletion, it is natural to ask whether the same kind of results can be obtained for immersions where the edge removals are considered instead of vertex removals. More precisely, fix a finite family of graphs $\mathcal{F}$ containing some planar subcubic graph and consider the following $\mathcal{F}$-Immersion Deletion problem: given a graph G and an integer k, determine whether it is possible to delete at most k edges of G in order to obtain a graph that does not admit any graph from $\mathcal{F}$ as an immersion. Notice that when $\mathcal{F} = \{K_2\}$ and $\mathcal{F} = \{K_3\}$, the problem of computing the minimum size of such a set of edges can be solved in polynomial time, while it is NP-hard when $\mathcal{F} = \{K_4^-\}$ (see e.g. [5]).

Parallel to the case of $\mathcal{F}$-Minor Deletion, for every fixed k, the graph class $\mathcal{G}_{k,\mathcal{F}}^{\mathrm{im}}$ consisting of the graphs in the YES-instances (G, k) of $\mathcal{F}$-Immersion Deletion is closed under taking of immersions[4], therefore $\mathcal{O}_k^{\mathrm{im}} = \mathbf{obs}_{\mathrm{im}}(\mathcal{G}_{k,\mathcal{F}}^{\mathrm{im}})$ is a finite set, by the well-quasi-ordering of graphs under immersions [33]. Together with the immersion-testing algorithm of Grohe et al. [22], this implies that $\mathcal{F}$-Immersion Deletion admits (non-constructively) an FPT-algorithm. This naturally induces the parallel project of optimizing the performance of such FPT-algorithms for various instantiations of $\mathcal{F}$. More concretely, is it possible to extend the general framework of Fomin et al. [14] to obtain efficient approximation, kernelization, and FPT algorithms also for $\mathcal{F}$-Immersion Deletion? Theorem 1 suggests that the suitable analogue of the assumption from the minor setting that $\mathcal{F}$ contains a planar graph should be the assumption that at least one graph from $\mathcal{F}$ is planar and subcubic.

Our results. In this work we give a definitive positive answer to this question. The following two theorems gather our main results; for a graph G, by $|G|$ and $\|G\|$ we denote the cardinalities of the vertex and edge sets of G, respectively.

▶ **Theorem 2** (Constant factor approximation). *Let $\mathcal{F}$ be a finite family of connected graphs with at least one member being planar and subcubic. Given a graph G, in $\mathcal{O}(\|G\|^3 \log \|G\| \cdot |G|^3)$ time one can output a subset of edges $F \subseteq E(G)$ such that $G - F$ is $\mathcal{F}$-immersion-free and the size of F is at most c_{apx} times larger than the optimum size of a subset of edges with this property, for some constant c_{apx} depending on $\mathcal{F}$ only.*

The constant-factor approximation can be generalized to work when $\mathcal{F}$ contains disconnected graphs as well, using the approach of Fomin et al. [14, 13].

[4] Notice that if we consider deletion of vertices instead of edges, then the graph class $\mathcal{G}_k^{\mathrm{im}}$ is *not* closed under taking immersions (for example, in a star on 7 vertices with duplicated edges, deleting one vertex makes it K_3-immersion-free, but this 'duplicated' star immerses $2K_3$, which has no such vertex). This is the main reason why we believe that *edge* deletion gives a more suitable counterpart to $\mathcal{F}$-Minor Deletion for the case of immersions.

▶ **Theorem 3** (Linear kernelization and obstructions). *Let $\mathcal{F}$ be a finite family of connected graphs with at least one member being planar and subcubic. Given an instance (G,k) of $\mathcal{F}$-*Immersion Deletion*, in time $\mathcal{O}(\|G\|^4 \log \|G\| \cdot |G|^3)$ one can output an equivalent instance (G',k) with $\|G'\| \leq c_{\mathrm{ker}} \cdot k$, for some constant c_{ker} depending on $\mathcal{F}$ only. Moreover, every graph in $\mathcal{O}_k^{\mathrm{im}}$ has at most $c_{\mathcal{F}} \cdot k$ edges (for a constant $c_{\mathcal{F}}$ non-constructively depending on $\mathcal{F}$).*

Thus, Theorems 2 and 3 mirror the approximation and kernelization results and the obstruction bounds of Fomin et al. [14]. However, this mirroring is not exact as we show that, in the immersion setting, a stronger kernelization procedure can be designed. Namely, the size of the kernel given by Theorem 3 is *linear*, with only the multiplicative constant depending on the family $\mathcal{F}$, whereas in the minor setting, the exponent of the polynomial bound on the kernel size provably must depend on $\mathcal{F}$ (under plausible complexity assumptions). This shows that the immersion and minor settings behave quite differently and in fact stronger results can be obtained in the immersion setting. Observe that using Theorem 3 it is trivial to obtain a decision algorithm for $\mathcal{F}$-Immersion Deletion working in time $\mathcal{O}(c_{\mathrm{fpt}}^k + \|G\|^4 \log \|G\| \cdot |G|^3)$ for some constant c_{fpt} depending on $\mathcal{F}$ only: one simply computes the kernel with a linear number of edges and checks all the subsets of edges of size k.

Our techniques. Our approach to proving Theorems 2 and 3 roughly follows the general framework of protrusion replacement of Fomin et al. [14] (see also [3]). We first define protrusions suited for the problem of our interest. In fact, our protrusions can be seen as the edge-analogue of those introduced in [14] (as in [5]). A protrusion for us is simply a vertex subset X that induces an $\mathcal{F}$-immersion-free subgraph (which hence has constant tree-cut width, by Theorem 1), and has a constant number of edges to the rest of the graph. When a large protrusion is localized, it can be replaced by a smaller gadget similarly as in the work of Fomin et al. [14]. However, we need to design a new algorithm for searching for large protrusions, mostly in order to meet the condition that the exponent of the polynomial running time of the algorithm *does not depend* on $\mathcal{F}$. For this, we employ the important cuts technique of Marx [27] and the randomized contractions technique of Chitnis et al. [6]. All of these yield an algorithm that exhaustively reduces all large protrusions.

Unfortunately, exhaustive protrusion replacement is still not sufficient for a linear kernel. However, we prove that in the absence of large reducible protrusions, the only remaining obstacles are large groups of parallel edges between the same two endpoints (called *thetas*), and, more generally, large "bouquets" of constant-size graphs attached to the same pair of vertices. Without these, the graph is already bounded linearly in terms of the optimum solution size. The approximation algorithm can thus delete *all* edges except for the copies included in bouquets and thetas, reducing the optimum solution size by a constant fraction of the deleted set. It then exhaustively reduces protrusions in the remaining edges, and repeats the process until the graph is $\mathcal{F}$-immersion-free.

To obtain a linear kernel we need more work, as we do not know how to reduce bouquets and thetas directly. Instead, we apply the following strategy based on the idea of *amortization*. After reducing exhaustively all larger protrusions, we compute a constant-factor approximate solution F_{apx}. Then we analyze the structure of the graph $G - F_{\mathrm{apx}}$, which has constant tree-cut width. It appears that every bouquet (and theta) in G can be reduced up to size bounded linearly in the number of solution edges F_{apx} that "affect" it. After applying this reduction, we can still have large bouquets in the graph, but this happens only when they are affected by a large number of edges of F_{apx}. However, every edge of F_{apx} can affect only a constant number of bouquets and hence a simple amortization arguments shows that the total size of bouquets is linear in $|F_{\mathrm{apx}}|$, so also linear in terms of the optimum.

We remark that this part of the reasoning (the above amortization argument in particular) are fully new contributions of this work. These deviate significantly from arguments by Fomin et al. [14], which aimed at a obtaining a polynomial kernel only, instead of linear. Also, we remark that, contrary to the work of Fomin et al. [14], all our algorithms are deterministic.

For the second part of Theorem 3, we show that protrusion replacements can be realized as immersions of the original graph. This implies that, in the equivalent instance (G', k) produced by our kernelization algorithm, the graph G' is an immersion of G. Therefore any immersion-obstruction of $\mathcal{G}^{\mathrm{im}}_{k-1,\mathcal{F}}$ must already have a linear, in k, number of edges.

Application: immersion-closed parameters. We would like to highlight one meta-algorithmic application of our results, which was our original motivation. Suppose $\mathbf{p}$ is a graph parameter, that is, a function that maps graphs to $\mathbb{N}$. We shall say that $\mathbf{p}$ is *closed under immersion* if $\mathbf{p}(H) \leq \mathbf{p}(G)$ whenever H is an immersion of G; $\mathbf{p}$ is *closed under disjoint union* if $\mathbf{p}(G_1 \uplus G_2) = \max(\mathbf{p}(G_1), \mathbf{p}(G_2))$ for any graphs G_1, G_2; here, $\uplus$ denotes disjoint union.

For a parameter $\mathbf{p}$ and a constant r, define the $\mathbf{p}$-at-most-r Edge Deletion problem as follows: given a graph G and an integer k, determine whether at most k edges can be deleted from G to obtain a graph with the value of $\mathbf{p}$ at most r. We also define the associated parameter $\mathbf{p}_r(G) = \min\{k \mid \exists S \subseteq E(G) : |S| \leq k \wedge \mathbf{p}(G \setminus S) \leq r\}$ and $\mathcal{G}_{k,\mathbf{p}_r} = \{G \mid \mathbf{p}_r(G) \leq k\}$. Then the following meta-result can be derived from Theorems 2 and 3 and the fact that immersion is a well-quasi-order; a proof can be found in the full version of the paper.

▶ **Theorem 4.** *Let $\mathbf{p}$ be a graph parameter that is closed under immersion and under disjoint union and moreover is large on the class of walls*[5]*. Then, for every constant r, the $\mathbf{p}$-at-most-r Edge Deletion problem admits a constant-factor approximation and a linear kernel. Moreover, there is a constant c_r, depending (non-constructively) on r, such that for every k, every graph H in $\mathbf{obs}_{\mathrm{im}}(\mathcal{G}_{k,\mathbf{p}_r})$ has at most $c_r \cdot k$ edges.*

Natural parameters that satisfy the prerequisites of Theorem 4 include cutwidth, carving width, tree-cut width, and edge ranking; see e.g. [34, 35, 36, 26, 23] for more details. Theorem 4 mirrors a corollary by Fomin et al. [14] for the Treewidth-η Deletion problem asserting a constant-factor approximation, a polynomial kernel, a polynomial bound for the corresponding minor-obstruction set, and a single-exponential FPT algorithm, for every constant η.

Organization. This extended abstract focuses on sketching the proofs of Theorems 2 and 3. The proofs of statements marked with $\star$ are omitted and can be found in the full version [19].

2 Preliminaries

For a positive integer p, we denote $[p] = \{1, 2, \ldots, p\}$. A graph G is a pair $(V(G), E(G))$, where $V(G)$ is the *vertex set*, and $E(G)$ is a multiset of *edges*. Each edge connects two different vertices, called the *endpoints* of the edge (we do not allow loops). Note that there might be several edges (called *parallel edges*) between two vertices. An edge is *incident* to a vertex if it is one of its two endpoints.

We write $|G|$ for $|V(G)|$ and $\|G\|$ for $|E(G)|$ (counting edges with multiplicities). For a subset of vertices $X \subseteq V(G)$, $G[X]$ is the subgraph induced by X. For a subset of edges

[5] A graph parameter $\mathbf{p}$ is *large on a graph class $\mathcal{C}$* if $\{\mathbf{p}(G) \mid G \in \mathcal{C}\}$ is not a bounded set.

$F \subseteq E(G)$, $G - F$ denotes the graph G with all edges from F removed. For two subsets $X, Y \subseteq V(G)$, not necessarily disjoint, $E_G(X,Y)$ denotes the set of edges of $E(G)$ of the form xy for some $x \in X$ and $y \in Y$. The *boundary* of X is $\delta_G(X) = E_G(X, V(G) \setminus X)$.

Tree-cut width. A *near-partition* of a set X is a family of (possibly empty) subsets $X_1, \ldots, X_k$ of X such that $\bigcup_{i=1}^{k} X_i = X$ and $X_i \cap X_j = \emptyset$ for every $i \neq j$.

A *tree-cut decomposition* of a connected graph G is a pair $(T, \mathcal{X})$ where T is a tree and $\mathcal{X} = \{X_t : t \in V(T)\}$ is a near-partition of the vertices of G. Sets $\{X_t : t \in V(T)\}$ are called the *bags* of the decomposition. For a subset $W \subseteq V(T)$, define X_W as $\bigcup_{t \in W} X_t$. By rooting T at some vertex, we can talk about a *rooted tree-cut decomposition*. When G is disconnected, a tree-cut decomposition is a forest consisting of one tree for each connected component.

For each edge $e = uv$ of T, $T - uv$ has exactly two components which we call T_{uv} and T_{vu}, that contain u and v respectively. Since $\mathcal{X}$ is a near-partition, sets $X_{V(T_{uv})}$ and $X_{V(T_{vu})}$ form a near-partition of $V(G)$ (provided G is connected). We define the *adhesion* of an edge $e = uv$ of T, denoted $\mathsf{adh}_{\mathcal{T}}(e)$, as the set $E_G(X_{V(T_{uv})}, X_{V(T_{vu})})$. We omit the subscript if $\mathcal{T}$ is clear from the context. An adhesion is *thin* if it has at most 2 edges, *bold* otherwise.

We now move to the definition of tree-cut width. In fact, we do not give the original definition (it can be found in the full version of the paper), but we instead give an alternative definition that is easier to handle. Let G be a graph and $(T, \mathcal{X} = \{X_t : t \in V(T)\})$ be a tree-cut decomposition of G. For a node t of T, let $w(t)$ be the number of edges incident to t that have bold adhesions. The *width′* of the decomposition, denoted $\mathsf{width}'(T, \mathcal{X})$, is equal to $\max\{\max_{e \in E(T)} |\mathsf{adh}(e)|, \max_{t \in V(T)} |X_t| + w(t)\}$. The *tree-cut width′* of G, denoted $\mathsf{tctw}'(G)$, is the minimum width' of a tree-cut decomposition of G. The standard tree-cut width of G, denoted $\mathsf{tctw}(G)$, is similarly defined as the minimum width of a tree-cut decomposition of G, where width is defined slightly differently. We prove that both notions are equivalent.

▶ **Lemma 5** (⋆). *For every graph G, it holds that $\mathsf{tctw}(G) = \mathsf{tctw}'(G)$. Moreover, given a tree-cut decomposition $\mathcal{T}$ of G, it holds that $\mathsf{width}(\mathcal{T}) \leq \mathsf{width}'(\mathcal{T})$, and a tree-cut decomposition $\mathcal{T}'$ with $\mathsf{width}'(\mathcal{T}') \leq \mathsf{width}(\mathcal{T})$ can be computed in time $\mathcal{O}(\|G\| \cdot |G|^2 \cdot \mathsf{width}(\mathcal{T}))$.*

Ganian et al. [16] showed that bounded tree-cut width implies bounded treewidth. Besides, Kim et al. [25] showed that the dependency cannot be improved to subquadratic.

▶ **Lemma 6** (see [16]). *For any graph G, $\mathsf{tw}(G) \leq 2\mathsf{tctw}(G)^2 + 3\mathsf{tctw}(G)$.*

In our algorithms we need to adjust tree-cut decompositions to our needs, and hence we define the notion of a *neat tree-cut decomposition*. A neat tree-cut decomposition is a rooted tree-cut decomposition $(T, \mathcal{X})$ of a connected graph G that has the following properties:

- For every $e = uv \in E(T)$, the graphs $G[X_{V(T_{uv})}]$ and $G[X_{V(T_{vu})}]$ are connected.
- Suppose t is a node of T with parent s, such that the adhesion of st is thin. Then $E_G(X_{V(T_{ts})}, X_{V(T_{t's})}) = \emptyset$ for every sibling t' of t.

The second property was used by Ganian et al. [16] under the name *niceness*. It appears that any tree-cut decomposition can be made neat without increasing the width by much; the proof follows closely the lines of [16, Lemma 1].

▶ **Lemma 7** (⋆). *Given a tree-cut decomposition of $\mathsf{width}' \leq k$, a neat tree-cut decomposition of the same graph with $\mathsf{width}' \leq k^2 + 1$ can be constructed in time $\mathcal{O}(\|G\| \cdot |G|^2 \cdot k^2)$.*

The following result shows why neat tree-cut decompositions are useful: if a node of a neat decomposition has many neighboring nodes, then all but a constant number of them are connected to it via very simple adhesions.

▶ **Lemma 8** (⋆). *Let G be a graph with a neat tree-cut decomposition $\mathcal{T} = (T, \mathcal{X})$ satisfying $\mathsf{width}'(\mathcal{T}) \leq r$. Let $t \in V(T)$. Then for all but at most $2r + 1$ of the edges e of T incident to t, $\mathsf{adh}(e)$ is thin and all of its edges have an endpoint in the bag at t.*

Finally, we need that the tree-cut width of a graph can be computed efficiently. For this, we can use the following 2-approximation algorithm of Kim et al. [25]. We remark that the width of the decomposition yielded is measured in terms of $\mathsf{width}(\cdot)$ and not $\mathsf{width}'(\cdot)$, but the decomposition can be adjusted to have also width' bounded by $2r$ using Lemma 5.

▶ **Theorem 9** (see [25]). *There is an algorithm that, given a graph G and an integer r, runs in time $2^{\mathcal{O}(r^2 \log r)} \cdot |G|^2$ and either concludes that $\mathsf{tctw}(w) > r$, or returns a tree-cut decomposition of G of width at most $2r$.*

For the whole paper we fix a finite family of graphs $\mathcal{F}$ with the following properties: all graphs of $\mathcal{F}$ are connected, and at least one is planar and subcubic. A graph G will be called $\mathcal{F}$-immersion-free, or $\mathcal{F}$-free for short, if G contains no graph from $\mathcal{F}$ as an immersion. By Theorem 1, the tree-cut width of an $\mathcal{F}$-free graph is bounded by a constant depending on $\mathcal{F}$ only, so by Lemma 6 also its treewidth is bounded by a constant. By combining this with Bodlaender's algorithm [2] and Courcelle's Theorem [7], we obtain the following:

▶ **Lemma 10** (⋆). *It can be checked in linear-time whether a given graph is $\mathcal{F}$-free.*

Moreover, by combining the bound on tree-cut width of an $\mathcal{F}$-free graph with Lemmas 5, 7 and Theorem 9, we obtain the following.

▶ **Lemma 11** (⋆). *There exists an algorithm that, given an $\mathcal{F}$-free graph G, runs in time $\mathcal{O}(\|G\| \cdot |G|^2)$ and computes a neat tree-cut decomposition $\mathcal{T}$ of G with $\mathsf{width}'(\mathcal{T}) \leq b_{\mathcal{F}}$, for some constant $b_{\mathcal{F}}$ depending on $\mathcal{F}$ only.*

For a graph G, by $\mathsf{OPT}(G)$ we denote the minimum number of edges that need to be deleted from G in order to obtain an $\mathcal{F}$-free graph.

3 Protrusions

Replacing protrusions. We now introduce the notion of a protrusion suited to the considered problem. In the sequel, we will only deal with $2b_{\mathcal{F}}$- and 2-protrusions, where $b_{\mathcal{F}}$ is the constructive bound on tctw' guaranteed by Lemma 11.

▶ **Definition 12.** An *r-protrusion* of a graph G is a set $X \subseteq V(G)$ such that $|\delta(X)| \leq r$ and $G[X]$ is $\mathcal{F}$-free.

As in [14], the base for our kernelization algorithm is *protrusion replacement*. That is, we iteratively find a protrusion X that is large but has small $\delta(X)$, and replace it with a smaller gadget X' that has the same behaviour. The following lemma formalizes this intuition.

▶ **Lemma 13** (⋆). *There is a constant $c_{\mathcal{F}}$ and algorithm that, given a graph G and a $2b_{\mathcal{F}}$-protrusion X in it with $\|G[X]\| > c_{\mathcal{F}}$, outputs in linear time a graph G' with $\mathsf{OPT}(G) = \mathsf{OPT}(G')$ and $\|G'\| < \|G\|$. Moreover, there is a linear-time algorithm working as follows: given a subset F' of edges of G' such that $G' - F'$ is $\mathcal{F}$-free, the algorithm computes a subset F of edges of G such that $G - F$ is $\mathcal{F}$-free and $|F| \leq |F'|$.*

The proof of Lemma 13 follows closely the strategy used by Fomin et al. [14]: Every $2b_{\mathcal{F}}$-protrusion can be assigned a type, where the number of types is bounded by a function

depending on $\mathcal{F}$ only. The type of a protrusion can be computed efficiently due to protrusions having constant treewidth. Protrusions with the same type behave in the same way with respect to the problem of our interest, and hence can be replaced by one another. Therefore, we store a replacement table consisting of the smallest protrusion of each type, so that every larger protrusion can be replaced by a smaller representative stored in the table. The lifting algorithm finds, using dynamic programming, a partial solution in the large protrusion that has the same behaviour as the given partial solution in the replacement protrusion, while being not larger. Note that while a replacement table exists and can be hard-coded into the algorithm (as it depends on the fixed family $\mathcal{F}$ only), giving an explicit bound on the size of the graphs in it (and thus on $c_{\mathcal{F}}$ in Lemma 13) would require additional arguments. The details can be found in the full version of the paper.

We henceforth define a *replaceable protrusion* in G as a $2b_{\mathcal{F}}$-protrusion X with $\|G[X]\| > c_{\mathcal{F}}$, where $c_{\mathcal{F}}$ is the constant given by Lemma 13.

Finding excessive protrusions. Recall that a replaceable protrusion in a graph G is a $2b_{\mathcal{F}}$-protrusion X with $\|G[X]\| > c_{\mathcal{F}}$. To find replaceable protrusions in the input graph, we need to assume some additional connectivity constraint (which will be implied from a connected tree-cut decomposition) – this is captured by the following definition. The larger protrusion size is needed to make any connected component of the protrusion replaceable.

▶ **Definition 14.** A $2b_{\mathcal{F}}$-protrusion B in a connected graph G is called *excessive* if $\|G[B]\| > 2b_{\mathcal{F}} \cdot c_{\mathcal{F}}$ and $G - B$ has at most two connected components.

Replaceable protrusions could be found easily if we allowed a (far worse) running time of the form $\|G\|^{\mathcal{O}(b_{\mathcal{F}})}$, but this would affect the running times in both our main results. With the above definition in hand, we use the techniques of *important cuts*, introduced by Marx [27] (see also the exposition in [8, Chapter 8.2]) and of *randomized contractions* by Chitnis et al. [6] instead. These two techniques allow us to reduce excessive protrusions: we use the randomized contractions technique to find a large enough subset of a presumed excessive protrusion, after which important cuts allow us to find a boundary that makes this subset a replaceable protrusion.

▶ **Lemma 15** ($\star$). *There is an algorithm that, given a connected graph G, runs in time $\mathcal{O}(\|G\| \log \|G\| \cdot |G|^2)$ and either correctly concludes that G does not contain any excessive protrusion, or it outputs some replaceable protrusion in G.*

We remark that we only defined excessive protrusions in connected graphs. Note that if B is an excessive protrusion in a connected component H of G, it would not necessarily be an excessive protrusion in G, since $G - B$ may have more components than $H - B$ (they are however not adjacent to B). We will say that *no component of G has an excessive protrusion* if for each connected component H of G, there is no excessive protrusion in H.

By exhaustively (at most $\|G\|$ times) executing the algorithm of Lemma 15 and replacing any obtained protrusion using Lemma 13, we can get rid of all excessive protrusions. We formalize this in the following lemma, which will serve as the abstraction of protrusion replacement in the sequel.

▶ **Lemma 16** (Exhaustive Protrusion Replacement). *There is an algorithm that, given a graph G, runs in time $\mathcal{O}(\|G\|^2 \log \|G\| \cdot |G|^2)$ and computes a graph G' such that $\mathsf{OPT}(G) = \mathsf{OPT}(G')$, $\|G'\| \leq \|G\|$, and no connected component of G' has an excessive protrusion.*

Moreover, there exists a solution-lifting algorithm that works as follows: given a subset F' of edges of G' for which $G' - F'$ is $\mathcal{F}$-free, the algorithm runs in time $\mathcal{O}(\|G\|^2)$ and outputs a subset F of edges of G such that $|F| \leq |F'|$ and $G - F$ is $\mathcal{F}$-free.

4 Constant-factor approximation

It would be ideal if just applying the Exhaustive Protrusion Replacement (Lemma 16) reduced the size of the graph to linear in OPT. Then, we would already have a linear kernel, and taking all its edges would yield a constant-factor approximation. Unfortunately, there are graphs with no excessive protrusions, where the size is not bounded linearly in OPT. To see this, observe that a large group of parallel edges is not a protrusion, so our current reduction rules will not reduce their multiplicity, even if they amount to 99% of the graph. Hence, we need to find a way to discover and account for such groups (we remark that reducing each to $\mathcal{O}(\mathsf{OPT})$ would be relatively easy, giving a quadratic kernel). More generally, the structures that turn out to be problematic are large groups of constant-size 2-protrusions attached to the same pair of vertices; a group of parallel edges is a degenerated case of this structure. To describe the problematic structures formally, we introduce the notion of a *bouquet*.

Bouquets. Let us define the following constant $d_{\mathcal{F}} := \max\{2b_{\mathcal{F}} \cdot c_{\mathcal{F}} + 2b_{\mathcal{F}},\ 3\mathsf{MAX}_{\mathcal{F}}\} + 1$ (where $\mathsf{MAX}_{\mathcal{F}} = \max_{H \in \mathcal{F}} \|H\|$). A bouquet is a family of at least $d_{\mathcal{F}}$ isomorphic 2-protrusions, while a theta is a set of at least $d_{\mathcal{F}}$ parallel edges.

▶ **Definition 17.** Consider a graph G, a set $U \subseteq V(G)$ and a family of 2-protrusions $\{S_i\}_{i \in I}$ such that for each $i \in I$:

- $N(S_i) = U$ (implying $|U| \leq 2$);
- $G[S_i]$ is connected; and
- $G[U \cup S_i]$ is isomorphic to $G[U \cup S_j]$ for all $i, j \in I$, with an isomorphism that maps each vertex of U to itself.

We call such a family a *bouquet attached to* U if it is maximal under inclusion (i.e. there is no proper superfamily which is also a bouquet) and has at least $d_{\mathcal{F}}$ elements. The edge set of the bouquet is the set of all edges incident to some S_i.

▶ **Definition 18.** For two vertices $u, v \in V(G)$, a *theta attached to* $\{u, v\}$ is a set of edges between u and v that is maximal under inclusion and has at least $d_{\mathcal{F}}$ elements.

The constant $d_{\mathcal{F}}$ is chosen so that a protrusion containing a set to which a bouquet (or theta) is attached is large enough to be excluded as an excessive protrusion, and so that any immersion of a graph of $\mathcal{F}$ cannot simultaneously intersect all elements of a bouquet. Indeed, in any immersion of some $H \in \mathcal{F}$ in a graph G, the image of an edge of H is a path in G, which visits every vertex of the bouquet's attachment at most once, and hence intersects at most three elements of the bouquet. Thus in total, the immersion model intersects at most $3 \cdot \max_{H \in \mathcal{F}} \|H\|$ elements of the bouquet or theta, which is less than $d_{\mathcal{F}}$.

We now show that the number of edges of a graph with no excessive protrusions, no bouquets, and no thetas is linearly bounded in the optimum solution size, which formalizes the intuition that only those structures prevent the graph from being a linear kernel.

▶ **Lemma 19** ($\star$). *Let G be a connected graph without excessive protrusions, bouquets, or thetas. Then G is $\mathcal{F}$-free, or $\|G\| \leq c \cdot \mathsf{OPT}(G)$, for some constant c depending on $\mathcal{F}$ only.*

The proof of Lemma 19 goes roughly as follows. Take some optimum solution F. Then $G - F$ is $\mathcal{F}$-free, so, by Theorem 11, it has a neat tree-cut decomposition $(T, \mathcal{X})$ of width at most $b_{\mathcal{F}}$. For simplicity suppose that $G - F$ is connected, so that T is a tree (the proof in the general case is essentially the same). Let M_0 be the set of all vertices of T whose bags contain a vertex incident to an edge of F; then $|M_0| \leq 2|F|$. Compute the *lowest common ancestor closure* M of M_0: start with $M := M_0$, and iteratively add to M any lowest common

ancestor of two nodes of M that is not yet included. As in Fomin et al. [14], we have that $|M| \leq 2|M_0| \leq 4|F|$, and each component of $T - M$ is adjacent to at most two nodes of M.

Let us consider some connected component T' of $T - M$, and let $X_{T'}$ be the union of the bags at the nodes of T'. Suppose first that T' is adjacent to exactly two nodes of M; note that there are at most $|M| - 1$ such components T'. Then one can easily see that $\|G[X_{T'}]\| \leq 2b_{\mathcal{F}}c_{\mathcal{F}}$, because otherwise $X_{T'}$ would be an excessive protrusion. Here, we crucially use the first condition of the neatness of T to argue that $G - X_{T'}$ has at most two connected components. Hence, the total number of edges in graphs $G[X_{T'}]$ for such components T' is bounded by $(|M| - 1) \cdot 2b_{\mathcal{F}}c_{\mathcal{F}}$, which is linear in $|F| = \mathsf{OPT}(G)$.

We are left with considering components T' that are adjacent to exactly one node of M. We again have that $\|G[X_{T'}]\| \leq 2b_F c_{\mathcal{F}}$ for each such component T', because otherwise $X_{T'}$ would be an excessive protrusion. However, a priori we do not have any bound on the number of such components. Suppose for a moment that a large number of such components T' is adjacent to the same node $t \in M$. By Lemma 8, all but a constant number of them are connected to t via edges of the decomposition with thin adhesions. Moreover, for each of these adhesions, all the (at most 2) edges of the adhesion have both endpoints in the bag X_t. Since the size of X_t is bounded by a constant, and each $X_{T'}$ induces a graph of constant size, we can infer that there is a constant number of isomorphism types for graphs $G[X_{T'}]$, together with the choice of the attachment points in X_t. So if the number of the considered components T' was very large, then some of them would form a bouquet, a contradiction.

This shows that, in fact, the number of components T' adjacent to only one vertex of M is also bounded linearly in $|M|$, so also in $\mathsf{OPT}(G)$. The fact that G has no thetas is used to bound the number of edges contained in graphs induced by the bags of M. By combining all these bounds, we conclude the proof of Lemma 19.

Finding a constant-factor approximation piece by piece. To handle bouquets and thetas, we first show that they are disjoint, as otherwise they would constitute a large protrusion.

▶ **Lemma 20** ($\star$). *Let G be a connected graph with no excessive protrusions. Then every two bouquets and/or thetas in G have disjoint edge sets. Furthermore, if a bouquet or theta is attached to $U \subseteq V(G)$, then U is disjoint with all elements of any bouquet.*

The following lemma is the crucial step for our approximation: we find a subset of edges Δ with a guarantee that a constant fraction of Δ is used in some optimum solution.

▶ **Lemma 21** ($\star$). *Given a connected graph G with no excessive protrusion that is not $\mathcal{F}$-free, one can find in in time $\mathcal{O}(|G|^3)$ a set $\Delta \subseteq E(G)$ such that (for some c depending on $\mathcal{F}$ only):* $\mathsf{OPT}(G - \Delta) < \mathsf{OPT}(G)$ *and* $|\Delta| \leq c \cdot (\mathsf{OPT}(G) - \mathsf{OPT}(G - \Delta))$.

The set Δ given by Lemma 21 is constructed as follows. First, we locate all thetas and bouquets in G; Lemma 20 ensures that they do not overlap. Δ is defined as the set of all edges of G, with the exception that in each bouquet and in each theta we exclude from Δ the edges of all but $d_{\mathcal{F}} - 1$ elements of the bouquet/theta. We show that the subgraph given by edges of Δ satisfies the assumptions of Lemma 19, thus bounding $|\Delta|$. The bound is linear in the size of the intersection of Δ with any optimal solution, allowing to conclude the claim.

To get a constant-factor approximation algorithm, we iteratively invoke the algorithm of Lemma 21 (extended to general graphs by considering each connected component separately). More precisely, we perform iteratively the following procedure, starting with $G_1 = G$. At step i, given a graph G_i, we first run the algorithm of Lemma 16 to remove excessive protrusions from G_i and obtain a new graph G_i'. Thus, in a sense, we reduce those parts

of the graph where no more edges need to be deleted. Then, we apply the algorithm of Lemma 21 to G'_i, thus finding a set Δ_i with the following property: the deletion of Δ_i reduces OPT by some number p, while increasing the total number of edges deleted so far by at most $c \cdot p$. We proceed to the next iteration with $G_{i+1} := G'_i - \Delta_i$. Eventually, we arrive at the situation when the current graph G_i is already $\mathcal{F}$-free, in which case we stop. A constant-factor approximate solution can be then obtained by reverting the iterations: Proceeding from the last iteration to the first, we always add the extracted set Δ_i to the constructed solution, and roll-back the protrusion reductions performed by the algorithm of Lemma 16 while lifting the current solution using the solution-lifting algorithm. This concludes the proof of Theorem 2 (the formal description is in the full version of the paper).

5 Linear kernel

In the previous section we observed (Lemma 19) that the only structures in the graph that prevent it from being a linear kernel are excessive protrusions, bouquets, and thetas. Using the Exhaustive Protrusion Replacement (Lemma 16) we can get rid of excessive protrusions, but bouquets and thetas can still be present in the graph. It would be ideal if we could reduce the size of every bouquet or theta to a constant, but unfortunately we are unable to do this. Instead, bouquets and thetas will be reduced to constant size in the amortized sense.

The next lemma is the crux of our approach: provided we know a "local" solution Δ that isolates a bouquet into an $\mathcal{F}$-free part, this bouquet can be pruned proportionally to the size of Δ without changing $\mathsf{OPT}(G)$. The proof is by a simple replacement argument, and the same reasoning can also be applied to limit the sizes of thetas.

▶ **Lemma 22** (⋆). *Let $\{X_i\}_{i\in I}$ be a bouquet attached to U in G. Suppose $\Delta \subseteq E(G)$ is such that all the connected components of $G - \Delta$ that intersect $U \cup \bigcup_{i\in I} X_i$ are $\mathcal{F}$-free. Then $\mathsf{OPT}(G) = \mathsf{OPT}(G')$, where G' is obtained from G by removing vertices of all except $d_{\mathcal{F}} + |\Delta|$ elements of the bouquet.*

We are now ready to show the main part of our reasoning: given some solution F, for example the one returned by the approximation algorithm of Theorem 2, we are able to reduce the graph, provided it is not already bounded linearly in $|F|$.

▶ **Lemma 23** (⋆). *Let G be a connected graph with no excessive protrusions and let $F \subseteq E(G)$ be such that $G - F$ is $\mathcal{F}$-free. Then either $\|G\| \leq c \cdot |F|$ for some constant c depending on $\mathcal{F}$ only, or given G and F, one can compute in time $\mathcal{O}(\|G\| \cdot |G|^2)$ a subgraph G' of G such that $\mathsf{OPT}(G) = \mathsf{OPT}(G')$ and $\|G'\| < \|G\|$.*

The proof uses the following strategy based on the idea of *amortization*. Given a solution F, we use parts of F as local solutions to locally bound bouquets and thetas. More precisely, we first perform a similar structural analysis of G with F removed as in the proof of Lemma 19; see the sketch following its statement. There, we considered a neat tree-cut decomposition $\mathcal{T} = (T, \mathcal{X})$ of $G - F$ of width $b_{\mathcal{F}}$. In this decomposition, we highlighted a subset $M \subseteq V(T)$, the lca-closure of those nodes of T whose bags are incident to F. We concluded that the only parts not yet bounded linearly in terms of $|F|$ were large bouquets and thetas with both attachment points contained in a bag X_t of some node $t \in M$. For such a node t, define $\Delta(t)$ as the set containing: (i) all the edges of F incident to X_t, and (ii) all the adhesions of edges of T incident to t that lead to components of $T - M$ containing other vertices of M. Then $\Delta(t)$ easily satisfies the prerequisites of Lemma 22. Hence, $d_{\mathcal{F}} + |\Delta(t)|$ can be used as a bound for reducing these bouquets and thetas. Summing these bounds through all nodes $t \in M$, we achieve an $\mathcal{O}(|F| + |M|)$ bound, thus $\mathcal{O}(|F|)$ due to $|M| \leq 4|F|$.

With Lemma 23, we can now easily conclude the proof of Theorem 3 (the formal description is in the full version of the paper). First, we get rid of all excessive protrusions in the graph (Lemma 16) and compute an approximate solution F_{apx} (Theorem 2). If $|F_{\mathrm{apx}}| > c_{\mathrm{apx}} \cdot k$, the input is a NO instance. Otherwise, we give F_{apx} to the algorithm of Lemma 23 which, provided the graph is still too large to be a kernel, computes a strictly smaller, but equivalent instance. We then recurse on this smaller instance, eventually returning a linear kernel.

Acknowledgements. The authors thank an anonymous referee for suggesting a more direct approach to finding excessive protrusions as well as Ignasi Sau, Petr Golovach, Eun Jung Kim, and Christophe Paul for preliminary discussions on the $\mathcal{F}$-Immersion Deletion problem.

Abstract

An out-branching and an in-branching of a digraph D are called k-distinct if each of them has k arcs absent in the other. Bang-Jensen, Saurabh and Simonsen (2016) proved that the problem of deciding whether a strongly connected digraph D has k-distinct out-branching and in- branching is fixed-parameter tractable (FPT) when parameterized by k. They asked whether the problem remains FPT when extended to arbitrary digraphs. Bang-Jensen and Yeo (2008) asked whether the same problem is FPT when the out-branching and in-branching have the same root.

By linking the two problems with the problem of whether a digraph has an out-branching with at least k leaves (a leaf is a vertex of out-degree zero), we first solve the problem of Bang-Jensen and Yeo (2008). We then develop a new digraph decomposition called the rooted cut decomposition and using it we prove that the problem of Bang-Jensen et al. (2016) is FPT for all digraphs. We believe that the *rooted cut decomposition* will be useful for obtaining other results on digraphs.

1 Introduction

While both undirected and directed graphs are important in many applications, there are significantly more algorithmic and structural results for undirected graphs than for directed ones. The main reason is likely to be the fact that most problems on digraphs are harder than those on undirected graphs. The situation has begun to change: recently there appeared a number of important structural results on digraphs, see e.g. [16, 17, 18]. However, the progress was less pronounced with algorithmic results on digraphs, in particular, in the area of parameterized algorithms.

In this paper, we introduce a new decomposition for digraphs and show its usefulness by solving an open parameterized problem on digraphs by Bang-Jensen, Saurabh and Simonsen [6]. We believe that our decomposition will prove to be helpful for obtaining further algorithmic and structural results on digraphs.

A digraph T is an *out-tree* (an *in-tree*) if T is an oriented tree with just one vertex s of in-degree zero (out-degree zero). The vertex s is the *root* of T. A vertex v of an out-tree

* A full version of the paper is available at https://arxiv.org/abs/1612.03607.
† Gutin's research was partially supported by Royal Society Wolfson Research Merit Award.

(in-tree) is called a *leaf* if it has out-degree (in-degree) zero. If an out-tree (in-tree) T is a spanning subgraph of a digraph D, then T is an *out-branching* (an *in-branching*) of D. It is well-known that a digraph D contains an out-branching (in-branching) if and only if D has only one strongly connected component with no incoming (no outgoing) arc [3].

A well-known result in digraph algorithms, due to Edmonds, states that given a digraph D and a positive integer ℓ, we can decide whether D has ℓ arc-disjoint out-branchings in polynomial time [15]. The same result holds for ℓ arc-disjoint in-branchings. Inspired by this fact, it is natural to ask for a "mixture" of out- and in-branchings: given a digraph D and a pair u, v of (not necessarily distinct) vertices, decide whether D has an arc-disjoint out-branching T_u^+ rooted at u and an in-branching T_v^- rooted at v. We will call this problem Arc- Disjoint Branchings.

Thomassen proved (see [2]) that the problem is NP-complete and remains NP-complete if we add the condition that $u = v$. The same result still holds for digraphs in which the out-degree and in-degree of every vertex equals two [7]. The problem is polynomial-time solvable for tournaments [2] and for acyclic digraphs [8, 10]. The single-root special case (i.e., when $u = v$) of the problem is polynomial time solvable for quasi-transitive digraphs[1] [4] and for locally semicomplete digraphs[2] [5].

An out-branching T^+ and an in-branching T^- are called *k-distinct* if $|A(T^+) \setminus A(T^-)| \geq k$. Bang-Jensen, Saurabh and Simonsen [6] considered the following parameterization of Arc-Disjoint Branchings.

k-Distinct Branchings parametrised by k

Input:	A digraph D, an integer k.
Problem:	Are there k-distinct out-branching T^+ and in-branching T^-?

They proved that k-Distinct Branchings is fixed-parameter tractable (FPT)[3] when D is strongly connected and conjectured that the same holds when D is an arbitrary digraph. Earlier, Bang-Jensen and Yeo [9] considered the version of k-Distinct Branchings where T^+ and T^- must have the same root and asked whether this version of k-Distinct Branchings, which we call Single-Root k-Distinct Branchings, is FPT.

The first key idea of this paper is to relate k-Distinct Branchings to the problem of deciding whether a digraph has an out-branching with at least k leaves via a simple lemma (see Lemma 4). The lemma and the following two results on out-branchings with at least k leaves allow us to solve the problem of Bang-Jensen and Yeo [9] and to provide a shorter proof for the above-mentioned result of Bang-Jensen, Saurabh and Simonsen [6] (see Theorem 6).

▶ **Theorem 1** ([1]). *Let D be a strongly connected digraph. If D has no out-branching with at least k leaves, then the (undirected) pathwidth of D is bounded by $O(k \log k)$.*

▶ **Theorem 2** ([12, 19]). *We can decide whether a digraph D has an out-branching with at least k leaves in time $O^*(4^k)$.*

---

[1] A digraph $D = (V, A)$ is quasi-transitive if for every $xy, yz \in A$ there is at least one arc between x and z, i.e. either $xz \in A$ or $zx \in A$ or both.

[2] A digraph $D = (V, A)$ is locally semicomplete if for every $xy, xz \in A$ there is at least one arc between y and z and for every $yx, zx \in A$ there is at least one arc between y and z. Tournaments and directed cycles are locally semicomplete digraphs.

[3] Fixed-parameter tractability of k-Distinct Branchings means that the problem can be solved by an algorithm of runtime $O^*(f(k))$, where O^* omits not only constant factors, but also polynomial ones, and f is an arbitrary computable function. The books [11, 13] are excellent recent introductions to parameterized algorithms and complexity.

The general case of k-Distinct Branchings seems to be much more complicated. We first introduce a version of k-Distinct Branchings called k-Rooted Distinct Branchings, where the roots s and t of T^+ and T^- are fixed, and add the arc ts to D (provided the arc is not in D) to make D strongly connected. This introduces a complication: we may end up in a situation where D has an out-branching with many leaves, and thereby potentially unbounded pathwidth, but the root of the out-branching is not s. To deal with this situation, our goal will be to *reconfigure* the out-branching into an out-branching rooted at s. In order to reason about this process, we develop a new digraph decomposition we call the *rooted cut decomposition*. The cut decomposition of a digraph D rooted at a given vertex r consists of a tree $\hat{T}$ rooted at r whose nodes are some vertices of D and subsets of vertices of D called *diblocks* associated with the nodes of $\hat{T}$.

Out strategy is now as follows. If $\hat{T}$ is *shallow* (i.e., it has bounded height), then any out-branching with sufficiently many leaves can be turned into an out-branching rooted at s without losing too many of the leaves. On the other hand, if $\hat{T}$ contains a path from the root of $\hat{T}$ with sufficiently many non-degenerate diblocks (diblocks with at least three vertices), then we are able to show immediately that the instance is positive. The remaining and most difficult issue is to deal with digraphs with decomposition trees that contain long paths of diblocks with only two vertices, called *degenerate* diblocks. In this case, we employ two reduction rules which lead to decomposition trees of bounded height.

The paper is organized as follows. In the next section, we provide some terminology and notation on digraphs used in this paper. In Section 3, we prove Theorem 6. Section 4 is devoted to proving that Rooted k-Distinct Branchings is FPT for all digraphs using cut decomposition and Theorems 1 and 2. We conclude the paper in Section 5, where some open parameterized problems on digraphs are mentioned. Due to space constraints, we only provide a short version of Section 4.3 in the main text. A complete version is available online[4].

2 Terminology and Notation

Let us recall some basic terminology of digraph theory, see [3]. A digraph D is *strongly connected* (*connected*) if there is a directed (oriented) path from x to y for every ordered pair x, y of vertices of D. Equivalently, D is connected if the underlying graph of D is connected. A vertex v is a *source* (*sink*) is its in-degree (out-degree) is equal to zero. It is well-known that every acyclic digraph has a source and a sink [3].

In this paper, we exclusively work with digraphs, therefore we assume all our graphs, paths, and trees to be directed unless otherwise noted. For a path $P = x_1x_2 \dots x_k$ of length $k-1$ we will employ the following notation for subpaths of P: $P[x_i, x_j] := x_i \dots x_j$ for $1 \leq i \leq j \leq k$ is the *infix* of P from x_i to x_j. For paths $P_1 := x_1 \dots x_k v$ and $P_2 := vy_1 \dots y_\ell$ we denote by $P_1P_2 := x_1 \dots x_k v y_1 \dots y_\ell$ their *concatenation*. For rooted trees T and some vertex $x \in T$, T_x stands for the subtree of T rooted at x (see Figure 1).

We will frequently partition the nodes of a tree around a path in the following sense (*cf.* Figure 1): Let T be a tree rooted at r and $P = x_1 \dots x_\ell$ a path from $r = x_1$ to some node $x_\ell \in T$. The *fins* of P are the sets $\{F_{x_i}\}_{x_i \in P}$ defined as $F_{x_i} := V(T_{x_i}) \setminus V(T_{x_{i+1}})$ for $i < \ell$ and $F_{x_\ell} := V(T_{x_\ell})$.

▶ **Definition 3** (Bi-reachable Set)**.** A set B in a digraph D is *bi-reachable* from a vertex r if for all $v \in B$ there exist two internally vertex-disjoint paths from r to v.

[4] https://arxiv.org/abs/1612.03607

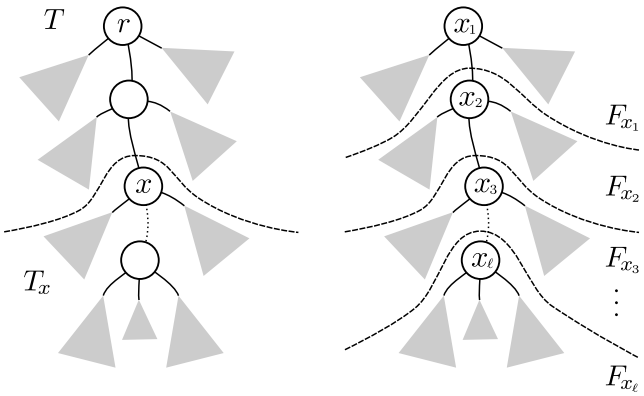

Figure 1 Subtree notation T_x for $x \in T$ (left) and the fins $F_{x_1}, \ldots, F_{x_\ell}$ for a path $x_1 \ldots x_\ell$ in T (right).

Given a digraph D and a vertex r, we can compute the set of vertices that are bi-reachable from r in polynomial time using network flows.

3 Strongly Connected Digraphs

Let us prove a simple fact on a link between out/in-branchings with many leaves and k-Distinct Branchings, which together with a structural result of Alon *et al.* [1] and an algorithmic result for the maximum leaf out-branching problem [12, 19] gives a short proof that both versions of k-Distinct Branchings are FPT for strongly connected digraphs.

▶ **Lemma 4.** *Let D be a digraph containing an out-branching and an in-branching. If D contains an out-branching (in-branching) T with at least $k+1$ leaves, then every in-branching (out-branching) T' of D is k-distinct from T.*

Proof. We will consider only the case when T is an out-branching since the other case can be treated similarly. Let T' be an in-branching of D and let L be the set of all leaves of T apart from the one which is the root of T'. Observe that all vertices of L have outgoing arcs in T' and since in T the incoming arcs of L are the only arcs incident to L in T, the sets of the outgoing arcs in T' and incoming arcs in T do not intersect. ◀

We will use the following standard dynamic programming result (see, e.g., [6]).

▶ **Lemma 5.** *Let H be a digraph of (undirected) treewidth τ. Then k-Distinct Branchings and Single-Root k-Distinct Branchings on H can be solved in time $O^*(2^{O(\tau \log \tau)})$.*

Note that if a digraph D is a positive instance of Single-Root k-Distinct Branchings then D must be strongly connected as an out-branching and an in-branching rooted at the same vertex form a strongly connected subgraph of D.

▶ **Theorem 6.** *k-Distinct Branchings and Single-Root k-Distinct Branchings on strongly connected digraphs can be solved in time $O^*(2^{O(k \log^2 k)})$.*

Proof. The proof is essentially the same for both problems and we will give it for Single-Root k-Distinct Branchings. Let D be an input strongly connected digraph. By Theorem 2 using an $O^*(4^k)$-time algorithm we can find an out-branching T^+ with at least $k+1$ leaves, or decide that D has no such out-branching. If T^+ is found, the instance of

Single-Root k-Distinct Branchings is positive by Lemma 4 as any in-branching T^- of D is k-distinct from T^+. In particular, we may assume that T^- has the same root as T^+ (a strongly connected digraph has an in-branching rooted at any vertex). Now suppose that T^+ does not exist. Then, by Theorem 1 the (undirected) pathwidth of D is bounded by $O(k \log k)$. Thus, by Lemma 5 the instance can be solved in time $O^*(2^{O(k \log^2 k)})$. ◀

4 The k-Distinct Branchings Problem

In this section, we fix a digraph D with terminals s, t and simply talk about *rooted out-branchings (in-branchings)* whose root we implicitly assume to be s (t). Similarly, unless otherwise noted, a *rooted out-tree (in-tree)* is understood to be rooted at s (t).

The problem k-Distinct Branchings in which T^+ and T^- must be rooted at s and t, respectively, will be called the Rooted k-Distinct Branchings problem. Clearly, to show that both versions of k-Distinct Branchings are FPT it is sufficient to prove the following:

▶ **Theorem 7.** Rooted k-Distinct Branchings *is FPT for arbitrary digraphs.*

In the rest of this section, (D, s, t) will stand for an instance of Rooted k-Distinct Branchings (in particular, D is an input digraph of the problem) and H for an arbitrary digraph. As noted in the previous section, the case in which $s = t$ implies strong connectivity and is therefore already solved. Consequently, we will assume that $s \neq t$ in the following. Let us start by observing what further restrictions on D can be imposed by polynomial-time preprocessing.

4.1 Preprocessing

Let (D, s, t) be an instance of Rooted k-Distinct Branchings with $s \neq t$. Recall that D contains an out-branching (in-branching) if and only if D has only one strongly connected component with no incoming (no outgoing) arc. As a first preprocessing step, we can decide in polynomial time whether D has a rooted out-branching and a rooted in-branching. If not, we reject the instance. Note that this in particular means that in a non-rejected instance, every vertex in D is reachable from s and t is reachable from every vertex.

Next, we test for every arc $a \in D$ whether there exists at least one rooted in- or out-branching that uses a as follows: since a maximal-weight out- or in-branching for an arc-weighted digraph can be computed in polynomial time [14], we can force the arc a to be contained in a solution by assigning it a weight of 2 and every other arc weight 1. If we verify that a indeed neither appears in any rooted out-branching or in-branching, we remove a from D and obtain an equivalent instance of Rooted k-Distinct Branchings.

After this polynomial-time preprocessing, our instance has the following properties: there exists a rooted out-branching, there exists a rooted in-branching, and every arc of D appears in some rooted in- or out-branching. We call such a digraph with a pair s, t *reduced*.

Lastly, by the following lemma we may assume that our instance is strongly connected by incurring a factor of two in the application of Lemma 4.

▶ **Lemma 8.** *Let (D, s, t) be reduced and let D' be the digraph obtained from D by adding the arc ts to it unless ts is already in D in which case $D' = D$. Then (D', s, t) is a positive instance of* Rooted k-Distinct Branchings *if and only if so is (D, s, t). Furthermore, if D' contains an out-tree (in-tree) with at least ℓ leaves, then D contains an out-tree (in-tree) with at least $\ell/2$ leaves.*

Proof. We may assume that $D' \neq D$. For the first claim, simply note that any rooted out-branching of D' cannot use the arc ts and the same holds for rooted in-branchings. For the second claim, assume T is an out-tree in D with ℓ leaves. Assume $ts \in T$ (otherwise the claim follows trivially). Let T_1 and T_2 be the two out-trees obtained by deleting the arc ts from T. Both are out-trees in D and one of them contains at least $\ell/2$ leaves, as claimed. ◀

The first claim of Lemma 8 shows that we may assume that D is strongly connected in Rooted k-Distinct Branchings. This implies the following simple claim required for further references.

▶ **Lemma 9.** *Let D be an input digraph of* Rooted k-Distinct Branchings. *Then every rooted out-tree with q leaves can be extended into a rooted out-branching with at least q leaves.*

In summary, we enforce the following properties for (D, s, t) by polynomial- time preprocessing:

1. Every arc of D is contained in at least one rooted in-branching or rooted out-branching,
2. D is strongly connected.

4.2 Decomposition and Reconfiguration

We work towards the following win-win scenario: either we find an out-tree with $\Theta(k)$ leaves that can be turned into a rooted out-tree with at least $k+1$ leaves, or we conclude that every out-tree in D has less than $\Theta(k)$ leaves. We refer to the process of turning an out-tree into a rooted out-tree as a *reconfiguration*. In the process we will develop a new digraph decomposition, the *rooted cut-decomposition*, which will aid us in reasoning about reconfiguration steps and ultimately lead us to a solution for the problem.

To make the notion of a bi-reachable set easier to use, the decomposition will employ a slightly broader notion as follows.

▶ **Definition 10.** Let H be a digraph with at least two vertices, and let $r \in V(H)$ such that every vertex of H is reachable from r. Let $B \subseteq V(H)$ be the set of all vertices that are bi-reachable from r. The *directed block (diblock) B_r of r in H* is the set $B \cup N^+[r]$, i.e., the bi-reachable vertices together with all out-neighbors of r and r itself.

Note that according to the above definition a diblock must have at least two vertices.

The following statement provides us with an easy case in which a reconfiguration is successful, that is, we can turn an arbitrary out-tree into a rooted out-tree without losing too many leaves. Later, the obstructions to this case will be turned into building blocks of the decomposition.

▶ **Lemma 11.** *Let $B_s \subseteq V(D)$ be the diblock of s and let T be an out-tree of D whose root r lies in B_s with ℓ leaves. Then there exists a rooted out-tree with at least $(\ell-1)/2$ leaves.*

Proof. We may assume that $r \neq s$. In case T contains s as a leaf, we remove s from T for the remaining argument and hence will argue about the $\ell - 1$ remaining leaves.

If r is bi-reachable from s, consider two internally vertex-disjoint paths P, Q from s to r. One of the two paths necessarily avoids half of the $\ell - 1$ leaves of T; let without loss of generality this path be P. Let further L be the set of those leaves of T that do *not* lie on P. If $r \in N^+(s)$, let $P = sr$.

We construct the required out-tree T' as follows: first, add all arcs and vertices of P to T'. Now for every leaf $v \in L$, let P_v be the unique path from r to v in T and let P'_v be the segment of P_v from the last vertex x of P_v contained in T. Add all arcs and vertices

of P'_v to T'. Observe that $x \neq v$ as v cannot be in T' already. Since P_v and thus P'_v contains no leaf of L other than v, in the end of the process, all vertices of L are leaves of T'. Since $|L| \geq (\ell - 1)/2$, the claim follows. ◀

Note that the definition of diblocks can be understood in terms of network flows. Let $v \neq r$. Consider the vertex-capacitated version of H where r and v both have capacity 2, and every other vertex has capacity 1, for some $v \in V(H) \setminus \{r\}$. Then v is contained in the diblock of r in H if and only if the max-flow from r to v equals 2 (note that if $v \in N^+(r)$, then such a flow exists trivially since arcs have infinite capacity). Dually, by Menger's theorem, v is *not* contained in the diblock if and only if there is a vertex $u \notin \{r, v\}$ such that all r-v paths P intersect u. This has the following simple consequence regarding connectivity inside a diblock.

▶ **Lemma 12.** *Fix $r \in V(H)$ and let $B_r \subseteq V(H)$ be the diblock of r in H. Then for every pair of distinct vertices $x, y \in B_r$, there exist an r-x-path P_x and an r-y-path P_y that intersect only in r.*

Proof. If $r \in \{x, y\}$, then clearly the claim holds since every vertex in B_r is reachable from r. Otherwise, add a new vertex z with arcs xz and yz, and note that the lemma holds if and only if z is bi-reachable from r. If this is not true, then by Menger's theorem there is a vertex $v \in B_r$, $v \neq r$, such that all paths from r to z, and hence to x and y, go through v. But as noted above, there is no cut-vertex $v \notin \{x, r\}$ for r-x paths, and no cut-vertex $v \notin \{y, r\}$ for r-y paths. We conclude that z is bi-reachable from r, hence the lemma holds. ◀

Next, we will use Lemma 12 to show that given a vertex r, the set of vertices not in the diblock B_r of r in H partitions cleanly around B_r.

▶ **Lemma 13.** *Let $r \in V(H)$ be given, such that every vertex of H is reachable from r. Let $B_r \subset V(H)$ be the diblock of r in H. Then $V(H) \setminus B_r$ partitions according to cut vertices in B_r, in the following sense: For every $v \in V(H) \setminus B_r$, there is a unique vertex $x \in B_r \setminus \{r\}$ such that every path from r to v intersects B_r for the last time in x. Furthermore, this partition can be computed in polynomial time.*

Proof. Assume towards a contradiction that for $v \in V(H) \setminus B_r$ there exist two r-v-paths P_1, P_2 that intersect B_r for the last time in distinct vertices x_1, x_2, respectively. We first observe that $r \notin \{x_1, x_2\}$, since the second vertices of P_1 and P_2 are contained in B_r by definition. By Lemma 12, we may assume that $P_1[r, x_1] \cap P_2[r, x_2] = \{r\}$. But then P_1 and P_2 intersect for the first time outside of B_r in some vertex v' (potentially in $v' = v$). This vertex is, however, bi-reachable from r, contradicting our construction of B_r. Hence there is a vertex $x \in B_r$ such that every path from r to v intersects B_r for the last time in x, with $x \neq r$, and clearly this vertex is unique. Finally, the set B_r can be computed in polynomial time, and given B_r it is easy to compute for each $x \in B_r$ the set of all vertices $v \in V(H)$ (if any) for which x is a cut vertex. ◀

We refer to the vertices $x \in B_r$ that are cut vertices in the above partition as the *bottlenecks of B_r*. Note that r itself is not considered a bottleneck in B_r. Using these notions, we can now define a *cut decomposition* of a digraph H.

▶ **Definition 14** (Rooted cut decomposition and its tree)**.** Let H be a digraph and r a vertex such that every vertex in H is reachable from r. The *(r-rooted) cut decomposition* of H is a pair $(\hat{T}, \mathcal{B})$ where $\hat{T}$ is a rooted tree with $V(\hat{T}) \subseteq V(H)$ and $\mathcal{B} = \{B_x\}_{x \in \hat{T}}$, $B_x \subseteq V(H)$ for each $x \in \hat{T}$, is a collection of diblocks associated with the nodes of $\hat{T}$, defined and computed recursively as follows.

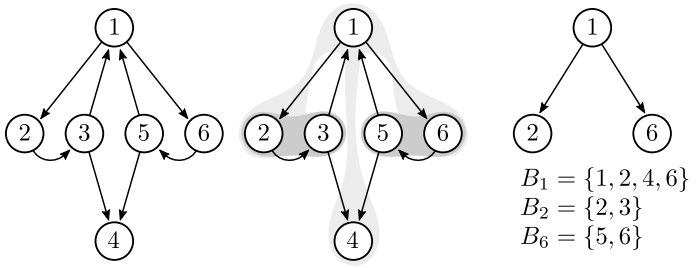

Figure 2 An example of a rooted cut decomposition.

1. Let B_r be the diblock of r in H, and let $L \subseteq B_r \setminus \{r\}$ be the set of bottlenecks in B_r. Let $\{X_x\}_{x \in L}$ be the corresponding partition of $V(H) \setminus B_r$.
2. For every $x \in L$, let $(\hat{T}_x, \mathcal{B}_x)$ be the x-rooted cut decomposition of $H[X_x \cup \{x\}]$.
3. $\hat{T}$ is the tree with root node r, where L is the set of children of r, and for every $x \in L$ the subtree of $\hat{T}$ rooted at x is $\hat{T}_x$.
4. $\mathcal{B} = \{B_r\} \cup \bigcup_{x \in L} \mathcal{B}_x$.

Furthermore, for every node $x \in \hat{T}$, we define $B^*_x = \bigcup_{y \in \hat{T}_x} B_y$ as the set of all vertices contained in diblocks associated with nodes of the subtree $\hat{T}_x$.

Figure 2 provides an illustration to Definition 14.

▶ **Lemma 15.** *Let a digraph H and a root $r \in V(H)$ be given, such that every vertex of H is reachable from r. Then the r-rooted cut decomposition $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ of H is well-defined and can be computed in polynomial time. Furthermore, the diblocks cover $V(H)$, i.e., $\bigcup_{x \in \hat{T}} B_x = V(H)$, and for every node $x \in \hat{T}$, every vertex of B^*_x is reachable from x in $H[B^*_x]$.*

Proof. By Lemma 13, the root diblock B_r as well as the set $L \subseteq B_r$ of bottlenecks and the partition $\{X_x\}_{x \in L}$ are well-defined and can be computed in polynomial time. Also note that for each $x \in L$, $r \notin X_x \cup \{x\}$, and every vertex of $H_x := H[X_x \cup \{x\}]$ is reachable from x in H_x by the definition of the partition. Hence the collection of recursive calls made in the construction is well-defined, and every digraph H_x used in a recursive call is smaller than H, hence the process terminates. Finally, for any two distinct bottlenecks $x, y \in L$ we have $V(H_x) \cap V(H_y) = \emptyset$. Thereby, distinct nodes of $\hat{T}$ are associated with distinct vertices of H, $|\hat{T}| \leq |V(H)|$, and the map $x \mapsto B_x$ is well-defined. It is also clear that the whole process takes polynomial time. ◀

We collect some basic facts about cut decompositions.

▶ **Lemma 16.** *Let a digraph H and a vertex $r \in V(H)$ be given, and let $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ be the r-rooted cut decomposition of H. Then the following hold.*

1. *The sets $\{B_x \setminus \{x\}\}_{x \in \hat{T}}$ are all non-empty and partition $V(H) \setminus \{r\}$.*
2. *For distinct nodes $x, y \in \hat{T}$, if x is the parent of y in $\hat{T}$ then $B_x \cap B_y = \{y\}$; in every other situation, $B_x \cap B_y = \emptyset$.*
3. *For every node $x \in \hat{T}$, the following hold:*
   - **(a)** *If y is a child of x in $\hat{T}$, then any arc leading into the set B^*_y from $V(H) \setminus B^*_y$ will have the form uy where $u \in B_x$.*
   - **(b)** *If y, y' are distinct children of x in $\hat{T}$, then there is no arc between B^*_y and $B^*_{y'}$.*

In particular, every arc of H is either contained in a subgraph of H induced by a diblock B_x, or it is a back arc *going from a diblock B_y to a diblock B_x, where x is an ancestor of y in $\hat{T}$.*

Proof. For the first claim, the sets $B_x \setminus \{x\}$ are non-empty by definition; we show the partitioning claim. By Lemma 13, for every $v \in V(H) \setminus \{r\}$ either $v \in B_r \setminus \{r\}$ or there is exactly one bottleneck $x \in B_r$ such that $v \in X_x$ in the construction of the decomposition. Also note that in the latter case, $v \neq x$ since $x \in B_r$. Applying the argument recursively and using that the diblocks cover $V(H)$, by Lemma 15, we complete the proof of the partitioning claim.

For the second claim, the partitioning claim implies that if $v \in B_x \cap B_y$ for distinct nodes $x, y \in \hat{T}$, then either $v = x$ or $v = y$, i.e., v must be a bottleneck. This is only possible in the situation described.

For Claim 3(b), first consider the diblock B_r and the partition $\{X_x\}$ given by Lemma 13. We show that for any two distinct sets X_x, X_y of the partition, there is no arc between X_x and X_y. Suppose for a contradiction that there is such an arc uv, $u \in X_x$, $v \in X_y$. By Lemma 12, there are paths P_x and P_y in B_r that intersect only in r, and by Lemma 15, there are paths P_u from x to u in X_x and P_v from y to v in X_y. But then the paths $P_x P_u uv$ and $P_y P_v$ form two r-v paths that are internally vertex-disjoint, showing that $v \in B_r$, contrary to our assumptions. Since the decomposition is computed recursively, this also holds in every internal node of $\hat{T}$.

For Claim 3(a), let uv be an arc such that $u \notin B_y^*$ and $v \in B_y^*$. Moreover, let $u \in B_{x'}$ and $v \in B_{y'}$. By construction of cut decomposition, there is a path $\hat{P}$ from x' to y' in $\hat{T}$ containing nodes x and y. Let x'' be the second node in $\hat{P}$ (just after x'). Thus, there is a path P from x'' to v in H containing the vertices of $\hat{P}$ apart from x'.

Assume that $u \neq x''$. Then by Lemma 12, there is an x'-u-path P' and an x'-x''-path P'' of H which intersect only at x'. Then $x'P'uv$ and $P''P$ are internally vertex-disjoint paths from x' to v. This means that v must be in $B_{x'}$, a contradiction unless $x' = x$, $u \in B_x$ and $v = y$. If $u = x''$, then P and uv are internally vertex-disjoint paths from u to v. This means that v must be in $B_{x''}$, a contradiction unless $x' = x$ and $v = y$. ◀

As we saw, for every diblock B_y, $y \in \hat{T}$, any path "into" the diblock must go via the bottleneck vertex y. By induction, for any $v \in B_y$, every node of $\hat{T}$ from r to y represents a bottleneck vertex that is unavoidable for paths from r to v. More formally, the following holds in cut decompositions:

▶ **Lemma 17.** *Let $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ be the cut decomposition of H rooted at r. Fix a diblock B_x for $x \in \hat{T}$. Consider a path P in H from r to $v \in B_x$ and let $x_1 \dots x_\ell$ be the sequence of bottleneck vertices that P encounters. Then $\hat{P} = x_0 x_1 \dots x_\ell$ with $x_0 = r$ is the path from r to x in $\hat{T}$.*

Proof. We prove the claim by induction over the depth d of x in $\hat{T}$. If $r = x$ then any path from r to $v \in B_r$ contains r itself and hence the base case for $d = 0$ holds.

Consider a diblock B_x, $x \in \hat{T}$ where x has distance d to r in $\hat{T}$ and let y be the parent of x in $\hat{T}$. We assume the induction hypothesis holds for diblocks at depth $d - 1$, hence it holds for B_y in particular. Because $x \in B_y$, this implies that every path from r to x will contain all ancestors of x in $\hat{T}$. Since by construction every path from r to a vertex $v \in B_x$ needs to pass through x, the inductive step holds. This proves the claim. ◀

As an immediate consequence, we can identify arcs in cut decompositions that cannot participate in any rooted out-branching.

▶ **Corollary 18.** *Let $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ be the cut decomposition of rooted at r and let $R := \{uv \in A(H) \mid u \in B_x \text{ and } x \in \hat{T}_v\}$ be all the arcs that originate in a diblock B_x and end in an ancestor v of x on $\hat{T}$. Then for every out-tree T rooted at r we have $A(T) \cap R = \emptyset$.*

Proof. Fix a bottleneck vertex $v \in \hat{T}$ of the decomposition and let the arc uv be in an out-tree T rooted at r. There must exist a path P_{su} from s to u that is part of T. By Lemma 17, this path will contain the vertex v. But then v is an ancestor of u in T and therefore the arc uv cannot be part of T, which is a contradiction. ◀

The decomposition actually restricts paths even further: a path that starts at the root and visits two bottleneck vertices x, y (in this order) cannot intersect any vertex of B^*_y before visiting y and cannot return to any set B^*_z, $z \in \hat{T}$, after having left it.

▶ **Lemma 19.** *Let $(\hat{T}, \{B_x\}_{x\in\hat{T}})$ be the cut decomposition of H rooted at r. Fix a diblock B_x for $x \in \hat{T}$. Consider a path P from r to $v \in B_x$ and let $\hat{P} = x_0 \dots x_\ell$ be the path from $r = x_0$ to $x = x_\ell$ in $\hat{T}$. Let further $F_0, \dots, F_\ell$ be the fins of $\hat{P}$ in $\hat{T}$. Then the subpath $P[x_i, x_{i+1}] \setminus \{x_{i+1}\}$ is contained in the union of diblocks of F_i for $0 \le i < \ell$.*

Proof. By Lemma 17 we know that the nodes of $\hat{P}$ appear in P in the correct order, hence the subpath $P[x_i, x_{i+1}]$ is well-defined. Let us first show that the subpath $P[x_i, x_{i+1}] \setminus \{x_{i+1}\}$ cannot intersect any diblock associated with $\hat{T}_{x_{i+1}}$. By Lemma 16, the only arcs from B_{x_i} into diblocks below x_{i+1} connect to the bottleneck x_{i+1} itself. Since x_{i+1} is already the endpoint of $P[x_i, x_{i+1}]$, this subpath cannot intersect the diblocks of $\hat{T}_{x_{i+1}}$. This already proves the claim for x_0; it remains to show that it does not intersect diblocks of $V(\hat{T}) \setminus V(\hat{T}_{x_i})$ for $i \ge 1$. The reason is similar: since the bottleneck x_i is already part of $P[x_i, x_{i+1}]$, this subpath could not revisit B_{x_i} if it enters any diblock B_y for a proper ancestor y of x_i in $\hat{T}$. We conclude that therefore it must be, with the exception of the vertex x_{i+1}, inside the diblocks of the fin F_i. ◀

▶ **Corollary 20.** *For every vertex $u \in V(H)$ and every set $X \subseteq V(H) \setminus (V(\hat{T}) \cup \{u\})$ of non-bottleneck vertices there exists a path P from r to u such that $|P \cap X| \le |X|/2$.*

Proof. Assume that $u \in B_x$ and let $\hat{P} = x_0 \dots x_\ell$ be a path from $x_0 = r$ to $x_\ell = x$ in $\hat{T}$. Let further $F_0, \dots, F_\ell$ be the fins of $\hat{P}$ in $\hat{T}$. We partition the set X into $X_1, \dots, X_\ell$ where $X_i = X \cap F_i$ for $0 \le i \le \ell$. Lemma 19 allows us to construct the path P iteratively: any path that leads to u will pass through bottlenecks x_i, x_{i+1} in succession and visit only diblocks associated with F_i in the process. Since there are two internally vertex-disjoint paths between x_i, x_{i+1} for $1 \le i \le \ell$, we can always choose the path that has the smaller intersection with X_i. Stringing these paths together, we obtain the claimed path P. ◀

We want to argue that one of the following cases must hold: either the cut decomposition has bounded height and we can 're-root' any out-tree with many leaves into a rooted out-tree with a comparable number of leaves, or we can directly construct a rooted out-tree with many leaves. In both cases we apply Lemmas 4 and 9 to conclude that the instance has a solution. This approach has one obstacle: internal diblocks of the decomposition that contain only two vertices.

▶ **Definition 21** (Degenerate diblocks)**.** Let $\{B_x\}_{x\in\hat{T}}$ be the cut decomposition rooted at s. We call a diblock B_x *degenerate* if x is an internal node of $\hat{T}$ and $|B_x| = 2$.

Let us first convince ourselves that a long enough sequence of non-degenerate diblocks provides us with a rooted out-branching with many leaves.

▶ **Lemma 22.** *Let $(\hat{T}, \{B_x\}_{x\in\hat{T}})$ be the cut decomposition rooted at s of H and let y be a node in $\hat{T}$ such that the path $\hat{P}_{sy}$ from s to y in $\hat{T}$ contains at least ℓ nodes whose diblocks are non-degenerate. Then H contains an out-tree rooted at s with at least ℓ leaves.*

Proof. We construct an s-rooted out-tree T by repeated application of Lemma 12. Let $x_1, \ldots, x_\ell$ be a sequence of nodes in $\hat{P}_{sy}$ whose diblocks are non-degenerate, and for each $1 \leq i < \ell$ let x_i^+ be the node after x_i in $\hat{P}_{sy}$. We construct a sequence of s-rooted out-trees $T_1, \ldots, T_\ell$ such that for $1 \leq i \leq \ell$, the vertex x_i is a leaf of T_i, and T_i contains i leaves. First construct T_1 as a path from s to x_1, then for every $1 \leq i < \ell$ we construct an out-tree T_{i+1} from T_i as follows. Let $v_i \in B_{x_i} \setminus \{x_i, x_i^+\}$, which exists since B_{x_i} is non-degenerate, and let $P_{x_i x_i^+}$, $P_{x_i v_i}$ be a pair of paths in $H[B^*_{x_i}]$ from x_i to x_i^+ and to v_i respectively, which intersect only in x_i. Such paths exist by Lemma 12, and since x_i is a leaf of T_i, Lemma 17 implies that T_i is disjoint from $B^*_{x_i} \setminus \{x_i\}$. Hence the paths can be appended to T_i to form a new r-rooted out-tree T_{i+1} in H which contains a leaf in every diblock B_{x_j}, $1 \leq i$. Finally, note that the final tree T_ℓ contains two leaves in $B_{x_{\ell-1}}$, hence T_ℓ is an r-rooted out-tree with ℓ leaves. ◀

The next lemma is the last assertion that we will use to prove shortly that Rooted k-Distinct Branchings is FPT for digraphs D whose cut decomposition rooted at s contains no degenerate diblocks.

▶ **Lemma 23.** *Let $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ be the cut decomposition of D rooted at s such that $\hat{T}$ is of height d and let T be an out-tree rooted at some vertex r with ℓ leaves. Then we can construct an out-tree T_s rooted at s with at least $(\ell - d)/2$ leaves.*

Proof. Assume that r is contained in the diblock B_x of the decomposition and let $x_p \ldots x_1 = \hat{P}_{sx}$ be a path from $s = x_p$ to $x = x_1$ in $\hat{T}$. Let L be the leaves of T and let $L' := L \setminus \hat{P}_{sx}$. Clearly, $|L'| \geq \ell - d$. Applying Corollary 20 with $X = L'$ and $u = r$, we obtain a path P_{sr} in D from s to r that avoids half of L'. We construct T_s in a similar fashion to the proof of Lemma 11. We begin with $T_s = P_{sr}$, then for every leaf $v \in L' \setminus P_{sr}$, proceed as follows: let P_v be the unique path from r to v in T and let P'_v be the segment of P_v from the last vertex x of P_v contained in T_s. Add all arcs and vertices of P'_v to T_s. Since P_v and thus P'_v contains no leaf of L' other than v, in the end of the process, all vertices of $L' \setminus P_{sr}$ are leaves of T_s. Since $|L' \setminus P_{sr}| \geq |L'|/2$, we conclude that T_s contains at least $(\ell - d)/2$ leaves, as claimed. ◀

The next lemma demonstrates that using Lemma 23 and a number of other results we can prove that if the height d of the cut decomposition of D is upper-bounded by a function in k, then Rooted k-Distinct Branchings on D is FPT. This shows that to prove that Rooted k-Distinct Branchings in general it suffices to consider separately the cases of bounded d and unbounded d. To provide an appropriate bound on d we will use further results on degenerate diblocks proved in Section 4.3.

▶ **Lemma 24.** *Let $(\hat{T}, \{B_x\}_{x \in \hat{T}})$ the cut decomposition rooted at s of height d. If $d \leq d(k)$ for some function $d(k) = \Omega(k)$ of k only, then we can solve* Rooted k-Distinct Branchings *on D in time $O^*(2^{O(d(k) \log^2 d(k))})$.*

Proof. By Theorem 2, in time $O^*(2^{O(d(k))})$ we can decide whether D has an out-branching with at least $2k + 2 + d(k)$ leaves. If D has such an out-branching, then by Lemma 23 D has a rooted out-tree with at least $k + 1$ leaves. This out-tree can be extended to a rooted out-branching with at least $k + 1$ leaves by Lemma 9. So by Lemma 4, (D, s, t) is a positive instance if and only if D has a rooted in-branching, which can be decided in polynomial time.

If D has no out-branching with at least $2k+2+d(k)$ leaves, by Theorem 1 the pathwidth of D is $O(d(k) \log d(k))$ and thus by Lemma 5 we can solve Rooted k-Distinct Branchings on D in time $O^*(2^{O(d(k) \log^2 d(k))})$. (Note that for the dynamic programming algorithm of

Lemma 5 we may fix roots of all out-branchings and all in-branchings of D by adding arcs $s's$ and tt' to D, where s' and t' are new vertices.) ◀

4.3 Handling degenerate diblocks

A full version of this section can be found in the complete version of the paper. Here is a key notion for our study of degenerate diblocks.

▶ **Definition 25** (Degenerate paths)**.** Let $(\hat{T}, \{B_x\}_{x\in\hat{T}})$ be a cut decomposition of D. We call a path $\hat{P}$ in $\hat{T}$ *monotone* if it is a subpath of a path from the root of $\hat{T}$ to some leaf of $\hat{T}$. We call a path $\hat{P}$ in $\hat{T}$ *degenerate* if it is monotone and every diblock B_x, $x \in \hat{P}$ is degenerate.

Let (D, s, t) be a strongly connected reduced instance of Rooted k-Distinct Branchings. As observed in Section 4.1, we can verify in polynomial time whether an arc participates in *some* rooted in- or out-branching. Let $R_s \subseteq A(D)$ be those arcs that do not participate in any rooted out-branching and $R_t \subseteq A(D)$ those that do not participate in any rooted in-branching. Since (D, s, t) is a reduced instance, we necessarily have that $R_s \cap R_t = \emptyset$.

▶ **Lemma 26.** *Let $\hat{P} = x_1 \dots x_\ell$ be a degenerate path of $(\hat{T}, \{B_x\}_{x\in\hat{T}})$ of D rooted at s. Then the following properties hold: every rooted out-branching contains $A(\hat{P})$, every arc x_jx_i with $j > i$ is contained in R_s, and there is no arc from x_i $(i < \ell)$ to B_y in D, where y is a descendant of x_i on $\hat{T}$, except for the arc x_ix_{i+1}.*

Let us fix a single degenerate path $\hat{P} = x_1 \dots x_\ell$. We categorize the arcs incident to $\hat{P}$ as follows: let A^+ contain all 'upward arcs' that originate in $\hat{P}$ and end in some diblock B_y where y is an ancestor of x_1, let A^0 contain all 'on-path arcs' x_jx_i, $j > i$, and let A^- contain all 'arcs from below' that originate from some diblock B_y where y is a (not necessarily proper) descendant of x_ℓ. By the lemma above this categorization is complete.

We will need the following reduction rules for (D, s, t):

Reduction Rule 1: If there are two arcs $x_iu, x_ju \in A^+ \cap R_t$ with $i < j$, remove x_ju.

Reduction Rule 2: If $\hat{P}[x, y] \subseteq \hat{P}$ is such that no vertex in $\hat{P}[x, y]$ is a tail of arcs in $A^+ \cup A^0$, contract $\hat{P}[x, y]$ into a single vertex.

Now we can state the main lemma of the section which finally enables us to proof the main result of this paper.

▶ **Lemma 27.** *Let $\hat{P}$ be a degenerate path in an instance reduced with respect to Rules 1 and 2. If $t \notin \hat{P}$, then $|\hat{P}| \leq 14k + 3$. Otherwise, $|\hat{P}| \leq 28k + 7$.*

Proof of Theorem 7. By Lemma 8, we may assume that D is strongly connected. Consider the longest monotone path $\hat{P}$ of $\hat{T}$. By Lemma 22, if $\hat{P}$ has at least $k + 1$ non- degenerate diblocks, then D has a rooted out-tree with at least $k + 1$ leaves. This out-tree can be extended to a rooted out-branching with at least $k+1$ leaves by Lemma 9. Thus, by Lemma 4, (D, s, t) is a positive instance if and only if D has a rooted in-branching, which can be decided in polynomial time.

Now assume that $\hat{P}$ has at most k non-degenerate diblocks. By Lemma 27 we may assume that before, between and after the non-degenerate diblocks there are $O(k)$ degenerate diblocks. Thus, the height of $\hat{T}$ is $O(k^2)$. Therefore, by Lemma 24, the time complexity for Theorem 7 is $O^*(2^{O(k^2 \log^2 k)})$. ◀

5 Conclusion

We showed that the Rooted k-Distinct Branchings problem is FPT for general digraphs parameterized by k, thereby settling open question of Bang-Jensen *et al.* [6]. The solution in particular uses a new digraph decomposition, the *rooted cut decomposition*, that we believe might be useful for settling other problems as well. We did not try to optimize the running time of the algorithm of Theorem 7. Perhaps, a more careful handling of degenerate diblocks may lead to an algorithm of running time $O^*(2^{O(k \log^2 k)})$.

Abstract

Sketching has emerged as a powerful technique for speeding up problems in numerical linear algebra, such as regression. In the overconstrained regression problem, one is given an $n \times d$ matrix A, with $n \gg d$, as well as an $n \times 1$ vector b, and one wants to find a vector $\hat{x}$ so as to minimize the residual error $\|Ax - b\|_2$. Using the sketch and solve paradigm, one first computes $S \cdot A$ and $S \cdot b$ for a randomly chosen matrix S, then outputs $x' = (SA)^\dagger Sb$ so as to minimize $\|SAx' - Sb\|_2$.

The sketch-and-solve paradigm gives a bound on $\|x' - x^*\|_2$ when A is well-conditioned. Our main result is that, when S is the subsampled randomized Fourier/Hadamard transform, the error $x' - x^*$ behaves as if it lies in a "random" direction within this bound: for any fixed direction $a \in \mathbb{R}^d$, we have with $1 - d^{-c}$ probability that

$$\langle a, x' - x^* \rangle \lesssim \frac{\|a\|_2 \|x' - x^*\|_2}{d^{\frac{1}{2}-\gamma}}, \tag{1}$$

where $c, \gamma > 0$ are arbitrary constants. This implies $\|x' - x^*\|_\infty$ is a factor $d^{\frac{1}{2}-\gamma}$ smaller than $\|x' - x^*\|_2$. It also gives a better bound on the generalization of x' to new examples: if rows of A correspond to examples and columns to features, then our result gives a better bound for the error introduced by sketch-and-solve when classifying fresh examples. We show that not all oblivious subspace embeddings S satisfy these properties. In particular, we give counterexamples showing that matrices based on Count-Sketch or leverage score sampling do not satisfy these properties.

We also provide lower bounds, both on how small $\|x' - x^*\|_2$ can be, and for our new guarantee (1), showing that the subsampled randomized Fourier/Hadamard transform is nearly optimal. Our lower bound on $\|x' - x^*\|_2$ shows that there is an $O(1/\epsilon)$ separation in the dimension of the optimal oblivious subspace embedding required for outputting an x' for which $\|x' - x^*\|_2 \leq \epsilon \|Ax^* - b\|_2 \cdot \|A^\dagger\|_2$, compared to the dimension of the optimal oblivious subspace embedding required for outputting an x' for which $\|Ax' - b\|_2 \leq (1+\epsilon)\|Ax^* - b\|_2$, that is, the former problem requires dimension $\Omega(d/\epsilon^2)$ while the latter problem can be solved with dimension $O(d/\epsilon)$. This explains the reason known upper bounds on the dimensions of these two variants of regression have differed in prior work.

1 Introduction

Oblivious subspace embeddings (OSEs) were introduced by Sarlos [23] to solve linear algebra problems more quickly than traditional methods. An OSE is a distribution of matrices $S \in \mathbb{R}^{m\times n}$ with $m \ll n$ such that, for any d-dimensional subspace $U \subset \mathbb{R}^n$, with "high" probability S preserves the norm of every vector in the subspace. OSEs are a generalization of the classic Johnson-Lindenstrauss lemma from vectors to subspaces. Formally, we require that with probability $1-\delta$,

$$\|Sx\|_2 = (1\pm\epsilon)\|x\|_2$$

simultaneously for all $x \in U$, that is, $(1-\epsilon)\|x\|_2 \le \|Sx\|_2 \le (1+\epsilon)\|x\|_2$.

A major application of OSEs is to regression. The regression problem is, given $b \in \mathbb{R}^n$ and $A \in \mathbb{R}^{n\times d}$ for $n \ge d$, to solve for

$$x^* = \arg\min_{x\in\mathbb{R}^d} \|Ax-b\|_2. \tag{2}$$

Because A is a "tall" matrix with more rows than columns, the system is overdetermined and there is likely no solution to $Ax = b$, but regression will find the closest point to b in the space spanned by A. The classic answer to regression is to use the Moore-Penrose pseudoinverse: $x^* = A^\dagger b$ where

$$A^\dagger = (A^\top A)^{-1}A^\top$$

is the "pseudoinverse" of A (assuming A has full column rank, which we will typically do for simplicity). This classic solution takes $O(nd^{\omega-1}+d^\omega)$ time, where $\omega < 2.373$ is the matrix multiplication constant [9, 25, 12]: $nd^{\omega-1}$ time to compute $A^\top A$ and d^ω time to compute the inverse.

OSEs speed up the process by replacing (2) with

$$x' = \arg\min_x \|SAx - Sb\|_2$$

for an OSE S on $d+1$-dimensional spaces. This replaces the $n\times d$ regression problem with an $m\times d$ problem, which can be solved more quickly since $m \ll n$. Because $Ax-b$ lies in the $d+1$-dimensional space spanned by b and the columns of A, with high probability S preserves the norm of $SAx-Sb$ to $1\pm\epsilon$ for all x. Thus,

$$\|Ax'-b\|_2 \le \frac{1+\epsilon}{1-\epsilon}\|Ax^*-b\|_2.$$

That is, S produces a solution x' which preserves the *cost* of the regression problem. The running time for this method depends on (1) the reduced dimension m and (2) the time it takes to multiply S by A. We can compute these for "standard" OSE types:

- If S has i.i.d. Gaussian entries, then $m = O(d/\epsilon^2)$ is sufficient (and in fact, $m \ge d/\epsilon^2$ is required [20]). However, computing SA takes $O(mnd) = O(nd^2/\epsilon^2)$ time, which is worse than solving the original regression problem (one can speed this up using fast matrix multiplication, though it is still worse than solving the original problem).
- If S is a subsampled randomized Hadamard transform (SRHT) matrix with random sign flips (see Theorem 2.4 in [26] for a survey, and also see [8] which gives a recent improvement) then m increases to $\widetilde{O}(d/\epsilon^2\cdot\log n)$, where $\widetilde{O}(f) = f\,\mathrm{poly}(\log(f))$. But now, we can compute SA using the fast Hadamard transform in $O(nd\log n)$ time. This makes the overall regression problem take $O(nd\log n + d^\omega/\epsilon^2)$ time.

- If S is a random sparse matrix with random signs (the "Count-Sketch" matrix), then $m = d^{1+\gamma}/\epsilon^2$ suffices for $\gamma > 0$ a decreasing function of the sparsity [5, 18, 19, 3, 6]. (The definition of a Count-Sketch matrix is, for any $s \geq 1$, $S_{i,j} \in \{0, -1/\sqrt{s}, 1/\sqrt{s}\}$, $\forall i \in [m], j \in [n]$ and the column sparsity of matrix S is s. Independently in each column s positions are chosen uniformly at random without replacement, and each chosen position is set to $-1/\sqrt{s}$ with probability 1/2, and $+1/\sqrt{s}$ with probability 1/2.) Sparse OSEs can benefit from the sparsity of A, allowing for a running time of $\widetilde{O}(\text{nnz}(A)) + \widetilde{O}(d^{\omega}/\epsilon^2)$, where $\text{nnz}(A)$ denotes the number of non-zeros in A.

When n is large, the latter two algorithms are substantially faster than the naïve $nd^{\omega-1}$ method.

1.1 Our Contributions

Despite the success of using subspace embeddings to speed up regression, often what practitioners are interested is not in preserving the cost of the regression problem, but rather in the *generalization* or *prediction* error provided by the vector x'. Ideally, we would like for any future (unseen) example $a \in \mathbb{R}^d$, that $\langle a, x' \rangle \approx \langle a, x^* \rangle$ with high probability.

Ultimately one may want to use x' to do classification, such as regularized least squares classification (RLSC) [22], which has been found in cases to do as well as support vector machines but is much simpler [27]. In this application, given a training set of examples with multiple (non-binary) labels identified with the rows of an $n \times d$ matrix A, one creates an $n \times r$ matrix B, each column indicating the presence or absence of one of the r possible labels in each example. One then solves the multiple response regression problem $\min_X \|AX - B\|_F$, and uses X to classify future examples. A commonly used method is for a future example a, to compute $\langle a, x_1 \rangle, \ldots, \langle a, x_r \rangle$, where $x_1, \ldots, x_r$ are the columns of X. One then chooses the label i for which $\langle a, x_i \rangle$ is maximum.

For this to work, we would like the inner products $\langle a, x'_1 \rangle, \ldots, \langle a, x'_r \rangle$ to be close to $\langle a, x^*_1 \rangle, \ldots, \langle a, x^*_r \rangle$, where X' is the solution to $\min_X \|SAX - SB\|_F$ and X^* is the solution to $\min_X \|AX - B\|_F$. For any $O(1)$-accurate OSE on $d + r$ dimensional spaces [23], which also satisfies so-called approximate matrix multiplication with error $\epsilon' = \epsilon/\sqrt{(d+r)}$, we get that

$$\|x' - x^*\|_2 \leq O(\epsilon) \cdot \|Ax^* - b\|_2 \cdot \|A^\dagger\|_2 \tag{3}$$

where $\|A^\dagger\|$ is the spectral norm of $A^\dagger$, which equals the reciprocal of the smallest singular value of A. To obtain a generalization error bound for an unseen example a, one has

$$|\langle a, x^* \rangle - \langle a, x' \rangle| = |\langle a, x^* - x' \rangle| \leq \|x^* - x'\|_2 \|a\|_2 = O(\epsilon)\|a\|_2 \|Ax^* - b\|_2 \|A^\dagger\|_2, \tag{4}$$

which could be tight if given only the guarantee in (3). However, if the difference vector $x' - x^*$ were distributed in a uniformly random direction subject to (3), then one would expect an $\widetilde{O}(\sqrt{d})$ factor improvement in the bound. This is what our main theorem shows:

▶ **Theorem 1** (Main Theorem, informal). *Suppose $n \leq \text{poly}(d)$. Let S be a subsampled randomized Hadamard transform matrix with $m = d^{1+\gamma}/\epsilon^2$ rows for an arbitrarily small constant $\gamma > 0$. For $x' = \arg\min_x \|SAx - Sb\|_2$ and $x^* = \arg\min_x \|Ax - b\|_2$, and any fixed $a \in \mathbb{R}^d$,*

$$|\langle a, x^* \rangle - \langle a, x' \rangle| \leq \frac{\epsilon}{\sqrt{d}} \|a\|_2 \|Ax^* - b\|_2 \|A^\dagger\|_2. \tag{5}$$

with probability $1 - 1/d^C$ for an arbitrarily large constant $C > 0$. This implies that

$$\|x^* - x'\|_\infty \leq \frac{\epsilon}{\sqrt{d}} \|Ax^* - b\|_2 \|A^\dagger\|_2 \tag{6}$$

with $1 - 1/d^{C-1}$ probability.

If $n > \text{poly}(d)$, then by first composing S with a Count-Sketch OSE with $\text{poly}(d)$ rows, one can achieve the same guarantee.

(Here γ is a constant going to zero as n increases, see Theorem 10 for a formal statement of Theorem 1).

Notice that Theorem 1 is considerably stronger than that of (4) provided by existing guarantees. Indeed, in order to achieve the guarantee (6) in Theorem 1, one would need to set $\epsilon' = \epsilon/\sqrt{d}$ in existing OSEs, resulting in $\Omega(d^2/\epsilon^2)$ rows. In contrast, we achieve only $d^{1+\gamma}/\epsilon^2$ rows. We can improve the bound in Theorem 1 to $m = d/\epsilon^2$ if S is a matrix of i.i.d. Gaussians; however, as noted, computing $S \cdot A$ is slower in this case.

Note that Theorem 1 also *makes no distributional assumptions* on the data, and thus the data could be heavy-tailed or even adversarially corrupted. This implies that our bound is still useful when the rows of A are not sampled independently from a distribution with bounded variance.

The ℓ_∞ bound (6) of Theorem 1 is achieved by applying (5) to the standard basis vectors $a = e_i$ for each $i \in [d]$ and applying a union bound. This ℓ_∞ guarantee often has a more natural interpretation than the ℓ_2 guarantee – if we think of the regression as attributing the observable as a sum of various factors, (6) says that the contribution of each factor is estimated well. One may also see our contribution as giving a way for estimating the pseudoinverse $A^\dagger$ *entrywise*. Namely, we get that $(SA)^\dagger S \approx A^\dagger$ in the sense that each entry is within additive $O(\epsilon\sqrt{\frac{\log d}{d}}\|A^\dagger\|_2)$. There is a lot of work on computing entries of inverses of a matrix, see, e.g., [1, 16].

Another benefit of the ℓ_∞ guarantee is when the regression vector x^* is expected to be *k-sparse* (e.g. [14]). In such cases, thresholding to the top k entries will yield an ℓ_2 guarantee a factor $\sqrt{k/d}$ better than (3).

One could ask if Theorem 1 also holds for sparse OSEs, such as the Count-Sketch. Surprisingly, we show that one cannot achieve the generalization error guarantee in Theorem 1 with high probability, say, $1 - 1/d$, using such embeddings, despite the fact that such embeddings do approximate the cost of the regression problem up to a $1 + \epsilon$ factor with high probability. This shows that the generalization error guarantee is achieved by some subspace embeddings but not all.

▶ **Theorem 2** (Not all subspace embeddings give the ℓ_∞ guarantee)**.** *The Count-Sketch matrix with $d^{1.5}$ rows and sparsity $d^{.25}$ – which is an OSE with exponentially small failure probability – with constant probability will have a result x' that does not satisfy the ℓ_∞ guarantee (6).*

We can show that Theorem 1 holds for S based on the Count-Sketch OSE T with $d^{O(C)}/\epsilon^2$ rows with $1 - 1/d^C$ probability. We can thus compose the Count-Sketch OSE with the SRHT matrix and obtain an $O(\text{nnz}(A)) + \text{poly}(d/\epsilon)$ time algorithm to compute $S \cdot TA$ achieving (6). We can also compute $R \cdot S \cdot T \cdot A$, where R is a matrix of Gaussians, which is more efficient now that STA only has $d^{1+\gamma}/\epsilon^2$ rows; this will reduce the number of rows to d/ϵ^2.

Another common method of dimensionality reduction for linear regression is *leverage score sampling* [10, 15, 21, 7], which subsamples the rows of A by choosing each row with probability proportional to its "leverage scores". With $O(d\log(d/\delta)/\epsilon^2)$ rows taken, the result x' will satisfy the ℓ_2 bound (3) with probability $1 - \delta$. However, it does not give a good ℓ_∞ bound:

▶ **Theorem 3** (Leverage score sampling does not give the ℓ_∞ guarantee)**.** *Leverage score sampling with $d^{1.5}$ rows – which satisfies the ℓ_2 bound with exponentially small failure probability – with constant probability will have a result x' that does not satisfy the ℓ_∞ guarantee (6).*

Finally, we show that the $d^{1+\gamma}/\epsilon^2$ rows that SRHT matrices use is roughly optimal:

▶ **Theorem 4** (Lower bounds for ℓ_2 and ℓ_∞ guarantees). *Any sketching matrix distribution over $m \times n$ matrices that satisfies either the ℓ_2 guarantee* (3) *or the ℓ_∞ guarantee* (6) *must have $m \gtrsim \min(n, d/\epsilon^2)$.*

Notice that our result shows the necessity of the $1/\epsilon$ separation between the results originally defined in Equation (3) and (4) of Theorem 12 of [23]. If we want to output some vector x' such that $\|Ax' - b\|_2 \leq (1+\epsilon)\|Ax^* - b\|_2$, then it is known that $m = \Theta(d/\epsilon)$ is necessary and sufficient. However, if we want to output a vector x' such that $\|x' - x^*\|_2 \leq \epsilon\|Ax^* - b\|_2 \cdot \|A^\dagger\|_2$, then we show that $m = \Theta(d/\epsilon^2)$ is necessary and sufficient.

1.1.1 Comparison to Gradient Descent

While this work is primarily about sketching methods, one could instead apply iterative methods such as gradient descent, after appropriately preconditioning the matrix, see, e.g., [2, 28, 5]. That is, one can use an OSE with constant ϵ to construct a preconditioner for A and then run conjugate gradient using the preconditioner. This gives an overall dependence of $\log(1/\epsilon)$.

The main drawback of this approach is that one loses the ability to save on storage space or number of passes when A appears in a stream, or to save on communication or rounds when A is distributed. Given increasingly large data sets, such scenarios are now quite common, see, e.g., [4] for regression algorithms in the data stream model. In situations where the entries of A appear sequentially, for example, a row at a time, one does not need to store the full $n \times d$ matrix A but only the $m \times d$ matrix SA.

Also, iterative methods can be less efficient when solving multiple response regression, where one wants to minimize $\|AX - B\|$ for a $d \times t$ matrix X and an $n \times t$ matrix B. This is the case when ϵ is constant and t is large, which can occur in some applications (though there are also other applications for which ϵ is very small). For example, conjugate gradient with a preconditioner will take $\widetilde{O}(ndt)$ time while using an OSE directly will take only $\widetilde{O}(nd + d^2t)$ time (since one effectively replaces n with $O(d)$ after computing $S \cdot A$), separating t from d. Multiple response regression, arises, for example, in the RLSC application above.

1.1.2 Proof Techniques

Theorem 1. As noted in Theorem 2, there are some OSEs for which our generalization error bound does not hold. This hints that our analysis is non-standard and cannot use generic properties of OSEs as a black box. Indeed, in our analysis, we have to consider matrix products of the form $S^\top S(UU^\top S^\top S)^k$ for our random sketching matrix S and a fixed matrix U, where k is a positive integer. We stress that it is the *same matrix* S appearing multiple times in this expression, which considerably complicates the analysis, and does not allow us to appeal to standard results on approximate matrix product (see, e.g., [26] for a survey). The key idea is to recursively reduce $S^\top S(UU^\top S^\top S)^k$ using a property of S. We use properties that only hold for specifics OSEs S: first, that each column of S is unit vector; and second, that for all pairs (i, j) and $i \neq j$, the inner product between S_i and S_j is at most $\sqrt{\log n}/\sqrt{m}$ with probability $1 - 1/\operatorname{poly}(n)$.

Theorems 2 and 3. To show that Count-Sketch does not give the ℓ_∞ guarantee, we construct a matrix A and vector b as in Figure 1, which has optimal solution x^* with all coordinates $1/\sqrt{d}$. We then show, for our setting of parameters, that there likely exists an

index $j \in [d]$ satisfying the following property: the jth column of S has disjoint support from the kth column of S for all $k \in [d+\alpha] \setminus \{j\}$ except for a single $k > d$, for which S_j and S_k share exactly one common entry in their support. In such cases we can compute x'_j explicitly, getting $|x'_j - x^*_j| = \frac{1}{s\sqrt{\alpha}}$. By choosing suitable parameters in our construction, this gives that $\|x' - x^*\|_\infty \gg \frac{1}{\sqrt{d}}$. The lower bound for leverage score sampling follows a similar construction.

Theorem 4. The lower bound proof for the ℓ_2 guarantee uses Yao's minimax principle. We are allowed to fix an $m \times n$ sketching matrix S and design a distribution over $[A\ b]$. We first write the sketching matrix $S = U\Sigma V^\top$ in its singular value decomposition (SVD). We choose the $d+1$ columns of the adjoined matrix $[A, b]$ to be random orthonormal vectors. Consider an $n \times n$ orthonormal matrix R which contains the columns of V as its first m columns, and is completed on its remaining $n - m$ columns to an arbitrary orthonormal basis. Then $S \cdot [A, b] = V^\top R R^\top \cdot [A, b] = [U\Sigma I_m, 0] \cdot [R^\top A, R^\top b]$. Notice that $[R^\top A, R^\top b]$ is equal in distribution to $[A, b]$, since R is fixed and $[A, b]$ is a random matrix with $d+1$ orthonormal columns. Therefore, $S \cdot [A, b]$ is equal in distribution to $[U\Sigma G, U\Sigma h]$ where $[G, h]$ corresponds to the first m rows of an $n \times (d+1)$ uniformly random matrix with orthonormal columns.

A key idea is that if $n = \Omega(\max(m, d)^2)$, then by a result of Jiang [13], any $m \times (d+1)$ submatrix of a random $n \times n$ orthonormal matrix has $o(1)$ total variation distance to a $d \times d$ matrix of i.i.d. $N(0, 1/n)$ random variables, and so any events that would have occurred had G and h been independent i.i.d. Gaussians, occur with the same probability for our distribution up to an $1 - o(1)$ factor, so we can assume G and h are independent i.i.d. Gaussians in the analysis.

The optimal solution x' in the sketch space equals $(SA)^\dagger Sb$, and by using that SA has the form $U\Sigma G$, one can manipulate $\|(SA)^\dagger Sb\|$ to be of the form $\|\tilde{\Sigma}^\dagger (\Sigma R)^\dagger \Sigma h\|_2$, where the SVD of G is $R\tilde{\Sigma}T$. We can upper bound $\|\tilde{\Sigma}\|_2$ by $\sqrt{r/n}$, since it is just the maximum singular value of a Gaussian matrix, where r is the rank of S, which allows us to lower bound $\|\tilde{\Sigma}^\dagger (\Sigma R)^\dagger \Sigma h\|_2$ by $\sqrt{n/r}\|(\Sigma R)^\dagger \Sigma h\|_2$. Then, since h is i.i.d. Gaussian, this quantity concentrates to $\frac{1}{\sqrt{r}}\|(\Sigma R)^\dagger \Sigma h\|$, since $\|Ch\|^2 \approx \|C\|_F^2/n$ for a vector h of i.i.d. $N(0, 1/n)$ random variables. Finally, we can lower bound $\|(\Sigma R)^\dagger \Sigma\|_F^2$ by $\|(\Sigma R)^\dagger \Sigma R R^\top\|_F^2$ by the Pythagorean theorem, and now we have that $(\Sigma R)^\dagger \Sigma R$ is the identity, and so this expression is just equal to the rank of ΣR, which we prove is at least d. Noting that $x^* = 0$ for our instance, putting these bounds together gives $\|x' - x^*\| \geq \sqrt{d/r}$. The last ingredient is a way to ensure that the rank of S is at least d. Here we choose another distribution on inputs A and b for which it is trivial to show the rank of S is at least d with large probability. We require S be good on the mixture. Since S is fixed and good on the mixture, it is good for both distributions individually, which implies we can assume S has rank d in our analysis of the first distribution above.

Notation. For a positive integer, let $[n] = \{1, 2, \ldots, n\}$. For a vector $x \in \mathbb{R}^n$, define $\|x\|_2 = (\sum_{i=1}^n x_i^2)^{\frac{1}{2}}$ and $\|x\|_\infty = \max_{i \in [n]} |x_i|$. For a matrix $A \in \mathbb{R}^{m \times n}$, define $\|A\|_2 = \sup_x \|Ax\|_2 / \|x\|_2$ to be the spectral norm of A and $\|A\|_F = (\sum_{i,j} A_{i,j}^2)^{1/2}$ to be the Frobenius norm of A. We use $A^\dagger$ to denote the Moore-Penrose pseudoinverse of $m \times n$ matrix A, which if $A = U\Sigma V^\top$ is its SVD (where $U \in \mathbb{R}^{m \times n}$, $\Sigma \in \mathbb{R}^{n \times n}$ and $V \in \mathbb{R}^{n \times n}$ for $m \geq n$), is given by $A^\dagger = V\Sigma^{-1}U^\top$. In addition to $O(\cdot)$ notation, for two functions f, g, we use the shorthand $f \lesssim g$ (resp. $\gtrsim$) to indicate that $f \leq Cg$ (resp. $\geq$) for an absolute constant C. We use $f \eqsim g$ to mean $cf \leq g \leq Cf$ for constants c, C.

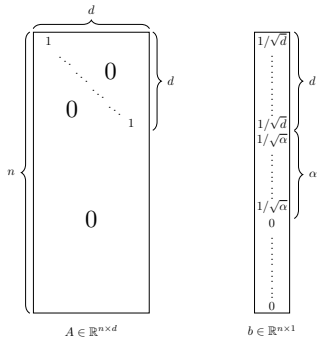

Figure 1 Our construction of A and b for the proof that Count-Sketch does not obey the ℓ_∞ guarantee. $\alpha < d$.

▶ **Definition 5** (Subspace Embedding). A $(1 \pm \epsilon)$ ℓ_2-subspace embedding for the column space of an $n \times d$ matrix A is a matrix S for which for all $x \in \mathbb{R}^d$, $\|SAx\|_2^2 = (1 \pm \epsilon)\|Ax\|_2^2$.

▶ **Definition 6** (Approximate Matrix Product). Let $0 < \epsilon < 1$ be a given approximation parameter. Given matrices A and B, where A and B each have n rows, the goal is to output a matrix C so that $\|A^\top B - C\|_F \leq \epsilon \|A\|_F \|B\|_F$. Typically C has the form $A^\top S^\top SB$, for a random matrix S with a small number of rows. In particular, this guarantee holds for the subsampled randomized Hadamard transform S with $O(\epsilon^{-2})$ rows [11].

Due to space constraints, several proofs are deferred to the full version of our paper.

2 Warmup: Gaussians OSEs

We first show that if S is a Gaussian random matrix, then it satisfies the generalization guarantee. This follows from the rotational invariance of the Gaussian distribution.

▶ **Theorem 7.** *Suppose $A \in \mathbb{R}^{n \times d}$ has full column rank. If the entries of $S \in \mathbb{R}^{m \times n}$ are i.i.d. $N(0, 1/m)$, $m = O(d/\epsilon^2)$, then for any vectors a, b and $x^* = A^\dagger b$, we have, with probability $1 - 1/\operatorname{poly}(d)$,*

$$|a^\top (SA)^\dagger Sb - a^\top x^*| \lesssim \frac{\epsilon\sqrt{\log d}}{\sqrt{d}} \|a\|_2 \|b - Ax^*\|_2 \|A^\dagger\|_2.$$

Because SA has full column rank with probability 1, $(SA)^\dagger SA = I$. Therefore

$$|a^\top (SA)^\dagger Sb - a^\top x^*| = |a^\top (SA)^\dagger S(b - Ax^*)| = |a^\top (SA)^\dagger S(b - AA^\dagger b)|.$$

Thus it suffices to only consider vectors b where $A^\dagger b = 0$, or equivalently $U^\top b = 0$. In such cases, SU will be independent of Sb, which will give the result. The proof is in the full version.

3 SRHT Matrices

We first provide the definition of the subsampled randomized Hadamard transform(SRHT): Let $S = \frac{1}{\sqrt{rn}} PH_n D$, where D is an $n \times n$ diagonal matrix with i.i.d. diagonal entries $D_{i,i}$, for which $D_{i,i}$ in uniform on $\{-1, +1\}$. Here H_n is the Hadamard matrix of size $n \times n$, and we assume n is a power of 2. Here, $H_n = [H_{n/2},\ H_{n/2}; H_{n/2},\ -H_{n/2}]$ and $H_1 = [1]$. The $r \times n$ matrix P samples r coordinates of an n dimensional vector uniformly at random.

For other subspace embeddings, we no longer have that SU and Sb are independent. To analyze them, we start with a claim that allows us to relate the inverse of a matrix to a power series.

▶ **Claim 8.** *Let $S \in \mathbb{R}^{m\times n}$, $A \in \mathbb{R}^{n\times d}$ have SVD $A = U\Sigma V^\top$, and define $T \in \mathbb{R}^{d\times d}$ by $T = I_d - U^\top S^\top SU$. Suppose SA has linearly independent columns and $\|T\|_2 \le 1/2$. Then*

$$(SA)^\dagger S = V\Sigma^{-1}\left(\sum_{k=0}^{\infty} T^k\right)U^\top S^\top S. \tag{7}$$

Proof.

$$(SA)^\dagger S = (A^\top S^\top SA)^{-1}A^\top S^\top S = (V\Sigma U^\top S^\top SU\Sigma V^\top)^{-1}V\Sigma U^\top S^\top S$$
$$= V\Sigma^{-1}(U^\top S^\top SU)^{-1}U^\top S^\top S = V\Sigma^{-1}(I_d - T)^{-1}U^\top S^\top S = V\Sigma^{-1}(\sum_{k=0}^{\infty} T^k)U^\top S^\top S,$$

where in the last equality, since $\|T\|_2 < 1$, the von Neumann series $\sum_{k=0}^{\infty} T^k$ converges to $(I_d - T)^{-1}$. ◀

We then bound the kth term of this sum:

▶ **Lemma 9.** *Let $S \in \mathbb{R}^{r\times n}$ be the subsampled randomized Hadamard transform, and let a be a unit vector. Then with probability $1 - 1/\mathrm{poly}(n)$, we have*

$$|a^\top S^\top S(UU^\top S^\top S)^k b| = O(\log^k n)\cdot(O(d(\log n)/r) + 1)^{\frac{k-1}{2}}$$
$$\cdot(\sqrt{d}\|b\|_2(\log n)/r + \|b\|_2(\log^{\frac{1}{2}} n)/r^{\frac{1}{2}}).$$

Hence, for r at least $d\log^{2k+2} n\log^2(n/\epsilon)/\epsilon^2)$, this is at most $O(\|b\|_2\epsilon/\sqrt{d})$.

We defer the proof of this lemma to the next section, and now show how the lemma lets us prove that SRHT matrices satisfy the generalization bound with high probability:

▶ **Theorem 10.** *Suppose $A \in \mathbb{R}^{n\times d}$ has full column rank with $\log n = d^{o(1)}$. Let $S \in \mathbb{R}^{m\times n}$ be a subsampled randomized Hadamard transform with $m = O(d^{1+\alpha}/\epsilon^2)$ for $\alpha = \Theta(\sqrt{\frac{\log\log n}{\log d}})$. For any vectors a, b and $x^* = A^\dagger b$, we have*

$$|a^\top(SA)^\dagger Sb - a^\top x^*| \lesssim \frac{\epsilon}{\sqrt{d}}\|a\|_2\|b - Ax^*\|_2\|\Sigma^{-1}\|_2$$

with probability $1 - 1/\mathrm{poly}(d)$.

Proof. Define $\Delta = \Theta\left(\frac{1}{\sqrt{m}}\right)(\log^c d)\|a\|_2\|b - Ax^*\|_2\|\Sigma^{-1}\|_2$. For a constant $c > 0$, we have that S is a $(1\pm\gamma)$ ℓ_2-subspace embedding (Definition 5) for $\gamma = \sqrt{\frac{d\log^c n}{m}}$ with probability $1 - 1/\mathrm{poly}(d)$ (see, e.g., Theorem 2.4 of [26] and references therein), so $\|SUx\|_2 = (1\pm\gamma)\|Ux\|_2$ for all x, which we condition on. Hence for $T = I_d - U^\top S^\top SU$, we have $\|T\|_2 \le (1+\gamma)^2 - 1 \lesssim \gamma$. In particular, $\|T\|_2 < 1/2$ and we can apply Claim 8.

As in Section 2, SA has full column rank if S is a subspace embedding, so $(SA)^\dagger SA = I$ and we may assume $x^* = 0$ without loss of generality.

By the approximate matrix product (Definition 6), we have for some c that

$$|a^\top V\Sigma^{-1}U^\top S^\top Sb| \le \frac{\log^c d}{\sqrt{m}}\|a\|_2\|b\|_2\|\Sigma^{-1}\|_2 \le \Delta, \tag{8}$$

with $1 - 1/\text{poly}(d)$ probability. Suppose this event occurs, bounding the $k = 0$ term of (7). Hence it suffices to show that the $k \geq 1$ terms of (7) are bounded by Δ.

By approximate matrix product, we also have with $1 - 1/d^2$ probability that

$$\|U^\top S^\top Sb\|_F \leq \frac{\log^c d}{\sqrt{m}}\|U^\top\|_F\|b\|_2 \leq \frac{\log^c d\sqrt{d}}{\sqrt{m}}\|b\|_2.$$

Combining with $\|T\|_2 \lesssim \gamma$ we have for any k that

$$|a^\top V\Sigma^{-1}T^kU^\top S^\top Sb| \lesssim \gamma^k(\log^c d)\frac{\sqrt{d}}{\sqrt{m}}\|a\|_2\|\Sigma^{-1}\|_2\|b\|_2.$$

Since this decays exponentially in k at a rate of $\gamma < 1/2$, the sum of all terms greater than k is bounded by the kth term. As long as

$$m \gtrsim \frac{1}{\epsilon^2}d^{1+\frac{1}{k}}\log^c n, \tag{9}$$

we have $\gamma = \sqrt{\frac{d\log^c n}{m}} < \epsilon d^{-1/(2k)}/\log^c n$, so that

$$\sum_{k'\geq k}|a^\top V\Sigma^{-1}T^{k'}U^\top S^\top Sb| \lesssim \frac{\epsilon}{\sqrt{d}}\|a\|_2\|\Sigma^{-1}\|_2\|b\|_2.$$

On the other hand, by Lemma 9 (increasing m by a C^k factor) we have for all k that

$$|a^\top V^\top\Sigma^{-1}U^\top S^\top S(UU^\top S^\top S)^kb| \lesssim \frac{1}{2^k}\frac{\epsilon}{\sqrt{d}}\|a\|_2\|b\|_2\|\Sigma^{-1}\|_2,$$

with probability at least $1 - 1/\text{poly}(d)$, as long as $m \gtrsim d(C\log n)^{2k+2}\log^2(n/\epsilon)/\epsilon^2$, for a sufficiently large constant C. Since the T^k term can be expanded as a sum of 2^k terms of this form, we get that

$$\sum_{k'=1}^{k}|a^\top V\Sigma^{-1}T^{k'}U^\top S^\top Sb| \lesssim \frac{\epsilon}{\sqrt{d}}\|a\|_2\|b\|_2\|\Sigma^{-1}\|_2,$$

with probability at least $1 - 1/\text{poly}(d)$, as long as $m \gtrsim d(C\log n)^{2k+2}\log^2(n/\epsilon)/\epsilon^2$ for a sufficiently large constant C. Combining with (9), the result holds as long as $m \gtrsim \epsilon^{-2}d\log^c n\max((C\log n)^{2k+2}, d^{\frac{1}{k}})$, for any k. Setting $k = \Theta(\sqrt{\frac{\log d}{\log\log n}})$ gives the result. ◀

Combining Different Matrices. In some cases it can make sense to combine different sketching matrices that satisfy the generalization bound. We defer the details to the full version.

▶ **Theorem 11.** *Let $A \in \mathbb{R}^{n\times d}$, and let $R \in \mathbb{R}^{m\times r}$ and $S \in \mathbb{R}^{r\times n}$ be drawn from distributions of matrices that are ϵ-approximate OSEs and satisfy the generalization bound* (6)*. Then RS satisfies the generalization bound with a constant factor loss in failure probability and approximation factor.*

4 Proof of Lemma 9

Proof. Each column S_i of the subsampled randomized Hadamard transform has the same distribution as σ_iS_i, where σ_i is a random sign. It also has $\langle S_i, S_i\rangle = 1$ for all i and $|\langle S_i, S_j\rangle| \lesssim \frac{\sqrt{\log(1/\delta)}}{\sqrt{r}}$ with probability $1 - \delta$, for any δ and $i \neq j$. See, e.g., [17].

By expanding the following product into a sum, and rearranging terms, we obtain

$$\begin{aligned} a^\top S^\top S(UU^\top S^\top S)^k b = & \sum_{i_0,j_0,i_1,j_1,\cdots,i_k,j_k} a_{i_0} b_{j_k} \sigma_{i_0}\sigma_{i_1}\cdots\sigma_{i_k}\sigma_{j_0}\sigma_{j_1}\cdots\sigma_{j_k} \\ & \cdot \langle S_{i_0}, S_{j_0}\rangle (UU^\top)_{j_0,i_1}\langle S_{i_1}, S_{j_1}\rangle \cdots (UU^\top)_{j_{k-1},i_k}\langle S_{i_k}, S_{j_k}\rangle \\ = & \sum_{i_0,j_k} a_{i_0} b_{j_k}\sigma_{i_0}\sigma_{j_k} \sum_{j_0,i_1,j_1,\cdots,i_k} \sigma_{i_1}\cdots\sigma_{i_k}\sigma_{j_0}\sigma_{j_1}\cdots\sigma_{j_{k-1}} \\ & \cdot \langle S_{i_0}, S_{j_0}\rangle (UU^\top)_{j_0,i_1}\langle S_{i_1}, S_{j_1}\rangle \cdots (UU^\top)_{j_{k-1},i_k}\langle S_{i_k}, S_{j_k}\rangle \\ = & \sum_{i_0,j_k} \sigma_{i_0}\sigma_{j_k} Z_{i_0,j_k} \end{aligned}$$

where Z_{i_0,j_k} is defined to be

$$Z_{i_0,j_k} \quad = \quad a_{i_0} b_{j_k} \sum_{\substack{i_1,\cdots i_k \\ j_0,\cdots j_{k-1}}} \prod_{c=1}^{k} \sigma_{i_c} \prod_{c=0}^{k-1} \sigma_{j_c} \cdot \prod_{c=0}^{k} \langle S_{i_c}, S_{j_c}\rangle \prod_{c=1}^{k} (UU^\top)_{i_{c-1},j_c}.$$

Note that Z_{i_0,j_k} is independent of σ_{i_0} and σ_{j_k}. We observe that in the above expression if $i_0 = j_0, i_1 = j_1, \cdots, i_k = j_k$, then the sum over these indices equals $a^\top(UU^\top)\cdots(UU^\top)b = 0$, since $\langle S_{i_c}, S_{j_c}\rangle = 1$ in this case for all c. Moreover, the sum over all indices conditioned on $i_k = j_k$ is equal to 0. Indeed, in this case, the expression can be factored into the form $\zeta \cdot U^\top b$, for some random variable ζ, but $U^\top b = 0$.

Let W be a matrix with $W_{i,j} = \sigma_i\sigma_j Z_{i,j}$. We need Khintchine's inequality:

▶ **Fact 12** (Khintchine's Inequality). *Let $\sigma_1, \ldots, \sigma_n$ be i.i.d. sign random variables, and let $z_1, \ldots, z_n$ be real numbers. Then there are constants $C, C' > 0$ so that* $\Pr[|\sum_{i=1}^n z_i\sigma_i| \geq Ct\|z\|_2] \leq e^{-C't^2}$.

We note that Khintchine's inequality sometimes refers to bounds on the moment of $|\sum_i z_i\sigma_i|$, though the above inequality follows readily by applying a Markov bound to the high moments.

We apply Fact 12 to each column of W, so that if W_i is the i-th column, we have by a union bound that with probability $1 - 1/\mathrm{poly}(n)$, $\|W_i\|_2 = O(\|Z_i\|_2\sqrt{\log n})$ simultaneously for all columns i. It follows that with the same probability, $\|W\|_F^2 = O(\|Z\|_F^2 \log n)$, that is, $\|W\|_F = O(\|Z\|_F\sqrt{\log n})$. We condition on this event in the remainder.

Thus, it remains to bound $\|Z\|_F$. By squaring Z_{i_0,j_0} and using that $\mathbf{E}[\sigma_i\sigma_j] = 1$ if $i = j$ and 0 otherwise, we have,

$$\mathop{\mathbf{E}}_{\sigma}[Z_{i_0,j_k}^2] = a_{i_0}^2 b_{j_k}^2 \sum_{\substack{i_1,\cdots i_k \\ j_0,\cdots j_{k-1}}} \prod_{c=0}^{k} \langle S_{i_c}, S_{j_c}\rangle^2 \prod_{c=1}^{k} (UU^\top)_{i_{c-1},j_c}^2. \tag{10}$$

Due to space considerations, we defer to the full version Appendix E the proof that

$$\mathop{\mathbf{E}}_{S}[\|Z\|_F^2] \leq (O(d(\log n)/r) + 1)^{k-1} \cdot (d\|b\|_2^2(\log^2 n)/r^2 + \|b\|_2^2(\log n)/r).$$

Note that we also have the bound:

$$(O(d(\log n)/r) + 1)^{k-1} \leq (e^{O(d(\log n)/r)})^{k-1} \leq e^{O(kd(\log n)/r)} \leq O(1),$$

for any $r = \Omega(kd\log n)$.

Having computed the expectation of $\|Z\|_F^2$, we now would like to show concentration. Consider a specific

$$Z_{i_0,j_k} = a_{i_0} b_{j_k} \sum_{i_k} \sigma_{i_k} \langle S_{i_k}, S_{j_k} \rangle \cdots \sum_{j_1} \sigma_{j_1} (UU^\top)_{j_1,i_2} \sum_{i_1} \sigma_{i_1} \langle S_{i_1}, S_{j_1} \rangle \sum_{j_0} \sigma_{j_0} \langle S_{i_0}, S_{j_0} \rangle (UU^\top)_{j_0,i_1}.$$

By Fact 12, for each fixing of i_1, with probability $1 - 1/\mathrm{poly}(n)$, we have

$$\sum_{j_0} \sigma_{j_0} \langle S_{i_0}, S_{j_0} \rangle (UU^\top)_{j_0,i_1} = O(\sqrt{\log n})(\sum_{j_0} \langle S_{i_0}, S_{j_0} \rangle^2 (UU^\top)_{j_0,i_1}^2)^{\frac{1}{2}}. \tag{11}$$

Now, we can apply Khintchine's inequality for each fixing of j_1, and combine this with (11). With probability $1 - 1/\mathrm{poly}(n)$, again we have

$$\begin{aligned} &\sum_{i_1} \sigma_{i_1} \langle S_{i_1}, S_{j_1} \rangle \sum_{j_0} \sigma_{j_0} \langle S_{i_0}, S_{j_0} \rangle (UU^\top)_{j_0,i_1} \\ = &\sum_{i_1} \sigma_{i_1} \langle S_{i_1}, S_{j_1} \rangle O(\sqrt{\log n})(\sum_{j_0} \langle S_{i_0}, S_{j_0} \rangle^2 (UU^\top)_{j_0,i_1}^2)^{\frac{1}{2}} \\ = &O(\log n)(\sum_{i_1} \langle S_{i_1}, S_{j_1} \rangle^2 \sum_{j_0} \langle S_{i_0}, S_{j_0} \rangle^2 (UU^\top)_{j_0,i_1}^2)^{\frac{1}{2}}. \end{aligned}$$

Thus, we can apply Khintchine's inequality recursively over all the $2k$ indexes $j_0, i_1, j_1, \cdots, j_{k-1}$, i_k, from which it follows that with probability $1 - 1/\mathrm{poly}(n)$, for each such i_0, j_k, we have $Z_{i_0,j_k}^2 = O(\log^k n) \mathop{\mathbf{E}}_S [Z_{i_0,j_k}^2]$, using (10). We thus have with this probability, that $\|Z\|_F^2 = O(\log^k n) \mathop{\mathbf{E}}_S [\|Z\|_F^2]$, completing the proof. ◀

5 Lower bound for ℓ_2 and ℓ_∞ guarantee

We prove a lower bound for the ℓ_2 guarantee, which immediately implies a lower bound for the ℓ_∞ guarantee.

▶ **Definition 13.** Given a matrix $A \in \mathbb{R}^{n \times d}$, vector $b \in \mathbb{R}^n$ and matrix $S \in \mathbb{R}^{r \times n}$, denote $x^* = A^\dagger b$. We say that an algorithm $\mathcal{A}(A, b, S)$ that outputs a vector $x' = (SA)^\dagger Sb$ "succeeds" if the following property holds: $\|x' - x^*\|_2 \lesssim \epsilon \|b\|_2 \cdot \|A^\dagger\|_2 \cdot \|Ax^* - b\|_2$.

▶ **Theorem 14.** *Suppose Π is a distribution over $\mathbb{R}^{m \times n}$ with the property that for any $A \in \mathbb{R}^{n \times d}$ and $b \in \mathbb{R}^n$, $\Pr_{S \sim \Pi}[\mathcal{A}(A, b, S)$ succeeds $] \geq 19/20$. Then $m \gtrsim \min(n, d/\epsilon^2)$.*

Proof. The proof uses Yao's minimax principle. Let $\mathcal{D}$ be an arbitrary distribution over $\mathbb{R}^{n \times (d+1)}$, then $\mathop{\mathbb{E}}_{(A,b) \sim \mathcal{D}} \mathop{\mathbb{E}}_{S \sim \Pi} [\mathcal{A}(A, b, S)$ succeeds $] \geq 1 - \delta$. Switching the order of probabilistic quantifiers, an averaging argument implies the existence of a fixed matrix $S_0 \in \mathbb{R}^{m \times n}$ such that $\mathop{\mathbb{E}}_{(A,b) \sim \mathcal{D}} [\mathcal{A}(A, b, S_0)$ succeeds $] \geq 1 - \delta$. Thus, we must construct a distribution $\mathcal{D}_{\mathrm{hard}}$ such that $\mathop{\mathbb{E}}_{(A,b) \sim \mathcal{D}_{\mathrm{hard}}} [\mathcal{A}(A, b, S_0)$ succeeds $] \geq 1 - \delta$ cannot hold for any $\Pi_0 \in \mathbb{R}^{m \times n}$ which does not satisfy $m = \Omega(d/\epsilon^2)$. The proof can be split into three parts. First, we prove a useful property. Second, we prove a lower bound for the case $\mathrm{rank}(S) \geq d$. Third, we show why $\mathrm{rank}(S) \geq d$ is necessary.

(I) We show that $[SA, Sb]$ are independent Gaussian, if both $[A, b]$ and S are orthonormal matrices. We can rewrite SA in the following sense,

$$\underbrace{S}_{m\times n}\cdot\underbrace{A}_{n\times d} = \underbrace{S}_{m\times n}\underbrace{R}_{n\times n}\underbrace{R^\top}_{n\times n}\underbrace{A}_{n\times d} \tag{12}$$
$$= S\begin{bmatrix}S^\top & \overline{S}^\top\end{bmatrix}\begin{bmatrix}S\\ \overline{S}\end{bmatrix}A = \begin{bmatrix}I_m & 0\end{bmatrix}\begin{bmatrix}S\\ \overline{S}\end{bmatrix}A = \begin{bmatrix}I_m & 0\end{bmatrix}\underbrace{\widetilde{A}}_{n\times d} = \underbrace{\widetilde{A}_m}_{m\times d}$$

where $\overline{S}$ is the complement of the orthonormal basis S, I_m is a $m \times m$ identity matrix, and $\widetilde{A}_m$ is the left $m \times d$ submatrix of $\widetilde{A}$. Thus, using [13] as long as $m = o(\sqrt{n})$ (because of $n = \Omega(d^3)$) the total variation distance between $[SA, Sb]$ and a random Gaussian matrix is small, i.e.,

$$D_{TV}([SA, Sb], H) \leq 0.01 \tag{13}$$

where each entry of H is i.i.d. Gaussian $\mathcal{N}(0, 1/n)$.

(II) Here we prove the theorem in the case when S has rank $r \geq d$ (we will prove this is necessary in part III. Writing $S = U\Sigma V^\top$ in its SVD, we have

$$\underbrace{S}_{m\times n}A = \underbrace{U}_{m\times r}\underbrace{\Sigma}_{r\times r}\underbrace{V^\top}_{r\times n}RR^\top A = U\Sigma G \tag{14}$$

where $R = \begin{bmatrix}V & \overline{V}\end{bmatrix}$. By a similar argument in Equation (12), as long as $r = o(\sqrt{n})$ we have that G also can be approximated by a Gaussian matrix, where each entry is sampled from i.i.d. $\mathcal{N}(0, 1/n)$. Similarly, $Sb = U\Sigma h$, where h also can be approximated by a Gaussian matrix, where each entry is sampled from i.i.d. $\mathcal{N}(0, 1/n)$.

Since U has linearly independent columns, $(U\Sigma G)^\dagger U\Sigma h = (\Sigma G)^\dagger U^\top U\Sigma h = (\Sigma G)^\dagger \Sigma h$.

The $r \times d$ matrix G has SVD $G = \underbrace{R}_{r\times d}\underbrace{\widetilde{\Sigma}}_{d\times d}\underbrace{T}_{d\times d}$, and applying the pseudo-inverse property again, we have

$$\|(SA)^\dagger Sb\|_2 = \|(\Sigma G)^\dagger \Sigma h\|_2 = \|(\Sigma R\widetilde{\Sigma}T)^\dagger \Sigma h\|_2 = \|T^\dagger(\Sigma R\widetilde{\Sigma})^\dagger \Sigma h\|_2 = \|(\Sigma R\widetilde{\Sigma})^\dagger \Sigma h\|_2$$
$$= \|\widetilde{\Sigma}^\dagger(\Sigma R)^\dagger \Sigma h\|_2,$$

where the the first equality follows by Equation (14), the second equality follows by the SVD of G, the third and fifth equality follow by properties of the pseudo-inverse when T has orthonormal rows and $\widetilde{\Sigma}$ is a diagonal matrix, and the fourth equality follows since $\|T^\dagger\|_2 = 1$ and T is an orthonormal basis.

Because each entry of $G = R\widetilde{\Sigma}T \in \mathbb{R}^{r\times d}$ is sampled from an i.i.d. Gaussian $\mathcal{N}(0, 1)$, using the result of [24] we can give an upper bound for the maximum singular value of G: $\|\widetilde{\Sigma}\| \lesssim \sqrt{\frac{r}{n}}$ with probability at least .99. Thus,

$$\|\widetilde{\Sigma}^\dagger(\Sigma R)^\dagger \Sigma h\|_2 \geq \sigma_{\min}(\widetilde{\Sigma}^\dagger)\cdot\|(\Sigma R)^\dagger \Sigma h\|_2 = \sigma_{\max}^{-1}(\widetilde{\Sigma})\|(\Sigma R)^\dagger \Sigma h\|_2 \gtrsim \sqrt{n/r}\|(\Sigma R)^\dagger \Sigma h\|_2.$$

Because h is a random Gaussian vector which is independent of $(\Sigma R)^\dagger\Sigma$, $\mathbf{E}_h[\|(\Sigma R)^\dagger \Sigma h\|_2^2] = \frac{1}{n}\cdot\|(\Sigma R)^\dagger\Sigma\|_F^2$, where each entry of h is sampled from i.i.d. Gaussian $\mathcal{N}(0, 1/n)$. Then, using the Pythagorean Theorem, $\|(\Sigma R)^\dagger\Sigma\|_F^2 = \|(\Sigma R)^\dagger\Sigma RR^\top\|_F^2 + \|(\Sigma R)^\dagger\Sigma(I - RR^\top)\|_F^2 \geq \|(\Sigma R)^\dagger\Sigma RR^\top\|_F^2 = \|(\Sigma R)^\dagger\Sigma R\|_F^2 = \text{rank}(\Sigma R) = \text{rank}(SA) = d$. Thus, $\|x' - x^*\|_2 \gtrsim \sqrt{d/r} \geq \sqrt{d/m} = \epsilon$.

(III) Now we show that we can assume that $\text{rank}(S) \geq d$.

We sample A, b based on the following distribution $\mathcal{D}_{\text{hard}}$: with probability $1/2$, A, b are sampled from $\mathcal{D}_1$; with probability $1/2$, A, b are sampled from $\mathcal{D}_2$. In distribution $\mathcal{D}_1$, A is a random orthonormal basis and d is always orthogonal to A. In distribution $\mathcal{D}_2$, A is a $d \times d$ identity matrix in the top-d rows and 0s elsewhere, while b is a random unit vector. Then, for any (A, b) sampled from $\mathcal{D}_1$, S needs to work with probability at least $9/10$. Also for any (A, b) sampled from $\mathcal{D}_2$, S needs to work with probability at least $9/10$. The latter two statements follow since overall S succeeds on $\mathcal{D}_{\text{hard}}$ with probability at least $19/20$.

Consider the case where A, b are sampled from distribution $\mathcal{D}_2$. Then $x^* = b$ and $\text{OPT} = 0$. Then consider x' which is the optimal solution to $\min_x \|SAx - Sb\|_2^2$, so $x' = (SA)^\dagger Sb = (S_L)^\dagger S_L b$, where S can be decomposed into two matrices $S_L \in \mathbb{R}^{r \times d}$ and $S_R \in \mathbb{R}^{r \times (n-d)}$, $S = \begin{bmatrix} S_L & S_R \end{bmatrix}$. Plugging x' into the original regression problem, $\|Ax' - b\|_2^2 = \|A(S_L)^\dagger S_L b - b\|_2^2$, which is at most $(1+\epsilon)\,\text{OPT} = 0$. Thus $\text{rank}(S_L)$ is d. Since S_L is a submatrix of S, the rank of S is also d. ◀

Abstract

Given an $n \times d$ matrix A, its Schatten-p norm, $p \geq 1$, is defined as $\|A\|_p = \left(\sum_{i=1}^{\mathrm{rank}(A)} \sigma_i(A)^p\right)^{1/p}$, where $\sigma_i(A)$ is the i-th largest singular value of A. These norms have been studied in functional analysis in the context of non-commutative ℓ_p-spaces, and recently in data stream and linear sketching models of computation. Basic questions on the relations between these norms, such as their embeddability, are still open. Specifically, given a set of matrices $A^1, \ldots, A^{\mathrm{poly}(nd)} \in \mathbb{R}^{n \times d}$, suppose we want to construct a linear map L such that $L(A^i) \in \mathbb{R}^{n' \times d'}$ for each i, where $n' \leq n$ and $d' \leq d$, and further, $\|A^i\|_p \leq \|L(A^i)\|_q \leq D_{p,q}\|A^i\|_p$ for a given approximation factor $D_{p,q}$ and real number $q \geq 1$. Then how large do n' and d' need to be as a function of $D_{p,q}$?

We nearly resolve this question for every $p, q \geq 1$, for the case where $L(A^i)$ can be expressed as $R \cdot A^i \cdot S$, where R and S are arbitrary matrices that are allowed to depend on $A^1, \ldots, A^t$, that is, $L(A^i)$ can be implemented by left and right matrix multiplication. Namely, for every $p, q \geq 1$, we provide nearly matching upper and lower bounds on the size of n' and d' as a function of $D_{p,q}$. Importantly, our upper bounds are *oblivious*, meaning that R and S do not depend on the A^i, while our lower bounds hold even if R and S depend on the A^i. As an application of our upper bounds, we answer a recent open question of Blasiok et al. about space-approximation trade-offs for the Schatten 1-norm, showing in a data stream it is possible to estimate the Schatten-1 norm up to a factor of $D \geq 1$ using $\tilde{O}(\min(n, d)^2/D^4)$ space.

1 Introduction

Given an $n \times d$ matrix A, its Schatten-p norm, $p \geq 1$, is defined as $\|A\|_p = \left(\sum_{i=1}^{r(A)} \sigma_i(A)^p\right)^{\frac{1}{p}}$, where $r(A)$ is the rank of A and $\sigma_i(A)$ is the i-th largest singular value of A, i.e., the square root of the i-th largest eigenvalue of $A^T A$. The Schatten-1 norm is the nuclear norm or trace norm, the Schatten-2 norm is the Frobenius norm, and the Schatten ∞-norm, defined as the limit of the Schatten-p norm when $p \to \infty$, is the operator norm. The Schatten 1-norm has applications in non-convex optimization [5], while Schatten-2 and Schatten-∞ norms are useful in geometry and linear algebra, see, e.g., [22]. Schatten-p norms for large p also provide approximations to the Schatten-∞ norm.

The Schatten norms appear to be significantly harder to compute or approximate than the vector ℓ_p-norms in various models of computation, and understanding the complexity of estimating them has led to new algorithmic ideas and lower bound techniques. The main difficulty is that we do not directly have access to the spectrum of A, and naïvely it is costly in space and time to extract useful information about it. A line of work has focused on understanding the complexity of estimating such norms in the data stream model with 1-pass over the stream [13] as well as with multiple passes [4], the sketching model [2, 12, 14], statistical models [9], as well as the general RAM model [17, 19]. Dimensionality reduction in these norms also has applications in quantum computing [8, 21]. It has also been asked in places if the Schatten-1 norm admits non-trivial nearest neighbor search data structures [1].

Our Results. In this paper we study the embeddability of the Schatten-p norm into the Schatten-q norm for linear maps implementable by matrix multiplication. More concretely, we first ask for the following form of embeddability: given n and t (where $t = \Omega(\log n)$), what is the smallest value of $D_{p,q}$, which we call the *distortion*, such that there exists a distribution $\mathcal{R}$ on $\mathbb{R}^{t\times n}$ satisfying, for any given $n \times d$ matrix A,

$$\Pr_{R\sim\mathcal{R}}\left\{\|A\|_p \le \|RA\|_q \le D_{p,q}\|A\|_p\right\} \ge 1 - \exp(-ct)?$$

Here $c > 0$ is an absolute constant. We can assume, w.l.o.g., that $n = d$ because we can first apply a so-called *subspace embedding* matrix (see, e.g., [22] for a survey) to the left or to the right of A to preserve each of its singular values up to a constant factor. We shall show that $D_{p,q} \gtrsim \hat{D}_{p,q}$, where

$$\hat{D}_{p,q} = \begin{cases} n^{\frac{1}{p}-\frac{1}{2}}/t^{\frac{1}{q}-\frac{1}{2}}, & 1 \le p \le q \le 2; \\ n^{\frac{1}{p}-\frac{1}{2}}, & 1 \le p \le 2 \le q; \\ \max\{(n/t)^{\frac{1}{2}-\frac{1}{p}}, t^{\frac{1}{p}-\frac{1}{q}}\}, & 2 \le p \le q; \\ n^{\frac{1}{2}-\frac{1}{p}}, & 1 \le q \le 2 \le p; \\ n^{\frac{1}{2}-\frac{1}{p}}/t^{\frac{1}{2}-\frac{1}{q}}, & 2 \le q \le p; \\ \max\{(n/t)^{\frac{1}{p}-\frac{1}{2}}, (t/\ln t)^{\frac{1}{q}-\frac{1}{p}}\}, & 1 \le q \le p \le 2, \end{cases} \tag{1}$$

and the notation $f \gtrsim g$ means $f \ge g/C$ for some constant $C > 0$. The constant C in the $\gtrsim$ notation above depends on p and q only. This distortion is asymptotically tight, up to logarithmic factors, as we also construct a distribution $\mathcal{R}$ on t-by-n matrices for which for any $n \times d$ matrix A,

$$\Pr_{R\sim\mathcal{R}}\left\{\|A\|_p \le \|RA\|_q \le \tilde{D}_{p,q}\left(\log\frac{n}{t}\right)\|A\|_p\right\} \ge 1 - \exp\left(-ct\right),$$

where $\tilde{D}_{p,q}$ differs from $D_{p,q}$ by a constant or a factor of $\log t$. Specifically,

$$\tilde{D}_{p,q} \lesssim \begin{cases} \max\{(n/t)^{\frac{1}{p}-\frac{1}{2}}, t^{\frac{1}{q}-\frac{1}{p}}\}, & 1 \le q \le p \le 2; \\ \hat{D}_{p,q}, & \text{otherwise}, \end{cases} \tag{2}$$

where $\hat{D}_{p,q}$ is given in (1). Replacing t with $t/(\ln(n/t))$, we arrive at a matching failure probability and distortion, while using a logarithmic factor more number of rows in R. Namely, we construct a distribution $\mathcal{R}$ on matrices with $t\ln(n/t)$ rows for which

$$\Pr_{R\sim\mathcal{R}}\left\{\|A\|_p \le \|RA\|_q \le \tilde{D}_{p,q}\|A\|_p\right\} \ge 1 - \exp\left(-ct\right).$$

We can also sketch RA on the right by a subspace embedding matrix S with $\Theta(t)$ rows, which yields

$$\Pr_{R,S}\left\{\|A\|_p \leq \left\|RAS^T\right\|_q \leq \tilde{D}_{p,q}\|A\|_p\right\} \geq 1 - \exp\left(-ct\right).$$

We show that this two-sided sketch is asympotically optimal for two-sided sketches in its product of number of rows of R and number of columns of S, up to logarithmic factors. Formally, we next ask: what is the smallest value of $D_{p,q}$ for which there exists a distribution $\mathcal{G}_1$ on $\mathbb{R}^{r\times n}$ and a distribution $\mathcal{G}_2$ on $\mathbb{R}^{n\times s}$ satisfying

$$\Pr_{R\sim\mathcal{G}_1, S\sim\mathcal{G}_2}\left\{\|A\|_p \leq \|RAS\|_q \leq D_{p,q}\|A\|_p\right\} \geq 1 - \exp(-c\min\{r,s\})?$$

Again we can assume, w.l.o.g, that $r = s$, because otherwise we can compose R or S with a subspace embedding to preserve all singular values up to a constant factor[1]. Henceforth for the two-sided problem, we assume that $\mathcal{G}_1$ and $\mathcal{G}_2$ are distributions on $\mathbb{R}^{t\times n}$. We also prove a matching lower bound that $D_{p,q} \gtrsim \hat{D}_{p,q}$ except in the case when $1 \leq q \leq p \leq 2$, where we instead obtain a matching lower bound up to logarithmic factors, namely, $D_{p,q} \gtrsim \max\{(n/t)^{\frac{1}{p}-\frac{1}{2}}/\log^{\frac{3}{2}} t, (t/\ln t)^{\frac{1}{q}-\frac{1}{p}}\}$.

In the important case when $p = q = 1$, our results show a space-approximation tradeoff for estimating the Schatten 1-norm (or trace norm) in a data stream, answering a question posed by Blasiok et al. [3]. This application crucially uses that R and S are oblivious to A, i.e., they can be sampled and succinctly stored without looking at A. Specifically, when each entry of A fits in a word of $O(\log n)$ bits, we can choose R and S to be Gaussian random matrices with entries truncated to $O(\log n)$ bits and with entries drawn from a family of random variables with bounded independence. For time-efficiency purposes, R and S can also be chosen to be Fast Johnson Lindenstrauss Transforms or sparse embedding matrices [6, 16, 18], though they will have larger dimension, especially to satisfy the exponential probability of failure in the problem statement (and even with constant failure probability, the dimension will be slightly larger; see [22] for a survey).

Choosing R and S to be Gaussian matrices, our result provides a data stream algorithm using $(n^2/D^4)\,\mathrm{polylog}(n)$ bits of memory, and achieving approximation factor D (taking $t = n/D^2$). While $\|A\|_2$, the Frobenius norm of A, provides a $\sqrt{n}$-approximation to $\|A\|_1$ and can be approximated up to a constant factor in a data stream using $O(1)$ words of space, if we want an algorithm achieving a better approximation factor then all that was known was an algorithm requiring $O(n^2)$ words of space, namely, the trivial algorithm of storing A exactly and achieving $D = 1$. It was asked in [3] if there is a smooth trade-off between the case when $D = 1$ and $D = \sqrt{n}$; our $(n^2/D^4)\,\mathrm{polylog}(n)$ space algorithm provides the first such trade-off, and is optimal at the two extremes. Our results are the first of their kind for large approximation factors $D \gg 1$ for estimating the Schatten-p norms in a data stream.

Finally, while in our upper bounds R and S are chosen obliviously to A, for our lower bounds we would like to rule out those R and S which are even allowed to depend on A. Clearly, if there is only a single matrix A, this question is ill-posed as one can just choose R and S to have a single row and column so that $\|RAS\|_q = \|A\|_p$. Instead, we ask the question analogous to the Johnson-Lindenstrauss transform (see e.g., [10]): given

[1] That is, if $r \leq s$, we can choose a subspace embedding matrix H of dimension $n \times \Theta(r)$ such that $\|RASH\|_q = \Theta(\|RAS\|_q)$ with probability $\geq 1 - \exp(-s)$, and then pad R with zero rows so that R has the same number of rows as columns of S, increasing the number of rows of R by at most a constant factor.

$A^1, \ldots, A^{\mathrm{poly}(n)}$, can we construct an R with t rows and an S with t columns for which $\|A^i\|_p \leq \|RA^iS\|_q \leq D_{p,q}\|A^i\|_p$ for all i? We show that our lower bound on the trade-off between $D_{p,q}$ and t given by (1) continues to hold even in this setting.

Our Techniques. We shall focus on the case $p = q$ in this description of our technical overview. For our upper bounds, a natural idea is to take R to be a (normalized) Gaussian random matrix, and the analysis of the quantity $\|RA\|_p$, when $p \geq 2$, follows fairly directly from the so-called non-commutative Khintchine inequality as follows.

▶ **Lemma 1** (Non-commutative Khintchine Inequality [15]). *Suppose that $C_1, \ldots, C_n$ are (deterministic) matrices of the same dimension and $g_1, \ldots, g_n$ are independent $N(0,1)$ variables. It holds that*

$$\mathop{\mathbb{E}}_{g_1,\ldots,g_n} \left\| \sum_i g_i C_i \right\|_p \simeq \max\left\{ \left\| \left(\sum_i C_i C_i^T \right)^{\frac{1}{2}} \right\|_p, \left\| \left(\sum_i C_i^T C_i \right)^{\frac{1}{2}} \right\|_p \right\}, \quad p \geq 2.$$

In order to estimate $\|RA\|_p$, we can write

$$RA = \sum_{i,j} r_{ij}(e_i e_j^T A) =: \sum_{i,j} r_{ij} C_{ij}$$

and it is straightforward to compute that

$$\sum_{i,j} C_{ij} C_{ij}^T = \mathrm{tr}(AA^T) I_t = \|A\|_F^2 I_t, \quad \sum_{i,j} C_{ij}^T C_{ij} = t \cdot A^T A.$$

It follows from the non-commutative Khintchine inequality that (recall that R is a normalized Gaussian matrix with $N(0, 1/t)$ entries)

$$\mathbb{E}\,\|RA\|_p \simeq \max\left\{ t^{\frac{1}{2}-\frac{1}{p}} \|A\|_F, \|A\|_p \right\}, \quad p \geq 2.$$

Using a concentration inequality for Lipschitz functions on Gaussian space, one can show that $\|RA\|_p$ is concentrated around $\mathbb{E}\,\|RA\|_p$, and using standard the standard relationship between $\|A\|_F$ and $\|A\|_p$ then completes the argument.

When $p < 2$, the non-commutative Khintchine inequality gives a much less tractable characterization, so we need to analyze $\|RA\|_p$ in a different manner, which is potentially of independent interest. Our analysis also works for non-Gaussian matrices R whenever R satisfies certain properties, which, for instance, are satisfied by a Fast Johnson-Lindenstrauss Transform.

Upper bound. We give an overview of our upper bound now, focusing on the one-sided case, since the two-sided case follows by simply right-multiplying by a generic subspace embedding S. Here we focus on the case in which R is an $r \times n$ Gaussian matrix, where $r = t \cdot \mathrm{polylog}(n)$. By rotational invariance of Gaussian matrices, and for the purposes of computing $\|AR\|_p$, we can assume that A is diagonal. Let A_1 be the restriction of A to its top $\Theta(t \log n)$ singular values. Since R is a Gaussian matrix with at least $t \log n$ rows, it is well-known that R is also a subspace embedding on A_1 (see, e.g., [20, Corollary 5.35]), namely, $\sigma_i(RA_1) \simeq \sigma_i(A_1)$ for all i, and thus $\|RA_1\|_p \simeq \|A_1\|_p = \Omega(\|A\|_p)$ when $\|A_1\|_p = \Omega(\|A\|_p)$.

If it does not hold that $\|A_1\|_p = \Omega(\|A\|_p)$, then the singular values of A are "heavy-tailed", and we show how to find a $\sigma_i(A)$ with $i < \Theta(t \log n)$ for which $\sigma_i^2(A)$ is relatively small compared to $\sigma_i^2(A) + \sigma_{i+1}^2(A) + \cdots + \sigma_n^2(A)$. More specifically, let A_2 be the restriction

of A to $\sigma_i(A), \ldots, \sigma_n(A)$. Then we have that $\|A_2\|_{op} \lesssim \|A_2\|_F/\sqrt{t}$. Since for a Gaussian matrix R it holds that $\|RA_2\|_{op} \lesssim \|A_2\|_{op} + \|A\|_F/\sqrt{r}$ (see Proposition 3), we thus have that $\|RA_2\|_{op} \lesssim \|A_2\|_F/\sqrt{t}$. On the other hand, $\|RA_2\|_F \simeq \|A_2\|_F$. This implies there exist $\Omega(t)$ singular values of RA_2 that are $\Omega(\|A_2\|_F/\sqrt{t})$, which yields that $\|RA_2\|_p \gtrsim \|A_2\|_p = \Omega(\|A\|_p)$. Therefore we have established the lower bound that $\|RA\|_p \geq \max\{\|RA_1\|_p, \|RA_2\|_p\}$ in terms of $\|A\|_p$.

To upper bound $\|RA\|_p$ in terms of $\|A\|_p$, note that $\|RA\|_p \leq \|RA_1\|_p + \|RA_2\|_p$ by the triangle inequality, where A_1, A_2 are as above. Again it follows from the subspace embedding property of R that $\|RA_1\|_p \lesssim \|A_1\|_p \leq \|A\|_p$. Regarding $\|RA_2\|_p$, we relate its Schatten-p norm to its Frobenius norm and use the fact that $\|RA_2\|_F \simeq \|A_2\|_F$. This gives an upper bound of $\|RA_2\|_p$ in terms of $\|A_2\|_p$, and using that $\|A_2\|_p \leq \|A\|_p$, it gives an upper bound in terms of $\|A\|_p$. This is sufficient to obtain an overall upper bound on $\|RA\|_p$.

Lower bound. Now we give an overview of our lower bounds for some specific cases. First consider one-sided sketches. We choose our hard distribution as follows: we choose an $n \times (10t)$ Gaussian matrix G padded with 0s to become an $n \times n$ matrix. For a sketch matrix R containing t rows, by rotational invariance of Gaussian matrices, $\|RG\|_p$ is identically distributed to $\|\Sigma_R G'\|_p$, where Σ_R is the $t \times t$ diagonal matrix consisting of the singular values of R, and where G' is a $t \times (10t)$ Gaussian matrix. It is a classical result that all singular values of G' are $\Theta(\sqrt{t})$ and thus $\|RG\|_p \simeq \sqrt{t}\|R\|_p$. This implies that

$$\sqrt{n}t^{\frac{1}{2}-\frac{1}{p}} \lesssim \sqrt{t}\|R\|_p \lesssim D_{p,p}\sqrt{n}t^{\frac{1}{2}-\frac{1}{p}}, \tag{3}$$

since all non-zero singular values of G are $\Theta(\sqrt{n})$. On the other hand, applying R to the $n \times n$ identity matrix gives that

$$n^{\frac{1}{p}} \leq \|R\|_p \leq D_{p,p}n^{\frac{1}{p}}. \tag{4}$$

Combining (3) and (4) gives that $D_{p,p} \geq \max\{(n/t)^{1/2-1/p}, (n/t)^{1/p-1/2}\}$.

For the two-sided sketch, we change the hard distribution to (i) $n \times n$ Gaussian random matrix F and (ii) the distribution of GH^T, where G and H are $n \times \Theta(t)$ Gaussian random matrices. The proof then relies on the analysis for $\left\|RFS^T\right\|_p$ and $\left\|RGH^TS^T\right\|_p$. When $p \geq 2$, non-commutative Khintchine inequality gives immediately that

$$\left\|RGH^TS^T\right\|_p \simeq \sqrt{t}\left\|RFS^T\right\|_p \simeq \sqrt{t}\max\{\|R\|_p\|S\|_{op}, \|R\|_{op}\|S\|_p\}, \quad p \geq 2. \tag{5}$$

When $p < 2$, a different approach is followed. We divide the singular values of R and S into bands, where each band contains singular values within a factor of 2 from each other. We shall consider the first $\Theta(\log t)$ bands only because the remaining singular values are $1/\operatorname{poly}(t)$ and negligible. Now, if all singular values of R' and S' are within a factor of 2 from each other, then $\left\|R'F(S')^T\right\|_p \simeq \|R'\|_{op}\|S'\|_{op}\|F\|_p$ and $\left\|R'GH^T(S')^T\right\|_p \simeq \|R'\|_{op}\|S'\|_{op}\left\|GH^T\right\|_p$. It is not difficult to see that

$$\|GH^T\|_p \simeq \sqrt{t}\|F\|_p \tag{6}$$

Since R' and S' consist of one of the $\Theta(\log t)$ bands of R and S, respectively, it follows that

$$\left\|RGH^TS^T\right\|_p \simeq \sqrt{t}/\operatorname{polylog}(t) \cdot \left\|RFS^T\right\|_p, \quad p < 2. \tag{7}$$

A lower bound of $D_{p,p}$ then follows from combining (6), (5) (or (7)) with

$$\|F\|_p \leq \left\|RFS^T\right\|_p \leq D_{p,p}\|F\|_p, \quad \text{and} \quad \left\|GH^T\right\|_p \leq \left\|RGH^TS^T\right\|_p \leq D_{p,p}\left\|GH^T\right\|_p.$$

To strengthen the lower bound for the sketches that even depend on the input matrix, we follow the approach in [10]. We first work with random hard instances, and then sample input matrices $A^1, \ldots, A^{\mathrm{poly}(n)}$ from the hard distribution, and apply a net argument on sketching matrices R and S to obtain a deterministic statement, which states that for any fixed R and S such that the distortion guarantee is satisfied with all samples $A^1, \ldots, A^{\mathrm{poly}(n)}$, the distortion lower bound remains to hold.

2 Preliminaries

Notation. Throughout the paper, we use $f \lesssim g$ to denote $f \leq Cg$ for some constant C, $f \gtrsim g$ to denote $f \geq Cg$ for some constant C, and $f \simeq g$ to denote $C_1 g \leq f \leq C_2 g$ for some constants C_1 and C_2.

Bands of Singular Values. Given a matrix A, we split the singular values of A, $\sigma_1(A) \geq \sigma_2(A) \geq \cdots$, into bands such that the singular values in each band are within a factor of 2 from each other. Formally, define the i-th singular value band of A to be

$$\mathcal{B}_i(A) = \left\{ k : \frac{\|A\|_{op}}{2^{i+1}} < \sigma_k(A) \leq \frac{\|A\|_{op}}{2^i} \right\}, \quad i \geq 0,$$

and let $N_i(A) = |\mathcal{B}_i(A)|$, the cardinality of the i-th band.

Extreme Singular Values of Gaussian Matrices. We shall repeatedly use the following results on Gaussian matrices.

▶ **Proposition 2** ([20, Corollary 5.35]). *Let G be an $r \times n$ ($r < n$) Gaussian random matrix of i.i.d. entries $N(0,1)$. With probability at least $1 - 2\exp(-u^2/2)$, it holds that $\sqrt{n} - \sqrt{r} - u \leq s_{\min}(G) \leq s_{\max}(G) \leq \sqrt{n} + \sqrt{r} + u$.*

Combining [11, Corollary 3.21] and the concentration bound in Gauss space [20, Proposition 5.34], we also have

▶ **Proposition 3.** *Let A be a deterministic $n \times n$ matrix and G be an $r \times n$ ($r < n$) Gaussian random matrix of i.i.d. entries $N(0,1)$. Then for any K, it holds that $\|GA\|_{op} \leq K(\|A\|_{op}\sqrt{r} + \|A\|_F)$ with probability at least $1 - \exp(-c\sqrt{K}r)$, where $c > 0$ is an absolute constant.*

Nets on Matrices. The following fact concerns nets of matrices and was used in [10]. We shall use it in our lower bound arguments.

▶ **Proposition 4** ([10, Lemma 2]). *There exists a net $\mathcal{R} \subset \bigcup_{t=1}^{t_0} \mathbb{R}^{t \times n}$ of size $\exp(O(t_0 n \ln(Dn/\eta))$ such that for any $R \in \mathbb{R}^{t \times n}$ ($1 \leq t \leq t_0$) with column norms in $[1, D]$, we can find $R' \in \mathcal{R}$ such that $\|R - R'\|_{op} \leq \eta$.*

3 Lower Bounds

In this section we show the full proof of the $(n/t)^{1/2-1/p}$ lower bound for one-sided sketches (Theorem 5) and the $(n/t)^{1/p-1/2}/\log^{3/2} t$ bound for two-sided sketches (Theorem 6), which demonstrates our techniques. Other cases can be found in the full version.

▶ **Theorem 5** (One-sided sketch). *Let $p > 2$ and $p > q$. There exist a set $T \subset \mathbb{R}^{n \times n}$ with $|T| = \mathrm{poly}(n)$ and an absolute constant $c \in (0,1)$ such that, if it holds for some matrix $R \in \mathbb{R}^{t \times n}$ with $t \leq cn$ and for all $A \in T$ that $\|A\|_p \leq \|RA\|_q \leq D_{p,q}\|A\|_p$, then it must hold that $D_{p,q} \gtrsim (n/t)^{\frac{1}{2}-\frac{1}{p}}$.*

Instead of proving this theorem, we prove the following rephrased version.

▶ **Theorem 5'** (rephrased). *Let $p > 2$ and $p > q$. There exists an absolute constant D_0 and a set $T \subset \mathbb{R}^{n\times n}$ with $|T| = O(n\ln(Dn))$ such that, if $D \geq D_0$ and it holds for some matrix $R \in \mathbb{R}^{t\times n}$ and for all $A \in T$ that*

$$\|A\|_p \leq \|RA\|_q \leq D^{\frac{1}{2}-\frac{1}{p}}\|A\|_p, \tag{8}$$

then it must hold that $t \gtrsim n/D$.

Proof. Let $r = n/(\rho^2 D)$ and $t_0 = \theta r$ for some constants $\rho > 1$ and $\theta \in (0,1)$ to be determined. We shall show that if $t \leq t_0$, it will not happen that R satisfies (8) for all A in a carefully chosen set T.

Let $\mathcal{D}$ be the distribution of Gaussian random matrices of dimension $n \times r$ with i.i.d. entries $N(0, 1/r)$. Let $R = U\Sigma V^T$ be the singular value decomposition of R and $A \sim \mathcal{D}$. Then by rotational invariance of the Schatten norm and Gaussian random matrices, we know that $\|RA\|_q$ is identically distributed to $\|\Sigma A\|_q = \|B^T\Sigma'\|_q$, where Σ' is the left $t \times t$ block of Σ and B is formed by the first t rows of A.

It follows from Proposition 2 that with probability $\geq 1 - \exp(-c_1c_2r)$, $s_{\max}(B) \leq 1 + 2c_1\sqrt{t/r} \leq 1 + 2\sqrt{\theta}c_1$, and thus

$$\|B^T\Sigma'\|_q \leq s_{\max}(B)\|\Sigma'\|_q \leq (1+2\sqrt{\theta}c_1)\|\Sigma'\|_q = (1+\sqrt{\theta}c_1)\|R\|_q \leq (1+2\sqrt{\theta}c_1)D^{\frac{1}{2}-\frac{1}{p}}n^{\frac{1}{p}},$$

that is, with probability $\geq 1 - \exp(-c_1c_2r)$,

$$\|RA\|_q \leq (1 + 2\sqrt{\theta}c_1)D^{\frac{1}{2}-\frac{1}{p}}n^{\frac{1}{p}}.$$

On the other hand, with probability $\geq 1 - \exp(-c_1c_2r)$, all singular values of A are at least $\sqrt{n/r} - 2c_1 = \rho\sqrt{D} - 2c_1 \geq (1-\epsilon)\rho\sqrt{D}$ if we choose $D_0 \geq 4c_1^2/\epsilon^2$. Then

$$\|RA\|_q \geq \|A\|_p \geq (1-\epsilon)sr^{\frac{1}{p}}\sqrt{D} = (1-\epsilon)\rho^{1-\frac{2}{p}}n^{\frac{1}{p}}D^{\frac{1}{2}-\frac{1}{p}}.$$

Also, with probability $\geq 1 - \exp(-c_1c_2r)$, all singular values of A are at most $\sqrt{n/r} + 2c_1 = \rho\sqrt{D} + 2c_1 \leq (1+\epsilon)\rho\sqrt{D}$ and thus

$$\|A\|_p \leq r^{\frac{1}{p}}(1+\epsilon)s\sqrt{D} = (1+\epsilon)\rho^{1-\frac{2}{p}}n^{\frac{1}{p}}D^{\frac{1}{2}-\frac{1}{p}}.$$

This motivates the following definitions of constraints for $R \in \mathbb{R}^{t\times n}$ and $A \in \mathbb{R}^{n\times n}$:

$$\mathrm{P}_1(R,A) : \|RA\|_q \leq (1+2\sqrt{\theta}c_1)D^{\frac{1}{2}-\frac{1}{p}}n^{\frac{1}{p}} \quad \mathrm{P}_2(R,A) : \|RA\|_q \geq (1-\epsilon)\rho^{1-\frac{2}{p}}n^{\frac{1}{p}}D^{\frac{1}{2}-\frac{1}{p}}$$
$$\mathrm{P}_3(A) : \|A\|_p \leq (1+\epsilon)\rho^{1-\frac{2}{p}}n^{\frac{1}{p}}D^{\frac{1}{2}-\frac{1}{p}}.$$

Now, for m samples $A_1, \ldots, A_m$ drawn from $\mathcal{D}$, it holds for any fixed R that

$$\Pr_{A_1,\ldots,A_m}\{\exists i \text{ s.t. } \mathrm{P}_1(R,A) \text{ and } \mathrm{P}_2(R,A) \text{ and } \mathrm{P}_3(A) \text{ hold}\} \geq 1 - e^{-c_1c_2mr}. \tag{9}$$

Since $1 \leq \|Ge_ie_i^T\|_q \leq D$ and $\|Ge_ie_i^T\|_q = \|R_i\|_2$, we can restrict the matrix R to matrices with column norm in $[1, D]$. Thus we can find a net $\mathcal{R} \subset \bigcup_{t=1}^{t_0}\mathbb{R}^{t\times n}$ of size $\exp(O(t_0n\ln(Dn/\eta))$ such that for any R with column norms in $[1, D]$, we can find $R' \in \mathcal{R}$ such that $\|R - R'\|_{op} \leq \eta$.

Now it follows from (9) that

$$\Pr_{A_1,\ldots,A_m}\{\forall R \in \mathcal{R}, \exists i,\ \mathrm{P}_1(R,A) \text{ and } \mathrm{P}_2(R,A) \text{ and } \mathrm{P}_3(R,A) \text{ hold}\}$$
$$\geq 1 - \exp\left(O\left(t_0n\ln\frac{Dn}{\eta}\right)\right)\exp\left(-\frac{c_1c_2}{D}mn\right) > 0,$$

provided that $m = \Theta(n \ln(Dn))$. Fix $A_1, \ldots, A_m$ such that for each $R \in \mathcal{R}$ there exists an i such that $\mathrm{P}_1(R, A_i)$ and $\mathrm{P}_2(R, A_i)$ and $\mathrm{P}_3(A_i)$ all hold.

Take $T = \{I_n, e_1 e_1^T, \ldots, e_n e_n^T, A_1, \ldots, A_m\}$. We know that if R satisfies (8) for all $A \in T$, then there exists R' such that $\|R' - R\|_{op} \leq \eta$, and there exists $1 \leq i \leq m$ such that $\mathrm{P}_1(R', A_i)$, $\mathrm{P}_2(R', A_i)$ and $\mathrm{P}_3(A_i)$ all hold. It follows that

$$\begin{aligned}\|RA_i\|_q \leq \|R'A_i\|_q + \|(R - R')A_i\|_q &\leq \|R'A_i\|_q + \|R - R'\|_{op}\|A_i\|_p \\ &\leq \left(1 + 2\sqrt{\theta}c_1 + (1+\epsilon)\rho^{1-\frac{2}{p}}\eta\right) D^{\frac{1}{2}-\frac{1}{p}} n^{\frac{1}{p}}\end{aligned}$$

and

$$\begin{aligned}\|RA_i\|_q \geq \|RA_i\|_q - \|(R - R')A_i\|_q &\geq \|R'A_i\|_q - \|R - R'\|_{op}\|A_i\|_p \\ &\geq \left((1-\epsilon) - (1+\epsilon)\eta\right) \rho^{1-\frac{2}{p}} D^{\frac{1}{2}-\frac{1}{p}} n^{\frac{1}{p}}\end{aligned}$$

We meet a contradiction when θ, ϵ and η are all sufficiently small and ρ is sufficiently large, for instance, when $\eta = \Theta(\epsilon)$, $\theta = \Theta(\epsilon^2/c_2^2)$ and $\rho = \Theta(1 + p\epsilon/(p-2))$. ◀

▶ **Theorem 6** (Two-sided sketch)**.** *Let $p < 2$. There exist a set $T \subset \mathbb{R}^{n \times n}$ with $|T| = \mathrm{poly}(n)$ and an absolute constant $c \in (0,1)$ such that, if it holds for some matrices $R, S \in \mathbb{R}^{t \times n}$ with $t \leq cn$ and for all $A \in T$ that $\|A\|_p \leq \left\|RAS^T\right\|_q \leq D_{p,q}\|A\|_p$, it must hold that $D_{p,q} \gtrsim (n/t)^{\frac{1}{p}-\frac{1}{2}} / \log^{\frac{3}{2}} t$.*

Instead of proving this theorem, we prove the following rephrased version.

▶ **Theorem 6'** (rephrased)**.** *Let $p < 2$, $p > q$ and $D \geq D_0$ for some an absolute constant D_0. There exists a set $T \subset \mathbb{R}^{n \times n}$ with $|T| = O(n \ln(Dn))$ such that it holds for some matrices $R, S \in \mathbb{R}^{t \times n}$ and for all $A \in T$ that*

$$\|A\|_p \leq \left\|RAS^T\right\|_q \leq D^{\frac{1}{p}-\frac{1}{2}}\|A\|_p, \tag{10}$$

then it must hold that $t \gtrsim n/(D \log^{3p/(2-p)} t)$.

We need two auxiliary lemmata, whose proofs are omitted owing to space limitations.

▶ **Lemma 7.** *Let A and B be deterministic $n \times n$ matrices and G be a Gaussian random matrix of i.i.d. $N(0,1)$ entries. It holds with probability $1 - O(1)$ that*

$$\|AGB\|_p \lesssim (\log^{\frac{5}{2}} n)(\log\log n)\|A\|_{op}\|B\|_{op}E_p(A,B),$$

where

$$E_p(A,B) = \max_{0 \leq i,j \leq 3\log n} \frac{1}{2^{i+j}} \cdot \min\left\{N_i(A), N_j(B)\right\}^{\frac{1}{p}} \cdot \max\left\{\sqrt{N_i(A)}, \sqrt{N_j(B)}\right\}. \tag{11}$$

▶ **Lemma 8.** *Let A and B be deterministic $n \times N$ matrices and G, H be $N \times r$ Gaussian random matrices of i.i.d. $N(0,1)$ entries. Suppose that $n \leq cr$ for some absolute constant $c \in (0,1)$. It holds with probability $1 - O(1)$ that $\|AGH^TB^T\|_p \gtrsim \sqrt{r}\|A\|_{op}\|B\|_{op}E_p(A,B)$, where $E_p(A,B)$ is as defined in (11).*

Now we are ready to show Theorem 6'.

Proof of Theorem 6'. Without loss of generality, we can assume that the maximum column norm of R and that of S are the same; otherwise we can rescale R and S.

Let $r = n/(\rho^2 D)$ and $t_0 = \theta r$ for some $\rho = \Theta(\log^{3p/(2-p)} t)$ and $\theta \in (0,1)$ to be determined. We shall show that if $t \le t_0$, it will not happen that R and S satisfy (10) for all $A \in T$.

Let $\mathcal{D}$ be the distribution of Gaussian random matrices of dimension $n \times r$ with i.i.d. entries $N(0,1)$ and let $G, H \sim \mathcal{D}$ be independent. It follows from Lemma 8 that with probability $\ge 1 - O(1)$,

$$\|\Sigma_R G H^T \Sigma_S^T\|_q \gtrsim \sqrt{r} E_q(R,S). \tag{12}$$

On the other hand, it follows from (10) that with probability $\ge 1 - \exp(-c_1 n)$,

$$\|\Sigma_R G H^T \Sigma_S^T\|_q \le D^{\frac{1}{2}-\frac{1}{p}} \|GH^T\|_p \lesssim D^{\frac{1}{2}-\frac{1}{p}} n r^{\frac{1}{p}}. \tag{13}$$

Now, let $\mathcal{F}$ be the distribution of an $n \times n$ Gaussian matrix of i.i.d. entries $N(0,1)$ and let F be drawn from $\mathcal{F}$. Then $\|RFS\|_q$ is identically distributed as $\Sigma_R F' \Sigma_S$, where F' is a random $t \times t$ Gaussian matrix of i.i.d. entries $N(0,1)$. It follows from Lemma 7 that with probability $\ge 1 - O(1)$,

$$\|\Sigma_R F' \Sigma_S^T\|_q \lesssim (\log^{\frac{5}{2}} t)(\log\log t) E_q(R,S) \le (\log^3 t) E_q(R,S) \tag{14}$$

On the other hand, it follows from (10) that with probability $\ge 1 - \exp(-c_2 n)$,

$$\|RFS^T\|_q \ge \|F\|_p \gtrsim n^{1/p}\sqrt{n}. \tag{15}$$

Define events $\mathrm{P}_1(G,H,R,S)$ and $\mathrm{P}_2(F,R,S)$ to be (12) and (14) respectively. Further define

$$\mathrm{P}_3(G,H):\ \left\|GH^T\right\|_p \lesssim n r^{1/p} \qquad \text{and} \qquad \mathrm{P}_4(F):\ \|F\|_p \lesssim n^{1/p}\sqrt{n}.$$

Both $\mathrm{P}_3(G,H)$ and $\mathrm{P}_4(F)$ hold with probability $\ge 1 - e^{-c_3 n}$ when $G, H \sim \mathcal{D}$ and $F \sim \mathcal{F}$.

Now, for $2m$ samples $G_1, \ldots, G_m, H_1, \ldots, H_m$ independently drawn from $\mathcal{D}$, and m samples $F_1, \ldots, F_m$ independently drawn from $\mathcal{F}$, it holds for any fixed R and S that

$$\Pr_{G_i,H_i,F_i}\{\exists i,\ \mathrm{P}_1(G_i,H_i,R,S), \mathrm{P}_2(F_i,R,S), \mathrm{P}_3(G_i,H_i), \mathrm{P}_4(F_i) \text{ all hold}\} \ge 1 - e^{-c_4 m}. \tag{16}$$

Since $1 \le \|R e_i e_j^T S^T\|_q = \|R_i\|_2 \|S_j\|_2 \le D$, we can restrict the matrix R and S to matrices with column norm in $[1, \sqrt{D}]$. Thus we can find a net $\mathcal{M} \subset \bigcup_{t=1}^{t_0} \mathbb{R}^{t \times n}$ of size $\exp(O(t_0 n \ln(Dn/\eta))$ such that for any M with column norms in $[1, \sqrt{D}]$, there exists $M' \in \mathcal{G}$ such that $\|M - M'\|_{op} \le \eta$.

Now it follows from (16) that

$$\Pr_{G_i,H_i,F_i}\{\forall R,S \in \mathcal{M}, \exists i,\ \mathrm{P}_1(G_i,H_i,R,S), \mathrm{P}_2(F_i,R,S), \mathrm{P}_3(G_i,H_i), \mathrm{P}_4(F_i) \text{ all hold}\}$$
$$\ge 1 - \exp\left(O\left(t_0 n \ln \frac{Dn}{\eta}\right)\right)\exp\left(-c_4 m\right) > 0,$$

provided that $m = \Theta(n \ln(Dn))$. Fix $\{G_i, H_i, F_i\}_i$ such that for each pair $R', S' \in \mathcal{M}$ there exists i such that $\mathrm{P}_1(G_i,H_i,R',S')$ and $\mathrm{P}_2(F_i,R',S')$ and $\mathrm{P}_3(G_i,H_i)$ and $\mathrm{P}_4(F_i)$ all hold.

Take $T = \{I_n\} \cup \{e_i e_j^T\}_{1 \le i,j \le n} \cup \{G_i H_i^T\}_{1 \le i \le m} \cup \{F_i\}_{1 \le i \le m}$. We know that if (R,S) satisfies (10) for all $A \in T$, then there exists R' and S' such that $\|R' - R\|_{op} \le \eta$ and $\|S' - S\|_{op} \le \eta$, and there exists $1 \le i \le m$ such that $\mathrm{P}_1(G_i,H_i,R',S')$ and $\mathrm{P}_2(F_i,R',S')$

and $\mathrm{P}_3(G_i, H_i)$ and $\mathrm{P}_4(F_i)$ all hold. One can then show that (12), (15) hold with slightly smaller constants and (13), (14) with slightly larger constants for R and S. It follows that

$$\frac{n^{\frac{1}{p}}\sqrt{n}}{\log^3 t} \lesssim D^{\frac{1}{p}-\frac{1}{2}}\sqrt{r}nr^{\frac{1}{p}}, \quad \text{or,} \quad \frac{1}{\log^3 t} \lesssim \left(\frac{rD}{n}\right)^{\frac{1}{p}-\frac{1}{2}} = \frac{1}{\rho^{\frac{2}{p}-1}},$$

which contradicts our choice of ρ (the hidden constant in $\lesssim$ above depends only on D_0, θ and η, and then we can choose the hidden constant in the Θ-notation for ρ). ◀

4 Upper Bounds

We shall only show the upper bounds for $1 \le p \le q \le 2$ in this section. Other cases can be found in the full version.

Let $G \in \mathbb{R}^{r\times n}$ ($r \ge Ct$) be a random matrix and $c, c', \eta > 0$ be absolute constants which satisfy the following properties:

(a) (subspace embedding) For a fixed t-dimensional subspace $X \subseteq \mathbb{R}^n$ it holds with probability $\ge 1 - \exp(-c't)$ that

$$(1-\eta)\|x\|_2 \le \|Gx\|_2 \le (1+\eta)\|x\|_2, \quad \forall x \in X;$$

(b) For a fixed $A \in \mathbb{R}^{n\times n}$ it holds with probability $\ge 1 - \exp(-c'r)$ that

$$\|GA\|_{op} \le c\left(\|A\|_{op} + \frac{1}{\sqrt{r}}\|A\|_F\right);$$

(c) For a fixed $A \in \mathbb{R}^{n\times n}$ it holds with probability $\ge 1 - \exp(-c'r)$ that

$$(1-\eta)\|A\|_F \le \|GA\|_F \le (1+\eta)\|A\|_F.$$

Consider the singular value decomposition $A = U\Sigma V^T$, where U and V are orthogonal matrices, $\Sigma = \mathrm{diag}\{\sigma_1, \ldots, \sigma_n\}$ with $\sigma_1 \ge \sigma_2 \ge \cdots$. For an index set $I \subseteq [n]$, define $A_I = U\Sigma_I V^T$, where Σ_I is Σ restricted to the diagonal elements with indices inside I (the diagonal entries with indices outside I are replaced with 0).

▶ **Theorem 9.** *Let $1 \le p \le q \le 2$. There exist constants $\theta = \theta(p,q) < 1$ small enough and $C = C(p,q)$ large enough such that for $t \le \theta n$ and matrix G satisfying the aforementioned properties, it holds for any (fixed) $A \in \mathbb{R}^{n\times n}$ with probabilty $1 - \exp(-c''t)$ that*

$$\frac{t^{\frac{1}{q}-\frac{1}{2}}}{n^{\frac{1}{p}-\frac{1}{2}}\log\frac{n}{t}}\|A\|_p \lesssim \|GA\|_q \lesssim \|A\|_p.$$

Note that for $t = \Omega(\log n)$ and $r = Ct$ for some large constant C, a Gaussian random matrix of i.i.d. entries $N(0, 1/r)$, or a randomized Hadamard Transform matrix of $r = \Theta(t\,\mathrm{polylog}(t))$ rows, satisfies the three conditions on G [7]. The following corollary of Theorem 9 is immediate.

▶ **Corollary 10.** *Suppose that $1 \le p \le q$ and $c\log n \le t \le \theta n$ for some absolute constants $\theta \in (0,1)$ and $c \ge 1$. There exists (random) $G \in \mathbb{R}^{r\times m}$ with $r \gtrsim t$ such that with probability $\ge 1 - \exp(-c''t)$,*

$$\|A\|_p \le \|GA\|_q \lesssim \frac{n^{\frac{1}{p}-\frac{1}{2}}}{t^{\frac{1}{q}-\frac{1}{2}}}\left(\log\frac{n}{t}\right)\|A\|_p.$$

In particular when $p = q$,

$$\|A\|_p \le \|GA\|_p \lesssim \left(\frac{n}{t}\right)^{\frac{1}{p}-\frac{1}{2}}\left(\log\frac{n}{t}\right).$$

Now we prove Theorem 9. We first need an auxiliary lemma.

▶ **Lemma 11.** *Let θ, t, C and G be as defined in Theorem 9 and $b = \Theta(\log(n/t))$. At least one of the following conditions will hold:*

$$\sum_{i=1}^{bt} \sigma_i^p \geq \frac{1}{2} \sum_{i=1}^{n} \sigma_i^p \tag{17}$$

and

$$\sigma_s^2 \leq \frac{2}{t} \sum_{i=s}^{n} \sigma_i^2 \quad \text{for some} \quad s \leq bt. \tag{18}$$

To prove the preceding lemma, consider the first b blocks of singular values of A each of size t, that is, $I_1 = \{\sigma_1, \ldots, \sigma_t\}$, $\ldots$, $I_b = \{\sigma_{(b-1)t+1}, \ldots, \sigma_{bt}\}$.

▶ **Lemma 12.** *If (18) does not hold for any $s \leq bt$, it must hold for all $2 \leq j \leq b$ that $\sigma_{jt} \leq \frac{1}{2}\sigma_{(j-1)t}$.*

Proof. If this is not true for some j then $\sum_{i=(j-1)t+1}^{jt} \sigma_i^2 \geq t\sigma_{jt}^2 > \frac{t}{2}\sigma_{(j-1)t}^2$, which contradicts (18) with $s = (j-1)t \leq bt$. ◀

Proof of Lemma 11. Suppose that (17) does not hold and we need to show that (18) holds for some $s \leq bt$. Otherwise, it follows from Lemma 12 that $\sigma_{bt+1} \leq \frac{\sigma_1}{2^b} \leq \left(\frac{t}{n}\right)^2 \sigma_1$ and thus

$$\sum_{i=bt+1}^{n} \sigma_i^p < n\sigma_{bt+1}^p \leq \frac{t^{2p}}{n^{2p-1}}\sigma_1^p \leq t\theta^{2p-1}\sigma_1^p, \tag{19}$$

On the other hand,

$$\sum_{i=1}^{bt} \sigma_i^p \geq t\sigma_1^p \left(\frac{1}{2} + \frac{1}{4} + \cdots + \frac{1}{2^b}\right) = \left(1 - \frac{1}{2^b}\right) t\sigma_1^p = (1-\theta^2)t\sigma_1^p. \tag{20}$$

Using the assumption on θ, we see that the rightmost side of (20) is bigger than the rightmost side of (19), which contradicts the assumption that (17) does not hold. ◀

▶ **Lemma 13.** *Let $1 \leq p \leq q \leq 2$, and t, b and G be defined as in Lemma 11. Suppose that s satisfies (18) and let $J = \{s, s+1, \ldots, n\}$. Then*

$$\|GA_J\|_q \gtrsim \frac{t^{\frac{1}{q}-\frac{1}{2}}}{n^{\frac{1}{p}-\frac{1}{2}}} \|A_J\|_p.$$

Proof. Combining Property (b) of G with (18) yields that

$$\|GA_J\|_{op} \leq \frac{c}{\sqrt{t}} \left(\sqrt{2} + \sqrt{\frac{1}{C}}\right) \|A_J\|_F =: \frac{K}{\sqrt{t}} \|A_J\|_F$$

On the other hand, Property (c) states that $\|GA_J\|_F \geq \frac{1}{2}\|A_J\|_F$. This implies that at least αr singular values of GA_J are at least $\frac{\gamma}{\sqrt{t}}\|A_J\|_F$, provided that $C\left((1-\alpha)\gamma^2 + \alpha K^2\right) < \frac{1}{4}$, which is satisfied if we choose $\gamma \simeq 1/\sqrt{C}$ and $\alpha \simeq 1/K^{2/q}$. It follows that

$$\|GA_J\|_q \geq (\alpha r)^{\frac{1}{q}} \frac{\gamma}{\sqrt{t}} \|A_J\|_F \geq (\alpha C)^{\frac{1}{q}} \gamma \cdot \frac{t^{\frac{1}{q}-\frac{1}{2}}}{n^{\frac{1}{p}-\frac{1}{2}}} \|A_J\|_p.$$ ◀

▶ **Lemma 14.** *Let $1 \le p \le q \le 2$, and t, b and G be defined as in Lemma 11. Suppose that s satisfies* (18) *and let $J = \{s, s+1, \ldots, n\}$. Then*

$$\|GA_J\|_q \lesssim \frac{1}{t^{\frac{1}{p}-\frac{1}{q}}} \|A_J\|_p$$

Proof. When $p \le 2$, it holds that $\|A_J\|_F^2 \le \|A_J\|_p^p \|A_J\|_{op}^{2-p}$. Using (18), we obtain that

$$\|A_J\|_p \ge \frac{\|A_J\|_F^{2/p}}{\|A_J\|_{op}^{2/p-1}} \ge \left(\frac{t}{2}\right)^{\frac{1}{p}-\frac{1}{2}} \|A_J\|_F.$$

On the other hand, it follows from Property (c) of G that

$$\|GA_J\|_q \le r^{\frac{1}{q}-\frac{1}{2}} \|GA_J\|_F \le (1+\eta) r^{\frac{1}{q}-\frac{1}{2}} \|A_J\|_F.$$

Therefore,

$$\|GA_J\|_q \le (1+\eta) r^{\frac{1}{q}-\frac{1}{2}} \left(\frac{2}{t}\right)^{\frac{1}{p}-\frac{1}{2}} \|A_J\|_p = (1+\eta)(Cbqt)^{\frac{1}{q}-\frac{1}{2}} \left(\frac{2}{t}\right)^{\frac{1}{p}-\frac{1}{2}} \|A_J\|_p \lesssim \frac{1}{t^{\frac{1}{p}-\frac{1}{q}}} \|A_J\|_p. \blacktriangleleft$$

Now we are ready to show Theorem 9.

Proof of Theorem 9. It follows from the subspace embedding property of G that

$$(1-\eta)\|A_{I_i}\|_q \le \|GA_{I_i}\|_q \le (1+\eta)\|A_{I_i}\|_q, \quad 1 \le i \le b$$

and thus

$$\frac{1-\eta}{t^{\frac{1}{p}-\frac{1}{q}}} \|A_{I_i}\|_p \le \|GA_{I_i}\|_q \le (1+\eta)\|A_{I_i}\|_p.$$

When (17) holds, there exists i^* $(1 \le i^* \le b)$ such that

$$\|A_{I_{i^*}}\|_p \ge \frac{1}{2^{\frac{1}{p}} b} \|A\|_p$$

and thus

$$\frac{1}{bt^{\frac{1}{p}-\frac{1}{q}}} \|A\|_p \lesssim \|GA_{I_{i^*}}\|_q \lesssim \|A\|_p.$$

When (17) does not hold, let J be as defined in Lemma 13 and

$$\frac{1}{2^{\frac{1}{p}}} \|A\|_p \le \|A_J\|_p \le \|A\|_p.$$

The claimed upper and lower bounds follow from combining the bounds above, together with Lemma 13, Lemma 14, and

$$\max\left\{\|GA_{I_1}\|_q, \ldots, \|GA_{I_b}\|_q, \|GA_J\|_q\right\} \le \|GA\|_q \le \sum_{i=1}^{b} \left\|GA_{[I_i]}\right\|_q + \|GA_J\|_q,$$

noticing that $t^{\frac{1}{2}-\frac{1}{p}} / n^{\frac{1}{2}-\frac{1}{p}} \le 1/t^{\frac{1}{p}-\frac{1}{q}}$. ◀

On Fast Decoding of High-Dimensional Signals from One-Bit Measurements*

Vasileios Nakos†

vasileiosnakos@g.harvard.edu

Abstract

In the problem of one-bit compressed sensing, the goal is to find a δ-close estimation of a k-sparse vector $x \in \mathbb{R}^n$ given the signs of the entries of $y = \Phi x$, where Φ is called the measurement matrix. For the one-bit compressed sensing problem, previous work [32, 19] achieved $\Theta(\delta^{-2}k\log(n/k))$ and $\tilde{\mathcal{O}}(\frac{1}{\delta}k\log(n/k))$ measurements, respectively, but the decoding time was $\Omega(nk\log(n/k))$. In this paper, using tools and techniques developed in the context of two-stage group testing and streaming algorithms, we contribute towards the direction of sub-linear decoding time. We give a variety of schemes for the different versions of one-bit compressed sensing, such as the for-each and for-all versions, and for support recovery; all these have at most a $\log k$ overhead in the number of measurements and $\text{poly}(k, \log n)$ decoding time, which is an exponential improvement over previous work, in terms of the dependence on n.

1 Introduction

1.1 Standard Compressed Sensing

The compressed sensing framework describes how to reconstruct a vector (signal) $x \in \mathbb{R}^n$ given the linear measurements $y = \Phi x$ where $\Phi \in \mathbb{R}^{m\times n}$ for some $m \ll n$. This is an under-determined system with n variables and m equations. In many applications, however, such as images, we know that the vector x can be approximated by a k-sparse vector in some known basis. In this case, the matrix Φ contains a sufficient amount of information to roughly recover x if m is large enough; in particular, as shown in [4, 5], the signal can be approximately reconstructed from $\Theta(k\log(n/k))$ measurements when Φ is a Gaussian matrix. In order to do this, however, one has to solve the non-convex program

$$\min\|x\|_0 \text{ s.t. } y = \Phi x$$

However, [9, 4] show it is possible to avoid the non-convex formulation and, alternatively, we can use Basis Pursuit (BP), which changes the objective to $\min\|x\|_1$, and still recover a decent approximation of x. This can be solved using linear programming.

Compressed sensing, and sparse recovery, have appeared to be very useful tools in many areas such as analog-to-digital conversion [25], threshold group testing [1], discrete

signal processing [12], streaming algorithms [29] and bioinformatics [26]. Depending on the application, one cares about optimizing different parameters of interest (measurements, decoding time, encoding time, failure probability).

Often we distinguish between the for-all model (or uniform recovery) and the for-each model (non-uniform recovery). In the for-all model, a single matrix is picked, which allows reconstruction of all k-sparse vectors. Whereas in the for-each model, the measurements are chosen at random such that, for some error probability p, they will contain sufficient information to reconstruct a single vector x with probability at least $1 - p$. We note that all aforementioned papers refer to the for-all model.

Moreover, it is desirable to achieve *sublinear* decoding time. The state of the art for the for-each model is [15]. The authors there achieve $k \cdot \text{poly}(\log n)$ decoding time with $\Theta(k \log(n/k))$ measurements. The failure probability was improved later in [17] using a much more complicated scheme. In the for-all model, Gilbert et.al. [18] give the first algorithm that runs in sublinear time with a number of measurements $\mathcal{O}(k\text{poly}(\log n))$. Porat and Strauss devised a scheme under a slightly weaker recovery guarantee with $\mathcal{O}(k \log(n/k))$ measurements accompanied with the first sublinear decoding procedure running in time $\mathcal{O}(k^{1-\alpha} n^{\alpha})$, for any constant α [33]. Subsequent work [16], the authors manage to bring the dependence of the approximation ϵ fact down to the right order of ϵ^{-1} and achieve runtime $\text{poly}(k, \log n)$, when $\epsilon \leq (\frac{\log k}{\log n})^{\gamma}$, for any constant γ.

1.2 One-Bit Compressed Sensing

Often in applications compressed sensing measurements must be quantized, since the requirement of infinite precision is not realistic: any measurement must be mapped to a small finite value in some universe [3]. Thus, one-bit compressed sensing emphasizes the compressed aspect of compressed sensing; many algorithms for standard compressed sensing rely on infinite precision in their real-valued inputs, relying on more precision than real sensors are capable of returning, an assumption which is unrealistic for real-world applications. Moreover, in hardware implementations, for example, where quantizers are implemented using comparators to zero [3], there is need of quantization to one-bit measurements. Comparators are indeed fast, but they are expensive, so minimizing their usage is really important. Moreover, dynamic range issues are a smaller problem in the case of one-bit quantizers.

It is clear that quantization increases the complexity of the decoding procedure and, additionally, is irreversible: given $y = \text{sign}(\Phi x)$ it is impossible to get the exact vector back. Previous results inquired the case in which the quantization maps each coordinate to $\{-1, +1\}$, which means that we learn only the sign of each coordinate. First, it is not obvious whether there is sufficient information to reconstruct a signal given its one-bit measurements. Of course, since we cannot know the length of the signal, nor the exact signal (even if its length were given), we can ask the following question: can we find its direction?

The problem was first studied in the work of Boufounos and Baraniuk [3], where the authors suggest recovering the signal x by solving the optimization problem

$$\min \|x\|_1 \text{ s.t.: } y \odot Ax \geq 0, \|x\|_2 = 1,$$

where $\odot$ stands for the element-wise product between two vectors. The goal is to find a vector y on the unit sphere such that $\|y - \frac{x}{\|x\|_2}\|_2^2 \leq \delta$. It is clear that this relaxation requires solving a non-convex program, an obstacle which Laska et al. [28] tried to remedy by giving an optimization algorithm that finds a stationary point of the aforementioned program; both papers, however, do not provide provable guarantees for the number of measurements needed. An alternative formulation was studied in [24], which showed that the number

of measurements could be brought down to $\mathcal{O}(\delta^{-1}k\log n)$, but the main obstacle of the non-convex formulation remained. In [31] Vershyin and Plan gave the first computationally tractable algorithm for the problem of one-bit compressed sensing by designing a compressed sensing scheme that approximately recovers a k-sparse vector from $\mathcal{O}(\delta^{-5}k\log^2(\frac{n}{k}))$ one-bit measurements via a linear programming relaxation. Their techniques were based on random hyperplane tessellations; the main geometric lemma they needed was that $\mathcal{O}(k\log(n/k))$ random hyperplanes partition the set of k-sparse vectors with unit norm into cells, each one having small diameter. In [32] the same authors improved the number of measurements to $\mathcal{O}(\delta^{-2}k\log(\frac{n}{k}))$ by analyzing a simple convex program. Their results can also be generalized to other sparsity structures, where the crucial quantity that determines the number of measurements is the gaussian mean-width of the set of all unit vectors having a specific sparsity pattern. Last but not least, they manage to handle gaussian noise and, most importantly, adversarial bit flips, though with a small worsening in the dependence on δ in their number of measurements. In [19] a two-stage algorithm with $\tilde{\mathcal{O}}(\frac{1}{\delta}k\log(n/k))$ measurements and $\mathcal{O}(nk\log(n/k)+\frac{1}{\delta^5}(k\log(n/k))^5)$ decoding time was proposed. Apart from recovering the vector, other algorithms that recover only the support of the signal have been proposed; see for example [19, 22].

In [20] it is conjectured that even if the support of the vector is known, the dependence of the number of measurements on δ must be at least $\frac{1}{\delta}$. In order to circumvent this, alternative quantization schemes were proposed, with the most common being Sigma-Delta quantization [21, 27]. In [2] Baraniuk, Foucart, Needell, Plan and Wootters manage to bring the dependence on δ down to $\log(\frac{1}{\delta})$ if the quantizer is allowed to be adaptive and the measurements take a special form of threshold signs.

1.3 Group Testing

In the group testing problem, we have a large population, which consists of "items", with a known number of defectives. The goal is to find the defectives using as few tests as possible, where a test is just a query whether a certain subset of items contains at least one defective. The group testing problem was first studied by Dorfman in [13]. There are two types of algorithms for this problem, namely adaptive and non-adaptive. In the first case, the outcome of previous tests can be used to determine future tests, whereas in non-adaptive algorithms all tests are performed at the same time. Group testing has many applications in DNA library screening and detection of patterns in data; more can be found in [6], [8].

Any solution for the group testing problem corresponds to a binary matrix, where the number of rows equals the number of tests and the number of columns equals the cardinality of the population. Given such a matrix M and a vector x indicating the positions of the defectives, we should be able to identify x from Mx, where the addition here corresponds to the OR operation of Boolean algebra. Since decoding time is important, the brute-force algorithm that iterates over each possible subset in order to recognise the defective set does not suffice. However, one can design matrices such that the naive decoding algorithm, which eliminates items belonging to negative tests and returns all the other items, correctly identifies all defective items [14]. In the literature these matrices are known as k-disjunct matrices.

In this paper, we are also interested in the so-called two-stage group testing problem, where two stages are allowed: the first stage recognises a superset of the defectives, and the second stage, which is performed after seeing the results of the first stage, recognizes the exact set of the defectives by querying separately for each one. We refer to (k,l) two-stage group testing as the case when there are k defectives and the superset is allowed to have up to $k+l$ elements. In fact, this is equivalent to the existence of a matrix M such that given

Mx one can find a set S with $k+l$ elements such that all defectives are included in S. The same naive algorithm, which eliminates all items that belong to a negative test and returns all other items, will be used here. A matrix is called (k,l) list-disjunct if this algorithm finds a superset of the support with at most $k+l$ elements. The term 'list-disjunct' appeared in [23], although it was also studied before in [11] under the name of super-imposed codes, and in [34] under the name of list-decoding super-imposed codes. In [30] Ngo, Porat and Rudra give efficient and strongly explicit constructions of matrices that allow two-stage group testing, which are also error-tolerant, in the sense that they can correct e_0 false positives and e_1 false negatives in sub-linear time and additional $\Theta(e_0 + k \cdot e_1)$ tests. They also prove matching lower bounds for several cases, including the case that $k = \Theta(l)$.

A group testing scheme is a tuple (M, R), where M is a matrix in $\{0,1\}^{m\times n}$ and R a procedure that takes as input Mx and outputs a vector y. Depending on the guaratee we want, we will either refer to it as two-stage group testing or (one-stage) group testing. The worst-case running time of the procedure R corresponds to the decoding time of the scheme.

1.4 Our Results

The main goal of our work is to make algorithms for one-bit compressed sensing not only "data-efficient" but also computationally efficient. Thus, we try to understand under which conditions and which number of measurements sublinear decoding time is possible. In the for-each version of noisy one-bit compressed sensing we give a scheme with almost-optimal measurements and sublinear decoding time. We also focus on decoding noiseless signals and presents several results towards this direction. We first give a scheme with sublinear decoding time with a small overhead in the number of measurements, by connecting the problem with Combinatorial Group Testing. Second, we try to understand whether it is possible to achieve a for-all guarantee for one-bit compressed sensing, while still keeping sublinear decoding time. We answer this question in the affirmative if we are allowed to use $\mathcal{O}(k^2 \log n)$ measurements. Our techniques also give a scheme for support recovery that outperforms the one in [19] by being exponentially faster than it; one additional aspect of our scheme is that the measurement matrix is explicit, which means that we can compute it in polynomial time.

For the case of general vectors, we define the δ-ℓ_2/ℓ_2 guarantee: For a unit vector $x \in \mathbb{R}^n$ we say that a scheme satisfies the δ-ℓ_2/ℓ_2 guarantee for one-bit compressed sensing if the output satisfies

$$\|\hat{x} - x\|_2^2 \leq c\|x_{\mathrm{tail}(k)}\|_2^2 + \delta,$$

while $x_{\mathrm{tail}(k)}$ is the vector that occurs after zeroing out the biggest k coordinates of x in magnitude and c is some absolute constant.

In the support recovery problem, one wants to construct a matrix Φ, such that for all k-sparse x, one is able to recover the support of the vector x, given measurements $y = \mathrm{sign}(\Phi x)$.

We present the results that we have in greater detail in Tables 1 and 2. We note that the decoding time of each scheme is $\mathrm{poly}(k, \log n)$.

- δ-ℓ_2/ℓ_2 for-each one-bit Compressed Sensing from $\mathcal{O}(k \log(n/k) \cdot (\log k + \log\log(n/k)) + \delta^{-2}k)$ measurements.
- For-each one-bit Compressed Sensing (noiseless signals) from $\mathcal{O}(k \log n + \log_k n \cdot \log\log_k n + \delta^{-2}k)$ measurements. This extends the result of [32], as it manages to also decrease the number of measurements for the for-each version of the problem for a wide range of parameters.

Table 1 Comparison of recovery schemes for one-bit compressed sensing.

Algorithm	Measurements	Decoding-Time	Model	Noise
[32]	$\delta^{-6}k\log(\frac{n}{k})$	$\text{poly}(n)$	For-all	Type 1
[32]	$\delta^{-2}k\log(\frac{n}{k})$	$\text{poly}(n)$	For-each	Type 2
[19]	$\tilde{\mathcal{O}}(\delta^{-1}k\log(\frac{n}{k}))$	$\mathcal{O}(nk\log n)+\text{poly}(k,\log n)$	For-all	No
This paper	$\delta^{-2}k+k\log(\frac{n}{k})(\log k+\log\log(\frac{n}{k}))$	$\text{poly}(k,\log n)$	For-each	Type 3
This paper	$k\log n+\delta^{-2}k+\log_k n\cdot\log\log_k n$	$\text{poly}(k,\log n)$	For-each	No
This paper	$k^2\log n\log\log_k n+\delta^{-6}k\log(\frac{n}{k})$	$\text{poly}(k,\log n)$	For-all	No

Table 2 Comparison of schemes for support recovery.

Algorithm	Measurements	Decoding time	Model
[19]	$k^3\log n$	$nk\log n$	For-all
This paper (Theorem 18)	$k^3\log n$	$k^3\text{poly}(\log n)$	For-all

- For-all one-bit Compressed Sensing (noiseless signals) in $\mathcal{O}(k^2\log n\log\log_k n+\delta^{-2}k\log n)$ measurements. This is the first scheme that allows sublinear decoding time in the for-all model of one-bit compressed sensing, although the dependence on k is k^2.
- Support recovery from one-bit measurement (noiseless signals) in $\mathcal{O}(k^3\log n)$ measurennts. This scheme is not only exponentially faster than the one presented in [19], but also explicit, in the sense that the matrix can be computed in polynomial time in n.

An interesting aspect of our results is that in the for-each model, the δ factor does not need to multiply the $k\log n$ factor, in contrast to the for-all version. We explain the three types of noise handled by the schemes in Table 1:

- Type 1 stands for adversarial bit flips. This means that after receiving $y=\text{sign}(\Phi x)$, an adversary can flip some of the entries of y, and then give it to the decoder. Here, we assume that x is exactly k-sparse. The result of [32] can tolerate up to $c\delta$ fraction of adversarial bit flips, where c is some absolute constant smaller than 1.
- Type 2 noise stands for gaussian random noise that is added to the k-sparse vector x after the matrix Φ has been applied to it. This means that $y=\text{sign}(Ax+u)$, where $u\sim c\mathcal{N}(0,I)$, where c is some absolute constant.
- Type 3 noise refers to general noise and is handled by the δ-ℓ_2/ℓ_2 guarantee. This means that $y=\text{sign}(\Phi(x_{\text{head}(k)}+x_{\text{tail}(k)}))$, where we can view the term $x_{\text{tail}(k)}$ as pre-measurement adversarial noise.

The ideas that are used in this paper to obtain sublinear decoding time are based on ideas that appeared in [30], as well as the dyadic trick, which has appeared in the streaming literature in the context of the Count-Min Sketch [10]. As far as we know, our work is the first that looks at sublinear decoding time in the one-bit compressed sensing framework and even achieves less measurements in some cases. Last but not least, we believe that a strong point of our schemes is their simplicity.

2 Preliminaries

We define the sign function as $\text{sign}(z)=+1$, for $z\geq 0$ and $\text{sign}(z)=-1$ for $z<0$. For a vector x, we define $\text{sign}(x)_i=\text{sign}(x_i)$, for all $i\in[n]$.

Any one-bit compressed sensing scheme is defined by a pair $(\mathcal{D}, \mathrm{Dec})$ where $\mathcal{D}$ is a distribution over $\mathbb{R}^{m\times n}$ and Dec is an algorithm that takes input $\mathrm{sign}(\Phi x)$ for some $x \in \mathbb{R}^n$ and gives back a vector $\hat{x}$. We will refer to Dec either as the "decoder" or "decoding procedure". We may also slightly abuse notation and refer to the pair (A, Φ), where A is a matrix coming from some distribution $\mathcal{D}$. We use m to denote the number of measurements, and *decoding time* refers to the running time of *Dec*. We also define $\Sigma_k = \{x : \|x\|_0 \leq k, \|x\|_2 \leq 1\}$ to be the set of all k-sparse vectors contained in the unit ℓ_2 ball, and $\Sigma_k^1 = \{x : \|x\|_2 = 1, \|x\|_0 \leq k\}$ the set of unit norm vectors with at most k non-zero coordinates.

For $x \in \mathbb{R}^n$ we denote its support set by $\mathrm{supp}(x)$. For a vector x, $\mathrm{head}(k)$ denotes the set of its k largest coordinates in magnitude, while $\mathrm{tail}(k)$ denotes the set of its $n-k$ smallest coordinates in magnitude. For a coordinate i, we say that i is a $\frac{1}{k}$-heavy hitter if, for some absolute constant C_h it holds that $x_i^2 \geq \frac{1}{C_h k}\|x_{\mathrm{tail}(k)}\|_2^2$. The constant C_h will be chosen later. For any x which we are sensing using a one-bit compressed sensing scheme, we assume that it $\|x\|_2 = 1$.

For each $S \subset n$, let $x_S \in \mathbb{R}^{|S|}$ denote the signal x restricted to coordinates in S. Similarly, for a matrix $M \in \mathbb{R}^{r\times n}$ and each $S \subset n$ let $M_S \in \mathbb{R}^{r\times|S|}$ be the matrix M restricted to columns in S.

▶ **Definition 1.** A scheme $(\mathcal{D}, \mathrm{Dec})$ satisfies the δ-ℓ_2/ℓ_2 guarantee for one-bit compressed sensing with failure probability p if for each $x \in \mathcal{S}^{n-1}$, it estimates a vector $\hat{x}$ such that

$$\forall x, P_{\Phi\sim\mathcal{D}}[\hat{x} = \mathrm{Dec}(\Phi x) : \|x - \hat{x}\|_2^2 \leq C\|x_{\mathrm{tail}(k)}\|_2^2 + \delta] \geq 1 - p,$$

where C is an absolute constant.

For function $f : \mathbb{R}^n \to \mathbb{R}^m$ and a vector $x \in \mathbb{R}^n$ we say that $y = f(x)$ is a sketch of x. In our case, f will always be of the form $f(x) = \mathrm{sign}(Ax)$, where $A \in \mathbb{R}^{m\times n}$.

We also give the definition of the tensor product of two matrices. We note that this is not the standard tensor product (or Kronecker product, as usually known) appearing in the literature.

▶ **Definition 2.** Let $A \in \{0,1\}^m \times \{0,1\}^N$ and $B \in \{0,1\}^{m'} \times \{0,1\}^N$. The tensor product $A \otimes B$ is an $mm' \times N$ binary matrix with rows indexed by the elements of $[m] \times [m']$ such that for $i \in [m]$ and $j \in [m']$, the row of $A \otimes B$ indexed by (i, j) is the coordinate-wise product of the i-th row of A and j- th row of B.

In order to proceed, we have to explain the difference between the for-all and the for-each model. Let P_x be the predicate that the sparse recovery scheme returns a vector $\hat{x}$ such that $\|x - \hat{x}\|_2^2 > \delta$, when the matrix Φ is chosen from the distribution $\mathcal{D}$. Let p be some target probability. In the for-each model the guarantee is that $\forall x \in \Sigma_k^1, \mathbb{P}[P_x] \leq p$. In the for-all model the guarantee is that $\mathbb{P}[\exists x \in \Sigma_k^1 : P_x] \leq p$. The randomness of the scheme is over the distribution $\mathcal{D}$.

The following result, appearing in [32] is a crucial component of most of our algorithms. This theorem is a special case of Theorem 1.1 from that paper, and it is also discussed in subsection 3.1 of the same paper (check "random noise before quantization" discussion).

▶ **Theorem 3.** *Let A be a random $m \times n$ matrix, with each entry being a standard gaussian, and all entries are independent. Let $x \in \Sigma_k^1$ and $y = \mathrm{sign}(Ax + v)$, where $v \sim \mathcal{N}(0, I)$. Then, the convex program*

$$z = \mathrm{argmax}\,\langle y, Az\rangle \;\; s.t. \;\; \|z\|_2 \leq 1, \|z\|_1 \leq \sqrt{k},$$

outputs a $\hat{x}$ such that $\|\hat{x} - x\|_2^2 \leq \delta$ with probability $1 - e^{-\Omega(k\log(n/k))}$, as long as $m = \Omega(\delta^{-2}k\log(n/k))$.

Algorithm 1 Naive Decoding Algorithm.

    $S \leftarrow S \cup \{i\}$
  end if
end for
Output S.

We should review some folklore definitions from Combinatorial Group Testing theory. For their proofs one can check [30].

▶ **Definition 4.** A $t \times n$ matrix M is k-disjunct if for every set $S \subset [n]$ with $|S| \leq k, \forall j \notin S, \exists i$ such that $M_{i,j} = 1$ but $\forall k \in S, M_{i,k} = 0$. In other words, $\text{supp}(M_j) - \cup_{l \in S}\text{supp}(M_l) \neq \emptyset$.

▶ **Definition 5.** A $t \times n$ matrix M is (k, l)-disjunct if for every two disjoint sets $S, T \subset [n]$ with $|S| \leq k, |T| = l$, there exists a row i such that $\forall j \in S, M_{i,j} = 0$, but $\exists j \in T, M_{i,j} = 1$.

In the noiseless case, we will make extensive use of the following two lemmas:

▶ **Lemma 6.** *Let M be a k-disjunct matrix. Then, given $y = Mx$, the naive decoding algorithm returns a set S such that $S = \text{supp}(x)$, i.e. the naive decoding algorithm correctly finds the support of x.*

▶ **Lemma 7.** *Let M be a (k, l)-disjunct matrix. Then, given $y = Mx$, the naive decoding algorithm returns a set S such that supp$(x) \subset S$ and $|S| \leq |\text{supp}(x)| + l$, i.e. the naive decoding algorithm finds a superset of the support of x with additional l elements.*

Of course, the two different definitions solve a different problem; the latter one solving a more relaxed version of Group Testing than the former. We will refer to the second version as two-stage group testing, whereas we will refer to the first version just as group testing.

2.1 Formal Statement of Results

▶ **Theorem 8.** *There exists a randomized construction of a scheme* $(\Phi,$ OneBitCS$())$ *which with probability* $1 - \mathcal{O}(\frac{1}{k \log(n/k)} + e^{-k})$ *satisfies the* δ-ℓ_2/ℓ_2 *guarantee. Moreover,* Φ *has* $\mathcal{O}(k \log(n/k)(\log k + \log\log(n/k)) + \delta^{-2}k)$ *rows and* OneBitCS$()$ *runs in time* $\text{poly}(k \log n)$.

▶ **Theorem 9.** *There exists a randomized construction of a scheme* $(\Phi,$ OneBitCS$())$ *such that*

$$\forall x \in \Sigma_k^1, \mathbb{P}[\hat{x} = \text{OneBitCS}(\Phi x), \|x - \hat{x}\|_2^2 > \delta] \leq e^{-k}.$$

The number of rows of Φ *is* $\mathcal{O}(k \log n + \log_k n \log\log_k n + \delta^{-2}k)$ *and the running time of* OneBitCS$()$ *is* $\text{poly}(k, \log n)$.

▶ **Theorem 10.** *There exists a randomized construction of a scheme* $(\Phi,$OneBitCS$())$ *such that*

$$\mathbb{P}[\exists x \in \Sigma_k^1 : \hat{x} = \text{OneBitCS}(\Phi x), \|x - \hat{x}\|_2^2 > \delta] \leq e^{-k \log(n/k)}.$$

The matrix Φ *has* $\mathcal{O}(k^2 \log(n/k) \log\log_k n + \delta^{-6}k \log(n/k))$ *rows and* OneBitCS$()$ *runs in poly*$(k, \log n)$ *time.*

▶ **Theorem 11.** *There exists a deterministic construction of a scheme* $(\Phi, \text{Support}())$*, where* $\text{Support}(\Phi x)$ *outputs a set* L *of at most* k *elements, and* $\forall x \in \Sigma_k^1, \text{Support}(\Phi x) = \text{supp}(x)$*. The matrix* Φ *has* $\mathcal{O}(k^3 \log n)$ *rows and* $\text{Support}()$ *runs in* $\text{poly}(k, \log n)$ *time.*

Complete proofs of these theorems are deferred to the full version.

2.2 Overview of techniques

All of our algorithms find the superset of the support of the vector x (noiseless case) or a small set containing the largest $\mathcal{O}(k)$ in magnitude coordinates (noisy case). This set contains the crucial information needed to approximate x. Then, by restricting to the set obtained, we show how the algorithm from [32] can give us the desired guarantees.

We first treat the noisy case. We sketch our approach to find a set of size $O(k)$ that contains all $\frac{1}{k}$-heavy hitters of our vector x. Let us first discuss the Count-Sketch [7] for finding heavy hitters in data streams (where we also have magnitude information). The Count-Sketch consists of $\log n$ different iterations: in each iteration r we hash every element to $\mathcal{O}(k)$ buckets using a 2-wise independent hash function $h_r : [n] \to [\mathcal{O}(k)]$, combined with random signs. This means that for each pair (r, b) the (r, b)-th measurement is $\sum_{i:h_r(i)=b} \sigma_{i,r} x_i$, where $\sigma_{i,r}$ are pairwise independent random signs. For each coordinate i and iteration r, we read the value of the bucket $h_r(i)$ multiplied by $\sigma_{i,r}$ to get an estimate for x_i. The median of all $\log n$ different estimates is our final estimate for x_i. This approach essentially solves a harder problem called ℓ_∞/ℓ_2 sparse recovery, but at this point we are interested in finding only the heavy hitters of x, not approximating their values; we will use the algorithm of [32] for that later. So, when we only have access to one-bit measurements an immediate approach is the following. Using the same hashing scheme as Count-Sketch, the decoding algorithm for every coordinate i and every iteration r checks if $\sigma_{i,r}$ agrees or disagrees with the sign of the value of the bucket $h_r(i)$, let this be $C_{r,h_{r(i)}}$. If this happens more than $\frac{3}{4}$ of the time we classify i as a heavy hitter. This happens because if i is a heavy hitter, with constant probability x_i will dominate the value of $h_r(i)$. Unfortunately, this does not suffice to give us sublinear decoding time.

What we need is a technique called the dyadic trick, which was introduced in [10], for the ℓ_1 case when all x_i are non-negative. In this case, we form a tree of size depth $\log n$, where level l corresponds to the decomposition of $[n]$ into 2^l equal-sized and disjoint intervals. The algorithm at each step keeps a list of size $\mathcal{O}(k)$ of "active" nodes, that is intervals that contain some heavy hitter. At every level we run a version of the Count-Min Sketch to find the heavy intervals (those that have ℓ_1 mass larger than $\frac{\|x_{\text{tail}(k)}\|_1}{k}$) and proceed by considering their children as active. The algorithm terminates when we reach the last level. Observe that at all times we want to guarantee that the list is of size $\mathcal{O}(k)$ and hence $\mathcal{O}(k \log n)$ nodes are visited in total.

In our case, however, we only have sign information about our measurements and we do not assume that x_i are non-negative. Remember that every node of the tree corresponds to an interval. For any interval I in each level of the tree we add a normal random variable in front of every x_i for $i \in I$ and when we hash nodes to buckets, we combine with a random sign. We explain what this means. Let us focus on some interval/node I. If we hash this node to U buckets using a hash function $h_r : [2^l] \to [U]$, then the contribution of the interval to the value of bucket $h_r(a)$ will be $\sigma_I \cdot \sum_{i \in I} g_i^I x_i$, where g_i^I is the gaussian corresponding to each $i \in I$ and σ_I is the sign associated with I. The idea is that $\sum_{i \in I} g_i^I x_i$ essentially approximates the ℓ_2 mass of the interval and hence one can expect $\sigma_I \cdot \sum_{i \in T} g_i^I x_i$ to be roughly $\sigma_I \cdot \|x_I\|_2$. This would mean that if I contains a heavy hitter, the sign of the

measurement it participates in should roughly be the same as the sign of $\sum_{i\in I} g_i^I x_i$ and hence, by repeating a lot of times, we can hope to clasify this interval as heavy. In this approach, however, there are technical hurdles, one of them being that we should not refresh the gaussians across iterations in the same level otherwise the signs will be uniformly at random. In the next section we show how to take care of all the details.

In the noiseless case, we use techniques and schemes developed in the context of two-stage group testing. More specifically, we show that if we take a (k, k)-disjunct matrix A and replace each non-zero entry with a normal random variable, we get a for-each scheme for identifying a superset S of the support of x. Using this idea and Lemma 7 we can detect a superset S of the support of x. If we also keep in parallel matrix G each entry of which is a normal random variable, we can use Theorem 3 by restricting G on the columns indexed by S to get the result of Theorem 9. We take a similar approach for the for-all version of the problem, namely Theorem 10. In this case we have to suffer an additional multiplicative factor of k in the measurements. More specifically, let $A \in \{0,1\}^{t\times n}$ be a (k, k)-disjunct matrix and let V be a $k \times n$ matrix. Then, the measurement matrix for is the vertical concatenation of $A \otimes V$ concatenated with G. For every i and x, $(a_i \otimes V)x$ can be seen as single test on x: $(a_i \otimes V)x = 0$ if and only if $\mathrm{supp(a_i)} \cap \mathrm{supp(x)} = \emptyset$. Vertically concatenating $(A \otimes V)$ and $((-A) \otimes V)$ we can check whether $(a_i \otimes V)x = 0$ or not. Then, a modification of Algorithm 1 and the for-all theorem of [32] (Result 1 from Table 1) gives us the desired result. For the support recovery problem, our approach is similar: We use a deterministic k-disjunct matrix A guaranteed by [23] and form the vertical concatenation of $A \otimes V$ and $(-A) \otimes V$. A similar reasoning as above, along with Lemma 6 gives the desired result. The reason we make use of a k-disjunct matrix and not a list-disjunct one is because we are interested in finding exactly the support.

3 For-each δ-ℓ_2/ℓ_2 One-Bit Compressed Sensing

As mentioned in the previous section, the algorithm is based on a two-stage approach. The first stage identifies the set S of the "heavy" coordinates of the vector x; these coordinates carry most of the ℓ_2 mass of x and hence the crucial information needed to approximate it. The second stage runs the convex program of [32] with the universe being S instead of $[n]$.

The most important part of the algorithm and essentially our contribution, that enables sublinear decoding time, is the procedure that finds the set S. As mentioned before, we turn our attention to the Count-Sketch and the dyadic trick [7, 10], and show that, with only a constant multiplicative increase in the measurement complexity, we can modify them so that they also work with one-bit measurements. We note that these algorithms appeared in the linear case of the very-relevant problem of finding heavy hitters in data streams.

In what follows, we assume that n is a power of 2. Let C_{-1}, C_0, C_1, C_2 be large enough constants to be defined later. For each l, we consider a partition of $[n]$ to 2^l equal-sized disjoint intervals and we denote by L_l^a the a-th interval in this partition. We also set $\Delta = \frac{1}{C_{-1}k\log n}, \Delta' = \log(\frac{1}{\Delta})$, where C_{-1} is an absolute constant larger than 1.

The sensing matrix Φ is the vertical concatenation of matrices $E^{(\log k)}, E^{(\log k+1)}, \ldots, E^{(\log n)}, A$. The number of rows of each $E^{(l)}$ is $C_0 \cdot C_1 \cdot C_2 \cdot k\Delta'$ and the number of rows of A is $\mathcal{O}(\delta^{-2}k)$. For $\log k \le l \le \log n$ let $E^{(l)}$ be the l-th matrix. $E^{(l)}$ consists of submatrices $E_1^{(l)}, \ldots, E_{C_2\Delta'}^{(l)}$. Each matrix $E_m^{(l)}$ consists of C_1 matrices $E_{m,t}^{(l)}$, $t = 1, \ldots, C_1$. Let $h_{l,m,t} : [2^l] \to [C_0k]$ be a hash function that maps intervals/nodes at level l to C_0k buckets. We define the q-th row of $E_{m,t}^{(l)}$ via its dot product with x:

$$\left\langle e_q^T E_{m,t}^{(l)}, x \right\rangle = \sum_{a:h_{l,m,t}(a)=q} \sigma_{m,t}^{l,a} \sum_{j\in L_l^a} g_{j,m}^{(l)} \cdot x_j,$$

OneBitHeavyHitters(y):

1. $S_{\log k-1} \leftarrow \{L^1_{\log k-1}, L^2_{\log k-1} \dots, L^{k/2}_{\log k-1}\}$
2. For $l = \log k$ to $\log n$:
3. For each L^i_{l-1} in S_{l-1} add L^{2i-1}_l and L^{2i}_l to S_l.
4. For every element L^a_l in S_l
5. If CheckIfHeavy(L^a_l) = 'light' remove L^a_l from S_l
6. Output every x in $S_{\log n}$

Figure 1 Recovery of ℓ_2 Heavy Hitters from One-Bit Measurements.

where $g^{(l)}_{j,m} \sim \mathcal{N}(0,1)$ and $\sigma^{l,a}_{m,t}$ are random signs. The above expression states that in each sketch $E^{(l)}_{m,t}$ we hash the nodes at level l in $C_2 k$ buckets.

In other words, every $E^{(l)}$ holds a hierarchical separation of $[n]$ into 2^l intervals of length $n/2^l$. Fix now some $m \in [C_2\Delta']$. Then, in each $E^{(l)}_{m,t}$, every node/interval is hashed to some bucket and the coordinates inside this interval are combined with standard Gaussians. Moreover, every interval is assigned a random sign. The intuition is that with constant probability, we do expect the term $\sum_{j \in L^a_l} g^{(l)}_{j,m,t} \cdot x_j$, to behave roughly like the l_2 mass of the interval itself. Then, by keeping the same gaussians, we take C_1 such hashing schemes (we refresh only the σ variables and the hash functions). For fixed m, l, this means that we use in total $C_1 C_2 \Delta'$ measurements, $C_2\Delta'$ for each of the C_1 rounds. Let this scheme be called Scheme 1. Then, for each level, we repeat the Scheme 1 $C_2\Delta'$ times, for $m = 1, \dots, C_2\Delta'$. Note now that across E^m_l for different m, l we use new g variables. The reason we have to make this additional repetition, in contrast to the standard dyadic trick, is that we only have sign information and we cannot use fresh gaussians at every measurement, since this would imply uniformity of the signs of the measurements. In other words, we would roughly see half $+1$ and half -1 and we would not be able to distinguish the 'heavy' intervals from the 'light' ones, as we will see next.

The decoding algorithm processes these intervals in increasing l for $l = \log k$ up to $\log n$ and keeps a list of intervals at each time (the list is denoted by S_l in the pseudocode). In the beginning of each step l, every node is hashed to $C_0 k$ buckets. Suppose for a moment, that we have the ℓ_2 mass of each interval and we hash these values, instead, into $C_0 k$ buckets combined with random signs. If an interval I contains a node that is 'heavy' and also is hashed to a bucket b, then we expect that its ℓ_2 mass dominates the ℓ_2 mass of other coordinates hashed to the same bucket. Thus, the sign of the sum must be determined by the sign of the 'heavy' interval. To overcome the fact that we do not have the ℓ_2 mass of the interval (since we can only make use of linear measurements) we add a standard random variable in front of every node in the inteval, before hashing. We exploit the aforementioned intuition, along with 2-stability of the Gaussian distribution , to show that we can identify all "heavy" intervals and that we do not introduce a big number of erroneous intervals (intervals that are not 'heavy'). We repeat this hashing scheme C_1 times with the same gaussians and try to find the intervals whose sign agrees or disagrees with the measurement they participate in most of the time. We consider them good. As mentioned in the previous paragraph, this whole hashing scheme called Scheme 1. Now, we repeat Scheme 1 $C_2\Delta'$ times with completely fresh randomness. We then find the intervals which were consider good at least $\frac{2}{3}C_2\Delta'$ times and add them to a list. At the end of each step l, every interval L^i_l that belongs to the list and is substituted by its two sub-intervals $L^{2i-1}_{l-1}, L^{2i}_{l-1}$.

CheckIfHeavy(L_l^a):

1. isheavy $\leftarrow 0$
2. For $m = 1$ to $C_2\Delta'$
3. cnt $\leftarrow 0$
4. For $t = 1$ to C_1
5. $y_q \leftarrow$ value of bucket $h_{l,m,t}(a)$
6. If $\text{sign}(y_q) = \sigma_{m,t}^{l,a}$
7. cnt $\leftarrow$ cnt $+ 1$
8. If cnt $> 0.8C_1$ *or* cnt $< 0.2C_1$
9. isheavy $\leftarrow$ isheavy $+ 1$
10. If isheavy $> \frac{2}{3}C_2\Delta'$
11. return 'heavy', else return 'light'

Figure 2 Check if an Interval at a Specific Level is Heavy.

OneBitCS(y):

1. $S \leftarrow$ OneBitHeavyHitters(y).
2. $\hat{x} = \text{argmax}\,\langle y, A_S z\rangle$ subject to $\|z\|_2 \leq 1, \|z\|_1 \leq \sqrt{k}$ (Algorithm of [32]).
3. Output $\hat{x}$.

Figure 3 One-Bit Compressed Sensing.

▶ **Definition 12.** For a coordinate i and a level l, let $b^l(i)$ be such that $i \in L_l^{b^l(i)}$. If the level l is implicit, we may simplify the notation to $b(i)$. In other words, $b^l(i)$ is the interval on level l which contains i.

Fix some matrix $E_{m_0}^l$ an an interval I in level l. Then, we will say that $E_{m_0}^l$ classifies interval I as good, if the variable isheavy is incremented in the execution of CheckIfHeavy(I) when $m = m_0$. Intuitively, $E_{m_0}^l$ classifies I as good if I appears to contain a heavy hitter in it. The next two lemmas are crucial components of our proof.

▶ **Lemma 13.** *Let C_h be an absolute constant. Fix m, l. Let $i \in [n]$ such that $|x_i|^2 > \frac{1}{C_h k}\|x_{\text{tail}(k)}\|_2^2$. Let I an interval at level l. Assume that $L_l^{b(i)}, I \in S_l$. Then, for some absolute constant c, the following claims hold:*

- *$E_m^{(l)}$ will classify $L_l^{b(i)}$ as good with constant probability, strictly larger than $\frac{1}{2}$.*
- *If there are at least ck intervals at the same level l which have greater ℓ_2 mass than I, then, with constant probabiliy, $E_m^{(l)}$ will not classify I as good.*

The proof of the aforementioned lemma is deferred to the full version.

▶ **Lemma 14.** *Let $S =$ OneBitHeavyHitters(y). then, with probability $1 - \mathcal{O}(\frac{1}{k\log(n/k)})$, for all $\log k \leq l \leq \log n$, the following holds for the set S_l:*

- *If $|x_i|^2 > \frac{1}{C_h k}\|x_{\text{tail}(k)}\|_2^2$ and $i \in L_l^{b(i)}$, then $i \in S$.*
- *$|S_l| \leq ck$, for some absolute constant c.*

Proof. For the proof of this lemma, we need to introduce some additional definitions. We will refer to any interval that contains a node i such that $|x_i|^2 > \frac{1}{10k}\|x_{\text{tail}(k)}\|_2^2$, as a type 1 interval. For a level l, we say that an interval at level l is of type 2, if there exist at least ck intervals at the same level that have greater ℓ_2 mass than this interval.

We now proceed by induction on the number of levels. The base case $l = \log k$ is trivial. We focus on some level l and assume that the induction hypothesis holds for all previous levels l. We prove the first bullet. Let i be a coordinate such that $|x_i|_2^2 > \frac{1}{C_h k}\|x_{\text{tail}(k)}\|_2^2$. By the induction hypothesis we get that $L_l^{b^l(i)} \in S_l$. From Lemma 14 we know that for any l, m, E_l^m will classify a type 1 interval as good with constant probability $> \frac{2}{3}$. Moreover, it will not classify any type 2 interval as good, again with constant probability $> \frac{2}{3}$. This implies that after repeating the same scheme $C_2\Delta' = C_2 \log(\frac{1}{\Delta})$ times, we will know, with probability at least $1 - \Delta$, if a specific interval is a type-1 interval or a type-2 interval or none of these. Because $\Delta = \Theta(\frac{1}{k \log(n/k)})$ we can take a union-bound over all possible intervals we might consider ($\mathcal{O}(k)$ at each of the $\log(n/k)$ levels), we can guarantee that every type-1 interval will remain in S_l, while any type-2 interval will be discarded from S_l. This implies that at any step we have at most ck intervals in S_l with every type-1 inteval belonging to S_l. ◀

We are now ready to prove the main result of this section.

Proof. By running OneBitCS(y), we obtain a set S that satisfies the guarantees of Lemma 14. Then, $y = \text{sign}(Ax) = \text{sign}(Ax_S + Ax_{[n]-S}) = \text{sign}(A_S x_S + v)$, where v is a vector each entry of which follows normal distribution with variance $\|x_{[n]-S}\|_2^2 \leq 1$. Clearly, A_S and v are independent and hence Theorem 3 applies. The number of rows needed equals $\Omega(\delta^{-2} k \log(ck/k)) = \Omega(\delta^{-2}k)$. The convex program of 3 outputs a vector $\hat{x}$ such that $\|\hat{x} - x_S\|_2^2 \leq \delta$. Since every coordinate i with $|x_i|^2 \geq \frac{1}{C_h k}\|x_{\text{tail}(k)}\|_2^2$ is contained in S,

$$\|x_{[n]-S}\|_2^2 \leq \|x_{\text{tail}(k)}\|_2^2 + ck\frac{1}{C_h k}\|x_{\text{tail}(k)}\|_2^2 = (1 + \frac{c}{C_h})\|x_{\text{tail}(k)}\|_2^2.$$

This implies that $\|x - \hat{x}\|_2^2 \leq (1 + \frac{c}{C_h})\|x_{\text{tail}(k)}\|_2^2 + \delta$, as desired. ◀

Abstract

The suffix array, perhaps the most important data structure in modern string processing, is often augmented with the longest common prefix (LCP) array which stores the lengths of the LCPs for lexicographically adjacent suffixes of a string. Together the two arrays are roughly equivalent to the suffix tree with the LCP array representing the tree shape.

In order to better understand the combinatorics of LCP arrays, we consider the problem of inferring a string from an LCP array, i.e., determining whether a given array of integers is a valid LCP array, and if it is, reconstructing some string or all strings with that LCP array. There are recent studies of inferring a string from a suffix tree shape but using significantly more information (in the form of suffix links) than is available in the LCP array.

We provide two main results. (1) We describe two algorithms for inferring strings from an LCP array when we allow a generalized form of LCP array defined for a multiset of cyclic strings: a linear time algorithm for binary alphabet and a general algorithm with polynomial time complexity for a constant alphabet size. (2) We prove that determining whether a given integer array is a valid LCP array is NP-complete when we require more restricted forms of LCP array defined for a single cyclic or non-cyclic string or a multiset of non-cyclic strings. The result holds whether or not the alphabet is restricted to be binary. In combination, the two results show that the generalized form of LCP array for a multiset of cyclic strings is fundamentally different from the other more restricted forms.

1 Introduction

For a string X of n symbols, the suffix array (SA) [23] contains pointers to the suffixes of X, sorted in lexicographical order. The suffix array is often augmented with a second array –

the longest common prefix (LCP) array – storing the length of the longest common prefix between lexicographically adjacent suffixes; i.e., LCP[i] is the length of the LCP of suffixes $X[\mathrm{SA}[i]..n)$ and $X[\mathrm{SA}[i-1]..n)$. The two arrays are closely connected to the suffix tree [32] – the compacted trie of all the string's suffixes: the entries of SA correspond to the leaves of the suffix tree, and the LCP array entries tell the string depths of the lowest common ancestors of adjacent leaves, defining the shape of the tree. For decades these data structures have been central to string processing; see [4] for a history and an overview, and [1, 3, 15, 30, 26] for further details on myriad applications.

Given both the suffix and the LCP array, the corresponding string is unique up to renaming of the characters and is easy to reconstruct: zeros in the LCP array tell where the first character changes in the lexicographical list of the suffixes, and the suffix array tells how to permute those first characters to obtain the string. Given the suffix array without the LCP array, we can easily reconstruct a corresponding string where all characters are different, and it is not difficult to characterize the set of all strings with a given suffix array [5, 28, 22]. In essence, the suffix array determines a set of positions in the LCP array that must be zero. Specifically, for any i let j and k be integers such that $\mathrm{SA}[j] = \mathrm{SA}[i-1]+1$ and $\mathrm{SA}[k] = \mathrm{SA}[i]+1$. Then, if $k < j$, we must have $\mathrm{LCP}[i] = 0$. For any other position, we can freely and independently decide whether the value is zero or not, and as described above, the zero positions together with the suffix array determine the string.

In this paper, we consider the problem of similarly reconstructing strings from an LCP array without the suffix array. As mentioned above, the LCP array determines the shape of the suffix tree, i.e., the suffix tree without edge or leaf labels. String inference from the suffix tree shape has recently been considered by three different sets of authors [19, 6, 31]. However, all of them assume that the suffix tree is augmented with significant additional information, namely *suffix links*, which makes the task much easier. Indeed, our new algorithms essentially reconstruct suffix links from the LCP array. According to Cazaux and Rivals [6], the case without suffix links was considered but not solved in [27]. We are also aware that others have considered it but without success [2].

To fully define the problem, we have to specify what kind of strings we are trying to infer. Often suffix trees and suffix arrays are defined for *terminated strings* that are assumed to end with a special symbol \$ that is different from and lexicographically smaller than any other symbol. The alternative is an *open-ended string* where no assumption is made on the last symbol. For suffix and LCP arrays the only change from omitting the terminator symbol is dropping the first element (which is always zero in the LCP array), but the suffix tree can change considerably because some suffixes can be prefixes of other suffixes and thus are not represented by a leaf. Inferring open-ended strings from a suffix tree (with suffix links) is studied by Starikovskaya and Vildhøj [31], who show that any string can be appended by additional characters without changing the suffix tree shape (thus the term open-ended). However, such an extension can change the suffix and LCP arrays a great deal, i.e., with the arrays a string is never truly open-ended but has at least an implicit terminator.

To get rid of even an implicit terminator, we consider a third type of strings, *cyclic strings*, where we use rotations in place of suffixes. For a terminated string, replacing suffixes with rotations causes no changes to the suffix/rotation array or the LCP array. Thus any integer array that is a valid LCP array for a terminated string is always a valid LCP array for a cyclic string too, but the opposite is not true. For example, the LCP array for the cyclic string *aababa* is $(2, 1, 3, 0, 2)$, which is not a valid LCP array for any non-cyclic string. In this sense, the cyclic string case is strictly more general. An even more striking example is a non-primitive string, such as *abab*, that has two or more identical rotations. For reasons

explained below, instead of rotations we use *cyclic suffixes* which are infinite repetitions of rotations. Thus the LCP array for the cyclic string $abab$ is $(\omega, 0, \omega)$, where ω denotes the positions of two adjacent identical cyclic suffixes.

As a further generalization, we may have a joint suffix array for a collection of strings, where we have all suffixes of all strings in lexicographical order, and the corresponding LCP array. In the terminated version, each string is terminated with a distinct terminator symbol. If we have an LCP array for a collection of open-ended strings, adding the terminator symbols simply prepends one zero for each terminator. The LCP array for a collection of terminated strings is identical to the LCP array of the concatenation of the strings. Thus the generalization from single strings to string sets does not add to the set of valid LCP arrays for terminated strings, but it does for cyclic strings. For example the LCP array for a string set $\{aa, b\}$ is $(\omega, 0)$, which is not a valid LCP array for any single string. For multiple cyclic strings, it is important to use cyclic suffixes instead of rotations because the result can be different (e.g., the set $\{ab, aba\}$).

Now we are ready to formally define the problem of String Inference from LCP Array (SILA). In the decision version, we are given an array of integers (and possibly ω's) and asked if the array is a valid LCP array of some string. If the answer is yes, the reporting version may also output some such string, and possibly a characterization of all such strings. Different variants are identified by a prefix: S for a string set; T, O, or C for terminated, open-ended or cyclic; and B for a binary alphabet (where terminators are not counted). For example, BCSSILA stands for Binary Cyclic String Set Inference from LCP Array. As discussed above, and summarized in the following result (see [21] for the proof), the non-cyclic variants are essentially equivalent, but the cyclic variants are more general.

▶ **Proposition 1.** *There are polynomial time reductions from BTSILA to BOSILA, BTSSILA, BOSSILA, TSILA, OSILA, TSSILA, and OSSILA.*

Our Contribution

Our first result is a linear time algorithm for BCSSILA. For a valid LCP array the algorithm outputs a string, which is the Burrows-Wheeler transform (BWT) of the solution string set. This relies on a generalization of the BWT for multisets of cyclic strings developed in [24, 20]. There can be more than one multiset of strings with the same BWT but the class of such string collections is simple and well characterized in [20]. The algorithm also outputs a set of substring swaps such that applying any combination of the swaps on the BWT produces another BWT of a solution, and any BWT of a solution can be produced by such a combination of swaps. Thus we have a complete characterization of all solutions. The number of swaps can be linear and thus the number of distinct solutions can be exponential. We also present an algorithm for CSSILA, i.e., without a restriction on the alphabet size, that has a polynomial time complexity for any constant alphabet size.

Our second result is a proof, by a reduction from 3-SAT, that (the decision version of) BCSILA, and thus CSILA, is NP complete. Therefore, even though the BCSSILA algorithm produces a characterization of all solutions, it is NP hard to determine whether one of the solutions is a single string. Furthermore, we modify the reduction to prove that BTSILA is NP complete too. By Proposition 1, this shows that all variants of SILA mentioned above except (B)CSSILA are NP complete. Since CSSILA is in P for constant alphabet sizes, this leaves the complexity of CSSILA for larger alphabets as an open problem.

Related Work

String inference from partial information is a classic problem in string processing, dating back some 40 years to the work of Simon [29], where reconstructing a string from a set of its subsequences is considered. Since then, string inference from a variety of data structures has received a considerable amount of attention, with authors considering border arrays [12, 11, 10], parameterized border arrays [18], the Lyndon factorization [25], suffix arrays [5, 22], KMP failure tables [11, 13], prefix tables [7], cover arrays [9], and directed acyclic word graphs [5]. The motivation for studying most string inference problems is to gain a deeper understanding of the combinatorics of the data structures involved, in order to design more efficient algorithms for their construction and use.

A (somewhat tangentially) related result to ours is due to He et al. [16], who prove that it is NP hard to infer a string from the longest-previous-factor (LPF) array. It is well known that LPF is a permutation of LCP [8] but otherwise it is a quite different data structure. For example, it is in no way concerned with lexicographical ordering. Like our NP-hardness proof, He et al.'s reduction is from 3-SAT, but the details of each reduction appear to be very different. Moreover, their construction requires an unbounded alphabet while our construction works for a binary alphabet and thus for any alphabet.

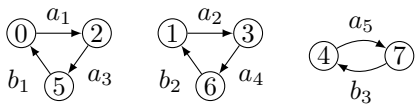
To the best of our knowledge, all of the previous string inference problems aim at obtaining a single non-cyclic string from some data structure, and we are the first to consider the generalizations to cyclic strings and to string sets, and as our results show, this makes a crucial difference. As explained in the next section, the generalizations arise naturally from the generalized BWT introduced in [24], which also played a central role in another recent result on the combinatorics of LCP arrays [20].

2 Basic notions

Let v be a string of length n and let $\widehat{v}$ be obtained from v by sorting its characters. The *standard permutation* [14, 17] of v is the mapping $\Psi_v : [0..n) \to [0..n)$ such that for every $i \in [0..n)$ it holds $\widehat{v}[i] = v[\Psi_v(i)]$ and for any $\widehat{v}[i] = \widehat{v}[j]$ the relation $i < j$ implies $\Psi_v(i) < \Psi_v(j)$. In other words, Ψ_v corresponds to the stable sorting of the characters. Let $C = \{c_i\}_{i=1}^{s}$ be the disjoint cycle decomposition of Ψ_v. We define the inverse Burrows–Wheeler transform IBWT as the mapping from v into a multiset of cyclic strings $W = \{\!\{w_i\}\!\}_{i=1}^{s}$ such that for any $i \in [1..s]$ and $j \in [0..|c_i|)$, $w_i[j] = v[\Psi_v(c_i[j])]$.

▶ **Example 2.** For $v = bbaabaaa$, we have $\mathrm{IBWT}(v) = \{\!\{aab, aab, ab\}\!\}$ as illustrated in the following table (showing $\widehat{v}$ and Ψ_v) and figure (showing the cycles of Ψ_v as a graph). The character subscripts are provided to make it easier to ensure stability.

i	0	1	2	3	4	5	6	7
$v[i]$	b_1	b_2	a_1	a_2	b_3	a_3	a_4	a_5
$\widehat{v}[i]$	a_1	a_2	a_3	a_4	a_5	b_1	b_2	b_3
$\Psi_v[i]$	2	3	5	6	7	0	1	4



The elements of W are primitive cyclic strings. *Cyclic* means that all rotations of a string are considered equal. For example, *aab*, *aba* and *baa* are all equal. A string is *primitive* if it is not a concatenation of multiple copies of the same string. For example, *aab* is primitive but *aabaab* is not. For any alphabet Σ, the mapping IBWT is a bijection between the set Σ^* of all (non-cyclic) strings and the multisets of primitive cyclic strings over Σ [24].

The set of positions of W is defined as the set of integer pairs $\mathrm{pos}(W) := \{\langle i,p\rangle \ : \ i \in [1..s],\ p \in [0..|w_i|)\}$. For a position $\langle i,p\rangle \in \mathrm{pos}(W)$ we define a *cyclic suffix* $W_{\langle i,p\rangle}$ as the infinite string that starts at $\langle i,p\rangle$, i.e., $W_{\langle i,p\rangle} = w_i[p]w_i[p+1 \bmod |w_i|]w_i[p+2 \bmod |w_i|],\ldots$. The multiset of all cyclic suffixes of W is defined as $\mathrm{suf}(W) := \{\!\{W_{\langle i,p\rangle} \ : \ \langle i,p\rangle \in \mathrm{pos}(W)\}\!\}$. We say that a string x occurs at position $\langle i,p\rangle$ in W if x is a prefix of the suffix $W_{\langle i,p\rangle}$.

The *(cyclic) suffix array* of a multiset of strings W is an array SA_W containing a permutation of $\mathrm{pos}(W)$ such that $W_{\mathrm{SA}_W[j-1]} \le W_{\mathrm{SA}_W[j]}$ for all $j \in [1..n)$. The *Burrows-Wheeler transform* (BWT) is a mapping from W into the string v defined as $v[j] = w_i[p-1 \bmod |w_i|]$, where $\langle i,p\rangle = \mathrm{SA}_W[j]$, i.e., $v[j]$ is the character preceding the beginning of the suffix $W_{\mathrm{SA}_W[j]}$. The BWT is the inverse of IBWT [24, 20].

The *longest-common-prefix array* $\mathrm{LCP}_W[1..n)$ is defined as $\mathrm{LCP}_W[j] = \mathrm{lcp}\big(W_{\mathrm{SA}_W[j-1]}, W_{\mathrm{SA}_W[j]}\big)$ for $0 < j < n$, where $\mathrm{lcp}(x,y)$ is the length of the longest common prefix between the strings x and y.

▶ **Example 3.** For $W = \{\!\{ab,\ aab,\ aab\}\!\}$ we have

$$\begin{aligned}\mathrm{suf}(W) &= \{\!\{(aab)^\omega, (aab)^\omega, (aba)^\omega, (aba)^\omega, (ab)^\omega, (baa)^\omega, (baa)^\omega, (ba)^\omega\}\!\}\\ \mathrm{SA}_W &= \big[\langle 2,0\rangle,\ \langle 3,0\rangle,\ \langle 2,1\rangle,\ \langle 3,1\rangle,\ \langle 1,0\rangle,\ \langle 2,2\rangle,\ \langle 3,2\rangle,\ \langle 1,1\rangle\big]\\ \mathrm{LCP}_W &= \big[\omega, 1, \omega, 3, 0, \omega, 2\big].\end{aligned}$$

The suffixes represented by the suffix array entries can also be expressed as follows.

▶ **Lemma 4.** *For $i \in [0..n)$, $W_{\mathrm{SA}_W[i]} = \widehat{v}[i]\widehat{v}[\Psi_v(i)]\widehat{v}[\Psi_v^2(i)]\widehat{v}[\Psi_v^3(i)]\ldots$.*

2.1 Intervals

Many algorithms on suffix arrays and LCP arrays are based on iterating over a specific types of array intervals. Next, we define these intervals and establish their key properties. For proofs and further details, we refer to [1, 26].

Let $v \in \{a,b\}^n$ and $W = IBWT(v)$. Let $\mathrm{SA} = \mathrm{SA}_W$ be the suffix array and $\mathrm{LCP} = \mathrm{LCP}_W$ the LCP array of W. Note that from now on, we will assume a binary alphabet.

▶ **Definition 5** (x-interval)**.** An interval $[i..j)$, $0 \le i \le j \le n$, is called the x-interval ($x \in \Sigma^*$) if and only if (1) x is not a prefix of $W_{\mathrm{SA}[i-1]}$ (or $i = 0$), (2) x is a prefix of $W_{\mathrm{SA}[k]}$ for all $k \in [i..j)$, and (3) x is not a prefix of $W_{\mathrm{SA}[j]}$ (or $j = n$).

In other words, in the suffix array the x-interval $\mathrm{SA}[i..j)$ consists of all suffixes of W with x as a prefix. Thus the size $j-i$ of the interval is the number of occurrences of x in W, which we will denote by n_x.

▶ **Definition 6** (ℓ-interval)**.** An interval $[i..j)$, $0 \le i < j \le n$, is called an ℓ-interval ($\ell \in \mathbb{N} \cup \{\omega\}$) if and only if (1) $LCP[i] < \ell$ (or $i = 0$), (2) $\min \mathrm{LCP}[i+1..j) = \ell$ (where $\min \mathrm{LCP}[j..j) = \omega$), and (3) $LCP[j] < \ell$ (or $j = n$).

▶ **Lemma 7.** *Every nonempty x-interval is an ℓ-interval for some (unique) $\ell \ge |x|$. Every ℓ-interval is an x-interval for some string x of length ℓ.*

▶ **Corollary 8.** *If an x-interval $[i..j)$ is an ℓ-interval for $\ell > |x|$, there exists a (unique) string y of length $\ell - |x|$ such that $[i..j)$ is the xy-interval.*

Thus the ℓ-intervals represent the set of all distinct x-intervals. This and the fact that the total number of ℓ-intervals is $\mathcal{O}(n)$ are the basis of many efficient algorithms for suffix arrays, see e.g., [1, 26].

Algorithm 1: Infer BWT from an LCP array.

Input: an array $\mathrm{LCP}[1..n)$ of integers and ω's
Output: a string $v \in \{a,b\}^n$ such that $\mathrm{LCP}_{\mathrm{IBWT}(v)} = \mathrm{LCP}$ together with a set S of swap intervals, or **false** if there is no such string v

```
1  S := ∅;
2  preprocess LCP for RMQs;
3  k := RMQ_LCP[1..n);
4  if LCP[k] ≠ 0 then
5      if LCP[k] = ω then return a^n, ∅;
6      else return false;
7  InferInterval([0,n), [0,k), [k,n));
8  compute W = IBWT(v), SA_W, and LCP_W;
9  if LCP_W ≠ LCP then return false;
10 return v, S;
```

3 Algorithm for BCSSILA

We are now ready to describe the algorithm for string inference from an LCP array. Given an LCP array $\mathrm{LCP}[1..n)$, our goal is to construct a string $v \in \{a,b\}^n$ such that $\mathrm{LCP} = \mathrm{LCP}_{\mathrm{IBWT}(v)}$. At first, we assume that such a string v exists, and consider later what happens if the input is not a valid LCP array.

Let $\mathrm{RMQ}_{\mathrm{LCP}}[i..j)$ denote the *range minimum query* over the LCP array that returns the position of the minimum element in $\mathrm{LCP}[i..j)$, i.e., $\mathrm{RMQ}_{\mathrm{LCP}}[i..j) = \arg\min_{k\in[i..j)} \mathrm{LCP}[k]$. The LCP array is preprocessed in linear time so that any RMQ can be answered in constant time (see for instance [26]). Then any x-interval can be split into two subintervals as shown in the following result.

▶ **Lemma 9.** *Let $[i..j)$ be an x-interval and an ℓ-interval for $\ell < \omega$, and let $k = \mathrm{RMQ}_{\mathrm{LCP}}[i+1..j)$. Then, for some string y of length $\ell - |x|$, $[i..k)$ is the xya-interval and $[k..j)$ is the xyb-interval.*

This approach makes it easy to recursively enumerate all ℓ-intervals. We will also keep track of ax- and bx-intervals together with any x-interval, even if we do not know x precisely. From the intervals we can determine the numbers of occurrences, n_{ax} and n_{bx}, which are useful in the inference of v:

▶ **Lemma 10.** *Let $[i..j)$ be the x-interval. Then $v[i..j)$ contains exactly n_{ax} a's and n_{bx} b's.*

In particular, when either n_{ax} or n_{bx} drops to zero, we have fully determined $v[i..j)$ for the x-interval $[i..j)$. In such a case, the LCP array intervals have to satisfy the following property.

▶ **Lemma 11.** *Let $[i_y..j_y)$ be the y-interval for $y \in \{x, ax, bx\}$. If $n_{ax} = j_{ax} - i_{ax} = 0$, then $\mathrm{LCP}[i_{bx}+1..j_{bx}) = 1 + \mathrm{LCP}[i_x+1..j_x)$, where $1+A$, for an array A, denotes adding one to all elements of A. Symmetrically, if $n_{bx} = 0$, then $\mathrm{LCP}[i_{ax}+1..j_{ax}) = 1 + \mathrm{LCP}[i_x+1..j_x)$.*

The main procedure is given in Algorithm 1. The main work is done in the recursive procedure InferInterval given in Algorithm 2. The procedure gets as input the x-, ax- and bx-intervals for some (unknown) string x, splits the x-interval into xya- and xyb-subintervals

Algorithm 2: InferInterval($[i_x..j_x)$, $[i_{ax}..j_{ax})$, $[i_{bx}..j_{bx})$).

Input: (nonempty) x-, ax- and bx-intervals
Output: Set $v[i_x..j_x)$ and add the swap intervals within $[i_x..j_x)$ to S

```
1  k_x := RMQ_LCP[i_x + 1..j_x); m_x := LCP[k_x];
2  if j_ax − i_ax = 1 then k_ax := i_ax; m_ax := ω;
3  else k_ax := RMQ_LCP[i_ax + 1..j_ax); m_ax := LCP[k_ax];
4  if j_bx − i_bx = 1 then k_bx := i_bx; m_bx := ω;
5  else k_bx := RMQ_LCP[i_bx + 1..j_bx); m_bx := LCP[k_bx];
6  if m_ax > m_x + 1 and m_bx > m_x + 1 then
7      if LCP[i_ax + 1..j_ax) = 1 + LCP[i_x + 1..k_x) then
8          v[i_x..k_x) = aa...a; v[k_x..j_x) = bb...b;
9          if LCP[i_ax + 1..j_ax) = 1 + LCP[k_x + 1..j_x) then add [i_x..j_x) to S ;
10     else
11         v[i_x..k_x) = bb...b; v[k_x..j_x) = aa...a;
12 else if m_ax > m_x + 1 then
13     if k_bx − i_bx = k_x − i_x then
14         v[i_x..k_x) = bb...b;
15         InferInterval([k_x..j_x), [i_ax..j_ax), [k_bx..j_bx));
16     else
17         v[k_x..j_x) = bb...b;
18         InferInterval([i_x..k_x), [i_ax..j_ax), [i_bx..k_bx));
19 else if m_bx > m_x + 1 then
20     if k_ax − i_ax = k_x − i_x then
21         v[i_x..k_x) = aa...a;
22         InferInterval([k_x..j_x), [k_ax..j_ax), [i_bx..j_bx));
23     else
24         v[k_x..j_x) = aa...a;
25         InferInterval([i_x..k_x), [i_ax..k_ax), [i_bx..j_bx));
26 else
27     InferInterval([i_x..k_x),[i_ax..k_ax),[i_bx..k_bx));
28     InferInterval([k_x..j_x),[k_ax..j_ax),[k_bx..j_bx));
```

based on Lemma 9, and tries to split ax- and bx-intervals similarly. If all subintervals are nonempty, the algorithm processes the two subinterval triples recursively (lines 27 and 28).

When trying to split the ax-interval, the result may be, for example, that the $axya$-interval is empty. In this case, we do not need to recurse on the xya-interval since the corresponding part of v must be all b's. The algorithm recognizes the emptiness of $axya$- or $axyb$-interval by the fact that $m_{ax} > m_x + 1$, but the problem is to decide which is the empty one. In most cases, this can be determined by comparing the sizes of the different subintervals or even the actual LCP-intervals (see Lemma 11).

There is one case, where the algorithm is unable to determine the empty subintervals, which is when $\mathrm{LCP}[i_{ax}{+}1..j_{ax}) = \mathrm{LCP}[i_{bx}{+}1..j_{bx}) = 1{+}\mathrm{LCP}[i_x{+}1..k_x) = 1{+}\mathrm{LCP}[k_x{+}1..j_x)$. Then, either the $axya$- and $bxyb$-intervals are empty or the $axyb$- and $bxya$-intervals are empty, but there is no way of deciding between the two cases. It turns out that both are valid

choices. The algorithm sets v according to one choice (line 8) but records the alternative choice by adding the interval to the set S. In such a case, the string xy is called a *swap core* and the xy-interval (equal to the x-interval) is called a *swap interval*.

For each swap interval $[i..j)$, the algorithm sets $v[i..k) = aa\dots a$ and $v[k..j) = bb\dots b$, where $k = (i+j)/2$, but swapping the two halves would be an equally good choice. Therefore, if the output of the algorithm contains s swap intervals, it represents a set of 2^s distinct strings. The following lemma shows that the swaps indeed do not affect the LCP array (the proof can be found in [21]).

▶ **Lemma 12.** *Let $v \in \{a,b\}^n$, $W = \mathrm{IBWT}(v)$, $\mathrm{SA} = \mathrm{SA}_W$ and $\mathrm{LCP} = \mathrm{LCP}_W$. Let x be a string that occurs in W and satisfies: (1) $\mathrm{LCP}[i_{xa}+1..j_{xa}) = \mathrm{LCP}[i_{xb}+1..j_{xb})$, and (2) $v[i_{xa}..j_{xa}) = aa\dots a$ and $v[i_{xb}..j_{xb}) = bb\dots b$, where $[i_z..j_z)$ is the z-interval for $z \in \{xa, xb\}$. Let v' be the same as v except that $v'[i_{xa}..j_{xa}) = bb\dots b$ and $v'[i_{xb}..j_{xb}) = aa\dots a$. Then $\mathrm{LCP}_{\mathrm{IBWT}(v')} = \mathrm{LCP}$.*

▶ **Theorem 13.** *Algorithm 1 computes in linear time a representation of the set of all strings $v \in \{a,b\}^*$ such that $\mathrm{LCP}_{\mathrm{IBWT}(v)}$ is the input array, or returns false if no such string exists.*

Proof. Since the algorithm verifies its result (lines 9 and 10), it will return false if the input is not a valid LCP array. Given a valid LCP array, Algorithm 2 sets all elements of v since it recurses on any subinterval that it doesn't set. All the choices made by the algorithm are forced by the lemmas in this and the previous section. The swap intervals record all alternatives in the cases where the content of v could not be fully determined, and all of those alternatives have the same LCP array by Lemma 12. It is also easy to see that the algorithm runs in linear time. ◀

4 Coupling Constrained Eulerian Cycle

We will now set out to prove the NP-completeness of the single string inference problems BCSILA and BTSILA. The proofs are done by a reduction from 3-SAT via an intermediate problem called Coupling Constrained Eulerian Cycle (CCEC) described in this section.

Consider a directed graph G of degree two, i.e., every vertex in G has exactly two incoming and two outgoing edges. If G is connected, it is Eulerian. An Eulerian cycle can pass through each vertex in two possible ways, which we call the *straight state* and the *crossing state* of the vertex as illustrated here:

We consider each vertex to be a *switch* that can be flipped between these two states. The combination of vertex states is called the *graph state*. For a given graph state, the paths in the graph form, in general, a collection of cycles. The Eulerian cycle problem can then be stated as finding a graph state such that there is only a single cycle; we call such a graph state Eulerian.

In the *Coupling Constrained Eulerian Cycle (CCEC) problem*, we are given a graph as described above, an initial graph state, and a partitioning of the set of vertices. If we flip a vertex state, we must simultaneously flip the states of all the vertices in the same partition, i.e., the vertices in a partition are coupled. A graph state that is achievable from the initial state by a set of such *partition flips* is called a *feasible state*. The CCEC problem is to determine if there exists a feasible graph state that is Eulerian.

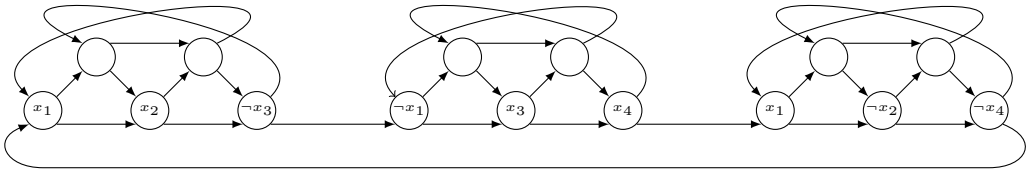


Figure 1 The CCEC graph corresponding to a 3-CNF formula $(x_1 \vee x_2 \vee \neg x_3) \wedge (\neg x_1 \vee x_3 \vee x_4) \wedge (x_1 \vee \neg x_2 \vee \neg x_4)$.

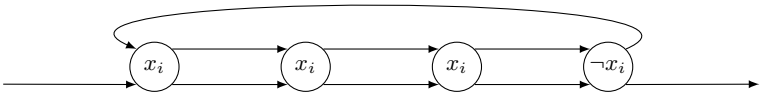
▶ **Theorem 14.** *CCEC is NP-complete.*

Proof. The proof is by reduction from 3-SAT. To obtain a CCEC graph from a 3-CNF formula, a gadget of five vertices is constructed from each clause and these gadgets are connected by a cycle. In each gadget, three of the vertices are labeled by the literals of the corresponding clause; the other two are called free vertices. See Fig. 1 for an illustration.

Each labeled vertex is in a straight state if the labeling literal is false and in a crossing state if the literal is true; their initial state corresponds to some arbitrary truth assignment to the variables. For each variable x_i, there is a vertex partition consisting of all vertices labeled by x_i or $\neg x_i$, so that flipping this partition corresponds to changing the truth value of x_i. Each free vertex forms a singleton partition and has an arbitrary initial state. Thus a graph state is feasible iff the labeled vertex states correspond to some truth assignment.

If a clause is false for a given truth assignment, the labeled vertices in the corresponding gadget are all in a straight state. This separates a part of the gadget from the main cycle and thus the graph state is not Eulerian. If a clause is true, at least one of the labeled vertices in the gadget is in a crossing state. Then we can always choose the state of the free vertices so that the full gadget is connected to the main cycle. Thus there exists a feasible Eulerian graph state iff there exists a truth assignment to the variables that satisfies all clauses. ◀

For purposes that will become clear later, we modify the above construction by adding some extra components to the graph without changing the validity of the reduction. Specifically, for each variable x_i in the 3-CNF formula we add the following gadget to the main cycle:



The vertices in the gadget are treated similarly to the other vertices in the graph: they belong to the partition with the other vertices labeled by x_i or $\neg x_i$, and the initial state is determined by the truth value of the labeling literal. It is easy to see that the gadget will be fully connected to the main cycle whether x_i is true or false. Thus the extra gadgets have no effect on the existence of an Eulerian cycle. Finally, we insert to the main cycle a single vertex labelled y with a self loop and forming a singleton partition.

5 BCSILA to CCEC

The next step is to establish a connection between the BCSILA and CCEC problems by showing a reduction from BCSILA to CCEC. Although the direction of the reduction is opposite to what we want, this construction plays a key role in the analysis of the main construction described in the next section.

Given a BCSILA instance (an integer array), we use Algorithm 1 to produce a representation of a set V of strings. The problem is then to decide if there exists $v \in V$ such that

IBWT(v) is a single (cyclic) string. We will write V as a string with brackets marking the swaps. For example, $V = b[ab][ab]a = \{bababa, babbaa, bbaaba, bbabaa\}$. In Example 2, we saw that the inverse BWT of a string $v \in V$ can be represented as a graph G_v where the vertices are labeled by positions in v and there is an edge between vertices i and j if, for some character $c \in \{a, b\}$ and some integer k, $\widehat{v}[i] = c$ is the kth occurrence of c in $\widehat{v}$ and $v[j] = c$ is the kth occurrence of c in v. Such an edge (i, j) is labeled by c_k. Note that $\forall v \in V$, $\widehat{v}$ is the same; we will denote it by $\widehat{V}$. We form a generalized graph G_V as a union of the graphs G_v, $v \in V$.

Consider a_k (the kth a) in $\widehat{V}$, say at position i. If a_k is outside any swap region in V, say at position j, there is a single edge (i, j) in G_V labeled by a_k. If a_k is within a swap region in V, it has two possible positions in the strings $v \in V$, say j and j'. That same pair of positions are also the possible positions of some b, say $b_{k'} = \widehat{V}[i']$. Then g_v has two edges, (i, j) and (i, j'), labeled with a_k and two edges, (i', j) and (i', j'), labeled with $b_{k'}$. The positions/vertices j and j' are called a *swap pair*.

To obtain a CCEC graph $\widetilde{G}_V$, we make two modifications to G_V. First, we merge each swap pair into a single vertex. Each merged vertex now has two incoming and two outgoing edges and all other vertices have one incoming and one outgoing edge. Second, we remove all vertices with degree one by concatenating their incoming and outgoing edges.

The initial state of the vertices in $\widetilde{G}_V$ is set so that the cycles in $\widetilde{G}_V$ correspond to the cycles in G_v for some $v \in V$. Two vertices in $\widetilde{G}_V$ belong to the same partition if their labels belong to the same swap interval in V. Then we have a one-to-one correspondence between swaps in V and partition flips in $\widetilde{G}_V$. If this CCEC instance has a solution, the Eulerian cycle spells a single string realizing the input LCP array. If the CCEC instance has no solution, the original BCSILA problem has no solution either.

6 BCSILA is NP-Complete

We are now ready to show that BCSILA is NP-complete using the reduction chain 3-SAT $\rightarrow$ CCEC $\rightarrow$ BCSILA. The first step was described in Section 4, and we will next describe the second. The latter reduction is not a general reduction from an arbitrary CCEC instance but works only for a CCEC instance obtained by the first reduction (including the extra gadgets).

The above BCSILA to CCEC reduction transforms each pair of swapped positions into a vertex and each swap interval into a vertex partition. Our construction creates a BCSILA instance such that the resulting BWT has the necessary swaps to produce the CCEC instance vertices and partitions. However, the BWT also has some unwanted swaps producing spurious vertices, but we will show that these spurious vertices do not invalidate the reduction.

Starting from a CCEC instance, we construct a set of cyclic strings and obtain the BCSILA instance as the LCP array of that string set. The construction associates two strings to each vertex and the cyclic strings are formed by concatenating the vertex strings according to the cycles in the graph in its initial state. The two passes of the cycles through a vertex must use different strings but it does not matter which pass uses which string.

Let n be the number of vertices in the CCEC graph and let m be the number of vertex partitions. We number the vertices from 1 to n and the partitions from 1 to m. The biggest partition number is assigned to the partition with the vertex y, the second biggest to the partition corresponding to the variable x_1, the third biggest to variable x_2, and so on. The three biggest vertex numbers are assigned to the vertices labeled x_1 in the extra gadget for the variable x_1, the next three biggest to the extra gadget vertices labeled x_2 and so on.

Within each extra gadget, the biggest number is assigned to the middle one of the three vertices. The strings associated with a vertex are ba^kba^{m+2h} and bba^kbba^{m+2h-1}, where k is the partition number and h is the vertex number. This completes the description of the transformation from a CECC instance to a BCSILA instance.

Let us now analyze the transformation by changing the BCSILA instance back to a CCEC instance using the construction of the preceding section. Specifically, we will analyze the swaps in the BWT produced from the LCP array. Let W be the set of cyclic strings constructed from the CCEC instance, and let V be the BWT with swaps constructed from LCP_W. An interval $[i..j)$ in V is a swap interval if and only if (1) $[i..j)$ is an x-interval for a string x such that either $occ(axa) = occ(bxb) = occ(x)/2$ or $occ(axb) = occ(bxa) = occ(x)/2$, where $occ(y)$ is the number of occurrences of y in W, and (2) $\mathrm{LCP}_W[i+1..k) = \mathrm{LCP}_W[k+1..j)$, where $k = (i+j)/2$. If $[i..j)$ is a swap interval, the string x is called its *swap core*. Our goal is to identify all swap cores.

Let us first consider strings of the form $x = ba^kb$. If $k > m$, $occ(x) \leq 1$ and x cannot be a swap core. For $k \in [1..m]$, x is always a swap core and corresponds to the CCEC partition numbered k. Let $v = \mathrm{BWT}(W)$ and let V' be v together with the swaps for cores of the form $x = ba^kb$, $k \in [1..m]$. It is easy to verify that a CCEC instance constructed from V' as described in the previous section is identical to the original CCEC instance. Thus, if there were no other swap cores, we would have a perfect reduction.

Unfortunately, there are other swap cores. A systematic examination of all strings (see [21] for details) shows that the other swap cores must be of the following forms: ba^{m+2n-1}, $a^{m+2n-1}b$, a^mba^m, a^mbba^m,a^kba^h, a^kbba^h, $a^kba^iba^h$ and $a^kbba^ibba^h$. Furthermore, it shows that each such swap core has exactly two occurrences, which means that the values k and/or h have to be sufficiently large. Each extra swap core adds a free vertex that is connected to the graph by making two existing edges to pass through the new vertex. Because of the way we chose to assign the biggest partition and vertex numbers, all the additional connections are within the extra gadgets, which does not change the existence of an Eulerian cycle. This completes the proof.

▶ **Theorem 15.** *BCSILA is NP-complete.*

7 BTSILA is NP-Complete

We will now show that BTSILA is NP-complete by modifying the above reduction for BCSILA to include a single terminator symbol \$ in the strings. The modification is applied to the set W of cyclic strings derived from the CCEC instance such that LCP_W is the BCSILA instance. Specifically, we replace the (unique) occurrence of a^{m+2n}, which is the longest consecutive run of a's, with $a^{m+2n+1}\$a^{m+2n}$ to obtain $W_\$$ and $\mathrm{LCP}_{W_\$}$. We will show that $\mathrm{LCP}_{W_\$}$ is a yes-instance of CSILA iff LCP_W is a yes-instance of BCSILA. Furthermore, if a cyclic string u is a solution to the CSILA instance, i.e., $\mathrm{LCP}_u = \mathrm{LCP}_{W_\$}$, then $\mathrm{LCP}_v = \mathrm{LCP}_{W_\$}$, where v is the rotation of u ending with \$ interpreted as a terminated string. Thus $\mathrm{LCP}_{W_\$}$ is a yes-instance of BTSILA iff it is a yes-instance of CSILA iff LCP_W is a yes-instance of BCSILA.

In general, adding even a single occurrence of a third symbol complicates the inference of the BWT from the LCP array and means that the set of equivalent BWTs can no more be described by a set of swaps. Consider how the operation of the procedure InferInterval (Algorithm 2) changes. First, it gets an extra $\$x$-interval as an input in addition to x-, ax- and bx-intervals. Second, the x-interval may be split into three subintervals, $xy\$$-, xya- and xyb-intervals, instead of two (which happens when the LCP interval contains two identical

minima). This leads to many more combinations to consider, and some of those combinations are more complicated.

Fortunately, in our case, having the single \$ surrounded by the two longest runs of a's simplifies things, and we will describe a modification of InferInterval to handle this case. Every call to InferInterval belongs to one of the following three types: (1) the x-interval is split into two and the $\$x$-interval is empty, (2) the x-interval is split into two and the $\$x$-interval is non-empty, and (3) the x-interval is split into three. The first case needs no modification at all. The other two cases mean that either $\$x$ or $x\$$ occurs in the produced string set, and since this property is not affected by swaps (or the threeway permutations described below), one of them occurs in every produced string set including $W_\$$. Since x must occur at least twice, one of the latter two cases happens iff $x = a^k$ for some $k \in [0..m + 2n]$. Although in general InferInterval cannot always know x, it is easy to keep track of x when $x = a^k$.

When InferInterval is called with $x = a^k$ for $k \leq m + 2n - 2$, the x-interval and the ax-interval are always split into three, the bx-interval is split into two, and there is a $\$x$-interval of size one. In general, we might not know whether the two subintervals of bx-interval are $bx\$$- and bxa-, or $bx\$$- and bxb-, or bxa- and bxb-intervals. However, since $x\$$- and $ax\$$-intervals both have size one, there can be no $bx\$$-interval, and thus all the subintervals can be uniquely determined and recursed on. When $x = a^{m+2n-1}$, the x-interval has size five and is split into three with the middle part (xa-interval) having size three. The ax interval has size three and is split into three. In this case too, only one combination of subintervals is possible.

When $x = a^{m+2n}$, the x-interval has size three and is split into three, and the $\$x$-, ax- and bx-intervals have size one. Therefore, the x-interval in the BWT contains some permutation of the three characters and all permutations are valid. This threeway permutation adds to the variation provided by the swaps in other parts of the BWT. A more careful analysis shows that the BWT x-interval of

- $\$ab$ or $\$ba$ implies an occurrence of $\$x\$$ which is only possible if $x\$$ is a separate string;
- $ba\$$ implies an occurrence of axa which is only possible if a single a is separate string;
- $a\$b$ implies occurrences of $ax\$$ and $\$xa$ which is only possible if $ax\$$ is a separate string;
- $ab\$$ implies an occurrence of $ax\$xb$; and
- $b\$a$ implies an occurrence of $bx\$xa$.

A single string solution is only possible in the last two cases, and any such solution corresponds to a solution for the BCSILA instance LCP_W (obtained by replacing $ax\$x$ or $x\$ax$ with x). Hence $\mathrm{LCP}_{W_\$}$ is a yes-instance of CSILA, and thus of BTSILA, if and only if LCP_W is a yes-instance of BCSILA, which proves the following result.

▶ **Theorem 16.** *BTSILA is NP-complete.*

8 Algorithm for CSSILA

In all of the above, we have assumed a binary alphabet (excluding the single symbol \$). In this section, we consider the CSSILA problem (i.e. Cyclic String Set Inference from LCP Array) without a restriction on the alphabet size (see [21] for more details).

Let $\mathcal{L}[1..n)$ be an instance of the CSSILA problem, i.e., an array of integers (and possibly ω's). Let $\sigma - 1$ be the number of zeroes in $\mathcal{L}$, and Σ an alphabet of size σ. As with the binary BCSSILA problem, we describe an algorithm that outputs a representation of the set $W_\mathcal{L} = \{w \in \Sigma^n : \mathrm{LCP}_{\mathrm{IBWT}(w)} = \mathcal{L}\}$; in this case the representation is an automaton that accepts $W_\mathcal{L}$. We show the following result.

▶ **Theorem 17.** *Given an array $\mathcal{L}[1..n)$ of integers (and possibly ω's) containing $\sigma-1$ zeroes, we can construct a deterministic finite automaton recognizing $W_{\mathcal{L}}$ in time $O(\sigma^2 2^\sigma(\frac{n}{\sigma}+1)^\sigma)$ and space $O(\sigma 2^\sigma(\frac{n}{\sigma}+1)^\sigma)$.*

Abstract

We prove that whenever G is a graph from a nowhere dense graph class $\mathcal{C}$, and A is a subset of vertices of G, then the number of subsets of A that are realized as intersections of A with r-neighborhoods of vertices of G is at most $f(r,\varepsilon)\cdot|A|^{1+\varepsilon}$, where r is any positive integer, ε is any positive real, and f is a function that depends only on the class $\mathcal{C}$. This yields a characterization of nowhere dense classes of graphs in terms of *neighborhood complexity*, which answers a question posed by Reidl et al. [26]. As an algorithmic application of the above result, we show that for every fixed integer r, the parameterized Distance-r Dominating Set problem admits an almost linear kernel on any nowhere dense graph class. This proves a conjecture posed by Drange et al. [9], and shows that the limit of parameterized tractability of Distance-r Dominating Set on subgraph-closed graph classes lies exactly on the boundary between nowhere denseness and somewhere denseness.

1 Introduction

Sparse graphs. The notion of nowhere denseness was introduced by Nešetřil and Ossona de Mendez [23, 24] as a general model of *uniform sparseness* of graphs. Many familiar classes of sparse graphs, like planar graphs, graphs of bounded treewidth, graphs of bounded degree, and, in fact, all classes that exclude a fixed (topological) minor, are nowhere dense. Notably, classes of bounded average degree or bounded degeneracy are not necessarily nowhere dense. In an algorithmic context this is reasonable, as every graph can be turned into a graph of degeneracy at most 2 by subdividing every edge once; however, the structure of the graph is essentially preserved under this operation.

▶ **Definition 1.** A *minor model* of a graph H in G is a family $(I_u)_{u\in V(H)}$ of pairwise vertex-disjoint connected subgraphs of G such that whenever $\{u,v\}$ is an edge in H, there are $u' \in I_u$ and $v' \in I_v$ for which $\{u',v'\}$ is an edge in G. The graph H is a *depth-r minor* of G, denoted $H \preccurlyeq_r G$, if there is a minor model $(I_u)_{u\in V(H)}$ of H in G such that each subgraph I_u has radius at most r.

▶ **Definition 2.** A class $\mathcal{C}$ of graphs is *nowhere dense* if there is a function $t : \mathbb{N} \to \mathbb{N}$ such that $K_{t(r)} \not\preccurlyeq_r G$ for all $r \in \mathbb{N}$ and all $G \in \mathcal{C}$.

Nowhere denseness turns out to be a very robust concept with several seemingly unrelated natural characterizations. These include characterizations by the density of shallow (topological) minors [23, 24], quasi-wideness [24] (a notion introduced by Dawar [6] in his study of homomorphism preservation properties), low tree-depth colorings [20], generalized coloring numbers [29], sparse neighborhood covers [16, 17], by a game called the splitter game [17] and by the model-theoretic concepts of stability and independence [1]. For a broader discussion we refer to the book of Nešetřil and Ossona de Mendez [25].

An important and related concept is the notion of a graph class of *bounded expansion* [20, 21, 22]. Precisely, a class of graphs $\mathcal{C}$ has bounded expansion if for any $r \in \mathbb{N}$, the ratio between the numbers of edges and vertices in any r-shallow minor of a graph from $\mathcal{C}$ is bounded by a constant depending on r only. Obviously, every class of bounded expansion is also nowhere dense, but the converse is not always true.

Domination problems. In the parameterized Dominating Set problem we are given a graph G and an integer parameter k, and the task is to determine the existence of a subset $D \subseteq V(G)$ of size at most k such that every vertex u of G is *dominated* by D, that is, u either belongs to D or has a neighbor in D. More generally, for fixed $r \in \mathbb{N}$ we can consider the Distance-r Dominating Set problem, where we are asked to determine the existence of a subset $D \subseteq V(G)$ of size at most k such that every vertex $u \in V(G)$ is within distance at most r from a vertex from D. The Dominating Set problem plays a central role in the theory of parameterized complexity, as it is a prime example of a W[2]-complete problem again with k as the paramenter, thus considered intractable in full generality from the parameterized point of view. For this reason, Dominating Set and Distance-r Dominating Set have been extensively studied in restricted graph classes, including the sparse setting.

The study of parameterized algorithms for Dominating Set on sparse and topologically constrained graph classes has a long history, and, arguably, it played a pivotal role in the development of modern parameterized complexity. A point of view that was particularly fruitful, and most relevant to our work, is *kernelization*. Recall that a kernelization algorithm is a polynomial-time preprocessing algorithm that transforms a given instance into an

equivalent one whose size is bounded by a function of the parameter only, independently of the overall input size. We are mostly interested in kernelization algorithms whose output guarantees are polynomial in the parameter, or maybe even linear. For Dominating Set on topologically restricted graph classes, linear kernels were given for planar graphs [2], bounded genus graphs [3], apex-minor-free graphs [12], graphs excluding a fixed minor [13], and graphs excluding a fixed topological minor [14]. All these results relied on applying tools of topological nature, most importantly deep decomposition theorems for graphs excluding a fixed (topological) minor. Notably, the research on kernelization for Dominating Set directly led to the introduction of the technique of *meta-kernelization* [3], which applies to a much larger family of problems on bounded-genus and H-minor-free graph classes.

Dawar and Kreutzer [7] showed that for every $r \in \mathbb{N}$ and every nowhere dense class $\mathcal{C}$, Distance-r Dominating Set is fixed-parameter tractable on $\mathcal{C}$. As far as polynomial kernelization is concerned, Drange et al. [9] gave a linear kernel for Distance-r Dominating Set on any graph class of bounded expansion[1], for every $r \in \mathbb{N}$, and an almost linear kernel for Dominating Set on any nowhere dense graph class; that is, a kernel of size $f(\varepsilon) \cdot k^{1+\varepsilon}$ for some function f. Drange et al. could not extend their techniques to larger domination radii r on nowhere dense classes, however, they conjectured that this should be possible. An important step was made recently by a subset of the authors [18], who gave a polynomial kernel for Distance-r Dominating Set on any nowhere dense class $\mathcal{C}$.

Nowhere dense classes are the limit for the fixed-parameter tractability of the problem: Drange et al. [9] showed that whenever $\mathcal{C}$ is a somewhere dense class closed under taking subgraphs, there is some $r \in \mathbb{N}$ for which Distance-r Dominating Set is $\mathsf{W}[2]$-hard on $\mathcal{C}$.

Neighborhood complexity. One of the crucial ideas in the work of Drange et al. [9] was to focus on the *neighborhood complexity* in sparse graph classes. For an integer $r \in \mathbb{N}$, a graph G, and a subset $A \subseteq V(G)$ of vertices of G, the *r-neighborhood complexity* of A, denoted $\nu_r(G, A)$, is defined as the number of different subsets of A that are of the form $N_r[u] \cap A$ for some vertex u of G; here, $N_r^G[u]$ denotes the ball of radius r around u. That is,

$$\nu_r(G, A) = |\{N_r^G[u] \cap A \ : \ u \in V(G)\}|.$$

It was proved by Reidl et al. [26] that linear neighborhood complexity exactly characterizes subgraph-closed classes of bounded expansion. More precisely, a subgraph-closed class $\mathcal{C}$ has bounded expansion if and only if for each $r \in \mathbb{N}$ there is a constant c_r such that $\nu_r(G, A) \leq c_r \cdot |A|$ for all graphs $G \in \mathcal{C}$ and vertex subsets $A \subseteq V(G)$. They posed as an open problem whether nowhere denseness can be similarly characterized by almost linear neighborhood complexity. The lack of a neighborhood complexity theorem for nowhere dense classes was a major, however not the only, obstacle preventing Drange et al. [9] from extending their kernelization results to Distance-r Dominating Set on any nowhere dense class. The neighborhood complexity result for nowhere dense classes for $r = 1$ was given by Gajarský et al. [15], and this result was used by Drange et al. [9] in their kernelization algorithm for Dominating Set (distance $r = 1$) on nowhere dense graph classes.

Conversely, if $\mathcal{C}$ is somewhere dense and closed under taking subgraphs, then for some $r \in \mathbb{N}$ it contains the exact r-subdivision of every graph [24]. In this case it is easy to see that the r-neighborhood complexity of a vertex subset A can be as large as $2^{|A|}$.

[1] Precisely, the kernelization algorithm of Drange et al. [9] outputs an instance of an annotated problem where some vertices are not required to be dominated; this will be the case in this paper as well.

Our results. In this paper we resolve in the affirmative both outlined conjectures. Let us first focus on neighborhood complexity.

▶ **Theorem 3.** *Let $\mathcal{C}$ be a graph class closed under taking subgraphs. Then $\mathcal{C}$ is nowhere dense if and only if there exists a function $f_{\mathrm{nei}}(r,\varepsilon)$ such that $\nu_r(G,A) \leq f_{\mathrm{nei}}(r,\varepsilon)\cdot|A|^{1+\varepsilon}$ for all $r\in\mathbb{N}$, $\varepsilon>0$, $G\in\mathcal{C}$, and $A\subseteq V(G)$.*

To prove the above, we carefully analyze the argument of Reidl et al. [26] for linear neighborhood complexity in classes of bounded expansion. This argument is based on the analysis of vertex orderings certifying the constant upper bound on the *weak coloring number* of any graph from a fixed class of bounded expansion. In the nowhere dense setting, we only have an n^{ε} upper bound on the weak coloring number, and therefore the reasoning breaks whenever one tries to use a bound that is exponential in this number. We circumvent this issue by applying tools based on model-theoretic properties of nowhere dense classes of graphs. More precisely, we use the fact that every nowhere dense class is *stable* in the sense of Shelah, and hence every graph H which is obtained from a graph G from a nowhere dense class via a first-order interpretation has bounded VC-dimension [1]. Then exponential blow-ups can be reduced to polynomial using the Sauer-Shelah Lemma. These tools were recently used by a subset of the authors to give polynomial bounds for uniform quasi-wideness [18], a fact that also turns out to be useful in our proof.

We remark that we were informed by Micek, Ossona de Mendez, Oum, and Wood [19] that they have independently proved the statement of Theorem 3 using different methods.

Having the almost linear neighborhood complexity for any nowhere dense class of graphs, we can revisit the argumentation of Drange et al. [9] and prove the following result.

▶ **Theorem 4.** *Let $\mathcal{C}$ be a fixed nowhere dense class of graphs, let r be a fixed positive integer, and let $\varepsilon>0$ be any fixed real. Then there is a polynomial-time algorithm that, given a graph $G\in\mathcal{C}$ and a positive integer k, returns a subgraph $G'\subseteq G$ and a vertex subset $Z\subseteq V(G')$ with the following properties:*

- *there is a set $D\subseteq V(G)$ of size at most k which r-dominates G if and only if there is a set $D'\subseteq V(G')$ of size at most k which r-dominates Z in G'; and*
- *$|V(G')|\leq f_{\mathrm{ker}}(r,\varepsilon)\cdot k^{1+\varepsilon}$, for some function $f_{\mathrm{ker}}(r,\varepsilon)$ depending only on the class $\mathcal{C}$.*

Just as in Drange et al. [9], the obtained triple (G',Z,k) is formally not an instance of Distance-r Dominating Set, but of an annotated variant of this problem where some vertices (precisely $V(G')\setminus Z$) are not required to be dominated. This is an annoying formal detail, however it can be addressed almost exactly as in Drange et al. by additional gadgeteering of annotations; see the full version for details.

Our proof of Theorem 4 revisits the line of reasoning of Drange et al. [9] for bounded expansion classes, and improves it in several places where the arguments could not be immediately lifted to the nowhere dense setting. The key ingredient is, of course, the usage of the newly proven almost linear neighborhood complexity for nowhere dense classes (Theorem 3), however, this was not the only piece missing. Another issue was that the algorithm of Drange et al. starts by iteratively applying the constant-factor approximation algorithm for Distance-r Dominating Set of Dvořák [10] in order to expose a certain structure in the instance. This part does not carry over to the nowhere dense setting, but we are able to circumvent it by using the new polynomial bounds for uniform quasi-wideness [18].

All proofs which are omitted in this extended abstract are marked with ($\star$). The full version of the paper can be found as an arxiv preprint [11].

2 Preliminaries

We use standard graph notation; see e.g. [8] for reference. All graphs considered in this paper are finite, simple, and undirected. For a graph G, by $V(G)$ and $E(G)$ we denote the vertex and edge sets of G, respectively.

Nowhere denseness (see Definition 2) admits several equivalent definitions, see [25] for a wider discussion. We next recall the ones used in this paper, as well as related concepts.

Weak coloring numbers. For a graph G we let $\Pi(G)$ denote the set of all linear orders of $V(G)$. For $L \in \Pi(G)$, $u, v \in V(G)$, and any $r \geq 0$, we say that u is *weakly r-reachable* from v with respect to L, if there is a path P of length at most r connecting u and v such that u is the smallest among the vertices of P with respect to L. By $\mathrm{WReach}_r[G, L, v]$ we denote the set of vertices that are weakly r-reachable from v with respect to L. For any subset $A \subseteq V(G)$, we let $\mathrm{WReach}_r[G, L, A] = \bigcup_{v \in A} \mathrm{WReach}_r[G, L, v]$. The *weak r-coloring number* $\mathrm{wcol}_r(G)$ of G is defined as

$$\mathrm{wcol}_r(G) \quad = \quad \min_{L \in \Pi(G)} \max_{v \in V(G)} \big|\mathrm{WReach}_r[G, L, v]\big|.$$

As proved by Zhu [29], the weak coloring numbers can be used to characterize bounded expansion and nowhere dense classes of graphs.

▶ **Theorem 5** ([29]). *Let $\mathcal{C}$ be a nowhere dense class of graphs. There is a function $f_{\mathrm{wcol}}(r, \varepsilon)$ such that $\mathrm{wcol}_r(H) \leq f_{\mathrm{wcol}}(r, \varepsilon) \cdot |V(H)|^{\varepsilon}$ for every $r \in \mathbb{N}$, $\varepsilon > 0$, and $H \subseteq G \in \mathcal{C}$.*

Quasi-wideness. A set $B \subseteq V(G)$ is called *r-independent* in G if for all distinct $u, v \in B$ we have $\mathrm{dist}_G(u, v) > r$.

▶ **Definition 6.** A class $\mathcal{C}$ of graphs is *uniformly quasi-wide* if there are functions $N \colon \mathbb{N} \times \mathbb{N} \to \mathbb{N}$ and $s : \mathbb{N} \to \mathbb{N}$ such that for all $r, m \in \mathbb{N}$ and all subsets $A \subseteq V(G)$ for $G \in \mathcal{C}$ of size $|A| \geq N(r, m)$ there is a set $S \subseteq V(G)$ of size $|S| \leq s(r)$ and a set $B \subseteq A \setminus S$ of size $|B| \geq m$ which is r-independent in $G - S$. The functions N and s are called the *margins* of the class $\mathcal{C}$.

It was shown by Nešetřil and Ossona de Mendez [24] that a class $\mathcal{C}$ of graphs is nowhere dense if and only if it is uniformly quasi-wide. For us it will be important that the margins N and s can be assumed to be polynomial in r and that the sets B and S can be efficiently computed. This was proved only recently by Kreutzer et al. [18].

▶ **Theorem 7** ([18]). *Let $\mathcal{C}$ be a nowhere dense class of graphs and let $t \colon \mathbb{N} \to \mathbb{N}$ be a function such that $K_{t(r)} \not\preccurlyeq_r G$ for all $r \in \mathbb{N}$ and all $G \in \mathcal{C}$. For every $r \in \mathbb{N}$ there exist constants $p(r)$ and $s(r) \leq t(r)$ such that for all $m \in \mathbb{N}$, all $G \in \mathcal{C}$, and all sets $A \subseteq V(G)$ of size at least $m^{p(r)}$, there is a set $S \subseteq V(G)$ of size at most $s(r)$ such that there is a set $B \subseteq A \setminus S$ of size at least m which is r-independent in $G - S$. Furthermore, there is an algorithm that, given an n-vertex graph $G \in \mathcal{C}$, $\varepsilon > 0$, $r \in \mathbb{N}$, and $A \subseteq V(G)$ of size at least $m^{p(r)}$, computes sets S and $B \subseteq A$ as described above in time $\mathcal{O}(r \cdot t \cdot |A|^{t+1} \cdot n^{1+\varepsilon})$.*

We remark that the running time of the algorithm of Theorem 7 is stated in the SODA version [18] only as $\mathcal{O}(r \cdot t \cdot n^{t+6})$. A finer analysis with the running times as stated above can be found in the arXiv version of that paper.

VC-dimension. Let $\mathcal{F} \subseteq 2^A$ be a family of subsets of a set A. For a set $X \subseteq A$, we denote $X \cap \mathcal{F} = \{X \cap F : F \in \mathcal{F}\}$. The set X is *shattered by* $\mathcal{F}$ if $X \cap \mathcal{F} = 2^X$. The *Vapnik-Chervonenkis dimension*, short *VC-dimension*, of $\mathcal{F}$ is the maximum size of a set X that is shattered by $\mathcal{F}$. Note that if X is shattered by $\mathcal{F}$, then also every subset of X is shattered by $\mathcal{F}$.

The following theorem was first proved by Vapnik and Chervonenkis [5], and rediscovered by Sauer [27] and Shelah [28]. It is often called the Sauer-Shelah Lemma in the literature.

▶ **Theorem 8** (Sauer-Shelah Lemma). *If $|A| \leq n$ and $\mathcal{F} \subseteq 2^A$ has VC-dimension d, then $|\mathcal{F}| \leq \sum_{i=0}^{d} \binom{n}{i} \in \mathcal{O}(n^d)$.*

Note that in the interesting cases $d \geq 2, n \geq 2$ it holds that $\sum_{i=0}^{d} \binom{n}{i} \leq n^d$, and in general it holds that $\sum_{i=0}^{d} \binom{n}{i} \leq 2 \cdot n^d$. For a graph G, the VC-dimension of G is defined as the VC-dimension of the family $\{N[v] \colon v \in V(G)\}$ of sets over the set $V(G)$.

VC-dimension and nowhere denseness. Adler and Adler [1] have proved that any nowhere dense class $\mathcal{C}$ of graphs is *stable*, which in particular implies that any class of structures obtained from $\mathcal{C}$ by means of a first-order interpretation has VC-dimension bounded by a constant depending only on $\mathcal{C}$ and the interpretation. In particular, the following is an immediate corollary of the results of Adler and Adler [1].

▶ **Corollary 9.** *Let $\mathcal{C}$ be a nowhere dense class of graphs and let $r \in \mathbb{N}$. For $G \in \mathcal{C}$, let $G_{=r}$ be the graph with the same vertex set as G and an edge $\{u, v\} \in E(G_{=r})$ if and only if $\mathrm{dist}_G(u, v) = r$. Define the graph $G_{\leq r}$ in the same manner, but putting an edge $\{u, v\}$ into $E(G_{\leq r})$ if and only if $\mathrm{dist}_G(u, v) \leq r$. Then there is an integer $c(r)$ such that both $G_{=r}$ and $G_{\leq r}$ have VC-dimension at most $c(r)$ for every $G \in \mathcal{C}$.*

By combining Corollary 9 with the Sauer-Shelah Lemma we infer the following.

▶ **Corollary 10.** *Let $\mathcal{C}$ be a nowhere dense class of graphs and $r \in \mathbb{N}$. Then $\nu_r(G, A) \leq |A|^{c(r)}$ for every graph $G \in \mathcal{C}$ and $A \subseteq V(G)$, where $c(r)$ is the constant given by Corollary 9.*

Thus, a polynomial bound on the neighborhood complexity for any nowhere dense class, and, in fact, for any stable class, already follows from known tools. Our goal in the next section will be to show that with the assumption of nowhere denseness we can prove an almost linear bound, as described in Theorem 3.

Distance profiles. In our reasoning we will need a somewhat finer view of the neighborhood complexity. More precisely, we would like to partition the vertices of the graph not only with respect to their r-neighborhood in a fixed set A, but also with respect to what are the exact distances of the elements of this r-neighborhood from the considered vertex. With this intuition in mind, we introduce the notion of a *distance profile*.

Let G be a graph and let $A \subseteq V(G)$ be a subset of its vertices. For a vertex $u \in V(G)$, the *r-distance profile* of u, denoted $\pi_r^G[u, A]$, is a function mapping vertices of A to $\{0, 1, \ldots, r, \infty\}$ defined as follows:

$$\pi_r^G[u, A](v) = \begin{cases} \mathrm{dist}_G(u, v) & \text{if } \mathrm{dist}_G(u, v) \leq r, \\ \infty & \text{otherwise.} \end{cases}$$

We say that a function $f \colon A \to \{0, 1, \ldots, r, \infty\}$ is *realized as an r-distance profile on A* if there is $u \in V(G)$ such that $f = \pi_r^G[u, A]$. We may drop the superscript if the graph is clear from the context.

Similarly to the neighborhood complexity, we define the *distance profile complexity* of a vertex subset $A \subseteq V(G)$ in a graph G, denoted $\widehat{\nu}_r(G, A)$, as the number of different functions realized as r-distance profiles on A in G. Clearly it always holds that $\nu_r(G, A) \leq \widehat{\nu}_r(G, A)$, thus Theorem 3 will follow directly from the following result, which will be proved in the next section.

▶ **Theorem 11.** *Let $\mathcal{C}$ be a nowhere dense class of graphs. Then there is a function $f_{\mathrm{nei}}(r, \varepsilon)$ such that for every $r \in \mathbb{N}$, $\varepsilon > 0$, graph $G \in \mathcal{C}$, and vertex subset $A \subseteq V(G)$, it holds that $\widehat{\nu}_r(G, A) \leq f_{\mathrm{nei}}(r, \varepsilon) \cdot |A|^{1+\varepsilon}$.*

Let us observe that the polynomial bound of Corollary 10 carries over to distance profiles.

▶ **Lemma 12 (⋆).** *Let $\mathcal{C}$ be a nowhere dense class of graphs. Then there is an integer $d(r)$ such that for every $r \in \mathbb{N}$, $\varepsilon > 0$, graph $G \in \mathcal{C}$, and vertex subset $A \subseteq V(G)$ with $|A| \geq 2$, it holds that $\widehat{\nu}_r(G, A) \leq |A|^{d(r)}$.*

3 Neighborhood complexity of nowhere dense classes

In this section we prove Theorem 11, which directly implies Theorem 3, as explained in the previous section. Our approach is to carefully analyze the proof of Reidl et al. [26] for bounded expansion classes, and to fix parts that break down in the nowhere dense setting using tools derived, essentially, from the stability of nowhere dense classes.

We first prove the following auxiliary lemma. We believe it may be of independent interest, as it seems very useful for the analysis of weak coloring numbers in the nowhere dense setting.

▶ **Lemma 13.** *Let $\mathcal{C}$ be a nowhere dense class of graphs and let $G \in \mathcal{C}$. For $r \geq 0$ and a linear order $L \in \Pi(G)$, let*

$$\mathcal{W}_{r,L} = \{\mathrm{WReach}_r[G, L, v] \,:\, v \in V(G)\}.$$

Then there is a constant $x(r)$, depending only on $\mathcal{C}$ and r (and not on G and L), such that $\mathcal{W}_{r,L}$ has VC-dimension at most $x(r)$.

Proof. Since $\mathcal{C}$ is nowhere dense, according to Theorem 5, it is uniformly quasi-wide, say with margins N and s. We fix a number m to be determined later, depending only on r and $\mathcal{C}$. Let $x = x(r) = N(2r, m)$ and $s = s(r)$. Assume towards a contradiction that there is a set $A \subseteq V(G)$ of size x which is shattered by $\mathcal{W}_{r,L}$. Fix sets $S \subseteq V(G)$ and $B \subseteq A \setminus S$ such that $|B| = m$, $|S| \leq s$, and B is $2r$-independent in $G - S$. We will treat L also as a linear order on the vertex set of $G - S$.

As a subset of A, the set B is also shattered by $\mathcal{W}_{r,L}$. That is, for every $X \subseteq B$ there is a vertex $v_X \in V(G)$ such that $X = \mathrm{WReach}_r[G, L, v_X] \cap B$. Note that since B is $2r$-independent in $G - S$, so is X, and we have $|\mathrm{WReach}_r[G - S, L, v_X] \cap B| \leq 1$.

For a vertex $\sigma \in S$, number $\rho \in \{0, \ldots, r-1\}$, and vertex $v \in V(G)$, let us consider the set $\mathcal{P}_{v,\sigma,\rho}$ of all paths of length (exactly) ρ that connect σ and v. We define $b_{\sigma,\rho}(v)$ to be the largest (with respect to L) vertex $b \in B$, for which there exists a path $P \in \mathcal{P}_{v,\sigma,\rho}$ such that every vertex on P is strictly larger than b with respect to L. If no such vertex in B exists, we put $b_{\sigma,\rho}(v) = \bot$. The *signature* of a vertex $v \in V(G)$ is defined as

$$\chi(v) = \big(b_{\sigma,\rho}(v)\big)_{\sigma \in S,\, 0 \leq \rho \leq r-1}.$$

It now follows that the number of possible signatures is small.

▶ **Claim 14** (⋆). *The set* $\{\chi(v)\colon v \in V(G)\}$ *has size at most* $(m+1)^{r\cdot s}$.

The next claim intuitively shows that for a vertex v, the signature of v plus the set of vertices of B that are weakly reachable from v in $G - S$ provide enough information to deduce precisely the set of vertices of B that are weakly reachable from v in G.

▶ **Claim 15** (⋆). *Suppose* $v, w \in V(G)$ *are such that*

$$\chi(v) = \chi(w) \quad \text{and} \quad \mathrm{WReach}_r[G-S, L, v] \cap B = \mathrm{WReach}_r[G-S, L, w] \cap B.$$

Then $\mathrm{WReach}_r[G, L, v] \cap B = \mathrm{WReach}_r[G, L, w] \cap B$.

By Claim 14 there are at most $(m+1)^{r\cdot s}$ possible signatures, while we argued that the intersection $\mathrm{WReach}_r[G-S, L, v] \cap B$ is always of size at most 1, hence there are at most $(m+1)$ possibilities for it. Thus, by Claim 15 we conclude that only at most $(m+1)^{r\cdot s}\cdot(m+1)$ subsets of B are realized as $B \cap W$ for some $W \in \mathcal{W}_{r,L}$. To obtain a contradiction with B being shattered by $\mathcal{W}_{r,L}$, it suffices to select m so that $(m+1)^{r\cdot s+1} < 2^m$. Since $s = s(r)$ is a constant depending on $\mathcal{C}$ and r only, we may choose m depending on $\mathcal{C}$ and r so that the above inequality holds. ◀

With Lemma 13 in hand, we now are ready to prove Theorem 11.

Proof of Theorem 11. Fix $r \geq 1$ and $\varepsilon > 0$. We also use small constants $\varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4 > 0$, which will be determined in the course of the proof.

The first step is to reduce the problem to the case when the size of the graph is bounded polynomially in $|A|$. Without loss of generality assume $|A| \geq 2$. According to Lemma 12, there is an integer $d(r)$ such that there are at most $|A|^{d(r)}$ different r-distance profiles on A. We therefore classify the elements of $V(G)$ according to their r-distance profiles on A, that is, we define an equivalence relation $\sim$ on $V(G)$ as follows:

$$v \sim w \quad \text{if and only if} \quad \pi_r^G[v, A] = \pi_r^G[w, A].$$

Construct a set A' by taking A and, for each equivalence class κ of $\sim$, adding an arbitrary element v_κ to A'. Then, construct a set A'' by starting with A', and, for each distinct $u, v \in A''$, performing the following operation: if $\mathrm{dist}_G(u, v) \leq r$, then add the vertex set of any shortest path between u and v to A''. Finally, let $G' = G[A'']$.

▶ **Claim 16** (⋆). *It holds that* $|A''| \leq |A|^{2\cdot d(r)+3}$.

▶ **Claim 17** (⋆). *It holds that* $\widehat{\nu}_r(G', A) \geq \widehat{\nu}_r(G, A)$.

The gain from this step is that the size of G' is bounded polynomially in terms of $|A|$, hence we can use better bounds on the weak coloring numbers, as explained next.

According to Theorem 5, there is a function f_{wcol} such that

$$\mathrm{wcol}_{2r}(G') \leq f_{\mathrm{wcol}}(2r, \varepsilon_4)\cdot |A''|^{\varepsilon_4} = f_{\mathrm{wcol}}(2r, \varepsilon_4)\cdot |A|^{(2\cdot d(r)+3)\cdot\varepsilon_4} = f_{\mathrm{wcol}}(2r, \varepsilon_4)\cdot |A|^{\varepsilon_3},$$

where $\varepsilon_4 = \varepsilon_3/(2\cdot d(r)+3)$. Let L be a linear order of $V(G')$ with $|\mathrm{WReach}_{2r}[G', L, v]| \leq f_{\mathrm{wcol}}(2r, \varepsilon_4)\cdot |A|^{\varepsilon_3}$. For each $v \in V(G')$, let us define the following set:

$$Y[v] = \mathrm{WReach}_r[G', L, v] \cap \mathrm{WReach}_r[G', L, A].$$

In other words, $Y[v]$ comprises all vertices that are weakly r-reachable both from v and from some vertex of A. Since $Y[v] \subseteq \mathrm{WReach}_r[G', L, v]$ for each $v \in V(G')$, we have $|Y[v]| \leq |\mathrm{WReach}_r[G', L, v]| \leq f_{\mathrm{wcol}}(2r, \varepsilon_4) \cdot |A|^{\varepsilon_3}$. Furthermore, as for each $v \in V(G')$ we have $Y[v] \subseteq \mathrm{WReach}_r[G, L, A] = \bigcup_{w \in A} \mathrm{WReach}_r[G, L, w]$, we have $\left|\bigcup_{v \in V(G')} Y[v]\right| \leq |A| \cdot \max_{w \in V(G')} |\mathrm{WReach}_r[G, L, w]| \leq f_{\mathrm{wcol}}(2r, \varepsilon_4) \cdot |A|^{1+\varepsilon_3}$.

We now classify the vertices $v \in V(G')$ according to their distance profiles $\pi_r^{G'}[v, Y[v]]$. More precisely, let $\equiv$ be the equivalence relation on $V(G')$ defined as follows:

$$v \equiv w \quad \text{if and only if} \quad Y[v] = Y[w] \text{ and } \pi_r^{G'}[v, Y[v]] = \pi_r^{G'}[w, Y[w]].$$

We next show that the equivalence relation $\equiv$ refines the standard partitioning according to r-distance profiles on A.

▶ **Claim 18** ($\star$). *For every $v, w \in V(G)$, if $v \equiv w$, then $\pi_r^{G'}[v, A] = \pi_r^{G'}[w, A]$.*

Claim 18 suggests the following approach to bounding $\widehat{\nu}_r(G', A)$: first give an upper bound on the number of possible sets of the form $Y[v]$, and then for each such set, bound the number of r-distance profiles on it. We deal with the second part first, as it essentially follows from Lemma 12. Let us set $\varepsilon_2 = \varepsilon_3 \cdot d(r)$, where $d(r)$ is the constant given by Lemma 12.

▶ **Claim 19** ($\star$). *There is $g(r, \varepsilon_4)$ such that for all $v \in V(G)$, we have $\widehat{\nu}_r(G, Y[v]) \leq g(r, \varepsilon_4)|A|^{\varepsilon_2}$.*

It remains to give an upper bound on the number of distinct sets $Y[v]$. Let us set $\varepsilon_1 = \varepsilon_3 \cdot x(r)$, where $x(r)$ is the constant given by Lemma 13.

▶ **Claim 20.** *It holds that $|\{Y[v] \colon v \in V(G')\}| \leq 1 + 2 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot |A|^{1+\varepsilon_1+\varepsilon_3}$.*

Proof. Let $\mathcal{Y} = \{Y[v] \colon v \in V(G')\} \setminus \{\emptyset\}$ be the family of all non-empty sets of the form $Y[v]$ for $v \in V(G')$; it suffices to show that $|\mathcal{Y}| \leq f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot |A|^{1+\varepsilon_1+\varepsilon_3}$. Define mapping $\gamma \colon \mathcal{Y} \to V(G')$ as follows: for $Z \in \mathcal{Y}$, $\gamma(Z)$ is the largest element of Z with respect to L.

Take any $v \in V(G')$ with $Y[v] \neq \emptyset$, and recall that every vertex in $Y[v]$ is weakly r-reachable from v. Observe that every vertex $w \in Y[v]$ is weakly $2r$-reachable from $\gamma(Y[v])$. To see this, concatenate the two paths of length at most r that certify that $w \in \mathrm{WReach}_r[G', L, v]$ and $\gamma(Y[v]) \in \mathrm{WReach}_r[G', L, v]$, and note that this path of length at most $2r$ certifies that $w \in \mathrm{WReach}_{2r}[G', L, \gamma(Y[v])]$. Consequently, for every $y \in \gamma(\mathcal{Y})$, we have

$$\bigcup \gamma^{-1}(y) \subseteq \mathrm{WReach}_{2r}[G', L, y].$$

Hence the union of all sets of $\mathcal{Y}$ that choose the same y via γ has size at most $\mathrm{wcol}_{2r}(G')$.

Fix any $y \in \gamma(\mathcal{Y})$ and denote $S_y = \bigcup \gamma^{-1}(y)$. Let us count how many distinct subsets of S_y belong to $\mathcal{Y}$. Every such $Z = Y[v]$, as a subset of S_y, satisfies $Y[v] \cap S_y = Y[v] = \mathrm{WReach}_r[G'L, v] \cap \mathrm{WReach}_r[G', L, A]$. As for all v the set $\mathrm{WReach}_r[G', L, A]$ is the same, this means that the number of different $Y[v] \in \mathcal{Y}$ that are mapped to a fixed y is not larger than the number of different sets $\mathrm{WReach}_r[G', L, v] \cap S_y$, for $v \in V(G')$.

By Lemma 13, the set $\mathcal{W}_{r,L} = \{\mathrm{WReach}_r[G', L, v] \colon v \in V(G')\}$ has VC-dimension at most $x(r)$, and so has the subfamily $\{S_y \cap \mathrm{WReach}_r[G', L, v] \colon v \in V(G')\}$. Hence, by the Sauer-Shelah Lemma, we infer that $|\{S_y \cap \mathrm{WReach}_r[G', L, v] \colon v \in V(G')\}| \leq 2 \cdot |S_y|^{x(r)}$.

Finally, we observe that $\gamma(\mathcal{Y}) \subseteq \bigcup \mathcal{Y}$ and recall that $|\bigcup \mathcal{Y}| \leq f_{\mathrm{wcol}}(2r, \varepsilon_4) \cdot |A|^{1+\varepsilon_3}$, hence

$$\begin{aligned}
|\mathcal{Y}| &\leq \sum_{y \in \gamma(\mathcal{Y})} |\{S_y \cap \mathrm{WReach}_r[G', L, v] \colon v \in V(G')\}| \\
&\leq 2 \cdot \sum_{y \in \gamma(\mathcal{Y})} |S_y|^{x(r)} \leq 2 \cdot |\gamma(\mathcal{Y})| \cdot (\mathrm{wcol}_{2r}(G'))^{x(r)} \\
&\leq 2 \cdot |\bigcup \mathcal{Y}| \cdot (f_{\mathrm{wcol}}(2r, \varepsilon_4) \cdot |A|^{\varepsilon_3})^{x(r)} \\
&\leq 2 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4) \cdot |A|^{1+\varepsilon_3} \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot |A|^{\varepsilon_1} \\
&\leq 2 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot |A|^{1+\varepsilon_1+\varepsilon_3}.
\end{aligned}$$

◀

By combining Claim 17, Claim 18, Claim 19, and Claim 20, we conclude that

$$\begin{aligned}
\widehat{\nu}_r(G, A) &\leq \widehat{\nu}_r(G', A) \leq \mathrm{index}(\equiv) \\
&\leq |\{Y[v] \ : \ v \in V(G')\}| \cdot g(r, \varepsilon_4) \cdot |A|^{\varepsilon_2} \\
&\leq (1 + 2 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot |A|^{1+\varepsilon_1+\varepsilon_3}) \cdot g(r, \varepsilon_4) \cdot |A|^{\varepsilon_2} \\
&\leq 3 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot g(r, \varepsilon_4) \cdot |A|^{1+\varepsilon_1+\varepsilon_2+\varepsilon_3}.
\end{aligned}$$

Now fix $\varepsilon_4 > 0$ so that $\varepsilon_1 + \varepsilon_2 + \varepsilon_3 < \varepsilon$ and set $f_{\mathrm{nei}}(r, \varepsilon) = 3 \cdot f_{\mathrm{wcol}}(2r, \varepsilon_4)^{x(r)+1} \cdot g(r, \varepsilon_4)$. ◀

4 Kernelization for distance-r dominating sets

In this section we use the neighborhood complexity tools to prove Theorem 4. Throughout the section we fix a nowhere dense class $\mathcal{C}$. Whenever we say that the running time of some algorithm on a graph G is *polynomial*, we mean that it is of the form $\mathcal{O}((|V(G)| + |E(G)|)^\alpha)$, where α is a universal constant that is independent of $\mathcal{C}$, r, ε, or any other constants defined in the context. However, the constants hidden in the $\mathcal{O}(\cdot)$-notation may depend on $\mathcal{C}$, r, and ε.

Projections and projection profiles. Let $G \in \mathcal{C}$ be a graph and let $A \subseteq V(G)$ be a subset of vertices. For vertices $v \in A$ and $u \in V(G) \setminus A$, a path P connecting u and v is called *A-avoiding* if none of its vertices apart from v belong to A. For a positive integer r, the *r-projection* of any $u \in V(G) \setminus A$ on A, denoted $M_r^G(u, A)$ is the set of all vertices $v \in A$ that can be connected to u by an A-avoiding path of length at most r. The *r-projection profile* of a vertex $u \in V(G) \setminus A$ on A is a function $\rho_r^G[u, A]$ mapping vertices of A to $\{0, 1, \ldots, r, \infty\}$, defined as follows: for every $v \in A$, the value $\rho_r^G[u, A](v)$ is the length of a shortest A-avoiding path connecting u and v, and ∞ in case this length is larger than r. Similarly as for r-neighborhoods and r-distance profiles, we define

$$\mu_r(G, A) = |\{M_r^G(u, A) \colon u \in V(G) \setminus A\}| \quad \text{and} \quad \widehat{\mu}_r(G, A) = |\{\rho_r^G[u, A] \colon u \in V(G) \setminus A\}|$$

to be the number of different r-projections and r-projection profiles realized on A, respectively. Clearly, again it always holds that $\mu_r(G, A) \leq \widehat{\mu}_r(G, A)$. The following lemma is a simple consequence of the results of the previous section.

▶ **Lemma 21** (⋆). *Suppose $\mathcal{C}$ is a nowhere dense class of graphs. Then there is a function $f_{\mathrm{proj}}(r, \varepsilon)$ such that for every $r \in \mathbb{N}$, $\varepsilon > 0$, graph $G \in \mathcal{C}$, and vertex subset $A \subseteq V(G)$, it holds that $\widehat{\mu}_r(G, A) \leq f_{\mathrm{proj}}(r, \varepsilon) \cdot |A|^{1+\varepsilon}$.*

We next recall the main tool for projections proved by Drange et al. [9], namely the *Closure Lemma*. Intuitively, it says that any vertex subset $A \subseteq V(G)$ can be "closed" to a set $\mathrm{cl}_r(A)$ that is not much larger than A, such that all r-projections on $\mathrm{cl}_r(A)$ are small. The next lemma follows from a straightforward adaptation of the proof of Drange et al.

▶ **Lemma 22** (⋆, Lemma 2.9 of [9], adjusted)**.** *There is a function $f_{\mathrm{cl}}(r,\varepsilon)$ and a polynomial-time algorithm that, given $G \in \mathcal{C}$, $X \subseteq V(G)$, $r \in \mathbb{N}$, and $\varepsilon > 0$, computes the* r-closure *of X, denoted $\mathrm{cl}_r(X)$ with the following properties.*

- $X \subseteq \mathrm{cl}_r(X) \subseteq V(G)$*;*
- $|\mathrm{cl}_r(X)| \leq f_{\mathrm{cl}}(r,\varepsilon) \cdot |X|^{1+\varepsilon}$*; and*
- $|M_r^G(u, \mathrm{cl}_r(X))| \leq f_{\mathrm{cl}}(r,\varepsilon) \cdot |X|^{\varepsilon}$ *for each $u \in V(G) \setminus \mathrm{cl}_r(X)$.*

We need another lemma from Drange et al., called the *Short Paths Closure Lemma*.

▶ **Lemma 23** (⋆, Lemma 2.11 of [9], adjusted)**.** *There is a function $f_{\mathrm{pth}}(r,\varepsilon)$ and a polynomial-time algorithm which on input $G \in \mathcal{C}$, $X \subseteq V(G)$, $r \in \mathbb{N}$, and $\varepsilon > 0$, computes a superset $X' \supseteq X$ of vertices with the following properties:*

- *whenever* $\mathrm{dist}_G(u,v) \leq r$ *for $u, v \in X$, then* $\mathrm{dist}_{G[X']}(u,v) = \mathrm{dist}_G(u,v)$*; and*
- $|X'| \leq f_{\mathrm{pth}}(r,\varepsilon) \cdot |X|^{1+\varepsilon}$.

For the rest of this section let us fix constants $r \in \mathbb{N}$ and $\varepsilon > 0$; they will be used implicitly in the proofs. Let us recall some terminology from Drange et al. [9], which is essentially also present in the approach of Dawar and Kreutzer [7]. For a graph G, and vertex subset $Z \subseteq V(G)$, we say that a subset of vertices D is a (Z,r)-*dominator* if $Z \subseteq N_r^G(D)$. We write $\mathbf{ds}_r(G,Z)$ for the smallest (Z,r)-dominator in G and $\mathbf{ds}_r(G)$ for the smallest $(V(G),r)$-dominator in G. The crux of the approach of Drange et al. [9] is to perform kernelization in two phases: first compute a small r-*domination core*, and then reduce the size of the graph in one step.

▶ **Definition 24.** An r-*domination core* of G is a subset $Z \subseteq V(G)$ such that every minimum size (Z,r)-dominator is also a distance-r dominating set in G.

We shall prove the following analogue of Theorem 4.11 of [9].

▶ **Lemma 25.** *There exists a function $f_{\mathrm{core}}(r,\varepsilon)$ and a polynomial-time algorithm that, given a graph $G \in \mathcal{C}$ and integer $k \in \mathbb{N}$, either correctly concludes that G cannot be r-dominated by k vertices, or finds an r-domination core $Z \subseteq V(G)$ of G of size at most $f_{\mathrm{core}}(r,\varepsilon) \cdot k^{1+\varepsilon}$.*

Starting with $Z = V(G)$, which is clearly an r-domination core of G, we try to iteratively remove vertices from Z while preserving the property that Z is an r-domination core of G. More precisely, we show the following lemma, which is the analogue of Theorem 4.12 of [9] and of Lemma 11 of [7].

▶ **Lemma 26.** *There exists a function $f_{\mathrm{core}}(r,\varepsilon)$ and a polynomial-time algorithm that, given a graph $G \in \mathcal{C}$, an integer $k \in \mathbb{N}$, and an r-domination core Z of G with $|Z| > f_{\mathrm{core}}(r,\varepsilon) \cdot k^{1+\varepsilon}$, either correctly concludes that Z cannot be r-dominated by k vertices, or finds a vertex $z \in Z$ such that $Z \setminus \{z\}$ is still an r-domination core of G.*

Observe that Lemma 25 follows by applying Lemma 26 iteratively until the size of the core is reduced to at most $f_{\mathrm{core}}(r,\varepsilon) \cdot k^{1+\varepsilon}$. This iteration is performed at most n times leading to an additional factor n in the running time in Lemma 25.

The first step of the proof of Lemma 26 is to find a suitable approximation of a (Z,r)-dominator. For this, we can rely on the classic $\mathcal{O}(\log \mathsf{OPT})$-approximation of Brönnimann and Goodrich [4] for the Hitting Set problem in set families of bounded VC-dimension, as explained in the next lemma.

▶ **Lemma 27 (⋆).** *There is a function $f_{\mathrm{apx}}(r,\varepsilon)$ and a polynomial-time algorithm that, given $G \in \mathcal{C}$ and $Z \subseteq V(G)$, computes a (Z,r)-dominator of size at most $f_{\mathrm{apx}}(r,\varepsilon)\cdot k^{1+\varepsilon}$, where k is the size of a minimum r-dominating set of Z.*

We are now ready to prove Lemma 26.

Proof of Lemma 26. The function $f_{\mathrm{core}}(r,\varepsilon)$ will be defined in the course of the proof. For convenience, for now we assume that $|Z| > f_{\mathrm{core}}(r,\varepsilon)\cdot k^{1+C\varepsilon}$ for some large constant C, for at the end we will rescale ε accordingly.

We first apply Lemma 27, to either conclude that there is no (Z,r)-dominator of size at most k or to compute a (Z,r)-dominator X of size at most $f_{\mathrm{apx}}(r,\varepsilon)\cdot k^{1+\varepsilon}$. This application takes polynomial time. In the first case we can reject the instance, hence assume that we are in the second case.

We apply the algorithm of Lemma 22 to the set X and distance parameter $3r$, thus computing its closure $\mathrm{cl}_{3r}(X)$, henceforth denoted by X_{cl}. By Lemma 22, we have

$$|X_{\mathrm{cl}}| \quad\leq\quad f_{\mathrm{cl}}(3r,\varepsilon)\cdot|X|^{1+\varepsilon} \leq f_{\mathrm{cl}}(3r,\varepsilon)\cdot f_{\mathrm{apx}}(r,\varepsilon)^{1+\varepsilon}\cdot k^{1+3\varepsilon},$$

and, for every $u \in V(G)\setminus X_{\mathrm{cl}}$,

$$|M^G_{3r}(u,X_{\mathrm{cl}})| \quad\leq\quad f_{\mathrm{cl}}(3r,\varepsilon)\cdot|X|^{\varepsilon} \leq f_{\mathrm{cl}}(3r,\varepsilon)\cdot f_{\mathrm{apx}}(r,\varepsilon)^{\varepsilon}\cdot k^{3\varepsilon}.$$

We now classify the elements of $Z\setminus X_{\mathrm{cl}}$ according to their $3r$-projection profiles on X_{cl}. More precisely, let us define an equivalence relation $\sim$ on $Z\setminus X_{\mathrm{cl}}$ as follows:

$$u \sim v \quad\text{if and only if}\quad \rho^G_{3r}[u,X_{\mathrm{cl}}] = \rho^G_{3r}[v,X_{\mathrm{cl}}].$$

By Lemma 21, the number of equivalence classes of $\sim$ is bounded as follows:

$$\mathrm{index}(\sim) \quad\leq\quad f_{\mathrm{nei}}(3r,\varepsilon)\cdot|X_{\mathrm{cl}}|^{1+\varepsilon} \leq f_{\mathrm{nei}}(3r,\varepsilon)\cdot f_{\mathrm{cl}}(3r,\varepsilon)^{1+\varepsilon}\cdot f_{\mathrm{apx}}(r,\varepsilon)^{(1+\varepsilon)^2}\cdot k^{1+7\varepsilon}.$$

Note that the partition of $V(G)$ into the equivalence classes of $\sim$ can be computed in polynomial time, by just computing the $3r$-projection profile for each vertex using breadth-first search, and then comparing the profiles pairwise.

Let $t(r)$, $p(r)$, and $s(r)$ be the functions provided by Theorem 7 for the class $\mathcal{C}$. Denote $\alpha = f_{\mathrm{cl}}(3r,\varepsilon)\cdot f_{\mathrm{apx}}(r,\varepsilon)^{\varepsilon}\cdot k^{3\varepsilon} + s(2r) + 1$ and $\beta = \alpha\cdot(r+2)^{s(r)}+1$. From the above inequalities on $|X_{\mathrm{cl}}|$ and $\mathrm{index}(\sim)$, it follows that setting $C = 7+3\cdot p(2r)$, we can fix the function $f_{\mathrm{core}}(r,\varepsilon)$ so that the following inequality is always satisfied:

$$f_{\mathrm{core}}(r,\varepsilon)\cdot k^{1+C\varepsilon} \geq |X_{\mathrm{cl}}| + \mathrm{index}(\sim)\cdot\beta^{p(2r)}.$$

Since we assumed that $|Z| > f_{\mathrm{core}}(r,\varepsilon)\cdot k^{1+C\varepsilon}$, it follows that $|Z\setminus X_{\mathrm{cl}}| > \mathrm{index}(\sim)\cdot\beta^{p(2r)}$. Hence, by the pigeonhole principle, there exists an equivalence class κ of $\sim$ that contains more than $\beta^{p(2r)}$ vertices. By applying the algorithm of Theorem 7 to any subset of κ of size exactly $\beta^{p(2r)}$, we find sets $S\subseteq V(G)$ and $L\subseteq\kappa\setminus S$ such that $|S|\leq s(r)$, $|L|\geq\beta$, and L is $2r$-independent in $G-S$. This application takes time $\mathcal{O}(r\cdot t(2r)\cdot\beta^{p(2r)\cdot(t(r)+1)}\cdot|V(G)|^{1+\varepsilon})$. Provided ε satisfies $3\cdot p(2r)\cdot(t(2r)+1)\cdot\varepsilon<1$, which we can assume without loss of generality, we have that $\beta^{p(2r)\cdot(t(2r)+1)}\leq\mathcal{O}(k)$; here, the constants hidden in the $\mathcal{O}(\cdot)$-notation may depend on $\mathcal{C}$. Since we can assume that $k\leq|V(G)|$, this application of the algorithm of Theorem 7 takes then time $\mathcal{O}(|V(G)|^{2+\varepsilon})$, which is polynomial with the degree independent of $\mathcal{C}$.

We now classify the elements of L according to their r-distance profiles on S. Note that $|L|\leq\beta$ and that the number of r-distance profiles on S is bounded by $(r+2)^{|S|}\leq(r+2)^{s(r)}$.

Since $\beta > \alpha \cdot (r+2)^{s(r)}$, by the pigeonhole principle we infer that there is a subset $R \subseteq L$ of size $|R| > \alpha$ such that

$$\pi_r^G(v, S) = \pi_r^G(w, S) \quad \text{for all} \quad v, w \in R.$$

At this point the situation is almost exactly as in Lemma 3.8 of [9]. More precisely, every vertex of R is an irrelevant dominatee, i.e., it can be excluded from Z without spoiling the property that Z is a domination core. The proof of the following claim is based on an exchange argument.

▶ **Claim 28** (⋆). *The set Z' is also a domination core of G.*

Claim 28 ensures us that vertex z is an irrelevant dominatee that can be returned by the algorithm. Note that we were able to find z provided $|Z| > f_{\mathrm{core}}(r, \varepsilon) \cdot k^{1+C\varepsilon}$ for some constant C depending on $\mathcal{C}$ and r. Hence, we conclude the proof by rescaling ε to ε/C throughout the reasoning. ◀

Finally, having computed a suitably small domination core, we can construct a kernel. This part of reasoning, encapsulated in the following lemma, is exactly the same as in [9].

▶ **Lemma 29** (⋆). *There exists a function $f_{\mathrm{fin}}(r, \varepsilon)$ and a polynomial-time algorithm that, given a graph $G \in \mathcal{C}$ and an r-domination core $Z \subseteq V(G)$ of G, computes a graph G' with at most $f_{\mathrm{fin}}(r, \varepsilon) \cdot |Z|^{1+\varepsilon}$ vertices such that $Z \subseteq V(G')$ and $\mathbf{ds}_r(G', Z) = \mathbf{ds}_r(G, Z)$.*

Theorem 4 follows by combining Lemma 25 and LEmma 29, and rescaling ε by factor 3.

Additive Spanners and Distance Oracles in Quadratic Time

Mathias Bæk Tejs Knudsen*

Abstract

Let G be an unweighted, undirected graph. An additive k-spanner of G is a subgraph H that approximates all distances between pairs of nodes up to an additive error of $+k$, that is, it satisfies $d_H(u,v) \leq d_G(u,v) + k$ for all nodes u, v, where d is the shortest path distance. We give a deterministic algorithm that constructs an additive $O(1)$-spanner with $O\big(n^{4/3}\big)$ edges in $O\big(n^2\big)$ time. This should be compared with the randomized Monte Carlo algorithm by Woodruff [ICALP 2010] giving an additive 6-spanner with $O\big(n^{4/3}\log^3 n\big)$ edges in expected time $O\big(n^2\log^2 n\big)$.

An (α,β)-approximate distance oracle for G is a data structure that supports the following distance queries between pairs of nodes in G. Given two nodes u, v it can in constant time compute a distance estimate $\tilde{d}$ that satisfies $d \leq \tilde{d} \leq \alpha d + \beta$ where d is the distance between u and v in G. Sommer [ICALP 2016] gave a randomized Monte Carlo $(2,1)$-distance oracle of size $O\big(n^{5/3}\operatorname{poly}\log n\big)$ in expected time $O\big(n^2\operatorname{poly}\log n\big)$. As an application of the additive $O(1)$-spanner we improve the construction by Sommer [ICALP 2016] and give a Las Vegas $(2,1)$-distance oracle of size $O\big(n^{5/3}\big)$ in time $O\big(n^2\big)$. This also implies an algorithm that in $O\big(n^2\big)$ time gives approximate distance for all pairs of nodes in G improving on the $O\big(n^2\log n\big)$ algorithm by Baswana and Kavitha [SICOMP 2010].

1 Introduction

Let $G = (V, E)$ be an unweighted, undirected graph on n nodes and m edges. A subgraph H of G is an *additive k-spanner* if the following holds for every pair u, v of nodes in G:

$$d_H(u,v) \leq d_G(u,v) + k\,,$$

where $d_H(u,v)$ and $d_G(u,v)$ is the distance between u and v in H and G respectively. This paper will only consider additive spanners and not multiplicative or mixed spanners, so we will simply say that H is a *k-spanner* when we mean that H is an additive k-spanner.

In this paper we consider algorithms constructing k-spanners, and there are therefore three interesting parameters: The distortion k, the running time of the algorithm, and the size of the spanner created. Elkin and Peleg [19] showed how to construct 2-spanners with $O\big(n^{3/2}\big)$ edges in $O\big(n^{5/2}\big)$ time, and Baswana et al [9] gave an algorithm that constructs 6-spanners with $O\big(n^{4/3}\big)$ edges in $O\big(n^{2/3}m\big)$ time.

Table 1 A summary of the performance of selected algorithms that creates a k-spanner H from a graph on n nodes. It shows the additive distortion, k, and an upper bound on the number of edges in H as well as the running time of the algorithm that constructs H.

k	Number of Edges	Running Time	Comment	Reference
2	$O(n^{3/2})$	$O(n^{5/2})$	Deterministic	[19]
2	$O(n^{3/2}\log^{1/2} n)$	$O(n^2\log^2 n)$	Deterministic	[18]
2	$O(n^{3/2})$	$O(n^2)$	Deterministic	Theorem 5
6	$O(n^{4/3})$	$O(n^{2/3}m)$	Deterministic	[9]
6	$O(n^{4/3}\log^3 n)$	$O(n^2\log^2 n)$	Randomized Monte Carlo	[33]
8	$O(n^{4/3})$	$O(n^2)$	Deterministic	Theorem 9

The running time of these algorithms can be improved if we allow the k-spanners to be larger by a $\operatorname{poly}\log n$ factor. Dor, Halperin and Zwick [18] showed that we can construct 2-spanners with $O\left(n^{3/2}\log^{1/2} n\right)$ edges in $O(n^2\log^2 n)$ time, and Woodruff [33] gave an algorithm to construct 6-spanners with $O(n^{4/3}\log^3 n)$ edges in $O(n^2\log^2 n)$ time. The construction of Woodruff is furthermore randomized Monte Carlo. These results are summarized in Table 1.

These improvements to the running time fit into the following paradigm. For a fixed k the authors find algorithms that produce spanners that are *almost* as small as the best known construction of k-spanners and have *near*-quadratic running time. We reverse this way of looking at the problem. We are now trying to find algorithms that yield k-spanners that are exactly as small as the best known constructions for any $k = O(1)$, i.e. $O(n^{4/3})$, and at the same time we want the algorithm to run as fast as possible. All known algorithms for creating $O(1)$-spanners that have close to optimal size run in time $\Omega(n^2)$. [1] So a natural question is to ask if there exists a $k = O(1)$ and an algorithm that constructs a k-spanner with $O(n^{4/3})$ edges in $O(n^2)$ time. In fact Sommer [28] mentioned at his talk at ICALP 2016 that the main obstacle towards getting a better running time for constructing the distance oracle he presented is the lack of such an algorithm. In his case the distortion $k = O(1)$ is only factored into the running time and not the distortion of oracle. Therefore, it does not matter what k is as long as it is constant.

We show that it possible to attain this goal by giving an algorithm that constructs 8-spanners deterministically with $O(n^{4/3})$ edges in $O(n^2)$ time. Comparing this with the algorithm by Woodruff [33] this gets rid of the $\log^3 n$ factor on the number of edges and a factor of $\log^2 n$ in the running time. Furthermore, the algorithm is deterministic and not randomized Monte Carlo. The price of these improvements is that the distortion is larger than 6. We note that there are no lower bounds ruling out the possibility of a 4-spanner with $O(n^{4/3})$ edges. For the application to the distance oracle by Sommer [28], the distortion is unimportant as long as it is constant. We also show how to construct 2-spanners with $O(n^{3/2})$ edges in $O(n^2)$ time. For a comparison to previous work see Table 1.

Related work. Elkin and Peleg [19] showed that[2] any graph on n nodes has a 2-spanner with $O(n^{3/2})$ edges, Chechik [15] showed that it has a 4-spanner with $O\left(n^{7/5}\log^{1/5} n\right)$ edges, and Baswana et al [9] showed that it has a 6-spanner with $O(n^{4/3})$ edges. These results are

[1] For instance the algorithm by Baswana et al [9] gives a 6-spanner with $O(n^{4/3})$ edges and is therefore only interesting when $m = \Omega(n^{4/3})$, in which case the running time is $\Theta(n^{2/3}m) = \Omega(n^2)$.

[2] Aingworth et al [5] earlier showed the same result up to logarithmic factors on the size of the spanner.

Table 2 For a given k an upper bound of $f(n)$ is a proof that any graph on n nodes has a k-spanner with no more than $f(n)$ edges. A lower bound of $g(n)$ is a proof that there exists a graph on n nodes for which any k-spanner must have at least $g(n)$ edges.

k	Upper Bound	Lower Bound	Reference
2 & 3	$O\big(n^{3/2}\big)$	$\Omega\big(n^{3/2}\big)$	[19]/[31]
4 & 5	$O\big(n^{7/5}\log^{1/5} n\big)$	$\Omega\big(n^{4/3}\big)$	[15]/[11]
≥ 6	$O\big(n^{4/3}\big)$	$n^{4/3-o(1)}$	[9]/[1]

complemented by a negative result of Abboud and Bodwin [1]. A consequence of their result is that for any $k = O(1)$ there exists a graph on n nodes such that any k-spanner of this graph has at least $n^{4/3-o(1)}$ edges.

Another negative result comes from Erdős's girth conjecture [20]. It states that for any constant k there exists graphs with n nodes and $\Omega\big(n^{1+1/k}\big)$ edges where the girth is $2k+2$. This conjecture has been proved for $k = 2, 3, 5$ [31, 11]. In particular if the conjecture is true this implies that there exists graphs for which any $(2k-1)$-spanner must have at least $\Omega\big(n^{1+1/k}\big)$ edges. Woodruff [32] proved that whether the conjecture is true or not, there exists a graph on n nodes such that any $(2k-1)$-spanner of the graph has at least $\Omega\big(k^{-1}n^{1+1/k}\big)$ edges.

There are also upper and lower bounds when we allow the distortion k to depend on n, see [14, 13, 15, 22]. In this paper, however, we are only interested in the case where $k = O(1)$. The upper and lower bounds for $k = O(1)$ are summarized in Table 2.

Techniques. Previous algorithms that construct k-spanners in $\tilde{O}\big(n^2\big)$ time all relied on constructing a hitting set for some set of neighbourhoods. In [18] this is done deterministically via a dominating set algorithm, and in [33] this is done via sampling. This approach will inherently come with the cost of a $\operatorname{poly}\log n$ factor. Furthermore, in the construction of 6-spanners by Woodruff [33] the number of neighbourhoods that need to be hit is so large that it seems impossible with current techniques to modify the algorithm to be Las Vegas. To avoid this we instead use a clustering approach described in Section 2. The algorithm in Theorem 9 is obtained using this clustering and a careful modification of the path-buying algorithm of [9].

Approximate Distance Oracles and All Pairs Almost Shortest Paths. Given an undirected an unweighted graph G an (α, β)-approximate distance oracle for G is a data structure that supports the following query. Given two nodes u, v it can compute a distance estimate $\tilde{d}$ that satisfies $d \leq \tilde{d} \leq \alpha d + \beta$ where d is the distance between u and v in G. For work on approximate distance oracles see e.g. [2, 3, 4, 6, 7, 8, 10, 12, 16, 17, 23, 24, 26, 27, 29, 30, 34]. Sommer [28] gave a randomized Monte Carlo $(2,1)$-distance oracle that can be constructed in $O\big(n^2 \operatorname{poly}\log n\big)$ time, has size $O\big(n^{5/3}\operatorname{poly}\log n\big)$ and can answer queries in $O(1)$ time. We improve the construction time and the size to $O\big(n^2\big)$ and $O\big(n^{5/3}\big)$ respectively, and our construction is randomized Las Vegas. As a corollary we can compute an estimate $\tilde{d}(u,v)$ for all pairs of nodes in G satisfying $d_G(u,v) \leq \tilde{d}(u,v) \leq 2d_G(u,v)+1$ in time $O\big(n^2\big)$. This improves upon the $O\big(n^2\log n\big)$ algorithm by Baswana and Kavitha [8].

Preliminaries. For a graph G and two nodes u, v we denote the distance from u to v in G by $d_G(u,v)$. All graphs considered in this paper are unweighted, and unless otherwise specified they are undirected as well. For an undirected graph G and a node u the neighbourhood of u is the set of nodes adjacent to u and is denoted by $\Gamma_G(u)$.

Overview. In Section 2 we introduce the clustering we use when constructing the spanners. In Section 3 we show how to create an 8-spanner with $O(n^{4/3})$ edges in $O(n^2)$ time and thereby prove Theorem 9. In Section 4 we provide the details on how to give an improved $(2,1)$-distance oracle.

2 Clustering

Our construction of additive spanners uses clustering techniques, and we present our clustering framework below. Let $G = (V, E)$ be a graph with n vertices and m edges. We let t be a parameter that can depend on our needs. For a sequence $u_1, \ldots, u_\ell$ of nodes we define the clusters $C_i, i \in \{1, \ldots, \ell\}$ by

$$C_i = (\Gamma_G(u_i) \cup \{u_i\}) \setminus (C_1 \cup \ldots \cup C_{i-1}) \,.$$

Furthermore we also define graphs $G_0, G_1, \ldots, G_\ell$ in the following way. We let $G_0 = G$, and for $i > 0$ we let G_i be the subgraph of G defined in the following way. The nodes of G_i are the same as the nodes of G. An edge (u, v) from G is contained in G_i unless both endpoints u and v are are contained in $C_1 \cup \ldots \cup C_i$. From each node u_i we let T_i be a BFS tree in G_{i-1} rooted at u_i.

▶ **Definition 1.** A sequence $u_1, \ldots, u_\ell$ is called a *t-clustering* if the following requirements are satisfied.

- The node u_i maximizes the size of $(\Gamma_G(u_i) \cup \{u_i\}) \setminus (C_1 \cup \ldots \cup C_{i-1})$.
- Every cluster C_i contains at least t nodes.
- For every node v we have $|(\Gamma_G(v) \cup \{v\}) \setminus (C_1 \cup \ldots \cup C_\ell)| < t$.

We say that a node v is *clustered* if $v \in C_1 \cup \ldots \cup C_\ell$ and *unclustered* otherwise. We note that since every cluster C_i contains at least t nodes and the clusters are disjoint we have $\ell \leq \frac{n}{t}$.

▶ **Lemma 2.** *Let $u_1, \ldots, u_\ell$ be a t-clustering of a graph $G = (V, E)$. For every $i = 1, 2, \ldots, \ell$ the number of edges in G_{i-1} is at most $n\,|C_i|$. The number of edges in G_ℓ is less than nt.*

Proof. The set of edges in G_{i-1} can be written as

$$\{\{u, v\} \mid u \in V, v \in (\Gamma_G(u)) \setminus (C_1 \cup \ldots \cup C_{i-1})\} \,.$$

Therefore, the number of edges in G_{i-1} is bounded by

$$\sum_{v \in V} |(\Gamma_G(v)) \setminus (C_1 \cup \ldots \cup C_{i-1})| \,. \tag{1}$$

Since every term in (1) is bounded by $|C_i|$, we conclude that the number of edges in G_i is at most $n\,|C_i|$.

In the same manner we see that the number of edges in G_ℓ is bounded by the sum $\sum_{v \in V} |(\Gamma_G(v)) \setminus (C_1 \cup \ldots \cup C_\ell)|$, which is clearly less than nt. ◀

▶ **Lemma 3.** *Let $u_1, \ldots, u_\ell$ be a t-clustering of $G = (V, E)$ and let $u, v \in V$ be a pair of nodes. Assume that some shortest path from u to v in G is not contained in G_ℓ from Lemma 2. Then there exists an index $i \in \{1, 2, \ldots, \ell\}$ such that*

$$d_{T_i}(u_i, u) + d_{T_i}(u_i, v) \leq d_G(u, v) + 2 \,.$$

Proof. Consider a shortest path p from u to v that is not contained in G_ℓ and let w be a clustered node on p such that $w \in C_i$. We choose w such that i is smallest possible. By choosing i smallest possible p is contained in G_{i-1}. Furthermore since the distance from w to u_i is at most 1 we see that

$$d_{G_{i-1}}(u_i, u) + d_{G_{i-1}}(u_i, v) \leq d_{G_{i-1}}(w, u) + d_{G_{i-1}}(w, v) + 2 = d_G(u, v) + 2\,.$$

Since T_i is a is shortest path tree in G_{i-1} the conclusion follows. ◀

▶ **Lemma 4.** *Given a graph G and a parameter $t > 0$ we can construct a t-clustering $u_1, \ldots, u_\ell$, the corresponding BFS trees $T_1, \ldots, T_\ell$ and G_ℓ in $O(n^2)$ time.*

Proof. The algorithm will work by finding the nodes $u_1, \ldots, u_\ell$ consecutively, i.e. first u_1, then u_2 and so on. The algorithm will maintain a graph G'. In the beginning of the algorithm we have $G' = G_0$, and after we add u_i we will alter G' such that $G' = G_i$. The total cost of altering all G' will be $O(m) = O(n^2)$.

We find u_i by looking at all nodes in $G' = G_{i-1}$ and count the number of neighbours not in $C_1 \cup \ldots \cup C_{i-1}$. Since G_{i-1} has at most $n\,|C_i|$ edges this takes $O(n\,|C_i|)$ time. Then the algorithm finds a BFS tree from u_i in G_{i-1} in $O(n\,|C_i|)$ time. Hence the total time used by the algorithm is:

$$O\left(m + \sum_{i=1}^{\ell} n\,|C_i|\right) = O(n^2)\,.$$ ◀

3 Constructing $O(1)$-Spanners

In this section we present our construction of an 8-spanner with $O\big(n^{4/3}\big)$ edges in $O\big(n^2\big)$ time. As a warmup we show how we can use the clustering from Section 2 to give a 2-spanner with $O\big(n^{3/2}\big)$ edges in $O\big(n^2\big)$ time.

▶ **Theorem 5.** *There exists an algorithm that given a graph G with n nodes constructs a 2-spanner of G with $\leq 2n^{3/2}$ edges in $O\big(n^2\big)$ time.*

Proof. Let $t = \sqrt{n}$ and construct a t-clustering $u_1, \ldots, u_\ell$ with Lemma 4. Let $H = T_1 \cup \ldots \cup T_\ell \cup G_\ell$. The number of edges in H is at most $n\ell + nt \leq 2n\sqrt{n}$ by Lemma 2 and the fact that $\ell \leq \frac{n}{t}$.

Now we just need to prove that H is a 2-spanner. Let u, v be arbitrary nodes and let p be a shortest path from u to v in G. We wish to prove that

$$d_H(u, v) \leq d_G(u, v) + 2\,. \tag{2}$$

If p is contained in G_ℓ then (2) is obviously true. Otherwise there exists an index i such that $d_{T_i}(u, v) \leq d_G(u, v) + 2$ by Lemma 3, and (2) is true since $T_i \subset H$. ◀

Next we turn to showing how to create an 8-spanner H with $O\big(n^{4/3}\big)$ edges in $O\big(n^2\big)$ time. The idea is the following. We start by creating a t-clustering $u_1, \ldots, u_\ell$ with $t = n^{1/3}$ and $\ell \leq n^{2/3}$. Using the BFS trees $T_1, \ldots, T_\ell$ along with Lemma 3 we can then get an additive 2-approximation of $d_G(u_i, u_j)$ for all pairs of indices i, j, which we will call $\delta_{i,j}$. The calculation of the BFS trees in $O\big(n^2\big)$ time relies on an idea similar to one in [5]. The BFS trees also gives us a path from u_i to u_j that is at most 2 longer than the shortest path. If we add all these shortest paths to our spanner along with G_ℓ and the neighbours in C_i of each

u_i we will get a 6-spanner. Unfortunately, adding a path could require adding up to $\Omega(\ell)$ edges, and since there are ℓ^2 pairs we can only guarantee that the spanner has $O(\ell^3)$ edges, which is $O(n^2)$ if $\ell \approx n^{2/3}$. (We only need to add edges on the path that are not already in G_ℓ) Instead we use an argument similar to the path-buying argument from [9] and the construction from [21]. We add the path from u_i to u_j unless we can guarantee that there is an additive 2-approximation of this path in the spanner already. We do this by maintaining an upper bound $\Delta_{i,j}$ on the distance from u_i to u_j in the spanner H. We then argue that if we add a path with k edges not already in the spanner, then there are $\Omega(k)$ pairs $u_{i'}, u_{j'}$ for which the upper bound $\Delta_{i',j'}$ is improved. Then, this will imply that at most $O(\ell^2)$ edges are added giving an upper bound of $O(n^{4/3})$ on the number of edges in H.

After this informal discussion of the construction we turn to the details. The algorithm is given a graph $G = (V, E)$ with n nodes and m edges, and will return a spanner $H = (V, F)$. Initially $F = \emptyset$ and we will add edges to H so that H becomes a 8-spanner of G. The algorithm starts by creating a t-clustering $u_1, \ldots, u_\ell$ with $t = n^{1/3}$ using Lemma 4 in $O(n^2)$ time. Since $\ell \leq \frac{n}{t}$ we have $\ell \leq n^{2/3}$. Then we add edges from u_i to all nodes in $C_i \setminus \{u_i\}$ to H for all $i \in \{1, 2, \ldots, \ell\}$. We add at most n edges this way. Then we add all edges from G_ℓ to H. This adds at most $nt = n^{4/3}$ edges to H.

We give each node $u \in V$ a color $c(u) \in \{0, 1, 2, \ldots, \ell\}$. If u is unclustered then u has color $c(u) = 0$. Otherwise $c(u) = i$ where i is the unique index such that $u \in C_i$. For each pair of indices $i, j \in \{1, 2, \ldots, \ell\}$ we define $\delta_{i,j}$ by:

$$\delta_{i,j} = \min_{k \in \{1,2,\ldots,\ell\}} \{d_{T_k}(u_k, u_i) + d_{T_k}(u_k, u_j)\} \,. \tag{3}$$

We first note that for a choice of i, j we can calculate the right hand side of (3) in $O(\ell)$ time since we are taking the minimum over ℓ different values. So in $O(\ell^3)$ time the algorithm calculates $\delta_{i,j}$ for all pairs of indices i, j. Since $\ell \leq n^{2/3}$ this is within the $O(n^2)$ time bound. As a consequence of Lemma 3 we get that $\delta_{i,j}$ is a good approximation of $d_G(u_i, u_j)$, more precisely:

$$d_G(u_i, u_j) \leq \delta_{i,j} \leq d_G(u_i, u_j) + 2 \,. \tag{4}$$

We now define T'_i to be the tree obtained from T_i by contracting each edge in G_ℓ. Since an edge is contained in G_ℓ iff at least one of its endpoints is unclustered we can construct T'_i from T_i in $O(n)$ time. The algorithm does so for all $i \in \{1, 2, \ldots, \ell\}$ in $O(n\ell) = O(n^{5/3})$ time. We note that the shortest path between two nodes u, v in T'_i contains exactly the edges on the shortest path between u, v in T_i excluding the edges that are contained in G_ℓ.

The algorithm initializes $\Delta_{i,j} = \infty$ for all pairs of indices i, j with $i \neq j$ and let $\Delta_{i,i} = 0$ for all i. We will maintain that $\Delta_{i,j}$ is an upper bound on $d_H(u_i, u_j)$ throughout the algorithm. Now the algorithm goes through all pairs u_i, u_j and adds a path of length at most 2 longer than a shortest path between the nodes if needed. Specifically, we do the following:

Let L be an upper bound on the number of nodes of the path p from u_i to u_j in T'_k on line 6. Then Algorithm 1 can implemented in $O(\ell^3 + \ell^2 L)$ time. Hence we just need to prove that $L = O(\ell)$ in order to conclude that it can be implemented in $O(\ell^3) = O(n^2)$ time. This follows from the fact that p is an almost shortest path and the following reasoning. If p contained $> C\ell$ nodes for some sufficiently large constant C it would contain more than C nodes of the same color. Since nodes of the same color have distance at most 2 in G this would imply that there was a much shorter path from u to v in G contradicting (4) if C was chosen large enough. The details with $C = 5$ are given in the following lemma:

▶ **Lemma 6.** *The path p contains no nodes of color 0, and at most 5 nodes of each color $\neq 0$.*

Algorithm 1

```
1  For each pair of indices i,j ∈ {1,2,...,ℓ}:
2      For all k ∈ {1,2,...,ℓ}:
3          Set Δ_{i,j} := min{Δ_{i,j}, Δ_{i,k} + Δ_{k,j}}.
4      If Δ_{i,j} > δ_{i,j} + 2 do:
5          Find a k ∈ {1,2,...,ℓ} such that d_{T_k}(u_k,u_i) + d_{T_k}(u_k,u_j) = δ_{i,j}.
6          Find the path p from u_i to u_j in T'_k.
7          Add all edges from p to H.
8          Write p = (w_0, w_1, w_2, ..., w_{s-1}).
9          For all x ∈ {0,1,2,...,s-1}:
10             Set y := d_{T_k}(u_i, w_x).
11             Set Δ_{i,c(w_x)} := min{Δ_{i,c(w_x)}, y + 1}
12             Set Δ_{c(w_x),j} := min{Δ_{c(w_x),j}, (δ_{i,j} − y) + 1}
```

Proof. Obviously p does not contain a node with color 0, since all its incident edges would be contained in G_ℓ and hence not in T'_k. Now assume for the sake of contradiction that p contains 6 nodes of some color $r \neq 0$. When traversing p from u_i to u_j let α and β be the first and the last node of color r respectively. The distance from α to β when following p must be at least 5 by assumption. On the other hand α and β have distance at most 2 in G. So there exists a path in G from u_i to u_j that is at least 3 edges shorter than p. This contradicts (4). Hence the assumption was wrong and p contains at most 5 nodes of each color $\neq 0$. ◀

Since there are ℓ different colors $\neq 0$ the path p contains at most 5ℓ nodes and the running time of Algorithm 1 is $O(n^2)$. So now we just need to prove that H is an 8-spanner and that H has at most $O(n^{4/3})$ edges. We start by proving that H is an 8-spanner. Here we will utilize that the $\Delta_{i,j}$ is an upper bound on the distance from u_i to u_j in H. Furthermore, Algorithm 1 guarantees that $\Delta_{i,j} \leq \delta_{i,j} + 2$. Together with (4) this gives that

$$d_H(u_i, u_j) \leq d_G(u_i, u_j) + 4\,. \tag{5}$$

▶ **Lemma 7.** *The subgraph H of G is an additive 8-spanner of G.*

Proof. Assume for the sake of contradiction that H is not an additive 8-spanner and let u, v be a pair of nodes with shortest possible distance in G such that:

$$d_H(u, v) > d_G(u, v) + 8\,. \tag{6}$$

Say that $d_G(u, v) = D$ and let $p = (w_0, w_1, \ldots, w_D)$ be a shortest path from u to v in G where $w_0 = u$ and $w_D = v$. Since the pair (u, v) has the smallest possible distance in G such that (6) holds and $d_G(w_1, v) = D - 1$ we have $d_H(w_1, v) \leq (D - 1) + 8$. In particular the edge (u, w_1) is not in H as it would contradict (6). Hence u cannot be unclustered, as all the edges incident to an unclustered node is contained in G_ℓ and therefore H. With the same reasoning we conclude that v is clustered. Let the colors of u and v be i and j respectively. The distances from u and v to u_i and u_j respectively are at most 1. Combining this insight with (5) we get:

$$d_H(u, v) \leq d_H(u_i, u_j) + 2 \leq d_G(u_i, u_j) + 6 \leq d_G(u, v) + 8\,.$$

But this contradicts the assumption (6). Hence the assumption was wrong and H is an additive 8-spanner of G. ◀

Lastly, we need to prove that H contains no more than $O(n^{4/3})$ edges. Informally, we argue the following way. Whenever the $s-1$ edges of p are added to H on line 7 of Algorithm 1 there are $\Omega(s)$ different colors on p. For each color r on p we then argue that either $\Delta_{i,r}$ or $\Delta_{r,j}$ are made smaller on line 11 or 12 of Algorithm 1. Lastly, we argue that $\Delta_{i,j}$ can only be updated $O(1)$ times, and since there are $\ell^2 \leq n^{4/3}$ variables $\Delta_{i,j}$ this implies that Algorithm 1 only adds $O(n^{4/3})$ edges to H. This intuition is formalized in Lemma 8 bellow:

▶ **Lemma 8.** *Algorithm 1 adds no more than $25\ell^2$ edges to H.*

Proof. Say that the algorithm adds the edges from the path $p = (w_0, w_1, \ldots, w_{s-1})$ on line 7 of Algorithm 1 where $w_0 = u_i, w_{s-1} = u_j$. First we note that since $d_G(u_i, u_j) \geq \delta_{i,j} - 2$ by (4) we have that $d_G(u_i, w_x) \geq y - 2$ for every $x \in \{0, 1, \ldots, s-1\}$, where we consider y to be a function of x defined by $y = d_{T_k}(u_i, w_x)$ as on line 10. Now fix x and let $r = c(w_x)$. Then there is an edge between w_x and u_r and therefore $d_G(u_i, u_r) \geq y-3$, i.e. $y+1 \leq d_G(u_i, u_r)+4$. So if Algorithm 1 decreases $\Delta_{i,r}$ on line 11 we have $\Delta_{i,r} \leq d_G(u_i, u_r) + 4$ after it is decreased. Since $\Delta_{i,r}$ is an upper bound on $d_H(u_i, u_r)$ and therefore also an upper bound on $d_G(u_i, u_r)$ we see that $\Delta_{i,r}$ can be decreased at most 5 times for each choice of i, r. By symmetry we see that we can also decrease $\Delta_{r,j}$ on line 12 at most 5 times. Since there are ℓ^2 pairs of indices the algorithm can change the values of $\Delta_{i,r}$ or $\Delta_{r,j}$ on line 11 and 12 of Algorithm 1 at most $5\ell^2$ times.

Let r be a color on p. After the execution of lines 9-12 we have

$$\Delta_{i,r} + \Delta_{r,j} \leq \delta_{i,j} + 2\,.$$

Due to the execution of lines 2 and 3 this was not the case before. Hence either $\Delta_{i,r}$ or $\Delta_{r,j}$ were updated. By Lemma 6 there are at least $\frac{s}{5}$ colors on p, so if the algorithm adds A edges in total it makes at least $\frac{A}{5}$ updates of upper bounds $\Delta_{i,r}$ or $\Delta_{r,j}$. Since there can be at most $5\ell^2$ such updates we conclude that $\frac{A}{5} \leq 5\ell^2$ and that Algorithm 1 adds no more than $25\ell^2$ edges. ◀

To summarize, the algorithm presented in this section runs in $O(n^2)$ time and gives an additive 8-spanner with no more than $26n^{4/3} + n = O(n^{4/3})$ edges. We have made no attempt to optimize the constant in the O-notation. Hence we get:

▶ **Theorem 9.** *There exists an algorithm that given a graph G with n nodes constructs an 8-spanner of G with $O(n^{4/3})$ edges in $O(n^2)$ time.*

4 Distance Oracles

In the following we show how to modify the construction by Sommer [28] to obtain a $(2,1)$-distance oracle of size $O(n^{5/3})$ that can be constructed in expected $O(n^2)$ time.

Let G be a given graph, and H an 8-spanner of G constructed by Theorem 9. H is constructed in $O(n^2)$ time and has $O(n^{4/3})$ edges. During the construction we use only $O(n^{5/3})$ space.

Let $u_1, u_2, \ldots, u_\ell$ be a $n^{1/3}$-clustering of G. Using Lemma 4 we obtain $T_1, \ldots, T_\ell$ and G_ℓ in $O(n^2)$ time. For each node v we define four *portals* $p_1(v), p_2(v), p_3(v), p_4(v)$. We define $p_1(v) = u_i$, where u_i is chosen such that the distance between v and u_i in T_i is minimized. In case of ties we choose the node u_i with the lowest index i. The node $p_{j+1}(v)$ for $j = 1, 2, 3$ is chosen depending on $p_j(v)$. If $p_j(v) = u_1$ we let $p_{j+1}(v) = u_1$. Otherwise $p_j(v) = u_i$ for some index i. We let $p_{j+1}(v) = u_{i'}$ where $u_{i'}$ is chosen among $u_1, u_2, \ldots, u_{i-1}$ such that the

distance between $u_{i'}$ and v in $T_{i'}$ is minimized. In case of ties we choose the node $u_{i'}$ with the lowest index i'. The portals for all nodes can be found in $O(n^{5/3})$ time.

We will use the following lemma by Pătraşcu and Roditty [23] to construct a $(2,1)$-distance oracle for G_ℓ, that uses space $O(n^{5/3})$.

▶ **Lemma 10** ([23]). *For any unweighted, undirected graph, there exists a distance oracle of size $O(n^{5/3})$ that, given any nodes u and v at distance d, returns a distance of at most $2d+1$ in constant time. The distance oracle can be constructed in expected time $O(mn^{2/3})$.*

In the proof in [23] they only claim a running time of $O(mn^{2/3}+n^{7/3})$, however, this can be fixed to give the correct running time of $O(mn^{2/3})$ [25]. By [23, Claim 9] it is easy to see how to get a running time of $O(mn^{2/3}+n^2)$ which suffice for our purposes.

We are now ready to define the distance oracle. For each $i=1,2,\ldots,\ell$ we store the distances $d_{T_i}(u_i,v)$ and $d_H(u_i,v)$ for all nodes v. The distances $d_H(u_i,v)$ can be calculated using a BFS in time $O(\ell n^{4/3})=O(n^2)$. For each node v we store its portals $p_j(v), j=1,2,3,4$. We augment this distance oracle with the Pătraşcu-Roditty distance oracle from Lemma 10 for G_ℓ.

We now show how to use the distance oracle to obtain approximate distances for a query u,v. We let $\delta_{PR}(u,v)$ be the approximate distance in G_ℓ returned by the Pătraşcu-Roditty distance oracle. We define $\delta_j(u,v)$ in the following way. Let $p_j(u)=u_i$. Then $\delta_j(u,v)=d_{T_i}(u_i,u)+\min\{d_{T_i}(u_i,v),d_H(u_i,v)\}$. The distance returned by the distance oracle is the minimum of $\delta_{PR}(u,v)$, $\delta_j(u,v)$ and $\delta_j(v,u)$ for $j=1,2,3,4$.

We will now argue that if the the distance between u and v is d, then the distance oracle returns a distance between d and $2d+1$. The distance returned is obviously at least d, so we just need to show that it is at most $2d+1$. Consider a shortest path between u and v in G. If there is at most one node on the shortest path which is incident to a node u_i in the clustering then the shortest path is contained in G_ℓ, and therefore:

$$\delta_{PR}(u,v)\leq 2d_{G_\ell}(u,v)+1=2d+1\,.$$

So assume that there exists an edge on the shortest path not in G_ℓ. Let i be the smallest index such that there is an edge (z,t) on the shortest path with $z,t\in C_1\cup\ldots\cup C_i$. Say that z is closer to u than to v in G. Assume that $z\in C_i$ and $t\in C_{i'}$ for some index $i'\leq i$ (the case where $z\in C_{i'}$ and $t\in C_i$ is handled symmetrically). Since the shortest path is contained in G_{i-1} and $G_{i'-1}$ we have that

$$d_{T_i}(u_i,u)+d_{T_{i'}}(u_{i'},v)\leq(d_G(u,z)+1)+(d_G(t,v)+1)=d+1\,,$$

and therefore:

$$\min\{d_{T_i}(u_i,u),d_{T_i}(u_i,v)\}\leq\frac{d+1}{2}\,.$$

Assume that $d_{T_i}(u_i,u)\leq\frac{d+1}{2}$. The other case is handled similarly. Say that $p_j(u)=u_{k_j}$ for $j=1,2,3,4$. First assume that $k_j>i$ for all $j=1,2,3,4$. Then we conclude that $d_{T_{k_1}}(p_1(u),u)\leq d_{T_i}(u_i,u)-4$. The distance returned by the distance oracle is at most

$$\begin{aligned}\delta_1(u,v)&\leq d_{T_{k_1}}(p_1(u),u)+d_H(p_1(u),v)\\&\leq d_{T_{k_1}}(p_1(u),u)+d_G(p_1(u),v)+8\\&\leq 2d_{T_{k_1}}(p_1(u),u)+d_G(u,v)+8\\&\leq 2(d_{T_i}(u_i,u)-4)+d+8\leq 2d+1\,.\end{aligned}$$

Now assume that $k_j \leq i$ for some $j \in \{1,2,3,4\}$ and let j be the smallest index such that $k_j \leq i$. By definition we have that $d_{T_{k_j}}(p_j(u),u) \leq d_{T_i}(u_i,u)$. Furthermore the shortest path is contained in G_{k_j-1} and therefore $d_{T_{k_j}}(p_j(u),v) \leq d_{T_{k_j}}(p_j(u),u) + d_G(u,v)$. The distance returned is at most

$$\begin{aligned}\delta_j(u,v) &\leq d_{T_{k_j}}(p_j(u),u) + d_{T_{k_j}}(p_j(u),v)\\ &\leq 2d_{T_{k_j}}(p_j(u),u) + d\\ &\leq 2d_{T_i}(u_i,u) + d \leq 2d+1\,.\end{aligned}$$

We conclude that the distance returned by the distance oracle is always between d and $2d+1$. The result is summarized in Theorem 11.

▶ **Theorem 11.** *For any unweighted, undirected graph, there exists a distance oracle of size $O(n^{5/3})$ that, given any nodes u and v at distance d, returns a distance of at most $2d+1$ in constant time. The distance oracle can be constructed in expected time $O(n^2)$.*

Acknowledgements. The author would like to thank Christian Sommer for helpful discussions on the application of the 8-spanner to his construction of distance oracles.

Abstract

We give algorithms with running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$ for the following problems. Given an n-vertex unit disk graph G and an integer k, decide whether G contains

- a path on exactly/at least k vertices,
- a cycle on exactly k vertices,
- a cycle on at least k vertices,
- a feedback vertex set of size at most k, and
- a set of k pairwise vertex-disjoint cycles.

For the first three problems, no subexponential time parameterized algorithms were previously known. For the remaining two problems, our algorithms significantly outperform the previously best known parameterized algorithms that run in time $2^{\mathcal{O}(k^{0.75}\log k)} \cdot n^{\mathcal{O}(1)}$. Our algorithms are based on a new kind of tree decompositions of unit disk graphs where the separators can have size up to $k^{\mathcal{O}(1)}$ and there exists a solution that crosses every separator at most $\mathcal{O}(\sqrt{k})$ times. The running times of our algorithms are optimal up to the $\log k$ factor in the exponent, assuming the Exponential Time Hypothesis.

1 Introduction

Unit disk graphs are the intersection graphs of unit circles in the plane. That is, given n-unit circles in the plane, we have a graph G where each vertex corresponds to a circle such that there is an edge between two vertices when the corresponding circles intersect. Unit disk graphs form one of the most well studied graph classes in computational geometry because of their use in modelling optimal facility location [40] and broadcast networks such as wireless, ad-hoc and sensor networks [25, 33, 42]. These applications have led to an extensive study of NP-complete problems on unit disk graphs in the realms of computational complexity and approximation algorithms. We refer the reader to [10, 18, 29] and the citations therein for these studies. However, these problems remain hitherto unexplored in the light of parameterized complexity with exceptions that are few and far between [1, 8, 23, 32, 38].

In this paper we consider the following basic problems about finding, hitting and packing cycles on unit disk graphs from the viewpoint of parameterized algorithms. For a given graph G and integer k,

- Exact k-Cycle asks whether G contains a cycle on exactly k vertices,
- Longest Cycle asks whether G contains a cycle on at least k vertices,
- Feedback Vertex Set asks whether G contains a vertex set S of size k such that the graph $G \setminus S$ is acyclic, and
- Cycle Packing asks whether G contains a set of k pairwise vertex-disjoint cycles.

Along the way, we also study Longest Path (decide whether G contains a path on exactly/at least k vertices) and Subgraph Isomorphism (SI). In SI, given *connected* graphs G and H on n and k vertices, respectively, the goal is to decide whether there exists a subgraph in G that is isomorphic to H. We also assume that a unit disk graph is given by a set of n points in $\mathbb{R}^2$ and there is a graph where vertices correspond to the points and there is an edge between two vertices if and only if the distance between the two points is at most 2.

In parameterized complexity each of these problems serves as a testbed for development of fundamental algorithmic techniques such as color-coding [2], the polynomial method [34, 35, 41, 4], matroid based techniques [20] for Longest Path and Longest Cycle, and kernelization techniques for Feedback Vertex Set [39]. We refer to [12] for an extensive overview of the literature on parameterized algorithms for these problems. For example, the fastest known algorithms solving Longest Path are the $1.66^k \cdot n^{\mathcal{O}(1)}$ time randomized algorithm of Björklund et al. [4], and the $2.597^k \cdot n^{\mathcal{O}(1)}$ time deterministic algorithm of Zehavi [43]. Moreover, unless the Exponential Time Hypothesis (ETH) of Impagliazzo, Paturi and Zane [30] fails, none of the problems above can be solved in time $2^{o(k)} \cdot n^{\mathcal{O}(1)}$ [30].

While all these problems remain NP-complete on planar graphs, substantially faster – *subexponential* – parameterized algorithms are known on planar graphs. In particular, by combining the bidimensionality theory of Demaine et al. [13] with efficient algorithms on graphs of bounded treewidth [17], Longest Path, Longest Cycle, Feedback Vertex Set and Cycle Packing are solvable in time $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ on planar graphs. The parameterized subexponential "tractability" of such problems can be extended to graphs excluding some fixed graph as a minor [15]. The bidimensionality arguments cannot be applied to Exact k-Cycle and this was one of the motivations for developing the new pattern-covering technique, which is used to give a randomized algorithm for Exact k-Cycle running in time $2^{\mathcal{O}(\sqrt{k}\log^2 k)}n^{\mathcal{O}(1)}$ on planar and apex-minor-free graphs [19]. The bidimensionality theory was also used to design (efficient) polynomial time approximation scheme ((E)PTAS) [14, 22] and polynomial kernelization [24] on planar graphs.

It would be interesting to find generic properties of problems, similar to the theory of bidimensionality for planar-graph problems, that could guarantee the existence of subexponential

parameterized algorithms or (E)PTAS on geometric classes of graphs, such as unit disk graphs. The theory of (E)PTAS on geometric classes of graphs is extremely well developed and several methods have been devised for this purpose. This includes methods such as shifting techniques, geometric sampling and bidimensionality theory [29, 27, 26, 28, 11, 37, 23]. However, we are still very far from a satisfactory understanding of the "subexponential" phenomena for problems on geometric graphs. We know that some problems such as Independent Set and Dominating Set, which are solvable in time $2^{\mathcal{O}(\sqrt{k})}n^{\mathcal{O}(1)}$ on planar graphs, are W[1]-hard on unit disk graphs and thus the existence of an algorithm of running time $f(k) \cdot n^{\mathcal{O}(1)}$ is highly unlikely for any function f [36]. The existence of a vertex-linear kernel for some problems on unit disk graphs such as Vertex Cover [9] or Connected Vertex Cover [32] combined with an appropriate separation theorem [1, 8, 38] yields a parameterized subexponential algorithm. A subset of the authors of this paper used a different approach based on bidimensionality theory to obtain subexponential algorithms of running time $2^{\mathcal{O}(k^{0.75}\log k)} \cdot n^{\mathcal{O}(1)}$ on unit disk graphs for Feedback Vertex Set and Cycle Packing in [23]. No parameterized subexponential algorithms on unit disk graphs for Longest Path, Longest Cycle, and Exact k-Cycle were known prior to our work.

Our Results. We design subexponential parameterized algorithms, with running time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot n^{\mathcal{O}(1)}$, for Exact k-Cycle, Longest Cycle, Longest Path, Feedback Vertex Set and Cycle Packing on unit disk graphs and unit square graphs. It is also possible to show by known NP-hardness reductions for problems on unit disk graphs [10] that an algorithm of running time $2^{o(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$ for any of our problems on unit disk graphs would imply that ETH fails. Hence our algorithms are asymptotically almost tight. Along the way we also design Turing kernels (in fact, many to one) for Exact k-Cycle, Longest Cycle, Longest Path and SI. That is, we give a polynomial time algorithm that given an instance of Exact k-Cycle or Longest Cycle or Longest Path or SI, produces polynomially many reduced instances of size polynomial in k such that the input instance is a Yes-instance if and only if one of the reduced instances is. As a byproduct of this we obtain a $2^{\mathcal{O}(k\log k)} \cdot n^{\mathcal{O}(1)}$ time algorithm for SI when G is a unit disk graph and H is an arbitrary connected graph. It is noteworthy to remark that a simple disjoint union trick implies that Exact k-Cycle, Longest Cycle, Longest Path, and SI do not admit a polynomial kernel on unit disk graphs [6]. Finally, we note that we do not use Turing kernels to design our subexponential time algorithms except for Exact k-Cycle. The subexponential time parameterized algorithm for Exact k-Cycle also uses a "double layering" of Baker's technique [3].

All our subexponential time algorithms have the following theme in common. If an input n-vertex unit disk graph G contains a clique of size $\mathsf{poly}(k)$ (such a clique can be found in polynomial time), then we have a trivial Yes-instance or No-instance, depending on the problem. Otherwise, we show that the unit disk graph G in a Yes-instance of the problem admits, sometimes after a polynomial time preprocessing, a specific type of (ω, Δ, τ)-decomposition, where the meaning of ω, Δ and τ is as follows. The vertex set of G is partitioned into cliques $C_1, \ldots, C_d$, each of size at most $\omega = k^{\mathcal{O}(1)}$. We also require that after contracting each of the cliques C_i to a single vertex, the maximum vertex degree Δ of the obtained graph $\tilde{G}$ is $\mathcal{O}(1)$, while the treewidth τ of $\tilde{G}$ is $\mathcal{O}(\sqrt{k})$. Moreover, the corresponding tree decomposition of $\tilde{G}$ can be constructed efficiently. We use the tree decomposition of $\tilde{G}$ to construct a tree decomposition of G by "uncontracting" each of the contracted cliques C_i. While the width of the obtained tree decomposition of G can be of order $\omega \cdot \tau = k^{\mathcal{O}(1)}$, we show that each of our parameterized problems can be solved in time $f(\Delta) \cdot \omega^{f(\Delta)\cdot\tau}$. Here we use dynamic programming over the constructed tree decomposition of G, however there

is a twist from the usual way of designing such algorithms. This part of the algorithm is problem-specific – in order to obtain the claimed running time, we have to establish a very specific property for each of the problems. Roughly speaking, the desired property of a problem is that it always admits an optimal solution such that for every pair of adjacent bags X, Y of the tree decomposition of G, the number of edges of this solution "crossing" a cut between X and Y is $\mathcal{O}(\sqrt{k})$. We remark that the above decomposition is *only* given in the introduction to present our ideas for all the algorithms in a unified way.

In this paper we restrict our attention to solving Exact k-Cycle and Feedback Vertex Set on unit disk graphs. We refer to the full version of the paper for all the proofs and the results.

2 Preliminaries

For a positive integer t, we use $[t]$ as a shorthand for $\{1, 2, \ldots, t\}$. Given a function $f : A \to B$ and a subset $A' \subseteq A$, let $f|_{A'}$ denote the restriction of the function f to the domain A'. For a function $f : A \to B$ and $B' \subseteq B$, $f^{-1}(B')$ denote the set $\{a \in A \ : \ f(a) \in B'\}$. For $t, t' \in \mathbb{N}$, a set $[t] \times [t']$, $i \in [t]$ and $j \in [t']$ we use $(*, j)$ and $(i, *)$ to denote the sets $\{(i', j) \ : \ i' \in [t]\}$ and $\{(i, j') \ : \ j' \in [t']\}$, respectively. For a set U, we use 2^U to denote the power set of U.

We use standard notation and terminology from the book of Diestel [16] for graph-related terms which are not explicitly defined here. Given a graph G, $V(G)$ and $E(G)$ denote its vertex-set and edge-set, respectively. When the graph G is clear from context, we denote $n = |V(G)|$ and $m = |E(G)|$. Given $U \subseteq V(G)$, we let $G[U]$ denote the subgraph of G induced by U, and we let $G \setminus U$ denote the graph $G[V(G) \setminus U]$. For an edge subset E, we use $V(E)$ to denote the set of endpoints of edges in E and $G[E]$ to denote the graph $(V(E), E)$. For $X, Y \subseteq V(G)$, we use $E(X)$ and $E(X, Y)$ to denote the edge sets $\{\{u, v\} \in E(G) \ : \ u, v \in X\}$ and $\{\{u, v\} \in E(G) \ : \ u \in X, v \in Y\}$, respectively. Moreover, we let $N(U)$ denote the open neighborhood of G. In case $U = \{v\}$, we denote $N(v) = N(U)$. Given an edge $e = \{u, v\} \in E(G)$, we use G/e to denote the graph obtained from G by contracting the edge e. In other words, G/e denotes the graph on the vertex-set $(V(G) \setminus \{u, v\}) \cup \{x_{\{u,v\}}\}$, where $x_{\{u,v\}}$ is a new vertex, and the edge-set $E(G) = E(G[V(G) \setminus \{u, v\}]) \cup \{\{x_{\{u,v\}}, w\} \mid w \in N(\{u, v\})\}$. A graph H is called a *minor* of G, if H can be obtained from G by a sequence of edge deletion, edge contraction and vertex deletion. Given $k \in \mathbb{N}$, we let K_k denote the complete graph on k vertices. For a set X, we use $K[X]$ to denote the complete graph on X. Given $a, b \in \mathbb{N}$, an $a \times b$ grid is a graph on $a \cdot b$ vertices, $v_{i,j}$ for $(i, j) \in [a] \times [b]$, such that for all $i \in [a - 1]$ and $j \in [b]$, it holds that $v_{i,j}$ and $v_{i+1,j}$ are neighbors, and for all $i \in [a]$ and $j \in [b - 1]$, it holds that $v_{i,j}$ and $v_{i,j+1}$ are neighbors. For ease of presentation, for any function $f : D \to [a] \times [b]$, $i \in [a]$ and $j \in [b]$, we use $f^{-1}(i, j)$, $f^{-1}(*, j)$, and $f^{-1}(i, *)$ to denote the sets $f^{-1}((i, j))$, $f^{-1}((*, j))$, and $f^{-1}((i, *))$, respectively.

We also need the standard notions of pathwidth, treewidth and nice tree decomposition. These definitions are given in the appendix for easy perusal (also in the appended version). However, we use slightly different but equivalent definition of path decomposition.

▶ **Definition 1.** A *path decomposition* of a graph G is a sequence $\mathcal{P} = (X_1, X_2, \ldots, X_\ell)$, where each $X_i \subseteq V(G)$ is called a *bag*, that satisfies the following conditions.

- $\bigcup_{i \in [\ell]} X_i = V(G)$.
- For every edge $\{u, v\} \in E(G)$ there exists $i \in [\ell]$ such that $\{u, v\} \subseteq X_i$.
- For every vertex $v \in V(G)$, if $v \in X_i \cap X_j$ for some $i \leq j$, then $v \in X_r$ for all $r \in \{i, \ldots, j\}$.

The *width* of $\mathcal{P}$ is $\max_{i \in [\ell]} |X_i| - 1$.

The *pathwidth* of G, $\mathsf{pw}(G)$, is the minimum width of a path decomposition of G.

▶ **Proposition 2** ([5, 7]). *Given a graph G and an integer k, in time $2^{\mathcal{O}(k)} \cdot n$, we can either decide that $\mathsf{tw}(G) > k$ or output a tree decomposition of G of width $5k$. Furthermore, given a graph G and a tree decomposition $\mathcal{T}$ of G, a nice tree decomposition $\mathcal{T}'$ of the same width as $\mathcal{T}$ can be computed in linear time.*

Given a set of geometric objects, O, we say that a graph G *represents* O if each vertex in $V(G)$ represents a distinct geometric object in O, and every geometric object in O is represented by a distinct vertex in $V(G)$. In this case, we abuse notation and write $V(G) = O$. The *intersection graph of* O is a graph G that represent O and satisfies $E(G) = \{\{u, v\} : u, v \in O, u \cap v \neq \emptyset\}$. Let $P = \{p_1 = (x_1, y_1), p_2 = (x_2, y_2), \ldots, p_n = (x_n, y_n)\}$ be a set of points in the Euclidean plane. In the *unit disk graph model*, for every $i \in [n]$, we let d_i denote the disk of radius 1 whose centre is p_i. Accordingly, we denote $D = \{d_1, d_2, \ldots, d_n\}$. Then, the *unit disk graph of* D is the intersection graph of D. Alternatively, the unit disk graph of D is the geometric graph of G such that $E(G) = \{\{p_i = (x_i, y_i), p_j = (x_j, y_j)\} \mid p_i, p_j \in D, i \neq j, \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \leq 2\}$.

3 Clique-Grid Graphs

In this section, we introduce a family of "grid-like" graphs, called clique-grid graphs, that is tailored to fit our techniques. Given a unit disk graph G, we extract the properties of G that we would like to exploit, and show that they can be captured by an appropriate clique-grid graph. Let us begin by giving the definition of a clique-grid graph. Roughly speaking, a graph G is a clique-grid graph if each of its vertices can be embedded into a single cell of a grid (where multiple vertices can be embedded into the same cell), ensuring that the subgraph induced by each cell is a clique, and that each cell can interact (via edges incident to its vertices) only with cells at "distance" at most 2. Formally,

▶ **Definition 3** (clique-grid graph). A graph G is a *clique-grid graph* if there exists a function $f : V(G) \to [t] \times [t']$, for some $t, t' \in \mathbb{N}$, such that the following conditions are satisfied.

1. For all $(i, j) \in [t] \times [t']$, it holds that $f^{-1}(i, j)$ is a clique.
2. For all $\{u, v\} \in E(G)$, it holds that if $f(u) = (i, j)$ and $f(v) = (i', j')$ then $|i - i'| \leq 2$ and $|j - j'| \leq 2$.

Such a function f is a *representation* of G.

We note that a notion similar to clique-grid graph was also used by Ito and Kadoshita [31]. For the sake of clarity, we say that a pair $(i, j) \in [t] \times [t']$ is a *cell*. The following lemma states that a unit disk graph is a clique-grid graph, and its proof is deferred to [21].

▶ **Lemma 4.** *Let D be a set of points in the Euclidean plane, and let G be the unit disk graph of D. Then, a representation f of G can be computed in polynomial time.*

Due to Lemma 4, throughout this paper, we assume that along with a input unit disk graph G, we are given a representation f of G. We conclude this section by introducing the definition of an ℓ-NCTD which is useful for doing our dynamic programming algorithms.

▶ **Definition 5.** A tree decomposition $\mathcal{T} = (T, \beta)$ of a clique-grid graph G with representation f is a *nice ℓ-clique tree decomposition*, or simply an *ℓ-NCTD*, if for the root r of T, it holds that $\beta(r) = \emptyset$, and for each node $v \in V(T)$, it holds that

- There exist at most ℓ cells, $(i_1, j_1), \ldots, (i_\ell, j_\ell)$, such that $\beta(v) = \bigcup_{t=1}^{\ell} f^{-1}(i_t, j_t)$, and
- The node v is of one of the following types.

- **Leaf**: v is a leaf in T and $\beta(v) = \emptyset$.
- **Forget**: v has exactly one child u, and there exists a cell $(i,j) \in [t] \times [t']$ such that $f^{-1}(i,j) \subseteq \beta(u)$ and $\beta(v) = \beta(u) \setminus f^{-1}(i,j)$.
- **Introduce**: v has exactly one child u, and there exists a cell $(i,j) \in [t] \times [t']$ such that $f^{-1}(i,j) \subseteq \beta(v)$ and $\beta(v) \setminus f^{-1}(i,j) = \beta(u) \setminus f^{-1}(i,j)$.
- **Join**: v has exactly two children, u and w, and $\beta(v) = \beta(u) = \beta(w)$.

A *nice ℓ-clique path decomposition*, or simply an *ℓ-NCPD*, is an ℓ-NCTD where T is a path. In this context, for convenience, we use the notation referring to a sequence presented in Section 2.

4 Turing Kernels

In this section we give an overview of a Turing kernel (actually a compression) for SI. The reason for stating our result in this way is, that this is how we use it in the next section to design a subexponential algorithm for Exact k-Cycle. We refer to the appended version for a Turing kernel for SI and Longest Cycle. More precisely, we show the following.

▶ **Theorem 6.** *Let (G, f, H, k) be an instance of* SI *on unit disk graphs, then in polynomial time, one can output a set $\mathcal{I}$ of instances of* SI *on clique-grid graphs such that (G, f, H, k) is a* Yes*-instance if and only if at least one instance in $\mathcal{I}$ is a* Yes*-instance, and for all $(\widehat{G}, \widehat{f} : V(\widehat{G}) \to [\widehat{t}] \times [\widehat{t'}], \widehat{H}, \widehat{k}) \in \mathcal{I}$, $\widehat{G}$ is either an induced subgraph of G or $K_{\widehat{k}}$, $\widehat{t}, \widehat{t'} \leq 2\widehat{k}$, $|\widehat{f}^{-1}(i,j)| < \widehat{k}$ for any $(i,j) \in [\widehat{t}] \times [\widehat{t'}]$, $\widehat{H} = H$, $\widehat{k} = k$, $|V(\widehat{G})| = \mathcal{O}(k^3)$, and $|E(\widehat{G})| = \mathcal{O}(k^4)$.*

Proof Sketch. First, suppose that there exists a cell $(i,j) \in [t] \times [t']$ such that $|f^{-1}(i,j)| \geq k$, then by Definition 3, $G[f^{-1}(i,j)]$ is a clique on at least k vertices. In particular, the pattern H is a subgraph of $G[f^{-1}(i,j)]$, and therefore it is also a subgraph of G. Thus, in this case, we conclude the proof by setting $\mathcal{I}$ to be the set that contains only one instance, $(K_k, \widehat{f} : V(K_k) \to [1] \times [1], H, k)$. From now on, suppose that for all cells $(i,j) \in [t] \times [t']$, it holds that $|f^{-1}(i,j)| < k$.

Now, our kernelization algorithm works as follows. For every $(p,q) \in [t] \times [t']$, it computes

$$G_{p,q} = G[\bigcup_{\substack{p \leq i < \min\{p+2k, t+1\} \\ q \leq j < \min\{q+2k, t'+1\}}} f^{-1}(i,j)].$$

Accordingly, it computes $f_{p,q} : V(G_{p,q}) \to [\min\{2k,t\}] \times [\min\{2k,t'\}]$ as follows. For every $v \in V(G_{p,q})$, compute $f_{p,q}(v) = (i-p+1, j-q+1)$ where $(i,j) = f(v)$. Note that for all $(i,j) \in [\min\{2k,t\}] \times [\min\{2k,t'\}]$, it holds that $f_{p,q}^{-1}(i,j) = f^{-1}(i+p-1, j+q-1)$. Thus, since f is a representation of G, it holds that $f_{p,q}$ is a representation of $G_{p,q}$. Finally, our kernelization algorithm outputs $\mathcal{I} = \{I_{p,q} = (G_{p,q}, f_{p,q}, H, k) : (p,q) \in [t] \times [t']\}$.

To conclude the proof, it remains to show that (G, f, H, k) is a Yes-instance if and only if at least one instance in $\mathcal{I}$ is a Yes-instance. Since for all $(G_{p,q}, f_{p,q}, H, k) \in \mathcal{I}$, it holds that $G_{p,q}$ is an induced subgraph of G, we have that if (G, f, H, k) is a No-instance, then every instance in $\mathcal{I}$ is No-instance as well. Next, suppose that (G, f, H, k) is a Yes-instance. Then, let H' be a subgraph of G that is isomorhpic to H. In order to complete the proof, we introduce a notion of *ℓ-stretched*. We say that H' is *ℓ-stretched* if there exist cells $(i,j), (i',j') \in [t] \times [t']$ such that the following conditions are satisfied: (i) $|i-i'| \geq 2\ell$ or $|j-j'| \geq 2\ell$ (or both); and (b) $V(H') \cap f^{-1}(i,j) \neq \emptyset$ and $V(H') \cap f^{-1}(i',j') \neq \emptyset$. One can show (see the appended version) that for any subgraph H' of G that is isomorphic to H, it holds that H' is not $2k$-stretched. Using this *claim* we can conclude. Denote $i_{\min} = \min\{i \in [t] : (\bigcup_{j \in [t']} f^{-1}(i,j)) \cap V(H') \neq \emptyset\}$,

$i_{\max} = \max\{i \in [t] : (\bigcup_{j\in[t']} f^{-1}(i,j)) \cap V(H') \neq \emptyset\}$, $j_{\min} = \min\{j \in [t'] : (\bigcup_{i\in[t]} f^{-1}(i,j)) \cap V(H') \neq \emptyset\}$ and $j_{\max} = \max\{j \in [t'] : (\bigcup_{i\in[t]} f^{-1}(i,j)) \cap V(H') \neq \emptyset\}$. From the above claim, it holds that both $i_{\max} - i_{\min} < 2k$ and $j_{\max} - j_{\min} < 2k$. Therefore, H' is a subgraph of $G_{i_{\min},j_{\min}}$, which implies that $I_{p,q}$ is a YES-instance. ◀

5 Exact k-Cycle

In this section we prove the following theorem.

▶ **Theorem 7.** EXACT k-CYCLE *on unit disk graphs can be solved in* $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ *time.*

By Theorem 6, we have seen that SI admits a polynomial sized Turing kernel. Hence to give an algorithm of running time $2^{\mathcal{O}(\sqrt{k}\log k)}|V(G)|^{\mathcal{O}(1)}$, we can restrict to instances returned by Theorem 6. More precisely, because of Theorem 6, we can assume that the input to our algorithm is $(G, f : V(G) \to [t] \times [t'], k)$ where G is a clique-grid graph with a representation f, $|f^{-1}(i,j)| < k$ for all $(i,j) \in [t] \times [t']$, and $t, t' \leq 2k$. Without loss of generality we can assume that f is a function from $V(G)$ to $[2k] \times [2k]$, because $[t] \times [t'] \subseteq [2k] \times [2k]$.

Given an instance $(G, f : V(G) \to [2k] \times [2k], k)$, the algorithm applies a method inspired by Baker's technique [3] and obtains a family, $\mathcal{F}$, of $2^{\mathcal{O}(\sqrt{k}\log k)}$ instances of EXACT k-CYCLE. The family $\mathcal{F}$ has following properties.

1. In each of these instances the input graph is an induced subgraph of G and has size $k^{\mathcal{O}(1)}$.
2. The input $(G, f : V(G) \to [2k] \times [2k], k)$ is a YES-instance if and only if there exists an instance $(H, f^* : V(H) \to [2k] \times [2k], k) \in \mathcal{F}$ which is a YES-instance.
3. More over, for any instance $(H, f^* : V(H) \to [2k] \times [2k], k) \in \mathcal{F}$, H has a nice $7\sqrt{k}$-clique path decomposition ($7\sqrt{k}$-NCPD).

We will call the family $\mathcal{F}$ satisfying the above properties as *good family*. Let $(H, f^* : V(H) \to [2k] \times [2k], k)$ be an instance of $\mathcal{F}$. Let $\mathcal{P} = (X_1, \ldots, X_q)$ be a $7\sqrt{k}$-NCPD of H. We first prove that if there is a cycle of length k in H, then there is a cycle C of length k in H such that for any two distinct cells (i,j) and (i',j') of f, the number of edges with one end point in (i,j) and other in (i',j') is at most 4. Let C be such a cycle in H. Then using the property of C we get the following important property.

> For any $i \in [q]$, the number of edges of $V(C)$ with one end point in X_i and other in $\bigcup_{i<j\leq q} X_j$ is in $\mathcal{O}(\sqrt{k})$.

The above mentioned property allows us to design a dynamic programming (DP) algorithm over $7\sqrt{k}$-NCPD, $\mathcal{P}$, for EXACT k-CYCLE in time $2^{\mathcal{O}(\sqrt{k}\log k)}$. Now we are ready to give formal details about the algorithm. As explained before, we assume that the number of vertices in the input graph is bounded by $k^{\mathcal{O}(1)}$.

▶ **Lemma 8.** *Let* $(G, f : V(G) \to [2k] \times [2k], k)$ *be an instance of* EXACT k-CYCLE*, where* G *is a clique-grid graph with representation* f*,* $|f^{-1}(i,j)| < k$ *for all* $(i,j) \in [2k] \times [2k]$ *and* $|V(G)| = k^{\mathcal{O}(1)}$*. Given* $(G, f : V(G) \to [2k] \times [2k], k)$*, there is an algorithm running in time* $2^{\mathcal{O}(\sqrt{k}\log k)}$ *that outputs a good family* $\mathcal{F}$*.*

Proof. Let C be a k length cycle in G. First we define a column of the $2k \times 2k$ grid. For any $j \in [2k]$ the set of cells $\{(i,j) \ : \ i \in [2k]\}$ is called a column. There are $2k$ columns for the $2k \times 2k$ grid. We partition $2k$ columns of the $2k \times 2k$ grid with k blocks of two consecutive columns and label them from the set of labels $[\sqrt{k}]$. That is, both columns $2i-1$ and $2i$,

where $i \in [k]$, are labelled with $i \mod \sqrt{k}$. Then by pigeon hole principle there is a label $\ell \in \{1, 2, \ldots, \sqrt{k}\}$ such that the number of vertices from $V(C)$ which are in columns labelled ℓ is at most $\sqrt{k}$. As $|V(G)| \leq k^{\mathcal{O}(1)}$, the number of vertices of G in columns labelled ℓ is at most $k^{\mathcal{O}(1)}$. We guess the vertices of $V(C)$ which are in the columns labelled ℓ. The number of potential guesses is bounded by $k^{\mathcal{O}(\sqrt{k})}$. Let Y be the set of guessed vertices of $V(C)$ which are in the columns labelled by ℓ. Notice that $|Y| \leq \sqrt{k}$. Then we delete all the vertices in columns labelled ℓ, except the vertices of Y. Let S be the set of deleted vertices. By the property 2 of clique-grid graph, $G \setminus (S \cup Y)$ is a disjoint union of clique-grid graphs each of which is represented by a function with at most $2\sqrt{k}$ columns. That is, let $G_1 = G[\bigcup_{j=1}^{2(\ell-1)} f^{-1}(*, j)]$, and $G_{i+1} = G[\bigcup_{j=i\cdot 2\ell+1}^{\min\{i\cdot 2\ell+2\sqrt{k}, 2k\}} f^{-1}(*, j)]$ for all $i \in \{1, \ldots, \lceil\sqrt{k}\rceil\}$. Notice that G_i is clique-grid graph with representation $f_i : V(G_i) \to [2k] \times [2\sqrt{k}]$ defined as, $f_i(u) = (r, j)$, when $f(u) = (r, (i-1)2\ell+j)$. By the property 2 of clique-grid graph, $G \setminus (S \cup Y) = G_1 \uplus \ldots \uplus G_{\lceil\sqrt{k}\rceil+1}$.

▶ **Claim 1.** *$G \setminus S$ has a nice $7\sqrt{k}$-clique path decomposition ($7\sqrt{k}$-NCPD).*

Proof. First, for each $i \in \{1, \ldots, \lceil\sqrt{k}\rceil + 1\}$, we will define a path decomposition of G_i (in the next paragraph) such that each bag is a union of at most $6\sqrt{k}$ many cells of f_i. As $G \setminus (S \cup Y) = G_1 \uplus \ldots \uplus G_{\lceil\sqrt{k}\rceil-1}$, and $|Y| \leq \sqrt{k}$, by adding Y to each bag of all path decompositions we can get a required nice $7\sqrt{k}$-clique path decomposition for $G \setminus S$.

Now, for each G_i, we define a path decomposition $\mathcal{P}_i = (X_{i,1}, X_{i,2}, \ldots X_{i,2k-2})$ where $X_{i,j} = f_i^{-1}(j, *) \cup f_i^{-1}(j+1, *) \cup f_i^{-1}(j+2, *)$. We claim that $\mathcal{P}_i$ is a path decomposition of G_i. Notice that $\bigcup_{j=1}^{k-1} X_{i,j} = f_i^{-1}(*, *) = V(G_i)$. By property 2 of clique-grid graph, we have that for each edge $\{u, v\} \in E(G)$, there exists $j \in [2k-2]$ such that $\{u, v\} \in X_{i,j}$. For each $u \in V(G)$, u is contained in at most three bags and these bags are consecutive in the sequence $(X_{i,1}, X_{i,2}, \ldots X_{i,2k-2})$. Hence $\mathcal{P}_i$ is a path decomposition of G_i. Since $X_{i,j} = f_i^{-1}(j, *) \cup f_i^{-1}(j+1, *) \cup f_i^{-1}(j+2, *)$, number of columns in f_i is at most $2\sqrt{k}$ and each cell of f_i is a cell of f, each $X_{i,j}$ is a union of $6\sqrt{k}$ many cells of f. Since $G \setminus (S \cup Y) = G_1 \uplus \ldots \uplus G_{\lceil\sqrt{k}\rceil+1}$, the sequence $\mathcal{P}' = (X_{1,1}, \ldots X_{1,2k-2}, X_{2,1}, \ldots X_{2,2k-2}, \ldots, X_{\lceil\sqrt{k}\rceil-1,1}, \ldots X_{\lceil\sqrt{k}\rceil-1,2k-2})$ is a path decomposition of $G \setminus (S \cup Y)$. More over, the vertices of each bag is a union of vertices from at most $6\sqrt{k}$ cells of f. Also, since $|Y| \leq \sqrt{k}$, the sequence $\mathcal{P} = (X_{1,1} \cup Y, \ldots X_{1,k-2} \cup Y, \ldots X_{\lceil\sqrt{k}\rceil-1,k-2} \cup Y)$ obtained by adding Y to each bag of $\mathcal{P}'$ we get a path decomposition of $G \setminus S$. More over, the vertices of each bag in $\mathcal{P}$ is a union of vertices from at most $7\sqrt{k}$ cells of f. We can turn the path decomposition $\mathcal{P}$ to a $7\sqrt{k}$-NCPD by an algorithm similar to the one mentioned in Proposition 2. ◀

The algorithm constructs a family $\mathcal{F}$ as follows. For each $\ell \in \{1, \ldots, \lceil\sqrt{k}\rceil\}$ and for two subsets of vertices S and Y such that $S \cup Y$ is a set of vertices in the columns labelled ℓ and $|Y| \leq \sqrt{k}$, our algorithm includes an instance $(G \setminus S, f|_{V(G)\setminus S}, k)$ in $\mathcal{F}$. The number of choices of S and Y is bounded by $2^{\mathcal{O}(\sqrt{k}\log k)}$ and thus the size of $\mathcal{F}$ is bounded by $2^{\mathcal{O}(\sqrt{k}\log k)}$. We claim that $\mathcal{F}$ is indeed a good family. Let C be a cycle of length k in G. Then, there is an $\ell \in \{1, \ldots, \lceil\sqrt{k}\rceil\}$ such that at most $\sqrt{k}$ vertices from $V(C)$ are in the columns labelled by ℓ. Let S' be the set of vertices in the columns labelled by ℓ. Let $Y = S' \cap V(C)$ and $S = S' \setminus Y$. The instance $(G \setminus S, f|_{V(G)\setminus S}, k)$ in $\mathcal{F}$ is a YES instance. This concludes the proof. ◀

Now we can assume that we are solving EXACT k-CYCLE on (H, f, k), where $(H, f, k) \in \mathcal{F}$ (here we rename the function $f|_{V(H)}$ with f for ease of presentation). Now we prove that if there is a cycle of length k in H, then there is a cycle C of length k in H such that for any two cells (i, j) and (i', j') of f, the number of edges of $E(C)$ with one end point in (i, j) and other (i', j') is at most 5.

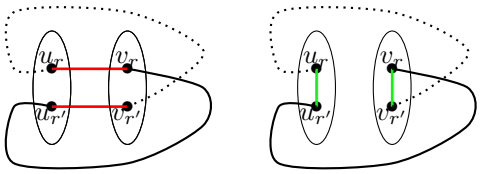

Figure 1 Illustration of Lemma 9. Figure on the left is the cycle $C = [u_r v_r]Q_1[u_{r'} v_{r'}]Q_2$ and the one on the right is the cycle $C' = [u_r u_{r'}]\overleftarrow{Q}_1[v_r v_{r'}]Q_2$.

▶ **Lemma 9.** *Let $(H, f : V(H) \to [2k] \times [2k], k)$ be a* Yes *instance of* Exact k-Cycle. *Then there is a cycle C of length k in H such that for any two distinct cells (i, j) and (i', j') of f, the number of edges of $E(C)$ with one end point in (i, j) and other (i', j') is at most* 5.

Proof. Let C be a k length cycle such that the number edges of $E(C)$ whose end points are in different cells is minimized. We claim that for any two disjoint cells (i, j) and (i', j'), the number of edges of $E(C)$ with one end point in (i, j) and other (i', j') is at most 5. Suppose not. Then there exist (i, j) and (i', j') such that the number of edges of $E(C)$ with one end point in (i, j) and other in (i', j') is at least 6. Let $C = P_1[u_1 v_1]P_2[u_2 v_2]P_3[u_3 v_3]P_4[u_4 v_4]P_5[u_5 v_5]P_6[u_6 v_6]$ where for each $\{u_r, v_r\}, r \in [6]$, one end point is in the cell (i, j) and other in the cell $(i'j')$, and each subpath $P_\ell, \ell \in [6]$, can be empty too. Since C is a cycle, at least 3 edges from $\{\{u_r, v_r\} : i \in [6]\}$ form a matching. Let $\{u_{r_1}, v_{r_1}\}, \{u_{r_2}, v_{r_2}\}$ and $\{u_{r_3}, v_{r_3}\}$ be a matching of size 3, where $\{r_1, r_2, r_3\} \subseteq [6]$. Then, by pigeon hole principle there exist $r, r' \in \{r_1, r_2, r_3\}$ such that either $u_r, u_{r'} \in f^{-1}(i, j)$ or $u_r, u_{r'} \in f^{-1}(i', j')$. Without loss of generality assume that $u_r, u_{r'} \in f^{-1}(i, j)$ (otherwise we rename cell (i, j) with (i', j') and vice versa). That is, $C = [u_r v_r]Q_1[u_{r'} v_{r'}]Q_2$ such that $u_r, u_{r'} \in f^{-1}(i, j)$ and $v_r, v_{r'} \in f^{-1}(i', j')$. Then, since $f^{-1}(i, j)$ and $f^{-1}(i', j')$ are cliques, $C' = [u_r u_{r'}]\overleftarrow{Q}_1[v_r v_{r'}]Q_2$ is a k length cycle in G, such that the number edges of $E(C')$ whose end points are in different cells is less than that of $E(C)$, which is contradiction to our assumption. See Fig. 1 for an illustration of C and C'. This completes the proof. ◀

Next we design a DP algorithm that finds a cycle of length k, if it exists, satisfying properties of Lemma 9.

▶ **Lemma 10.** *Let $(H, f : V(H) \to [2k] \times [2k], k) \in \mathcal{F}$ be an instance of* Exact k-Cycle. *and $\mathcal{P}$ be a $7\sqrt{k}$-NCPD of H. Then, given $(H, f : V(H) \to [2k] \times [2k], k)$ and $\mathcal{P}$, there is an algorithm $\mathcal{A}$ which runs in time $2^{\mathcal{O}(\sqrt{k} \log k)}$, and outputs* Yes, *if there is a cycle C in H such that for any two distinct cells (i, j) and (i', j') of f, the number of edges with one end point in (i, j) and other (i', j') is at most* 5. *Otherwise algorithm $\mathcal{A}$ will output* No.

Proof Sketch. Algorithm $\mathcal{A}$ is a DP algorithm over the $7\sqrt{k}$-NCPD $\mathcal{P} = (X_1, \ldots X_q)$ of H. For any $\ell \in [q]$, we define H_ℓ be the induced subgraph $H[\bigcup_{i \leq \ell} X_i]$ of H. Define $\mathcal{C}$ to be the set of k-length cycles in H such that for any $C \in \mathcal{C}$ and two disjoint cells (i, j) and (i', j') of f, the number of edges of $E(C)$ with one end point in (i, j) and other (i', j') is at most 5. Let $C \in \mathcal{C}$. Since $\mathcal{P}$ is a $7\sqrt{k}$-NCPD and the fact that for any two distinct cells (i, j) and (i', j') of f, the number of edges of C with one end point in (i, j) and other (i', j') is at most 5, we have that for any bag X_ℓ of $\mathcal{P}$, the number of vertices of $V(C) \cap X_\ell$ which has a neighbour in $V(H) \setminus X_\ell$ is bounded by $\mathcal{O}(\sqrt{k})$. This allows us to keep only $2^{\mathcal{O}(\sqrt{k} \log k)}$ states in the DP algorithm. Fix any $\ell \in [q]$ and define C_L the set of paths of C (or the cycle C itself) when we restrict C to H_ℓ. That is $C_L = H_\ell[E(C)]$. Let $\widehat{C}_L = \{\{u, v\} \mid \text{there is a } u\text{-}v \text{ path in } C_L\}$. Notice that $\bigcup_{P \in \widehat{C}_L} P$ is the set of vertices of degree 0 or 1 in C_L and $\bigcup_{P \in \widehat{C}_L} P \subseteq X_\ell$. Since

X_ℓ is a union of vertices from at most $7\sqrt{k}$ many cells of f and for any two distinct cells (i,j) and (i',j') of f, the number of edges of $E(C)$ with one end point in (i,j) and other (i',j') is at most 5, and by property 2 of the clique-grid graph, we have that the cardinality of $\bigcup_{P \in \widehat{C}_L} P$ is at most $5 \cdot 24 \cdot 7\sqrt{k} = 840\sqrt{k}$. In our DP algorithm we will have state indexed by $(\ell, \widehat{C}_L, |E(C_L)|)$ which will be set to 1. Formally, for any $\ell \in [q]$, $k' \in [k]$ and a family $\mathcal{Z}$ of vertex disjoint sets of size at most 2 of X_ℓ with the property that the cardinality of $\bigcup_{Z \in \mathcal{Z}} Z$ is at most $840\sqrt{k}$, we will have a DP table entry $\mathcal{A}[\ell, \mathcal{Z}, k']$. For each $\ell \in [q]$, we maintain the following correctness invariant.

Correctness Invariants: (i) For every $C \in \mathcal{C}$, let $C_L = H_\ell[E(C)]$. For every $C \in \mathcal{C}$, let $\widehat{C}_L = \{\{u,v\} \mid$ there is a connected component P in C_L and P is a u-v path as well$\}$. Then $\mathcal{A}[\ell, \widehat{C}_L, |E(C_L)|] = 1$, (ii) for any family $\mathcal{Z}$ of vertex disjoint sets of size at most 2 of X_ℓ with $0 < |\bigcup_{Z \in \mathcal{Z}} Z| \leq 840\sqrt{k}$, $k' \in [k]$, and $\mathcal{A}[\ell, \mathcal{Z}, k'] = 1$, there is a set $\mathcal{Q}$ of $|\mathcal{Z}|$ vertex disjoint paths in H_ℓ where the end points of each path are specified by a set in $\mathcal{Z}$ and $|E(\mathcal{Q})| = k'$, and (iii) if $\mathcal{A}[\ell, \emptyset, k] = 1$, then there is a cycle of length k in H_ℓ.

The correctness of the our algorithm will follow from the correctness invariant. We fill the DP table entries similar to the way it is done for dynamic programming algorithms on graphs of bounded treewidth. That is, we fill the table entries by considering various cases for bags (introduce and forget) and using the previously computed DP table entries. A complete detailed proof is provided in the appended version. ◀

Theorem 7 follows from Theorem 6 and Lemmata 8, 9, and 10.

6 Feedback Vertex Set

In this section, we show that Feedback Vertex Set (FVS) admits a subexponential-time parameterized algorithm. More precisely, we prove the following.

▶ **Theorem 11.** FVS *on unit disk graphs can be solved in time* $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$.

For an algorithm for FVS and other problems such as Cycle Packing, we need more compact representations of clique-grid graphs. In the next section we introduce these notions.

6.1 The Cell Graph of a Clique-Grid Graph

We introduce two compact representations of clique-grid graphs. By examining these representations, we are able to infer information on the structure of clique-grid graphs that are also unit disk graphs.

▶ **Definition 12** (backbone)**.** Given a clique-grid graph G with representation $f : V(G) \to [t] \times [t']$, an induced subgraph H of G is a *backbone* for (G, f) if for any two distinct cells $(i,j), (i',j') \in [t] \times [t']$ for which there exist $u \in f^{-1}(i,j)$ and $v \in f^{-1}(i',j')$ such that $\{u,v\} \in E(G)$, there also exist $u' \in f^{-1}(i,j)$ and $v' \in f^{-1}(i',j')$ such that $\{u',v'\} \in E(H)$. If no induced subgraph of H is a backbone for (G,f), then H is a *minimal backbone* for (G,f).

First, we bound the maximum degree of a minimal backbone.

▶ **Lemma 13.** *Let G be a clique-grid graph with representation f, and let H be a minimal backbone for (G,f). Then, for all $(i,j) \in [t] \times [t']$, it holds that $|f^{-1}(i,j) \cap V(H)| \leq 24$. Furthermore, the maximum degree of H is at most* 599.

Proof. By Condition 2 in Definition 3, we have that for all cells $(i,j) \in [t] \times [t']$, it holds that $f^{-1}(i,j) \cap V(H) \leq |\{(i',j') \in [t] \times [t'] \setminus \{(i,j)\} \mid |i-i'| \leq 2, |j-j'| \leq 2\}| \leq 24$. Thus, for all $(i,j) \in [t] \times [t']$, the degree in H of a vertex in $f^{-1}(i,j) \cap V(H)$ is bounded by $|(\bigcup_{\{(i',j') \in [t] \times [t'] \mid |i-i'| \leq 2, |j-j'| \leq 2\}} f^{-1}(i,j) \cap V(H)) \setminus \{v\}| \leq |\{(i',j') \in [t] \times [t'] \mid |i-i'| \leq 2, |j-j'| \leq 2\}| \cdot 24 - 1 = 25 \cdot 24 - 1 = 599$. ◀

We compute a minimal backbone as follows. Initializes $H = G$; then, for every vertex $v \in V(G)$, it checks if the graph $H \setminus \{v\}$ has the same backbone as H, in which case it updates H to $H \setminus \{v\}$. Thus, a minimal backbone H for (G,f) can be computed in polynomial time. To analyze the treewidth of a backbone, we need the following.

▶ **Proposition 14** ([23]). *Let G be a unit disk graph with maximum degree Δ. Then G contains a $\frac{\mathsf{tw}}{100\Delta^3} \times \frac{\mathsf{tw}}{100\Delta^3}$ grid as a minor.*

▶ **Lemma 15.** *Given a clique-grid graph G that is a unit disk graph, a representation f of G and an integer $\ell \in \mathbb{N}$, in time $2^{\mathcal{O}(\ell)} \cdot n^{\mathcal{O}(1)}$, one can either correctly conclude that G contains a $\frac{\ell}{100 \cdot 599^3} \times \frac{\ell}{100 \cdot 599^3}$ grid as a minor, or obtain a minimal backbone H for (G,f) with a nice tree decomposition $\mathcal{T}$ of width at most 5ℓ.*

We will use Lemma 15 with $\ell = \mathcal{O}(\sqrt{k})$. Next, we define a more compact representation of a clique-grid graph.

▶ **Definition 16** (cell graph). Given a clique-grid graph G with representation $f : V(G) \to [t] \times [t']$, the *cell graph* of G, denoted by $\mathsf{cell}(G)$, is the graph on the vertex-set $\{v_{i,j} : i \in [t], j \in [t'], f^{-1}(i,j) \neq \emptyset\}$ and edge-set $\{\{v_{i,j}, v_{i',j'}\} : (i,j) \neq (i',j'), \exists u \in f^{-1}(i,j) \exists v \in f^{-1}(i',j')$ such that $\{u,v\} \in E(G)\}$.

By Definitions 12 and 16, and the that for any graph G and a minor H of G, it holds that $\mathsf{tw}(H) \leq \mathsf{tw}(G)$, we conclude the following.

▶ **Observation 17.** *For a clique-grid graph G, a representation f of G and a backbone H for (G,f), it holds that $\mathsf{cell}(G)$ is a minor of H and $\mathsf{tw}(\mathsf{cell}(G)) \leq \mathsf{tw}(H)$.*

Note that a nice tree decomposition of $\mathsf{cell}(G)$ of width 5ℓ corresponds to a 5ℓ-NCTD of G. In other words, from Lemma 15 and Observation 17, we directly have the following..

▶ **Corollary 18.** *Given a clique-grid graph G that is a unit disk graph, a representation f of G and an integer $\ell \in \mathbb{N}$, in time $2^{\mathcal{O}(\ell)} \cdot n^{\mathcal{O}(1)}$, one can either correctly conclude that G contains a $\frac{\ell}{100 \cdot 599^3} \times \frac{\ell}{100 \cdot 599^3}$ grid as a minor, or compute a 5ℓ-NCTD of G.*

6.2 Outline of an Algorithm for FVS

First, we observe that if we find a large grid, we can answer No (see also [15, 12]).

▶ **Observation 19.** *Let (G,k) be an instance of* FVS. *If G contains a $2\sqrt{k} \times 2\sqrt{k}$ grid as a minor, then (G,k) is a* No*-instance.*

This observation leads us to the following.

▶ **Lemma 20.** *Let (G,O,k) be an instance of* FVS *on unit disk graphs. Then, in time $2^{\mathcal{O}(\sqrt{k}\log k)} \cdot |V(G)|^{\mathcal{O}(1)}$, one can either solve (G,O,k) or obtain an equivalent instance (G,f,k) of* FVS *on clique-grid graphs together with an $\mathcal{O}(\sqrt{k})$-NCTD of G.*

Proof. First, by using Lemma 4, we obtain a representation f of G. Then, by using Corollary 18 with $\ell = 200 \cdot 599^3 \cdot \sqrt{k} = \mathcal{O}(\sqrt{k})$, we either correctly conclude that G contains a $2\sqrt{k} \times 2\sqrt{k}$ grid as a minor, or compute an $\mathcal{O}(\sqrt{k})$-NCTD of G. In both cases, by Observation 19, we are done. ◀

Because of Lemma 20, to prove Theorem 11, we can focus on FVS on clique-grid graphs, where the input also contains a $\mathcal{O}(\sqrt{k})$-NCTD. That is, the input of FVS on clique-grid graphs is a tuple $(G, f, k, \mathcal{T})$ where G is a clique-grid graph with representation f and $\mathcal{T} = (T, \beta)$ is a $\mathcal{O}(\sqrt{k})$-NCTD of G. Notice that if there is a cell (i, j) of f, such that $|f^{-1}(i, j)| \geq k + 3$, then there is no feedback vertex set of size at most k in G, because $f^{-1}(i, j)$ is a clique of size at least $k + 3$ in G.

▶ **Observation 21.** *Let $(G, f, k, \mathcal{T})$ be an instance of* FVS*, where G is a clique-grid graph with representation f. If there is a cell (i, j) in f such that $|f^{-1}(i, j)| \geq k+3$, then $(G, f, k, \mathcal{T})$ is a* No*-instance.*

The following observation follows from the fact that $\mathcal{T} = (T, \beta)$ is a $\mathcal{O}(\sqrt{k})$-NCTD and $|f^{-1}(i, j)| \leq k + 2$ for any cell (i, j) of f.

▶ **Observation 22.** *For any $v \in V(T)$, $|\beta(v)| = \mathcal{O}(k^{1.5})$.*

Notice that G has a feedback vertex set of size at most k if and only if there is a vertex subset $F \subseteq V(G)$ of cardinality at least $|V(G)| - k$ such that $G[F]$ is a forest. Hence, instead of stating the problem as finding a k sized feedback vertex set in G, we can state it as finding an induced subgraph H of G with maximum number of vertices such that H is a forest.

Max Induced Forest (MIF) **Parameter:** k
Input: A clique-grid graph G with representation f and an integer k such that $\mathcal{T}$ is a $c\sqrt{k}$-NCTD of G and for any cell (i, j) in f, $\lvert f^{-1}(i, j)\rvert \leq k + 2$, where c is a constant
Question: Is there subset $W \subseteq V(G)$ such that $G[W]$ is a forest and $\lvert W\rvert \geq \lvert V(G)\rvert - k$

▶ **Observation 23.** *Let $(G, f, k, \mathcal{T})$ be an instance of* MIF*. Then $(G, f, k, \mathcal{T})$ is a* Yes*-instance of* MIF *if and only if $(G, f, k, \mathcal{T})$ is a* Yes*-instance of* FVS*.*

By Lemma 20 and Observations 21 and 23, to prove Theorem 11, it is sufficient that we prove the following result (which is the focus of the rest of this section).

▶ **Lemma 24.** MIF *on clique-grid graphs can be solved in time $2^{\mathcal{O}(\sqrt{k} \log k)} \cdot n^{\mathcal{O}(1)}$.*

Proof sketch. We explain a DP algorithm which given as input $(G, f, k, \mathcal{T})$ where G is a clique-grid graph with representation f, $\mathcal{T} = (T, \beta)$ is a $c\sqrt{k}$-NCTD, c is a constant and $|f^{-1}(i, j)| \leq k + 2$ for any cell (i, j) of f and outputs Yes if there is an induced forest with at least $|V(G)| - k$ vertices and outputs No otherwise. Here we use the term solution for a vertex subset $S \subseteq V(G)$ with the property that $G[S]$ is a forest. First notice that any solution S contains at most 2 vertices from $f^{-1}(i, j)$ for any cell (i, j). Now, the following claim follows from the fact that $\mathcal{T}$ is a $c\sqrt{k}$-NCTD and any solution contain at most 2 vertices from $f^{-1}(i, j)$ for any cell (i, j).

▶ **Claim 2.** *For any $v \in V(T)$ and any solution S, $|S \cap \beta(v)| \leq 2c\sqrt{k}$.*

We first briefly explain what is the table entries in a standard DP algorithm for our problem on graphs of bounded treewidth [12]. Then we explain that in fact many of the entries we compute in the standard DP table is redundant in our case, because of Observation 22 and Claim 2. That is, Observation 22 and Claim 2, shows that only $2^{\mathcal{O}(\sqrt{k} \log k)} |V(G)|^{\mathcal{O}(1)}$ many

states in the DP table are relevant in our case. Recall that for any $v \in V(T)$, $\gamma(v)$ denote the union of the bags of v and its descendants. The standard DP table for our problem will have an entry indexed by $(v, U, U_1 \uplus U_2 \ldots U_\ell = U)$ where $v \in V(T)$, $U \subseteq \beta(v)$. The table entry $\mathcal{A}[v, U, U_1 \uplus U_2 \ldots U_\ell]$ stores the following information: the maximum cardinality of a vertex subset $W \subseteq G[\gamma(v)]$ such that $W \cap \beta(v) = U$, $G[W]$ is a forest with a set of connected components $\mathcal{C}$ and for any $C \in \mathcal{C}$, either $V(C) \cap \beta(v) = \emptyset$ or $V(C) \cap \beta(v) = U_i$ for some $i \in [\ell]$. Notice that the total number of DP table entries is bounded by $\mathsf{tw}^{\mathcal{O}(\mathsf{tw})}|V(G)|^{\mathcal{O}(1)}$ where tw is the width of the tree decomposition $\mathcal{T}$. One can easily show that the computation of the DP table at a node can be done in time polynomial in the size of the tables of its children.

By Observation 22 and Claim 2, we know that for any bag $\beta(v)$ in $\mathcal{T}$, the potential number of subsets of $\beta(v)$ which can be part of any solution is at most $2^{\mathcal{O}(\sqrt{k}\log k)}$. This implies that we only need to compute the DP table entries for indices $(v, U, U_1 \uplus U_2 \ldots U_\ell = U)$ where $v \in V(T)$, $U \subseteq \beta(v)$ and $|U| \leq 2c\sqrt{k}$. Thus, the size of DP table, and hence the time to compute it takes $2^{\mathcal{O}(\sqrt{k}\log k)}n^{\mathcal{O}(1)}$ time. This concludes the description. ◀

A Polynomial-Time Randomized Reduction from Tournament Isomorphism to Tournament Asymmetry*

Pascal Schweitzer

RWTH Aachen University, Aachen, Germany
schweitzer@informatik.rwth-aachen.de

Abstract

The paper develops a new technique to extract a characteristic subset from a random source that repeatedly samples from a set of elements. Here a characteristic subset is a set that when containing an element contains all elements that have the same probability.

With this technique at hand the paper looks at the special case of the tournament isomorphism problem that stands in the way towards a polynomial-time algorithm for the graph isomorphism problem. Noting that there is a reduction from the automorphism (asymmetry) problem to the isomorphism problem, a reduction in the other direction is nevertheless not known and remains a thorny open problem.

Applying the new technique, we develop a randomized polynomial-time Turing-reduction from the tournament isomorphism problem to the tournament automorphism problem. This is the first such reduction for any kind of combinatorial object not known to have a polynomial-time solvable isomorphism problem.

1 Introduction

The graph automorphism problem asks whether a given input graph has a non-trivial automorphism. In other words the task is to decide whether a given graph is asymmetric. This computational problem is typically seen in the context of the graph isomorphism problem, which is itself equivalent under polynomial-time Turing reductions to the problem of computing a generating set for all automorphisms of a graph [17]. As a special case of the latter, the graph automorphism problem obviously reduces to the graph isomorphism problem. However, no reduction from the graph isomorphism to the graph automorphism problem is known. In fact, while many computational problems surrounding structural equivalence of combinatorial objects can all be Turing-reduced to one another, the relationship between the graph automorphism and the graph isomorphism problem remains a repeatedly posed open question (see for example [1, 2, 12, 14]).

With Babai's new ground-breaking algorithm [7] that solves the graph isomorphism problem and thereby also the graph automorphism problem in quasi-polynomial time, the question arises whether it is possible to go further and devise a polynomial-time algorithm.

For such an endeavor to succeed, special cases such as the group isomorphism and the tournament isomorphism problem, for which the currently fastest algorithms have a running time of $n^{O(\log n)}$, should also be solvable in polynomial time. Tournaments, which are graphs in which between every pair of vertices there exists exactly one directed edge, also have an automorphism problem associated with them, asking whether a given tournament is asymmetric[1]. Again, for this problem the currently best running time is $n^{O(\log n)}$ and analogously to general graphs there is a simple reduction from the automorphism problem to the isomorphism problem, but no reverse reduction has been known.

In this paper we show that there is a randomized polynomial-time Turing reduction from the tournament isomorphism problem to the tournament automorphism problem. This is the first such reduction for any kind of combinatorial object (apart from polynomial-time solvable cases of course).

The main new technical tool that we develop in the first part of the paper is a technique to exploit an oracle to the graph automorphism problem in order to obtain a non-trivial automorphism-invariant partition of a graph that is finer than the orbit partition (Sections 2–5). We call the parts of such a partition suborbits. This technique is essentially applicable to all graph classes, not just tournaments. It hinges on a method to extract a characteristic subset from a random source that repeatedly samples from a set of elements. Here we say that a set is characteristic if it is a union of level sets of the probability function.

In the second part of the paper we show that, for tournaments, access to suborbits suffices to compute automorphism groups (Section 6). For this we adapt the group-theoretic divide and conquer approach of Luks [16] to our situation. We exploit that automorphism groups of tournaments are solvable and we leave it as an open question whether something similar can be forged that is applicable to the group isomorphism problem (see Section 7).

It might be worth noting that the techniques actually do not use any of the new structural insights from the quasi-polynomial-time algorithm of [7]. Rather, the randomized sampling idea is heavily based on an older practical randomized algorithm designed to quickly detect non-isomorphism ([15, 21]). It appears to be one of the few cases where randomization helps to derive a theoretical result for an isomorphism problem. We also borrow some ideas from a paper of Arvind, Das, and Mukhopadhyay concerned with tournament canonization [4].

The necessity for randomization to obtain theoretical results in the context of isomorphism checking appears to be quite rare. The earliest result exploiting randomization seems to go to back to Babai [5] and is a randomized algorithm for checking isomorphism of graphs of bounded color class size. However that algorithm is actually a Las Vegas algorithm (an algorithm that does not make errors), and in the meantime deterministic algorithms are available [11]. However, for the new reduction in this paper it seems unclear how to remove the use of randomization and even how to remove the possibility for errors.

Related work

With respect to related work, we focus on results concerning graph automorphism as well as results concerning tournaments and refer the reader to other texts (for example [6, 7, 14, 18,

[1] Many publications in the context of graph isomorphism use the term rigid graph. However, the literature is inconsistent on the notion of a rigid graph, which can for example refer to having no non-trivial automorphism or no non-trivial endomorphism. We will use the notion asymmetric, which only ever means the former. Furthermore, we suggest the name graph asymmetry problem over graph automorphism problem, so as not to confuse it with the computational problem to compute the automorphism group.

22]) for a general introduction to the graph isomorphism problem, current algorithms and overviews over complexity theoretic results.

Tournament automorphism. Let us start by highlighting two results specifically concerned with the tournament automorphism problem. Arvind, Das, and Mukhopadhyay [4] show that if tournament isomorphism is polynomial-time solvable then tournament canonization can be reduced in polynomial time to canonization of asymmetric tournaments. This implies now, with the result of the current paper, that from a canonization algorithm for asymmetric tournaments we can obtain a randomized canonization algorithm for tournaments in general. (In other words, the main theorem of our paper transfers to canonization.) On the hardness side, Wager [25, 27] shows that tournament automorphism is hard for various circuit complexity classes (NL, $\mathsf{C_=L}$, PL, DET, $\mathsf{MOD_kL}$) under $\mathsf{AC^0}$ reductions.

Graph automorphism A lot of information on the complexity of graph automorphism can be found in the book by Köbler, Schöning, and Torán [14]. Concerning hardness of the automorphism problem, improving previous results of Torán [24], Wagner shows hardness results for graphs of bounded maximum degree [26, 27]. Agrawal and Arvind show truth table equivalence of several problems related to graph automorphism [1] and Arvind, Beigel, and Lozano study modular versions of graph automorphism [3] which for $k \in \mathbb{N}$ ask whether the number of automorphisms of a given graph is divisible by k.

The graph automorphism problem is of interest in quantum computing since it can be encoded as a hidden shift problem, as opposed to the graph isomorphism problem that is only known to be encodable as a hidden subgroup problem [10, 13].

Recently, Allender, Grochow, and Moore [2] developed a zero-error randomized reduction from graph automorphism to MKTP, the problem of minimizing time-bounded Kolmogorov complexity, a variant of the minimum circuit size problem. In that paper they also extend this to a bounded-error randomized reduction from graph isomorphism to MKTP.

Tournament isomorphism. Concerning the tournament isomorphism problem, the currently fastest algorithm [8] has a running time of $n^{O(\log n)}$. With respect to hardness, Wagner's results for tournament automorphism also apply to tournament isomorphism [25].

Ponomarenko showed that isomorphism of cyclic tournaments can be decided in polynomial time [19], where a cyclic tournament is a tournament that has an automorphism that is a permutation with a single cycle spanning all vertices. Furthermore he showed that isomorphism of Schurian tournaments can be decided in polynomial time [20].

2 Sampling characteristic subsets

Let M be a finite set. We define a *sampler* S over M to be a probability measure $\mathrm{Pr_S}\colon M \to [0,1]$ on the elements of M. We think of a sampler as an oracle that we can invoke in order to obtain an element of M. That is, given a sampler, we can sample a sequence of elements $m_1, \ldots, m_t$ where each m_i is sampled independently from M according to $\mathrm{Pr_S}$.

We call a subset M' of M *characteristic* with respect to S if for all $m, m' \in M$ it holds that $m \in M'$ and $\mathrm{Pr_S}(m') = \mathrm{Pr_S}(m)$ implies $m' \in M'$. Another way of formulating this condition is that M' is invariant under all probability-preserving bijections $\varphi\colon M \to M$, that is, those bijections that satisfy $\mathrm{Pr_S}(m) = \mathrm{Pr_S}(\varphi(m))$ for all $m \in M$.

When considering sampling algorithms we will not assume that we know the size of the set M. Our goal is to repeatedly invoke a sampler M so as to find a characteristic subset.

The main difficulty in this is that we can never precisely determine the probability $\Pr_S(m)$ of an element m. Indeed, the only thing we can hope for is to get a good estimate for such a probability. The following lemma indicates that this might be helpful since the set of probabilities cannot be arbitrarily dense.

▶ **Lemma 1.** *Let* $\Pr_S$ *be a discrete probability measure on the set* M*. Let* $P = \{\Pr_S(m) \mid m \in M\}$ *be the set of probabilities that occur. For every positive integer* i *there is a* $j \in \{6i+1, \ldots, 8i\}$ *such that* $[(j-1/4)/(8i^2), (j+1/4)/(8i^2)] \cap P = \emptyset$*.*

Using the lemma we can design an algorithm that, with high probability, succeeds at determining a characteristic set.

▶ **Theorem 2.** *There is a deterministic algorithm that, given* $\varepsilon > 0$ *and given access to a sampler* S *over an unknown set* M *of unknown size, runs in expected time polynomial in* $1/(\max_{m \in M} \Pr_S(m)) \leq |M|$ *and* $\ln 1/\varepsilon$ *and outputs a non-empty subset of* M *that is characteristic with probability* $1 - \varepsilon$*.*

The proof of the theorem makes repeated use of Chernoff bounds. The main difficulty is that $|M|$ is not known to the algorithm. The lengthy proof can be found in the full version [23].

We note several crucial observations about any algorithm solving the problem just described. There is no algorithm that for every set M and sampler S always outputs the same set M' with high probability.

Indeed, consider the set $M = \{a, b\}$. Choosing $\Pr_S(a) = \Pr_S(b) = 1/2$ means that M' must be $\{a, b\}$. Choosing $\Pr_S(a) = 1$ and $\Pr_S(b) = 0$ implies that M' must be $\{a\}$. However, there is a continuous deformation between these two samplers, while possibilities for the set M' are discrete. It is not difficult to see that the probability distribution of the output set M' must be continuous in the space of samplers, and thus, whatever the algorithm may be, there must be samplers for which the algorithm sometimes outputs $\{a\}$ and sometimes outputs $\{a, b\}$.

The theorem only establishes polynomial running time. If we are however interested in small running times, one might even ask whether it is possible to devise an algorithm running in time sublinear in $|M|$. However, recalling the coupon collector theorem and considering uniform samplers one realizes that one cannot expect to make do with $o(|M| \log |M|)$ samplings. However, if the set M is of algebraic nature, for example forms a group, then there might be meaningful ways to sample characteristic substructures (see Section 7).

3 Gadget constructions for asymmetric tournaments

There are several computational problems fundamentally related to the graph isomorphism problem. This relation manifests formally as polynomial-time Turing (or even many-one) reductions between the computational tasks. Such reductions are typically based on gadget constructions which we revisit in this section.

While the *graph isomorphism problem* GI asks whether two given graphs are isomorphic, in the search version of this decision problem an explicit isomorphism is to be found, whenever one exits. The *graph automorphism problem* GA asks whether a given graph has a non-trivial automorphism (i.e., an automorphism different from the identity). In other words the task is to decide whether the given graph is asymmetric. Two other related problems are the task AUT to determine generators for the automorphism group $\mathrm{Aut}(G)$ and the task to determine the size of the automorphism group $|\mathrm{Aut}(G)|$.

For all named problems there is a colored variant, where the given graphs are vertex colored and isomorphisms are restricted to be color preserving. We denote the respective problems by col-GI, col-GA and col-AUT.

It is well known that between all these computational problems – except GA – there are polynomial-time Turing reductions (we refer for example to [9], [14], [17]). Concerning the special case of GA, while there is a reduction from GA to the other problems, a reverse reduction is not known.

The reductions are typically stated for general graphs, but many of the techniques are readily applicable to restricted graph classes. By a *graph class* we always mean a collection of possibly directed graphs closed under isomorphism. The *isomorphism problem for graphs in* $\mathcal{C}$, denoted $\mathsf{GI}_{\mathcal{C}}$, is the computational task to decide whether two given input graphs from $\mathcal{C}$ are isomorphic. If one of the input graphs is not in $\mathcal{C}$ the answer of an algorithm may be arbitrary, in fact the algorithm may even run forever. Analogously, for each of the other computational problems that we just mentioned, we can define a problem restricted to $\mathcal{C}$ giving us for example $\mathsf{GA}_{\mathcal{C}}$, and $\mathsf{AUT}_{\mathcal{C}}$ and the colored versions $\text{col-}\mathsf{GI}_{\mathcal{C}}$, $\text{col-}\mathsf{GA}_{\mathcal{C}}$, and $\text{col-}\mathsf{AUT}_{\mathcal{C}}$.

As remarked in [4], most of the reduction results for general graphs transfer to the problems for a graph class $\mathcal{C}$ if one has, as essential tool, a reduction from $\text{col-}\mathsf{GI}_{\mathcal{C}}$ to $\mathsf{GI}_{\mathcal{C}}$.

▶ **Theorem 3** (Arvind, Das, Mukhopadhyay [4]). *Suppose that for a graph class* $\mathcal{C}$ *there is a polynomial-time many-one reduction from* $\text{col-}\mathsf{GI}_{\mathcal{C}}$ *to* $\mathsf{GI}_{\mathcal{C}}$ *(i.e.,* $\text{col-}\mathsf{GI}_{\mathcal{C}} \leq_m^p \mathsf{GI}_{\mathcal{C}}$*)*[2]*. Then*

1. $\mathsf{GA}_{\mathcal{C}}$ *polynomial-time Turing-reduces to* $\mathsf{GI}_{\mathcal{C}}$ *(i.e.,* $\mathsf{GA}_{\mathcal{C}} \leq_T^p \mathsf{GI}_{\mathcal{C}}$*),*
2. *The search version of* $\mathsf{GI}_{\mathcal{C}}$ *polynomial-time Turing-reduces to the decision version of* $\mathsf{GI}_{\mathcal{C}}$*, and*
3. $\mathsf{AUT}_{\mathcal{C}}$ *polynomial-time Turing-reduces to* $\mathsf{GI}_{\mathcal{C}}$ *(i.e.,* $\mathsf{AUT}_{\mathcal{C}} \leq_T^p \mathsf{GI}_{\mathcal{C}}$*).*

In this paper we are mainly interested in two classes of directed graphs, namely the class of tournaments Tour and the class of asymmetric tournaments AsymTour. For the former graph class, a reduction from the colored isomorphism problem to the uncolored isomorphism problem is given in [4].

▶ **Theorem 4** (Arvind, Das, Mukhopadhyay [4]). *The colored tournament isomorphism problem is polynomial-time many-one reducible to the (uncolored) tournament isomorphism problem (i.e.,* $\text{col-}\mathsf{GI}_{\mathsf{Tour}} \leq_m^p \mathsf{GI}_{\mathsf{Tour}}$*).*

However, for our purposes we also need the equivalent statement for asymmetric tournaments. Taking a closer look at the reduction described in [4] yields the desired result. In fact it also shows that the colored asymmetry problem reduces to the uncolored asymmetry problem. Denoting for a graph class $\mathcal{C}$ by $\mathsf{Asym}\mathcal{C}$ the class of those graphs in $\mathcal{C}$ that are asymmetric (i.e., have a trivial automorphism group), we obtain the following.

▶ **Lemma 5.**

1. *The isomorphism problem of colored asymmetric tournaments is polynomial-time many-one reducible to the isomorphism problem for (uncolored) asymmetric tournaments (i.e.,* $\text{col-}\mathsf{GI}_{\mathsf{AsymTour}} \leq_m^p \mathsf{GI}_{\mathsf{AsymTour}}$*).*
2. *The colored tournament asymmetry problem is polynomial-time many-one reducible to the (uncolored) tournament asymmetry problem (i.e.,* $\text{col-}\mathsf{GA}_{\mathsf{Tour}} \leq_m^p \mathsf{GA}_{\mathsf{Tour}}$*).*

[2] Let us remark for completeness that a Turing reduction assumption $\text{col-}\mathsf{GI}_{\mathcal{C}} \leq_T^p \mathsf{GI}_{\mathcal{C}}$ actually suffices for the theorem.

As mentioned above, reductions for computational problems on general graphs can often be transferred to the equivalent problems restricted to a graph class $\mathcal{C}$. However, let us highlight a particular reduction where this is not the case. Indeed, it is not clear how to transfer the reduction from GI to AUT (which involves taking unions of graphs) to a reduction from $\mathsf{GI}_{\mathcal{C}}$ to $\mathsf{AUT}_{\mathcal{C}}$, even when provided a reduction of $\mathsf{col\text{-}GA}_{\mathcal{C}}$ to $\mathsf{GI}_{\mathcal{C}}$. For the class of tournaments however, we can find such a reduction, of which we can make further use.

▶ **Lemma 6.**

1. *The isomorphism problem for tournaments polynomial-time Turing-reduces to the task to compute a generating set for the automorphism group of a tournament (i.e.,* $\mathsf{col\text{-}GI}_{\mathsf{Tour}} \leq_T^p \mathsf{AUT}_{\mathsf{Tour}}$*).*
2. *The isomorphism problem for colored asymmetric tournaments is polynomial-time many-one reducible to tournament asymmetry (i.e.,* $\mathsf{col\text{-}GI}_{\mathsf{AsymTour}} \leq_m^p \mathsf{GA}_{\mathsf{Tour}}$*).*
3. *The search version of the isomorphism problem for colored asymmetric tournaments Turing-reduces to tournament asymmetry.*

Proof. Suppose we are given two tournaments T_1 and T_2 on the same number of vertices n for which isomorphism is to be decided. By Theorem 4 we can assume that the tournaments are uncolored. Let $\mathrm{Tri}(T_1, T_2)$ be the tournament obtained by forming the disjoint union of the three tournaments T_1, T_1' and T_2 where $T_1 \cong T_1'$. We add edges from all vertices of T_1 to all vertices of T_1', from all vertices of T_1' to all vertices of T_2 and from all vertices of T_2 to all vertices of T_1. We observe that two vertices that are contained in the same of the three sets $V(T_1)$, $V(T_2)$, $V(T_1')$ have n common out-neighbors. However, two vertices that are not contained in the same of these three sets have at most $n-1$ common out-neighbors. We conclude that an automorphism of $\mathrm{Tri}(T_1, T_2)$ preserves the partition of $V(\mathrm{Tri}(T_1, T_2))$ into the three sets $V(T_1)$, $V(T_1')$ and $V(T_2)$.

Given a generating set for $\mathrm{Aut}(\mathrm{Tri}(T_1, T_2))$ it holds that there is some generator that maps a vertex from $V(T_1)$ to a vertex from $V(T_2)$ if and only if T_1 and T_2 are isomorphic. This proves the first part of the lemma.

Suppose additionally that T_1 and T_2 are asymmetric. We then further conclude that the tournament $\mathrm{Tri}(T_1, T_2)$ has a non-trivial automorphism if and only if T_1 and T_2 are isomorphic. This shows that the decision version of asymmetric tournament isomorphism reduces to tournament asymmetry. Since the search version is Turing-reducible to the decision version of isomorphism (Theorem 3) this finishes the proof. ◀

For Turing reductions, the converse of the previous lemma also holds. In fact the converse holds for arbitrary graph classes. The first part of this converse is a well known techniques that goes back to Mathon [17].

▶ **Lemma 7.** *Let $\mathcal{C}$ be a graph class.*

1. *The task to compute a generating set for the automorphism group of graphs in $\mathcal{C}$ Turing-reduces to the isomorphism problem for colored graphs in $\mathcal{C}$ (i.e.,* $\mathsf{AUT}_{\mathcal{C}} \leq_T^p \mathsf{col\text{-}GI}_{\mathcal{C}}$*).*
2. *Asymmetry checking for graphs in $\mathcal{C}$ polynomial-time Turing-reduces to isomorphism checking of asymmetric colored graphs in $\mathcal{C}$ (i.e.,* $\mathsf{GA}_{\mathcal{C}} \leq_T^p \mathsf{col\text{-}GI}_{\mathsf{Asym}\mathcal{C}}$*).*

4 Invariant automorphism samplers from asymmetry tests

As discussed before, the asymmetry problem of a class of graphs reduces to the isomorphism problem of graphs in this class. However, whether there is a reduction in the reverse, or whether the asymmetry problem may actually be computationally easier than the isomorphism

Algorithm 1 An invariant automorphism sampler for tournaments using an asymmetry oracle.

Input: A tournament T that is not asymmetric and an oracle O for tournament asymmetry.
Output: An automorphism $\varphi \in \mathrm{Aut}(T) \setminus \{\mathrm{id}\}$. As a random variable, the outputs of the algorithm form an invariant automorphism sampler for T.

$T_{\mathrm{next}} \leftarrow T$
while $\mathrm{Aut}(T_{\mathrm{next}}) \neq \{\mathrm{id}\}$ **do**
  Pick a vertex v independently, uniformly at random among all non-singleton color classes in T_{next}.
  $T \leftarrow T_{\mathrm{next}}$
  $T_{\mathrm{next}} \leftarrow T_{(v)}$ // individualize v
end while // at this point T_{next} is asymmetric
Let V' be the set of those vertices that have the same color in T as v.
Let V'' be the set of those vertices v'' in $V' \setminus \{v\}$ for which $\mathrm{Aut}(T_{(v'')}) = \{\mathrm{id}\}$.
Let V''' be the set of those vertices v''' in V'' for which $T_{\mathrm{next}} \cong T_{(v''')}$.
// use Part 2 of Lemma 6
Pick a vertex $u \in V'''$ uniformly at random.
Compute an isomorphism φ from T_{next} to $T_{(u)}$. // there is only one such isomorphism
return φ

problem is not known. To approach this question, we now explore what computational power we could get from having available an oracle for the asymmetry problem.

An *invariant automorphism sampler for a graph* G is a sampler over $\mathrm{Aut}(G) \setminus \{\mathrm{id}\}$ which satisfies the property that if $\Pr_{\mathrm{S}}(\varphi) = p$ then $\Pr_{\mathrm{S}}(\psi^{-1} \circ \varphi \circ \psi) = p$ for all $\psi \in \mathrm{Aut}(G)$. We first show how to use an oracle for asymmetry to design an invariant automorphism sampler for a tournament T.

▶ **Lemma 8.** *Given an oracle for asymmetry of tournaments* ($\mathsf{GA}_{\mathsf{Tour}}$) *we can construct for every given colored (or uncolored) tournament* T *that is not asymmetric an invariant automorphism sampler. The computation time (and thus the number of oracle calls) required to sample once from* S *is polynomial in* $|V(T)|$.

Proof. Let O_1 be an oracle for uncolored tournament asymmetry. By Lemma 5, we can transform the oracle O_1 for the asymmetry of uncolored tournaments into an oracle O_2 for asymmetry of colored tournaments. By Lemma 6 Part 2, we can also assume that we have an oracle O_3 that decides the isomorphism problem of colored asymmetric tournaments. More strongly, Lemma 6 Part 3 makes a remark on the search version, thus we can assume that O_3 also solves the isomorphism search problem for asymmetric tournaments.

To obtain the desired sampler S we proceed as follows. In the given tournament T we repeatedly fix (by individualization, i.e., giving it a special color) uniformly, independently at random more and more vertices until the resulting tournament is asymmetric. This gives us a sequence of colored tournaments $T = T_0, T_1, \ldots, T_t$ such that $\mathrm{Aut}(T_t) = \{\mathrm{id}\}$, $\mathrm{Aut}(T_{t-1}) \neq \{\mathrm{id}\}$ and such that $T_t = (T_{t-1})_{(v)}$ for some vertex v. In other words, T_t is obtained from T_{t-1} by individualizing v which makes the graph asymmetric. Using the available oracle O_2, we can compute the set V'' of those vertices v'' in $V(T) \setminus \{v\}$ that have the same color as v such that $\mathrm{Aut}((T_{t-1})_{(v'')}) = \{\mathrm{id}\}$. There must be at least one vertex in V'' since T_{t-1} is not asymmetric. Using the oracle O_3, we can then compute the subset $V''' \subseteq V''$ of those vertices v''' for which $(T_{t-1})_{(v''')}$ and T_t are isomorphic. Next, we pick a vertex $u \in V'''$

uniformly at random. Since both $(T_{t-1})_{(u)}$ and T_t are asymmetric, using the oracle O_3 for the isomorphism search problem we can compute an isomorphism φ from $(T_{t-1})_{(u)}$ to T_t. This isomorphism φ is unique and it is a non-trivial automorphism of $\mathrm{Aut}(T)$. Algorithm 1 gives further details.

Invariance. he invariance follows directly from the fact that all steps of the algorithm either consist of choosing a vertex uniformly at random or computing an object that is invariant with respect to all automorphisms fixing all vertices that have been randomly chosen up to this point.

Running time. Concerning the running time, one call of Algorithm 1 uses less than $2n$ calls to oracle O_2 and at most n calls to oracle O_3. The overall running time is thus polynomial. ◀

Let us comment on whether the technique of the lemma can be applied to graph classes other than tournaments. For the technique to apply to a graph class $\mathcal{C}$, we require the oracle O_2, which solves colored asymmetry $\mathcal{C}$, and the oracle O_3 which solves the isomorphism search problem for asymmetric colored objects in $\mathcal{C}$. (The oracle O_1 is a special case of O_2.) In the case of tournaments, having an oracle O_1 (i.e., an oracle for uncolored asymmetry) is sufficient to simulate the oracles O_2 and O_3, but this is not necessarily possible for all graph classes $\mathcal{C}$. It is however possible to simulate such oracles for every graph class that satisfy some suitable (mild) assumptions, as can be seen from the discussion in Section 3. In particular, given an oracle for asymmetry of all graphs we can construct an invariant automorphism sampler for all graphs that are not asymmetric.

5 Invariant suborbits from invariant automorphism samplers

Let G be a directed graph. Let S be an invariant automorphism sampler for G. We now describe an algorithm that, given access to an asymmetry oracle, constructs a non-discrete partition of $V(G)$ which is finer than or at least as fine as the orbit partition of G under $\mathrm{Aut}(G)$ and invariant under $\mathrm{Aut}(G)$. Here, a partition π is invariant under $\mathrm{Aut}(G)$ if $\pi = \psi(\pi)$ for all $\psi \in \mathrm{Aut}(G)$. (A partition is discrete if it consists only of singletons.)

▶ **Theorem 9.** *For every $c \in \mathbb{N}$, there is a randomized polynomial-time algorithm that, given a graph G and an invariant automorphism sampler* S *for G constructs with error probability at most $\frac{1}{|G|^c}$ a non-discrete partition π of $V(G)$ such that*
1. *π is finer than or at least as fine as the orbit partition of $V(G)$ under* $\mathrm{Aut}(G)$ *and*
2. *π is invariant under* $\mathrm{Aut}(G)$.

The algorithm also provides a set of certificates $\Phi = \{\varphi_1, \ldots, \varphi_m\} \subseteq \mathrm{Aut}(G)$ such that for every pair of vertices $v, v' \in V(G)$ that lie in the same class of π there is some φ_i with $\varphi_i(v) = v'$.

Proof. Let $M = \{(v, w) \mid v, w \in V(G), v \neq w, \exists \varphi \in \mathrm{Aut}(G) \colon \varphi(v) = w\}$ be the set of pairs of two distinct vertices lying in the same orbit. With the sampler S we can simulate a sampler S′ over M invariant under $\mathrm{Aut}(G)$ as follows. To create an element for S′ we sample an element φ from S and uniformly at random choose an element v from the support $\mathrm{supp}(\varphi) = \{x \in V(G) \mid \varphi(x) \neq x\}$ of φ. Then the element for S′ is $(v, \varphi(v))$. It follows form the construction that S′ is a sampler for M. Moreover, since all random choices are independent and uniform, S′ is invariant under automorphisms.

Using the algorithm from Theorem 2 we can thus compute a characteristic subset M' of M. Since S′ is $\mathrm{Aut}(G)$-invariant, the fact that M' is characteristic implies that it is also

$\mathrm{Aut}(G)$-invariant. For the given $c \in \mathbb{N}$, to obtain the right error bound, we choose ε to be $\frac{1}{|G|^c}$ for the algorithm from Theorem 2. Then the error probability is at most $\varepsilon = \frac{1}{|G|^c}$ and the running time is polynomial in $|M| = O(|G|^2)$ and $\ln |G|^c = O(|G|)$ and thus polynomial in the size of the graph.

Regarding M' as a binary relation on $V(G)$ we compute the transitive closure and let π be the partition of $V(G)$ into equivalence classes of said closure, where vertices that do not appear at all as entries in M' form their own class. By construction, elements that are in the same class of π are in the same orbit under $\mathrm{Aut}(G)$. Moreover π is $\mathrm{Aut}(G)$-invariant since M' is $\mathrm{Aut}(G)$-invariant.

To provide certificates for the elements in M' we store all elements given to us by S. For each $(v, w) \in M'$ we can thus compute an automorphism of $\varphi_{v,w} \in \mathrm{Aut}(G)$ with $\varphi_{v,w}(v) = w$. For pairs in the transitive closure of M' we then multiply suitable automorphisms. ◀

If a partition π satisfies the conclusion of the lemma, we call it an *invariant collection of suborbits*. We call the elements of Φ the *certificates*. Let us caution the reader that the set Φ returned by the algorithm is not necessarily characteristic. Moreover, the orbits of the elements in Φ might not necessarily be contained within classes of π. An *oracle for invariant suborbits* returns (π, Φ), where for asymmetric inputs π is discrete and $\Phi = \{\mathrm{id}\}$.

6 Computing the automorphism group from invariant suborbits

To exploit invariant suborbits we make use of the powerful group-theoretic technique to compute stabilizer subgroups.

▶ **Theorem 10** (Luks [16]). *There is an algorithm that, given a permutation group Γ on $\{1, \ldots, n\}$ and subset $B \subseteq \{1, \ldots, n\}$, computes (generators for) the setwise stabilizer of B. If Γ is solvable, then this algorithm runs in polynomial time.*

We will apply the theorem in the following form: Let G be a graph and Γ a solvable permutation group on $V(G)$. Then $\Gamma \cap \mathrm{Aut}(G)$ can be computed in polynomial time. This follows directly from the theorem by considering the induced action of Γ on pairs of vertices from $V(G)$ and noting that $\Gamma \cap \mathrm{Aut}(G)$ consists of those elements that stabilize the edge set.

In our algorithm we will also use the concept of a quotient tournament (that can for example implicitly be found in [4], see also [22]). Let T be a tournament and let π be a partition of $V(T)$ in which all parts have odd size. We define T/π, the *quotient of T modulo π*, to be the tournament on π (i.e., the vertices of T/π are the parts of π) where for distinct $C, C' \in V(T/\pi) = \pi$ there is an edge from C to C' if and only if in T there are more edges going from C to C' than edges going from C' to C. Note that since both $|C|$ and $|C'|$ are odd there are either more edges going from C to C' or more edges going from C' to C. This implies that T/π is a tournament.

▶ **Theorem 11.** *Suppose we are given as an oracle a randomized Las Vegas algorithm that computes invariant suborbits for tournaments in polynomial time. Then we can compute the automorphism group of tournaments in polynomial time.*

Proof. We describe an algorithm that computes the automorphism group of a colored tournament given a randomized oracle that provides invariant suborbits.

Algorithm 2 Computing the automorphism of a tournament using invariant suborbits.

Input: A (colored) tournament T and an oracle O for invariant suborbits with certificates.
Output: A generating set for the automorphism group $\mathrm{Aut}(T)$.

if T is not monochromatic **then** // Case 0
  Let Col be the set of vertex colors of T.
  for $c \in COL$ **do**
    Let V^c be the set vertices in T of color c.
    $\Psi^c \leftarrow \mathrm{Aut}(T[V^c])$ // recursion
    Let $\widehat{\Psi^c}$ be the set of extensions of Ψ^c to $V(T)$ obtained by fixing vertices outside V^c.
  end for
  $\Psi = \bigcup_{c \in \mathrm{Col}} \widehat{\Psi^c}$
  return $\langle \Psi \rangle \cap \mathrm{Aut}(T)$ // solvable group stabilizer
end if
$(\pi, \Phi) \leftarrow O(T)$ // π forms invariant suborbits of T, Φ the set of certificates
if π is discrete **then** // T is asymmetric
  return $\{\mathrm{id}\}$
else if $\pi = \{V(T)\}$ **then** // Case 1
  Choose $v \in V(T)$ arbitrarily.
  Let T' be obtained from T by coloring v with 1, all in-neighbors of v with 2 and other vertices with 3.
  return $\Phi \cup \mathrm{Aut}(V(T'))$ // recursion
else if $\exists C, C' \in \pi \colon |C| \neq |C'|$ **then** // Case 2
  Let T' be obtained from T by coloring each vertex v with color $|[v]_\pi|$.
  return $\mathrm{Aut}(V(T'))$ // recursion
else // Case 3
  For $C \in \pi$ we let T_C be the graph obtained from $T[C]$ by picking an arbitrary vertex $v \in C$ and coloring v with 1, all in-neighbors of v with 2 and other vertices with 3.
  for $\{(C, C') \in \pi \mid C \neq C'\}$ **do**
    Compute $\mathrm{Aut}(\mathrm{Tri}(T_C, T'_C))$ and extract an isomorphism $\varphi_{(C,C')} \colon T[C] \to T[C']$ whenever such an isomorphism exists. // recursion
  end for
  if $\exists C, C' \in \pi \colon T[C] \ncong T[C']$ **then** // Case 3a
    Let T' be obtained from T by coloring $V(T)$ so that v and v' have the same color if and only if $T[([v])] \cong T[([v'])]$.
    return $\mathrm{Aut}(T')$ // recursion
  else // Case 3b
    $\Psi \leftarrow \mathrm{Aut}(T/\pi)$ // recursion on the quotient
    $\widehat{\Psi} \leftarrow \{\widehat{g} \mid g \in \Psi\}$, where $\widehat{g}(v) = \varphi_{([v], g([v]))}(v)$.
    for $\{C \in \pi\}$ **do**
      $\Upsilon_C \leftarrow \mathrm{Aut}(T[C])$ // recursion
      Compute $\widehat{\Upsilon}_C$ the lifts of elements in Υ_C by fixing vertices outside C.
    end for
    return $\langle \widehat{\Psi} \cup \bigcup_{C \in \pi} \widehat{\Upsilon}_C \rangle \cap \mathrm{Aut}(T)$ // solvable group stabilizer
  end if
end if

Description of the algorithm. Let T be a given colored tournament.

Case 0: T is not monochromatic. If T is not monochromatic then we proceed as follows:
Let Col be the set of colors that appear in T. For $c \in \mathrm{Col}$, let V^c be the set of vertices of color c and let $T^c = T[V^c]$ be the subtournament induced by the vertices in V^c.
We recursively compute $\mathrm{Aut}(T^c)$ for all $c \in \mathrm{Col}$. Let Ψ^c be the set of generators obtained as an answer. We lift every generator to a permutation of $V(T)$ by fixing all vertices outside of V^c. Let $\widehat{\Psi^c}$ be the set of lifted generators of Ψ^c and let $\Psi = \bigcup_{c\in\mathrm{Col}} \widehat{\Psi^c}$ be the set of all lifted generators. Since $\mathrm{Aut}(T^c) = \langle \Psi^c \rangle$ is solvable, we conclude that $\langle \Psi \rangle$ is a direct product of solvable groups and thus solvable. We can thus compute $\langle \Psi \rangle \cap \mathrm{Aut}(T)$ using Theorem 10 and return the answer.
This concludes Case 0.
In every other case we first compute a partition π into suborbits using the oracle and a corresponding set of certificates Φ. For a partition π of some set V we denote for $v \in V$ by $[v]_\pi$ the element of π containing v. We may drop the index when it is obvious from the context. If $|T| = 1$ then we simply return the identity.

Case 1: π is trivial. In case π is trivial (i.e., $\pi = \{V(T)\}$), we know that T is transitive. We choose an arbitrary vertex $v \in V(T)$. Let λ be the coloring of $V(T)$ satisfying $\lambda(u) = 1$ if $u = v$, $\lambda(u) = 2$ if $(u, v) \in E(T)$, and $\lambda(u) = 3$ otherwise. We recursively compute a generating set Ψ for $\mathrm{Aut}(T')$, where T' is T recolored with λ. We then return $\Psi \cup \Phi$.

Case 2: not all classes of π have the same size. We color every vertex with the size of the class of π in which it is contained. Now T is not monochromatic anymore and we recursively compute $\mathrm{Aut}(T)$ with T having said coloring. (In other words, we proceed as in Case 0.)

Case 3: all classes of π have the same size but π is non-trivial. We compute for each pair of distinct equivalence classes C and C' of π an isomorphism $\varphi_{(C,C')}$ from $T[C]$ to $T[C']$ or determine that no such isomorphism exists, as follows: We choose for each C an arbitrary vertex $v \in C$. We let T_C be the tournament obtained from $T[C]$ by coloring v with 1, all in-neighbors of v with 2 and other vertices with 3. We let $T_{C,C'} = \mathrm{Tri}(T_C, T_{C'})$ be the triangle tournament of T_C and $T_{C'}$ where $(T_C)'$ is an isomorphic copy of T_C (as defined in Section 3 in the proof of Lemma 6).
Using recursion we compute $\mathrm{Aut}(T_{C,C'})$. From the result we can extract an isomorphism from $T[C]$ to $T[C']$ since $V(T[C])$ and $V(T[C'])$ are blocks of $T_{C,C'}$.
Case 3a: If it is not the case that for every pair C, C' of color classes there is an isomorphism from $T[C]$ to $T[C']$ then we color the vertices of T so that v, v' have the same color if and only if there is an isomorphism from $T[([v])]$ to $T[([v'])]$, where as before for every vertex u we denote by $[u]$ the class of π containing u. With this coloring, T is not monochromatic anymore and we recursively compute $\mathrm{Aut}(T)$ with T having said coloring. (In other words, we proceed as in Case 0.)
Case 3b: Otherwise, for every pair C, C' of color classes, there is an isomorphism from $T[C]$ to $T[C']$. Note that all color classes are of odd size since $T[C]$ is transitive (as dictated by π). Thus, we can compute the quotient tournament T/π. We recursively compute a generating set $\Psi = \{g_1, \ldots, g_t\}$ for the automorphism group of T/π.
We lift each g_i to a permutation $\widehat{g_i}$ of $V(T)$ as follows. The permutation $\widehat{g_i}$ maps each vertex v to $\varphi_{([v],g_i([v]))}(v)$. Since g_i is a permutation and each $\varphi_{(C,C')}$ is a bijection, the map $\widehat{g_i}$ is a permutation of $V(T)$. Let $\widehat{\Psi} = \{\widehat{g_1}, \ldots, \widehat{g_t}\}$ be the set of lifted generators.
As next step, for each class C we recursively compute a generating set Υ_C for $\mathrm{Aut}(T[C])$. We lift each generator in Υ_C to a permutation of $V(T)$ by fixing all vertices outside of C obtaining the set $\widehat{\Upsilon}_C$ of lifted generators.

Consider the group Γ generated by the set $\widehat{\Psi} \cup \bigcup_{C \in \pi} \widehat{\Upsilon}_C$. As a last step, using Theorem 10 we compute the subgroup $\Gamma' = \Gamma \cap \mathrm{Aut}(T)$.

The details of this algorithm are given in Algorithm 2. For the running time analysis and the correctness argument of the algorithm we refer to the full version of the paper [23]. ◀

We have now assembled all the required parts to prove the main theorem of the paper.

▶ **Corollary 12.**

1. *There is a randomized (one-sided error) polynomial-time Turing reduction from tournament isomorphism to asymmetry testing of tournaments (i.e.,* $\mathsf{GI}_{\mathsf{Tour}} \leq^p_{r,T} \mathsf{GA}_{\mathsf{Tour}}$*).*
2. *There is a randomized polynomial-time Turing reduction from the computational task to compute generators of the automorphism group of a tournament to asymmetry testing of tournaments (i.e.,* $\mathsf{AUT}_{\mathsf{Tour}} \leq^p_{r,T} \mathsf{GA}_{\mathsf{Tour}}$*).*

Proof. Recall that a two-sided error algorithm for an isomorphism search problem can be readily turned into a one-sided error algorithm by checking the output isomorphism for correctness. Thus, by Lemma 6 Part 1 it suffices to prove the second part of the corollary.

Combining Lemma 8 and Theorem 9, from an oracle to tournament asymmetry we obtain a randomized Monte Carlo (i.e., with possible errors) algorithm that computes invariant suborbits. Given a Las Vegas algorithm (i.e., no errors) for suborbits, the previous theorem provides us with a computation of the automorphism group of tournaments.

It remains to discuss the error probability we get from using a Monte Carlo algorithm instead of a Las Vegas algorithm. Since there is only a polynomial number of oracle calls, and since the error bound in Theorem 9 can be chosen smaller than $\frac{1}{|G|^c}$ for every fixed constant c, the overall error can be chosen to be arbitrarily small. ◀

7 Discussion and open problems

This paper is concerned with the relationship between the asymmetry problem $\mathsf{GA}_{\mathcal{C}}$ and isomorphism problem $\mathsf{GI}_{\mathcal{C}}$. While under mild assumptions there is a reduction from the former to the latter, a reduction in the other direction is usually not known. However, for tournaments we now have such a randomized reduction.

The first question that comes to mind is whether the technique described in this paper applies to other graph classes. While the sampling techniques from Sections 2 to 5 can be applied to all graph classes that satisfy mild assumptions (e.g., $\mathsf{col\text{-}GI}_{\mathcal{C}} \leq^p_t \mathsf{GI}_{\mathcal{C}}$ and $\mathsf{col\text{-}GI}_{\mathsf{Asym}\mathcal{C}} \leq^p_t \mathsf{GI}_{\mathsf{Asym}\mathcal{C}}$) the algorithm described in Section 6 crucially uses the fact that automorphism groups of tournaments are solvable. This is not the case for general graphs, so for the open question of whether GI reduces to GA this may dampen our enthusiasm. However, what may bring our enthusiasm back up is that there are key classes of combinatorial objects that share properties similar to what we need.

In particular, this brings us to the question whether the techniques of the paper can be applied to group isomorphism. Just like for tournament isomorphism, finding a faster algorithm for group isomorphism (given by multiplication table) is a bottleneck for improving the run-time bound for isomorphism of general graphs beyond quasi-polynomial. Since outer-automorphism groups of simple groups are solvable, we ask: Can we reduce the group isomorphism problem to the isomorphism problem for asymmetric groups? This question is significant since an asymmetry assumption on groups is typically a strong structural property and may help to solve the entire group isomorphism problem. However, here one has to be careful to find the right notion of asymmetry since all groups have inner automorphisms. For such notions different possibilities come to mind.

A second natural open question would be whether there is a deterministic version of the algorithms given in this paper.

As a last open problem recall that it was shown in Section 2 that one can extract a characteristic subset for a sampler over a set M in time that depends polynomially on M. Since the automorphism group of a graph can be superpolynomial in the size of the graph, we had to take a detour via suborbits in Section 5. There can be no general way to extract a characteristic subset of M in polynomial time if $|M|$ is not polynomially bounded, since we might never see an element twice. However, if M has an algebraic structure, in particular if M is a permutation group over a polynomial size set, this is not clear. Thus we ask: Is there a polynomial-time (randomized) algorithm that extracts a characteristic subgroup using a sampler Γ over a permutation group?

A $(1+\epsilon)$-Approximation for Unsplittable Flow on a Path in Fixed-Parameter Running Time*

Andreas Wiese

awiese@dii.uchile.cl

Abstract

Unsplittable Flow on a Path (UFP) is a well-studied problem. It arises in many different settings such as bandwidth allocation, scheduling, and caching. We are given a path with capacities on the edges and a set of tasks, each of them is described by a start and an end vertex and a demand. The goal is to select as many tasks as possible such that the demand of the selected tasks using each edge does not exceed the capacity of this edge. The problem admits a QPTAS and the best known polynomial time result is a $(2+\epsilon)$-approximation. As we prove in this paper, the problem is intractable for fixed-parameter algorithms since it is W[1]-hard. A PTAS seems difficult to construct. However, we show that if we combine the paradigms of approximation algorithms and fixed-parameter tractability we can break the mentioned boundaries. We show that on instances with $|OPT| = k$ we can compute a $(1+\epsilon)$-approximation in time $2^{O(k \log k)} n^{O_\epsilon(1)} \log u_{\max}$ (where $u_{\max}$ is the maximum edge capacity). To obtain this algorithm we develop new insights for UFP and enrich a recent dynamic programming framework for the problem. Our results yield a PTAS for (unweighted) UFP instances where $|OPT|$ is at most $O(\log n / \log \log n)$ and they imply that the problem does not admit an EPTAS, unless W[1] = FPT.

1 Introduction

The Unsplittable Flow on a Path problem is motivated by many different settings such as scheduling, bandwidth allocation, and caching. We are given an undirected path $G = (V, E)$ with a capacity $u(e) \in \mathbb{N}$ for each edge $e \in E$. Also, we are given a set of n tasks T. Each task $i \in T$ is specified by a subpath $P(i) \subseteq V$ between (and including) the start (i. e., leftmost) vertex $s(i) \in V$ and the end (i. e., rightmost) vertex $t(i) \in V$, and a demand $d(i) \in \mathbb{N}$. For instance, the tasks can be seen as jobs with start and end times that need some portion of a shared resource. The goal is to select a subset $T' \subseteq T$ of tasks of maximum total size such that for each edge e the total demand of the selected tasks using e does not exceed $u(e)$.

UFP is NP-hard [7, 14] and therefore approximation algorithms have been studied for the problem. The best known polynomial time algorithm yields a $(2+\epsilon)$-approximation [3] (improving previous results [5, 7]) and for some cases even a $(1+\epsilon)$-approximation is known [6, 17, 12]. Also, there is a QPTAS [4, 6] which makes it plausible that also a PTAS

exists. However, despite the recent progress on the problem [6, 17] the best known polynomial time result is still the mentioned $(2+\epsilon)$-approximation [3], and a PTAS seems difficult to construct. We note that all above algorithms even work in the weighted case of the problem in which each task has a profit associated with it and one wants to maximize the total profit of the selected tasks. However, as it is typical in the FPT-literature, in this paper we restrict ourselves to the unweighted case, i.e., we assume that each task yields a profit of one. No better results than the above are known for this case.

Another approach for NP-hard problems are fixed-parameter algorithms. For any instance one identifies a parameter k, e.g., the value of the optimal solution, and searches for an exact algorithm with a running time of $f(k) \cdot n^{O(1)}$ for some (typically exponential) function f. A problem is called fixed-parameter tractable (FPT) if it admits such an algorithm. We refer the reader to the recent textbook by Cygan et al. [13] for an introduction to FPT algorithms. For UFP, throughout this paper our parameter will be the size of the optimal solution. Unfortunately, as we show in this paper, it is unlikely that UFP is FPT since the problem is W[1]-hard.

1.1 Our Contribution

In this paper we show that if we combine the paradigms of approximation and fixed-parameter algorithms then we can break the mentioned barriers of $2+\epsilon$ and W[1]-hardness for UFP. We present an algorithm with a running time of $2^{O(k \log k)} n^{O_\epsilon(1)} \log u_{\max}$ that computes a $(1+\epsilon)$-approximation for any instance with $|OPT| = k$, i.e., the computed solution contains at least $k/(1+\epsilon)$ tasks, where $u_{\max} = \max_e u(e)$. Hence, we obtain a PTAS for (unweighted) UFP for instances where $|OPT| \leq O(\log n / \log \log n)$.

We first consider the special case where the number of different task demands in the input is bounded by a parameter k'. We show that then there exists an optimal solution that has a special structure. We can guess this structure in FPT-time (i.e., the number of possibilities is bounded by a function $f(k, k')$) and based on this we can construct the solution deterministically.

Then, we generalize this result to the setting where the tasks have arbitrary demands and the edge capacities are in a bounded range. There, we show that if we have k tasks with relatively small demand (of at most a $1/k$-fraction of the capacities of the edges they are using) then they form a feasible solution and we are done. Otherwise, in FPT-time we can guess which of these tasks are contained in the optimal solution and then focus on the remaining, relatively large tasks. For those we use a result from [6] that shows that there is a $(1+\epsilon)$-approximative solution in which (essentially) each edge has some slack that equals the minimum size of a large task. Thus, there is still a near-optimal solution if we round up the task demands so that they have only $f(k)$ many different demands. On the resulting instance, we apply our FPT-algorithm from above.

To obtain an algorithm for the general case with arbitrary task demands and edge capacities we use the machinery that was introduced in [17] in order to turn a PTAS for UFP with resource augmentation (i.e., where the edge capacities are increased by a factor $1+\epsilon$) to a PTAS without resource augmentation. In order to apply it in our setting, we need several new ideas.

First, we prove that we can identify at most k vertices of the input path such that each input task uses one of them (for instances in which no k such vertices exist we can find a solution with k tasks using a greedy algorithm). These vertices divide the path into $k+1$ *segments*. Our algorithm proceeds in phases and in each phase we process some set of tasks. These tasks are divided into tiny and non-tiny tasks. A crucial difficulty is to

estimate how much capacity should be given to each of these groups on each edge. We cannot afford to guess this for each edge separately. However, we show that there exists a $(1+\epsilon)$-approximative solution in which this allocation has a structure that we can guess in FPT-time. For each segment S we can essentially argue that (i) either it is not used by non-tiny tasks and in this case we can give the whole edge capacity to the tiny tasks (ii) or all tiny tasks use the same capacity on each edge of S which we can guess. Then, for the remaining decisions for the tiny tasks we call the FPT-algorithm for the case of a bounded range of edge capacities. For the non-tiny tasks we know that each segment is used by at most $O_\epsilon(1)$ of them and we can guess them step by step in polynomial time.

Finally, we prove that UFP is W[1]-hard (if parametrized by the size of the optimal solution) which makes it unlikely that there is a fixed-parameter algorithm for it that computes an optimal solution, instead of an approximation. Also, this implies that UFP does not admit an EPTAS (i.e., an $(1+\epsilon)$-approximation algorithm with a running time of $f(\epsilon)\cdot n^{O(1)}$ for some function f), unless W[1] = FPT.

We hope that our new techniques yield progress for eventually finding a PTAS for UFP. For instance, many algorithms for UFP are based on a recursive decomposition of the problem, embedded into a DP [3, 6, 17]. Using our new algorithm we can now stop such a recursion once the optimal solution of a considered subproblem has a size of at most $O(\log n/\log\log n)$. Also, for the setting of bounded edge capacities we proved that there exist optimal solutions with a special structure (inherited from the case of few different task demands). This insight might be useful beyond our result. Note that even for uniform edge capacities no PTAS is known for UFP.

We would like to point out that in the literature there exists the notion of an FPT-approximation scheme (FPT-AS) which is a $(1+\epsilon)$-approximation algorithm with a running time of $f(\epsilon,k)\cdot n^{O(1)}$ for some suitable function f, while our algorithm has a running time of $2^{O(k\log k)}n^{O_\epsilon(1)}\log u_{\max}$ and thus ϵ appears in the exponent of n. For UFP, we cannot hope for an FPT-AS since otherwise we could choose e.g., $\epsilon := 1/(2k)$ and obtain an FPT-algorithm for UFP, thus contradicting that the problem is W[1]-hard. There are many FPT-ASs known in the literature, see [18] and references therein.

We note that due to space constraints many proofs and details are omitted in this extended abstract.

1.2 Other related work

If all input tasks of a UFP instance have (relatively) small demand compared to the capacities of the edges they use, Chekuri et al. [12] proved that there is a $(1+\epsilon)$-approximation via LP-rounding. This unifies (and improves) previously known results for the special cases of uniform edge capacities [8] and the no-bottleneck-assumption (NBA) [9] which requires that $\max_{i\in T} d(i) \leq \min_{e\in E} u(e)$. Under the latter assumption, tasks with relatively large demands can be handled via dynamic programming, and thus $O(1)$- and $(2+\epsilon)$-approximation algorithms were known for these cases [8, 9, 12] and later such algorithms were also found for the general case of the problem [7, 3]. Another line of research on UFP is to find good LP-relaxations for the problem.

The natural LP-relaxation suffers from an integrality gap of $\Omega(n)$ [9] but with additional constraints Chekuri et al. [11] reduced it to $O(\log^2 n)$ (which was later improved to $O(\log n)$ by the same authors [10]). Anagnostopoulos et al. [2] found a compact LP for the cardinality case of UFP with constant integrality gap and an extended formulation with a constant gap for the weighted case. Grandoni et al. [16] prove the currently best integrality gap for an LP-relaxation without additional variables of $O(\log n/\log\log n)$.

1.3 Preliminaries and Notation

In a UFP instance, for each edge $e \in E$, let $T_e \subseteq T$ be the subset of tasks i using edge e, i. e., with $e \in P(i)$. For every set of tasks T' we define $d(T') := \sum_{i \in T'} d(i)$. The goal of (unweighted) UFP is to select set of tasks T' with maximum cardinality $|T'|$ such that $d(T' \cap T_e) \leq u(e)$ for each edge e. For a given instance of UFP we denote by OPT an optimal solution. Without loss of generality, we may assume that $|V| = 2n$, that each vertex is either the start-vertex or the end-vertex of exactly one input task, and that each task alone yields a feasible solution [4]. Throughout this paper, we use the notation $O_\epsilon(f(n))$ for functions that are in $O(f(n))$ if ϵ is a constant. In particular, $O_\epsilon(1)$ represents a value that depends only on ϵ.

2 Bounded task demands or edge capacities

In this section we first present an algorithm for the special case that the number of different task demands in the input instance is bounded by a parameter k'. Afterwards we will use it as a subroutine for the case where the range of edge capacities is bounded by a parameter k'' (without a bound on the task demands).

2.1 Bounded number of task demands

Suppose we are given an instance with at most k' different task demands where $|OPT| = k$. We present an algorithm with a running time of $f(k, k') \cdot n^{O(1)}$ that computes an optimal solution.

We first guess some properties of OPT. We can assume w.l.o.g. that OPT does not contain any task i such that there is a task $i' \in T \setminus OPT$ with $d(i) = d(i')$ and $P(i') \subseteq P(i)$ (otherwise we could replace i by i'). Assume that $OPT = \{i(1), ..., i(k)\}$ such that $s(i(\ell))$ lies on the left of $s(i(\ell'))$ if and only if $\ell < \ell'$. We use color-coding (see [1]) to split the input tasks into k pair-wise disjoint groups $T^1, ..., T^k$ such that for each ℓ the group T^ℓ contains $i(\ell)$. Note that in [1] the authors present a version of the color-coding method that does not require randomization.

▶ **Lemma 1** (implied by [1]). *By increasing the running time by a factor $2^{O(k)} \log n$ we can assume that the input tasks are colored with k colors $\{1, ..., k\}$ such that for each $\ell \in [k]$ the task $i(\ell)$ is colored with color ℓ.*

Next, we guess for each $\ell \in \{1, ..., k\}$ the demand of the task $i(\ell)$. Since for each task there are k' possibilities, the total number of guesses is $(k')^k$. We remove from T^ℓ all tasks whose demand does not equal the demand that we guessed for $i(\ell)$. Furthermore, we remove from T^ℓ each task i such that there is another task $i' \in T^\ell$ with $i \neq i'$ and $P(i') \subseteq P(i)$. Note that by our assumption about OPT above this does not remove the task $i(\ell)$. Denote by $\bar{T}^\ell$ the resulting set for each $\ell \in [k]$.

In the next lemma we define an (optimal) solution OPT' with k tasks. It will turn out that the information guessed so far is sufficient to construct OPT'. We say that a task $i \in T$ is *compatible* with a set of tasks T' if $T' \cup \{i\}$ is a feasible solution.

▶ **Lemma 2.** *There is a solution $OPT' = \{i'(1), ..., i'(k)\}$ (with $|OPT'| = k$) that satisfies for each $\ell \in \{1, ..., k\}$ that the task $i'(\ell)$ is the task in $\bar{T}^\ell$ with the leftmost start vertex that is compatible with the tasks $i'(1), ..., i'(\ell - 1)$.*

Proof. We prove the lemma by transforming $OPT =: OPT_0$ step by step into OPT'. For each $\ell \in \{1, ..., k\}$ let OPT_ℓ be the solution obtained after ℓ steps. We will ensure that each OPT_ℓ is feasible and contains k tasks. Let $i'(1)$ be the task in $\bar{T}^1$ with the leftmost start vertex. If $i'(1) \in OPT_0$ then we define $OPT_1 := OPT$. If $i'(1) \notin OPT_0$ then we replace $i(1)$ by $i'(1)$ and we define $OPT_1 := OPT \setminus \{i(1)\} \cup \{i'(1)\}$. We claim that OPT_1 is feasible. To this end, let us first consider all edges on the left of $s(i(1))$. By definition of $i(1)$, there is no task in OPT starting on the left of $s(i(1))$. By assumption, the task $i'(1)$ alone yields a feasible solution. Thus, for each edge e on the left of $s(i(1))$ we have that $d(OPT_1 \cap T_e) \leq u(e)$. By construction of the set $\bar{T}^1$ we know that $P(i(1)) \not\subseteq P(i'(1))$ and thus $t(i'(1))$ lies on the left of $t(i(1))$. Since $d(i(1)) = d(i'(1))$ and OPT is feasible we have that $d(OPT_1 \cap T_e) \leq u(e')$ for each edge e' on the right of $s(i(1))$.

Assume by induction that we constructed a feasible solution $OPT_\ell = \{i'(1), ..., i'(\ell), i(\ell + 1), ..., i(k)\}$ such that for each $\ell' \in \{1, ..., \ell\}$ the task $i'(\ell')$ is the task in $\bar{T}^{\ell}$ with the leftmost start vertex that is compatible with the tasks $i'(1), ..., i'(\ell' - 1)$ and that OPT_ℓ contains k tasks. Let $i'(\ell + 1)$ be the task in $\bar{T}^{\ell+1}$ with the leftmost start vertex that is compatible with the tasks $i'(1), ..., i'(\ell)$. Define $OPT_{\ell+1} := OPT_\ell \setminus \{i(\ell + 1)\} \cup \{i'(\ell + 1)\}$. Clearly, $OPT_{\ell+1}$ contains k tasks. We claim that $OPT_{\ell+1}$ is feasible. Let e be an edge on the left of $s(i(\ell + 1))$. Then e is not used by the tasks $i(\ell + 1), ..., i(k)$. By definition, $i'(\ell + 1)$ is compatible with the tasks $i'(1), ..., i'(\ell')$ and thus $d(OPT_{\ell+1} \cap T_e) \leq u(e)$. Let e' be an edge on the right of $s(i(\ell + 1))$. Again, by construction of the set $\bar{T}^{\ell+1}$ we know that $t(i'(\ell + 1))$ lies on the left of $t(i(\ell + 1))$. Thus, if e' is used by $i'(\ell + 1)$ then it is also used by $i(\ell + 1)$. Since by induction OPT_ℓ is feasible, this implies that also $OPT_{\ell+1}$ is feasible. ◀

Note that the start vertices of $i'(1), ..., i'(k)$ are not necessarily ordered, i.e., it could be that $s(i'(\ell))$ lies on the right of $s(i'(\ell + 1))$. Nevertheless, due to Lemma 2 we can use now the following algorithm to find a solution of size k. We define $i'(1)$ to be the task in $\bar{T}^1$ with the leftmost start vertex. Then, for each $\ell \in \{2, ..., k\}$ we inductively define $i'(\ell)$ to be the task in $\bar{T}^{\ell}$ with the leftmost start vertex that is compatible with the tasks $i'(1), ..., i'(\ell - 1)$. This yields the solution OPT' due to Lemma 2.

▶ **Theorem 3.** *Suppose we are given an UFP instance with k' different task demands in the input. Then there is an algorithm that computes a solution of size k in time $(k \cdot k')^k n^{O(1)}$ if such a solution exists.*

2.2 FPT-range of edge capacities

We give now a $(1 + \epsilon)$-approximation algorithm with a running time of $f(k, k'') \cdot n^{O_\epsilon(1)}$ for the case that the edge capacities differ by some parameter k''. Here, we allow arbitrary task demands in the input and thus lift the assumption from the previous section. Formally, our algorithm outputs a solution of size at least $k/(1 + \epsilon)$ or asserts that there is no solution of size k.

Let $u_{\min} = \min_{e \in E} u(e)$ and $u_{\max} = \max_{e \in E} u(e)$. We assume that $u_{\max} \leq k'' \cdot u_{\min}$ where k'' is a parameter. For each task i we define its bottleneck capacity $b(i) := \min_{e \in P(i)} u(e)$. We define a task i to be *large* if $d(i) \geq b(i)/k$ and small otherwise. The next lemma shows that if there are at least k small tasks then any k of them will form a feasible solution (and hence we are done). It holds even for arbitrary edge capacities.

▶ **Lemma 4.** *Any set of at most k small tasks forms a feasible solution.*

Proof. Let T' be a set of k small tasks. We want to prove that T' is a feasible solution. Let e be an edge. We have that $d(T' \cap T_e) = \sum_{i \in T' \cap T_e} d(i) < \sum_{i \in T' \cap T_e} b(i)/k \leq \frac{1}{k} \sum_{i \in T' \cap T_e} u(e) \leq u(e)$. ◀

If there are at least k small tasks in the input then we output k of them and we are done. Otherwise, denote by OPT_S the small tasks from OPT. We guess in time 2^{k-1} the set OPT_S, select all these tasks for our final solution, and discard all other small tasks. We focus on the large tasks now. Denote by OPT_L the set of large tasks in OPT.

We borrow an idea from [6, Lemma 2.6] to achieve the following: we sacrifice a factor of $1+O(\epsilon)$ in the objective and remove some tasks from OPT_L such that if an edge e is used by at least $1/\epsilon$ tasks in OPT_L we remove at least one task from $T_e \cap OPT_L$.

▶ **Lemma 5** ([6]). *There is a set $\overline{OPT}_L \subseteq OPT_L$ with $|\overline{OPT}_L| \leq O(\epsilon) \cdot |OPT_L|$ such that for each edge e with $|T_e \cap OPT_L| \geq 1/\epsilon$ we have that $|T_e \cap \overline{OPT}_L| \geq 1$.*

We define $OPT' := OPT \setminus \overline{OPT}_L$ with $\overline{OPT}_L$ being defined as in Lemma 5. Assume for a moment that each edge is used by at least one task in $\overline{OPT}_L$. Then we know that $d(T_e \cap OPT') \leq u(e) - \min_{i \in OPT_L} d(i)$. Since all tasks in OPT_L are large we have that $\min_{i \in OPT_L} d(i) \geq \frac{1}{k} \cdot u_{\min}$. On the other hand, $|OPT'| \leq k$. Thus, OPT' remains feasible if we increase the demand of each large task to the next higher integral multiple of $\frac{1}{k^2} u_{\min}$. Since $d(i) \leq u_{\max}$ for each task $i \in T$, this yields an instance with only $\frac{u_{\max}}{\frac{1}{k^2} \cdot u_{\min}} \leq k^2 \cdot k''$ different demands. We can then apply the exact FPT-algorithm from Section 2.1 on the resulting instance.

This procedure fails if there are edges not used by tasks in $\overline{OPT}_L$. Denote those edges by E_f. However, such edges are used by only few tasks in OPT_L, at most $1/\epsilon$ many. Thus, we can employ a dynamic program (DP) that guesses those edges step by step and guess their corresponding tasks. Any two consecutive edges e_L, e_R in E_f yield a subproblem for which (like above) we can increase the demands of the tasks whose path lies strictly between e_L and e_R and then invoke the exact FPT-algorithm from Section 2.1 as a subroutine.

▶ **Theorem 6.** *There is a $(1+\epsilon)$-approximation algorithm with a running time of $(k \cdot k'')^{O(k)} n^{O(1/\epsilon)}$ for UFP-instances with $|OPT| = k$ in which the edge capacities lie within a factor k''.*

3 General case

In this section we present our main result. For any $\epsilon > 0$ and any $k \in \mathbb{N}$ we present an algorithm with a running time of $2^{O(k \log k)} \cdot n^{O_\epsilon(1)}$ that computes a solution consisting of at least $k/(1+\epsilon)$ tasks on any instance with $|OPT| = k$ or asserts that there is no solution of size k. We will assume for the moment that the input numbers are bounded by a polynomial in the input size and later explain how to lift this assumption. Our argumentation consists of the following steps:

- In Section 3.1 we use techniques from [17] in order to gain some slack (i.e., unused capacity) on the edges while losing only a factor of $1+\epsilon$ in the objective. Then we classify edges into types and supertypes according to their respective amount of slack. We do a similar classification into types/supertypes for the tasks.
- Afterwards in Section 3.2, we identify a set $\bar{V}$ of k vertices such that each input task uses at least one of them. They split the input path into $k+1$ segments for which we establish some structural properties.
- We present the main algorithm in Section 3.3, described as a (possibly exponential time) recursion. It processes the tasks in phases with one phase for each supertype.
- Finally, we embed our recursive algorithm into a dynamic program with the claimed running time and lift the assumption that the input numbers are polynomially bounded.

3.1 Classification of tasks and edges

In this subsection, we apply the machinery presented in [17] in order to classify edges via how much unused capacity (i.e., *slack*) they have in some near-optimal solution. Also, we group tasks into tiny, medium, and huge tasks. Several times we apply some standard shifting arguments to ensure that we lose at most a factor $1 + O(\epsilon)$ in the process.

▶ **Lemma 7** ([17]). *Let $\epsilon > 0$ be a constant. Given a UFP instance with optimal solution OPT, there exists a feasible solution OPT' with $|OPT'| \geq (1 - O(\epsilon)) \cdot |OPT|$ such that for each edge e there is a value $\delta_e \geq 0$ satisfying the following conditions:*

1. *either $\delta_e = (1/\epsilon^2)^j$ for some integer $j \geq 0$, or $\delta_e = 0$;*
2. *$d(T_e \cap OPT') \leq u(e) - \delta_e$;*
3. *there are at most $1/\epsilon^5$ tasks $i \in T_e \cap OPT'$ such that $d(i) \geq \epsilon^2 \cdot \delta_e$;*
4. *the total demand of all tasks $i \in T_e \cap OPT'$ such that $d(i) < \epsilon^2 \cdot \delta_e$ is at most $5\delta_e/\epsilon^3$.*

In our reasoning, we will aim at computing a solution with nearly as many tasks as OPT'. Like in [17] we group the edges and the input tasks according to the amount of slack (i.e., the δ_e-values) that they have/that the edges on their respective paths have.

For each edge $e \in E$, we define its *type* type(e) as follows: If $\delta_e = (1/\epsilon^2)^j$ for some $j \in \mathbb{N}$, then define type$(e) := j$; and if $\delta_e = 0$, then define type$(e) := -1$. We denote by $E^{(j)}$ the set of edges of type j in E. We say that a task $i \in T$ is of *type* j if $P(i)$ uses an edge of type j and no edge of type $j-1$ or lower. Let $T^{(j)} \subseteq T$ denote all tasks of type j. We write type(i) to denote the type of task i.

▶ **Definition 8.** A task $i \in T$ of type j is *huge* if $d(i) \geq \epsilon^2 \cdot \delta^{(j)}$.

Next, we group the tasks into supertypes. Each supertype consists of $1/\epsilon - 1$ (usual) types. We remove the tasks of all types $a + \ell/\epsilon - 1$ with $\ell \in \mathbb{N}$ for some offset $a \in \{0, ..., 1/\epsilon - 1\}$ and define the tasks supertypes $\mathcal{T}^{(\ell)} := \bigcup_{\ell'=a+\ell/\epsilon}^{a+\ell/\epsilon+1/\epsilon-2} T^{(\ell')}$, one for each $\ell \in \mathbb{Z}$. For a task i we say that i is of *supertype* ℓ if $i \in \mathcal{T}^{(\ell)}$ and we write stype$(i) = \ell$. Similarly, we define for the edges the supertypes $\mathcal{E}^{(\ell)} := \bigcup_{\ell'=a+\ell/\epsilon}^{a+\ell/\epsilon+1/\epsilon-2} E^{(\ell')}$ (for the same offset a as above) and write stype$(e) := \ell$ if $e \in \mathcal{E}^{(\ell)}$. This implies that edges of supertype ℓ have slacks in the range $[\left(\frac{1}{\epsilon^2}\right)^{a+\ell/\epsilon}, \left(\frac{1}{\epsilon^2}\right)^{a+\ell/\epsilon+1/\epsilon-2}] =: [s^{(\ell)}_{\min}, s^{(\ell)}_{\max}]$. The following proposition follows from a simple shifting argument.

▶ **Proposition 9.** *There exists an offset $a \in \{0, ..., 1/\epsilon - 1\}$ such that by reducing the number of tasks in OPT' by a factor $1 + O(\epsilon)$ we can assume that $OPT' \subseteq \bigcup_{\ell \in \mathbb{N}} \mathcal{T}^{(\ell)}$.*

Since we removed the tasks of all types $a + \ell/\epsilon - 1$ with $\ell \in \mathbb{N}$ we can guarantee that all non-huge tasks of a supertype $\mathcal{T}^{(\ell)}$ fit into the slack of each edge of supertype $\ell + 1$ or larger. Let $OPT'_{NH} \subseteq OPT'$ denote the tasks in OPT' that are not huge.

▶ **Lemma 10.** *Let $\mathcal{T}^{(\ell)}$ be a supertype and let $e \in \mathcal{E}^{(\ell)}$. Then $d(T_e \cap OPT'_{NH} \cap \mathcal{T}^{(\ell)}) \leq 10 \cdot \frac{1}{\epsilon^3} \cdot (\frac{1}{\epsilon^2})^{a+\ell/\epsilon+1/\epsilon-2} := d^{(\ell)}_{\max}$. Moreover, for each edge $e' \in \mathcal{E}^{(\ell')}$ with $\ell' \geq \ell + 1$ we have that $d(T_e \cap OPT'_{NH} \cap \mathcal{T}^{(\ell)}) \leq d^{(\ell)}_{\max} \leq 10\epsilon \cdot s^{(\ell+1)}_{\min} \leq 10\epsilon \cdot \delta_{e'}$.*

We split the non-huge tasks into tiny and medium tasks. Let $\mu_1, \mu_2 > 0$ with $\mu_1 < \mu_2$ be two constants to be defined later. We say that a non-huge task $i \in \mathcal{T}^{(\ell)}$ is *tiny* if $d(i) \leq \mu_1 \cdot s^{(\ell)}_{\min}$ and it is *medium* if $d(i) \geq \mu_2 \cdot s^{(\ell)}_{\min}$. Note that there are some tasks that are neither tiny nor medium, i.e., a task i with $\mu_1 \cdot s^{(\ell)}_{\min} < d(i) < \mu_2 \cdot s^{(\ell)}_{\min}$. We will neglect such tasks. Due to the following lemma, we can find values for μ_1, μ_2 such that this is justified. Also, there is a large gap between these two values which we will exploit later.

▶ **Lemma 11.** *For each $\epsilon > 0$ we can find a set of $1/\epsilon$ pairs $(\mu_1^{(1)}, \mu_2^{(1)}), ..., (\mu_1^{(1/\epsilon)}, \mu_2^{(1/\epsilon)})$ such that for one pair $(\mu_1^{(r)}, \mu_2^{(r)})$ it holds that $\mu_1 \leq \frac{\epsilon}{\alpha_\epsilon}$ with $\alpha_\epsilon := \frac{1}{\epsilon} \cdot \left(\frac{2}{\epsilon^6} + \frac{10\epsilon}{\mu_2} \cdot (1/\epsilon)^{1/\epsilon}\right)$ and the set $OPT' \cap \bigcup_\ell \{i \in \mathcal{T}^{(\ell)} | \mu_1^{(r)} \cdot s_{\min}^{(\ell)} < d(i) < \mu_2^{(r)} \cdot s_{\min}^{(\ell)}\}$ contains at most $\epsilon \cdot |OPT'|$ tasks.*

We assume that we guess the correct pair $(\mu_1^{(r)}, \mu_2^{(r)})$ and define the sets of tiny and medium tasks according to it.

3.2 Structure via segments

Next, we show that we can compute a set of at most k vertices such that the path of each input task uses one of them (otherwise we can directly find a solution with k tasks).

▶ **Lemma 12.** *In polynomial time we can identify (i) a set $\bar{V} \subseteq V$ of at most k vertices such that for each task $i \in T$ there is a vertex $v \in \bar{V}$ such that $v \in P(i)$ or (ii) a set of k tasks that form a feasible solution.*

Proof. Let i be the task with leftmost end vertex $t(i)$. We define $\bar{T} := \{i\}$ and $\bar{V} := \{t(i)\}$. We remove all tasks using $t(i)$ from the input. Note that all remaining tasks start and end on the right of $t(i)$. We iterate this process $k-1$ more times: among the remaining tasks we identify the task i' with left most end vertex $t(i')$ and we add $t(i')$ to $\bar{T}$, we add $t(i')$ to $\bar{V}$, and we remove all tasks using $t(i')$. At the end, we have that $|\bar{T}| = |\bar{V}|$ and by construction, no two tasks in $\bar{T}$ share a vertex (and thus also no edge) and each input task uses one vertex in $\bar{V}$. Hence, if $|\bar{T}| \geq k$ then we found a feasible solution with k tasks. Otherwise, the set $\bar{V}$ is the set satisfying the claim of the lemma. ◀

The vertices in $\bar{V}$ divide the path into a set of at most $k+1$ *segments* $\mathcal{S}$, i.e., any two vertices $v, v' \in \bar{V}$ such that there is no vertex of $\bar{V}$ between v and v' induce a segment $S \subseteq E$ which contains all edges between v and v'. Additionally, $\mathcal{S}$ contains a segment containing all edges between the leftmost vertex of G and the leftmost vertex in $\bar{V}$ and a segment between the rightmost vertex in $\bar{V}$ and the rightmost vertex in G. For each supertype $\mathcal{T}^{(\ell)}$ we can bound the number of huge tasks starting or ending within a segment.

▶ **Lemma 13.** *Let $\mathcal{T}^{(\ell)}$ be a supertype and let S be a segment. Then there can be at most $\frac{2}{\epsilon^6}$ huge tasks in $\mathcal{T}^{(\ell)} \cap OPT'$ that use an edge of S.*

A core problem for our algorithm is that we do not know how to allocate the edge capacities between the tiny, the medium, and the huge tasks. To this end, we prove the following lemma that will later allow us to essentially guess this allocation in FPT-time.

▶ **Lemma 14.** *By reducing the number of tasks in OPT' by at most a factor $1 + O(\epsilon)$ we can assume that for each segment $S \in \mathcal{S}$ and each supertype ℓ one of the following holds:*

- *there is no huge or medium task of supertype ℓ using any edge of S or*
- *at most α_ϵ tiny tasks of supertype ℓ start or end in S. In this case, the total demand of all tiny tasks of type j starting or ending in S is bounded by $\alpha_\epsilon \cdot \mu_1 \cdot s_{\min}^{(\ell)} \leq \epsilon \cdot s_{\min}^{(\ell)}$.*

Proof. Consider a segment S and assume that there is a huge or medium task using some edge e of S. By Lemma 13 there can be at most $\frac{2}{\epsilon^6}$ such huge tasks. Moreover, there can be at most $\frac{d_{\max}^{(\ell)}}{\mu_2 \cdot s_{\min}^{(\ell)}} \leq \frac{10\epsilon \cdot s_{\min}^{(\ell+1)}}{\mu_2 \cdot s_{\min}^{(\ell)}} \leq \frac{10\epsilon}{\mu_2} \cdot (1/\epsilon)^{1/\epsilon}$ such medium tasks and hence at most $\epsilon \cdot \alpha_\epsilon$ medium or huge tasks in total. If there are more than α_ϵ tiny tasks starting or ending in S then we remove all medium and huge tasks using an edge of S. We do this operation with

all segments S. We charge the cost of the removed huge and medium tasks to the tiny tasks. Let n' be the number of removed tasks. Then $OPT' \geq \frac{1}{2\epsilon}n'$ and thus $n' \leq 2\epsilon \cdot OPT'$. ◀

If for a segment S and a supertype ℓ the first case of Lemma 14 applies then we say that the pair (S, ℓ) is *tiny*, otherwise we say that (S, ℓ) is *huge*. As we show in the next lemma, in time FPT-time we can guess which task supertypes appear in the optimal solution.

▶ **Lemma 15.** *In time* $(\log n)^{O(k)} \leq n \cdot 2^{O(k)}$ *we can guess the set* $L = \{\ell \mid OPT \cap \mathcal{T}^{(\ell)} \neq \emptyset\}$.

Proof. Each supertype ℓ arising in the optimal solution is an integer between -1 and $\log_{1/\epsilon^2} \max_{e \in E} u(e)$. Since the input numbers are polynomially bounded this yields at most $O(\log n)$ many supertypes. For each of the k tasks in OPT' there are $O(\log n)$ options for its supertype. Thus, in time $O(\log n)^k$ we can guess all supertypes arising in OPT'. ◀

Next, we use color-coding [1] in order to guess the correct supertype of each tiny task from OPT'. More precisely, we use it in order to obtain sets $\bar{\mathcal{T}}^{(\ell)}$ for $\ell \in \mathbb{N}$ such that each tiny task $i \in OPT'$ of supertype ℓ is contained in the set $\bar{\mathcal{T}}^{(\ell)}$ (but the set $\bar{\mathcal{T}}^{(\ell)}$ possibly contains more tasks). Note that then we know the set $T \setminus \bigcup_\ell \bar{\mathcal{T}}^{(\ell)}$ which contains all medium and huge tasks in OPT'.

▶ **Lemma 16** ([1])**.** *By increasing the running time by a factor* $2^{O(k)} \cdot \log n$ *we can assume that we are given sets* $\bar{\mathcal{T}}^{(\ell)}$, $\ell \in \mathbb{N}$, *such that each tiny task* $i \in OPT'$ *of supertype* ℓ *is contained in the set* $\bar{\mathcal{T}}^{(\ell)}$.

3.3 Recursive algorithm

Denote by OPT'_T, OPT'_M, and OPT'_H the tiny, medium and huge tasks in OPT', respectively. We describe now a recursive algorithm that constructs a solution with $|OPT'|$ many tasks. We will show later how to embed it into a dynamic program that runs in FPT-time. Our algorithm proceeds in phases, each phase corresponds to one supertype ℓ. Let ℓ be the supertype of the first phase. We assume that stype$(e) \geq \ell$ for each edge e (otherwise we can reduce the instance to a set of smaller instances in which this holds).

First, in time 2^{k+1} we guess for each segment S whether (S, ℓ) is huge or tiny. For each edge $e \in S$ we allocate a certain amount of capacity $u_\ell(e)$ for the tiny tasks of supertype ℓ. A special case arises for the supertype ℓ containing the type $j = -1$. There are no tiny tasks of this supertype and we define $u_\ell(e) := 0$. Otherwise, if (S, ℓ) is huge then this means that the tiny tasks of supertype ℓ starting or ending in S have very little total capacity, at most $\epsilon \cdot s^{(\ell)}_{\min}$. However, there might be more tiny tasks that use the edges of S but do not start or end in S. Denote by x their total capacity and note that $x \leq d^{(\ell)}_{\max}$. We assign the same amount of capacity to the tiny tasks in $\bar{\mathcal{T}}^{(\ell)}$ on each edge $e \in S$. We guess the value $\bar{x} := \min\left\{d^{(\ell)}_{\max}, \left(\left\lceil x/(s^{(\ell)}_{\min} \cdot \epsilon)\right\rceil + 1\right) \cdot \epsilon \cdot s^{(\ell)}_{\min}\right\}$ and we define $u_\ell(e) := \bar{x}$ for each edge $e \in S$. There are only $O_\epsilon(1)$ many options for $\bar{x}$. Since there are at most $k+1$ segments there are only $2^{O_\epsilon(k)}$ many guesses for the huge pairs (S, ℓ).

▶ **Lemma 17.** *Let* e *be an edge of a segment* S *such that* (S, ℓ) *is huge. Then* $d(OPT'_T \cap T_e \cap \bar{\mathcal{T}}^{(\ell)}) \leq u_\ell(e)$.

Now assume that (S, ℓ) is tiny. We do not know the supertype of each edge $e \in S$. However, we know that for each edge $e \in S$ of supertype ℓ there is no huge or medium task of supertype ℓ that uses e. For each edge $e \in S$ of supertype $\ell + 1$ or larger we know that the tiny tasks of supertype ℓ use at most $d^{(\ell)}_{\max}$ units of its capacity. Therefore,

we can give to the tiny tasks of supertype ℓ the capacity of each edge $e \in S$ that is not used by the previously guessed huge tasks, up to a maximum of $d^{(\ell)}_{\max}$. We define $u_\ell(e) := \min\{u(e) - d(OPT'_{H,\geq \ell-1} \cap T_e) - (1-\epsilon)s^{(\ell)}_{\min}, d^{(\ell)}_{\max}\}$ for each edge $e \in S$ where $OPT'_{H,\geq \ell-1}$ is the set of huge tasks $i \in OPT'$ that satisfy $d(i) \geq \epsilon^2 \cdot s^{(\ell-1)}_{\min}$.

▶ **Lemma 18.** *Let ℓ be a supertype. Let e be an edge of a segment S such that (S,ℓ) is tiny. Then $d(OPT'_T \cap T_e \cap \bar{\mathcal{T}}^{(\ell)}) \leq u_\ell(e)$.*

The following lemma implies that after we assigned $u_\ell(e)$ units of capacity to the tiny tasks the remaining capacity is sufficient for the huge and medium tasks in OPT' (in particular the not yet selected ones of supertype ℓ or larger). This holds even if we assign the capacity of the tiny tasks in this manner for all supertypes $\ell' \leq \ell$.

▶ **Lemma 19.** *For each edge e of a segment S we have that $\sum_{\ell':\ell'\leq\ell} u_{\ell'}(e) + d(OPT'_H \cap T_e) + d(OPT'_M \cap T_e) \leq u(e) - \frac{1}{2} \cdot s^{(\ell)}_{\min}$ where $\ell := \text{stype}(e)$.*

For each edge e we have that $u_\ell(e) \in [\epsilon \cdot s^{(\ell)}_{\min}, d^{(\ell)}_{\max}]$, independent on whether e is in a huge or in a tiny segment. Thus, the $u_\ell(e)$ values are in a constant range. We call our FPT-algorithm for this case (see Theorem 6) with the input consisting of $\bar{\mathcal{T}}^{(\ell)}$ and the edge capacities u_ℓ. Due to Lemmas 17 and 18 it will output a solution consisting of at least $|OPT'_T \cap \bar{\mathcal{T}}^{(\ell)}|$ tasks.

Next, we want to guess the huge and medium tasks of supertype ℓ in OPT' and split the path into subpaths such that each subpath E' has the property that $\text{stype}(e') \geq \ell+1$ for each edge $e' \in E'$. First, we guess which segments S have the property that for some edge $e \in S$ we have that $\text{stype}(e) = \ell$. We can do this in time 2^{k+1}. Denote by $\mathcal{S}'$ the resulting set of segments. We process the segments in $\mathcal{S}'$ from left to right, starting with the leftmost such segment $S \in \mathcal{S}'$. We guess the leftmost and the rightmost edge in S of supertype ℓ, denote them by e_L and e_R, respectively. Then we guess the at most $O_\epsilon(1)$ medium and huge tasks of supertype ℓ that use e_L or e_R. We recurse on the subpath consisting all edges on the left of e_L. There, each edge is of supertype at least $\ell+1$. On the subpath on the right of e_R we continue splitting the remaining path into subpaths. To this end, we take the next segment $S' \in \mathcal{S}'$, guess its leftmost and rightmost edges e'_L and e'_R of supertype ℓ, and guess the $O_\epsilon(1)$ medium and huge tasks of supertype ℓ using one of them. We recurse on the subpath between e_R and e'_L, knowing that each of its edges is of supertype at least $\ell+1$. Also, there cannot be any task whose path lies strictly between e_L and e_R since each input task has to use some vertex in $\bar{V}$. We proceed with splitting the remaining segments in $\mathcal{S}'$ on the right of S'. To this end, it suffices to know e'_R and the $O_\epsilon(1)$ medium and huge tasks using it, rather than also e_L, e_R, and e'_L and the medium and huge tasks using those (apart from those that use also e'_R).

We can embed our whole recursive algorithm into a dynamic program whose running time is FPT. Here we use ideas from [17], in particular for using the slack on the edges in order to be able to "forget" some of the previously taken decisions. Crucial here is that in order to define the $u_\ell(e)$-values it is not necessary to remember all previously guessed tasks and all values $u_{\ell'}(e)$ for all $\ell' < \ell$, but only the tasks in $OPT'_{H,\geq\ell-1}$ that use the leftmost or the rightmost edge of the subpath of the respective subproblem. One can show that those can be only $O_\epsilon(1)$ many. Thus, each arising subproblem can be described by a supertype ℓ, a subpath E' of E, and the $O_\epsilon(1)$ tasks in $OPT'_{H,\geq\ell-1}$ using the leftmost or the rightmost edge of E'. This bounds the number subproblems and thus the number of DP-cells by $n^{O_\epsilon(1)} \cdot \log u_{\max}$. With an additional color coding step and some slight extensions to the above routine one can remove the assumption that the input values are polynomially bounded.

▶ **Theorem 20.** *There exists a $(1+\epsilon)$-approximation algorithm with a running time of $2^{O(k \log k)} n^{O_\epsilon(1)} \log u_{\max}$ for UFP-instances with $|OPT| = k$.*

▶ **Corollary 21.** *There is a PTAS for UFP instances that have satisfy the property that $|OPT| \leq O(\log n / \log \log n)$.*

4 W[1]-hardness

In this section we prove that UFP is W[1]-hard if the parameter k represents the number of tasks in the optimal solution.

▶ **Theorem 22.** *The unweighted Unsplittable Flow on a Path problem is W[1]-hard when parametrized by the number of tasks in the optimal solution.*

We give a reduction from the k-subset sum problem which is W[1]-hard [15]. Given a set of n values $A = \{a_1, ..., a_n\}$, a target value B and an integer k, the goal is to choose exactly k values from A that sum up to exactly B. Suppose we are given an instance of k-subset sum. First, we claim that we can assume w.l.o.g. the following properties for it.

▶ **Lemma 23.** *W.l.o.g. we can assume that there are values $\epsilon_1, ..., \epsilon_n$, not necessarily positive, such that $a_i = B/k + \epsilon_i$ for each $i \in [n]$ and that $\sum_{i=1}^{n} |\epsilon_i| < B/k$.*

We construct an instance of UFP that admits a solution with $2k$ tasks if and only if the given k-subset sum is a yes-instance. Our UFP instance has a path with $n+2$ vertices $v_0, v_1, ..., v_{n+1}$. Denote the leftmost and the rightmost edge by e_L and e_R, respectively. We define $u(e_L) = u(e_R) = B$. For all other edges e we define $u(e) := B + k \cdot \max_i |\epsilon_i|$. Assume that the values in S are ordered such that $a_1 \geq a_2 \geq ... \geq a_n$. Let $j \in [n]$. We introduce two tasks $i(j), i'(j)$ with $s(i(j)) := v_0$, $t(i(j)) := v_i$, $d(i(j)) := a_j$ $s(i'(j)) := v_i$, $t(i'(j)) = v_{n+1}$, and $d(i'(j)) := 2B/k - a_j$. See Figure 1 for a sketch.

In order to get some intuition about the constructed instance, we observe the following.

▶ **Lemma 24.** *In the constructed instance there can be no solution with more than $2k$ tasks.*

In the next lemma we show that we can construct a solution with $2k$ tasks if the given k-subset sum instance is a yes-instance: for a given set $J \subseteq [n]$ of k indices such that $\sum_{j \in J} a_j = B$ we select the tasks $i(j)$ and $i'(j)$ for each $j \in J$. One can easily verify that this yields a feasible solution.

▶ **Lemma 25.** *If the given k-subset sum instance is a yes-instance, then the constructed UFP instance has a solution with $2k$ tasks.*

Conversely, we show that if the UFP instance has a solution with $2k$ tasks then the k-subset sum instance is a yes-instance. Suppose we are given such a solution for the UFP instance. First, we establish that for each $j \in [n]$ the solution selects either both $i(j)$ and $i'(j)$ or none of these two tasks.

▶ **Lemma 26.** *Given a solution T' to the UFP instance with $2k$ tasks. Then there is a solution T'' with $2k$ tasks such that for each $j \in [n]$ we have that either $\{i(j), i'(j)\} \subseteq T''$ or $\{i(j), i'(j)\} \cap T'' = \emptyset$.*

Proof. Let j be an index such that neither $\{i(j), i'(j)\} \subseteq T'$ nor $\{i(j), i'(j)\} \cap T' = \emptyset$. First assume that $i(j) \in T'$ but $i'(j) \notin T'$. Then by construction the edge $\{v_j, v_{j+1}\}$ is used by at most $k-1$ tasks. Let j' be the smallest index greater than j such that the edge $\{v_{j'}, v_{j'+1}\}$

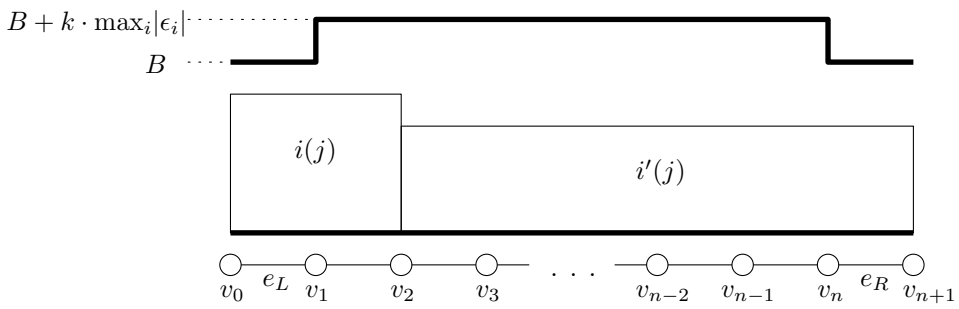

Figure 1 Sketch of the reduction used in order to prove Theorem 22. The sketch shows the tasks $i(j)$ and $i'(j)$ for only one index j.

is used by k tasks. Such an index must exist since e_R is used by k tasks from T'. Since the edge $\{v_{j'-1}, v_{j'}\}$ is used by only $k-1$ tasks this implies that $i'(j') \in T'$ but $i(j') \notin T'$. We define $\tilde{T} := T' \cup \{i'(j)\} \setminus \{i'(j')\}$. We claim that $\tilde{T}$ is feasible. The task $i'(j)$ does not use e_L and thus $\tilde{T}$ does not violate the capacity bound of e_L. Furthermore, $s(i'(j))$ lies on the left of $s(i'(j'))$ and thus $a_j \geq a_{j'}$. Hence, $d(i'(j)) = 2B/k - a_j \leq 2B/k - a_{j'} = d(i'(j'))$. Hence, $\tilde{T}$ does not violate the capacity bound of e_R. Each edge e with $e_L \neq e \neq e_R$ is used by at most k tasks. Hence, we do not violate its capacity bound (same calculation as in the proof of Lemma 25). The case that $i(j) \notin T'$ but $i'(j) \in T'$ can be handled with a similar argumentation. We repeat this process until we cannot find another index j that violates the property of the lemma. Denote by T'' the resulting set. ◀

Suppose we are given a solution T' to the UFP instance with $2k$ tasks that satisfies Lemma 26. Let J' be the set of indices j such that $i(j) \in T'$. We show in the next two lemmas that J' is a solution to the k-subset sum instance. Lemma 27 follows from our assumption that each value a_i almost equals B/k (see Lemma 23) and the fact that the edges e_L and e_R have capacity B each.

▶ **Lemma 27.** *The set T' contains exactly k tasks using e_L and exactly k tasks using e_R. Furthermore, we have that $|J'| = k$.*

▶ **Lemma 28.** *We have that $\sum_{j \in J'} a_j = B$.*

Proof. Let $T'_L \subseteq T'$ and $T'_R \subseteq T'$ denote the set of tasks in T' using e_L and e_R, respectively. Then $B = u(e_L) \geq \sum_{i \in T'_L} d(i) = \sum_{j \in J'} a_j$. On the other hand, due to Lemma 26 we have that $B = u(e_R) \geq \sum_{i \in T'_R} d(i) = \sum_{j \in J'} 2B/k - a_j$ and hence $\sum_{j \in J'} a_j \geq (\sum_{j \in J'} 2B/k) - B = B$. Therefore $\sum_{j \in J'} a_j = B$. ◀

Hence, we proved that the constructed UFP instance has a solution with $2k$ tasks if and only if the k-subset sum instance is a yes-instance. This completes the proof of Theorem 22.

▶ **Corollary 29.** *There is no EPTAS for the unweighted Unsplittable Flow on a Path problem, unless* W[1] = FPT.

Acknowledgments. The author would like to thank Tobias Mömke and Hang Zhou for helpful discussions on the topic and many comments on an earlier draft, and the anonymous referees for many helpful suggestions and comments.

Linear-Time Kernelization for Feedback Vertex Set*

Yoichi Iwata†

National Institute of Informatics, Tokyo, Japan
yiwata@nii.ac.jp

Abstract

In this paper, we give an algorithm that, given an undirected graph G of m edges and an integer k, computes a graph G' and an integer k' in $O(k^4m)$ time such that (1) the size of the graph G' is $O(k^2)$, (2) $k' \leq k$, and (3) G has a feedback vertex set of size at most k if and only if G' has a feedback vertex set of size at most k'. This is the first linear-time polynomial-size kernel for Feedback Vertex Set. The size of our kernel is $2k^2 + k$ vertices and $4k^2$ edges, which is smaller than the previous best of $4k^2$ vertices and $8k^2$ edges. Thus, we improve the size and the running time simultaneously. We note that under the assumption of NP $\not\subseteq$ coNP/poly, Feedback Vertex Set does not admit an $O(k^{2-\epsilon})$-size kernel for any $\epsilon > 0$.

Our kernel exploits *k-submodular relaxation*, which is a recently developed technique for obtaining efficient FPT algorithms for various problems. The dual of k-submodular relaxation of Feedback Vertex Set can be seen as a half-integral variant of A-path packing, and to obtain the linear-time complexity, we give an efficient augmenting-path algorithm for this problem. We believe that this combinatorial algorithm is of independent interest.

A solver based on the proposed method won first place in the 1st Parameterized Algorithms and Computational Experiments (PACE) challenge.

1 Introduction

In the theory of parameterized complexity, we introduce parameters to problems and analyze the complexity with respect to both the input length $n = |x|$ and the parameter value k. If an algorithm runs in $f(k)n^{O(1)}$ time for any input of length n and a parameter k, it is called a *fixed-parameter tractable (FPT) algorithm*. If the $n^{O(1)}$ factor is linear, it is called a *linear-time FPT*. The typical goal of parameterized algorithms is to develop FPT algorithms with a small $f(k)$ (e.g., c^k for a small constant c) and a small $n^{O(1)}$ (e.g., linear in n). Although there are many algorithms that have been developed with smaller $f(k)$ *or* $n^{O(1)}$, achieving the smallest $f(k)$ and $n^{O(1)}$ *simultaneously* is a difficult task, and the smallest $f(k)$ factors and the smallest $n^{O(1)}$ factors are often achieved by different algorithms. Moreover, when trying to improve the $f(k)$ factor, the $n^{O(1)}$ factor is often ignored by using the O^* notation, which hides factors polynomial in n, and when trying to improve the $n^{O(1)}$ factor, the $f(k)$ factor is often ignored by assuming k is a constant.

For example, in recent papers, Iwata, Oka, and Yoshida [18], and Ramanujan and Saurabh [27] have independently obtained $O(4^km)$-time algorithms for Almost 2-SAT,

which is a parameterized version of Max 2-SAT where a parameter is the number of unsatisfied clauses; on the other hand, when allowing the $n^{O(1)}$ factor to be super-linear, there exists an $O^*(2.32^k)$-time algorithm [23]. These two algorithms are not comparable: the former runs faster when the input is large but the latter runs faster when the parameter is large. Typically, only algorithms with the smallest $f(k)$ factor or the smallest $n^{O(1)}$ factor have been studied. However, if there were three algorithms running in time $O(8^k n)$, $O(4^k n^2)$, and $O(2^k n^3)$, all of them are incomparable: the first is fastest when $4^k < n$, the second is fastest when $2^k < n < 4^k$, and the third is fastest when $n < 2^k$. Do we need to develop algorithms with the smallest possible $f(k)$ factor for each n^d? We observe that *kernelization*, which is another basic research object of the parameterized complexity, is useful for avoiding this incomparability.

A kernelization algorithm (or *kernel*) for a parameterized problem is an algorithm that, given an instance (x, k) in time polynomial in $n = |x|$ and k, returns an equivalent instance (x', k') of the same problem such that $k' \leq k$ and $|x'| \leq g(k)$ for some function g. When the $n^{O(1)}$ factor in the running time is linear in n (i.e., $k^{O(1)}n$), it is called a *linear-time kernel*. If there is a kernel (and the problem is decidable), by solving the reduced instance exhaustively, we can obtain an FPT algorithm. Actually, the converse is also true; if there exists an $f(k)n^{O(1)}$-time FPT algorithm, there also exists a kernel of size $f(k)$. On the other hand, the existence of a polynomial-size (i.e., $|x'| \leq k^{O(1)}$) kernel is non-trivial and, actually, there are known to exist FPT problems which (unconditionally) do not have any sub-exponential-size kernels [4]. As in the case of FPT algorithms, the typical goal is to develop kernelization algorithms with a small size $g(k)$ (e.g., linear in k) and a fast running time (e.g., linear in n).

Compared with linear-time FPT algorithms, the number of studies for linear-time polynomial-size kernels is small. Examples include d-Hitting Set [29], Dominating Set on planar graphs [30, 16], $n-k$ Clique Covering [9], and Max Cut Above Edwards-Erdős Bound [14]. One of the major reasons is that when assuming the parameter k is a constant, which is often done when studying linear-time FPT algorithms, kernels become uninteresting because we cannot distinguish between $f(k)$ and $k^{O(1)}$. Nevertheless, improving the $n^{O(1)}$ factor in the running time of kernels is very important because such kernels can be used as preprocessing for FPT algorithms. Let us assume that we have a $k^{O(1)}n^d$-time polynomial-size kernel and an $f(k)n^{O(1)}$-time FPT algorithm. Then, by applying the FPT algorithm against the instance reduced by the kernelization, we obtain a $k^{O(1)}(f(k) + n^d)$-time FPT algorithm. Thus, the $n^{O(1)}$ factor of any FPT algorithm can be replaced by n^d. Therefore, if we have a linear-time polynomial-size kernel, we obtain a linear-time FPT algorithm that simultaneously achieves the smallest possible $f(k)$ factor (ignoring factors polynomial in k). This also implies that after obtaining a linear-time polynomial-size kernel, we can safely ignore the $n^{O(1)}$ factor and focus on improving the $f(k)$ factor only. Moreover, it can also be combined with another kernel of smaller size. Let us assume that we have a $k^{O(1)}n^d$-time polynomial-size kernel and a $g(k)$-size kernel. Then, by applying the second kernel against the instance reduced by the first kernelization, we obtain a $k^{O(1)}n^d$-time $g(k)$-size kernel. Therefore, in contrast to the case of FPT algorithms, we can always achieve the smallest size and the fastest running time simultaneously.

In this paper, we give a linear-time quadratic-size kernel for Feedback Vertex Set. This is the first linear-time polynomial-size kernel for this problem. Feedback Vertex Set is a problem to decide whether a given undirected graph has a vertex set of size at most a given parameter k whose removal makes the graph a forest. Feedback Vertex Set is one of the most comprehensively studied problems in the field of parameterized complexity and

many different FPT algorithms and kernels have been developed. Moreover, the problem was chosen as a target problem of the 1st Parameterized Algorithms and Computational Experiments (PACE) challenge[1]. Actually, this research is strongly motivated by the PACE challenge. The proposed methods are easy to implement, and a solver[2] based on the proposed methods won first place in the challenge.

The first FPT algorithm for Feedback Vertex Set was given by Downey and Fellows [13]. This algorithm and subsequent improved algorithms [21, 26] use the strategy to branch on short cycles and the $f(k)$ factor of the running time is not a single exponential in k. The first single-exponential FPT algorithms were obtained independently by Dehne et al. [11] and Guo et al. [15], and several improved algorithms have been obtained [8, 7, 22]. The current smallest $f(k)$ factor for deterministic algorithms is 3.62^k given by Kociumaka and Pilipczuk [22]. These single-exponential FPT algorithms use the *iterative compression* technique. For a graph with n vertices and m edges[3], a naive implementation of iterative compression requires n iterations and each iteration takes $f(k)\Omega(m)$ time. Therefore, the total running time is $f(k)\Omega(nm)$. For the case of Feedback Vertex Set, by combining it with 2-approximation algorithms [1, 3], we can solve the problem using only a single iteration; however, this increases the running time for one iteration to $f(2k)\Omega(m)$. Thus, for obtaining a linear-time FPT algorithm, the $f(k)$ factor needs to grow from 3.62^k to 3.62^{2k}. When allowing randomness, a simple $O(4^k km)$-time FPT algorithm using random sampling of edges was given by Becker et al. [2]. The current smallest $f(k)$ factor for randomized FPT algorithms is 3^k given by Cygan et al. [10]. This algorithm uses dynamic programming on tree-decompositions and takes $3^k k^{O(1)} n^2$ time after obtaining a tree-decomposition of width at most k. As discussed above, by using our linear-time polynomial-size kernel, we can obtain a $k^{O(1)}(3.62^k + m)$-time deterministic FPT algorithm and a $k^{O(1)}(3^k + m)$-time randomized FPT algorithm.

The first polynomial-size kernel was given by Burrage et al. [6]. The size of this kernel is $O(k^{11})$, which was improved to $O(k^3)$ by Bodlaender and Van Dijk [5], and to $O(k^2)$ by Thomassé [28]. Finally, Dell and Van Melkebeek [12] showed that there are no kernels of size $O(k^{2-\epsilon})$ for any constant $\epsilon > 0$ unless NP $\subseteq$ coNP/poly. The size of the current smallest kernel by Thomassé is $4k^2$ vertices and $8k^2$ edges. Although the precise running time of each of these kernels was not analyzed, we can easily check that all of them take at least $k^{O(1)}nm$ time. As discussed above, if there is a linear-time polynomial-size kernel, by combining it with the smallest kernel, we can achieve the linear running time and the smallest kernel size simultaneously. However, our linear-time quadratic-size kernel does not rely on such a combination.

Before providing a description of our kernel, we first give a brief description of a key idea behind the existing kernels. All the existing kernels for Feedback Vertex Set exploit *s-flowers*. A set of simple cycles is called an s-flower if each cycle contains the vertex s and no two cycles share any vertex other than s. If the degree of s is large and the graph is well-connected, there exists a large s-flower. Because the size of an s-flower (i.e., the number of cycles) gives a lower bound of the size of the minimum feedback vertex set that does not contain s, if it is larger than the parameter k, we can remove s and decrement k. Otherwise, the degree of s is small, or the graph is not well-connected. In the former case, we know that the graph is small, and in the latter case, we can apply another reduction rule.

[1] `https://pacechallenge.wordpress.com/`
[2] `https://github.com/wata-orz/fvs`
[3] If a graph has a feedback vertex set of size at most k, we have $m = O(kn)$.

In our kernel, instead of s-flowers, we exploit *k-submodular relaxation*, which is a recently developed technique for obtaining efficient FPT algorithms for various problems. The concept of k-submodular relaxation was introduced by Iwata, Wahlström, and Yoshida [19]. The k-submodular relaxation is a technique to obtain *half-integral* and *persistent* relaxations and many existing half-integral LP relaxations (e.g., the LP relaxation of Vertex Cover [24]) can be re-derived by this technique. If a problem admits such a relaxation, the branch-and-bound method gives an FPT algorithm. By applying k-submodular relaxation, they obtained an $O^*(4^k)$-time FPT algorithm for Feedback Vertex Set. A detailed description of the k-submodular for Feedback Vertex Set is given in Section 2. By exploiting k-submodular relaxation, we obtain a very simple kernel for Feedback Vertex Set, which is described in Section 3. The size of our kernel is $2k^2 + k$ vertices and $4k^2$ edges, which is smaller than the previous best of $4k^2$ vertices and $8k^2$ edges [28].

We observe that there is a strong relationship between the k-submodular relaxation of Feedback Vertex Set and s-flowers; the problem of computing a maximum s-flower is the integral dual of the k-submodular relaxation of Feedback Vertex Set. This resembles the situation for Almost 2-SAT. For Almost 2-SAT, Raman et al. [25] obtained an $O^*(9^k)$-time FPT algorithm by a reduction to Vertex Cover above Maximum Matching, and then both the $f(k)$ factor [23] and $n^{O(1)}$ factor [18, 27] were improved by a reduction to Vertex Cover above LP. Here, the maximum matching is the integral dual of the LP relaxation of Vertex Cover. Because the fractional minimum of the primal LP is always at least the integral maximum of the dual LP, by using the half-integral relaxation instead of the integral dual, we can obtain a better lower bound. Moreover, by using the half-integral relaxations, we can directly exploit the persistency of the relaxations.

For obtaining linear-time kernel, we give a max-flow-like augmenting-path algorithm for solving the k-submodular relaxation of Feedback Vertex Set in Section 4. This is the most technical part of the paper. Our algorithm can compute a minimum solution in $O(km)$ time. By combining this algorithm with the simple kernel, we give a linear-time kernel in Section 5. Due to space limitations, some of the proofs are omitted. Lemmas with omitted proofs are marked with ($\star$) and these proofs can be found in the full version [17].

We note that this algorithm can be used not only for the linear-time kernel but also for improving the $n^{O(1)}$ factor of the $O^*(4^k)$-time FPT branch-and-bound algorithm for Feedback Vertex Set. By applying k-submodular relaxations, $O^*(4^k)$-time FPT algorithms for two general versions, Subset Feedback Vertex Set and Group Feedback Vertex Set, have been obtained [19]. Following up our work, Iwata, Yamaguchi, and Yoshida [20] obtained linear-time FPT algorithms for many problems including these general versions of Feedback Vertex Set by developing efficient augmenting-path algorithm for solving k-submodular relaxations in general.

2 Preliminaries

2.1 Definitions

A *multiplicity function* of a multiset S is denoted by $\mathbf{1}_S$; e.g., when $S = \{a, a, b\}$, $\mathbf{1}_S(a) = 2$, $\mathbf{1}_S(b) = 1$, and $\mathbf{1}_S(c) = 0$. Let $f : U \to \mathbb{R}$ be a function. For a multiset S, we write the sum of $f(a)$ over $a \in S$ as $f(S) = \sum_{a \in S} f(a)$; e.g., when $S = \{a, a, b\}$, $f(S) = 2f(a) + f(b)$. We denote the preimage of $i \in \mathbb{R}$ under f by $f^{-1}(i) = \{a \in U \mid f(a) = i\}$.

Let $G = (V, E)$ be an undirected graph. We assume that G may contain a self-loop and multiple edges. We will often denote the number of vertices by n and the number of edges by m. We denote the set of edges incident to a vertex v by $\delta_G(v)$ and define the *degree*

of v as $d_G(v) = |\delta_G(v)|$. Here, we note that multiple edges contribute to the degree by its multiplicity, and we never refer to the degree of a vertex having a self-loop. We omit the subscript G if it is clear from the context. An edge $e \in E$ is called a *bridge* if its removal increases the number of connected components.

For a vertex set S, we denote the graph obtained by removing S and their incident edges by $G - S$. When S is a singleton $\{v\}$, we simply write $G - v$. A vertex set $S \subseteq V$ is called a *feedback vertex set* if $G - S$ is a forest. We denote the size of the minimum feedback vertex set of G by $\mathrm{fvs}(G)$.

A *walk* is an ordered list $(v_0, e_1, v_1, e_2, \ldots, v_{\ell-1}, e_\ell, v_\ell)$ such that $\ell \geq 1$ and each edge e_i connects vertices v_{i-1} and v_i. Note that it may contain a vertex or an edge multiple times. For a walk $W = (v_0, e_1, \ldots, v_\ell)$, we denote the multiset of vertices appearing on W by $V(W) = \{v_0, \ldots, v_\ell\}$ and the multiset of edges appearing on W by $E(W) = \{e_1, \ldots, e_\ell\}$.

2.2 Basic Reductions

We introduce basic reductions that have been commonly used in kernelization algorithms for Feedback Vertex Set [6, 5, 28]. The correctness of these reductions is almost trivial.

1. If there is a vertex v containing a self-loop, remove v and decrease k by one.
2. If there is a vertex of degree at most one, remove it.
3. If there is a vertex of degree two, remove it and connect its two neighbors by an edge.
4. If two vertices are connected by more than two edges, replace these edges with a double edge.

Note that rule 3 can remove a vertex that is only incident to a double edge; in this case, it creates a self-loop on its neighbor. These basic reductions never increase the degree of any vertex and can be fully applied in $O(m)$ time. After the reduction, the obtained graph has no self-loops and has minimum degree at least three.

We will use the following lemma to bound the size of the kernel. This is a general version of the lemma in [28], and a modified proof can be found in the full version [17].

▶ **Lemma 1** (Thomassé [28]). *If a graph without self-loops satisfies both of the following for an integer d, the size of the minimum feedback vertex set is larger than k:*

- *At least one of $n > dk + k$ or $m > 2dk$ holds; and*
- *for any $v \in V$, it holds that $3 \leq d(v) \leq d$.*

In [28], a kernel of $4k^2$ vertices and $8k^2$ edges is obtained by applying the lemma against $d = 4k - 1$. In the next section, we obtain a kernel of $2k^2 + k$ vertices and $4k^2$ edges by applying the lemma against $d = 2k$.

2.3 k-submodular Relaxation of Feedback Vertex Set

A walk $W = (v_0, e_1, \ldots, v_\ell)$ is called an *s-cycle* if $v_0 = v_\ell = s$, $v_i \neq s$ for all $i \in \{1, \ldots, \ell - 1\}$, $e_i \neq e_{i+1}$ for any $i \in \{1, \ldots, \ell - 1\}$ (i.e., there are no U-turns), and each edge is contained in the walk at most twice. For example, walks $(s, e_1, u, e_2, v, e_3, s)$ and $(s, e_1, u, e_2, v, e_3, w, e_4, u, e_1, s)$ are s-cycles but a walk $(s, e_1, u, e_2, v, e_2, u, e_1, s)$ is not. Note that in this definition, we distinguish each of multiple edges; e.g., if there is only a single edge e between s and v, a walk (s, e, v, e, s) is not an s-cycle; however, if there is a double edge $\{e_1, e_2\}$ between s and v, a walk (s, e_1, v, e_2, s) is an s-cycle.

For a graph $G = (V, E)$ without self-loops and a vertex $s \in V$, a function $x : V \to \mathbb{R}_{\geq 0}$ is called an *s-cycle cover* if it satisfies that (1) $x(s) = 0$ and (2) for any s-cycle C, $x(V(C)) \geq 1$.

Note that $V(C)$ is the multiset of vertices on C, and therefore if $x(v) = \frac{1}{2}$ holds for a vertex v contained twice in C, we have $x(V(C)) \geq 1$. The *size* of an s-cycle cover x is defined as $x(V)$, and when the size $x(V)$ is minimum among all the possible s-cycle covers, it is called a *minimum s-cycle cover*.

By introducing the idea of k-submodular relaxation, Iwata, Wahlström, and Yoshida [19] obtained the following lemma.

▶ **Lemma 2** (Iwata, Wahlström, and Yoshida [19]). *For any graph $G = (V, E)$ without self-loops and $s \in V$, the following holds:*

- *The size of any feedback vertex set of G that does not contain s is at least the size of the minimum s-cycle cover.*
- *There exists a minimum s-cycle cover that takes values $\{0, \frac{1}{2}, 1\}$ (half-integrality).*
- *If there exists a minimum feedback vertex set that does not contain s, then for any half-integral minimum s-cycle cover x, there also exists a minimum feedback vertex set S such that $x^{-1}(1) \subseteq S$ and $s \notin S$ (persistency).*

3 Simple Quadratic-size Kernel

In this section, we give a simple polynomial-time quadratic-size kernel for Feedback Vertex Set. By exploiting the persistency of the k-submodular relaxation, we give the following reduction rule called *s-cycle cover reduction*.

For a graph $G = (V, E)$, a vertex $s \in V$, and a half-integral minimum s-cycle cover x, create a graph $G' = (V, E')$ as follows. Let $X = x^{-1}(1)$ and let $B \subseteq \delta(s)$ be the set of bridges of $G - X$ connecting s and tree components of $G - X - s$. Then, G' is obtained from G by inserting a double edge between s and each of $v \in X$ and removing the edges B.

▶ **Lemma 3.** *For a graph $G = (V, E)$, a vertex $s \in V$, and a half-integral minimum s-cycle cover x, let $G' = (V, E')$ be a graph obtained by applying the s-cycle cover reduction. Then, $\mathrm{fvs}(G) = \mathrm{fvs}(G')$ holds.*

Proof. ($\geq$) Let S be a minimum feedback vertex set of G. Observe that all the inserted edges are between s and $X = x^{-1}(1)$. If $s \in S$, S is also a feedback vertex set of G'. Otherwise, from the persistency, we can assume that S contains all the vertices of X. Thus, S is also a feedback vertex set of G'.

($\leq$) Let S be a minimum feedback vertex set of G'. If $s \in S$, S is also a feedback vertex set of G. Otherwise, because all the vertices of X are connected to s by double edges in G', S must contain all of X. Because all the deleted edges are bridges in $G - X$, S is also a feedback vertex set of G. ◀

After applying this reduction, the degree of s can be bounded as the following shows.

▶ **Lemma 4.** *For a graph $G = (V, E)$, a vertex $s \in V$, and a half-integral minimum s-cycle cover x, let $G' = (V, E')$ be a graph obtained by applying the s-cycle cover reduction. Then, $d_{G'}(s) \leq 2x(V)$ holds.*

Proof. First, we show that x is also an s-cycle cover of G'. Let us assume that there is an s-cycle C of G' such that $x(C) < 1$. Because $x(v) = 1$ for $v \in X = x^{-1}(1)$, C contains none of X. Because all the inserted edges are incident to X, C is also an s-cycle of G, which is a contradiction.

For $i \in \{1, 2\}$, let N_i denote the set of vertices that are connected to s by edges of multiplicity i in G'. For each $v_i \in N_1$, we define a vertex w_i as follows.

Algorithm 1 Simple quadratic-size kernelization for Feedback Vertex Set.

```
1:  procedure Kernelize(G, k)
2:      while true do
3:          Apply the basic reductions
4:          if k < 0 then return NO
5:          if n ≤ 2k^2 + k and m ≤ 4k^2 then return (G, k)
6:          if ∀v ∈ V, d(v) ≤ 2k then return NO
7:          Pick a vertex s of degree larger than 2k
8:          Compute a half-integral minimum s-cycle cover x
9:          if x(V) > k then G ← G − s; k ← k − 1
10:         else apply the s-cycle cover reduction
```

If the edge sv_i is a bridge in $G' - X$, let C_i be the connected component of $G' - X - s$ containing v_i. Because the reduction removes all the bridges between s and tree components, C_i is not a tree. Thus, there exists an s-cycle contained in $C_i \cup \{s\}$ and, therefore, there must exist a vertex $w_i \in C_i$ with $x(w_i) = \frac{1}{2}$.

If sv_i is not a bridge in $G' - X$, there exists a path P_i from v_i to $N_1 \setminus \{v_i\}$ in $G' - X - s$. Fix an arbitrary path P_i and let w_i be the first vertex on the path such that $x(w_i) = \frac{1}{2}$. Because x is an s-cycle cover, there always exists such a vertex.

If $w_i = w_j$ holds for some $i \neq j$, there exists an s-cycle C such that $x(C) = \frac{1}{2}$, which is a contradiction. Therefore, all w_i are distinct. Thus, we have $d_{G'}(s) = |N_1| + 2|N_2| \leq |x^{-1}(\frac{1}{2})| + 2|x^{-1}(1)| = 2x(V)$. ◀

Now, we describe our simple quadratic-size kernelization algorithm (see Algorithm 1). First, we apply the basic reductions. If k becomes negative, we return a NO instance. If the graph becomes small enough, we return it. If all the vertices have degree at most $2k$, we return a NO instance. Otherwise, pick an arbitrary vertex s of degree larger than $2k$, and compute a half-integral minimum s-cycle cover x. If the size of the s-cycle cover is larger than k, we remove s and decrement k. Otherwise, we apply the s-cycle cover reduction.

▶ **Lemma 5.** *Algorithm 1 runs in $(k+m)^{O(1)}$ time and correctly computes (G', k') satisfying $k' \leq k$ and $\mathrm{fvs}(G) \leq k \Leftrightarrow \mathrm{fvs}(G') \leq k'$. The size of G' is at most $2k^2 + k$ vertices and $4k^2$ edges.*

Proof. It obviously holds that $k' \leq k$ and the size of G' is at most $2k^2 + k$ vertices and $4k^2$ edges. From Lemma 4, after applying the s-cycle cover reduction, the degree of s changes from more than $2k$ to at most $2k$. Therefore, the number of edges strictly decreases for each iteration. Thus, it stops in at most m iterations. Because each iteration can be done in time polynomial in k and m, the total running time is also polynomial in k and m.

Next, we show the correctness. By applying Lemma 1 against $d = 2k$, when the maximum degree is at most $2k$ and at least one of $n > 2k^2 + k$ and $m > 4k^2$ holds, $\mathrm{fvs}(G) > k$ holds. Thus, we can safely return a NO instance (line 6). From Lemma 2, if $x(V) > k$, there is no feedback vertex set of size at most k that does not contain s. Thus, we can safely remove s (line 9). The correctness of the s-cycle cover reduction follows from Lemma 3. ◀

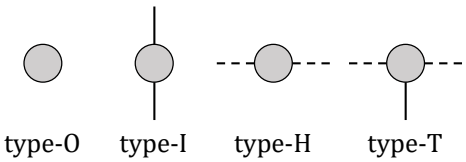

Figure 1 Four types of vertices.

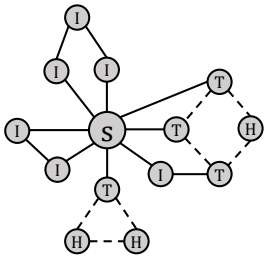

Figure 2 Example of the basic s-cycle packing.

4 Efficient Computation of a Half-integral Minimum s-cycle Cover

In this section, we prove the following theorem.

▶ **Theorem 6.** *Given a graph $G = (V, E)$ without self-loops, a vertex $s \in V$, and an integer k, in $O(km)$ time, we can compute a half-integral minimum s-cycle cover or conclude that there are no s-cycle covers of size at most $\frac{k}{2}$.*

First, we give several definitions. Let $\mathcal{C}_s$ denote the set of all s-cycles. A function $y : \mathcal{C}_s \to \mathbb{R}$ is called an *s-cycle packing* if for any vertex $v \in V \setminus \{s\}$, it holds that $\sum_{C \in \mathcal{C}_s} \mathbf{1}_{V(C)}(v) y(C) \leq 1$. The *size* of an s-cycle packing y is defined as $y(\mathcal{C}_s)$, and when the size $y(\mathcal{C}_s)$ is the maximum among all the possible s-cycle packings, it is called a *maximum s-cycle packing*. Because the problem of finding a maximum s-cycle packing is the LP dual of the problem of finding a minimum s-cycle cover, the size of the minimum s-cycle cover is equal to the size of the maximum s-cycle packing. Thus, if we can find a pair of an s-cycle cover x and an s-cycle packing y of the same size, we can confirm that x is a minimum s-cycle cover and y is a maximum s-cycle packing.

▶ **Definition 7.** A function $f : E \to \{0, \frac{1}{2}, 1\}$ is called a *basic s-cycle packing* if it satisfies the following three conditions.

1. For any $e \in \delta(s)$, $f(e) \in \{0, 1\}$.
2. Each vertex $v \in V \setminus \{s\}$ satisfies exactly one of the following four conditions (see Figure 1):
   a. $f(e) = 0$ for all edges $e \in \delta(v)$ (called type-O);
   b. $f(e) = 1$ for exactly two edges $e \in \delta(v)$ and $f(e) = \frac{1}{2}$ for none of $e \in \delta(v)$ (called type-I);
   c. $f(e) = 1$ for none of $e \in \delta(v)$ and $f(e) = \frac{1}{2}$ for exactly two edges $e \in \delta(v)$ (called type-H);
   d. $f(e) = 1$ for exactly one edge $e \in \delta(v)$ and $f(e) = \frac{1}{2}$ for exactly two edges $e \in \delta(v)$ (called type-T).
3. For each vertex $v \in V \setminus \{s\}$ of type-H or type-T, the cycle obtained by following edges of value $\frac{1}{2}$ from v contains an odd number of type-T vertices.

We call the cycle in the third condition the *half-integral cycle of v*. The size of a basic s-cycle packing f is defined as $\frac{1}{2} f(\delta(s))$. Figure 2 illustrates an example of the basic s-cycle packing, where solid lines denote edges of value 1, and dotted lines denote edges of value $\frac{1}{2}$.

▶ **Lemma 8** ($\star$). *If there exists a basic s-cycle packing of size k, there also exists an s-cycle packing of size k.*

Note that this lemma only says that the size of the maximum basic s-cycle packing is always at most the size of the maximum s-cycle packing and does not imply these two are equal. The equality is shown at the end of this section.

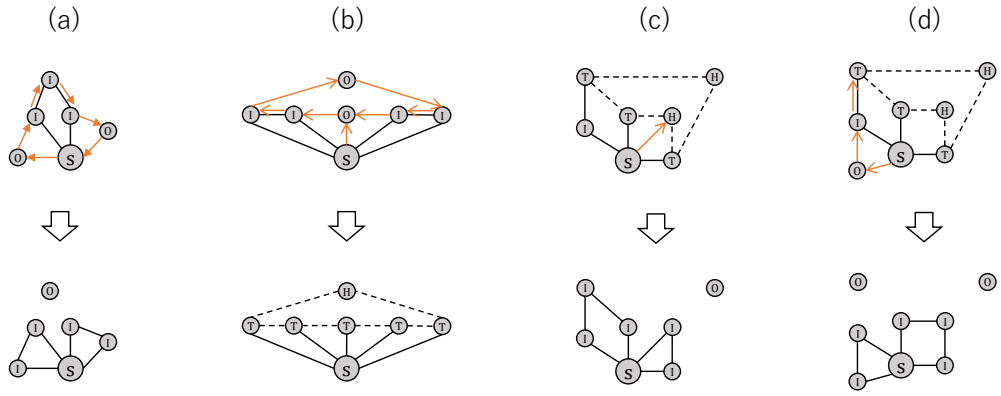

Figure 3 Examples of augmenting walks.

▶ **Definition 9.** For a basic s-cycle packing f, a walk $W = (v_0, e_1, \ldots, v_\ell)$ is called an *f-augmenting walk* if it satisfies all the following conditions.

1. We have $v_0 = s$.
2. We have $f(e_1) = 0$.
3. All the edges $\{e_1, \ldots, e_\ell\}$ are distinct.
4. The vertices $\{v_0, \ldots, v_{\ell-1}\}$ are distinct (the last vertex v_ℓ can be identical to v_i for some $i < \ell$).
5. For each $i \in \{1, \ldots, \ell - 1\}$, exactly one of the following holds:
   a. v_i is type-O;
   b. v_i is type-I and $f(e) = 1$ holds for at least one of $e \in \{e_i, e_{i+1}\}$.
6. If $v_\ell = v_i$ for some $i < \ell$, exactly one of the following holds:
   a. $v_\ell = s$ and $f(e_\ell) = 0$;
   b. v_ℓ is type-O;
   c. v_ℓ is type-I and $f(e) = 1$ holds for at least one of $e \in \{e_i, e_\ell\}$.
7. If $v_\ell \notin \{v_0, \ldots, v_{\ell-1}\}$, v_ℓ is type-H or type-T.

For a basic s-cycle packing f and an f-augmenting walk $W = (v_0, e_1, \ldots, v_\ell)$, let $f_W : E \to \{0, \frac{1}{2}, 1\}$ be a function defined as follows. First, set $f_W(e) = f(e)$ for all edges $e \in E$. If $v_\ell \neq s$ and $v_\ell = v_i$ holds for some $i < \ell$, let $h = i$; otherwise, let $h = \ell$. Then, for each edge $e \in \{e_1, \ldots, e_h\}$, set $f_W(e) = 1 - f(e)$. If $v_\ell = s$, we finish (see Figure 3-(a)). Otherwise, we further modify f_W depending on the type of v_ℓ.

(Case 1) If v_ℓ is type-O or type-I, for each edge $e \in \{e_{h+1}, \ldots, e_\ell\}$, set $f_W(e) = \frac{1}{2}$ (see Figure 3-(b)).

(Case 2) If v_ℓ is type-H, let C be the half-integral cycle of v_ℓ and let $\{t_0 = v_\ell, t_1, \ldots, t_{q-1}\}$ be the vertex set consisting of the vertex v_ℓ and the type-T vertices on C ordered along C (i.e., v_ℓ is located on the path from t_{q-1} to t_1 along the cycle C). We use the notation $t_q = t_0$. Let P_i be the path from t_i to t_{i+1} along the cycle C. For each even i, set $f_W(e) = 0$ for all the edges on P_i, and for each odd i, set $f_W(e) = 1$ for all the edges on P_i (see Figure 3-(c)).

(Case 3) If v_ℓ is type-T, let C be the half-integral cycle of v_ℓ and let $\{t_0 = v_\ell, t_1, \ldots, t_{q-1}\}$ be the type-T vertices on C ordered along C. Then, we proceed in exactly the same way as in case 2 (see Figure 3-(d)). We note that, in case 2, q is even; thus, v_ℓ is connected to t_{q-1} by edges of value one in f_W. On the other hand, in case 3, q is odd; thus, v_ℓ is connected to none of t_1 and t_{q-1}.

We call this operation that creates f_W from f as *augmenting f along W*.

Algorithm 2 Algorithm for computing an f-augmenting walk.

```
1: procedure FindAugmentingWalk(G, s, f)
2:     S ← {s}
3:     prev(v) = ϵ for all v ∈ V
4:     while S ≠ ∅ do
5:         Pick a vertex u ∈ S and remove u from S
6:         for e = uv ∈ δ(u) do
7:             if e = prev(u) then continue
8:             if e ∈ δ(s) and f(e) = 1 then continue
9:             if u is type-I and f(prev(u)) = f(e) = 0 then continue
10:            if v is type-H or type-T then
11:                prev(v) ← e
12:                return the walk from s to v along the search tree
13:            else if prev(v) = ϵ then
14:                prev(v) ← e; S ← S ∪ {v}
15:            else if v is type-O or f(prev(v)) + f(e) ≥ 1 then
16:                return the walk s → u → v → w along the search tree
17:    return NO
```

▶ **Lemma 10 (⋆).** *For a basic s-cycle packing f and an f-augmenting walk $W = (v_0, e_1, \ldots, v_\ell)$, let $f_W : E \to \{0, \frac{1}{2}, 1\}$ be the function obtained by augmenting f along W. Then, f_W is a basic s-cycle packing. Moreover, if $v_\ell = s$, the size of f_W is the size of f plus one; and otherwise, the size of f_W is the size of f plus $\frac{1}{2}$.*

Now, we give an algorithm to compute an f-augmenting walk (see Algorithm 2). First, we initialize a set S and a table $\mathrm{prev} : V \to E \cup \{\epsilon\}$. The set S stores vertices we need to process and is initialized to $\{s\}$. We ensure that only the vertex s and vertices of type-O or type-I are stored in S. The table $\mathrm{prev}(v)$ represents an edge to the parent of v in the search tree and initialized to the dummy edge ϵ, which indicates that the vertex is not visited (or the vertex is the root s). Then, while S is not empty, pick up an arbitrary vertex u from S and process each incident edge $e = uv \in \delta(u)$ as described below. If S becomes empty, the algorithm returns NO.

First, we check whether the edge $e = uv$ is valid by testing the following three conditions. If $e = \mathrm{prev}(u)$, because we have already processed this edge, we skip it. If e is incident to s and $f(e) = 1$, because such an edge cannot be used in an augmenting walk, we skip it. Note that, when $v = s$, at least one of these two conditions are satisfied. Similarly, if u is type-I and both of $f(\mathrm{prev}(u))$ and $f(e)$ are zero, because we cannot use both of $\mathrm{prev}(u)$ and e simultaneously, we skip it.

If v is type-H, or type-T, we return the walk from s to v in the search tree by using the table prev. If $\mathrm{prev}(v) = \epsilon$, we set $\mathrm{prev}(v) = e$ and insert it to S. If v is already visited and v is type-O, let w be the lowest common ancestor of u and v in the search tree. Then, we return the walk obtained by going down from s to u along the search tree, jumping from u to v by the edge e, and then by going up from v to w along the search tree. If v is already visited and v is type-I, we basically do the same; however, we need one additional constraint. If both of $f(\mathrm{prev}(v))$ and $f(e)$ are zero, the walk created as above does not satisfy the condition 6(c) of Definition 9; thus, we skip the edge without returning the walk.

From the construction of our algorithm, we obtain the following lemma.

▶ **Lemma 11.** *A walk returned by Algorithm 2 is an f-augmenting walk.*

Note that this lemma does not say that Algorithm 2 returns an f-augmenting walk whenever there exists an f-augmenting walk; it only says that if the algorithm returns a walk, it is an f-augmenting walk, and the algorithm might return NO even when there exists an f-augmenting walk. We now show that, if the algorithm returns NO, we can construct an s-cycle cover x whose size is equal to the size of f. From Lemma 8 and the LP duality of s-cycle packings and s-cycle covers, the size of a basic s-cycle packing is always at most the size of an s-cycle cover. Therefore, this equality implies that the current basic s-cycle packing f is the maximum and the constructed s-cycle packing x is the minimum. This also implies that when the algorithm returns NO, there are no f-augmenting walks.

To construct such an s-cycle cover x, we first prove a property of the table prev. We call a vertex $v \in V$ *reachable* if $v = s$ or $\mathrm{prev}(v) \neq \epsilon$. For each edge $e \in \delta(s)$ with $f(e) = 1$, by following edges of value 1 from e, we can obtain a simple cycle returning to s or a simple path to a type-T vertex. We denote such a cycle or a path by W_e. Note that when W_e is a cycle, $W_e = W_{e'}$ for another edge $e' \in \delta(s)$.

▶ **Lemma 12 (⋆).** *If Algorithm 2 returns NO, exactly one of the following holds for each edge $e \in \delta(s)$ with $f(e) = 1$:*

1. $\mathrm{prev}(v) = \epsilon$ *for any vertex* $v \in V(W_e)$*;*
2. W_e *is a cycle, all the vertices on* W_e *are reachable, and exactly one vertex* $v \in V(W_e) \setminus \{s\}$ *satisfies* $\mathrm{prev}(v) \notin E(W_e)$*.*

When Algorithm 2 returns NO, by using the obtained table prev, we construct a function $x : V \to \{0, \frac{1}{2}, 1\}$ as follows. For each edge $e = su \in \delta(s)$ with $f(e) = 1$, if W_e is a cycle satisfying the second condition of Lemma 12, we set $x(v) = 1$ for the unique vertex v satisfying $\mathrm{prev}(v) \notin E(W_e)$. Otherwise, we set $x(u) = \frac{1}{2}$. If $x(u)$ is already set to $\frac{1}{2}$, e.g., $W_{e_1} = W_{e_2} = (s, e_1, u, e_2, s)$ for a double edge $\{e_1, e_2\}$, we set $x(u) = 1$.

▶ **Lemma 13 (⋆).** *If Algorithm 2 returns NO, the function x is a minimum s-cycle cover.*

Proof of Theorem 6. Because each augmentation increases the size of f by at least $\frac{1}{2}$, after $k+1$ steps, we can obtain a half-integral minimum s-cycle cover of size at most $\frac{k}{2}$, or conclude that there are no s-cycle covers of size at most $\frac{k}{2}$. Because Algorithm 2 runs in $O(m)$ time, the total running time is $O(km)$. ◀

5 Linear-time Quadratic-size Kernel

In this section, we improve the running time of the quadratic-size kernel presented in Section 3 to $O(k^4 m)$. By using the $O(km)$-time algorithm for computing the minimum s-cycle cover presented in Section 4, each iteration can be done in $O(km)$ time. However, because the number of iterations is only bounded by $O(m)$, the total running time becomes $O(km^2)$. We show that, by a slight modification to Algorithm 1, the number of iteration can be bounded by $O(k^3)$; thus, the total running time becomes $O(k^4 m)$.

We add the following two rules just after line 6 of Algorithm 1. The safeness of these two rules is almost trivial.

- If there is a vertex v incident to more than k double edges, remove v, decrement k, and continue the iteration.
- If there are more than k^2 double edges, return NO.

For bounding the number of iterations, we use the following lemma.

▶ **Lemma 14.** *For a graph $G = (V, E)$ of minimum degree at least three, a vertex $s \in V$, and a half-integral minimum s-cycle cover x, if $2x(V) < d_G(s)$ holds, then $x^{-1}(1) \neq \emptyset$.*

Proof. From Lemma 4, for a graph G' obtained by applying the s-cycle cover reduction, it holds that $d_{G'}(s) \leq 2x(V)$. When $x^{-1}(1) = \emptyset$, the reduction inserts no new edges and only removes the bridges of G connecting s and tree components of $G - s$. Because the graph $G - s$ has minimum degree at least two, it has no tree components. Thus, we have $G' = G$, which is a contradiction. ◀

Now, we can prove the upper bound on the number of iterations.

▶ **Lemma 15.** *The modified Algorithm 1 stops in $O(k^3)$ iterations.*

Proof. Initially, all the double edges are blue, and after applying the s-cycle cover reduction, we color all the double edges incident to s red (not only newly inserted double edges but also blue colored edges are recolored to red). The other double edges, which are created by the deletion of degree two vertices in the basic reductions, are colored blue. Let α denote the number of red double edges and β denote the number of vertices of degree larger than $2k$ and incident to at least one red double edge. Let k_0 be the initial value of k and ϕ be a potential defined as $\phi = (2k_0^2 + 4k_0 + 3)k - 2\alpha + \beta$. Observe that, because red double edges are created only by the s-cycle cover reduction, each vertex can be incident to at most $k_0 + 1$ red double edges, and that the number of red double edges is always at most $k_0^2 + k_0$ (at most k_0^2 edges before applying the s-cycle cover reduction and the reduction can create at most k_0 red double edges).

Initially, there are no red edges; thus, the initial potential is $(2k_0^2 + 4k_0 + 3)k_0 = O(k_0^3)$. If ϕ becomes negative, we have $k < 0$ or $\alpha > k_0^2 k \geq k^2$. Thus, the algorithm returns NO.

When k is decremented, α can decrease by at most $k_0 + 1$. Because there are at most $k_0^2 + k_0$ red double edges, β can increase by at most $2k_0^2 + 2k_0$. Thus, ϕ decreases by at least $(2k_0^2 + 4k_0 + 3) - 2(k_0 + 1) - (2k_0^2 + 2k_0) \geq 1$.

When applying the s-cycle cover reduction, if the reduction creates c (≥ 1) new red double edges, α increases by c and β can increase by at most c. Thus, ϕ decreases by at least $2c - c = c \geq 1$. After applying the s-cycle cover reduction, from Lemma 14, s is incident to at least one double edge. Thus, if the reduction does not create any new red double edges, s must be incident to at least one red double edge before the reduction. From 4, the degree of s becomes at most $2k$ after the reduction. Therefore β decreases by at least one; thus, ϕ decreases by at least one.

Now, we have shown that each iteration decreases the potential ϕ by at least one. Because ϕ is initially $O(k^3)$ and is always non-negative, the number of iterations is $O(k^3)$. ◀

Abstract

We consider the family of Φ-Subset problems, where the input consists of an instance I of size N over a universe U_I of size n and the task is to check whether the universe contains a subset with property Φ (e.g., Φ could be the property of being a feedback vertex set for the input graph of size at most k). Our main tool is a simple randomized algorithm which solves Φ-Subset in time $(1+b-\frac{1}{c})^n N^{O(1)}$, provided that there is an algorithm for the Φ-Extension problem with running time $b^{n-|X|}c^k N^{O(1)}$. Here, the input for Φ-Extension is an instance I of size N over a universe U_I of size n, a subset $X \subseteq U_I$, and an integer k, and the task is to check whether there is a set Y with $X \subseteq Y \subseteq U_I$ and $|Y \setminus X| \leq k$ with property Φ. We also derandomize this algorithm at the cost of increasing the running time by a subexponential factor in n, and we adapt it to the enumeration setting where we need to enumerate all subsets of the universe with property Φ. This generalizes the results of Fomin et al. [STOC 2016] who proved them for the case $b = 1$. As case studies, we use these results to design faster deterministic algorithms for

- checking whether a graph has a feedback vertex set of size at most k,
- enumerating all minimal feedback vertex sets,
- enumerating all minimal vertex covers of size at most k, and
- enumerating all minimal 3-hitting sets.

We obtain these results by deriving new $b^{n-|X|}c^k N^{O(1)}$-time algorithms for the corresponding Φ-Extension problems (or the enumeration variant). In some cases, this is done by simply adapting the analysis of an existing algorithm, in other cases it is done by designing a new algorithm. Our analyses are based on Measure and Conquer, but the value to minimize, $1+b-\frac{1}{c}$, is unconventional and leads to non-convex optimization problems in the analysis.

broad class of subset problems, where for an input instance I on a universe U_I, the question is whether there is a subset S of the universe satisfying certain properties. For example, in the Feedback Vertex Set problem, the input instance consists of a graph $G = (V, E)$ and an integer k, the universe is the vertex set and the property to be satisfied by a subset S is the conjunction of "$|S| \leq k$" and "$G - S$ is acyclic".

More formally, and using definitions from [5], an *implicit set system* is a function Φ that takes as input a string $I \in \{0,1\}^*$ and outputs a set system $(U_I, \mathcal{F}_I)$, where U_I is a universe and $\mathcal{F}_I$ is a collection of subsets of U_I. The string I is referred to as an *instance* and we denote by $|U_I| = n$ the size of the universe and by $|I| = N$ the size of the instance. We assume that $N \geq n$. The implicit set system Φ is *polynomial time computable* if (a) there exists a polynomial time algorithm that given I produces U_I, and (b) there exists a polynomial time algorithm that given I, U_I and a subset S of U_I determines whether $S \in \mathcal{F}_I$. All implicit set systems discussed in this paper are polynomial time computable.

Φ-Subset	
Input:	An instance I
Output:	A set $S \in \mathcal{F}_I$ if one exists.

Φ-Extension	
Input:	An instance I, a set $X \subseteq U_I$, and an integer k.
Question:	Does there exists a subset $S \subseteq (U_I \setminus X)$ such that $S \cup X \in \mathcal{F}_I$ and $\lvert S\rvert \leq k$?

In recent work, Fomin et al. [5] showed that $c^k N^{O(1)}$ time algorithms ($c \in O(1)$) for Φ-Extension lead to competitive exponential-time algorithms for many Φ-Subset problems. The main tool was a simple randomized algorithm which solves Φ-Subset in time $(2 - \frac{1}{c})^n N^{O(1)}$ if there is an algorithm that solves Φ-Extension in time $c^k N^{O(1)}$. A derandomization was also given, turning the randomized algorithm into a deterministic one at the cost of a $2^{o(n)}$ factor in the running time. The method was also adapted to enumeration algorithms and combinatorial upper bounds. This framework, together with a large body of work in parameterized algorithmics [3], where $c^k N^{O(1)}$ time algorithms are readily available for many subset problems, led to faster algorithms for around 30 decision and enumeration problems.

In this paper, we extend the results of Fomin et al. [5] and show that a $b^{n-|X|}c^k N^{O(1)}$ time algorithms ($b, c \in O(1)$) for Φ-Extension lead to randomized $(1 + b - \frac{1}{c})^n N^{O(1)}$ time algorithms for Φ-Subset. Our result can be similarly derandomized and adapted to the enumeration setting. Observe that for $b = 1$, the results of [5] coincide with ours, but that ours have the potential to be more broadly applicable and to lead to faster running times. The main point is that if we use a $c^k N^{O(1)}$ time algorithm as a subroutine to design an algorithm exponential in n, we might as well allow a small exponential factor in n in the running time of the subroutine.

Similar as in [5], the Φ-Extension problem can often be solved by preprocessing the elements in X in a simple way and then using an algorithm for a subset problem. In the case of Feedback Vertex Set, the vertices in X can simply be deleted from the input graph. Whereas the literature is rich with $c^k N^{O(1)}$ time algorithms for subset problems, algorithms with running times of the form $b^n c^k N^{O(1)}$ with $b > 1$ are much less common.[1] One issue is

[1] One notable exception is by Eppstein [4], who showed that all maximal independent sets of size at most k in a graph on n vertices can be enumerated in time $(4/3)^n (81/64)^k n^{O(1)}$.

that there is, in general, no obviously best trade-off between the values of b and c for such algorithms. However, the present framework gives us a precise objective: we should aim for values of b and c that minimize the base of the exponent, $(1 + b - \frac{1}{c})$.

Our applications consist of three case studies centered around some of the most fundamental problems considered in [5], feedback vertex sets and hitting sets. For the first case study, we considered the Feedback Vertex Set problem: given a graph G and an integer k, does G have a feedback vertex set of size at most k? For this problem, we re-analyze the running time of the algorithm from [6]. In [6, 10], the algorithm was analyzed using Measure and Conquer: using a measure that is upper bounded by αn and aiming for a running time of $2^{\alpha n} n^{O(1)}$ the analysis of the branching cases led to constraints lower bounding the measure and the objective was to minimize α subject to these constraints. In our new analysis, we add an additive term $w_k \cdot k$ to the measure and adapt the constraints accordingly. If all constraints are satisfied, we obtain a running time of $2^{\alpha n + w_k k} n^{O(1)}$. Our framework naturally leads us to minimize $2^{\alpha} - 2^{-w_k}$. This approach leads to a $O(1.5422^n \cdot 1.2041^k)$ time algorithm, which, combined with our framework gives a deterministic $O(1.7117^n)$ time algorithm for Feedback Vertex Set. This improves on previous results giving $O(1.8899^n)$ [13], $O(1.7548^n)$ [6], $O(1.7356^n)$ [14], $O(1.7347^n)$ [9], and $O(1.7216^n)$ [5] time algorithms for the problem. We note that adapting the analysis of other existing exact and parameterized algorithms did not give faster running times. Also, if we allow randomization, the $O(1.6667^n)$ time algorithm by [5] (which can also be achieved using our framework) remains fastest.

Our second case study is more involved. Simply using an existing algorithm and adapting the measure was not sufficient to improve upon the best known enumeration algorithms (and combinatorial upper bounds) for minimal feedback vertex sets. Here, the task is, given a graph G, to output each feedback vertex set that is not contained in any other feedback vertex set. We design a new algorithm for enumerating all minimal feedback vertex sets. We also need a new combinatorial upper bound for the number of minimal vertex covers of size at most k to handle one special case in the enumeration of minimal feedback vertex sets.[2] We obtain a $O(1.7183^n \cdot 1.1552^k)$ time algorithm for enumerating all minimal feedback vertex sets. Our framework thus leads to a running time of $O(1.8527^n)$, improving on the previous best bound of $O(1.8638^n)$ [6]. The current best lower bound for the number of minimal feedback vertex sets is $O(1.5926^n)$ [6]. We would like to highlight that the enumeration of minimal feedback vertex sets is completely out of scope for the more restricted framework of [5]: the number of minimal feedback vertex sets of size at most k cannot be upper bounded by $c^k n^{O(1)}$ for any $c \in O(1)$, as evidenced by a disjoint union of k cycles of length n/k.

Our last case study gives a new algorithm for enumerating all minimal 3-hitting sets, also known as minimal transversals of rank-3 hypergraphs. These are minimal sets S of vertices of a hypergraph where each hyperedge has size at most 3 such that every hyperedge contains at least one vertex of S. We re-analyze an existing algorithm [2] for this enumeration problem, adapting the measure in a similar way as in the first case study, and we obtain a multivariate running time of $O(1.5135^n \cdot 1.1754^k)$, leading to an $O(1.6627^n)$ time enumeration algorithm. This breaks the natural time bound of $O(1.6667^n)$ of the previously fastest algorithm [5]. The current best lower bound gives an infinite family of rank-3 hypergraphs with $\Omega(1.5848^n)$ minimal transversals [2].

Lastly, all random selection is done from a uniform distribution and all randomized algorithms in this paper are Monte Carlo algorithms with one-sided error. On No-instances

[2] Previous work [1, 4] focused on small maximal independent sets, whose bounds were insufficient for us. We need better bounds on large maximal independent sets or small minimal vertex covers.

they always return No, and on Yes-instances they return Yes (or output a certificate) with probability $> \frac{1}{2}$.

2 Results

Our first main result gives exponential-time randomized algorithms for Φ-Subset based on single-exponential multivariate algorithms for Φ-Extension with parameter k.

▶ **Theorem 1.** *If there is an algorithm for* Φ-Extension *with running time* $b^{n-|X|}c^k N^{O(1)}$ *then there is a randomized algorithm for* Φ-Subset *with running time* $(1+b-\frac{1}{c})^n N^{O(1)}$.

The next main result derandomizes the algorithm of Theorem 1 at a cost of a subexponential factor in n in the running time.

▶ **Theorem 2.** *If there is an algorithm for* Φ-Extension *with running time* $b^{n-|X|}c^k N^{O(1)}$ *then there is an algorithm for* Φ-Subset *with running time* $(1+b-\frac{1}{c})^{n+o(n)} N^{O(1)}$.

We require the following notion of *(b,c)-uniform* to describe our enumeration algorithms. Let $c, b \geq 1$ be real valued constants and Φ be an implicit set system. Then Φ is *(b,c)-*uniform if for every instance I, set $X \subseteq U_I$, and integer $k \leq n - |X|$, the cardinality of the collection $\mathcal{F}^k_{I,X} = \{S \subseteq U_I \backslash X : |S| = k \text{ and } S \cup X \in \mathcal{F}_I\}$ is at most $b^{n-|X|}c^k n^{O(1)}$. Then the following theorem provides new combinatorial bounds for collections generated by (b, c)-uniform implicit set systems.

▶ **Theorem 3.** *Let* $c, b \geq 1$ *and* Φ *be an implicit set system. If* Φ *is* (b, c)*-uniform then* $|\mathcal{F}_I| \leq \left(1+b-\frac{1}{c}\right)^n n^{O(1)}$ *for every instance* I.

We say that an implicit set system is *efficiently* (b, c)*-uniform* if there exists an algorithm that given I, X and k enumerates all elements of $\mathcal{F}^k_{X,I}$ in time $b^{n-|X|}c^k N^{O(1)}$. In this case, we enumerate $\mathcal{F}_I$ in the same time, up to a subexponential factor in n.

▶ **Theorem 4.** *Let* $c, b \geq 1$ *and* Φ *be an implicit set system. If* Φ *is efficiently* (b, c)*-uniform then there is an algorithm that given as input* I *enumerates* $\mathcal{F}_I$ *in time* $\left(1+b-\frac{1}{c}\right)^{n+o(n)} N^{O(1)}$.

3 Random Sampling and Multivariate Subroutines

In this section, we prove Theorem 1. To do this, we first need the following lemmas.

▶ **Lemma 5.** *If* $b, c \geq 1$ *then* $b \cdot c^{\frac{1}{bc}} \leq 1 + b - \frac{1}{c}$

Proof. As both sides of the inequality are positive, it suffices to show that $\log(bc^{\frac{1}{bc}}) \leq \log(1+b-1/c)$. So we let $y = \log(1+b-1/c) - \log b - \frac{1}{bc}\log c$ and prove that $y \geq 0$ for all $b, c \geq 1$. When $c = 1$ we have that $y = 0$ for all b. We will show that for any fixed $b \geq 1$ we have that $y \geq 0$ by showing that y increases with $c \geq 1$. For fixed b, the partial derivative with respect to c is $\frac{\partial y}{\partial c} = \frac{(bc+c-1)\log c - c + 1}{bc^2(bc+c-1)}$. When $c = 1$ then for all b, $\frac{\partial y}{\partial c} = 0$. As the denominator is positive for $b, c \geq 1$ it is sufficient to show that the numerator $z = (bc + c - 1)\log c - c + 1$ is non-negative. To show that $z \geq 0$, we consider the partial derivative again with respect to c: $\frac{\partial z}{\partial c} = (b+1)\log c + b - \frac{1}{c}$ For $b, c \geq 1$, we have that $b - \frac{1}{c} \geq 0$ and $(b+1)\log(c) \geq 0$. Since $\frac{\partial z}{\partial c} \geq 0$, we conclude that z is increasing and non-negative which implies y is also increasing and non-negative, for all $b, c \geq 1$. This proves the lemma. ◀

The proof of the next lemma follows the proof of Lemma 2.2 from [5], who proved it for $b = 1$.

▶ **Lemma 6.** *Let $b, c \geq 1$, n and $k \leq n$ be non-negative integers. Then, there exists $t \geq 0$ such that*

$$\frac{\binom{n}{t}}{\binom{k}{t}} b^{n-t} c^{k-t} = \left(1 + b - \frac{1}{c}\right)^n n^{O(1)}, \quad \textit{specifically when } t = \frac{cbk - n}{cb - 1}.$$

Proof. We consider two cases. First suppose $k \leq \frac{n}{bc}$. Then for $t = 0$ the LHS (left-hand side) is at most $b^n c^k \leq b^n c^{\frac{n}{bc}} \leq (1 + b - 1/c)^n$ by Lemma 5. Now if $k > \frac{n}{bc}$ then we rewrite the LHS as

$$\frac{\binom{n}{t}}{\binom{k}{t}} b^{n-t} c^{k-t} = \frac{\binom{n}{k} b^{n-k}}{\binom{n-t}{k-t} \left(\frac{1}{bc}\right)^{k-t}}.$$

Let us lower bound the denominator. For any $x \geq 0$ and an integer $m \geq 0$,

$$\sum_{i \geq 0} \binom{m+i}{i} x^i = \sum_{i \geq 0} \binom{m+i}{m} x^i = \frac{1}{(1-x)^{m+1}}, \tag{1}$$

by a known generating function. For $m = n - k$ and $x = \frac{1}{bc}$, the summand at $i = k - t$ equals the denominator $\binom{n-t}{k-t} \left(\frac{1}{bc}\right)^{k-t}$. Since $\frac{n}{k} < bc$ we have that $\frac{m+k}{k} < \frac{1}{x}$ and the terms of this sum decay exponentially for $i > k$. Thus, the maximum term $\frac{(m+i)(m+i-1)\ldots(m+1)}{i(i-1)\ldots 1} x^i$ for this sum occurs for $i \leq k$, and its value is $\Omega\left(\left(\frac{1}{1-x}\right)^m\right)$ up to a lower order factor of $O(k)$. So by the binomial theorem the expression is at most

$$\binom{n}{k} b^{n-k} (1-x)^{n-k} n^{O(1)} = \left(1 + b - \frac{1}{c}\right)^n n^{O(1)}.$$

Specifically, the maximum term for Equation (1) occurs when $\frac{m+i}{i} = \frac{1}{x}$, that is when $\frac{n-t}{k-t} = cb$, and therefore, $t = \frac{cbk-n}{cb-1}$. ◀

▶ **Lemma 7.** *If there exist constants $b, c \geq 1$ and an algorithm for* Φ-Extension *with running time $b^{n-|X|} c^k N^{O(1)}$ then there exists a randomized algorithm for* Φ-Extension *with running time $\left(1 + b - \frac{1}{c}\right)^{n-|X|} N^{O(1)}$.*

Proof. Our proof is similar to Lemma 2.1 in [5]. Let $\mathcal{B}$ be an algorithm for Φ-Extension with running time $b^{n-|X|} c^k N^{O(1)}$. We now present a randomized algorithm $\mathcal{A}$, for the same problem for an input instance (I, X, k') with $k' \leq k$.

1. Choose an integer $t \leq k'$ depending on b, c, n, k' and $|X|$, the choice of which will be discussed later. Then select a random subset Y of $U_I \backslash X$ of size t.
2. Run Algorithm $\mathcal{B}$ on the instance $(I, X \cup Y, k' - t)$ and return the answer.

Algorithm $\mathcal{A}$ has a running time upper bounded by $b^{n-|X|-t} c^{k'-t} N^{O(1)}$. Algorithm $\mathcal{A}$ returns yes for (I, X, k') when $\mathcal{B}$ returns yes for $(I, X \cup Y, k' - t)$. In this case there exists a set $S \subseteq U_I \backslash (X \cup Y)$ of size at most $k' - t \leq k - t$ such that $S \cup X \cup Y \in \mathcal{F}_I$. This, $Y \cup S$ witnesses that (I, X, k) is indeed a yes-instance.

Next we lower bound the probability that $\mathcal{A}$ returns yes if there exists a set $S \subseteq U_I \backslash X$ of size exactly k' such that $X \cup S \in \mathcal{F}_I$. The algorithm $\mathcal{A}$ picks a set Y of size t at random from $U_I \backslash X$. There are $\binom{n-|X|}{t}$ possible choices for Y. If $\mathcal{A}$ picks one of the $\binom{k'}{t}$ subsets of S as Y then $\mathcal{A}$ returns yes. Thus, given that there exists a set $S \subseteq U_I \backslash X$ of size k' such that $X \cup S \in \mathcal{F}_I$, we have that

$$\Pr[\mathcal{A} \text{ returns yes}] \geq \Pr[Y \subseteq S] = \binom{k'}{t} / \binom{n - |X|}{t}.$$

Let $p(k') = \binom{k'}{t}/\binom{n-|X|}{t}$. For each $k' \in \{0, ..., k\}$, our main algorithm runs $\mathcal{A}$ independently $\frac{1}{p(k')}$ times with parameter k'. The algorithm returns yes if any of the runs of $\mathcal{A}$ return yes. If (I, X, k') is a yes-instance, then the main algorithm returns yes with probability at least

$$\min_{k' \leq k} \left\{ 1 - (1 - p(k'))^{\frac{1}{p(k')}} \right\} \geq 1 - \frac{1}{e} > \frac{1}{2}.$$

Next we upper bound the running time of the main algorithm, which is

$$\sum_{k' \leq k} \frac{1}{p(k')} b^{n-|X|-t} c^{k'-t} N^{O(1)} \leq \max_{k' \leq k} \frac{\binom{n-|X|}{t}}{\binom{k'}{t}} b^{n-|X|-t} c^{k'-t} N^{O(1)} \tag{2}$$

$$\leq \max_{k' \leq n-|X|} \frac{\binom{n-|X|}{t}}{\binom{k}{t}} b^{n-|X|-t} c^{k-t} N^{O(1)}. \tag{3}$$

The choice of t in algorithm $\mathcal{A}$ is chosen to minimize the value of $\frac{\binom{n-|X|}{t}}{\binom{k}{t}} b^{n-|X|-t} c^{k-t}$. For fixed n and $|X|$ the running time of the algorithm is upper bounded by

$$\max_{0 \leq k \leq n-|X|} \left\{ \min_{0 \leq t \leq k} \left\{ \frac{\binom{n-|X|}{t}}{\binom{k}{t}} b^{n-|X|-t} c^{k-t} N^{O(1)} \right\} \right\}. \tag{4}$$

By application of Lemma 6 we choose $t = \frac{cbk-(n-|X|)}{cb-1}$ to obtain the upper bound $\left(1 + b - \frac{1}{c}\right)^{n-|X|} (n - |X|)^{O(1)}$, which, combined with $n < N$, completes the proof. ◀

Running algorithm $\mathcal{A}$ with $X = \emptyset$ and for each value of $k \in \{0, ..., n\}$ results in an algorithm for Φ-Subset with running time $\left(1 + b - \frac{1}{c}\right)^n N^{O(1)}$, proving Theorem 1.

4 Derandomization

In this section we prove Theorem 2, by derandomizing the algorithm in Theorem 1.

▶ **Theorem 2.** *If there is an algorithm for* Φ-Extension *with running time* $b^{n-|X|} c^k N^{O(1)}$ *then there is an algorithm for* Φ-Subset *with running time* $(1 + b - \frac{1}{c})^{n+o(n)} N^{O(1)}$.

Given a set U and an integer $q \leq |U|$ let $\binom{U}{q}$ represent the set of sets which contain q elements of U. From [5] we define a pseudo-random object, the *set-inclusion-family*, as well as an almost optimal sub-exponential construction of these objects.

▶ **Definition 8.** Let U be a universe of size n and let $0 \leq q \leq p \leq n$. A family $\mathcal{C} \subseteq \binom{U}{q}$ is an (n, p, q)-set-inclusion family, if for every set $S \in \binom{U}{p}$, there is a set $Y \in \mathcal{C}$ such that $Y \subseteq S$.

Let $\kappa(n, p, q) = \binom{n}{q}/\binom{p}{q}$. We also make use of the following theorem.

▶ **Theorem 9** ([5])**.** *There is an algorithm that given* n, p *and* q *outputs an* (n, p, q)*-set-inclusion-family* $\mathcal{C}$ *of size at most* $\kappa(n, p, q) \cdot 2^{o(n)}$ *in time* $\kappa(n, p, q) \cdot 2^{o(n)}$.

We are now ready to prove Lemma 10, by a very similar proof to Lemma 7.

▶ **Lemma 10.** *If there exists constants* $b, c \geq 1$ *and an algorithm for* Φ-Extension *with running time* $b^{n-|X|} c^k N^{O(1)}$ *then there exists a deterministic algorithm for* Φ-Extension *with running time* $\left(1 + b - \frac{1}{c}\right)^{n-|X|} \cdot 2^{o(n)} \cdot N^{O(1)}$.

Proof. Let $\mathcal{B}$ be an algorithm for Φ-Extension with running time $b^{n-|X|}c^k N^{O(1)}$. We can then adapt Algorithm $\mathcal{A}$ from the proof of Lemma 7. Let $\mathcal{A}'$ be a new algorithm which has an input instance (I, X, k') with $k' \leq k$. Choose $t = \frac{cbk' - (n-|X|)}{cb-1}$.

1. Compute an $(n-|X|, k', t)$-set-inclusion-family $\mathcal{C}$ using the algorithm from Theorem 9 of size at most $\kappa(n-|X|, k', t) \cdot 2^{o(n)}$, in $\kappa(n-|X|, k', t) \cdot 2^{o(n)}$ time.
2. For each set Y in the set-inclusion-family $\mathcal{C}$ run algorithm $\mathcal{B}$ on the instance $(I, X \cup Y, k'-t)$ and return Yes of at least one returns Yes and No otherwise.

The running time of $\mathcal{A}'$ is upper bounded by $\kappa(n-|X|, k', t) \cdot 2^{o(n)} \cdot b^{n-|X|-t}c^{k'-t}N^{O(1)}$, a term encountered in Equation 2 with a new subexponential factor in n,

$$\max_{k' \leq k} \frac{\binom{n-|X|}{t}}{\binom{k'}{t}} \cdot b^{n-|X|-t}c^{k'-t}N^{O(1)} \cdot 2^{o(n)}.$$

From here the proof follows that of Lemma 7. ◀

The proof of Theorem 2 follows by inclusion of the factor $2^{o(n)}$.

5 Enumeration

We now proceed to prove Theorems 3 and 4 on combinatorial upper bounds and enumeration algorithms. Consider the following random process.

1. Choose an integer t based on b, c, n and k, then randomly sample a subset X of size t from U_I.
2. Uniformly at random pick a set S from $\mathcal{F}_{I,X}^{k-t}$, and output $W = X \cup S$. In the special case where $\mathcal{F}_{I,X}^{k-t}$ is empty output the empty set.

▶ **Theorem 3.** *Let $c, b \geq 1$ and Φ be an implicit set system. If Φ is (b,c)-uniform then $|\mathcal{F}_I| \leq \left(1+b-\frac{1}{c}\right)^n n^{O(1)}$ for every instance I.*

Proof. Let I be an instance, $k \leq n$. We will prove that the number of sets in $\mathcal{F}_I$ of size exactly k is upper bounded by $|\mathcal{F}_I| \leq \left(1+b-\frac{1}{c}\right)^n n^{O(1)}$, where k is chosen arbitrarily. We follow the random process described above, which picks a set W of size k from $\mathcal{F}_I$.

For each set $Z \in \mathcal{F}_I$ of size exactly k, let E_Z denote the event that the set W output in step 2 is equal to Z. We then have the following lower bound on the probability of the event E_Z:

$$\Pr[E_Z] = \Pr[X \subseteq Q \wedge S = Z \backslash X] = \Pr[X \subseteq Z] \times \Pr[S = Z \backslash Z | X \subseteq Z] = \frac{\binom{k}{t}}{\binom{n}{t}} \cdot \frac{1}{|\mathcal{F}_{I,X}^{k-t}|}$$

Since Φ is (b,c)-uniform then $\left|\mathcal{F}_{I,X}^{k-t}\right| \leq b^{n-|X|}c^k n^{O(1)}$ and X is selected such that $|X| = t$, this results in the lower bound

$$\Pr[E_Z] \geq \frac{\binom{k}{t}}{\binom{n}{t}} b^{-(n-t)}c^{-(k-t)}n^{-O(1)}.$$

A choice of t is made to minimize the lower bound, and this choice is given by Lemma 6 which states that for every $k \leq n$ there exists a $t \leq k$ such that we obtain a new lower bound

$$\Pr[E_Z] \geq \left(1+b-\frac{1}{c}\right)^{-n} \cdot n^{O(1)}$$

for every $Z \in \mathcal{F}_I$ of size k. For every individual set $Z \in \mathcal{F}_I$, the event E_Z occurs disjointly, and we have that $\sum_{Z \in \mathcal{F}_I, |Z|=k} \Pr[E_Z] \leq 1$. This fact with the lower bound of $\Pr[E_Z]$ implies an upper bound on the number of sets in $\mathcal{F}_I$ of $(1+b-\frac{1}{c})^n n^{O(1)}$, completing the proof. ◀

▶ **Theorem 4.** *Let $c, b \geq 1$ and Φ be an implicit set system. If Φ is efficiently (b, c)-uniform then there is an algorithm that given as input I enumerates $\mathcal{F}_I$ in time $\left(1 + b - \frac{1}{c}\right)^{n+o(n)} N^{O(1)}$.*

Proof. We alter the random process used to prove Theorem 3 to a deterministic one:
1. Construct a (n, k, t)-set inclusion family $\mathcal{C}$ using Theorem 6 from [5]. Loop over $X \in \mathcal{C}$.
2. For each $X \in \mathcal{C}$, loop over all sets $S \in \mathcal{F}_{I,X}^{k-t}$.

Then we output $W = X \cup S$ from these two loops. Looping over $\mathcal{C}$ instead of random sampling for X incurs a $2^{o(n)}$ overhead in the running time. As Φ is efficiently (b, c)-uniform, the inner loop requires $(1 + b - \frac{1}{c})^n N^{O(1)}$ time. In order to avoid enumerating duplicates, we save the sets which have been output in a trie and check first in linear time if a set has already been output. The product of the running times for these two nested loops results in the running time claimed by the theorem statement. ◀

6 Case Studies

This section briefly outlines case studies which used Theorem 2 and Theorem 4 in order to design faster deterministic algorithms.

6.1 Preliminaries

Let $G = (V, E)$ be a graph with a set of vertices V and a set of edges $E \subseteq \{uv : u, v \in V\}$. The *degree* $d(u)$ of a vertex u is the number of neighbors of u in G. The *degree* of a graph $\Delta(G)$ is the maximum $d(u)$ across all $u \in V$. A graph $G' = (V', E')$ is a *subgraph* of G if $V' \subseteq V$ and $E' \subseteq E$ and G' is an *induced subgraph* of G if, in addition, G has no edge uv with $u, v \in V'$ but $uv \notin E'$. In this case, we also denote G' by $G[V']$. A forest is an acyclic graph. A subset $F \subseteq V$ is acyclic if $G[F]$ is a forest. An acyclic subset $F \subseteq V$ is *maximal* in G if it is not a subset of any other acyclic subset. For an acyclic subset $F \subseteq V$, we denote the set of maximal acyclic supersets of F as $\mathcal{M}_G(F)$ and the set of maximum (i.e., largest) acyclic supersets of F as $\mathcal{M}_G^*(F)$.

Let T be a subgraph of G. Define $\mathrm{Id}(T, t)$ as an operation on G which contracts all edges of T into one vertex t, removing induced loops. This may create multiedges in G. Define $\mathrm{Id}^*(T, t)$ as the operation $\mathrm{Id}(T, t)$ followed by removing all vertices connected to t by multiedges. A *non-trivial* component of a graph G is a connected component on at least two vertices. The following propositions from [6] will be useful.

▶ **Proposition 11.** *[6] Let $G = (V, E)$ be a graph, $F \subseteq V$ be an acyclic subset of vertices and T be a non-trivial component of $G[F]$. Denote by G' the graph obtained from G by the operation $Id^*(T, t)$ and let $F' = F \cup \{t\} \backslash T$. Then for $X' = X \cup \{t\} \backslash T$ where $X, X' \subseteq V$*
- *$X \in \mathcal{M}_G(F)$ if and only if $X' \in \mathcal{M}_{G'}(F')$, and*
- *$X \in \mathcal{M}_G^*(F)$ if and only if $X' \in \mathcal{M}_{G'}^*(F')$.*

Using operation Id^* on each non-trivial component of $G[F]$, results in an independent set F'.

▶ **Proposition 12.** *[6] Let $G = (V, E)$ be a graph and F be an independent set in G such that $V \backslash F = N(t)$ for some $t \in F$. Consider the graph $G' = G[N(t)]$ and for every pair of vertices $u, v \in N(t)$ having a common neighbor in $F \backslash \{t\}$ add an edge uv to G'. Denote the obtained graph by H and let $I \subseteq N(t)$. Then $F \cup I \in \mathcal{M}_G(F)$ if and only if I is a maximal independent set in H . In particular, $F \cup I \in \mathcal{M}_G^*(F)$ if and only if I is a maximum independent set in H.*

For an acyclic subset F, a so-called *active* vertex $t \in F$ and a neighbor $v \in N(t) \setminus F$, we will now define the concept of generalized neighbors of v, also known as (v)-*generalized neighbors*. Denote by K the set of vertices of F adjacent to v other than t. Let G' be the graph obtained after the operation $\mathrm{Id}(K \cup \{v\}, u)$. A vertex $w \in V(G') \setminus \{t\}$ is a (v)-generalized neighbor in G if w is a neighbor of u in G'. Denote by $\mathrm{gd}(v)$ the *generalized degree* of v which is the number of (v)-generalized neighbors for a given v.

6.2 Feedback Vertex Set

First we describe the extension variant of Feedback Vertex Set

Feedback Vertex Set Extension	
Input:	A graph $G = (V, E)$, vertex subset $X \subseteq V$ and an integer k
Question:	Does there exist subset $S \subseteq V \setminus X$ such that $S \cup X$ is a FVS and $\lvert S \rvert \leq k$?

Instead of directly finding the feedback vertex set in a graph, we present algorithm $\texttt{mif}(G, F, k)$ [6] which computes for a given graph G and an acylic set F the maximum size of an induced forest F' containing F with $|F'| \geq n - k$. This means that $G - F$ is a minimal feedback vertex set of size at most k. This algorithm can easily be turned into an algorithm computing at least one such set.

During the execution of `mif` one vertex $t \in F$ is called an *active vertex*. Algorithm `mif` then branches on a chosen neighbor of t. Let $v \in N(t)$. Let k be the set of all vertices of $F \setminus \{t\}$ that are adjacent to v and parameter k which represents a bound on the size of the feedback vertex set.

As well as describing the algorithm we simultaneously perform the running time analysis which uses the Measure and Conquer framework and Lemma 13 at its core.

▶ **Lemma 13.** *[10] Let A be an algorithm for a problem P, B be an algorithm for a class C of instances of P, $c \geq 0$ and $r > 1$ be constants, and $\mu(\cdot), \mu_B(\cdot), \eta(\cdot)$ be measures for P, such that for any input instance I from C, $\mu_B(\cdot) \leq \mu(I)$, and for any input instance I, A either solves P on $I \in C$ by invoking B with running time $O(\eta(I)^{c+1} r^{\mu B(I)})$, or reduces I to k instances $I_1, ..., I_k$, solves these recursively, and combines their solutions to solve I, using time $O(\eta(I)^c)$ for the reduction and combination steps (but not the recursive solves),*

$$(\forall i) \quad \eta(I_i) \leq \eta(I) - 1, \qquad \text{and} \qquad \sum_{i=1}^{k} r^{\mu(I_i)} \leq r^{\mu(I)}. \tag{5}$$

Then A solves any instance I in time $O(\eta(I)^{c+1} r^{\mu(I)})$.

Branching constraints of the form $\sum_{i=1}^{j} 2^{-\delta_i} \leq 1$ are given as branching vectors $(\delta_1, ..., \delta_j)$.

6.2.1 Measure

To upper bound the exponential time complexity of the algorithm `mif` we use the measure

$$\mu = |N(t) \setminus F| w_1 + |V \setminus (F \cup N(t))| w_2 + k \cdot w_k.$$

In other words, each vertex in F has weight 0, each vertex in $N(t)$ has weight w_1, each other vertex has weight w_2 and each unit of budget for the feedback vertex set has weight w_k, in the measure with an active vertex t.

6.2.2 Algorithm

The description of `mif` consists of a sequence of cases and subcases. The first case which applies is used, and inside a given case the hypotheses of all previous cases are assumed to be false. Preprocessing procedures come before main procedures.

Preprocessing

1. If G consists of $j \geq 2$ connected components $G_1, G_2, ..., G_j$, then the algorithm is called on each component. For $F_i = G_i \cap F$ for all $i \in \{1, 2, ..., j\}$ and $\sum_{i=1}^{j} k_i \leq k$ then

$$\texttt{mif}(G, F, k) = \sum_{i=1}^{j} \texttt{mif}(G_i, F_i, k_i)\,.$$

2. If F is not independent, then apply operation $\mathrm{Id}^*(T, v_T)$ on an arbitrary non-trivial component T of F. If T contains the active vertex then v_T becomes active. Let G' be the resulting graph and let F' be the set of vertices of G' obtained from F. Then

$$\texttt{mif}(G, F, k) = \texttt{mif}(G', F', k) + |T| - 1\,.$$

Main Procedures

1. If $k < 0$ then $\texttt{mif}(G, F, k) = 0$.
2. If $F = \emptyset$ and $\Delta(G) \leq 1$ then $\mathcal{M}_G(F) = \{V\}$ and $\texttt{mif}(G, F, k) = |V|$.
3. If $F = \emptyset$ and $\Delta(G) \geq 2$ then the algorithm chooses a vertex $t \in G$ of degree at least 2. Then t is either contained in a maximum induced forest or not. The algorithm branches on two subproblems and returns the maximum:

$$\texttt{mif}(G, F, k) = \max\{\texttt{mif}(G, F \cup \{t\}, k), \texttt{mif}(G \backslash \{t\}, F, k-1)\}.$$

   The first branch reduces the weight of t to zero, as it is in F, and at least 2 neighbors have a reduced degree from w_2 to w_1. In the second branch we remove t from the graph, meaning it will be in the feedback vertex set. We thus also gain a reduction of w_k in the measure. Hence this rule induces the branching constraint

$$(w_2 + 2(w_2 - w_1), w_2 + w_k).$$

4. If F contains no active vertex then choose an arbitrary vertex $t \in F$ as an active vertex. Denote the active vertex by t from now on.
5. If $V \backslash F = N(t)$ then the algorithm constructs the graph H from Proposition 12 and computes a maximum independent set I in G of maximum size $n - k$. Then

$$\texttt{mif}(G, F, k) = |F| + |I|.$$

6. If there is $v \in N(t)$ with $\mathrm{gd}(v) \leq 1$ then add v to F.

$$\texttt{mif}(G, F, k) = \texttt{mif}(G, F \cup \{v\}, k).$$

7. If there is $v \in N(t)$ with $\mathrm{gd}(v) \geq 4$ then either add v to F or remove v from G.

$$\texttt{mif}(G, F, k) = \max\{\texttt{mif}(G, F \cup \{v\}, k), \texttt{mif}(G \backslash \{v\}, F, k-1)\}.$$

   The first case adds v to F reducing the measure by w_1, and a minimum of $4(w_2 - w_1)$ for all the (v)-generalized neighbors. The other case removes v this decreasing the measure by w_k. Hence this rule induces the branching constraint

$$(w_1 + 4(w_2 - w_1), w_1 + w_k).$$

8. If there is $v \in N(t)$ with $\text{gd}(v) = 2$ then denote the (v)-generalized neighbors by u_1 and u_2. Either add v to F or remove v from G but add u_1 and u_2 to F. If adding u_1 and u_2 to F induces a cycle, we just ignore the last branch.

$$\texttt{mif}(G, F, k) = \max\{\texttt{mif}(G, F \cup \{v\}, k), \texttt{mif}(G \backslash \{v\}, F \cup \{u_1, u_2\}, k-1)\}.$$

Let $i \in \{0, 1, 2\}$ be the number of vertices adjacent to v with weight w_2. The first case adds v to F, and hence all i w_2-weight neighbors of v reduce to w_1, and the other $2-i$ vertices of weight w_1 induce a cycle, hence we remove them from G and reduce the measure by $(2-i)w_k$. The second case removes v and adds both u_1 and u_2 to F. This causes a reduction of iw_2 for the relevant vertices and $(2-i)w_1$ for the other vertices, and a single w_k reduction due to the removal of v. This rule induces the branching constraint

$$(w_1 + i(w_2 - w_1) + (2-i)w_1 + (2-i)w_k, w_1 + iw_2 + (2-i)w_1 + w_k).$$

9. If all vertices in $N(t)$ have exactly three generalized neighbors then at least one of these vertices must have a generalized neighbor outside $N(t)$, since the graph is connected and the condition of the case Main 6 does not hold. Denote such a vertex by v and its generalized neighbors by u_1, u_2 and u_3 in such a way that $u_1 \notin N(t)$. Then we either add v to F; or remove v from G but add u_1 to F; or remove v and u_1 from G and add u_2 and u_3 to F. Similar to the previous case, if adding u_2 and u_3 to F induces a cycle, we just ignore the last branch.

$$\begin{aligned}\texttt{mif}(G, F) = \max\{&\texttt{mif}(G, F \cup \{v\}, k), \texttt{mif}(G \backslash \{v\}, F \cup \{u_1\}, k-1),\\ &\texttt{mif}(G \backslash \{v, u_1\}, F \cup \{u_2, u_3\}, k-2)\}.\end{aligned}$$

Let $i \in \{1, 2, 3\}$ be the number of vertices adjacent to v with weight w_2. The first and last cases are analogous to the analysis done in Main 8. The second case removes v from the forest hence adding it to the minimum feedback vertex set and reducing the measure by $w_1 + w_k$. A reduction of w_2 is gained by adding u_1 to F. Then this rule induces the branching constraint

$$(w_1 + i(w_2 - w_1) + (3-i)w_1 + (3-i)w_k, w_1 + w_2 + w_k, w_1 + iw_2 + (3-i)w_1 + 2w_k).$$

6.2.3 Results

▶ **Theorem 14.** *Let G be a graph on n vertices. Then a minimal feedback vertex set in G can be found in time $O(1.7117^n)$.*

Proof. Using the algorithm above along with the measure μ, the following values of weights can be shown to satisfy all the branching vector constraints generated above.

$$w_1 = 0.2775 \qquad w_2 = 0.6250 \qquad w_k = 0.2680$$

These weights result in an upper bound for the running time of `mif` as $O(1.5422^n \cdot 1.2041^k)$ for computing a maximally induced forest of size a least $n-k$, and hence we have the running time for Feedback Vertex Set Extension of $O(1.5422^{n-|X|} \cdot 1.2041^k)$. By Theorem 2 this results in a $O(1.7117^n)$ algorithm for computing a minimal feedback vertex set. ◀

6.3 Minimal Vertex Covers

The following result on minimal vertex covers of size at most k is needed in the next section.

▶ **Theorem 15.** *Let γ be a constant with $0.169925 \approx 2\log_2 3 - 3 \leq \gamma \leq 1$. For every $n \geq k \geq 0$, and every graph G on n vertices, the number of minimal vertex covers of size at most k of G is at most $2^{\beta n+\gamma k}$, where $\beta = (1-\gamma)/2$.*

For $\gamma = \frac{1}{3}$, this implies that G has at most $2^{(n+k)/3}$ minimal vertex covers of size at most k.

6.4 Minimal Feedback Vertex Sets

We apply a similar methodology to enumerating minimal feedback vertex sets on an undirected graph with n vertices. The algorithm is similar in construction to one used in [6] yet a large amount of case analysis was added, along with potential functions in combination with the Measure and Conquer framework.

▶ **Theorem 16.** *For a graph G with n vertices, all minimal feedback vertex sets can be enumerated in time $O(1.8527^n)$.*

6.5 Minimal Hitting Sets

Based on [2] we once again apply a multivariate analysis to enumerating all minimal hitting sets on a hypergraph of rank 3.

▶ **Theorem 17.** *For a hypergraph H with n vertices and rank 3, all minimal hitting sets can be enumerated in time $O(1.6627^n)$.*

7 Conclusion

The main contribution of this paper is a framework allowing us to turn many $b^n c^k N^{O(1)}$ time algorithms for subset and subset enumeration problems into $(1 + b - \frac{1}{c})^n N^{O(1)}$ time algorithms, generalizing a recent framework of Fomin et al. [5].

The main complications in using the framework are, firstly, that new algorithms or running-time analyses are often needed, and, secondly, that such analyses need solutions to non-convex programs in the Measure and Conquer framework. In the usual Measure and Conquer analyses [7],the objective is to upper bound a single variable (α) which upper bounds the exponential part of the running time ($2^{\alpha n}$) subject to convex constraints. Thus, it is sufficient to solve a convex optimization problem to minimize the running time [10, 12] resulting from the constraints derived from the analysis. Here, the objective function ($2^{\alpha} - 2^{-w_k}$) is non-convex. While experimenting with a range of solvers (Couenne, IPOPT, MINOS, SNOPT), either guaranteeing to find a global optimum (slow and used for optimality checks) or only a local optimum (faster and used mainly in the course of the algorithm design), we experienced on one hand that the local optima found by solvers are often the global optimum, but on the other hand that weakening non-tight constraints can sometimes lead to a better globally optimum solution.

Abstract

A simple digraph is *semi-complete* if for any two of its vertices u and v, at least one of the arcs (u, v) and (v, u) is present. We study the complexity of computing two layout parameters of semi-complete digraphs: cutwidth and optimal linear arrangement (Ola). We prove that:

- Both parameters are NP-hard to compute and the known exact and parameterized algorithms for them have essentially optimal running times, assuming the Exponential Time Hypothesis.
- The cutwidth parameter admits a quadratic Turing kernel, whereas it does not admit any polynomial kernel unless $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. By contrast, Ola admits a linear kernel.

These results essentially complete the complexity analysis of computing cutwidth and Ola on semi-complete digraphs. Our techniques can be also used to analyze the sizes of minimal obstructions for having small cutwidth under the induced subdigraph relation.

1 Introduction

A directed graph (digraph) is *simple* if it does not contain a self-loop or multiple arcs with the same head and tail. A simple digraph is *semi-complete* if for any pair of its vertices u and v, at least one of the arcs (u, v) or (v, u) is present. If moreover exactly one of them is present for each pair u, v, then a semi-complete digraph is called a *tournament*. Tournaments and semi-complete digraphs form a rich and interesting subclass of directed graphs; we refer to the book of Bang-Jensen and Gutin [1] for an overview.

We study two layout parameters for tournaments and semi-complete digraphs: cutwidth and optimal linear arrangement (Ola). Suppose π is an ordering of the vertices of a digraph D. With each prefix of π we associate a *cut* defined as the set of arcs with head in the prefix and tail outside of it. The *width* of π is defined as the maximum size among the cuts associated with the prefixes of π. The *cutwidth* of D, denoted $\mathsf{ctw}(D)$, is the minimum width among orderings of the vertex set of D. Optimal linear arrangement (Ola) is defined

* A full version of the paper is available at https://arxiv.org/abs/1706.00617.

similarly, but when defining the width of π, called in this context the *cost* of π, we take the sum of the cutsizes associated with prefixes, instead of the maximum. Then the Ola-cost of a digraph D, denoted $\textsc{Ola}(D)$, is the minimum cost among vertex orderings of D.

Known results. The study of cutwidth in the context of tournaments and semi-complete digraphs started with the work of Chudnovsky, Fradkin, and Seymour [3, 4, 10], who identified this layout parameter as the right dual notion to immersions in semi-complete digraphs. In particular, it is known that excluding a fixed digraph as an immersion yields a constant upper bound on the cutwidth of a semi-complete digraph [3, 16]. Due to this connection, cutwidth played a pivotal role in the proof of Chudnovsky and Seymour that the immersion order is a well quasi-order on tournaments [4].

The algorithmic properties of cutwidth were preliminarily investigated by Chudnovsky, Fradkin, and Seymour [3, 10, 9]. In Fradkin's PhD thesis [9], several results on the tractability of computing the cutwidth are presented. In particular, it is shown that the cutwidth of a tournament can be computed optimally by just sorting vertices according to their outdegrees, whereas in semi-complete digraphs a similar approach yields a polynomial-time 2-approximation algorithm. The problem becomes NP-hard on super-tournaments, that is, when multiple parallel arcs are allowed. Later, the third author together with Fomin proposed a parameterized algorithm for computing the cutwidth of a semi-complete digraph with running time $2^{\mathcal{O}(\sqrt{k \log k})} \cdot n^2$ [8, 17], where n is the number of vertices and k is the target width. Using the same techniques, Ola in semi-complete digraphs can be solved in time $2^{\mathcal{O}(k^{1/3}\sqrt{\log k})} \cdot n^2$ [8, 17], where k is the target cost. It was left open whether the running times of these parameterized algorithms are optimal [17]. In fact, even settling the NP-hardness of computing cutwidth and Ola in semi-complete digraphs was open [9, 17].

Our contribution. We study two aspects of the computational complexity of computing cutwidth and Ola of semi-complete digraphs: optimality of parameterized algorithms and kernelization. First, we prove that these problems are NP-hard and we provide almost tight lower bounds for the running times of algorithms solving them, based on the Exponential Time Hypothesis (ETH). Second, we describe the kernelization complexity of the two parameters in semi-complete digraphs. In particular, we show, somewhat surprisingly, that the problem of computing the cutwidth admits a quadratic Turing kernel, while the existence of a classic polynomial kernel would imply that $\mathsf{NP} \subseteq \mathsf{coNP/poly}$. The proofs of these main results yield complementary algorithmic and structural results that we discuss later.

Our algorithmic lower bounds are encapsulated in the following theorem.

▶ **Theorem 1.** *For semi-complete digraphs, both computing the cutwidth and computing the* Ola*-cost are* NP*-hard problems. Moreover, unless the Exponential Time Hypothesis fails:*

- *the cutwidth cannot be computed in time $2^{o(n)}$ nor in time $2^{o(\sqrt{k})} \cdot n^{\mathcal{O}(1)}$; and*
- *the* Ola*-cost cannot be computed in time $2^{o(n)}$ nor in time $2^{o(k^{1/3})} \cdot n^{\mathcal{O}(1)}$.*

Here, n is the vertex count of the input semi-complete digraph, and k is the target width/cost.

Thus, Theorem 1 shows that the known parameterized algorithms of Fomin and Pilipczuk [8] are optimal under ETH, up to $\sqrt{\log k}$ factor in the exponent. Note that both cutwidth and Ola can be computed in time $2^n \cdot n^{\mathcal{O}(1)}$ using standard dynamic programming on subsets, so we obtain tight lower bounds also for exact exponential-time algorithms.

Next, we turn our attention to kernelization. Recall that a *kernelization algorithm* (or *kernel*, for short) is a polynomial-time algorithm that given some instance of a parameterized problem, returns an equivalent instance whose size is bounded by a computable function of

the input parameter; this function is called the *size* of the kernel. We are mostly interested in finding polynomial kernels, as admitting a kernel of any computable size is equivalent to fixed-parameter tractability of the problem [6, 5]. Consider the parameterized problems of deciding whether a given semi-complete digraph has cutwidth, respectively Ola-cost, bounded by a given integer c, which is considered to be the parameter. As shown by the next two theorems, the kernelization complexity of these two problems is quite different.

▶ **Theorem 2.** *There exists a polynomial-time algorithm that given an arbitrary digraph D and an integer c, either correctly concludes that $\textsc{Ola}(D) > c$, or finds a digraph D' on at most $2c$ vertices such that $\textsc{Ola}(D') = \textsc{Ola}(D)$.*

▶ **Theorem 3.** *Unless $\mathsf{NP} \subseteq \mathsf{coNP}/poly$, there exists no polynomial-size kernelization algorithm for the problem of computing the cutwidth of a semi-complete digraph.*

The proofs of these two theorems directly follow from the understanding of the contribution of strongly connected components in optimal orderings. On one side, the contribution to the Ola-cost of each strongly connected component is at least linear in its size, implying Theorem 2. On the other side, we can observe that the cutwidth of a digraph is the maximum over the cutwidth of its strongly connected components, which implies that, like many other width parameters, cutwidth is an AND-*composable* parameter [7, 5].

However, an alternative notion of kernelization, called *Turing kernelization*, has been also studied intensively in the literature; cf. the discussion in [5]. In this framework, it is not required that the instance at hand is reduced to one equivalent small instance, but rather that the whole problem can be solved in polynomial time assuming oracle access to an algorithm solving instances of size bounded by a function of the parameter. Somewhat surprisingly, we prove that the problem of computing the cutwidth of a semi-complete digraph admits a quadratic Turing kernel, which is encapsulated in the following theorem.

▶ **Theorem 4.** *There exists a polynomial-time algorithm that given a semi-complete digraph D and integer c, either correctly concludes that $\mathsf{ctw}(D) > c$ or outputs a list of at most n induced subdigraphs $D_1, \ldots, D_\ell$ of D, each with at most $\mathcal{O}(c^2)$ vertices, such that $\mathsf{ctw}(D) \leq c$ if and only if $\mathsf{ctw}(D_i) \leq c$ for each $i \in \{1, 2, \ldots, \ell\}$.*

Theorem 4 gives a so-called AND-*Turing kernel*, meaning that the algorithm just computes the output list without any oracle calls, and the answer to the input instance is the conjunction of the answers to the output small instances. This places the problem of computing the cutwidth of a semi-complete digraph among very few known examples of natural problems where classic and Turing kernelization have different computational power [2, 15, 11, 18, 21]. Moreover, this is the first known to us polynomial AND-Turing kernel for a natural problem: examples of Turing kernelization known in the literature are either OR-Turing kernels [2, 11, 18], or adaptative kernels that fully exploit the oracle model [15, 21]. As separating classic and Turing kernelization is arguably one of the most important complexity-theoretical open problems within parameterized complexity [6, 13, 5], we find this new example intriguing.

As a byproduct of our approach to proving Theorem 4, we obtain also polynomial upper bounds on the sizes of minimal obstructions to having small cutwidth. More precisely, for a positive integer c, a digraph D is called *c-cutwidth-minimal* if the cutwidth of D is at least c, but the cutwidth of every proper induced subdigraph of D is smaller than c.

▶ **Theorem 5.** *For every positive integer c, every c-cutwidth-minimal semi-complete digraph has at most $\mathcal{O}(c^2)$ vertices.*

▶ **Theorem 6.** *For every positive integer c, every c-cutwidth-minimal tournament has at most $2c + 2\lceil\sqrt{2c}\rceil + 1$ vertices.*

The bound of Theorem 6 is almost tight, as there exist c-cutwidth-minimal tournaments with $2c+1$ vertices. Theorems 5 and 6 have direct algorithmic applications for parameterized graph modification problems related to cutwidth, e.g., c-Cutwidth Vertex Deletion: remove at most k vertices from a given digraph to obtain a digraph of cutwidth at most c.

Approach. The starting point of our study is the approach used in the earlier works by Fradkin [9] and by the third author [17, 16], namely to sort the vertices of the given semi-complete digraph according to non-decreasing indegrees, and argue that this ordering has to resemble an optimum one. As shown by Fradkin [9], this statement may be made precise for tournaments: any indegree ordering has optimum cutwidth.

We present a somewhat finer study of this argument using the notion of a *minimum ordering*. Namely, a vertex ordering π of a digraph D is *minimum* if for any other vertex ordering π' of D and any $i \in \{1, 2, \ldots, n-1\}$, the cutsize in π between the prefix of length i and the complementary suffix is smaller or equal than the cutsize defined in the same manner in π'. The sorting argument of Fradkin [9] in fact yields the following: a vertex ordering of a tournament is minimum if and only if it is sorted according to indegrees. In particular, every tournament admits a minimum ordering, computable in polynomial time. Since every minimum ordering optimizes both the cutwidth and the Ola-cost, we obtain the following.

▶ **Theorem 7.** *The cutwidth and* Ola *of a tournament can be computed in polynomial time.*

Unfortunately, general semi-complete digraphs may not admit minimum orderings. However, a semi-complete digraph can be relaxed to a *fractional tournament* with a loss of factor 2 on the cutwidth and the Ola-cost. The ordering argument for tournaments may be applied to fractional tournaments as well, and thus we obtain a polynomial-time 2-approximation.

▶ **Theorem 8.** *There exists a polynomial-time algorithm that given a semi-complete digraph D, outputs an ordering of its vertices of width, and respectively cost, upper bounded by twice the cutwidth, respectively* Ola*-cost, of D.*

While Theorems 7 and 8 for cutwidth were already proved by Fradkin [9], the applicability of the approach to Ola is a new contribution of this work. We choose to include the proofs of Theorems 7 and 8 in this work for two reasons. First, the fine understanding of minimum orderings is a basic tool needed in the proofs of our main results. Second, the abovementioned results of Fradkin [9] were communicated only in her PhD thesis and, to the best of our knowledge, were neither included in any published work, nor we have found any reference to them. We believe that these fundamental observations deserve a better publicity.

For the proof of Theorem 1, we construct a reduction from NAE-3SAT, a variant of 3SAT. In case the input formula is satisfiable, the output semi-complete digraph admits a minimum vertex ordering with a precisely specified vector of cutsizes. On the other hand, admitting any ordering of width bounded by the maximum of these cutsizes implies satisfiability of the input formula. Thus, the same reduction may serve to certify the hardness of both computing the cutwidth and computing the Ola-cost of a semi-complete digraph.

For the proof of Theorem 4, we use the notion of a *lean ordering*; see e.g. [12, 20]. Intuitively, a vertex ordering is lean if it is tight with respect to cut-flow duality: there are systems of arc-disjoint paths which certify that cutsizes along the ordering cannot be improved. Lean orderings and decompositions are commonly used in the analysis of obstructions for various width notions, as well as for proving well quasi-order results. In particular, the concept of a lean ordering for cutwidth of digraphs was used by Chudnovsky and Seymour in their proof that the immersion order is a well quasi-order on tournaments [4].

Lean orderings are used in the proof of Theorem 4 as follows. We first compute a 2-approximate ordering using Theorem 8, and then we exhaustively improve it until it becomes lean. Let σ be the obtained ordering, and consider the sequence of cutsizes along σ. The next observation is crucial. Due to leanness, if some cutsize in this sequence is smaller or equal than $\Omega(c)$ cutsizes to the left and to the right, then there is some optimum-width ordering that uses the corresponding cut; that is, the prefix of σ up to this cut is also a prefix of some optimum-width ordering. We call such cuts *milestones*. It is not hard to prove that a milestone can be found every $\mathcal{O}(c^2)$ vertices in the ordering σ. Thus we are able to partition the digraph into pieces of size $\mathcal{O}(c^2)$ that may be treated independently. Each of these pieces gives rise to one digraph D_i in the output of the kernelization algorithm.

Theorem 5 follows easily from Theorem 4; basically, the algorithm applied to a c-cutwidth minimal semi-complete digraph cannot output only smaller digraphs. For Theorem 6 we use our finer understanding of minimum orderings in tournaments. We remark that from the well-quasi order result of Chudnovsky and Seymour [4], it follows that the number of minimal *immersion* obstructions for tournaments of cutwidth at most c is finite. However, this holds only for tournaments, yields a non-explicit upper bound on obstruction sizes, and applies to immersion and not induced subdigraph obstructions.

Organization. In Section 2 we introduce notation, recall basic definitions, and prove Theorems 7 and 8. In Sections 3 and 4 we prove Theorems 4 and 1, respectively. The proofs of statements marked with ♠ will appear in the full version of the paper.

2 Preliminaries and basic results

Notation. We use standard graph notation for digraphs. All digraphs considered in this paper are simple, i.e., they do not contain a self-loop or multiple arcs with the same head and tail. For definitions of tournaments and semi-complete digraphs, see the first paragraph of Section 1. If present in a digraph, the arcs (u, v) and (v, u) are called *symmetric arcs*.

For two integers $p \leq p'$, let $[p, p'] \subseteq \mathbb{Z}$ be the set of integers between p and p'. If $p < p'$, we set $[p', p] = \emptyset$ by convention. A *vertex ordering* of a digraph D is a bijective mapping $\pi \colon V(D) \to [1, n]$, where $n = |V(D)|$. A vertex $u \in V(D)$ is *at position* i *in* π if $\pi(u) = i$. We denote this unique vertex by π_i. The *prefix* of length i of π is $\pi_{\leq i} = \{\pi_j \colon j \in [1, i]\}$; we set $\pi_{\leq i} = \emptyset$ when $i \leq 0$, and $\pi_{\leq i} = V(D)$ when $n \leq i$. We extend this notation to prefixes and suffixes of orderings naturally, e.g., $\pi_{>i} = V(D) \setminus \pi_{\leq i}$ is the set of the last $n - i$ vertices in π. The notions of restriction and concatenation of ordering(s) are defined naturally.

An arc $(\pi_i, \pi_j) \in E(D)$ is a *feedback arc for* π if $i > j$, that is, if π_i is after π_j in π. Given a digraph $D = (V, E)$, an ordering π of V and an integer i, we define the *cut* E^i_π as the set of feedback arcs $E(\pi_{>i}, \pi_{\leq i})$. The tuple $\mathsf{cuts}\langle D, \pi\rangle = (|E^0_\pi|, |E^1_\pi|, \ldots, |E^n_\pi|)$ is called the *cut vector* of π, and we denote $\mathsf{cuts}\langle D, \pi\rangle(i) = |E^i_\pi|$. Let $\preceq$ be the product order on tuples: for n-tuples A, B, we have $A \preceq B$ iff $A(i) \leq B(i)$ for all $i \in [0, n]$. We define $A \prec B$ as $A \preceq B$ and $A \neq B$. We say that a vertex ordering π is *minimum for* D if for all vertex orderings π' of D we have $\mathsf{cuts}\langle D, \pi\rangle \preceq \mathsf{cuts}\langle D, \pi'\rangle$. Note that a minimum vertex ordering may not exist.

The *width* of a vertex ordering π of a digraph D, denoted $\mathsf{ctw}(D, \pi)$, is equal to $\max\{\mathsf{cuts}\langle D, \pi\rangle\}$, where max on a tuple yields the largest coordinate. The *cutwidth* of D, denoted $\mathsf{ctw}(D)$, is the minimum width among vertex orderings of D. Similarly, the *cost* of π, denoted $\textsc{Ola}(D, \pi)$, is equal to $\sum\{\mathsf{cuts}\langle D, \pi\rangle\}$, where $\sum$ on a tuple yields the sum of coordinates. This is equivalent to summing $j - i$ for all feedback arcs (π_j, π_i) in π. The

OLA-cost of D, denoted $\textsc{Ola}(D)$, is the minimum cost among vertex orderings of D. A vertex ordering π of D satisfying $\mathsf{ctw}(D) = \mathsf{ctw}(D, \pi)$, or $\textsc{Ola}(D) = \textsc{Ola}(D, \pi)$, is respectively called ctw-*optimal* or $\textsc{Ola}$-*optimal* for D. Note that a minimum ordering for D, if existent, is always ctw-*optimal* and $\textsc{Ola}$-*optimal* for D.

Exponential-Time Hypothesis. The *Exponential Time Hypothesis* (ETH) of Impagliazzo et al. [14] states that for some constant $c > 0$, there is no algorithm for 3SAT that would run in time $2^{cn} \cdot (n+m)^{\mathcal{O}(1)}$, where n and m are the numbers of variables and clauses of the input formula, respectively. Using the *Sparsification Lemma* [14] one can show that under ETH, there is a constant $c > 0$ such that 3SAT cannot be solved in time $2^{cm} \cdot (n+m)^{\mathcal{O}(1)}$. In this work we use the NAE-3SAT problem (for Not-All-Equal), which is a variant of 3SAT where a clause is considered satisfied only when at least one, but not all of its literals are satisfied. Schaefer [19] gave a linear reduction from 3SAT to NAE-3SAT, which immediately yields:

▶ **Corollary 9.** *Unless ETH fails,* NAE-3SAT *cannot be solved in time* $2^{o(m)} \cdot (n+m)^{\mathcal{O}(1)}$, *where* n *and* m *are the numbers of variables and clauses of the input formula, respectively.*

Theorems 7 and 8. We now proceed to proving Theorems 7 and 8; recall that for cutwidth, these results have been already established by Fradkin [9]. However, we use this opportunity to present the reasoning in a more insightful manner and more general context, which also yields a better combinatorial understanding that will be helpful later. The core idea is to work in a more general setting of linear relaxations of tournaments, as defined next.

A *fractional tournament* is a pair $T = (V, \omega)$, where V is a finite vertex set and $\omega \colon V^2 \to \mathbb{R}_{\geq 0}$ is a weight function that satisfies the following properties: $\omega(u,u) = 0$ for all $u \in V$, and $\omega(u,v) + \omega(v,u) = 1$ for all pairs of different vertices u, v. Thus, by requiring the weights to be integral we recover the original definition of a tournament. We extend the notation for digraphs to fractional tournaments as follows. For $X, Y \subseteq V$ we define $\omega(X,Y) = \sum_{x \in X,\, y \in Y} \omega(x,y)$, and for $u \in V$ we define $\omega^-(u) = \omega(V, \{u\})$ and $\omega^+(u) = \omega(\{u\}, V)$. The notions of (minimum) vertex orderings, cut vectors, cutwidth, and OLA-cost are extended naturally: the cardinality of any cut $E(X,Y)$ is replaced by the sum of weights $\omega(X,Y)$.

Suppose $T = (V, \omega)$ is a fractional tournament. We say that a vertex ordering π of T is *sorted* if for any pair of different vertices u and v, if $\omega^-(u) < \omega^-(v)$, then $\pi(u) < \pi(v)$; in other words, the vertices are sorted according to their indegrees. The following lemma encapsulates the essence of our approach.

▶ **Lemma 10 (♠).** *A vertex ordering of a fractional tournament is minimum iff it is sorted.*

The proof of Theorem 7, even in the more general setting of fractional tournaments, is now immediate. We just sort the vertices according to their indegrees ω^-. By Lemma 10, the obtained ordering is minimum, hence it is both ctw-optimal and $\textsc{Ola}$-optimal.

Lemma 10 cannot be generalized to the semi-complete setting, as there are semi-complete digraphs that do not admit any minimum ordering.

We now give a 2-approximation algorithm for general semi-complete digraphs. The main idea is to relax a given semi-complete digraph to a fractional tournament. Precisely, for a semi-complete digraph D, consider its *relaxation* T_D which is a fractional tournament on the vertex set $V(D)$, where for every pair of different vertices u and v, we put

- $\omega(u,v) = 1$ and $\omega(v,u) = 0$, when (u,v) is present in D but (v,u) is not present; and
- $\omega(u,v) = \omega(v,u) = 1/2$, when (u,v) and (v,u) is a pair of symmetric arcs in D.

We put $\omega(u,u) = 0$ for every vertex u, thus T_D is indeed a fractional tournament. Observe that for any pair of vertices u, v, we have $|E(\{u\},\{v\})|/2 \leq \omega_{T_D}(\{u\},\{v\}) \leq |E(\{u\},\{v\})|$.

Therefore, for every vertex ordering π of D and every index $i \in [0, n]$, it holds that

$$\mathsf{cuts}\langle D, \pi\rangle(i)/2 \leq \mathsf{cuts}\langle T_D, \pi\rangle(i) \leq \mathsf{cuts}\langle D, \pi\rangle(i).$$

In particular we have $\mathsf{ctw}(D)/2 \leq \mathsf{ctw}(T_D) \leq \mathsf{ctw}(D)$ and $\textsc{Ola}(D)/2 \leq \textsc{Ola}(T_D) \leq \textsc{Ola}(D)$. The proof of Theorem 8 is now immediate: just output any sorted ordering of T_D.

3 Turing kernel

In this section we prove Theorem 4, that is, we give a quadratic Turing kernel for the problem of computing the cutwidth of a semi-complete digraph. The essence of our approach is encapsulated in the following lemma. Intuitively, it provides a sufficient condition for a cut in a given ordering π so that it can be assumed to be used in an optimum ordering σ.

▶ **Lemma 11.** *Let $D = (V, E)$ be a semi-complete digraph. Let π and σ be two vertex orderings of D such that $\mathsf{ctw}(D, \sigma) \leq \mathsf{ctw}(D, \pi) = c$. Suppose further that $m \in [4c, |V| - 4c]$ is such that in D there is a family of $|E^m_\pi|$ arc-disjoint paths leading from $\pi_{>m+4c}$ to $\pi_{\leq m-4c}$. Then there exists a vertex ordering σ^* such that:*

- $\sigma^*_{\leq m} = \pi_{\leq m}$;
- *for every j with $j \leq m - 4c$ or $j > m + 4c$, we have $\sigma^*_j = \sigma_j$;*
- $\mathsf{ctw}(D, \sigma^*) \leq \mathsf{ctw}(D, \sigma)$.

The intuition behind Lemma 11 is as follows. Consider σ^* as rearranged σ. The second condition says that this rearrangement is local: it affects only vertices at positions in the range $[m-4c+1, m+4c]$. The third condition says that the rearrangement does not increase the width. Finally, the first condition is crucial: σ^* uses the prefix $\pi_{\leq m}$ of π as one of its prefixes. Thus, any ordering can be locally rearranged while preserving the width so that prefix $\pi_{\leq m}$ is used, provided there is a large arc-disjoint flow locally near m.

Proof of Lemma 11. We first establish the following basic observation on the relation between orderings π and σ.

▶ **Claim 12 (♠).** *In the ordering σ, every vertex of $\pi_{\leq m-4c}$ is placed before every vertex of $\pi_{>m}$, and every vertex of $\pi_{\leq m}$ is placed before every vertex of $\pi_{>m+4c}$.*

The proof of the claim naturally follows by finding, say for each $u \in \pi_{\leq m-4c}$ and $v \in \pi_{>m}$, sufficiently many vertices that are both outneighbors of u and inneighbors of v.

Let $\sigma_\leq$ and $\sigma_>$ denote the restriction of σ to $\pi_{\leq m}$ and $\pi_{>m}$, respectively. Then, define σ^* to be the concatenation of $\sigma_\leq$ and $\sigma_>$. By the construction we have $\pi_{\leq m} = \sigma^*_{\leq m}$, so the first condition is satisfied. For the second condition, observe that by Claim 12, every vertex of $\pi_{\leq m-4c}$ is before every vertex of $\pi_{>m}$ in σ. It follows that in σ, the first vertex of $\pi_{>m}$ appears only after a prefix of at least $m - 4c$ vertices of $\pi_{\leq m}$. In the construction of σ^* from σ, the vertices of that prefix stay at their original positions, so $\sigma^*_j = \sigma_j$ for all $j \leq m - 4c$. A symmetric argument shows that $\sigma^*_j = \sigma_j$ also for all $j > m + 4c$.

It remains to prove that $\mathsf{ctw}(D, \sigma^*) \leq \mathsf{ctw}(D, \sigma)$. Consider any $j \in [0, |V|]$; we need to prove that $|E^j_{\sigma^*}| \leq \mathsf{ctw}(D, \sigma)$. By the second condition we have that $E^j_{\sigma^*} = E^j_\sigma$ when $j \leq m - 4c$ or $j \geq m + 4c$, and $|E^j_\sigma| \leq \mathsf{ctw}(D, \sigma)$ by definition. Hence, we are left with checking the inequality for j satisfying $m - 4c < j < m + 4c$.

In the following, for a vertex subset A we denote $\delta(A) = |E(V \setminus A, A)|$. We will use the submodularity of directed cuts: $\delta(A \cap B) + \delta(A \cup B) \leq \delta(A) + \delta(B)$ for all vertex subsets A, B. In these terms, we need to prove that $\delta(\sigma^*_{\leq j}) \leq \mathsf{ctw}(D, \sigma)$.

Let x be the vertex at position j in σ^* and let X be the set of all vertices placed not after x in σ, including x itself. Suppose first that $j \leq m$. Then, by the construction we have $x \in \pi_{\leq m}$ and $\sigma^*_{\leq j} = X \cap \pi_{\leq m}$. By the submodularity of cuts we have

$$\delta(\sigma^*_{\leq j}) = \delta(X \cap \pi_{\leq m}) \leq \delta(X) + \delta(\pi_{\leq m}) - \delta(X \cup \pi_{\leq m}). \tag{1}$$

As X is a prefix of σ by definition, we have $\delta(X) \leq \mathsf{ctw}(D, \sigma)$. Hence, by (1), in order to prove that $\delta(\sigma^*_{\leq j}) \leq \mathsf{ctw}(D, \sigma)$, it suffices to prove that $\delta(X \cup \pi_{\leq m}) \geq \delta(\pi_{\leq m})$.

Denote $d = \delta(\pi_{\leq m}) = |E^m_\pi|$ and recall that there is a family of d arc-disjoint paths leading from $\pi_{>m+4c}$ to $\pi_{\leq m-4c}$. In particular, this means that for each set A with $A \supseteq \pi_{\leq m-4c}$ and $A \cap \pi_{>m+4c} = \emptyset$, each of these paths has to contribute to $\delta(A)$, implying $\delta(A) \geq d$.

Therefore, it suffices to show that $X \cup \pi_{\leq m} \supseteq \pi_{\leq m-4c}$ and $(X \cup \pi_{\leq m}) \cap \pi_{>m+4c} = \emptyset$. While the first assertion is trivial, the second is equivalent to $X \cap \pi_{>m+4c} = \emptyset$. For this, observe that by definition all elements of X are placed not after x in σ, and x belongs to $\pi_{\leq m}$. However, by Claim 12 all vertices of $\pi_{>m+4c}$ are placed in σ after all vertices of $\pi_{\leq m}$, in particular after x. This implies that X and $\pi_{>m+4c}$ are disjoint, which proves that $\delta(X \cup \pi_{\leq m}) \geq d$ and, consequently as discussed above, also that $\delta(\sigma^*_{\leq j}) \leq \mathsf{ctw}(D, \sigma)$.

The proof for the case $j > m$ is completely symmetric, however we need to observe that now $x \in \pi_{>m}$ and $\sigma^*_{\leq j} = X \cup \pi_{\leq m}$. By applying the same submodularity argument (1), we are left with proving that $\delta(X \cap \pi_{\leq m}) \geq \delta(\pi_{\leq m})$, which follows by a symmetric reasoning. ◀

Our goal now is to construct an approximate ordering π where we will be able to find many positions m to which Lemma 11 can be applied. We first recall the concept of a lean ordering, which will be our main tool for finding families of arc-disjoint paths.

▶ **Definition 13.** A vertex ordering π of a digraph $D = (V, E)$ is called *lean* if for each $0 \leq a \leq b \leq n$, the maximum size of a family of arc-disjoint paths from $\pi_{>b}$ to $\pi_{\leq a}$ in D is equal to $\min_{a \leq i \leq b} |E^i_\pi|$.

Note that by Menger's theorem, the maximum size of a family of arc-disjoint paths from $\pi_{>b}$ to $\pi_{\leq a}$ is equal to the minimum size of an arc cut separating $\pi_{>b}$ from $\pi_{\leq a}$. Thus, in a lean ordering we have that the minimum cutsize between any disjoint prefix and suffix is actually realized by one of the cuts along the ordering.

The notion of a lean ordering is the cutwidth analogue of a *lean decomposition* in the treewidth setting, cf. [20]. An essentially equivalent notion of *linked orderings* was used by Chudnovsky and Seymour [4] in the context of immersions in tournaments. Also, Giannopoulou et al. [12] used this concept to study immersion obstructions for the cutwidth of undirected graphs. A careful analysis of the arguments of [4, 12] yields the following.

▶ **Lemma 14** ([4, 12])**.** *There is a polynomial-time algorithm that given a vertex ordering π of a digraph D, computes a lean vertex ordering π^* of D satisfying $\mathsf{ctw}(D, \pi^*) \leq \mathsf{ctw}(D, \pi)$.*

Next, we introduce the concept of a *milestone*. Intuitively, a milestone is a position where Lemma 11 can be applied, provided the ordering is lean.

▶ **Definition 15.** Let π be a vertex ordering of a digraph $D = (V, E)$, and let α be a positive integer. An integer $m \in [0, |V|]$ is a *π-milestone of D of span α* if $|E^m_\pi| \leq |E^i_\pi|$ for each integer i with $m - \alpha \leq i \leq m + \alpha$.

Note that if π is lean and m is a π-milestone of span α, then $\min_{m-\alpha \leq i \leq m+\alpha} |E^i_\pi| = |E^m_\pi|$, hence there is a family of $|E^\pi_m|$ arc-disjoint paths leading from $\pi_{>m+\alpha}$ to $\pi_{\leq m-\alpha}$. Thus, a π-milestone of span $4c$ satisfies the prerequisite of Lemma 11 about the existence of arc-disjoint paths. We now observe that in an ordering of small width milestones occur often.

▶ **Lemma 16 (♠).** *Let $D = (V, E)$ be a digraph and let π be a vertex ordering of D of width at most c. Then for any integers $p \in [0, |V|]$ and $\alpha \geq 0$, there exists a π-milestone $m \in [p - \alpha \cdot c, p + \alpha \cdot c]$ of span α.*

Having gathered all the tools, we are finally ready to prove Theorem 4.

Proof of Theorem 4. By Theorem 8, we can compute in polynomial time a vertex ordering π_0 of D such that $\mathsf{ctw}(D, \pi_0) \leq 2 \cdot \mathsf{ctw}(D)$. If $\mathsf{ctw}(D, \pi_0) > 2c$, we can conclude that $\mathsf{ctw}(D) > c$ and report this answer, so let us assume that $\mathsf{ctw}(D, \pi_0) \leq 2c$. By applying the algorithm of Lemma 14 to π_0, we can compute in polynomial time a lean ordering π such that $\mathsf{ctw}(D, \pi) \leq \mathsf{ctw}(D, \pi_0) \leq 2c$. In the following we assume w.l.o.g. that $|V| > 16c$, for otherwise we can output a list consisting only of D.

Call a set of π-milestones *dispersed* if these π-milestone pairwise differ by more than $16c$. Observe that 0 and $|V|$ are always π-milestones, and they differ by more than $16c$. Starting from the set $\{0, |V|\}$, we compute an inclusion-wise maximal dispersed set $0 = m_0 < m_1 < m_2 < \ldots < m_\ell = |V|$ of π-milestones of span $8c$. More precisely, whenever some π-milestone of span $8c$ can be added to the set without spoiling the dispersity requirement, we do it, until no further such milestone can be added. Observe that then we have that $m_{i+1} - m_i \leq 32c^2 + 32c + 1$ for each $i \in [1, \ell - 1]$, for otherwise the range $[m_i + 16c + 1, m_{i+1} - 16c - 1]$ would contain more than $32c^2$ vertices, so by Lemma 16 we would be able to find in it a π-milestone of span $8c$ that could be added to the constructed dispersed set.

Thus, π is partitioned into ℓ blocks $B_1, \ldots, B_\ell$, each of length at most $32c^2 + 32c + 1$, such that the j-th block B_j is equal to $\{\pi_{m_{j-1}+1}, \pi_{m_{j-1}+2}, \ldots, \pi_{m_j}\}$. For each $j \in [1, \ell]$, let A_j be defined as B_j augmented with the following vertices:

- vertices at positions in ranges $[\max(1, m_{j-1} - 8c + 1), m_{j-1}]$ and $[m_j + 1, \min(|V|, m_j + 8c)]$,
- all heads of arcs from $E_\pi^{m_{j-1}-8c}$, and all tails of arcs from $E_\pi^{m_j+8c}$.

Since the width of π is at most $2c$, we have that $|A_j| \leq |B_j| + 20c = \mathcal{O}(c^2)$.

For $j \in [1, \ell]$, let us denote $D_j = D[A_j]$. To prove the theorem, it now suffices to show that $\mathsf{ctw}(D) \leq c$ if and only if $\mathsf{ctw}(D_j) \leq c$ for each $j \in [1, \ell]$. The forward direction is trivial, since cutwidth is closed under taking induced subdigraphs. Hence, we are left with showing that if $\mathsf{ctw}(D_j) \leq c$ for each $j \in [1, \ell]$, then $\mathsf{ctw}(D) \leq c$.

Take any $j \in [1, \ell - 1]$. As m_j is a π-milestone of span $8c$, we have $\min_{m_j - 8c \leq i \leq m_j + 8c} |E_\pi^i| = |E_\pi^{m_j}|$. Since π is lean, there is a family $\mathcal{F}_j$ of $|E_\pi^{m_j}|$ arc-disjoint paths in D leading from $\pi_{>m_j+8c}$ to $\pi_{\leq m_j-8c}$. We can assume w.l.o.g. that each internal (non-endpoint) vertex of each of these paths has position between $m_j + 8c + 1$ and $m_j - 8c$ in π. Hence, in particular, each path of $\mathcal{F}_j$ starts with an arc of $E_\pi^{m_j+8c}$ and ends with an arc of $E_\pi^{m_j-8c}$. This implies that for each $j \in [1, \ell]$, all the paths of $\mathcal{F}_j$ are entirely contained both in D_j and in D_{j+1}.

Consider any $j \in [1, \ell]$, and for simplicity assume for now that $j \neq 1$ and $j \neq \ell$. Let π' be the restriction of π to the vertex set of D_j; obviously the width of π' is at most $2c$. Further, let m' be the position of $\pi_{m_{j-1}}$ in π', so that $\pi'_{\leq m'} = \pi_{\leq m_{j-1}} \cap V(D_j)$. Observe that since all vertices at positions between $m_{j-1} - 8c + 1$ and $m_{j-1} + 8c$ in π are included in the vertex set of D_j, they are at positions between $m' - 8c + 1$ and $m' + 8c$ in π', and hence the paths of $\mathcal{F}_{j-1}$ in D_j lead from $\pi'_{>m'+8c}$ to $\pi'_{\leq m'-8c}$. Their number is $|E_\pi^{m_{j-1}}|$, which is equal to the cutsize at position m' in π', by the construction of D_j and π'.

We conclude that Lemma 11 can be applied to position m' in the ordering π' of D_j. If we now use it on any ctw-optimal vertex ordering σ of D_j, we obtain a ctw-optimal vertex ordering σ^* of D_j such that $\sigma^*_{\leq m'} = \pi'_{\leq m'} = \pi_{\leq m_{j-1}} \cap V(D_j)$. Note that by Lemma 11, σ^* differs from σ by a rearrangement of vertices at positions between $m' - 8c + 1$ and $m' + 8c$.

Now we define m'' to be the position of π_{m_j} in π', so that $\pi'_{\leq m''} = \pi_{\leq m_j} \cap V(D_j)$. A symmetric reasoning, which uses the fact that $\mathcal{F}_j$ is also entirely contained in D_j, shows that Lemma 11 can be also applied to position m'' in the ordering π' of D_j. Then we can use this lemma on the ctw-optimal vertex ordering σ^*, yielding a ctw-optimal ordering σ^{**} such that $\sigma^{**}_{\leq m''} = \pi'_{\leq m''} = \pi_{\leq m_j} \cap V(D_j)$. Again, by Lemma 11 we have that σ^* and σ^{**} differ by a rearrangement of vertices at positions $m'' - 8c + 1$ and $m'' + 8c$. Since $m_j - m_{j-1} > 16c$ by construction, we infer that this rearrangement does not change the prefix of length m', and hence we still have $\sigma^{**}_{\leq m'} = \pi'_{\leq m'} = \pi_{\leq m_{j-1}} \cap V(D_j)$. The ordering σ^{**} obtained in this manner shall be called σ^j. For $j = 1$ and $j = \ell$ we obtain σ^j in exactly the same way, except we apply Lemma 11 only once, for the position not placed at the end of the sequence.

All in all, for each $j \in [1, \ell]$ we have obtained a ctw-optimal ordering σ^j of D_j such that the vertices of B_j form an infix (a sequence of consecutive elements) of σ^j, while vertices to the left of this infix are the vertices of $V(D_j) \cap \pi_{\leq m_{j-1}}$ and vertices to the right of this infix are the vertices of $V(D_j) \cap \pi_{>m_j}$. Define an ordering σ of D by first restricting every ordering σ^j to B_j, and then concatenating all the obtained orderings for $j = 1, 2, \ldots, \ell$. Since we assumed that $\mathsf{ctw}(D_j) \leq c$ for each $j \in [1, \ell]$, and each ordering σ^j is ctw-optimal on D_j, we have that $\mathsf{ctw}(D_j, \sigma^j) \leq c$ for each $j \in [1, \ell]$. From the construction of D_j, and in particular the fact that all the arcs of $E_\pi^{m_{j-1}}$ and $E_\pi^{m_j}$ are contained in D_j, it follows that the infix of cutvector $\mathsf{cuts}\langle D^j, \sigma^j \rangle$ corresponding to the vertices of B_j is equal to the infix of the cutvector $\mathsf{cuts}\langle D, \sigma \rangle$ corresponding to the vertices of B_j. This shows that

$$\mathsf{ctw}(D, \sigma) = \max_{i \in [0, |V|]} \mathsf{cuts}\langle D, \sigma \rangle(i) \leq \max_{\substack{j \in [0,\ell] \\ i \in [0, |V(D_j)|]}} \mathsf{cuts}\langle D^j, \sigma^j \rangle(i) = \max_{j \in [0,\ell]} \mathsf{ctw}(D_j, \sigma^j) \leq c,$$

hence we are done. ◀

Regarding the bounds on sizes of c-cutwidth-minimal semi-complete digraphs (Theorems 5 and 6), we will give a full exposition in the complete version of the paper. Essentially, Theorem 5 follows easily by considering applying the algorithm of Theorem 4 on a c-cutwidth-minimal semi-complete digraph for parameter $c - 1$, while for Theorem 6 we need to use the understanding of minimum orderings in tournaments in the spirit of Lemma 10.

4 Lower bounds

In this section, we prove Theorem 1, which provides almost tight lower bounds for the complexity of computing the cutwidth and the Ola-cost of a semi-complete digraph. We start our reduction from an instance of the NAE-3SAT problem, which was defined in Section 2 and for which a complexity lower bound under ETH is given by Corollary 9.

Let us introduce some notation. For a formula φ in CNF, the variable and clause sets of φ are denoted by $\mathrm{vars}(\varphi)$ and $\mathrm{cls}(\varphi)$, respectively. A variable assignment $\alpha \colon \mathrm{vars}(\varphi) \to \{\bot, \top\}$ *NAE-satisfies* φ if every clause of φ has at least one, but not all literals satisfied. Formula φ is *NAE-satisfiable* if there is a variable assignment α that NAE-satisfies it; equivalently, both α and its negation $\neg\alpha$ satisfy φ. A digraph is called *basic* if it is simple and has no pair of symmetric arcs. For an integer $m > 0$, let λ_m be the tuple of size $14m + 1$ such that:

$$\lambda_m(i) = \begin{cases} 2i, & \text{when } i \in [0, 5m] \\ 5m + i, & \text{when } i \in [5m + 1, 6m] \\ 11m, & \text{when } i \in [6m + 1, 7m] \\ 18m - i, & \text{when } i \in [7m + 1, 12m] \\ 42m - 3i, & \text{when } i \in [12m + 1, 14m] \end{cases}$$

The following lemma encapsulates the first, main step of our reduction.

▶ **Lemma 17.** *There exists a polynomial-time algorithm that, given a 3CNF formula φ with m clauses, returns a basic digraph $D(\varphi)$ with $14m$ vertices and $24m$ edges such that:*

1. *for every vertex ordering π, we have $\mathsf{cuts}\langle D(\varphi), \pi\rangle \preceq \lambda_m$;*
2. *if φ is NAE-satisfiable, then there exists a vertex ordering π with $\mathsf{cuts}\langle D(\varphi), \pi\rangle = \lambda_m$;*
3. *if there is a vertex ordering π with $\max\{\mathsf{cuts}\langle D(\varphi), \pi\rangle\} \geq 11m$, then φ is NAE-satisfiable.*

Note that Lemma 17 expresses a reduction from NAE-3SAT to a maximization problem: NAE-satisfiability of φ is equivalent to $D(\varphi)$ admitting a vertex ordering of width *at least* $11m$. The main idea is that this maximization will be later turned into minimization by complementing the digraph, which also yields a semi-complete digraph since $D(\varphi)$ is basic.

Proof of Lemma 17. Without loss of generality, we may assume that each clause of φ contains exactly 3 literals, by repeating some literal if necessary. Then, we may also assume that every variable of $\mathrm{vars}(\varphi)$ appears at least twice, because a variable that appears only once can always be set in order that the clause in which it appears is NAE-satisfied, and thus such a variable and its associated clause may be safely removed. For every variable $x \in \mathrm{vars}(\varphi)$, let p_x be the number of occurrences of x in the clauses of φ; hence $3m = \sum_{x \in \mathrm{vars}(\varphi)} p_x$ and $p_x \geq 2$ for each $x \in \mathrm{vars}(\varphi)$. We finally assume the clauses and literals are ordered, so we may say that a literal ℓ_x is the i_xth occurrence of variable x in the clauses of φ, with $i_x \in [1, p_x]$.

We now describe the construction of $D(\varphi)$. For every variable $x \in \mathrm{vars}(\varphi)$ construct a *variable gadget* G_x, which is a directed cycle of length $2p_x$ with vertices named as follows:

$$\bot^x_1 \to \top^x_1 \to \bot^x_2 \to \top^x_2 \to \ldots \to \bot^x_{p_x} \to \top^x_{p_x} \to \bot^x_1.$$

Note that this cycle has no symmetric arcs since $p_x > 1$.

Then, for every clause $C \in \mathrm{cls}(\varphi)$, where $C = \ell_x \vee \ell_y \vee \ell_z$ for literals of variables $x, y, z \in \mathrm{vars}(\varphi)$, respectively, construct the following *$\top$-clause gadget* $G^C_\top$. Introduce a vertex $\top^C$ and a set of vertices $V^C_\top = \{\top^C_{\ell_x}, \top^C_{\ell_y}, \top^C_{\ell_z}\}$ together with the following arcs:

- A directed 3-cycle $(\top^C_{\ell_x}, \top^C_{\ell_y}), (\top^C_{\ell_y}, \top^C_{\ell_z}), (\top^C_{\ell_z}, \top^C_{\ell_x})$.
- The arcs $(\top^C, \top^C_{\ell_x}), (\top^C, \top^C_{\ell_y})$ and $(\top^C, \top^C_{\ell_z})$ from $\top^C$ to the vertices of V^C_T.

Similarly, construct the *$\bot$-clause gadget* $G^C_\bot$, which is isomorphic to $G^C_\top$, but with vertices named $\bot$. Gadgets $G^C_\top$ and $G^C_\bot$ will differ in how we connect them with the rest of the graph.

Intuitively, the variable assignment α, intended to NAE-satisfy φ, is encoded by choosing, in each variable gadget G_x, which vertices are placed in the first half of π, and which are placed in the second. We use the gadget $G^C_\top$ to verify that α satisfies C, whereas the gadget $G^C_\bot$ verifies that $\neg\alpha$ also satisfies C. For this purpose, connect the clause gadgets to variable gadgets as follows. Suppose $\ell_x \in C$ is the i_xth occurrence of x. If $\ell_x = x$ then add two arcs $(\top^C_{\ell_x}, \bot^x_{i_x})$ and $(\bot^C_{\ell_x}, \top^x_{i_x})$, and if $\ell_x = \neg x$ then add two arcs $(\top^C_{\ell_x}, \top^x_{i_x})$ and $(\bot^C_{\ell_x}, \bot^x_{i_x})$.

This concludes the construction of $D(\varphi)$. Clearly $D(\varphi)$ is basic, and a straightforward verification using the equality $3m = \sum_{x \in \mathrm{vars}(\varphi)} p_x$ shows that conditions $|V(D(\varphi))| = 14m$ and $|E(D(\varphi))| = 24m$ hold as well. The complete proof of the three lemma statements will appear in the full version of the paper. In order to show the main gist of the reduction, we sketch now the proof of the third claim.

We prove the following statement: for any vertex subset $A \subseteq V$, it always holds that $|E(A, V \setminus A)| \leq 11m$. Note that this in particular implies that the cutwidth of any ordering of $D(\varphi)$ is at most $11m$, which is a part of the verification of the first claim. Denote $F = E(A, V \setminus A)$. First, consider any variable $x \in \mathrm{vars}(\varphi)$. Since G_x is a directed cycle of length $2p_x$, it can easily be seen that $|F \cap E(G_x)| \leq p_x$ and the equality holds if and only if A contains every second vertex of the cycle G_x. Second, consider any clause $C = \ell_x \vee \ell_y \vee \ell_z \in \mathrm{cls}(\varphi)$. Let $R^C_\top$ be the set of three arcs connecting G^C with the variable

gadgets G_x, G_y, and G_z. Since $\top^C$ has no incoming arcs, we can assume without loss of generality that $\top^C \in A$, as putting $\top^C$ into A can only increase $|E(A, V \setminus A)|$. We now distinguish cases depending on the size of $A \cap V_\top^C = A \cap \{\top_{\ell_x}^C, \top_{\ell_y}^C, \top_{\ell_z}^C\}$. The following implications follow from a straightforward analysis of the situation in $G_\top^C$ and on incident arcs.

- If $|A \cap V_\top^C| = 0$ then $|F \cap R_\top^C| = 0$ and $|F \cap E(G_\top^C)| = 3$.
- If $|A \cap V_\top^C| = 1$ then $|F \cap R_\top^C| \leq 1$ and $|F \cap E(G_\top^C)| = 3$.
- If $|A \cap V_\top^C| = 2$ then $|F \cap R_\top^C| \leq 2$ and $|F \cap E(G_\top^C)| = 2$.
- If $|A \cap V_\top^C| = 3$ then $|F \cap R_\top^C| \leq 3$ and $|F \cap E(G_\top^C)| = 0$.

In all the cases, we conclude that $|F \cap (E(G_\top^C) \cup R_\top^C)| \leq 4$; note that the equality can hold only in the two middle ones. The same analysis applies to the $\bot$-clause gadgets, yielding $|F \cap (E(G_\bot^C) \cup R_\bot^C)| \leq 4$, where $R_\bot^C$ is defined analogously. Since the sets $E(G_x)$ for $x \in \mathrm{vars}(\varphi)$ and $E(G_\top^C) \cup R_\top^C \cup E(G_\bot^C) \cup R_\bot^C$ for $C \in \mathrm{cls}(\varphi)$ form a partition of $E(D(\varphi))$, we immediately get that $|F| \leq \sum_{x \in \mathrm{vars}(\varphi)} p_x + 8|\mathrm{cls}(\varphi)| = 11m$.

To verify the third claim of the lemma, note that if there is some vertex ordering of cutwidth at least $11m$, then there is some set A with $|E(A, V \setminus A)| \geq 11m$. Hence, for such all the inequalities used above are in fact equalities. In particular, in every variable gadget G_x, the vertices belong to A and to $V(D) \setminus A$ alternately. This gives us two possibilities for every variable gadget, which naturally defines a variable assignment α for the formula φ. The fact that we have equalities also in each clause gadget $G_\top^C$ and $G_\bot^C$ ensures that each clause C is satisfied both by α and $\neg\alpha$. Hence α NAE-satisfies φ. ◀

We now proceed to complementing the obtained digraph. Precisely, given a simple digraph $D = (V, E)$, define its *complement* as $\bar{D} = (V, \bar{E})$, where $\bar{E} = V^2 \setminus (E \cup \{(u, u) \colon u \in V\})$. That is, we take the complete digraph without self-loops on the vertex set V, and we remove all the arcs that are present in D. Note that the complement of a basic digraph is semi-complete.

Now, let $\bar{\lambda}_m$ be the tuple such that for all $i \in [0, 14m]$, we have $\lambda_m(i) + \bar{\lambda}_m(i) = i(14m - i)$. It is not hard to check that $\max\{\bar{\lambda}_m\} = \bar{\lambda}_m(7m) = 49m^2 - 11m$. A simple verification of how the conditions of Lemma 17 are transformed under complementation yields the following.

▶ **Lemma 18 (♠).** *The complement of $D(\varphi)$ is a semi-complete digraph $\bar{D}(\varphi)$ satisfying:*

1. *for every vertex ordering π, we have $\bar{\lambda}_m \preceq \mathsf{cuts}\langle \bar{D}(\varphi), \pi \rangle$;*
2. *if φ is NAE-satisfiable, then there exists a vertex ordering π with $\mathsf{cuts}\langle \bar{D}(\varphi), \pi \rangle = \bar{\lambda}_m$;*
3. *if $\bar{D}(\varphi)$ admits a vertex ordering π of width at most $49m^2 - 11m$, then φ is NAE-satisfiable.*

Thus, Lemma 18 shows that NAE-satisfiability of φ is equivalent to $\bar{D}(\varphi)$ having cutwidth at most $49m^2 - 11m$. However, the fact that NAE-satisfiability of φ implies that $\bar{D}(\varphi)$ admits a vertex ordering with a very concrete cut vector $\bar{\lambda}_m$, which is the best possible in the sense of the first claim of Lemma 18, also enables us to derive a lower bound for OLA. All these observations, together with the linear bound on the number of vertices of $\bar{D}(\varphi)$, make the proof of Theorem 1 essentially complete.

The reduction of Lemma 17 constructs a basic digraph whose complement has a pair of symmetric arcs between almost every pair of vertices. On the other hand, on tournaments the problem is polynomial-time solvable, which suggests looking at the parameterization by the number of vertices incident to symmetric arcs. We indeed show that this parameterization leads to an FPT problem, even in a larger generality. Call a vertex u of a simple digraph D *pure* if for any other vertex v, exactly one of the arcs (u, v) or (v, u) is present in D.

▶ **Theorem 19 (♠).** *There is an algorithm that, given a simple digraph D on n vertices, computes the cutwidth and the OLA-cost of D in time $2^k \cdot n^{\mathcal{O}(1)}$, where k is the number of non-pure vertices in D. The algorithm can also report orderings certifying the output values.*

Abstract

The Cycle Packing problem asks whether a given undirected graph $G = (V, E)$ contains k vertex-disjoint cycles. Since the publication of the classic Erdős-Pósa theorem in 1965, this problem received significant scientific attention in the fields of Graph Theory and Algorithm Design. In particular, this problem is one of the first problems studied in the framework of Parameterized Complexity. The non-uniform fixed-parameter tractability of Cycle Packing follows from the Robertson–Seymour theorem, a fact already observed by Fellows and Langston in the 1980s. In 1994, Bodlaender showed that Cycle Packing can be solved in time $2^{\mathcal{O}(k^2)} \cdot |V|$ using exponential space. In case a solution exists, Bodlaender's algorithm also outputs a solution (in the same time). It has later become common knowledge that Cycle Packing admits a $2^{\mathcal{O}(k \log^2 k)} \cdot |V|$-time (deterministic) algorithm using exponential space, which is a consequence of the Erdős-Pósa theorem. Nowadays, the design of this algorithm is given as an exercise in textbooks on Parameterized Complexity. Yet, no algorithm that runs in time $2^{o(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, beating the bound $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, has been found. In light of this, it seems natural to ask whether the $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$ bound is essentially optimal. In this paper, we answer this question negatively by developing a $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$-time (deterministic) algorithm for Cycle Packing. In case a solution exists, our algorithm also outputs a solution (in the same time). Moreover, apart from beating the bound $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, our algorithm runs in time linear in $|V|$, and its space complexity is polynomial in the input size.

associated with a parameter k that is a non-negative integer, and a problem is said to be *fixed-parameter tractable (FPT)* if the combinatorial explosion in the time complexity can be confined to the parameter k. More precisely, a problem is FPT if it can be solved in time $f(k) \cdot |I|^{\mathcal{O}(1)}$ for some function f, where $|I|$ is the input size. For more information, we refer the reader to recent monographs such as [14] and [10].

In this paper, we study the Cycle Packing problem from the perspective of Parameterized Complexity. In the standard parameterization of Cycle Packing, the parameter is the number k of vertex-disjoint cycles. The non-uniform fixed-parameter tractability of Cycle Packing follows from the Robertson–Seymour theorem [38],[1] a fact already observed by Fellows and Langston in the 1980s. In 1994, Bodlaender showed that Cycle Packing can be solved in time $2^{\mathcal{O}(k^2)} \cdot |V|$ using exponential space [5]. Notably, in case a solution exists, Bodlaender's algorithm also outputs a solution in time $2^{\mathcal{O}(k^2)} \cdot |V|$.

The Erdős-Pósa theorem states that there exists a function $f(k) = \mathcal{O}(k \log k)$ such that for each non-negative integer k, every undirected graph either contains k vertex-disjoint cycles or it has a feedback vertex set consisting of $f(k)$ vertices [15]. It is well known that the treewidth (tw) of a graph is not larger than its feedback vertex set number (fvs), and that a naive dynamic programming (DP) scheme solves Cycle Packing in time $2^{\mathcal{O}(tw \log tw)} \cdot |V|$ and exponential space (see, e.g., [10]). Thus, the existence of a $2^{\mathcal{O}(k \log^2 k)} \cdot |V|$-time (deterministic) algorithm that uses exponential space can be viewed as a direct consequence of the Erdős-Pósa theorem. Nowadays, the design of this algorithm is given as an exercise in textbooks on Parameterized Complexity such as [14] and [10]. In case a solution exists, this algorithm does not output a solution (though we remark that with a certain amount of somewhat non-trivial work, it is possible to modify this algorithm to also output a solution).

Prior to our work, no algorithm that runs in time $2^{o(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, beating the bound $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, has been found. In light of this, it seemed tempting to ask whether the $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$ bound is essentially optimal. In particular, two natural directions to explore in order to obtain a faster algorithm necessarily lead to a dead end. First, Erdős and Pósa [15] proved that the bound $f(k) = \mathcal{O}(k \log k)$ in their theorem is essentially tight as there exist infinitely many graphs and a constant c such that these graphs do not contain k vertex-disjoint cycles and yet their feedback vertex set number is larger than $ck \log k$. Second, Cygan et al. [11] proved that the bound $2^{\mathcal{O}(tw \log tw)} \cdot |V|^{\mathcal{O}(1)}$ is also likely to be essentially tight in the sense that unless the Exponential Time Hypothesis (ETH) [20] is false, Cycle Packing cannot be solved in time $2^{o(tw \log tw)} \cdot |V|^{\mathcal{O}(1)}$ (however, it might still be true that Cycle Packing is solvable in time $2^{o(fvs \log fvs)} \cdot |V|^{\mathcal{O}(1)}$).

1.1 Related Work

The Cycle Packing problem admits a factor $\mathcal{O}(\log |V|)$ approximation algorithm [30], and it is quasi-NP-hard to approximate within a factor of $\mathcal{O}(\log^{\frac{1}{2}-\epsilon} |V|)$ for any $\epsilon > 0$ [18]. In the context of kernelization with respect to the parameter k, Cycle Packing does not admit a polynomial kernel unless NP $\subseteq$ coNP/Poly [4]. Recently, Lokshtanov et al. [31] obtained a 6-approximate kernel with $\mathcal{O}((k \log k)^2)$ vertices along with a $(1+\epsilon)$-approximate kernel with $k^{\mathcal{O}(f(\epsilon))}$ vertices for some function f. We would like to mention that in case one seeks k edge-disjoint cycles rather than k vertex-disjoint cycles, the problem becomes significantly simpler in the sense that it admits a kernel with $\mathcal{O}(k \log k)$ vertices [4].

Focusing on structural parameters, Bodlaender et al. [2] obtained polynomial kernels with respect to the vertex cover number, vertex-deletion distance to a cluster graph and

[1] The paper [38] was already available as a manuscript in 1986 (see, e.g., [5]).

the max leaf number. In planar graphs, Bodlaender et al. [3] solved Cycle Packing in subexponential time $2^{\mathcal{O}(\sqrt{k})} \cdot |V|^{\mathcal{O}(1)}$, and showed that this problem admits a linear kernel. In the more general class of H-minor-free graphs, Dorn et at. [13] also solved Cycle Packing in subexponential time $2^{\mathcal{O}(\sqrt{k})} \cdot |V|^{\mathcal{O}(1)}$. Moreover, for apex-minor-free graphs, Fomin et al. [17] showed that Cycle Packing admits a linear kernel, and Fomin et al. [16] showed that it also admits an EPTAS. When the input graph is a directed graph, Cycle Packing is W[1]-hard [39], but it admits an FPT approximation scheme [19]. In fact, Cycle Packing in directed graphs was the first W[1]-hard problem shown to admit such a scheme. Krivelevich et al. [30] obtained a factor $\mathcal{O}(|V|^{\frac{1}{2}})$ approximation algorithm for Cycle Packing in directed graphs and showed that this problem is quasi-NP-hard to approximate within a factor of $\mathcal{O}(\log^{1-\epsilon} |V|)$ for any $\epsilon > 0$.

Several variants of Cycle Packing have also received significant scientific attention. For example, the variant of Cycle Packing where one seeks k *odd* vertex-disjoint cycles has been widely studied [36, 40, 35, 29, 27, 28]. Another well-known variant, where the cycles need to contain a prescribed set of vertices, has also been extensively investigated [24, 33, 25, 23, 26]. Furthermore, a combination of these two variants has been considered in [23, 22].

Finally, we briefly mention that inspired by the Erdős-Pósa theorem, a class of graphs $\mathcal{H}$ is said to have the Erdős-Pósa property if there is a function $f(k)$ for which given a graph G, it either contains k vertex-disjoint subgraphs such that each of these subgraphs is isomorphic to a graph in $\mathcal{H}$, or it contains a set of $f(k)$ vertices that hits each of its subgraphs that is isomorphic to a graph in $\mathcal{H}$. A fundamental result in Graph Theory by Robertson and Seymour [37] states the the class of all graphs that can be contracted to a fixed planar graph H has the Erdős-Pósa property. Recently, Chekuri and Chuzhoy [6] presented a framework that leads to substantially improved functions $f(k)$ in the context of results in the spirit of the Erdős-Pósa theorem. Among other results, these two works are also related to the recent breakthrough result by Chekuri and Chuzhoy [7], which states that every graph of treewidth at least $f(k) = \mathcal{O}(k^{98} \cdot \text{polylog}(k))$ contains the $k \times k$ grid as a minor (the constant 98 has been improved to 36 in [8] and to 19 in [9]). Following the seminal work by Robertson and Seymour [37], numerous papers (whose survey is beyond the scope of this paper) investigated which other classes of graphs have the Erdős-Pósa property, which are the "correct" functions f associated with them, and which generalizations of this property lead to interesting discoveries.

1.2 Our Contribution

In this paper, we show that the running time of the algorithm that is a consequence of the Erdős-Pósa theorem is not essentially tight. For this purpose, we develop a $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$-time (deterministic) algorithm for Cycle Packing. In case a solution exists, our algorithm also outputs a solution (in time $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$). Moreover, apart from beating the bound $2^{\mathcal{O}(k \log^2 k)} \cdot |V|^{\mathcal{O}(1)}$, our algorithm runs in time linear in $|V|$, and its space complexity is polynomial in the input size. Thus, we also improve upon the classical $2^{\mathcal{O}(k^2)} \cdot |V|$-time algorithm by Bodlaender [5]. Our result is summarized in the following theorem.

▶ **Theorem 1.** *There exists a (deterministic) polynomial-space algorithm that solves* Cycle Packing *in time* $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$. *In case a solution exists, it also outputs a solution.*

At a high level to prove Theorem 1, the main idea is to look back at the classic algorithm based on the Erdős-Pósa property and to perform some trade-offs to get an improvement. Specifically, the idea is to compute a "relaxed feedback vertex set": a set S of size

$\mathcal{O}(k \log k / \log\log k)$ so that $G - S$ is not necessarily a forest, but it has no short cycles (of length $\mathcal{O}(\log k / \log\log k)$), even after contracting long detached paths to single edges. This creates a "relaxed" modulator that is smaller by a $\mathcal{O}(\log\log k)$ multiplicative factor than if we required S to be a feedback vertex set. After some cleaning step on this structure, and using the relaxed modulator, one can roughly guess the interaction between S and $G - S$ in the solution; this step amounts to guessing one of around $|S|!$ options, which is $\mathcal{O}(2^{k \log^2 k / \log\log k})$. Having fixed the interaction, we can contract any remaining long paths so that the whole remaining graph has $\mathcal{O}(k \log^{3/2} k)$ vertices; it is important here that this step goes through even when we work with the "relaxed" modulator S as explained above, instead of a normal feedback vertex set as in the classic algorithm. As the size of the graph is already bounded, a simple dynamic programming on subsets suffices to finish the proof. In order to achieve polynomial space usage, we employ a standard inclusion-exclusion procedure instead.

2 Preliminaries

We use standard terminology from the book of Diestel [12] for those graph-related terms that are not explicitly defined here. We only consider finite graphs possibly having self-loops and multi-edges. Moreover, using an appropriate reduction rule we restrict the maximum multiplicity of an edge to be 2. For a graph G, we use V and E to denote the vertex and edge sets of the graph G, respectively. For a vertex $v \in V$, we use $\deg_G(v)$ to denote the degree of v, i.e the number of edges incident on v, in the (multi) graph G. We also use the convention that a self-loop at a vertex v contributes 2 to its degree. For a vertex subset $S \subseteq V$, we let $G[S]$ and $G - S$ denote the graphs induced on S and $V \setminus S$, respectively. For a vertex subset $S \subseteq V$, we use $N_G(S)$ and $N_G[S]$ to denote the open and closed neighborhoods of S in G, respectively. That is, $N_G(S) = \{v \mid \{u, v\} \in E, u \in S\} \setminus S$ and $N_G[S] = N_G(S) \cup S$. In case $S = \{v\}$, we simply let $N(v) = N(S)$ and $N[v] = N[S]$. For a graph $G = (V, E)$ and an edge $e \in E$, we let G/e denote the graph obtained by contracting e in G. For $E' \subseteq \binom{V}{2}$, i.e. a subset of edges, we let $G + E'$ denote the (multi) graph obtained after adding the edges in E' to G, and we let G/E' denote the (multi) graph obtained after contracting the edges of E' in G. The girth of a graph is denoted by $\mathrm{girth}(G)$, its minimum degree by $\delta(G)$, and its maximum degree by $\Delta(G)$. A graph with no cycles has infinite girth.

A *path* in a graph is a sequence of distinct vertices $v_0, v_1, \ldots, v_\ell$ such that $\{v_i, v_{i+1}\}$ is an edge for all $0 \leq i < \ell$. A *cycle* in a graph is a sequence of distinct vertices $v_0, v_1, \ldots, v_\ell$ such that $\{v_i, v_{(i+1) \mod \ell+1}\}$ is an edge for all $0 \leq i \leq \ell$. Both a double edge and a self-loop are cycles. If P is a path from a vertex u to a vertex v in the graph G then we say that u and v are the end vertices of the path P and P is a (u, v)-path. For a path P, we use $V(P)$ and $E(P)$ to denote the sets of vertices and edges in the path P, respectively, and length of P is denoted by $|P|$ (i.e, $|P| = |V(P)|$). For a cycle C, we use $V(C)$ and $E(C)$ to denote the sets of vertices and edges in the cycle C, respectively, and the length of C, denoted by $|C|$, is $|V(C)|$. For a path or a cycle Q we use $N_G(Q)$ and $N_G[Q]$ to denote the sets $N_G(V(Q))$ and $N_G[V(Q)]$, respectively. For a collection of paths/cycles $\mathcal{Q}$, we use $|\mathcal{Q}|$ to denote the number of paths/cycles in $\mathcal{Q}$ and $V(\mathcal{Q})$ to denote the set $\bigcup_{Q \in \mathcal{Q}} V(Q)$. We say a path P in G is a *degree-two path* if all vertices in $V(P)$, including the end vertices of P, have degree exactly 2 in G. We say P is a *maximal degree-two path* if no proper superset of P also forms a degree-two path. We note that the notions of *walks* and *closed walks* are defined exactly as paths and cycles, respectively, except that their vertices need not be distinct. Finally, a *feedback vertex set* is a subset F of vertices such that $G - F$ is a forest.

Below we formally state some of the key results that will be used throughout the paper, starting with the classic Erdős-Pósa theorem [15].

▶ **Proposition 2** ([15]). *There exists a constant c' such that every (multi) graph either contains k vertex-disjoint cycles or it has a feedback vertex set of size at most $c'k\log k$.*

Observe that any (multi) graph $G=(V,E)$ whose feedback vertex set number is bounded by $c'k\log k$ has less than $(2c'k\log k+1)\cdot|V|$ edges (recall that we restrict the multiplicity of an edge to be 2). Indeed, letting F denote a feedback vertex set of minimum size, the worst case (in terms of $|E|$) is obtained when $G-F$ is a tree, which contains $|V|-|F|-1$ edges, and between every pair of vertices $v\in F$ and $u\in V$, there exists an edge of multiplicity 2. Thus, by Proposition 2, in case $|E|>(2c'k\log k+1)\cdot|V|$, the input instance is a yes-instance, and after we discard an arbitrary set of $|E|-(2c'k\log k+1)\cdot|V|$ edges, it remains a yes-instance. A simple operation which discards at least $|E|-(2c'k\log k+1)\cdot|V|$ edges and can be performed in time $\mathcal{O}(k\log k\cdot|V|)$.

▶ **Assumption 3.** *We assume that $|E|=\mathcal{O}(k\log k\cdot|V|)$.*

Now, we state our algorithmic version of Proposition 2. The proof partially builds upon the proof of the Erdős-Pósa theorem in the book [12], and it is given in the full version of the paper.

▶ **Theorem 4.** *There exists a constant c and a polynomial-space algorithm such that given a (multi) graph G and a non-negative integer k, in time $k^{\mathcal{O}(1)}\cdot|V|$ it either outputs k vertex-disjoint cycles or a feedback vertex set of size at most $ck\log k=r$.*

Next, we state two results relating to cycles of average and short lengths.

▶ **Proposition 5** ([1]). *Any (multi) graph $G=(V,E)$ on n vertices with average degree d contains a cycle of length at most $2\log_{d-1}n+2$.*

Itai and Rodeh [21] showed that given a (multi) graph $G=(V,E)$, an "almost" shortest cycle (if there is any) in G can be found in time $\mathcal{O}(|V|^2)$. To obtain a linear dependency on $|V|$ (given a small feedback vertex set), we prove the following result. A complete proof will appear in the full version of the paper.

▶ **Lemma 6.** *Given a (multi) graph $G=(V,E)$ and a feedback vertex set F of G, a shortest cycle (if there is any) in G can be found in time $\mathcal{O}(|F|\cdot(|V|+|E|))$.*

Finally, we state a result that will be used (in Lemma 11) to bound the size of a graph we obtain after performing simple preprocessing operations as well as repetitive removal of short cycles.

▶ **Proposition 7** ([34], Lemma 9). *Let $T=(V,E)$ be a forest on N vertices. Let $M'=\{\{i,j\}\in E\mid deg_T(i)=deg_T(j)=2\}$ and $L=\{a\in V\mid deg_T(a)\leq 1\}$. Then there exists $M\subseteq M'$ such that M is a matching and $|W|\geq\frac{N}{4}$ where $W=L\cup M$.*

3 Removing Leaves, Induced Paths, and Short Cycles

As is usually the case when dealing with cycles in a graph, we first define three rules which help getting rid of vertices of degree at most 2 as well as edges of multiplicity larger than 2. It is not hard to see that all three Reduction Rules A1, A2, and A3 are safe, i.e. they preserve solutions in the reduced graph.

▶ **Reduction Rule A1.** *Delete vertices of degree at most 1.*

▶ **Reduction Rule A2.** *If there is a vertex v of degree exactly 2 that is not incident to a self-loop, then delete v and connect its two (not necessarily distinct) neighbors by a new edge.*

▶ **Reduction Rule A3.** *If there is a pair of vertices u and v in V such that $\{u, v\}$ is an edge of multiplicity larger than 2, then reduce the multiplicity of the edge to 2.*

Observe that the entire process that applies these rules exhaustively can be done in time $\mathcal{O}(|V| + |E|) = \mathcal{O}(k \log k \cdot |V|)$. Indeed, in time $\mathcal{O}(|V|)$ we first remove the vertex-set of each maximal path between a leaf and a degree-two vertex. No subsequent application of Rule A2 or Rule A3 creates vertices of degree at most one. Now, we iterate over the set of degree-two vertices. For each degree-two vertex that is not incident to a self-loop, we apply Rule A2. Next, we iterate over E, and for each edge of multiplicity larger than two, we apply Rule A3. At this point, the only new degree-two vertices that can be created are vertices incident to exactly one edge, whose multiplicity is two. Therefore, during one additional phase where we exhaustively apply Rule A2, the only edges of multiplicity larger than two that can be created are self-loops. Thus, after one additional iteration over E, we can ensure that no rule among Rules A1, A2 and A3 is applicable.

Since these rules will be applied dynamically and iteratively, we define an operator, denoted by $\mathsf{reduce}(G)$, that takes as input a graph G and returns the (new) graph G' that results from an exhaustive application of Rules A1, A2 and A3.

▶ **Definition 8.** For a (multi) graph G, we let $G' = \mathsf{reduce}(G)$ denote the graph obtained after an exhaustive application of Reduction Rules A1, A2 and A3. $|\mathsf{reduce}(G)|$ denotes the number of vertices in $\mathsf{reduce}(G)$. Moreover, $\mathsf{img}(\mathsf{reduce}(G))$ denotes the pre-image of $\mathsf{reduce}(G)$, i.e. $\mathsf{img}(\mathsf{reduce}(G))$ is the set of vertices in G which are not deleted in $\mathsf{reduce}(G)$.

▶ **Observation 9.** *For a graph $G = (V, E)$ and a set $E' \subseteq \binom{V}{2}$ it holds that $|\mathsf{reduce}(G+E')| \leq |\mathsf{reduce}(G)| + 2|E'|$.*

The first step of our algorithm consists of finding, in time linear in $|V|$, a set S satisfying the conditions specified in Lemmata 10 and 11. Intuitively, S will contain vertices of "short" cycles in the input graph, where short will be defined later.

▶ **Lemma 10.** *Given a (multi) graph $G = (V, E)$ and two integers $k > 0$ and $g > 6$, there exists an $k^{\mathcal{O}(1)} \cdot |V|$-time algorithm that either finds k vertex-disjoint cycles in G or finds a (possibly empty) set $S \subseteq V$ such that girth$(\mathsf{reduce}(G - S)) > g$ and $|S| < gk$.*

Proof. We proceed by constructing such an algorithm. First, we apply the algorithm of Theorem 4 which outputs either k vertex-disjoint cycles or a feedback vertex set F of size at most $ck \log k = r$. In the former case we are done. In the latter case, i.e. the case where a feedback vertex set F is obtained, we apply the following procedure iteratively (initially, we set $S = \emptyset$):

(1) Apply Lemma 6 to find a shortest cycle C in $\mathsf{reduce}(G)$.
(2) If no cycle was found or $|C| > g$ then return S.
(3) Otherwise, i.e. if $|C| \leq g$, then add the vertices of C to S, delete those vertices from G to obtain G', set $G = G'$, and repeat from Step (1).

Note that if Step (3) is applied k times then we can terminate and return the corresponding k vertex-disjoint cycles in G. Hence, when the condition of Step (2) is satisfied, i.e. when the described procedure terminates, the size of S is at most $g(k-1) < gk$ and girth$(\mathsf{reduce}(G - S)) > g$. Since the algorithm of Theorem 4 runs in time $k^{\mathcal{O}(1)} \cdot |V|$, and each iteration of Steps (1)-(3) is performed in time $\mathcal{O}((k \log k)^2 \cdot |V|)$, we obtain the desired time complexity. ◀

▶ **Lemma 11.** *Given a (multi) graph $G = (V, E)$ and two integers $k > 0$ and $g > 6$, let S denote the set obtained after applying the algorithm of Lemma 10 (assuming no k vertex-disjoint cycles obtained). Then $|\mathsf{reduce}(G - S)| \leq (2ck \log k)^{1+\frac{6}{g-6}} + 3ck \log k$.*

Proof. Let $G' = (V', E') = \mathsf{reduce}(G - S)$ and $|V'| = n'$. First, recall that G admits a feedback vertex set of size at most $ck \log k = r$. Since Reduction Rules A1, A2 and A3 do not increase the feedback vertex set of the graph (see, e.g., [34], Lemma 1), G' also admits a feedback vertex set F of size at most r. Let T denote the induced forest on the remaining $N = n' - r$ vertices in G'. Moreover, from Lemma 10, we know that $\text{girth}(G') > g > 6$.

Next, we apply Proposition 7 to T to get W. Now with every element $a \in W$ we associate an unordered pair of vertices of F as follows. Assume $a \in L$, i.e. a is a vertex of degree 0 or 1. Since the degree of a is at least 3 in G', a has at least two neighbors in F. We pick two of these neighbors arbitrarily and associate them with a. We use $\{x_a, y_a\}$ to denote this pair. If $a = \{u, v\}$ is an edge from M then each of u and v has degree at least 3 in G' and each has at least one neighbor in F. We pick one neighbor for each and associate the pair $\{x_u, x_v\}$ with a. Note that since $\text{girth}(G') > 6$, $x_u \neq x_v$ and $x_a \neq y_a$.

We now construct a new multigraph $G^\star = (V^\star, E^\star)$ with vertex set $V^\star = F$ as follows. For every vertex $a \in W$ we include an edge in $E^\star$ between x_a and y_a, and for every edge $a = \{u, v\} \in W$ we include an edge in $E^\star$ between x_u and x_v. By Proposition 7, we know that W is of size at least $\frac{N}{4}$. It follows that $G^\star$ has at least $\frac{N}{4}$ edges and hence its average degree is at least $\frac{N}{2r}$ as $|V^\star| = ck \log k = r$. Note that if $G^\star$ has a cycle of length at most ℓ, then G' has a cycle of length at most 3ℓ, as any edge of the cycle in $G^\star$ can be replaced by a path of length at most 3 in G'. Combining this with the fact that $\text{girth}(G') > g > 6$, we conclude that $G^\star$ contains no self-loops or parallel edges. Hence $G^\star$ is a simple graph with average degree at least $\frac{N}{2r}$. By Proposition 5, $G^\star$ must have a cycle of length at most

$$2 \log_{\frac{N}{2r}-1} r + 2 = \frac{2 \log r}{\log(\frac{N}{2r} - 1)} + 2$$

which implies that G' must have a cycle of length at most

$$\frac{6 \log r}{\log(\frac{N}{2r} - 1)} + 6.$$

Finally, by using the fact that $\text{girth}(G') > g$ and substituting N and r, we get

$$\begin{aligned}
\frac{6 \log r}{\log(\frac{N}{2r} - 1)} + 6 > g \quad &\iff \log r > \frac{(g-6)}{6} \log\left(\frac{N - 2r}{2r}\right) \\
&\iff \log r > \frac{(g-6)}{6} \log(N - 2r) - \frac{(g-6)}{6} \log(2r) \\
&\iff \frac{\log r + \frac{(g-6)}{6} \log(2r)}{\frac{(g-6)}{6}} > \log(N - 2r) \\
&\implies \frac{\log(2r) + \frac{(g-6)}{6} \log(2r)}{\frac{(g-6)}{6}} > \log(N - 2r) \\
&\iff (1 + \frac{6}{g-6}) \log(2r) > \log(N - 2r) \\
&\iff (1 + \frac{6}{g-6}) \log(2ck \log k) > \log(n' - 3ck \log k) \\
&\iff (2ck \log k)^{1+\frac{6}{(g-6)}} + 3ck \log k > n'.
\end{aligned}$$

This completes the proof. ◀

The usefulness of Lemma 11 comes from the fact that by setting $g = \frac{48 \log k}{\log \log k} + 6$, we can guarantee that $|\mathsf{reduce}(G - S)| < 3ck \log k + 2ck \log^{1.5} k$, and therefore we can beat the $\mathcal{O}(k \log^2 k)$ bound. That is, we have the following consequence.

▶ **Corollary 12.** *Given a (multi) graph $G = (V, E)$ and an integer $k > 0$, let S denote the set obtained after applying the algorithm of Lemma 10 with $g = \frac{48 \log k}{\log \log k} + 6$ (assuming no k vertex-disjoint cycles obtained). Then $|\mathsf{reduce}(G - S)| \leq 3ck \log k + 2ck \log^{1.5} k$.*

Proof. By Lemma 11, $|\mathsf{reduce}(G - S)| \leq (2ck \log k)^{1+\frac{\log \log k}{8 \log k}} + 3ck \log k$. Assuming $k > \log k > c > 2$, we have $(2ck \log k)^{1+\frac{\log \log k}{8 \log k}} = (2ck \log k)(2ck \log k)^{\frac{\log \log k}{8 \log k}} \leq (2ck \log k)k^{\frac{4 \log \log k}{8 \log k}}$. Now note that $k^{\frac{4 \log \log k}{8 \log k}} \leq \log^{0.5} k$. Hence, $(2ck \log k)^{1+\frac{\log \log k}{8 \log k}} \leq 2ck \log k \log^{\frac{1}{2}} k \leq 2ck \log^{1.5} k$. This completes the proof. ◀

4 Bounding the Core of the Remaining Graph

At this point, we assume, without loss of generality, that we are given a graph $G = (V, E)$, a positive integer k, $g = \frac{48 \log k}{\log \log k} + 6$, and a set $S \subseteq V$ such that $\mathrm{girth}(\mathsf{reduce}(G - S)) > g$, $|S| < gk$, and $|\mathsf{reduce}(G - S)| \leq 3ck \log k + 2ck \log^{1.5} k$.

Even though the number of vertices in $\mathsf{reduce}(G - S)$ is bounded, the number of vertices in $G - S$ is unbounded. In what follows, we show how to bound the number of "objects" in $G - S$, where an object is either a vertex in $G - S$ or a degree-two path in $G - S$. The next lemma is a refinement extending a lemma by Lokshtanov et al. [31] (Lemma 5.2).

▶ **Lemma 13.** *Let $G = (V, E)$ be a (multi) graph and let $X \subseteq V$ be any subset of the vertices of G. Suppose there are more than $|X|^2(2|X| + 1)$ vertices in $G - X$ whose degree in $G - X$ is at most one. Then, there is either an isolated vertex w in $G - X$ or an edge $e \in E$ such that (G, k) is a yes-instance of* Cycle Packing *if and only if either $(G - \{w\}, k)$ or $(G/e, k)$ is a yes-instance. Moreover, there is an $\mathcal{O}(|X|^2 \cdot k \log k \cdot |V|)$-time algorithm that given G and X, outputs sets $V_X \subseteq V \setminus X$ and $E_X \subseteq E(G - X)$ such that, for the graph $G' = (G/E_X) - V_X$, it holds that (G, k) is a yes-instance of* Cycle Packing *if and only if (G', k) is a yes-instance of* Cycle Packing*, and $G' - X$ contains at most $|X|^2(2|X| + 1)$ vertices whose degree in $G' - X$ is at most one.*

Armed with Lemma 13, we are now ready to prove the following result. For a forest T, we let $T_{\leq 1}$, T_2, and $T_{\geq 3}$, denote the sets of vertices in T having degree at most one in T, degree exactly two in T, and degree larger than two in T, respectively. Moreover, we let $\mathcal{P}$ denote the set of all maximal degree-two paths in T.

▶ **Lemma 14.** *Let $G = (V, E)$, S, k, and g be as defined above. Let $R = \mathsf{img}(\mathsf{reduce}(G - S)) \subseteq (V \setminus S)$ denote the pre-image of $\mathsf{reduce}(G - S)$ in $G - S$. Then, $T = G - S - R$ is a forest and for every maximal degree-2 path in $\mathcal{P}$ there are at most two vertices on the path having neighbors in R (in the graph $G - S$). Moreover, in time $k^{\mathcal{O}(1)} \cdot |V|$, we can guarantee that $|T_{\leq 1}|$, $|\mathcal{P}|$, and $|T_{\geq 3}|$ are bounded by $k^{\mathcal{O}(1)}$.*

Proof. To see why $T = G - S - R$ must be a forest it is sufficient to note that for any cycle in $G - S$ at least one vertex from that cycle must be in $R = \mathsf{img}(\mathsf{reduce}(G - S))$ (see Figure 1). Recall that, since $\mathrm{girth}(\mathsf{reduce}(G - S)) > 6$, every vertex in R has degree at least 3 in $G - S$. Now assume there exists some path $P \in \mathcal{P}$ having exactly three (the same argument holds for any number) distinct vertices u, v and w (in that order) each having at least one neighbor in R (possibly the same neighbor). We show that the middle vertex v must have been in R,

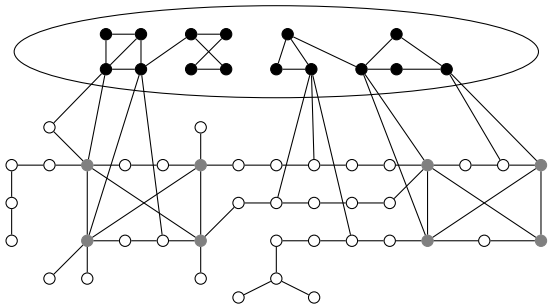

Figure 1 A graph G (not all edges shown), the set S (in black), the set R (in gray), and the set $T = G - R - S$ (in white).

contradicting the fact that $T = G - S - R$. Consider the graph $G - S$ and apply Reduction Rules A1, A2 and A3 exhaustively (in $G - S$) on all vertices in the tree containing P except for u, v and w. Regardless of the order in which we apply the reduction rules, the path P will eventually reduce to a path on three vertices, namely u, v, and w. To see why v must be in R observe that even if the other two vertices have degree two in the resulting graph, after reducing them, v will have degree at least three (into R) and is therefore non-reducible.

Next, we bound the size of $T_{\leq 1}$, which implies a bound on the sizes of $T_{\geq 3}$ and $\mathcal{P}$. To do so, we simply invoke Lemma 13 by setting $X = S \cup R$. Since $|S| < gk$, $g = \frac{48 \log k}{\log \log k} + 6$ and $|R| \leq 3ck \log k + 2ck \log^{1.5} k$, we get that $|T_{\leq 1}| \leq |S \cup R|^2(2|S \cup R| + 1) = k^{\mathcal{O}(1)}$. Since in a forest, it holds that $|T_{\geq 3}| < |T_{\leq 1}|$, the bound on $|T_{\geq 3}|$ follows. Moreover, in a forest, it also holds that $|\mathcal{P}| < |T_{\leq 1}| + |T_{\geq 3}|$ – if we arbitrarily root each tree in the forest at a leaf, one end vertex of a path in $\mathcal{P}$ will be a parent of a different vertex from $T_{\leq 1} \cup T_{\geq 3}$ – the bound on $|\mathcal{P}|$ follows as well. ◀

5 Guessing Permutations

This section is devoted to proving the following lemma. Note that assuming the statement of the lemma, the only remaining task (to prove Theorem 1) is to develop an algorithm running in time $\mathcal{O}(2^{|V|} \cdot \text{poly}(|V|))$ and using polynomial space, which we present in Section 6.

▶ **Lemma 15.** *Given an instance (G, k) of* Cycle Packing*, we can in time $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$ and polynomial space compute $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})}$ instances of* Cycle Packing *of the form (G', k), where the number of vertices in G' is bounded by $\mathcal{O}(k \log^{1.5} k)$, such that (G, k) is a yes-instance if and only if at least one of the instances (G', k) is a yes-instance.*[2]

Proof. We fix $g = \frac{48 \log k}{\log \log k} + 6$. Using Lemma 10, we first compute a set S in time $k^{\mathcal{O}(1)} \cdot |V|$. Then, we guess which vertices to delete from S – that is, which vertices do not participate in a solution – in time $\mathcal{O}(2^{gk}) = 2^{\mathcal{O}(\frac{k \log k}{\log \log k})}$. Here, guesses refer to different choices which lead to the construction of different instances of Cycle Packing that are returned at the end (recall that we are allowed to return up to $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})}$ different instances). Combining Lemma 10 and Corollary 12, we now have a set $S \subseteq V$ such that $|S| = \mathcal{O}(\frac{k \log k}{\log \log k})$, and $|\mathsf{reduce}(G - S)| = \mathcal{O}(k \log^{1.5} k)$.

[2] In practice, to use polynomial space, we output the instances one-by-one.

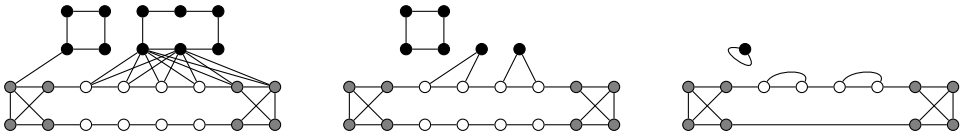

Figure 2 [Left] A graph G (not all edges shown), the set S (in black), the set R (in gray), and the set $T = G - R - S$ (in white). [Center] the graph obtained after guessing vertices in S and their neighbors in a solution. [Right] Example of a reduced instance.

Applying Lemma 14 with $R = \mathsf{img}(\mathsf{reduce}(G-S)) \subseteq (V \setminus S)$, we get a forest $T = G-(S \cup R)$ such that for every maximal degree-two path in $\mathcal{P}$ there are at most two vertices on the path having neighbors in R (in the graph $G - S$). In addition, the size of R is bounded by $\mathcal{O}(k \log^{1.5} k)$, and the sizes $|T_{\leq 1}|$, $|\mathcal{P}|$ and $|T_{\geq 3}|$ are bounded by $k^{\mathcal{O}(1)}$ (see Figure 1).

For every vertex in S (which is assumed to participate in a solution), we now guess its two neighbors in a solution (see Figure 2). Note however that we only have a (polynomial in k) bound for $|S|$, $|R|$, $|T_{\leq 1}|$, $|\mathcal{P}|$ and $|T_{\geq 3}|$, but not for the length of paths in $\mathcal{P}$ and therefore not for the entire graph G. We let $Z_{\mathcal{P}}$ denote the set of vertices in $V(\mathcal{P})$ having neighbors in R. The size of $Z_{\mathcal{P}}$ is at most $2|\mathcal{P}|$. Moreover, we let $\mathcal{P}^\star$ denote the set of paths obtained after deleting $Z_{\mathcal{P}}$ from $\mathcal{P}$. Note that the size of $\mathcal{P}^\star$ is upper bounded by $|\mathcal{P}| + |Z_{\mathcal{P}}| \leq 3|\mathcal{P}|$, and that vertices in $V(\mathcal{P}^\star)$ are adjacent only to vertices in $V(\mathcal{P}^\star) \cup Z_{\mathcal{P}} \cup S$. Now, we create a set of "objects", $O = S \cup R \cup T_{\leq 1} \cup T_{\geq 3} \cup Z_{\mathcal{P}} \cup \mathcal{P}^\star$. We also denote $\widetilde{O} = O \setminus \mathcal{P}^\star$. We then guess, for each vertex in S, which two objects in O constitute its neighbors, denoted by $\ell(v)$ and $r(v)$, in a solution. It is possible that $\ell(v) = r(v)$. Since $|O| = k^{\mathcal{O}(1)}$, we can perform these guesses in $k^{\mathcal{O}(\frac{k \log k}{\log \log k})}$, or equivalently $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})}$, time. We can assume that if $\ell(v) \in \widetilde{O}$, then $\ell(v)$ is a neighbor of v, and otherwise v has a neighbor on the path $\ell(v)$, else the current guess is not correct, and we need not try finding a solution subject to it. The same claim holds for $r(v)$. If $\ell(v) = r(v) \in \widetilde{O}$, then $\{v, \ell(v)\}$ is an edge of multiplicity two, and otherwise if $\ell(v) = r(v)$, then v has (at least) two neighbors on the path $\ell(v)$.

Next, we fix some arbitrary order on $\mathcal{P}^\star$, and for each path in $\mathcal{P}^\star$, we fix some arbitrary orientation. We let $S^\star$ denote the multiset containing two occurrences of every vertex $v \in S$, denoted by v_ℓ and v_r. We guess an order of the vertices in $S^\star$. The time spent for guessing such an ordering is bounded by $|S|!$, which in turn is bounded by $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})}$. The ordering, assuming it is guessed correctly, satisfies the following conditions. For each path $P \in \mathcal{P}^\star$, we let $\ell(P)$ and $r(P)$ denote the sets of vertices $v \in S$ such that $\ell(v) \in V(P)$ and $r(v) \in V(P)$, respectively. Now, for any two vertices $u, v \in \ell(P)$, if $u_\ell < v_\ell$ according to the order that we guessed, then the neighbor $\ell(u)$ of u appears before the neighbor $\ell(v)$ of v on P. Similarly, for any two vertices $u, v \in r(P)$, if $u_r < v_r$, then $r(u)$ appears before $r(v)$ on P. Finally, for any two vertices $u \in \ell(P)$ and $v \in r(P)$, if $u_\ell < v_r$, then $\ell(u)$ appears before $r(v)$ on P, and otherwise $r(v)$ appears before $\ell(u)$ on P.

Given a correct guess of $\ell(v)$ and $r(v)$, for each v in S, as well as a correct guess of a permutation of $S^\star$, for each path in $\mathcal{P}^\star$, we let $\{x_v, y_v\}$ denote the two guessed neighbors of a vertex v in S. Note that if $\ell(v)$ ($r(v)$) is in $\widetilde{O}$ then $x_v = \ell(v)$ ($y_v = r(v)$). Otherwise, we assign neighbors to a vertex by a greedy procedure which agrees with the guessed permutation on $S^\star$; that is, for every path $P \in \mathcal{P}^\star$, we iterate over $\ell(P) \cup r(P)$ according to the guessed order, and for each vertex in it, assign its first neighbor on P that is after the last vertex that has already been assigned (if such a vertex does not exist, we determine that the current guess is incorrect and proceed to the next one). We let $X = \{x_v \mid v \in S\}$ and $Y = \{y_v \mid v \in S\}$. We also let E_S be the set of edges incident on a vertex in S, and we let $E' = \{\{x_v, y_v\} \mid v \in S\}$

denote the set of all pairs of guesses. Finally, to obtain an instance (G', k), we delete the vertex set $W = S \setminus (X \cup Y)$ from G, we delete the edge set E_S from G, we add instead the set of edges E', and finally we apply the reduce operator, i.e. $G' = \mathsf{reduce}((G - W - E_S) + E')$.

▶ **Claim 16.** *Let (G', k) be one of the instances generated by the above procedure. Then, the number of vertices in G' is bounded by $\mathcal{O}(k \log^{1.5} k)$.*

Proof. Recall that by Corollary 12, we know that $|\mathsf{reduce}(G - S)| = \mathcal{O}(k \log^{1.5} k)$. Moreover, we have $|E'| = |S| = \mathcal{O}(\frac{k \log k}{\log \log k})$. Combining Observation 9 with the fact that $G' = \mathsf{reduce}((G - W - E_S) + E')$, we get $|\mathsf{reduce}((G - W - E_S) + E')| \leq |\mathsf{reduce}(G - W - E_S)| + 2|E'|$. Since in $G - W - E_S$ all vertices of S have degree zero, $|\mathsf{reduce}(G - W - E_S)| \leq |\mathsf{reduce}(G - S)|$. Hence, we conclude that $|\mathsf{reduce}((G - W - E_S) + E')| = \mathcal{O}(k \log^{1.5} k)$, as needed. ◀

▶ **Claim 17.** *(G, k) is a yes-instance if and only if at least one of the generated instances (G', k) is a yes-instance.*

Proof. Assume that (G, k) is a yes-instance and let $\mathcal{C} = \{C_1, C_2, \ldots\}$ be an optimal cycle packing, i.e set of maximum size of vertex-disjoint cycles, in G. Note that if no cycle in $\mathcal{C}$ intersects with S then $\mathcal{C}$ is also an optimal cycle packing in $G - S$. By the safeness of our reduction rules, $\mathcal{C}$ is also an optimal cycle packing in $\mathsf{reduce}(G - S)$. Since we generate one instance for every possible intersection between an optimal solution and S, the case where no vertex from S is picked corresponds to the instance (G', k), with $G' = \mathsf{reduce}(G - S)$. Hence, in what follows we assume that some cycles in $\mathcal{C}$ intersect with S. Consider any cycle C which intersects with S and let $P_C = \{u_0, u_1, \ldots, u_f\}$ denote any path on this cycle such that $u_0, u_f \notin S$ but $u_i \in S$ for $0 < i < f$. We claim that, for some G', all such paths will be replaced by edges of the form $\{u_0, u_f\}$ in $\mathsf{reduce}((G - W - E_S) + E')$. Again, due to our exhaustive guessing, for some G' we would have guessed, for each i, $\ell(u_i) = u_{i-1}$ and $r(u_i) = u_{i+1}$. Consequently, $P_C \setminus \{u_0, u_f\}$ is a degree-two path in $(G - W - E_S) + E'$ and therefore an edge in $\mathsf{reduce}((G - W - E_S) + E')$. Using similar arguments, it is easy to show that if C is completely contained in S then this cycle is contained in G' as a loop on some vertex of the cycle.

For the other direction, let (G', k) be a yes-instance and let $\mathcal{C}' = \{C'_1, C'_2, \ldots\}$ be an optimal cycle packing in G'. We assume, without loss of generality, that $\mathcal{C}'$ is a cycle packing in $(G - W - E_S) + E'$, as one can trace back all reduction rules to obtain the graph $(G - W - E_S) + E'$. If no cycle in $\mathcal{C}'$ uses an edge $\{u_0, u_f\} \in E'$ then we are done, as $(G - W - E_S)$ is a subgraph of G. Otherwise, we claim that all such edges either exist in G or can be replaced by vertex disjoint paths $P = \{u_0, u_1, \ldots, u_f\}$ (on at least three vertices) in G such that $u_i \in S$ for $0 < i < f$. If either u_0 or u_f is in $X \cup Y \subseteq S$ then the former case holds. It remains to prove the latter case. Recall that for every vertex in S we guess its two neighbors from $O = S \cup R \cup T_{\leq 1} \cup T_{\geq 3} \cup Z_{\mathcal{P}} \cup \mathcal{P}^\star$. Hence, if $\{u_0, u_f\} \subseteq \widetilde{O} = O \setminus \mathcal{P}^\star$ then one can easily find a path (or singleton) in $G[S]$ to replace this edge by simply backtracking the neighborhood guesses. Now assume that $\{u_0, u_f\} \not\subseteq \widetilde{O}$ and recall that no vertex in a path in $\mathcal{P}^\star$ can have neighbors in R. Hence, any cycle containing such an edge must intersect with S (in G). Assuming we have correctly guessed the neighbors of vertices in S (as well as a permutation for $\mathcal{P}^\star$), we can again replace this edge with a path in S. ◀

Combining Claims 16 and 17 concludes the proof of the theorem. ◀

6 Dynamic Programming and Inclusion-Exclusion

Finally, we give an exact exponential-time algorithm for Cycle Packing. For this purpose, we use DP and the principle of inclusion-exclusion, inspired by the work of Nederlof [32]. Due to space constraints, the details are given in the full version of the paper.

▶ **Lemma 18.** *There exists a (deterministic) polynomial-space algorithm that in time* $\mathcal{O}(2^{|V|} \cdot \text{poly}(|V|))$ *solves* Cycle Packing. *In case a solution exists, it also outputs a solution.*

We would like to mention that if one does not care about polynomial space, then Lemma 18 can be obtained by a straightforward dynamic programming on subsets.

7 Conclusion

In this paper we have beaten the best known $2^{\mathcal{O}(k \log^2 k)} \cdot |V|$-time algorithm for Cycle Packing that is a consequence of the Erdős-Pósa theorem. For this purpose, we developed a deterministic algorithm that solves Cycle Packing in time $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$. Two additional advantageous properties of our algorithm is that its space complexity is polynomial in the input size and that in case a solution exists, it outputs a solution (in time $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})} \cdot |V|$). Our technique relies on combinatorial arguments that may be of independent interest. These arguments allow us to translate any input instance of Cycle Packing into $2^{\mathcal{O}(\frac{k \log^2 k}{\log \log k})}$ instances of Cycle Packing whose sizes are small and can therefore be solved efficiently.

It remains an intriguing open question to discover the "true" running time, under reasonable complexity-theoretic assumptions, in which one can solve Cycle Packing on general graphs. In particular, we would like to pose the following question: Does there exist a $2^{\mathcal{O}(k \log k)} \cdot |V|^{\mathcal{O}(1)}$-time algorithm for Cycle Packing? This is true for graphs of bounded maximum degree as one can easily bound the number of vertices by $\mathcal{O}(k \log k)$ and then apply Lemma 18. Moreover, Bodlaender et al. [4] proved that this is also true in case one seeks k edge-disjoint cycles rather than k vertex-disjoint cycles. On the negative side, recall that (for general graphs) the bound $f(k) = \mathcal{O}(k \log k)$ in the Erdős-Pósa theorem is essentially tight, and that it is unlikely that Cycle Packing is solvable in time $2^{o(tw \log tw)} \cdot |V|^{\mathcal{O}(1)}$ [11]. However, we do not rule out the existence of an algorithm solving Cycle Packing in time $2^{\mathcal{O}(fvs)} \cdot |V|^{\mathcal{O}(1)}$. Thus, the two most natural attempts to obtain a $2^{\mathcal{O}(k \log k)} \cdot |V|^{\mathcal{O}(1)}$-time algorithm – either replacing the bound $\mathcal{O}(k \log k)$ in the Erdős-Pósa theorem by $\mathcal{O}(k)$ or speeding-up the computation based on DP to run in time $2^{\mathcal{O}(tw)} \cdot |V|^{\mathcal{O}(1)}$ – lead to a dead end.

Acknowledgements. We would like to thank the reviewers for several suggestions and insightful remarks that have improved the presentation of the paper.

Abstract

In this paper we study the problem of maintaining the strongly connected components of a graph in the presence of failures. In particular, we show that given a directed graph $G = (V, E)$ with $n = |V|$ and $m = |E|$, and an integer value $k \geq 1$, there is an algorithm that computes in $O(2^k n \log^2 n)$ time for any set F of size at most k the strongly connected components of the graph $G \setminus F$. The running time of our algorithm is almost optimal since the time for outputting the SCCs of $G \setminus F$ is at least $\Omega(n)$. The algorithm uses a data structure that is computed in a preprocessing phase in polynomial time and is of size $O(2^k n^2)$.

Our result is obtained using a new observation on the relation between strongly connected components (SCCs) and reachability. More specifically, one of the main building blocks in our result is a restricted variant of the problem in which we only compute strongly connected components that intersect a certain path. Restricting our attention to a path allows us to implicitly compute reachability between the path vertices and the rest of the graph in time that depends logarithmically rather than linearly in the size of the path. This new observation alone, however, is not enough, since we need to find an efficient way to represent the strongly connected components using paths. For this purpose we use a mixture of old and classical techniques such as the heavy path decomposition of Sleator and Tarjan [29] and the classical Depth-First-Search algorithm. Although, these are by now standard techniques, we are not aware of any usage of them in the context of dynamic maintenance of SCCs. Therefore, we expect that our new insights and mixture of new and old techniques will be of independent interest.

1 Introduction

Computing the strongly connected components (SCCs) of a directed graph $G = (V, E)$, where $n = |V|$ and $m = |E|$, is one of the most fundamental problems in computer science. There are several classical algorithms for computing the SCCs in $O(m + n)$ time that are taught in any standard undergraduate algorithms course [9].

In this paper we study the following natural variant of the problem in dynamic graphs. What is the fastest algorithm to compute the SCCs of $G \setminus F$, where F is any set of edges or vertices. The algorithm can use a polynomial size data structure computed in polynomial time for G during a preprocessing phase.

The main result of this paper is:

▶ **Theorem 1.** *There is an algorithm that computes the SCCs of $G \setminus F$, for any set F of k edges or vertices, in $O(2^k n \log^2 n)$ time. The algorithm uses a data structure of size $O(2^k n^2)$ computed in $O(2^k n^2 m)$ time for G during a preprocessing phase.*

Since the time for outputting the SCCs of $G \setminus F$ is at least $\Omega(n)$, the running time of our algorithm is optimal (up to a polylogarithmic factor) for any fixed value of k.

This dynamic model is usually called the fault tolerant model and its most important parameter is the time that it takes to compute the output in the presence of faults. It is an important theoretical model as it can be viewed as a restriction of the deletion only (decremental) model in which edges (or vertices) are deleted one after another and queries are answered between deletions. The fault tolerant model is especially useful in cases where the worst case update time in the more general decremental model is high.

There is wide literature on the problem of decremental SCCs. Recently, in a major breakthrough, Henzinger, Krinninger and Nanongkai [18] presented a randomized algorithm with $O(mn^{0.9+o(1)})$ total update time and broke the barrier of $\Omega(mn)$ for the problem. Even more recently, Chechik et al. [7] obtained an improved total running time of $O(m\sqrt{n \log n})$.

However, these algorithms and in fact all the previous algorithms have an $\Omega(m)$ worst case update time for a single edge deletion. This is not a coincidence. Recent developments in conditional lower bounds by Abboud and V. Williams [1] and by Henzinger, Krinninger, Nanongkai and Saranurak [19] showed that unless a major breakthrough happens, the worst case update time of a single operation in any algorithm for decremental SCCs is $\Omega(m)$. Therefore, in order to obtain further theoretical understanding on the problem of decremental SCCs, and in particular on the worst case update time it is only natural to focus on the restricted dynamic model of fault tolerant.

In the recent decade several different researchers used the fault tolerant model to study the worst case update time per operation for dynamic connectivity in undirected graphs. Pătraşcu and Thorup [26] presented connectivity algorithms that support edge deletions in this model. Their result was improved by the recent polylogarithmic worst case update time algorithm of Kapron, King and Mountjoy [21]. Duan and Pettie [13, 14] used this model to obtain connectivity algorithms that support vertex deletions.

In directed graphs, very recently, Georgiadis, Italiano and Parotsidis [16] considered the problem of SCCs but only for a single edge or a single vertex failure, that is $|F| = 1$. They showed that it is possible to compute the SCCs of $G \setminus \{e\}$ for any $e \in E$ (or of $G \setminus \{v\}$ for any $v \in V$) in $O(n)$ time using a data structure of size $O(n)$ that was computed for G in a preprocessing phase in $O(m + n)$ time. Our result is the first generalized result for any constant size F. This comes with the price of an extra $O(\log^2 n)$ factor in the running time, a slower preprocessing time and a larger data structure. In [16], Georgiadis, Italiano and Parotsidis also considered the problem of answering strong connectivity queries after one failure. They show construction of an $O(n)$ size oracle that can answer in constant time whether any two given vertices of the graph are strongly connected after failure of a single edge or a single vertex.

In a previous work [2] we considered the problem of finding a sparse subgraph that preserves single source reachability. More specifically, given a directed graph $G = (V, E)$ and

a vertex $s \in V$, a subgraph H of G is said to be a k-Fault Tolerant Reachability Subgraph (k-FTRS) for G if for any set F of at most k edges (or vertices), a vertex $v \in V$ is reachable from s in $G \setminus F$ if and only if v is reachable from s in $H \setminus F$. In [2] we proved that there exists a k-FTRS for s with at most $2^k n$ edges.

Using the k-FTRS structure, it is relatively straightforward to obtain a data structure that, for any pair of vertices $u, v \in V$ and any set F of size k, answers in $O(2^k n)$ time queries of the form:

"*Are u and v in the same SCC of $G \setminus F$?*"

The data structure consists of a k-FTRS for every $v \in V$. It is easy to see that u and v are in the same SCC of $G \setminus F$ if and only if v is reachable from u in k-FTRS$(u) \setminus F$ and u is reachable from v in k-FTRS$(v) \setminus F$. So the query can be answered by checking, using graph traversals, whether v is reachable from u in k-FTRS$(u) \setminus F$ and whether u is reachable from v in k-FTRS$(v) \setminus F$. The cost of these two graph traversals is $O(2^k n)$. The size of the data structure is $O(2^k n^2)$.

This problem, however, is much easier since the vertices in the query reveal which two k-FTRS we need to scan. In the challenge that we address in this paper *all* the SCCs of $G \setminus F$, for an arbitrary set F, have to be computed. However, using the same data structure as before, it is not really clear a-priori which of the k-FTRS we need to scan.

We note that our algorithm uses the k-FTRS which seems to be an essential tool but is far from being a sufficient one and more involved ideas are required. As an example to such a relation between a new result and an old tool one can take the deterministic algorithm of Łącki [23] for decremental SCCs in which the classical algorithm of Italiano [20] for decremental reachability trees in directed acyclic graphs is used. The main contribution of Łącki [23] is a new graph decomposition that made it possible to use Italiano's algorithm [20] efficiently.

1.1 An overview of our result

We obtain our $O(2^k n \log^2 n)$-time algorithm using several new ideas. Interestingly, one of the main building blocks is the following restricted variant of the problem.

> *Given any set F of k failed edges and any path P which is intact in $G \setminus F$, output all the SCCs of $G \setminus F$ that intersect with P (i.e. contain at least one vertex of P).*

To solve this restricted version, we implicitly solve the problem of reachability from x (and to x) in $G \setminus F$, for each $x \in P$. Though it is trivial to do so in time $O(2^k n|P|)$ using k-FTRS of each vertex on P, our goal is to preform this computation in $O(2^k n \log n)$ time, that is, in running time that is *independent* of the length of P (up to a logarithmic factor). For this we use a careful insight into the structure of reachability between P and V. Specifically, if $v \in V$ is reachable from $x \in P$, then v is also reachable from any predecessor of x on P, and if v is not reachable from x, then it cannot be reachable from any successor of x as well. Let w be any vertex on P, and let A be the set of vertices reachable from w in $G \setminus F$. Then we can split P at w to obtain two paths: P_1 and P_2. We already know that all vertices in P_1 have a path to A, so for P_1 we only need to focus on set $V \setminus A$. Also the set of vertices reachable from any vertex on P_2 must be a subset of A, so for P_2 we only need to focus on set A. This suggests a divide-and-conquer approach which along with some more insight into the structure of k-FTRS helps us to design an efficient algorithm for computing all the SCCs that intersect P.

In order to use the above result to compute all the SCCs of $G \setminus F$, we need a clever partitioning of G into a set of vertex disjoint paths. A Depth-First-Search (DFS) tree plays a crucial role here as follows. Let P be any path from root to a leaf node in a DFS tree T. If we compute the SCCs intersecting P and remove them, then the remaining SCCs must be contained in subtrees hanging from path P. So to compute the remaining SCCs we do not need to work on the entire graph. Instead, we need to work on each subtree. In order to pursue this approach efficiently, we need to select path P in such a manner that the subtrees hanging from P are of small size. The heavy path decomposition of Sleator and Tarjan [29] helps to achieve this objective. [1]

Our algorithm and data structure can be extended to support insertions as well. More specifically, we can report the SCCs of a graph that is updated by insertions and deletions of k edges in the same running time.

1.2 Related work

The problem of maintaining the SCCs of a graph was studied in the decremental model. In this model the goal is to maintain the SCCs of a graph whose edges are being deleted by an adversary. The main parameters in this model are the worst case update time per an edge deletion and the total update from the first edge deletion until the last. Frigioni et al.[15] presented an algorithm that has an *expected* total update time of $O(mn)$ if all the deleted edges are chosen at random. Roditty and Zwick [28] presented a Las-Vegas algorithm with an *expected* total update time of $O(mn)$ and *expected* worst case update time for any single edge deletion of $O(m)$. Łącki [23] presented a deterministic algorithm with a total update time of $O(mn)$, and thus solved the open problem posed by Roditty and Zwick in [28]. However, the worst case update time per a single edge deletion of his algorithm is $O(mn)$. Roditty [27] improved the worst case update time of a single edge deletion to $O(m \log n)$. Recently, in a major breakthrough, Henzinger, Krinninger and Nanongkai [18] presented a randomized algorithm with $O(mn^{0.9+o(1)})$ total update time. Very recently, Chechik et al. [7] obtained a total update time of $O(m\sqrt{n \log n})$. Note that all the previous works on decremental SCC are with $\Omega(m)$ worst case update time. Whereas, our result directly implies $O(n \log^2 n)$ worst case update time as long as the total deletion length is constant.

Most of the previous work in the fault tolerant model is on variants of the shortest path problem. Demetrescu, Thorup, Chowdhury and Ramachandran [10] designed an $O(n^2 \log n)$ size data structure that can report the distance from u to v avoiding x for any $u, v, x \in V$ in $O(1)$ time. Bernstein and Karger [3] improved the preprocessing time of [10] to $O(mn \text{ polylog } n)$. Duan and Pettie [12] designed such a data structure for two vertex faults of size $O(n^2 \log n)$. Weimann and Yuster [31] considered the question of optimizing the preprocessing time using Fast Matrix Multiplication (FMM) for graphs with integer weights from the range $[-M, M]$. Grandoni and Vassilevska Williams [17] improved the result of [31] based on a novel algorithm for computing all the replacement paths from a given source vertex in the same running time as solving APSP in directed graphs.

For the problem of single source shortest paths Parter and Peleg [25] showed that for unweighted graphs there is a subgraph with $O(n^{3/2})$ edges that supports one fault. They also showed a matching lower bound. Recently, Parter [24] extended this result to two faults with $O(n^{5/3})$ edges for undirected graphs. She also showed a lower bound of $\Omega(n^{5/3})$.

[1] We note that the heavy path decomposition was also used in the fault tolerant model in STACS'10 paper of [22], but in a completely different way and for a different problem.

Baswana and Khanna [22] showed that there is a subgraph with $O(n \log n)$ edges that preserves the distances from s up to a multiplicative stretch of 3 upon failure of any single vertex. For the case of edge failures, sparse fault tolerant subgraphs exist for general k. Bilò et al. [4] showed that we can compute a subgraph with $O(kn)$ edges that preserves distances from s up to a multiplicative stretch of $(2k+1)$ upon failure of any k edges. They also showed that we can compute a data structure of $O(kn \log^2 n)$ size that is able to report the $(2k+1)$-stretched distance from s in $O(k^2 \log^2 n)$ time.

The questions of finding graph spanners, approximate distance oracles and compact routing schemes in the fault tolerant model were studied in [11, 8, 5, 6].

1.3 Organization of the paper

We describe notations, terminologies, some basic properties of DFS, heavy-path decomposition, and k-FTRS in Section 2. In Section 3, we describe the fault tolerant algorithm for computing the strongly connected components intersecting any path. We present our main algorithm for handling k failures in Section 4. The details on how to extend our algorithm and data structure to support insertions as well is provided in the full version.

2 Preliminaries

Let $G = (V, E)$ denote the input directed graph on $n = |V|$ vertices and $m = |E|$ edges. We assume that G is strongly connected, since if it is not the case, then we may apply our result to each strongly connected component of G. We first introduce some notations that will be used throughout the paper.

- T: A DFS tree of G.
- $T(v)$: The subtree of T rooted at a vertex v.
- $Path(a, b)$: The tree path from a to b in T. Here a is assumed to be an ancestor of b.
- $depth(Path(a, b))$: The depth of vertex a in T.
- G^R: The graph obtained by reversing all the edges in graph G.
- $H(A)$: The subgraph of a graph H induced by the vertices of subset A.
- $H \setminus F$: The graph obtained by deleting the edges in set F from graph H.
- In-Edges(v, H): The set of all incoming edges to v in graph H.
- $P[a, b]$: The subpath of path P from vertex a to vertex b, assuming a and b are in P and a precedes b.
- $P::Q$: The path formed by concatenating paths P and Q in G. Here it is assumed that the last vertex of P is the same as the first vertex of Q.

Our algorithm for computing SCCs in a fault tolerant environment crucially uses the concept of a k-fault tolerant reachability subgraph (k-FTRS) which is a sparse subgraph that preserves reachability from a given source vertex even after the failure of at most k edges in G. A k-FTRS is formally defined as follows.

▶ **Definition 2** (k-FTRS)**.** Let $s \in V$ be any designated source. A subgraph H of G is said to be a k-Fault Tolerant Reachability Subgraph (k-FTRS) of G with respect to s if for any subset $F \subseteq E$ of k edges, a vertex $v \in V$ is reachable from s in $G \setminus F$ if and only if v is reachable from s in $H \setminus F$.

In [2], we present the following result for the construction of a k-FTRS for any $k \geq 1$.

▶ **Theorem 3** ([2]). *There exists an $O(2^k mn)$ time algorithm that for any given integer $k \geq 1$, and any given directed graph G on n vertices, m edges and a designated source vertex s, computes a k-FTRS for G with at most $2^k n$ edges. Moreover, the in-degree of each vertex in this k-FTRS is bounded by 2^k.*

Our algorithm will require the knowledge of the vertices reachable from a vertex v as well as the vertices that can reach v. So we define a k-FTRS of both the graphs – G and G^R with respect to any source vertex v as follows.

- $\mathcal{G}(v)$: The k-FTRS of graph G with v as source obtained by Theorem 3.
- $\mathcal{G}^R(v)$: The k-FTRS of graph G^R with v as source obtained by Theorem 3.

The following lemma states that the subgraph of a k-FTRS induced by $A \subset V$ can serve as a k-FTRS for the subgraph $G(A)$ given that A satisfies certain properties.

▶ **Lemma 4.** *Let s be any designated source and H be a k-FTRS of G with respect to s. Let A be a subset of V containing s such that every path from s to any vertex in A is contained in $G(A)$. Then $H(A)$ is a k-FTRS of $G(A)$ with respect to s.*

Proof. Let F be any set of at most k failing edges, and v be any vertex reachable from s in $G(A) \setminus F$. Since v is reachable from s in $G \setminus F$ and H is a k-FTRS of G, so v must be reachable from s in $H \setminus F$ as well. Let P be any path from s to v in $H \setminus F$. Then (i) all edges of P are present in H and (ii) none of the edges of F appear on P. Since it is already given that every path from s to any vertex in A is contained in $G(A)$, therefore, P must be present in $G(A)$. So every vertex of P belongs to A. This fact combined with the inferences (i) and (ii) implies that P must be present in $H(A) \setminus F$. Hence $H(A)$ is k-FTRS of $G(A)$ with respect to s. ◀

The next lemma is an adaptation of Lemma 10 from Tarjan's classical paper on Depth First Search [30] to our needs (for proof see the full version).

▶ **Lemma 5.** *Let T be a DFS tree of G. Let $a, b \in V$ be two vertices without any ancestor-descendant relationship in T, and assume that a is visited before b in the DFS traversal of G corresponding to tree T. Every path from a to b in G must pass through a common ancestor of a and b in T.*

2.1 A heavy path decomposition

The heavy path decomposition of a tree was designed by Sleator and Tarjan [29] in the context of dynamic trees. This decomposition has been used in a variety of applications since then. Given any rooted tree T, this decomposition splits T into a set $\mathcal{P}$ of vertex disjoint paths with the property that any path from the root to a leaf node in T can be expressed as a concatenation of at most $\log n$ subpaths of paths in $\mathcal{P}$. This decomposition is carried out as follows. Starting from the root, we follow the path downward such that once we are at a node, say v, the next node traversed is the child of v in T whose subtree is of maximum size, where the size of a subtree is the number of nodes it contains. We terminate upon reaching a leaf node. Let P be the path obtained in this manner. If we remove P from T, we are left with a collection of subtrees each of size at most $n/2$. Each of these trees hangs from P through an edge in T. We carry out the decomposition of these trees recursively. The following lemma is immediate from the construction of a heavy path decomposition.

▶ **Lemma 6.** *For any vertex $v \in V$, the number of paths in $\mathcal{P}$ which start from either v or an ancestor of v in T is at most $\log n$.*

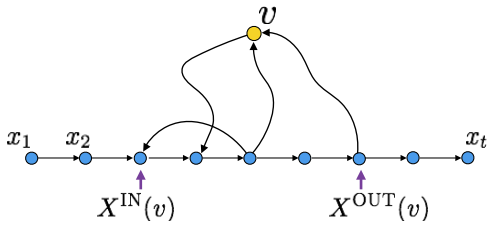

Figure 1 Depiction of $X^{\text{IN}}(v)$ and $X^{\text{OUT}}(v)$ for a vertex v whose SCC intersects X.

We now introduce the notion of ancestor path.

▶ **Definition 7.** A path $Path(a_1, b_1) \in \mathcal{P}$ is said to be an ancestor path of $Path(a_2, b_2) \in \mathcal{P}$, if a_1 is an ancestor of a_2 in T.

In this paper, we describe the algorithm for computing SCCs of graph G after any k edge failures. Vertex failures can be handled by simply splitting each vertex v into edge (v_{in}, v_{out}), where the incoming and outgoing edges of v are directed to v_{in} and from v_{out}, respectively.

3 Computation of SCCs intersecting a given path

Let F be a set of at most k failing edges, and $X = (x_1, x_2, \ldots, x_t)$ be any path in G from x_1 to x_t which is intact in $G \setminus F$. In this section, we present an algorithm that outputs in $O(2^k n \log n)$ time the SCCs of $G \setminus F$ that intersect X.

For each $v \in V$, let $X^{\text{IN}}(v)$ be the vertex of X of minimum index (if exists) that is reachable from v in $G \setminus F$. Similarly, let $X^{\text{OUT}}(v)$ be the vertex of X of maximum index (if exists) that has a path to v in $G \setminus F$. (See Figure 1).

We start by proving certain conditions that must hold for a vertex if its SCC in $G \setminus F$ intersects X.

▶ **Lemma 8.** *For any vertex $w \in V$, the SCC that contains w in $G \setminus F$ intersects X if and only if the following two conditions are satisfied.*

(i) *Both $X^{\text{IN}}(w)$ and $X^{\text{OUT}}(w)$ are defined, and*

(ii) *either $X^{\text{IN}}(w) = X^{\text{OUT}}(w)$, or $X^{\text{IN}}(w)$ appears before $X^{\text{OUT}}(w)$ on X.*

Proof. Consider any vertex $w \in V$. Let S be the SCC in $G \setminus F$ that contains w and assume S intersects X. Let w_1 and w_2 be the first and last vertices of X, respectively, that are in S. Since w and w_1 are in S there is a path from w to w_1 in $G \setminus F$. Moreover, w cannot reach a vertex that precedes w_1 in X since such a vertex will be in S as well and it will contradict the definition of w_1. Therefore, $w_1 = X^{\text{IN}}(w)$. Similarly we can prove that $w_2 = X^{\text{OUT}}(w)$. Since w_1 and w_2 are defined to be the first and last vertices from S on X, respectively, it follows that either $w_1 = w_2$, or w_1 precedes w_2 on X. Hence conditions (i) and (ii) are satisfied.

Now assume that conditions (i) and (ii) are true. The definition of $X^{\text{IN}}(\cdot)$ and $X^{\text{OUT}}(\cdot)$ implies that there is a path from $X^{\text{OUT}}(w)$ to w, and a path from w to $X^{\text{IN}}(w)$. Also, condition (ii) implies that there is a path from $X^{\text{IN}}(w)$ to $X^{\text{OUT}}(w)$. Thus w, $X^{\text{IN}}(w)$, and $X^{\text{OUT}}(w)$ are in the same SCC and it intersects X. ◀

The following lemma states the condition under which any two vertices lie in the same SCC, given that their SCCs intersect X.

▶ **Lemma 9.** *Let a, b be any two vertices in V whose SCCs intersect X. Then a and b lie in the same SCC if and only if $X^{\text{IN}}(a) = X^{\text{IN}}(b)$ and $X^{\text{OUT}}(a) = X^{\text{OUT}}(b)$.*

Algorithm 1: Binary-Search(i, j, A)

```
1 if (i = j) then
2 |   foreach v ∈ A do X^OUT(v) = x_i;
3 else
4 |   mid ← ⌈(i + j)/2⌉;
5 |   B ← Reach(x_mid, A);            /* vertices in A reachable from x_mid */
6 |   Binary-Search(i, mid-1, A\B);
7 |   Binary-Search(mid, j, B);
8 end
```

Proof. In the proof of Lemma 8, we show that if SCC of w intersects X, then $X^{\text{IN}}(w)$ and $X^{\text{OUT}}(w)$ are precisely the first and last vertices on X that lie in the SCC of w. Since SCCs forms a partition of V, vertices a and b will lie in the same SCC if and only if $X^{\text{IN}}(a) = X^{\text{IN}}(b)$ and $X^{\text{OUT}}(a) = X^{\text{OUT}}(b)$. ◀

It follows from the above two lemmas that in order to compute the SCCs in $G \setminus F$ that intersect with X, it suffices to compute $X^{\text{IN}}(\cdot)$ and $X^{\text{OUT}}(\cdot)$ for all vertices in V. It suffices to focus on computation of $X^{\text{OUT}}(\cdot)$ for all the vertices of V, since $X^{\text{IN}}(\cdot)$ can be computed in an analogous manner by just looking at graph G^R. One trivial approach to achieve this goal is to compute the set V_i consisting of all vertices reachable from each x_i by performing a BFS or DFS traversal of graph $\mathcal{G}(x_i) \setminus F$. Using this straightforward approach it takes $O(2^k nt)$ time to complete the task of computing $X^{\text{OUT}}(v)$ for every $v \in V$, while our target is to do so in $O(2^k n \log n)$ time.

Observe the nested structure underlying V_i's, that is, $V_1 \supseteq V_2 \supseteq \cdots \supseteq V_t$. Consider any vertex $x_\ell, 1 < \ell < t$. The nested structure implies for every $v \in V_\ell$ that $X^{\text{OUT}}(v)$ must be on the portion $(x_\ell, \ldots, x_t)$ of X. Similarly, it implies for every $v \in V_1 \setminus V_\ell$ that $X^{\text{OUT}}(v)$ must be on the portion $(x_1, \ldots, x_{\ell-1})$ of X. This suggests a divide and conquer approach to efficiently compute $X^{\text{OUT}}(\cdot)$. We first compute the sets V_1 and V_t in $O(2^k n)$ time each. For each $v \in V \setminus V_1$, we assign NULL to $X^{\text{OUT}}(v)$ as it is not reachable from any vertex on X; and for each $v \in V_t$ we set $X^{\text{OUT}}(v)$ to x_t. For vertices in set $V_1 \setminus V_t$, $X^{\text{OUT}}(\cdot)$ is computed by calling the function Binary-Search$(1, t-1, V_1 \setminus V_t)$. See Algorithm 1.

In order to explain the function Binary-Search, we first state an assertion that holds true for each recursive call of the function Binary-Search. We prove this assertion in the next subsection.

Assertion 1: If Binary-Search(i, j, A) is called, then A is precisely the set of those vertices $v \in V$ whose $X^{\text{OUT}}(v)$ lies on the path $(x_i, x_{i+1}, \ldots, x_j)$.

We now explain the execution of function Binary-Search(i, j, A). If $i = j$, then we assign x_i to $X^{\text{OUT}}(v)$ for each $v \in A$ as justified by Assertion 1. Let us consider the case when $i \neq j$. In this case we first compute the index $mid = \lceil (i + j)/2 \rceil$. Next we compute the set B consisting of all the vertices in A that are reachable from x_{mid}. This set is computed using the function Reach(x_{mid}, A) which is explained later in Subsection 3.2. As follows from Assertion 1, $X^{\text{OUT}}(v)$ for each vertex $v \in A$ must belong to path $(x_i, \ldots, x_j)$. Thus, $X^{\text{OUT}}(v)$ for all $v \in B$ must lie on path $(x_{mid}, \ldots, x_j)$, and $X^{\text{OUT}}(v)$ for all $v \in A \setminus B$ must lie on path $(x_i, \ldots, x_{mid\text{-}1})$. So for computing $X^{\text{OUT}}(\cdot)$ for vertices in $A \setminus B$ and B, we invoke the functions Binary-Search$(i, mid\text{-}1, A \setminus B)$ and Binary-Search(mid, j, B), respectively.

3.1 Proof of correctness of algorithm

In this section we prove that Assertion 1 holds for each call of the Binary-Search function. We also show how this assertion implies that $X^{\text{OUT}}(v)$ is correctly computed for every $v \in V$.

Let us first see how Assertion 1 implies the correctness of our algorithm. It follows from the description of the algorithm that for each $i, (1 \leq i \leq t-1)$, the function Binary-Search(i, i, A) is invoked for some $A \subseteq V$. Assertion 1 implies that A must be the set of all those vertices $v \in V$ such that $X^{\text{OUT}}(v) = x_i$. As can be seen, the algorithm in this case correctly sets $X^{\text{OUT}}(v)$ to x_i for each $v \in A$.

We now show that Assertion 1 holds true in each call of the function Binary-Search. It is easy to see that Assertion 1 holds true for the first call Binary-Search$(1, t-1, V_1 \setminus V_t)$. Consider any intermediate recursive call Binary-Search(i, j, A), where $i \neq j$. It suffices to show that if Assertion 1 holds true for this call, then it also holds true for the two recursive calls that it invokes. Thus let us assume A is the set of those vertices $v \in V$ whose $X^{\text{OUT}}(v)$ lies on the path $(x_i, x_{i+1}, \ldots, x_j)$. Recall that we compute index mid lying between i and j, and find the set B consisting of all those vertices in A that are reachable from x_{mid}. From the nested structure of the sets $V_i, V_{i+1}, \ldots, V_j$, it follows that $X^{\text{OUT}}(v)$ for all $v \in B$ must lie on path $(x_{mid}, \ldots, x_j)$, and $X^{\text{OUT}}(v)$ for all $v \in A \setminus B$ must lie on path $(x_i, \ldots, x_{mid\text{-}1})$. That is, B is precisely the set of those vertices whose $X^{\text{OUT}}(v)$ lies on the path $(x_{mid}, \ldots, x_j)$, and $A \setminus B$ is precisely the set of those vertices whose $X^{\text{OUT}}(v)$ lies on the path $(x_i, \ldots, x_{mid\text{-}1})$. Thus Assertion 1 holds true for the recursive calls Binary-Search$(i, mid\text{-}1, A \setminus B)$ and Binary-Search(mid, j, B) as well.

3.2 Implementation of function Reach

The main challenge left now is to find an efficient implementation of the function Reach which has to compute the vertices of its input set A that are reachable from a given vertex $x \in X$ in $G \setminus F$. The function Reach can be easily implemented by a standard graph traversal initiated from x in the graph $\mathcal{G}(x) \setminus F$ (recall that $\mathcal{G}(x)$ is a k-FTRS of x in G). This, however, will take $O(2^k n)$ time which is not good enough for our purpose, as the total running time of Binary-Search in this case will become $O(|X|2^k n)$. Our aim is to implement the function Reach in $O(2^k|A|)$ time. In general, for an arbitrary set A this might not be possible. This is because A might contain a vertex that is reachable from x via a single path whose vertices are not in A, therefore, the algorithm must explore edges incident to vertices that are not in A as well. However, the following lemma, that exploits Assertion 1, suggests that in our case as the call to Reach is done while running the function Binary-Search we can restrict ourselves to the set A only.

▶ **Lemma 10.** *If* Binary-Search(i, j, A) is called and $\ell \in [i, j]$, then for each path P from x_ℓ to a vertex $z \in A$ in graph in $G \setminus F$, all the vertices of P must be in the set A.

Proof. Assertion 1 implies that A is precisely the set of those vertices in V which are reachable from x_i but not reachable from x_{j+1} in $G \setminus F$. Consider any vertex $y \in P$. Observe that y is reachable from x_i by the path $X[x_i, x_\ell]::P[x_\ell, y]$. Moreover, y is not reachable from x_{j+1}, because otherwise z will also be reachable from x_{j+1}, which is not possible since $z \in A$. Thus vertex y lies in the set A. ◀

Lemma 10 and Lemma 4 imply that in order to find the vertices in A that are reachable from x_{mid}, it suffices to do traversal from x_{mid} in the graph G_A, the induced subgraph of A in $\mathcal{G}(x) \setminus F$, that has $O(2^k|A|)$ edges. Therefore, based on the above discussion, Algorithm 2 given below, is an implementation of function Reach that takes $O(2^k|A|)$ time.

Algorithm 2: Reach(x_{mid}, A)

```
1 H ← G(x_mid) \ F;
2 G_A ← (A, ∅);                                   /* an empty graph */
3 foreach v ∈ A do
4 |   foreach (y, v) ∈ In-Edges(v, H) do
5 |   |   if y ∈ A then E(G_A) = E(G_A) ∪ (y, v);
6 |   end
7 end
8 B ← Vertices reachable from x_mid obtained by a BFS or DFS traversal of graph G_A;
9 Return B;
```

The following lemma gives the analysis of running time of Binary-Search$(1, t-1, V_1 \setminus V_t)$.

▶ **Lemma 11.** *The total running time of* Binary-Search$(1, t-1, V_1 \setminus V_t)$ is $O(2^k n \log n)$.

Proof. The time complexity of Binary-Search$(1, t-1, V_1 \setminus V_t)$ is dominated by the total time taken by all invocation of function Reach. Let us consider the recursion tree associated with Binary-Search$(1, t-1, V_1 \setminus V_t)$. It can be seen that this tree will be of height $O(\log n)$. In each call of the Binary-Search, the input set A is partitioned into two disjoint sets. As a result, the input sets associated with all recursive calls at any level j in the recursion tree form a disjoint partition of $V_1 \setminus V_t$. Since the time taken by Reach is $O(2^k|A|)$, so the total time taken by all invocations of Reach at any level j is $O(2^k|V_1 \setminus V_t|)$. As there are at most $\log n$ levels in the recursion tree, the total time taken by Binary-Search$(1, t-1, V_1 \setminus V_t)$ is $O(2^k n \log n)$. ◀

We conclude with the following theorem.

▶ **Theorem 12.** *Let F be any set of at most k failed edges, and $X = \{x_1, x_2, \ldots, x_t\}$ be any path in $G \setminus F$. If we have prestored the graphs $\mathcal{G}(x)$ and $\mathcal{G}^R(x)$ for each $x \in X$, then we can compute all the SCCs of $G \setminus F$ which intersect with X in $O(2^k n \log n)$ time.*

4 Main Algorithm

In the previous section we showed that given any path P, we can compute all the SCCs intersecting P efficiently, if P is intact in $G \setminus F$. In the case that P contains ℓ failed edges from F then P is decomposed into $\ell + 1$ paths, and we can apply Theorem 12 to each of these paths separately to get the following theorem:

▶ **Theorem 13.** *Let P be any given path in G. Then there exists an $O(2^k n|P|)$ size data structure that for any arbitrary set F of at most k edges computes the SCCs of $G \setminus F$ that intersect the path P in $O((\ell+1)2^k n \log n)$ time, where ℓ $(\ell \leq k)$ is the number of edges in F that lie on P.*

Now in order to use Theorem 13 to design a fault tolerant algorithm for SCCs, we need to find a family of paths, say $\mathcal{P}$, such that for any F, each SCC of $G \setminus F$ intersects at least one path in $\mathcal{P}$. As described in the Subsection 1.1, a heavy path decomposition of DFS tree T serves as a good choice for $\mathcal{P}$. Choosing T as a DFS tree helps us because of the following reason: let P be any root-to-leaf path, and suppose we have already computed the SCCs in $G \setminus F$ intersecting P. Then each of the remaining SCCs must be contained in some subtree hanging from path P. The following lemma formally states this fact.

Algorithm 3: Compute SCC(G, F)

```
1  C ← ∅;                                          /* Collection of SCCs */
2  W ← ∅;                          /* A subset of V whose SCC have been computed */
3  P ← A heavy-path decomposition of T, where paths are sorted in the non-decreasing
     order of their depths;
4  foreach Path(a, b) ∈ P do
5  |  A ← Vertices lying in the subtree T(a);
6  |  (S_1, ..., S_t) ← SCCs intersecting Path(a, b) in G(A) \ F computed using D_{a,b};
7  |  foreach i ∈ [1, t] do
8  |  |  if (S_i ⊈ W) then Add S_i to collection C and set W = W ∪ S_i;
9  |  end
10 end
11 Return C;
```

▶ **Lemma 14.** *Let F be any set of failed edges, and $Path(a, b)$ be any path in $\mathcal{P}$. Let S be any SCC in $G \setminus F$ that intersects $Path(a, b)$ but does not intersect any ancestor path of $Path(a, b)$ in $\mathcal{P}$. Then all the vertices of S must lie in the subtree $T(a)$.*

Proof. Consider a vertex u on $Path(a, b)$ whose SCC S_u in $G \setminus F$ is not completely contained in the subtree $T(a)$. We show that S_u must contain an ancestor of a in T, thereby proving that it intersects an ancestor-path of $Path(a, b)$ in $\mathcal{P}$. Let v be any vertex in S_u that is not in the subtree $T(a)$. Let $P_{u,v}$ and $P_{v,u}$ be paths from u to v and from v to u, respectively, in $G \setminus F$. From Lemma 5 it follows that either $P_{u,v}$ or $P_{v,u}$ must pass through a common ancestor of u and v in T. Let this ancestor be z. Notice that all the vertices of $P_{u,v}$ and $P_{v,u}$ must lie in S_u. In particular, z must also lie in S_u. Moreover, since $v \notin T(a)$ and $u \in T(a)$, their common ancestor z in T is an ancestor of a. Since $z \in S_u$ and it is an ancestor of a in T, the lemma follows. ◀

Lemma 14 suggests that if we process the paths from $\mathcal{P}$ in the non-decreasing order of their depths, then in order to compute the SCCs intersecting a path $Path(a, b) \in \mathcal{P}$, it suffices to focus on the subgraph induced by the vertices in $T(a)$ only. This is because the SCCs intersecting $Path(a, b)$ that do not completely lie in $T(a)$ would have already been computed during the processing of some ancestor path of $Path(a, b)$.

We preprocess the graph G as follows. We first compute a heavy path decomposition $\mathcal{P}$ of DFS tree T. Next for each path $Path(a, b) \in \mathcal{P}$, we use Theorem 13 to construct the data structure for path $Path(a, b)$ and the subgraph of G induced by vertices in $T(a)$. We use the notation $\mathcal{D}_{a,b}$ to denote this data structure. Our algorithm for reporting SCCs in $G \setminus F$ will use the collection of these data structures associated with the paths in $\mathcal{P}$ as follows.

Let $\mathcal{C}$ denote the collection of SCCs in $G \setminus F$ initialized to $\emptyset$. We process the paths from $\mathcal{P}$ in non-decreasing order of their depths. Let $Path(a, b)$ be any path in $\mathcal{P}$ and let A be the set of vertices belonging to $T(a)$. We use the data structure $\mathcal{D}_{a,b}$ to compute SCCs of $G(A) \setminus F$ intersecting $Path(a, b)$. Let these be $S_1, \ldots, S_t$. Note that some of these SCCs might be a part of some bigger SCC computed earlier. We can detect it by keeping a set W of all vertices for which we have computed their SCCs. So if $S_i \subseteq W$, then we can discard S_i, else we add S_i to collection $\mathcal{C}$. Algorithm 3 gives the complete pseudocode of this algorithm.

Note that, in the above explanation, we only used the fact that T is a DFS tree, and $\mathcal{P}$ could have been any path decomposition of T. We now show how the fact that $\mathcal{P}$ is a heavy-path decomposition is crucial for the efficiency of our algorithm. Consider any vertex

$v \in T$. The number of times v is processed in Algorithm 3 is equal to the number of paths in $\mathcal{P}$ that start from either v or an ancestor of v. For this number to be small for each v, we choose $\mathcal{P}$ to be a heavy path decomposition of T. On applying Theorem 13, this immediately gives that the total time taken by Algorithm 3 is $O(k2^k n \log^2 n)$. In the next subsection, we do a more careful analysis to give a bound of $O(2^k n \log^2 n)$.

4.1 Analysis of time complexity of Algorithm 3

For any path $Path(a,b) \in \mathcal{P}$ and any set F of failing edges, let $\ell(a,b)$ denote the number of edges of F that lie on $Path(a,b)$. It follows from Theorem 13 that the time spent in processing $Path(a,b)$ by Algorithm 3 is $O\big((\ell(a,b)+1) \times 2^k |T(a)| \times \log n\big)$. Hence the time complexity of Algorithm 3 is of the order of

$$\sum_{Path(a,b)\in\mathcal{P}} (\ell(a,b)+1) \times 2^k |T(a)| \times \log n\,.$$

In order to calculate this we define a notation $\alpha(v, Path(a,b))$ as $\ell(a,b)+1$ if $v \in T(a)$, and 0 otherwise, for each $v \in V$ and $Path(a,b) \in \mathcal{P}$. So the time complexity of Algorithm 3 becomes

$$\begin{aligned} & 2^k \log n \times \Big(\sum_{Path(a,b)\in\mathcal{P}} (\ell(a,b)+1) \times |T(a)| \Big) \\ = {} & 2^k \log n \times \Big(\sum_{Path(a,b)\in\mathcal{P}} \sum_{v\in V} \alpha(v, Path(a,b)) \Big) \\ = {} & 2^k \log n \times \Big(\sum_{v\in V} \sum_{Path(a,b)\in\mathcal{P}} \alpha(v, Path(a,b)) \Big)\,. \end{aligned}$$

Observe that for any vertex v and $Path(a,b) \in \mathcal{P}$, $\alpha(v, Path(a,b))$ is equal to $\ell(a,b)+1$ if a is either v or an ancestor of v, otherwise it is zero. Consider any vertex $v \in V$. We now show that $\sum_{Path(a,b)\in\mathcal{P}} \alpha(v, Path(a,b))$ is at most $k + \log n$. Let P_v denote the set of those paths in $\mathcal{P}$ which starts from either v or an ancestor of v. Then $\sum_{Path(a,b)\in\mathcal{P}} \alpha(v, Path(a,b)) = \sum_{Path(a,b)\in P_v} \ell(a,b) + 1$. Note that $\sum_{Path(a,b)\in P_v} \ell(a,b)$ is at most k, and Lemma 6 implies that the number of paths in P_v is at most $\log n$. This shows that $\sum_{Path(a,b)\in\mathcal{P}} \alpha(v, Path(a,b))$ is at most $k + \log n$ which is $O(\log n)$, since $k \le \log n$.

Hence the time complexity of Algorithm 3 becomes $O(2^k n \log^2 n)$. We thus conclude with the following theorem.

▶ **Theorem 15.** *For any n-vertex directed graph G, there exists an $O(2^k n^2)$ size data structure that, given any set F of at most k failing edges, can report all the SCCs of $G \setminus F$ in $O(2^k n \log^2 n)$ time.*

Abstract

Preservers and additive spanners are sparse (hence cheap to store) subgraphs that preserve the distances between given pairs of nodes exactly or with some small additive error, respectively. Since real-world networks are prone to failures, it makes sense to study fault-tolerant versions of the above structures. This turns out to be a surprisingly difficult task. For every small but arbitrary set of edge or vertex failures, the preservers and spanners need to contain *replacement paths* around the faulted set. Unfortunately, the complexity of the interaction between replacement paths blows up significantly, even from 1 to 2 faults, and the structure of optimal preservers and spanners is poorly understood. In particular, no nontrivial bounds for preservers and additive spanners are known when the number of faults is bigger than 2.

Even the answer to the following innocent question is completely unknown: what is the worst-case size of a preserver for a *single pair* of nodes in the presence of f edge faults? There are no super-linear lower bounds, nor subquadratic upper bounds for $f > 2$. In this paper we make substantial progress on this and other fundamental questions:

- We present the first truly sub-quadratic size fault-tolerant single-pair preserver in unweighted (possibly directed) graphs: for any n node graph and *any* fixed number f of faults, $\tilde{O}(fn^{2-1/2^f})$ size suffices. Our result also generalizes to the single-source (all targets) case, and can be used to build new fault-tolerant additive spanners (for all pairs).
- The size of the above single-pair preserver grows to $O(n^2)$ for increasing f. We show that this is necessary even in undirected unweighted graphs, and even if you allow for a small additive error: If you aim at size $O(n^{2-\varepsilon})$ for $\varepsilon > 0$, then the additive error has to be $\Omega(\varepsilon f)$. This surprisingly matches known upper bounds in the literature.
- For weighted graphs, we provide matching upper and lower bounds for the single pair case. Namely, the size of the preserver is $\Theta(n^2)$ for $f \geq 2$ in both directed and undirected graphs, while for $f = 1$ the size is $\Theta(n)$ in undirected graphs. For directed graphs, we have a superlinear upper bound and a matching lower bound.

Most of our lower bounds extend to the distance oracle setting, where rather than a subgraph we ask for any compact data structure.

1 Introduction

Distance preservers and additive spanners are (sparse) subgraphs that preserve, either exactly or with some small additive error, the distances between given critical pairs P of nodes. This has been a subject of intense research in the last two decades [18, 11, 4, 3, 15, 6, 1, 34].

However, real-world networks are prone to failures. For this reason, more recently (e.g. [16, 14, 17, 32, 30, 9, 33, 8, 21, 27, 19, 28]) researchers have devoted their attention to fault-tolerant versions of the above structures, where distances are (approximately) preserved even in the presence of a few edge (or vertex) faults. For the sake of simplicity we focus here on edge faults, but many of these results generalize to the case of vertex faults where $F \subseteq V$.

▶ **Definition 1.** Given an n-node graph $G = (V, E)$ and $P \subseteq V \times V$, a subgraph $H \subseteq G$ is an f-fault tolerant (f-FT) β-additive P-pairwise spanner if

$$dist_{H \setminus F}(s,t) \leq dist_{G \setminus F}(s,t) + \beta, \quad \forall (s,t) \in P, \forall F \subseteq E, |F| \leq f.$$

If $\beta = 0$, then H is an f-FT P-pairwise preserver.

Finding sparse FT spanners/preservers turned out to be an incredibly challenging task. Despite intensive research, many simple questions have remained open, the most striking of which arguably is the following:

▶ **Question 1.** *What is the worst-case size of a preserver for a single pair (s,t) and $f \geq 1$ faults?*

Prior work [31, 32] considered the single-source $P = \{s\} \times V$ unweighted case, providing super-linear lower bounds for any f and tight upper bounds for $f = 1, 2$. However, first, there is nothing known for $f > 2$, and second, the lower bounds for the $\{s\} \times V$ case do not apply to the single pair case where much sparser preservers might exist. Prior to this work, it was conceivable that in this case $O(n)$ edges suffice for arbitrary fixed f.

Our first result is a *complete* answer to Question 1 for weighted graphs. For $f = 1$ and undirected graphs, we show that a $O(n)$ size preserver exists. Our result is achieved by proving the following interesting fact: for any replacement path $P_{s,t,e}$ protecting against a single edge fault e, there is an edge $(x, y) \in P_{s,t,e}$ such that there is no shortest path from s to x in G that includes e, and there is no shortest path from t to y in G that includes e. Therefore it is sufficient to build shortest path trees from s and to t, and then add one extra edge per possible fault e along the shortest path from s to t. With a trivial union bound, we get that any set P of node pairs can be preserved using $O(\min(n|P|, n^2))$ edges. It is natural to wonder if one can improve this union bound by doing something smarter in the construction. Surprisingly, the answer is NO: we are able to provide a matching lower bound.

▶ **Theorem 2.** *For any undirected n-node weighted graph G and any set P of p pairs of nodes, there exists a P-pairwise 1-FT preserver of size $O(\min(np, n^2))$. Furthermore, for any integer $1 \leq p \leq \binom{n}{2}$, there exists an undirected weighted graph G and a set P of p node pairs such that every 1-FT P-pairwise preserver of G contains $\Omega(\min(n|P|, n^2))$ edges.*

The lower bound part obtained by adapting the lower bound of [32] to the weighted case; this allows us to a lower bound graph whose number of edges is a function of the number of pairs.

For $f = 1$ and directed graphs, we achieve the following. Let $\mathtt{DP}(n)$ denote a tight bound for the sparsity of a pairwise distance preserver in directed weighted graphs with n nodes and $O(n)$ pairs.

▶ **Theorem 3.** *For every directed weighted n-node graph $G = (V, E)$ and for every pair of nodes $s, t \in V$, there is a 1-FT (s, t) preserver with $O(\mathtt{DP}(n))$ edges. For every n, there exists a directed weighted n-node graph $G = (V, E)$ and a node pair $s, t \in V$ such that any 1-FT (s, t) preserver for G has $\Omega(\mathtt{DP}(n))$ edges.*

Coppersmith and Elkin [18] show that $\Omega(n^{4/3}) \leq \mathtt{DP}(n) \leq O(n^{3/2})$. It is a major open question to close this gap, and we show that the no-fault n-pair distance preserver question is equivalent to the 1-fault single pair preserver question, thereby fully answering the latter question, up to resolving the major open problem for n-pair preservers.

We show that the situation dramatically changes for $f \geq 2$.

▶ **Theorem 4.** *There exists an undirected weighted graph G and a single node pair (s, t) in this graph such that every 2-FT (s, t) preserver of G requires $\Omega(n^2)$ edges.*

For unweighted graphs, we achieve several non-trivial upper and lower bounds concerning the worst-case size of (s, t) preservers and spanners. First of all, we address the following question.

▶ **Question 2.** *In unweighted graphs, is the worst-case size of an f-FT (s, t) preserver subquadratic for every constant $f \geq 2$?*

Prior work showed that the answer is YES for $f = 1, 2$ [31, 33], but nothing is known for $f \geq 3$. We show that the answer is YES. Indeed, our result is more general. First, it extends to the single-source case (i.e., $P = \{s\} \times V$) and even to a small enough set of sources (i.e., $P = S \times V$ for small $|S|$). Second, the same result holds for *any* fixed number f of vertex faults. Prior work was only able to address the simple case $f = 1$ [30]. We also remark that our preserver can be computed very efficiently in $O(fmn)$ time, and its analysis is relatively simple (e.g., compared to the cumbersome case analysis in [31]).

▶ **Theorem 5.** *For every directed or undirected unweighted graph $G = (V, E)$, integer $f \geq 1$ and $S \subseteq V$, one can construct in time $O(f\, n\, m)$ an f-FT S-sourcewise (i.e. $P = S \times V$) preserver of size $\widetilde{O}(f \cdot |S|^{1/2^f} \cdot n^{2-1/2^f})$, both in the case of edge and vertex faults.*

By standard techniques, we can exploit our S-sourcewise preserver to build an additive spanner (for all pairs): Let L be an integer parameter to be fixed later on. A vertex u is *low-degree* if it has degree less than L, otherwise it is *high-degree*. Let S be a random sample of $\Theta(\frac{n}{L} \cdot f \log n)$ vertices. Our spanner H consists of the f-VFT S-sourcewise preserver from Theorem 5 plus all the edges incident to low-degree vertices. This way we achieve:

▶ **Theorem 6.** *For every undirected unweighted graph $G = (V, E)$ and integer $f \geq 1$, there exists a randomized $\widetilde{O}(fnm)$-time construction of a $+2$-additive f-FT spanner of G of size $\widetilde{O}(f \cdot n^{2-1/(2^f+1)})$ that succeeds w.h.p.*[1].

In the above result the size of the preserver grows quickly to $O(n^2)$ for increasing f. This raises the following new question:

[1] The term w.h.p. (with high probability) here indicates a probability exceeding $1 - 1/n^c$, for an arbitrary constant $c \geq 2$. Since randomization is only used to select hitting sets, the algorithm can be derandomized.

▶ **Question 3.** *Does there exist a universal constant $\varepsilon > 0$ such that all unweighted graphs have an f-FT (s,t) preserver of size $O_f(n^{2-\varepsilon})$? What if we allow a small additive error?*

The only result with *strongly sub-quadratic* size in the above sense is an $O(f \cdot n^{4/3})$ size spanner with additive error $\Theta(f)$ [14, 8]. Can we remove or reduce the dependence of the error on f? We show that the answer is NO:

▶ **Theorem 7.** *For any two integers $q, h > 0$ and a sufficiently large n, there exists an unweighted undirected n-node graph $G = (V, E)$ and a pair $s, t \in V$ such that any $2hq$-FT $(2q-1)$-additive spanner for G for the single pair (s,t) has size $\Omega((\frac{n}{hq})^{2-2/(h+1)})$.*

▶ **Corollary 8.** *For any fixed constants $\varepsilon > 0$ and f, there exists an unweighted undirected n-node graph $G = (V, E)$ and a pair $s, t \in V$ such that any f-FT additive spanner for G for the single pair (s,t) of size $O(n^{2-\varepsilon})$ must have additive error $\Omega(\varepsilon f)$.*

Proof. This follows from Theorem 7 by choosing proper $h = \Theta(1/\varepsilon)$ and $q = \Theta(\varepsilon f)$. ◀

Hence the linear dependence in f in the additive error in [14, 8] is indeed necessary. We found this very surprising.

In Section 3 we present other related lower bounds which exploit the same basic construction plus ideas in [1, 10]: see Theorems 18, 19, and 20. In particular, we are able to achieve super-linear lower bounds for any $f \geq 2$, even if we allow for a small enough polynomial additive error n^{δ}.

So far we have focused on sparse distance preserving *subgraphs*. However, suppose that the distance estimates can be stored in a different way in memory. Data structures that store the distance information of a graph in the presence of faults are called *distance sensitivity oracles*. Distance sensitivity oracles are also intensely studied [20, 7, 38, 26, 22, 23]. Our main goal here[2] is to keep the size of the data structure as small as possible, leading to the following question.

▶ **Question 4.** *How much space do we need to preserve (exactly or with a small additive error) the distances between a given pair of nodes in the presence of f faults?*

Clearly all our preserver/spanner upper bounds extend to the oracle case, however the lower bounds might not: in principle a distance oracle can use much less space than a preserver/spanner with the same accuracy. Our main contribution here are the following incompressibility results:

▶ **Theorem 9.** *There exists an undirected weighted graph G and a single node pair (s,t) in this graph such that every 2-FT distance sensitivity oracle for the single pair (s,t) in G requires $\Omega(n^2)$ bits of space.*

Note that the optimal size for $f = 1$ is $\Theta(n)$ by simple folklore arguments, so our result completes our understanding in this setting.

We are able to achieve a super-linear lower bound for 3 faults even in the case of a small enough *polynomial additive error*: see Theorem 21 in Section 3.

[2] Other typical goals are to minimize preprocessing and query time - we will not address these.

1.1 Related Work

Fault-tolerant spanners were introduced in the geometric setting [27] (see also [28, 19]). FT-spanners with multiplicative stretch are relatively well understood: the error/sparsity for f-FT and f-VFT multiplicative spanners is (up to a small polynomial factor in f) the same as in the nonfaulty case. For f edge faults, Chechik et al. [16] showed how to construct f-FT $(2k-1)$-multiplicative spanners with size $\tilde{O}(fn^{1+\frac{1}{k}})$ for any $f, k \geq 1$. They also construct an f-VFT spanner with the same stretch and larger size. This was later improved by Dinitz and Krauthgamer [21] who showed the construction of f-VFT spanners with $2k-1$ error and $\tilde{O}\left(f^{2-\frac{1}{k}}n^{1+\frac{1}{k}}\right)$ edges.

FT additive spanners were first considered by Braunschvig, Chechik and Peleg in [14] (see also [8] for slightly improved results). They showed that FT $\Theta(f)$-additive spanners can be constructed by combining FT multiplicative spanners with (non-faulty) additive spanners. This construction, however, supports only edge faults. Parter and Peleg showed in [33] a lower bound of $\Omega(n^{1+\varepsilon_\beta})$ edges for single-source FT β-additive spanners. They also provided a construction of single-source FT-spanner with additive stretch 4 and $O(n^{4/3})$ edges that is resilient to one edge fault. The first constructions of FT-additive spanners resilient against *one vertex* fault were given in [30] and later on in [8]. Prior to our work, no construction of FT-additive spanners was known for $f \geq 2$ vertex faults.

As mentioned earlier, the computation of preservers and spanners in the non-faulty case (i.e. when $f = 0$) has been the subject of intense research in the last few decades. The current-best preservers can be found in [18, 11, 12]. Spanners are also well understood, both for multiplicative stretch [4, 25] and for additive stretch [3, 15, 6, 39, 1, 11, 15, 34, 2]. There are also a few results on "mixed" spanners with both multiplicative and additive stretch [24, 36, 6]

Distance sensitivity oracles are data structures that can answer queries about the distances in a given graph in the presence of faults. The first nontrivial construction was given by Demetrescu et al. [20] and later improved by Bernstein and Karger [7] who showed how to construct $\tilde{O}(n^2)$-space, constant query time oracles for a single edge fault for an m-edge n-node graph in $\tilde{O}(mn)$ time. The first work that considered the case of two faults (hence making the first jump from one to two) is due to Duan and Pettie in [22]. Their distance oracle has nearly optimal size of $\widetilde{O}(n^2)$ and query time of $\widetilde{O}(1)$. The case of bounded edge weights, and possibly multiple faults, is addressed in [38, 26] exploiting fast matrix multiplication techniques. The size of their oracle is super-quadratic.

The notion of FT-preservers is also closely related to the problem of constructing *replacement paths*. For a pair of vertices s and t and an edge e, the replacement path $P_{s,t,e}$ is the s-t shortest-path that avoids e[3]. The efficient computation of replacement paths is addressed, among others, in [29, 35, 38, 37]. A single-source version of the problem is studied in [26]. Single-source FT structures that preserve strong connectivity have been studied in [5].

1.2 Preliminaries and Notation

Assume throughout that all shortest paths ties are broken in a consistent manner. For every $s, t \in V$ and a subgraph $G' \subseteq G$, let $\pi_{G'}(s,t)$ be the (unique) u-v shortest path in G' (i.e., it is unique under breaking ties). If there is no path between s and t in G', we define

[3] Replacement paths were originally defined for the single edge fault case, but later on extended to the case of multiple faults as well.

$\pi_{G'}(s,t) = \emptyset$. When $G' = G$, we simply write $\pi(u,v)$. For any path P containing nodes u, v, let $P[u \rightsquigarrow v]$ be the subpath of P between u and v. For $s, t \in V$ and $F \subseteq E$, we let $P_{s,t,F} = \pi_{G \setminus F}(s,t)$ be the s-t shortest-path in $G \setminus F$. We call such paths *replacement paths*. When $F = \{e\}$, we simply write $P_{s,t,e}$. By m we denote the number of edges in the graph currently being considered.

The structure of the paper is as follows. In Sec. 2, we describe an efficient construction for FT-preservers and additive spanners with a subquadratic number of edges. Then, in Sec. 3, we provide several lower bound constructions for a single s-t pair, both for the exact and for the additive stretch case. All the proofs which are omitted due to lack of space appear in the full version of the paper (see [13]).

2 Efficient Construction of FT-Preservers and Spanners

In this section we prove Theorem 5. We next focus on the directed case, the undirected one being analogous and simpler. We begin by recapping the currently-known approaches for handling many faults, and we explain why these approaches fail to achieve interesting space/construction time bounds for large f.

The limits of previous approaches. A known approach for handling many faults is by *random sampling* of subgraphs, as introduced by Weimann and Yuster [38] in the setting of distance sensitivity oracles, and later on applied by Dinitz and Kraughgamer [21] in the setting of fault tolerant spanners. The high level idea is to generate multiple subgraphs $G_1, \ldots, G_r$ by removing each edge/vertex independently with sufficiently large probability p; intuitively, each G_i simultaneously captures many possible fault sets of size f. One can show that, for a sufficiently small parameter L and for any given (*short*) replacement path $P_{s,t,F}$ of length at most L (avoiding faults F), w.h.p. in at least one G_i the path $P_{s,t,F}$ is still present while all edges/vertices in F are deleted. Thus, if we compute a (non-faulty) preserver $H_i \subseteq G_i$ for each i, then the graph $H = \bigcup_i H_i$ will contain every short replacement path. For the remaining (*long*) replacement paths, Weimann and Yuster use a random decomposition into short subpaths. Unfortunately, any combination of the parameters p, r, L leads to a quadratic (or larger) space usage.

Another way to handle multiple faults is by extending the approach in [32, 33, 30] that works for $f \in \{1, 2\}$. A useful trick used in those papers (inspired by prior work in [35, 37]) is as follows: suppose $f = 1$, and fix a target node t. Consider the shortest path $\pi(s,t)$. It is sufficient to take the *last* edge of each replacement path $P_{s,t,e}$ and charge it to the node t; the rest of the path is then charged to other nodes by an inductive argument. Hence, one only needs to bound the number of *new-ending* paths – those that end in an edge that is not already in $\pi(s,t)$. In the case $f = 1$, these new-ending paths have a nice structure: they diverge from $\pi(s,t)$ at some vertex b (*divergence point*) above the failing edge/vertex and collide again with $\pi(s,t)$ only at the terminal t; the subpath connecting b and t on the replacement path is called its *detour*. One can divide the s-t replacement paths into two groups: short (resp., long) paths are those whose detour has length at most (resp., at least) $\sqrt{n}$. It is then straightforward enough to show that each category of path contributes only $\widetilde{O}(n^{1/2})$ edges entering t, and so (collecting these last edges over all nodes in the graph) the output subgraph has $\widetilde{O}(n^{3/2})$ edges in total. Generalizing this to the case of multiple faults is non-trivial already for the case of $f = 2$. The main obstacle here stems from a lack of structural understanding of replacement paths for multiple faults: in particular, any given divergence point $b \in \pi(s,t)$ can now be associated with many new-ending paths and not

only one! In the only known positive solution for $f = 2$ [31], the approach works only for edge faults and is based on an extensive case analysis whose extension to larger f is beyond reasonable reach. Thus, in the absence of new structural understanding, further progress seems very difficult.

A second source of difficulties is related to the *running time* of the construction. A priori, it seems that constructing a preserver H should require computing all replacement paths $P_{s,t,F}$, which leads to a construction time that scales *exponentially* in f. In particular, by deciding to omit an edge e from the preserver H, we must somehow check that this edge does not appear on *any* of the replacement paths $P_{s,t,F}$ (possibly, without computing these replacement paths explicitly).

Our basic approach. The basic idea behind our algorithm is as follows. Similar to [32, 33, 30], we focus on each target node t, and define a set E_t of edges incident to t to be added to our preserver. Intuitively, these are the last edges of new-ending paths as described before. The construction of E_t, however, deviates substantially from prior work. Let us focus on the simpler case of edge deletions. The set E_t is constructed recursively, according to parameter f. Initially we consider the shortest path tree T from the source set S to t, and add to E_t the edges of T incident to t (at most $|S|$ many). Consider any new-ending replacement path P for t. By the previous discussion, this path has to leave T at some node b and it meets T again only at t: let D be the subpath of P between b and t (the *detour* of P). Note that D is edge-disjoint from T, i.e. it is contained in the graph $G' = G \setminus E(T)$. Therefore, it would be sufficient to compute recursively the set E'_t of final edges of new-ending replacement paths for t in the graph G' with source set S' given by the possible divergence points b and w.r.t. $f - 1$ faults (recall that one fault must be in $E(T)$, hence we avoid that anyway in G'). This set E'_t can then be added to E_t.

The problem with this approach is that S' can contain $\Omega(n)$ many divergence points (hence E_t $\Omega(n)$ many edges), leading to a trivial $\Omega(n^2)$ size preserver. In order to circumvent this problem, we classify the divergence points b in two categories. Consider first the nodes b at distance at most L from t along T, for some parameter L. There are only $O(|S|L)$ many such nodes S^{short}, which is sublinear for $|S|$ and L small enough. Therefore we can safely add S^{short} to S'. For the remaining divergence points b, we observe that the corresponding detour D must have length at least L: therefore by sampling $\tilde{O}(n/L)$ nodes S^{long} we hit all such detours w.h.p. Suppose that $\sigma \in S^{long}$ hits detour D. Then the portion of D from σ to t also contains the final edge of D to be added to E_t. In other terms, it is sufficient to add S^{long} (which has sublinear size for polynomially large L) to S' to cover all the detours of nodes b of the second type. Altogether, in the recursive call we need to handle one less fault w.r.t. a larger (but sublinear) set of sources S'. Our approach has several benefits:

- It leads to a subquadratic size for any f (for a proper choice of the parameters);
- It leads to a very fast algorithm. In fact, for each target t we only need to compute a BFS tree in f different graphs, leading to an $O(fnm)$ running time;
- Our analysis is very simple, much simpler than in [31] for the case $f = 2$;
- It can be easily extended to the case of vertex faults.

Algorithm for Edge Faults. Let us start with the edge faults case. The algorithm constructs a set E_t of edges incident to each target node $t \in V$. The final preserver is simply the union $H = \bigcup_{t \in V} E_t$ of these edges. We next describe the construction of each E_t (see also Alg. 1). The computation proceeds in rounds $i = 0, \ldots, f$. At the beginning of round i we are given a subgraph G_i (with $G_0 = G$) and a set of sources S_i (with $S_0 = S$).

Algorithm 1 Construction of E_t in our f-FT S-Sourcewise Preserver Algorithm.

procedure ComputeSourcewiseFT(t, S, f, G)
Input: A graph G with a source set S and terminal t, number of faults f.
Output: Edges E_t incident to t in an f-FT S-sourcewise preserver H.
Set $G_0 = G$, $S_0 = S$, $E_t = \emptyset$.
  for $i \in \{0, \ldots, f\}$ **do**
    Compute the partial BFS tree $T_i = \bigcup_{s \in S_i} \pi_{G_i}(s, t)$.
    $E_t = E_t \cup \{\texttt{LastE}(\pi_{T_i}(s, t)) \mid s \in S_i\}$.
    Set distance threshold $d_i = \sqrt{n/|S_i| \cdot f \log n}$.
    Let $S_i^{short} = \{v \in V(T_i) \mid \texttt{dist}_{T_i}(v, t) \leq d_i\}$.
    Sample a collection $S_i^{long} \subseteq V(G_i)$ of $\Theta(n/d_i \cdot f \log n)$ vertices.
    Set $S_{i+1} = S_i^{short} \cup S_i^{long}$ and $G_{i+1} = G_i \setminus E(T_i)$.

We compute a partial BFS tree $T_i = \bigcup_{s \in S_i} \pi_{G_i}(s, t)$[4] from S_i to t, and add to E_t (which is initially empty) the edges $\{\texttt{LastE}(\pi_{T_i}(s, t)) \mid s \in S_i\}$ of this tree incident to t. Here, for a path π where one endpoint is the considered target node t, we denote by $\texttt{LastE}(\pi)$ the edge of π incident to t. The source set S_{i+1} is given by $S_i^{short} \cup S_i^{long}$. Here $S_i^{short} = \{v \in V(T_i) \mid \texttt{dist}_{T_i}(v, t) \leq d_i\}$ is the set of nodes at distance at most $d_i = \sqrt{n/|S_i| \cdot f \log n}$ from t, while S_i^{long} is a random sample of $\Theta(n/d_i \cdot f \log n)$ vertices. The graph G_{i+1} is obtained from G_i be removing the edges $E(T_i)$[5].

Adaptation for Vertex Faults. The only change in the algorithm is in the definition of the graph G_i inside the procedure to compute E_t. We cannot allow ourselves to remove all the vertices of the tree T_i from G_i and hence a more subtle definition is required. To define G_{i+1}, we first remove from G_i: (1) all edges of $S_i^{short} \times S_i^{short}$, (2) the edges of $E(T_i)$, and (3) the vertices of $V(T_i) \setminus S_i^{short}$. Finally, we delete all remaining edges incident to S_i^{short} which are directed towards any one of these vertices (i.e., the incoming degree of the S_i^{short} vertices in G_{i+1} is zero).

Analysis. We now analyze our algorithm. Since for each vertex t, we compute f (partial) BFS trees, we get trivially:

▶ **Lemma 10** (Running Time). *The subgraph H is computed within $O(f\, n\, m)$ time.*

We proceed with bounding the size of H.

▶ **Lemma 11** (Size Analysis). $|E_t| = \widetilde{O}(|S|^{1/2^f} \cdot (fn)^{1-1/2^f})$ *for every $t \in V$, hence* $|E(H)| = \widetilde{O}(f|S|^{1/2^f} n^{2-1/2^f})$.

Proof. Since the number of edges collected at the end each round i is bounded by the number of sources S_i, it is sufficient to bound $|S_i|$ for all i. Observe that for every $i \in \{0, \ldots, f-1\}$,

$$|S_{i+1}| \leq |S_i^{long}| + |S_i^{short}| \leq d_i \cdot |S_i| + \Theta(n/d_i \cdot f \log n) = \Theta(d_i \cdot |S_i|).$$

By resolving this recurrence starting with $|S_0| = |S|$ one obtains

$$|S_i| = O(|S|^{1/2^i} (fn \log n)^{1-1/2^i}).$$

The claim follows by summing over $i \in \{0, \ldots, f\}$. ◀

[4] If $\pi_{G_i}(s, t)$ does not exist, recall that we define it as an empty set of edges.
[5] Note that for $f = 1$, the algorithm has some similarity to the replacement path computation of [35]. Yet, there was no prior extension of this idea for $f \geq 2$.

We next show that the algorithm is correct. We focus on the vertex fault case, the edge fault case being similar and simpler. Let us define, for $t \in V$ and $i \in \{0, \ldots, f\}$,

$$\mathcal{P}_{t,i} = \{\pi_{G_i \setminus F}(s,t) \mid s \in S_i,\ F \subseteq V(G_i),\ |F| \leq f - i\}.$$

▶ **Lemma 12.** *For every $t \in V$ and $i \in \{0, \ldots, f\}$, it holds that*

$$\texttt{LastE}(\pi) \in E_t \quad \textit{for every} \quad \pi \in \mathcal{P}_{t,i}.$$

Proof. We prove the claim by decreasing induction on $i \in \{f, \ldots, 0\}$. For the base case $i = f$, $\mathcal{P}_{t,f} = \{\pi_{G_f}(s,t) \mid s \in S_f\}$. Since we add precisely the last edges of these paths to the set E_t, the claim holds. Assume that the lemma holds for rounds $f, f-1, \ldots, i+1$ and consider round i. For every $\pi_{G_i \setminus F}(s,t) \in \mathcal{P}_{t,i}$, let $P'_{s,t,F} = \pi_{G_i \setminus F}(s,t)$. [6] Consider the partial BFS tree $T_i = \bigcup_{s \in S_i} \pi_{G_i}(s,t)$ rooted at t. Note that all (interesting) replacement paths $P'_{s,t,F}$ in G_i have at least one failing vertex $v \in F \cap V(T_i)$ as otherwise $P'_{s,t,F} = \pi_{G_i}(s,t)$.

We next partition the replacement paths $\pi \in \mathcal{P}_{t,i}$ into two types depending on their last edge $\texttt{LastE}(\pi)$. The first class contains all paths whose last edge is in T_i. The second class contains the remaining replacement paths, which end with an edge that is not in T_i. We call this second class of paths *new-ending* replacement paths. Observe that the first class is taken care of, since we add all edges incident to t in T_i. Hence it remains to prove the lemma for the set of new-ending paths.

For every new-ending path $P'_{s,t,F}$, let $b_{s,t,F}$ be the last vertex on $P'_{s,t,F}$ that is in $V(T_i) \setminus \{t\}$. We call the vertex $b_{s,t,F}$ the *last divergence point* of the new-ending replacement path. Note that the detour $D_{s,t,F} = P'_{s,t,F}[b_{s,t,F} \rightsquigarrow t]$ is vertex disjoint with the tree T_i except for the vertices $b_{s,t,F}$ and t. From now on, since we only wish to collect last edges, we may restrict our attention to this detour subpath. That is, since $\texttt{LastE}(D_{s,t,F}) = \texttt{LastE}(P'_{s,t,F})$, it is sufficient to show that $\texttt{LastE}(D_{s,t,F}) \in E_t$.

Our approach is based on dividing the set of new-ending paths in $\mathcal{P}_{t,i}$ into two classes based on the position of their last divergence point $b_{s,t,F}$. The first class $\mathcal{P}_{short}$ consists of new-ending paths in $\mathcal{P}_{t,i}$ whose last divergence point is at distance at most $d_i = \sqrt{n/|S_i|} \cdot f \log n$ from t on T_i. In other words, this class contains all new-ending paths whose last divergence point is in the set S_i^{short}. We now claim the following.

▶ **Claim 13.** *For every $P'_{s,t,F} \in \mathcal{P}_{short}$, the detour $D_{s,t,F}$ is in $\mathcal{P}_{t,i+1}$.*

Proof. Since $D_{s,t,F}$ is a subpath of the replacement path $P'_{s,t,F}$, $D_{s,t,f}$ is the shortest path between $b_{s,t,F}$ and t in $G_i \setminus F$. Recall that $D_{s,t,F}$ is vertex disjoint with $V(T_i) \setminus \{b_{s,t,F}, t\}$.

Since $b_{s,t,F}$ is the last divergence point of $P'_{s,t,F}$ with T_i, the detour $D_{s,t,F}$ starts from a vertex $b_{s,t,F} \in S_i^{short}$ and does not pass through any other vertex in $V(T_i) \setminus \{t\}$. Recall that in the construction of G_{i+1} we delete from G_i the edges directed *towards* S_i^{short}. In particular, the outgoing edge connecting $b_{s,t,F}$ to its neighbor x on $D_{s,t,F}[b_{s,t,F} \rightsquigarrow t]$ remains (i.e., this vertex x is not in $V(T_i) \setminus \{t\}$), this implies that the detour $D_{s,t,F}$ exists in G_{i+1}. In particular, note that the vertex $b_{s,t,F}$ cannot be a neighbor of t in T_i. Indeed, if $(b_{s,t,F}, t)$ were an edge in T_i, then we can replace the portion of the detour path between $b_{s,t,F}$ and t by this edge, getting a contradiction to the fact that $P'_{s,t,F}$ is a new-ending path[7].

Next, observe that at least one of the failing vertices in F occurs on the subpath $\pi_{G_i}[b_{s,t,F}, t]$, let this vertex be $v \in F$. Since $v \in S_i^{short}$, all the edges incident to v are

[6] We denote these replacement paths as $P'_{s,t,F}$ as they are computed in G_i and not in G.

[7] For the edge fault case, the argument is much simpler: by removing $E(T_i)$ from G_i, we avoid at least one of the failing edges in G_{i+1}.

directed away from v in G_{i+1} and hence the paths going out from the source $b_{s,t,F}$ in G_{i+1} cannot pass through v. Letting $F' = F \setminus V(T_i)$, it holds that (1) $|F'| \leq f - i - 1$ and (2) since the shortest path ties are decided in a consistent manner and by definition of G_{i+1}, it holds that $D_{s,t,F} = \pi_{G_{i+1} \setminus F'}(b_{s,t,F}, t)$. As $b_{s,t,F} \in S_i^{short}$, it holds that $D_{s,t,F} \in \mathcal{P}_{t,i+1}$. ◀

Hence by the inductive hypothesis for $i+1$, $\texttt{LastE}(P'_{s,t,F})$ is in E_t for every $P'_{s,t,F} \in \mathcal{P}_{short}$. We now turn to consider the second class of paths $\mathcal{P}_{long}$ which contains all remaining new-ending paths; i.e., those paths whose last divergence point is at distance at least d_i from t on T_i. Note that the detour $D_{s,t,F} = P'_{s,t,F}[b_{s,t,F} \rightsquigarrow t]$ of these paths is long – i.e., its length is at least d_i. For convenience, we will consider the internal part $D'_{s,t,F} = D_{s,t,F} \setminus \{b_{s,t,F}, t\}$ of these detours, so that the first and last vertices of these detours are not on T_i.

We exploit the lengths of these detours $D'_{s,t,F}$ and claim that w.h.p, the set S_i^{long} is a hitting set for these detours. This indeed holds by simple union bound overall possible $O(n^{f+2})$ detours. For every $P'_{s,t,F} \in \mathcal{P}_{long}$, let $w_{s,t,F} \in V(D'_{s,t,F}) \cap S_i^{long}$. (By the hitting set property, w.h.p., $w_{s,t,F}$ is well defined for each long detour). Let $W_{s,t,F} = P'_{s,t,F}[w_{s,t,F}, t]$ be the suffix of the path $P'_{s,t,F}$ starting at a vertex from the hitting set $w_{s,t,F} \in S_i^{long}$. Since $\texttt{LastE}(P'_{s,t,F}) = \texttt{LastE}(W_{s,t,F})$, it is sufficient to show that $\texttt{LastE}(W_{s,t,F})$ is in E_t.

▶ **Claim 14.** *For every $P'_{s,t,F} \in \mathcal{P}_{long}$, it holds that $W_{s,t,F} \in \mathcal{P}_{t,i+1}$.*

Proof. Clearly, $W_{s,t,f}$ is the shortest path between $w_{s,t,F}$ and t in $G_i \setminus F$. Since $W_{s,t,F} \subseteq D'_{s,t,F}$ is vertex disjoint with $V(T_i)$, it holds that $W_{s,t,F} = \pi_{G_{i+1} \setminus F'}(w_{s,t,F}, t)$ for $F' = F \setminus V(T_i)$. Note that since at least one fault occurred on T_i, we have that $|F'| \leq f - i - 1$. As $w_{s,t,F} \in S_i^{long}$, it holds that $W_{s,t,F} \in \mathcal{P}_{t,i+1}$. The lemma follows. ◀

By applying the claim for $i = 0$, we get that $\texttt{LastE}(P'_{s,t,F})$ is in E_t as required for every $P'_{s,t,F} \in \mathcal{P}_{long}$. This completes the proof. ◀

▶ **Lemma 15.** *(Correctness) H is an f-FT S-sourcewise preserver.*

Proof. By using Lemma 12 with $i = 0$, we get that for every $t \in V$, $s \in S$ and $F \subseteq V$, $|F| \leq f$, $\texttt{LastE}(P_{s,t,F}) \in E_t$ (and hence also $\texttt{LastE}(P_{s,t,F}) \in H$). It remains to show that taking the last edge of each replacement path $P_{s,t,F}$ is sufficient. The base case is for paths of length 1, where we have clearly kept the entire path in our preserver. Then, assuming the hypothesis holds for paths up to length $k-1$, consider a path $P_{s,t,F}$ of length k. Let $\texttt{LastE}(P_{s,t,F}) = (u, t)$. Then since we break ties in a consistent manner, $P_{s,t,F} = P_{s,u,F} \circ \texttt{LastE}(P_{s,t,e})$. By the inductive hypothesis $P_{s,u,F}$ is in H, and since we included the last edge, $P_{s,t,F}$ is also in H. The claim follows. ◀

Theorem 5 now immediately follows from Lemmas 10, 11, and 15.

3 Lower Bounds for FT Preservers and Additive Spanners

In this section, we provide the first non-trivial lower bounds for preservers and additive spanners for a single pair s-t.

We start by proving Theorem 7. The main building block in our lower bound is the construction of an (undirected unweighted) tree T^h, where h is a positive integer parameter related to the desired number of faults f. Tree T^h is taken from [31] with mild technical adaptations. Let d be a *size* parameter which is used to obtain the desired number n of nodes. It is convenient to interpret this tree as rooted at a specific node (though edges in this construction are undirected). We next let $rt(T^h)$ and $L(T^h)$ be the root and leaf set

of T^h, respectively. We also let $\ell(h)$ and $n(h)$ be the height and number of nodes of T^h, respectively.

Tree T^h is constructed recursively as follows. The base case is given by T^0 which consists of a single isolated root node $rt(T^0)$. Note that $\ell(0) = 0$ and $n(0) = 1$. In order to construct T^h, we first create d copies $T_0^{h-1}, \ldots, T_{d-1}^{h-1}$ of T^{h-1}. Then we add a path $v_0, \ldots, v_{d-1}$ of length $d-1$ (consisting of new nodes), and choose $rt(T^h) = v_0$. Finally, we connect v_j to $rt(T_j^{h-1})$ with a path (whose internal nodes are new) of length $(d-j) \cdot (\ell(h-1)+3)$. Next lemma illustrates the crucial properties of T^h.

▶ **Lemma 16.** *The tree T^h satisfies the following properties:*

1. $n(h) \leq \frac{3}{2}(h+1)(d+1)^{h+1}$
2. $|L(T^h)| = d^h$
3. *For every $\ell \in L(T^h)$, there exists $F_\ell \subseteq E(T)$, $|F_\ell| = h$, such that $\texttt{dist}_{T^h \setminus F_\ell}(s, \ell) \leq \texttt{dist}_{T^h \setminus F_\ell}(s, \ell') + 2$ for every $\ell' \in L(T^h) \setminus \{\ell'\}$.*

We next construct a graph S^h as follows. We create two copies T_s and T_t of T^h. We add to S^h the complete bipartite graph with sides $L(T_s)$ and $L(T_t)$, which we will call the *bipartite core* B of S^h. Observe that $|L(T_s)| = |L(T_t)| = d^h$, and hence B contains d^{2h} edges. We will call $s = sr(S^h) = rt(T_s)$ the source of S^h, and $t = tg(S^h) = rt(T_t)$ its target.

▶ **Lemma 17.** *Every $2h$-FT (s,t) preserver (and 1-additive (s,t) spanner) H for S^h must contain each edge $e = (\ell_s, \ell_t) \in B$.*

Proof. Assume that $e = (\ell_s, \ell_t) \notin H$ and consider the case where F_{ℓ_s} fails in T_s and F_{ℓ_t} fails in T_t. Let $G' := S^h \setminus (F_{\ell_s} \cup F_{\ell_t})$, and d_s (resp., d_t) be the distance from s to ℓ_s (resp., from ℓ_t to t) in G'. By Lemma 16.3 the shortest s-t path in G' passes through e and has length $d_s + 1 + d_t$. By the same lemma, any path in G', hence in $H' := H \setminus (F_{\ell_s} \cup F_{\ell_t})$, that does not pass through ℓ_s (resp., ℓ_t) must have length at least $(d_s + 2) + 1 + d_t$ (resp., $d_s + 1 + (d_t + 2)$). On the other hand, any path in H' that passes through ℓ_s and ℓ_t must use at least 3 edges of B, hence having length at least $d_s + 3 + d_t$. ◀

Our lower bound graph S_q^h is obtained by taking q copies $S_1, \ldots, S_q$ of graph S^h with $d = (\frac{n}{3q(h+1)} - 1)^{\frac{1}{h+1}}$, and chaining them with edges $(tg(S_i), sr(S_{i+1}))$, for $i = 1, \ldots, q-1$. We let $s = sr(S_1)$ and $t = tg(S_q)$.

Proof of Theorem 7. Consider S_q^h. By Lemma 16.1–2 this graph contains at most n nodes, and the bipartite core of each S_i contains $d^{2h} = \Omega((\frac{n}{qh})^{2-2/(h+1)})$ edges.

Finally, we show that any $(2q-1)$-additive (s,t) spanner needs to contain all the edges of at least one such bipartite core. Let us assume this does not happen, and let e_i be a missing edge in the bipartite core of S_i for each i. Observe that each s-t shortest path has to cross $sr(S_i)$ and $tg(S_i)$ for all i. Therefore, it is sufficient to choose $2h$ faulty edges corresponding to each e_i as in Lemma 17. This introduces an additive stretch of 2 in the distance between s and t for each e_i, leading to a total additive stretch of at least $2q$. ◀

The same construction can also be extended to the setting of $(2h)$-FT $S \times T$ preservers. To do that, we make *parallel* copies of the S^h graph.

▶ **Theorem 18.** *For every positive integer f, there exists a graph $G = (V, E)$ and subsets $S, T \subseteq V$, such that every $(2f)$-FT 1-additive $S \times T$ spanner (hence $S \times T$ preserver) of G has size $\Omega(|S|^{1/(f+1)} \cdot |T|^{1/(f+1)} \cdot (n/f)^{2-2/(f+1)})$.*

Improving over the Bipartite Core. The proof above only gives the trivial lower bound of $\Omega(n)$ for the case of two faults (using $h = q = 1$). We can strengthen the proof in this special case to show instead that $\Omega(n^{1+\varepsilon})$ edges are needed, and indeed this even holds in the presence of a *polynomial additive stretch*:

▶ **Theorem 19.** *A 2-FT distance preserver of a single (s,t) pair in an undirected unweighted graph needs $\Omega(n^{11/10-o(1)})$ edges.*

▶ **Theorem 20.** *There are absolute constants $\varepsilon, \delta > 0$ such that any $+n^{\delta}$-additive 2-FT preserver for a single (s,t) pair in an undirected unweighted graph needs $\Omega(n^{1+\varepsilon})$ edges.*

Finally, by tolerating one additional fault, we can obtain a strong incompressibility result:

▶ **Theorem 21.** *There are absolute constants $\varepsilon, \delta > 0$ such that any $+n^{\delta}$-additive 3-FT distance sensitivity oracle for a single (s,t) pair in an undirected unweighted graph uses $\Omega(n^{1+\varepsilon})$ bits of space.*

The proofs of Theorems 19, 20 and 21 are similar in spirit. The key observation is that the structure of T_s, T_t allows us to use our faults to select leaves ℓ_s, ℓ_t and enforce that a shortest ℓ_s-ℓ_t path is kept in the graph. When we use a bipartite core between the leaves of T_s and T_t, this "shortest path" is simply an edge, so the quality of our lower bound is equal to the product of the leaves in T_s and T_t. However, sometimes a better graph can be used instead. In the case $h = 1$, we can use a nontrivial lower bound graph against (non-faulty) subset distance preservers (from [10]), which improves the cost per leaf pair from 1 edge to roughly $n^{11/10}$ edges, yielding Theorem 19. Alternatively, we can use a nontrivial lower bound graph against $+n^{\delta}$ spanners (from [1]), which implies Theorem 20. The proof of Theorem 21 is similar in spirit, but requires an additional trick in which *unbalanced trees* are used: we take T_s as a copy of T^1 and T_t as a copy of T^2, and this improved number of leaf-pairs is enough to push the incompressibility argument through.

4 Open Problems

There are lots of open ends to be closed. Perhaps the main open problem is to resolve the current gap for f-FT single-source preservers. Since the lower bound of $\Omega(n^{2-1/(f+1)})$ edges given in [31] has been shown to be tight for $f \in [1,2]$, it is reasonable to believe that this is the right bound for $f \geq 3$. Another interesting open question involves lower bounds for FT additive spanners. Our lower-bounds are super linear only for $f \geq 2$. The following basic question is still open though: is there a lower bound of $\Omega(n^{3/2+\epsilon})$ edges for some $\epsilon \in (0,1]$ for 2-additive spanners with *one* fault? Whereas our lower bound machinery can be adapted to provide non trivial bounds for different types of f-FT P-preservers (e.g., $P = \{s,t\}, P = S \times T$, etc.), our upper bounds technique for general $f \geq 2$ is still limited to the sourcewise setting. Specifically, it is not clear how to construct an f-FT $S \times S$ preserver other than taking a (perhaps wasteful) f-FT S-sourcewise preserver. As suggested by our lower bounds, these questions are interesting already for a single pair.

Abstract

In the 2-reachability problem we are given a directed graph G and we wish to determine if there are two (edge or vertex) disjoint paths from u to v, for given pair of vertices u and v. In this paper, we present an algorithm that computes 2-reachability information for all pairs of vertices in $\mathcal{O}(n^\omega \log n)$ time, where n is the number of vertices and ω is the matrix multiplication exponent. Hence, we show that the running time of all-pairs 2-reachability is only within a log factor of transitive closure. Moreover, our algorithm produces a witness (i.e., a separating edge or a separating vertex) for all pair of vertices where 2-reachability does not hold. By processing these witnesses, we can compute all the edge- and vertex-dominator trees of G in $\mathcal{O}(n^2)$ additional time, which in turn enables us to answer various connectivity queries in $\mathcal{O}(1)$ time. For instance, we can test in constant time if there is a path from u to v avoiding an edge e, for any pair of query vertices u and v, and any query edge e, or if there is a path from u to v avoiding a vertex w, for any query vertices u, v, and w.

1 Introduction

The *all-pairs reachability problem* consists of preprocessing a directed graph (digraph) $G = (V, E)$ so that we can answer queries that ask if a vertex y is reachable from a vertex x. This problem has many applications, including databases, geographical information systems, social networks, and bioinformatics [11]. A classic solution to this problem is to compute the transitive closure matrix of G, either by performing a graph traversal (e.g., depth-first or breadth-first search) once per each vertex as source, or via matrix multiplication. For a

digraph with n vertices and m edges, the former solution runs in $\mathcal{O}(mn)$ time, while the latter in $\mathcal{O}(n^\omega)$, where ω is the matrix multiplication exponent [4, 13, 17]. Here we study a natural generalization of the all-pairs reachability problem, that we refer to as *all-pairs 2-reachability*, where we wish to preprocess G so that we can answer fast the following type of queries: For a given vertex pair $x, y \in V$, are there two edge-disjoint (resp., internally vertex-disjoint) paths from x to y? Equivalently, by Menger's theorem [15], we ask if there is an edge $e \in E$ (resp., a vertex $z \in V$) such that there is no path from x to y in $G \setminus e$ (resp., $G \setminus z$). We call such an edge (resp., vertex) *separating* for the pair x, y.

One solution to the all-pairs 2-reachability problem is to compute all the dominator trees of G, with each vertex as source. The dominator tree of G with start vertex s is a tree rooted at s, such that a vertex v is an ancestor of a vertex w if and only if all paths from s to w include v [14]. All the separating edges and vertices for a pair s, v, appear on the path from s to v in the dominator tree rooted at s, in the same order as they appear in any path from s to v in G. Given all the dominator trees, we can process them to compute the 2-reachability information for all pairs of vertices (see Section 6). Since a dominator tree can be computed in $\mathcal{O}(m)$ time [2, 3], the overall running time of this algorithm is $\mathcal{O}(mn)$.

Our Results. In this paper, we show how to beat the $\mathcal{O}(nm)$ bound for dense graphs. Specifically, we present an algorithm that computes 2-reachability information for all pairs of vertices in $\mathcal{O}(n^\omega)$ time in a strongly connected digraph, and in $\mathcal{O}(n^\omega \log n)$ time in a general digraph. Hence, we show that the running time of all-pairs 2-reachability is only within a log factor of transitive closure. This result is tight up to a log factor, since it can be shown that all-pairs 2-reachability is at least as hard as computing the transitive closure, which is asymptotically equivalent to Boolean matrix multiplication [6]. Moreover, our algorithm produces a witness (separating edge or vertex) whenever 2-reachability does not hold. By processing these witnesses, we can find all the dominator trees of G in $\mathcal{O}(n^2)$ additional time. Thus, we also show how to compute all the dominator trees of a digraph in $\mathcal{O}(n^\omega \log n)$ time (in $\mathcal{O}(n^\omega)$ time if the graph is strongly connected), which improves the previously known $\mathcal{O}(mn)$ bound for dense graphs. This in turn enables us to answer various connectivity queries in $\mathcal{O}(1)$ time. E.g., we can test in $\mathcal{O}(1)$ time if there is a path from u to v avoiding an edge e, for any pair of query vertices u and v, and any query edge e, or if there is a path from u to v avoiding a vertex w, for any query vertices u, v, and w. We can also report all the edges or vertices that appear in all paths from u to v, for any query vertices u and v.

Related Work. To the best of our knowledge, ours is the first work that considers the all-pairs 2-reachability problem and gives a fast algorithm for it. In recent work Georgiadis et al. [9] investigate the effect of an edge or a vertex failure in a digraph G with respect to strong connectivity. Specifically, they show how to preprocess G in $\mathcal{O}(m + n)$ time in order to answer various sensitivity queries regarding strong connectivity in G under an arbitrary edge or vertex failure. For instance, they can compute in $\mathcal{O}(n)$ time the strongly connected components (SCCs) that remain in G after the deletion of an edge or a vertex, or report various statistics such as the number of SCCs in constant time per query (failed) edge or vertex. This result, however, cannot be applied for the solution of the 2-reachability problem. The reason is that if the deletion of an edge e leaves two vertices u and v in different SCCs in $G \setminus e$, the algorithm of [9] is not able to distinguish if there is still a path or no path from u to v in $G \setminus e$. Previously, King and Sagert [12] gave an algorithm that can quickly answer sensitivity queries for reachability in a directed acyclic graph (DAG) [12]. Specifically, they show how to process a DAG G so that, for any pair of query vertices x and y, and a query

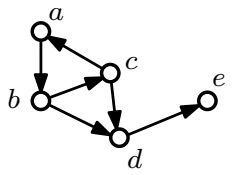
edge e, one can test in constant time if there is a path from x to y in $G \setminus e$. Note that the result of King and Sagert does not yield an efficient solution to the all-pairs 2-reachability problem, since we need $\mathcal{O}(m)$ queries just to find if there is a separating edge for a single pair of vertices. Moreover, their preprocessing time is $\mathcal{O}(n^3)$. Another interesting fact that arises from our work is that, somewhat surprisingly, computing all dominator trees in dense graphs is currently faster than computing a spanning arborescence from each vertex. The best algorithm for this problem is given by Alon et al. [1], who studied the problem of constructing a BFS tree from every vertex, and gave an algorithm that runs in $\mathcal{O}(n^{(3+\omega)/2})$ time.

Our Techniques. Our result is based on two novel approaches, one for DAGs and one for strongly connected digraphs. For DAGs we develop an algebra that operates on paths. We then use some version of 1-superimposed coding to apply our path algebra in a divide and conquer approach. This allows us to use Boolean matrix multiplication, in a similar vein to the computation of transitive closure. Unfortunately, our algebraic approach does not work for strongly connected digraphs. In this case, we exploit dominator trees in order to transform a strongly connected digraph G into two auxiliary graphs, so as to reduce 2-reachability queries in G to 1-reachability queries in those auxiliary graphs. This reduction works only for strongly connected digraphs and does not carry over to general digraphs. Our algorithm for general digraphs is obtained via a careful combination of those two approaches.

2 Preliminaries

We assume that the reader is familiar with standard graph terminology, as contained for instance in [5]. Let $G = (V, E)$ be a directed graph (digraph). Given an edge $e = (x, y)$ in E, we denote x (resp., y) as the *tail* (resp., *head*) *of* e. A *directed path* in G is a sequence of vertices v_1, v_2, ..., v_k, such that edge $(v_i, v_{i+1}) \in E$ for $i = 1, 2, \ldots, k-1$. The path is said to contain vertex v_i, for $i = 1, 2, \ldots, k$, and edge (v_i, v_{i+1}), for $i = 1, 2, \ldots, k-1$. The *length* of a directed path is given by its number of edges. As a special case, there is a path of length 0 from each vertex to itself. We write $u \rightsquigarrow v$ to denote that there is a path from u to v, and $u \not\rightsquigarrow v$ if there is no path from u to v. A *directed cycle* is a directed path, with length greater than 0, starting and ending at the same vertex. A *directed acyclic graph* (in short *DAG*) is a digraph with no cycles. A DAG has a *topological ordering*, i.e., a linear ordering of its vertices such that for every edge (u, v), u comes before v in the ordering (denoted by $u < v$). A digraph G is *strongly connected* if there is a directed path from each vertex to every other vertex. The *strongly connected components* of a digraph are its maximal strongly connected subgraphs. Given a subset of vertices $V' \subset V$, we denote by $G \setminus V'$ the digraph obtained after deleting all the vertices in V', together with their incident edges. Given a subset of edges $E' \subset E$, we denote by $G \setminus E'$ the digraph obtained after deleting all the edges in E'.

2-Reachability and 2-Reachability closure. We write $u \rightsquigarrow_{2e} v$ (resp., $u \rightsquigarrow_{2v} v$) to denote that there are two *edge-disjoint* (resp., internally *vertex-disjoint*) paths from u to v, and $u \not\rightsquigarrow_{2e} v$ (resp., $u \not\rightsquigarrow_{2v} v$) otherwise. As a special case, we assume that $v \rightsquigarrow_{2e} v$ (resp., $v \rightsquigarrow_{2v} v$) for each vertex v in G. We define an abstract set $E^+ = E \cup \{\top, \bot\}$. The semantic of this set is as follows: $e \in E$ corresponds to an edge e separating two vertices, $\top$ corresponds to $\rightsquigarrow_{2e}$ (there is no single separating edge) and $\bot$ corresponds to $\not\rightsquigarrow$ (there is no path). Given a digraph G,



$$\begin{bmatrix} \top & (a,b) & (a,b) & (a,b) & (a,b) \\ (b,c) & \top & (b,c) & \top & (d,e) \\ (c,a) & (c,a) & \top & \top & (d,e) \\ \bot & \bot & \bot & \top & (d,e) \\ \bot & \bot & \bot & \bot & \top \end{bmatrix}$$

Figure 1 A graph and its (not unique) 2-reachability closure matrix.

we define a 2-*reachability closure* of G, denoted by $G^{\rightsquigarrow 2e}$, to be a matrix such that:

$$G^{\rightsquigarrow 2e}[u,v] \stackrel{\text{def}}{=} \begin{cases} \top & \text{if } u \rightsquigarrow_{2e} v \\ \bot & \text{if } u \not\rightsquigarrow v \\ e & \text{where } e \text{ is any separating edge for } u \text{ and } v. \end{cases}$$

Since $v \rightsquigarrow_{2e} v$ for each $v \in V$, $G^{\rightsquigarrow 2e}[v,v] = \top$. An example of a graph with a 2-reachability closure matrix is given in Figure 1. Note that a 2-reachability closure matrix is not necessarily unique, as there might be multiple separating edges for a given vertex pair. We define the 2-*reachability left closure* $G_L^{\rightsquigarrow 2e}$ by replacing *any separating edge* with *first separating edge* and the 2-*reachability right closure* $G_R^{\rightsquigarrow 2e}$ by replacing it with *last separating edge*.

Note that if there is only one edge separating u and v, then $G^{\rightsquigarrow 2e}[u,v] = G_L^{\rightsquigarrow 2e}[u,v] = G_R^{\rightsquigarrow 2e}[u,v]$. Given any 2-reachability closure matrix, one can compute efficiently the 2-reachability left and right closure matrices. We sketch below the basic idea for the left closure (the right closure is completely symmetric). Let u and v be any two vertices. If $G^{\rightsquigarrow 2e}[u,v]$ is either $\top$ or $\bot$, then $G_L^{\rightsquigarrow 2e}[u,v] = G^{\rightsquigarrow 2e}[u,v]$. Otherwise, let $G^{\rightsquigarrow 2e}[u,v] = (x,y)$: if $u \rightsquigarrow_{2e} x$ (i.e., if $G^{\rightsquigarrow 2e}[u,x] = \top$) then (x,y) is the first separating edge for u and v and $G_L^{\rightsquigarrow 2e}[u,v] = (x,y)$; otherwise, $u \not\rightsquigarrow_{2e} x$ (i.e., $G^{\rightsquigarrow 2e}[u,x] \neq \top$) and $G_L^{\rightsquigarrow 2e}[u,v] = G_L^{\rightsquigarrow 2e}[u,x]$. We show how to compute $G_L^{\rightsquigarrow 2e}$ and $G_R^{\rightsquigarrow 2e}$ from $G^{\rightsquigarrow 2e}$ in a total of $\mathcal{O}(n^2)$ worst-case time.

3 All-pairs 2-reachability in DAGs

In this section we present our $\mathcal{O}(n^\omega \log n)$ time algorithm for all-pairs 2-reachability in DAGs. The high-level idea is to mimic the way Boolean matrix multiplication can be used to compute the transitive closure of a graph: recursively along a topological order, combine the transitive closure of the first and the second half of the vertices in a single matrix multiplication. However, while in transitive closure for each pair (i,j) we have to store only information on whether there is a path from i to j, for all-pairs 2-reachability this is not enough. First, we describe a path algebra, used by our algorithm to operate on paths between pairs of vertices in a concise manner. We then continue with the description of a matrix product-like operation, which is the backbone of our recursive algorithm. Finally, we show how to implement those operations efficiently using some binary encoding and decoding at every step of the recursion.

Before introducing our new algorithm, we need some terminology. Let $G = (V,E)$ be a DAG, and let E_1, E_2 be a partition of its edge set E, $E = E_1 \cup E_2$. We say that a partition is an *edge split* if there is no triplet of vertices x, y, z in G such that $(x,y) \in E_2$ and $(y,z) \in E_1$ simultaneously. Informally speaking, under such split, any path in G from a vertex u to a vertex v consists of a sequence of edges from E_1 followed by a sequence of edges from E_2 (as a special case, any of those sequences can be empty). We denote the edge split by $G = (V, E_1, E_2)$ (See Figure 2). We say that vertex x in $G = (V, E_1, E_2)$ is on the *left* (resp., *right*) *side* of the partition if x is adjacent only to edges in E_1 (resp., E_2). We assume without loss of generality that the vertices of G are given in a topological ordering $v_1, v_2, \ldots, v_n$.

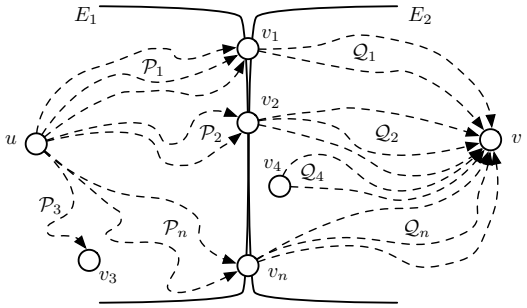


Figure 2 An edge split of a DAG $G = (V, E_1, E_2)$.

3.1 Algebraic approach

Consider a family of paths $\mathcal{P} = \{P_1, P_2, \ldots, P_\ell\}$, all sharing the same starting and ending vertices u and v. We would like to distinguish between the following three possibilities: (i) $\mathcal{P}$ is empty; (ii) at least one edge e belongs to every path $P_i \in \mathcal{P}$; or (iii) there is no edge that belongs to all paths in (nonempty) $\mathcal{P}$. To do that, we define the *representation* $\text{repr}(\mathcal{P})$:

$$\text{repr}(\mathcal{P}) \stackrel{\text{def}}{=} \bigcap_{i=1}^{\ell} P_i = \begin{cases} \mathbb{U} & \text{if } \mathcal{P} = \emptyset \\ \emptyset & \text{if no edge belongs to all } P_i \\ \{e \in E : e \in P_i,\ 1 \le i \le \ell\} & \text{otherwise.} \end{cases}$$

where $\mathbb{U}$ denotes the top symbol in the Boolean algebra of sets (i.e., the complement of $\emptyset$). We also define a *left representation* $\text{repr}_L(\mathcal{P}) \in E^+$, where $E^+ = E \cup \{\top, \bot\}$, as follows:

$$\text{repr}_L(\mathcal{P}) \stackrel{\text{def}}{=} \begin{cases} \bot & \text{if } \mathcal{P} = \emptyset \\ \top & \text{if no edge belongs to all } P_i \\ e & \text{such that } e \in P_i, 1 \le i \le \ell, \text{ and } \text{tail}(e) \text{ is } \textit{minimum} \\ & \text{in the topological order} \end{cases}$$

A *right representation* $\text{repr}_R(\mathcal{P}) \in E^+$ is defined symmetrically to $\text{repr}_L(\mathcal{P})$, by replacing *minimum* with *maximum*. If $\text{repr}_L(\mathcal{P}) \in E$ (resp., $\text{repr}_R(\mathcal{P}) \in E$), we say that $\text{repr}_L(\mathcal{P})$ (resp., $\text{repr}_R(\mathcal{P})$) is the *first* (resp., *last*) *common edge* in $\mathcal{P}$. Note that if $\mathcal{P}$ is the set of *all the paths* from u to v, then $\text{repr}(\mathcal{P})$ contains all the information about $G^{\rightsquigarrow 2e}[u, v]$. Additionally, $G_L^{\rightsquigarrow 2e}[u, v] = \text{repr}_L(\mathcal{P})$ and $G_R^{\rightsquigarrow 2e}[u, v] = \text{repr}_R(\mathcal{P})$. With a slight abuse of notation we also say that $G^{\rightsquigarrow 2e}[u, v] \in \text{repr}(\mathcal{P})$.

▶ **Observation 1.** *Let $G = (V, E_1, E_2)$ be an edge split of a DAG, and let u and v be two arbitrary vertices in G. For $1 \le i \le n$, let $\mathcal{P}_i = \{P \subseteq E_1 : P$ is a path from u to $v_i\}$, and $\mathcal{Q}_i = \{Q \subseteq E_2 : Q$ is a path from v_i to $v\}$ (See Figure 2) and let $\mathcal{S}$ be the family of all paths from u to v. Then:* $\text{repr}(\mathcal{S}) = \bigcap_{i=1}^{n} \Big(\text{repr}(\mathcal{P}_i) \cup \text{repr}(\mathcal{Q}_i)\Big)$

A straightforward application of Observation (1) yields immediately a polynomial time algorithm for computing $G^{\rightsquigarrow 2e}$. However, this algorithm is not very efficient, since the size of $\text{repr}(\mathcal{P})$ can be as large as $(n-1)$. In the following we will show how to obtain a faster algorithm, by replacing $\text{repr}(\mathcal{P})$ with a suitable combination of $\text{repr}_L(\mathcal{P})$ and $\text{repr}_R(\mathcal{P})$.

We next define two operations, denoted as *serial* and *parallel*. Although those operations are formally defined on $E^+ = E \cup \{\top, \bot\}$, they have a more intuitive interpretation as

operations on path families. We start with the serial operation $\otimes$. For $a, b \in E^+$, we define:

$$a \otimes b \stackrel{\text{def}}{=} \begin{cases} (\bot, \bot) & \text{if } a = \bot \text{ or } b = \bot \\ (a, b) & \text{otherwise.} \end{cases}$$

We define $\oplus$ as the parallel operator. Namely, for arbitrary $a \in E^+$: $a \oplus \bot \stackrel{\text{def}}{=} a$, $\bot \oplus a \stackrel{\text{def}}{=} a$, $a \oplus \top \stackrel{\text{def}}{=} \top$, $\top \oplus a \stackrel{\text{def}}{=} \top$, and otherwise, for $e, e' \in E$:

$$e \oplus e' \stackrel{\text{def}}{=} \begin{cases} \top & \text{if } e \neq e' \\ e & \text{if } e = e' \end{cases}$$

We extend the definition of $\oplus$ to operate on elements of $E^+ \times E^+$, as follows: $(a_1, b_1) \oplus (a_2, b_2) \stackrel{\text{def}}{=} (a_1 \oplus a_2, b_1 \oplus b_2)$. Ideally, we want the operator $\oplus$ either to preserve consistently the first common edge or to preserve consistently the last common edge, under the union of path families. If for instance we preserve the first common edge, that means that if $\mathcal{P}$ and $\mathcal{P}'$ are two path families sharing the same endpoints then we want $\text{repr}_L(\mathcal{P} \cup \mathcal{P}') = \text{repr}_L(\mathcal{P}) \oplus \text{repr}_L(\mathcal{P}')$ to hold. However, this is not necessarily the case, as for example both $\mathcal{P}$ and $\mathcal{P}'$ could consist of a single path, with both paths sharing an intermediate edge e', but both with two different initial edges, respectively e_1 and e_2. Thus $\text{repr}_L(\mathcal{P}) \oplus \text{repr}_L(\mathcal{P}') = e_1 \oplus e_2 = \top$ while $\text{repr}_L(\mathcal{P} \cup \mathcal{P}') = e'$. As shown in the following lemma, this is not an issue if the path families considered are exhaustive in taking every possible path between a pair of vertices.

▶ **Lemma 2.** *Let $G, \mathcal{P}_i, \mathcal{Q}_i$ and $\mathcal{S}$ be as in Observation 1. Then:*
(a) $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\bot, \bot)$ *iff* $\text{repr}(\mathcal{S}) = \mathbb{U}$*;*
(b) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (e_1, \top)$ *then* $\text{repr}(\mathcal{S}) \ni e_1$*;*
(c) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\top, e_2)$ *then* $\text{repr}(\mathcal{S}) \ni e_2$*;*
(d) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (e_1, e_2)$ *then* $\text{repr}(\mathcal{S}) \ni e_1, e_2$*;*
(e) $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\top, \top)$ *iff* $\text{repr}(\mathcal{S}) = \emptyset$*.*

We now consider the special case where one side of the partition defined in Observation 1 contains only paths of length one. In particular, we say that the edge set $E' \subseteq E$ is *thin*, if there exists no triplet of vertices x, y, z such that $(x, y) \in E'$ and $(y, z) \in E'$.

▶ **Lemma 3.** *Let $G, \mathcal{P}_i, \mathcal{Q}_i$ and $\mathcal{S}$ be as in Observation 1. Additionally, let E_1 be thin. Then*
(a) $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\bot, \bot)$ *iff* $\text{repr}_R(\mathcal{S}) = \bot$*;*
(b) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (e_1, \top)$ *then* $\text{repr}_R(\mathcal{S}) = e_1$*;*
(c) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\top, e_2)$ *then* $\text{repr}_R(\mathcal{S}) = e_2$*;*
(d) *if* $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (e_1, e_2)$ *then* $\text{repr}_R(\mathcal{S}) = e_2$*;*
(e) $\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i)) = (\top, \top)$ *iff* $\text{repr}_R(\mathcal{S}) = \top$*.*

We define the following projection operator π: $\pi(\bot, \bot) \stackrel{\text{def}}{=} \bot$, $\pi(\top, \top) \stackrel{\text{def}}{=} \top$, $\pi(e', e) = \pi(\top, e) = \pi(e, \top) \stackrel{\text{def}}{=} e$. With this new terminology, Lemma 2 and Lemma 3 can be simply restated as follows:

▶ **Corollary 4.** *Let $G, \mathcal{P}_i, \mathcal{Q}_i$ and $\mathcal{S}$ be as in Observation 1. Then*
(i) $\pi(\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i))) = \top$ *iff* $\text{repr}(\mathcal{S}) = \emptyset$*,*
(ii) $\pi(\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i))) = \bot$ *iff* $\text{repr}(\mathcal{S}) = \mathbb{U}$*, and*
(iii) $\pi(\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i))) \in \text{repr}(\mathcal{S})$ *otherwise.*

▶ **Corollary 5.** *Let $G, \mathcal{P}_i, \mathcal{Q}_i$ and $\mathcal{S}$ be as in Observation 1, and let E_1 be thin. Then* $\pi(\bigoplus_{i=1}^{n}(\text{repr}_L(\mathcal{P}_i) \otimes \text{repr}_R(\mathcal{Q}_i))) = \text{repr}_R(\mathcal{S})$*.*

Matrix product. Now we define a *path-based matrix product* based on the previously defined operators: $(A \circ B)[i,j] \stackrel{\text{def}}{=} \pi\big(\bigoplus_k A[i,k] \otimes B[k,j]\big)$. Throughout, we assume that the vertices of G are sorted according to a topological ordering. In the following lemma $\mathbf{B}$ represents a thin set of edges (i.e., the set of edges from a subset of vertices to another disjoint subset of vertices).

▶ **Lemma 6.** *Let* $\begin{bmatrix} A & B \\ 0 & C \end{bmatrix}$ *be the adjacency matrix of a DAG* $G = (V, E)$*, where* A, B *and* C *are respectively* $k \times k$*,* $k \times (n-k)$ *and* $(n-k) \times (n-k)$ *submatrices. If* $\mathbf{B}$ *is the matrix containing* $\perp$ *for every* 0 *in* B *and the appropriate* $e \in E$ *for every* 1 *in* B*, then:*

$$\begin{bmatrix} A_L^{\rightsquigarrow 2e} & A_L^{\rightsquigarrow 2e} \circ (\mathbf{B} \circ C_R^{\rightsquigarrow 2e}) \\ \perp & C_R^{\rightsquigarrow 2e} \end{bmatrix}$$

is a 2-reachability closure of G *(not necessarily unique).*

By Lemma 6, the 2-reachability closure can be computed by performing path-based matrix products on the left and right 2-reachability closures of smaller matrices. This gives immediately a recursive algorithm for computing the 2-reachability closure: indeed, as already shown in Section 2, one can compute the left and right 2-reachability closures in $\mathcal{O}(n^2)$ time from any 2-reachability closure. In the next section we show how to implement this recursion efficiently by describing how to compute efficiently path-based matrix products.

3.2 Encoding and decoding for Boolean matrix product

We start this section by showing how to efficiently compute path-based matrix products using Boolean matrix multiplications. The first step is to encode each entry of the matrix as a bitword of length $8k$ where $k = \lceil \log_2(n+1) \rceil$. We use Boolean matrix multiplication of matrices of bitwords, with bitwise AND/OR operations, denoted respectively with symbols $\wedge$ and $\vee$. Our bitword length is $\mathcal{O}(\log n)$, so matrix multiplication takes $\mathcal{O}(n^\omega \log n)$ time by performing Boolean matrix multiplication for each coordinate separately.

We make use of the fact that after each multiplication we can afford a post-processing phase, where we perform actions which guarantee that the resulting bitwords represent a valid 2-reachability closure.

First, we note that when encoding a specific matrix, we know whether it is used as a left-side or a right-side component of multiplication. The main idea is to encode left-side and right-side $\perp$ as $\{0\}^{8k}$, left-side and right-side $\top$ as $\{1\}^{8k}$. For any other value, append $\{1\}^{4k}$ as a prefix or suffix (depending on whether it is used as a left-side or right-side component), to the encoding of an edge. The encoding of an edge is a simple 1-superimposed code: concatenation of the edge ID and complement of the edge ID. To be more precise, whenever a bitword represents an edge e in a left-closure, then it is of the form $\mathrm{ID}_e\overline{\mathrm{ID}_e}\{1\}^{4k}$; whenever a bitword represents an edge e in a right-closure, then it is of the form $\{1\}^{4k}\mathrm{ID}_e\overline{\mathrm{ID}_e}$, where $\overline{w}$ denotes the complement of bitword w.

The serial operator $\otimes$ is implemented by coordinate-wise AND over two bitwords. Recall that the operator $\otimes$ always has as its first (left) operand an element from a left-closure matrix and as its second (right) operand an element from a right-closure. It is easy to verify that result of AND is a concatenation of two bitwords of length $4k$ encoding either $\perp, \top$ or $e \in E$. We observe that $\otimes$ is calculated properly in all cases: (let $e, e_1, e_2 \in E, e_1 \neq e_2$)

1. $e \otimes \top = (e, \top)$ since $\mathrm{ID}_e\overline{\mathrm{ID}_e}\{1\}^{4k} \wedge \{1\}^{8k} = \mathrm{ID}_e\overline{\mathrm{ID}_e}\{1\}^{4k}$,
2. $\top \otimes e = (e, \top)$ since $\{1\}^{8k} \wedge \{1\}^{4k}\mathrm{ID}_e\overline{\mathrm{ID}_e} = \{1\}^{4k}\mathrm{ID}_e\overline{\mathrm{ID}_e}$,
3. $e_1 \otimes e_2 = (e_1, e_2)$ since $\mathrm{ID}_{e_1}\overline{\mathrm{ID}_{e_1}}\{1\}^{4k} \wedge \{1\}^{4k}\mathrm{ID}_{e_2}\overline{\mathrm{ID}_{e_2}} = \mathrm{ID}_{e_1}\overline{\mathrm{ID}_{e_1}}\mathrm{ID}_{e_2}\overline{\mathrm{ID}_{e_2}}$,
4. $e \otimes \perp = \top \otimes \perp = \perp \otimes \perp = \perp \otimes e = \perp \otimes \top = (\perp, \perp)$ since $\{0,1\}^{8k} \wedge \{0\}^{8k} = \{0\}^{8k}$,
5. $\top \otimes \top = (\top, \top)$ since $\{1\}^{8k} \wedge \{1\}^{8k} = \{1\}^{8k}$.

The parallel operator $\oplus$ is implemented as coordinate-wise OR over bitwords of length $8k$. Note that all bitwords can be binary representations of pairs of elements in E^+ of the form $(e_1, e_2), (e_1, \top), (\top, e_2), (\bot, \bot), (\top, \top)$, since only those forms appear as a result of an $\otimes$ operation. Recall that $\oplus$ satisfies $(a_1, b_1) \oplus (a_2, b_2) = (a_1 \oplus a_2, b_1 \oplus b_2)$, thus w.l.o.g. it is enough to verify the correctness of the implementation over the first $4k$ bits of encoding. Observe that all cases, except when both bitwords include encoded edges, are managed correctly by the execution of coordinate-wise OR: (let $e \in E$)

1. $\bot \oplus \bot = \bot$ since $\{0\}^{4k} \vee \{0\}^{4k} = \{0\}^{4k}$,
2. $\bot \oplus e = e \oplus \bot = e$ since $\mathrm{ID}_e\overline{\mathrm{ID}_e} \vee \{0\}^{4k} = \mathrm{ID}_e\overline{\mathrm{ID}_e}$,
3. $\bot \oplus \top = \top \oplus \bot = \top$ since $\{1\}^{4k} \vee \{0\}^{4k} = \{1\}^{4k}$,
4. $e \oplus \top = \top \oplus e = \top$ since $\mathrm{ID}_e\overline{\mathrm{ID}_e} \vee \{1\}^{4k} = \{1\}^{4k}$.

We are only left to take care of operations of the form $e_1 \oplus e_2$ for $e_1, e_2 \in E$. According to the definition of the parallel operator $\oplus$, we would like $e_1 \oplus e_2 = e \in E$ iff $e_1 = e_2 = e$ and otherwise $e_1 \oplus e_2 = \top$. This special case is handled by the fact that we encode edges using 1-superimposed codes. That is, the binary representation of ID_e has the property that $\mathrm{ID}_e[1 \,..\, 2k] = \overline{\mathrm{ID}_e[2k+1 \,..\, 4k]}$. Moreover, the coordinate-wise OR of two encodings of edges, that is $\mathrm{X} = \mathrm{ID}_{e_1} \vee \mathrm{ID}_{e_2}$, has such property iff $e_1 = e_2$. Thus in order to successfully decode the result of chained $\oplus$ from coordinate-wise OR, we need to distinguish the following cases (our result is encoded as $\mathrm{X} = \mathrm{X}[1 \,..\, 2k]\mathrm{X}[2k+1 \,..\, 4k]$):

1. $\mathrm{X} = \{0\}^{4k}$, then the result is $\bot$,
2. $\mathrm{X}[1 \,..\, 2k] = \overline{\mathrm{X}[2k+1 \,..\, 4k]}$, then X is the encoding of the resulting edge,
3. otherwise the result is $\top$.

The implementation of a projection operator follows trivially.

The operations needed to compute the l-th coordinate of all entries of the final path-based matrix product (before decoding of entries) can be implemented as a Boolean matrix product of the l-th coordinate of the entries of $A_L^{\rightsquigarrow 2e}$ and $B_R^{\rightsquigarrow 2e}$. All the tools developed in this section allow us to compute the 2-reachability closure for DAGs. Our recursive algorithm follows closely Lemma 6.

▶ **Lemma 7.** *Given a DAG with n vertices, its 2-reachability closure can be computed in time $\mathcal{O}(n^\omega \log n)$.*

4 All-pairs 2-reachability in strongly connected graphs

In this section we focus on strongly connected graphs. In this case reachability is simple: for any pair of vertices $(u, v) \in V \times V$ we have $u \rightsquigarrow v$ in G. But in case that $u \not\rightsquigarrow_{2e} v$ in G, finding a separating edge that appears in all paths from u to v in G can still be a challenge. We show that we can report such an edge in constant time after $\mathcal{O}(n^\omega)$ preprocessing. The main result of this section is the following theorem.

▶ **Theorem 8.** *The 2-reachability closure of a strongly connected graph can be computed in time $\mathcal{O}(n^\omega)$.*

Our construction is based on the notion of auxiliary graph and it will be given in Section 4.3. Its running time will be analyzed in Lemma 13 and its correctness hinges on Lemma 15.

4.1 Reduction to two single-source problems

Let $G = (V, E)$ be a strongly connected digraph. Let s be a fixed but arbitrary vertex of G. The proof of the following lemma is immediate.

▶ **Lemma 9.** *For any pair of vertices u and v: If there is an edge $e \in E(G)$ such that $u \not\to v$ in $G \setminus e$, then either $u \not\to s$ in $G \setminus e$ or $s \not\to v$ in $G \setminus e$.*

Let $\mathcal{P}_{u,s}$ be the family of all paths from u to s and let $\mathcal{P}_{s,v}$ be the family of all paths from s to v. We denote by e_u the first edge on all paths in $\mathcal{P}_{u,s}$, and by e_v the last edge on all paths in $\mathcal{P}_{s,v}$. Note that there might be no edge that is on all paths of $\mathcal{P}_{u,s}$: in this case we say that e_u does not exist. If there are several edges on all paths in $\mathcal{P}_{u,s}$, then they are totally ordered, so it is clear which is the *first* edge (similarly for e_v and $\mathcal{P}_{s,v}$). We now show that in order to search for a separation witness for (u, v), it suffices to focus on e_u and e_v.

▶ **Lemma 10.** *If there is some e such that $u \not\to v$ in $G \setminus e$, then at least one of the following statements is true:*

- *e_u exists and $u \not\to v$ in $G \setminus e_u$.*
- *e_v exists and $u \not\to v$ in $G \setminus e_v$.*

Hence, in order to check whether there is an edge that separates u from v in G, it suffices to look at the reachability information in $G \setminus e_u$ (a graph which does not depend on u) and at the reachability information in $G \setminus e_v$ (a graph which does not depend on v). Unfortunately, this is not enough to derive an efficient algorithm, since we would have still to look at as many as $2n$ different graphs (as we explain later, and as it was first shown in [10], there can be at most $2n - 2$ edges whose removal can affect the strong connectivity of the graph). As a result, computing the transitive closures of all those graphs would require $\mathcal{O}(n^{\omega+1})$ time. The key insight to reduce the running time to $\mathcal{O}(n^{\omega})$ is to construct an auxiliary graph H, whose reachability is identical to $G \setminus e_v$ for any query pair (u, v), and a second auxiliary graph H' whose reachability is identical to $G \setminus e_u$ for any query pair (u, v). Note that the edge that is missing from the graph depends always on one of the two endpoints of the reachability query. As a consequence, we have to consider only n^2 and not n^3 different queries for H and H'.

4.2 Strong bridges and dominator tree decomposition

Before we construct these auxiliary graphs, we need some more terminology and prior results.

Flow graphs, dominators, and bridges. A *flow graph* $G_s = (V, E, s)$ is a digraph with a distinguished *start vertex* s. We denote by $G_s^R = (V, E^R, s)$ the reverse flow graph of G_s; the graph resulted by reversing the direction of all edges $e \in E$. Vertex u is a *dominator* of a vertex v (u *dominates* v) if every path from s to v in G_s contains u; u is a *proper dominator* of v if u dominates v and $u \neq v$. The dominator relation is reflexive and transitive. Its transitive reduction is a rooted tree, the *dominator tree* D: u dominates v if and only if u is an ancestor of v in D. If $v \neq s$, the parent of v in D, denoted by $d(v)$, is the *immediate dominator* of v: it is the unique proper dominator of v that is dominated by all proper dominators of v. For any vertex v, we let $D(v)$ denote the set of descendants of v in D, i.e., the vertices dominated by v. Dominators can be computed in linear time [2, 3, 7]. An edge (x, y) is a *bridge* of the flow graph G_s if all paths from s to y include (x, y).

Strong bridges. Let $G = (V, E)$ be a strongly connected digraph. An edge e of G is a *strong bridge* if $G \setminus e$ is no longer strongly connected. Let s be an arbitrary start vertex of G. Since G is strongly connected, all vertices are reachable from s and reach s, so we can view both G and G^R as flow graphs with start vertex s, denoted respectively by G_s and G^R_s.

▶ **Property 11** ([10]). *Let s be an arbitrary start vertex of G. An edge $e = (x, y)$ is a strong bridge of G if and only if it is a bridge of G_s or a bridge of G^R_s (or both).*

As a consequence of Property 11, all the strong bridges of the digraph G can be obtained from the bridges of the flow graphs G_s and G^R_s, and thus there can be at most $(2n-2)$ strong bridges in a digraph G. Using the linear time algorithms for computing dominators, we can thus compute all strong bridges of G in time $\mathcal{O}(m + n) \subseteq \mathcal{O}(n^\omega)$. We use the following lemma from [8] that holds for a flow graph G_s of a strongly connected digraph G.

▶ **Lemma 12** ([8]). *Let G be a strongly connected digraph and let (x, y) be a strong bridge of G. Also, let D and D^R be the dominator trees of the corresponding flow graphs G_s and G^R_s, respectively, for an arbitrary start vertex s.*

(a) *Suppose $x = d(y)$. Let w be any vertex that is not a descendant of y in D. Then there is a path from w to x in G avoiding all proper descendants of y in D. Moreover, all paths in G from w to any descendant of y in D contain the edge $(d(y), y)$.*

(b) *Suppose $y = d^R(x)$. Let w be any vertex that is not a descendant of x in D^R. Then there is a path from x to w in G avoiding all proper descendants of x in D^R. Moreover, all paths in G from any descendant of x in D^R to w contain the edge $(x, d^R(x))$.*

Bridge decomposition. After deleting from the dominator trees D and D^R respectively the bridges of G_s and G^R_s, we obtain the *bridge decomposition* of D and D^R into forests $\mathcal{D}$ and $\mathcal{D}^R$. Throughout this section, we denote by T_v (resp., T^R_v) the tree in $\mathcal{D}$ (resp., $\mathcal{D}^R$) containing vertex v, and by r_v (resp., r^R_v) the root of T_v (resp., T^R_v). Given a digraph $G = (V, E)$, and a set of vertices $S \subseteq V$, we denote by $G[S]$ the subgraph induced by S. In particular, $G[D(r)]$ denotes the subgraph induced by the descendants of vertex r in D.

4.3 Overview of the algorithm and construction of auxiliary graphs

The high-level idea of our algorithm is to compute two auxiliary graphs H and H' from G and G^R, respectively, with the following property: Given two vertices u and v, we have that $u \rightsquigarrow_{2e} v$ in G if and only $u \rightsquigarrow v$ in H and $v \rightsquigarrow u$ in H'. To construct the auxiliary graphs H and H', we use the bridge decompositions of D and D^R, respectively.

The two extremal edges e_u and e_v, defined in Section 4.1, can be also defined in terms of the bridge decompositions. In particular, e_v is the bridge entering the tree T_v of the bridge decomposition of D, so $e_v = (d(r_v), r_v)$, and e_u is the reverse bridge entering the tree D^R_u of the bridge decomposition of D^R, so $e_u = (r^R_u, d^R(r^R_u))$. Hence if there exists a path from u to v avoiding each of the strong bridges e_v and e_u, then $u \rightsquigarrow_{2e} v$ in G. By Lemma 10, it is enough if H models the reachability of $G \setminus e_v$ and H' the reachability of $G \setminus e_u$. So H is responsible for answering whether u has a path to v avoiding e_v, while H' is responsible for answering whether u has a path to v avoiding e_u. Then, if any of the reachability queries in H and H' returns false, we immediately have an edge that appears in all paths from u to v.

We next show to compute the auxiliary graphs H and H' in $\mathcal{O}(n^2)$ time. In particular, the auxiliary graph $H = (V, E')$ of the flow graph $G_s = (V, E, s)$ is constructed as follows. Initially, $E' = E \setminus BR$, where BR is the set of bridges of G_s. For all bridges (p, q) of G_s do the following: For each edge $(x, y) \in E$ such that $x \in D(q), y \notin D(q)$, we add the edge (p, y)

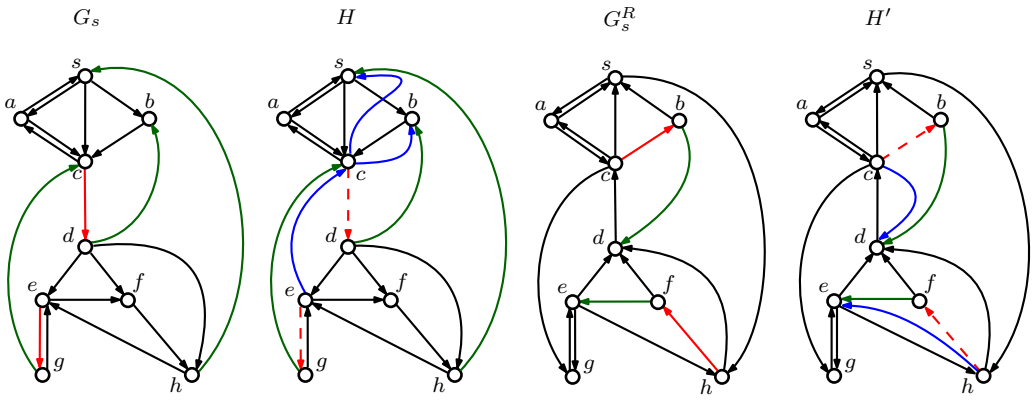

Figure 3 Auxiliary graphs H and H' which are derived from G_s and G_s^R, respectively. The deleted edges, the bridges of G_s and G_s^R, are shown in red, the newly added edges are shown in blue. The blue edges are drawn along the green edges from G_s and G_s^R which are the reason for their insertion. Here we see, that for example b is 2-reachable from e, since there are two (edge and vertex) disjoint paths (e, g, c, d, b) and (e, f, h, s, b) in G. In H, e reaches b through the path (e, c, b), and in H', b reaches e through the path (b, s, h, e). We also see, that edge (c, d) separates a and f in G, and even though f reaches a in H' through the path (f, d, c, a), a does not reach f in H. To illustrate why both H and H' are relevant in Lemma 15, consider the following example: vertex c is unreachable from b in $G \setminus (b, c)$, which we also detect as there is no c-b path in H' (even though there is a b-c path in H).

in E', i.e., we set $E' = E' \cup (p, y)$. A detailed implementation can be found in full version of the paper. Together with graph H, the algorithm outputs an array of edges ("witnesses") W, such that for each vertex $v \neq s$, $W[v] = (d(r_v), r_v)$ is a candidate separating edge for v and any other vertex. The computation of H' is completely analogous.

Once H and H' are computed, their transitive closure can be computed in $\mathcal{O}(n^\omega)$ time, after which reachability queries can be answered in constant time. Thus, we can preprocess a strongly connected digraph G in total time $\mathcal{O}(n^\omega)$ and answer 2-reachability queries in constant time, as claimed by Theorem 8.

▶ **Lemma 13.** *The auxiliary graph H can be computed in $\mathcal{O}(n^2)$ time and space.*

▶ **Lemma 14.** *For all $w \in V$, no edge $(x, y) \in E(H)$ exists with $x \notin D(r_w)$ and $y \in D(r_w)$.*

To show the correctness of our approach, we consider queries where we are given an ordered pair of vertices (u, v), and we wish to return whether there exists an edge e such that $u \not\rightsquigarrow v$ in $G \setminus e$. We can answer this query in constant time by answering the queries $u \rightsquigarrow v$ in H and $v \rightsquigarrow u$ in H'. Given Lemma 10, it is sufficient to prove the following:

▶ **Lemma 15.** *The auxiliary graphs H and H' satisfy these two conditions:*
- *If e_v exists, then $u \rightsquigarrow v$ in $G \setminus e_v$ if and only if $u \rightsquigarrow v$ in H.*
- *If e_u exists, then $u \rightsquigarrow v$ in $G \setminus e_u$ if and only if $v \rightsquigarrow u$ in H'.*

5 All-pairs 2-reachability in general graphs

In this section, we show how to compute the 2-reachability of a general digraph by suitably combining the previous algorithms for DAGs and for strongly connected digraphs. First, note that the 2-reachability closure of a strongly connected graph G can be constructed as follows: $G^{\rightsquigarrow 2e}[i, j] = \top$ if i has two edge-disjoint paths to j and $G^{\rightsquigarrow 2e}[i, j] \in E$ if there is

an edge $e \in E$ such that $i \not\rightsquigarrow j$ in $G \setminus e$. No entry of $G^{\rightsquigarrow 2e}$ contains $\perp$ since G is strongly connected. After $\mathcal{O}(n^\omega)$ time preprocessing all the above queries can be answered in constant time. Therefore, the 2-reachability closure can be computed in $\mathcal{O}(n^\omega)$ time.

Let G be a general digraph. The condensation of G is the DAG resulting after the contraction of every strongly connected component of G into a single vertex. We assume, without loss of generality, that the vertices are ordered as follows: The vertices in the same strongly connected component of G appear consecutively in an arbitrary order, and the strongly connected components are ordered with respect to the topological ordering of the condensation of G. Moreover, we assume that we have access to a function `stronglyConnected`(u, v) that answers whether the vertices u and v are strongly connected.

The key insight is that every idea presented in Section 3 never truly used the fact that the input graph is a DAG, just the properties of an edge split, that is finding edge partition into two sets so that no vertex has incoming edge from second set and outgoing edge from first set simultaneously. If we are able to extend the definition of an edge split to a general graph in a way highlighted above, and the definitions of $\text{repr}(), \text{repr}_R()$ and $\text{repr}_L()$, then all of the results from Section 3 carry over to a general graph G. Note that given *arbitrary* path family $\mathcal{P}$, $\text{repr}_L(\mathcal{P})$ and $\text{repr}_R(\mathcal{P})$ might be ill-defined, since paths in an arbitrary path family might not share the order of common edges. However, we are only using this notation for path families containing exactly all of paths connecting a given pair of vertices in the graph: for such families, the order of common edges is shared.

The high-level idea behind our approach is to extend the 2-reachability closure algorithm for DAGs, as follows. At each recursive call, the algorithm attempts to find a balanced separation of the set of vertices, with respect to their fixed precomputed order, into two sets such that there is no pair across the two sets that is strongly connected. If such a balanced separation can be found, then the instance is (roughly) equally divided into two instances. Otherwise, if there is no balanced separation of the set of vertices into two subsets, then one of the following properties holds: (i) the larger instance is a strongly connected component, or (ii) the recursive call on the larger instance separates a large strongly connected component, on which we can compute the 2-reachability closure in $\mathcal{O}(n^\omega)$ time.

▶ **Theorem 16.** *The 2-reachability closure for general graphs on n vertices can be computed in time $\mathcal{O}(n^\omega \log n)$.*

6 An application: computing all dominator trees

Let s be an arbitrary vertex of G. Recall the bridge decomposition $\mathcal{D}$ of (vertex-)dominator tree D and its tree T_v and root r_v from Section 4.2. We define the *edge-dominator tree* $\widetilde{D}$ of G with start vertex s, as the tree that results from D after contracting all vertices in each tree T_v into its root r_v. For any vertex v and edge $e = (x, y)$, e is contained in all paths in G from s to v if and only if (r_x, r_y) is in the path from s to r_v in $\widetilde{D}$. We denote by $\widetilde{d}(y)$ the parent of a vertex in $\widetilde{D}$. (Both y and $\widetilde{d}(y)$ are roots in $\mathcal{D}$.)

▶ **Theorem 17.** *We can compute all sources vertex- and edge-dominator trees from $G_R^{\rightsquigarrow 2e}$ in time $\mathcal{O}(n^2)$.*

We can preprocess each edge-dominator tree $\widetilde{D}$ in $\mathcal{O}(n)$ so as to answer ancestor-descendant relations in constant time [16]. We can also compute in $\mathcal{O}(n)$ time the number of descendants in D of every root r in $\mathcal{D}$. This allows us to answer various queries very efficiently:

- Given a pair of vertices s and t and an edge $e = (x, y)$, we can test if $G \setminus e$ contains a path from s to t in constant time. This is because e is contained in all paths from s to t

in G if and only if the following conditions hold: e is a bridge of flow graph G with start vertex s (i.e., $r_y = y$ and $\widetilde{d}(y) = r_x$) and y is an ancestor of r_t in $\widetilde{D}$.

- Similarly, given a vertex s and an edge $e = (x, y)$, we can report how many vertices become unreachable from s if we delete e from G. If e is a bridge of flow graph G with start vertex s, then this number is equal to the number of descendants of y in D. Hence, we find the edge whose removal disconnects the most pairs of vertices in time $\mathcal{O}(n^2)$.

By computing all vertex-dominator trees of G, we can answer analogous queries for vertex-separators. Moreover, we can answer efficiently queries regarding junctions. A vertex s is a *junction* of vertices u and v in G, if G contains a path from s to u and a path from s to v that are vertex-disjoint (i.e., s is the only vertex in common in these paths). Yuster [18] gave a $\mathcal{O}(n^\omega)$ algorithm to compute a single junction for every pair of vertices in a DAG. By having all dominator trees of a digraph G, we can also answer the following queries.

- Given vertices s, u and v, test if s is a junction of u and v. This is true if and only if u and v are descendants of distinct children of s in D. Hence, we perform this test in constant time.
- Similarly, we can report all junctions of a given a pair of vertices in $\mathcal{O}(n)$ time. Note that two vertices may have n junctions (e.g., in a complete graph).

Acknowledgments. We would like to thank Paolo Penna and Peter Widmayer for many useful discussions on the problem.

Abstract

Canonical orderings and their relatives such as st-numberings have been used as a key tool in algorithmic graph theory for the last decades. Recently, a unifying link behind all these orders has been shown that links them to well-known graph decompositions into parts that have a prescribed vertex-connectivity.

Despite extensive interest in canonical orderings, no analogue of this unifying concept is known for edge-connectivity. In this paper, we establish such a concept named *edge-orders* and show how to compute *(1,1)-edge-orders* of 2-edge-connected graphs as well as *(2,1)-edge-orders* of 3-edge-connected graphs in linear time, respectively. While the former can be seen as the edge-variants of *st-numberings*, the latter are the edge-variants of *Mondshein sequences* and *non-separating ear decompositions*. The methods that we use for obtaining such edge-orders differ considerably in almost all details from the ones used for their vertex-counterparts, as different graph-theoretic constructions are used in the inductive proof and standard reductions from edge- to vertex-connectivity are bound to fail.

As a first application, we consider the famous *Edge-Independent Spanning Tree Conjecture*, which asserts that every k-edge-connected graph contains k rooted spanning trees that are pairwise edge-independent. We illustrate the impact of the above edge-orders by deducing algorithms that construct 2- and 3-edge independent spanning trees of 2- and 3-edge-connected graphs, the latter of which improves the best known running time from $O(n^2)$ to linear time.

1 Introduction

Canonical orderings serve as a fundamental tool in various fields of algorithmic graph theory, see [2, 26] for a wealth of over 30 applications. Under this name, canonical orderings were published in 1988 for maximal planar graphs [8] and soon after generalized to 3-connected planar graphs [14]. Interestingly, it turned out only recently [26] that the well-known *non-separating ear decompositions* [6] are in fact strict generalizations of canonical orderings to arbitrary 3-connected graphs, and that this generalization was, independently, already known as *(2,1)-sequences* [19] in 1971 long before canonical orderings were even proposed (anticipating many of their later planar features).

Mondshein [19] characterized (2,1)-sequences, or *(2,1)-orders*, as we will call them, by decomposing a graph into 2-connected and connected parts. Indeed, the unifying link above

allows to describe any canonical ordering of a graph $G = (V, E)$ as a total order on V such that for certain i, the first i vertices induce a 2-connected graph and the remaining vertices induce a connected graph in G [26] (and hence, does not use any reference to planarity). The general concept behind canonical orderings is thus connectivity, with all of its implications for planarity, instead of planarity itself.

Several publications [20, 7, 4] extended this approach to (k,l)-*orders* with $(k,l) \neq (2,1)$. Such (k,l)-orders may be described canonically as total orders on V such that for certain i, the first i vertices induce a k-connected graph and the remaining vertices induce a l-connected graph (a related description for planar triangulations is given in [4]). We note that this is not a definition, as "certain i" has to be quantified for every particular (k,l). This is usually done in dependence of a graph decomposition, which tend to become more complex, as k or l grow: e.g. for $(2,1)$-orders, "certain i" is quantified by taking every vertex i that completes an ear with the predecessors of i in a fixed open ear decomposition of G.

Several relatives of (2,1)-orders fit into the context of (k,l)-orders: The well-known *st-numberings* and *st-orientations* are actually (1,1)-orders of 2-connected graphs, where i ranges over all vertices, the *chain decompositions* of [7] are (2,2)-orders of 4-connected graphs, and more orders on restricted graph classes such as planar graphs and triangulations are known (see Table 1 left).

The purpose of this paper is to extend this unifying view further to (k,l)-*edge-orders*, each of which can be described as a total order on E such that for certain i, the first i edges induce a k-edge-connected graph and the remaining edges induce a l-edge-connected graph. Despite the many known and heavily used vertex-orders above, these natural edge-variants do not seem to be well-studied. In fact, we are only aware of one technical report by Annexstein et al. [1], which deals with (1,1)-edge-orders (under the name *st-edge-orderings*). For the $(1,1)$-edge-order we present, i ranges over all edges except st; for the $(2,1)$-edge-order, i ranges over all edges that complete an ear with the predecessors of i in a fixed ear decomposition of G.

We show a simple algorithm how a (1,1)-edge-order can be computed and prove that it has running time $O(m)$. Our main contribution is then an algorithm that computes a (2,1)-edge-order of a 3-edge-connected graph in time $O(m)$ (see Table 1 right), of which the corresponding result for the vertex-counterpart took over 40 years.

Just like (2,1)-orders, which immediately led to improvements on the best-known running time for five applications [5, 26], (2,1)-edge-orders seem to be an important and useful tool for many graph algorithms. We give an application of them, which is related to the edge-independent spanning tree conjecture [13]: By using a (2,1)-edge-order, we show that three edge-independent spanning trees of 3-edge-connected graphs can be computed in time $O(m)$, improving the best-known running time $O(n^2)$ by Gopalan et al. [11].

We also considered the *3-edge-partition problem*, but surprisingly did not find an easy reduction to $(2,1)$-edge-orders. However, we note that this problem can be solved in linear time using existing algorithms: A 3-edge-partition can be computed by two linear-time reductions, first to the *vertex-subset tripartitioning problem* [28, Theorem 2b], and then [27] to the problem of computing a non-separating ear decomposition. It is also possible to find an alternative simple and direct linear-time reduction along the lines of [26, Application 5].

After giving preliminary facts on ear decompositions, we explain the linear-time algorithms for computing (1,1)- and (2,1)-edge-orders in Sections 3–5. Section 6 then shows algorithms for computing two and three edge-independent spanning trees.

1.1 Vertex-connectivity vs. edge-connectivity

In many cases, the vertex-variant of a connectivity problem is more challenging than its edge-variant, as the latter may be reduced to the former by taking its line-graph or by using the reduction from k-edge- to k-vertex-connectivity of Galil and Italiano [10]. From a top-level perspective, our (2,1)-edge-order algorithm follows the proof outline of its vertex-counterpart in [26]. Thus, it needs to be motivated that there is no obvious linear-time reduction to [26] that produces the results of this paper (of course there is a non-obvious reduction that just takes the algorithm of this paper and does not invoke [26] at all).

Clearly, a reduction to line-graphs is not possible, as this may involve a quadratic blow-up in the graph size and thus in the running time. Using the reduction of Galil-Italiano, we can reduce a 3-edge-connected graph G to a 3-connected graph G', and then compute a (2,1)-order of G' in linear time using [26]. However, it can be shown that there is no obvious way of transforming the (2,1)-order of G' back to a (2,1)-edge-order of G.

Another hint that such a reduction might be elusive is given by our application to edge-independent spanning trees. Despite extensive research, it is still not known how to reduce these to vertex-independent spanning trees (which may in turn be computed from a (2,1)-order [26]), not even for the corresponding existence results. In fact, an attempt trying to prove this turned out to be false [12]. If there was a reduction to (2,1)-orders, it would directly imply a reduction to vertex-independent spanning trees.

Hence, there is no obvious way of producing our results using old ones. Indeed, the different parts of our proof require substantially new ideas and non-trivial formalizations in comparison to [26]: Mader-sequences differ from the (BG)-sequences used in [26] (and, although they are not too far apart, it took a 27-page paper to show that the former can be computed in linear time as well [18]), the notions of non-separateness and $\overline{G_i}$ differ considerably, and, here, we need last-values in addition to just birth-values.

2 Preliminaries

We use standard graph-theoretic terminology and consider only graphs that are finite and undirected, but may contain parallel edges and self-loops. In particular, cycles may have length one or two. A separator of size one is called a *cut-vertex*. The *2-connected components* of a graph are its inclusion-wise maximal connected subgraphs having no cut-vertex. For $k \geq 1$, let a graph G be *k-edge-connected* if $n := |V| \geq 2$ and G has no edge-cut of size less than k.

▶ **Definition 1** ([15, 29]). An *ear decomposition* of a graph $G = (V, E)$ is a sequence $(P_0, P_1, \ldots, P_k)$ of subgraphs of G that partition E such that (i) P_0 is a cycle that is no self-loop and (ii) every P_i, $1 \leq i \leq k$, is either a path that intersects $P_0 \cup \cdots \cup P_{i-1}$ in its

endpoints or a cycle that intersects $P_0 \cup \cdots \cup P_{i-1}$ in a unique vertex q_i (which we call *endpoint* as well). Each P_i is called an *ear*. An ear is *short* if it is an edge and *long* otherwise.

▶ **Theorem 2** ([22]). *A graph is 2-edge-connected if and only if it has an ear decomposition.*

According to Whitney [29], every ear decomposition has exactly $m-n+1$ ears ($m := |E|$). For any i, let $G_i = (V_i, E_i) := P_0 \cup \cdots \cup P_i$ and $\overline{E_i} := E - E_i$. We denote the subgraph of G that is induced by $\overline{E_i}$ as $\overline{G_i} = (\overline{V_i}, \overline{E_i})$. Clearly, $\overline{G_j} \subset \overline{G_i}$ for every $i < j$. We note that this definition of $\overline{G_i}$ differs from the definition $\overline{G_i} := G - V_i$ that was used for (2,1)-vertex-orders [26], due to the weaker edge-connectivity assumption.

For any ear P_i, let $inner(P_i) := V(P_i) - G_{i-1}$ be the set of *inner vertices* of P_i (for P_0, every vertex is an inner vertex). Hence, for a cycle $P_i \neq P_0$, $inner(P_i) = V(P_i) - q_i$. Every vertex of G is an inner vertex of exactly one long ear, which implies that, in an ear decomposition, the inner vertex sets of the long ears partition V.

▶ **Definition 3.** Let $D = (P_0, P_1, \ldots, P_{m-n})$ be an ear decomposition of G. For an edge e, let $birth_D(e)$ be the index i such that P_i contains e. For a vertex v, let $birth_D(v)$ be the index i such that P_i contains v as inner vertex and let $last_D(v)$ be the maximal index $birth(vw)$ over all neighbors w of v. Whenever D is clear from the context, we will omit the subscript D.

Thus, $P_{last(v)}$ is the last ear that contains v and, seen from another perspective, the first ear P_i such that $\overline{G_i}$ does not contain v. Clearly, a vertex v is contained in $\overline{G_i}$ if and only if $last(v) > i$.

3 The (1,1)-edge-order

Although (1,1)-edge-orders can be seen as edge-counterparts of *st*-numberings, they do not seem to be well-known. Let two edges be *neighbors* if they share a common vertex. Annexstein et al. gave essentially the following definition.

▶ **Definition 4** ([1]). Let $G = (V, E)$ be a graph with an edge st that is not a self-loop. A *(1,1)-edge-order through st* of G is a total order $<$ on the edge set $E - st$ such that $m \geq 2$,

- every edge e, except for one incident to s, has a neighbor e' with $e' < e$ and
- every edge e, except for one incident to t, has a neighbor e' with $e < e'$.

Hence, the two exceptional edges incident to s and t must be, respectively, the minimal and maximal edge of $E - st$ with respect to $<$. Clearly, if G has a (1,1)-edge-order through st, G is 2-edge-connected, as neither st nor any other edge can be a bridge of G (note that this requires $m \geq 2$). The converse statement was shown in [1, Prop. 4] using a special type of ear decompositions based on breadth-first-search (however, without giving details of the linear-time algorithm). Here, we aim for a simple and direct (unlike, e.g., reducing to (1,1)-orders via line-graphs) exposition of the underlying idea and show that *any* ear decomposition can be transformed to a (1,1)-edge-order in linear time.

We will use the *incremental list order-maintenance problem*, which maintains a total order subject to the operations of (i) *inserting* an element after a given element and (ii) *comparing* two distinct given elements by returning the one that is smaller in the order. Bender et al. [3] show a simple solution for an even more general problem with amortized constant time per operation; we will call this the *order data structure*.

▶ **Lemma 5.** *Let G be a 2-edge-connected graph with an edge st that is not a self-loop. Then a (1,1)-edge-order through st can be computed in time $O(m)$.*

Proof. We compute an ear decomposition D of G such that $st \in P_0$. This can be done in linear time by any text-book-algorithm; see [24] for a simple one. Let $<_0$ be the total order that orders the edges in $P_0 - st$ consecutively from s to t. Thus, every edge has a smaller and a larger neighbor, except for st and the two exceptional edges incident to s and t. Clearly, $<_0$ is a (1,1)-edge-order through st of the 2-edge-connected graph G_0. We extend $<_{i-1}$ iteratively to a (1,1)-edge-order $<_i$ of G_i by adding the next ear P_i of D; then $<_{m-n}$ gives the claim.

The order itself is stored in the *order data structure*. For every vertex x in G_{i-1}, let $min(x)$ be the smaller of its two incident edges in $P_{birth(x)}$ with respect to $<_{i-1}$ (for later arguments, define $max(x)$ analogously as the larger such edge); clearly, $min(x)$ and $max(x)$ can be computed in constant time while adding P_j. When adding the ear P_i with (not necessarily distinct) endpoints x and y, let e be the smallest edge in $\{min(x), min(y)\}$ with respect to $<_{i-1}$ (this needs amortized constant time by using at most one comparison of the data structure). Consider all edges of P_i in consecutive order starting with a neighbor of e. We obtain $<_i$ from $<_{i-1}$ by inserting these edges as one consecutive block immediately after the edge e (if P_i is a cycle with endpoint s the edges are insert in front of the other edges); this takes amortized time proportional to the length of P_i. Then the first edge of P_i has a smaller neighbor in $<_i$ while the last has a larger neighbor in $<_i$ (for cycles $P_i \neq P_0$, this exploits that q_i has another incident edge in G_{i-1} or the exceptional edge incident to s (or t) might change), which implies that $<_i$ is a (1,1)-edge-order. ◀

This (special) (1,1)-edge-order will allow for a very easy computation of two edge-independent spanning trees in Section 6 and serve as a building block for the computation of three such trees. If one wants to keep the root-paths in two edge-independent spanning trees short, a different (1,1)-edge-order [1] may be computed by maintaining $min(x)$ as the incident edge of x that is minimal in G_i in the above algorithm (this can be done efficiently by updating $min(x)$ whenever an ear with endpoint x is added). However, the latter order cannot be used for three edge-independent spanning trees.

4 The (2,1)-edge-order

We define (2,1)-orders as special ear decompositions.

▶ **Definition 6.** Let G be a graph with distinct edges rt and ru ($t = u$ is possible). A *(2,1)-edge-order* through rt and avoiding ru (see Figure 1) is an ear decomposition D of G such that

1. $rt \in P_0$,
2. $P_{m-n} = ru$, and ▷ i.e., the last ear is the short ear ru
3. for every $0 \leq i < m - n$, $\overline{G_i}$ contains $inner(P_i)$ and, if P_i is short, at least one endpoint of P_i.

Property 6.2 implies that $\overline{G_i}$ contains the vertices r and u for every $0 \leq i < m - n$. We call Property 6.3 the *non-separateness* of D. The non-separateness of D states that every inner vertex of a long ear P_i has an incident edge in G that is in $\overline{G_i}$, and that every short ear P_i (seen as edge) has a neighbor in $\overline{G_i}$. The name refers to the following helpful property.

▶ **Lemma 7.** *Let D be a (2,1)-edge-order. Then, for every $0 \leq i < m - n$, $\overline{G_i}$ is connected.*

Proof. Consider any $i < m - n$ and let e be any edge in $\overline{G_i}$. By Property 6.2, $r \in \overline{G_i}$. We show that $\overline{G_i}$ contains a path from one of the endpoints of e to r. This gives the claim, as $\overline{G_i}$ is an edge-induced graph and therefore does not contain isolated vertices.

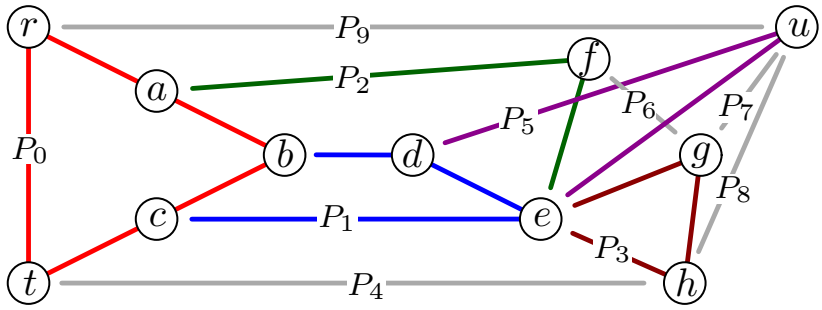

Figure 1 A (2,1)-edge-order of a 3-edge connected graph.

Let P_j be the unique ear that contains e. If P_j is short, $P_j = e$ and e has a neighbor in $\overline{G_j}$ due to the non-separateness of D. If P_j is long, at least one endpoint of e must be an inner vertex of P_j and e has a neighbor in $\overline{G_j}$ for the same reason. Hence, in both cases we find a neighbor that is contained in an ear P_k with $k > j$. By applying induction on the indices of these ears, we find a path that starts with an endpoint of e and ends with the only edge left in $\overline{G_{m-n-1}}$, namely ru. ◀

Next, we show that the existence of a (2,1)-edge-order proves the graph to be 3-edge-connected.

▶ **Lemma 8.** *If G has a (2,1)-edge-order, G is 3-edge-connected.*

Proof. Let D be a (2,1)-edge-order through rt and avoiding ru. Consider any vertex v of G. By transitivity of edge-connectivity, it suffices to show that G contains three edge-disjoint paths between v and r. Let P_i be the ear that contains v as inner vertex. In particular $i < m - n$, as P_i is long. Then G_i has an ear decomposition and, due to Theorem 2, contains two edge-disjoint paths between v and r. By Properties 6.2+3, $\overline{G_i}$ contains v and r. According to Lemma 7, $\overline{G_i}$ is connected. Thus, $\overline{G_i}$ contains a third path between v and r, which is edge-disjoint from the first two, as G_i and $\overline{G_i}$ are edge-disjoint. ◀

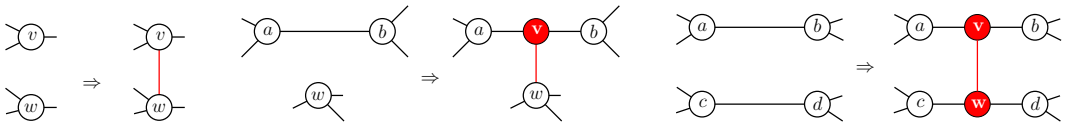
Let G have a (2,1)-edge-order. Then Lemma 8 implies $\delta(G) \geq 3$. This in turn gives that, for every vertex v, $P_{last(v)}$ is not the first ear that contains v, which implies that $P_{last(v)}$ must have v as endpoint. In particular, if vw is an edge and $last(v) = last(w) = birth(vw)$, $P_{birth(vw)}$ is the short ear vw and, according to the non-separateness of D, we have $i = m-n$, which implies $vw = ru$.

▶ **Lemma 9.** *For any vertex v, $P_{last(v)}$ has v as an endpoint. For any edge vw satisfying $last(v) = last(w) = birth(vw)$, $vw = ru$.*

The converse of Lemma 8 is also true: If G is 3-edge-connected, G has a (2,1)-edge-order. This gives a full characterization of 3-edge-connected graphs; however, proving the latter direction is more involved than Lemma 8. In the next section, we will prove the stronger statement that such a (2,1)-edge-order does not only exist but can actually be computed efficiently.

5 Computing a (2,1)-edge-order

At the heart of our algorithm is the following classical construction of 3-edge-connected graphs due to Mader.



(a) vertex-vertex-addition: $v = w$ is allowed.

(b) edge-vertex-addition: $w \in \{a, b\}$ is allowed.

(c) edge-edge-addition: $a, b \in \{c, d\}$ is allowed.

Figure 2 Mader-operations.

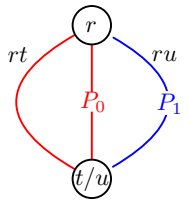


Figure 3 A (2,1)-edge-order of K_2^3 through rt and avoiding ru.

▶ **Definition 10.** The following operations on graphs are called *Mader-operations* (see Figure 2).

(a) *vertex-vertex-addition*: Add an edge between the not necessarily distinct vertices v and w (possibly a parallel edge or, if $v = w$, a self-loop).

(b) *edge-vertex-addition*: Subdivide an edge ab with a vertex v and add the edge vw for a vertex w.

(c) *edge-edge-addition*: Subdivide two distinct edges ab and cd with vertices v and w, respectively, and add the edge vw.

The edge vw is called the *added edge* of the Mader-operation. Let K_2^3 be the graph that consists of exactly two vertices and three parallel edges.

▶ **Theorem 11** ([16]). *A graph G is 3-edge-connected if and only if G can be constructed from K_2^3 using Mader-operations.*

According to Theorem 11, applying Mader-operations on 3-edge-connected graphs preserves 3-edge-connectivity. We will call a sequence of Mader-operations that constructs a 3-edge-connected graph a *Mader-sequence*. It has been shown that a Mader-sequence can be computed efficiently.

▶ **Theorem 12** ([18, Thm. 4]). *A Mader-sequence of a 3-edge-connected graph can be computed in time $O(n + m)$.*

Our algorithm for computing a (2,1)-edge-order works as follows. Assume we want a (2,1)-edge-order of G through $r\bar{t}$ and avoiding $r\bar{u}$. We first compute a suitable Mader-sequence of G using Theorem 12 and start with a (2,1)-edge-order of its first graph K_2^3. This (2,1)-edge-order is easy to find (see Figure 3). The crucial part of the algorithm is then to iteratively modify the given (2,1)-edge-order to a (2,1)-edge-order of the next graph in the sequence efficiently.

There are several technical difficulties to master. First, the edges $r\bar{t}$ and $r\bar{u}$ may be contained in different 2-connected components A' and B' (implying that r is a cut-vertex). As this would raise problems in the computation of the initial K_2^3 later, we perform in such a case the following reduction in advance. Let $\overline{A}$ be the connected component of $G \setminus \{r\}$

containing $\bar{t}$, $A := G[V(\overline{A}) \cup \{r\}]$ and $B := G \setminus V(\overline{A})$ (note that r may still be a cut-vertex of B). Since r is a cut-vertex of G, A and B are still 3-edge-connected. We compute a (2,1)-edge-order D_A of A avoiding $r\bar{t}$ through an arbitrary edge $ru_A \in A' \setminus \{r\bar{t}\}$, and a (2,1)-edge-order D_B of B avoiding an arbitrary edge $rt_B \in B' \setminus \{r\overline{u}\}$ through $r\overline{u}$. Then concatenating D_A with D_B gives a (2,1)-edge-order of G. Hence, we assume from now on that $r\bar{t}$ and $r\overline{u}$ are in the same 2-connected component of the input graph G.

Second, the edge $r\bar{t}$ (and analogously $r\overline{u}$) of G is not necessarily contained in the previous graph of the Mader-sequence, as it may have been created by a Mader-operation that subdivided a previous edge rt with the new vertex $\bar{t}$ (a more general view on this dynamics follows from the bijection between the graphs H of the Mader-sequence and H-subdivisions that are contained in G as subgraphs [18, Thm.+Cor. 1]; we refer to [23, Sections 2.3 and 4] for details of this bijection). In such cases, we take t as *replacement* vertex for $\bar{t}$ (and likewise u for $\overline{u}$) in the previous graph, and iterate this procedure to obtain replacement vertices for t and u in the graph before that previous graph, and so forth. This way, the replacement vertices t and u in any graph of the Mader-sequence containing r are neighbors of r.

Now a special Mader-sequence is used to harness the dynamics of the vertices r, t and u: Choose a DFS-tree of G with root r such that $r\bar{t}$ and $r\overline{u}$ are backedges (this is possible, since r has degree at least three) and compute a Mader-sequence of this DFS-tree that contains these two edges in its initial K_2^3 (this is possible, since $r\bar{t}$ and $r\overline{u}$ are in the same 2-connected component of G). This way the K_2^3 consists of the two vertices r and $t = u$ by the construction of [18, p. 6], and thus all graphs in the Mader-sequence contain r (and t and u are always neighbors of r). The vertices $\bar{t}$ and $\overline{u}$ are not present in this initial K_2^3 unless they are identical to $t = u$ (they are however contained in the two paths from r to $t = u$ of the K_2^3-subdivision the bijection maps to). For every graph in the Mader-sequence, we will compute a (2,1)-edge-order through rt and avoiding ru using the previous (2,1)-edge-order (which depends on the previous and possibly different replacement vertices); then the choice of t and u ensures that the final (2,1)-edge-order of G is indeed through $r\bar{t}$ and avoids $r\overline{u}$, as desired.

Thus, consider a graph G of the above Mader-sequence for which we know a (2,1)-edge-order D and let G' be the next graph in that sequence. Then G' is only one Mader-operation away and we aim for an efficient modification of D into a (2,1)-edge-order D' of G'. We will prove that there is always a modification that is local in the sense that the only ears that are modified are "near" the added edge of the Mader-operation.

▶ **Lemma 13.** *Let $D = (P_0, P_1, \ldots, P_{m-n})$ be a (2,1)-edge-order of a 3-edge-connected graph G through rt and avoiding ru for replacement vertices t and u. Let G' be obtained from G by applying one Mader-operation Γ and let t' and u' be the replacement vertices of G'. Then a (2,1)-edge-order D' of G' through rt' avoiding ru' can be computed from D using only constantly many amortized constant-time modifications.*

Lemma 13 is our main technical contribution and we split its proof into the following three sections. First, we introduce the operations *leg*, *belly* and *head* in order to combine several cases that can be handled similarly for the different types of Γ. Second, we show how to modify D to D' and, third, we discuss computational issues.

For all three sections, let vw be the added edge of Γ such that v subdivides the edge $ab \in E(G)$ and w subdivides $cd \in E(G)$ (if applicable). Thus, the vertex t' in G' is either t, v or w, and the vertex u' in G' is either u, v or w (hence, $t'r$ and ru' will never be self-loops). In all three sections, *birth* and *last* will always refer to D, unless stated otherwise.

Let $P_i \neq P_0$ be an ear with a given orientation and let x be a vertex in P_i. If P_i is a path, we define $P_i[, x]$ and $P_i[x,]$ as the *maximal subpaths* of P_i that end and start at x,

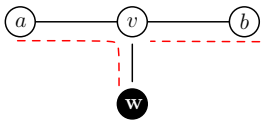

Figure 4 The result of operation *leg* (dashed lines), black vertices are in $G_{birth(ab)-1}$.

respectively; if P_i is a cycle, we take the same definition with the additional restriction that $P_i[, x]$ starts at q_i and $P_i[x,]$ ends at q_i. Occasionally, the orientation of P_i will not matter; if none is given, an arbitrary orientation can be taken. For paths A and B, let $A + B$ be the *concatenation* of A and B.

5.1 Legs, bellies and heads

While the operations *leg* and *belly* are inspired by the ones in [26], the operation *head* is new. All three operations will show for some special cases how D can be modified to a (2,1)-edge-order D'. A complete description for all cases (using these operations) will be given in the next section.

5.1.1 Legs

Let Γ be either an edge-vertex-addition such that $ab \neq ru$ and $last(w) < birth(ab)$ or an edge-edge-addition such that $ab \neq ru$ and $birth(cd) < birth(ab)$. If $P_{birth(ab)}$ is long, at least one of a and b is an inner vertex, say w.l.o.g. b. Otherwise, $P_{birth(ab)} = ab$ is short and, as D is non-separating, at least one of a and b, say w.l.o.g. b, has an incident edge in $\overline{G_{birth(ab)}}$ (note that this requires $ab \neq ru$). In both cases, orient $P_{birth(ab)}$ from a to b. The operation *leg* constructs D' from D by replacing the ear $P_{birth(ab)}$ of D by the two consecutive ears $P_{birth(ab)}[, a] + av + vw$ and $vb + P_{birth(ab)}[b,]$ in that order and, if Γ is an edge-edge-addition, additionally subdividing the edge cd in $P_{birth(cd)}$ with w (see Figure 4). Note that this definition is well-defined also for cycles $P_{birth(ab)}$, including self-loops.

We omit the proof that D' is a (2,1)-edge-order through rt' avoiding ru'.

5.1.2 Bellies

Let Γ be either an edge-vertex-addition such that $last(w) = birth(ab)$ and $w \notin \{a, b\}$ or an edge-edge-addition such that $birth(cd) = birth(ab)$ (note that $c, d \in \{a, b\}$ is allowed.) Consider the shortest path in $P_{birth(ab)}$ from an endpoint to one of the vertices $\{a, b\}$, say w.l.o.g. b, such that w is contained in this path. We orient $P_{birth(ab)}$ from a to b. $P_{birth(ab)}$ is a long ear with b as inner vertex. If Γ is an edge-edge-addition, one of the vertices $\{c, d\}$, say w.l.o.g. c, is contained in $P_{birth(ab)}[, w]$.

If $birth(ab) > 0$, the operation *belly* constructs D' from D by replacing the ear $P_{birth(ab)}$ of D by the two consecutive ears $P_{birth(ab)}[, a] + av + vw + P_{birth(ab)}[w,]$ and $vb + P_{birth(ab)}[b, w]$ in that order (if edge-vertex-addition) and by the two consecutive ears $P_{birth(ab)}[, a] + av + vw + wd + P_{birth(ab)}[d,]$ and $vb + P_{birth(ab)}[b, c] + cw$ (if edge-edge-addition), see Figure 5. Note that this definition is well-defined also if $P_{birth(ab)}$ is a cycle. If $birth(ab) = 0$, the vertices v and w cut P_0 in two distinct paths $P_{0,1}$ and $P_{0,2}$ having endpoints v and w. Let $P_{0,1}$ be the path containing r. Then the operation *belly* constructs D' from D by replacing the ear $P_{birth(ab)}$ of D by the two consecutive ears $P_{0,1} + vw$ and $P_{0,2}$ in this order. If $rt \in \{ab, cd\}$, then either $v = t'$ or $w = t'$, respectively.

We omit the proof that D' is a (2,1)-edge-order through rt' avoiding ru'.

Figure 5 The result of the operation *belly* (dashed lines).

Figure 6 The dashed lines show the result of the operation *head*.

5.1.3 Heads

Let Γ be an edge-vertex-addition such that $w \in \{a, b\}$, $last(a) = birth(ab)$ and, if $ab = ru$, then $r \neq a$. W.l.o.g. let $w = a$. Then a is an endpoint of $P_{birth(ab)}$ ($P_{birth(ab)}$ cannot be a self-loop, as $last(a) = birth(ab)$). We orient $P_{birth(ab)}$ from a to b. The operation *head* constructs D' from D by replacing the ear $P_{birth(ab)}$ of D by the two consecutive ears $av + va$ and $vb + P_{birth(ab)}[b,]$ in that order (see Figure 6). Note that this definition is well-defined also for cycles $P_{birth(ab)}$.

We omit the proof that D' is a (2,1)-edge-order through rt' avoiding ru'.

5.2 Modifying D to D'

We will now show how to obtain a (2,1)-edge-order D' through rt' avoiding ru' from D. By symmetry, assume w.l.o.g. that $birth(ab) \geq birth(cd)$. Note that applying the operations *belly*, *leg* and *head* preserves all properties of a $(2,1)$-edge-order. Recall that, for every subdivision the Mader-sequences does on rt or ru, respectively, the subdividing vertex is t' or u', as explained after Figure 3. We have the following case distinctions:

1. **Γ is a vertex-vertex-addition.** (See Figure 2a.)
   - **(a)** vw is a self-loop at v ($v = w$): Obtain D' from D by adding the new short ear vv directly after the ear $P_{last(v)-1}$. This ensures that the new ear is non-separating.
   - **(b)** $v \neq w$ and $vw \neq \{rt, ru\}$: If $last(v) \leq last(w)$, D' is obtained from D by adding the new short ear vw directly after the ear $P_{last(w)-1}$, ensuring that the new ear is non-separating. If $last(v) > last(w)$, the new short ear vw is added directly after the ear $P_{last(v)-1}$.
   - **(c)** $vw = rt$ (the added edge is a parallel edge): the Mader-sequence gives us the information whether rt is rt' or the new added edge is rt'. If $rt = rt'$ then add the new edge immediately after the ear $P_{last(t)-1}$. Otherwise obtain D' from D by replacing rt with rt' in P_0 and adding the old edge rt as an short ear immediately after the ear $P_{last(t)-1}$.
   - **(d)** $vw = ru$ (the added edge is a parallel edge): the Mader-sequence gives us the information whether ru is ru' or the new added edge is ru'. Depending on this information, obtain D' from D by either adding the new edge directly before or directly after the last ear of D.
5. **Γ is an edge-vertex-addition.** (See Figure 2b.)
   - **(a)** $birth(ab) < last(w)$: Obtain D' from D by adding the new short ear vw directly after the ear $P_{last(w)-1}$ and subdivide the ear $P_{birth(ab)}$ with v. This operation is also well-defined when $P_{birth(ab)}$ is a cycle or self-loop. Also, the new ear is non-separating and, since v is incident to w, the ear $P_{birth(ab)}$ remains non-separating.

- **(b)** $last(w) < birth(ab)$ and $ab \neq ru$: Apply *leg*
- **(c)** $birth(ab) = last(w)$ and $w \notin \{a, b\}$: Apply *belly*.
- **(d)** $birth(ab) = last(w)$ and $w \in \{a, b\}$; if $ab = ru$, then $r \neq w$: Apply *head*.
- **(e)** $ab = ru$ and if $birth(ab) = last(w)$ and $w \in \{a, b\}$ then $r = w$: Obtain D' from D by replacing the ear ru by the two consecutive ears $wv + vu$ and rv.

6. **Γ is an edge-edge-addition.** (See Figure 2c.)
   - **(a)** $birth(ab) = birth(cd)$: Apply *belly*.
   - **(b)** $birth(ab) > birth(cd)$ and $ab \neq ru$: Apply *leg*.
   - **(c)** $ab = ru$: Let w.l.o.g. $r = a$. Obtain D' from D by replacing the last ear of D by the two consecutive ears $bv + vw$ and rv in this order.

In all cases, D' is clearly an ear decomposition. Properties 6.1–3 are satisfied due to the given case distinction and the mentioned properties. Hence, D' is a $(2, 1)$-edge-order through rt' avoiding ru'.

There are several subtleties in sorting out the computational complexity of this approach, mostly raised by the question how fast we can compute one of the above cases in which we are in. The proof of the linear runtime is omitted due to space constraints.

▶ **Theorem 14.** *Given edges tr and ru of a 3-edge-connected graph G, a (2,1)-edge-order D of G through tr and avoiding ru can be computed in time $O(m)$.*

The proposed algorithms for (1,1)-edge-orders and (2,1)-edge-orders (as well as the computation of edge-independent spanning trees in the next section) are *certifying* in the sense of [17]: For (1,1)-edge-orders through st, it suffices to check that every edge $e \neq st$ has indeed a smaller and larger neighboring edge. For (2,1)-edge-orders, it suffices to check in linear time that D is an ear decomposition of G and that D satisfies Properties 6.1–3.

6 Edge-Independent Spanning Trees

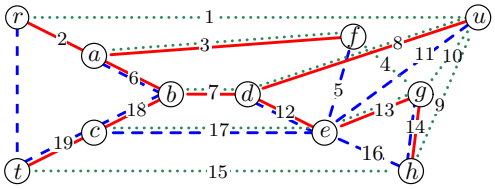
Let k spanning trees of a graph be *edge-independent* if they all have the same root vertex r and, for every vertex $x \neq r$, the paths from x to r in the k spanning trees are edge disjoint. The following conjecture was stated 1988 by Itai and Rodeh.

▶ **Conjecture** (Edge-Independent Spanning Tree Conjecture [13]). *Every k-edge-connected graph contains k edge-independent spanning trees.*

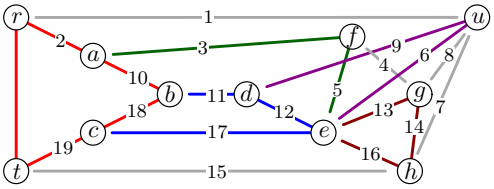
The conjecture has been proven constructively for $k \leq 2$ [13] and $k = 3$ [11] with running times $O(m)$ and $O(n^2)$, respectively, for computing the corresponding edge-independent spanning trees. For every $k \geq 4$, the conjecture is open. We first give a short description of an algorithm for $k = 2$ and then show the first linear-time algorithm for $k = 3$.

For $k = 2$, compute the (1,1)-edge-order $<$ through tr using Lemma 5. The first tree T_1 consists of the edges $min(x)$ for all vertices $x \neq r$ (as defined in Lemma 5), while the second tree T_2 consists of tr and the edges $max(x)$ for all vertices $x \notin \{r, t\}$. Then T_1 and T_2 are spanning, as no edge can be taken twice, and edge-independent, as, from every vertex x, the path of smaller edges to r obtained by iteratively applying $min()$ must be edge-disjoint from the path of larger edges to r.

For $k = 3$, choose any vertex r and two distinct edges tr and ru in the 3-edge-connected graph G. Compute a (2,1)-edge-order D through tr and avoiding ru in time $O(m)$ using Theorem 14. For every vertex $x \in V$, the idea is now to find *two* edge-disjoint paths from x to r in $G_{birth(x)}$ (after all, $G_{birth(x)}$ is 2-edge-connected and thus contains a (1,1)-edge-order)



(a) A consistent order $<$ and the resulting three edge-independent spanning trees.



(b) Although $<$ is a (1,1)-edge-order for every G_i, $0 \leq i \leq m-n$, $<$ is not consistent: Any down-consistent tree contains the root-paths $12, 11, 10, 2$ in G_2 and $6, 5, 3, 2$ in G_5, which implies a cycle.

Figure 7 (1,1)-edge-orders that are consistent and not consistent to the (2,1)-edge-order of Figure 1.

and a *third* path from x to r in $\overline{G_{birth(x)}}$ using the non-separateness of D. The subtle part is to make this idea precise: We have to construct the first tree T_1 in such a consistent way that the paths of smaller edges from x to r for *all* vertices $x \in V$ are contained in T_1 (and the same for T_2 and paths of larger edges).

For a (1,1)-edge-order $<$ through tr of G, let a spanning tree $T_1 \subseteq G$ be *down-consistent* to a given (2,1)-edge-order through tr if (a) every path in T_1 to r is strictly decreasing in $<$ and (b) for every $0 \leq i \leq m-n$, $T_1 \cap G_i$ is a spanning tree of G_i (analogously, *up-consistent* spanning trees T_2 of $G - r$ are defined by strictly increasing paths to t). Now let a (1,1)-edge-order be *consistent* to a given (2,1)-edge-order D' if G contains r-rooted spanning trees T_1 and T_2 that are down- and up-consistent to D', respectively. By the very same argument as used for $k = 2$, T_1 and $T_2 + tr$ are edge-independent and, in addition, do not use any edge of $\overline{G_{birth(x)}}$ for any $x \in V$.

In fact, the special (1,1)-edge-order that is computed by Lemma 5 is consistent to D: There, the trees T_1 and T_2 consist of the edges $min(x)$ and $max(x)$ for $x \in V$, which makes T_1 down-consistent and $T_2 + tr$ up-consistent to D (see Figure 7a). We note that a simpler definition of consistent as used for the vertex-variant [6], i.e., as *orders that remain (1,1)-edge-orders for all subgraphs* G_i, $0 \leq i \leq m-n$, does not suffice here (see Figure 7b).

It remains to construct the third edge-independent spanning tree. For every edge $e \neq ru$ of G, we compute a pointer to an arbitrary neighboring edge e' in $\overline{G_{birth(e)}}$. This edge e' exists, as D is non-separating, and satisfies $birth(e') > birth(e)$. Similarly, for every vertex $x \in V - r - u$, we compute a pointer to an incident edge e' of x with $birth(e') > birth(x)$. Both computations take linear total time by comparing *birth* values. The third edge-independent spanning tree is then the union of ur and the u-rooted spanning tree of $G - r$ that interprets the pointers as parent edges. Hence, we obtain the following theorem.

▶ **Theorem 15.** *Given the two edges rt and ru of a 3-edge-connected graph G, three edge-independent spanning trees of G rooted at r (such that two of them contain rt and ru as unique root edges, respectively) can be computed in time $O(m)$.*

Similarly as for the more general (2,1)-edge-orders, one could be interested why the reduction from k-edge- to k-vertex-connectivity by Galil and Italiano [10] does not give edge-independent spanning trees from their vertex-counterparts; we omit the argument due to space constraints.

Abstract

We introduce a nonlocal game that captures and extends the notion of graph isomorphism. This game can be won in the classical case if and only if the two input graphs are isomorphic. Thus, by considering quantum strategies we are able to define the notion of quantum isomorphism. We also consider the case of more general non-signalling strategies, and show that such a strategy exists if and only if the graphs are fractionally isomorphic. We prove several necessary conditions for quantum isomorphism, including cospectrality, and provide a construction for producing pairs of non-isomorphic graphs that are quantum isomorphic.

We then show that both classical and quantum isomorphism can be reformulated as feasibility programs over the completely positive and completely positive semidefinite cones respectively. This leads us to considering relaxations of (quantum) isomorphism arrived at by relaxing the cone to either the doubly nonnegative (DNN) or positive semidefinite (PSD) cones. We show that DNN-isomorphism is equivalent to the previous defined notion of graph equivalence, a polynomial-time decidable relation that is related to coherent algebras. We also show that PSD-isomorphism implies several types of cospectrality, and that it is equivalent to cospectrality for connected 1-walk-regular graphs. Finally, we show that all of the above mentioned relations form a strict hierarchy of weaker and weaker relations, with non-singalling/fractional isomorphism being the weakest. The techniques used are an interesting mix of algebra, combinatorics, and quantum information.

1 Introduction

Given graphs G and H, an *isomorphism* from G to H is a bijection $\varphi : V(G) \to V(H)$ such that $\varphi(g)$ is adjacent to $\varphi(g')$ if and only if g is adjacent to g'. When such an isomorphism exists, we say that G and H are *isomorphic* and write $G \cong H$. The notion of isomorphism is central to a broad area of mathematical research encompassing algebraic and structural graph theory, but also combinatorial optimization, parameterized complexity, and logic. The *graph isomorphism (GI) problem* consists of deciding whether two graphs are isomorphic. It is a question with fundamental practical interest due to the number of problems that can be reduced to it. Additionally, the GI problem has a central role in theoretical computer science as it is one of the few naturally defined problems in NP which is not known to be polynomial-time solvable or NP-complete. While there is a deterministic quasipolynomial algorithm for the GI problem [5], regardless of its worst case behavior, the problem can be solved with reasonable efficiency in practice (*e.g.* see [17]). In relation to the context of this paper, it is valuable to notice that the discussion around graph isomorphism has branched into the analysis of many equivalence relations that form hierarchical structures. Prominent instances are, for example, cospectrality, fractional isomorphism, *etc.* [4, 12, 26].

In this work we introduce the graph isomorphism game, which is played by non-communicating players and allows us to capture and extend the notion of graph isomorphism. We investigate three classes of strategies for this game: classical, quantum, and non-signalling. In the classical case, players can win the (G, H)-isomorphism game with certainty if and only if $G \cong H$. This motivates the definition of graphs G and H being quantum, or non-signalling, isomorphic if there exists a perfect quantum, resp. non-signalling, strategy for this game. These two relations are denoted by $G \cong_q H$ and $G \cong_{ns} H$ respectively. We are able to prove two algebraic characterizations of quantum isomorphism, one of which implies that quantum isomorphic graphs are cospectral. We also show that non-signalling isomorphism is equivalent to the previously studied linear relaxation of isomorphism known as *fractional isomorphism* [22].

Another approach we take is to develop characterizations of isomorphism and quantum isomorphism in terms of conic feasibility programs over the completely positive and completely positive semidefinite cones respectively. This is similar to work done in [13, 24, 25], but in our case the programs can be somewhat simplified due the highly structured form of the isomorphism game. By relaxing to either the doubly nonnegative ($\mathcal{DNN}$) or positive semidefinite ($\mathcal{S}_+$) cones, we are able to use this conic feasibility program to define $\mathcal{DNN}$- and $\mathcal{S}_+$-isomorphism, denoted $\cong_{\mathcal{DNN}}$ and $\cong_{\mathcal{S}_+}$ respectively. Interestingly, these semidefinite relaxations of quantum isomorphism are still stronger than non-signalling isomorphism. Therefore, for any graphs G and H we have that $G \cong H \Rightarrow G \cong_q H \Rightarrow G \cong_{\mathcal{DNN}} H \Rightarrow G \cong_{\mathcal{S}_+} H \Rightarrow G \cong_{ns} H$. Moreover, we are able to show that none of these implications can be reversed. In particular, we give a general method for constructing quantum isomorphic graphs that are not isomorphic, based on binary linear systems that are not satisfiable but are *quantum satisfiable*.

Interestingly, the notion of $\mathcal{DNN}$-isomorphism turns out to be equivalent to a previously studied relation in graph theory. This relation, known as graph *equivalence*, is defined in terms of an isomorphism between a certain matrix algebra associated to each of the graphs. To prove this equivalence, the main idea is to use the matrix in the conic feasibility program definition of $\mathcal{DNN}$-isomorphism as the Choi matrix of a linear map from the space of matrices indexed by $V(G)$ to the space of matrices indexed by $V(H)$. Like fractional isomorphism, there exists a polynomial time algorithm for deciding graph equivalence.

We also prove a similar algebraic characterization for $\mathcal{S}_+$-isomorphism, but this appears to be a new relation. However, we are able to prove that this relation is strictly stronger than cospectrality. We also show that classical, quantum, $\mathcal{DNN}$-, and $\mathcal{S}_+$-isomorphism can be characterized in terms of whether the Lovász theta function, or an appropriate generalization, achieves a particular value on a certain product graph. This is similar to the results of [24].

The full version of this work, including all of the proofs, is given in [3] and [16].

2 The Graph Isomorphism Game

Given graphs G and H, the (G, H)-isomorphism game is a nonlocal game whose inputs and outputs are vertices of the graphs G and H. For a detailed explanation of general nonlocal games see the full version of the paper [3]. The (G, H)-isomorphism game is played as follows: A referee/verifier selects uniformly at random a pair of vertices $x_A, x_B \in V(G) \cup V(H)$ and sends x_A to Alice and x_B to Bob respectively. The players respond with vertices $y_A, y_B \in V(G) \cup V(H)$. Throughout, we assume that $V(G)$ and $V(H)$ are disjoint so that players know which graph their vertex is from. As with any nonlocal game, Alice and Bob may agree on a strategy for playing the game beforehand, but they are not allowed to communicate after the game has commenced. In order to concisely state the conditions under which Alice and Bob win the (G, H)-isomorphism game, we let $\mathrm{rel}(g, g')$, for vertices g, g' of some graph G, denote the *relationship* of the vertices g and g', i.e., whether they are equal, adjacent, or distinct and non-adjacent.

The first winning condition is that each player must respond with a vertex from the graph that the vertex they received was *not* from. In other words we require that:

$$x_A \in V(G) \Leftrightarrow y_A \in V(H) \text{ and } x_B \in V(G) \Leftrightarrow y_B \in V(H)\,. \tag{1}$$

If condition (1) is not met, the players lose. Assuming (1) holds we define g_A to be the unique vertex of G among x_A and y_A, and we define g_B, h_A, and h_B similarly. In order to win, the answers of the players must also satisfy the following condition:

$$\mathrm{rel}(g_A, g_B) = \mathrm{rel}(h_A, h_B)\,. \tag{2}$$

In other words, if Alice and Bob are given the same vertex, then they must respond with the same vertex. If they receive (non-)adjacent vertices, they must return (non-)adjacent vertices. Also, assuming that Alice receives g_A and Bob h_B, Alice's output h_A must be related to h_B the same way Bob's output g_B is related to g_A. Note that we do not explicitly require that G and H have the same number of vertices. It is also worth pointing out that the (G, H)-isomorphism game is equivalent to the $(\overline{G}, \overline{H})$-isomorphism game, where $\overline{G}$ denotes the *complement* of G, i.e., the graph obtained by switching edges and non-edges of G.

In general one may be interested in the best probability with which Alice and Bob can win this game for some particular G and H. In this work however, we will only be interested in whether or not they can win *perfectly*, i.e., with probability 1. Thus, from henceforth when we say that Alice and Bob cam win the (G, H)-isomorphism game, we mean that they can win with probability 1. Similarly, a *winning* or *perfect strategy* is one that allows them to win with certainty.

Given any fixed strategy for the (G, H)-isomorphism game, we denote by $p(y_A, y_B|x_A, x_B)$ the joint conditional probability of Alice and Bob responding with y_A and y_B upon receiving inputs x_A and x_B respectively. We call such a joint conditional probability distribution a *correlation*. An easy but important observation is that a given strategy for the (G, H)-

isomorphism game is perfect if and only if its corresponding correlation p satisfies

$$p(y_A, y_B|x_A, x_B) = 0, \text{ whenever conditions (1) or (2) fail.} \tag{3}$$

In this work we will focus on three classes of strategies/correlations for the isomorphism game: classical, quantum, and non-signalling.

2.1 Classical strategies

A *deterministic classical strategy* for a nonlocal game is one in which Alice's response is determined by her input, and similarly for Bob. In a general classical strategy, the players may use shared randomness to determine their responses. Once the value that their shared randomness takes is fixed, Alice and Bob's strategy becomes deterministic. This means that the set of (perfect) classical correlations is equal to the convex hull of (perfect) classical deterministic correlations.

Suppose that $\varphi : V(G) \to V(H)$ is an isomorphism of graphs G and H. Then we can construct a perfect strategy for the (G, H)-isomorphism game as follows: if Alice receives $g \in V(G)$ as her input, then she responds with $\varphi(g)$ as her output, and if she receives $h \in V(H)$ as her input, then she responds with $\varphi^{-1}(h)$ as her output. Bob behaves identically. It is not hard to see that this allows Alice and Bob to win the game perfectly. It is not much more difficult to prove the converse (see [3]), and thus we have the following:

▶ **Theorem 1.** *For graphs G and H, the (G, H)-isomorphism game can be won perfectly with a classical strategy if and only if $G \cong H$.*

3 Quantum Isomorphism

In a quantum strategy for the (G, H)-isomorphism game, Alice and Bob are allowed to share and make joint measurements on an entangled state (see [3] for a detailed explanation of shared states and measurements). As any classical post-processing of the outcomes that Alice and Bob perform can be incorporated into the measurements themselves, we may assume that both Alice and Bob have a measurement for each input (an element of $V(G) \cup V(H)$) whose outcomes are indexed by their possible outputs (elements of $V(G) \cup V(H)$). Upon receiving input x, Alice performs her measurement corresponding to x and obtains some outcome y, which she uses as her output, and Bob behaves similarly. Formally, for each $x \in V(G) \cup V(H)$, Alice has a measurement $\mathcal{E}_x = \{E_{xy} \in \mathbb{C}^{d_A \times d_A} : y \in V(G) \cup V(H)\}$ where $E_{xy} \succeq 0$ and $\sum_{y \in V(G) \cup V(H)} E_{xy} = I$, and similarly Bob has measurement $\mathcal{F}_x = \{F_{xy} \in \mathbb{C}^{d_B \times d_B} : y \in V(G) \cup V(H)\}$. They perform these measurements on their shared state $\psi \in \mathbb{C}^{d_A} \otimes \mathbb{C}^{d_B}$. Note that there are no restrictions on $d_A, d_B \in \mathbb{N}$. The corresponding correlation p for this strategy is given by $p(y, y'|x, x') = \psi^\dagger \left(E_{xy} \otimes F_{x'y'}\right) \psi$. If there exists such a strategy that allows Alice and Bob to win the (G, H)-isomorphism game perfectly, then we say that G and H are *quantum isomorphic* and write $G \cong_q H$.

An important property of the isomorphism game is that if Alice and Bob are given the same inputs, they must respond with the same outputs. Games with this property are called *synchronous*, and the perfect quantum strategies for such games are known to have a particular form [14, 23, 15, 8, 21]. Using this we are able to give the following reformulation of quantum isomorphism, the full proof of which is given in [3]:

▶ **Theorem 2.** *Let G and H be graphs. Then $G \cong_q H$ if and only if there exists $d \in \mathbb{N}$ and orthogonal projectors $E_{gh} \in \mathbb{C}^{d \times d}$ for $g \in V(G)$ and $h \in V(H)$ such that*

(i) $\sum_{h\in V(H)} E_{gh} = I$, *for all* $g \in V(G)$;
(ii) $\sum_{g\in V(G)} E_{gh} = I$, *for all* $h \in V(H)$;
(iii) $E_{gh}E_{g'h'} = 0$, *if* $\mathrm{rel}(g,g') \neq \mathrm{rel}(h,h')$.

The projectors in the above theorem correspond to Alice's (or Bob's) measurement operators in a perfect quantum strategy. One consequence of this is that any winning quantum correlation p for the (G,H)-isomorphism game is *input-output symmetric*, i.e.,

$$p(y,y'|x,x') = p(x,y'|y,x') = p(y,x'|x,y') = p(x,x'|y,y') \text{ for all } x,x',y,y' \in V(G)\cup V(H).$$

Given a set of projectors as in the theorem above, one thing that we could do with them is to make them elements of a block matrix with rows indexed by $V(G)$ and columns indexed by $V(H)$. Investigating the properties of such a matrix leads to the following definition:

▶ **Definition 3.** A block matrix $\mathcal{P}$ with blocks of size d is called a *projective permutation matrix (of block size d)* if it is unitary and all of its blocks are orthogonal projectors.

Note that a projective permutation matrix of block size one is a unitary matrix whose entries square to themselves, *i.e.*, a permutation matrix. The following lemma (see [3] for full proof) shows that projective permutation matrices can be built out of projectors satisfying the first two conditions of Theorem 2.

▶ **Lemma 4.** *A block matrix* $\mathcal{P}$ *with blocks* E_{ij} *for* $i,j \in [n]$ *is a projective permutation matrix if and only if the matrix* E_{ij} *is a projector for all* $i,j \in [n]$ *and*
(i) $\sum_{j=1}^{n} E_{ij} = I$, *for all* $i \in [n]$;
(ii) $\sum_{i=1}^{n} E_{ij} = I$, *for all* $j \in [n]$.

We note that in the special case where all of the blocks E_{ij} of a projective permutation matrix are of rank one, then the unit vectors that the E_{ij} project onto form a *quantum Latin square*, a notion introduced in [18].

A useful reformulation of graph isomorphism can be stated in terms of the adjacency matrices of the corresponding graphs. Given a graph G, the adjacency matrix of G, denoted A_G, is the symmetric 01-matrix whose gg'-entry is 1 if and only if g is adjacent to g', which we denote by $g \sim g'$. Graphs G and H are isomorphic if and only if there exists a permutation matrix P such that $A_G P = PA_H$, or equivalently $P^T A_G P = A_H$. The motivation for considering projective permutation matrices is that they play the role of permutation matrices in an analogous formulation for quantum isomorphism. This is made precise by the following theorem, whose proof is given in [3]:

▶ **Theorem 5.** *For any two graphs* G *and* H *we have that* $G \cong_q H$ *if and only if there exists* $d \in \mathbb{N}$ *and a projective permutation matrix* $\mathcal{P}$ *of block size* d *such that*

$$(A_G \otimes I_d)\mathcal{P} = \mathcal{P}(A_H \otimes I_d). \tag{4}$$

Since projective permutation matrices are unitary, we can rewrite Equation (4) as $\mathcal{P}^\dagger(A_G \otimes I_d)\mathcal{P} = (A_H \otimes I_d)$. Again, since $\mathcal{P}$ is unitary, this implies that $A_G \otimes I_d$ and $A_H \otimes I_d$, and thus also A_G and A_H, have the same multiset of eigenvalues. Thus we have the following:

▶ **Corollary 6.** *If* $G \cong_q H$, *then* G *and* H *are cospectral with cospectral complements.*

3.1 Separating Classical and Quantum Isomorphism

In order to construct graphs that are quantum isomorphic but not isomorphic, we introduce a type of game investigated by Cleve and Mittal [9] known as *binary constraint system* (BCS) games. We will show that, in the linear case, one can reduce the existence of a perfect classical (quantum) strategy for a BCS game to the existence of a perfect classical (quantum) strategy to a corresponding isomorphism game.

A linear binary constraint system (BCS) $\mathcal{F}$ consists of a family of binary variables $x_1, \ldots, x_n$ and *constraints* $C_1, \ldots, C_m$, where each C_ℓ is a linear equation over $\mathbb{F}_2$ in some subset of the variables. Thus C_ℓ takes the form $\sum_{x_i \in S_\ell} x_i = b_\ell$ for some $S_\ell \subseteq \{x_1, \ldots, x_n\}$ and $b_\ell \in \{0, 1\}$. We say that a BCS is *satisfiable* if there is an assignment of values from $\mathbb{F}_2$ to the variables x_i such that every constraint C_ℓ is satisfied. Such an assignment is known as a *satisfying assignment*.

An example of a linear BCS is the following:

$$\begin{aligned} x_1 + x_2 + x_3 &= 0 & x_1 + x_4 + x_7 &= 0 \\ x_4 + x_5 + x_6 &= 0 & x_2 + x_5 + x_8 &= 0 \\ x_7 + x_8 + x_9 &= 0 & x_3 + x_6 + x_9 &= 1 \end{aligned} \tag{5}$$

where addition is over $\mathbb{F}_2$. Note that the BCS given above is not satisfiable. Indeed, every variable appears in exactly two constraints and thus summing up all equations modulo 2 we get $0 = 1$.

To any linear BCS $\mathcal{F}$ we associate the following nonlocal game, which we call the *BCS game*. In the BCS game, the verifier gives Alice a constraint C_ℓ and Bob a constraint C_k. In order to win, they must each respond with an assignment of values to the variables in their respective constraints such that those constraints are satisfied. Furthermore, for the variables in $S_\ell \cap S_k$, Alice and Bob must agree on their assignment. Note that if they are given the same constraint, these conditions imply that they must give the same response. We note that in [9], Cleve and Mittal also define a nonlocal game for any linear BCS. This game is very similar, though not identical to the above (Bob is only asked single variables in the game of [9]). However, their results imply that in the quantum and classical cases, these two games are equivalent.

As with the other nonlocal games we have considered in this work, it is not difficult to see that Alice and Bob can win the BCS game classically with probability 1 if and only if the corresponding BCS is satisfiable. This motivates the following definition.

▶ **Definition 7.** A linear BCS is called *quantum satisfiable* if there exists a perfect quantum strategy for the corresponding BCS game.

To any linear BCS $\mathcal{F}$ with m constraints we associate the graph $G_\mathcal{F}$ which is defined as follows: For each constraint C_ℓ, and each assignment $f : S_\ell \to \mathbb{F}_2$ that *satisfies* C_ℓ we include a vertex (ℓ, f). Furthermore, we add an edge between two vertices (ℓ, f) and (k, f') if they are *inconsistent*, *i.e.*, if there exists $x_i \in S_\ell \cap S_k$ such that $f(x_i) \neq f'(x_i)$. We remark that this construction is related to the FGLSS reduction from [10], which is well known in approximability literature.

Given any linear BCS $\mathcal{F}$, we define the *homogenization* of $\mathcal{F}$, denoted by $\mathcal{F}_0$, to be the linear BCS obtained from $\mathcal{F}$ by changing the righthand sides of all of the constraints to 0. Note that the homogenization of a linear BCS always has a solution, namely the all-zero assignment. Also note that $G_\mathcal{F}$ and $G_{\mathcal{F}_0}$ have the same number of vertices.

Using these constructions, we are able to prove the following (see [3] for proof), where $\alpha(G)$ denotes the independence number of the graph G:

▶ **Theorem 8.** *Let $\mathcal{F}$ be a linear BCS with m constraints. Then the following are equivalent:*

(i) *$\mathcal{F}$ is satisfiable;*
(ii) *The graphs $G_{\mathcal{F}}$ and $G_{\mathcal{F}_0}$ are isomorphic;*
(iii) *$\alpha(G_{\mathcal{F}}) = m$.*

Using the notions of quantum independence number, denoted α_q, and projective packings, we can also prove the following quantum analog of the above (see [3]):

▶ **Theorem 9.** *Let $\mathcal{F}$ be a linear BCS with m constraints. Then the following are equivalent:*

(i) *$\mathcal{F}$ is quantum satisfiable;*
(ii) *The graphs $G_{\mathcal{F}}$ and $G_{\mathcal{F}_0}$ are quantum isomorphic;*
(iii) *There exists a projective packing of $G_{\mathcal{F}}$ of value m;*
(iv) *$\alpha_q(G_{\mathcal{F}}) = m$.*

Thus, to find a pair of graphs that are quantum isomorphic but not isomorphic, it suffices to find a linear BCS that is quantum satisfiable but not satisfiable. One such example is the one given in (5), which corresponds to the well-known Mermin-Peres magic square game. The pair of graphs obtained from this BCS are shown in [3]. In fact, Arkhipov has shown how to construct such a BCS from any non-planar graph [1].

We note here that the first separating example, which was found with the help of Albert Atserias, was slightly different than the one presented above. It was a version of the celebrated CFI construction, named after Cai, Fürer and Immerman [7]. The original CFI construction was designed to produce pairs of non-isomorphic graphs that cannot be distinguished by the d-dimensional Weisfeiler-Lehman algorithm for any fixed d. The CFI construction was reinterpreted by Atserias, Bulatov, and Dawar [2] to view it as an encoding of special systems of linear equations over $\mathbb{Z}_2$, where each variable appears in precisely two equations. Our first separating example was literally the CFI construction corresponding to a system of linear equations as in [2], in which each variable appears in exactly two equations, and that is classically unsatisfiable over $\mathbb{Z}_2$ but quantum satisfiable. The Mermin-Peres magic square game gives rise to such a system of linear equations. The final construction which we described above is a simplified version of this, in which several vertices have been merged together, and several others have been removed, without changing the outcome. The final graphs have a few dozens of vertices. As it turns out, this streamlined version of the construction is quite similar to the FGLSS reduction from the theory of hardness of approximation [10], which interpreted in this context is a reduction from the feasibility problem for arbitrary systems of linear equations over $\mathbb{Z}_2$ to the graph isomorphism problem. As it turns out, the FGLSS construction was also used in the context of the graph isomorphism problem in [19].

4 Non-signalling Isomorphism

An important property of any quantum strategy for the (G, H)-isomorphism game (or any nonlocal game), is that it does not allow the players to communicate any information about their inputs to one another. Formally, this corresponds to

$$\begin{aligned}
&\sum_{y_B} p(y_A, y_B|x_A, x_B) = \sum_{y_B} p(y_A, y_B|x_A, x'_B), \text{ for all } x_A, y_A, x_B, x'_B, \text{ and} \\
&\sum_{y_A} p(y_A, y_B|x_A, x_B) = \sum_{y_A} p(y_A, y_B|x'_A, x_B), \text{ for all } x_B, y_B, x_A, x'_A
\end{aligned} \tag{6}$$

Any correlation which obeys this condition is known as *non-signalling*, and this is known to be a strictly larger class than quantum correlations. Note that this is a condition on correlations rather than strategies, and indeed there may not be any way to physically realize a given non-signalling correlation. Still, there are good reasons for considering this class of correlations. First, they are a linear relaxation of quantum correlations, and so they often allow us to obtain useful bounds on what is possible with quantum strategies, which are notoriously difficult to analyze. Second, they are interesting in their own right since they represent the extreme class of correlations in two senses. In the physical sense, the non-signalling condition can be thought of as encoding the notion that nothing, including information, can travel faster than the speed of light. Thus if Alice and Bob are separated by a great distance and must respond with their answers within a short window of time, then their strategy must be non-signalling. From a mathematical perspective, non-signalling correlations are the most general class of correlations it makes sense to consider for nonlocal games since any larger class would, by definition, allow the parties to communicate to a certain extent. This would essentially violate the definition of a nonlocal game which requires that the parties cannot communicate.

Using the non-signalling condition and the winning conditions of the isomorphism game, one can prove the following lemma (proof given in [3]):

▶ **Lemma 10.** *Let p be a winning non-signalling correlation for the (G, H)-isomorphism game. Then $p(h, h|g, g) = p(g, h|h, g) = p(h, g|g, h) = p(g, g|h, h)$, for all $g \in V(G)$, $h \in V(H)$.*

Note that for a winning correlation p for the (G, H)-isomorphism game, for $g \in V(G)$ we have that $p(y, y'|g, x') = 0$ unless $y \in V(H)$, and similarly with Alice and Bob or G and H switched. This, along with the above lemma allows us to take any winning non-signalling correlation for the (G, H)-isomorphism game and construct the following *doubly stochastic* matrix: $D_{gh} = p(h, h|g, g)$.

It turns out that this matrix has the interesting property that $A_G D = D A_H$. Whenever such a doubly stochastic matrix exists, one says that G and H are *fractionally isomorphic*, denoted $G \cong_f H$. Thus, non-signalling isomorphic graphs are always fractionally isomorphic.

To prove the converse of the above, we need a result of Ramana, Scheinerman, and Ullman [22] which shows that fractional graph isomorphism is equivalent to deciding whether the graphs have a common equitable partition. To explain this result we first need to introduce some definitions.

Let $\mathcal{C} = \{C_1, \ldots, C_k\}$ be a partition of $V(G)$ for some graph G. The partition $\mathcal{C}$ is called *equitable* if there exist numbers c_{ij} for $i, j \in [k]$ such that any vertex in C_i has exactly c_{ij} neighbors in C_j. Note that c_{ij} and c_{ji} are not necessarily equal, but $c_{ij}|C_i| = c_{ji}|C_j|$. We refer to the numbers c_{ij} as the *partition numbers* of an equitable partition $\mathcal{C}$. A trivial example of this is the partition where each part has size 1. Less trivially, if G is regular, the partition with only one cell is equitable.

Equivalently, a partition $\mathcal{C} = \{C_1, \ldots, C_k\}$ is equitable if for any $i \in [k]$, the subgraph induced by the vertices in C_i is regular, and for any $i \neq j \in [k]$ the subgraph with vertex set $C_i \cup C_j$ and containing the edges between C_i and C_j is a semiregular bipartite graph.

We say that $\mathcal{C}$ and $\mathcal{D}$ have a *common equitable partition* if there exist equitable partitions $\mathcal{C} = \{C_1, \ldots, C_k\}$ and $\mathcal{D} = \{D_1, \ldots, D_{k'}\}$ for G and H respectively, satisfying $k = k'$, $|C_i| = |D_i|$ for all $i \in [k]$, and lastly, $c_{ij} = d_{ij}$ for all $i, j \in [k]$. As an example, if G and H are both d-regular and have the same number of vertices, then the single cell partitions form a common equitable partition, and thus, by Theorem 11, any such graphs are fractionally isomorphic. This makes it seem like fractional isomorphism is a weak condition, but in fact it

is known [6] that asymptotically almost surely no graphs are fractionally isomorphic to any graphs that they are not isomorphic to. Since non-signalling/fractional isomorphism is the coarsest relation we will consider in this work, the same holds for all the other relations we will see. As mentioned above, common equitable partitions characterize fractional isomorphism.

▶ **Theorem 11** ([22]). *Two graphs are fractionally isomorphic if and only if they have a common equitable partition.*

Given a common equitable partition $\mathcal{C} = \{C_1, \dots, C_k\}$ and $\mathcal{D} = \{D_1, \dots, D_k\}$ for graphs G and H respectively, one can construct a perfect non-signalling strategy for the (G, H)-isomorphism game. The details are given in [3], but the idea is that if Alice is given $g \in C_i$ and Bob given $g' \in C_j$ and g and g' are adjacent/non-adjacent/equal, then they respond uniformly at random with $h \in D_i$ and $h' \in D_j$ that are adjacent/non-adjacent/equal. The fact that the corresponding correlation is non-signalling follows from the fact that $\mathcal{C}$ and $\mathcal{D}$ form a common equitable partition of G and H. Therefore, we have the following:

▶ **Theorem 12.** *For any graphs G and H we have that $G \cong_f H$ if and only if $G \cong_{ns} H$.*

5 Conic Formulations

Given graphs G and H and a winning correlation p for the (G, H)-isomorphism game, define the matrix M^p to be the matrix with rows and columns indexed by $V(G) \times V(H)$ to have entries $M^p_{gh,g'h'} = p(h, h'|g, g')$.

Note that the matrix M^p does not contain all of the probabilities of p, only those corresponding to inputs from $V(G)$ and outputs from $V(H)$. Thus, in general the matrix M^p may not completely determine the correlation p. However, if p is input-output symmetric, as in the case of classical or quantum correlations, then p is determined by the matrix M^p. Also note that in the classical and quantum cases Alice and Bob are symmetric, i.e., $p(y, y'|x, x') = p(y', y|x', x)$ for all $x, x', y, y' \in V(G) \cup V(H)$, and thus M^p is symmetric.

Since p is a correlation, sums of certain entries of M^p must be 1. Furthermore, since p is winning, certain entries of M^p must be 0. This motivates the following definition:

▶ **Definition 13.** Let G and H be graphs and $\mathcal{K}$ a matrix cone. We say that a matrix M with rows and columns indexed by $V(G) \times V(H)$ is a *$\mathcal{K}$-isomorphism matrix for G to H* if $M \in \mathcal{K}$ and

$$\sum_{h,h' \in V(H)} M_{gh,g'h'} = 1 \text{ for all } g, g' \in V(G) \tag{7}$$

$$\sum_{g,g' \in V(G)} M_{gh,g'h'} = 1 \text{ for all } h, h' \in V(H) \tag{8}$$

$$M_{gh,g'h'} = 0 \text{ if } \mathrm{rel}(g, g') \neq \mathrm{rel}(h, h'). \tag{9}$$

We will say that graphs G and H are $\mathcal{K}$-isomorphic, and write $G \cong_{\mathcal{K}} H$, whenever there exists a $\mathcal{K}$-isomorphism matrix for G to H.

Though we have defined them for any matrix cone $\mathcal{K}$, we will mainly be interested in just four cones in this work. The first cone is the positive semidefinite cone, denoted $\mathcal{S}_+$. Recall that a matrix M is positive semidefinite if and only if it is the Gram matrix of a set of vectors $v_1, \dots, v_n$, i.e., $M_{ij} = v_i^T v_j$. We will also be interested in the *doubly nonnegative cone*, denoted $\mathcal{DNN}$, which consists of all positive semidefinite matrices that are also entrywise nonnegative. The next cone we will consider is the recently introduced [13] *completely positive semidefinite*

cone, denoted $\mathcal{CS}_+$, which will correspond to quantum correlations. A matrix M is completely positive semidefinite if it is the Gram matrix of positive semidefinite matrices $\rho_1, \ldots, \rho_n$, i.e., $M_{ij} = \langle \rho_i, \rho_j \rangle := \mathrm{Tr}(\rho_i^\dagger \rho_j)$. Note that this inner product is equal to the usual inner product if we think of the matrices ρ_i as vectors, and thus $\mathcal{CS}_+ \subseteq \mathcal{S}_+$. Moreover, $\mathrm{Tr}(AB) \geq 0$ for any positive semidefinite matrices A and B, with equality if and only if $AB = 0$, and thus $\mathcal{CS}_+ \subseteq \mathcal{DNN}$. Lastly, the *completely positive cone*, denoted $\mathcal{CP}$, will correspond to the classical correlations. A matrix is completely positive if it is the Gram matrix of entrywise nonnegative vectors $v_1, \ldots, v_n$. Note that if D_i is the diagonal matrix with diagonal entries equal to the entries of v_i, then D_i is positive semidefinite and $v_i^T v_j = \mathrm{Tr}(D_i D_j)$. Therefore, $\mathcal{CP} \subseteq \mathcal{CS}_+$. Altogether we have that $\mathcal{CP} \subseteq \mathcal{CS}_+ \subseteq \mathcal{DNN} \subseteq \mathcal{S}_+$. Moreover, it is known that these containments are all strict for square matrices of dimension at least 5. With the above notions, we can prove the following (full proof given in [16]):

▶ **Theorem 14.** *Suppose G and H are graphs and p is a correlation for the (G, H)-isomorphism game. Then p is winning classical correlation if and only if p is input-output symmetric and M^p is a $\mathcal{CP}$-isomorphism matrix.*

▶ **Theorem 15.** *Suppose G and H are graphs and p is a correlation for the (G, H)-isomorphism game. Then p is a winning quantum correlation if and only if p is input-output symmetric and M^p is a $\mathcal{CS}_+$-isomorphism matrix.*

The above motivates us to investigate the notions of $\mathcal{DNN}$- and $\mathcal{S}_+$-isomorphism. In order to do this, we need to define something we call an isomorphism map.

After submission of this work, a referee informed us that the graph isomorphism problem has been formulated as a completely positive program previously in [11].

5.1 Isomorphism Maps

Given a $\mathcal{K}$-isomorphism matrix M for G to H, the *isomorphism map* Φ_M is a linear map from the space of complex matrices indexed by $V(G)$ to the space of complex matrices indexed by $V(H)$ defined as $(\Phi_M(X))_{h,h'} = \sum_{g,g'} M_{gh,g'h'} X_{g,g'}$.

For $\mathcal{K} \subseteq \mathcal{S}_+$, this map has some remarkable properties. In particular, it is completely positive, meaning that $\Phi_M \otimes \mathrm{id}$ maps psd matrices to psd matrices, where id can be an identity map of any size. This is not related to the completely positive cone, an unfortunate ambiguity. The map Φ_M is trace-preserving and unital, meaning that $\Phi_M(I) = I$. It also preserves the sum of the entries of a matrix, and maps the all ones matrix J to itself. If $\mathcal{K} \in \mathcal{DNN}$, then Φ_M maps entrywise nonnegative matrices to entrywise nonnegative matrices. These last three properties define a notion of being doubly stochastic purely in terms of linear maps. The adjoint of an isomorphism map from G to H is an isomorphism map from H to G. Lastly, one can show that $\Phi_M(A_G) = A_H$ and $\Phi_M^*(A_H) = A_G$, where Φ_M^* is the adjoint of Φ_M which will be an isomorphism map for H to G. Since the eigenvalues of a Hermitian matrix X majorize those of a Hermitian matrix Y if and only if there exists a completely positive, trace-preserving, unital map taking X to Y, this last property implies Lemma 16 below. None of these properties are difficult to show, and the details are given in [16].

▶ **Lemma 16.** *If G and H are $\mathcal{S}_+$-isomorphic graphs, then they are cospectral.*

The idea of isomorphism maps is borrowed from Ortiz and Paulsen who constructed similar linear maps from winning correlations for the *homomorphism* game in [20]. These isomorphism maps will allow us to give characterizations of $\mathcal{DNN}$- and $\mathcal{S}_+$-isomorphisms in terms of certain algebras associated to graphs. But first we must introduce these algebras.

5.2 Coherent and Partially Coherent Algebras

A subspace of $\mathbb{C}^{n\times n}$ which is also closed under matrix multiplication is an *algebra*. If $\mathcal{A}$ is a subalgebra of $\mathbb{C}^{n\times n}$, then $\mathcal{A}$ is a *coherent algebra* if it contains the identity and the all ones matrix, is closed under Schur (entrywise) product, and is closed under conjugate transpose, *i.e.*, is self-adjoint. The simplest example of a coherent algebra is $\text{span}\{I, J-I\}$. Of course, $\mathbb{C}^{n\times n}$ is itself a coherent algebra. Less trivially, if A is the adjacency matrix of any *strongly regular graph*, then $\text{span}\{I, A, J-I-A\}$ is a coherent algebra.

It follows from the fact that a coherent algebra $\mathcal{A}$ is closed under Schur product that it must have an orthogonal (with respect to the Hilbert-Schmidt inner product) basis of 01 matrices $A_1, \ldots, A_r$. To each of the matrices A_i, we can associate a subset of $V(G)\times V(G)$, namely the set of ordered pairs (g, g') such that the gg'-entry of A_i is 1. This gives a partition of the ordered pairs of vertices of G. One can reformulate the properties of being a coherent algebra in terms of this partition, and a partition with these properties is known as a *coherent configuration*. Conversely, any coherent configuration corresponds to some coherent algebra. The parts in a coherent configuration are usually referred to as its *classes*.

Coherent algebras of graphs

It is not hard to see that the intersection of two coherent algebras is a coherent algebra. We can therefore define the *coherent algebra of a graph* G, denoted $\mathcal{A}_G$, to be the intersection of all coherent algebras containing its adjacency matrix A_G, *i.e.*, the smallest coherent algebra containing A_G. Equivalently, this is the set of all matrices that can be written as a finite expression involving I, A, J, and the operations of addition, scalar multiplication, matrix multiplication, Schur multiplication, and conjugate transpose.

An *isomorphism* between coherent algebras $\mathcal{A}$ and $\mathcal{B}$ is a bijective linear map $\phi : \mathcal{A} \to \mathcal{B}$ that preserves all operations of a coherent algebra, *i.e.*,

- $\phi(M^\dagger) = \phi(M)^\dagger$ for all $M \in \mathcal{A}$;
- $\phi(MN) = \phi(M)\phi(N)$ for all $M, N \in \mathcal{A}$;
- $\phi(M \bullet N) = \phi(M) \bullet \phi(N)$ for all $M, N \in \mathcal{A}$.

As a consequence of the above, we must have that $\phi(I) = I$ and $\phi(J) = J$. More generally, if ϕ is an isomorphism of coherent algebras $\mathcal{A}$ and $\mathcal{B}$, then ϕ maps the elements of the unique 01 basis of $\mathcal{A}$ to those of $\mathcal{B}$ in a manner that preserves how the basis elements relate to one another (this is made precise in [16]).

▶ **Definition 17.** If G and H are two graphs with respective adjacency matrices A_G and A_H and coherent algebras $\mathcal{A}_G$ and $\mathcal{A}_H$, then we say that G and H are *equivalent* if there exists an isomorphism ϕ from $\mathcal{A}_G$ to $\mathcal{A}_H$ such that $\phi(A_G) = A_H$. We refer to the map ϕ as an *equivalence* of G and H.

Note that the condition $\phi(A_G) = A_H$ completely determines the function ϕ on $\mathcal{A}_G$. In Section 5.4, we show that two graphs are $\mathcal{DNN}$-isomorphic if and only if they are equivalent.

5.3 Partially Coherent Algebras

Suppose that S is some subset of $\mathbb{C}^{n\times n}$. We say that an algebra $\mathcal{A}$ is an *S-partially coherent algebra* if $\mathcal{A}$ contains the identity, is self-adjoint, contains the all ones matrix, and is closed under Schur multiplication by any matrix in S.

As with coherent algebras, it is easy to see that the intersection of two S-partially coherent algebras is an S-partially coherent algebra. Therefore, there is some minimal S-partially

coherent algebra for any S. This will be equal to the set of matrices that can be expressed using the elements of $S \cup \{I, J\}$ and a finite number of the operations of addition, scalar multiplication, matrix multiplication, conjugate transposition, and Schur multiplication where at least one of the factors is an element of S.

We define the *partially coherent algebra of a graph* G, denoted $\hat{\mathcal{A}}_G$, to be the minimal S-partially coherent algebra where $S = \{I, A_G\}$. Note that this will also be S'-partially coherent for $S' = \{I, A_G, A_{\overline{G}}\}$ since $A_{\overline{G}} = J - I - A_G$ and J is the Schur identity.

▶ **Definition 18.** Let G and H be graphs with adjacency matrices A_G and A_H and partially coherent algebras $\hat{\mathcal{A}}_G$ and $\hat{\mathcal{A}}_H$ respectively. We say that G and H are *partially equivalent* if there exists a linear bijection $\phi : \hat{\mathcal{A}}_G \to \hat{\mathcal{A}}_H$ such that

1. $\phi(M^\dagger) = \phi(M)^\dagger$ for all $M \in \hat{\mathcal{A}}_G$;
2. $\phi(MN) = \phi(M)\phi(N)$ for all $M, N \in \hat{\mathcal{A}}_G$;
3. $\phi(I) = I$, $\phi(A_G) = A_H$, and $\phi(J) = J$;
4. $\phi(M \bullet N) = \phi(M) \bullet \phi(N)$ for all $M \in \{I, A_G\}$ and $N \in \hat{\mathcal{A}}_G$.

We refer to ϕ as a *partial equivalence* of G and H.

5.4 Characterizations of $\mathcal{DNN}$- and $\mathcal{S}_+$-Isomorphisms

Using the ideas from the previous sections we can now give our characterizations of $\mathcal{DNN}$- and $\mathcal{S}_+$-isomorphisms (full proof given in [16]):

▶ **Theorem 19.** *Let G and H be graphs. Then $G \cong_{\mathcal{DNN}} H$ if and only if G and H are equivalent. Also, $G \cong_{\mathcal{S}_+} H$ if and only if G and H are partially equivalent.*

The proof of the above goes roughly as follows: If $G \cong_{\mathcal{DNN}} H$, then there exists a $\mathcal{DNN}$-isomorphism matrix M and corresponding isomorphism map Φ_M. When restricted to the coherent algebra $\mathcal{A}_G$, the map Φ_M is an equivalence of G and H. Conversely, suppose ϕ is an equivalence of G and H, and let Π be the orthogonal projection of $\mathbb{C}^{V(G)\times V(G)}$ to $\mathcal{A}_G$, then the Choi matrix of the map $\phi \circ \Pi$ is a $\mathcal{DNN}$-isomorphism matrix for G to H. The proof for $\mathcal{S}_+$-isomorphism is similar.

There is a well known algorithm, known as the Weisfeiler-Lehman algorithm, that determines whether two graphs are equivalent. Thus $\mathcal{DNN}$-isomorphism is polynomial time decidable. We do not yet know the complexity of $\mathcal{S}_+$-isomorphism, but we suspect it is also polynomial time decidable.

We can use the above characterizations of $\mathcal{DNN}$- and $\mathcal{S}_+$-isomorphisms to prove the following results for 1-walk-regular and distance regular graphs (proofs given in [16]):

▶ **Theorem 20.** *Let G be a connected 1-walk-regular graph. If H is a graph, then $G \cong_{\mathcal{S}_+} H$ if and only if H is a connected 1-walk-regular graph that is cospectral to G.*

▶ **Theorem 21.** *Let G be a distance regular graph. If H is a graph, then $G \cong_{\mathcal{DNN}} H$ if and only if H is a distance regular graph that is cospectral to G.*

▶ **Lemma 22.** *If $G \cong_{\mathcal{DNN}} H$, then G and H have the same radius and diameter.*

6 Separations

In Section 3.1 we saw that isomorphism and quantum isomorphism are distinct relations. In this section we show that the rest of relations we have defined are distinct from one another. Here we give examples and brief explanations, but the full details are in [16].

Quantum vs. $\mathcal{DNN}$-Isomorphism. The 4×4 rook's graph and the Shrikhande graph are cospectral distance regular graphs. Therefore, they are $\mathcal{DNN}$-isomorphic by Theorem 21. However, we show that their complements have different quantum chromatic numbers, a parameter that is preserved by quantum isomorphism (see [3] for details).

$\mathcal{DNN}$-Isomorphism vs. $\mathcal{S}_+$-Isomorphism. The 4-cube graph has the binary strings of length 4 as its vertices, two being adjacent if they differ in exactly one bit. The Hoffman graph is the unique cospectral mate of the 4-cube, and they are both connected and 1-walk-regular. Therefore they are $\mathcal{S}_+$-isomorphic by Theorem 20. However, the 4-cube has radius 4 and the Hoffman graph has radius 3, thus they are not $\mathcal{DNN}$-isomorphic by Lemma 22.

$\mathcal{S}_+$-Isomorphism vs. Non-signalling Isomorphism. By Lemma 16, any pair of k-regular graphs on n vertices for some n and k that are not cospectral will work for this. For example, the 6-cycle and two disjoint 3-cycles will do.

Acknowledgements. The authors would like to especially thank Albert Atserias who was instrumental in finding the first separation between isomorphism and quantum isomorphism.

Honest Signaling in Zero-Sum Games Is Hard, and Lying Is Even Harder*†

Aviad Rubinstein

UC Berkeley, Berkeley, CA, USA
aviad@eecs.berkeley.edu

Abstract

We prove that, assuming the exponential time hypothesis, finding an ϵ-approximately optimal signaling scheme in a two-player zero-sum game requires quasi-polynomial time $(n^{\tilde{\Omega}(\lg n)})$. This is tight by [8] and resolves an open question of Dughmi [12]. We also prove that finding a multiplicative approximation is NP-hard.

We also introduce a new model where a dishonest signaler may publicly commit to use one scheme, but post signals according to a different scheme. For this model, we prove that even finding a $(1 - 2^{-n})$-approximately optimal scheme is NP-hard.

1 Introduction

Many classical questions in economics involve extracting information from strategic agents. Lately, there has been growing interest within algorithmic game theory in *signaling*: the study of how to *reveal information* to strategic agents (see e.g. [16, 13, 14, 12, 8] and references therein). Signaling has been studied in many interesting economic and game theoretic settings. Among them, Zero-Sum Signaling proposed by Dughmi [12] stands out as a canonical problem that cleanly captures the computational nature of signaling. In particular, focusing on zero-sum games clears away issues of equilibrium selection and computational tractability of finding an equilibrium.

▶ **Definition 1** (Zero-Sum Signaling [12])**.** Alice and Bob play a Bayesian zero-sum game where the payoff matrix M is drawn from a publicly known prior. The signaler Sam privately observes the state of nature (i.e. the payoff matrix), and then publicly broadcasts a signal $\varphi(M)$ to both Alice and Bob. Alice and Bob Bayesian-update their priors according to $\varphi(M)$'s and play the Nash equilibrium of the expected game; but they receive payoffs according to the true M. Sam's goal is to design an efficient signaling scheme φ (a function from payoff matrices to strings) that maximizes Alice's expected payoff.

Dughmi's [12] main result proves that assuming the hardness of the Planted Clique problem, there is no additive FPTAS for Zero-Sum Signaling. The main open question

left by [12] is whether there exists an additive PTAS. Here we answer this question in the negative: we prove that assuming the Exponential Time Hypothesis (ETH) [15], obtaining an additive-ϵ-approximation (for some constant $\epsilon > 0$) requires quasi-polynomial time $(n^{\tilde{\Omega}(\lg n)})$. This result is tight thanks to a recent quasi-polynomial $(n^{\frac{\lg n}{\text{poly}(\epsilon)}})$ time algorithm by Cheng et al. [8]. Another important advantage of our result is that it replaces the hardness of Planted Clique with a more believable worst-case hardness assumption (see e.g. the discussion in [7]).

▶ **Theorem 2** (Main Result). *There exists a constant $\epsilon > 0$, such that assuming ETH, approximating* Zero-Sum Signaling *with payoffs in $[-1, 1]$ to within an additive ϵ requires time $n^{\tilde{\Omega}(\lg n)}$.*

Using a similar construction, we also obtain NP-hardness for computing a multiplicative-$(1-\epsilon)$-approximation. Unfortunately, in our example Alice can receives both negative and positive payoffs, which is somewhat non-standard (but not unprecedented [9]) in multiplicative approximation. One main reason that multiplicative approximation with negative payoffs is problematic is that this is often trivially intractable for any finite factor: Start with a tiny additive gap, where Alice's expected payoff is c in the "yes" case, and $s = c - \epsilon$ in the "no" case; subtract $(c + s)/2$ from all of Alice's payoffs to obtain an infinite multiplicative hardness. We note, however, that the combination of negative and positive payoffs in our construction serves only to obtain structural constraints on the resulting equilibria; the hardness of approximation is not a result of cancellation of negative with positive payoffs: Alice's payoff can be decomposed as a difference of non-negative payoffs $U = U^+ - U^-$, such that it is hard to approximate Alice's optimal payoff to within $\epsilon \cdot \mathsf{E}[U^+ + U^-]$. Nevertheless, we believe that extending this result to non-negative payoffs could be very interesting.

▶ **Theorem 3.** *There exists a constant $\epsilon > 0$, such that it is* NP*-hard to approximate* Zero-Sum Signaling *to within a multiplicative $(1-\epsilon)$ factor.*

Finally, we note that since all our games are zero-sum, the hardness results for Zero-Sum Signaling also apply to the respective notions of additive- and multiplicative-ϵ-Nash equilibrium.

1.1 The computational complexity of lying

As a motivating example, consider the purchase of a used car (not a zero-sum game, but a favorite setting in the study of signaling since Akerlof's seminal "Market for Lemons" [2]), and let us focus on the information supplied by a third party such as a mechanic inspection. The mechanic (Sam) publishes a signaling scheme: report any problem found in a one-hour inspection. Unbeknownst to the buyer (Bob), the mechanic favors the seller (Alice), and chooses to use a different signaling scheme: always report that the car is in excellent condition. Notice that it is crucial that the buyer does not know that the mechanic is lying (and more generally, we assume that neither party knows that the signaler is lying).

Much of the work in economics is motivated by selfish agents manipulating their private information. Here we introduce a natural extension of Dughmi's signaling model, where the signaler manipulates his private information. We formalize this extension in the Zero-Sum Lying problem, where the signaling scheme consists of two functions φ_{ALLEGED} ("report any problem found") and φ_{REAL} ("car is in excellent condition") from payoff matrices to signals. Sam promises Alice and Bob to use φ_{ALLEGED}, which is what Alice and Bob use to compute the posterior distribution given the signal (i.e. the seller and buyer look at the mechanic's

report and negotiate a price as if the state of the car is correctly reflected). But instead Sam signals according to φ_{REAL}.

We formally define the Zero-Sum Lying problem below; notice that the original Zero-Sum Signaling (Definition 1) corresponds to the special case where we restrict $\varphi_{\text{REAL}} = \varphi_{\text{ALLEGED}}$.

▶ **Definition 4** (Zero-Sum Lying)**.** Alice and Bob play a Bayesian, one-shot, zero-sum game where the payoff matrix is drawn from a publicly known prior. A *dishonest signaling scheme* consists of two (possibly randomized) functions $\varphi_{\text{ALLEGED}}, \varphi_{\text{REAL}}$ from payoff matrices to signals, that induce the following protocol:

- Nature draws a private payoff matrix $M \sim \mathcal{D}_{\text{NATURE}}$.
- Alice and Bob observe the scheme φ_{ALLEGED} and the signal $\sigma \triangleq \varphi_{\text{REAL}}(M)$. (But they don't know the scheme φ_{REAL}!)
- Alice and Bob choose a Nash equilibrium $(\mathbf{x}; \mathbf{y})$ for the zero-sum game with payoff matrix $\mathsf{E}[M' \mid \varphi_{\text{ALLEGED}}(M') = \sigma]$[1].
  - (We assume that the support of φ_{REAL} is contained in the support of φ_{ALLEGED}.)
- Alice and Bob receive payoffs $\mathbf{x}^\top M \mathbf{y}$ and $-\mathbf{x}^\top M \mathbf{y}$, respectively.

Sam's goal is to compute a pair $(\varphi_{\text{ALLEGED}}, \varphi_{\text{REAL}})$ that maximizes Alice's expected payoff.

In the toy-setting of a biased car inspection, the Sam's optimal strategy was very simple. In contrast, we show that for a general distribution over zero-sum games, it is NP-hard to find a pair $(\varphi_{\text{ALLEGED}}, \varphi_{\text{REAL}})$ that is even remotely close to optimal. Notice that this is very different from the honest case where, as we mentioned earlier, NP-hardness of additive approximation is unlikely given the additive quasi-PTAS of [8].

▶ **Theorem 5.** *Approximating* Zero-Sum Lying *with Alice's payoffs in* $[0, 1]$ *to within an additive* $(1 - 2^{-n})$ *is* NP*-hard.*

Further discussion of dishonest signaling

It is important to note that the dishonest signaling model has a few weaknesses:

- Alice and Bob must believe the dishonest signaler. (See also further discussion below.)
- In particular, Sam cheats in favor of Alice, but Alice doesn't know about it – so what's in it for Sam? Indeed, we assume that Sam has some intrinsic interest in Alice winning, e.g. because Sam loves Alice or owns some of her stocks.
- The game for which players' strategies are at equilibrium may be very different from the actual game. Note, however, that this is also the case for the honest signaling model (when the signaling scheme is not one-to-one).
- The players may receive different payoffs for different equilibria; this may raise issues of equilibrium selection.

Despite those disadvantages, we believe that our simple model is valuable because it already motivates surprising results such as our Theorem 5. On a higher level, we hope that it will inspire research on many other interesting aspects on dishonest signaling. For example, notice that in our model Sam lies without any reservation; if, per contra, the game was repeated infinitely many times, one would expect that Alice and Bob will eventually stop

[1] When $\varphi_{\text{ALLEGED}}, \varphi_{\text{REAL}}$ are randomized, we have $\sigma \sim \varphi_{\text{REAL}}(M)$ and expectation conditioned on $\mathsf{E}\left[M' \mid \sigma \sim \varphi_{\text{ALLEGED}}\left(M'\right)\right]$.

believing the signals, hence only honest signaling is possible. There is also a spectrum of intermediate situations, where Alice and Bob observe some partial information about past games (e.g. marginal distribution of signals) and may encounter questions about distribution testing.

Another related direction of potential future research is to think about Sam's incentives. When is honest signaling optimal for Sam? When is it approximately optimal? How should one design an effective "punishing" mechanism?

1.2 Concurrent work of Bhaskar et al.

In independent concurrent work by Bhaskar et al. [5], quasi-polynomial time hardness for additive approximation of Zero-Sum Signaling was obtained assuming the hardness of the Planted Clique problem (among other interesting results[2] about network routing games and security games). Although we are not aware of a formal reduction, hardness of Planted Clique is a qualitatively stronger assumption than ETH in the sense that it requires average case instances to be hard. Hence in this respect, our result is stronger.

1.3 Techniques

Our main ingredient for the quasi-polynomial hardness is the technique of "birthday repetition" coined by [1] and recently applied in game theoretic settings in [7, 4]: We reduce from a 2-ary constraint satisfaction problem (2-CSP) over n variables to a distribution over N zero-sum $N \times N$ games, with $N = 2^{\Theta(\sqrt{n})}$. Alice and Bob's strategies correspond to assignments to tuples of $\sqrt{n}$ variables. By the birthday paradox, the two $\sqrt{n}$-tuples chosen by Alice and Bob share a constraint with constant probability. If a constant fraction of the constraints are unsatisfiable, Alice's payoff will suffer with constant probability. Assuming ETH, approximating the value of the CSP requires time $2^{\tilde{\Omega}(n)} = N^{\tilde{\Omega}(\lg N)}$.

1.3.0.1 The challenge

The main difficulty is that once the signal is public, the zero-sum game is tractable. Thus we would like to force the signaling scheme to output a satisfying assignment. Furthermore, if the scheme would output partial assignments on different states of nature (aka different zero-sum games in the support), it is not clear how to check consistency between different signals. Thus we would like each signal to contain an entire satisfying assignment. The optimal scheme may be very complicated and even require randomization, yet by an application of the Caratheodory Theorem the number of signals is, wlog, bounded by the number of states of nature [12]. If the state of nature can be described using only $\lg N = \tilde{\Theta}(\sqrt{n})$ bits[3], how can we force the scheme to output an entire assignment?

To overcome this obstacle, we let the state of nature contain a partial assignment to a random $\sqrt{n}$-tuple of variables. We then check the consistency of Alice's assignment with nature's assignment, Bob's assignment with nature's assignment, and Alice and Bob's assignments with each other; let $\tau^{A,Z}, \tau^{B,Z}, \tau^{A,B}$ denote the outcomes of those consistency checks, respectively. Alice's payoff is given by:

$$U = \delta\tau^{A,Z} - \delta^2\tau^{B,Z} + \delta^3\tau^{A,B}$$

[2] For zero-sum games, Bhaskar et al. also rule out an additive FPTAS assuming $\mathsf{P} \neq \mathsf{NP}$. This result follows immediately from our Theorem 14.

[3] In other words, N, the final size of the reduction, is an upper bound on the number of states of nature.

for some small constant $\delta \in (0,1)$. Now, both Alice and Bob want to maximize their chances of being consistent with nature's partial assignment, and the signaling scheme gains by maximizing $\tau^{A,B}$.

Of course, if nature outputs a random assignment, we have no reason to expect that it can be completed to a full satisfying assignment. Instead, the state of nature consists of N assignments, and the signaling scheme helps Alice and Bob play with the assignment that can be completed.

Several other obstacles arise; fortunately some can be handled using techniques from previous works on hardness of finding Nash equilibrium [3, 10, 4].

2 Preliminaries

Exponential Time Hypothesis

▶ **Hypothesis 6** (Exponential Time Hypothesis (ETH) [15]). *3SAT takes time* $2^{\Omega(n)}$.

PCP Theorem and CSP

▶ **Definition 7** (2CSP). 2-CSP (2-ary Constraint Satisfaction Problem) is a maximization problem. The input is a graph $G=(V,E)$, alphabet Σ, and a constraint $C_e \subseteq \Sigma \times \Sigma$ for every $e \in E$.

The output is a labeling $\varphi : V \to \Sigma$ of the vertices. Given a labeling, we say that a constraint (or edge) $(u,v) \in E$ is *satisfied* if $\varphi(u), \varphi(v) \in C_{(u,v)}$. The *value of a labeling* is the fraction of $e \in E$ that are satisfied by the labeling. The value of the instance is the maximum fraction of constraints satisfied by any assignment.

▶ **Theorem 8** (PCP Theorem [11]; see e.g. [6, Theorem 2.11] for this formulation). *Given a 3SAT instance ϕ of size n, there is a polynomial time reduction that produces a 2CSP instance ψ, with size $|\psi| = n \cdot \mathrm{polylog} n$ variables and constraints, and constant alphabet size, such that:*

Completeness. *If ϕ is satisfiable, then so is ψ.*

Soundness. *If ϕ is not satisfiable, then at most a $(1-\eta)$-fraction of the constraints in ψ can be satisfied, for some $\eta = \Omega(1)$.*

Balance. *Every variable in ψ participates in exactly $d = O(1)$ constraints.*

Finding a good partition

▶ **Lemma 9** (Essentially [4, Lemma 6]). *Let $G=(V,E)$ be a d-regular graph and $n \triangleq |V|$. We can partition V into n/k disjoint subsets $\{S_1, \ldots, S_{n/k}\}$ of size at most $2k$ such that:*

$$\forall i,j \quad |(S_i \times S_j) \cap E| \leq 8d^2k^2/n\,. \tag{1}$$

See full version for proof [17].

How to catch a far-from-uniform distribution

The following lemma due to [10] implies that:

▶ **Lemma 10** (Lemma 3 in the full version of [10]). *Let $\{a_i\}_{i=1}^n$ be real numbers satisfying the following properties for some $\theta > 0$: (1) $a_1 \geq a_2 \geq \cdots \geq a_n$; (2) $\sum a_i = 0$; (3) $\sum_{i=1}^{n/2} a_i \leq \theta$. Then $\sum_{i=1}^n |a_i| \leq 4\theta$.*

3 Additive hardness

▶ **Theorem 11.** *There exists a constant $\epsilon > 0$, such that assuming ETH, approximating* Zero-Sum Signaling *with payoffs in $[-1, 1]$ to within an additive ϵ requires time $n^{\tilde{\Omega}(\lg n)}$.*

Construction overview

Our reduction begins with a 2CSP ψ over n variables from alphabet Σ. We partition the variables into n/k disjoint subsets $\{S_1, \ldots, S_{n/k}\}$, each of size at most $2k$ for $k = \sqrt{n}$ such that every two subsets share at most a constant number of constraints.

Nature chooses a random subset S_i from the partition, a random assignment $\vec{u} \in \Sigma^{2k}$ to the variables in S_i, and an auxiliary vector $\hat{b} \in \{0,1\}^{\Sigma \times [2k]}$. As mentioned in Section 1.3, $\vec{u}$ may not correspond to any satisfying assignment. Alice and Bob participate in one of $|\Sigma|^{2k}$ subgames; for each $\vec{v} \in \Sigma^{2k}$, there is a corresponding subgame where all the assignments are XOR-ed with $\vec{v}$. The goal of the auxiliary vector $\hat{b}$ is to force Alice and Bob to participate in the right subgame, i.e. the one where the XOR of $\vec{v}$ and $\vec{u}$ can be completed to a full satisfying assignment. In particular, the optimum signaling scheme reveals partial information about $\hat{b}$ in a way that guides Alice and Bob to participate in the right subgame. The scheme also outputs the full satisfying assignment, but reveals no information about the subset S_i chosen by nature.

Each player has $\left(|\Sigma|^{2k} \times 2\right) \times \left(n/k \times \binom{n/k}{n/2k} \times |\Sigma|^{2k}\right) = 2^{\Theta\left(\sqrt{n}\right)}$ strategies. The first $|\Sigma|^{2k}$ strategies correspond to a Σ-ary vector $\vec{v}$ that the scheme will choose after observing the random input. The signaling scheme forces both players to play (w.h.p.) the strategy corresponding to $\vec{v}$ by controlling the information that corresponds to the next 2 strategies. Namely, for each $\vec{v}' \in \Sigma^{2k}$, there is a random bit $b(\vec{v}')$ such that each player receives a payoff of 1 if they play $(\vec{v}', b(\vec{v}'))$ and 0 for $(\vec{v}', 1 - b(\vec{v}'))$. The b's are part of the state of nature, and the optimal signaling scheme will reveal only the bit corresponding to the special $\vec{v}$. Since there are $|\Sigma|^{2k}$ bits, nature cannot choose them independently, as that would require $2^{|\Sigma|^{2k}}$ states of nature. Instead we construct a pairwise independent distribution.

The next n/k strategies correspond to the choice of a subset S_i from the specified partition of variables. The $\binom{n/k}{n/2k}$ strategies that follow correspond to a gadget due to Althofer [3] whereby each player forces the other player to randomize (approximately) uniformly over the choice of subset.

The last $|\Sigma|^{2k}$ strategies correspond to an assignment to S_i. The assignment to each S_i is XOR-ed entry-wise with $\vec{v}$. Then, the players are paid according to checks of consistency between their assignments, and a random assignment to a random S_i picked by nature. (The scheme chooses $\vec{v}$ so that nature's random assignment is part of a globally satisfying assignment.) Each player wants to pick an assignment that passes the consistency check with nature's assignment. Alice also receives a small bonus if her assignment agrees with Bob's; thus her payoff is maximized when there exists a globally satisfying assignment.

See formal construction below, or refer to summary table in full version [17].

Formal construction

Let ψ be a 2CSP-d over n variables from alphabet Σ, as guaranteed by Theorem 8. In particular, ETH implies that distinguishing between a completely satisfiable instance and $(1-\eta)$-satisfiable requires time $2^{\tilde{\Omega}(n)}$. By Lemma 9, we can (deterministically and efficiently) partition the variables into n/k subsets $\{S_1, \ldots, S_{n/k}\}$ of size at most $2k = 2\sqrt{n}$, such that every two subsets share at most $8d^2k^2/n = O(1)$ constraints.

States of nature. Nature chooses a state $\left(\hat{b}, i, \vec{u}\right) \in \{0,1\}^{\Sigma\times[2k]} \times [n/k] \times \Sigma^{2k}$ uniformly at random. For each $\vec{v}$, $b(\vec{v})$ is the XOR of bits from $\hat{b}$ that correspond to entries of $\vec{v}$:

$$\forall \vec{v} \in \Sigma^{2k} \;\; b(\vec{v}) \triangleq \left(\bigoplus_{(\sigma,\ell):\ [\vec{v}]_\ell = \sigma} \left[\hat{b}\right]_{(\sigma,\ell)} \right).$$

Notice that the $b(\vec{v})$'s are pairwise independent and each marginal distribution is uniform over $\{0,1\}$.

Strategies. Alice and Bob each choose a strategy $(\vec{v}, c, j, T, \vec{w}) \in \Sigma^{2k} \times \{0,1\} \times [n/k] \times \binom{[n/k]}{n/2k} \times \Sigma^{2k}$. We use $\vec{v}^A, c^A$, etc. to denote the strategy Alice plays, and similarly $\vec{v}^B, c^B$, etc. for Bob. For $\sigma, \sigma' \in \Sigma$, we denote $\sigma \oplus_\Sigma \sigma' \triangleq \sigma + \sigma' \pmod{|\Sigma|}$, and for vectors $\vec{v}, \vec{v}' \in \Sigma^{2k}$, we let $\vec{v} \oplus_\Sigma \vec{v}' \in \Sigma^{2k}$ denote the entry-wise $\oplus_\Sigma$.

Payoffs. Consider state of nature $\left(\hat{b}, i, \vec{u}\right)$ and players' strategies $\left(\vec{v}^A, c^A, j^A, T^A, \vec{w}^A\right)$ and $\left(\vec{v}^B, c^B, j^B, T^B, \vec{w}^B\right)$.

When $\vec{v}^A = \vec{v}^B = \vec{v}$, we set $\tau^{A,Z} = 1$ if assignments $\vec{w}^A$ and $(\vec{v} \oplus_\Sigma \vec{u})$ to subsets S_{j^A} and S_i, respectively, satisfy all the constraints in ψ that are determined by $\left(S_i \cup S_{j^A}\right)$, and $\tau^{A,Z} = 0$ otherwise. Similarly, $\tau^{B,Z} = 1$ iff $\vec{w}^B$ and $(\vec{v} \oplus_\Sigma \vec{u})$ satisfy the corresponding constraints in ψ; and $\tau^{A,B}$ checks $\vec{w}^A$ and $\vec{w}^B$. When $\vec{v}^A \neq \vec{v}^B$, we set $\tau^{A,Z} = \tau^{B,Z} = \tau^{A,B} = 0$.

We decompose Alice's payoff as:

$$U^A \triangleq U^A_b + U^A_{\text{Althofer}} + U^A_\psi,$$

where

$$U^A_b \triangleq \mathbf{1}\left\{c^A = b\left(\vec{v}^A\right)\right\} - \mathbf{1}\left\{c^B = b\left(\vec{v}^B\right)\right\},$$

$$U^A_{\text{Althofer}} \triangleq \mathbf{1}\left\{j^B \in T^A\right\} - \mathbf{1}\left\{j^A \in T^B\right\},$$

and

$$U^A_\psi \triangleq \delta\tau^{A,Z} - \delta^2\tau^{B,Z} + \delta^3\tau^{A,B}, \tag{2}$$

for a sufficiently small constant $0 < \delta \ll \sqrt{\eta}$.

Completeness

▶ **Lemma 12.** *If ψ is satisfiable, there exists a signaling scheme and a mixed strategy for Alice that guarantees expected payoff $\delta - \delta^2 + \delta^3$.*

Proof. Fix a satisfying assignment $\vec{\alpha} \in \Sigma^n$. Given state of nature $\left(\hat{b}, i, \vec{u}\right)$, let $\vec{v}$ be such that $(\vec{v} \oplus_\Sigma \vec{u}) = [\vec{\alpha}]_{S_i}$. The scheme outputs the signal $(\vec{v}, b(\vec{v}), \vec{\alpha})$. Alice's mixed strategy sets $\left(\vec{v}^A, c^A\right) = (\vec{v}, b(\vec{v}))$, picks j^A and T^A uniformly at random, and sets $\vec{w}^A = [\vec{\alpha}]_{S_{j^A}}$.

Because Bob has no information about $b(\vec{v}')$ for any $\vec{v}' \neq \vec{v}$, he has probability $1/2$ of losing whenever he picks $\vec{v}^B \neq \vec{v}$, i.e. $\mathsf{E}\left[U^A_b\right] \geq \frac{1}{2}\Pr\left[\vec{v}^B \neq \vec{v}\right]$. Furthermore, because Alice chooses T^A and j^A uniformly, $\mathsf{E}\left[U^A_{\text{Althofer}}\right] = 0$.

Since $\vec{\alpha}$ completely satisfies ψ, we have that $\tau^{A,Z} = 1$ as long as $\vec{v}^B = \vec{v}$ (regardless of the rest of Bob's strategy). Bob's goal is thus to maximize $\mathsf{E}\left[\delta^2\tau^{B,Z} - \delta^3\tau^{A,B}\right]$. Notice that $\vec{w}^A$ and $(\vec{v} \oplus_\Sigma \vec{u})$ are two satisfying partial assignments to uniformly random subsets from the

partition. In particular, they are both drawn from the same distribution, so we have that for any mixed strategy that Bob plays, $\mathsf{E}\left[\tau^{B,Z}\right] = \mathsf{E}\left[\tau^{A,B}\right]$. Therefore Alice's payoff is at least

$$\left(\delta - \delta^2 + \delta^3\right) \Pr\left[\vec{v}^B = \vec{v}\right] + \frac{1}{2} \Pr\left[\vec{v}^B \neq \vec{v}\right] \geq \delta - \delta^2 + \delta^3. \qquad \blacktriangleleft$$

Soundness

▶ **Lemma 13.** *If at most a $(1-\eta)$-fraction of the constraints are satisfiable, Alice's maxmin payoff is at most $\delta - \delta^2 + (1 - \Omega_\eta(1))\,\delta^3$, for any signaling scheme.*

Proof. Fix any mixed strategy by Alice; we show that Bob can guarantee a payoff of at least $-\left(\delta - \delta^2 + (1 - \Omega_\eta(1))\,\delta^3\right)$. On any signal, Bob chooses $\left(\vec{v}^B, c^B\right)$ from the same distribution that Alice uses for $\left(\vec{v}^A, c^A\right)$. He chooses j^B uniformly, and picks T^B so as to minimize $\mathsf{E}\left[U^A_{\text{Althofer}}\right]$. Finally, for each j^B, he draws $\vec{w}^B$ from the same marginal distribution that Alice uses for $\vec{w}^A$ conditioning on $j^A = j^B$ (and uniformly at random if Alice never plays $j^A = j^B$). By symmetry, $\mathsf{E}\left[U^A_b\right] = 0$ and $\mathsf{E}\left[U^A_{\text{Althofer}}\right] \leq 0$.

In this paragraph, we use Althoefer's gadget to argue that, wlog, Alice's distribution over the choice of j^A is approximately uniform. In Althofer's gadget, Alice can guarantee an (optimal) expected payoff of 0 by randomizing uniformly over her choice of j^A and T^A. By Lemma 10, if Alice's marginal distribution over the choice of j^A is $8\delta^2$-far from uniform (in total variation distance), then Bob can guess that j^A is in some subset $T^B \in \binom{[n/k]}{n/2k}$ with advantage (over guessing at random) of at least $2\delta^2$. Therefore $\mathsf{E}\left[U^A_{\text{Althofer}}\right] \leq -2\delta^2$; but this would imply $\mathsf{E}\left[U^A\right] \leq -2\delta^2 + \mathsf{E}\left[U^A_\psi\right] \leq \delta - 2\delta^2 + \delta^3$. So henceforth we assume wlog that Alice's marginal distribution over the choice of j^A is $O\left(\delta^2\right)$-close to uniform (in total variation distance).

Since Alice's marginal distribution over j^A is $O\left(\delta^2\right)$-close to uniform, we have that Bob's distribution over $\left(j^B, \vec{w}^B\right)$ is $O\left(\delta^2\right)$-close to Alice's distribution over $\left(j^A, \vec{w}^A\right)$. Therefore $\mathsf{E}\left[\tau^{B,Z}\right] \geq \mathsf{E}\left[\tau^{A,Z}\right] - O\left(\delta^2\right)$, and so we also get:

$$\mathsf{E}\left[U^A\right] \leq \mathsf{E}\left[U^A_\psi\right] \leq \delta - \delta^2 + \delta^3 \mathsf{E}\left[\tau^{A,B}\right] + O\left(\delta^4\right). \tag{3}$$

Bounding $\mathsf{E}\left[\tau^{A,B}\right]$. To complete the proof, it remains to show an upper bound on $\mathsf{E}\left[\tau^{A,B}\right]$. In particular, notice that it suffices to bound the probability that Alice's and Bob's induced assignments agree. Intuitively, if they gave assignments to uniformly random (and independent) subsets of variables, the probability that their assignments agree cannot be much higher than the value of the 2CSP; below we formalize this intuition.

By the premise, any assignment to all variables violates at least an η-fraction of the constraints. In particular, this is true in expectation for assignments drawn according to Alice's and Bob's mixed strategy. This is a bit subtle: in general, it is possible that Alice's assignment alone doesn't satisfy many constraints and neither does Bob's, but when we check constraints between Alice's and Bob's assignments everything satisfied (for example, think of the 3-Coloring CSP, where Alice colors all her vertices blue, and Bob colors all his vertices red). Fortunately, this subtlety is irrelevant for our construction since we explicitly defined Bob's mixed strategy so that conditioned on each set S_j of variables, Alice and Bob have the same distribution over assignments.

The expected number of violations between pairs directly depends on the value of the 2CSP. To bound the *probability* of observing at least one violations, recall that every pair of subsets shares at most a constant number of constraints, so this probability is within a

constant factor of the expected number of violations. In particular, an $\Omega(\eta)$-fraction of the pairs of assignments chosen by Alice and Bob violate ψ.

Finally, Alice doesn't choose j^A uniformly at random; but her distribution is $O(\delta^2)$-close to uniform. Therefore, we have $\mathsf{E}\left[\tau^{A,B}\right] \leq 1 - \Omega(\eta) + O(\delta^2)$. Plugging into (3) completes the proof. ◀

4 Multiplicative hardness

▶ **Theorem 14.** *There exists a constant $\epsilon > 0$, such that it is* NP*-hard to approximate* Zero-Sum Signaling *to within a multiplicative $(1-\epsilon)$ factor.*

Construction overview

Our reduction begins with a 2CSP ψ over n variables from alphabet Σ.

Nature chooses a random index $i \in [n]$, a random assignment $u \in \Sigma$ for variable x_i, and an auxiliary vector $\vec{b} \in \{0,1\}^{\Sigma}$. Notice that u may not correspond to any satisfying assignment. Alice and Bob participate in one of $|\Sigma|$ subgames; for each $v \in \Sigma$, there is a corresponding subgame where all the assignments are XOR-ed with v. The optimum signaling scheme reveals partial information about $\vec{b}$ in a way that guides Alice and Bob to participate in the subgame where the XOR of v and u can be completed to a full satisfying assignment. The scheme also outputs the full satisfying assignment, but reveals no information about the index i chosen by nature.

Alice has $(|\Sigma| \times 2) \times (n \times n \times |\Sigma|) = \Theta(n^2)$ strategies, and Bob has an additional choice among n strategies (so $\Theta(n^3)$ in total). The first $|\Sigma|$ strategies correspond to a value $v \in \Sigma$ that the scheme will choose after observing the state of nature. The signaling scheme forces both players to play (w.h.p.) the strategy corresponding to v by controlling the information that corresponds to the next 2 strategies. Namely, for each $v' \in \Sigma$, there is a random bit $b(v')$ such that each player receives a small bonus if they play $(v', b(v'))$ and not $(v', 1 - b(v'))$. The b's are part of the state of nature, and the signaling scheme will reveal only the bit corresponding to the special v.

The next n strategies correspond to a choice of a variable $j \in [n]$. The n strategies that follow correspond to a hide-and-seek gadget whereby each player forces the other player to randomize (approximately) uniformly over the choice of j. For Bob, the additional n strategies induce a hide-and-seek game against nature, which serves to verify that the scheme does not reveal too much information about the state of nature (this extra verification was unnecessary in the reduction for additive inapproximability).

The last $|\Sigma|$ strategies induce an assignment for x_j. The assignment to each x_j is XOR-ed with v. Then, the players are paid according to checks of consistency between their assignments, and a random assignment to a random x_i picked by nature. (The scheme chooses v so that nature's random assignment is part of a globally satisfying assignment.) Each player wants to pick an assignment that passes the consistency check with nature's assignment. Alice also receives a small bonus if her assignment agrees with Bob's; thus her payoff is maximized when there exists a globally satisfying assignment.

Formal construction

Let ψ be a 2CSP-d over n variables from alphabet Σ, as guaranteed by Theorem 8. In particular, it is NP-hard to distinguish between ψ which is completely satisfiable, and one

where at most a $(1-\eta)$-fraction of the constraints can be satisfied. We denote $(i,j) \in \psi$ if there is a constraint over variables (x_i, x_j).

States of nature. Nature chooses a state $\left(\vec{b}, i, u\right) \in \{0,1\}^{\Sigma} \times [n] \times \Sigma$ uniformly at random.

Strategies. Alice chooses a strategy $\left(v^A, c^A, j^A, t^A, w^A\right) \in \Sigma \times \{0,1\} \times [n] \times [n] \times \Sigma$, and Bob chooses $\left(v^B, c^B, j^B, t^B, q^B, w^B\right) \in \Sigma \times \{0,1\} \times [n] \times [n] \times [n] \times \Sigma$. For $\sigma, \sigma' \in \Sigma$, we denote $\sigma \oplus_{\Sigma} \sigma' \triangleq \sigma + \sigma' \pmod{|\Sigma|}$, and for a vector $\vec{\alpha} \in \Sigma^n$ we let $(\sigma \oplus_{\Sigma} \vec{\alpha}) \in \Sigma^n$ denote the $\oplus_{\Sigma}$ of σ with each entry of $\vec{\alpha}$.

Payoffs. Consider players' strategies $\left(v^A, c^A, j^A, t^A, w^A\right)$ and $\left(v^B, c^B, j^B, t^B, q^B, w^B\right)$ and state of nature $\left(\vec{b}, i, u\right)$.

When $v^A = v^B = v$, we set $\tau^{A,Z} = 1$ if ψ contains a constraint for variables $\left(j^A, i\right)$, and the assignments w^A and $(v \oplus_{\Sigma} u)$ to those variables, respectively, satisfy this constraint, and $\tau^{A,Z} = 0$ otherwise. Similarly, $\tau^{B,Z} = 1$ iff w^B and $(v \oplus_{\Sigma} u)$ satisfy a corresponding constraint in ψ; and $\tau^{A,B}$ checks w^A with w^B. When $v^A \neq v^B$, we set $\tau^{A,Z} = \tau^{B,Z} = \tau^{A,B} = 0$.

We decompose Alice's payoff as:

$$U^A \triangleq U^A_b + U^A_{\text{seek}} + U^A_{\psi},$$

where

$$U^A_b \triangleq \mathbf{1}\left\{c^A = \left[\vec{b}\right]_{v^A}\right\}/n - \mathbf{1}\left\{c^B = \left[\vec{b}\right]_{v^B}\right\}/n,$$

$$U^A_{\text{seek}} \triangleq 2 \cdot \mathbf{1}\left\{j^B = t^A\right\} - \mathbf{1}\left\{j^A = t^B\right\} - \mathbf{1}\left\{i = q^B\right\},$$

and[4]

$$U^A_{\psi} \triangleq \delta^3 \tau^{A,Z} - \delta^4 \tau^{B,Z} + \delta^5 \tau^{A,B},$$

for a sufficiently small constant $0 < \delta \ll \sqrt{\eta}$.

Completeness

▶ **Lemma 15.** *If ψ is satisfiable, there exists a signaling scheme, such that for every signal $\mathbf{s}$ in the support, Alice can guarantee an expected payoff of $\frac{d}{n}\left(\delta^3 - \delta^4 + \delta^5\right)$.*

Notice that the *for every signal in the support* qualification is different than the corresponding Lemma 12 (and there is a similar difference between Lemma 16 and Lemma 13). Indeed, this is stronger than we need for proving Theorem 14, but will come handy in Section 5.

Proof. Fix a satisfying assignment $\vec{\alpha} \in \Sigma^n$. Given state of nature $\left(\hat{b}, i, u\right)$, let v be such that $(v \oplus_{\Sigma} u) = [\vec{\alpha}]_i$. The scheme outputs the signal $\mathbf{s} \triangleq \left(v, \vec{b}_v, \vec{\alpha}\right)$. Alice's mixed strategy sets $\left(v^A, c^A\right) = \left(v, \vec{b}_v\right)$; picks j^A and t^A uniformly at random; and sets $w^A = [\vec{\alpha}]_{j^A}$. See full version for details [17]. ◀

[4] We use $\delta^3\tau^{A,Z} - \delta^4\tau^{B,Z} + \delta^5\tau^{A,B}$ instead of $\delta^1\tau^{A,Z} - \delta^2\tau^{B,Z} + \delta^3\tau^{A,B}$ as in 2, because the square of the first coefficient appears in the proof. We have $\left(\delta^3\right)^2 \ll \delta^5$, but $\delta^2 \gg \delta^3$.

Soundness

▶ **Lemma 16.** *If at most a* $(1-\eta)$*-fraction of the constraints are satisfiable, then for any signaling scheme and every signal* $\mathbf{s}$ *in the support, Alice's maxmin payoff is at most* $\frac{d}{n}\left(\delta^3-\delta^4+\left(1-\Omega\left(1\right)\right)\delta^5\right)$.

Proof. On any signal, Bob chooses $\left(v^B,c^B\right)$ from the same distribution that Alice uses for $\left(v^A,c^A\right)$. He draws j^B uniformly at random, and picks t^B and q^B so as to minimize $\mathsf{E}\left[U^A_{\text{seek}}\mid\mathbf{s}\right]$. Finally, for each j^B, Bob draws w^B from the same distribution that Alice uses for w^A conditioning on $j^A=j^B$ (and uniformly at random if Alice never plays $j^A=j^B$). By symmetry, $\mathsf{E}\left[U^A_b\mid\mathbf{s}\right]=0$ and $\mathsf{E}\left[U^A_{\text{seek}}\mid\mathbf{s}\right]\leq 0$. See full version for details [17]. ◀

5 Lying is even harder

▶ **Theorem 17.** *Approximating* Zero-Sum Lying *with Alice's payoffs in* $[0,1]$ *to within an additive* $(1-2^{-n})$ *is* NP*-hard.*

Construction

Consider the construction from Section 4 for the honest signaling problem. Lemmata 15 and 16 guarantee that there exists a distribution $\mathcal{D}_{\text{HONEST}}$ of $n\times n$ zero-sum games and constants $c_1>c_2$ such that it is NP-hard to distinguish between the following:

Completeness. If ψ is satisfiable, there exists a signaling scheme φ_{HONEST}, such that for any signal in φ_{HONEST}'s support, Alice's maxmin payoff is at least c_1/n.

Soundness. If ψ is $(1-\eta)$-unsatisfiable, for every signaling scheme φ'_{HONEST} and every signal in the support, Alice's maxmin payoff is at most c_2/n.

For Zero-Sum Lying, we construct a hard distribution of $n\times(n+1)$ zero-sum games as follows. With probability 2^{-n} Alice's payoffs matrix is of the form:

$$\begin{pmatrix} & -\left(c_1+c_2\right)/2n \\ -A^{\top}_{\text{HONEST}} & \vdots \\ & -\left(c_1+c_2\right)/2n \end{pmatrix}, \tag{4}$$

where Alice chooses a row (Bob chooses a column), and A_{HONEST} is an $n\times n$ matrix drawn from $\mathcal{D}_{\text{HONEST}}$. In other words, Bob has to choose between receiving payoff $\left(c_1+c_2\right)/2n$, or playing a game drawn from $\mathcal{D}_{\text{HONEST}}$, but with the roles reversed.

Otherwise (with probability $1-2^{-n}$), Alice's payoff depends only on Bob: it is 1 if Bob chooses any of his first n actions, and 0 otherwise; we call this the *degenerate game*.

Notice that we promised payoffs in $[0,1]$, whereas (4) has payoffs in $[-1,0]$. $[0,1]$ payoffs can be obtained, without compromising the inapproximability guarantee, by scaling and shifting the entries in (4) in a straightforward manner.

Completeness

▶ **Lemma 18.** *If* ψ *is satisfiable, there exists a dishonest signaling scheme, such that Alice's expected payoff is at least* $1-2^{-n}$.

Proof. We first construct φ_{ALLEGED} as follows. Whenever nature samples a payoff matrix as in (4), φ_{ALLEGED} outputs the signal that φ_{HONEST} would output for A_{HONEST}. Whenever Alice and Bob play the degenerate game, φ_{ALLEGED} outputs a special symbol $\perp$.

When Bob observes any symbol from the support of φ_{HONEST}, he can guarantee a payoff of $c_1/n > (c_1 + c_2)/2n$ by playing a mix of his first n strategies. Therefore he only uses his last strategy when observing the special symbol $\perp$.

Our true signaling scheme φ_{REAL} always outputs an (arbitrary) signal from the support of φ_{HONEST}, regardless of the state of nature. With probability $1 - 2^{-n}$, Alice and Bob are actually playing the degenerate game, so Alice's payoff is 1. ◀

Soundness

▶ **Lemma 19.** *If ψ is $(1-\eta)$-unsatisfiable, then for any dishonest signaling scheme $\left(\varphi'_{\text{ALLEGED}}, \varphi'_{\text{REAL}}\right)$, Alice's expected payoff is negative.*

Proof. Any signal in the support of $\varphi'_{\text{ALLEGED}}$ corresponds to a mixture of the degenerate game, and the distribution induced by some signal $\mathbf{s}'$ in the support of some honest signaling scheme φ'_{HONEST} for $\mathcal{D}_{\text{HONEST}}$. In the degenerate game, Bob always prefers to play his last strategy. For any $\mathbf{s}'$, Bob again prefers a payoff of $(c_1 + c_2)/2n$ for playing his last strategy over a maxmin of at most c_2/n when playing any mixture of his first n strategies. Therefore, Bob always plays his last strategy, regardless of the signal he receives, which guarantees him a payoff of $(c_1 + c_2)/2^{n+1}n > 0$. ◀

Abstract

A $(k \times l)$-*birthday repetition* $\mathcal{G}^{k\times l}$ of a two-prover game $\mathcal{G}$ is a game in which the two provers are sent random sets of questions from $\mathcal{G}$ of sizes k and l respectively. These two sets are sampled independently uniformly among all sets of questions of those particular sizes. We prove the following *birthday repetition theorem*: when $\mathcal{G}$ satisfies some mild conditions, $val(\mathcal{G}^{k\times l})$ decreases exponentially in $\Omega(kl/n)$ where n is the total number of questions. Our result positively resolves an open question posed by Aaronson, Impagliazzo and Moshkovitz [Aaronson et al., CCC, 2014].

As an application of our birthday repetition theorem, we obtain new fine-grained inapproximability results for dense CSPs. Specifically, we establish a tight trade-off between running time and approximation ratio by showing conditional lower bounds, integrality gaps and approximation algorithms; in particular, for any sufficiently large i and for every $k \geq 2$, we show the following:

- We exhibit an $O(q^{1/i})$-approximation algorithm for dense Max k-CSPs with alphabet size q via $O_k(i)$-level of Sherali-Adams relaxation.
- Through our birthday repetition theorem, we obtain an integrality gap of $q^{1/i}$ for $\tilde{\Omega}_k(i)$-level Lasserre relaxation for fully-dense Max k-CSP.
- Assuming that there is a constant $\varepsilon > 0$ such that Max 3SAT cannot be approximated to within $(1-\varepsilon)$ of the optimal in sub-exponential time, our birthday repetition theorem implies that any algorithm that approximates fully-dense Max k-CSP to within a $q^{1/i}$ factor takes $(nq)^{\tilde{\Omega}_k(i)}$ time, almost tightly matching our algorithmic result.

As a corollary of our algorithm for dense Max k-CSP, we give a new approximation algorithm for Densest k-Subhypergraph, a generalization of Densest k-Subgraph to hypergraphs. When the input hypergraph is $O(1)$-uniform and the optimal k-subhypergraph has constant density, our algorithm finds a k-subhypergraph of density $\Omega(n^{-1/i})$ in time $n^{O(i)}$ for any integer $i > 0$.

of the celebrated PCP Theorem [6] and the intricate web of polynomial-time reductions developed over the past two decades. During this period, an extensive set of reduction techniques such as parallel repetition and long-codes have been proposed and a variety of mathematical tools including discrete harmonic analysis, information theory and Gaussian isoperimetry have been applied towards analyzing these reductions. These developments have led to an almost complete understanding of the approximability of many fundamental combinatorial optimization problems like Set Cover and Max 3SAT. Yet, there are a few central problems such as computing approximate Nash equlibria, Densest k-Subgraph and Small Set Expansion, that remain out of reach of the web of polynomial-time reductions.

A promising new line of work proposes to understand the complexity of these problems through the lens of *sub-exponential time reductions*. Specifically, the idea is to construct a sub-exponential time reduction from 3SAT to the problem at hand, say, the Approximate Nash Equilibrium problem. Assuming that 3SAT does not admit sub-exponential time algorithms (also known as the Exponential Time Hypothesis (ETH) [35]), this would rule out polynomial time algorithms for the Approximate Nash Equilibrium problem.

At the heart of this line of works, lies the so-called *birthday repetition* of two-prover games. To elaborate on this, we begin by formally defining the notion of two-prover games.

▶ **Definition 1.** A *two-prover game* $\mathcal{G}$ consists of

- A finite set of questions X, Y and corresponding answer sets (aka alphabets) Σ_X, Σ_Y.
- A distribution $\mathcal{Q}$ over pairs of questions $X \times Y$.
- A verification function $P : X \times Y \times \Sigma_X \times \Sigma_Y \to \{0, 1\}$.

The value of $\mathcal{G}$ is the maximum over all strategies $\phi : X \cup Y \to \Sigma_X \cup \Sigma_Y$ of the output of P, i.e., $val(\mathcal{G}) = \max_{\phi: X\cup Y \to \Sigma_X \cup \Sigma_Y} \mathbb{E}_{(x,y)\sim\mathcal{Q}}[P(x, y, \phi(x), \phi(y))]$. We use n and q to denote the number of variables $|X| + |Y|$ and the alphabet size $|\Sigma_X| + |\Sigma_Y|$ respectively.

Two prover games earn their name from the following interpretation of the above definition: The game $\mathcal{G}$ is played between a verifier V and two cooperating provers $Merlin_1$ and $Merlin_2$ who have agreed upon a common strategy, but cannot communicate with each other during the game. The verifier samples two questions $(x, y) \sim \mathcal{Q}$ and sends x to $Merlin_1$ and y to $Merlin_2$. The provers respond with answers $\phi(x)$ and $\phi(y)$, which the verifier accepts or rejects based on the value of the verification function $P(x, y, \phi(x), \phi(y))$.

Two-prover games and, more specifically, a special class of two-prover games known as Label Cover are the starting points for reductions in a large body of hardness of approximation results. The PCP theorem implies that for some constant ε_0, approximating the value of a two prover game to within an additive ε_0 is **NP**-hard. However, this hardness result on its own is inadequate to construct reductions to other combinatorial optimization problems. To this end, this hardness result can be strengthened to imply that it is **NP**-hard to approximate the value of two-prover games to any constant factor, using the *parallel repetition theorem*.

For an integer k, the k-parallel repetition $\mathcal{G}^{\otimes k}$ of $\mathcal{G}$ can be described as follows. The question and answer sets in $\mathcal{G}^{\otimes k}$ consist of k-tuples of questions and answers from $\mathcal{G}$. The distribution over questions in $\mathcal{G}^{\otimes k}$ is given by the product distribution $\mathcal{Q}^k$. The verifier for $\mathcal{G}^{\otimes k}$ accepts the answers if and only if the verifier for $\mathcal{G}$ accepts each of the k individual answers.

Roughly speaking, the parallel repetition theorem asserts that the value of $\mathcal{G}^k$ decays exponentially in k. The theorem forms a key ingredient in obtaining hardness of approximation results, and have aptly received considerable attention in literature [51, 34, 50, 25, 46, 14].

Birthday repetition, introduced by Aaronson et al. [2], is an alternate transformation on two-prover games defined as follows.

▶ **Definition 2.** The $(k \times l)$-*birthday repetition* of a two-prover game $\mathcal{G}$ consists of

- The set of questions in $\mathcal{G}^{k\times l}$ are $\binom{X}{k}$ and $\binom{Y}{l}$ respectively, i.e., each question is a subset $S \subseteq X$ of size k and subset $T \subseteq Y$ of size l.
- The distribution over questions is the uniform product distribution over $\binom{X}{k} \times \binom{Y}{l}$.
- The verifier accepts only if, for every $(x, y) \in S \times T$ such that (x, y) form a valid pair of questions in $\mathcal{G}$, i.e., $(x, y) \in \text{supp}(\mathcal{Q})$, the answers to x and y are accepted $\mathcal{G}$.

The basic idea of birthday repetition can be traced back to the work of Aaronson et al. [1] on quantum multiprover proof systems $\mathbf{QMA}(k)$ for 3SAT. Subsequent work by Aaronson et al. [2] on the classical analogue of $\mathbf{QMA}(k)$ formally defined birthday repetition for two-prover games, and set the stage for applications in hardness of approximation.

Unlike parallel repetition, birthday repetition is only effective for large values of k and l. In particular, if $k, l < o(\sqrt{n})$, then, for most pairs of S and T, there is no $(x, y) \in S \times T$ such that (x, y) belongs to the support of the questions in the original game. However, if we pick $k = l = \omega(\sqrt{n})$, then by the birthday paradox, with high probability the sets S, T contain an edge (x, y) from the original game $\mathcal{G}$. Hence, for this choice of k and l, the game played by the provers is seemingly at least as difficult to succeed, as the original game $\mathcal{G}$. Aaronson et al. [2] confirmed this intuition by proving the following theorem.

▶ **Theorem 3** ([2]). *For any two-prover game $\mathcal{G}$ such that $\mathcal{Q}$ is uniform over its support, if the bipartite graph induced by $(X, Y, \text{supp}(\mathcal{Q}))$ is biregular, then $val(\mathcal{G}^{k\times l}) \leq val(\mathcal{G}) + O(\sqrt{\frac{n}{kl}})$.*

On the one hand, birthday repetition is ineffective in that it has to incur a blowup of $2^{\sqrt{n}}$ in the size, to even simulate the original game $\mathcal{G}$. The distinct advantage of birthday repetition is that the resulting game $\mathcal{G}^{k,l}$ has a distinct structure – in that it is a *free game*.

▶ **Definition 4.** A *free game* is a two-player game such that $\mathcal{Q}$ is uniform over $X \times Y$.

The birthday repetition theorem of [2] immediately implies a hardness of approximation for the value of free games. Specifically, they show that it is ETH-hard to approximate free games to some constant ratio in almost quasi-polynomial time. Interestingly, this lower bound is nearly tight in that free games admit a quasipolynomial time approximation scheme [10, 2].

Following Aaronson et al.'s work, birthday repetition has received numerous applications, which can be broadly classified in to two main themes. On the one hand, there are problems such as computing approximate Nash equilibria [16, 8, 54], approximating free games [2], approximating learning dimensions [43], and approximate symmetric signaling in zero sum games [53], where the underlying problems admit quasipolynomial-time algorithms [26, 38, 28] and birthday repetition can be used to show that such a running time is necessary, assuming ETH. On the other hand, there are computational problems like Densest k-Subgraph [15, 39], injective tensor norms [1, 33, 9], 2-to-4-norms [1, 33, 9] wherein an **NP**-hardness of approximation result seems out of reach of current techniques. But the framework of birthday repetition can be employed to show a quasi-polynomial hardness assuming ETH[1].

Unlike the parallel repetition theorem, the birthday repetition theorem of [2] does not achieve any reduction in the value of the game. It is thus natural to ask whether birthday repetition can also be used to decrease the value of a game. Aaronson et al. conjectured that the value of the birthday repetition game indeed deteriorates exponentially in $\Omega(kl/n)$, which is the expected number of edges between S and T in birthday repetition. Our main contribution is that we resolve the conjecture positively by showing the following theorem.

[1] Although the hardness results for injective tensor norms and 2-to-4-norms build over quantum multiprover proof systems, the basic idea of birthday repetition [1] lies at the heart of these reductions.

▶ **Theorem 5** (Birthday Repetition Theorem (informal)). *Let $\mathcal{G} = (X, Y, \mathcal{Q}, \Sigma_X, \Sigma_Y, P)$ be a two-prover game such that $\mathcal{Q}$ is uniform over its support, $(X, Y, \mathrm{supp}(\mathcal{Q}))$ is biregular and $|\Sigma_X|, |\Sigma_Y|$ are constant. If $val(\mathcal{G}) = 1 - \varepsilon$, then $val(\mathcal{G}^{k\times l}) \leq 2(1 - \varepsilon/2)^{\Omega(\varepsilon^5 kl/n)}$.*

Note that our result is more general than stated above and can handle irregular graphs and non-constant alphabet sizes as well (see Theorem 12 and Theorem 13).

By definition, our theorem immediately implies the following inapproximability of free games.

▶ **Corollary 6.** *Unless ETH is false, no polynomial time algorithm can approximate the value of a free game to within a factor of $2^{\tilde{\Omega}(\log(nq))}$.*

1.1 Dense CSPs

Free games can be viewed as 2-ary constraint satisfaction problems (CSP). From this perspective, free games are *dense*, in that there are constraints on a constant fraction of all pairs of variables. As an application of our birthday repetition theorem, we show almost-tight lower bounds for dense CSPs. To this end, we begin by defining CSPs and its density.

▶ **Definition 7.** A Max k-CSP instance $\mathcal{G}$ consists of

- A finite set of variables V and a finite alphabet set Σ.
- A distribution $\mathcal{Q}$ over k-tuple of variables V^k.
- A predicate $P : V^k \times \Sigma^k \to [0, 1]$.

Similar to two-prover games, $val(\mathcal{G})$ is defined as $\max_{\phi:V\to\Sigma} \mathbb{E}_{S\sim\mathcal{Q}}[P(S, \phi|_S)]$ where $\phi|_S$ is the restriction of the assignment to S, and we use n to denote the number of variables $|V|$ and q to denote the alphabet size $|\Sigma|$ of $\mathcal{G}$. Finally, $\mathcal{G}$ is called Δ-*dense* if $\Delta \cdot \mathcal{Q}(S) \leq 1/|V|^k$ for every $S \in V^k$. The 1-dense instances are also said to be fully-dense.

There has been a long line of works on approximating dense CSPs. Arora et al. were first to devise a polynomial-time approximation scheme for the problem when alphabet size is constant [5]. Since then, numerous algorithms have been invented for approximating dense CSPs using variety of techniques such as combinatorial algorithms with exhaustive sampling [5, 21, 44, 58, 40, 29], subsampling of instances [3, 10], regularity lemmas [30, 20] and LP/SDP hierarchies [22, 11, 31, 60]. Among the known algorithms, the fastest is Yaroslavtsev's [58] that achieves $(1 + \varepsilon)$-approximation in $q^{O_k(\log q)} + (nq)^{O(1)}$ time[2].

Unfortunately, when q is (almost-)polynomial in n, none of the above algorithms run in polynomial time. CSPs in such regime of parameters have long been studied in hardness of approximation (e.g. [12, 52, 7, 24, 47, 45]) and have recently received more attention from the approximation algorithm standpoint, both in the general case [48, 17, 41, 19] and the dense case [40]. The approximabilities of these two cases are vastly different. In the general case, approximating Max 2-CSP to within a factor of $2^{\log^{1-\varepsilon}(nq)}$ is **NP**-hard for any constant $\varepsilon > 0$ [24]. Moreover, the long-standing Sliding Scale Conjecture [12] states that this ratio can be improved to $(nq)^{\varepsilon}$ for some constant $\varepsilon > 0$. On the other hand, aforementioned algorithms for dense CSPs rule out such hardnesses for the dense case.

While the gap between known approximation algorithms and inapproximability results in the general case is tiny ($2^{\log^{\varepsilon}(nq)}$ for any constant $\varepsilon > 0$), the story is different for the dense case, especially when we restrict ourselves to polynomial-time algorithms. Aaronson et al. only ruled out, assuming ETH, polylog(nq)-approximation for such algorithms [2].

[2] [58] states that the algorithm takes $q^{O_k(1)} + (nq)^{O(1)}$ time, which is incorrect [59].

However, for $k > 2$, no non-trivial polynomial-time algorithm for dense Max k-CSP on large alphabet is even known. In this paper, we settle down the complexity of approximating dense Max k-CSP almost completely by answering the following fine-grained question: for each $i \in \mathbb{N}$, what is the best approximation for dense Max k-CSP, achievable in time $(nq)^i$?

Manurangsi and Moshkovitz developed an algorithm for dense Max 2-CSP that, when the instance has value $\Omega(1)$, obtains $O(q^{1/i})$-approximation in $(nq)^{O(i)}$ time [40]. Unfortunately, the algorithm does not work for dense Max k-CSP when $k > 2$. Using a conditioning-based rounding technique developed in [11, 49, 60], we show that the Sherali-Adams (SA) relaxation [56] exhibits a similar approximation even when $k > 2$, as stated below.

▶ **Theorem 8** (Informal). *For every $i > 0$ and any dense* Max k-CSP *instance of value $1-\varepsilon$, an $O_{k,\varepsilon}(i/\Delta)$-level of the SA relaxation yields an $O(q^{1/i})$-approximation for the instance.*

Using our birthday repetition theorem, we prove that the above tradeoff between run-time and approximation ratio cannot be improved even with the stronger Lasserre hierarchy [37]. Specifically, by applying the birthday repetition theorem with $k, l = \Omega(n \log i/i)$ on an $\Omega(n)$-level Lasserre integrality gap for Max 3XOR [55], we show the following.

▶ **Lemma 9** (Informal). *For every sufficiently large $i > 0$, there is a fully-dense* Max k-CSP *instance of value $1/(nq)^{1/i}$ such that the value of $\tilde{\Omega}_k(i)$-level Lasserre relaxation is one.*

Instead, if we assume that there exists a constant $\varepsilon > 0$ so that Max 3SAT cannot be approximated to $1 - \varepsilon$ in sub-exponential time (which we call the Exponential Time Hypothesis for Approximating 3SAT (ETHA)[3]), we can similarly arrive at the following hardness result.

▶ **Lemma 10** (Informal). *Unless ETHA is false, for every sufficiently large $i > 0$, no $(nq)^{\tilde{O}_k(i)}$-time algorithm approximates fully-dense* Max k-CSP *to within a factor of $(nq)^{1/i}$.*

Thus, assuming ETHA, our results resolve complexity of approximating dense CSPs up to a factor of polylog i and a dependency on k in the exponent of the running time.

1.2 Densest k-Subhypergraph

As a by-product of our algorithm for dense Max k-CSP, we give an approximation algorithm for the following Densest k-Subhypergraph problem: given a hypergraph (V, E), find $S \subseteq V$ of k vertices that maximizes the number of edges contained in S.

When the input hypergraph is simply a graph, the problem becomes Densest k-Subgraph, which has been extensively studied dating back to the early '90s [36, 27, 28, 57, 13]. On the other hand, Densest k-Subhypergraph was first studied in 2006, when Hajiaghayi et al. [32] proved that, if 3SAT $\notin$ **DTIME**$(2^{n^{3/4+\varepsilon}})$ for some $\varepsilon > 0$, then no polynomial-time algorithm approximates the problem to within a factor of $2^{\log^{\delta} n}$ for some $\delta > 0$. Later, Applebaum [4] showed, under a cryptographic assumption, that, for sufficiently large d, Densest k-Subhypergraph on d-uniform hypergraph is hard to approximate to a factor of n^{ε} for some $\varepsilon > 0$. More recently, Chlamtác et al. [18] provided the first non-trivial approximation algorithm for the problem; their algorithm works only on 3-uniform hypergraph and achieves $O(n^{4(4-\sqrt{3})/13+\varepsilon})$-approximation for any constant $\varepsilon > 0$ in polynomial time.

[3] ETHA is also introduced independently as gap-ETH by Dinur [23] who uses it to provide a supporting evidence to the Sliding Scale Conjecture.

Thanks to Charikar et al.'s [17] reduction from Densest k-Subgraph to Max 2-CSP, which can be adapted to reduce Densest k-Subhypergraph on d-uniform hypergraph to Max d-CSP, Theorem 8 implies the following algorithm for Densest k-Subhypergraph.

▶ **Corollary 11** (Informal). *There is a randomized algorithm that, given a d-uniform hypergraph on n vertices whose densest k-subhypergraph is Δ-dense and an integer $i > 0$, runs in $n^{O_d(i/\Delta)}$ time and outputs a k-subhypergraph of density $\Omega_k(\Delta/n^{1/i})$ with high probability.*

Here the density of a d-uniform hypergraph is defined as $d!|E|/|V|^d$. Note that the density condition required is on the optimum not the input. Moreover, when Δ and d are constant, the algorithm provides an $O(n^{1/i})$ approximation in $n^{O(i)}$ time for every $i > 0$. When $d = 2$, this matches the previously known algorithms for Densest k-Subgraph [28, 57, 40].

Organization of the Paper

In Section 2, we provide preliminaries and notations used in the paper. Then, in Section 3, we outline the proofs of our main theorems; the full proofs are deferred to the full version of this work [42]. Next, the algorithm for dense CSPs is described in Section 4. Finally, we conclude by proposing open questions in Section 5. Note that the lower bounds for dense CSPs and the algorithm for Densest k-Subhypergraph are also deferred to the full version.

2 Preliminaries and Notations

For $n \in \mathbb{N}$, we use $[n]$ to denote $\{1, \dots, n\}$. For two sets X and S, define X^S to be the set of tuples $(x_s)_{s\in S}$. We sometimes view $(x_s)_{s\in S}$ as a function from S to X. For a set S and $n \in \mathbb{N}$, $\binom{S}{n}$ denotes the collection of subsets of S of size n. Moreover, let $\binom{S}{0} = \{\emptyset\}$ and $\binom{S}{[n]} = \binom{S}{0} \cup \cdots \cup \binom{S}{n}$. For any bipartite graph (A, B, E) and $S \subseteq A, T \subseteq B$, let $E(S, T)$ denote the set of all edges with one endpoint in S and the other in T.

Let $\mathcal{X}$ be a probability distribution over a finite probability space Θ. We use $x \sim \mathcal{X}$ to denote a random variable x sampled from $\mathcal{X}$. Sometimes we abuse the notation and write Θ in place of the uniform distribution over Θ. For each $\theta \in \Theta$, we denote $\Pr_{x\sim\mathcal{X}}[x = \theta]$ by $\mathcal{X}(\theta)$. The *support* of $\mathcal{X}$ or $\mathrm{supp}(\mathcal{X})$ is the set of all $\theta \in \Theta$ such that $\mathcal{X}(\theta) \neq 0$. For any event E, we use $\mathbb{1}[E]$ to denote the indicator variable for the event.

The *informational divergence* between distributions $\mathcal{X}$ and $\mathcal{Y}$ is defined as $D_{KL}(\mathcal{X}\|\mathcal{Y}) = \sum_{\theta\in\mathrm{supp}(\mathcal{X})} \mathcal{X}(\theta)\log(\mathcal{X}(\theta)/\mathcal{Y}(\theta))$. The *total correlation* between random variables $x_1, \dots, x_n$ is $C(x_1; \dots; x_n) = D_{KL}(\mathcal{X}_{1,\dots,n}\|\mathcal{X}_1 \times \cdots \times \mathcal{X}_n)$ where $\mathcal{X}_{1,\dots,n}$ is the joint distribution of $x_1, \dots, x_n$ and $\mathcal{X}_i$ is the marginal distribution of x_i. Finally, the *conditional total correlation* is defined as $C(x_1; \dots; x_{n-1}|x_n) = \mathbb{E}_{\theta\sim\mathrm{supp}(\mathcal{X}_n)}[C(x_1; \dots; x_{n-1})|x_n = \theta]$.

For Max k-CSP, we use N to denote the instance size $(nq)^k$. For convenience, we write the predicates as $P_S(\phi|_S)$ instead of $P(S, \phi|_S)$. Moreover, for an assignment ϕ of $\mathcal{G} = (V, \mathcal{W}, \{P_S\})$, its value is $val_{\mathcal{G}}(\phi) = \mathbb{E}_{S\sim\mathcal{W}}[P_S(\phi|_S)]$. When $\mathcal{G}$ is clear from the context, we simply write $val(\phi)$. Note that $val(\mathcal{G}) = \max_\phi val_{\mathcal{G}}(\phi)$. For any $S, T \subseteq V$, $\phi_S \in \Sigma^S$ and $\phi_T \in \Sigma^T$ are said to be *consistent* if they agree on $S \cap T$ and *inconsistent* otherwise. For consistent ϕ_S, ϕ_T, we define $\phi_S \circ \phi_T \in \Sigma^{S\cup T}$ by $\phi_S \circ \phi_T(x) = \phi_S(x)$ if $x \in S$ and $\phi_S \circ \phi_T(x) = \phi_T(x)$ otherwise. Similar notations are also used for two-prover games. Finally, recall that a game $(X, Y, \mathcal{Q}, \Sigma_X, \Sigma_Y, \{P_{(x,y)}\})$ is a *projection game* if, for each $(x, y) \in \mathrm{supp}(\mathcal{Q})$, there is $f : \Sigma_X \to \Sigma_Y$ such that, for all $\sigma_x \in \Sigma_X, \sigma_y \in \Sigma_Y$, $P_{(x,y)}(\sigma_x, \sigma_y) = \mathbb{1}[f(\sigma_x) = \sigma_y]$.

3 Birthday Repetition Theorem: Proof Overview

In this section, we outline the proofs of our birthday repetition theorems. We first state our main theorems formally, starting with the birthday repetition theorem for general games.

▶ **Theorem 12.** *There exists a constant $\alpha > 0$ such that the following is true. Let $\mathcal{G} = (X, Y, E, \Sigma_X, \Sigma_Y, \{P_{(x,y)}\})$ be any two-prover game of value $1 - \varepsilon$. Let d_{max} be the maximum degree of a vertex in (X, Y, E) and $c = \log |\Sigma_X||\Sigma_Y|$. For all $0 \le k \le |X|$ and $0 \le l \le |Y|$,*

$$val(\mathcal{G}^{k\times l}) \le 2(1 - \varepsilon/2)^{\frac{\alpha\varepsilon^5 kl|E|}{d_{max}|X||Y|c^2}}$$

For projection games, we can improve the dependency on ε and avoid the dependency on c:

▶ **Theorem 13.** *There exists a constant $\alpha > 0$ such that the following is true. Let $\mathcal{G} = (X, Y, E, \Sigma_X, \Sigma_Y, \{P_{(x,y)}\})$ be any projection game of value $1 - \varepsilon$. Let d_{max} be the maximum degree of a vertex in (X, Y, E). For all $0 \le k \le |X|$ and $0 \le l \le |Y|$, we have*

$$val(\mathcal{G}^{k\times l}) \le 2(1 - \varepsilon/2)^{\frac{\alpha\varepsilon^3 kl|E|}{d_{max}|X||Y|}}$$

In short, we will to show that $\mathcal{G}^{k\times l}$ has small value by "embedding" an $\Omega\left(\frac{kl|E|}{d_{max}|X||Y|}\right)$-parallel repetition game, which has low value by the parallel repetition theorem, into it.

For convenience, let s denote $\frac{kl|E|}{|X||Y|}$, the expected number of edges in $E(S, T)$ when S and T are independently uniformly sampled from $\binom{X}{k}$ and $\binom{Y}{l}$ respectively. Let s_1 and s_2 be $s(1 + \delta)$ and $s(1 - \delta)$ respectively for some $\delta \in [0, 1/2]$ that will be chosen later. We will use $r = \beta s/d_{max}$ rounds of parallel repetition where $\beta \in [0, \delta/40]$ will be specified later. Lastly, let $E^r = \{((x_1, \ldots, x_r), (y_1, \ldots, y_r)) \mid (x_1, y_1), \ldots, (x_r, y_r) \in E\}$.

▶ Remark. δ and β will be chosen based on ε, c and whether $\mathcal{G}$ is a projection game. When ε and c are constant, both δ and β are small constants. This is the most representative case and is good to keep in mind when reading through the proof.

Our overall strategy is to reduce $\mathcal{G}^{\otimes r}$ to $\mathcal{G}^{k\times l}$. Since $val(\mathcal{G}^{\otimes r})$ is exponentially small in $r = \Omega\left(\frac{kl|E|}{d_{max}|X||Y|}\right)$ due to the parallel repetition theorem, such reduction would give a similar upper bound on $val(\mathcal{G}^{k\times l})$. Unfortunately, we do not know how to do this in one step so we will have to go through a sequence of reductions. The sequence of games that we reduce to are $\mathcal{G}^{\otimes r}_{\text{set}}, \mathcal{G}^{k\times l}_{\text{em}}, \mathcal{G}^{k\times l}_{\text{em},[s_1,s_2]}$ and $\mathcal{G}^{k\times l}_{[s_1,s_2]}$ respectively. The game $\mathcal{G}^{\otimes r}_{\text{set}}$ share the same questions, alphabet sets and predicates with $\mathcal{G}^{\otimes r}$ while $\mathcal{G}^{k\times l}_{\text{em}}, \mathcal{G}^{k\times l}_{\text{em},[s_1,s_2]}$ and $\mathcal{G}^{k\times l}_{[s_1,s_2]}$ share those with $\mathcal{G}^{k\times l}$. The distribution of each game is defined as follows.

- The distribution of $\mathcal{G}^{\otimes r}_{\text{set}}$ is uniform over the set E^r_{set} of all $((x_1, \ldots, x_r), (y_1, \ldots, y_r)) \in E^r$ such that $x_1, \ldots, x_r, y_1, \ldots, y_r$ are all distinct. Note that this distribution is simply $\mathcal{G}^{\otimes r}$'s distribution conditioned on $x_1, \ldots, x_r, y_1, \ldots, y_r$ being all distinct.
- We will try to make the distribution $\mathcal{Q}^{k\times l}_{\text{em}}$ of $\mathcal{G}^{k\times l}_{\text{em}}$ reflect an embedding of the game $\mathcal{G}^{\otimes r}_{\text{set}}$. We define $\mathcal{Q}^{k\times l}_{\text{em}}$ based on the following sampling process for $(S, T) \sim \mathcal{Q}^{k\times l}_{\text{em}}$. First, sample $((x_1, \ldots, x_r), (y_1, \ldots, y_r))$ uniformly at random from E^r_{set}. Then, sample $\tilde{S}$ and $\tilde{T}$ independently uniformly from $\binom{X-\{x_1,\ldots,x_r\}}{k-r}$ and $\binom{Y-\{y_1,\ldots,y_r\}}{l-r}$ respectively. Finally, set $S = \{x_1, \ldots, x_r\} \cup \tilde{S}$ and $T = \{y_1, \ldots, y_r\} \cup \tilde{T}$.
- The distribution $\mathcal{Q}^{k\times l}_{\text{em},[s_1,s_2]}$ of $\mathcal{G}^{k\times l}_{\text{em},[s_1,s_2]}$ is the distribution $\mathcal{Q}^{k\times l}_{\text{em}}$ conditioned on the number of edges between the two sets being in the range $[s_1, s_2]$. In other words, $\mathcal{Q}^{k\times l}_{\text{em},[s_1,s_2]}(S, T) = \Pr_{(S',T')\sim\mathcal{Q}^{k\times l}_{\text{em}}}[S = S' \wedge T = T' \mid s_1 \le |E(S', T')| \le s_2]$.

- Finally, the distribution of $\mathcal{G}^{k\times l}_{[s_1,s_2]}$ is uniform over the set $E^{k\times l}_{[s_1,s_2]}$ of all (S,T) such that $|E(S,T)| \in [s_1,s_2]$. In other words, we ignore weights in $\mathcal{Q}^{k\times l}_{\mathrm{em},[s_1,s_2]}$ and use the uniform distribution over $\mathrm{supp}(\mathcal{Q}^{k\times l}_{\mathrm{em},[s_1,s_2]})$.

Before we present the overview of the proofs, let us list simple bounds that will be useful in understanding the intuitions. Their proofs can be found in the full version of this work [42].

▶ **Lemma 14.** *Let (X,Y,E) be any bipartite graph with maximum degree d_{max}. For any non-negative integers $k \le |X|$ and $l \le |Y|$, let $s = \frac{kl|E|}{|X||Y|}$. For any $0 \le \gamma < 1/2$, we have*

$$\Pr_{S\sim\binom{X}{k},T\sim\binom{Y}{l}}[|E(S,T)| \notin [(1-\gamma)s,(1+\gamma)s]] \le 4\exp\left(-\frac{\gamma^2 s}{54 d_{max}}\right).$$

▶ **Lemma 15.** *Let $\mathcal{G}$ and $\mathcal{G}'$ be two games on the same questions, alphabets, and predicates but on different distributions $\mathcal{Q}$ and $\mathcal{Q}'$ respectively. If, for some α, $\mathcal{Q}(x,y) \le \alpha\cdot\mathcal{Q}'(x,y)$ for all $x\in X, y\in Y$, then $val(\mathcal{G}) \le \alpha\cdot val(\mathcal{G}')$. In particular, when $\mathcal{Q}$ and $\mathcal{Q}'$ are uniform distributions on some $E\subseteq E'$, $val(\mathcal{G}) \le \frac{|E'|}{|E|}\cdot val(\mathcal{G}')$.*

▶ **Lemma 16.** *Let $\mathcal{G} = (X,Y,\mathcal{Q},\Sigma_X,\Sigma_Y,\{P_{x,y}\}_{(x,y)\in\mathrm{supp}(\mathcal{Q})})$ be any two player game and let A be any event occurring with probability $1-p>0$ (w.r.t. $\mathcal{Q}$). Let $\mathcal{Q}'$ be the conditional probability $\mathcal{Q}$ given A, i.e., $\mathcal{Q}'(\tilde{x},\tilde{y}) = \Pr_{(x,y)\sim\mathcal{Q}}[x=\tilde{x}\wedge y=\tilde{y} \mid A]$. For the game $\mathcal{G}' = (X,Y,\mathcal{Q}',\Sigma_X,\Sigma_Y,\{P_{x,y}\}_{(x,y)\in\mathrm{supp}(\mathcal{Q}')})$, we have $val(\mathcal{G}) - p \le val(\mathcal{G}') \le val(\mathcal{G}) + 2p$.*

We will next give intuitions on why $val(\mathcal{G}^{\otimes r}) \approx val(\mathcal{G}^{\otimes r}_{\mathrm{set}}) \approx val(\mathcal{G}^{k\times l}_{\mathrm{em}}) \approx val(\mathcal{G}^{k\times l}_{\mathrm{em},[s_1,s_2]}) \approx val(\mathcal{G}^{k\times l}_{[s_1,s_2]}) \approx val(\mathcal{G}^{k\times l})$ where each $\approx$ hides some multiplicative or additive losses in each step. With the right choice of δ and β, we can ensure that each loss is significantly smaller than $val(\mathcal{G}^{\otimes r})$, and, thus, we will be able to bound $val(\mathcal{G}^{k\times l})$. Below, we state these losses more precisely and summarize the overview of each proof.

▶ **Lemma 17.** $val(\mathcal{G}^{\otimes r}_{set}) \le \left(\frac{1}{1-2\beta}\right)^r \cdot val(\mathcal{G}^{\otimes r})$

Proof Idea. From Lemma 15, it suffices to lower bound the ratio $|E^r_{\mathrm{set}}|/|E^r|$. This is the probability that r random edges from E do not share any endpoints, which is easy to bound. ◀

▶ **Lemma 18.** $val(\mathcal{G}^{k\times l}_{em}) \le val(\mathcal{G}^{\otimes r}_{set})$

Proof Idea. Based on how $\mathcal{Q}^{k\times l}_{\mathrm{em}}$ is defined, it induces a canonical map from each strategy in $\mathcal{G}^{k\times l}_{\mathrm{em}}$ to a "mixed strategy" in $\mathcal{G}^{\otimes r}_{\mathrm{set}}$. We can show that each strategy ϕ in $\mathcal{G}^{k\times l}_{\mathrm{em}}$ has value no more than the value of the mixed strategy in $\mathcal{G}^{\otimes r}_{\mathrm{set}}$ that ϕ maps to, which yields the lemma. ◀

▶ **Lemma 19.** $val(\mathcal{G}^{k\times l}_{em,[s_1,s_2]}) \le val(\mathcal{G}^{k\times l}_{em}) + 8\exp\left(-\frac{\delta^2 r}{432\beta}\right)$

Proof Idea. $\mathcal{Q}^{k\times l}_{\mathrm{em},[s_1,s_2]}$ is $\mathcal{Q}^{k\times l}_{\mathrm{em}}$ conditioned on the event $E(S,T)\in[s_1,s_2]$. From Lemma 16, it suffices to bound the probability of such event. From the definition of $\mathcal{Q}^{k\times l}_{\mathrm{em}}$, S and T can be sampled by first sampling $x_1,\ldots,x_r,y_1,\ldots,y_r$ according to E^r and then sampling the rest of S and T from $X-\{x_1,\ldots,x_r\}$ and $Y-\{y_1,\ldots,y_r\}$ respectively. When r is small enough, we can show, with the help of Lemma 14, that, for any $x_1,\ldots,x_r,y_1,\ldots,y_r$, $|E(S,T)|$ concentrates around s. This gives us the desired bound. ◀

▶ **Lemma 20.** $val(\mathcal{G}^{k\times l}_{[s_1,s_2]}) \le \left(\frac{1+\delta}{1-\delta-2\beta}\right)^{2r} \cdot val(\mathcal{G}^{k\times l}_{em,[s_1,s_2]})$

Proof Idea. We will show that the two distributions are (multiplicatively) close and evoke Lemma 15 to arrive at the bound. Since the distribution of $\mathcal{G}^{k\times l}_{[s_1,s_2]}$ is uniform, we only need to show that the maximum and the minimum (non-zero) probabilities in $\mathcal{Q}^{k\times l}_{\text{em},[s_1,s_2]}$ are close.

Fortunately, we know that $\mathcal{Q}^{k\times l}_{\text{em},[s_1,s_2]}$ is $\mathcal{Q}^{k\times l}_{\text{em}}$ conditioned on an event. This means that, when $\mathcal{Q}^{k\times l}_{\text{em},[s_1,s_2]}(S,T)$ is not zero, it is proportional to $\mathcal{Q}^{k\times l}_{\text{em}}(S,T)$. The latter, in turn, is proportional to the number of edges $(x_1,y_1),\ldots,(x_r,y_r)\in E^r$ such that $x_1,\ldots,x_r,y_1,\ldots,y_r$ are all distinct and $x_1,\ldots,x_r\in S$ and $y_1,\ldots,y_r\in T$. In other words, we want to upper bound and lower bound the number of r edges in $E(S,T)$ with distinct endpoints. This is feasible since we know that $|E(S,T)|\in[s_1,s_2]$ and r is so small that with a reasonable probability r edges picked will not share any endpoint with each other. ◀

▶ **Lemma 21.** $val(\mathcal{G}^{k\times l})\le val(\mathcal{G}^{k\times l}_{[s_1,s_2]})+4\exp\left(-\frac{\delta^2 r}{54\beta}\right)$

Proof Idea. By realising that $\mathcal{G}^{k\times l}_{[s_1,s_2]}$'s distribution is simply $\mathcal{G}^{k\times l}$'s distribution conditioned on $|E(S,T)|\in[s_1,s_2]$, this follows immediately from Lemma 14 and Lemma 16. ◀

We defer proofs of the above lemmas to the full version [42]. Let us now use them to prove the birthday repetition theorems. To avoid repeating arguments for general games and projection games, we prove the following lemma. Its proof, mostly calculations, is deferred to the full version.

▶ **Lemma 22.** *Let $\mathcal{G}$ be any game of value $1-\varepsilon$ and k,l,β,δ,r be as above. If $val(\mathcal{G}^{\otimes r})\le(1-\varepsilon/2)^R$ for some R such that $\frac{200\delta r}{\varepsilon}\le R\le\min\{r,\frac{\delta^2 r}{1000\beta\varepsilon}\}$, then $val(\mathcal{G}^{k\times l})\le 2(1-\varepsilon/2)^{R/10}$.*

The final ingredient for our main proof is the parallel repetition theorem. For general games, we use Holenstein's version of the theorem [34], which is stated below.

▶ **Theorem 23** ([34])**.** *There is a constant $C>0$ such that, for every $k>0$ and any two-prover game $\mathcal{G}=(X,Y,\mathcal{Q},\Sigma_X,\Sigma_Y,\{P_{(x,y)}\})$ of value $1-\varepsilon$, $val(\mathcal{G}^{\otimes k})\le(1-\varepsilon/2)^{C\varepsilon^2 k/\log(|\Sigma_X||\Sigma_Y|)}$.*

Equipped with Lemma 22 and the parallel repetition theorem, we can now prove our birthday repetition theorems just by selecting the right δ and β.

Proof of Theorem 12. Pick $\delta=\frac{\varepsilon^3 C}{10^3 c}$ and $\beta=\frac{\varepsilon^3 C}{10^{10}c}$ where C is the constant from Theorem 23. From Theorem 23, we have $val(\mathcal{G}^{\otimes r})\le(1-\varepsilon/2)^{C\varepsilon^2 r/c}$. Let $R=C\varepsilon^2 r/c$. We can see that R,δ,β satisfy the conditions in Lemma 22. Hence, we can conclude that $val(\mathcal{G}^{k\times l})\le 2(1-\varepsilon/2)^{R/10}=2(1-\varepsilon/2)^{(C^2/10^{11})\left(\frac{\varepsilon^5 kl|E|}{c^2|X||Y|d_{max}}\right)}$ as desired. ◀

In the case of projection games, we can improve dependency on ε and get rid of dependency on c thanks to the stronger bound in Rao's parallel repetition theorem for projection games [50].

▶ **Theorem 24** ([50])**.** *There exists a constant $C>0$ such that, for any projection game $\mathcal{G}$ of value $1-\varepsilon$ and for every $k>0$, we have $val(\mathcal{G}^{\otimes k})\le(1-\varepsilon/2)^{C\varepsilon k}$.*

Proof of Theorem 13. Pick $\delta=\frac{\varepsilon^2 C}{10^3}$ and $\beta=\frac{\varepsilon^2 C}{10^{10}}$ where C is the constant from Theorem 24. From the theorem, we have $val(\mathcal{G}^{\otimes r})\le(1-\varepsilon/2)^{C\varepsilon r}$. Let $R=C\varepsilon r$. By evoking Lemma 22, we have $val(\mathcal{G}^{k\times l})\le 2(1-\varepsilon/2)^{R/10}=2(1-\varepsilon/2)^{(C^2/10^{11})\left(\frac{\varepsilon^3 kl|E|}{|X||Y|d_{max}}\right)}$ as desired. ◀

4 Improved Approximation Algorithm for Dense CSPs

To describe our algorithm, we first explain ingredients central in conditioning-based algorithms: a LP/SDP hierarchy, a conditioning operator, and an independent rounding procedure.

Sherali-Adams (SA) relaxation of Max k-CSP. An *r-level SA solution* μ of $\mathcal{G} = (V, \mathcal{W}, \{P_S\})$ is a collection $\{\mathcal{X}_S\}$ of distributions $\mathcal{X}_S$ on Σ^S for every $S \in \binom{V}{[r]}$ such that, for every $S, T \in \binom{V}{[r]}$, the marginal probability of $\mathcal{X}_S$ and $\mathcal{X}_T$ on $\Sigma^{S\cap T}$ agrees. For $r \geq k$, the value of μ is $val_{SA}(\mu) = \mathbb{E}_{S\sim\mathcal{W}}[\mathbb{E}_{x_S\sim\mu}[P_S(x_S)]]$ where $\mathbb{E}_{x_S\sim\mu}[P_S(x_S)]$ is a shorthand for $\mathbb{E}_{\phi_S\sim\mathcal{X}_{\{i_1,\dots,i_k\}}}[P_S(\phi_S)]$ when $S = (x_{i_1}, \dots, x_{i_k})$. The optimum of the r-level SA relaxation of $\mathcal{G}$, $opt^r_{SA}(\mathcal{G})$, is the maximum value among all the r-level SA solutions. Clearly, finding $opt^r_{SA}(\mathcal{G})$ can be formulated as a LP and can be computed in $(nq)^{O(r)}$ time.

Conditioning SA Solution. Let $\mu = \{\mathcal{X}_S\}$ be any r-level SA solution. For any $T \subseteq V$ and $\phi_T \in \Sigma^T$ such that $\mathcal{X}_T(\phi_T) > 0$, μ conditioned on ϕ_T is $\mu|\phi_T = \{\tilde{\mathcal{X}}_S\}_{|S|\leq r-|T|}$ where

$$\tilde{\mathcal{X}}_S(\phi_S) = \begin{cases} \mathcal{X}_{S\cup T}(\phi_S \circ \phi_T)/\mathcal{X}_T(\phi_T) & \text{if } \phi_S \text{ is consistent with } \phi_T, \\ 0 & \text{otherwise.} \end{cases}$$

It is not hard to see that $\mu|\phi_T$ is an $(r - |T|)$-level SA solution.

Independent Rounding. A natural way to round a SA solution $\{\mathcal{X}_S\}$ is to independently assign each variable x based on $\mathcal{X}_x$. This gives a solution with expected value at least $\mathbb{E}_{S=(x_{i_1},\dots,x_{i_k})\sim\mathcal{W}}\left[\mathbb{E}_{\phi_S\sim\mathcal{X}_{i_1}\times\cdots\times\mathcal{X}_{i_k}}[P_S(\phi_S)]\right]$ and can be easily derandomized.

Without going into too much detail, conditioning-based algorithms typically proceed as follows. First, solve a LP/SDP relaxation of the problem. As long as the solution has large "total correlation", try conditioning it on an assignment to a random variable. Once the solution has small total correlation, use independent rounding on the solution to get the desired assignment. The intuition here is that, if the solution has large total correlation, conditioning on one variable substantially reduces the total correlation. Hence, after a certain number of rounds of conditioning, the total correlation becomes small. At this point, the solution is quite independent and independent rounding gives a good approximation.

Our algorithm will also follow this framework. In fact, it remains largely unchanged from [60] except that we use a stronger relaxation to avoid arguing about values of conditioned solutions. However, our main contribution lies in the analysis: we will show that independent rounding does well even when the total correlation is large (super-constant). This is in contrast to the previously known conditioning-based algorithms [11, 49, 60], all of which require their measures of correlation to be small constants to get any meaningful result.

The new relaxation, which we call the r-level SA with Conditioning (SAC), is defined below.

$$\begin{aligned} &\text{maximize } \lambda \\ &\text{subject to } \{\mathcal{X}_S\}_{|S|\leq r} \text{ is a valid } r\text{-level SA solution} \\ &\qquad \mathop{\mathbb{E}}_{S\sim\mathcal{W}}\Big[\mathop{\mathbb{E}}_{\phi_S\sim(\mu|\phi_T)}[P_S(\phi_S)]\Big] \geq \lambda \qquad\qquad \forall T, \phi_T \text{ s.t. } |T| \leq r-k, \mathcal{X}_T(\phi_T) > 0. \end{aligned}$$

If λ is a constant, the program can be easily written as a LP. Thus, the relaxation can be solved to within arbitrarily small error in $(nq)^{O(r)}$ time by binary search on λ.

Algorithm 1 Approximation Algorithm for Dense CSPs

Input: a Δ-dense MAX k-CSP instance $\mathcal{G}$, an integer i
Output: An assignment $\phi : V \to \Sigma$

```
r ← k, λ ← 0
while (r − k)λ < k²i/Δ and r < n do
    r ← r + 1
    μ, λ ← solve r-level of SAC relaxation for G
for T ∈ (V choose [r−k]), φ_T ∈ Σ^T do
    φ ← independent rounding of μ|φ_T
return φ from the previous step with maximum value
```

Figure 1 Approximation Algorithm for Dense CSPs. The difference between this and the above summary is that we iteratively increase the number of levels r. This is because the number of levels depends on the value of the solution (see Lemma 28). Specifically, we need $r \geq k^2 i/(\Delta\lambda) + k$.

Roughly speaking, our algorithm first solves an $O(\frac{k^2 i}{\Delta} + k)$-level SAC relaxation for the instance. We then try every possible conditioning (i.e., every assignment to $T \subseteq V$ of size $\leq k^2 i/\Delta$). For each conditioned solution, we use independent rounding to arrive at an assignment. Finally, output the best such assignment. The pseudo-code for the full algorithm is shown in Figure 1. This algorithm yields the following approximation for the problem.

▶ **Theorem 25** (Theorem 8, Restated). *On any Δ-dense* MAX k-CSP *instance of value $1-\delta$, Algorithm 1 outputs an assignment of value at least $(1-\delta)\delta^{\frac{\delta}{1-\delta}}/q^{1/i}$ in time $N^{O\left(\frac{ki}{(1-\delta)\Delta}\right)}$.*

We spend the rest of the section sketching the proof of Theorem 25. First, we define and state a bound on the total correlation of conditioned solutions in Section 4.1. Then, in Subsection 4.2, we state our main contribution of this section, i.e., that even when the total correlation is super-constant, independent rouding still yields non-trivial approximation.

4.1 Total Correlation of Conditioned Sherali-Adams Solution

For a k-level SA solution $\mu = \{\mathcal{X}_S\}$ and a tuple $S = (x_{i_1}, \ldots, x_{i_j}) \in V^j$ where $j \leq k$, the total correlation of S is $C_\mu(x_S) = C(\sigma_{i_1}; \ldots; \sigma_{i_j})$ where $\sigma_{i_1}, \ldots, \sigma_{i_j}$ are jointly sampled from $\mathcal{X}_{\{x_{i_1}, \ldots, x_{i_j}\}}$. The total correlation of μ is then defined as $C(\mu) = \mathbb{E}_{S\sim\mathcal{W}}[C_\mu(x_S)]$. μ is said to be *κ-independent* if $C(\mu) \leq \kappa$. Yoshida and Zhou [60] show that, for any $l > 0$ and any $(l+k)$-level SA solution μ, there exists an assignment $\phi_T \in \Sigma^T$ to a subset T of size $\leq l$ such that the total correlation of $(\mu|\phi_T)$ is at most $3^k \log q/(l\Delta)$. Here we can improve this bound as stated below. Since the proof is similar to that of [60], we defer it to the full version of this work [42].

▶ **Lemma 26.** *Let μ be a r-level SA solution of a Δ-dense* MAX k-CSP *instance $(V, \mathcal{W}, \{P_S\})$. Then, for any $0 < l \leq r - k$, there is $t \leq l$ such that $\mathbb{E}_{T\sim V^t, \phi_T\sim\Sigma^T}[C(\mu|\phi_T)] \leq \frac{k^2 \log q}{l\Delta}$.*

4.2 New Bound on Rounding κ-independent Solution

For the known conditioning-based algorithms, once the solution is fairly independent, it is easy to show that independent rounding gives a good solution. Specifically, [49] and [60] conclude this step using the Pinsker's inequality, which states that, for any distributions $\mathcal{X}$ and $\mathcal{Y}$, $D_{KL}(\mathcal{X}\|\mathcal{Y}) \geq (2\log 2)\|\mathcal{X} - \mathcal{Y}\|_1^2$. Roughly speaking, $\mathcal{X}$ is the distribution in the LP

solution whereas $\mathcal{Y}$ is the distribution from independent rounding. Hence, once $D_{KL}(\mathcal{X}\|\mathcal{Y})$ is at most a small constant ε, it follows that, for any predicate f, $|\mathbb{E}_{x\sim\mathcal{X}}[f(x)] - \mathbb{E}_{y\sim\mathcal{Y}}[f(y)]| \leq \sqrt{\varepsilon/(2\log 2)}$. Thus, if $\mathbb{E}_{x\sim\mathcal{X}}[f(x)]$, the value of the LP solution, is large, then $\mathbb{E}_{y\sim\mathcal{Y}}[f(y)]$, the expected value of a solution from independent rouding, is also large.

While this works for small ε, it completely fails when ε is larger than a certain constant. In this regard, we prove the following lemma, which gives a non-trivial bound even for large ε. For convenience, 0^0 is defined to be 1 and $(\delta^\delta e^{-\kappa})^{\frac{1}{1-\delta}}(1-\delta)$ is defined to be 0 when $\delta = 1$.

▶ **Lemma 27.** *For any two probability distributions $\mathcal{X}, \mathcal{Y}$ over Θ such that $D_{KL}(\mathcal{X}\|\mathcal{Y}) \leq \kappa$ and any $f : \Theta \to [0,1]$, if $\mathbb{E}_{x\sim\mathcal{X}}[f(x)] = 1-\delta$, then $\mathbb{E}_{y\sim\mathcal{Y}}[f(y)] \geq \left(\delta^\delta e^{-\kappa}\right)^{\frac{1}{1-\delta}}(1-\delta)$.*

Lemma 27 can then be used to prove a new lower bound for the value of the output from independent rounding on a κ-independent k-level SA solution as stated below.

▶ **Lemma 28.** *If $\{\mathcal{X}_S\}$ is a κ-independent k-level SA solution of value $1-\delta$ for a* Max k-CSP *instance, then independent rounding gives an assignment of value at least $(\delta^\delta e^{-\kappa})^{\frac{1}{1-\delta}}(1-\delta)$.*

Theorem 25 can now be proved by combining Lemma 26 and 28. Due to space constraint, we omit the proofs of Lemma 27, Lemma 28 and Theorem 25 from this extended abstract.

5 Conclusion and Open Problems

While we settle down the approximability of dense Max k-CSP up to a $k\,\mathrm{polylog}(ki)$ factor in the exponent, our work raises many interesting questions such as the two listed below:

- *Can Lemma 27 be used to prove new approximation guarantees for other problems?* Lemma 27 is a generic bound relating expectations of a function on two distributions based on their informational divergence. Thus, it may help yield new approximation guarantees for other correlation-based algorithms.
- *What is the right dependency on ε and c in the birthday repetition theorem?* It is likely that the dependency of ε and c in our birthday repetition is not tight. In particular, parallel repetition for general games only has $1/c$ factor in the exponent whereas our theorem has $1/c^2$; would it be possible to reduce the dependency to $1/c$ in birthday repetition? Similar question also applies to ε.

Acknowledgements. PM would like to thank Aviad Rubinstein, Dana Moshkovitz, Grigory Yaroslavtsev and Madhur Tulsiani for useful discussions. We also thank Irit Dinur for informing us about her result based on gap-ETH.

Inapproximability of Maximum Edge Biclique, Maximum Balanced Biclique and Minimum k-Cut from the Small Set Expansion Hypothesis*†

Pasin Manurangsi

University of California, Berkeley, CA, USA
pasin@berkeley.edu

Abstract

The *Small Set Expansion Hypothesis* (SSEH) is a conjecture which roughly states that it is NP-hard to distinguish between a graph with a small set of vertices whose expansion is almost zero and one in which all small sets of vertices have expansion almost one. In this work, we prove conditional inapproximability results for the following graph problems based on this hypothesis:

- *Maximum Edge Biclique* (MEB): given a bipartite graph G, find a complete bipartite subgraph of G with maximum number of edges. We show that, assuming SSEH and that NP $\not\subseteq$ BPP, no polynomial time algorithm gives $n^{1-\varepsilon}$-approximation for MEB for every constant $\varepsilon > 0$.
- *Maximum Balanced Biclique* (MBB): given a bipartite graph G, find a balanced complete bipartite subgraph of G with maximum number of vertices. Similar to MEB, we prove $n^{1-\varepsilon}$ ratio inapproximability for MBB for every $\varepsilon > 0$, assuming SSEH and that NP $\not\subseteq$ BPP.
- *Minimum k-Cut*: given a weighted graph G, find a set of edges with minimum total weight whose removal splits the graph into k components. We prove that this problem is NP-hard to approximate to within $(2 - \varepsilon)$ factor of the optimum for every $\varepsilon > 0$, assuming SSEH.

The ratios in our results are essentially tight since trivial algorithms give n-approximation to both MEB and MBB and 2-approximation algorithms are known for Minimum k-Cut [35].

Our first two results are proved by combining a technique developed by Raghavendra, Steurer and Tulsiani [33] to avoid locality of gadget reductions with a generalization of Bansal and Khot's long code test [4] whereas our last result is shown via an elementary reduction.

1 Introduction

Since the PCP theorem was proved two decades ago [2, 3], our understanding of approximability of combinatorial optimization problems has grown enormously; tight inapproximability results have been obtained for fundamental problems such as Max-3SAT [15], Max Clique [14] and Set Cover [27, 9]. Yet, for other problems, including Vertex Cover and Max Cut, known NP-hardness of approximation results come short of matching best known algorithms.

The introduction of the Unique Games Conjecture (UGC) by Khot [19] propelled another wave of development in hardness of approximation that saw many of these open problems resolved (see e.g. [23, 21]). Alas, some problems continue to elude even attempts at proving

* A full version of the paper is available at https://arxiv.org/abs/1705.03581.

† This material is based upon work supported by the National Science Foundation under Grants No. CCF 1540685 and CCF 1655215.

UGC-hardness of approximation. For a class of such problems, the failure stems from the fact that typical reductions are local in nature; many reductions from unique games to graph problems could produce disconnected graphs. If we try to use such reductions for problems that involve some forms of expansion of graphs (e.g. Sparsest Cut), we are out of luck.

One approach to overcome the aforementioned issue is through the *Small Set Expansion Hypothesis* (SSEH) of Raghavendra and Steurer [32]. To describe the hypothesis, recall that, on a d-regular undirected unweighted graph $G = (V, E)$, the edge expansion $\Phi(S)$ of $S \subseteq V$ is defined as

$$\Phi(S) = \frac{|E(S, V \setminus S)|}{d \min\{|S|, |V \setminus S|\}}$$

where $E(S, V \setminus S)$ is the set of edges across the cut $(S, V \setminus S)$. The small set expansion problem $\mathrm{SSE}(\delta, \eta)$, where η, δ are two parameters that lie in (0, 1), can be defined as follows.

▶ **Definition 1** ($\mathsf{SSE}(\delta, \eta)$)**.** Given a regular graph $G = (V, E)$, distinguish between:
- *(Completeness)* There exists $S \subseteq V$ of size $\delta|V|$ such that $\Phi(S) \leqslant \eta$.
- *(Soundness)* For every $S \subseteq V$ of size $\delta|V|$, $\Phi(S) \geqslant 1 - \eta$.

For simplicity, we always assume that the input graphs of SSE are regular and unweighted and defer the treatment of arbitrary weighted graphs to the full version.

Roughly speaking, SSEH asserts that it is NP-hard to distinguish between a graph that has a small non-expanding subset of vertices and one in which all small subsets of vertices have almost perfect edge expansion. More formally, the hypothesis can be stated as follows.

▶ **Conjecture 1** (SSEH [32])**.** *For every $\eta > 0$, there is $\delta > 0$ such that SSE(δ, η) is NP-hard.*

Interestingly, SSEH not only implies UGC [32], but it is also equivalent to a stregthened version of the latter, in which the graph is required to have almost perfect small set expansion [33].

Since its proposal, SSEH has been used as a starting point for proving inapproximability of many problems whose hardnesses are not known otherwise. Most relevant to us is the work of Raghavendra, Steurer and Tulsiani (henceforth RST) [33] who devised a technique that exploited structures of SSE instances to avoid locality in reductions. In doing so, they obtained hardness of approximation for Min Bisection, Balanced Separator, and Minimum Linear Arrangement; these problems are not known to be hard to approximate under UGC.

1.1 Maximum Edge Biclique and Maximum Balanced Biclique

Our first result is adapting RST technique to prove inapproximability results for Maximum Edge Biclique (MEB) and Maximum Balanced Biclique (MBB). For both problems, the input is a bipartite graph. The goal for the former is to find a complete bipartite subgraph that contains as many edges as possible whereas, for the latter, the goal is to find a balanced complete bipartite subgraph that contains as many vertices as possible.

Both problems are NP-hard. MBB was stated (without proof) to be NP-hard in [12, page 196]; several proofs of this exist such as one provided in [17]. For MEB, it was proved to be NP-hard more recently by Peeters [31]. Unfortunately, much less is known when it comes to approximability of both problems. Similar to Maximum Clique, folklore algorithms give $O(n/\operatorname{polylog} n)$ approximation ratio for both MBB and MEB, and no better algorithm is known. However, not even NP-hardness of approximation of some constant ratio is known for the problems. This is in stark contrast to Maximum Clique for which strong inapproximability

results are known [14, 18, 22, 39]. Fortunately, the situation is not completely hopeless as the problems are known to be hard to approximate under stronger complexity assumptions.

Feige [10] showed that, assuming that random 3SAT formulae cannot be refuted in polynomial time, both problems[1] cannot be approximated to within n^{ε} of the optimum in polynomial time for some $\varepsilon > 0$. Later, Feige and Kogan [11] proved $2^{(\log n)^{\varepsilon}}$ ratio inapproximability for both problems for some $\varepsilon > 0$, assuming that 3SAT $\notin$ DTIME($2^{n^{3/4+\delta}}$) for some $\delta > 0$. Moreover, Khot [20] showed, assuming 3SAT $\notin$ BPTIME($2^{n^{\delta}}$) for some $\delta > 0$, that no polynomial time algorithm achieves n^{ε}-approximation for MBB for some $\varepsilon > 0$. Ambühl et al. [1] subsequently built on Khot's result and showed a similar hardness for MEB. Recently, Bhangale et al. [6] proved that both problems are hard to approximate to within[2] $n^{1-\varepsilon}$ factor for every $\varepsilon > 0$, assuming a certain strengthened version of UGC and NP $\neq$ BPP. In addition, while not stated explicitly, the author's recent reduction for Densest k-Subgraph [25] yields $n^{1/\operatorname{polyloglog} n}$ ratio inapproximability for both problems under the Exponential Time Hypothesis [16] (3SAT $\notin$ DTIME($2^{o(n)}$)) and this ratio can be improved to $n^{f(n)}$ for any $f \in o(1)$ under the stronger Gap Exponential Time Hypothesis [8, 26] (no $2^{o(n)}$ time algorithm can distinguish a fully satisfiable 3SAT formula from one which is only $(1-\varepsilon)$-satisfiable for some $\varepsilon > 0$); these ratios are better than those in [11] but worse than those in [20, 1, 6].

In this work, we prove strong inapproximability results for both problems, assuming SSEH:

▶ **Theorem 2.** *Assuming SSEH, there is no polynomial time algorithm that approximates MEB or MBB to within $n^{1-\varepsilon}$ factor of the optimum for every $\varepsilon > 0$, unless NP $\subseteq$ BPP.*

We note that the only part of the reduction that is randomized is the gap amplification via randomized graph product [5, 7]. If one is willing to assume only that NP $\neq$ P (and SSEH), our reduction still implies that both are hard to approximate to within any constant factor.

Only Bhangale et al.'s result [6] and our result achieve the inapproximability ratio of $n^{1-\varepsilon}$ for every $\varepsilon > 0$; all other results achieve at most n^{ε} ratio for some $\varepsilon > 0$. Moreover, only Bhangale et al.'s reduction and ours are candidate NP-hardness reductions, whereas each of the other reductions either uses superpolynomial time [11, 20, 1, 25] or relies on an average-case assumption [10]. It is also worth noting here that, while both Bhangale et al.'s result and our result are based on assumptions which can be viewed as stronger variants of UGC, the two assumptions are incomparable and, to the best of our knowledge, Bhangale et al.'s technique does not apply to SSEH. Due to space constraint, we defer a more in-depth discussion on the differences between the two assumptions to a longer version of this work.

Along the way, we prove inapproximability of the following hypergraph bisection problem, which may be of independent interest: given a hypergraph $H = (V_H, E_H)$ find a bisection[3] (T_0, T_1) of V_H such that the number of uncut hyperedges is maximized. We refer to this problem as *Max UnCut Hypergraph Bisection* (MUCHB). Roughly speaking, we show that, assuming SSEH, it is hard to distinguish a hypergraph whose optimal bisection cuts only ε fraction of hyperedges from one in which every bisection cuts all but ε fraction of hyperedges:

[1] While Feige only stated this for MBB, the reduction clearly works for MEB too.
[2] In [6], the inapproximability ratio is only claimed to be n^{ε} for *some* $\varepsilon > 0$. However, it is not hard to see that their result in fact implies $n^{1-\varepsilon}$ factor hardness of approximation as well.
[3] (T_0, T_1) is a bisection of V_H if $|T_0| = |T_1| = |V_H|/2, T_0 \cap T_1 = \emptyset$ and $V_H = T_0 \cup T_1$.

▶ **Lemma 3.** *Assuming SSEH, for every $\varepsilon > 0$, it is NP-hard to, given a hypergraph $H = (V_H, E_H)$, distinguish between the following two cases:*

- (Completeness) *There is a bisection (T_0, T_1) of V_H s.t.*

$$|E_H(T_0)|, |E_H(T_1)| \geqslant (1/2 - \varepsilon)|E_H|\,.$$

- (Soundness) *For every set $T \subseteq V_H$ of size at most $|V_H|/2$, $|E_H(T)| \leqslant \varepsilon |E_H|$.*

Here $E_H(T) \triangleq \{e \in E_H \mid e \subseteq T\}$ denotes the set of hyperedges inside of the set $T \subseteq V_H$.

Our result above is similar to Khot's quasi-random PCP [20]; roughly speaking, Khot's result states that it is hard (if 3SAT $\notin \bigcap_{\delta>0}$ BPTIME(2^{n^δ})) to distinguish between a d-uniform hypergraph where $1/2^{d-2}$ fraction of hyperedges are uncut in the optimal bisection from one where roughly $1/2^{d-1}$ fraction of hyperedges are uncut in any bisection. In this sense, [20] provides better soundness at the expense of worse completeness compared ours.

1.2 Minimum k-Cut

In addition to the above biclique problems, we prove an inapproximability result for the Minimum k-Cut problem, in which a weighted graph is given and the goal is to find a set of edges with minimum total weight whose removal paritions the graph into (at least) k connected components. For any fixed k, the problem was proved to be in P by Goldschmidt and Hochbaum [13], who also showed that, when k is part of the input, the problem is NP-hard. To circumvent this, Saran and Vazirani [35] devised two simple polynomial time $(2 - 2/k)$-approximation algorithms for the problem. In the ensuing years, different approximation algorithms [29, 38, 34, 37] have been proposed for the problem, none of which are able achieve an approximation ratio of $(2-\varepsilon)$ for some $\varepsilon > 0$. In fact, Saran and Vazirani themselves conjectured that $(2-\varepsilon)$-approximation is intractible for the problem [35]. In this work, we show that their conjecture is indeed true, if the SSEH holds:

▶ **Theorem 4.** *Assuming SSEH, it is NP-hard to approximate Minimum k-Cut to within $(2-\varepsilon)$ factor of the optimum for every constant $\varepsilon > 0$.*

Note that the problem was claimed to be APX-hard in [35]. However, to the best of our knowledge, the proof has never been published and no other inapproximability is known.

2 Inapproximability of Minimum k-Cut

We now proceed to prove our main results. Let us start with the simplest: Minimum k-Cut.

Proof of Theorem 4. The reduction from SSE(δ, η) to Minimum k-Cut is simple; the graph G remains the input graph for Minimum k-Cut and we let $k = \delta n + 1$ where $n = |V|$.

Completeness. If there is $S \subseteq V$ of size δn such that $\Phi(S) \leqslant \eta$, then we partition the graph into k groups where the first group is $V \setminus S$ and each of the other groups contains one vertex from S. The edges cut are the edges in $E(S, V \setminus S)$ and the edges within the set S itself. There are $d|S|\Phi(S) \leqslant \eta d|S|$ edges of the former type and only at most $d|S|/2$ of the latter. Hence, the number of edges cut in this partition is at most $(1/2 + \eta)d|S| = (1/2 + \eta)\delta dn$.

Soundness. Suppose that, for every $S \subseteq V$ of size δn, $\Phi(S) \geqslant 1-\eta$. Let $T_1, \ldots, T_k \subseteq V$ be any k-partition of the graph. Assume w.l.o.g. that $|T_1| \leqslant \cdots \leqslant |T_k|$. Let $A = T_1 \cup \cdots \cup T_i$ where i is the maximum index such that $|T_1 \cup \cdots \cup T_i| \leqslant \delta n$.

We claim that $|A| \geqslant \delta n - \sqrt{n}$. To see that this is the case, suppose for the sake of contradiction that $|A| < \delta n - \sqrt{n}$. Since $|A \cup T_{i+1}| > \delta n$, we have $T_{i+1} > \sqrt{n}$. Moreover, since $A = T_1 \cup \cdots T_i$, we have $i \leqslant |A| < \delta n - \sqrt{n}$. As a result, we have $n = |T_1 \cup \cdots \cup T_k| \geqslant |T_{i+1} \cup \cdots \cup T_k| \geqslant (k-i)|T_i| > \sqrt{n} \cdot \sqrt{n} = n$, which is a contradiction. Hence, $|A| \geqslant \delta n - \sqrt{n}$.

Now, note that, for every $S \subseteq V$ of size δn, $\Phi(S) \geqslant 1-\eta$ implies that $|E(S)| \leqslant \eta d \delta n/2$ where $E(S)$ denote the set of all edges within S. Since $|A| \leqslant \delta n$, we also have $|E(A)| \leqslant \eta d \delta n/2$. As a result, the number of edges in the cut $(A, V \setminus A)$ is at least

$$d|A| - \eta d \delta n \geqslant (1-\eta) d \delta n - d\sqrt{n} = \left(1 - \eta - \frac{1}{\delta\sqrt{n}}\right) \delta d n.$$

For every constant $\varepsilon > 0$, by setting $\eta = \varepsilon/20$ and $n > 100/(\varepsilon^2\delta^2)$, the ratio between the two cases is at least $(2-\varepsilon)$, which concludes the proof of Theorem 4. ◀

3 Inapproximability of MEB and MBB

Let us now turn our attention to MEB and MBB. First, note that we can reduce MUCHB to MEB/MBB by just letting the two sides of the bipartite graph be E_H and creating an edge (e_1, e_2) iff $e_1 \cap e_2 = \emptyset$. This immediately shows that Lemma 3 implies the following:

▶ **Lemma 5.** *Assuming SSEH, for every $\delta > 0$, it is NP-hard to, given a bipartite graph $G = (L, R, E)$ with $|L| = |R| = n$, distinguish between the following two cases:*

- (Completeness) *G contains $K_{(1/2-\delta)n,(1/2-\delta)n}$ as a subgraph.*
- (Soundness) *G does not contain $K_{\delta n,\delta n}$ as a subgraph.*

Here $K_{t,t}$ denotes the complete bipartite graph in which each side contains t vertices.

Note that Theorem 2 follows from Lemma 5 by gap amplification via randomized graph product [5, 7]. Since this has been analyzed before even for biclique [20, Appendix D], we do not repeat the argument here.

We are now only left to prove Lemma 3; we devote the rest of this section to this task.

3.1 Preliminaries

Before we continue, we need additional notations and preliminaries. For every graph G and every vertex v, we will write $G(v)$ to denote the uniform distribution on its neighbors.

It will be convenient for us to use a different (but equivalent) formulation of SSEH. To state it, we will define a variant of SSE(δ, η) called SSE(δ, η, M); the completeness remains the same whereas the soundness is strengthened to include all S of size between $\frac{\delta|V|}{M}$ and $\delta|V|M$.

▶ **Definition 6** (SSE(δ, η, M))**.** Given a regular graph $G = (V, E)$, distinguish between:

- *(Completeness)* There exists $S \subseteq V$ of size $\delta|V|$ such that $\Phi(S) \leqslant \eta$.
- *(Soundness)* For every $S \subseteq V$ with $|S| \in \left[\frac{\delta|V|}{M}, \delta|V|M\right]$, $\Phi(S) \geqslant 1-\eta$.

The new formulation of the hypothesis can now be stated as follows.

▶ **Conjecture 2.** *For every $\eta, M > 0$, there is $\delta > 0$ such that SSE(δ, η, M) is NP-hard.*

Raghavendra et al. [33] showed that this formulation is equivalent to the earlier formulation (Conjecture 1); please refer to Appendix A.2 of [33] for more details of the proof.

While our reduction can be understood without notation of unique games, it is best described in a context of unique games reductions. We provide a definition of unique games below.

▶ **Definition 7** (Unique Game (UG)). A unique game instance $(\mathcal{G}, [R], \{\pi_e\}_{e\in E})$ consists of a bipartite graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, a label set $[R] = \{1, \dots, R\}$, and, for each $e \in \mathcal{E}$, a permutation $\pi_e : [R] \to [R]$. The goal is to find an assignment $F : V \to [R]$ such that, for as many edges $(u, v) \in \mathcal{E}$ as possible, we have $\pi_{(u,v)}(F(u)) = F(v)$; these edges are said to be *satisfied*.

Khot's UGC [19] states that, for every $\varepsilon > 0$, it is NP-hard to distinguish between a unique game in which there exists an assignment satisfying at least $(1 - \varepsilon)$ fraction of edges from one in which every assignment satisfies at most ε fraction of edges.

Finally, we need some preliminaries in discrete Fourier analysis. We state here only few facts that we need. We refer interested readers to [30] for more details about the topic.

For any discrete probability space Ω, $f : \Omega^R \to [0, 1]$ can be written as $\sum_{\sigma\in[|\Omega|]^R} \hat{f}(\sigma)\phi_\sigma$ where $\{\phi_\sigma\}_{\sigma\in[|\Omega|]^R}$ is the product Fourier basis of $L^2(\Omega^R)$ (see [30, Chapter 8.1]). The degree-d influence on the j-th coordinate of f is $\mathrm{infl}_j^d(f) \triangleq \sum_{\sigma\in[|\Omega|]^R, \sigma_j\neq 1, \#\sigma\leqslant d} \hat{f}^2(\sigma)$ where $\#\sigma \triangleq |\{i \in [R] \mid \sigma_i \neq 1\}|$. It is well known that $\sum_{j=1}^R \mathrm{infl}_j^d(f) \leqslant d$ (see [28, Proposition 3.8]).

We also need the following theorem. It follows easily[4] from the so-called "It Ain't Over Till It's Over" conjecture, which is by now a theorem [28, Theorem 4.9].

▶ **Theorem 8** ([28]). *For any $\beta, \varepsilon_T, \gamma > 0$, there exists $\kappa > 0$ and $t, d \in \mathbb{N}$ such that, if any functions $f_1, \dots, f_t : \Omega^R \to \{0, 1\}$ where Ω is a probability space whose probability of each atom is at least β satisfy*[5]

$$\forall i \in [t], \mathop{\mathbb{E}}_{x\in\Omega^R}[f_i(x)] \leqslant 0.99 \quad \text{and} \quad \forall j \in [R], \forall 1 \leqslant i_1 \neq i_2 \leqslant t, \min\{\mathrm{infl}_j^d(f_{i_1}), \mathrm{infl}_j^d(f_{i_2})\} \leqslant \kappa,$$

then

$$\Pr_{x\in\Omega^R, D\sim S_{\varepsilon_T}(R)}\left[\bigwedge_{i=1}^t f_i(C_D(x)) \equiv 1\right] < \gamma$$

where $D \sim S_{\varepsilon_T}(R)$ is a random subset of $[R]$ where each $i \in [R]$ is included independently w.p. ε_T, $C_D(x) \triangleq \{x' \mid x'_{[R]\setminus D} = x_{[R]\setminus D}\}$ and $f_i(C_D(x)) \equiv 1$ is short for $\forall x' \in C_D(x), f_i(x') = 1$.

3.2 Bansal-Khot Long Code Test and A Candidate Reduction

Theorem 8 leads us nicely to the Bansal-Khot long code test [4]. For UGC hardness reductions, one typically needs a *long code test* (aka dictatorship gadget) which, on input $f_1, \dots, f_t : \{0, 1\}^R \to \{0, 1\}$, has the following properties:

- *(Completeness)* If $f_1 = \cdots = f_t$ is a long code[6], the test accepts with large probability.
- *(Soundness)* If $f_1, \dots, f_t$ are balanced (i.e. $\mathbb{E} f_1 = \cdots = \mathbb{E} f_t = 1/2$) and are "far from being a long code", then the test accepts with low probability.

  A widely-used notion of "far from being a long code", and one we will use here, is that the functions do not share a coordinate with large low degree influence (i.e. for every $j \in [R]$ and every $i_1 \neq i_2 \in [t]$, at least one of $\mathrm{infl}_j^d(f_{i_1})$, $\mathrm{infl}_j^d(f_{i_2})$ is small),

[4] For more details on how this version follows from there, please refer to [36, page 769].
[5] 0.99 could be replaced by any constant less than one; we use it to avoid introducing more parameters.
[6] A long code is simply j-junta (i.e. a function that depends only on the x_j) for some $j \in [R]$.

Input: A unique game $(\mathcal{G} = (\mathcal{V}, \mathcal{E}), [R], \{\pi_e\}_{e\in E})$ and parameters $\ell \in \mathbb{N}$ and $\varepsilon_T \in (0, 1)$.
Output: A hypergraph $H = (V_H, E_H)$.
The vertex set V_H is $\mathcal{V} \times \{0, 1\}^R$ and the hyperedges are distributed as follows:

- Sample $u \sim \mathcal{V}$ and sample $v_1 \sim \mathcal{G}(u), \ldots, v_\ell \sim \mathcal{G}(u)$.
- Sample $x \sim \{0, 1\}^R$ and a subset $D \sim S_{\varepsilon_T}(R)$.
- Output a hyperedge $e = \{(v_p, x') \mid p \in [\ell], x' \in C_D(x)\}$.

Figure 1 A Candidate Reduction from UG to MUCHB.

Bansal and Khot's long code test works as follows: pick $x \sim \{0, 1\}^R$ and $D \sim S_{\varepsilon_T}(R)$. Then, test whether f_i evaluates to 1 on the whole $C_D(x)$. Note that this can be viewed as an "algorithmic" version of Theorem 8; more specifically, the theorem (with $\Omega = \{0, 1\}$) immediately implies the soundness property of this test. On the other hand, it is obvious that, if $f_1 = \cdots = f_t$ is a long code, then the test accepts with probability $1/2 - \varepsilon_T$.

Bansal and Khot used this test to prove tight hardness of approximation of Vertex Cover. The reduction is via a natural composition of the test with unique games. Their reduction also gives a cadidate reduction from UG to MUCHB, which is stated below in Figure 1.

As is typical for gadget reductions, for $T \subseteq V_H$, we view the indicator function $f_u(x) \triangleq \mathbb{1}[(u, x) \in T]$ for each $u \in \mathcal{V}$ as the intended long code. If there exists an assignment ϕ to the unique game instance that satisfies nearly all the constraints, then the bisection corresponding to $f_u(x) = x_{\phi(u)}$ cuts only small fraction of edges, which yields the completeness of MUCHB.

As for the soundness, we would like to decode an UG assignment from $T \subseteq V_H$ of size at most $|V_H|/2$ which contains at least ε fraction of hyperedges. In terms of the tests, this corresponds to a collection of functions $\{f_u\}_{u\in\mathcal{V}}$ such that $\mathbb{E}_{u\sim\mathcal{V}} \mathbb{E}_{x\sim\{0,1\}^R} f_u(x) = 1/2$ and the Bansal-Khot test on $f_{v_1}, \ldots, f_{v_t}$ passes with probability at least ε where $v_1, \ldots, v_t$ are sampled as in Figure 1. Now, if we assume that $\mathbb{E}_x f_u(x) \leqslant 0.99$ for all $u \in \mathcal{V}$, then such decoding is possible via a similar method as in [4] since Theorem 8 can be applied here.

Unfortunately, the assumption $\mathbb{E}_x f_u(x) \leqslant 0.99$ does not hold for an arbitrary $T \subseteq V_H$ and the soundness property indeed fails. For instance, imagine the constraint graph $\mathcal{G}$ of the starting unique game instance consisting of two disconnected components of equal size; let $\mathcal{V}_0$ and $\mathcal{V}_1$ be the set of vertices in the two components. In this case, if we set $T_0 = \mathcal{V}_0$ and $T_1 = \mathcal{V}_1$, then the bisection (T_0, T_1) does not even cut a single edge! This is regardless of whether there exists an assignment to the UG that satisfies a large fraction of edges.

3.3 RST Technique and The Reduction from SSE to MUCHB

The issue described above is common for graph problems that involves some form of expansion of the graph. The RST technique [33] was indeed invented to specifically circumvent this issue. It works by first reducing SSE to UG and then exploiting the structure of the constructed UG instance when composing it with a long code test; this allows them to avoid extreme cases such as one above. There are four parameters in the reduction: $R, k \in \mathbb{N}$ and ε_V, β. Before we describe the reduction, let us define additional notations here:

- Let $G^{\otimes R}$ denote the R-tensor graph of G; the vertex set of $G^{\otimes R}$ is V^R and there is an edge between A, B if and only if there is an edge between A_i, B_i in G for every $i \in [R]$.
- For each $A \in V^R$, $T_V(A)$ denote the distribution on V^R where the i-th coordinate is set to A_i with probability $1 - \varepsilon_V$ and is randomly sampled from V otherwise.

- Let $\Pi_{R,k}$ denote the set of all permutations π's of $[R]$ such that, for each $j \in [k]$, $\pi(\{R(j-1)/k+1, \ldots, Rj/k\}) = \{R(j-1)/k+1, \ldots, Rj/k\}$.
- Let $\{0,1,\perp\}_\beta$ denote the probability space such that the probability for $0,1$ are both $\beta/2$ and the probability for $\perp$ is $1-\beta$.

The first step of reduction takes an $\mathrm{SSE}(\delta, \eta, M)$ instance $G = (V, E)$ and produces a unique game $\mathcal{U} = (\mathcal{G} = (\mathcal{V}, \mathcal{E}), [R], \{\pi_e\}_{e \in E})$ where $\mathcal{V} = V^R$ and the edges are distributed as follows:

1. Sample $A \sim V^R$ and $\tilde{A} \sim T_V(A)$.
2. Sample $B \sim G^{\otimes R}(\tilde{A})$ and $\tilde{B} \sim T_V(B)$.
3. Sample two random $\pi_A, \pi_B \sim \Pi_{R,k}$.
4. Output an edge $e = (\pi_A(\tilde{A}), \pi_B(\tilde{B}))$ with $\pi_{(A,B)} = \pi_B \circ \pi_A^{-1}$.

Here ε_V is a small constant, k is large and R/k should be think of as $\Theta(1/\delta)$. When there exists a set $S \subseteq V$ of size $\delta|V|$ with small edge expansion, the intended assignment is to, for each $A \in V^R$, find the first block $j \in [k]$ such that $|A(j) \cap S| = 1$ where $A(j)$ denotes the multiset $\{A_{R(j-1)/k+1}, \ldots, A_{Rj/k}\}$ and let $F(A)$ be the coordinate of the vertex in that intersection. If no such j exists, we assign $F(A)$ arbitrarily. Note that, since $R/k = \Theta(1/\delta)$, $\Pr[|A(j) \cap S| = 1]$ is constant, which means that only $2^{-\Omega(k)}$ fraction of vertices are assigned arbitrarily. Moreover, it is not hard to see that, for the other vertices, their assignments rarely violate constraints as ε_V and $\Phi(S)$ are small. This yields the completeness. In addition, the soundness was shown in [32, 33], i.e., if every $S \subseteq V$ of size $\delta|V|$ has near perfect expansion, no assignment satisfies many constraints in $\mathcal{U}$ (see Lemma 13).

The second step is to reduce this UG instance to a hypergraph $H = (V_H, E_H)$. Instead of making the vertex set $V^R \times \{0,1\}^R$ as in the previous candidate reduction, we will instead make $V_H = V^R \times \Omega^R$ where $\Omega = \{0,1,\perp\}_\beta$ and β is a small constant. This does not seem to make much sense from the UG reduction standpoint because we typically want to assign which side of the bisection $(A, x) \in V_H$ is in according to $x_{F(A)}$ but $x_{F(A)}$ could be $\perp$ in this construction. However, it makes sense when we view this as a reduction from SSE directly: let us discard all coordinates i's such that $x_i = \perp$ and define $A(j, x) \triangleq \{A_i \mid i \in \{R(j-1)/k+1, \ldots, Rj/k\} \wedge x_i \neq \perp\}$. Then, let $j^*(A, x) \triangleq \min\{j \mid |A(j, x) \cap S| = 1\}$ and let $i^*(A, x)$ be the coordinate in the intersection between $A(j^*(A, x), x)$ and S, and assign (A, x) to $T_{x_{i^*(A,x)}}$. (If $j^*(A, x)$ does not exists, then assign (A, x) arbitrarily.)

Observe that, in the intended solution, the side that (A, x) is assigned to does not change if (1) A_i is modified for some $i \in [R]$ s.t. $x_i = \perp$ or (2) we apply some permutation $\pi \in \Pi_{R,k}$ to both A and x. In other words, we can "merge" two vertices (A, x) and (A', x') that are equivalent through these changes together in the reduction. For notational convenience, instead of merging vertices, we will just modify the reduction so that, if (A, x) is included in some hyperedge, then every (A', x') reachable from (A, x) by these operations is also included in the hyperedge. More specifically, if we define $M_x(A) \triangleq \{A' \in V^R \mid A'_i = A_i \text{ for all } i \in [R] \text{ such that } x_i \neq \perp\}$ corresponding to the first operation, then we add $\pi(A', x)$ to the hyperedge for every $A' \in M_x(A)$ and $\pi \in \Pi_{R,k}$. The full reduction is shown in Figure 2.

Note that the test we apply here is slightly different from Bansal-Khot test as our test is on $\Omega = \{0,1,\perp\}_\beta$ instead of $\{0,1\}$ used in [4]. Another thing to note is that now our vertices and hyperedges are weighted, the vertices according to the product measure of $V^R \times \Omega^R$ and the edges according to the distribution produced from the reduction. We write μ_H to denote the measure on the vertices, i.e., for $T \subseteq V^R \times \{0,1,\perp\}^R$, $\mu_H(T) = \Pr_{A \sim V^R, x \sim \Omega^R}[(A, x) \in T]$, and we abuse the notation $E_H(T)$ and use it to denote the probability that a hyperedge as generated in Figure 2 lies completely in T. We note here that, while the MUCHB as stated

Input: A graph G with vertex set V and parameters $R, k, \ell \in \mathbb{N}$ and $\varepsilon_T, \varepsilon_V, \beta \in (0,1)$.
Output: A hypergraph $H = (V_H, E_H)$.
$V_H \triangleq V^R \times \Omega^R$ where $\Omega \triangleq \{0, 1, \perp\}_\beta$ and the hyperedges are distributed as follows:

- Sample $A \sim V^R$ and $\tilde{A}^1, \dots, \tilde{A}^\ell \sim T_V(A)$.
- Sample $B^1 \sim G^{\otimes R}(\tilde{A}^1), \dots, B^\ell \sim G^{\otimes R}(\tilde{A}^\ell)$ and $\tilde{B}^1 \sim T_V(B^1), \dots, \tilde{B}^\ell \sim T_V(B^\ell)$
- Sample $x \in \Omega^R$ and a subset $D \sim S_{\varepsilon_T}(R)$.
- Output a hyperedge $e = \{\pi(B', x') \mid p \in [\ell], \pi \in \Pi_{R,k}, x' \in C_D(x), B' \in M_{x'}(\tilde{B}^p)\}$.

Figure 2 Reduction from SSE to Max UnCut Hypergraph Bisection.

in Lemma 3 is unweighted, it is not hard to see that we can go from weighted version to unweighted by copying each vertex and each edge proportional[7] to their weights.

The advantage of this reduction is that the vertex "merging" makes gadget reduction non-local; for instance, it is clear that even if the starting graph V has two connected components, the resulting hypergraph is now connected. In fact, Raghavendra et al. [33] show a much stronger quantitative bound. To state this, let us consider any $T \in V_H$ with $\mu_H(T) = 1/2$. From how the hyperedges are defined, we can assume w.l.o.g. that, if $(A, x) \in T$, then $\pi(A', x) \in T$ for every $A' \in M_x(A)$ and every $\pi \in \Pi_{R,k}$. Again, let $f_A(x) \triangleq \mathbb{1}[(A, x) \in T]$. The following bound on the variance of $\mathbb{E}_x f_A(x)$ is implied by the proof of Lemma 6.6 in [33]:

$$\mathop{\mathbb{E}}_{A \sim V^R} \left(\mathop{\mathbb{E}}_{x \sim \Omega^R} f_A(x) - 1/2 \right)^2 \leqslant \beta.$$

The above bound implies that, for most A's, the mean of f_A cannot be too large. This will indeed allow us to ultimately apply Theorem 8 on a certain fraction of the tuples $(\tilde{B}^1, \dots, \tilde{B}^\ell)$ in the reduction, which leads to an UG assignment with non-negligible value.

3.4 Completeness

In the completeness case, we define a bisection similar to that described above. This bisection indeed cuts only a small fraction of hyperedges; quantitatively, this yields the following lemma. Since its proof consists mainly of calculations, we omit it from this extended abstract.

▶ **Lemma 9.** *If there is a set $S \subseteq V$ such that $\Phi(S) \leqslant \eta$ and $|S| = \delta|V|$ where $\delta \in \left[\frac{k}{10\beta R}, \frac{k}{\beta R}\right]$, then there is a bisection (T_0, T_1) of V_H such that $E_H(T_0), E_H(T_1) \geqslant 1/2 - O(\varepsilon_T/\beta) - O(\eta\ell/\beta) - O(\varepsilon_V \ell/\beta) - 2^{-\Omega(k)}$ where $O(\cdot)$ and $\Omega(\cdot)$ hide only absolute constants.*

3.5 Soundness

Let us consider any set T such that $\mu_H(T) \leqslant 1/2$. We would like to give an upper bound on $E_H(T)$. From how we define hyperedges, we can assume w.l.o.g. that $(A, x) \in T$ if and only if $\pi(A', x) \in T$ for every $A' \in M_x(A)$ and $\pi \in \Pi_{R,k}$. We call such T $\Pi_{R,k}$*-invariant*.

Let $f : V^R \times \Omega^R \to \{0, 1\}$ denote the indicator function for T, i.e., $f(A, x) = 1$ if and only if $(A, x) \in T$. Note that $\mathbb{E}_{A \sim V^R, x \sim \Omega^R} f(A, x) = \mu_H(T) \leqslant 1/2$. Following notation from [33], we write $f_A(x)$ as a shorthand for $f(A, x)$. In addition, for each $A \in V^R$, we will write $\tilde{B} \sim \Gamma(A)$ as a shorthand for $\tilde{B}$ generated randomly by sampling $\tilde{A} \sim T_V(A)$, $B \sim G^{\otimes R}(\tilde{A})$

[7] Note that this is doable since we can pick $\beta, \varepsilon_V, \varepsilon_T$ to be rational.

and $\tilde{B} \sim T_V(B)$ respectively. Let us restate Raghavendra et al.'s [33] Lemma regarding the variance of $\mathbb{E}_x f_A(x)$ in a more convenient formulation below.

▶ **Lemma 10** ([33, Lemma 6.6][8]). *For every $A \in V^R$, let $\mu_A \triangleq \mathbb{E}_{x\sim\Omega^R} f_A(x)$. We have*

$$\mathop{\mathbb{E}}_{A\sim V^R}\left(\mathop{\mathbb{E}}_{\tilde{B}\sim\Gamma(A)}\mu_{\tilde{B}} - \mu_H(T)\right)^2 \leqslant \beta.$$

To see how the above lemma helps us decode an UG assignment, observe that, if our test accepts on $f_{\tilde{B}^1}, \ldots, f_{\tilde{B}^\ell}, x, D$, then it also accepts on any subset of the functions (with the same x, D); hence, to apply Theorem 8, it suffices that t of the functions have means $\leqslant 0.99$. We will choose ℓ to be large compared to t. Using above lemma and a standard tail bound, we can argue that Theorem 8 is applicable for almost all tuples $\tilde{B}^1, \ldots, \tilde{B}^\ell$, as stated below. Due to space constraint, we omit its proof from this extended abstract.

▶ **Lemma 11.** *For any positive integer $t \leqslant 0.01\ell$,*

$$\Pr_{A\sim V^R, \tilde{B}^1,\ldots,\tilde{B}^\ell\sim\Gamma(A)}[|\{i \in [\ell] \mid \mu_{\tilde{B}^i} \leqslant 0.99\}| \geqslant t] \geqslant 1 - 10\beta - 2^{-\ell/100}.$$

3.5.1 Decoding an Unique Games Assignment

With Lemma 11 ready, we can now decode an UG assignment via a similar technique from [4].

▶ **Lemma 12.** *For any $\varepsilon_T, \gamma, \beta > 0$, let $t = t(\varepsilon_T, \gamma, \beta), \kappa = \kappa(\varepsilon_T, \gamma, \beta)$ and $d = d(\varepsilon_T, \gamma, \beta)$ be as in Theorem 8. For any integer $\ell \geqslant 100t$, if there exists $T \subseteq V_H$ of such that $\mu_H(T) \leqslant 1/2$ and $E_H(T) \geqslant 2\gamma + 10\beta + 2^{-\ell/100}$, then there exists $F : V^R \to [R]$ such that*

$$\Pr_{A\sim V^R, \tilde{B}\sim\Gamma(A), \pi_A, \pi_B\sim\Pi_{R,k}}[\pi_A^{-1}(F(\pi_A(\tilde{A}))) = \pi_B^{-1}(F(\pi_B(\tilde{B})))] \geqslant \frac{\gamma\kappa^2}{4d^2\ell^2}.$$

Proof. The decoding procedure is as follows. For each $A \in V^R$, we construct a set of candidate labels $\mathrm{Cand}[A] \triangleq \{j \in [R] \mid \mathrm{infl}_j^d(f_A) \geqslant \kappa\}$. We generate F randomly by, with probability $1/2$, setting $F(A)$ to be a random element of $\mathrm{Cand}[A]$ and, with probability $1/2$, sampling $\tilde{B} \sim \Gamma(A)$ and setting $F(A)$ to be a random element from $\mathrm{Cand}[B]$. Note that, if the candidate set is empty, then we simply pick an arbitrary assignment.

From our assumption that T is $\Pi_{R,k}$-invariant, it follows that, for every $A \in V^R, \pi \in \Pi_{R,k}$ and $j \in [R]$, $\Pr_F[\pi^{-1}(F(\pi(A))) = j] = \Pr_F[F(A) = j]$. In other words, we have

$$\begin{aligned}\Pr_{F,A\sim V^R, \tilde{B}\sim\Gamma(A), \pi_A, \pi_B\sim\Pi_{R,k}}&[\pi_A^{-1}(F(\pi_A(\tilde{A}))) = \pi_B^{-1}(F(\pi_B(\tilde{B})))] \\ &= \Pr_{F,A\sim V^R, \tilde{B}\sim\Gamma(A)}[F(\tilde{A}) = F(\tilde{B})]. \qquad (1)\end{aligned}$$

Next, note that, from how our reduction is defined, $E_H(T)$ can be written as

$$E_H(T) = \Pr_{A\sim V^R, \tilde{B}^1,\ldots,\tilde{B}^\ell\sim\Gamma(A), x\sim\Omega^R, D\sim S_{\varepsilon_T}(R)}\left[\bigwedge_{i=1}^{\ell} f_{\tilde{B}^i}(C_D(x)) \equiv 1\right].$$

[8] Lemma 6.6 in [33] involves symmetrizing f's, but we do not need it here since T is $\Pi_{R,k}$-invariant.

From $E_H(T) \geqslant 2\gamma + 10\beta + 2^{-\ell/100}$ and from Lemma 11, we can conclude that

$$\Pr_{A,\tilde{B}^1,\ldots,\tilde{B}^\ell,x,D}\left[\left(\bigwedge_{i=1}^{\ell} f_{\tilde{B}^i}(C_D(x)) \equiv 1\right) \wedge \left(|\{i \in [\ell] \mid \mu_{\tilde{B}^i} \leqslant 0.99\}| \geqslant t\right)\right] \geqslant 2\gamma.$$

From Markov's inequality, we have

$$\begin{aligned}\gamma &\leqslant \Pr_{A,\tilde{B}^1,\ldots,\tilde{B}^\ell}\left[\Pr_{x,D}\left[\left(\bigwedge_{i=1}^{\ell} f_{\tilde{B}^i}(C_D(x)) \equiv 1\right) \wedge \left(|\{i \in [\ell] \mid \mu_{\tilde{B}^i} \leqslant 0.99\}| \geqslant t\right)\right] \geqslant \gamma\right] \\ &= \Pr_{A,\tilde{B}^1,\ldots,\tilde{B}^\ell}\left[\left(\Pr_{x,D}\left[\bigwedge_{i=1}^{\ell} f_{\tilde{B}^i}(C_D(x)) \equiv 1\right] \geqslant \gamma\right) \wedge \left(|\{i \in [\ell] \mid \mu_{\tilde{B}^i} \leqslant 0.99\}| \geqslant t\right)\right].\end{aligned}$$

A tuple $(A, \tilde{B}^1, \ldots, \tilde{B}^\ell)$ is said to be *good* if $\Pr_{x\sim\Omega^R, D\sim S_{\varepsilon_T}(R)}\left[\bigwedge_{i=1}^{\ell} f_{\tilde{B}^i}(C_D(x)) \equiv 1\right] \geqslant \gamma$ and $|\{i \in [\ell] \mid \mu_{\tilde{B}^i} \leqslant 0.99\}| \geqslant t$. For such tuple, Theorem 8 implies that there exist $i_1 \neq i_2 \in [\ell], j \in [R]$ s.t. $\mathrm{infl}^d_j(f_{\tilde{B}^{i_1}}), \mathrm{infl}^d_j(f_{\tilde{B}^{i_2}}) \geqslant \kappa$. This means that $\mathrm{Cand}(\tilde{B}^{i_1}) \cap \mathrm{Cand}(\tilde{B}^{i_2}) \neq \emptyset$.

Hence, if we sample a tuple $(A, \tilde{B}^1, \ldots, \tilde{B}^\ell)$ at random, and then sample two different $\tilde{B}, \tilde{B}'$ randomly from $\tilde{B}^1, \ldots, \tilde{B}^\ell$, then the tuple is good with probability at least γ and, with probability $1/\ell^2$, we have $\tilde{B} = \tilde{B}^{i_1}, \tilde{B}' = \tilde{B}^{i_2}$. This gives the following bound:

$$\Pr_{A,\tilde{B},\tilde{B}'}\left[\mathrm{Cand}(\tilde{B}) \cap \mathrm{Cand}(\tilde{B}') \neq \emptyset\right] \geqslant \frac{\gamma}{\ell^2}.$$

Now, observe that $\tilde{B}$ and $\tilde{B}'$ above are distributed in the same way as if we pick both of them independently with respect to $\Gamma(A)$. Recall that, with probability $1/2$, $F(A)$ is a random element of $\mathrm{Cand}(\tilde{B})$ where $\tilde{B} \sim \Gamma(A)$ and, with probability $1/2$, $F(\tilde{B}')$ is a random element of $\mathrm{Cand}(\tilde{B}')$. Moreover, since the sum of degree d-influence is at most d [28, Proposition 3.8], the candidate sets are of sizes at most d/κ. As a result, the above bound yields

$$\Pr_{A\sim V^R, \tilde{B}'\sim\Gamma(A)}[F(A) = F(\tilde{B}')] \geqslant \frac{\gamma\kappa^2}{4d^2\ell^2},$$

which, together with (1), concludes the proof of the lemma. ◀

3.5.2 Decoding a Small Non-Expanding Set

To relate our decoded UG assignment back to a small non-expanding set in G, we use the following lemma of [33], which roughly states that, with the right parameters, the soundness case of SSEH implies that only small fraction of constriants in the UG can be satisfied.

▶ **Lemma 13** ([33, Lemma 6.11]). *If there exists $F : V^R \to [R]$ such that*

$$\Pr_{A\sim V^R, \tilde{B}\sim\Gamma(A), \pi_A, \pi_B\sim\Pi_{R,k}}[\pi_A^{-1}(F(\pi_A(\tilde{A}))) = \pi_B^{-1}(F(\pi_B(\tilde{B})))] \geqslant \zeta,$$

then there exists a set $S \subseteq V$ with $\frac{|S|}{|V|} \in \left[\frac{\zeta}{16R}, \frac{3k}{\varepsilon_V R}\right]$ with $\Phi(S) \leqslant 1 - \frac{\zeta}{16k}$.

By combining the above lemma with Lemma 12, we immediately arrive at the following:

▶ **Lemma 14.** *For any $\varepsilon_T, \gamma, \beta > 0$, let $t = t(\varepsilon_T, \gamma, \beta), \kappa = \kappa(\varepsilon_T, \gamma, \beta)$ and $d = d(\varepsilon_T, \gamma, \beta)$ be as in Theorem 8. For any integer $\ell \geqslant 100t$ and any $\varepsilon_V > 0$, if there exists $T \subseteq V_H$ with $\mu_H(T) \leqslant 1/2$ such that $E_H(T) \geqslant 2\gamma + 10\beta + 2^{-\ell/100}$, then there exists a set $S \subseteq V$ with $\frac{|S|}{|V|} \in \left[\frac{\zeta}{16R}, \frac{3k}{\varepsilon_V R}\right]$ with $\Phi(S) \leqslant 1 - \frac{\zeta}{16k}$ where $\zeta = \frac{\gamma\kappa^2}{4d^2\ell^2}$.*

3.6 Putting Things Together

We can now deduce inapproximability of MUCHB by simply picking appropriate parameters.

Proof of Lemma 3. The parameters are chosen as follows:

- Let $\beta = \varepsilon/30, \gamma = \varepsilon/6$, and $k = \Omega(\log(1/\varepsilon))$ so that the term $2^{-\Omega(k)}$ in Lemma 9 is $\leqslant \varepsilon/4$.
- Let $\varepsilon_T = O(\beta\varepsilon)$ so that the error term $O(\varepsilon_T/\beta)$ in Lemma 9 is at most $\varepsilon/4$.
- Let $t = t(\varepsilon_T, \gamma, \beta), \kappa = \kappa(\varepsilon_T, \gamma, \beta)$ and $d = d(\varepsilon_T, \gamma, \beta)$ be as in Theorem 8.
- Let $\zeta = \frac{\gamma\kappa^2}{4d^2\ell^2}$ be as in Lemma 14 and let $\ell = \max\{100t, 1000\log(1/\varepsilon)\}$.
- Let $\varepsilon_V = O(\varepsilon\beta/\ell)$ where so that the error term $O(\varepsilon_V\ell/\beta)$ in Lemma 9 is at most $\varepsilon/4$.
- Let $\eta = \min\{\frac{\zeta}{32k}, O(\varepsilon\beta/\ell)\}$ so that the error term $O(\eta\ell/\beta)$ in Lemma 9 is at most $\varepsilon/4$.
- Let $M = \max\{\frac{16k}{\beta\zeta}, \frac{3\beta}{\varepsilon_V}\}$.
- Finally, let $R = \frac{k}{\beta\delta}$ where $\delta = \delta(\eta, M)$ is the parameter from the SSEH (Conjecture 2).

Let $G = (V, E)$ be an instance of $\mathrm{SSE}(\eta, \delta, M)$ and let $H = (V_H, G_H)$ be the hypergraph resulted from our reduction. If there exists $S \subseteq V$ of size $\delta|V|$ of expansion at most η, Lemma 9 implies that there is a bisection (T_0, T_1) of V_H such that $E_H(T_0), E_H(T_1) \geqslant 1/2 - \varepsilon$.

As for the soundness, Lemma 14 with our choice of parameters implies that, if there exists a set $T \subseteq V_H$ with $\mu(T) \leqslant 1/2$ and $E_H(T_0) \geqslant \varepsilon$, there exists $S \subseteq V$ with $|S| \in \left[\frac{\delta|V|}{M}, \delta|V|M\right]$ whose expansion is less than $1-\eta$. The contrapositive of this yields the soundness property. ◀

4 Conclusion

In this work, we prove essentially tight inapproximability of MEB, MBB and Minimum k-Cut based on SSEH. Our results, expecially for the biclique problems, demonstrate further the applications of the hypothesis and particularly the RST technique [33] in proving hardness of graph problems that involve some form of expansion. An obvious but intriguing research direction is to try to utilize the technique to other problems. One plausible candidate problem to this end is the 2-Catalog Segmentation Problem [24] since a natural candidate reduction for this problem fails due to a similar counterexample as in Section 3.2.

Acknowledgement. I am grateful to Prasad Raghavendra for providing his insights on the Small Set Expansion problem and techniques developed in [32, 33] and Luca Trevisan for lending his expertise in PCPs with small free bits. I would also like to thank Haris Angelidakis for useful discussions on Minimum k-Cut and Daniel Reichman for inspiring me to work on Maximum Edge Biclique and Maximum Balanced Biclique. Finally, I thank anonymous reviewers for their useful comments and, more specifically, for pointing me to [6].

Abstract

It has often been claimed in recent papers that one can find a degree d Sum-of-Squares proof if one exists via the Ellipsoid algorithm. In [16], Ryan O'Donnell notes this widely quoted claim is not necessarily true. He presents an example of a polynomial system with bounded coefficients that admits low-degree proofs of non-negativity, but these proofs necessarily involve numbers with an exponential number of bits, causing the Ellipsoid algorithm to take exponential time. In this paper we obtain both positive and negative results on the bit complexity of SoS proofs.

First, we propose a sufficient condition on a polynomial system that implies a bound on the coefficients in an SoS proof. We demonstrate that this sufficient condition is applicable for common use-cases of the SoS algorithm, such as Max-CSP, Balanced Separator, Max-Clique, Max-Bisection, and Unit-Vector constraints.

On the negative side, O'Donnell asked whether every polynomial system containing Boolean constraints admits proofs of polynomial bit complexity. We answer this question in the negative, giving a counterexample system and non-negative polynomial which has degree two SoS proofs, but no SoS proof with small coefficients until degree $\Omega(\sqrt{n})$.

1 Introduction

The Sum of squares (SoS) proof system is a versatile and powerful approach to certifying polynomial inequalities. SoS certificates can be shown to underlie a vast number of algorithms in combinatorial optimization. On the one hand, SoS certificates hold the promise of yielding algorithms that possibly refute the notorious unique games conjecture [3, 2, 10]. On the other hand, a flurry of recent works have applied SoS proofs to develop algorithms for problems ranging from constraint satisfaction problems to tensor problems.

To illustrate sum of squares certificates, let us consider the example of the Balanced Separator problem. Here we are given a graph $G = (V, E)$ and the goal is to find a balanced cut $(S, \overline{S})$ with the minimum number of crossing edges. Like many problems in combinatorial optimization, it can be reformulated as a low-degree polynomial optimization problem. Specifically if we associate $\{0, 1\}$ variables $\{x_1, \ldots, x_n\}$ for the vertices of the graph

* This work partially supported by NSF Graduate Research Fellowship (DGE 1106400), NSF Career Award, NSF CCF-1407779 and the Alfred. P. Sloan Fellowship.

G then we can rewrite the Balanced Separator problem as follows:

$$\text{Minimize} \quad \sum_{(i,j)\in E} (x_i - x_j)^2 \quad \text{subject to} \left\{ x_i^2 = x_i \forall i \ , \ \frac{n}{3} \leq \sum_i x_i \leq \frac{2n}{3} \right\} .$$

Here the constraint $x_i^2 = x_i$ ensures $x_i \in \{0,1\}$ while the inequalities enforce the condition that the cut is balanced. More generally, a low-degree polynomial optimization is of the form:

Minimize $r(x)$ subject to
equalities $\mathcal{P} = \{p_i(x) = 0 | i \in [n]\}$ and inequalities $\mathcal{Q} = \{q_i(x) \geq 0 | i \in [m]\}$.

An SoS certificate of a lower bound $r(x) \geq \theta$ is given by a polynomial identity of the form

$$r(x) - \theta = \sum_i h_i(x)^2 + \sum_{i\in[m]} \left(\sum_j^{t_i} s_j^2(x) \right) \cdot q_i(x) + \sum_{i\in[n]} \lambda_i(x) p_i(x) .$$

Notice that for all x satisfying the equalities $\mathcal{P}$ and the inequalities $\mathcal{Q}$, the right hand side of the above identity is manifestly non-negative, thereby certifying that $r(x) \geq \theta$. The degree of the SoS certificate is the maximum degree of the polynomials involved, i.e., $d = \max\{\deg h_i^2, \deg s_j^2 q_i, \deg \lambda_i p_i\}$.

The main appeal of SoS certificates for polynomial optimization is that the existence of a degree d SoS certificate can be formulated as the feasibility of a semidefinite program (SDP). This is the degree d SoS relaxation first introduced by Shor [18], and expanded upon by later works of Nesterov [15], Grigoriev and Vorobjov [9], Lasserre [12, 11] and Parrilo [17]. (see, e.g., [13, 4] for many more details).

The degree d SoS SDP has $n^{O(d)}$ variables, and if the coefficients of p and q are reasonably bounded (smaller than $2^{n^{O(d)}}$), the resulting SDP has a compact description of size $n^{O(d)}$. From this, several works including those by the authors, asserted that the resulting feasibility SDP can be solved in time $n^{O(d)}$ using the Ellipsoid algorithm.

In a recent work, O'Donnell [16] observed that this often repeated claim is far from true. Specifically, O'Donnell exhibited systems of polynomial inequalities with bounded coefficients such that only degree 2 SoS certificates of non-negativity involve coefficients that are doubly exponential in size. Thus all SoS certificates need an exponential number of bits to represent and consequently, the ellipsoid algorithm will incur an exponential running time.

As pointed out by O'Donnell, the issue at hand here is not just that of additive error in the solution, i.e., the difference between testing feasibility and near-feasibility. Indeed, semidefinite programming via the ellipsoid algorithm can only test feasibility up to a very small additive error. However, in a majority of applications of SoS SDP relaxations in combinatorial optimization, the variables in the underlying polynomial system are explicitly bounded (also known as Archimedian). Specifically, these include constraints such as $\{x_i^2 \leq 1 | i \leq [n]\}$, which yield explicit bounds on the values of the variables. In these settings, if there is an approximate SoS certificate for $r(x) \geq \theta$, then there exists a proper SoS certificate for a slightly weaker lower bound $r(x) \geq \theta - o(1)$. Therefore, additive error incurred in semidefinite programming can often be traded off for a slightly weaker objective value. The issue highlighted by O'Donnell is far more serious in that the coefficients of the SoS certificate are too large – thereby directly affecting the runtime of the ellipsoid algorithm.

On a positive note, O'Donnell shows that a polynomial system whose only constraints are the Boolean constraints $\{x_i^2 = x_i | i \in [n]\}$ always admit SoS certificates with polynomial

bit complexity. He proceeds to ask whether all polynomial systems that include Boolean constraints, potentially among others, always admit bounded SoS certificates.

1.1 Our Results

In this work, we further explore the issue of bit complexity of SoS proofs, and obtain both positive and negative results.

First, we present an easily verifiable and broadly applicable set of sufficient conditions under which a polynomial optimization problem has small SoS certificates. Roughly speaking, we show that polynomial systems with *rich* sets of solutions have bounded SoS certificates of non-negativity. Consider a system consisting of polynomial equalities $\mathcal{P}$ and inequalities $\mathcal{Q}$. Our approach consists of looking for assignments S satisfying three criteria (see Definition 5 and Theorem 10 for formal statements).

▶ **Theorem 1.** *Assume $(\mathcal{P}, \mathcal{Q}, S)$ satisfies:*

1. *The assignments S robustly satisfy the inequalities in $\mathcal{Q}$.*
2. *The polynomial calculus (also called Nullstellensatz) proof system is both complete and efficient over S. In other words, all degree d polynomial identities over S can be derived using a degree $O(d)$ polynomial derivation from the equalities $\mathcal{P}$.*
3. *The assignments S are spectrally rich in that smallest non-zero eigenvalue of their covariance matrix is at least $2^{-\operatorname{poly}(n^d)}$.*

Then if r has a degree d proof of non-negativity from $\mathcal{P}$ and $\mathcal{Q}$, it also has a degree $O(d)$ proof of non-negativity with coefficients bounded by $2^{\operatorname{poly}(n^d)}$.

We demonstrate the broad applicability of the above set of sufficient conditions by using them to show upper bounds on bit complexity for Max-CSP, Max-Clique, Matching, Balanced Separator, Max-Bisection, and optimization over the unit sphere. In each case, the above sufficient conditions can be verified easily.

The above set of sufficient conditions are widely applicable in combinatorial optimization, wherein the polynomial system is typically a relaxation of a well-known set of integer solutions. In such a setup with integer solutions, we observe in Section 3 that spectral richness is an immediate consequence of the discrete nature of the set of solutions. Therefore, in all these setups, the only non-trivial thing to verify is the efficiency of the polynomial calculus proof system.

The work of O'Donnell [16] exhibited a polynomial system with bounded coefficients which admitted degree 2 SoS certificate, whose coefficients were necessarily doubly-exponential. However, the variables in this polynomial system were not all Boolean, i.e. did not have the $x_i^2 = x_i$ constraint. In fact, O'Donnell asked whether every polynomial system with Boolean constraints admits a small SoS proof. Moreover, the polynomial system in [16] admits a degree 4 SoS certificate with small bit complexity. This opens up the possibility that one can effectively reduce the bit-complexity by raising the degree of the proof. For instance, if a system admits a degree d SoS certificate then does it always admit a degree 2^d SoS certificate with small bit complexity (even under Boolean constraints)? Unfortunately, we refute both of the above possibilities by exhibiting a counterexample. Formally, we show the following:

▶ **Theorem 2.** *There exists a system of quadratic equations on n variables such that*

- *The system includes the equation $x_i^2 - x_i = 0$ for each $i \in [n]$.*
- *There exists a polynomial with a degree 2 SoS certificate of non-negativity, albeit with doubly exponentially large coefficients.*
- *No SoS certificate of degree $d \leq \sqrt{n}$ has coefficients smaller than $\Omega\left(\frac{1}{n^d} \cdot 2^{\exp(\sqrt{n})}\right)$.*

2 Preliminaries

For a set of real polynomials $\mathcal{P} = \{p_1, p_2, \ldots, p_m\}$, we denote their generated ideal in $\mathbb{R}[x]$ by $\langle \mathcal{P} \rangle$ or $\langle p_1, \ldots, p_m \rangle$. We will be working with systems of polynomial constraints, and we will use the $\mathcal{P}$ to denote the equality constraints, and $\mathcal{Q}$ to denote the inequality constraints, i.e. $p(x) = 0$ and $q(x) \geq 0$ for $p \in \mathcal{P}$ and $q \in \mathcal{Q}$. We will usually use S for the set of points satisfying these constraints. We use $\mathbb{R}[x]_d$ for the set of polynomials of degree at most d, and $\mathbb{S}^d_+$ for the cone of positive semidefinite $d \times d$ matrices. We write $\mathbf{v}_d$ for the vector of polynomials whose entries are the elements of the usual monomial basis of $\mathbb{R}[x]_d$. Similarly, we use $\mathbf{v}(\alpha)_d$ for the vector of reals whose entries are the entries of $\mathbf{v}_d$ evaluated at α. We usually omit the dependencies on d as it is clear from context.

2.1 Polynomial Proofs

Let $\mathcal{P} = \{p_1, \ldots, p_n\}$ be a set of polynomials, and let $S = \{x \in \mathbb{R}^n | \forall p \in \mathcal{P} : p(x) = 0\}$. We define a proof of membership in $\langle \mathcal{P} \rangle$ as follows:

▶ **Definition 3.** We say that $r(x)$ has a *derivation* from $\mathcal{P}$ if there is a polynomial identity of the form

$$r(x) = \sum_i^n \lambda_i(x) p_i(x).$$

We say that the proof has degree d if $\max_i \{\deg \lambda_i p_i\} = d$.

A set of polynomials forming a derivation is called a *Polynomial Calculus* (PC) or *Nullstellensatz* proof. The above proof system is useful for proving when polynomials are zero on S, but often we want to prove that they are positive. To that end, let $\mathcal{P} = \{p_1, \ldots, p_n\}$ and $\mathcal{Q} = \{q_1, \ldots, q_m\}$ be two sets of polynomials, and let $S = \{x \in \mathbb{R}^n | \forall p \in \mathcal{P} : p(x) = 0, \forall q \in \mathcal{Q} : q(x) \geq 0\}$. We define a proof of non-negativity as follows:

▶ **Definition 4.** We say that $r(x)$ has a *Sum-of-Squares proof of non-negativity from* $\mathcal{P}$ *and* $\mathcal{Q}$ if there is a polynomial identity of the form

$$r(x) = \sum_i^{t_0} h_i^2(x) + \sum_i^m \left(\sum_j^{t_i} s_j^2(x) \right) q_i(x) + \sum_i^n \lambda_i(x) p_i(x).$$

We say the proof has degree d if $\max\{\deg h_i^2, \deg s_j^2 q_i, \deg \lambda_i p\} = d$.

The idea behind this terminology is that if such a proof exists, then r must be non-negative on S since the first two terms are non-negative, and the last term is zero. We will be concerned with not just the degree of these proofs, but also their bit complexity. To this end, we define the following norms on polynomials and proofs: For $p(x) \in \mathbb{R}[x]$, we write $\|p\|$ for the maximum absolute value of coefficients of p in the standard monomial basis, and for any collection of polynomials $\mathcal{P}$, we write $\|\mathcal{P}\| = \max_{p \in \mathcal{P}} \|p\|$. For a vector $\alpha \in \mathbb{R}^n$, we also write $\|\alpha\|$ for the maximum absolute value of entries of α, and we write $\|S\| = \max_{\alpha \in S} \|\alpha\|$. These norms are usually called *infinity norms* and denoted $\|\cdot\|_\infty$ in other works, but since we do not use other norms in this work we will omit the subscript. Throughout this paper we will assume that the solutions α are *explicitly bounded* by $\|\alpha\| \leq 2^{\text{poly}(n^d)}$.

2.2 Rich Solution Spaces

In this section we define the conditions we require in order to guarantee that SoS proofs from $\mathcal{P}$ and $\mathcal{Q}$ have low bit-complexity. For a polynomial system $(\mathcal{P}, \mathcal{Q})$ and a set $S \subseteq \{x \mid \forall p \in \mathcal{P} : p(x) = 0\}$, define the moment matrix as

$$M_{S,d} \coloneqq E_{\alpha \in S}[\mathbf{v}(\alpha)_d \mathbf{v}(\alpha)_d^T],$$

where the expectation is over the uniform distribution over S. We will omit the subscripts and write M, if S and d are clear from the context.

▶ **Definition 5.** With the above definitions,

- We say that S is δ-*spectrally rich for* $(\mathcal{P}, \mathcal{Q})$ *up to degree* d if every nonzero eigenvalue of $M_{S,d}$ is at least δ.
- We say that $(\mathcal{P}, \mathcal{Q})$ is k-*complete on* S *up to degree* d if every zero eigenvector c of $M_{S,d}$ (which can be seen as a degree d polynomial $c^T \mathbf{v}_d$) has a degree k derivation from $\mathcal{P}$.
- We say that S is ϵ-*robust for* $\mathcal{Q}$ if $\forall q \in \mathcal{Q}, \forall \alpha \in S : q(\alpha) > \epsilon$.

Spectral richness of the solutions S is equivalent to requiring if $p(x)$ is small on S, then there is a polynomial q which agrees with p on S and that has small coefficients. If $(\mathcal{P}, \mathcal{Q}, S)$ satisfies all three conditions then we say that S is (δ, k, ϵ)-*rich* for $(\mathcal{P}, \mathcal{Q})$ up to degree d. If $1/\delta = 2^{\mathrm{poly}(n^d)}$, $k = O(d)$, and $1/\epsilon = 2^{\mathrm{poly}(n^d)}$ we simply say S is rich for $(\mathcal{P}, \mathcal{Q})$ or simply rich. We choose these bounds because Theorem 10 will imply that any constraints with a rich solution space has proofs of non-negativity that can be taken to have polynomial bit complexity.

▶ Remark. There is nothing special about the uniform distribution on S for these definitions. In fact, our results hold if there is *any* distribution over a set $S \subseteq \{x \mid \forall p \in \mathcal{P} : p(x) = 0\}$ with the above properties. In this work we consider mostly combinatorial problems where S is finite, and the uniform distribution is sufficient for all of our examples, so we restrict to this case for simplicity.

Before we get into the proof of the main theorem, we exhibit polynomial systems that admit rich solutions.

3 Examples with Rich Solution Spaces

In this section we present examples of polynomial systems that admit rich solution spaces. First, we consider the case $S \subseteq \{0,1\}^n$. In this case, the spectral richness is a consequence of the following easy observation.

▶ **Lemma 6.** *Let $M \in \mathbb{S}_+^N$ be an integer matrix with $|M_{ij}| \leq B$ for all $i, j \in [N]$. The smallest non-zero eigenvalue of M is at least $(BN)^{-N}$.*

Proof. Let A be a full-rank principal minor of M (which must exist because M is PSD and has a Cholesky decomposition), and for convenience let it be at the upper-left block of M (by permuting rows and columns if necessary). We claim the least eigenvalue of A lower bounds the least nonzero eigenvalue of M. Since M is symmetric, there must be a C such that

$$M = \begin{bmatrix} I \\ C \end{bmatrix} A \begin{bmatrix} I & C^T \end{bmatrix}.$$

Let $P = [I, C^T]$, ρ be the least eigenvalue of A, and x be a unit vector perpendicular to the zero eigenspace of M. Then we have $x^T M x = (Px)^T A (Px) \geq \rho x^T P^T P x$. Now $P^T P$ has

the same nonzero eigenvalues as $PP^T = I + C^T C \succeq I$, and the zero eigenspace of $P^T P$ is the same as the zero eigenspace of M. Because x is perpendicular to the zero eigenspace, $x^T P^T P x \geq 1$, and so every nonzero eigenvalue of M is at least ρ. Now A is a full-rank bounded integer matrix with dimension at most N. The magnitude of its determinant is at least 1 and all eigenvalues are at most $N \cdot B$. Therefore, its least eigenvalue must be at least $(BN)^{-N}$ in magnitude. ◀

▶ **Lemma 7.** *Let $\mathcal{P}$ and $\mathcal{Q}$ be such that $S \subseteq \{0,1\}^n$. Then S is δ-spectrally rich with $\frac{1}{\delta} = 2^{\text{poly}(n^d)}$.*

Proof. Recall $M = E_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T]$, and note that $|S| \cdot M$ is an integer $O(n^d) \times O(n^d)$ matrix with entries at most 2^n. The proof follows by applying Lemma 6. ◀

To prove completeness, we typically want to show two things. First, that every degree d polynomial in $\langle \mathcal{P} \rangle$ has a degree at most k derivation. Second, that there are no polynomials outside $\langle \mathcal{P} \rangle$ that are zero on S. This second condition can be thought of as saying that the set of equations $\mathcal{P}$ is somehow maximal, i.e., if there are extra polynomial equalities implied by $\mathcal{Q}$, they should be included in $\mathcal{P}$. Here we consider a few examples.

Max-CSP: $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\}$

Here $S = \{0,1\}^n$. Any polynomial p of degree d can be multilinearized one monomial at a time. Specifically, we can find degree d multilinear p^* such that $p - p^* = 0$ has a degree d derivation from $\mathcal{P}$. Furthermore, the multilinear polynomial p^* is zero over S if and only if all its coefficients are zero. Thus $\mathcal{P}$ is d-complete up to degree d for all $d \in \mathbb{N}$.

Max-Clique: $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\} \cup \{x_i x_j | (i,j) \notin E\}$

Here S is the set of all cliques in the graph. Suppose p is a polynomial that is identically zero over S. Without loss of generality, we may assume p is multilinear, if otherwise we can multilinearize it using $\{x_i^2 - x_i | i \in [n]\}$. For a multilinear polynomial $p(x) = \sum_{\alpha \subset [n]} \hat{p}_\alpha x_\alpha$, we claim that if $p(x) = 0 \forall x \in S$ then for all cliques $\alpha \subset [n]$, the corresponding coefficient $\hat{p}_\alpha = 0$, i.e., all non-zero coefficients of p are non-cliques. Suppose not, then let α be the smallest clique with $\hat{p}_\alpha \neq 0$. Then, we will have $p(\mathbb{I}_\alpha) = \hat{p}_\alpha \neq 0$, a contradiction. Since all coefficients of p are non-cliques, each monomial in p can be eliminated using an appropriate polynomial from $\{x_i x_j | (i,j) \notin E\}$.

▶ Remark. More generally, the above two cases are special cases of the following general setup: $\mathcal{Q}$ is empty, and $\mathcal{P}$ is a Gröbner basis. A Gröbner basis for an ideal is a generating set of polynomials that allow a well-defined multivariate polynomial division (see [1] for more information). Computing the Gröbner basis is often the first step in practical polynomial equation solvers, and we note the following easy lemma:

▶ Lemma 8. *If $\mathcal{Q} = \emptyset$ and $\mathcal{P}$ is a Gröbner basis for $\langle \mathcal{P} \rangle$, then S is d-complete up to degree d.*

Proof. If $\mathcal{P}$ is a Gröbner basis, then every degree d polynomial in $\langle \mathcal{P} \rangle$ has a degree d derivation via multivariate division. Because $\mathcal{Q} = \emptyset$, the polynomials that are zero on S are exactly the polynomials in $\langle \mathcal{P} \rangle$. ◀

Balanced Separator: $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\}$, $\mathcal{Q} = \{2n/3 - \sum_i x_i, \sum_i x_i - n/3\}$

The solution space S here is all bit strings with hamming weight between $n/3$ and $2n/3$. Suppose r is a polynomial that is zero on S. Without loss of generality, we may assume that r is multilinear by using the constraints $\{x_i^2 - x_i | i \in [n]\}$. Suppose r is a non-zero multilinear polynomial which is zero on S, then its symmetrized version $r^* = \frac{1}{n!}\sum_{\sigma \in \mathcal{S}_n} \sigma r$ must also be zero on S, where σ acts by permuting the variable names. However, r^* is a univariate polynomial in $\sum_i x_i$ (modulo the Boolean constraints). This univariate polynomial has $n/3$ zeros, and thus must have degree at least $n/3$. Since symmetrizing does not change degree, we conclude that r also has degree at least $n/3$. Thus every non-zero multilinear polynomial that is zero on S but not in $\langle \mathcal{P} \rangle$, has degree at least $n/3$. Therefore the system is d-complete up to degree d for $d \leq \frac{n}{3}$. The polynomials in $\mathcal{Q}$ can be perturbed by $1/2$ to make them $1/2$-robust, and thus S is rich for $(\mathcal{P}, \mathcal{Q})$.

Matching: $\mathcal{P} = \{x_{ij}^2 - x_{ij} | i, j \in [n]\} \cup \{\sum_i x_{ij} - 1 | i \in [n]\} \cup \{x_{ij}x_{ik} | i, j, k \in [n]\}$

These constraints are $2d$-complete as proven in [5].

Max-Bisection: $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\} \cup \{\sum_i x_i - n/2\}$

We will prove in Section 6 that these constraints are d-complete. The proof will be very similar to the one for MATCHING, due to the similar symmetry of the constraints.

Unit-Vector: $\mathcal{P} = \{\sum_i x_i^2 - 1\}$

Here $S = \{x : \|x\| = 1\}$. This constraint appears frequently in tensor norm problems as a way to enforce scaling. Since $\mathcal{Q} = \emptyset$, it is clearly robust. It may be well-known that $\mathcal{P}$ is d-complete, but we could not find a reference so we record it here for completeness. Let $p(x)$ be any degree d polynomial which is zero on the unit sphere, and define $p_0(x) = p(x) + p(-x)$. Clearly p_0 is also zero on the unit sphere, with degree $k = 2\lfloor (d+1)/2 \rfloor$. Note that p_0 has only terms of even degree. Define a sequence of polynomials $\{p_i\}_{i \in \{0,\ldots,k\}}$ as follows. Define q_i to be the part of p_i which has degree strictly less than k, and let $p_{i+1} = p_i + q_i \cdot (\sum_i x_i^2 - 1)$. Then each p_i is zero on the unit sphere and has no monomials of degree strictly less than $2i$. Thus $p_{k/2}$ is homogeneous of degree k. But then $p(tx) = t^k p_k(x) = 0$ for any unit vector x and $t > 0$, and thus $p_k(x)$ must be the zero polynomial. This implies that p_0 is a multiple of $\sum_i x_i^2 - 1$. The same logic shows that $p(x) - p(-x)$ is also a multiple of $\sum_i x_i^2 - 1$, and thus so is $p(x)$. Now $\langle \mathcal{P} \rangle$ is principal, so every degree d polynomial in it has a degree d derivation, so $(\mathcal{P}, \mathcal{Q}, S)$ is d-complete.

To prove spectral-richness, we note that in [7] the author gives an exact formula for each entry of the matrix $M = \int_S p(x)$ for any polynomial p. The formulas imply that $(n+d)!\pi^{-n/2}M$ is an integer matrix with entries (very loosely) bounded by $(n+d)!d!2^n$. By Lemma 6, we conclude that S is δ-spectrally rich with $1/\delta = 2^{\mathrm{poly}(n^d)}$.

We collect the examples discussed in this section here:

▶ **Corollary 9.** *The following constraints admit rich solutions:*

- MAX-CSP*:* $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\}$.
- MAX-CLIQUE*:* $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\} \cup \{x_i x_j | (i,j) \notin E\}$.
- BALANCED SEPARATOR*:* $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\}$, $\mathcal{Q} = \{2n/3 - \sum_i x_i, \sum_i x_i - n/3\}$.
- MATCHING*:* $\mathcal{P} = \{x_{ij}^2 - x_{ij} | i, j \in [n]\} \cup \{\sum_i x_{ij} - 1 | i \in [n]\} \cup \{x_{ij}x_{ik} | i, j, k \in [n]\}$.
- MAX-BISECTION*:* $\mathcal{P} = \{x_i^2 - x_i | i \in [n]\} \cup \{\sum_i x_i - n/2\}$.
- UNIT-VECTOR*:* $\mathcal{P} = \{\sum_i x_i^2 - 1\}$.

3.1 Limitations

While Theorem 10 allows us to prove that many different systems of polynomial constraints have well-behaved SoS proofs, there are a few areas where it comes up short. Most noticeably, to contain a rich set of solutions the solution space has to be nonempty. This can be a problem when trying to find SoS proofs of infeasibility. For example, one common technique is to introduce lower bounds on an objective function $f(x)$ of a maximization problem as constraints and attempt to use SoS to find a refutation, i.e. a proof of non-negativity for the constant polynomial -1. We are unable to show that these proofs can be taken to have polynomial bit complexity since they have empty solution spaces. As another example, we are unable to use our framework to show that refutations of the knapsack constraints use only polynomially many bits, even though it is clear by simply examining these known refutations that they only involve small coefficients.

4 Rich Solution Spaces Yield Bounded SoS Proofs

In this section we prove our main theorem:

▶ **Theorem 10.** *Let $\mathcal{P} = \{p_1, \ldots, p_m\}$ and $\mathcal{Q} = \{q_1, \ldots, q_\ell\}$ be sets of polynomials with $S \subseteq \{\alpha \in \mathbb{R}^n | \forall p \in \mathcal{P} : p(\alpha) = 0\}$. Assume that the set S is (k, δ, ϵ)-rich for $(\mathcal{P}, \mathcal{Q})$.*

Let $r(x)$ be a polynomial non-negative on S, and assume r has a degree d sum-of-squares proof of non-negativity

$$r(x) = \sum_{i=1}^{t_0} h_i^2 + \sum_{i=1}^{\ell} \left(\sum_{j=1}^{t_i} s_j^2 \right) q_i + \sum_{i=1}^{m} \lambda_i p_i.$$

Then r has a degree k sum-of-squares proof of non-negativity such that the coefficients of every polynomial appearing in the proof are bounded by $2^{\mathrm{poly}(n^k, \log \frac{1}{\delta}, \log \frac{1}{\epsilon})}$. In particular, if S is rich then every coefficient can be written down with only $\mathrm{poly}(n^d)$ bits.

Proof. First, we rewrite the proof into a more convenient form before proving bounds on each individual term. Because the elements of $\mathbf{v}$ are a basis for $\mathbb{R}[x]_d$, every polynomial in the proof can be expressed as $c^T \mathbf{v}$, where c is a vector of reals:

$$\begin{aligned} r(x) &= \sum_{i=1}^{t_0} (c_i^T \mathbf{v})^2 + \sum_{i=1}^{\ell} \left(\sum_{j=1}^{t_i} (d_{ij}^T \mathbf{v})^2 \right) q_i + \sum_{i=1}^{m} \lambda_i p_i \\ &= \langle C, \mathbf{v}\mathbf{v}^T \rangle + \sum_{i=1}^{\ell} \langle D_i, \mathbf{v}\mathbf{v}^T \rangle q_i + \sum_{i=1}^{m} \lambda_i p_i \,. \end{aligned}$$

for PSD matrices C, $D_1, \ldots, D_\ell$. Next, we average this polynomial identity over all the points $\alpha \in S$:

$$\mathop{\mathbb{E}}_{\alpha \in S}[r(\alpha)] = \langle C, \mathop{\mathbb{E}}_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T] \rangle + \sum_{i=1}^{\ell} \langle D_i, \mathop{\mathbb{E}}_{\alpha \in S}[q_i(\alpha)\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T] \rangle + 0 \,.$$

The LHS is at most $\mathrm{poly}(\|r\|, \|S\|)$, and the RHS is a sum of positive numbers, so the LHS is a bound on each term of the RHS. We would like to say that since S is δ-spectrally rich, the first term is at least $\delta \operatorname{Tr}(C)$. Unfortunately the averaged matrix may have zero eigenvectors, and it is possible that C could have very large eigenvalues in these directions. However

these eigenvectors must correspond to polynomials that are zero on S. Because $(\mathcal{P}, \mathcal{Q}, S)$ is complete, these can be absorbed into the final term. More formally, let $\Pi = \sum_u uu^T$ be the projector onto the zero eigenspace of $M = \mathbb{E}_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T]$. Because $(\mathcal{P}, \mathcal{Q}, S)$ is complete, for each u we have a degree k derivation $u^T\mathbf{v} = \sum_i \sigma_{ui} p_i$. Then $\Pi\mathbf{v}\mathbf{v}^T = \sum_u (u^T\mathbf{v})u\mathbf{v}^T$. Thus we can write

$$\begin{aligned}\langle C, \mathbf{v}\mathbf{v}^T\rangle &= \langle C, (\Pi + \Pi^\perp)\mathbf{v}\mathbf{v}^T(\Pi + \Pi^\perp)\rangle \\ &= \langle C, \Pi^\perp \mathbf{v}\mathbf{v}^T \Pi^\perp\rangle + \sum_u u^T\mathbf{v}\left(\langle C, \Pi^\perp \mathbf{v}u^T + \mathbf{v}u^T\Pi^\perp + \mathbf{v}u^T\Pi\rangle\right) \\ &= \langle \Pi^\perp C \Pi^\perp, \mathbf{v}\mathbf{v}^T\rangle + \sum_i \sigma_i p_i.\end{aligned}$$

Doing the same for the other terms and setting $C' = \Pi^\perp C \Pi^\perp$ and similarly for D'_i, we get a new proof:

$$r(x) = \langle C', \mathbf{v}\mathbf{v}^T\rangle + \sum_{i=1}^{\ell} \langle D'_i, \mathbf{v}\mathbf{v}^T\rangle q_i + \sum_{i=1}^{m} \lambda'_i p_i.$$

Now after averaging over S, the zero eigenspaces of C' and each D'_i are contained in the zero eigenspace of M. Furthermore, ϵ-robustness implies, for each i,

$$\langle D'_i, \mathop{\mathbb{E}}_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T q_i(\alpha)]\rangle \geq \epsilon \langle D'_i, \mathop{\mathbb{E}}_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T]\rangle .$$

Taken with the δ-spectral richness, we have

$$\text{poly}(\|r\|, \|S\|) \geq \delta \operatorname{Tr}(C') + \sum_{i=1}^{\ell} \epsilon\delta \operatorname{Tr}(D'_i).$$

The Frobenius norm of any PSD matrix is bounded by its trace, so we conclude that C' and each D'_i have entries bounded by $\text{poly}(\|r\|, \|S\|, \frac{1}{\delta}, \frac{1}{\epsilon})$.

The only thing left to do is to bound the coefficients λ'_i, but this is easy because the SoS proof is linear in these coefficients. If we imagine the coefficients of the λ'_i as variables, then the linear system induced by the polynomial identity

$$r(x) - \langle C', \mathbf{v}\mathbf{v}^T\rangle - \sum_{i=1}^{\ell} \langle D'_i, \mathbf{v}\mathbf{v}^T\rangle = \sum_{i=1}^{m} \lambda'_i p_i$$

is clearly feasible, and the coefficients of the LHS are bounded by $\text{poly}(\|r\|, \|S\|, \frac{1}{\delta}, \frac{1}{\epsilon})$. There are $O(n^k)$ variables, so by Cramer's rule, the coefficients of the λ'_i can be taken to be bounded by $\text{poly}(\|\mathcal{P}\|^{n^k}, \frac{1}{\delta}, \frac{1}{\epsilon}, \|r\|, \|S\|, n!)$. $\|\mathcal{P}\|, \|r\| \leq 2^{\text{poly}(n^d)}$ as they are considered part of the input, $\|S\| \leq 2^{\text{poly}(n^d)}$ by the explicitly bounded assumption, and $d \leq k$. Thus, this bound is at most $2^{\text{poly}(n^k, \log\frac{1}{\delta}, \log\frac{1}{\epsilon})}$. ◀

5 Boolean Systems With No Small-Coefficient Proofs

In [16], the author gives an example of a polynomial system for which degree two SoS proofs can certify non-negativity of a certain polynomial, but the proofs necessarily involves coefficients of doubly-exponential size. However, there are two weaknesses in his example system. First, it is not a Boolean one, i.e. it contains variables y_i for which the constraint $y_i^2 - y_i = 0$ is not present in the constraints. Many practical optimization problems have

Boolean constraints, and in [16], the author hoped that having those constraints might suffice to imply that all proofs could have small bit complexity. Second, while the degree two proofs must have exponential bit complexity, there were degree four proofs of non-negativity with polynomial bit complexity. In this section, we strengthen his counterexample, giving an example of a Boolean system with n variables for which there is a polynomial that has a degree two proof of non-negativity, but no proof with polynomial bit complexity until degree $\Omega(\sqrt{n})$.

5.1 A First Example

The original example given in [16] essentially contains the following system whose repeated squaring is responsible for the blowup of the coefficients in the proofs:

$$y_1^2 - y_2 = 0, \quad y_2^2 - y_3 = 0, \quad \ldots, \quad y_{n-1}^2 - y_n = 0, \quad y_n^2 = 0.$$

Clearly, the only solution to the system is $(0, 0, 0, \ldots, 0)$, and therefore the polynomial $\epsilon - y_1$ must be non-negative over the solution space for any $\epsilon > 0$. It is not as obvious whether or not an SoS proof of this non-negativity exists. It turns out that there is a degree two SoS proof as follows:

$$\epsilon - y_1 \equiv \left(\sqrt{\frac{\epsilon}{n}} - \left(\frac{n}{4\epsilon}\right)^{1/2} y_1\right)^2 + \left(\sqrt{\frac{\epsilon}{n}} - \left(\frac{n}{4\epsilon}\right)^{3/2} y_2\right)^2 + \left(\sqrt{\frac{\epsilon}{n}} - \left(\frac{n}{4\epsilon}\right)^{7/2} y_3\right)^2 + \\ + \cdots + \left(\sqrt{\frac{\epsilon}{n}} - \left(\frac{n}{4\epsilon}\right)^{(2^n-1)/2} y_n\right)^2. \qquad (*)$$

where the $\equiv$ is equality modulo the ideal generated by the constraints. Of course, this proof involves coefficients of doubly-exponential size, but one can prove that they are required. We will take $\epsilon < 1/2$ for simplicity. We will define a linear functional $\phi : \mathbb{R}[Y]_d \to \mathbb{R}$ satisfying the following:

- $\phi[\epsilon - y_1] = -\epsilon$
- $\phi[p^2] \geq 0$ for any p^2 of degree at most d
- $\phi[\sigma_i(y_i^2 - y_{i+1})] = 0$ for any $i \leq n-1$ and σ_i of degree at most $d-2$
- $|\phi[\lambda y_n^2]| \leq (2\epsilon)^{2^{n-1}} n^d \|\lambda\|$.

If such a ϕ exists, then for any degree d SoS proof of non-negativity

$$\epsilon - y_1 = \sum_i h_i(y)^2 + \sum_{i=1}^{n-1} \sigma_i(y_i^2 - y_{i+1}) + \lambda \cdot y_n^2,$$

apply ϕ to both sides. We obtain $-\epsilon \leq P + 0 + \phi[\lambda y_n^2]$, where $P \geq 0$. Because $|\phi[\lambda y_n^2]| \leq (2\epsilon)^{2^{n-1}} n^d \|\lambda\|$, λ must contain a coefficient of size at least $\Omega(\frac{1}{n^d}\left(\frac{1}{2\epsilon}\right)^{2^n})$.

To show that such a ϕ exists, we define it as follows. By the constraints, every monomial is equivalent to some power of y_1. For example, $y_1 y_2 y_3 \equiv y_1^7$. More generally, the constraints imply that $\prod_{i=1}^n y_i^{\beta_i} = y_1^{\sum_{j=1}^n 2^{j-1}\beta_j}$. Define ϕ by,

$$\phi\left(\prod_{i=1}^n y_i^{\beta_i}\right) = (2\epsilon)^{\sum_i 2^{i-1}\beta_i}.$$

One can easily check that this ϕ satisfies the above. Note that none of the variables y_i in the above system are Boolean, which we achieve in the upcoming section.

5.2 A Boolean System

One simple way to try to make the system Boolean is to just add the constraints $y_i^2 = y_i$ to the system. Unfortunately, in that case it is easy to prove that $y_i - y_j = 0$ for each i and j, and of course $y_n = y_n^2 = 0$. It is too easy for SoS to figure out what each y_i should look like. Previously, the variables were unconstrained in any way, and we want to imitate that. We draw inspiration from the Knapsack problem, and we instead replace each instance of the variable y_i with a sum of $2k$ Boolean variables

$$y_i \to \sum_j w_{ij} - k,$$

and we consider the non-negative polynomial $\epsilon - (\sum_j w_{1j} - k)$. Clearly there is a degree two proof of non-negativity for this polynomial since we can just replace each instance of y_i with $\sum_j w_{ij} - k$ in $(*)$.

It remains to show that there are no other proofs that have only small coefficients. Here, we use the fact that the Knapsack problem is hard for SoS: there is no SoS proof of degree less than $\Omega(k)$ that $\sum_j w_{ij} - k$ is not equal to any number $r \in (0, 1)$ [8]. This allows us to use the Knapsack pseudodistribution to "pretend" that $\sum_j w_{ij} - k = (2\epsilon)^{2^{i-1}}$. Specifically, for each $r \in (0, 1)$, there is a linear functional ϕ_r defined on polynomials of $2k$ Boolean variables which satisfies

- $\phi_r[\sigma_{ij}(w_{ij}^2 - w_{ij})] = 0$ for any σ_{ij} up to degree $O(k)$
- $\phi_r[\lambda \cdot ((\sum_j w_{ij} - k) - r)] = 0$ for any polynomial λ up to degree $O(k)$
- $\phi_r[p^2] \geq 0$ for any polynomial p^2 of degree at most $O(k)$.

Now, take the linear functional Φ defined on each polynomials of $2kn$ variables defined in the following way: Let $T = T_1 \cup T_2 \cup \cdots \cup T_n$ where T_i is a multiset that contains only the variables corresponding to y_i, and let w_T denote the associated monomial. Then define

$$\Phi[w_T] = \phi_{2\epsilon}(w_{T_1})\phi_{(2\epsilon)^2}(w_{T_2}) \ldots \phi_{(2\epsilon)^{2^{n-1}}}(w_{T_n}).$$

Clearly Φ is non-negative on squares and $\Phi[\sigma_{ij}(w_{ij}^2 - w_{ij})] = 0$ for any σ_{ij} up to degree $\Omega(k)$. Because $\Phi[\lambda(\sum_j w_{ij} - k)] = \Phi[(2\epsilon)^{2^{i-1}}\lambda]$, Φ also satisfies $\Phi[\lambda((\sum_j w_{ij} - k)^2 - (\sum_j w_{i+1,j} - k))] = 0$ for each λ and $1 \leq i \leq n-1$. Finally, because each variable is Boolean, Φ of any monomial is at most one, so for any monomial w_M, $\Phi[w_M(\sum_j w_{nj} - k)^2] = \Phi[(2\epsilon)^{2^{n-1}} w_M] \leq (2\epsilon)^{2^{n-1}}$. There are at most $(nk)^d$ monomials, so $\Phi[\lambda(\sum_j w_{nj} - k)^2] \leq (nk)^d (2\epsilon)^{2^{n-1}} \|\lambda\|$. Just as before, the existence of Φ implies that any degree d proof of non-negativity for $\epsilon - (\sum_j w_{1j} - k)$ must contain coefficients of size at least $\Omega(\frac{1}{(nk)^d} \cdot \left(\frac{1}{2\epsilon}\right)^{2^n})$. If we set $k = n$, then there are n^2 variables and no proof of non-negativity with coefficients smaller than doubly-exponential until degree n. This proves Theorem 2.

6 Max-Bisection Constraints

In this section, we prove our earlier claim that the Max-Bisection constraints admit rich solutions. Recall the constraints:

$$\mathcal{P}(n) = \left\{x_i^2 - x_i | i \in [2n]\right\} \cup \left\{\sum_i x_i - n\right\}.$$

Recall that to prove S is rich, we have to prove that it is spectrally rich, robust, and complete. Since the solution space lies in the hypercube, it is spectrally rich by Lemma 7, and it is clearly robust since $\mathcal{Q}$ is empty. It remains to prove that it is complete for some k. This proof follows a very similar path to [5], due to the similar symmetry of the constraints.

▶ **Lemma 11.** *$\mathcal{P}(n)$ is d-complete for any $d \leq n$.*

▶ Remark. A reviewer has pointed out that this is already essentially known by combining Corollary B.6 of [14] with Theorem 3.5 of [6]. We include a proof here for completeness.

Proof. Let $S(n)$ denote the solution space of $\mathcal{P}(n)$, and let $M = \mathbb{E}_{\alpha \in S}[\mathbf{v}(\alpha)\mathbf{v}(\alpha)^T]$. Any zero eigenvector c of M can be associated with a polynomial $c^T\mathbf{v}$. Since $c^T M c = E_{\alpha \in S}[(c^T v(\alpha))^2]$ and $c^T M c = 0$, we must have $c^T v(\alpha) = 0$ for each $\alpha \in S$. We argue that any degree d polynomial which is identically zero on $S(n)$ must have a degree d derivation from $\mathcal{P}(n)$.

We proceed by induction on d. If $d = 0$, the only constant polynomial zero on $S(n)$ is the zero polynomial, which has the trivial derivation. Now consider the case of $d = c + 1$. We proceed in two parts. First, if r is fully symmetric, we show that it has a degree d derivation. Secondly, for any polynomial p which is zero on $S(n)$, we prove that $p - \frac{1}{(2n)!}\sum_{\sigma \in \mathcal{S}_n} \sigma p$ has a degree d derivation from $\mathcal{P}$, where σ acts on p by permuting the labels of the variables. Taken together, these two facts imply that r has a degree d derivation from $\mathcal{P}(n)$.

To prove the first part, note that a symmetric polynomial r is a linear combination of the elementary symmetric polynomials $e_1, \ldots, e_c$, and it is clear that $e_k(x)$ can be derived by taking the polynomial $(\sum_i x_i - n)^k$, reducing it to multilinear using the Boolean constraints, and then reducing by $e_l(x)$ for each $l < k$. This will result in a constant polynomial, which must be the zero polynomial since we are only adding polynomials which are zero on $S(n)$, so the resulting polynomial must be zero on $S(n)$.

To prove the second part, let σ_{ij} be the transposition of labels i and j, and consider the polynomial $r - \sigma_{ij} r$. Writing $r = r_i x_i + r_j x_j + r_{ij} x_i x_j + q_{ij}$, where none of r_i,r_j,r_{ij}, nor q_{ij} depend on x_i or x_j, we can rewrite

$$r - \sigma_{ij} r = (r_i - r_j)(x_i - x_j).$$

Now because $r - \sigma_{ij} r$ evaluates to zero on any Boolean string with exactly n ones, if we set $x_i = 1$ and $x_j = 0$, we know that $r_i - r_j$ is a polynomial that must evaluate to zero on any Boolean string with exactly $n - 1$ ones. Because $\deg(r_i - r_j) = d - 1$, by the inductive hypothesis, $r_i - r_j$ has a degree $d-1$ proof from $\mathcal{P}(n-1)$ (since $d \leq n$, clearly $d - 1 \leq n - 1$). This implies that $(r_i - r_j)(x_i - x_j)$ has a degree $d - 1$ proof from $\mathcal{P}(n)$:

$$\begin{aligned}
(r_i - r_j)(x_i - x_j) &= \left[\sum_{t \neq i,j} \lambda_t (x_t^2 - x_t) + \lambda \left(\sum_{t \neq i,j} x_t - (n-1)\right)\right](x_i - x_j) \\
&= \sum_t \lambda'_t (x_t^2 - x_t) + \lambda \left(\sum_{t \neq i,j} x_t - (n-1) + (x_i + x_j - 1)\right)(x_i - x_j) \\
&= \sum_t \lambda'_t (x_t^2 - x_t) + \lambda' \left(\sum_t x_t - n\right)
\end{aligned}$$

where we used the fact that $(x_i + x_j - 1)(x_i - x_j) - (x_i^2 - x_i) + (x_j^2 - x_j) = 0$. The degree of this derivation is at most d because each λ_t has degree at most $d - 3$, and $\lambda'_t = \lambda_t(x_i - x_j)$, and similarly for λ. Thus the inductive hypothesis implies that $r - \sigma_{ij} r$ has a degree d derivation, and since transpositions generate the symmetric group, this implies that $r - \frac{1}{(2n)!}\sum_{\sigma \in \mathcal{S}_n} \sigma r$ has a degree d proof from $\mathcal{P}(n)$. ◀

▶ Remark. In this example, $\mathcal{P}$ is not a Gröbner basis for its ideal $\langle \mathcal{P} \rangle$. Indeed, the Gröbner basis for this ideal has exponential size. This is an example where our framework is applicable, even though Gröbner bases are intractable to compute.

Abstract

We introduce the *dependent doors problem* as an abstraction for situations in which one must perform a sequence of possibly dependent decisions, without receiving feedback information on the effectiveness of previously made actions. Informally, the problem considers a set of d doors that are initially closed, and the aim is to open all of them as fast as possible. To open a door, the algorithm knocks on it and it might open or not according to some probability distribution. This distribution may depend on which other doors are currently open, as well as on which other doors were open during each of the previous knocks on that door. The algorithm aims to minimize the expected time until all doors open. Crucially, it must act at any time without knowing whether or which other doors have already opened. In this work, we focus on scenarios where dependencies between doors are both positively correlated and acyclic.

The fundamental distribution of a door describes the probability it opens in the best of conditions (with respect to other doors being open or closed). We show that if in two configurations of d doors corresponding doors share the same fundamental distribution, then these configurations have the same optimal running time up to a universal constant, no matter what are the dependencies between doors and what are the distributions. We also identify algorithms that are optimal up to a universal constant factor. For the case in which all doors share the same fundamental distribution we additionally provide a simpler algorithm, and a formula to calculate its running time. We furthermore analyse the price of lacking feedback for several configurations governed by standard fundamental distributions. In particular, we show that the price is logarithmic in d for memoryless doors, but can potentially grow to be linear in d for other distributions.

We then turn our attention to investigate precise bounds. Even for the case of two doors, identifying the optimal sequence is an intriguing combinatorial question. Here, we study the case of two cascading memoryless doors. That is, the first door opens on each knock independently with probability p_1. The second door can only open if the first door is open, in which case it will open on each knock independently with probability p_2. We solve this problem almost completely by identifying algorithms that are optimal up to an additive term of 1.

1 Introduction

Often it is the case that one must accomplish multiple tasks whose success probabilities are dependent on each other. In many cases, failure to achieve one task will tend to have a more negative affect on the success probabilities of other tasks. In general, such dependencies may be quite complex, and balancing the work load between different tasks becomes a computational challenge. The situation is further complicated if the ability to detect whether a task has been accomplished is limited. For example, if task B highly depends on task A then until A is accomplished, all efforts invested in B may be completely wasted. How should one divide the effort between these tasks if feedback on the success of A is not available?

In this preliminary work we propose a setting that captures some of the fundamental challenges that are inherent to the process of decision making without feedback. We introduce the *dependent doors* problem, informally described as follows. There are $d \geq 2$ doors (representing tasks) which are initially closed, and the aim is to open all of them as fast as possible. To open a door, the algorithm can "knock" on it and it might open or not according to some governing probability distribution, that may depend on other doors being open or closed[1]. We focus on settings in which doors are positively correlated, which informally means that the probability of opening a door is never decreased if another door is open. The governing distributions and their dependencies are known to the algorithm in advance. Crucially, however, during the execution, it gets no direct feedback on whether or not a door has opened unless all d doors have opened, in which case the task is completed.

This research has actually originated from our research on heuristic search on trees [4]. Consider a tree of depth d with a treasure placed at one of its leaves. At each step the algorithm can "check" a vertex, which is child of an already checked vertex. Moreover, for each level of the tree, the algorithm has a way to compare the previously checked vertices on that level. This comparison has the property that if the ancestor of the treasure on that level was already checked, then it will necessarily be considered as the "best" on that level. Note, however, that unless we checked all the vertices on a given level, we can never be sure that the vertex considered as the best among checked vertices in the level is indeed the correct one. With such a guarantee, and assuming that the algorithm gets no other feedback from checked vertices, any reasonable algorithm that is about to check a vertex on a given level, will always choose to check a child of the current best vertex on the level above it. Therefore, the algorithm can be described as a sequence of levels to inspect. Moreover, if we know the different distributions involved, then we are exactly at the situation of the dependent doors problem. See the full version for more details on this example.

Another manifestation of d dependent doors can arise in the context of cryptography. Think about a sequence of d cascading encryptions, and separate decryption protocols to attack each of the encryptions. Investing more efforts in decrypting the i'th encryption would increase the chances of breaking it, but only if previous encryptions where already broken. On the other hand, we get no feedback on an encryption being broken unless all of them are.

The case of two doors can serve as an abstraction for exploration vs. exploitation problems, where it is typically the case that deficient performances on the exploration part may result in much waste on the exploitation part [10, 17]. It can also be seen as the question of balance between searching and verifying in algorithms that can be partitioned thus [1, 15]. In both

[1] Actually, the distribution associated with some door i may depend on the state of other doors (being open or closed) not only at the current knock, but also at the time of each of the previous knocks on door i.

examples, there may be partial or even no feedback in the sense that we don't know that the first procedure succeeded unless the second one also succeeds.

For simplicity, we concentrate on scenarios in which the dependencies are *acyclic*. That is, if we draw the directed dependency graph between doors, then this graph does not contain any directed cycles. The examples of searching and verifying and the heuristic search on trees can both be viewed as acyclic. Moreover, despite the fact that many configurations are not purely acyclic, one can sometimes obtain a useful approximation that is.

To illustrate the problem, consider the following presumably simple case of two dependent memoryless doors. The first door opens on each knock independently with probability 1/2. The second door can only open if the first door is open, in which case it opens on each knock independently, with probability 1/2. What is the sequence of knocks that minimizes the expected time to open both doors, remembering that we don't know when door 1 opens? It is easy to see that the alternating sequence $1, 2, 1, 2, 1, 2, \ldots$ results in 6 knocks in expectation. Computer simulations indicate that the best sequence gives a little more than 5.8 and starts with $1, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 2, 1, 2, 1, 2$. Applied to this particular scenario, our theoretical lower bound gives 5.747, and our upper bound gives a sequence with expected time 5.832.

1.1 Context and Related Work

This paper falls under the framework of decision making under uncertainty, a large research subject that has received significant amount of attention from researchers in various disciplines, including computer science, operational research, biology, sociology, economy, and even psychology and cognition, see, *e.g.,* [2, 3, 5, 6, 7, 8, 9, 16].

Performing despite limited feedback would fit the framework of reinforced learning [17] and is inherent to the study of exploration vs. exploitation type of problems, including Multi-Armed Bandit problems [10]. In this paper we study the impact of having no feedback whatsoever. Understanding this extreme scenario may serve as an approximation for cases where feedback is highly restricted, or limited in its impact. For example, if it turns out that the price of lacking feedback is small, then it may well be worth to avoid investing efforts in complex methods for utilizing the partial feedback.

Of particular interest is the case of two doors. As mentioned, difficulties resulting from the lack of feedback can arise when one aims to find a solution by alternating between two subroutines: Producing promising candidate solutions and verifying these candidates. Numerous strategies are based on this interplay, including heuristics based on brute force or trail and error approaches [1, 15], sample and predict approaches [11, 14, 17], iterative local algorithms [12, 13], and many others. Finding strategies for efficiently balancing these two tasks can be therefore applicable.

1.2 Setting

There are $d \geq 2$ doors and each door can be either open or closed. Doors start closed, and once a door opens it never closes. To open a door, an algorithm can knock on it and it might open or not according to some probability distribution. The goal is to minimize the expected number of knocks until all doors open. Crucially, the algorithm has no feedback on whether or not a door has opened, unless all doors have opened, in which case the task is completed.

The probability that a door opens may depend on the state of other doors (being open or closed) at the time of the current knock as well as on their state during each of the previous knocks on the door. For example, the probability that a certain knock at door i succeeds may depend on the number of previous knocks on door i, but counting only those that were

made while some other specific door j was open. The idea behind this definition is that the more time we invest in opening a door the more likely it is to open, and the quality of each knock depends on what is the state of the doors it depends on at the time of the knock.

Below we provide a semi-formal description of the setting. The level of detail is sufficient to understand the content of the main text, which is mainly concerned with independent and cascading configurations. The reader interested in a more formal description of the model is referred to the full version.

A specific setting of doors is called a *configuration* (normally denoted $\mathcal{C}$). This includes a description of all dependencies between doors and the resulting probability distributions. In this paper we assume that the dependency graph of the doors is acyclic, and so we may assume that a configuration describes an ordering of the doors, such that each door depends only on lower index doors. Furthermore, we assume that the correlation between doors is positive, *i.e.*, a door being open can only improve the chances of other doors to open.

Perhaps the simplest configuration is when all doors are *independent* of each other. In this case, door i can be associated with a function $p_i : \mathbb{N} \to [0, 1]$, where $p_i(n)$ is the probability that door i is not open after knocking on it n times. Another family of acyclic configurations are *cascading* configurations. Here, door i cannot open unless all doors of lower index are already open. In this case, the configuration can again be described by a set of functions $\{p_i\}_{i=1}^{d}$, where $p_i(n)$ describes the probability that door i is not open after knocking on it n times, where the count starts only after door $i-1$ is already open.

In general, given a configuration, each door i defines a non-decreasing function $p_i : \mathbb{N} \to [0, 1]$, called the *fundamental distribution* of the door, where $p_i(n)$ is the probability that the door is not open after knocking on it n times in the best of conditions, *i.e.*, assuming all doors of lower index are open. In the case of independent and cascading configurations, the fundamental distribution p_i coincides with the functions mentioned above. Two doors are *similar* if they have the same fundamental distribution. Two configurations are *similar* if for every i, door i of the first configuration is similar to door i of the second.

When designing an algorithm, we will assume that the configuration it is going to run in is known. As there is no feedback, a deterministic algorithm can be thought of as a possibly infinite sequence of door knocks. A randomized algorithm is therefore a distribution over sequences, and as all of them will have expected running time at least as large as that of an optimal sequence (if one exists), the expected running time of a randomized algorithm cannot be any better. Denote by $\mathbb{T}_{\mathcal{C}}(\pi)$, the expected time until all doors open when running sequence π in configuration $\mathcal{C}$. We define $\mathbb{T}_{\mathcal{C}} = \min_{\pi} \mathbb{T}_{\mathcal{C}}(\pi)$. As proved in the full version of the paper, there exists a sequence achieving this minimum. Therefore, by the aforementioned arguments, we can restrict our discussion to deterministic algorithms only.

If we had feedback we would knock on each door until it opens, and then continue to the next. Denoting by $E_i = \sum_{n=0}^{\infty} p_i(n)$ the expected time to open door i on its own, the expected running time then does not depend on the specific dependencies between doors at all, and is $\sum_i E_i$. Also, this value is clearly optimal. To evaluate the impact of lacking feedback for a configuration $\mathcal{C}$, we therefore define:

$$\texttt{Price}(\mathcal{C}) = \frac{\mathbb{T}_{\mathcal{C}}}{\sum_i E_i} .$$

Obviously $\texttt{Price}(\mathcal{C}) \geq 1$, and for example, if all doors start closed and open after just 1 knock, it is in fact equal to 1. In the full version of this paper we also show that $\texttt{Price}(\mathcal{C}) \leq d$.

1.3 Our Results

We have two main results. The first one, presented in Section 2, states that any two similar configurations have the same optimal running time up to a constant factor. We stress that this constant factor is universal in the sense that it does not depend on the specific distributions or on the number of doors d.

Furthermore, given a configuration, we identify an algorithm that is optimal for it up to a constant factor. We then show that for configurations where all doors are similar, there is a much simpler algorithm which is optimal up to a constant factor, and describe a formula that computes its approximate running time. We conclude Section 2 by analysing the price of lacking feedback for several configurations governed by standard fundamental distributions. In particular, we show that the price is logarithmic in d for memoryless doors, but can potentially grow to be linear in d for other distributions.

We then turn our attention to identify exact optimal sequences. Perhaps the simplest case is the case of two cascading memoryless doors. That is, the first door opens on each knock independently with probability p_1. The second door can only open if the first door is open, in which case it opens on each knock independently, with probability p_2. In Section 3 we present our second main result: Algorithms for these configurations that achieve the precise optimal running time up to an additive term of 1.

On the technical side, to establish such an extremely competitive algorithm, we first consider a semi-fractional variant of the problem and find a sequence that achieves the precise optimal bound. We then approximate this semi-fractional sequence to obtain an integer solution losing only an additive term of 1 in the running time. A nice anecdote is that in the case where $p_1 = p_2$ and are very small, the ratio of 2-knocks over 1-knocks in the sequence we get approaches the golden ratio. Also, in this case, the optimal running time approaches $3.58/p_1$ as p_1 goes to zero. It follows that in this case, the price of lacking feedback tends to $3.58/2$ and the price of dependencies, *i.e.*, the multiplicative gap between the cascading and independent settings, tends to $3.58/3$.

2 Near Optimal Algorithms

The following important lemma is proved in the full version using a coupling argument:

▶ **Lemma 1.** *Consider similar configurations $\mathcal{C}, \mathcal{X}$ and $\mathcal{I}$, where $\mathcal{X}$ is cascading and $\mathcal{I}$ is independent. For every sequence π, $\mathbb{T}_{\mathcal{I}}(\pi) \leq \mathbb{T}_{\mathcal{C}}(\pi) \leq \mathbb{T}_{\mathcal{X}}(\pi)$. This also implies that $\mathbb{T}_{\mathcal{I}} \leq \mathbb{T}_{\mathcal{C}} \leq \mathbb{T}_{\mathcal{X}}$.*

The next theorem presents a near optimal sequence of knocks for a given configuration. In fact, by Lemma 1, this sequence is near optimal for any similar configuration, and so we get that the optimal running time for any two similar configurations is the same up to a universal multiplicative factor.

▶ **Theorem 2.** *There is a polynomial algorithm[2], that given a configuration $\mathcal{C}$ generates a sequence π such that $\mathbb{T}_{\mathcal{C}}(\pi) = \Theta(\mathbb{T}_{\mathcal{I}})$. In fact, $\mathbb{T}_{\mathcal{C}}(\pi) \leq 2 + 4\mathbb{T}_{\mathcal{I}} \leq 2 + 4\mathbb{T}_{\mathcal{C}}$.*

Proof. Denote by $p_1, \ldots, p_d$ the fundamental distributions of the doors of $\mathcal{C}$. For a finite sequence of knocks α, denote by $\mathtt{SC}_{\mathcal{C}}(\alpha)$ the probability that after running α in configuration

[2] A polynomial algorithm in our setting generates the next knock in the sequence in polynomial time in the index of the knock and in d, assuming that reading any specific value of any of the fundamental distributions of a door takes constant time.

$\mathcal{C}$, some of the doors are still closed. Note that if α is *sorted*, that is, if all knocks on door 1 are done first, followed by the knocks on doors 2, etc., then $\mathtt{SC}_{\mathcal{X}}(\alpha) = \mathtt{SC}_{\mathcal{I}}(\alpha)$.

We start by showing that for any T, we can construct in polynomial time a finite sequence α_T of length T that maximizes the probability that all doors will open, *i.e.*, minimizes $\mathtt{SC}_{\mathcal{I}}(\alpha_T)$. As noted above, if we sort the sequence, this is equal to $\mathtt{SC}_{\mathcal{X}}(\alpha_T)$.

The algorithm follows a dynamic programming approach, and calculates a matrix A, where $A[i,t]$ holds the maximal probability that a sequence of length t has of opening all of the doors $1, 2, \ldots, i$. All the entries $A[0, \cdot]$ are just 1, and the key point is that for each i and t, knowing all of the entries in $A[i, \cdot]$, it is easy to calculate $A[i+1, t]$:

$$A[i+1,t] = \max_{k=0}^{t} A[i, t-k] \cdot (1 - p_{i+1}(k)) \ .$$

Calculating the whole table takes $O(dT^2)$ time, and $A[d,T]$ will give us the highest probability a sequence of length T can have of opening all doors. Keeping tabs on the choices the max in the formula makes, we can get an optimal sequence α_T, and can take it to be sorted.

Consider the sequence $\pi = \alpha_2 \cdot \alpha_4 \cdots \alpha_{2^n} \cdots$. The complexity of generating this sequence up to place T is $O(dT^2)$, and so this algorithm is polynomial. Our goal will be to compare $\mathbb{T}_{\mathcal{X}}(\pi)$ with $\mathbb{T}_{\mathcal{I}}(\pi^\star)$, where $\pi^\star$ is the optimal sequence for $\mathcal{I}$.

The following observation stems from the fact that for any natural valued random variable X, $\mathtt{E}[X] = \sum_{n=0}^{\infty} \mathtt{Pr}[X > n]$ and $\mathtt{Pr}[X > n]$ is a non-increasing function of n.

▶ **Observation 3.** *Let $\{a_n\}_{n=1}^{\infty}$ be a strictly increasing sequence of natural numbers, and X be some natural valued random variable. Then:*

$$\sum_{n=1}^{\infty} (a_{n+1} - a_n) \mathtt{Pr}[X > a_{n+1}] \leq \mathtt{E}[X] \leq a_1 + \sum_{n=1}^{\infty} (a_{n+1} - a_n) \mathtt{Pr}[X > a_n] \ .$$

For a sequence π, denote by $\pi[n]$ the prefix of π of length n. In this terminology, $\mathbb{T}_{\mathcal{C}}(\pi) = \sum_{n=0}^{\infty} \mathtt{SC}_{\mathcal{C}}(\pi[n])$. Setting $a_n = 2 + 4 + \ldots + 2^n$ in the right side of Observation 3, and letting X be the number of rounds until all doors open when using π, we get:

$$\begin{aligned}
\mathbb{T}_{\mathcal{X}}(\pi) &\leq 2 + \sum_{n=1}^{\infty} 2^{n+1} \cdot \mathtt{SC}_{\mathcal{X}}(\pi[2 + \ldots + 2^n]) \leq 2 + \sum_{n=1}^{\infty} 2^{n+1} \cdot \mathtt{SC}_{\mathcal{X}}(\alpha_{2^n}) \\
&= 2 + \sum_{n=1}^{\infty} 2^{n+1} \cdot \mathtt{SC}_{\mathcal{I}}(\alpha_{2^n}) \leq 2 + \sum_{n=1}^{\infty} 2^{n+1} \cdot \mathtt{SC}_{\mathcal{I}}(\pi^\star[2^n]) \leq 2 + 4\mathbb{T}_{\mathcal{I}}(\pi^\star)
\end{aligned}$$

The last step is using Observation 3 with $a_n = 2^{n-1}$. Theorem 2 concludes. ◀

2.1 Configurations where all Doors are Similar

In this section we focus on configurations where all doors have the same fundamental distribution $p(n)$. We provide simple algorithms that are optimal up to a universal constant, and establish the price of lacking feedback with respect to a few natural distributions. Corresponding proofs appear in the full version of the paper.

2.1.1 Simple Algorithms

Let us consider the following very simple algorithm $A_{\mathtt{simp}}$. It runs in phases, where in each phase it knocks on each door once, in order. As a sequence, we can write $A_{\mathtt{simp}} = (1, 2, \ldots, d)^{\infty}$. Let $X_1, \ldots, X_d$ be i.i.d. random variables taking positive integer values, satisfying $\mathtt{Pr}[X_i > n] = p(n)$. The following is straightforward:

▶ **Claim 4.** $\mathbb{T}_{\mathcal{I}}(A_{\texttt{simp}}) = \Theta\left(d \cdot \mathtt{E}\left[\max\left\{X_1, \ldots, X_d\right\}\right]\right)$

This one is less trivial:

▶ **Claim 5.** *If all doors are similar then* $\mathbb{T}_{\mathcal{I}}(A_{\texttt{simp}}) = \Theta(\mathbb{T}_{\mathcal{I}})$

The claim above states that $A_{\texttt{simp}}$ is optimal up to a multiplicative constant factor in the independent case, where all doors are similar. As a result, we can also show:

▶ **Claim 6.** *Denote by* α_n *the sequence* $1^{2^n}, \ldots, d^{2^n}$. *If all doors are similar then for any configuration* $\mathcal{C}$, $\mathbb{T}_{\mathcal{C}}\left(\alpha_0 \cdot \alpha_1 \cdot \alpha_2 \cdots\right) = \Theta(\mathbb{T}_{\mathcal{C}})$.

In plain words, the above claim states that the following algorithm is optimal up to a universal constant factor for any configuration where all doors are similar: Run in phases where phase n consists of knocking 2^n consecutive times on each door, in order.

2.1.2 On the Price of Lacking Feedback

By Claims 4 and 5, investigating the price of lacking feedback when all doors are similar boils down to understanding the expected maximum of i.i.d. random variables.

$$\texttt{Price} = \Theta\left(\frac{\mathtt{E}\left[\max\left\{X_1, \ldots, X_d\right\}\right]}{\mathtt{E}\left[X_1\right]}\right) \tag{1}$$

Note that we omitted dependency on the configuration, as by Theorem 2, up to constant factors, it is the same price as in the case where the doors are independent. Let us see a few examples of this value. First:

▶ **Lemma 7.** *If* $X_1, \ldots, X_d$ *are i.i.d. random variables taking natural number values, then:*

$$\mathtt{E}\left[\max(X_1, \ldots, X_d)\right] = \Theta\left(\kappa + d\sum_{n=\kappa}^{\infty} \mathtt{Pr}\left[X_i > n\right]\right)$$

Where $\kappa = \min\left\{n \in \mathbb{N} \,|\, \mathtt{Pr}\left[X_1 > n\right] < 1/d\right\}$

▶ **Example 8.** After the first knock on it, each door opens with probability $1 - 1/d$ and if it doesn't, it will open at its $d+1$'st knock. The expected time to open each door on its own is 2. By Lemma 7, as $\kappa = d + 1$, we get that $\texttt{Price} = \Omega(\kappa) = \Omega(d)$. Since always $\texttt{Price} \leq d$, $\texttt{Price} = \Theta(d)$.

▶ **Example 9.** If $p(n) = q^n$ for some $1/2 < q < 1$, then $\texttt{Price} = \Theta(\log(d))$.

▶ **Example 10.** If for some $c > 0$ and $a > 1$, $p(n) = \min(1, c/n^a)$, then $\texttt{Price} = \Theta(d^{\frac{1}{a}})$.

Sometimes we know a bound on some moment of the distribution of opening a door. If $\mathtt{E}\left[X_1\right] < M$, since $\texttt{Price} \leq d$, then $\mathbb{T} = O(d^2 M)$. Also,

▶ **Example 11.** If $\mathtt{E}\left[X_1^a\right] < M$ for some $a > 1$, then $\mathbb{T} = O\left(d^{1+\frac{1}{a}} M^{1/a}(1 + \frac{1}{a-1})\right)$.

For example, if the second moment of the time to open a door on its own is bounded, we get an $O(d^{3/2})$ algorithm.

3 Two Memoryless Cascading Doors

One can say that by Theorem 2 we solved much of the dependent doors problem. There is an equivalence of the independent and cascading models, and we give an up to constant factor optimal algorithm for any situation. However, we still find the question of finding the true optimal sequences for cascading doors to be an interesting one. What is the precise cost of having no feedback, in numbers? Even the simple case of two doors, each opening with probability 1/2 on each knock, turns out to be quite challenging and has a not so intuitive optimal sequence.

In this section, we focus on a very simple yet interesting case of the cascading door problem, and solve it almost exactly. We have two doors. Door 1 opens with probability p_1 each time we knock on it, and door 2 opens with probability p_2. We further extend the setting to consider different durations. Specifically, we assume that a knock on door 1 takes one time unit, and a knock on door 2 takes c time units. Denote $q_1 = 1 - p_1$ and $q_2 = 1 - p_2$. For brevity, we will call a knock on door 1 a *1-knock*, and a knock on door 2 a *2-knock*.

The Semi-Fractional Model. As finding the optimal sequence directly proved to be difficult, we introduce a relaxation of our original model, termed the *semi-fractional model*. In this model, we allow 1-knocks to be of any length. A knock of length t, where t is a non-negative real number, will have probability of $1 - q_1^t$ of opening the door. In this case, a sequence consists of the alternating elements 1^t and 2, where 1^t describes a knock of length t on door 1. We call sequences in the semi-fractional model *semi-fractional sequences*, and to differentiate, we call sequences in the original model *integer sequences*.

As our configuration $\mathcal{C}$ will be clear from context, for a sequence π, we define $\mathtt{E}[\pi] = \mathbb{T}_{\mathcal{C}}(\pi)$ to be the expected running time of the sequence. Clearly, every integer sequence has a similar semi-fractional sequence with the same expected running time. As we will see, the reverse is not far from being true. That being so, finding the optimal semi-fractional sequence will give an almost optimal integer sequence.

3.1 Equivalence of Models

▶ **Theorem 12.** *Every semi-fractional sequence π has an integer sequence π', s.t.,* $\mathtt{E}[\pi'] \leq \mathtt{E}[\pi] + 1$.

For this purpose, in this subsection only, we describe a semi-fractional sequence π as a sequence of non-decreasing non-negative real numbers: $\pi_0, \pi_1, \pi_2, \ldots$, where $\pi_0 = 0$. This sequence describes the following semi-fractional sequence (in our original terms):

$$1^{\pi_1 - \pi_0} \cdot 2 \cdot 1^{\pi_2 - \pi_1} \cdot 2 \cdots$$

This representation simplifies our proofs considerably. Here are some observations:

- 1-knocks can be of length 0, yet we still consider them in our indexing.
- The sequence is an integer sequence iff for all i, $\pi_i \in \mathbb{N}$.
- The i-th 2-knock starts at time $\pi_i + c(i-1)$ and ends at $\pi_i + ci$.
- The probability of door 1 being closed after the completion of the i-th 1-knock is $q_1^{\pi_i}$, and so the probability it opens at 1-knock i is $q_1^{\pi_{i-1}} - q_1^{\pi_i}$

▶ **Lemma 13.** *For two sequences $\pi = (\pi_0, \pi_1, \ldots)$ and $\pi' = (\pi'_1, \pi'_2, \ldots)$, if for all i, $\pi_i \leq \pi'_i \leq \pi_i + 1$ then $\mathtt{E}[\pi'] \leq \mathtt{E}[\pi] + 1$.*

Lemma 13 is the heart of our theorem. Indeed, once proven, Theorem 12 follows in a straightforward manner. Given a semi-fractional sequence π, define $\pi'_i = \lceil \pi_i \rceil$. Then, π' is an integer sequence, and it satisfies the conditions of the lemma, so we are done. The lemma makes sense, as the sequence π' in which for all $i > 0$, $\pi'_i = \pi_i + 1$, can be thought of as adding a 1-knock of length one in the beginning of the sequence. Even if this added 1-knock did nothing, the running time would increase by at most 1. However, the proof is more involved, since in the lemma, while some of the 2-knocks may have an increased chance of succeeding, some may actually have a lesser chance.

Proof. Given a sequence π and an event X, we denote by $\mathtt{E}[\pi \mid X]$ the expected running time of π given the event X. Let X_i denote the event that door 1 opens at its i-th 1-knock. As already said:

$$\mathtt{Pr}[X_i] = q_1^{\pi_{i-1}} - q_1^{\pi_i} = \int_{\pi_{i-1}}^{\pi_i} q_1^x \ln(q_1)\,\mathrm{d}x$$

Where the last equality comes as no surprise, as it can be seen as modelling door 1 in a continuous fashion, having an exponential distribution fitting its geometrical one. Now:

$$\mathtt{E}[\pi] = \sum_{i=1}^{\infty} \mathtt{Pr}[X_i]\,\mathtt{E}[\pi \mid X_i] = \sum_{i=1}^{\infty} \int_{\pi_{i-1}}^{\pi_i} q_1^x \ln(q_1)\,\mathrm{d}x \cdot \mathtt{E}[\pi \mid X_i] = \int_0^{\infty} q_1^x \ln(q_1) \cdot \mathtt{E}\left[\pi \,\middle|\, X_{i(x)}\right] \mathrm{d}x$$

Where $i(x) = \max_i \{x \geq \pi_{i-1}\}$, that is, the index of the 1-knock that x belongs to when considering only time spent knocking on door 1. Defining X'_i and $i'(x)$ in an analogous way for π', we want to show that for all x,

$$\mathtt{E}\left[\pi' \,\middle|\, X'_{i'(x)}\right] \leq 1 + \mathtt{E}\left[\pi \,\middle|\, X_{i(x)}\right]$$

as using it with the last equality will prove the lemma. We need the following three claims:

1. If $j \leq i$, then $\mathtt{E}[\pi \mid X_j] \leq \mathtt{E}[\pi \mid X_i]$
2. For all x, $i'(x) \leq i(x)$
3. For all i, $\mathtt{E}[\pi' \mid X'_i] \leq 1 + \mathtt{E}[\pi \mid X_i]$

Together they give what we need:

$$\mathtt{E}\left[\pi' \,\middle|\, X'_{i'(x)}\right] \leq 1 + \mathtt{E}\left[\pi \,\middle|\, X_{i'(x)}\right] \leq 1 + \mathtt{E}\left[\pi \,\middle|\, X_{i(x)}\right]$$

The first is actually true trivially for all sequences, as the sooner the first door opens, the better the expected time to finish. For the second, since for all i, $\pi'_i \geq \pi_i$, then $x \geq \pi'_i$ implies that $x \geq \pi_i$, and so:

$$i'(x) = \max_i \left\{x \geq \pi'_{i-1}\right\} \leq \max_i \{x \geq \pi_{i-1}\} = i(x)$$

For the third, denote by Y_j the event that door 2 opens at the j'th 2-knock. Then:

$$\mathtt{E}[\pi \mid X_i] = \sum_{j=i}^{\infty} (\pi_j + cj)\mathtt{Pr}[Y_j \mid X_i]$$

Let us consider this same expression as it occurs in π'. First note that $\mathtt{Pr}[Y_j \mid X_i] = \mathtt{Pr}\left[Y'_j \,\middle|\, X'_i\right]$, as all that matters for its evaluation is $j - i$. Therefore:

$$\begin{aligned}\mathtt{E}[\pi' \mid X'_i] &= \sum_{j=i}^{\infty} (\pi'_j + cj)\mathtt{Pr}\left[Y'_j \,\middle|\, X'_i\right] \leq \sum_{j=i}^{\infty} (\pi_j + 1 + cj)\mathtt{Pr}[Y_j \mid X_i] \\ &= \mathtt{E}[\pi \mid X_i] + \sum_{j=i}^{\infty} \mathtt{Pr}[Y_j \mid X_i] \leq \mathtt{E}[\pi \mid X_i] + 1\,.\end{aligned}$$

3.2 The Optimal Semi-Fractional Sequence

A big advantage of the semi-fractional model is that we can find an optimal sequence for it. For that we need some preparation:

▶ **Definition 14.** For a semi-fractional sequence π, and some $0 \leq x \leq 1$, denote by $\mathtt{E}_x[\pi]$ the expected running time of π when started with door 1 being closed with probability x. In this notation, $\mathtt{E}[\pi] = \mathtt{E}_1[\pi]$.

▶ **Lemma 15.** *Let $y = x/(q_2 + p_2 x)$. Then:*

$$\mathtt{E}_x\left[1^t \cdot \pi\right] = t + \mathtt{E}_{q_1^t x}[\pi] \qquad \mathtt{E}_x[2 \cdot \pi] = c + \frac{x}{y}\mathtt{E}_y[\pi]$$

Proof. The first equation is clear, since starting with door 1 being closed with probability x, and then knocking on it for t rounds, the probability that this door is closed is $q_1^t x$.

As for the second equation, if door 1 is closed with probability x, then knocking on door 2, we have a probability of $p_2(1-x)$ of terminating, and so the probability we did not finish is:

$$1 - p_2(1-x) = 1 - p_2 + p_2 x = q_2 + p_2 x = \frac{x}{y}$$

It remains to show that conditioning on the fact that we indeed continue, the probability that door 1 is closed is y. It is the following expression, evaluated after a 2-knock:

$$\frac{\mathtt{Pr}[\text{door 1 is closed}]}{\mathtt{Pr}[\text{door 1 is closed}] + \mathtt{Pr}[\text{door 1 is open but not door 2}]} = \frac{x}{x + (1-x)q_2} = y\,. \qquad \blacktriangleleft$$

Applying Lemma 15 iteratively on a finite sequence w, we get:

$$\mathtt{E}_x[w\pi] = a(x,w) + b(x,w)\mathtt{E}_{\delta(x,w)}[\pi] \tag{2}$$

Of specific interest is $\delta(x,w)$. It can be thought of as the *state*[3] of our algorithm after running the sequence w, when we started at state x. Lemma 15 and Equation (2) give us the behaviour of $\delta(x,w)$:

$$\delta(x,1^t) = q_1^t x\,, \qquad \delta(x,2) = \frac{x}{q_2 + p_2 x}\,, \qquad \delta(x,aw) = \delta(\delta(x,a),w)\,.$$

We start with the state being 1, since we want to calculate $\mathtt{E}_1[\pi]$. Except for this first moment, as we can safely assume any reasonable algorithm will start with a 1-knock, the state will always be in the interval $(0,1)$. A 1-knock will always decrease the state and a 2-knock will increase it.

Our point in all this, is that we wish to exploit the fact that our doors are memoryless, and if we encounter a state we've already been at during the running of the sequence, then we should probably make the same choice now as we did then. The following definition and lemma capture this point.

▶ **Definition 16.** We say a non-empty finite sequence w is x-invariant, if $\delta(x,w) = x$.

The following Lemma is proved in the full version of this paper, and formalizes our intuition about how an optimal algorithm should behave.

▶ **Lemma 17.** *If w is x-invariant, and $\mathtt{E}_x[w\pi] \leq \mathtt{E}_x[\pi]$ then $\mathtt{E}_x[w^\infty] \leq \mathtt{E}_x[w\pi]$.*

[3] There is an intuitive meaning behind this. Going through Lemma 15, we can see that $\delta(1,w)$ is actually the probability that after running w, door 1 is closed conditioned on door 2 being closed. Indeed, After running some finite sequence, the only feedback we have is that the algorithm did not finish yet. We can therefore calculate from our previous moves what is the probability that door 1 is closed, and that is the only information we need for our next steps.

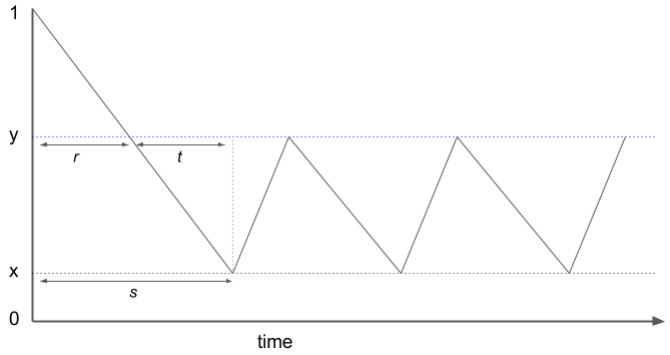

Figure 1 How the state evolves as a function of time. 1-knocks decrease the state, and 2-knocks increase it. Note that $r = \log_{q_1}(y)$ and $s = \log_{q_1}(x)$.

3.2.1 The Actual Semi-Fractional Sequence

▶ **Theorem 18.** *There is an optimal semi-fractional sequence $\pi^\star$ of the form $1^s(21^t)^\infty$, for some positive real values s and t, and its running time is:*

$$\mathtt{E}\left[\pi^\star\right] = \min_{z\in[0,1]}\left(\log_{q_1}(1-z) + \frac{c + (1-p_2 z)\log_{q_1}(1-p_2 z)}{p_2 z}\right).$$

Proof. In the full version of this paper, we prove that there is an optimal semi-fractional sequence π. It clearly starts with a non-zero 1-knock, and so we can write $\pi = 1^s 2\pi'$. Intuitively, in terms of its state, this sequence starts at 1, goes down for some time with a 1-knock, and then jumps back up with a 2-knock. The state it reaches now was already passed through on the first 1-knock, and so as this is an optimal sequence we can assume it will choose the same as it did before, and keep zig-zaging up and down.

We next prove that indeed there is an optimal sequence following the zig-zaging form above. Again, take some optimal π, and write $\pi = 1^s 2\pi'$. Denote $x = \delta(1, 1^s)$ and $y = \delta(1, 1^s 2) = \delta(x, 2) > x$ (see Figure 1). Taking $r = \log_{q_1}(y) < s$, we get $\delta(1, 1^r) = y$. Denoting $t = s - r$, this means that $1^t 2$ is y-invariant. Since π is optimal, then:

$$\mathtt{E}\left[\pi\right] = \mathtt{E}\left[1^r(1^t 2)\pi'\right] \leq \mathtt{E}\left[1^r\pi'\right] \quad \text{which implies:} \quad \mathtt{E}_y\left[1^t 2\pi'\right] \leq \mathtt{E}_y\left[\pi'\right].$$

So by Lemma 17:

$$\mathtt{E}_y\left[(1^t 2)^\infty\right] \leq \mathtt{E}_y\left[1^t 2\pi'\right] \quad \text{which implies:} \quad \mathtt{E}\left[1^r(1^t 2)^\infty\right] \leq \mathtt{E}\left[1^r 1^t 2\pi'\right] = \mathtt{E}\left[\pi\right].$$

Therefore, $1^r(1^t 2)^\infty = 1^s(21^t)^\infty$ is optimal. We denote this sequence $\pi^\star$.

Now for the analysis of the running time of this optimal sequence. We will use Lemma 15 many times in what follows.

$$\mathtt{E}_1\left[1^s(21^t)^\infty\right] = s + \mathtt{E}_x\left[(21^t)^\infty\right].$$

Denote $\alpha = (21^t)^\infty$.

$$\mathtt{E}_x\left[\alpha\right] = \mathtt{E}_x\left[21^t\alpha\right] = c + \frac{x}{y}\mathtt{E}_y\left[1^t\alpha\right] = c + \frac{x}{y}(t + \mathtt{E}_x\left[\alpha\right]).$$

Since $t = s - r = \log_{q_1}(x/y)$:

$$\mathtt{E}_x\left[\alpha\right] = \frac{c}{1-\frac{x}{y}} + \frac{\frac{x}{y}}{1-\frac{x}{y}}\log_{q_1}(x/y).$$

By Lemma 15, as our y is the state resulting from a 2-knock starting at state x, it follows that $y = x/(q_2 + p_2 x)$. Since $x/y = q_2 + p_2 x$, then $1 - x/y = p_2(1 - x)$ and then we get:

$$\frac{c}{p_2(1-x)} + \frac{q_2 + p_2 x}{p_2(1-x)} \log_{q_1}(q_2 + p_2 x) .$$

And in total:

$$\mathtt{E}_1\left[1^s(21^t)^\infty\right] = \log_{q_1}(x) + \frac{c + (q_2 + p_2 x)\log_{q_1}(q_2 + p_2 x)}{p_2(1-x)} .$$

Changing variable to $z = 1 - x$, results in $q_2 + p_2 x = 1 - p_2 z$, and we get the expression in the statement of the theorem. ◀

3.3 Actual Numbers

Theorem 18 gives the optimal semi-fractional sequence and a formula to calculate its expected running time. This formula can be approximated as accurately as we wish for any specific values of p_1, p_2 and c, but it is difficult to obtain a closed form formula from it. In the full version, we show an approximation with an additive error term $p2/\log(1/q_1)$. This is pretty close to p_2/p_1, and so when $p_1 \geq p_2$ it is just an additive error of 1.

In general, when p_1 is small, then the running time is shown to depend on $\theta \approx cp_1/p_2$, which is the expected time to open door 2 on its own, divided by the time to open door 1 on its own - a natural measure of the system. Then, ignoring the additive mistake, we show there that the lower bound is approximately $\mathcal{F}(\theta)/p_1$, where $\mathcal{F}$ is some function not depending on the parameters of the system. For example $\mathcal{F}(1) = 3.58$. So opening two similar doors without feedback when p is small takes about 3.58 times more time than opening one door as opposed to the case with feedback, where the factor is only 2.

We also note, that when the two doors are independent and similar, it is quite easy to see that the optimal expected running time is at most $3/p$. As a last interesting point, if $c = 1$ and $p = p_1 = p_2$ approaches zero, then the ratio between the number of 2-knocks and the number of 1-knocks approaches $\frac{1}{2}(1 + \sqrt{5})$, which is the golden ratio. These last two points are also shown in the full version of the paper.

3.4 Examples

For $p_1 = p_2 = 1/2$ and $c = 1$, the lower bound is 5.747. Simulations show that the best algorithm for this case is slightly more than 5.8, so the lower bound is quite tight, but our upper bound is 6.747 which is pretty far. However, the sequence we get from the upper bound proof starts with:

$$1, 1, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 2, 1, 2, 1, 2, \ldots$$

The value it gives is about 5.832, which is very close to optimal. For $p_1 = p_2 = 1/100$ and $c = 1$, the sequence we get is:

$$1^{97}, 2, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 2, 1, 2, 1, 2, 2, 1, 2, 2, 1, 2, 1, 2, \ldots$$

And the value it gives is about 356.756, while the lower bound can be calculated to be approximately 356.754. As we see this is much tighter than the +1 that our upper bound promises.

Abstract

For the game of *Cops and Robbers*, it is known that in 1-cop-win graphs, the cop can capture the robber in $O(n)$ time, and that there exist graphs in which this capture time is tight. When $k \geq 2$, a simple counting argument shows that in k-cop-win graphs, the capture time is at most $O(n^{k+1})$, however, no non-trivial lower bounds were previously known; indeed, in their 2011 book, Bonato and Nowakowski ask whether this upper bound can be improved. In this paper, the question of Bonato and Nowakowski is answered on the negative, proving that the $O(n^{k+1})$ bound is asymptotically tight for any constant $k \geq 2$. This yields a surprising gap in the capture time complexities between the 1-cop and the 2-cop cases.

1 Introduction

The game of *Cops and Robbers* is a perfect information two-player zero-sum game played on an undirected n-vertex graph $G = (V, E)$, where the first player is identified with $k \geq 1$ *cops*, indexed by the integers $0, \ldots, k-1$, and the second player is identified with a single *robber*. In round 0, the cop player chooses the initial (not necessarily distinct) cop locations $c_0(0), \ldots, c_{k-1}(0) \in V$ and following that, the robber player chooses the initial robber location $r(0) \in V$. Then, in round $t = 1, 2, \ldots$, the cop player chooses the next (not necessarily distinct) cop locations $c_0(t), \ldots, c_{k-1}(t) \in V$ under the constraint that $c_i(t) \in N^+(c_i(t-1))$ for every $0 \leq i \leq k-1$, where $N^+(v)$ denotes the neighborhood of vertex v in G including v itself; following that, the robber player chooses the next robber location $r(t) \in N^+(r(t-1))$.

The goal of the cop player is to ensure that $r(t-1) \in \{c_0(t), \ldots, c_{k-1}(t)\}$ for some finite round t, referred to as *capturing* the robber. Conversely, the goal of the robber player is to

avoid being captured indefinitely. Graph G is said to be a *k-cop-win* graph if it admits a cop strategy $\mathcal{S}$ that guarantees capture. The *capture time* of $\mathcal{S}$ is defined to be the maximum number of rounds until capture is achieved, assuming optimal play by the robber. The *capture time* of graph G is then defined to be the minimum capture time of any cop strategy over G (notice that in this definition, it is assumed that k is clear from the context).

Bonato et al. [7] studied the capture time in single cop games and proved that every 1-cop-win graph admits a cop strategy that captures the robber in $\mathcal{O}(n)$ rounds. By considering a path, it is straightforward to verify that this bound is asymptotically tight. A simple configuration-counting argument (see, e.g., [5, 7]) shows that for any constant $k \geq 2$, if G is a k-cop-win graph, then its capture time is $\mathcal{O}(n^{k+1})$. One may suspect that this simple upper bound can be improved as it does not generalize the tight $\mathcal{O}(n)$ bound in the 1-cop setting. Answering an open question from Bonato and Nowakowski's book [9, Chapter 8], the main result of our paper is that perhaps surprisingly, this is not the case.

▶ **Theorem 1.** *There exist a universal positive constant α such that for every $k \geq 2$, there exists an infinite family $\mathcal{G}$ of k-cop-win graphs such that the capture time of any n-vertex graph $G \in \mathcal{G}$ is at least $(n/(\alpha k))^{k+1}$. Moreover, the smallest graph in $\mathcal{G}$ has $n = \mathcal{O}(k^2)$ vertices.*

Notice that for constant $k \geq 2$, this theorem provides an (existential) $\Omega(n^{k+1})$ lower bound on the capture time in k-cop-win graphs. Furthermore, it can be extended to non-constant values of $k = k(n)$ up to the conjectured maximum of $k(n) = \Theta(\sqrt{n})$ (see the related literature discussion), stating that in some k-cop-win graphs, the capture time is exponential in k and stretched exponential in n.

Related Literature

The Cops and Robbers game with a single cop was introduced by Quilliot [21] and independently by Nowakowski and Winkler [19] who also provided a full characterization of 1-cop-win graphs. This was generalized to the multiple cop setting by Aigner and Fromme [2] who defined the *cop number* of graph G to be the minimum number of cops that guarantees that the robber can be captured (that is, the minimum k for which G is a k-cop-win graph). Cast in this terminology, Aigner and Fromme proved that the cop number of any planar graph is at most 3. An upper bound of $\mathcal{O}(r^2)$ on the cop number of graphs excluding K_r as minor was established by Andreae [4]; this result lies at the heart of the recent graph decomposition technique of Abraham et al. [1] for the same family of graphs. For general graphs, the maximum possible cop number is still an open question: the famous Meyniel's Conjecture [14, 6] states that this number is $\Theta(\sqrt{n})$, where the state of the art is that it is bounded between $\Omega(\sqrt{n})$ [20] and $\mathcal{O}(n/2^{(1-o(1))\sqrt{\log n}})$ [17]. Several characterizations of graphs with cop number k are presented in [11].

As mentioned earlier, Bonato et al. [7] established a tight linear bound on the capture time in 1-cop-win graphs. For $k > 1$ cops, non-trivial bounds on the capture time in k-cop-win graphs were obtained mainly in the context of special graph classes, e.g., hypercubes [8] and Cartesian products of trees [18]. To the best of our knowledge, the linear lower bound of [7] is the (asymptotically) best previously known lower bound on the capture time in any class of graphs for any $k \geq 1$.

The capture time has been studied also for variants of the classic Cops and Robbers game. For example, the multiple robber setting was investigated by Förster et al. [13] who showed that the capture time may increase linearly with the number of robbers. Kehagias and Pralat [16] analyzed the expected capture time of a *drunk robber* whose strategy is

simply a random walk on the graph. For a broader overview of the results on the game of Cops and Robbers, the reader is referred to the book of Bonato and Nowakowski [9] and recent surveys [3, 10, 12, 15].

Techniques

Our lower bound proof relies on designing a bad (from the perspective of the cops) graph G that consists of several components, of which each has a different role (see the overview in Section 2.1). Here, we provide a glimpse into this design from an alternative (strictly informal and somewhat inaccurate) angle that may shed additional light on the techniques we use. At the heart of our construction lies the concept of forcing each entity (cop or robber) to follow a designated (non-simple) path in G, where in the scope of this discussion, we assume that every vertex in G admits a self-loop so that these paths may include null moves. Specifically, graph G contains equally long paths $\chi_0, \ldots, \chi_{k-1}$ and ρ, referred to in this discussion as the *canonical paths* of the cops and robber, respectively. The best strategy of the cop player is then to assign one cop, say Cop i, to each path χ_i so that $c_i(t) = \chi_i(t)$ for every t; in response to that, the best strategy of the robber is to play $r(t) = \rho(t)$. This induces a sequence σ of (distinct) configurations and the analysis is completed by showing that σ is sufficiently long and that the robber is captured only at its end.

The most challenging part in the design of such canonical paths is to prove that the aforementioned strategies are indeed optimal. To that end, we show that if the robber deviates from her canonical path at time t, then she is either captured immediately or the game shifts forward to a more advanced configuration $\sigma(t')$ for some $t' > t$. Conversely, if some cop deviates from her canonical path at time t, then the game shifts backwards to a less advanced configuration $\sigma(t')$ for some $t' < t$. The main feature in the latter argument is an *exit component* $\mathcal{X}$; if the robber manages to reach $\mathcal{X}$, then she can force the game to shift backwards to the beginning, i.e., to $\sigma(0)$. This threat is the key ingredient in the analysis of the cop strategy: we construct the cops' components so that they must strictly follow their canonical paths in order to cover all exits in $\mathcal{X}$.

Due to the verbosity of our construction and to the space limitations, we defer all the proofs and the discussion of the case of more than 2 cops to the full version.

Technical Terminology

We call the set $\{c_0(t), c_1(t), \ldots, c_{k-1}(t)\}$, for some t, a *cop combination*. We say that Cop i *covers* node v at time t if $v \in N^+(c_i(t))$. We may omit t if it is clear from the context. We extend this covering notion to more than one cop and more than one node, e.g., we say that *the* cops cover a set of nodes $\{v_1, v_2, \ldots, v_j\}$ if each of the v_i is covered by at least one of the cops. Also, we say that a node is covered, resp. *uncovered*, if at least one cop covers it, resp. if no cop covers it.

2 The Case of 2 Cops

2.1 Overview

In this section, we construct a family $\{G_{\hat{n}}\}_{\hat{n} \geq 3, \hat{n} \equiv 0 \pmod 3}$ of 2-cop-win graphs, where $\hat{n} \in \Theta(n)$.[1] Then, we show that the capture time for 2 cops in $G_{\hat{n}}$ is $\Omega(n^3)$ by giving an

[1] Throughout the paper, we denote the number of nodes of a graph by n.

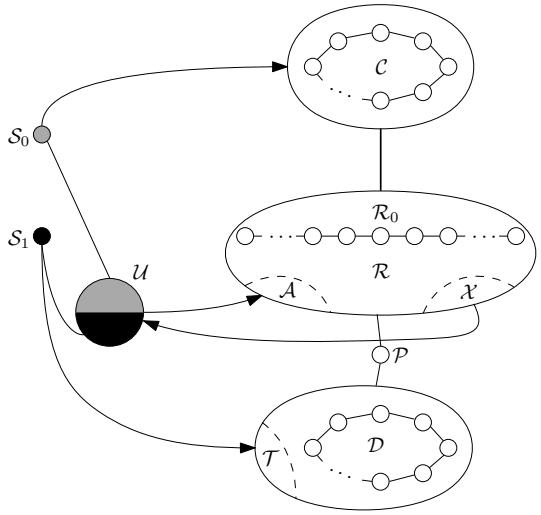

Figure 1 The graph $G_{\hat{n}}$ with its different components.

explicit strategy for the robber that achieves this capture time against any cop strategy. We conclude by presenting a cop strategy for 2 cops that achieves a capture time of $\mathcal{O}(n^3)$ against any robber strategy, which also serves as a proof that the graphs are indeed 2-cop-win. The other reason for explicitly specifying such a cop strategy (which *must* exist in 2-cop-win graphs, by the aforementioned simple configuration-counting argument) is that it forms the basis for a generalized cop strategy in the case of $k \geq 2$ cops. For a simplified overview of our graph construction, please refer to Figure 1.

The general idea behind the graph construction and the specified strategies for the cops and the robber is as follows: Our graph $G_{\hat{n}}$ contains a $\mathcal{U}$ component, where the robber cannot be captured, simply because each node in $\mathcal{U}$ has enough neighbors so that 2 cops cannot cover all of these neighbors simultaneously. Moreover, the robber can always stay in $\mathcal{U}$ (because each node in $\mathcal{U}$ has enough neighbors *in* $\mathcal{U}$) except if the cops go to two special nodes $\mathcal{S}_0$ and $\mathcal{S}_1$ which together cover all of $\mathcal{U}$.

When the robber is thereby flushed out of $\mathcal{U}$, she has to go to the $\mathcal{R}$ component of the graph. Note that the nodes of $\mathcal{R}$ induce a simple path on $G_{\hat{n}}$ and that after being flushed out of $\mathcal{U}$, the robber is located in the middle of this path. Now, the cops will continuously prevent the robber from escaping $\mathcal{R}$ and slowly force the robber to one end of the path where they will finally capture her. In order for this to take a long time, each node in $\mathcal{R}$ is connected to a set of so-called *exits* which are nodes that together form the $\mathcal{X}$ component of the graph. If the robber should manage to get to some exit, then she will be able to go back to her preferred $\mathcal{U}$ component, unless the cops go again to the special $\mathcal{S}_0$ and $\mathcal{S}_1$ nodes, in which case the robber can go back to the middle of the $\mathcal{R}$ path and thereby revert to a previous configuration. Hence, in order to capture the robber, the cops have to continuously cover these exits.

Unfortunately for the cops, there are only a few cop combinations that actually cover all exits of a node in $\mathcal{R}$. Moreover, only some of these cop combinations are *proper* in the sense that they also prevent the robber from moving back on the $\mathcal{R}$ path towards the middle which is essential for the cops in order to capture the robber. These proper *exit-covering* cop combinations are described in the following. For an illustration of the underlying graph structure, we refer to Figure 2.

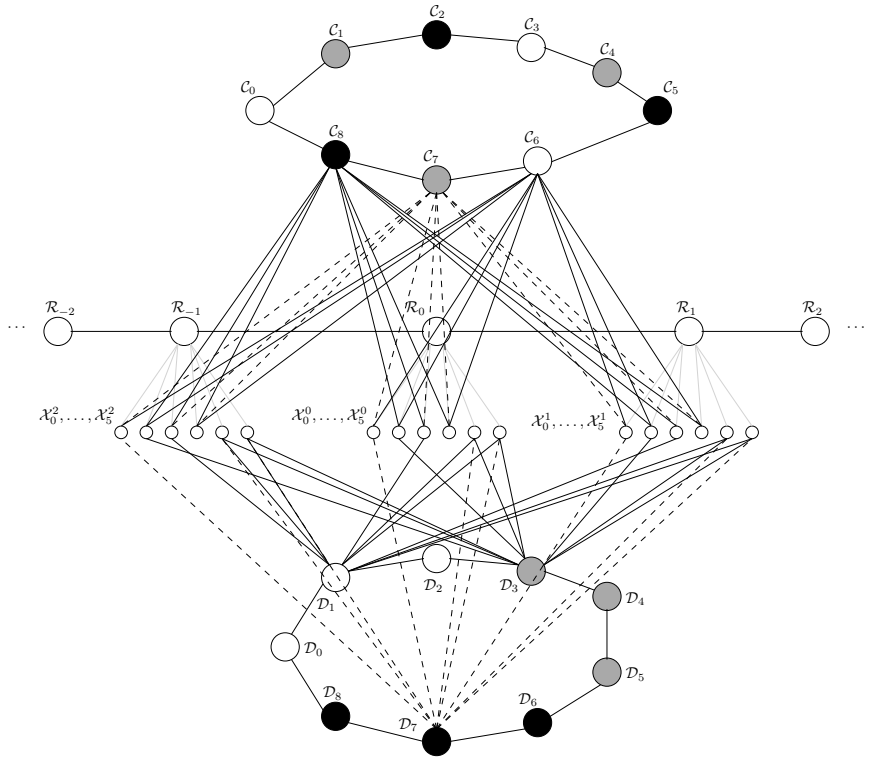

Figure 2 A part of the structure of $G_{\hat{n}}$ around the $\mathcal{X}$ nodes. A $\mathcal{C}$ node and a $\mathcal{D}$ node together cover the exits of an $\mathcal{R}$ node if and only if they have the same color.

One cop, say Cop 0, has to be in the $\mathcal{C}$ component of $G_{\hat{n}}$ and the other one (Cop 1) in the $\mathcal{D}$ component. The nodes in the $\mathcal{C}$ (resp., $\mathcal{D}$) component induce a simple cycle on $G_{\hat{n}}$. Assume for simplicity that the number of nodes in these two cycles are both multiples of 3. Now, we can imagine that the nodes in the $\mathcal{C}$ cycle are consecutively colored $0, 1, 2, 0, 1, 2, \ldots$ and that the nodes in the $\mathcal{D}$ cycle are colored $0, \ldots, 0, 1, \ldots, 1, 2, \ldots, 2$, resulting in three equally-sized monochromatic blocks. Now, the nodes in $\mathcal{C}$ and $\mathcal{D}$ are connected to the nodes in $\mathcal{X}$ in so that Cop 0 (in $\mathcal{C}$) and Cop 1 (in $\mathcal{D}$) cover all exits of an $\mathcal{R}$ node if and only if the nodes the two cops are occupying have the same color. Thus, if Cop 0 wants to move, e.g., clockwise, in her $\mathcal{C}$ cycle, then between any two consecutive steps, she has to wait for Cop 1 to travel roughly a third of her $\mathcal{D}$ cycle.

Similarly, using an independent color pallet, we color the nodes along the $\mathcal{R}$ path $3, 4, 5, 3, 4, 5, \ldots$ and color the nodes along the $\mathcal{C}$ cycle $3, \ldots, 3, 4, \ldots, 4, 5, \ldots, 5$. To prevent the robber from moving back towards the middle of her $\mathcal{R}$ path, we construct $G_{\hat{n}}$ so that a $\mathcal{C}$ node covers an $\mathcal{R}$ node if and only if they do *not* have the same color. Thus, if Cop 0 proceeds along her $\mathcal{C}$ cycle, then as soon as the color of the $\mathcal{C}$ node changes, the robber is forced to move one step forward along the $\mathcal{R}$ path. This accounts for Cop 0 traversing roughly a third of the $\mathcal{C}$ cycle for each step of the robber along the $\mathcal{R}$ path. The direction of the robber's movement (towards either end of the $\mathcal{R}$ path) is determined by the direction (clockwise or counterclockwise) of the movement of Cop 0 along the $\mathcal{C}$ cycle. We refer to Figure 3 for an illustration of how the robber is pushed along the $\mathcal{R}$ by a cop residing in $\mathcal{C}$.

Now, we design the graph $G_{\hat{n}}$ so that the $\mathcal{C}$, $\mathcal{D}$, and $\mathcal{R}$ components consist of roughly $\hat{n}$ nodes. Thus, the robber takes $\Omega(\hat{n})$ steps until she is captured, for each of her steps Cop 0

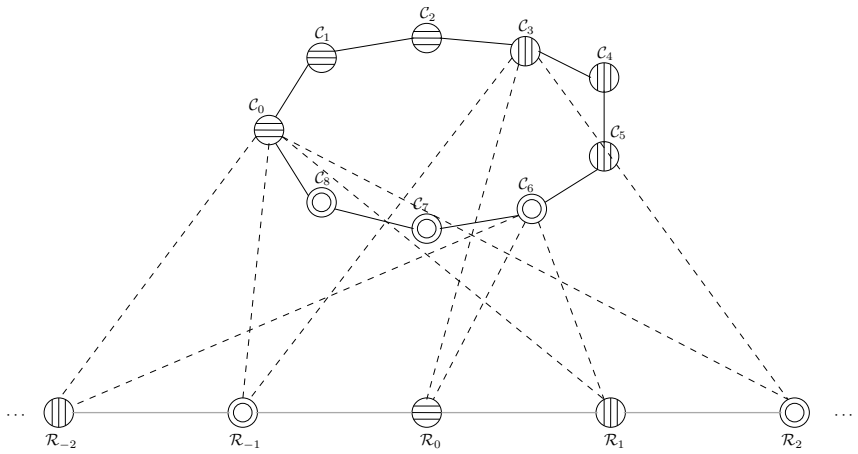

Figure 3 The edge structure between the $\mathcal{C}$ nodes and the $\mathcal{R}$ nodes. If a cop is in a $\mathcal{C}$ node and the robber in an $\mathcal{R}$ node, then the robber has to make sure that that these two nodes have the same color in order to avoid capture in the next move. By circling clockwise in $\mathcal{C}$, the cop can force the robber towards one end of the $\mathcal{R}$ path, by circling counterclockwise towards the other.

has to take $\Omega(\hat{n})$ steps, and for each step of Cop 0, Cop 1 has to take $\Omega(\hat{n})$ steps, resulting in a total capture time of $\Omega(\hat{n}^3)$. Since every component of the $G_{\hat{n}}$ except $\mathcal{R}$, $\mathcal{C}$ and $\mathcal{D}$ is of constant size, $\hat{n}$ is linear in the number n of nodes. Hence, we obtain a capture time of $\Omega(n^3)$ for the graph class $\{G_{\hat{n}}\}_{\hat{n}\geq 3,\hat{n}\equiv 0 \pmod 3}$.

Before proceeding to the exact details of the graph construction, four remarks are in order. Firstly, when the robber is flushed out of $\mathcal{U}$ to $\mathcal{R}$, there is an intermediate step between leaving $\mathcal{U}$ and arriving in $\mathcal{R}$ for technical reasons: Flushed out of $\mathcal{U}$, the robber actually has to go to a graph component called $\mathcal{A}$. Then, one cop moves to another graph component denoted $\mathcal{T}$ from which she covers all of $\mathcal{A}$ while ensuring that all nodes in $\mathcal{U}$ the robber could go to are covered. Thus, the robber is flushed out of $\mathcal{A}$ and is forced to go to $\mathcal{R}$ so that we can proceed as explained above.

Secondly, since Cop 0 has to be able to cover nodes from $\mathcal{R}$ when she is in $\mathcal{C}$, there have to be edges between $\mathcal{R}$ and $\mathcal{C}$. To prevent the robber from escaping $\mathcal{R}$ by going to a node in $\mathcal{C}$ via one of these edges, we augment the graph with a special $\mathcal{P}$ node. If, after the robber indeed moves to the $\mathcal{C}$ component, Cop 1 moves to $\mathcal{P}$ and Cop 0 moves to $\mathcal{S}_0$, then together they cover all $\mathcal{C}$ nodes and all their neighbors, ensuring that the robber will be captured in the next round.

Thirdly, the robber does not have to start in $\mathcal{U}$, but in fact it is best for her if she does (in the sense of increasing the capture time against the best cop strategy), provided that she cannot be captured immediately. In turn, this means that the cops should start in $\mathcal{S}_0$ and $\mathcal{S}_1$ in order to force the robber to start elsewhere. Even if the robber starts elsewhere, the cop strategy explained above forces the robber to the $\mathcal{R}$ component. Moreover, the robber can simply start in the middle of the $\mathcal{R}$ path and the cops cannot avoid having to go through the exit-covering routine explained above.

Fourthly, while the cop strategy explained above chases the robber from the middle of the $\mathcal{R}$ path to one of its ends, for simplicity, we will formally present a slightly simplified version where the end of the path the robber is chased to is fixed in advance (so the robber will be chased from one end of the path to the other end in the worst case for the cops).

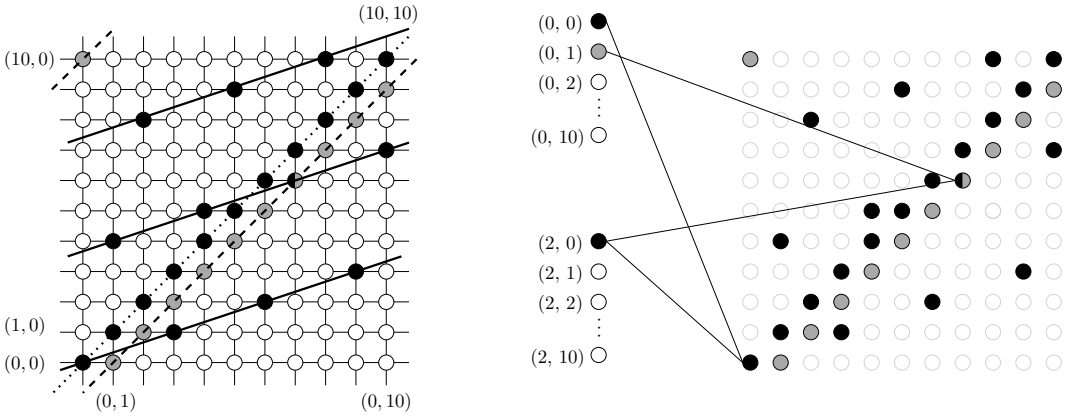

Figure 4 The construction of $\mathcal{U}$. On the left side, we see the 11×11 grid constituting $\mathcal{E}$ and three example lines $\mathcal{L}_{0,0}$, $\mathcal{L}_{0,1}$ and $\mathcal{L}_{2,0}$ from $\mathcal{L}$. On the right side, we see the nodes of the bipartite graph $G_{\mathcal{E},\mathcal{L}}$ where the left-hand column of nodes constitutes (a part of) one side of the bipartition, $\mathcal{L}$, and the right-hand grid the other side, $\mathcal{E}$. The edges between $\mathcal{E}$ and $\mathcal{L}$ are determined by the incidence relation of the nodes and lines in the left-hand 11×11 grid.

2.2 The Graph Construction

As explained above, the graphs $G_{\hat{n}}$ we are about to construct contain a component $\mathcal{U}$ in which the robber cannot be captured and from which the robber can only be flushed out by a specific cop combination outside of $\mathcal{U}$. Hence, the subgraph of any $G_{\hat{n}}$ induced by (the respective) $\mathcal{U}$ cannot be a 2-cop-win graph. As we want to generalize our graph construction to the case of more than 2 cops, we thus need a way to construct a graph where k cops cannot capture the robber. For this, inspired by the use of projective planes for constructing graphs with high cop numbers in [20], we will use incidence graphs of objects resembling affine planes. An explicit construction (for the case of 2 cops) is given in the following. For an illustration of the construction, we refer to Figure 4.

Let $\mathcal{E} = \{\mathcal{E}_{i,j} \mid 0 \leq i \leq 10 \wedge 0 \leq j \leq 10\}$ be a set of *elements* which we can imagine as arrayed in an 11×11 grid. Let $\mathcal{L} = \{\mathcal{L}_{i,j} \mid 0 \leq i \leq 9 \wedge 0 \leq j \leq 10\}$ be a set of *lines* where each $\mathcal{L}_{i,j}$ is defined as $\mathcal{L}_{i,j} = \{\mathcal{E}_{h,h(i+1)+j \pmod{11}} \mid 0 \leq h \leq 10\}$. Thus, each line $\mathcal{L}_{i,j}$ may be considered as a "line modulo 11" in our grid which goes through the element $\mathcal{E}_{0,j}$ and whose slope is determined by the parameter i (or more precisely $i+1$).

Now consider the *incidence graph* $G_{\mathcal{E},\mathcal{L}}$ for $\mathcal{E}$ and $\mathcal{L}$ which is defined as follows: The nodes of $G_{\mathcal{E},\mathcal{L}}$ are exactly the elements and lines defined above, i.e., $V(G_{\mathcal{E},\mathcal{L}}) = \mathcal{E} \cup \mathcal{L}$, and there is an edge between some node $\mathcal{E}_{i,j}$ and some node $\mathcal{L}_{i',j'}$ if and only if $\mathcal{E}_{i,j}$ is contained in the set $\mathcal{L}_{i',j'}$ (i.e., if and only if $\mathcal{E}_{i,j}$ lies on the line $\mathcal{L}_{i',j'}$). There are no other edges, hence $G_{\mathcal{E},\mathcal{L}}$ is bipartite where one side of the bipartition is given by $\mathcal{E}$ and the other side by $\mathcal{L}$.

▶ **Lemma 2.** *In $G_{\mathcal{E},\mathcal{L}}$, any two nodes in $\mathcal{E}$ have at most one common neighbor in $\mathcal{L}$. Also, any two nodes in $\mathcal{L}$ have at most one common neighbor in $\mathcal{E}$.*

▶ **Lemma 3.** *Let $i \in \{0, \ldots, 10\}$ be fixed. Any node from $\mathcal{L}$ has exactly one neighbor in $G_{\mathcal{E},\mathcal{L}}$ of the form $\mathcal{E}_{i,j}$ and exactly one neighbor in $G_{\mathcal{E},\mathcal{L}}$ of the form $\mathcal{E}_{j,i}$.*

▶ **Lemma 4.** *Let $i \in \{0, \ldots, 9\}$ be fixed. Any node from $\mathcal{E}$ has exactly one neighbor in $G_{\mathcal{E},\mathcal{L}}$ of the form $\mathcal{L}_{i,j}$.*

For the construction of $G_{\hat{n}}$, we will *borrow* nodes from $G_{\mathcal{E},\mathcal{L}}$ and we will assume that the borrowed nodes take along their relationship concerning edges between them, i.e., there is an

edge between two borrowed nodes in our graph construction if and only if there is an edge between those two nodes in $G_{\mathcal{E},\mathcal{L}}$.

We construct $G_{\hat{n}}$ as given in the following. The vertex set of $G_{\hat{n}}$ is defined as the (disjoint) union of smaller vertex sets that constitute different parts of the graph with different purposes:

$$
\begin{aligned}
V(G_{\hat{n}}) &= \mathcal{E} \cup \mathcal{L}^* \cup \mathcal{S} \cup \mathcal{A} \cup \mathcal{T} \cup \mathcal{R} \cup \mathcal{C} \cup \mathcal{D} \cup \{\mathcal{P}\} \cup \mathcal{X}, \text{ where} \\
\mathcal{L}^* &= \{\mathcal{L}_{i,j} \mid 0 \leq i \leq 3 \wedge 0 \leq j \leq 10\} \\
\mathcal{S} &= \{\mathcal{S}_0, \mathcal{S}_1\} \\
\mathcal{A} &= \{\mathcal{A}_0, \ldots, \mathcal{A}_3\} \\
\mathcal{T} &= \{\mathcal{T}_0, \ldots, \mathcal{T}_3\} \\
\mathcal{R} &= \{\mathcal{R}_{-\hat{n}}, \ldots, \mathcal{R}_{\hat{n}}\} \\
\mathcal{C} &= \{\mathcal{C}_0, \ldots, \mathcal{C}_{\hat{n}-1}\} \\
\mathcal{D} &= \{\mathcal{D}_0, \ldots, \mathcal{D}_{\hat{n}-1}\} \\
\mathcal{X} &= \mathcal{X}^0 \cup \mathcal{X}^1 \cup \mathcal{X}^2 \\
\mathcal{X}^j &= \{\mathcal{X}^j_0, \ldots, \mathcal{X}^j_5\} \text{ for all } 0 \leq j \leq 2
\end{aligned}
$$

The edges of $G_{\hat{n}}$ are specified in Table 1. Moreover, we set $\mathcal{U} = \mathcal{E} \cup \mathcal{L}^*$. Furthermore, we call the nodes in $\mathcal{X}$ *exits*, and for each node $\mathcal{R}_i \in \mathcal{R}$ we call the nodes from $\mathcal{X}$, that are connected to $\mathcal{R}_i$, the *exits of* $\mathcal{R}_i$.

The node subsets $\mathcal{E}$ and $\mathcal{L}^*$ are borrowed from $G_{\mathcal{E},\mathcal{L}}$, but also the (renamed) nodes in $\mathcal{X}$ are borrowed from $G_{\mathcal{E},\mathcal{L}}$: We consider $\mathcal{X}$ as a subset of $\mathcal{L} \setminus \mathcal{L}^*$. To ensure that no node in $\mathcal{E}$ covers too many exits of some $\mathcal{R}$ node, the exits of any $\mathcal{R}$ node are borrowed (disjointly) from a set of $\mathcal{L} \setminus \mathcal{L}^*$ nodes of the same slope. More precisely,

$$
\begin{aligned}
&\mathcal{X}^0 \text{ is borrowed from } \{\mathcal{L}_{4,j} \mid 0 \leq j \leq 10\} \text{ ,} \\
&\mathcal{X}^1 \text{ is borrowed from } \{\mathcal{L}_{5,j} \mid 0 \leq j \leq 10\} \text{ ,} \\
&\mathcal{X}^2 \text{ is borrowed from } \{\mathcal{L}_{6,j} \mid 0 \leq j \leq 10\} \text{ .}
\end{aligned}
$$

As long as the above conditions are met, we do not care about the explicit choice of $\mathcal{X}$ as a subset of $\mathcal{L} \setminus \mathcal{L}^*$. We obtain the following corollary from Lemma 2:

▶ **Corollary 5.** *Any two nodes in $\mathcal{E}$ have at most one common neighbor in $\mathcal{L}^*$. Any two nodes in $\mathcal{L}^* \cup \mathcal{X}$ have at most one common neighbor in $\mathcal{E}$.*

2.3 Observations

Before specifying asymptotically best strategies for the robber and the cops in $G_{\hat{n}}$, we gather some useful observations about the structure of $G_{\hat{n}}$. In particular, we examine which cop combinations cover certain neighbors of certain nodes. We start by showing that the cops have to be in $\mathcal{S}_0$ and $\mathcal{S}_1$ in order to flush the robber out of $\mathcal{U}$.

▶ **Lemma 6.** *Consider any $u \in \mathcal{U}$. The only cop combination not containing u that covers all neighbors of u in $\mathcal{U}$ is $\{\mathcal{S}_0, \mathcal{S}_1\}$.*

We proceed by showing that if the robber has been flushed out of $\mathcal{U}$ to some node $\mathcal{A}_i$, then the cops can only make progress by going to $\{\mathcal{S}_0, \mathcal{T}_i\}$ because otherwise the robber can go back to $\mathcal{U}$ (or there is no progress if the cops simply stay in $\{\mathcal{S}_0, \mathcal{S}_1\}$).

▶ **Lemma 7.** *Consider any $\mathcal{A}_i$. The only cop combinations not containing $\mathcal{A}_i$ that cover all neighbors of $\mathcal{A}_i$ in $\mathcal{U}$ are $\{\mathcal{S}_0, \mathcal{S}_1\}$ and $\{\mathcal{S}_0, \mathcal{T}_i\}$.*

Table 1 A listing of the edges of $G_{\hat{n}}$. In each block, the nodes listed in the right column are the neighboring nodes of the node listed in the left column. For simplicity, we omit a separate block for specifying the neighbors of the $\mathcal{X}$ nodes. They can be inferred from the other blocks. The $\mathcal{X}$ nodes do not have any edges connecting them to each other since they are borrowed from the $\mathcal{L}$ part of $G_{\mathcal{E},\mathcal{L}}$.

Node	Neighbors
$\mathcal{E}_{i,j}$	$\mathcal{L}^*$ nodes as determined by $G_{\mathcal{E},\mathcal{L}}$ $\mathcal{S}_i \pmod 2$ $\mathcal{A}_j \pmod 4$ $\mathcal{T}_j \pmod 4$ if $i \pmod 2 = 1$ $\mathcal{X}$ nodes as determined by $G_{\mathcal{E},\mathcal{L}}$
$\mathcal{L}_{i,j}$	$\mathcal{E}$ nodes as determined by $G_{\mathcal{E},\mathcal{L}}$ $\mathcal{S}_i \pmod 2$ $\mathcal{A}_i \pmod 4$ $\mathcal{T}_i \pmod 4$

Node	Neighbors
$\mathcal{S}_0$	$\mathcal{C}_i$ for all i $\mathcal{X}_i^j$, where $j \in \{0,1,2\}$ and $i \in \{0,1,2\}$ every $\mathcal{E}_{i,j}$ with $i \pmod 2 = 0$ every $\mathcal{L}_{i,j}$ with $i \pmod 2 = 0$
$\mathcal{S}_1$	$\mathcal{T}_i$ for all i $\mathcal{X}_i^j$, where $j \in \{0,1,2\}$ and $i \in \{3,4,5\}$ every $\mathcal{E}_{i,j}$ with $i \pmod 2 = 1$ every $\mathcal{L}_{i,j}$ with $i \pmod 2 = 1$
$\mathcal{A}_i$	$\mathcal{T}_j$ for all j $\mathcal{R}_0$ $\mathcal{D}_j$ for all j $\mathcal{E}_{j,h}$ for all $h \pmod 4 = i$ $\mathcal{L}_{j,h}$ for all $j \pmod 4 = i$
$\mathcal{T}_i$	$\mathcal{S}_1$ $\mathcal{A}_j$ for all j $\mathcal{T}_j$ for all $j \neq i$ $\mathcal{D}_j$ for all j $\mathcal{P}$ $\mathcal{X}_h^j$, where $j \in \{0,1,2\}$ and $h \in \{3,4,5\}$ $\mathcal{E}_{j,h}$ for all $j \pmod 2 = 1$ and $h \pmod 4 = i$ $\mathcal{L}_{j,h}$ for all $j \pmod 4 = i$

Node	Neighbors
$\mathcal{R}_i$	$\mathcal{A}_j$ for all j if $i = 0$ $\mathcal{R}_j$ for $j = i-1$ and $j = i+1$ $\mathcal{C}_j$ for all $0 \le j \le \hat{n}/3$ if $i \pmod 3 = 0$ $\mathcal{C}_j$ for all $\hat{n}/3 \le j \le 2\hat{n}/3$ if $i \pmod 3 = 1$ $\mathcal{C}_0$ and $\mathcal{C}_j$ for all $2\hat{n}/3 \le j \le \hat{n}-1$ if $i \pmod 3 = 2$ $\mathcal{P}$ $\mathcal{X}_h^j$ where $j = i \pmod 3$ and $h \in \{0,1,2,3,4,5\}$
$\mathcal{C}_i$	$\mathcal{S}_0$ $\mathcal{R}_j$ for all $j \pmod 3 = 0$ if $0 \le i \le \hat{n}/3$ $\mathcal{R}_j$ for all $j \pmod 3 = 1$ if $\hat{n}/3 \le i \le 2\hat{n}/3$ $\mathcal{R}_j$ for all $j \pmod 3 = 2$ if $i = 0$ or $2\hat{n}/3 \le i \le \hat{n}-1$ $\mathcal{C}_j$ for $j \equiv i-1 \pmod{\hat{n}}$ and $j \equiv i+1 \pmod{\hat{n}}$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{0,1,3\}$ if $i \pmod 3 = 0$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{0,2,3\}$ if $i \pmod 3 = 1$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{1,2,3\}$ if $i \pmod 3 = 2$
$\mathcal{D}_i$	$\mathcal{A}_j$ for all j $\mathcal{T}_j$ for all j $\mathcal{D}_j$ for $j \equiv i-1 \pmod{\hat{n}}$ and $j \equiv i+1 \pmod{\hat{n}}$ $\mathcal{P}$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{2,4,5\}$ if $0 \le i \le \hat{n}/3-1$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{1,4,5\}$ if $\hat{n}/3 \le i \le 2\hat{n}/3-1$ $\mathcal{X}_h^j$ where $j \in \{0,1,2\}$ and $h \in \{0,4,5\}$ if $2\hat{n}/3 \le i \le \hat{n}-1$
$\mathcal{P}$	$\mathcal{T}_i$ for all i $\mathcal{R}_i$ for all i $\mathcal{D}_i$ for all i $\mathcal{X}_i^j$ where $j \in \{0,1,2\}$ and $i = 3$

The following lemma shows that if the cops allow the robber to go to an exit of some $\mathcal{R}$ node, then they have to go back to $\{\mathcal{S}_0, \mathcal{S}_1\}$ in order to prevent the robber from going to $\mathcal{U}$.

▶ **Lemma 8.** *Consider any $\mathcal{X}_i^j$. The only cop combination not containing $\mathcal{X}_i^j$ that covers all neighbors of $\mathcal{X}_i^j$ in $\mathcal{U}$ is $\{\mathcal{S}_0, \mathcal{S}_1\}$.*

As Lemma 8 already indicates, the cops do not want the robber to be able to go to an exit from an $\mathcal{R}$ node. The next lemma characterizes the cop combinations from where they can prevent the robber from doing that.

▶ **Lemma 9.** *Consider any $\mathcal{R}_i$. The only cop combinations not containing any $\mathcal{R}_j$ with $j \equiv i \pmod 3$ that cover all exits of $\mathcal{R}_i$ are $\{\mathcal{S}_0, \mathcal{S}_1\}$, $\{\mathcal{S}_0, \mathcal{T}_j\}$ for any j, and $\{\mathcal{C}_j, \mathcal{D}_h\}$ for any pair (j,h) satisfying one of the following three conditions:*

1. $j \pmod 3 = 0$ *and* $0 \le h \le \hat{n}/3 - 1$,
2. $j \pmod 3 = 1$ *and* $\hat{n}/3 \le h \le 2\hat{n}/3 - 1$,
3. $j \pmod 3 = 2$ *and* $2\hat{n}/3 \le h \le \hat{n} - 1$.

Observe that the cop combinations from Lemma 9 are independent of the choice of the considered $\mathcal{R}_i$ which implies that these cop combinations cover all nodes in $\mathcal{X}$. We call such

Table 2 The robber's strategy.

$\{c_0(t), c_1(t)\}$	$r(t-1)$	$r(t)$
$\neq \{\mathcal{S}_0, \mathcal{S}_1\}$	some node in $\mathcal{U}$	some uncovered node in $\mathcal{U}$

not covering all exits of $\mathcal{R}_i$	$\mathcal{R}_i$	some uncovered exit of $\mathcal{R}_i$
covering all exits of $\mathcal{R}_i$	$\mathcal{R}_i$	the uncovered node from $\{\mathcal{R}_{i-1}, \mathcal{R}_i, \mathcal{R}_{i+1}\}$ with smallest absolute index; if all are covered, stay in $\mathcal{R}_i$
$\neq \{\mathcal{S}_0, \mathcal{S}_1\}$	$\mathcal{X}_i^j$	some uncovered node in $\mathcal{U}$
$\{\mathcal{S}_0, \mathcal{S}_1\}$	$\mathcal{X}_i^j$	some node from $\{\mathcal{R}_{-1}, \mathcal{R}_0, \mathcal{R}_1\}$

a cop combination *exit-blocking*. Furthermore, we call an exit-blocking cop combination *proper* if it does not contain a node from $\mathcal{S}$ (i.e., it consists of a node from $\mathcal{C}$ and a node from $\mathcal{D}$). Lastly, we call a proper exit-blocking cop combination $\{\mathcal{C}_i, \mathcal{D}_j\}$ *forcing* if there exist $h, h' \in \{-1, 0, 1\}$, $h \neq h'$, such that the cops cover all $\mathcal{R}_{h \pmod 3}$ and all $\mathcal{R}_{h' \pmod 3}$. A close look at the construction of $G_{\hat{n}}$ shows that a proper exit-blocking cop combination $\{\mathcal{C}_i, \mathcal{D}_j\}$ is forcing if and only if $i \in \{0, \hat{n}/3, 2\hat{n}/3\}$.

Proper exit-blocking cop combinations prevent the robber from going back (too much) towards the middle of the $\mathcal{R}$ path since they contain a $\mathcal{C}$ node which by its nature is connected to every third $\mathcal{R}$ node. Thus, in order to be able to chase the robber towards one end of the $\mathcal{R}$ path, the cops have to stay in proper exit-blocking cop combinations.

The $\mathcal{C}$ node in a forcing proper exit-covering cop combination covers more $\mathcal{R}$ nodes than the $\mathcal{C}$ node in a usual proper exit-covering cop combination and thereby forces the robber to move one step towards the end of her $\mathcal{R}$ path. In order to chase the robber another step, the cops have to go to a forcing proper exit-covering cop combination containing a different $\mathcal{C}$ node. The following lemma shows a lower bound on the time it takes the cops to go from one forcing proper exit-covering cop combination to another with a different $\mathcal{C}$ node, while using only proper exit-covering cop combinations on the way. Refer to Figures 2 and 3 for illustrations of the underlying idea.

▶ **Lemma 10.** *Let* $(\{\mathcal{C}_i, \mathcal{D}_j\} = \{c_0(t), c_1(t)\}, \{c_0(t+1), c_1(t+1)\}, \ldots, \{c_0(t+h), c_1(t+h)\} = \{\mathcal{C}_{i'}, \mathcal{D}_{j'}\})$ *be a sequence of proper exit-blocking cop combinations describing the combined movement of the two cops from time* t *to time* $t+h$*. If* $\{\mathcal{C}_i, \mathcal{D}_j\}$ *and* $\{\mathcal{C}_{i'}, \mathcal{D}_{j'}\}$ *are forcing and* $i \neq i'$*, then* $h \geq \hat{n}/3 \cdot (\hat{n}/3 - 1) \in \Omega(\hat{n}^2)$.

2.4 The Robber's Strategy

Here, we explicitly specify a strategy for the robber that ensures that 2 cops need time $\Omega(n^3)$ to capture the robber in $G_{\hat{n}}$:

If the cops are in $\mathcal{S}_0$ and $\mathcal{S}_1$ in round 0, then the robber starts in $\mathcal{R}_0$, otherwise the robber starts in some node in $\mathcal{U}$ that is not covered by any of the cops (which exists by Lemma 6). Depending on where the cops are, the robber moves as specified in Table 2 (as long as she is not captured yet).

We show now that the specified strategy is well-defined, i.e., that the robber can perform any step in the strategy and that no other situations than the specified ones can occur if the robber follows the strategy. For the first part, we go through the table line by line:

Table 3 The cops' strategy.

$r(t-1)$	$(c_0(t-1), c_1(t-1))$	$(c_0(t), c_1(t))$
$\mathcal{A}_i$	$(\mathcal{S}_0, \mathcal{S}_1)$	$(\mathcal{S}_0, \mathcal{T}_i)$
$\neq \mathcal{A}_i$ for all i	$(\mathcal{S}_0, \mathcal{S}_1)$	$(\mathcal{S}_0, \mathcal{T}_j)$ for some j
arbitrary	$(\mathcal{S}_0, \mathcal{T}_i)$	$(\mathcal{C}_0, \mathcal{D}_0)$
$\neq \mathcal{C}_h$ for all h	$(\mathcal{C}_i, \mathcal{D}_j)$	$\left(\mathcal{C}_{i+1 \pmod{\hat{n}}}, \mathcal{D}_{j+1 \pmod{\hat{n}}}\right)$ if this covers all nodes in $\mathcal{X}$ $\left(\mathcal{C}_i, \mathcal{D}_{j+1 \pmod{\hat{n}}}\right)$ otherwise
$\mathcal{C}_h$	$(\mathcal{C}_i, \mathcal{D}_j)$	$(\mathcal{S}_0, \mathcal{P})$

By Lemma 6, if the robber is in some node $u \in \mathcal{U}$, then she can always go to some uncovered node in $\mathcal{U}$, provided the cops are not in $\mathcal{S}_0$ and $\mathcal{S}_1$. She can also go from u to some node in $\mathcal{A}$ since any node in $\mathcal{U}$ has some node in $\mathcal{A}$ as a neighbor, by the construction of $G_{\hat{n}}$. Similarly, the robber can go from any node in $\mathcal{A}$ to $\mathcal{R}_0$. By Lemma 7, if the robber is in some node $\mathcal{A}_i$, then she can always go to some uncovered node in $\mathcal{U}$, provided the cops are not in $\mathcal{S}_0$ and $\mathcal{S}_1$ or in $\mathcal{S}_0$ and $\mathcal{T}_i$. The instructions where to go to from $\mathcal{R}_i$ are trivially satisfiable. From $\mathcal{X}_i^j$, the robber can always go to some uncovered node in $\mathcal{U}$ if the cops are not in $\mathcal{S}_0$ and $\mathcal{S}_1$, by Lemma 8. She can also go to either $\mathcal{R}_{-1}$, $\mathcal{R}_0$ or $\mathcal{R}_1$ from $\mathcal{X}_i^j$ since each $\mathcal{X}_i^j$ is connected to exactly one of those three $\mathcal{R}$ nodes, by the construction of $G_{\hat{n}}$.

Moreover since the robber starts in a node in $\mathcal{U}$ or $\mathcal{R}$, Table 2 covers all situations where the robber is in some node in $\mathcal{U}$, $\mathcal{A}$, $\mathcal{R}$ or $\mathcal{X}$, and each instruction ends with the robber being in one of those nodes, the presented strategy specifies what the robber has to do for every possibly occurring situation.

2.5 The Cops' Strategy

Now, we explicitly specify a strategy for the cops that ensures that the robber is captured in time $\mathcal{O}(n^3)$ in $G_{\hat{n}}$:

Cop 0 starts in $\mathcal{S}_0$ and Cop 1 starts in $\mathcal{S}_1$ in round 0. Depending on where the robber is, the cops move as specified in Table 3. There is one exception however: If a cop can capture the robber immediately, then she does so, overriding any possible instruction from the table.

We show now that the specified strategy is well-defined, i.e., that the cops can actually perform any step in the strategy and that no other situations than the specified ones can actually occur[2] if the cops follow the strategy:

The construction of $G_{\hat{n}}$ ensures that the cops can actually move from the cop combinations at time $t-1$ given in Table 3 to the cop combinations at time t. Since the cops start in $\mathcal{S}_0$ and $\mathcal{S}_1$, the only thing that is left to show is that from $(\mathcal{S}_0, \mathcal{P})$ (which is the only output combination that is not dealt with on the input side) the cops can capture the robber at time $t+1$, provided that the robber is in some $\mathcal{C}_h$ at time $t-1$. For that, it is sufficient to observe that any neighbor of $\mathcal{C}_h$, and $\mathcal{C}_h$ itself, is covered by $\mathcal{S}_0$ or $\mathcal{P}$.

2.6 A Lower Bound for the Robber's Strategy

Here, we show that the strategy for the robber specified in Table 2 ensures that the cops need time $\Omega(n^3)$ to capture the robber in $G_{\hat{n}}$. For convenience, we assume throughout the

[2] More precisely, if a situation occurs that is not specified in Table 3, then the cops can capture the robber immediately.

following lower bound considerations that if a cop can capture the robber immediately, then she does so. This certainly cannot worsen any strategy the cops follow.

We start by observing that the set of $\mathcal{R}$ nodes can be partitioned into three roughly equally-sized sets such that the $\mathcal{R}$ nodes in each such set have exactly the same exits. As the following lemma shows, if the robber is in an $\mathcal{R}$ node, then she does not need to worry about a cop being in another $\mathcal{R}$ node that has (and therefore covers) the same exits, since such a situation cannot occur if the robber follows the specified strategy.

We proceed by determining the nodes the robber can be captured in. Then, using Lemma 11 and Lemma 12, we give a lower bound on the capture time of $G_{\hat{n}}$.

▶ **Lemma 11.** *If the robber follows the strategy specified in Section 2.4, then the following holds: If the robber is in some node $\mathcal{R}_i$ at time t and is not captured at time $t+1$, then neither of the 2 cops can be in some node $\mathcal{R}_j$ with $j \equiv i \pmod 3$ at time $t+1$.*

▶ **Lemma 12.** *If the robber follows the strategy specified in Section 2.4, then she can only be captured in $\mathcal{R}_{\hat{n}}$ or $\mathcal{R}_{-\hat{n}}$.*

▶ **Lemma 13.** *If the robber follows the strategy specified in Section 2.4, then 2 cops need time $\Omega(\hat{n}^3)$ to capture the robber in $G_{\hat{n}}$.*

2.7 An Upper Bound for the Cops' Strategy

While the aim of this work is a lower bound, we need to show that 2 cops can actually capture the robber in $G_{\hat{n}}$, in order to use $G_{\hat{n}}$ as a lower bound graph for the capture time for 2 cops in 2-cop-win graphs. We start by showing that from a proper exit-blocking cop combination the cops can always go to another proper exit-blocking cop combination by doing one of the following: Both cops move to the next node in their respective cycle or only the cop in the $\mathcal{D}$ cycle moves to the next node.

▶ **Lemma 14.** *If $(\mathcal{C}_i, \mathcal{D}_j)$ is an exit-blocking cop combination, then it holds that at least one of $(\mathcal{C}_i, \mathcal{D}_{j+1 \pmod{\hat{n}}})$ and $(\mathcal{C}_{i+1 \pmod{\hat{n}}}, \mathcal{D}_{j+1 \pmod{\hat{n}}})$ is an exit-blocking cop combination.*

The following lemma shows that, once the cops reach $\mathcal{C}_0$ and $\mathcal{D}_0$, the robber cannot ever leave $\mathcal{R}$ without being captured in the next two moves. Then, using Lemma 14 and Lemma 15, we give an upper bound on the capture time of $G_{\hat{n}}$.

▶ **Lemma 15.** *Let $r(t) \in \mathcal{R}$ and $(c_0(t+1), c_1(t+1)) = (\mathcal{C}_0, \mathcal{D}_0)$ for some point in time t. If the robber leaves $\mathcal{R}$ at some later point in time t', i.e., if $r(t') \notin \mathcal{R}$ for some $t' > t$, then the robber will be captured at time $t'' \leq t' + 2$, provided the two cops follow the strategy specified in Section 2.5.*

▶ **Lemma 16.** *If the two cops follow the strategy specified in Section 2.5, then they capture the robber in time $\mathcal{O}(\hat{n}^3)$ in $G_{\hat{n}}$.*

Finally, by Lemma 13 we get that for the case of 2 cops, the capture time of the graph family $\{G_{\hat{n}}\}_{\hat{n} \geq 3, \hat{n} \equiv 0 \pmod 3}$ is $\Omega(\hat{n}^3) \subseteq \Omega(n^3)$ and by Lemma 16 we get that every graph in $\{G_{\hat{n}}\}_{\hat{n} \geq 3, \hat{n} \equiv 0 \pmod 3}$ is 2-cop-win. Together, these lemmas yield Theorem 1 for 2 cops.

The Case of $k > 2$

Our graph construction and the corresponding lower bound proofs follow closely the design of the case of two cops. To accommodate a third cop, Cop 2, we essentially copy the $\mathcal{D}$ component and ensure, that for every step of Cop 1, Cop 2 has to perform $\Omega(\hat{n})$ steps. For the case of $k > 3$ cops, we simply apply this trick inductively. Due to space limitations, we defer the detailed discussion of the case of $k > 2$ cops to the full version.

Abstract

Consider an agent trying to bring a system to an acceptable state by repeated probabilistic action. Several recent works on algorithmizations of the Lovász Local Lemma (LLL) can be seen as establishing sufficient conditions for the agent to succeed. Here we study whether such stochastic control is also possible in a noisy environment, where both the process of state-observation and the process of state-evolution are subject to adversarial perturbation (noise). The introduction of noise causes the tools developed for LLL algorithmization to break down since the key LLL ingredient, the sparsity of the causality (dependence) relationship, no longer holds. To overcome this challenge we develop a new analysis where entropy plays a central role, both to measure the rate at which progress towards an acceptable state is made and the rate at which noise undoes this progress. The end result is a sufficient condition that allows a smooth tradeoff between the intensity of the noise and the amenability of the system, recovering an asymmetric LLL condition in the noiseless case.

1 Introduction

Consider a system with a large state space Ω, hidden from view inside a box. On the outside of the box there are lightbulbs and buttons. Each lightbulb corresponds to a set $f_i \subseteq \Omega$ and is lit whenever the current state of the system is in f_i. We think of each set f_i as containing all states sharing some negative feature $i \in [m]$ and refer to each such set as a *flaw*, letting $F = \{f_1, f_2, \ldots, f_m\}$. For example, if the system corresponds to a graph G with n vertices each of which can take one of q colors, then $\Omega = [q]^n$, and we can define for each edge e_i of G the flaw f_i to contain all assignments of colors to the vertices of G that assign the same color to the endpoints of e_i. Following linguistic convention, instead of mathematical, we will say that flaw f is present in state σ whenever $f \ni \sigma$ and that state σ is *flawless* if no flaw is present in σ. The buttons correspond to actions, i.e., to mechanisms for state evolution. Specifically, taking action a while in state σ moves the system to a new state τ, selected from a probability distribution that depends on both σ and a.

Outside the box, an agent called the *controller* observes the lightbulbs and pushes buttons, in an effort to bring the system to a flawless state. Specifically, if $O(\sigma) \in \{0,1\}^m$ denotes the lightbulb bitvector, with 1 corresponding to lit, the controller repeatedly applies a function P, called a *policy*, that maps $O(\sigma)$ to a distribution over actions. Thus, overall, state evolution proceeds as follows: if the current (hidden) state is $\sigma \in \Omega$, the controller observes $O(\sigma)$ and samples an action from $P(O(\sigma))$; after she takes the chosen action, the system, internally and probabilistically, moves to a new (hidden) state τ, selected from a distribution that depends on both σ and the action taken.

Our work begins with the observation that several recent results [23, 24, 18, 14, 3, 15, 2, 19] on LLL algorithmization can be seen as giving sufficient conditions for a controller as above to be able to bring the system to a flawless state quickly, with high probability. Motivated by this viewpoint we ask if conditions for LLL algorithmizations can be seen as *stability criteria* and give results for more general settings, e.g., Partially Observable Markov Decision Processes (POMDPs). Given the capacity of LLL algorithmization arguments to establish convergence in highly non-convex domains, a major pain point in control theory, we believe that bringing such arguments to stochastic control is a first step in a fruitful direction. In order to move in that direction we generalize the setting described so far in two ways:

- The mapping O from states to observations is *stochastic*: the lightbulbs are unreliable, exhibiting both false-positives and false-negatives.
- Both the environment surrounding the system and the implementation of actions are *noisy*: the controller is not the only agent affecting state evolution and flaws may be introduced into the state for reasons unrelated to her actions, even spontaneously.

Naturally, the question is whether sufficient conditions for quick convergence to flawless states can still be established in this setting. We answer the question affirmatively and show, in a precise mathematical sense, that the less internal conflict there is in the system, the more noise the controller can tolerate. In order to prove this we require the controller to be *focused* and to *prioritize*. That is, we will assume that the flaws are ordered by priority according to an arbitrary but fixed permutation π of F, and we will ascribe the action taken by the controller in each step to the present flaw (focus) of highest priority (prioritization). The analysis will then take into account both how good the actions are at ridding the state of that flaw and how damaging they are in terms of introducing new flaws. In particular, with this attribution mechanism in place, and similarly to LLL algorithmization arguments, we will say that flaw f_i can cause flaw f_j if there exists a state transition with non-zero probability under the policy, from a state in which f_i is the highest priority flaw and f_j is absent, to a state in which f_j is present.

The main challenge we face is that in the presence of noise the causality relationship becomes dense. To overcome this we develop a new analysis in which causality is not a binary relationship, but one weighted by the *frequency* of interactions. In particular, our condition guaranteeing that the controller will succeed within a reasonable amount of time allows the causality graph to become arbitrarily dense, if the frequency of interactions is sufficiently small. Turning the sparsity of the causality relationship into a *soft* requirement is a major departure from the LLL setting and our main technical contribution. We do this by developing an entropy compression argument, in which we carefully amortize the entropy injected into the system to encode the effect of noise on the state trajectory. It is worth pointing out that even though our technique applies to the far more general noisy setting, in the absence of noise it recovers the main result of [3], thus providing a smooth relationship between lack of internal conflict and robustness to noise.

2 Formal Setting and Statement of Results

In the absence of observational and environmental noise we can think of the state evolution under a policy P as a random walk on a certain digraph on Ω. Specifically, at each flawed state $\sigma \in \Omega$, for each action in the support of $P(O(\sigma))$, there is a bundle of outgoing arcs of total probability 1, corresponding to the state-transitions from σ under this action. The convolution of $P(O(\sigma))$ with the distribution inside each bundle yields the state-transition probability distribution from each flawed state σ.

The presence of observational and environmental noise both distorts the transition probabilities and introduces new transitions. For example, whenever observational noise causes $O(\sigma)$ to differ from the set of flaws truly present in σ, the controller may chose an action (from the support of $P(O(\sigma))$) under which there are transitions from σ that were not present in the noise-free digraph. We model the overall distortion induced by noise by taking the noise-free digraph, which we think of as the *principal* mechanism for state evolution, reducing the probabilities on all its edges uniformly by a factor of $1-p$, and allowing the leftover probability mass to be distributed arbitrarily, in order to form the noise. More precisely:

- Let D_{po} be the digraph on Ω of possible state-transitions under policy P, with a self-loop added at every flawless state. Let ρ_{po} be the P-induced state-transition probability distribution, augmented so that all self-loops at flawless states have probability 1.
- Let D_{ns} be an **arbitrary** digraph on Ω. For each vertex σ in D_{ns}, let $\rho_{\text{ns}}(\sigma,\cdot)$ be an **arbitrary** probability distribution on the arcs leaving σ.
- We will analyze the Markov chain on Ω which at every $\sigma \in \Omega$, with probability p follows an arc in D_{ns} and with probability $1-p$ follows an arc in D_{po}. Formally, for every $\sigma \in \Omega$,

$$\rho(\sigma,\cdot) = (1-p)\cdot\rho_{\text{po}}(\sigma,\cdot) + p\cdot\rho_{\text{ns}}(\sigma,\cdot) \ .$$

  We assume that the system starts at a state σ_1, according to some unknown probability distribution θ.

Requiring that the effect of noise is captured by a mixture of the original (principal) chain and an arbitrary chain is the only assumption that we make. In particular, by allowing D_{ns} and ρ_{ns} to be arbitrary we forego the need to posit specific models of observational and environmental noise, lending greater generality to our results. To see this, let $U(\sigma)$ denote the set of flaws actually present in σ (and, slightly abusing notation, also the characteristic vector of $U(\sigma) \subseteq F$). In any step where the state transition distribution is not the principal one, we can think of this as occurring because $O(\sigma) \neq U(\sigma)$ and the distribution corresponds to $P(O(\sigma))$, or because $O(\sigma) \neq U(\sigma)$ and the distribution does not *even* correspond to $P(O(\sigma))$, or because $O(\sigma) = U(\sigma)$ but, silently, the distribution followed is different from $P(O(\sigma))$. In particular, notice that whenever $O(\sigma) = \mathbf{0}$, the controller thinks she has arrived at a flawless state and, thus, authorizes a self-loop with probability 1. In such a case, the fact that the system will follow ρ_{ns} with probability p means that we are allowing the noise not only to trick the controller to inactivity but also to silently move the system to a new state. Similarly, after the system arrives at a flawless state, i.e., $U(\sigma) = \mathbf{0}$, with probability p it will then follow an arc in D_{ns}, potentially to a flawed state. We allow this to occur to be consistent with (i) the idea that observational noise can occur at any state, even a flawless one, thus causing unneeded, potentially detrimental action, and (ii) with the idea that flaws can be introduced spontaneously from the environment at any state. Our goal is, thus, to prove that from *any* initial state, after a small number of steps, the system will

reach a flawless state, despite the noise. As we will see, what will matter about the noise is the extent to which noise-induced transitions introduce flaws in the state.

Let $D = D_{\rm po} \cup D_{\rm ns}$. To avoid certain trivialities we will assume that there exists a constant $B < \infty$ such that $2^{-B} < \rho(\sigma, \tau) < 1 - 2^{-B}$ for every arc $(\sigma, \tau) \in D$. For each state σ, we denote the highest priority flaw present in σ by $\pi(\sigma)$; if $\pi(\sigma) = f_i$, we label all arcs leaving σ as $\sigma \xrightarrow{i} \cdot$, i.e., with the index of the flaw to which we attribute the transition (we use i instead of f_i as the label to lighten notation). We will refer to $\pi(\sigma)$ as the flaw *addressed* at σ.

▶ **Causality.** *For an arc $\sigma \xrightarrow{i} \tau$ in D and a flaw f_j present in τ we say that f_i causes f_j if $f_j \not\ni \sigma$. The digraph on $[m]$ where $i \to j$ iff D contains an arc such that f_i causes f_j is the causality digraph $C(D)$.*

▶ **Neighborhood.** *The* neighborhood *of a flaw f_i in $C = C(D)$ is $\Gamma(f_i) = \{f_i\} \cup \{f_j : i \to j$ exists in $C\}$.*

For our condition we will need to bound from *below* the entropy injected into the system in each step. To that end we define the potential of each flaw f_i to be

$$\text{Potential}(f_i) = \min_{\sigma:\pi(\sigma)=f_i} H[\rho(\sigma, \cdot)] \ . \tag{1}$$

We extend the definition to sets of flaws i.e., $\text{Potential}(S) = \sum_{f \in S} \text{Potential}(f)$, where $\text{Potential}(\emptyset) = 0$.

In the absence of noise, $\text{Potential}(f_i)$ expresses a lower bound on the diversity of ways to address flaw f_i, by bounding from below the "average number of random bits consumed" whenever f_i is addressed. Thus, it bounds from below the rate at which the controller explores the state space *locally*. The presence of noise may decrease or may increase the potential. For example, if all arcs in $D_{\rm ns}$ are self-loops, then the noise is equivalent to the action-buttons "sometimes not working" and its only (and very benign) effect is to slow down the exploration by a constant factor. At the other extreme, if $D_{\rm ns}$ is the complete digraph on Ω and $\rho_{\rm ns}$ is uniform, then (unless p is extremely small) the situation is, clearly, hopeless. Correspondingly, even though the potential has been greatly increased, the causality relationship is complete. We note that, trivially, the potential of each flaw is bounded from below by the minimum entropy injected by the principal alone whenever the flaw is addressed, i.e., $\text{Potential}(f_i) \geq (1-p) \min_{\sigma:\pi(\sigma)=f_i} H[\rho_{\rm po}(\sigma)]$.

The other important characteristic of each flaw f_i is its congestion, i.e., the maximum number of arcs with label i that lead to the same state. For the same reason we would like the potential of a flaw to be big, we would like its congestion to be small: if arcs from different states in f_i lead to the same state, then exploration slows down and the entropy injected into the system must be appropriately discounted in order to yield a good measure of the rate of state space exploration. To see this observe that $\text{Potential}(f_i)$ is independent of the destinations of the arcs leaving f_i and compare the case where these destinations are all distinct with the case where they all lie in a small (bottleneck) set. As the congestion due to the principal and the congestion due to noise will have different effects, we need to account for them separately. Let $A_{\rm po}(\sigma)$ denote the support of $\rho_{\rm po}(\sigma, \cdot)$ and $A_{\rm ns}(\sigma)$ denote the support of $\rho_{\rm ns}(\sigma, \cdot)$.

▶ **Congestion.** *For any flaw $f_i \in F$, let*

$$\begin{aligned} \text{Congestion}_{\rm po}(f_i) &= \max_{\tau \in \Omega} |\{\sigma \in f_i : \tau \in A_{\rm po}(\sigma)\}| \\ \text{Congestion}_{\rm ns}(f_i) &= \max_{\tau \in \Omega} |\{\sigma \in f_i : \tau \in A_{\rm ns}(\sigma)\}| \ . \end{aligned}$$

Let $\mathrm{b}_{\mathrm{po}}^{f_i} = \log_2 \mathrm{Congestion}_{\mathrm{po}}(f_i)$. *Let* $\mathrm{b}_{\mathrm{ns}}^{f_i} = \log_2 \mathrm{Congestion}_{\mathrm{ns}}(f_i)$. *Let* $\mathrm{b}_{\mathrm{ns}} = \max_{f_i \in F} \mathrm{b}_{\mathrm{ns}}^{f_i}$.

Let C_{po} and C_{ns} be the causality graphs of D_{po} and D_{ns}, respectively, and let $\Gamma_{\mathrm{po}}(f_i)$ and $\Gamma_{\mathrm{ns}}(f_i)$ be the corresponding neighborhoords. Let $\Delta_i = |\Gamma_{\mathrm{ns}}(f_i)|$. Recall that $h(p) = -p\log_2 p - (1-p)\log_2(1-p)$ is the *binary entropy* of $p \in [0,1]$. To express the lost efficiency due to noise in addressing flaw f_i, we let

$$\begin{aligned} q_i(p) &= p\left(\Delta_i\left(\mathrm{b}_{\mathrm{ns}} + \frac{5}{2} + h(p)\right) - 2 - h(p)\right) \\ &\leq p\,\Delta_i(\mathrm{b}_{\mathrm{ns}} + 4) \ . \end{aligned}$$

Observe that $q_i(p)$ is independent of the policy and that its leading term is $p\Delta_i$. This means that, unlike the LLL, the number, Δ_i, of different flaws that may be introduced when addressing a flaw can be arbitrarily large if the *frequency of interactions* between flaws, captured by p, is sufficiently small. Our main result establishes a condition under which the probability of not reaching a flawless state within $O(\log_2|\Omega| + m)$ steps is exponentially small. To state it define for each flaw f_i,

$$\mathrm{Amenability}(f_i) = \mathrm{Potential}(f_i) - \mathrm{b}_{\mathrm{po}}^{f_i} \ .$$

▶ **Theorem 1.** *If for every flaw* $f_i \in F$,

$$\sum_{f_j \in \Gamma_{\mathrm{po}}(f_i)} 2^{-\mathrm{Amenability}(f_j) + q_j(p)} < 2^{-(2+h(p))} \ , \tag{2}$$

then there exists a constant $R > 0$ *depending on the slack in* (2)*, such that for every* $s > 1/2$*, the probability of not reaching a flawless state after* $Rs(\log_2|\Omega| + m)$ *steps is less than* $\exp(-s)$.

▶ Remark. In the noiseless case, i.e., when $p = 0$, equation (2) becomes an asymmetric LLL criterion. In particular, the main result of [3] is that if $\mathrm{b}_{\mathrm{po}}^{f_i} = 0$ and all distributions $\rho_{\mathrm{po}}(\sigma, \cdot)$ are uniform over their support $A_{\mathrm{po}}(\sigma)$, then, a sufficient condition for reaching a flawless state quickly is that for every $f_i \in F$, $\sum_{f_j \in \Gamma_{\mathrm{po}}(f_i)} 1/a_j < 1/\mathrm{e}$, where $a_j = \min_{\sigma \in f_j : \pi(\sigma) = f_j} |A_{\mathrm{po}}(\sigma)|$. We see that in this setting our condition (2) recovers this, up to the constant on the right hand side, i.e., $1/4$ vs. $1/\mathrm{e}$.

3.1 POMDPs and the Reachability Problem

Markov Decision Processes (MDPs) are widely used models for describing problems in stochastic dynamical systems [13, 28, 7], where an agent repeatedly takes actions to achieve a specific goal while the environment reacts to these actions in a stochastic way. In an MDP the agent is assumed to be able to *perfecty* observe the current state of the system and take action based on her observations. In a *partially* observable Markov Decision Process (POMDP) the agent only receives limited, and possibly inaccurate, information about the current state of the system. POMDPs have been used to model and analyze problems in artificial intelligence and machine learning such as reinforcement learning [9, 17], planning under uncertainty [16], etc.

Formally, a discrete POMDP is defined by the following primitives (all sets are assumed finite): (i) a *state space* Ω, (ii) a finite alphabet of *actions* $\mathcal{A}$, (iii) an observation space $\mathcal{O}$, (iv) an *action*-conditioned state transition model $\Pr(\tau|\sigma, a)$, where $\sigma, \tau \in \Omega$ and $a \in \mathcal{A}$,
